The preceding diacetate (0.5 g) in methanol (150 ml) was heated under reflux in the presence of the resin Rexyn 101 (2 g) for 3–4 h, the resin removed by filtration, and the filtrate evaporated *in vacuo* to give **2** (323 mg) which after recrystallization from EtOAc–hexane had mp 80–81°C; ir (KBr): 3500–2700, 2080 cm^{-1}. *Anal.* calcd. for $C_6H_{10}N_6O_2$: C36.36, H5.09, N42.41; found: C36.43, H5.12, N42.26.

2,5-Dideoxystreptamine Dihydrochloride

A solution of the preceding diazido diol **2** (0.20 g) in ethanol (10 ml) was shaken under a pressure of 48 psi of hydrogen over Raney Ni at room temperature. After 2 h, the mixture was worked up in the usual manner, the residue treated with ethanolic HCl to give in quantitative yield, the title compound, mp 290–293°C (lit. (4) mp 290–295°C) identical in every respect with an authentic specimen (1).

A solution of the diazido diol **2** (1.265 g) in dry DMF (11.3 ml) was mixed under nitrogen at room temperature with $CaSO_4$ (4.13 g) (preheated to 240°C for 4 h) and after stirring for 10 min, the temperature was raised to 80°C and a solution of 6-deoxy-6-azido-2,3,4-tris(*O*-benzyl)-α-D-glucopyranosyl chloride (3.158 g) (5) in DMF (11.3 ml) added dropwise (30 min) followed by the addition of $Hg(CN)_2$ (4.735 g). The mixture was stirred at 80°C for 23 h, 2.35 g of $Hg(CN)_2$ added, and heating to 87°C maintained for another 7 h. After standing overnight at room temperature, CH_2Cl_2 was added and the precipitate filtered off and the solids washed repeatedly with CH_2Cl_2. The combined filtrate and washings were washed with water, dried and evaporated to yield a dark syrup heterogeneous by tlc. Chromatography on silica ($CHCl_3$–hexane 1:1 as the eluent) gave a crude fraction (3.61 g) R_f 0.14 ($CHCl_3$) which was rechromatographed on thick plates of silica ($CHCl_3$–hexane 1:1). The major band was treated with acetic anhydride in pyridine in the usual manner and after work-up, the product chromatographed on thick plates of silica ($CHCl_3$–hexane 1:1). The band with R_f 0.5–0.6 appeared to consist of the two diastereomers ***6a*** and ***6b*** as judged by nmr spectroscopy. On standing in ethanol one of the isomers crystallized (151 mg), mp 96–97°C; ir (KBr): 2100, 1710 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.25 (15H, m, 3 C_6H_5); 5.10–4.25 (8H, m, 3 benzylic-CH_2, H, and 6H), 4.25–2.90 (9H, m, at 2′,3′,4′,5′,6′ and 1,3,4), 2.06 (3H, s, CH_3CO) and 2.90–1.18 (4H, m, at 2,5); $[\alpha]_D^{25}$ 50° (*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{35}H_{39}N_9O_7$: C60.24, H5.63, N18.07; found: C60.30, H5.70, N17.84. It was not possible to obtain the other isomer in crystalline form from the mother liquors.

cis-*4,8-Dithiatricyclo[5.1.0.0^{3,5}]octane (7)* (cis-*1,4-Cyclohexadiene bisepisulfide*)

The bisepoxide **1** (1.12 g) was added at 0°C to a stirred suspension of thiourea (2.064 g) in 2 *N* H_2SO_4 (10 ml) under nitrogen. The icebath was removed and stirring continued for 1 h during which time the product dissolved gradually to be replaced by a white precipitate of the bisisothiouronium salt **11**. Aqueous Na_2CO_3 was added to bring the pH to 8.5 and the mixture immediately extracted with benzene. The combined extracts were dried and evaporated to give the bisepisulfide **7** (1.2 g; 83%), mp 64–65°C (hexane–$CHCl_3$). The spectral characteristics are given in Table 1. *Anal.* calcd. for $C_6H_8S_2$: C49.95, H5.59, S44.45; found: C50.07, H5.58, S44.47.

trans-*4,8-Dithiatricyclo[5.1.0.0^{3,5}]octane (9)* (trans-*1,4-Cyclohexadiene bisepisulfide*)

The preceding procedure was followed using 0.336 g of *trans*-1,4-cyclohexadiene bisepoxide (1) and 0.456 g of thiourea in 3 ml of 2 *N* H_2SO_4. After work-up, **9** was obtained (0.28 g; 64.8%) as an oil which upon sublimation *in vacuo* gave crystals, mp 47–48°C. See Table 1 for spectral data. *Anal.* calcd. for $C_6H_8S_2$: C49.95, H5.59, S44.45; found: C49.97, H5.72, S44.51.

cis-*4-Oxa-8-thiatricyclo[5.1.0.0^{3,5}]octane (8)*

To a suspension of *trans*-1,4-cyclohexadienebisepoxide (1) (0.336 g) and thiourea (0.228 g) in water (9 ml) was added at 5°C under nitrogen 1.5 ml of 2 *N* H_2SO_4. The icebath was removed and after 20 min a white precipitate had separated. Stirring was continued for 20 min, the pH brought to 8.5 with aqueous $NaHCO_3$, and the mixture extracted with benzene. The combined extracts were combined, dried and evaporated to give a semisolid mass which was purified on thick plates of silica ($CHCl_3$–hexane 4:1). The major band yielded 0.158 g (36.5% yield) of the *trans*-bisepisulfide **9** (identical to the above product) and the minor band yielded a 0.047 g (12.3% yield) of **8** as an unstable colorless oil, bp 40°C/0.1 Torr. The spectral characteristics are given in Table 1. Reliable microanalyses could not be obtained because of its instability. Unchanged starting material was recovered in 44.6% yield.

trans-*4-Oxa-8-thiatricyclo[5.1.0.0^{3,5}]octane (10)*

Application of the preceding procedure to 0.896 g of **1** and 0.729 g of thiourea in 4 ml of 2 *N* H_2SO_4, led after work-up and chromatography on thick plates of silica ($CHCl_3$–CH_3OH 96:4) to 0.230 g (20% yield) of **10** which after sublimation had mp 62–63°C. See Table 1 for spectral data. *Anal.* calcd. for C_6H_8OS: C56.24, H6.29, S25.02; found: C56.10, H6.23, S24.53.

trans-trans-*1,4/2,5-2,5-Dichloro-1,4-cyclohexanedithiol Diacetate (12)*

A solution of the bisepisulfide **7** (0.65 g) in acetyl chloride was stirred under nitrogen at room temperature for 17 h after which time the mixture was evaporated *in vacuo*, the residue taken up in CH_2Cl_2, the solution washed with aqueous NaCl, dried, and evaporated. From hexane, crystals mp 89–90°C, were obtained (0.587 g or 43.5% yield); ir (KBr): 1680 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.03 (4H, m), 2.70–2.40 (4H, m), 2.40 ppm (6H, s); ^{13}C nmr ($CDCl_3$) δ: 192.55 (C—O), 57.68 (C—Cl), 45.00 (C—S), 36.16 (CH_2), 30.38 ppm (CH_3); M^+ 300. *Anal.* calcd. for $C_{10}H_{14}Cl_2O_2S_2$: C40.05, H4.67, S21.22; found: C40.01, H4.72, S21.21.

cis-*1,4-Cyclohexanedithiol Diacetate (**13**)*

A solution of **7** (1.12 g) in dry THF (30 ml) was added dropwise to a refluxing suspension of LAH (0.5 g) in dry ether (30 ml) under nitrogen and heating continued for 2 h after which time a mixture of aqueous HCl–THF was carefully added while cooling in ice. The organic layer was separated, dried and evaporated to give a colorless oil which was taken up in pyridine–acetic anhydride. After standing at room temperature overnight, the mixture was worked up in the usual manner to yield a semisolid consisting of **13** (0.542 g or 30% yield). Sublimation gave white crystals mp 63–65°C; ir (KBr): 1685 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.60 (2H, m), 2.30 (6H, s), 1.80 ppm (8H, m); ^{13}C nmr ($CDCl_3$) δ: 30.401 (CH_2 groups), 30.759 (CH_3), 40.92 (C—S), 195.065 ppm (C=O); M^+ 232. *Anal.* calcd. for $C_{10}H_{16}O_2S_2$: C51.69, H6.94, S27.60; found: C51.60, H6.87, S27.63.

trans-trans-*1,5/2,4-2,4-Dithiol-1,5-cyclohexanediol Tetraacetate (**15**)*

A solution of **7** (0.458 g) in dry THF (80 ml) was heated under reflux for 17 h in the presence of $Hg(OAc)_2$ (2.02 g) under nitrogen. Water (5 ml) was added and a stream of H_2S passed through the mixture until precipitation of HgS was complete. Ethyl acetate (100 ml) was added, the mixture filtered, the filtrate washed with aqueous NaCl, dried and evaporated to give an oil which was taken up in pyridine–acetic anhydride. After 16 h, the solution was worked up in the usual manner and the resulting oil purified on thick plates of silica ($CHCl_3$). The major band yielded 0.24 g (21.7% yield) of **15** which crystallized from hexane–$CHCl_3$; mp 121°C; ir (KBr): 1730, 1690 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.93 (2H, m), 3.90 (2H, m), 3.00–1.80 (4H, m), 2.40 ppm (6H, s); ^{13}C nmr ($CDCl_3$) δ: 193.13 (S—CO), 169.61 (O—CO), 70.13 (C—O—), 41.65 (C—S), 33.02 and 30.64 (CH_2), 20.93 ppm (CH_3); *m/e* 289 (M^+ – AcO). *Anal.* calcd. for $C_{14}H_{20}O_6S_2$: C48.27, H5.79, S18.41; found: C48.38, H5.70, S18.47.

Phenol sulfate esters: ultraviolet, infrared, ^1H and ^{13}C nuclear magnetic resonance spectroscopic investigation

MARK A. RAGAN[1]

Institute of Marine Biochemistry, N-7034 Trondheim-N.T.H., Norway

Received April 25, 1978

MARK A. RAGAN. Can. J. Chem. **56**, 2681 (1978).

Renewed interest in naturally occurring phenol sulfate ester salts has necessitated modern spectroscopic investigation of these compounds. Synthetic methods, plus spectroscopic (uv, ir, ^1H nmr, ^{13}C nmr), chromatographic, and electrophoretic properties are given for the potassium salts of phenyl sulfate (**1**), pyrocatechol disulfate (**2**), resorcinol disulfate (**3**), hydroquinone disulfate (**4**), phloroglucinol mono- (**5**), di- (**6**), and tri- (**7**) sulfates, and for the 2-sulfate (**8**) and 2,5-disulfate (**9**) of 1,2,3,5-tetrahydroxybenzene (**10**). ^{13}C nmr chemical shift effects resulting from the replacement of phenolic —OH with —OSO_3K are reported. Spectroscopic properties of the related compounds 1,2,3-tribenzyloxybenzene (**11**), 2,6-dibenzyloxy-1,4-benzoquinone (**12**), 2,6-dimethoxy-1,4-benzoquinone (**13**), 1,3-dibenzyloxy-2,5-dihydroxybenzene (**14**), and of a tentatively identified 1,3-dibenzyloxy-2,5-dihydroxybenzene monoethyl ether (**15**) are available as supplementary material.

MARK A. RAGAN. Can. J. Chem. **56**, 2681 (1978).

Un intérêt renouvelé pour les sels de sulfates d'esters de phénols se retrouvant dans la nature a nécessité une étude spectroscopique moderne de ces composés. On a effectué la synthèse et l'on a déterminé les spectres (uv, ir, rmn du ^1H, rmn du ^{13}C) ainsi que les propriétés chromatographiques et électrophorétiques de sels de potassium du sulfate de phényle (**1**), du disulfate de pyrocatéchol (**2**), du disulfate de résorcinol (**3**), du disulfate d'hydroquinone (**4**) et des mono- (**5**), di- (**6**) et tri- (**7**) sulfates du phloroglucinol ainsi que du sulfate-2 (**8**) et du disulfate-2,5 (**9**) tétrahydroxy-1,2,3,5 benzène (**10**). On rapporte l'influence sur les déplacements chimiques en rmn du ^{13}C, du remplacement du —OH phénolique par un —OSO_3K. Les propriétés spectroscopiques des composés apparentés comme le tribenzyloxy-1,2,3 benzène (**11**), la dibenzyloxy-2,6 benzoquinone-1,4 (**12**), le diméthoxy-2,6 benzoquinone-1,4 (**13**), le dibenzyloxy-1,3 dihydroxy-2,5 benzène (**14**) et le composé identifié d'une façon non-définitive comme étant l'éther méthylique du dibenzyloxy-1,3 dihydroxy-2,5 benzène (**15**) sont disponibles sous forme de données supplémentaires.

Introduction

Although it has been recognized for many years that phenols may occur as sulfate ester salts in higher animals and plants (1, 2), until about 1950 these compounds were considered to be of infrequent occurrence and minor importance. Eventually sulfate ester salts were implicated as end products in the detoxification of certain phenols by higher animals (3). More recently, Harborne and co-workers (4) have shown that flavonoids often occur as sulfate ester salts in a wide range of higher plants, particularly those growing in marine, estuarine, or freshwater environments; and Jensen and Ragan (5) have demonstrated the presence of the new natural product 1,2,3,5-tetrahydroxybenzene 2,5-disulfate in the marine brown alga *Ascophyllum nodosum* (L.) LeJol. (Phaeophyceae).

Sulfated anthraquinones (6), betacyanins (7), flavonoids (4), and other polyphenols (5) may occur in only small quantities in the plant source and upon extraction may be very unstable. Hence classical methods for determining the position of sulfate groups, usually requiring moderately large quantities of the sulfate, are ill suited to investigation of their structures. It is now demonstrated that spectroscopic methods, particularly ^{13}C nuclear magnetic resonance spectroscopy, provide a rapid and powerful approach to complete structural determination of phenol sulfate ester salts.

The compounds synthesized for spectroscopic (uv, ir, ^1H nmr, ^{13}C nmr), chromatographic and electrophoretic investigation were the potassium salts of (mono)phenyl sulfate (**1**); the disulfates of pyrocatechol (**2**), resorcinol (**3**), and hydroquinone (**4**); the mono- (**5**), di- (**6**), and tri- (**7**) sulfates of phloroglucinol; and the 2-sulfate (**8**) and 2,5-disulfate (**9**) of 1,2,3,5-tetrahydroxybenzene (**10**). Although not **1** (1, 8–21), or **2** (16), or **4** (22, 23) is a new product, no spectroscopic data have been reported for them; **3**, **5**, **6**, and **7** appear to be new compounds. Some spectroscopic data for **8** and **9** have been reported earlier (5).

Results and Discussion

Of the methods examined for the preparation of phenol sulfate ester salts (1, 8–12, 15, 20, 24, 25), the one found to be most suitable for routine application

*Values in column A from phenol and **1**; values in column B from resorcinol and **3**; values in column C from **5** and **6** vis-a-vis phloroglucinol; see text.

on the 0.05–0.10 mol scale was a modification of that of Feigenbaum and Neuberg (15), in which the phenol (dissolved in pyridine) was added in one portion to a cooled pyridine solution of the pyridine–SO_3 complex (see Experimental). Compounds **1** → **4** and **7** were white or nearly-white solids which could be crystallized (with slight decomposition) from aqueous methanol or ethanol, and with the exception of **1** were extremely soluble in cool water. The trisulfate **7** was less soluble in methanol or ethanol than were the disulfates **2** → **4**, which were in turn less soluble than **1** or **8**. Although relatively stable at room temperature when dry, in aqueous solution the sulfate salts underwent progressive hydrolysis (12, 26–28). Attempted replacement of the K^+ counterions with H^+ on Dowex 50-W caused considerable decomposition.

Analytical separation of **1** → **9** was carried out more successfully by paper electrophoresis (pH 1.5–5.0, usually pH 4.0) than by paper chromatography (see Experimental). The former method allowed separation of investigated monosulfates ($R_{\text{phloroglucinol trisulfate}} \equiv R_7 = 0.44$–$0.60$) and disulfates ($R_7 = 0.78$–$0.89$) from trisulfates ($R_7$ around 1.00) (4, 25).

The sulfate ester salts exhibited bimodal uv spectra, with aromatic absorption at about 270 nm, together with a characteristic absorption at 220–225 nm not present in the corresponding free phenols and possibly involving the sulfate group(s): compare the 220–225 nm extinction coefficients of **1** vs. **2** → **4**, and of **8** vs. **9**.

In addition to the expected strong ester sulfate ir bands at 1040–1070 (C—O—S) and 1225–1290 (S=O) cm^{-1} (25), additional ir bands not seen with the corresponding free phenols were observed in spectra of *o*- and *p*-sulfate ester salts at 625–640, 685–725, and 840–870 cm^{-1}. Although the precise position of these bands differed for each investigated phenol sulfate ester salt, both monosulfates (**1**, **8**) absorbed at 640 and 690–695 cm^{-1}, and both *p*-disulfates (**4**, **9**) at 620–630 and 850–870 cm^{-1}. The *m*-substituted sulfate ester salts **3** and **7** showed more complex ir bands which could not be easily reconciled with this pattern. No evidence was found for contamination of the preparations with potassium sulfate (found upon addition of potassium sulfate: 1110 and 615 cm^{-1}).

In comparison with ^1H nmr signals of the corresponding free phenols, ring proton signals of **1** → **4** and **7** → **9** appeared farther downfield relative to TMS (solvent: D_2O). The spin–spin systems were in all cases as expected (29).

^{13}C nmr proved to be very useful for detecting the pattern of sulfate substitution. Although the replacement of a phenolic —OH group by —OSO_3K had little effect on either the relative signal intensities per nucleus (and hence on relative relaxation and nuclear Overhauser enhancement) or the magnitude of ^{13}C–^1H coupling constants, the ^{13}C chemical shifts were changed in a predictable manner (Table 1). The replacement effects for conversion of —OH to —OSO_3K were calculated as follows (solvent, D_2O): ^{13}C nmr chemical shifts of phenol itself were assigned from published data (30) and from nondecoupled spectra, enabling signals of **1** to be assigned from chemical shift (C-1), ^{13}C–^1H coupling (C-2,6 vs. C-3,5) and signal intensity (C-1; also C-4 vs. C-2,6) data. Thus substituent effects for —OH (30) and —OSO_3K on the benzene ring could be determined, and the replacement effect for conversion of —OH to —OSO_3K was calculated by subtraction (Table 1, column A). Using these substituent effects, signals in the spectra of resorcinol and of **3** were assigned, and the assignments were again confirmed from nondecoupled spectra. From these shifts, substituent effects for —OH and —OSO_3K were again calculated, and replacement effects for —OH → —OSO_3K determined by subtraction (Table 1, column B). The latter replacement effects were found to be valid for estimation of chemical shifts of sulfate ester salts of all the other simple polyphenols investigated, when calculated from the shifts of the corresponding free phenols.

A further refinement was, however, possible: from these replacement effects (column B), it was possible to assign ^{13}C signals from **5** and **6** in spectra of a mixture containing phloroglucinol, **5**, **6**, and **7**. To the extent possible, these assignments were confirmed (*i*) by proton-decoupled ^{13}C spectra of phloro-

glucinol and of **7** individually; (*ii*) by nondecoupled spectra, using convolution difference methods (31) where necessary; and (*iii*) by correlation of relative signal intensity (separately for ^{13}C—H and ^{13}C—O— nuclei) with compound abundance as estimated from paper chromatography and paper electrophoresis. From these eight shifts, the replacement effects for —OH → —OSO_3K were calculated directly for **5** and **6**. Owing to slight inconsistencies between individual substituent effects in **5** and **6**, a rough estimate of the imprecision of the calculated values was also obtained (Table 1, column C).

These replacement effects (Table 1, column C) were used to calculate expected ^{13}C chemical shifts for all possible symmetrical sulfate esters of 1,2,3,5-tetrahydroxybenzene (**10**), allowing the 'phenolic precursor' in exudates of *Ascophyllum nodosum* to be identified as 1,2,3,5-tetrahydroxybenzene 2,5-disulfate; this was confirmed by synthesis (5). It is likely that these replacement effects will in similar fashion prove useful in the eventual assignment of ^{13}C nmr spectra of sulfated flavonoids and related natural products. In favorable situations (such as that reported here with mixtures of phloroglucinol and **5** → **7**), simple mixtures of sulfated polyphenols may be resolved by this approach.

Experimental

Ultraviolet spectra (ε in parentheses) were recorded in methanol (for **10**), 9:1 (v/v) methanol–water (**1**), or 4:1 methanol–water (**2** → **4**, **7**) using a Coleman-Hitachi 124. Infrared spectra were recorded in KBr using a Hitachi Perkin-Elmer 257. Mass spectra were taken at 70 eV using an AEI MS-902 with on-line PDP 8/1 computer. ^1H nmr (99.6 MHz) and ^{13}C nmr (25.05 MHz) spectra of the sulfate ester salts and of the corresponding free phenols were recorded using a JEOL FX-100 operated in FT mode. Proton-decoupled ^{13}C spectra were recorded in D_2O, and non-decoupled ^{13}C spectra (either with or without retention of nOe) in approximately 1:1 (v/v) H_2O–D_2O. Chemical shifts (δ and δ_C) are reported relative to TMS (10% in $CDCl_3$ in a coaxial capillary). Nondecoupled ^{13}C spectra were enhanced, when necessary, by convolution difference techniques (31). The resolution was 1.2 Hz or better for **1** → **10**. Ascending mode paper chromatography was done on Whatman No. 1 paper using 20% (w/v) aqueous KCl (32). Paper electrophoresis was carried out as described earlier (5). Sulfate ester salts were detected on paper by the usual spray reagents (33) applied after mild acid hydrolysis (15% concentrated HCl in ethanol with gentle heating) or with acidic spray reagents such as vanillin–HCl, Ehrlich's reagent, anisaldehyde–HCl, or diazo reagents in excess HNO_2. With vanillin–HCl, the temporal order of color development upon gentle heating was phloroglucinol > **5** > **6** > **7**.

All reagents were AR grade. The pyridine–SO_3 complex was routinely prepared from pyridine and chlorosulfuric acid (9,12) (see below) but for critical small-scale work was instead prepared from solid SO_3 and pyridine (12, 34).

Complete Sulfation of Polyphenols

General procedure (**1** → **4**, **7**): pyridine (ca. 50 ml) was cooled to −20°C and 0.115 mol (7.5 ml) chlorosulfuric acid (chlorosulfonic acid) was added dropwise (CAUTION!) with manual stirring and efficient cooling. After cooling again to −20°C, a solution of the *anhydrous* polyphenol (0.10 mol equiv.) in pyridine (ca. 30 ml) was added in one portion and the solution was stirred overnight at room temperature. Thereafter, excess solvent was evaporated *in vacuo* (<40°C). The syrupy residue was redissolved in distilled water (200 ml) and the pH adjusted to 8.0–8.5 with dilute aqueous KOH. After 10–15 min, the solvent was removed *in vacuo* (<35°C). The residue was redissolved in boiling ethanol (for **1**) or alternatively was washed with boiling ethanol to remove color, filtered immediately (Whatman GF/C), redissolved in boiling, very slightly basic methanol–water (4:1 v/v for **2** → **4**; 7:3 for **7**), and filtered hot (GF/C) before crystallization. With **7**, this entire procedure was repeated once; for **1** → **4**, one sulfation was sufficient and yields were 80–95% of theoretical. Elemental analyses tended to be 5–8% low after crystallization, owing largely to contaminating inorganic salts which, however, did not interfere with spectroscopic investigation.

Attempts to form pyrogallol trisulfate by repeated application of this method were unsuccessful, giving primarily a mixture of mono- and disulfate esters, plus uncharacterized by-products.

Partial Sulfation

Compounds **5** and **6** were synthesized by the above method from phloroglucinol *dihydrate* (0.15 mol equiv.), using only 0.075 mol of chlorosulfuric acid; after work-up (see **7**) the product, which contained contaminating phloroglucinol and **7**, was not purified further but ^{13}C signals of **5** and **6** individually could be identified unambiguously in spectra of the mixture (see text). Compound **9** was synthesized similarly from **8** (5).

Phenyl sulfate, potassium salt (***1***) — λ_{max}: 271 (190), 264 (260), 259 (250), 252 (sh, 200), 221 nm (620); ν_{max}: 640m, 690m, 695m, 720w, 735m, 775ms, 820w, 865ms, 905w, 915w, 1010w, 1020w, 1060s, 1125w, 1160w, 1210m, 1235s, 1255s, 1260s, 1280s, 1450w, 1485m, 1585m, 3060w cm^{-1}; δ: complex, asymmetric multiplet (unlike that of phenol in D_2O), with major signals at 7.29, 7.32, 7.36, 7.40, 7.46 ppm; δ_C and J_{CH}: see Table 2; pc: R_f = 0.81; pe: R_7 = 0.60.

Pyrocatechol (1,2-dihydroxybenzene) disulfate ester, dipotassium salt (***2***) — λ_{max}: 271 (455), 266 (540), 221 (1090), 215 (sh, 1030); ν_{max}: 635m, 725ms, 775ms, 845m, 885w, 895m, 960w, 1040s, 1060s, 1115w, 1165w, 1190w, 1245w, 1270s, 1455w, 1465w, 1495m, 1595w, 1620-1640w cm^{-1}; δ: AA′BB′ system (14 lines resolved), ($\nu_A - \nu_B$) approximately 20–25 Hz, symmetrical around centroid 7.52 ppm; δ_C and J_{CH}: see Table 2; pc: R_f = 0.94; pe: R_7 = 0.89. *Monosulfate, monopotassium salt* (16, 17, 28, 35): pc: R_f = 0.85; pe: R_7 = 0.50.

Resorcinol (1,3-dihydroxybenzene) disulfate ester, dipotassium salt (***3***) — λ_{max}: 271.5 (330), 265 (395), 220nm (1130). ν_{max}: 625w, 680m, 690w, 730m, 760m, 795w, 805w, 845m, 870m, 960ms, 1050s, 1055s, 1070m, 1090m, 1120m, 1225s, 1240s, 1275s, 1290s, 1465w, 1480m, 1590m, 1605m, 3065w, 3125w cm^{-1}; δ: AB_2X system (approximately 25 signals resolved) with major signal at 7.35 ppm; δ_C and J_{CH}: see Table 2; pc: R_f = 0.91; pe: R_7 = 0.84. *Monosulfate, monopotassium salt* (16): pc: R_f = 0.78; pe: R_7 = 0.53.

Hydroquinone (1,4-dihydroxybenzene) disulfate ester, dipotassium salt (***4***) — λ_{max}: 268 (510), 224nm (1280); ν_{max}: 620m, 630ms, 700m, 715ms, 850s, 860s, 870s, 975w, 1010w, 1020wm, 1055s, 1095w, 1100wm, 1190ms, 1240s, 1265s, 1280s, 1285s, 1500s, 1895w, 1930w, 3110w cm^{-1}; δ: 7.38 ppm; δ_C and J_{CH}: see Table 2; pc: R_f = 0.91; pe: R_7 = 0.86. *Monosulfate, monopotassium salt* (16, 18, 19, 22, 36): pc: R_7 = 0.80; pe: R_f = 0.48.

Phloroglucinol (1,3,5-trihydroxybenzene) monosulfate ester, potassium salt (***5***) — δ_C and J_{CH}: see Table 2. In nondecoupled

spectra (mixtures of phloroglucinol, **5**, **6**, and **7**), the signals from C-1 were partially obscured by those of C-1,3 of **6** and C-1,3,5 of **7**, while signals from C-4,6 of **6** obscured one of the $^1J_{CH}$ doublets of C-4 and of C-2,6; pc: $R_f = 0.81$; pe: $R_7 = 0.78$.

Phloroglucinol disulfate ester, dipotassium salt (***6***) — δ_C and J_{CH}: see Table 2; pc: $R_f = 0.71$; pe: $R_7 = 0.44$.

Phloroglucinol trisulfate ester, tripotassium salt (***7***) — λ_{max}: 270 (170), 266 (180), 215 nm (1260); ν_{max}: 670m, 685m, 715w, 740w, 755m, 805wm, 890wm, 990s, 1055s, 1125wm, 1255s, 1450m, 1605m, 3090w cm^{-1}; δ: 7.39 ppm; δ_C and J_{CH}: see Table 2; pc: $R_f = 0.89$.

1,2,3,5-Tetrahydroxybenzene 2-sulfate ester, potassium salt (***8***) — uv, ir, and ^1H nmr data have been presented earlier (5); δ_C and J_{CH}: see Table 2; pc: $R_f = 0.73$; pe: $R_7 = 0.56$. Most preparations also contained a disulfate of unknown structure as a very minor contaminant: pc: $R_f = 0.85$; pe: $R_7 = 0.83$.

1,2,3,5-Tetrahydroxybenzene 2,5-disulfate ester, dipotassium salt (***9***) — uv, ir, ^1H nmr, and ^{13}C nmr data have been presented earlier (5), see also Table 2; pc: $R_f = 0.87$; pe: $R_7 = 0.76$. Native preparations from *Ascophyllum nodosum* contain a monosulfate of unknown structure presumably based on **10**; pc of monosulfate: $R_f = 0.72$; pe: $R_7 = 0.56$ (compare with **8**). Preparations from *A. nodosum* also contain traces of a disulfate tentatively identified as the 1,3-disulfate ester of **10** (5).

1,2,3,5-Tetrahydroxybenzene (***10***)—Compound **10** was formed by catalytic hydrogenolysis of 2,6-dibenzyloxy-1,4-benzoquinone (**12**) (ref. 37 and footnote 2). In contrast to the report of Baxter and Brown (37), but in agreement with the older literature (see references cited in ref. 37), the product discolored slowly in air, although **12** had been thrice crystallized; mp (capillary, uncorrected) 166–169°C (lit. (37) mp 168–170°C, (38) mp 165–167°C); λ_{max}: 266–290 (broad, flat absorption; 560), 239 nm (550); ν_{max}: 650w, 680w, 790m, 810m, 820w, 835w, 1000ms, 1005ms, 1045s, 1140s, 1155s, 1180s, 1195s, 1300s, 1380m, 1485s, 1520m, 1530s, 1630s, 3280s cm^{-1}; δ: 6.01 ppm. δ_C and J_{CH}: see Table 2. The protons directly bonded to C-4,6 were exchangeable into D_2O, as evidenced by the gradual loss of ^{13}C–^1H couplings during 24 to 48 h (cf. ref. 39); ms (90°C) *m/e*: 142 (M^+; 100%), 141 (6%), 140 (5%), 113 (5%), 96 (31%), 78 (10%), 71 (10%), 69 (13%).

A facile synthesis of methyl 3,6-dideoxy-α-L-*xylo*-hexopyranoside (colitose)[1]

DAVID R. BUNDLE AND STAFFAN JOSEPHSON[2]

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received May 15, 1978

DAVID R. BUNDLE and STAFFAN JOSEPHSON. Can. J. Chem. **56**, 2686 (1978).

Methyl 3,6-dideoxy-α-L-*xylo*-hexopyranoside (**7**) has been synthesised in four steps from methyl α-L-fucopyranoside. The intermediate methyl 3,4-*O*-benzylidene-α-L-fucopyranoside was separated into the *S* (**1***a*) and *R* (**1***b*) diastereoisomers and the absolute configuration established by proton and carbon-13 nmr spectroscopy. Under the conditions of the Hanessian–Hullar reaction methyl 4-*O*-benzoyl-3-bromo-3,6-dideoxy-α-L-gulopyranoside was the major product. Each diastereoisomer **1***a* or **1***b* gave identical products and product ratios; the stereochemistry and relative proportions of these products were determined by proton and carbon-13 nmr. The synthesis of ascarylose from methyl α-L-rhamnopyranoside by an analogous route is also reported. The bromo deoxy intermediates were reduced to the dideoxy sugars by catalytic hydrogenation with palladium.

DAVID R. BUNDLE et STAFFAN JOSEPHSON. Can. J. Chem. **56**, 2686 (1978).

On a synthétisé le didéoxy-3,6 α-L-*xylo*-hexapyrannoside (**7**) de méthyle en quatre étapes à partir de l'α-L-fucopyrannoside de méthyle. On a séparé l'intermédiaire *O*-benzylidène-3,4 α-L-fucopyrannoside de méthyl en diastéréoisomères *S* (**1***a*) et *R* (**1***b*) et on en a établi la configuration absolue par spectroscopie rmn du proton et du carbone 13. Faisant appel aux conditions de la réaction de Hanessian–Hullar, le produit principal est le *O*-benzoyl-4 bromo-3 didéoxy-3,6 α-L-gulopyrannoside de méthyle. Chacun des diastéréoisomères **1***a* ou **1***b* conduit à des produits et à des rapports de produits identiques; on a déterminé la stéréochimie et les proportions relatives de ces produits par rmn du proton et du carbone 13. On rapporte aussi la synthèse de l'ascarylose à partir de l'α-L-rhamnopyrannoside de méthyle par une voie analogue. On a réduit les intermédiaires bromo-déoxy en sucres didéoxy par une hydrogénation catalytique avec du palladium.

[Traduit par le journal]

Introduction

Colitose, 3,6-dideoxy-L-*xylo*-hexose, is a constituent of several lipopolysaccharides (LPS) (1, 2). Unlike the other 3,6-dideoxyhexoses tyvelose, paratose, and abequose, which also occur in the LPS of various strains of *Salmonella* (1), colitose is the only dideoxy hexose that also occurs in the LPS of *Escherichia coli* (2). Although colitose has been synthesised as a racemic mixture with its optical antipode abequose (3) no practical synthesis of this important sugar has been reported. The synthesis of this sugar for subsequent use in halide ion (4) catalysed glycosylation reactions was necessary to provide a route to artificial antigens. This was achieved starting from readily available L-fucose. To compare certain nmr parameters of the intermediate 3-bromo-3,6-dideoxyhexopyranosides, ascarylose, 3,6-dideoxy-L-*arabino*-hexose was synthesised. This latter synthesis utilised essentially the same route as that reported in a publication that appeared whilst this work was in progress (5).

Results and Discussion

The synthesis of 3,6-dideoxyhexopyranosides in a form suitable for subsequent use in either halide ion (4) catalysed glycosylation or modified Koenigs–Knorr (6, 7) conditions generally proceeds by one of two routes. Either a 3-deoxy-4,6-*O*-benzylidene-hexopyranoside is used to introduce the 6-deoxy function (8), or alternatively a readily available 6-deoxyhexopyranoside possessing either a suitable epoxide (9) or benzylidene acetal of the 1,3-dioxalane type is used to introduce the 3-deoxy function by way of a bromo deoxy derivative (5, 8). In the synthesis reported here we have used the latter route starting from readily available L-fucose (6-deoxy-L-galactose), which provides the title compound (**7**) in five steps from the 6-deoxyaldohexose.

Methyl α-L-fucopyranoside was converted to a mixture of *S* and *R* isomers of the 3,4-*O*-benzylidene acetals, **1***a* and **1***b* using either α,α-dimethoxytoluene (10) or α,α-dibromotoluene in pyridine (11). Although the latter method resulted in the preferential formation of the *S* isomer (H-*endo*) to the extent, **1***a*:**1***b*, 2:1 the product required chromatographic purification before the next step. The acetal exchange method (10), however, provided **1***a* and **1***b* in the ratio 1:1 from which a 15% yield of pure *R* isomer (**1***b*) could be readily crystallised. The remaining mixture of diastereoisomers could be used directly in the next step or resolved by column chromatography after conversion to the *p*-nitrobenzoates **2***a* and **2***b*.

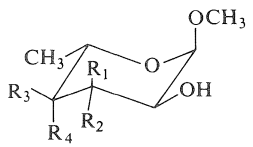
1*a* $R_1 = R_3 = H, R_2 = C_6H_5$
1*b* $R_1 = C_6H_5, R_2 = R_3 = H$
2*a* $R_1 = H, R_2 = C_6H_5, R_3 = p\text{-}NO_2C_6H_4CO$
2*b* $R_1 = C_6H_5, R_2 = H, R_3 = p\text{-}NO_2C_6H_4CO$

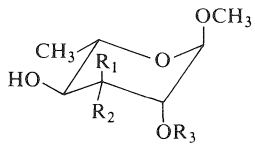
Treatment of **1***a* or **1***b* with *N*-bromosuccinimide (NBS) in refluxing carbon tetrachloride (12) yielded the bromo sugar (**3**) in greater than 80% yield. When either the pure *R* or *S* isomer was used as starting material a 5:1 ratio of methyl 4-*O*-benzoyl-3-bromo-3,6-dideoxy-α-L-gulopyranoside (**3**) to methyl 3-*O*-benzoyl-4-bromo-4,6-dideoxy-α-L-glucopyranoside (**4**) was obtained. If the crude syrup obtained from the acetylation step was used directly in the Hanessian–Hullar reaction (12) the ratio of gulopyranoside (**3**) to glucopyranoside (**4**) was found to be 2:1. However, if this syrup was first triturated with Skellysolve B to remove α,α-dimethoxytoluene and other impurities and then dried, the product ratio was again 5:1. Deliberate contamination of crystalline starting material **1***a* or **1***b* with 10% α,α-dimethoxytoluene did not produce the larger proportion of glucopyranoside (**4**) relative to gulopyranoside (**3**), that had been observed for crude syrup. The nature of the impurity causing the change of product ratios remains obscure. Several bromination reactions were conducted using crystalline samples of **1***a*, **1***b*, and mixtures of **1***a* and **1***b*. The reaction products without chromatographic treatment were quantified by ^{13}C nmr spectroscopy and in each case the ratio of gulopyranoside (**3**) to glucopyranoside (**4**) remained 5:1 even for syrups of **1***a* and **1***b*. It should be noted that, whereas crystalline starting material always reacted rapidly in less than 20 minutes under the conditions of the Hanessian–Hullar reaction (12) (a period much shorter than those previously reported (12, 13)), syrups invariably took at least 3 h to react completely.



3 $R_1 = Br, R_2 = R_3 = H, R_4 = C_6H_5COO$
4 $R_1 = R_4 = H, R_2 = C_6H_5COO, R_3 = Br$
5 $R_1 = R_2 = R_3 = H, R_4 = C_6H_5COO$
6 $R_1 = R_3 = R_4 = H, R_2 = C_6H_5COO$
7 $R_1 = R_2 = R_3 = H, R_4 = OH$

Proton nmr spectra (Table 1) of compounds **1***a* and **1***b* establish that these acetals exist as distorted $^1C_4$ chairs owing to the constraints imposed by the 1,3-dioxalane ring. Assignment of absolute configuration at the acetal carbon is based on established rules (14, 15) relating relative chemical shifts of benzylic protons to stereochemistry. In contrast, comparison of ^{13}C chemical shifts (Table 2) of the acetal carbon atoms for *R* and *S* isomers shows the reverse order; that is *R* isomer (H-*exo*) at lower field than the *S* isomer (H-*endo*). Although the aforementioned observation is to be expected an additional consequence of the *endo*-phenyl substituent of **1***b* is the deshielding, to the extent of 1.9 ppm of the C-2 resonance, owing presumably to the anisotropic deshielding influence of the phenyl ring. All other ring carbons for both isomers **1***a* and **1***b* possess very similar chemical shifts. Based on these observations, ^{13}C nmr may also be used by analogy with ^1H nmr to assign absolute configuration of acetals.

Despite significant 1,3-*syn*-diaxial interactions present in the $^1C_4$ conformation of the gulopyranoside (**3**), the three-bond coupling constants (Table 1) are consistent with a somewhat distorted $^1C_4$ chair and exclude any of the alternate higher energy boat or skew-boat conformations. The proton, H-5, of the gulopyranoside (**3**) is deshielded by 0.5 ppm relative to the H-5 proton of either the acetal **1***b* or the altropyranoside (**9**), which also possesses a *syn*-axial bromine substituent. However, this deshielding may be attributed to the combined effects of a vicinal *trans*-axial, benzoate group and the *syn*-axial bromine atom (16). The ^1H and ^{13}C nmr parameters for the compounds **1**–**11** (Tables 1 and 2) provide proof of the configuration and conformation assigned to these structures **1**–**11**.



9 $R_1 = Br, R_2 = H, R_3 = C_6H_5CO$
10 $R_1 = R_2 = H, R_3 = C_6H_5CO$
11 $R_1 = R_2 = R_3 = H$

Selective proton decoupling was used to unequivocally assign the ^{13}C resonances in several instances (Table 2). Carbon-13 nmr was most effective in monitoring the regiospecificity of the NBS reaction and in conjunction with the proton–proton coupling constant data of Table 1, clearly show that the stereochemistry of the products of the Hanessian–Hullar reaction is consistent with the mechanism first proposed by Hanessian and Plessas (12). It has been pointed out by Thiem and Elvers (17) that this reac-

‡Those compounds for which assignments are based on selective decoupling experiments.

tion has received limited application to pyranosides possessing benzylidene acetals of the 1,3-dioxalane type. The example reported here for the pure diastereoisomers **1***a* and **1***b* provide further evidence that the stereochemistry of the benzylidene acetal does not affect the regiospecificity of the Hanessian–Hullar reaction and that the brominated carbon atom experiences inversion of configuration in the absence of neighbouring group participation.

The bromo sugars **3**, **4**, and **9** were readily and cleanly reduced to the respective benzoylated dideoxyhexosides **5**, **6**, and **10** by hydrogenation over palladium in ethanol solution. Compound **11** previously prepared by Florent and co-workers (5) by reduction of **9** with lithium aluminium hydride had similar chemical characteristics to those reported. We have found it more convenient in larger scale work to perform this and related reductions by catalytic hydrogenation. In the case of the 4-*O*-benzoyl-*xylo*-hexopyranoside (**5**) this approach allows selective blocking at C-2 as has been demonstrated by Garegg and co-workers (7).

The specific rotation of methyl 3,6-dideoxy-α-L-*xylo*-hexopyranoside (**7**) was determined in water, −126.0°, and in chloroform, −149.6°, and compares with the value, +148° obtained for the optical antipode, abequose (**9**). The rotation of the methyl glycoside (**11**) of ascarylose exhibits a similar although less marked dependence upon solvent. High resolution 220 MHz proton spectra (Table 1) for the

glycosides **7** and **11** both in D_2O and $CDCl_3$ require each compound exist as $^1C_4$ chairs (18). The solvent dependence of optical rotation may be either the result of small conformational distortions or the favouring in aqueous solution of that conformer possessing an antiparallel relationship for the aglyconic carbon and ring oxygen atoms. The dihydric nature of water is known to favour this possibility (19–21). The nmr data available to us at present do not allow a choice between these explanations especially since small changes of the torsional angle, $H_a—C_a—C_b—H_b$, need not result in detectable variations of $^3J_{H_a,H_b}$, particularly for complex multiplets, such as those of the axial and equatorial protons at C-3 (22). Further experiments are in progress in an attempt to distinguish between conformational distortion of the $^1C_4$ chair or specific solvation of aglycon rotamers.

Experimental

Thin-layer chromatography was performed with Merck precoated silica gel 60 F-254 plates, and the detection of compounds was achieved by quenching of uv fluorescence and with 5% sulphuric acid in ethanol. Column chromatography utilised silica gel G60 (70–230 mesh) and redistilled solvents. Skellysolve B refers to hexane supplied by Getty Refining and Marketing Company, Tulsa, Oklahoma. Palladium 10% on charcoal was purchased from Engelhard Industries, Newark, New Jersey. Solvents were purified and dried according to standard procedures (23). Processed solutions were dried over anhydrous sodium sulphate and solvent removal was achieved with bath temperatures 40°C or lower unless otherwise stated. Melting points were determined on a Fisher-Johns apparatus and are uncorrected. Optical rotations at the sodium line were measured in a 1-decimetre cell at room temperature (20–23°C). Carbon-13 and ^1H nmr spectra were recorded at 20 and 79.9 MHz, respectively, in the pulsed Fourier transform mode on a Varian CFT-20 spectrometer. Proton spectra recorded at 220 MHz were purchased from the Canadian 220 MHz NMR Centre, University of Toronto. Proton chemical shifts are expressed relative to 1% tetramethylsilane (TMS) for deuteriochloroform solutions and in the case of deuterium oxide, relative to sodium 3-trimethylsilylpropionate-2,2,3,3-d_4 (TSP) 1 mg/ml. Carbon-13 shifts are expressed relative to internal and external TMS for deuteriochloroform and deuterium oxide solutions. Selective heteronuclear decoupling was used to confirm assignments of ^{13}C resonances and homonuclear spin decoupling was used throughout for ^1H nmr.

*Methyl 3,4-*O*-Benzylidene (*S *and* R*)-*α*-L-*fucopyranoside (**1***a and **1***b)*

Methyl α-L-fucopyranoside (24) (20 g, 115 mmol) was added to a solution of α,α-dimethoxytoluene (28 g, 184 mmol) in dry acetonitrile (200 ml) containing toluenesulphonic acid (200 mg). The solution was stirred overnight and then warmed (~50°C) under reduced pressure to complete the reaction. Triethylamine (2 ml) was added before concentration and the syrup which was dissolved in ethyl acetate (300 ml) was extracted with 5% potassium bicarbonate and water. Solvent removal left a colourless syrup (38.5 g) consisting of both diastereoisomers and α,α-dimethoxytoluene. The syrup was dissolved in ethanol and Skellysolve B was added. After several days at room temperature crystals (4.5 g), of pure *R* (H-*exo*) isomer **1***b* were obtained. Further treatment of the mother liquors gave 6.0 g of a crystalline mixture, consisting of *S* and *R* isomers in the ratio 1:2. Trituration of the concentrated mother liquors, 17 g with Skellysolve B removed impurities of α,α-dimethoxytoluene and provided 12.5 g of a homogeneous syrup containing both isomers **1***a* and **1***b*. The total yield of the title compound was 23 g, 77%.

Conversion of the syrup to the *p*-nitrobenzoates **2***a* and **2***b* allowed separation and recovery of pure **1***a* and **1***b*. Crude syrup (8.8 g) containing **1***a* and **1***b* was dissolved in chloroform (100 ml) containing triethylamine (6 ml), *p*-nitrobenzoylchloride (8.2 g) was added and after 16 h the reaction was worked-up in the usual manner. Thin-layer chromatography in Skellysolve B, ethyl acetate 2:1 showed two spots which were separated by column chromatography utilising 600 g of silica gel and the solvent system used for tlc. The *S* isomer **2***a* eluted first (4.0 g), closely followed by the *R* isomer **2***b* (2.3 g). Although both fractions were homogeneous by tlc neither crystallised and after confirmation of purity by ^1H nmr (Table 1), they were immediately converted to the required acetals **1***a* and **1***b*. The syrups were dissolved in dry methanol (50 ml) to which freshly prepared 0.1 *M* sodium methoxide solution (1 ml) was added. After 16 h transesterification was complete and following deionisation with Rexyn 101 (H^+) resin the syrups were applied to short columns of silica gel (1 × 40 cm) and eluted with Skellysolve B – ethyl acetate 3:1 and then ethyl acetate. Pure H-*endo* (**1***a*) and H-*exo* (**1***b*) were recovered from the ethyl acetate solutions and crystallised spontaneously on concentration. Recrystallisation from ethanol – Skellysolve B (*R* isomer) and ether (*S* isomer) gave analytical samples of **1***a* and **1***b*. The physical and analytical data for each isomer were as follows.

S *Isomer*—mp 92–93°C; $[\alpha]_D$ −148.0° (*c* 0.9, $CHCl_3$). *Anal.* calcd. for $C_{14}H_{18}O_5$: C 63.15, H 6.81; found: C 63.41, H 6.90.

R *Isomer*—mp 104–105°C, $[\alpha]_D$ −105.8° (*c* 1.8, $CHCl_3$). *Anal.* found: C 63.29, H 6.78.

*Methyl 4-*O*-Benzoyl-3-bromo-3,6-dideoxy-*α*-*L*-gulopyranoside (**3***) and Methyl 3-*O*-Benzoyl-4-bromo-4,6-dideoxy-*α*-*L*-glucopyranoside (**4***)*

N-Bromosuccinimide (3.6 g, 20.4 mmol) was added to a crystalline mixture of **1***a* and **1***b* (2:1; 4.1 g, 15.4 mmol) and barium carbonate suspended in 200 ml of carbon tetrachloride. The mixture was refluxed with stirring for 30 min, diluted with methylene chloride (200 ml), and filtered. The filtrate was washed with water and concentrated to a syrup. Thin-layer chromatography (Skellysolve B – ethyl acetate 3:1) showed one major and one minor component. Silica gel chromatography with the same solvent system yielded pure **3** (4.2 g, 79%) as a syrup $[\alpha]_D$ −149.1° (*c* 1.3, $CHCl_3$), R_F 0.37, and pure **4** (0.9 g 17%), mp 143–145°C (recrystallized from ether) $[\alpha]_D$ −69.5° (*c* 1.1, $CHCl_3$), R_F: 0.27. *Anal.* calcd. for $C_{14}H_{17}BrO_5$: C 48.71, H 4.96, Br 23.15; found: C 48.61, H 5.01, Br 23.20.

To establish the ratio of products the reaction was carried out exactly as described above but on a 200–300 mg scale with pure samples of **1***a* and **1***b*. After extraction the recovered syrup was dissolved in deuteriochloroform and the ^{13}C nmr spectrum was recorded. Product ratios were based upon peak heights and integrated peak areas for several resonances.

*Methyl 4-*O*-Benzoyl-3,6-dideoxy-*α*-*L*-xylo-hexopyranoside (**5***)*

The 3-bromo compound (**3**) (2.0 g, 5.8 mmol) was hydrogenated at 65 psi at room temperature with 10% palladium-on-charcoal (0.5 g) in ethanol (100 ml) containing triethylamine (1.0 g 10 mmol) for 16 h.

After filtration and concentration, the crystalline residue was dissolved in methylene chloride, washed with aqueous sodium bicarbonate, water, and dried. The concentrated residue was

purified on 200 g of silica gel with the solvent Skellysolve B – ethyl acetate 3:1 to yield pure **5** (1.1 g, 73% yield), mp 118–119°C (recrystallized from Skellysolve B – ethyl acetate), $[\alpha]_D$ −115.1° (*c* 1.0, $CHCl_3$). *Anal.* calcd. for $C_{14}H_{18}O_5$: C 63.15, H 6.81; found: C 62.96, H 6.78.

*Methyl 3-*O*-Benzoyl-4,6-dideoxy-*α*-*L*-*arabino*-hexopyranoside (**6**)*

The 4-bromo compound (**4**) (0.52 g, 1.5 mmol) was hydrogenated with 10% palladium-on-charcoal (0.2 g) in ethanol (30 ml) containing triethylamine (0.25 g, 2.5 mmol) and worked up in precisely the manner described above for compound **5**.

Column chromatography in similar fashion but with Skellysolve B – ethyl acetate, 2:1 yielded crystalline **6** (0.27 g, 68%) mp 79–81°C, $[\alpha]_D$ −178.3° (*c* 1.0, $CHCl_3$). Recrystallisation was effected from ethyl acetate – Skellysolve B.

*Methyl 3,6-Dideoxy-*α*-*L*-xylo-hexopyranoside (**7**)*

The benzoate (**5**) (0.4 g, 1.5 mmol) in methanol solution (50 ml) was stirred overnight with a catalytic amount of sodium methoxide. Deionisation with Rexyn 101 (H^+) resin provided a residue on concentration, which was purified on a silica gel column using ethyl acetate – methanol – water 85:10:5 as solvent. The title compound **7** was obtained as a homogeneous syrup (0.2 g, 80%) which has resisted attempts at crystallisation; $[\alpha]_D$ −126.0° (*c* 1.0, H_2O), $[\alpha]_D$ −149.6° (*c* 1.0, $CHCl_3$), R_F 0.49 (ethyl acetate – methanol – water 85:10:5).

*Methyl 2,3-*O*-Benzylidene-*α*-*L*-rhamnopyranoside (**8**)*

A solution of methyl α-L-rhamnopyranoside (25) (10.0 g, 56.2 mmol) and α,α-dimethoxytoluene in dry acetonitrile (50 ml) containing 2 g of Rexyn 101 (H^+) resin was rotated under reduced pressure on the rotary evaporator at a temperature of 50°C. The pressure was adjusted so as to avoid excessive evaporation of solvent. After 2 h the acetonitrile was evaporated and the residue dissolved in methylene chloride was filtered, dried, and concentrated. Purification on a silica gel column (Skellysolve B – ethyl acetate 3:1) gave pure **8** (10.1 g, 73%), a 1:1 mixture by ^1H nmr of both diastereoisomers; $[\alpha]_D$ −25.5° (*c* 1.1, $CHCl_3$). *Anal.* calcd. for $C_{14}H_{18}O_5$: C 63.15, H 6.81; found: C 62.98, H 6.89.

*Methyl 2-*O*-Benzoyl-3-bromo-3,6-dideoxy-*α*-*L*-altro-hexopyranoside (**9**)*

The benzylidene acetal (**8**) was subjected to the Hanessian–Hullar reaction in the same molar quantities as were compounds **1***a* and **1***b*. Reaction was complete after 45 min and work-up was conducted in the normal way. Column chromatography silica gel with Skellysolve B – ethyl acetate, 3:1) gave pure **9** (4.5 g, 85%) as a syrup $[\alpha]_D$ +11.3° (*c* 1.3, $CHCl_3$) (lit. (5) $[\alpha]_D^{20}$ +12°).

*Methyl 2-*O*-Benzoyl-3,6-dideoxy-*α*-*L*-arabino-hexopyranoside (**10**)*

The hydrogenation of compound **9** was conducted in a similar manner to that described for the gulopyranoside (**3**). Silica gel column chromatography with Skellysolve B – ethyl acetate 1:1 as solvent gave **10** (1.1 g, 71%) as a homogeneous syrup $[\alpha]_D$ −37.2° (*c* 1.0, $CHCl_3$).

*Methyl 3,6-Dideoxy-*α*-*L*-arabino-hexopyranoside (**11**)*

The benzoate compound (**10**) (0.53 g, 2.0 mmol) was added to a solution of methanol (50 ml) containing a catalytic amount of sodium methoxide. After 16 h the reaction was worked up as described for **7**. Column chromatography in a manner similar to that used for compound **7** gave **11** (0.28 g, 87%), mp 82–84°C, $[\alpha]_D$ −118.7° (*c* 0.9, H_2O), $[\alpha]_D$ −127.7° (*c* 1.0, $CHCl_3$). Recrystallisation was effected from chloroform (lit. (5) mp 80–81°C, $[\alpha]_D^{20}$ −103° (H_2O)).

Solvent effects on the structure of S_N2 transition states

KENNETH CHARLES WESTAWAY

Department of Chemistry, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received April 11, 1978

KENNETH CHARLES WESTAWAY. Can. J. Chem. **56**, 2691 (1978).

Two research groups have used heavy atom leaving group kinetic isotope effects to determine how the structure of an S_N2 transition state is affected by a change in solvent. Two completely different types of behaviour were observed in these studies. In one case, the leaving group kinetic isotope effect, and thus the transition state structure, changed markedly when the solvent was varied over a reasonably narrow range. In the other study, the leaving group kinetic isotope effect (transition state structure) remained constant over a wide range of solvents. A model describing the interaction between solvent molecules and S_N2 transition states is developed and a *Solvation rule for S_N2 reactions* which rationalizes the different experimental results is explained and justified. Finally, predictions based on the solvation rule are shown to be in agreement with the results of theoretical calculations of solvent effects on S_N2 transition states and secondary α deuterium kinetic isotope effect measurements.

KENNETH CHARLES WESTAWAY. Can. J. Chem. **56**, 2691 (1978).

Deux groupes de recherches ont déjà utilisé les effets isotopiques cinétiques d'atomes lourds agissant comme nucléofuges dans le but de déterminer quel est l'effet d'un changement de solvant sur un état de transition S_N2. Deux ensembles de comportement complètement différents ont pu être observés au cours de ces études. Dans un cas, un faible changement de solvant produit un changement sensible dans l'effet isotopique cinétique du nucléofuge, et par conséquent dans la structure de l'état de transition. Dans l'autre étude, malgré des changements de solvants importants l'effet isotopique cinétique du nucléofuge (ainsi que la structure de l'état de transition) demeure relativement constant. On a développé un modèle décrivant l'interaction entre des molécules de solvants et les états de transition S_N2; on explique aussi, en y apportant les justifications nécessaires, une *Règle de solvatation des réactions S_N2* qui rationalise les différents résultats expérimentaux. Enfin, on montre que des prédictions faites sur la base de la Règle de solvatation sont en bon accord avec les résultats de calcul théoriques des effets de solvants sur les états de transition S_N2 et avec les mesurages de l'effet isotopique cinétique secondaire d'un deuterium en α.

In recent years considerable attention has been focused on the effects of changing the solvent on the rates, products, and mechanisms of organic reactions (1–4). One area of study that has been of particular interest is an investigation of the effect of a solvent change on simple bimolecular nucleophilic substitution reactions (S_N2) at saturated carbon (1, 5). In fact, several workers have attempted to measure and understand the interaction of solvents with reactants and transition states by examining the changes in (*i*) the rates of reaction (1, 6, 7), (*ii*) the thermodynamic properties of both the initial and the transition states (1–3), and most recently (*iii*) the effect of solvent change on the structure of the transition states in S_N2 reactions (8, 9).

Two sets of workers, Hargreaves, Katz, and Saunders (8) and Graczyk, Taylor, and Turnquist (9), have used leaving group heavy atom kinetic isotope effects to examine the effect of changing the solvent on the structure of the transition states of simple bimolecular (S_N2) nucleophilic substitution reactions. At present, the results from these two different groups are in serious conflict. Saunders and co-workers found that both the rate constant and the leaving group heavy atom (sulfur) kinetic isotope effect varied markedly when the composition of the solvent was changed from ethanol to various mixtures of ethanol and dimethylsulfoxide in the S_N2 reaction of ethoxide ion with trimethylsulfonium ion, reaction [1], and concluded that the structure of the transition state is altered significantly when the solvent is changed.

$$[1]\quad C_2H_5O^- + CH_3\text{—}\overset{+}{S}(CH_3)_2 \rightarrow [C_2H_5\overset{\delta-}{O}\text{---}CH_3\text{---}\overset{\delta+}{S}(CH_3)_2] \rightarrow C_2H_5OCH_3 + (CH_3)_2S$$

Taylor and co-workers, on the other hand, observed that although the rate constant changed by three orders of magnitude when the solvent was changed in the S_N2 reaction of thiophenoxide ion with *n*-butylchloride, reaction [2],

$$[2]\quad C_6H_5S^- + n\text{-}C_4H_9Cl \rightarrow [C_6H_5\overset{\delta-}{S}\text{---}\overset{CH_3}{\overset{|}{(CH_2)_2}}\text{---}\overset{\delta-}{Cl}] \rightarrow C_6H_5S(CH_2)_3CH_3 + Cl^-$$

the leaving group heavy atom (chlorine) kinetic isotope effect, and thus the structure of the transition state, did not change appreciably even over a wide range of protic and aprotic solvents.

The apparent discrepancy between these two studies, in which the structure of the transition state changes markedly with solvent in the one case and remains unchanged in the other case, can be rationalized by the solvation rule presented in this paper.

Development of the Basis for the Solvation Rules

A closer examination of Tables 1 and 2, which present the experimental results obtained for reactions [1] and [2], respectively, shows that the rate constants become larger as the solvent is changed from a protic to a dipolar aprotic solvent. These changes are expected because it is well known that the rate constants of S_N2 reactions become larger as the solvent becomes more aprotic in character (1, 10, 11). The increase in rate constant is the result of two factors. (*1*) Several studies (1, 12, 13) have demonstrated that negatively charged nucleophiles and small, highly charged nucleophiles in particular, are less solvated (higher free energy) in dipolar aprotic solvents than in protic solvents. Changing to a more dipolar aprotic solvent leads to an increase in the free energy of the reactants and thus to an increase in rate. (*2*) Haberfield and co-workers (5, 14–16) and Fuchs and Cole (17) have shown that the free energies of S_N2 transition states that do not have very small highly charged nucleophiles are more highly solvated in dipolar aprotic solvents than in protic solvents regardless of the charges on the nucleophiles in the transition state. In fact, Haberfield concluded that increased solvation of the transition state is the major contributor to the larger rate constants in the dipolar aprotic solvents. In any case, a combination of these two factors easily accounts for the increases observed in the rate constants for the S_N2 reactions in Tables 1 and 2.

Haberfield's studies, which indicate that the transition state undergoes large changes in free energy when the solvent is changed, suggest that the structure of the transition state should change when the solvent is altered. If this were the case, the magnitude of the leaving group heavy atom kinetic isotope effect, which is a measure of the carbon–leaving group bond length in the transition state, would be expected to change as the solvent is changed. This is obviously consistent with the results obtained by Hargreaves, Katz, and Saunders (Table 1) but is completely opposite to those of Graczyk, Taylor, and Turnquist who found an almost constant chlorine kinetic isotope effect (1.00944 ± 0.00012, with a maximum error of 0.00015 in each isotope effect) over a wide range of protic and aprotic solvents (Table 2). These unexpectedly constant chlorine kinetic isotope effects suggested that the interaction between solvent and an S_N2 transition state could influence the actual bond lengths in the transition state. The following arguments suggest a mechanism for the stabilization of S_N2 transition states by solvent and lead to a *Solvation rule for S_N2 reactions*. This rule rationalizes the results obtained by both research groups and successfully predicts how the structure of an S_N2 transition state is altered when the solvent is varied.[1]

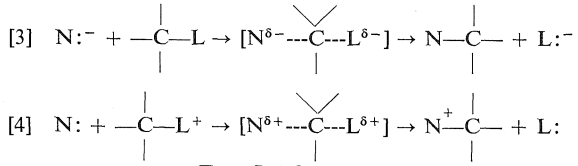
The first assumption required in this theory of solvent effects on transition state structure is that the solvent influences the free energy of an S_N2 transition state by interacting (solvating) primarily, if not exclusively, with the entering and leaving

[1]Although theoretical calculations of the transition state structure for the reaction $F^- + CH_3F' \rightarrow CH_3F + F'^-$ do not agree in detail, they do indicate that the transition state is a very polar species (18–20). The average amount of positive charge on the α carbon is 0.43 ± 0.15 and the average charge on the fluorides is -0.64 ± 0.2. These results are in general agreement with the charge densities reported in other studies (18, 20).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

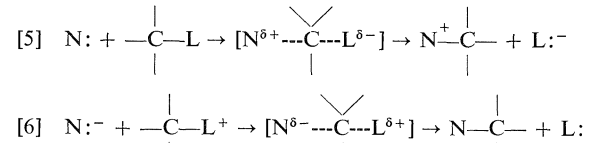
groups, which are both nucleophiles. This assumption is reasonable because (*i*) theoretical calculations indicate that the α carbon in an S_N2 transition state bears a relatively small positive charge, whereas the nucleophiles are more highly charged (18–21),[1] and because (*ii*) the smaller positive charge on the α carbon in the transition state is shielded from solvent. The electron deficient α carbon is bonded to three hydrogens and/or bulky alkyl or aryl groups in addition to the attacking nucleophile and the leaving group. As a result, the partial positive charge on the α carbon is surrounded or buried in the pentavalent transition state and any interaction with the solvent would be expected to be small,[2] especially compared to the interaction between solvent and the more highly charged, less sterically crowded nucleophiles at the axial positions of the trigonal bipyramid. Thus, the substantial amount of negative charge on the nucleophiles in an S_N2 transition state, coupled with the steric hindrance to solvation of the smaller positive charge on the α carbon, strongly suggests that the solvent interacts mainly, if not exclusively, with the entering and leaving nucleophiles. This hypothesis is supported by the chlorine kinetic isotope effects measured by Cromartie and Swain (22, 23) as well as theoretical calculations of chlorine leaving group kinetic isotope effects for an S_N1 reaction by Sims and co-workers (24, 25). Both sets of workers have concluded from work on different S_N reactions that the interaction between the solvent and the nucleophiles in the transition state is very important.

In considering the interaction between the solvent and the nucleophiles in an S_N2 transition state, it was apparent that there are two different types of transition states. First, there is the case where both the attacking nucleophile, N, and the leaving group, L, have the same charge, i.e., both are negatively charged or both are neutral, reactions [3] and [4], respectively. These reactions are identified as Type I S_N2 reactions.



Type I S_N2 Reactions

A Type II S_N2 reaction is defined as one involving a neutral and a negatively charged nucleophile, reactions [5] and [6].



Type II S_N2 Reactions

If the transition state of a Type I S_N2 reaction, with both nucleophiles negatively charged, is transferred from the gas phase to solution, the solvent will interact with the two partially charged nucleophiles, $N^{\delta-}$ and $L^{\delta-}$, and lower the free energy of the transition state. If this transition state were then transferred to a different solvent, the interaction between the partially charged nucleophiles, $N^{\delta-}$ and $L^{\delta-}$, and the solvent (solvation energies) would be different. The free energy of the transition state will vary from one solvent to another depending on the solvation energies of N and L and the rate constant should change with solvent. This is observed (1, 8, 9).

A second assumption required by this theory is that the change in the solvation energy of the negatively charged nucleophiles in the transition state resulting from a change in solvent will be equal or very nearly equal. This is reasonable because both N and L will have the same kind of partial charge in the transition state and may even have approximately the same charge density.[3] If this is the case, each new solvent will interact either more or less strongly with each nucleophile but whether the change in solvent lowers the free energy by solvating (bonding) more tightly or strongly with the nucleophiles or increases the free energy by solvating the nucleophiles less strongly (i.e., either more loosely, by shedding solvent molecules, or by a different mechanism such as a weak anion–dipole interaction in a dipolar aprotic solvent rather than the stronger hydrogen bonding in a protic solvent) the change in the interaction between the negatively charged nucleophiles in the transition state and the solvent will be the same or virtually the same for both nucleophiles. As a result, the *relative* electron density or nucleophilicity of N and L would not be altered by a change of solvent and the structure of the transition state would not be changed even though its free energy had been changed.

It might be expected that the absolute electron density on both N and L would be changed by a variation in solvent and that this should cause a

[2]Any interaction between the more polarized α carbon–hydrogen bonds of the transition state and the solvent would also be small.

[3]This suggests that the lengths of the N—C_α and the C_α—L bonds are such that the charge density on N and L will be approximately the same in the transition state. Although this may be the case, there is no firm evidence to establish this point. In any case, the charge on N and L should be reasonably close for most reactions. (See the section on Limitations of Applying the Solvation Rule.)

tightening or loosening of the transition state. This would not occur, however, since the solvent would only interact with the electron density at the back of the nucleophiles but not with the electron density in the area between N and L and along the N---C---L bond axis. The electron density in the area between the nucleophiles is held very strongly by the positively charged N, C_α, and L nuclei and would only be altered by a large change in the electron density at N, at L, or at both N and L. Since solvent molecules only interact with the less sterically crowded and more loosely held electron density at the back of the nucleophiles, and since this would occur equally at N and L, the change in electron density at N and L resulting from a change in solvation would not be sufficient to alter the more strongly held electron density in the area between N and L. Consequently, the structure of the transition state would not be altered by a change in solvent. This theory should also apply to the case where both the attacking nucleophile and the leaving group are neutral species since the two nucleophiles in the transition state would again have the same charge and interact similarly with a given solvent.

In a Type II S_N2 transition state, on the other hand, a neutral nucleophile and a negatively charged nucleophile are present. Here the charges on the two nucleophiles are different, and thus the solvation energies of the two nucleophiles would be quite different. For example, if the reaction involved a negatively charged nucleophile and a neutral leaving group (reaction [6]) then a protic solvent would interact with the partial negative charge on the attacking nucleophile, $N^{\delta-}$, via a strong hydrogen bonding interaction, whereas it would solvate the partial positive charge on the leaving nucleophile, $L^{\delta+}$, by a much weaker ion–dipole type of interaction. If the solvent were changed to a dipolar aprotic solvent, the two nucleophiles would again interact with solvent in a different fashion. The partially negative nucleophile, $N^{\delta-}$, would now be solvated by an ion–dipole interaction involving the positive end of the solvent dipole whereas the partially positive nucleophile, $L^{\delta+}$, would be solvated by an ion–dipole interaction with the negative end of the solvent dipole.

Thus the solvation energies of the two nucleophiles would be substantially different in every solvent. Of even greater importance, however, is the fact that changing from a protic to a dipolar aprotic solvent, for example, will result in a very large difference in the relative solvation energies of the two nucleophiles in the transition state. In these circumstances, the change in the solvation energies at the two nucleophiles $N^{\delta-}$ and $L^{\delta+}$ would be large enough to cause a shift in the electron density in the area between the N and L atoms along the N---C_α---L bond axis of an S_N2 transition state. As a result, the structure of the transition state would be altered. Obviously this prediction should apply to the equivalent case in which the attacking nucleophile is a neutral species and the leaving group is negatively charged.

Finally, a *Solvation Rule for S_N2 Reactions* can be formulated. It states that *A change in solvent will not lead to a change in the structure of an S_N2 transition state if the charges on the two nucleophiles in the transition state are the same* (a Type I reaction), *but will lead to a change in the structure of the transition state when a negatively charged nucleophile and a neutral nucleophile* (a Type II reaction) *are present in the transition state.*

The *Solvation rule for S_N2 reactions* can be applied to the reactions shown in [1] and [2]. Reaction [1], in which a neutral nucleophile, dimethylsulfide, is displaced by a negatively charged nucleophile, ethoxide ion, is an example of a Type II S_N2 reaction. The solvation rule predicts that a change in solvent will lead to a change in structure of the transition state for Type II reactions and this is what is observed. The sulfur leaving group kinetic isotope effects decrease markedly from almost 1% in ethanol to a third of this value, 0.35%, in 65 mol% DMSO. Since theoretical calculations have shown that the magnitude of the leaving group kinetic isotope effect increases linearly with the amount of C_α---S bond rupture in the transition state (26), it must be concluded that the C_α---S bond is substantially shorter in the more dipolar aprotic solvent and that the structure of the transition state changed significantly when the solvent was varied over even a reasonably small range.

The solvation rule for S_N2 reactions is also consistent with the results reported by Graczyk, Taylor, and Turnquist for the Type I S_N2 reaction in which a negatively charged attacking nucleophile, thiophenoxide ion, displaces a negatively charged leaving group, chloride ion, from *n*-butyl chloride (reaction [2], Table 2). In this case, the chlorine kinetic isotope effects do not change over a very wide range of solvents and thus the length of the C_α---Cl bond in the transition state is not altered significantly by a change of solvent. Since it is unlikely that the structure of the transition state could shift without a change in the C_α---Cl bond length, it was concluded that a change in solvent did not lead to a change in the structure of the transition state, as the rule predicts.

Justification for the Solvation Rule

A better understanding of the solvation rule can be obtained by examining the ionic free energy of transfer between protic and dipolar aprotic solvents

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(ΔG_{tr}). Cox (12) has recently reported the ionic enthalpies and entropies of transfer of ions from water to dimethylsulfoxide (DMSO). The corresponding ionic free energies of transfer calculated from these values are shown in Table 3. The cations are all more strongly solvated (lower free energy) in DMSO and a comparison of these data with those of Parker (1), Choux and Benoit (13), and others (27–29) suggests that all monovalent cations have very similar ionic free energies of transfer. This means that the average cationic species is 3.1 ± 0.6 kcal/mol more stable in a dipolar aprotic solvent and this average value can be used in the following calculations without introducing a substantial error. Anions, on the other hand, are less solvated in DMSO than in water, and the differences in the solvation energies are larger, i.e., the average value based on the nucleophiles in Table 3 and others (1, 17) would appear to be about 6.1 ± 3 kcal/mol. In fact, most of the nucleophiles used in S_N2 reactions have ionic free energies of transfer of about 6 kcal/mol.

The effect of changing the solvent from water to DMSO on a Type II S_N2 transition state can be estimated in the following manner. The polar transition state can be approximated by a three atom molecule with a positively charged atom at one end, a neutral atom in the middle, and a negatively charged atom at the other end. If this species were transferred from water to DMSO, the free energy of the positively charged atom would be lowered (more strongly solvated) on the average by 3.1 kcal/mol. The average anion in the model transition state would be less strongly solvated by 6.1 kcal/mol in DMSO. The total (absolute) difference in solvation between the two ionic species in the model of the transition state would be large, i.e., approximately 9.2 kcal/mol for the average nucleophile. The extreme differences are 12.3 kcal/mol for chloride ion (the least solvated anion in DMSO) and 6.3 kcal/mol for iodide (the most strongly solvated anion in DMSO).[4] This simplified approach illustrates the direction of the difference in solvation energies of the partially charged nucleophiles but overestimates the magnitude of this difference for two reasons. First, the nucleophiles are only partially charged in the transition state and, secondly, only the backside of the nucleophile is free to interact with solvent molecules. As a result, only a portion of the total difference in energy described above should be observed for a real transition state. For example, if the magnitude of the effect is arbitrarily taken as

[4]Some other anions such as fluoride and hydroxide ions would lead to even larger values than 12.3 kcal/mol. Iodide ion has the smallest ionic free energy of transfer of all the anions.

TABLE 3. Free energies of transfer of ions from water to dimethylsulfoxide at 25°C (12)

25% of that calculated for the fully charged totally free ions, the differences in the free energy of solvation between the two nucleophiles, $N^{\delta+}$ and $L^{\delta-}$, in a transition state would be between 3.1 and 1.6 kcal/mol with most values near 2.3 kcal/mol. In Type II S_N2 transition states these differences in free energies of solvation of the nucleophiles is large enough to cause a distortion in the electron density between the nucleophiles in the transition state and, as a result, the structure of the transition state should change when the solvent is changed.

For a Type I S_N2 transition state with both nucleophiles negatively charged, the change in the solvation energy of the two nucleophiles, $N^{\delta-}$ and $L^{\delta-}$, is much smaller. It can be seen from Table 3 that the maximum difference in the solvation energies associated with a change in solvent from water to DMSO would occur when the nucleophiles in the transition state were chloride and iodide ions. In this case the difference in solvation energies in the two solvents is only 6.0 kcal/mol. For any other combination of nucleophiles the difference would be less than 2.5 kcal/mol and, for most combinations, the difference would be less than 1 kcal/mol. If the magnitude of the difference in free energy of solvation of the two nucleophiles in the transition state is again taken as 25% of that for the free ions, the *maximum* difference expected for a Type I S_N2 transition state is 1.5 kcal/mol and most reactions would have a difference in the range of 0.6–0.2 kcal/mol. Obviously the difference in the solvation energies of two neutral nucleophiles, which would bear partial positive charges in the transition state, would be very small (<0.2 kcal/mol). Because the differences in the solvation free energies of the nucleophiles in a Type I S_N2 transition state are only about one fourth of those found in Type II S_N2 transition state, it follows that solvent variations would not distort the more strongly held electron density in the area between the nucleophiles significantly. As a result, the structure of the transition state would not change appreciably when the solvent is varied.

It is worth re-examining reactions [1] and [2] in the light of the above discussion. The free energies of transfer of the ethoxide ion and the trimethyl-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

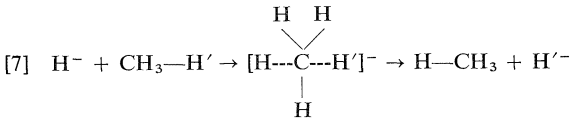
sulfonium ion involved in reaction [1], as well as the thiophenoxide ion used in reaction [2], can be estimated from data published by Parker (1). The free energy of transfer from water to DMSO for the ethoxide ion should be slightly less than that observed for chloride ion, i.e., about 8 kcal/mol, while the value for the trimethylsulfonium ion should be near that for the rubidium cation (−2.6 kcal/mol). Using the method described above, the difference in the solvation energies of the nucleophiles in water and in DMSO for the transition state of reaction [1] would be approximately $|8.0 - (-2.6)| \times 25/100 = 2.7$ kcal/mol. This is near the upper limit predicted for a Type II S_N2 reaction and it is, therefore, not surprising that Saunders and co-workers found that the structure of the transition state was extremely sensitive to a change in solvent.

The free energy of transfer from water to DMSO for the thiophenoxide ion used in reaction [2] should be approximately equal to that observed for bromide ion (1), i.e., about 6 kcal/mol. The change in the solvation energies of the nucleophiles expected when the S_N2 transition state for reaction [2] is transferred from water to DMSO would be approximately $|9.2 - 6| \times 25/100 = 0.8$ kcal/mol. This difference in solvation energies is larger than that expected for most Type I S_N2 reactions. The observation that a large change in solvent does not lead to a change in the structure of the transition state for a Type I reaction even when the difference in solvation energies of the nucleophiles is large, suggests that the *Solvation rule for S_N2 reactions* will be very successful in predicting the effects of changing the solvent on the structure of the transition state.

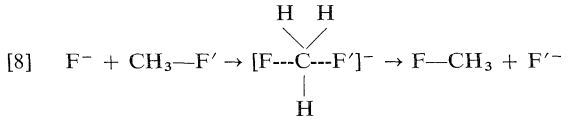
Finally, if enough information on the free energies of transfer of ionic species from water to DMSO were available, it should be possible to determine the minimum value for the difference in solvation energies of the nucleophiles which would lead to a change in structure of the transition state when the solvent is changed. At present this value cannot be determined, although the results obtained for reaction [2] suggest that a value significantly greater than 0.8 kcal/mol would be required before the structure of the transition state would respond to a change in solvent.

Theoretical Calculations of Solvent Effects on Transition State Structure

Simonetta and co-workers (20, 30) have estimated the solvent effect on transition state structure by using *ab initio* and CNDO 2 calculations to define the structure of a transition state in different solvents. In particular, the structure of the transition states for two Type I S_N2 reactions, hydride ion with methane, reaction [7], and fluoride ion with methyl fluoride, reaction [8], have been calculated in both the gas phase and in an approximation of an aqueous medium



[7] $H^- + CH_3—H' \rightarrow [H---C(H)(H)---H']^- \rightarrow H—CH_3 + H'^-$



[8] $F^- + CH_3—F' \rightarrow [F---C(H)(H)---F']^- \rightarrow F—CH_3 + F'^-$

In both cases the structure of the transition state did not change substantially when the solvent was changed. The C---H bonds in the transition state of reaction [7] were 1.225 Å when no solvent was present and when each hydride ion was solvated by one water molecule. The methyl fluoride transition state was essentially the same in the gas phase and in solution where each fluoride ion was solvated by four water molecules. In fact, the only difference in the structure of the transition state was that the C---F bonds were 1.8% longer (1.466 Å from 1.439 Å) in solution. The observation of a virtually constant C---F bond length is especially important in this system because eight very strong hydrogen bonds are formed and the energy of the transition state is decreased by over 100 kcal/mol. In fact, the solvent change in this calculation probably represents a greater change in solvent than could be realized experimentally in a kinetic study. Finally, the fact that the carbon–nucleophile and the carbon – leaving group bonds in the transition state are not changed significantly by large changes in solvent in these systems is strong support for the *Solvation rule for S_N2 reactions* which predicts that Type I S_N2 transition states should be independent of solvent.

Implications on Theoretical Calculations of Transition State Structure

The solvation rule has important implications for those calculating the structure of the transition states for S_N2 reactions. The solvation rule states that Type I S_N2 transition states are not altered by a change in solvent. This means that theoretical calculations will give accurate structures for the transition states of these reactions whether they are carried out in gas phase or in solution. As a result, theoretical calculations should provide a valuable contribution to our understanding of this important class of reaction.

Unfortunately, this does not apply to all S_N2 reactions since the structure of a Type II S_N2 transition state is strongly solvent dependent. Thus theoretical (gas phase) calculations can only provide a very crude approximation of the structure of the

[a]These error limits are the standard deviations corresponding to the average value of the isotope effects.
[b]2,2,2-Trifluoroethanol.
[c]The error limits for these isotope effects were not given. These values were obtained from rate constants obtained using a conductometric method of analysis and should have errors of approximately ±0.002.
[d]This isotope effect was determined for $C_6H_5CH_2Cl$ and $C_6D_5CD_2Cl$. The isotope effect for ring deuteration in these S_N2 reactions would be extremely small and the total isotope effect observed can be attributed to the α deuterium atoms.
[e]Unpublished results from this laboratory indicate that this reaction proceeds by an S_N2 mechanism within a triple ion of the form $[(R_4N^+)_2Br^-]^+$.

transition state for reactions in solution and theoretical calculations will be of little use in studying these reactions.

Evidence Based on Secondary α Deuterium Kinetic Isotope Effects

Secondary α deuterium kinetic isotope effects $(k_H/k_D)_\alpha$ have been measured for several S_N2 reactions in different solvents. Although the relationship between the magnitude of these isotope effects and transition state structure is not known, current theory states that these isotope effects arise primarily from changes that occur in the C_α—H out-of-plane bending vibrations when the substrate is converted into the transition state (31, 32). A change of solvent does not alter the force constants for the C_α—H bending vibrations in the substrate significantly (33) and the same should be true for the transition state provided that the structure of the transition state is the same in the two solvents.[2] If this were the case, the changes in the C_α—H out-of-plane bending vibrations would be identical and the magnitude of the secondary α deuterium kinetic isotope effect would be the same in the two solvents. If the structure of the transition state was different in the two solvents, the changes in the C_α—H out-of-plane bending vibrations would be different and the magnitude of the isotope effect would change with solvent. Thus, the magnitudes of the secondary α deuterium kinetic isotope effect in different solvents can be used to indicate if the structure of the transition state is altered by a change in solvent. As a result, these isotope effects can be used to test the validity of the *Solvation rule for S_N2 reactions.*

An examination of the isotope effects in Table 4 shows that the results are consistent with the predictions of the solvation rule. The magnitudes of the secondary α deuterium kinetic isotope effects for the Type II S_N2 reactions of the *para*-substituted benzylbrosylates change significantly over a relatively narrow range of protic solvents. In all but one case, the isotope effects differ by at least ten times the standard deviations for the individual isotope effects. Thus, each isotope effect is significantly different and it must be concluded that the structure of the transition state is altered by a change in solvent. The isotope effect for the reaction between bromide ion and benzyldimethylphenylammonium ion also

For personal use only.

changes markedly even though the two solvents are closely related dipolar aprotic solvents. The structure of the transition state for this reaction is also very sensitive to a change in solvent. A similar variation is observed in the inverse isotope effects (transition state structure) measured for the S_N2 reaction between methyl iodide and pyridine. The very high precision of these isotope effects forces one to conclude that the structure of the transition state in Type II S_N2 reactions is altered by a change in solvent. This is predicted by the solvation rule.

Type II S_N2 reactions, which require either a neutral nucleophile or a neutral leaving group, can be monitored by measuring the conductivity of the reaction mixture (34–36). This method has produced the most accurate rate constants reported and leads to very precise kinetic isotope effects. Unfortunately, conductivity cannot be used to study Type I S_N2 reactions where both nucleophiles are negatively charged. This means that the isotope effects for these reactions are less precise and thus provide a less stringent test of the solvation rule. The results for the Type I reactions of benzyl chloride illustrate this point. The standard deviations for the individual isotope effects are two to nine times larger than those of the Type II reactions. Within these limitations, however, the magnitudes of the secondary α deuterium kinetic isotope effects are the same. This indicates that the structure of the transition state is not altered by a change in solvent. This conclusion is justified for two reasons. First, the difference between the maximum and minimum values of the isotope effects is less (3.5%) than those observed for the Type II reactions (4.4, 5.6, 4.9, and 6.1%). The second reason is that the isotope effects for the Type I reaction are constant over a much broader range of solvent, i.e. the solvent is changed from the dipolar aprotic solvents, DMSO and DMF, to the protic solvent, *n*-BuOH. In the Type II reactions, larger changes in isotope effect are observed over a relatively narrow range of protic (34) and over a very narrow range of dipolar aprotic solvents (35, 36). Finally, although the case is weaker for Type I reactions, the results for all six reactions are consistent with the predictions of the solvation rule.

Possible Limitations in Applying the Solvation Rule for S_N2 Reactions

It is possible to conceive some circumstances in which the *Solvation rule for S_N2 reactions* might fail to predict the experimental result correctly. For example, a problem could arise if one of the partially charged nucleophiles in the transition state were much more sterically shielded from the solvent than the other in a Type I S_N2 transition state. In this case, a change in solvent would probably produce large differences in the solvation energies of the two nucleophiles in the transition state (a result opposite to that predicted by the *Solvation rule for S_N2 reactions*) and a change in the transition state might be observed.

The solvation rule could also fail if an ionic group which interacted strongly with solvent was either on the α carbon or on a group bonded to the α carbon. For example, if one of the groups on the α carbon were a phenoxide ion, the solvation of this group would be different in each solvent, and could alter the charge density on the α carbon in the transition state. If this occurred, a substantial and unexpected change in the structure of the transition state might result.

Another area of concern is for a Type I S_N2 reaction with a very small highly charged anion such as fluoride ion or hydroxide ion, and a large polarizable anion such as iodide ion, in the transition state. The differences in the solvation energies of the anions in water and a dipolar aprotic solvent could easily be as large for the $F^{\delta-}$---C---$I^{\delta-}$ transition state as for a Type II S_N2 transition state.[5] In these circumstances, a change of solvent may well lead to a change of structure in the transition state.

A similar problem might be expected with very reactant-like (early) or very product-like (late) Type I S_N2 transition states. One nucleophile is essentially neutral while the other is almost fully charged in these transition states and the difference between the solvation energies of the nucleophiles will be large. In fact, the difference in solvation energies could be large enough to cause the structure of the transition state to change with a change in solvent. Although the solvation rule would be expected to fail in these circumstances, there is some evidence to suggest that this is not probable. The leaving group heavy atom kinetic isotope effects measured for a wide variety of S_N2 reactions are reasonably large; their magnitude varies from approximately 30 to 70% of the theoretical maximum isotope effect (8, 9, 24, 38–41). This means that the α carbon – leaving group bond is substantially, but not nearly completely, broken in the transition state (26). The nucleophile – α carbon bond is also fairly long in three related S_N2 transition states (41). If this is a general phenomenon, S_N2 transition states are close to the symmetrical model on which the solvation rule is based and exceptions to the rule should be rare.

Finally, extensive aggregation or ion-pairing of salts in aprotic solvents could lead to incorrect

[5]If the free energy of transfer (ΔG_{tr}) of a fluoride ion is 10 kcal/mol, the difference in the solvation energies of the transition states would be $|10 - 3.2| \times 25/100 = 1.7$ kcal/mol. This value is in the range predicted for Type II S_N2 reactions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

predictions by the solvation rule. Many ionic compounds are only sparingly soluble in aprotic solvents and exist primarily, if not completely, as ion-pairs in solution (42). In cases where ion-pairing is important, incorrect predictions might result from the solvation rule because the properties of a nucleophile would be expected to be quite different when it is tied together with a cation in an ion-pair than when it exists as a totally free ion in solution. Thus, when extensive ion-pairing accompanied a change in solvent, the nucleophile would, in effect, be changed. This would be equivalent to a change in one of the reacting species and a change in the structure of the transition state would be expected regardless of the predictions of the solvation rule. Unfortunately, there are no experimental results which clearly illustrate this or the other possible limitations in applying the solvation rule.

In conclusion, the *Solvation rule for S_N2 reactions* provides a model for the interaction between S_N2 transition states and the solvent and predicts how the structure of the transition state will be altered by a change in solvent. Finally, the results of two studies involving leaving group heavy atom kinetic isotope effects, six studies using secondary α deuterium kinetic isotope effects, and two theoretical studies of S_N2 reactions are in complete agreement with the predictions based on the solvation rule. The extension of the *Solvation rule for S_N2 reactions* to S_N reactions involving carbonium ion intermediates will be discussed in a subsequent paper.

Stereospecific synthesis of (−)-α-multistriatin from D-glucose

PHAIK-ENG SUM AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received July 24, 1978

PHAIK-ENG SUM and LARRY WEILER. Can. J. Chem. **56**, 2700 (1978).

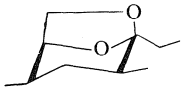
A totally stereospecific synthesis of the insect pheromone, (−)-α-multistriatin, is reported starting from D-glucose.

PHAIK-ENG SUM et LARRY WEILER. Can. J. Chem. **56**, 2700 (1978).

On rapporte la synthèse totalement stéréospécifique de la phéromone d'insecte, la (−)-α-multistriatine, à partir du D-glucose.

[Traduit par le journal]

α-Multistriatin (**1**) is one of the essential components of the aggregation pheromone of the European elm bark beetle, *Scolytus multistriatus*, which is the principal vector of Dutch elm disease in North America (1). The severe devastation of elm populations in eastern North America has resulted in extensive studies on the isolation (2), structure elucidation (3), synthesis (4), and field utilization (5) of α-multistriatin. The three other diastereomers of **1** have been



1

found to be biologically ineffective as attractants (5); however, all previous syntheses (4) of α-multistriatin have been nonstereoselective and have led to formation of the diastereomers of **1** in various amounts. We report a fully stereoselective synthesis of naturally occurring (−)-α-multistriatin with the relative and absolute configuration shown in **1**.

The epoxide **3** (6), prepared from D-glucose (**2**), gave a 75% yield of the 2-deoxy sugar **4** (7) on treatment with dimethyllithium cuprate. The alcohol **4** was converted into the corresponding xanthate **5** (7) in 94% yield and the resulting xanthate was deoxygenated with tri-*n*-butylstannane (8) to yield compound **6**, $[\alpha]_D^{28}$ +82.7° (142 mg/ml, ether), mp 70–72°C, in 90% yield from **5**. The benzylidene group in **6** was hydrolyzed (7) in 91% yield to give the diol **7** which was converted into the trityl ether **8**, $[\alpha]_D^{26}$ +26.0° (200 mg/ml, chloroform), mp 147–149°C, in 87% yield (9). Alcohol **8** was oxidized with chromium trioxide – pyridine (10) producing ketone **9**, $[\alpha]_D^{28}$ +98.8° (200 mg/ml, chloroform), ir 1730 cm^{-1}, as a white solid, mp 88–89°C, in 85% yield. A Wittig reaction (11) of **9** proceeded in 80% yield to give the alkene **10** which showed the appearance of two new vinyl hydrogens in the nmr spectrum at ca. δ 4.5. Compound **10** was also a crystalline solid, mp 153–154°C, $[\alpha]_D^{22}$ +45.4° (74 mg/ml, chloroform).

In the next very crucial step the 1,3-diaxial methyl system was generated in a stereoselective hydrogenation of **10** using Wilkinson's catalyst (12) to produce **11**, mp 140–142°C, $[\alpha]_D^{24}$ +27.0° (66 mg/ml, chloroform), in 81% yield. The nmr spectrum ($CDCl_3$) of **11** had the following features: δ 0.70 (d, J = 6 Hz, 3H), 0.94 (d, J = 7 Hz, 3H), 1–2 (m, 4H), 3.1 (m, 2H), 3.47 (s, 3H), 4.0 (br t, 1H), 4.23 (d, J = 5 Hz, 1H), and 7–7.6 (m, 15H). The new high-field, three-proton doublet clearly showed that reduction of the exocyclic double bond had occurred and the low-field doublet at δ 4.23 due to the hydrogen on the anomeric carbon indicated that **11** retained the chair conformation shown although the 5 Hz coupling with the hydrogen on C-2 did point to some flattening of the pyranose ring due to the 1,3-diaxial methyl interaction. It was clear from an examination of molecular models of the two possible chair conformations of **10** that the α-face of the olefin was the more accessible. This steric effect should be amplified with the bulky Wilkinson's catalyst. It has been established that axial methyl goups in cyclohexane rings normally have ^{13}C signals at δ 15–18 whereas the corresponding equatorial methyl groups are usually found at δ 18–25 (13). The ^{13}C nmr spectrum of **11** showed *only two* signals above δ 30, at 15.93 and 18.30 ppm from TMS. This would suggest that the methyl groups in **11** are both axial. Thus carbons 2,4 and 5 in **11** have the correct relative and absolute stereochemistry for conversion into natural (−)-α-multistriatin.

(*a*) Me_2CuLi, ether; (*b*) NaH, CS_2, MeI, ether; (*c*) $(nBu)_3SnH$, toluene; (*d*) TsOH, methanol; (*e*) trityl chloride, pyridine; (*f*) $CrO_3 \cdot 2Py$, dichloromethane; (*g*) $\phi_3\overset{+}{P}-\bar{C}H_2$, ether; (*h*) H_2, $(\phi_3P)_3RhCl$, benzene; (*i*) $HS(CH_2)_3SH$, $BF_3 \cdot Et_2O$, dichloromethane; (*j*) TsOH, 2,2-dimethoxypropane; (*k*) *tert*-butyllithium, hexane followed by iodoethane, HMPA; (*l*) TsOH, methanol; (*m*) $HgCl_2$, HgO, acetonitrile.

The synthesis of **1** was completed using a sequence of reactions which should prove useful in the synthesis of more complex carbohydrates and in the utilization of carbohydrates as chiral precursors for the synthesis of natural products (14). Treatment of compound **11** with 1,3-propanedithiol and boron trifluoride etherate (15*a*) led to cleavage of the trityl group and formation of the dithioacetal **12** in 80% yield. The resulting diol was protected by formation (16) of the isopropylidene **13**, $[\alpha]_D^{25}$ $-6.2°$ (150 mg/ml, ether), bp 120°C/0.1 Torr, in almost quantitative yield. We were unsuccessful in generating the anion of **13** using alkyllithium reagents in ether solvents (15). However, when the dithiane **13** was treated with *tert*-butyllithium in hexane at -20°C for 2 h and -10°C for 6 h a white precipitate formed. This mixture was alkylated with iodoethane in HMPA to produce **14**, $[\alpha]_D^{24}$ $-28.0°$ (50 mg/ml, ether), bp 128°C/0.1 Torr, in 80% yield. The isopropylidene group in **14** was cleaved in 90% yield to give **15**, $[\alpha]_D^{24}$ $-42.6°$ (50 mg/ml, chloroform), as a colourless oil.

Many of the previous syntheses of α-multistriatin involve an acid catalyzed cyclization of an epoxy ketone or a keto diol to generate the bicyclic ketal of **1**. These conditions lead to epimerization of the methyl group adjacent to the carbonyl. Hence we felt that it would be advantageous if we could

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

cyclize **15** without epimerization of carbon 4 in **15**. A solution of dithioketal **15** in *anhydrous* acetonitrile containing mercuric chloride and mercuric oxide (17) was refluxed for 4 h to yield **1** in 80% yield. The structure of our synthetic material was fully confirmed by comparison of the spectral data of our synthetic material with that reported for α-multistriatin (3, 4). The nmr spectrum (4*a*) is particularly diagnostic in distinguishing the isomers of multistriatin. Our synthetic material had an optical rotation $[\alpha]_D^{24}$ −46.0° (10 mg/ml, hexane) compared with a rotation $[\alpha]_D^{25}$ −47° (1.9 mg/ml, hexane) for the natural material (1, 4*b*). Finally vpc analysis of our synthetic (−)-α-multistriatin with a 3% OV 101 column, under a variety of conditions which separated the multistriatin isomers, demonstrated that our product was >99.7% pure and no trace of the other multistriatin isomers could be detected. This confirms the absolute configuration of the natural (−)-α-multistriatin as that shown in **1** (4*b*, *d*, *e*).

La formation des liaisons éthériques lors de la production du polytéréphthalate d'éthylène glycol

VLADIMIR HORNOF ET LEOŠ ZEMAN[1]

Département de génie chimique, Université d'Ottawa, Ottawa (Ont.), Canada K1N 6N5

Reçu le 29 décembre 1977

VLADIMIR HORNOF et LEOŠ ZEMAN. Can. J. Chem. **56**, 2703 (1978).

Des liaisons du type éther sont formées comme sous-produits lors de la préparation du polytéréphthalate d'éthylène glycol à partir du téréphthalate de diméthyle et de l'éthylène glycol. Incorporées par la suite dans la chaîne du polymère, ces liaisons influencent ses propriétés physiques et mécaniques telles que la force de rupture à la tension, le point de fusion et la résistance à l'oxydation. Une méthode chimique d'analyse a été perfectionnée permettant la détermination quantitative des liaisons éthériques dans les fibres polyesters avec une bonne précision. Basée sur l'oxydation sélective de l'éthylène glycol avec de l'acide périodique, cette méthode se sert d'une hydrolyse par l'eau sous pression pour décomposer le polymère. La méthode a été utilisée pour l'étude de la dépendence de la formation des éthers sur la concentration du catalyseur de la polycondensation.

VLADIMIR HORNOF and LEOŠ ZEMAN. Can. J. Chem. **56**, 2703 (1978).

Ether-type linkages are formed as by-products during the preparation of polyethylene terephthalate from dimethyl terephthalate and ethylene glycol. Incorporated in the polymer, these linkages affect its physical and mechanical properties such as tensile strength, melting point, and resistance to oxidation. An improved chemical method of analysis has been developed allowing an accurate determination of ether bonds in polyester fibers. The method is based on the selective oxidation of ethylene glycol with periodic acid and takes advantage of hydrolysis with water under pressure to decompose the polymer. The method has been employed to study the effect of the concentration of polycondensation catalyst on the formation of ethers.

Introduction

Les fibres du type polyester occupent à l'heure actuelle une place très importante dans l'industrie de textiles. Le plus important membre de la famille de polyesters, le téréphthalate d'éthylène glycol, est normalement préparé à partir du téréphthalate de diméthyle et de l'éthylène glycol (1). La présence d'un catalyseur est nécessaire pour atteindre un bon rendement du polymère. L'activité de différents catalyseurs métalliques a été étudiée par Tomita et Ida (2). Leurs résultats indiquent que les catalyseurs actifs dans la polycondensation peuvent également promouvoir la formation de sous-produits.

Parmi les sous-produits est peut-être le plus important le diéthylène glycol, dont l'incorporation dans la chaîne apporte un effet nuisible à la qualité des fibres. La détermination analytique du diéthylène glycol dans le polyester est donc très importante. Les méthodes chimiques d'analyse sont en général basées sur l'oxydation sélective d'α-glycols par l'acide périodique (3). Francis (4) s'est servi de cette réaction pour analyser des faibles quantités de diéthylène glycol dans l'éthylène glycol. Plus récemment, Mifune et Ishida (5) et puis Kirby, Baldwin et Heidner (6) ont développés des méthodes analytiques permettant la détermination du diéthylène glycol dans les fibres polyesters.

La recherche discutée ici a été entreprise avec le but d'étudier l'influence de différents catalyseurs et de leurs concentrations sur la teneur en diéthylène glycol dans le polyester. Puisque les résultats obtenus en utilisant les méthodes analytiques déjà publiées n'avaient pas été satisfaisantes, il a été nécessaire de

les modifier. L'article présenté ici décrit la nouvelle procédure et son application à l'analyse de quelques séries de polyesters.

Méthode analytique

Procédure

On pèse à peu près 0.2 g de fibres avec la précision de 0.0001 g. Les fibres sont placés dans une ampoule ou un petit autoclave où ils sont décomposés avec de l'eau distillée à 200°C. Après 48 h d'hydrolyse, l'acide téréphthalique est enlevé par filtration et le filtrat est subi à l'oxydation par de l'acide périodique en utilisant 0.3 g de ce dernier pendant 20 min. Ensuite, l'excès de HIO_4 est réduit à l'iodide par du dioxyde de souffre. L'iodide produit par la réduction est précipité par l'addition de 0.25 g du carbonate d'argent. Le précipitat est enlevé par filtration et le liquide est mis dans un ballon 250 ml et dilué à 200 ml avec de l'eau distillée. Le ballon est fourni d'un condenseur et on en distille le liquide jusqu'à ce que le volume est réduit à 30 ml. On ajoute encore 100 ml d'eau et continue la distillation jusqu'à ce qu'il n'y est plus d'aldéhydes dans le distillat.[2] Ensuite, le résidu est refroidi à la température de chambre et transféré quantitativement dans un bocal volumétrique 100 ml. Après l'ajustement du volume à la marque avec de l'eau distillé, on pipette 50 ml (ou un autre volume aliquot) dans un Erlenmeyer 500 ml. On ajoute 20 ml de 0.1 N $K_2Cr_2O_7$ et 70 ml de l'acide sulfurique concentré. Le mélange est laissé à refluxer pendant 45 min et finalement, l'excédant du dichromate est déterminé par la titration iodométrique avec du thiosulfate de sodium.

Calculs

Selon Whitman et Roecker (7) c'est 20 équivalents du dichromate de potassium qui réagissent avec 1 mol du diglycol. La teneur en diéthylène glycol de l'échantillon (DEG) peut être calculée selon l'équation [1]:

$$[1] \qquad \text{DEG (mol)} = 0.050\,\frac{(B - A)N_{TS}}{1000X}$$

ou B est consommation de la solution de $Na_2S_2O_3$ pour le témoin; A est consommation de la solution de $Na_2S_2O_3$ pour l'échantillon; N_{TS} est normalité exacte de la solution de $Na_2S_2O_3$; et X est partie aliquote prise pour l'analyse (par exemple, si l'on prend 50 ml à partir de 100 ml, $X = 0.5$).

Le pourcentage molaire du diethylène glycol dans le polyester peut être calculé selon la formule dérivée par Kirby *et al.* (6):

$$[2] \qquad \%\text{DEG} = \frac{192.2\text{DEG}}{W - 44.0\text{DEG}} \times 100$$

ou W est poids de l'échantillon des fibres (g); DEG est moles de diéthylène glycol trouvées dans W g de l'échantillon.

Résultats et discussion

Méthode analytique

La procédure analytique comprend deux phases importantes: dans la première, la fibre est hydrolysée pour donner une solution des glycols; cette dernière est analysée dans la seconde phase en utilisant l'oxydation sélective par de l'acide périodique. L'oxydation par l'acide périodique sert à enlever l'éthylène glycol mais elle ne peut enlever d'autres produits organiques qui pourrait être présents dans le mélange après l'hydrolyse. Par exemple, la méthode analytique développée par Kirby *et al.* (6) utilise de l'hydroxyde de potassium alcoolique pour décomposer les fibres. Ceci résulte dans l'introduction d'une substance oxydable, à savoir l'éthanol, dans le mélange. L'éthanol pourrait par la suite intervenir lors de la détermination du diglycol.

Mifune et Ishida (5) ont évité ce problème en faisant le décomposition des fibres avec de l'hydroxyde de baryum. Après la décomposition, l'excès de l'hydroxyde a été précipité avec de l'acide sulfurique. Cette procédure diminuait la précision des résultats, probablement à cause de l'adsorption du diéthylène glycol sur le précipitat volumineux du sulfate de baryum.

Dans le travail actuel, les fibres ont été décomposées par de l'eau sous pression à 200°C. L'avantage de cette méthode est évident en ce qu'elle n'introduit aucune contamination; elle exige cependant plus longtemps pour complèter l'hydrolyse. Pour une analyse plus rapide, il serait possible de faire la décomposition dans un autoclave à une température encore plus élevée.

Essais de contrôle

Quelques échantillons-modèles ont été analysés afin de vérifier l'applicabilité de la procédure. Les résultats de ces essais sont assemblés dans le tableau 1.

Essai 1 démontre qu'une certaine quantité de diéthylène glycol est détectée même si l'on n'en a pas ajouté. Ce fond peut être attribué au diéthylène glycol présent dans l'éthylène glycol comme l'impureté, aussi bien qu'à d'autres impuretés oxydables qui peuvent se présenter dans l'éthylène glycol ou dans l'acide téréphthalique et qui ne sont pas enlevées par la procédure. De même on trouve un peu de diéthylène glycol dans l'essai 2.

Dans l'essai 3, on a analysé un mélange éthylène glycol – diéthylène glycol (9:1 par mol) en présence de l'acide téréphthalique. Le résultat obtenu a été un peu plus élevé que la valeur exigée (% DEG = 10). Pourtant cette déviation peut être diminuée si l'on soustrait la quantité trouvée dans l'essai 1 du résultat de l'essai 3. L'utilisation des essais-témoins semble d'être la meilleure méthode pour éliminer les erreurs systématiques dues aux impuretés.

Le dernier essai a été fait avec un échantillon du bis-β,β′-(hydroxyethyl) téréphthalate. Ce dernier a été préparé par la réestérification du téréphthalate de diméthyl avec de l'éthylène glycol à 190°C en présence du catalyseur ($Zn(OCOCH_3)_2$). Il est évident que cette étape préliminaire de polycondensation résulte déjà dans la formation du diéthylène glycol.

[2]Vérifié à l'aide de la réaction indicatrice avec de la fuchsine.

3	Éthylène glycol (0.1038 g) Diéthylène glycol (0.0197 g) Acide téréphthalique (0.3086 g)	186.0	193.0	10.00	10.38
4	Bis-β,β′-(hydroxyethyl) téréphthalate (0.2848 g)	0	12.0	0	0.54

Reproductibilité d'analyse

La reproductibilité de la méthode analytique a été vérifiée sur deux échantillons de polytéréphthalate d'éthylène glycol. Le tableau 2 démontre les résultats obtenus avec un polyester industriel (Tesil 11), tandis que les résultats compilés dans le tableau 3 appartiennent à un polytéréphthalate d'éthylène glycol préparé au laboratoire. Les deux séries de données démontrent que la précision obtenu avec la nouvelle méthode est très satisfaisante, la déviation standarde étant de 0.04 dans le premier cas et de 0.06 dans l'autre.

Effet du catalyseur sur l'éthérification

La méthode analytique décrite ci-haut a été employée pour étudier la dépendance de formation des liaisons éthériques sur la concentration du catalyseur durant la polycondensation. Avec ce but, une série de neuf polyesters a été préparée en variant la concentration de l'acétate de zinc comme catalyseur. Dans tous les cas, la réestérification a été effectuée à 180°C, puis la température a été augmentée à 280°C pour commencer la polycondensation. La réaction a été arrêtée après 10 h.

Les résultats obtenus avec les concentrations du catalyseur entre 5×10^{-4} et 5×10^{-3} mol par rapport à 1 mol du téréphthalate de diméthyl sont démontrés dans le tableau 4. Il est évident que la teneur en diéthylène glycol dans le polyester augmente légèrement avec l'augmentation de la concentration du catalyseur.

[c]Moyenne de trois déterminations.
[d]Téréphthalate de diméthyl.

La dernière colonne du tableau 4 compile les points de fusion des fibres qui correspondent à ces différents échantillons de polyesters. Il a été suggéré par Yoda (8) qu'une augmentation de la teneur en diéthylène glycol dans les fibres provoquerait une chute de point de fusion. De même, dans la publication de Jannsen *et al.* (9) on trouve que le point de fusion des fibres tombe de 270°C à 250°C en allant de 0.60% à 3.64% du diéthylène glycol. Les résultats obtenus dans ce travail démontrent que le point de fusion est presque constant pour les échantillons étudiés, bien qu'on observe une légère baisse de ce dernier lorsque la teneur en diéthylène glycol est plus élevée. On s'aperçoit cependant d'une inconsistance assez importante lorsqu'on compare les trois travaux. Dans le travail de Yoda (8) par exemple, la teneur en diéthylène glycol obtenue avec de l'acétate de zinc comme catalyseur est 7.5%; le point de fusion correspondant est 259°C. Presque le même point de fusion est obtenu dans le présent travail pour des polyesters dont la teneur en diéthylène glycol n'est que de 3.5%. Ce désaccord avec la variation très importante du point de fusion décrite par Jannsen *et al.* (9) indique la nécessité de la recherche supplémentaire pour mieux caractériser ce système.

Apparent molal volumes and heat capacities of low molecular weight peptides in water at 25°C

CARMEL JOLICOEUR AND JEANNINE BOILEAU

Department of Chemistry, University of Sherbrooke, Sherbrooke, P.Q., Canada J1K 2R1

Received June 26, 1978

CARMEL JOLICOEUR and JEANNINE BOILEAU. Can. J. Chem. **56**, 2707 (1978).

The apparent molal volumes ϕ_v and heat capacities ϕ_c of oligopeptides of glycine, alanine, and serine have been determined in water at 25°C by flow densimetry and flow microcalorimetry. The data are reported for the homologous series: glycine to pentaglycine, L-alanine to tetra-L-alanine and L-serine to tri-L-serine. From the limiting ϕ_v^0 and ϕ_c^0 values of the glycine oligomers, the contributions of the glycyl residue in an extended polypeptide chain has been evaluated as: $\Delta\phi_v^0$(glycyl) = 38.0 ± 0.5 cm^3 mol^{-1} and $\Delta\phi_c^0$(glycyl) = 98 ± 5 J K^{-1} mol^{-1}. The data for the other peptides are discussed in terms of contributions from the amino acid side chains, i.e. —CH_3 and —CH_2OH, and end-group hydration effects. Some necessary conditions for obtaining useful additivity schemes for predicting ϕ_v^0 and ϕ_c^0 of extended polypeptides and proteins are indicated.

CARMEL JOLICOEUR et JEANNINE BOILEAU. Can. J. Chem. **56**, 2707 (1978).

Nous avons déterminé, à l'aide d'un densimètre et d'un microcalorimètre dynamiques, le volume molal apparent ϕ_v et la capacité calorifique molale apparente ϕ_c d'oligopeptides en solution aqueuse à 25°C. L'étude a porté sur les séries homologues suivantes: glycine à pentaglycine, L-alanine à tetra-L-alanine et L-serine à tri-L-serine. A partir des valeurs de ϕ_v^0 et ϕ_c^0 (dilution infinie) des oligomères de la glycine, nous avons pu évaluer la contribution du groupe glycyl dans une chaine polypeptidique allongée: $\Delta\phi_v^0$(glycyl) = 38.0 ± 0.5 cm^3 mol^{-1} et $\Delta\phi_c^0$(glycyl) = 98 ± 5 J K^{-1} mol^{-1}. Les données sur les autres peptides sont discutées en termes de la contribution due aux chaines latérales (—CH_3 ou —CH_2OH) des acides aminés et de l'influence de l'hydratation des groupes terminaux. L'examen des résultats suggère quelques conditions essentielles à l'établissement d'une échelle de valeurs de groupes utile à la prédiction de ϕ_v^0 et ϕ_c^0 de polypeptides et protéines dépliés.

Introduction

The thermodynamic stability of the native structure of proteins has provided one of the great challenges in biochemistry and currently remains the subject of extensive investigations (1). Although the structural features of proteins are being progressively elucidated through amino acid sequencing, X-ray diffraction, and active site studies, important questions persist concerning the thermodynamic quantities which characterize the various levels of structural organisation of proteins in solution.

In an idealistic approach, the thermodynamic information would be obtained by measuring the changes associated with the unfolding of the protein, from its native state (one specified native state if there are many) to a reference state. The latter should be independent of the initial state of the protein and, hopefully, would be accessible to all proteins. Presumably, a suitable reference state would be one where the protein is extended in such a way that there remains minimal interactions between amino acid side chains and each constituent amino acid is optimally accessible to the solvent. An obvious obstacle to this simple procedure, however, is that known means of inducing protein unfolding (temperature, pressure, addition of chemicals) usually do not lead to the required well defined final state (1*b*, 3). In the case of chemical denaturation, further complication arises since the comparison of initial and final states reflects thermodynamic changes due to the changes in solvent composition as well as from the protein structural modifications.

In another idealized approach, one could calculate some of the thermodynamic properties of 'extended' proteins in solution using group contributions derived from the properties of constituent amino acids and peptides. By comparing these results with measured values on the native proteins, the changes for the unfolding process could also be obtained. This procedure, as already applied to the apparent specific volumes of proteins (ref. 4, p. 374 *ff*), requires that appropriate additivity rules be established with good accuracy.

The present work was undertaken in relation to the latter strategy, namely, to investigate the additivity of amino acid contributions to apparent molal volumes and heat capacities of oligopeptides in solution. Since apparent molal heat capacities have been shown to be highly sensitive to hydration effects (e.g. discriminating between the hydration of ionic, polar, and apolar groups), it should provide a critical assessment of the group contribution approach. The

study was initiated on low molecular weight oligopeptides of glycine, alanine, and serine, chosen as to emphasize the influence of side chains having similar size, but different solvation effects.

Experimental

The amino acids glycine, L-alanine, and L-serine, as well as the homopeptides of glycine and alanine were purchased from Sigma. Di- and triserine were obtained from Vega Fox Biochemicals. Except for the latter two peptides, the compounds were recrystallized in various alcohol–water mixtures and tested to give a single TLC spot. The materials were dried several days in vacuum over P_2O_5 and their moisture content was assessed by Karl Fisher titration. With di- and triserine, the amount of material available was minimal and only the drying procedure was followed.

All solutions were prepared by weight in molality using distilled, deionized water (Continental deionizer). In the case of the higher peptides, the dissolution sometimes required hours of vigorous agitation in a thermostated shaker bath.

The solution densities d, and volumetric specific heats σ, were measured using a flow digital densimeter and a flow microcalorimeter described elsewhere (5, 6). For most of this study, the instruments were used under their highest sensitivity conditions, detection limits being respectively 10^{-6} g cm^{-3} and 10^{-5} J K^{-1} cm^{-3}. The flow densimeter and microcalorimeter were connected in series so both d and σ of each sample could be measured simultaneously. Since the common circulating thermostat was set at 25.00°C, and since the temperature rise during the heat capacity measurements was 2.0°C, the specific heat data are obtained at the mean temperature of 26.0°C.

Results

The apparent molal volumes ϕ_v and heat capacities ϕ_c were calculated from the solution densities and specific heats using the standard expressions (7):

$$[1] \qquad \phi_v = \frac{M_2}{d} - \frac{1000(d - d_0)}{mdd_0}$$

and

$$[2] \qquad \phi_c = \phi_v\sigma_0 + \frac{1000(\sigma - \sigma_0)}{c}$$

where M_2 is the molecular weight of the solute, and m and c represent the molal and molar concentrations. Since ϕ_v and ϕ_c were found to vary linearly with concentration, the results were fitted by least-squares method to equations of the form:

$$[3] \qquad \phi_v = \phi_v^0 + B_v c$$

and

$$[4] \qquad \phi_c = \phi_c^0 + B_c c$$

The resulting ϕ^0 and B parameters are reported in Table 1 along with the concentration range investigated and the number of data for each compound.[1]

[1]Detailed values of d, σ, ϕ_v, and ϕ_c are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The standard deviation on the results are also given in parentheses below each parameter. For the tetrapeptides (or higher homologs) the slopes were obtained over a very narrow range of concentration, so their reliability is questionable.

A comparison of the present results with several literature data is presented in Table 2. For the ϕ_v^0 data, the present results are in good agreement with those of previous authors, though several discrepancies are found in the comparisons of ϕ_c^0 data. Except for the data on diglycine however, these discrepancies are within the uncertainties of the methods used by previous investigators. For diglycine, the values reported here are believed to be more reliable than earlier data, since they could be reproduced within 1 J K^{-1} mol^{-1} at a one year interval, using different batches of the compound.

Discussion

In dilute aqueous solutions, amino acids and linear peptides are present in the form of dipolar ions. The ratio of the dipolar ion species to the neutral species is usually many orders of magnitude (ref. 4, p. 96) so, for the present purpose, we may consider only the zwitterionic state of the molecules.

The solution conformation of low molecular weight peptides has been, in many cases, thoroughly investigated using nmr, dielectric, and optical methods (21). Studies on oligopeptides of increasing lengths have shown that the formation of α-helix (or other) structure generally requires a minimum number of 6 to 12 amino acid units, depending on both the amino acids and the solvent. Below this minimum number, the non-cyclic peptides retain considerable conformational mobility, so preferred conformations cannot be identified, i.e. the peptide molecule undergoes rapid conversion among its many possible conformational states. Hence, the peptides studied here may be envisaged as dipolar ions, having conformations sufficiently extended so that each portion of the molecule is accessible to the solvent.

The thermodynamic properties of the amino acids and peptides are, of course, highly influenced by hydration of their ionic end groups. Recent studies on partial molal volumes and heat capacities of nonelectrolytes (22, 24) and various amino acids (8–10, 13, 15, 16, 25) offer important information pertaining to the present investigation. First, with ω-aminocarboxylic acids ($H_2N(CH_2)_nCOOH$) which also exist mainly as dipolar ions, the hydration of the $-NH_3^+$ and $-COO^-$ ions may be considered independent only when there are ca. six methylene groups separating these two ions (9, 13). For shorter alkyl chains, hydration of the end groups interferes with the hydration of the methylene groups, and the incremental

contribution of the latter to ϕ_c^0, i.e., $\Delta\phi_c^0(CH_2)$, is much lower than that found in homologous series of monofunctional aliphatic molecules (24). On this basis, we must expect similar end-group effects for peptides and, presumably, a minimum of six C—C or C—N bonds will be required to minimize interference in the hydration of the end groups, or influence of the latter on the hydration of the center portion of the peptide.

A second important result can be recalled from studies on a series of α-aminoacids containing aliphatic residues of increasing size (e.g. glycine, alanine, valine, leucine). The contribution of these side chains to ϕ_c^0 are remarkably close to those found in other series of polar molecules or organic ions. This suggests that, in contrast to methylene groups located between the ionic end groups, the hydration of hydrocarbon side chain is not too strongly perturbed by the terminal ions. Analysis of the peptide data reported here will show both analogies and differences in the additivity effects observed with α- and ω-amino acids.

(1) Additivity of Amino Acid Contributions to ϕ_v^0 and ϕ_c^0 in Peptides

To evaluate the incremental contribution of amino

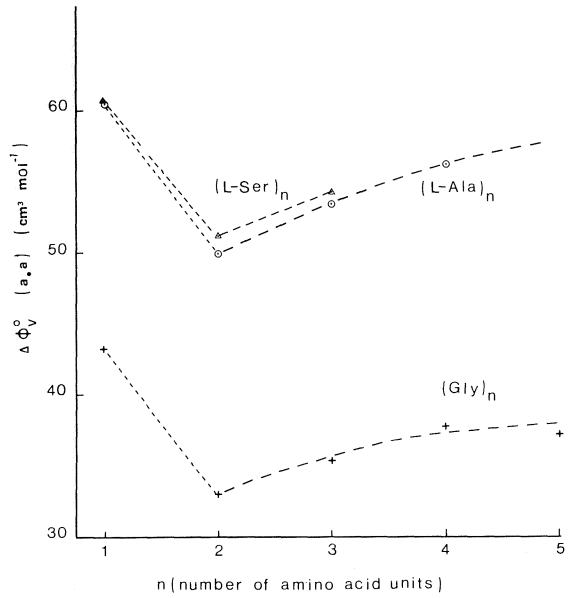

FIG. 1. Incremental contributions of amino acids to ϕ_v^0 of oligopeptides in water at 25°C.

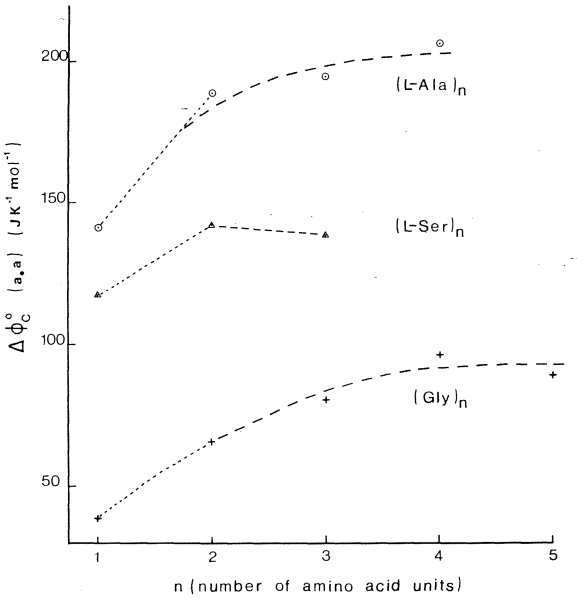

FIG. 2. Incremental contributions of amino acids to ϕ_c^0 of oligopeptides in water at 25°C.

acids to ϕ_v^0 and ϕ_c^0 ($\Delta\phi^0$(a.a)) in each homologous series, we have plotted the increments of these properties against the number of amino acids (n) in the peptides (Figs. 1 and 2). It is apparent from these data that the variation of $\Delta\phi_v^0$(a.a) with n is remarkably similar in each series, while significantly different behaviours are found with $\Delta\phi_c^0$(a.a). The origin of these differences will be discussed below (Section 3).

The results for glycine and its oligomers show that the apparent molal volume of the second amino acid is much smaller than that of the monomer. Hydration of ionic groups such as $-NH_3^+$ and $-COO^-$ will decrease ϕ_v^0 of the monomer (4, 9) and, to first order, this effect is constant within a series of peptides. On the other hand, the formation of the peptide bond decreases $\Delta\phi_v^0$(a.a) assigned to the second amino acid. Clearly the latter effect is dominant. The contribution of further glycyl units increases regularly, tending to a constant value for n between 4 and 6. This behavior most certainly reflects the decreasing influence of end group hydration on $\Delta\phi_v^0$ of the central glycyl units. In peptides, the number of atoms separating the $-NH_3^+$ and $-COO^-$ groups is given as $(3n - 2)$ so it can be expected from the earlier discussion that $\Delta\phi_v^0$ will reach its 'unperturbed' value for the tripeptide and higher homologs. If, as is appropriate in the present case, we neglect the backbone atoms of the glycyl unit considered, the number of atoms separating the end groups is $(3n - 5)$ and, hence, the tetramer will be required to eliminate end-group effects on $\Delta\phi_v^0$(a.a). The levelling-off of $\Delta\phi_v^0$(a.a) at $n \simeq 4$ supports this interpretation and allows the evaluation of the volume of the glycyl residue in the polypeptide chain as: $\Delta\phi_v^0$(glycyl) = 38.0 ± 0.5 cm^3 mol^{-1}. The large uncertainty on this value is due mainly to the difficulty in obtaining accurate data for tetra- and pentaglycine.

With the oligopeptides of L-serine and L-alanine, $\Delta\phi_v^0$(a.a) do not reach a constant value within the series investigated. However, the similar variations of $\Delta\phi_v^0$(a.a) in the three series suggest that side chain/side chain interactions do not contribute significantly to ϕ_v^0; hence L-seryl and L-alanyl group contributions could be extrapolated in a way analogous to the data for the glycine oligomers. Alternately it could be obtained from $\Delta\phi_v^0$(glycyl), if the side chain contributions (CH_3 and CH_2OH) can be assessed reliably.

The $\Delta\phi_c^0$(a.a) data exhibit a common behavior for the three series of peptides, namely a marked increase for the second amino acid compared to the monomer. This might be expected since most 1:1 electrolytes (26) have negative apparent molal heat capacities. As for the ϕ_v^0 data discussed above, this effect will reduce ϕ_c^0(monomer), whereas formation of the peptide bond will reduce the $\Delta\phi_c^0$ assigned to the second glycyl residue. By contrast to ϕ_v^0 data, however, the difference in ϕ_c^0 of glycine and of the glycyl unit originates mainly in hydration effects.

From the data for the higher glycine oligomers, $\Delta\phi_c^0$(a.a) is seen to reach a constant value at $n \simeq 4$, 5, leading to a glycyl unit contribution of 95 ± 5 J K^{-1} mol^{-1}. For the other peptides, $\Delta\phi_c^0$(a.a) is not readily extrapolated to larger n values. Variations of

[a]Results tabulated from differences in the incremental values of glycyl, alanyl, and seryl as a function of n.

$\Delta\phi_c^0$(a.a) within the series (L-alanine)$_n$ and (glycine)$_n$ appear related, though different from the behavior of the L-serine peptides.

(2) Additivity of Side Chain Contributions

Having established a reasonable basis for calculating ϕ_v^0 and ϕ_c^0 of 'extended' polyglycine molecules in water, we turn to examine the side chain contributions in the L-alanine and L-serine peptides. These contributions can be expressed as the changes in ϕ_v^0 and ϕ_c^0 for the substitution of a glycyl C—H by a —CH_3 or a —CH_2OH group: $\Delta\phi^0(H \rightarrow CH_3)$ and $\Delta\phi^0(H \rightarrow CH_2OH)$. The latter quantities were obtained as a function of n from appropriate differences of the data in Figs. 1 and 2 and are reported in Table 3. (Because these data are differences between incremental values ($\Delta\phi^0$(a.a)), their uncertainty is expected to increase with n.)

It is readily seen from the data in Fig. 1 or Table 3 that the magnitudes of $\Delta\phi_v^0(H \rightarrow CH_3)$ and $\Delta\phi_v^0(H \rightarrow CH_2OH)$, as well as their variation with n, are very similar. This is in accordance with the rather general observation that $\Delta\phi_v^0(CH_3 \rightarrow CH_2OH) \simeq 0$ cm^3 mol^{-1}; the latter is usually true within 1 cm^3 mol^{-1}, and appears quite independent of the nature of neighboring substituents (23, 27, 28).

The variation of $\Delta\phi_v^0(H \rightarrow CH_3)$ and $\Delta\phi_v^0(H \rightarrow CH_2OH)$ with n indicates some influence of the ionic end groups on the hydration of the side chains.[2] Hence, the $\Delta\phi_v^0(H \rightarrow CH_3, CH_2OH)$ obtained from comparison of the amino acid ϕ_v^0 data are lower (by $\sim$1 cm^3 mol^{-1}) than the values derived from $\Delta\phi_v^0$(a.a) at larger n. It thus seems preferable for predictive purposes, to obtain the side chain contributions from peptide data or, perhaps, from data on analogous non-electrolytes as suggested in early studies (4).

The side chain contributions to the heat capacities $\Delta\phi_c^0(H \rightarrow CH_2OH)$ and $\Delta\phi_c^0(H \rightarrow CH_3)$ exhibit sharp differences in their magnitudes as well as in their variations as a function of n. Judging from the data in Table 3, $\Delta\phi_c^0(H \rightarrow CH_3)$ levels-off at $\sim$105 J K^{-1} mol^{-1} for $n \simeq 4, 5$. This value is remarkably close to that obtained directly by comparing $\Delta\phi_c^0$ of glycine and alanine, i.e. 102 J K^{-1} mol^{-1}, in accordance with the results quoted at the beginning of this discussion, i.e. $\Delta\phi_c^0$ of aliphatic residues on α-amino acids. However, in view of the end group influence upon $\Delta\phi_v^0(H \rightarrow CH_3)$, this agreement may be fortuitous resulting from the opposite effects of ionic and apolar groups on ϕ_c^0. Possibly, the apolar side chain hinders the hydration of the ionic groups (29), thereby increasing ϕ_c^0 of the amino acids.

The values obtained for $\Delta\phi_c^0(H \rightarrow CH_2OH)$ decrease for $n > 2$ and a linear extrapolation from the di- and triserine data yields $\Delta\phi_c^0(H \rightarrow CH_2OH) \simeq 40$ J K^{-1} mol^{-1} for the tetrapeptide. This is only one-half the value obtained directly from ϕ_c^0 of the amino acids, indicating important end-group effects. Qualitatively, this behavior can be rationalized from data on various other compounds.

With aliphatic alcohols (23), the $H \rightarrow CH_2OH$ substitution (e.g. *n*-propanol $\rightarrow$ 1,4-butanediol) leads to $\Delta\phi_c^0(H \rightarrow CH_2OH) \simeq 0$ J K^{-1} mol^{-1}, i.e. the —OH hydration effects cancel out the methylene group contribution (88 J K^{-1} mol^{-1}) to ϕ_c^0. Contrastingly, the same substitution occurring α to a charged nitrogen center (e.g. $CH_3\overset{+}{N}H_3 \rightarrow HOCH_2$-$CH_2\overset{+}{N}H_3$) leads to a $\Delta\phi_c^0$ of 54 J K^{-1} mol^{-1} (2). Clearly, the presence of the neighboring ionic charge has a strong influence on ϕ_c^0 of the —CH_2OH group, an effect which again can be interpreted as due to interference between the hydration of the polar and ionic group. In the case of amino acids, both the NH_3^+ and COO^- can interfere with the hydration of the CH_2OH side chain, and this could explain the large $\Delta\phi_c^0(H \rightarrow CH_2OH)$ found here. An important consequence of these findings is that for the amino acids having polar groups on their side chains, the contribution of the latter to ϕ_c^0 should be derived from polypeptide data, or possibly, from data on non-electrolyte analogues. Contributions obtained by straightforward differences among amino acid data could be grossly misleading.

[2]The effects involved here must be related to those invoked for explaining ϕ_v^0 data in homologous series of aliphatic monofunctional compounds (20), but probably in a still more complex way.

(3) Contribution of the Peptide Linkage

The contribution of the peptide bond (CO—NH) constitutes a fundamental quantity for predicting the properties of the polypeptide backbone in proteins. Both, $\Delta\phi_v^0$(CO—NH) and $\Delta\phi_c^0$(CO—NH) have been estimated previously from data on non-electrolytes, mainly amides and dipeptides.

For the $\Delta\phi_v^0$ contribution, estimates based on early volume data (4) have yielded 20.0 cm^3 mol^{-1} for the —CO—NH— group and 36.3 cm^3 mol^{-1} for the —CH_2—CO—NH(glycyl) residue. The present result $\Delta\phi_v^0(CH_2—CO—NH) = 38.0 \pm 0.5$ cm^3 mol^{-1} confirms the earlier value within the uncertainty expected from the group additivity scheme used in previous studies. The glycyl contribution derived directly from polypeptide data should be a more representative quantity and, in that sense, is more reliable.

The magnitude of $\Delta\phi_c^0$(CO—NH) has also been obtained by Nichols *et al.* (24) from group additivity analysis of data for aqueous amides; the result is $\Delta\phi_c^0(CO—NH) = -61$ J K^{-1} mol^{-1}. From similar considerations on data for cyclic mono- and dipeptides, Cabani *et al.* (18) reported that $\Delta\phi_c^0$(CO—NH) should be near 0 J K^{-1} mol^{-1}. These authors also remarked that this group contribution behaves differently in cyclic compared to linear peptides. Presumably, this indicates that with such complex molecules, detailed group additivity rules are accurate only within categories of similar compounds or homologous series.

As reported above, we have determined for the glycyl unit $\Delta\phi_c^0(CH_2—CO—NH) = 98 \pm 5$ J K^{-1} mol^{-1} which can be compared with the estimates obtained by Krescheck and Benjamin (14) from dipeptides (128 ± 25 J K^{-1} mol^{-1}) and by Cabani *et al.* (18) from di- and triglycine (50 ± 21 J K^{-1} mol^{-1}). Since it was shown that $\Delta\phi_c^0$(a.a) varies significantly with n, the previous estimates should be compared with the corresponding di- and tripeptide data reported here. For such comparison, the present results agree reasonably with those of Cabani *et al.* but differ significantly from the data of Krescheck and Benjamin.

Finally, it is interesting to compare the glycyl contribution to ϕ_v^0 and ϕ_c^0 of peptides with that of an aliphatic hydrocarbon. The apparent molal volume of the glycyl unit is ca. 2.4 times larger than the methylene group contribution in an alkyl chain (16.0 cm^3 mol^{-1} (23)). On the other hand, its apparent molal heat capacity is only ca. 1.1 times $\Delta\phi_c^0(CH_2)$ in homologous series of non-electrolytes (88 J K^{-1} mol^{-1} (24)). Hence, if the methylene group in the glycyl unit is assigned the same contribution as in alkyl chains, the peptide bond indeed appears to have a very minor contribution to ϕ_c^0(ca. 7 J K^{-1} mol^{-1}) in agreement with the suggestion of Cabani *et al.* (18).

Conclusions

The results of this investigation show that ϕ_v^0 and ϕ_c^0 of the low molecular weight oligopeptides vary in a regular fashion with n, and that a minimum value of $n = 4$ is required before the incremental contribution of the amino acid becomes constant. This is taken as evidence for interference of the ionic end groups of the peptides upon the hydration of its middle portion and side chains, an effect noted previously in other homologous series (20). Although contributions from segmental motions or conformational changes as a function of n cannot be ignored, there is no indication that such effects have a significant influence on ϕ_v^0 and ϕ_c^0 of the peptides studied here.

The glycyl group contribution to ϕ_v^0 and ϕ_c^0 derived from the data, together with an additivity scheme for side chain contributions, should provide a basis for predicting ϕ_v^0 and ϕ_c^0 of extended polypeptides and proteins in solution. However, the reliability of such calculations will depend on a proper evaluation of side chain effects; the data reported here show that in some cases, side chain contributions should not be taken directly from amino acid data. This is particularly clear from the ϕ_c^0 data for amino acids having a side chain functional group.

Photoelectron spectra of 4-substituted stilbenes

E. J. McAlduff[1] and Tammy Chan

Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received April 13, 1978

E. J. McAlduff and Tammy Chan. Can. J. Chem. **56**, 2714 (1978).

The photoelectron spectra of stilbene and 4-R-stilbene (R = CH_3O, CH_3, F, Cl, NO_2) has been determined and the five highest π ionization potentials assigned. By considering the stilbenes to be formally constituted by union of a styrene and substituted benzene the influence of substituent on molecular orbital energies has been rationalized. The data suggest that the stilbenes exist in a planar or nearly planar configuration in the gas phase. CNDO/2 calculations have been performed on a wider variety of 4-R-stilbenes (R = NH_2, CH_3, OH, F, CN, CF_3, NO_2) and it is suggested that planar configurations also predominate for those stilbenes. First ionization potentials of some of the stilbenes are correlated with bromination and ozonolysis rate data.

E. J. McAlduff et Tammy Chan. Can. J. Chem. **56**, 2714 (1978).

On a déterminé les spectres photoélectroniques du stilbène et de stilbènes substitués par un groupe R en position 4 (R = CH_3O, CH_3, F, Cl, NO_2) et on a attribué les cinq potentiels d'ionisation π les plus élevés. En faisant l'hypothèse que les stilbènes sont constitués d'une façon formelle par l'union d'un styrène et d'un benzène substitué, on a rationalisé l'influence des substituants sur les énergies des orbitales moléculaires. Les données suggèrent que les stilbènes existent à l'état gazeux dans une configuration plane ou presque plane. On a effectué des calculs CNDO/2 sur plusieurs stilbènes substitués en position 4 par un groupe R (R = NH_2, CH_3, OH, F, CN, CF_3, NO_2) et ces calculs suggèrent que les configurations planes prédominent aussi dans ces stilbènes. On a relié les premiers potentiels d'ionisation de quelques-uns de ces stilbènes avec des données de vitesse de bromation et d'ozonolyse.

[Traduit par le journal]

Introduction

As part of a continuing investigation of the influence of substituents on the photoelectron spectra of benzene derivatives, the PE spectra of a series of monosubstituted *trans*-stilbenes has been determined. A study of the PE spectra of stilbenes provides an opportunity to study the interaction between benzene rings through an intervening ethylene group. In addition, monosubstituted stilbenes may be regarded as formally constituted by union of a substituted benzene with styrene. The extent of this interaction may be studied by comparing the PE spectra of stilbenes and analogous substituted benzenes. Semi-empirical MO calculations (CNDO/2) can be used as an aid to assignment of molecular orbitals even though their qualitative predicting ability of molecular orbital energies is not good.

Maier and Turner (1) have shown that certain bands in the PE spectra of diphenylethylenes are sensitive to conformational changes. Distefano *et al.* (2) determined the PE spectra of *trans*-styrylpyridines and noted the effect of α-methyl addition which had the result of distorting the benzene and pyridine rings from coplanarity. Novak *et al.* (3) determined the PE spectra of several *trans*-dipyridylethylenes but were unable to determine their conformations in the gas phase. However, their results indicated that the angle of twist between the pyridine rings was probably less than 30°.

Introduction of a substituent on benzene removed the degeneracy of the benzene e_{1g} orbitals. Electron releasing substituents interact conjugatively with the phenyl orbital via a high lying occupied lone pair orbital to produce a new π ionization (Ph_S) substantially shifted to lower IP. The other phenyl orbital, Ph_A, is found essentially unchanged from its position in benzene. Electron withdrawing groups shift both bands to higher IP. The PE spectrum of styrene has been determined by a number of workers (1, 4*a*)[2]. In styrene, the conjugation between the ethylenic and phenyl π electrons split the degeneracy of the phenyl π orbitals, shifting the b_1 component by ~1 eV to lower energy while the a_2 component remains essentially unperturbed. The ethylenic π orbital is shifted to higher energy by ~0.04 eV as a result of this conjugation. Thus the highest occupied molecular orbital (IP 8.48 eV) can be regarded as an anti-bonding combination of the Ph_S orbital of benzene and the vinyl π ($Ph_S - \pi$). The second highest occupied orbital in styrene (IP 9.28 eV) is the Ph_A orbital which is confined to the phenyl moiety. The third highest occupied orbital (IP 10.55 eV) is the bonding

combination of Ph_S and π (π + Ph_S). This orbital will be more vinyl-like whereas the HOMO will be more phenyl-like. Interaction of the styryl moiety with the phenyl moiety in the stilbenes will produce the five highest occupied π orbitals of the stilbene.

Results and Discussion

The interactions between the doubly degenerate HOMO of benzene with the three highest occupied orbitals of styrene to produce the five highest orbitals of *trans*-stilbene are shown in Fig. 1. The HOMO of stilbene (π_7) results from an anti-bonding combination of Ph_S − π of styrene with Ph_S of the benzene. π_6 is a Ph_A-type orbital which is confined mainly to the substituted ring and is an orbital with high electron density at the *ortho* and *meta* positions and a node at the position of substitution and *para* to it. For purposes of this discussion, it will be designated Ph_A(sub). π_5 is also a Ph_A-type orbital but resides primarily on the unsubstituted benzene ring. Substituents should have only a secondary effect on its IP and, therefore, its value should change to a lesser extent than the other orbitals.

π_4 is a composite orbital made up of the bonding combination of Ph_S − π of styrene plus Ph_S benzene. In addition, it contains a contribution from the anti-bonding combination of π + Ph_S of styrene and Ph_S of benzene. The combination of these two types of orbitals produces a molecular orbital which has a node on the ethylenic portion of the stilbene and Ph_S-like character on both benzene rings. It will be termed Ph_S − Ph_S in this discussion.

π_3 is the last distinguishable π orbital and is made up of the bonding combination of the π + Ph_S of styrene and Ph_S of benzene. It will be designated Ph_S + π + Ph_S in this discussion but probably also contains some minor contribution from the lower lying phenyl orbital of benzene. Figure 2 shows the PE spectra of stilbene and the five mono-substituted stilbenes (4-CH_3O, 4-CH_3, 4-F, 4-Cl, 4-NO_2). The IP's and assignments are listed in Table 1. The stilbene spectrum shows a band centred at 7.96 eV which is assigned to Ph_S − π − Ph_S(π_7), the larger band at 9.19 eV is assumed to contain both Ph_A orbitals (Ph_A(sub) and Ph_A(unsub)) which are degenerate in the absence of substituents. The shoulder on this band at 9.51 eV is assigned to the Ph_S − Ph_s band (π_4). The third band which is well separated from the

$\pi_7 - \pi_4$	1.58	1.56	1.55	1.64	1.54	1.42

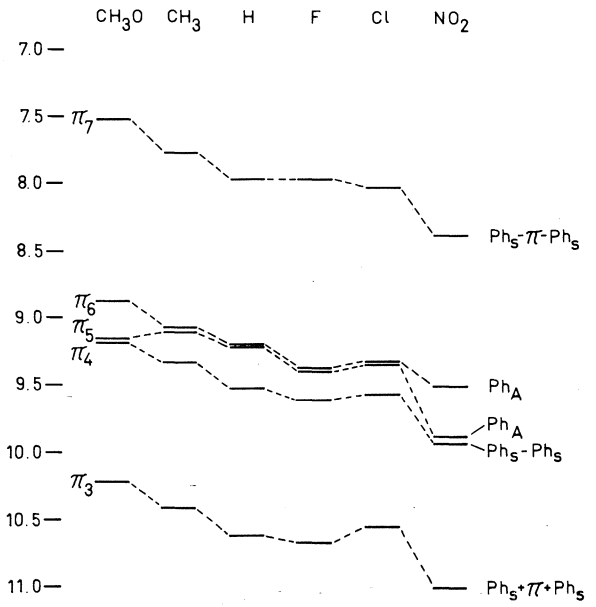

FIG. 3. Correlation diagram of five highest IP's in stilbene and substituted stilbenes.

others at 10.61 eV is assigned to $Ph_S + \pi + Ph_S$. These assignments and IP values agree within experimental error to those already reported for stilbene (1, 2). Figure 3 is a correlation diagram showing the effect of substituents on each of the five highest π levels of stilbene. The assignment for each of these five IP's and the nature of substituent effects will be discussed separately for each orbital.

$Ph_S - \pi - Ph_S$

This IP is clearly separated from the nearest ones for each substituted stilbene and can be seen (Table 1) to vary from 7.57 eV in 4-OCH_3 stilbene to 8.36 eV in 4-NO_2 stilbene. As found for substituted benzenes, electron releasing groups (OCH_3, CH_3) decrease the IP from its value in stilbene and an electron withdrawing group (NO_2) increases the IP.[3]

[3]Substituted benzene IP's used in this investigation and their sources: R = CH_3O, 8.39 eV; CH_3, 8.85 eV (5*a*); R = Cl, 9.06 eV; F, 9.19 eV (5*b*); R = H, 9.24 eV (5*c*); R = NO_2, 9.99 eV (5*d*).

Figure 4 shows a plot of $Ph_s - \pi - Ph_S$ IP for substituted stilbenes vs. Ph_S IP for substituted benzenes. A linear relationship such as this has been obtained for several series of disubstituted benzene IP's vs. monosubstituted benzene IP's (6). Similar behavior has been reported for the relationship between substituted styrylpyridine IP's and substituted benzene IP's (2). The slope of Fig. 4 is ~0.5 which indicates that the sensitivity of the stilbene system to the substituent is much lower than that of benzene. Furthermore the stilbene HOMO at 7.96 eV is at a considerably higher energy than the benzene HOMO at 9.24 eV and hence less influenced by interaction with donor orbitals. In contrast the low lying vacant orbitals of the acceptor groups are now closer in energy to stilbene than they were to benzene and hence produce a larger interaction. The smaller slope can then be considered to result from both decreased interaction by donor groups and enhanced interaction by acceptor groups on stilbene in comparison to benzene.

CNDO/2 calculations (7) have been performed on several monsubstituted stilbenes including four of the ones studied here (4-CH_3, 4-F, 4-NO_2, and stilbene). The results of these calculations are listed in Table 2. Standard geometries were used throughout and all calculations were done assuming planar molecules. The calculation overestimates the ionization potential by several electron volts in each case which is a common occurrence for this type of calculations. Nevertheless, a linear relationship is obtained be-

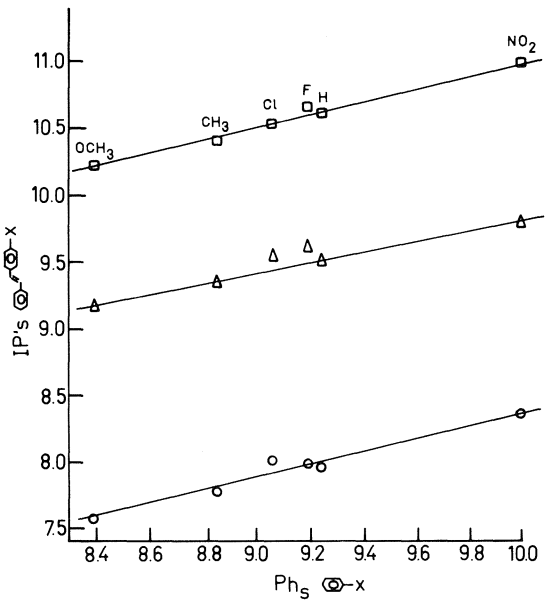

FIG. 4. IP's stilbenes vs. Ph_S IP benzenes (5); ○, $Ph_S - \pi - Ph_S$; △, $Ph_S - Ph_S$; □, $Ph_S + \pi + Ph_S$.

TABLE 2. CNDO/2 calculated ionization potentials for 4-substituted stilbenes

	NH_2	OH	CH_3	F	H	CN	CF_3	NO_2
π_7	9.80	10.24	10.38	10.57	10.64	10.67	11.02	11.21
π_6	13.94	14.10	13.90	14.31	13.98	14.21	14.46	14.78
π_5	13.75	13.84	13.88	13.95	13.87	14.01	14.09	14.24
π_4	12.77	13.52	13.82	14.11	14.48	13.94	14.83	14.90
π_3	16.48	17.27	17.69	17.99	18.46	17.44	18.56	18.58

tween calculated and experimental first IP's which suggests that this overestimation is by a constant amount for each stilbene and, hence, the CNDO/2 calculations can be used as a qualitative aid for the assignment of the ionization potentials.

$Ph_A(sub)$ (π_6) and $Ph_A(unsub)$ (π_5)

These two levels are degenerate in stilbene and are located in the large band at 9.19 eV. This degeneracy is not removed by substitution of CH_3, F, or Cl. It is only for the cases of the strongest donor group (OCH_3) and the strongest acceptor group (NO_2) that the two Ph_A levels are separated. In the case of 4-MeO stilbene Ph_A(sub) has been destabilized to 8.86 eV whereas Ph_A(unsub) is located at 9.15 eV virtually unchanged from its value in stilbene. As expected the electron withdrawing NO_2 group also separates these two IP's with Ph_A(sub) being stabilized to 9.78 eV and Ph_A(unsub) to a lesser extent to 9.48 eV. The change in Ph_A(sub) from stilbene to 4-NO_2 stilbene (0.59 eV) is larger than the change in $Ph_S - \pi - Ph_S$ from stilbene to 4-NO_2 stilbene (0.40 eV). This is analogous to what is observed from benzene to nitrobenzene where Ph_S changes by 0.75 eV and Ph_A by 1.08 eV.[3]

The Ph_A orbital associated with the unsubstituted phenyl ring undergoes the least change in IP of any of the five π orbitals across the series of substituents from CH_3O to NO_2 (0.33 eV) which is to be expected as the substituents are remote from this orbital. Ph_A(sub) undergoes a change in IP of 0.92 eV over the same range of substituents. A comparison between the effect of substituent on Ph_A(sub) and the corresponding effect on Ph_A of benzenes is illustrated in Fig. 5 where Ph_A(sub) IP is plotted against Ph_A of substituted benzenes. A good linear relationship results with the exception of the parent stilbene and the OCH_3 substituent.

$Ph_S - Ph_S$

Figure 4 shows a plot of $Ph_S - Ph_S$ (π_4) IP's vs. Ph_S for substituted benzenes. A linear relationship is observed with a slope of ~0.4. This is of the same order of magnitude to that observed for the plot of $Ph_S - \pi - Ph_S$ IP vs. Ph_S of substituted benzenes indicating that the sensitivity of the stilbene system to substituents is much lower than that of benzene,

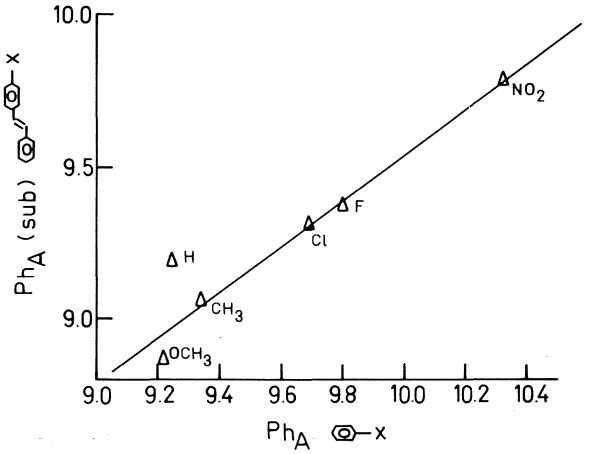

FIG. 5. Ph_A(sub) stilbenes vs. Ph_A benzenes.

which is due in part to the fact that the substituent effect spreads out over a larger π system.

The assignments arrived at here for π_6, π_5, and π_4 are subject to some uncertainty due to the overlapping of the bands involved. However, in postulating the above assignments consideration has been taken into account of the effects of these substituents on Ph_S and Ph_A orbitals of benzene (5) and the relationships observed in Figs. 4 and 5.

$Ph_S + \pi + Ph_S$

The IP's of $Ph_S + \pi + Ph_S$ (π_3) are tabulated in Table 1. From Fig. 3 it can be seen that this band is located in the region of 10–11 eV for each of the stilbenes and is well separated from the broad band containing π_6, π_5, and π_4 and also from the higher energy σ bands. Figure 4 also contains a plot of $Ph_S + \pi + Ph_S$ IP vs. Ph_S IP for substituted benzenes. A linear relationship with a slope similar to that obtained for π_7 and π_4 is observed.

Conformational Effects

π_7 and π_3 represent the anti-bonding and bonding interactions between the styryl and phenyl moieties. The difference between these two levels has been used as an indication (1, 2) of the extent of interaction between these moieties and, hence, as an indication of the extent of departure of the system from coplanarity. As can be seen from Table 1 this difference

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

is virtually constant (2.63–2.70 eV) for all substituents except Cl (2.53 eV). Thus this difference is essentially constant wthin experimental error and is taken to be evidence of the coplanarity of the phenyl rings in the stilbenes. Table 1 also lists the difference in IP between π_7 and π_4. This difference should also provide information about the conformation of the stilbenes since it represents a measure of the extent of interaction between the phenyl groups. Hence, any change in coplanary of the phenyl rings should result in a difference in the separation between π_7 and π_4. With the exception of 4-NO_2 stilbene the difference between π_7 and π_4 is constant within experimental error. Therefore, the relatively constant difference between π_7 and π_3 and between π_7 and π_4 for the substituents suggests that all the stilbenes studied here are planar or nearly planar species. Further confirmation of this comes from the linear relationship between calculated and experimental $Ph_S - \pi - Ph_S$ IP's. All calculations were performed using planar configurations and hence maximum interaction between the phenyl rings through the intervening ethylene. If any of the substituted stilbenes existed in non-planar conformations, this fact should have resulted in less correlation between experimental and calculated IP.

Calculations

CNDO/2 calculations (7) have been performed for a variety of monosubstituted stilbenes and the calculated IPs are listed in Table 2. Three common deficiencies of CNDO/2 calculations are demonstrated by the results: overestimation of the ionization potentials, incorrect order of energy levels, and orbitals placed at too high energies. An attempt has been made to compare the calculated π_7 IP's in Table 2 for those compounds for which the PE spectra have not been determined to some experimental quantity. Thus, Fig. 6 contains a plot of π_7 or $Ph_S - \pi - Ph_S$ IP (calcd) vs. Ph_S IP (expt) of the corresponding substituted benzenes. A linear relationship is obtained except for 4-CN stilbene. This suggests that when the PE spectra are determined for those compounds in Table 2 which have not been previously investigated that the first IP will be found to follow the same linear relationship observed in Fig. 4. In addition, it is predicted that the conformation of 4-NH_2, 4-OH, 4-CF_3 stilbene is the same as that for the stilbenes investigated here. There seems to be no obvious reason why the 4-CN stilbene deviates from the other stilbenes in Table 2.

Reactivity Correlations

The effect of substituent on the kinetics of bromination (8) and ozonolysis (9) of stilbenes are two examples of a large number of reactions of stilbenes

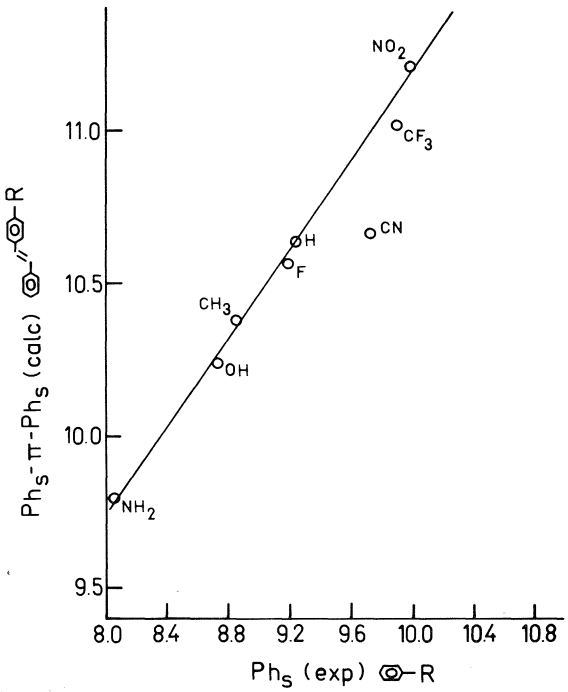

FIG. 6. $Ph_S - \pi - Ph_S$ IP (calcd) vs. Ph_S IP benzenes.

for which reactivity data are available. In this study an attempt has been made to correlate the observed kinetic parameters with ionization potential data. Figure 7 shows a plot of log. k vs. IP (π_7) for four of the substituted stilbenes studied. Both the bromination reaction (upper curve) and ozonolysis (lower curve) show linear relationships between log k and IP. Both reactions are electrophilic so that any substituent which increases the electron density on the ethylenic moiety should increase the rate. This is observed since both curves show negative slopes with the rate decreasing with IP. A more precise method of depicting the reactivity pattern might be to plot log k against some weighted average of π_7 and π_3 since the latter orbital also contains significant electron density on the ethylenic carbons and the magnitude of this electron density is influenced by the substituent. Another way to consider the bromination reaction is that since the intermediate species is postulated to go through either a carbonium or bromonium ion transition state (8) then any substituent which stabilizes this state such as a donor group is going to enhance the rate. For the ozonolysis reaction (9) the initial electrophilic attack is assumed to proceed rapidly via an irreversible 1,3-dipolar cycloaddition to give the final product. Thus, any substituent which causes an increase in the polarizability of the ethylenic C—C bond should enhance its dipolarophilic nature (10).

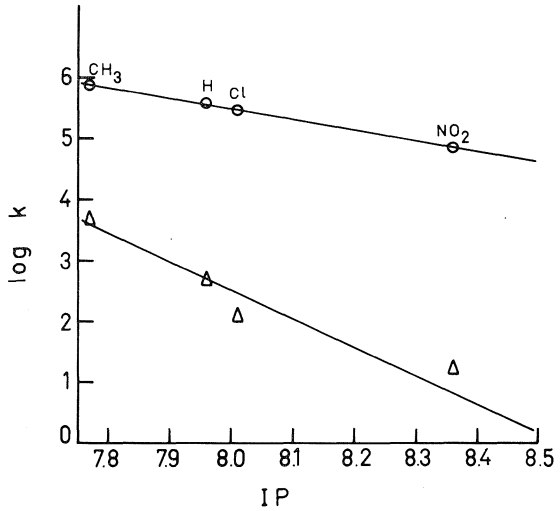

FIG. 7. log k vs. IP ($Ph_s - \pi - Ph_s$) stilbenes: ○, bromination rate data (8); △, ozonolysis rate data (9).

Further studies are in progress on the photoelectron spectra of a wider variety of substituted stilbenes with a view to investigating the influence of the number and location of substituents on the electronic structure and conformation of the stilbenes.

Experimental

The stilbenes were synthesized by a standard procedure (11) and purified by recrystallization. Photoelectron spectra were determined on a Perkin-Elmer PS-18 photoelectron spectrometer with heated probe. Xenon and argon were used as internal standards and the resolution as measured on the 15.76 eV peak of Ar was 25–35 meV. Peak positions listed in Table 1 are the average of at least five determinations.

β-Lactams. II. The synthesis of *cis*-*N*-(2′-carboxyphenyl)-3-*N*-phenylacetamido-4-methoxymethyl-2-azetidinone

GEORGE JUST AND ROBERT ZAMBONI[1]
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6
Received May 8, 1978

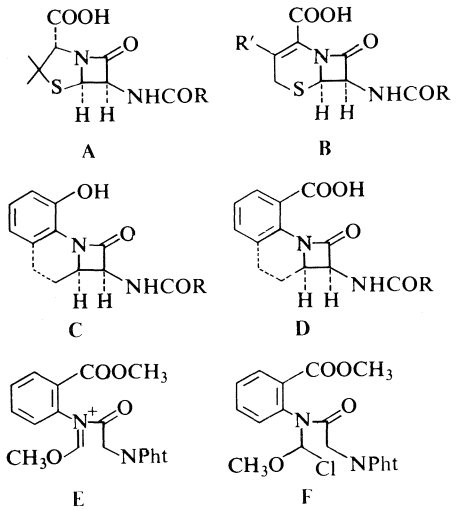
GEORGE JUST and ROBERT ZAMBONI. Can. J. Chem. **56**, 2720 (1978).
The synthesis of the β-lactam **19** from anthranilic acid is described.

GEORGE JUST ET ROBERT ZAMBONI. Can. J. Chem. **56**, 2720 (1978).
La synthèse du β-lactame **19** à partir de l'acide anthranilique est décrite.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The essential features of the classical β-lactam antibiotics penicillin **A** and cephalosporin **B** (1) are (*a*) a *cis*-fused β-lactam ring; (*b*) an acylamino side chain which can be considerably varied; (*c*) an acidic function, the nature of which is not critical since the carboxylic acid can be replaced by a phosphonic acid; (*d*) a five-membered ring or six-membered ring containing a double bond conjugated with the β-lactam nitrogen conferring enough ring strain so as to raise the β-lactam frequency to ≥ 1765 cm^{-1}. It has been shown that the sulphur atom can be replaced by oxygen or carbon without substantial loss of antimicrobial activity, (ref. 2 and references therein).

In this and the following paper, we wish to describe the synthesis of β-lactams identical to penicillin and cephalosporin in points *a* and *b* but differing in that the acidic function is attached to an aromatic ring (see **C** and **D**), and in which the strain of



the β-lactam is generated by electron withdrawing groups attached to the benzene ring, and/or by fusing the aromatic and β-lactam rings by an additional ring as indicated.

Whilst this work was in progress Doyle published the synthesis of bicyclic compounds of type **C** (3), in which the phenolic group was in the 3-position and which exhibited 'weak' antimicrobial activity.

In the first paper, we shall deal with the synthesis of bicyclic compounds of type **D**, and in the following papers, the synthesis of the tricyclic compounds of type **C** and **D** will be described.

As a model compound, the known benzylidene anthranilic acid **1** (4) was condensed with phthalimidoacetyl chloride (5). Instead of the expected β-lactam, a crystalline compound, the spectral data of which were consistent with **2**, was obtained. When Schiff base **1** was silylated *in situ* (6) before the addition of the phthalimidoacetyl chloride, the trans β-lactam **3** was obtained in 70% yield. Its structure followed from its spectral and analytical data and the stereochemistry of the ring junction from the fact that $J_{3,4} = 2$ Hz (7).

The acid was characterized as its *p*-methoxybenzyl ester, obtained by reacting **3** with *p*-methoxybenzyl alcohol and 1.2 equiv. of dineopentylformamide acetal in acetonitrile (8). The benzyl ester **3***a* was converted to the free amine **4** by means of hydrazine. We next attempted to isomerize the amine function using the method described by Christensen and co-workers (9) which involves the formation of the *p*-nitrobenzylidene Schiff base **5**, followed by carbanion formation using phenyl lithium, and kinetic protonation at low temperature. We were not successful in effecting the transformation and only recovered approximately 20% of **5**. An adaptation of the method described by Yanagisawa *et al.* (10) which involved formation of Schiff base **6**, followed by oxidation to the quinone methine and quenching with $ZnBH_4$, was equally unsuccessful.

We suspected that the difficulties in obtaining a *cis*-β-lactam may have been due to the relatively bulky phenyl group and therefore performed a

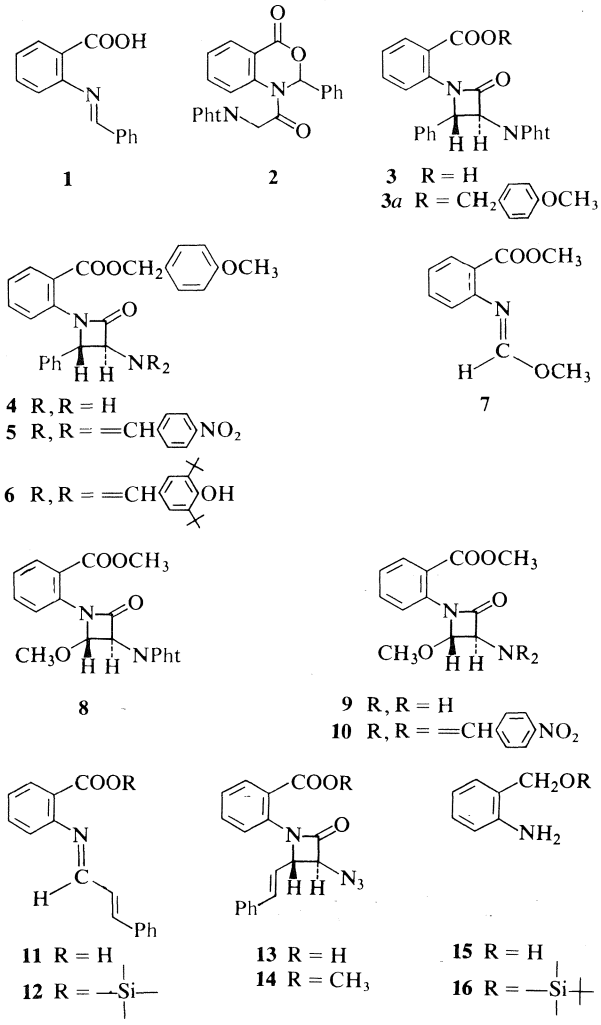
For personal use only.



similar series of reactions using imino ether **7** as the starting material. Considerable difficulty was experienced preparing **7** and the reaction conditions described in the Experimental are critical for its obtention. Addition of phthalimidoacetyl chloride to imino ether **7** afforded a 35% yield of β-lactam **8** when the reaction was allowed to proceed for 24 h. When the reaction was stopped after 2 h, a 1:1 mixture of β-lactam **8** and of methyl *N*-phthalimidoacetyl anthranilate was obtained in 30% overall yield. This suggested that the reaction did not proceed through a 2 + 2 addition of phthalimido ketene and the imine **7**, but in two stages, the first intermediate having structure **E** suggested by Doyle *et al.* (1), which is trapped presumably as the chloride **F** (13). Quenching of **F** with water during work-up would give methyl *N*-phthalimidoacetyl anthranilate, whereas a prolonged reaction time may lead to further formation of β-lactam. No β-lactam was obtained when imine **7** was treated with azidoacetyl chloride. Hydrolysis of the phthalimide function in **8** gave a low yield of amine **9**. Isomerization of *trans*-β-lactam **9** to its *cis* isomer via Schiff base **10** was unsuccessful.

Not having been able to prepare a *cis*-fused β-lactam using the approaches described, we next investigated the method recently published by Doyle *et al.* (1), which consisted in reacting azidoacetyl chloride with cinnamylidene Schiff bases, which has been reported to afford *exclusively cis*-β-lactams. Reaction of the silylated cinnamylidene Schiff base of anthranilic acid **12** with azidoacetyl chloride gave a 15–20% yield of *trans*-β-lactam **13**, characterized as its methyl ester **14**. Since cinnamylidene Schiff bases of electron-rich anilines seemed to consistently give *cis*-β-lactams in high yield,[2] it was decided to use the readily available *o*-aminobenzyl alcohol **15** as a starting material, and to oxidize the alcohol to the carboxylic acid at a later stage. Silylation of **15** gave, in quantitative yield, silyl ether **16**, which was converted to Schiff base **17**. Treatment with azido acetyl chloride gave *cis*-β-lactam **18**, mp 91–92°C, in excellent yield. Reduction with hydrogen sulfide – triethyl amine (1) followed by acylation with phenylacetyl chloride and triethylamine gave **19**, mp 108.5–109°C, $\nu_{C=O}$ 1750 cm^{-1}, in 60% yield based on **18**. Ozonolysis of **19** gave a poorly defined mixture of oxidation products. However, ozonolysis of azide **18** in redistilled isopropanol or CH_2Cl_2–ethanol (1:5) at −78°C, followed by sodium borohydride reduction at −50°C, gave, after work-up with pH 4.5 buffer, azido alcohol **20**, mp 95–96°C, $\nu_{C=O}$ 1755 cm^{-1}, in 76% yield. To differentiate the two alcohol functions, **20** was converted to its methyl ether **21** by means of diazomethane – boron trifluoride etherate. Reduction and acylation of the azide function gave amide **22**, $\nu_{C=O}$ 1750, 1665 cm^{-1}, which was converted to alcohol **23**, using aqueous trifluoroacetic acid. Alcohol **23** was easily oxidized to aldehyde **24** with pyridinium chlorochromate (11). Oxidation of **24** with silver oxide – sodium cyanide (12) in methanol led to opening of the β-lactam ring. Carboxylic acid **25** could be obtained in low yield from **23** using chromic acid in acetic acid – water. Its structure followed from its spectral data and the stereochemistry of the ring junction from the fact that $J_{3,4} = 5$ Hz (7). The mass spectrum of the corresponding methyl ester **26** showed a molecular ion, a peak at $M^+ - 31$ which is consistent with a methyl ester, and peaks at *m/e* 205 and 177 for the fragmentation shown on **25**. This fragmentation is characteristic of β-lactams. Carboxylic acid **25** showed no activity toward a variety of bacteria. This is not unexpected if we consider that $\nu_{C=O}$ of **25** is only 1755 cm^{-1},

whereas known active cephalosporins have $\nu_{C=O}$ of at least 1765 cm^{-1}.

Experimental

Solvents were of reagent grade unless otherwise specified. Infrared spectra were run on Unicam SP1000 and P.E. 257 spectrophotometers. Nuclear magnetic resonance spectra were run on Varian T-60, T-60A, or Brucker 90 MHz FT spectrophotometers. Mass spectra were taken on an AEI-MS-902 mass spectrometer using the direct sample inlet system with a 70 eV ionization energy or on a LKB 9000 mass spectrometer. Melting points were determined on a Gallenkamp block in open capillary tubes and are uncorrected. Merck SI60 silica gel was used for column chromatography. Merck silica gel HF_{254} was used for thick-layer chromatography (1 mm) on glass plates (20 × 20 cm). Elemental analyses were performed by Heterocyclic Chemical Corporation, Missouri, or Midwest Microlab Ltd., Indianapolis, IN.

Lactone **2**

To a solution of benzylidene anthranilic acid **1** (900 mg) in dry benzene (25 ml) containing triethylamine (0.8 g) was added dropwise a solution of phthalimidoacetyl chloride in dry benzene (6 ml) over a period of 20 min. The reaction mixture was stirred for 1 h more and the salt filtered off. The filtrate was washed with 1% HCl (2 × 10 ml), dried, and evaporated. Chromatography of the filtrate on thick-layer plates using $CHCl_3$–ether 3:1 as eluent afforded ~100 mg of lactone **2**, mp 185°C (dec.); ^{1}Hmr ($DCCl_3$) δ: 4.9 (q, 2H, CH_2), 7.0–8.0 ppm (m, 14H, aromatic + OC*H*Ph); ir ($HCCl_3$) ν_{max}: 1780 (weak), 1740 cm^{-1}; ms *m/e*: 412 (M^+).

Phthalimido β*-Lactam* **3**

To Schiff base **1** (1.7 g, 7.6 mmol) and triethylamine (1.8 g, 18 mmol) in dry CH_2Cl_2 (50 ml) was added quickly trimethylchlorosilane (1.75 g, 16 mmol) in CH_2Cl_2 (5 ml). The mixture was stirred for 5–10 min and then triethylamine (0.8 g, 8 mmol) was added. To the solution was added over 1.5 h a solution of phthalimidoacetyl chloride (1.7 g, 7.6 mmol) in dry CH_2Cl_2 (100 ml). After the addition was complete the mixture was stirred for 2 h more. After the addition of methanol (3 ml), the solution was washed with H_2O (50 ml), saturated NaCl solution (50 ml), dried ($MgSO_4$), and evaporated. The resulting solid was chromatographed on 60 g silica gel activity III. Elution with CH_2Cl_2 and then ethyl ether – chloroform (1:1) afforded, after crystallization with $CHCl_3$–CCl_4, 1.7 g (55%) of β-lactam **3**, mp 214–215°C; ^{1}Hmr ($DCCl_3$) δ: 5.3 (d, 1H, CH, J = 2.5 Hz), 5.6 (d, 1H, CH, J = 2.5 Hz), 6.9–8.0 (m, 13H, C_6H_4 + C_6H_5), 11.2 ppm (bs, 1H, COOH); ir (Nujol) ν_{max}: 2300–3500 (COOH), 1770 (β-lactam), 1720 (phthalimide), 1690 cm^{-1} (COOH); ms: *m/e*: 412 (M^+), 249, 225, 187, 163. *Anal.* calcd. for $C_{24}H_{16}N_2O_5$: C 69.90, H 3.91, N 6.79; found: C 70.29, H 4.09, N 7.03.

Ester **3**a

To acid **3** (2.47 g, 6 mmol) in dry acetonitrile (60 ml) was added methoxybenzyl alcohol (0.91 g, 6.6 mmol) and dineopentyl *N,N*-dimethylformamide acetal (2.04 g, 8.7 mmol). After sealing the flask under nitrogen, the solution was stirred at room temperature 24 h. Concentration down to 20 ml and filtration afforded 2.1 g (66%) of pure ester **3***a*, mp 189–190°C; ^{1}Hmr ($DCCl_3$) δ: 3.7 (s, 3H, OCH_3), 5.0 (d, 1H, CH, J = 2.5 Hz), 5.6 (d, 1H, CH, J = 2.5 Hz), 5.1 (bs, 2H, CH_2), 6.4–7.8 ppm (m, 17H, aromatic); ir (Nujol) ν_{max}: 1780 (β-lactam), 1720 cm^{-1} (ester and phthalimido).

Amine **4**

To ester **3***a* (1.59 g, 3 mmol) in CH_2Cl_2 (75 ml) was added hydrazine (120 μl, 3.8 mmol). The solution was stirred 48 h at room temperature and the solid that formed was filtered off. Evaporation of the solvent afforded an oil which was chromatographed on silica gel activity III using first $CHCl_3$–CH_2Cl_2 1:1 as eluant. Elution with chloroform–ether (3:1) afforded 0.66 g (50%) of amine **4** as an oil; ^{1}Hmr ($DCCl_3$) δ: 1.9 (bs, 2H, NH_2), 3.9 (d, 1H, C*H*NH_2, J = 2.5 Hz), 4.8 (d, 1H, *CH*Ph, J = 2.5 Hz), 5.2 (s, 2H, CH_2), 6.6–7.7 ppm (m, 13H, aromatic); ir ($CHCl_3$) ν_{max}: 3400 (NH_2), 1770 (β-lactam), 1730 (ester), 1120 cm^{-1}.

Schiff Base **5**

A solution of amine **4** (210 mg, 0.52 mmol) and *p*-nitrobenzaldehyde (78 mg, 0.52 mmol) in benzene (50 ml) was refluxed 1.5 h using a Dean–Stark trap. Removal of benzene afforded Schiff base **5** in quantitative yield; ^{1}Hmr ($DCCl_3$) δ: 3.8 (s, 3H, OCH_3), 4.7 (m, 1H, *CH*—N=C), 5.3 (bs, 2H, CH_2), 5.5 (s, 1H, CHPh, J = 2.5 Hz), 6.7–7.5 (m, 13H, C_6H_4 and C_6H_5), 8.0 (q, 4H, $NO_2C_6H_4$), 8.4 ppm (s, 1H, HC=N); ir ($CHCl_3$) ν_{max}: 1775 (β-lactam), 1730 cm^{-1} (ester and phthalimido).

Formimidate **7**

Into methyl anthranilate (10 g, 66 mmol) and trimethyl orthoformate (15 g, 141 mmol) was bubbled HCl gas for a few seconds. The mixture was heated at 110°C and the methanol formed distilled off. Near the end of the distillation a few crys-

For personal use only.

tals of TsOH were added. When 4 g of methanol was collected, the distillation was stopped and 2 g of anhydrous K_2CO_3 was added. Excess orthoformate was then distilled off at ~60°C/60 Torr. Fractional distillation of the residue gave 5.5 g (43%) of almost colourless formimidate **7**; ^{1}Hmr ($DCCl_3$) δ: 3.7 (s, 3H, OCH_3), 3.8 (s, 3H, OCH_3), 6.4–7.8 (m, 5H, C_6H_4 and HC=N); ir (neat) ν_{max}: 3000, 1730 (C=O), 1660 cm^{-1} (C=N); ms *m/e*: 193 (M^+).

β-*Lactam Ester* ***8***

To formimidate **7** (9 g, 46 mmol) in CH_2Cl_2 (150 ml) and triethylamine (5.0 g, 50 mmol) under N_2 was added dropwise over 2 h phthalimidoacetyl chloride (12.25 g, 54 mmol) in CH_2Cl_2 (100 ml). After 24 h, the solution was washed with H_2O (2 × 100 ml), dried ($MgSO_4$), and evaporated. Crystallization from $CHCl_3$–hexane, afforded 6 g (33%) of β-lactam **8**, mp 175–176.5°C; ^{1}Hmr ($CDCl_3$) δ: 3.3 (s, 3H, OCH_3), 3.81 (s, 3H, $COOCH_3$), 5.4 (s, 1H, CH, J = 2 Hz), 5.9 (s, 1H, CH, J = 2 Hz), 7.0–7.8 ppm (m, 8H, C_6H_4); ir ($CHCl_3$) ν_{max}: 1775 (β-lactam), 1730 (ester), 1400 cm^{-1}; ms *m/e*: 380 (M^+).

When the reaction was stopped after 2 h, a crystalline side product, methyl *N*-phthalimidoacetylanthranilate, could be isolated by repeated chromatography on SiO_2 activity III and recrystallization from $CHCl_3$–hexane, mp 188–190°C; ^{1}Hmr ($DCCl_3$) δ: 3.8 (s, 3H, OCH_3), 4.7 (s, 2H, CH_2), 7.0–9.0 (m, 8H, C_6H_4), 11.5 ppm (s, 1H, NH); ir ($CHCl_3$) ν_{max}: 3300 (NH), 1780, 1725 (phthalimido, ester), 1690 cm^{-1} (amide).

Amine β-*Lactam* ***9***

To β-lactam **8** (2.7 g, 7.1 mmol) in CH_2Cl_2 (50 ml) was added hydrazine (0.246 ml, 7.6 mmol). After stirring at room temperature for 3 days, the orange solid was filtered off and washed with CH_2Cl_2. The filtrate was extracted with ice-cold 1% HCl (2 × 100 ml). After neutralization with 1 *N* NaOH, the aqueous phase was extracted with chloroform (2 × 200 ml). Drying ($MgSO_4$) and evaporation afforded 500 mg (28%) of amine **9** as an orange gum; ^{1}Hmr ($DCCl_3$) δ: 1.8 (s, 2H, NH_2), 3.4 (s, 3H, OCH_3), 3.8 (s, 3H, $COOCH_3$), 4.1 (bs, 1H, *CH*NH_2), 5.2 (bs, 1H, *CH*OMe), 7.0–7.8 (m, 4H, C_6H_4); ir ($CHCl_3$) ν_{max}: 3400 (NH), 1770 (β-lactam), 1730 cm^{-1} ($COOCH_3$); ms *m/e*: 250 (M^+), 192.

Schiff Base ***10***

A solution of amine β-lactam **9** (125 mg, 0.5 mmol) and *p*-nitrobenzaldehyde (76 mg, 0.5 mmol) in benzene (30 ml) was heated at reflux for 2 h using a Dean–Stark trap. Evaporation of benzene afforded Schiff base **10**; ^{1}Hmr ($DCCl_3$) δ: 3.3 (s, 3H, OCH_3), 3.7 (s, 3H, CO_2CH_3), 4.8 (t, 1H, *CH*N=C), 5.5 (d, 1H, *CH*OCH_3), 7.0–8.1 (m, 8H, C_6H_4), 8.3 ppm (bs, 1H, N=*CH*); ir (neat) ν_{max}: 1775 (β-lactam), 1730 (ester), 1620 cm^{-1} (C=N).

β-*Lactams* ***13*** *and* ***14***

Anthranilic acid (2.7 g, 20 mmol) and cinnamaldehyde (2.64 g, 20 mmol) was heated for 4 h using a Dean–Stark trap, and the solvent evaporated. To the resulting Schiff base **11** was added triethylamine (6 g, 60 mmol) in dry CH_2Cl_2 (200 ml) and then dropwise trimethyl silyl chloride (4 g, 37 mmol) in CH_2Cl_2 (10 ml) at −5°C. After stirring for 10 min a solution of azidoacetyl chloride (2.4 g, 20 mmol) in CH_2Cl_2 (50 ml) was added at −5°C. After stirring 30 min more at room temperature, methanol (5 ml) was added. The solution was washed with H_2O (2 × 100 ml), dried, and evaporated. Chromatography on SiO_2 (200 g) activity III using first CH_2Cl_2 and then ether afforded 1 g of impure acid **13**. An ethereal solution of **13** was treated with CH_2N_2. Chromatography on SiO_2 activity III (20 g) using $CHCl_3$ as eluent gave 250 mg of ester **14** as a red oil; ^{1}Hmr ($CDCl_3$) δ: 3.8 (s, 3H, OCH_3), 4.5 (d, 1H, CHN_3, J = 2 Hz), 4.7 (q, 1H, C*H*—CH=CH—Ph, J_1 = 2 Hz, J_2 = 7 Hz), 6.0 (q, 1H, J_1 = 7 Hz, J_2 = 18 Hz, CH*CH*=CHPh), 6.7 (d, 1H, HC=C*H*Ph, J = 18 Hz), 6.9–7.5 ppm (m, 8H, C_6H_5 and C_6H_3); ir ($CHCl_3$ ν_{max}: 1760 (β-lactam), 1725 cm^{-1} (ester); ms *m/e*: 320 (M^+).

Silylether Amine ***16***

To *o*-aminobenzyl alcohol **15** (1.23 g, 10 mmol) in dry DMF (15 ml) was added imidazole (1.75 g, 25 mmol) and *tert*-butyldimethylsilyl chloride (1.65 g, 11 mmol). The solution was stirred at room temperature and partitioned between H_2O (50 ml) and ether (100 ml). The ether layer was washed with water (4 × 50 ml), dried, and evaporated. A quantitative yield of silylether amine **16** was obtained; ^{1}Hmr ($DCCl_3$) δ: 0.05 (s, 6H, Si(CH_3)$_2$), 0.9 (s, 9H, Si*t*Bu), 4.0 (bs, 2H, NH_2), 4.6 (s, 2H, *CH*$_2$OH), 6.9–7.0 ppm (m, 4H, C_6H_4); ir (film) ν_{max}: 3460, 3370, 2910, 1630, 1420, 1050 cm^{-1}.

Schiff Base ***17***

A solution of amine **16** (4.72 g, 20 mmol) and cinnamaldehyde (2.7 g, 20 mmol) in benzene (50 ml) was heated at reflux for 8 h using a Dean–Stark trap. Evaporation of benzene afforded a quantitative yield of Schiff base **17** as a yellow oil; ^{1}Hmr ($DCCl_3$) δ: 0.05 (s, 6H, $SiMe_2$), 0.9 (s, 9H, Si*t*Bu), 4.9 (s, 2H, —CH_2O—), 6.8–7.4 (m, 9H, aromatic), 7.9 ppm (t, 1H, *HC*=NPh); ir (film) ν_{max}: 2910, 1640 (C=N) cm^{-1}.

β-*Lactam Azide* ***18***

To a solution of Schiff base **17** (7.0 g) and triethylamine (2.4 g, 1.2 equiv.) in CH_2Cl_2 (200 ml) at −20°C under nitrogen was added dropwise over 1 h azidoacetyl chloride (2.8 g, 1.15 equiv.) in CH_2Cl_2 (100 ml). The solution was stirred for 1 h at room temperature, washed with H_2O (2 × 100 ml), dried ($MgSO_4$), and evaporated. Treatment of the red oil with charcoal in ether gave, after crystallization from pentane, 6.0 g (74%) of β-lactam **18** as a white solid, mp 91–92°C; ^{1}Hmr ($DCCl_3$) δ: 0.1 (s, 6H, $SiMe_2$), 0.95 (s, 9H, Si*t*Bu), 4.6 (s, 2H, *CH*$_2$O), 4.6–5.0 (m, 2H, C*H*—*CH*N_3), 5.8–6.6 ppm (m, 2H, PhC*H*=*CH*—); ir (KBr) ν_{max}: 2900, 2100 (N_3), 1745 cm^{-1} (C=O); ms *m/e*: 434 (M^+), 406 ($M^+ - N_2$), 377 ($M^+ - 57$). *Anal.* calcd. for $C_{24}H_{30}N_4O_2Si$: C 66.40, H 6.97, N 12.92; found: C 66.31, H 6.85, N 12.91.

β-*Lactam Amide* ***19***

Hydrogen sulphide was bubbled into a solution of azide **18** (450 mg, 1.1 mmol) and triethylamine (150 mg, 1.5 mmol) in CH_2Cl_2 (20 ml) at 0°C. After 1 h, the solution was purged with N_2, washed with H_2O (2 × 20 ml), dried, and evaporated. To the crude product in CH_2Cl_2 (20 ml) and triethylamine (150 mg, 1.5 mmol) was added dropwise phenylacetyl chloride (0.237 g, 1.5 mmol) in CH_2Cl_2 (1 ml). After stirring for 30 min more, the solution was washed with pH 4.5 buffer (20 ml), water (20 ml), dried ($MgSO_4$), and evaporated. The crude product was chromatographed on SiO_2 (20 g) activity III using first CH_2Cl_2 as eluent. Elution with $CHCl_3$–ether 1:1 afforded after crystallization from pentane–chloroform 300 mg (60%) of amide **20** as a white solid, mp 108.5–109°C; ^{1}Hmr ($DCCl_3$) δ: 0.1 (s, 6H, $SiMe_2$), 0.95 (s, 9H, Si*t*Bu), 3.4 (s, 2H, —CH_2Ph), 4.8 (s, 2H, CH_2OTBDMS), 4.9 (q, 1H, *CH*CH—CHϕ, J_1 = 7 Hz, J_2 = 5 Hz), 5.6 (q, 1H, C*H*NH, J_1 = 5 Hz, J_2 = 7 Hz), 6.2 (q, 1H, C*H*=CHPh, J_1 = 7 Hz, J_2 = 18 Hz), 6.5 (d, CH=C*H*Ph, 1H, J = 18 Hz), 7.0–7.5 ppm (m, 10H, C_6H_5, C_6H_4, and NH); ir ($HCCl_3$) ν_{max}: 3450 (NH), 2900 (N_3), 1750 (β-lactam), 1680 (amide), 1080 cm^{-1}; ms *m/e*: 524 (M^+), 467 ($M^+ - 57$).

Alcohol ***20***

Ozone was passed for 1.5 h through a solution of azide **18** (4 g) in CH_2Cl_2 (80 ml) and ethanol (160 ml) at −78°C. After

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

purging with N_2, $NaBH_4$ (0.8 g) was added and the solution allowed to warm up to room temperature (2 h). The reaction was quenched with pH 4.5 buffer (150 ml), evaporated, and partitioned between $CHCl_3$ (200 ml) and H_2O (100 ml). Evaporation and drying ($MgSO_4$) afforded, after crystallization from hexane–CCl_4, 2.5 g of alcohol **20** (76%), mp 95–96°C; ^{1}Hmr ($DCCl_3$) δ: 0.15 (s, 6H, $SiMe_2$), 0.9 (s, 9H, Si*tBu*), 2.6 (bs, 1H, OH), 3.8 (bs, 2H, CH_2OH), 4.3 (q, 1H, CH), 4.7 (s, 2H, CH_2OTBDMS), 4.8 (d, 1H, CHN_3, J = 5 Hz), 7.0–7.4 ppm (m, 4H, C_6H_4); ir ($HCCl_3$) ν_{max}: 3350 (OH), 2900, 2100 (N_3), 1755 (C=O), 1050 cm^{-1}.

Methyl Ether ***21***

To a solution of alcohol **20** (450 mg) in dry CH_2Cl_2 (50 ml) at 0°C was added 5 drops of a solution containing 0.5 ml $BF_2{\cdot}Et_2O$ in ether (25 ml). To this pink solution was added excess (~10 equiv.) of CH_2N_2 in ether over 30 min. After stirring for an additional hour, the suspension was filtered, washed with H_2O (25 ml), dried ($MgSO_4$), and evaporated. Chromatography of the residue on SiO_2 activity III (20 g) using chloroform as eluent afforded 340 mg (74%) of methyl ether **21** as a clear colorless syrup; ^{1}Hmr ($DCCl_3$) δ: 0.1 (s, 6H, $SiMe_2$), 0.95 (s, 9H, Si*tBu*), 3.2 (s, 3H, OCH_3), 3.3–3.7 (m, 2H, CH_2OCH_3), 4.3 (q, 1H, $CHCH_2OCH_3$), 4.5 (q, 2H, CH_2 OTBDMS), 4.6 (d, 1H, CHN_3, J = 5 Hz), 6.9–7.4 ppm (m, 4H, C_6H_4); ir (neat) ν_{max}: 2900, 2100 (N_3), 1760 (C=O) cm^{-1}.

Methoxy Amide ***22***

Into a solution of methoxy azide **21** (340 mg, 0.9 mmol) in CH_2Cl_2 (20 ml) and Et_3N (0.25 ml, 1.8 mmol) at 0°C was bubbled hydrogen sulfide for 5 min. The ice bath was removed and the solution let stand 1 h, washed with H_2O (2 × 25 ml), dried (Na_2SO_4), and evaporated. To the crude product in CH_2Cl_2 (10 ml) was added pyridine (0.5 ml, 6 mmol) and then phenylacetylchloride (0.2 ml, 1.5 mmol). After stirring at room temperature for 20 min, the solution was washed with pH 4.5 buffer (25 ml), dried ($MgSO_4$), and evaporated. The crude product after chromatography on SiO_2 activity III using chloroform as eluent afforded 280 mg (65%) of amide **22** as a yellow syrup; ^{1}Hmr ($DCCl_3$) δ: 0.15 (6H, d, $SiMe_2$), 0.9 (s, 9H, Si*tBu*), 2.9 (3H, s, OMe), 3.2–3.6 (m, 2H, CH_2OCH_3), 4.2–4.4 (m, 1H, $CHCH_2OMe$), 4.8 (q, 2H, CH_2OTBDMS), 5.7 (q, 1H, $CHNH$, J_1 = 5 Hz, J_2 = 7 Hz), 7.0–7.5 ppm (m, 10H, C_6H_5, C_6H_4 + CHN*H*); ir ($HCCl_3$) ν_{max}: 3350, 2900, 1750 (β-lactam), 1665 (amide), 1100 cm^{-1}.

Benzyl Alcohol ***23***

To a solution of amide **22** (280 mg) in THF (10 ml) – H_2O (2 ml) was added dropwise trifluoroacetic acid (2 ml). After stirring 10 min at room temperature the solution was poured onto 5% $NaHCO_3$ (50 ml) and extracted with ethyl acetate (2 × 50 ml). Drying ($MgSO_4$), evaporation, and chromatography on thick-layer plates (SiO_2, 20 × 20 cm) using ether – ethyl acetate (2:1) as eluent afforded 110 mg (52%) of alcohol **23** as a colourless syrup; ^{1}Hmr ($DCCl_3$) δ: 2.95 (s, 3H, OCH_3), 3.2–3.6 (m, 2H, CH_2OCH_3), 3.7 (s, 2H, CH_2Ph), 3.8–4.2 (m, 1H, CH_2OH), 4.3–4.5 (m, 1H, $CHCH_2OCH_3$), 4.6 (s, 2H, CH_2OH), 5.7 (q, 1H, $CHNH$, J_1 = 5 Hz, J_2 = 7 Hz), 6.7–7.6 ppm (m, 10H, NH, aromatic); ir ($CHCl_3$) ν_{max}: 3350 (NH), 1745 (C=O), 1670 cm^{-1} (C=O of amide).

Aldehyde ***24***

To a slurry of pyridinium chlorochromate (100 mg, 0.46 mmol) and NaOAc (24 mg, 0.3 mmol) in CH_2Cl_2 (2 ml) was added a solution of alcohol **23** (100 mg, 0.3 mmol) in CH_2Cl_2 (1 ml). After stirring for 1 h, the reaction mixture was poured into ether (50 ml). The solution was filtered (Celite), washed with H_2O (2 × 50 ml), and dried (Na_2SO_4). Evaporation of ether gave 70 mg (70%) of aldehyde **24**, mp 137–138°C; ^{1}Hmr ($CDCl_3$) δ: 2.9 (s, 3H, OCH_3), 3.4 (m, 2H, CH_2OMe), 3.7 (s, 2H, CH_2Ph), 4.4–4.7 (m, 1H, $CHCH_2OMe$), 5.8 (q, 1H, $CHNH$, J_1 = 5 Hz, J_2 = 7 Hz), 6.7 (bd, 1H, NH, J = 7 Hz), 7.0–8.0 (m, 9H, aromatic), 10 ppm (s, 1H, CHO); ir (KBr) ν_{max}: 3300, 2880, 1755 (β-lactam), 1680 cm^{-1} (amide and aldehyde); ms *m/e*: 352 (M^+), 351 ($M^+ - 1$), 205, 146.

Carboxylic Acid ***25*** *and Methyl Ester* ***26***

To a solution of alcohol **23** (85 mg) in acetic acid (4 ml) was added 1 ml of a solution of CrO_3 (800 mg) in AcOH (9 ml) and H_2O (1 ml). The solution was stirred overnight at room temperature, poured into H_2O (50 ml), and extracted with $HCCl_3$ (3 × 50 ml). The organic phase was washed with water (2 × 20 ml) and then extracted with $NaHCO_3$ (2 × 50 ml). Neutralization of the $NaHCO_3$ extracts with dilute HCl to pH 1 and extraction with chloroform (2 × 100 ml) afforded after drying ($MgSO_4$) and evaporation 25 mg of acid **26**; ^{1}Hmr ($DCCl_3$) δ: 2.9 (s, 3H, OCH_3), 3.2 (bd, 2H, CH_2OCH_3), 3.6 (s, 2H, CH_2Ph), 4.3 (bd, 1H, $CHCH_2OCH_3$), 5.6 (q, 1H, $CHNH$, J_1 = 5 Hz, J_2 = 7 Hz), 6.8 (d, 1H, NH, J = 7 Hz), 6.8–7.8 ppm (m, 9H, C_6H_5 and C_6H_4); ir ($HCCl_3$) ν_{max}: 2500–3500 (NH, OH), 1755 (β-lactam), 1710 (COOH), 1670 cm^{-1} (C=O amide). Treatment with diazomethane in ether gave methyl ester **26**; ms *m/e*: 382 (M^+), 351 ($M^+ - 31$), 205 (base peak), 177.

β-Lactams. III. The synthesis of 7-β-phenylacetamido-3′-carboxybenzo[3,4]-*O*-2-isocephem

GEORGE JUST AND ROBERT ZAMBONI[1]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received May 8, 1978

GEORGE JUST and ROBERT ZAMBONI. Can. J. Chem. **56**, 2725 (1978).

The synthesis of the β-lactam **34** from 3-methoxy-2-nitrobenzaldehyde is described.

GEORGE JUST et ROBERT ZAMBONI. Can. J. Chem. **56**, 2725 (1978).

La synthèse du β-lactame **34** à partir du 3-methoxy-2-nitrobenzaldehyde est décrite.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In the preceding paper we described the synthesis of bicyclic anthranyl azetidinones, in which the β-lactam frequency was 1755 cm^{-1}, and which, not surprisingly, showed no significant anti-microbial activity. To raise the β-lactam frequency it was decided to prepare the tricyclic anthranyl azetidinone **34**, which we expected to absorb at considerably higher frequency and which should therefore be similar to classical β-lactams, except for the position of the carboxylic acid (1).

The commercially available 3-methoxy-2-nitrobenzoic acid (**1**) was reduced to amine **2** with PtO_2 in ethanol and the resulting aminobenzoic acid **2** transformed to its methyl ester **3** with diazomethane. Attempts to convert **3** to its cinnamylidene Schiff base failed. The free amino acid **2** was therefore directly converted to Schiff base **4** by reaction with cinnamaldehyde in benzene using a Dean–Stark apparatus. Reaction of **4** with trimethylsilyl chloride – triethylamine in CH_2Cl_2, followed by azidoacetyl chloride (2) gave, after methylation with diazomethane and extensive chromatography, a mixture of

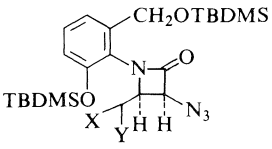
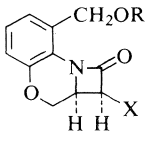
trans- and *cis*-β-lactams **6** and **8** in approximately 25% yield. The nmr spectrum after addition of $Eu(fod)_3$ clearly showed the presence of the *cis* isomer **8**, $J_{3,4} = 5$ Hz, and of the *trans* isomer **6**, $J_{3,4} = 2$ Hz, in addition to all other appropriate signals.

It was therefore decided to reduce the electron withdrawing carboxyl function, which was responsible for the low yield of the reaction and the formation of the *trans* isomer, to an alcohol before carrying out the cyclo addition, and to eventually reoxidize the benzyl alcohol to the corresponding benzoic acid. 3-Methoxy-2-nitrobenzaldehyde **9** was quantitatively demethylated with BBr_3 (3) in CH_2Cl_2 to phenol **10**, which was benzylated to benzyl ether **11**, mp 77–79°C. $NaBH_4$ reduction gave alcohol **12** which was transformed to aniline **13** by means of catalytic hydrogenation (PtO_2). Silylation with *tert*-butyldimethylsilyl chloride gave 2-amino-3-benzyloxybenzyl alcohol *tert*-butyldimethylsilyl ether **14** in 40% yield, based on **9**. Aniline **14** was transformed to its cinnamylidene Schiff base **15**, which gave *cis*-β-lactam **16** in 84% yield upon reaction with azidoacetyl chloride and triethylamine in CH_2Cl_2 at −20°C. Ozonolysis of **16** in ethanol – methylene chloride (3:1) at −78°C, followed by sodium borohydride reduction at low temperature gave alcohol **17**, which was transformed to mesylate **18**. Treatment of **18** with trifluoroacetic acid – THF – water and oxidation of the resulting alcohol **19** with CrO_3 in acetic acid – water gave a 30% yield of acid **20**, mp 153–155°C. Treatment of **20** with diphenyldiazomethane gave the benzhydryl ester **21**. Reduction of the azido group of **21**, followed by acylation of the resulting amine function gave β-lactam amide ester **22**, mp 128–129°C. Attempts to remove the benzyl groups by catalytic hydrogenation and to cyclize the resulting phenol mesylate with DBU or triethylamine failed, as evidenced by nmr which showed the presence of the mesylate group.

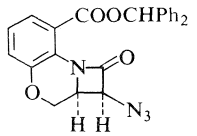
Since we had indications, based on model studies, that the desired cyclization proceeded well, when it was effected on a silyl phenol mesylate of type **28**, the sequence was repeated with a *tert*-butyldimethylsilyl ether instead of the benzyl ether. Reduction of **10** first with $NaBH_4$ in ethanol and then catalytically (PtO_2) afforded, after silylation with *tert*-butyldimethylsilyl chloride, amine **24** in 68% yield from **9**. Aniline **24** was transformed to its cinnamylidene Schiff base **25**, which gave *cis*-β-lactam **26** in approximately 80% yield. Ozonolysis of **26** in ethanol–CH_2Cl_2 (5:1) followed by reduction with $NaBH_4$ afforded, after chromatography, crystalline alcohol **27**, mp 112–112.5°C, in 53% yield. It was transformed



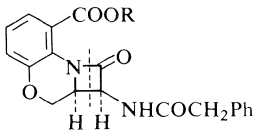


26 X, Y = CH=CHPh
27 X, Y = H, OH
28 X, Y = H, OSO_2CH_3

29*a* R = TBDMS, X = N_3
29*b* R = TBDMS, X = $NHCOCH_2Ph$
30 R = H, X = N_3
31 R = H, X = $NHCOCH_2Ph$



32



33 R = $CHPh_2$
34 R = H
35 R = CH_3

to its mesylate **28** with MsCl–Et_3N. Cyclization of **28** with 1 equiv. of freshly prepared tetra-*n*-butylammonium fluoride in THF, or better still, with approximately 2 equiv. of KF and 18-crown-6 (0.3 equiv.), gave a 90–95% yield of cyclized product **29***a*, $\nu_{C=O}$ 1775 cm^{-1}, as an oil. Reduction of the azide group with NEt_3–H_2S followed by acylation with phenylacetyl chloride – NEt_3 and deblocking with TFA–H_2O–THF gave amide **31**. Attempts to oxidize the benzyl alcohol **31** with RuO_2–$NaIO_4$, CrO_3–AcOH–H_2O, and $KMnO_4$–pyridine only gave the corresponding aldehyde and no acid **34**. Since the oxidation did not give the desired product we next attempted to oxidize azide benzyl alcohol **30**, obtained from the silyl ether **29***a* by acid treatment. Oxidation with CrO_3–AcOH–H_2O gave the desired carboxylic acid, which was converted to the benzhydryl ester **32** by means of diphenyldiazomethane in acetonitrile. NEt_3–H_2S reduction followed by acylation gave the desired amide **33**. Attempts to remove the benzhydryl ester with TFA–anisole at 0°C failed and resulted in decomposition of the β-lactam ester **33**. However, catalytic hydrogenation, using Pd/C in ethanol, gave the desired acid **34** as a light yellow powder, $\nu_{C=O}$(KBr) 1780, 1685, and 1650 cm^{-1}, fully characterized as its methyl ester **35**. Its structure followed from its spectral data and the stereochemistry of the ring junction from the fact that $J_{3,4} = 4.8$ Hz (4). The mass spectrum of methyl ester **35** showed a molecular ion, a peak at $M^+ - 31$ which is consistent with a methyl ester and peaks at m/e 175 and 192 typical of the fragmentation of β-lactams as indicated on structure **35** (5).

Carboxylic acid **34** showed no activity toward a variety of bacteria. It therefore seems that the position of the carboxyl function in cephalosporins is critical for antimicrobial activity.

Experimental

Solvents are of reagent grade unless otherwise specified. Infrared spectra were run on Unicam SP1000 and P.E. 257 spectrophotometers. Nuclear magnetic resonance spectra were run on Varian T-60, T-60A or Brucker FT-90 spectrophotometers. Mass spectra were taken on a AE1 MS-902 or on a LKB 9000 mass spectrophotometer using the direct sample inlet system with a 70 eV ionization energy. Melting points were determined on a Gallenkamp block in open capillary tubes and are uncorrected. Merck silica gel 60 was used for column chromatography. Merck silica gel HF 254 was used for thick-layer chromatography (1 mm) on glass plates (20 × 20 cm). Elemental analyses were performed by Midwest Microlab Ltd., Indianapolis, IN.

*β-Lactams **6** and **8***

3-Methoxyanthranilic acid (0.8 g, 5 mmol) and cinnamaldehyde (0.66 g, 5 mmol) in 50 ml benzene were heated at reflux for 24 h using a Dean–Stark trap. After evaporation of the benzene, Me_3SiCl (0.65 ml, 5.1 mmol) in 10 ml CH_2Cl_2 was added dropwise to a solution of **4** in 50 ml CH_2Cl_2 containing Et_3N (1.4 g, 15 mmol). The mixture was then cooled to −20°C and azidoacetyl chloride (0.6 g, 5 mmol) in CH_2Cl_2 (10 ml) was added dropwise over 15 min. The reaction mixture was stirred for an additional 30 min and after the usual work-up, the crude product was chromatographed on SiO_2 activity III (40 g). Elution with CH_2Cl_2 and then with $CHCl_3$–ether (1:1) afforded crude acid **5** and **7** as a mixture. An ethereal solution of the acid was methylated with CH_2N_2, washed with 5% HCl (4 × 50 ml) to remove anthranilic acid, and purified by thick-layer plates (20 × 20 × 1 mm, SiO_2) using $CHCl_3$–ether (5:1), yield 300 mg; ^{1}Hmr ($CHCl_3$) δ: 3.8 (d, 6H, OCH_3), 4.2–5.0 (m, 2H, CH and CHN_3), 6.0–6.6 (m, 2H, PhCH=CH), 6.8–7.5 ppm (m, 8H, C_6H_3 and C_6H_5); ir ($CHCl_3$) ν_{max}: 1750, 1730 cm^{-1}; addition of Eu(fod)$_3$ separated doublet at 3.8 into four singlets and multiplets at 4.2–5.0 to a doublet (1 H) for CHN_3 of the *cis* isomer ($J_{3,4}$ = 5 Hz) and doublet (1 H) for CHN_3 of the *trans* isomer ($J_{3,4}$ = 2 Hz).

*3-Hydroxy-2-nitrobenzaldehyde (**10**)*

To a suspension of 3-methoxy-2-nitrobenzaldehyde (12 g, 66 mmol) in CH_2Cl_2 (300 ml) at −78°C was added dropwise over ½ h a solution of BBr_3 (20 ml, 210 mmol) in CH_2Cl_2 (200 ml). After the addition was complete, the Dry Ice – acetone bath was removed and the red solution allowed to warm up to 20°C (3 h). The red solution was poured into crushed ice (500 g) and extracted with ethyl acetate (1 ℓ). Drying ($MgSO_4$) and evaporation *in vacuo* afforded 11 g (94%) of crude 3-hydroxy-2-nitrobenzaldehyde, mp 140°C (dec.); ^{1}Hmr (DMSO-d_6) δ: 7.4–7.8 (m, 3H, C_6H_3), 10.4, (s, 1H, *CHO*), 11.4 ppm (s, C_6H_3OH); ir (CH_2Cl_2) ν_{max}: 3300(OH), 3000, 1710(C=O), 1610 cm^{-1}.

*3-Benzyloxy-2-nitrobenzaldehyde (**11**)*

To 3-hydroxy-2-nitrobenzaldehyde (5 g, 29 mmol) in DMSO (17 ml) was added benzyl bromide (5 g, 29 mmol) and K_2CO_3 (5 g, 36 mmol). The suspension was stirred overnight at room temperature. The reaction mixture was poured into water (500 ml) and extracted with ether (2 × 300 ml). The ether layer was washed with water (4 × 100 ml). Drying ($MgSO_4$) and evaporation afforded 7 g of crude benzyl ether. Crystallization from chloroform–ether afforded 3.6 g (50%) of **11**, mp 77–79°C; ^{1}Hmr ($CDCl_3$) δ: 5.2 (s, 2H, CH_2O), 7.0–7.5 (m, 8H, C_6H_5 and C_6H_3), 9.8 ppm (s, 1H, CHO); ir (KBr): ν_{max} 3000, 2900, 1705 cm^{-1} (CHO).

*3-Benzyloxy-2-nitrobenzyl Alcohol (**12**)*

To aldehyde **11** (8 g, 48 mmol) suspended in EtOH (300 ml) and MeOH (50 ml) at 0°C was added $NaBH_4$ (0.4 g, 41 mmol) in portions. After stirring for 1 h, excess $NaBH_4$ was destroyed with acetic acid (2 ml). The residue, after evaporation of the solvent, was partitioned between 1% HCl (200 ml) and ethyl acetate (300 ml). Drying ($MgSO_4$) and evaporation afforded in quantitative yield alcohol **12**; ^{1}Hmr (acetone-d_6) δ: 2.8 (bs, 1H, CH_2OH), 4.4 (s, 2H, CH_2OH), 5.1 (s, 2H, $PhCH_2O$), 6.4–7.2 (m, 3H, C_6H_3), 7.3 ppm (s, 5H, C_6H_5); ir (film) ν_{max}: 3550, 3350 (OH), 2900 cm^{-1}.

*Amine **14***

A solution of alcohol **12** (5.2 g) and PtO_2 (400 mg) was hydrogenated at 40 psi, using a Parr hydrogenator, for 2 h. The residue, after filtration of catalyst through Celite and evaporation, was dissolved in ethyl acetate (200 ml) and washed with 5% NaOH (2 × 100 ml). Drying ($MgSO_4$) and evaporation of the ethyl acetate afforded 3.7 g (16 mmol) of almost colourless amine **13** as a semisolid. The amine in DMF (75 ml) was immediately treated with *tert*-butyldimethylsilyl chloride (3.0 g, 20 mmol) and imidazole (3.3 g, 48 mmol). After stirring overnight at room temperature, the solution was partitioned between ether (200 ml) and water (500 ml). The ether layer was washed with water (4 × 100 ml) and dried ($MgSO_4$). Evaporation afforded a quantitative yield of silyl amine **14**; ^{1}Hmr ($CDCl_3$) δ: 0.05 (s, 6H, $SiMe_2$), 0.90 (s, 9H, Si*t*Bu), 4.4 (bs, 2H, NH_2), 4.7 (s, 2H, $CH_2OTBDMS$), 5.0 (s, 2H, $PhCH_2O$), 6.6–6.8 (m, 3H, C_6H_3), 7.4 ppm (s, 5H, C_6H_5); ir (film) ν_{max}: 3370, 3460 (NH_2), 2960, 2940 cm^{-1}.

*Azide β-Lactam **16***

A solution of cinnamaldehyde (3.3 g, 25 mmol), amine **14** (8.3 g, 24 mmol), and a few crystals of TsOH in benzene (200 ml) was heated at reflux overnight using a Dean–Stark trap. Evaporation of the solvent afforded Schiff base **15** as a light yellow oily solid. To the Schiff base dissolved in CH_2Cl_2 (200 ml) and triethylamine (3.3 g, 33 mmol) at −20°C under N_2 was added dropwise over 1 h azidoacetyl chloride (3.6 g, 30 mmol) in CH_2Cl_2 (100 ml). The red brown solution was stirred at −20°C for 1 h more. Washing with water (2 × 100 ml), drying ($MgSO_4$), and evaporation afforded, after treatment with charcoal and filtration through Al_2O_3 (300 g) using CH_2Cl_2 as eluent, 11 g (84%) of fairly pure azido β-lactam **16** as an orange oil; ir (film) ν_{max}: 2900, 2100(N_3), 1770 cm^{-1} (C=O).

*Alcohol **17***

Ozone (8 mmol/h) was bubbled through a solution of crude β-lactam **16** (1.7 g) in EtOH (100 ml) and methylene chloride (20 ml) at −78°C for 35 min. Excess ozone was removed with N_2 and $NaBH_4$ (850 mg) was added. After warming to room temperature (2 h), 100 ml of pH 4.5 buffer was added. Removal of solvent on a rotary evaporator and extraction with CH_2Cl_2 (2 × 300 ml) afforded, after drying ($MgSO_4$) and evaporation, crude alcohol (1.6 g). Careful column chromatography on SiO_2 activity III (30 g) using chloroform as eluent afforded 850 mg (58%) of pure alcohol **17**; ^{1}Hmr ($DCCl_3$ + D_2O) δ: 0.1 (s, 6H, s, $SiMe_2$), 0.95 (s, 9H, Si*t*Bu), 3.7 (d, 2H, CH_2OH), 4.2–4.5 (m, 1H, $CHCH_2OH$), 4.6 (d, 1H, CHN_3, J = 5 Hz), 4.71 (q, 2H, $CH_2OTBDMS$), 5.0 (s, 2H, $PhCH_2$), 6.8–7.3 (m, 3H, C_6H_3), 7.4 ppm (s, 5H, C_6H_5); ir (film) ν_{max}: 3400 (OH), 2900, 2100 (N_3), 1760 (C=O), 1240, 1100 cm^{-1}; ms *m/e*: 411 (M^+ − 57). *Anal.* calcd. for $C_{24}H_{32}N_4O_4Si$: C 61.54, H 6.84, N 11.95; found: C 61.41, H 7.12, N 12.17.

*Mesylate **18***

To alcohol **17** (130 mg) in CH_2Cl_2 (10 ml) and triethylamine (80 μl) at −78°C was added methanesulphonyl chloride (35 μl).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

After warming to 20°C, usual work-up afforded a quantitative yield of mesylate **18**; ^{1}Hmr ($DCCl_3$) δ: 0.15 (s, 6H, $SiMe_2$), 1.0 (s, 9H, Si*tBu*), 2.6 (s, 3H, SO_2CH_3), 4.5 (d, 2H, $CH_2OSO_2CH_3$), 4.8 (q, 1H, $CHCH_2$), 4.8 (s, 2H, $CH_2OTBDMS$), 4.9 (d, 1H, CHN_3, J = 5 Hz), 5.1 (s, 2H, OCH_2Ph), 6.9–7.3 (m, 3H, C_6H_3), 7.4 ppm (s, 5H, C_6H_5); ir ($CHCl_3$) ν_{max}: 2900, 2100 (N_3), 1770 cm^{-1} (C=O).

Benzyl Alcohol ***19***

To mesylate **18** (850 mg) in THF (25 ml) and H_2O (10 ml) was added dropwise trifluoroacetic acid (3 ml). The homogeneous solution was stirred at room temperature 20 min and poured into 5% $NaHCO_3$ (200 ml). Extraction with ethyl acetate (2 × 200 ml), drying ($MgSO_4$), and evaporation afforded crude mesylate benzyl alcohol **19**. The crude benzyl alcohol was chromatographed on SiO_2, activity III, using first $CHCl_3$–ether (1:1) as eluent. Elution with ether afforded 470 mg (72%) of alcohol as a colorless syrup; ^{1}Hmr ($DCCl_3$) δ: 2.7 (s, 3H, CH_3), 3.2 (bs, 1H, CH_2OH), 4.4 (d, 2H, CH_2OMs), 4.6 (s, 2H, CH_2OH), 4.7 (q, 1H, CH—CH_2), 4.9 (d, 1H, CHN_3, J = 5 Hz), 5.1 (s, 2H, CH_2Ph), 6.8–7.4 (m, 3H, C_6H_3), 7.4 ppm (s, 5H, C_6H_5); ir (film) ν_{max}: 3450 (OH), 2900, 2100 (N_3), 1770 (C=O), 1350, 1180, 1100 cm^{-1}.

Carboxylic Acid ***20***

Alcohol **19** (440 mg, 1 mmol) was dissolved in acetic acid and 4.4 ml (2.6 mmol) of a CrO_3 solution (600 mg CrO_3 in 9 ml AcOH, 1 ml H_2O) was added. After stirring overnight at room temperature, most of the acetic acid was evaporated. The residue was poured into pH 1.8 buffer (30 ml) and extracted with $CHCl_3$ (3 × 100 ml). Drying ($MgSO_4$), evaporation of $CHCl_3$, and trituration with ether, afforded 190 mg (42%) of acid **20** as a nearly white solid, mp 153–155°C; ^{1}Hmr ($CDCl_3$) δ: 2.7 (s, 3H, SO_2CH_3), 4.3–4.7 (m, 3H, $CHCH_2$), 4.9 (bd, 1H, CHN_3), 5.1 (s, 2H, CH_2OPh), 7–7.4 (m, 8H, C_6H_3 and C_6H_5), 10.8 ppm (s, 1H, CO_2H); ir ($CHCl_3$) ν_{max}: 2700–3200 (CO_2H), 2080(N_3), 1775 (β-lactam), 1720 cm^{-1} (acid); ir (KBr) ν_{max}: 1740 cm^{-1} (b, C=O).

Ester ***21***

Acid **20** (400 mg, 0.9 mmol) was suspended in CH_3CN (20 ml) and treated with a 1 *M* solution of Ph_2CHN_2 in CH_3CN (1 ml). After stirring 1 h at room temperature a few drops of acetic acid were added. Chromatography of the crude product, on thick layer plates (20 × 20 cm) using $CHCl_3$–ether (5:1) as eluent, afforded 420 mg (77%) of ester **21** as a white foam; ^{1}Hmr ($CDCl_3$) δ: 2.6 (s, 3H, SO_2CH_3), 4.2–4.6 (m, 4H, $CHCH_2$ and CHN_3), 5.1 (s, 2H, OCH_2Ph), 7.2–7.6 ppm (m, 14H, $CHPh_2$ and C_6H_3); ir ($CHCl_3$) ν_{max}: 2100 (N_3), 1780 (β-lactam), 1730 cm^{-1} (ester).

Amide ***22***

H_2S was bubbled into a solution of **21** (390 mg, 0.6 mmol) in 20 ml CH_2Cl_2 and Et_3N (0.1 ml, 0.7 mmol) at 0°C for 5 min. After stirring 1 h at 20°C, the solution was purged with nitrogen (5 min). The reaction mixture was washed with H_2O (20 × 20 ml), dried, and evaporated. To the crude product in CH_2Cl_2 (10 ml) and Et_3N (0.1 ml, 0.7 mmol) was added dropwise a solution of phenylacetyl chloride (108 mg, 0.7 mmol) in CH_2Cl_2 (2 ml). After stirring for 1 h at 0°C, the solution was washed with H_2O (2 × 20 ml), dried, and evaporated. Chromatography of the residue on SiO_2 activity III (20 g) afforded, after elution with ether, 275 mg (64%) of amide **22**, mp 128–129°C (dec.); ^{1}Hmr ($CDCl_3$—DMSO-d_6) δ: 2.90 (s, 3H, CH_3), 3.75 (s, 2H, $COCH_2Ph$), 4.7 (m, 3H, $CHCH_2$, 5.4 (s, 2H, OCH_2Ph), 5.4 (m, 1H, CHNH), 7.25 (s, 1H, $CHPh_2$), 7.25–8.0 ppm (m, 13H, aromatic); ir (KBr) ν_{max}: 3300 (NH), 1770 (β-lactam), 1720 (ester), 1660 cm^{-1} (amide).

3-Hydroxy-2-nitrobenzyl Alcohol ***23***

Crude phenol **10** (11 g, 65 mmol) was dissolved in absolute ethanol (500 ml) and cooled to 0°C. $NaBH_4$ (5g, 131 mmol) was added in portions. The ice bath was removed and the red slurry stirred for 2 h at 20°C. Acetic acid (5 ml) was added and the ethanol was removed on a rotary evaporator. The residue was dissolved in water (200 ml) and acidified with HCl to pH < 1. Extraction with ethyl acetate (2 × 300 ml), drying ($MgSO_4$), and evaporation afforded 10 g (90%) of 3-hydroxy-2-nitrobenzyl alcohol, mp 104–110°C (dec.); ^{1}Hmr (acetone-d_6) δ: 4.6 (s, 2H, CH_2OH), 4.5 (bs, 1H, CH_2OH), 6.8–7.5 (m, 3H, C_6H_3), 10.4 ppm (bs, 1H, C_6H_3OH).

Amine ***24***

Alcohol **23** (10 g, 57 mmol) was dissolved in ethanol (200 ml) and PtO_2 (0.7 g) was added. The mixture was hydrogenated for 2 h in a Parr hydrogenator at 40 psi and filtered through Celite. Evaporation of the filtrate afforded 8 g of the amine as a brown semicrystalline solid. The amine was added to a solution of *tert*-butyldimethylsilyl chloride (21 g, 136 mmol) and imidazole (23.5 g, 350 mmol) in dry DMF (75 ml). The solution was stirred overnight at room temperature and partitioned between ether (300 ml) and water (750 ml). The ether layer was washed with water (4 × 200 ml), dried ($MgSO_4$) and evaporated. The crude product was chromatographed on SiO_2, activity III (300 g). Elution with methylene chloride afforded 16 g (77%) of amine **24**; ^{1}Hmr ($CHCl_3$) δ: 0.05 (s, 6H, $Si(CH_3)_2$), 0.25 (s, 6H, $Si(CH_3)_2$), 0.9 (s, 9H, Si*t*Bu), 1.0 (s, 9H, Si*t*Bu), 4.2 (bs, 2H, NH_2), 4.6 (s, 2H, CH_2O), 6.3–6.8 ppm (m, 3H, C_6H_3); ir (film) ν_{max}: 3500, 3400(NH_2), 3000, 1630 cm^{-1}.

Azide β-Lactam ***26***

Amine **24** (4.4 g, 11 mmol) and cinnamaldehyde (1.6 g, 12 mmol) and a few crystals of TsOH dissolved in dry benzene (150 ml) were refluxed overnight using a Dean–Stark trap to remove the water formed. The crude product, after evaporation of benzene, was dissolved in CH_2Cl_2 (100 ml) and Et_3N (1.8 ml, 13 mmol). To the solution under N_2 at −20°C was added dropwise azidoacetyl chloride (1.5 g, 13 mmol) in CH_2Cl_2 (80 ml) over 1 h. The reaction mixture was stirred for 1 h more and washed with H_2O (2 × 50 ml). Drying ($MgSO_4$) and evaporation afforded the crude product. Filtration through 100 g of Al_2O_3, activity III, using CH_2Cl_2 as eluent afforded 5.5 g (81%) of β-lactam azide **26**, suitable for the next reaction; ir (film) ν_{max}: 2900, 2100 (N_3), 1770 cm^{-1} (C=O).

Alcohol ***27***

Into a solution of crude azide **26** (2.8 g) in ethanol (150 ml) and CH_2Cl_2 (30 ml) at −78°C was passed ozone (8 mmol/h) for 45 min. After removing excess ozone with nitrogen (15 min), $NaBH_4$ (400 mg) was added. The solution was allowed to warm up to room temperature over a period of 2 h. To the slightly yellow solution was added pH 4.5 buffer (150 ml). The ethanol was removed on a rotary evaporator and the residue extracted with $CHCl_3$ (2 × 100 ml). Drying ($MgSO_4$) and evaporation afforded 2.5 g of crude alcohol. Chromatography of the crude alcohol on SiO_2, activity III (45 g), using $CHCl_3$ as eluent, afforded, after crystallization from pentane, 1.3 g (53%) of pure alcohol **27**, mp 112–112.5°C; ^{1}Hmr ($CDCl_3$) δ: 0.05 (d, 6H, $SiMe_2$), 0.25 (d, 6H, $SiMe_2$), 0.90 (s, 9H, Si*t*Bu), 1.0 (s, 9H, Si*t*Bu), 3.1 (bs, 1H, OH), 3.7 (bd, 2H, CH_2OH), 4.2–4.4 (m, 1H, $CHCH_2OH$), 4.7 (q, 2H, $CH_2OTBDMS$), 4.7 (d, 1H, CHN_3, J = 5 Hz), 6.6–7.2 ppm (m, 3H, C_6H_3); ir (KBr) ν_{max}: 3450 (OH), 2900, 2150 (N_3), 1770 (C=O), 1600 cm^{-1} (C=C); ms m/e: 435 (M^+ − 57), 407 (M^+ − 57 − 28). *Anal.* calcd. for $C_{24}H_{40}N_4O_4Si$: C 56.06, H 8.18, N 11.36; found: C 55.95, H 8.03, N 11.38.

Mesylate ***28***

To alcohol **27** (2 g, 4.1 mmol) in CH_2Cl_2 (50 ml) and Et_3N (0.8 ml, 0.56 mmol) at −78°C was added dropwise MsCl (0.35 ml, 4.5 mmol) in CH_2Cl_2 (5 ml). The solution was stirred for 30 min at −78°C and allowed to warm up to room temperature (1 h). The reaction mixture, after washing with water (2 × 50 ml), drying ($MgSO_4$), and evaporation *in vacuo*, afforded 2.2 g (95%) of mesylate **28** as an oily solid; ^{1}Hmr ($CDCl_3$) δ: 0.05 (d, 6H, $SiMe_2$), 0.25 (d, 6H, $SiMe_2$), 0.9 (s, 9H, Si*t*Bu), 1.0 (s, 9H, Si*t*Bu), 2.75 (s, 3H, CH_3), 4.4 (m, 2H, $CH_2OSO_2CH_3$), 4.7 (m, 1H, CH_2CH), 4.7 (s, 2H, CH_2OTBDMS), 5.0 (d, 1H, CHN_3, J = 5 Hz), 6.7–7.4 ppm (m, 3H, C_6H_3).

Azido β-Lactam ***29****a*

To mesylate **28** (1 g, 1.7 mmol) in CH_3CN (20 ml) was added KF (116 mg, 2 mmol) and 18-crown-6 (75 mg, 0.3 mmol). After stirring 5 h at room temperature, more KF (50 mg) and 18-crown-6 (75 mg) were added. After 4 h more at room temperature, the reaction mixture was poured into water (200 ml) and extracted with CH_2Cl_2 (2 × 200 ml). Drying ($MgSO_4$) and evaporation afforded crude product contaminated with 18-crown-6. Chromatography on SiO_2, activity III (20 g), using CH_2Cl_2 as eluent, afforded 580 mg (92%) of cyclized β-lactam ***29****a* as a colourless oil; ^{1}Hmr (benzene-d_6) δ: 0.2 (s, 6H, $SiMe_2$), 1.1 (s, 9H, Si*t*Bu), 3.0–4.0 (m, 3H, OCH_2CH), 4.2 (d, 1H, CHN_3, J = 5 Hz), 5.4 (q, 2H, CH_2OTBDMS, J = 16 Hz), 6.6–7.6 (m, 3H, C_6H_3); ir ($CHCl_3$) ν_{max}: 2900, 2100 (N_3), 1780 (C=O), 1600 cm^{-1} (C=C).

Benzyl Alcohol ***30***

To azide ***29****a* (580 mg) in THF (20 ml) and H_2O (6 ml) was added dropwise trifluoroacetic acid (3 ml). After stirring for 20 min at room temperature the reaction mixture was poured into 5% $NaHCO_3$ (200 ml) and extracted with CH_2Cl_2 (2 × 100 ml). The combined organic phases were dried ($MgSO_4$) and evaporated. Trituration of the oily residue with ether afforded 300 mg (75%) of alcohol **30**, mp 128–129°C; ^{1}Hmr ($CDCl_3$–DMSO-d_6, few drops D_2O) δ: 3.8–4.4 (m, 3H, CH_2CH), 4.8 (q, 2H, CH_2OH, J = 17 Hz), 5.6 (d, 1H, CHN_3, J = 5 Hz), 7.0 ppm (m, 3H, C_6H_3); ir (KBr): ν_{max} 3380 (OH), 2900, 2100 (N_3), 1775 cm^{-1} (C=O); ms *m/e*: 246 (M^+), 218 (M^+ − 28). *Anal.* calcd. for $C_{11}H_{10}N_4O_3$: C 53.66, H 4.09, N 22.76; found: C 53.57, H 4.32, N 22.44.

Ester ***32***

To alcohol **30** (420 mg, 1.7 mmol) in AcOH (5 ml) was added 4.5 ml of CrO_3 solution (1 g CrO_3 in 1 ml H_2O and 9 ml AcOH). After stirring at 20°C for 24 h, more CrO_3 solution (2.5 ml) was added. After a total time of 48 h the acetic acid was evaporated at 20°C. The residue was partitioned between pH 1.8 buffer (20 ml) and chloroform (100 ml). The aqueous phase was extracted again with $CHCl_3$ (2 × 50 ml). The combined $CHCl_3$ extracts were washed with pH 1.8 buffer (2 × 20 ml), dried ($MgSO_4$), and evaporated. To the crude acid, 260 mg dissolved in CH_3CN (20 ml), was added 9 ml (1.8 mmol) of a solution of diphenyldiazomethane in CH_3CN (2 g Ph_2CN_2 in 100 ml CH_3CN). The red reaction mixture was stirred 1 h at room temperature and quenched with acetic acid (3 drops). The crude product after evaporation of the solvent was chromatographed on thick-layer plates (SiO_2) using $CHCl_3$–ether (9:1) as eluent. Extraction of band with $R_f \simeq 0.7$ afforded 280 mg (39%) of ester **32** as a colourless foam; ^{1}Hmr (C_6D_6, 90 MHz) δ: 3.2–3.4 (m, 1H, CH_2CH), 3.3 (t, 1H, $CHHCH$, $J_1 = J_2$ = 10 Hz), 3.8 (q, 1H, $CHHCH$, J_1 = 3, J_2 = 10 Hz), 4.2 (d, 1H, CHN_3, J = 5 Hz), 6.4–7.6 ppm (m, 13H, aromatic); ir ($CHCl_3$) ν_{max}: 3000, 2100 (N_3), 1795 (β-lactam), 1730 (ester); ms *m/e*: 426 (M^+), 397 (M^+ − 28), 343 (M^+ − N_3-CHCO), 215 (M^+ − CO_2CHPh_2).

Amide ***33***

Hydrogen sulphide was bubbled into a solution of ester **32** (250 mg, 0.6 mmol) and Et_3N (0.1 ml, 0.7 mmol) in CH_2Cl_2 at 0°C for 5 min. The ice bath was removed and the orange solution stirred at room temperature. After 1 h, excess H_2S was purged with nitrogen. The yellow solution was washed with H_2O (2 × 25 ml), dried ($MgSO_4$), and evaporated. To the resulting yellow gum dissolved in CH_2Cl_2 (20 ml) and Et_3N (0.1 ml, 0.7 mmol) was added at 0°C phenylacetyl chloride (90 μl, 0.68 mmol). After stirring for 1 h at 0°C, the solution was washed with pH 4.5 buffer (2 × 25 ml). Drying ($MgSO_4$), evaporation, and chromatography on thick-layer plates using $CHCl_3$–ether (10:1) afforded 235 mg (77%) of amide **33** as a slightly yellow foam; ^{1}Hmr ($CDCl_3$, 90 MHz) δ: 3.5 (s, 2H, CH_2Ph), 3.7 (t, 1H, $CHHCH$, $J_1 = J_2$ = 10 Hz), 4.0–4.5 (m, 2H, $CHHCH$), 5.4 (q, 1H, $CHNH$, J_1 = 4.5, J_2 = 7 Hz), 6.8 (d, 1H, NH, J = 7 Hz), 7.0–7.6 ppm (m, 19H, aromatic and $CHPh_2$); ir ($CHCl_3$) ν_{max}: 3400 (NH), 2900, 1785 (β-lactam), 1730 (ester), 1690 cm^{-1} (amide).

Alcohol Amide ***31***

To amide ***29****b* (180 mg) in THF (5 ml) and H_2O (2 ml) was added dropwise trifluoroacetic acid (0.8 ml). After stirring at room temperature 15 min, the solution was poured onto 10% $NaHCO_3$ and extracted with chloroform (2 × 50 ml). Drying ($MgSO_4$), evaporation, and trituration with ether afforded 80 mg (60%) of alcohol amide **31** as white solid, mp 183–185°C; ^{1}Hmr (acetone-d_6) δ: 3.6 (s, 2H, $CH_2\phi$), 4.0–4.6 (m, 3H, CH_2CH), 4.8 (bs, 3H, CH_2OH), 5.6 (q, 1H, $CHNH$, J_1 = 4.5, J_2 = 7 Hz), 6.6–7.2 (m, 3H, C_6H_3), 7.2 ppm (s, 5H, C_6H_5); ir (KBr) ν_{max}: 3400(OH), 3350(NH), 1775 (C=O of β-lactam), 1660 cm^{-1} (C=O of amide), ms *m/e*: 338(M^+).

Amide ***29****b*

Into azide **29** (500 mg, 1.4 mmol) dissolved in CH_2Cl_2 (20 ml) and Et_3N (0.2 ml, 1.4 mmol) at 0°C was bubbled H_2S for 5 min. After stirring for 1 h at room temperature, the solution was washed with H_2O (2 × 20 ml), dried ($MgSO_4$), and evaporated. To the crude product at 0°C in CH_2Cl_2 (20 ml) and Et_3N (0.2 ml, 1.3 mmol) was added dropwise phenylacetyl chloride (0.23 g, 1.5 mmol) in CH_2Cl_2 (2 ml) over a period of 5 min. After stirring for 1 h at room temperature, the solution was washed with pH 4.5 buffer (30 ml) and H_2O (30 ml), dried ($MgSO_4$), and evaporated. Chromatography of the residue on SiO_2 activity II (20 g) using CH_2Cl_2 up to CH_2Cl_2–ether (1:1) afforded 530 mg (80%) of amide ***29****b* as a colourless foam; ^{1}Hmr ($CDCl_3$) δ: 0.05 (s, 6H, Si(CH_3)$_2$), 0.90 (s, 9H, Si*t*Bu), 4.3 (s, 2H, $CH_2\phi$), 3.6–4.6 (3H, m, CH_2CH), 6.6–7.2 (m, 3H, C_6H_3), 7.3 ppm (bs, 6H, C_6H_5 and NH); ir ($CHCl_3$) ν_{max}: 3400(NH), 2900, 1765 (β-lactam C=O), 1680 cm^{-1} (amide C=O).

Ester ***35*** *and Acid* ***34***

Ester **33** (250 mg) in EtOH (50 ml) containing 10% Pd/C (250 mg) was hydrogenated for 1 h at 40 psi using a Parr hydrogenator. Filtration through Celite and evaporation of the ethanol gave the crude acid. Trituration of the residue with ether afforded (65%) of acid **34** as a pale yellow solid, mp 140°C (dec); ir (KBr) ν_{max}: 3350 (NH), 2500–3600 (OH), 1780 (β-lactam), 1685 (acid), 1650 (amide), 1380 cm^{-1}.

Treatment with ethereal CH_2N_2 and chromatography on thick-layer plates using $CHCl_3$–ether (1:1) afforded, after crystallization from benzene (70%) of ester **35** as a solid, mp (148–150°C); ^{1}Hmr ($CDCl_3$, 90 MHz) δ: 3.6 (s, 2H, CH_2Ph), 3.7 (t, 1H, $CHHCH$, J = 10 Hz), 3.9 (s, 3H, OCH_3), 4.0–4.4 (m, 1H, CH_2CH), 4.5 (q, 1H, $CHHCH$, J_1 = 3.5, J_2 = 10 Hz), 5.5 (q, 1H, $CHNH$, J_1 = 4.5, J_2 = 7 Hz), 6.8 (bd, 1H, NH, J = 7 Hz), 7.0–7.6 ppm (m, 8H, C_6H_3 and C_6H_5); ir ($CHCl_3$)

ν_{max}: 3300, 1780 (β-lactam), 1730 (ester), 1680 cm^{-1} (amide); ms *m/e*: 366 (M^+), 335 ($M^+ - 31$), 192, 175, 160. *Anal.* calcd. for $C_{20}H_{18}N_2O_5$: C 65.56, H 4.95, N 7.65; found: C 65.59, H 5.45, N 7.09.

Synthèse de cétones encombrées via réduction de nitriles tertiaires en présence de métaux alcalins

JEAN-PAUL MAZALEYRAT
Groupe de Recherche No 12, C.N.R.S., 94320-Thiais, France

Reçu le 28 mars 1978

JEAN-PAUL MAZALEYRAT. Can. J. Chem. **56**, 2731 (1978).

L'action d'un métal alcalin sur un nitrile possédant un C_α tertiaire peut conduire, après protonation, à une imine. Par hydrolyse de cette dernière on obtient une cétone possédant des carbones α-tertiaires. Cette réaction implique des radicaux anions intermédiaires et constitue une méthode simple de synthèse de cétones symétriques encombrées.

JEAN-PAUL MAZALEYRAT. Can. J. Chem. **56**, 2731 (1978).

The reaction of alkali metals with tertiary alkyl nitriles eventually gives, after protonation, an imine. α-*tert*-Alkylketones are produced by the hydrolysis of these imines. This reaction, involving radical anion intermediates, is a simple method for the synthesis of highly hindered symmetric ketones.

Il existe différentes voies de synthèse de cétones encombrées (réf. 1 et références citées), mais ces méthodes ne permettent que très rarement d'obtenir un composé possédant deux carbones tertiaires en α du groupement carbonyle. L'obstacle est soit dû à la méthode de synthèse, qui aboutit nécessairement à la présence d'un hydrogène sur un des deux carbones α, soit d'ordre stérique (1; réf. 2 et références citées).

Nous nous sommes intéressés à une voie de préparation très peu exploitée jusqu'à présent (3), faisant appel à la réduction des nitriles tertiaires par les métaux alcalins.

Il est connu que les métaux alcalins dans l'ammoniac liquide ou le HMPT, provoquent la rupture de la liaison C—CN des nitriles et conduisent à l'hydrocarbure correspondant (4*a*). Les mêmes réductions peuvent être réalisées par voie électrochimique (4*b*). Le mécanisme de ces réactions fait intervenir la formation intermédiaire d'un radical alcoyle R·, formé certainement par décomposition d'un radical anion nitrile $RCN^{\bullet -}$, et qui subit ensuite une réduction en anion R^- (schéma 1).

$$RCN \xrightarrow{e^-} RCN^{\bullet -} \longrightarrow R^\bullet \xrightarrow{e^-} R^- \xrightarrow{H^+} RH$$

SCHÉMA 1

Cependant, le comportement de la combinaison anthracène–lithium dans l'éther éthylique vis à vis des nitriles tertiaires **1** apporte des informations supplémentaires sur le comportement des nitriles en présence de réactifs donneurs d'électrons (5). A cause de la grande affinité électronique de l'anthracène, cette réaction n'aboutit pas à la réduction du nitrile en hydrocarbure RH, mais à la formation d'un alcoyl-9 dihydro-9,10 anthracène **2** résultant de la recombinaison entre un radical alcoyle R· et un radical anion anthracène (schéma 2). Toutefois, on enregistre également dans cette réaction la formation d'une imine **3**, et si ce composé provient, comme on peut le supposer, de la recombinaison entre un radical anion anthracène et un radical anion nitrile, cela suggère qu'un tel radical anion nitrile $RCN^{\bullet -}$ possède une durée de vie suffisante pour donner une réaction autre que sa décomposition en R· et CN^-.

Si cette hypothèse est juste, on doit s'attendre à ce que dans certaines conditions, le radical alcoyle R· puisse se recombiner avec le radical anion nitrile présent dans le milieu pour conduire, après hydrolyse, à une imine symétrique **4** (schéme 3).

Effectivement, il est connu que certains α-aminonitriles tertiaires, pour lesquels le radical anion $RCN^{\bullet -}$ a une durée de vie suffisante pour être observable en RPE (6), donnent une réaction tout à fait similaire (schéma 3, R = $(CH_3)_2\overset{|}{C}—N(CH_3)_2$; $(CH_3)_2\overset{|}{C}—N$ ⟨⟩) et conduisent après hydrolyse à une aminoimine correspondant à **4** (7, 8).

Cependant, dans le cas des nitriles ordinaires, on ne connaissait jusqu'à présent qu'un seul exemple de ce type de réaction: celui du pivalonitrile **1***a* qui, traité par le sodium dans le pentane, conduit à la di-*tert*-butyl cétimine **4***a* avec de très bons rendements (3).

Comme les additions radicalaires sont souvent moins sensibles aux contraintes stériques que les réactions ioniques correspondantes (9), un tel schéma est a priori susceptible de constituer une méthode de synthèse d'imines et de cétones encombrées à partir des nitriles tertiaires, et c'est la raison pour laquelle nous avons examiné si cette réaction pouvait être étendue à d'autres composés que le pivalonitrile.

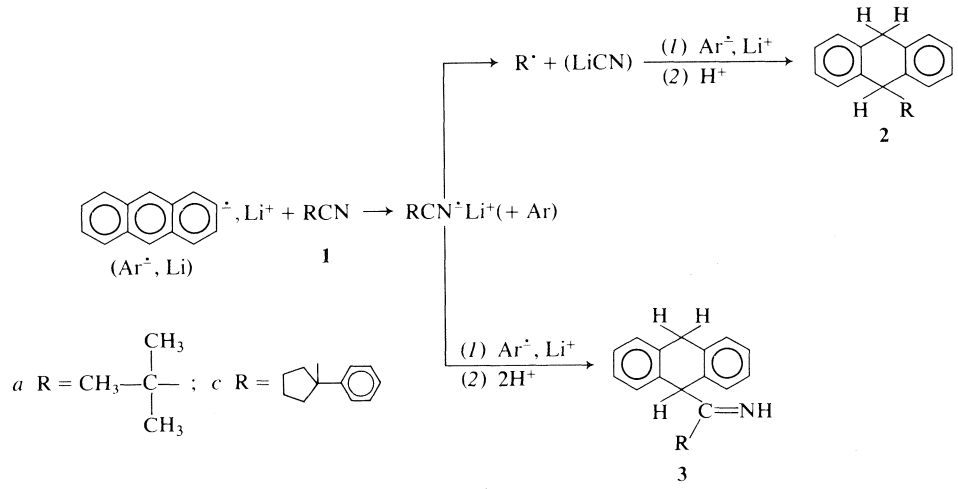

SCHÉMA 2

Résultats et discussion

Considérations générales

Les réactions ont été conduites avec une série de nitriles **1***a–g* (schéma 4), en présence de métaux alcalins, sodium ou lithium, dans différents solvants. Les imines **4** éventuellement formées sont obtenues à l'état pur par simple extraction acido-basique, et converties ensuite en cétones **5** correspondantes, par hydrolyse acide.

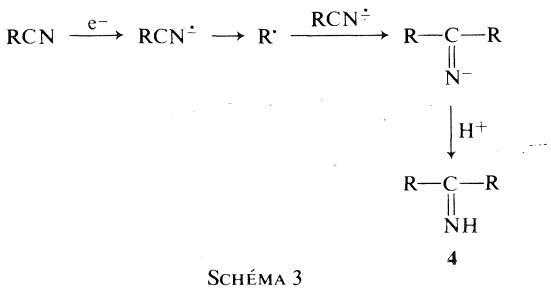

SCHÉMA 3

Le tableau 1 montre que les rendements en imines sont très variables et dépendent beaucoup du nitrile mis en jeu. Le métal alcalin et le solvant ont également une grande influence (voir *b* et *c*). Ils doivent être recherchées dans chaque cas particulier, selon la structure du nitrile, mais il semble cependant que l'utilisation du lithium dans l'éther éthylique constitue un bon choix pour les nitriles **1***c–f* dans lesquels le groupement CN est en position benzylique.

Les variations de rendement enregistrées en fonction des conditions expérimentales sont certainement liées à l'intervention de la réaction de réduction totale du nitrile en hydrocarbure (schéma 1). Nous avons mis en évidence les composés RH provenant de cette réaction compétitive, à chaque fois que nous les avons recherchés dans les parties neutres. La formation d'un hydrocarbure de structure R—R a également été observée lors de la réduction du nitrile **1***c*.

La réduction totale est responsable des mauvais rendements, ou même de l'absence de l'imine **4**, parfois enrégistrés. Avec le nitrile **1***c*, elle est la seule à intervenir lorsque le métal alcalin est le sodium, ou lorsque le solvant est le THF. De même dans le cas du nitrile **1***g*, le diphényl 1,1-éthane est obtenu quantitativement, et l'absence d'imine **4***g* est bien due à l'évolution rapide de la réaction vers la réduction en anions R^-, car l'hydrolyse du mélange réactionnel par D_2O conduit au deutéro-1 diphényl-1,1 éthane (schéma 5). Il est concevable qu'il soit difficile de maîtriser la réduction totale afin de faire évoluer le système dans le sens voulu. Pour que le rendement en imine soit bon, il faut que la réduction de R· en anion R^- soit plus lente que le couplage de ce radical avec un radical anion $RCN^{\cdot-}$, il faut de plus que la rupture de $RCN^{\cdot-}$ soit assez lente. Les vitesses de ces diverses réactions ne sont pas nécessairement influencées de la même façon par la structure de R, le métal alcalin et le solvant, d'où la difficulté de déterminer les conditions expérimentales qui soient

SCHÉMA 5

générales. Il est possible aussi que le couplage radical – radical anion soit toujours la réaction la plus rapide et que l'évolution vers l'anion R^- n'intervienne qu'à cause de la réversibilité de ce couplage, dont nous discutons plus loin.

Enfin, il existe une autre alternative mécanistique que nous n'avons pas considéré jusqu'à présent, selon laquelle l'imine **4** résulterait de l'addition d'un anion R^- sur une molécule de nitrile. Cet anion R^- peut être formé soit directement par réduction d'un radical anion $RCN^{\cdot-}$, accompagnée par le départ de l'ion cyanure (schéma 6*a*), soit par réduction d'un radical R· intermédiaire (schéma 6*b*). Cependant la chute des rendements observée lors de l'addition des organolithiens sur des nitriles encombrés (réf. 10 et références citées) est en defaveur du mécanisme du schéma 6, mais on ne peut l'exclure complétement

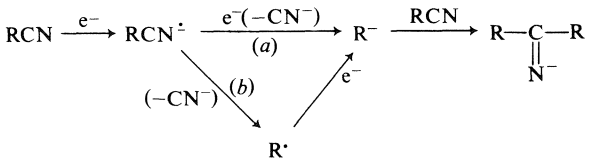

SCHÉMA 6

car l'addition du *tert*-butyl lithium sur le pivalonitrile **1***a* peut bien avoir lieu (11).

La réversibilité de la réaction

Un autre aspect du mécanisme de cette réaction est mis en lumière par l'expérience suivante, au cours de laquelle nous avons réduit le nitrile **3***c* par le lithium dans l'éther éthylique en présence d'un excès de chlorure de *tert*-butyle, avec l'idée que le radical anion du phényl-1 cyclopentane nitrile, en présence de radicaux *tert*-butyle, se recombinerait avec un de ces derniers avant que la rupture de la liaison C—CN intervienne, conduisant à l'anion **A**, ce qui permettrait d'obtenir l'imine mixte **4***h* (schéma 7).

En fait, après hydrolyse, l'imine **4***h* est seulement isolée à l'état de traces, les parties basiques étant constituées essentiellement de l'imine **4***a*. Ce résultat montre que la recombinaison radical – radical anion[1] qui conduit à l'anion **A** est réversible. La réaction inverse peut soit redonner le radical anion **3***c* et le radical *tert*-butyle, soit conduire au radical phényl-cyclopentyle et au radical anion du pivalonitrile **3***a*. Ce radical anion se trouvant en présence de radicaux *tert*-butyle conduit alors à l'anion **B**, avec un degré de réversibilité certainement moindre que dans le cas de **A**, vu l'absence de stabilisation par un noyau phényle des entités $t\text{BuCN}^{\cdot-}$ et $t\text{Bu}^{\cdot}$. La suite d'équilibres étant ainsi déplacée vers **B** explique l'obtention largement prépondérante de l'imine **4***a* après hydrolyse.

Une réversibilité semblable existe également dans l'addition des radicaux anions anthracène sur les nitriles (5), et a été démontrée dans certains cas pour l'addition des organolithiens sur ces mêmes composés (12).

D'un point de vue synthétique, la réversibilité de la formation de l'anion précurseur de l'imine présente à la fois un désavantage et un intérêt. L'inconvénient réside dans la possibilité d'un degré de réversibilité très élevé pour des structures admettant l'existence de radicaux très stables, interdisant alors l'obtention de l'imine à moins de réussir à piéger l'anion correspondant au fur et à mesure de sa formation. Cela pourrait expliquer par exemple l'absence d'imine à l'issue de la réaction dans le cas de la structure **3***g* (schéma 8).

[1]Par souci de clarté, nous ne considérons pas ici l'alternative précédemment envisagée dans le schéma 6, mais la même explication demeure si l'anion **A** est formé par addition de R^- sur le nitrile.

SCHÉMA 7

L'intérêt peut résider en la possibilité d'obtenir une cétone encombrée $(R_1)_2C{=}O$ à partir de l'halogénure correspondant R_1X (lequel peut être plus accessible que le nitrile), en présence d'un nitrile

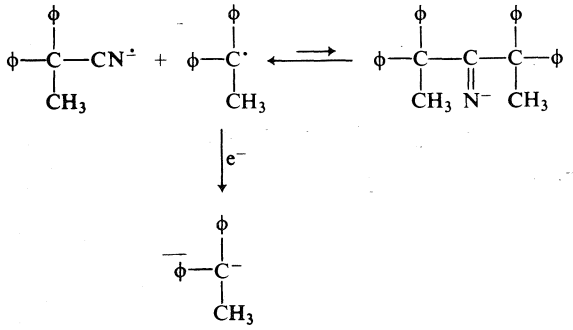

SCHÉMA 8

donnant un grand degré de réversibilité, selon une évolution correspondant au schéma 7.

Conclusion

En définitive, il apparaît que l'action des métaux alcalins sur les nitriles tertiaires n'aboutit pas nécessairement à la réduction totale en hydrocarbure correspondant, mais peut dans des conditions appropriées, constituer une méthode de synthèse d'imines symétriques encombrées, facilement hydrolysables en cétones correspondantes. Ces imines sont obtenues à un haut degré de pureté, par simple extraction acido–basique, ce qui les rend très facilement accessibles, même dans les cas où les rendements sont faibles. En outre, étant donné la grande similitude entre les réductions réalisées par action des réactifs donneurs d'électrons tels que les métaux alcalins ou les combinaisons métaux alcalins – hydrocarbures aromatiques, et les réductions cathodiques (4*b*, 13), on peut supposer que des synthèses similaires pourront être réalisées par voie électrochimique.

Partie expérimentale

Les points de fusion ont été déterminés en tubes capillaires, sur un appareil Tottoli. Les spectres infrarouge ont été enregistrés sur un spectromètre EPI 62 Hitachi. Les spectres de rmn ont été enregistrés sur un spectromètre Varian T 60 pour le proton et sur un spectromètre Varian CFT 20 pour le carbone-13, le tétraméthylsilane étant pris comme référence interne. Les analyses élémentaires et les spectres de masses ont été effectués par le Centre de Microanalyse de Thiais.

Les nitriles **1***a–g* sont commerciaux. Les réactions sont effectuées à température ambiante, sous atmosphère d'azote, par action directe d'un excès de métal alcalin dans un solvant donné. Après hydrolyse, la phase organique est décantée, lavée à l'eau puis traitée par un excès d'acide chlorhydrique "pur" (environ 11 *M*). La phase acide est lavée à l'éther et les phases organiques réunies lavées à l'eau et séchées fournissent les parties neutres du mélange réactionnel brut. La phase acide est neutralisée par la soude ou la potasse diluée, jusqu'à pH fortement basique. L'extraction à l'éther fournit les parties basiques du mélange réactionnel. Dans ces conditions d'extraction, les imines **4** ne subissent pratiquement pas d'hydrolyse acide, la présence des cétones correspondantes n'étant pas détectée dans les parties neutres.

Di-tert-*butyl cétimine* **4**a

Par action de 4 g (0.048 mol) de pivalonitrile **1***a* sur 1.5 g (0.065 at-g) de sodium dans 30 cm^3 de pentane, pendant 48 h, on obtient 2.39 g (68%) de parties basiques correspondant au composé **4***a* déjà connu (3); ir: 3400 cm^{-1}, ^1H rmn ($CDCl_3$) : 1.24 ppm (s).

Di-tert-*butyl cétone* **5**a *(2, 3)*

On obtient le composé **5***a* quantitativement par chauffage au reflux de **4***a* dans un mélange benzène–HCl 20%; ir: 1680 cm^{-1}.

Di-(adamantyl-1) cétimine **4**b

Par action de 4.5 g (0.028 mol) de cyano-1 adamantane **1***b* sur 2 g (0.09 at-g) de sodium dans un mélange pentane–éther 1 : 2 pendant 48 h, on obtient 1.2 g de parties basiques dont le spectre de rmn ($CDCl_3$): 2H à 2.33 (s), 2H à 2.00 (m) 15H à 1.70 (m) et 1.47 ppm (m), et le spectre ir (3300–3400 cm^{-1}) sont en accord avec une structure $R—CH_2NH_2$ provenant sans doute de la réduction du nitrile **1***b* par le sodium dans l'éthanol ajouté en fin de réaction.

Par action de 8 g (0.05 mol) de **1***b* sur 1 g (0.15 at. g) de lithium dans 100 cm^3 d'éther éthylique pendant 7 h, on obtient 1.16 g (15%) de parties basiques constituées de l'imine **4***b*. Les parties neutres sont constituées essentiellement du nitrile de départ **1***b* inchangé, l'hydrolyse ayant été effectuée après prélèvement de la solution à la seringue, en l'absence de l'excès de lithium.

Par action de 4 g (0.025 mol) de **1***b* sur 0.5 g (0.075 at-g) de lithium dans 75 cm^3 de THF, pendant 24 h, on obtient 2.4 g (65%) de parties basiques constituées de **4***b*. Le spectre ir des parties neutres montre l'absence de bande CN à 2220 cm^{-1} correspondant au nitrile **1***b*. **4***b*: pf (acétone) 126–127°C; ^1H rmn ($CDCl_3$): 1H à 8 (m), 30H à 1.74 et 2.02 ppm (m); ir: 3300, 1595 cm^{-1}; ^{13}C rmn ($CDCl_3$): 194.08 (s), 44.97 (s), 44.19 (t), 36.81 (t), 28.94 (d); sm (70 eV): pic moléculaire à *m/e* 297. *Anal.* calc. pour $C_{21}H_{31}N$: C 84.78, H 10.50, N 4.71; trouvé: C 84.43, H 10.51, N 4.28.

Diadamantyl-1 cétone **5**b

Obtenue quantitativement par chauffage au reflux de **4***b* pendant 48 h dans 30 cm^3 de benzène et 50 cm^3 de HCl 40%; pf (acétone) 175–178°C; ^1H rmn ($CDCl_3$): 2.00 et 1.74 ppm (m); ^{13}C rmn ($CDCl_3$): 216.93 (s); 49.32 (s); 39.42 (t); 36.80 (t); 28.54 (d); ir: 1660 cm^{-1}; sm (70 eV): pic moléculaire à *m/e* 298. *Anal.* calc. pour $C_{21}H_{30}O$: C 84.51, H 10.13, O 5.36; trouvé: C 84.21, H 10.10, O 5.79.

Di(phényl-1 cyclopentyl) cétimine **4**c

Par action du phényl-1 cyclopentane **1***c* sur un excès de sodium dans le pentane, l'éther ou le THF, ou de lithium dans le THF, le milieu prend une forte coloration rouge brun caractéristique de l'anion phénylcyclopentyle, et après hydrolyse, on n'obtient aucune partie basique. Le nitrile **1***c* est absent des parties neutres qui sont constituées principalement de phénylcyclopentane.

Par action de 1.7 g (0.01 mol) de nitrile **1***c* sur 0.21 g (0.03 at-g) de lithium dans 100 cm^3 d'éther pendant 3 h, on obtient 0.53 g (34%) de parties basiques constituées de l'imine **4***c*. Les parties neutres (0.51 g) sont constituées d'un mélange de cristaux et de liquide.

Cristaux: pf (pentane) 134–136°C; ^1H rmn ($CDCl_3$): 10H à 7.08 (m), 16H entre 0.8 et 2.5 ppm (m); ^{13}C rmn ($CDCl_3$): 148.09 (s), 132.43 (d), 130.75 (d), 129.28 (d), 61.87 (s), 37.69 (t), 26.35 (t); sm (70 eV): pic moléculaire à *m/e* 290. *Anal.* calc. pour $C_{22}H_{26}$: C 90.98, H 9.02; trouvé: C 90.94, H 9.07. L'ensemble de ces caractéristiques est en accord avec la structure du (diphényl-1,1′)-bicyclopentyle.

Liquide: En cpg, par comparaison avec des échantillons témoins, on observe que le liquide est constitué principalement de phénylcyclopentane, accompagné de (diphényl-1,1′) bicyclopentyle ainsi que de nitrile de départ **1***c* en faible proportion. Les rendements respectifs de ces différents composés n'ont pas été déterminés.

Dans une autre réaction menée parallèlement dans les mêmes conditions, en présence de 0.7 g (0.005 mol) de diphényle, on obtient 0.54 g (34%) de parties basiques constituées de l'imine **4***c*: pf (pentane) 86–88°C; ^1H rmn ($CDCl_3$): 1H à 9.63 (m), 10H à 7.17 (m), 16H à 1.95 et 1.40 ppm (m); sm (70 eV): pic moléculaire à *m/e* 317. *Anal.* calc. pour $C_{23}H_{27}N$: C 87.01, H 8.57, N 4.41; trouvé: C 86.99, H 8.76, N 4.31.

Di(phényl-1 cyclopentyl) cétone **5**c

Obtenue quantitativement par chauffage au reflux de **4***c* pendant 4 jours, dans 50 cm^3 de benzène et 25 cm^3 de HCl 20%; pf (EtOH) 94–97°C; ^{13}C rmn ($CDCl_3$): 211.91 (s), 142.31 (s), 128.11 (d), 127.07 (d), 126.33 (d), 66.03 (s), 36.55 (t), 22.71 (t); sm (70 eV): pic moléculaire à *m/e* 318. *Anal.* calc. pour $C_{23}H_{26}O$: C 86.74, H 8.23, O 5.02; trouvé: C 86.71, H 8.29, O 5.04.

*Di(*p*-tolyl-1 cyclopentyl) cétimine* **4**d

Par action de 18.5 g (0.1 mol) de *p*-tolyl-1 cyclopentane nitrile **1***d* sur 2.1 g (0.3 at-g) de lithium dans 250 cm^3 d'éther, pendant 4 h, 30 min, on obtient 14.63 g (85%) de parties basiques constituées de l'imine **4***d*; pf (EtOH) 126–128°C; ^1H rmn ($CDCl_3$): 1H à 8.64 (m), 8H à 7.09 (m), 6H à 2.30 (s), 16H à 1.97 et 1.41 ppm (m); ^{13}C rmn ($CDCl_3$): 189.19 (s), 141.04 (s), 135.42 (s), 128.66 (d), 126.79 (d), 61.76 (s), 37.22 (t), 22.22 (t), 20.90 (q); ir: 3400, 1595 cm^{-1}; sm (70 eV): pic moléculaire à *m/e* 345. *Anal.* calc. pour $C_{25}H_{31}N$: C 86.90, H 9.04, N 4.05; trouvé: C 86.51, H 9.02, N 3.85.

*Di(*p*-tolyl-1 cyclopentyl) cétone* **5**d

Obtenue quantitativement par chauffage au reflux de **4***c* pendant 2 jours dans 50 cm^3 de benzène et 100 cm^3 de HCl 50%; pf (acétone) 133–135°C; ^1H rmn ($CDCl_3$): 8H à 7.10 (m), 6H à 2.32 (s), 16H à 2.06 et 1.33 ppm (m); ^{13}C rmn ($CDCl_3$): 212.09 (s), 139.23 (s), 135.74 (s), 128.72 (d), 126.89 (d), 65.55 (s), 36.44 (t), 22.65 (t), 20.88 (q); ir: 1670 cm^{-1}; sm (70 eV): pic moléculaire à *m/e* 346. *Anal.* calc. pour $C_{25}H_{30}O$: C 86.65, H 8.73, O 4.62; trouvé: C 86.45, H 8.72, O 4.35.

Di(phényl-1 cyclohexyl)cétone **5**e

Par action de 18.5 g (0.1 mol) de phényl-1 cyclohexane nitrile **1***e* sur 2.1 (0.3 at-g) de lithium dans 250 cm^3 d'éther pendant 24 h on obtient 4.83 g (28%) de parties basiques constituées de di(phényl-1 cyclohexyl) cétimine **4***e*. Les parties neutres sont constituées pour environ 80% (d'après les surfaces de pics en cpg) de nitrile de départ **1***e* et pour environ 20% de phénylcyclohexane résultant de la réduction totale. (L'hydrolyse a été effectuée ici en absence de l'excès de lithium.) Le composé **4***e* (pf (EtOH) 103–105°C) présente des données spectrales correctes: en ^1H rmn: 1H à 9.00 (m), 10H à 7.25 (m), 20H à 2.00 et 1.25 ppm (m); ir: 3350 et 1590 cm^{-1}; sm (70 eV): pic moléculaire à 345. Cependant son analyse centésimale (85.88 pour C calculé 86.90) indique la présence d'une impureté qui reste présente après plusieurs cristallisations. Ce composé par chauffage à reflux en présence de 20 cm^3 de benzène et 50 cm^3 de HCl 40% pendant 3 jours conduit à la cétone **5***e*; pf (acétone) 150–152°C; ^1H rmn ($CDCl_3$): 10H à 7.18 (m), 20H à 1.95 et 1.22 ppm (m); ^{13}C rmn ($CDCl_3$): 211.92 (s), 141.71 (s), 128.24 (d), 127.95 (d), 126.22 (d), 58.03 (s), 35.52 (t), 25.88 (t), 22.64 (t); ir: 1675 cm^{-1}; sm (70 eV): pic moléculaire à *m/e* 346. *Anal.* calc. pour $C_{25}H_{30}O$: C 86.65, H 8.73, O 4.62; trouvé: C 86.79, H 8.45, O 4.74.

Di(phényl-1 cyclopropyl) cétimine **4**f

Par action de 15.3 g (0.107 mol) de phényl-1 cyclopropane nitrile **1***f* sur 2.1 (0.3 at-g) de lithium dans 250 cm^3 d'éther, pendant 5 h, on obtient 13.78 g (98%) de parties basiques constituées de **4***f*. Le composé **4***f* est un liquide qui se décompose[2] en cours de distillation (pé 128–132°C/0.05 Torr). Les constantes physiques indiquées ci-dessous pour **4***f* sont celles des parties basiques brutes, sans aucun traitement; ^1H rmn

[2]Le spectre de rmn indique qu'il se produit une ouverture du (des) cyclopropane.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

($CDCl_3$): 1H à 8.75 (m), 10H à 7.08 (m), 8H à 1.08 ppm (m); ^{13}C rmn ($CDCl_3$): 185.59 (s), 141.31 (s), 129.21 (d), 127.98 (d), 126.52 (d), 33.88 (s), 15.30 (t); ir: 1595 et 1610 cm^{-1}; sm (70 eV): pic moléculaire à *m/e* 261. *Anal.* calc. pour $C_{19}H_{19}N$: C 87.31, H 7.33, N 5.36; trouvé: C 87.04, H 7.47, N 5.32.

Di(phényl-1 cyclopropyl) cétone **5**f

Par chauffage au reflux de **4***f* en présence de 20 cm^3 de benzène et 50 cm^3 de HCl 40% pendant 15 h, on obtient la cétone **5***f* accompagnée d'une forte proportion de produits de décomposition.[2] Afin d'effectuer l'hydrolyse dans des conditions plus douces, le chlorhydrate de l'imine **4***f* est préparé en additionnant à **4***f* (parties basiques brutes) en solution dans de l'éther anhydre, un très léger excès de HCl "pur" 11 *M*. On obtient un précipité. Après addition de 50 cm^3 d'éthanol absolu, et élimination des solvants à l'évaporateur rotatif (bain-marie à 70°C environ), on obtient une poudre jaune-marron qui est abondamment lavée à l'acétone, sur Büchner. On obtient une poudre blanche (chlorhydrate d'imine; **4***f*·HCl); pf 122–123°C; ^1H rmn ($CDCl_3$): 2H à 12.50 (m), 10H à 7.10 (m), 8H à 1.73 ppm (m); ^{13}C rmn ($CDCl_3$): 199.53 (s), 137.52 (s), 129.83 (d), 128.39 (d), 127.80 (d), 33.66 (s), 19.96 (t); sm (70 eV): pic *M* − HCl à *m/e* 261. *Anal.* calc. pour $C_{19}H_{20}NCl$: C 76.62, H 6.77, N 4.70, Cl 11.91; trouvé: C 76.55, H 6.90, N 4.48, Cl 12.43.

Par agitation à température ambiante, des cristaux **4***f*·*HCl* dans un mélange d'eau distillée et de benzène, pendant une semaine, on obtient la cétone **5***f* exempte de produits de décomposition; pf (pentane) 63–65°C; ^1H rmn ($CDCl_3$): 10H à 7.04 (m) et 6.75 (m), 8H à 1.23 ppm (m); ^{13}C rmn ($CDCl_3$): 208.31 (s), 139.83 (s), 129.44 (d), 127.81 (d), 126.09 (d), 36.74 (s); 17.20 (t); sm: pic moléculaire à *m/e* 262. *Anal.* calc. pour $C_{19}H_{18}O$: C 86.98, H 6.92, O 6.10; trouvé: C 87.22, H 7.01, O 5.98.

Cas du nitrile **1**g

Par action de 20.7 g (0.1 mol) de 2,2-diphénylpropionitrile **1***g* sur 2.1 g (0.3 at-g) de lithium dans 300 cm^3 d'éther, pendant 4h, on obtient une coloration rouge brun intense. L'hydrolyse effectuée en l'absence de l'excès de lithium, ne fournit aucune partie basique. Les parties neutres (16.45 g) sont constituées uniquement de 1,1-diphényléthane; ^1H rmn ($CDCl_3$): 10H à 7.16, 1H à 4.10 (q, J = 7 Hz), 3H à 1.56 ppm (d, J = 7 Hz). Dans une expérience identique, mais en effectuant l'hydrolyse par D_2O, le spectre rmn ($CDCl_3$) des parties neutres montre la disparition totale du quadruplet à 4.10 ppm et la transformation du doublet à 1.56 ppm en singulet élargi.

Une expérience similaire effectuée en présence de lithium dans un mélange pentane–éther 4:1 pendant 30 h, ne fournit aucune partie basique. Les parties neutres sont constituées de diphényl-1,1 éthane et de nitrile de départ **1***g*.

Réaction en présence de chlorure de tert-*butyle*

Par action d'un mélange de 1.73 g (0.01 mol) de phényl-1 cyclopentane nitrile **1***e* et de 9.34 g (0.1 mol) de chlorure de *tert*-butyle, sur 0.7 g (0.1 at-g) de lithium dans 100 cm^3 d'éther, pendant 20 h, on obtient 1.22 g de parties basiques, dont le spectre de rmn ($CDCl_3$) indique qu'elles sont constituées en très grande majorité de l'imine **4***a*. (Présence d'un signal du groupement *tert*-butyle très largement prépondérant à 1.24 ppm). Le composé **4***a* est isolé par distillation des parties basiques (pé 45–46°C/10 Torr). Par chromatographie sur plaques du résidu de distillation (support: Kieselgel 60 F 254 Merck; éluant pentane 80% – acétate d'éthyle 20%) on isole en quantités très faibles l'imine **4***c*, ainsi qu'un composé dont le spectre de rmn ($CDCl_3$) est compatible avec la structure de l'imine mixte **4***h*: 1H à 8.57 (m), 5H à 7.26 (m), 9H entre 1.1 et 2.2 (m), 9H à 0.96 ppm (s). D'autres composés non identifiés sont présents à l'état de traces dans les autres fractions chromatographiques. Dans les parties neutres, on isole des cristaux correspondant au (diphényl-1,1′)-bicyclopentyl déjà caractérisé précédemment.

In nmr spectroscopy involving organic substrates, one often has a situation in which there is a dominant species in rapid equilibrium with one or more minor components. In general, one knows, a priori, neither the population of these minor components nor the rate constants involved in the equilibrium process. In fact, from the physical appearance of these spectra, one cannot normally even deduce that such an equilibrium exists. For example, in cases involving ^{13}C nmr spectroscopy, this minor component may not be observable under slow exchange nmr conditions because of signal-to-noise ratio problems and hence is referred to as a 'hidden' exchange partner. In this paper, we have analyzed the extent of nmr line broadening to be expected from a two-component system of this type, varying the populations, chemical shift separations, and intrinsic line widths. Thus, the presence of a 'hidden' partner can sometimes be detected by a characteristic, but often very subtle, peak broadening–resharpening sequence involving first of all the 'averaged' peak and finally the peak of the dominant component, these peaks being virtually identical in area and very similar in chemical shift so that one is not easily alerted. Assuming there is some experimental line broadening, equations developed in this paper, together with chemical shift estimates for this 'hidden' partner, allow one to quickly estimate both the amount of the minor partner and the rate constant involved. Three 'real life' situations are subsequently analyzed.

NANCY OKAZAWA et TED S. SORENSEN. Can. J. Chem. **56**, 2737 (1978).

En spectroscopie rmn impliquant des substrats organiques, on se trouve souvent en face de la situation où une espèce dominante est en équilibre avec un ou plusieurs composants minoritaires. D'une manière générale, on ne connaît à priori ni la population de ces composants minoritaires ni les constantes de vitesse impliquées dans le processus d'équilibre. De fait, en se basant sur l'apparence physique de ces spectres, on ne peut normalement pas déduire qu'un tel équilibre existe. Par exemple dans les cas impliquant la spectroscopie rmn du ^{13}C, il est possible, à cause de problèmes du rapport signal-à-bruit, que ce composé minoritaire ne puisse pas être observable dans des conditions de rmn impliquant des échanges lents; on réfère souvent à ces composés comme des partenaires d'échanges "masqués." Dans cette publication, nous avons analysé jusqu'à quel point on peut s'attendre à un élargissement des raies de rmn dans des systèmes à deux composants de ce type; à cette fin, nous avons fait varier les populations, les séparations des déplacements chimiques et les largeurs intrinsèques des raies. Ainsi la présence d'un partenaire "masqué" peut quelquefois être mise en évidence par une séquence caractéristique mais subtile d'un élargissement et d'affinement des raies impliquant en premier lieu la raie "pondérée" et finalement la raie du composant principal: ces raies pouvant être virtuellement identiques en superficie et très semblables en déplacements chimiques et il est quelquefois difficile de les remarquer. Faisant l'hypothèse qu'il se produit un certain élargissement des bandes expérimentales, il est possible, grâce aux équations développées dans cette publication prises de concert avec les évaluations des déplacements chimiques pour le partenaire "masqué," d'évaluer rapidement la quantité du partenaire minoritaire ainsi que la constante de vitesse impliquée. On a subséquemment analysé trois situations réelles.

[Traduit par le journal]

Introduction

The use of dynamic nmr spectroscopy for studying the kinetics of chemical reactions is a well-known and well-reviewed process (1). Briefly, these can be broken down into two distinct types: (*i*) degenerate processes, e.g., $A \rightleftarrows A'$, naturally involving equal populations, and (*ii*) reactions $A \rightleftarrows B$, where the equilibrium constant (K) is not generally 1.

For either situation, total line-shape analysis and matching ultimately provides the most reliable method for determining the rate constant corresponding to a particular line-shape and is almost mandatory for Arrhenius $\Delta H^{\ddagger}$ evaluation. However, for various practical reasons, there are many instances when one wants a simple procedure from which one can obtain a reasonably accurate *single* rate measurement, usually then converted to a free energy of activation barrier $\Delta G^{\ddagger}$. Of the various simplified procedures for the $A \rightleftarrows A'$ case, the most widely used is the restricted Gutowsky–Holm coa-

lescence line-shape relationship (2), where $\delta\nu$ is the chemical shift separation of the two sites under slow exchange or 'frozen-out' conditions and k is the

$$k = \pi\delta\nu/\sqrt{2} \quad [1]$$

rate constant. This coalescence behavior has been extended to nonequal populations using a graphical procedure (ref. 3*a*; for examples of various other expressions see ref. 3*b*) but, in general, A $\rightleftarrows$ B ($K \neq 1$) processes are treated by total line-shape analysis.

Particularly with the recent advent of routine ^{13}C nmr spectroscopy, a somewhat different situation can arise. A typical scenario would be the following: In a compound where the *possibility* exists for an equilibrium process with another (minor) isomer, conformer, etc., one obtains a ^{13}C nmr spectrum at some particular temperature at which the equilibrium rate constants are expected to be very large (complete averaging). This spectrum looks quite 'normal' in terms of both the expected chemical shifts and the line width of the signals. Suppose one now cools down the sample so that the equilibrium rate constants (if they exist) might be expected to be in the nmr intermediate exchange region. The basic question we wish to pose is the following: What concentration of this minor equilibrium partner is then needed in order to see an observable line-broadening effect? Or the corollary of this: What is the maximum possible concentration of this minor equilibrium partner if one *does not observe* any line-shape changes?

Our analysis is further based on the premise that one may not always be able to see the 'frozen-out' minor partner nmr spectrum. This is particularly true in ^{13}C nmr spectroscopy where signal-to-noise ratio problems can occur. An unfavorable Boltzmann factor further hinders one in this regard. However, one has no comparable problems with measuring ^{13}C nmr line widths and it is possible to detect (and thus verify) the presence of exchange phenomena by simply focusing on the changes which occur to the observable 'major peak' as one varies the exchange rate (usually by varying the temperature). We use quotation marks because the line-shape changes involve going from the averaged peak to a situation where we see only the major species. However, the minor component may be so small in concentration that this change will cause no detectable area change in the peak one sees and any small chemical shift changes which may occur can be easily overlooked. In this paper, we have examined this problem with a view to determining what range of values of K, $\delta\nu$, intrinsic peak half-width, and rate constants result in observable effects and have developed several simple *empirical* equations which apply to these situations. Subsequently we show how these equations can be used to treat particular problems. One involves a cyclooctane conformation analysis study by Anet (4), in which this situation arises, another involves a carbocation equilibrium.

Results

In any phenomenon involving line-shape changes, it is advantageous to have some well-defined, *experimentally determinable*, parameter which can then be compared to some theoretical results, this theoretical result having been determined for changes in K, $\delta\nu$ etc. We believe that minimum intensity (MI) or maximum line width (MLW) are the two most readily obtained parameters. Because of the complexity of the GH expression, an analytical solution for such quantities as the half-width at half-height of the maximally broadened single peak was not attempted. Instead, an empirical approach was used in the solution. Three Fortran IV computer programs were devised, their difference being the particular line-shape characteristic chosen: (*i*) a minimum intensity with the further stipulation that only one peak maximum is allowed (MI,1); (*ii*) a minimum intensity with the further stipulation of only two inflection points (MI,2); (*iii*) a maximum line width at half-height with the stipulation of only one peak maximum (MLW).

Since most ^{13}C nmr applications involve single (uncoupled) peaks and two site exchange, we have restricted our analysis to these cases. The standard exchange equation of Gutowsky and Holm (GH) was used (2,5). This general solution involves some standard assumptions, e.g., $T_{2A} = T_{2B}$, slow passage, negligible lifetimes during site exchange. The variables in each case were the 'frozen-out' frequency separation of A and B ($\delta\nu$, in Hz), the natural line width in the absence of exchange (W^0), the fractional population of B (p_B) and the rate constant (k_A). In practise, one begins with large rate constants and gradually reduces these until the particular result is obtained. The computer program automatically reduces the Δk_A increments in the critical region.

Interdependence of k_A, $\delta\nu$, *and* p_B

$$k_A$$

For the process A $\rightleftharpoons$ B, we have arbitrarily chosen to use the forward rate constant k_A. Fractional populations are expressed in terms of p_B, where $p_A > p_B$, and were varied from $p_B = 0.001$ to 0.5. Frequency separations varying from 10–10 000 Hz were used for $\delta\nu$.

A value for $p_B = 0.5$ corresponds, of course, to equal populations of A and B and was used so that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

we could tie our results in with the GH coalescence eq. [1]. As well, by choosing some relatively large p_B values, one can better show the range of p_B values over which our results are useful.

Plots of k_A (i.e., that k_A characterizing the specific line-shape solutions) vs. $\delta\nu$ give straight lines intersecting at the origin (or with very slight deviations). The only exception to this behavior was found in the MLW results between $p_B = 0.35 - 0.40$. The cause of this discrepancy will be commented on later. This leads to the empirical relationship:

$$[2] \qquad k_A \text{ (characteristic)} = c''_{(p_B)}\,\delta\nu$$

where c'' is a proportionality constant for fixed values of p_B. The form of this equation is identical to the GH coalescence expression (eq. 1). For $p_B = 0.5$, we find $c''_{(p_B)} = 2.19$. This differs by only 1.4% from the GH constant of $\pi/\sqrt{2}$ (2.22) and the source of this small difference relates to the GH definition of coalescence, i.e., where $\nu_A = \nu_B$, which characterizes a single peak which is not quite at maximum half-width or minimum intensity.

One can replace $c''_{(p_B)}$ by incorporating p_B into the expression:

$$[3] \qquad k_A \text{ (characteristic)} = c'_{(p_B)} p_B \delta\nu$$

where $c'_{(p_B)}$ is a new proportionality constant dependent on p_B (the zero-order Taylor expansion term is zero since $c'' \to 0$ as $p_B \to 0$).

We have plotted the proportionality constant $c'_{(p_B)}$ against p_B and these results are shown in Fig. 1 for the three line-shape criteria. The dashed region in the MLW curve corresponds to the region where the k_A vs. $\delta\nu$ plot, although linear, does not intersect at the origin. For values of $p_B \leq 0.2$, the Fig. 1 relationship is nearly linear, although the slope varies slightly depending upon whether the MLW or MI criteria are used. Making appropriate substitution in eq. [3] gives:

$$[4] \qquad k_A \text{ (characteristic)} = c_0' p_B \delta\nu - c p_B^2 \delta\nu$$

where $c = 3.90$ and $c_0' = 6.32$, for the MLW case, where k_A is expressed in s^{-1}. For the MI case, $c = 5.94$ and $c_0' = 6.19$. The MLW criterion will be used in the actual examples described at the end of this paper. For values of $p_B \leq 0.02$, one can neglect the second term, therefore k_A (characteristic) = 6.32 $p_B\delta\nu$, rather close to $k_A = 2\pi p_B\delta\nu$. A drawback to an empirical approach is that the origin of proportionality constants is lost.

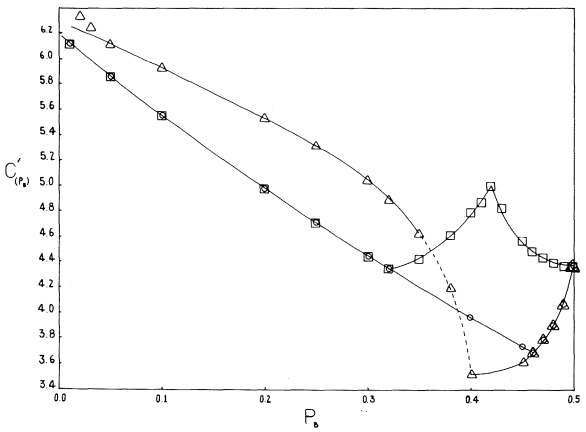

FIG. 1. The behavior of the proportionality constant $c'_{(p_B)}$ as a function of the population of the minor isomer p_B. The proportionality constant $c'_{(p_B)}$ is derived from the linear plot of k_A and $\delta\nu$. The - - - line region is discussed in the text.

The Nonlinear Deviations in Figure 1

Although we are primarily concerned with p_B values of ≤ 0.2, we will briefly discuss the region from $p_B = 0.2$–0.5. In the MI,1 case, the slope change deviations in Fig. 1 result from an abrupt change in the two criteria characteristic of this case. As one lowers k_A from high (complete coalescence) values, the intensity will decrease and then at some further point, start to increase. However, one may also have the situation where the (major) peak intensity is still decreasing but a second maximum occurs and this criterion then determines the k_A value. From $p_B = 0.46$ to 0.5, this second criterion is met first, whereas for $p_B < 0.46$, the first criterion applies. In the MLW case, similar situations arise. An additional complication occurs when the 'single peak' shoulder from the B isomer moves from just above half-height to just below half-height of the curve as a whole. In this region, the k_A vs. $\delta\nu$ plot, although linear, does not intersect at the origin. In the MI,2 case, between $p_B = 0.32$ and 0.5, the 'no more than two inflection points' criteria is met before the minimum intensity one, whereas for $p_B < 0.32$, the results are identical to the MI,1 results. In general, the MI,2 results should mimic closest the true coalescence ($\nu_A = \nu_B$) behavior for the system.

In our further analysis, we will restrict our treatment to cases where $p_B \leq 0.2$ and in most experimental situations, in fact, p_B will be less than 0.1. The observable curve characterizing such p_B values should show the following experimental behavior as one lowers the rate (reduces the temperature): (*i*) the intensity will decrease or the peak half-width will increase; (*ii*) a minimum intensity or a maximum peak half-width will be reached; (*iii*) the peak intensity will then increase or the peak half-width decrease. Observation number three is very *important* in practical situations since observations *i* and *ii* could be due to viscosity broadening or a gradual field

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

homogeneity deterioration. In addition to the above observations, the averaged peak position will change because of the Boltzmann distribution factor (discussed subsequently).

Interdependence of the Maximum Line Width (W_{max}), $\delta\nu$, *and the Intrinsic Line Widths* (W^0)

From eq. 4, one could calculate a single k_A (at a particular temperature and hence $\Delta G^{\ddagger}$) *if* one knew the values for p_B, ν_A and ν_B. The value for ν_A can be easily obtained since this is simply the chemical shift position of the 'observable' peak after the 'resharpening' observation discussed in the previous section. Thus $\delta\nu$ is a single variable. To define allowable values for p_B and $\delta\nu$, one must make numerical use of the actual maximum width of the observed peak (denoted as W_{max}). This numerical value will depend of course on the natural peak line width in the absence of exchange (denoted W^0). Plots of W_{max} (MLW criterion) vs. $\delta\nu$ are linear, with an intercept equal to W^0 (except for $0.35 \leq p_B \leq 0.4$, i.e., the region of shoulder inclusion–exclusion, where the plot is linear but the intercept is not W^0). This leads to the relationship:

$$[5] \qquad W_{max} = b_{(p_B)}\delta\nu + W^0$$

where $b_{(p_B)}$ is a proportionality constant for a particular value of p_B. A plot of $b_{(p_B)}$ vs. p_B is shown in Fig. 2. At small values of p_B, this relationship is nearly linear and with close to unit slope, i.e., $b_{(p_B)} \sim p_B$. This observation helps one in empirically fitting the curve in Fig. 2 and the following approximations can be formulated:

$$[6] \qquad W_{max} = \delta\nu(p_B + p_B^2/2p_A^2) + W^0$$

or

$$[7] \qquad W_{max} = \delta\nu(p_A p_B + p_B^2/p_A^2) + W^0$$

where $p_A = 1 - p_B$. Equation [6] appears to be slightly superior. Both of these simplify to eq. [8] when p_B is small.

$$[8] \qquad W_{max} = \delta\nu p_B + W^0$$

or

$$W_{max} - W^0 = \delta\nu p_B$$

(a type of uncertainty relationship)

The Boltzmann Distribution Factor

The equations derived in this work give p_B values applicable *only* at the temperature corresponding to the W_{max} condition. From the Boltzmann equation, p_B will decrease with decreasing temperature, adding in fact to the difficulty in detecting *B* under 'frozen-out spectra' temperature conditions. The Boltzmann factor can also lead to detectable chemical shift changes in an averaged peak as one lowers the temperature. This behavior continues, of course, even in the broadening region covered by our analysis and is a characteristic experimental observation which can be used to further collaborate that one has indeed an equilibrium situation. This shift is, of course, unrelated to the rate processes, i.e., k_A, our primary concern. It should also be noted that ν_B (and hence $\delta\nu$) and p_B are related, since the $\nu_{AV} - \nu_A$ value, in combination with either ν_B or p_B, will define the other. However, this p_B value is not so easily determined at the temperature corresponding to W_{max}, since the peak is broadened.

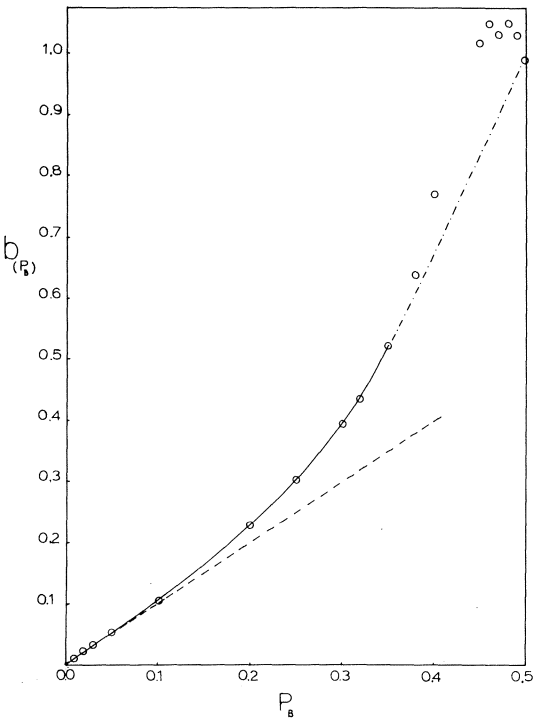

FIG. 2. The behavior of the proportionality constant $b_{(p_B)}$ as a function of the population of the minor isomer p_B. The proportionality constant $b_{(p_B)}$ is derived from the linear plot of W_{max} and $\delta\nu$. The dashed line - - - represents the case where $p_B = b_{(p_B)}$. The reason for the ····· line is commented on in the text.

Practical Applications

The major unknown quantity is k_A and this will be calculated using eq. [4]. It is also evident from eq. [8] that an experimental value of $W_{max} - W^0$ will characterize a particular $\delta\nu p_B$ product and this may be of use in some cases. In practise, the following situations might arise:

(I) For the larger p_B situation, one might determine ν_B (and hence $\delta\nu$) experimentally from 'frozen-out spectra.' From the ν_{AV} position *or* by using eqs. [6–8] (but not from the 'frozen-out spectra') one can ap-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

proximately determine p_B for the temperature corresponding to W_{max}. Equation [4] can then be used to calculate k_A.

(II) From model systems etc., one may be able to estimate a value for ν_B. The remaining steps follow as in I above.

(III) For a given experimental value of W^0, one may wish to calculate the minimum population of B(p_B) which could result in an experimentally observable result, if we have reason to believe, from model systems etc., that our temperature range has spanned the applicable kinetic region.

The latter two situations will now be examined using actual experimental data. Since the last one is hypothetical, this will be treated first.

Case III

In a ^{13}C nmr spectrum of a carbocation, one observes a 'single' peak of $W^0 = 5$ Hz, characteristic of a particular carbon in the 'major' isomer. From model system comparisons, a possible 'minor' isomer would have this same carbon at approximately 4000 Hz separation, i.e., $\delta\nu \sim 4000$ Hz (24 kG field). If we can accept a $W_{max} - W^0$ value of 4 Hz as being observable, then one should be able to detect a p_B value of 0.001, using eq. [8]. This corresponds to $k_A = 24.7\ s^{-1}$, using eq. [4]. A more usual situation in neutral molecules might have $\delta\nu = 200$ Hz, whereby $p_B = 0.020$. At 72 kG fields, the first listed p_B values will be lowered to 0.0003 and 0.007, respectively, and the advantages of superconducting magnets is readily apparent. In any case, we note that rather *minor concentrations of equilibrium partners can lead to experimentally detectable results.*

Case I

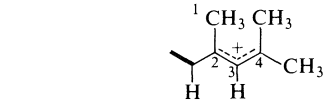
Anet and Basus (4)[1], in a ^{13}C study of the cyclooctane ring, report that the single sharp line observed at 25°C gradually broadens to a maximum half-width of 9 Hz at −45°C, whereupon the line resharpens as one goes to lower temperatures. The minor conformer could be observed at −89°C, 367 Hz downfield from the main peak. Using eq. 8, and assuming their W^0 to be about 2 Hz, one obtains:

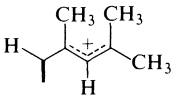
$$p_B = (9 - 2)/367 \sim 2\%$$

Using eq. 4, $k_A = 6.32 \times 0.02 \times 367 \sim 46\ s^{-1}$ at −45°C ($\Delta G^* = 11.5$ kcal/mol). These values are essentially as reported, using the general GH expression. One should note that this case is an unusually favorable one for seeing minor components since 25% solutions were used.

Case II

The previously reported (6) carbocation, **1**, can exist (in theory) in two conformers, **1***a* and **1***b*, respectively. In both conformers, the cyclopropyl ring is expected to be in the 'bisected' orientation, in which the plane of the ring is at right angles to the paper.





— ≡ Cyclopropyl ring

1*a* **1***b*

In the ^1H nmr spectrum, the C-3 proton signal shifts to lower field on cooling, eventually broadens, and finally resharpens. At this lower temperature, no new signals for a second conformer could be detected under our particular signal-to-noise conditions. The ^{13}C nmr spectrum of this cation has recently been obtained (7). In this case, two of the carbon signals are particularly broadened, the C-3 carbon and the C-1 methyl. In addition, the former shifts to lower field while the latter moves upfield as one lowers the temperature through the line broadening and into the resharpening temperature region. Once again, none of the ^{13}C peaks for this second conformer could be observed in the 'frozen-out spectrum.' Both these ^1H and ^{13}C nmr observations fit our second category. One can show that the observed chemical shifts are consistent with **1***a* being the major isomer, although this fact is basically irrelevant to the analysis.

In the ^1H case, maximum broadness (15 Hz) occurred at −80°C, with $W^0 = 3$ Hz. From eq. [6] $12 = (p_B + p_B^2/2p_A^2)\delta\nu$. From this, one could draw a graph of permissible p_B and $\delta\nu$ values and this is shown in Fig. 3. Note that the spectrometer signal-to-noise characteristics will allow one to set an approximate upper limit for permissible p_B values (i.e., B will be directly observed if p_B is large enough) and thus narrow the range of possible combinations. In practise however, one would not normally plot a graph of this type. Instead, one would estimate $\delta\nu$ by whatever means possible, and in the present instance, one can estimate $\delta\nu$ as ~70 Hz (7) from a comparison to closely related systems where both conformers are detectable. Solving numerically for p_B gives 0.155. For the ^{13}C spectra, $W_{max} - W^0$ is about 27 Hz and we can estimate $\delta\nu$ as 200 Hz (6). This gives $p_B = 0.125$ from eq. 6. Using $p_B = 0.125$ (which seems more reasonable, in that isomer B is

[1]After completion of this study, we became aware that Anet and co-workers had developed essentially the same limiting equations from an actual mathematical solution of the GH equation (8,9). However, our parallel approach allows one to clearly see what range of p_B values apply to these limiting cases.

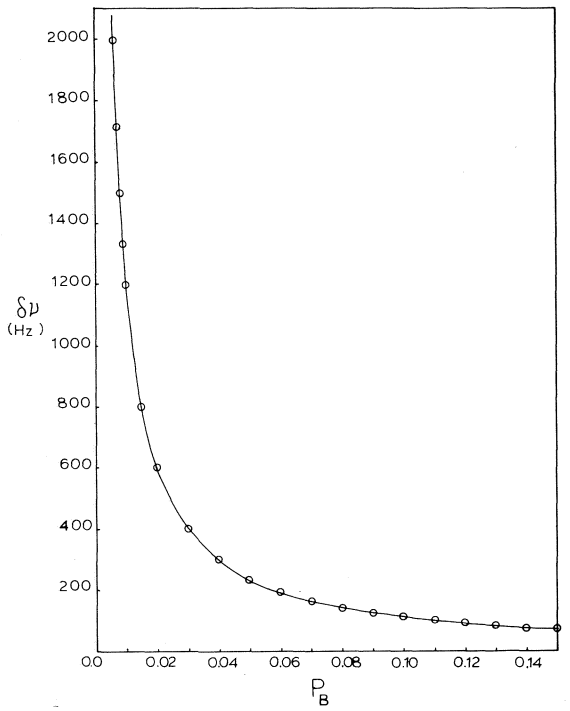


FIG. 3. A graph showing the permissible p_B and δν(H-3 protons) values for the equilibrium mixture of the two cations **1***a* and **1***b*, at the temperature of maximum line broadening.

not detectable at low temperatures), k_A is calculated as 146 s^{-1} from eq. [4], $\Delta G^{\ddagger} = 8.9$ kcal/mol. To reckon the change in p_B from the W_{max} temperature condition to a temperature corresponding to slow exchange kinetics, i.e., 'frozen-out spectra,' requires two basic assumptions (7). The first assumes $\Delta S^{\ddagger} = 0$, which allows one to make $\Delta G^{\ddagger}$ a constant and hence automatically to calculate rates for a series of lower and lower temperatures. The second assumes $\Delta S = 0$, which allows one to define p_B with the only variable again being temperature, i.e., ΔG is treated as a constant in the expression, $\Delta G = -RT \ln K$. In the present case, the above calculations show that p_B will be <0.1 under the low temperature 'frozen-out spectrum' conditions where one could expect to see sharp **1***b* peaks.

We have done this latter calculation only as an illustration of the expected p_B variation. It is in no way a requirement in the analysis.

Concluding Remarks

In conclusion, we would like to emphasize several practical points:

(*i*) The experimental observation of a line broadening–resharpening phenomena can be easily missed if the temperature jumps between sequentially taken spectra are too large.

(*ii*) It may be impractical to obtain ^{13}C spectra corresponding 'exactly' to maximum line width but this will have a rather small effect on a $\Delta G^{\ddagger}$ determination.

(*iii*) Only eq. [4] and [8] are needed in the analysis, for the usual case where $p_B \leq 0.1$.

(*iv*) If one can obtain 'frozen-out' spectra but still 'see' no minor peak, one can plot on the actual observed spectrum, on the basis of eq. [8], the permissible p_B and ν_B values. Where this line enters the noise region of the spectrum will determine the minimum δν separation for A and B and the maximum possible p_B value.

N,N'-Dibenzoyl-2,5-dideoxystreptamine (**8***b*) reacted with thionyl chloride to form the bisoxazoline **9** and the latter compound was treated with thiobenzoic acid to produce the dithiobenzoate **10***a*. Removal of the protective groups in **10***a* afforded (1,3/4,6)-4,6-diamino-1,3-cyclohexanedithiol (**1**) dihydrochloride. Reaction of **8***b* with triethyl orthoacetate in the presence of boron trifluoride yielded the monooxazoline **12** which, on reaction with thiobenzoic acid followed by deprotection of the resulting **13***a*, afforded (*d,l*)-(1,3/4,6)-4,6-diamino-3-hydroxycyclohexanethiol (**2**) dihydrochloride. Similarly, 3-*N*-benzoyl-1-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**15**) and 1-*N*-benzoyl-3-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**20**) were converted via their respective oxazolines **17***a* and **22***a*, to the enantiomeric aminothiols **3** and **4**. Protected derivatives of **1**–**4** are also described.

GERRY KAVADIAS et ROBERT DROGHINI. Can. J. Chem. **56**, 2743 (1978).

La *N,N'*-dibenzoyldidéoxy-2,5 streptamine (**8***b*) réagit avec le chlorure de thionyle pour former la bisoxazoline **9** et ce dernier composé, par traitement avec de l'acide thiobenzoïque, produit le dithiobenzoate **10***a*. L'enlèvement des groupes protecteurs de **10***a* conduit au dichlorhydrate du (1,3/4,6) diamino-4,6 cyclohexanedithiol-1,3 (**1**). La réaction de **8***b* avec l'orthoacétate de triéthyle en présence de trifluorure de bore conduit à la mono-oxazoline **12** qui, par réaction avec l'acide thiobenzoïque suivie par une déprotection du composé **13***a* qui en résulte, fournit le (*d,l*)(1,3/4,6) diamino-4,6 hydroxy-3 cyclohexanethiol (**2**) sous forme de dichlorhydrate. De la même manière, la *N*-benzoyl-3 *N*-éthoxycarbonyl-1 didéoxy-2,5 streptamine (**15**) et la *N*-benzoyl-1 *N*-éthoxycarbonyl-3 didéoxy-2,5 streptamine (**20**) ont pu être transformés, par l'intermédiaire de leurs oxazolines **17***a* et **22***a* respectives, en aminothiols énantiomères **3** et **4**. On décrit aussi la préparation des dérivés protégés **1**–**4**.

[Traduit par le journal]

In a research project directed at the synthesis of thioanalogues of aminoglycoside antibiotics (kanamycins, gentamycins, tobramycin etc., in which the C-5 hydroxyl group is replaced by a hydrogen atom and one or both of the glycosidic oxygens are replaced by sulfur(s)), the aminothiols **1**–**4**, properly protected, were needed as the aglycon components in the glycosidation reactions. In addition, the aminothiols **1**–**4** were needed for biosynthetic studies. In recent years, deoxystreptamine-negative mutants from a number of aminoglycoside-antibiotic-producing microorganisms have been used to obtain novel antibiotics by the addition of 2-deoxystreptamine analogues to the fermentation broth (1–7).

The present paper describes the synthesis of the aminothiols **1**–**4** and their derivatives and gives evidence for their assigned structures. The easily available 2,5-dideoxystreptamine (**8***a*) (8) served as the starting material in these syntheses.

Our first approach to the syntheses of these compounds involved inversion of one or both of the hydroxyls in **8***a*, conversion of the inverted hydroxyl(s) to tosylate(s) and replacement of the latter group(s) with a sulfur nucleophile such as the thiocyanate, thioacetate and thiobenzoate anions. This approach was unsuccessful and soon abandoned, mainly because the major product in the replacement step was an olefin. For example, the reaction of the tosylates **I***a* and **I***b* with sodium thioacetate yielded the olefins **II***a* and **II***b*, respectively.[2]

A most promising potential route for the conversion of **8***a* to the aminothiols **1**–**4** and, in general, for the conversion of a *trans*-1,2-aminoalcohol to *trans*-1,2-aminothiol with the same configuration appeared to be a process involving the following steps: (*a*) Conversion of the *trans*-1,2-aminoalcohol to *trans*-1,2-benzamidoalcohol; (*b*) conversion of the latter to *cis*-oxazoline; (*c*) ring-opening reaction of the oxazoline with thiobenzoic acid to *trans*-1,2-benzamidothiol benzoate; and (*d*) removal of the protective groups. It is well established that when a benzamido group is *trans* oriented, diaxially or diequatorially to a leaving group at the C-2 position, *cis*-oxazolines are formed by intramolecular replacement of the leaving group by an attack of the oxygen of the benzamido function (9–14). Reaction of 2-oxazolines with thiobenzoic acid causes ring opening and amide formation, with addition of the thiobenzoxy group to the original oxazoline ring (15). For example, the reaction of 2-phenyl-2-oxazoline with thiobenzoic acid produced 2-benzamidoethylthiol benzoate in high yield (15*a*). To examine the practicality of this approach and to establish workable experimental conditions for the conversion of **8***a* to the aminothiols **1**–**4**, *trans*-2-benzamidocyclohexanol (**5**) was used as a model.

Reaction of **5** with thionyl chloride at the reflux temperature gave the known (11) oxazoline **6** in yields varying with the reaction time. A maximum yield of 85% was obtained after 3 min refluxing and was thereafter reduced to 30% after 1 h.

Treatment of the oxazoline **6** with thiobenzoic acid (2 h, 100°C) caused ring opening of the oxazoline and produced *trans*-2-benzamidocyclohexanethiol benzoate (**7***a*) in 85% yield. Alkaline hydrolysis of **7***a* yielded the known *trans*-2-benzamidocyclohexanethiol (**7***b*) (16) which afforded *trans*-2-aminocyclohexanethiol hydrochloride (**7***c*) (16) upon acidic hydrolysis (Scheme 1).

b $R^1 = Bz, R^2 = H$
c $R^1 = R^2 = H$

Bz = C_6H_5CO—; Ph = C_6H_5

SCHEME 1

Treatment of **8***b* with thionyl chloride at the reflux temperature for 3 min produced the crystalline bisoxazoline **9** in 72% yield (Scheme 2). The yield of **9** was reduced as the refluxing period was increased and was nil after 45 min. Treatment of the bisoxazoline **9** with excess thiobenzoic acid in DMF (2 h, 115°C) opened both of the oxazoline rings and formed **10***a* in 63% yield. Removal of the protective groups in **10***a* to form **1** was best effected in a two stage hydrolysis: alkaline hydrolysis of **10***a* removed the *S*-benzoyl groups and yielded **10***b* which was then hydrolyzed by refluxing in a hydrochloric acid – acetic acid mixture to produce the dihydrochloride salt of **1**. The structure of **1** was confirmed by ^{1}Hmr spectroscopy. The ^{1}Hmr spectrum of the dihydrochloride salt of **1** showed a two-proton double triplet at δ 3.32 with coupling constants of 11.0 and 3.8 Hz which were assigned to the magnetically equivalent protons at the carbons attached to the amino groups. It also showed a two-proton double triplet at δ 2.88 with coupling constants of 11.0 and 3.8 Hz which were assigned to the protons at the carbons attached to the thio groups. Thus, all the substituents in **1** are equatorially oriented as expected.

For personal use only.

discussed above would involve the difficult task of protecting one of the two hydroxyls in **8***b* before reaction with thionyl chloride. A more promising route for the synthesis of **12** appeared to be the reaction of **8***b* with triethyl orthoacetate in the presence of an acid catalyst. It was anticipated that the ortho ester **11***a* would be formed initially and, in the presence of the acid catalyst, would be converted to the 1,3-dioxan-2-ylium cation **11***b* (see ref. 17 for a review of 1,3-dioxan-2-ylium cations) which would suffer ring opening by an attack of the oxygen of the benzamido group to form the oxazoline **12**. Indeed, reaction of **8***b* with triethyl orthoacetate in DMF in the presence of boron trifluoride at room temperature did produce **12** in 80% yield. Treatment of the oxazoline **12** with thiobenzoic acid gave the thiobenzoate **13***a* in 79% yield. The acetyl group in **13***a* was selectively removed by controlled acid hydrolysis to produce **13***c*. Compound **13***c*, with all its functional groups protected except the hydroxyl group, could be used in glycosidation reactions. Alkaline hydrolysis of **13***a* removed the *O*-acetyl and the *S*-benzoyl groups and produced **13***b* which was then converted to the dihydrochloride salt of the aminothiol **2** by acidic hydrolysis. The structure of **2** which can be deduced from simple mechanistic considerations was confirmed by ^{1}Hmr spectroscopy. Thus, the characteristic ^{1}Hmr absorptions of **2** hydrochloride at δ 3.78 (d of t, O—C—H—, J_1 = 10.4, J_2 = 4.5 Hz), 3.36 (d of t, N—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 3.28 (d of t, N—C—H, J_1 = 10.4, J_2 = 4.5 Hz), and 3.08 (d of t, S—C—H, J_1 = 10.4, J_2 = 4.5 Hz) indicate that all the substituents in **2** are in equatorial orientations.

Attempts to resolve **2** into the optical isomers **3** and **4** with optically active acids such as *d*- and *l*-tartaric acids and *d*- and *l*-2-nitrotartranilic acids were unsuccessful.

The syntheses of **3** and **4** and their derivatives were accomplished by the routes outlined in Schemes 3 and 4, respectively. 1-*N*-Ethoxycarbonyl-2,5-dideoxystreptamine (**14**) (8) was *N*-benzoylated to give **15**. Treatment of **15** with triethyl orthoacetate in DMF in the presence of boron trifluoride produced, presumably via the intermediate **16**, the oxazoline **17***a* ($[\alpha]_D^{25}$ −64.2) in 78.5% yield. Reaction of the oxazoline **17***a* with thiobenzoic acid gave the thiobenzoate **18***a* ($[\alpha]_D^{25}$ −9.7) in 76.5% yield which, by alkaline hydrolysis, was converted to **18***b* ($[\alpha]_D^{25}$ +32.9). Acid hydrolysis of **18***b* (hydrochloric acid-acetic acid) afforded the dihydrochloride salt of **3** ($[\alpha]_D^{25}$ +2.8). Assignment of the absolute configuration to **3** was based on the mode of its synthesis and the mechanisms of the reactions involved. Since it was derived from the aminocyclitol **14** of known

ethanol with a catalytic amount of sodium ethoxide at room temperature. The oxazoline **17***b* ($[\alpha]_D^{25}$ −98.6) thus obtained was reacted with thiobenzoic acid to give the thiobenzoate **18***c* ($[\alpha]_D^{25}$ +45.2) in 71% yield. Compound **18***c* has all its functional groups protected except the hydroxyl group and can be used in glycosidation reactions.

The aminothiol **4** was prepared in a manner analogous to that described for the synthesis of its enantiomer **3**. 3-*N*-Ethoxycarbonyl-2,5-dideoxystreptamine (**19**) (8) was *N*-benzoylated to give **20**. Reaction of **20** with triethyl orthoacetate in DMF in the presence of boron trifluoride produced, presumably via the intermediate **21**, the oxazoline **22***a* ($[\alpha]_D^{25}$ +63.7) in 88% yield. The acetyl group in **22***a* was removed by saponification (sodium ethoxide in ethanol) and the oxazoline **22***b* ($[\alpha]_D^{25}$ +100.6) thus obtained was reacted with thiobenzoic acid to give the thiobenzoate **23***c* ($[\alpha]_D^{25}$ −46.3) in 63% yield. Compound **23***c* has all its functional groups protected except the hydroxyl group and can be used in glycosidation reactions. Alkaline hydrolysis of **23***c* yielded **23***b* which by acid hydrolysis afforded the dihydrochloride salt of **4** ($[\alpha]_D^{25}$ −2.8).

In summary then, we have shown that aminothiols of known configuration are readily obtained by a combination of internal and external displacement reactions.

Experimental

The melting points were determined on a Mel-Temp melting point apparatus and are not corrected. The ir spectra were recorded on a Unicam SP-200G grating ir spectrometer. ^{1}Hmr spectra were taken with a Varian EM-360A 60 MHz spectrometer. Tetramethylsilane (for solutions other than deuterium oxide) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (for solutions of deuterium oxide) were used as internal standards. Thin-layer chromatography (tlc) was carried out on microscope slides coated with silica gel and the spots were visualized with perchloric or sulfuric acid. Optical rotations were measured with a Perkin-Elmer Model 141 polarimeter. The analyses were performed by Micro-Tech Laboratories, Skokie, Ill.

d,l-cis-*2-Phenyl-4,5-cyclohexanooxazoline (**6**)*

A mixture of 9.0 g (41 mmol) of *d,ℓ-trans*-2-benzamidocyclohexanol (9) and 45 ml thionyl chloride was stirred at room temperature for 3 min and then heated on a steam bath for 2 min. The solution was cooled in an ice bath and then evaporated to dryness on a rotary evaporator at 30°C. The residue, on trituration with dry ether (100 ml), solidified. The ether phase was decanted and the grey oxazoline hydrochloride was treated with ether once more. After removal of the ether phase by decantation, the solid residue was partitioned between 6% aqueous sodium hydroxide (140 ml) and ether (140 ml). The ether phase was separated and the aqueous phase was extracted with ether (100 ml). The combined ethereal extracts, after drying, were evaporated to dryness to give 6.96 g (85%) of crystalline oxazoline **6**, mp 45–47°C (lit. (11) mp 45–47°C). Thin-layer chromatography with ether showed, under uv, a major spot of R_f 0.66 (**6**) and a trace of starting material (R_f 0.28); ir ($CHCl_3$): 1640, 1570 cm^{-1}.

When the heating time was extended to 1 h, the yield of **6** was reduced to 30%.

d,l-trans-*2-Benzamidocyclohexanethiol Benzoate (**7**a)*

Into a flame-dry and nitrogen-purged, 100 ml, three-neck flask, equipped with condenser, magnetic stirrer, and nitrogen inlet and outlet tubes, was added 7.30 g (53 mmol) thiobenzoic acid (Aldrich Chemical Co., Inc.) and placed under a slow stream of nitrogen. The flask was slightly warmed to melt the thiobenzoic acid, oxazoline **6** (4.9 g, 24.4 mmol) was added and the mixture was stirred at room temperature until it became a homogeneous solution (5–10 min) and then heated on a steam bath for 2 h. A solid material was formed. After cooling to room temperature, ether (50 ml) was added and stirred to break the lumps into a fine powder. Filtration gave 6.97 g (84.5%) of *d,ℓ-trans*-2-benzamidocyclohexanethiol benzoate, mp 156–158°C. Thin-layer chromatography (ether) showed, under uv, a single spot (R_f 0.71). Recrystallization from ethanol afforded the analytical sample, mp 158–159°C; ir ($CHCl_3$): 3400, 1650, 1640, 1570, 1530 cm^{-1}. *Anal.* calcd. for $C_{20}H_{21}NO_2S$: C 70.76, H 6.24, N 4.13, S 9.45; found: C 70.59, H 6.24, N 4.03, S 9.47.

d,l-trans-*2-Benzamidocyclohexanethiol (**7**b)*

To a solution of 2.0 g sodium hydroxide in 50 ml of 80% ethanol was added 5.76 g (17 mmol) of *d,ℓ-trans*-2-benzamidocyclohexylthiol benzoate and the suspension was stirred at room temperature under nitrogen for 2 h. (After 15 min, it became a clear solution). The reaction mixture was neutralized with carbon dioxide and evaporated to dryness. The residue was treated with water (50 ml) and extracted with chloroform (3 × 50 ml). The chloroform solution, after drying, was evaporated to dryness to give 3.87 g (97%) of *d,ℓ-trans*-2-benzamidocyclohexanethiol, mp 159–162°C. Thin-layer chromatography (10% ethanol–chloroform) showed, under uv, one spot of R_f 0.46. Recrystallization from ethanol (13 ml) gave 3.0 g of **7***b*, mp 162–163°C (lit. (16), mp 161–162°C). *Anal.* calcd. for $C_{13}H_{17}NOS$: C 66.34, H 7.28, N 5.95, S 13.62; found: C 66.38, H 7.29, N 5.84, S 13.40.

d,l-trans-*2-Aminocyclohexanethiol (**7**c) Hydrochloride*

A solution of 2.0 g (8.5 mmol) of *trans*-2-benzamidocyclohexanethiol (**7***b*) in glacial acetic acid (15 ml) was diluted with an equal volume of concentrated hydrochloric acid (15 ml) and refluxed under nitrogen for 17 h. After removal of the solvent by evaporation, the residue was dissolved in water (40 ml) and extracted with ether (2 × 40 ml) to remove the benzoic acid. The aqueous phase was evaporated to dryness to give 1.35 g (95%) of **7***c* hydrochloride, mp 220–222°C (EtOH) (lit. (16) mp 225°C, (18) mp 226–227°C). *Anal.* calcd. for $C_6H_{13}NS\cdot HCl$: C 42.97, H 8.41, N 8.35, S 19.12; found: C 42.97, H 8.65, N 8.28, S 18.91.

N,N′-*Dibenzoyl-2,5-dideoxystreptamine (**8**b)*

To an ice-cold solution of 17.8 g (122 mmol) of 2,5-dideoxystreptamine (**8***a*) (8) and 35 g (330 mmol) of sodium carbonate in 210 ml water and 70 ml methanol, was added dropwise (15 min) with stirring, a solution of 44.4 g (305 mmol) of benzoyl chloride in 70 ml dry acetone. After stirring at 0°C for 30 min and at room temperature for 1 h, the reaction mixture was diluted with water (400 ml). The resulting precipitate was collected by filtration, washed successively with water (2 × 130 ml), ethanol (100 ml) and ether (2 × 130 ml), and dried to give 40.8 g of **8***b*, mp 278–282°C. This product was stirred in boiling ethanol and filtered to give 39.0 g (90%) of **8***b*, mp 280–282°C (dec.). This material was used in the next reaction. The analytical sample was prepared by recrystallization from DMF–EtOH(1:1), mp 283–285°C, resolidified, and melted at 294–295°C; ir (Nujol): 3400, 3300, 1625, 1615,

1575, 1565 cm^{-1}. *Anal.* calcd. for $C_{20}H_{22}N_2O_4$: C 67.78, H 6.25, N 7.90; found: C 67.70, H 6.26, N 8.03.

Bisoxazoline ***9***

Powdered **8***b* (20.0 g, 56.4 mmol) was added to 100 ml of thionyl chloride and the mixture was stirred at room temperature for 3 min and then heated on a steam bath for 3 min. The solution was cooled in an ice bath and then evaporated to dryness at 30°C. The residue, on trituration with ether (150 ml), solidified. The ether phase was decanted and the crystalline oxazoline dihydrochloride was treated with 6% aqueous sodium hydroxide (250 ml) and extracted with chloroform (250 ml). The chloroform solution, after drying, was evaporated to dryness to give 15.3 g of crude **9**. Thin-layer chromatography (10% ethanol–chloroform) showed, under uv, one major spot of R_f 0.23 (compound **9**) and four minor spots of R_f 0, 0.37, 0.43, and 0.50. The crude product was boiled and stirred with 70 ml acetone (5–10 min) and then cooled in an ice bath and filtered to give 12.8 g (72%) of the bisoxazoline **9**, mp 191–195°C. Thin-layer chromatography showed one major spot (R_f 0.23) and a trace of the spot with R_f 0.37. This material was used in the next reaction. The analytical sample was obtained by recrystallization from ethanol (twice), mp 196–198°C; ir ($CHCl_3$): 1650, 1585, 1500 cm^{-1}. *Anal.* calcd. for $C_{20}H_{18}N_2O_2$: C 75.45, H 5.70, N 8.80; found: C 75.68, H 5.75, N 8.69.

When the heating period was extended to 45 min, no oxazoline **9** was detected (tlc) in the product.

*(1,3|4,6)-4,6-Dibenzamido-1,3-cyclohexanedithiol Dibenzoate (**10**a)*

A mixture of 3.50 g (11.0 mmol) of bisoxazoline **9**, 7.90 g (57 mmol) of thiobenzoic acid, 50 mg of anhydrous *p*-toluenesulfonic acid, and 3.5 ml of dry DMF was heated in an oil bath at 115°C under nitrogen with stirring. The reaction mixture, upon heating, became a clear solution and then solidified. At this point, stirring was discontinued and heating was continued for 2 h. After cooling to room temperature, ether (60 ml) was added and the mixture was stirred to break the lumps. The fine suspension was filtered off, washed with ether, and dried to give 4.81 g of **10***a*, mp 300–310°C. The crude product was dissolved in DMF (30 ml), the solution diluted with chloroform (60 ml) and allowed to crystallize at room temperature. The crystalline product was collected by filtration, washed with ethanol (15 ml) and ether (30 ml) and dried to give 4.14 g (63%) of **10***a*, mp 308–310°C; ir (Nujol): 3250, 1670, 1660, 1640, 1630, 1560, 1540 cm^{-1}. *Anal.* calcd. for $C_{34}H_{30}N_2O_4S_2$: C 68.66, H 5.08, N 4.71, S 10.78; found: C 68.33, H 5.11, N 4.67, S 11.02.

*(1,3|4,6)-4,6-Dibenzamido-1,3-cyclohexanedithiol (**10**b)*

A suspension of 7.90 g (13.3 mmol) of **10***a* in 2 *N* sodium hydroxide in 80% ethanol (70 ml) was heated under reflux under nitrogen with stirring until it became a clear solution (5 min). Heating was then discontinued and the reaction mixture was stirred at room temperature for 1.5 h. The reaction mixture was diluted with water (140 ml) and the clear solution was neutralized with carbon dioxide. The crystalline precipitate was collected by filtration, washed with water, and dried to give 4.8 g (93.5%) of **10***b*, mp 289–290°C; ir (Nujol): 3300 (NH), 1640, and 1550 cm^{-1}. *Anal.* calcd. for $C_{20}H_{22}N_2O_2S_2$: C 62.14, H 5.74, N 7.25, S 16.59; found: C 62.21, H 5.68, N 7.23, S 16.38.

*(1,3|4,6)-4,6-Diamino-1,3-cyclohexanedithiol (**1**) Dihydrochloride*

Compound **10***b* (4.5 g, 11.6 mmol) was hydrolyzed with a 1:1 mixture of glacial acetic acid – concentrated hydrochloric acid (170 ml), as in the procedure given for the hydrolysis of **7***b*, to yield 2.90 g of crystalline product. Thin-layer chromatography with H_2O–NH_4OH–MeOH–$CHCl_3$ (1:1:4:1) sprayed with ninhydrin, showed one major spot of R_f 0.64 (compound **1**) and a minor of R_f 0.52. The crude product was stirred with boiling ethanol (25 ml), the mixture cooled to room temperature, and the insoluble dihydrochloride of **1** was collected by filtration (2.68 g, 92%), mp 305–307°C (dec.); ^{1}Hmr (D_2O) δ: 3.32 (d of t, 2H, N—C—H, J_1 = 11.0, J_2 = 3.8 Hz), 2.88 (d of t, 2H, S—C—H, J_1 = 11.0, J_2 = 3.8 Hz), 2.90–2.46 (m, 2H, H_e of CH_2), 2.11–1.50 (m, 2H, H_a of CH_2). *Anal.* calcd. for $C_6H_{14}N_2S_2 \cdot 2HCl$: C 28.68, H 6.42, N 11.15, S 25.52; found: C 28.60, H 6.61, N 10.95, S 25.47.

Oxazoline ***12***

To a suspension of 14.2 g (40 mmol) of **8***b* in 80 ml dry DMF, was added 30 ml of triethyl orthoacetate and 10 ml of boron trifluoride etherate and the mixture, protected from moisture, was stirred at room temperature for 24 h. (After about 1 h, compound **8***b* had dissolved.) On tlc with ether–ethanol (10:1) the solution showed a major spot of R_f 0.55 (**12**). The reaction mixture was poured into a cold solution of 8% sodium bicarbonate (500 ml) and the precipitate was collected and washed with water (3 × 100 ml). After drying, the crystalline product was dissolved in chloroform (200 ml), filtered to remove some insoluble matter, and the filtrate evaporated to dryness. The solid residue was treated with a 1:1 ether – petroleum ether solution (60 ml) and filtered to give 12.1 g, mp 186–189°C. Recrystallization from ethanol (200 ml) gave 10.2 g of **12**, mp 189–190°C. A further 1.1 g of **12** was recovered from the mother liquor after evaporation and recrystallization from ethanol (30 ml). The two crops were combined to a total of 11.3 g (75%); ir (Nujol): 3350, 1740, 1660, 1530 cm^{-1}. *Anal.* calcd. for $C_{22}H_{22}N_2O_4$: C 69.83, H 5.85, N 7.40; found: C 69.80, H 5.86, N 7.34.

*(d,l)-(1,3|4,6)-3-Acetoxy-4,6-dibenzamidocyclohexanethiol Benzoate (**13**a)*

The procedure described above for the preparation of **10***a* was used. Thus, a mixture of 6.4 g (17 mmol) of **12**, 7.20 g (52 mmol) of thiobenzoic acid, 5.0 ml of dry DMF, and 100 mg of anhydrous *p*-toluenesulfonic acid was heated at 115°C for 1.5 h. Work-up as in **10***a* gave 7.93 g of crude **13***a*, mp 268–276°C. Thin-layer chromatography with 5% EtOH in ether showed, under uv, one major spot of R_f 0.34 (**13***a*) and a minor of R_f 0.60. Recrystallization from DMF (24 ml) – ethyl acetate (50 ml) gave 6.9 g (79%) of **13***a*, mp 276.5–277.5°C; ir (Nujol): 3300, 1735, 1660, 1640, and 1540 cm^{-1}. *Anal.* calcd. for $C_{29}H_{28}N_2O_5S$: C 67.42, H 5.46, N 5.42, S 6.20; found: C 67.29, H 5.48, N 5.35, S 5.97.

The yield of **13***a* was reduced (45–50%) when the reaction was carried out without DMF.

*(d,l)-(1,3|4,6)-4,6-Dibenzamido-3-hydroxycyclohexanethiol (**13**b)*

A suspension of 2.07 g (4.0 mmol) of **13***a* in 20 ml 1 *N* sodium hydroxide (80% ethanol–water) was stirred at room temperature under nitrogen for 1.5 h. The solution was neutralized with carbon dioxide and the product isolated as in the synthesis of **10***b* above to give 1.40 g (95%) of **13***b*, mp 289–292°C (dec.). Thin-layer chromatography (10% ethanol–ether) showed (uv or $HClO_4$) one spot of R_f 0.50; ir (Nujol): 3300, 1640, 1540 cm^{-1}. *Anal.* calcd. for $C_{20}H_{22}N_2O_3S$: C 64.83, H 5.98, N 7.56, S 8.65; found: C 64.68, H 5.86, N 7.45, S 8.45.

*(d,l)-(1,3|4,6)-4,6-Dibenzamido-3-hydroxycyclohexanethiol Benzoate (**13**c)*

A suspension of 2.0 g (3.9 mmol) of **13***a* in 33 ml glacial acetic acid and 8 ml concentrated hydrochloric acid was heated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

under reflux under nitrogen. When all **13***a* had dissolved, the solution was diluted with 33 ml of water and refluxed for 15 min. After cooling to room temperature, the crystalline precipitate was collected, washed with water, and dried to give 1.37 g (75%) of **13***c*, mp 254–257°C. Thin-layer chromatography (20% ethanol–ether) showed, under uv, one major spot of R_f 0.38 and a trace of another compound of R_f 0.73; ir (Nujol): 3400, 3300, 1665, 1640, 1540 cm^{-1}. *Anal.* calcd. for $C_{27}H_{26}N_2O_4S$: C 68.33, H 5.52, N 5.90, S 6.76; found: C 68.43, H 5.55, N 5.74, S 6.86.

*(d,l)-(1,3/4,6)-4,6-Diamino-3-hydroxycyclohexanethiol (**2**) Dihydrochloride*

A hot solution of 3.20 g (8.5 mmol) of **13***b* in 40 ml glacial acetic acid was diluted with an equal volume of concentrated hydrochloric acid and the solution was heated under reflux under nitrogen for 17 h. Work-up, as in the synthesis of **1** above, gave 2.02 g (100%) crude **2** dihydrochloride. Thin-layer chromatography with water – ammonium hydroxide – methanol – chloroform (1:1:4:1) sprayed with ninhydrin showed one major spot of R_f 0.54 (**2**) and a minor of R_f 0.35. Recrystallization from water (4 ml) – ethanol (28 ml) gave 1.33 g of **2** dihydrochloride, mp 341–345°C (dec.) (it turned brown at 265°C and started to decompose at 302°C); ^{1}Hmr (D_2O) δ: 3.78 (d of t, 1H, O—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 3.36 (d of t, 1H, N—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 3.28 (d of t, 1H, N—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 3.08 (d of t, 1H, S—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 2.76–2.38 (m, 2H, H_e of CH_2), 2.11–1.44 (m, 2H, H_a of CH_2). *Anal.* calcd. for $C_6H_{14}N_2O{\cdot}2HCl$: C 30.63, H 6.84, N 11.91, S 13.63; found: C 30.38, H 6.98, N 11.82, S 13.50.

*3-N-Benzoyl-1-N-ethoxycarbonyl-2,5-dideoxystreptamine (**15**)*

To a solution of 7.81 g (35.6 mmol) of **14** (8) ($[\alpha]_D^{25}$ −38.0) and 5.04 g (60 mmol) of sodium bicarbonate in 40 ml water, was added 40 ml acetone and 5 ml methanol and the mixture was cooled in an ice bath while stirring. A solution of 7.03 g (50 mmol) of benzoyl chloride in 15 ml dry acetone was added dropwise. After the addition (15 min), the reaction mixture was stirred at room temperature for 1.5 h and then evaporated *in vacuo*. The residue was treated with water (50 ml) and the solid product collected by filtration, washed with water (2 × 30 ml) and ether (50 ml), and dried first at room temperature, then at 100°C, to give 8.90 g of **15**, mp 254–256°C. The aqueous filtrate was extracted continuously with ethyl acetate to give 2.2 g of **15**, mp 254–256°C. The two crops were combined to a total of 11.1 g (96.5%). A sample was recrystallized from ethanol–ether (1:3), mp 240–245°C, solidified and remelted at 254–256°C; $[\alpha]_D^{25}$ −18.6 (*c* 0.8, EtOH); ir (Nujol): 3350, 1700, 1650, 1550 cm^{-1}. *Anal.* calcd. for $C_{16}H_{22}N_2O_5{\cdot}\frac{1}{2}H_2O$: C 57.99, H 6.99, N 8.45; found: C 57.66, H 6.90, N 8.19.

*Oxazoline **17**a*

To a solution of 37.1 g (112 mmol) of **15** in dry DMF, (110 ml) was added 50 ml triethyl orthoacetate and 15 ml boron trifluoride etherate and the solution, protected from moisture, was stirred at room temperature for 20 h. The mixture was then poured into a cold solution of 8% sodium bicarbonate (1 ℓ) and extracted with ether (4 × 350 ml). The ether solution was washed with water (2 × 250 ml), dried ($MgSO_4$), and evaporated to dryness to yield a syrup which crystallized on trituration with ether to give 31.2 g (78.5%) of **17***a*, mp 108–112°C. Thin-layer chromatography with 5% ethanol–ether showed, under uv, a major spot of R_f 0.54 (**17***a*) and a minor one of R_f 0.85. This material was used in the next experiment without further purification. A small sample was recrystallized from ethyl acetate-petroleum ether (1:3), mp 111–113°C; $[\alpha]_D^{25}$ −64.2 (*c* 1.0, EtOH); ir (Nujol): 3350, 1730, 1690, 1660, 1640, 1540 cm^{-1}. *Anal.* calcd. for $C_{18}H_{22}N_2O_5$: C 62.41, H 6.40, N 8.09; found: C 62.54, H 6.43, N 7.95.

*Oxazoline **17**b*

To a solution of 2.0 g (5.8 mmol) of **17***a* in 25 ml dry ethanol, was added 25 mg sodium hydride (a 55% suspension in oil from which the oil was removed by washing with benzene) and stirred at room temperature for 30 min. The solution was filtered to remove some insoluble matter, the filtrate was neutralized with carbon dioxide and evaporated to dryness. The residue was taken up in chloroform (30 ml) and the solution washed with water (2 × 30 ml), dried, and evaporated to yield 1.75 g (100%) **17***b*, mp 147–150°C. Recrystallization from benzene (6 ml) – petroleum ether (10 ml) gave 1.42 g, mp 149–150°C; tlc (5% ethanol–ether, uv) showed a single spot of R_f 0.55; $[\alpha]_D^{25}$ −98.6 (*c* 1.0, EtOH); ir (Nujol): 3300, 3200, 1700, 1645, 1610 cm^{-1}. *Anal.* calcd. for $C_{16}H_{20}N_2O_4$: C 63.14, H 6.62, N 9.20; found: C 63.39, H 6.81, N 8.47.

*(1S,2S,4R,5R)-5-Acetoxy-2-benzamido-4-ethoxycarbonylaminocyclohexanethiol Benzoate (**18**a)*

The procedure was the same as in the synthesis of **10***a* above except that no *p*-toluenesulfonic acid was added. Thus, a mixture of 31.0 g (89.5 mmol) of powdered **17***a*, 35.0 g (250 mmol) of thiobenzoic acid and 24 ml of dry DMF was heated in an oil bath at 115°C under nitrogen for 1.5 h. Work-up as in **10***a* gave 33.2 g (76.5%) of **18***a*, mp 240–247°C; $[\alpha]_D^{25}$ −9.7 (*c* 1.0, $CHCl_3$); ir (Nujol): 3350, 1730, 1700, 1665, 1585, 1540 cm^{-1}. *Anal.* calcd. for $C_{25}H_{28}N_2O_6S$: C 61.97, H 5.82, N 5.71, S 6.62; found: C 61.81, H 5.86, N 5.84, S 6.66.

*(1S,2S,4R,5R)-2-Benzamido-4-ethoxycarbonylamino-5-hydroxycyclohexanethiol (**18**b)*

A suspension of 32.8 g (68 mmol) of **18***a* in 330 ml of a 1 *N* solution of sodium hydroxide in 80% ethanol–water was stirred under nitrogen at room temperature for 1.5 h. Work-up as in the cases of **10***b* and **13***b* above gave 21.2 g (92%) of **18***b*, mp 260–265°C (dec.) (decomposition started at 252°C with an offensive odor). Thin-layer chromatography with 20% ethanol–ether showed one spot (R_f 0.38). This material was used in the next experiment. A sample was recrystallized from ethanol, mp 266–270°C (dec.); $[\alpha]_D^{25}$ +32.9 (*c* 1.0, pyridine); ir (Nujol): 3300, 1735, 1640, 1550 cm^{-1}. *Anal.* calcd. for $C_{16}H_{22}N_2O_4S$: C 56.78, H 6.55, N 8.82, S 9.47; found: C 56.50, H 6.35, N 8.14, S 9.24.

*(1S,2S,4R,5R)-2-Benzamido-4-ethoxycarbonylamino-5-hydroxycyclohexanethiol Benzoate (**18**c)*

This compound was prepared by the procedure given above for the synthesis of **10***a*. A mixture of 2.41 g (7.9 mmol) of **17***b*, 5.5 g (50 mmol) of thiobenzoic acid and 2.0 ml of DMF was heated at 115°C for 1.5 h and the product isolated as above to give 2.49 g (71%) of **18***c*, mp 225–230°C. Recrystallization from ethanol (85 ml) yielded 1.96 g, mp 230–232°C. Thin-layer chromatography with 5% ethanol–chloroform showed one spot of R_f 0.49; $[\alpha]_D^{25}$ +45.2 (*c* 1.0, DMF); ir (Nujol): 3400, 1700, 1660, 1640, 1540 cm^{-1}. *Anal.* calcd. for $C_{23}H_{26}N_2O_5S$: C 62.42, H 5.92, N 6.33, S 7.24; found: C 62.45, H 5.96, N 6.36, S 7.32.

*(1S,2S,4R,5R)-2,4-Diamino-5-hydroxycyclohexanethiol (**3**) Dihydrochloride*

Compound **18***b* (6.0 g, 17.8 mmol) was hydrolyzed with hydrochloric acid as in the procedure given for **2** to yield 3.64 g (87%) of **3** dihydrochloride, mp: decomposes above 290°C (turns black) with an offensive smell. Thin-layer chro-

matography (H_2O–NH_4OH–MeOH–$CHCl_3$, sprayed with ninhydrin) showed a single spot; $[\alpha]_D^{25}$ +2.8 (*c* 1.0, H_2O); ^{1}Hmr (D_2O) δ: 3.78 (d of t, 1H, O—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 3.36 (d of t, 1H, N—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 3.28 (d of t, 1H, N—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 3.08 (d of t, 1H, S—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 2.76–2.38 (m, 2H, H_e of CH_2), 2.11–1.44 (m, 2H, H_a of CH_2). *Anal.* calcd. for $C_6H_{14}N_2OS \cdot 2HCl$: C 30.64, H 6.86, N 11.91, S 13.63; found: C 30.33, H 6.92, N 11.61, S 13.25.

*1-N-Benzoyl-3-N-ethoxycarbonyl-2,5-dideoxystreptamine (**20**)*

Compound **19** (8) ($[\alpha]_D^{25}$ +37.3) was *N*-benzoylated by the procedure described above for the synthesis of **15** to give **20** (91%), mp 244°C, resolidified and melted at 254–256°C; $[\alpha]_D^{25}$ +17.6 (*c* 0.8, EtOH); ir (Nujol): 3350, 1700, 1650, 1550 cm^{-1}. *Anal.* calcd. for $C_{16}H_{22}N_2O_5$: C 59.61, H 6.88, N 8.69; found: C 59.65, H 7.01, N 8.70.

Oxazoline **22**a

Compound **20**, (6.0 g, 18.2 mmol) was reacted with triethyl orthoacetate (9 ml) and boron trifluoride etherate (2.0 ml) in dry DMF (19 ml), as described in the preparation of **17***a*, to give 5.5 g (88%) crude **22***a* as a solid. Thin-layer chromatography with 5% ethanol–ether showed one major spot of R_f 0.53 and a minor one of R_f 0.90. This material was used in the next reaction. The analytical sample was obtained after three recrystallizations from ethyl acetate (1.5 ml/g) – petroleum ether (6 ml/g), mp 111–113°C; one spot on tlc; $[\alpha]_D^{25}$ +63.7 (*c* 1.0, EtOH); ir (Nujol): 3350, 1745, 1700, 1655, 1550 cm^{-1}. *Anal.* calcd. for $C_{18}H_{22}N_2O_5$: C 62.41, H 6.40, N 8.09; found: C 62.35, H 6.43, N 8.09.

Oxazoline **22**b

Compound **22***a* (5.4 g, 15.6 mmol) was treated with a catalytic amount of sodium ethoxide in ethanol, following the procedure described in the preparation of **17***b*, to give 4.5 g (95%) of **22***b*, mp 145–150°C; one spot on tlc (5% methanol–ether) of R_f 0.61. Recrystallization from benzene (3.5 ml/g) – petroleum ether (4.5 ml/g) gave the analytical sample, mp 148–150°C; $[\alpha]_D^{25}$ +100.6 (*c* 1.0, EtOH); ir ($CHCl_3$): 3450, 1735, 1640, 1550 cm^{-1}. *Anal.* calcd. for $C_{16}H_{20}N_2O_4$: C 63.14, H 6.62, N 9.20; found: C 63.39, H 6.81, N 8.47.

*(1R,2R,4S,5S)-2-Benzamido-4-ethoxycarbonylamino-5-hydroxycyclohexanethiol Benzoate (**23**c)*

This compound was prepared by the procedure described above for the synthesis of **18***c*. A mixture of 3.7 g (12.2 mmol) of **22***b*, 8.0 g of thiobenzoic acid, and 2.5 ml of DMF was heated at 115°C for 1.5 h and the product isolated as above to give 3.4 g (63%) of **23***c*, mp 225–231°C. Recrystallization from ethanol yielded 3.0 g, mp 230–231°C; $[\alpha]_D^{25}$ −46.3 (*c* 1.0, DMF); ir (Nujol): 3300, 1700, 1660, 1640, 1540 cm^{-1}. *Anal.* calcd. for $C_{23}H_{26}N_2O_5S$: C 62.42, H 5.92, N 6.33, S 7.24; found: C 62.49, H 5.96, N 6.36, S 7.37.

*(1R,2R,4S,5S)-2-Benzamido-4-ethoxycarbonylamino-5-hydroxycyclohexanethiol (**23**b)*

A mixture of 300 mg of **23***c* and 3.3 ml of 1 *N* sodium hydroxide in 80% ethanol was stirred at room temperature under nitrogen for 1 h. It was then diluted with water (7 ml), neutralized with carbon dioxide (gas), and the crystalline precipitate was collected by filtration and washed with water (3 × 5 ml). Drying at 100°C under vacuum, gave 200 mg of **23***b*, mp 268–272°C; $[\alpha]_D^{25}$ −33.0 (*c* 1.0, pyridine); ir (Nujol): 3250, 3310, 1690, 1640, 1540 cm^{-1}.

*(1R,2R,4S,5S)-2,4-Diamino-5-hydroxycyclohexanethiol (**4**) Dihydrochloride*

Compound **23***b* was hydrolyzed with a hydrochloric acid – acetic acid mixture as in the procedure given for **2** to yield the dihydrochloride of **4**, mp: decomposes above 290°C with an offensive smell; $[\alpha]_D^{25}$ −2.8; ^{1}Hmr (D_2O) δ: 3.78 (d of t, 1H, O—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 3.36 (d of t, 1H, N—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 3.28 (d of t, 1H, N—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 3.08 (d of t, 1H, S—C—H, J_1 = 10.4, J_2 = 4.5 Hz), 2.76–2.38 (m, 2H, H_e of CH_2), 2.11–1.44 (m, 2H, H_a of CH_2).

Field desorption mass spectrometry of carboxylate salts: characteristic spectra and effects of added complexing agents[1]

GORDON WALTER WOOD,[2] EMILY JANE OLDENBURG, AND PUI-YAN LAU
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received May 12, 1978

GORDON WALTER WOOD, EMILY JANE OLDENBURG, and PUI-YAN LAU. Can. J. Chem. **56**, 2750 (1978).

Field desorption mass spectra are reported for a series of sodium carboxylates. Above 20 mA the major ions in the spectra belong to the series $[x\mathrm{Na}^+ + (x - 1)\mathrm{RCOO}^-]^+$ with values of x normally extending throughout the measurable mass range. Desorption characteristics and spectral composition have been shown to be strongly modified by the addition of fructose and other polyhydroxy compounds. Thus, the sodium acetate spectrum is more intense and contains higher aggregates when 0.1–0.2 mol of fructose is added. With further additions the ionized free acid, $\mathrm{AcOH}^{+}\cdot$, becomes the base peak in a low intensity spectrum recorded at 17–18 mA. The main ion from fructose is the sodium complex which does not exceed 20% of the base peak. Added fructose also has a beneficial effect on sodium 12-hydroxystearate but the improvement is less dramatic and there are some complications in the interpretation. A sample of technical lithium stearate contains the usual complexes up to $[\mathrm{Li}_4(\mathrm{RCOO})_3]^+$ and the presence of important amounts of palmitate gives rise to all possible combinations of the two carboxylate anions in these complexes. Smaller amounts of $\mathrm{Li}_2\mathrm{Na}$, $\mathrm{Li}_3\mathrm{Na}$, and $\mathrm{Li}_3\mathrm{K}$ complexed with the appropriate number of anions give evidence of alkali metal impurity.

GORDON WALTER WOOD, EMILY JANE OLDENBURG et PUI-YAN LAU. Can. J. Chem. **56**, 2750 (1978).

On rapporte les spectres de masse par désorption de champs d'une série de carboxylates de sodium. Au-dessus de 20 mA, les ions prépondérants dans le spectre de masse proviennent des séries $[(x\mathrm{Na}^+ + (x - 1)\mathrm{RCOO}^-)]^+$ dans lesquelles les valeurs de x s'étendent normalement à travers toutes les masses pouvant être mesurées. On a montré que les caractéristiques de désorption et les compositions spectrales sont fortement modifiées par l'addition de fructose et d'autres composés polyhydroxylés. Ainsi le spectre de l'acétate de sodium est plus intense et contient des agrégats supérieurs si l'on additionne 0.1–0.2 mol de fructose. Si l'on effectue des additions supplémentaires, l'acide libre ionisée $\mathrm{AcOH}^{+}\cdot$ devient le pic prépondérant dans le spectre à basse intensité enregistré à 17–18 mA. L'ion principal du fructose est un complexe de sodium qui ne représente pas plus de 20% du pic prépondérant. L'addition de fructose conduit aussi à un effet bénifique sur l'hydroxy-12 stéarate de sodium mais l'amélioration est moins dramatique et amène quelques complications dans l'interprétation. Un échantillon de stéarate de lithium de qualité technique contient les complexes habituels allant jusqu'à $[\mathrm{Li}_4(\mathrm{RCOO})_3]^+$ et la présence de quantités importantes de palmitate donne lieu à toutes les combinaisons possibles des deux anions carboxylate dans ces complexes. Des quantités plus faibles de $\mathrm{La}_2\mathrm{Na}$, $\mathrm{Li}_2\mathrm{Na}$ et $\mathrm{Li}_3\mathrm{K}$ complexés avec un nombre approprié d'anions indiquent que les métaux alcalins sont impurs.

[Traduit par le journal]

Introduction

Mixtures of long chain carboxylic acids and their salts are common commercial materials whose properties depend critically on their composition. In a previous paper (1) we have reported on the application of field desorption mass spectrometry (fdms) to analysis of mixtures and impure samples of such carboxylic acids. We now report fdms results on a variety of carboxylate salts, mainly sodium. Although fdms is particularly suited for the handling of non-volatile samples (2–5), early work on sodium acetate (6) and other alkali metal salts (7) showed that collection of useful data from these compounds presented a considerable challenge. For example, the fd spectrum originally reported for sodium acetate (6) was obtained at very high temperature (30–32 mA) and contained few ions of structural significance. We have shown that some improvement in the characteristics of this compound may be obtained by complexation of the sodium ion with a cryptand (8). The present work examines the behavior of a variety of carboxylate salts and the effect on fdms of added complexing agents, especially fructose.

Experimental

The instrumental parameters and methods of sample introduction have been described previously (1).

Fructose, inositol, and other polyhydroxy compounds were

Na 12-OHstearate		$CHCl_3/CH_3OH$	20.5	99	100	1	

[a]Intensities are expressed as % of base peak.
[b]Anode heating current (mA).
[c]For this low formula weight salt, the high-mass cutoff is arbitrary. Thus the ion with $x = 5$ amounts to as much as 5% in some scans and traces of $x = 6$, $x = 7$ generally are present.
[d]Evidence that this salt is impure is found in ions *m/e* 301 (up to 18%) and traces of *m/e* 357, 385. These peaks are assigned as the $x = 2$ complexes of C_{16}, C_{20}, and C_{22} salts, respectively.

purchased from Aldrich Chemical. Cryptands (Krypto fixes) were purchased from EM Laboratories, Elmsford, NY. Carboxylate salts were kindly donated by Imperial Oil Enterprises Ltd., Sarnia.

All solvents and other reagents were ACS grade and were used without further purification.

Results and Discussion

In addition to some preliminary experiments with sodium salts which ultimately led to the work reported in this paper, a few measurements were made on calcium propionate and calcium hexanoate. Although both of these salts gave ions which appeared to be the usual net monopositive complexes, i.e. *m/e* 299 for the propionate corresponding to $3CH_3CH_2COO^- + 2Ca^{2+}$, a number of complications led us to postpone further work on salts of divalent metals. Our sample of calcium propionate was significantly contaminated with both sodium and potassium ions. Further, this material gave fd mass spectra containing ions of unknown composition at all anode temperatures tried (23.5, 32, 44 mA). At the highest temperature the only significant ions corresponded to Ca^+ (*m/e* 40, 100; 42, 1.4; 43, 1.1; 44, 3.1), which raises questions as to its origin and possible presence in complex ions at lower temperatures.

Carboxylates related to the univalent, monoisotopic sodium ion are considerably simpler, as the examples in Table 1 show. The major ions for each of the five salts all belong to the series $[xNa^+ + (x-1)RCOO^-]^+$. Since the relative intensity of the various complexes is very sensitive to temperature, duplication of the exact values shown is difficult. Another factor which influences the spectrum is the solvent used. For example, deposition of sodium stearate from a water suspension gives Na^+ as base peak. In general the degree of complexation appears to be a function of solvent, with methanol favoring formation of aggregates more than water.

We have tried a number of strategies to improve on the high desorption temperatures, low ion intensities, and short-time fluctuations of ion current characteristic of sodium salts under fdms conditions. Following our earlier approach using ligands for sodium ion complexation (8), we determined the fd spectrum of an equimolar mixture of sodium 12-hydroxystearate and [2.2.1]-cryptand. As expected desorption occurred smoothly and at lower temperature (12 mA). The base peak at *m/e* 355 corresponds to the cryptate Na^+ + ligand. Ions at *m/e* 654 (cryptate + 12-OHstearate) and *m/e* 610 (decarboxylation product of *m/e* 654) were about 2–3% relative intensity and thus not easily reproduced. Combination of the same cryptand with sodium stearate yielded either empty cryptand, cryptate, or free sodium ion as base peak, depending on the temperature. No peaks of significance contained the carboxylate portion of the salt. A similar experiment with the [2.2.1]-cryptand and sodium acetate in chloroform solution gave some evidence of cryptate formation, but the main effect noted was a lower desorption temperature. We therefore turned to other potential complexing agents for the sodium ion, with the aim of finding a ligand less easily desorbed so that ions related to the carboxylate portion of the salt would be of greater relative intensity.

Of several sugars and related compounds evaluated, fructose appeared most promising. Table 2 presents the results obtained for a series of sodium acetate samples to which up to equimolar amounts of fructose have been added. By comparison with the first column for pure sodium acetate, it can be seen that 0.1:1 molar ratio of fructose-to-salt increases the overall intensity almost threefold and, more importantly, increases the intensity of the structurally significant $[Na_2OAc]^+$ on a relative basis. At 0.2:1 molar ratio of fructose-to-salt, the next member of this series of complexes, $[Na_3OAc_2]^+$, becomes the base peak and the total intensity again increases almost threefold. Notice should be taken at this stage that the first evidence of fructose in the sample appears as *m/e* 203 (Na^+ + fructose) with intensity of 1%. The only other fructose-related peaks ob-

[a]Sample was loaded from aqueous solution. Intensities are expressed as % of base peak. All *m/e* values are reported where at least one mixture consistently gave a peak of 1% or more. At fructose levels below 0.5:1, minor peaks were also found for Na_6OAc_5, Na_7OAc_6, and Na_8OAc_7. Other minor peaks appeared to derive from sodium formate and propionate (see text).
[b]Anode heating current (mA).
[c]Total ion beam intensity in an arbitrary unit roughly equivalent to 1000 ions.

served correspond to dehydration (*m/e* 162, 144, etc.) and are very weak. With 0.5:1 or more molar ratio of fructose-to-salt, there is a dramatic change in the result. Spectra are now obtained at much lower temperatures and with much lower intensity. The base peak at molar ratios of fructose-to-salt at 0:5:1 and 1:1 is *m/e* 60, $[AcOH]^+\cdot$! The complexed fructose ion *m/e* 203 is relatively important and is found as base peak for 1:1 mixture below 13 mA, but the usual complexes of sodium and acetate ions have almost disappeared. In summary, the addition of 0.1–0.5 mole of fructose per mole of sodium acetate has been shown to significantly increase the relative amount of structurally significant ions, largely at the expense of Na^+, and with virtually no interference from the fructose. The formation of the conjugate acid of the original anion at 0.5:1 molar ratio of fructose-to-salt and above is interesting, and raises the possibility that with a less volatile compound this process would yield more useful ion intensities. With this point in mind we have repeated the series of fructose additions with sodium stearate. The free acid (*m/e* 284) is the base peak in some scans with 0.5:1 or 1:1 molar ratio of fructose-to-salt, and there is evidence for the formation of $Na_x(RCOO)_{x-1}$ complexes at least as far as the mass-scale cut-off ($x = 3$). However, apparent decarboxylation and oligomer formation complicates the results.

In the sodium acetate/fructose mixtures we observed minor ions at *m/e* 91, 119, 173, 201, 255, 337 which we assign to two series as follows:

$$[Na_2OOCH]^+ + x(NaOAc) = 91, 173, 255, 337 \quad \text{for } x = 0, 1, 2, 3$$

$$[Na_2OOCCH_2CH_3]^+ + x(NaOAc) = 119, 201 \quad \text{for } x = 0, 1$$

Intensities of these ions are quite variable, and rarely greater than 1% of base peak. However, the presence of *m/e* 74 in some scans of the 0.5:1 mixture at moderate ahc values suggests that these ions may reflect sodium formate and sodium propionate in the original sample. An alternate interpretation which considers the above complexes to be "products of thermally field-induced decomposition reactions" (2) appears to us unlikely in view of the apparent lack of field or temperature dependence. Experiments designed to resolve the discrepancies among previous reports on sodium acetate behavior (2, 6, 7) and to clarify the structural assignments are in progress.

Addition of varying amounts of fructose to a series of 12-OH stearate samples gave the results in Table 3. Although in some respects the results here are less dramatic than for sodium acetate, the presence of structurally important ions from 0.2–1.0 molar ratio of fructose-to-salt must be viewed in the context of the result for the original sample. The base peak at *m/e* 345 and the ion at *m/e* 667 belong to the usual prominent series of complex ions, $[xNa^+ + (x - 1)RCOO^-]^+$. Apparent loss of 2H from the hydroxyanions of *m/e* 667 gives *m/e* 665 and the ions at *m/e* 183, 184 present complications for identification. We suggest that the latter may represent doubly charged ions of mass 368, 366 which would then correspond to $[3Na^+ + RCOO^-]^{2+}$ and a similar ion with two less H atoms. The mode of loss of these H atoms is unknown, but ions at *m/e* 345, 343 and 506, 505 appear to be other pairs where this process is occurring, the former from singly charged species and the latter from $[5Na^+ + 3RCOO^-]^{2+}$. Whereas the formation of doubly charged ions may be associated with coordination of an extra sodium ion at the hydroxyl function, the as yet unexplained

presence of doubly charged ions in technical grade samples of the free acid (1) where no sodium is involved provides the possibility of another mechanism. Another result of this experiment is the identification of minor ions *m/e* 329, 651, apparently from the presence of sodium stearate impurity in the samples.

An attempt to compare cation effects on stearate spectra was largely frustrated by poor desorption characteristics of calcium and ammonium stearates. Both gave very weak spectra, the former not readily interpreted and the latter showing only *m/e* 284, 283, apparently $M^{+\cdot}$ and $[M - 1]^+$ for stearic acid. Clarification of these results and those for lithium stearate will require scrupulously pure samples. However, the technical lithium salt gave a number of assignable ions as shown in Scheme 1. Note that in addition to sodium and potassium ion impurities, there is sufficient apparent C_{16} homologue that the base peak in each of the three most intense scans contains the species $C_{15}H_{31}COO$. It is also striking that for both the prominent Li_3 and Li_4 species all possible combinations of the two carboxylates are found.

The behavior of mixtures of sodium acetate with inositol (the common *myo* isomer) was quite different from that found with the fructose mixtures. Considering that inositol appears to bind to Na^+ at least as strongly as most polyhydroxy compounds and that fructose is not known to form particularly stable complexes (9, 10), our results may suggest that the effects we are observing should properly be considered as matrix effects rather than the direct result of complexation. Further study of this point is in progress. Our inositol sample gave extremely weak spectra with the maximum intensity of M at 14–16 mA. Later scans showed dehydration peaks and, above 25 mA, M + Na (*m/e* 203). Addition of 0.2, 0.5, and 1.0 mol of inositol to 1.0 mol of sodium acetate gave spectra of intermediate intensity in

which the acetic acid ion was prominent. For example, the 0.2:1 mixture showed *m/e* 60 as base peak up to 20 mA. At 19 mA and a total intensity of 0.8 units (see Table 2, footnote *c*) the spectrum consisted of: *m/e* (%) 60 (100); 203 (8). At higher temperatures *m/e* 23 quickly became the base peak, but the usual complex ions were not very important. Thus, at 26 mA *m/e* 23 (100); 105 (6); 187 (2); 269 (0.4). With 0.5:1 mixtures *m/e* 60 was marginally stronger: 16 mA, intensity 1.1 units gave *m/e* 60 (100); 23 (62); 203 (41). The acetic acid ion was also more persistent in this mixture, so that at 20 mA where *m/e* 23 was base peak, *m/e* 60 (10) still accounted for 3.0 units. Increasing the inositol level to 1:1 generally gave more *m/e* 60 ions at lower ahc values: at 14.5 mA, *m/e* 60 (100, 0.8 units); 203 (5), 126 (2). In the next scan, 16 mA, *m/e* 23 appeared and the apparent dehydration product of inositol, *m/e* 126, increased to 13%. In summary, inositol is more effective than fructose in generating the conjugate acid, *m/e* 60, from sodium acetate but much less effective in promoting complexation reactions.

The considerable complications in obtaining useful spectra from sodium carboxylates have somewhat dimmed our hopes of analyzing mixtures containing these salts in combination with free acids. However, one brief study was done on a technical mixture of stearic acid and its sodium salt. At 9 mA the two most important ions are *m/e* 284, 285 ($M^{+\cdot}$ and $M + 1^+$ for the acid). At 27 mA *m/e* 23, 329, and 635 no doubt represent $[Na_x(C_{17}H_{35}COO)_{x-1}]^+$ with $x = 1$, 2, and 3. However, the presence of equally intense ions *m/e* 357, 691 strongly suggests the presence of a C_{20} homologue and an ion *m/e* 522 at intermediate temperatures may even represent a stearyl stearate ester. These uncertainties could no doubt be resolved by preparation of authentic mixtures for comparison with this technical product. However, one is left with a broad range of desorption temperatures, all of which would have to be monitored and the appropriate ion intensities summed in order to arrive at an estimate of the composition of the original mixture. The necessary techniques should not be too different from those employed for quantitation of a mixture introduced via the direct probe in electron impact mass spectrometry.

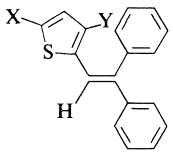
Introduction

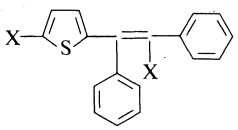
In connection with our previous work on reactivity and stereochemistry of stilbene systems containing heterocyclic rings (1–10), we here report the results of an investigation on the nitration and bromination of 1,1-diphenyl-2-(2-thienyl)ethylene (**1***a*).

An isomeric product of **1***a*, whose geometrical configuration has not been determined (**2***a*), has been reported by Nam *et al.* (ref. 11, and references cited therein), the bromination of which, in contrast with these results, leads to dibromo derivative **2***b*.



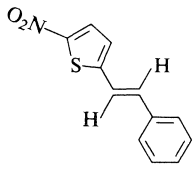
1

a X = Y = H
b X = NO_2, Y = H
c X = Y = Br



2

a X = H
b X = Br



3

Results and Discussion

1,1-Diphenyl-2-(2-thienyl)ethylene (**1***a*) was prepared by a Wittig reaction from benzophenone and 2-thienylmethyltriphenyl-phosphonium chloride (see Experimental).

The nitration of **1***a* with nitric acid (slight molar excess) in acetic anhydride at 0°C gave a mono-nitration product (elemental analysis). The bromination with bromine (1 mol) in acetic acid afforded a mixture of products not yet identified; bromination with excess bromine at 0–5°C gave, in good yields, a dibromo compound as indicated by elemental analysis.

Ultraviolet Spectra

The electronic spectral data (λ_{max}, log ε) in 95% ethanol of the compounds investigated are reported in the Depository of Unpublished Data.[1]

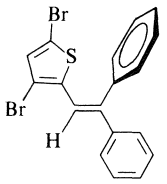
The conjugation band of 1,1-diphenyl-2-(2-thienyl)ethylene (**1***a*) is located at higher wavelengths in comparison with that of triphenylethylene (12) owing to the presence of the heterocyclic ring ($\Delta\lambda$ = 23 nm), as already observed in the analogous diarylethylenes (2). The substitution in the thiophene ring shifts the absorption to longer wavelengths.

The strict similarity between absorption data of the nitration compound and *trans*-5-nitro-2-styryl-thiophene (**3**) is consistent with the proposed structure **1***b* for the former, as subsequently confirmed by ^1H nmr spectrum.

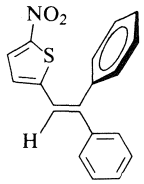
^1H Nuclear Magnetic Resonance Spectra

The analytical combustion data of the bromination product reveal the presence of two bromine atoms in the molecule (see Experimental). The ^1H nmr spectrum is available from the Depository of Unpublished Data.[1] The ratio between the integrated intensities of the sharp singlet at δ 6.83 and the complex signal in the range δ 7.1–7.5, is 1:11. ^1H nmr features are in agreement only with structure **1***c* where the thiophene nucleus for steric reasons is biased in the *s-trans*

[1]Photocopies are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.



1*c*
s-trans



1*b*
s-trans

conformation. The assignment of the signal at δ 6.83 is still ambiguous between H_4 and the olefinic proton. All structures without bromine atoms on the thiophene nucleus can be excluded because of the absence in the ^1H nmr spectrum of ABX or AMX pattern of three heterocyclic protons. The absence of the characteristic AB or AM pattern of the heterocyclic protons on the ^1H nmr spectrum excludes the structure with only one bromine atom on the thiophene. Both bromine atoms are then situated on the heterocyclic ring. If the 3-position were free the signal at δ 6.83, which should be attributed to H_3 or H_{o1}, should resonate as doublet because of long-range coupling between H_3 and H_{o1} (9).

Likewise if the 5-position were free we should notice on the same signal a characteristic stereospecific W_5 plan coupling between H_5 and H_{o1} according to the *trans*-coplanar disposition of the H_{o1} and H_5 in the *s-trans* rotamer (9, 10). Consequently the sharp singlet at δ 6.83 can be interpreted only with structure **1***c*.

The analysis of the ^1H nmr spectrum of the mononitration compound is in agreement with structure **1***b*.[1] In fact the spectrum shows the pattern AMX respectively of the protons H_4, H_{o1}, and H_3, with the characteristic value (13) of the thiophene coupling constants between H_4 and H_3. The failure of the stereospecific W_5 plan coupling between H_4 and H_{o1} ($J^5_{H_4-H_{o1}} = 0.0$ Hz) (9) suggests that the *s-trans* conformation of the heterocyclic nucleus is preferred.

Electric Dipole Moments

Theoretical dipole moments for the three possible isomers of the bromination compound bearing Br atoms in 4,5-, 3,4-, and 3,5-position of the thiophene ring were calculated by means of the chemical vector addition method. The component moments used were the measured moment of **1***a* and the $\overrightarrow{C-Br}$ group moment assumed as 1.57 D (14).

By considering the very small difference between the experimental moments of **1***a* and thiophene (0.53 D) (14) moieties, we assumed the direction of action of the resultant moment of **1***a* to be the same as in thiophene, i.e., from the ring to the hetero atom. The geometry of the thiophene fragment was deduced from microwave spectroscopic data (15).

The occurrence of the possible structures 4,5- and 3,4-Br-substituted was thus ruled out on the basis of the large difference observed between the calculated theoretical moments for these structural isomers (2.42 and 2.15 D, respectively) and the measured value of 1.11 D.

Conversely, the calculated dipole moment for the remaining isomer bearing the Br atoms in 3,5-positions (0.85 D) agrees with the experimental value within the limit of accuracy of the vector addition method (±0.2–0.3 D). This dipole moment evidence thus allows us to decide unambiguously in favour of the 3,5-isomer as reaction product (**1***c*), consistent with above discussed ^1H nmr spectroscopic data.

Experimental

Melting points were taken on a Büchi melting point apparatus and are uncorrected. Ultraviolet absorption spectra were determined on a Hitachi Perkin-Elmer Model EPS-3T recording spectrometer in 95% ethanol solutions (1×10^{-5} mol). Proton magnetic resonance spectra were recorded with a Varian A-60D instrument in deuteriochloroform, using tetramethylsilane as internal standard. Electric dipole moments of **1***a* and of its brominated compound **1***c* were measured in benzene solutions at 25°C (±0.01°C) using apparatus and techniques described earlier in detail (16). The Halverstadt–Kumler method (17) was employed for calculating the total polarization ($P_{2\infty}$). The sum of the electronic and atomic polarizations ($P_E + P_A$) required for the calculation was assumed to be equal to the measured molar refraction (R_D, sodium D line). The estimated error in the measured dipole moment values (μ, Debye units) is ±0.03 D. The experimental results are available from the Depository of Unpublished Data.[1]

*1,1-Diphenyl-2-(2-thienyl)ethylene (***1***a)*

To a solution of 12 g of 2-thienylmethyltriphenylphosphonium chloride (18) (from 2-chloromethylthiophene (19) and triphenylphosphine in chloroform) and 3.64 g of benzophenone in 30 ml of ethanol, under nitrogen, was added portionwise with stirring a solution of EtONa (0.7 g of sodium in 25 ml of ethanol). The reaction mixture was refluxed for 6 h and then poured into water (50 ml). After cooling, the solid precipitate was filtered off and recrystallized from aqueous acetic acid (68% yield), mp 59°C. *Anal.* calcd. for $C_{18}H_{14}S$: C 82.40, H 5.38; found: C 82.50, H 5.22.

*Nitration of 1,1-Diphenyl-2-(2-thienyl)ethylene (***1***a)*

A solution of 1.3 g of olefin in 15 ml of acetic anhydride was nitrated at 0–5°C with nitric acid (1 g) in acetic acid (5 ml). The precipitate obtained was filtered off and washed with water; crystallization from ethanol gave a yellow product of mononitration (**1***b*) (65% yield), mp 153°C. *Anal.* calcd. for $C_{18}H_{13}NO_2S$: C 70.34, H 4.26, N 4.56; found: C 70.31, H 4.30, N 4.25.

*Bromination of 1,1-Diphenyl-2-(2-thienyl)ethylene (***1***a)*

A solution of bromine (1.6 g) in acetic acid (10 ml) was added to a cooled solution (10°C) of **1***a* (1.3 g) in the same solvent (20 ml) and the mixture kept for 24 h at room tem-

Stereochemistry and mechanisms of the reactions of acylsilanes with alkoxides

ADRIAN G. BROOK, TEUNIS J. D. VANDERSAR, AND WILLIAM LIMBURG
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 15, 1978

ADRIAN G. BROOK, TEUNIS J. D. VANDERSAR, and WILLIAM LIMBURG. Can. J. Chem. **56**, 2758 (1978).

Using chiral NpPhMeSiCOMe it is shown that the 'cleavage' pathway for the reaction of alkoxides with acylsilanes involves nucleophilic attack at the carbonyl group, followed by subsequent rearrangements which result in optically active NpPhMeSiOR and aldehyde. The 'rearrangement' pathway involves stereospecific migrations of the naphthyl and phenyl groups from silicon to different faces of the adjacent carbonyl group, resulting in chiral naphthylethanol and phenylethanol of opposite absolute configurations.

ADRIAN G. BROOK, TEUNIS J. D. VANDERSAR et WILLIAM LIMBURG. Can. J. Chem. **56**, 2758 (1978).

Faisant appel au NpPhMeSiCOMe chiral, on a montré que les réactions des alcoolates avec les acylsilanes qui se produisent par clivage impliquent une attaque nucléophile au niveau du groupe carbonyle qui est suivie par des transpositions subséquentes qui conduisent à un NpPhMeSiOR optiquement actif et un aldéhyde. Les réactions qui se produisent par transposition impliquent des migrations stéréospécifiques des groupes naphtyle et phényle du silicium vers différentes faces du groupement carbonyle adjacent et conduisent à des naphtyle- et phényléthanols chiraux de configurations absolues opposées.

Interest in the process whereby acylsilanes were readily hydrolyzed by aqueous base to silanol and aldehyde (1) (eq. [1]) led us to attempt to shed light

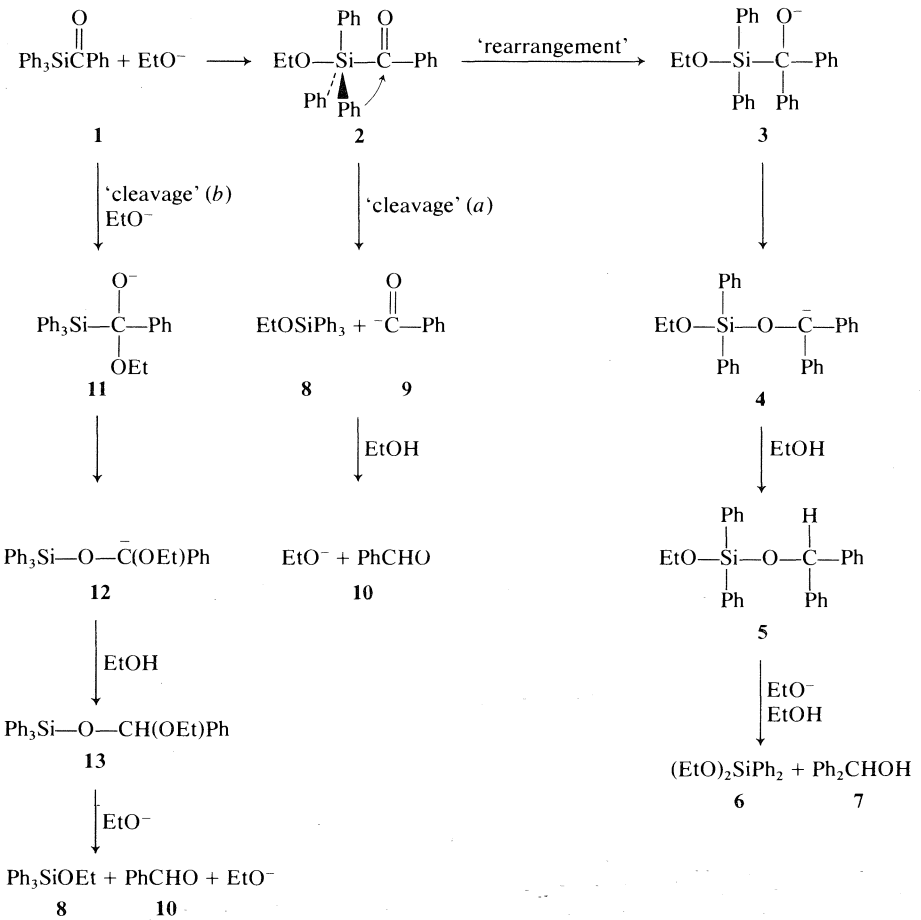
$$[1] \qquad R_3SiC(=O)R' \xrightarrow[H_2O]{OH^-} R_3SiOH + HC(=O)R'$$

on the process by replacing the aqueous base with alcoholic alkoxide. Under these conditions we were able to observe two distinct reaction pathways (2). One of these, 'rearrangement,' clearly involves the migration of a group (aryl ≫ alkyl) originally attached to silicon to the neighbouring carbonyl carbon atom (see **2** → **3** in Scheme 1 which uses benzoyltriphenylsilane and ethoxide ion as an example). This migration logically is followed by a second step in which the anion **3** undergoes the well-known silylcarbinol → alkoxysilane rearrangement (3, 4) via carbanion **4** yielding the bis(alkoxy)silane **5**, which subsequently, in part, undergoes alkoxide exchange giving **6** and **7**. Thus this overall process converts acylsilane **1** to a mixture of **5**, **6**, and **7**. The last step of the process, **5** → **6** + **7**, was shown independently to occur under the reaction conditions (2, 5).

The second pathway, 'cleavage' (previously called 'displacement' (2)), followed by acylsilane **1** was the direct counterpart of the originally observed hydrolysis; for example, benzoylsilane (**1**) yielded triphenylethoxysilane (**8**) and benzaldehyde (**10**). Two pathways appeared possible for this latter reaction: (*a*) the original pentavalent intermediate **2** formed ethoxysilane **8** by loss of acyl anion **9**, which on protonation yielded benzaldehyde (**10**) or (*b*) attack of alkoxide ion on the carbonyl carbon of the acylsilane yielded the oxyanion **11**, which then underwent the silylcarbinol → alkoxysilane type rearrangement yielding carbanion **12** which on protonation gave **13**. Alkoxide exchange involving **13**, which would be expected to occur easily, would yield the observed ethoxysilane **8** and benzaldehyde (**10**).

The following experiments using chiral acylsilanes confirm proposals previously made and lead to a clearer understanding both of the stereochemistry associated with the 'rearrangement' component of the reaction and of the manner by which the 'cleavage' reaction occurs.

Consider first the 'rearrangement' process. Treatment of (−)-acetylnaphthylphenylmethylsilane (**14**) (6) having the absolute configuration shown in Scheme 2, with alkoxide (tBuO$^-$ will be used as the example, other alkoxides should behave similarly) can lead to the intermediate **15**, from which naphthyl, phenyl, or methyl migration to the carbonyl carbon could occur. Previous observations suggest little or no methyl migration will occur in the presence of aryl groups (2) and none was detected. The experimental observations described below are explained if naphthyl migration occurs primarily to the back face of the C=O group as depicted, giving alkoxide **16**, which following the known inversion chemistry previously observed on rearrangement and protona-



1 2 3 11 8 9 4 5 12 10 13 8 10 6 7

SCHEME 1. Rearrangement and cleavage reactions of acylsilanes with alkoxides.

tion (7, 8) gives **17**. Reduction of **17** under conditions known to cleave silicon–oxygen bonds (9) without affecting the configuration at carbon, would lead to the (−)-enantiomer of 1-naphthylethanol and phenyl methylsilane (**19**), as depicted and observed.

Phenyl migration appears to occur primarily to the top face of the carbonyl group of **15** giving **20**, which on rearrangement and protonation with inversion, as observed previously (7), would give **21**. Reduction of **21** would lead to (+)-1-phenylethanol and naphthylmethylsilane as isolated.

Alkoxides **17** and **21** are expected to be susceptible to alkoxide exchange which, if it occurs, would also lead to the formation of carbinols with retention of configuration at the chiral carbon centres and, in addition, to the formation of di-*tert*-butoxysilanes.

At the conclusion of these reactions but before reduction, a complex mixture of products would be present which would be difficult to separate. However, by reducing the entire reaction mixture, the products of greatest interest, **18** and **22** (and **25**, see below) which carry with them a record of the overall stereochemistry from the sequence of reactions, could be readily isolated by glc and their yields and optical purities determined. These results are found in Table 1.

It is significant that the predominant enantiomers of 1-phenylethanol, ((+)-**22**) and of 1-naphthylethanol, ((−)-**18**) isolated are of opposite relative configuration, consistent with the migrating aryl groups preferentially attacking the opposite faces of the carbonyl group. With sodium ethoxide the optical purities of both the 1-phenylethanol ($\simeq 56\%$ optical purity) and naphthylethanol ($\simeq 35\%$ optical purity) are quite high at either 9 or $-60°C$, and it appears that temperature has little effect on the stereochemical course in terms of specificity. However, temperature does have a significant effect on the relative amounts of phenyl vs. naphthyl migration, phenyl migration being favoured at both temperatures but being relatively more favoured at the lower temperature since the migration ratio of phenyl

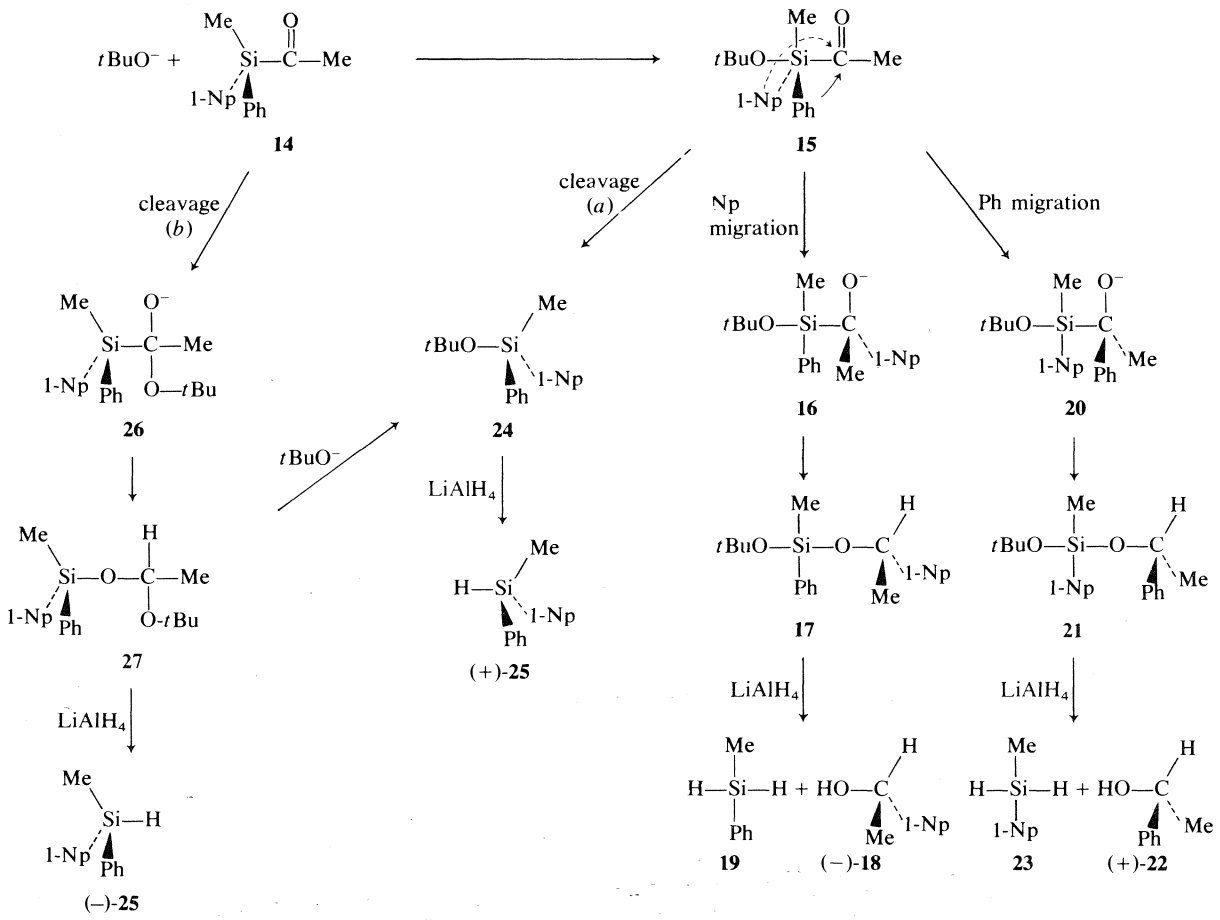

SCHEME 2. Reactions of (−)-acetylsilane with *tert*-butoxide ion.

to naphthyl rose from 6.7:1 to 29:1 on going from +9 to −60°C. This seems reasonable because the bulkier 1-naphthyl group can be expected to have more severe steric effects to overcome in achieving the transition state.

The 'cleavage' process also occurs at the same time that the above 'rearrangements' are occurring. The stereochemical consequences of the two proposed reaction pathways are also described in Scheme 2. If 'cleavage' arises from **15**, then the *tert*-butoxysilane **24** should be formed with effective overall inversion of configuration at silicon relative to **14**. Reduction of **24** would lead, with retention of configuration, to the (+)-silane **25**, although experiments have shown that under the reaction conditions employed, this reduction is at best very slow (9); thus, since *tert*-butoxysilane could not be detected among the products of reduction, it seems probable that little if any of it was ever formed. If nucleophilic attack of the alkoxide ion on the carbonyl group of **14** occurred, the ion formed, **26**, would rearrange to **27** with retention of configuration at silicon, as found previously (4). Reduction of **27** with lithium aluminum hydride would yield (−)-naphthylphenylmethylsilane, the opposite enantiomer to that expected from the route involving **15** → **24**. (In principle some **24** could arise from **17** by alkoxide exchange but this seems very unlikely, in view of the lack of evidence for the formation of *tert*-butoxysilane **24**.) It follows then that the configuration of the naphthylphenylmethylsilane isolated can distinguish between the two proposed pathways for 'cleavage.' The results are given in Table 1. In each reaction carried out the (−)-enantiomer was the predominant naphthylphenylmethylsilane formed. Greater optical purities were observed at lower temperatures (22% at 9°C vs. 35% at −60°C) and with the bulkier alkoxide (EtO⁻ gave 22% optical purity; tBuO⁻ gave 65%.) Thus these results are fully consistent with a pathway which involves nucleophilic attack by the alkoxide at the carbonyl group as the predominant route by which 'cleavage' occurs.

It is also evident that the relative proportions of 'cleavage' to 'rearrangement' depend on the steric

bulk of the alkoxide, the proportions changing from about 8:92 with EtO^- to 60:40 with $iPrO^-$ to 72:28 with $tBuO^-$ in further experiments done under identical standard conditions with each alkoxide. This suggests that bulkier alkoxides find it more difficult to attack at silicon to give the intermediate **15** and consequently, attack at the carbonyl group becomes relatively easier, favouring 'cleavage' rather than 'rearrangement.'

An experiment using (+)-benzoyl-1-naphthylphenylmethylsilane provides interesting complementary results (see Scheme 3). After reacting with *tert*-butoxide ion in toluene – *tert*-butyl alcohol at 0°C for 4 days, by which time the acylsilane had disappeared, followed by reduction with excess lithium aluminum hydride as described above, and work-up by a combination of distillation and column chromatography, 'rearrangement' of both phenyl and 1-naphthyl groups was observed, since both benzhydrol and (+)-naphthylphenylcarbinol with a maximum specific rotation of 11.7° were obtained in yields of about 50 and 10%, respectively (ratio of phenyl to naphthyl migrations, 5:1). Neither the absolute configuration of (+)-1-naphthylphenylcarbinol nor its maximum specific rotation appears to be known but application of Brewster's rules (10) predicts that the *R* enantiomer should be (+)-rotatory (at the sodium D line). If the configurational assignment is correct, these results suggest that the predominant direction of attack on the carbonyl group by naphthyl is as shown in Scheme 3 and opposite to that observed with the acetylsilane.

About 13% 'cleavage' accompanied the observed 60% overall 'rearrangement' (ratio 4.4:1) and the 1-naphthylphenylmethylsilane isolated was again the (−)-enantiomer having an optical purity of about 41%. The amount of 'cleavage' effected by $tBuO^-$ was significantly less than observed with the acetylsilane but the results of these experiments with the benzoylsilane are quantitatively less reliable. How-

ever, it is clear that the stereochemistry and approximate optical purity of the $R_3\overset{*}{S}iH$ product from the benzoylsilane are the same as observed from the acetylsilane, so that their modes and stereochemistries of formation almost certainly follow the same general reaction pathway, as illustrated by **14** → **26** → **27** → (−)-**25**.

Based on the above results, it is clear that the observed 'cleavage' reactions arise from attack of alkoxide at the carbonyl group. The manner by which the optically active 'rearrangement' products are formed via nucleophilic attack of alkoxide ion at silicon is more speculative and obviously other conformations or configurations of a pentavalent intermediate such as **15** (or its benzoyl analog) may be involved; the above proposals represent the most concise interpretation of the observations and further speculation is not warranted at this time.

Experimental

Identification of Reaction Products and Their Proportions

The complex mixtures of compounds were quantitatively estimated by glc using two techniques (*a*) internal standard method (using 3-phenylpropanol) and (*b*) calibration graphs, employing a Varian Aerograph Model 202-B Gas Chromatograph with linear temperature programming between 150 and 330°C at a constant heating rate of 10°/min: injection port 250°C; dual-thermal conductivity detector 350°C; column, 5 ft 20% SE-30 on 60–80 acid-washed Chromosorb W. Under these conditions retention times were: 1-phenylethanol, 2.6 min; 3-phenylpropanol, 4.9 min; 1-naphthylmethylsilane, 7.1 min; 1-naphthylethanol, 10.4 min; 1-naphthylphenylmethylsilane, 14.4 min. Under the conditions of work-up, phenylmethylsilane was generally removed with the volatile solvents. Percentages of various components were calculated using the formula

$$\%X = A_X W_{is} 100 / A_{is} W_s$$

where A_X = area under peak of component X
A_{is} = area under peak for 3-phenylpropanol
W_{is} = weight of 3-phenylpropanol injected
W_s = weight of sample injected

Since the above method is strictly applicable only for homologous series of compounds, the results were also determined from calibration curves prepared from known weights of compound injected in 9.5 μl of benzene plotted against peak area from the resulting chromatograph peak for the three compounds of greatest interest, 1-phenylethanol, 1-naphthylethanol, and 1-naphthylphenylmethylsilane. The calibration curves were linear for the ranges 0–130 × 10^{-5} g/9.5 μl of benzene solution injected. This latter method, which was judged to be the more reliable, gave results close to those obtained by the internal standard technique.

By passage of the various optically active components through a preparative glc column under the same conditions used for analysis of the mixtures and then isolation, it was demonstrated that each was optically stable and did not undergo racemization.

In some cases it was convenient to separate large quantities of reaction products into two fractions by chromatography on a 18 in. × ½ in. alumina column. A 50:50 cyclohexane–benzene solvent mixture eluted a mixture of naphthylphenylmethylsilane and naphthylmethylsilane, and subsequent elution with ether yielded a mixture of 1-phenylethanol and 1-naphthylethanol.

Rearrangement of (−)-Acetyl-1-naphthylphenylmethylsilane with Potassium tert-*Butoxide at 9°C*

To a solution of 5.0 g (0.018 mol) of (−)-acetylsilane (6) in 80 ml of dry toluene at −10°C was added 3.0 ml of *tert*-butyl alcohol containing 0.179 g (9.7 × 10^{-4} mol) of potassium *tert*-butoxide. After 5 h stirring under nitrogen at 9°C, the reaction mixture was still yellow, indicating the reaction was incomplete, so an additional 0.120 g (6.6 × 10^{-4} mol) of potassium *tert*-butoxide in *tert*-butyl alcohol was added. After a total of 24 h stirring, an infrared spectrum of the mixture still showed the acetylsilane carbonyl stretch at 6.08 μ, indicative of unreacted acylsilane so an additional 0.129 g (9.7 mmol) of potassium *tert*-butoxide (total KO*t*Bu added = 2.6 × 10^{-3} mol) was added. After 24 h further stirring, all of the acylsilane had reacted and the reaction mixture was poured into water and was extracted with ether. Removal of the solvents left a viscous red oil which was reduced with 2.5 g of lithium aluminum hydride in 175 ml of diisopropyl ether and 50 ml of diethyl ether under reflux (58–60°C) for 24 h. The composition of the reduction mixture obtained after work-up with 10% HCl, a yellow liquid, was determined by glc as described above. The results are listed in Table 1.

Rearrangement of (−)-Acetyl-1-naphthylphenylmethylsilane with Sodium Ethoxide at 9°C

To a solution of 5.0 g (0.018 mol) of acetylsilane in 80 ml of dry toluene cooled to −10°C was added 4.0 ml of absolute ethanol containing 8.9 × 10^{-3} mol of sodium ethoxide. The reaction mixture immediately turned olive green in colour and then slowly changed to opaque brown while being stirred for 24 h at 9°C (cold water bath), after which time a sample showed the absence of the 6.08 μ C=O absorption band of the acetylsilane. The reaction mixture was poured onto water, which was ether extracted. After drying, removal of the ether layer gave a pale yellow oil which was refluxed with 2.5 g of lithium aluminum hydride in 175 ml of diisopropyl ether and 50 ml of diethyl ether for 48 h. Work-up with 10% HCl and ether extraction gave, after removal of the ether, a yellow liquid which was analyzed by glc as described above. The results are listed in Table 1.

A similar rearrangement was also carried out at −60°C, using Dry Ice – CCl_4 as the cooling mixture.

Synthesis and Attempted Reduction of 1-Naphthylphenylmethyl tert-*Butoxysilane*

To 2.0 g (0.012 mol) of (+)-1-naphthylphenylmethylsilane $[\alpha]_D$ +31.0° (*c* 7.7, C_6H_{12}) (90% optical purity) in 20 ml of dry *tert*-butyl alcohol was added 1.64 g (8.8 × 10^{-3} mol) of potassium *tert*-butoxide. The solution was heated at 82°C for 4.5 h and, after addition of pentane, was treated with water. The dried pentane extracts gave, on distillation at 162–165°C/0.13 Torr, (−)-naphthylphenylmethyl-*tert*-butoxysilane, as a clear colourless liquid $[\alpha]_D^{28}$ −23.1° (*c* 3.2 pentane) (lit. $[\alpha]_D$ −28° (9)).

A suspension of 0.5 g of lithium aluminum hydride in 35 ml of diisopropyl ether and 10 ml of diethyl ether and 1.00 g (3.13 × 10^{-3} mol) of the above *tert*-butoxysilane was refluxed for 24 h at 58–60°C. The excess hydride was decomposed with acetone and work-up gave a material whose nmr spectrum showed *tert*-butoxysilane signals but which showed no signal at δ 5.30 ppm, indicating that less than 1–2% of naphthylphenylmethylsilane, the potential reduction product, was present.

Racemization of 1-Naphthylphenylmethylethoxysilane

(−)-1-Naphthylphenylmethylethoxysilane, $[\alpha]_D^{27}$ −9.14° (*c* 10.1, pentane) 89% optically pure, was prepared from 1.5 g of (+)-naphthylphenylmethylsilane, $[\alpha]_D^{28}$ +31.0° (*c* 7.7, cyclohexane) (90% optical purity), 0.8 ml (0.014 mol) of absolute ethanol, and 0.13 g of 5% Pd-on-C in 13 ml dry pentane, using chromatography on silica gel to remove a trace of silanol contaminant.

To 0.24 g (8.2×10^{-4} mol) of the above ethoxysilane in 40 ml of dry toluene was added 5.6×10^{-3} mol of sodium ethoxide in 2 ml of ethanol. After stirring at 6°C for 17.5 h, aqueous work-up gave ethoxysilane with $[\alpha]_D$ −6.02° (*c* 2.2, pentane), corresponding to 58% optical purity, a decrease of 31%.

Rearrangement of Racemic Benzoyl-1-naphthylphenylmethylsilane with Potassium tert-*Butoxide*

A solution of 4.7 g (0.0133 mol) of racemic acylsilane in 95 ml of toluene at −15°C was treated with 5 ml of *tert*-butyl alcohol containing 0.0077 mol of potassium *tert*-butoxide. After 2 days at 0°C, the mixture was poured into 100 ml of 2.5% hydrochloric acid and the ether extracts were dried over sodium sulphate. Removal of the solvents left 5.8 g of oily residue which was dissolved in 25 ml ether and was treated with 2.0 g (0.3 equiv.) of lithium aluminum hydride in 50 ml of ether and 30 ml of di-*n*-butyl ether. The mixture was refluxed and diethyl ether was removed until the contents of the flask reached 83°C, at which temperature they were heated for 20 h. Cooling and normal work-up gave an oil, with strong 2.75 μ (OH) and 4.65 μ (Si–H) infrared absorption, which was distilled under reduced pressure to give the following compounds, identified by infrared, nmr, and mixture melting point: bp 44–62°C/0.07 Torr, a mixture of naphthylmethylsilane and phenylmethylsilane; 100–108°C/0.07 Torr, benzhydrol, mp 67–68°C, 26%; 138–143°C/0.05 Torr, naphthylphenylmethylsilane, 10%; 144–149°C/0.05 Torr, naphthylphenylcarbinol, mp 81–83°C, 7%.

Rearrangement of (+)-Benzoyl-1-naphthylphenylmethylsilane with Potassium tert-*Butoxide*

A solution of 10.0 g (0.028 mol) of (+)-benzoylsilane (4) $[\alpha]_D^{23}$ +5.94° (*c* 8.26, benzene) in 240 ml of toluene at −10°C was treated with 10 ml of *tert*-butyl alcohol containing 0.0077 mol of potassium *tert*-butoxide. After 4 days at 0°C, work-up as described above gave 10.6 g of a yellow material, $[\alpha]_D^{23}$ −0.07° (*c* 7.8, benzene). No residual benzoylsilane could be detected in the infrared spectra (C=O at 6.18 μ absent). Reduction as above with 4.0 g (0.61 equiv.) of lithium aluminum hydride in diethyl ether plus dibutyl ether for 17 h at 83°C, followed by work-up gave 8.9 g of oily residue which was distilled to give 12 fractions of which the following were important: bp 104–114°C/0.005 Torr, benzhydrol, 2.23 g (49.7%); bp 127–129°C/0.005 Torr, 1-naphthylphenylmethylsilane, $[\alpha]_D^{23}$ −13.55° (*c* 2.3, C_6H_{12}), 0.95 g (13.4%); 135–148°C/0.001 Torr, 1-naphthylphenylcarbinol, $[\alpha]_D^{25}$ +5.91° (*c* 3.0, chloroform), 0.65 g (9.9%), which after chromatography on silica gel, eluting with 1:1 hexane–benzene had $[\alpha]_D^{25}$ +11.7° (*c* 1.1, chloroform).

Rearrangement of Racemic Acetylsilane with Various Alkoxides

Using the general conditions described above samples of racemic naphthylphenylmethylsilane in toluene were treated with equal amounts of either sodium ethoxide in ethanol, sodium isopropoxide in isopropyl alcohol or potassium *tert*-butoxide in *tert*-butyl alcohol. On completion of the reactions, work-up indicated the following total amounts of aryl migration: from EtO^-, 92%; from $iPrO^-$, 40%; from $tBuO^-$, 28%.

Complex fluoroanions in solution. IX. BF_3–anion complexes and their disproportionation[1]

S. BROWNSTEIN AND G. LATREMOUILLE

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received May 2, 1978

S. BROWNSTEIN and G. LATREMOUILLE. Can. J. Chem. **56**, 2764 (1978).

Complex fluoroanions have been prepared with boron trifluoride and perchlorate, nitrate, nitrite, acetate, formate, azide, cyanide, cyanate, thiocyanate, and thiophenolate ions. The complexes formed from the anions of the strong acids, except the hydrogen halides, do not disproportionate to $BF_2(anion)_2^-$. Complexes of anions of weaker acids may disproportionate and, or, complex a second molecule of BF_3. Regularities in fluorine–boron coupling constants are tabulated.

S. BROWNSTEIN et G. LATREMOUILLE. Can. J. Chem. **56**, 2764 (1978).

On a préparé des fluoroanions complexes du trifluorure de bore avec les ions perchlorate, nitrate, nitrite, acétate, formate, azoture, cyanure, cyanate et thiocyanate et thiophénolate. Les complexes qui se forment à partir des anions des acides forts, à l'exception des halogénures d'hydrogène, ne donnent pas lieu à une disproportionation conduisant au $BF_2(anion)_2^-$. Les complexes des anions des acides plus faibles peuvent donner lieu à une disproportionation et, ou à une complexation d'une deuxième molécule de BF_3. On rapporte un tableau présentant les régularités dans les constantes de couplage fluor–bore.

[Traduit par le journal]

Introduction

Mixed boron haloanions have been prepared and undergo slow exchange and disproportionation reactions (1). Complex formation and disproportionation has been observed with the trifluoroacetate ion (2), but only complex formation is found with fluorosulfate and trifluoromethane sulfonate ions (3). This study is an attempt to determine the effect of the anion upon the fluorine chemical shift, boron–fluorine spin coupling constant and extent of disproportionation of the 1:1 adduct between BF_3 and an anion. More than one equivalent of BF_3 is complexed by fluoride ion (4) and trifluoroacetate ion (2) but not by fluorosulfate nor trifluoromethanesulfonate ions (3). When all volatile materials are pumped off under vacuum no BF_3 beyond a 1:1 ratio is retained in the solid phase with the above anions. It is of interest to determine if other mixed anions are capable of complexing a second molecule of BF_3 and if any of them can retain the extra BF_3 in the solid phase.

Experimental

Fluorine resonance spectra were obtained at 94.18 MHz with a Varian Associates XL-100A spectrometer equipped with a Nicolet Instruments TT100A Fourier transform accessory. Spectral widths of 20 kHz were observed using a 5 μs pulse and storing the data in 16K memory channels. Normally the accumulation of 400 transients gave a good signal-to-noise ratio. Chemical shifts are reported in ppm with respect to $CFCl_3$ as zero and with shifts to high field considered negative. Infrared spectra of the tetramethylammonium salts dispersed in potassium bromide pellets were recorded on a Beckman Acculab 4 spectrometer. Ultra-violet spectra were obtained with a Cary 14 spectrometer. Vapor pressure studies were done in a manner previously described except for pressure measurement by a Baratron diaphragm manometer rather than a constant volume mercury manometer (4). Samples were prepared with great care to exclude moisture using standard vacuum line and dry box techniques. Boron trifluoride, sulfur dioxide, and methylene chloride were purified and stored as previously described (4). Tetramethylammonium perchlorate, nitrate, acetate, formate, and cyanide were prepared by neutralization of a tetramethylammonium hydroxide solution with the corresponding acid followed by evaporation of all volatile material under vacuum. The reaction of equivalent quantities of a tetramethylammonium hydroxide solution with one of ammonium thiocyanate followed by evaporation to remove ammonia and water produced tetramethylammonium thiocyanate. Tetramethylammonium and tetrabutylammonium nitrites were prepared by reaction of a solution of the corresponding chloride with one of silver nitrite, removal of the silver chloride, and concentration of the resultant solution. A similar procedure using silver cyanate gave tetramethylammonium cyanate. Tetramethylammonium thiophenolate was prepared by the literature method (5). Most of the tetramethylammonium salts were recrystallized from methanol–water. Tetrabutylammonium azide was purchased from Fluka A.G. All the salts have been reported previously in the literature.

Results and Discussion

The chemical shift of the fluorines in complex fluoborate ions is sensitive to temperature, concentration, and the nature of the solvent. For the purposes of this work all chemical shifts were measured with a 0.34 *m* solution of tetramethylammonium salt in sulfur dioxide as solvent at 203 K except for nitrite, azide, and the mixed haloanions already reported (1). In these cases the shift of BF_4^- was taken to be that used in the present study and

the other chemical shifts adjusted accordingly. The chemical shifts are listed in Table 1. There is no well established trend for fluorine chemical shifts nor boron–fluorine spin coupling constants with K_a of the parent acid of the anion nor whether it is 'hard' or 'soft'. The correlation between fluorine chemical shifts and boron–fluorine spin coupling constants observed previously (1) is also observed with the present series of mixed anions. This is illustrated in Fig. 1. Deviations from this correlation are probably due to anomalies in chemical shift values since there appears to be a constant contribution to boron–fluorine spin coupling with each additional substituent on boron. For those anions with the largest shift to high field the correlation would be improved if the spin coupling constant were of opposite sign, as suggested previously (6). The spin coupling constant may be expressed by $J_{B-F} = nJ_i$, where J_i is the contribution from substituent i and n is the number of these substituents bonded to boron. Values of J_i are listed in Table 2. The above approach is similar in principle but different in detail from that originally presented by Vladimiroff and Malinowski (7) and applied by Hartman and co-workers (1, 6). These results, taken together with those of ref. 6, suggest that co-ordination of BF_3 and NO_2^- is via nitrogen rather than oxygen.

If disproportionation of BF_3A^- proceeds by way of reactions [1] to [4],

$$[1] \qquad BF_3 + A \rightarrow BF_3A^-$$

$$[2] \qquad 2BF_3A^- \rightleftharpoons BF_4^- + BF_2A_2^-$$

$$[3] \qquad 3BF_3A^- \rightleftharpoons 2BF_4^- + BFA_3^-$$

$$[4] \qquad 4BF_3A^- \rightleftharpoons 3BF_4^- + BA_4^-$$

that is, with no displacement which produces fluoride ion in the solution, then the ratio of the concentrations of the substituted anions should be independent of the concentration of A^- provided that reaction [1] goes to completion. It was found that with trifluoroacetate, nitrite, cyanide, and acetate the extent of disproportionation is independent of the excess of added anion.

If disproportionation and redistribution of the ligands in BF_3A^- were completely random one would

obtain the proportions of the various species listed in Table 3 (8). None of the systems studied show random behaviour. In every case except azide there is less disproportionation than if it were random. Equilibrium constants for reaction [2] are also listed in Table 3.

Solutions containing the anions cyanide, acetate, and thiophenolate complex more than one equivalent of BF_3. In methylene chloride at 0°C from vapor pressure measurements it is found that complexing of one equivalent of BF_3 is at least 99.4% complete for both cyanide and acetate when only one equivalent of BF_3 has been added. With the addition of two equivalents of BF_3 complexing to give the 2:1 species is 93% complete with cyanide and 89% complete with acetate. Upon evaporation of all volatile materials under vacuum and repetition of the vapor pressure measurements with the residues no further uptake of BF_3 is observed. This indicates that the complexes containing two equivalents of BF_3 are stable towards dissociation even in the absence of gaseous BF_3. The vapor pressure results also exclude, in these cases with an excess of BF_3, disproportionation according to reactions [2] to [4]. Although BF_4^- reacts with BF_3 to produce $B_2F_7^-$ the reaction is readily reversible, while the vapor pressure measurements indicate an irreversible uptake of BF_3.

The vapor pressure results were confirmed, in the case of cyanide ion, by X-ray powder patterns which were different for the starting material and the residues from evaporation of solutions containing one and two equivalents of BF_3. For acetate ion a similar confirmation of different products with one and two equivalents of BF_3 was done by infrared spectroscopy of the residues. Also from the infrared spectra of the residues it was found that the BF_3 complexes of perchlorate, nitrate, fluorosulfate, and trifluoromethanesulfonate ions are stable upon evaporation, under vacuum, of all volatile material.

In solutions containing one equivalent of BF_3 for each cyanide or acetate there is no evidence from fluorine resonance spectra for formation of any complex containing two molecules of BF_3. Therefore reaction [5] does not proceed to any significant degree.

$$[5] \qquad 2BF_3A^- \rightarrow A^- + (BF_3)_2A^-$$

The fluorine resonance spectrum of a sulfur dioxide solution with one equivalent of thiophenoxide ion and BF_3 has signals from both the 1:1 and the 2:1 BF_3 complexes. A sulfur dioxide solution of tetramethylammonium thiophenoxide is yellow because of an interaction between the thiophenoxide ion and the solvent. When complex formation with BF_3 is complete the solution has no visible color. The maximum in the absorption curve for the thiophenoxide – sulfur dioxide complex is masked by the cutoff of the solvent at 3200 Å. Nevertheless the absorption of a shoulder of this complex at 3500 Å is easily measured with the molar extinction co-efficient (ε) of 9 600. From the change in absorptions at this wavelength, with addition of BF_3, an equilibrium constant of 0.15 ± 0.09 at 298 K was calculated for reaction [5]. The relative areas of the fluorine resonance peaks at 203 K, for a solution 250 times more concentrated gave an equilibrium constant of 0.18. If the reaction were statistically random an equilibrium constant of 0.25 would be expected, therefore this reaction behaves in an essentially random fashion with the thiopenolate ion.

The fluorine resonance spectra of the complexes containing two equivalents of BF_3 for each acetate or thiophenolate ion have only a single peak from fluorine bonded to boron. Therefore the two BF_3 moieties are either identical or undergo rapid exchange on the nmr time scale. Their chemical shifts are −136.7 for acetate and −140.2 for thiophenolate. Separate peaks are observed for the two complexed BF_3 species with cyanide ion. A comparison of the spin coupling constants for the 1:1

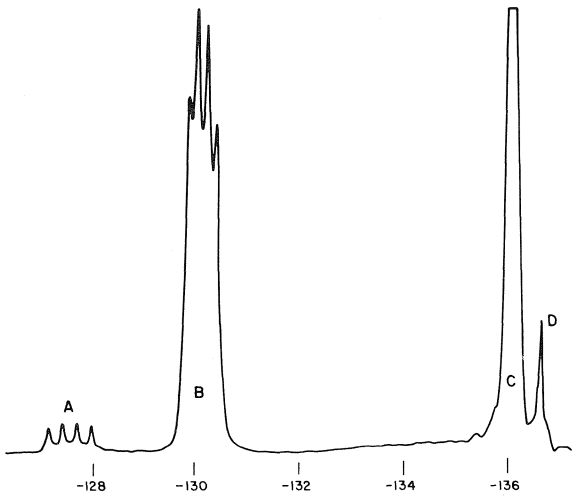

FIG. 2. Fluorine resonance spectrum of a sulfur dioxide solution of tetramethylammonium cyanide and two equivalents of boron trifluoride: (*a*) BF_3CN^-; (*b*) BF_3 co-ordinated to N; (*c*) BF_3 co-ordinated to C; (*d*) BF_4^-.

and 2:1 complexes with those of other BF_3 complexes suggests that boron is co-ordinated to nitrogen in the 1:1 complex. Structure **1** is proposed for the 2:1 complex with the fluorines of BF_3 co-ordinated to nitrogen having a chemical shift of −130.1 and a boron–fluorine coupling constant of 24.4 Hz. The chemical shift of the fluorines on boron co-ordinated to carbon is −136.1 and the ratio of areas of the two peaks is 1.03 to 1.00. A spectrum is shown in Fig. 2.

Conclusions

Complexing of boron trifluoride with anions appears to be a general phenomenon and disproportionation of the resultant complexes is widespread. In some cases room temperature stable complexes containing more than one boron trifluoride may be obtained.

KELVIN K. OGILVIE, SERGE L. BEAUCAGE, ARIA L. SCHIFMAN, NICOLE Y. THERIAULT, and KRISHAN L. SADANA. Can. J. Chem. **56**, 2768 (1978).

The synthesis of oligonucleotides derived from uridine and adenosine using the *tert*-butyldimethylsilyl protecting group and the trichloroethylphosphorodichloridite condensation procedure is described. These procedures involve rapid preparation of protected starting materials and equally rapid condensation of units to form nucleotides. Optimum yields using collidine as base in tetrahydrofuran as solvent are between 65 and 80%. The utility of the procedure is rendered complete by the capability to remove both the phosphate protecting groups and the alkylsilyl groups in a single 30 min step using tetrabutylammonium fluoride in tetrahydrofuran.

KELVIN K. OGILVIE, SERGE L. BEAUCAGE, ARIA L. SCHIFMAN, NICOLE Y. THERIAULT et KRISHAN L. SADANA. Can. J. Chem. **56**, 2768 (1978).

On décrit la synthèse d'oligonucléotides dérivés de l'uridine et de l'adénosine utilisant le groupe protecteur *tert*-butyldiméthylsilyle et la méthode de condensation faisant appel à la trichloroéthylphosphorodichloridite. Ces méthodes impliquent une préparation rapide des produits de départ protégés et une condensation également rapide des unités conduisant aux nucléotides. Les meilleurs rendements sont obtenus en faisant appel à la collidine comme base dans le tétrahydrofuranne utilisé comme solvant et ils sont de l'ordre de 65 à 80%. L'utilité de cette méthode est rendue complète par sa capacité d'enlever à la fois les groupes protecteurs phosphates et les groupes alkylsilyles dans une seule étape de 30 m utilisant le fluorure de tétrabutylammonium dans le tétrahydrofuranne.

[Traduit par le journal]

Introduction

There are two important challenges in the chemical synthesis of oligonucleotides: the synthesis of oligodeoxynucleotides leading ultimately to the synthesis of genetic material and the synthesis of oligoribonucleotides leading to the synthesis of molecules such as transfer RNA and messenger RNA. Developments in these two areas are similar in that the methods used to date to condense protected monomers into oligomers are virtually the same for both cases. However, they differ greatly in the availability of suitably protected monomers. The lack of procedures for the rapid synthesis of suitably protected ribonucleosides is the major reason that while the chemical synthesis of oligodeoxynucleotides has contributed significantly to the synthesis of a gene (7) no development of equivalent magnitude has occurred in the ribose area.

Of the numerous attempts to prepare oligoribonucleotides only three main approaches have led to significant developments. Khorana developed the diester approach for ribonucleotides (8) but this method suffers from the limits on quantities used and the complexity of protection–deprotection procedures. Reese (9) extensively explored acyl and tetrahydropyranyl protecting groups in ribonucleotide synthesis and van Boom *et al.* (10) have succeeded in extending this work using the triester approach. Werstiuk and Neilson (11) have also had some success with extending the Reese approach reaching a nonanucleotide. Ikehara and co-workers (12) have employed photolabile protecting groups with both the diester and triester methods in successfully preparing a trinucleotide.

For some time we have been exploring new methods for protection–deprotection of ribonucleosides and methods of condensation. Our efforts in exploiting the alkyl silyl protecting groups for ribonucleosides and use of fluoride ion to not only remove silyl groups but phosphate protecting groups as well (5, 13), when combined with the Letsinger phosphite condensation procedure (14), have allowed us to present (6) a new and versatile route to oligoribonucleotides. We believe this method offers the first practical procedure for the chemical synthesis of a transfer RNA. In this manuscript we wish to detail the procedures for the synthesis of protected adenosine and uridine nucleosides and their condensation to nucleotides. In developing this series we will

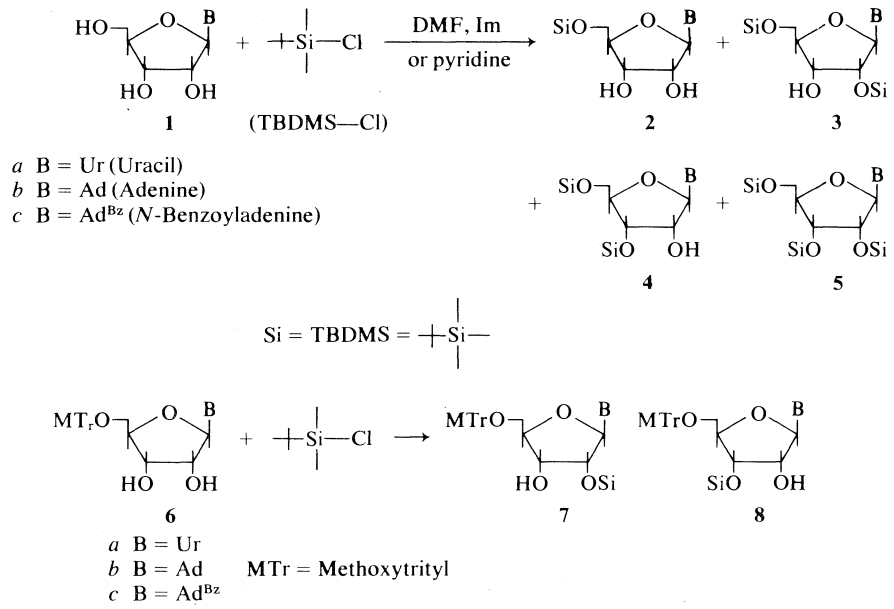

SCHEME 1

present the first complete set of fully protected ribonucleosides of synthetic utility using a single protecting group for all the ribonucleosides.

This manuscript details all of the isomeric derivatives of uridine and adenosine using the *tert*-butyldimethylsilyl (TBDMS) protecting group promoted by Corey and Venkateswarlu (15) in the prostaglandin area. While we have also developed (3, 4) other more stable silyl groups such as the triisopropylsilyl and *tert*-butyltetramethylenesilyl groups, the *tert*-butyldimethylsilyl chloride reagent is commercially available (Aldrich Chemical Co.). The other silyl groups offer unique advantages of stability and will soon be available commercially from the same supplier. Methods described herein for the TBDMS group are directly applicable to the other silylating reagents.

Preparation of the Silylated Nucleosides

The major advantage of the TBDMSCl reagent is that it rapidly converts the ribonucleoside (Scheme 1) into derivatives that can be directly used in forming nucleotides. We have compared two solvent systems for these reactions: (*i*) dimethylformamide and imidazole (DMF + Im) and (*ii*) pyridine. The DMF–Im system seems to give the most rapid rates with the reaction being over in a matter of minutes in most cases. Pyridine reactions are slower but give much more selectivity in derivatization of the 2′-hydroxyl vs. the 3′-hydroxyl. Such selectivity in pyridine has been observed by Blackburne *et al.* (16) in other systems. Although the reactions in DMF with imidazole are over very quickly some slight changes in product distribution may occur with time. Table 1 lists the conditions we have found that lead to optimum yields of compounds **2**, **3**, and **4**.

One excellent synthetic feature of the silylated nucleosides is that isomeric compounds, e.g., **3** and **4**, separate very cleanly on silica gel chromatography (see Table 2). Consequently the products can rapidly be obtained by thick-layer chromatography or by short column chromatography often in solvents such as ether and hexane. Products containing silyl groups on exocyclic amino groups are not obtained in any quantity in these reactions. It appears that *N*-silylated adenosines may be intermediates in the reactions but they either act as silylating agents themselves (i.e., transferring the *N*-silyl to a hydroxyl) or are hydrolyzed during work-up.

We have tried many ways of mixing reagents together but the procedures described give nearly maximum results and are based on direct addition of the silylating agent to the dissolved nucleoside.

Since there are several phosphorylating procedures that require *N*-protection we have also prepared the silylated derivatives of *N*-benzoyl adenosine. From Table 2 it can be seen that *N*-protection causes a remarkable increase in the separation of isomers such as **3***c* and **4***c*. The silyl groups are also completely compatible with the methoxytrityl group and together they provide an ideal protection system for nucleosides. These derivatives (**7** and **8**) are fully described.

Hydrolysis of Silyl Groups

Acid

Another very useful feature of the silylated

*For details see Experimental.

nucleosides is the fact that the 5′-silyl group is much more labile toward acid than either the 2′- or 3′-silyl (Scheme 2). Consequently compounds **3** and **4** can be treated with 80% HOAc either at room temperature or on heating to give yields of **9** and **10** up to 75%. These results are summarized in Table 3. The 5′-methoxytrityl group can be removed from **7** or **8** to give yields of **9** and **10** as high as 98%.

When the 2′- and 3′-positions both bear silyl groups as in the case of **5**, the 5′-silyl can be removed to give good yields of the 2′,3′-disilylated nucleosides **9***c* and **10***c*. All the silyls can be removed within 2 h using 0.1 *N* methanolic HCl at room temperature. It is clear from these experiments that in multisilylated nucleosides, each silyl is more resistant toward hydrolysis than in the monosilylated compounds. For example, **2***a* is 95% converted to uridine after heating with 80% HOAc for 15 min at 100°C whereas in **3***a* and **4***a*, 10% of the 5′-silyl is still intact after 30 min. Compound **2***a* is 98% converted to uridine after 18 h with 80% HOAc at room temperature whereas **5***a* was 32% intact after 28 h under the same conditions. The silyl groups on adenosine appear to be slightly more resistant to acid than in the uridine case.

SCHEME 2

Bases

Silyl groups can be removed from the 5′- and 2′- or 3′-positions (**2**, **3**, **4**) with base. However it is very difficult to remove either or both silyl groups from a molecule such as **5** where both 2′- and 3′-positions are protected. Furthermore the 2′- or 3′-silyls are more sensitive to base hydrolysis than the 5′-position. For example with 9 *M* NH_4OH in ethanol at 70°C, **9***a* is 90% converted to uridine in 4 h while after 3 h under these conditions **2***a* is unaffected. Compound **9***c* was unaffected by these conditions even after 55 h. Compound **3***a* was 35% converted to **2***a* under these conditions showing once more the effect of poly-substitution. Compound **4***a* was only 10% converted to **2***a* after 5 h under the same conditions indicating that the 3′-silyl is more stable than the 2′-silyl. Using 0.5 *N* NaOH (dioxane–H_2O, 1:1) we found that compounds **3***a* and **3***b* could be completely converted to the parent nucleoside within 36 h.

‡Eastman chromagram sheets 6060. Solvents used were (*a*) ether–hexane (2:1); (*b*) ether; (*c*) ethyl acetate; (*d*) tetrahydrofuran; (*e*) ethyl acetate – ether (1:1); (*f*) chloroform–ethanol (9:1).

*Tetra-*n*-butylammonium Fluoride (TBAF)*

Silyl groups, regardless of their position or number were completely cleaved within 30 min by TBAF in tetrahydrofuran as solvent. A mixture of pyridine–THF–water (1:8:1) was also very effective as a solvent. TBAF is less reactive in pure methanol solutions probably owing to the solvation of fluoride ions. When **3***a* was treated with 20 molar equiv. of TBAF in THF–MeOH (5:3), there was present after 24 h ~50% of 5′-OTBDMSU and the remainder was uridine. Clearly the 2′-silyl group was cleaved more rapidly than the 5′-silyl. This may reflect a hydrogen bonding between the fluoride ion and the 3′-hydroxyl, thus increasing the rate of fluoride attack at the 2′-silyl due to the proximity effect. Such H-bond interactions have recently been exploited by Clark and Miller (17).

The rate of fluoride ion attack can also be moderated by the presence of acetic acid (5) and under such conditions no 2′–3′ isomerization is observed in the unhydrolyzed material after 5 h.

2′–3′ Isomerization of Silyl Groups

Although the silyl groups seem to be stable in most pure solvents we have observed some conditions under which the silyl groups will migrate between 2′- and 3′-positions. For example when preparative tlc plates were allowed to stand for 4 h or longer after development, the eluted products **3** and **4** were no longer pure but contained traces of the other isomer. If the contact time was 24 h at room temperature or 3 h at 100°C up to 20% of the disilyl derivative had isomerized. Although this provides a method to convert more of the 3′,5′-isomer (**4**) into the generally more useful compound **3**, it represents a feature that must be taken into account during work-up.

We have not been able to detect any isomerization during acid treatment of **3** or **4** using either acetic acid or methanolic HCl under a variety of conditions. Similarly these compounds are stable to anhydrous pyridine or triethylamine solutions for at least 24 h. This is in marked contrast to the rapid isomerization of acyl derivatives (18). However, the presence of water with these amines can cause isomerization. For example in pyridine containing 10% water **4***a* was 40% converted to **3***a* after 24 h. Compounds **3***a* and **4***a* are, however, stable in solutions of pyridine–water

†Balance is unreacted starting material unless otherwise indicated.
‡The remainder consisted of a mixture of unreacted starting material and several nucleotides with more than one silyl removed.

when either triisopropylbenzenesulfonic acid or its chloride are added. Isomerization occurs rapidly in DMF and DMF–imidazole mixtures. For example, **3***a* is about 30% isomerized in 17 h at room temperature. This undoubtedly explains some of the differences in product distribution between pyridine and DMF. We have found that on standing in 95% EtOH about 10% isomerization occurs in 7 days whereas in DMSO there is about 20% isomerization observed on standing for 24 h.

Isomerization does not appear to occur during any of the conditions of phosphorylation in anhydrous pyridine using sulfonyl chlorides or their derivatives as condensing agents. However when dicyclohexylcarbodiimide is used in the absence of phosphorylating agent nearly 40% of **3***a* isomerizes after 24 h in dry pyridine. No isomerization is observed during phosphorylations using phosphoryl chlorides.

Characterization of Derivatives

Because the silyl derivatives represent a new class of protected ribonucleosides it was necessary to characterize the products in detail. This was done by chemically converting the new derivatives into known derivatives of uridine and adenosine. In addition satisfactory elemental analyses were obtained on all new compounds and the mass spectra were obtained for all the silylated nucleosides. We have found that the position of silylation can be determined directly from the ^{13}C spectra.[3] Proton nmr is not quite as generally useful as ^{13}C but does serve to distinguish some isomers very well and this will be discussed later below. The nmr results are summarized in Table 4.

Uridine

5′-SiU (**2***a*) was easily characterized by conversion to the 2′,3′-dibenzoyl derivative and subsequent removal of the silyl group to leave 2′,3′-dibenzoyluridine of known structure (19). Compounds **3***a* and **4***a* were sulfonylated in separate experiments with *p*-toluenesulfonyl chloride. On removal of the silyl

groups from the product from **3***a*, the known 3′-*O*-*p*-toluenesulfonyluridine (20) was obtained. However from the sulfonated product of **4***a*, O^2,2′-anhydrouridine was obtained. This was not an unexpected product since the ready formation of the 2′-anhydro compound has been well documented (21, 22). These reactions clearly establish the structures of **2***a*, **3***a*, and **4***a*.

Compound **9***c* was characterized by conversion to the 5′-methoxytrityl derivative and subsequent removal of the silyl groups to yield the known 5′-*O*-monomethoxytrityluridine (23). Compounds **7***a* and **8***a* were acetylated and after removal of the methoxytrityl groups they yielded the same compounds as produced by acetylating **3***a* and **4***a*, respectively, and subsequently removing the 5′-silyl group selectively with 80% acetic acid. The trisilylated compound **5***a* was not obtained crystalline and was characterized by high resolution mass spectrometry.

Although there was little doubt as to the identity of **9***a* and **9***b* (since isomerization does not occur under the acid conditions used to produce them) they were nevertheless derivatized by methoxytrityl chloride to produce, respectively, the compounds **7***a* and **8***a* characterized above.

Adenosine

Compound **2***b* was converted to its 2′,3′-ditosyl derivative which after removal of the silyl group, yielded the known 2′,3′-ditosyladenosine (24). Compound **4***b* was converted in the same manner to 2′-*O*-tosyladenosine (24*b*). Compound **3***b* was tosylated to produce a compound isomeric to the 3′,5′-disilyl-2′-tosyladenosine produced from **4***b*. Because of the analogy to the uridine system and the lack of isomerization during acid hydrolysis of the 5′-silyl group, the structures of **10***a*, **10***b*, and **10***c* were not in question. Their mass spectra and ^{1}Hmr spectra fully supported the proposed structures and the ^{13}C spectra[3] were conclusive (Table 4).

Synthesis of Nucleotides

The silylated nucleosides are easy to prepare. They are also easily coupled together to form nucleotides. The Letsinger chlorophosphite procedure (14) which does not require *N*-protection (25), is uniquely suited to the silylated nucleosides. We have adapted the procedure making changes in duration of reaction and ratio of reactants. The general approach is outlined in Scheme 3 and the results are summarized in Table 5.

We have found that nearly optimum yields are obtained using ratios of reactants of initial nucleoside (5′-protected): trichloroethylphosphorodichloridite ($TCEOPCl_2$): second nucleoside (5′-open) which are 1:1.1:0.8 (or 0.9). These are higher ratios than used in the deoxy series (14). We have also consistently used times of 1 h at −78°C followed by warming to room temperature for 1 h during the condensation step involving the second nucleoside component (5′-open). The subsequent oxidation with iodine and treatment with sodium bisulfite are as previously described (14). All protected nucleotides were isolated as solids from preparative tlc.

We have gravitated toward collidine as the base used during condensation procedures. Yields using pyridine were generally lower. Lutidine gave good but not consistent results and difficulties of solubility arise at −78°C with this base. Collidine on the other hand gave consistently high yields with no experimental difficulties.

From Table 5 it can be seen that yields in the 50–70% range are general although yields of nucleotides

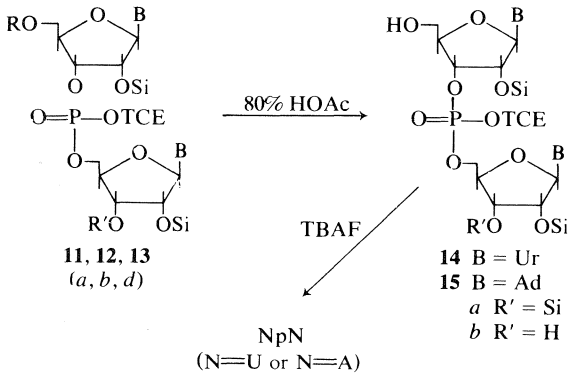
*The general procedure is fully described in the experimental. Ratios of all reactants are relative to the starting material. The solvent in all cases was tetrahydrofuran at −78°C. The time of the second step was 1 h at −78°C followed by 1 h at room temperature in all cases.



SCHEME 4

containing adenosine are consistently high and are very easy to work up.

The synthesis of dinucleotides such as **11***a* and **11***b* illustrate nucleotide synthesis using a single protecting group. The condensation of 2′,5′-diTBDMSuridine (**3***a*) with 2′-TBDMSuridine (**9***a*, prepared directly from **3***a*) gives a good yield of **11***a*. As will be shown below all of the protecting groups from **11***a* (**11***b* etc.) can be removed in a single 30 min treatment with TBAF to produce uridylyl-3′,5′-uridine.

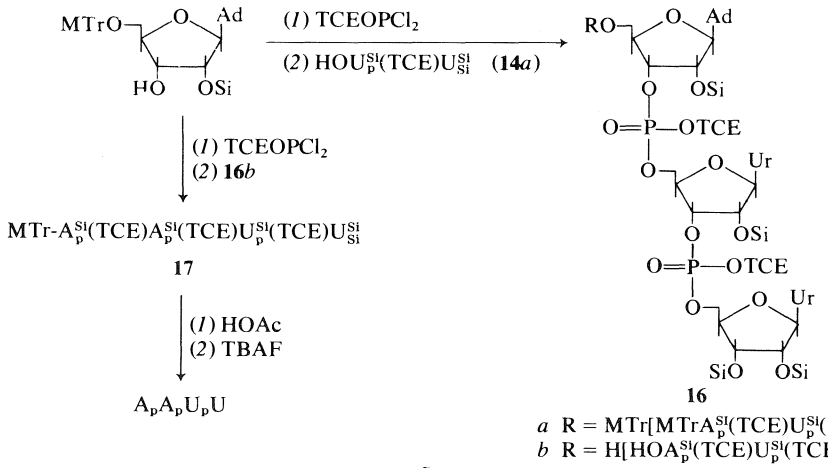
The methoxytrityl group is an ideal protecting group to use with the silyl groups. A methoxytrityl group on the 5′-position in a growing nucleotide chain also serves as a label because of the coloration which arises with acid spray. Yields of nucleotides using the methoxytrityl group on the 5′-position are often between 69% (**11***c*) and 80% (**13***d*). Because *N*-protection is not required for adenosine, methoxytrityl groups and silyl groups can be removed from the 5′-position with acid without cleavage of the adenine ring. The methoxytrityl group can be cleaved from **11***d* and **13***d* in high yield to give **14***a* and **15***a*, respectively. By contrast the 5′-silyl group can be removed from **11***b* to give only a 65% yield of **14***a* (Scheme 4).

The ease of removal of the 5′-protecting group allows for chain extension to occur in a stepwise fashion. The synthesis of the protected tetranucleotide MTr-A_p^{Si}(TCE)A_p^{Si}(TCE)U_p^{Si}(TCE)U_{Si}^{Si} (**17**) is shown in Scheme 5. Yields are good at each stage of the synthesis with **16***a* (MTr-A_p^{Si}(TCE)U_p^{Si}(TCE)U_{Si}^{Si}) being obtained in 66% yield. Detritylation gives **16***b* in 83% yield from which the tetranucleotide **17** is obtained in 57% yield.

Block syntheses are also viable and the condensation between **11***e* (MTr-U_p^{Si}(TCE)U_{OH}^{Si}) and **14***b* (HO-U_p^{Si}(TCE)U_{OH}^{Si}) produced the protected tetranucleotide of uridine in 40% yield. We feel that in general it is best to protect the 3′-hydroxyl during chain extension, whether units are being added one at a time or in blocks. The reason for this is that on repeated reaction and work up via chromatography some migration of the 2′-silyl group to the 3′-position is bound to occur at the terminal nucleoside. For stepwise chain extension the use of compounds **9***c* and **10***c* containing silyl groups on both 2′- and 3′-positions at the 3′-terminus of the growing chain is ideal as described for the synthesis of **16** and **17**. However for multiple block condensations other 3′-protecting groups which are compatible with the silyl groups will be necessary and will be described in later publications.

Deprotection of Nucleotides

The removal of trityl (or other acid labile) protecting groups is easily carried out since *N*-protection on adenosine is not necessary. The silyl and trichloroethyl groups are both removed within 30 min using the TBAF in THF reagent. In some cases after this treatment we have noticed <5% of material containing a silyl group on the 2′-position adjacent to a 3′-phosphodiester. Apparently if a trace of moisture is present and the protected phosphate group is converted to a *p*-O^- group before the removal of an



SCHEME 5

For personal use only.

adjacent silyl group, fluoride attack at that silyl position is severely retarded. Such a silyl group can easily be removed by mild acid (26).

All of the free nucleotides had paper chromatographic and electrophoretic mobilities consistent with their structures. These nucleotides were completely degraded by snake venom, and spleen phosphodiesterases and uridine containing nucleotides were degraded with pancreatic ribonuclease.

Conclusion

The *tert*-butyldimethylsilyl group provides an excellent method of protecting the hydroxyl functions of nucleosides which can then be easily condensed via the chlorophosphite procedure to produce nucleotides. This represents the first general procedure whereby ribonucleosides can be directly converted, often in a single step, into derivatives which can be immediately incorporated into nucleotide chains. This feature along with the facile removal of silyl groups and phosphate protecting groups in a single 30 min step at room temperature makes this procedure complete.

This manuscript demonstrates the procedures used to produce the protected derivatives of uridine and adenosine. Similar procedures for the incorporation of cytidine and guanosine will be described in the next article in this series.

Experimental

General Methods

Descending paper chromatography was carried out using Whatman 3MM paper. The solvent systems employed were: solvent *A*, isopropyl alcohol – concentrated ammonium hydroxide – water (7:1:2); solvent *B*, *n*-butanol – acetic acid – water (5:2:3); solvent *B'*, *n*-butanol – ethanol – water (4:1:5, organic phase); solvent *C*, 1 *M* ammonium acetate – ethanol (3:7); solvent *E*, 0.5 *M* ammonium acetate – ethanol (3:7, adjusted to pH 3.5 with acetic acid); solvent *F*, *n*-propanol – concentrated ammonium hydroxide – water (55:10:35). The solvents were prepared on a volume basis. Thin-layer chromatography was carried out employing the ascending technique in closed jars which were not coated with absorbent paper. All thin-layer chromatography was run on Eastman chromagram sheets 13181 (formerly 6060), silica gel with fluorescent indicator, on strips 10 cm × 2 cm. Thick-layer chromatography was carried out on glass plates (20 cm × 20 cm) coated with a 1-mm thick layer of silica gel DSF-5 (Terrochem Laboratories). Paper electrophoresis was performed using Whatman 3MM paper in a Savant Flat Plate electrophoretic chamber with a Savant Model HB power supply operated at 2000 V for 1 h; the solution was a triethylammonium bicarbonate buffer (0.05 *M*, pH 7.5), prepared by making 15.15 g triethylamine up to 31 volume with water and then bubbling 20 g carbon dioxide through the solution. Nucleosides and their derivatives were detected on paper chromatograms, thin- and thick-layer sheets using a uv light source (Mineralite, output ~254 nm). Compounds containing trityl or *p*-monomethoxytrityl groups were detected on chromatography by spraying with 10% perchloric acid solution and drying them in a stream of warm air. Imidazole was detected by placing the tlc in a jar containing iodine whereupon imidazole turns black very rapidly (within 3 min).

Spectra

All uv spectra reported were obtained on a Cary 17 recording spectrophotometer. Routine mass spectra were obtained on a Finnigan 1015 RF quadrupole mass spectrometer, a Hitachi-Perkin Elmer RMU-6D single focussing mass spectrometer and an AEI, MS-9. High resolution spectra were obtained on a CEC-110-B double-focussing mass spectrometer (the Upjohn Co., Kalamazoo, Michigan). Proton magnetic resonance spectra were recorded on a Bruker WH-90 FT nmr.

Melting points were determined on a Fisher-Johns melting point apparatus and are reported uncorrected. Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, Tennessee and by the Analytical Laboratory, H. C. Ørsted Institute, Copenhagen, Denmark. All new compounds reported gave satisfactory elemental analyses. Samples submitted were prepared by crystallization, lyophilization, or precipitation from tetrahydrofuran with hexane followed by heating in a drying apparatus over P_2O_5.

Reagents and Chemicals

Reagent grade pyridine and lutidine were distilled first from *p*-toluenesulfonyl chloride, redistilled from calcium hydride, and stored over molecular sieves (Type 4A). *N,N*-Dimethylformamide and collidine were dried by distillation from calcium hydride and stored over molecular sieves (Type 4A). Tetrahydrofuran was refluxed with benzophenone and sodium for 3 h under nitrogen and distilled directly onto molecular sieves (Type 4A) and stored in the dark.

2,2,2-Trichloroethylphosphorodichloridite was prepared from phosphorus trichloride and 2,2,2-trichloroethanol as described in the literature (27). Nucleosides were obtained from Sigma Chemical Co. 5-*O*-Methoxytrityluridine (mp 103–105°C) (23), isopropylideneuridine (mp 159–160°C) (28), *N*-benzoyladenosine (mp 159–164°C) (29), 5'-*O*-methoxytrityladenosine (mp 189–191°C) (30), and 5'-*O*-methoxytrityl-*N*-benzoyladenosine (mp 133–137°C) (31) were all prepared according to literature procedures.

Enzyme Assays

(a) Spleen Phosphodiesterase

Lyophilized spleen phosphodiesterase (10–15 units) obtained from Nutritional Biochemicals Corp. was dissolved in 1 ml of 0.01 *M* sodium pyrophosphate buffer adjusted to pH 6.5 with phosphoric acid. An aliquot (0.1 ml) of this solution, 0.2 ml of 0.05 *M* ammonium acetate (adjusted to pH 6.5 with acetic acid), and 0.1–1 mg of the nucleotide substrate were incubated at 37°C. The solution was then applied to Whatman 3MM paper as a band and developed with solvent A. Nucleoside and nucleotide bands were cut out, eluted with water, and diluted to a volume of 10 ml. Absorbances were adjusted by using blanks cut from papers treated in the same way as the sample material. The term od unit refers to the extinction of the absorbing material in 1 ml of neutral solution in a quartz cell with a 1-cm path length.

(b) Snake Venom Phosphodiesterase

Two hundred units of snake venom phosphodiesterase obtained from Calbiochem were dissolved in 1 ml of tris(hydroxymethyl)aminomethane buffer (adjusted to pH 9.2 with 0.1 *N* HCl). An aliquot (0.2 ml) of the enzyme solution was added to the nucleotide material (~1 mg) and incubated at 37°C. The same procedure as in section *a* was then followed.

(c) Pancreatic Ribonuclease A

The enzyme (5 mg, protease free, Type XII A, Sigma

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 05/05/12

For personal use only.

Chemical Co.) was dissolved in 1 ml of Tris buffer (pH 7.8). About 30 μl of the enzyme solution was added to 0.1–0.5 mg of the nucleotide in 0.2 ml of Tris buffer (pH 7.5) and the solution was incubated at 37°C for 3 h. The procedure described in section *a* was then followed.

Silylating Conditions

DMF

The ribonucleoside and imidazole were dissolved in DMF and the TBDMS-Cl was then added. In general 1 ml of DMF is used per millimole of ribonucleoside and 2 molar equiv. of imidazole are used for each mol of TBDMS-Cl.

Reactions are all carried out at room temperature for various times although most reactions seem to be complete within 30 min. Yields under the best conditions used are described in Table 1. Compounds were isolated in all cases by chromatography on tlc plates usually employing three plates per millimole of starting nucleoside. The solvents used to separate the desired product are shown in Table 6.

Pyridine

The nucleoside was dissolved in pyridine (2 ml/mmol of nucleoside) and the TBDMS-Cl was added to the solution which was stirred at room temperature. Yields and product distributions are shown in Table 1. Products were again isolated by tlc using the solvents in Table 6.

Preparative Hydrolysis of 5′-TBDMS and 5′-Methoxytrityl Groups from Silylated Nucleosides

These reactions were all carried out in 80% acetic acid (10 ml/mmol) either at room temperature or with heating. Products were isolated after removal of the solvents at reduced pressure followed by tlc purification. Product yields are given in Table 3 while properties of the products are listed in Table 2.

Stability of Silyl Groups Toward Acid, Base, and TBAF

Acid

Various conditions for the removal of a 5′-silyl group with acetic acid are summarized in Table 3. In addition we found that 2′- or 3′-TBDMS groups can be removed with 0.1 *M* methanolic HCl within 2 h at room temperature. No isomerization of 2′ or 3′-TBDMS groups has been observed under any acid condition tried to date.

Base

5′-Silyl groups are very stable to basic conditions requiring about 36 h with 0.5 *M* NaOH in dioxane–water (1:1) at room temperature. Using 7 *M* ammonia in ethanol at 70°C, 2′- or 3′-TBDMS groups are ~90% cleaved from **9***a* and **9***b* whereas as the TBDMS groups are completely unaffected in **2***a* and **9***c* under these conditions. The latter compound is stable for at least 55 h. Under these same conditions **3***a* is 35% isomerized after 5 h and 35% hydrolyzed to **2***a*.

TBAF in THF

This reagent has been prepared in several ways which seem to give similar results. We regularly prepare the reagent as follows. After titration of a dilute (~10%) aqueous solution of tetra-*n*-butylammonium hydroxide with a dilute (~5%) aqueous solution of HF, the neutral solution is lyophilized. The colorless and hydroscopic solid is shattered to a powder (simply by shaking the flask) and dried further over P_2O_5 for periods up to 24 h without heating. The dry powder is then dissolved in freshly distilled THF and stored over molecular sieves (Type 4A) in a tightly stoppered plastic bottle as a 0.7 *M* solution.

An alternate procedure has been published by Kuwajima *et al.* (32). We have modified the procedure by lyophilizing the clathrate and then drying as above. The activity of the reagent is the same as prepared above. Pless (33) has described a procedure which involves ion-exchange chromatography and other preparations have been described by Wen *et al.* (34) and Makosza and Bialecka (35).

TABLE 6. Solvent systems used to develop tlc plates during the isolation of silylated nucleosides

Compound isolated	Solvent used	Number of developments
2*a*	Chloroform–ethanol (9:1)	1
3*a*, **4***a*	Ether–hexane (4:1)	1
5*a*	Ether–hexane (2:1)	1
2*b*	Ethyl acetate – THF (1:1)	1
3*b*, **4***b*	Ether	3
5*b*	Ether–hexane (2:1)	1
2*c*	Ethyl acetate	1
3*c*, **4***c*	Ether	2
7*a*, **8***a*	Ether–hexane (3:2)	2
7*b*, **8***b*	Ethyl acetate	1
7*c*, **8***c*	Ether	2

The general use of this reagent has been described previously (5, 13). Some additional solvent tests studied during the course of this work are as follows: (*i*) **9***a* was treated with 3 molar equiv. of TBAF in a solution of pyridine–THF–water (1:8:1, v/v/v). Complete desilylation to uridine was observed after 30 min; (*ii*) **9***a* was treated with TBAF in acetic acid – water – THF (20:16:1, molar ratio) and after 24 h 50% conversion to uridine was observed; (*iii*) **3***a* was treated with the standard reagent in methanol (1:4; v/v) and after 24 h the solution contained uridine and **2***a* in about equal amounts.

Conversion of **2**a *to 2′,3′-Di-O-benzoyluridine*

Compound **2***a* was treated with a 10-fold molar excess of benzoic anhydride in pyridine at room temperature for 24 h. The reaction mixture was poured into ice water which was extracted with chloroform. The chloroform extracts were concentrated at reduced pressure and applied to tlc plates which were developed in ether–hexane (2:1). The desired product was eluted with ether and crystallized from ether–hexane (98% yield, mp 184–186°C, *m/e* 509 *M* − 57). This product was heated with 80% HOAc for 40 min on a steam bath and the solvents were removed at reduced pressure. The residue was applied to tlc plates which were developed twice in ether to separate the product from the unreacted starting material. 2′,3′-Di-*O*-benzoyluridine crystallized from ether–hexane with a melting point of 194–195°C (lit. (19) mp 195–197°C). The compound had λ_{max} 257 nm (95% EtOH) and showed a prominent peak at *m/e* 341 (*M* − base).

Conversion of **3**a *to 3′-O-Toluenesulfonyluridine*

Compound **3***a* was treated with a five-fold excess of *p*-toluenesulfonyl chloride (TsCl) in pyridine at 5°C for 36 h. After addition of methanol and evaporation of solvents, the residue was applied to tlc plates developed in benzene–ether (2:1). The product was eluted with ether to yield a white solid (65%, λ_{max} (EtOH) 262, 224 nm; *m/e* 569 (*M* − 57)).

The above compound was treated with 8 molar equiv. of TBAF reagent in THF and after 45 min the solution was applied to a tlc plate which on development in THF yielded a product which on crystallization from absolute ethanol produced 3′-*O*-*p*-toluenesulfonyluridine of mp 204–206°C (lit. (20) mp 205–206°C) and showing λ_{max} (EtOH) at 261 and 225 nm with the parent ion at *m/e* 398 in the mass spectrum.

Conversion of **4**a *to* O^2*,2′-Anhydrouridine*

Compound **4***a* was treated exactly as above for **3***a*. The

initial product, 3′,5′-DiTBDMS-2′-*p*-toluenesulfonyluridine (66%; mp 121–125°C; *m/e* 569 (*M* − 57)) on treatment with TBAF produced O^2,2′-anhydrouridine (λ_{max} (EtOH) 249, 224 nm, identical to an authentic sample).

Conversion of **9***c to 5′-Methoxytrityluridine*

Compound **9***c* was treated with 1.5 molar equiv. of methoxytrityl chloride in pyridine for 20 h. After work-up on tlc plates in ether–hexane (2:1) the fully protected compound was obtained (74%, mp 101–105°C). On treatment with TBAF in THF in the usual manner the material was completely converted to 5′-*O*-methoxytrityluridine, identical to an authentic sample (23).

3′-O-Acetyl-2′-O-TBDMSuridine

Method A

Compound **7***a* was treated with an excess of acetic anhydride in pyridine for 16 h. After evaporation of the solvents and treatment with 80% HOAc for 5 h at 20°C, the title compound was isolated from tlc plates developed in ether–hexane (2:1). The product (60%) crystallized from ether–hexane (mp 201–203°C, *m/e* 343 (*M* − 57); R_f 0.27 (ether–hexane; 2:1)).

Method B

Compound **3***a* was treated in the same manner as **7***a* above except that the acetic acid treatment was on a steam bath for 2 h. The title compound was obtained in 70% yield (mp 200–202°C, undepressed when mixed with the product from method *A*.

2′-O-Acetyl-3′-O-TBDMSuridine

Method A

Compound **8***a* was treated in a manner identical to **7***a* above to yield 2′-*O*-acetyl-3′-*O*-TBDMSuridine in 68% yield (mp 207–209°C, *m/e* 343 (*M* − 57); R_f 0.17 (ether–hexane; 2:1)).

Method B

Compound **4***a* was treated in a manner identical to **3***a* above to yield (60%) of the title compound (mp 209–211°C, undepressed when mixed with the product from method *A*).

*2′,3′,5′-TriTBDMSuridine (***5***a)*

This compound could not be obtained crystalline but a high resolution mass spectrum along with the data in Table 2 confirm its identity. The first fragment ion (*M* − 57) was observed at 529.258 (calcd. for $C_{23}H_{45}Si_3N_2O_6$: 529.259).

*5′-O-Monomethoxytrityl-2′-O-TBDMSuridine (*7a*)*

Compound **9***a* (prepared from **3***a*) was treated with methoxytrityl chloride in pyridine under the usual conditions. Work-up on tlc plates (ether–hexane; 1:1) gave **7***a* which crystallized from benzene–hexane (mp 141–143°C, 70%) and was identical in all respects to the major compound isolated from the silylation of methoxytrityluridine (see Tables 1 and 2).

*5′-O-Monomethoxytrityl-3′-O-TBDMSuridine (***8***a)*

Compound **9***b* (prepared from **4***a*) was treated with methoxytrityl chloride as for **9***a* above to yield **8***a* (mp 109–112°C) identical to the minor product obtained on the silylation of methoxytrityl uridine.

Conversion of **2**b *to 2′,3′-Di-*O-p-*Toluenesulfonyladenosine*

Compound **2***b* was treated with 8 molar equiv. of TsCl in pyridine at room temperature for 14 h. Work-up in the usual manner including chromatography on tlc plates in ether–benzene (2:1) gave the 5′-*O*-TBDMS-2′,3′-di-*O*-*p*-toluenesulfonyladenosine (mp 157–159°C; λ_{max} (CH_3OH) 260, 236, 272 (5h) nm; *m/e* 674 (*M* − 15) and 632 (*M* − 57). This compound was treated with 80% HOAc on a steam bath for 1 h. Work-up on tlc plates in ether gave the known 2′,3′-di-*O*-*p*-toluenesulfonyluridine, mp 205–207°C (lit. (24) mp 207–209°C).

Conversion of **4**b *to 2′-*O-p-*Toluenesulfonyladenosine*

Compound **4***b* was treated with 5 molar equiv. of TsCl at 0°C for 64 h in pyridine. Work-up as above using ether–benzene (1:1) gave 3′,5′-DiTBDMS-2′-*O*-*p*-toluenesulfonyladenosine (78%, mp 173–176°C; λ_{max} (EtOH) 261, 228 nm; *m/e* 592 (*M* − 57)). This product was treated with TBAF in THF for 35 min and the product was isolated on tlc plates developed in ethyl acetate – THF (1:1). The product, 2′-*O*-*p*-toluenesulfonyladenosine was crystallized from methanol–water (92%, mp 227–229°C (lit. (25) mp 229–230°C); λ_{max} (EtOH) 261, 228 nm).

Conversion of **3**b *to 2′,5′-DiTBDMS-3′-*O-p-*Toluenesulfonyladenosine*

Compound **3***b* was treated exactly as above for **4***b* to produce the title compound in 65% yield. Its mass spectral characteristics were very similar to the isomeric compound produced above from **4***b* but its R_f in ether–benzene (1:1) was 0.43 compared to 0.50 for the isomeric compound.

General Procedure for the Synthesis of Dinucleotides

The general procedure can best be illustrated by the synthesis of MTr-U_p^{Si}(TCE)U_{ISP} (**11***c*). The experiments with isopropylideneuridine were initial experiments undertaken to determine optimum conditions. Reactions were carried out in tubes or flasks closed by a rubber septum. Reagents in solution were injected via syringe. A syringe filled with magnesium perchlorate was used to equalize the pressure in reaction vessels.

To a cold solution (−78°C) of collidine (2.46 mmol) in THF (0.75 ml) was added trichloroethylphosphorodichloridite (90 μl, 0.61 mol). A solution of MTr-U_{OH}^{Si} (**7***a*, 0.558 mmol) dissolved in THF (0.75 ml) was added dropwise over a period of 5 min. The reaction mixture was stirred at −78°C for an additional 30 min. At this point a solution of isopropylideneuridine (143 mg) dissolved in THF (1.0 ml) was added and stirring was continued at −78°C for 1 h followed by warming to room temperature for an additional 1 h. A solution of iodine (0.61 mmol) in a mixture of THF (2 ml) and water (1.0 ml) was added followed by 0.5 ml of collidine. After 15 min at 22°C the solution was concentrated at reduced pressure and the residue was dissolved in chloroform (20 ml). The chloroform solution was washed with an aqueous sodium bisulfite solution (4 ml of saturated sodium bisulfite solution in 20 ml of water). The aqueous phase was separated and back-extracted twice with chloroform (20 ml each). The combined chloroform extracts were concentrated to a small volume and the residue was applied to tlc plates which were developed twice in ether–hexane (4:1). The desired product was eluted with ethyl acetate which on concentration yielded 375 mg (67%) of MTr-U_p^{Si}(TCE)U_{ISP} (**11***c*).

All of the reactions reported in Table 5 were carried out in this fashion. Yields are based on the limiting nucleoside (isopropylideneuridine in the above example). The physical properties of the fully protected nucleotides are described in Table 7. Their structures were further established by completely deprotecting the compounds to the known free nucleotides which were completely degradable by snake venom and spleen enzymes. The uridine nucleotides were also degraded by pancreatic ribonuclease.

It should be noted that 5′-5′ and 3′-3′ linked dinucleotides were obtained as byproducts and were easily separated on tlc. In the above illustration we obtained a 17% yield of the nucleotide formed by coupling two molecules of **7***a* and a 16% yield of the 5′-5′-linked dinucleotide formed by coupling 2 molecules of isopropylideneuridine. Such by-products were obtained in varying amounts in all condensation reactions.

Removal of Protecting Groups

Selective Removal of 5′-Protecting Groups

We have found that the most efficient way to remove the 5′-silyl group from a dinucleotide is to stir the nucleotide (e.g., **11***b*) in 80% HOAc for 3 days. In this way a 65% yield of **14***a* is obtained and 21% of the starting **11***b* was recovered. Heating **11***b* at 90°C for 3 h led to a 55% yield of **14***a* with several other multiply deprotected by-products being formed. The methoxytrityl group can be removed by heating for example **13***d* in 80% HOAc for 15 min at 80°C. Work-up on tlc yielded **15***a* in 93%. Yields are nearly always of the order of 90% in these reactions (see Table 3).

Complete Removal of Silyls and Trichloroethyl Groups

Both of these protecting groups are removed within 30 min on treating 10–50 mg of the protected nucleotide with 1 ml of the standard TBAF reagent. At the end of this period the solution is applied to Whatman 3MM paper and developed in solvent *A*. The pure nucleotide is always the major product. There are sometimes traces (< 5%) of material containing a silyl group, presumably on the 2′-position adjacent to the internucleotide linkage.

The pure nucleotides obtained in this fashion were all fully characterized by comparison to authentic standards on paper chromatography and electrophoresis. They were also shown to contain only 3′-5′ linkages by their complete enzymatic degradation using snake venom, spleen and pancreatic ribonuclease.

Synthesis of the Trinucleotide $SiU_p^{Si}(TCE)U_p^{Si}(TCE)U_{OH}^{Si}$

To a solution of lutidine (0.11 ml) in THF (0.35 ml) at −78°C was added $TCEOPCl_2$ (42 µl) followed by a solution of **3***a* (118 mg) in THF (0.9 ml). The solution was stirred an additional 30 min at −78°C whereupon a solution of **14***b* (135 mg) in THF (1 ml) was added. The solution was stirred for 1 h at −78°C and allowed to warm to room temperature for an additional 1 h. The system was treated with iodine and worked up in the general manner. The product was isolated from tlc plates which were developed twice in ether–hexane (4:1). $SiU_p^{Si}(TCE)U_p^{Si}(TCE)U_{OH}^{Si}$ (131 mg) was isolated in 56% yield (mp 145–150°C; λ_{max} (EtOH) 259 nm; R_f 0.76 (THF)).

Synthesis of the Tetranucleotide MTr-$U_p^{Si}(TCE)U_p^{Si}(TCE)U_p^{Si}$-$(TCE)U_{OH}^{Si}$

To a solution of pyridine (72 µl) in the THF (0.5 ml) was added $TCEOPCl_2$ (32 µl) followed by a solution of **11***e* (0.2 mmol) in THF (0.75 ml). The suspension was stirred for a further 10 min at −78°C whereupon **14***b* (105 mg, 0.115 mmol) in THF (0.5 ml) was added. After stirring at −78°C for 1 h followed by 1 h at room temperature the reaction was worked up with iodine in the usual manner. The product was isolated on tlc plates developed first in ether–hexane (3:1) and then in ether–hexane (4:1). The product was not further characterized at this point but was completely deprotected first with 80% HOAc at 80°C for 15 min and then with TBAF for 30 min to produce the nucleotide $U_pU_pU_pU$ (40% overall) which was fully characterized (R_f^A 0.01, R_f^F 0.27, R_m^{Tp} 0.79; λ_{max} (H_2O) 259 nm).

*Synthesis of MTr-$A_p^{Si}(TCE)U_p^{Si}(TCE)U_{Si}^{Si}$(**16**a)*

To a solution of collidine (0.14 ml) in THF (0.35 ml) at −78°C was added $TCEOPCl_2$ (39 µl) followed by a solution of **7***b* (156 mg) in THF (0.5 ml). The solution was stirred a total of 45 min at −78°C whereupon a solution of **14***b* (220 mg) in THF (0.75 ml) was added. The solution was stirred for 1 h at −78°C and allowed to warm to room temperature during the next hour. The solution was treated with iodine and worked up in the usual manner. The product was isolated from tlc plates (4) which were developed in ether – ethyl acetate (3:1, three times). The product was eluted from the plates with chloroform–ethanol (2:1) and on evaporation of the solvents 266 mg of **16***a* (66%, mp 140–144°C; λ_{max} (EtOH) 260, 238 nm (sh)); R_f 0.85 (THF)) was obtained.

*Preparation of HO-$A_p^{Si}(TCE)U_p^{Si}(TCE)U_{Si}^{Si}$(**16**b)*

Compound **16***a* (225 mg) was heated at 80°C in 80% acetic acid (6 ml) for 15 min. The solvent was removed at reduced pressure and the residue was applied to four tlc plates developed in chloroform–ethanol (9:1). The product band was eluted with $CHCl_3$–EtOH (2:1) and on evaporation of the solvent 159 mg of **16***b* (83%, mp 150–155°C; R_f 0.6 (THF); λ_{max} (EtOH) 260 nm) was obtained.

Synthesis of the Tetranucleotide MTr-A_p^{Si}(TCE)A_p^{Si}(TCE)U_p^{Si}-(TCE)U_{Si}^{Si}(17)

To a solution of collidine (44 μl) in THF (0.11 ml) at −78°C was added $TCEOPCl_2$ (12 μl) followed by a solution of **7***b* (49 mg) in THF (0.11 ml). The solution was stirred a total of 45 min at −78°C (whereupon a solution of **16***b* (96 mg) in THF (0.5 ml) was added. The solution was stirred for 1 h at −78°C and allowed to warm to room temperature during the next hour. The solution was treated with iodine and worked-up in the usual manner. The product was isolated from tlc plates which were developed in chloroform–ethanol (9:1, two times) and the product **17** was eluted with chloroform–ethanol (2:1) and on evaporation of the solvents 84 mg of **17** (57%, R_f 0.8 (THF), λ_{max} (EtOH)) 259, 238 nm (sh). The structure of the compound was further proven by removal of the methoxytrityl group followed by the TBDMS and trichloroethyl groups to give $A_pA_pU_pU$.

Received March 20, 1978

CLAUDE RULLIÈRE, JEAN-CLAUDE RAYEZ, and PIERRE C. ROBERGE. Can. J. Chem. **56**, 2781 (1978).

The triplet–triplet absorption spectra of three naphthyl-1,3,4 oxadiazoles have been measured from 400 to 620 nm. The spectra are analyzed in terms of naphthalene perturbed in the α or β position using a theoretical simulation of the perturbation based on Pariser–Parr–Pople approximation. It is concluded that the lowest triplet state of these molecules must involve an important contribution of charge transfer configurations.

CLAUDE RULLIÈRE, JEAN-CLAUDE RAYEZ et PIERRE C. ROBERGE. Can. J. Chem. **56**, 2781 (1978).

Les spectres d'absorption triplet–triplet de trois dérivés naphtyles du 1,3,4 oxadiazole ont été obtenus dans le domaine de 400 à 620 nm. Ces spectres présentent des similitudes avec ceux de naphtalènes perturbés en position α ou β. La perturbation en position α ou β est simulée en utilisant la méthode Pariser–Parr–Pople. Il semble que l'interprétation des spectres triplet–triplet doive faire intervenir une importante contribution de configurations de transfert de charge dans le premier état triplet de ces molécules.

Introduction

Aryl-substituted 1,3,4-oxadiazoles are extensively used as laser dyes (1). In the framework of a general search for the best candidates for laser action, we study the substituent effects on triplet–triplet (T–T) absorption in these compounds. We report here preliminary results on the following naphthyl oxadiazoles: 2-(1-naphthyl)-5-phenyl-1,3,4-oxadiazole (αNPD), 2-(2-naphthyl)-5-phenyl-1,3,4-oxadiazole (βNPD) and 2,5-di-(1-naphthyl)-1,3,4-oxadiazole (αNND). The structural formulas of these compounds are given as inserts in Figs. 1 and 2.

The $S_n \leftarrow S_0$ absorption spectra of these molecules (2) indicate a strong interaction between the different fragments (phenyl, naphthyl, and oxadiazole) in the ground state. The β compounds show more resolved vibrational structure than the α compounds. However, in all cases, the fluorescence spectra exhibit a well resolved vibrational structure. This result can be related to a planar or near planar configuration in the first singlet excited state. Berlman has already suggested the occurrence of hydrogen bonding with the nitrogen atoms of the oxadiazole ring in these compounds (3). According to his analysis, 2,3-diphenyl-1,3,4-oxadiazole (PPD) would present the strongest hydrogen bonding, followed by βNND, αNND, and, finally, αNPD. SCF MO calculations show that in the ground state the bond order of the ring–ring bonds and the electronic density on the nitrogen atoms are not significantly different in all these compounds (4). So, hydrogen bonding strength should be mainly dependent on geometrical factors. The β compounds (and PPD which present the same ring–ring geometry) should present a less preferable geometry for hydrogen bonding (five-membered cycle) than the α compounds (six-membered cycle with a closest approach of the hydrogen atom to the nitrogen atom). This is contrary to Berlman's statement. Korneeva and Kuzina (5) have shown that the introduction of a hydroxy group in the 2 position of the phenyl ring in PPD narrows the corresponding absorption band and attributed this effect to a restriction of rotation around the ring–ring bond due to hydrogen bonding. This suggestion offers another explanation of Berlman's results: in PPD and in the β compounds, rotation of the phenyl and/or naphthyl groups is not as restricted by steric hindrance as it is in α-naphthyl compounds. It would appear from the vibrational structure of the $S_n \leftarrow S_0$ spectra, and also by comparison of calculated and experimental oscillator strengths in these compounds (4) that β compounds are more nearly planar in the ground state than α compounds. However, it cannot be excluded that the loss of vibrational structure and the lowering of the expected oscillator strengths in the α compounds are due to intramolecular hydrogen bonding. In any case, it seems quite clear that the interaction between hydrogen and nitrogen atoms

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(steric hindrance or hydrogen bonding) is more important in the α compounds than in the β compounds.

Experimental

The compounds αNND, αNPD, and βNPD were all Koch-Light products; chromatography on silica gel did not show any impurity and so they were used as received. Cyclohexane (Fisher spectroanalyzed) was used as the solvent without further purification. The description of the flash apparatus used for the T–T absorption measurements and the procedure for outgassing the solutions have already been described elsewhere (6). Each spectrum given here is the result of more than 400 flashes on different solutions.

Results and Discussion

Analysis of the Absorption Spectra

The T–T absorption spectra of αNND, αNPD, and βNPD are assembled in Figs. 1 and 2. The behavior of the short wavelength band in these spectra shows close similarity to that of the short wavelength band in quinoline and isoquinoline (7): it is broader and of lower extinction coefficient in the α compounds (quinoline type) than in the β compounds (isoquinoline type). This result might suggest that the T–T spectra of these substituted oxadiazoles can be interpreted in terms of naphthalene perturbed in the α or β position. The short wavelength band in the spectra of the three substituted oxadiazoles would correspond to an overlap of possibly up to three transitions as in the quinolines (7).

The energy of the first two transitions, which are clearly discernible in the spectrum of αNND, are compared in Fig. 1*a* with the energy of the $^3A_g^+ \leftarrow {}^3B_{2u}^+$ and $^3B_{3u}^- \leftarrow {}^3B_{2u}^+$ transitions[1] in naphthalene as calculated by Meyer *et al.* (8). The agreement is good. Intensification of the transitions towards the $^3B_{3u}^-$ and $^3A_g^+$ states could be explained by a lowering of the symmetry in the αNND molecule (C_{2v} at the most). The total oscillator strength for the three transitions (0.14) is close to the oscillator strength of the $^3B_{1g}^- \leftarrow {}^3B_{2u}^+$ transition in naphthalene (0.12).

The spectrum of αNPD, when compared to the one of αNND, shows an increase of the intensity in the red part of the spectrum (Fig. 1*b*). This would not be inconsistent with an intensification of the $^3A_g^+ \leftarrow {}^3B_{2u}^+$ transition due to the destruction of pairing in the naphthalene fragment (the symmetry of αNPD being at the most C_s). The total oscillator strength for all of the observed transitions in αNPD (0.19) is, however, larger than in naphthalene.

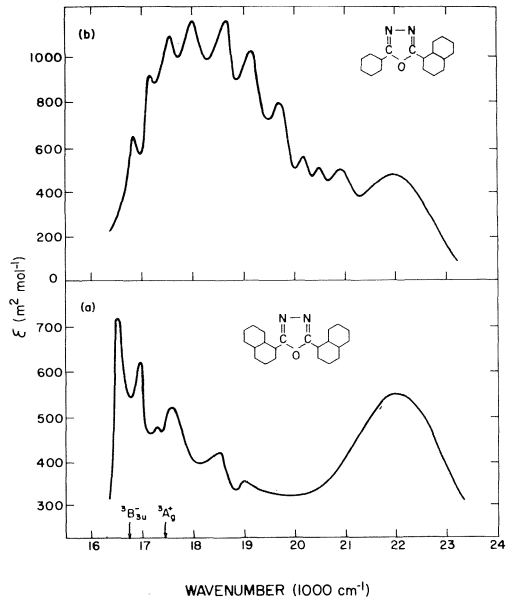

FIG. 1. Triplet–triplet absorption spectra in cyclohexane at room temperature: (*a*) αNND, (*b*) αNPD. The energies of the $^3B_{3u}^- \leftarrow {}^3B_{2u}^+$ and $^3A_g^+ \leftarrow {}^3B_{2u}^+$ transitions in naphthalene are indicated by the arrows at the bottom of the figure.

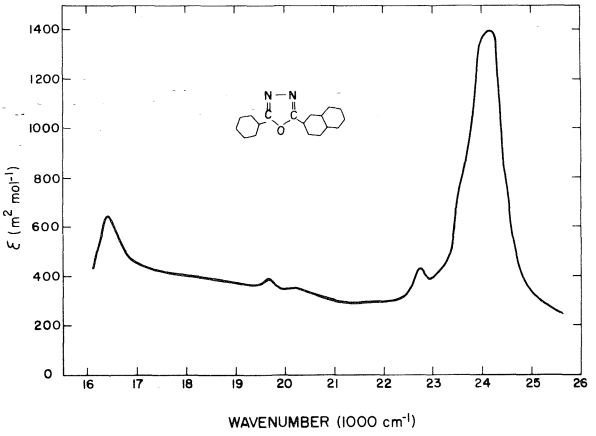

FIG. 2. Triplet–triplet absorption spectrum of βNPD in cyclohexane at room temperature.

The T–T spectrum of βNPD (Fig. 2) could also be interpreted in terms of naphthalene perturbed in the β position. The intensification of the $^3A_g^+ \leftarrow {}^3B_{2u}^+$ transition, polarized along the short axis of naphthalene, should be much less important than in the α compounds. The total oscillator strength of the observed transitions in βNPD (0.15) is also close

[1]The spectroscopic notations for naphthalene correspond to Pariser's choice of axis (as in refs. 7 or 8): *y* along the short axis and *x* along the long axis of naphthalene.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

to the oscillator strength of the ${}^3B_{1g}^- \leftarrow {}^3B_{2u}^+$ transition in naphthalene.

The preceding analysis of the T–T spectra of the naphthyl oxadiazoles is based on the hypothesis that the loss of symmetry and the related destruction of pairing in the naphthalene fragment upon substitution induce an intensity increase of sign forbidden and symmetry forbidden transitions. In the case of quinoline and isoquinoline, Lavalette and co-workers (7) concluded on the basis of theoretical and experimental evidence that spectral dilution by interaction with the ${}^3B_{1g}^-$ state of naphthalene did not cause any perceptible absorption in the region of the first ${}^3A_g^+$ or ${}^3B_{3u}^-$. However, the perturbation of naphthalene by oxadiazole or phenyl oxadiazole group is much more important than the perturbation introduced by the nitrogen atom in the case of quinoline and isoquinoline. A larger perturbation might induce an intensification of the sign and/or symmetry forbidden transitions towards low lying states. Theoretical calculation should be able to show if this interpretation is correct.

Theoretical Calculations

We decided to simulate perturbations in the α or β position of naphthalene using the Pariser–Parr–Pople (P.P.P.) method. To simulate a perturbation of variable strength, the value of the atomic valence state ionization potential (W_{2p}) for the α or β carbon atom was varied from the normal value of −11.22 eV in naphthalene up to a value of −29 eV. The effect of the perturbation on the other parameters entering into the P.P.P. calculation was considered as a second order effect and neglected. The parameters used were: $R_{C-C} = 1.40$ Å; $W_{2p} = -11.22$ eV for all carbon atoms except the α or β ones; $\beta_{CC} = -2.39$ eV; $\alpha_{CC} = 10.53$ eV; γ_{pq} as computed from Nishimoto-Mataga relation (9). All the singly excited configurations with respect to the ground state were included in the configuration interaction. The results of this calculation are shown in Figs. 3 and 4.

It can be seen that for $|W_{2p}| > 23$ eV, there appear transitions with important oscillator strengths in the region of the naphthalene ${}^3A_g^+$ and ${}^3B_{3u}^-$ in both of the α- and β-perturbed systems.

A possible assignment of the observed spectra of αNND and αNPD in terms of naphthalene perturbed in the α position is given in Table 1. Considering the crudeness of the theoretical approach, the agreement between theory and experiment could be considered satisfactory. The physical meaning of the high values of W_{2p} needed to account for the αNND ($W_{2p} \simeq -25$ eV) and αNPD ($W_{2p} \simeq -23$ eV) spectra is questionable. Such a strong perturbation would

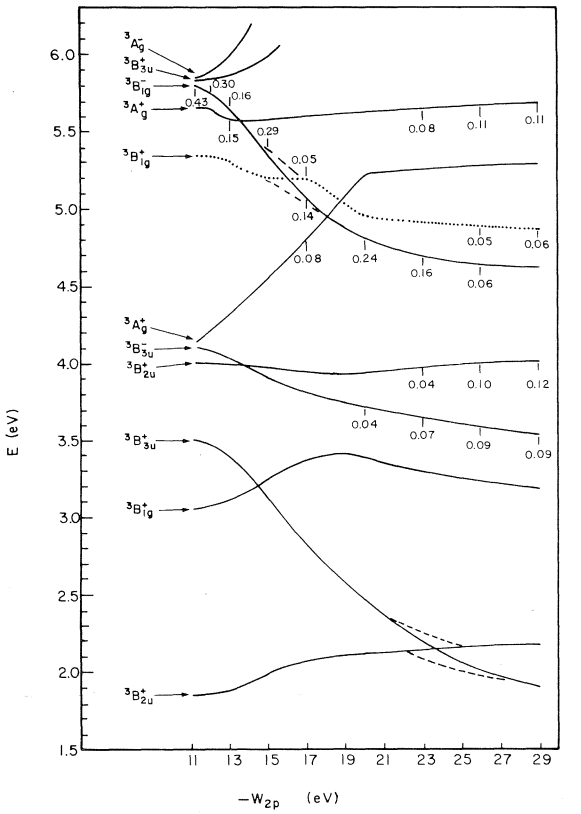

FIG. 3. The calculated energies of the lowest triplet states relative to the ground-state energy, as a function of W_{2p} of the α carbon atom of naphthalene. Oscillator strengths are indicated when larger than 0.04.

surely indicate a planar or quasiplanar lowest triplet state. In contrast to the $S_n \leftarrow S_0$ spectra, the $T_n \leftarrow T_1$ spectra of both αNND and αNPD show well resolved vibrational structure with progressions of ~500 and ~350 cm^{-1}. This observation is surely consistent with planar or quasiplanar lowest triplet state for both of these molecules. However according to Table 1, one would expect an observable transition at ca. 800 nm in αNND and αNPD. The spectral study of αNND was extended to 900 nm but we did not observe any transition in the range 600–900 nm. Moreover the calculation shows that as a result of the perturbation the naphthalene ${}^3B_{1g}^-$ state interacts with adjacent forbidden levels. Such an interaction, as expected in a naphthalene molecule of reduced symmetry (7), leads to the dilution of the intensity of the ${}^3B_{1g}^- \leftarrow {}^3B_{2u}^+$ transition over a group of transitions formerly forbidden in naphthalene. This dilution process requires that the total oscillator strength for all of the observed transitions in αNPD

[e]Original state in unperturbed triplet naphthalene.

or αNND is not much larger than 0.10.[2] The total experimental oscillator strength for αNPD (0.19) is twice this expected value.

The absorption spectrum of βNPD does not show much vibrational structure, which could indicate a nonplanar lowest triplet state for this molecule. The perturbation of the naphthalene fragment by the phenyl oxadiazole fragment would necessarily be less important than in αNPD. However, there is no way to explain the long wavelength absorption band of αNPD in terms of a weakly perturbed naphthalene (see Fig. 4). A rather strong perturbation would be needed. Such a perturbation, ca. $W_{2p} \simeq -21$ eV, would in turn be associated with a strong absorption band in the region 450–500 nm (see Table 1) which is not observed experimentally. So there seems to be no way to explain the T–T absorption spectrum of βNPD in terms of a β perturbed naphthalene molecule.

It is thus believed that the long wavelength absorption band of βNPD is due to an important contribution of charge transfer configurations due to a delocalization of π electrons over the entire molecule. Therefore contribution of charge transfer configurations in the more nearly planar αNND and αNPD triplets should be even more important.

Conclusions

The apparent similarity between the calculated T–T spectrum of a strongly α perturbed naphthalene and the T–T spectra of αNND and αNPD is probably accidental. An understanding of the T–T spectra of aryl-substituted 1,3,4-oxadiazoles will necessitate consideration of π electron delocalization over

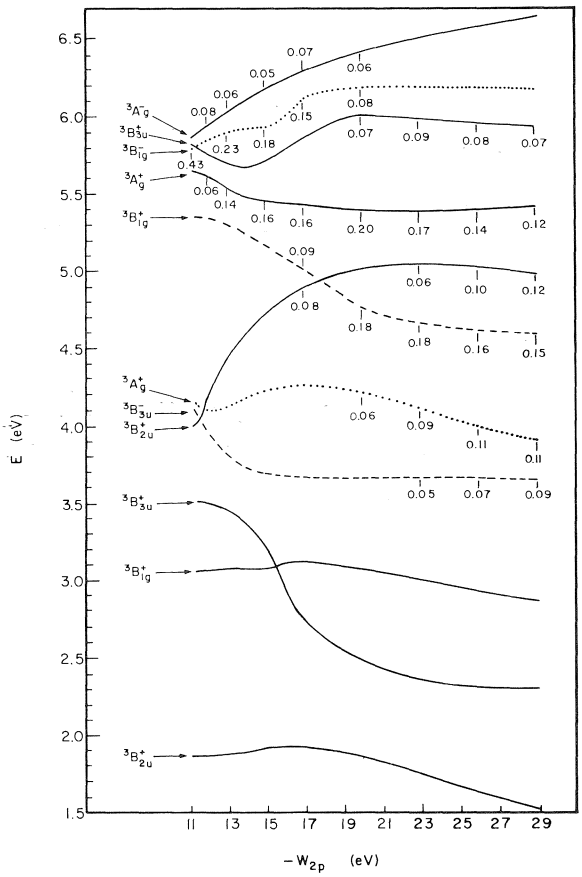

FIG. 4. The calculated energies of the lowest triplet states relative to the ground-state energy, as a function of W_{2p} of the β carbon atom of naphthalene. Oscillator strengths are indicated when larger than 0.04.

[2]One has to remember that the present calculation overestimates the energy of the transitions in the blue part of the spectrum and the oscillator strength of the transitions. The $^3B_{1g}^- \leftarrow {}^3B_{2u}^+$ transition in naphthalene is observed at 3.0 eV ($f = 0.12$) (8). The present calculation would predict it at 3.9 eV ($f = 0.43$). A large part of the discrepancy is due to the omission in our calculation of the excited configurations which are doubly excited with respect to the ground state but singly excited with respect to the first triplet state.

A new regiospecific synthesis of α,β-unsaturated ketones via acetylene derivatives[1]

JOHN HOOZ AND RICHARD D. MORTIMER

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 18, 1978

JOHN HOOZ and RICHARD D. MORTIMER. Can. J. Chem. **56**, 2786 (1978).

The reaction of trialkylalkynylborate salts with benzeneselenenyl chloride, followed by selective oxidation, provides a new synthetic pathway from acetylenes to acyclic *trans*-α,β-unsaturated ketones. The method is especially useful for preparing unsymmetric acyclic enones which are difficultly accessible using current procedures.

JOHN HOOZ et RICHARD D. MORTIMER. Can. J. Chem. **56**, 2786 (1978).

La réaction de sels trialcylakynlborates avec le chlorure de benzènesélénenyl et l'oxidation sélective subséquente offre une nouvelle voie pour la synthèse de cétones acyclics *trans*-α,β-insaturés à partir des acétylènes. La méthode est particulièrement utile pour la préparation d'énones acyclic asymétriques qui sont difficiles à obtenir par les méthodes connues présentement.

[Traduit par le journal]

The direct approach to α,β-enone synthesis (i.e., oxidation of the corresponding saturated ketone) frequently involves as the initial step the requirement of specific enol(ate) formation, and in the case of *unsymmetric* acyclic ketones, is often problematic[2] (proton transfer, etc.). We have previously reported that trialkylalkynylborate salts **1** (easily available from R_3B and $R'CH_2C{\equiv}CLi$) react stereoselectively with certain electrophiles (Sn, Se) and that this process can be useful for di- and tri-substituted olefin synthesis (5). We now wish to describe the application of reagents **1** to the synthesis of *trans*-α,β-unsaturated ketones which avoids the aforementioned problems.

The solution is outlined in the conversion **1** → **5**. This scheme owes its success to the extremely rapid rearrangement of salts **1** induced by benzeneselenenyl chloride and the selective unmasking of an α-keto-selenide **3** by initial oxidation at boron of the mixed vinyl organometallic **2**. *trans*-Enones **5** are then formed in good yield by subsequent oxidation at selenium and precedented fragmentation (6) of the intermediate ketoselenoxides **4**. In several cases we have isolated intermediates **2** and **3**; however, the entire sequence may be conveniently performed in a single reaction vessel by appropriately treating the crude mixture with the reagents sequentially.

Since the process specifically preassembles masked enones **2** directionally, it is especially applicable to synthesis of acyclic unsymmetric enones. To illustrate the method, a solution of tricyclopentylborane (3 mmol) in ether[3] (15 ml) was added to a solution of 1-lithiohexyne (from 10 mmol 1-hexyne and 10 mmol *n*-butyllithium in hexane (Alfa)) at −25°C under nitrogen with magnetic stirring. The cold bath was removed and stirring was continued for ca. 30 min. The reaction mixture was then cooled to ca. −116°C (ether – liquid N_2 slush) before the dropwise addition of the red-brown solution of C_6H_5SeCl (10.5 mmol) in 12 ml ether.[3,4]

[1]Dedicated to Professor Herbert C. Brown on the occasion of his 66th birthday.

[2]Summaries of the problems and solutions relating to the traditional method, α-bromination–dehydrobromination, appear in refs. 1–4.

[3]All organoboranes were prepared by hydroboration of the corresponding olefin with $H_3B{\cdot}DMS$ (Aldrich) in ether (7).

[4]Hydroboration with $H_3B{\cdot}THF$ and subsequent reaction with C_6H_5SeCl in THF results in significant *inter*molecular transfer of R groups from **1** (31% C_6H_5SeEt from **1**, R = Et, R′ = nC_4H_9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

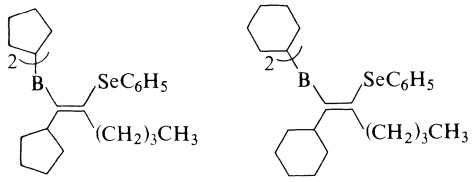
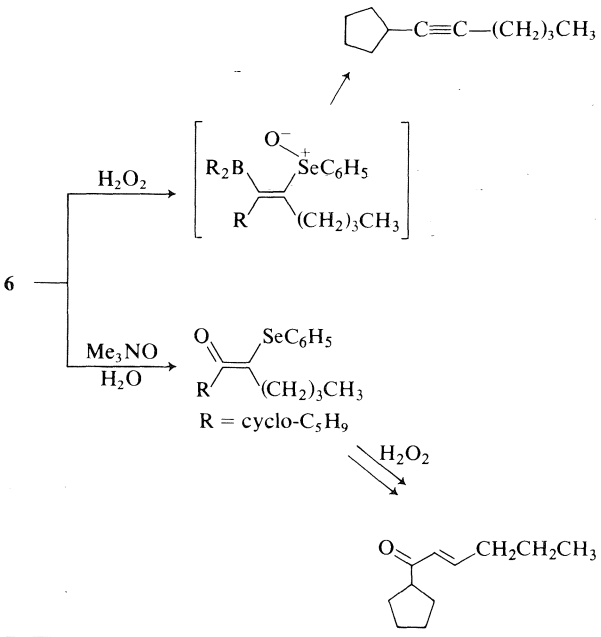
Here, as in all examples described, the reaction is essentially instantaneous at ca. −116°C as judged by the immediate discharge of color. The solution was warmed to room temperature by removing the cold bath and **6** (mp 38–39.5°C) was isolated[5] (89%)



6 **7**

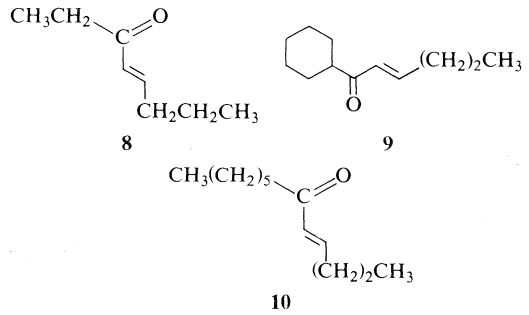
by chromatography (silica gel, hexane elution). Cyclohexyl analog **7**[5] was isolated (82%) similarly.

Successful conversion of intermediates **2** to enones depends dramatically on the choice of oxidant.[6] Compound **6**, for example, was converted to butylcyclopentylacetylene (70%) on treatment with 3 *N* NaOAc–H_2O_2 or H_2O_2 (pH 7), presumably via initial oxidation at Se and subsequent *cis*-elimination.[7] On the other hand, selective oxidation at boron is achieved with anhydrous trimethylamine *N*-oxide[8] (9) to provide the corresponding selenoketone. This



may be isolated[9] if desired (79%),[5] or the mixture further oxidized *in situ* (30% H_2O_2 (10), room temperature, 1.5 h) to the enone (69%), bp (Kugelrohr) 90°C 0.1 Torr; ir[10] (neat): 3030, 1695, 1669, 1630, 980 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 7.01, 6.73 (1H, dt, J = 16, 6.5 Hz), 6.26, 5.99 (1H, dt, J = 16, 1.2 Hz), 3.05 (1H, m), 2.15 (2H, br q), 1.9–1.2 (10H, m), 0.92 (3H, br t); ms (*m/e*) 166. *Anal.* calcd. for $C_{11}H_{18}O$: C 79.52, H 10.84; found: C 79.30, H 11.06.

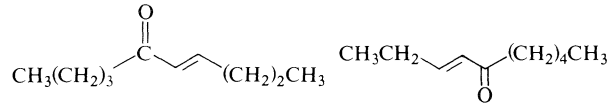
α,β-Unsaturated ketones **8**, **9**, and **10** were similarly obtained[5] (71, 75, and 61%, respectively) from their corresponding organoborane and lithioalkyne precursors.



8 **9**

10

An example of its application to the synthesis of a positional isomeric pair is the preparation of **11** (64%) and **12** (60%), substrates which are inaccessible by methods relying on specific enol(ate) formation (1, 3, 4, 12).



11 **12**

In view of the mildness and unambiguity of the method, it should augment considerably the range of enone structures available from selenoxide fragmentation.[11]

The heat of mixing of hydrogen cyanide and hydrogen fluoride in the liquid phase

JOHN L. COLLISTER AND HUW O. PRITCHARD
Chemistry Department, York University, Downsview, Ont., Canada M3J 1P3

Received June 27, 1978

JOHN L. COLLISTER and HUW O. PRITCHARD. Can. J. Chem. **56**, 2788 (1978).

An approximate measurement is reported for the heat of mixing of hydrogen cyanide and hydrogen fluoride in the liquid phase.

JOHN L. COLLISTER et HUW O. PRITCHARD. Can. J. Chem. **56**, 2788 (1978).

On rapporte une mesure approximative de la chaleur dégagée lorsque sont mêlés, en phase liquide, le cyanure d'hydrogen et le fluorure d'hydrogen.

[Traduit par le journal]

There has been considerable interest recently in hydrogen-bonded dimers, both experimentally and theoretically. In the case of the gas-phase redistribution reaction

$$(HCN)_2 + (HF)_2 \rightarrow 2HCN{\cdot}HF$$

the available experimental data (1–3) would suggest an endothermicity of about 1.0 kcal mol^{-1} (of HCN·HF product) whereas *ab initio* calculations predict that the reaction might be as much as 1.5 kcal mol^{-1} exothermic (4, 5). In considering this problem, we noticed that there is no experimental information available for liquid mixtures of HCN and HF, and we have conducted a brief exploration which shows that the liquids are miscible in all proportions, and that the temperature rise on mixing can exceed 50°C.

Liquid samples of hydrogen cyanide (mp −14°C) and hydrogen fluoride (mp −92°C) were mixed at −10°C in all rational volume ratios from 1:9 to 9:1, and the instantaneous temperature rises were measured by using a Teflon-coated thermocouple. The sum of the initial volumes of HCN and HF was always 10 ml, measured with an accuracy of about ±5% by syringe. Mixing was conducted in a polythene tube of 20 ml capacity supported in an air space held at −10°C by thermostat, and in view of the suddenness of the temperature rise, heat losses were considered to be small. The measured temperature rises, which were reproducible to better than ±2°C, are listed in column 2 of Table 1; those temperature rises which exceed 40°C are probably slightly underestimated since the final temperature was then higher than the boiling points of the two liquids, 27°C and 20°C, respectively, and vigorous boiling ensued.

We note in passing that, as with HCl and HBr (6, 7), liquid HF appears to be miscible with liquid HCN in all proportions, and no phase separation occurs when 50/50 v/v HCN/HF mixtures are cooled to −80°C.

Columns 3, 4, and 5 of Table 1 give respectively

the mole fraction of HCN and the estimated values for the heat of mixing on a cal g^{-1} and cal mol^{-1} (of liquid mixture) basis; these estimates are made from the densities of the liquids, i.e. HCN, liq., $\rho \simeq 0.7$ g cm^{-3}, HF, liq., $\rho \simeq 1.0$ g cm^{-3}, and their heat capacities, i.e., HCN, liq., $C_p \simeq 17$ cal deg^{-1} mol^{-1} (8), HF, liq., $C_p \simeq 12$ cal deg^{-1} mol^{-1} (9), assuming additivity. In view of these approximations, taken together with the experimental uncertainties, the mixing heats are probably reliable to within $\pm 20\%$.

Allene–methylacetylene isomerization over silica-supported cobalt and iron catalysts

C. P. KHULBE[1] AND R. S. MANN
Department of Chemical Engineering, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received February 20, 1978

C. P. KHULBE and R. S. MANN. Can. J. Chem. **56**, 2791 (1978).

Equilibrium between allene and methylacetylene was studied over iron catalyst in the temperature range of 165 to 200°C, with allene or methylacetylene as the initial reactant. In both cases similar equilibrium product-distribution (allene 16% and methylacetylene 84%), fairly close to the calculated value, is observed.

Kinetics of allene–methylacetylene isomerization was studied between 70 and 165°C. The order of reaction was always one and temperature independent. Both activity and calculated energy of activation (11.8 and 11.2 kcal/mol over iron and cobalt respectively) were similar for the two catalysts, suggesting that active sites for the reaction were also similar. This similarity, as well as the first order kinetics, are fully explained by a reaction mechanism based on adsorbate migration.

C. P. KHULBE et R. S. MANN. Can. J. Chem. **56**, 2791 (1978).

On a étudié l'équilibre entre l'allène et le méthylacétylène sur un catalyseur de fer à des températures allant de 165 à 200°C; on a utilisé soit l'allène soit le méthylacétylène comme produit de départ. Dans les deux cas, on a pu observer des distributions de produits à l'équilibre qui sont semblables soit 16% d'allène et 84% de méthylacétylène; ces valeurs sont en bon accord avec celles qui avaient été calculées.

On a étudié la cinétique de l'isomérisation allène–méthylacétylène entre 70 et 165°C. L'ordre de la réaction est toujours égale à l'unité et est indépendante de la température. L'activité ainsi que l'énergie d'activation calculées (11.8 et 11.2 kcal/mol respectivement pour le fer et le cobalt) sont semblables pour les deux catalyseurs; ces résultats suggèrent que les sites actifs pour la réaction sont aussi semblables. Cette similarité de même que la cinétique du premier ordre sont expliquées par un mécanisme réactionnel basé sur une migration du produit adsorbé.
[Traduit par le journal]

Introduction

While the isomerization (double bond migration) of olefins, diolefins, and substituted diolefins (1–9) has been studied extensively, very little has been reported about acetylene–allene isomerization.

On treatment of acetylenic compounds with a base, hydrogen from a propargylic methylene group migrates to the triple bond carbon atom, thus giving allenic compounds or, on further migration, a mixture of acetylenic compounds including allene derivatives. The alkoxide-catalyzed rearrangement of ethylacetylene to dimethylacetylene was described as a prototropic rearrangement with methylallene as an intermediate (9). The postulation of an allenic intermediate in this process was supported by the rearrangement of isopropylacetylene to 3-methylbuta-1,2-diene catalyzed by KOH–ETOH at 170°C, the subsequent formation of 2-alkyne being impossible in this case by the fact that *tert*-butylacetylene was unchanged under comparable conditions (10). In his review, Iwai (11) has summarized acetylene–allene isomerization.

Kamentzy and Markovich (12) calculated equilibrium data for the isomerization of allene

TABLE 1. Equilibrium constants for allene–methylacetylene isomerization (ref. 12)

T (°C)	κ	% of allene
82	15.5	6.0
200	9.9	10.0
400	5.5	15.3
500	4.7	17.4
600	4.2	19.2

at different temperatures by the statistical method using spectroscopic data obtained by Linnett and Avery (13) for allene, and by Crawford (14) for methylacetylene, and the heat of hydrogenation obtained by Kistiakowsky and co-workers (15). Table 1 shows the equilibrium constants and percentage of allene in equilibrium mixture at various temperatures.

On the basis of equilibrium data calculated by Kamentzy and Markovich (12), Bond and Sheridan (16) suggested that the reaction should occur on supported or unsupported metals. In the hydrogenation of allene on pumice-supported nickel, palladium, and platinum (16), they could not obtain even traces of methylacetylene. Though the rearrangement of allenes and acetylenes could be obtained by different means, nothing has been reported about the allene–methylacetylene isomerization reaction catalyzed by supported or unsupported metals.

Chang and Kokes (17) studied the isomerization of methylacetylene over zinc oxide. The kinetics of the first half of allene isomerization to methylacetylene could be represented fairly well by first order. The infrared studies show a similarity between the adsorbed state of allene and methylacetylene, indicating the same adsorbed species for both the compounds.

Preliminary studies of allene isomerization over unsupported and silica-supported copper, nickel–copper alloy, and the transition metals of Group VIII showed that only silica-supported iron and cobalt were active for the isomerization reaction. The present paper deals with the equilibrium and kinetic studies and mechanism of allene–methylacetylene isomerization over silica supported cobalt and iron catalysts.

Experimental

The experiments were performed in a constant volume static conventional high vacuum system. The details of the apparatus are given elsewhere (18).

Metal catalysts containing 5% metal were prepared using Fisher Scientific Co. certified $Co(NO_3)_2 \cdot 6H_2O$ and $Fe(NO_3)_2 \cdot 9H_2O$, which in turn contained less than 0.05 wt.% metals as impurity. Silica (EH-5), supplied by Cabot Corporation, Boston, was heated at 650°C for about 12 h and then mixed with a solution of about 0.5 g of the desired compound in about 100 cm^3 of acetone. The slurry thus obtained was stirred and dried at room temperature. The impregnated catalyst was then crushed into fine powder.

The reaction vessel containing the catalyst was sealed and evacuated until a high vacuum (10^{-4} Torr) was obtained. A stream of hydrogen (80 cm^3/min) was passed through the reactor and the temperature raised slowly to 400°C in about 12 h and then maintained constant for 24 h. The hydrogen stream was stopped and the reaction vessel allowed to cool to room temperature in about 200 mm Hg of hydrogen. Following hydrogenation the catalyst was reduced again and evacuated for 4 h at 450°C and then cooled to room temperature under vacuum for isomerization studies.

To stabilize its activity the catalyst was aged by introducing allene (50 mm) at room temperature. The reactor was connected to the liquid nitrogen trap after 30 min. Allowing sufficient time for condensation, the trap was disconnected and the gases were analyzed with the help of a Hewlett-Packard Research Gas Chromatograph employing 16 ft × 1/4 in. column at 35°C, packed with 30% dimethylsulpholane on acid washed 20–60 mesh chromosorb P using helium (25 cm^3/min) as the carrier gas. After about ten treatments when a constant activity (same distribution) was obtained, the desired temperature was maintained with the help of a temperature controller. A definite amount of allene (50 mm Hg) was introduced into the reactor and the gas was analyzed after a certain time. The same amount of gas was introduced again and the analysis made at different time intervals. Runs were made for different allene pressures, to obtain the order of reaction with respect to initial allene pressure, and at several temperatures.

Results and Discussion

Equilibrium Studies

Equilibrium between allene and methylacetylene was studied over silica-supported 5% iron (weight = 0.67585 g) catalysts between 165 and 200°C. Starting with a 50 mm sample of pure allene, the distribution of isomers was followed by analyzing the samples at various time intervals, and that at 185°C in Fig. 1 is shown. The analysis showed that equilibrium could be obtained in about 12 h and that equilibrium values were nearly constant (5.275 ± 0.025) within the studied temperature range. Similar values were obtained for the equilibrium distribution (κ = 5.393 ± 0.143) when methylacetylene was taken as the reactant and samples were analyzed after a time interval of 12, 24, and 36 h.

At 200°C, the equilibrium mixture should contain about 90% methylacetylene (12). Slobodine (19) studied the equilibrium of allene–methylacetylene isomerization by passing these substances over "Floridine" between 167 and 350°C. With methylacetylene as the initial substance, the resulting mixture contained about 61.5 to 67.8% methylacetylene at 325°C. On the other hand, with allene as the initial substance, except at 325°C, the resulting mixture contained a much lower percentage of methylacetylene. No direct determination of the allene content of the mixtures were carried out. The polymeri-

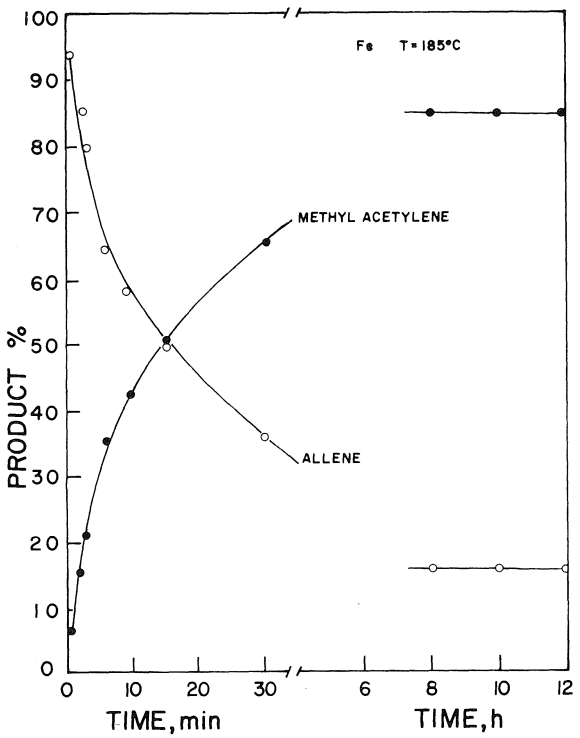

FIG. 1. Allene–methylacetylene distribution on silica supported iron catalyst.

zation and decomposition reactions must have proceeded to a considerable extent and their products diluting the resulting mixture. It seems, therefore, quite natural that the methylacetylene contents of the mixture were, in all cases, lower than the theoretical value. Cordes and Gungler (20) obtained an equilibrium mixture containing 20% allene and 80% methylacetylene at 300°C by heating these isomers as the initial substance in the presence of activated charcoal. In the present study, starting with allene or methylacetylene, an equilibrium mixture containing about 16% allene and 84% methylacetylene was obtained in the studied temperature range. This is fairly close to the calculated values (12).

Kinetics

Varying amounts of allene were introduced into the reactor and the samples analyzed after various time intervals. As no pressure change was observed during the reaction polymerization could not have occurred. Analysis showed that only allene and methylacetylene were present in the products and thus neither isomer could have been fragmented. To established the kinetics, results were analyzed using two different approaches. In one case, the initial rate of allene isomerization was calculated assuming a first order reversible reaction. In another case the initial rate of methylacetylene was obtained using the initial rate method. The initial rate of allene isomerization was always equal to the initial rate of methylacetylene formation.

Initial Rate of Allene Isomerization

Assuming a first order reversible reaction for allene–methylacetylene isomerization, the following equation was developed

$$[1] \qquad r_i = (1 - y_e)\frac{P}{t}\ln\left(\frac{1 - y_e}{y - y_e}\right)$$

where r_i = initial rate of allene isomerization mm/min; y = fraction of allene left after time t; y_e = fraction of allene at equilibrium; P = initial pressure of allene in mm; and t = time in min.

For all calculations y_e value obtained in the present study was used. At a particular initial pressure and temperature, r_i was calculated using product analysis values at different time intervals and eq. [1]. The initial rate calculated was found to be constant (Table 2). This indicates that the assumption of a first order reversible reaction is valid.

Initial Rate Method

Partial pressures of methylacetylene were plotted against time. Initial rate, at a particular initial allene pressure and temperature, was obtained by drawing a tangent on the pressure time curve at $t = 0$ (Figs. 2 and 3). The slope of the tangent gave the initial rate of methylacetylene formation (r_G values, Table 2), which was always equal to the calculated initial rate of allene isomerization.

TABLE 2. Kinetics of isomerization on iron catalyst at 135°C

Figures 2 and 3 show the pressure–time curves for methylacetylene on Fe and Co respectively. Using these curves or eq. [1] the isomerization reaction was observed to be of first order and temperature independent on both catalysts. Hence the initial rate expression for allene isomerization can be written as

$$[2] \qquad r_0 = kP_{\text{allene}}$$

The energy of activation was calculated to be 11.8 and 11.2 kcal/mol for Fe and Co, respectively. The activity (defined as the rate constant per g of catalyst for initial allene pressure of 50 mm Hg at 127°C) was nearly equal for iron ($k_{127} = 0.0250$ min^{-1}/g) and cobalt ($k_{127} = 0.0253$ min^{-1}/g) catalysts. No direct comparison can be made with other catalysts or their physical characteristics as only iron and cobalt were active for the isomerization reaction.

In the hydrogenation of allene on silica-supported cobalt catalysts, traces of methylacetylene were observed at higher allene pressures (18). No such mention is made by previous workers on the hydrogenation of allene or methylacetylene (16, 21–23). However, Kokes *et al.* (24, 25) observed a first order methylacetylene–allene isomerization reaction catalyzed by ZnO.

Reaction Mechanism

The infrared studies of allene adsorbed on cobalt/silica catalyst revealed the presence of only

$$CH_2{=}C{-}CH_2$$
$$\quad\;\; |\quad\; |$$
$$\quad\;\; *\quad\; *$$

species (18) on the surface of the catalyst. No absorption bands assigned to the $-CH_3$ group was observed. On the addition of hydrogen to allene

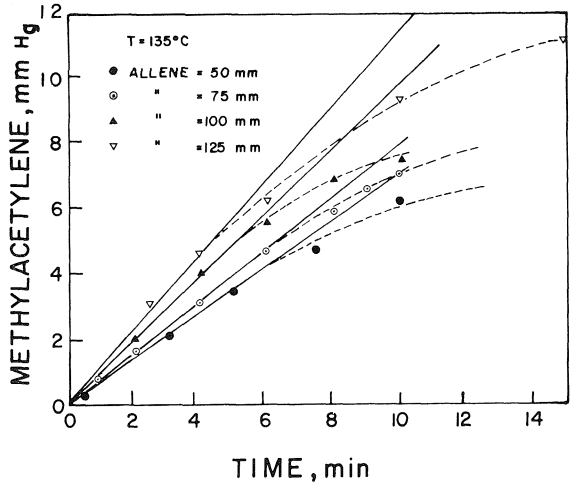

FIG. 2. Formation of methylacetylene (Fe catalyst).

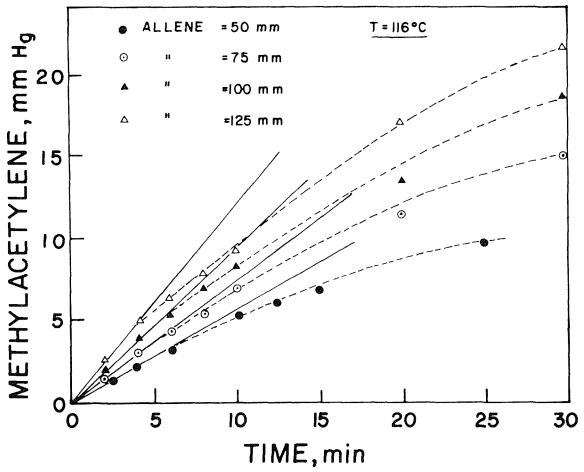

FIG. 3. Formation of methylacetylene (Co catalyst).

exposed catalyst, the

$$CH_2{=}C{-}CH_2$$
$$\quad\;\; |\quad\; |$$
$$\quad\;\; *\quad\; *$$

species converted to $CH_3{-}CH_2{-}CH_2{-}M$ species, indicating that the dissociative adsorption of allene was not taking place and any methylacetylene formed was not retained on the catalyst surface.

In the hydrogenation of allene over Co–silica catalyst at higher allene pressures (allene/H_2 ratio of 3.0 or more) traces of methylacetylene were observed. At an allene/H_2 ratio of 2.5 or less, no methylacetylene was observed in the product. This indicates that probably hydrogenation and isomerization reactions were taking place at different active sites and the rate of hydrogenation was much higher than the rate of allene isomerization.

Though unsupported Fe and Co and other supported or unsupported catalysts were active for allene hydrogenation they were inactive for allene isomerization, possibly because of the irreversible adsorption of allene or methylacetylene on the catalyst surface. It is logical to assume that unsupported Fe and Co were inactive for isomerization reaction as they were active for allene or methylacetylene hydrogenation (16, 18, 21, 22). If the inability of Fe and Co for allene–methylacetylene isomerization was due to irreversible adsorption of allene or methylacetylene, these catalysts should not be active for allene or methylacetylene hydrogenation. In the present study Fe–silica catalyst deactivated continuously on hydrogenation of allene, probably because of the formation of surface carbides. This is also an indication that the isomerization reaction was not occurring on the metal surface as the Fe–silica catalyst was active and stable for the isomerization reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

The nearly equal activity and energy of activation for the two catalysts suggests that the isomerization reaction was occurring on the same active sites, probably the silica surface, and the rate-determining step was the same. In the present study silica showed no activity for the isomerization reaction.

For many years, it was generally believed that the support was inert and simply acted as a carrier for the metal in a finely divided high area form. There is now growing evidence that the support may not be inert but may influence the catalytic activity in any of several ways: it may interact chemically with the metal thereby modifying the properties of the metal; the support may exert an influence on the actual structure of the metal; or the support may act either as a source of reactive intermediates or as a seat of reaction, through the migration of adsorbed species between metal and support.

The phenomenon of surface migration between metal and support, "Spill-over" (27), has been shown to be of particular importance with hydrogen on supported metals. Altham and Webb (28), who used tritium and radioactive approach to monitor the extent of hydrogen spill-over on platinum–silica and platinum—alumina catalysts, observed that in the absence of platinum, neither alumina nor silica was active for olefin exchange at temperatures below 250°C. However, when the metal was present, both silica and alumina possessed an appreciable activity for olefin and hydrogen exchange at ambient temperatures, although neither oxide was active for olefin hydrogenation.

Evidence for the participation of the support in the reaction of olefins and acetylenes over supported metals has been obtained by the use of catalyst poisons. Webb and MacNabb (29) studied the hydrogenation, hydroisomerization, and deuterium exchange of 1-butene over rhodium–silica in the temperature range 0–69°C. The results have been satisfactorily interpreted by considering the hydrogenation and 1-butene exchange to be confined to the surface of metals only, and the isomerization occurring on the support and involving the migration of hydrocarbon from the metal to the support. Since, in the absence of rhodium, silica itself showed no isomerization activity in the temperature range studied and the reversible adsorption of 1–butene on silica did not occur to any appreciable extent, rhodium must have therefore activated the surface of silica by adsorbing the hydrocarbon which then migrated to the support before undergoing reaction.

On the basis of present observations and related literature, it can be assumed that the isomerization of allene to methylacetylene was occurring on the surface of silica activated by Fe and Co. It is possible that other metals are not active for the surface migration of allene from metal to silica support.

The thermal isomerization of alkadienes apparently involves "detachment" of hydrogen (26)

$$H_2C{=}C{=}CH_2 \rightleftarrows [\dot{H}C{=}C{-}\dot{C}H_2 + H] \rightleftarrows HC{\equiv}C{-}CH_3$$

$$H_2C{=}C{=}\underset{\displaystyle CH_3}{\underset{|}{C}}{-}CH_3 \rightleftarrows [\dot{H}_2C{=}C{-}\underset{\displaystyle CH_3}{\underset{|}{\dot{C}}}{-}\dot{C}H_2 + H]$$

$$\uparrow\downarrow$$

$$H_2C{=}\underset{\displaystyle H}{\underset{|}{C}}{-}\underset{\displaystyle CH_3}{\underset{|}{C}}{=}CH_2$$

When allene was heated with ether and sodium at 100°C, allene yielded the sodium derivative of methylacetylene (19). Allene treated for 12 h at 160 to 170°C with alcoholic potash gave methylacetylene and ethyl isopropenyl ether (intermediate product) together with unreacted allene (10).

$$H_2C{=}C{=}CH_2 + C_2H_5OH \rightleftarrows H_2C{=}\underset{\displaystyle OC_2H_5}{\underset{|}{C}}{-}CH_3$$

$$\rightleftarrows HC{\equiv}C{-}CH_3 + C_2H_5OH$$

The reaction path for the base catalyzed acetylene–allene isomerization is presumed to be (11):

$$RCH_2{-}C{\equiv}CH + B^- \rightleftharpoons \dot{R}\dot{C}H{-}\dot{C}{=}\dot{C}H + HB$$

$$\downarrow\uparrow$$

$$RCH{=}C{=}CH_2 + B^-$$

Though in the present study there is no evidence of hydrogen detachment from the allene molecule, for simplicity it can be assumed that on the silica surface the reaction was occurring as base catalyzed allene–methylacetylene isomerization. Considering the above-mentioned assumptions the overall reaction mechanism can be represented as follows

$$\text{Allene (g)} \rightleftarrows \text{allene (adsorbed on metal)}$$

$$\downarrow\uparrow$$

$$[\dot{C}H_2{-}\dot{C}{=}CH] \underset{+H}{\overset{-H}{\rightleftharpoons}} \text{allene (adsorbed on silica)}$$

$$+H\downarrow\uparrow -H$$

$$CH_3{-}C{\equiv}CH \text{ (adsorbed on silica)} \rightleftarrows CH_3{-}C{\equiv}CH \text{ (adsorbed on metal)}$$

$$\downarrow\uparrow$$

$$CH_3{-}C{\equiv}CH \text{ (gas)}$$

To confirm the isomerization reaction mechanism, further work is in progress.

The nature of green alkaline iron sulfide solutions and the preparation of sodium iron(III) sulfide, $NaFeS_2$

PETER TAYLOR AND DAVID W. SHOESMITH

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received April 12, 1978

PETER TAYLOR and DAVID W. SHOESMITH. Can. J. Chem. **56**, 2797 (1978).

The intense emerald green solutions formed by the reaction of iron salts with alkali metal sulfides at pH 11–13 have been found to contain colloidal $MFeS_2$, M = Li, Na, K. Solid $KFeS_2$ and $NaFeS_2$ have been recovered from these systems. X-ray powder diffraction studies confirmed the identity of $KFeS_2$, and showed $NaFeS_2$ to have a structure different from those of other $MFeS_2$ compounds, and related to that of the mineral rasvumite, $K_3Fe_9S_{14}$. Some aspects of the crystal structures and chemistry of different $MFeS_2$ compounds are discussed. A mechanism for the formation of colloidal $MFeS_2$ is proposed on the basis of kinetic data. It is likely that colloidal $NaFeS_2$ is responsible for the colour of the "green liquor" of the pulp and paper industry.

PETER TAYLOR et DAVID W. SHOESMITH. Can. J. Chem. **56**, 2797 (1978).

On a trouvé que les solutions d'un vert émeraude intense qui se forment par réaction des sels de fer avec les sulfures des métaux alcalins à des pH de 11–13 contiennent du $MFeS_2$, M = Li, Na, K à l'état colloïdal. On a pu récupérer du $KFeS_2$ et du $NaFeS_2$ à l'état solide à partir de ces systèmes. Des études de diffraction de rayons-X sur des poudres ont confirmé l'identité du $KFeS_2$ et ont démontré que le $NaFeS_2$ possède une structure différente de celle des autres composés $MFeS_2$ et qu'elle est reliée à celle de la rasvumite minérale, $K_3Fe_9S_{14}$. On discute de quelques aspects des structures cristallines et de la chimie des différents composés $MFeS_2$. On propose un mécanisme pour la formation du $MFeS_2$ à l'état colloïdal en se basant sur les données cinétiques. Il est vraisemblable que le $NaFeS_2$ à l'état colloïdal soit responsable pour la couleur de la "liqueur verte" de l'industrie des pâtes et papiers.

[Traduit par le journal]

Introduction

The existence of an intense green iron sulfide species in alkaline solution has been known since 1801 (1). It was reported extensively in the early literature on iron sulfide chemistry, and a compilation of many of these observations is given by Mellor (ref. 2, pp. 144–183). It does not appear to have been characterized satisfactorily, and has been variously identified as colloidal ferrous sulfide (ref. 2, p. 146), $FeS{\cdot}4Na_2S$ (ref. 2, p. 166, ref. 3), hydrated ferric sulfide (ref. 2, p. 181), colloidal $MFeS_2$, M = K, NH_4 (ref. 2, p. 182, ref. 4), $Na_3[Fe(S)(OH)_3]$ (5, 6), and even colloidal sulfur (7). We first observed the green species in the course of an electrochemical study of the reaction of aqueous sodium sulfide solutions with iron (8), performed as part of an investigation of carbon steel corrosion by aqueous hydrogen sulfide in heavy water plants. It was desirable to establish the identity of the green material, in order to understand the electrochemical processes involved, and to resolve the confusion in the literature. It is curious that there are few references to this material in the recent literature when it was so commonly encountered, but not satisfactorily characterized, by earlier workers.

Results and Discussion

Preparation and Identification of the Green Species

Intense green solutions giving similar visible spectra have been obtained from reactions of a variety of iron-containing materials with excess MSH (M = Li, Na, K) in aqueous solution at pH 11 to 12. The green species formed rapidly with ferric nitrate, but with ferrous salts it appeared more slowly, and only on exposure to the air. It was also produced electrochemically under conditions appropriate for the generation of Fe^{3+} at an iron electrode (8).

For M = Na or K, the green material could be precipitated as a green–black solid by the addition of an equal volume either of acetone, or of 1 mol dm^{-3} MOH or MCl. Total, irreversible precipitation occurred, indicating that flocculation of colloidal material, rather than precipitation by depression of solubility or a common ion effect, had occurred. This is consistent with the many early references (ref. 2, pp. 144–183) to the green material as a colloid. For M = Li, the colloid was more difficult to flocculate, and its chemical stability was lower, so that the lithium-containing solid was not readily isolable, and was not studied further.

*A, major lines from pattern in Table 1; B, diffractometer data for material prepared on 200 mg scale and heated to 400°C *in vacuo* (major lines only); C, unidentified material prepared by Erd *et al.* (12); D, material prepared by Böttcher (footnote 1 in text) and analyzed as $Na_{0.95}Fe_{0.96}S_2.1.84\ H_2O$; no intensities were given.

The solid recovered from potassium-containing solutions was identified by X-ray powder diffraction (9) as poorly crystallized $KFeS_2$. Larger scale reactions, using a modified experimental procedure, showed that conversion of $Fe(NO_3)_3 \cdot 9H_2O$ to $KFeS_2$ was quantitative. Sodium-containing solutions yielded a solid with a diffraction pattern completely different from that of $KFeS_2$ or any other ABS_2 solid listed in the file of the Joint Committee for Powder Diffraction Standards up to volume 27 (1977). Diffraction lines are broad, as a consequence of small crystallite size, but reproducible, and the pattern has been indexed satisfactorily on the basis of a monoclinic unit cell ($a = 1069$, $b = 910$, $c = 551$ pm, $\beta = 92.1°$) (Table 1) similar to the orthorhombic cell ($a = 1108$, $b = 912$, $c = 547$ pm) of the mineral rasvumite (10), $K_3Fe_9S_{14}$. The diffraction pattern is also very similar to those obtained by Bronger (11) and Böttcher[1] from material prepared in attempts to synthesize $NaFeS_2$ from Na_2S_2, Fe, and S or Na_2CO_3, Fe, and S, and by Erd *et al.* (12) from material prepared by the reaction between solutions of $FeCl_3$ and NaSH at pH 11 (Table 2). The apparent structural similarity between the sodium salt and rasvumite, $K_3Fe_9S_{14}$ (ref. 9, card 25-263, ref. 10) suggests that the former is $Na_3Fe_9S_{14}$ rather than $NaFeS_2$, but this is not consistent with the preparative evidence discussed below. It is easier to reconcile the $K_3Fe_9S_{14}$-like structure with the $NaFeS_2$ stoichiometry if $K_3Fe_9S_{14}$ is formulated as a salt of the FeS_2^- anion, $K_3(Fe^{II})_2(Fe^{III}S_2)_7$, with four alkali metal atoms in an $MFeS_2$ structure replaced by two Fe^{II} atoms and two vacant sites.

The preparation of the sodium salt parallels

exactly that of $KFeS_2$, which strongly suggests that it is $NaFeS_2$; this conclusion is supported by the similarity of the visible spectra. Freshly flocculated $KFeS_2$ and $NaFeS_2$ in suspension gave the same spectrum as the colloidal suspensions, although less well defined due to the increase in particle size. After filtration, the solid appears black, but dried thin films remain intense green in transmitted light, so it is unlikely that any structural change occurs during the process of flocculation and isolation of the solid. Although the weights of sodium salt obtained from larger-scale preparations were consistent with the formulation $NaFeS_2 \cdot 2H_2O$, this water was removed by continuous pumping at ca. 100°C without any observable change in the diffraction pattern. Further heating *in vacuo* at 450°C for 88 h produced no change in the diffraction pattern, other than sharpening of the peaks due to improved crystallinity, and the appearance of peaks attributable to pyrite (cubic FeS_2) and pyrrhotite ($Fe_{1-x}S$). These phases may have been present as impurities, or arisen from partial decomposition of the sample. There are three possible interpretations of the lack of major changes in the diffraction pattern upon dehydration. The water may occupy channels within the $NaFeS_2$ structure; it may be adsorbed or occluded rather than incorporated in the crystal structure, or it is possible that the initial product consisted in part of an X-ray amorphous hydrated salt $NaFeS_2 \cdot xH_2O$. It is not possible to distinguish between these three models without more detailed structural data, although the consistent formation of material with the approximate stoichiometry $NaFeS_2 \cdot 2H_2O$ favours the first model. Schneider (ref. 2, p. 183) reported the synthesis of $NaFeS_2 \cdot 4H_2O$ under conditions analogous to those he used to prepare $KFeS_2$, and the products prepared by Bronger (11) and Böttcher[1] analyzed as $Na_{1+x}Fe_{1-x}S_2 \cdot yH_2O$, with $0.19 \geq x \geq -0.08$ and $2 \geq y \geq 1.4$. Elemental analyses of the very finely divided, air-sensitive material produced in this work were irreproducible. However, three separate preparative experiments yielded iron content, based on weights of starting material and product, of 37.3, 38.2, and 40.9% (calcd. for $NaFeS_2$, 39.1%), while sulfur analysis of freshly prepared material gave a mean value for five determinations of 41.0% (calcd. 44.9%). The combination of preparative, spectroscopic, crystallographic, and analytical data thus strongly supports the identity of the material as $NaFeS_2$, although the nature of its hydration is uncertain.

It is interesting that $NaFeS_2$ adopts a different structure from the other alkali metal thioferrates, $MFeS_2$, M = K, Rb, Cs, all three of which have closely related structures. The similar visible spectra of $NaFeS_2$ and $KFeS_2$ indicate that the anion has the same structure in both salts. $KFeS_2$ is known (14) to consist of infinite linear di-μ-sulfido-bridged polymeric chains, each iron being tetrahedrally coordinated by sulfur while each potassium has eight neighboring sulfur atoms. It is likely that $NaFeS_2$ consists of similar $(FeS_2)_n^{n-}$ chains, but that they are constrained to a different crystal packing arrangement by the preference of the smaller sodium ion for a lower coordination number than potassium. A more detailed structural discussion is not possible without single crystal data for $NaFeS_2$.

Teder (15) has prepared green solutions by dissolving sodium sulfide (prepared by reduction of reagent grade sodium sulfate with hydrogen in an alumina tube at 500°C) in water, and the spectra he observed are very similar to those we obtained from samples of colloidal $MFeS_2$. He attributed these spectra, and hence the "green liquor" obtained by dissolution of sodium sulfide/carbonate mixtures prepared in recovery furnaces in the pulp and paper industry, to some unidentified sulfide species, but it is likely that they arise from traces of colloidal $MFeS_2$. The colour of "green liquor" had been previously, and we believe correctly, attributed to iron compounds (16).

The Chemistry of Formation of Colloidal $MFeS_2$

A series of experiments was performed to study the rate of formation of $NaFeS_2$ as a function of NaSH and $Fe(NO_3)_3$ concentration at pH = 11 to 13, maintaining constant ionic strength by addition of $NaNO_3$ solution. Below pH ≃ 11, colloidal $MFeS_2$ was not formed, while above pH ≃ 13, it tended to flocculate. The three peaks in the visible spectrum at 640 nm (ε = 11 600), 530 nm (ε = 5300), and 435 nm (ε = 7000) developed in unison (Fig. 1), confirming that all three peaks arise from the same species. Extinction coefficients were obtained from

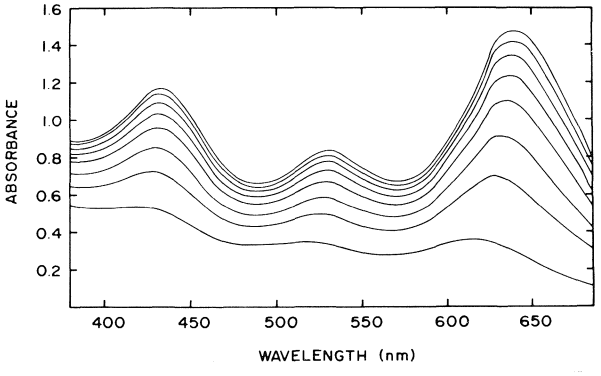

FIG. 1. Development of the spectrum of colloidal $NaFeS_2$ during a typical kinetic experiment ($[Fe^{3+}] = 2.12 \times 10^{-4}$ mol dm^{-3}; $[SH^-] = 2 \times 10^{-2}$ mol dm^{-3}); pH 11; first scan started 1 min after mixing; subsequent scans at 2 min intervals but alternate scans omitted.

the spectra of solutions in which the reaction was complete, and are based on iron concentrations. The high values of these coefficients indicate that all three features arise from charge transfer transitions. The initial appearance of the spectrum occurred with approximately first order reaction kinetics in both iron and sulfide concentrations (Figs. 2 and 3), but a lack of knowledge of the relationship between extinction coefficient and polymer chain length of the product anion precludes a detailed treatment of the initial kinetics.

Assuming only that the initial iron moiety is monomeric and that the final product is the polymeric anion, $(FeS_2)_n^{n-}$, the reaction must involve the coordination of two SH^- or S^{2-} ions to each Fe, a polymerization process, and the elimination of hydroxide ions and water molecules. Dissociation data for H_2S (17, 18) and ferric ion (19) indicate

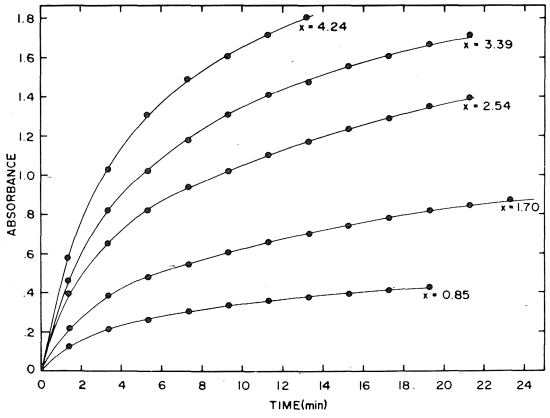

FIG. 2. Plots of absorbance at the maximum of the peak at ca. 630 nm as a function of time; pH 11; $[SH^-] = 10^{-2}$ mol dm^{-3}; $[Fe^{3+}] = 10^{-4}x$ mol dm^{-3}.

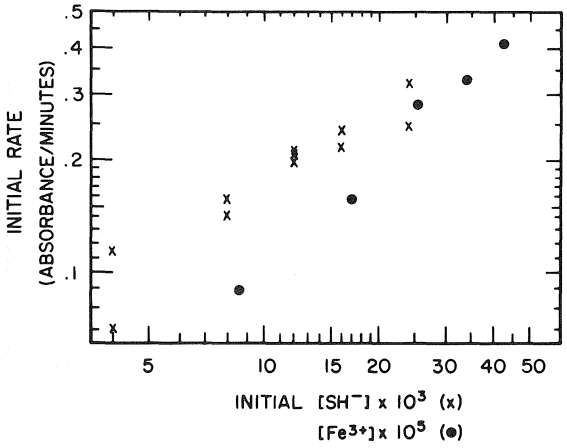

FIG. 3. Plots of initial rate of reaction as a function of (*a*) initial $[Fe^{3+}]$ at an initial $[SH^-]$ of 10^{-2} mol dm^{-3}; (*b*) initial $[SH^-]$ at an initial $[Fe^{3+}]$ of 2.12×10^{-4} mol dm^{-3}.

that SH^- and $Fe(OH)_4^-$ are the predominant sulfur and iron species, respectively, present under our reaction conditions. Reaction rates were similar at both pH 11 and 13, consistent with SH^- and $Fe(OH)_4^-$ being the reactive species. The reaction rate was reduced when the ferric solution was permitted to stand after the addition of NaOH to adjust the pH, but before addition of NaSH, for as little as 5 s. After longer periods of aging of the ferric solution, an induction period became apparent (Fig. 4). This can be attributed to retardation of the formation of $NaFeS_2$ by polymerization of the initial ferric species. We were constrained by the stability and detection limits of $NaFeS_2$ to work with supersaturated iron solutions.

No significant difference in rate or final yield of $NaFeS_2$ was observed between reactions performed in N_2-saturated and air-saturated solutions. If the redox reaction between Fe^{3+} and SH^- was competitive with the formation of $MFeS_2$, then a higher yield of $MFeS_2$ would accrue from the reaction in the presence of air, in which ferric ion would be regenerated. This result implies that the polymerization process is very fast, since the redox reaction is facile.

A slight shift of the spectral peaks to longer wavelength as the reaction proceeds is consistent with a progressive increase in polymer chain length of the product. When $NaFeS_2$ was prepared electrochemically, it was formed rapidly by generation of Fe^{3+} at an electrode surface, and continually swept into solution, where reaction ceased, since Fe^{3+} was absent (12). Under these circumstances, no shift in the spectrum with increasing $NaFeS_2$ concentration was observed.

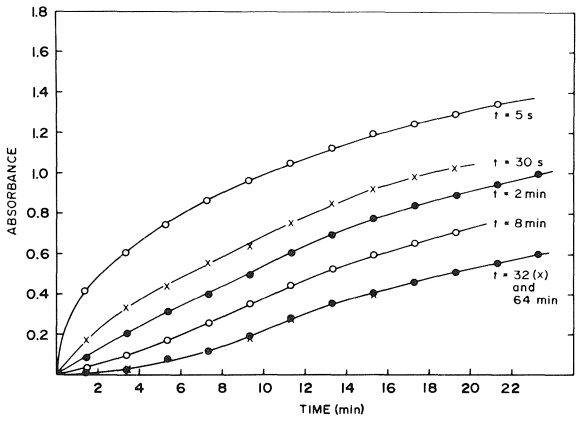

FIG. 4. Plots of absorbance at the maximum of the peak at ca. 630 nm as a function of time, showing the variation of reaction rate with the time interval, *t*, between making the iron solution alkaline, and adding the sulfide solution. $[Fe^{3+}] = 2.12 \times 10^{-4}$ mol dm^{-3}; $[SH^-] = 2 \times 10^{-2}$ mol dm^{-3}; pH 11.

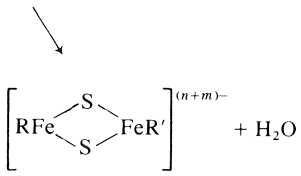
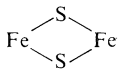
A plausible simplified mechanism for the formation of $MFeS_2$, which is consistent with all of these observations, is outlined by reactions [1] and [2], the first reaction being rate determining. The unit $RFe(OH)_2$ represents $Fe(OH)_4^-$ initially, and growing polymeric species of the type  in the subsequent stages of reaction.

[1] $[RFe(OH)_2]^{n-} + SH^- \rightarrow [RFe(OH)(SH)]^{n-} + OH^-$

[2] $[RFe(OH)(SH)]^{n-} + [R'Fe(OH)(SH)]^{m-}$



We note that a large number of compounds with



linkages have been prepared as model compounds for ferredoxins (20) and that $KFeS_2$ has been of some interest in this regard (21).

Decomposition of $MFeS_2$

Both $NaFeS_2$ and $KFeS_2$ decompose rapidly in acid solution with production of H_2S and sulfur (ref. 2, p. 183, ref. 5). This reaction can be represented by the overall stoichiometry [3], and probably proceeds by protonation of the S-bridges [4] and

[3] $2MFeS_2 + 6H^+ \rightarrow 2M^+ + 2Fe^{2+} + 3H_2S + \frac{1}{8}S_8$

[4] 
subsequent redox reaction of Fe^{III}—SH groups. At pH 11 or greater the $MFeS_2$ salts are stable in the presence of SH^-, without special precautions to exclude air. In the absence of SH^-, the salts decompose quite rapidly. At 80°C, $NaFeS_2$ decomposes rapidly in alkaline solution in the absence of air, even in the presence of SH^-, with production of polysulfides, identified by uv–visible spectroscopy (22). These observations suggest that $[FeS_2]_n^{n-}$ is somewhat susceptible to nucleophilic attack by base, [5]

[5] 
and subsequent redox reaction, and that this reaction is suppressed by SH^-. The evidence that terminal Fe^{III}—SH or Fe^{III}—S^- groups readily undergo redox reaction supports the conclusion that the postulated polymerization steps [2] in the formation of $MFeS_2$ must be rapid. The stability of the $[FeS_2]_n^{n-}$ structure towards internal redox reaction is further exemplified by the high thermal stability of $MFeS_2$, M = K, Rb, Cs, which are prepared by fusion reactions at 800°C (5, 11); $KFeS_2$ also occurs as a by-product in cement furnaces (23). This is in sharp contrast with ferric sulfide itself, the very existence of which is open to question (13), and which is constrained by its stoichiometry to have a structure quite different from the $[FeS_2]_n^{n-}$ anion.

Finally, a rather remarkable reaction occurred when dry solid $NaFeS_2$ or $KFeS_2$ was added to 1 mol dm^{-3} lithium hydroxide solution. An intense green colour developed rapidly in the solution, the spectrum of which showed the three characteristic $MFeS_2$ peaks. The colour persisted only for a few minutes, after which a brown precipitate, presumably a ferric oxide/hydroxide, appeared. In corresponding reactions with 1 mol dm^{-3} NaOH, only a very faint green colour was observed, but a brown solid was formed, and the solution turned yellow overnight. The solution was shown by its uv–visible spectrum to contain polysulfides. The reason for the redispersal of $MFeS_2$ in LiOH is not clear, but it may involve electrophilic attack on sulfur bridges by Li^+, [6], analogous to the protonation reaction [4], with consequent fragmentation of the polymer and redox reaction between Fe^{3+} and sulfide.

[6] 
Experimental

Reagent grade salts were used without further purification, as was Matheson C.P. grade H_2S. Solutions were prepared with double-distilled water. Alkali metal sulfide solutions were prepared by purging 1 mol dm^{-3} solutions of the appropriate hydroxide with nitrogen, saturating with H_2S and repurging with nitrogen; they were diluted immediately before use. Electrochemical experiments in which $MFeS_2$ salts were observed are described elsewhere (8). Mackinawite was prepared by electrochemical oxidation of iron in 1 mol dm^{-3} NaSH, saturated with H_2S, at an anodic current density of 5 mA cm^{-2}. Most preparations were performed in screw-top polypropylene bottles without taking special precautions to exclude air, as preliminary experiments indicated that colloidal suspensions of $MFeS_2$ are stable to air in the presence of excess sulfide for several weeks in a stoppered bottle. Visible–uv spectra were obtained with a Unicam SP800 spectrometer. X-ray diffraction data were obtained with a 114.6 mm diameter Debye–Scherrer camera and Co K_α radiation, and with a Philips model PW-1050 diffractometer, equipped with a diffracted beam monochromator, using Cu K_α radiation.

Preparation of $MFeS_2$ (M = Na, K; mg Scale)

In a typical experiment, 100 cm^3 each of ca. 4×10^{-4} mol dm^{-3} ferric nitrate and 2×10^{-2} mol dm^{-3} MOH solutions were mixed and 10 cm^3 of 1 mol dm^{-3} MSH solution was added. The solution was allowed to stand overnight, after

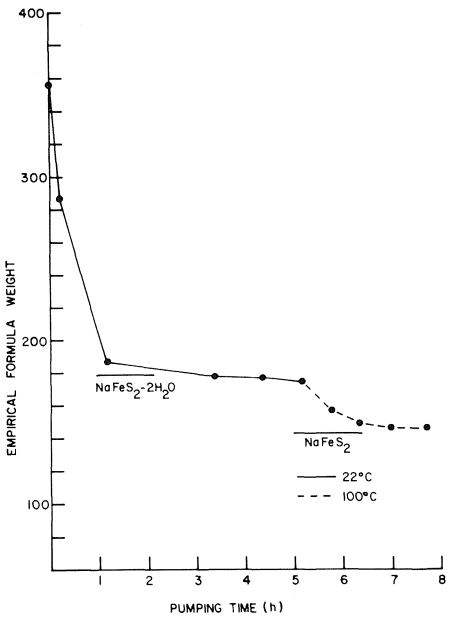


FIG. 5. Plot of weight loss vs. time of pumping for dehydration of sample of $NaFeS_2$.

which the green material was precipitated by addition of an equal volume of 1 mol dm^{-3} MOH, 1 mol dm^{-3} MCl or acetone, filtered, washed with 10^{-2} mol dm^{-3} MOH and then with acetone. Samples were stored under nitrogen in sealed glass vials, as they were quite susceptible to air oxidation. Syntheses of $NaFeS_2$ were also carried out using ferrous and ferric ammonium sulfates and synthetic mackinawite (13) (tetragonal FeS_{1-x}) as starting materials. As mackinawite is comparatively insoluble, it was added to the reaction mixture as a solid.

Preparation of $KFeS_2$ (100 mg Scale)

In a typical experiment, $Fe(NO_3)_3 \cdot 9H_2O$ (0.698 g, 1.73 mmol) was dissolved in water (80 cm^3) and 10 cm^3 each of 5 mol dm^{-3} KOH and 1 mol dm^{-3} KSH were added. After addition of KOH a flocculent brown precipitate of $Fe(OH)_3$ formed; this turned black instantly on addition of KSH. After standing overnight a black solid had settled; this was filtered, washed with 10^{-2} mol dm^{-3} KOH and acetone, dried, and identified as $KFeS_2$ by X-ray diffraction (0.277 g, 1.74 mmol). The supernatant liquor contained less than 0.1 mg of iron.

Preparation of $NaFeS_2$ (100 mg Scale)

These preparations were carried out paralleling exactly the synthesis of $KFeS_2$, above, but the weight of product recovered indicated that it contained a considerable amount of water; it was also much bulkier than a corresponding amount of $KFeS_2$. The water was removed by continuous pumping at about 10 Pa, first at room temperature, then at ca. 100°C; a plot of weight vs. time of pumping for one experiment is shown in Fig. 5. At room temperature, after initial rapid loss, the weight levelled out at a value corresponding approximately to the formulation $NaFeS_2 \cdot 2H_2O$, with only a very slow further weight loss. On heating to 100°C very rapid loss occurred again, leading to a final constant weight in reasonable agreement with the stoichiometry $NaFeS_2$ (for three experiments, calcd. 0.669, 0.511, 0.395 g; obsd. 0.640, 0.522, 0.415 g). It was difficult to obtain this material in a high degree of purity, due to its sensitivity to oxidation and hydrolysis, and the observation of pyrrhotite and pyrite in material heated at 450°C suggests that these may have been present as impurities in the initial product.

Kinetic Experiments

Aliquots of stock solutions of $Fe(NO_3)_3$, $NaNO_3$, NaOH, and NaSH were mixed to give the appropriate concentrations. Unless otherwise stated, NaOH was added to an acidic solution of $Fe(NO_3)_3$ to adjust the pH immediately before the addition of NaSH. A portion of the mixed solution was transferred rapidly to the uv–visible spectrometer cell, and the spectrum was recorded at 2-min intervals over the wavelength range 700 to 400 nm.

Thermal expansivities of water + tetrahydrofuran mixtures at 298.15 K[1]

OSAMU KIYOHARA,[2] PATRICK J. D'ARCY, AND GEORGE C. BENSON

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received May 29, 1978

OSAMU KIYOHARA, PATRICK J. D'ARCY, and GEORGE C. BENSON. Can. J. Chem. **56**, 2803 (1978).

Densities of water + tetrahydrofuran mixtures were measured at 5 K intervals of temperature from 288.15 to 308.15 K. Excess thermal expansion coefficients and partial molar excess thermal expansivities at 298.15 K over the whole mole fraction range were derived from the results. The significance of the expansivities is discussed in terms of the structural changes accompanying the formation of the mixture.

OSAMU KIYOHARA, PATRICK J. D'ARCY et GEORGE C. BENSON. Can. J. Chem. **56**, 2803 (1978).

On a mesuré la densité de mélanges d'eau et de tétrahydrofuranne à tous les 5 K entre les températures de 288.15 et 308.15 K. On a déduit de ces résultats les coefficients d'expansion thermique d'excès et les expansivités thermiques molaires partielles d'excès à 298.15 K pour le domaine complet de fractions molaires. On discute de la signification des expansivités en rapport avec les changements de structure qui accompagnent la formation du mélange.

Excess enthalpies and volumes of water + tetrahydrofuran (THF) mixtures were reported in a previous paper (1). As an extension of the investigation of the thermodynamic properties of this system, excess thermal expansion coefficients at 298.15 K were obtained from measurements of density at various temperatures around 298.15 K. These values are needed to derive isothermal compressibilities and heat capacities at constant volume from measurements of ultrasonic velocities and heat capacities at constant pressure, which are currently in progress in our laboratory.

Experimental

Materials

The source and purification of the THF were the same as in our previous work (1). Mixtures with deionized distilled water were prepared by mass taking into account the effect of buoyancy. The error of the mole fractions is estimated to be less than $\pm 2 \times 10^{-5}$.

Measurements of Density

Densities of the mixtures were determined with a flow type oscillating tube densimeter (Sodev Inc., Model 02D). Details of the apparatus and its operating procedure have been described by Picker *et al.* (2). Briefly, the density of a fluid is obtained by measuring the resonant frequency of a U-shaped stainless steel tube filled with the fluid. The equation

$$[1] \qquad \rho = A + B\tau^2$$

relates the density ρ to the period τ of the oscillator. A and B are constants of the instrument which can be determined by calibration with fluids of known densities.[3]

For the present work, calibration of the densimeter was based on measurements for water and THF at each temperature, and densities of the mixtures were obtained from the equation

$$[2] \qquad \rho - \rho(H_2O) = \frac{[\tau^2 - \tau^2(H_2O)][\rho(H_2O) - \rho(THF)]}{[\tau^2(H_2O) - \tau^2(THF)]}$$

where $\rho(H_2O)$ and $\rho(THF)$ are the densities of water and THF, and $\tau(H_2O)$ and $\tau(THF)$ are the corresponding periods. Values of the density of water were taken from the review by Kell (5), and densities of THF were determined in our Anton Paar densimeter. The latter was calibrated at each temperature by measurements on a series of solvents.

The temperature of the Picker densimeter was monitored with a calibrated quartz thermometer and was kept constant by a Sodev programmable circulating thermostat. Temperature differences are believed to be accurate to ± 0.002 K in the range 283.15 to 303.15 K. The uncertainty of the values of the density is estimated to be less than $\pm 3 \times 10^{-5}$ g cm^{-3}.

Results and Discussion

Densities of the mixtures and pure components at

[3]The manual for the densimeter recommends the use of distilled water and dry nitrogen gas for this purpose. Originally we attempted to calibrate the densimeter by measuring nitrogen gas, water, and several organic solvents whose densities had been determined in our Anton Paar densimeter (3). However, it was found that the point for water deviated considerably from the calibration line (by nearly 7×10^{-4} g cm^{-3} at 298.15 K), and that the amount of the deviation depended on the temperature. Although the reason for this anomaly is not clear, the discrepancies could be eliminated by readjusting the driving power applied to the oscillator tube at each temperature (4). This mode of operation proved to be inconvenient since drifts of the oscillator frequency necessitated frequent checks of the calibration and readjustments of the driving power. Nevertheless, because of its quick response and good thermal stability within ± 10 K of the ambient temperature we found the Picker densimeter to be more suitable than the Anton Paar densimeter for the precise determinations of density differences required in our present work.

[a] From reference 5

[b] Values of ρ/g cm^{-3} for pure THF from the literature are: 0.88194 (6), 0.88436 (7) at 298.15 K; 0.8730 (8) at 303.15 K; 0.87333 (7) at 308.15 K.

288.15, 293.15, 298.15, 303.15, and 308.15 K are summarized in Table 1, where x_1 is the mole fraction of water. Literature values of the density of pure THF (6–8) are given in the footnote of the table for comparison. Molar excess volumes $\bar{V}^E(T)$ calculated from the results are also listed.

The difficulty in finding a suitable smoothing function to represent $\bar{V}^E$ has been pointed out previously (1). In order to estimate thermal expansion coefficients for the mixtures at 298.15 K, smoothed values of $\bar{V}^E$ (298.15) were obtained by fitting the results at that temperature with a set of least-squares cubic splines. Deviations of the results at other temperatures were fitted with the smoothing equation

$$[3]\quad \Delta\bar{V}^E(T) = \bar{V}^E(T) - \bar{V}^E(298.15) = x_1(1-x_1)\sum_{i=1}^{n}\sum_{j=1}^{2} a_{ij}(T-298.15)^j(1-x_1)^{(i-1)/2}$$

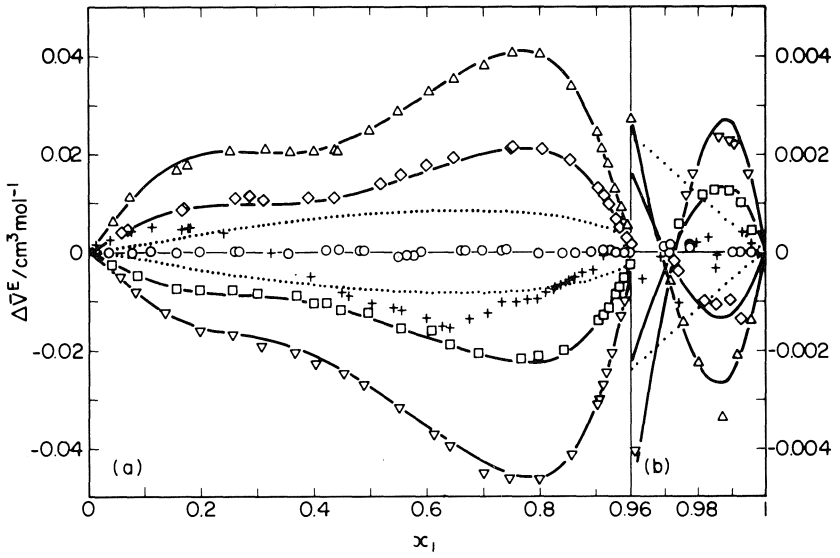

FIG. 1. Deviations of excess volumes for $H_2O(1)$ + THF(2) mixtures at various temperatures from smoothed results at 298.15 K: ▽, 288.15 K; □, 293.15 K; ○, 298.15 K; ◇, 303.15 K; △, 308.15 K; +, 298.15 K from ref. 1; —, calculated from eq. [3] with coefficients from Table 2; ···, ±1% deviation. Note that different scales are used in (*a*) and (*b*).

where a quadratic form of temperature dependence is assumed. The values of the coefficients a_{ij} calculated by the method of least squares with all points weighted equally are listed in Table 2.

A plot of the experimental values of $\Delta\overline{V}^E(T)$ and their smoothed representations by [3] is given in Fig. 1. Also shown are the deviations of the results of our previous dilatometric studies at 298.15 K (1). Most of these deviations fall within the 1% limits shown in the figure but some amount to nearly 2%. Although the values of $\overline{V}^E$ derived from our dilatometric studies are believed to be more accurate, the present results should provide good estimates of the temperature variation of $\overline{V}^E$.

The excess thermal expansion coefficient α^E is defined by

$$[4] \qquad \alpha^E = \alpha - \sum\phi_i\alpha_i^0$$

where α is the thermal expansion coefficient of the mixture, ϕ_i is the volume fraction of component i referred to the unmixed state, and α_i^0 is the thermal expansion coefficient of pure component i. At 298.15 K the value of α_1^0 is 0.257 kK^{-1} (5), and our densities of THF lead to a value of 1.243 kK^{-1} for α_2^0. The latter may be compared with the values 1.33 kK^{-1} (9), 1.085 kK^{-1} (10), and 1.226 kK^{-1} (11) given in the literature. Values of α^E for mixtures at 298.15 K were calculated from the relation

$$[5] \qquad \alpha^E = \frac{1}{\overline{V}}\left[\frac{\partial\Delta\overline{V}^E}{\partial T} - \overline{V}^E\sum\phi_i\alpha_i^0\right]$$

where $\overline{V}$ is the molar volume of the mixture. The value of $\partial\Delta\overline{V}^E/\partial T$ was obtained from [3], and $\overline{V}$ and $\overline{V}^E$ were calculated from the densities of the components and the smoothing equation for $\overline{V}^E$ given in ref. 1. In Fig. 2, the plot of α^E against x_1 is highly skewed and rises approximately linearly to a maximum near $x_1 = 0.8$. This corresponds roughly to the mole fraction at which there is a minimum of the excess enthalpy (1).

Values of the partial molar excess thermal expansivities defined by

$$[6] \qquad \bar{E}_i^E = (\partial\overline{V}_i^E/\partial T)_p$$

where $\overline{V}_i^E$ is the partial molar excess volume of component i, are shown in Fig. 3. For the most part, these were calculated from eq. [3], however, that representation is not suitable for evaluating $\bar{E}_2^E$ in very dilute THF mixtures since it implies an infinite limiting slope for the curve for $\bar{E}_2^E$ against x_1. Polynomial forms in x_1 were used to smooth the

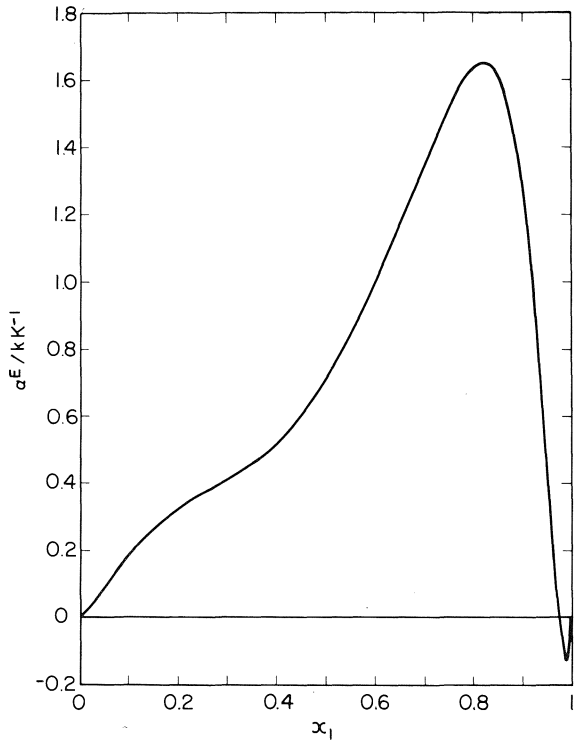

FIG. 2. Excess thermal expansion coefficient of $H_2O(1)$ + THF(2) mixtures at 298.15 K.

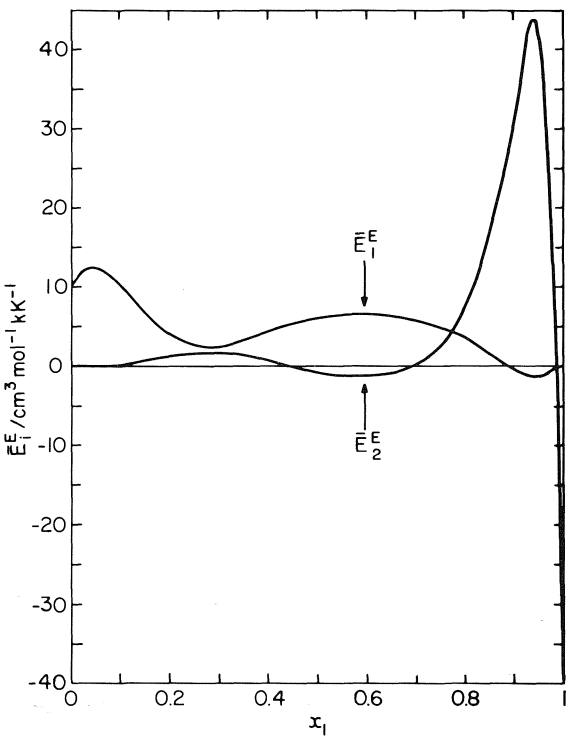

FIG. 3. Partial molar excess thermal expansivities of $H_2O(1)$ + THF(2) at 298.15 K.

$\Delta\bar{V}^E$ results at high dilutions of THF, and to evaluate $\bar{E}_2^E$. In this range it appears that THF molecules severely restrict mutual molecular motions within the mixture, and lead to negative values of both $\bar{E}_1^E$ and $\bar{E}_2^E$. However, with increasing THF concentration, $\bar{E}_2^E$ increases rapidly, becoming positive and reaching a maximum at $x_1 = 0.94$. The molecular significance of this peak is not clear, but similar behavior has been reported for *tert*-butyl alcohol + water mixtures (12).

Previously we found that the partial molar excess enthalpies of H_2O + THF mixtures are nearly constant over the central range of mole fractions (1). The variations of the partial molar excess expansivities are also relatively minor in this range. This finding supports the suggestion that the system consists of stabilized water clusters in equilibrium with a random mixture of H_2O and THF molecules (1). The small broad peak of $\bar{E}_1^E$ in the THF-rich region may be due to hydrogen bonding between unlike species in the mixture.

Several previous authors have studied the volumetric behavior of highly dilute H_2O + THF mixtures. Our results lead to a value of $\phi_E^0 = 62.5$ cm^3 mol^{-1} kK^{-1} at 298.15 K for the apparent molar expansivity of THF at infinite dilution. This appears reasonable in comparison with the literature values $\phi_E(0.153\ m) = 62.0$ cm^3 mol^{-1} kK^{-1} (11) and $\phi_E(0.39\ m) = 68.6$ cm^3 mol^{-1} kK^{-1} (13).

The densities and heat capacities per unit volume of aqueous solutions of propionamide, methylacetate, ethylacetate, methylethylketone and diethylketone, and bis(2-ethoxyethyl)ether were measured over the whole solubility range with a flow densimeter and a flow microcalorimeter. Most systems were studied at 10, 25, and 40°C. Properties of the pure liquids were also measured whenever possible. The derived apparent molal volumes ϕ_V all decrease with concentration in the water-rich region, except with ethyl acetate which increases at high temperature. In general the more hydrophobic the solute the more negative the initial slope. All apparent molal heat capacities ϕ_C decrease as a function of concentration and the decrease is more important for more hydrophobic solutes. The apparent molal expansibilities ϕ_E are obtained from $\Delta\phi_V/\Delta T$. They are positive for all solutes but, at low concentrations, they are smaller than the corresponding molar value of the pure liquid. Various factors affecting hydrophobic interactions are examined.

GENEVIÈVE ROUX, GÉRALD PERRON et JACQUES E. DESNOYERS. Can. J. Chem. **56**, 2808 (1978).

Les masses volumiques et capacités calorifiques des solutions aqueuses de proprionamide, d'acétates de méthyle et d'éthyle, des diéthyl et méthyléthyl cétone et du bis(2-éthoxy éthyl) éther ont été mesurées sur tout le domaine de solubilité avec un densimètre et un microcalorimètre à écoulement continu. La plupart des systèmes ont été étudiés à 10, 25 et 40°C. Lorsque possible les propriétés des liquides purs ont aussi été mesurées. A l'exception de l'acétate d'éthyle, les volumes molaires apparents ϕ_V décroissent avec la concentration dans la région riche en eau et en général les pentes initiales sont plus négatives les plus hydrophobes sont les solutés. Toutes les capacités calorifiques molaires apparentes décroissent en fonction de la concentration et l'effet augmente avec le caractère hydrophobe du soluté. Les expansibilités molaires apparentes ϕ_E, obtenues à partir de $d\phi_V/dT$, sont toutes positives mais sont aux basses concentrations inférieures aux valeurs molaires des liquides purs. Différents facteurs influençant les interactions hydrophobes sont discutés.

Introduction

Recent work in this laboratory (1–3) has been concerned with transitions in aqueous liquid mixtures. Through heat capacity measurements the apparent molal heat capacity ϕ_C of many simple liquids which are completely miscible in water, such as dimethylformamide (4), dimethylsulfoxide (5), and dioxane (6), decreases in a regular way from the standard (infinite dilution) partial molal heat capacity, $\phi_C^0 = \bar{C}_p^0$, to the molar heat capacity of the pure organic liquid C_p^0. On the other hand, with some liquids such as *tert*-butylalcohol (1), piperidine (6), triethylamine (7), and 2-*n*-butoxyethanol (3), ϕ_C goes through a maximum and then decreases sharply to C_p^0. The changes are much sharper if partial molal heat capacities $\bar{C}_p$ are plotted (2) and the concentration dependence of $\bar{C}_p$ suggests the existence of some pseudo-phase transition in the water region analogous to micellization.

The exact reason why some liquid mixtures show these sharp changes in ϕ_C and $\bar{C}_p$ is not clear and could be related to the hydrophobic character, the tendency of these systems to unmix, the geometry of the molecules, or the nature of the polar group on the molecule. The present study was undertaken to throw some light on the importance of some of these factors. Therefore amides, ketones, and esters of similar geometries were examined as a function of temperature and whenever possible over the whole solubility range. A polyether which unmixes at high temperatures was also investigated.

Heat capacities measured by flow microcalorimetry require the simultaneous determination of the solution densities. From the densities, obtained with a flow densimeter, apparent molal volumes ϕ_V were derived, and from their temperature dependence apparent molal expansibilities were calculated, $\phi_E = d\phi_V/dT$.

Experimental

The origin and purification procedure of the chemicals are as follows. Propionamide, from Baker Chemicals, was recrystallized from acetone and dried under vacuum over P_2O_5.

Methylacetate, from Baker Chemicals, ethylacetate and methylethylketone, both from Fisher Scientific (Certified A.C.S.), were used as such. Diethylketone, from Aldrich, was redistilled and the central fraction (30%) was collected. Bis(2-ethoxyethyl)ether, from Baker Chemicals and Eastman Kodak, was redistilled under vacuum with a fine stream of nitrogen.

The purity of all chemicals was verified to be better than 99.8% with vapor phase chromatography on carbowax 20 *M* at 10% or SE 30 at 10%, and all liquids were kept over 4 Å molecular sieves. All solutions were prepared by weight with distilled deionized water (Continental Deionized Water System).

The densities d and heat capacities per unit volume σ of the solutions were measured relative to pure water, d_0 and σ_0, with a SODEV flow digital densimeter (8) and a Picker flow microcalorimeter (9, 10). Differences in densities $d - d_0$ were measured to $\pm 3 \times 10^{-6}$ g cm^{-3} and differences in heat capacities $\sigma - \sigma_0$ to $\pm 7 \times 10^{-5}$ J K^{-1} cm^{-3}. The flow rate in the microcalorimeter was maintained at about 0.45 cm^3 min^{-1} and the basic power at 21.5 mW causing an increase in temperature during the measurements of 0.7 K. The absolute temperature was determined to ± 0.01 K with a Hewlett-Packard quartz thermometer. The general procedure and uncertainties at other temperatures have been described elsewhere (1, 10).

Results

The apparent molal volumes and heat capacities are calculated in the usual way from the differences in densities $d - d_0$ and specific heat capacities $c_p - c_{p0}$;

$$[1] \qquad \phi_V = \frac{M}{d} - \frac{1000(d - d_0)}{mdd_0}$$

and

$$[2] \qquad \phi_C = Mc_p + \frac{1000(c_p - c_{p0})}{m}$$

where M is the solute molecular weight and m the molality. The data for pure water were taken from Kell (11) and Stimson (12). The difference $c_p - c_{p0}$ is calculated from

$$[3] \qquad c_p - c_{p0} = c_{p0}\left\{\frac{\sigma - \sigma_0}{\sigma_0} + 1\right\}\frac{d_0}{d} - c_{p0}$$

where $\sigma_0 = d_0 c_{p0}$.

The original data for Δd and $\Delta\sigma/\sigma_0$ and the derived values ϕ_V and ϕ_C are given elsewhere (13). The measurements were made over the whole mole fraction range whenever the liquids were completely miscible and up to saturation in the other cases. In the dilute range, the apparent molal quantities ϕ_Y can be fitted with an expression of the type

$$[4] \qquad \phi_Y = \phi_Y^{\theta} + A_Y m$$

where Y refers to V or C_p. The linear region where eq. [4] applies varies with the system and temperature. The values of $\bar{V}^{\theta}$, $\bar{C}_p^{\theta}$, A_V, and A_C, obtained from a least-squares analysis, and the concentration limit of the linear region are given in Table 1. Similar data for other related systems taken from the literature are also given. The molar values V^0 and C_p^0 for the pure liquids are also given whenever they were measured.

With bis(2-ethoxyethyl)ether two samples were used. The sample from Baker was taken in the measurements at 25°C and that from Eastman Kodak at 10 and 40°C. Some densities were also repeated at 25°C with the Eastman Kodak chemical and the ϕ_V fell on the same curve as the data obtained with the Baker sample.

Relatively few measurements of densities were made previously over the whole concentration range with the present aqueous systems. On the other hand some relatively good $\bar{V}^{\theta}$ and V^0 are available at 25°C in the literature and can be used to verify the accuracy of the present measurements.

For proprionamide $\bar{V}^{\theta}$ was determined by Herskowits and Kelly (14) as 70.9 cm^3 mol^{-1} and by Dunstan and Mussell (15) as 71 cm^3 mol^{-1}. Shahidi *et al.* (16) calculated $\bar{V}^{\theta}$ from the intrinsic volumes of the solute and interaction terms taking into account the geometry of the molecule and found, depending on the relation used, to be 72.0 or 71.3 cm^3 mol^{-1}. The present $\bar{V}^{\theta}$, 71.47 cm^3 mol^{-1}, agrees with these values.

For ethyl acetate Edwards *et al.* (17) obtained 88.8 $\pm$ 0.3 cm^3 mol^{-1} compared with the present 88.97 cm^3 mol^{-1}. The densities of pure ethyl acetate were also studied by various authors (18) and the present V^0 agrees inside the experimental uncertainty with these.

Methylethylketone was studied by Bøje and Hvidt (19) and by Edwards *et al.* (17). Their $\bar{V}^{\theta}$ values (82.5 and 82.9 cm^3 mol^{-1} respectively) are comparable with the present value of 82.52 cm^3 mol^{-1} Bøje and Hvidt also determined ϕ_V over the whole mole fraction range and their data, inside their quoted uncertainty, agree with ours. The suggested value for V^0, 90.14 cm^3 mol^{-1} is identical to ours.

Edwards *et al.* (17) obtained 165.0 $\pm$ 0.3 cm^3 mol^{-1} for $\bar{V}^{\theta}$ of bis(2-ethoxyethyl)ether which compares with the present value of 164.16 cm^3 mol^{-1}.

The precision of the $\bar{V}^{\theta}$ data is of the order of ± 0.05 cm^3 mol^{-1} and the generally good agreement with literature data fixes the accuracy at ± 0.5 cm^3 mol^{-1} or better.

To our knowledge there are no data in the literature on the heat capacities of the present organic aqueous mixtures. Pure methylethylketone was studied as a function of temperature by Sinke and Oetting (20) and by Andon *et al.* (21) and their C_p^0 are in good agreement with ours at 25°C but significant differences (a few percent) are observed at other temperatures. However, the generally good agreement of $\bar{V}^{\theta}$ and V^0 with the literature and the proven

reliability of the flow microcalorimetric technique for the measurement of heat capacities lead us to believe that the present data on ϕ_C are accurate to 1 $J\ K^{-1}\ mol^{-1}$ or better, at least in the water-rich region.

Discussion

Standard Quantities

The standard partial molal quantities $\bar{C}_p^{\theta}$ and $\bar{V}^{\theta}$ are useful in predicting the temperature and pressure dependence of equilibrium quantities and give information on solute–solvent interactions. For this purpose it is important to develop additivity schemes from which the properties of complex molecules can be predicted from those of simpler ones. Data exist in the literature on $\bar{V}^{\theta}$ of ketones, ethers, esters, and amides in water but little is known about their $\bar{C}_p^{\theta}$.

Various additivity schemes (16, 17, 22–25) have been proposed recently for $\bar{V}^{\theta}$ and $\bar{C}_p^{\theta}$. Nichols *et al.* (22) have made a fairly exhaustive study of $\bar{C}_p^{\theta}$ of molecules of biological interest and Perron and Desnoyers (23) made a similar study of aromatic molecules. The main difference in these two schemes lies in the value given to the H atom. The scheme of Perron and Desnoyers is an extension of the approach of Jolicoeur and Lacroix (24) and has the advantage of being applicable to $\bar{V}^{\theta}$ also. Recently Guthrie (25) has proposed a much more sophisticated group additivity scheme which can in principle yield a much better agreement between the predicted and experimental $\bar{C}_p^{\theta}$ but requires up to 49 parameters. With the present state of knowledge it is better to concentrate on the simpler additivity schemes of Nichols *et al.* and of Perron and Desnoyers. Also Edwards and co-workers (16, 17) have proposed a relatively simple theory for the prediction of $\bar{V}^{\theta}$ from van der Waals volumes corrected for void space and interactions, but this is not, strictly speaking, an additivity scheme.

The main group contributions to $\bar{C}_p^{\theta}$ and $\bar{V}^{\theta}$ of Nichols *et al.* and Perron and Desnoyers are summarized in Table 2. Assuming these contributions correct, average values for the —C(=O)—, —CO—, and —CNH_2 group were derived and are also given in Table 2. The average deviations between the calculated and measured $\bar{C}_p^{\theta}$ and $\bar{V}^{\theta}$ for the data in Table 1 are 5 $J\ K^{-1}\ mol^{-1}$ for the $\bar{C}_p^{\theta}$ schemes of both Nichols *et al.* and Perron and Desnoyers and 0.5 $cm^3\ mol^{-1}$ for the $\bar{V}^{\theta}$ scheme of Perron and Desnoyers. The agreement is worse with the molecules which contain more than one polar group, e.g., with the polyether. This has been noted before (22, 26).

The expansibilities $\bar{E}^{\theta}$ can be estimated from $\Delta\bar{V}^{\theta}/\Delta T$ and for ethyl acetate, methylethylketone, and bis(2-ethoxyethyl)ether the values are found to be 0.112, 0.076, and 0.126 $cm^3\ K^{-1}\ mol^{-1}$, respectively, at 25°C. On the other hand, if we calculate $\bar{E}^{\theta} - E^{o}$, the values are now −0.022, −0.046, and −0.060. This indicates that the expansibility of an organic molecule surrounded by water is less than that of an organic molecule surrounded by similar organic molecules. This is consistent with models which suggest that hydrophobic hydration occurs with a reduction of free space near the solute.

O ‖ —CO—	−10	−50	19.4
—OH	−4	12	12
$-CONH_2$	5	−14	28.8
—O—	−57	−72	4.1

Depending on the solute, the values of $\bar{C}_p^\theta$ increase or decrease with temperature. On the other hand $\bar{C}_p^\theta - C_p^0$ decreases with temperature with most systems suggesting that hydrophobic hydration is largest near the freezing temperature of water. Bis(2-ethoxyethyl)ether is an exception to this rule since $\bar{C}_p^\theta - C_p^0$ is approximately independent of T.

Concentration Dependence

The main objective of the present study was to examine some of the factors that could influence the concentration dependence of ϕ_C and ϕ_V of organic molecules in water. Some amines and alcohols show anomalous ϕ_C or $\bar{C}_p$ which suggests the existence of transitions similar to micellization although molecules like *tert*-butylalcohol and triethylamine could hardly be considered surfactants. The maximum observed in the ϕ_C of these molecules occurs around 0.05 mole fraction and is very temperature dependent. Unfortunately much of the data in the literature were aimed at deriving additivity schemes and were limited to 25°C and low concentrations or else were aimed at the measurement of excess functions and only mole fractions between 0.1 and 0.9 were considered. In order to throw some light on this problem ϕ_C and ϕ_V of a series of ketones, esters, amides, and ethers of similar geometries and sizes are compared in Fig. 1. The initial slopes are given in Table 1. With all these solutes A_C is negative and the order is very nearly inversely proportional to the value of $\bar{C}_p^\theta$. In none of these systems do we observe maxima in ϕ_C as in the case of alcohols (1), some amines (6, 7), and larger alkoxyethanols (3). It would therefore appear that with the present system the leading effect giving the sign and magnitude of A_C is the reduction of hydrophobic hydration as the concentration increases. This is consistent with the destructive cosphere overlap models (7).

The parameter A_V follows the same order as A_C

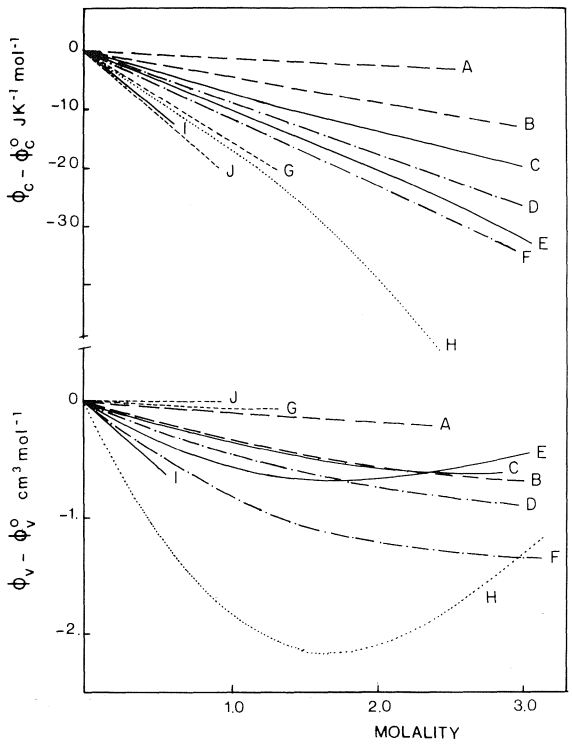

FIG. 1. Apparent molal heat capacities and volumes of various polar solutes in water in the water-rich region at 25°C: *A*, acetamide; *B*, propionamide; *C*, acetone; *D*, 2-methoxyethanol; *E*, methylethylketone; *F*, 2-ethoxyethanol; *G*, methylacetate; *H*, bis(2-ethoxyethyl)ether; *I*, diethylketone; *J*, ethyl acetate.

with the exception of the two esters. The volumes have the general trends of most organic liquids in water; ϕ_V decreases with concentration and, if the solubility is high enough, goes through a minimum and reaches a value V^0 which is larger than $\bar{V}^\theta$. The temperature dependence of ϕ_C and ϕ_V of ethyl acetate is shown in Fig. 2. As seen the initial slope A_V is even positive at 40°C. At present we have no explanation for the anomalous concentration dependences of ϕ_V of the esters.

The concentration dependence of ϕ_C and ϕ_V of methylethylketone at various temperatures is given in Fig. 3. Here the trends are fairly typical of this class of solutes except for 40°C. A_C and A_V are negative and become less negative as the temperature increases. Also, except at high temperature, ϕ_V goes through a minimum.

The present investigation therefore shows that the maximum in ϕ_C is not a general effect since most types of molecules do not show any anomalous concentration dependence. With alcohols, amines and amine salts (27) additional interactions, such as hydrogen bonding, could be responsible for the positive contribution to ϕ_C.

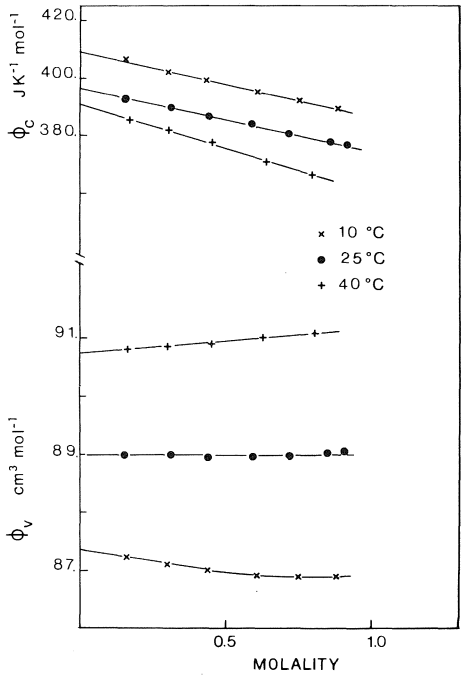

FIG. 2. Apparent molal heat capacities and volumes of ethyl acetate at various temperatures.

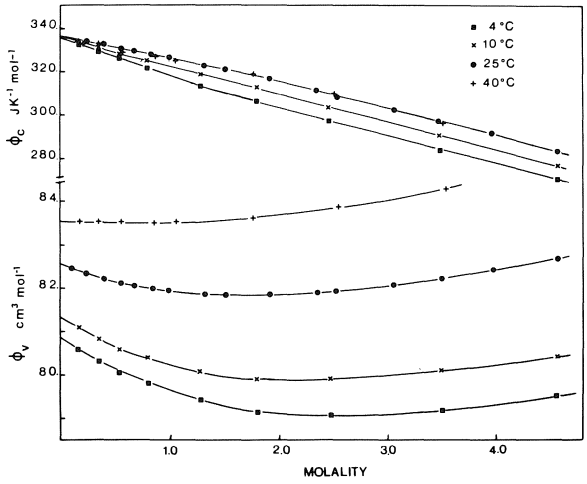

FIG. 3. Apparent molal heat capacities and volumes of methylethylketone at various temperatures.

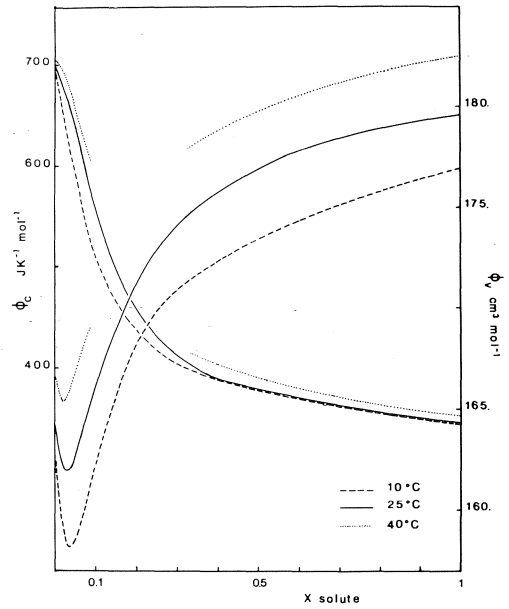

FIG. 4. Apparent molal heat capacities and volumes of bis(2-ethoxyethyl)ether at various temperatures.

The ϕ_C and ϕ_V of bis(2-ethoxyethyl)ether was investigated since this aqueous system shows a lower critical solution temperature at 28°C (28, 29). It is therefore possible to study its properties very close to the unmixing region. The ϕ_C and ϕ_V are plotted against the mole fraction at temperatures above and below the critical solution temperature in Fig. 4. Although the initial slopes A_V and A_C fall in a general pattern with the other liquid mixtures (Fig. 1), the large drop in ϕ_C and large increase in ϕ_V beyond the minimum suggests that a transition is occurring beyond 0.05 mole fraction. In this respect this ether resembles alcohols, etheralcohols, amines, and carboxylic acids at high concentration. The $\bar{C}_p$ and $\bar{V}$ rapidly tend to the values of C_p^0 and V^0 beyond 0.1 mole fractions indicating that an additional molecule will only see other ether molecules when added to the solution. On the other hand there is no anomaly in ϕ_C in the water-rich region contrary to alcohols and amines. ϕ_C decreases in a regular way to C_p^0. The slight hump in the concentration dependence of ϕ_C at high temperature does not appear very significant. On the other hand, if ϕ_C is plotted against the volume fraction X_V (Fig. 5), a different picture emerges. It was shown that with liquids such as dimethylformamide (7) ϕ_C is nearly linear in volume fraction. Therefore, if we consider the straight line between $\phi_C - \phi_C^\theta$ and C_p^0 as the ideal behavior, then it seems that the anomalies occur mainly in the water-rich region and increase with temperature.

The most interesting feature of bis(2-ethoxyethyl)-ether is that data were obtained very close to the phase separation region. At 25°C we are at 3° from the lower critical solution temperature and at 40°C measurements were made on both sides of the phase diagram. All these data near the two phase region are qualitatively very similar to the data at lower temperatures and a smooth curve can be drawn joining the data points at 40°C (see Figs. 4 and 5). This was also observed with 2-butoxyethanol (3).

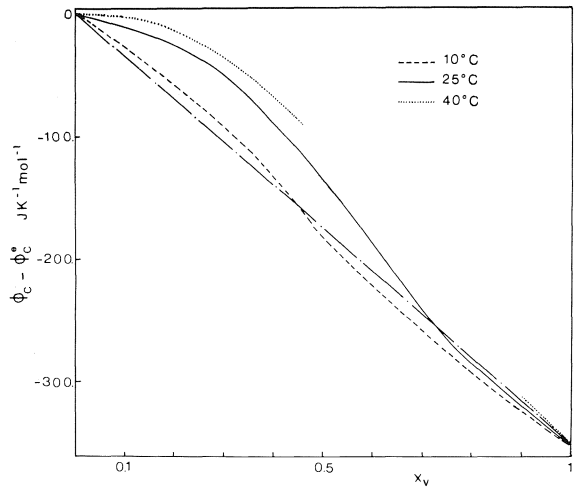

FIG. 5. Apparent molal heat capacities of bis(2-ethoxyethyl)ether as a function of volume fraction at various temperatures.

The positive deviation observed in Fig. 5 at high temperature might be due to anomalous energy fluctuations near the two phase region but these deviations are certainly small compared with those observed with alcohols, etheralcohols, and amines (1–3, 6, 7). This does not rule out the possibility that pseudo-transitions in aqueous organic mixtures may be related to the existence of an *upper* critical solution temperature since recent studies (30) suggest that 2-butoxyethanol has such a critical temperature below 0°C and the anomalies in ϕ_C are largest at the lowest temperature investigated (2, 3).

Since ϕ_V data are available as a function of temperature and concentration it is possible to calculate ϕ_E as a function of concentration. This was done in Fig. 6 for bis(2-ethoxyethyl)ether and methylethylketone at 17.5°C. These have the same general shape as alcohols in water (1, 3) although the maximum is not quite as sharp.

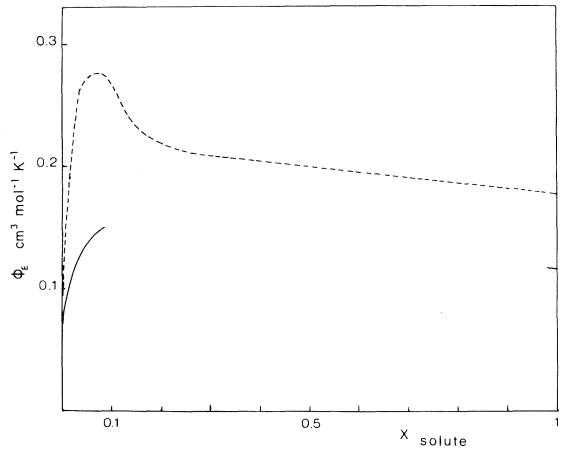

FIG. 6. Apparent molal expansibilities of bis(2-ethoxyethyl)ether (---) and methylethylketone at 17.5°C.

The present study eliminates some of the possible factors that could be responsible for the anomalous concentration dependence of ϕ_C of some organic molecules or ions in water. Polar molecules which do not contain alcohol or amine (and possibly carboxyl) groups show little anomaly. Also there is no increase in anomaly near the lower critical solution temperature. The hydrophobic character certainly plays an important role in this non-ideality and it is quite possible that the existence of strong hydrogen bonding or ionizing groups like alcohols and amines enhances the solubility of hydrophobic molecules more than other polar groups. On the other hand bis(2-ethoxyethyl)ether appears to be more hydrophobic than *tert*-butylalcohol or butoxyethanol but its non-ideality is much smaller.

The geometry of the molecules probably has some influence on the non-ideality but this effect has not been properly investigated yet.

Finally the maximum and the large decrease in ϕ_C is certainly related to some structural changes taking place in the solution. Heat capacity is related to the shift in equilibrium of the system during a unit increase in temperature. This shift in equilibrium contribution to ϕ_C will probably be larger if the corresponding changes in enthalpies are large. For example, current work on the enthalpy of dilution of 2-butoxyethanol in water indicates that the increase in relative enthalpy is very large with this system in the region where ϕ_C shows extrema. Unfortunately not sufficient data are available at present on the enthalpy of other organic aqueous mixtures in the water-rich region to establish such a correspondence.

A. OKAGAWA, G. J. ENNIS, and S. G. MASON. Can. J. Chem. **56**, 2815 (1978).

When a suspension of nearly monodisperse rigid axisymmetric particles in a Newtonian liquid is sheared, the orientation distributions of the particle undergo damped oscillations of frequency twice that of the rotating particles. If the flow is stopped and then reversed, the oscillations regrow under certain restricted conditions until the initial state is fully restored: the system has perfect memory. Removing some of the restrictions causes imperfect recovery of the initial orientation distribution, so that when the flow is reversed cyclically back and forth, the orientation distribution eventually becomes time-independent: the system has lost all of its memory. A number of sources of memory impairment are considered theoretically, several of which are amenable to experimental verification and are illustrated by numerical calculation.

A. OKAGAWA, G. J. ENNIS et S. G. MASON. Can. J. Chem. **56**, 2815 (1978).

Lorsqu'on applique un cisaillement à une suspension de particules rigides axisymétriques presque monodispersées se trouvant dans un liquide newtonien, les distributions d'orientations des particules subissent des oscillations atténuées dont la fréquence est le double de celle des particules en rotation. Si l'on stoppe l'écoulement et qu'on en change le sens alors que certaines conditions critiques sont remplies, les oscillations recommencent à croître jusqu'à ce que le système reprenne tout à fait son était initial: le système possède une mémoire parfaite. Lorsque certaines de ces restrictions sont levées, le système ne reprend qu'imparfaitement la distribution initiale d'orientations et si l'on change alternativement le sens de l'écoulement, la distribution d'orientations devient éventuellement indépendante du temps: le système a complètement perdu la mémoire. On examine d'un point de vue théorique plusieurs causes de perte de mémoire, dont certaines peuvent être soumises à une vérification expérimentale et décrites au moyen de calculs numériques.

[Traduit par le journal]

Introduction

In a fluid suspension undergoing simple shear flow, each particle rotates, translates, and interacts with others. When the velocity field is reversed, the translational and rotational loci of each particle can be exactly retraced under certain restricted conditions (1–5): the system thus shows perfect memory. In this paper we extend earlier work on the statistical mechanics of flowing dispersions (6–9) and examine some aspects of memory impairment in dilute suspensions of rigid spheroids. In the following paper (10) we present experimental evidence which confirms and extends these principles.

Qualitative demonstrations of such reversibility have been given by Heller (11), in a cine-film by Taylor (12), by Goldsmith and Mason (13), and others. For example, letters of a dyed liquid inscribed in the annulus between two concentric cylinders filled with the same undyed liquid were made to disappear by rotating one of the cylinders for a number of turns and then to reappear, slightly blurred by diffusion of the dye, on rotating the same number of turns backwards (4). Okagawa and Mason (3, 6) demonstrated reversible orientation distributions in dilute suspensions of nearly monodisperse rigid rods in a Newtonian liquid: when shear was applied the orientation distribution functions exhibited damped oscillations of frequency twice that of the individually rotating particles; on reversing flow the oscillations regrew perfectly reversibly until the initial conditions were fully restored. For a system with perfect memory, this process can be repeated indefinitely. However, if the system does not satisfy the reversibility requirements, some of the memory is lost during each reversal. This loss is cumulative and eventually it becomes complete so that the orientation distribution is time-independent.

The same behavior will be exhibited by any macroscopic property which depends upon particle orientation, for example, the rheological (7), optical (14), and electrical (15) properties. The same is true of properties determined wholly or in part by spatial distributions, although we will not consider these further since they appear to be much less important.

The formal theory of time-reversal in fluid flow has been given by Bretherton (1), Slattery (2), and elaborated for suspension rheology by Cox (16). The

general requirements for perfect reversibility of particle translation and rotation in a suspension are: (*i*) the fluid motion is given by the linearized form of the Navier–Stokes equation (i.e., for the regime of creeping flow), and (*ii*) the boundary conditions are identical for both forward and backward flows. Specifically these conditions require that the particles are rigid, their surfaces are smooth and free of singularities (17), non-sedimenting, have no interaction forces or torques such as those arising from Coulombic and/or molecular dispersion forces, possess no thermal (Brownian) motion so that the behavior is truly orthokinetic (5), and are suspended in a viscous Newtonian fluid flowing at effectively zero Reynolds number (3, 6, 8, 9). Relaxing any of these conditions introduces some irreversibility, as can be realized, for example, by applying an external electric field, using non-Newtonian suspending media, or using particles with appreciable Brownian motion, all of which we have done in the experiments on spheroidal-like particles described in the following paper (10).

In this paper, we consider a number of pertinent theoretical principles for dilute suspensions of rigid spheroids suspended in a Newtonian dielectric liquid of the same density.

We first discuss briefly the motion of single spheroids in a simple shear flow and the resulting oscillations of the orientation distribution functions in dilute suspension thereof. In the systems with perfect memory, we consider the effects of dispersion in particle shape and of 2-body hydrodynamic interactions. In the final part, various disturbances which may cause memory loss are considered, several of which are illustrated numerically.

Perfect Memory

When the conditions mentioned above are satisfied, reversibility occurs in any general laminar flow; we shall, however, limit our treatment to simple shear (or Couette) flow whose undisturbed velocity components v_i in a space-fixed Cartesian coordinate system x_i are

$$[1] \qquad v_1 = v_2 = 0, \quad v_3 = Gx_2$$

where v_i is the velocity of undisturbed fluid along the X_i axis and G is the velocity gradient or rate of shear; when flow is reversed $v_3 = -Gx_2$. It is to this flow that the calculations in this and the experiments described in the following paper (10) apply.

(a) Single Particles

Since we will be concerned primarily with effects of particle rotation it is convenient to eliminate translation by placing a single spheroid at the origin of the coordinate system shown in Fig. 1. If the axis

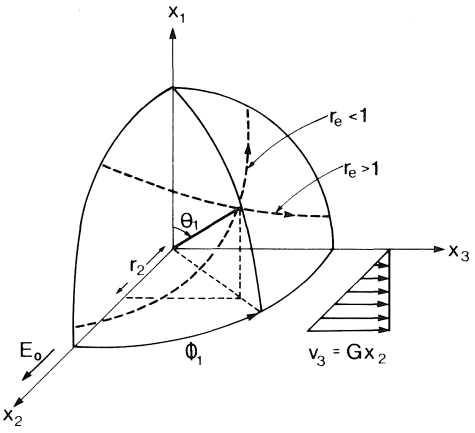

FIG. 1. Coordinate system x_i and spherical polar angles θ_1 and ϕ_1 for unit length of the axis of revolution of a spheroid in simple shear flow $v_3 = \pm Gx_2$. In some instances, an electric field of strength E_0 is also applied along the X_2-axis. Typical rotational orbits (spherical ellipses) of the ends of the axis of revolution of a prolate spheroid ($r_e > 1$) and an oblate spheroid ($r_e < 1$) in shear flow alone ($E_0 = 0$) are indicated by the dashed lines. The relative projected length r_2 of the semi-axis on the X_2-axis is also indicated.

of revolution of the spheroid is on x_1' of the particle-fixed Cartesian coordinate system x_i', the particle surface is given by

$$[2] \qquad \frac{x_1'^2}{a^2} + \frac{x_2'^2}{b^2} + \frac{x_3'^2}{b^2} = 1$$

where a is the semi-axis of revolution and b is the other semi-axis. The orientation is given by the spherical polar angles θ_1, ϕ_1, and the spin angle ψ_1 of the axis of revolution. However, we will ignore further consideration of ψ_1 since for spheroids (and other bodies of revolution) it is difficult to measure and is of little importance in our experiments, although in principle it can be treated quantitatively in ways similar to those considered below for θ_1 and ϕ_1. The rotation of the axis of the particle of revolution, first described by Jeffery (18), is given by

$$[3a] \qquad \omega = \frac{d\phi_1}{dt} = \frac{G}{(r_e^2 + 1)}(r_e^2 \cos^2 \phi_1 + \sin^2 \phi_1)$$

$$[3b] \qquad \frac{d\theta_1}{dt} = \frac{G}{4}\frac{(r_e^2 - 1)}{(r_e^2 + 1)} \sin 2\theta_1 \sin 2\phi_1$$

which integrate to yield

$$[4a] \qquad \tan \theta_1 = \frac{Cr_e}{(r_e^2 \cos^2 \phi_1 + \sin^2 \phi_1)^{1/2}}$$

$$[4b] \qquad \tan \phi_1 = r_e \tan\left(\frac{2\pi t}{T} + \kappa\right)$$

where C and κ are the orbit constant and phase angle (7), $r_e = a/b$ is the ellipsoidal axis ratio, t is time, and T, the period of one complete rotation about the

vorticity axis X_1 through $\phi_1 = 2\pi$, is

$$[5] \qquad T = \frac{2\pi}{G}(r_e + r_e^{-1})$$

The particle axis thus rotates periodically in a closed spherical elliptical orbit at a fixed C and κ, the locus of an end in one quadrant being shown in Fig. 1. Due to the linearity of the equations of motion of the particle and the surrounding medium (18), [3]–[5] are also valid when the flow is reversed so that the particle retraces exactly the forward rotational (and when appropriate, translational) path. The rotations described by [3] and [4] have been confirmed experimentally using rigid rods which behave like prolate spheroids, $r_e > 1$ (19), and discs like oblate spheroids, $r_e < 1$ (20) when r_e is calculated from the measured T by means of [5] is used in [3] and [4].

(b) Dilute Suspensions

Consider now an infinitely dilute suspension of monodisperse spheroids with each particle rotating according to [3] and [4] at a fixed C and κ determined by its initial orientation. The instantaneous orientation probability distribution $p_t(\theta_1,\phi_1)$ for an initially randomly oriented population is (7):

$$[6] \qquad p_t(\theta_1, \phi_1) = \frac{\sin\theta_1}{4\pi(\cos^2\theta_1 + \chi^2 \sin^2\theta_1)^{3/2}}$$

where

$$[7a] \qquad \chi^2 = \chi_1 \sin^2\phi_1 + \chi_2 \sin\phi_1 \cos\phi_1 + \chi_3 \cos^2\phi_1$$

$$[7b] \qquad \chi_1 = \frac{1}{2}\left\{1 + r_e^{-2} + (1 - r_e^{-2}) \cos\frac{4\pi t}{T}\right\}$$

$$[7c] \qquad \chi_2 = (r_e^{-1} - r_e) \sin\frac{4\pi t}{T}$$

$$[7d] \qquad \chi_3 = \frac{1}{2}\left\{1 + r_e^{2} + (1 - r_e^{2}) \cos\frac{4\pi t}{T}\right\}$$

Since each χ_i is an oscillating function with a period of $T/2$, $p_t(\theta_1,\phi_1)$ for a specified r_e and θ_1, ϕ_1 oscillates with a frequency of $2/T$ as long as shear is applied. As shown in [3] the rotational velocity of each particle is linear in G and hence reversible, so that $p_t(\theta_1,\phi_1)$ is also reversible when flow is reversed.[1]

[1]The magnitudes of $+G$ (forward) and $-G$ need not be identical, nor constant. The critical quantity for perfect restoration is the amount of shear strain of the suspension which should be identical in both directions so that the net macroscopic strain is zero. Thus the initial conditions are restored after shearing at an arbitrary rate $G_1(t)$ from 0 to t_1' and then reversing at $-G_2(t)$ from t_1' to t_2' such that

$$\int_0^{t_1'} G_1(t)\,dt - \int_{t_1'}^{t_2'} G_2(t)\,dt = 0$$

As a matter of convenience, and without ambiguity, we generally employ as the measure of shear strain the mean number of particle rotations $t/\overline{T}$ through $\phi_1 = \pm 2\pi$.

A convenient single measure of the distribution of orientation is a mean projected linear dimension, for example, the projection $r_2 = \sin\theta_1 \cos\phi_1$ of unit length of the axis of revolution on the X_2-axis (Fig. 1). The mean $\overline{r_2}$, averaged over all particles is thus given by

$$[8] \qquad \overline{r_2} = \overline{S_{13}} = \int_0^{2\pi} \int_0^{\pi} \sin\theta_1 |\cos\phi_1| p_t(\theta_1, \phi_1)\,d\theta_1\,d\phi_1$$

where S_{13} is defined below.

Integration of [8] yields complicated elliptic functions (7) which we do not reproduce here. Although $\overline{r_2}$ can be used for all $0 < r_e < \infty$, it is best employed only for $r_e > 1$. With oblate spheroids ($r_e < 1$) a mean projected area, for example, the projection $S_{13} = \sin\theta_1 \cos\phi_1$ of unit area of the equatorial cross section on the X_1X_3-plane is more convenient (7). Since the two are identical, i.e., $r_2 = S_{13}$, [8] is thus valid for all r_e's; in this paper we limit considerations to prolate spheroids ($r_e > 1$) and hence employ $\overline{r_2}$ but it should be remembered that the same principles and many equations apply to oblate spheroids ($r_e < 1$ and S_{13}) which, incidentally, are used in some of the experiments to be described (10). For initially random orientations $\overline{r_2} = \overline{S_{13}} = 0.5$, both quantities oscillate at constant amplitude with minima at $t/\overline{T} = 0.25$, 0.75, etc. and maxima at $t/\overline{T} = 0.5$, 1.0, etc.

In practice, however, the oscillations of $p_t(\theta_1,\phi_1)$ are usually damped and the suspension assumes a steady state $p_\infty(\theta_1,\phi_1)$ which is time-independent (3, 6, 7). Although the oscillations are damped, there are certain cases which are completely reversible and thus exhibit perfect memory. Two of these are now considered.

The most obvious cause of reversible damping is the dispersion of r_e, inevitable in real systems, which causes variations in TG and hence mixing of phase angles κ as shear proceeds (7, 21); $p_t(\theta_1,\phi_1)$ is then given by averaging over all r_e's. If the probability distribution of r_e is denoted by $g(r_e)$, the mean projected length is now given by the integral:

$$[9] \qquad \overline{r_{2\sigma}} = \int_0^{\infty} \overline{r_2} g(r_e)\,dr_e$$

where the subscript σ designates the value due to variations in r_e. The oscillations of $\overline{r_{2\sigma}}$ become damped as shear proceeds but can be exactly restored to their forward ($+G$) values when flow is reversed ($G < 0$) (3, 7). Thus the system has perfect memory.

This is demonstrated by the numerical example in Fig. 2, in which the distribution of r_e is assumed to

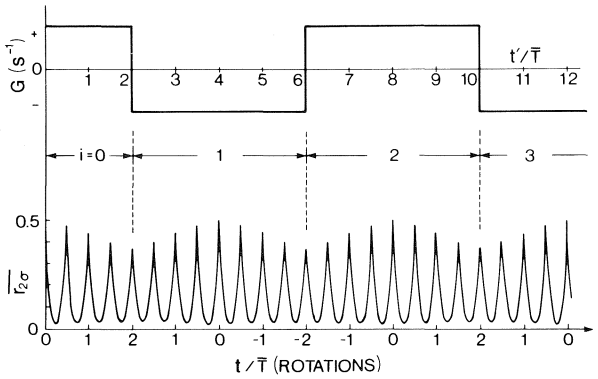

FIG. 2. Perfect memory in an initially isotropic ($r_{2\sigma 0} = 1/2$) suspension of non-interacting prolate spheroids of $\bar{r}_e = 10$ and $\sigma_e = 0.2$ calculated and drawn by computer using [9], for square-wave cycles $\pm G$ with flow reversal at real dimensionless times $t'/\bar{T} = 2, 6, 10$, etc. (upper part) for $i = 3$ reversals after $R_T = 2$ mean particle rotations during each 1/2 cycle about the X_1 (vorticity) axis of flow. The corresponding damped oscillation of $\bar{r}_{2\sigma}$ are shown by the computer calculated and drawn curves in the bottom portion, and show perfect memory even when $R_T, i \to \infty$. Since the time scale is dimensionless, the magnitude of G is immaterial as long as the flow regime is creeping and thermal (Brownian) motion is absent, i.e., $Br_r \to \infty$.

be Gaussian:

$$[10] \qquad g(r_e) = \frac{1}{\sqrt{2\pi}\sigma_e} \exp\left[\frac{-(r_e - \bar{r}_e)^2}{2\sigma_e^2}\right]$$

where σ_e is the standard deviation of r_e from the mean $\bar{r}_e$. Numerical calculations from [8]–[10] were made for an initially isotropic ($\bar{r}_{2\sigma} = 1/2$) dilute suspensions of non-interacting prolate spheroids of $\bar{r}_e = 10$, and $\sigma_e = 0.2$ (numerical values selected to correspond to previous calculations (7)) subjected to square-wave cycles of $\pm G$ in which the initial $G(>0)$ is applied until $t'/\bar{T} = 2$, where t' is the actual time and which corresponds to 4 semi-rotations of the mean-sized particle, and reversed ($G < 0$) until $t'/\bar{T} = 6$, then restored to $G > 0$ and so on indefinitely. The changes in $\bar{r}_{2\sigma}$ are shown by the computer drawn curves at the bottom of Fig. 2. It is seen that the amplitude of the oscillations of $\bar{r}_{2\sigma}$ at constant G decreases until flow is reversed and then increases reproducibly to the initial value at $t/\bar{T} = 0$ (where t now can have either positive or negative values relative to the initial time ($t = 0$) indicated in Fig. 2) or $t'/\bar{T} = 4, 8, 12$, etc. This process can be repeated indefinitely even when the flow is reversed at very large $t/\bar{T}$ where the amplitude of the oscillations becomes vanishingly small. For the more general case in which R_T is the mean number of particle rotations before the flow is reversed and i is the number of flow reversals, we note that even when R_T and/or $i \to \infty$ the system will show perfect memory.

The damped oscillations of $\bar{r}_{2\sigma}$ can be characterized by a relaxation time τ_1 during which the amplitude is reduced to e^{-1} of the undamped oscillation observed in a monodisperse suspension of $r_e = \bar{r}_e$ (i.e., $\sigma_e = 0$). A detailed analysis (7) of such damping, which has been confirmed experimentally (6), for a spread given by [10] yields:

$$[11] \qquad \tau_1 = \frac{(\bar{r}_e^2 + 1)^2}{\sqrt{2}G\sigma_e|\bar{r}_e^2 - 1|} \qquad \text{for } r_e \gtrless 1$$

A second mechanism for reversibly damped oscillations is shear-induced particle interactions: when two or more rigid particles pass in close proximity C and κ of each particle can change reversibly (22, 23). It is difficult to estimate the changes even for 2-body interactions, but an approximate analysis for long slender rods (7), also confirmed experimentally (6), yields a relaxation time τ_2:

$$[12] \qquad \tau_2 = \frac{\ln r_e}{GNl^3}$$

where N is the number density of particles and $l = 2a$, and is valid for $r_e \gg 1$. When both mechanisms operate simultaneously, the effects are reciprocally additive, i.e., $\tau_{net}^{-1} = \tau_1^{-1} + \tau_2^{-1}$ (6, 7). For n-body interactions, where $n > 2$, the analysis is thus far intractable; these interactions should nevertheless be reversible as has been demonstrated experimentally with rigid spheres, rods, and discs (22–24).

A third mechanism is non-uniform shear G such as that occurring in Poiseuille flow, e.g., between fixed parallel plates or through a circular tube, where the variation in G causes reversible mixing of phase angles κ. This should produce reversible damping similar to that considered above but with the added feature of a superimposed reversible pulse of lower frequency. Cox *et al.* discuss this interesting phenomenon elsewhere (25).

Memory Loss

We now consider several causes of partial or complete irreversibility with resulting impairment of memory of orientation distributions which have been studied experimentally; several of these have been examined further by numerical analysis.

(a) Electric Fields

When an external electrical field is superimposed on the suspension as it undergoes shear flow, each particle experiences an electrical torque which introduces an additional term involving the electric field strength E_0 on the right hand side of each of [3*a*, *b*], and hence modification of [4*a*, *b*] (26–28).

Thus when E_0 is applied across the flow, i.e., along the X_2-axis as in Fig. 1, a prolate spheroid experiences an algebraically greater ($d\theta_1/dt$) and smaller ($d\phi_1/dt$)

than given by [3*a*, *b*]; for example $(d\phi_1/dt)$ is decreased when $0 \leq \phi_1 \leq \pi/4$ and increased when $\pi/4 \leq \phi_1 \leq \pi/2$, a pattern which is repeated in alternate quadrants. Integration of the rotational equations yields the analogues of [4] and [5] for a single spheroid of dielectric constant K_1 suspended in a dielectric medium of K_2 (28):

$$[13] \quad \tan\theta_1 = \frac{C_0 r_e}{(r_e^2\cos^2\phi_1 + \sin^2\phi_1 - f r_e \sin 2\phi_1)^{1/2}} \times \exp\left[\frac{-K_2 E_0^2 P(q,r_e)}{\eta} t\right]$$

$$[14] \quad \tan\phi_1 = r_e(1-f^2)^{1/2}\tan\left(\frac{2\pi t}{T_1} + \kappa_1\right) + f r_e$$

and the period of rotation T_1 by

$$[15] \quad T_1 = \frac{2\pi}{G(1-f^2)^{1/2}}(r_e + r_e^{-1})$$

where C_0 (orbit) and κ_1 (phase angle) are integration constants analogous to C and κ in [4] and the dimensionless parameter

$$[16] \quad f = \frac{-K_2 E_0^2 P(q,r_e)(r_e^2+1)}{G\eta r_e}$$

gives the ratio of the electrical to hydrodynamic torques. For the remaining quantities in [13]–[16]: η is the viscosity of the suspending medium, $P(q,r_e)$ a known analytic function of r_e (> 0 for $r_e < 1$, < 0 for $r_e > 1$) and $q = K_1/K_2$ is the dielectric ratio.

When $f^2 < 1$, it follows from [15] that T_1 is real and finite; thus a particle executes complete rotations through $\phi_1 = 2\pi$. However, when $f^2 \geq 1$, corresponding to a supercritical electrical field (26, 28), it assumes a steady calculable orientation. Although all values of f are amenable to analysis, for simplicity we consider only the case of sub-critical electric fields $f^2 < 1$ when a particle rotates in a spiral orbit which drifts towards $\theta_1 = \pi/2$ when $r_e > 1$, and 0 when $r_e < 1$. Since [13]–[16] contain G and E_0^2, the sign of E_0 does not affect the rotations whereas that of G does. Thus applying $\pm E_0$ (and indeed applying an ac field and using the rms E_0 in the equations (28)) regardless of the sign of G causes each particle to drift to the limiting θ_1. As will be seen this causes memory loss.

As in the experiments (10) and in the numerical calculations below we consider only prolate spheroids ($r_e > 1$) at very low concentrations where interactions (especially electrical) are negligible although similar methods can be employed with oblate spheroids ($r_e < 1$). We examine the effect of an electric field which is applied in two ways: first with constant f^2 and then with occasional shocks administered at the point of flow reversal. Since it is so experimentally convenient (10), the particles are initially aligned along the X_2-axis so that $\overline{r_2} = 1$ and $\kappa = 0$. Memory retention (or loss) on reversing flow can then be expressed by the change in $\overline{r_2}$.

(b) Steady Electrical Fields

For continuous application of E_0 at constant f integration of [14], the details of which we omit, yields for $\sigma_e = 0$

$$[17] \quad \overline{r_2} = \left[1 + \left\{r_e(1-f^2)^{1/2}\tan\left(\frac{2\pi t}{T_1} + \kappa_1\right) + f r_e\right\}^2\right]^{-1/2}$$

where $\kappa_1 = \tan^{-1}(-f(1-f^2)^{-1/2})$ which oscillates at constant E_0, G with a period $T_1/2$ between $\overline{r_2} = 0$ and 1. The oscillations are undamped but it should be noted from [17] that they are not symmetrical about the maxima ($\phi_1 = 0, \pi/2$, etc.) or minima ($\phi_1 = \pi/4, 3\pi/4$, etc.); they are, however, identical in alternate 1/2 cycles. Thus, strictly speaking, the waves are not truly reversible except when they coincide at $\overline{r_2} = 1$ or 0 but can be made so by shifting the time scale by $\pm T_1/4$ after each reversal of flow.

In the case we are considering here $p_0(\theta_1,\phi_1) = \delta(\phi_1)\delta(\theta_1 - \pi/2)$ using the Dirac δ-function. For distributions in which there are particles with $0 < \theta_1 < \pi/2$, including initially random orientations $p_0(\theta_1,\phi_1) = \sin\theta_1/4\pi$ (as in Fig. 2), $\overline{r_2}$ undergoes oscillations of frequency $2/T_1$ whose amplitude changes, often increasing, as a result of the drift of all particles towards $\theta_1 = \pi/2$ until a steady state is reached at which the amplitude asymptotically reaches a constant value < 1 (28). Such systems are therefore irreversible and will exhibit memory loss. We do not discuss these examples further here, although we note that the same principles may be applied for numerical computations.

Returning to our case in which $p_0(\pi/2,\phi_1) = \delta(\phi_1)$ but now with $\sigma_e > 0$ as in some of our experiments (10), we calculate $\overline{r_{2\sigma}}$ by means of [9] and [17] for square-wave cycles $\pm G$ as in Fig. 2 but with $0 < f^2 < 1$. Because of the spread in r_e, phase mixing occurs as at $f = 0$ but at an enhanced rate (10), and damped oscillations occur (Fig. 3). The oscillations (now of frequency $2/T_1$) are similar to those in Fig. 2 except that they are not reversible. Thus during the first half cycle ($i = 0$, Fig. 3*a*) the oscillations are damped as in Fig. 2 except that the initial values of $\overline{r_{2\sigma}}$ are different (1/2 in Fig. 2, and 1 in Fig. 3*a*) because of the different initial orientation distributions. On reversing flow, however, the oscillations of

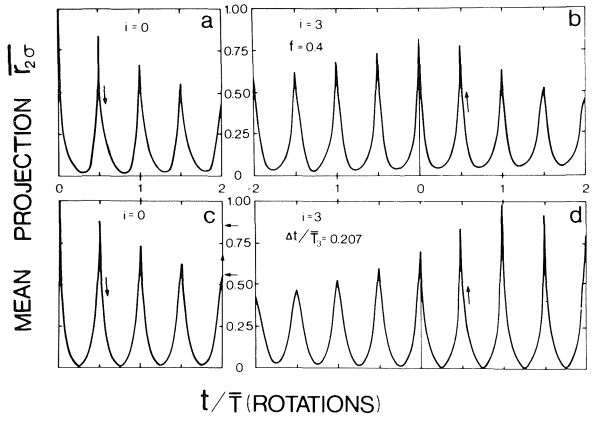

FIG. 3. (*a*) Oscillations at $f = 0.4$ of $\overline{r}_{2\sigma}$ calculated from [9] and [17] for the first-half cycle of the system shown in Fig. 2, but with the particles initially aligned so that $r_{2\sigma 0} = 1$. (*b*) As for (*a*) but during 3rd cycle of G (Fig. 2). Note that at $t/T_1 = 0$ the maximum $\overline{r}_{2\sigma 3}$ has decreased from 1 to 0.822 and that the left-hand portion ($t/T_1 < 0$) is not a mirror image of the right. (*c*) Oscillations of $\overline{r}_{2\sigma}$ at $f = 0$ for the same system as in part (*a*). On stopping flow at $R_T = 2$ and applying a shock at $\Delta t/T_3 = 0.2073$, $\overline{r}_{2\sigma}$ increased from 0.553 to 0.863 (shown by the horizontal arrows on the right ordinate scale). (*d*) Oscillations of $\overline{r}_{2\sigma}$ for the same system as in part (*c*) after $i = 3$ with the application of an electric shock at $\Delta t/T_3 = 0.207$ between each flow reversal. Note that the maximum $\overline{r}_{2\sigma}$ (< 1) in this case occurs at $t/T = +1$.

$\overline{r}_{2\sigma}$ increase in amplitude to reach a maximum < 1 at $t/T_1 = 0$, and then on continuing into negative time yield damped oscillations which are not mirror images of those in positive time. This is illustrated in Fig. 3*b* where the third cycle ($i = 3$) is shown corresponding to $G < 0$ (see Fig. 2, top): the maximum $\overline{r}_{2\sigma} = 0.822$ at $t/T_1 = 0$.

On increasing i the maximum $\overline{r}_{2\sigma}$ continues to change. It should be noted that the asymmetry about the maxima (and minima) $\overline{r}_{2\sigma}$ is generally too small to be discernible in Fig. 3 because of the small values of f.

A convenient measure of the memory retained by the suspension under this mode of cycling is given by (3):

$$[18] \qquad M_i = \frac{\overline{r}_{2\sigma i} - \overline{r}_{2\sigma\infty}}{\overline{r}_{2\sigma 0} - \overline{r}_{2\sigma\infty}}$$

where $\overline{r}_{2\sigma i}$ is the value at $t/T_1 = 0$ after i reversals of G, $\overline{r}_{2\sigma 0}$ is the initial value and $\overline{r}_{2\sigma\infty}$ the equilibrium value. While this definition is useful in the present context it has some serious limitations for general use. It is not a continuous function of time but is defined only for discrete values $(t/T)_i = 0$, and is applicable only when $\overline{r}_{2\infty}$ is time-independent. Thus $M_i = 1$ and 0 correspond respectively to complete retention and complete loss of memory; and $(1 - M_i)$ is the fractional memory loss.

When the suspension assumes a steady value of $\overline{r}_{2\infty}$, as is the case for $\sigma_e \neq 0$ and all values of $0 \leq f^2 < 1$, a steady state orientation is established given by (26):

$$[19] \qquad p_\infty(\phi_1, \pi/2) = \frac{r_e(1 - f^2)^{1/2}}{2\pi(r_e^2 \cos^2\phi_1 + \sin^2\phi_1 - f r_e \sin 2\phi_1)}$$

from which the mean $\overline{r}_{2\sigma\infty}$ can be obtained by the integral:

$$[20] \qquad \overline{r}_{2\sigma\infty} = \int_0^{2\pi} |\cos\phi_1| p_\infty(\phi_1, \pi/2)\, d\phi_1$$

Equation [20], whose solution is $\frac{1}{2}B_0$ given in analytic form by [93]-(7) and numerically in Table II-(7),[2] is used to calculate $\overline{r}_{2\infty}$ for use in [18].

Calculated values of M_i for the system in Fig. 3*a*, *b* are shown in Fig. 4*a* for various values of i at $1 > f^2 > 0$. Because of limitations in defining M_i and the lack of symmetry of ω ($= d\phi_1/dt$) about the X_2-axis (e.g., the maximum ω occurs at $\phi_1 = 0$ for $f = 0$ and $-\pi/8 < \phi_1 < 0$ for $f^2 > 0$ (10)), M_i shows fluctuations at small values of i and then a steady decline. For the largest f ($= 0.6$) M_i decreases to almost 1/2 after the first reversal. In all cases considered in Fig. 4*a*, $M_\infty = 0$; further calculations (not given here) show that this applies for all values of $R_T > 1$, i.e., the memory eventually becomes completely lost.

(c) Electric Shocks

We now consider a square-wave variation of G as in Fig. 2 except that at each reversal the flow is stopped for an interval Δt during which a field of strength E_0 is applied along the X_2-axis thus causing rotation of each particle in accord with (28)

$$[21] \qquad \tan\theta_1 = \frac{C_E}{\sqrt{\sin 2\phi_1}} \exp\left(\frac{\pi t}{T_3}\right)$$

$$[22] \qquad \tan\phi_1 = \exp\left(\frac{2\pi t}{T_3} + \kappa_E\right)$$

where C_E and κ_E are the orbit constant and phase angle, and T_3 is a characteristic time-scale:

$$[23] \qquad T_3 = \frac{\pi\eta}{K_2 E_0^2 |P(q,r_e)|}$$

Since $P(q,r_e) < 0$ for $r_e > 1$, the X_1' axes of prolate spheroids rotate toward the direction of E_0 (i.e., X_2), whereas those of oblate spheroids ($r_e < 1$) for which $P(q,r_e) > 0$ move toward the normal to E_0 (i.e., towards the X_1X_3 plane). After removal of E_0, the flow is then reversed at $f = 0$.

Using the same system as before numerical calculations of $\overline{r}_{2\sigma}$ are shown for $i = 0$ and 3 in Fig. 3*c*, *d*.

[2]Designating eq. [93] and Table II of ref. 7.

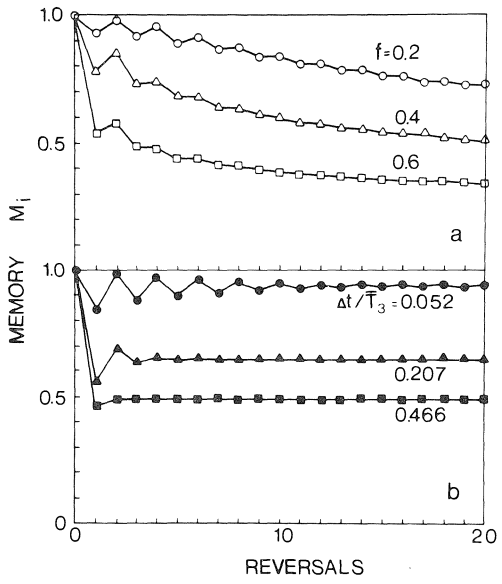

FIG. 4. Variation of M_i with i calculated from [18] for the same system as in Fig. 3*a* for various values of f (steady fields, part *a*) and for various electric shocks of magnitude $\Delta t/T_3$ (part *b*). Note that in (*a*) M_i initially fluctuates and then diminishes steadily until $M_\infty = 0$ (see text), while in (*b*) $M_\infty > 0$, i.e., the memory is not completely lost when shocks are applied although the loss increases from 0 as $\Delta t/T_3$ increases from 0 (the case corresponding to Fig. 2).

When $i = 0$, $\overline{r_2}$ for a particular value of r_e in a suspension of mean $\overline{r_e}$ is, from [4],

$$[24] \quad \overline{r_2} = \left[1 + r_e^2 \tan^2 \left\{\frac{2\pi t(\overline{r_e} + \overline{r_e}^{-1})}{\overline{T}(r_e + r_e^{-1})}\right\}\right]^{1/2}$$

from which $\overline{r_{2\sigma}}$ is calculated by means of [9]. When flow is stopped at $t/\overline{T} = 2$, the κ_E for each r_e is calculated from the final ϕ_1 given by [4*b*] using [22] and setting $t = 0$. When an electric shock corresponding to the dimensionless value $\Delta t/\overline{T}_3 = 0.2073$ is applied, the mean $\overline{r_2}$ for a particular r_e can readily be shown from [21]–[23] to be

$$[25] \quad \overline{r_2} = [1 + \exp(4\pi\Delta t/T_3 + 2\kappa_E)]^{-1/2}$$

which with the aid of [9] is used to calculate $\overline{r_{2\sigma}}$. Applying this shock after $R_T = 2$ causes $\overline{r_{2\sigma}}$ to increase from 0.553 to 0.863 (Fig. 3*c*).

For $i = 1$, the new phase angle κ for each r_e is then obtained using [4] with $t = 0$ from the final orientation given by [22], and during the reverse flow, $\overline{r_2}$ for a given r_e can then be calculated by adding κ to the bracketed argument for $\tan^2$ in [24] from which new equation $\overline{r_{2\sigma}}$ is calculated again with the aid of [9]. This process is continued for successive cycles.

The result for $i = 3$ shown in Fig. 3*d* is typical for all values of $i > 0$. In Fig. 3*d* the amplitude increases to a maximum at $t/T = 1$ (rather than 0) and then decreases as t/T decreases to -2; similar behavior is shown at all odd values of i, with the oscillations diminishing in amplitude as i increases; when i (> 0) is even the maxima occur at $t/T = -1$. M_i is calculated from [18] as before with $\overline{r_{2\sigma\infty}}$ evaluated by means of [19] and [20] at $f = 0$, yielding

$$[26] \quad \overline{r_{2\sigma\infty}} = \frac{1}{\pi\sqrt{\overline{r_e}^2 - 1}} \ln \frac{\overline{r_e} + \sqrt{\overline{r_e}^2 - 1}}{\overline{r_e} - \sqrt{\overline{r_e}^2 - 1}}$$

which gives $\overline{r_{2\sigma\infty}} = 0.1915$ for the system.

The same procedure can be followed for other values of $\Delta t/T_3$, with the results shown in Fig. 4*b* which shows initial fluctuations which then damp out and reach a constant asymptotic value $M_\infty \neq 0$, i.e., the memory is never completely lost although for the values shown the eventual memory loss increases from 0 at $f = 0$ (which is identical to the case considered in Fig. 2 except for the initial orientation $p_0(\phi_1,\theta_1)$) to about 1/2 for $\Delta t/T_3 = 0.466$. If we take the maximum value of $\overline{r_{2\sigma}}$ obtained during each 1/2 cycle of G, which incidentally occurs at $t/T = \pm 1/2$, ± 1, ± 2 for $\Delta t/T_3 = 0.0518$, 0.2073, and 0.4663, respectively, with $\pm$ for odd and even values of i, respectively, and use it instead of $\overline{r_{2\sigma i}}$ at $t/T = 0$ the steady-state memories $M_\infty' = 0.964$, 0.991, and 0.95, respectively, are appreciably greater than those shown in Fig. 4*b*. It is curious that for the three values of $\Delta t/T_3$ employed, the M_∞' is greatest for the intermediate value, a result for which we have no explanation. It is clear from these examples that there are limitations to the definition of M_i in [18] but the results given here show, nevertheless, that applying electric shocks causes only partial memory loss.

(d) Brownian Rotation

If the particles are small enough to exhibit Brownian movement, [3] and [4] are disturbed by superimposed random displacements which are totally irreversible. The effect of Brownian rotation on the rotation in shear is determined by the dimensionless rotary Brenner number Br_r (5)

$$[27] \quad Br_r = G/2D_r$$

where D_r is the rotary diffusion coefficient of a particle about its axis of revolution; Br_r is thus a measure of the ratio of orthokinetic (and reversible) and perikinetic (irreversible) rotations (5).

Translational Brownian motion also influences the spatial distribution by an amount determined by the translational Br_t (5) which is analogous to [27]. However, as already mentioned, these effects are not important in the present context and are not considered further.

The time-dependent orientation distribution function for spheroidal particles with Brownian rotation

is given by the Fokker–Planck equation in the form

$$[28]\quad \frac{\partial p_t(\theta_1,\phi_1)}{\partial t} = -\nabla\cdot\boldsymbol{\omega} p_t(\theta_1,\phi_1) + D_r\nabla^2 p_t(\theta_1,\phi_1)$$

where $\boldsymbol{\omega}$ (which is proportional to G) is the angular velocity vector for the axis of revolution of particles in shear alone. The general solution of [28], which clearly involves Br_r, is not available, but is for several specific cases.

When $Br_r = \infty$, e.g., when $D_r = 0$, the solution for an initially isotropic suspension is [6]. A semi-quantitative solution has been found for small $D_r \neq 0$, i.e. large but finite Br_r, and $r_e \gg 1$ (29) which predicts that the oscillations of $p_t(\theta_1,\phi_1)$ are damped with two successive relaxation modes. In the first, rapid diffusion occurs with a relaxation time $\tau = 0(D_r r_e^4)^{-1}$ in which phase mixing dominates; this is followed by the second mode with $\tau = O(D_r r_e^2)^{-1}$ due to a redistribution of particle orbits C so that a steady state orientation distribution $p_\infty(\theta_1,\phi_1)$ is eventually achieved; in this condition it is clear that all memory would be lost.

The general solution for $p_\infty(\theta_1,\phi_1)$, which is important, e.g., in the theory of streaming double refraction, obtained by setting the right hand side of [28] equal to zero, is given by a series expansion (29). On the other hand Brownian diffusion alone (or $Br_r = 0$) is predicted to cause an exponential decay to random orientations (30) with $\tau = O(6D_r)^{-1}$. Since Brownian rotations are random, they are independent of shear rotations over short time intervals. Therefore when flow is reversed, particle rotation is not retraced exactly, thus causing some loss of memory.

Thus on the basis of these considerations we would expect that at $0 < Br_r < \infty$, M_i would decrease with increasing i and asymptotically approach zero.

We can illustrate the effect by an example, admittedly somewhat artificial, in which in lieu of the electric shocks administered at each flow reversal considered above, the particles are allowed to undergo identical bursts of randomization of the phase angle κ (in a manner similar to the administration of electric shocks described above), corresponding to bursts of rotary Brownian diffusion in the X_2X_3 plane. As before, we take an infinitely dilute suspension with $\overline{r_e} = 10$, $\sigma_e = 0.2$ initially aligned along the X_2 axis and assume that all the particles remain in the orbit $C = \infty$ so that the equilibrium orientation is given by [19] with $f = 0$; the corresponding probability distribution of κ is random (7), i.e.,

$$[29a]\quad p_\infty(\kappa) = 1/2\pi$$

Since all the particles are initially aligned at $\phi_1 = 0$, $\theta_1 = \pi/2$, the initial distribution is

$$[29b]\quad p_0(\kappa) = \delta(\kappa)$$

At the point of flow reversal after R_T mean rotations κ becomes randomized according to a Gaussian distribution $g(\kappa)$ as in [10] except that κ and σ_{κ_1} replace r_e and σ_κ respectively, σ_{κ_1} being the standard deviation from $\overline{\kappa_1}$ $(= 0)$ after the first flow reversal. Flow is then reversed as in Fig. 1 until $t/T = -R_T$ when a similar random burst in κ occurs which when added to the first burst yields $\sigma_{\kappa_2} = \sqrt{2}\sigma_{\kappa_1}$. After i similar reversals $\sigma_{\kappa_i} = \sqrt{i}\sigma_{\kappa_1}$. At any point during flow $\overline{r}_{2\sigma}$ is calculated from the integral

$$[30]\quad \overline{r}_{2\sigma} = \int_0^\infty \int_{-\infty}^\infty \overline{r}_2 g(r_e) g(\kappa_i)\, d\kappa_i\, dr_e$$

Figure 5 shows the numerical values calculated from [30] for the same system as in Fig. 2 but with $\sigma_{\kappa_1} = 0.2$ radian and $R_T = 9$. Similar results, which we do not give here, are obtained for other values of σ_{κ_1} and R_T for the same system and, as might be

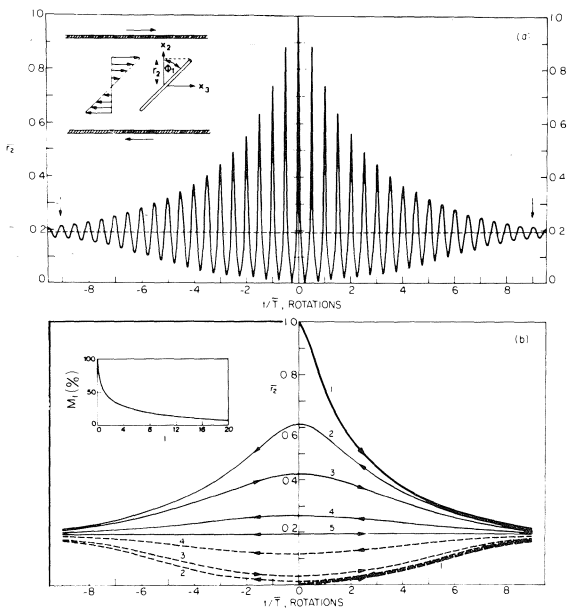

FIG. 5. (*a*) Damped oscillations similar to the same system as in Fig. 2 but for $R_T = 9$ mean particle rotations and $r_{2\sigma 0} = 1$. The broken line indicates the equilibrium value $r_{2\sigma\infty} = 0.1915$ calculated from [26]. (*b*) The envelope of the maxima and minima of the oscillations in $\overline{r_2}$ after random bursts of κ at the points shown by the arrows for $\sigma_{\kappa_1} = 0.2$ radians shown as solid and broken lines respectively obtained by numerical integration of [30]. Curve *1* corresponds to the oscillations shown in part *a*. Curves *2*, *3*, *4* are for the first, fourth, and sixteenth reversals following perturbations of κ at $t/T = \pm 9$, and curve *5* (which is flat) is the equilibrium value $r_{2\sigma\infty}$. The memory of the system M_i vs. i calculated from [18] is shown by the inset and asymptotically approaches 0 when all memory is lost.

expected, show that M_i decreases monotonically (but not exponentially) with i at a rate which increases with increasing σ_{κ_1} and R_T, and asymptotically approaches zero, i.e., all memory is lost as $i \to \infty$.

Thus even though we are not yet able to perform the calculations for continuous 3-dimensional Brownian (random) displacement ($Br_r < \infty$) it is reasonable to conclude that eventually all memory would be destroyed (31). This has been confirmed experimentally (10).

(e) Other Disturbances

Several other disturbances are known to cause memory loss. With the exception of hydrodynamic interactions of spheres and to a limited extent with rods and discs cited below they have not yet been analyzed theoretically. As will be seen in the following paper (10) it is exceedingly difficult to avoid memory impairment in theoretically reversible systems because of unavoidable effects such as buoyancy due to small (but never zero) density differences between particles and suspending medium, convection due to thermal gradients, and most important of all irreversible hydrodynamic interactions.

Hydrodynamic interactions between geometrically perfect rigid spheres, rods, and discs have been shown to be reversible (8, 20, 22, 23) for $Br = \infty$ as would be expected when the reversibility conditions cited in the Introduction are satisfied. Recent careful observations, however, of 2-body interactions in which a pair of spheres (9) or rods (17) approach each other very closely are not strictly reversible as a result of small but inevitable surface asperities and, additionally with rods, sharp edges. Another cause of irreversibility is inertia which introduces a non-linear term into the Navier–Stokes equation and strictly speaking invalidates [3] and [4] at non-zero Reynolds numbers R_e, but at $Br_r = \infty$ have been shown (32) to cause a drift in the orbit constant defined in [4] towards $C = 0, \infty$ for single rigid discs ($r_e < 1$) and rods ($r_e > 1$). The rate and direction of the drift are independent of the sign of G, so that any oscillations in $\overline{r_2}$ would be partially irreversible. This drift has been analyzed theoretically, but only with partial success (32). Similar drifts occur at $R_e = 0$, $Br_r = \infty$ for rigid rods and discs in various non-Newtonian media (33–36). Recently (37) theoretical calculations for long slender rods ($r_e \gg 1$) in a second order fluid have predicted a drift towards $C = 0$, i.e., memory impairment should occur.

Some of these effects are, in addition to those considered earlier, examined experimentally in the following paper (10).

Experiments on the reversibility of particle orientation distributions in suspensions of nearly monodisperse rigid rods and hardened red blood cells (HRBC) subjected to cyclic shearing are described.

The orientation distributions of initially aligned rods measured by direct observation exhibited a gradual loss in memory as flow was reversed back and forth which was attributed mainly to non-reversible particle interactions. When an electric field was applied continuously during cyclic shear flow, the rate of memory loss was increased. However, if an electrical shock was applied momentarily between each reversal of flow, the suspension maintained some memory. These results are generally in agreement with the theory presented in the preceding paper.

With suspensions of HRBC, the particles were initially randomly oriented and the light transmittance across the planes of shear was used to measure changes in orientation distribution. Since HRBC are small enough to exhibit appreciable rotary Brownian motion, memory loss was inevitable and increased with the duration of each shear cycle and the cell concentration.

Memory loss was also observed for rods and HRBC in non-Newtonian media and was attributed to drift in the rotational orbit constants of the particles.

G. J. ENNIS, A. OKAGAWA et S. G. MASON. Can. J. Chem. **56**, 2824 (1978).

On décrit certaines expériences portant sur la réversibilité des distributions d'orientations de particules dans des suspensions de globules rouges durcis et de bâtonnets rigides presque monodispersés, qu'on soumet alternativement à des cisaillements dans des sens opposés.

On a mesuré par observation directe les distributions d'orientations de bâtonnets initialement alignés et l'on a noté qu'un changement alternatif du sens de l'écoulement provoque une perte graduelle de mémoire, qu'on a principalement attribuée à des interactions irréversibles entre les particules. Si un champs électrique était maintenu durant l'écoulement cisaillé alternatif, le système perdrait la mémoire plus rapidement. Cependant, si la suspension recevait une secousse électrique momentanée entre chaque changement de sens de l'écoulement, elle conserverait la mémoire dans une certaine mesure. En général, ces résultats sont en accord avec la théorie exposée dans le mémoire précédent.

Dans les suspensions de globules rouges durcis, les particules étaient initialement orientées au hasard et la lumière transmise au travers des plans de cisaillement servait à mesurer les variations dans la distribution d'orientations. Etant donné que les globules sont assez petits pour donner lieu à un mouvement Brownien rotationnel appréciable, la perte de mémoire était inévitable et elle s'accentuait avec la durée de chaque cycle de cisaillement et la concentration des globules.

Dans les milieux non-Newtoniens, les bâtonnets et les globules subissaient une perte de mémoire qu'on a attribuée à la dérive des constantes rotationnelles orbitales des particules.

[Traduit par le journal]

Introduction

In the preceding paper (1) we considered some theoretical aspects of memory loss in dilute suspensions of spheroids of nearly uniform size subjected to alternating cycles of simple shear flow. In this paper we present some experimental tests of the theory using two different methods: one lengthy and tedious, based on microscopic measurements of the mean orientation distributions of individual rods (used to model prolate spheroids, $r_e > 1$ (2) at $Br_r = \infty$[1]) and the other rapid and simple using macroscopic measurements of the turbidity of hardened red blood cells (HRBC) (used to model oblate spheroids, $r_e < 1$, $0 < Br_r < \infty$ (3)). The rods were initially aligned in one direction ($\theta_1 = 90°$ and $\phi_1 = 0°$ or $p_0(\theta_1,\phi_1) = \delta(\theta_1 - \pi/2)\delta\phi_1$ and $\kappa = 0$) by applying an external electric field along the X_2-axis (Fig.

[1]Most of the symbols used in this paper are the same as in the preceding paper (1) and will generally be used here without further definition.

1-(1))[2] prior to applying cyclic shear flow. From the measurements of θ_1 and ϕ_1 of each particle at $Br_r = \infty$ at any given time t, the mean value $\overline{r_2}$ was determined and used as a single measure of orientation (4, 5); thus $\overline{r_2} = 1, 1/2, 0$ correspond respectively to complete alignment along the X_2-axis (Fig. 1-(1)), three-dimensional random orientation, and complete orientation in the direction of flow (i.e., the X_3-axis). In general $\overline{r_2}$ shows damped oscillations when the suspension is first subjected to shear, which are restored with varying degrees of perfection when the shear is reversed. The change of particle orientation distribution on restoring the initially zero shear strain (1) is taken as the memory loss, a convenient, although not perfect, definition of which is $(1 - M_i)$, where [18]-(1):

$$[1] \qquad M_i = \frac{\overline{r_{2\sigma i}} - \overline{r_{2\sigma\infty}}}{\overline{r_{2\sigma 0}} - \overline{r_{2\sigma\infty}}}$$

The effect of an electric field on M_i of rods was studied by subjecting them to combined shear and sinusoidal electric fields ($f^2 < 1$ (1)) and to shock, i.e., an electric field E_0 (at $G = 0$) for an interval Δt between each flow reversal. The rods were also suspended in an elastico-viscous solution and subjected to cyclic shear flow, causing the orbits C to drift and hence, as expected, memory loss.

With HRBC which scatter light, or silvered HRBC (AgHRBC) which absorb it, an initially random orientation was obtained due to Brownian rotation at $Br_r = 0$ and the optical transmittance at $Br_r \geq 0$ along the X_2-axis was used as a single measure of orientation distribution (6, 7). The transmittance T' (not to be confused with the periods T, T_1, T_3 defined in ref. 1 and also used later) decreases with increase in the optical scattering cross section C_{sca} for scattering particles (HRBC) and the geometrical cross section S for absorbing particles (AgHRBC) (7); for spheroids (and discs) C_{sca}, S pass through maxima when the light beam impinges on the particle when it is edge-on and face-on respectively. Since only relative changes in T' were measured, the memory retained was calculated from the maxima for HRBC or of the minima for AgHRBC using the analogue of [1]:

$$[2] \qquad M_i' = \frac{T_i' - T_\infty'}{T_0' - T_\infty'}$$

where T_i' is the maximum or minimum transmittance at $t/\overline{T} = 0$ after i flow reversals (Fig. 2-(1)) and T_∞' is the equilibrium value after the amplitude of the oscillations approach zero.

[2]Designating Fig. 1 of ref. 1; a similar convention is adopted for designating numbered equations for referenced papers.

Various effects on M_i' were examined, e.g., by changing the medium viscosity, particle concentration, the velocity gradient G, and by using a non-Newtonian medium. As will be seen, the experimental findings were, with one unaccountable exception, in qualitative agreement with the theory (1).

Before presenting the results, it should be pointed out that the quantities M_i and M_i' are expressed as 'point' values at $t/T = 0$ and not continuous functions of time. Therefore in the graphical displays of M_i, M_i', vs. t, no attempts were made to draw best fit lines for any given set of experimental points; lines were drawn merely to connect points and such illustrations are really histograms although we have not drawn them in conventional histogram form.

Experimental Materials

(a) Suspensions of Rods

Electrically conductive rods (so chosen to facilitate electrical alignment and to simplify the electrical calculations (8, 9)) as uniform as possible in length (900 μm) were prepared by microtoming A1-coated Nylon monofilaments (175 μm diameter) embedded in blocks of wax (Tissuemat, Fisher, mp = 67°C) thus obtaining rods of mean axis ratio $\overline{r_p} = 5.14$ with a nearly Gaussian distribution of standard deviation $\sigma_p = 0.11$ (2.1%). The equivalent prolate spheroidal axis ratios r_e (2) were calculated from the measured period of rotation T at known G using [5]-(1); for 60 particles $\overline{r_e} = 3.95$ and $\overline{\sigma_e} = 0.15$ (3.8%). The rods were suspended in two kinds of fluid at concentrations $N = 20\ ml^{-1}$ (volume fraction $c = 0.43 \times 10^{-3}$). One medium was oxidized castor oil which proved to have a Newtonian viscosity $\eta = 4.90$ Pa s up to $G = 100\ s^{-1}$; the other was an elastico-viscous solution of 3% polyisobutylene (PIB) in decalin (10). To avoid particle sedimentation over periods of several days tetrabromoethane was added to the media to match the particle and fluid densities.

(b) Suspensions of HRBC

The cells were prepared from fresh human blood erythrocytes by fixing them with glutaraldehyde by the method of Goldsmith and Marlow (3) slightly modified (11) to minimize cell destruction. They were rigid biconcave discs of mean diameter 5.0 μm and maximum thickness 1.3 μm with $\overline{r_p} = 0.26$ and $\sigma_p = 0.014$ (5.4%). The HRBC were also rendered opaque (and light absorbing) by silvering their surfaces in an aqueous solution of $AgNO_3$ and NH_4OH (11) following a standard procedure for silvering cellulose fibers (12). The AgHRBC thus obtained were slightly larger (average diameter 5.6 μm, thickness 1.8 μm) with $\overline{r_p} = 0.31$ and $\sigma_p = 0.027$ (8.7%) measured from scanning electron micrographs, and $\overline{r_e} = 0.49$ from measured values of TG (1). Both the HRBC and AgHRBC were suspended in various concentrations of aqueous glycerol (Newtonian) to which $SnCl_4$ was added to match densities. Concentrations were determined by counting cells using a Spencer hemacytometer (Fisher) and ranged from $N = (0.4 \text{ to } 1.4) \times 10^8$ cells/cm^3 corresponding to volume fractions $c = (2 \text{ to } 3.5) \times 10^{-3}$.

As a non-Newtonian elastico-viscous medium, an aqueous polyacrylamide (PAA) solution (2.5% wt./vol.) was used (10).

The properties of all the suspensions used are summarized in Table 1.

TABLE 1. Description of suspensions, temperature = 21.0 ± 0.5°C

	Rods		Discs		
	A1-coated nylon		HRBC	AgHRBC	
d (μm)	175		5.0	5.6	
l (μm)	900		1.3	1.76

Experimental Methods

(a) Direct Observations

The experiments on rods were performed in a Couette apparatus (a modified version of that described in (13)) which provides simple shear flow by means of two counter-rotating concentric metal cylinders. The outer cylinder (diameter 30.47 cm) is electrically insulated from the inner one (diameter 26.71 cm and grounded) so that an electric field can be applied across the annulus. The suspensions of rods in the annulus were floated on a much less viscous and insoluble layer of a denser liquid (e.g., glycerine) to avoid end effects which would distort the flow field (8). Applying an electric field (1.06 kV/cm at 60 Hz) for a few minutes across the cylinders caused the rods to align close to the direction of the field, i.e., along the X_2-axis (Fig. 1-(1)), so that $\theta_1 = 90°$ and $\phi_1 = 0°$ approx.; there was no evidence of electrical field distortion by the interface between the two liquid layers. After removing the electric field, a shear flow was applied (with or without a superimposed 60 Hz external electric field E_0 along the X_2-axis) and photographs of the rods were taken at regular time intervals of 1 to 5 s^{-1} along the X_1-axis using an automatic camera (Robot motor recorder 36 ME) equipped with a Tessovar lens (Carl Zeiss). The time of each frame was recorded from a digital clock through a separate lens on the camera on the upper right corner of each photographic frame. The two quantities, the projected length l_{23} on the X_2X_3-plane and the angle ϕ_1 of each rod were measured from the photographs which were projected frame-by-frame on an analyzing table. The angle ϕ_1 of each rod was calculated from the geometrical relationship $\sin\phi_1 = l_{23}/\bar{l}$ where $\bar{l}$ is the mean rod length; since σ_p was small, using $\bar{l}$ instead of l of each rod introduced a negligible error in determining θ_1. The orientations were also described by the projected length $r_2 = \sin\theta_1 \cos\phi_1$ along the X_2-axis (1, 4, 5). To obtain the mean projected length $\bar{r}_2$ of 100 to 200 rods, it was necessary to photograph several different fields of view since each frame contained only about 50 rods.

(b) Rheo-optical Measurements

The optical transmittance T' of the HRBC and AgHRBC suspensions was measured in a second Couette apparatus (14) equipped with transparent concentric cylinders (of outer and inner radii 5.455 and 5.725 cm so that the gap width = 0.270 cm) by passing white light from a tungsten microscope illuminator with an ir heat filter from the inside cylinder through the annulus, i.e., along the X_2-axis of the flow field (Fig. 1-(1)). The transmitted light was measured by a silicon photocell through a Tessovar lens (Carl Zeiss) focussed from the outside cylinder on the suspension so as to cover a 1 cm^2 area of the light beam. The photocell output was displayed on a power meter (Coherent Radiation, Model 212) and recorded through an amplifier on a chart recorder (Keithley, Model 370). To eliminate end effects, the suspensions were floated in a Freon substrate. A shear rate $G = \pm0.5$ to 3 s^{-1} was applied by rotating the inner cylinder with the outer one stationary. In both sets of experiments (*a*) and (*b*) the ratios of particle

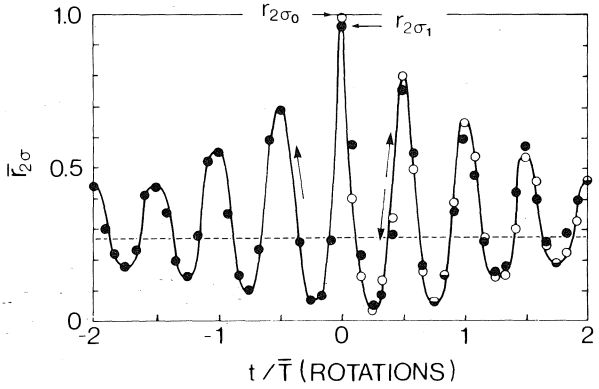

FIG. 1. Oscillations in $\bar{r}_{2\sigma}$ of rods ($\bar{r}_e = 3.95$, $\bar{\sigma}_e = 0.15$) showing nearly perfect memory of particle orientations after reversing the flow at $t/\bar{T} = 2$. Values for forward flow ($G > 0$, open circles) are nearly the same as for $G < 0$, and the damped oscillations at $t \leq 0$ are nearly the mirror images of those at $t \geq 0$. Note that on returning to $t = 0$ after the first flow reversal $i = 1$, $\bar{r}_{2\sigma 0} = 0.997$ and $\bar{r}_{2\sigma 1} = 0.964$ (indicated by the arrows) there is a slight loss of memory during the first cycle. The equilibrium value $\bar{r}_{2\sigma\infty} = 0.270$ for $p(C) = \delta(\infty)$ calculated from [20]-(1) is shown by the horizontal dashed line, so that in this experiment $M_1 = 0.955$. $G = \pm0.44$ s^{-1}, $N = 20$ ml^{-1}, and $E_0 = 0$.

dimensions to gap widths were such that wall effects were negligible (26).

Results and Discussion

(a) Rods

(i) Simple Shear (f = 0; $Br_r = \infty$)

In simple shear ($+G$) the rods, initially aligned very closely to $\phi_1 = 0°$, $\theta_1 = 90°$, i.e., with $\overline{r_{2\sigma 0}} = 1$, $C = \infty$, $\kappa = 0$ (1, 5), exhibited the damped oscillations of $\overline{r_2}$ as expected (1, 4, 5) with θ_1 remaining close to $\pi/2$ (i.e., $C = \infty$) over several particle rotations. As shown in Fig. 1, on reversing to $-G$ after $R_T = 2$ mean particle rotations, the oscillations were almost perfectly restored, with $\overline{r_{2\sigma 1}}$ reaching 0.96. On continuing the reversed flow during $i = 1$ to $t/\overline{T} < 0$, i.e., into 'negative' time, the damped oscillations were approximately the mirror images of those at $t \geq 0$. As the flow was cycled back and forth between $R_T = \pm 2$ (see Fig. 2-(1)), the amplitudes of these oscillations gradually diminished, but were still clearly discernible at $i > 15$. However, eventually they disappeared until a constant $\overline{r_{2\sigma\infty}}$ was reached when the memory of the initial state was completely lost.

The spread in orientation at $t/\overline{T} = 0$ after various values of the reversal number i for this series of experiments is illustrated by the integral distributions $P(\phi_1)$ in Fig. 2. Initially all of the rods were aligned in the region of $\phi_1 = \pm 10°$, but after only 3 flow reversals this was reduced to less than 40%. As G was cycled back and forth, θ_1 remained constant at $\pi/2$ (i.e., $C = \infty$) and $P(\phi_1)$ went through that corresponding to random orientations and approached the steady state orientation distribution $P_\infty(\phi)$ calculated from the integration of the probability distribution $P_\infty(\phi_1)$ ([19]-(1) for $f = 0$): which yields

$$[3] \qquad P_\infty(\phi_1) = \int_0^{\phi_1} p_\infty(\phi_1)\, d\phi_1 = \frac{1}{2\pi} \tan^{-1}\left(\frac{\tan \phi_1}{r_e}\right)$$

Values of M_i of the system calculated by means of [1] with $\overline{r_{2\sigma 0}} = 0.997$ (measured) and $\overline{r_{2\sigma 0}} = 0.270$ (calculated from [20]-(1)) are shown in Fig. 3 for cyclic flows of $R_T = 1$, 2, and 4 rotations from $t/T = 0$. It is seen that the memory of the suspension gradually faded. Thus, for example, the memory loss $(1 - M_i)$ after 7 flow reversals was 0.12, 0.26, and 0.52 for $R_T = 1$, 2, and 4 respectively, i.e., the memory loss was roughly doubled with each doubling of R_T. This suggests that under these conditions M_i was determined by the total real elapsed time of shear flow whether or not the flow was reversed. However, when M_i was plotted against real time t'/T (Fig. 3, bottom) the points did not fall on a single line.

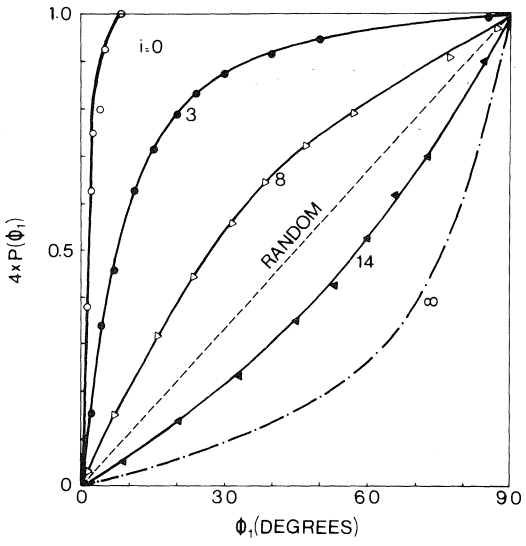

FIG. 2. Integral distributions of particle orientations $P(\phi_1)$, the fraction of particles oriented above ϕ_1, for the same experiment as in Fig. 1 at $t/\overline{T} = 0$ for various values of i showing the change from initial to final alignment, the measured values being shown as points. The straight (broken) line represents isotropic (or random) values of ϕ_1, and that for $i = \infty$ is calculated from [3]. Since the distributions are identical in all quadrants between $0 < \phi_1 < 2\pi$ the range of ϕ_1 in the graph is restricted to the first quadrant.

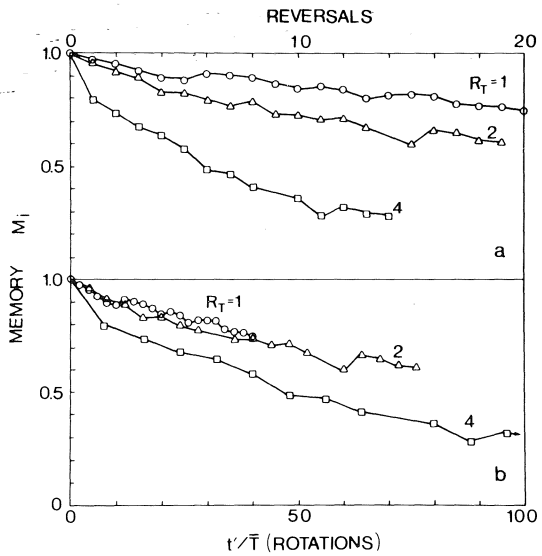

FIG. 3. Change in M_i of rods ($\overline{r_e} = 3.95$, $N = 20\ ml^{-1}$) calculated from [1] from the measured $\overline{r_2}$ at $t/\overline{T} = 0$ when the flow ($G = \pm 0.44\ s^{-1}$) is reversed at $R_T = 1$ (open circles), 2 (open triangles), and 4 (open squares) are plotted against the number of flow reversals i (upper part) and against $t'/\overline{T}$ (lower part). M_i decreased nearly monotonically with i at rates which increased with R_T. When plotted against total time elapsed $t'/\overline{T}$, the points did not fall onto a single line.

Possible mechanisms for memory loss in these experiments have been discussed in the preceding paper (1). For particles of the dimensions used in these experiments the interparticle forces (which would lead to irreversibility) were negligible compared to the reversible hydrodynamic forces (15), and $D_r \simeq 10^{-13}$ s^{-1} which would lead to a calculated (1) diffusional relaxation time of 10^6 years whereas the longest experiment in this series took only 100 min. Thermal convection due to fluctuations in room temperature was examined by observing the suspension at rest in the apparatus. The measured $\overline{r_2}$ showed no appreciable change from $\overline{r_2} = 0.997$ over 1 h which corresponds to 60 particle rotations at the G employed in experiments, and 2.5 h later was still $\overline{r_2} = 0.93$. Therefore, these three mechanisms for memory loss clearly do not explain these observations.

As already mentioned the particle orbits did not change appreciably from $C = \infty$ during the experiments, so that the memory loss observed was due entirely to the change in the probability distribution $p_i(\kappa)$ of phase angles κ. It is interesting to compare the observations of memory impairment due to disturbances in κ with the calculations given in ref. 1 in which M_i decreased monotonically (Fig. 5*b*-(1)) with i in a manner similar to that shown in Fig. 3.

From earlier studies of shear-induced interactions between rigid particles in the creeping flow regime, it was concluded that they were reversible (2, 16–18). More recently (19), however, careful examination of 2-body interactions of rods showed that this was not exactly true for very close approach presumably as a result of surface asperities over the whole surface and sharp edges at the ends of the rods. Calculations, following ref. 17, show that the number of close collisions was about 10 per flow cycle of $R_T = \pm 2$ for the 150 particles of the mean populations taken for each measurement of $\overline{r_{2\sigma}}$ in this series of experiments so that, for example, for $i = 20$ (Fig. 3) each particle could have undergone at least 1 close collision each of which would cause a substantial change in κ and hence $p(\kappa)$ of the assembly.

We conclude, therefore, that the memory losses in these experiments were due to interactions, mostly 2-body (2), due to imperfections in the surfaces of the particles. Reducing surface roughness of the rods to molecular dimensions and eliminating any sharp edges (e.g., rounding the ends) should eliminate the losses (15); this, however, would be very difficult in practice for systems in which $Br_r = \infty$ which generally require that the particles be large.

(ii) Effects of Electric Fields

(1) Steady Electric Fields

When a cyclic shear of $G = \pm 0.44$ s^{-1} and an ac electric field of rms $E_0 = 280$ V/cm corresponding to $f = 0.024$ were applied to an initially aligned suspension of rods ($\overline{r_e} = 3.95$), the $\overline{r_2}$ at $i = 0$ showed damped oscillations similar to those shown in Fig. 1. Since $f = 0.024$ corresponds to an increase of only 0.03% in the period of rotation given by [15]-(1)[3] over $f = 0$, the effect of the electric field was small. However, when the flow was reversed, the recovery of the initial $\overline{r_{2\sigma}}$ was less than that at $f = 0$ and the difference increased with the number of cycles. This is shown in Fig. 4 where for $R_T = 1$ and 2 are compared with $f = 0$. It is seen that memory impairment was increased by applying the electric field, and that at corresponding values of i, the losses $(1 - M_i)$ for $R_T = 2$ were nearly double those for $R_T = 1$.

From the theory given in the preceding paper (1), the calculated values M_i (Fig. 4*a*-(1)) showed practically no change up to 10 reversals indicating nearly perfect memory at this small value of f; as f increases the theory predicts increasing memory loss. Clearly there is a discrepancy between theory and experiment, much larger than for $f = 0$; again we attribute it to particle interactions. In the theory for $f > 0$ both hydrodynamic and electric interactions were neglected. Theoretically hydrodynamic interactions should not cause any memory loss (1), but as shown above they do in practice. Electric interactions resulting from intense Coulombic attraction (and in certain cases repulsion) between dipoles induced on the particles (20–22) cause cumulative memory loss even under conditions when none occurs at $f = 0$. The theory of memory loss taking interactions into account for $f > 0$ has not yet been worked out, however, and will prove to be complicated except possibly for dilute suspensions of electrically conducting spheres where the equations describing two-body interactions have been derived (21) and confirmed experimentally (22). However, it is safe to predict that the memory loss at $1 > f^2 > 0$ (1) will increase with increasing f, r_e, and c and that eventually $M_\infty = 0$ (1).

(2) Electric Shocks

In these experiments with the rods, the principles of which are given in ref. 1, electric shocks $E_0 = 2$ kV/cm corresponding to $T_3 = 82.7$ s ([23]-(1)) were applied at each flow reversal.

With the initially aligned rods damped oscillations

[3]Strictly speaking, for non-spheroidal particles such as the rods of particle axis ratio $r_p = 5.14$ used, we should employ r_{eH} and r_{eE} (with $r_{eE} > r_p > r_{eH}$), the hydrodynamically and electrically equivalent spheroidal axis ratios (9), in [13]-(1) and related equations. In the calculations presented here we do not distinguish between the two r_e's and, in effect, simply use $r_{eH} = r_{eE} = r_e$ where r_e is determined from the period of rotation T at $E_0 = 0$ using [5]-(1).

For personal use only.

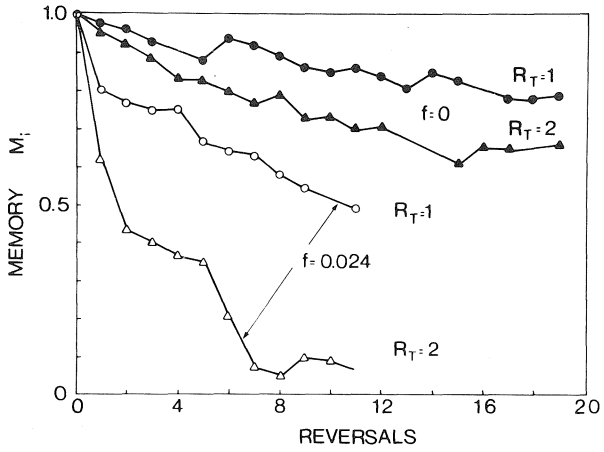

FIG. 4. Change in M_i of the same suspension as in Fig. 3 at $f = 0$ (solid points) and at $f = 0.024$ (open points) when flow is reversed at $R_T = 1$ (circles) and $R_T = 2$ (triangles). As predicted (1) there is an enhanced memory loss in the presence of a steady electric field.

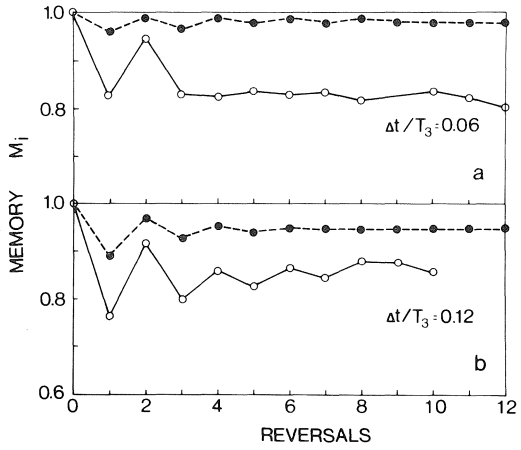

FIG. 5. Change in M_i for the same suspension as Fig. 1 when subjected to electric shocks $\Delta t/T_3 = 0.06$ (part *a*) and 0.12 (part *b*) when the flow was stopped after $R_T = 1$ for an interval Δt before resuming flow in the reverse direction. The broken lines correspond to the theory developed in ref. 1 for suspensions without hydrodynamic or electric interactions of the rods.

of $\overline{r_2}$ at $i = 0$ were similar to those shown in Fig. 1. When the flow was stopped at $R_T = 1$ the E_0 applied for an interval Δt, each rod rotated toward the X_2-axis (8, 9) so that $\overline{r_{2\sigma}}$ increased from 0.592 to 0.810 after $\Delta t = 10$ s in qualitative accord with [69*b*]-(8). Upon reversing flow, the amplitude of the oscillation increased first to $\overline{r_{2\sigma}} = 0.965$ at $t/\overline{T} = 0.5$, then decreased to yield $\overline{r_{2\sigma 1}} = 0.837$ at $t/\overline{T} = 0$ similarly to Fig. 3*d*-(1) corresponding to a memory loss $(1 - M_1) = 0.24$. Changes of M_i for $R_T = 1$ with 5 and 10 s electric bursts, corresponding to $\Delta t/T_3 = 0.0605$ and 0.1209 are shown in Fig. 5. It is seen that initially M_i fluctuated with increasing i but then appeared to approach steady non-zero value. This behavior differs considerably from that observed at $f = 0$ and 0.024 (Fig. 4) where $M_\infty = 0$. Theoretical values of M_i calculated (1) for these experiments are shown by broken lines in Fig. 5 with M_i showing initial fluctuations and then approaching constant non-zero values considerably higher than those observed experimentally. Although the absolute values of M_i from theory and the experiments differ considerably, the general variations of M_i with i and $\Delta t/T_3$ parallel one another. It is safe to conclude, however, that just as with $f^2 \geq 0$ discussed earlier, the differences can be attributed to irreversible hydrodynamic and electric interactions between the rods used.

(iii) Elastico-viscous Medium

In PIB/decalin, damped oscillations of $\overline{r_{2\sigma}}$ similar to those in Fig. 1 were observed, but as expected (1) with a much higher rate of damping. Values of M_i calculated from measured $\overline{r_{2\sigma}}$ at $t/\overline{T}$ for $R_T = 1$, 2, and 3 are shown in Fig. 6. To calculate M_i from [1],

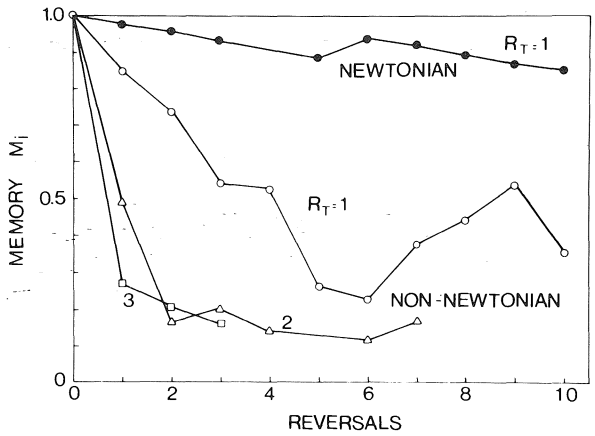

FIG. 6. M_i of rods ($\overline{r_e} = 3.95$, $N = 20\ \text{ml}^{-1}$) suspended in 3% PIB/decalin solution at $R_T = 1$ (open circles), 2 (open triangles), and 3 (open squares) compared with the results for the Newtonian fluid (Fig. 3*a*) at $R_T = 1$ (closed circles). No explanation can be offered for the wide fluctuations at $R_T = 1$ in the non-Newtonian fluid.

$\overline{r_{2\sigma\infty}} = 0.138$ (somewhat less than calculated for the Newtonian medium, Fig. 1) obtained from the measured steady state orientation distribution achieved after several hundred particle rotations in a steady non-cyclic shear was used. It is seen from Fig. 6 that M_i decreased more rapidly than with the Newtonian medium. For $R_T = 1$, M_i after $i = 5$ fluctuated widely for no apparent reason. For $R_T = 2$ and 3, M_i decreased rapidly up to $i = 2$, then slowly decreased over the range of i. The memory loss observed in these experiments can be attributed to two causes: orbital drift and particle interaction, both

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

irreversible. It has been shown that a single rod in the medium used here at $f = 0$ and low G rotated with respect to ϕ_1 as in a Newtonian fluid but showed a drift of orbit constant toward $C = 0$, i.e., $\theta_1 = 0$ and $r_2 = 0$ (23). Since the rate and direction of drift of C were independent of the flow direction, $\overline{r}_{2\sigma}$ of the suspension continued to decrease gradually to the steady value, causing M_i to decrease as the rods drifted toward $C = 0$. We believe that the irreversible interactions are primarily the consequence of irreversible drift in C and only secondarily due to imperfections in the rods noted earlier (17). Thus, combining the orbit drift and interaction effects caused the system to lose memory much more rapidly than in Newtonian fluids (Fig. 6).

(b) Red Blood Cells

(i) Simple Shear ($Br_r < \infty$)

Unlike the experiments with the rods considered above, here the particles had sufficient rotary Brownian motion so that the initial orientations were random, i.e., $\overline{r}_{2\sigma 0} = 1/2$. Also the measurements of turbidity T' were macroscopic (on a large population of cells) and rapid, rather than microscopic (on a large number of individuals rods) and tedious.

Typical examples of the variation of T' for HRBC and AgHRBC for cyclic shear flows and at $G = 0$ ($Br_r = 0$) are shown in Fig. 7.

For HRBC (Fig. 7*a*) T' initially increased rapidly to a maximum when shear was applied and was followed by damped oscillations qualitatively similar to Fig. 1. This is in accord with the rheoptical theory of light scattering by oblate spheroids (7) which

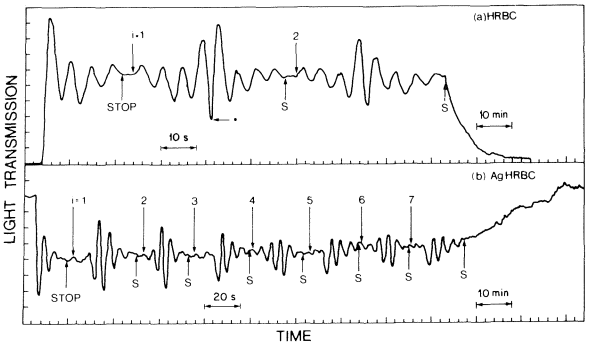

FIG. 7. Typical recorder charts of the light transmittance T' (arbitrary linear scale) for aqueous glycerine suspensions of HRBC (part *a*) and AgHRBC (part *b*) sheared at $G = \pm 1.53$ s^{-1}. Note that initially T' increased for HRBC and decreased for AgHRBC in accord with theory (7). Stopping flow (at $+G$) is indicated by the upward arrows (labelled STOP and *S*) and reversing at $-G$ by the downward arrows at various values of *i*. Gradual decay (part *a*) or recovery (part *b*) in T' occurred when flow stopped between flow reversals and at the end of each experiment (i.e., after the last 5) as a result of rotary Brownian motion of the particles.

relates changes in T' to the changes in orientation distribution due to flow at $Br_r > 0$. When flow was stopped (indicated by vertical arrows in Fig. 7*a*) and after a short interval reversed in direction ($i = 1$) regrowth of the oscillations in the first half of the shearing cycle (corresponding to $t/T > 0$, Fig. 1) and decay in the second half ($t/T < 0$) were observed. As indicated in Fig. 7*a* by the horizontal asterisked arrow, T' did not decrease to the initial value corresponding to random orientation, thus indicating some memory loss. Upon reversing flow again ($i = 2$), behavior similar to the cycle for $i = 1$ was exhibited but with still lower amplitudes. This process could be repeated many times with reducing amplitudes in successive cycles, reaching zero amplitude after some 50 reversals when the memory was completely lost (cf. curve *5* in Fig. 5*b*-(1)).

The suspension of opaque AgHRBC showed similar behavior except, as predicted (7), T' first decreased (Fig. 7*b*).

As with $\overline{r}_{2\sigma}$ for rods the period of oscillation of T' corresponds to $\overline{T}/2$ from which mean axis ratio of particles was calculated to yield $\overline{r_e} = 0.45$ and 0.49 for HRBC and AgHRBC. This is in reasonably good agreement with $\overline{r_e} = 0.38$ obtained by direct measurements of $\overline{TG}$ on individual HRBC's from another sample (3).

Upon stopping flow permanently (at the point indicated by the last *S* in Fig. 7) both suspensions showed the gradual recovery in T' to the initial level for random orientation as a result of rotary Brownian motion; this has been discussed elsewhere (7) and will not be considered further here except to point out that $Br_r = 0$ leads to complete loss of memory as $t \to \infty$ (1).

Values of M_i' for AgHRBC calculated from measured values of T_i' using [2] for $R_T = 0.5$, 1, and 2 are shown in Fig. 8. It is evident that as in Fig. 3 for rods the rate of memory loss increased with increasing R_T. In the experiments with rods the major contribution to memory loss was attributed to partially irreversible particle interactions, also a possible mechanism here. However, in the present case, what immediately comes to mind as the main source of the loss was rotary Brownian motion (1) for which $D_r = 1.6 \times 10^{-4}\ s^{-1}$ when calculated from [32]-(7) for oblate spheroids of the same overall dimensions as those used in these experiments, so that for $G = 1.53\ s^{-1}$, $Br_r = 4.9 \times 10^3$. Recent calculations (24) of the effect of continuous Brownian rotation on the particle orientation distribution shows that for a given $Br_r \gg 1$ the memory of the suspension should be independent of R_T and depends only on the total elapsed time. In Fig. 8*b*, M_i' is plotted against the dimensionless real time

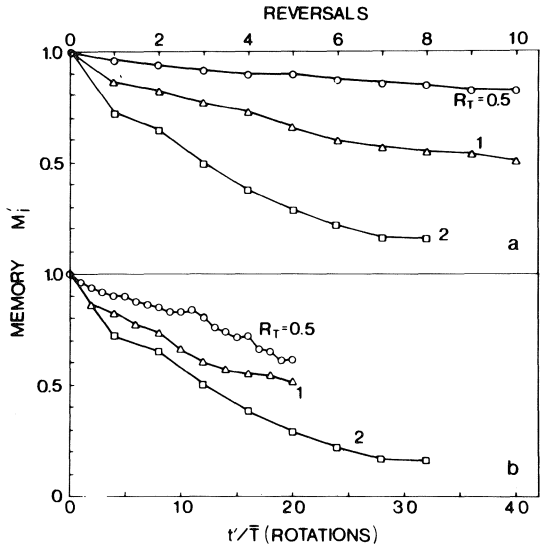

FIG. 8. Memory M_i' for AgHRBC at $N = 0.46 \times 10^8$ ml^{-1} suspended in 75% aqueous glycerine with $R_T = 0.5$, 1, 2 plotted against i (upper) and $t'/\bar{T}$ (lower) at $G = \pm 1.53$ s^{-1}. $Br_r = 4900$.

scale $t'/\bar{T}$. As with the rods (Fig. 3) the points for the different R_T's did not fall on a single line. Contrary to the prediction (24) based solely on rotary Brownian motion we attribute the difference to particle interactions. It should be mentioned that, strictly speaking, these two mechanisms are not independent of each other, since Brownian motion influences both translational and rotational motions of particles in a shear flow, so that all types of particle interaction should become irreversible when flow is reversed. Thus the memory loss effect is enhanced in two ways by the Brownian motion.

(ii) Effect of Concentration

The effect of cell concentration is illustrated in Fig. 9 for $R_T = 1$ at $Br_r = 4900$, where M_i' is plotted against number concentration N for various i's, showing linear variation up to $i = 5$. As N increased, the collision frequency between particles also increased (8) to that the memory loss from imperfections in the particles is expected to be greater (1, 15). The linearity of M_i' with respect to N suggests that the dominant interactions involved are 2-body (4, 17) and that n-body interactions where $n \geq 3$ are not significant over the concentration range studied.

(iii) Effect of Velocity Gradient

M_i' of AgHRBC at $N = 0.41 \times 10^8$ ml^{-1} at $G = 1.07$, 1.61, and 3.25 s^{-1} when the flow was reversed at $R_T = 2$ is shown in Fig. 10 where M_i' is plotted against G for various i. It is seen that M_i' decreased linearly and at nearly identical rates for all $i \leq 8$. When G (and hence Br_r) increased at given D_r, the

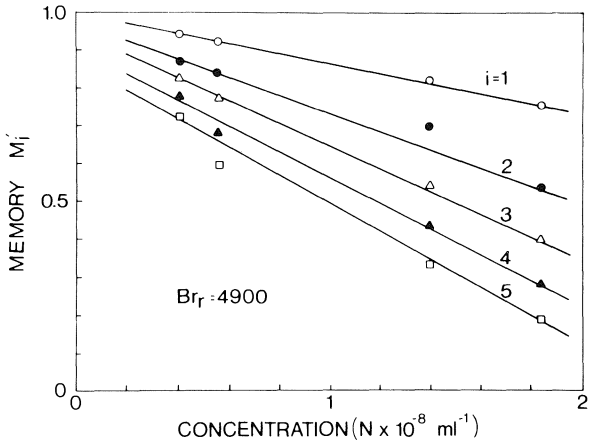

FIG. 9. Memory M_i' vs. N for AgHRBC when flow was reversed at $R_T = 1$ with $G = \pm 1.53$ s^{-1}. (When $i > 5$, the linearity between M_i' and N was lost and these data are omitted.)

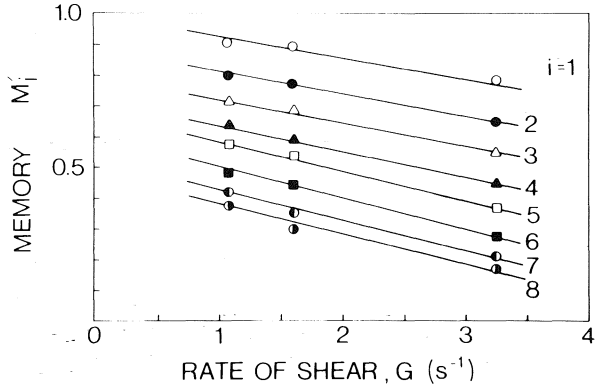

FIG. 10. M_i' vs. G for AgHRBC at $N = 0.41 \times 10^8$ ml^{-1} with $R_T = 2$ for various i over a range of $Br_r = (3.5\text{–}10) \times 10^3$. The decrease of M_i' with G was unexpected and is not understood.

effect of rotary Brownian motion on particle orientation distributions and hence memory loss should become smaller (1, 4, 5). To our surprise the opposite occurred, although it should be noted that Br_r in these experiments was high ((3.5 to 10) $\times 10^3$). Other possible causes for this behavior are (*i*) the development of secondary flows (25), and (*ii*) fluid and particle inertia (26).

In the experimental arrangement used here, secondary flows would only be expected at values of $G\,10^4 \times$ those employed and, in any case, could never be detected in the experiments; they do not provide an explanation. The effects of inertia were discussed in (1) and would be expected to show appreciable memory impairment at particle Reynolds numbers $Re_G (= 4b^2 G\rho_2/\eta$, ρ_2 being the density of the medium) above 10^{-2} (26). In the present experiments Re_G was of the order 10^{-7}, much too low to account

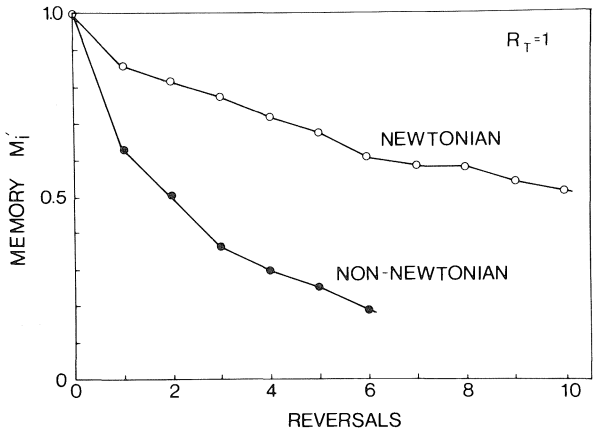

FIG. 11. Effect of non-Newtonian suspending medium (2.5% PAA solution) on the memory of suspensions of AgHRBC at $N = 0.36 \times 10^8$ ml^{-1} when flow is reversed at $R_T = 1$, $G = \pm 0.51$ s^{-1}. The corresponding points for the Newtonian medium (from Fig. 8, $R_T = 1$, $N = 0.46 \times 10^8$ ml^{-1}) show that the rate of memory impairment is roughly 3 times as great in the non-Newtonian medium even though N was less.

for the results. The unexpected variation of M_i' with G is inexplicable.

(iv) Non-Newtonian Medium

M_i' for AgHRBC at $N = 0.36 \times 10^{-8}$ ml^{-1} in the elastico-viscous PAA was measured as above for $R_T = 1$. It is clearly seen from Fig. 11 that the memory loss was much more rapid (about 3×) than in the Newtonian medium even though N was less. As observed with rods (Fig. 6) the memory loss in PAA was primarily due to drift in particle orbits (23) of the disc-shaped cells toward $C = \infty$ (27, 28). At $C = \infty$, the AgHRBC preferentially faced toward the incident light beam thus reducing T' (7) and causing M_i' to decrease, reaching 0 as $i \rightarrow \infty$. This process was probably accelerated by interactions as in the non-Newtonian media (Fig. 8).

(c) Concluding Remarks

To a large extent the experimental findings confirm, qualitatively at least, all of the theoretical predictions presented in ref. 1. A number of additional effects, with one exception (Fig. 10), can be attributed to particle interactions which are too complicated to evaluate theoretically at this stage. As indicated in the previous paper similar behavior will be exhibited by all macroscopic properties which are governed by particle orientations, in addition to the optical properties considered here.

Crystals of 2,2,4,4,6,8,8-heptamethyl-6-methylamino-1,3,5-triaza-2,4,6,8(P^V)-tetraphosphorin are monoclinic, $a = 11.639(4)$, $b = 11.957(7)$, $c = 12.114(4)$ Å, $\beta = 94.07(2)°$, $Z = 4$, space group $P2_1/n$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.032$ and R_w of 0.041 for 2012 reflections with $I \geq 3\sigma(I)$. Crystals of 2,2,4,4,6,8,8-heptamethyl-6-methylamino-7-benzoyl-1,3,5-triaza-2,4,6,8(P^V)-tetraphosphorin are triclinic, $a = 15.513(1)$, $b = 8.422(1)$, $c = 8.933(1)$ Å, $\alpha = 89.24(1)$, $\beta = 100.18(1)$, $\gamma = 107.30(1)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by Patterson and Fourier syntheses and was refined to a final R of 0.041 and R_w of 0.044 for 3654 reflections with $I \geq 3\sigma(I)$. The eight-membered P_4N_3C rings in both structures have 'tub' conformations. The mean bond lengths (corrected for libration) are: P—N(*endo*), 1.609(9), P—N(*exo*), 1.679(2), P—C(*endo*), 1.717(2), and P—C(*exo*), 1.815(8) Å for $Me_7(MeNH)P_4N_3CH$ and 1.595(4), 1.655(2), 1.763(4), and 1.804(5) Å respectively for $Me_7(MeNH)P_4N_3CC(O)Ph$. The near-equivalence of the endocyclic P—N bond lengths in the azaphosphorins is discussed in terms of opposing changes in the in-plane and out-of-plane π-systems.

HARRY P. CALHOUN, RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **56**, 2833 (1978).

Les cristaux de l'heptaméthyl-2,2,4,4,6,8,8 méthylamino-6 triaza-1,3,5 tétraphosphorine-2,4,6,8(P^V) sont monocliniques, $a = 11.639(4)$, $b = 11.957(7)$, $c = 12.114(4)$ Å, $\beta = 94.07(2)°$, $Z = 4$, groupe d'espace $P2_1/n$. La structure a été résolue par méthodes directes et l'affinement par moindres carrés (matrice complète), effectué sur 2012 réflexions ayant $I \geq 3\sigma(I)$, a conduit aux valeurs finales de $R = 0.032$ et $R_w = 0.041$. Les cristaux de l'heptaméthyl-2,2,4,4,6,8,8 méthylamino-6 benzoyl-7 triaza-1,3,5 tétraphosphorine-2,4,6,8(P^V) sont tricliniques, $a = 15.513(1)$, $b = 8.422(1)$, $c = 8.933(1)$ Å, $\alpha = 89.24(1)$, $\beta = 100.18(1)$, $\gamma = 107.30(1)°$, $Z = 2$, groupe d'espace $P\bar{1}$. La structure a été résolue au moyen de synthèses de Patterson et de Fourier, et l'affinement, effectué sur 3654 réflexions ayant $I \geq 3\sigma(I)$, a conduit aux valeurs finales $R = 0.041$ et $R_w = 0.044$. Dans les deux structures, le cycle P_4N_3C à huit atomes possède une conformation "tub". Les valeurs moyennes des longueurs de liaisons (corrigées pour la libration) sont: P—N(*endo*), 1.609(9), P—N(*exo*), 1.679(2), P—C(*endo*), 1.717(2), et P—C(*exo*), 1.815(8) Å pour $Me_7(MeNH)P_4N_3CH$ et 1.595(4), 1.655(2), 1.763(4) et 1.804(5) Å, respectivement, pour $Me_7(MeNH)P_4N_3CC(O)Ph$. On discute de la quasi-équivalence des longueurs de liaisons P—N endocycliques dans les azaphosphorines en fonction des changements compétitifs dans les systèmes π dans le plan et hors du plan.

[Traduit par le journal]

Introduction

Many studies have been made of the structural changes which occur upon perturbing the π-electron distribution in cyclic phosphazenes, either by inhomogeneous substitution of the phosphorus atoms or by complexation at nitrogen. In the azaphosphorins **1**, **2** (1) a third type of perturbation is found, in which one nitrogen atom of the N_3P_3 or N_4P_4 skeleton is replaced by a $\equiv$CH group. Substitution is possible both at the ring carbon atom and at the exocyclic nitrogen atom, and the structure of the *N*-benzoyl-*C*-benzoyl derivative **3** has been determined (2). Structural relationships in tetrameric phosphazenes are often especially informative, and we have therefore determined the crystal and molecular structures of the parent azaphosphorin **2** and its *C*-benzoyl derivative **4**.

Experimental

2,2,4,4,6,8,8-Heptamethyl-6-methylamino-1,3,5-triaza-2,4,6,8(P^V)-tetraphosphorin (2)

Colourless crystals of 2,2,4,4,6,8,8-heptamethyl-6-methylamino-1,3,5-triaza-2,4,6,8(P^V)-tetraphosphorin were grown from *n*-hexane (1). The crystals were handled in a dry box, as the compound is extremely sensitive to atmospheric moisture. The crystal, sealed in a Lindemann glass capillary, was mounted with *b* parallel to the goniostat axis and had dimensions of ca. 0.5 × 0.9 × 0.4 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 17 reflections measured on a diffractometer with MoK_α radiation (λ = 0.71069 Å). Crystal data (at 22°C) are:

$C_9H_{26}N_4P_4$ fw = 314.23

Monoclinic, a = 11.639(4), b = 11.957(7), c = 12.114(4) Å, β = 94.07(2)°, V = 1682(1) Å^3, Z = 4, ρ_c = 1.241 g cm^{-3}, $F(000)$ = 672, $\mu(MoK_\alpha)$ = 4.4 cm^{-1}. Absent reflections: $0k0$, $k \neq 2n$ and $h0l$, $h + l \neq 2n$ define uniquely the space group $P2_1/n$ (non-standard setting of $P2_1/c$, C_{2h}^5, No. 14).

Intensities were measured with zirconium-filtered MoK_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. 20 s background counts were measured at each end of the scan. Data were measured to 2θ = 50°. The intensities of the check reflections, measured every 30 reflections throughout the data collection, remained constant to within ±3%. After data reduction, an absorption correction was applied using the Gaussian integration method (3, 4). Transmission factors ranged from 0.802 to 0.850. Of the 2965 independent reflections measured, 2012 (68%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + B + (0.04S)^2$ with S = scan count and B = time-averaged background count.

The structure was solved by direct methods (5). The positions of the eight ring atoms and two of the methyl carbon atoms were determined from an *E*-map. The remaining non-hydrogen atoms and 22 of the 26 hydrogen atoms were located from subsequent difference syntheses. Refinement of the ordered model converged at R = 0.065. Possible disorder of P(1) and its exocyclic substituents was suggested both by the appearance of a large peak (2.4 e Å^{-1}) between N(1) and C(2) on a difference map and by the anisotropic thermal parameters for P(1), N(1), C(2), and C(9) which were inconsistent with those for the other atoms. Careful examination of a Fourier map led to a twofold disordered model with unbalanced site occupancies of 0.7 and 0.3 estimated from relative peak heights. The site occupancies were kept fixed throughout the refinement, but the final thermal parameters of the disordered atoms indicate that these values are quite satisfactory. The disordered non-hydrogen atoms were included in the refinement first with isotropic, then with anisotropic thermal parameters, reducing R to 0.036. A difference map gave positions for all of the disordered hydrogen atoms which were included (with isotropic thermal parameters) in all subsequent cycles of refinement. The scattering factors of ref. 6 were used for non-hydrogen atoms and those of ref. 7 for hydrogen atoms. Anomalous scattering factors from ref. 8 were used for the phosphorus atoms. The weighting scheme ($w = (|F_o|/7.5)^2$ if $|F_o| < 7.5$, $w = 1.0$ if $7.5 \leq |F_o| \leq 20.0$, $w = (20.0/|F_o|)^2$ if $|F_o| > 20.0$, and $w = 0.0625$ for the unobserved reflections) gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. A type I anisotropic extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (9–11). Extinction parameters are given in Table 1. Convergence was reached at R = 0.032 and R_w of 0.041 for 2012 reflections with $I \geq 3\sigma(I)$. For all 2965 reflections R = 0.051 and R_w = 0.043.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.10 and 0.92σ respectively. The mean error in an observation of unit weight was 0.5698.

2,2,4,4,6,8,8-Heptamethyl-6-methylamino-7-benzoyl-1,3,5-triaza-2,4,6,8(P^V)-tetraphosphorin (4)

The preparation of this compound has been described previously (1). The crystal used for data collection was mounted with b^* parallel to the goniostat axis and had dimensions of ca. 0.18 × 0.20 × 0.36 mm. Twenty planes measured with CuK_α radiation (λ = 1.5418 Å) were used in the refinement of the unit-cell parameters. Crystal data are:

$C_{16}H_{30}N_4OP_4$ fw = 418.34

Triclinic, a = 15.513(1), b = 8.422(1), c = 8.933(1) Å, α = 89.24(1), β = 100.18(1), γ = 107.30(1)°, V = 1095.8(2) Å^3, Z = 2, ρ_c = 1.268 g cm^{-3}, $F(000)$ = 636, $\mu(CuK_\alpha)$ = 32.4 cm^{-1}. Space group $P\bar{1}$ (C_i^1, No. 2).

The intensity of the check reflection remained constant to within ±4% during the data collection. Of 4385 independent reflections measured (to 2θ = 146°, CuK_α radiation), 3679 (84%) had intensities greater than 3σ(I) above background. The data were corrected for absorption, transmission factors ranging from 0.44 to 0.67.

The centrosymmetric space group $P\bar{1}$ was strongly indicated by the $|E|$ statistics. The structure was solved by Patterson and Fourier syntheses. Full-matrix least-squares refinement of the non-hydrogen atoms with isotropic, then with anisotropic thermal parameters proceeded routinely to convergence at R = 0.088. A difference map then gave the positions of all 30 hydrogen atoms which were included in all subsequent cycles of refinement with isotropic thermal parameters. The entire

structure was refined for four cycles giving a final R value of 0.041 and R_w of 0.044 for 3654 reflections with $I \geq 3\sigma(I)$ (25 planes which had $|F_o| - |F_c| \geq 3\sigma(F)$ were treated as unobserved in the final stages of refinement; instrumental error was suspected for these reflections). For all 4385 reflections $R = 0.051$ and $R_w = 0.048$. An isotropic secondary extinction correction was approximated by minimizing $\Sigma w[|F_o| - |F_c|/(1 + gI)|]^2$ where I is the uncorrected intensity; the final value of g was $9.1(1) \times 10^{-8}$. The weighting scheme used was: $w = (|F_o|/11.3)^2$ if $|F_o| < 11.3$, $w = (11.3/|F_o|)^2$ if $|F_o| \geq 11.3$, and $w = 0.12$ for the unobserved reflections.

On the final cycle of refinement the mean and maximum

*The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression: $f = f^0 \exp(-2\pi^2 \Sigma_i \Sigma_j U_{ij} h_i h_j a_i^* a_j^*)$. For isotropic atoms: $f = f^0 \exp(-8\pi^2 U \sin^2\theta/\lambda^2)$.

parameter shifts corresponded to 0.28 and 1.04σ respectively. The mean error in an observation of unit weight was 0.3796.

The final positional and thermal parameters for both compounds appear in Tables 2 and 3 respectively; measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The thermal motions of both molecules have been analysed in terms of rigid-body modes of translation, libration, and screw motion (12) using the computer program MGTLS. For compound **2** (rms $\sigma U_{ij} = 0.0017$ Å^2 for ordered atoms) analysis of each of the phosphorus tetrahedra gave physically reasonable results (rms $\Delta U_{ij} = 31, 25, 14, 8$, and 10×10^{-4} Å^2 for P(1b)—P(4) respectively). For molecule **4** (rms $\sigma U_{ij} = 0.0016$ Å^2) analyses were successful for the four phosphorus tetrahedra and for the phenyl group (rms $\Delta U_{ij} = 11, 13, 16, 12$, and 19×10^{-4} Å^2 respectively). The appropriate bond distances have been corrected for libration (13), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values. Changes in bond angles were less than 1σ, thus only the uncorrected values are given in Table 5.

Results and Discussion

General views of the two isomers of **2** and the molecule **4**, with their crystallographic numbering schemes, are shown in Fig. 1, and the packing arrangements in Fig. 2. The crystal structure of 2,2,4,4,6,8,8 - heptamethyl - 6 - methylamino - 1,3,5 - triaza-2,4,6,8(P^V)-tetraphosphorin (**2**) consists of discrete molecules each linked to two others (related by the *n* glide plane) by N—H...N hydrogen bonds (Fig. 2*a*), a situation which occurs for both positions of the disordered group P(1)N(1)C(9). The hydrogen bond geometry is more favourable for the 30% occupied site HN(1a)Me (see Table 6). In the crystal structure of the *C*-benzoyl derivative (**4**), the molecules associate via weak N—H...O hydrogen bonds (N...O = 3.024(3) Å) and weak C—H...O interactions to form centrosymmetric dimers (Fig. 2*b*). There are weak intramolecular C—H...O (and N) interactions present as well. Details are given in Table 6. Other intermolecular distances in all three structures correspond to normal van der Waals interactions, and justify discussion of the structures in molecular terms.

The molecular conformations are closely related; intra-annular torsion angles defining them are given in Table 7. The two slightly different ring conformations of the azaphosphorins **2***a* and **2***b* (Fig. 1*a*, *b*) can both be regarded as tubs. The tub conformation ($\bar{4}$) is known to be flexible, and can be inverted, as Fig. 3 shows, by torsional motion about the ring bonds, only small changes in non-bonded interactions being involved. The transformation proceeds through the saddle conformation ($\bar{4}2m$) (Fig. 3*b*), in which the four phosphorus atoms are coplanar, a structure closely approached by the parent molecule $N_4P_4Me_8$ (14).

The two azaphosphorins *a* and *b* differ in two ways. They are primarily configurational isomers, P(1) being an asymmetric centre. They can be interconverted by a reflection, followed by conformational inversion, in the sense of Fig. 3*a–c*, the two molecules then being nearly superposable, but with the NMe group on different sides of the ring.

This last feature causes slight changes in ring geometry arising from steric interactions. The cross-ring distance C(5)C(2) in *a* is maintained at 4.26 Å in *b* (C(5)C(9)) by an outward rotation of the C(2)P(1)N(1)C(9) group (in *b*) about an axis through C(1)N(4).

The ring in the *C*-benzoyl derivative **4** is less regular again, principally because the N(2)P(3)C(5)-C(6) grouping is displaced away from the phenyl

[2]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

group. The C(16)C(5) and C(16)C(9) distances are 4.23, 4.06 Å respectively, the C(5)C(9) cross-ring distance being lengthened to 4.93 Å. The interaction is not large enough to distort the phenyl group, which is planar within experimental error ($\chi^2 = 6.4$), and the mean phenyl C—C distance of 1.386(10) Å is as expected. The P—Me distances (**2**, 1.807–1.826; **4**, 1.795–1.810 Å) are slightly longer than those in the trimeric derivative (mean 1.796(4) Å (2)) but similar to those in the methylphosphazenes $(NPMe_2)_{3-8}$ (14–19), where mean distances range from 1.801 to 1.811 Å. There is an especially close relationship to $N_4P_4Me_8$ (14).

The introduction of a carbon atom into the ring evidently causes no profound conformational change, but it has an unexpected effect on the bond lengths, which is discussed first for the azaphosphorins **2**. In $Ph_3P{=}CH_2$, P=C = 1.661 Å (20) and the mean endocyclic P—C bond length of 1.717(2) Å in **2** can reasonably be taken to correspond to the change from a 2-centre to a 3-centre bond; as expected, the bond lengths are similar to those in a Wittig intermediate (21). The P—N bond lengths present more of a problem. One of them (P(1a)N(4) in **2***a*) is excessively long (1.683(5) Å), partly because of hybridization differences which alone would cause this bond to be about 0.03 Å longer than its counterpart P(1b)—N(4) (1.598(3) Å). The much larger

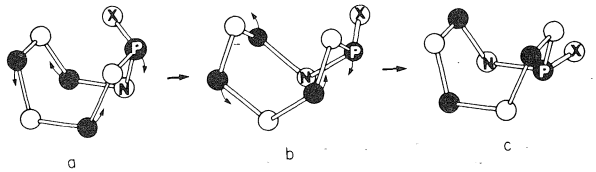

FIG. 3. Conformational inversion path in $(NPX_2)_4$, $\bar{4}$ symmetry. The change takes place by torsional motion about the ring bonds in the sense of the arrows. The diagram shows the change in conformation of one X-group from *endo* to *exo*.

actual difference may either be real or a result of some inadequacy in the disordered model used in the refinement of the structure of **2**. It should be noted, however, that N(4) showed no signs of being disordered. An additional point of interest in the structure of **2** is the involvement of the ring atom N(2) in the hydrogen bonding which increases the mean N(2)—P distance to 1.620(4) Å compared to a mean N(3)—P distance of 1.606(2) Å, a significant increase in bond length.

Apart from these two features, the PN bonds in the ring are nearly equal among themselves, and their lengths are close to that of the PN bond in $N_4P_4Me_8$ (1.596 Å) (14). At first sight, the equality is surprising. Modification of the electronic structure of a cyclic phosphazene, either by inhomogeneous substitution at phosphorus (22), or protonation (23) or alkylation (24) at nitrogen, or by a perturbation at both centres (25) leads to pronounced bond length inequalities which have been interpreted in terms of the effect of the substituent on a double π-system, and the substitution of carbon for nitrogen is equally drastic. As explained below, the substitution has only a small structural effect because it has opposite and compensating effects on the in-plane and out-of-plane π-systems.

In $N_4P_4Me_8H^+$, the proton localises two electrons on nitrogen, so that the in-plane π-system is confined to the P_4N_3 fragment, leading to inequalities of bond order in the sense of the bond lengths shown in Fig. 4 (23). The single $p\pi$-orbital at the protonated nitrogen atom then makes a normal contribution to the out-of-plane π-system. In the azaphosphorin, **2**, two electrons are again localised, now in a covalent bond from the endocyclic carbon atom to hydrogen, and the in-plane π-system formed by the P_4N_3 fragment is therefore similar to that in the $N_4P_4Me_8H^+$ ion, and by itself would be expected to induce the same bond length inequalities. However, the out-of-plane system of **2** differs from that of $N_4P_4Me_8H^+$, in that the substitution of the less electronegative carbon for nitrogen in the ring concentrates electron density in the bonds to carbon, primarily at the expense of the neighbouring bonds to nitrogen, so that the changes in the two π-systems tend to compensate one another, an effect not previously found in phosphazene chemistry.

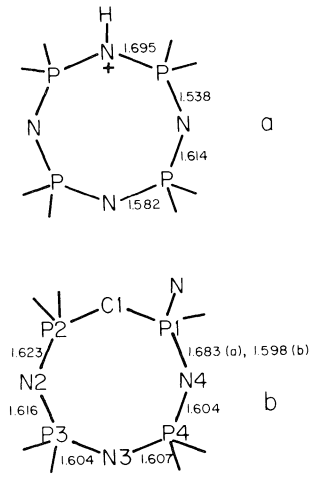

FIG 4. (*a*) Mean bond lengths in $N_4P_4Me_8H^+$; (*b*) ring bond lengths in **2**, showing the approximate cancellation of the inequalities in (*a*) as a result of the substitution of carbon for nitrogen.

The equality of the P—N bond lengths in **2** can then be understood in terms of calculations on a simple planar model, in which the phosphorus atoms are assumed to be homogeneously substituted, and the Coulomb parameter of carbon is taken to be the mean of those of phosphorus and nitrogen. HMO calculations then show that the π-bond order of P(1)N(1) is modified in two ways. In the out-of-plane system, the concentration of π-electron density in the P—C bond weakens the adjacent P—N bond. In the in-plane system, this P—N bond is especially strong, because it is a terminal bond in the P_4N_3 fragment. The qualitative compensation of the two effects, which in detail depends on the assumed parameters, improves with increasing distance from the perturbing centre.

The structure of the benzoyl compound **4** confirms and extends these results. Moderate conjugative electron withdrawal by the benzoyl group is suggested by the near planarity of the environments of C(1) and C(10) (both atoms are within ±0.04 Å of the mean planes of their substituents) and by the comparatively short exocyclic C(1)—C(10) bond (1.434(3) Å, compared to the 1.485 Å expected for a $C(sp^2)$—$C(sp^2)$ single bond (26)). The interaction is perhaps a little weaker than that in the trimeric derivative **3** (2), in agreement with the torsion angles about the CC bond to the azaphosphorin ring (**4**, 29.5°; **3**, 7.7°). The large torsion angle about the C—Ph bond (41.5°) and the length of the C(10)—C(11) bond (1.508(3) Å) both indicate that conjugation with the phenyl group is negligible.

In simple ylids, the P=C bond is lengthened by the attachment of electron-withdrawing substituents to carbon, as can be seen by a comparison of the structures of $Ph_3P{=}CH_2$ (P=C = 1.661 Å (20)) and $Ph_3P{=}CClC(O)Ph$ (P=C = 1.736 Å (27)). In the latter molecule, the partial positive charge on carbon induced (in different ways) by the two substituents increases the electronegativity difference between the phosphorus and carbon atoms and decreases the bond order, as shown by the increase in the length of the P=C bond.[3] In the same way, the benzoyl group in **4** lengthens the endocyclic P—C bonds, and causes a further electronic migration, which appears to be delocalised over the entire ring. The mean endocyclic P—C distance of 1.717(2) Å in **2** is significantly increased to 1.763(4) Å in **4**, and the mean endocyclic P—N bond is decreased correspondingly from 1.609(9) Å in **2**[4,5] to 1.595(4) Å in **4**. Calculations similar to those referred to above show that an increase of electronegativity of C(1) decreases the order of the ring P—C bonds, and increases the mean order of the ring P—N bonds.

The geometry and the electronic interactions of the exocyclic MeNH group are also of interest. The exocyclic PN distances in **2** and **4** are similar to those found in the dimethylaminophosphazenes $(NP(NMe_2)_2)_{3,4,6,8}$ (28–31), in which exocyclic π-bonding seems established. In agreement, the *exo*-PN bond in **4** is slightly shorter than in **2**, reflecting the increase in exocyclic π-bonding that occurs as electron-withdrawing substituents are introduced elsewhere. Quantitatively, the *exo*-π-bonding may be weaker than these geometrical features would suggest. Simple calculations show that if it were strong, it would measurably lengthen the P(1)N(4) bond relative to the others (this may indeed occur to some extent, see above). Experimentally, the coordination round N(1) is significantly non-planar, the mean bond angles at this atom being 113° (**2***a*), 116.4° (**2***b*), 116.1° (**4**). The (limited) π-bonding is evidently easily displaced, because in **3** the *exo*-PN distance is long (1.742 Å) and the amide ν(C=O) is low (1), showing that the *N*-benzoyl group competes effectively with the phosphazene ring for electron density.

A further feature is common to all the molecules. The C(2)P(1)N(1)C(9) groups are rigorously planar within experimental error in **2** and nearly planar in **4** (Fig. 1), the torsion angles about the P(1)N(1) bond being respectively 178(2)°, −179.8(9)°, and −164.8(2)°. The possibility that this is predominantly a π-electron effect is countered by the argument

[3]The secondary effect of *d*-orbital stabilisation is less important.

[4]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

[5]This does not include the distance P(1a)—N(4) (see above).

above, and by the fact that the same relationship holds in the *N*-benzoyl derivative **3** (2), in which the torsion angle is 177.6(2)°. It is likely that exocyclic π-bonding has some effect, but non-bonded (including polar) interactions appear to be decisive.

H. BRIAN DUNFORD, W. DONALD HEWSON, and HÅKAN STEINER. Can. J. Chem. **56**, 2844 (1978).

The kinetics of the reactions of hydrogen peroxide and cyanide with native horseradish peroxidase, as well as reactions of compounds I and II with ferrocyanide have been studied in ordinary water and in deuterium oxide at 25°C and ionic strength 0.11 using a stopped-flow apparatus. Rate constants for all reactions were measured over a wide range of acidity in both solvents from which equilibrium and kinetic isotope effects were evaluated. Protonation of an ionizable group on the enzyme with a pK_a value of 4.15 ± 0.05 in water inhibits the reactions with both hydrogen peroxide and cyanide. A significant kinetic isotope effect, k_H/k_D = 1.6 ± 0.1, was measured for compound I formation whereas no significant kinetic isotope effect was found for cyanide binding. On the basis of these findings, a partial mechanism for compound I formation is proposed in which the group of pK_a 4.15 plays a crucial role. The pH dependencies of the ferrocyanide reaction in the pH interval 4.5–10.8 confirmed the role of an acid group with a pK_a of 5.2 for compound I and for compound II a pK_a of 8.6 and another with a value lower than that encompassed by the pH range of the study. Equilibrium isotope effects were found but no kinetic isotope effects for either the reaction of compound I or of compound II. This suggests that there are no rate-limiting proton transfers in the reactions between ferrocyanide and compounds I and II of horseradish peroxidase. The only reducing substrates which exhibit positive k_H/k_D values possess a labile proton.

H. BRIAN DUNFORD, W. DONALD HEWSON et HÅKAN STEINER. Can. J. Chem. **56**, 2844 (1978).

Faisant appel à un appareil à flux stoppé, on a étudié la cinétique des réactions du peroxyde d'hydrogène et du cyanure avec le peroxydase naturelle du raifort, de même que les réactions du composé I et II avec le ferrocyanure dans l'eau ordinaire et dans l'oxyde de deutérium à 94% à 25°C et une force ionique de 0.11. On a mesuré les constantes de vitesse pour toutes les réactions dans les deux solvants à divers degrés d'acidité, en se basant sur ces constantes de vitesse, on a pu évaluer l'équilibre et les effets isotopiques cinétiques. Dans l'eau la protonation d'un groupe ionisable de l'enzyme, pK_a de 4.15 ± 0.05 inhibe les réactions tant avec le peroxyde d'hydrogène qu'avec le cyanure. On a mesuré un effet isotopique cinétique important, k_H/k_D = 1.6 ± 0.1, pour la formation du composé I alors que l'on n'a pas trouvé d'effet isotopique cinétique pour la fixation du cyanure. Sur la base de ces données, on propose un mécanisme partiel pour la formation du composé I dans lequel le groupe pK_a 4.15 joue un rôle crucial. Le fait que la réaction du ferrocyanure dépend du pH dans l'intervalle de 4.5–10.8 confirme qu'un groupe acide de pK_a = 5.2 joue un rôle pour le composé I; dans le cas du composé II, il existerait deux groupes acides l'un de pK_a 8.6 et l'autre avec une valeur plus faible que celle couverte par l'intervalle de pH étudié. On a trouvé les effets isotopiques d'équilibre mais l'on n'a trouvé aucun effet isotopique cinétique pour les réactions soit du composé I soit du composé II. Ceci suggère qu'il n'y a pas de transfert du proton qui détermine la vitesse des réactions entre le ferrocyanure et les composés I et II de la peroxydase du raifort. Les seuls substrats réducteurs qui présentent des valeurs positives de k_H/k_D possèdent un proton labile.

[Traduit par le journal]

Introduction

Near neutral pH, compound I formation is a fast reaction with an Arrhenius activation energy similar in magnitude to the activation energy of diffusion in aqueous solution (1); however, this reaction rate was shown not to be diffusion controlled by studies in solutions of high viscosity (2). The same conclusion has been reached for compound I formation from cytochrome c peroxidase (3). It has been shown that the rates of compound I formation and cyanide binding are both inhibited by ethanol, which probably acts as a ligand in the sixth coordination position of the heme iron (2), and that cyanide inhibits compound I formation (4, 5). The main purpose of the present kinetic study of these two reactions in water and deuterium oxide was under-

taken for further comparisons between these two reactions in the hope of obtaining a more detailed picture of their mechanisms. A study of the ionic strength dependence for the rate of compound I formation was undertaken as a further test as to whether hydrogen peroxide, or its conjugate base, is the diffusing substrate.

The kinetics of the reactions of compounds I and II with several different reducing substrates have been studied in our laboratory (6–11). The pH dependencies of reaction rates have indicated that an acid group with a pK around 5.2 is important in compound I catalyzed reactions. In compound II two groups, one with pK 8.6, the other with a very low pK, have varying influence on reaction rates. To gain further insight into the mechanisms of proton transfer in these redox reactions the effect of changing from water to deuterium oxide was studied (12, 13). A preliminary study involved the oxidation of iodide, *p*-cresol, and ferrocyanide by compound II in deuterium oxide which represented the first attempt to get kinetic and equilibrium H/D ratios for peroxidase reactions (12). *p*-Aminobenzoic acid (PABA) has a pH–rate profile similar to that of ferrocyanide in its reaction with compound II; in later more intensive studies the reactions of PABA with both compound I and compound II were examined in both water and deuterium oxide (10, 13). A self-consistent and rather detailed picture emerged of the mechanisms, particularly of the compound II reactions (12–16). However, there remained certain anomalies about the ferrocyanide reaction with compound II. The present kinetic isotopic study conducted over a wide range of pH (pD) was undertaken to resolve details about the reaction of ferrocyanide ion with compound II and to extend the results to its reaction with compound I.

Experimental

Horseradish peroxidase (E.C.1.11.1.7 donor–H_2O_2–oxidoreductase) was purchased from Sigma as a lyophilized salt-free powder (Type VI, lot 25C-9570) and from Boehringer-Mannheim as purified ammonium sulfate precipitates (lots 7315529, 1366531, and 1067433). The enzyme was prepared for use by extensive dialysis against multiply distilled water (17) followed by Millipore filtration. After dialysis the purity numbers, the ratio of absorbance at 403 to 280 nm, for the four lots were 3.1, 3.3, 3.4, and 3.5. It has been determined that isozyme C (18, 19) is the major component of many commercial preparations (20, 21).

Deuterium oxide was purchased from Diaprep and Columbia Organic Chemicals, Co. with stated isotopic purities of 99.7% or greater. All other chemicals were reagent grade and used without further purification.

Absorbance spectra and measurements were obtained with a Cary 14 spectrophotometer. Kinetic measurements were obtained with a Gibson-Durrum stopped-flow apparatus model D-110. Greater than a 10-fold excess of hydrogen peroxide, cyanide, or ferrocyanide relative to the enzyme concentration was used which ensured pseudo-first-order kinetics. The enzyme concentration for all kinetic experiments was 0.6–0.8 μM. Reaction rates were monitored at 403 nm for compound I formation and 420 nm for cyanide binding. Because of the big difference in reaction rates of compounds I and II with ferrocyanide both reactions could be studied by starting with compound I which was prepared using slightly less than a molar equivalent of hydrogen peroxide. First the compound I reaction was followed at 410 nm, the isobestic wavelength between compound II and native HRP. Then the monochromator was reset at 422 nm and the compound II reaction was followed. For most experiments both drive syringes of the stopped-flow apparatus contained 0.1 M potassium nitrate and buffer of an ionic strength of 0.01 for a total ionic strength of 0.11. However, to avoid the denaturation of the enzyme in acidic solutions below pH 3.7 a pH jump method was used in which only the drive syringe containing the substrate held the buffer with an ionic strength of 0.02. This pH jump method is viable since the rate of compound I formation or cyanide binding is faster than the rate of denaturation but slower than the rate of protonation of the enzyme when mixed with the buffer. At most pH values one substrate concentration was used and between 5 and 10 traces were collected in the absorbance mode. The best parameters for the recorded single exponentials were found from a non-linear least-squares analysis as earlier described (11). The reported second-order rate constants are mean values obtained by dividing the first-order constant by the substrate concentration, which for compound II reactions had been corrected for the decrease caused by converting compound I to II.

The concentration of horseradish peroxidase was determined spectrophotometrically at 403 nm using a molar absorptivity of $1.02 \times 10^5\ M^{-1}\ cm^{-1}$ (22) and that of hydrogen peroxide was checked weekly using the horseradish peroxidase assay (9). Potassium cyanide solutions were prepared immediately before the experiments were carried out and were not used for more than a few hours.

The acidity of the solutions in ordinary water and 94% deuterium oxide was measured with a Fisher 420 digital pH meter equipped with a Fisher combination glass electrode calibrated to ± 0.03 pH units. Measurements of pD were made using this glass electrode in the deuterium oxide solutions (23, 24). The usual equation of Glasoe and Long was modified to account for solutions less than 100% deuterium oxide. In eq. [1] pH_{obs} is the observed meter reading in the deuterium

$$[1] \qquad pD = pH_{obs} + 0.38$$

oxide solution when the glass electrode had been calibrated with standard buffers in ordinary water. The pH (pD) measurements were made using the purged solutions from the stopped-flow apparatus.

Results

Compound I Formation

The values of the apparent second-order rate constants, k_a, for compound I formation in ordinary water and 94% deuterium oxide are plotted against pH (pD) in Fig. 1. Seven of the values of k_a in ordinary water from pH 3.19 to 9.76 were obtained as slopes of linear plots of k_{obs} vs. the concentration of hydrogen peroxide, which had zero intercepts (25). These order-with-respect-to-concentration data were obtained with the preparation of horseradish peroxidase from the Sigma Chemical Company. The agreement among the rate constants determined for

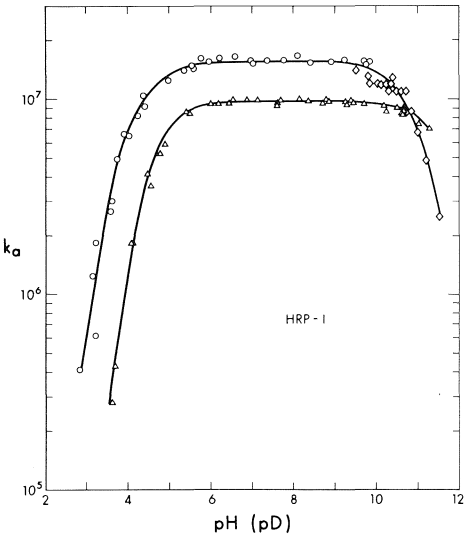

FIG. 1. Compound I formation as a function of pH (pD). Semilogarithmic plots of the apparent second-order rate constant in ordinary water (○, this work); (◇, taken from ref. 28) and 94% deuterium oxide (△). The curves were calculated using eq. [3] which yielded the constants in Table 1.

this enzyme from separate sources, Sigma and Boehringer-Mannheim, is excellent.

The rate of compound I formation has been studied carefully at lower pH values in light water, with two acid groups of pK_a values 3.2 and 3.9 appearing to influence the kinetics (26). The alkaline transition of peroxidases is also well documented (27–33) which leads to reaction [2] for which K_1

$$\begin{array}{lcl} & EH_3 & \\ & \uparrow\downarrow & \\ & EH_2 & \\ & {\scriptstyle K_2}\uparrow\downarrow & \\ [2] \quad & EH + H_2O_2 \xrightarrow{k_a} & \text{Compound I} \\ & {\scriptstyle K_1}\uparrow\downarrow & \\ & E & \end{array}$$

represents the alkaline transition of HRP and K_2 an acid ionization in the active site. From the results of the present study the influence of the most acid group could not be detected, so that values for the three parameters only, labelled in eq. [2], are quoted. The restricted kinetic scheme based upon [2] leads to [3].

$$[3] \qquad k_{app} = \frac{k_a}{1 + \frac{K_1}{[H^+]} + \frac{[H^+]}{K_2}}$$

Above pH 10 saturation kinetics are observed in water, so that a more complicated analysis is required. The values of k_{app} quoted in (28) are also plotted in Fig. 1 and were used in the nonlinear least-squares analysis of [3]. The study in D_2O was terminated at pD = 11.28 and the decrease in rate at the highest pD values should be fairly accurately defined, although order-with-respect-to-concentration plots were not conducted in this region. The values of K_1, K_2, and k_a, obtained for both water and deuterium oxide, are compiled in Table 1 and were used to calculate the smooth curves in Fig. 1. The substrate species which diffuses to the enzyme is uncharged hydrogen peroxide, as indicated by absence of any ionic strength dependence (Table 2) which confirms the results obtained using the diffusion-controlled limit rule (14).

Much of the hydrogen in a protein is readily exchanged with deuterium when the protein is dissolved in deuterium oxide (34–37). However, longer incubation times are required to exchange the less labile amide hydrogen of the protein backbone (35). To determine the effect of the extent of deuterium exchange upon the rate of compound I formation, solutions at pD values of 5.45, 7.59, and 9.41 were incubated for 1.2 hours at 25°C in 94% deuterium oxide. The normal incubation time ranged from 15 to 20 min. No slowly exchanging hydrogen had an effect upon the rate of compound I formation at these pD values.

The hydrogen in hydrogen peroxide can also exchange with deuterium as demonstrated using nuclear magnetic resonance. The resonance peak of hydrogen peroxide, which was observed when 50 μl of 98% hydrogen peroxide were dissolved in 0.4 ml of acetone-d_6, disappeared when the hydrogen peroxide was dissolved in a readily exchangeable solvent such as acetic acid-d_4. The exchangeability of hydrogen in hydrogen peroxide has been proven by other methods (38).

Cyanide Binding

The values of the apparent second-order rate constants for cyanide binding to horseradish peroxidase in ordinary water and in 94% deuterium oxide are plotted semilogarithmically against pH (pD) in Fig. 2. In acid solution the binding of cyanide has been carefully studied in ordinary water with the influence of acid groups of pK_a values of 2.9 and 3.9 being detected (26). The reaction is also inhibited by the ionization of hydrocyanic acid near pH 9 and by the alkaline ionization of HRP (28, 39). There also is a barely discernible inhibition between pH 6 and 7 which was deduced previously by applying the principle of detailed balancing (39). However, this ionizable group is not adequately defined in 94% deuterium oxide and it has been ignored in the

present analysis. Thus the pH profile for the rate of cyanide binding in ordinary water involves a minimum of three ionizations on the enzyme and the ionization of hydrocyanic acid. This leads to the kinetic scheme [4] where K_3 and K_4 are acid dissocia-

[4]
$$\begin{array}{ccccc} EH_3 & & & & \\ \uparrow\downarrow & & & & \\ EH_2 & & & & \\ K_4\uparrow\downarrow & & & & \\ EH & + HCN & \xrightarrow{k_b} & ECN & + H^+ \\ K_3\uparrow\downarrow & & \uparrow\downarrow K_5 & & \\ E & & CN^- & & \end{array}$$

tion constants of the enzyme, K_5 is the acid dissociation constant of hydrocyanic acid, and k_b is the pH independent second-order rate constant. Our data do not extend to sufficiently acid solutions to duplicate earlier measurements of the most acid ionization (26). Using only the above parameters, [4] leads to [5].

[5]
$$k_{app} = \frac{k_b}{\left(\frac{K_3}{[H^+]} + 1 + \frac{[H^+]}{K_4}\right)\left(1 + \frac{K_5}{[H^+]}\right)}$$

Further cyanide kinetic results for the alkaline region in H_2O were added to the analysis (28). The experimental data are displayed in Fig. 2 along with the best-fit curves computed on the basis of nonlinear least-squares analysis of eq. [5] and its analog for deuterium oxide. The best-fit parameters are listed in Table 3.[5]

A sample of the enzyme was incubated in 94% deuterium oxide for 1.2 h at 25°C and at pD 6.92, and reacted with cyanide at the same rate as a sample incubated at this pD for only 15 min.

Reactions of Compounds I and II with Ferrocyanide

The reactions under all conditions are first order with respect to ferrocyanide and enzyme as shown earlier (8, 9, 12). The second-order rate constants as a function of pH in light and heavy water for the reaction of ferrocyanide with compounds I and II

[5]All of the experimental data in Figs. 1 and 2 are available upon request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

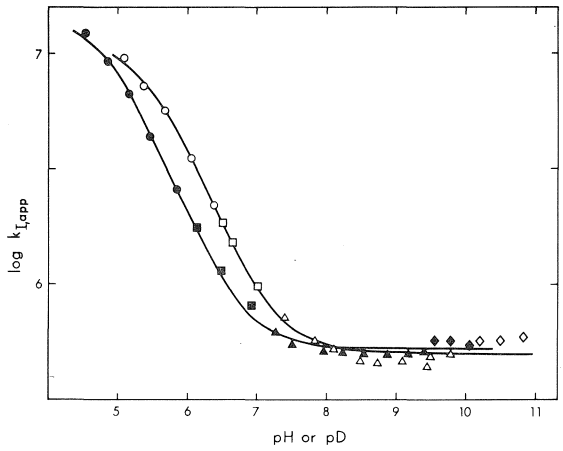

FIG. 3. Plot of the logarithm of the second-order rate constant, $k_{I,app}$, for the reaction of HRP-I with $Fe(CN)_6^{4-}$ vs. pH (solid symbols) and pD (open symbols). The curves were generated by a nonlinear least-squares fit of eq. [7]. The buffers were: acetate, ○ and ●; phosphate, □ and ■; Tris, △ and ▲; bicarbonate, ◇ and ◆.

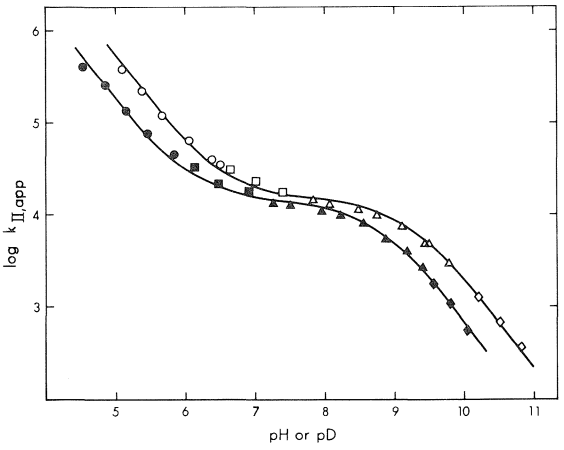

FIG. 4. Plot of the logarithm of the second-order rate constant, $k_{II,app}$, for the reaction of HRP-II with $Fe(CN)_6^{4-}$ vs. pH (solid symbols) and pD (open symbols). The curves were generated by a nonlinear least-squares fit of eq. [9]. Buffers as in Fig. 3.

are given in Figs. 3 and 4. The results in ordinary water are in good agreement with the earlier studies.

For compound I the following model was used. EH and E represent HRP-I with a catalytically important group protonated and deprotonated; K_6 is the corresponding acid dissociation constant and k_1 and k_2 are second-order rate constants.

[6]
$$\begin{array}{ccc} EH + S & \xrightarrow{k_1} & \text{products} \\ H^+\uparrow\downarrow K_6 & & \\ E + S & \xrightarrow{k_2} & \text{products} \end{array}$$

The apparent second-order rate constant, $k_{I,app}$, is given by eq. [7] which gave a best fit to the experimental data with the parameter values given in Table 4. The model seems equally appropriate in both H_2O and D_2O.

[7]
$$k_{I,app} = \frac{k_1 + k_2\dfrac{K_6}{[H^+]}}{1 + \dfrac{K_6}{[H^+]}}$$

For compound II reaction [8] expressed in terms of ionization of the native enzyme adequately describes the observed rates. An alternative but equivalent explanation in terms of a transition state ionization constant has been given (9).

[8]
$$\begin{array}{ccc} EH_2 + S & \xrightarrow{k_3} & \text{products} \\ H^+\uparrow\downarrow K_7 & & \\ EH + S & \xrightarrow{k_4} & \text{products} \\ H^+\uparrow\downarrow K_8 & & \\ E & & \end{array}$$

EH_2, EH, and E are three differently protonated forms of HRP-II; K_7 and K_8 are the corresponding molecular acid dissociation constants and k_3 and k_4 are second-order rate constants. The apparent second-order rate constant, $k_{II,app}$, for this scheme

isotope effects are shown in Table 5.

Discussion

Reactions of Cyanide and Hydrogen Peroxide

In ordinary water the protonation of an ionizable group with a pK_a value of 4.15 $\pm$ 0.05 inhibits both compound I formation and cyanide binding (see Table 2, pK_2, for hydrogen peroxide and Table 4, pK_4, for cyanide) in reasonable agreement with previous results (26). In 94% deuterium oxide, pK_2 has shifted to 4.56 for compound I formation and pK_4 to 4.70 for cyanide binding, the same within their standard deviations. Therefore, pK_2 and pK_4 likely refer to the same ionizable group on the enzyme.

Both reactions have pH independent apparent rate constants near neutral pH, with an exception for the small effect of $pK_a = 6.4$ for cyanide binding in light water (39); the latter effect has been detected by nmr (40). For compound I formation, this pH independent region extends approximately from pH 5.5 to 9.5. In the case of cyanide binding, the apparent rate constant decrease in the alkaline region is readily attributed to the ionization of hydrocyanic acid, $pK_5 = 9.14$. The rate constant for cyanide binding is not sufficiently large to invoke the diffusion controlled limit rule unequivocally (14) but one does obtain an abnormally large rate constant if it is assumed that CN^- is the diffusing reactant (26).

Only the data for compound I formation were obtained with sufficient accuracy to quantify the equilibrium isotope effect on the pK_a value of the ionizable group responsible for the conversion of horseradish peroxidase to its alkaline form. From Table 5, a pK_1 value of 10.89 agrees well with previous values determined by kinetic and other methods (27–33). With the exception of the negligible ΔpK_5 for hydrocyanic acid, discussed elsewhere (58), conventional magnitudes for the equilibrium isotope effects are observed (41–44).

Since compound I formation and cyanide binding have large regions where the k_{app} is pH independent, it is possible to draw certain conclusions about the kinetic isotope effects. For k_a of compound I formation, the value of k_H/k_D is 1.6. Therefore the rate of compound I formation is influenced by the rate of proton (deuteron) transfer. This provides another piece of evidence that the rate of compound I formation at neutral pH is not diffusion controlled (2). In contrast, the binding of cyanide shows no appreciable kinetic isotope effect.

The finding of a kinetic isotope effect for compound I formation supports a partial mechanism which involves the heterolytic breaking and forming of oxygen–hydrogen covalent bonds (45). Com-

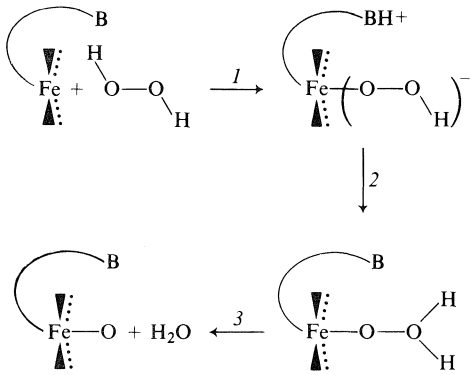

FIG. 5. Schematic representation of compound I formation. The basic group B on the enzyme has a pK_a of 4.15 ± 0.05 in H_2O. The kinetic isotope effect might occur in reaction *1*, where H_2O_2 is converted into the excellent nucleophile OOH^-, or in reaction *2* where a hydroxide ion is converted into the much better leaving group H_2O.

pound I formation results in no net gain or loss of protons (46) and a proposed mechanism involves proton transfer from hydrogen peroxide to the enzyme, formation of an iron–oxygen bond, followed by proton transfer to the bound HO_2^- ion and departure of water as illustrated in Fig. 5. It is not possible to ascertain which of the two proton transfers in this mechanism is part of the rate-determining step, since supporting evidence can be found for either of the two possibilities. In either case, the small magnitude of the kinetic isotope effect would indicate either that the proton transfer is not the sole rate-limiting step but that it is occurring in concert with a second process or there is a considerable isotope effect in the transition state cancelling the zero point energy difference of the initial reactants (47).

The first proton transfer (reaction *1* in Fig. 5) from hydrogen peroxide to the enzyme results in formation of the excellent nucleophile HO_2^- so that the first proton transfer and the initial binding step to the ferric ion might be concerted processes. An essential feature of acid–base catalysis is that there is a large shift in the pK_a values during the course of the reaction (48, 49) and a large downward shift would occur in the pK_a value of hydrogen peroxide as it binds to the ferric ion. Appropriate positioning of the basic group B could facilitate compound I formation from the bent hydrogen peroxide molecule and retard cyanide binding from the linear HCN molecule. (There is a 100-fold difference in rate.) The second proton transfer (reaction *2*, Fig. 5), which has no counterpart in cyanide binding, converts hydroxide ion into the much better leaving group H_2O, so that again there may be two processes occurring in a concerted fashion. Evidence is accumulating that the product release is often the rate-determining step in an enzymatic reaction (50). The partial mechanism outlined in Fig. 4 shows the transfer of two oxidizing equivalents by an oxygen atom to the iron center of the heme. It does not take into account the ultimate formation of free radical and Fe(IV) species. (For a review, see ref. 16.) The absence of a kinetic isotope effect for cyanide binding could indicate that a step such as transfer of the hydrocyanic acid molecule from the outer to the inner coordination sphere of the ferric ion is rate limiting.

The role of a basic group in facilitating the initial peroxide binding step has been discussed (51). The pH–rate profile for HRP (26) and turnip peroxidase (52) and the present isotope study provide evidence as to the actual nature of the group. A pK_a of 4.0 ± 0.1 could indicate a carboxyl group and there are many aspartate and glutamate residues present. However, studies on peroxidases with modified prosthetic groups suggest that a propionate side chain of the hemin group may be involved (53, 54). Although both propionate groups are hydrogen bonded to protein residues in other heme proteins, and thus contribute to the tightness of the heme binding to apoprotein, there is at present no direct evidence of a similar situation for peroxidase. The hemin vinyl groups of peroxidase are deeply buried in a hydrophobic region and they may contribute to the stability of binding of the prosthetic group (55). Space-filling models show that a propionate group may be positioned appropriately to act as both proton acceptor and donor. A related role for a propionate group had been postulated for metmyoglobin ligand binding reactions (56).

Compounds I and II Plus Ferrocyanide

The two substrates of intermediate reactivity with compound II, i.e. ferrocyanide and PABA, have pH–rate profiles consistent with a combined mechanism in which they are oxidized according to a general acid catalysis mechanism at high pH (group of pK_a 8.6) and a specific acid catalysis mechanism at low pH (group of pK_a ~ 0). In the PABA case the isotope effects were completely consistent with this combined mechanism (13). For the ferrocyanide reaction with compound II the same equilibrium isotope effect was found at low pH but in the neutral and basic regions both the equilibrium and kinetic isotope effects appeared small and reversed (12). The present intensive study in both water and deuterium oxide confirms the equilibrium effect with a reasonable pK isotopic shift for the group with pK ~ 0. It also indicates a reasonable equilibrium isotopic shift for the group with pK of 8.6 and no kinetic

isotope effect in neutral or basic solutions. The lack of a kinetic isotope effect could be due to the fact that complete or partial proton transfer is not part of the reaction or at least not rate limiting. The fact that the ferrocyanide does not differ from the product ferricyanide in proton content should not be taken as evidence for protons not taking part in the reaction. There is a net uptake of one proton by the enzyme when ferrocyanide is reducing compound II as well as compound I (46). The participation of protons is also obvious from the influence on reaction rates of differently protonated enzyme species. A possible alternative explanation of the lack of a kinetic isotope effect is that there is a rate-limiting proton transfer but the transition state resembles the reactants. For a partial proton transfer as has been suggested (12) this explanation would mean the same as no proton transfer at all. The present studies do not bring support to the idea of a rate-limiting, partial proton transfer from a distal group to a ligand in compound II with ferrocyanide as a substrate. The rate of an internal proton transfer between two groups in the enzyme should not be influenced to this extent by changing the substrate but merely be set by the difference in pK between the two groups if $pK_{donor} - pK_{acceptor}$ is positive (57). Part of the problem in the original explanation of the HRP-II–ferrocyanide isotope effects was caused by trying to attribute all effects in the neutral and alkaline regions to one acid group on the enzyme; the proton balance work shows clearly that another proton is involved.

The pD–rate profile for compound I reduction with $Fe(CN)_6^{4-}$ in D_2O is identical with the one obtained in H_2O except for a normal pK_a shift of 0.52 ± 0.11. This behaviour is a further indication that the obtained pK_a value reflects a single group being titrated and not more complex prototropic equilibria.

The PABA study (13) and the present one of ferrocyanide are the only complete studies of isotope effects as a function of pH for both compounds I and II. A further comparison of the two sets of results seems worthwhile. The pH–rate profiles for compound II are similar for both substrates. So are the profiles for compound I except that there are some special features at low pH for the PABA reaction, most likely owing to protonation of the substrate. The parallelism between compounds I and II with respect to the behaviour upon isotopic substitution is remarkable: a kinetic isotope effect for both reactions when PABA is employed as a substrate and no kinetic effect for either of them when ferrocyanide is the substrate. It is not less remarkable when considering the fact that the proton transfers are rate limiting with the less reactive substrate, PABA, and not for ferrocyanide which reacts 100 times faster. The two behaviours appear to emanate from a fundamental difference in the mechanism of reaction of the substrates. The most striking difference that could be the cause is the protons carried on the amino group of PABA (or the proton on the phenolic group of *p*-cresol). Removal of a proton from these functional groups could be the rate-limiting step for the reactions of compounds I and II with both of these substrates. For ferrocyanide the proton needed in the overall reaction could be derived from the solvent after a rate-limiting electron transfer.

In summary, the most self-consistent explanation of all of the results on PABA and ferrocyanide to date is that two acid groups in compound II and one in compound I facilitate electron transfer to the enzyme through proton equilibria. When a positive k_H/k_D effect is observed the required proton for conversion of compound I to II or II to the native enzyme (46) is derived from the substrate in a rate-controlling step; where there is no kinetic isotope effect the proton is derived from the solvent in a non rate-controlling step.

Selective reduction of a carboxyl group with diborane. Synthesis of specifically carbon-14 labelled D,L-2-Amino-4-(2-aminoethoxy)butanoic acid

YU-YING LIU, EDNA THOM, AND ARNOLD A. LIEBMAN
Chemical Research Department, Hoffmann-La Roche Inc., Nutley, NJ 07110, U.S.A.

Received May 23, 1978

YU-YING LIU, EDNA THOM, and ARNOLD A. LIEBMAN. Can. J. Chem. **56**, 2853 (1978).

Specific labelling of the title compound was achieved through intermediate **3***a*, methyl 2-(2-phthalimidoethoxy)acetate, derived from methyl bromoacetate-*2*-^{14}C. Conversion to the corresponding acid (**4**) was followed with selective diborane reduction which provided 2-(2-phthalimidoethoxy)ethanol-*2*-^{14}C (**5**). Treatment with thionyl chloride yielded the chloride **6** which is identical with the intermediate used in the nonlabelled synthesis and reaction with sodium ethyl phthalimidomalonate provided the title compound after hydrolytic work-up.

YU-YING LIU, EDNA THOM et ARNOLD A. LIEBMAN. Can. J. Chem. **56**, 2853 (1978).

On a réalisé le marquage spécifique du composé mentionné dans le titre par l'intermédiaire de **3***a*, le (phtalimido-2 éthoxy)-2 acétate de méthyle à partir du bromoacétate-*2*-^{14}C de méthyle. On a effectué la transformation en acide correspondant (**4**) par une réduction sélective avec le diborane qui a fourni le (phtalimido-2 éthoxy)-2 étanol-*2*-^{14}C (**5**). Par réaction avec le chlorure de thionyle, ce composé conduit au chlorure **6** qui est identique avec l'intermédiaire utilisé dans les synthèses non-marquées; la réaction avec le sel de sodium du phtalimidomalonate d'éthyle conduit au composé mentionné dans le titre après une extraction impliquant une hydrolyse.

[Traduit par le journal]

L-2-Amino-4-(2-aminoethoxy)butanoic acid (**7**) is an amino acid isolated from a fermentation broth of *Streptomyces* sp. x-11,085. It was shown (1) to be identical with the chemical reduction product of L-2-amino-4-(2-aminoethoxy)-*trans*-but-3-enoic acid, an antimetabolite antibiotic previously isolated from this unclassified species of *Streptomyces* (2). Synthesis of the saturated compound was effected by condensation of 2-(2-phthalimidoethoxy)ethyl chloride with sodium ethyl phthalimidomalonate followed by hydrolytic removal of protecting groups and decarboxylation. Enzymatic resolution then provided the L-amino acid (1).

These compounds possess interesting biological activities among which is their effect on ethylene production and subsequent ripening of fruits (2) when applied to these fruits. We wished to prepare the saturated amino acid specifically carbon-14 labelled at C-3 or C-4 for testing as a possible ethylene precursor, as such or after enzymatic resolution and/or enzymatic conversion to the Δ^3 dehydro analog. Since the starting material used in the normotopic synthesis, bischloroethyl ether, if labelled, would lead to a multiple labelled product because of symmetry, alternate starting materials and routes to this compound were investigated.

In a projected labelling synthesis, formation of the ether linkage could be achieved by the reaction of a suitably protected 2-aminoethanol with an ester of bromoacetic-*1*-^{14}C acid. Reduction of the resulting aminoethoxy ester **3** to the alcohol **5** (Scheme 1) and conversion to the corresponding chloride **6** provides an intermediate that would be closely related, if not identical to that used in the nonlabelling synthesis and could be carried on to the final product using established procedures. This sequence would allow labelling at C-2 from malonate or C-3 or C-4 from acetate as indicated.

It appeared that the *N*-phthalimido protecting group was necessary to the success of the conversion of **6** → **7** and we investigated its use at the outset. Susceptibility of the phthalimide group to reduction under the conditions effecting ester reduction required that **3** first be converted to the acid **4**. The carboxyl group is readily reduced with borane and in the presence of the phthalimide group selective reduction occurred only at the carboxyl carbon to yield alcohol **5** quantitatively. The acid **4** could be formed by the action of lithium iodide on the methyl ester **3***a* or in better yield by hydrogenolysis of the benzyl ester **3***b*.

By these procedures, **7** was prepared specifically labelled at C-4 using bromoacetic-*2*-^{14}C acid as the starting material and at C-2 using ethyl phthalimidomalonate-*2*-^{14}C for inserting the label. Because of the quantities required, these materials were prepared from barium carbonate-^{14}C according to literature procedures.

Experimental

Melting points were determined on a Thomas–Hoover capillary melting point apparatus and are uncorrected. Radio-

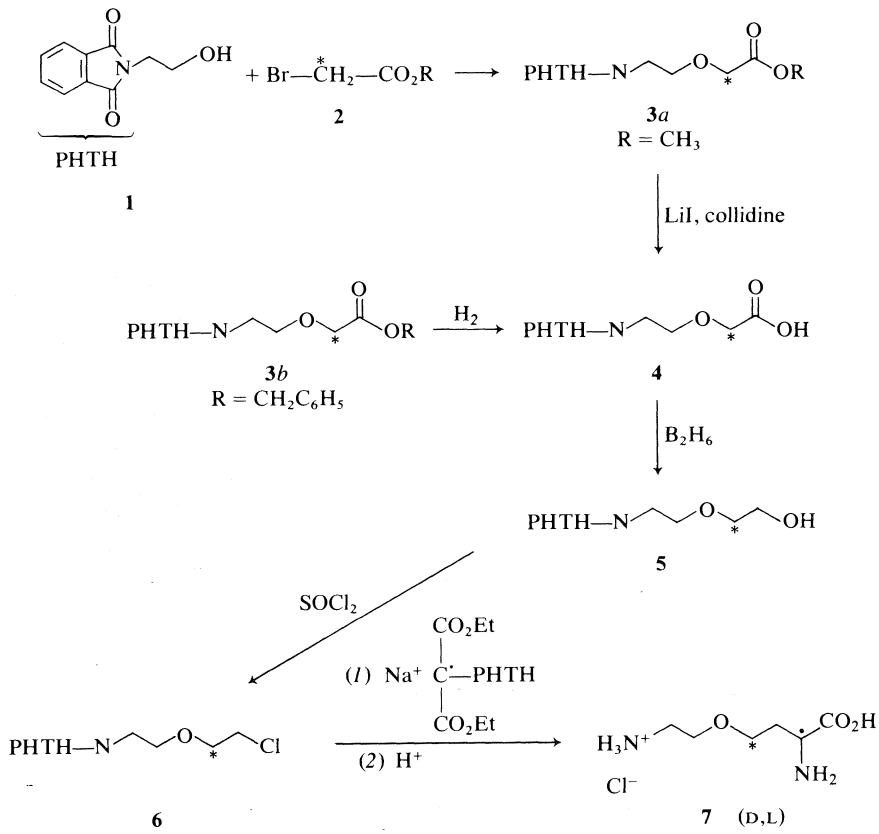

SCHEME 1. Preparation of carbon-14 labelled **7**.

chemical purity was determined on thin-layer chromatograms (Brinkmann pre-coated silica gel F-254) with a Packard Model 7201 Radiochromatogram Scanner System and radioactivity was measured by the liquid scintillation technique with a Packard Tricarb Model 2010 spectrometer. Spectral measurements were recorded as follows: infrared on either Perkin Elmer Model 137 or Model 621 or Beckman Model IR-9 spectrometers, ultraviolet on Carey 14 and 15 spectrophotometers, nmr on Varian T-60A, A-60 and HA-100 spectrometers and mass spectra on CEC 110-21B and JEOL Co. 015G double focusing and Hitachi RMU 6L single focus spectrometers.

*Methyl 2-(2-Phthalimidoethoxy)acetate (**3**a)*

Two millimoles (282 mg) of 2-phthalimidoethanol in 20 ml of anhydrous benzene was added to a suspension of sodium hydride (84 mg, 2 mmol of 57% mineral oil dispersion in benzene) and the resulting mixture was stirred and heated under reflux for 2 h. After cooling, 153 mg (1 mmol) of methyl bromoacetate was added and again the mixture was stirred under reflux for 2 h, then cooled, treated with 20 ml of water, and extracted with several portions of methylene chloride. The combined organic extracts were concentrated, *in vacuo*, and the residue purified by column chromatography on 25 g of silica gel using chloroform–acetone, 6:1 elution. The yield of **3***a* was 171 mg (0.65 mmol, 65%) of white solid, mp 142–144°C; ^{1}Hmr ($CDCl_3$) δ: 3.64 (s, 3H,—OCH_3), 3.85 (m, 4H,—CH_2—CH_2—), 4.08 (s, 2H,—O—CH_2—CO—), 7.75 (m, 4H, Ar). *Anal.* calcd. for $C_{13}H_{13}NO_5$: C 59.3, H 5.0, N 5.3; found: C 59.6, H 5.1, N 5.5.

*Benzyl 2-(2-Phthalimidoethoxy)acetate (**3**b)*

In a similar manner, the benzyl ester was also prepared on a 1 mmol scale. Reflux was continued for 20 h after the addition of benzyl bromoacetate and the product was purified by hplc on silica gel (E. Merck 60) with a chloroform – ethyl acetate gradient elution to yield 203 mg (60%) of white solid, mp 97–98°C. *Anal.* calcd. for $C_{19}H_{17}NO_5$: C 67.3, H 5.1, N 4.1; found: C 67.4, H 5.0, N 4.2.

*2-(2-Phthalimidoethoxy)acetic Acid (**4**)*

*By Hydrolysis of **3**a*

A 526 mg (2 mmol) sample of **3***a* and 798 mg (5.96 mmol) of lithium iodide were heated under reflux in 3 ml of collidine for 2 h. After cooling, the entire mixture was dissolved in chloroform which was then extracted with 30 ml of 2 *N* HCl. A chloroform wash of the acidic extract was combined with the original organic solution which was washed several times with water. Evaporation then afforded the crude product which was purified by crystallization from ethanol–water yielding 230 mg (0.92 mmol, 46%) of **4**, mp 167–168°C; ^{1}Hmr ($CDCl_3$) δ: 3.75 (m, 6H), 7.56 (m, 4H, Ar), 9.50 (s, 1H, COO*H*). *Anal.* calcd. for $C_{12}H_{11}NO_5$: C 57.8, H 4.5, N 5.6; found: C 57.7, H 4.5, N 5.6.

*By Hydrogenolysis of **3**b*

A solution of **3***b*, 678 mg (2 mmol) in 15 ml of ethyl acetate was hydrogenated over 160 mg of 10% Pd/C at room temperature and 1 atm until uptake of hydrogen ceased. The catalyst was removed by filtration and concentration of the filtrate, *in vacuo*, left pure **4**, 482 mg, (1.93 mmol, 96.7%).

*2-(2-Phthalimidoethoxy)ethanol (**5**)*

A solution of 3.5 ml of 0.97 *M* diborane in tetrahydrofuran was added to a stirred solution of **4**, (425 mg, 1.7 mmol) in 2 ml of dry tetrahydrofuran. The addition was carried out under N_2 and at 0°C, conditions which were maintained for an additional hour. Methanol, 1 ml, was then added and the resulting mixture was evaporated to dryness, treated with 10 ml of water, and then extracted with chloroform. The organic extracts were combined, dried ($MgSO_4$), filtered and concentrated *in vacuo* to yield pure **5**, 385 mg (96.3%), mp 59–60°C; ir (3% $CHCl_3$ solution): 3600, 1775, 1710 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.3 (s, 1H, —O*H*), 3.56 (s, 4*H*, —CH_2—O—CH_2—), 3.76 (m, 4H, N—CH_2—OH), 7.64 (m, 4H, Ar). *Anal.* calcd. for $C_{12}H_{13}NO_4$: C 61.3, H 5.6, N 5.6; found: C 61.3, H 5.7, N 5.9.

2-(2-Phthalimidoethoxy)ethanol-2-^{14}C [**5**-*(2-*^{14}C*)*]

The sequence described above was carried out using methyl bromoacetate-*2-*^{14}*C* (**2**) derived from $Ba^{14}CO_3$ (200 mCi) using literature procedures (ref. 3, p. 326).

2-(2-Phthalimidoethoxy)ethyl-2-^{14}C *Chloride* [**6**-*(2-*^{14}C*)*]

On a 0.4 mmol scale, 95 mg of alcohol [**5**-*(2-*^{14}*C)*] prepared as described above, was treated with 0.2 ml thionyl chloride and 0.25 ml pyridine in 2.5 ml benzene under reflux for 2.5 h. After cooling, the mixture was concentrated *in vacuo* and the residue was chromatographed over silica gel using a gradient elution of chloroform, chloroform–ethyl acetate (1:1) resulting in 92 mg of product (0.36 mmol, 91%), mp 68°C (lit. (4) mp 70°C) which was homogeneous by tlc and >99% radiochemically pure.

D,L-*2-Amino-4-(2-aminoethoxy)butanoic-4-*^{14}C *Acid Hydrochloride* [*7-(4-*^{14}C*)*]

The chloro derivative **6**-*(2-*^{14}*C)*, 253 mg (1 mmol), sodium ethylphthalimido malonate (5), 327 mg, (1 mmol), and potassium iodide (0.2 mmol) were dissolved in 2 ml of anhydrous DMF and the resulting solution was heated at 155°C for 4 h. After cooling, 20 ml of water was added and the resulting clear solution was decanted from the brown precipitate and co-distillation with several portions of chloroform–ethanol effectively concentrated the solution to a solid residue. This was chromatographed on a 25 g silica gel column with chloroform to provide 189 mg (36.2%) of adduct which was >95% radiochemically pure. Treatment with hydrazine hydrate, 100 mg of 98% material, in 3 ml of ethanol under reflux for 2 h yielded a white solid after removing excess hydrazine. This was heated with 4 ml of 6 *N* HCl for 2 h under reflux then cooled and filtered. The filtrate was concentrated *in vacuo* and the residue, dissolved in water, was applied to 10 g of Bio Rad AG 50W-X8 (80–100 mesh) cation exchange resin (H^+). Elution was accomplished first with 100 ml of water, then 80 ml of 20% pyridine in water, then 100 ml of 1 *N* NH_4OH. The latter was concentrated to a small volume and the pH then adjusted to 3.5 with 0.1 *N* HCl. The resulting product was recrystallized from ethanol to yield 47.7 mg (66% from **6**) of **7**-*(4-*^{14}*C)* with specific activity of 18.6 μCi/mg. Radiochemical purity was >99% and the radiochemical yield from methyl bromoacetate-*2-*^{14}*C* (**2**) was 2.4%. Dilution with nonradioactive intermediates was effected at several stages of the synthesis.

Specific activity of **7** ^{14}C-labelled at C-2 was 57.7 μCi/mg. The preparation was carried out as described above using ethyl phthalimidomalonate-*2-*^{14}*C* as the ^{14}C carrier. This was prepared from ethyl malonate-*2-*^{14}*C* derived from $Ba^{14}CO_3$ via literature procedures (ref. 3, pp. 40, 438, 453, and 899).

Nine trialkylamines, triethyl- to trihexylamine trioctyl-, tridodecyl, tri(methyl-2-butyl)-, and dimethyldodecylamine have been used for heats of mixing of the following systems at 298 K: *A*, fourteen systems made of all the possible binary mixtures (except one) of the six shorter amines; *B*, twelve systems made of a long chain amine, trioctyl-, tridodecyl- or dimethyldodecylamine with the four shorter members of the series; *C*, two systems consisting of the mixture of two long-chain compounds, trioctylamine with tridodecyl- and dimethyldodecylamine. Heats for the class *A* systems are less than or equal to 40 J/mol, indicating no net effect of the small polarity of the shorter members of the series. The experimental H^E of these mixtures are compared with two theories. The Monte Carlo approach gives good predictions but the heats calculated with the Snider–Herrington theory are too negative. Heats of the class *B* systems are suitable for the investigation of two new contributions to the heats of mixing, the positive heat of disordering of long-chains H^E(dis.) and the negative heat found in systems where one of the components is sterically hindered, H^E(ster.hindr.). H^E(dis.) found with the long-chain amines indicates an orientational order larger than in the case of the *n*-alkane of the same chain-length but equivalent to that found in the tetraalkyltin compounds of the same length. Recent work has shown that the tetrapropyl and tetraethyltin derivatives when mixed with long-chain alkanes or tin derivatives give rise to a H^E(ster.hindr.) contribution. From this work and the present study, the steric hindrance contributions of five sterically hindered compounds tetraethyltin and tetrapropyltin, triethyl- and tripropylamine, and 3,3-diethylpentane mixed with different second components are calculated. The steric hindrance contribution is found proportional to the volume of the second component and increasing in the following order of the sterically hindered component: triethyl- < tripropylamine < tetraethyl- < tetrapropyltin < 3,3-diethylpentane. Heats of the class *C* systems are small without significant contribution of H^E(dis.) due to the fitting of the long-chains in solution.

ROBERT PHILIPPE, GENEVIÈVE DELMAS et PHUONG NGUYEN HONG. Can. J. Chem. **56**, 2856 (1978).

Neuf trialkylamines, triethyl à trihexylamine, trioctyl, tridodecyl-, tri(methyl-2-butyl)- et dimethyldocecyl amine ont été utilisées pour la mesure de chaleurs de mélange des systèmes suivants à 298 K: *A*, quatorze systèmes faits de toutes les combinaisons binaires possible (sauf une) des six plus petites amines; *B*, douze systèmes faits d'une amine à longue chaine trioctyl-, tridodecyl-, ou diméthyldodecylamine avec les quatre plus petites amines; *C*, deux systèmes consistant du mélange de deux composés à longue chaine. Les chaleurs de mélanges des systèmes *A* sont toutes inférieures ou égales à 40 J/mol ce qui indique un effet global nul de la faible polarité des plus petites amines. Les valeurs expérimentales de H^E de ces mélanges sont comparées avec les théories. La méthode de Monte Carlo donne de bonne prédictions mais les chaleurs calculées avec la théorie de Snider–Herrington sont trop négatives. Les chaleurs des systèmes de la classe *B* permettent d'obtenir des informations au sujet de deux contributions aux chaleurs de mélange, la contribution positive de désordre des longues chaines H^E(dis.) et la contribution négative trouvée dans les systèmes dont un des constituants est empêché stériquement, H^E(ster.hind.). H^E(dis.) trouvé avec les amines à longues chaines indique que les corrélations d'orientations sont plus importantes que dans les alcanes ayant la même longeur mais sont semblables à celles des composés tétraalkylés. Des mesures de chaleurs sur les dérivés tétraalkylés de l'étain ont montré que le dérivé ethylé et propylé donnent une contribution d'empêchement stérique. A partir de ces résultats, les contributions d'empêchement stérique à H^E de cinq composés empêchés stériquement, les dérivés éthylés et propylés de l'étain et de l'azote et le 3,3-diéthylpentane sont obtenues quand ils sont mélangés à différents deuxièmes constituants. On a trouvé que la contribution d'empêchement stérique est proportionnelle au volume de deuxième constituant et croit dans l'ordre suivant du composé stériquement empêché triéthyl- < tripropylamine tetraethyl- < tetrapropylétain < 3,3-diéthylpentane. Les chaleurs de mélange de la classe *C* sont petites puisque l'adaptation des corrélations d'orientations des longues chaines en solution ne donne pas lieu à un H^E(dis.).

Introduction

Heats of mixing of non-polar systems depend on the energy of unlike contacts compared with that of like contacts. This first contribution H^E(chem.) is positive and has been recognized since early on (1). It can be predicted by current theories based on the analysis of heats by group interactions (2). The second contribution, H^E(f.v.) is negative and is derived from the difference in degree of thermal expansion or free volume of the two components. In most non-polar systems, the first contribution is larger than the second one, so that the total heat is positive. However, in mixtures of atactic non-polar polymers with non-polar solvents, the second contribution is larger than in mixtures of small molecules and therefore the experimental heat is quite often negative (3, 4). H^E(f.v.) can be calculated from the state of expansion of the liquids. Different models have been used by Prigogine (5), Delmas and Patterson (3, 6), and Orwell and Flory (7). The Van der Waals model of Flory is widely used because of its simplicity and because of the good results it gives. Recent and systematic measurements of heats of mixing of linear and branched alkanes (8), tetraalkyltin derivatives (9), and trialkylamines (10) with branched and linear alkanes and mixtures of tetraalkyl tin derivatives (11) have shown that two additional contributions arise from molecular shape. The origin of the third contribution H^E(dis.) is to be found in the correlations of orientations present in the pure state in some liquids, e.g. *n*-alkanes. Systematic comparison of the thermodynamical and optical (12) properties of linear alkanes with those of branched alkanes was instrumental in the recognition of the importance of orientational order in liquids. The correlations of orientations are destroyed when ordered liquids are mixed with globular molecules, and this gives rise to H^E(dis.). H^E(dis.) does not occur or occurs to a lesser extent in two cases: when the two liquids mixed are both composed either of globular molecules (since their more isotropic shape does not favour correlations of orientations) or of ordered molecules (since the solution is as ordered as the pure liquids).

The fourth contribution to H^E, H^E(ster.hindr.) has been recognized only recently (11, 12*a*). Unexpectedly, it is negative (13) but cannot be explained by a free volume difference and seems to be related to the presence of one sterically hindered molecule among the two liquids mixed. It was given the name condensation contribution (12*a*), alternatively it may be called a steric hindrance (11) contribution. More details will be given later. Analysis of the heats of mixing of liquids which are similar in volatility and chemical nature but whose molecules have different shapes shows that H^E(dis.), or H^E(ster.hindr.), or a combination of both, are the main contributions to the experimental heats. Examples of the first two cases are (*1*) the system tetrabutyltin + n-C_{16} for which the experimental heat of mixing is 360 J/mol (9), a value which corresponds to the heat of disordering of n-C_{16}, and (*2*) the system 3,3-diethylpentane + n-C_8 (20) for which the experimental heat of mixing (-82 J/mol) corresponds to H^E(ster.hindr.) due to 3,3-diethylpentane.

Heats of mixing measurements of trialkylamines with other trialkylamines is a study similar to that made on mixtures of tetraalkyltin derivatives (10). Some of the aims of the present work are similar to those we had then, i.e. to obtain more information on the disorder and steric hindrance contributions (systems involving long-chain compounds) and to compare the experimental heats with those predicted by the theories (mixtures of the globular short-chain compounds). The heats of trialkylamine systems may give some further information concerning (*a*) the effect on the heats of the small polarity of the shorter members of the series, (*b*) the possibility of *intra*-molecular correlations of orientations in the tetraalkyl- and trialkyl-derivatives which would not occur in linear alkanes, and (*c*) the generality of the result found on the tetraalkyltin derivatives, i.e. the ethyl and propyl derivatives seem much more sterically hindered than those of methyl and butyl.

The nine compounds used were all trialkylamines. For eight of them, the central nitrogen atom bore three identical alkyl radicals. In seven cases, these were straight-chain radicals with 2, 3, 4, 5, 6, 8, and and 12 carbon atoms while the other was the methyl-2-butyl radical. The remaining amine was dimethyldodecylamine. Heats of mixing were measured at 298 K on the following systems: *A*, fourteen systems of all the possible binary combinations (except one) of the five short-chain amines: triethylamine to trihexylamine and tri(methyl-2-butyl)amine (The system not measured was tripropylamine + tri(methyl-2-butyl)amine.); *B*, twelve systems where one of the components is a long-chain amine (four systems mixing tridodecylamine with the four shorter members of the series, four systems with trioctylamine, and the same four systems with dimethyldodecylamine); *C*, two systems with long-chain compounds mixed together: trioctylamine mixed with tridodecylamine and with dimethyldodecylamine.

To simplify matters, the following abbreviations are used in the text and the tables: NEt_3, NPr_3, $NBut_3$, $NPent_3$, $NHex_3$, $NOct_3$, and $NDodec_3$, corresponding to the radicals in 2, 3, 4, 5, 6, 8, and 12 carbon atoms. The dimethyldodecylamine and the tri(methyl-2-butyl)amine are replaced by NMe_2-

Experimental

Apparatus

The heats of viscous systems and in particular the heats for mixtures of two components having a relatively large difference of densities and viscosities ($NOct_3$ and $NDodec_3$ with the shorter members of the series) have been obtained with a tilting Tian–Calvet calorimeter to assure good mixing. Details of the instrument, the cells, and the calibration can be found in refs. 4 and 9. Agreement was better than 2% with the reference system, benzene + carbon tetrachloride (14). For each system, seven to ten runs were made in order to obtain the value of the maximum and the concentration dependence of the heat.

The other systems were measured with the Picker Flow Microcalorimeter (15) Technеurop Inc., Montreal. As shown by Grolier and Inglese (16), the best results are obtained when measurements are taken at a constant flow ratio of the two constituents. Curves are also obtained at about seventeen flow ratios. Heats by the Calvet or Picker calorimeters gave good agreement (better than 1%) with non-viscous mixtures. For viscous systems, the heats measured by the flow calorimeter were smaller (10 to 30%) than those measured by the static calorimeter.

Chemicals

The amines come from the same sources as in previous work (10, 17), namely, the Eastman, Aldrich Companies and the Chemical Procurement Laboratories. Densities of the compounds were measured as a test of their purities and can be found in Table 1.

Calculation of the Free Volume Contribution

We have chosen to apply the approximate form (8, 12) of the Prigogine theory which separates the interactional and free volume contribution. H^E(f.v.) is given by eq. [1]

$$[1]\quad H^E(\text{f.v.})/(x_1U_1^* + x_2U_2^*) = \tilde{C}_p(\tilde{T}_U)[\psi_1\tilde{T}_1 + \psi_2\tilde{T}_2 - \tilde{T}_U]$$

Here, $\tilde{T}_U$ is an average reduced temperature for the solution appropriate to the energy, U, and is defined by:

$$[2]\quad \tilde{U}(\tilde{T}_U) = \psi_1\tilde{U}(\tilde{T}_1) + \psi_2\tilde{U}(\tilde{T}_2)$$

The reducing parameter for the energy U^*, ($\tilde{U} = U/U^*$), can be obtained from experimental data since $U^* = P^*\cdot V^*$. In the Van der Waals model used by Flory, $\tilde{U} = -1/\tilde{v}$, so that eq. [2] becomes $1/\tilde{v}_U = \psi_1/\tilde{v}_1 + \psi_2/\tilde{v}_2$. The ψ's are energy fractions, i.e. $\psi_1 = x_1U_1^*/(x_1U^* + x_2U_2^*)$. The reduced volumes of the pure components are obtained from their expansion coefficients α and

$$\tilde{v}^{1/2} = (\tfrac{4}{3}\alpha T + 1)/(\alpha T + 1)$$

and their reduced temperatures $\tilde{T}_1$ and $\tilde{T}_2$ by

$$\tilde{T} = \tilde{v}^{-1}(1 - \tilde{v}^{-1/3})$$

$\tilde{C}_p(\tilde{T}_U)$ in eq. [1] is $(\frac{4}{3}\tilde{v}_U{}^{-1/3} - 1)^{-1}$. The interactional contribution expressed in terms of the Flory parameter X_{12} is obtained from the experimental heat and H^E(f.v.):

$$[3]\quad \frac{[H^E(\text{exp}) - H^E(\text{f.v.})]}{(x_1U_1^* + x_2U_2^*)} = X_{12}\psi_1\frac{\theta_2}{P_1^*}f(\tilde{v}_U)$$

$f(\tilde{v}_U) = (4\tilde{v}_U - 3\tilde{v}_U{}^{4/3})^{-1}$ corresponds to $[-\tilde{U}(\tilde{T}_U) + \tilde{T}_U\tilde{C}_p(\tilde{T}_U)]$ in the Van der Waals model. Its value is not far from 1. θ_2 is a surface fraction defined by $x_2V_2^*s_2/(x_2V_2^*s_2 + x_1V_1^*s_1)$. The s's are surface-to-volume ratios used in the Flory theory to characterize the shape of the molecule. The values of s depend to some extent on the model used but the X_{12} parameter does not. The parameter $X_{12}s_1{}^{-1}$ has been tabulated instead of X_{12} because it does not depend on which compound has been chosen as the first component ($X_{12}s_1{}^{-1} = X_{21}s_2{}^{-1}$).

Parameters for the Pure Components

The densities (d), expansion coefficients (α), and thermal pressure coefficients (γ) necessary to obtain $\tilde{v}$, V^*, P^* have been measured (17) or are obtained from literature (17). d, α, P^*, V^* are reported in Table 1. In the van der Waals model, $P^* = \gamma\tilde{v}^2T$. The surface-to-volume ratios, calculated by methods usual for the alkanes (7), are given in Table 1. The reduced volumes, $\tilde{v}$, of the pure components necessary for the calculation of the free volume contribution, the reduced temperature, $\tilde{T}_{11}$, used in the Monte Carlo approach, and the ξ parameters of the Snider–Herrington theory have been added in the last four columns.

Results and Discussion

Table 2 summarizes the results for all the systems. The experimental heats H^E have been fitted to the equation:

$$[4]\quad H^E = x_1x_2\sum_{i=0}A_i(x_1 - x_2)^i$$

where x is the mole fraction.

[a]All A's in J mol^{-1}.
[b]Systems measured with the tilting Tian–Calvet calorimeter.

The first two columns of Table 2 list the maximum of the heats and the concentration of the maximum. The next four columns give the parameters A_i of eq. [1]. The average difference between the actual experimental points and the calculated values is about 0.6% for all the systems. The next column indicates the heat per cm^3 calculated through the equation:

$$[5] \qquad H_v^E = H^E/(x_1V_1^* + x_2V_2^*)$$

The denominator of eq. [5] is the average core volume of the pure components in the solution. To compare heats of systems for which the molar volume is quite different, the heat of mixing per unit volume is more suited than H^E. The results of the comparison would not be significantly different if the molar volumes were used instead of the core volumes. The last two columns list the calculated free volume term in the Van der Waals model and the corresponding $X_{12}s_1^{-1}$ parameter of the Flory theory.

The diverse contributions described in the Introduction have different weights in the experimental heats. The qualitative or semi-quantitative analysis of the H^E will show if one contribution is dominant in a given system. Figures for H^E listed in Table 2 indicate that in the mixtures made up of NR_3 + NR_3', where R and R′ are taken from the ethyl to hexyl radicals (class A in Table 2), thirteen out of the fourteen systems have heats smaller than 40 J/mol. These results show that none of the contributions described previously is very large. In particular, the small polarity of NEt_3 is not revealed in non-polar surroundings. A similar result was found when the same compounds were mixed with alkanes (10). In this class of systems, no separation of contributions is possible, and these mixtures may better be analysed with theories which predict global heats from parameters on the pure components, as will be done later.

Disorder Contribution

The system which does not fit its own class A (made of mixtures of globular, less-oriented molecules) is $N(Me\text{-}2\text{-}But)_3$ + $NHex_3$. Its heat of mixing is large (75 J/mol) compared to that of the very similar system, $NPent_3$ + $NHex_3$ (11 J/mol). The interpretation of this difference is that the two methyl groups at the end of the alkyl chain in $N(Me\text{-}2\text{-}But)_3$ prevent a good fitting between the chains of the two compounds. $N(Me\text{-}2\text{-}But)_3$ acts as an order-breaker of the small orientational order of $NHex_3$ while $NPent_3$ does not.

For eleven systems (class B in Table 2), consisting of a globular and one long-chain molecule (trioctyl or tridodecyl and dimethyldodecylamines), the heats are larger, between 70 and 290 J/mol. They increase with the chain length of the long-chain component while varying less with the size of the globular component. The heat per cm^3, H_v^E, follows the same trend as can be seen in Fig. 1. This increase cannot be due to the change in free volume since the difference in size and expansion coefficient of the two components becomes increasingly negative, so that the free volume contribution would tend to lower the total heat. The interpretation of this increase in the

[a]The systems for which H^E(dis.) is in parentheses have a steric hindrance contribution which lowers H^E(dis.).

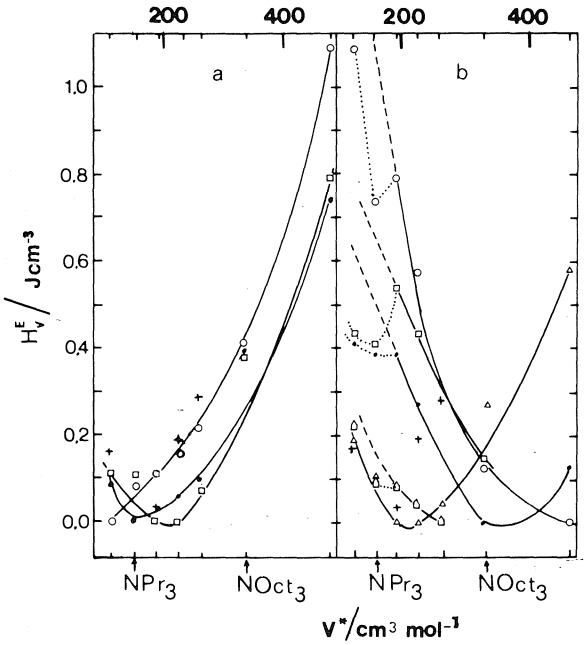

FIG. 1. Heats of mixing H_v^E in J/cm^3 vs. the core volume of one constituent. (*a*) For the shorter amines: (○) NEt_3, (●) NPr_3, (□) $NBut_3$, (+) N(Me-2-But)$_3$ with the series. (*b*) For the longer amines: (○) $NDodec_3$, (●) $NOct_3$, (□) NMe_2-Dodec, (⌒) $NHex_3$, (△) $NPent_3$, (+) N(Me-2-But)$_3$ with the series. The H^E(ster.hindr.) contribution is the difference between the dashed line and the dotted line. The higher values with N(Me-2-But)$_3$ (+) compared to $NPent_3$ (△) illustrate the nonfitting of branched and linear chains.

experimental heats is that the trend of the heats versus the molar or chain length of the second component is due mainly to the H^E(dis.) contribution. A finer separation of the contribution in H^E(chem.), H^E(dis.), and eventually H^E(ster.hindr.) is, in principle, difficult but may be made easier in practice by simple considerations. The free volume contribution is maximum for the NEt_3 + $NDodec_3$ mixture where the calculated value (penultimate column of Table 2) reaches a quarter of all the other contributions. For the other systems in this class, the free volume term is a smaller fraction of the total heat because the calculated value drops rapidly when the difference of expansion coefficients diminishes. A more definite validation of the assumption in the type *B* systems that H^E(exp) $\simeq$ H^E(dis.) is the reasonable range found within this approximation for H^E(dis.) of the same component with different order-breakers. Table 3 gives such values for the dodecyl chain in NR_3, SnR_4, n-C_{12}, and dimethyldodecylamine in J/cm^3. One sees that with most of the order-breakers, the heat of disordering is 1.15 J/cm^3 for $NDodec_3$ and 1.25 J/cm^3 for $SnDodec_4$. The values in parentheses correspond to the sterically hindered order-breakers for which H^E(dis.) is found to be lower due to the negative steric hindrance contribution. Dodecane appears to be less ordered by about one-third than the tri- or tetradodecyl chains due to its greater mobility. The lower values of H^E(dis.) for NMe_2Dodec may be due to the presence of the two CH_3's which prevent at one extremity of the molecule the correlation of orientations of neighbouring molecules. The last three rows of the table seem to indicate that the octyl chain in $NOct_3$ and $SnOct_4$ has about twice as intense correlation of orientations as n-octane. Rayleigh scattering measurements on alkanes show that orientational order is negligible in n-heptane but measurable in n-octane. These measurements have not been undertaken on NR_3 or SnR_4 compounds. It has been found previously, as seen in Table 3, that volatile order-breakers like NEt_3 give higher heats of disordering. H^E(dis.) have been obtained with similar results for hexadecane chains (10).

The third class of systems (class *C* in Table 2) corresponds to mixtures of two ordered compounds, both of which are ordered in the pure state and whose heats are small because there is no extensive destruction of correlation of orientations in the solution by contact with unlike molecules in the solution. Two systems, $NOct_3$ with $NDodec_3$ and $NOct_3$ with NMe_2Dodec, belong to this group.

Figure 1*a* shows H_v^E for the *A* and *B* type systems. The left part of the diagram indicates the small heats for mixtures of globular molecules, the right-hand side corresponding to large heats when the chain-

length of the second component increases. The curves are drawn by joining the points for the same order-breaker. The points for NMe_2Dodec and the shorter amines have not been inserted in the graph. To illustrate more clearly the irregularities of the heats in the series and for the discussion on the steric hindrance contribution, the heats for one long-chain amine have been plotted in Fig. 1*b* versus the core volume of the order-breaker and lines are drawn through the heats for the same long-chain compounds. This diagram is intended to show two features: the lower heats with NPr_3 and NEt_3 which do not have the values expected from the tributyl, tripentyl points (downward part of the curve). Note the difference between the dashed and dotted lines in the four series (○, □, ●, ⌓). The lower part of the figure indicates the extent of the fitting of the chains for mixtures of compounds different in size. For instance, $NPent_3$ (△) and probably $NHex_3$ (⌓) can fit their chains onto molecules in the series between NEt_3 and about $NOct_3$ and consequently these systems show small heats. The non-fitting of the linear and branched chains are indicated by the higher heats for the branched isomer of $NPent_3$, $N(Me\text{-}2\text{-}But)_3$. Compare the sixteenth result of Table 2 with the last two ones.

Steric Hindrance Contribution

There are a few examples of heats of mixing of non-polar compounds whose heats are too negative to be explained by the free volume contribution. An interesting case is the system *n*-C_8 + 3,3-diethylpentane (DEP) whose heat of mixing measured by Mathot and Prigogine (13) was found to be −82 J/mol. Recent measurements of other systems involving 3,3-diethylpentane have shown that the heats of mixing are smaller than expected. If the second component of the mixture with DEP is a long chain, there will be a disorder contribution added to the H^E(ster.hindr.) so that the total experimental heat will be less positive than expected rather than negative. Recent measurements of such systems have confirmed this possibility (12). We think that a similar effect occurs in the systems measured here. The kink downwards seen in Fig. 1*b* when NPr_3 is mixed with $NDodec_3$, NMe_2Dodec, $NOct_3$, and even $NHex_3$ would be explained by the fact that H^E(ster.hindr.) is larger for NPr_3 than for $NBut_3$.

Criteria for a Steric Hindrance Contribution

The first component is the sterically hindered molecule, i.e. NEt_3 and NPr_3 in the case of the present systems. The second component is one not sterically hindered. In previous work, linear alkanes have constituted the second components while long-chain triamines are used in this work. Globular molecules, such as cyclohexane and $SnBut_4$, seem to give a much smaller contribution. The molecular origin of the effect is not clear except that the sign of the heat corresponds to a diminution of the mobility or to a better fitting of the molecules in solution compared to the state in the pure components. It is not sure whether the compound, whose mobility is changed by contact with the unlike molecule, is the sterically hindered compound or the second component, or both. Probably non-thermodynamic data could give information on this.

Comparison of H^E(ster.hindr.) for Different Systems

An estimation of H^E(ster.hindr.) can be obtained from the difference between the expected value and the measured value of the heats of mixing. The expected value can be found in Fig. 1*b* on the dashed line drawn by extrapolation of the points for the higher amines at the abscissa corresponding to the core volume of the sterically hindered compound, for example, NPr_3. Because the heats with NMe_3 as first component were not measurable, the last point on the dashed line is lacking. This diminishes the reliability of the position of the expected value. However, since diagrams similar to Fig. 1*b* had been made on the SnR_4 + SnR_4' compounds and SnR_4 + alkanes with greater confidence because the heats with $SnMe_4$ were available and since data were also available with DEP, it was thought worthwhile to compare data on H^E(ster.hindr.) at this point. Figure 2 gives H^E(ster.hindr.) with five sterically hindered compounds versus the molar volume of the second component. The lines are drawn through the points corresponding to the same sterically hindered compound. The results for NEt_3 and NPr_3 with the trialkylamines as second component come from this work (curves *1* and *2*). The other points are calculated from previous work on the systems NPr_3 + alkanes (curve *5*), $SnPr_4$ + SnR_4' (curve *4*), $SnPr_4$ + alkanes (curve *6*), and DEP + alkanes (curve *7*). Details on the curve with DEP will be given since H^E(ster.hindr.) are not obtained in exactly the same way as they are with the series. Heats of mixing of *n*-C_{16} with many branched nonanes vary considerably with the number and position of the methyl groups on the chain. For instance, the molar heat at its maximum is 235 J/mol with 2,2,4,4-tetramethylpentane and 78 J/mol with 2,3,3,4-tetramethylpentane. Since the value with 2,2,5-trimethylhexane is about the largest for all the isomers, 315 J/mol, this compound is chosen as the one having little steric hindrance contribution. As the other contributions, chemical, disorder, and free volume must be about the same for the two isomers, the steric hindrance contribution of 2,3,3,4-tetramethylpentane would be equal to the difference 78 − 315, i.e. = −237 J/mol. Since the effect is larger with the ethyl-substituted

For personal use only.

nonane isomer DEP, and since that compound (DEP or CEt_4) has a structure similar to $SnEt_4$ and similar enough to NEt_3, the corresponding point has been inserted in Fig. 2. H^E(*n*-C_{16} + DEP) is 18 J/mol, and by the same argument H^E(ster.hindr.) is 18 − 316 = −298 J/mol. With *n*-C_8, the heats with 2,2,5-trimethylhexane and DEP being respectively +82 J/mol and −83 J/mol, H^E(ster.hindr.) for this system is −165 J/mol, the value of which is about half that with *n*-C_{16} as second component. With the same sterically hindered compound, H^E(ster.hindr.) seems proportional to the volume of the second component, as seen in Fig. 2. However, if the second component becomes globular when its size diminishes, as in the case of the SnR_4 and NR_3 compounds, H^E(ster. hindr.) becomes zero (curves *1–4*). For the alkanes, on the other hand, H^E(ster.hindr.) becomes zero only when $V^* = 0$ since curves *5–7* extrapolate to the origin. Curves *1–4* will superpose with curves *5–7* if the plots are made with the 'useful' volume ($V^* - 200$) cm^3, rather than V^*. This would indicate that linear chains in the second component as well as a sterically hindered compound are necessary to have the steric hindrance contribution. The difference between curves *1–4* and *5–7* should not arise from the way H^E(ster.hindr.) has been obtained because the method is identical for an alkane or a long-chain trialkylamine as a second component. The sterically hindered character decreases in the following order: DEP, $SnPr_4$, $SnEt_4$, NPr_3, NEt_3. Due to their small size and the uncertainty in extrapolation, data for NEt_3 and NPr_3 are less dependable than the others. It is realized that there is perhaps a subjective and approximate element in this evaluation by supposing that other contributions are very similar for the sterically hindered and non-sterically hindered molecules. However, the apparent consistency of the data presented in Fig. 2, particularly the fact that H^E(ster.hindr.), when expressed per cm^3, do seem to depend only on the sterically hindered component and not on the second component, would give some confidence in this analysis. Furthermore, such semi-quantitative evaluation of steric hindrance as seen by calorimetry may be useful for comparison of steric hindrance observed by other methods.

Evaluation of the disordering and steric hindrance contributions has been done directly on H^E. In Fig. 3, the $X_{12}s_1^{-1}$ of the systems measured in this work have been plotted with the same coordinate as Fig. 1 *a* and *b*. Since the general trends of the curves in Figs. 1 and 3 are the same, a qualitative discussion of the contributions to the heats, except for the free volume contribution, could be made on the X_{12} parameters. X_{12}(dis.) positive and X_{12}(ster.hindr.) negative could be obtained. However, as some of the X_{12} are made very large by a very negative calculated free volume contribution (note the NEt_3 + $NDodec_3$ system), it was not thought that an analysis of the disordering and steric hindrance contributions in terms of X_{12}, while less direct than that made on H^E, would give either greater physical insight in the present systems or even more comparable values between the systems. The magnitude of the steric hindrance contribution to the $X_{12}s_2^{-1}$ parameter in J cm^{-3} Å calculated as was done for H^E(ster.hindr.) is small for the amine systems (between −0.6 and −1.6), larger for the SnR_4 systems, reaching possibly −6.0 for 3,3-diethylpentane with *n*-C_{16}. It is interesting to note that the global X_{12} parameter has been found negative only for very few non-polar systems. The conditions necessary for this occurrence are: no disordering contribution, no large free volume, and one sterically hindered compound in the mixture. $X_{12}s_1^{-1}$ has been found to be −0.89 for $SnBut_4$ + br-C_{16} (2,2,4,4,6,8,8-heptamethylnonane) and −2.0 for $SnPr_4$ + br-C_{16} (10).

Comparison with Predictions of Theories

Theories of liquids and mixtures are developed usually for simple molecules. In applying them to mixtures of molecules of different size, one should not expect a quantitative agreement with the experimental data. However, the effect of the size and energy parameters and of the mixing rules on the predictions may be analysed and compared with interest with the experimental data.

A. Use of a State Equation Generated by the Monte Carlo Calculation Method

The simplest description for a solution is that of a pure liquid (one-fluid model) for which the parameters of size σ_m and energy ε_m are an average of those of the components.

Excess thermodynamic properties such as heats can be obtained from either a model or from experimental values of the energy for a reference component.

The size and energy difference between the two components are expressed by two parameters. Keeping only the terms in squares of the parameters in the expansion, one obtains (18)

$$[6]\quad \frac{H^E}{x_1x_2} = \frac{-\Delta\varepsilon}{x_1x_2\varepsilon_{12}^{0}}(-U + TC_p) - 2\delta^2T^2\frac{dC_p}{dT}$$

The first term corresponds to H^E(chem.), the second to H^E(f.v.), and $\Delta\varepsilon$ is a function of the two parameters η and δ.

$$[7]\qquad \eta = \frac{\sigma_{11}}{\sigma_{12}^{0}} - 1 \qquad \delta = \frac{\varepsilon_{11}}{\varepsilon_{12}^{0}} - 1$$

where σ is the hard sphere diameter. Liquid 1 is compared to a reference liquid which follows the

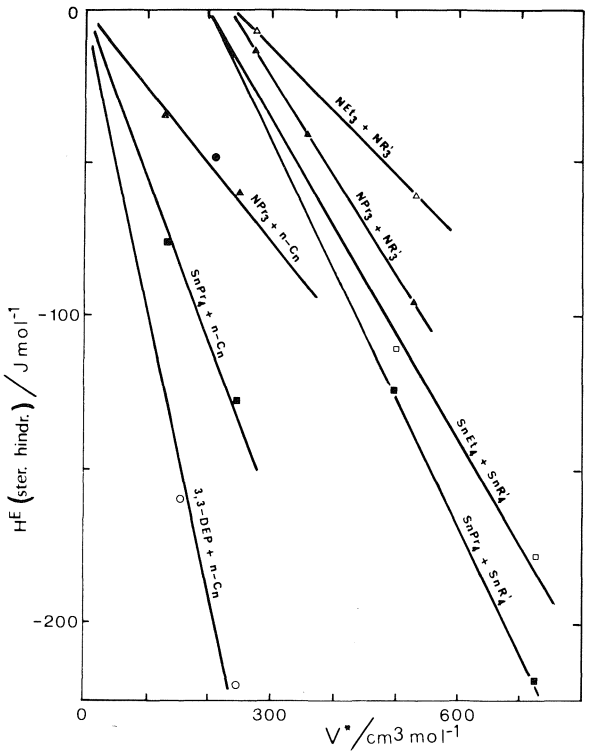

FIG. 2. Estimated values of the steric hindrance contribution in J/mol with five sterically hindered molecules (△) NEt_3, (▲) NPr_3, (□) $SnEt_4$, (■) $SnPr_4$, (○) 3,3-diethylpentane (DEP) vs. the core volume of the second component. Lines are drawn through the points corresponding to systems with the same first component and second components as indicated on the lines. One point (●) corresponds to the system $NPr_3 + NMe_2Dodec$.

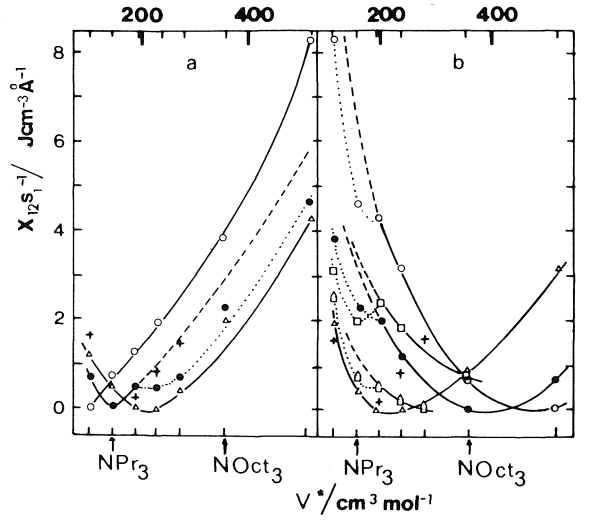

FIG. 3. $X_{12}S_1^{-1}$ in J/cm^3 Å. (*a*) For the three shorter amines: (○) NEt_3, (●) NPr_3, (△) $NBut_3$, (+) N(Me-2-But)$_3$ with the series. (*b*) For the longer amines: (○) $NDodec_3$, (●) $NOct_3$, (□) NMe_2Dodec, (⌓) $NHex_3$, (△) $NPent_3$, (+) N(Me-2-But)$_3$ with the series.

Berthelot–Lorentz rules:

$$[8] \qquad \varepsilon_{12}^{0} = \varepsilon_{11}^{1/2}\varepsilon_{22}^{1/2}$$

$$\sigma_{12}^{0} = (\sigma_{11} + \sigma_{22})/2$$

From the Monte Carlo calculations, Singer and Singer (18) give the following expression for H

$$[9] \quad H = RT^*(-8.6961 + 0.3042\tilde{T} + 0.7854\tilde{T}^2)$$

From the first and second derivatives of H, it is possible to obtain C_p and dC_p/dT required in eq. [6]. After some simple arrangement, H^E can be calculated as follows:

$$[10] \quad \frac{H^E}{x_1x_2RT} = (\sigma - 2\eta)^2\left(\frac{9.6961}{\tilde{T}} + 0.7854\tilde{T}\right) - 2\delta^2(1.5708\tilde{T})$$

Using the Flory combining rule, $(\delta - 2\eta)^2$ has been used for $-\Delta\varepsilon/\varepsilon_{12}^{0}$. In eq. [10], $\tilde{T}$ represents the reference liquid, in eq. [9], $\tilde{T}^* = T/\tilde{T}$ and $\tilde{T}$ is calculated from α.

Parameters for the Pure Components

The reduced volume and reduced temperature can be obtained from αT in the two equations

$$\alpha T = (-0.1648\tilde{T} - 0.4130\tilde{T}^2) \times (1.068 - 0.1648\tilde{T} - 0.2065\tilde{T}^2)^{-1}$$

and

$$\tilde{v} = (1.068 - 0.1648\tilde{T} - 0.2065\tilde{T}^2)^{-1}$$

The size parameter σ can be calculated from $\tilde{v}$ and the molar volume. ε is $kT/\tilde{T}$ and ε_{12}^{0} from eq. [8]. Table 1 gives the pure component reduced temperatures $\tilde{T}_{11}$. The parameter $\tilde{T}_{12}$ corresponds to the reference liquid, and the difference parameters η and δ are reported in Table 4 as well as H^E_{calcd} and H^E_{exp}.

The predictions of the Monte Carlo calculations are fairly good but not as good as with the $SnR_4 + SnR_4'$ systems with quite similar parameters. The less good agreement may come from the fact that experimental heats with the amine systems are much smaller even when compared by cm^3. For example, $SnBut_4 + SnDodec_4 = 1.24$ J/cm^3 while $NBut_3 + NDodec_3 = 0.79$ J/cm^3. The physical reason for this difference is not clear. One can speculate that the amines in solution lose less of their cohesive energy than the tin derivatives because there is more room to fit the three alkyl chains of one molecule with the alkyl chains of other surrounding molecules than it is with four alkyl chains on the same atom. The greater flexibility of the first N—C bond compared to the Sn—C bond may help the stacking in solution.

B. The Snider–Herrington Theory

A new equation of state was developed by Snider and Herrington (19) and applied successfully to

mixtures of simple liquids.

$$[11] \qquad p/nkT = \chi(\xi) - (an/kT)$$

where p is the pressure, n is the number density ($= N_{Avog}/V$), and a is a cohesive energy similar to that used in the Van der Waals equation of state, multiplied by a volume parameter.

$$\xi = \tfrac{1}{6}\pi r^3 n$$

where r is the hard-sphere diameter.

$$[12] \qquad \chi(\xi) = (1 + \xi + \xi^2)/(1 - \xi)^3$$

r and a for the pure components are obtained from ξ: the ξ values from the heats of vaporization:

$$[13] \qquad \triangle H_{vap}/RT = \chi(\xi) + 1$$

or from the expansion coefficient

$$[14] \qquad \alpha T = \frac{[(1 + \xi + \xi^2)(1 - \xi)]}{\left[-1 + 4\left(\xi + \xi^2 + \frac{\xi^3}{2}\right)\right]}$$

are listed in Table 1. Equations [11] and [12] may be generalized for a mixture. The solution hard-sphere diameter is $r_m^3 = x_1 r_1^3 + x_2 r_2^3$. a_m and ξ_m are given by eqs. [8] and [9] of ref. 19. A deviation from the geometrical rule can be introduced by the constant k_{12}. A k_{12} smaller than 1 will make the H^E values more positive.

$$\frac{a_{12}/kT}{r_m^3} = k_{12}\left(\frac{a_{11}/kT}{r_1^3}\right)^{1/2}\left(\frac{a_{22}/kT}{r_2^3}\right)^{1/2}$$

H^E is given by the difference between the $\chi(\xi)$ for the solution and the $\chi(\xi)$ for the pure liquids since p/nkT can be neglected.

$$H^E = RT[-\chi(\xi_m) + x_1\chi(\xi_1) + x_2\chi(\xi_2)]$$

$$\chi(\xi_m) = \frac{(1 + \xi_m + \xi_m^2)}{(1 - \xi_m)^3 - f[(r_1 - r_2), x_1]}$$

One sees that the excess heats will be very sensitive to the curvature of the function $\chi(\xi)$.

The results are the balance of two large terms, one negative due to the difference in free volume between the two components, and the other positive due to the difference in size. With $k_{12} = 0$, the negative term is larger in absolute value, so that the predicted heats are too negative. This is the case for the system consisting of two liquids with a relatively large free volume difference, i.e. mixtures of the globular amines and mixtures of a long-chain compound with a globular one. For the systems having a size difference but a relatively small free volume term, the positive size difference term is larger so that the heats are predicted to be positive. In the next column, the k_{12} value needed to fit the experimental heats has been given. Predicted values of V^E have been added for $k_{12} = 1$ and the k_{12} value which fits the heats. Measurements of V^E are being carried out to investigate whether the fitted k_{12} gives a good prediction for V^E. The diminution of the k_{12} value which fits the heats is not unreasonable physically since the cohesive energy between unlike molecules must diminish when the size difference increases. It was thought that the heats of vaporization would give a better prediction than the expansion coefficient which is a more strenuous test of the theory. However, the H^E calculated from $\xi(\alpha)$ (7th column) are nearer H^E_{exp} than H^E_{calcd} from $\xi(\triangle H_{vap})$ (last column of Table 4).

Rotamers arising from restricted motions and electronic interactions of acetoxymethyl groups in carbohydrates

S. PEREZ,[1] J. ST-PIERRE, AND R. H. MARCHESSAULT

Department of Chemistry, University of Montreal, Montreal, P.Q., Canada H3C 3V1

Received August 30, 1977[2]

S. PEREZ, J. ST-PIERRE, and R. H. MARCHESSAULT. Can. J. Chem. **56**, 2866 (1978).

The two dimensional conformational spaces available for acetoxymethyl groups in carbohydrates are reported. The studies were performed on two molecules differing in their C-4 configurations, i.e. *gluco* and *galacto*. The acetoxymethyl group was assigned a mean geometry derived from the computation of 19 equivalent groups as found in pertinent acetylated carbohydrates. The internal energy calculations were performed by including the partitioned contributions arising from the non-bonded energies, electrostatic interactions, and torsion energy. An instability rating of 3 kcal/mol was assigned to conformations involving *peri* interactions, i.e., *trans–gauche* and *gauche–gauche* forms in *gluco* and *galacto* carbohydrates, respectively. The results which are best described in term of topology show that several conformations corresponding to the *trans* and *gauche* states of the C—O single bond are preferred. However, significant shifts from perfect staggering are observed. The predicted regions of low energy are found to be in good agreement with experimental data from crystal structures of acetylated carbohydrates.

S. PEREZ, J. ST-PIERRE et R. H. MARCHESSAULT. Can. J. Chem. **56**, 2866 (1978).

On présente l'espace conformationnel à deux dimensions accessible aux groupes acétoxyméthyles dans les carbohydrates. Les études ont porté sur deux molécules présentant des conformations différentes à l'atome C-4, soit *gluco* et *galacto*. On a attribué au groupe acétoxyméthyle une géométrie moyenne déduite de calculs effectués sur 19 groupes semblables se trouvant dans des carbohydrates acétylés appropriés. Dans le calcul de l'énergie interne, on a tenu compte des contributions respectives des énergies d'interaction non-liée, des interactions électrostatiques et de l'énergie de torsion. On a attribué une instabilité évaluée à 3 kcal/mol aux conformations faisant intervenir des interactions *péri*, c'est-à-dire les formes *trans–gauche* et *gauche–gauche* dans les carbohydrates *gluco* et *galacto* respectivement. Les résultats, dont on donne une description topologique, montrent une préférence pour certaines conformations correspondant aux états *trans* et *gauche* de la liaison simple C—O. Cependant, il y a des écarts significatifs au décalage parfait. Les prévisions quant aux régions de basses énergies sont en bon accord avec les résultats expérimentaux tirés des structures cristallines de carbohydrates acétylés.

[Traduit par le journal]

Introduction

The allowed torsional angle variations around the inter-glycosidic linkages, usually described in terms of (Φ,ψ) maps, determine the conformation of polysaccharides. Furthermore a knowledge of the most probable conformation of the lateral substituents with respect to the backbone is important for a complete conformational specification. Since many of the naturally occuring polysaccharides are found to be partially acetylated (1, 2), the number of conformational variables is considerable. Although some computation methods can minimize simultaneously a large number of parameters (3, 4), an a priori knowledge of the allowed ranges for certain structural parameters as well as their interdependence is valuable.

An acetate group at the primary hydroxyl of a polysaccharide can adopt various conformations around the *exo*-cyclic C(5)—C(6) bond (torsion angle χ). In aldohexopyranoses the rotamer populations of the C(5)—CH_2OAc group fall into three preferred conformations: *gauche–trans*, *gauche–gauche*, and *trans–gauche* (5). A recent survey (6) of the rotations about the *exo*-cyclic bond of 125 primary hydroxyl and esterified hydroxyl groups from 71 crystal structures of carbohydrates showed that in glucosides, the *gauche–gauche* conformer is preferred (60%) along with the *gauche–trans* (40%) form. In galactosides, the *gauche–trans* (58%) and the *trans–gauche* (34%) are the two favoured conformers. The *gauche–gauche* form which involves *peri* interactions has been found in only two structures, associated with the occurrence of intramolecular hydrogen bonds.

Complete knowledge of the conformation of the primary acetate group requires two other torsion angles: torsion angle ω describing the conformation of the ester group and torsion angle θ around the

C(6)—O(6) bond. It seems well established that the barrier to rotation around the former is very high and that only small departures from planarity of the ester group are possible (7, 8). The conformation around the C(6)—O(6) bond can be rationalized on the basis of non-bonded and electrostatic interactions alone. An analysis of the problem using data for methyl formate has led to the proposal that the torsion potential for this rotation is zero (9).

The purpose of the present study is to establish the allowed variations for rotation around the C(6)—O(6) bond of the acetoxymethyl group in aldohexopyranoses. The theoretically calculated energy minima will be related to experimental evidence from crystal structure determinations of simple acetylated carbohydrates.

Method of Calculation

The purpose of the present work lies in the establishment of the conformationally-allowed region for an acetoxymethyl group in carbohydrates and oligosaccharides. One way to arrive at such a result is to perform a statistical survey of relevant crystal data. The complementary way is to perform a conformational analysis on such a molecular fragment. We choose an empirical method of calculation because it is the one used in all polysaccharide structural determinations (4). Ultimately if the two approaches coincide, i.e. the predicted and observed results (from the crystal data survey) agree, this would confirm the validity (within a given and accepted degree of confidence) for such a method of calculation.

The molecular geometry and conformation for the aldohexopyranose were those found in the crystal structure of 1,2,3,4,6-penta-*O*-acetyl-α-D altropyranose (10). However, the acetoxymethyl group was assigned a mean geometry derived from the computation of 19 equivalent groups as found in pertinent acetylated carbohydrates (Table 1). The bond distances and angles used for the acetoxymethyl group are schematically depicted, Fig. 1*a*, along with the torsion angles relevant for discussion. The sign of torsion angles is in adherence to the IUPAC nomenclature (11). χ will be used to describe the rotations around the C(5)—C(6) bond. When more specific descriptions are needed $\chi^{O(5)}$ (O(5)—C(5)—C(6)—O(6)) and $\chi^{C(4)}$ (C(4)—C(5)—C(6)—O(6)) will be employed.

The potential energy of the molecule was calculated by including the partitioned contributions arising from the non-bonded energies, electrostatic interactions, and torsion energy about the different torsion angles.

The van der Waals interactions between non-bonded atoms were evaluated using 6-12 potential functions with the parameters proposed by Scott and Scheraga (12, 13). The following expression was used:

$$V_{nb} = -\frac{A_{ij}}{R_{ij}^{6}} + \frac{B_{ij}}{R_{ij}^{12}}$$

where R_{ij} is the distance between atoms. The atomic polarizability for the CH_3 group, which was treated as a spherical domain of fixed size, the number of polarizable electrons, and the van der Waals radius are 1.77, 7.0, and 1.9 Å, respectively. The charge distribution in aldohexopyranose pentaacetate was taken from a previous study by Vijayalakshmi and Rao (14). The electrostatic interactions were calcu-

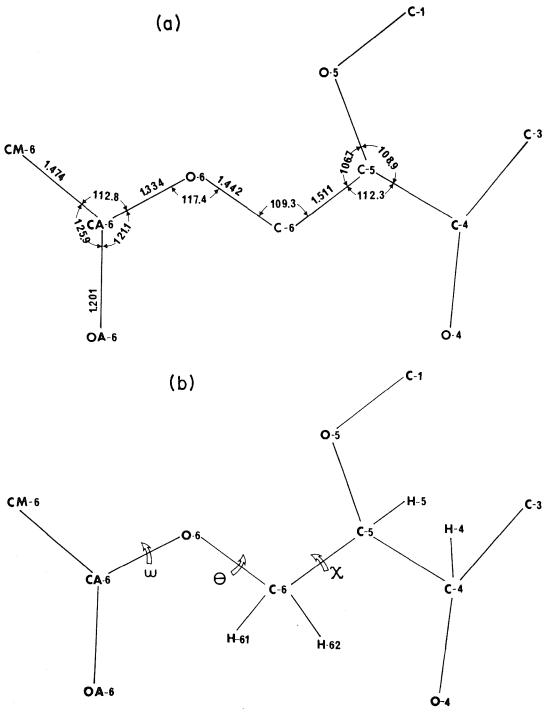

FIG. 1. Schematic representation of the acetoxymethyl group. (*a*) Molecular geometry derived by averaging 19 equivalent groups. (*b*) Torsion angles χ, θ, and ω.

lated using a Coulomb's law potential

$$V_{es} = \frac{332 e_i e_j}{\varepsilon R_{ij}}$$

where R_{ij} is the interatomic distance between atoms i and j, and e_i and e_j are expressed in fraction of electronic charge. ε, which is the effective dielectric constant of the medium, was assigned a value of 2.0 (15, 18). In the calculation of the potential energies there was no limit for the interaction distances for non-bonded and electronic terms. An intrinsic torsional potential with a three-fold barrier of 2.7 kcal/mol was assigned to rotation about C(5)—C(6). For rotation around the C(6)—O(6) bond, torsional angle θ, the value of the torsional potential was taken as zero. Because of resonance within the acetate group, rotation around the O(6)—CA(6) bond (rotation ω) was not allowed. As found in all carbohydrate acetates, the secondary acetate groups were fixed in the position where the carbonyl is coplanar with the hydrogen at the corresponding pyranose ring carbon atom.

The disposition of the substituent at C(4) is known to be one of the parameters fostering preferred conformations around the C(5)—C(6) *exo*-cyclic bond (6). Therefore two iso-energy contour maps were prepared, one corresponding to the *gluco* configuration (O(4)—C(4)—C(5)—O(5) = 180° for $^4C_1$ (*D*) ring) and another one corresponding to the *galacto* configuration (O(4)—C(4)—C(5)—O(5) = −60° for $^4C_1$ (*D*) ring). The conformations involving *peri* interactions, i.e. *trans–gauche* in *gluco* carbohydrates and *gauche–gauche* in *galacto* carbohydrates were systematically assigned an instability rating of 3 kcal/mol (6). The energy maps were calculated at intervals of 5° in χ and θ.

Results and Discussion

Gluco *Carbohydrates: Conformational Map and Comparison with Experimental Data*

It was noticed throughout this work that among the potential energy terms, the non-bonded part as well as the torsion potential about the C(5)—C(6) bond are predominant.

The energy map calculated for rotations of the acetoxymethyl group in *gluco* carbohydrates is given in Fig. 2, while the values of χ and θ angles for all the calculated minima are given in Table 2. The general features of the map arise from a combination of restricted motions around the *gauche–gauche* and *gauche–trans* (χ angle) conformations and a large region of allowed values for θ (about θ = 180°) ranging from −60° to 60°. The two lowest energy minima are found for the *gauche–gauche* conformation at C(5)—C(6). These two minima, [(*gauche–gauche*)–g^-] and [(*gauche–gauche*)–*t*], belong clearly to a large

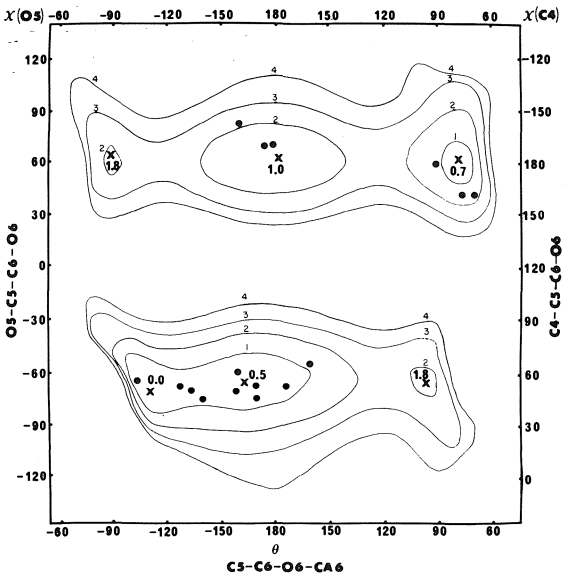

FIG. 2. Energy diagram computed for acetoxymethyl group in *gluco* carbohydrates, in terms of (χ,θ). Contours given at intervals of 1 kcal/mol are expressed relative to the minimum marked by 0.0. ● denotes an observed combination of (χ,θ) as found in simple acetylated carbohydrates in solid state.

TABLE 2. Preferred conformations and associated energies for the rotations of acetoxymethyl group in *gluco* carbohydrates

χ (deg)		θ		Relative energy
$\chi^{O(5)}$	$\chi^{C(4)}$	(deg)	Symbol	(kcal/mol)
−70	50	−110	[(*gauche–gauche*)–g^-]	0.0
−65	55	165	[(*gauche–gauche*)–*t*]	0.5
−65	55	95	[(*gauche–gauche*)–g^+]	1.8
60	180	85	[(*gauche–trans*)–g^+]	0.7
60	180	180	[(*gauche–trans*)–*t*]	1.0
60	180	−90	[(*gauche–trans*)–g^-]	1.8

valley ranging from $\theta = -100°$ to $\theta = 160°$. The third minimum [(*gauche–gauche*)–g^+] found for this conformation of χ corresponds to a somewhat higher energy. It is noticeable that the calculated values of χ corresponding to the energy minima depart slightly from perfect staggering. This is in agreement with the mean values found for $\chi^{O(5)} = -66.5°$ and $\chi^{C(4)} = 54.8°$ when averaging 61 equivalent *gauche–gauche* conformations in *gluco* carbohydrates (6).

The other low energy minima are found when the *gauche–trans* form around C(5)—C(6) exists. One of these minima is found to correspond to a perfect *trans* conformation around θ [(*gauche–trans*)–*t*]. Another one corresponds to a g^+ form [(*gauche–trans*)–g^+] which is, however, significantly shifted from perfect staggering. The same departure from perfect staggering is observed with the third minimum [(*gauche–trans*)–g^-].

The observed combinations of (χ,θ) as found in crystal structures of simple acetylated *gluco* carbohydrates are represented in the iso-energy map (Fig. 2). Among the six theoretically predicted conformations of low energy, only the four lowest minima are found experimentally. The most populated area corresponds to the low energy valley described previously. All the observed conformations lie within the 1.2 kcal/mol contour. The experimental ranges of χ angles are restricted ($-73° \leq \chi^{O(5)} \leq -52°$; $46° \leq \chi^{C(4)} \leq 64°$), whereas the distribution of θ angle is spread over 90°. The two other types of conformations found in the solid state correspond to the [(*gauche–trans*)–g^+] and [(*gauche–trans*)–*t*] minima. Here again the experimental distribution is in good agreement with the general topology of the calculated low energy regions. The two other calculated minima, which correspond to a somewhat higher energy, are not found in the solid state thus far.

With respect to the conformations displayed around the C(5)—C(6) bond, the statistical distribution found for acetoxymethyl groups (*gauche–gauche* form: 62.5% and *gauche–trans* form: 37.5%) is very comparable to that obtained when considering hydroxymethyl and esterified hydroxymethyl groups together (6).

Galacto *Carbohydrates: Conformational Maps and Comparison with Experimental Data*

The energy map calculated for rotations of the

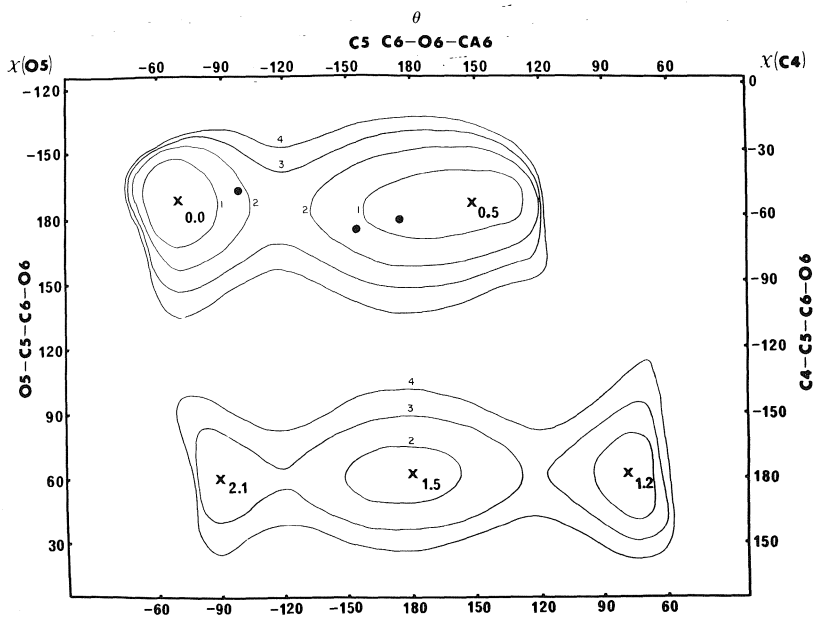

FIG. 3. Energy diagram computed for acetoxymethyl group in *galacto* carbohydrates, in terms of (χ,θ). Contours given at intervals of 1 kcal/mol are expressed relative to the minimum marked by 0.0. ● denotes an observed combination of (χ,θ) as found in simple acetylated carbohydrates in solid state.

TABLE 3. Preferred conformations and associated energies for the rotations of acetoxymethyl group in *galacto* carbohydrates

χ (deg)		θ		Relative energy
$\chi^{O(5)}$	$\chi^{C(4)}$	(deg)	Symbol	(kcal/mol)
−170	−50	−70	[(*trans–gauche*)–g^-]	0.0
−170	−50	150	[(*trans–gauche*)–*t*]	0.5
60	180	80	[(*gauche–trans*)–g^+]	1.2
60	180	−175	[(*gauche–trans*)–*t*]	1.5
60	180	−90	[(*gauche–trans*)–g^-]	2.1

acetoxymethyl group in *galacto* carbohydrates is depicted in Fig. 3. The values of χ and θ angles which correspond to the calculated minima are listed in Table 3.

Here again, the most restricted parameter is the torsion angle χ. The two lowest energy minima are found when the *trans–gauche* conformation around C(5)—C(6) occurs. The lowest minimum corresponds to a g^- conformation of θ angle: [(*trans–gauche*)–g^-]. The second minimum is located in a somewhat extended region of low energy which is spread over 70° along θ.

The three other low energy minima are found for the (*gauche–trans*) form about C(5)—C(6). In term of rotations about θ, these conformations occur around the non-eclipsed forms: [(*gauche–gauche*)–g^+], [(*gauche–trans*)–*t*], and [(*gauche–trans*)–g^-], respectively, with a significant shift from perfect staggering in the case of conformations g^+ and g^-.

The number of observed combinations of (χ,θ) from crystal structures of acetylated *galacto* carbohydrates is limited. Although the favoured conformations of hydroxymethyl groups in galactosides are the *gauche–trans* (58%) and the *trans–gauche* (34%) (6), only the latter form is observed so far when the primary hydroxyl group is acetylated. The reported conformations occur near the two lowest energy regions of the map: [(*trans–gauche*)–g^-] and [(*trans–gauche*)–*t*].

Conclusions

The comparison between the calculated energy minima and the experimental conformations reveals a close agreement. The relatively small number of energy minima can be understood on the basis of the usual partitioned energy method and upon consideration of *peri* interactions. The data and calculations presented here suggest that the conformation of the primary acetate group in an aldohexopyranose is mainly governed by intramolecular forces and that packing interactions play a minor role.

The foregoing analysis will be useful in the conformational understanding of complex polysaccharides. For example, in the *Klebsiella* type 59 polysaccharide, the primary hydroxyl of the mannose residues are reported to be acetylated (16). Similarly in the important commercial polysaccharide from *Xanthomonas compestris*, Xanthan gum (17), mannose is *O*-acetylated at the primary position.

The energy maps in Figs. 2 and 3 provide a probability distribution of conformations for primary acetate groups attached to *gluco* and *galacto* carbohydrates in any poly, oligo, or monosaccharide in solution. Eventually such information should be reconcilable with certain solution property data such as nmr spectra and circular dichroism curves.

Synthesis of the 3,3′-dinitro and 3,3′-diamino derivatives of α,α-trehalose and its D-*gluco*,D-*manno* and D-*manno*,D-*manno* isomers[1]

HANS H. BAER AND ANNA J. BELL

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received July 12, 1978

HANS H. BAER and ANNA J. BELL. Can. J. Chem. **56**, 2872 (1978).

The tetraaldehyde **2** obtained from α,α-trehalose (**1**) by periodate oxidation was cyclized with nitromethane in the presence of sodium methoxide to give a mixture of 3,3′-dideoxy-3,3′-dinitro disaccharides in good yield. Acetalation of the product with benzaldehyde followed by chromatographic separation of the bisacetals afforded crystalline 4,6;4′,6′-di-*O*-benzylidene derivatives (**3**, **4**, and **5**) of 3-deoxy-3-nitro-α-D-glucopyranosyl 3-deoxy-3-nitro-α-D-glucopyranoside (**6**, 3,3′-dideoxy-3,3′-dinitro-α,α-trehalose), 3-deoxy-3-nitro-α-D-glucopyranosyl 3-deoxy-3-nitro-α-D-mannopyranoside (**7**), and 3-deoxy-3-nitro-α-D-mannopyranosyl 3-deoxy-3-nitro-α-D-mannopyranoside (**8**), respectively. Acid debenzylidenation then gave crystalline **6**–**8**, and these were hydrogenated catalytically to produce the corresponding diamino disaccharide dihydrochlorides **9**–**11**.

HANS H. BAER et ANNA J. BELL. Can. J. Chem. **56**, 2872 (1978).

Le tétraaldéhyde **2**, préparé par oxydation au periodate de l'α,α-tréhalose (**1**), a été cyclisé avec le nitrométhane en présence de méthanolate de sodium. On a obtenu un mélange de 3,3′-didésoxy-3,3′-dinitro disaccharides avec un bon rendement. Par acétalation du mélange avec le benzaldéhyde suivie d'une séparation chromatographique des bis-acétals on a isolé a l'état cristallin les dérivés 4,6;4′,6′-di-*O*-benzylidène (**3**, **4** et **5**) du (3-désoxy-3-nitro-α-D-glucopyranosyl)-3-désoxy-3-nitro-α-D-glucopyranoside (**6**), du (3-désoxy-3-nitro-α-D-glucopyranosyl)-3-désoxy-3-nitro-α-D-mannopyranoside (**7**) et du (3-désoxy-3-nitro-α-D-mannopyranosyl)-3-désoxy-3-nitro-α-D-mannopyranoside (**8**), respectivement. L'hydrolyse acide des groupements benzylidènes a conduit aux composés cristallins **6**–**8**, qui, par hydrogénation catalytique, ont donné les dichlorhydrates des diamino disaccharides correspondants (**9**–**11**).

The disaccharide α,α-trehalose (α-D-glucopyranosyl α-D-glucopyranoside, **1**) is widely distributed in nature and has been isolated from such diversified sources as bacteria, fungi and yeasts, algae, insects and other invertebrates, and also from some higher plants. Its chemistry (2) and more recently its metabolism (3) have been reviewed. The biological significance of the disaccharide is emphasized by its varied roles as a structural component (e.g., in the cord factor of mycobacteria), as a reserve supply of energy (e.g., in insects during flight), and as a possible intermediate in glucose resorption. Among the facets that continue to draw much attention is the mechanism of action of the hydrolytic enzyme, trehalase, which is present not only in the types of organisms mentioned but also in mammals including man. Further interest in trehalose chemistry arose from the discovery of the 2-amino-2-deoxy derivative (trehalosamine) (4) and 2-amino-2-deoxy-α-D-glucopyranosyl α-D-mannopyranoside (5) as antibiotically active metabolites of *Streptomyces* species.

In continuation of our synthetic work (1, 6) on nitrogenous carbohydrates of potential biological interest we have decided to attempt the preparation of some new trehalose-type sugars for possible evaluation in biochemical studies. This was prompted by a suggestion of Dr. J. Defaye (Grenoble) whose laboratory in collaboration with that of J. E. Courtois (Paris) is engaged in detailed studies (7–11) of structure–activity relationships in the mechanism of trehalase action, for which there is a need for structurally and stereochemically modified trehalose analogs to be evaluated as substrates or inhibitors. A number of such compounds have been synthesized and assayed jointly by the French teams (7–11) while comprehensive work on the chemical modification of the disaccharide has also been performed by a group of British authors (12*a*–*j*). Several synthetic amino, diamino, and tetraamino analogs have been described. These include the 2-amino-2-deoxy (13) and 6-amino-6-deoxy (14) derivatives of trehalose and the 3-amino-3-deoxy-D-*altro* isomer (12*e*) as well as 6,6′-diamino-6,6′-dideoxytrehalose (15), the 2,2′-diamino-2,2′-dideoxy-D-*altro*,D-*altro* isomer (12*e*), the 4,4′,6,6′-tetraamino analog of D-*galacto*,D-*galacto* configuration (12*i*), and various 2,2′, 3,3′, 4,4′, 6,6′, and 4,4′,6,6′ diamines and tetraamines having additional deoxy functions (12*d*, *f*–*h*). However, no nitro derivatives of α,α-trehalose or its stereoisomers

[1]Part 18 in a series on cyclizations of dialdehydes with nitromethane. For Part 17 see ref. 1.

are known although we previously prepared (16) a structurally related nitro disaccharide (and the corresponding amine) which contained a β-linked heptuloside moiety. We have now employed the same method, starting with **1**, and obtained 3,3′-dideoxy-3,3′-dinitro-α,α-trehalose and two stereoisomers as well as the corresponding diamino sugars.

The tetraaldehyde **2**, quantitatively produced (17) from commercial **1** by periodate oxidation, was doubly cyclized with nitromethane in the presence of sodium methoxide according to the general procedure previously elaborated for sugar dialdehydes (18–20). Although a large number of stereoisomeric nitro sugars can theoretically arise in the reconstitution of two pyranose rings by this reaction, it was expected on the basis of earlier experiences that the D-*gluco*

and D-*manno* configurations would be favored under the conditions of kinetic control that were employed (16, 18, 19). This proved in fact to be the case. The mixture of nitro disaccharides formed in high yield consisted chiefly of three major components that were identified as 3-deoxy-3-nitro-α-D-glucopyranosyl 3-deoxy-3-nitro-α-D-glucopyranoside (**6**), 3-deoxy-3-nitro-α-D-glucopyranosyl 3-deoxy-3-nitro-α-D-mannopyranoside (**7**), and 3-deoxy-3-nitro-α-D-mannopyranosyl 3-deoxy-3-nitro-α-D-mannopyranoside (**8**). They were accompanied by minor proportions of other products, which were not identified.[2] Since a direct separation of the products could not be achieved the mixture was benzylidenated to give the corresponding bis-4,6-acetals **3**, **4**, and **5** which were isolated in crystalline form by preparative thin-layer chromatography. The yields were 22, 25, and 9% based on the crude acetal mixture which had been obtained in 81% yield. When the D-*gluco*,D-*manno* bisacetal **4** was treated briefly with ethanolic potassium hydroxide at room temperature, it partially incurred epimerization to the thermodynamically more stable D-*gluco*,D-*gluco* isomer **3** which was isolated in 34% yield although no attempts were made to optimize the conditions for this transformation. Similarly, it was demonstrated by means of tlc that the D-*manno*,D-*manno* isomer **5** is in the same fashion convertible into **4** and thence **3**. This facile epimerization, known (21) from studies in analogous monosaccharide derivatives where it was found to be virtually quantitative under appropriate conditions, was to serve at this time only to corroborate the configurational assignments of the products; it could doubtless be used as an aid to improving the yield of **3** in case the latter is the principal target of the synthesis.

The configurations of **3–5** followed clearly from ^1H nmr spectra. Two of the compounds, namely those having the highest and lowest mobilities in tlc, gave relatively simple spectra showing only one signal for each set of positionally identical protons in the two monosaccharidic moieties and thus proved themselves to be symmetrically constituted disaccharides (**3** and **5**). By contrast, the compound of intermediate chromatographic mobility (**4**) exhibited a more complicated spectrum in which most sets of positionally identical protons (except for the aromatic ones) gave, as far as the signals could be discerned, an individual signal for each of the two molecule halves, with differing chemical shifts and coupling constants, thus indicating an unsymmetrical disaccharide structure (Table 1). Compound **3** could readily be assigned the D-*gluco*,D-*gluco* configuration on account of the signal character of H-3, the proton at the nitro-substituted position.[3] The signal was a quartet containing two large splittings (9.0 and 10.5 Hz), re-

[2]Apart from other configurational isomers, by-products might, in this reaction, conceivably be formed by cross cyclization of **2**, with a nitromethane molecule linking C-2 and C-2′ to give a six-membered ring, although there was no evidence for this to have occurred to any large extent.

[3]In 3-deoxy-3-nitro sugar derivatives this signal is normally located without difficulty as we know from a large body of experience (22). Barring *O*-acylation at other ring positions it occurs at lower field than those of the remaining sugar protons, with the possible exception of an equatorial (α-anomeric) H-1 signal which, however, is distinguished by its multiplicity.

quiring axial orientation for H-2, H-3, and H-4. In agreement therewith, H-2 gave a quartet (after deuterium exchange of OH-2) showing 10.5 and 3.6 Hz splittings, with the latter corresponding to that present in the anomeric doublet. The analogous signals in **5**, namely an H-3 quartet (J = 10.5 and 3.5 Hz), an H-2 quartet (J = 3.5 and 1.2 Hz), and the anomeric doublet (J = 1.2 Hz) indicated the D-*manno*,D-*manno* configuration. In compound **4**, the lowest-field ring proton signal, a quartet with splittings of 10.5 and 3.5 Hz at δ 5.55, was attributable to H-3 of a D-*manno* moiety, and although the signal of the adjacent H-2 could not be used for confirmation as it was not resolved from other resonances upfield, it became discernible after debenzylidenation of **4** (i.e., in **7**) and was then found to agree with the assignment. (Moreover, the D-*galacto* configuration, the only alternative that would also have been compatible with a similar H-3 quartet, was ruled out by the aforementioned alkali-induced epimerization of **4** to **3**.) Another H-3 signal was located at δ 5.08 as a quartet having two large splittings (10.5 and 9.5 Hz) indicative of the D-*gluco* configuration of the second monosaccharide moiety. Again, this was confirmed by the spectrum of **7**. As a point of incidental interest the chemical shifts of the benzylidene methine protons may be compared (Table 1). It has been observed (23) in 4,6-*O*-benzylidenated methyl 3-nitrohexopyranosides that this shift is a fairly sensitive indicator of over-all configuration. Thus, in DMSO-d_6 solution, it occurred in the methyl α-D-glucoside 0.1 ppm to higher field than in the methyl α-D-mannoside. This phenomenon recurs in **3**–**5**. Finally, it may be worth noting that the hydroxyl protons produced doublets with J = 9–10 Hz in *gluco* moieties (**3** and **4**) and J = 5 Hz in *manno* moieties (**4** and **5**). In summary, a comparison of the three spectra reveals close similarities of the signals present in **4** with the respective ones in **3** and **5**, as should be expected in view of the configurational relation. However, the spectrum of **4** is not an exact superposition of those of its symmetrical isomers. The most notable divergence is associated with the shift position of the H-3 and H-3′ protons in **4**: in the *gluco* entity it is shifted upfield, and in the *manno* entity, it is displaced downfield (by about 0.2 ppm each way), relative to H-3 in the corresponding symmetrical isomers.

The bisacetals **3**–**5** upon de-*O*-benzylidenation by trifluoroacetic acid furnished the crystalline nitro disaccharides **6**–**8** in yields of 72–85%. The ^{1}H nmr spectra of these pure sugars provided full confirmation for the configurations. In every case the signals of H-1, H-2, and H-3 were amenable to analysis and accorded with the expected patterns (Table 1). The molecular rotations of **6**–**8** show a good correspondence with those of the nonnitro analogs. In order to make this comparison, we took cognizance of the fact that substitution of a nitro group for 3-OH in methyl α-D-glucopyranoside increases the $[M]_D$ value by 6370 whereas such substitution in methyl α-D-mannopyranoside decreases it by 5410, and we applied these increments[4] to the molecular rotations of α,α-trehalose and its α-D-*gluco*,α-D-*manno* and α-D-*manno*,α-D-*manno* isomers, for each glycosyl unit present (Table 2). The values so calculated for **6**–**8** deviate from those found by 3–8%.

An interesting feature of the nitrodisaccharides **6**–**8** was their propensity for retaining solvent of crystallization which was difficult to remove by heating *in vacuo*. Thus, **6** and **7** were obtained as solvates incorporating tetrahydrofuran, and **8** crystallized with chloroform. The organic solvent could be dislodged by evaporation with water, but highly stable hydrates were then obtained (see Experimental). Catalytic hydrogenation of **6**–**8** over platinum in the presence of a stoichiometric amount of hydrochloric acid afforded the corresponding diamino sugar dihydrochlorides, 3,3′-diamino-3,3′-dideoxy-α,α-trehalose dihydrochloride (**9**) and its *gluco*,*manno* (**10**) and *manno*,*manno* (**11**) isomers, as analytically pure solids.

NOTE ADDED IN PROOF: Dr. J. Defaye kindly arranged to have compounds **6**–**11** in 20 millimolar concentration tested for hydrolysis by cockchafer trehalase and reported that they show no enzyme affinity. This is in accord with recent findings (7) which indicate that at least one unmodified α-D-glucopyranosyl moiety must be present for recognition.

Experimental

Melting points were taken in glass capillaries in an electrically heated aluminum block apparatus and are not corrected. Optical rotations were determined at room temperature in a Perkin-Elmer 141 automatic polarimeter. Infrared spectra were obtained from KBr discs in a Unicam SP 1100 spectrometer. The nmr data refer to 100-MHz spectra with tetramethylsilane lock signal, obtained on a Varian HA-100 instrument, and the coupling constants were measured at 250 Hz sweep width (Table 1). For qualitative tlc, precoated silica gel plates SIL G-25 UV_{254} (Macherey-Nagel & Co, West Germany) were used and the spots were made visible by spraying with 5% sulfuric acid in ethanol, followed by heating. Preparative tlc was performed on 18 cm × 40 cm glass plates coated with a 1.5-mm layer of MN Kieselgel G/UV_{254} (Macherey-Nagel & Co.). Unless otherwise indicated, solvent systems employed for development were (A), 3:1 chloroform–methanol; (B), 4:1 chloroform – ethyl acetate; and (C), 7:3

[4]The data are tied to the configurations from which they were derived; comparison of other glycosides with their respective 3-nitro derivatives reveals effects on molecular rotation that are similar in trend but different in magnitude.

ether – petroleum ether. Here and elsewhere in the text, petroleum ether refers to the fraction boiling at 30–60°C.

*Periodate Oxidation of α,α-Trehalose (**1**)*

To a solution of α,α-trehalose dihydrate (**1**) (2.05 g, 5.42 mmol) in water (20 ml) was added a solution of sodium metaperiodate (4.87 g, 22.7 mmol, i.e., a 5% excess over 4 molar equiv.) in water (50 ml). The reaction mixture was kept in the dark at room temperature for 24 h, during which the pH value of the medium was periodically adjusted to approximately 6 by the portionwise addition of sodium hydrogen carbonate (0.89 g) in water (20 ml). Examination by tlc (double irrigation with solvent A) showed that the very slow-moving **1** was eventually replaced by a single, fast-moving product, the tetraaldehyde **2**. Several spots having intermediate mobilities were seen during early stages of the oxidation and were attributable to reaction intermediates. For processing, ethanol (30 ml) was added to the reaction mixture and, after cooling with ice water, the inorganic precipitate was filtered off and washed with chilled ethanol. The filtrate was concentrated to a small volume by evaporation and fresh ethanol (30 ml) was added to precipitate further inorganic material, which was removed. This operation was repeated three or four times, with evaporations being conducted to near dryness, until eventually the oxidation product dissolved clearly and was then obtained as a dry, white foam upon solvent evaporation; yield, 1.70 g of **2**.

*Nitromethane Cyclization of **2***

The tetraaldehyde **2** (1.70 g) and nitromethane (1.0 ml) were dissolved in absolute methanol (20 ml), and the mixture was rendered alkaline to pH 10 (measured potentiometrically) by dropwise addition of a dilute, methanolic sodium methoxide solution (freshly prepared from sodium hydride; *c*, 0.5% Na). It was important to avoid an excessive amount of base as this tended to give impure, discolored products; on the other hand, too low an alkalinity caused inconveniently slow reaction. The mixture, which became deep-yellow and deposited some precipitate (nitronate salts), was allowed to stand in a closed vessel at room temperature for 3.5 h. It was then deionized by stirring with a cation exchange resin (3 ml of Amberlite IR-120-H^+ or equivalent) whereby the precipitate dissolved. The resin was filtered off and washed with methanol, and the filtrate was evaporated to give a dry, yellow solid of nitro sugars (2.0 g, about 90% based on **1**). The product mixture was dissolved in ethyl acetate and recovered as an off-white powder (1.67 g, 77%) by precipitation with anhydrous ether.

Benzylidenation and Separation

The above mixture of nitro sugars (1.67 g), benzaldehyde (10 ml), and finely divided anhydrous zinc chloride (2.5 g) were placed under a nitrogen atmosphere in a closed vessel protected from light and vigorously stirred at room temperature for 4.5 days. The reaction mixture was then poured into, and agitated with, crushed ice and an equal amount of petroleum ether. The solid organic product which separated was collected, washed well with petroleum ether, and dried in the air. It was then dissolved in ether and recovered by precipitation, under ice cooling, with chilled petroleum ether. The pale yellow material (1.96 g, 81%) showed three well-separated, major spots in tlc. By triple irrigation with solvent B on a 9-cm plate, these migrated approximately 6, 4, and 2 cm. There were also several minor spots between the fastest and the second, and just above and below the third main spot. The main spots represented compounds **3**, **4**, and **5**, in order of decreasing mobility. These products were then isolated by preparative tlc using two to four successive irrigations with solvent B. Seven plates of 18 cm × 40 cm were used to accommodate 1.82 g of the product mixture. There was obtained, in almost pure condition, crystalline **3** (0.40 g) and **4** (0.46 g), which represented 22 and 25%, respectively, of the mixture applied. The third fraction, which consisted mainly of **5**, was obtained as a gum (0.34 g, 18.7%) that was revealed by tlc (solvent C) to contain small proportions of several contaminants. It yielded crystalline **5** upon purification by a second, preparative tlc (solvent C). Material moving even more slowly than **5**, isolated in the first chromatography and amounting to 0.6 g, was inhomogeneous and not investigated further.

*4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-glucopyranosyl 4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-glucopyranoside (**3**)*

Recrystallized from chloroform, **3** consisted of fine, colorless needles, mp 259°C (dec.); $[\alpha]_D$ +111.6° (*c* 0.4, acetone); $\nu_{max}^{(KBr)}$: 3580 (OH), 1550, 1360 (NO_2), and 760, 703 cm^{-1} (benzylidene). *Anal.* calcd. for $C_{26}H_{28}N_2O_{13}$ (576.5): C 54.16, H 4.90, N 4.86; found: C 54.05, H 4.86, N 4.80.

*4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-glucopyranosyl 4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-mannopyranoside (**4**)*

Recrystallized from chloroform, the fine colorless needles of **4** decomposed at 225°C; $[\alpha]_D$ +81.5° (*c* 0.5, acetone); $\nu_{max}^{(KBr)}$: 3450 (broad, OH), 1552, 1365 (NO_2), and 760, 703 cm^{-1} (benzylidene). *Anal.* calcd. for $C_{26}H_{28}N_2O_{13}$ (576.5): C 54.16, H 4.90, N 4.86; found: C 54.07, H 4.81, N 4.96.

When a sample of **4** (900 mg) was dissolved at room temperature in 12 ml of 0.13 *M* ethanolic potassium hydroxide solution and, after 15 min, deionized by cation exchange, the isomer **3** was a prominent product among remnant **4** and some minor decomposition products, according to tlc (solvent B). By preparative tlc of the reaction mixture, 260 mg of pure **3** could be isolated. The remainder of the material recovered from this operation was subjected to a second, identical

treatment with base, and another 50 mg of **3** could subsequently be isolated.

4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-mannopyranosyl 4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-mannopyranoside (5)

Compound **5** as obtained from the chromatography was recrystallized from ethanol – ether – petroleum ether to give fine needles (0.16 g), mp 175–176°C; $[\alpha]_D$ +51.4° (*c* 0.4, acetone); $\nu_{max}^{(KBr)}$: 3550 (broad, OH), 1552, 1365 (NO_2), and 765, 705 cm^{-1} (benzylidene). *Anal.* calcd. for $C_{26}H_{28}N_2O_{13}$ (576.5): C 54.16, H 4.90, N 4.86; found: C 53.98, H 5.04, N 4.74.

Compound **5** was shown by tlc (solvent B) to epimerize to a mixture of **3** and **4** by brief treatment with 0.1 *M* ethanolic potassium hydroxide followed by deionization.

De-O-benzylidenation

Each of the acetals **3**–**5** (0.35–1.0 g) was treated with 90% trifluoroacetic acid (27) at 0°C for 0.5 h. The acid (5 ml) was removed by evaporation *in vacuo* followed by coevaporation with several successive portions of ethanol. The residues were recrystallized as stated below, to furnish pure **6**, **7**, and **8** in yields of 77, 72, and 85%, respectively.

3-Deoxy-3-nitro-α-D-glucopyranosyl 3-Deoxy-3-nitro-α-D-glucopyranoside (6)

Recrystallized from tetrahydrofuran–ether, the white needles of **6**, mp 167–169°C, contained 1 mol of tetrahydrofuran of crystallization as evidenced by the nmr spectrum (multiplets of 4H intensity at δ 1.80 and 3.64). This solvent could not be removed *in vacuo* at 110°C unless the analytical sample was first treated with a small amount of water and then dried (4 h, 110°C). However, **6** then appeared to exist as a monohydrate, according to the elemental analysis. It showed mp 159–161°C, $[\alpha]_D$ +187° (*c* 0.3, water), $\nu_{max}^{(KBr)}$: 3700–3300 (very broad, OH), 1555, 1370 cm^{-1} (NO_2). *Anal.* calcd. for $C_{12}H_{20}N_2O_{13}\cdot H_2O$ (418.3): C 34.45, H 5.30, N 6.70; found: C 34.67, 34.39, H 5.25, 5.28, N 6.61, 6.72.

3-Deoxy-3-nitro-α-D-glucopyranosyl 3-Deoxy-3-nitro-α-D-mannopyranoside (7)

After repeated recrystallizations from tetrahydrofuran–ether, **7** was obtained as a solvate with tetrahydrofuran, according to the nmr spectrum and elemental analysis. It showed mp 145–147°C, $[\alpha]_D$ +133° (*c* 0.3, water), $\nu_{max}^{(KBr)}$: 3700–3300 (very broad, OH), 1560, 1365 cm^{-1} (NO_2). The analytical sample was dried *in vacuo* at 110°C for 4 h. *Anal.* calcd. for $C_{12}H_{20}N_2O_{13}\cdot C_4H_8O$ (472.4): C 40.68, H 5.98, N 5.93; found: C 40.81, H 6.01, N 5.85.

When another analytical sample was evaporated with added water before drying it lost the tetrahydrofuran but analyzed as a hemihydrate. *Anal.* calcd. for $C_{12}H_{20}N_2O_{13}\cdot 0.5\,H_2O$ (409.3): C 35.21, H 5.17, N 6.85; found: C 35.19, H 5.33, N 6.50.

3-Deoxy-3-nitro-α-D-mannopyranosyl 3-Deoxy-3-nitro-α-D-mannopyranoside (8)

Compound **8** was recrystallized from chloroform–methanol; mp 185–192°C (dec.), $[\alpha]_D$ +83° (*c* 0.3, water); $\nu_{max}^{(KBr)}$: 3700–3300 (very broad, OH), 1550, 1370 cm^{-1} (NO_2). The analytical sample, dried *in vacuo* at 110°C for 4 h, retained chloroform of crystallization, which was confirmed by its nmr spectrum in DMSO-d_6. *Anal.* calcd. for $C_{12}H_{20}N_2O_{13}\cdot\frac{1}{3}CHCl_3$ (440.05): C 33.65, H 4.66, N 6.37; found: C 33.66, H 4.98, N 6.37.

Catalytic Hydrogenations

Platinum dioxide catalyst (200 mg) suspended in 0.5 *M* hydrochloric acid (2 ml) was prehydrogenated and a solution of **6** (160 mg) in 0.5 *M* hydrochloric acid (4 ml) was then introduced. With efficient shaking under hydrogen at room temperature and ordinary pressure the hydrogenation was finished within 2 h. The catalyst was removed and washed well with at least seven 10-ml portions of water; the product showed a considerable tendency to remain adsorbed. The combined aqueous solution and washings were evaporated to dryness to give the amino sugar dihydrochloride **9** (140 mg) as a white solid. The isomers **10** and **11** were obtained in the same way from **7** and **8**, respectively. The products gave single spots, indicated by ninhydrin spray, in paper chromatography (descending, on Whatman No. 1 paper) using the Fischer–Dörfel (28) solvent system, 5:5:3:1 pyridine – ethyl acetate – acetic acid – water, with 11:40:6 pyridine – ethyl acetate – water in the bottom of the tank. The $R_{GN\cdot HCl}$ values were 0.43 (**9**), 0.39 (**10**), and 0.35 (**11**). Occasionally, somewhat lower values were found owing to minor fluctuations in solvent composition or temperature, but the ratio was remarkably constant for values obtained in the same run.

3-Amino-3-deoxy-α-D-glucopyranosyl 3-Amino-3-deoxy-α-D-glucopyranoside Dihydrochloride (9)

The crude hydrogenation product was dissolved in a minimum amount of methanol, recovered by careful precipitation with ethyl acetate, dried *in vacuo* at 56°C for 4 h and then represented a somewhat hygroscopic, fine white powder (possibly a microcrystalline hydrate) that decomposed at 230°C; $[\alpha]_D$ +168° (*c* 0.3, water); $\nu_{max}^{(KBr)}$: 3500–3100 (OH, NH_3^+), ~1620 and 1510 cm^{-1} (NH_3^+). For analysis, a sample was dried further, at 80°C and 1 Torr, whereby it lost 6.52% of its weight. *Anal.* calcd. for $C_{12}H_{26}Cl_2N_2O_9$ (413.3): C 34.87, H 6.34, N 6.78; found: C 34.97, H 6.46, N 6.67.

3-Amino-3-deoxy-α-D-glucopyranosyl 3-Amino-3-deoxy-α-D-mannopyranoside Dihydrochloride (10)

Prepared in the same way as just described for **9**, the isomer **10** was similar in appearance and in its ir data; it decomposed at 208°C and showed $[\alpha]_D$ +124.5° (*c* 0.3, water). Dried to constant weight at 80°C and 1 Torr, the analytical sample lost only 3.94% of its weight and then gave values corresponding to a monohydrate. *Anal.* calcd. for $C_{12}H_{26}Cl_2N_2O_9\cdot H_2O$ (431.3): C 33.42, H 6.54, N 6.50; found: C 33.21, H 6.45, N 6.41.

3-Amino-3-deoxy-α-D-mannopyranosyl 3-Amino-3-deoxy-α-D-mannopyranoside Dihydrochloride (11)

The crude product **11** was purified by dissolution in methanol and careful precipitation with ether. The dry white powder showed similar ir bands as **9**. It decomposed at 200–202°C and had $[\alpha]_D$ +84.3° (*c* 0.3, water). When dried to constant weight at 100°C and 2 Torr, it still retained water and analyzed as a dihydrate. *Anal.* calcd. for $C_{12}H_{26}Cl_2N_2O_9\cdot 2H_2O$ (449.3): C 32.08, H 6.73, N 6.24; found: C 32.00, H 6.55, N 6.15.

Acknowledgments

This work was supported financially by the National Research Council of Canada. H.H.B. wishes to express his appreciation to Dr. Jacques Defaye for generous hospitality and stimulating discussions during a sojourn at his laboratory in the Centre de Recherches sur les Macromolécules Végétales, C.N.R.S., Grenoble, France, where the present work was conceived. The National Research Council of Canada and the Centre National de la Recherche Scientifique are thanked for the award of a travel stipend under the auspices of their scientific exchange program.

Nuclear analogs of β-lactam antibiotics. IX.[1] Synthesis of 7-methoxy 2-isocephems and *O*-2 isocephems

JAMES L. DOUGLAS, DONALD E. HORNING, AND TERRY T. CONWAY

Bristol Laboratories of Canada, 100 Industrial Blvd., Candiac, P.Q., Canada J5R 1J1

Received February 23, 1978

JAMES L. DOUGLAS, DONALD E. HORNING, and TERRY T. CONWAY. Can. J. Chem. **56**, 2879 (1978).

The syntheses of 7-methoxy-7-phenoxyacetamido-3-methyl-Δ^3-isocephem-4-carboxylic acid **11***a*, 7-methoxy-7-phenoxyacetamido-3-methyl-Δ^3-*O*-2-isocephem-4-carboxylic acid **11***b* and 7-methoxy-7-(2-thienyl)acetamido-3-acetoxymethyl-Δ^3-*O*-2-isocephem-4-carboxylic acid **11***c* are described. A sequence analogous to that used to prepare 7-methoxy cephalosporins was used: Schiff base anions were thiomethylated and the Schiff bases hydrolyzed to free amines. The amines were acylated and thiomethyl to methoxyl conversion effected with mercuric ion catalysis. Removal of protective esters gave the acids **11***a*, **11***b*, and **11***c*. Compound **11***c* showed a modest level but broad spectrum of antibacterial activity.

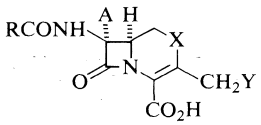
JAMES L. DOUGLAS, DONALD E. HORNING et TERRY T. CONWAY. Can. J. Chem. **56**, 2879 (1978).

On décrit les synthèses des acides méthoxy-7 phénoxyacétamido-7 méthyl-3 Δ^3 isocéphem-carboxylique-4 (**11***a*), méthoxy-7 phénoxyacétamido-7 méthyl-3 Δ^3 isocéphem-*O*-2 carboxylique-4 (**11***b*) et méthoxy-7 (thiényl-2)acétamido-7 acétoxyméthyl-3 Δ^3 isocéphem-*O*-2 carboxylique-4 (**11***c*). On a eu recours à une séquence semblable à celle qui a permis de préparer les méthoxy-7 céphalosporines: on a thiométhylé les anions des bases de Schiff et on a hydrolysé les bases de Schiff pour obtenir les amines libres. On a acylé les amines et effectué la conversion du thiométhyl en méthoxyl avec catalyse de l'ion mercurique. Les acides **11***a*, **11***b* et **11***c* ont été obtenus en enlevant les groupes esters. Le composé **11***c* a manifesté une activité antibactérienne modérée, mais étendue.

[Traduit par le journal]

Discussion

In previous communications (1–3) we have described the synthesis of 2-isocephems and *O*-2-isocephems (**1** and **2**). In view of the reported broadening of the antibacterial spectrum of cephalosporins by substitution with a 7-methoxy group (4), we decided to prepare 7-methoxy analogs of the 2-iso- and *O*-2-isocephems (**3** and **4**).



1 X = S, A = H
2 X = O, A = H
3 X = S, A = OMe
4 X = O, A = OMe

Several procedures have been reported for introducing a 7-methoxy substituent into the cephalosporin nucleus. We chose the method of Spitzer and Goodson (5) for introducing a 7-thiomethyl group and Applegate's modification (**6**) for conversion of the thiomethyl to a methoxyl group. In this manner, two simple isocephems substituted with a 7-methoxy group were prepared (Scheme 1, **11***a* and **11***b*). As well, the more highly substituted analog **11***c* was prepared to provide a compound structurally similar to clinically useful antibiotics.

The starting materials **5***a* and **5***b* for the synthesis of **11***a* and **11***b*, respectively, have been reported (1, 2). Starting material **5***c* was prepared from compound **12** (1) by the method previously used to prepare the benzyl ester (3) corresponding to **5***c* (Scheme 2).

The amines **5***a*, **5***b*, and **5***c* were converted to the Schiff bases **6***a*, **6***b*, and **6***c* by treatment with *p*-nitrobenzaldehyde. Anion formation at the 7-position with lithium diisopropylamide followed by treatment with methoxycarbonyl methyl disulfide (syntheses of the ethyl analog are described in ref. 7) gave the 7-thiomethyl derivatives **7***a*, **7***b*, and **7***c*. The Schiff bases were hydrolyzed to give amines **8***a*, **8***b*, and **8***c*. Acylation of the amines with the appropriate carboxylic acid and EEDQ (8) gave the amides **9***a*, **9***b*, and **9***c*. Mercuric acetate in methanol replaced the thiomethyl groups for methoxyl groups (**10***a*, **10***b*, and **10***c*). The ester protecting groups were removed by hydrogenolysis over palladium to give acids **11***a*, **11***b*, and **11***c*.

Spectral[2] and analytical data provide confirmation

a series: X = S, Y = H, Ar = CH_2—C$_6$H$_4$—NO_2, R = $PhOCH_2$

b series: X = O, Y = H, Ar = CH_2Ph, R = $PhOCH_2$

c series: X = O, Y = $OCOCH_3$, Ar = CH_2—C$_6$H$_4$—NO_2, R = 2-thienylacetyl

SCHEME 1

of the structures proposed for the compounds synthesized. The only point of uncertainty is the stereochemistry of the 7-methoxy group. However, by analogy to 7-methoxy cephalosporins (6) prepared by the same method, it is expected that the 7-methoxy substituent in compounds **11***a*, **11***b*, and **11***c* has the α configuration.

A summary of the antibacterial activity of compounds **11***a*, **11***b*, and **11***c* along with two cephalosporins is given in Table 1. In retrospect, it is not surprising that **11***a* and **11***b* show no antibacterial activity since 7-methoxycephalosporins with a 3-methyl group are also devoid of antibacterial activity (9). A comparison between the 3-acetoxymethyl derivatives **11***c* and **16** shows that the *O*-2-isocephem **11***c* has appreciably poorer activity than the cephalosporin. However, **11***c* does show some activity against the cephalothin resistant *Proteus morganii*.

Experimental

The ir spectra were recorded on a Unicam SP-200G ir spectrophotometer. The uv spectra were recorded on a Unicam SP-800 UV spectrophotometer. The nmr spectra were de-

termined in deuteriochloroform solution (unless otherwise noted) on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois. All reaction solvents were reagent grade and had been stored over molecular sieve before use. Tetrahydrofuran had been distilled from lithium aluminum hydride immediately before use. Anhydrous sodium sulfate was used to dry extraction solutions.

p-*Nitrobenzyl 7-β-Azido-3-acetoxymethyl-Δ³-O-2-isocephem-4-carboxylate (**15**)*

A solution of enol **12** (28.0 g, 61.5 mmol) in 300 ml of dichloromethane was cooled to −10°C and trifluoromethyl sulfonic anhydride (18.0 g, 61.5 mmol) was added. A solution of triethylamine (18.2 ml, 130 mmol) in 50 ml of dichloromethane was added slowly. The resulting solution was allowed to warm to 20°C,[3] then a solution of iodine (13.9 g, 55 mmol) in 300 ml of dichloromethane was added. After remaining for 45 min at 23°C, the solution was washed with water, dilute potassium iodide solution, and saturated sodium chloride (500 ml each). The solution was dried and the solvent was evaporated *in vacuo* to give the crude diiodide (**14**; 42 g) as a brown oil.

A mixture of diiodide **14** (42 g), potassium acetate (18 g, finely powdered), and dimethylformamide (400 ml) was stirred at 23°C for 3½ h. The resulting mixture was poured into 1500 ml of dilute sodium chloride solution and extracted with ether (3 × 400 ml). The combined ether extracts were washed with water four times, then with 10% sodium bicarbonate solution, water, 10% hydrochloric acid, water, and saturated sodium chloride solution (1000 ml each). The ether extract was dried and the solvent was evaporated in vacuo to give an oil, 6.5 g. The oil was chromatographed in 210 g of silica gel (activity 3) by the dry column technique. Elution with ether gave first several by-products then pure *O*-2-isocephem **15** (4.8 g; 19% overall yield from **12**).

[3]The triflate could be isolated at this point (if only 1 equiv. of triethylamine was used) by washing the solution with water and evaporating the solvent *in vacuo* to give the triflate **13** as a yellow oil.

p-*Nitrobenzyl 7-β-Amino-3-acetoxymethyl-Δ³-O-2-isocephem-4-carboxylate (**5***c*)*

Hydrogen sulfide was bubbled vigorously for 1 min into a solution of the azido compound **15** (4.7 g, 11.3 mmol) and triethylamine (1.8 ml, 12.5 mmol) in 200 ml of dichloromethane. The solution was stirred for 30 min, then nitrogen was bubbled through to expel the excess hydrogen sulfide. The solvent was evaporated *in vacuo* and the residue was extracted with 1:1 ether and 10% hydrochloric acid (3 × 50 ml). The acid extracts were neutralized with solid sodium bicarbonate and extracted with dichloromethane (3 × 30 ml). The extract was dried and the solvent was evaporated *in vacuo* to give the amine **5***c* (2.5 g; 58% yield).

p-*Nitrobenzyl 7-(*p-*Nitrophenylimino)-3-methyl-Δ³-isocephem-4-carboxylate (**6**a), Benzyl 7-(*p-*Nitrophenylimino-3-methyl-Δ³-O-2-isocephem-4-carboxylate (**6**b), and* p-*Nitrobenzyl 7-(*p-*Nitrophenylimino)-3-acetoxymethyl-Δ³-O-2-isocephem-4-carboxylate (**6**c)*

A solution of amino compound **5***a*, **5***b*, or **5***c* (10.0 mmol) and *p*-nitrobenzaldehyde (1.51 g, 10.0 mmol) in 150 ml of dichloromethane was heated under reflux under a trap filled with molecular sieve (4 Å) for 2 h. The solvent was evaporated *in vacuo* to give the imine **6***a*, **6***b*, or **6***c* in quantitative yield. The imines could be used in subsequent reactions without purification. Imine **6***b* was purified by chromatography on silica gel (elution with ether) to give material with mp 147–148°C. *Anal.* calcd for $C_{22}H_{19}N_3O_6$: C 62.70, H 4.54, N 9.97; found: C 62.59, H 4.63, N 9.96.

p-*Nitrobenzyl 7-(*p-*Nitrophenylimino)-7-thiomethyl-3-methyl-Δ³-isocephem-4-carboxylate (7*a*), Benzyl 7-(*p-*Nitrophenylimino)-7-thiomethyl-3-methyl-Δ³-O-2-isocephem-4-carboxylate (7*b*), and* p-*Nitrobenzyl 7-(*p-*Nitrophenylimino)-7-thiomethyl-3-acetoxymethyl-Δ³-O-2-isocephem-4-carboxylate 7*c

A solution of *n*-butyllithium in hexane (6.6 ml, 11 mmol) was added with stirring to a solution of diisopropylamine (1.11 g, 11 mmol) in 10 ml of dimethylformamide at −78°C under nitrogen. After 2 min, a solution of imine **6***a*, **6***b*, or **6***c* (10 mmol) in 40 ml of dimethylformamide was added slowly to the lithium diisopropylamide solution. After a further 5 min, a solution of methoxycarbonyl methyl disulfide (2.84 g, 18 mmol) in 20 ml of dimethylformamide was added. The reaction mixture was stirred at −78°C for 15 min then allowed to warm to 23°C. The solution was poured into 300 ml of pH 6.5 buffer (235 ml of 0.1 *M* potassium dihydrogenphosphate plus 65 ml of 0.1 *M* sodium hydroxide solution). This mixture was extracted with dichloromethane (3 × 200 ml). The organic phase was washed with dilute sodium chloride solution (3 × 300 ml), dried, and the solvent was evaporated *in vacuo* to give the crude thiomethyl compounds.

Thiomethyl compound **7***a* was purified sufficiently for further reactions by recrystallizing from methanol then benzene and was obtained thus in 50% yield.

Thiomethyl compound **7***b* was purified by chromatography on 250 g of silica gel (activity 3, elution with benzene then ether). Compound **7***b* was obtained in 65.5% yield and was recrystallized from methanol, mp 122.5–123.5°C. *Anal.* calcd. for $C_{23}H_{21}N_3O_6S$: C 59.09, H 4.53, N 8.99; found: C 59.22, H 4.55, N 8.95.

Thiomethyl compound **7***c* was purified by chromatography on 250 g of silica gel (activity 3, elution with ether) and was obtained in 42% yield.

p-*Nitrobenzyl 7-Amino-7-thiomethyl-3-methyl-*Δ^3*-isocephem-4-carboxylate (***8***a), Benzyl 7-Amino-7-thiomethyl-3-methyl-*Δ^3*-O-2-isocephem-4-carboxylate (***8***b), and* p*-Nitrobenzyl-7-amino-7-thiomethyl-3-acetoxymethyl-*Δ^3*-O-2-isocephem-4-carboxylate* ***8***c*

A solution of the imine **7***a*, **7***b*, or **7***c* (3.0 mmol), *p*-toluenesulfonic acid monohydrate (850 mg, 4.5 mmol), and water (0.8 ml, 45 mmol) in 25 ml of ethyl acetate was stirred for ½ h. The precipitate was collected and washed with ethyl acetate and ether to give the pure *p*-toluenesulfonate salts of amines **8***a*, **8***b*, and **8***c*. Salt **8***a* had mp 161–163°C (dec.). *Anal.* calcd. for $C_{16}H_{17}N_3O_5S_2 \cdot C_7H_8O_3S$: C 48.66, H 4.44, N 7.40; found: C 48.74, H 4.31, N 7.47. Salt **8***b* had mp 140–142°C (dec.). *Anal.* calcd. for $C_{16}H_{18}N_2O_4S \cdot C_7H_8O_3S$: C 54.33, H 5.17, N 5.53, S 12.66; found: C 54.66, H 5.19, N 5.62, S 12.56.

The free bases were obtained by treating the salts with an excess of 10% sodium bicarbonate solution and extracting with dichloromethane. The extracts were dried and the solvent was evaporated *in vacuo* to give amine **8***a* (90% yield), **8***b* (67% yield), or **8***c* (53% yield).

p-*Nitrobenzyl 7-Thiomethyl-7-(phenoxyacetamido)-3-methyl-*Δ^3*-isocephem-4-carboxylate (***9***a), Benzyl 7-Thiomethyl-7-(phenoxyacetamido)-3-methyl-*Δ^3*-O-2-isocephem-4-carboxylate (***9***b), and* p*-Nitrobenzyl 7-Thiomethyl-7-(2-thienylacetamido)-3-acetoxymethyl-*Δ^3*-O-2-isocephem-4-carboxylate (***9***c)*

A solution of the amine **8***a*, **8***b*, or **8***c* (1.85 mmol), phenoxyacetic acid (290 mg, 1.9 mmol) or 2-thienylacetic acid (270 mg, 1.9 mmol), EEDQ (518 mg, 1.9 mmol), and dichloromethane (40 ml) was stirred at 23°C for 4 h. The solution was washed with 10% hydrochloric acid, 1% sodium bicarbonate and saturated sodium chloride solutions (40 ml each) then dried, and the solvent was evaporated *in vacuo* to give the amide in sufficient purity for subsequent reactions.

Amide **9***a* was obtained in 90% yield.

Amide **9***b* was obtained in 94% yield and was crystallized from benzene–pentane, mp 153–155°C. *Anal.* calcd. for $C_{24}H_{24}N_2O_6S$: C 61.52, H 5.15, N 5.98, S 6.84; found: C 61.73, H 5.14, N 5.98, S 6.70.

Amide **9***c* was obtained in 96% yield.

p-*Nitrobenzyl 7-Methoxy-7-(phenoxyacetamido)-3-methyl* Δ^3*-isocephem-4-carboxylate (***10***a), Benzyl 7-Methoxy-7-(phenoxyacetamido)-3-methyl-*Δ^3*-O-2-isocephem-4-carboxylate (***10***b), and* p*-nitrobenzyl 7-Methoxy-7-(2-thienylacetamido)-3-acetoxymethyl-*Δ^3*-O-2-isocephem-4-carboxylate (***10***c)*

A mixture of thiomethyl compound **9***a*, **9***b*, or **9***c* (1.0 mmol) and mercuric acetate (319 mg, 1.0 mmol) in 110 ml of methanol was stirred at 23°C for 1 h. The solvent was evaporated *in vacuo* and the residue was mixed with benzene (50 ml). The benzene mixture was washed with water (50 ml), dried, and the solvent was evaporated *in vacuo* to give the crude methoxy compounds which were purified by chromatography on 30 g of silica gel (activity 3).

Compound **10***a* was eluted from the column with benzene–chloroform 1:1 and was obtained in 44% yield.

Compound **10***b* was eluted from the column with the sequence benzene, chloroform, ether and was obtained in 93% yield. It was crystallized from benzene–pentane, mp 150–151°C.

Compound **10***c* was eluted from the column with ether and was obtained in 30% yield.

7-Methoxy-7-(phenoxyacetamido)-3-methyl-Δ^3*-isocephem-4-carboxylic Acid* ***11***a

A mixture of the ester **10***a* (230 mg, 0.45 mmol), tetrahydrofuran (12 ml), methanol (2.3 ml), and 10% palladium-on-charcoal (140 mg) was hydrogenated with shaking for 4 h at 23°C and 50 psi. The catalyst was removed by filtration and the solvent was evaporated *in vacuo*. The residue was dissolved in ethyl acetate (15 ml), washed with 10% hydrochloric acid and water (15 ml each), and extracted with 1% sodium bicarbonate solution (2 × 15 ml). The extract was acidified to pH 2 with 10% hydrochloric acid and extracted with ethyl acetate (2 × 15 ml). The combined ethyl acetate extracts were washed with saturated sodium chloride (15 ml), dried, and the solvent was evaporated *in vacuo* to give the acid **11***a*, 129 mg (77% yield). It was recrystallized from acetonitrile, mp 208–209°C (dec.). *Anal.* calcd. for $C_{17}H_{18}N_2O_6S$: C 53.96, H 4.79, N 7.40, S 8.47; found: C 53.64, H 4.90, N 7.55, S 8.47.

7-Methoxy-7-(phenoxyacetamido)-3-methyl-Δ^3*-O-2-isocephem-4-carboxylic Acid (***11***b)*

A mixture of ester **10***b* (110 mg, 0.244 mmol), tetrahydrofuran (10 ml), and 10% palladium-on-charcoal (55 mg) was hydrogenated at 23°C and atmospheric pressure for 10 min. The catalyst was removed by filtration and the solvent was evaporated in vacuo. The residue was recrystallized from ether to give acid **11***b*, 64 mg (73% yield), mp 190–191°C (dec.); uv λ_{max} (EtOH): 270 nm (ε 7850).

7-Methoxy-7-(2-thienylacetamido)-3-acetoxymethyl-Δ^3*-O-2-isocephem-4-carboxylic Acid (***11***c)*

A mixture of ester **10***c* (212 mg, 0.39 mmol), ethyl acetate (50 ml), *n*-butyl alcohol (12 ml), 1 *M* hydrochloric acid (0.4 ml), and 20% palladium-hydroxide-on-charcoal (212 mg) was hydrogenated with shaking for 3½ h at 23°C and 50 psi. The catalyst was removed by filtration and the solvent was evaporated *in vacuo*. The residue was mixed with ether and extracted with 1% sodium bicarbonate solution (2 × 25 ml) and water (25 ml). The combined aqueous extracts were cooled to 0°C, acidified to pH 2 with 10% hydrochloric acid, and extracted with ethyl acetate (3 × 30 ml). The combined organic extracts were dried and the solvent was evaporated *in vacuo*. The residue was purified by trituration with ether to give acid **11***c*, 32 mg (20% yield), mp 150–155°C (dec.); uv λ_{max} (THF): 270 nm (ε 9340). *Anal.* calcd. for $C_{17}H_{18}N_2O_8S$: C 49.75, H 4.42, N 6.83; found: C 49.63, H 4.59, N 6.89.

Reaction of dimethyl sulfoxide with chlorothiolformates, hydrogen chloride, hydrogen fluoride, and hexafluoroisopropanol[1]

ALAN QUEEN, ALBERTA E. LEMIRE, ALEXANDER F. JANZEN, AND MICHAEL N. PADDON-ROW

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 23, 1978

ALAN QUEEN, ALBERTA E. LEMIRE, ALEXANDER F. JANZEN, and MICHAEL N. PADDON-ROW. Can. J. Chem. **56**, 2884 (1978).

Dimethyl sulfoxide reacts with phenyl chlorothiolformate according to the stoichiometry:

$$2\ PhSCOCl + 3\ Me_2SO \rightarrow PhSSPh + Me_2S + MeSCH_2Cl + Me_2SO{:}HCl + 2\ CO_2$$

p-Chlorophenyl and *tert*-butyl chlorothiolformate appeared to react in a similar manner. The 1:1 hydrogen chloride adduct $Me_2SO{:}HCl$ was characterized by elemental analysis and proton and carbon nmr. A cryoscopic molecular weight determination of the adduct $Me_2SO{:}HOCH(CF_3)_2$ showed it to be monomeric at low concentrations but associated at higher concentrations, suggesting a monomer–dimer equilibrium. The 1:2 adduct $Me_2SO{:}2HF$ is formed by the addition of anhydrous HF to dimethyl sulfoxide.

ALAN QUEEN, ALBERTA E. LEMIRE, ALEXANDER F. JANZEN et MICHAEL N. PADDON-ROW. Can. J. Chem. **56**, 2884 (1978).

Le diméthyl sulfoxyde réagit avec le chlorothiolformiate de phényle selon la stoëchiométrie:

$$2PhSCOCl + 3Me_2SO \rightarrow PhSSPh + Me_2S + MeSCH_2Cl + Me_2SO{:}HCl + 2CO_2$$

Le chlorothiolformiate de *p*-chlorophényle et de *tert*-butyle paraissent réagir de manière analogue. On a caractérisé par l'analyse chimique et par rmn du ^1H et ^{13}C le composé d'addition 1:1 de formule $Me_2SO{:}HCl$. La détermination cryoscopique de la masse moléculaire du composé d'addition $Me_2SO{:}HOCH(CF_3)_2$ indique qu'il se forme une espèce monomère aux faibles concentrations, mais qu'une association se produit aux concentrations supérieures, ce qui laisse supposer l'existence d'un équilibre monomère–dimère. On obtient un composé d'addition 1:2 de formule $Me_2SO{:}2HF$ lors de l'addition de HF anhydre au diméthyl sulfoxyde.

[Traduit par le journal]

Introduction

Sulfonium salts (**1**; Y = O, X = Cl) can be obtained by reacting dimethyl sulfoxide (DMSO) with chloroformate esters (1), hence, it seemed reasonable that the corresponding sulfur analogues (**1**; Y = S, X = Cl) would be produced using DMSO and chlorothiolformate esters **2**. Instead, when these reactions were carried out in an inert solvent, the products were disulfide **3**, chloromethyl methyl sulfide **4**, the HCl adduct of DMSO **5**, dimethyl sulfide, and carbon dioxide. This paper describes the reactions of DMSO with phenyl chlorothiolformate and is also concerned with the structure and reactivity of $Me_2SO{:}HCl$ and the corresponding $Me_2SO{:}HOCH(CF_3)_2$.

[1]Presented at the 8th International Symposium on Organic Sulfur Chemistry. Portoroz, Yugoslavia, June 18–23, 1978.

Results and Discussion

The overall equation for the reaction of phenyl chlorothiolformate with DMSO can be written as in [1]. The products, with the exception of $Me_2SO{:}HCl$

$$[1]\quad 2PhSCOCl + 3Me_2SO \rightarrow PhSSPh + Me_2S + MeSCH_2Cl + Me_2SO{:}HCl + 2CO_2$$

(*vide infra*), were identified by comparison with authentic samples. To determine the stoichiometry, various ratios of reactants were mixed and the products analyzed (Table 1). In support of [1], it was found that complete conversion of PhSCOCl only occurred when the ratio of DMSO to PhSCOCl exceeded 3:2. For these conditions, the formation of 1 mol of PhSSPh was accompanied by 1 mol of $Me_2SO{:}HCl$, within experimental error. When smaller amounts of DMSO were used, equal but smaller quantities of PhSSPh and $Me_2SO{:}HCl$ were obtained. Nuclear magnetic resonance integration of the reaction mixture showed clearly that the ratio of Me_2S to $MeSCH_2Cl$ was 1:1. The amount of liberated CO_2 was not measured but its presence was confirmed by ir spectroscopy.

Reaction [1] was carried out in CCl_4 because $Me_2SO{:}HCl$ precipitates in this solvent and further

TABLE 1. Reaction of phenyl chlorothiolformate with DMSO in CCl_4

PhSCOCl (mmol)	DMSO (mmol)	Unreacted PhSCOCl (mmol)	PhSSPh (mmol)	Me_2SO:HCl (mmol)
20	10	9	3.0	2.6
20	20	7	6.5	6.6
20	30	0	9.4	9.6
20	40	0	9.8	9.7

reaction or decomposition of Me_2SO:HCl is prevented.

Reaction [1] is obviously a multistep process but its stoichiometry can be accounted for by [2–5].

[2] $2PhS{-}C(=O){-}Cl + 2Me_2S{=}O \longrightarrow 2\left[\begin{array}{l} Me \\ Me \end{array}\!\!>\!S{-}O{-}C(=O){-}SPh \;\; Cl\right] \longrightarrow 2Me_2S + 2CO_2 + 2ClSPh$

[3] $Me_2S + 2Cl{-}SPh \longrightarrow [Me_2SCl_2] + PhSSPh$

[4] $Me_2S{-}CH_2{-}Cl \xrightarrow[-HCl]{\text{four-center}} [Me_2S{=}CH_2] \xrightarrow{\text{three-center Cl transfer}} MeSCH_2Cl$

[5] $HCl + Me_2SO \longrightarrow Me_2SO{:}HCl$

Equation [2] is analogous to the reaction of DMSO with chloroformate esters (1), whereas [4] is identical to the postulated conversion of Me_2SF_2 to $MeSCH_2F$ (2). In a separate experiment it was found that reaction of Me_2S with PhSCl gave PhSSPh and $MeSCH_2Cl$ in a 1:1 ratio, as required by [3]. Equation [5] was also confirmed in a separate experiment, as described below.

The reactions of DMSO with *p*-chlorophenyl and *tert*-butyl chlorothiolformate were briefly investigated and found to give di-*p*-chlorophenyl disulfide (85%) and di-*tert*-butyl disulfide (87%).

With thiophosgene, Me_2SO:HCl and $MeSCH_2Cl$ were isolated in 63 and 40% yield, respectively, while COS was identified by mass spectrometry suggesting the stoichiometry of [6]. Presumably, the intermediate Me_2SCl_2 reacts further to give $MeSCH_2Cl$ and Me_2SO:HCl, as in [4] and [5].

[6] $Cl_2C{=}S + 2Me_2SO \rightarrow MeSCH_2Cl + Me_2SO{:}HCl + COS$

Me_2SO:HCl, Me_2SO:2HF, and Me_2SO:HOCH$(CF_3)_2$

Previous attempts to characterize Me_2SO:HCl have been only partially successful,[2] although other adducts such as Ar_2SO:HCl (5) or $Me_2SO{:}HNO_3$ (6) are well known. We find that Me_2SO:HCl may be prepared most conveniently by adding anhydrous HCl to DMSO in CCl_4. Under these conditions, Me_2SO:HCl precipitates as a white solid which may be dried under vacuum, mp 56–57°C, 80% yield, and which gave satisfactory elemental analysis.

The addition of anhydrous HF to DMSO gave an oily 1:2 adduct Me_2SO:2HF, identified by NaOH titration (equiv. wt. calcd.: 118.1; found: 117) and ^{19}F and ^1H nmr. On contact with glass, the adduct gave a white solid tentatively assumed to be $Me_2SOH^+SiF_5^-$.

Various structures (**6–10**) have been proposed for $R_2SO{:}HA$ and $R_2SO{:}2HA$ adducts (HA = HCl, HNO_3, H_2SO_4, H_2O, HOR, HSR), mainly on the basis of reactivity, and cryoscopic and spectroscopic studies (5, 7, 8). To gain further structural information about DMSO adducts, we carried out a cryoscopic molecular weight determination of $Me_2SO{:}HOCH(CF_3)_2$. This adduct is soluble and stable in benzene, whereas Me_2SO:2HF is too reactive in glass apparatus and Me_2SO:HCl is insoluble in benzene, cyclohexane and CCl_4 but decomposes in CH_2Cl_2. As seen in Fig. 1, $Me_2SO{:}HOCH(CF_3)_2$ is

$R_2\overset{+}{S}OH\ A^-$ (**6**) $\quad R{-}\overset{O}{\overset{\|}{S}}{}^{+}{-}R\ A^-$ (**7**) $\quad R{-}S{-}R$ (OH, A) (**8**)

$R_2S{=}O\cdots HOH$ (**9**) $\quad R_2S{=}O\cdots HOR$, $\cdots HOR$ (**10**)

[2]The Me_2SO:HCl adduct has been described as a "semi-crystalline mush" (3). In another report (4) the adduct was not dried nor its melting point determined and the chemical analysis was slightly low (HCl calcd.: 31.9%; found: 30.2%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

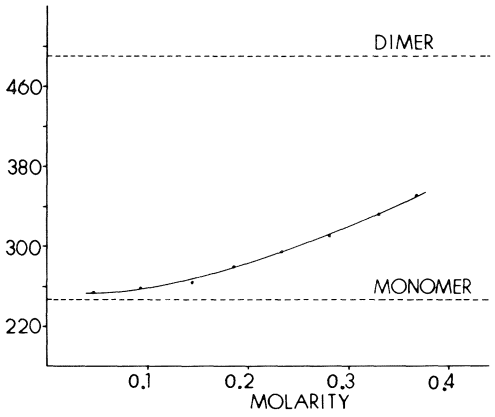

FIG. 1. Cryoscopic molecular weight determination of $Me_2SO{:}HOCH(CF_3)_2$ in benzene as a function of concentration.

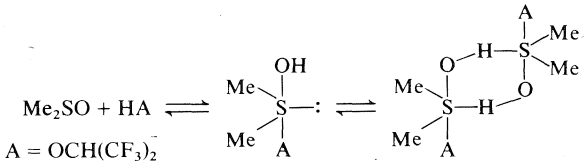
essentially monomeric in benzene at low concentration, $\sim 0.2\ M$, but the apparent molecular weight increases at higher concentration suggesting a monomer–dimer equilibrium, perhaps involving the structures depicted in [7].



The ^1H nmr spectrum of $Me_2SO{:}HOCH(CF_3)_2$ shows only a single averaged methyl peak at 35°C and the ^{19}F nmr spectrum shows only a single averaged CF_3 group, therefore, the equilibrium of [7] must be rapid on the nmr time scale. Similarly, the ^1H and ^{13}C nmr spectra of $Me_2SO{:}HCl$ show only single methyl peaks, consistent with rapid exchange. DMSO was added to $Me_2SO{:}HCl$ but only a single averaged methyl peak was observed down to −60°C. A comparison of the ^1H and ^{13}C nmr data for $Me_2SO{:}HCl$ and DMSO is shown in Table 2.

DMSO was recovered from $Me_2SO{:}HCl$ by addition of a suitable base, such as pyridine *N*-oxide. Addition of anhydrous HCl to $Me_2SO{:}HCl$ in CH_2Cl_2 produced $MeSCH_2Cl$, presumably via the intermediate Me_2SCl_2, (eq. [4]).

DMSO and Proton Exchange

The addition of DMSO is known to suppress rapid proton exchange in alcohol solutions (9, 10) and this effect has been ascribed to the strong hydrogen bonding of DMSO with hydroxyl groups (ref. 8, p. 35). Another explanation is reasonable, namely, that DMSO forms adducts with trace impurities which are known to catalyze proton exchange, such as H_2O, HF, or HCl (the latter from chlorinated solvents (9)). Removal of these impurities may then suppress catalyzed proton exchange in alcohol solutions. In an analogous situation, rapid fluorine exchange can be suppressed by chemically removing trace impurities such as HF and H_2O (11).

Experimental

General

Volatile materials were handled in a conventional glass vacuum line. Starting compounds were obtained commercially or prepared by literature methods: C_6H_5SCOCl (K & K), *p*-ClC_6H_4SCOCl (K & K), CH_3SSCH_3 (Eastman), $(CH_3)_2SO$ (Fisher), $(CF_3)_2CHOH$ (Aldrich), C_6H_5SH (Aldrich), CH_3SCH_3, $C_6H_5SSC_6H_5$ (12), $(CH_3)_3CSSC(CH_3)_3$ (13), C_6H_5SCl (14), and $(CH_3)_2SO{:}HOCH(CF_3)_2$ (15).

Proton and fluorine nmr spectra were obtained on a Varian A-56/60A spectrometer and carbon nmr spectra on a Varian CFT-20 spectrometer using TMS and $CFCl_3$ as internal references. Mass spectra were obtained on Perkin–Elmer RMU-6D and Finnigan 1015 mass spectrometers. Elemental analyses were performed by Analytische Laboratorien, Engelskirchen, Germany.

Reaction of Phenyl Chlorothiolformate with DMSO

To determine the stoichiometry of the reaction of PhSCOCl with DMSO, various ratios of reactants were mixed and the products analyzed (Table 1). Typically, DMSO in CCl_4 was slowly added to PhSCOCl in CCl_4 at 0°C and the mixture stirred at room temperature for 30 min (solution A). Several methods were then used to isolate and identify the products. Analysis for PhSSPh was carried out by neutralizing solution A with aqueous $NaHCO_3$ followed by removing solvent and volatile products under vacuum. The resulting yellow solid contained PhSSPh which was purified by column chromatography (silica gel), weighed, and identified by mp, ir, nmr, and ms.

To estimate the amount of unreacted PhSCOCl, the yellow solid above was redissolved in CCl_4 and excess diisopropylamine was added to convert PhSCOCl to the less reactive amide derivative *N*-diisopropyl-*S*-phenylthiolcarbamate $(iC_3H_7)_2NCOSC_6H_5$. The ratio of thiolcarbamate to disulfide could be estimated accurately by nmr integration. This procedure was tested by treating known amounts of PhSSPh and PhSCOCl in CCl_4 with excess diisopropylamine. Attempts to separate the disulfide and thiolcarbamate by column chromatography introduced errors of 5–10%. The thiolcarbamate was recrystallized from methanol, mp 93°C. *Anal.* calcd. for $C_{13}H_{19}NSO$: C 65.77, H 8.08, N 5.71, S 13.53; found: C 65.99, H 8.07, N 5.71, S 13.53.

Volatile products were removed under vacuum from solution A and separated by trap-to-trap distillation. The liquid nitrogen trap contained CO_2 which was identified by ir. The acetone – Dry Ice bath contained MeSMe which was redistilled, weighed, and identified by its bp, ir, nmr, and ms.

The ratio of MeSMe to $MeSCH_2Cl$ was conveniently estimated by nmr integration of solution A. The molar ratio was found to be 1:1 irrespective of the ratio of starting compounds PhSCOCl and DMSO.

$Me_2SO{:}HCl$ was found to be insoluble in CCl_4, therefore its yield was estimated by filtering solution A, followed by weighing or titrating with standardized NaOH.

Reaction of p*-Chlorophenyl Thiolchloroformate with DMSO*

DMSO (0.02 mol) in CCl_4 (5 ml) was added to *p*-ClC_6H_4SCOCl (0.01 mol) in CCl_4 (5 ml) at 0°C and the mixture stirred

[e]Reference 20.

at room temperature for 30 min. Neutralization with aqueous $NaHCO_3$ followed by removal of solvent and volatile material left a solid (p-$ClC_6H_4S)_2$, mp 72°C, 85% yield, which was purified by column chromatography (silica gel).

Reaction of tert-*Butyl Thiolchloroformate with DMSO*

DMSO (0.05 mol) in CH_2Cl_2 (2 ml) was added to $Me_3CSCOCl$ (0.03 mol) in CH_2Cl_2 (3 ml) at 0°C and the mixture stirred at room temperature for 3 h. The solution was neutralized with aqueous $NaHCO_3$ and the products extracted with CH_2Cl_2 and dried (Na_2SO_4). Distillation gave $(Me_3CS)_2$ 130°C/150 Torr, 87%, identified by comparison of its ir, nmr, and refractive index with those of an authentic sample.

Reaction of Benzenesulfenyl Chloride with Dimethyl Sulfide

Me_2S (0.19 g, 3.1 mmol) and C_6H_5SCl (0.72 g, 5.0 mmol) in CCl_4 (10 ml) were stirred at room temperature for 12 h. The nmr spectrum indicated that CH_3SCH_2Cl and PhSSPh were produced in a 1:1 ratio. Removal of volatile material left behind a solid identified as PhSSPh on the basis of its nmr and mass spectrum.

Synthesis of Me_2SO:HCl

From HCl and DMSO

Anhydrous HCl was bubbled through a solution of dry DMSO (3.9 g, 0.05 mol) in CCl_4 (20 ml) at 0°C for 3 min. The resultant white precipitate was filtered under vacuum, washed with CCl_4, dried under vacuum for 12 h, and identified as Me_2SO:HCl, mp 56–57°C, 78% yield. *Anal.* calcd. for C_2H_7ClOS: C 20.96, H 6.16; found: C 20.91, H 6.28. Titration with standardized NaOH gave equivalent weight of 112.0 (calcd. 114.6) and potentiometric titration with $AgNO_3$ solution gave chloride 30.5% (calcd. 30.94).

Nuclear magnetic resonance examination of the CCl_4 fraction in the above reaction showed only unreacted DMSO. Me_2SO:HCl is soluble in CH_2Cl_2 but solutions decompose slowly at room temperature giving Me_2S as one of the major decomposition products.

From DMSO and Thiophosgene

Addition of DMSO (10 mmol) to Cl_2CS (5 mmol) in CCl_4 (10 ml) at 0°C gave a precipitate identified as Me_2SO:HCl, 63% yield. The filtrate contained $MeSCH_2Cl$ (2.1 mmol) and a small amount of Me_2S (0.6 mmol). The gas given off during the reaction was identified as COS by mass spectrometry. A uv spectrum of the filtrate showed that all Cl_2CS was consumed.

DMSO and Hexafluoroisopropanol

Me_2SO:$HOCH(CF_3)_2$ was prepared by mixing equimolar amounts of DMSO and $HOCH(CF_3)_2$ (15). Heat was evolved on mixing. The ir spectrum (neat) showed a broad absorption centred at 3100 cm^{-1}, ^1H nmr (neat) δ: 2.58 (s, CH_3), 4.55 (sept, CH), 7.60 (s, OH). The mass spectrum of Me_2SO:$HOCH(CF_3)_2$ was essentially that of DMSO and $HOCH(CF_3)_2$.

The apparent molecular weight of Me_2SO:$HOCH(CF_3)_2$ was determined cryoscopically in benzene over a concentration range 0–0.4 M and the results compared with naphthalene under identical conditions. The temperature of the system was measured with the aid of a thermistor bridge and a recorder. A plot of solute (grams) vs. temperature (arbitrary units) for Me_2SO:$HOCH(CF_3)_2$ and naphthalene was prepared and the apparent molecular weight of Me_2SO:$HOCH(CF_3)_2$ was obtained by comparing the ratio of solute (g) at various temperatures. The results are shown in Fig. 1.

DMSO and HF

Anhydrous HF was bubbled through a solution of DMSO (1.8 g, 0.02 mol) in CCl_4 (10 ml) in a Teflon beaker for 3 min at 0°C to give an oily top layer. The bottom layer was withdrawn with a syringe and the oil washed twice with 5 ml of CCl_4. Volatile material was removed from the oil at reduced pressure (10 cm Hg) and titration of the oil with 0.1 M NaOH, using phenolphthalein as an indicator, gave an equivalent weight of 117 (calcd. for $(CH_3)_2SO$:2HF:118.1). The ^{19}F nmr spectrum in CH_2Cl_2 gave a singlet at 176 ppm, close to that of an HF solution (16), while the ^1H nmr spectrum gave singlets at 8.03 and 2.67 ppm.

If the oil was allowed to come into contact with glass apparatus, a white solid, mp 86–88°C, recrystallized from CH_3CN, was slowly formed. Its ^{19}F nmr spectrum showed a slightly broadened singlet at 142 ppm, close to that of $(nC_3H_7)_4N^+SiF_5^-$ (16), while the ^1H nmr spectrum showed singlets at 8.78 and 2.87 ppm, of relative intensity 1:6.

Synthesis and stereochemistry of 2-pyrone derivatives related to some fungal metabolites

SUZANNE LESAGE AND ARTHUR S. PERLIN

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7

Received June 7, 1978

SUZANNE LESAGE and ARTHUR S. PERLIN. Can. J. Chem. **56**, 2889 (1978).

Some stereochemistry of 'asperlin' (**1**) and related fungal metabolites containing a 5,6-dihydro-2-pyrone moiety, has been deduced through correlation of nmr and ord parameters with those of reference compounds derived from carbohydrates of known stereochemistry. The reference compounds are 4,6-di-*O*-acetyl-2,3-dideoxy-D-*threo*- and -D-*erythro*-hex-2-enono-1,5-lactones obtained by modification of D-galactal and D-glucal, respectively, and the D-enantiomer of **1**, synthesized in a multistep sequence from D-galactose. It is shown that the 5,6-substituents of the pyrone ring of **1** have the L-*threo* configuration and also that the exocyclic epoxypropyl moiety is *trans*.

SUZANNE LESAGE et ARTHUR S. PERLIN. Can. J. Chem. **56**, 2889 (1978).

On a recueilli des renseignements sur la stéréochimie de l'asperlin' (**1**) et de métabolites fongiques apparentés contenant l'ensemble dihydro-5,6 pyrone-2, en établissant des corrélations entre les paramètres tirés de la rmn et de la dro, d'une part, et ceux de composés de référence dérivés de carbohydrates de stéréochimie connue, d'autre part. Les composés de référence sont le di-*O*-acétyl-4,6 didésoxy-2,3 D-*thréo*- et D-*érythro*-hexène-2 lactones-1,5 obtenues par modification du D-galactal et du D-glucal, respectivement, ainsi que l'énantiomère D de **1**, synthétisé par une séquence à plusieurs étapes à partir du D-galactose. On montre que les substituants en position 5 et 6 du cycle pyrone de **1** possèdent la configuration L-*thréo* et que le groupe époxypropyle exocyclique est en position *trans*.

[Traduit par le journal]

Introduction

A large number of natural products contain α,β-unsaturated lactone structures (1). These include compounds of the coumarin series, macrolides, the steroid withaferin, and 2-pyrones of fungal origin. Among the latter group is 5-acetoxy-5,6-dihydro-6-(1,2-epoxypropyl)-2-pyrone (**1**) (2–4), produced by *Aspergillus nidulans* and termed 'asperlin,' which possesses antibiotic and antitumor activity. Asperlin and related metabolites bear a close structural similarity to α,β-unsaturated δ-lactones such as **2**, that are readily accessible from carbohydrates; e.g., **2** has been prepared by the oxidation of aldose **3** with methyl sulfoxide in the presence of pyridine – sulfur trioxide complex and triethylamine (5, 6) or from the δ-lactone corresponding to **3** by a base-catalyzed α,β-elimination (7). Because the absolute configurations of chiral centres in such carbohydrate derivatives are known, it should be feasible to draw stereochemical correlations between the appropriate carbohydrates and the lactones of fungal origin. This is demonstrated, in fact, in the current report, which also furnishes information about the stereochemistry of the epoxypropyl side chain of asperlin (**1**).

Results and Discussion

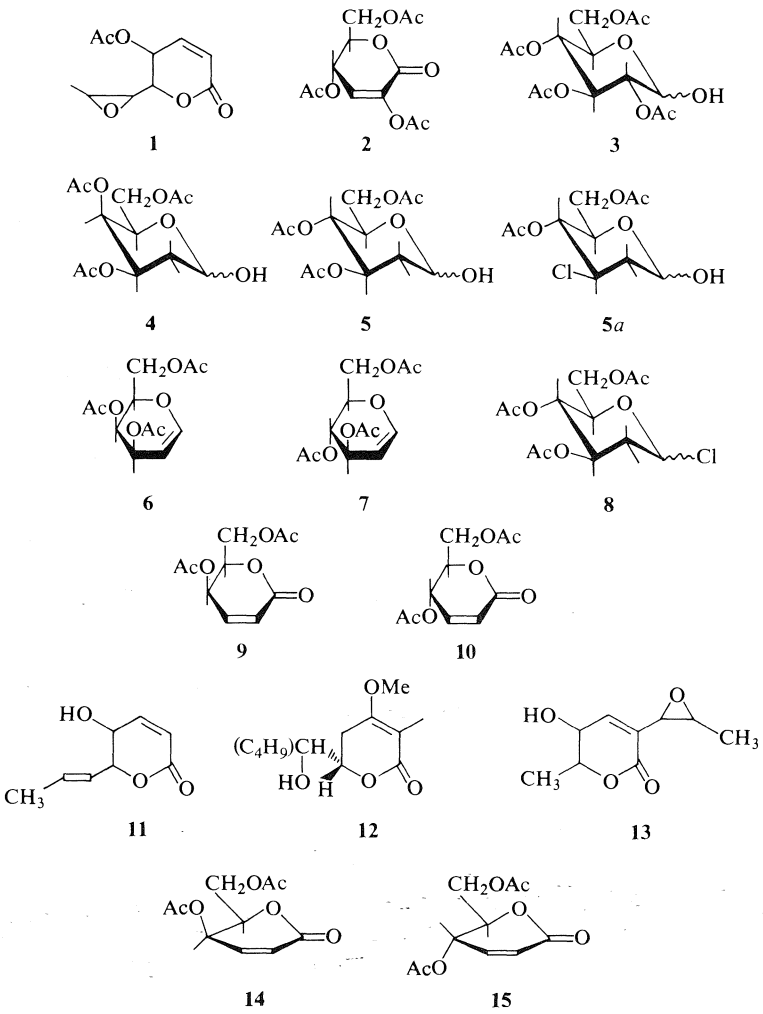
Stereochemistry of the 2-Pyrone ring of 1. Synthesis of Model Compounds

The lactone ring of **2** differs from that of **1** in having an acetoxyl group at C-2.[1] Presumably, in synthesizing compounds related to asperlin this difference could be removed simply by starting with a 2-deoxy analog of **3**. There was evidence (4) to suggest that an appropriate 2-deoxy sugar should possess the *threo* configuration at C-4, C-5 (rather than the *erythro*, as in **2** and **3**), because $J_{H\text{-}4,H\text{-}5}$ of **1** is small (3.0 Hz). Nevertheless, since this coupling would be determined by the conformation of the lactone ring, an *erythro* isomer also might exhibit a small H-4,H-5 coupling if its 4,5-substituents were quasi-axial (antiperiplanar); indeed, it is known (8) that allylic acetoxyl groups are stable in the axial orientation, due probably to σ*–π orbital overlap (9). Consequently, to circumvent such ambiguity, syntheses in both the *threo* and *erythro* series have been carried out. This has involved application of the oxidation–elimination sequence (5, 6) mentioned above to 3,4,6-tri-*O*-acetyl-2-deoxy-D-*lyxo*-(**4**)- and -D-*arabino*-(**5**)-hexopyranose.

In principle, these latter compounds should be accessible directly by hydration of the corresponding glycal triacetates (**6** and **7**), by analogy with the well-known route to 2-deoxy sugars (10, 11). However, this has proven not to be a practical method for

[1]For consistency in numbering, **1** is regarded below as a lactone related to **2** and analogous compounds. Accordingly, its carbonyl carbon is position-1 rather than, as in the pyrone system, position **2**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



preparation of **4** and **5** because it is accompanied by extensive elimination and rearrangement (12–16). Alternatively, a two-step sequence of reactions was used. Glycals **6** and **7** were each treated with hydrogen chloride in toluene (17) to afford glycosyl chlorides (e.g., **8**), which were converted into the required aldoses (**4** and **5**) with aqueous acetone in the presence of silver carbonate. Product **5** showed ^{1}H nmr spectral properties similar to those of a preparation of **5** from 1,3,4,6-tetra-*O*-acetyl-2-deoxy-D-*arabino*-hexopyranose (18) and also to one obtained via the addition of hydrogen bromide to **7** (19). A second product isolated in this latter reaction appeared (19) to be the allylic hydrobromination product and evidence was obtained that the corresponding chloro derivative (**5***a*) was formed in the present instance.

Compounds **4**, **5**, and **5***a* were then each subjected to oxidation with methyl sulfoxide and pyridine–sulfur trioxide complex in the presence of triethylamine. Two different α,β-unsaturated δ-lactones (**9** and **10**) were obtained, one (**10**) from the two *arabino* isomers (**5** and **5***a*), and the other (**9**) from the *lyxo* isomer (**4**); i.e., the formation of **10** involved the facile elimination of either a 3-acetoxy group (from **5**) or a 3-chloro substituent (from **5***a*). It is possible that **4**, which also was an oil, contained some of the 3-chloro isomer (corresponding to **5***a*), but the material was oxidized without checking this possibility because the same lactone (**9**) as from **4** was to be anticipated, as in the *arabino* series.

A structural resemblance between **9** and **10** and the unsaturated lactone structure of asperlin (**1**) is shown by broad similarities in the ^{1}H and ^{13}C nmr data (Table 1) for the three compounds, as well as their characteristic infrared absorption bands at 1700 and 1645 cm^{-1}. However, there is a much closer correspondence between the spectral properties of asperlin and lactone **9**: as the data of Table 1 imply, signals H-2, -3, and -4 of **1** and **9** are virtually super-

[b]^{13}C assignments from ref. 5.

imposable. Therefore, the lactone ring of asperlin must be configurationally related to **9**, rather than **10**.

Associated with the chiral centers at C-4 and C-5 of **9** is an optical rotation of $[\alpha]_D$ −199° and an ord spectrum exhibiting a negative cotton effect ($\phi = -7.3 \times 10^3$ at 280 nm). By contrast, asperlin exhibits $[\alpha]_D$ 345° and a positive cotton effect ($\phi = +9.2 \times 10^3$ at 280 nm) (4). Hence, since the configuration of **9** is D-*threo*, that of asperlin must be L-*threo*.[2]

A comparison of these ord data with those for several other metabolites should permit the absolute stereochemistry of the latter compounds to be defined as well. Consideration of the ring geometry of an α,β-unsaturated δ-lactone (20) by analogy with the 'octant rule' for cyclohexanones, as in Fig. 1, suggests that the pattern of substitution at C-5 should largely govern the shape of ord curves observed. According to Fig. 2, the exocyclic C-5 side chain of asperlin is located in the upper left quadrant. Analogously, 5-hydroxy-6-(propenyl)-5,6-dihydro-2-pyrone (**11**), which also exhibits a positive Cotton effect (21), should be configurationally related to asperlin. In fact, the latter has been obtained (21) by *O*-acetylation and epoxidation of **11**. By contrast, in

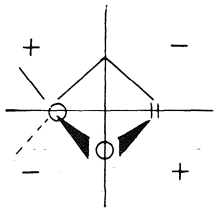

FIG. 1. Quadrant representation for an α,β-unsaturated δ-lactone (5,6-dihydro-2-pyrone), according to Snatzke (20).

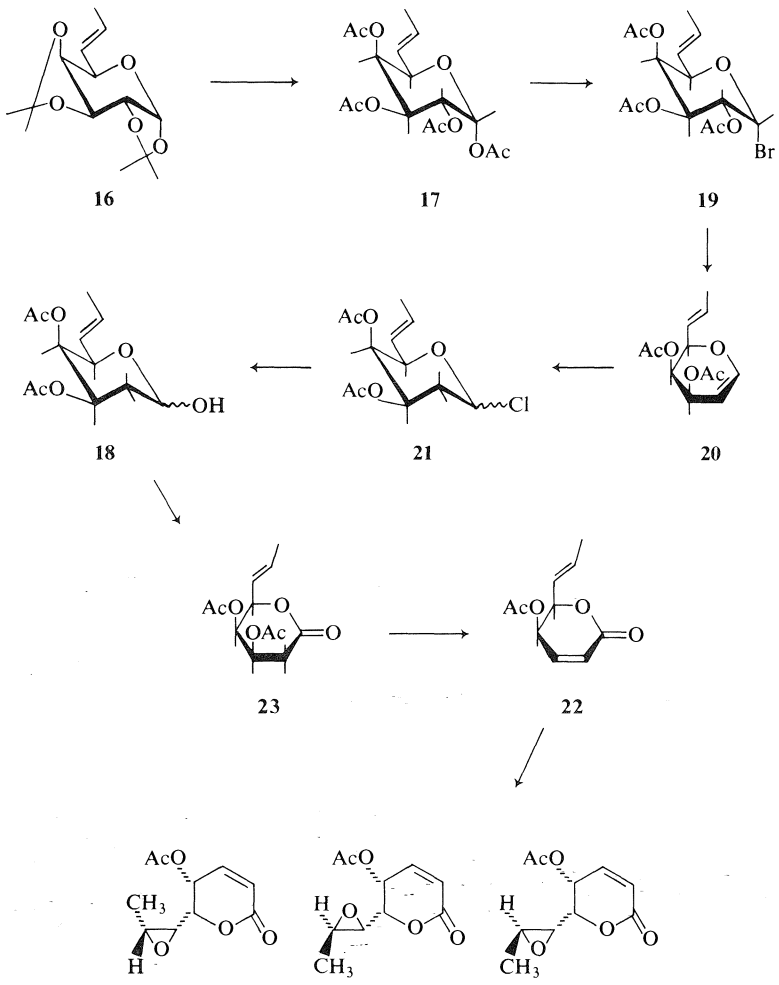
(−)-pestalotin (**12**) (22, 23) and 3-(1,2-epoxypropyl)-5,6-dihydro-5-hydroxy-6-methyl-2-pyrone (**13**) (24, 25), each of which shows a negative Cotton effect, the ring substituent at C-5 would be depicted as in the lower left quadrant, as for the CH_2OAc substituent of lactone **9**.

Some information also was obtained about the conformations of asperlin and synthetic lactones **9** and **10**. Long-range coupling (^4J) is observed between H-2 and H-4 of **10**, whereas neither **9** nor asperlin exhibits this long-range effect (Table 1). Since coupling of this type involving an allylic proton varies from 0 to 3 Hz as the dihedral angle (with H-2) varies from 0 to 90° (26), it appears that, on the average, H-4 of **10** is oriented out of plane with respect to the double bond. By contrast, **9** and asperlin favor a conformation in which the C-4, H-4 bond approaches coplanarity with the olefinic bond. The 4-acetoxyl group of **1** or **9** would then be in a *trans*-diaxial relationship with respect to H-5, and that of

[2]According to the *R* and *S* convention, lactone **9** is D-(−)-4*R*,5*R*, whereas asperlin must be designated as L-(+)-4*S*,5*R*. This seeming contradiction for the configuration of C-5 stems from the fact that in asperlin, priority must be given to the epoxypropyl side chain over the atoms of the ring, whereas in **9** the 6-CH_2OAc group has the low priority.



10 would be in a *gauche* relationship, as in **14** and **15**. Turning to the interrelated coupling between H-4 and H-3, it is seen (Table 1) that $J_{3,4}$ for **10** is 3.0 Hz, whereas it is 5.5–5.8 Hz for **1** and **9**. According to a geometric relationship deduced (27) for vicinal allylic coupling in simple olefins, these J values correspond to dihedral angles of ~70 and ~25°, respectively. Although the molecules under consideration here also contain a carbonyl group in conjugation and nearby carbon–oxygen bonds, which might affect the magnitude of J, the conformations depicted in **14** and **15** are compatible with the relatively smaller H-3,H-4 dihedral angle predicted for asperlin and lactone **9**, than for **10**. Hence, the mirror image of **14** should closely represent the lactone ring conformation of asperlin.

Synthesis of the D-*Enantiomer of Asperlin*

Continuing with these structural analogies between asperlin (**1**) and carbohydrate model compounds, a synthesis has been effected of the D-enantiomer of asperlin. This has served not only to confirm the findings above as to the geometry of the lactone ring but also to provide information about the stereochemistry of the epoxypropyl side chain of asperlin.

A comparison of asperlin with a variety of *cis* and *trans* epoxides by ^{13}C nmr spectroscopy has suggested (28) that the epoxypropyl side chain of asperlin has a *trans* configuration. In view of this, the starting point for the synthesis was an eight-carbon sugar derivative having a *trans*-propenyl side chain and a D-*galacto* configuration, i.e., compound **16**. The latter was prepared from the previously known *cis* olefin (29) by photochemical isomerization, because attempts to synthesize **16** directly were unsuccessful. However, about 25% of the *cis* isomer remained unchanged and was not separated out. Subsequent steps were carried out, therefore, with the isomerization mixture. This proved to be feasible because the major products derived from **16** generally

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

were identifiable by nmr spectroscopy without serious interference from their minor *cis* isomers. In the following discussion reference is made, for simplicity, to reactions in the *trans* series, although it is clear that each step was paralleled on a smaller scale in the *cis* series as well.

Acetolysis of **16** with acetic anhydride and boron trifluoride etherate at 0°C (30) for 0.5 h yielded 1,2,3,4-tetra-*O*-acetyl-6,7,8-trideoxy-α-D-*galacto*-oct-6-*trans*-enopyranose (**17**); under these conditions the olefin was essentially unaffected.[3] By analogy with reactions described above, the next step required synthesis of an appropriate 2-deoxyaldose derivative (**18**). Accordingly, compound **17** was treated with hydrogen bromide at 30°C for 1 h to give a glycosyl halide (**19**) which, on reduction with zinc, afforded the glycal (**20**); the 2-deoxyaldose (**18**) was then obtained via the hydrogen chloride adduct (**21**) by reaction of **20** with hydrogen chloride for 10 min at 0°C, followed by hydrolysis in the presence of silver carbonate.

Formation of the α,β-unsaturated lactone (**22**) from **18** was then effected. Unexpectedly, however, the combined oxidation–elimination reaction that had so readily furnished **9** and **10** from **4** and **5**, proved to be very sluggish when applied to **18**. By contrast, oxidation proceeded smoothly when aldose **18** was treated with pyridinium chlorochromate in methylene chloride (31) to give the aldonolactone (**23**) and α,β-elimination to yield **22** was then induced by the introduction of triethylamine.

The reaction of **22** with *m*-chloroperbenzoic acid gave a mixture of diastereomeric epoxides (**24**, **25**). According to the ^1H and ^{13}C nmr spectra of the reaction products, three species were formed on epoxidation, including a minor one from the *cis* olefin corresponding to **22**. Judging from the relative intensities of three signals attributable to H-5, which are particularly well resolved (Fig. 2A), the *trans* isomers (**24**) were present in a ratio of 3:2, whereas only one *cis* epoxide (**25**) had been formed in appreciable yield from the *cis* olefin.

It is evident from the accompanying spectrum of authentic asperlin (Fig. 2B) that the major synthetic product corresponds to the natural material; the spectral identity of the two was confirmed by adding a small proportion of asperlin to the solution of the mixed products, whereupon the relative intensities of the signals ascribed to **24***a* increased. Furthermore, the major group of signals in the ^{13}C spectrum of the mixture corresponds to the ^{13}C spectrum of asperlin. Hence, **24** is the D-enantiomer of asperlin.

[3]These, and other reaction conditions described below, were selected following preliminary model experiments, so as to minimize addition to the exocyclic olefin.

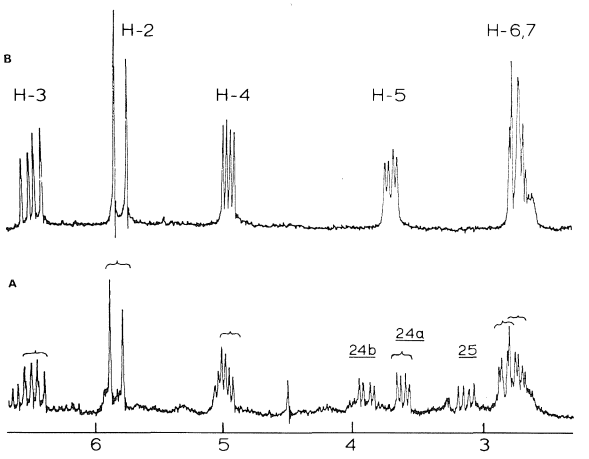

FIG. 2. ^1H nmr spectra at 100 MHz of products (**24***a*,*b* and **25**) obtained from synthesis of the D-enantiomer of asperlin (*A*) and of authentic asperlin (**1**) (*B*). Solvent, C_6D_6. (Upfield signals due to the acetoxyl and 8-CH_3 protons are not shown.) *The introduction of a small portion of authentic asperlin, promoted a commensurate increase in the relative intensities of the bracketed signals, i.e., those of the major product* (designated **24***a*; see Table 2).

TABLE 2. ^{13}C nuclear magnetic resonance data for **24***a*,*b* and asperlin (**1**)[a]

	Chemical shift (δ)		
Carbon	**1**	**24***a*[b]	**24***b*
C-1	161.5	161.3	160.8
C-2	124.7	124.9	124.9
C-3	140.6	140.5	140.8
C-4	62.1	62.1	62.4
C-5	78.3	78.9	—
C-6	55.1	55.0	52.9
C-7	53.7	54.5	52.5
C-8	16.9	17.0	17.0
CH_3	20.4	20.5	20.5

[a]At 22.6 MHz; solvent, $CDCl_3$; the signal assignments given for **24***a* and **24***b* are based on general considerations of ^{13}C chemical shifts, and have not been verified.
[b]Group of strongest signals. Designated by analogy with the strongest signals in Fig. 2*A*.

These results demonstrate that the configuration of the epoxypropyl group of asperlin is *trans*, although which of the two possible diastereomers of **24** it represents, remains to be determined. Moreover, since the starting compound (**16**) has a *galacto* configuration, its conversion into **24** confirms the *threo* configuration at C-4 and C-5 of asperlin. It is worth noting also that the ord spectrum of the mixture of **24** and **25** exhibited a negative Cotton effect ($\phi = -2.8 \times 10^3$ at 280 nm) which, being opposite in sign to that of asperlin, as noted above, emphasizes the fact that the latter contains the L-*threo* configuration.

Experimental

General Methods

Evaporations were carried out under reduced pressure at or below 60°C (bath temperature). Melting points were determined on a Fisher Johns apparatus. Infrared spectra were measured as liquid films on silver chloride plates, with a Unicam SP200 spectrophotometer. Optical rotary dispersion curves were obtained with a JASCO ORD-UV-5 spectrophotometer. Proton magnetic resonance spectra were determined with a Varian HA-100 spectrometer and carbon-13 magnetic resonance spectra with a Bruker WH-90 spectrometer; in each instance, tetramethylsilane was used as an internal standard. Microanalyses were performed by Dr. C. Daesslé (Organic Microanalyst, Montreal) or by Schwarzkopf Microanalytical Laboratory (New York). Chromatographic columns were packed with silica gel, 0.02–0.05 mm particle size (Macherey Nagel and Co., Germany), or with silica gel 60, 0.60–0.20 particle size (E. Merck, Germany). For thin-layer chromatography (tlc) silica gel G. (Macherey Nagel Co., Germany) was used as adsorbent. The following solvent systems were used: (*A*) CH_2Cl_2–acetone (9:1); (*B*) CH_2Cl_2–acetone (3:1); (*C*) CH_2Cl_2–acetone (1:1). Compounds were detected by spraying with 25% aqueous sulfuric acid and heating at 110°C, or where applicable, by irradiation with uv light.

3,4,6-Tri-O-*acetyl-2-deoxy*-D-arabino-*hexopyranose* (***5***) *and 4,6-Di*-O-*acetyl-3-chloro-2,3-dideoxy*-D-arabino-*hexopyranose* (***5a***)

3,4,6-Tri-*O*-acetyl-1,5-anhydro-1,2-dideoxy-D-*arabino*-hex-1-enitol (**7**) (960 mg) was dissolved in toluene (50 ml) and anhydrous HCl was bubbled in at 0°C. After 1 h, more toluene (100 ml) was added and the solution was neutralized by washing with saturated sodium bicarbonate, followed with water. The toluene was evaporated off and replaced with acetone (50 ml), and the solution was stirred with silver carbonate at room temperature for several hours, after which the suspension was filtered through Celite and the filtrate concentrated. The resulting oil was chromatographed on a column using chloroform as the eluant. Two main fractions were recovered: **5***a* as a syrup (0.20 g) and compound **5** (0.29 g) which was recrystallized from ethyl acetate – petroleum ether, mp 94–97°C (lit. (19) mp 93–95°C); ^{1}Hmr data for **5** δ: 2.0–2.1 (3 × 3H, s, CH_3CO—); 2.0–2.2 (2-H, m, H-2,2′); 4–4.2 (3H, m, H-3,6,6′); 4.8–5.4 (3H, m, H-5,1,4); for **5***a* δ: 2.0–2.1 (2 × 3H, s, CH_3CO—); 2.2–2.7 (2H, m, H-2,2′); 4.0–4.5 (3H, m, H-3,6,6′); 4.6–5.5 (3 overlapping 1H, m, H-1,4,5).

3,4,6-Tri-O-*acetyl-2-deoxy*-D-arabino-*hexopyranose* (***5***)

A saturated solution of HCl in toluene (20 ml) containing 1,3,4,6-tetra-*O*-acetyl-2-deoxy-D-*arabino*-hexopyranose (0.70 g) was stirred at 0°C for 1 h; the reaction was then complete (tlc solvent *A*). The treatment with water and silver carbonate and work-up, were as described above, but only **5** was obtained (0.50 g, 80%), mp 94–97°C.

4,6-Di-O-*acetyl-2,3-dideoxy*-D-erythro-*hex-2-enono-1,5-lactone* (***10***)

(*a*) The triacetate (**5**) (0.26 g) was added to a mixture of methyl sulfoxide (12 ml), triethylamine (1.5 ml), and pyridine – sulfur trioxide complex (0.94 g), the resulting homogeneous solution being stirred for 0.5 h. Cold $CHCl_3$ (100 ml) was added and the organic layer was washed successively with aqueous tartaric acid (100 ml), saturated sodium bicarbonate (100 ml), and water (2 × 100 ml), then it was dried over $MgSO_4$ and concentrated. The yellow oil (**10**) (0.19 g) obtained was distilled at 125–130°C (bath temperature/0.5 Torr); $[\alpha]_D^{25}$ +158° (*c* 5.7, $CHCl_3$); ^{1}Hmr and ^{13}Cmr spectroscopic data are given in Table 1; ir: 1700–1780 (C=O, acetyl and lactone), 1645 cm^{-1} (C=C). *Anal.* calcd. for $C_{10}H_{12}O_6$: C 52.6, H 5.3; found: C 52.4, H 5.9.

(*b*) The 3-chloro-analog of **5** (**5***a*) when subjected to oxidation with pyridine – sulfur trioxide as described above, gave the same lactone (**10**) as confirmed by tlc (solvent *A*) and ^{1}Hmr spectroscopy.

4,6-Di-O-*acetyl-2,3-dideoxy*-D-threo-*hex-2-enono-1,5-lactone* (***9***)

3,4,6-Tri-*O*-acetyl-1,5-anhydro-1,2-dideoxy-D-*lyxo*-hex-1-enitol (**6**) (0.98 g) was hydrochlorinated in toluene as described for the *arabino* isomer (**7**). Similarly, the product was treated with silver carbonate in aqueous acetone. The crude material recovered (presumably a mixture of 3,4,6-tri-*O*-acetyl-2-deoxy-D-*lyxo*-hexopyranose (**4**) and its 3-chloro-3-deoxy analog, according to ^{1}Hmr spectroscopy) was subjected to oxidation, as described above. Lactone **9** was obtained as a pale yellow oil (0.20 g) which was distilled (0.5 Torr, 125–130°C bath temperature); $[\alpha]_D^{25}$ −199° (*c* 5.6, $CHCl_3$); ord: negative Cotton effect (280 mm, $\Phi = 7.3 \times 10^3$); ^{1}Hmr data for **4** δ: 1.95, 2.03, 2.12 (3 × 3H, singlets, CH_3CO—); 2.01, 2.07 (2 × 3H, singlets, CH_3CO—, 3-chloro analog ~25%); 2.0–2.2 (2H, overlapping CH_3, H-2, H-2′); 2.3–2.8 (m, H-2,2′ of 3-chloro analog), 4.0–4.5 (3H, m, H-3,6,6′), 5.2–5.5 (3 × 1H overlapping m, H-1,4,5). *Anal.* calcd. for $C_{10}H_{12}O_6$: C 52.6, H 5.3; found: C 52.9, H 5.7.

Proton and carbon-13 nmr spectroscopic data for **9** are given in Table 1.

6,7,8-Trideoxy-1,2: *3,4-di*-O-*isopropylidene*-α-D-galacto-*oct-6*-trans-*enopyranose* (***16***)

A cyclohexane solution (300 ml) of the *cis* olefin (28, 29) (4.5 g) was irradiated in a water-cooled quartz cell with unfiltered uv light (450 W Hanovia Type of mercury arc lamp, Model 679A) under a stream of N_2 for four to five periods of 2 h. After each treatment polymeric material in suspension was filtered off and a portion of the filtrate (10 ml) was concentrated and monitored (^{1}Hmr) until no further change was observed. The final solution was concentrated to a yellow syrup, which was chromatographed (eluent, CH_2Cl_2) to yield a colourless syrup (4.0 g) containing a mixture (3:1, from ^{1}Hmr spectra) of the *trans* (**16**) and *cis* olefins. ^{1}H nmr data for **15** δ: 1.40 (6H, s, CH_3 isopropylidene); 1.54 (3H, s, CH_3 isopropylidene); 1.59 (3H, s, CH_3 isopropylidene); 1.80 (3H, d, H-8,8′,8″, J = 5 Hz); 4.1–4.4, 4.6–4.8 (4H, overlapping m); 5.60 (1H, d, H-1, J = 5 Hz); 5.68–5.90 (2H, m, H-6, H-7); ^{13}C nmr data for **15** δ: 17.8, (C-1); 24.3, 24.8, 25.9, 26.8 (CH_3-isopropylidene); 69.0 (C-5); 70.9, 73.2 (C-2,3,4); 96.5 (C-1); 108.2, 109.0 (C-isopropylidene); 126.8, (C-6); 129.7, (C-7).

1,2,3,4-Tetra-O-*acetyl-6,7,8-trideoxy*-α-D-*lyxo-oct-6*-trans-*enopyranose* (***17***)

The product of photolysis (olefin **16**) (5.0 g) was dissolved in acetic anhydride (20 ml) and the solution cooled at 0°C. Boron trifluoride – etherate (redistilled over sodium hydride) (10 ml) was added and the solution was stirred for 10 min at 0°C, after which it was poured onto a slurry of ice and NaOH (~5%). This was followed by extraction with ether (3 × 250 ml). The combined extracts were washed with saturated sodium bicarbonate, and water, dried over sodium sulfate, and the solvent was evaporated off. The residual brown syrup (8 g), on purification by column chromatography (eluent, CH_2Cl_2) gave a yellow oil (4.5 g), which was found by ^{1}Hmr to consist of **17**, accompanied by about 25% of the *cis* isomer; ^{1}Hmr data for **17** δ: 1.70 (3-H, dd, H-8,8′,8″, $J_{7,8} \simeq 7$ Hz, $J_{6,8} \simeq 1$ Hz); 1.97, 2.12 (2 × 6H, s, CH_3, acetoxyls); 4.0–5.5 (4H, poorly resolved m, H-2,3,4,5); 5.5–5.9 (2H, overlapped m, H-6,7); 6.36 (1H, d, H-1, $J_{1,2} \simeq 3$ Hz).

*1,5-Anhydro-3,4-di-*O*-acetyl-1,2,6,7,8-pentadeoxy-*D*-lyxo-oct-1,6-trans-dienitol (**20**)*

The oil obtained above (**17**) (4.5 g) was dissolved in acetic acid (15 ml), HBr (30% in acetic acid; 3.0 ml) was introduced and the solution was stirred at 0°C for 0.5 h. A previously-mixed slurry of Zn (4.5 g), sodium acetate (10 g), and cupric sulfate pentahydrate (0.5 g) in water (12 ml) was then added, and the suspension was stirred vigorously at 0°C for 2–3 h, after which it was filtered and the solid residue was rinsed with cold 50% aqueous acetic acid. The filtrate was extracted with methylene chloride (3 × 250 ml) and the organic layer was washed successively with saturated sodium bicarbonate and water, dried over sodium sulfate, and concentrated. A clear colourless syrup (3.2 g) obtained was found to consist of a mixture of several products (tlc, solvent A). Separation by column chromatography (eluent: CH_2Cl_2) afforded **20** as a colourless syrup (0.62 g). The slower moving components were combined and subjected to the same series of reactions, which provided a further 0.3 g of product; ^{1}Hmr data for **20** (major component; 25% *cis*-isomer present) δ: 1.72 (3H, d, H-8,8′,8″, $J_{7,8} \simeq 7$ Hz; 1.97, 2.10 (2 × 3H, s, CH_3, acetoxyl); 4.64 (1H, q, H-2, $J_{1,2} = 6.5$ Hz, $J_{2,3} = 2$ Hz); 5.3–6.0 (5H, overlapped m, H-3,4,6,7); 6.47 (1H, q, H-1, $J_{1,3} = 2$ Hz); ^{13}Cmr data for **20** δ: 17.4 (C-8); 20.1, 20.2 (CH_3-acetoxyl); 64.3 (C-4); 65.6 (C-3); 75.4 (C-5); 98.0 (C-2); 125.2 (C-7); 130.6 (C-6); 145.6 (C-7); 169.7 and 168.8 (C=O, acetoxyl); ^{13}Cmr data for the 6-*cis*-isomer of **20** δ: 13.1 (C-8); 64.1 (C-4); 65.3 (C-3); 70.7 (C-5); 98.0 (C-2); 124.4 (C-7); 129.9 (C-6); 145.7 (C-1); 169.4, 169.3 (C=O, acetoxyl).

*3,4-Di-*O*-acetyl-2,6,7,8-tetradeoxy-*D*-lyxo-oct-6-trans-enopyranose (**18**)*

The glycal (**20**) (0.92 g) was stirred at 0°C in ether (10 ml) containing 5% HCl for 0.5 h, more ether (100 ml) was added, and the solution was washed with bicarbonate. The rest of the work-up and treatment with silver carbonate in aqueous acetone was performed as described above for preparation of **5**. The 2-deoxy octose (**18**) was obtained as an oil (0.65 g); ^{1}Hmr data for **18** δ: 1.68 (3H, d, H-8,8′,8″, $J_{7,8} = 7$ Hz); 1.94, 2.08 (2 × 3H, s, CH_3-acetoxyls); ~2 (2H, overlapped by CH_3CO, H-2,2′); 4.0–6.0 (6H, overlapping m, H-1,3,4,5,6,7); ^{13}Cmr data for **18** δ: 17.8 (C-8); 20.7, 20.8 (CH_3, acetoxyls); 30.4 (C-2); 66.5 (C-3); 69.4, 69.9 (C-4, C-5); 92.0 (C-1); 125.9 (C-6); 129.0 (C-7); 158.3, 158.8 (C=O, acetoxyls).

*3,4-Di-*O*-acetyl-2,6,7,8-tetradeoxy-*D*-lyxo-oct-6-trans-enono-1,5-lactone (**23**)*

The 2-deoxy aldose derivative (**18**) (0.65 g) was dissolved in dichloromethane (15 ml) to which pyridinium chlorochromate (1.0 g) was added and the mixture was stirred for 2 h at room temperature or until the reaction was complete (tlc, solvent A). Ether (75 ml) was then added, the mixture was filtered through a layer of silica gel, and the solvents were evaporated off. The product was purified by column chromatography (eluent, CH_2Cl_2) affording a clear oil (0.25 g); ^{1}Hmr data for (**23**) δ: 1.70 (3H, d, H-8,8′,8″, $J_{7,8} = 6.5$ Hz, $J_{6,8} = 1$ Hz); 2.00, 2.12 (2 × 3H, s, CH_3, acetoxyls); 2.80 (2H, m, H-2,2′); 4.85 (1H, br d, H-4); 5.1–5.5 (2H, m, H-3,5); 5.5–6.0 (2H, m, H-6,7, $J_{6,7} = 15.5$ Hz, $J_{5,7} = 1.0$ Hz).

*4-*O*-Acetyl-2,3,6,7,8-pentadeoxy-*D*-threo-oct-2,6-trans-dienono-1,5-lactone (**22**)*

Lactone **23** (0.25 g) was dissolved in a 1:1 mixture of dichloromethane and triethylamine (5 ml). After 5 h the solvent was evaporated off, the residue was dissolved in CH_2Cl_2 (75 ml), and the solution was washed with water and dried over $MgSO_4$; removal of the solvent afforded **22** as an oil (0.20 g); ^{1}Hmr data for **22** δ: 1.74 (3H, d, H-8,8′, d, H-8,8′,8″); 2.08 (3H, s, CH_3-acetoxyl); 4.90 (1H, q, H-5, $J_{5,6} = 6.8$ Hz); 5.21 (1H, q, H-4, $J_{4,5} = 3.2$ Hz); 5.4–6.0 (2H, m, H-6,7, $J_{6,7} = 15.5$ Hz, $J_{7,8} = 6.5$ Hz); 6.15 (1H, d of d, H-2, $J_{2,3} = 9.6$ Hz, $J_{2,4} = 1.5$ Hz); 6.90 (1H, d of q, H-3, $J_{3,5} = 1$ Hz).

*Epoxidation of **22**. D-Enantiomer of asperlin (**24**)*

m-Chloroperbenzoic acid (0.20 g) was added to a solution of **22** (0.20 g) in dichloromethane (10 ml) and the solution was stirred at room temperature for 24 h. The volume of solvent was increased (100 ml), the solution was washed with saturated sodium bicarbonate and water, then dried over Na_2SO_4, and the solvent was evaporated. The resulting pale yellow oil (0.14 g), which was purified by column chromatography (eluent, CH_2Cl_2–hexane (3:1)), consisted of a mixture of the diastereomeric *trans*-epoxides (**24***a*,*b*) and ~25% of the *cis*-epoxide (**25**). The ^{1}Hmr spectrum is compared with that of asperlin in Fig. 2, and ^{13}C data for **24***a*,*b* and **1** are compared in Table 2.

Acknowledgements

The authors express their gratitude to the National Research Council of Canada for generous support. They also acknowledge with thanks the kind assistance of Dr. P. G. Farrell, Dr. B. Fraser-Reid, and R. Simoneau and the gift of a sample of 'asperlin' from the Upjohn Co.

The aminium radicals generated from the photolysis of *N*-nitroso-*endo*-2-methylaminomethylbicyclo[2.2.1]hept-5-en and *N*-nitroso-*endo*-2-methylaminomethylbicyclo[2.2.2]oct-5-ene cyclize at the C-6 position, since the relevant reacting centers can achieve excellent orbital overlap with minimum molecular motion in comparison to the alternative cyclization path at the C-5 position. The photolysis of the former compound gave a *C*-nitroso compound which underwent a series of unusual intramolecular cleavages, deoximations, and redox reactions during the work-up. Stereoelectronic requirements for these intramolecular reactions are discussed. Thermolysis of *N*-chloro-*endo*-2-methylaminomethylbicyclo[2.2.2]oct-5-en in methanol also gave the product with azaisotwistane skeleton.

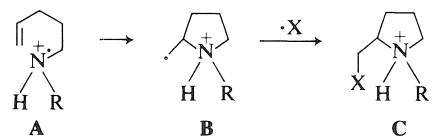
ROBERT W. LOCKHART, MASAYUKI KITADANI, FREDERICK W. B. EINSTEIN et YUAN L. CHOW. Can. J. Chem. **56**, 2897 (1978).

Les radicaux aminium produits par photolyse du *N*-nitroso *endo*-méthylaminométhyl-2 bicyclo[2.2.1]heptène-5 et du *N*-nitroso *endo*-méthylaminométhyl-2 bicyclo[2.2.2]octène-5 se cyclisent à la position C-6, puisque les centres réactifs appropriés peuvent donner lieu à un excellent recouvrement d'orbitales avec un minimum de déplacements moléculaires, ce qui n'est pas le cas pour l'autre voie de cyclisation possible à la position C-5. La photolyse du premier composé a conduit à un composé *C*-nitroso qui a subi une série inhabituelle de clivages intramoléculaires, de désoximations et de réactions d'oxydoréduction pendant qu'on l'isolait. On discute des exigences stéréoélectroniques pour ces réactions intramoléculaires. La thermolyse du *N*-chloro *endo*-méthylaminométhyl-2 bicyclo[2.2.2] octène-5 dans le méthanol a également conduit au produit ayant un squelette azaisotwistane.

[Traduit par le journal]

Introduction

In continuation of our interests in the application of the aminium radical cyclization route in the synthesis of azapolycyclic compounds (2), the photolysis of $\Delta^{4,5}$-alkenyl nitrosamines as a route to azapolycyclic systems has been investigated. It is well established that $\Delta^{4,5}$-alkenyl aminium radicals (**A**) generated from the corresponding nitrosamines and chloramines readily cyclize to yield five- (but not six-) membered ring systems (**B**) by a kinetically controlled process (2). The *C*-radical intermediate **B** then reacts with a radical (·NO or ·Cl or their donors) to give the azacyclic compounds (**C**; X = Cl or NO).



A **B** **C**

Eventually our goal is to define the nature of the orbital overlap requirements in cyclizations initiated by radicals as proposed in our previous publication (2). In this paper intramolecular photoaddition of two bridged bicyclic alkenyl nitrosamines and subsequent rearrangements of the cyclization product are described. The accompanying paper (3) is concerned with the interception of the cyclized *C*-radical intermediates with trapping agents in an effort to modify the synthetic process and obtain other complementary products.

Results

Two alkenylamines, 2-*endo*-methylaminomethylbicyclo[2.2.1]hept-5-ene (**1**) and 2-*endo*-methylaminomethylbicyclo[2.2.2]oct-5-ene (**2**), were prepared by known methods as outlined in the Experimental; the former contained about 30% of the corresponding *exo*-isomer which could not be removed. The corresponding nitrosamines **3** and **4** were readily prepared by nitrosation with dinitrogen tetraoxide or nitrosyl borofluoride.

Photolysis of nitrosamine **3** in acidic methanol solution under nitrogen gave rise to a strong ab-

[1]Some of these results have been published in a preliminary communication (see ref. 1).

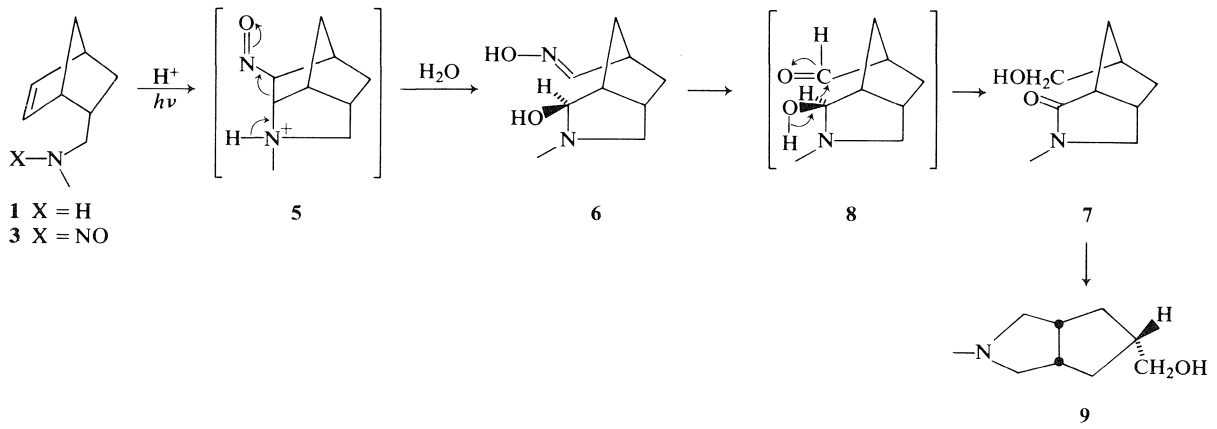

SCHEME 1

sorption at 290 nm typical of a *C*-nitroso dimer (4). The major products were the unstable aldoxime **6** and the water soluble lactam **7** in addition to minor products, some of which were derived from the *exo*-nitrosamine. The structure of the hydroxy lactam (**7**) was suggested by the analytical results and by the ir absorption at 1660 (5) and 3300 cm^{-1}; these absorptions might be interpreted as being due to a γ-lactam group internally hydrogen bonded to the hydroxyl group. The prominent mass spectral peak at *m/e* 98 has been assigned as being that peak characteristic of *N*-methylpyrrolidone derivatives (6). The spectra were in agreement with the proposed structure but were not definitive. Lactam **7** was reduced with sodium bis(2-methoxyethoxy)aluminium hydride to give a tertiary amine (**9**) which showed a sharp doublet at τ 6.38 (J = 5 Hz) for the magnetically equivalent CH_2OH protons in contrast to the complex multiplet for the corresponding CH_2OH protons at τ 6.4 in **7**. This observation indicated that the CH_2OH's were magnetically nonequivalent in **7** and were transformed to magnetically equivalent protons as the result of reduction. From the mechanistic consideration that the formation of **7** arises from photocyclization, cleavage reaction, and intramolecular redox reaction (*vide infra*), the reduction product must be assigned structure **9** which possesses a plane of symmetry cutting across the CH_2OH and N—CH_3 groups.

The nmr signal at τ 2.72 (J = 7 Hz), together with the ir absorption at 3300, 920, 890, and 860 cm^{-1}, suggest that **6** is the *syn*-aldoxime and the broad doublet at τ 5.30 (J = 5.5 Hz) may be assigned to the C—H proton geminal to the OH and amine groups. Attempted deoximation of aldoxime **6** with sodium bisulfite solution led to the formation of lactam **7**, indicating that hydrolysis to an aldehyde group (see **8**) was accompanied by a rarely observed intramolecular redox reaction. This probably occurred during the work-up to give **7**, owing to the proximity of the relevant functional groups. The reaction pattern might be represented as shown in Scheme 1; cleavage of primary products, such as the *C*-nitroso compound **5**, has frequently been found in photoadditions of nitrosamines (7). In the present case, cleavage to give **6** was such a facile process that various measures (such as control of temperature, light source, and/or irradiation time) taken to circumvent the cleavage processes and to obtain the expected tricyclic oxime did not meet with success. It was realized that other approaches had to be used for the synthesis of these azatricyclic compounds (3).

Irradiation of bicyclic alkenyl nitrosamine **4** under nitrogen gave the tricyclic *syn* (53%) and corresponding *anti* (18%) oximes **10** (Scheme 2). Both oximes (**10**), alone or as a mixture, were deoximated with sodium bisulfite to give amino ketone **11** which exhibited an ir absorption at 1720 cm^{-1} and the nmr signal for H_a at τ 6.98 (d, J = 5 Hz). *syn*-Oxime **10** was fairly soluble in water and formed the methylene chloride soluble hydrochloride salt. Oximes **10** exhibited the necessary ir absorption for the oximino group and had similar mass spectra. In agreement with other amino oximes (8), *syn*-**10** showed a doublet at τ 6.02 (J = 4 Hz) for H_a and *anti*-**10** a triplet at τ 6.25 (J = 6.5 Hz) for H_e and a doublet at 6.86 (J = 4.5 Hz) for H_a. In all these tricyclic amines **10** and **11**, a double doublet in the τ 6.7–6.9 region and a partially hidden signal (a doublet) in the τ 7.5 region could be assigned to H_b and H_c, respectively. Although on the basis of the Karplus relation these assignments do not contradict the structural assignment of the azaisotwistane skeletons **10** and **11**, the azatwistane skeleton resulting from the six-membered ring cyclization cannot be entirely ruled out. The hydrochloride of *syn*-oxime **10** was, therefore, in-

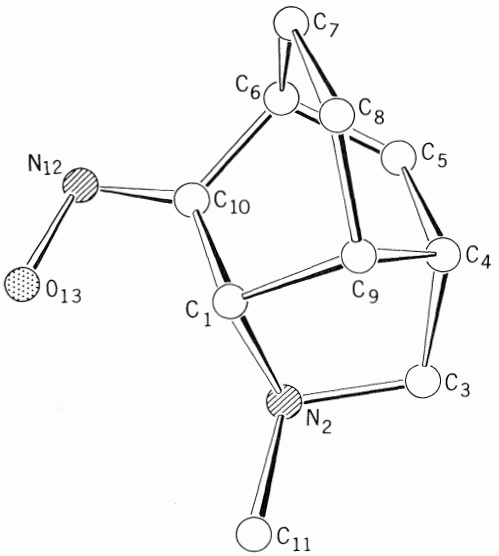

FIG. 1. The proposed crystal structure for the hydrochloride of *syn*-oxime **10**.

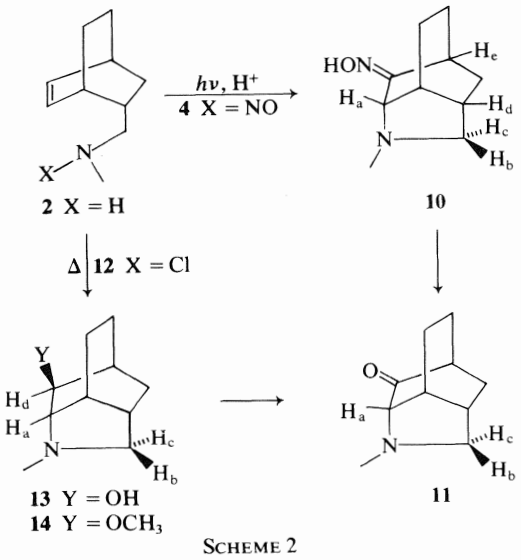

SCHEME 2

vestigated by X-ray structural analysis to confirm the proposed structure[4] as shown in Fig. 1; some relevant data on the dimensions are given in Table 1. Crystal data for the hydrochloride of *syn*-oxime **10**: $(C_{10}H_{17}N_2O)^+Cl^-$, colorless crystals, orthorhombic, space group P_{bca}, $a = 11.655(5)$, $b = 12.574(5)$, $c = 14.947(6)$ Å, $U = 2180.0$ Å^3, $D_m = 1.31$ g cm^{-3}, $Z = 8$, $D_c = 1.32$. The structure has been refined to $R = 0.066$ for 653 observed reflections measured with a computer-controlled diffractometer using single-crystal monochromatized Mo-K_α radiation.

Although the final electron density map could be further refined, particularly around the environment of the oxime function, it is interesting to note the dimensions of 1.41 and 1.30 Å for the C=N and the N—O bonds, respectively: the former is significantly longer than the normal bond length for a C=N bond (1.26 Å) and the latter shorter than that for the N—O bond (1.42 Å) characteristic of oximes (10). These data suggest a significant contribution of the polar resonance form of the oximes e.g., $\rangle C{=}N{-}O{-}H\ldots Cl^- \leftrightarrow \rangle \bar{C}{-}N{=}O\ldots H{-}Cl$, in which the double bond character is distributed across the C—N—O system. The contacts N(2)---Cl (3.11 Å) within the same molecule and O(13)---Cl (3.12 Å) between the adjacent molecules indicate there is a weak hydrogen bond; this is further supported by an examination of the angles (161 and 180°, respectively) subtended at the hydrogen atoms.

Failure to obtain the azatwistane skeleton as indicated above led us to investigate the thermolysis of *N*-chloramines for which nitrenium ions (11) or amine radicals (12) have been proposed as reactive intermediates. On refluxing in dioxane–water, chloramine **12** decomposed quickly (1.25 h as indicated by iodimetric titration) to amino alcohol **13** (12%) and starting amine **2**, in addition to a small yield of chlorine-containing amines. The last fraction was unstable and was shown to contain one chlorine atom but was probably not a homogeneous fraction. Amino alcohol **13** (3) was readily converted to ketone **11** by Jones' oxidation. The thermal decomposition of chloramine **12** in methanol, however, took a considerably longer time (11 h for the disappearance of the positive chlorine) and gave one major product, methoxy amine **14** (59%), and starting amine **2** (6.5%), in addition to two more unidentified products (8%) as shown by gc–ms analysis. The major product was isolated by preparative vpc and was shown to possess structure **14** by X-ray crystallographic analysis of the corresponding picrate (Fig. 2). Some relevant data on the dimensions are given in Table 1. The crystal data for the picrate of **14** are as follows: $C_{17}H_{22}N_4O_8$, yellow needles, monoclinic, space group $P_{2_1/c}$, $a = 7.651(4)$, $b = 12.441(6)$, $c = 19.793(8)$ Å and $B = 94.08°(4)$, $U = 1884.0$ Å^3, $D_m = 1.44$ g cm^{-1}, $Z = 4$, $D_c = 1.44$. The structure was refined to $R = 0.080$ for 1502 observed reflections.

For H_b and H_c, hydroxyamine **13** (3) exhibited signals at 7.44 (dd, $J = 10$ and 4.5 Hz) and 7.26

[4]The details of the method and molecular dimensions are described in ref. 9.

(d, J = 10 Hz) whereas methoxy amine **14** displayed them at τ 7.58 (d, J = 9 Hz) and 7.32 (dd, J = 9 and 4.5 Hz) (14). In considering the Karplus relation, it appeared to us that the coupling patterns of **14** were quite different from those of **13**, and that **14** agreed with the azatwistane skeleton when the dihedral angles were measured. This led us to erroneously report in our preliminary communication (1), the structure to be the azatwistane derivative. At about the same time, Waegell and co-workers (13) solvolysed the same chloramine **12** in methanol in the presence of silver oxide to give the methoxy amine for which they postulated structure **14**.[5] More recently, the same group synthesised the parent *N*-methyl-2-azatwistane and *N*-methyl-2-azaisotwistane (14); on the basis of the similarity of the 250 MHz nmr spectra of the latter and those of **14**, the azaisotwistane structure was assigned to **14**.

Discussion

It has been demonstrated that the regiospecificity of the cyclization of $\Delta^{4,5}$-alkenylaminium radicals generated from the photolysis of the corresponding nitrosamines is controlled by the degree of *p*-orbital overlap in the transition state; in every case except one (15) this leads to exclusive formation of the five-membered ring carrying the apparently thermodynamically less stable *C*-radical, i.e., the intramolecular radical attacks are mainly governed by kinetic controls and not, to any significant extent, by the thermodynamic stability of the transition states (2). It is conceivable that in certain cases the energy barrier arising from nonbonded interactions in the transition state might be sufficiently high to retard cyclization to a five-membered ring formation. Such

[5]We are grateful to Professor B. Waegell who has confirmed the identity of our compound by comparison of its ir spectra with those of his sample.

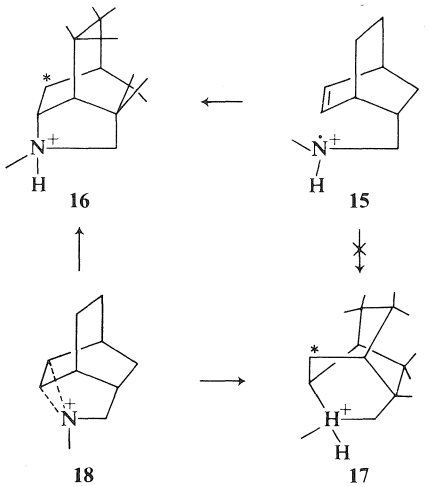
a case can be seen in the aminium radical cyclization reported by Heusler (15) in which *N*-chloro-*cis*-octahydroisoquinoline cyclizes to the azatwistane structure (six-membered ring formation) instead of cyclizing to the alternative five-membered ring compound commonly observed in other cases.

The aminium radicals derived from **3** and **4** undergo five-membered ring cyclization exclusively as shown by the product patterns. The cyclization of the former aminium radical, a rigid bicyclo[2.2.1] system, to give **5** (as the final product) can be understood in terms of bond formation involving the readily available and better overlapping *p*-orbitals of the C-6 position of the double bond and the radical center. In this case it is also true that the alternative cyclization to the C-5 position is disfavored since it has to overcome considerable strain energy. For the cyclization of the aminium radical **15**, a more flexible bicyclo[2.2.2] system, the kinetically driven attack on the C-6 *p*-orbital has to surmount various 1,2-eclipsing and 1,3-diaxial interactions in the transition state to give **16**; these extra nonbonded interactions would be relieved in the transition state of the alternative attack at the C-5 *p*-orbital leading to **17**, in which the cyclohexane ring systems are staggered. The failure to observe twistane products clearly indicates that these stereochemical barriers are not sufficient to overcome the driving force in the five-membered ring cyclization. The different modes of cyclization for the present isoazatwistane and Heusler's (15) azatwistane product may provide an interesting case for investigation in conformational analysis.



16 **15** **18** **17**

The thermal decomposition of *N*-chloroalkenylamine in neutral hydroxylic solvents has been investigated by various groups (11–13); among them, Edwards *et al.* (12) and other groups (13) have provided good evidence that the reaction follows the homolytic amino radical route initiated by adventitious radicals (16, 17) rather than the nitrenium ion route by assisted ionizations (11). Further, Edwards *et al.* (12) have concluded that *trans*-*C*-halo compounds, such as **13** where Y = Cl, undergo skeletal rearrangements via aziridinium ions, such as **18**, to give more stable *trans*-substituted polycyclic amines. The thermolysis of *N*-chloramine **12** is also expected to follow the homolytic pathway using the amine radical cyclization as the key step which might lead to the formation of the *C*-chloro compound **13** (Y = Cl) as the primary product. If the final products **13** and **14** are assumed to arise from this *C*-chloro compound by a similar solvolytic mechanism as proposed by Edwards *et al.* (12), the opening of aziridinium ion **18** by nucleophilic attack would yield both isoazatwistanes, **13** and **14**, and the alternative azatwistane compounds; on the basis of a conformational analysis similar to that discussed above, the latter formation should be favoured. However, this assumption poses a serious dilemma as it fails to explain the failure to isolate azatwistane derivatives in the thermolysis of **12**. A similar difficulty has been encountered in the solvolysis of **13** (where Y = Br); possible explanations are discussed in the succeeding paper (3). Since the vpc spectrum of the crude oil from the thermolysis of **12** in methanol is considerably simpler than that from the solvolysis of **13** (where Y = Br) (3), it is speculated that CH_3OH (or water in dioxane) might directly participate in the kinetically driven radical cyclization process. The slow thermolysis in methanol indicates that a chain process, such as that observed in the Ag^+-catalysed reaction (13, 14), might be very short.

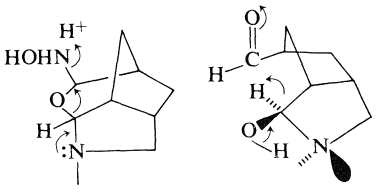
The complex product pattern observed in the photolysis of nitrosamine **3** is attributed to the cleavage reaction of β-nitroso ammonium salts often observed in the nitrosamine photoreaction (7). The structures of oxime **6**, lactam **7**, and bicyclic amine **9** have been deduced from the spectral data in conjunction with mechanistic considerations. The key to the structural proof rests on the observation that the complex multiplet due to the magnetically nonequivalent CH_2OH in **7** is transformed to a sharp doublet, i.e., the magnetically equivalent CH_2OH in **9**, as the result of the reduction of the γ-lactam ring to the pyrrolidine ring.

The facile cleavage of *C*-nitroso compound **5** stands in contrast to the stability of the corresponding *C*-nitroso compound obtained from photocyclization of **4**; the latter readily tautomerizes to the oximes **10**, a process common to most *C*-nitroso compounds (4). The driving force for the cleavage is most likely derived from the strain energies associated with the rigid bicyclo[2.2.1] system as has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

demonstrated in the photoaddition of nitrosamines to norbornene (7). Although we have concluded that a coplanar *cis*-orientation of the functional groups is required for the cleavage reaction (7), this configuration could not be confirmed in **5** because of rapid decomposition.

It is suspected that ready hydrolysis of the oxime group in **6** is facilitated by *endo*-OH group participation (the isomer of **6**) under acidic conditions via an intermediate such as **6***a*, leading to the unisolated aldehyde **8** (or its epimer). The intramolecular redox



6*a* **8***a*

reaction of an aldehyde and a *gem*-aminoalcohol group requires a stereochemical orientation of the functional groups as shown in **8** for the hydride transfer and may be analogous to the intramolecular redox process of ajaconine derivatives (18). Recently Deslongchamps (19) has elegantly demonstrated that ejection or migration of anionic species from a tetrahedral carbon carrying heteroatomic (nitrogen or oxygen) substituents is stereoelectronically assisted by the lone-pair orbitals oriented antiperiplanar to the departing groups. Although this new stereoelectronic theory is primarily demonstrated in the decomposition of hemiacetals, hemiorthoesters, and hemiorthoamides, the author has suggested that it also applies to the haloform reaction, retro-aldol and allied reactions, various fragmentations involving ejection of anions, the benzylic acid rearrangement, and various other anionoid reactions. The unusual over-the-space redox process is believed to be controlled by stringent stereoelectronic factors; it is the ready orientation of the nitrogen lone-pair orbital antiperiplanar to the C—H bond as in **8***a* that effectively promotes hydride shift.

Experimental

Unless otherwise specified, nmr spectra were recorded with a Varian A56/60 spectrometer in $CDCl_3$ using TMS as the internal standard. Infrared spectra were recorded as Nujol mulls or neat liquids with a Perkin Elmer model 457 grating spectrophotometer, uv spectra with a Unicam SP800 spectrometer, and mass spectra with a Hitachi-Perkin-Elmer RMU-6E instrument at 80 eV. Melting points were recorded with a Fisher Johns hot stage apparatus and were uncorrected. Microanalyses were performed by Mr. M. K. Yang, Department of Biological Sciences, Simon Fraser University.

For the photolyses, Hanovia medium pressure mercury lamps (654A36, 200 W and 8A36, 100 W) were used in conjunction with a Pyrex apparatus equipped with a Nonex filter (50% transmission at 320 nm). The photolysis products were isolated in the usual way (4).

Synthesis of N-*Nitroso-2*-endo-*methylaminomethylbicyclo[2.2.1]hept-5-ene (**3**)*

Allyl bromide (56 g) was treated with cyclopentadiene (25 g) by the described method (18). Distillation of the crude product gave a clear oil (50 g, 70.5%) consisting principally of 2-*endo*-bromomethylbicyclo[2.2.1]hept-5-ene and about 30% of the corresponding *exo*-isomer; ir: 3060(m), 720(s), and 630(s) cm^{-1}.

A solution of methylamine (27 g) and the above sample (25 g) in ether (125 ml) was placed in an autoclave which was heated in an oil bath at 100°C for 67 h. The product was extracted with 1.0 *N* HCl (3 × 50 ml) which was washed with ether. The acidic aqueous phase was basified to pH 10–11 with aqueous NaOH and extracted with CH_2Cl_2 which was dried over $MgSO_4$, filtered, and evaporated to give 2-*endo*-methylaminomethylbicyclo[2.2.1]hept-5-ene (**1**) as a light yellow oil (12.8 g); ir: 3300(w), 3060(m), 1250, and 720(s) cm^{-1}; nmr τ: 3.90 (dd, J = 6 and 3 Hz, 1H), 4.12 (dd, J = 6 and 3 Hz, 1H), 7.20 (m, 2H), 7.40 (d, J = 7 Hz, 0.7H), 7.55 (s, *N*—CH_3, 0.9H), 7.61 (s, *N*—CH_3, 2.1H), 7.80 (m, 2H), 8.68 (m, 2H), 9.04 (s, D_2O exch., 1H), and 9.50 (br d, J = 10 Hz, 0.7H); ms m/e: 137 (M^+, 10), 71(66), 70(61), and 44(100). This oil contains 30% of the *exo*-isomer as shown by the ratio of the *N*—CH_3 signals at τ 7.55(s) and 7.61 which was 0.9:2.1.

The amine (2 g, 0.015 mol) and anhydrous sodium acetate (4 g, 0.5 mol) in CH_2Cl_2 (125 ml) were stirred and cooled in an acetone–ice bath. A cold solution of N_2O_4 (1.5 g, 0.016 mol) in CH_2Cl_2 (50 ml) was added dropwise over 1 h. The mixture was stirred at −10°C for another 10 min, filtered, and washed with dilute Na_2CO_3 (10%). The solvent was dried and evaporated to give an oil (2.4 g) which was purified by chromatography to give nitrosamine **3**: ir: 3060(m), 1430(s), 1270, 1155, 1035(s), and 720(s) cm^{-1}; ms *m/e*: 167(1), 166(M^+, 1), 165(1), 149(22), 136(24), 101(35), 91(40), 82(88), and 66(100); uv (methanol): 344 nm (ε, 97). The olefinic protons appeared in the nmr spectrum as a pair of double doublets at τ 3.75 (J = 6 and 3 Hz) and 3.98 (J = 6 and 3 Hz). The *N*-methyl protons attributed to the *syn*-isomer resonated at τ 6.92(s) and the C8 protons of this isomer appeared as a complex pattern centered at τ 6.0. The *N*-methyl signal of the corresponding *anti*-isomer appeared at τ 6.20(s). The ratio of the *N*-methyl signals for the *syn*- and *anti*-isomers was 81:19. Other resonances appeared at τ 7.20 (m, 3H), 8.10 (m, H3-*exo*), 8.65 (m, 2H), and 9.30 (ddd, J = 11.5, 4, and 2.5 Hz, H3-*endo*). The sample contained about 30% of the *exo*-isomer as shown by the corresponding nmr signals.

Synthesis of N-*Nitroso-2*-endo-*methylaminomethylbicyclo[2.2.2]oct-5-ene (**4**)*

Acrylic acid (30 g) was treated with cyclohexadiene (25 g) as described before (19). Distillation of the reaction product at 148–150°C/13 Torr gave an oily solid which was recrystallized from pentane several times to give 2-*endo*-carboxylbicyclo[2.2.2]oct-5-en (35.4 g, 67%): mp 57–59°C (lit. (19) mp 56–57°C); ir: (Nujol): 3200–2500 (s,br), 1700(s), 1240(s), 940 and 700(s) cm^{-1}.

The acid (10 g, 0.066 *M*) was mixed with pyridine (6.0 g) and thionyl chloride (9.45 g) in dry benzene (200 ml) at 0°C for 20 min. Methylamine was bubbled into this solution until it was basic to moist pH paper. The benzene solution was washed with 10% aqueous Na_2CO_3 solution, and water, dried over $MgSO_4$, filtered, and evaporated to give a solid. Recrystallization from hexane gave white needles of *N*-methyl-2-*endo*-carboxamidobicyclo[2.2.2]oct-5-en (9.1 g, 83%); mp 136–138°C; ir: 3285(s), 3040(w), 1640(s), 1555(s), and 690(m)

cm^{-1}; nmr τ: 3.70 (m, 2H), 4.2 (br m, D_2O exch.), 7.25 (d, J = 4.5 Hz, 3H), 7.40 (m, 2H), and 8.0–9.0 (unresolved, 6H). *Anal.* calcd. for $C_{10}H_{15}NO$: C 72.69, H 9.15, N 8.48; found: C 72.86, H 9.14, N 8.41.

The amide (8.8 g, 0.053 mol) was added slowly in portions to a stirring suspension of lithium aluminum hydride (4.05 g, 0.1 mol) in ether and the mixture was stirred at room temperature for 20 h. After the usual work-up the ether solvent was distilled through a Vigreaux column leaving 2-*endo*-methylaminomethylbicyclo[2.2.2]oct-5-en (**2**) as a light yellow oil (7.47 g, 94%); ir: 3280(w), 3040(m), 1610(w), 1150, 1130, and 700 cm^{-1}; nmr τ: 3.80 (m, 2H), 7.4–7.8 (unresolved, 3H), 7.61 (s, N—CH_3), 8.0–9.0 (unresolved, 6H), and 9.10 (m, 1H); ms *m/e*: (15 eV) 151 (M^+, 16), 85(75), 83(100), and 44(66).

Amine **2** (5 g, 0.033 mol) was added to a suspension of $NOBF_4$ (6.4 g, 0.055 mol) (2) in CH_2Cl_2 (100 ml) at 0°C. Pyridine (4.32 g, 0.055 mol) in CH_2Cl_2 (50 ml) was added dropwise over 15 min. After 1 h the mixture was filtered then washed with Na_2CO_3 (10%), dilute HCl (0.1 *N*), and then water. The solution was dried and filtered, and the solvent was evaporated to give *N*-nitrosamine **4** (3.64 g); ir: 3040(w), 1430(s), 1330, 1310, 1268, 1155(m), 1030(s), and 700(s) cm^{-1}; ms *m/e*: 180 (M^+, 32), 163(18), 150(35), and 79(100); uv (methanol): 345 nm (ε, 100). The olefinic protons appeared as a two-proton multiplet at τ 3.70. The *N*-methyl protons attributed to the *syn*-isomer appeared at τ 6.97(s) and the C9 protons of this isomer appeared as a complex pattern at τ 6.1. The *N*-methyl signal of the corresponding *anti*-isomer resonated at τ 6.25(s) while the C9 protons appeared as a complex pattern centered at τ 6.7. The ratio of the *N*-methyl signals for the *syn*- and *anti*-isomers was 82:18. The remaining protons appeared as unresolved multiplets at τ 7.3–9.2 (9H). An analytical sample of **4** was prepared by repeated distillation at 25°C/0.05 Torr. *Anal.* calcd. for $C_{10}H_{16}N_2O$: C 66.64, H 8.95, N 15.54; found: C 66.90, H 9.12, N 15.71.

Photolysis of N-*Nitroso-2*-endo-*methylaminomethylbicyclo[2.2.1]hept-5-ene (3)*

A solution of nitrosamine **3** (1.5 g, 0.009 mol) and concentrated HCl (0.8 ml, 0.048 *N*) in methanol (200 ml) was irradiated under N_2 for 1.5 h. The usual work-up gave a neutral fraction (80 mg) and a basic fraction (*A*, 850 mg). The mother liquor was further basified from pH 9 to 13 with NaOH solution then continuously extracted for 5 days with CH_2Cl_2 to yield 200 mg of additional extract, *B*.

A portion of the basic extract *A* (750 mg) was chromatographed on silica gel. Elution with 2% methanol–CH_2Cl_2 gave crystals (237 mg, 22%) which were rechromatographed on a preparative scale tlc plate (silica gel, 10% methanol–CH_2Cl_2) to give *syn*-aldoxime **6**: mp 109–112°C; ir: 3200 (w, br), 3040 (w, br), 1260, 920(s), and 890(s) cm^{-1}; nmr τ: 2.72 (d, J = 7 Hz, 1H), 5.30 (d, J = 5.5 Hz, 1H), 6.55 (br d, J = 8 Hz, 1H), 7.28 (s, N—CH_3), 7.5–8.0 (unresolved, 4H), and 8.5 (m, 3H); ms *m/e*: 184 (M^+, 1), 183(5), 182.1037 (11, calcd. for $C_9H_{14}N_2O_2$: 182.1055), 168(22), 152(17), 82(78), 57(100), and 49(89). *Anal.* calcd. for $C_9H_{16}N_2O_2$: N 15.19; found: N 15.20.

Elution with 5% methanol–CH_2Cl_2 gave a mixture of aldoxime and olefinic material: ir: 3300 (s, br), 3060(w), 920(m), and 870 cm^{-1}; nmr τ: 2.60(m), 3.10 (m, D_2O exchangeable), and 3.90 (t, J = 1.5 Hz).

The material isolated by continuous extraction (*B*) was vacuum distilled (40°C/0.025 Torr) to give hydroxy lactam **7** (29%): ir: 3400 (s, br), 1662(s), 1500(m), 1400, 1300, 1270(m), 1115, 1070, 1045, and 1015(m) cm^{-1}; nmr τ: 6.00 (m, D_2O exchangeable), 6.42 (m, 3H), 6.92 (dd, J = 10 and 1 Hz, 1H), 7.18 (s, N—CH_3) and ~7.8 (m, 7H); ms *m/e*: 169 (M^+, 90), 152(10), 98(100), 86(50) and 84(77). *Anal.* calcd. for $C_9H_{15}NO_2$: C 63.88, H 8.93, N 8.28; found: C 63.51, H 8.83, N 8.39.

An aqueous ethanol (50%) solution of crude aldoxime **6** (600 mg) was refluxed with $NaHSO_3$ (1.3 g) for 4 h (20). The solvent was removed by distillation (78–80°C) and the residue was acidified with dilute HCl (0.1 *N*). Extraction with $CHCl_3$ (3 × 20 ml) gave no neutral extract. The aqueous mother liquor was basified (pH 13) with aqueous NaOH and continuously extracted with CH_2Cl_2 for 5 days to give hydroxy lactam **7** (403 mg; ir 1662 cm^{-1}) containing a small amount of nitrile impurity (ir 2220(w) cm^{-1}).

A mixture of **7** (100 mg, 0.006 mol) and a 70% benzene solution of sodium bis(2-methoxyethoxy)aluminum hydride, 0.43 g, 0.015 mol) in benzene (10 ml) was stirred at 50°C for 0.5 h then at room temperature for another 2 h. The mixture was decomposed with water and filtered. The residual solid was washed with additional benzene and the combined benzene filtrate was dried and evaporated to an oil (45 mg) which was distilled at 25°C/0.5 Torr to give bicyclic amino alcohol **9**; ir: 3300 (s, br), 1150, 1135(w), 1020(m), 985(w), and 865(m) cm^{-1}; nmr τ: 6.38 (d, J = 5 Hz, CH_2OH), 6.84 (s, D_2O exchangeable), 7.39 (d, J = 8.5 Hz, 2H), 7.70, (s, N—CH_3), 7.4–8.1 (m, 6H), and 8.3–9.2 (m, 3H); ms *m/e*: 155 (M^+, 10), 154(17), 124(19), and 57(100). The signal at τ 6.38 was collapsed to a singlet when irradiated at τ 8.6 but the signal was not affected when irradiated at the τ 7.2–8.1 area. The picrate of **9** was recrystallized twice from ethanol to give yellow needles, mp 138–139°C. *Anal.* calcd. for $C_{15}H_{20}N_4O_8$: C 46.88, H 5.52, N 14.58; found: C 46.64, H 5.52, N 14.53.

Photolysis of N-*Nitroso-2*-endo-*methylaminomethylbicyclo[2.2.2]oct-5-ene (4)*

A solution of nitrosamine **4** (1 g, 0.0055 mol) and concentrated HCl (0.5 ml, 0.03 *N*) in methanol (200 ml) was irradiated under nitrogen for 1.5 h. The usual work-up gave a neutral fraction (20 mg) and a basic fraction (620 mg). In addition, continuous liquid–liquid extraction of the basic mother liquor with CH_2Cl_2 gave a semisolid (150 mg).

The basic extract (600 mg) was chromatographed on a silica gel column (40 g). Elution with 5% methanol–CH_2Cl_2 gave crude *syn*-oxime **10** (233 mg, 23%) which was purified by preparative scale tlc (silica gel; 10% methanol–CH_2Cl_2) to give a clear oil: ir: 3220 (s, br) 3060 (m, br), 1660(w), 1285(w), 1130(m), 940(s), and 918(s) cm^{-1}; nmr τ: 3.49 (m, D_2O exchangeable), 6.02 (br d, J = 5 Hz, H_a), 6.98 (dd, J = 9.5 and 4 Hz, H_b), 7.40 (s, N—CH_3), 7.4–7.9 (unresolved, 5H), and 8.30 (m, $W_{1/2}$ = 5.5 Hz, 7H); ms *m/e*: 180 (M^+, 15), 164(24), 163(100), 162(28), 108(24), 94(49), and 82(16). The nmr spectrum of oxime **10** in the presence of $Eu(DPM)_3$ shift reagent (29 mg) showed doublet at τ 6.08 (d, J = 9.5 Hz) which was originally part hidden at τ 7.5. The downfield shifts of H_a and N—CH_3 protons were much faster than others.

Elution with 5–8% methanol–CH_2Cl_2 gave a 1:1 mixture of *syn*-oxime **10** and *anti*-oxime **10** (80 mg, 8%). Crystallization from CH_2Cl_2 gave *anti*-oxime **8** (20 mg); mp 153–154°C; ir: 3180(w), 3060(w), 1600(w), 1210, 1138, 965(s), 920(s), 868, 770, and 720 cm^{-1}; nmr τ: 6.25 (t, J = 6.5 Hz, H_e), 6.72 (dd, J = 11 and 4.5 Hz, H_b), 6.87 (d, J = 4.5 Hz, H_a), 7.40 (part of H_e doublet), 7.50 (s, N—CH_3), 7.70 (m, 3H), and 8.33 (m, 5H); ms *m/e*: 181(7), 180.1249 (M^+, 42, calcd. for $C_{10}H_{16}N_2O$: 180.1263), 179(4), 164(54), 163(100), 162(39), 108(40), 94(55), and 82(22). Irradiation at τ 7.75 resulted in collapse of the double doublet pattern at τ 6.72 (H_b) to a doublet (J = 11 Hz) and the coalescence of the doublet at τ 6.87 (H_a). Irradiation at τ 8.3 collapsed the triplet at τ 6.25 (H_e) to a singlet.

Finally, elution of the silica gel column with 20% methanol–CH_2Cl_2 gave an unidentified olefinic fraction (50 mg); ir: 3040(m) and 750(s) cm^{-1}; nmr τ: 3.66(m).

The semisolid, isolated by continuous extraction, was re-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

crystallized several times from ethanol – ethyl acetate to give the hydrochloride of *syn*-oxime **10**: mp 215–219°C; ir (Nujol): 3125(s), 3060(s), 2660(m), 2580(m), 2550(m), 1040(m), 990, 958(s), 945(s), 905(s), and 745 cm^{-1}; ms *m/e*: 180(s), 163(22), 108(88), 94(18), and 83(100). *Anal.* calcd. for $C_{10}H_{17}N_2OCl$: C 55.42, H 7.91, N 12.92; found: C 55.28, H 8.04, N 12.94.

This compound caused a green flame when subjected to the Beilstein test for halogens. The hydrochloride (600 mg) was dissolved in water, basified to pH 13–14 with aqueous NaOH, and extracted with CH_2Cl_2 (3 × 50 ml) to yield *syn*-oxime **10** (80 mg). Continuous extraction of the aqueous solution with CH_2Cl_2 recovered crystalline hydrochloride of **10** (300 mg).

Treatment of *syn*-oxime **10** (120 mg) with bisulfite gave a ketone (48 mg) containing some nitrile impurity; ir: 2220(w) and 1720(s) cm^{-1}. The bisulfite hydrolysis of a mixture of *syn*-oxime **7** and *anti*-oxime **8** gave the identical mixture which was chromatographed on neutral alumina with CH_2Cl_2 to give amino ketone **11**: ir: 1720(s), 1220, 1130, and 1100 cm^{-1}; nmr τ: 6.78 (dd, J = 9 and 4 Hz, H_b), 6.98 (d, J = 5 Hz, H_a), 7.40 (s, N—CH_3), 7.50 (m, 2H), 7.72 (m, 2H), and 8.12 (m, $W_{1/2}$ = 4.5 Hz, 5H); ms *m/e*: 165.1151 (M^+, 18, calcd. for $C_{10}H_{15}NO$: 165.1154), 137(100), 96(31), 95(47), 94(78), and 82(82).

Thermolysis of N-*Chloro-2*-endo-*methylaminomethylbicyclo*[*2.2.2*]*oct-5-ene* (**12**)

N-Chloramine **12** was prepared by stirring the corresponding amine (0.01 mol) in CH_2Cl_2 (50 ml) with a sodium hypochlorite solution (50 ml, Prefex Bleach®) at 0°C for 1 h. The CH_2Cl_2 solution was worked up to give a crude product: ir: 3040(m), 1615(w), 1180, 1170(m), and 710(s) cm^{-1}; nmr τ: 3.75 (m, 2H), 7.05 (m, 2H), 7.10 (s, 2H), 7.45 (m, 3H), and 8.0–9.2 (m, 7H); uv (methanol): 277 nm (ε, 315). The sample contained >95% of positive chlorine as determined by iodimetric titration.

A solution of a crude chloramine **12** (1.68 g, 0.009 mol) in methanol (150 ml) was refluxed for 10.75 h. Iodimetric titrations showed that the positive chlorine decreased <5% during the first hour and 90% in the following 8 h. The methanol was evaporated and the residue was portioned into neutral (76 mg) and basic fractions (1.07 g). The basic fraction was shown by gc–ms (20% SE30, 155°C) to contain several minor and one major component: peak 1 (2.5%, 5.8 min) had ms fragments at *m/e* 149(25) and 70(100); peak 2 (6.5%, 6.9 min) had the same ms fragmentation pattern as that of authentic amine **2**; peak 3 (5.5%, 10.0 min) had ms fragments at *m/e* 146(57), 145(43), and 44(100); and peak 4 (59%, 11.1 min) had ms fragments at *m/e* 181(28), 167(19), 166(100), 96(20), 95(20), 94(29), and 82(35). The major component of this basic fraction (peak 4) was isolated by preparative scale gc (20% SE30, 135°C) to afford methoxy amine **14**: ir: 2765(m), 1225, 1095(s), 1020, 965, and 830 cm^{-1}; nmr τ: 6.65 (s, OCH_3), 6.71 (d, J = 4.5 Hz, H_d), 7.32 (dd, J = 9 and 4.5 Hz, H_b), 7.49 (s, N—CH_3), 7.65 (high-field portion of H_c doublet), and 7.8–9.0 (unresolved, 11H); ^{13}C nmr in benzene: 84.4(d), 67.3(d), 64.6(t), 55.9(q), 42.0(q), 35.6(d), 34.6(d), 32.8(t), 26.7(d), 19.5(t), and 17.7(t) ppm; ms: the pattern same as that of the peak 4 above. When the proton nmr spectrum was recorded in the presence of $Eu(fod)_3$ shift reagent a signal at τ 5.38, attributed to H_a originally at approximately τ 7.5, began to emerge from beneath the *N*-methyl signal. A doublet originally at τ 7.58 (J = 9 Hz, H_c) was clearly resolved in the presence of shift reagent. The picrate methoxyamine **14** was recrystallized three times from ethanol as yellow needles: mp 171–171.5°C. *Anal.* calcd. for $C_{17}H_{22}N_4O_8$: C 49.76, H 5.40, N 13.65; found: C 49.77, H 5.38, N 13.80.

A solution of *N*-chloramine **12** (2 g, 0.011 mol) in 60% aqueous dioxane was refluxed in the dark for 1.25 h until iodimetric titration showed the major part of **12** had disappeared. The solvent was evaporated and the acidic residue was worked up in the usual manner to give basic extract (1.14 g), a portion (1 g) of which was chromatographed on silica gel using methanol – ethyl acetate as eluent to give three main fractions. The second fraction eluted with 1–10% methanol in ethyl acetate was the starting amine (164 mg). The third fraction eluted with 50% methanol gave the tricyclic amino alcohol **13** (260 mg, 12%). Alcohol **13** was oxidized with a Jones' reagent to give ketone **11** which showed the identical ir, nmr, and mass spectra with those obtained above.

The first fraction (146 mg) eluted with ethyl acetate was rechromatographed to give a colorless oil which was contaminated with a small amount of the starting amine as shown by vpc and gave the following spectra data: ir: 1670(w), 1110(m), 852, 730, and 695 cm^{-1}; nmr τ: 3.75(m), 5.97 (d, J = 6.5 Hz, 1H), 6.35(m), 7.22 (d, J = 8 Hz, 1H), 7.45 (s, 3H), 7.60 (dd, J = 8 and 3 Hz, 1H), 8.0 (m, 2H), and 8.39 (m, 9H); gc–ms *m/e*: 187(10), 186(5), 185 (M^+, 31), 184(5), 150(66), 95(26), 94(100), and 82(49). The picrate of this compound decomposed on attempted recrystallization. The structure was not identified.

Syntheses of azapolycyclic compounds by aminium radical routes: trapping of the radical intermediates[1]

RICHARD A. PERRY, ROBERT W. LOCKHART,[2] MASAYUKI KITADANI,[3] AND YUAN L. CHOW

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received March 27, 1978

RICHARD A. PERRY, ROBERT W. LOCKHART, MASAYUKI KITADANI, and YUAN L. CHOW. Can. J. Chem. **56**, 2906 (1978).

Photolysis of three alkenyl nitrosamines in the presence of oxygen or bromotrichloromethane resulted in the interception of the intermediate *C*-radicals by these radical trapping agents and the reaction pathways were cleanly diverted leading to the formation of the nitrate esters or halides with pyrrolidine rings as the primary products. The *exo*-nitrates in the oxidative photolyses decomposed by secondary ionic pathways; these reactions were hydrolysis, nitrous acid elimination and a cleavage reaction (promoted by a β-amino group), among others. The efficiency of the cleavage reaction is controlled by a stereoelectronic factor that requires the participating bonds and the lone-pair nitrogen orbital be oriented in an antiperiplanar conformation. When such a conformation exists in a rigid or semiflexible framework, cleavage occurs extensively. However, in freely rotating acyclic systems, cleavage does not occur even when the required conformation can be attained. Only halides resistant to intramolecular nucleophilic displacement to form the aziridinium intermediates were isolated in the bromotrichloromethane trapping experiments. Other *exo*-halides underwent solvolysis via aziridinium ion intermediates.

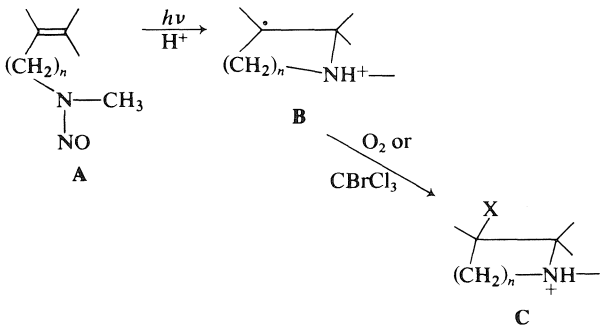
RICHARD A. PERRY, ROBERT W. LOCKHART, MASAYUKI KITADANI et YUAN L. CHOW. Can. J. Chem. **56**, 2906 (1978).

La photolyse de trois alkénylnitrosamines en présence d'oxygène ou de bromotrichlorométhane a donné lieu à l'interception des *C*-radicaux intermédiaires par ces pièges à radicaux et les chemins réactionnels ont été nettement déviés vers la formation d'esters nitrates ou d'halogénures avec des noyaux pyrrolidines comme produits primaires. Les nitrates *exo* en photolyse oxydante se décomposaient par voies ioniques secondaires; ces réactions étaient, entre autres, l'hydrolyse, l'élimination d'acide nitreux ou une réaction de clivage (favorisée par un groupe β-amino). L'efficacité de la réaction de clivage est sous le contrôle d'un facteur stéréoélectronique exigeant que les liaisons participantes et l'orbitale de l'azote renfermant la paire libre se trouvent dans des conformations antipériplanaires. Quand une telle conformation existe dans une structure rigide ou semiflexible, le clivage se produit bien. Cependant, dans les systèmes acycliques en rotation libre, le clivage ne se produit pas, même quand les conformations exigées peuvent exister. Les seuls halogénures isolés ont été ceux qui possèdent une barrière d'énergie élevée pour le déplacement nucléophilique intramoléculaire menant aux intermédiaires aziridinium. Les autres halogénures *exo* ont subi une solvolyse passant par l'intermédiaire de l'ion aziridinium.

[Traduit par le journal]

Introduction

As shown in the preceding report (2), applications of the intramolecular photoaddition of the alkenyl nitrosamines in the synthesis of azatricyclic compounds may be complicated by the ring-opening reaction promoted by a β-ammonium group partly due to cumulative ring strain. Since photoreaction occurs by a stepwise radical addition (3, 4), it is envisaged that the *C*-radical intermediate **B** might be intercepted by a suitable radical trapping reagent so that a stable and isolable azapolycyclic derivative could be obtained.



Efficient interception of a *C*-radical intermediate by oxygen in intermolecular photoadditions of nitrosamines (4–7), nitroamines,[4] and tetrazenes (8)

to olefins has been demonstrated: in the oxidative photoaddition of nitrosamine the mechanism has been assumed to follow [1]–[3] to give nitrate esters (7). The key step is the fast conversion of a *C*-radical to a peroxy radical (eq. [1]); the latter is much less reactive than the former. A peroxynitrite, the primary product in the present case, has recently been shown to rearrange spontaneously to the nitrate ester (eq. [3]) (9), although other decomposition pathways, such as elimination of HNO_2 to form a carbonyl compound, might also occur under the reaction conditions.

[1] $$R^{\bullet} + O_2 \rightarrow R{-}O{-}O$$

[2] $$R{-}O{-}O^{\bullet} + {}^{\bullet}NO \rightarrow R{-}O{-}O{-}NO$$

[3] $$R{-}O{-}O{-}NO \rightarrow R{-}O{-}NO_2$$

A good radical trapping agent in the present case should react sluggishly with electrophilic aminium radicals but vigorously with nucleophilic alkyl radicals. As well as oxygen, shown above, bromotrichloromethane is expected to fill the requirements since it has been shown to be a good bromine atom donor to alkyl radicals (10–14). Furthermore, owing to its polarity, its reaction with aminium radicals may not occur readily. This compound has been used in radical-initiated additions to olefins (15, 16) and brominations of alkyl groups (11–13) in which, under certain conditions (10), the chain carrier is the trichloromethyl radical. In the intramolecular nitrosamine photoaddition sequence, bromotrichloromethane may participate by the following mechanism (eqs. [4]–[5]) to give bromo derivatives and nitrosotrichloromethane as the products. As the trichloromethyl radical possesses electrophilic character, it is not expected to react with a proton-associated nitrosamine to regenerate an aminium radical as in [6].

[4] $$R^{\bullet} + BrCCl_3 \rightarrow RBr + {}^{\bullet}CCl_3$$

[5] $$^{\bullet}CCl_3 + {}^{\bullet}NO \rightarrow ONCCl_3$$

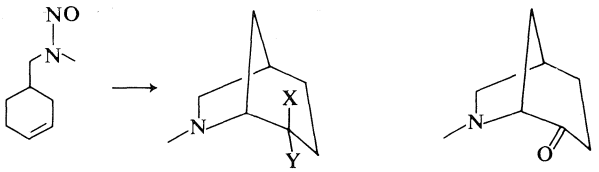
[6] $$^{\bullet}CCl_3 + R_2N{-}NO{-}{-}{-}H^+ \nrightarrow NOCCl_3 + R_2NH^{\ddagger}$$

On the basis of these assumptions, photolyses of some alkenyl nitrosamines possessing a double bond at the C_4—C_5 position were carried out in the presence of oxygen or of bromotrichloromethane.

Results

Trapping experiments with *C*-radical intermediates were first done using previously prepared (17) alkenyl nitrosamine **1** as a model compound. Photolysis, under oxygen, of a methanol solution of **1** in the presence of hydrochloric acid gave *endo*-nitrate **3** (15%), amino ketone **7** (31%), and *exo*-alcohol **4** (20%); the latter two were decomposition products of the primary products, the nitrates (or the pernitrite). Missing in the crude product was *exo*-nitrate **5** which was prepared from *exo*-alcohol **4** and was found to decompose readily on storage to give ketone **7**; decomposition was even faster in basic solution. In contrast, *endo*-nitrate decomposed to ketone **7** only in a sodium hydroxide solution but was stable on storage. Reduction of the crude product with lithium aluminium hydride followed by Jones' oxidation gave ketone **7** in 55% overall yield; the low yield was attributed to the volatility of alcohols **2** and **4** (*vide infra*) and poor yields from the Jones' oxidation. In a photolysis reaction carried out in the presence of perchloric acid, we failed to obtain salts of the amine nitrates by crystallization. This attempt also showed that the nitrate esters decomposed extensively during acid–base treatments of the crude products. A small amount of *endo*-alcohol **2** was also isolated in this reaction.

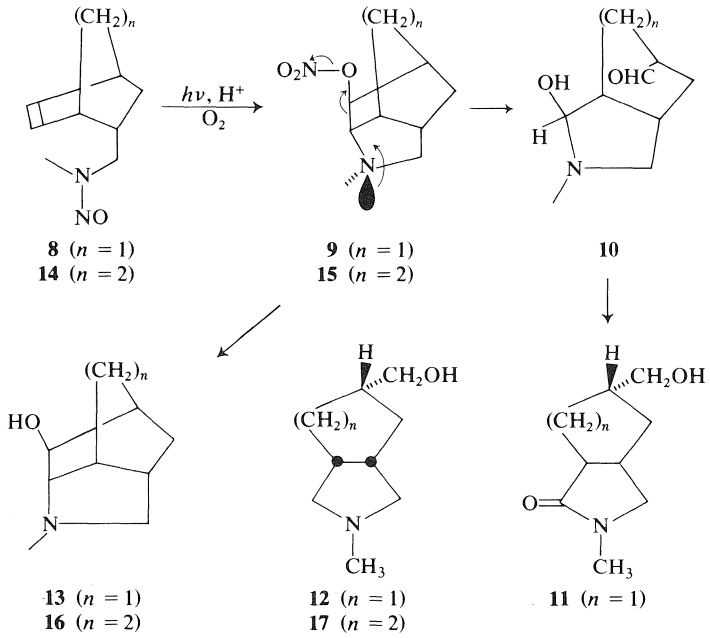
Both *exo*-alcohol **4** and *endo*-alcohol **2**, particularly the latter, codistilled with the solvents during evaporation and were oxidized readily to previously identified ketone **7** (17). The remarkable volatility of



1 **2** X = H; Y = OH; **3** X = H; Y = ONO_2; **4** X = OH; Y = H; **5** X = ONO_2; Y = H; **6** X = H; Y = Br; **7**

endo-alcohol **2** might arise from the *cis* orientation of the proximate functional groups facilitating intramolecular hydrogen bonding; such peculiar properties have been noticed by others (18) in azabicyclic alcohols. The *endo*-nitrate **3** showed the typical ir absorptions for nitrate at 1620, 1275, and 860 cm^{-1} and an nmr signal at τ 5.25 for the axial proton of C*H*—ONO_2. This compound was reduced with lithium aluminium hydride to *endo*-alcohol **2**.

Photolysis of nitrosamine **1** in a mixture of methanol–bromotrichloromethane (25%) containing hydrochloric acid gave rise to a blue solution. The compound showing the blue color (λ_{max} 580 nm) codistilled with the solvents and was assumed to be trichloronitrosomethane monomer (19), by analogy to the assignment made in nitrite photolysis in the presence of this trapping agent (20). The neutral fraction contained a major product having the molecular formula Cl_2CNOH as shown by gc–ms analysis; this species was believed to be phosgene oxime derived from trichloronitrosomethane. The



basic fraction was almost pure *endo*-bromide **6** (55%) and exhibited the axial C*H*—Br proton at τ 5.98 as a double doublet of a doublet. The corresponding *exo*-bromide was not obtained in spite of careful searching. These radical-trapping experiments demonstrate that the expected products were formed in the photolysis, as outlined above, but that some of them might have decomposed by secondary pathways.

Photolysis, under oxygen, of *N*-nitroso-2-*endo*-methylaminomethylbicyclo[2.2.1]hept-5-ene (**8**) (2), containing ca. 30% of the corresponding *exo*-isomer, gave a basic fraction exhibiting strong ir absorptions for nitrate at 1620 and 1275 cm^{-1} and for carbonyl at 1720 cm^{-1}; an aldehyde proton nmr signal at τ 0.25 was also observed. Since the basic fraction decomposed gradually, freshly obtained crude product was reduced with lithium aluminium hydride to afford tricyclic alcohol **13** (12%), the known bicyclic alcohol **12** (40%), and some unknown olefinic amines. The OH group in **13** was assumed to be in the *exo*-orientation from the narrow nmr signal at τ 5.90 for the C*H*OH proton which should couple weakly to the vicinal protons (6). Continuous extraction of the aqueous phase of the reduction mixture afforded lactam **11** (2). This indicates that ring scission has occurred, as in **9** → **10**, and is similar to what is observed in the oxidative photoaddition of *N*-nitrosamine to norbornene (6), as well as in the intramolecular redox reaction **10** → **11** (2). It is likely that under strongly basic LAH reduction conditions, aldehyde **10** is rapidly transformed to lactam **11** which is reduced further to **12**. However, direct reduction of **10** → **12** cannot be entirely discounted.

In view of the observed extensive decomposition described above, the crude basic products from the oxidative photolysis of *N*-nitroso-2-*endo*-methylaminomethylbicyclo[2.2.2]oct-5-ene (**14**) were immediately LAH reduced to give tricyclic alcohol **16** (13%) and a compound tentatively assigned as bicyclic alcohol **17** (13%), in addition to some unknown olefinic amines. Alcohol **16** was oxidized to the corresponding ketone which has been synthesized previously (2); the *endo*-orientation of the C*H*OH proton was inferred from the similarity of the coupling pattern to that of the methoxy derivative, the stereochemical structure of which has been determined by X-ray crystallography (2).

Bicyclic alcohol **17** is a homologue of **12** and is believed to be formed by cleavage and redox pathways analogous to those of **9** → **10** → **11** → **12**. However, in the present case the lactam corresponding to **11** was not isolated and a redox process similar to **10** → **11** has not been substantiated. The nmr multiplet at τ 6.50 was attributed to the magnetically nonequivalent CH_2OH protons and that at τ 7.0–7.7 overlapping with the *N*—CH_3 singlet (τ 7.62) was due to the four CH_2—N protons. Although these and the ir data are in agreement with **17** they are not unambiguous proof of the structure.

Photolysis, under nitrogen, of nitrosamine **8** in a heterogeneous mixture of trichlorobromomethane and hydrochloric acid produced the typical blue color and gave a basic fraction which showed a major and minor product on tlc analysis. The nmr spectrum was essentially that of bromoamine **18** with weak signals due to chloroamine **19**. Both compounds **18** and **19** were isolated as oils by chroma-

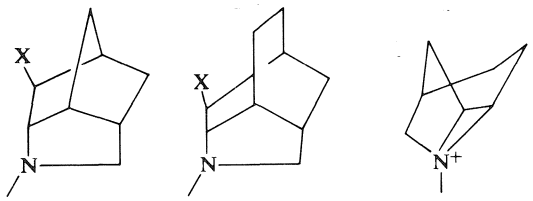
tography but attempts to purify them by preparation of derivatives and/or by distillation caused extensive decomposition. Both **18** and **19** exhibited the strong high resolution ms M^+ peaks corresponding to their molecular formulae and narrow nmr signals at τ 6.15 and 6.25 for the *endo*-protons of the C*H*—X group, in agreement with the corresponding signal for the alcohol **13**. Furthermore, the spectra[5] of **19** were identical with those of the chloro compound obtained from the Ag_2O-catalysed decomposition of *N*-chloramine.

A similar photolysis of nitrosamine **14** in the presence of trichlorobromomethane, followed by the usual basic work-up in aqueous solution, however, gave a low yield of the basic fraction. Analysis by gc–ms showed that the major products were the parent alkenylamine and bromine-containing amines, in addition to some olefinic amine. The amine fraction containing bromine, however, decomposed rapidly during work up. The crude product obtained after evaporation of solvent was examined by nmr in trifluoroacetic acid. That the expected product of bromoamine **20** was formed in a relatively good yield in this acidic photolysis was indicated by the fairly clean nmr spectrum, and a narrow signal at $\tau \sim 5.6$ for the C*H*Br proton. The reaction of this residue with sodium methoxide in methanol, however, gave a low yield of basic fraction which contained methoxy amine **21** (ca 20% yield) as the major product and a number of minor components as shown by a complex vpc spectrum.



18 X = Br
19 X = Cl

20 X = Br
21 X = OCH_3

22

The substituted azatricyclic compounds **13**, **16**, **18**, **19**, and **21** exhibited nmr signals for the protons vicinal to the nitrogen in the expected range of ca. τ 7.0; a nicely resolved 250 MHz nmr spectrum of **21** has been published by Waegell and co-workers (21). The methine protons of all these compounds were observed as doublets with weak couplings ($J = 4 \sim 4.5$ Hz). The magnetically nonequivalent methylene protons appeared as doublets and double doublets with geminal coupling constants of $8 \sim 10.5$ Hz. However, the chemical shifts of the corresponding protons in these compounds varied considerably depending on the nature of the substituent groups. Correlations of the coupling patterns with structural assignments by application of the Karplus relation were frustrated by the unknown anisotropic factors of the substituents.

The addition of iodine as a radical-trapping agent in the photolysis of **1** was not successful owing to the internal filter effect of iodine which has an intense absorption at ca. 350 nm. Additions of carbon tetrachloride and tributyltin hydride as trapping agents also gave unsatisfactory results.

Discussion

In the photolysis of alkenylnitrosamines in acidic solution, the corresponding aminium radicals cyclize exclusively to form the *C*-radicals with a pyrrolidine ring, presumably owing to better overlapping of the reacting orbitals. This propensity to five-membered ring formation has been well established not only in nitrosamine cyclizations (2, 17) but also in *N*-chloramine cyclizations under acidic conditions (18, 22); only one exception has been reported so far (23). The *C*-radicals are trapped by oxygen or bromotrichloromethane according to the sequence outlined in the Introduction to give the nitrates and bromides. As this is a stepwise radical reaction, both *endo* (*cis*)- and *exo*(*trans*)-isomers of the nitrate and bromide are expected to be formed in photocyclization of nitrosamine **1**. The latter formation is probably favored in view of predominate *trans*-addition of nitrosamines to cyclohexene derivatives under acidic conditions (25). Edwards *et al.* (24) have reported that the thermolysis of *N*-chloro-*N*-methyl-3-cyclohexenylmethylamine (**1**, NO = Cl) in methanol gives both *exo*- and *endo*-chloro derivatives from the five-membered cyclization (i.e., **3**, X = H, Y = Cl; and **5**, Y = Cl, X = H) as the primary products by the amino radical route; the former is believed to rearrange via the aziridinium ion (**22**) (25–27) to give the *exo*-methoxy derivatives with bicyclo[2.2.1] (**3**, X = H, Y = OCH_3) as well as bicyclo[2.2.2] skeletons; the yield of the latter is slightly higher. In the present case, failure to isolate *exo*-nitrate **5** and the *exo*-bromide (**5**, ONO_2 = Br) indicates that these compounds also rearrange via aziridinium intermediate **22** by a mechanism similar to that suggested by Edwards *et al.* (24). The *exo*-bromide from the $CBrCl_3$ trapping experiment may have decomposed extensively during the rearrangement on neutralization with an aqueous sodium carbonate solution. A similar rearrangement (24) of *exo*-nitrate **5** is expected to give **4** and the corresponding amino alcohol with the bicyclo[2.2.2] skeleton when carried out under basic conditions; the latter has not been detected, presumably owing to its solubility in water. Although eliminations of HNO_2 from these types of nitrate esters to form ketones are known (6), the

[5]The authors are grateful to Professor B. Waegell who has compared our spectra with his.

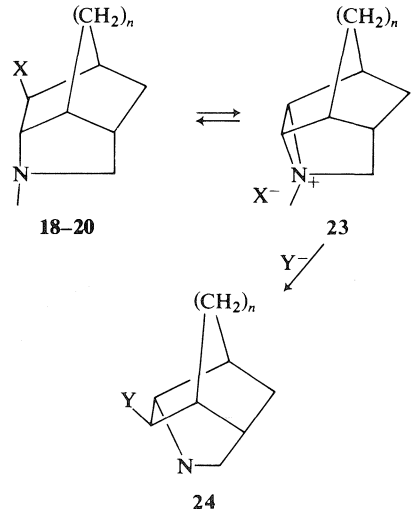
For personal use only.

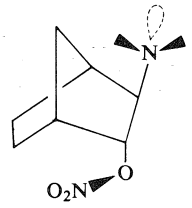
decomposition of **5** to form ketone **7** might be particularly enhanced by the orientation of the functional group. It is suspected that the proximate amino lone-pair electrons act as the receptor for the departing proton. Although the results are in general agreement with the predictions, there are certain differences between the results observed in the present case and those of Edwards *et al.* (24); these differences could arise from a dissimilarity in the solvolytic conditions.

The isolation of tricyclic haloamines **18** and **19** following photolysis of nitrosamine **8** in the presence of bromotrichloromethane is a useful alternative method of building this tricyclic skeleton because of the facile cleavage pathways in the photolysis under nitrogen and oxygen. While excessive heating of these haloamines causes decomposition, their rigid framework prevents aziridinium ion (**23**, $n = 1$) formation, even though the halo and amino groups are oriented in an *anti*-configuration. By analogy to the acidic photolysis of nitrosamines described in this and the preceding paper, the stable protonated bromoamine **20** was probably formed in good yield, judging from the fairly clean nmr spectrum of the crude residues remaining after evaporation of the photolysates. Neutralization with aqueous sodium carbonate causes extensive rearrangement giving a mixture in low yield. The instability of bromoamine **20**, in contrast to **18** and **19**, might arise from the ease of formation of aziridinium ion **23** ($n = 2$) since the bicyclo[2.2.2] system is relatively flexible. It is envisaged that aziridinium intermediate **23** ($n = 2$), if intercepted by a strong nucleophile such as methoxide anion, might open up to the strain-free azatwistane skeleton **24** ($n = 2$, X = OCH_3) which might be less susceptible to solvolysis (2). As discussed previously (2), the opening of aziridinium ion

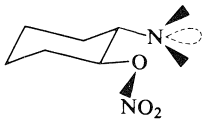


23 ($n = 2$) by methoxide ion is not expected to favor the formation of **21** owing to steric reasons. The low yield of **21** in the solvolysis of **20** is in agreement with this assumption. However, as the major part of the remaining material decomposed to a complex mixture, it might be suspected that methoxy azatwistane **24** (X = OCH_3, $n = 2$) and allied compounds, if formed at all, are susceptible to solvolytic rearrangement under the isolation conditions. Alternatively,[6] it might be speculated that the transition state of a nucleophilic attack on **23** ($n = 2$) shifts (or tunnels) to other energy surfaces before collapsing to **24**. Derivatives of another type of azatwistane have been shown to rearrange readily on solvolysis (19).

The nitrate esters obtained from the oxidative photoreactions of **8** and **14** may have the *exo*-orientation exclusively, since the *endo*-approach of a trapping agent is considerably hindered. The alcohols isolated after LAH reduction in both cases contain only the *exo*-isomers **13** and **16** although the yields are low. The low yields are due to the facile amino-group-assisted cleavage reaction of the nitrates **9** and **15** to give the bicyclic aldehydes **10**, which occurs in the free bases but not in the protonated forms as in the nitrosamine cleavage reaction (2). This reaction is another case of a stereoelectronically assisted rearrangement, the general principles of which have been described by Deslongchamps (29).



25



26

In the *exo*-nitrates **9** and **15**, the antiperiplanar orientation of the lone-pair electron orbital of the amine center and the departing NO_2 moiety, with respect to the cleaving C—C bond, satisfies nicely the stereoelectronic requirements for the rearrangement. The photoaddition of *N*-nitrosodimethylamine to norbornane and cyclohexene in the presence of oxygen (6), yields 2-*exo*-dimethylamino-3-*endo*-nitratonorbornene (**25**) and *trans*-1-dimethylamino-2-nitratocyclohexane (**26**), respectively; we have shown that the same cleavage reaction under basic conditions occurs more extensively with the former than

[6]We acknowledge, with appreciation, a referee's suggestion that, in the transition state of the opening of the aziridinium ring, a nucleophile would select *the weaker* bond giving **21** rather than **24** owing to the unsymmetrical nature of the aziridinium ion **23** ($n = 2$). On inspecting the Dreiding Models, it is uncertain which N—C bond is weaker since the bicyclo[2.2.2] system is semiflexible.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the latter and is facilitated by a *trans* orientation of the functional groups. Again, the antiperiplanar orientation of the relevant electron pairs and bonds in a rigid and a semiflexible framework fulfills the stereoelectronic requirement for ejection of the nitrite group.

For acyclic 1-dimethylamino-2-nitratohexane, obtained from acidic photoaddition, under oxygen,[4] no such cleavage reaction is observed although the functional groups can rotate freely about the relevant bonds to assume an antiperiplanar conformation. It might be concluded that the observed amino-group-assisted cleavage reaction occurs more easily when the nitrogen lone-pair orbital is in the antiperiplanar conformation with respect to the relevant bonds and is held in a rigid framework. Obviously the rigidity decreases in the order **9** > **15** > **25** > **26** and the extent of cleavage also decreases qualitatively in the same order.

Experimental

The general experimental conditions are the same as those described in the preceding paper (2).

N-*Nitroso*-N-*methyl-3-cyclohex-1-ylmethylamine* (**1**) *Under* O_2

(*a*) Nitrosamine **1** (1 g, 6 mmol) (17) in methanol (225 ml) containing concentrated HCl (0.6 ml) was photolyzed for 3.5 h while oxygen gas was bubbled through the solution. The uv spectra showed no *C*-nitroso peak at ca. 290 nm. Following the normal work-up procedure (6, 7), the photolysate was evaporated and the residue was taken up and washed with ether to afford neutral fractions. The aqueous layer was made basic with Na_2CO_3 solution and was extracted with CH_2Cl_2. This gave unreacted nitrosamine (0.18 g) in the acidic fraction and basic material (0.64 g). The remaining basic aqueous solution was continuously extracted with ether to afford only a small amount (< 10 mg) of material.

A portion of the basic material (0.42 g) was chromatographed on basic alumina (50 g) and elution with 1% MeOH–CH_2Cl_2 gave *endo*-nitrate **3** (0.07 g): ir: 2940, 2860, 2790, 1620, 1450, 1275, 860; nmr τ: 5.25 (ddd, J = 10, 6, and 2 Hz, 1H), 6.80 (bd, J = 6.5 Hz, 1H), 7.0–7.6 (m, 2H), 7.53 (s, 3H), 7.6–8.8 (m, 7H); ms (75°C) *m/e* (%): 186 (M^+, 0), 140 (14), 138 (14), 124 (7), 96 (21), 82 (100), 58 (43), 55 (29), 42 (57), 41 (59). The next three fractions (0.18 g), eluted with 1–3% MeOH–CH_2Cl_2, contained aminoketone **7**, with a minor amount of nitrate **3**. Eluted with 10–50% MeOH in CH_2Cl_2 was *exo*-alcohol **4**: 0.1 g; ir: 3350 (b), 2940, 2860, 2790, 1450, 1005; nmr τ: 6.10 (bt, J = 5 Hz, 1H), 6.5 (s, D_2O exchangeable), 6.9–7.4 (m, 3H), 7.50 (s, 3H), 7.51–8.7 (m, 7H); ms 141 (M^+, 18), 96 (15), 82 (100), 42 (15). Jones' oxidation of *exo*-alcohol **4** gave ketone **7** (53%), which was identical with the previously prepared sample (17). The yields after chromatography, based on reacted nitrosamine (0.82 g), were *endo*-nitrate **3**, 15%; ketone **7**, 31%; and *exo*-alcohol **4**, 20%. The yields, estimated from the nmr spectrum of the crude basic fraction, were 15, 35, and 45%, respectively.

The ir absorption (1620 cm^{-1}) of *endo*-nitrate **3** was not significantly decreased relative to that (1720 cm^{-1}) of ketone **7** when a mixture (1:1.6 ratio) was examined either after storage for 2 months (25°C) or after being stirred with 0.5 *N* HCl for 21 h at 25°C. Treatment with 0.7 *N* NaOH aqueous solution for 21 h caused a decrease in the nitrate peak relative to the ketone peak (ir ratio 1:2.2). *endo*-Nitrate **3** was relatively stable in pyridine but decomposed more when treated with 5 *N* NaOH for 1.5 h to give a 1:3 ratio of the nitrate to ketone ir absorption intensities.

Reaction of *exo*-alcohol **2** for 0.75 h with concentrated HNO_3 (0.25 ml) in concentrated H_2SO_4 (0.6 ml), followed by basification and extraction, gave an impure nitrate: ir: 1720 (w), 1620, 1275, 860. The ratio of product ir peaks at 1715 and 1620 cm^{-1} was 1:1.2 after 20 h at 25°C and 3:1 after 2 months.

LAH (0.8 g) reduction of the basic fraction (0.21 g) in ether for 28 h at 25°C, followed by removal of the solvent through a Vigreaux column gave a mixture of *endo*- and *exo*-alcohols **2** and **4** in the ratio of 1:1.25 as shown by vpc analysis. A Jones' oxidation of this mixture (0.059 g) produced ketone **7** (0.032 g, 55%). LAH reduction of *endo*-nitrate **3** (0.05 g) gave *endo*-alcohol **2** (0.020 g) as the hydrochloride after continuous extraction with CH_2Cl_2.

(*b*) Nitrosamine **1** (3 g, 0.019 mol) in MeOH (220 ml) containing 70% $HClO_4$ (3 ml, 0.02 mol) was photolyzed for 4.5 h and the solvent was evaporated. All attempts to crystallize perchlorate salts from a variety of solvents failed.

The crude photolysate was basified, extracted with benzene, and was worked up in the usual manner to give a basic fraction (1.53 g). The aqueous phase was extracted with CH_2Cl_2 and worked up to give a mixture which was separated into ether soluble and CH_2Cl_2 soluble compounds. The ether soluble material (0.11 g) was found by gc (125°C) to contain 50% *endo*-alcohol **2** (12.4 min), 40% *exo*-alcohol **4** (13.5 min), and 10% of an unknown compound. The CH_2Cl_2 soluble fraction was shown to contain the HCl salt of *endo*-alcohol **2**: ir: 3500 (b), 3050 (b, m), 2950, 2880, 2005 (w), 1450, 1100 (b); nmr (D_2O) τ: 6.3 (m, 1H), 6.5–6.8 (m, 2H), 6.88 (s, 3H), 7.4–7.9 (m, 5H), 8.05–8.6 (m, 3H); ms (170°C): 141 (M^+, 28), 97 (26), 96 (37), 82 (100), 55 (11), 42 (26). Jones' oxidation of this salt gave ketone **7** (50%, *vide supra*).

The major basic fraction, obtained above, was chromatographed on neutral alumina (70 g). The fractions eluted with 1% MeOH in CH_2Cl_2 (0.49 g) contained *endo*-nitrate **3** as the major component. Continued elution with the same eluant gave a mixture (0.3 g) of nitrate **3** and ketone **7**. Using 2% MeOH–CH_2Cl_2, a mixture (0.16 g) of nitrate, ketone, and *exo*-alcohol **4** was obtained. The remaining fractions (0.5 g), eluted with 5–50% MeOH–CH_2Cl_2, contained *exo*-alcohol **4** (*vide supra*).

The total yields of the various products were 0.3 g of neutral products, 0.55 g of *endo*-nitrate **3** (15%), 0.3 g of ketone **7** (11%), 0.8 g of *exo*-alcohol **4** (29%), and 0.3 g of the hydrochloride salt of *endo*-alcohol **2** (9%).

Photolysis of **1** *in the Presence of* $BrCCl_3$

Nitrosamine **1** (0.95 g, 6 mmol) and concentrated HCl (1.7 ml) in a mixture of $BrCCl_3$ (42 ml, 100 g) and MeOH (170 ml) were photolyzed for 3 h to give greenish yellow solution. After removal of the solvent through a Vigreaux column, the residue was separated into acidic/neutral material (0.12 g) and basic material (0.69 g) using a Na_2CO_3 solution to make the solution basic in the usual fashion. Further, continuous extraction of the basic aqueous phase with ether yielded a small amount (< 15 mg) of an oil which was discarded. The distilled solvent had a light blue color (λ_{max} 580 nm) which disappeared after 2 weeks of refrigerated storage.

The basic residue contained one major component (> 98%, retention time 12.9 min) and a minor component (retention time 8.7 min) when examined by gc (135°C). The major product also showed one peak on programmed temperature gc and was distilled to give *endo*-bromoamine **6** (55%): ir: 2940, 2860, 2840, 2780, 1450, 765 (m); nmr τ: 5.98 (ddd, J = 9, 7.5,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and 1.5 Hz, 1H), 6.75–7.2 (m, 2H), 7.47 (s, 3H), 7.4–8.7 (m, 8H); ms: 205 (M^+, ^{81}Br, 22), 203.0304 (M^+, *calcd.* for $C_8H_{14}N^{79}Br$: 203.0310, 22), 124 (56), 82 (100), 42 (27).

The acidic/neutral fraction was shown to be composed of five principal components by gc analysis (120°C), with one being the major (64%) component (2.3 min): gc–ms analysis showed that the major peak could be phosgen oxime: 115 ($^{35,37}Cl$, 65), 113 ($^{35}Cl_2$, 87), 98 (11), 96 (15), 80 (46), 79 (35), 78 (100), 77 (74), 63 (11), 61 (30), 47 (13), 43 (22). The distilled blue solvent showed a peak which corresponded to a minor peak of the neutral fraction and was assumed to be that due to trichloronitrosomethane.

Photolysis of Nitrosamine ***8***

Under Oxygen

A solution of *N*-nitrosamine **8** (2 g, 0.011 mol) and concentrated HCl (1.0 ml, 0.06 *N*) in methanol (200 ml) was photolysed under oxygen for 3 h. The usual work-up gave a neutral fraction (130 mg); ir: 3350 (m, br), 3055 (w), 1715 (w), 1640 (m), 1550 (m) cm^{-1}; nmr τ: 0.20 (d, J = 2.5 Hz), 3.90 (m). The mother liquor was basified and extracted with CH_2Cl_2 (3 × 50 ml) which was dried and evaporated to a crude basic residue (1.8 g): ir: 3300 (w, br), 3060 (w), 1720 (m), 1670 (m), 1620 (s), 1275 (m), and 865 (m) cm^{-1}. After 24 h the ir band at 1720 cm^{-1} became stronger relative to the others.

In a similar experiment the basified mother liquor was extracted with ether (4 × 50 ml); the extracts were dried and immediately treated with LAH (2 g), and on work up gave a yellow oil (*A*, 1.2 g). The aqueous layer was further extracted with CH_2Cl_2 (3 × 50 ml) to give oil *B* (130 mg). Finally, the aqueous layer was continuously extracted with CH_2Cl_2 for 3 days to afford crude hydroxy lactam **11** (180 mg): ir: 3380 (s, br), 1655 (s), 1065, 1040, and 1020 (m) cm^{-1}; nmr τ: 6.45 (m, 3H) and 6.92 (dd, J = 10 and 1 Hz, 1H) (2).

Oil *A* (1.0 g) was chromatographed on neutral alumina (50 g). Elution with 0.4% methanol–CH_2Cl_2 gave a crude olefinic alcohol (110 mg): ir: 3380 (m), 3055 (m), 1660 (w), 1030 (m), 778, and 705 (s) cm^{-1}; ms *m/e*: 124 (8), 106 (6), and 66 (100); nmr τ: 3.93 (m, 2H), 6.40 (dd, J = 6 and 2 Hz, 1H), 7.05 (m, D_2O exchangeable), 7.22 (m, 3H), 7.75 (m, 3H), and 8.70 (m, 5H). Elution with 1% methanol–CH_2Cl_2 gave an unidentified mixture (200 mg). Elution with 2% methanol–CH_2Cl_2 gave an oil (267 mg, 30%) which was distilled at 25°C/0.5 Torr to give bicyclic amino alcohol **12**; the ir, nmr, and mass spectra were superimposable on those of an authentic sample (2). The picrate of **12** was recrystallized twice from ethanol to give yellow needles, mp and mp on admixture with an authentic sample (2) 138–139°C. Continued elution with 3–5% methanol–CH_2Cl_2 gave tricyclic amino alcohol **13** (216 mg, 12.5%): ir: 3350 (s, br), 1650 (w), 1130, 1040 (m), and 1015 (s) cm^{-1}; nmr τ: 6.31 (m, $W_{1/2}$ = 3.5 Hz, H_d), 7.05 (m, D_2O exchangeable), 7.27 (m, 3H), 7.50 (s, N—CH_3), 7.68 (m, 1H), 7.90 (m, 3H), 8.2–9.1 (m, 4H); ms *m/e*: 154 (4), 153 (M^+, 37), 152 (7), 136 (12), 124 (22), 96 (91), 95 (36), 94 (100), 82 (62), 57 (45); nmr (HCl salt) τ: 5.28 (m, D_2O exchangeable), 5.90 (m, $W_{1/2}$ = 3 Hz, H_d), 6.69 (d, J = 5 Hz, H_a), 6.72 (d, J = 10.5 Hz, H_c), 7.02 (dd, J = 10.5 and 5 Hz, H_b), 7.20 (s, N—CH). The picrate of **13** was recrystallized three times from ethanol, mp 185–187°C. *Anal.* calcd. for $C_{15}H_{18}N_4O_8$: C 47.12, H 4.76, N 14.65; found: C 46.84, H 4.66, N 14.55.

Basic extract *B* (95 mg) was reduced with LAH (2 g) in THF (200 ml) and was worked up and purified in the usual manner to give a crude amino alcohol **12** (46 mg, 55%).

In the Presence of Bromotrichloromethane

A mixture of nitrosamine **8** (1 g, 0.006 mol), concentrated HCl (0.55 ml), and $CBrCl_3$ (100 ml) was photolysed under N_2 for 2 h. The fluorescent blue mixture was removed under vacuum and the residue was separated into neutral (350 mg) and basic (666 mg) fractions. The neutral fraction exhibited no *N*-methyl signal in the nmr spectrum. The basic fraction exhibited only one major spot at R_f 0.37 and a faint spot at R_f 0.19 on a silica gel tlc plate (10% methanol–CH_2Cl_2); the nmr spectrum was essentially that of **18** (ca. 90%) with weak signals of **19**. Silicic acid chromatography (1% methanol–CH_2Cl_2) of this fraction (500 mg) afforded an oily bromo amine **18** (148 mg); ir: 1185, 1165 (s), 935 (s), and 6.90 (s) cm^{-1}; nmr τ: 6.15 (m, $W_{1/2}$ = 4 Hz, H_d), 6.56 (d, J = 4.5 Hz, H_a), 7.10 (dd, J = 9.5 and 5 Hz, H_b), 7.50 (d, J = 9.5 Hz, H_c), 7.50 (s, superimposed on doublet, N—CH_3), 7.80 (m, 2H), and 8.4–9.0 (m, 3H); ms *m/e* (%): 217 (16), 215.0310 (M^+, calcd. for $C_9H_{14}N^{79}Br$: 215.0295, 16), 136 (100), 96 (38), 95 (27), 94 (100), and 82 (30).

The bromo amine **18** gave a dark tar on attempted vacuum distillation and the picrate derivative (mp 180–190°C, dec.) decomposed on repeated recrystallization.

The minor component (ca. 5% of the major component) of the basic fraction was isolated by preparative scale vpc (6 ft × ¼ in., 20% SE30, 150°C, retention time 10.8 min) as an oily chloro amine **19**: ir 1630 (vw), 940 (m), and 740 (m) cm^{-1}; nmr τ: 6.25 (m, $W_{1/2}$ = 3.5 Hz, H_d), 6.80 (d, J = 5 Hz, H_a), 7.10 (dd, J = 9.5 and 5 Hz, H_b), 7.50 (d, J = 9.5 Hz, H_c), 7.50 (s, superimposed on the doublet, N—CH_3), 7.80 (m, 3H), and 8.0–9.0 (m, 3H); ms *m/e* (%): 173 (10), 171.0825 (calcd. for $C_9H_{14}NCl$: 171.0814, 30), 136 (85), 96 (46), 95 (29), 94 (100), and 82 (19).

Photolysis of N*-Nitrosamine* ***14***

Under Oxygen

A solution of nitrosamine **14** (2 g, 0.011 mol) and concentrated HCl (1.0 ml, 0.06 *N*) in methanol (200 ml) was photolysed under oxygen for 1.5 h. The work-up gave an oily neutral fraction (80 mg). The aqueous solution was basified and extracted with ether (3 × 50 ml). The ether solution was dried and stirred overnight with LAH (2 g). Work-up in the usual way gave the reduced product (980 mg). The aqueous layer was further extracted with CH_2Cl_2 (3 × 50 ml) to give an additional basic extract (420 mg): ir: 3380 (m, br), 3040 (m), 1700 (s), 1625 (s), 1270 (m), and 1050 (m) cm^{-1}; nmr τ: 6.2 (m), 6.67 (s), 7.15 (m), 7.48 (s), 7.6 (m), and 8.2 (m).

The reduced extract (980 mg) was chromatographed on neutral alumina (50 g). Elution with 0.5% methanol–CH_2Cl_2 gave an olefinic fraction (340 mg); ir: 3040 (m) and 692 (s) cm^{-1}; nmr τ: 3.70 (m). Examination of this fraction by gc–ms (20% SE30, 170°C) showed it to contain the parent amine, **16**, and **17**, and an unknown olefinic compound as the major component. Elution with 1% methanol–CH_2Cl_2 gave bicyclic amino alcohol **17** (254 mg, 13%) which distilled at 30°C/0.05 Torr: ir: 3350 (s, br) and 1040 (s) cm^{-1}; nmr τ: 6.58 (m, 2H), 7.0–7.75 (m, 4H), 7.62 (s, N—CH_3), 7.8–8.2 (m, 2H), and 8.4 (m, 6H); ms *m/e* (%): 169.1446 (M^+, calcd. for $C_{10}H_{19}NO$: 169.1467, 33), 168 (38), 152 (10), 138 (45), and 57 (100). Irradiation at τ 8.4 resulted in collapse of the pattern at τ 6.58 to a broadened singlet ($W_{1/2}$ = 4 Hz). Attempts to prepare the *p*-nitrobenzoate and picrate derivatives of **17** were unsuccessful.

Elution with 2% methanol–CH_2Cl_2 gave *exo*-amino alcohol **16** (269 mg, 13%) as an oil which on sublimation at 30°C/0.05 Torr gave white crystals: mp 73–74°C; ir: 3350 (s, br), 1052 (s), 1025 (s), and 980 cm^{-1}; nmr τ: 6.01 (m, D_2O exchangeable), 6.20 (d, J = 4 Hz, 1H), 7.19 (d, J = 4.5 Hz, 1H), 7.26 (d, J = 10 Hz, 1H), 7.47 (dd, J = 10 and 4.5 Hz, 1H), 7.48 (s, N—CH_3), 8.0 (m, 2H), 8.20 (m, 3H), 8.67 (m, 1H), and 8.85 (m, 1H); ms *m/e* (%): 168 (11), 167.1302 (M^+, calcd. for $C_{10}H_{17}NO$: 167.1310, 77), 166 (29), 150 (16), 110 (71), 97 (17), 96 (21), 95 (60), 94 (100), and 82 (100). Irradiation at τ 8.0 resulted in collapse of the doublet at τ 6.20 to a singlet and coalescence of the doublet at τ 7.19.

Treatment of **16** with a saturated benzene solution of picric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

acid gave a picrate (yellow needles, slow decomposition 160–200°C) which decomposed on repeated attempts at recrystallization. An acetone solution (3 ml) of amino alcohol **16** (65 mg) was treated with CrO_3–H_2SO_4 in acetone at 0°C. The green solution was stirred for 1.5 h. The acetone was evaporated and the residue was basified with aqueous Na_2CO_3 and extracted with CH_2Cl_2 (4 × 15 ml) to give a clear oil (25 mg). The nmr and ir spectra of this oil were identical with those of the corresponding ketone isolated previously (2).

In Bromotrichloromethane

A mixture of nitrosamine **14** (0.5 g, 0.0028 mol), concentrated HCl (0.3 ml), and $CBrCl_3$ (100 ml) was photolysed under N_2 for 2.75 h. The mixture was distilled under vacuum at 20°C and the blue distillate was trapped in a cooled receiver. The neutral extract (204 mg) was a mixture of at least six components as determined by vpc and exhibited no *N*-methyl signal in the nmr. The basic fraction (205 mg) had the following physical constants: ir: 3300 (w, br), 3040 (m), 1720 (w), 1660 (w), 1162, 950, and 700 (m) cm^{-1}; nmr τ: 3.75 (m), 5.60 (m), 5.80 (m, D_2O exchangeable), and 7.0–9.0 (unresolved). Analysis of this fraction by gc–ms (20% SE30, 150°C) showed three peaks in the ratio of 1.2:4.1:1.0; peak 1 (3.2 min) was not identified; peak 2 (3.5 min) exhibited an ms pattern identical to that of the parent amine; and peak 3 (9.3 min) which exhibited ms fragments at *m/e*: 231 (7), 229 (7), 150 (46), 94 (100), and 82 (40). An attempt to isolate the third component by silicic acid chromatography was unsuccessful.

In a separate experiment, a solution consisting of nitrosamine **14** (4.9 g), methanol (120 ml), concentrated hydrochloric acid (3.5 ml), and $CBrCl_3$ (230 ml) was irradiated at −20°C until the absorption maximum at 350 nm disappeared. The photolysate was rapidly evaporated to dryness. The nmr spectrum of this residue in trifluoroacetic acid showed a narrow signal ($W_{1/2}$ = 4 Hz) at τ ~ 5.6. To the residue (4.7 g) taken up in methanol (10 ml) was added with sodium methoxide (10%) in methanol until strongly alkaline to litmus tests. The basic solution was worked up in the usual manner to afford brown crude basic fraction (2.7 g). The vpc spectrum of this crude oil showed one major peak corresponding to **21** (yield, ca. 20%) and at least 40 minor peaks. Chromatography of this oil in benzene–ether gave a forerun (230 mg) followed by a mixture; the forerun was distilled to give methoxy amine **21**; picrate mp and mixture mp 171.5–172.5°C (2).

Received May 9, 1978

DOUGLAS C. ROHRER, JEAN-CLAUDE FISCHER, DEREK HORTON, and WOLFGANG WECKERLE. Can. J. Chem. **56**, 2915 (1978).

Grignard addition of phenylmagnesium bromide to 3,5-*O*-benzylidene-1-deoxy-D-*erythro*-2-pentulose (**1**) affords *C*-phenyl branched-chain pentitols having exclusively either the D-*arabino* (**2**) or D-*ribo* (**5**) stereochemistry according to the mode of substitution of **1**. In order to determine the chirality of these products conclusively, the crystal and molecular structure of the unsubstituted pentitol **6** (from **2**) has been determined. Crystals of 1-deoxy-2-*C*-phenyl-D-arabinitol (**6**; $C_{11}H_{16}O_4$) are orthorhombic, space group $P2_12_12_1$, with cell dimensions $a = 8.9420(6)$, $b = 18.910(1)$, $c = 6.4263(6)$ Å, and $Z = 4$. The structure was solved by multi-solution direct methods and refined to a final discrepancy index of 5.6%. The molecule has an extended, planar zigzag conformation with the phenyl ring nearly perpendicular to this plane. Compound **6** forms one intramolecular (between 2-OH and O-4) and three intermolecular hydrogen bonds. Palladium-catalyzed hydrogenolysis of the 2-phenylcarbamate of **2** results in deoxygenation of the benzylic center with complete inversion of configuration, as established by crystal-structure determination of the product **7**. Crystals of 2(*S*)-4-*O*-acetyl-3,5-*O*-benzylidene-1,2-dideoxy-2-*C*-phenyl-D-*erythro*-pentitol (**7**; $C_{20}H_{22}O_4$) are monoclinic, space group C_2, with cell dimensions $a = 19.102(1)$, $b = 6.1925(5)$, $c = 16.098(1)$ Å, $\beta = 108.325(9)°$, and $Z = 4$. The structure was solved by multi-solution direct methods and refined to a final discrepancy index of 5.9%. The molecule has an almost ideal planar, zigzag backbone conformation which incorporates the 1,3-dioxane ring. Comparison of the conformation observed in the crystal with that calculated from proton–proton coupling constants shows good agreement.

DOUGLAS C. ROHRER, JEAN-CLAUDE FISCHER, DEREK HORTON et WOLFGANG WECKERLE. Can. J. Chem. **56**, 2915 (1978).

La réaction de Grignard du bromure de phénylmagnesium sur le 3,5-*O*-benzylidène-1-désoxy-D-*érythro*-2-pentulose (**1**) conduit à des *C*-phényl pentitols à chaîne ramifiée dont la stéréochimie est exclusivement soit D-*arabino* (**2**) soit D-*ribo* (**5**) selon le mode de substitution de **1**. Dans le but de déterminer sans ambiguité la chiralité de ces produits, on a établi la structure cristalline et moléculaire du pentitol non substitué **6** (obtenue de **2**). Les cristaux de 1-désoxy-2-*C*-phényl-D-arabinitol (**6**; $C_{11}H_{16}O_4$) sont orthorombiques, groupe d'espace $P2_12_12_1$, avec des dimensions de maille $a = 8.9420(6)$, $b = 18.910(1)$, $c = 6.4263(6)$ Å et $Z = 4$. La structure a été résolue à l'aide des méthodes directes, méthode de multi solutions, avec affinement jusqu'à une valeur finale de R de 0.056. La molécule a une conformation allongée et en zigzag, le cycle phényle étant pratiquement perpendiculaire au plan moyen du squelette carboné. Le composé **6** forme une liaison hydrogène intramoléculaire (entre OH-2 et O-4) et trois liaisons hydrogène intermoléculaires. La détermination de la structure des cristaux du produit **7** a établi que l'hydrogénation catalytique sur palladium du 2-phénylcarbamate de **2** conduit à la désoxygénation du centre benzylique avec totale inversion de configuration. Les cristaux de 2(*S*)-4-*O*-acetyl-3,5-*O*-benzylidène-1,2-didésoxy-2-*C*-phényl-D-*érythro*-pentitol (**7**; $C_{20}H_{22}O_4$) sont monocliniques, groupe d'espace C_2, avec des dimensions de maille $a = 19.102(1)$, $b = 6.1925(5)$, $c = 16.098(1)$ Å, $\beta = 108.325(9)°$ et $Z = 4$. La struc-

ture a été résolue à l'aide des méthodes directes, méthode de multi solutions, avec affinement jusqu'à une valeur finale de R de 0.059. Le squellette carboné de la molécule a une conformation pratiquement plane et en zigzag, le cycle 1,3-dioxane se trouvant dans le plan. La conformation de la molécule observée dans le cristal est en bon accord avec celle qui avait été calculée à partir des constantes de couplage entre protons.

Introduction

Grignard addition of phenylmagnesium bromide to 3,5-*O*-benzylidene-1-deoxy-D-*erythro*-2-pentulose (**1**) afforded (1) a single, *C*-phenyl branched-chain pentitol formulated tentatively as 3,5-*O*-benzylidene-1-deoxy-2-*C*-phenyl-D-arabinitol (**2**). Compound **2** was subsequently converted into the syrupy *tert*-butyldimethylsilyl ether **3** having $[\alpha]_D - 57°$ in chloroform. When the sequence of reactions was reversed, however, with initial silylation of **1** to give **4** and then Grignard addition, a totally different syrupy product (**5**) having $[\alpha]_D + 42°$ in chloroform was obtained exclusively (1), in high yield. Although it is well known (2) that the stereoselectivity of reactions of Grignard reagents with carbonyl-sugar derivatives may be considerably *modified* by change of the reaction conditions or change of a substituent, in this case the mode of addition is evidently *completely reversed* according to the prior mode of substitution (**1** or **4**) of the given substrate (1-deoxy-D-*erythro*-2-pentulose).

This remarkable sequence may prove extremely useful in asymmetric synthesis, as there are many examples of biologically important compounds (such as cholinergic agents (2, 3) and hormones and drugs related to atropine (4) and epinephrine (adrenalin) (5)) that contain an asymmetric, benzylic carbon atom for which these Grignard addition-products may serve as chiral precursors. The potential synthetic utility of these compounds is extended even further by the observation (1) that the tertiary benzylic center can be deoxygenated with complete retention of optical purity, by palladium-catalyzed hydrogenation to give, for example, compound **7**, to which the 2(*S*) configuration was tentatively ascribed.

The configurational assignment of such asymmetric, tertiary alcohols as in **2** generally poses considerable difficulties (6) and the determination of configuration of the chiral benzylic center in **7** is scarcely feasible by standard physical or reasonable chemical methods. We therefore undertook an X-ray diffraction study of the unsubstituted pentitol **6** (obtained (1) from **2** by acid hydrolysis) and the benzylidene acetal **7**, with the objective of providing, first, final proof of their stereochemistry, and second, information on their conformation.

Experimental

For details of synthesis and nmr measurements, see ref. 1.

Experimental Crystal Data for Tertiary Alcohol **6**
1-Deoxy-2-*C*-phenyl-D-arabinitol (**6**)

$C_{11}H_{16}O_4$ fw = 212.2
Orthorhombic, $a = 8.9420(6)$, $b = 18.910(1)$, $c = 6.4263(6)$ Å, $V = 1086.5$ Å^3, $\rho_c = 1.298$ g cm^{-3}, $Z = 4$, room temperature (~20°C), Ni-filtered CuK$_\alpha$, $\lambda = 1.5418$ Å, space group: $P2_12_12_1$, crystal size 0.10 × 0.11 × 0.03 mm^3.

Integrated diffraction intensities for 1313 independent reflections with $2\theta < 150°$ were measured with an Enraf–Nonius CAD-4 diffractometer using ω–2θ scans. Of these, 1045 intensities were determined to be observed above background ($I > 2\sigma_I$).

Phase angles sufficient to locate the nonhydrogen atoms were derived by using the direct-methods program MULTAN (7). The hydrogen atoms were located on a difference electron-density map at an intermediate stage of the least-squares refinement. In the final cycles of full-matrix, least-squares refinement, positional parameters for all atoms, anisotropic thermal parameters for the nonhydrogen atoms, and isotropic thermal parameters for the hydrogen atoms were varied. The quantities $(1/\sigma_F^2)$, where σ_F is as defined by Stout and Jensen (8), but with an instability constant of 0.06, were used to weight the refinement; data determined to be unobserved were given zero weight. The scattering factors used were calculated from the coefficients given in the International Tables for X-ray Crystallography, Vol. IV (9). The final value of the residual, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, was 0.037 for the observed data and 0.056 for all measured data. Final atomic positions are listed in Table 1 and tables of anisotropic thermal parameters and of observed and calculated structure amplitudes are in the Depository of Unpublished Data.[1]

Experimental Crystal Data for the Deoxygenated Product **7**
2(*S*)-4-*O*-Acetyl-3,5-*O*-benzylidene-1,2-dideoxy-2-*C*-phenyl-D-*erythro*-pentitol (**7**)

$C_{20}H_{22}O_4$ fw = 326.4
Monoclinic, $a = 19.102(1)$, $b = 6.1925(5)$, $c = 16.098(1)$ Å, $\beta = 108.325(9)°$, $V = 1807.6$ Å^3, $\rho_c = 1.199$ g cm^{-3}, $Z = 4$, room temperature (~20°C); Ni-filtered CuK$_\alpha$, $\lambda = 1.5418$ Å, space group: C_2, crystal size 0.40 × 0.40 × 0.80 mm^3.

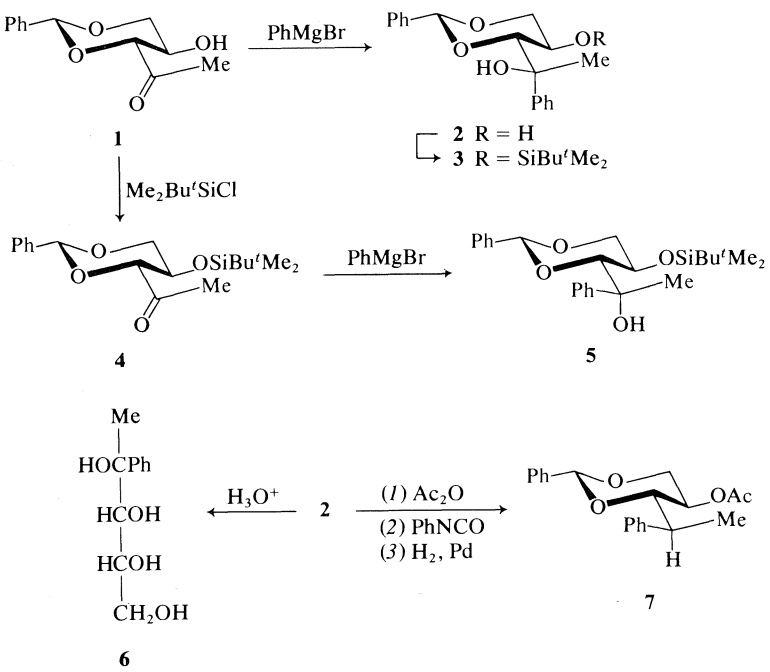
Using the same data-measurement procedure used for **6**, 2033 independent intensities ($2\theta < 150°$) were measured with 1887 intensities determined to be observed above background ($I > 2\sigma_I$).

The atomic positions were determined and refined by the same methods described for **6**. The final value of the residual R was 0.055 for the observed data and 0.059 for all measured data. The final atomic coordinates are listed in Table 2. Tables containing the thermal parameters and the observed and calculated structure-factor amplitudes are in the Depository of Unpublished Data.[1]

Results and Discussion

Figures 1 and 2 show similar three-dimensional views of the two *C*-phenyl pentitols **6** and **7** having

[1]Complete set of data may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.



the planar, zigzag arrangement in the plane of the paper. The bond lengths shown in Figs. 1 and 2 and the valence angles given in Tables 3 and 4 are all within the range of values expected for this type of compound. Figure 3 depicts Newman projections along each carbon–carbon and, for **7**, along the relevant carbon–oxygen bonds, to illustrate the torsion angles.

The Structure of the Tertiary Alcohol **6**

The configuration at C-2 of **2**, **3**, and **5** could be predicted, with reasonable confidence, on the basis of mechanistic arguments (compare, for example, ref. 10) regarding the Grignard addition reactions with **1** and its 4-*tert*-butyldimethylsilyl ether **4**, respectively. In the original paper (1), the assignment was convincingly achieved by nuclear Overhauser experiments (after the present investigation had been initiated), with a suitably protected derivative of **2**, thus firmly establishing the D-*arabino* stereochemistry. The D-*ribo* configuration must, therefore, be attributed to the other product (**5**). These earlier results are now unambiguously affirmed and extended by crystal-structure determination of the unprotected pentitol **6**.

The C-6, C-2 → C-5 carbon chain of **6** (Fig. 1) adopts the extended, essentially planar, zigzag arrangement, in accord with the general conforma-

tional predictions that may be made for open-chain sugar derivatives (11–13). The phenyl ring is almost perpendicular to the plane of the carbon backbone, generating (Fig. 3*d*) torsion angles of 83.5° and −94.1°, respectively. Interestingly, C-1, rather than C-6 (namely, the phenyl group), is rotated out-of-plane C-1—C-2—C-3—C-4 by −54.5°. This orientation implies the parallel alignment of the C-2—O-2 and C-4—O-4 bonds (1,3-interaction)[2] that is associated with an estimated[3] instability factor of about 1.5 kcal/mol and is, therefore, generally considered (11, 12, 15) to be unfavorable. In the case of **6**, however, this conformation permits formation of an intramolecular hydrogen-bond (16) involving O-4 and the hydroxyl group at C-2 (O-2 · · · O-4 separation is 2.630 Å, and the 2-OH · · · O-4 distance is 1.92 Å). In any case, this rotamer is definitely of lower energy than the other two staggered C-2—C-3 rotamers, which would have a higher energy as a result of the loss of the hydrogen-bond stabilization and a 1,3 steric interaction between either C-1 or C-6, and O-4, if the planar, zigzag arrangement of atoms C-2 to C-5 is maintained.

[2]For criticism of this term in conformational analysis of acyclic compounds, see ref. 12.

[a]Numbers in parentheses are estimated standard deviations.

The terminal hydroxyl group is also disposed out of the plane of the carbon backbone (see Fig. 3*c*). This conformation is almost certainly determined by the intermolecular hydrogen-bonding (see Table 5). It would be expected, however, that dissolution would permit equilibration to afford almost equal proportions of this rotamer and the extended one; the third staggered rotamer would generate a parallel (*peri*) interaction between O-3 and O-5 and is, therefore, unlikely.

Unfortunately, no coupling constants could be extracted (1) from the very complex nmr spectra of **6** in a variety of solvents. Therefore, no information is available about the conformation of **6** in the liquid state that might have been compared with data for crystalline **6** by way of the Karplus equation (17–19) that correlates spin–spin coupling constants of vicinal protons ($^3J_{H,H}$) with the dihedral angle in the various H—C—C—H units of the molecule.

Molecule **6** forms three intermolecular hydrogen-bonds with symmetry-related molecules and one intramolecular hydrogen-bond between O-2 and O-4, as already mentioned. The details of the hydrogen-bond distances are given in Table 5. The only other intermolecular non-bonded contacts less than 3.5 Å involve C-3 to O-5 (3.396 Å) and C-4 to O-2 (3.309 Å).

Structure of the Deoxygenated Product 7

The stereospecific deoxygenation of the benzylic center (**2** → **7**) is somewhat reminiscent of the palladium-catalyzed hydrogenolysis of phenylurethanes to give (20) arenes. The literature precedent, however, does not involve an asymmetric carbon center. Therefore, in the absence of firm evidence not readily obtainable other than by crystallographic methods, a tentative configurational assignment [2(*S*)] for the benzylic center at C-2 in **7** was made (1) that rested on mechanistic arguments: it is known from a wealth of experimental data (21) that catalytic

[a]By using the Karplus (17) equation: $^3J_{H,H} = 4.22 - 0.5 \cos\phi + 4.50 \cos 2\phi$.
[b]By using a modified (19) equation: $^3J_{H,H} = (7.8 - \cos\phi + 5.6 \cos 2\phi)(1 - 0.1X)$, where $X = \Sigma_1^4(X_n - X_H)$ and X_n is the electronegativity of substituent n, X_H that of hydrogen.
[c]At 100 MHz in chloroform-*d*.
[d]The unmodified Karplus equation does not allow for vicinal coupling-constants larger than 9.22 Hz.
[e]With the specified mode of substitution, the modified Karplus equation does not provide for vicinal coupling constants larger than 9.69 Hz.

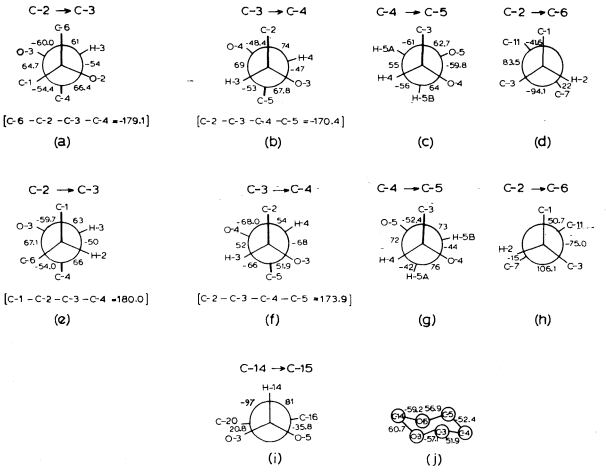

FIG. 3. Newman projections along each carbon–carbon bond and relevant carbon–oxygen bonds for molecule **6** (*a* to *d*) and molecule **7** (*e* to *j*).

hydrogenolysis of benzyl derivatives of the general type Ph—C—X → Ph—C—H shows substantial stereospecificity. Furthermore, depending on the electronegativity of the displaced group X as well as the chemical nature of the catalyst metal, either retention or inversion may occur, and it appears that palladium-catalyzed hydrogenolysis generally proceeds with a high degree of configurational inversion.

In keeping with these arguments, single-crystal X-ray diffraction analysis of **7** now verifies that the product obtained was indeed the one resulting from inversion, namely 2(*S*)-4-*O*-acetyl-3,5-*O*-benzylidene-1,2-dideoxy-2-*C*-phenyl-D-*erythro*-pentitol (**7**). As a view of the crystal structure (Fig. 2) reveals, the carbon backbone of **7** adopts an almost ideal planar zigzag conformation (the torsion angles along C-2—C-3 and C-3—C-4 being 180.0° and 173.9°; see Fig. 3 *e* and *f*) part of which (C-3, C-4, and C-5) is incorporated into the 1,3-dioxane ring. The latter exists in the expected (22) chair conformation, and is indeed more puckered than cyclohexane in the O—C—O region, as manifested by the torsion angles (~60°) along the bonds C-14—O-3 and C-14—O-5 (Fig. 3*j*) that deviate significantly from the value (56°) observed (23) for cyclohexane. On the other hand, and in contrast to a literature report (24) on 2-*p*-chlorophenyl-1,3-dioxane, the two torsion angles in the 'cyclohexane' part (each being 52°) are distinctively smaller than the quoted value for cyclohexane and are indicative of considerable flattening in this region of the molecule.

The acetalic phenyl group at C-14 rotates slightly about the C-14—C-15 bond to generate (Fig. 3*i*) torsion angles of 20.8° and −35.8° involving O-3 with C-20 and O-5 with C-16. This staggered disposition results in the least amount of steric crowding, with both C-16 and C-20 positioned between an oxygen atom and H-14 rather than one between the two oxygen atoms, the other between an oxygen atom and H-14. This conformer is frequently observed in other crystal structures (24, 25) and constitutes an energy-minimum conformation.

Molecule **7** has no hydrogen atoms capable of being involved in a hydrogen bond. The only intermolecular nonhydrogen contacts less than 3.5 Å involve C-19 with O-12 (3.364 Å) and O-5 with O-5 (3.346 Å).

The equatorially attached C_2 chain at C-3 of the 1,3-dioxane ring adopts, as a means of relieving non-bonded interaction strain, an orientation (Fig. 3*e*) such that the phenyl group at C-2 is perpendicular to the dioxane ring (compare Fig. 2). Furthermore, the phenyl group rotates about the C-2—C-6 bond (Fig. 3*h*) so that it is disposed broadside to the axial proton at C-4.

Table 6 presents a comparison of proton–proton couplings measured (1) with a solution of **7** in chloroform-*d*, with values calculated from the dihedral angles in the crystal by use of the Karplus equation, either with (19) or without (17) correction for electronegativity effects. In addition, two columns are included listing values for the dihedral angles that were calculated similarly from the observed coupling-constants. The data show reasonable qualitative correlation that is sufficient to assume a conformation of **7** in solution similar to that adopted in the solid state.

Extraction of cadmium salicylate with some nitrogen-containing organic bases

J. M. SINGH AND S. N. TANDON

Department of Chemistry, University of Roorkee, Roorkee 247672, India

Received January 23, 1978[1]

J. M. SINGH and S. N. TANDON. Can. J. Chem. **56**, 2922 (1978).

$Cd(HSal)_2$ is extracted from aqueous solutions into *n*-butanol, but not into non-hydroxylic solvents (such as benzene and chloroform) at pH 4.5 to 6.0. Addition of N bases, which have no effect alone, causes extraction into the latter solvents, apparently by displacement of co-ordinated water, giving $Cd(HSal)_2 \cdot 2B$. This synergistic effect varies with B (β-picoline > pyridine > quinoline). Formation and distribution constants are given for the experimental conditions.

J. M. SINGH et S. N. TANDON. Can. J. Chem. **56**, 2922 (1978).

De solutions aqueuses entre pH 4.5 et 6.0, on peut extraire $Cd(HSal)_2$ dans le *n*-butanol, mais non pas dans les solvants non-hydroxylés tels que le benzène et le chloroforme. L'addition de bases azotées, qui par elles-mêmes sont sans effet, favorise l'extraction dans ces derniers solvants, en déplaçant probablement l'eau de coordination pour former $Cd(HSal)_2 \cdot 2B$. L'effet synergique varie selon la nature de B (β-picoline > pyridine > quinoline). On rapporte les constantes de formation et de distribution correspondant aux conditions expérimentales utilisées.

[Traduit par le journal]

Introduction

Earlier workers (1–3) have studied the extraction of some bivalent metal salicylates in hydroxylic solvents and identified the extracted species. In contrast to the behaviour of hydroxylic solvents negligible extractions of metal salicylates are observed in non-polar solvents, but the presence of neutral donors like tributyl phosphate in non-polar solvents makes the species less hydrophilic and the extractions are then increased by several orders of magnitude (4). Aggett *et al.* (5–7) carried out extensive studies on the extraction of some metal salicylates in tributyl phosphate. We have studied the extraction of metal salicylates in the presence of organic bases like pyridine, picolines, and quinoline, which will be more effective in displacing water from the coordination sphere so larger synergistic effects may be observed. By using different bases their relative effectiveness as synergists can be obtained.

A survey of literature revealed that practically no work has been done on the extraction of cadmium salicylate either in hydroxylic solvents or in non-polar solvents in the presence of organic bases. The present article reports the extraction behaviour of cadmium salicylate in *n*-butanol and the extracting species is identified. The addition of organic bases to *n*-butanol does not increase the extraction, but the addition of these bases to non-polar solvents like benzene brings about a synergistic enhancement in the extraction. The cadmium salicylate base species has been identified and the extraction and formation constants are calculated. The stability of different mixed complexes is compared.

[1]Revision received August 9, 1978.

Over the pH range studied (4.5–6.0), only the species H_2Sal and $HSal^-$ of salicylic acid need be considered in the aqueous phase. Although dimerization of salicylic acid occurs in benzene, it can reasonably be expected to be small or negligible in polar or hydroxylic solvents (such as *n*-butanol) that can act as acceptors for hydrogen bonds (8).

Experimental

Reagents

A.R. cadmium sulphate was dissolved in doubly distilled water and the solution was standardized by EDTA solution using xylenol orange indicator. Freshly prepared solutions of salicylic acid (BDH, AR) were used throughout the investigations. *n*-Butanol, pyridine, picolines, and quinoline were also of analytical grade. ^{115m}Cd radioisotope supplied by Bhabha Atomic Research Centre, Bombay (India) was used for distribution studies.

Analytical Procedure

In each set equal volumes (10 ml) of the aqueous (10^{-4} *M* cadmium(II) and 0.0125 *M* salicylic acid, or other concentration) and organic phases were shaken at room temperature 30 ± 2.0°C. After equilibration the two phases were separated and the pH of the aqueous phase was determined by a Cambridge bench pH-meter. Suitable aliquots of the two phases were counted using a G.M. counter and the distribution ratio was calculated by the usual method. The optimum pH for the extraction of cadmium(II) in the presence of salicylic acid alone and with the bases extends from 4.0 to 6.0. Optimum concentrations with regard to the bases are 0.5, 1, and 4 *M* for β-picoline, pyridine, and quinoline respectively for maximum extraction with a salicylic acid concentration of 0.025 *M* overall. The ionic strength of the aqueous phase was maintained constant (0.1 *M*) with sodium perchlorate. Bases alone do not influence the extraction of cadmium under the experimental conditions.

For the determination of the distribution ratio of pyridine and β-picoline, 10 ml aqueous solutions of known concentration adjusted to a definite pH by adding either perchloric acid or sodium hydroxide and to an ionic strength of 0.1 *M* with

For personal use only.

sodium perchlorate, were equilibrated with Analar benzene (10 ml) and shaken for about 20 h at 30 ± 2°C. After separation of both phases, the pH of the aqueous layer was measured. The concentration of pyridine in the aqueous phase was measured by the cyanogen bromide and aniline method (9). For the determination of the β-picoline concentration in the aqueous phase, the bromide–thiocyanate method in the presence of sulphanilic acid (10) was used. Values of partition coefficients (P_β) were calculated from the D-values determined by the above procedures.

For ir studies, the solid complexes were prepared by liquid–liquid extraction. Base (0.02 M pyridine or β-picoline) was added to an aqueous solution of cadmium sulphate (0.01 M) and the mixture was warmed to dissolve all the base. After being cooled, the solution was treated with an aqueous solution of sodium salicylate (0.02 M) when the mixed complex separated. This dissolved when the mixture was extracted with an equal volume of benzene. The benzene layer was separated and allowed to evaporate slowly at room temperature. The colourless crystals of the complex were washed with benzene. The infrared spectra of the ligands and solid complexes were taken in a KBr medium with Beckman IR-20, range 4000–250 cm^{-1}.

Results and Discussion

For the extraction of cadmium(II) into n-butanol with salicylic acid alone plots of log D vs. pH (Fig. 1, curve a) and log D vs. log $[H_2Sal]_{total}$ (Fig. 2, curve a) gave straight lines of slope near 2. This indicates the release of two protons and the utilization of two acid molecules per cadmium atom for complexation. Since the species is not extracted into benzene or any solvent other than alcohol, it is probable that the species is highly hydrophilic and

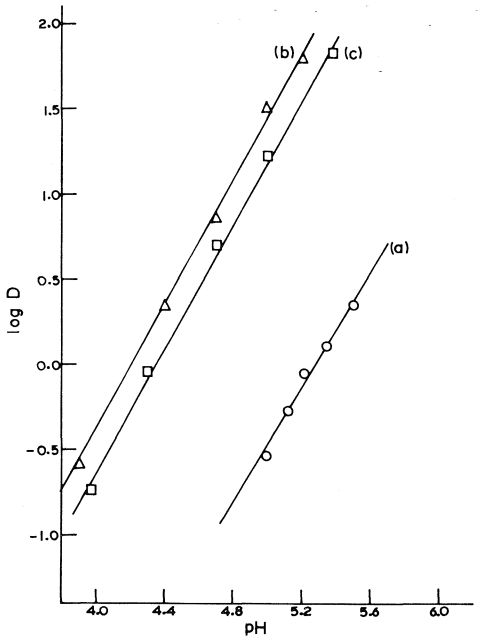

FIG. 1. The effect of pH on the extraction of Cd^{2+} with salicylic acid at constant acid concentration: (*a*) n-butanol; (*b*) benzene–β-picoline; (*c*) benzene–pyridine.

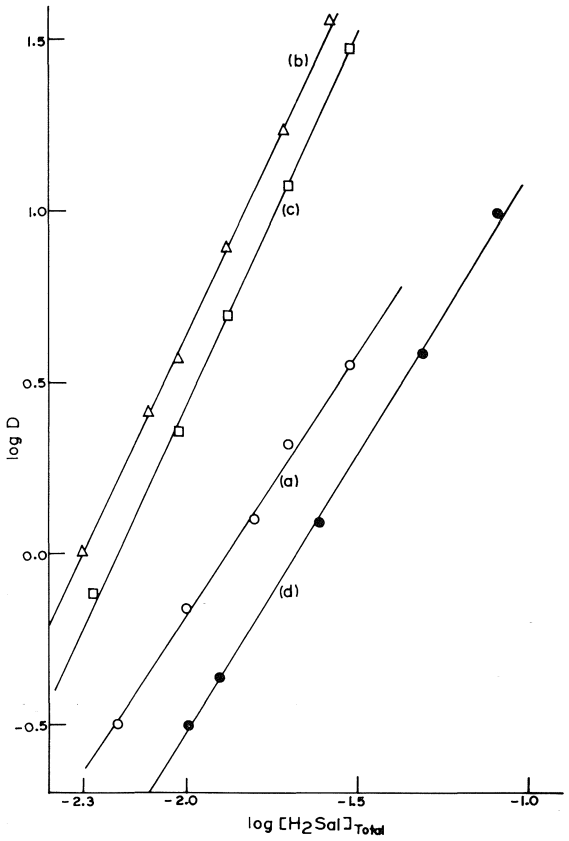

FIG. 2. The effect of salicylic acid concentration on the extraction of Cd^{2+} at constant pH and metal ion concentration: (*a*) n-butanol; (*b*) benzene–β-picoline; (*c*) benzene–pyridine; (*d*) benzene–quinoline.

that only alcohol as solvent can replace water molecules from the coordination sphere. When log D was plotted against log [ROH] using benzene as a neutral diluent (Fig. 3), a straight line of slope near 1 was obtained, suggesting the ratio 1:1 for cadmium-to-alcohol. Thus the species in n-butanol can be represented as $[Cd(HSal)_2 \cdot BuOH \cdot H_2O]$ assuming the coordination number of cadmium to be 4.

Benzene as a neutral diluent produces a negligible extraction of cadmium salicylate, but if it contains pyridine, β-picoline, or quinoline, much higher values of the extraction are obtained due to the replacement of the water molecules from coordination sphere by the neutral donor.

For the extraction of cadmium(II) salicylate into benzene in the presence of organic bases, plots of log D vs. pH (Fig. 1, curves b and c) and log D vs. log $[H_2Sal]_{total}$ (Fig. 2, curves b, c, and d) gave slopes near 2, suggesting the release of two protons and the utilization of two acid molecules per cadmium atom for the formation of the mixed complex also. Again log D was plotted against log $[B]_{total}$ (Fig. 4, curves a, b, and c) and straight lines of slope near 2 were

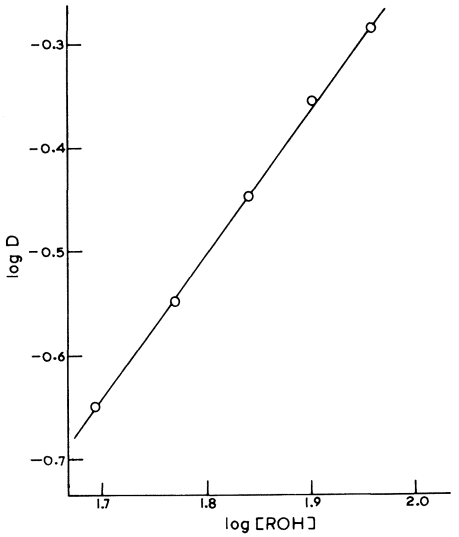

FIG. 3. Effect of *n*-butanol concentration on the extraction of Cd^{2+} with salicylic acid.

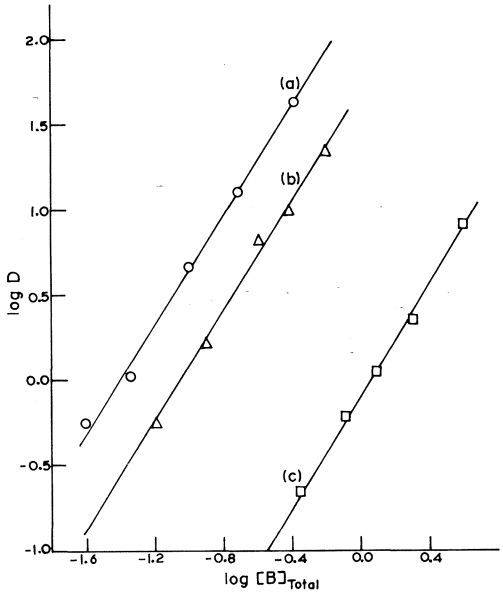

FIG. 4. Effect of base concentration on the extraction of Cd^{2+} with salicylic acid at constant pH and acid concentration: (*a*) benzene–β-picoline; (*b*) benzene–pyridine; (*c*) benzene–quinoline.

obtained suggesting the utilization of two base molecules per cadmium atom. Thus the extracting species may be represented as $[Cd(HSal)_2 \cdot 2B]$. The absence of water molecule in the species is indicated by almost quantitative extractions of cadmium salicylate in the presence of these bases at most of the experimental conditions. It has been noticed that of the different nitrogen-containing organic bases used in the study, α-picoline is quite unable to enhance extractions. This may be due to the poor basicity of α-picoline; steric factors may also play a role.

The equation for the formation of the mixed complex can be represented as:

$$Cd^{2+} + 2HSal^-{}_{aq} + 2B_{aq} \rightleftharpoons Cd(HSal)_2 \cdot 2B$$

The equilibrium constant for the reaction is given by

$$K_{ex} = \frac{[Cd(HSal)_2 \cdot 2B]_0}{[Cd^{2+}]_{aq}[HSal^-]_{aq}{}^2[B]_{aq}{}^2}$$

Hence

$$[1] \quad \log D = \log K_{ex} + 2 \log [HSal^-]_{aq} + 2 \log [B]_{aq}$$

where

$$D = \frac{[Cd(HSal)_2 \cdot 2B]_0}{[Cd^{2+}]_{aq}}$$

The mass balance for salicylic acid is given by the relation

$$\begin{aligned}[H_2Sal]_{total} &= [H_2Sal]_0 + [H_2Sal]_{aq} + [HSal^-]_{aq} \\ &\quad + [Cd(HSal)_2 \cdot 2B]_0 + 2[(H_2Sal)_2]_0 \\ &= [HSal^-]_{aq}\{(ps + 1)([H^+]/K_1) + 1\} \\ &\quad + 2[Cd(HSal)_2 \cdot 2B]_0 \\ &\quad + 2K_{dim}\{[HSal^-]_{aq} ps [H^+]/K_1\}^2\end{aligned}$$

where ps (4) is the partition coefficient, K_1 is the first dissociation constant, and K_{dim} is the dimerization constant of salicylic acid in benzene.

Since the values of $[H_2Sal]_{total} < 1$, the $[HSal^-]_{aq}{}^2$ term can be neglected compared to the $[HSal^-]_{aq}$ term and the above relation simplifies to

$$[2] \quad [HSal^-]_{aq} = \frac{[H_2Sal]_{total} - 2[Cd(HSal)_2 \cdot 2B]_0}{\{(ps + 1)([H^+]/K_1) + 1\}}$$

The mass balance for the base is given by

$$[B]_{total} = [B]_{org} + [B]_{aq} + [BH^+]_{aq} + 2[Cd(HSal)_2 \cdot 2B]_0$$

and hence

$$[3] \quad [B]_{aq} = \frac{[B]_{total} - 2[Cd(HSal)_2 \cdot 2B]_0}{\{P_B + 1 + [H^+]/K_{BH^+}\}}$$

where P_B and K_{BH^+} are the partition coefficient and ionization constant of BH^+ of the base. K_{BH^+} values are taken from the literature (11, 12) and P_B values are calculated by using the expression:

$$\begin{aligned}[B]_{total} &= [B]_{org} + [B]_{aq} + [BH^+]_{aq} \\ &= [B]_{aq}[1 + P_B + [H^+]/K_{BH^+}]\end{aligned}$$

TABLE 1. Variation of $[HSal^-]_{aq}$ at constant $[B]_{total}$ and pH

log $[H_2Sal]_{total}$	log D	log $[HSal^-]_{aq}$	log $[B]_{aq}$	log K_{ex}	log K
(*a*) β-Picoline, $[B]_{total}$ = 0.25 *M* and pH = 5.0					
−2.301	−0.009	−2.319	−1.455		
−2.000	0.563	−2.015	−1.455	7.58	6.50
−1.690	1.229	−1.712	−1.455		
−1.601	1.558	−1.614	−1.455		
(*b*) Pyridine, $[B]_{total}$ = 0.5 *M* and pH = 5.0					
−2.301	−0.104	−2.317	−0.944		
−2.000	0.346	−2.015	−0.944	6.38	5.46
−1.690	1.079	−1.712	−0.944		
−1.523	1.473	−1.534	−0.944		

TABLE 2. Variation of $[B]_{aq}$ at constant $[H_2Sal]_{total}$ and pH

log $[B]_{total}$	log D	log $[B]_{aq}$	log $[HSal^-]_{aq}$	log K_{ex}	log K
(*a*) β-Picoline, $[H_2Sal]_{total}$ = 0.02 *M* and pH 5.0					
−1.602	−0.245	−2.456	−1.712		
−1.301	−0.013	−2.154	−1.712	7.81	6.73
−1.000	0.666	−1.854	−1.712		
−0.301	1.105	−1.552	−1.712		
(*b*) Pyridine, $[H_2Sal]_{total}$ = 0.02 *M* and pH 5.0					
−1.204	−0.244	−1.844	−1.712		
−0.903	0.225	−1.544	−1.712	6.72	5.80
−0.602	0.819	−1.242	−1.712		
−0.426	0.997	−1.066	−1.712		

Thus

$$P_B = \frac{[B]_{total}}{[B]_{aq}} - (1 + [H^+]/K_{BH^+})$$

where

$$P_B = \frac{[B]_{org}}{[B]_{aq}}$$

and

$$K_{BH^+} = \frac{[H^+][B]_{aq}}{[BH^+]_{aq}}$$

The average values of partition coefficients obtained are 1.95 and 1.85 for pyridine and β-picoline respectively.[2] Equilibrium concentrations $[HSal^-]_{aq}$ and $[B]_{aq}$ are calculated using eqs. [2] and [3].

The extraction constant (K_{ex}) is calculated using eq. [1] and the formation constant (K) by the relation log K = log K_{ex} − log P(complex). Partition coefficient values of the complex (P(complex)) are calculated from the limiting values of their percent extraction. The results for β-picoline and pyridine systems are given in Tables 1 and 2. The data for quinoline are not given. As its distribution (11) is highly in favour of organic phase (ps > 100) when compared with other bases, it is quite likely that in this case a mixed complex is formed in the organic phase.

As shown by the extraction data the different bases are effective in synergism in the order β-picoline > pyridine > quinoline. The stabilities of the mixed complexes follow the order β-picoline > pyridine > α-picoline. A similar sequence of stability of complexes has been observed in other systems both the strength of the base and steric factors (13) of which are also considered.

The infrared spectra of cadmium salicylate–pyridine and β-picoline complexes are almost the same. The spectra is quite complicated in the region 1650–400 cm^{-1} and the interpretation is somewhat difficult due to the overlap of frequencies of coordinated bases with those of coordinated salicylate. In 1650–1500 cm^{-1} region both C=N and C=C of pyridine and asymmetric OCO stretching of salicylate ion occur. The peak at 1630 cm^{-1} may be due to the absorption of coordinated pyridine and peak at 1580 cm^{-1} may be assigned to asymmetric OCO absorption. The peak around 1390 cm^{-1} is due to cadmium salicylate complex. However the doublet at 1480 cm^{-1} and 1460 cm^{-1} may be due to sym-

[2]Data for the determination of partition coefficients are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

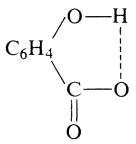
For personal use only.

metric OCO stretching vibrations of the salicylate ion.

As the spectra in the region 1650–400 cm^{-1} gives no conclusive information, attention was concentrated on the hydroxyl absorption region. The following bonding possibilities in the complex may be present: (*i*) the complex may be an ionised salt such as $[Cd(py)_2]^{2+}[HSal^-]_2$; (*ii*) the complex is an adduct of formally neutral complex $[Cd(HSal)_2]\cdot 2py$; (*iii*) all ligands are coordinated $[Cd(HSal)_2\cdot 2py]$.

If the complex is an ionised salt (case (*i*)), the $HSal^-$ would be present as an intramolecularly hydrogen bonded species.



Therefore the spectra of such complex would only show vibrations due to associated OH-groups (O—H...O) at around 3000–2500 cm^{-1} and no peak due to free OH group would be expected. The absence of peak in the region 3000–2500 cm^{-1} rules out the possibility (*i*) where the complex is a simple salt type. It will be difficult to distinguish between the possibilities (*ii*) and (*iii*) where both the salicylate ions are coordinated. In both the cases, strong absorption due to O—H...O should be absent, whereas vibration due to the M—O...H group would be present with lower vibration frequency than that of OH in water. Considerable absorptions occur at $\sim 3420\ cm^{-1}$ and $3080\ cm^{-1}$. These two peaks can safely be assigned to the OH absorption of the bonded (M—O...H) OH groups. No such peak around $3400\ cm^{-1}$ has been observed in case of sodium salicylate, where the phenolic OH group is involved in hydrogen bonding.

The crystal structures of $S_7NSN(CH_3)_2$ and $(C_6H_{11})_2NSN(C_6H_{11})_2$

ROBERT B. BRUCE, RONALD J. GILLESPIE,[1] AND DAVID R. SLIM
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 1, 1978

ROBERT B. BRUCE, RONALD J. GILLESPIE, and DAVID R. SLIM. Can. J. Chem. **56**, 2927 (1978).

The compound $S_7NSN(CH_3)_2$ has been prepared by the reaction of S_7NH with $S[N(CH_3)_2]_2$. Crystals are orthorhombic with $a = 12.412(4)$, $b = 23.894(6)$, $c = 8.132(2)$ Å, $Z = 8$, space group *Pbca*. The structure was refined to a final agreement index R_1 of 0.051 for 1721 observed reflections. The structure of $S[N(C_6H_{11})_2]$ was also determined for comparison. The crystals are monoclinic with $a = 13.74(2)$, $b = 6.196(8)$, $c = 13.74(2)$ Å, $\beta = 91.26(8)°$, $Z = 2$, space group *I*2. The structure was refined to a final agreement index, R_1, of 0.052 for 1024 observed reflections.

ROBERT B. BRUCE, RONALD J. GILLESPIE et DAVID R. SLIM. Can. J. Chem. **56**, 2927 (1978).

Le composé $S_7NSN(CH_3)_2$ a été preparé par la réaction de S_7NH avec $S[N(CH_3)_2]_2$. Les cristaux sont orthorhombiques $a = 12.412(4)$, $b = 23.894(6)$, $c = 8.132(2)$ Å, $Z = 8$, groupe d'espace *Pbca*. On a raffiné la structure jusqu'à une valeur finale de R_1 de 0.051 pour 1721 réflexions observées. Pour faire une comparaison avec celle de $S_7NSN(CH_3)_2$ la structure de $S[N(C_6H_{11})_2]$ a été aussi determinée. Les cristaux sont monocliniques, $a = 13.74(2)$, $b = 6.196(8)$, $c = 13.75(2)$ Å, $\beta = 91.26(8)°$, $Z = 2$, groupe d'espace *I*2. On a raffiné la structure jusqu'à une finale de R_1 de 0.052 pour 1024 réflexions observées.

Introduction

As part of a wider investigation of the chemistry of S_7NH, S_4N_4, and other sulfur nitrogen compounds, we have prepared the compound $S_7NSN(CH_3)_2$ and determined its crystal structure by X-ray crystallography. In order to facilitate an understanding of the bonding in the NSN system we have also determined the structure of $S[N(C_6H_{11})_2]_2$ as the only previous study of a compound of the type $S(NR_2)_2$ had been made by electron diffraction (1).

Heptasulfurimide has a remarkably acidic proton which reacts readily even with weak bases. For example, it donates a proton to bis(trimethyl)silylamine to give the trimethylsilyl derivative (2).

$$S_7NH + [(CH_3)_3Si]_2NH \rightarrow S_7NSi(CH_3)_3 + (CH_3)_3SiNH_2$$

A similar reaction occurs with *NN'*-thiobisamines

$$S_7NH + S(NR_2)_2 \rightarrow S_7NSNR_2 + HNR_2$$

The methyl, ethyl, isopropyl, and cyclohexyl derivatives were all prepared by this reaction. They are pale yellow crystalline solids of relatively low melting point. The methyl derivative, which gave the best-shaped crystals, was chosen for X-ray studies.

Experimental

(a) $S_7NSN(CH_3)_2$

Heptasulfurimide was prepared by a method similar to that described by Brauer (3). Dimethylformamide (3.5 ℓ) was saturated with ammonia at −20°C and while ammonia was continually bubbled through the solution, sulfur monochloride (350 ml) was added in 15 ml aliquots below the surface of the solution by means of a syringe. Since the reaction was vigorous the solution was cooled to −20°C before each addition of S_2Cl_2. When all the S_2Cl_2 had been added, the bubbling of ammonia was continued for another 15 min. The deep blue solution was allowed to stand for a further 30 min and then added slowly to 50 ℓ of 1% aqueous HCl with constant stirring. The purple–pink mixture was then neutralised with 10% HCl which caused the colour of the solution to turn slightly brown and then to orange at the equivalence point. The suspension was allowed to settle overnight and the solution was decanted, leaving a yellow solid. After drying in air for 24 h, it was extracted with tetrahydrofuran which was then removed on a rotary extractor and the resultant brown oil dissolved in a minimum of hot methanol. Upon cooling pale yellow plate-like crystals were obtained which were vacuum dried and recrystallised from carbon disulfide to remove traces of sulfur. The typical yield was 30 g of pale yellow rectangular block shaped crystals (mp 113°C, literature 113°C (3)).

Powdered S_7NH (0.01 mol, 2.39 g) and an excess of *NN'*-thiobisdimethylamine (0.03 mol, 11.8 g) were added to benzene (10 ml) at 50°C. After stirring for 90 min a red solution was obtained. The solvent was removed under vacuum leaving a red oil which was separated into its components on a silica gel column using hexane as the eluent. The first fraction off the column gave $S_7NSN(CH_3)_2$ as yellow crystals on evaporation of the hexane (yield 2 g, mp 55°C). *Anal.* calcd. for $S_8N_2C_2H_6$: S 81.54, N 8.91, C 7.63, H 1.92; found: S 81.70, N 8.88, C 7.76, H 1.87. The second fraction, on evaporation of the hexane, gave a yellow oil consisting of a mixture of the compounds $(CH_3)_2NS_xN(CH_3)_2$ where $x > 1$.

(b) NN'-Thiobisdicyclohexylamine

A solution of SCl_2 (0.2 mol, 12.7 ml) in ether (200 ml) was added dropwise to dicyclohexylamine (0.8 mol, 160 ml) in 3 ℓ of ether at 0°C with vigorous stirring. The mixture was allowed to warm to room temperature and, after filtering, the solvent was removed on a rotary extractor. The resultant yellow oil was dissolved in a minimum amount of hot benzene. Pale yellow crystals resulted on cooling and were purified by two further recrystallisations. A typical yield was 30 g of colourless crystals (mp 149–150°C, literature 150°C (4)).

*Anisotropic temperature factors (U_{ij}) are given by the expression $\exp[-2\pi^2(a^{*2}h^2U_{11} + b^{*2}k^2U_{22} + c^{*2}l^2U_{33} + 2a^*b^*hkU_{12} + 2a^*c^*hlU_{13} + 2b^*c^*klU_{23})]$.

Crystal Data

$S_7NSN(CH_3)_2$ fw = 314.4
Orthorhombic, a = 12.412(4), b = 23.894(6), c = 8.132(2) Å, U = 2412.3 Å^3, Z = 8, D_c = 1.74 g cm^{-3}, $F(100)$ = 1280, λ(Mo-K$\bar{\alpha}$) = 0.71069 Å, μ(Mo-K$\bar{\alpha}$) = 14 cm^{-1}.

The unit cell parameters were obtained from a least-squares refinement of 15 reflections in the region $20° < 2\theta < 25°$. Weissenberg and precession photographs indicated that reflections were absent for $hk0$ when $h = 2n + 1$, $0kl$ when $k = 2n + 1$, and $h0l$ when $l = 2n + 1$, characteristic of the space group *Pbca* (No. 61 D_{2h}^{15}) (5).

$(C_6H_{11})_2NSN(C_6H_{11})_2$ fw = 392.1
Monoclinic a = 13.74(2), b = 6.196(6), c = 13.75(2) Å, β = 91.26(5)°, U = 1170.2 Å^3, Z = 2, D_c = 1.11 g cm^{-3}, $F(000)$ = 436, λ(Mo-K$\bar{\alpha}$) = 0.71069 Å, μ(Mo-K$\bar{\alpha}$) = 1.6 cm^{-1}.

The unit cell parameters were obtained from a least-squares refinement of 15 reflections in the region $20° < 2\theta < 25°$. Weissenberg and precession photographs indicated that reflections were absent for hkl when $h + k + l = 2n + 1$, characteristic of the space groups $I2$, Im, and $I2/m$. Refinement was successfully completed in the non-standard space group $I2$ which is an alternative setting for the space group $C2$ (No. 7, C_s^2) (5). The equivalent positions of $I2$ are: x, y, z; $\bar{x}, y, \bar{z}$; $1/2 + x, 1/2 + y, 1/2 + z$; $1/2 - x, 1/2 + y, 1/2 - z$.

X-ray Measurements

(a) $S_7NSN(CH_3)_2$

The crystal, which was an approximate cube of side 0.40 mm, was attached to a glass fibre and mounted on a Syntex $P\bar{1}$ diffractometer with the c axis almost coincident with the ϕ axis of the diffractometer. Intensities were measured with graphite monochromated radiation, using a θ–2θ scan, with a scan rate varying from 8.0 to 24.0°/min in 2θ, so that the weaker reflections were examined more slowly to minimize counting errors. Stationary background counts, with a time equal to one-half the scan time for each reflection, were made at each end of the scan range. One standard reflection was regularly checked every 50 reflections to monitor the stability of the crystal and its alignment, but no significant variation was observed. A total of 3980 reflections within a quadrant with $2\theta < 55°$ were measured. Subsequent averaging resulted in a total of 2133 independent reflections, of which 1721 were considered observed at the significance level $I/\sigma(I) = 3$ where $\sigma(I)$ is the standard deviation from counting statistics. Lorentz and polarisation corrections were applied to the observed intensities, but an absorption correction was not considered necessary (μ = 14 cm^{-1}).

(b) $(C_6H_{11})_2NSN(C_6H_{11})_2$

The crystal which was an irregular block of approximate dimensions 0.25 × 0.30 × 0.22 mm was attached to a glass fibre and mounted on a Syntex $P\bar{1}$ diffractometer with its 0.25 mm edge, which was perpendicular to the (110) face almost coincident with the ϕ axis of the diffractometer. Data were collected in a similar manner to that described above.

A total of 1432 reflections within a quadrant with $2\theta < 50°$ were measured and subsequent averaging resulted in 1101 independent reflections of which 1024 were considered observed at the significance level $I/(\sigma)I = 3$ where $\sigma(I)$ is the standard deviation from counting statistics. Lorentz and polarisation corrections were applied but an absorption correction was not considered necessary (μ = 1.6 cm^{-1}).

Structure Determination

(a) $S_7NSN(CH_3)_2$

The structure factors were put on an absolute scale by accurately calculating the distribution of E-values for all intensities. The most consistent set of signs for 138 of the 168 reflections which had E values above 1.8 was determined using the direct methods programs SINGEN and PHASE from the X-ray 71 system (6). The E map, computed using the calculated phases revealed eight large peaks, which were assumed to correspond to sulfur atoms. A full-matrix least-squares refinement, using scattering curves of neutral atoms and position and isotropic thermal parameters gave a value of $R_1 = [(\Sigma|F_o|^2 - |F_c|^2)/\Sigma F_o^2]^{1/2}$ of 0.21. The positions of the two carbon and two nitrogen atoms were located from an electron density map and further refinement reduced R_1 to 0.15. Anisotropic temperature factors were introduced and R_1 was lowered to 0.062. The positions of the six hydrogen atoms

*Anisotropic temperature factors (U_{ij}) are given by the expression exp $[-2\pi^2(a^{*2}h^2U_{11} + b^{*2}k^2U_{22} + c^{*2}l^2U_{33} + 2a^*b^*hkU_{12} + 2a^*c^*hlU_{13} + 2b^*c^*klU_{23})]$.

were located from a three-dimensional difference electron density map. Isotropic temperature factors were introduced for the hydrogen atoms and further least-squares refinement converged to a final R_1 value of 0.064 for the 2133 independent reflections or 0.051 for the 1721 observed reffections and the largest shift Δ/σ in the final cycle was 0.1. A final difference electron density map showed no peak greater than 0.5 e/Å^3. The final positional coordinates and thermal parameters are given in Table 1. The asymmetric unit is shown in Fig. 1 and a projection of the unit cell down the *a* axis is given in Fig. 2.

(b) $(C_6H_{11})_2NSN(C_6H_{11})_2$

Since there are two molecules in the cell then for the space group to be *I*2/*m* the sulfur atom would have to be situated at the origin and the NSN bond angle would have to be 180°. As this is a very improbable bond angle for S(II) this space group was rejected and the space group *I*2 was assumed. Since there were 10 large peaks of similar intensity on the three-dimensional Patterson map, they were assumed to correspond to S—N or S—C vectors. The sulfur atom was placed at 000 and the positions of six light atoms, assumed to be carbon, were located from a sharpened Patterson function. Least-squares refinement of the positional and isotropic thermal parameters, using scattering curves for neutral atoms, gave an R_1 index of 0.37. The positions of the remaining non-hydrogen atoms were located from a three-dimensional electron density map and further refinement reduced R_1 to 0.15. Also the coordinates of all atoms were examined to investigate the possibility of the space group being *Im* but this proved to be unsuccessful. The refinement was continued in *I*2. The positions of the hydrogen atoms were computed assuming tetrahedral HCH bond angles and a C—H bond length of 1.00 Å. The hydrogen atoms were assigned an isotropic temperature factor of $U = 0.09$ and their positions were fixed. Anisotropic temperature factors were introduced for all the non-hydrogen atoms and refinement converged to a final R_1 of 0.056 for the 1101 independent reflections or 0.052 for the 1024 observed reflections. The largest shift Δ/σ was less than 0.1 and a final difference electron density map showed no peak greater than 0.4 e/Å^3. The final positional coordinate and thermal parameters are given in Table 2. The asymmetric unit is shown in Fig. 3 and a projection of the unit cell down the *b* axis is given in Fig. 4.

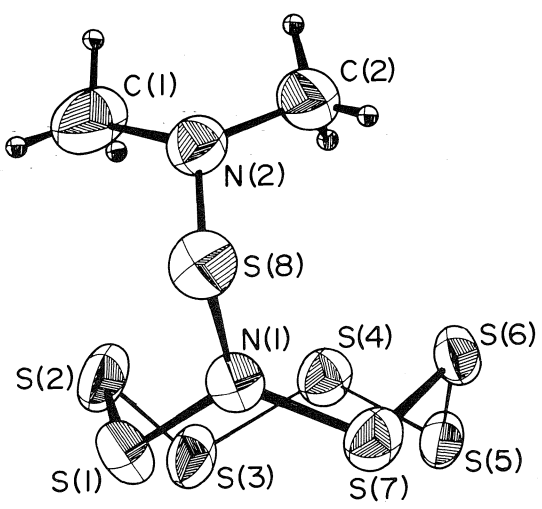

FIG. 1. The $S_7NSN(CH_3)_2$ asymmetric unit.

Tabulations of observed and calculated structure factor tables are available.[2]

Discussion

(a) The Structure of $(C_6H_{11})_2NSN(C_6H_{11})_2$

Table 3 lists the interatomic distances and angles for $(C_6H_{11})_2NSN(C_6H_{11})_2$. The most important features of the structure are the near planarity of the three bonds around both nitrogen atoms, the comparatively short N—S distances of 1.657 Å and the NSN bond angle of 110°. These parameters are not significantly different from those observed in an electron diffraction study of $(CH_3)_2NSN(CH_3)_2$ (1). The N—S bond lengths are shorter than the value of 1.74 Å expected for a single bond, and indicate a bond order of approximately 1.2 (7). This shortening, together with the near planarity of the bonds about nitrogen, can be explained if there is delocalisation of the nitrogen lone-pair onto the S atom. This can be described as a $d\pi$–$p\pi$ bond and such delocalisation can be expected whenever a second row element with a filled shell of eight electrons is bonded to a third row element with an incomplete valence shell (8). The enhanced repulsion between these short, partially double, bonds would tend to open up the NSN bond angle from the tetrahedral angle. It is interesting to note that the four carbon atoms C(1), C(7),

C(1′), and C(7′) attached to the two nitrogens are coplanar. If it is assumed that a single *d* orbital on the central sulfur atom is used in bonding with the nitrogen *p* orbitals maximum overlap is obtained if the axes of the nitrogen *p* orbitals are parallel which in turn causes the four carbon atoms to be coplanar. The two nitrogen *p* orbitals and the sulfur *d* orbital may be used to construct a bonding, a non-bonding, and an anti-bonding molecular orbital. The bonding and non-bonding orbitals are occupied by the four electrons from the two nitrogen atoms. The N—C bond lengths are shorter than a normal N—C single bond, e.g. ethylenediamine (1.47 Å) (9) which is consistent with a formal positive charge on nitrogen due to the partial double bonding postulated for the N—S bonds. The two C_6H_{11} rings have the expected chair conformation with a mean C—C bond length of 1.511 Å which is similar to that found in cyclohexane (1.52 Å) (10).

(b) The Structure of $S_7NSN(CH_3)_2$

Table 4 lists the bond lengths and angles for $S_7NSN(CH_3)_2$. The structure shows a number of interesting features. Both nitrogen atoms have an almost planar geometry indicating delocalisation of the nitrogen lone-pairs onto sulfur. However, the NSN group is not symmetrical. The bonds between the ring nitrogen and the adjacent ring sulfur atoms are short (mean 1.60 Å) indicating a bond order of 1.5 (7), which suggests essentially complete delocalisation of the lone-pair into the ring. In contrast the N(1)—S(8) bond length (1.73 Å) indicates a single bond. Thus there appears to be a strong tendency for this nitrogen lone-pair to be delocalised into the

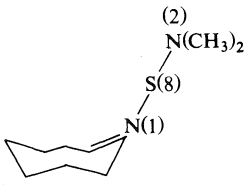
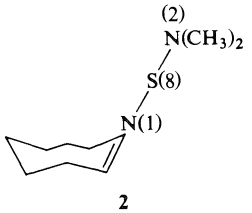
ring and not onto the S(8) bridging sulfur. The bonding at the nitrogen in the ring can, therefore, be described in terms of the two resonance structures **1** and **2**.



1

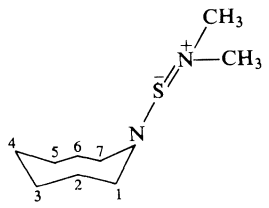


2

The dimethylamino nitrogen N(2) forms a rather short bond with S(8) (1.61 Å) indicating a bond order of approximately 1.5. This bond is stronger than that found in $(C_6H_{11})_2NSN(C_6H_{11})_2$ and appears to compensate for the relatively weak bond formed to the sulfur by N(1). The contraction in the N—C bond lengths (mean 1.37 Å) over those observed in $(C_6H_{11})_2NSN(C_6H_{11})_2$ can also be attributed to the greater formal charge in N resulting from increased delocalisation of the N(2) lone-pair.

Since the two N—S bond lengths in the ring are considerably shorter than those in S_7NH (mean 1.68 Å) (11) it appears that the delocalisation of the nitrogen lone-pair is more extensive in $S_7NSN(CH_3)_2$ than in S_7NH. This can be plausibly attributed to the repulsive effect of the formal negative charge on S(8) which results from the contribution of the resonance form **3**.

The delocalisation of the nitrogen lone-pair seems to have interesting consequences for the structure of



3

the ring. The average S—S bond length (1.99 Å) is very slightly less than that in S_7NH (2.02 Å) (11) and, as in S_7NH, there is a significant alternation of the S—S bond lengths between the nitrogen atom and the opposite sulfur atom. Moreover, the bond angle at S(4) is significantly smaller than the other ring angles, which do not differ significantly from those in S_7NH (11) or in S_8 (12). Unfortunately, at present, we do not understand the nature of the bonding in the S_7NH or S_8 rings sufficiently well to be able to interpret these bond length and bond angle changes in a meaningful way. However, both the relatively high acidity of the hydrogen in S_7NH and the structure of the present compound indicate clearly that there is a strong tendency for delocalisation of the nitrogen lone pair into the sulfur ring, i.e., that this ring is unsaturated in the sense that it is a strong electron pair acceptor and that acceptance of such an electron pair appears to strengthen the bonding in the ring.

Temperature dependence of rate constants for the reactions of oxygen atoms, O(^3P), with HBr and HI[1]

D. L. SINGLETON AND R. J. CVETANOVIĆ

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received May 30, 1978

D. L. SINGLETON and R. J. CVETANOVIĆ. Can. J. Chem. **56**, 2934 (1978).

Rate constants for the reactions O(^3P) + HX → OH + X (X = Br, I) have been determined by a phase shift technique. Oxygen atoms were generated by modulated mercury photosensitized decomposition of nitrous oxide, and were monitored by the chemiluminescence from the reaction with nitric oxide. Over the temperature interval 298–554 K, the rate constants are satisfactorily represented by the Arrhenius expressions $k_{O+HBr} = (8.09 \pm 0.86) \times 10^9 \exp(-3.59 \pm 0.08)/RT$ and $k_{O+HI} = (2.82 \pm 0.27) \times 10^{10} \exp(-1.99 \pm 0.07)/RT$, where the units are ℓ mol^{-1} s^{-1} and kcal mol^{-1}. The indicated uncertainties are one standard deviation. The results of bond energy – bond order calculations, incorporating recently proposed modifications, are discussed.

D. L. SINGLETON et R. J. CVETANOVIĆ. Can. J. Chem. **56**, 2934 (1978).

On a déterminé par la technique du déphasage les constantes de vitesse des réactions O(^3P) + HX → OH + X (où X = Br, I). Les atomes d'oxygène provenaient de la décomposition d'oxyde nitreux photosensibilisée au mercure et ils étaient détectés grâce à chemiluminescence produite par leur réaction avec l'oxyde nitrique. Dans le domaine de température 298–554 K, les constantes de vitesse sont décrites d'une manière satisfaisante par les équations d'Arrhénius $k_{O+HBr} = (8.09 \pm 0.86) \times 10^9 \exp(-3.59 \pm 0.08)/RT$ et $k_{O+HI} = (2.82 \pm 0.27) \times 10^{10} \exp(-1.99 \pm 0.07)/RT$, les unités étant ℓ mol^{-1} s^{-1} et kcal mol^{-1}. Les incertitudes indiquées ci-dessus correspondent à l'écart-type. On discute des résultats de calculs d'énergie de liaison et d'indice de liaisons, en tenant compte de modifications récemment proposées.

[Traduit par le journal]

Introduction

The reactions of ground state oxygen atoms with hydrogen halides are of interest in the chemistry of combustion because of the tendency of halogenated agents to extinguish flames. Also, the reactions of HCl and HBr are of interest in determining the impact of halogen compounds on the chemistry of the stratosphere, particularly with regard to the ozone layer. While there are a few determinations reported for the temperature dependence of the O + HCl reaction (1, 2), there is only one reported for the reaction with HBr (2), and none with HI.

Various attempts have been made to clarify the dynamics of the O(^3P) + HCl → OH($^2\Pi$) + Cl(^2P) reaction. Recently, Macdonald and Moore (3) have concluded that the reaction appears to occur adiabatically on the lowest triplet surface instead of involving a significant crossing of triplet and singlet surfaces (4).

The bond energy – bond order (BEBO) method has been fairly useful as a simple technique for predicting activation energies, at least for many reactions involving the abstraction of hydrogen by doublet species. Recently Gilliom (5, 6) proposed slight modifications in the parameters of the BEBO method, and compared calculated and experimental results for many hydrogen abstractions, although abstractions by O(^3P) were not included. Since the BEBO method generally underestimated activation energies for abstraction by O(^3P) when the older parameters were used, it was of interest in the present work to determine what improvements, if any, result when the modifications proposed by Gilliom are used for the reactions O + HX → OH + X (X = Cl, Br, I).

Experimental

The technique has been described previously (7–9). In a flowing mixture of Hg, N_2O, NO, and HX (X = Br, I), ground state oxygen atoms are formed and react according to the sequence:

$$\mathrm{Hg}(^1S_0) + h\nu(254\ \mathrm{nm}) \rightarrow \mathrm{Hg}(^3P_1)$$

$$\mathrm{Hg}(^3P_1) + \mathrm{N_2O} \rightarrow \mathrm{Hg}(^1S_0) + \mathrm{N_2} + \mathrm{O}(^3P)$$

[1] $$\mathrm{O}(^3P) + \mathrm{HX} \rightarrow \mathrm{OH} + \mathrm{X}$$

[2] $$\mathrm{O}(^3P) + \mathrm{NO} + \mathrm{M} \rightarrow \begin{cases} \mathrm{NO_2}^* + \mathrm{M} \\ \mathrm{NO_2} + \mathrm{M} \end{cases}$$

By modulating the 254 nm light, the oxygen atom concentration is modulated, as is the intensity of chemiluminescence from reaction [2]. The phase difference, ϕ, between the 254 nm light and the chemiluminescence is related to the rates of reactions [1] and [2]:

$$2\pi\nu/\tan\phi = k_1[\mathrm{HX}] + k_2[\mathrm{NO}][\mathrm{M}]$$

where ν is the modulation frequency. The phase angles are

[a]The indicated uncertainties are one standard deviation.
[b]Calculated from the previously determined (9) Arrhenius expression for this reaction.

measured with photomultipliers and a lock-in amplifier. The photomultiplier viewing the chemiluminescence was fitted with a Corning 3-70 filter. A 7-54 filter and $CoSO_4/NiSO_4$ filter were used to isolate the 254 nm light incident on the reaction cell, and interference filters were attached to the photomultipliers monitoring the incident and transmitted 254 nm light.

Flow rates were measured using a calibrated rotameter for N_2O and calibrated capillaries for NO and HX, with DC-704 oil manometers to measure the pressure drops. Temperatures were measured with a chromel–alumel thermocouple inserted into the reaction cell.

Modulation frequencies were between 1.3 and 6 kHz. The total pressure was varied at each temperature by a factor of two in the range 22–83 Torr. The approximate relative concentrations $[N_2O]/[NO]/[HX]$ were, for HBr, 100/10/(1–10) and, for HI, 100/10/(0.1–1). The residence time of gas in the reaction cell was less than 2.5 s for HBr and less than 0.4 s for HI. Oxygen atoms were generated at the rate of 10^{12} atoms cm^{-3} s^{-1} as determined by gas chromatographic determination of the products of the O(^3P) + 1-butene reaction. The extent of consumption of HX was less than 0.004% for HBr and 0.02% for HI.

The gases had the following stated purity levels (for the liquid phase, except for NO): N_2O, 98.0%; NO, 99.0%; HBr, 99.8%; HI, 98.0%. The NO was passed through Linde 13X molecular sieve to remove traces of NO_2. The HI was degassed at liquid nitrogen temperature to remove H_2 and distilled at −78°C to separate it from I_2. Exposure of the hydrogen halides to light was minimized. Also, HBr and HI were admitted to the N_2O, NO, Hg mixture downstream from the mercury saturator and just prior to the reaction cell. The reaction of Hg with HI is negligibly slow under the present conditions (10).

Results

Determination of Rate Constants

Rate constants were obtained from linear least squares treatment of plots of $2\pi\nu/[HX] \tan\phi$ vs. $[NO][M]/[HX]$. The intercepts give k_1 and the slopes, k_2. A typical plot is shown in Fig. 1. The results at each temperature are given in Table 1. The values of k_2 determined in the present work are always within 10% of the values of k_2 determined previously (9) in mixtures of N_2O, NO, and Hg.

The rate constants can be adequately represented by linear Arrhenius expressions, as shown in Fig. 2. The values of the Arrhenius parameters determined

by least squares, with each k_i weighted (11) by $1/\sigma_{k_i}^2$, are given in Table 2.

Estimation of the Extent of Reaction of O(^{3}P) with Reaction Products

In the determination of the rate constants for reaction [1], it is assumed that reaction of oxygen atoms with products of the initial reactions [1] and [2] is negligible. This is a fair assumption because of the low concentration of oxygen atoms. The sequence of reactions considered most important is given in Table 3. Hydroxyl reacts with HX (reaction [3]) and with NO (reaction [4]), and the ratio of the rates of the two reactions is r_3/r_4. In the case of HBr, the conditions are such that $2 < r_3/r_4 < 19$, and for HI, $0.05 < r_3/r_4 < 0.7$ at 298 K. These ratios increase at higher temperatures because of the temperature coefficients of k_3 and k_4. The rate of oxygen atom production is too slow for the reaction O + OH → O_2 + H to compete with reactions [3] and [4]. Thus, each oxygen atom consumed in reaction [1] generates two reactive molecules, either XNO or HNO_2.

An estimate, or upper limit, of the extent of secondary reactions of oxygen atoms can be made by comparing the rates of reactions [1′] and [6′],

$$[1'] \quad O + HX \xrightarrow{(HX, NO)} 2XNO$$

$$[6'] \quad O + XNO \rightarrow \text{products}$$

assuming reactions [3] and [5] dominate over reactions [4] and [7] (although reactions [4] and [7] lead to a similar scheme, and reaction [7] could be represented by reaction [6′]). The ratio $r_{6'}/r_{1'} = k_4[XNO]/k_1[HX]$ is evaluated by taking as an upper limit, $[XNO]/[HX] \leq 2I_0/F_{HX}$, where I_0 is the rate of generation of oxygen atoms and F_{HX} is the flow rate of hydrogen halide (i.e., the ratio of concentrations of two species is equal to the ratio of their flow rates). In the worst case, i.e. at 298 K, the extreme values of F_{HBr} lead to $0.006 \leq r_{6'}/r_{1'} \leq 0.04$. For HI, the ratio is $0.0005 \leq r_{6'}/r_{1'} \leq 0.0014$. A more complicated, but also an approximate scheme, based on reactions in Table 3 and including removal of products by flow, gave values of $(r_6 + r_7)/(r_1 + r_2)$ which were between 1/4 and 1/10 of the values given above for $r_{6'}/r_{1'}$. It is therefore concluded that consumption of oxygen atoms by reactions other than [1] and [2] is negligible.

There is no interference from chemiluminescence from $X + X + M \rightarrow X_2 + M$, the rate of which is insignificant because of the low concentration of atoms. The faster route to formation of X_2 is reaction [10], and from an analysis similar to that described for secondary reactions, $r_{10}/r_5 = k_{10}[XNO]/k_5[NO][M] \leq 2I_0k_{10}/k_5[M]F_{NO}$, which has maximum values at 298 K of 0.03 and 0.06 for X = Br and X = I, respectively. The reaction $O + X_2 \rightarrow XO + X$, even if it occurred at collision frequency, would, on the time scale of the chemiluminescence measurements, be even less important than reaction [6′], which has already been shown not to be significant.

Discussion

Comparison of k_1 *with Reported Values*

The present results for O + HBr are in reasonable agreement with the results of Brown and Smith (2), as shown in Fig. 2. These authors used a discharge-flow technique and determined the concentration of oxygen atoms using the chemiluminescence from reaction [2]. They made corrections for secondary reactions of oxygen atoms by numerically integrating a set of six reactions. The uncertainties in the rate constants of these reactions and in the wall recombination rate of Br used in their model could possibly account for the differences between their results at lower temperatures and the extrapolated Arrhenius plot in the present work. There could, perhaps, also be a genuine slight curvature in the Arrhenius plot.

The present room temperature value for HBr and the value of Takacs and Glass (18) are within the reported uncertainties. Using a discharge flow system, Takacs and Glass monitored the concentrations of oxygen atoms and bromine atoms by esr spectroscopy and corrected for secondary consumption of oxygen atoms using a model consisting of four reactions.

The only reported value of k_1 for O + HI is an approximate value referred to by Takacs and Glass (18). Their value is in approximate agreement with the presently determined value at room temperature.

Bond Energy – Bond Order (BEBO) Calculations

Brown and Smith (2) have reported the results of BEBO calculations for the O + HCl and O + HBr reactions. The calculated activation energies were much smaller than the experimental values, even when they doubled the triplet repulsion energy term, as originally suggested by Mayer and Schieler (19). In a very recent paper, Brown and Smith (20) reported experimental results and theoretical calculations (BEBO and trajectory) for O + DCl and O + DBr. A quasiclassical trajectory calculation using a LEPS potential proved to be fairly successful in giving rate constants consistent with experimental results for the first three vibrational levels of HCl. On the other hand, since conventional BEBO calculations gave activation energies much too low for these reactions, Brown and Smith (20) arbitrarily varied the BEBO parameter p for HCl and HBr until calculated and observed activation energies were identical, and then used the same values of p for calculations on the deuterated molecules. The agreement between calculated and observed kinetic isotope effects was moderate.

Recently, Gilliom (5, 6), in a reply to Jordan and Kaufman's criticism (21) of the BEBO method, reported that, if in addition to modern values of the inert gas intermolecular potentials, a modified Pauling constant were used, the BEBO method would give good agreement with experimental results, even for some cases where the method had previously failed. Reactions of $O(^3P)$ were not included, however, in the many examples reported. In the present work, we have examined the results of BEBO calculations on reactions of $O(^3P)$ with HCl, HBr, and HI, using Gilliom's parameters.

In the BEBO formulation, taking O + HBr as an example, a value of the potential energy of activation, V^*, is obtained by finding the value of n, the bond order of the breaking H—Br bond, that makes V a maximum, subject to the constraint that the sum of the bond orders of the incipient O—H bond and of the breaking H—Br bond is unity (22).

$$V = D_{HBr}(1 - n^p) - D_{OH}(1 - n)^q + C_1 D_{BrO} B(n - n^2)^\gamma \{1 + B(n - n^2)^\gamma\}$$

where

$$B = 0.5 \exp[-\beta(R_{OH} + R_{HBr} - R_{BrO})]$$

$$\gamma = C_2\beta$$

In these expressions, C_1 is a constant used to scale the Sato anti-Morse function ($C_1 = 1$ in ref. 22), C_2 is the Pauling constant, β is the Morse function parameter for BrO, D and R are the normal single bond energy (corrected for zero point energy) and distance for the indicated molecules. The BEBO parameters p and q are given by

$$p = C_2 \ln(D_{HBr}/D_{HeH})/(R_{HeKr} - R_{HBr})$$

$$q = C_2 \ln(D_{OH}/D_{HeH})/(R_{HeNe} - R_{OH})$$

Gilliom recommended $C_2 = 0.28$, based on data for single, double, and triple carbon–carbon bonds, rather than the older value of 0.26. Also Marschoff and Jatem (23), using the same values of the inert gas intermolecular potentials as Gilliom, did BEBO calculations in which C_2 was varied between 0.23 and 0.29, a range they considered to represent a reasonable uncertainty in C_2. They obtained the best

TABLE 4. Potential energies of activation calculated by BEBO and Zavitsas methods[a]

Method	Parameters	O + HCl	O + HBr	O + HI
BEBO	Old	0.8	0.3	0.07
BEBO	Old modified[b]	2.3	0.9	0.2

agreement between calculated and experimental results of 71 reactions using $C_2 = 0.277$.

Zavitsas and Melikian (24) have developed a BEBO-like method which gives good agreement with experimental activation energies in their reported examples, although O(^3P) reactions were not included. This method differs from BEBO in assuming that in the transition state the bond energies of the making and the breaking bonds are equal, and that the bond energies are given by Morse functions. As in BEBO calculations, the Sato anti-Morse function is used to obtain the triplet repulsion energy between, for example, O and Br.

In Table 4 are given the potential energies of activation calculated by the BEBO method using the old ($C_1 = 1$), old-modified ($C_1 = 2$, as suggested by Mayer and Schieler (19)), and Gilliom's parameters ($C_1 = 1.8$ (5, 6) and, modified, $C_1 = 3.6$). Also, the results of the Zavitsas calculation ($C_1 = 1.8$) are shown.[2] For the BEBO calculations, the correction for zero point energy is made using the calculated frequencies of the transition state and the stretching frequency of the reactant. For the Zavitsas model, the correction is made as recommended (24). Comparisons between calculated BEBO potential energies of activation and experimental Arrhenius activation energies are made, although the experimental values have incorporated in them any slight temperature dependence of the pre-exponential factor. Because the calculated bending vibrational frequency of the transition state is very small in most cases in Table 4, a full transition state calculation to obtain an Arrhenius activation energy would not give very meaningful results (2, 25).

With the exception of the calculation using Gilliom's parameters with $C_1 = 3.6$, these models fail to give values of activation energies consistent with the experimental values. The model of Zavitsas gives exceptionally poor agreement, since negative activation energies are predicted for HBr and HI. It would be necessary to use values of C_1 of ~2.9, 5.0, and 9.0 to obtain agreement with the experimental values for HCl, HBr, and HI, respectively. Also, for HI, varying D_{IO}, R_{IO}, or the stretching frequency of IO by 10% raises the calculated activation energy at most to −5.4 kcal mol^{-1}. The failure of the Zavitsas calculation is probably due to the value chosen for the resonance stabilization energy of the activated complex. In the model, −10.6 kcal mol^{-1} is assumed, based on the allyl radical. The stabilization energy is probably much different in the case of O—H—Br type structures, where the relative contributions from resonance structures are likely to be very much different.

A common problem in both the BEBO and the Zavitsas methods is the uncertainty in the magnitude and shape of the triplet repulsion curve. Both approaches scale the Sato anti-Morse function to match particular portions of theoretically calculated curves for triplet H_2. (Calculations using a different form of the triplet repulsion term suggested by Arthur, Donchi, and McDonell (26) did not give improved results.) Mayer and Schieler (19) suggested doubling the triplet repulsion term in cases where the approaching atom is a triplet. Since the BEBO calculations reported by Gilliom (in which the approaching species are doublets) give fairly good agreement with experimental results, it was of interest to try Mayer and Schieler's suggestion, using Gilliom's parameters, for the O(^3P) + HX reactions. As seen in Table 4, this calculation gives the best fit with experimental values for all three hydrogen halides. For HCl, the calculated activation energy is within the range of reported values. Although the calculated values for HBr and HI are about 1.5 kcal mol^{-1} lower than the observed values, the agreement must be considered reasonable for this type of calculation. (It would be necessary to let $C_1 = 5.0$ and 7.9 to match the experimental values for HBr and HI, respectively.)

However, calculations using Gilliom's parameters

[2]The input data for all the calculations and a complete tabulation of the results are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

were made also for other oxygen atom reactions involving abstractions of hydrogen. Without doubling the triplet repulsion term ($C_1 = 1.8$), for the reactions of oxygen atoms with H_2, H_2O, CH_4, and CH_3CHO, activation energies of 11.3, 20.0, 12.3,[3] and 6.2[3] were calculated. The experimental Arrhenius activation energies are ~9 (28), 18.5 (28), 9.1 (28), and 1.9 (29). For these reactions, the calculated values are all larger than the experimental values, although the discrepancy exceeds 2 kcal mol^{-1} only for the latter two reactions involving C—H bonds. Thus, it does not appear justified to double the triplet repulsion term in the HCl, HBr, and HI reactions.

If Gilliom's correction for zero point energy (6) is used, the disparity between calculated and experimental activation energies is further increased in all cases except for HCl, for which the calculated value is 4.5 kcal mol^{-1} with $C_1 = 1.8$. Evidently the BEBO method does not consistently predict activation energies for hydrogen abstractions by oxygen atoms, even when Gilliom's parameters are used. The exact reasons for the inconsistencies are not certain.

Standard thermodynamic transfer functions from water to water + acetone mixtures for a n-nonylcarbon chain attached to different ionic groups

RAYMOND BURY AND CLAUDE TREINER[1]

Laboratoire d'Electrochimie, Université Pierre et Marie Curie, 4, Place Jussieu 75005 Paris, France

Received April 11, 1978

RAYMOND BURY and CLAUDE TREINER. Can. J. Chem. **56**, 2940 (1978).

The standard enthalpy of transfer of trimethyldecylammonium bromide, tetramethylammonium bromide, methyl and decylsodium sulfate have been determined from water to water + acetone mixtures from calorimetric measurements at 298.15 K. The standard entropy function has been calculated using standard Gibbs free energy of transfer data for the same compounds. It is shown that the standard enthalpy and entropy of transfer of a n-nonylhydrocarbon chain attached to the sulfate or to the trimethylammonium groups are quite different whereas the standard Gibbs free energy functions are practically equal in the mixed solvents. It is concluded that the sign of the charge on the ionic groups is responsible for this behaviour and that the influence of this effect extends to a large number of solvent molecules. It is suggested that a similar effect may contribute to the standard enthalpy of so called reference ions: e.g. tetraphenylboron ion casting some doubt on the reliability of these extrathermodynamic approaches at least in mixed solvents, as far as the standard enthalpy function is concerned.

RAYMOND BURY et CLAUDE TREINER. Can. J. Chem. **56**, 2940 (1978).

L'enthalpie standard de transfert, ΔH_t^0, du bromure de triméthyldécylammonium, du bromure de tétraméthylammonium, des sulfates de méthylsodium et de décylsodium, a été déterminée à 298.15 K à partir de mesures calorimétriques, de l'eau à des mélanges eau + acétone. Connaissant l'enthalpie libre standard de transfert, ΔG_t^0 des mêmes composés, l'entropie standard de transfert, ΔS_t^0 a été calculée. On montre que les valeurs de ΔH_t^0 et ΔS_t^0 pour la chaine n-nonylhydrocarbonée sont très différentes selon que cette chaine est attachée au groupe sulfate ou triméthylammonium, mais que les valeurs de ΔG_t^0 sont pratiquement identiques dans les mélanges eau–acétone. Il est proposé que le signe de la charge de la tête ionique soit responsable de cet effet et que son influence s'étend à un grand nombre de molécules de solvant autour de l'ion. On suggère qu'un effet similaire doit contribuer à la valeur ΔH_t^0 pour les ions dits de référence: ion tétraphénylborure par exemple, ce qui rend suspect les résultats utilisant ces approches extrathermodynamiques, au moins dans les solvants mixtes, en ce qui concerne la fonction enthalpique.

Introduction

The search for group additivity rules for organic molecules or ions is one of the most promising approach to the study of complex molecules in aqueous solutions (1). In particular the methylene group has been the subject of numerous thermodynamic studies through the determination of standard properties of homologous series of compounds differing from each other only by a CH_2 group.

Thus it has been recognized long ago that the thermodynamic properties of the methylene group in aqueous solution may strongly depend on its nearest neighbours on the molecule to which it is attached. In a classical study, Cohn and Edsall (2) had shown that the Gibbs standard free energy of transfer of a CH_2 group from water to ethanol is constituted of additive contributions only when the number of carbon atoms between the amino group and the carboxylic group is equal to or greater than $n = 3$. Numerous examples may be found in the literature to illustrate this behaviour (3). We shall give two striking examples particularly relevant to the present study: (*1*) The enthalpy of micellization ΔH_m^0 of a CH_2 group of a nonionic surfactant in water is negative when it is remote from the head groups, but positive for a methylene group situated between the sulfoxide and the hydroxyl group (4). (*2*) The enthalpy of transfer ΔH_t^0 from water to dimethylsulfoxide (DMSO) of alcohols and tetraalkylammonium compounds is strongly dependent upon the number of carbon atoms on a normal alkylchain whereas ΔH_t^0 is almost constant for alkylsulfonates salts from $n = 2$ to $n = 8$ (15). This means that the properties of a CH_2 group is not only dependent upon its position in a given molecule but also on the structure and shape of the whole molecule itself. We found it interesting to investigate the problem of the influence of polar groups on their nearest neighbours in mixed aqueous solvents by studying the standard free energy entropy and enthalpy of transfer from water

to aqueous binary mixtures of compounds with different head-groups.

Let us consider a standard thermodynamic property of transfer from solvent to solvent ΔX_t^0, one can write

$$[1]\quad \Delta X_t^0[(CH_3)_3N{-}(CH_2)_9{-}CH_3Br] \approx \Delta X_t^0[(CH_3)_4NBr] + \Delta X_t^0[(CH_2)_9]$$

$$\Delta X_t^0[(CH_3{-}(CH_2)_9{-}OSO_3Na] \approx \Delta X_t^0[CH_3OSO_3Na] + \Delta X_t^0[(CH_2)_9]$$

We assume then that the standard thermodynamic properties of the two ionic surfactants, trimethyldecylammonium bromide (TMDABr) and sodium decylsulfate (SDS), can be split into, respectively, tetramethylammonium bromide (Me_4NBr) and methylsodiumsulfate ($MeOSO_3Na$), plus two n-nonylhydrocarbon chains. The position of the terminal methyl group is the same for both ionic surfactants and for the classical electrolytes, so that ΔX_t^0-$[(CH_2)_9]$ will measure the remaining influence of the ionic groups on their nearest neighbours.

The standard Gibbs free energy of transfer from water to water + acetone mixtures for the compounds involved in relation [1] are known (6). How-

ever, new experimental results have been obtained in the water-rich region which somewhat affect the previously published values. We present in this paper the new results, the corrected ΔG_t^0 values, together with the enthalpy ΔH_t^0 (and hence the entropy ΔS_t^0) of transfer for the four solutes considered in relation [1].

Experimental

Vapour Pressure Measurements

The standard free energy of transfer $\Delta G_t^0{}_{w\to s}$ of both surfactants from water to water + acetone mixtures have been obtained using a vapour pressure method. Full details have been given previously (7). The variation of vapour pressure of the binary solvent with solute concentration are used to determine the rate of change of the change of the standard chemical potential $\bar{G}_0$ of the solute with solvent composition Z_1, $\partial\bar{G}_0/\partial Z_1$. Integration of this quantity for different Z_1 values with respect to Z_1 leads to ΔG_t^0 with water as the reference solvent. Solute molality was always kept below 0.03 mol kg^{-1}. (The critical micelle concentration for TMDABr and SDS at 298.15 K in water are respectively equal to 0.066 and 0.035 mol kg^{-1} and increase with acetone concentrations.)

Table 1 presents the experimental results obtained in the water-rich region. $(\partial\bar{G}_0/\partial Z_1)_{Z_1\to 1}$ has been calculated as described before (8). Using these results and the $\partial\bar{G}_0/\partial Z_1$ values obtained previously for acetone concentrations above 20 wt.% we obtain the integrated ΔG_t^0 results of Table 2. They have been calculated for acetone concentrations corresponding to the enthalpy experiments.

Calorimetric Measurements

The calorimeter and method developed by Bury *et al.* (9) for measuring the heat of solutions of urea in aqueous organic mixtures were used for the present determinations. The accuracy of these measurements were of the order of ±0.5%. Since the final concentrations of electrolytes (0.001–0.005 mol kg^{-1}) were close to infinite dilution, any small concentration dependence of heat of solution ΔH_s being within the experimental error, the heat of solution at infinite dilution ΔH_0 was taken to be the average of a number (2–5) of ΔH_s measurements (Table 3).[2]

Discussion

Thermodynamic Transfer Functions for Ionic Surfactants from Water to Water + Acetone Mixtures

Before discussing the behaviour of the hydrocarbon chains it is useful to briefly consider the results concerning the neutral electrolytes. Their essential features may be summarized as follows:

(*1*) The standard free energies of transfer of both surfactants are very close in the entire solvent composition range studied and similar to that of classical electrolytes with large organic ions (10) (Fig. 1). Differences only appear in the enthalpy and entropy functions. The large endothermic effect in the water-rich region can be attributed to the particular water-like structure of these rather highly organized solvent mixtures (11–13).

(*2*) The difference in standard enthalpy and entropy of transfer between the two surfactants is much larger above $Z_2 = 0.10$ where water structure may be believed to be entirely destroyed.

(*3*) In the acetone-rich mixtures there is a convergence of ΔH_t^0 and ΔS_t^0 of each surfactant with its

[2]This may not always be true. (We are grateful to J. E. Desnoyers for drawing our attention to this point.) At low dielectric constant mixtures a more important dependence of ΔH on concentration may be found. As an example we have measured the heat of dilution of SDS in a 60 wt.% of acetone mixtures using a Calvet microcalorimeter which has been described previously (32). The experimental results were treated by a least-squares method using the extended Debye–Hückel equation; they are presented in Table 4 where ϕ_L^m is the relative apparent molal heat of dilution.

TABLE 4. Enthalpy of solution for SDS in a water + acetone mixture (60.00%) as a function of surfactant concentration

m (mol kg^{-1})	ϕ_L^m (kcal mol^{-1})	ΔH_s^m (kcal mol^{-1})
0.0	0.0	5.695
0.0005	0.056	5.751
0.001	0.079	5.774
0.005	0.141	5.836
0.010	0.175	5.870

Between 0.01 *m* and infinite dilution the variation of ΔH_s^m is 0.175 mol kg^{-1}. Our original result (Table 3) for m_f = 0.00432 mol kg^{-1}, ΔH^0 = 5.80 kcal mol^{-1}, is still compatible with the more precise extrapolation. It is clear, however, that for ΔH^0 values of the utmost precision, measurements down to 0.0005 mol kg^{-1} should be necessary; these are not easy to make. We have thus shown that the small concentration dependence of ΔH_s below 0.005 mol kg^{-1} may introduce a few percent uncertainty in the absolute ΔH_t^0 values (3% in the case just studied).

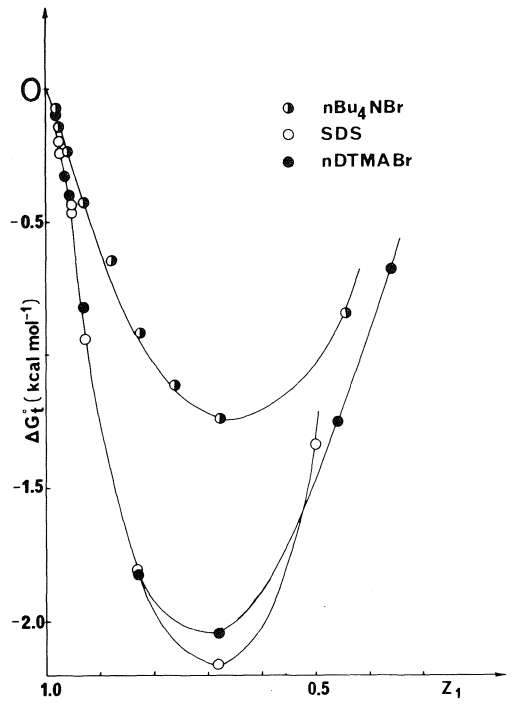

FIG. 1. Gibbs standard free energy of transfer of electrolytes from water to water + acetone mixtures at 298.15 K.

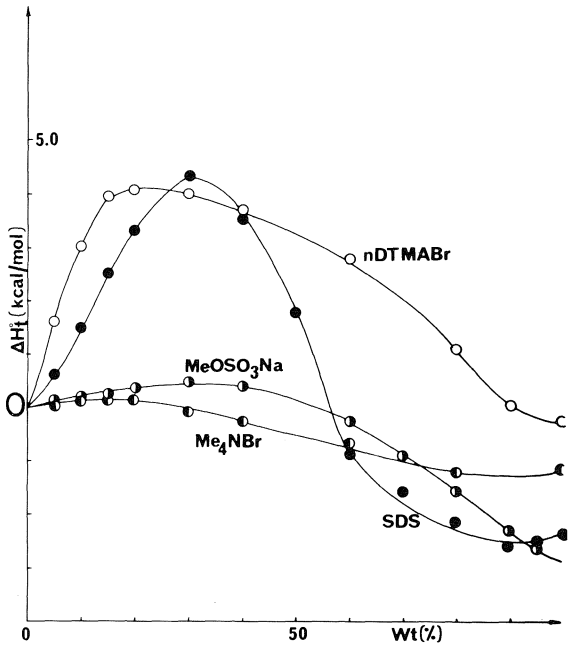

FIG. 2. Standard enthalpy of transfer of electrolytes from water to water + acetone mixtures at 298.15 K.

lower homologue. $MeOSO_3Na$, Me_4NBr, and SDS were not sufficiently soluble in pure acetone for their enthalpy of dissolution to be measured. However, in the case of Me_4NBr, the least soluble solute, a ΔH_t^0 value from water to acetone could be obtained by combination of Abraham's estimate (14) for the standard entropy of transfer ΔS_t^0 and De Ligny's results for ΔG_t^0 (15) ($\Delta S_t^0 = -34$ cal mol^{-1} deg^{-1}. $\Delta G_t^0 = 9.04$ kcal mol^{-1} both on mole fraction basis). Hence $\Delta H_t^0 = -1.10$ kcal mol^{-1}. This value is of course approximate and should be used as such. We observe then that the difference between ΔH_t^0 for TMDABr and Me_4NBr is of the order of +0.8 kcal mol^{-1}. Extrapolation of the results for the more soluble SDS and $MeOSO_3Na$ to pure acetone shows the same convergence with a difference of about +0.5 kcal mol^{-1} only (see Fig. 2). This means that ΔH_t^0 from water to pure acetone is essentially independent of the number of carbon atoms on the linear chain. This is the more noteworthy as usually some dependence is found with chain length at least between the first and the second homologue of a given series even if this dependence almost disappears for the higher homologues. Krishnan and Friedman find the same trend for sulfonates from water to pure DMSO (5) (ΔH_t^0 is almost constant from $n = 2$ to $n = 8$ carbon atoms in the chain); other similar findings have been reported for shorter hydrocarbon chains (16). One interesting feature of these results is that whereas a very large dependence is observed for ΔH_t^0 upon n for the tetraalkylammonium series, such a dependence is not found for the trimethylammonium series studied here. One might suggest that a linear hydrocarbon chain can be more easily accommodated in any structure than a bulky solute.

Behaviour of an n-Nonylhydrocarbon Chain Attached to a Sulfate or a Trimethylammonium Group

If we substract the ΔG_t^0, ΔH_t^0, and ΔS_t^0 results for Me_4NBr and $MeOSO_3Na$ from those for the two surfactants we obtain the contributions of an n-nonylhydrocarbon chain to the transfer functions according to relation [1]. Let us call $(CH_2)_9^{\varepsilon+}$ the hydrocarbon chain obtained from the cationic surfactant and $(CH_2)_9^{\varepsilon-}$ the chain obtained from the anionic one. Figures 3, 4, 5, show that indeed the two chains are not identical and that even with the head-group effects removed, large differences remain on some of the standard thermodynamic transfer functions.

Following previous authors (17, 18) we may consider four different effects contributing to any standard function ΔX_t^0:

$$\Delta X_t^0 = \Delta X_t^0(\text{cav}) + \Delta X_t^0(\text{el}) + \Delta X_t^0(\text{spec}) + \Delta X_t^0(\text{struct})$$

where the subscripts stand for cavity, electric, specific, and structural effects, respectively.

Clearly the work of cavity formation should be exactly the same for the two linear chains. The main part of the electric effect has been subtracted as well as the specific effect. Also geometrical aspects which can be related to structural effects should be similar in both cases. There remains only the effect of the charge on the solvent molecules which surround the methylene groups nearest to the head group; in particular the effect of the sign of the charge needs to be examined. It is now commonly accepted that, in most cases of binary aqueous solvents cation and anion exhibit an opposite behaviour (19). The minimum of ΔG_t^0 for Bu_4NBr and TMDABr in aqueous acetone mixtures has been explained by that opposite effect (6, 10). $\Delta G_t^0(Br^-)$ is positive for the bromide ion because anions are preferentially solvated by water. The work of cavity formation as can be calculated from the scaled-particle theory (20–22) and preferential solvation of most univalent cations by organic molecules (19) explains the negative ΔG_t^0 values ($\Delta G_t^0 = \Delta G_t^{0-} + \Delta G_t^{0+}$). The sum of the two contributions (negative and positive) is responsible for the minimum observed. Furthermore we note that, within experimental error,

$$\Delta G_t^0\{(CH_2)_9^{\varepsilon-}\} \approx \Delta G_t^0\{(CH_2)_9^{\varepsilon+}\}$$

in the mixed solvents. This near equality rules out the possibility that the electric charge per se still plays a significant role in these cases; it may be considered as another example of the well-known compensation phenomena in aqueous solvents between enthalpy and entropy.

The study of the behaviour of the enthalpy and entropy functions give more information. For example we have pointed out that the difference $\delta\Delta H_t^0$ from water to pure acetone for homologues of each series (sulfate or trimethylammonium) was 0.5 and 0.8 kcal mol^{-1} respectively. Thus

$$\Delta H_t^0\{(CH_2)_9{}^{\varepsilon-}\} \approx \Delta H_t^0\{(CH_2)_9{}^{\varepsilon+}\}$$

The large difference observed especially in the intermediate region must be due to the presence of both acetone and water molecules. It is interesting to compare ΔH_t^0 for Bu_4NBr (22) and TMDABr (Fig. 6). The curve corresponding to Bu_4NBr is shifted to higher endothermic values with respect to TMDABr but the shapes of the curves are very similar. In these cases the electric charge is somewhat shielded from the solvent whereas for the sulfate group the charge is much more exposed to the solvent molecules which surround it. Thus the difference between the enthalpy (and entropy) for $(CH_2)_9{}^{\varepsilon-}$ and $(CH_2)_9{}^{\varepsilon+}$ seems to be essentially due to the orientation of water molecules next to the linear carbon chain induced by the sign of the electrical charge. This effect, which may be called structural, must concern a large number of molecules around the electric charge in order to create such a decrease in enthalpy. It is nonspecific, otherwise it would have showed up somewhat on ΔG_t^0. One may suggest that water dipoles are diluted in acetone which acts as an 'inert' solvent as far as the dipole effect is concerned.

It might be worthwhile to recall a similar behaviour in the case of tetraaryl ions. In order to evaluate single-ion thermodynamic quantities the tetraphenylboron assumption has often been used; it is assumed that the tetraphenylarsonium ion (ϕ_4As^+) and the tetraphenylboron ion (ϕ_4B^-) are weakly solvated to the same extent in different solvents (24, 25). Treiner (26) has shown, using the scaled-particle theory (SPT), that it seems to be the case as far as the ΔG_t^0 function is concerned for ϕ_4As^+ and ϕ_4B^- from water to some pure and mixed aqueous solvents; however, ΔH_t^0 could not be calculated by the SPT. Figure 7 presents ΔH_t^0 for ϕ_4BNa and ϕ_4PBr from water to water–dioxane mixtures (27). The similarity with the shape of curves for $(CH_2)_9{}^{\varepsilon-}$ and $(CH_2)_9{}^{\varepsilon+}$ is real (and also with those corresponding to TMDABr and SDS of course), even if the changes observed are more important in the former than in the latter case. Similar observations can be made with tetraaryl negative and tetraalkyl positive ions in water + *tert*-butanol mixtures (23).

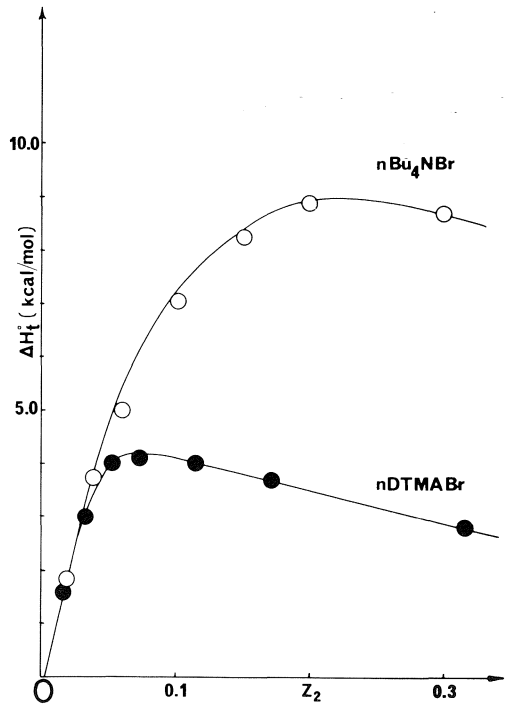

FIG. 6. Standard enthalpy of transfer of a linear and bulky tetraalkylammonium salt from water to water + acetone mixtures at 298.15 K.

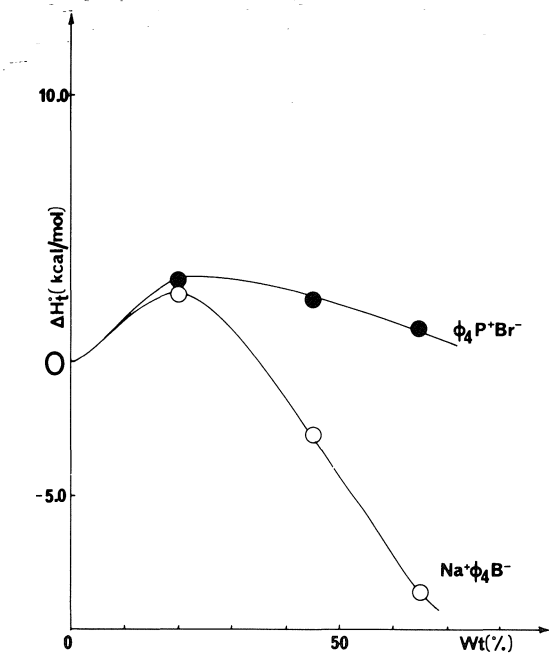

FIG. 7. Standard enthalpy of transfer of tetraaryl salts from water to water + dioxane mixtures at 298.16 K (ref. 27).

The analogies observed lead us to the following suggestion. Part of the large difference in ΔH_t^0 for ϕ_4BNa and ϕ_4AsCl might be due to the different properties of ϕ_4B^- and ϕ_4As^+ because of the effect of the sign of the charge on the surrounding water molecules just like in the case of the hydrocarbon chains where the remaining sign effect contributes heavily to ΔH_t^0.

Finally Feakins *et al.* (28) from their calorimetric study on $Na\phi_4B$ in water + dioxane mixtures conclude that ϕ_4B^- behaves like a small monoatomic ion. This conclusion may be reconciled with ours. For small ions an exothermic effect is predominant ($\Delta H_t^0(spec) < 0$). The scaled-particle theory predicts a large endothermic effect for a neutral particle in these mixed solvents ($\Delta H_t^0(cav) > 0$). If anions are more strongly hydrated than cations, then for two large ions of opposite charges and equal size, $\Delta H_t^0(exp)$ will be less endothermic for the anion than for the cation, in agreement with experimental observation. Hence the comparison between the effect of large and small ions on the binary aqueous solvents studied indicates that in the case of large anions the effect of the charge on water dipole predominates over the nonspecific (cavity) effect; in the case of large cations the nonspecific effect seems predominant.

The Raman spectra of tetrachloroantimony(V) dichloro nonafluorodiantimonate(V), tetrachloroantimony(V) undecafluoroantimonate(V), and related molecules

JACK G. BALLARD AND THOMAS BIRCHALL

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 27, 1978

JACK G. BALLARD and THOMAS BIRCHALL. Can. J. Chem. **56**, 2947 (1978).

The Raman spectra of $[SbCl_4^+][Sb_2Cl_2F_9^-]$, $[SbCl_4^+][Sb_2F_{11}^-]$, $[AsCl_4^+][SbF_6^-]$, and $SbCl_4F(NbF_5)_x$ are reported. The spectra of all compounds except the last are interpreted in terms of a tetrahedral cation with weak association between the cation and anion. The spectra of the adduct found between $SbCl_4F$ and NbF_5 are interpreted in terms of polymeric fluorine bridged arrangements.

JACK G. BALLARD et THOMAS BIRCHALL. Can. J. Chem. **56**, 2947 (1978).

On rapporte les spectres Raman de $[SbCl_4^+][Sb_2Cl_2F_9^-]$, $[SbCl_4^+][Sb_2F_{11}^-]$, $[AsCl_4^+][SbF_6^-]$ et $SbCl_4F(NbF_5)_x$. On interprète les spectres des trois premiers composés en fonction d'un cation tétraédrique et d'une faible association entre le cation et l'anion. On interprète les spectres du composé d'addition entre $SbCl_4F$ et NbF_5 en fonction d'arrangements polymériques comportant des ponts fluor.

Introduction

Antimony(V) chloride fluorides $SbCl_{5-x}F_x$ have had various structures assigned to them. They have been reported to be trigonal bipyramidal (1), or ionic such as $[SbCl_4^+][F^-]$ for $SbCl_4F$ (2). Antimony(V) dichloride trifluoride has been variously described as ionic, $[SbCl_4^+][SbF_6^-]$ (3), trigonal bipyramidal monomeric (4), and as a halo-bridged species (5). More recently, Preiss (6) has shown $SbCl_4F$ to be a fluorine bridge tetramer and Beattie *et al.* (7) have interpreted the Raman spectrum in terms of this structure. The molecule $SbCl_3F_2$ has recently been shown to be a fluorine bridged tetramer (8) and its Raman spectrum (9) assigned by comparison to that of $SbCl_4F$. In 1972 Preiss (10) repeated the preparation of $SbCl_2F_3$, using Kolditz and Lieth's method (3), and showed that the molecule had the formulation $[SbCl_4^+][Sb_2Cl_2F_9^-]$. Raman data were presented in this paper (10), but these were simply a reassignment of the spectra reported earlier by Dehnicke and Weidlein (4). Since it was not clear that these latter two groups were in fact examining the same molecules we have prepared a sample of $[SbCl_4^+][Sb_2Cl_2F_9^-]$, identified it by X-ray crystallography and Mössbauer spectroscopy (11), and reexamined its Raman spectrum. The Raman spectra of several related compounds are also presented here.

Experimental

$[SbCl_4^+][Sb_2Cl_2F_9^-]$ was prepared by the method of Kolditz (12) and confirmed as being identical to that of Preiss (10) by measurement of the unit cell parameters ($a = 11.7$, $b = 10.4$, $c = 13.2$, $\beta = 94.2°$). The melting point was 49–53°C and ^{121}Mössbauer data have already been reported (11).

$[SbCl_4^+][Sb_2F_{11}^-]$ was prepared by the reaction of a 4:1 mixture of SbF_5 and $SbCl_5$ or by the reaction of $SbCl_4F$ with 2 mol of SbF_5 in liquid SO_2 at 20°C in a sealed tube. The product is a white solid mp 81–82°C. Mössbauer spectra have already been reported (11).

$[AsCl_4^+][SbF_6^-]$ was isolated while attempting to prepare $[SbCl_4^+][AsF_6^-]$ by the reaction of $SbCl_4F$ and AsF_5. Halogen rearrangement occurred and the hexafluoroantimonate(V) salt of $[AsCl_4^+]$ was obtained as a white solid which decomposed before melting.

In a typical preparation of $SbCl_4F{\cdot}NbF_5$ a weighed amount ($\sim$1.0 g) of $SbCl_4F$ was introduced into one arm of a previously dried reaction vessel in a glove box and a stoichiometric amount of NbF_5 was added to a second arm. The vessel was transferred to a vacuum line and evacuated. Sulphur dioxide was then condensed onto the NbF_5, the vessel sealed and allowed to warm to room temperature. The NbF_5 dissolved in the liquid SO_2 and this solution was poured through a frit separating the two arms of the reaction vessel onto the $SbCl_4F$. The mixture was allowed to react overnight after which the SO_2 was removed and the sample washed several times with fresh liquid SO_2. The white adduct melted at 55–57°C.

Raman spectra were recorded using an Ar ion laser (5145 Å) with a Spex 1400 Spectrophotometer system. Samples were contained in carefully dried sealed capillary tubes.

Results and Discussion

The Raman data for $[AsCl_4^+][SbF_6^-]$, $[SbCl_4^+][Sb_2Cl_2F_9^-]$, and $[SbCl_4^+][Sb_2F_{11}^-]$ are shown in Fig. 1 and Table 1.

Weidlein and Dehnicke (13) have reported Raman data for $[AsCl_4^+][AsF_6^-]$ and this is compared to our data for the $[SbF_6^-]$ analogue. The assignments are based on a tetrahedral cation and an octahedral anion. If the cation $[AsCl_4^+]$ has T_d symmetry, then a total of four fundamentals are Raman active. The strongest band in the spectrum at 415 cm^{-1} is assigned to ν_1. This agrees with the assignment made

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

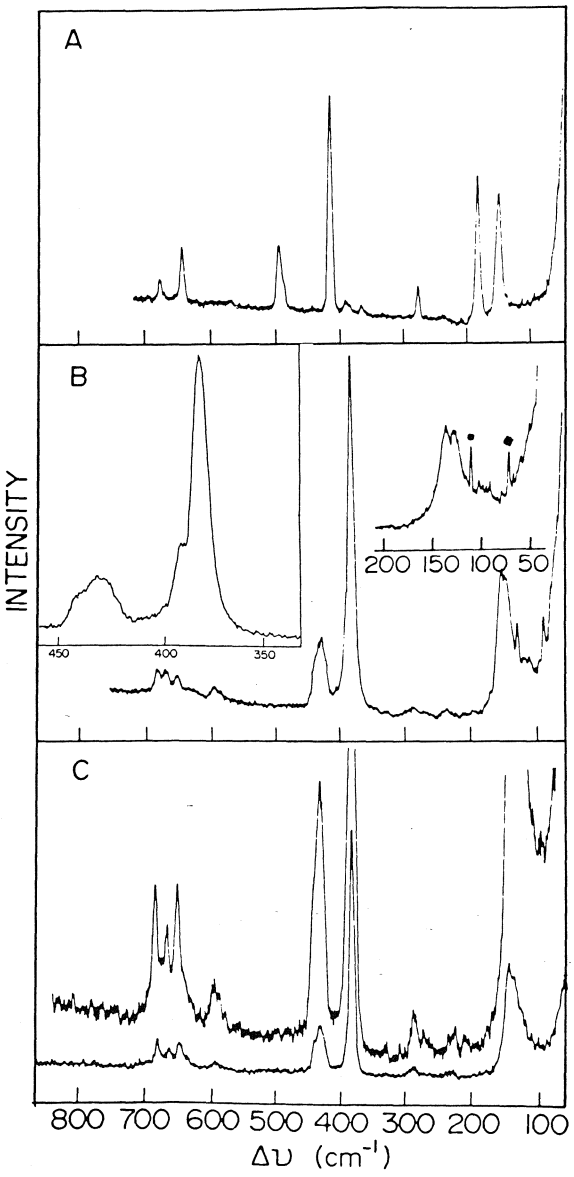

FIG. 1. Raman spectra at 20°C of (*a*) solid $[AsCl_4^+][SbF_6^-]$; (*b*) solid $[SbCl_4^+][Sb_2Cl_2F_9^-]$, inset (450–350 cm^{-1}) region expanded; (*c*) solid $[SbCl_4^+][Sb_2F_{11}^-]$. The spectra were recorded in glass melting point tubes (*glass lines).

for the $[AsF_6^-]$ analogue, where ν_1 is at 422 cm^{-1} (13). The $\nu_2(e)$ vibration is assigned to the band at 149 cm^{-1}; in $[AsCl_4^+][AsF_6^-]$ this occurs at 156 cm^{-1}; ν_3 and ν_4 were assigned to the bands at 490 and 184 cm^{-1}, the 490 cm^{-1} band being split into two bands at 496 and 488 cm^{-1}. This is attributed to cation–anion interaction and evidence for such interaction is also found in the anion spectrum. No corresponding lowering of symmetry was reported in $[AsCl_4^+][AsF_6^-]$ (13).

An undistorted anion having O_h symmetry would have only three Raman active vibrations, namely, $\nu_1(a_{1g})$, $\nu_2(e_g)$, and $\nu_5(t_{2g})$, but there are more than three bands to be assigned to the $[SbF_6^-]$ anion. Cation–anion interaction, alluded to above, would lower the symmetry and allow additional vibrations to be Raman active. These bands are assigned as indicated in Table 1 and agree favourably with the assignments made for the distorted $[SbF_6^-]$ ion in $[Xe_2F_3^+][SbF_6^-]$ (14). No evidence for cation–anion interaction was found in $[PCl_4^+][PCl_6^-]$ (15), $[PCl_4^+][SbCl_6^-]$ (16), or $[AsCl_4^+][AsF_6^-]$ (13). Figure 1 also shows the spectra of $[SbCl_4^+][Sb_2Cl_2F_9^-]$ and $[SbCl_4^+][Sb_2F_{11}^-]$ as solids. One can see the similarity between these spectra and that discussed above in that the strongest bands in each of these spectra arise from the cation. The positions of the bands representing the asymmetric stretch and bend are, of course, appropriately shifted due to the increased mass of the ion. We have assigned the cation bands by analogy to those for the $[AsCl_4^+]$ ion and this has been aided by being able to carry out polarization measurements on the melts. Earlier investigation of "$SbCl_2F_3$" by Dehnicke and Weidlein (4) had resulted in the erroneous conclusion that this molecule was trigonal bipyramidal. A reinterpretation of these data was made by Preiss (10) as a result of his X-ray analysis of this compound, but a complete analysis was not possible at that time. We have been able to observe all four Raman active bands for the $[SbCl_4^+]$ cation and these are listed in Table 1. The band at 385 cm^{-1}, which occurs at 388 cm^{-1} in the melt and is totally polarized, is assigned to $\nu_1(a_1)$. The $\nu_2(e)$ mode, which was not detected by the previous workers, is at 128 cm^{-1} and is broadened. The asymmetric stretch at 436 cm^{-1} is presumably the result of a lowering of symmetry due to cation–anion interaction as suggested by both Mössbauer (11) and X-ray analysis (17). The remaining cation band, $\nu_2(t_2)$ occurs at 137 cm^{-1}. These assignments hold also for the $[Sb_2F_{11}^-]$ analogue. In the melt, the splitting observed for $\nu_3(t_2)$ disappears, while $\nu_2(e)$ becomes sharper, as might have been expected since cation–anion interactions would be reduced in the liquid state. All of these assignments are completely consistent within the $[PCl_4^+]$, $[AsCl_4^+]$, $[SbCl_4^+]$ series, with a steady decrease in frequency of all bands which represent the asymmetric stretch as the mass of the central atom increases. The only notable difference within this series is found in the degree of cation–anion interaction which is most noticeable for $[SbCl_4^+]$, the largest and hence the most easily distorted.

The anion bands of the $[SbCl_4^+]$ compounds are weak by comparison with those of the cation (Fig. 1). This appears to be a general feature of all $[Sb_2F_{11}^-]$ spectra and these are rarely, if ever,

assigned. A partial, somewhat tentative assignment is made in Table 1 by comparison with those of the $[SbF_6^-]$ ion. The spectra of the $[Sb_2Cl_2F_9^-]$ and $[Sb_2F_{11}^-]$ anions appear little different. However, the former should have an Sb—Cl stretching vibration and Preiss (10) had in fact assigned the band at 393 cm^{-1} to the Sb—Cl stretch of both the anion $[SbCl_2F_9^-]$ and the $[SbCl_4^+]$ cation. Expansion of the Sb—Cl stretching region shows an additional band, at 392 cm^{-1}, in the spectrum of the $[Sb_2Cl_2F_9^-]$ anion (Fig. 1) which is not present in the $[Sb_2F_{11}^-]$ spectrum which we assign to the anion Sb—Cl stretch. The anion spectra again simplify on melting, for the reasons discussed above, but depolarization ratios could not be measured because of the low intensities of the anion bands.

Raman data recorded for the adduct formed between $SbCl_4F$ and NbF_5 are 98(12), 110(24), 117(24), 139sh, 147(22), 161(36), 232(3), 260(3), 343(100), 370(20)sh, 382(55), 403(12)sh, 651(1), 705sh, 711(6), 740(9), 748sh, 761(11), 784(4). There are a number of possible products of this reaction. Niobium pentafluoride could abstract a fluoride from $SbCl_4F$ to produce $[SbCl_4^+][NbF_6^-]$ or $[SbCl_4^+][Nb_2F_{11}^-]$. A halogen rearrangement could occur, as it did with $SbCl_4F$ and AsF_5, to produce $[NbCl_4^+][SbF_6^-]$. Since both reactants have tetrameric fluorine bridged structures, the third possibility for the structure of the reaction product would be a mixed antimony–niobium fluorine bridged compound, which may be tetrameric in nature. It is apparent, upon examination of the data, that there is a similarity between the spectrum of the adduct and those of the reactants (7). Comparison of the band positions with the data in Table 1 also indicates that neither $[SbCl_4^+]$ nor $[SbF_6^-]$ are present in this compound, nor can any bands be convincingly assigned to a $[NbCl_4^+]$ cation. The first two structures suggested above are therefore ruled out. A fluorine bridged polymer is therefore the most likely possibility. Antimony-121 Mössbauer measurements (18) are also consistent with this suggestion but further work will be necessary to completely characterize this compound.

Received May 12, 1978

JOHN C. DAY, BOHUMIL ALINCE, and A. ALLEN ROBERTSON. Can. J. Chem. **56**, 2951 (1978).

Measurements of the penetration of porous substrates (porous glasses) by non-sorbing macromolecules (dextrans) have yielded penetration curves that relate the degree of penetration to molecular size. Combinations of well-characterized polymer fractions with a series of uniformly porous glasses have demonstrated that, in agreement with the theory, the penetration is dependent only on the relative size of the molecule and the pore. Several models differing in the methods of characterizing the sizes of the pores and solute molecules have been compared. The predictions of the shape of the penetration curves are similar for most models and are in similar agreement with the experimental data.

JOHN C. DAY, BOHUMIL ALINCE et A. ALLEN ROBERTSON. Can. J. Chem. **56**, 2951 (1978).

Au moyen de mesures de la pénétration de substrats poreux (verres poreux) par des macromolécules inertes (dextranes), on a déterminé des courbes reliant le degré de pénétration à la taille des molécules. En réunissant des fractions bien caractérisées de polymères et une série de verres uniformément poreux, on a démontré qu'en accord avec la théorie, la pénétration ne dépend que des tailles relatives de la molécule et de la pore. On a comparé plusieurs modèles qui diffèrent quand à la méthode utilisée pour caractériser les tailles des pores et des molécules de soluté. Pour la plupart des modèles, on prévoit pour les courbes de pénétration des allures semblables et on note un accord semblable entre ces prévisions et les résultats expérimentaux.

Introduction

The interaction of polymer molecules in solution with porous substrates depends initially on their ability to penetrate the pores and then on their interaction with the pore walls, which may vary from strong attraction resulting in adsorption to strong repulsion. This study reports the penetration of a porous material by a polymer in solution in which the interaction of the polymer and surface is shown to be minimal. The behaviour is relevant to the mechanism of separation by molecular size in gel permeation chromatography (GPC), and to the determination of pore-size distributions by the degree to which molecules of different sizes are excluded from polydisperse pore systems. It is important, in the context of this work, to an understanding of the mechanism of polymer adsorption on internal surfaces.

During adsorption on a porous material, the concentration of the adsorbate solution in the pores is determined by the bulk concentration, the relative rate of penetration and adsorption, the degree of interaction of the polymer with the pore-wall surface, and the relative size of the polymer and the pore. Using a non-sorbing polymer as the penetrating solute provides a means of identifying and studying the factors affecting the penetration.

The dependence of the ratio of the equilibrium concentration attainable within a pore to the external solution concentration on the relative size of the solute molecules and the pore has been derived by Casassa (1) for the case where the interactive forces between the polymer and the pore wall are negligible. Few data to verify this have been published (2). The influence of interaction has been included in a more general treatment by Pouchly (3), where the chain segment concentration near the pore-wall surface is determined by both the degree of interaction with and the conformational restrictions imposed by the pore wall.

Molecular size separation by the penetration of non-absorbing macromolecules into porous materials was first accomplished using flexible polymer gels (4), then by using rigid polymer gels (5) and porous silica (6). Interest in the mechanism of separation has led to theories based on diffusion or on the degree of penetration and these have been extensively reviewed (4, 7–10). The relative influence of the two mechanisms in GPC procedures was investigated by Yau (ref. 10, p. 105, refs. 11, 12), who found that separation is primarily due to the extent of permeation and that kinetic processes contribute only in a minor way.

The correlation obtained between the penetration

determined by static experiments and the elution of the same polymers from columns packed with the same porous material (11) indicates that the separation is independent of the flow rate of the eluant and is not dependent on the attainment of equilibrium conditions during column operation. In his review, Coll (ref. 10, p. 135) points out that as long as a solute molecule undergoes a large number of exchanges between the mobile phase (bulk solution) and stationary phase (pores) in the column, the elution volume of a molecular species is independent of the flow rate, and the equilibrium model for the partition of the solute between the bulk solution and the pores is applicable. However, a true comparison of the theoretical penetration curves can only be made with the data obtained from static penetration experiments. In this study, the penetration of characterized porous glass by fractionated samples of dextran in water solution is compared with model penetration curves.

Materials and Methods

Dextran

Characterized dextran fractions were obtained from Pharmacia, Uppsala, Sweden. Molecular weights, determined by light scattering and osmometry, and intrinsic viscosities are listed in Table 1. Molecular weight distributions, determined by gel filtration on 'Sephadex' (cross-linked dextran gel), are shown in Fig. 1. All data were supplied by the manufacturer.

The structure (14–16) and the hydrodynamic properties (14, 17–19) of dextran have been extensively studied. The molecules are randomly branched and sedimentation behaviour suggests that the sphere is a reasonable model for the molecule in solution and any asymmetry decreases at higher molecular weights. Several methods (14, 17, 19) have been applied to calculate the dimensions of dextran molecules in solution. For the purpose of the present investigation, the equivalent hydrodynamic radius, r_h (Table 1), was calculated using the Einstein viscosity relation (ref. 20, p. 606).

$$[1] \qquad r_h = (3.0 \times 10^{22} \overline{M}_w[\eta]/N\pi)^{1/3}$$

where r_h is the equivalent hydrodynamic radius (nm), $\overline{M}_w$ is the weight average molecular weight, $[\eta]$ is the intrinsic viscosity (dl g^{-1}), and N is the Avogadro number.

The relation between the equivalent hydrodynamic radius and the root-mean-square radius of gyration of dextran is examined in the Discussion section.

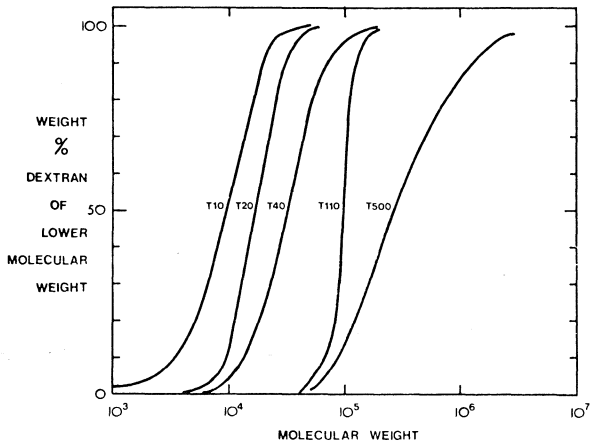

FIG. 1. Molecular weight distributions of dextran fractions (supplied by Pharmacia).

The dextran fractions were stored in air-tight containers to prevent contamination and sorption of moisture from the atmosphere. Since dextran solutions are growth media for micro-organisms, sodium azide (final concentration, 10 mg ℓ^{-1}) was added to prevent degradation of the macromolecule during equilibration. The specific conductance of the distilled water was less than 1.5×10^{-6} ohm^{-1} cm^{-1}. The disaccharide, maltose, provided a probe of smaller effective dimensions in solution, for comparison with the dextran fractions.

Porous Glass

Three different CPG-10 controlled pore glasses (Corning Glass Works, Corning, NY; Electro-Nucleonics Inc., Fairfield, NJ) were used as the porous substrate. After washing the glasses to remove fines and colloidal glass particles from the pore system, the benzene sorption–desorption isotherm of each was determined, from which the values of the parameters required to characterize the pore system were calculated by established methods (21, 22) (Table 2). The surface areas were obtained by BET analysis of the isotherms and were in agreement with areas obtained by nitrogen adsorption. The pore volume was determined from the plateau in the adsorption isotherm above a relative vapour pressure of 0.95 (22) and the mean pore size and pore-size distribution were determined by an analysis of the desorption isotherm, based on the Kelvin equation (21), which gives a Kelvin radius, a, that is interpreted either as the radius of equivalent cylindrical pores or as the separation distance of parallel-walled slits. It is relevant here to consider both alternatives since the porous glass is believed to

have a network of highly interconnected pores with properties intermediate between slits and cylinders.

Procedure

Approximately 2 g of CPG-10 porous glass was accurately weighed in screw-capped glass bottles (capacity 30 cm^3), to which 15 cm^3 of dextran solution was then added. The mixture was equilibrated at 25 ± 1°C tumbling at 10 rpm to keep the glass particles in suspension. Although all measurable concentration change occurred in the first hour, each suspension was allowed to equilibrate for 24 h. Control mixtures consisting of glass and solvent only were simultaneously equilibrated. Exclusion of the polymer from the pore volume results in an increased concentration of the supernatant. The ratio of pore volume to solution was chosen so that the increase in concentration was large enough to be measured accurately.

For all dextran–glass combinations tested, the ratio of the concentrations in the pores and in the bulk solution was independent of the concentration of polymer solution added over the range from 1 g ℓ^{-1} to 20 g ℓ^{-1}. Most of the data were obtained with solutions of initial concentration, 10 g ℓ^{-1}.

The supernatant concentration was compared with that of the original solution in a 10 cm cell in a Hilger–Watts differential refractometer thermostatted at 25°C. Refractive index increments due to changes in dextran concentration and to substances eluted from the glass were found to be additive; the simultaneous control readings were therefore subtracted from those of test mixtures. The refractometer was calibrated with dextran solutions of known concentration; no variation in the calibration with molecular weight of the dextran was found.

To verify that no air was trapped within the pore volume when the dextran solution was added to dry glass, weighed samples of glass were evacuated in the equilibration bottles and then immersed in distilled water before the dextran solution was added. A degree of exclusion equal to that without evacuation was obtained. This result is consistent with the open structure of the pore system of CPG-10 glass (23).

Calculation of Penetration Coefficient

Casassa (1) defines a distribution coefficient, K, as the ratio of the polymer concentration within the pores, C_p, to the concentration in the supernatant solution, C_s.

$$[2] \qquad K = C_p/C_s$$

The system is assumed to consist of monodisperse polymers within monodisperse pores of given geometry, in which the whole pore volume is considered accessible to the polymer, but the concentration attainable within the pores is lower than that in the bulk solution. This is due to conformational entropy restrictions, imposed by the pore walls, which are directly dependent on the relative size of the polymer and the pores (1).

This coefficient equals unity when the relative size is zero, and decreases as the relative size increases. It is therefore directly related to penetration and inversely to exclusion. The term 'penetration coefficient' describes this behaviour logically, and is used throughout this paper for the parameter, K.

When a quantity of porous glass is immersed in a volume of solution, V_0, of concentration, C_0, the solute is partitioned between the pore volume present, V_p, at concentration C_p, and the supernatant solution volume, V_s, at concentration C_s. At equilibrium, the following two relations apply:

$$[3] \qquad V_0 = V_p + V_s$$

$$[4] \qquad C_0V_0 = C_pV_p + C_sV_s$$

Upon substituting V_s from eq. [3] into eq. [4] and re-arranging,

$$C_p = C_s + \frac{V_0}{V_p}(C_0 - C_s)$$

Substituting from eq. [2]

$$[5] \qquad K = 1 - \frac{V_0}{V_p}\left(1 - \frac{C_0}{C_s}\right)$$

All quantities on the right hand side of eq. [5] are measurable, so that K may be calculated directly from experimental observations.

Results and Discussion

Experimental Results

The degree of penetration of three porous glasses (CPG-10-75C, CPG-10-240C, CPG-10-170EN) by five dextran fractions and maltose was measured. The average penetration coefficient and relative size of each combination are presented in Table 3. The relative size of polymer and pore is given by r_h/a and σr_h where r_h is the hydrodynamic radius of the polymer molecules, a is the Kelvin radius of the pores, and σ is the surface area/pore volume ratio. Where sufficient measurements were made, the 95% confidence interval of the penetration coefficient is given. The range of the size ratio which includes 80% of both molecules and pore volume is also listed.

For each glass, the penetration coefficient decreases as the relative size increases (i.e. as the molecular size increases). For the combinations of dextran T110 and T500 with CPG-10-75C, in which the molecular size of the dextran exceeds the pore size (i.e. $r_h/a > 1.0$), the penetration coefficient is close to zero and does not alter significantly as r_h/a increases. This indicates that the pore volume estimated from the benzene sorption isotherms (V_p in eq. [5]) coincides with the maximum volume from which the dextran is excluded.

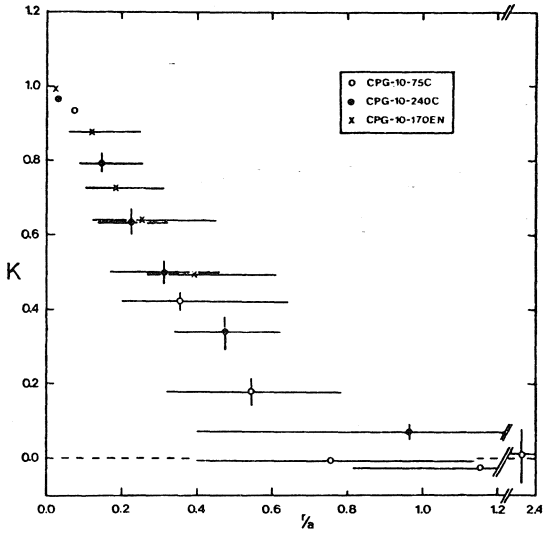

FIG. 2. Effect of relative size on penetration coefficient.

The data in Table 3 including the confidence limits are plotted in Fig. 2. The penetration curves for the three glasses coincide within experimental error. The relative size appears to be the major factor determining the partition of homologous polymer molecules between bulk solution and pore volume, when no adsorption occurs. These data may be compared with theoretical predictions of the variation of the penetration coefficient with relative size.

The equilibration distribution of macromolecules between bulk solution and pores has been discussed in reviews of GPC (e.g. refs. 7, 9) as one of the mechanisms of separation. Static mixing experiments have shown that the penetration of a single porous glass by a series of polystyrene samples decreases as the molecular weight (i.e. molecular size) increases (11). The behaviour parallels that of the series eluted at low flow rates from a column packed with the same material (12). However, no published data have been found which indicate the concurrence of penetration curves when substrates of distinctly different pore size are employed.

Theoretical Models

A number of theoretical models have been developed which employ simple geometric equivalents of the macromolecule and the pore system, and the concept that the penetration coefficient is equal to the fraction of the pore volume available to the molecule. Variation in the shape of the molecule (24) and in the geometric components used to simulate the pore system (ref. 10, p. 119, refs. 25, 26) have resulted in expressions for the penetration coefficient in terms of several combinations of parameters describing the relative size of the molecule and pore (Table 4).

The definition of the penetration coefficient based on the fraction of pore volume available to the molecule is a special case, derived from more general

TABLE 4. Theoretical variation of penetration coefficient with relative size

Curve No.	Geometry: Molecule	Geometry: Pore	Expression for penetration coefficient*	Reference
1	Rigid sphere	Any	$K = 1 - \sigma r$	ref. 10, p. 119
2	Rigid sphere	Slit	$K = 1 - r/a$	ref. 10, p. 119
3	Rigid sphere	Cylinder	$K = 1 - 2r/a$ (at low r/a)	ref. 10, p. 119
4	Rigid sphere	Cylinder	$K = (1 - r/a)^2$ (accounting for curvature)	24
5	Rigid sphere	Isotropic network of randomly oriented planes	$K = \exp(-\sigma r)$	
6	Any rigid shape		$K = \exp(-\sigma \bar{L}/2)$	24
7	Flexible chain	Slit	$K = \frac{8}{\pi^2} \sum_{m=0}^{\infty} \frac{1}{(2m+1)^2} \times \exp\left(-\frac{(2m+1)^2\pi^2(\sigma s)^2}{4}\right)$	ref. 10, p. 119
8	Flexible chain	Cylinder	$K = 4 \sum_{m=1}^{\infty} \frac{1}{\beta_m^2} \exp\left(-\beta_m^2 \frac{s^2}{a^2}\right)$	2
9	Flexible chain	Random solid spheres	$K = \exp\left(-\frac{2}{\sqrt{\pi}}\sigma s + \frac{(\sigma s)^2}{3 \ln f}\right)$	27

*σ = surface area/pore volume ratio ($\sigma = 1/a$ for slits; $\sigma = 2/a$ for cylinders); r = radius of rigid sphere; a = half-separation of parallel planes of slit; cylinder radius; $\bar{L}$ = Mean external length (the average cross-section dimension of the molecule projected in all directions); s = root-mean-square radius of gyration; β_m = mth root of $J_0(\beta) = 0$, where $J_0(\beta)$ is a Bessel function of the first kind, of zero order; f = pore volume fraction of total volume of porous material.

definitions as follows. In statistical thermodynamic terms, the penetration coefficient is defined as the ratio of the partition functions for molecules in pores and in the bulk solution. This becomes the ratio of configuration integrals for a random walk chain in the presence or absence of pore boundaries under the conditions assumed in the models to simplify calculation (ref. 10, p. 119, refs. 24, 27). In practical terms, the penetration coefficient is equal to the ratio of concentrations inside and outside the pores (eq. [2]). For models based on simple rigid geometric components, the number of dimensions over which the configuration integrals must be determined is reduced to those of physical space; the penetration coefficient is then equivalent to the fraction of the pore volume available to the molecule.

Using the statistical thermodynamic approach, Casassa (1) derived expressions for the penetration coefficient of linear chains in slit and cylindrical pores (curves *7*, *8* in Table 4). Doi (27) recently proposed an expression for linear flexible chains in the voids among randomly-distributed, uniform solids (curve *9* in Table 4). In both models, the root-mean-square (rms) radius of gyration is used to describe molecular size.

Theory for linear chains may be inappropriate for dextran because of the effects of branching. Casassa and Tagami (2) have considered the influence of branching on penetration and have shown that the curves derived for polymer molecules of the same molecular weight but different degrees of branching are superposed if the radius of gyration of the equivalent linear chain is multiplied in each case by $g^{1/6}$ where g is defined by the ratio of the unperturbed mean square radius of the branched polymer molecule to that of a linear polymer chain of the same mass.

$$[6] \qquad g = R_{br}^2/R_{lin}^2$$

The evaluation of g is determined, practically, from the intrinsic viscosity ratio of the branched and unbranched polymers which is experimentally found (28–30) to be equal to $g^{0.5(\pm 0.1)}$. Thus if the Flory–Fox equation (31) can be assumed to be valid for both branched and linear polymers,

$$[7] \qquad [\eta] = \phi' s^3 M^{-1}$$

where $[\eta]$ is the intrinsic viscosity, ϕ' is the Flory constant, s is the rms radius of gyration, and M is the molecular weight. The influence of branching on the intrinsic viscosity (and hence on the equivalent hydrodynamic volume) is accounted for by multiplying the rms radius of gyration by $g^{1/6}$. Thus coincidence of the theoretical penetration curves for branched and linear polymers would be expected if the hydrodynamic size determines the partition of polymers between the bulk solution and the pores.

A demonstration of the identity of the equivalent sphere diameter of dextran molecules obtained by

viscosity measurements with the minimum diameter of pore that can be penetrated is provided in a recent study by Haller (32). However, it has been pointed out (33) that the hydrodynamic size may provide good agreement between polymers of a similar type (e.g., between linear molecules and those with a limited amount of long-chain branching, such as dextran), but that it should not be extended uncritically to more highly-branched molecules.

Comparison of Theory and Experiment

It is possible to compare directly the data in Table 3, where the molecular size is specified by the equivalent hydrodynamic radius, with curves *1* to *5* in Table 4 in which the molecule is considered to be a rigid sphere and the pores are considered cylindrical, slit-shaped, or equivalent to the voids among randomly-oriented planes. In Fig. 3, the data curve lies slightly above, but has a shape similar to the curve for a rigid sphere in a cylindrical pore when the influence of curvature is considered (curve *4*). If curvature is neglected (curve *3*), a reasonable prediction of the variation of the penetration coefficient is obtained only at relative sizes below $r/a = 0.3$.

Since the position of the data points is dependent on arbitrary molecular size and pore-size parameters, the suitability of a penetration model can only be indicated by a similarity in shape of the theoretical penetration curve to the plot of the experimental data. The chosen molecular size and pore-size diameters do, however, produce an experimental curve lying close to the theoretical curves. This near-coincidence is fortuitous (1), but the theoretical curve may be used to predict with some confidence the degree of penetration of CPG-10 porous glass by dextran, when the experimental system is described by these parameters.

In Fig. 4, the data coincide with the theoretical penetration coefficient for slit geometry (curve *1*) as the relative size increases up to $\sigma r = 0.7$. Above this value, the theoretical penetration coefficient decreases more rapidly than the data. For the model in which the pores are considered as voids among randomly-oriented planes, curve *5* maintains a higher value of the penetration coefficient above $\sigma r = 0.5$ than observed. This pore model is more open than the pore system of CPG-10 glass and is unsuitable as a model for this substrate.

A suitable method is now sought to convert the equivalent hydrodynamic radius, r_h, to the rms radius of gyration, s, to permit comparison of the data with curves *7*, *8*, and *9* in Table 4 that are derived in terms of s.

A factor relating r_h and s may be calculated from the Einstein viscosity relation (eq. [1]) (ref. 20, p. 606) and the Flory–Fox equation (eq. [7]) (31).

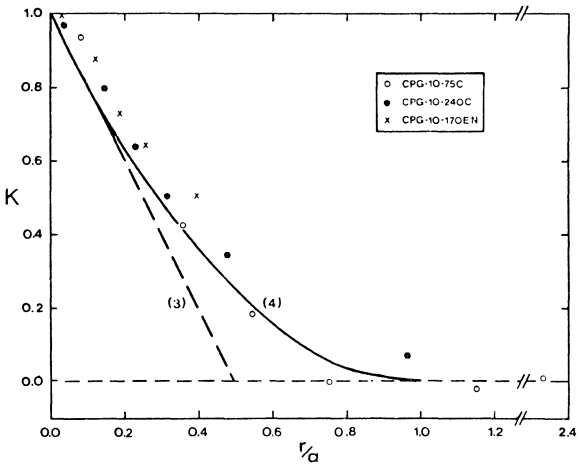

FIG. 3. Comparison of penetration data with a model of rigid sphere molecules in cylindrical pores.

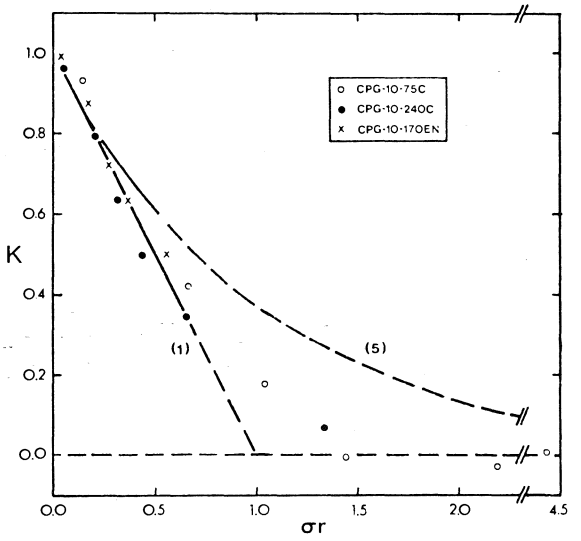

FIG. 4. Comparison of penetration data with models of rigid sphere molecules in slits and random plane pores.

Using the value of the Flory constant, ϕ', given by Senti (55.2×10^{21}) for dextran solutions (19), r_h/s is found to be 0.957.

The effects of branching and departures from θ-conditions have been taken into account by analyzing the results obtained by Wales *et al.* (17) from viscosity measurements. These provided values of $g = 3.47\overline{M}_w^{-0.13}$ and $\alpha = 0.56\overline{M}_w^{0.061}$. The factor α is defined as the ratio of the rms radius of gyration of the polymer under non-θ-conditions (25°C) to that under θ-conditions. These data were, however, based on a Flory constant of 30.8×10^{21} and, for consistency, the above value of g was adjusted by the factor $(30.8/55.2)^{2/3}$ to conform to Senti's value for ϕ'.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The data from Table 3 were converted to the values shown in Fig. 5 using these factors. An alternative approach by Granath (14) to the study of Pharmacia dextrans was based on the Stockmayer modification of the Flory–Fox equation. This provided another evaluation of g but its use gave similar data to that in Fig. 5 over most of the range and these have not been plotted.

It is seen that the conversion of the molecular size from hydrodynamic terms to statistical terms does not greatly alter the position of the experimental data. Although the data are displaced above the curve for flexible molecules in cylindrical pores (curve *8*) it is evident that they show a similar trend.

In Fig. 6, the comparison of the adjusted data with the curves for models of the flexible chain in slit pores (curve *7*) and the voids among random spheres (curve *9*) is made. As expected from the earlier comparison of the rigid sphere models (Figs. 5 and 6), the similarity of the variation of the data with that of the theoretical curve for slit geometry is as good as with that for cylindrical geometry.

Of all the models in Table 4, the 'voids among random spheres' model of the pore system might be considered, from the description of the structure of CPG-10 porous glass (23) to simulate the pore system most closely. The position and shape of the curves for this model are dependent on the void fraction of the total volume of the porous material (factor, f, in the expression for curve *9* in Table 4). Unless the void fraction is constant, this treatment does not predict that different glass samples would produce coincident penetration curves. However, the difference among the theoretical curves for the three glasses used are not great enough to be distinguishable in the scattered data.

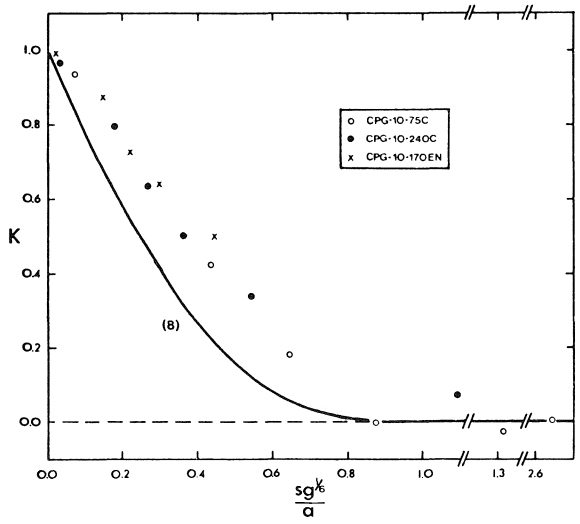

FIG. 5. Comparison of penetration data with a model of flexible chain molecules in cylindrical pores.

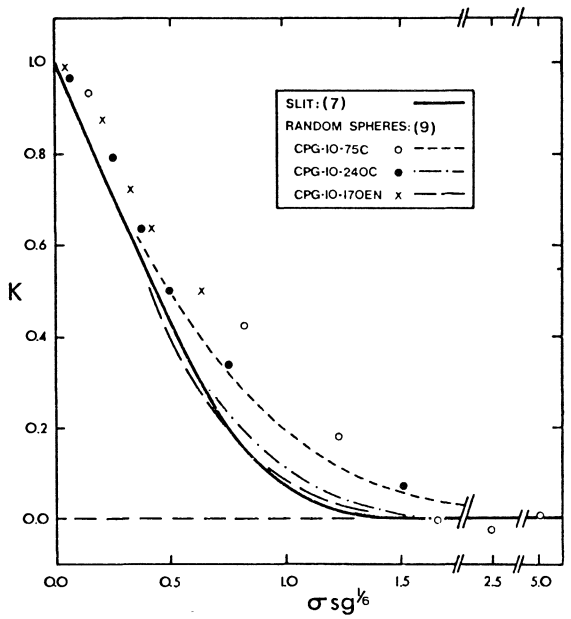

FIG. 6. Comparison of penetration data with models of flexible chain molecules in slit pores and voids among random spheres.

Two major sources of difference remain between the theoretical models and real systems. Although the pore geometry of CPG-10 glass appears to be more uniform than that of many materials previously available, the difference between the actual geometry and that of the models may influence the partition. The concurrence of experimental data with curves based on ideal geometry may support but cannot confirm the mechanism of partition (1).

Secondly, although the polydispersity of both the polymer and the pore system used in this study is low, the condition of monodispersity of both, assumed in the theoretical treatments, is not fulfilled. Scatter in the penetration data of the dextran series for each glass may result from differences in variance and skewness of the dextran molecular weight distributions. Differences in the shape of curves obtained with different glasses are more likely due to differences in the size distributions of the pore systems.

Conclusions

In this study of the penetration of CPG-10 porous glass by dextran fractions, the degree of penetration is expressed as a penetration coefficient, equal to the ratio of the concentration attainable within the pores to that in the bulk solution. The observed behaviour is consistent with theory which predicts that the value of this parameter is determined primarily by the size of the polymer in solution relative to that of the pore.

The penetration curves for this series of dextrans on three CPG-10 glasses of distinctly different pore sizes coincide.

The molecules are assumed to be either solid spheres or random coils and the pore geometry to be cylindrical, slit-shaped, or equivalent to the voids among random spheres. Among these models, the more sophisticated (e.g., random coils in the voids among random spheres) may simulate the actual 'polymer in pore' more realistically. However, the data obtained with components of narrow size distribution do not show a significantly better conformity with any particular model since, except for solid spheres in slit-shaped pores, the curves do not vary markedly in shape. The experimental data lie close to most of the theoretical curves and their position is not greatly influenced by the choice of the relative size parameter. Thus, these theoretical curves can be used to predict the degree of penetration for this system.

Factor analysis as a complement to band resolution. V. Complexing of pentachlorophenol and acetone in carbon tetrachloride solution

J. KORPPI-TOMMOLA AND H. F. SHURVELL

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received June 27, 1978

J. KORPPI-TOMMOLA and H. F. SHURVELL. Can. J. Chem. **56**, 2959 (1978).

Complex formation between pentachlorophenol and acetone and acetone-d_6 in carbon tetrachloride solution has been studied in both the hydroxyl and carbonyl stretching regions of the infrared spectrum. Factor analysis of the digitized spectra indicates three absorbing components for each set of solutions in the hydroxyl stretching region. Concentration studies revealed roughly linear relationships between the areas of the 'free' ν(OH) band and both of the resolved complex bands, suggesting that two different 1:1 complexes occur in CCl_4 solution. In the ν(CO) region only one band due to complex formation was detected. Equilibrium constants for the isotopically different complexes at about 30°C are reported. In the hydroxyl stretching region, band resolution was also carried out using four components which gave a better fit to the observed spectrum. A set of equilibrium constants were then obtained. However, considerable difficulties were met in the calculations and in the interpretation of these results, so that the three band, two complex model is preferred.

J. KORPPI-TOMMOLA et H. F. SHURVELL. Can. J. Chem. **56**, 2959 (1978).

On a étudié la formation de complexes entre l'acétone ou l'acétone-d_6 et le pentachlorophénol en solution dans le tétrachlorure de carbone, en utilisant les régions du spectre infrarouge correspondant aux vibrations de valence des groupes hydroxyle et carbonyle. Une analyse factorielle des spectres digitalisés indique la présence de trois composantes d'absorbtion dans la région de l'hydroxyle pour chaque série de solutions. Des études en fonction de la concentration révèlent l'existence d'une relation approximativement linéaire entre l'aire de la bande ν(OH) "libre" et celle de chacune des bandes résolues des complexes, ce qui laisse supposer la formation de deux complexes 1:1 distincts dans les solutions de CCl_4. Dans la région ν(CO), on n'a décelé qu'une seule bande attribuable à la formation de complexe. On rapporte des constantes d'équilibre à environ 30°C pour les différentes variétés isotopiques de complexes. Pour la région de l'hydroxyle, on a également réussi à résoudre les bandes en quatre composantes, ce qui a donné un meilleur accord avec les spectres observés. On a obtenu de cette manière une série de constantes d'équilibre. Cependant, les calculs et l'interprétation de ces résultats ont posé de sérieuses difficultés et l'on préfère le modèle à trois bandes et deux complexes.

[Traduit par le journal]

Introduction

Pentachlorophenol (PCP) has three properties which make it very convenient for the study of complex formation: it is a solid alcohol, it does not undergo self-association in solution (1), and it has no CH stretching bands (ν(CH)) to interfere with the broad ν(OH) complex band in the infrared spectrum. Complex formation of PCP and various nitrogen compounds in solution have been studied extensively (2–5). Infrared and Raman spectra of PCP have been published recently (6). A phase transition of solid PCP at about 60°C has been investigated using infrared (1) and Raman (7) spectroscopic methods.

The band contour of the ν(CO) band of acetone has been studied in various solvents (8, 9) and as a function of temperature (10). The interactions between several combination modes (11) and the ν(CO) mode can be considered as an explanation of the different shapes of the ν(CO) band found in various solvents and at various temperatures. However, if only one solvent is used and the acetone concentration is kept below 0.2 *M* the ν(CO) band is a 'good' band for complex formation studies.

The application of factor analysis to digitized infrared spectra leads to the determination of the number of absorbing components in a complex band. This number is an essential input parameter for band resolution and is independent of any assumed band shapes in the subsequent band resolution procedure (12, 13). Band areas of the resolved components can be used to calculate the molar absorption coefficients for the absorbing species if data are available for several solutions. Once the molar absorption coefficients are known, the concentration of each absorbing component can be obtained and various models of complexation can be tested to produce consistent equilibrium constants. In principle, the above procedure gives quantitative as well as qualitative information con-

cerning the type of complexation. It has been applied to the study of complex formation of pentachlorophenol and acetone and pentachlorophenol and acetone-d_6 in both the hydroxyl and carbonyl stretching regions. The initial concentration of PCP was kept at about 0.05 *M* for two sets of solutions, i.e. for PCP acetone and PCP acetone-d_6 systems. For one set of PCP acetone solutions the initial PCP concentration was kept at about 0.1 *M*. Acetone concentration was varied from 0.005 to 1.0 *M*. Details of the solutions and of the pathlengths used in the two spectral regions are not given here, but these are available from the authors on request.

Experimental

Pentachlorophenol was purchased from the J. T. Baker Chemical Company. Deuterated acetone (Ac-d_6) was obtained from Merck, Sharp, Dohme (Canada) Ltd. These reagents were used without further purification. Spectroscopic grade acetone and carbon tetrachloride (Fisher Scientific) were stored over molecular sieves (type 4A) for at least 24 h before use. Spectra were recorded using R.I.I.C. variable pathlength cells on a Perkin-Elmer 180 spectrometer. The instrument was flushed with dry air and wavenumber calibration was checked using standard compounds. Pathlengths were determined using the fringe method from 0.05 to 0.2 mm and linearity was assumed over the range used in this work. All spectra were recorded using an absorbance scale. Identical cells with equal pathlengths were placed in both infrared beams. The cell in the reference beam contained the base in CCl_4 at the same initial concentration as in the sample cell. The same solutions were used in both the ν(OH) and ν(CO) regions, with the pathlengths adjusted accordingly. Concentrations were corrected for the thermal expansion of CCl_4 produced by the higher temperature of the sample compartment of the spectrometer.

Computational Techniques

The observed spectra were digitized at 2.5 cm^{-1} intervals in the hydroxyl monomer band region while the rest of the spectrum was digitized at 5.0 cm^{-1} intervals using the manual technique described previously (14). A computer program EXTEND was written to interpolate the ordinate values to make the digitizing interval 2.5 cm^{-1} over the total range, giving about 400 data points. In the ν(CO) region the digitization interval was 2.0 cm^{-1}, which gives about 100 data points per spectrum.

A description of factor analysis can be found in refs. 12–14. The factor analysis programme (CHISQ) was applied to three sets of digitized spectra obtained for the solutions studied. For band resolution a programme originally written by Jones *et al.* (15) was modified to perform the calculations in absorbance units. Baseline subtraction and band area computation subroutines were added to the programme. A standard linear regression programme (LINREG 2, available from Queen's University Computing Centre, Programme Library) was used to solve for the molar absorption coefficients (ε_i). Two sets of ε_i were calculated in the hydroxyl stretching region. One set using three and the other set using four components to reproduce the observed spectrum. It was found that the linear regression programme gives most reliable results if the data are available from more than 20 solutions. Half-band widths were calculated using the PC121 programme from the library of Jones *et al.* (15).

Chemical Equilibrium

Our results in the hydroxyl stretching region suggest that there are two 1:1 pentachlorophenol–acetone complexes in CCl_4 solution. Accordingly, the following equations were used to calculate the equilibrium constants:

$$[1] \quad C_D^T = C_D + C_{11}^{(1)} + C_{11}^{(2)} = (A_D/\varepsilon_D l) + (A_1/\varepsilon_1 l) + (A_2/\varepsilon_2 l)$$

$$[2] \quad C_A = C_A^T - C_D^T + C_D = C_A^T - C_D^T + (A_D/\varepsilon_D l)$$

$$[3] \quad K_{11}^{(i)} = C_{11}^{(i)}/(C_D \times C_A) = (\varepsilon_D/\varepsilon_i)(A_i/A_D)(1/C_A)$$

where C_D^T and C_A^T are the initial concentrations and C_D and C_A are the equilibrium concentrations of the proton donor (PCP) and the proton acceptor (Ac), respectively. $C_{11}^{(i)}$ is the concentration of the *i*th 1:1 complex in the solution. A_D is the band area of the 'free' OH stretching band and ε_D the corresponding molar absorptivity coefficient. A_i refers to the band area of the *i*th resolved complex and ε_i to the corresponding molar absorption coefficient. *l* is the pathlength.

In the ν(CO) region the calculations were made in the same way, except that only one 1:1 complex was assumed to occur in the solution. For comparison, 1:1 equilibrium constants were also calculated using the areas of the 'free' ν(OH) band.

Results and Discussion

A preliminary study of the hydroxyl stretching region of the infrared spectrum of pentachlorophenol in 0.1 *M* CCl_4, CS_2, C_6H_6, and C_6F_6 solutions was made. The spectra are shown in Fig. 1. Each spectrum consists of a strong, singlet monomer band, at 3524, 3515, 3442, and 3537 cm^{-1}, respectively, and each shows traces of a band due to associated species. The monomer band in benzene shows an asymmetric contour, a large shift to lower frequencies, and a half width about three times that in the other solutions. The shift and the large half width might be the result of a solvent–solute interaction. From an examination of Fig. 1 it seems reasonable to assume that neither self-association nor conformational isomerism occurs for PCP in carbon tetrachloride solutions.

Typical behaviour of the OH stretching band of solutions of PCP and acetone in CCl_4 is shown in Fig. 2. For a fixed PCP concentration, the sharp monomer band at 3524 cm^{-1} decreases in intensity relative to the broad complex band on the lower frequency side as the acetone concentration is increased. The broad band in the spectra of PCP/acetone-d_6 solutions (Fig. 2) is a 'pure' complex band, since neither the proton donor nor the proton acceptor has fundamental (CH stretching) modes in the frequency region concerned. Visual inspection would suggest three absorbing components to occur in the region. No traces of an 'end group' band were

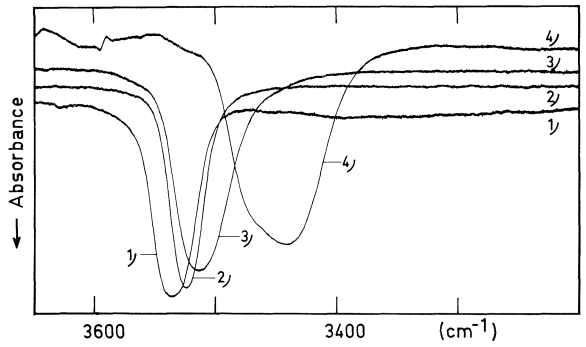

FIG. 1. The hydroxyl stretching band of PCP in various solvents: (*1*) C_6F_6, (*2*) CCl_4, (*3*) CS_2, (*4*) C_6H_6. Concentrations 0.10 *M* and pathlengths 1.00 mm in all solutions.

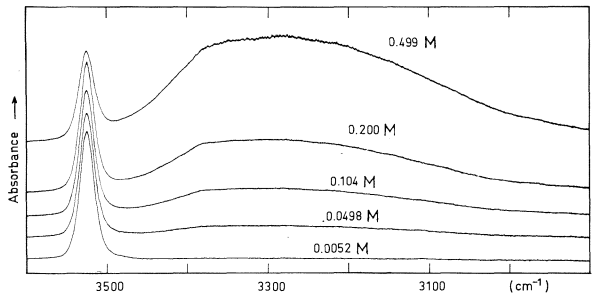

FIG. 2. The hydroxyl stretching band of PCP/acetone-d_6 solutions. Acetone-d_6 concentrations are given in the figure.

detected in the spectrum, which is an expected result for complexing between PCP and acetone.

Factor Analysis

For all three sets of solutions studied, factor analysis indicated three absorbing components in the OH stretching region. The results for the PCP – acetone-d_6 system will be given as an illustration of the method. Similar results were obtained for the other two systems.

The number of absorbing components NC in a complex band is taken as the number of non-zero eigenvalues of the matrix $\mathbf{Q} = \mathbf{A}^T\mathbf{A}$, where $\mathbf{A}$ is the absorbance and $\mathbf{A}^T$ its transpose. Due to experimental error and computational procedures, all calculated eigenvalues are non-zero. However, several statistical tests have been described (12) to determine when an eigenvalue is really non-zero. If an eigenvalue is less than the residual standard deviation or less than the square root of the estimated variance, then it is statistically zero. The results of these tests on the bands of the PCP/acetone-d_6 system are shown in Table 1 for an estimated experimental error in absorbance measurements DA = 0.01. Both criteria clearly indicate only three non-zero eigenvalues.

Another useful test is to regenerate the absorbance

TABLE 1. Factor analysis of eight CCl_4 solutions of PCP and acetone-d_6 in the ν(OH) region using the residual standard deviation and square root of eigenvalue variance criteria

No. of eigenvectors	Eigenvalue	Residual standard deviation[a]	Square root of estimated variance[a]
1	390.82046	0.11542	0.26438
2	42.21191	0.01142	0.14355
3	0.35470	0.00439	0.20714
4	0.04223	0.00246	0.15011
5	0.01211	0.00150	0.13602
6	0.00363	0.00105	0.13594
7	0.00243	0.00059	0.19765
8	0.00107	0.00026	0.10628

[a]Experimental absorbance error DA = 0.01.

matrix $\mathbf{A}$ using from 1 to *m* eigenvectors of $\mathbf{Q}$. The smallest number of eigenvectors to give a satisfactory fit with the experimental $\mathbf{A}$ is then NC. In Table 5 it is seen for DA = 0.01 that three eigenvectors are sufficient to regenerate $\mathbf{A}$. A final criterion is the calculation of χ_m^2 using from one to eight eigenvectors of $\mathbf{Q}$. The results are summarized in the last two columns of Table 2. The expectation values of χ_m^2 are given by $(N_W - m)(N_S - m)$, where N_W is the number of points in a digitized spectrum (400 in the present case) and $N_S = 8$ is the number of solutions. It is seen that χ_3^2 is of the same order of magnitude as the expectation value. Again, three absorbing components are indicated.

In the carbonyl stretching region of the three sets of solutions, factor analysis again indicates three components. However, the interpretation here is different. In the spectra of acetone, there are combination bands which may interact with the ν(CO) fundamental. This interaction gives rise to a broad shoulder on the high frequency side of ν(CO) in acetone, while in acetone-d_6 a Fermi doublet (9–11) is observed in the spectrum (Fig. 3). Thus, with two bands assigned to the 'free' carbonyl stretching vibration we are left with only one absorbing component to be assigned to the complex. This component is found as an asymmetry, which shows a concentration dependence, on the lower frequency side of the ν(CO) band (Fig. 3). According to our results in the hydroxyl stretching region, two complexes should occur in CCl_4 solution, while in the carbonyl stretching region, only one complex is indicated between PCP and acetone. However, it is not unknown that the ν(OH) mode should be more affected by complexing than the ν(CO) mode.

To explain the observation of only one complex band in the ν(CO) stretching region, we suggest that either one of the complexes does not affect the ν(CO) vibration significantly, or that both complexes

contribute to the ν(CO) vibration in the same way and we cannot resolve the components in the spectrum.

Band Contour Resolution

As suggested by factor analysis, we carried out band resolution using three Cauchy–Gauss product functions in the hydroxyl stretching region. Plots of typical resolved spectra are shown in Fig. 4. In the top diagram the worst misfits occur from 3200 to 3400 cm^{-1}, with the fit getting better at lower concentrations. In the three component fit the left wing of the lower frequency complex band extends over the monomer ν(OH) band. To reduce the overlap and to improve the fit, we tried adding a fourth component to the resolution procedure. The result is seen in the bottom diagram of Fig. 4. The fit is perfect and although the three complex bands overlap, the overlap between the monomer band and any of the complex bands is negligible. From this result we attempted to calculate the molar absorption coefficients (ε_i) for the four bands. However, no consistent values for ε_i were obtained for the various solutions and, in fact, even negative values were sometimes calculated. Since the four-component model is also chemically unreasonable, we were

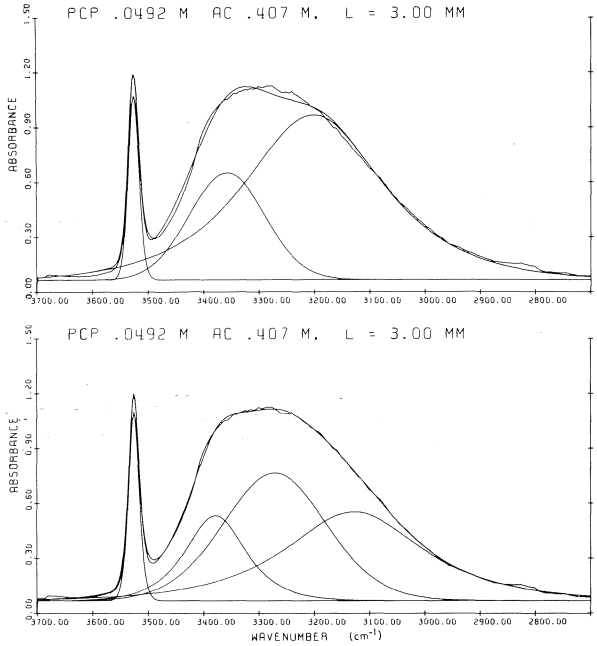

FIG. 4. Band resolution results for PCP/acetone complexes using three and four component fit in the hydroxyl stretching region.

forced to accept the three-component fit. Average wavenumbers and half-widths of the three resolved components are given in Table 3. Both wavenumber and half-width of the ν(OH) monomer band show very small standard deviations in all three sets of solutions. The PCP/acetone-d_6 system shows the most consistent wavenumbers and half-widths, which is expected since there are no CH stretching bands to interfere with the complex band. The wavenumbers of $(1:1)^2$ complex bands for the PCP (0.05 *M*)/Ac and for the PCP (0.05 *M*)/Ac-d_6 systems are almost the same, which means that this frequency does not depend on isotopic substitution

in acetone, but rather on the initial concentration of PCP in solution (Table 3).

Band resolution in the ν(CO) region was carried out using a three-component fit for acetone and acetone-d_6 spectra (Fig. 3). Small bands on both sides of the main peaks were added to reproduce the experimental spectra better. These bands were not included in further calculations. Frequency and half-width consistency for the three main bands is excellent, as seen in Table 4. The Δν values for the nearest ν(CO) monomer band and the complex band are 7.2 and 6.4 cm^{-1} for PCP/Ac and PCP/Ac-d_6 complexes, respectively. The ratio of the frequency differences is very close to the mass ratio of the two isotopic acetones.

Molar Absorption Coefficients and Equilibrium Constants

Molar absorption coefficients were calculated by inserting the band areas and total concentrations of the proton donor into eq. [3] and subsequently solving a set of linear equations. For the PCP (0.1 *M*)/acetone and PCP (0.05 *M*)/acetone systems in the ν(OH) region, we assumed equal ε_i's and data from 18 solutions were included. As indicated by standard deviations of the ε_i's (Table 3), the computation is very sensitive to the values of the band areas obtained from the fitting procedure. In the ν(CO) region, three ε_i's were also calculated using the band areas obtained for each set of solutions. These results are shown in Table 4.

To investigate the type of complexing, the complex band areas were plotted as a function of the monomer band areas, i.e. the concentration of the complex is plotted as a function of the concentration of free PCP in solution. The result is seen in Fig. 5, where graphs are shown for the various component band areas in the ν(OH) region. Both complex band areas show linear dependence on the monomer band areas up to an acetone concentration of 0.4 *M* (A_D about 10 000). According to eq. [3], this dependence indicates that both the resolved complex bands arise from (1:1)-complexes. We call the complex corresponding to the higher frequency complex band a $(1:1)^1$-complex and the other complex a $(1:1)^2$-complex. For the solutions where the initial PCP concentration was 0.1 *M* and the acetone concentration over 0.4 *M*, the concentrations of the $(1:1)^1$-complex seem to diminish at the expense of increasing $(1:1)^2$-complex concentration, the corresponding curve shows a maximum at about A_D = 11 000 (Fig. 5). It is also seen that at high acetone concentrations for solutions where the initial PCP concentration is 0.05 *M*, the $(1:1)^1$-complex concentration is relatively higher than for the solutions with double the PCP initial concentration (see the top diagram in Fig. 5).

The equilibrium constants are given in Table 5. Average values were calculated for solutions in which

[a] $K_{11} \simeq K_{11}^{(1)} + K_{11}^{(2)}$. The numbers in parentheses are standard deviations.

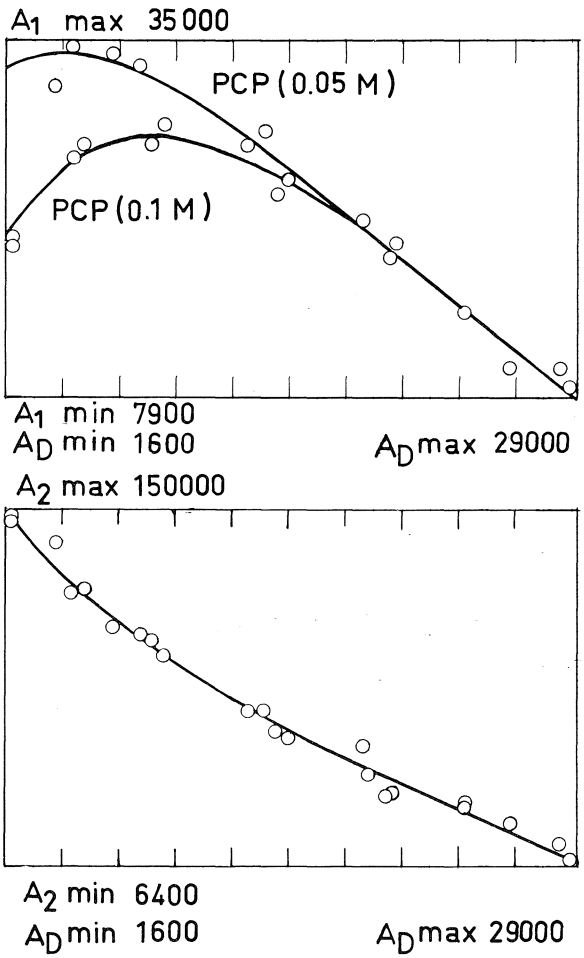

FIG. 5. Band areas (A_1 and A_2) of the resolved complex bands as a function of the area of the monomer ν(OH) band (A_D) for all three sets of solutions studied. The band areas have been normalized to unit pathlength. Areas for the PCP (0.1 *M*) acetone system have been divided by two for this plot.

the acetone concentrations were less than 0.4 *M*. The values of the equilibrium constants indicate that a decrease in initial concentration of PCP favours the formation of the $(1:1)^1$-complex ($K_{11}^{(1)}$). Also, an isotopic effect on the equilibrium is found, acetone-d_6 forms relatively more of the $(1:1)^1$-complex than does the non-deuterated acetone. The $K_{11}^{(2)}$ equilibrium constant, however, seems to be almost independent of the initial PCP concentration and of the isotopic substitution of the proton acceptor.

In the ν(CO) region it was assumed that only one (1:1)-complex occurs in the solution. For these calculations, the free acetone concentration was assumed to be proportional to the sum of the areas of the two highest wavenumber components in the region. The same type of calculation was also performed using the areas of the monomer ν(OH) band. The two equilibrium constants (Table 5) obtained from different parts of the infrared spectrum are comparable and in good agreement with the value $K_{11} = 9.11$ mol^{-1} ℓ previously reported for the PCP/acetone complex in CCl_4 solution (4).

Conclusions

This work clearly shows that hydrogen bonding between PCP and acetone in CCl_4 solution manifests itself much more in the OH stretching region of PCP than in the CO stretching region of acetone. Thus, more information on this system is available from the OH stretching band. The band resolution procedure provides a powerful method for studying complex formation in solution. However, it is seen that an independent technique such as factor analysis is valuable to establish the number of absorbing components in the spectra. This reduces the temptation to add more bands to improve the fit. Matrix isolation spectra, where the broad ν(OH) association or complex band is resolved into several components (16), could also be used to find the number of absorbing components.

In the present study, we used three and four components to reproduce the experimental spectrum in the hydroxyl stretching region. Although the three-component fit does not reproduce the experimental spectrum perfectly, factor analysis clearly indicates that there are only three absorbing components in the band. The present work does not give any information on the structures of the complexes. Nevertheless, it is possible to suggest *two* chemically reasonable structures for PCP/acetone (1:1)-complexes in CCl_4 solution. In one structure, the hydroxyl proton could interact with one of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

carbonyl lone pairs, while in the other, the interaction could be between the hydroxyl proton and both lone pairs. It is not possible to suggest three chemically reasonable structures for (1 : 1)-complexes. This conclusion, together with the factor analysis result, leads us to reject the four-component model.

Fluorinated alkoxides. Part XIII. The reduction of β-imino-alkoxy complexes to give stable, polydentate, amino-alcohols; their coordination to Co^{2+}, Ni^{2+}, and Cu^{2+}

JOHN W. L. MARTIN AND C. J. WILLIS

Chemistry Department, University of Western Ontario, London, Ont., Canada N6A 5B7

Received March 17, 1978

JOHN W. L. MARTIN and C. J. WILLIS. Can. J. Chem. **56**, 2966 (1978).

The amino-alcohols $HOC(CF_3)_2CH_2CH(CH_3)NH(CH_2)_3NHCH(CH_3)CH_2C(CF_3)_2OH$ and $HOC(CF_3)_2CH_2CH(CH_3)NH(CH_2)_3NH(CH_2)_3NHCH(CH_3)CH_2C(CF_3)_2OH$ have been prepared by reduction of the corresponding imino-alcohols coordinated to, e.g., Cu^{2+}, by use of $LiAlH_4$. The products are capable of acting as polydentate, dinegative, ligands (following ionization of the fluorinated alcohol groups) and the second compound gives stable, neutral, complexes of Co^{2+}, Ni^{2+}, and Cu^{2+} in which the metal atom is five-coordinate.

JOHN W. L. MARTIN et C. J. WILLIS. Can. J. Chem. **56**, 2966 (1978).

On a préparé les amino-alcools $HOC(CF_3)_2CH_2CH(CH_3)NH(CH_2)_3NHCH(CH_3)CH_2C(CF_3)_2OH$ et $HOC(CF_3)_2CH_2CH(CH_3)NH(CH_2)_3NH(CH_2)_3NHCH(CH_3)CH_2C(CF_3)_2OH$ par réduction avec $LiAlH_4$ des imino-alcools correspondants coordonnés à un ion tel que Cu^{2+}. Ces produits peuvent jouer le rôle de ligands polydentates porteurs de deux charges négatives (après ionisation des groupes alcools fluorés) et le second composé forme des complexes neutres stables avec Co^{2+}, Ni^{2+} et Cu^{2+} dans lesquels l'atome métallique est pentacoordonné.

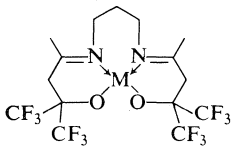
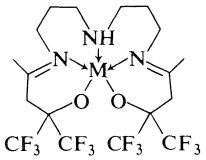
In previous parts of this series, we have reported the preparation of metal complexes in which chelation occurs from an ionized, fluorinated, tertiary alkoxy group, $-C(CF_3)_2O^-$, and a nitrogen donor atom. Such a ligand can be formed in two ways, either by the synthesis and subsequent coordination of a fluorinated amino-alcohol (1), or by template synthesis of β-imino-alkoxy ligands (2). The latter are formed by condensation of hexafluorodiacetone-alcohol, $CH_3COCH_2C(CF_3)_2OH$ (HFDA), with a diamine or triamine in the presence of the metal ion, and variation in the amine used allows the preparation of tetradentate (type **1**) or pentadentate (type **2**) ligands

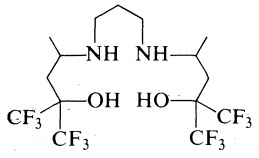


1*a*, M = Ni^{2+}
1*b*, M = Cu^{2+}

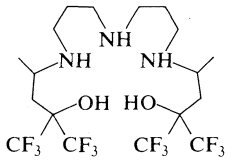


2*a*, M = Ni^{2+}
2*b*, M = Cu^{2+}

Although these neutral complexes are very stable, the unsaturated ligands themselves cannot be displaced without decomposition, so their general applicability to the formation of complexes with a variety of metals cannot be easily tested. We have therefore undertaken a study of the reduction of the above systems in the hope of removing the unsaturation and forming the more stable, isolable, amino-alcohols **3** and **4** from **1** and **2** respectively:

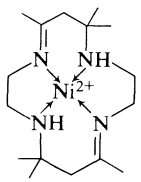


3

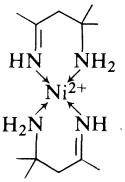


4

Previous workers have reported the reduction of coordinated imino-groups in a number of complexes. Curtis (3) has shown that the cationic nickel complex of the unsaturated tetra-azamacrocyclic ligand **5** may be reduced by H_2/Pt, by $NaBH_4$, by Al/OH^-, or by cathodic reduction, while **6** has been successfully reduced with $NaBH_4$.[1]



5



6

In both these systems, reduction of the analogous copper complex led to decomposition and the production of metallic copper, and Busch and co-

[1]N. F. Curtis and J. W. L. Martin. Unpublished results.

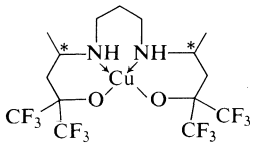
For personal use only.

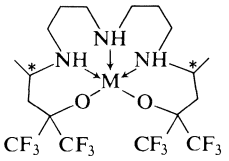
workers (5) have similarly reported success only with nickel complexes in the reduction of a number of macrocycles. All coordination is through nitrogen in the above systems, but a cationic nickel complex of a β-imino alcohol has been successfully reduced by Curtis and Martin (6).

Preparation of Reduced Ligands

The tetradentate ligand **3** was prepared by borohydride reduction of the nickel complex **1***a* in ethanol, followed by treatment with hydrochloric acid to remove the metal; the reduced ligand nickel complex was not isolated. In the case of the copper complex **1***b*, reaction with lithium aluminum hydride (LAH) immediately precipitated a pale yellow material which we assume to be a copper(I) complex. Hydrolysis and work-up with free access of air restored the blue colour characteristic of copper(II), and led to the isolation of the neutral copper complex **7**



7

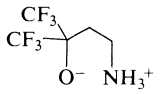


8*a*, M = Co^{2+}
8*b*, M = Ni^{2+}
8*c*, M = Cu^{2+}

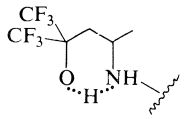
The pentadentate ligand **4** was most easily prepared by LAH reduction of the copper complex **2***b* (which was more easily synthesised than its nickel analogue) leading, as before, through an apparent copper(I) complex to the reduced copper(II) complex **8***c*. The ligand **4**, as the hydrochloride, was then isolated from this by treatment with hydrochloric acid. A similar sequence using borohydride in place of LAH for reduction of **2***b* led to the same products, but in poor yield.

The successful use of copper complexes in these imino reduction reactions is surprising, in view of the failures quoted by previous workers. A contributing factor may be the neutral nature of the complexes in the current work, which may be more resistant to decomposition through nucleophilic attack than the cationic complexes studied by previous workers. However, it is also likely that our systems gave more stable copper(I) intermediates which did not tend to disproportionate; it is significant that previous workers have reported metallic copper as a decomposition product.

We have previously reported (1) that molecules containing a fluorinated tertiary alcohol and an amine group exhibit strong interactions between the two, sometimes to the point of complete proton transfer to give zwitterionic structures as **9**:



9



10

The same possibility exists in the compounds now under study, which both contain the partial structure **10**, and studies of their infrared spectra show that a similar interaction is occurring, although hydrogen-bonding seems more likely than complete proton transfer. In neither **3** nor **4** was there an absorption band associated with free —O—H. We have previously reported that the γ-amino fluorinated alcohol **9** shows no $—NH_2$ absorptions above 3200 cm^{-1}, but instead has strong, very broad, absorption in the region 2200–3000 cm^{-1} characteristic of $—NH_3^+$ and similar to glycine, whereas the analogous β-amino fluorinated alcohol shows fairly sharp absorption at 3330 and 3400 cm^{-1}, suggesting an intramolecularly H-bonded structure. In both **3** and **4**, two N—H stretching absorptions are seen; at 3276 and 2450–2750 (broad) for **3** and 3246 and 2740–2780 (broad) for **4**, (as the monohydrochloride) with N—H bending modes at 1519 and 1525 cm^{-1} respectively. A direct comparison with the other amino-alcohols is complicated by the fact that the amine groups are now secondary, and that, with two or three amine groups in the molecule, inter-amino H-bonding may be present.

As would be expected, coordination to a metal ion caused a considerable sharpening in the spectra in this region as H-bonding was removed, and strong, sharp, absorptions in the region 3120–3280 cm^{-1} (Table 1), characteristic of coordinated secondary amine, were now present.

Metal Complex Formation

The tetradentate ligand **3** readily coordinated to copper(II) to give complex **7**. However, attempts to prepare the nickel(II) analogue did not give a stable product. Although an interaction of Ni^{2+} with ligand occurred, giving a red solution consistent with the expected square-planar complex, attempts to isolate and purify a product led only to decomposition. Similarly, we could not isolate the nickel complex which was presumably an intermediate in the reduction of **1***a* to give ligand **3**. This result is surprising, in view of the well-established stability of neutral nickel(II) complexes of this type (1, 2, 7) and no obvious reason for this instability can be given.

The pentadentate ligand **4** proved more versatile.

*Analyzed as the hydrochloride.

As noted above, the copper(II) complex **8***c* was readily isolated as a direct product of the reduction; it was also readily re-formed by interaction of the ligand with Cu^{2+} ions. The complex was apparently monomeric in the vapour phase (mass spectrum) and in solution (osmometric in acetonitrile) and there is little reason to doubt that the metal atom is five-coordinate. The visible spectrum (Table 1) was similar to those reported for similar five-coordinate copper complexes (2), although this is not a good discriminator for copper.

With nickel, the picture was clearer. The complex **8***b* formed readily from the ligand and Ni^{2+} and gave stable green crystals. Its visible spectrum was very similar to those previously reported for similar five-coordinate nickel complexes (2), as was its magnetic moment of 3.15 BM.

The cobalt(II) analogue also formed readily. It had magnetic moment 4.64 BM (300 K), typical of high-spin five-coordinate Co^{2+} (8) and was resistant to oxidation to a cobalt(III) complex, either by air or by such oxidizing agents as bromine or hydrogen peroxide. A similar resistance to oxidation in five-coordinate cobalt(II) complexes has been noticed by other workers (4, 10).

No significant change in the visible spectrum of any complex studied occurred in the presence of donor solvent (pyridine), showing that additional coordination was not occurring. We have noted similar effects before (2, 7) with complexes of these bulky fluorinated ligands, where solvation appears to be sterically restricted.

Considerable opportunity for asymmetry exists in these complexes, both through permanent chiral centres on the ligands (marked *) and through co-ordination. No attempt to separate possible isomers has yet been made.

We conclude that reduction of imino-alkoxy complexes, which are readily available through template synthesis reactions, offers a useful synthetic route to polydentate ligands in the fluorinated alcohol field. The considerable stability of this type of complex is demonstrated by the ready in situ hydrogenation of an imino group in a ligand bound to copper, an approach not previously reported to be successful, and we attribute this in part to the neutral nature of the complexes formed by coordination of the ionized alcohols. The applicability of the approach to related systems is being studied.

Experimental

General

Infrared spectra were recorded on a Perkin-Elmer 621 instrument, visible spectra on Cary 14 and 118 spectrometers, mass spectra on a Varian MAT 311A, and molecular weights determined osmometrically on a Hewlett-Packard 301A vapour-pressure osmometer. Magnetic moments were determined by the Gouy method at 300 K. Microanalyses were performed by Malissa-Reuter Laboratories, West Germany; all analytical data are in Table 2.

Reduction of Ligands

(a) Tetradentate

The nickel and copper imino-complexes **1***a* and **1***b* were prepared by the method described previously (2). In the reduction of the nickel complex, **1***a* was dissolved in ethanol and $NaBH_4$ added in a 5:1 molar ratio with constant stirring. The

For personal use only.

resulting black precipitate was removed by centrifuging and a little more $NaBH_4$ added to the now nearly colourless solution. Aqueous (1:1) hydrochloric acid was added to decompose both the excess borohydride and the nickel complex, and the reduced ligand was extracted from the solution into ether. Evaporation to dryness followed by extraction with dichloromethane gave the free reduced ligand **3**, colourless crystals from hexane, in approximately 60% yield.

The copper complex **1***b* was dissolved in anhydrous ether and $LiAlH_4$ in dry ether added in a 6:1 molar ratio. Immediate reaction occurred to precipitate a yellow solid. On addition of wet ether followed by water to decompose excess hydride, the precipitate went black. The system was left exposed to air for several hours with occasional stirring, during which time the ethereal layer became blue. Ether extraction and aeration of the aqueous layer was continued until no further colour was seen, after which evaporation of the ether solution gave the reduced copper(II) complex **7**, blue crystals from ethanol/chloroform. Molecular weight calcd., 552; parent ion in mass spectrum *m/e* 551.

The free ligand **3** was obtained from the copper complex by decomposing it with excess concentrated hydrochloric acid in ethanol solution, followed by extraction into ether and recrystallization as before.

(b) Pentadentate

The copper complex **2***b* was reduced with $LiAlH_4$ and the product worked up as before to yield the reduced copper(II) complex **8***c*, blue crystals from ethanol. Molecular weight calcd., 609; parent ion in mass spectrum, *m/e* 608.

The free ligand was prepared by adding concentrated hydrochloric acid to an ethanol/*n*-butanol solution of **8***c* followed by neutralization with potassium hydroxide and extraction into ether. Evaporation of the ether followed by recrystallization from hexane gave the reduced pentadentate ligand **4**, overall yield 45–50% from **2***b*. The ligand was isolated in the form of a monohydrochloride which was not deprotonated to the free base even by the use of excess aqueous base in the extraction.

Metal Complexes

Preparation of the copper complex of the tetradentate ligand **3** by direct reduction is described above; the same compound was prepared in virtually quantitative yield by interaction of the ligand with copper(II) chloride in ethanol with addition of potassium hydroxide to precipitate potassium chloride.

Attempts to make the nickel analogue were not successful. Interaction of nickel(II) chloride with ligand **3** in the presence of base produced a red solution, with absorption maxima at 18 800 and 24 600 cm^{-1}, but a green precipitate separated on work-up and no product could be characterized.

With the pentadentate ligand **4** the metal complexes were prepared similarly. A slight molar excess of the ligand was added to the metal chloride (Co^{2+}, Ni^{2+}, or Cu^{2+}) in ethanol and the stoichiometric amount of potassium hydroxide in ethanol added. After removal of precipitated potassium chloride, the solution was evaporated to give the metal complex in high yield: cobalt complex, **8***a*, purple plates from benzene, molecular weight calcd., 604; parent ion peak in mass spectrum, *m/e* 603; copper complex, **8***c*, identical with that obtained by direct reduction.

Mechanism of bromination of a quaternary pyrimidinium cation. Change of rate determining step with acidity

OSWALD S. TEE,[1] DAVID C. THACKRAY, AND CHARLES G. BERKS
Department of Chemistry, Concordia University, Montreal, P.Q., Canada H3G 1M8

Received June 2, 1978

OSWALD S. TEE, DAVID C. THACKRAY, and CHARLES G. BERKS. Can. J. Chem. **56**, 2970 (1978).

The kinetics of bromination of the 1,2-dihydro-1,3-dimethyl-2-oxopyrimidinium cation (Q^+) in aqueous media (pH 0–5) have been studied using the stopped-flow method. At the higher acidities (pH < 2) the results are consistent with rate determining attack by bromine upon the pseudobase (QOH), whereas at low acidities (pH > 4) it appears that pseudobase formation is rate determining. The change occurs because at high acidity the reversal of the pseudobase QOH to the cation is fast relative to bromine attack, whereas at low acidity the converse is true. Results obtained at intermediate acidities (pH 2–4) are consistent with this interpretation.

A separate kinetic study of pseudobase formation (and decomposition) yielded rate constants in good agreement with those derived from the bromination study.

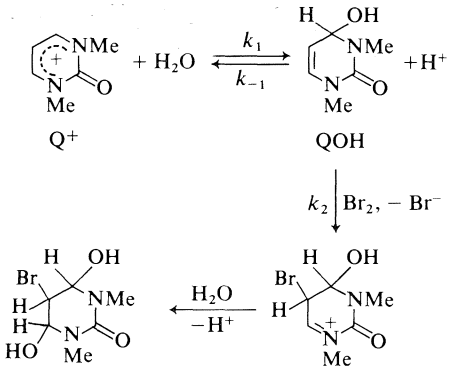
OSWALD S. TEE, DAVID C. THACKRAY et CHARLES G. BERKS. Can. J. Chem. **56**, 2970 (1978).

Les cinétiques de bromation de l'ion dihydro-1,2-dimethyl-1,3-oxo-2-pyrimidinium (Q^+) dans des solutions aqueuses (pH 0–5) ont été mesurées par la méthode de flux stoppé. Les résultats des aidités plus hautes (pH < 2) indiquent que l'attaque du brome sur la pseudobase (QOH) est déterminante de la vitesse, tandis qu'il paraîtrait que la formation de la pseudobase est déterminante de la vitesse à des acidités plus faibles (pH > 4). Le changement se présente parce que le retour de la pseudobase QOH au cation Q^+ est plus rapide que l'attaque du brome dans les solutions plus acides, mais l'inverse s'obtient dans les solutions moins acides. Il y a un bon accord entre cette interprétation et les résultats qu'on a obtenus aux acidités intermédiaires (pH 2–4).

Une étude distincte des cinétiques de formation (et de décomposition) de la pseudobase a donnée des constantes de vitesse approchant celles de l'étude de bromation.

Introduction

The 1,2-dihydro-1,3-dimethyl-2-oxopyrimidinium cation (Q^+) readily forms its pseudobase (QOH) in neutral aqueous solution (1, 2). Since this species is an enamine it should be very susceptible to electrophilic attack and so we have proposed (3) that the facile aqueous bromination of the cation Q^+ proceeds by way of attack of bromine upon the pseudobase QOH which leads to the observable adduct **1** (Scheme 1) (3). Slow acid-catalyzed dehydration of this adduct leads to the substitution product having a 5-bromo substituent (3). The processes $Q^+ \rightarrow \rightarrow \rightarrow \mathbf{1}$ occur too rapidly in aqueous solution to be followed by conventional spectrophotometry. However, by use of the stopped-flow method we have now obtained sound kinetic evidence for the primary steps of the Scheme 1.



SCHEME 1

Results and Discussion

Our initial experiments, carried out in aqueous sulphuric acid (1 and 0.1 *N*), showed pseudo-first-order kinetics for the disappearance of bromine in the presence of an excess of the cation Q^+. During the course of these experiments Lloyd *et al.* (4) reported to us the observation that in aqueous solution (no acid or buffer) and with an excess of Q^+ the reaction obeyed zero-order kinetics. We hypothesized that the difference between the two observations was due to a change of rate determining step with decreasing acidity. Upon carrying out experiments at much lower acidity (pH = 4.27, 4.80) we observed pseudo-zero-order kinetics, in support of our hypothesis. Finally experiments carried out at inter-

mediate acidities (pH = 2.67, 3.04) showed mixed zero- and first-order kinetics.

These results can be interpreted using a mechanism which involves either preequilibrium formation of, or rate determining formation of the pseudobase QOH. To corroborate this interpretation we also studied the kinetics of pseudobase formation and decomposition.

Our studies required the equilibrium constant for pseudobase formation

[1] $$Q^+ + H_2O \rightleftharpoons QOH + H^+$$

defined as $K_{R^+} = [QOH][H^+]/[Q^+]$ (5). Although values were available from earlier work (1, 2), we redetermined the value under the same conditions of temperature and ionic strength as the kinetic experiments, and found $K_{R^+} = 6.92 \times 10^{-8}$ M ($pK_{R^+} = 7.16$).

pH 0–2

In 0.1 and 1 N sulphuric acid (pH = 1.26, and pH $\simeq H_0 = 0.11$) the disappearance of bromine is strictly first order in the presence of an excess ($\geq$10-fold) of the substrate cation Q^+. First-order rate constants (k_1^{obs}) increase in proportion to the cation concentration (Table 1) and so overall the reaction is second order: first order in cation and first order in bromine. Furthermore, the derived second-order rate constants (k_2^{obs}) increase monotonically with pH (Table 1).

These observations are consistent with the bromination reaction involving rate determining attack of bromine upon the pseudobase QOH (eq. [2])

[2] $$Q^+ + H_2O \underset{}{\overset{K_{R^+}}{\rightleftharpoons}} H^+ + QOH \xrightarrow[Br_2]{k_2} \text{products}$$

This mechanism [2] requires that

[3] $$\text{rate} = -d[Br_2]/dt = k_2K_{R^+}[Q^+][Br_2]/[H^+]$$

Since $[H^+] \gg K_{R^+}$ ($=6.92 \times 10^{-8}$ M), $[Q^+] \simeq$ the stoichiometric concentration of cation Q^+, and eq. [3] is compatible with the experimental results for $k_2^{obs} = k_2K_{R^+}/[H^+]$. Clearly the quantity $k_2^{obs}[H^+]$ should be a constant ($=k_2K_{R^+}$) and the data (Table 1) are in reasonable agreement with this. Accordingly the data suggest $k_2 \simeq 7 \times 10^8$ M^{-1} s^{-1}.

pH 4–5

For experiments carried out in acetate buffers (pH = 4.27 and 4.80) with a 10-fold (or more) excess of cation Q^+ over bromine, the disappearance of the bromine shows zero-order kinetic behaviour for most (>90%) of the reaction. Zero-order rate constants (k_0^{obs}) increase in proportion to $[Q^+]$ (Table 2) suggesting, in fact, that reaction is simply first order in the cation Q^+. In support of this, experiments carried out with cation concentrations more nearly equal to that of bromine showed first-order behaviour with rate constants ($k_1^{obs\prime}$) comparable to those derived from zero-order data (Table 2). Within experimental error, the rate constants are not affected by acidity in this region.

These results suggest that at low acidity the forma-

tion of the pseudobase QOH is rate determining and that attack by bromine occurs in a subsequent very fast step.

$$[4] \quad Q^+ + H_2O \xrightarrow{k_1} H^+ + QOH \xrightarrow[\text{fast}]{Br_2} \text{products}$$

Under these circumstances we simply have

$$[5] \quad \text{rate} = -d[Br_2]/dt = k_1[Q^+]$$

Thus for a large excess of cation zero-order behaviour should be observed with the rate constants $k_0^{obs} = k_1[Q^+]$ being a linear function of the cation concentration. Alternatively, if $[Q^+] \simeq [Br_2]$ the cation and bromine should disappear at comparable rates and the reaction should show first-order behaviour with rate constants $k_1^{obs'} = k_1$, as observed (Table 2). On this basis the formation of the pseudobase QOH has $k_1 \simeq 1.3\ s^{-1}$.

pH 2–4

In this region of acidity mixed-order kinetics are observed which are intermediate between the types described for the previous two pH regions. Employing an excess of the substrate cation Q^+ one observes a gradual change of order from pseudo-zero to pseudo-first during the course of the bromination reaction. Accordingly, analysis of the experimental data is more difficult.

The behaviour in this region of acidity is readily understandable if one assumes a steady state concentration of the pseudobase QOH. Moreover, the equations which result from a steady state treatment can also accommodate the behaviour observed in the other two regions of acidity. For mechanism [6]

$$[6] \quad Q^+ + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H^+ + QOH \xrightarrow[Br_2]{k_2} \text{products}$$

assumption of a steady state concentration of QOH leads to

$$[7] \quad \text{rate} = \frac{-d[Br_2]}{dt} = \frac{k_1k_2[Q^+][Br_2]}{k_{-1}[H^+] + k_2[Br_2]}$$

Therefore the observed order of reaction should depend upon the relative magnitudes of the denominator terms $k_{-1}[H^+]$ and $k_2[Br_2]$ of eq. [7], that is, upon the relative rates of pseudobase reversal and of bromine attack.

If $k_{-1}[H^+] \gg k_2[Br_2]$ eq. [7] simplifies to eq. [3], since $K_{R^+} = k_1/k_{-1}$. This situation is consistent with the results obtained at high acidity (pH < 2) and corresponds to the pseudobase QOH reverting to the cation Q^+ faster than it reacts with bromine.

Alternatively, if bromine attack is faster than pseudobase reversal, $k_2[Br_2] \gg k_{-1}[H^+]$, [7] simplifies to [5] in agreement with the results obtained at low acidity (pH > 4). Note, however, that at some stage of the reaction, when sufficient of the bromine has been consumed, the inequality must reverse, and [5] be superceded by [3]. Accordingly, as the reaction proceeds the order changes from pseudo-zero to pseudo-first. At pH > 4 this occurs only after most (>94%) of the bromine has been consumed.

From the experiments carried out at high acidity (pH < 2) it appears that $k_2 \simeq 7 \times 10^8\ M^{-1}\ s^{-1}$. On the other hand, the studies at low acidity (pH > 4) yielded $k_1 \simeq 1.3\ s^{-1}$ and so $k_{-1} \simeq 1.9 \times 10^7\ M^{-1}\ s^{-1}$ since $K_{R^+} = k_1/k_{-1} = 6.92 \times 10^{-8}\ M$. Thus at pH 3, for example, the term $k_{-1}[H^+] = 1.9 \times 10^4\ s^{-1}$, whereas $k_2[Br_2] = 3.5 \times 10^4\ s^{-1}$ initially and thereafter decreases as the bromine is consumed. In other words, around pH 3 the denominator terms of [7] are of comparable magnitude and so mixed-order kinetics are to be expected.

The values of k_1, k_{-1}, and k_2 given above also justify the use of the steady-state approximation inasmuch as the processes which consume the pseudobase QOH are both much faster than that by which it is produced.

For analysis of the experimental data obtained at intermediate acidities (pH = 2.67 and 3.04) the full steady-state equation [7] must be used since the terms $k_{-1}[H^+]$ and $k_2[Br_2]$ are of comparable magnitude for much of the reaction. Integration of [7], assuming $[Q^+]$ is constant, yields [8].

$$[8] \quad \frac{k_{-1}[H^+]}{k_2} \ln \frac{[Br_2]_0}{[Br_2]} + ([Br_2]_0 - [Br_2]) = k_1[Q^+]t$$

This equation contains a first-order term and a zero-order term whose relative importance depends upon $[H^+]$ and $[Br_2]$. The form of the combination of the logarithmic and linear terms precludes simple fitting of [8] to data. We have tried various approaches to this problem and have settled upon the following: (*a*) treat k_1 as known, subtract the zero-order component, find the ratio k_{-1}/k_2 by least-squares fitting, and calculate a first-order rate constant $k_1^{obs} = k_1k_2[Q^+]/k_{-1}[H^+]$; (*b*) assume a value of k_{-1}/k_2, subtract the first-order term, and find a zero-order rate constant $k_0^{obs} = k_1[Q^+]$ by fitting. Both approaches give good fits (correlation coefficients >0.999) up to 90% reaction.

The values of k_1^{obs} obtained by procedure *a*, assuming $k_1 = 1.3\ s^{-1}$, are shown in Table 1 in parentheses. They show the required dependence upon cation concentration and yield values of k_2^{obs} which increase with pH in the same manner as those

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

obtained at lower pH. Thus the quantity $k_2^{obs}[H^+]$ remains sensibly constant (Table 1). Procedure *a* yields values of k_{-1}/k_2 in the range 0.026–0.031. By way of comparison, $k_2 = 7.0 \times 10^8\ M^{-1}\ s^{-1}$ and $k_{-1} = 1.9 \times 10^7\ M^{-1} s^{-1}$ (from above) require $k_{-1}/k_2 = 0.027$. This good agreement and the compatibility of all the k_2^{obs} values in Table 1 supports our use of procedure *a*.

Values of k_0^{obs} derived from experimental data by way of procedure *b* and assuming $k_{-1}/k_2 = 0.03$ are shown in parentheses in Table 2. They show the required dependence upon $[Q^+]$ and yield values of k_1^{obs} close to 1.3 s^{-1} which are independent of pH.

In summary, the data obtained at intermediate acidities are of mixed order but may be described by the steady-state equations [7] and [8], and employing the values of the rate constants k_1, k_{-1}, and k_2 derived from the data obtained in the regions of high and low acidity. Altogether the data indicate that as the acidity is decreased there is a change of rate determining step due to a reduction in the acid-catalyzed rate of pseudobase reversal to the cation relative to the rate of bromine attack.

Pseudobase Formation and Decomposition

To provide independent evidence for the validity of the interpretation given above we also studied the kinetics of pseudobase formation and decomposition by the stopped-flow method. The approach used was that which Bunting and co-workers have employed so successfully in their extensive studies of various quaternary heterocyclic cations (ref. 5 and references therein).

A solution of the heterocyclic cation Q^+ (or its pseudobase QOH) was rapidly mixed with a buffer solution of pH > pK_{R^+} (or pH < pK_{R^+}) and the rate at which the system attained a new equilibrium was measured. The approach to equilibrium follows first-order kinetics and the observed rate constant k_{obs} is the sum of the rate constants for formation (k_f) and decomposition (k_d) of the pseudobase QOH. Since $k_f[Q^+]_e = k_d[QOH]_e$ at equilibrium and $K_{R^+} = [QOH]_e[H^+]/[Q^+]_e$ one can write

$$[9] \qquad k_f = k_{obs}K_{R^+}/(K_{R^+} + [H^+])$$

and

$$[10] \qquad k_d = k_{obs}[H^+]/(K_{R^+} + [H^+])$$

Values of k_{obs}, and hence k_f and k_d, were obtained in the pH range 5.5–9.5. Outside this range the equilibrations are too fast to measure. Throughout the experimental conditions were kept as close as possible to those employed in the bromination studies.

The pH dependencies of the rate constants are displayed in Figs. 1 and 2. They may be described by

$$[11] \qquad k_f = k_1 + k_{OH}[OH^-]$$

and

$$[12] \qquad k_d = k + k_{-1}[H^+]$$

where k_1 and k_{-1} have their former meaning (eq. [6]), and k and k_{OH} refer to

$$[13] \qquad Q^+ + OH^- \underset{k}{\overset{k_{OH}}{\rightleftharpoons}} QOH$$

The curves shown in Fig. 2 were calculated from [11] and [12] using $k_1 = 1.5\ s^{-1}$, $k_{-1} = 2.2 \times 10^7\ M^{-1} s^{-1}$, $k = 0.31\ s^{-1}$, and $k_{OH} = 2.1 \times 10^6\ M^{-1} s^{-1}$. The curve for Fig. 1 was then calculated using $k_{obs} = k_f + k_d$.

The values of k_1 and k_{-1} just given, although a little high, are in good agreement with those (1.3 $\times$ s^{-1} and 1.9 $\times$ $10^7\ M^{-1} s^{-1}$) derived from the bromination studies. The magnitude of these values

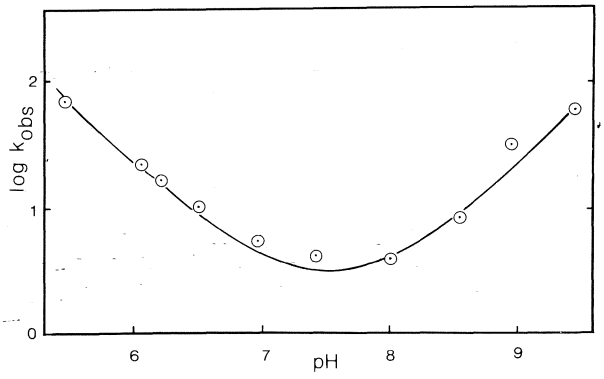

FIG. 1. pH dependence of k_{obs} for formation and decomposition of pseudobase QOH.

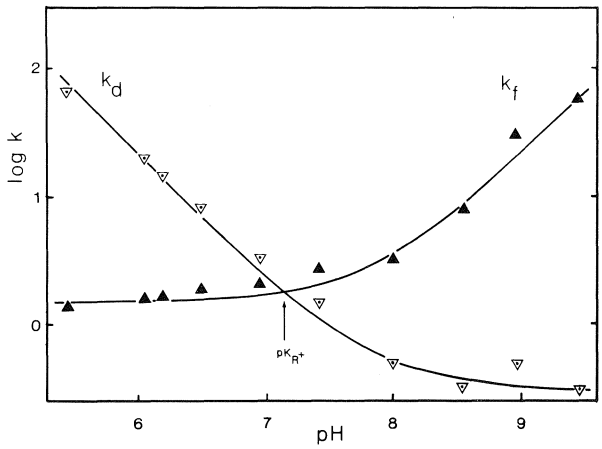

FIG. 2. pH dependence of rate constants for formation (k_f) and decomposition (k_d) of pseudobase QOH.

For personal use only.

and the deviation of points in Figs. 1 and 2 *above* the calculated curves may be due to buffer catalysis. More specifically, pseudobase formation may involve general base-assisted nucleophilic attack by water and the reverse reaction, decomposition, is then general acid-catalyzed [14].

[14] $$Q^+ + H_2O + B^- \rightleftarrows QOH + HB$$

On the basis of buffer catalysis, solvent isotope effects, and entropies of activation, Bunting has concluded that a mechanism like [14] applies to the cation–pseudobase systems he has studied (5, 6). A possible manifestation of [14] in the present work is that at pH = 6.05 we found $k_{obs} = 28.8 \pm 2.0\ s^{-1}$ in a succinate buffer and $k_{obs} = 22.8 \pm 1.0\ s^{-1}$ in a phosphate buffer. Bunting and Meathrel (6) also found that the ratio k_{OH}/k_1 varied little (0.35×10^7 to $4.7 \times 10^7\ M^{-1}$) for a variety of cations whose K_{R^+} values covered a 10^6 range. The observation was rationalized (6) in terms of a mechanism like [14], the constants k_{OH} and k_1 being ascribed to hydroxide ion and a water molecule, respectively, operating as general bases facilitating the nucleophilic attack of water as in mechanism [14]. According to this view the ratio k_{OH}/k_1 largely reflects the relative basicities of hydroxide ion and water rather than their relative nucleophilicities towards a particular cation. For our system the ratio is $0.14 \times 10^7\ M^{-1}$, which is close to those cited above and consistent with the views of Bunting and Meathrel (6).

As a final point we note that our values of k_1 ($1.3\ s^{-1}$ from bromination studies, $1.5\ s^{-1}$ from pseudobase studies) at 30°C agree with the observations of Lloyd.[2] At 25°C he found that $5 \times 10^{-3}\ M$ bromine in the presence of 0.101 M cation Q^+ was consumed in 50 ms.[2] This corresponds to a zero-order rate constant $k_0^{obs} \sim 0.1\ M\ s^{-1}$ and thus a value of $k_1 \sim 1\ s^{-1}$ (at 25°C).

Relative Reactivities

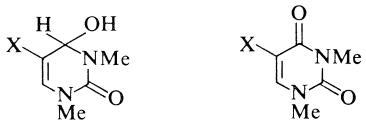
We now consider the reactivity ascribed to the pseudobase QOH in relation to the proposed mechanism (Scheme 1) and the analysis of the data given above. The value of $k_2 = 7 \times 10^8\ M^{-1}\ s^{-1}$ cited previously is based upon the total bromine concentration and does not take into account the depletion of free bromine owing to the formation of tribromide ion. At 30°C the dissociation constant of tribromide $K = [Br_2][Br^-]/[Br_3^-] = 0.0554\ M$ (7) and thus the fraction of free bromine in the presence of 0.1 M bromide ion is $K/(K + [Br^-]) = 0.356$. Thus attack of bromine upon the pseudobase QOH actually has $k_2 = 2 \times 10^9\ M^{-1}\ s^{-1}$, which is close to diffusion controlled.

[2]Details provided by D. Lloyd.

Recently Dubois and Toullec (8) argued that since chlorine, bromine, and iodine all attack the enol of acetone at the same rate they do so at a diffusion controlled rate ($\sim 10^9\ M^{-1}\ s^{-1}$). A simple enamine should be more reactive than this enol for reasons of electronegativity (cf. [15] and [16]). How-

[15] 
[16] 
ever, if [15] is diffusion controlled then [16] must be also. The pseudobase QOH contains an enamine moiety attached to a presumably deactivating carbamoyl substituent (—CONMe—). It appears therefore, that the magnitude of the deactivation is insufficient to depress the rate of [16] significantly below the diffusion controlled limit.

The value of $k_2 \simeq 2 \times 10^9\ M^{-1}\ s^{-1}$ for bromine attack upon the pseudobase **2** (X = H) may be compared to values we have obtained for related systems under similar conditions.



2 **3**

	$k_2\ (M^{-1}s^{-1})$	
X	**2**	**3**
H	2×10^9	10^5
Br	4×10^6	20

By conducting experiments in strong aqueous acid we recently showed that the 5-bromo analogue of cation Q^+ reacts with bromine via its pseudobase **2** (X = Br) with a second-order rate constant of $4 \times 10^6\ M^{-1}\ s^{-1}$ (9). Thus the presence of X = Br in **2** causes a rate retardation of 500. By way of comparison, the same substitution in 1,3-dimethyluracil **3** brings about a reduction in rate of 5000 (10). The large retardations, while partly electronic in origin, probably have a large steric contribution resulting from the fact that attack occurs *ipso* to the 5-bromine when X = Br in **2** or **3**. In contrast, phenol, which has a reactivity ($1.8 \times 10^5\ M^{-1}\ s^{-1}$ at 25°C) close to that of 1,3-dimethyluracil **3** (X = H), is only 56 times as reactive as *p*-bromophenol ($k_2 = 3.2 \times 10^3\ M^{-1}\ s^{-1}$) (11).[3]

[3]The value of k_2 given for *p*-bromophenol in ref. 11 is in error. R. P. Bell, personal communication.

For personal use only.

Finally, with respect to the reactivity of Q^+ and QOH in equilibration, we point out that the rate constants we have obtained are very similar to those which Bunting and Meathrel (12) found for the 2-cyanomethyl-5-nitroisoquinolium cation (**4**) and its pseudobase. Of the many cations they studied, the cation **4** has a value of pK_{R+} most similar to that of Q^+. Again, this may be a consequence of the involvement of mechanism [14].

Cation	pK_{R+}	k_1 (s^{-1})	k_{-1} (M^{-1} s^{-1})	k (s^{-1})	k_{OH} (M^{-1} s^{-1})	Temperature (°C)
Q^+	7.16	1.5	2.2×10^7	0.31	2.1×10^6	30
4	7.26	0.22	6.4×10^6	0.54	1.9×10^6	25

Conclusions

The bromination kinetics lead us to the conclusion that the 1,2-dihydro-1,3-dimethyl-2-oxopyrimidinium cation Q^+ does indeed react with bromine via its pseudobase QOH (Scheme 1). At high pH (>4) the rate of formation of this pseudobase is rate determining [4]. At low pH (<2) the pseudobase undergoes rapid acid-catalyzed decomposition back to Q^+ and the diffusion controlled attack of bromine upon QOH is rate determining [2]. These conclusions are supported by a study of the kinetics of pseudobase formation and decomposition. Furthermore, pseudobase formation is probably general base-catalyzed, and the microscopic reverse, decomposition, general acid-catalyzed as shown in [14].

Experimental

Materials

The 1,2-dihydro-1,3-dimethyl-2-oxopyrimidinium cation was employed as the hydrogen sulphate salt which was prepared as previously (3). Aqueous sulphuric acid solutions (0.1 *N*, pH = 1.26 and 1.0 *N*, H_0 = 0.11 (13)) were made up from volumetric concentrates. Buffer solutions of constant ionic strength (0.01 *M*) were made up following Perrin (14) and checked using a Corning digital 110 pH meter. Since all kinetic solutions were 0.1 *M* in potassium bromide, the total ionic strength was 0.11 *M* for experiments using buffers.

Bromine solutions in sulphuric acid were prepared by use of the bromate–bromide reaction (15). For bromine solutions in buffers, where this reaction is too slow, a relatively concentrated solution was made up by weight and then diluted appropriately. In all the bromination experiments the initial bromine concentration was 5×10^{-5} *M* after 1:1 mixing in the stopped-flow apparatus.

Methods

The value of pK_{R+} appropriate to the conditions of the kinetics experiments ([KBr] = 0.1 *M*, total ionic strength = 0.11 *M*, 30°C) was determined spectrophotometrically (16). Using an analytical wavelength of 239 nm (λ_{max} of QOH) gave 7.15 ± 0.04, whereas using 314 nm (near λ_{max} of Q^+) gave 7.17 ± 0.03. Accordingly, in the text we use pK_{R+} = 7.16.

Kinetics experiments were carried out using an Aminco-Morrow stopped-flow accessory attached to an Aminco DW-2 uv–visible spectrophotometer operating in the dual wavelength mode. Temperature in the observation cell and the drive syringes was maintained at 30.0 ± 0.1°C using a Lauda RC-20B circulating bath. Absorbance changes were recorded using a Biomation 805 waveform recorder and the stored signal was viewed using an oscilloscope. Acceptable traces were plotted out on large graph paper by connecting the Biomation 805 to the X—Y recorder of the Aminco DW-2 through an adjustable dropping resistor.

For bromination studies one drive syringe contained cation Q^+ in the chosen medium, and the other contained bromine (1×10^{-4} *M*) in the same medium. All concentrations given in the text are *after* mixing. Reactions were followed by monitoring the change at 267 nm (λ_{max} Br_3^-) relative to that at 240 nm where there is little or no change. For pH < 2 strictly first-order behaviour was observed for >94% reaction. Pseudo-first-order rate constants (k_1^{obs}) were obtained from least-squares analysis of ln ($A - A_\infty$) vs. time for the first 80–90% of reaction ($r \geq 0.9995$). For pH > 4 and large excess of cation Q^+ zero-order behaviour was observed over much of the reaction. Pseudo-zero-order constants (k_0^{obs}) were obtained by analysis of ($A - A_\infty$) vs. time for the first 50–60% of the reaction ($r \geq 0.9995$). The slope (dA/dt) from this analysis relates to k_0^{obs} through an apparent extinction coefficient ε[4] and the following equations:

$$k_0^{obs} = \frac{-d[Br_2]}{dt} = -\frac{1}{\varepsilon l}\frac{dA}{dt}$$

$$A_0 - A_\infty = \varepsilon[Br_2]_0 l$$

Therefore

$$k_0^{obs} = \frac{[Br_2]_0}{(A_0 - A_\infty)}\frac{dA}{dt}$$

For the first-order disappearance of bromine which results from the first-order disappearance of Q^+ when pH > 4 and $[Q^+]_0$ only slightly greater than $[Br_2]_0$ analysis of the data requires an imaginary (and negative) infinity reading A_∞'. The observed A_∞ corresponds to the actual total consumption of bromine, whereas A_∞' corresponds to the imaginary total consumption of cation Q^+. For an apparent[4] extinction coefficient ε the following relationships hold.

$$A_0 - A_\infty = \varepsilon[Br_2]_0 l \qquad A_0 - A_\infty' = \varepsilon[Q^+]_0 l$$

Therefore

$$A_\infty' = A_0 - (A_0 - A_\infty)[Q^+]_0/[Br_2]_0$$

On this basis we analyzed ln ($A - A_\infty'$) vs. time covering about 90% reaction and obtained good straight lines ($r \geq 0.9995$) whose slopes gave values of $k_1^{obs'}$. Bromination data obtained at pH = 2.67 and 3.04 which are of mixed order were analyzed by procedures *a* and *b* described in the text.

The pseudobase kinetic studies were conducted in the manner of Bunting and Meathrel (6). One drive syringe contained a 5×10^{-4} *M* solution of Q^+ (or QOH) in 0.1 *M* aqueous potassium bromide, while the other contained a buffer of pH > pK_{R+} (or pH < pK_{R+}) also in 0.1 *M* aqueous KBr and of twice the concentration given in Perrin (14). Thus, after mixing; the solution conditions were the same as those in the

[4]Apparent because of contributions to the absorbance from Q^+ as well as Br_3^-. Also because of the nature of a dual wavelength experiment.

bromination studies. The disappearance of Q^+ (or QOH) was monitored at 316 nm (or 239 nm) relative to 270 nm (spectrum minimum). Good first-order behaviour was observed for $>90\%$ reaction and analysis of ln $(A - A_\infty)$ vs. time gave pseudo-first-order rate constants k_{obs} with $r \geq 0.9995$. The reproducibility of k_{obs} depends upon the speed of the reaction. For the fastest runs near the limit of the apparatus it is about 10% but for the slowest runs it is less than 5%.

The $\{Li(NH_3)_n\}^+$ and $\{Na(NH_3)_n\}^+$ systems. A CNDO/2 study of the Li^+ and Na^+ ion solvation

C. SIEIRO, P. CAÑAS, AND P. MARTINEZ

Centro Coordinado del CSIC, Facultad de Ciencias, Universidad Autónoma, Canto Blanco, Madrid 34, Spain

Received February 13, 1978

C. SIEIRO, P. CAÑAS, and P. MARTINEZ. Can. J. Chem. **56**, 2977 (1978).

We present the CNDO/2 calculations of Li^+ and Na^+ solvation in ammonia solvent. The results indicate a solvation number of $n = 6$ for Li^+ and $n \geq 8$ for Na^+, at equilibrium distances of $Li^+ \ldots N = 2.3$ Å and $Na^+ \ldots N = 2.9$ Å. The charge transfer from ammonia to both ions is analyzed.

C. SIEIRO, P. CAÑAS et P. MARTINEZ. Can. J. Chem. **56**, 2977 (1978).

On présente les calculs selon la méthode CNDO/2 pour la solvatation de Li^+ et Na^+ dans l'ammoniac. Les résultats indiquent un degré de solvatation $n = 6$ pour l'ion Li^+ et $n \geq 8$ pour l'ion Na^+, les distances à l'équilibre étant $Li^+ \ldots N$, 2.3 Å, et $Na^+ \ldots N$, 2.9 Å. On analyse les transferts de charge des molécules d'ammoniac vers ces deux ions.

Introduction

The theoretical study of ion solvation has been, to date, fundamentally realized on the hydration case. In general, studies on solvation with other non-aqueous solvents have not been widely done.

The earlier works on solvation used, fundamentally, the Born model, which is based on the continuum theory of the solvent. The consecutive refinements of this model have reached the limit of usefulness (1–4).

Quantum mechanical studies have recently been carried out using the *ab initio* SCF MO computation on the most simple systems and more extensively the semi-empirical methods (CNDO/2, INDO, EHT, etc.) for the study of the most complex systems in aqueous and non-aqueous media (5–31).

In this paper we present the study of the solvation of the Li^+ and Na^+ ions in ammonia solvent. We consider the primary solvation sheath as being the bulk solvent. In this case, the difference between the total energy of the whole system at infinite distance and the total energy, corresponding to equilibrium, refers to the solvation energy at absolute zero. We omitted the corrections of $\Delta H_{298.16}$ to $\Delta E_{0\ K}$ which were negligible in this particular case.

$$\Delta E = E_{eq} - E_\infty = E_{M^+(MN_3)_n}\,(r = r_{eq}) - E_{M^+(NH_3)_n}\,(r = \infty)$$

or

$$[1] \qquad \Delta E = E_{M^+(NH_3)_n} - (E_{M^+} + nE_{NH_3})$$

where n is the solvation number, $E_{M^+(NH_3)_n}$, E_{M^+}, and E_{NH_3} are the energies of the solvated ion, isolated ion, and the ammonia molecule, respectively.

We have used the by now classical CNDO/2 method in its original parametrization of Pople–Santry–Segal (32, 33). The program used was a modified version of the QCPE 141 program. The geometric input data for the ammonia molecule is the latest available experimental value d(N—H) = 1.014 Å and $\angle$ HNH = 106.7°.

The CNDO/2 method uses only the valence orbitals as "the minimum basis set" and thus the energy of the cation M^+ is zero, consequently:

$$[2] \qquad \Delta E = E_{M^+(NH_3)_n} - nE_{NH_3}$$

We also obtain the stabilization energies considering the diatomic ($M^+ \ldots N$) energy terms for different solvation numbers.

The Solvation Model

As we have mentioned before, the bulk solvent is approximate to a first sheath around the ions. We considered 1 to 8 molecules of ammonia in the geometrically most symmetric orientation around the central ion. In all cases of $M^+ \ldots NH_3$ complexes, the M^+ ion was along the lone-pair direction.

Figure 1 shows the geometrical distribution of ammonia considered for the different numbers of solvation. The potential energy curves of the $\{M(NH_3)_n\}^+$ systems are obtained by varying the $M^+ \ldots N$ distances within the range of 0.5 to 5 Å. At this last distance the interaction energy approaches zero and the whole system is described as being n molecules of ammonia and one ion, all being independent. That is to say this situation corresponds to the above mentioned energy, E_∞.

Gupta and Rao (21) have studied the solvated lithium system for $n = 1$, 2, and 4 molecules of ammonia, but for the last coordination number, they considered a square planar model whereas we have considered a tetrahedral one. The results in all three cases practically coincide with ours.

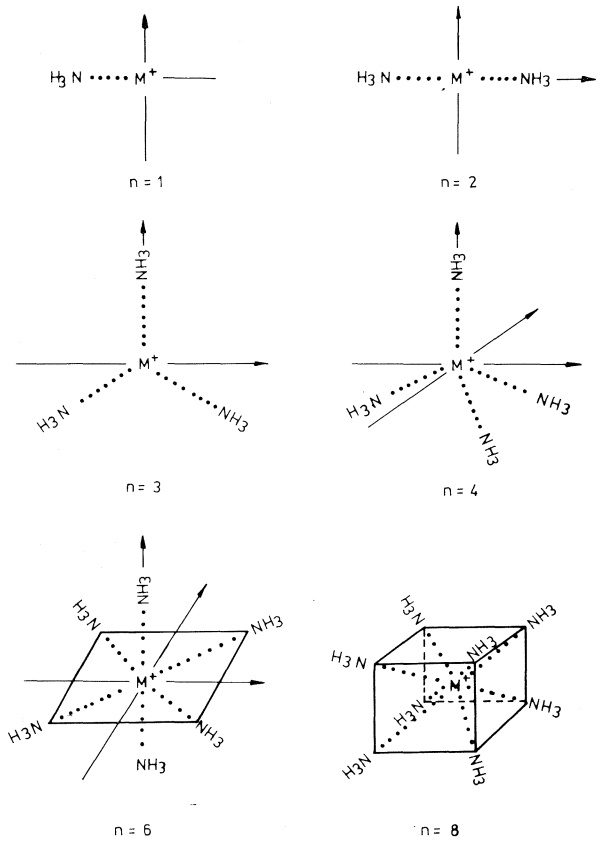

FIG. 1. Coordinate system and solvation model for $M^+(NH_3)_n$ ($M^+ = Li^+$ and Na^+).

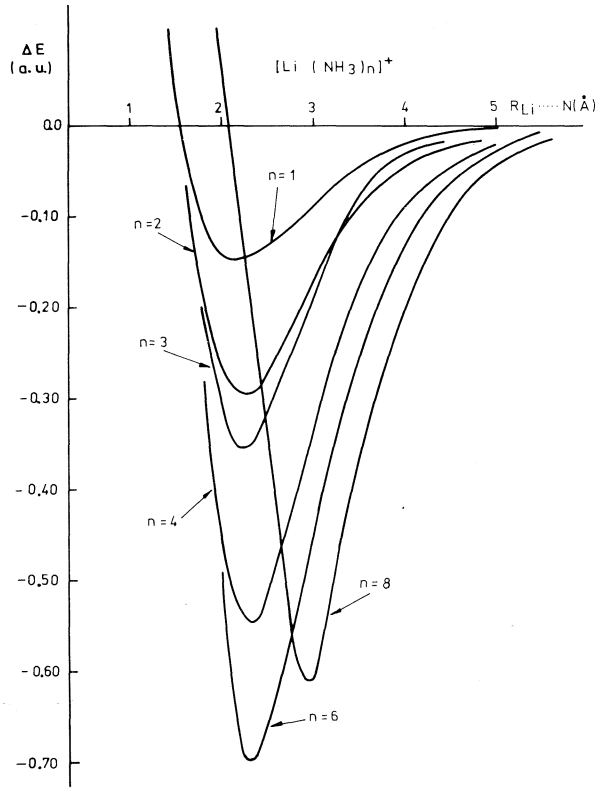

FIG. 2. Potential energy curves for the (LiN) variation of the $Li^+(NH_3)_n$ system.

Results and Discussion

In Figs. 2 and 3, we present the potential energy curves obtained for the $\{Li(NH_3)_n\}^+$ and $\{Na(NH_3)_n\}^+$ systems, respectively, where n = 1, 2, 3, 4, 6, and 8. Table 1 shows the results for the equilibrium N ... M^+ (Li^+ and Na^+) bond length, stabilization energy, diatomic energy terms, and charge transfer for all the complexes studied.

(a) Lithium Solvation

As shown in Fig. 2, all curves show that the interaction of the lithium ion with ammonia molecules stabilize the ion with respect to the subsystems, and furthermore indicate a strong ordering effect of ions on the ammonia molecules. This was the first result of the classical ion-solvent theory. The ordering effect does not mean a static but a dynamic and statistical arrangement.

The ammoniation energies are higher than the hydration ones in all n values studied (see Table 1). The most stable complex corresponds to a value of $n = 6$, but the stabilization energies per Li^+ ... N bond decrease as the solvation number increases. The solvation sheath corresponding to the predicted most stable octahedral system has a radius of 2.3 Å. There are no experimental data for this n value, and the only experimental Li^+ ... N distance available corresponds to the $\{Li(NH_3)_n\}^+$ complex and $R_{Li \ldots N}$ = 1.94 Å (34). The *ab initio* calculation of Støgard (35) for $n = 1$ yields $R_{Li \ldots N}$ = 1.98 Å, which is more exact than the CNDO/2 prediction (see Table 1).

The ammonia is an electron donor molecule and there is a great charge transfer to the lithium ion in all the systems, this charge transfer decreases with increasing solvation number. This feature is a logical consequence of an increase in the Li^+ ... N equilibrium distance with the number of ammonia molecules around the ion. The charge transfer process decreases as the nitrogen lone pair recedes. The unrealistically high values of charge transfer represent a systematic artificial error of the CNDO/2 treatment as a final consequence of the neglect of the inner shell electrons. The alkali ions are represented as screened nuclei and it is not possible to take into account the polarization of the inner shell electrons.

TABLE 1. Solvation number, total energy, sheath radius, stabilization energies, transfer charge, and diatomic energy terms of the lithium and sodium solvated systems*

System	n	E_T (au)	$d_{M^+ \ldots N}$ (Å)	$-\Delta E$ (kcal/mol) Cation–ammonia complex	$-\Delta E$ (kcal/mol) Cation–water complex	q_T	Diatomic energy terms (au)
$\{Li(NH_3)_n\}^+$	1	−14.0198	2.1	93	44	−0.30	−0.378
	2	−28.0342	2.2	92	44	−0.30	−0.359
	3	−42.0370	2.3	88	41	−0.24	−0.315
	4	−56.0259	2.3	85	38	−0.24	−0.295
	6	−83.9200	2.3	72	33	−0.18	−0.240
	8	−111.5818	2.9	48	30	−0.10	−0.130
$\{Na(NH_3)_n\}^+$	1	−14.2238	2.6	220	32	−0.34	−0.663
	2	−28.4234	2.7	213	31	−0.34	−0.622

	8	−113.2337	2.9	177	26	−0.26	−0.487

*ΔE is the average stabilization energy per $Li^+ \ldots N$ bond; E_T of NH_3 is −13.8710 au. The diatomic energy terms refer to energy per $Li^+(Na^+)$—N bond. q_T is the charge transfer per $Li^+(Na^+) \ldots N$ bond.

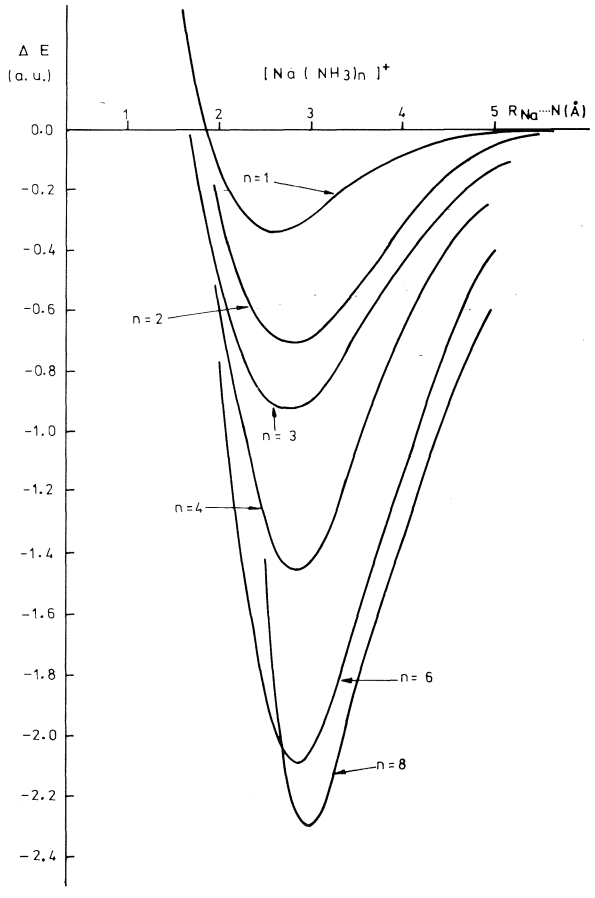

FIG. 3. Potential energy curves for the (NaN) variation of the $Na^+(NH_3)_n$ system.

(b) Sodium Solvation

Figure 3 shows the potential curves obtained for the solvated sodium ion. The stabilization energy increases continually with the coordination number. This result is analogous to that obtained in the hydration case for the Li^+ and Na^+ ions. The equilibrium bond lengths for all n values are higher than the lithium complex systems. There are no experimental data available for this system and the higher solvation number and sheath radius than in the solvated lithium system is consistent with the greater ionic radius of the sodium ion. The charge transfer of the ammonia molecules to the Na^+ ion is larger than in the lithium case and decreases in the same sense.

The two systems studied contain only monovalent cations and the number of surrounding ammonia molecules depends on the ion size and the steric hindrance of the ammonia molecules comprising the solvation sheath. We have also calculated for the H^+ cation case, and obtained four molecules of ammonia for the primary solvent sheath. Figure 4 shows the solvation energy for H^+ and Li^+ in water and ammonia media at different values for n. In the case of H^+ in H_2O solvent, there is a maximum in the stabilization energy at approximately $n = 6$, but in ammonia the stabilization energy is practically the same from $n = 2$ to $n = 5$, due to the greater molecular volume with respect to that of the H_2O. In the $\{Li(NH_3)_n\}^+$ and $\{Na\ NH_3)_n\}^+$ systems the results obtained are analogous. In NH_3 solvent, there is a maximum in the ammoniation energy at $n = 6$ but this maximum does not exist in the range $n = 1$ to $n = 8$ when water solvent is considered.

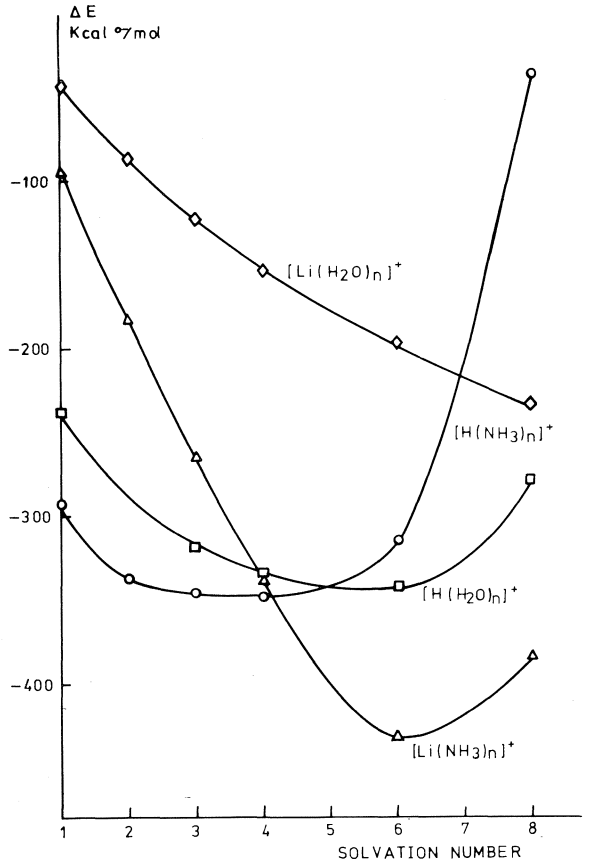

FIG. 4. Variation of the stabilization energies with n for the $Li^+(NH_3)_n$, $Li^+(H_2O)_n$, $H^+(NH_3)_n$, and $H^+(H_2O)$ systems.

We can conclude that the CNDO/2 method predicts a solvation number of 6 and ≥ 8 for Li^+ and Na^+ ions, respectively, as being the energetically most favourable of all the coordinations studied. The solvation energy calculated cannot be compared with the experimental data, but the results in the Na^+ case appear to be excessively high. This is a consequence of the whole CNDO/2 procedure. However, in the case of a hydrated complex (1:1), more accurate calculations obtain poorer results than the CNDO/2 ones, depending on the basis set used (11). Only the extremely accurate calculations of Clementi *et al.* obtain, in the $Li(H_2O)^+$ case, values approximating to the experimental ones. The greater value of the size of the octahedral cation–ammonia complex is also obtained, in the case of hydrated complexes, using more accurate calculations. With cation–ammonia complexes, this value might be due to the steric hindrance among the ammonia molecules. The CNDO/2 results differ considerably from the *ab initio* calculations; however, in the latter, the basis set used is very limited when the complex is great and a definite conclusion cannot be reached. Moreover, the inclusion of a second solvation sheath would probably improve our results. This will constitute a further study.

Enrichment of nitrogen-15 by the direct laser photolysis of ammonia-d_3 in the $\tilde{A}$–$\tilde{X}$ transition[1]

P. A. HACKETT, R. A. BACK, AND S. KODA[2]

PIE Group, Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received May 24, 1978

P. A. HACKETT, R. A. BACK and S. KODA. Can. J. Chem. **56**, 2981 (1978).

Ammonia-d_3 of differing $^{14}N/^{15}N$ ratios has been photolysed in the $\tilde{A}$–$\tilde{X}$ transition using a narrow-band-width, frequency-doubled, pulsed dye laser. At specific excitation wavelengths, chosen by absorption spectroscopy, the product nitrogen is enriched in ^{15}N, a maximum enrichment factor of 4.8 being attained. The initial isotopic selectivity of excitation is largely retained in the nitrogen product, even though the primary photodissociation forms free radicals and N_2 is formed only after a sequence of secondary reactions. Quantum yields of nitrogen and hydrogen formation have been measured at very low conversions as a function of the time of irradiation. The initial yield of nitrogen appears to be zero and that of hydrogen 0.25.

P. A. HACKETT, R. A. BACK et S. KODA. Can. J. Chem. **56**, 2981 (1978).

On a utilisé un laser à colorant en mode déclenché, de largeur de bande spectrale étroite et doublé en fréquence pour photolyser de l'ammoniaque-d_3 dans la transition $\tilde{A}$–$\tilde{X}$ pour divers rapports $^{14}N/^{15}N$. A certaines longueurs d'ondes d'excitation, choisies d'après le spectre d'absorption, le produit est enrichi en ^{15}N et le facteur d'enrichissement maximum est 4.8. La sélectivité isotopique initiale est presque complètement retenue par le produit azoté même si N_2 n'est produit qu'après une suite de réactions secondaires impliquant les radicaux libres formés dans la photodissociation primaire. On a mesuré les rendements quantiques de formation d'azote et d'hydrogène à très faible niveau de décomposition en fonction des temps d'irradiation. Le rendement quantique initial d'azote est nul et celui de l'hydrogène est 0.25.

Introduction

The identification and characterization of photochemical systems useful for isotope separation is of much immediate interest. Most attention has been paid to infrared multiphoton decomposition and to simple ultraviolet photolysis, although a variety of more complicated 2- or 3-photon schemes have also been studied or proposed. For successful isotope separation by a simple one-photon uv photolysis, the lifetime of the excited state must fall within rather narrow limits. It must be short enough that the quantum yield of decomposition is high, but not so short that the line width of the absorption spectrum is so broadened that optical isotopic selectivity is lost. The photolysis of formaldehyde meets these requirements almost ideally, but few other systems have been successfully demonstrated. The ammonia photolysis (1) provides an example of an excited-state lifetime that is too short; the predissociation broadens the spectrum so much that ^{14}N–^{15}N optical selectivity is completely lost; the NH_3–NDH_2 selectivity is reduced to a maximum value of about 10, and even this modest selectivity would probably be lost in secondary reactions that lead to H–D exchange in the products (2). In ammonia-d_3, however, the predissociation is appreciably slower and the spectrum sharper, showing resolved rotational structure in bands corresponding to the first two vibrational levels of the excited state (3). There appears to be sufficient optical selectivity to permit a useful ^{14}N–^{15}N separation if it is retained in the secondary reactions following dissociation. The present paper describes a study of this isotope separation system.

Experimental

Ammonia-d_3 (99% D, natural abundance $^{14}N/^{15}N$) and $^{15}ND_3$ (98% ^{15}N, 99% D) were obtained from Merck, Sharp and Dohme of Canada Ltd., and were used without further purification. Research grade propane (Matheson) was used without further purification as glc analysis showed negligible olefin content.

High resolution absorption spectra of both ammonias were obtained in the first order of the spectrograph previously described (4). The pathlength was 10 cm, pressures varied from several to several hundred Torr, and temperatures from ambient to 400°C. Line positions were obtained by comparison to lines of a copper arc and band origins were determined by graphical methods.

Following the photographic survey of the absorption spectra, a Molectron DL200 dye laser equipped with potassium pentaborate frequency doubling crystals and pumped by a Molectron UV 1000 pulsed nitrogen laser was used to obtain quantitative absorption spectra in those specific spectral regions where optical selectivity could be expected. The spectra were obtained by comparing the output of two Hammamatsu R788 solar blind photodiodes in a logarithmic ratiometer. One diode monitored a portion of the incident laser intensity, the other monitored the intensity transmitted through a 10 cm

$00–02^+$	45 355.1	+10.1	45 355.1
$00–03^+$	44 887.7	+15.7	44 887.1

*From ref. 3.

long thermostated cell containing the sample. As the wavelength of the dye laser was scanned, the angle of the frequency doubling crystal was adjusted by a stepping motor locked to the diffraction grating stepping motor through a digital frequency divider. Optimum wavelengths and temperatures to selectively excite $^{15}ND_3$, and the numerical value of this selectivity were determined with this system. The effective linewidth of the ultraviolet laser radiation was estimated by using the system to measure the apparent widths of isolated lines in the (0,0) band of the $A^2\Sigma^+ \leftarrow X^2\Pi$ absorption system of nitric oxide, known to be much narrower than the laser linewidth.

Photolyses were then carried out at 300 Torr pressure of ND_3 in cylindrical quartz cells 10 cm long and 2 cm in diameter with a volume of 46 cm^3, with the laser tuned to an optimum wavelength. After irradiation, ND_3 and N_2D_4 were condensed at −196°C, and the residual pressure of noncondensable gases measured by a sensitive capacitance manometer connected to the cell. These gases were then removed and their composition determined by removing D_2 through a hot palladium thimble and measuring the residual pressure of N_2. The ND_3 and N_2D_4 were then returned to the reaction vessel for further irradiation. Repeated irradiation of the same sample in this way, with irradiation times typically from 5 to 20 min, gave measurements of product yields as a function of total irradiation time. These yields were converted to absolute quantum yields by comparison with the amount of hydrogen produced in the presence of 300 Torr of propane used as a hydrogen atom scavenger ($\Phi_{H_2} = 1$) (2).

The isotopic composition of the product nitrogen was determined in a separate series of experiments. All quartz reaction vessels, equipped with break-seals, and flamed before filling with mixtures of $^{14}ND_3$ and $^{15}ND_3$, were used. The ^{15}N content varied from natural abundance to equimolar and the pressure was 1200 Torr, enough to ensure complete absorption of the ultraviolet radiation in all samples. After irradition noncondensable gases were analysed in a Hitachi-Perkin Elmer RMU-60 mass spectrometer, by observing the peaks *m/e* 28, 29, and 30. The ratios of these peaks were independent of the electron energy (70–20 eV). The isotopic content of the starting mixtures was determined by complete decomposition of a small sample of each by Tesla discharge at low pressure, and subsequent mass spectral analysis of the N_2 product.

Results and Discussion

Each band of $^{15}ND_3$ showed a small isotope shift in the band origin, when compared to the data Douglas (3) on $^{14}ND_3$. The rotational structure of the bands was completely unchanged, however. This is not unreasonable as the upper state is planar, and the ground-state constants C'' for the two species are equal whilst B'' differs only by 0.37%. The observed isotope shifts are tabulated in Table 1.

At first sight, because the bands with $v_2' = 1$ are sharper than those with $v_2' = 0$ (linewidths 0.8 and 2.5 cm^{-1} respectively (3)), better optical selectivity might be expected in the former. However, such ($01–0m^-$) bands are overlapped by the tails of the P and Q branches of the ($00–0m^+$) bands as was seen in a previous study in which high resolution emission spectroscopy showed that the cadmium resonance line at 2144 Å excites both Q(1) of the $01–01^-$ band and P(8) of the $00–00^+$ band (4). The selectivity may be further affected by other sequence bands, by absorption due to the 3% ND_2H present, and perhaps by the weak underlying continuum postulated by Gregory and Lipsky (5). These facts, together with the non-negligible linewidth of the dye laser (1.4 cm^{-1}) made it essential to determine empirically the best wavelengths for selective excitation from the laser absorption spectrum. The best region found for optical selectivity is illustrated in Fig. 1. For excitation near the Q head of the $00–02^+$ band, at 220.39

ERRATA Fig. 2 appears above the caption for Fig. 1

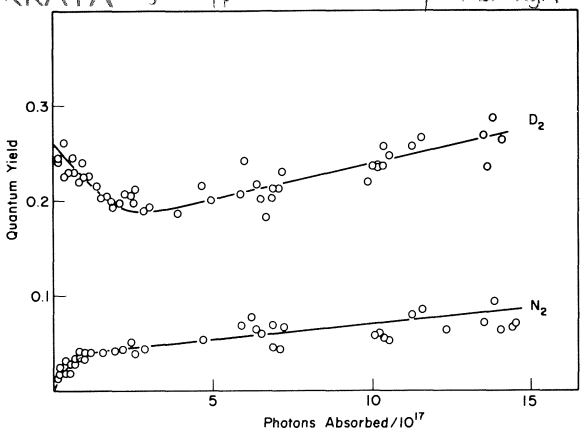

FIG. 1. Laser absorption spectrum of ammonia-d_3. The solid lines refer to $^{14}ND_3$, the dashed line to $^{15}ND_3$. The insert shows a complete spectrum of the band. Band and line assignments for $^{14}ND_3$ were taken from ref. 3 and used as wavelength calibration points. The arrow indicates a region where selective excitation of $^{15}ND_3$ is possible.

nm a maximum optical selectivity of 5.18 was obtained at room temperature.

Photolysis at this wavelength yielded N_2 with the isotopic composition given in Table 2. Typically, ultraviolet pulse energies in these experiments were 5×10^{-6} J, pulse repetition rates 10 Hz, and photolysis times 3 h. Conversions were about 0.04%, so that the isotopic composition of the nitrogen product should represent an initial value for the selectivity of the overall photolysis process. It is well established that the initial reactions in the photolysis are:

[1] $$ND_3 + h\nu \rightarrow ND_2 + D$$

[2] $$2ND_2 \xrightarrow{M} N_2D_4$$

[3] $$D + ND_2 \xrightarrow{M} ND_3$$

[4] $$2D \xrightarrow{M} D_2$$

It is generally agreed that N_2 arises from subsequent secondary reactions of N_2D_4 with ND_2 and D, although the precise mechanism is not clear. The average enrichment observed in the N_2 product ($\alpha = 4.5$) is only slightly less than the selectivity of excitation (5.2), which implies that there is little loss of selectivity in the transformation of the initial photofragment ND_2 into the final product nitrogen. Thus exchange of nitrogen atoms between hydrazine and ammonia, and the reaction

[5] $$^{15}ND_2 + {}^{14}ND_3 \rightarrow {}^{15}ND_3 + {}^{14}ND_2$$

or the reaction of D atoms with ammonia

[6] $$D + {}^{14}ND_3 \rightarrow D_2 + {}^{14}ND_2$$

must be unimportant in the present system. This bodes well for the practical separation of nitrogen isotopes by the ammonia photolysis, although the relatively low value of α would require at least 5 stages to achieve a useful enrichment of ^{15}N starting from natural abundance ND_3. However, it may now be worthwhile to exploit the ir-activated hot band

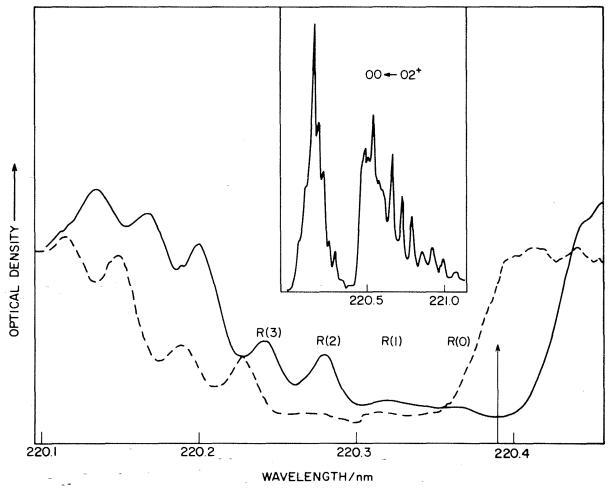

FIG. 2. Dose-dependent quantum yields in the laser photolysis of ammonia-d_3, $\lambda_{ex} \simeq 220.5$ nm.

ERRATA Fig 1 appears above the caption for Fig. 2.

photolysis of ND_3 (6) with the prior knowledge provided by this study that the secondary chemistry retains selectivity.

The time-dependent quantum yields shown in Fig. 2 deserve some comment. The yield of N_2 appears to approach zero at zero time, confirming previous conclusions that N_2 was formed from secondary reactions of hydrazine. The experimental accuracy permits an upper limit for the reaction

[7] $$2ND_2 \rightarrow N_2 + 2D_2$$

a suggested primary source of N_2, of about 5% of reaction [2]; there is no positive evidence that it occurs at all (7, 8).

The initial quantum yield of D_2 reflects the competition between the combination reactions [2], [3], and [4], and the value of about 0.25 suggests an almost statistical ratio of 1:2:1 for the three reactions. Estimates of rates of diffusion and radical lifetimes in the system indicate that these reactions should have been complete within the laser beam

(diameter 4 mm) and the observed ratio should correspond to homogeneous surface-free reaction

As hydrazine accumulates in the system, the yield of N_2 rises and that of D_2 falls. Reactions involved initially must be

[8] $$D + N_2D_4 \rightarrow D_2 + N_2D_3$$

and

[9] $$ND_2 + N_2D_4 \rightarrow ND_3 + N_2D_3$$

followed by further reactions of N_2D_3 and perhaps other transient intermediates, leading finally to formation of N_2, D_2, and some regeneration of ND_3 in a mechanism that has not yet been fully delineated. Reaction [8] by itself would enhance the yield of D_2, and the observed decrease implies that loss of D atoms in other reactions, probably with N_2D_3, must more than compensate for reaction [8]. As hydrazine concentration builds up further, however, reaction [8] will begin to predominate, and the yield of D_2 will increase again as observed. If enough N_2D_4 were present, the yield of D_2 would become unity; this is stoichiometrically impossible in the present system, and the final value of the D_2 yield when N_2D_4 has reached its steady state will depend on a complex competition between reactions [1], [2], [3], [8], and [9] subsequent further reactions of N_2D_3 and other species. The same competition will also control the final quantum yield of nitrogen which in the steady state must be 1/3 that of D_2. The data in Fig. 2 indicate a final value of about 0.1, so that conversion of the photofragment ND_2 into N_2 is only about 20% efficient.[3] This suggests the use of a scavenger for ND_2 to improve yields for isotope separation. Possible scavengers are O_2, to take advantage of the reaction sequence

[10] $$ND_2 + O_2 \xrightarrow{\text{slow}} NO + D_2O$$

[11] $$ND_2 + NO \xrightarrow{\text{fast}} N_2 + D_2O$$

or ^{15}NO, using reaction [11] alone, which Srinivasan has shown retains selectivity for nitrogen atoms (10). Both systems look promising but might be complicated by reactions of DNO and DO_2 formed from reactions of D with NO and O_2.

In summary, we have demonstrated separation of nitrogen isotopes by simple photolysis of ND_3 at 220.39 nm. The chemistry is clean and the optical selectivity is largely retained in the N_2 product. The separation factor of about 4.5 is limited chiefly by the linewidth of the absorption spectrum, and little improvement can be expected. The quantum yield of N_2 of about 0.1 could probably be improved by suitable scavengers.

Radical ions in photochemistry. 6. The photosensitized (electron transfer) ring opening of aryloxiranes[1]

ANGELO ALBINI[2] AND DONALD R. ARNOLD[3]

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received May 17, 1978

ANGELO ALBINI and DONALD R. ARNOLD. Can. J. Chem. **56**, 2985 (1978).

The photosensitized (electron transfer) irradiation of *cis*- and *trans*-2,3-diphenyloxirane (**1** and **2**) led to cleavage of the oxirane carbon–carbon bond and subsequent formation of the carbonyl ylide. The resulting carbonyl ylides have been trapped with the dipolarophiles, acrylonitrile, maleonitrile, and fumaronitrile. The resulting isomeric tetrahydrofuran derivatives have been characterized. Sensitizers (electron acceptors) which are effective include 1,4-dicyanonaphthalene, 1,4-dicyanobenzene, dimethyl terephthalate, and methyl 4-cyanobenzoate; 1-cyanonaphthalene was not effective. The proposed mechanism involves formation and cleavage of the oxirane radical cation followed by back electron transfer from the sensitizer radical anion to give the carbonyl ylide. Electrochemical and photophysical evidence which supports the proposed mechanism was obtained.

ANGELO ALBINI et DONALD R. ARNOLD. Can. J. Chem. **56**, 2985 (1978).

L'irradiation photosensibilisée (transfert d'électron) du *cis*- et du *trans*-diphényl-2,3 oxiranne (**1** et **2**) a conduit au clivage de la liaison carbone–carbone de l'oxiranne et la formation subséquente de l'ylure de carbonyle. Les ylures de carbonyle ont été piégés au moyen des dipolarophiles acrylonitrile, maléonitrile et fumaronitrile. On a obtenu des dérivés isomères du tétrahydrofuranne qu'on a caractérisés. Au nombre des sensibilisateurs (accepteurs d'électrons) qui sont efficaces, citons le dicyano-1,4 naphtalène, le dicyano-1,4 benzène, le téréphtalate de diméthyle et le cyano-4 benzoate de méthyle; le cyano-1 naphtalène était inefficace. Le mécanisme proposé implique la formation et le clivage du cation radicalaire oxiranne, puis le transfert d'électron depuis l'anion radicalaire du sensibilisateur pour donner l'ylure de carbonyle. On a obtenu des indices de nature électrochimique et photophysique qui appuient le mécanisme proposé.

[Traduit par le journal]

Introduction

We recently reported the photosensitized (electron transfer) cleavage of acyclic β-phenethyl ethers (1*b*); a typical example is shown in reaction [1].

$$[1]\quad (C_6H_5)_2CHCH_2{-}O{-}CH(CH_3)_2 + CH_3OH \xrightarrow[CH_3CN]{h\nu,\ \text{sensitizer}} (C_6H_5)_2CH_2 + CH_3OCH_2OCH(CH_3)_2$$

sensitizer = 1,4-dicyanonaphthalene
(1-cyanonaphthalene was *ineffective*)

The proposed mechanism for this reaction involves electron transfer from the ether to the excited singlet state of the sensitizer. The ether radical cation then cleaves in the direction which yields the more stable fragments; in this case the diphenylmethyl radical and the α-oxycarbonium ion. The radical is then reduced to the anion by the radical anion of the sensitizer. Protonation of the anion and reaction of the α-oxycarbonium ion with alcohol then account for the observed products.

Since aryloxiranes can be viewed as β-arylethyl ethers is seemed reasonable to expect this type of reaction could be used to cleave these compounds as well. If the reaction takes an analogous course, a useful technique for generating the corresponding carbonyl ylides would result. Carbonyl ylides have been produced from aryloxiranes by both direct (2) and sensitized (triplet–triplet transfer) (3) irradiation, as well as by thermal (4) activation, but there are no examples which have been recognized as involving the photosensitized (electron transfer) process.

In this paper we report (*1*) the *cis–trans* isomerization of the 2,3-diphenyloxiranes by photosensitization (electron transfer); (*2*) the preparation and characterization of the isomeric tetrahydrofuran derivatives which result from the cycloaddition of the carbonyl ylides, generated by the photosensitized (electron transfer) cleavage of the 2,3-diphenyloxiranes, to acrylo-, maleo-, and fumaronitrile; and (*3*) an analysis of photophysical and electrochemical data which support the radical ion mechanism for carbonyl ylide formation.

TABLE 1. The photosensitized (electron transfer) isomerization of *cis*- and *trans*-2,3-diphenyloxirane (**1** and **2**)

Sensitizer[a]	Solvent	Composition at equilibrium (**1**:**2**)
1,4-Dicyanonaphthalene (DCN)	Acetonitrile	0.22
1,4-Dicyanonaphthalene (DCN)	Methanol	0.25
1,4-Dicyanonaphthalene (DCN)	Benzene	0.28
1,4-Dicyanobenzene (DCB)	Acetonitrile	0.19
Dimethyl terephthalate (DMT)	Acetonitrile	0.21
Methyl 4-cyanobenzoate (MCB)	Acetonitrile	0.20
Acetone[b]	Acetonitrile	0.22
1-Cyanonaphthalene (MCN)	Acetonitrile	No isomerization
2-Acetonaphthone[c]	Acetonitrile	No isomerization
1,4-Dimethoxynaphthalene	Acetonitrile	No isomerization
Benzophenone[c]	Acetonitrile	No isomerization

[a]The initial concentration of **1** or **2** was 0.15 *M* and the sensitizer concentration was $1–2 \times 10^{-2}$ *M* unless otherwise noted. A Pyrex filter which absorbed wavelengths < ca. 290 nm was used.
[b]2 *M* in sensitizer.
[c]4×10^{-2} *M* in sensitizer.

Results

cis and *trans*-2,3-Diphenyloxirane (**1** and **2**) were prepared by oxidation of the isomeric stilbenes with 3-chloroperbenzoic acid (5). The isomerization of **1** and **2** was studied as a function of sensitizer and solvent. The ratio of isomers was determined by vapor phase chromatography (vpc) and, in those cases where isomerization was observed, the same ratio was obtained starting with either isomer.

Secondary reactions which consume **1** and **2** were relatively minor (<5%), during the irradiation time required to reach equilibrium when acetonitrile or benzene was the solvent. The oxiranes were not stable to prolonged irradiation in methanol (2*b*); however, isomerization was observed. The sensitizer was almost totally recovered in every case. These results are summarized in Table 1.

[2] 
sensitizer = 1,4-dicyanonaphthalene (DCN), 1,4-dicyanobenzene (DCB), dimethyl terephthalate (DMT), methyl 4-cyanobenzoate (MCB), and acetone; 1-cyanonaphthalene (MCN) was ineffective.

The sensitized (electron transfer) irradiation of **1** and **2** in the presence of acrylonitrile leads to the formation of the tetrahydrofuran derivatives **3***a*, *b* and **4***a*, *b* (reaction [3]). All four possible isomeric products have been isolated and characterized. The yields reported in Table 2 were determined by vpc and were in fair agreement with isolated yields following column chromatography. The formation of the cycloaddition products effectively competes with the isomerization of **1** and **2** since little or no isomeric oxirane was observed during the course of the irradiation.

The total yield of adducts was essentially quantitative when 1,4-dicyanonaphthalene was the sensitizer. The ratio of isometric products was not the same starting with **1** or **2**. The ratio of products was also different when acetone was used as sensitizer and when the oxiranes were excited by direct irradiation; however, since the material balance was low in these cases it is more difficult to attach significance to the observed variation. The ratios of products under these different conditions are summarized in Table 2.

The sensitized (electron transfer) irradiation of **1** and **2** in the presence of maleonitrile (**5**) or fumaronitrile (**6**) likewise leads to formation of the analogous tetrahydrofuran derivatives (reaction [4]). In this case, there are six possible isomers and all of them have been isolated and characterized. The configuration of the products now depends upon the configuration of both the oxirane and the dinitrile. These results are summarized in Table 3.

The gross structures assigned to the tetrahydrofurans were based on their spectroscopic (ir and nmr), chemical properties, and elemental analysis. The stereochemical assignments (ignoring chirality) rest largely on the nmr spectral data. Proton–proton coupling constants could not be used since the tetrahydrofuran ring can assume various conformations and the differences between *cis* and *trans* vicinal coupling is not large (4*c*). An analysis of the observed chemical shift data does, however, provide sufficient evidence (Table 4).

Considering first the mono cyano derivatives, the relationship between **3***a* and **3***b* and between **4***a* and **4***b* was established by equilibrating these isomeric pairs upon treatment with base. At equilibrium **3***b*

TABLE 2. The yields of cycloadducts obtained upon irradiation of **1** or **2** in the presence of acrylonitrile[a]

Oxirane	Sensitizer	Yield 3*a*	3*b*	4*a*	4*b*	Total yield of adducts
1	None[b]	11	10	1	1	23
2	None[b]	2	1	12	10	25
1	DCN	47	40	6	7	ca. 100
2	DCN	38	32	16	16	ca. 100
1	Acetone	25	21	5	6	57
2	Acetone	12	10	10	10	42

[a]Typical conditions were oxirane (0.15 *M*) and sensitizer (DCN 2×10^{-2} *M*; acetone 2 *M*) and acrylonitrile (1 *M*) in acetonitrile solution. Irradiation was through a Pyrex filter. The yields (%) were determined by vpc.
[b]Irradiation through quartz.

TABLE 3. The yields of cycloadducts obtained upon photosensitized (electron transfer) irradiation of **1** and **2** in the presence of maleonitrile (**5**) and fumaronitrile (**6**)[a]

Oxirane	Dinitrile	Yield 3*c*	3*d*	3*e*	4*c*	4*d*	4*f*	Total yield of adducts
1	**6**		87			7	5	ca. 100
2	**6**		75			16	12	ca. 100
1	**5**	53		35	9			97
2	**5**	42		28	21			91

[a]Typical conditions were oxirane (0.15 *M*), dinitrile (0.4 *M*), and 1,4-dicyanonaphthalene (2×10^{-2} *M*) in acetonitrile. Irradiation was through a Pyrex filter. Yields (%) were determined by vpc and were in fair agreement with isolated yields.

and **4***b* predominate (ca. 90%) providing evidence that these are the less hindered isomers where the vicinal phenyl and cyano groups are *trans*. This assignment is consistent with the nmr spectra which show the proton on the carbon bearing the cyano group of **3***b* and **4***b* absorbs at higher field than for **3***a* and **4***a*. Protons *cis* to a vicinal phenyl group in a five-membered ring are well known to appear at higher field (4*c*, 6).

The remaining choice between **3***a*, *b* and **4***a*, *b* cannot be rigorously made from an analysis of the nmr spectra but must rest partially upon the relative product ratios observed from **1** and **2** and reasoning by analogy (see below) with the dicyano derivatives where an unambiguous assignment can be made. However, these assignments are then strengthened by the recognition of a consistent pattern in the nmr spectra of all the isomeric pairs. That is, the protons

on carbon 2 and 5 absorb at considerably lower field when the phenyl groups are *trans* to one another (i.e. **4***a–f*).

While this work was in progress the methyl esters analogous to **3***a*, *b* and **4***a*, *b* were characterized (3*c*). The nmr spectra of the esters are similar to those of the nitriles and the reported structural assignments are consistent.

The stereochemical assignments for the dicyano derivatives **3***c–e* and **4***c*, *d*, and *f* were similarly established from an analysis of their nmr spectra (Table 4). The symmetric isomers were easily distinguished by the A_2B_2 proton coupling pattern. As previously mentioned, protons in the 3 and 4 positions absorb at higher field if they are *cis* to the vicinal phenyl group.

Some electrochemical and photophysical experiments were carried out in order to provide data relevant to the discussion of the proposed electron transfer mechanism for the oxirane ring opening process. The oxidation potentials of **1** ($E_{1/2}^{ox}$ = 1.88 V vs. $Ag/AgNO_3$ in acetonitrile) and **2** (1.89 V) were estimated from cyclic voltammetry measurements. The anodic oxidation process was not reversible (100 mV s^{-1} sweep rate) and so the derived oxidation potentials do not have thermodynamic significance. Nevertheless, reactivity correlations using such data have been shown to be useful (1).

[a]Reference 1*b*.
[b]No decrease (< 2%) in fluorescence intensity was observed with a concentration of **1** or **2** > 0.05 *M*.

Fluorescence quenching studies were performed in order to determine the excited state multiplicity involved in the sensitization process. The fluorescence quenching rate constants were determined from the Stern–Volmer plots of fluorescence intensity versus the concentration of **1** and **2**, and the measured fluorescence lifetime of the sensitizer. These observations are summarized in Table 5.

Discussion

The mechanism we propose for reactions [2]–[4] is summarized in Scheme 1. The first step, excitation of the sensitizer, is assured through the use of a light filter (Pyrex) which prevents direct excitation of the oxiranes. Neither **1** nor **2** absorb at wavelengths longer than 280 nm (0–0 band at 272 nm) (7).

Direct excitation is not occurring since when the oxiranes **1** and **2** are excited by direct irradiation, the major product along with the stereoisomerization is deoxybenzoin which results from cleavage of the carbon–oxygen bond (3*c*). In the reactions reported here, using effective photosensitizers (electron transfer), no deoxybenzoin was detected and the yields of products derived from carbon–carbon bond cleavage were essentially quantitative.

Step *2* leads from the excited singlet state of the photosensitizer to the oxirane radical cation. It seems likely that several intermediate stages (e.g. collision encounter complex, exciplex, radical ion pair) are involved during the electron transfer process; however, we have no evidence for this view. The energy associated with this electron transfer process, within an encounter complex, can be estimated from eq. [5] originally used by Weller and co-workers to correlate fluorescence quenching results (8).

$$[5]\quad \Delta G(\text{kcal mol}^{-1}) = 23.06[E(D/D^+)_V - E(A/A^-)_V - e_0^2/\varepsilon\alpha] - \Delta E_{0-0}(\text{kcal mol}^{-1})$$

The quantity in brackets (the oxidation poten-

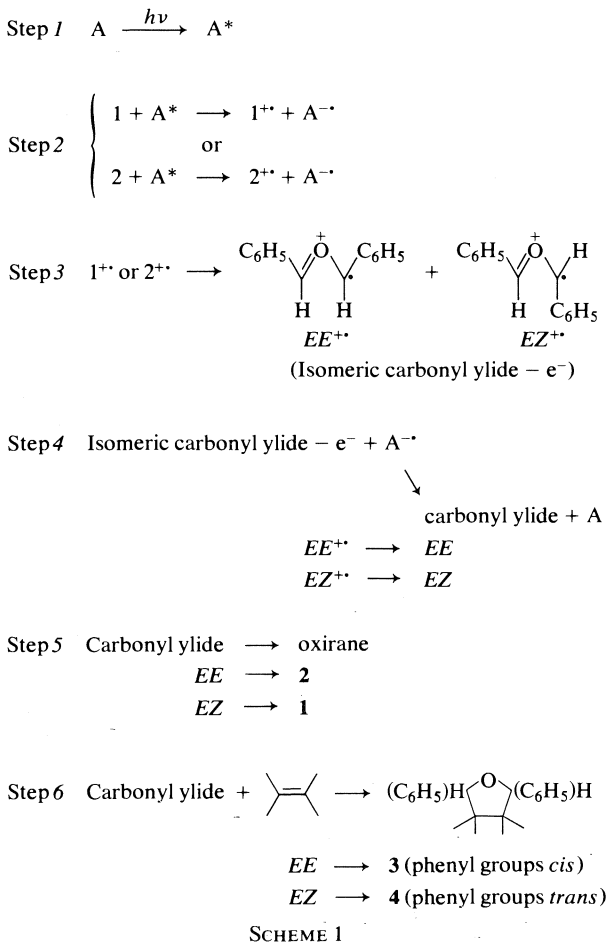

SCHEME 1

tial of the donor, the reduction potential of the acceptor, and a Coulombic attraction term) represents the energy required for the electron transfer process, while the energy available is the sensitizer singlet (or triplet) energy. With the exception of the oxidation potentials of **1** and **2** the necessary data were available in the literature. We therefore determined the required oxidation potentials of **1** and **2** using cyclic voltammetry. The calculated free-energy change (ΔG) for the electron transfer process between **1** and the singlet and triplet states of several potential sensitizers are listed in Table 6. Note that for DCN, DCB, and MCB, all effective sensitizers, the calculated energy for the electron transfer involving the sensitizer singlet is favorable; while for MCN, an ineffective sensitizer, the calculated ΔG is positive.

Fluorescence quenching studies confirm that the sensitizer singlet is the excited state involved. The fluorescence of DCN was quenched by **1** and **2** at almost the diffusion-controlled rate,[4] while the fluorescence of MCN was not measurably quenched by either **1** or **2**.

The ring cleavage of **1** and **2** photosensitized by acetone has recently been reported and was attributed to triplet–triplet transfer (3*c*). This explanation still seems reasonable since the electron transfer process with the acetone singlet or triplet is, according to eq. [5], so unfavorable. Furthermore, triplet–triplet transfer is conceivable because of the relatively high triplet energy of acetone.

It is unlikely that the triplet of DCN, DCB, or MCB could be effective by either the electron transfer process or by triplet–triplet transfer. The calculated free-energies for the electron transfer process involving the sensitizer triplet are positive in every case, and the triplet energies of these sensitizers are undoubtedly too low since acetophenone, with a higher triplet energy (E_T = 72 kcal mol^{-1}), was ineffective (3*c*).

Two additional considerations consistent with the lack of involvement of the triplet in the case of DCN are pertinent. 1,4-Dicyanonaphthalene has a very inefficient intersystem crossing process yet it is an efficient sensitizer. Furthermore, if its triplet were involved we would have observed competitive photosensitized isomerization of maleonitrile and fumaronitrile in those experiments where these dinitriles were present since the isomerization of these dinitriles can be brought about with sensitizers having a triplet energy as low as 49 kcal mol^{-1} (9). In fact, no isomerization of the dinitriles was observed during the course of reaction [4].

Before leaving the discussion of step *2*, Scheme 1, it will be important later on that we consider where the electron is coming from during the electron transfer process; that is, should the oxirane radical cation be viewed largely as an aryl radical cation or as an oxirane (i.e. ether) radical cation? The currently accepted view of aryl substituted three-membered rings maintains there is some conjugative interaction involving the strained ring bonds (Walsh orbitals) and the π-electron system (10). However, from the similarity in the oxidation potential of **1** and **2** and the value we reported (1*b*) for 2,2-diphenylethyl isopropyl ether ($E_{1/2}^{ox}$ = 1.81 V), in connection with our study of reaction [1], we can conclude that any interaction between the phenyl and the oxirane moiety is not evident from the cyclic voltammagrams. Furthermore, the similar distinction between effective (DCN) and ineffective (MCN) sensitizers and the ability of **1**, **2**, and 2,2-diphenylethyl isopropyl ether to quench the fluorescence of DCN but not the fluorescence of MCN indicates that the photosensitized electron transfer process is also insensitive to any interaction between the phenyl group and the oxirane ring which might be present. In our study of

[4]We looked for emission which might have originated from an exciplex in strongly quenched solutions (acetonitrile and benzene solution), however, none was observed.

TABLE 6. Calculated ΔG values, using eq. [5], for the electron transfer process involving the singlet and triplet states of the sensitizer as potential acceptors and **1** ($E_{1/2}^{ox}$ = 1.88 V, Ag/0.1 *M* Ag^+) as donor

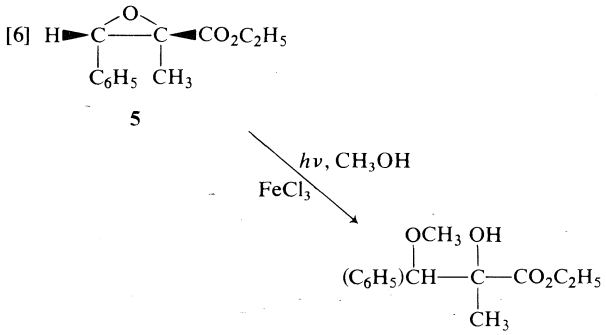
reaction [1], we concluded that the electron donated by the ether was in fact from the phenyl moiety (1*b*). The similarities between reaction [1] and reactions [2], [3], and [4] now lead us to suggest that this is also true for **1** and **2**.

There is a recent report which describes the photoaddition of methanol to an aryl oxirane (5) sensitized by ferric ion (reaction [6]) (11).



The carbon–oxygen bond of **5** is cleaved in this reaction. It was not possible to detect stereoisomerization of the oxirane since the *Z*-isomer reacted under the reaction conditions even in the dark. The mechanism proposed in this case involves electron transfer from the oxirane moiety to the ferric ion. If this mechanism pertains it seems likely that the ferric ion is in fact partially bonded to the oxygen prior to the cleavage. This would explain the preference for carbon–oxygen bond cleavage. It would obviously be interesting to compare these ferric ion sensitized results with those using DCN.

We next consider step *3* in the proposed Scheme 1, the oxirane ring cleavage process. We first thought of this step as analogous to the previously observed bond cleavage of 2,2-diphenylethyl isopropyl ether (reaction [1]) which in this case would give the isomeric carbonyl ylides $- e^-$. Back electron transfer from the sensitizer anion radical then gives the stereoisomeric carbonyl ylides (step *4*). This simple picture may not be adequate since it ignores the likely possibility that the cleavage process may be influenced by orbital symmetry. It will therefore be of interest to compare the stereochemical behavior of step *3* with the cleavage of **1** and **2** induced by thermal activation, by direct irradiation, and by photosensitization (triplet–triplet transfer).

There are three possible stereoisomeric carbonyl ylides, the *EE*, *EZ*, and the *ZZ* configuration. The *ZZ* isomer must suffer steric repulsion relative to the other isomers and therefore need not be considered. It is known that such isomeric carbonyl ylides are not rapidly equilibrated thermally (4).

The thermal ring cleavage of **1** and **2** requires high temperature (ca. 200°C). There is a strong preference for the orbital symmetry allowed conrotatory ring opening (and closing). This knowledge comes from an elegant study of the *cis–trans* isomerization and the racemization of the optically active *trans*-isomer (12); thermally induced cycloadditions have not been reported with this system; however, 2,3-di(4-nitrophenyl)oxirane has been studied and the carbonyl ylide resulting from conrotatory ring opening has been trapped with dipolarophiles (dimethyl maleate and fumarate) (13).

Direct irradiation of **1** and **2** leads via the orbital symmetry allowed disrotatory opening to the *EE* and *EZ* carbonyl ylides, respectively. Step *6* is well known to occur with retention of stereochemistry in both the carbonyl ylide and the trapping olefin. The direct irradiation of **1** and **2** in the presence of methyl acrylate and maleic anhydride gave the isomeric tetrahydrofurans with stereospecificity as high as 90% (3*c*). In marked contrast the acetone triplet–triplet transfer sensitized ring cleavage gave the same mixture of isomeric tetrahydrofurans from both **1** and **2**.[5] This result can be interpreted in terms of a common intermediate or the relatively rapid equilibration of intermediates preceding the carbonyl ylide (3*c*).

From an analysis of the dependence of the ratio of stereoisomeric products (**3** and **4**) obtained from the

[5]This preliminary communication does not mention if the oxiranes were equilibrated during the irradiation (3*c*).

isomeric oxiranes, we conclude that while step *3* does not occur stereospecifically, the isomeric carbonyl ylides $- e^-$ are not formed in equal amounts from **1** and **2** and once formed preserve stereochemical integrity.

With acrylonitrile as the dipolarophile the ratio of (**3***a* + **3***b* : **4***a* + **4***b*) from **1**, divided by this ratio from **2**, is about 3. This factor should be independent of the trapping agent and in fact the observed ratios (2.5 with fumaronitrile and 3 with maleonitrile) are all within experimental error. This indicates there is a small but significant preference for formation of the *EE* relative to the *EZ* isomeric carbonyl ylide $- e^-$ from **1** relative to **2**.

The observed preference for formation of the *EE* carbonyl ylide $- e^-$ from **1** can be attributed to the difference in steric interaction of the vicinal phenyl rings in the oxirane radical cation. The repulsion of the phenyl rings in $\mathbf{1}^{+\cdot}$ directs the ring opening to the less hindered $EE^{+\cdot}$ configuration. Presumably, the carbonyl ylides $- e^-$ are essentially planar and resonance delocalization preserves stereochemical integrity until back electron transfer from the sensitizer radical anion (step *4*) gives the carbonyl ylides.

It is interesting to compare the oxirane radical cation cleavage observed here with the cleavage which results upon electrochemical oxidation of **2** and 2,2,3,3-tetraphenyloxirane (14). Products obtained from the anodic oxidation of **2**, benzophenone (27%), and diphenylacetic acid (17%) indicate some carbon–oxygen bond cleavage. The tetraphenyl derivative gives a good yield of benzophenone (96%) under these conditions which is indicative of carbon–carbon bond cleavage. The difference was attributed to the ability of the initial radical cation of **2** to lose a proton and another electron; the sequence of these steps could not be determined from the data.

If the electrochemical reactions involve a two electron oxidation before the product determining step, the difference between the electrochemical oxidation and the photosensitized (electron transfer) reactions can be readily explained. While transfer of two electrons at the anode is not unlikely, the photosensitized electron transfer can remove only one. The initial oxirane radical cation is of course in a reducing environment; that is, near the sensitizer radical anion.

The cleavage of the oxirane radical cation in the mass spectrometer also occurs via competitive routes (15). The mass spectrum fragmentation pattern of **2** gives evidence of direct cleavage, loss of benzaldehyde (the base peak is $m/e = 90$), and rearrangement followed by fragmentation ($m/e =$ 167 equivalent to $(C_6H_5)_2CH^{+\cdot}$).

It is thus apparent that even though photochemical electron transfer, anodic oxidation, and ionization in the mass spectrometer all involve the formation of the oxirane radical cation, the conditions are so different there is little obvious analogy with regard to ultimate product formation.

Step *5* in the proposed scheme is the well known thermal conrotatory electrocyclic ring closure of the isomeric carbonyl ylides. Since the ring cleavage process is not stereospecific the sequence of steps *4* and *5* results in isomerization of the oxirane. The photostationary state, which favors the *trans*-isomer (**2**) (Table 1), is not markedly dependent upon the sensitizer or solvent used. In fact, the acetone sensitized isomerization, which involves triplet–triplet transfer, gave a similar ratio. We believe this similarity is fortuitous for the limited range of sensitizers employed in this study and for the system **1**–**2**.

The photosensitized (electron transfer) stationary state should depend to some extent upon the relative rates of the fluorescence quenching process, which subsequently leads to electron transfer, by the isomeric oxiranes (**1** and **2**). The measured fluorescence quenching rate constants of DCN with **1** and **2** are essentially diffusion controlled; furthermore, **1** and **2** have similar oxidation potentials so the rate of electron transfer is expected to be similar. This need not be the case in general. We anticipate examples where the photosensitized (electron transfer) isomerization yields an equilibrium mixture quite different from those obtained by other methods of isomerization (i.e., thermal[6] and photochemical by direct and photosensitized (triplet–triplet transfer) irradiation).

To our knowledge, this is the first reported example of the configurational isomerization of an oxirane photosensitized by the electron transfer process. Close analogy can be found in a report of the *cis–trans*-isomerization of the 1,2-diphenylcyclopropanes which was attributed to the electron transfer mechanism (16). Hixson and co-workers found that the fluorescence of 1-cyanonaphthalene (MCN) was quenched by 1,2-diphenylcyclopropane and that MCN was an effective photosensitizer (electron transfer) for the *cis–trans*-isomerization. We must now ask why 1-cyanonaphthalene is an effective sensitizer for the isomerization of the 1,2-diphenylcyclopropanes, but is ineffective in the case of **1** and **2**. The explanation lies in the observation that 1,2-diphenylcyclopropane has a significantly lower oxidation potential ($E_{1/2}{}^{ox} = 1.09$ V vs.

[6]The thermodynamic equilibrium strongly favors **2** over **1** ($k_{eq} = 9.5$) (12).

TABLE 7. Melting points and analytical data of new compounds

Ag/Ag^+ in acetonitrile (17)) than **1** or **2**. In fact, the calculated (eq. [5]) free-energy for the electron transfer indicates the process should be spontaneous ($\Delta G = -12$ kcal mol^{-1}).

Step *6* in the proposed scheme is the thermally allowed ($4\pi s + 2\pi s$) cycloaddition reaction (18). This reaction involving the carbonyl ylide has been extensively studied, particularly by Huisgen and co-workers (4). Photosensitization by electron transfer may offer some advantages over the alternative thermal and photochemical modes of formation of the carbonyl ylide. For example, the reaction can be brought about at low temperature and under mild conditions. Relatively long wavelength light can be used to activate the photosensitizer. A sensitizer with a high triplet energy is not required so that possible isomerization of the dipolarophile can be avoided.

It is interesting that the cycloaddition reaction with acrylonitrile, fumaronitrile, and maleonitrile can compete effectively with ring closure (step *5*). It should also be mentioned that in the cycloadditions involving maleonitrile, **3***c*, where the phenyl and cyano groups are all *cis*, is formed in preference (1.5 to 1) to **3***e*. When the *EE* carbonyl ylide, formed by direct irradiation of **2**, was trapped with maleic anhydride the analogous all *cis* adduct was again slightly (1.2 to 1) preferred (3*c*). In contrast, *trans*-2,3-di(4-nitrophenyl)oxirane gives, upon heating in the presence of dimethyl maleate, the isomeric tetrahydrofuran derivatives with the all *cis* configuration the minor (0.7 to 1) product (13). Clearly, neither steric factors involved in the "two-planes orientation complex" (19) nor electronic factors associated with secondary orbital interactions (20) are strong enough to greatly favor one isomer over the other.

Experimental

General

Acetonitrile (Aldrich Gold Label) was refluxed overnight over calcium hydride under a dry nitrogen atmosphere and fractionally distilled. The other solvents (Fischer spectroscopic grade) were used as received. 1-Cyanonaphthalene was sublimed under vacuum. Methyl 4-cyanobenzoate, 1,4-dicyanobenzene, and dimethyl terephthalate were purified by repeated recrystallization. 1,4-Dicyanonaphthalene was prepared by reaction of 1,4-dibromonaphthalene with cuprous cyanide and purified by chromatography on alumina and recrystallization from nitroethane. The stilbene oxides were prepared by oxidation of the corresponding stilbene with 3-chloroperbenzoic acid in chloroform at room temperature, and purified by repeated crystallization first from methanol and then from hexanes. Their purity was checked by vpc (10% SE-30 on Chromosorb W 60/80, 5 ft at 180°C). Fumaronitrile (Aldrich) was freshly sublimed in vacuum. Maleonitrile was prepared from fumaronitrile by heating in the presence of iodine and purified by fractional distillation, column chromatography on alumina, eluting with benzene–hexane, and recrystallization from pentane–ether. Tetramethylammonium perchlorate was recrystallized from ethanol four times and dried under vacuum at 65°C. Silver nitrate, for the reference electrode, was purified by recrystallization from water. Nuclear magnetic resonance spectra were obtained with a Varian HA-100 spectrometer. Infrared spectra were recorded on a Perkin-Elmer 621 spectrometer and mass spectra on a Matt 311A spectrometer. Vapour phase chromatograph analyses were performed on a Varian 90-P instrument. Melting points are corrected. The combustion analyses were performed by Chemalytics, Inc., Tempe, Arizona.

Quenching Experiments

Stern–Volmer plots were obtained using a conventional 90° two-monochromator spectrofluorimeter at room temperature, from the intensity of the spectra at the maximum. The samples were degassed on a mercury-free vacuum line using three freeze–pump–thaw cycles.

Oxidation Potential Measurements

Cyclic voltametric data were obtained using a three-electrode cell with a Princeton Applied Research Electrochemistry System Model 170. The working electrode was a platinum wire. A Ag/Ag^+ (0.1 *M*) electrode was used as a reference electrode and 0.1 *M* tetraethylammonium perchlorate as a supporting electrolyte. The solvent was acetonitrile.

Irradiations

All irradiations were carried out using a General Electric Co. 1 kW medium pressure mercury vapour lamp at 10°C. The progress of the reaction was followed by nmr and/or vpc (15% Apiezon or 10% SE-30 on Chromosorb W). Solutions (0.15 *M*)

of **1** or **2** were used with a 2×10^{-2} *M* concentration of sensitizer in the case of the aromatic sensitizers (1×10^{-2} *M* DCN in methanol or benzene) or 2 *M* in the case of acetone. A 4×10^{-2} *M* concentration of 2-acetonaphthone or benzophenone was used for the attempted triplet sensitization. For the cycloaddition reactions, a 0.4–1 *M* concentration of the olefin was used. The solutions were deoxygenated either by argon bubbling or by three freeze–pump–thaw cycles. Only the sensitizer absorbed light with the Pyrex filter used in these experiments. No reaction took place under these conditions omitting the sensitizer. Products were separated by column chromatography on silica gel, using cyclohexane–benzene mixtures as eluent. Melting point, recrystallization solvents, and analytical data on the new compounds are reported in Table 7. Major ir bands are tabulated in Table 8.

Base Catalyzed Isomerization of **3**a *and* **4**a

Both **3***a* and **4***a* (20 mg) were refluxed 1/2 h in sodium methoxide (0.5 *M*) in methanol, maintaining a nitrogen stream through the reaction vessel. Treatment with water and extraction with benzene gave a mixture containing ~90% of **3***b* and **4***b*, respectively. Similar treatment of **3***b* and **4***b* lead to the same mixture.

Simultaneous determination of relative and absolute rate constants in racemization studies; applications to kinetic isotope effects

MICHAL TENCER AND ALLAN R. STEIN[1]

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received May 25, 1978

MICHAL TENCER and ALLAN R. STEIN. Can. J. Chem. **56**, 2994 (1978).

The method reported allows the simultaneous determination of relative and absolute rate constants for two substances in a single kinetic run. The approach is of special interest for kinetic isotope effect determinations where rate ratios are often near one and failure to exactly duplicate reaction conditions can lead to uncertainties in the values calculated from independently measured rate constants. For racemization studies, using two optically active materials with opposite signs of rotation, knowing their initial rotational contribution and having the faster racemizing one in higher concentration, the rates can be calculated if the times required to reach zero net rotation and the extremum value are measured. Other systems to which the method can be extended are suggested.

MICHAL TENCER et ALLAN R. STEIN. Can. J. Chem. **56**, 2994 (1978).

On décrit une méthode qui permet de déterminer simultanément les constantes de vitesse relatives et absolues pour deux substances au cours d'un seul et même essai de cinétique. Cette méthode présente un intérêt particulier pour la détermination de l'effet isotopique cinétique, alors que les rapports entre les vitesses sont souvent voisins de un et que les valeurs calculées au moyen de mesures indépendantes de constantes de vitesse peuvent être entachées d'erreurs si l'on ne réussit pas à reproduire parfaitement les conditions de la réaction. Pour des études de racémisation, si l'on utilise deux substances optiquement actives possédant des rotations de signes opposés, si l'on connaît les contributions initiales respectives de ces substances à la rotation et que la substance qui se racémise le plus rapidement possède la concentration la plus élevée, on peut calculer les vitesses à partir de mesures du temps nécessaire pour que la rotation nette devienne nulle, d'une part, et passe par sa valeur extremum, d'autre part. On suggère d'autres systèmes auxquels la méthode est applicable.

Introduction

Frequently it is not possible to precisely duplicate reaction conditions. Consequently precision and accuracy of rate and rate constant determinations suffer. When it is important to be able to compare rates or reactivities, one commonly used approach is to use a competitive reaction with two or more substrates in the same reaction mixture and to follow the reactions by the appearance of products or the disappearance of starting materials. In this way more reliable relative rates can sometimes be obtained.

It is perhaps in the area of kinetic isotope effects, where rate ratios are often very near unity, that the greatest problems arise. If the isotope effect is to be determined by comparing two independently obtained rates, extreme precision is required. Temperature must be very carefully controlled, solvents and reagents must be equally pure (or impure), concentrations of reagents must be identical or precisely known and so on, conditions which are often difficult to meet and reproducibility becomes a problem (1). Unfortunately, it is in just such systems that the competitive approach is most difficult to apply. Normally isotope-specific methods such as mass spectrometry or nuclear magnetic resonance, methods which frequently are not precise enough for subtle kinetic purposes, must be used to follow the reactions. These methods usually require either very high concentrations of the species (2) or, more commonly, concentration or isolation of the species (3) (or materials derived from them) which may introduce errors due to equilibration and, if recoveries are not quantitative, fractionation. Even such methods are not useable for, for example, secondary deuterium kinetic isotope effects in 'symmetrical' reactions of the type illustrated in reaction [1] where the product and the starting material are the same.

[1] 
Here the only available methods for following the reaction are *radio*-tracer techniques (e.g., if the nucleophile-leaving group is a halide, a *radio*-halide can be used) (4) and/or racemization kinetics (if optically active starting material is available) (5).

There are a number of cases where considerable kinetic data were extracted from single runs. Thus,

[1]To whom all correspondence should be addressed.

for example Ahlberg (6) and others have calculated activation parameters from single variable temperature runs and Albery and Robinson (7) developed a differential method for enthalpies and heat capacities of activation. Such sequential or simultaneous measurement eliminates many of the empirical problems associated with independently determining and comparing the rates for two solutions. The method we wish to report is a 'differential' method but is quite different from the Albery and Robinson approach (7) since the two substrates are in a single solution. Using optically active substrates and following the optical rotation as a function of time it is possible to determine relative and absolute rates for the two substances in a single run.

Derivation

For a racemization reaction of the type in reaction [1], the rate expression below applies (8).

$$[2a] \qquad \ln\frac{\alpha_0}{\alpha} = 2kt\,[\mathrm{X}]^q$$

or

$$[2b] \qquad \alpha = \alpha_0 \exp(-2kt[\mathrm{X}]^q)$$

In the equation, α_0 is the initial rotation, α that at time t, [X] is the concentration of the nucleophile/leaving group and is, of course, constant throughout any given run, while the exponent q expresses the order of the reaction with respect to X, i.e. $q = 0$ for a reaction which is first order, that is, the rate depends only upon the concentration of the substrate, $q = 1$ for a second order reaction, and so on. The factor of '2' arises from the fact that inversion of one molecule cancels the rotation of another.

If two compounds with opposite rotations, A and B, are placed in the same cell and A, which is the faster racemizing compound, has the higher absolute initial rotation, the observed rotation α at any time will be the sum of the contributions of each component. One of these rotational contributions will be positive, the other negative; but since it is not specified which is which, absolute values can be used (eq. [3]). Reaction of A and B must, of course, show the same dependence upon nucleophile concentration, i.e. $q_A \equiv q_B \equiv q$.

$$[3a] \qquad \alpha = |\alpha_A| - |\alpha_B|$$

$$[3b] \qquad \alpha = |\alpha_{0A}| \exp(-2k_A t\,[\mathrm{X}]^q) - |\alpha_{0B}| \exp(-2k_B t\,[\mathrm{X}]^q)$$

At some time t_Z, the observed rotation will be zero and

$$|\alpha_{0A}| \exp(-2k_A t_Z[\mathrm{X}]^q) = |\alpha_{0B}| \exp(-2k_B t_Z[\mathrm{X}]^q)$$

from which eq. [4] arises.

$$[4] \qquad k_A - k_B = \frac{1}{2t_Z[\mathrm{X}]^q} \ln\frac{|\alpha_{0A}|}{|\alpha_{0B}|}$$

Later, at time t_E, the observed rotation reaches a minimum (or maximum) value before again approaching zero, this time asymptotically. At this extremum:

$$\frac{d\alpha}{dt} = 0$$

Since $[\mathrm{X}]^q$ is constant, differentiating eq. [3*b*] gives:

$$-2k_A[\mathrm{X}]^q|\alpha_{0A}| \exp(-2k_A t_E[\mathrm{X}]^q) + 2k_B[\mathrm{X}]^q|\alpha_{0B}| \exp(-2k_B t_E[\mathrm{X}]^q) = 0$$

which, on rearranging, gives eq. [5].

$$[5] \qquad \frac{k_A}{k_B} = \frac{|\alpha_{0B}|}{|\alpha_{0A}|}\exp\{2(k_A - k_B)t_E[\mathrm{X}]^q\}$$

Substituting for $k_A - k_B$ from eq. [4] allows derivation of eq. [6].

$$[6a] \qquad \frac{k_A}{k_B} = \frac{|\alpha_{0B}|}{|\alpha_{0A}|}\exp\left\{\frac{t_E}{t_Z}\cdot\ln\frac{|\alpha_{0A}|}{|\alpha_{0B}|}\right\}$$

or

$$[6b] \qquad \frac{k_A}{k_B} = \frac{|\alpha_{0A}|}{|\alpha_{0B}|}(t_E/t_Z - 1)$$

Thus determining the rate ratio requires that the ratio of the initial rotations due to A and B be measured and that t_Z and t_E be determined. To calculate the rate constants themselves using eqs. [4] and [6], the nucleophile concentration and the order of the reaction with respect to the nucleophile, q, must also be known. The values obtained for k_A and k_B will be dependent upon the various uncertainties that affect a single run but at least any resultant errors should be the same or similar for the two components in the simultaneous determination.

Results and Discussion

Typical curves for several runs are shown in Fig. 1 and additional results are tabulated along with data obtained by conventional methods in Table 1. While it is probably in the area of kinetic isotope effects that the approach outlined is most useful, data for other cases are included to illustrate its usefulness over a range of rate ratios. In all the cases reported, the reactions are first order in nucleophile, the bromide ion (i.e. $q = 1$), and the reactants are variously *para*-substituted α-phenylethyl bromides with *deuterium*-substitution, if any, on the α-carbon.

From eqs. [4] and [5], it is apparent that if the ratio of the initial rotations $|\alpha_{0A}|/|\alpha_{0B}|$ is excessive or if

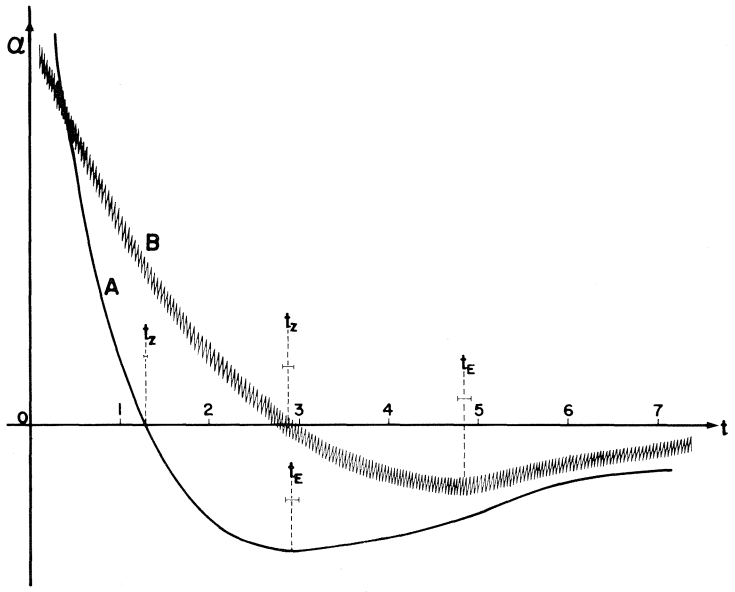

FIG. 1. Rotation as a function of time. [g]Average value for [LiBr] = 0.00200 *M* over the temperature range 25–45°C.

the concentration of the nucleophile [X] is too low, a long, flat curve results and extracting t_Z and, especially, t_E is difficult. Instrument instability also increases uncertainties in such long runs. On the other hand, very fast runs (i.e. $|\alpha_{0A}|/|\alpha_{0B}| \gtrsim 1.0$ and high [X]) exaggerate uncertainties due to the zero time (t_0) value (see Experimental) and result in low rotations unless very high concentrations of the reactant are used. As expected from the above considerations, the best curves are obtained by choosing concentrations of the two reactants such that $|\alpha_{0A}|/|\alpha_{0B}|$ is approximately equal to the expected k_A/k_B value.

As can be seen from Fig. 1, there is some uncertainty in the graphically determined t_Z and t_E values. These uncertainties are greater for the deuterium isotope effect determination with 1-bromo-1-phenylethane (curve *B*) than for the rate of the *para*-bromo-

versus the unsubstituted case (curve *A*) because the very low initial rotation resulted in a poor signal-to-noise ratio in the former case. Calculated k_A/k_B values, k_H/k_D values in this case, are quite insensitive to errors in t_Z and t_E since the ratio of the initial rotations is near unity. Thus relatively small changes in the value k_H/k_D are observed with changes in the power to which the initial rotation ratio is raised (see eq. [6*b*]). When the rate constants differ greatly, much larger rotation changes are possible. The curves look much better (curve *A*) but because of the larger $|\alpha_{0A}|/|\alpha_{0B}|$ values, calculated rate ratios are much more sensitive to errors in t_Z and t_E.

As is apparent from Table 1, the rate constant ratios and the absolute rate constants obtained with the single-run method are generally in good agreement with the independently determined values. Discrepancies can be attributed to the lack of exact reproducibility of experimental conditions from one run to the next. This would affect the independently determined values and the rate constants (but hopefully not the rate ratio) from the single run method. Errors in initial time, t_Z and t_E estimation, are other possible sources of discrepancies.

While the described approach has so far only been applied to symmetrical racemization reactions in which the nucleophile and the leaving group are the same, it is not limited to such systems. Any reactions involving loss of optical activity can be used. Eliminations forming achiral alkenes from chiral substrates and rearrangements from chiral to achiral substrates are among the systems amenable to study. For such systems, of course, the equations would have to be modified by eliminating the '2' first introduced in eq. [2].

The inability to use linear regression analysis on the single-run data reduces its reliability. This last problem could largely be overcome by using more data points and calculating the best curve fit by successive approximations of k_A and k_B. In fact, by curve-fitting techniques, the empirical problems associated with obtaining curves of the type illustrated can be eliminated but this approach also eliminates a major advantage of the described method: the rate constants and ratios can be readily calculated without recourse to a computer facility.

Experimental

Synthesis and resolution of the compounds used was by the procedures (8) or by procedures analogous to those already described.[2] The *deuterium*, if any, was introduced by $LiAlD_4$ reduction of the corresponding ketone. The resultant alcohol was resolved and converted to the labelled bromide by essentially the same procedures as were used for the unlabelled analogue.

Reagent grade acetone which was freshly distilled from molecular sieves under dried nitrogen was used as a solvent for the runs reported in the Table. Reagent grade lithium bromide was oven-dried at 250°C. All manipulations, transfers and dilutions of the solutions, were done in a dry nitrogen-filled glove bag.

The initial rotations, α_{0A} and α_{0B}, were determined in acetone solutions. Two millilitres of each solution and the amount of the lithium bromide in acetone required to give the desired concentration were mixed and the 10 cm cell of the polarimeter quickly filled in the glove bag. The stoppered cell was transferred to the Perkin-Elmer Model 141 recording polarimeter used for this study and time measured from the instant the circulating, constant temperature bath was connected to the cell. Thus the errors introduced due to racemization starting at the instant of mixing and the time required for the solution to equilibrate at the higher bath temperature at least partially compensate for each other.

Reçu le 3 mars 1978

LOUIS CAZAUX, JEAN-PIERRE GORRICHON, PIERRE MARONI et MARCEL PERRY. Can. J. Chem. **56**, 2998 (1978).

Les deux composés du titre sont des modèles pour l'étude structurale ultérieure de deux séries plus complexes. Leur analyse spectrale à haut champ a permis de caractériser par la technique INDOR ou par effet de solvant à peu près tous les protons et de déterminer les structures en conformation double chaise. Enfin, les déplacements chimiques dans CCl_4 ont été utilisés pour évaluer l'influence des oxygènes intracycliques sur les résonances des protons 2′ et 6′ du spirobicyclohexane.

LOUIS CAZAUX, JEAN-PIERRE GORRICHON, PIERRE MARONI, and MARCEL PERRY. Can. J. Chem. **56**, 2998 (1978).

The two title compounds serve as models for an eventual structural study of two more complex series. High field nmr spectral analysis using INDOR or solvent effects allows us to assign nearly all proton signals and to propose that these compounds exist in the double chair conformation. Finally, chemical shifts in CCl_4 have been used to evaluate the effect of the intracyclic oxygen atoms on the 2′ and 6′ proton nmr resonances of the spirobicyclohexane.
[Journal translation]

Les spirodioxannes en position 2 et 5 ont fait l'objet de plusieurs études d'inversion de cycle en rmn (2, 5). A notre connaissance, les composés à jonction spiro en 4 ont été, en revanche peu étudiés (6). Dans le cadre d'un travail portant sur l'addition de dérivés magnésiens (7, 8) ou zinciques (8, 9) à des cétones conformationnellement homogènes, nous avons pu obtenir ce type de molécules. Elles proviennent de β-cétols ou de β-hydroxyesters tertiaires, par réduction en β-diols au moyen de $LiAlH_4$, puis acétalisation de ces derniers par l'éthanal (schéma 1). Tous les composés étudiés sont des liquides qui ont été séparés par chromatographie sur couche mince préparative. Les spectres de rmn du proton pour les divers spirodioxannes ainsi synthétisés sont relativement complexes. Les protons de la partie

dioxannique sont cependant facilement localisés. En revanche, l'attribution des résonances est beaucoup plus compliquée pour la partie cyclohexanique.

Un des problèmes importants posés par ces composés lorsqu'ils comportent plusieurs molécules isomères est la détermination de configuration au niveau notamment du carbone C_4 de jonction spiro. Sa résolution permet de remonter aux structures des β-diols et β-cétols précurseurs. Avant son extension à des cas plus complexes, nous l'avons résolu par l'étude des spectres rmn du proton des deux méthyl-2-dioxannes-1,3-4-spiro-*tert*-butyl-4′ cyclohexanes-

*Spectres enregistrés à 300 MHz.
†Spectres enregistrés à 250 MHz.

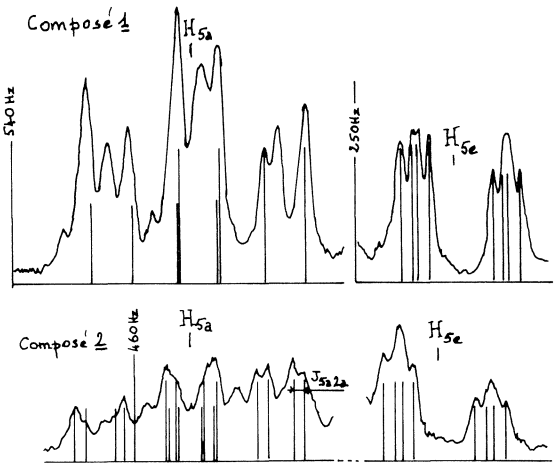

FIG. 2. Agrandissements des résonances des protons H_{5a} et H_{5e} des deux isomères **1** et **2**.

cis (**1**) et -*trans* (**2**) (série I, schéma 1) qui fait l'objet du présent mémoire. Ces deux isomères[2] sont représentés dans leur conformation préférentielle sur la fig. 1 et par un seul énantiomère.

Spectres à 300 MHz dans le benzène

Nous avons enregistré les spectres de rmn de ces composés sur un appareil Varian HR 300.[3] Afin de différencier le plus possible les hydrogènes de la partie cyclohexanique, nous avons utilisé le benzène comme solvant (fig. 1). Les résultats de l'analyse de ces spectres sont rassemblés dans le tableau 1.

L'attribution des résonances des protons dioxanniques H_{2a}, H_{6a} et H_{6e} ne pose aucun problème. Comme dans les dioxannes, les signaux correspondants sont fortement déblindés par la présence des oxygènes.

La connaissance des constantes de couplage J_{56}, déterminées sur la partie du spectre concernant H_{6e} et H_{6a}, permet de prévoir la forme des signaux relatifs aux protons H_{5e} et H_{5a} et de les localiser sur le spectre (fig. 2).

On remarque sur le proton H_{5a} de **2**, un dédoublement des raies lié à une constante de couplage à distance avec le proton $H_{2'a}$ (voir figs 1 et 2).

Nous avons conduit de façon similaire, l'étude de la partie cyclohexanique. A partir des valeurs des constantes de couplage déterminées pour des cyclohexanes méthylés (10) on peut attendre, pour les protons $H_{2'e}$ et $H_{6'e}$, un quadruplet ($^3J_{ea} \sim {}^3J_{ee} \sim {}^4J_{ee} \sim 3$ Hz) dédoublé par une grande constante

[2]L'énergie conformationnelle du groupement méthyle en 2 étant de l'ordre de 4.1 kcal, seuls les diastéréoisomères ayant ce substituant équatorial ont été isolés.

[3]Nous remercions très vivement MM. Anteunis et Tavernier, Professeurs à l'Université de Gand, pour l'enregistrement de ces spectres et pour de fructueuses discussions.

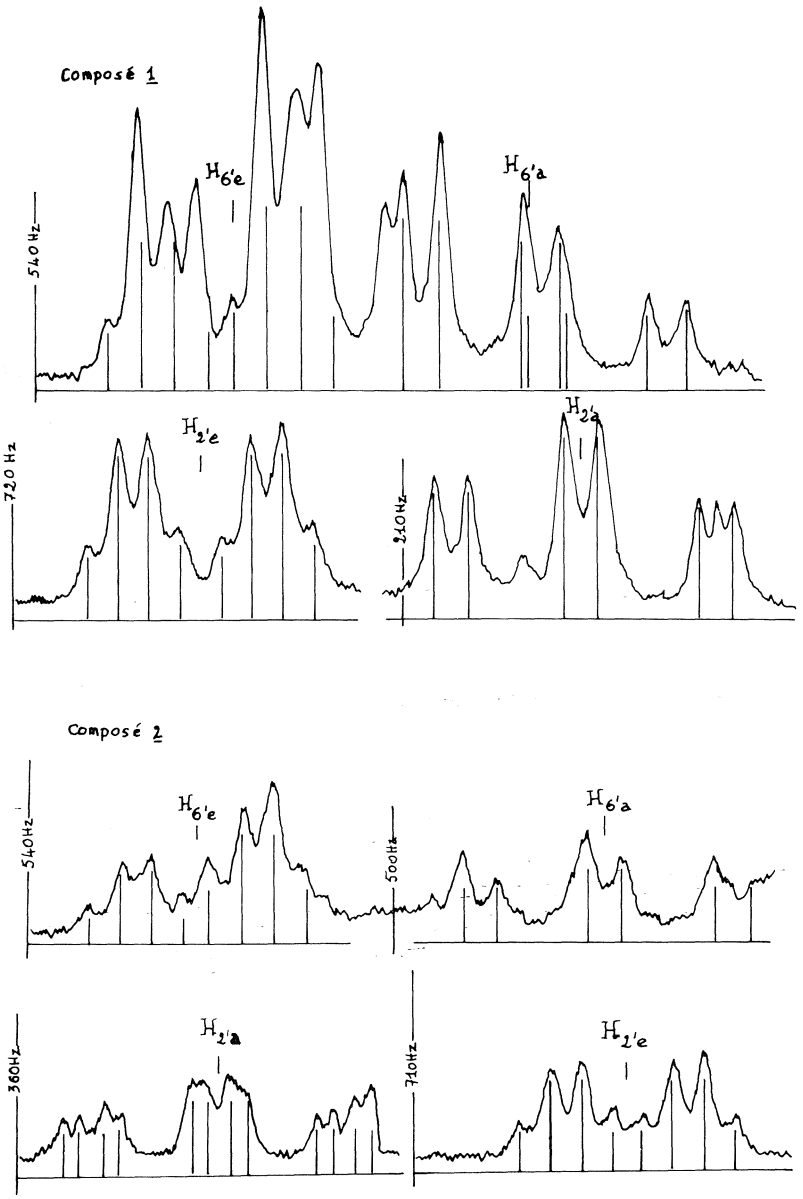

FIG. 3. Agrandissements des résonances des protons $H_{2'e}$, $H_{2'a}$, $H_{6'e}$ et $H_{6'a}$ des composés **1** et **2**.

($^2J_{gem} \sim$ 13–14 Hz), pour les protons $H_{2'a}$ et $H_{6'a}$ un triplet à grande constante ($^2J_{gem} \sim {}^3J_{aa} \sim$ 13–14 Hz) dédoublé par une petite constante ($^3J_{ae}$). Nous avons pu, sur des agrandissements réalisés à partir des spectres complets, trouver de telles figures de résonance (fig. 3).

Comme nous l'avons déjà remarqué pour H_{5a}, seul le proton $H_{2'a}$ du composé **2** possède un couplage en W (1.7 Hz). Sa résonance est modifiée en conséquence et *ce seul fait permet de distinguer les deux isomères* et d'attribuer au proton $H_{2'a}$ le signal à champ fort dans l'isomère **2**; une expérience d'irradiation INDOR permet d'associer à ce proton le signal à champ faible (δ = 2.29 ppm) comme étant celui de $H_{2'e}$.

La disposition des liaisons C—C et C—O du cycle dioxannique est la même dans les deux isomères vis à vis de $H_{2'e}$ et $H_{2'a}$ d'une part, de $H_{6'e}$ et $H_{6'a}$ d'autre part. En effet, la seule différence entre les deux isomères est le changement de position de l'oxygène O_3 mais il reste dans le plan de symétrie du cycle cyclohexanique. Pour cette raison, nous avons attribué à $H_{2'a}$ et $H_{2'e}$ de l'isomère **1**, respectivement les résonances à champ le plus fort et le plus faible.

Les déplacements chimiques des hydrogènes

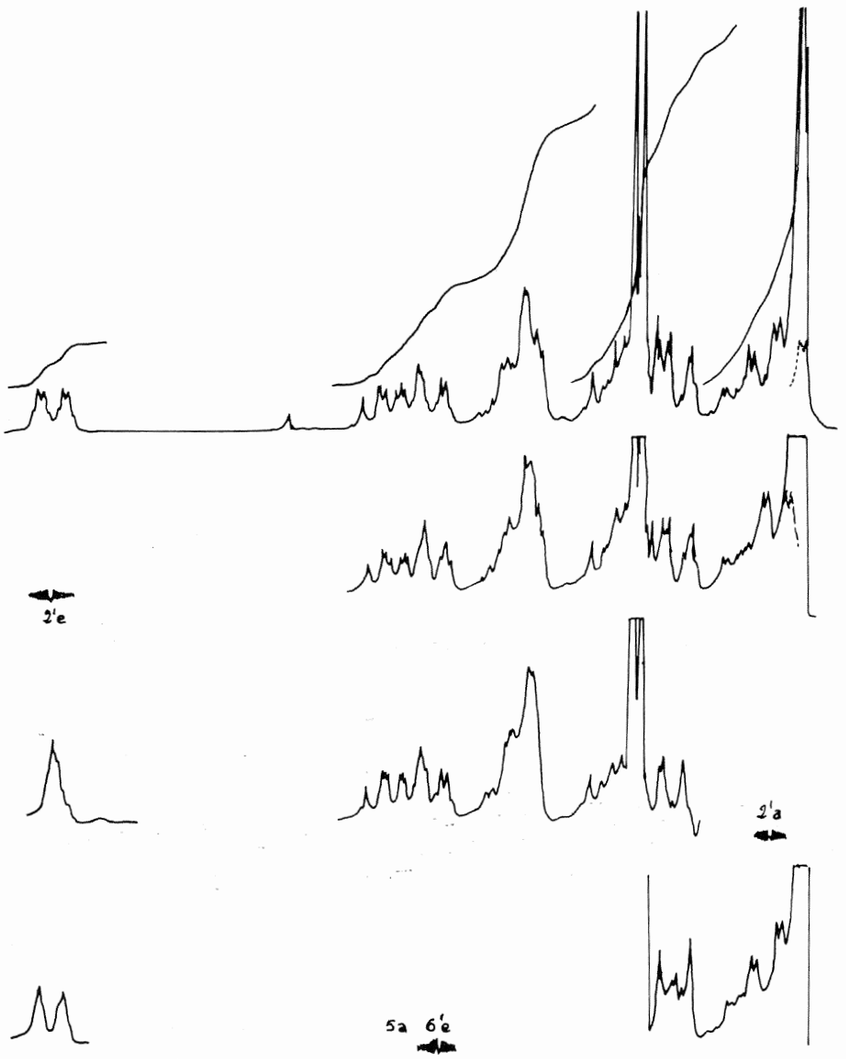

FIG. 4. Expériences d'irradiation pour le composé **1** dans CCl_4.

portés par les carbones 3′ et 5′ ont été déterminés par les mêmes méthodes. Toutefois, certaines incertitudes (notamment pour le composé **2**) demeurent du fait de la complication apportée par leur couplage avec le proton $H_{4'a}$.

Les valeurs des constantes de couplage, relevées sur ces spectres et réunies dans le tableau 1, confirment que la conformation préférentielle de telles molécules est bien la double chaise.

Spectres à 250 MHz dans le tétrachlorure de carbone

Dans ce solvant, le recouvrement des massifs relatifs aux protons cyclohexaniques ne permet pas l'interprétation directe des spectres. Pour résoudre ce problème nous nous sommes servis des résultats de l'étude précédente et de la technique d'irradiation mise en oeuvre sur un appareil CAMECA travaillant à 250 MHz.

Isomère 1

On localise facilement le proton $H_{2'e}$ (quadruplet dédoublé) à 2.54 ppm. L'irradiation du massif correspondant permet de situer les résonances de $H_{6'e}$ (disparition de la constante $^4J_{2'e6'e}$: quadruplet dédoublé → triplet dédoublé) et de $H_{2'a}$ (disparition de la constante $^2J_{gem} \sim 13$ Hz : triplet de doublets → doublet de doublets). Une irradiation vers 225 Hz confirme le déplacement chimique de $H_{2'a}$ (δ = 0.85 ppm.). En effet, on obtient pour $H_{2'e}$ la dis-

TABLEAU 2. Influence des liaisons O—C sur le δ des protons en fonction de leurs orientations mutuelles (les valeurs pour les cyclohexanols sont relevées dans la réf. 15; pour les dioxannes voir la réf. 16)

Conformation	Composé	δ	δ	Composé	δ
$[G^-G^+]_o$		+0.61 ($H_{2'e}$ de **1**)	+0.52 ($H_{2'e}$ de **2**)		+0.46
$[TG^-]_o$		+0.19 ($H_{6'e}$ de **1**)	+0.17 ($H_{6'e}$ de **2**) +0.23 ($H_{6'a}$ de **2**)		+0.07
$[G^-T]_o$		+0.03 ($H_{2'a}$ de **1**)	−0.20 (H_{5e} du dioxanne) −0.20 (H_{5e} de **1**) −0.15 (H_{5e} de **2**)		−0.27
$[G^+G^+]_o$		+0.32 ($H_{2'a}$ de **2**)	+0.41 (H_{5a} du dioxanne) +0.28 (H_{5a} de **1**) +0.35 (H_{5a} de **2**)	—	
$[TT]_o$		+0.27 ($H_{6'a}$ de **1**)			+0.01

parition de $^2J_{gem}$ conduisant à un singulet très élargi (cf. fig. 4).

Pour ces deux irradiations, on note en outre, des modifications dans les massifs situés vers 1.45 et 1.15 ppm. D'après la forme de ces signaux on peut y situer respectivement $H_{3'e}$ et $H_{3'a}$.

En irradiant $H_{6'e}$ (δ = 1.65 ppm), on vérifie que ce proton est bien couplé avec $H_{2'e}$. On irradie aussi le massif proche (δ = 1.7 ppm) attribuable à H_{5a} (comme le prouve l'observation des signaux de H_{6e} et H_{6a} vers 3.75 ppm) et on modifie le quadruplet dédoublé situé à 1.06 ppm. On a ainsi localisé H_{5a} et H_{5e} (cf. fig. 4).

On peut alors penser que $H_{5'e}$ et $H_{5'a}$ ont des résonances voisines de celles de $H_{3'e}$ et $H_{3'a}$ respectivement et que le proton $H_{4'a}$ se trouve masqué par le signal du groupement tertiobutyle comme c'est le cas dans les *tert*-butylcyclohexanes (10). Par différence, nous pensons que $H_{6'a}$ résonne vers 1.45 ppm.

Isomère 2

On trouve $H_{2'e}$ à 2.45 ppm. L'irradiation de ce massif modifie les signaux situés autour de 1.7 et 1.1 ppm. En irradiant alors à 286 Hz (1.14 ppm) et 405 Hz (1.62 ppm) et en observant les modifications apportées au massif du proton $H_{2'e}$, on localise sans ambiguité respectivement $H_{2'a}$ et $H_{6'e}$.

On détermine d'autre part, par irradiation de H_{6e} et H_{6a} (δ_{irr} = 3.66 ppm), les positions de H_{5e} (1.63 ppm) et de H_{5a} (1.51 ppm). Notons que l'on observe bien, sur le massif correspondant à ce dernier proton le dédoublement dû au couplage à distance avec $H_{2'a}$.

Nous situons finalement $H_{3'a}$ et $H_{5'a}$, $H_{3'e}$ et $H_{5'e}$ respectivement vers 1.05 et 1.7 ppm. En effet, compte tenu des effets des groupes méthyles situés en γ, les protons axiaux doivent être blindés par rapport à ceux de l'isomère **1** alors que les équatoriaux ne subissent qu'une faible influence (voir tableau 2 et fig. 5).

Comme précédemment $H_{4'a}$ doit être masqué par le signal du groupement tertiobutyle; on peut alors, par différence, trouver $H_{6'a}$ à 1.41 ppm.

Influence des oxygènes intracycliques sur les déplacements chimiques des protons du spirobicyclohexane

Dans les dioxannes-1,3, il est connu que les résonances des protons H_{5e} et H_{5a} sont, en général,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

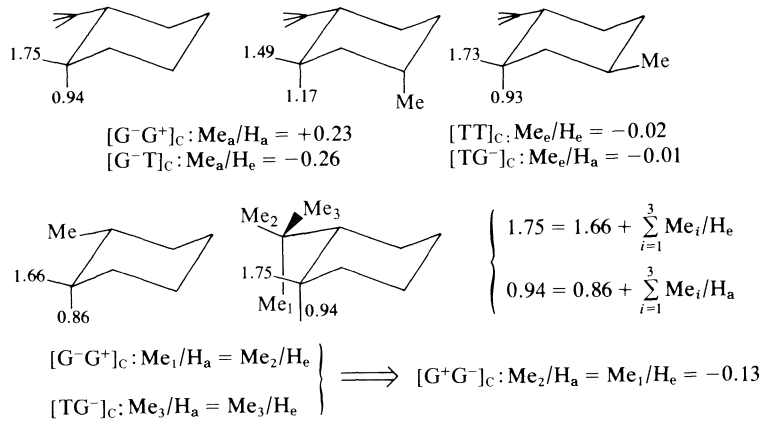

FIG. 5. Incréments d'effets γ (en ppm dans CCl_4) pour divers enchaînements.

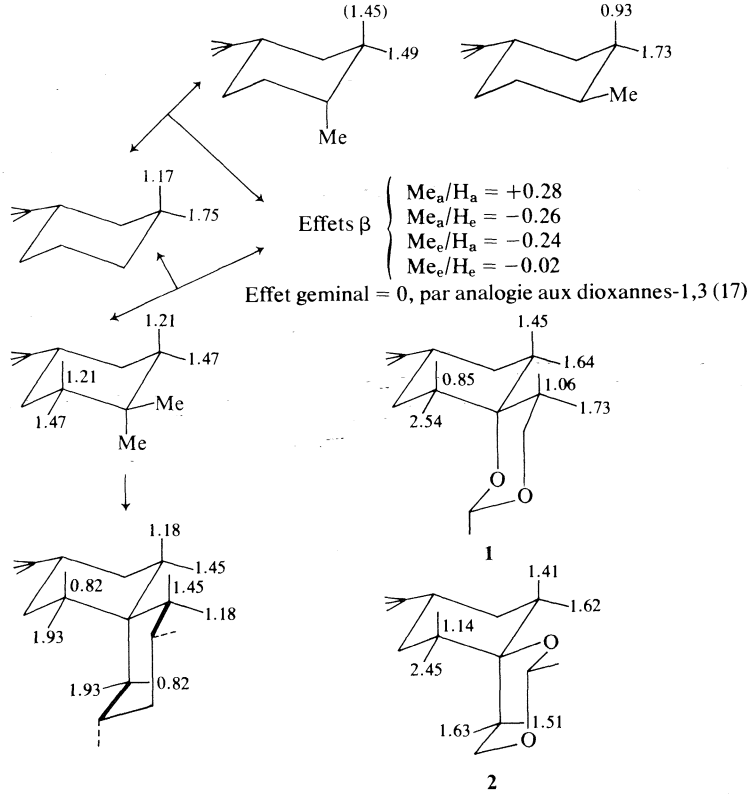

FIG. 6. Calcul des δ dans CCl_4 du *tert*-butyl-4′ méthyl-3 spirobicyclohexane et valeurs expérimentales de **1** et **2**.

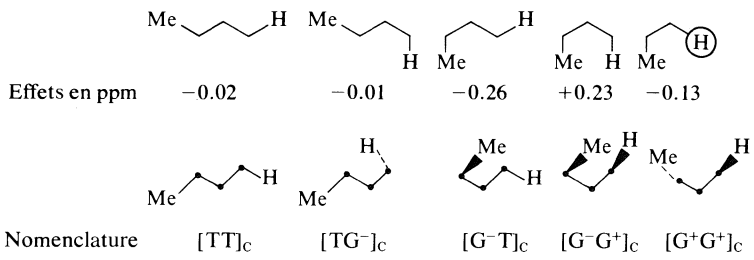
inversées par rapport à celles des mêmes protons dans les cyclohexanes (11–13). Cette anomalie, liée à la présence des oxygènes dans le cycle, n'a pas reçu d'explication satisfaisante (14).

Pour tenter de mieux comprendre les phénomènes qui agissent sur les déplacements chimiques du proton, en présence d'oxygènes intracycliques, nous avons déduit l'effet du remplacement d'un groupement méthylénique par un oxygène, de la comparaison des deux spirodioxannes étudiés **1** et **2** et du *tert*-butyl-4′ méthyl-3 spirobicyclohexane (fig. 6). Malheureusement, aucune donnée n'apparaît dans la littérature pour ce composé; nous avons donc tenté d'obtenir les valeurs de δ nécessaires, à partir du *tert*-butyl cyclohexane et d'incréments déterminés à partir de résultats de la littérature (10) (voir fig. 5).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



Incréments d'effet γ

Plusieurs enchaînements entre groupement méthyle et proton sont à considérer. Nous les avons représentés ci-dessous.[4]

Ces divers effets sont déterminés à partir des *tert*-butylcyclohexanes (10) dans la fig. 5. Ces incréments ont des valeurs proches de celles déjà données dans la littérature (10) sauf pour l'arrangement $[G^-T]_C$ pour lequel une valeur voisine de zéro a aussi été proposée (18). Le paramètre correspondant à l'enchaînement $[G^+G^+]_C$ n'avait pas été déterminé.

Déplacements chimiques des protons du tert-*butyl-4' méthyl-3 spirobicyclohexane*

Ce calcul est résumé dans la fig. 6.

Effets de la liaison C—O

En supposant raisonnablement les effets du deuxième hétéroatome négligeables vis à vis des protons du cycle cyclohexanique, nous avons déterminé l'influence du remplacement d'un CH_2 par un oxygène. Les résultats sont rassemblés dans le tableau 2. Nous y donnons également les orientations des liaisons C—O vis à vis des protons considérés et à titre de comparaison les effets de la liaison C—O dans les alcools cycliques (15).

Les enchaînements $[TG^-]_O$ et $[G^-G^+]_O$ ont des effets comparables dans les spirodioxannes et les cyclohexanols, notamment en ce qui concerne $[G^-G^+]_O$ pour lequel on retrouve un fort déblindage lié à une disposition diaxiale-1,3. L'arrangement $[G^+G^+]_O$ conduit à une influence tout à fait semblable à celle déterminée pour le proton H_{5a} des dioxannes (16, 17).

En revanche, on note pour l'enchaînement plan $[TT]_O$, un effet de +0.27 ppm. Dans les hydrocarbures et alcools cycliques, cet effet est pratiquement nul. Ceci est peut être lié à l'orientation particulière d'une des orbitales de l'oxygène (en W plan par rapport au proton étudié).

D'autre part, on relève aussi un désaccord entre les influences de l'enchaînement $[G^-T]_O$ dans les spirodioxannes (+0.03) et les dioxannes (−0.20 ppm sur H_{5e}). Cette "anomalie" pourrait trouver une explication, soit dans un effet particulier dû à la présence de deux oxygènes (dans les dioxannes), soit plus sûrement dans une estimation erronée du paramètre correspondant à l'enchaînement $[G^-T]_C$. En effet, la valeur de ce paramètre est contestée dans la littérature (−0.26 selon réf. 10; ∼0 selon réf. 18).

[4]Les conformations sont repérées par les orientations "*trans*" (T) ou "*gauche*" (G) du méthyle et de l'hydrogène en γ considérées par rapport à la chaise carbonée et notées dans l'ordre Me, H (19).

Laboratoire de Synthèse et Physicochimie organique, ERA no 686 du CNRS, 118 route de Narbonne, 31077 Toulouse Cédex, France

Reçu le 3 mars 1978

LOUIS CAZAUX, JEAN-PIERRE GORRICHON, YAHIA KOUDSI et PIERRE MARONI. Can. J. Chem. **56**, 3006 (1978).

Les spectres de deux séries de quatre et huit diastéréoisomères des dioxannes-1,3-4-spirocyclohexanes du titre sont analysés à 60, 100 et 250 MHz dans CCl_4. A l'aide notamment du calcul empirique des déplacements chimiques, les structures ont été déterminées sans ambiguité en dehors de toute filiation chimique; à deux exceptions près, les conformations sont des double chaises. Dans ces molécules les effets γ intercycles des groupes méthyles en position 5 sont calculés.

LOUIS CAZAUX, JEAN-PIERRE GORRICHON, YAHIA KOUDSI, and PIERRE MARONI. Can. J. Chem. **56**, 3006 (1978).

The nmr spectra at 60, 100, and 250 MHz in CCl_4 of two series of four and eight diastereoisomers of the title 1,3-dioxanespiro-4-cyclohexanes have been analysed. In particular, use of the empirical calculation of chemical shifts allows for the unambiguous determination of structure without the need for chemical methods. With two exceptions, these compounds exist in the double chair conformation. In these molecules the γ intercyclic effect of the methyl groups in position 5 have been calculated.

Nous avons synthétisé, outre les deux composés de la série I, **1** et **2** décrite dans le mémoire précédent (partie X, réf. 1) et les quatre composés **3** à **6** étudiés dans le suivant (partie XIV) deux séries de spirodioxannes (schéma 1) à partir de la triméthyl-3,3,5

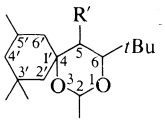

SCHÉMA 1. Spirodioxannes des séries II (R′ = H) et III (R′ = CH_3).

cyclohexanone et de dérivés magnésiens de la diméthyl-3,3 butanone-2 (R′ = H, série II) ou de la diméthyl-2,2 pentanone-3 (R′ = CH_3, série III). Ces deux séries comportent respectivement quatre et huit diastéréoisomères (schéma 2).[2] Ce sont des produits liquides qui ont été séparés par chromatographie sur couche mince préparative.

Nous déterminons les structures de ces molécules indépendamment de toute filiation chimique, en utilisant les déplacements chimiques des protons dans le tétrachlorure de carbone. Les conformations sont alors connues en appliquant les résultats du calcul empirique des déplacements chimiques (2). De plus, les écarts observés entre valeurs calculées et expérimentales de ces paramètres, sont révélateurs de modification de la conformation des cycles (3).

Le passage des β-cétols aux dioxannes, lors de la synthèse, ne modifie pas la configuration des carbones C_4, C_5 et C_6. La détermination de structure des β-cétols de départ et des β-diols intermédiaires peut donc être traitée (4) comme application de ce travail.

Notation

Nous avons représenté dans le schéma 2, les divers isomères obtenus : les carbones asymétriques y sont nommés dans l'ordre successif où ils apparaissent au cours de la synthèse: $C_{5'}$, $C_{spiro(1'\text{ ou }4)}$, $C_{5(cétols)}$, $C_{6(diols)}$ et $C_{2(dioxannes)}$. Dans la série III, les notations "a" et "e" se réfèrent à l'orientation axiale ou équatoriale du groupement méthyle en 5. Il y a dans cette série, une inversion de nomenclature du carbone 5 quand on passe du cétol au diol, par suite de la modification de l'ordre séquentiel des substituants. Quelques relations topologiques simples entre les divers isomères permettent de construire facilement les modèles moléculaires. Dans la série II, ou dans un même type a ou e de la série III, on peut passer de **7** aux isomères **8**, **9** et **10**, en faisant subir au cycle cyclohexanique et aux substituants méthyles en 3′ et 5′, les changements respectifs: **7** → $\bar{\mathbf{8}}$: passage de $Me_{3'a}$ en $Me_{5'a}$; **7** → $\bar{\mathbf{9}}$: passage de $Me_{5'e}$

[1]Partie précédente, voir réf. 1.

[2]L'énergie conformationnelle du méthyle en position 2 étant de 4.1 kcal mol^{-1} (11) seuls les diastéréoisomères pour lesquels ce méthyle est équatorial ont été isolés.

SCHÉMA 2. Filiation chimique conduisant aux spirodioxannes non substitués en 5, **7** à **10** (série II) et monométhylés en 5, **7***ae* à **10***ae* (série III).

en $Me_{5'a}$ et inversion du cycle cyclohexanique; **7** → **10**: passage de $Me_{3'e}$ en $Me_{5'a}$ et inversion du cycle cyclohexanique.[3]

Abstraction faite du méthyle axial en 3′, il faut noter, enfin, que les composés **7** et **8** sont images l'un de l'autre, ainsi que **9** et **10** (schéma 2).

Etude conformationnelle

Si l'on excepte les composés **9***e* et **10***e*, la conformation préférentielle de ces molécules devrait être la double chaise.

Partie cyclohexanique

Les composés de type **7** et **8** présentent une interaction diaxiale-1,3 $Me_{3'a}\cdots C_4O_3$ d'environ 2.5 kcal mol^{-1} (5) et les composés **9** et **10**, une interaction diaxiale-1,3, $Me_{3'a}\cdots C_4—C_5$ de l'ordre de 3.7 kcal mol^{-1} (6). Dans tous les isomères étudiés, on trouve une interaction $Me_{3'a}\cdots H$ estimée à 0.8–0.9 kcal mol^{-1} (7). Mais ces tensions n'apparaissent pas suffisantes pour déplacer l'équilibre conformationnel vers une forme croisée.[4] Les contraintes précédentes demeurent, en effet, inférieures aux enthalpies ΔH^0 entre conformations chaise et croisée déterminées pour le cyclohexane lui-même, 4.8 à 7.9 kcal mol^{-1} (7). On doit aussi tenir compte du facteur entropique qui conduirait selon Anteunis *et al.* (6) à une enthalpie libre $\Delta G^0 \sim 5.1$ kcal mol^{-1} dans le cas du cyclohexane pour un $\Delta H^0 = 6$ kcal mol^{-1}. Mais les molécules qui nous intéressent sont dissymétriques et la variation d'entropie doit être plus faible.

D'après la littérature (9) on constate aussi, que les constantes de couplage homologues demeurent très voisines dans les triméthyl-3,3,5 et tétraméthyl-3,3,5,5 cyclohexylamines (schéma 3). Cette similitude montre que l'interaction diaxiale-1,3 présente dans le composé tétraméthylé n'introduit que des modifications négligeables dans la géométrie du cycle. L'analyse des δ conduit au même résultat: l'effet Δδ exercé par le groupe méthyle axial en 5, sur les protons H_A, H_B et H_X est respectivement −0.42, +0.25 et +0.13 ppm. Ces valeurs sont tout à fait comparables à celles déterminées pour des cyclohexanols ne comportant pas d'interaction diaxiale-1,3 soit −0.40, +0.19 et +0.18 ppm (réf. 2 et références citées).

Partie dioxannique

Pour le dioxanne-1,3 non substitué, la valeur élevée de la différence d'enthalpie chaise-croisée ΔH^0 (6 à 8 kcal mol^{-1}) (10) est très défavorable à une conformation croisée. De plus les substituants tertiobutyle en 6 et méthyle en 2 sont tous les deux

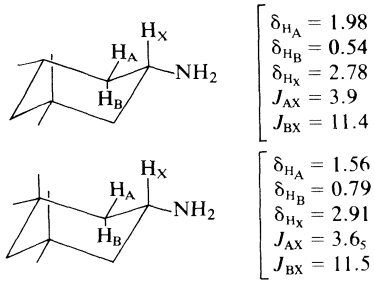

SCHÉMA 3. Déplacements chimiques (en ppm) et constantes de couplage (en Hz) pour des cyclohexylamines.

équatoriaux sur le cycle puisque leurs énergies conformationnelles sont respectivement >5 kcal mol^{-1} et d'environ 4.1 kcal mol^{-1} (11).

Toutes ces considérations permettent d'admettre que, dans les spirodioxannes, la conformation privilégiée est la double chaise.

En revanche, pour les isomères **9***e* et **10***e* de la série III, il devient nécessaire d'envisager une conformation non chaise. Il y a en effet une contrainte considérable (voir schéma 2) entre le méthyle équatorial en 5 et le cycle cyclohexanique. Cette interaction entre méthyles 5e et 3′a est analogue à une interaction diaxiale-1,3 entre substituants méthyle et tertiobutyle. Elle est en tout état de cause, très supérieure à l'énergie conformationnelle d'un tertiobutyle axial sur un cyclohexane (≥ 5.8 kcal mol^{-1}). L'inversion de la chaise cyclohexanique n'est pas suffisante car elle fait apparaître trois interactions diaxiales-1,3, une $Me\cdots C—CH_2$ et deux $Me\cdots C—O$ ce qui correspond à une énergie d'environ 8.7 kcal mol^{-1} (5, 6).

Analyse des spectres dans CCl_4

Les spectres des composés de la série II ont été enregistrés à 60 et 100 MHz sur des appareils Varian A-60 et HA-100 pour des solutions à 20% dans CCl_4. Ceux des composés de la série III ont été enregistrés à 60 et 100 MHz sur les mêmes appareils et à 250 MHz sur un appareil Cameca pour des solutions à 20% dans CCl_4. Les déplacements chimiques des différents protons et groupes de protons ainsi que les constantes de couplage sont rassemblés dans les tableaux 1 et 2.

Protons méthyliques (2e, 5e ou 5a, 3′e, 3′a, 5′e)

Les groupements méthyles en position 2e, 5e, 5a et 5′e apparaissent sous forme de doublets. On les distingue (*i*) par leurs constantes de couplage avec le proton géminé: Me_{2e} (5 Hz), $Me_{5e\ ou\ 5a}$ (7 Hz) et $Me_{5'e}$ (6 Hz). Ces valeurs sont normales pour des composés dioxanniques (12 et références citées) et

[3] $\bar{n}$ désigne l'énantiomère de *n*.

[4] La forme croisée du cyclohexane est plus stable que la forme bateau d'environ 1.6 kcal mol^{-1} (8).

*Spectres enregistrés sur des appareils Varian A 60 et HA 100.

cyclohexaniques (13). Signalons que la résonance du Mc_{5a} est élargie (par rapport à celle du Me_{5e}) par un couplage en W avec H_{6a}; (*ii*) par leurs déplacements chimiques : le méthyle en 2e est le plus déblindé (12).

Les méthyles en 3′a et 3′e sont des singulets; dans tous les cas, le signal de $Me_{3'a}$ (toujours le plus déblindé) a la plus grande largeur à mi-hauteur en raison de couplages longue distance avec les protons $H_{2'a}$ et $H_{4'a}$.

Protons dioxanniques (2a, 5a ou 5e, 6a)

Le signal du proton H_{2a} se présente sous la forme d'un quadruplet et celui de H_{6a} comme un doublet de doublet (série II) ou un doublet unique (série III). Ces deux protons axiaux ont des déplacements chimiques normaux (2), environ 5 ppm pour H_{2a} et 3 ppm pour H_{6a}. Les protons H_{5e} et H_{5a} ont pu être repérés, grâce aux constantes de couplage.

Protons cyclohexaniques (2′e, 2′a, 6′e, 6′a)

Les protons $H_{2'e}$ et $H_{2'a}$ constituent les parties A et B d'un système AB; $H_{6'e}$ et $H_{6'a}$ respectivement les parties A (ou X) et X (ou A) de systèmes ABX ou AMX, B ou M étant le proton $H_{5'a}$.

De plus, sur les signaux des protons $H_{2'e}$ et $H_{6'e}$, on relève deux constantes de couplage à longue distance d'environ 2 Hz, puisqu'ils sont en situation W coplanaire entre eux et avec le proton $H_{4'e}$.

Dans tous les isomères étudiés, nous avons pu situer les protons $H_{2'e}$ et $H_{6'e}$. Les protons axiaux correspondants sont, en revanche, plus difficilement localisables.

La fig. 1 présente un exemple caractéristique de spectre à 60 MHz et l'allure des massifs représentatifs des protons $H_{2'e}$ et $H_{6'e}$.

Correlation structure: déplacements chimiques

Composés de la série II

Calcul empirique des δ des protons $H_{2'e}$, $H_{2'a}$, $H_{6'e}$ et $H_{6'a}$

Ce calcul a été effectué à partir des résultats obtenus dans le cas des méthyl-2 dioxanne-1,3-4-spiro-*tert*-butyl-4′ cyclohexanes *cis* et *trans* **1** et **2** (série I (2)).

Nous avons d'abord déduit de la comparaison des méthyl- et *tert*-butylcyclohexanes et d'incréments déjà déterminés (13), l'influence d'un tertiobutyle sur les protons en γ.

Nous résumons dans la fig. 3 le résultat du calcul des déplacements chimiques dans les quatre diastéréoisomères de la série II.

Identification des diastéréoisomères

En comparant les valeurs des déplacements chimiques calculées et expérimentales, il apparait que l'identification des isomères est possible sans ambiguité.

Les protons les plus déblindés ($H_{2'e}$ et $H_{6'e}$) permettent un classement en deux groupes distincts: **7** et **9** d'une part, **8** et **10** de l'autre. Il faut noter que les δ des protons $H_{2'e}$ sont calculés avec une excellente précision ($\leq$0.02 ppm) alors que l'écart est plus grand pour $H_{6'e}$ (~0.1 ppm).

Les protons $H_{2'a}$ (ou $H_{6'a}$) différencient **7** de **9** et **8** de **10**; on retrouve en effet entre leurs déplacements chimiques le même écart d'environ 0.30 ppm qui existe déjà dans les composés **1** et **2**.

Sur les protons dioxanniques, si on examine les modèles moléculaires on remarque que H_{2a} de **7** et **8** est dans une situation semblable du point de vue de

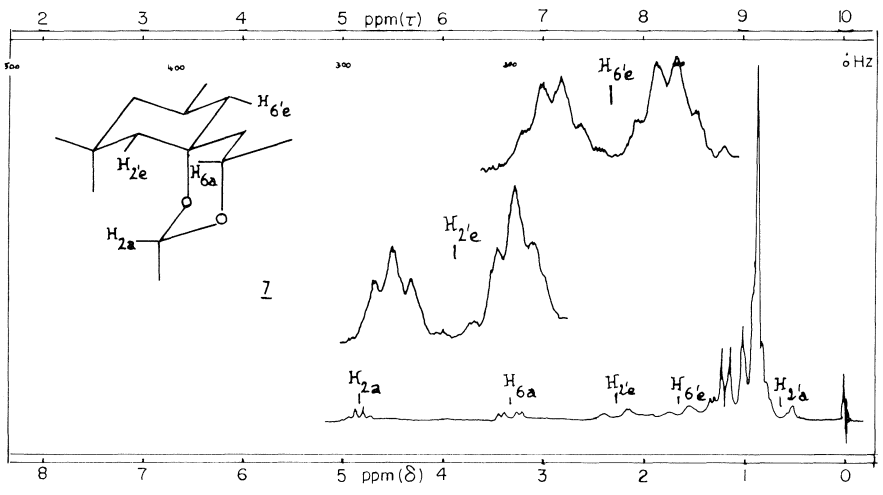

FIG. 1. Spectre à 60 MHz du composé **7**.

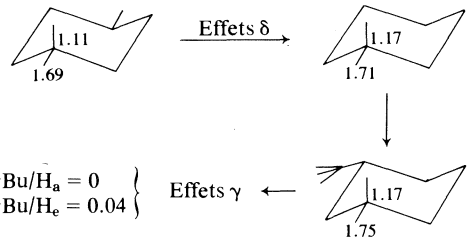

FIG. 2. Incréments d'effet γ d'un groupement tertiobutyle.

l'environnement spatial, notamment vis à vis de la liaison $C_{2'}$—$C_{3'}$, à celle du proton H_{6a} dans **9** et **10**. H_{2a} de **9** et **10** et H_{6a} de **7** et **8** ne devraient pas subir la même influence.

Si on se refère aux δ de ces divers protons (tableau 1) on constate que $\delta_{H_{2a}}$ (**7** et **8**) $-\delta_{H_{2a}}$ (**9** et **10**) $\simeq -0.13$ ppm et $\delta_{H_{6a}}$ (**9** et **10**) $- \delta_{H_{6a}}$ (**7** et **8**) $\simeq -0.06$ ppm. On a donc là aussi un moyen de connaitre l'isomérie portant sur l'orientation de la liaison C_4—O_3. Ceci est encore confirmé par les différences notées pour les spirodioxannes **1** et **2**. En effet $\delta_{H_{2a}}(\mathbf{1}) - \delta_{H_{2a}}(\mathbf{2}) = -0.12$ ppm et $\delta_{H_{6a}}(\mathbf{2}) - \delta_{H_{6a}}(\mathbf{1}) = -0.15$ ppm.

Composés de la série III

Les résultats acquis pour la série II au niveau du cycle cyclohexanique sont maintenant perturbés par les influences intercycles (effet γ) des groupements méthyles substitués sur le carbone 5. Ces effets γ étant peu décrits dans la littérature, nous avons, avec ces molécules, un moyen de les déterminer. Pour différencier les diastéréoisomères de cette série, nous avons aussi effectué un calcul de déplacement chimique des protons dioxanniques.

Calcul empirique des δ des protons H_{2a} et H_{6a}

Ce calcul a été réalisé à partir des déplacements chimiques expérimentaux des protons analogues dans la série II (cf. tableau 1). En raison de l'influence non négligeable des interactions gauches Me···*t*Bu, sur les incréments Δδ déjà décrits (2), liés à un méthyle en position 5, nous sommes conduits à déterminer de nouveaux paramètres. Pour cela, nous avons extrapolé les δ du *tert*-butyl-6 diméthyl-4,4 dioxanne-1,3 à partir de ceux du *tert*-butyl-4 dioxanne-1,3 (3) et d'incréments connus (2). Nous rappelons aussi les δ des protons dans les *tert*-butyl-6 triméthyl-4,4,5 dioxannes-1,3 *cis* et *trans* (14). La comparaison de ces diverses valeurs fournit les incréments cherchés (fig. 4). Les déplacements chimiques des protons H_{2a} et H_{6a} des huit diastéréoisomères de la série III, sont alors obtenus en ajoutant ces paramètres aux δ des protons correspondants des spirodioxannes de la série II (tableau 3).

Attribution de configuration

Les différences de déplacements chimiques du proton 6a (tableau 3) et les valeurs des constantes de couplage J_{5a6a} et J_{5e6a} (tableau 2) permettent de distinguer la série e de la série a. A partir des calculs du tableau 3, on peut alors, attribuer à chacun des huit isomères un couple de valeurs de façon que l'écart $\delta_{calc} - \delta_{exp}$ soit minimal. On a ainsi un moyen d'identifier chaque isomère et de remonter à la configuration des produits dont ils sont issus. Cependant les variations de δ entre isomères, ne différant que par la substitution méthylée sur le cycle cyclohexanique restent dans les limites de l'incertitude expérimentale. L'attribution faite sur 2a et 6a a donc du être confirmée par l'analyse des effets intercycles des Me_5 sur les protons 2′e et 6′e qui sont soumis directement à l'influence des $Me_{3'}$ et du $Me_{5'}$ (*vide infra*).

Les résultats obtenus justifient les hypothèses

faites sur les conformations de ces molécules; en particulier seuls les composés **9***e* et **10***e* présentent un écart $\Delta\delta$ important (>0.1 ppm) que nous pouvons corréler à une modification conformationnelle (3).

Conformations des composés **9**e *et* **10**e

Spirodioxanne **9**e—Nous observons sur le spectre rmn enregistré dans CCl_4, un massif de quatre bandes centrées à 2.08 ppm et un doublet à 1.49 ppm que nous attribuons respectivement à $H_{6'e}$ et $H_{2'e}$. L'allure particulière de ces signaux est probablement due à une plus faible amplitude des couplages à distance que dans le cas des autres isomères (cf. fig. 5). Nous lisons sur le doublet, la constante $^2J_{2'} = -13.4$ Hz et sur le multiplet (partie X d'un système ABX) la somme $|^2J_{6'} + {}^3J_{6'e5'a}| = 18.2$ Hz. La première constante est normale pour un couplage géminé dans les cyclohexanes. En prenant pour $^2J_{6'}$ une valeur de −13.1 Hz (moyenne des valeurs relevées pour les composés en conformation chaise, tableau 2) nous en déduisons $^3J_{6'e5'a} \sim 5.1$ Hz. Cette forte valeur ($^3J_{6'e5'a} = 2.2$ Hz dans les autres isomères) et la diminution des couplages à longue distance $^4J_{2'e4'e}$, $^4J_{2'e6'e}$ et $^4J_{6'e4'e}$ impliquent une déformation importante de la partie cyclohexanique.

La valeur de la constante $^3J_{5a6a} = 8$ Hz (cette constante est de l'ordre de 10 Hz dans les composés sous forme chaise) indique également une modification conformationnelle de la partie dioxannique.

Spirodioxanne **10**e—Seul le signal du proton $H_{2'e}$ est visible à 1.60 ppm ($^2J_{2'} = -13.9$ Hz). Dans ce cas aussi, les couplages en W ne sont pas apparents et nous pouvons en conclure que la partie cyclohexanique est déformée. Le cycle dioxannique ne serait que peu perturbé puisque la constante $^3J_{5a6a} = 9.2$ Hz.

Qu'il y ait participation de formes croisées dans les conformations de ces deux molécules apparaît encore très nettement sur les valeurs d'incréments d'effets γ intercycles dont nous abordons la détermination dans le paragraphe suivant (cf. tableau 4).

Effets γ intercycles des groupes méthyles en position 5a et 5e

Nous avons vu (schéma 2) que si l'on ne tient pas compte du substituant $Me_{3'a}$, les spirodioxannes **7***a* et **8***a*, **7***e* et **8***e*, **9***a* et **10***a*, **9***e* et **10***e* sont images dans un miroir. Il en résulte que la comparaison de chaque molécule de la série III au composé correspondant de la série II permet de définir deux fois le même effet du groupement méthyle 5 sur les protons $H_{2'e}$ et $H_{6'e}$. Nous donnons dans le tableau 4 les valeurs ainsi calculées avec l'enchaînement impliqué.

L'enchaînement $[G^-G^+]$ correspond à l'influence d'un méthyle axial sur un proton axial en situation diaxiale-1,3. Les valeurs relevées dans le tableau 4 (+0.15 à +0.40 ppm) sont en grandeur et en signe comparables à celles observées dans les cyclohexanes (+0.27 ppm (13)), les cyclohexanols (+0.18 à 0.23 ppm (15)) et les dioxannes (+0.11 à +0.20 ppm (2)) pour un même arrangement méthyl–proton.

La valeur de $[TG^-]$ (+0.23 ppm en moyenne) est très forte vis à vis de celle notée dans les cyclohexanes (+0.01 ppm (13)). En revanche, l'enchaînement $[G^+G^+]$ dans **7***e* et **8***e* a une valeur moyenne (−0.32 ppm) de même signe mais plus grande que celle que nous avons déterminée à partir du tertiobutylcyclohexane (cf. fig. 4 dans réf. 1, $[G^+G^+]_c =$

	6'e (**8***a*)	+0.23	
	2'e (**9***a*)	+0.21	
	6'e (**10***a*)	+0.23	
	6'e (**7***a*)	+0.15	 [G⁻G⁺]
	2'e (**8***a*)	~+0.17	
	6'e (**9***a*)	~+0.31	
	2'e (**10***a*)	~+0.39	
Me_{5e}	2'e (**7***e*)	−0.35	 [G⁺G⁺]
	6'e (**8***e*)	−0.38	
	2'e (**9***e*)	~−0.68	
	6'e (**7***e*)	−0.30	
	2'e (**8***e*)	−0.25	
	6'e (**9***e*)	~+0.53	
	2'e (**10***e*)	~+0.17	
	2'a (**7***e*)	~+0.20	[G⁻G⁺]
	6'a (**8***e*)	~+0.20	

−0.13 ppm). On observe donc, un bon accord entre les diverses valeurs d'un même incrément d'effet γ intercycle pour les composés **7***a* à **10***a* et **7***e*, **8***e*. En revanche, les forts écarts notés pour les produits **9***e* et **10***e*, renforcent l'hypothèse de la présence de conformations croisées pour l'un ou l'autre (ou les deux) cycle(s).

Dans le cas où les méthyles en 3' et 5' seraient inversés (**7**ae → **8**ae, **9**ae → **10**ae), les effets intercycles deviennent aberrants: TG^- (−0.35 à −0.62), G^-G^+ (+0.95 à +1.00) et G^+G^+ (+0.44 à −1.07). De plus la dispersion de ces résultats et l'homogénéité de ceux qui découlent des attributions précédentes confirment notre analyse structurale.

Stéréochimie de β-diols et de leurs dérivés cycliques. XIV.[1] Analyse structurale de dioxanne-1,3-4-spirocyclohexanes par résonance magnétique nucléaire du ^{13}C

LOUIS CAZAUX, JEAN-PIERRE GORRICHON ET PIERRE MARONI

Laboratoire de Synthèse et Physicochimie organique, ERA no 686 du CNRS, 118, route de Narbonne, 31077 Toulouse Cédex, France

Reçu le 3 mars 1978

LOUIS CAZAUX, JEAN-PIERRE GORRICHON et PIERRE MARONI. Can. J. Chem. **56**, 3016 (1978).

Le calcul empirique du déplacement chimique en rmn du ^{13}C selon Grant et Saunders est envisagé dans cinq séries de dioxanne-1,3-4-spirocyclohexanes dont une comporte huit diastéréoisomères. Les incréments nécessaires à ce calcul sont déduits de la littérature ou établis à partir de molécules modèles et leur application conduit à des attributions de structure non ambiguës.

LOUIS CAZAUX, JEAN-PIERRE GORRICHON, and PIERRE MARONI. Can. J. Chem. **56**, 3016 (1978).

Following the methods of Grant and Saunders the empirical calculation of the ^{13}C chemical shift in five series of 1,3-dioxanespiro-4-cyclohexanes, including one with eight diastereoisomers, is reported. The increments used in these calculations have been derived from the literature or determined from model compounds and their use leads to unambiguous structural assignments.

[Journal translation]

Introduction

Dans les mémoires précédents (1, 2), nous avons utilisé le calcul empirique du déplacement chimique en rmn du proton (3, 4) pour l'étude conformationnelle de dioxanne-1,3-4-spirocyclohexanes. Nous poursuivons ce travail en rmn du ^{13}C à partir de deux méthodes de calcul proposées dans la littérature, l'une par Grant et coll. (5–8), l'autre par Saunders et coll. (9–12).

La structure spirodioxannique des composés étudiés impose la définition préalable de nouveaux incréments que nous avons testés par ailleurs sur des hydrocarbures, alcools cycliques et dioxannes-1,3 de conformation connue (25). Dans ce mémoire nous établissons, dans un premier temps, les systèmes d'incréments des deux méthodes pour les molécules choisies comme modèles; puis nous les appliquons au calcul des déplacements chimiques des dioxannes-1,3-4-spirocyclohexanes schématisés dans le tableau 1 et à l'analyse conformationnelle de ces dérivés indépendamment de l'étude précédente (1, 2) en rmn du proton.

Systèmes d'incréments utilisés

Méthode de Grant

Hydrocarbures cycliques à six chaînons

A partir d'une investigation systématique de 15 cyclohexanes méthylés, Dalling et Grant (5) ont caractérisé les effets de la substitution d'un hydrogène par un groupement méthyle sur les carbones du cycle. Ces résultats ont été développés et les paramètres réajustés dans une publication plus récente de ces auteurs (6). Malgré les difficultés rencontrées pour justifier telle valeur des paramètres par un phénomène physique bien défini, on peut néanmoins prédire le déplacement chimique de carbones dans ces cycles à partir de formules simples: $\delta_{C/TMS} = 27.1 + \sum A$ pour les carbones du cycle; $\delta_{C/TMS} = 23.1 + \sum B$ pour les groupements méthyles (27.1 est la valeur expérimentale pour la résonance des carbones du cyclohexane; 23.1 la valeur moyenne expérimentale pour un groupe méthyle équatorial sur le cyclohexane). Les valeurs des incréments A et B sont données dans les réfs 5 et 6.

Alcools cycliques

Les travaux de Roberts et coll. (13) sur les alcools linéaires et les cyclohexanols d'une part, de Grover et Stothers (14) d'autre part, permettent de déterminer les effets du substituant hydroxyle[2] en prenant comme base $\delta_0 = 27.1$ ppm pour les cyclohexanols et les δ des carbones de la décaline-*trans* pour les décalols.

Dioxannes-1,3

Effets des substituants méthyles—Kellie et Riddell (15, 16) ont mesuré le déplacement chimique des carbones cycliques de 25 dioxannes-1,3. Ces auteurs déterminent les incréments liés à l'effet de groupes méthyles d'une manière analogue à celle utilisée par Grant pour les cyclohexanes. Ces paramètres ne sont pas les mêmes suivant la position du substituant

[1]Pour la partie XIII, voir réf. 2.

[2]Nous avons vérifié (25) que dans le cas des cyclohexanols, la présence d'un groupe hydroxyle ne modifiait pas les paramètres d'effet du groupement méthyle définis par Grant pour les cyclohexanes. Nous n'avons évidemment examiné que le cas où n'existe aucune interaction (géminée ou vicinale) entre ces deux substituants.

puisque les carbones 2,4 ou 6 et 5 dans un dioxanne-1,3 ne sont pas équivalents. Les bases sont les déplacements chimiques des carbones 2, 4 et 5 du dioxanne-1,3 lui-même.

Effets des oxygènes—L'effet α des oxygènes intracycliques est très important. Par comparaison du dioxanne-1,3 et du cyclohexane on peut le chiffrer à environ +39 ppm pour un oxygène (δ_{C_4} = 66.2 ppm, $\delta_{C(cyclohexane)}$ = 27.1 ppm) et à +66 ppm pour deux oxygènes (δ_{C_2} = 93.1). L'additivité de ces effets n'est donc pas respectée.

Quelques résultats de la littérature (17, 18) permettent de préciser l'effet γ pour des enchaînements O—C_α—C_β—C_γ gauche ou antipériplanaire. Pour des liaisons C_β—C_γ et O—C_α *gauche*, l'effet est relativement faible (−2.1 à −3.3 ppm dans les dioxannes) en revanche pour un enchaînement antipériplanaire l'effet paraît très sensible à la substitution du carbone étudié et peut devenir important (−1.4 à −2.3 ppm pour un $\geq$C—, −8.3 pour un CH_2, −11 pour un méthyle-5 équatorial).

Nous avons entrepris pour notre part (25) la détermination des incréments liés à l'effet β de ces oxygènes à la fois en fonction de l'orientation des hétéroatomes (enchaînements C—O—C_α—C_β *gauche* ou *anti*) et du degré de substitution du carbone C_α. Les résultats de cette étude sont rassemblés dans les tableaux 2 et 5.

On constate tout d'abord que la valeur de l'incrément *A* est tout à fait comparable à la différence d'effet β existant entre des substituants hydroxyle et méthyle ($\delta_C^{ROH}(\beta) - \delta_C^{RCH_3}(\beta) = -0.5$ ppm; cf. réf. 13). Ceci montrerait encore que l'effet β est peu sensible à la nature d'un substituant (19–21), un groupement O—CH_2 intracyclique ayant la même influence qu'un groupe hydroxyle exocyclique.

Les différences observées entre les incréments *A* et *B*, *B* et *C* d'une part, *D* et *E* d'autre part pourraient s'expliquer par une modification de l'effet inducteur des groupes méthyles portés par le carbone α en raison de la polarisation de la liaison O—C_α. Les écarts (~1.5 et 0.5 ppm respectivement) et le nombre d'exemples sont cependant trop faibles pour caractériser un tel effet de façon sûre. Il faut noter que l'on retrouve une différence d'environ 1.5 ppm entre les effets β_e et β_a déterminés pour des méthyles substitués sur le cyclohexane (9.0 et 5.4 ppm) et ceux substitués en 4 sur le dioxanne (7.3 et 3.7 ppm).

Il semble donc que, pour l'effet β d'oxygènes intracycliques, l'effet de substitution soit plus important que celui d'orientation.

Méthode de Saunders

Hydrocarbures à six chaînons

A partir des résultats obtenus par Grant pour les décalines (7) et d'une mise en cause de la signification réelle de l'effet β, qui ne serait pas une contribution inductive, Saunders et Beierbeck (9) proposent une interprétation en fonction des interactions gauches présentes dans les molécules étudiées.

L'effet α, en général non additif d'après ces auteurs, est éliminé du calcul en utilisant comme "bases" les déplacements chimiques des carbones primaire, secondaire, tertiaire et quaternaire respectivement dans l'éthane, le propane, l'isobutane et le néopentane. Quatre incréments suffisent alors pour calculer les déplacements chimiques suivant la formule:

$$\delta_C = A + \sum I$$

Les valeurs de ces incréments sont fournies dans la réf. 9.

Alcools cycliques

Les effets à longue distance (δ, ε) du groupement hydroxyle dans les décalols sont faibles (14). On peut donc admettre que, pour les carbones situés dans ces positions, les incréments déterminés par Beierbeck et Saunders (9) pour les décalines sont encore valables.

Pour les carbones situés en β ou γ du substituant hydroxyle, il est nécessaire d'introduire quatre nouveaux incréments, définis dans les réfs 10 et 25, tenant compte d'interactions dues à la présence de l'oxygène.

Dioxannes-1,3

Nous avons déterminé les incréments d'interaction nécessaire au calcul de l'effet β par cette méthode soit sur le carbone non substitué en position 5 dans le cycle dioxannique, soit sur les carbones de méthyles équatoriaux ou axiaux en position 4. On peut, pour ces carbones, conserver les valeurs de base (16.1 et 5.9 ppm respectivement) déjà utilisées par Saunders pour éliminer l'effet α.

Nous avons tout d'abord choisi comme modèles les molécules représentées dans la fig. 1. A partir des déplacements chimiques expérimentaux des carbones de ces molécules, on peut écrire:

$$25.2 = 16.1 + 2HO + 2CO''$$

$$33.6 = 16.1 + 2HO + 2CO'' + 2HC$$

$$21.6 = 5.9 + 2HO + 2HC$$

$$35.9 = 16.1 + 2HO + 2CO'' + 3HC + 1CC'$$

Les notations des incréments sont les mêmes que dans le cas des cyclohexanes et cyclohexanols. Elles sont précisées dans la fig. 2. Les trois premières valeurs ne sont pas fondamentalement différentes de celles déterminées dans les cyclohexanes et cyclohexanols. Les valeurs numériques des paramètres HC et HO sont seulement plus faibles dans le cas des

FIG. 1. Déplacements chimiques des carbones des dioxannes "modèles" relevés sur des spectres enregistrés dans $CDCl_3$ avec le TMS pour référence interne (réf. 24 et tableau 3).

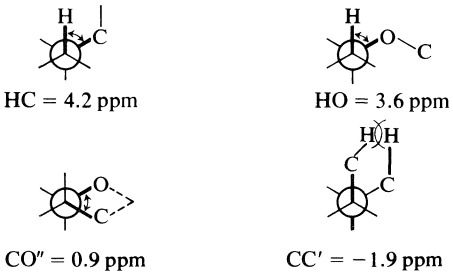

FIG. 2. Incréments d'interactions pour les dioxannes-1,3.

dioxannes-1,3. L'incrément d'interaction *gauche* intracyclique (CO″) n'est plus nul comme dans le cas de deux liaisons C—C (CC″ = 0). La valeur de l'incrément CC′ est plus surprenante (elle est de +1.74 ppm dans les cyclohexanes et cyclohexanols). Il faut noter qu'elle correspond à une interaction avec un méthyle axial en 4 sur le cycle dioxannique. Le fait que ce groupement présente une interaction de type diaxiale-1,3 avec l'hydrogène synaxial en 2 plus

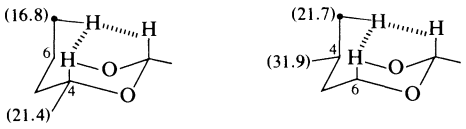

FIG. 3. Déplacements chimiques des carbones des groupes méthyles du triméthyl-2-*r*,4-*c*,6-*t* dioxanne-1,3 (24) et du triméthyl-2,4,4 dioxanne-1,3 (**14** dans le tableau 3). Incréments d'effet γ.

forte que dans le cas des cyclohexanes, pourrait être responsable de ce changement.

Il nous reste à déterminer un dernier paramètre: celui qui tient compte d'une situation diaxiale-1,3 de la liaison portant le carbone étudié vis-à-vis de deux hydrogènes synaxiaux portés par des carbones en γ (γ_{HH}). Pour cela nous avons comparé les résonances des carbones de groupements méthyles équatoriaux (pris comme références puisqu'on peut les calculer à l'aide des incréments précédents) et axiaux dans les deux dioxannes de la fig. 3.

La différence entre ces deux valeurs de $2\gamma_{HH}$ est probablement liée au degré de substitution du carbone en position 4 ou 6, Dalling et Grant (6) avait déjà noté et étudié un tel phénomène dans les cyclohexanes, décalines et spirobicyclohexane. Des déformations de cycle ou d'angle, augmentant les énergies d'éclipsage entre liaisons, pourraient être responsables de ces variations. Le cas des dioxannes-1,3 est un peu particulier. La différence de longueurs entre liaisons C—C et C—O laisse prévoir deux valeurs possibles pour ces effets γ_{HH} (voir fig. 4). L'hydrogène axial en position 2 est, en effet, plus proche dans l'espace du groupement méthyle étudié que l'hydrogène axial en 4. La valeur de $2\gamma_{HH}$ (−4.6 ppm) relevée pour le premier dioxanne est faible. Elle peut s'expliquer essentiellement par des déformations de la molécule (comme dans le cas des cyclohexanes). Dans le dioxanne diméthylé en 4, l'effet Thorpe–Ingold diminue les possibilités de déformations et la valeur de l'incrément est considérablement augmentée. Nous avons rassemblé dans la fig. 5 quelques résultats expérimentaux relatifs aux effets $2\gamma_{HH}$ pour des méthyles axiaux dans les modèles étudiés.

Applications à l'étude structurale de dioxanne-1,3-4-spirocyclohexanes

Méthyl-2 dioxanne-1,3-4-spiro-tert-*butyl-4′ cyclohexane*-cis *et* -trans *(1 et 2) et Méthyl-2 dioxanne-1,3-4-spiro-1′*-r *diméthyl-3′*-c,*5′*-c *ou 3′*-t,*5′*-t *(3 et 4)*

Nous avons représenté dans le tableau 1, un énantiomère de chacun des deux diastéréoisomères *cis* et *trans* existant pour ces types de composés et ce, dans leur conformation préférentielle.

FIG. 4. Interactions γ_{HH} dans les dioxannes-1,3 (pour un méthyle 4 axial).

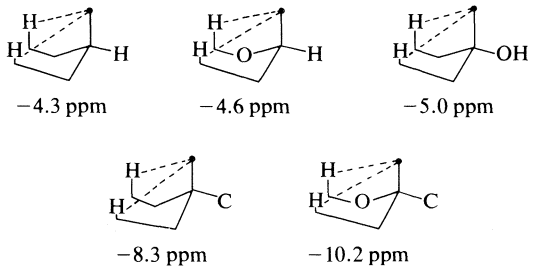

FIG. 5. Effets $2\gamma_{HH}$ pour des carbones de méthyles axiaux seuls ou *gem*-diméthylés (ces valeurs sont les différences expérimentales entre résonances des méthyles équatoriaux et axiaux portés par le même carbone).

Nous avons vu, au cours de l'étude préliminaire, que l'effet β des oxygènes (tableau 2), pour une substitution donnée, dépendait de l'orientation anti ou *gauche* des liaisons O—C par rapport à la liaison C_α—C_β. Pour le carbone 2′ (liaison O_3—C_2 *gauche* par rapport à C_1′—C_2′; incrément $C = -3.4$ du tableau 2) l'influence de O_3 sera la même pour les quatre composés étudiés. Il en est de même pour le carbone 6′ (liaison O_3—C_2 anti par rapport à C_1′—C_6′; incrément $D = -2.1$ du tableau 2). L'environnement de ce premier oxygène et la présence du deuxième hétéroatome n'apporteront qu'une différenciation très faible, difficile à chiffrer.

Le carbone en position 5, dans le cycle dioxannique occupe en revanche, une situation particulière. Il est équatorial sur le cycle cyclohexanique dans les isomères **1** et **3**, axial pour **2** et **4**. Ce seul fait devrait permettre de différencier les spirodioxannes *cis* et *trans*.

Méthode de Grant

(i) Déplacements chimiques des carbones C_2′ et C_6′

Nous avons voulu reconstruire les spirodioxannes (cf. fig. 6) à l'aide des paramètres établis dans la première partie et de la valeur δ_0 des carbones du cyclohexane (27.1 ppm). Nous avons donc tout d'abord introduit la *gem*-diméthylation sur le cyclohexane (cycle A), fermé le deuxième cycle B (spirobicyclohexane) puis introduit les oxygènes (spirodioxanne) et enfin les substituants sur les deux cycles. Nous calculons donc les $\delta_{C_2'}$ et $\delta_{C_6'}$ du spirocyclohexane en les assimilant pour commencer aux δ_{C_2} et δ_{C_6} du diméthyl-1,1 cyclohexane soit

$$\delta_{C_2} = \delta_{C_6} = 27.1 + 9.0 + 5.4 - 1.3G_\beta = 40.2 \text{ ppm}$$

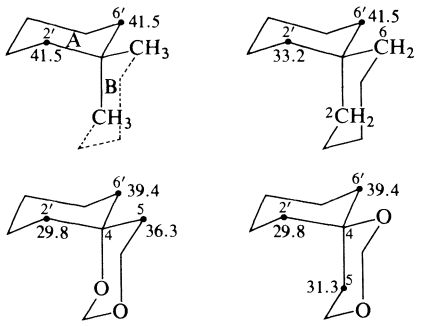

FIG. 6. Spirobicyclohexane et spirodioxannes non substitués.

Toutefois, les hydrogènes des groupes méthyléniques en 2′ et 6′ ont une orientation bien déterminée du fait des contraintes imposées par le reste du cycle A. De plus, leur polarisabilité est bien plus faible que celle des groupements méthyles. Pour ces raisons l'incrément G_β ne semble plus représentatif et peut être négligé (22). Par conséquent:

$$\delta_{C_2'} = \delta_{C_6'} = 27.1 + 9.0 + 5.4 = 41.5 \text{ ppm}$$

Pour tenir compte de la partie du cycle B à refermer (en pointillés sur la fig. 6), on considère les carbones C_2′ et C_6′, comme substituants respectivement axial et équatorial sur ce cycle B. D'autre part on constate que $\delta_{C(\text{Me eq cyclohexane})} = 23.1$ ppm est très voisin de $\delta_{C(\text{Me isobutane})} = 24.5$ ppm; le reste du cycle n'a donc que très peu d'influence sur $\delta_{C(\text{Me eq})}$. En revanche, le fait qu'un substituant méthyle soit axial rend la résonance de son carbone très sensible aux interactions *gauches* avec les liaisons du cycle et à la substitution du carbone en α (cf. fig. 5). Ainsi, le passage d'un méthyle seul de la position équatoriale à la position axiale se traduit par un blindage de −4.3 ppm alors qu'entre les méthyles géminés du triméthyl-1,1,4 cyclohexane on observe une différence de −8.3 ppm (cf. fig. 5). Dans le spirobicyclohexane, on peut alors écrire:

$$\delta_{C_2'} = 41.5 - 8.3 = 33.2 \text{ ppm}$$

($\delta_{exp} = 32.0$ selon réf. 6 à basse température)

$$\delta_{C_6'} = 41.5 - 0 = 41.5 \text{ ppm}$$

($\delta_{exp} = 43.2$ selon réf. 6 à basse température)

En introduisant ensuite les incréments qui se réfèrent à l'influence des oxygènes (tableau 2), on détermine les déplacements chimiques pour un spirodioxanne non substitué:

$$\delta_{C_2'} = 33.2 - 3.4 = 29.8$$

et

$$\delta_{C_6'} = 41.5 - 2.1 = 39.4$$

 **13**	98.6	21.3	83.8	33.4	$C_{4\beta}$ 25.1	25.1	—	66.0	—	—
 **14**	92.6	21.7	78.4	31.9	21.7	35.9	—	63.1	—	—

La comparaison des δ des carbones en position 3 sur le cyclohexane (27.1 ppm) et le *tert*-butyl-1 cyclohexane (27.8 selon réf. 13) fournit l'incrément du tertiobutyle: $t\text{Bu}/C_\gamma = +0.7$. L'application des incréments de Grant (5, 6) donne celui du groupement diméthyl-3,5: $\beta_e + \delta_e = 8.8$ ppm.

Nous avons rassemblé les valeurs δ_{calc} et δ_{exp} dans le tableau 1. L'écart maximal observé est de 1.5 ppm. On confirme ainsi l'attribution des carbones $C_{2'}$ et $C_{6'}$, mais ce calcul ne permet pas de différencier les deux isomères dans chaque série, cette différenciation étant faite sur le carbone C_5.

(ii) Déplacements chimiques des carbones C_5

A partir du déplacement chimique du carbone en position 2 sur le diméthyl-1,1 cyclohexane (40.2 ppm) et en tenant compte des incréments du tableau 2, on calcule le déplacement chimique du carbone 5 du triméthyl-2,4,4 dioxanne-1,3:

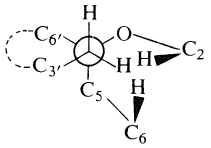
$$\delta_{C_5} = 40.2 - 3.4 - 0.5 = 36.3 \text{ ppm}$$

$$(\delta_{exp} = 35.9)$$

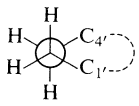
Lorsque l'on referme le cycle (à partir du *gem*-diméthyl-4,4) tout se passe comme si le carbone 5 de la partie dioxannique (cf. fig. 6) était celui d'un groupement méthyle soit équatorial soit axial sur le cycle cyclohexanique. En effet la différence $\Delta\delta = -5.0$ ppm entre les méthyles axial et équatorial en 1 des deux triméthyl-1,3,5 cyclohexanols est très proche de celle observée pour la même situation dans les cyclohexanes. D'autre part l'influence des substituants alkyles en γ ou δ portés par le cycle cyclohexanique peut être considérée comme nulle. Le déplacement chimique du carbone 5 est donc de 36.3 ppm dans les spirodioxannes *cis* et de 36.3 − 5.0 ppm = 31.3 ppm dans leurs isomères *trans*. On peut donc, sans ambiguité, caractériser chacun des isomères dans les deux couples de composés étudiés.

Méthode de Saunders

Les résultats précédents ont été confirmés par cette deuxième méthode. Nous détaillons ci-dessous, à titre d'exemple le calcul dans le cas du composé **2** (cf. tableau 1). Les interactions relatives au carbone $C_{2'}$ peuvent être représentées comme suit:



projection selon $C_{2'}$—$C_{1'}$



projection selon $C_{2'}$—$C_{3'}$

On peut alors écrire:

$$\delta_{C_{2'}} = 16.1 + 3HC + 2HO + 2CC'' + 1CC' + 2\gamma_{HH}$$

$$= 31.5 \text{ ppm}^3$$

$$(\delta_{exp} = 30.8)$$

Pour le carbone $C_{6'}$, on peut écrire de la même façon:

$$\delta_{C_{6'}} = 16.1 + 3HC + 2HO + 2CC'' + 1CC'$$

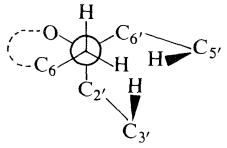
$$= 41.7 \text{ ppm}$$

$$(\delta_{exp} = 41.3)$$

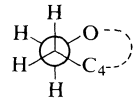
[3]Nous avons choisi pour $2\gamma_{HH}$, la valeur (−10.2) déterminée pour un carbone de groupement méthyle axial géminé en 4 sur le cycle dioxannique (cf. fig. 5) puisque la situation de $C_{2'}$ est analogue.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

La représentation des interactions relatives au carbone C_5 permet d'écrire:



projection selon C_5—C_4



projection selon C_5—C_6

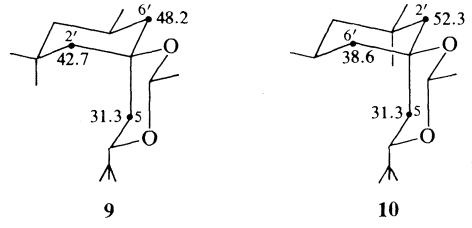
$$\delta_{C_5} = 16.1 + 3HC + 2HO + 2CO'' + 1CC' + 2\gamma_{HH}$$

$$= 30.9 \text{ ppm}^4$$

$$(\delta_{exp} = 30.6)$$

Méthyl-2 dioxanne-1,3-trans *ou* -cis-*4-spiro-triméthyl-3',3',5' cyclohexanes*-trans *(5 et 6) et* tert-*butyl-6*-c *méthyl-2*-r *dioxanne-1,3-4*-t *ou* -c-*spiro-triméthyl-3',3',5' cyclohexanes*-trans *(7 et 8)*

Ces différents composés sont représentés dans le tableau 1. Comme nous l'avons noté dans l'étude en rmn du proton, l'introduction d'un groupe méthyle axial en position 3' conduit à une asymétrie supplémentaire et donc à quatre diastéréoisomères. Cependant, nous n'avons étudié, en rmn du ^{13}C que les composés issus des diols ayant un groupe hydroxyle axial sur le cycle cyclohexanique car nous disposions de quantités trop faibles des spirodioxannes isomères (liaison C_4—O_3 équatoriale) pour pouvoir enregistrer les spectres; de ce fait les conséquences de l'isomérie de position de la liaison C_4—O_3 sur les déplacements chimiques ne peuvent plus être atteintes par comparaison directe. Toutefois les déplacements chimiques du carbone 5 des composés **5**, **6**, **7** et **8** peuvent être atteints à partir du composé **3** puisqu'un méthyle 3' axial n'a pas d'influence sur ce carbone (effet δ_a des réfs 5 et 6). Ainsi, les dérivés tétraméthylés **5** et **6** possèdent bien une liaison C_4—O_3 axiale sur le cycle cyclohexanique puisque les déplacements chimiques trouvés pour le carbone 5 sont respectivement 37.4 et 36.8 ppm en parfait accord avec les valeurs expérimentales et calculées pour le composé **3** (tableau 1). Le fait que, dans les composés analogues **7** et **8**, tertiobutylés en 6, le carbone 5 résonne aussi vers 37 ppm et donc que le substituant tertiobutyle semble n'avoir que peu d'influence sur le carbone en β, peut paraître surprenant. Pour le vérifier nous avons synthétisé le *tert*-butyl-4-*c* méthyl-2-*r* dioxanne-1,3 **13** et enregistré son spectre (tableau 3). Il s'avère que δ_{C_5} égale 25.1 ppm, valeur identique à celle du même carbone dans le méthyl-2 dioxanne-1,3 (15).



9 **10**

FIG. 7. Déplacements chimiques calculés pour les carbones $C_{2'}$ et $C_{6'}$ des isomères **9** et **10** dont les spectres n'ont pu être enregistrés. Nous avons également fait figurer la valeur de δ_{C_5} extrapolée à partir du composé **4**.

Il faut alors différencier **5** de **6** et **7** de **8**. En ajoutant aux valeurs calculées pour $\delta_{C_{2'}}$ et $\delta_{C_{6'}}$, dans le composé **3**, l'incrément β relatif à un groupe méthyle axial géminé (cf. réfs 5 et 6: $\beta_a + G_\beta$), on obtient les déplacements chimiques de ces mêmes carbones dans les quatre composés étudiés. Nous avons rassemblé les résultats de ce calcul dans le tableau 1. La comparaison avec les valeurs expérimentales permet la caractérisation non ambiguë des différents isomères. On peut également prévoir les déplacements chimiques de ces mêmes carbones dans les isomères **9** et **10** (fig. 7).

La méthode de Saunders conduit à de bons résultats (cf. tableau 1) pour les $\delta_{C_{6'}}$ et δ_{C_5} de **5**, **6**, **7** et **8**; il n'en est pas de même pour $\delta_{C_{2'}}$, dont l'écart peut atteindre 7 ppm. Nous avons trouvé un tel écart en calculant le δ_{C_2} dans le tétraméthyl-1,3,3,5-*t* cyclohexanol-1-*r* (25). On peut penser que l'interaction diaxiale-1,3 entre le groupe méthyle en position 3' et la liaison C_4—O_3 est responsable de la variation de certains paramètres de calcul ou qu'elle nécessiterait l'introduction d'un nouvel incrément $\delta_{OHH} \sim -4.0$ ppm (compte tenu des erreurs du calcul).

tert-*Butyl-6*-c *diméthyl-2*-r, *5*-t *ou 5*-c *dioxanne-1,3-4*-t *ou* -c-*spiro-triméthyl-3',3',5' cyclohexanes*-trans *(7*e, *7*a, *8*e, *8*a*) ou* -cis *(9*e, *9*a, *10*e, *10*a*)*

Nous savons que dans cette série, il existe huit isomères puisque la présence d'un groupe méthyle en position 5 introduit une asymétrie supplémentaire (cf. schéma dans la réf. 2). Nous avons pu enregistrer les spectres[5] pour ces huit composés.

L'application de la méthode de Saunders conduit à de mauvais résultats. Ceci était prévisible du fait des fortes interactions entre groupements méthyle en 5 et tertiobutyle en 6 sur le cycle dioxannique dont on ne peut tenir compte avec les incréments déter-

[4]Dans ce cas pour tenir compte de la présence de la liaison C—O portée par le carbone $C_{1'}$, nous avons utilisé la valeur de $2\gamma_{HH} = -5.0$ ppm déterminée à partir des cyclohexanols (cf. fig. 5).

[5]Nous remercions vivement M. Jean-Yves Lallemand, Laboratoire de Chimie de l'E.N.S. Paris, pour l'enregistrement de ces spectres.

*Les valeurs entre crochets ou parenthèses peuvent être échangées.

minés plus haut. En revanche la méthode de Grant semble mieux adaptée puisqu'elle permet de compléter le système d'incréments pour évaluer les interactions nouvelles créées par le nombre grandissant de substitutions.

Dans ce but, nous avons enregistré les spectres des *tert*-butyl-6-*c* tétraméthyl-2-*r*, 4,4,5-*c* et 5-*t* dioxannes-1,3 (**11** et **12** (tableau 3)). On remarque tout d'abord, que les carbones des groupements méthyles axial 5α′ (isomère *cis*) ou équatorial 5α (isomère *trans*) résonnent respectivement à 9.6 et 14.0 ppm. On a donc un moyen de distinguer, dans la série de spirodioxannes étudiée, les isomères qui relèvent de ce changement d'orientation.

D'autre part, nous avons déjà noté que le groupement tertiobutyle en position 6 n'apporte aucune perturbation au δ_{C_5}. La comparaison directe du triméthyl-2,4, et des *tert*-butyl-6-*c* tétraméthyl-2-*r*, 4,4,5 dioxannes-1,3-*cis* et -*trans* nous conduit à l'évaluation des effets α d'un groupe méthyle en 5:

$$\alpha_e = 40.9 - 35.9 = +5.0$$

$$\alpha_a = 37.6 - 35.9 = +1.7$$

Ces deux valeurs tiennent compte des effets secondaires dus aux substituants vicinaux en 4 et 6 ce qui explique qu'elles soient différentes de celles relevées par ailleurs ($\alpha_e = \alpha_a = 3.1$ ppm (15, 16)).

On peut alors déterminer δ_{C_5} pour les huit composés étudiés à partir des valeurs calculées lues pour ce carbone dans le tableau 1 (**7** et **8**) et la fig. 7 (**9** et **10**) et classer les huit diastéréoisomères en quatre groupes de deux composés chacun: liaison C_4—O_3 axiale: Me_{5e} (**7***e*, **8***e*) → $\delta_{C_5} = 36.3 + 5.0 = 41.3$; Me_{5a} (**7***a*, **8***a*) → $\delta_{C_5} = 36.3 + 1.7 = 38.0$; liaison C_4—O_3 équatoriale: Me_{5e} (**9***e*, **10***e*) → $\delta_{C_5} = 31.3 + 5.0 = 36.3$; Me_{5a} (**9***a*, **10***a*) → $\delta_{C_5} = 31.3 + 1.7 = 33.0$. Le classement ainsi obtenu est en accord avec la remarque précédente sur les valeurs de δ des groupements méthyles 5α et 5α′.

Nous avons vu dans la série non méthylée en 5, comment l'on pouvait distinguer les isomères dans ces groupes de deux, par le calcul de $\delta_{C_{2'}}$ et $\delta_{C_{6'}}$. Dans le cas présent, il suffit de connaître les incréments d'effets intercycles liés à la présence du groupe méthyle en 5. Bien que ces effets soient très sensibles à toutes variations de géométrie dans les molécules étudiées (6), on peut toutefois utiliser les paramètres suivants de la fig. 8.

Les déplacements chimiques ainsi déterminés en ajoutant les incréments de la fig. 8 aux valeurs de $\delta_{C_{2'}}$ et $\delta_{C_{6'}}$ des composés **7**, **8**, **9** et **10** (tableau 1 et fig. 7) figurent dans le tableau 1. Ils ont permis de distinguer sans ambiguité **7***e* de **8***e*, **7***a* de **8***a* et **9***a* de **10***a*.

Les écarts observés (parfois supérieurs à 2.5 ppm)

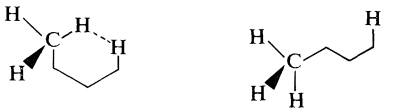

FIG. 8. Incréments d'effets intercycles déduits des résultats de la réf. 6.

sont plus grands que ceux notés précédemment. Ceci provient, à notre avis, d'une part de l'accumulation des erreurs lorsque l'on utilise un nombre toujours plus grand d'incréments et de la variation des incréments utilisés pour ce dernier calcul.

Les composés **9***e* et **10***e* posent un problème conformationnel. Si l'on admet la conformation double chaise, la présence d'un méthyle équatorial en 5 crée une interaction très importante avec le méthyle axial en 3′. On doit alors envisager une conformation croisée pour l'un ou l'autre (ou les deux) cycle(s) de ces molécules. Les spectres de rmn du ^{13}C pour ces deux isomères sont très voisins. L'attribution faite dans le tableau 1 n'a pu l'être qu'à partir des analyses des spectres de rmn du proton et des filiations chimiques établies lors de la synthèse (23) de ces deux produits.

On peut toutefois noter que: (*i*) dans le composé **9***e*, les fortes valeurs des résonances des carbones C_2, C_5, C_6 et $C_{5\alpha}$ suggèrent une légère déformation du cycle dioxannique. Les valeurs relevées pour les mêmes carbones dans **10***e* semblent plus "normales." (*ii*) Dans les deux composés: les résonances des carbones $C_{3'\alpha}$ et $C_{3'\alpha'}$ sont très proches alors que dans **9***a* et **10***a*, $\Delta\delta_{C_{3'\alpha}-C_{3'\alpha'}} \simeq 7$ ppm (cf. tableau 4); on trouve pour les carbones $C_{2'}$ et $C_{6'}$ comparables des valeurs de déplacements chimiques pratiquement identiques.

$$\delta_{C_{2'}}(\mathbf{9}e) = \delta_{C_{6'}}(\mathbf{10}e) \simeq 40.5 \text{ ppm}$$

et

$$\delta_{C_{6'}}(\mathbf{9}e) = \delta_{C_{2'}}(\mathbf{10}e) \simeq 47 \text{ ppm}$$

Ces remarques, et celles déjà notées lors de l'étude en rmn du proton, conduisent à proposer pour ces deux molécules des structures où le cycle cyclohexanique se trouverait en conformation croisée; le cycle dioxannique ne serait que peu (**9***e*) ou pas (**10***e*) déformé.

Conclusion

Au cours du présent travail, nous avons établi des systèmes d'incréments permettant le calcul empirique du déplacement chimique en rmn du ^{13}C. Ces paramètres, déterminés à partir de nos propres résultats et de ceux de la littérature, peuvent être employés, indépendamment de tout autre technique, à la détermination de structure de molécules complexes.

Toute méthode de calcul empirique peut être envisagée, soit à partir de l'expérience par un traitement statistique des données (Dalling et Grant (5–8) ont opéré de cette façon dans le cas des cyclohexanes polyméthylés), soit en donnant une signification précise au phénomène que l'on étudie et en déterminant les incréments correspondants (c'est le procédé choisi par Saunders et coll. (9–12) dans une étude des effets β en série décalinique).

Nous avons, pour des cycles à six chaînons, les

cyclohexanols et les dioxannes, appliqué ces deux méthodes à la détermination des influences de substituants méthyles et d'oxygènes intra ou exocycliques. De cette étude il ressort que (*i*) la méthode de Grant conduit à des valeurs de δ en excellent accord avec l'expérience. En effet, on peut généralement trouver un incrément pour décrire une situation nouvelle. Le système comporte donc un grand nombre de paramètres dont la signification réelle reste toutefois à préciser; (*ii*) la méthode de Saunders, en revanche, ne nécessite qu'un petit nombre de paramètres reliés aux interactions gauches et spatiales entre liaisons. Il est alors plus difficile d'introduire de nouveaux incréments et on ne rend pas compte de toutes les situations possibles.

Dans le cas particulier des dioxannes-1,3-4-spirocyclohexanes, ces modes de calcul du déplacement chimique permettent des attributions de structure non ambiguës. En ce qui concerne l'analyse conformationnelle de tels dérivés, les renseignements obtenus par l'étude des déplacements chimiques des carbones sont comparables à ceux atteints en rmn du proton.

CHRISTOPHER OWEN BENDER, DEE W. BROOKS, WILLIAM CHENG, DOUGLAS DOLMAN, SEAMUS F. O'SHEA, and SIDNEY S. SHUGARMAN. Can. J. Chem. **56**, 3027 (1978).

The direct photolysis of 2-cyanobenzobarrelene (**4**) yields 5- and 7-cyanobenzocyclooctatetraene (**6**, $\Phi = 0.08$ and **7**, $\Phi = 0.25$) and 1-cyanobenzosemibullvalene (**8**, $\Phi = 0.05$), whereas the acetophenone sensitized irradiation of **4** yields only **8** ($\Phi = 0.35$). Deuterium labelling studies suggest that **7** derives from an initial $2\pi + 2\pi$ cycloaddition between the vinyl and vinylcyano bridges of **4**, whereas **8**, resulting from direct or sensitized irradiations of **4**, derives from di-π-methane rearrangement involving initial vinyl–vinylcyano bridging. The observed initial bonding preferences of the $2\pi + 2\pi$ cycloadditions and di-π-methane rearrangement of **4** are in accord with predictions based upon CNDO-CI calculations of changes in atom–atom interaction energies between possible bridging sites in singlet and triplet excited states of **4**.

CHRISTOPHER OWEN BENDER, DEE W. BROOKS, WILLIAM CHENG, DOUGLAS DOLMAN, SEAMUS F. O'SHEA et SIDNEY S. SHUGARMAN. Can. J. Chem. **56**, 3027 (1978).

La photolyse directe du cyano-2 benzobarrelène (**4**) conduit au cyano-5 et -7 benzocyclooctatetraène (**6**, $\Phi = 0.08$ et **7**, $\Phi = 0.25$) et au cyano-1 benzo semi-bullvalène (**8**, $\Phi = 0.05$), tandis que l'irradiation sensibilisée par l'acétophenone de **4** conduit à **8** uniquement ($\Phi = 0.35$). Des études de marquages au deuterium suggerènt que **7** dérive d'une réaction initiale de cycloaddition $2\pi + 2\pi$ qui procède par liaison entre les ponts vinyle et vinylcyano de **4**, tandis que **8**, resultant de la photolyse directe ou sensibilisée de **4**, provient d'un réarrangement di-π-méthane qui procède par liaison entre les ponts vinyle et vinylcyano de **4**. Les liaisons initiales observées des cycloadditions $2\pi + 2\pi$ et du réarrangement di-π-méthane sont en accord avec les prédictions qui proviennent de calculs des changements d'énergies d'interactions atome–atome entre les sites de liaisons possibles de l'état excité singulet et triplet de **4**.

Introduction

Zimmerman and co-workers (1) have reported that benzobarrelene (**1**) undergoes two types of photochemical rearrangement, one leading to cyclooctatetraene (COT) product **2**, which was rationalized as proceeding from the singlet excited state of **1** via $2\pi + 2\pi$ cycloaddition, and the other leading to semibullvalene (SB) product **3** from the triplet excited state via di-π-methane rearrangement (1). Furthermore, deuterium labelling studies revealed that of the two bonding routes (Scheme 1, routes *i* and *ii*) which could a priori furnish the COT product (**2**), the benzo–vinyl pathway (Scheme 1, route *i*) was mainly utilized, while the SB product (**3**) which could also arise a priori from two bonding routes (Scheme 1, routes *iii* and *iv*) was uniquely provided by the vinyl–vinyl pathway (Scheme 1, route *iii*).

Within the perspective of these two rearrangement types, the potential for mechanistic variation and hence challenge to theoretical predictions can, in principle, be maximized by the introduction of a substituent in a vinyl location, so that the symmetry of the benzobarrelene skeleton is destroyed and hence the number of possible initial bonding modes is increased to three $2\pi + 2\pi$ cycloadditions and six di-π-methane rearrangements. In this paper we report on the mechanistic aspects of the photochemistry of 2-cyanobenzobarrelene (**4**) and comment on the ability of some predictive methods to rationalize the product formations.[1]

Results

2-Cyanobenzobarrelene (**4**) was prepared by the addition of benzyne to bromobenzene, followed by treatment of the bromobarrelene **5** with cuprous cyanide (see Scheme 2). The structure of **4** follows from the mode of synthesis, the similarity of the nmr spectrum to that of the naphtho analogue (**9**) of **4**, and the observation that it undergoes retro-Diels–Alder reaction in the presence of lithium cyclohexylamide to yield naphthalene (45%) (cf. the formation of anthracene from **9** under similar conditions; ref. 5).

The direct irradiation of **4** yields three primary photoproducts isomeric with the starting material: 5- and 7-cyanobenzo-COT (**6** and **7**) and 1-cyanobenzotricyclo[3.3.0.$0^{2,8}$]octa-3,6-diene (i.e., 1-cyanobenzosemibullvalene (**8**)) (see Scheme 3). The photoproducts were separated by chromatography and were obtained in crystalline form.

[1]Some preliminary details of the photochemistry of **4** have appeared in two communications (2, 3).

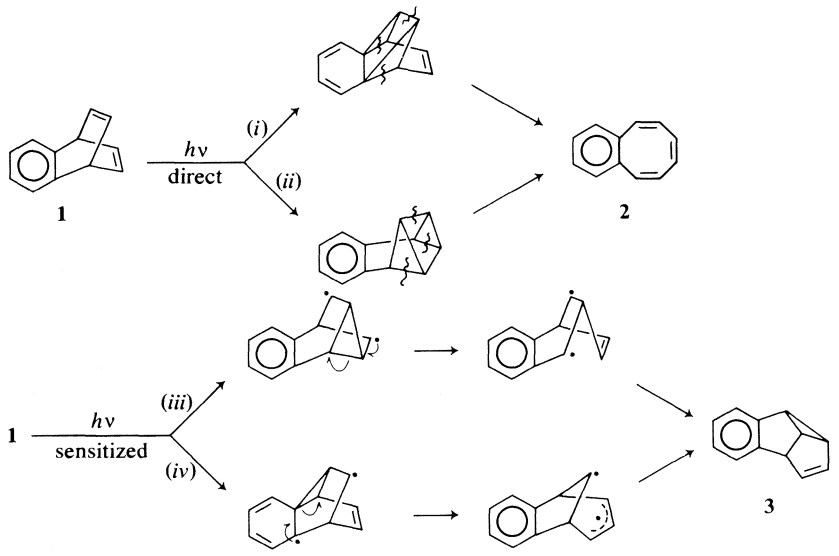
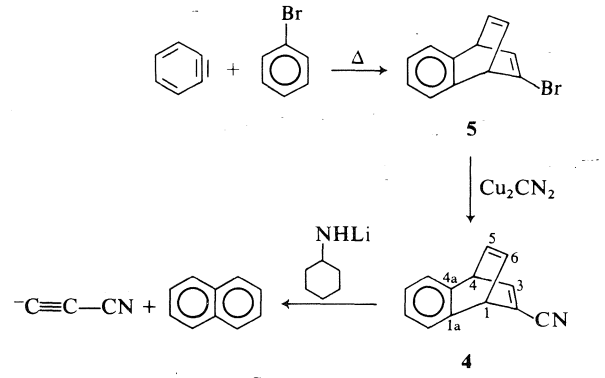


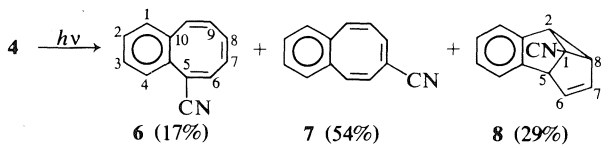
SCHEME 1

The structures of **6** and **7** were deduced from nmr spectral evidence. As expected for COT derivatives only absorptions in the aromatic-olefinic region of the spectra were observed. The nmr data are shown in Table 1 and for the purposes of comparison also



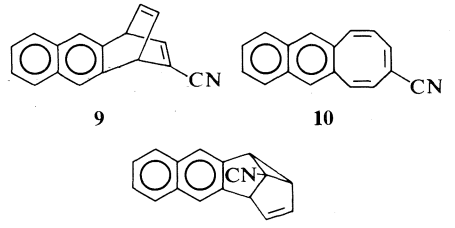
SCHEME 2

included are those of the known COT's **2** (1) and **10** (5). Additional support for the assigned structures comes from spin-decoupling experiments (see footnotes in Table 1) and, in the case of **6**, from examination of the nmr spectrum of the 8-deuterio derivative **17** (see Table 1), unambiguously provided by the direct irradiation of 5-deuterio-2-cyanobenzobarrelene (**15**) (*vide infra*; see Scheme 5).



SCHEME 3

The structure of the SB product **8** was ascertained from the nmr spectrum (see Experimental) which was closely similar to that reported for **11** (5). Further evidence in favour of the assignment stems from the observation that **8** isomerizes to 6-cyanobenzo-COT (**13**) upon direct irradiation (cf. the photoisomeriza-



tion of **3** to **2** (1)) (see Scheme 4). The nmr data for **13** are given in Table 1. Assistance with the signal assignments was obtained from examination of the nmr spectrum of the 8-deuterio derivative **14**. Compound **14** was prepared from the direct irradiation of 7-deuterio-1-cyanobenzo-SB (**12**) (*vide infra*), envisaged, by analogy to observations with perdeuteriobenzo-SB (1), to result from cleavage of the C-2—C-8 and C-1—C-5 bonds.

In accord with the assigned structures, the deshielding effect of the cyano group on the adjacent

coplanar vinyl protons of **6** (H-6), **7** (H-8), and **13** (H-5) relative to the corresponding protons in **2** lies within the range 0.73–0.83 ppm and compares well with the reported chemical shift substituent constant of 0.8 for the *cis*-proton of acrylonitrile (6).

The COT's **6** and **7** were irradiated separately under the same conditions as used for **4** in order to examine for secondary photochemical processes. Both were found to be reasonably stable and long irradiation times were required to cause any disappearance of starting material. In the case of **6**, identifiable product was not obtained. Semibullvalene **8** (18% yield), however, was formed from COT **7** together with much polymeric material. The sensitized irradiation of **7** with benzophenone at 328 nm did not lead to detectable amounts of SB **8**. Since the photoreduction of benzophenone was efficiently quenched in the presence of **7**, it seems certain that triplet energy transfer to the COT had been successful; **8**, therefore, derives from the singlet excited state of **7**.

In contrast to the direct irradiation of **4**, sensitization with acetophenone leads cleanly to the formation of a single product, 1-CN-SB (**8**). The quantum yields for this and other transformations observed in this study are given in Table 2. In the case of the conversion of **8** to **13** attempts to sensitize the reaction with either acetophenone or acetone failed; the starting material slowly disappeared to give unidentified products but the formation of **13** was shown to be absent by nmr and tlc.

Singlet and Triplet Energies of 4

The singlet energy of **4** in cyclohexane solution at room temperature was determined to be 96 kcal mol^{-1} from intersection of the absorption and fluorescence spectra. The triplet energy of **4** could not

be obtained spectrometrically since no phosphorescence in isopentane – methylcyclohexane glass at 77 K could be detected. However, an 'effective' triplet energy at room temperature in benzene solution of $> 56 < 59$ kcal mol^{-1} was determined from triplet sensitization experiments: the triplet sensitizers acetophenone (74 kcal mol^{-1}), benzophenone (69 kcal mol^{-1}), thioxanthone (65 kcal mol^{-1}), Michler's ketone (61 kcal mol^{-1}), and 2-acetonaphthone (59 kcal mol^{-1}) gave $\Phi_8 = 0.33 \pm 0.03$, whereas 1-acetonaphthone (56 kcal mol^{-1}) gave $\Phi_8 \simeq 0.00$.

Mechanistic Considerations

Inspection of the possible modes of $2\pi + 2\pi$ cycloadditions available to barrelene **4** shows that whereas **6** can derive from only one route (Scheme 5, route *i*), that involving initial bridging between the benzo and vinylcyano group, there are two a priori cycloaddition pathways that can account for the formation of **7**: initial benzo-vinyl bridging (Scheme 5, route *ii*) and initial vinyl–vinylcyano bridging (Scheme 5, route *iii*).

To evaluate the relative importance of routes *ii* and *iii* the direct irradiation of the deuterated barrelene **15** (93% d_1 at C-5; prepared as in the case of **4** but replacing the bromobenzene by *p*-deuteriobromobenzene) was investigated. The nmr spectrum of the deuterated 7-CN-COT product isolated from the photolysate was consistent only with the β-labelled compound **22**; the olefinic region of the nmr spectrum showed a doublet centered at τ 3.32 (H-5, $J = 11.5$ Hz), a singlet at τ 3.35 (H-10), a singlet at τ 3.46 (H-8), and a doublet at τ 4.11 (H-6, $J = 11.5$ Hz). (See Table 3 for H-distributions.) Thus 7-CN-COT (**7**) is uniquely provided by the vinyl–vinylcyano pathway (Scheme 5, route *iii*).

As anticipated for the single $2\pi + 2\pi$ cycloaddition pathway capable of leading to **6** (Scheme 5, route *i*), the deuterated material isolated from the photolysis of **15** contained exclusive labelling at C-8 (see Table 1 for nmr data) and hence is **17**.

Nuclear magnetic resonance examination of the labelled SB product **12** from either the direct or the sensitized irradiations of barrelene **15** showed the deuterium to be located at C-7 (see Scheme 6). However, this labelling does not allow delineation of a unique pathway for the di-π-methane rearrangement of the barrelene since there are two routes which could furnish **12**: route *i* (Scheme 6), which commences with aromatic–vinylcyano bonding (between C-3 and C-4*a*), and route *ii* (Scheme 6), initiating with vinyl–vinylcyano bonding (between C-3 and C-5).

A means of determining the occurrence of routes *i* and/or *ii* (Scheme 6) was obtained by examining the photolysis of the mixture of deuterated barrelenes **23***b*. The mixture consisted of an equal amount of two singly labelled isomers, one incorporating deuterium

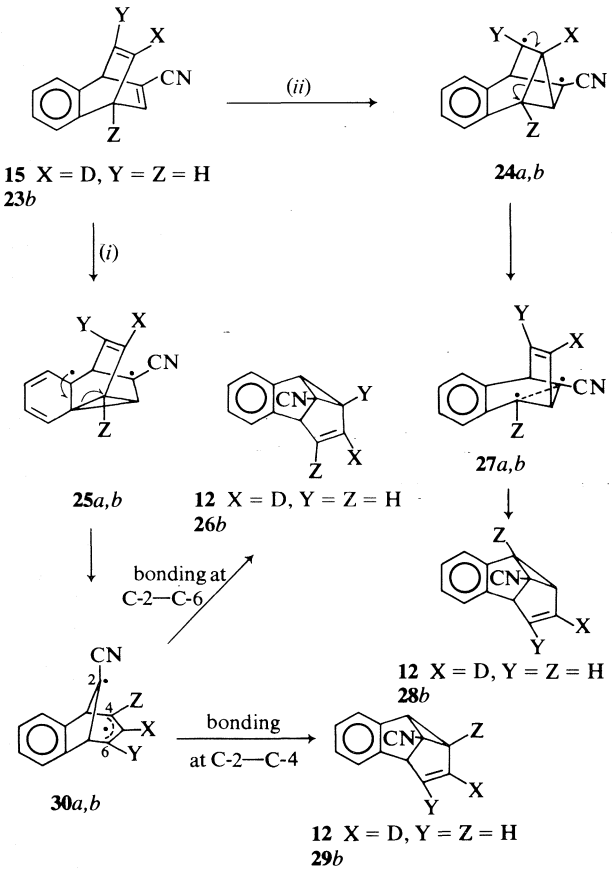

SCHEME 6. For series *a*, X = D, Y = Z = H. For series *b*, individual structures represent an approximately 50:50 mixture of two component compounds, each singly labelled with deuterium at the positions designated by Y and Z; X = H.

(94 ± 3%) at C-4 and the other deuterium (92 ± 4%) at C-6, and was prepared as in the case of **4** but replacing the bromobenzene by *m*-deuteriobromobenzene. Within experimental error, no deuterium isotope effects were discernible in the benzyne addition stage or in the subsequent photoisomerizations.

The hydrogen distributions of the 1-CN-SB material isolated from the direct, acetophenone, and 2-acetonaphthone sensitized irradiations of deuterobarrelene mixture **23***b* are the same within experimental error (see Table 4); half of the deuterium is located at C-2 and half at C-6 (i.e., consistent with **28***b*). Thus route *ii* (Scheme 6) alone accounts for the di-π-methane rearrangement of barrelene **4** during the formation of SB product from direct or sensitized irradiations of **4**.

With the SB mixture **28***b* at hand, it was pertinent to investigate its photolysis to ascertain whether a vinylcyclopropane rearrangement leading to the SB mixture **31** occurs. Such a photoisomerization with the dicarbomethoxy-SB **33** has previously been found to yield **34** (see Scheme 7) (7). The nmr spectrum of the SB material recovered from the direct irradiation of mixtures **28***b* (>80% loss of starting material, 63% being converted to deuterated mixture **32**, containing equal amounts of deuterium at C-5 and C-9) was essentially identical to that of the starting material (see Table 4, case *6*). Irradiation with acetone as sensitizer resulted in the slow disappearance of **28***b* to give unidentified products but again there was no

detectable change in the labelling pattern in the recovered starting material after >80% consumption (see Table 4, case *7*). Thus the photochemical vinylcyclopropane rearrangement does not operate in 1-CN-SB (**8**).

Finally, the direct irradiation of COT **35** (**35** was isolated as the major product of the direct irradiation of **23***b*) was carried out. This was important to do because of the possibility that some of the SB **8** formed during the direct irradiation of barrelene **4** derives, in part, from the secondary photolysis of the primary COT **7** photoproduct. That this is not so, was demonstrated by the fact that COT **35** leads to SB **36**, containing a different labelling pattern than SB **28***b* formed from the direct irradiation of **23***b*, i.e., in **36**, the available deuterium is located at C-5 (50%) and at C-8 (50%); no SB product containing deuterium at C-6 and C-1 was observable (see Scheme 8). Thus SB **8** formed from the direct irradiation of **4** appears to be due entirely to the primary photolysis of **4**, under the conditions of irradiation used in this study. Since the quantum yield for the formation of **8** from **7** is so low and the formation of intermediates has not been excluded, mechanistic speculation as to the production of **8** is deferred.

Discussion

The excited state of **4**, yielding SB **8** upon sensitization with sensitizers of triplet energy ranging from 59 to 74 kcal mol^{-1}, can reasonably be assigned to T_1 since (*a*) the quantum yields for the formation of **8** remain essentially constant over the sensitizer energy range and (*b*) the deuterated barrelene mixture **23***b*, employed in runs with the lowest and highest sensitizers (i.e., 2-acetonaphthone and acetophenone), gives SB product containing the same label distributions in both cases (see Table 4). The excited state responsible for the formation of COT's **6** and **7** upon direct irradiation of **4** with 276 nm light (103 kcal mol^{-1}) is attributed to S_1 ($E_{s_1} \simeq 97$ kcal mol^{-1}); they are not formed during sensitized runs. In the case of **8**, when generated from the direct irradiation of **4**, T_1 may be involved since the deuterated barrelene mixture **23***b* leads to SB material (**28***b*) containing the same label distributions from direct and sensitized irradiations. Furthermore, the quantum yield data (Table 2) show the formation of **8** from the direct irradiation of **4** to be much less efficient than from sensitized runs as expected for a process involving intersystem crossing. However, these data do not rule out the possibility that the S_1 excited state of **4** provides **8** since it is not known that S_1 would have followed an alternative mechanistic course.

With respect to the COT formations from **4**, the results from the labelling experiments with **15** (see Table 3 and Scheme 5) reveal a dramatic substitution effect on the initial $2\pi + 2\pi$ bonding preferences. Thus for benzobarrelene itself Zimmerman and his co-workers (1) have shown that the benzo–vinyl bonding pathway (Scheme 1, route *i*) predominates to the extent of $94 \pm 2\%$ (1). In the present case bridging to the benzo moiety constitutes only a minor route (24%, Scheme 5, route *i*) and then only to the more substituted ethylene.

This result was of considerable interest when first reported by us (2) because it did not support the pericyclic formulations proposed by Epiotis. Epiotis (8) had reasoned that polar $2\pi + 2\pi$ cyclizations occurring from the first excited singlet state are expected to be [s + a] stereoselective and that in systems where geometric constraints demand an [s + s] cyclization mode, the reaction is pericyclically forbidden. Extension of this concept to the case of barrelene **4**, where there are three different $2\pi + 2\pi$ initial bridging options, would lead to the conclusion that bonding between the least polar bridges (i.e., route *ii*, Scheme 5) should be the most favored. This is not seen to be the case for **4** nor for any of the polar benzobarrelene examined to date (2, 7, 9). Epiotis has subsequently pointed out to us that revised and more detailed calculations indicate that for *intramolecular* photocycloadditions, the skeletal restrictions prohibit the introduction of a sufficient number of donor and/or acceptor groups to render the reaction 'highly polar.'[2] Thus previous examples suggested by Epiotis to be in accord with prediction are now inappropriate (8).

Another predictive method is also rendered inutile by the present work. We had previously reported, in connection with the photochemistry of dimethyl 2,3-benzobicyclo[2.2.2]octatetraene-5,6-dicarboxylate, and its 10-methoxy derivative, that alterations in initial $2\pi + 2\pi$ bonding preferences of polarly substituted benzobarrelenes seem to be related to changes in donor–acceptor, (i.e., charge–transfer) properties of the addend–addend complexes engendered in the bridging process (7, 9). However, the limiting factor that invalidates this interpretation in the case of **4**, is that for models approximating the individual addends

[2]We thank the author for a preprint of his manuscript (10).

(e.g., benzene, IP_V = 9.25 eV (11), ethylene, IP_V = 10.51 eV (11), and acrylonitrile, IP_V = 10.88 eV (12)), the aromatic moiety always has a smaller vertical ionization potential (IP_V) than the noncyanolated vinyl bridge, at any consistent level of substitution (e.g., *o*-xylene, IP_V = 8.57 eV (11) and *cis*-2-butene, IP_V = 9.13 eV (12); or tetralin, IP_V = 8.44 eV (11) and cyclohexene, IP_V = 9.12 eV (11)). Thus, contrary to observation, excited-state charge–transfer interaction, and hence bonding, involving the aromatic addend would erroneously be predicted to be favored.

A rationale which is in accord with observations derives from CNDO-CI calculations of changes in atom–atom interaction energies between possible bridging sites resulting from excitation to the singlet excited state of **4**. The total molecular energy calculated by NDO-type methods can be rewritten in terms of a sum of one-atom energies plus a sum of two-atom interaction energies for all distinct pairs of atoms in the molecule (14); this is a consequence of the neglect of all three- and four-centre electron interaction integrals which, in *ab initio* calculations give rise to interaction energies involving three and four atoms simultaneously. Naively, one can say that the changes in atom–atom interaction energies that result from electron excitation give rise to forces which make the atoms move. By resolving the excitation energy into atom–atom components one can make predictions about the initial motions and, in rigid systems, the possible product.

Related approaches using the changes in the bond-order matrix elements provide the basis for the Woodward–Hoffman rules and a similar scheme which is based on orbital–orbital interaction energies was recently reported by Zimmerman *et al.* (13). Both the bond-order and orbital–orbital energy approaches were investigated for the present system. However, it was felt that the additional difficulty introduced by the nonplanar structure gives rise to ambiguities; for example, the changes in the 16 orbital–orbital interaction energies for a given pair of atoms are not all of the same sign, unlike the case of planar conjugated systems where one need only consider the effects of the interaction of the π orbitals belonging to the atoms in question. The atom–atom energy, the sum of all orbital–orbital interactions between the pair of atoms, seems better suited to the discussion of nonplanar molecules, where the strict σ–π separation is lost. The extension of the atom–atom analysis to excitation energies follows in a straightforward (but tedious) way from the method used for ground states; details are available from the authors.

This approach has a number of strengths and weaknesses. It is simple to implement and understand. The interpretations of the results is reasonably straightforward: atom pairs for which the change in interaction energy is attractive tend to move towards one another and atoms which are repelled from one another move apart.

There is no ambiguity about the geometry of the molecule, an important consideration since the molecular energy is a sensitive function of the geometry, and there are no difficulties relating to partitioning the molecule. On the other hand the CNDO method is an approximation, and our assumption of the relationship between the changes in the atom–atom energies and the reaction coordinate is questionable; a more extensive study of this point is underway.

The predictions for the product distributions of the photolyses of the parent benzobarrelene and the 2-cyanobenzobarrelene are given in Table 5 for both the singlet and triplet (*vide infra*) mediated reactions. The calculations refer to the structure which minimizes the ground-state molecular energy in the CNDO/2 approximation;[3] the CI calculations for the excited state were performed in three different parameterizations: theoretical (14), Pariser, and Mataga (ref. 15 and references cited therein), the last two being designed to give the best descriptions of the triplet and singlet states respectively. For the singlet excited state (S_1) the results suggest the formation of the intermediate **20**, and hence the product **22**, as the most probable pathway with the intermediate **16**, and product **6**, as the next most probable pathway, in agreement with the experimental findings. As may also be seen from Table 5, the pathway predicted by this method to be most probable in the singlet photolysis of benzobarrelene (**1**) is again consistent with experimental results (1).

Finally with respect to the singlet cycloadditions of **4**, the observation that **7** but no **13** is formed from the proposed intermediate **20***a* can be attributed to the preferred rupture of the C-1—C-2 bond of **20***a*, since favorable stabilization from the cyano and benzo groups is afforded both radical centres in the ensuing species **21***a*. An alternative explanation is provided by the fact that in cyclopropanes, electron withdrawing substituents (here, the cyano group in **20***a*), strengthen the bond opposite, while weakening the bonds adjacent (16).

Turning now to the triplet excited state of **4**, the main reactivity appears to be similar to that of benzobarrelene (*1*), namely, efficient semibullvalene formation (cf. Φ = 0.35 for **8** and 0.52 for **3** (17)), deriving from di-π-methane rearrangement involving initial bridging between the vinyl bridges (Scheme 6,

[3]Calculations were performed using a modified and extended version of the CNDO/M program (QCPE #315) originally written by Jaffé and co-workers (21).

TABLE 5. Changes in atom–atom energies (eV) accompanying electronic excitation to the lowest singlet (S_1) and triplet (T_1) states of **1** and **4**[a]

[a]Calculated by the CNDO/CI method using the theoretical (T), Pariser (P), and Mataga (M) parameterizations. The underlined values are the most enhanced interactions calculated for the given transition using the specified integral.

route *ii*). The regiospecificity observed in the vinyl–vinylcyano bonding in the case of **4** can be attributed to the availability of stabilization of the radical centre at C-2 in species **24** via the cyano group.

Recently Santiago and Houk (18) reported a molecular orbital model to account for the direction of preferred di-π-methane bridging in polarly substituted benzonorbornadienes and for barrelene **4**. In this approach, CNDO-CI calculations were performed on a model transition state consisting of a stacked, parallel plane of addends approximating the individual bridging moieties. Although the correct bridging preferences were obtained for the benzonorbornadienes, the predictions for **4** were found to be incorrect (3). The atom–atom interaction energies for the triplet state of **4**, resulting from our rigid model calculations (*vide supra*), Table 5, suggest that the formation of intermediate **24** leading to the product **12** is the preferred pathway, in agreement with experiment. The second most probable pathway involves bridging between C-2 and C-6 and would lead to products which are not observed. The Mataga parameterization predicts a slight preference for this pathway over that involving **24** but this discrepancy is not too disturbing since the Mataga integrals are optimized with respect to the singlet calculation. For the parent benzobarrelene (**1**) the predicted most probable pathway for the triplet excited-state reaction is also consistent with experimental results (1) (see Table 5). In view of the simplicity of the approach the agreement between the predictions and the observed results is encouraging; it remains to be seen if the method is useful under more general conditions.

Experimental

The nmr spectra were recorded on Varian HA-100 or A-60 instruments with TMS as internal standard. The ir spectra were recorded on a Perkin-Elmer Model 337 spectrophotometer, the uv spectra on a Cary 15 spectrophotometer, and the mass spectra on an MS 9 (A.E.I.). All melting points are uncorrected. Elemental analyses were performed by Galbraith Labs. Inc., Knoxville, TN. Cyclohexane and benzene solvents were prepared for photolyses by scrubbing with 10% of their volume of 30% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. Solid triplet sensitizers were sublimed and recrystallized before use and liquid sensitizers were distilled. Nuclear magnetic resonance chemical shifts are given in τ units and *J* values in hertz; uv maxima are given in nanometres (ε); ir bands are given in reciprocal centimetres. Thin-layer chromatographic separations were carried out on Merck plates, 20 cm × 20 cm, 0.25 mm layer of Silica Gel 60 F-254.

2-Bromo-1,4-dihydro-1,4-ethenonaphthalene (5)

A 12.5 ml portion of isoamyl nitrite was added to a stirred, ice-cooled mixture of 6.85 g (49.95 mmol) of anthranilic acid and 0.08 g of trifluoroacetic acid in 75 ml of dioxane. The stirred mixture was allowed to warm to room temperature during 80 min. The benzene diazonium carboxylate salt was centrifuged and the supernatant liquid discarded. The salt was then washed via centrifugation, twice with dioxane and once with bromobenzene. The salt, slurried in bromobenzene (30 ml), was added to 500 ml of bromobenzene and stirred at 45°C for 24 h under a dry nitrogen atmosphere. The mixture was concentrated *in vacuo* and the residue, dissolved in 10 ml of benzene, was column chromatographed on silicic acid (100–200 mesh). Elution with cyclohexane gave crude **5** from early fractions and crystallization from ethanol gave 187 mg (1.6%) of colorless crystals, mp 50–51°C: uv (cyclohexane): 246 sh (1050), 260 (760), 268 (720), and 277 (640); nmr (60 MHz, CCl_4): 2.80–3.45 (m, 7H, aromatic and vinyl), and 5.12–5.52 (m, 2H, bridgehead). *Anal.* calcd. for $C_{12}H_9Br$: C 61.83, H 3.98, Br 34.28; found: C 61.79, H 3.90, Br 34.20.

2-Cyano-1,4-dihydro-1,4-ethenonaphthalene (4)

A solution of 187 mg (0.80 mmol) of **5** and 171 mg (0.86 mmol) of cuprous cyanide in 40 ml of dry DMF was stirred under reflux for 4 h. The cooled mixture was diluted with 200 ml of benzene and extracted in turn with 5% aqueous $FeCl_3$ (2 × 50 ml), 5% aqueous NaOH (50 ml), and water (50 ml). The benzene solution was concentrated *in vacuo* and the residue column chromatographed on silica gel (60–200 mesh). Elution with cyclohexane removed unreacted starting

material. Elution with 1% ether–cyclohexane gave crude **4** and crystallization from ethanol gave 126.5 mg (74%) of colorless crystals, mp 66–67°C: ir (KBr): 2210, C≡N; uv (cyclohexane): 266 sh (1080), 268 (1120), 273 (1090), 276 (1080), and 283 sh (710); nmr (100 MHz, CCl_4): 2.62 (dd, 1H, H-3, $J_{3,4} = 6$, $J_{1,3} = 2$), 2.78–3.36 (m, 6H, aromatics, H-5 and H-6), 4.95–5.23 (m, 2H, bridgeheads); LIS nmr (100 MHz) with 16.0 mg of **4** and 35.4 mg of Eu(fod)$_3$ d_{30} in 0.25 ml CCl_4: 1.74 (dd, 1H, H-3, $J_{3,4} = 6$, $J_{1,3} = 1.5$), 2.46–3.13 (m, 6H, aromatic, H-5 and H-6), 4.23 (dt, 1H, H-1, $J_{1,6} = 5$, $J_{1,3} = J_{1,5} = 2.0$), and 4.66 (dt, 1H, H-4, $J_{3,4} = J_{4,5} = 6$, $J_{4,6} = 2$); spin-decoupling experiments on LIS spectra: irradiation of H-3 left aromatics, H-5, H-6 m unchanged, collapsed H-1 to a dd ($J_{1,6} = 5$, $J_{1,5} = 2$), and collapsed H-4 to a dd ($J_{4,5} = 6$, $J_{4,6} = 2$); irradiation of H-1 left H-4 unchanged, collapsed H-3 to a d ($J_{3,4} = 6$), and modified the aromatics, H-5, H-6 m; irradiation of H-4 collapsed H-3 to a d ($J_{1,3} = 2$), modified the aromatic H-5, H-6 m, and left H-1 unchanged. *Anal.* calcd. for $C_{13}H_9N$: C 87.12, H 5.06, N 7.82; found: C 87.10, H 5.10, N 7.80.

Action of Lithium Cyclohexylamide on Cyanobarrelene ***4***

A solution of 293.8 mg (1.48 mmol) of **4**, 45 ml of cyclohexylamine (CaH_2 dried and distilled), and 4 ml (8.0 mmol) of 2 *M* butyllithium hexane was stirred at 85–90°C for 48 h in a nitrogen atmosphere. The cooled mixture was quenched with 50 ml of water, diluted with 250 ml of benzene, and extracted with 10% HCl (2 × 100 ml) and then with water (2 × 100 ml). The benzene solution was dried ($MgSO_4$), concentrated *in vacuo*, and the residue column chromatographed on silicic acid (100–200 mesh) with cyclohexane solvent. Crystallization of the contents of the initial bands from ethanol gave 96.2 mg (45%) of colorless crystals, mp 78–80°C, which were shown by tlc, ir, and mixture mp to be identical to naphthalene.

Preparative Photolysis Apparatus

The apparatus consisted of a 450W Hanovia medium-pressure mercury arc surrounded by a water-cooled quartz immersion well. For direct irradiations the light was filtered through a Corex sleeve. For acetone and acetophenone sensitized irradiations a Pyrex sleeve was used. Sample solutions were deoxygenated by flushing with argon, before and during irradiations.

Direct Irradiation of Cyanobarrelene ***4***

A solution of 103.5 mg (0.58 mmol) of **4** in 250 ml of cyclohexane was photolysed directly for 15 min. The photolysate was concentrated *in vacuo* and the residue chromatographed on a silicic acid column with 1% ether–cyclohexane. The first band contained 55.3 mg (53%) of a mixture of the COT's **6** and **7**, and crystallization from ethanol gave 26.1 mg (25%) of pale yellow **7**, mp 102–103°C; ir (KBr): 2205, C≡N; uv (cyclohexane): 227 sh (15 700), 241 (15 200), and 288 (1050); nmr, see Table 1. *Anal.* found: C 87.28, H 5.09, N 7.80.

The mother liquors were concentrated and applied in equal portions to two tlc plates; four irrigations with 8% ether–hexane gave complete separation of **6** and **7**. The first band contained 12.3 mg (12%) of **7**. The second band contained 12.8 mg (12%) of **6** which, after crystallization from ethanol, gave 7.2 mg of colorless **6**, mp 66–68°C; ir (KBr): 2200, C≡N; uv (cyclohexane): 237 (11 250) and 274 (815); nmr, see Table 1. Mass spectrum (70 eV, direct inlet) showed molecular ion at *m/e* 179.0740 (79%), $C_{13}H_9N$ requires 179.0735.

Crystallization (ethanol) of the contents of the second band from the column chromatography yielded 5.6 mg (5%) of **8** as a colorless solid, mp 95–96°C; ir (KBr): 2230, C≡N; uv (cyclohexane): 259 sh (290), 266 (410), 272 (560), and 279 (590); nmr (100 MHz, $CDCl_3$): the aliphatic-olefinic region comprises an ABMXY spin system, 2.56–3.00 (m, 4H, aromatics), 4.30 (*A*BM q, 1H, H-6, $J_{5,6} = 2.5$, $J_{6,7} = 5$), 4.80 (A*B*X q, 1H, H-7, $J_{6,7} = 5$, $J_{7,8} = 2.5$), 5.78 (A*M* d, 1H, H-5, $J_{5,6} = 2.5$), 6.34 (X*Y* d, 1H, H-2, $J_{2,8} = 7$), and 6.67 (B*XY* q, 1H, H-8, $J_{7,8} = 2.5$, $J_{2,8} = 7$). *Anal.* found: C 87.22, H 4.98, N 7.87.

The mother liquors from the crystallization were concentrated *in vacuo* and applied in equal portions to two tlc plates; four irrigations with 8% ether–hexane gave complete separation of **8** and starting material (**4**). The first band contained 36.9 mg (36%) of **4** and the second 2.7 mg (3%) of **8**.

Sensitized Photolysis of Cyanobarrelene ***4***

A solution of 101.2 mg (0.57 mmol) of **4** and 1 ml of acetophenone in 250 ml of cyclohexane was photolysed for 20 min. The photolysate was concentrated *in vacuo* and the acetophenone was removed by short-path distillation (40°C/0.1 Torr). The residue was crystallized from ethanol to give 40.3 mg (40%) of **8**. The mother liquors were concentrated and applied in equal portions to two tlc plates; after four irrigations with 8% ether–hexane 41.6 mg (41%) of starting material (**4**) and 10.2 mg (10%) of **8** were obtained from the first and second bands, respectively.

*5-Deuteriocyanobarrelene (**15**) and the 4- and 6-Deuteriocyanobarrelene Mixture **23**b*

The deuterated compound **15** and the deuterated mixture **23***b* were obtained in ≃1.5% overall yields (based on benzyne precursor) using essentially the same method as that used to prepare **4**, except that bromobenzene was replaced by *p*-deuteriobromobenzene (5) in the case of **15** and by *m*-deuteriobromobenzene (5) in the case of **23***b*. For **15**, mp 66–67°C, nmr (100 MHz, CCl_4): 2.55 (dd, 1.00H, H-3, $J_{1,3} = 2$, $J_{3,4} = 6$), 2.73–3.25 (m, 5.07 ± 0.06H, aromatics, H-6 and residual H-5), 4.96–5.12 (m, 1.97 ± 0.04H, bridgeheads), i.e., 93 ± 6% deuteration at C-5 based on the assumption of 0% d_1 at H-3. For **23***b*, LIS nmr (100 MHz): with 7.1 mg of **23***b* and 12.7 mg of Eu(fod)$_3$-d_{30} in 0.25 ml CCl_4: 2.04–2.18 (m, 1.03 ± 0.04H, aromatics, H-5, and residual H-6), 4.51–4.68 (m, 0.97 ± 0.05H, H-1), 4.78–4.94 (m, 0.53 ± 0.03H, H-4), i.e., this corresponds to an approximately 50:50 mixture of two component compounds one containing 94 ± 3% d_1 at C-4 and the other 92 ± 4% d_1 at C-6.

*Direct Photolysis of 5-Deuteriocyanobarrelene (**15**)*

A solution of 119.0 mg (0.66 mmol) of **15** in 250 ml of cyclohexane was photolysed for 20 min. The photolysate was worked up as previously described for the direct irradiation of **4** and yielded a total of 55.1 mg (46%) of **22**, mp 101–103°C, 18.1 mg (15%) of **17**, mp 66–68°C, 12.3 mg (10%) of **12**, mp 94–96°C, and 7.2 mg (6%) of starting material (**15**). The nmr spectrum of **22** is described in Table 2 and the results section and that of **17** in Table 1; the nmr of **12** (100 MHz, CCl_4): 2.60–3.03 (m, 4.00H, aromatics), 4.30 (d, 1.04 ± 0.05H, H-6, $J_{5,6} = 2.5$), 4.40–5.70 (no discernible signal, 0.05 ± 0.5H, residual H-7), 5.80 (d, 1.01 ± 0.05H, H-5, $J_{5,6} = 2.5$), 6.35 (d, 1.0 ± 0.04H, H-2, $J_{2,8} = 7$), and 6.70 (d, 0.06 ± 0.04H, H-8, $J_{2,8} = 7$).

*Sensitized Photolysis of 5-Deuteriocyanobarrelene (**15**)*

A solution of 35.8 mg (0.20 mmol) of **15** and 1.0 ml of acetophenone in 250 ml of cyclohexane was photolysed for 7 min. The photolysate was worked up as previously described for the sensitized irradiation of **4** and yielded a total of 14.6 mg (41%) of **12**, mp 94–96°C, and 16.3 mg (46%) of starting material (**15**). The nmr spectrum of **12** is essentially the same as that described for **12** obtained from the direct irradiation of **15**.

*Direct Photolysis of 1-Cyanobenzosemibullvalene (**8**)*

A solution of 82.6 mg (0.46 mmol) of **8** in 250 ml of cyclohexane was photolysed directly for 41 min. The photolysate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was concentrated *in vacuo* and the residue was chromatographed on a silicic acid column; elution was with 1% ether–cyclohexane. Crystallization from ethanol of the contents of the first band gave 39.2 mg (47%) of colorless **13**, mp 73–74°C; ir (KBr): 2220, C≡N; uv (cyclohexane): 241 (22 700) and 281 (1530); nmr see Table 1; mass spectrum (70 eV, direct inlet) showed molecular ion at *m/e* 179.0744 (75%).

The second band contained 38.4 mg (46%) of recovered starting material.

*Direct Photolysis of 8-Deuterio-2-cyanosemibullvalene (**12**)*

A solution of 17.6 mg (0.10 mmol) of **12** in 250 ml of cyclohexane was photolysed directly for 12 min. The photolysate was worked up as previously described for the undeuterated case to give 6.2 mg (35% of **14**, mp 73–74°C, and 8.1 mg (46%) of recovered starting material; see Table 1 for nmr data of **14**.

*Direct Photolysis of Deuterated Barrelene Mixture **23**b*

A solution of 216.4 mg (1.21 mmol) of mixture **23***b* in 250 ml of cyclohexane was photolysed directly for 8 min. From the photolysate, which was worked up as in the deuterated case, 179.2 mg (82%) of **23***b* was recovered and 1.2 mg (0.6%) of SB mixture **28***b* was obtained, mp 95–96°C; see Table 4 (case *3*) for the nmr H distributions. In addition, 15.2 mg (7%) of **35** was isolated from crystallization of the COT fraction, mp 101–103°C; nmr (100 MHz, $CDCl_3$): 2.62–3.07 (m, 4.00H aromatics), 3.16–3.37 (m, 2.53 ± 0.04H, H-5, -10, and -8), and 3.86–4.11 (m, 1.55 ± 0.05H, H-6 and -9). That the available deuterium was located 50% at C-6 and 50% at C-10 is suggested by the following nmr details: H-10 (τ 3.26) occurs as a doublet ($J_{9,10}$ = 11.5), as does H-8 (τ 3.32, $J_{8,9}$ = 4.0) and H-6 (τ 4.04, $J_{5,6}$ = 11.5). For H-5 there are two types of signals since C-6 is 50% deuterated: a doublet with limbs at τ 3.17 and 3.29 ($J_{5,6}$ = 11.5) and a singlet at τ 3.23. For H-9 there are also two types of spin systems discernible, since H-10 is 50% deuterated: two doublets centred at τ 3.88 and 4.00 ($J_{8,9}$ = 4.0, $J_{9,10}$ = 11.5), and broad lines between the inner limbs of the two doublets (τ 3.92–3.97). There are no lines between the doublet centred at τ 3.88, indicating the total absence of deuterium at C-8 (Note: the doublet centred at τ 4.00 is partially coincidental with the H-6 doublet).

*Sensitized Photolysis of Deuterated Barrelene Mixture **23**b*

(a) With Acetophenone

A solution of 32.6 mg (0.18 mmol) of mixture **23***b* and 1 ml of acetophenone in 250 ml of cyclohexane was photolysed for 9 min. The photolysate was worked up as in the undeuterated case to give 14.3 mg (44%) of starting material and 14.7 mg (45%) of deuterated semibullvalene mixture **28***b*, mp 95–96°C; see Table 4 (case *4*) for the nmr H distributions.

(b) With 2-Acetonaphthone

A solution of 34.0 mg (0.19 mmol) of mixture **23***b* and 176.3 mg of 2-acetonaphthone in 35 ml of cyclohexane was photolysed with light of wavelength 328 nm for 105 min in the 'merry-go-round' apparatus. The photolysate was submitted to column chromatography on silicic acid with 1% ether–cyclohexane was eluting agent. The sensitizer came off first, followed by a band containing **23***b* and **28***b*. This second band was concentrated *in vacuo* and applied in equal portions to two tlc plates; after four irrigations with 8% ether–hexane, 21.6 mg (64%) of **23***b* and 9.6 mg (28%) of **28***b* were obtained from the first and second bands, respectively. See Table 4 (case *5*) for the nmr H distributions of **28***b*.

*Direct Photolysis of Deuterated Semibullvalene Mixture **28**b*

A solution of 17.7 mg (0.10 mmol) of mixture **28***b* in 250 ml cyclohexane was irradiated directly for 30 min. The photolysate was worked up as in the undeuterated case to give 3.5 mg (20%) of recovered starting material (see Table 4, case *7*, for nmr H distributions) and 11.2 mg (63%) of deuterated COT mixture **32**, mp 72–74°C; nmr (100 MHz, Me_2CO-d_6): 2.52 (s, 0.50 ± 0.04H, H-5), 2.55–2.97 (m, 4.00H, aromatics), 3.33 (d and s, 0.99 ± 0.03H, H-10, $J_{9,10}$ = 11.5), 3.72–3.94 (m, 1.56 ± 0.03H, H-8, -9), and 4.13 (d, 0.97 ± 0.03H, H-7, $J_{7,8}$ = 11.5).

*Sensitized Photolysis of Deuterated Semibullvalene Mixture **28**b*

A solution of 9.7 mg (0.05 mmol) of **28***b* and 1 ml of acetone in 250 ml of cyclohexane was photolysed for 20 min. The photolysate was concentrated *in vacuo* and the residue was applied to a tlc plate; three irrigations with 8% ether–hexane led to the recovery of 1.6 mg (16.5%) of starting material; no COT products could be detected on the tlc plate. The nmr H distributions for the recovered starting material are given in Table 4 (case *7*).

*Direct Photolysis of COT **7***

A solution of 135.2 mg (0.76 mmol) of **7** in 250 ml of cyclohexane was photolysed directly for 370 min. The photolysate was concentrated *in vacuo* and the residue chromatographed on a silicic acid column with 1% ether–cyclohexane. The first band contained 113.2 mg (84%) of recovered **7**. The second band contained mostly SB **8** but the tlc showed several other minor components to be present. The contents of the second band were applied to a tlc plate; after two irrigations with 8% ether–hexane, 4.0 mg (3%) of **8** was obtained from the first band. Crystallization from ethanol gave 2.8 mg of pure **8**, mp 94–96°C.

*Direct Photolysis of Deuterated COT **35***

A solution of 42.8 mg (0.24 mmol) of **35** in 250 ml of cyclohexane was photolysed directly for 339 min. The photolysate was worked up as in the undeuterated case to give 32.8 mg (77%) of recovered **35** and 3.1 mg (7%) of SB **36**, mp 94–96°C; nmr (100 MHz, $CDCl_3$): 2.58–2.96 (m, 4.00H, aromatics), 4.23–4.34 (m, 1.01 ± 0.03H, H-6), 4.74–4.84 (m, 0.98 ± 0.04H, H-7) 5.78 (d, 0.56 ± 0.04H, H-5, $J_{5,6}$ = 2.5), 6.26–6.38 (m, 1.01 ± 0.02H, H-2), and 6.67 (dd, 0.58 ± 0.04H, H-8, $J_{7,8}$ = 2.5, $J_{2,8}$ = 7).

*Direct Photolysis of COT **6***

A solution of 48.9 mg (0.27 mmol) of **6** in 250 ml of cyclohexane was photolysed directly for 150 min. The photolysate was concentrated *in vacuo* and the residue chromatographed on a silicic acid column with 1% ether–cyclohexane. The first band contained 41.9 mg (86%) of **6** and the second contained 0.5 mg of a mixture of compounds. The nmr spectrum and tlc of the contents of the second band showed that **8** was not present.

Quantum Yield Determinations

Quantum yields were determined on a 'merry-go-round' fitted with a 450 W Hanovia medium pressure mercury arc and surrounded by a water-cooled quartz immersion well. Light of wavelength 276 nm was isolated by a two compartment quartz cell fitting concentrically around the immersion well. The first compartment contained a 2.0-cm path length of a solution of 533 g of nickel sulfate hexahydrate and 300 g of cobaltous sulfate heptahydrate per litre of 5% aqueous H_2SO_4. The second compartment contained a 0.2-cm path length of a solution of 1 g of bismuth trichloride per 0.5 litre of 10% aqueous HCl; transmittance was 263–290 nm with a maximum at 276 nm (8%).

For sensitized irradiations at 328 nm, the solution used in the first compartment was diluted with 0.5 ℓ of 5% aqueous H_2SO_4; the solution used in the second compartment was replaced by one prepared from 10.4 g of cupric chloride dihydrate per litre of 10% aqueous HCl. This combination showed transmittance between 304–357 nm with a maximum at 328 nm (32%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Light of wavelength 312 nm was isolated by using a solution of 310 g of cobaltous sulfate heptahydrate per litre of water in the first compartment and a solution of 1 g of potassium chromate in 300 ml of water in the second. This combination showed transmittance between 301–325 nm with a maximum at 312 nm (26%).

Before irradiation, solutions of reactants (ca. 0.50 mmol) (and acetophenone, ca. 5.5 mmol or acetone, ca. 7.0 mmol, if any) in cyclohexane solvent (ca. 35 ml) contained in calibrated (for differences in light transmittance) 20 mm × 150 mm quartz test-tube-like photolysis cells were deoxygenated by flushing with argon. The tubes were sealed under a positive pressure of argon which was maintained throughout the course of the irradiation. The lamp output was determined by potassium ferrioxalate actinometry (19). For the direct photolysis of **4**, the photolysates were concentrated *in vacuo* and chromatographed on silicic acid (*vide supra*). The first fraction (containing **6** and **7**) was weighed and analyzed by nmr as was the second fraction (containing **8** and unreacted starting material). Otherwise photolysates were concentrated *in vacuo* and acetophenone sensitizer, if any, removed by short-path distillation at 40°C/0.1 Torr, a known amount of β-naphthyl methyl ketone was added as internal standard, and the product compositions were determined by nmr analysis. In all cases nmr peak areas were calibrated against authentic mixtures of similar constitution. The product appearance quantum yield data are given in Table 2; $\Phi_{dis} < 0.05$ was found for both the acetone and acetophenone sensitized irradiations of **8**.

Phosphorescence and Fluorescence Studies of Barrelene ***4***

The fluorescence spectrum of **4** was measured in cyclohexane solution at room temperature on an Aminco-Bowman Spectrometer. Intersection of the fluorescence (λ_{max} = 340 nm) and absorption spectra of **4** occurred at 296 nm, suggesting a singlet energy of 97 kcal mol^{-1}.

The phosphorescence study was carried out on a modified Aminco-Bowman apparatus (20) in an isopentane–methylcyclohexane (1:4) glass at 77 K. No detectable phosphorescence peak could be observed.

Effective Triplet Energy of ***4***

Sensitization studies were carried out on the 'merry-go-round' apparatus, set up for quantum yield determinations, using light of 328 nm wavelength. The procedure and concentrations of reactants used in the runs were similar to those described for other quantum yield determinations (*vide supra*), except that benzene solvent was used instead of cyclohexane, and after photolyses, the photolysates were chromatographed on silicic acid to remove the sensitizer (acetophenone sensitizer was removed by short-path distillation); product compositions were determined by nmr as before. The quantum yields for the appearance of **8** from **4** were acetophenone, 0.36; benzophenone, 0.34; thioxanthone, 0.36; Michler's ketone, 0.31; 2-acetonaphthone, 0.33; 1-acetonaphthone, <0.001. The conversions were kept below 20%. The cut-off for the sensitized formation of **8** on going from 2- to 1-acetonaphthone indicates the effective triplet energy of **4** to lie between 56–59 kcal mol^{-1}.

Acknowledgements

The authors thank the Spectroscopic Services Laboratory of the University of Alberta for the 100-MHz nmr and mass spectra, Professor Brian Henry of the University of Manitoba for phosphorescence studies, and the University of Lethbridge Computing Centre for use of facilities. Financial support from the National Research Council of Canada and the University of Lethbridge Research Committee is gratefully acknowledged.

Notes for authors of papers presenting the results of X-ray crystal-structure analysis

The crystallographic nomenclature should correspond to that given in the *International tables for X-ray crystallography, Vol. I* (1).

The following primary crystallographic data should be given: chemical formula, formula weight, unit cell dimensions, unit cell volume, observed density, number of formula units in cell, calculated density, working temperature, and the assumed value for the wavelength or other reference parameter used in calculating the cell dimensions. All measured quantities should be accompanied by an estimate of the accuracy, and the basis for the estimate should be stated. The crystal data should be presented in a condensed form such as:

$C_6H_4N_2O_4$ fw = 168.1
Orthorhombic, $a = 13.20(3)$, $b = 13.97(3)$, $c = 3.800(5)$ Å, $V = 700.7$ Å^3, $\rho_o = 1.57(1)$, $Z = 4$, $\rho_c = 1.583$ (20°C; CuKα_1, $\lambda = 1.54050$ Å).

Authors are reminded that for presentation in such compilations as *Crystal data* (2), certain conventions regarding the choice of unit cell are mandatory. Confusion in the literature can be avoided if these conventions are adopted in primary publication. Full details are given in *Crystal data*, and in the *International tables for X-ray crystallography, Vol. II* (1).

The space group should be reported in the Hermann–Mauguin notation. If the setting differs from the standard setting in the *International tables for X-ray crystallography, Vol. I* (1), the corresponding Schoenflies symbol and the systematic absences should be given also. If there is any ambiguity in the choice of space group, the manner of its resolution should be stated. It must be emphasized that the space-group symbol given, and the origin implied by the symbol, should correspond to the setting and origin actually used.

The following information pertaining to the measurement of intensity data should be given: method of recording and measurement, the region of reciprocal space explored, and the number of accessible and observed reflections in this region, specimen size and shape, the radiation used, and details of any special corrections such as absorption or extinction.

The final refinement should be reported in sufficient detail to enable the reader to assess its reliability and completeness and, if necessary, to repeat or extend it. The origin of the scattering factors used should be specified, together with details of any corrections for anomalous scattering. A suitable table of observed and calculated structure amplitudes must accompany the paper. This table will not be published, but will be placed in the Depository of Unpublished Data, which will supply copies on request; it must, therefore, be suitable for limited duplication and circulation. The existence of this table, and of any other deposited material, is indicated in the printed article by a footnote in the following format: 'Tables of observed and calculated structure factor amplitudes, of temperature factors (and of ---) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2'. A final agreement index ($R = \sum||F_o| - |F_c||/\sum|F_o|$) should be given and defined with respect to the treatment of unobserved reflections. For least-squares refinement, any approximation (e.g., block-diagonal) should be specified, as should the quantity minimized. The weighting scheme should be given, and should include a statement of any reflections assigned zero weight. Where possible, the correctness of the reported structure should be checked by a method independent of that used for refinement (e.g., by a difference-Fourier synthesis) and the result of this procedure briefly reported.

The final positional parameters should be given in a single table, with the coordinates expressed as fractions of the cell edges. If the space-group setting is non-standard, a statement of the equivalent positions should be given also. The table should preferably include, or at least be accompanied by, an estimate of the standard deviations of the parameters. The asymmetric unit defined by the coordinates should, where possible, specify a single molecule or

other appropriate chemical entity. Atoms of the same chemical species should be distinguished by appended arabic numerals in parentheses. Subscripts are not acceptable, as they may lead to confusion in chemical contexts. Temperature factors should normally be placed in the Depository.

Bond lengths and angles may be given in a table or on a diagram. However, extensive tables of normal bond lengths and angles (particularly those involving hydrogen atoms) should be placed in the Depository, as should extensive tables of intermolecular distances and deviations of atoms from mean planes.

The volume of information required for compliance with these notes is formidable, and it is essential that the presentation be concise and relevant. It should not be a narrative account of the progress of the analysis, or a discussion of method, unless these elements have a direct bearing on the chemical conclusions.

Recommandations aux auteurs d'articles décrivant la détermination de structures cristallines par diffraction des rayons X

La nomenclature cristallographique doit se conformer à celle qu'on trouve dans les *International tables for X-ray crystallography, Vol. I* (1).

Les données cristallographiques suivantes doivent être fournies: la formule chimique, la masse moléculaire correspondante, les dimensions de la maille, le volume de la maille, la densité observée, le nombre de motifs par maille, la densité calculée, la température, ainsi que la valeur employée pour la longueur d'onde ou pour tout autre paramètre de référence lors du calcul des dimensions de la maille. On évaluera la précision de toutes les quantités mesurées et on indiquera les critères sur lesquels se fonde cette évaluation. Les données cristallographiques doivent être présentées sous une forme condensée telle que:

$C_6H_4N_2O_4$ m = 168.1
Orthorhombique, $a = 13.20(3)$, $b = 13.97(3)$, $c = 3.800(5)$ Å, $V = 700.7$ Å^3, $\rho_o = 1.57(1)$, $Z = 4$, $\rho_c = 1.583$ (20°C; CuKα_1, $\lambda = 1.54050$ Å).

On rappelle aux auteurs que les résultats devant figurer dans des tables comme les *Crystal Data* (2) doivent correspondre à une maille définie selon certaines conventions. On évitera de la confusion dans la littérature si l'on adopte ces conventions dès la publication initiale. On trouvera tous les détails à ce sujet dans les *Crystal data* et dans les *International tables for X-ray crystallography, Vol. II* (1).

On doit rapporter le groupe d'espace dans la notation de Hermann–Mauguin. Si l'on a adopté une définition qui diffère de la définition conventionnelle des *International tables for X-ray crystallography, Vol. I* (1), on doit en outre spécifier le symbole de Schoenflies correspondant et énumer les extinctions systématiques. S'il existe une ambiguïté dans le choix du groupe d'espace, on indiquera la façon dont elle a été résolue. Il faut insister sur le fait que le symbole du groupe d'espace et l'origine qu'il implique doivent correspondre à la définition du groupe et à l'origine qui ont de fait été utilisées.

On donnera aussi les informations suivantes concernant la mesure des intensités diffractées: la méthode d'enregistrement et de mesure, la portion de l'espace réciproque qui a été explorée, le nombre de réflexions accessibles et le nombre de réflexions observées dans cette portion, les dimensions et la forme du spécimen, le rayonnement utilisé et les détails touchant toute correction particulière, telle que l'absorption ou l'extinction.

La description de l'affinement doit être suffisamment détaillée pour permettre au lecteur de déterminer s'il est complet et satisfaisant, et au besoin, de le répéter ou de le prolonger. On doit aussi spécifier la source des facteurs de diffusion atomique utilisés, de même que les détails relatifs aux corrections apportées pour la dispersion anomale. La publication doit être accompagnée d'un tableau des valeurs observées et calculées des amplitudes des facteurs de structure. Ce tableau ne sera pas publié, mais il sera confié au "Dépôt de données non publiées," qui en fournira des copies sur demande; il doit donc être sous une forme qui se prête à une duplication et à une mise en circulation limitées. L'existence de ce tableau et de tout autre matériel déposé doit être indiquée dans l'article même par une note en bas de page rédigée comme suit: "Les tableaux des amplitudes des facteurs de structure, des facteurs d'agitation thermique (et de ---) sont disponibles. On peut les obtenir à un prix nominal en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa (Ont.), Canada K1A 0S2." On donnera un indice d'accord final ($R = \sum||F_o| - |F_c||/\sum|F_o|$), en définissant de quelle manière on a tenu compte des réflexions non observées. En ce qui a trait à l'affinement par moindres carrés, on doit indiquer la fonction minimisée et signaler toute approximation (comme les blocs diagonaux) qu'on aurait utilisée. On décrira la méthode de pondération et on indiquera les critères sur lesquels on s'est basé pour attribuer un poids nul à certaines réflexions. Dans la mesure du possible, on vérifiera si la structure rapportée est juste, à l'aide d'une méthode indépendante de celle utilisée pour l'affinement (comme une synthèse de Fourier différence), et l'on décrira brièvement le résultat de cette vérification.

On réunira dans un même tableau les coordonnées atomiques finales, qui seront exprimées sous forme de fractions de l'arête de la maille. Si l'on a utilisé pour le groupe d'espace une définition non conventionnelle, on dressera en plus la liste des positions équivalentes. Une évaluation de l'écart-type sur ces paramètres devrait faire partie de ce tableau. Le motif asymétrique défini par les coordonnées doit, si possible, spécifier une seule et même molécule ou autre entité chimique appropriée. On distinguera les atomes de même nature par des chiffres arabes ajoutés entre parenthèses. L'emploi d'indices est inacceptable puisque ceux-ci peuvent prêter à confusion dans un contexte chimique. On doit normalement placer en dépôt les facteurs d'agitation thermique.

On peut présenter les longueurs de liaisons et les angles soit dans un tableau, soit dans un diagramme. Toutefois, on mettra en dépôt tout tableau renfer-

mant un grand nombre de valeurs normales de longueurs et d'angles de liaisons (en particulier ceux qui impliquent les atomes d'hydrogène); on fera de même pour les grands tableaux des distances intermoléculaires et des écarts entre atomes et plans moyens.

Pour se conformer à ces recommandations, les auteurs devront réunir une quantité imposante d'informations, mais il est essentiel que la présentation en soit concise et au point. On évitera les longs exposés sur les principes des méthodes utilisées ou sur le déroulement de la résolution de la structure, à moins que ces éléments n'aient une relation directe avec les conclusions d'ordre chimique.

Substituent and steric effects in the oxidation of alkyl aryl sulfides by peroxydisulfate

C. SRINIVASAN, P. KUTHALINGAM, AND N. ARUMUGAM
School of Chemistry, Madurai University, Madurai 625 021, India

Received January 21, 1978[1]

C. SRINIVASAN, P. KUTHALINGAM, and N. ARUMUGAM. Can. J. Chem. **56**, 3043 (1978).

The kinetics of oxidation of a number of alkyl aryl sulfides with potassium peroxydisulfate in aqueous ethanol have been investigated. The effect of substituents on the oxidation has been studied by employing a number of *p*- and *m*-substituted phenyl methyl sulfides: the reaction is accelerated by electron-releasing and retarded by electron-withdrawing substituents, indicating a rate-determining electrophilic attack by the peroxydisulfate ion at the reaction site, sulfur. A good correlation is found to exist between the rate constants and the Hammett σ^+/σ^- constants, the ρ^+ value for the reaction being -0.56 with a correlation coefficient of 0.979. The activation parameters have also been determined.

Studies with different alkyl phenyl sulfides clearly indicate that the reaction is quite sensitive to steric congestion around the reaction site. The results obtained in this study are compared with those found for the oxidation of the same set of sulfides with different oxidants.

C. SRINIVASAN, P. KUTHALINGAM et N. ARUMUGAM. Can. J. Chem. **56**, 3043 (1978).

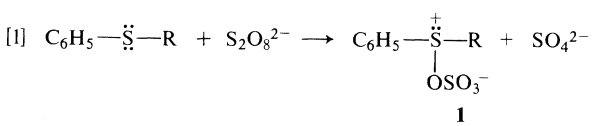
On a examiné la cinétique de l'oxydation de plusieurs sulfures d'alkyle et d'aryle avec le peroxydisulfate de potassium dans l'éthanol aqueux. On a étudié l'influence des substituants sur la réaction d'oxydation à l'aide d'une série de sulfures possédant un groupe alkyle et un groupe phényle substitué aux positions *méta* et *para*. Les substituants électro-donneurs accélèrent la réaction, tandis que les substituants électro-attracteurs la ralentissent. Cet effet indique que l'étape déterminante est une attaque électrophile de l'ion peroxydisulfate sur la site de réaction, soit le soufre. On observe une bonne corrélation entre les constantes de vitesse et les constantes σ^+/σ^- de Hammett; on obtient pour cette réaction une valeur de ρ^+ de -0.56 avec un coefficient de corrélation de 0.979. On a également déterminé les paramètres d'activation.

Des études sur différents sulfures d'alkyle et de phényle montrent clairement que la réaction est grandement influencée par l'encombrement stérique au voisinage du site réactionnel. On compare les résultats recueillis dans le présent travail avec ceux qui ont été rapportés pour l'oxydation de la même série de sulfures avec différents oxydants.

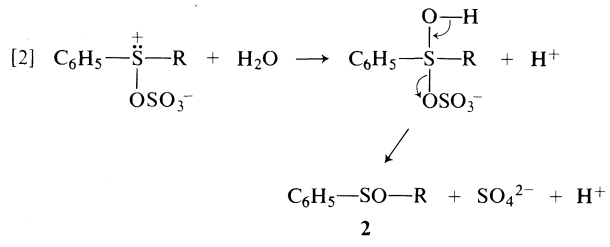
[Traduit par le journal]

Introduction

In our earlier paper (1), we have proposed that the oxidation of alkyl aryl sulfides with peroxydisulfate in 50% aqueous ethanol (v/v) proceeds by a rate-determining electrophilic attack of the peroxydisulfate ion [1] at sulfur of the sulfide to form sulfoxide.

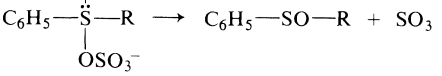


1



2

The intermediate **1** may decompose to give the sulfoxide **2** by the attack of water as indicated in [2] or according to the step [3] which is very similar to that proposed by Ogata and Akada (2) in the kinetics of peroxydisulfate oxidation of *p*-nitrosophenol.



However, the question regarding the origin of the sulfoxide oxygen, whether from water or from peroxydisulfate ion, has not been solved. The present work describes the substituent and steric effects on the reaction of alkyl aryl sulfides with peroxydisulfate.

The sulfides studied are listed in Tables 1 and 2. Twelve *m*- and *p*-substituted phenyl methyl sulfides are used to study the effect of structure on reactivity by keeping the steric effects constant at the reaction centre (Table 1). Five alkyl phenyl sulfides are chosen to study the steric effects and in these sulfides there is a gradual increase in the size of the alkyl group attached to sulfur (Table 2).

‡Values from ref. 32.
§Values from ref. 33.
‖Since the rate is very slow k_2 value has been calculated from the initial rates.

Experimental

Materials

Potassium peroxydisulfate (G.R., E. Merck) was used after recrystallization from double distilled water. Methyl phenyl sulfide, *p*-methoxyphenyl methyl sulfide, methyl *p*-tolyl sulfide, and *p*-methylthioacetophenone were prepared as described earlier (1). *p*-Chlorophenyl methyl sulfide and *p*-bromophenyl methyl sulfide were prepared by the methylation of the corresponding benzenethiols obtained by the reduction of their respective benzenesulfonyl chlorides (3). *p*-Isopropylphenyl methyl sulfide was prepared by the methylation of *p*-isopropylbenzenethiol (4). The procedure adopted by Baliah, Shanmuganathan, and Varadachari (5) was employed for the preparation of *p*-methylthiobenzoic acid. Methyl *p*-nitrophenyl sulfide (6), *p*-fluorophenyl methyl sulfide (7), methyl *m*-tolyl sulfide (8), *m*-chlorophenyl methyl sulfide (9), and *m*-methoxyphenyl methyl sulfide (10) were prepared as described in literature.

Ethyl phenyl sulfide (11) was prepared by using benzenethiol and diethyl sulfate. Phenyl *n*-propyl and phenyl isopropyl sulfides (12) were prepared by the alkylation of benzenethiol with the appropriate alkyl bromides in the presence of sodium ethoxide. *tert*-Butyl phenyl sulfide was obtained by passing isobutylene (13) into sulfuric acid followed by the addition of benzenethiol (12).

Kinetic Measurements

The procedure employed for the kinetic studies was essentially the same as described in our earlier paper (1). Measurements were carried out under pseudo first-order conditions in 50% aqueous ethanol (v/v) at constant ionic strength (14, 15).[2] All the reactions were homogeneous. The rate of the reaction was followed by estimating the unreacted peroxydisulfate by the iodometric procedure of Kolthoff and Carr (16). The kinetics were generally followed up to 60–70% of the reaction. The second-order rate constants were calculated from the pseudo first-order rate constants as described in ref. 1. The rate constants were confirmed in each substrate by performing at least a set of duplicate runs in all of them at all the temperatures mentioned here (Table 1).

Product Analysis

TLC analysis showed that alkyl phenyl sulfides are oxidised

[2]Oxidation of 50% aqueous ethanol (v/v) by peroxydisulfate is found to be negligible in our experimental conditions. See also refs. 14 and 15.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

by peroxydisulfate solely to their sulfoxides (see also ref. 1). Product analyses were carried out with the same initial concentration of the reactants employed in the kinetic measurements.

Results and Discussion

Substituent Effects

The results of the kinetic studies with substituted phenyl methyl sulfides show that the reaction is first-order in peroxydisulfate and in sulfide for over 60–70% of the reaction. From the data in Table 1, it is evident that electron-releasing substituents accelerate and electron-withdrawing substituents retard the rate of the reaction.

It is generally known that the linear free-energy relationships apply to a reaction series in which either the entropies of activation for the series are constant or in which the variation in activation entropy is linearly related to changes in enthalpy of activation (17–20). An examination of the activation parameters in Table 1 shows clearly that the reaction under investigation has nearly constant entropies of activation, favouring a linear free-energy relationship.

Hence the reactivity pattern is brought out by two different correlations[3] at 40°C; one, log k_2 with σ and the other log k_2 with σ^+/σ^-. Since sulfur can act as an electron-donor or an electron-acceptor depending on the substituent present *para* to the methylthio group (21), we have used both σ^+ and σ^- simultaneously in the latter correlation. It may be pointed out here that in some reactions (22), both σ^+ and σ^- are employed simultaneously. A fair correlation (23) is obtained with Hammett's σ constants ($\rho = -0.87$, $r = 0.930$, $s = 0.11$); but a good correlation is found to exist when σ^+/σ^- values are plotted against the logarithms of rate constants. The ρ^+ value obtained for the latter correlation by the method of least squares is -0.56 ($r = 0.979$ and $s = 0.06$).

The negative ρ^+ value indicates that the nucleophilic sulfur atom of the sulfide is more positively charged in the transition state of the rate-determining step of the oxidation reaction than it is in the reactant. This is consistent with step [1] being the rate-determining. The small ρ^+ value obtained in our case may be attributed to the fact that the dinegative peroxydisulfate ion is not a typical electrophilic reagent (27). Such small ρ values are commonly observed in most studies of other electrophilic reactions at sulfur centre. For instance, ρ value of -1.13 has been observed in the oxidation of aryl alkyl sulfides by hydrogen peroxide (28). But the higher ρ value observed in the reactions of aryl alkyl sulfides with chloramine-T (29) and bromine (30) may be due to the strong electrophilic character of the attacking species.

Steric Effects in the Oxidation of Alkyl Phenyl Sulfides

The steric effect on the oxidation of sulfides with peroxydisulfate was also studied by changing the alkyl moiety from methyl to *tert*-butyl in a series of alkyl phenyl sulfides. The rate data are given in Table 2. The rate decreases in the order PhSMe > PhSEt > PhSPr^n > PhSPr^i > PhSBu^t.

The results show that the reaction is sensitive to steric congestion at the reaction centre. It is evident from Table 2, which exhibits the results obtained by us and those of Modena (31, 32) and Oae and coworkers (33) with other oxidizing agents, that the steric retardation in the oxidation of alkyl phenyl sulfides depends on the nature and size of the oxidizing agent. The rate constants in the present study (Table 2) decreased monotonically with the increasing bulkiness of the alkyl groups. The retardation observed here is larger than those found for the oxidation of the same sulfides by bromine (31), hydrogen peroxide (32), and chloramine-T (33). This is probably due to the larger size of the peroxydisulfate ion. This is also supported by the observation that steric effect is almost absent in the chloramine-T oxidation (33) of these sulfides, which is presumably due to the smaller size of the attacking species Cl^+.

Acknowledgements

One of the authors (P.K.) thanks the U.G.C., New Delhi, and the Madurai University, for the award of a Fellowship under the Faculty Improvement Programme. P.K. also wishes to thank the Principal and Management of Aditanar College of Arts and Science, Tiruchendur, for making it possible for him to accept the Fellowship mentioned. Our thanks are also due to referees of this paper for their helpful and constructive comments.

[3]We have used σ_p and σ_m values (24) for the log $k_2 - \sigma$ correlation. In the log $k_2 - \sigma^+/\sigma^-$ correlation, σ_p^+ values (24) have been used for *p*-methoxy, *p*-methyl, *p*-isopropyl, *p*-chloro, *p*-bromo, and *p*-fluoro substituents. σ_p^- values (25) are used for *p*-acetyl and *p*-carboxylic groups. σ^- value given by Bordwell and Andersen (26) has been used for *p*-nitro group. σ_m^+ values were used for the *meta* substituents (24).

Absolute rate constants for hydrocarbon autoxidation. 25. Rate constants for hydrogen atom abstraction from alkanes by the *tert*-butylperoxy radical[1]

J. H. B. CHENIER, S. B. TONG,[2] AND J. A. HOWARD[3]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received May 29, 1978

J. H. B. CHENIER, S. B. TONG, and J. A. HOWARD. Can. J. Chem. **56**, 3047 (1978).

Rate constants for abstraction of secondary and tertiary hydrogens from structurally different alkanes by the *tert*-butylperoxy radical in solution at 30°C have been determined by competitive experiments in the presence of *tert*-butyl hydroperoxide. Rate constants fall in the range 1×10^{-4} to 9×10^{-4} and $1 \times 10^{-3} - 2 \times 10^{-2}$ M^{-1} s^{-1} for secondary and tertiary aliphatic C—H bonds, respectively. The most reactive secondary hydrogen is, therefore, almost as reactive as the least reactive tertiary hydrogen. Differences in reactivity within a type of aliphatic C—H bond are governed by differences in steric hindrance to attack by the peroxy radical and by relief of steric strain upon removal of the labile hydrogen. Rate constants for reaction of perdeuterated methylcyclohexane and 3-methylpentane are much smaller than the values calculated from the maximum primary kinetic isotope effect for this reaction.

J. H. B. CHENIER, S. B. TONG et J. A. HOWARD. Can. J. Chem. **56**, 3047 (1978).

Certaines expériences de compétition effectuées en solution à 30°C en présence d'hydroperoxyde de *tert*-butyle ont permis de déterminer les constantes de vitesse correspondant à l'arrachement, par le radical *tert*-butylperoxy, d'atomes d'hydrogène secondaires et tertiaires présents dans des alcanes de différentes structures. Les constantes de vitesse se situent dans les domaines de $1 \times 10^{-4} - 9 \times 10^{-4}$ et $1 \times 10^{-3} - 2 \times 10^{-2}$ M^{-1} s^{-1} pour les liaisons C—H aliphatiques secondaires et tertiaires respectivement. L'hydrogène secondaire le plus réactif est donc presque aussi réactif que l'hydrogène tertiaire le moins réactif. A l'intérieur d'une même catégorie de liaisons C—H aliphatiques, les différences de réactivité sont régies par des différences d'empêchement stérique lors de l'attaque du radical peroxy et par une diminution de la tension stérique lors de l'arrachement de l'atome d'hydrogène labile. Les constantes de vitesses correspondant aux réactions du méthylcyclohexane et du méthyl-3 pentane perdeutérés sont beaucoup inférieures aux valeurs prévues en supposant le maximum de l'effet isotopique primaire pour cette réaction.

Introduction

Most of the rate constants for reactions of alkylperoxy radicals (ROO·) with oxidizable substrates (RH), reaction [1], reported in this series (1) have been determined *directly* by solving

$$\text{[1]} \qquad \mathrm{ROO^{\cdot} + RH \xrightarrow{k_p} ROOH + R^{\cdot}\ (or\ ROORH^{\cdot})}$$

the rate expression [2]

$$\text{[2]} \qquad \frac{-\mathrm{d[O_2]}}{\mathrm{d}t} = \frac{k_p[\mathrm{RH}]R_i^{1/2}}{(2k_t)^{1/2}}$$

where $-\mathrm{d[O_2]}/\mathrm{d}t$ is the rate of autoxidation of RH, R_i is the rate of free-radical chain initiation, and k_p and $2k_t$ are the rate controlling propagation and termination rate constants.

Very often more accurate values of the relative reactivity of two substrates AH and BH to a common peroxy radical can be obtained from competitive experiments in which the relative amounts of AH and BH consumed or the yields of the hydroperoxides AOOH and BOOH produced after co-oxidation are measured (2).

The number of substrates that can usefully be studied by the co-oxidation method can be greatly increased by performing the reactions in the presence of >0.5 M *tert*-butyl hydroperoxide. This is because substrates that are resistant to autoxidation oxidize with significant chain lengths in the presence of this hydroperoxide. Furthermore, kinetic analysis is simplified because of a substantial decrease in the number of elementary reactions. In this paper we report rate constants for reaction of the *tert*-butylperoxy radical with a variety of structurally different alkanes in solution which were determined by this technique.

Experimental

Materials

The hydrocarbons and most of the alcohols were obtained from commercial sources and were usually >99% pure by glc. Purification of the hydrocarbons was achieved by percolation down a column of basic alumina and distillation while the alcohols, which were used as glc standards, were used without further purification. 2,4-Dihydroxy-2,4-dimethylpentane

was prepared by the thermally initiated (di-*tert*-butyl peroxide, 1 *M*) autoxidation of 2,4-dimethylpentane at 100°C and 10 atm of oxygen. The reaction was taken to about 10% conversion and the hydroperoxides produced were reduced with triphenylphosphine. The diol was then isolated from the reaction mixture by preparative glc. *tert*-Butyl hydroperoxide was purified as described previously (1) and di-*tert*-butyl hyponitrite was prepared by the method of Kiefer and Traylor (3).

Procedures

Binary mixtures of hydrocarbons were oxidized in the presence of α,α′-azobisisobutyronitrile (0.06 *M*) and *tert*-butyl hydroperoxide (0.5–2.0 *M*) to 1–5% conversion. The total hydroperoxide was then reduced with triphenylphosphine and the hydrocarbons and alcohols were distilled from AIBN, $(C_6H_5)_3P$, and $(C_6H_5)_3PO$ by vacuum distillation. Alcohol yields were determined by glc techniques using a Varian 2800 Chromatograph equipped with 12 ft 12% OV-101 and 12% FFAP on Chromosorb W columns and flame ionization detectors.

Steady-state concentrations of *tert*-butylperoxy radicals produced during *tert*-butyl hyponitrite initiated autoxidation of the alkanes in the presence of *tert*-butyl hydroperoxide were determined by epr spectroscopy relative to a standard solution of 1,1-diphenyl-2-picrylhydrazyl.

Results and Discussion

The simplest reaction scheme that describes the α,α′-azobisisobutyronitrile (In_2) initiated co-oxidation of two alkanes, R_1H and R_2H, in the presence of *tert*-butyl hydroperoxide is

Initiation

[3] $$In_2 \xrightarrow{O_2} InO_2\cdot \xrightarrow{t\text{-BuOOH}} t\text{-}BuO_2\cdot$$

Propagation

[4] $$t\text{-}BuO_2\cdot + R_1H \xrightarrow{k_p^{(1)}} t\text{-BuOOH} + R_1\cdot$$

[5] $$t\text{-}BuO_2\cdot + R_2H \xrightarrow{k_p^{(2)}} t\text{-BuOOH} + R_2\cdot$$

[6] $$R_1\cdot + O_2 \rightarrow R_1O_2\cdot$$

[7] $$R_2\cdot + O_2 \rightarrow R_2O_2\cdot$$

Chain Transfer

[8] $$t\text{-}BuO_2\cdot + t\text{-}BuO_2\cdot \rightarrow 2t\text{-}BuO\cdot + O_2$$

[9] $$t\text{-}BuO\cdot + t\text{-BuOOH} \rightarrow t\text{-BuOH} + t\text{-}BuO_2\cdot$$

[10] $$R_1O_2\cdot + t\text{-BuOOH} \rightarrow R_1OOH + t\text{-}BuO_2\cdot$$

[11] $$R_2O_2\cdot + t\text{-BuOOH} \rightarrow R_2OOH + t\text{-}BuO_2\cdot$$

Termination

[12] $$2t\text{-}BuO_2\cdot \rightarrow t\text{-BuOOBu-}t + O_2$$

Provided that R_1OOH and R_2OOH are only formed in reactions [10] and [11] and that conversion is low (< 1%) the ratio of rate constants $k_p^{(1)}/k_p^{(2)}$ can be calculated from

[13] $$\frac{k_p^{(1)}}{k_p^{(2)}} = \frac{[R_1OOH]_t[R_2H]_0}{[R_2OOH]_t[R_1H]_0}$$

where $[R_1OOH]_t$ and $[R_2OOH]_t$ are the yields of the hydroperoxides and $[R_1H]_0$ and $[R_2H]_0$ are the initial hydrocarbon concentrations. In practice mixtures of hydroperoxides are best analyzed after quantitative reduction to the alcohols with triphenylphosphine.

[14] $$R_1OOH + (C_6H_5)_3P \rightarrow R_1OH + (C_6H_5)_3PO$$

The majority of the competitive experiments reported in this work were performed using 3-methylpentane as one of the reactants because absolute rate constants for abstraction of the secondary and tertiary hydrogens from this substrate by $t\text{-}BuO_2\cdot$ are known (1). Furthermore, keeping one reactant constant reduces cumulative errors although some relative reactivities were checked by 'circular' experiments. For instance the relative reactivities of cyclohexane and cyclopentane to 3-methylpentane were confirmed by co-oxidations of cyclohexane and cyclopentane and the relative reactivities of the various positions in an alkane were checked by autoxidation of the alkane in the absence of a second substrate.

Secondary Aliphatic C—H Bonds

Yields of secondary alcohols formed by co-oxidations of alkanes containing reactive secondary C—H bonds with 3-methylpentane are summarized in Table 1. Cyclopentane and cyclohexane have only one type of secondary C—H bond and gave only one alcohol whereas *n*-hexane and 2-methylpentane gave two secondary alcohols. Although methylcyclopentane should give two secondary alcohols (2- and 3-methylcyclopentanol) they were not separated by our analytic technique while two of the three secondary alcohols from methylcyclohexane were resolved.

In some experiments low yields of 2- and 3-hexanone and cyclohexanone were observed in co-oxidations containing *n*-hexane and cyclohexane although cyclopentanone was not detected from co-oxidations containing cyclopentane. These ketones could be formed in a cross-termination reaction [15], or by autoxidation of the secondary hydroperoxide, reaction [16] (4).

[15] 
[16] 
We were able to demonstrate that reaction [15] is unimportant by measuring the steady-state alkylperoxy radical concentration, $[RO_2\cdot]_{ss}$, for di-*tert*-butyl hyponitrite initiated autoxidations of *n*-hexane

[a]Di-*tert*-butyl hyponitrite.

and cyclohexane containing *tert*-butyl hydroperoxide at 30°C. Values of $[RO_2\cdot]_{ss}$ are listed in Table 2 and are close to the values predicted from rates of initiation and our best value of 1.2×10^3 M^{-1} s^{-1} for the termination rate constant for *tert*-butylperoxy radicals (5). The occurrence of reaction [15] would significantly reduce $[RO_2\cdot]_{ss}$ because the rate constant for reaction [15] is expected to be about three orders of magnitude larger than the termination rate constant for *t*-$BuO_2\cdot$ (6, 7).

With regards to reaction [16] Hendry *et al.* (4) have demonstrated that cyclohexyl hydroperoxide is ~13 times more reactive than cyclohexane (per molecule) towards *t*-$BuO_2\cdot$ at 80°C. The yields of secondary alcohols could, therefore, be reduced by this reaction. Because of this we have only considered experiments in which the yield of ketone was less than one tenth the yield of the corresponding alcohol.

Absolute rate constants for secondary aliphatic C—H bonds fall in the rage 1×10^{-4} to 9×10^{-4}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

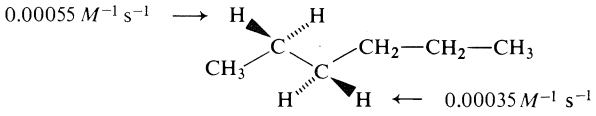
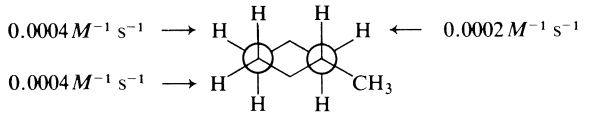
M^{-1} s^{-1} per active hydrogen (Table 1). Although some of this difference in reactivity must be due to experimental error there is no doubt that the secondary hydrogens of *n*-hexane are more reactive than the secondary hydrogens of 3-methylpentane (k_p/H = 0.0002 M^{-1} s^{-1}) and that those attached to the penultimate carbon are more reactive than those on C-3 (structure **1**). A similar difference in the reactivity of the secondary hydrogens attached to C-2 and C-3 of a *n*-alkane towards abstraction by alkylperoxy radicals has been found in the autoxidation of dodecane (8) and hexadecane[4,5] at higher temperatures while other radicals show a preference for the secondary hydrogens on C-2 (7, 9). The two types of secondary hydrogens in 2-methylpentane exhibit the same difference in reactivity towards *t*-BuOO$^\bullet$ although both positions are less reactive than the corresponding sites in *n*-hexane.



1

The hydrogens in cyclohexane are somewhat less reactive than the two types of secondary hydrogens in *n*-hexane and are slightly more reactive than the somewhat more protected secondary hydrogens in 3-methylpentane. Not unexpectedly cyclopentane is more reactive (per hydrogen) than cyclohexane to *t*-$BuO_2^\bullet$, a situation that is found for other free radicals such as Br$^\bullet$, $C_6H_5^\bullet$, and $CCl_3^\bullet$ (10, 11).

The overall rate constant (per H) for abstraction of a secondary hydrogen from methylcyclopentane is slightly smaller than the value for cyclopentane while the reactivity of the secondary hydrogens of methylcyclohexane depends to some extent on the distance from the methyl group (structure **2**).



2

Tertiary Aliphatic C—H Bonds

The yields of the tertiary alcohols produced by co-oxidation of alkanes containing reactive tertiary C—H bonds and 3-methylpentane in the presence of *tert*-butyl hydroperoxide at 30°C are summarized in Table 3. All these alkanes gave only one tertiary alcohol with the exception of 2,3-dimethylpentane which gave 2- and 3-hydroxy-2,3-dimethylpentane. 2,4-Dimethylpentane could, in principle, give 2,4-dihydroxy-2,4-dimethylpentane by intramolecular hydrogen abstraction (12, 13). It would, however, appear that in the presence of 1.0 *M tert*-butyl hydroperoxide this reaction does not compete with abstraction of the hydroperoxidic hydrogen.

Absolute rate constants for tertiary aliphatic C—H bonds fall in the rage $1 \times 10^{-3} - 2 \times 10^{-2}$ M^{-1} s^{-1} (Table 3) depending on the structure of the alkane. These rate constants along with the Neuman projections of the hydrocarbons are presented in Scheme 1.

It is possible to draw two general conclusions from an examination of Scheme 1. First, the reactivity of a tertiary aliphatic C—H bond to *t*-$BuO_2^\bullet$ depends on the size of the alkyl substituent on the adjacent carbon. Thus reactivity increases in the order 2,2,4-trimethylpentane < 2,4-dimethylpentane < 2-methylpentane ~ 2-methylbutane which is consistent with a decrease in reactivity with an increase in size.

Secondly, the reactivity of a *t*-C—H bond is less sensitive to the bulk of an alkyl group attached to the carbon bearing the reactive hydrogen than it is to the size of the alkyl group on the adjacent carbon. Thus 2,2,3-trimethylpentane is more than twice as reactive as 2,2,4-trimethylpentane, a difference that is almost certainly due to the relief of steric strain on removal of a hydrogen atom from a sterically crowded sp^3 carbon.

In addition the tertiary hydrogens of methylcyclopentane and methylcyclohexane exhibit the expected enhanced reactivity with methylcyclopentane more reactive than methylcyclohexane.

Arrhenius Parameters

Arrhenius parameters for selected alkanes relative to the parameters for abstraction of the tertiary C—H in 3-methylpentane by *t*-$BuO_2^\bullet$ were determined from co-oxidations conducted from 30 to 80°C and the results are listed in Table 4. In general these parameters serve to demonstrate that differences in reactivity are the result of differences in both the entropy and enthalpy of activation. More specifically the high *A*-factors for cyclohexane and the secondary hydrogens in methylcyclohexane are consistent with the suggestion that there is an increase in entropy upon conversion of a tight cyclohexane ring to a looser cyclohexyl radical while the high activation energy for this compound arises because an unstrained sp^3 hybridized carbon is converted to a strained sp^2 carbon (10).

The *A*-factor for cyclopentane is similar to the *A*-factor for an acyclic aliphatic *s*-C—H which means that the enhanced reactivity of this substrate is entirely due to a low activation energy. A low acti-

[e]2,3-Dimethylpentan-3-ol.

vation energy probably reflects the relief of strain upon removal of a H-atom from cyclopentane. It is interesting to note that the activation energy difference, $E_p^{c\text{-}C_6H_{12}} - E_p^{c\text{-}C_5H_{10}} = 2.75$ kcal mol^{-1}, is very similar to the difference in activation energies for reaction of Br• with these cyclanes obtained by Ferguson and Whittle ($\Delta E_{Br\bullet} = 2.1$ kcal mol^{-1}) (10) and Bunce and Hadley ($\Delta E_{Br\bullet} = 2.7$ kcal mol^{-1}) (11).

In the case of the tertiary C—H bonds 2,2,4-trimethylpentane is less reactive than 3-methylpentane because $\Delta S^{\ddagger}_{3MP} - \Delta S^{\ddagger}_{2,2,4\text{-}TMP} = 6$ cal deg^{-1} mol^{-1} which more than compensates for $E_{3MP} - E_{2,2,4TMP} = 0.8$ kcal mol^{-1}. The low reactivity of 2,2,4-trimethylpentane to autoxidation has been noted previously (2) and attributed to shielding of the tertiary hydrogen from peroxy radical attack.

It is interesting to note that the *t*-C—H bond in 2,2,3-trimethylbutane is 1.5 times more reactive than the *t*-C—H in 3-methylpentane despite a lower entropy of activation. In this case the decrease in activation energy of 3 kcal mol^{-1} because of relief of steric strain upon removal of the tertiary hydrogen more than compensates for the difference in entropy of activation.

In summary it would appear that a bulky group near the reaction centre either accelerates the rate of transfer of a hydrogen atom to a peroxy radical because of the relief of steric strain or decreases the rate by lowering the probability of forming the activated complex. Furthermore when the bulky group is attached to the β-carbon the decrease in rate because of a decrease in $\Delta S^{\ddagger}$ more than compensates for the increase in rate due to a decrease in E while the reverse is operative when the bulky group is attached to the α-carbon.

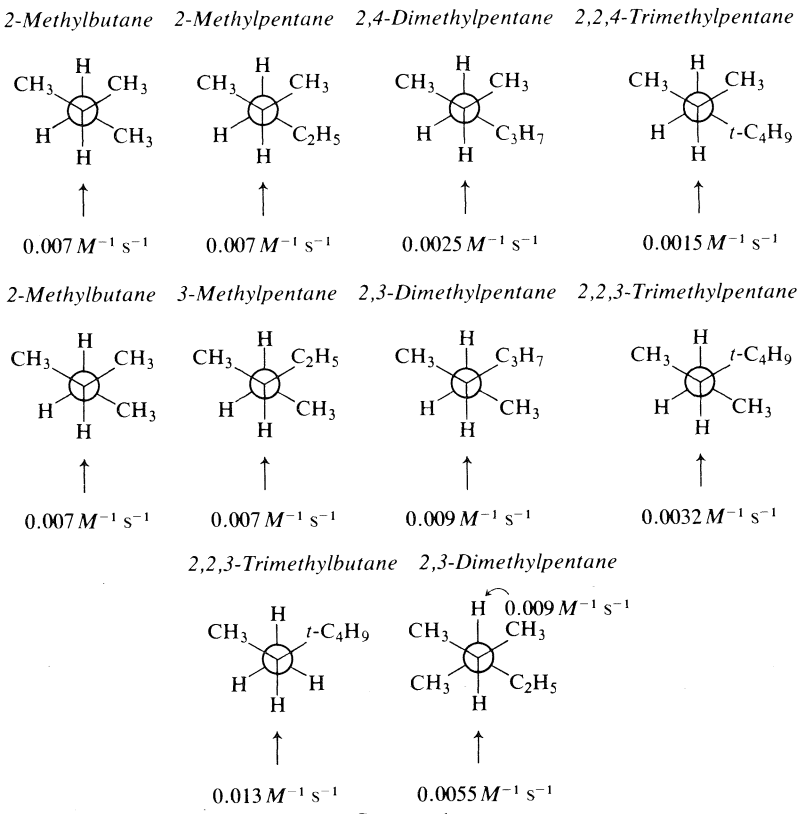

SCHEME 1

Aliphatic C—D Bonds

Rate constants and Arrhenius parameters for reaction of perdeuterated methylcyclohexane and 3-methylpentane with the *tert*-butylperoxy radical are gathered in Table 5. The kinetic data for methylcyclohexane-d_{14} were obtained relative to 3-methylpentane while the data for 3-methylpentane-d_{14} were obtained relative to 2,2,4-trimethylpentane. The kinetic isotope effects (k_p^H/k_p^D) of 24–28 are significantly larger than the isotope effects that we obtained for reaction of t-$BuO_2^\bullet$ with aralkanes, cyclohexane, and tetrahydrothiophene (14). Furthermore an isotope effect of ~25 is well above the theoretical limit of 9.5 for breaking a C—H bond (15) which suggests that factors other than complete loss of zero-point energies of stretching and bending vibrations in the transition state influence the magnitude of k_p^H/k_p^D. There could, of course, be additional contributions to this ratio because of secondary deuterium isotope effects. These are, however, usually small and it is unlikely that they would increase the isotope effect from 9.5 to 25.

Relative reactivities for methylcyclohexane-d_{14} were determined over a temperature range and the estimated activation parameters are compared with the values for protiated methylcyclohexane in the last two columns in Table 5. For the tertiary and secondary hydrogens $A_p^D = 3\text{–}5 \times A_p^H$ and $E_p^D = E_p^H + 2.5$ to 3.1 kcal mol^{-1}. These activation parameters suggest an entropy of activation difference of ~3 cal deg^{-1} mol^{-1} in favor of the fully deuterated compound and an enthalpy of activation difference of ca. 1.5 kcal mol^{-1} above the maximum. Clearly further work on the reactivity of deuterated alkanes to t-$BuO_2^\bullet$ is needed to clarify these anomalous differences.

Comparison with Other Work

We have previously (5) used the direct method to measure rate constants for reaction of cyclohexane, tridecane, and hexadecane with t-$BuO_2^\bullet$ and where a comparison can be made the two methods give results that are in excellent agreement. For instance the direct method gave k_p(overall) = 0.0031 M^{-1} s^{-1} for cyclohexane at 30°C while the competitive method gives an identical value. Hendry and coworkers (4) have also used the direct method to measure the reactivity of this cyclane to t-$BuO_2^\bullet$ and report a value of 0.175 M^{-1} s^{-1} at 80°C. Our value at this temperature calculated from the Arrhenius

parameters in Table 4 is 0.25 M^{-1} s^{-1}. The direct method has been used by Niki and Kamiya (16) to determine overall reactivities of several alkanes to *t*-$BuO_2^{\bullet}$ at 90°C and their results and the rate constants estimated from our Arrhenius parameters are in satisfactory agreement. For instance, we estimate that the overall reactivity of 3-methyloctane should be ~0.7 M^{-1} s^{-1} at 90°C while Niki and Kamiya report a value of 0.66 to 0.74 M^{-1} s^{-1}.

Synthesis of two in vivo metabolites of *N*-(*n*-propyl)phentermine

RONALD T. COUTTS, ABRAHAM BENDERLY, ALLAN L. C. MAK, AND WESLEY G. TAYLOR
Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alta., Canada T6G 2N8

Received April 26, 1978

RONALD T. COUTTS, ABRAHAM BENDERLY, ALLAN L. C. MAK, and WESLEY G. TAYLOR. Can. J. Chem. **56**, 3054 (1978).

The phenolic metabolite, 1-(4-hydroxyphenyl)-2-methyl-2-(*n*-propylamino)propane (**1***e*) was prepared by a Ritter reaction from either 3-(4-methoxyphenyl)-2-methyl-1-propene or 3-(4-methoxyphenyl)-2-methyl-2-propanol and propionitrile. Three other products of the Ritter reaction were isolated and identified by interpretation of their mass spectra. Another phenolic metabolite, 1-(4-hydroxy-3-methoxyphenyl)-2-methyl-2-(*n*-propylamino)propane (**1***f*) could not be prepared by a Ritter reaction but was obtained from the product of the reaction between 3-(4-benzyloxy-3-methoxyphenyl)-2-methyl-1-propene and iodine isocyanate.

RONALD T. COUTTS, ABRAHAM BENDERLY, ALLAN L. C. MAK et WESLEY G. TAYLOR. Can. J. Chem. **56**, 3054 (1978).

On a préparé le métabolite phénolique (hydroxy-4 phényl)-1 méthyl-2 (*n*-propylamino)-2 propane (**1***e*) par réaction de Ritter à partir du propionitrile et du (méthoxy-4 phényl)-3 méthyl-2 propène-1 ou du (méthoxy-4 phényl)-3 méthyl-2 propanol-2. On a isolé trois autres produits de la réaction de Ritter et on les a identifiés par interprétation de leurs spectres de masse. Un autre métabolite phénolique, l'(hydroxy-4 méthoxy-3 phényl)-1 méthyl-2 (*n*-propylamino)-2 propane (**1***f*), qu'on n'a pas réussi à préparer par réaction de Ritter, a été obtenu à partir du produit de la réaction entre l'isocyanate d'iode et le (benzyloxy-4 méthoxy-3 phényl)-3 méthyl-2 propène-1.

In a continuation of studies on the effect on in vitro and in vivo metabolism of increasing the length of the *N*-alkyl chain of clinically useful drugs (1, 2), *N*-(*n*-propyl)phentermine (**1***d*, NPP), a higher homolog of the anorectic sympathomimetic drug mephentermine (**2***b*) was metabolized in vivo in the rat and two major phenolic metabolites were isolated.[1] Interpretation of their mass spectra suggested that these new metabolites were 1-(4-hydroxyphenyl)-2-methyl-2-(*n*-propylamino)propane (**1***e*) and 1-(4-hydroxy-3-methoxyphenyl)-2-methyl-2-(*n*-propylamino)propane (**1***f*). Conclusive identification of the metabolites was not possible in the absence of authentic samples of **1***e* and **1***f*. Both metabolites were also required for quantitative analysis studies. This note describes our approaches to the synthesis of **1***e* and **1***f*.

Phentermines are not as readily obtained synthetically as amphetamines (1). Patented procedures for the synthesis of phentermine (**2***a*) and mephentermine (**2***b*) are complex (3) and are not easily applicable to phenolic derivatives of phentermine. The Ritter reaction (4), however, provides a direct synthetic route to these compounds. Treatment of the alkene (**3**) or the tertiary alcohol (**4**) with propionitrile under Ritter conditions was more complex than anticipated and gave four products which were readily separated by gc. The mass spectra of the two major products were readily interpretable in terms of

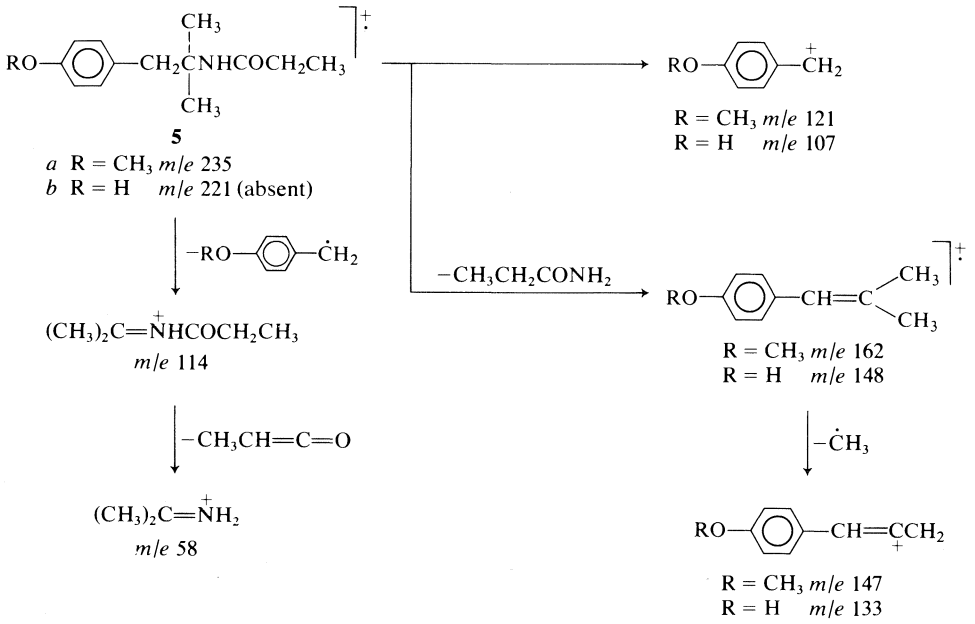
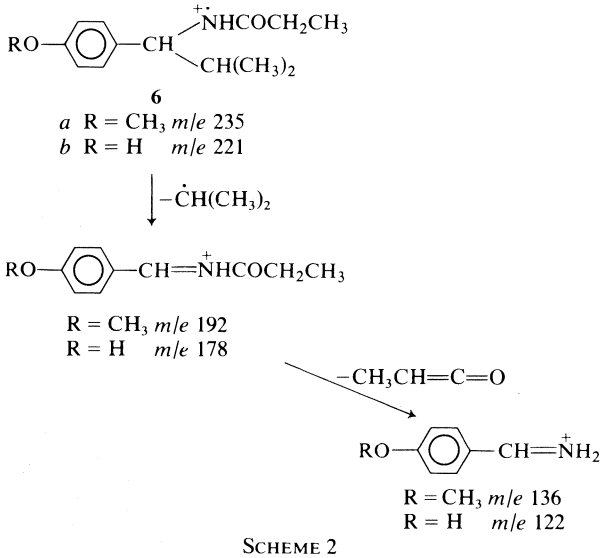


SCHEME 1

structures **5***a* and **5***b* (Scheme 1). Comparable fragmentation patterns are observed in the spectra of structurally related methoxylated and phenolic amines (5). The two minor products had very simple mass spectra, each containing only three ions. These spectra were also readily interpreted (Scheme 2) and indicated that the structures of the minor reaction products were **6***a* and **6***b*. The formation of the latter two products is consistent with the formation of significant quantities of the benzylic carbonium ion (**7**) in addition to the expected tertiary ion (**8**) during the course of the Ritter reaction.



SCHEME 2

An effort was made to improve the yield of the desired compound (**5***a*) by altering the conditions of the Ritter reaction. The ratio of sulfuric acid to glacial acetic acid used proved to be critical; by suitably altering this ratio, either the phenol (**5***a*) or the methyl ether (**5***b*) was the major product of the reaction with **3** or **4** (Table 1). The phenolic compounds **5***a* and **6***a* were separated from **5***b* and **6***b* by alkaline extraction and from each other by column chromatography or fractional crystallization. Reduction of **5***a* with diborane (6) gave the desired 1-(4-hydroxyphenyl)-2-methyl-2-(*n*-propylamino)propane (**1***e*).

The Ritter reaction was not applicable to the synthesis of 1-(4-hydroxy-3-methoxyphenyl)-2-methyl-2-(*n*-propylamino)propane (**1***f*). The presence of the electron-donating group at the C-3 position of **9** promoted ring closure (3) to a mixture of the 3,4-dihydroisoquinoline derivative (**10***a*), the corresponding phenol (**10***b*) and the phenol acetate (**10***c*) (Scheme 3). An alternative method of synthesizing **1***f* was sought. It is well documented that iodine isocyanate (INCO) adds regioselectively to unsymmetrical alkenes, whereby the isocyanate function appears at the more substituted double-bond carbon atom (7). When this reagent and the unsymmetrical alkene (**9**) were allowed to react, the desired addition occurred and 4-benzyloxy-3-methoxyphentermine (**12**, R = H) was subsequently obtained as illustrated in Scheme 4. The *N*-propionyl derivative (**12**, R = $COCH_2CH_3$) was prepared and reduced with diborane to 1-(4-benzyloxy-3-methoxyphenyl)-2-

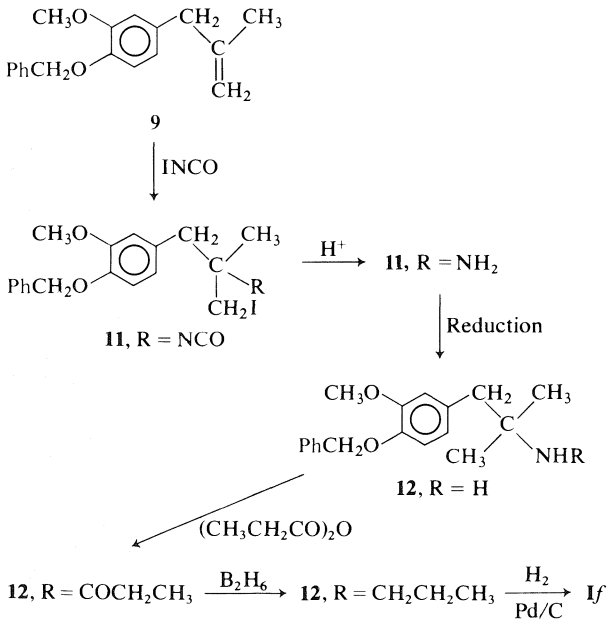

SCHEME 4

Experimental

Melting points are uncorrected. The ^{1}Hmr spectra were determined for solutions in deuteriochloroform with a Varian Associates EM 360A (60 MHz) spectrometer, with TMS as internal standard. Combined gc–ms was performed on a Hewlett Packard 5710A gas chromatograph – Hewlett Packard 5980A mass spectrometer using a glass column, 0.85 m long, 4 mm id, packed with 5% OV-101 on Chromosorb 750 at 160°C, helium flow rate 60 ml/min. Accurate mass measurements were made on an A.E.I., MS-9 or MS-12 mass spectrometer at an ionizing potential of 70 eV. The starting materials, 1-(4-benzyloxy-3-methoxy)phenyl-2-propanone and 1-(4-methoxy)-phenyl-2-propanone were prepared by a reported procedure (8).

*1-(4-Methoxyphenyl)-2-methyl-2-propanol (**4**)*

A benzene solution (40 ml) of 1-(4-methoxy)phenyl-2-propanone (19.2 g, 0.1 mol) was added dropwise (40 min) to an ether solutions of methyllithium (Alfa Inorganic, Inc., 250 ml of 0.6 *M*) at −65°C under N_2. After stirring for 2 h and warming up to room temperature (1 h), the reaction mixture was quenched with 5% aqueous NH_4Cl (100 ml) and extracted with ether (3 × 50 ml). The organic phase was then dried (Na_2SO_4) and concentrated. Bulb-to-bulb distillation of the residue (70°C/0.02 Torr) provided 17 g (95%) of **4** as a colorless solid, mp 37.5–38.5°C; ^{1}Hmr δ: 1.22 (6H, s, $C(CH_3)_2$), 1.6 (1H, s, br, OH), 3.8 (3H, s, CH_3), 7.0 (4H, q, *J* = 8–9 Hz, C_6H_4); ms *m/e* (% relative abundance): 181 (1), 180 (9), 165 (9), 123 (10), 122 (100), 121 (38), 107 (18), 92 (4), 91 (11), 79 (5), 78 (11), 65 (5), 59 (66). *Exact mass* calcd. for $C_{11}H_{16}O_2$: 180.1146; found: 180.1152. *Anal.* calcd. for $C_{11}H_{16}O_2$: C 73.30, H 8.95; found: C 73.04, H 8.81.

*3-(4-Benzyloxy-3-methoxyphenyl)-2-methyl-1-propene (**9**)*

To a magnetically-stirred suspension of triphenylphosphonium bromide (10.49 g, 0.029 mol) in THF (50 ml) at −78°C was added dropwise, *n*-butyllithium solution (18.5 ml, 1.55 *M* in hexane) under N_2. The reaction mixture was allowed to warm up to room temperature and it was maintained at this temperature for 2 h. The solution was cooled again to −78°C and the ketone, 1-(4-benzyloxy-3-methoxyphenyl)-2-propanone (7.2 g, 0.029 mol) in THF (70 ml) was then added dropwise (1 h). The reaction mixture was warmed up to room temperature (1 h), stirred at this temperature for 2 h then at reflux temperature for 20 h. After cooling, the mixture was concentrated and 40 ml of ether–pentane (5:1) solution was added. The resulting precipitate of triphenylphosphine oxide was filtered off. Elution chromatography of the concentrated filtrate on silica gel (cyclohexane–ether, 4:1) afforded 7.2 g (94%) of **9**. Molecular distillation (70°C/0.02 Torr) resulted in a colorless oil which solidified on standing, mp 29–30°C; ^{1}Hmr δ: 1.63 (3H, s, CH_3), 3.3 (2H, s, $ArCH_2$), 3.9 (3H, s, OCH_3), 4.85 (2H, s, br, $C{=}CH_2$), 5.25 (2H, s, OCH_2), 6.8 (3H, m, C_6H_3), 7.6 (5H, m, C_6H_5); ms *m/e* (% relative abun-

dance): 268 (33), 177 (27), 117 (7), 107 (5), 91 (100), 55 (5). *Exact mass* calcd. for $C_{18}H_{20}O_2$: 268.1458; found: 268.1463. *Anal.* calcd. for $C_{18}H_{20}O_2$: C 80.56, H 7.51; found: C 80.40, H 7.50.

*3-(4-Methoxyphenyl)-2-methyl-1-propene (**3**)*

Using a procedure similar to that employed in the preparation of **9**, 1-(4-methoxy)phenyl-2-propanone (3.3 g) was reacted to give 3.05 g (94%) of the alkene **3**, bp 44–45°C 0.12 Torr; ^{1}Hmr δ: 1.63 (3H, s, CH_3), 3.25 (2H, s, $ArCH_2$), 3.8 (3H, s, OCH_3), 4.75 (2H, s, br, $C{=}CH_2$), 7.0 (4H, q, J = 8–9 Hz, C_6H_4); ms *m/e* (% relative abundance): 163 (22), 162 (100), 161 (10), 149 (7), 147 (88), 137 (16), 135 (5), 121 (56), 117 (9), 115 (10), 103 (8), 91 (26), 78 (14), 77 (13). *Exact mass* calcd. for $C_{11}H_{14}O$: 162.1040; found: 162.1048. *Anal.* calcd. for $C_{11}H_{14}O$: C 81.44, H 8.70; found: C 81.78, H 8.66.

N-*[1-(4-Hydroxyphenyl)-2-methyl-2-propyl]propionamide (5a)*

Concentrated H_2SO_4 (3 ml, Baker, 96%) was added to a stirred solution of propionitrile (0.66 g, 0.012 mol) in glacial acetic acid (2.5 ml) at ice bath temperature. The alcohol (**4**) (1.8 g, 0.01 mol) dissolved in acetic acid (1 ml) was added dropwise and the mixture was stirred at room temperature for 18 h, neutralized with 10% Na_2CO_3 and extracted (3 × 20 ml) with ether – methylene chloride (14:11). Gas chromatographic analysis showed four peaks, the retention times of which were **5***b*, 10.51 min; **6***b*, 12.66 min; **5***a*, 13.94 min; **6***a*, 14.88 min; gc–ms *m/e* (% relative abundance) **5***b*: 235 (5), 162 (65), 147 (12), 121 (30), 114 (42), 58 (100); **6***b*, m/e 235 (5), 192 (74), 136 (100); **5***a*, m/e 148 (41), 133 (21), 114 (50), 77 (14), 58 (100); **6***a*: 221 (12), 178 (81), 122 (100).

To separate the phenolic compounds, the organic layer was washed with 10% NaOH. After acidification, the aqueous layer was extracted with CH_2Cl_2 and the combined extracts were washed with brine and dried (Na_2SO_4). Removal of the solvent produced 0.98 g (42%) of **5***a*, mp 138–139°C (from ether–hexane); ^{1}Hmr δ: 1.0–1.5 (9H, m, $C(CH_3)_2$, CH_2CH_3), 2.0 (2H, q, J = 7 Hz, CH_2), 3.0 (2H, s, $ArCH_2$), 5.2 (H, s, br, OH), 6.4 (4H, q, J = 8–9 Hz, C_6H_4). *Exact mass* calcd. for $C_{13}H_{19}NO_2$: 221.1411; found: 221.1413. *Anal.* calcd. for $C_{13}H_{19}NO_2$: C 70.56, H 8.65, N 6.33; found: C 70.59, H 8.72, N 6.02.

*1-(4-Hydroxyphenyl)-2-methyl-2-(*n*-propylamino)propane (**1e**)*

To a solution of borane in THF (8 ml, 0.10 *M*) in a 50 ml flask equipped with a reflux condenser, dropping funnel, and a magnetic stirring bar and maintained under N_2, was added 0.5 g (2.3 mmol) of the amide (**5***a*) in THF (8 ml) over 15 min. The temperature was maintained at 0°C during the addition. The colorless solution was then refluxed for 10 h, cooled to room temperature, and treated with 6 *N* HCl (5 ml). After stirring for 0.5 h, the aqueous layer was separated, washed with ether, basified with 20% Na_2CO_3 (pH 9–9.5), and extracted (2 × 15 ml) with ether–CH_2Cl_2 (14:11). The combined extract was washed with brine and dried (Na_2SO_4). Removal of the solvent gave 0.4 g (86%) of **1***e*, mp 89.5–90.5°C (from hexane–CCl_4); ^{1}Hmr δ: 0.7–1.9 (11H, m, $C(CH_3)_2$, $CH_2CH_2CH_3$), 2.4–3.0 (4H, m, $ArCH_2$, $CH_2CH_2CH_3$), 5.3 (2H, s, br, NH, OH), 6.9 (4H, q, J = 8–9 Hz, C_6H_4); ms *m/e* (% relative abundance): 192 (2), 101 (7), 100 (100), 58 (60). *Exact mass* calcd. for $C_{12}H_{18}NO$ $(M - CH_3)^+$: 192.1384; found: 192.1386. *Anal.* calcd. for $C_{13}H_{21}NO$: C 75.32, H 10.21, N 6.76; found: C 75.11, H 10.03, N 6.67.

*1-Ethyl-7-hydroxy-6-methoxy-3,3-dimethyl-3,4-dihydroisoquinoline (**10**b)*

Concentrated H_2SO_4 (14 ml) was added to a stirred mixture of glacial acetic acid (40 ml) and propionitrile (1.3 ml, 0.018 mol) at 0°C. The alkene (**9**) (4 g, 0.015 mol) in glacial acetic acid (10 ml) was added dropwise at ice-bath temperature. The resulting mixture was stirred at room temperature for 15 h. The mixture was neutralized with 20% Na_2CO_3, then extracted with methylene chloride (2 × 30 ml) and the combined extracts were dried and evaporated *in vacuo*. The residue (4.05 g) was shown by ^{1}Hmr to be a mixture of **10***b* (60%), **10***a* (24%), and **10***c* (16%). The phenolic compound **10***b* was separated from the remainder (3 g) of the mixture (**10***a–c*) as described for **5***a* and 1.5 g of **10***b* was obtained, mp 146–148°C (from chloroform); ^{1}Hmr δ: 1.0–1.5 (9H, m, $C(CH_3)_2$, CH_2CH_3), 2.4–2.9 (4H, m, $ArCH_2$, CH_2CH_3), 3.9 (3H, s, OCH_3), 6.7 (1H, s, C_6H), 7.2 (1H, s, C_6H), 8.9 (1H, s, br, OH); ms *m/e* (% relative abundance): 234 (13), 233 (79), 232 (41), 219 (16), 218 (100), 216 (10), 204 (8), 203 (16), 191 (36), 190 (23), 177 (6), 164 (9), 163 (10), 161 (11), 145 (8), 117 (10), 91 (12). *Exact mass* calcd. for $C_{14}H_{19}NO_2$: 233.1411; found: 233.1412.

*1-(4-Benzyloxy-3-methoxyphenyl)-2-iodomethyl-2-propylisocyanate (**11**, R = NCO)*

A slurry of iodine (9 g, 0.035 mol) and freshly prepared silver isocyanate (6.88 g, 0.046 mol) in dry ether (10 ml) was stirred for 1 h at 25°C under dry N_2. The mixture was then cooled to −20°C and the alkene (**9**) (6.7 g, 0.025 mol) in ether (25 ml) was added dropwise. After stirring at room temperature for 36 h, the reaction mixture was filtered through Celite and washed with a saturated Na_2SO_3 solution to remove excess iodine. The ether layer was then washed with brine, dried (Na_2SO_4), and evaporated, to yield 9.18 g of a pale yellow oil (mixture by ^{1}Hmr of 73% **11**, R = NCO and 20% **9**); ir (neat) ν_{max} 2250 (NCO) cm^{-1}; ^{1}Hmr of **11**, R = NCO δ: 1.45 (3H, s, CH_3), 2.85 (2H, s, CH_2I), 3.3 (2H, s, $ArCH_2$), 3.85 (3H, s, OCH_3), 5.2 (2H, s, OCH_2), 6.8 (3H, m, C_6H_3), 7.5 (5H, m, C_6H_5).

*1-(4-Benzyloxy-3-methoxyphenyl)-2-methyl-2-aminopropane (**12**, R = H)*

To the crude iodoisocyanate (**11**, R = NCO) (9.18 g, containing 20% of **9**) in ether (100 ml) was added dropwise concentrated HCl (35 ml). The mixture was stirred for 6 h, and the precipitate of the iodoamine (**11**, R = NH_2) hydrochloride salt which formed was filtered and washed with ether (5.6 g, 68%).

To a suspension of LAH (2 g) in dry DME (125 ml) under N_2 the dried hydrochloride salt of **11**, R = NH_2 (5.6 g) was added portionwise. After refluxing for 36 h, the mixture was cooled to 0°C and was treated with 40 ml of 4 *N* HCl. The mixture was stirred (3 h), filtered through Celite, and washed with water. The resulting solution was basified with solid NaOH, and extracted with ether (3 × 50 ml). Evaporation of the combined ether extracts gave 2.1 g (57%) of **12**, R = H, as a colorless solid; ^{1}Hmr δ: 1.2 (6H, s, $C(CH_3)_2$), 1.6 (2H, s, br, NH_2), 2.65 (2H, s, $ArCH_2$), 3.9 (3H, s, OCH_3), 5.25 (2H, s, OCH_2), 6.8 (3H, m, C_6H_3), 7.5 (5H, m, C_6H_5); ms *m/e* (% relative abundance): 286 (1), 285 (3), 270 (4), 229 (4), 228 (24), 137 (6), 107 (8), 91 (61), 65 (20), 59 (23), 58 (100), 51 (5). *Exact mass* calcd. for $C_{18}H_{23}NO_2$: 285,1727; found: 285.1728. The hydrochloride of the title compound had mp 178–179°C. *Anal.* calcd. for $C_{18}H_{24}ClNO_2$: C 67.17, H 7.52, N 4.35, Cl 11.02; found: C 67.13, H 7.30, N 4.14, Cl 11.15.

*1-(4-Benzyloxy-3-methoxyphenyl)-2-methyl-2-(*n*-propylamino)propane (**12**, R = $CH_2CH_2CH_3$)*

To a solution of **12**, R = H (2.10 g, 7.37 mmol) in dry THF (40 ml) and triethylamine (3.1 ml, 22.1 mmol) was added dropwise and with stirring, a solution of propionic anhydride (1.5 ml, 11 mmol) in THF (10 ml). Stirring was continued for

15 h then a solution of 2 *N* NaOH (10 ml) was added and the mixture was stirred for a further 2 h. The organic layer was separated and the aqueous layer extracted with CH_2Cl_2 (2 × 25 ml). The combined organic extracts were dried (Na_2SO_4) and evaporated to provide the amide (**12**, R = $COCH_2CH_3$) as a colorless oil 2.4 g (97%) which solidified on standing, mp 80–82°C (diethyl ether).

A solution of the amide **12**, R = $COCH_2CH_3$ (2 g, 5.87 mmol) in THF (15 ml) was reduced with diborane (23.5 ml, 1 *M* in THF) according to the procedure described in the preparation of **1***e*, and **12**, R = $CH_2CH_2CH_3$ (1.51 g, 79%) was obtained as the hydrochloride salt, mp 190°C; ^{1}Hmr of base δ: 0.8–1.2 (9H, m, $C(CH_3)_2$, $CH_2CH_2CH_3$), 1.4 (2H, m, $CH_2CH_2CH_3$), 2.4–2.8 (5H, m, $ArCH_2$, NH, $RNHCH_2R$), 3.95 (3H, s, OCH_3), 5.2 (2H, s, OCH_2), 6.7 (3H, m, C_6H_3), 7.5 (5H, m, C_6H_5); ms *m/e* (% relative abundance): 327 (2), 268 (6), 223 (5), 177 (6), 150 (5), 149 (31), 114 (16), 101 (43), 100 (100), 92 (4), 91 (64), 70 (8), 58 (69). *Exact mass* calcd. for $C_{21}H_{29}NO_2$: 327.2190; found: 327.2193.

*1-(4-Hydroxy-3-methoxyphenyl)-2-methyl-2-(*n*-propylamino)propane (**1***f*)*

A solution of the amine (**12**, R = $CH_2CH_2CH_3$) (1.5 g, 4.59 mmol) in ethanol (100 ml) was hydrogenated over palladium–charcoal (2.7 g) at 40 psi for 17 h. The mixture was filtered through Celite and concentrated to give 0.7 g (82%) of **1***f*; ^{1}Hmr δ: 0.8–1.2 (9H, m, $C(CH_3)_2$, $CH_2CH_2CH_3$), 1.8 (2H, m, $CH_2CH_2CH_3$), 2.6–2.8 (4H, m, $ArCH_2$, $CH_2CH_2CH_3$), 3.85 (3H, s, OCH_3), 5.5 (2H, s, br, NH, OH), 6.8 (3H, m, C_6H_3); ms *m/e* (% relative abundance): 222 (1), 137 (5), 122 (2), 116 (1), 100 (100), 98 (2), 94 (2), 91 (2), 77 (2), 71 (1), 58 (27). *Exact mass* calcd. for $C_{13}H_{20}NO_2(M - CH_3)^+$: 222.1489; found: 222.1492. A sample for analysis was purified by gc (Varian aerograph 90-P instrument) and the product with retention time 9.1 min on a 180 cm × 4 mm id stainless steel column containing 3% OV-101 on Chromosorb W (column temperature 160°C; He flow rate 60 ml/min) was collected as colorless needles, mp 114–115°C. *Anal.* calcd. for $C_{14}H_{23}NO_2$: C 70.85, H 9.77, N 5.90; found: C 70.38, H 9.68, N 5.86.

Inductive substituent constants from dissociation of methyl-substituted 2-picolinium ions[1]

ALFRED FISCHER, MURRAY JOHN KING, AND FRANK PRICE ROBINSON
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received April 20, 1978

ALFRED FISCHER, MURRAY JOHN KING, and FRANK PRICE ROBINSON. Can. J. Chem. **56**, 3059 (1978).

The dissociation constants of a series of 28 α-substituted 2-methylpyridinium ions in water at 25°C have been measured by potentiometric and spectrophotometric methods. Correlation of the $-pK$ values with σ_I values gives slope $\rho_I = 5.45$, intercept $-pK_0 = -5.81$, correlation coefficient $r = 0.991$, and enables new σ_I values to be evaluated. Dissociation constants for the 2-pyridinylmethylammonium ion and its *N*-methyl and *N,N*-dimethyl derivatives are also reported.

ALFRED FISCHER, MURRAY JOHN KING et FRANK PRICE ROBINSON. Can. J. Chem. **56**, 3059 (1978).

Faisant appel à des méthodes potentiométrique et spectrophotométrique, on a mesuré à 25°C pour des solutions aqueuses, les constantes de dissociation d'une série de 28 ions méthyl-2 pyridinium substitués en α. La corrélation des valeurs de $-pK$ avec les valeurs σ_I fournit une pente $\rho_I = 5.45$, une ordonnée à l'origine $-pK_0 = -5.81$, un coefficient de corrélation $r = 0.991$ et elle permet d'évaluer de nouvelles valeurs σ_I. On rapporte aussi les constantes de dissociation de l'ion méthylammonium-2 pyridinyle et de ses dérivés *N*-méthyle et *N,N*-diméthyle.

[Traduit par le journal]

Introduction

The analysis of substituent electronic effects in aromatic systems has been carried out using both single substituent parameter and dual substituent parameter treatments. The single substituent parameter approach involves the use of the Hammett equation (1–5).

$$\log (k/k_o) = \rho\sigma$$

In this approach the substituent constant (σ) is a function of both the substituent and its position, i.e., *meta* and *para* substituents have different σ values, whereas the reaction constant (ρ), a susceptibility measure, is independent of the position of the substituent within the aromatic ring. As Taft has pointed out (6) the Hammett equation is a polar (inductive) effect relationship,[2] substituent constants measuring the inductive effect of the substituents *m,p*-XC_6H_4, relative to that of C_6H_5, operating across the Ar—Y bond in the general reaction:

$$Ar—Y + Ph—Y' \rightleftharpoons Ar—Y' + Ph—Y$$

A common cause of deviation from the Hammett equation, most evident in the case of *para*-substituted phenyl groups, is the existence of π delocalization (resonance) effects operating across the Ar—Y bond. Additional classes of substituent constants have been developed in attempts to allow for the situations where the π acceptor properties of Y and Y′ differ significantly (σ^+) and, in the converse situations, where the π donor properties of Y and Y′ are different (σ^-) (2, 9). Although the use of modified substituent constants (σ^+, σ^-) in addition to the purely inductive substituent constants (σ^0) does extend the number of successful reactivity correlations, it has long been evident (10, 11) that aromatic reactivities do not fall neatly into three classes and dual substituent parameter treatments have been developed in attempts to accommodate this reality. One approach, initially developed by Yukawa and Tsuno (12, 13), has followed that of the single substituent parameter treatment in regarding the aryl group as the substituent and using Hammett type substituent constants to measure its inductive (σ^0) and resonance ($\sigma^+ - \sigma^0$, $\sigma^- - \sigma^0$) effects. An alternative approach, most thoroughly exploited by Taft and his co-workers, considers the group X as the substituent and the C_6H_4Y group as the reaction centre (6, 11, 14, 15). In this approach the inductive (σ_I) and resonance (σ_R) effects of the X group operating across the X—C_6H_4 bond are the quanti-

[1]From the Ph.D. Thesis of Murray John King, University of Victoria, Victoria, B.C., 1973.

[2]There is a considerable variation in the use of nomenclature concerning substituent effects (7). We use the terms 'polar' and 'inductive' to refer to that part of the substituent electronic effect not dependent on π delocalization across the R—Y bond (R is a substituent; Y is a reaction centre). Use of the term 'inductive' is not intended to imply that the effect is necessarily transmitted by the classical bond-relay mechanism: field effects may be important or dominant but would still be included in the 'inductive' effect. That part of the substituent electronic effect which is dependent on π delocalization across the R—Y bond we describe as a π delocalization or 'resonance' effect (often called the mesomeric effect, following Ingold (8)).

ties of interest and the correlation equation takes the form:

$$\log (k/k_o) = \sigma_I\rho_I + \sigma_R\rho_R$$

In this treatment *meta* and *para* substituents have the same σ_I and σ_R values and the difference in their effect on reactivity is accommodated by a change in the susceptibility coefficients, ρ_I and ρ_R.

Values of σ_I were derived by Taft from rates of acid- and base-catalysed hydrolysis of substituted acetate esters. Since Taft's initial work additional data have become available on reactivities of rigid aliphatic systems which provide good data sets for the evaluation of σ_I values. Such systems include 4-substituted bicyclo[2.2.2]octane-1-carboxylic acids (16–19), 4-substituted *trans*-cyclohexanecarboxylic acids (20, 21), 3-substituted adamantane 1-carboxylic acids (22), α-substituted *meta*- and *para*-toluic acids (23), and 4-substituted quinuclidines (24, 25). Charton (26) has evaluated a set of σ_I values from the dissociation constants of substituted acetic acids, on the assumption that steric effects are negligible.

In this paper we report the dissociation constants of an extensive set of α-substituted 2-picolinium ions (substituted 2-methylpyridinium ions). Subsequent papers will deal with the α-substituted 3- and 4-picolinium ions. The picolyl system is an excellent probe for the investigation of the inductive effects of substituents because (*a*) it meets the requirement of separating function centre and substituent by a rigid structure; (*b*) the reaction is particularly sensitive to substituent effects: compare $\rho = 6.0$ for dissociation of pyridinium ions (27) with $\rho = 1.4$ for ionization of benzoic acids in 50% ethanol and $\rho = 1.6$ for dissociation of benzoic acids in 80% aqueous methyl cellosolve (15), the conditions used by Exner for the study of the substituted toluic acids (23); (*c*) a large number of substituted derivatives is available without great difficulty; (*d*) it is possible to study substituted 2-, 3-, and 4-picolines and thus obtain three independent values of σ_I for each substituent. In contrast with the situation in the benzene series, reactivity studies of substituted pyridines have not been extensively investigated. The substituted picolines are of course pyridine derivatives and, focussing attention on the XCH_2 group as the substituent, our study provides additional data on the dissociation of substituted pyridines.

Experimental

Preparation of Compounds

Melting points were determined on a Bock-Monoscop hot-stage microscope and are uncorrected. The nmr spectra, in CCl_4 with TMS as internal standard, were obtained with Varian HA-60-IL or Perkin-Elmer R-12A spectrometers unless specified otherwise. Mass spectra were obtained on a Hitachi Perkin-Elmer RMU-7 mass spectrometer. Analyses were performed by the Microanalysis Laboratory, Toronto or by Dr. D. McGillivray, University of Victoria.

The purities of the substituted methylpyridines whose hydrochlorides could satisfactorily be prepared were, for the most part, verified by sharp melting points and the absence of impurity peaks in the nmr spectra. However, for some compounds the hydrochlorides were too hygroscopic for satisfactory melting points to be obtained. The purities of these compounds along with the compounds whose hydrochlorides could not be prepared, were verified by glc using one of the following columns: PEGA, QF1, FFAP, or SE30. Still other hydrochlorides melted over a 5–10°C range but elemental analysis gave values in good agreement with those calculated.

Benzoic acid (Fisher, 'Primary Standard') was used without further purification. Pyridine (Fisher, Certified) was distilled from potassium hydroxide pellets and stored over molecular sieves, bp 117°C (lit. (28) bp 115°C). The hydrochloride was prepared by dissolving the base in ether and bubbling in dry hydrogen chloride until precipitation was complete. The hygroscopic hydrochloride was recrystallized from chloroform – ethyl acetate. The following substituted 2-picolines were commercially available: 2-picoline (Aldrich, hydrochloride hygroscopic), 2-ethylpyridine (Reilly, hydrochloride hygroscopic), 2-*n*-propylpyridine (Reilly, hydrochloride mp 127.5–128.5°C), 2-benzylpyridine (Reilly, hydrochloride mp 106–108°C), 2-picolylamine (2-pyridinemethanamine, Aldrich, monohydrochloride mp 128–129°C), 2-chloromethylpyridine hydrochloride (Baker, mp 121–122.5°C), 2-pyridylcarbinol (2-pyridinemethanol, Aldrich, hydrochloride mp 107–108.5°C). 2-Trimethylsilylpyridine was supplied by Dr. M. W. Morgan, University of Victoria. Hydrochlorides were prepared as described above for pyridine and were purified by recrystallization from chloroform – ethyl acetate or from methanol – ethyl acetate and/or by sublimation. These liquid compounds which were used in the free base form in the p*K* measurements were distilled and middle fractions collected.

2-Bromomethylpyridine hydrobromide was prepared by reacting 2-pyridylcarbinol with PBr_3 (29). After recrystallization from anhydrous ethanol followed by sublimation the hydrobromide had mp 147–148.5°C (lit. (29) mp 145–146°C).

Phenyl 2-picolyl sulfone was prepared in 78% yield from 2-chloromethylpyridine hydrochloride by reaction with sodium benzene sulfinate (30). The product was recrystallized from anhydrous ethanol, mp 110–112.5°C (lit. (30) mp 111.5–112.5°C); nmr ($CDCl_3$) τ: 1.58 (m, 1, 6-*H*), 2.40 (m, 8, C_6H_5, 3-*H*, 4-*H* and 5-*H*), 5.44 (s, 2, CH_2).

2-Pyridinemethanethiol. A solution of 2-chloromethylpyridine hydrochloride (16.5 g) and thiourea (81 g) in ethanol (75 cm^3) was refluxed for 6 h. Filtration and recrystallization from methanol afforded 2-pyridylmethyl isothiuronium chloride hydrochloride in 84% yield. A solution of the hydrochloride (18 g) in water (25 cm^3) was treated with sodium hydroxide and then acidified to pH 6 with acetic acid. The solution was extracted with ether and the 2-pyridinemethanethiol was obtained in 18% yield after distillation at 35–40°C under reduced pressure (lit. (31) bp 57–58°C/80 Pa); nmr τ: 1.60 (m, 1, 6-*H*), 2.73 (m, 3, 3-*H*, 4-*H* and 5-*H*), 6.3 (d, 2, $J = 13.0$ Hz, CH_2, becomes singlet on D_2O exchange), 7.95 (t, 1, S*H*, removed on D_2O exchange); mass spectrum (70 eV) *m*/*e* (relative intensity): 125 (41, M_r (C_6H_7NS) = 125), 124(27), 93(100), 92(27), 66(37), 65(24), 39(25). The hydrochloride was sublimed but was too hygroscopic to give a sharp mp.

2-Pyridylmethyl acetate (2-pyridinemethanol acetate ester). 2-Pyridylcarbinol (21.8 g, 0.2 mol) was heated with acetic anhydride (61.2 g, 0.6 mol) for 3 h at 145°C. The resulting solution was concentrated, diluted with water (50 cm^3), and

For personal use only.

then made weakly basic with solid potassium carbonate. Following extraction with $CHCl_3$, the acetate was distilled at 80–90°C under reduced pressure (lit. (32) bp 103–104°C/2 kPa) and was obtained in 78% yield; nmr τ: 1.50 (m, 1, 6-*H*), 2.41 (m, 1, 4-*H*), 2.81 (m, 2, 3-*H* and 5-*H*), 4.88 (s, 2, CH_2), 7.95 (s, 3, CH_3); mass spectrum (70 eV) *m/e* (relative intensity): 109(63), 108(100, $M - COCH_3$), 92(13), 80(12), 79(16), 78(14), 65(12), 43(28). Attempts at the preparation of the hydrochloride resulted in decomposition of the compound.

Ethyl-2-pyridylacetate was prepared by esterification of 2-pyridylacetic acid hydrochloride (33). The acid hydrochloride was added to a cold mixture of concentrated sulfuric acid and absolute ethanol. The product was obtained in 75% yield after distillation at 95°C under reduced pressure (lit. (34) bp 109–112°C/0.8 kPa); nmr τ: 1.54 (m, 1, 2-*H*), 2.46 (m, 1, 4-*H*), 2.91 (m, 2, 3-*H* and 5-*H*), 5.90 (q, 2, $J = 7.0$ Hz, CH_2CH_3), 6.29 (s, 2, CH_2CO), 8.82 (t, 3, CH_2CH_3); mass spectrum (70 eV) *m/e* (relative intensity): 165 (27, M_r ($C_9H_{11}NO_2$) = 165), 20(38), 93(100), 92(86), 65(23), 39(18), 29(46). The attempted preparation of the hydrochloride resulted in partial hydrolysis of the compound.

Methyl 2-pyridylacetate was prepared by a similar method to that used for the ethyl ester. It was obtained in 67% yield after distillation at 100°C under reduced pressure (lit. (34) bp 122–125°C/2.8 kPa); nmr τ: 1.54 (m, 1, 6-*H*), 2.40 (m, 1, 4-*H*), 2.83 (m, 2, 3-*H* and 5-*H*), 6.28 (s, 2, CH_2), 6.41 (s, 3, CH_3). The hydrochloride was recrystallized from methanol – ethyl acetate and had mp 163–164°C; mass spectrum (70 eV) *m/e*: (relative intensity) 151 (3, M_r ($C_8H_9NO_2$) = 151), 136(3), 120(6), 119(5), 106(10), 93(76), 92(100), 79(15), 65(95), 39(50).

Methyl 2-picolyl sulfone. Methanesulfonyl chloride (114 g, 1 mol) was treated successively with hydrazine hydrate (50 g, 1 mol) and a solution of sodium hydroxide (80 g, 2 mol) in water (500 cm^3) (35). The reaction mixture was evaporated to dryness and the residue was dissolved in anhydrous ethanol and refluxed for 2 h. The sodium chloride formed was removed by filtration and the filtrate evaporated to give the sodium salt of methanesulfinic acid (62 g). A mixture of methanesulfinic acid sodium salt (13 g), sodium acetate (16 g) 2-chloromethylpyridine hydrochloride (16.4 g), and 1-butanol (70 cm^3) was refluxed for 5 h. After cooling, the mixture was poured into water (700 cm^3) and extracted with chloroform. After removal of the chloroform and 1-butanol, the residue was recrystallized from anhydrous ethanol. Sublimation gave methyl 2-picolyl sulfone (60%), mp 121–122°C; nmr ($CDCl_3$) τ: 1.40 (m, 1, 6-*H*), 2.49 (m, 3, 3-*H*, 4-*H*, and 5-*H*), 5.55 (s, 2, CH_2), 7.10 (s, 3, CH_3); mass spectrum (70 eV) *m/e* (relative intensity): 156.008 (19, M_r ($^{12}C_6{}^1H_6{}^{14}N^{32}S^{16}O_2$) = 156.012, $M - CH_3$), 93(26), 92(100), 65(33), 39(15). *Anal.* calcd. for $C_7H_9NSO_2$: C 49.07, H 5.31, N 8.19; found: C 49.16, H 5.23, N 7.93.

Ethyl 2-picolyl sulfone. The sodium salt of ethanesulfinic acid was prepared in the same manner as the methane derivative. Reaction with 2-chloromethylpyridine hydrochloride and sodium acetate afforded the sulfone in 48% yield after recrystallization from anhydrous ethanol, followed by sublimation. The sulfone had mp 104–105°C (lit. (31) mp 105°C); nmr ($CDCl_3$) τ: 1.40 (m, 1, 6-*H*), 2.48 (m, 3, 3-*H*, 4-*H* and 5-*H*), 5.70 (s, 2, CH_2), 6.99 (q, 2, $J = 7.6$ Hz, CH_2CH_3), 8.62 (t, 3, CH_2CH_3); mass spectrum (70 eV) *m/e* (relative intensity): 156.009 (12, M_r ($^{12}C_6{}^1H_6{}^{14}N^{32}S^{16}O_2$) = 156.012, $M - C_2H_5$), 93(56), 92(100), 65(20), 39(14).

2-Pyridylacetonitrile was prepared by the reaction of 2-chloromethylpyridine hydrochloride with sodium cyanide in DMSO (36) and was obtained in 36% yield after distillation at 88–90°C under reduced pressure (lit. (36) bp 118–120°C/1.7 kPa); nmr τ: 1.49 (m, 1, 6-*H*), 2.52 (m, 3, 3-*H*, 4-*H* and 5-*H*), 6.12 (s, 2, CH_2). The hydrochloride was prepared and recrystallized from anhydrous ethanol and then sublimed. The compound decomposed on heating above 125°C and had mass spectrum (70 eV) *m/e* (relative intensity): 118 (64, M_r ($C_7H_6N_2$) = 118), 91(26), 78(100), 64(23), 51(57), 36(68). *Anal.* calcd. for $C_7H_7H_2Cl$: C 54.35, N 18.13, H 4.56; found: C 54.13, N 18.32, H 4.49.

2-Methoxymethylpyridine was prepared from 2-chloromethylpyridine hydrochloride by refluxing with sodium methoxide (37). It was obtained in 43% yield after distillation at 24–26°C under reduced pressure (lit. (37) bp 76–78°C/2.4 kPa); nmr τ: 1.55 (m, 1, 6-*H*), 2.68 (m, 3, 3-*H*, 4-*H*, and 5-*H*), 5.50 (s, 2, CH_2), 6.61 (s, 3, OCH_3); mass spectrum (70 eV) *m/e* (relative intensity): 93(100), 92(14), 78(15), 66(15), 65(19). The hydrochloride was prepared and sublimed but was too hygroscopic to obtain a satisfactory melting point.

2-Pyridylacetone (1-(2-pyridinyl)-2-propanone). Phenyllithium was prepared under a N_2 atmosphere in 80% yield, from lithium (14.7 g, 2.1 mol) and bromobenzene (157 g, 1 mol). A solution of diisopropylamine (101 g, 1 mol) in anhydrous ether (50 cm^3) was added at such a rate that the ether refluxed gently. A solution of 2-picoline (93 g, 1 mol), previously dried over KOH pellets, in ether (50 cm^3) was added, followed by a solution of methyl acetate (74 g, 1 mol) in ether (50 cm^3). The reaction mixture was then refluxed for an additional 3 h. Water (250 cm^3) was added and the mixture was extracted several times with ether. After drying the combined extracts ($MgSO_4$) and evaporation of the ether, 2-pyridylacetone (34 g) was obtained in 26% yield after distillation under reduced pressure (lit. (38) bp 101°C/1.3 kPa). The hydrochloride was prepared and purified by recrystallization from anhydrous ethanol, followed by sublimation. It had mp 125–126°C; nmr (CF_3CO_2H) τ: 1.6 (m, 4, 3-*H*, 4-*H*, 5-*H* and 6-*H*), 5.43 (s, 2, CH_2), 7.47 (s, 3, CH_3); mass spectrum (70 eV) *m/e* (relative intensity): 135 (15, M_r (C_8H_9NO) = 135), 120(14), 93(100), 92(27), 66(18), 65(18), 43(30), 36(18).

2-Phenacylpyridine (1-phenyl-2-(2-pyridinyl)ethanone) was prepared by the reaction of the 2-picolyl anion, formed from 2-picoline and phenyllithium, with methylbenzoate. The liquid was distilled at 150–155°C under reduced pressure (lit. (39) bp 145–153°C/0.3 kPa) to give a heavy yellow liquid which solidified on standing. The product was recrystallized from petroleum ether and then sublimed. It had mp 50–52°C (lit. (39) mp 52.5–54°C); nmr τ: 1.60 (m, 1, 6-*H*), 2.6 (m, 8, C_6H_5, 3-*H*, 4-*H* and 5-*H*), 4.0 (s, 1, $CH{=}C$, removed after prolonged D_2O exchange), 5.59 (s, 1, OH, removed on D_2O exchange).

C-Methylation product of 2-phenacylpyridine. A solution of 2-phenacylpyridine (10 g, 0.05 mol) in methanol was added to a solution of sodium methoxide (from 1.25 g of sodium) and to this mixture methyl iodide (7.0 g) was added. After refluxing the solution on a water bath for 1 h the methanol was evaporated. After the addition of water, the solution was extracted (×3) with ether. The ether was evaporated and the α-benzoyl-2-ethylpyridine distilled at 115–120°C under reduced pressure; nmr τ: 5.08 (q, 1, $J = 7.0$ Hz, $CHCH_3$), 8.50 (d, 3, $CHCH_3$).

O-Methylation product of 2-phenacylpyridine. Potassium *tert*-butoxide (5.6 g, 0.05 mol) was dissolved in anhydrous DMSO (100 cm^3). After addition of 2-phenacylpyridine (10 g, 0.05 mol) and dimethyl sulfate (6.3 g, 0.05 mol) the mixture was stirred for 2 h. Water was added and the mixture was extracted several times with methylene chloride. The combined extracts were dried ($MgSO_4$) and after evaporation of the solvent a heavy dark oil remained. On standing for 3 days α-methoxy-β-2-pyridylstyrene separated and was recrystallized from anhydrous ethanol. It had mp 125–126°C; nmr ($CDCl_3$) τ: 4.40 (s, 1, CH), 6.61 (s, 3, $O{-}CH_3$).

2-Thiocyanatomethylpyridine hydrochloride. A solution of 2-chloromethylpyridine hydrochloride (8.2 g) in benzene (8 cm^3) was added to a boiling solution of potassium thiocyanate (5 g) in acetone (50 cm^3) and the mixture was heated on a steam bath for 2.5 h (31). The precipitated potassium chloride and excess potassium thiocyanate were filtered from the hot mixture. On cooling the filtrate, 2-thiocyanatomethylpyridine hydrochloride separated and was recrystallized from methanol mp 163–165°C (lit. (40) mp 167–170°C). *Anal.* calcd. for $C_7H_7N_2SCl$: C 45.01, N 15.02, H 3.78; found: C 44.87, N 15.37, H 3.78.

2-Methylthiomethylpyridine. Methanethiol (9.8 g, 0.2 mol) and 2-chloromethylpyridine hydrochloride (16.4 g, 0.1 mol) were added to a solution of sodium ethoxide (from 4.6 g, 0.2 mol sodium) in ethanol (100 cm^3) and the mixture was heated on a steam bath for 2 h. After removal of the solvent, the residue was distilled at 90°C under reduced pressure (lit. (41) bp 100–105°C/2.3 kPa) to give a 73% yield of product which had nmr τ: 1.60 (m, 1, 6-*H*), 2.69 (m, 3, 3-*H*, 4-*H* and 5-*H*), 6.31 (s, 2, CH_2), 8.04 (s, 3, CH_3). The hydrochloride was prepared and recrystallized from methanol, mp 137–138.5°C; mass spectrum (70 eV) *m/e* (relative intensity): 93(100), 92(15), 65(23), 64(17), 39(17), 36(13).

2-Acetamidomethylpyridine (N-2-pyridinylmethylacetamide). Acetic anhydride (30 cm^3) was added to cold 2-aminomethylpyridine (18 g). The resulting solution was poured into water and then extracted with chloroform. After evaporation of the chloroform and distillation at 145°C under reduced pressure, 2-acetamidomethylpyridine was obtained in 56% yield (lit. (42) bp 160–163°C/0.7 kPa). The product solidified upon standing and was recrystallized from benzene – petroleum ether, mp 56.5–57°C (lit. (42) mp 59–60°C); nmr ($CDCl_3$) τ: 1.51 (m, 1, 6-*H*), 1.78 (m, 1, N*H*), 2.38 (m, 1, 4-*H*), 2.77 (m, 2, 3-*H* and 5-*H*), 5.50 (d, 2, J = 5.5 Hz, CH_2), 8.04 (s, 3, CH_3); mass spectrum (70 eV) *m/e* (relative intensity): 150 (20, M_r ($C_8H_{10}N_2O$) = 150), 149(24), 135(12), 107(100), 92(33), 80(17), 79(15), 43(14).

2-Methylaminomethylpyridine (N-methyl-2-pyridinemethanamine). A solution of 2-chloromethylpyridine hydrochloride (46.8 g) in ethanol (300 cm^3) was added to an ice-cold 40% aqueous solution of methylamine (300 g) and the resulting solution was stirred at room temperature for 1 h and then heated at 90°C for 1 h. The solution was saturated with solid potassium hydroxide and extracted with ether–chloroform. The product was obtained in 70% yield after distillation at 70–73°C under reduced pressure. It had nmr τ: 1.50 (s, 1, 6-*H*), 2.71 (m, 3, 3-*H*, 4-*H* and 5-*H*), 6.23 (s, 2, CH_2), 7.65 (s, 3, CH_3), 8.18 (s, 1, N*H*, removed by D_2O); mass spectrum (70 eV) *m/e* (relative intensity): 119(29), 93(100), 92(38), 80(22), 65(18), 44(40). The dipicrate was recrystallized from 95% ethanol, mp 178–180°C. *Anal.* calcd. for $C_{19}H_{16}N_8O_{14}$: C 39.30, N 19.31, H 2.78; found: C 39.04, N 19.24, H 2.60.

2-Dimethylaminomethylpyridine (N,N-dimethyl-2-pyridinemethanamine) was prepared from 2-aminomethylpyridine by reaction with 90% formic acid and 37% aqueous formaldehyde solution according to the method described for the 3-isomer (43). The product was obtained in 38% yield after distillation at 56–58°C under reduced pressure (lit. (44) bp 195°C); nmr τ: 1.58 (m, 1, 6-*H*), 2.52 (m, 2, 3-*H*, 4-*H*), 2.93 (m, 1, 5-*H*), 6.43 (s, 2, CH_2), 7.80 (s, 6, CH_3); mass spectrum (70 eV) *m/e* (relative intensity): 93(100), 92(23), 65(18), 58(36), 42(14).

2-Phenylthiomethylpyridine was prepared from 2-chloromethylpyridine hydrochloride and benzenethiol in the presence of base (45) and was obtained in 86% yield after distillation at 145–150°C under reduced pressure (lit. (45) bp 123–127°C/0.5 kPa); nmr τ: 1.66 (m, 1, 6-*H*), 2.80 (m, 8, 3-*H*, 4-*H*, 5-*H* and C_6H_5), 5.83 (s, 2, CH_2). The hydrochloride was recrystallized from anhydrous ethanol–ether, followed by sublimation, mp 128–130°C (lit. (45) mp 137–138°C).

2-Phenoxymethylpyridine was prepared from 2-chloromethylpyridine hydrochloride by reaction with sodium phenoxide in methanol (46). It was distilled at 165°C under reduced pressure (lit. (46) bp 140–143°C/70 Pa). The product solidified on standing. The hydrochloride was purified by sublimation and had mp 90–92°C; nmr (CF_3CI_2H) τ: 1.55 (m, 2, 3-*H*, 6-*H*), 2.35 (m, 2, 4-*H*, 5-*H*) 3.30 (m, 5, C_6H_5). 4.90 (s, 2, CH_2); mass spectrum (70 eV) *m/e* (relative intensity): 185 (4, M_r ($C_{12}H_{11}NO$) = 185), 184(4), 94(33), 92(48), 78(45), 66(27), 65(63), 51(35), 39(51), 36(100).

2-N-Acetylmethylaminomethylpyridine (N-methyl-N-2-pyridinylmethylacetamide). 2-Methylaminomethylpyridine (12 g) was heated with acetic anhydride (15 cm^3) for 30 min. The solution was diluted with water, made strongly alkaline with solid sodium hydroxide and then extracted with chloroform. The product was obtained in 75% yield after distillation at 140–145°C under reduced pressure and had mass spectrum (70 eV) *m/e* (relative intensity): 121(17), 94(21), 93(100), 92(18), 65(12), 44(17). The picrate was recrystallized from 95% ethanol, mp 158–160°C. *Anal.* calcd. for $C_{15}H_{15}N_5O_8$: C 45.78, N 17.81, H 3.84; found: C 45.58, N 18.02, H 3.74.

The hydrochloride was sublimed and had mp 127–129°C; nmr (CF_3CO_2H) τ: 1.70 (m, 2, 3-*H* and 6-*H*), 2.35 (m, 2, 4-*H* and 5-*H*), 5.36 (s, 2, CH_2), 7.17 (s, 3, N-CH_3), 8.03 (s, 3, $COCH_3$).

2-Nitromethylpyridine. Sodium 2-picolylnitronate was prepared from 2-picoline, sodium amide, and *n*-propylnitrate (47). The crude sodium salt was acidified with glacial acetic acid and the product was extracted with chloroform. Distillation of the chloroform extract under reduced pressure resulted in a violent explosion. In a subsequent preparation the compound was purified by chromatography on silica gel and elution with ether–chloroform (1:1 v/v) before distillation at 90–95°C under reduced pressure (lit. (47) bp 70°C/30 Pa). On standing a few days the compound darkened considerably and was chromatographed again before use. The picrate was recrystallized from 95% ethanol and had mp 136–138°C (lit. (47) mp 152°C). *Anal.* calcd. for $C_{12}H_9N_5O_9$: C 39.24, N 19.07, H 2.47; found: C 39.02, N 18.72, H 2.47.

Apparatus

Potentiometric titrations were carried out in aqueous solution at 25.0 ± 0.1°C using a glass electrode (Beckman #39000) and a calomel reference electrode (Beckman #39071). Water from a Calora constant temperature bath was circulated through the water jacket of the titration cell to maintain constant temperature during a titration. Electromotive force values were measured using an electrometer (Keithley model 610C) fitted with a pH electrode adaptor (Keithley model 6107) and the values are read out using a digital voltmeter (Vidar 520). The titrant was added from an autoburette (Radiometer model ABU11). Standardization of electrode potentials was carried out using the buffers (48): saturated potassium hydrogen tartrate (pH 3.557 at 25°C), potassium hydrogen phthalate (0.05 mol kg^{-1}, pH 4.008 at 25°C), equimolar potassium dihydrogen phosphate – disodium hydrogen phosphate (each 0.025 mol kg^{-1}, pH 6.865 at 25°C), borax (0.01 mol kg^{-1}, pH 9.180 at 25°C), and potassium tetroxalate (0.05 mol kg^{-1}, pH 1.679 at 25°C). Before and after each potentiometric titration the emf readings of buffers which encompassed the range of pH values to be measured were determined and the mean of the before and after readings used in the pH calculation (below). Normally the emf values for the standard buffers before and after a run agreed to within a few tenths of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

a millivolt. If the values differed by more than 1 mV or if the emf differences between the two standard buffers differed by more than 1 mV the run was discarded. The pH values were obtained from [1] where pH_1 and E_1 are the pH value and emf reading of standard buffer 1, pH_2 and E_2 are the pH value and emf reading of standard buffer 2, and pH_3 is the unknown pH value and E_3 the emf reading of the titration solution:

$$[1] \quad pH_3 = pH_1 + (pH_2 - pH_1)(E_3 - E_1)(E_2 - E_1)^{-1}$$

The pK values of those compounds which could not be measured by potentiometric titration were determined by uv spectrophotometry at 25.0 ± 0.2°C. Absorbance values were measured with a Cary model 17 uv spectrometer.

Solutions

Potassium tetroxalate and potassium hydrogen phthalate were BDH AnalaR. Potassium hydrogen tartrate, disodium hydrogen phosphate and potassium dihydrogen phosphate were Fisher Certified and sodium borate was Baker Analyzed. Solutions were prepared in distilled deionized water of conductivity < 0.2 mS m^{-1} (48). A small amount of thymol was added to the tartrate solution to retard mold growth. Buffer solutions were freshly prepared every 4 weeks.

Sodium hydroxide and hydrochloric acid solutions (0.5 mol dm^{-3}) used in potentiometric titrations were prepared from concentrated volumetric solutions (BDH) and standardized against potassium hydrogen phthalate and anhydrous sodium carbonate, respectively.

Formic acid (BDH AnalaR) was stirred with boric anhydride and then distilled, bp 100–101°C (lit. (28) bp 100.5°C). Acetic acid (Baker Analyzed) was purified by heating with chromium trioxide and acetic anhydride (49) and fractionally distilled, bp 118–119°C (lit. (49) bp 118°C). Aqueous solutions (0.1 mol dm^{-3}) were prepared by weight and standardized with sodium hydroxide (0.1 mol dm^{-3}). For each acid seven buffer solutions were prepared containing 10 mmol dm^{-3} of the formate (acetate) and from 3–40 mmol dm^{-3} of formic acid (acetic acid) by combining the calculated weights of the standard solution of the acid with a fixed weight of standard sodium hydroxide. Succinic acid (BDH AnalaR) was recrystallized twice from acetone and dried under reduced pressure (49). A series of 10 buffers was prepared by dissolving 5 mmol of the acid in 60–100 cm^3 of aqueous sodium hydroxide (0.1 mol dm^{-3}) followed by dilution to 500 cm^3. These acidic buffers were used in the spectrophotometric pK determinations.

A series of 15 aqueous hydrochloric acid solutions of known concentrations ranging from 0.6–400 mmol dm^{-3} was prepared by dilution from concentrated volumetric solution (BDH). These solutions were used in the spectrophotometric pK determinations of those picolinium ions which were too acidic to be measured by the potentiometric method.

*Measurement of p*K *Values*

For dissociation of the acid HB in aqueous solution pK is given by [2]:

$$[2] \quad pK_{HB} = -\log a_H - \log([B]/[HB]) - \log f_B + \log f_{HB}$$

Most pK values were determined by potentiometric titration (50) but some values not accessible by this method were determined by spectrophotometry (50). In the majority of cases titration of an aqueous solution (100 cm^3) of the picoline hydrochloride (1 mmol) with standard sodium hydroxide (0.5 mol dm^{-2}) was preferred to titration of the picoline with hydrochloric acid because (in these cases) the hydrochloride could be readily purified on a small scale by vacuum sublimation immediately before use. The free bases were liquids and small scale distillation was less convenient than sublimation. In some other cases the substituent group, e.g., ethoxycarbonyl, was not stable to hydrogen chloride gas under the conditions used for preparation of the hydrochlorides. In such cases and other cases where the hydrochloride could not be obtained pure (most diacidic bases) the picoline, if sufficiently soluble in water, was titrated with hydrochloric acid. Some picolines were not soluble at 10 mmol dm^{-3} and concentrations of 5 mmol dm^{-3} or 2.5 mmol dm^{-3} were used. For less soluble compounds the potentiometric titration method is unsuitable and pK values of these picolines were determined by the spectrophotometric method using appropriate buffers. For those compounds whose pK values were well beyond the limits of the potentiometric method (p$K < 2.5$) the value was determined by the spectrophotometric method in hydrochloric acid solutions.

In the titration the emf of the cell containing the solution being titrated was measured after each successive addition of 0.2 cm^3 of titrant until 1.8 cm^3 had been added. In the cases in which the hydrochloride was titrated with sodium hydroxide the solution was finally titrated to three emf values in the range 125–175 mV past the half-neutralization emf reading and the pair of consistent (±0.5%) titre values from this set were averaged to give the end-point titre (t_f). Generally this value agreed with that calculated from the known weight of hydrochloride taken to about 1%. The small discrepancy is attributed to the difficulty in accurately weighing the hygroscopic hydrochlorides and the value of t_f, rather than the initial weight of hydrochloride, was used in deriving the pK value.

In the calculation of the pK value from the emf readings and titration values it was assumed that $-\log a_H = pH$, that activity coefficients were given by the Güntelberg extension of the Debye–Hückel limiting law (51), [3] (I is ionic strength), and that $f_0 = 1$, $f_- = f_+$, $f_{+2} = 4f_+$.

$$[3] \quad -\log f_+ = 0.509\, I^{1/2}/(1 + I^{1/2})$$

It follows that the H^+ and OH^- concentrations are given by [4] and [5]

$$[4] \quad [H^+] = f_+^{-1}\, 10^{-pH}$$

$$[5] \quad [OH^-] = f_+^{-1}\, 10^{(pH - 14)}$$

From the condition for electroneutrality of the titrated solution, the conservation of the sum of the amounts of B and HB, the fact that $[OH^-]$ is negligible for $pH < 7$ and that $[H^+]$ is negligible for $pH > 7$ expressions were derived relating I, [B], and [HB] to the titration values. These expressions take different forms, according to whether a neutral acid (p$K < 7$) is titrated with sodium hydroxide (I), a univalent cationic acid (p$K < 7$) is titrated with sodium hydroxide (II), a univalent cationic acid (p$K > 7$) is titrated with sodium hydroxide (II*a*), a neutral base (p$K < 7$) is titrated with hydrochloric acid (III), a neutral diacidic base ($pK_1 < 7 < pK_2$) is titrated with hydrochloric acid (IV), or a divalent cationic dibasic acid ($pK_1 < 7 < pK_2$) is titrated with sodium hydroxide (V). For case I, applicable to benzoic acid, the relevant expressions are as follows where n = concentration (mol dm^{-3}) of titrant, t = volume (cm^3) of titrant added, t_f is the end-point titre, v = initial volume (cm^3) of the solution being titrated:

$$I = nt/(v + t) + [H^+]$$

$$[B] = nt/(v + t) + [H^+]$$

$$[HB] = n(t_f - t)/(v + t) - [H^+]$$

Related expressions apply to the other cases cited. For each emf/titre pair I was calculated by an iterative method starting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with the assumption that $[H^+] = 0$ (or $[OH^-] = 0$, as appropriate) and then calculating $[H^+]$ from [4] (or $[OH^-]$ from [5]) and repeating the cycle until the difference between successive values of I was insignificant: the final value of I was then used to calculate $[H^+]$ from [4] (or $[OH^-]$ from [5]), [B], [HB], and finally pK_{HB}.

Each titration run generated nine pairs of emf readings and titre values from which nine values of the pK could be calculated. The calculations were carried out on a computer. The program determined the mean pK value for the run, the deviations of the individual pK values, and rejected the pK value corresponding to the largest deviation if the modulus of the latter was greater than 0.03, recalculated a new mean and new deviations, and repeated this cycle until no deviation was larger than 0.03. In only 53 of 265 titration runs (involving $9 \times 265 = 2385$ pK calculations) was more than one value rejected.[3] The majority of the 53 runs involved situations in which a lower precision could be expected such as determination of the second pK of a dibasic acid or determination of a pK value close to the limit of the potentiometric method (~ 2.5). Thus although measurements were made over the range of [B]/[HB] from 9:1 to 1:9 excellent precision was achieved. A minimum of three titration runs was made for each compound. There was excellent agreement between the pK values determined in triplicate. In 88 sets of triplicate pK values two sets covered a range of 0.04 pK units and two a range of 0.03 pK units. Three of these sets involved the determination of second pK values of dibasic divalent cationic acids. For all other sets the pK values covered a range of 0.02 or less. The root-mean-square deviation of all pK values measured by the potentiometric method was less than 0.01.

For spectrophotometric pK determinations a solution of known concentration of the acid HB (or base B) was prepared in distilled deionized water. To obtain the spectra of both acid and base forms of the pyridine, absorbances were measured for the compound in hydrochloric acid (5 mmol dm^{-3}) and sodium hydroxide (5 mmol dm^{-3}) over the range 200–300 nm, and the wavelength at which the two spectra differed the most was chosen as the analytical wavelength. Equal volumes (5 cm^3) of the solutions of the pyridine and acid (10 mmol dm^{-3}) were mixed and the absorbance of the solution at the analytical wavelength was recorded. This was repeated twice more and the mean of the three values was taken as the absorbance of the protonated form D_{HB}. A similar procedure using sodium hydroxide solution[4] gave the absorbance of the basic form, D_B. Finally, the absorbance (D) of the pyridine in a series of buffer solutions whose pH encompassed the pK of HB was determined. From the indicator ratio, $i = [B]/[HB^+] = (D - D_{HB})/(D_B - D)$, the individual values of [B] and $[HB^+]$ could be obtained since the sum of the concentrations was known. From the electroneutrality condition, the fact that $[OH^-]$ is negligible ($pH < 7$) the conservation of the sum of the amounts of the buffer acid HA and its conjugate base A, the expressions for the dissociation of the indicator acid HB and the buffer acid HA, expressions for I, $[H^+]$, the buffer ratio [A]/[HA] and pK_{HB} can be derived. A number of cases can arise requiring different forms for the equations depending upon the charge type of HA and HB and whether HB or B is added to the buffer mixture. For the case of neutral substrate base B and neutral buffer acid HA (acetic and formic acids were used) eqs. [6], [7], and [8] are applicable (the superscript asterisk denote a stoichiometric concentration).

$$[6] \qquad I = [{}^*A^-] + [HB^+] + [H^+]$$

$$[7] \qquad [H^+] = f_+^{-1} f_-^{-1} 10^{-pK_{HA}} [HA]/[A^-]$$

$$[8] \qquad pK_{HB} = pK_{HA} + \log([A^-]/[HA]) - \log([B]/[HB^+]) + \log f_- + \log f_+$$

The buffer ratio is given by [9], for the case (VI) where the picoline was added as its hydrochloride, and by [10] for case (VI*a*) when the picoline itself was the substrate

$$[9] \qquad [A^-]/[HA] = ([{}^*A^-] - [B] + [H^+])/([{}^*HA] + [B] - [H^+])$$

$$[10] \qquad [A^-]/[HA] = ([{}^*A^-] + [HB^+] + [H^+])/([{}^*HA] - [HB^+] - [H^+])$$

The values of I and $[H^+]$ can be determined by iteration over the cycle [6], [9], [7] (or [6], [10], [7]), starting from $[H^+] = 0$, although in practice the cycle [6], [7] was used since I was determined with sufficient accuracy if $[H^+]$ was evaluated from [7] on the assumption that $[HA]/[A^-] = [{}^*HA]/[{}^*A^-]$. The calculations were carried out on a computer and individual pK values which deviated by more than 0.05 from the mean pK value for a run were rejected and a new mean calculated. Runs were carried out in duplicate.

The buffer action of the second dissociation of succinic acid was used in determining the pK values of the trimethylsilylpyridines (case VII). In principle it is possible to calculate pK_{HB} from an equation similar to [8] where HA and A are the monoanion and dianion, respectively, of succinic acid. However, a complicated set of iterations is necessary to take account of the effect of the first dissociation equilibrium for succinic acid on the concentrations of the mono- and dianions. In practice the pH of the succinic acid buffers was determined by the potentiometric method and pK_{HB} was then evaluated from [11]

$$[11] \qquad pK_{HB} = pH - \log([B]/[HB^+]) + \log f_+$$

A few calculations were also carried out using the measured pH and the first dissociation constant to evaluate the ratio of succinic acid to monoanion and then using the electroneutrality condition and the conservation of succinic acid plus its two anions to evaluate the concentrations of the mono- and dianions. These values on substitution into [8] gave pK_{HB} values which agreed with those evaluated from [11] to better than 0.01 pK units.[5]

For those picolinium ions for which pK was less than 2.5, standard solutions of hydrochloric acid were used to fix the hydrogen ion concentration (case VIII). The indicator ratios (D_{HB} was measured in hydrochloric acid of concentration 1 mol dm^{-3} and D_B was measured in phosphate buffer) were determined and pK_{HB} evaluated from [12]

$$[12] \qquad pK_{HB} = -\log[H^+] - \log([B]/[HB]) - \log(f_B/f_{HB})$$

The pK obtained using activity coefficients derived from the Güntelberg extension of Debye–Hückel limiting law were regressed against I to find pK_{HB} at $I = 0$.

Results

The pK values determined for benzoic acid and for

[3]The statistics relate to data for α-substituted 2-, 3-, and 4-picolines. There was no noticeable variation of the precision between the three series.

[4]In the case of dibasic acids for which $pK_1 < 7 < pK_2$ the absorbance of the base form for pK_1 (the half acid) was determined in phosphate buffer.

[5]For succinic acid $pK_1 = 4.21$, $pK_2 = 5.64$ (52).

pyridinium ion, from individual runs, are shown in Table 1 and pK values for substituted 2-picolines are shown in Table 2. 2-Thiocyanatomethylpyridine reacted with water, as indicated by emf and uv readings which changed rapidly with time. Its pK value could not be determined.

Accuracy of pK *Values*

The validity of the assumption that $-\log a = \text{pH}$ is limited to ± 0.02 pH units and this in turn sets a similar limit to the accuracy of pK values derived by the potentiometric method. The precision of the potentiometric pK values is rather better than this (see Experimental). Dissociation constants measured by uv spectrophotometry in buffer solutions were reproducible to ± 0.02 pK units. However, 2-trimethylsilylmethylpyridine reacted in solution and was particularly unstable in acid solution. The concentrations of the hydrochloric acid and sodium hydroxide solutions used for determining D_{HB} and D_B were reduced to 1 mmol dm^{-3} and absorbance readings, which changed with time, were recorded over 2 min and extrapolated back to zero time. The pK of this compound is therefore of lower reliability (± 0.1). The pK values measured in hydrochloric acid solutions were determined by an extrapolation technique. Because of a significant variation in the calculated pK values with ionic strength, these values are also less accurate (± 0.1) although the reproductivity of the measurements was rather better than this. As a check on the accuracy of the potentiometric method, the pK value of benzoic acid was determined (Table 1). The mean value (4.22) agrees with the accepted literature value (4.20) to within the limits of accuracy (± 0.02). The literature value is the mean of eight thermodynamic values measured by conductance and eight thermodynamic values measured by potentiometry (53).

The measurement of the acid dissociation constant of pyridinium ion (Table 1) by potentiometric titration of the hydrochloride with sodium hydroxide (5.20) potentiometric titration of the free base with hydrochloric acid (5.18) and by uv spectrophotometry (5.19) provides a check on the reproducibility of the pK values obtained by different methods. This reproducibility is further established by the pK value for ethyl 2-picolyl sulfone measured by titration of the hydrochloride (2.52) and by titration of the free base (2.51) and by that for 2-pyridinemethanethiol for which the corresponding values are 4.40 and 4.39.

Inductive Substituent Constants (σ_I Values)

Correlation of the $-$pK values with σ_I values (15) gave, for $n = 13$, slope $\rho_I = 5.449$, intercept $-pK_0 = -5.81$, correlation coefficient $r = 0.991$, standard deviation $s = 0.15$, standard deviation of the slope $s_\rho = 0.23, f = 0.07$.[6] The points for the trimethylsilyl and nitropicolines were left out of the correlation because of the relatively large error (± 0.1) in the pK measurements and because, in the case of the nitro point, of the large deviation from the linear relation-

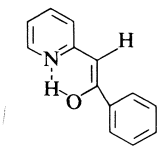
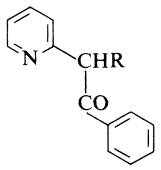
ship (see below). The mean of the pK values for the methyl and ethyl 2-pyridyl acetates was used in the correlation, since Taft only lists a σ_I value for CO_2R. The linear correlation is excellent, as is shown by the high value of the correlation coefficient and low value of the standard deviation, the latter equivalent to 0.03 in the σ value, the limit of precision found in other well-behaved systems (6). Our basic assumption, that the substituent effects measured in the substituted 2-picoline system reflect inductive effects alone, is therefore validated. Further confirmation of this is provided by the results of a dual substituent parameter correlation using σ_I and σ_R^0 (15). This gave $\rho_I = 5.43$ $\rho_R = 0.17$, $\lambda(\equiv \rho_R/\rho_I) = 0.03$, $s = 0.16$.[7] The very low value of λ and the lack of any improvement in the fit of the data as compared with that of the single substituent parameter equation, point to the absence of resonance effects in this system.

Derived $\bar{\sigma}_I$ values, evaluated from the relationship $\bar{\sigma}_I = (5.81 - pK)/5.45$ are shown in Table 2 together with Taft's values for σ_I. There are twelve substituents not listed by Taft for which σ_I values are obtained from the present study. With the exception of the value for the nitro group, there is good agreement between Taft's σ_I values and those determined in the present work for the common substituents. This agreement confirms that steric interaction between the substituent and reaction centre is not a complicating factor in the dissociation of substituted 2-picolinium ions. For the nitro group $\bar{\sigma}_I$ is 0.2 units larger than Taft's value, corresponding to a pK value for the nitropicolinium ion approximately one unit more acidic than would be predicted. Feuer and Lawrence have shown that the 2-nitromethylpicoline is present to the extent of 9% as the nitronate tautomer in dimethylsulfoxide solution (47). Such tautomerism would affect the measured pK value and could have a particularly serious effect on the pK value determined by spectrophotometry if the extinction coefficient of the nitronate tautomer was markedly different from that of the nitro tautomer. They obtained $pK = 3.92$ by potentiometric titration but this value would lead to $\bar{\sigma}_I = 0.35$, a result even more deviant (in the opposite direction) than that of Table 2. Clearly, further study of this system is required.

The $\bar{\sigma}_I$ value of the benzoyl group is 0.1 unit lower than that derived from the corresponding 3- and 4-phenacylpyridine. 2-Phenacylpyridine exists as the enol **1** in the solid state and predominantly as the enol in both ethanol and cyclohexane solution (54); the intramolecular hydrogen bond contributes to an enhanced stability. We confirmed the previous report that methylation of the sodio derivative with methyl iodide in methanol gives the *C*-methylation product (55). This exists in the keto form **2***b* as



1



2
a R = H
b R = CH_3

shown by the ir carbonyl stretch at 1700 cm^{-1} and the τ 8.50 doublet (CH_3) and 5.08 quartet (CH) in the nmr spectrum. Replacement of the vinylic hydrogen in **1** by the more bulky methyl group would result in the introduction of steric strain, the consequence of which is that the hydrogen bonded enol form is forced out of the favourable planar state. Alkylation with dimethyl sulfate in dimethyl sulfoxide gave the *O*-methyl product: nmr τ: 6.61 (OCH_3), 4.40 (CH), both singlets. 2-Phenacylpyridine underwent D_2O exchange in two steps to give first **1** with the hydroxylic hydrogen replaced by deuterium and subsequently **1** with both the hydroxylic hydrogen and the vinylic hydrogen replaced by deuterium. It is evident that 2-phenacylpyridine exists predominantly as its tautomer **1** and that the measured pK is therefore not that of the benzoyl form.

Dissociation of 2-Picolylammonium Ions

pK values of 2-picolylammonium ion and its *N*-methyl and *N*,*N*-dimethyl derivates are shown in Table 3. The pK values for methylammonium ion dimethylammonium ion and trimethylammonium ion are 10.62, 10.77, and 9.80, respectively (56). Thus, introduction of the 2-pyridyl substituent into a methyl group of the methylammonium ion and its dimethyl and trimethyl counterparts, lowers the pK value by ca. 2 units. Compared to hydrogen the

TABLE 3. Dissociation of 2-picolylammonium ions

Ion	pK	Method

For personal use only.

2-pyridinyl substituent is electron withdrawing. It is also electron-withdrawing compared to the phenyl substituent: the pK of benzylammonium ion is 9.38 (57). From the Hammett correlation of the data for dissociation of benzylammonium ions (57) and the measured dissociation constants of 2-picolylammonium ion the σ^0 value for the 2-aza substituent is obtained as 0.78, closely similar to the mean σ value (0.77) derived from hydrolysis of methyl and ethyl picolinates in aqueous methanol, aqueous ethanol, aqueous acetone and aqueous dioxan (58) and to the σ^0 value of 0.81 from hydrolysis of 2-pyridylmethyl acetate in aqueous acetone (59).

Inductive substituent constants from dissociation of methyl-substituted 3-picolinium ions

ALFRED FISCHER, MURRAY JOHN KING, AND FRANK PRICE ROBINSON
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received April 25, 1978

ALFRED FISCHER, MURRAY JOHN KING, and FRANK PRICE ROBINSON. Can. J. Chem. **56**, 3068 (1978).

The dissociation constants of 30 α-substituted 3-methylpyridinium ions in water at 25°C have been measured by potentiometric and spectrophotometric methods. Correlation of the pK values with σ_I values gives, for $n = 16$, slope $\rho_I = 3.044$, intercept $-pK_0 = -5.59$, correlation coefficient $r = 0.993$, and enables new σ_I values to be evaluated. Application of the dual substituent parameter equation gives $\lambda(\equiv \rho_R/\rho_I) = 0.04$, confirming that resonance effects are negligible in this series. Dissociation constants of the 3-pyridinylmethylammonium ion and its *N*-methyl and *N,N*-dimethyl derivatives are also reported.

ALFRED FISCHER, MURRAY JOHN KING et FRANK PRICE ROBINSON. Can. J. Chem. **56**, 3068 (1978).

Faisant appel à des méthodes potentiométrique et spectrophotométrique, on a mesuré à 25°C et pour des solutions aqueuses, les constantes de dissociation de 30 ions méthyl-3 pyridinium substitués en α. La corrélation des valeurs de pK avec les valeurs σ_I fournit, pour $n = 16$, une pente ρ_I 3.044, une ordonnée à l'origine $-pK_0 = -5.59$, un coefficient de corrélation $r = 0.993$ et elle permet aussi d'évaluer de nouvelles valeurs de σ_I. Une application de l'équation pour paramètres à doubles substituants conduit à un $\lambda(\equiv \rho_R/\rho_I) = -0.04$, ce qui confirme que, dans cette série, les effets de résonance sont négligeables. On rapporte aussi les constantes de dissociation de l'ion méthylammonium-3 pyridinyle et de ses dérivés *N*-méthyle et *N,N*-diméthyle.

[Traduit par le journal]

In a previous paper we reported the dissociation constants of a series of α-substituted 2-picolinium ions (α-substituted 2-methylpyridinium ions) and a set of σ_I values derived from the dissociation constants (1). We now report the dissociation constants of an extensive set of α-substituted 3-picolinium ions, measured as described in the earlier paper.

The pK values for the 3-picolines are shown in Table 1. The values are estimated to be accurate to ± 0.02. None of the 3-picolinium ions is sufficiently acidic to require measurement of the dissociation constant in hydrochloric acid solutions. This is fortunate since, in the 2-picolinium ion series, pK values measured in hydrochloric acid solutions were of lower accuracy (± 0.1). Thus the values for the 3-picolinium ions containing the substituents NH_3^+, $NH_2CH_3^+$, $NH(CH_3)_2^+$, NO_2, and $SO_2C_6H_5$ are more accurate than those of the correspondingly substituted 2-picolinium ions. 2-Nitromethylpyridine (and presumably also 2-nitromethylpyridinium ion) is tautomeric (2). As a result of the tautomeric equilibrium (or equilibria) the measured dissociation constant is not simply that of the nitropicolinium ion to nitropicoline. 2-Phenacylpyridine is likewise tautomeric, existing predominantly in the intramolecularly hydrogen-bonded enol form (3). The corresponding 3-picoline derivatives are not tautomeric since the resonance interaction which stabilizes the nitronate form of 2-nitromethylpyridine is absent in the 3-isomer and there is no strong intramolecular hydrogen bond to stabilize the enol form of 3-phenacylpyridine. Thus the measured pK values of the 3-nitromethyl- and 3-phenacylpyridines are, in each case, attributable to the equilibrium between the picolinium ion and the pyridine plus hydrogen ion.

Correlation of the $-pK$ values with the σ_I values (4) listed in the righthand column of Table 1 gave, for $n = 16$, slope $\rho_I = 3.044$, intercept $-pK_0 = -5.59$, correlation coefficient $r = 0.993$, standard deviation $s = 0.08$, standard deviation of the slope $s_\rho = 0.10$, root-mean-square deviations/root-mean-square of $(pK_H - pK)\,f = 0.07$. Derived $\bar{\sigma}_I$ values, evaluated from the relationship $\bar{\sigma}_I = (5.59 - pK)/3.044$, are also shown in column 4 of Table 1.

There is excellent agreement between the $\bar{\sigma}_I$ values determined in the present work and Taft's σ_I values, for common substituents. The largest difference between the pairs of values is 0.05 and the standard deviation is 0.03. This is about the limit to which the σ values are 'constant' from one reaction series to another.[1] The accuracy of the 3-picolinium ion dissociation constant data is such that the $\bar{\sigma}_I$ values are measured to ± 0.01. Thus, in this work, the limiting factor in the determination of $\bar{\sigma}_I$ values is the reliability of the assumption that σ values are constants.

Taft has argued against the introduction of a

variable intercept parameter in correlation analysis of substituent effects (4). Correlation of (pK_H − pK) with σ_I with this constraint gave $\rho_I = 3.210$, $s = 0.10$, $f = 0.08$. Values of $\bar{\sigma}_I$ calculated from (pK_H − pK)/3.21 are listed in column 5 of Table 1. They are not significantly different from the values obtained using the Hammett equation in the variable intercept form (column 4).

The excellent correlation obtained with σ_I values in the single substituent parameter (Hammett) equation clearly indicates that the substituents in the methyl group exhibit only inductive effects on the dissociation of the 3-picolinium ions. Further confirmation that this is so is provided by the results of a correlation using the dual substituent parameter equation (σ_I and σ_R^0). This gives $\rho_I = 3.191$, $\rho_R = -0.141$, $s = 0.09$, $f = 0.07$. The value of λ ($\equiv \rho_R/\rho_I$) = −0.04 is not significantly different from zero, and a factor of 10 smaller than the value ~0.4 observed generally for *meta* reactivities and, specifically, the value of 0.43 observed for dissociation of 3-X-pyridinium ions (4).

The dissociation of 3-X-pyridinium ions conforms with good precision to the Hammett equation, using σ^0 values (5) as the measure of substituent effect, and gives $\rho = 6.01$, $pK_0 = 5.19$ (6). This is also shown by the results of the dual substituent parameter analysis using σ_R^0 which gives a good fit with $\lambda = 0.43$. Accordingly it is possible to derive substituent constants (σ^0 values) for the XCH_2 groups from the expression $\bar{\sigma}^0 = (5.19 - pK)/6.01$. These values are shown in column 6 of Table 1 and encompass the range from −0.12 ($CH_2Si(CH_3)_3$) to +0.41 ($CH_2NH(CH_3)_2^+$).

Table 2 lists pK values of the 3-picolylammonium ion (3-pyridinemethanamine conjugate acid) and its *N*-methyl and *N*,*N*-dimethyl derivatives. The substituent constant (σ^0) for the 3-aza substituent (i.e., 3-pyridinyl relative to phenyl) evaluated from the fit of the pK value for the picolylammonium ion to the

Hammett plot for benzylammonium ions (7) is 0.75. The value is in satisfactory agreement with the σ^0 value of 0.72, from hydrolysis of benzyl acetates in aqueous acetone (8) and is somewhat larger than the mean σ value of 0.65 from hydrolysis of methyl and ethyl picolinates in aqueous methanol, aqueous ethanol, aqueous acetone, and aqueous dioxan (9).

Experimental

General experimental methods are described in the previous paper (1). The following substituted 3-picolines were commercially available: 3-picoline (Aldrich, hydrochloride hygroscopic), 3-ethylpyridine (Reilly, hydrochloride hygroscopic), 3-picolylamine (3-pyridinemethanamine, Reilly, monohydrochloride mp 162–163°C), 3-pyridyleacetonitrile (Aldrich, hydrochloride mp 158–160°C), 3-chloromethylpyridine hydrochloride (Aldrich, mp 135–137°C), 3-pyridylcarbinol (3-pyridinemethanol, Aldrich, hydrochloride mp 113–114.5°C). 3-Trimethylsilylmethylpyridine was supplied by Dr. M. W. Morgan (10).

The following substituted 3-picolines were prepared by methods similar to those described for their 2-isomers (1). Phenyl 3-picolyl sulfone, mp 129–130°C (lit. (11) mp 134.5–135.5°C); nmr ($CDCl_3$) τ: 1.42 (m, 1, 2-*H*), 1.79 (m, 1, 6-*H*), 2.50 (m, 7, C_6H_5, 4-*H* and 5-*H*), 5.70 (s, 2, CH_2). 3-Pyridinemethanethiol (12); nmr τ: 1.60 (m, 2, 2-*H* and 6-*H*), 2.39 (m, 1, 4-*H*), 2.89 (m, 1, 5-*H*), 6.30 (d, 2, J = 7.5 Hz, CH_2, becomes singlet on D_2O exchange), 8.09 (t, 1, S*H*, removed on D_2O exchange); mass spectrum (70 eV) *m/e* (relative intensity): 125 (46, M_r (C_6H_7NS) = 125), 93(27), 92(100), 65(50), 39(25). 3-Pyridylmethylacetate (3-pyridinemethanol acetate ester), nmr τ: 1.50 (m, 2, 2-*H* and 6-*H*), 2.40 (m, 1, 4-*H*), 2.81 (m, 1, 5-*H*), 4.94 (s, 2, CH_2), 8.80 (s, 3, CH_3); hydrochloride (recrystallized from methanol – ethyl acetate), mp 95–97°C (lit. (13) mp 96–98°C); mass spectrum (70 eV) *m/e* (relative intensity): 151 (4, M_r ($C_8H_9NO_2$) = 151), 136 (2), 109(17), 108(11), 92(27), 91(25), 80(22), 65(36), 43(100), 39(50), 36(87). Ethyl 3-pyridylacetate, nmr τ: 1.54 (m, 2, 2-*H* and 6-*H*), 2.43 (m, 1, 4-*H*), 2.86 (m, 1, 5-*H*), 5.96 (q, 2, J = 7 Hz, CH_2CH_3), 6.49 (s, 2, CH_2CO), 8.84 (t, 3, CH_2CH_3); hydrochloride (from methanol–ethyl acetate), mp 142.5–144.5°C; mass spectrum (70 eV) *m/e* (relative intensity): 165 (34, M_r ($C_9H_{11}NO_2$) = 165), 121(13), 120(11), 93(40), 92(100), 65(35), 39(33), 36(42), 29(54). The hydrochloride was sublimed, mp 114–117°C.

3-Propylpyridine was prepared by alkylation of the anion of 3-picoline, itself generated from 3-picoline using sodamide in ammonia, with ethyl bromide (16). After distillation at 30–40°C under reduced pressure the 3-propylpyridine was obtained in 31% yield and had nmr τ: 1.68 (m, 2, 2-*H* and 6-*H*), 2.62 (m, 1, 4-*H*), 2.96 (m, 1, 5-*H*), 7.42 (t, 2, J = 8.8 Hz, CH_2CH_2-CH_3), 8.37 (m, 2, $CH_2CH_2CH_3$), 9.08 (t, 3, J = 6.9 Hz, $CH_2CH_2CH_3$). The hydrochloride was recrystallized from chloroform – ethyl acetate, mp 135–136°C; mass spectrum (70 eV) *m/e* relative intensity): 121 (30, M_r ($C_8H_{11}N$) = 121), 106(9), 93(19), 92(100), 65(26), 51(12), 39(40), 36(37).

3-Benzylpyridine was prepared from 3-chloromethylpyridine hydrochloride by a Friedel–Crafts reaction using benzene and powdered $AlCl_3$ (17). The product was obtained in 55% yield after distillation at 110°C under reduced pressure and solidified on standing; nmr τ: 1.56 (m, 2, 2-*H* and 6-*H*), 2.79 (m, 7, 4-*H*, 5-*H*, and C_6H_5), 6.05 (s, 2, CH_2). The hydrochloride was recrystallized from chloroform – ethyl acetate, mp 146.5–148.5°C; mass spectrum (70 eV) *m/e* (relative intensity): 169 (25, M_r ($C_{12}H_{11}N$) = 169), 168(26), 115(13), 91(16), 65(25), 51(23), 39(39), 39(30), 36(100).

3-Bromomethylpyridine hydrobromide was prepared by refluxing 3-pyridylcarbinol (40 g) with 48% HBr (360 cm^3) for 4 h. Concentration of the solution, dilution with ethanol (200 cm^3) and cooling gave the hydrobromide (64.7 g, 70%) which was recrystallized from methanol and then sublimed, mp 147.5–149°C (lit. (18) mp 148–149°C).

3-Pyridylacetone (1-(3-pyridinyl)-2-propanone) was prepared by condensation of 3-pyridylacetic acid with acetic anhydride followed by decarboxylation of the resulting β-keto acid (19) and was obtained in 13% yield after distillation at 130–140°C under reduced pressure; nmr τ: 1.61 (m, 2, 2-*H* and 6-*H*), 2.53 (m, 1, 4-*H*), 2.82 (m, 1, 5-*H*), 6.34 (s, 2, CH_2), 7.98 (s, 3, CH_3). The hydrochloride after sublimation had mp 143–145°C; mass spectrum (70 eV) *m/e* (relative intensity): 135 (15, M_r (C_8H_9NO) = 135), 93(100), 92(20), 65(14), 43(45), 39(16).

3-Phenacylpyridine (1-phenyl-2-(3-pyridinyl) ethanone) was prepared by reaction of the anion of 3-picoline, formed by reaction of 3-picoline with lithium diisopropylamide, with methyl benzoate. After distillation at 160°C under reduced pressure, the product had nmr ($CDCl_3$) τ: 1.41 (m, 2, 2-*H* and 6-*H*), 1.93 (m, 2, 4-*H* and 5-*H*), 2.48 (m, 5, C_6H_5), 5.72 (s, 2, CH_2). The hydrochloride was recrystallized from methanol and than sublimed but a sharp melting point was not obtained. *Anal.* calcd. for $C_{13}H_{12}NOCl$: C 66.82, N 6.00, H 5.18: found: C 66.65, N 5.84, H 5.16.

3-Thiocyanatomethylpyridine thiocyanate. A solution of 3-chloromethylpyridine hydrochloride (8.2 g, 0.05 mol) in methanol (50 cm^3) was mixed with potassium thiocyanate (9.7 g, 0.1 mol) and refluxed for 2 h. The precipitated potassium chloride was filtered off and the product crystallized from the filtrate on cooling, in 89% yield. Recrystallization from methanol followed by sublimation gave mp 100.5–102°C, (lit. (20) mp 110°C); mass spectrum (70 eV) *m/e* relative intensity): 150 (34, M_r ($C_7H_6N_2S$) = 150), 93(19), 92(100), 65(40), 59(15), 39(31), 31(84).

3-Iodomethylpyridine hydriodide. 3-Pyridylcarbinol (20 g) was refluxed for 20 h with 55% hydriodic acid (180 cm^3) and a trace of red phosphorus. The solution was concentrated on the rotary evaporator and the solid product (22.1 g, 50% yield) was filtered and recrystallized from 95% ethanol, mp 177–179°C; mass spectrum (70 eV) *m/e* (relative intensity): 219 (17, M_r (C_6H_6NI) = 219), 128(33), 127(20), 92(100), 65(32), 39(17). *Anal.* calcd. for $C_6H_7NI_2$: C 20.76, N 4.04, H 2.04; found: C 20.98, N 4.20, H 2.04.

3-Nitromethylpyridine was prepared by the method of Feuer and Lawrence (2), except that *n*-propyl nitrate was used in place of the suggested ethyl nitrate. It was purified by chromatography on silica gel, eluting with $CHCl_3$; nmr ($CDCl_3$) τ: 1.34 (m, 2, 2-*H* and 6-*H*), 2.20 (m, 1, 4-*H*), 2.66 (m, 1, 5-*H*), 4.59 (s, 2, CH_2). The picrate was recrystallized from 95% EtOH, mp 147–149°C (lit. (2) mp 150–151°C).

Inductive substituent constants from dissociation of methyl-substituted 4-picolinium ions[1]

ALFRED FISCHER, MURRAY JOHN KING, AND FRANK PRICE ROBINSON

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received May 31, 1978[2]

ALFRED FISCHER, MURRAY JOHN KING, and FRANK PRICE ROBINSON. Can. J. Chem. **56**, 3072 (1978).

The dissociation constants of 29 α-substituted 4-methylpyridinium ions in water at 25°C have been measured by potentiometric or spectrophotometric methods. Correlation of the log K values with σ_I values gives, for $n = 13$, slope $\rho = 2.922$, intercept log $K_0 = 5.93$, correlation coefficient $r = 0.990$. Effective σ_I values evaluated from the dissociation of substituted 4-picolinium ions are in good agreement with those calculated from dissociation of substituted 2- and 3-picolinium ions and with literature values. pK values of the 4-pyridinylmethylammonium ion and its *N*-methyl and *N*,*N*-dimethyl derivatives are 8.22, 8.48, and 7.63, respectively.

ALFRED FISCHER, MURRAY JOHN KING et FRANK PRICE ROBINSON. Can. J. Chem. **56**, 3072 (1978).

Au moyen de méthodes potentiométriques et spectrophotométriques, on a mésure dans l'eau à 25°C les constantes de dissociation de 29 ions méthyl-4 pyridinium substitués en position α. De la relation entre les valeurs de log K et celles de σ_I, on tire pour $n = 13$, une pente ρ de 2.922, une ordonnée à l'origine log K_0 de 5.93 et un coefficient de corrélation r de 0.990. Les valeurs effectives de σ_I évaluées au moyen de la dissociation des ions picolinium-4 substitués sont en bon accord avec celles qu'on calcule à partir de la dissociation des ions picolinium-2 et -3 substitués et avec les valeurs de la littérature. Les valeurs de pK de l'ion pyridinyl-4 méthylammonium et de ses dérivés *N*-méthyl et *N*,*N*-diméthyl sont de 8.22, 8.48 et 7.43, respectivement.

[Traduit par le journal]

In this paper we report the dissociation constants of a series of α-substituted 4-picolinium ions (α-substituted 4-methylpyridinium ions) and derived σ_I values. The latter are compared with values derived from the 2- and 3-picolinium ion series (1, 2) and with literature values.

The pK values for the 4-picolines are shown in Table 1. Values are estimated to be accurate to ±0.02 although the precision and, presumably, the relative accuracy of the values measured by potentiometry is rather better than this. 4-Trimethylsilylmethylpyridine reacted in solution (as did its 2-isomer) and the extinction coefficients had to be determined by an extrapolation technique (1). For this reason its pK value is less accurate, ±0.1.

Correlation of values of ($pK_H - pK$) with σ_I values (3) gave, for $n = 13$, slope $\rho = 2.922$, intercept 0.074, correlation coefficient $r = 0.990$, standard deviation $s = 0.09$, standard deviation of the slope $s_\rho = 0.13$, root-mean-square deviations/root-mean-square observations $f = 0.07$.[3] Effective σ values evaluated from the relation $\bar{\sigma}_I = (pK_H - pK - 0.074)/2.922$ are shown in Table 1 and are repeated in Table 2 for comparison with similar values from the 2- and 3-picolinium ion series and other values evaluated from literature data or taken directly from the literature.

For the picolinium ions the accuracy with which pK values are generally determined, ±0.02, is much greater than the precision with which the values correlate with σ_I values, for which s ranges from 0.08 (3-picolinium ions) to 0.15 (2-picolinium ions). Thus the limiting factor in the determination of $\bar{\sigma}_I$ values is not generally the accuracy of the pK data but the precision with which substituent effects are proportional from one reaction series to another. The measure of the precision with which $\bar{\sigma}_I$ values are determined is given by s/ρ and this ranges from 0.027 (3-picolinium ions) to 0.030 (4-picolinium ions). The same limiting precision (0.03) was found by Taft for σ^0 reactivities (8).

The trimethylsilylmethyl group appears to be a much better electron donor in the 4-picolinium ion series than in the 3-picolinium ion series and in the other reactivities. It is possible that this is a consequence of the error in the pK value resulting from the problems in this measurement (see above). It is more likely that the enhanced $\bar{\sigma}_I$ value reflects the powerful resonance (hyperconjugative) effect of the trimethylsilylmethyl group. It is a basic assumption of our analysis that the resonance effect, on the pyridinium ion – pyridine equilibrium, of methyl and

[2]Revision received August 9, 1978.

[3]The Hammett equation in the variable intercept parameter form was used. The data for the substituents NO_2 and $Si(CH_3)_3$ were not used in the correlation and the mean pK value (5.00) for the 4-picolinic acid esters was used as a single datum. The dual substituent parameter correlation with nonvariable intercept and using σ_I and σ_R^0 (3) gave, for $n = 12$, $\rho_I = 3.11$, $\rho_R = 0.035$, λ ($\equiv \rho_R/\rho_I$) $= 0.01$, $s = 0.10$, $f = 0.08$.

[a]Described in ref. 1.
[b]Calculated from $\bar{\sigma}_I = (5.926 - pK)/2.922$.

substituted methyl groups is either constant or proportional to the inductive effect of the substituent of the substituted methyl group. This assumption is likely to be violated for the trimethylsilylmethyl group since the trimethylsilylmethyl group has a much stronger electron-donating resonance effect than does methyl (9).

The $\bar{\sigma}_I$ value for the nitro group is substantially greater in the 4-picolinium ion series than in the 3-picolinium ion series which itself is in excellent agreement with literature values. 4-Nitromethylpyridinium ion is 1.16 pK units stronger as an acid than predicted by the σ_I for the nitro group of 0.65. This is similar to the behaviour of 2-nitromethylpyridinium ion and the same explanation presumably applies: tautomerism of the nitromethylpyridine results in the formation of a more weakly basic nitronate form (Fig. 1). If this is the correct explanation for the observation that 4-nitromethylpyridine is a weaker base than expected then 93% of the nitromethylpyridine must exist in the nitronate form. Feuer and Lawrence (10) have shown that the nitronate form is present to the extent of 33% in dimethyl sulfoxide solution and it is not unreasonable that even more of this (polar) form should be present in aqueous solution.

The reduced basicity of 2-phenacylpyridine has been commented on (1). For all other substituents with the exception of $NH(CH_3)_2^+$ there is excellent agreement between the $\bar{\sigma}_I$ values derived from the three picolinium ion series. In the case of the $NH(CH_3)_2^+$ substituent the range of values is 0.08 and the somewhat greater range in this instance is probably a consequence of the greater error in the pK value of the 2-picolinium ion derivative, measured in hydrochloric acid solutions (1).

Mean $\bar{\sigma}_I$ values from the dissociation of picolinium ions are shown in column 5 of Table 2. In deriving these mean $\bar{\sigma}_I$ values deviant individual values were rejected (the values derived from 2- and 4-nitromethylpyridine, 2- and 4-trimethylsilylmethylpyridine, 2-phenacylpyridine) and the values derived from the less accurate pK values (such as in the case of the $NH(CH_3)_2^+$ substituent from the 2-picoline series) were assigned proportionately lower (20%) weights. Also shown in Table 2 are $\bar{\sigma}_I$ values calculated from literature pK data for 4-substituted quinuclidines (column 6), substituted acetic acids (column 7), 4-substituted bicyclo[2.2.2]octane-1-carboxylic acids (column 8), 4-substituted bicyclo[2.2.2]-oct-2-ene-1-carboxylic acids (column 9), α-substituted 4-toluic acids (column 10), and Taft's σ_I values (column 11). All of the $\bar{\sigma}_I$ values were obtained from linear correlation of pK with σ_I with a variable intercept parameter. Only data for those substituents common to two or more reaction series have been included in Table 2. Extensive tables of σ_I values evaluated from ^{19}F nmr shifts and also from aromatic reactivities are available (11) but we have restricted our comparisons to acid dissociation reactions in order to assess the constancy of $\bar{\sigma}_I$ values in a similar set of reactivities. Other data for other acid dissociation reactions are available from which $\bar{\sigma}_I$ values may be determined but have not been included in Table 2 either because a too restricted range of substituents is encompassed (dissociation of 3-substituted adamantane-1-carboxylic acids (12)) or too few (<6) substituents for which σ_I values are listed in the primary set have been studied (dissociation of *trans*-4-substituted cyclohexane-1-carboxylic acids (13)) or because the correlation is of lower precision with $s/\rho > 0.03$ (dissociation of substi-

tuted 3-toluic acids (7) and of substituted 4-toluic acids in 80% methyl cellosolve (7*b*)).

In general, within the precision implied by the standard deviation (s/ρ) of 0.03 for the individual reaction series, there is excellent agreement between the $\bar{\sigma}_I$ values determined from dissociation of picolinium ions, the values calculated from other dissociation reactions and Taft's σ_I values. Grob and Schlageter (4) state that the correlation of the quinuclidine data (of $\sigma_I^q \equiv pK_H - pK$) with σ_I is only fair with $r = 0.906$. Examination of their plot reveals that the correlation is good but there is a very marked deviation in the case of the CO_2^- substituent, which, according to the quinuclidine p*K*

value, is *electron attracting* whereas the $\bar{\sigma}_I$ values from the carboxylic and dissociation series show that it is quite strongly electron repelling. Substituent effects of charged groups can show marked variations from one reaction series to another and it is inappropriate to place much weight on the marked deviation of the CO_2^- substituent in the quinuclidine series. For the same correlation, restricting our choice of σ_I values to Taft's primary set (3) which, significantly, does not include a value for CO_2^-, we obtained $r = 0.988$, for $n = 17$. The datum point for X = H was significantly deviant with $\bar{\sigma}_H = -0.08$. When the correlation was repeated without this point ($n = 16$) an even better correlation was obtained with $r = 0.992$, $s = 0.13$, $s/\rho = 0.027$, $f = 0.05$ and the point for X = H was even more deviant with $\bar{\sigma}_H = -0.10$. We conclude that the quinuclidine data exhibit an excellent correlation with σ_I (although the hydrogen datum point is deviant) and that it is unnecessary (and indeed undesirable) to introduce a set of σ_I^q values. In the analysis of the quinuclidine (and other) data we have used a variable intercept parameter. Taft has argued against the introduction of a variable intercept parameter, particularly in the application of the dual substituent parameter equation (3). In the case of the quinuclidine dissociation, where analysis using the variable intercept parameter form of the single substituent parameter (Hammett) equation shows the hydrogen datum point is significantly deviant, it seems unreasonable to assume that this point is 'correct' as would be implied by application of the equation without a variable intercept parameter. It is noteworthy that, like hydrogen, the alkyl substituents appear to be more strongly electron donating ($\bar{\sigma}_I$ more negative) in the quinuclidines than in the acetic acids. It is possible that this reflects a specific difference between the two systems. Alternatively it may represent the incursion of a systematic error of measurement in the high pH range.

There are marked discrepancies between the substituent effects of the positively charged ammonio and substituted ammonio groups in the picolines and in the acetic acids. For these groups the $\bar{\sigma}_I$ values from the acetic acids are 0.20–0.28 units smaller than the values from the picolines, i.e., the ammonio-substituted acetic acids are 0.8–1.1 pK units weaker than would be predicted from the $\bar{\sigma}_I$ values derived from the dissociation of picolinium ions. We are unable to account for this. It is of interest that $\bar{\sigma}_I$ for the trimethylammonio substituent which, at 0.71, is consistent with other ammonio and methylammonio values derived from the acetic acid series, is 0.95, from bicyclooctane carboxylic acids, and 0.98, from bicyclooctene carboxylic acids, consistent with the values for the other ammonio substituents derived from the picolines. This suggests that the values obtained from the acetic acid series are anomalous. The $\bar{\sigma}_I$ values for the ammonio, methylammonio, and dimethylammonio substituents derived from the picolines increase in that order. Successive replacement of hydrogen of the ammonio group by methyl should result in increased dispersal of the positive charge and a smaller substituent effect of the substituted ammonio group. However if the ammonio group is extensively solvated through hydrogen bonding its positive charge will be extensively distributed into the solvent. Successive replacement of hydrogen by methyl will then reduce such solvation and increase the concentration of positive charge on the substituent. Evidently the latter factor, the reduction in solvation, is more important than the former, the electron-donating effect of the methyl group.

For dissociation of substituted 2-, 3-, and 4-picolines ρ_I values are 5.449, 3.044, and 2.922, respectively. Qualitatively, these results confirm the conclusion based on the results of the analysis of the pK data for substituted pyridines, in terms of the dual substituent parameter equation (3), that the inductive effect of substituents, as measured by ρ_I is much greater at the 2 position than at the 3 and 4 positions. More quantitatively, the ratio of the ρ_I values for dissociation of substituted picolines and pyridines is 0.51 at the 2 position, 0.51 at the 3 position, and 0.57 at the 4 position. These values measure the attenuation of the inductive effect of substituents produced by the interposition of a methylene group. The attenuation appears to be independent of position and is somewhat smaller (the fall-off factor is closer to unity) than the value often cited, a fall-off factor across a methylene group of 1/2.8 (14). However similar fall-off factors have apparently been observed in some other systems.[4]

The pK values of the 4-picolylammonium ion (4-pyridinemethanamine conjugate acid) and its *N*-methyl and *N*,*N*-dimethyl derivatives are shown in Table 3. The values parallel those of the 2 and 3 isomers and as in those cases the introduction of the first methyl group increases the pK value whereas the second methyl group lowers the pK. The substituent constant (σ^0) for the 4-aza substituent (4-pyridinyl

relative to phenyl) evaluated from the pK value for 4-picolylammonium ion is 1.12. This is significantly larger than the value of 0.95, from hydrolysis of benzyl acetates in aqueous acetone (15) and which itself is in excellent agreement with the mean σ value of 0.96 obtained from hydrolysis of methyl and ethyl picolinates in aqueous methanol, aqueous ethanol, aqueous acetone, and aqueous dioxan (16).

Experimental

General experimental methods are described in a previous paper (1).

The following compounds were commercially available: 4-picoline (Aldrich, hydrochloride hygroscopic), 4-*n*-propylpyridine (Baker, hydrochloride mp 158–163°C, dec.), 4-benzylpyridine (Reilly, hydrochloride mp 142–144°C), 4-picolylamine (4-pyridinemethanamine, Reilly), 4-chloromethylpyridine hydrochloride (Aldrich, transformation at 160°C but no melting occurred), 4-pyridylcarbinol (4-pyridinemethanol, Reilly, hydrochloride mp 183–184°C). 4-Trimethylsilylmethylpyridine was supplied by Dr. M. W. Morgan (17).

The following substituted 4-picolines were prepared by methods similar to those described for their 2-isomers (1). Phenyl 4-picolyl sulfone, mp 199–200.5°C (lit. (18) mp 203–204°C); nmr ($CDCl_3$) τ: 1.46 (m, 2, 2-*H* and 6-*H*), 2.93 (d, 2, 3-*H* and 5-*H*), 2.40 (m, 5, C_6H_5), 5.71 (s, 2, CH_2). 4-Pyridinemethanethiol, nmr τ: 1.55 (m, 2, 2-*H* and 6-*H*), 2.83 (m, 2, 3-*H* and 5-*H*), 6.36 (d, 2, J = 8.0 Hz, CH_2, becomes singlet on D_2O exchange), 8.22 (t, 1, S*H*, removed on D_2O exchange); ms (70 eV) *m/e* (relative intensity): 125 (98, M_r (C_6H_7NS) = 125), 93(55), 92(100), 66(24), 65(61), 39(51); picrate (recrystallized from 95% ethanol) mp 153–154°C, *anal.* calcd. for $C_{12}H_{10}N_4O_7S$: C 40.66, N 15.82, H 2.85; found: C 40.89, N 16.35, H 2.74; hydrochloride (recrystallized from methanol – ethyl acetate), mp 154.5–155.5°C; *anal.* calcd. for C_6H_8NSCl: C 44.55, N 8.67, H 4.99; found: C 44.11, N 8.94, H 4.88. 4-Pyridylmethyl acetate (4-pyridinemethanol acetate ester), nmr τ: 1.50 (m, 2, 2-*H* and 6-*H*), 2.82 (m, 2, 3-*H* and 5-*H*), 4.98 (s, 2, CH_2), 7.97 (s, 3, CH_3); hydrochloride (recrystallized from methanol), mp 159–160°C (lit. (19) mp 154–156°C); ms (70 eV) *m/e* (relative intensity); 151 (9, M_r ($C_8H_9NO_2$) = 151), 109(43), 108(20), 92(14), 80(23), 65(18), 43(100), 39(23), 38(28), 36(83). Methyl 4-picolyl sulfone, mp 133.5–134.5°C; nmr ($CDCl_3$) τ: 1.30 (m, 2, 2-*H* and 6-*H*), 2.61 (m, 2, 3-*H* and 5-*H*), 5.75 (s, 2, CH_2), 7.20 (s, 3, CH_3); ms (70 eV) *m/e* (relative intensity): 171.027 (26, M_r ($^{12}C_7{}^1H_9{}^{14}N^{32}S^{16}O_2$) = 171.035), 93(9), 92(100), 65(34), 39(23). *Anal.* calcd. for $C_7H_9NSO_2$: C 49.07, H 5.31, N 8.19; found: C 49.01, H 5.24, N 7.89. Ethyl 4-picolyl sulfone, mp 86–87.5°C; nmr ($CDCl_3$) τ: 1.31 (m, 2, 2-*H* and 6-*H*), 2.60 (m, 2, 3-*H* and 5-*H*), 5.77 (s, 2, CH_2), 7.03 (q, 2, J = 7.0 Hz, CH_2CH_3), 8.63 (t, 3, CH_2CH_3); ms (70 eV) *m/e* (relative intensity): 185.056 (74, M_r ($^{12}C_8{}^1H_{11}{}^{14}N^{32}S^{16}O_2$) = 185.051), 93(35), 92(100), 65(48), 39(22). *Anal.* calcd. for $C_8H_{11}NSO_2$: C 51.84, H 6.00, N 7.57; found: C 51.71, H 5.96, N 7.46. 4-Methoxymethylpyridine, nmr τ: 1.42 (m, 2, 2-*H* and 6-*H*), 2.85 (d, 2, 3-*H* and 5-*H*), 5.63 (s, 2, CH_2), 6.67 (s, 3, OCH_3); hydrochloride (recrystallized from methanol – ethyl acetate), mp 134.5–135.5°C; ms (70 eV) *m/e* (relative intensity): 123 (45, M_r (C_7H_9NO) = 123), 108(41), 93(64), 92(41), 80(48), 65(55), 51(43), 45(78), 39(100), 36(91). 4-Pyridylacetone (1-(4-pyridinyl)2-propanone), hydrochloride (sublimed), mp 149–151°C; nmr (CF_3CO_2H) τ: 1.20 (m, 2, 2-*H* and 6-*H*), 1.94 (d, 2, 3-*H* and 5-*H*), 5.59 (s, 2, CH_2), 7.48 (s, 3, CH_3); ms (70 eV) *m/e* (relative intensity): 135 (18, M_r (C_8H_9NO) = 135), 93(100), 92(20), 65(14), 43(45), 36(29). 4-Phenacylpyridine (1-phenyl-2-(3-pyridinyl)ethanone), mp 114–117°C (lit. (21) mp 142–144°C). 4-Phenoxymethylpyridine; hydrochloride (recrystallized from methanol–ether), mp 153–156°C; nmr (D_2O) τ: 0.90 (d, 2, 2-*H* and 6-*H*), 1.52 (d, 2, 3-*H* and 5-*H*), 2.39 (m, 5, C_6H_5), 4.22 (s, 2, CH_2); ms (70 eV) *m/e* (relative intensity): 185 (100, M_r ($C_{12}H_{11}NO$) = 185), 94(78), 92(91), 65(50), 39(27), 36(40). 4-*N*-Acetylmethylaminomethylpyridine (*N*-methyl-4-pyridinylmethylacetamide), mp 48–49.5°C; nmr τ: 1.55 (m, 2, 2-*H* and 6-*H*), 2.95 (d, 2, 3-*H* and 5-*H*), 5.55 (s, 2, CH_2), 7.08 (s, 3, N—CH_3), 7.91 (s, 3, $COCH_3$); ms (70 eV) *m/e* (relative intensity): 164 (100, M_r ($C_9H_{12}N_2O$) = 164), 121(69), 107(75), 93(31), 92(30), 79(37), 44(70), 43(55). *Anal.* calcd. for $C_9H_{12}N_2O$: C 65.80, N 17.07, H 7.38; found: C 65.86, N 16.99, H 7.38. 4-Nitromethylpyridine, mp 119–120°C (lit. (10) mp 97°C). *Anal.* calcd. for $C_6H_6N_2O_2$: C 52.15, N 20.29, H 4.38; found: C 52.39, N 20.07, H 4.38.

The following substituted 4-picolines were prepared by methods similar to those described for their 3-isomers. 4-Bromomethylpyridine hydrobromide (recrystallised from absolute ethanol and sublimed), did not melt on slow heating but fast heating gave a mp of 200°C (lit. (22) mp 185–187°C). *Anal.* calcd. for $C_6H_7NBr_2$: C 28.47, H 2.80, N 5.54; found: C 28.35, H 2.78, N 5.68. 4-Thiocyanatomethylpyridine thiocyanate mp 115–116.5°C (lit. (23) mp 120°C); ms (70 eV) *m/e* relative intensity): 150 (7, M_r ($C_7H_6N_2S$) = 150), 92(63), 65(61), 59(72), 39(100), 32(68).

Methyl 4-pyridyl acetate. Carbonation of 4-picolyllithium (from 4-picoline and phenyllithium) gave the lithium salt of 4-pyridylacetic acid. Dissolution of the latter in methanol followed by saturation with hydrogen chloride gave the ester which was distilled at 105–110°C under reduced pressure, nmr τ: 1.54 (m, 2, 2-*H* and 6-*H*), 2.89 (m, 2, 3-*H* and 5-*H*), 6.41

(s, 3, CH_3), 6.50 (s, 2, CH_2); hydrochloride (recrystallized from methanol), mp 204.5–207°C; ms (70 eV) *m/e* (relative intensity): 151 (100, M_r ($C_8H_9NO_2$) = 151), 107(25), 106(25), 92(87), 65(44), 59(42), 39(25), 36(41). Ethyl 4-pyridylacetate was prepared similarly, nmr τ: 1.55 (m, 2, 2-*H* and 6-*H*), 2.88 (m, 2, 3-*H* and 5-*H*), 5.90 (q, 2, J = 7.0 Hz, CH_2CH_3), 6.50 (s, 2, CH_2CO), 8.82 (t, 3, CH_2CH_3); ms (70 eV) *m/e* (relative intensity): 165 (100, M_r ($C_9H_{11}NO_2$) = 165), 154(81), 106(40), 93(77), 92(81), 65(38), 29(55). The hydrochloride could not be satisfactorily prepared.

4-Pyridylacetonitrile was prepared by refluxing 4-chloromethylpyridine hydrochloride with potassium cyanide in aqueous methanol. After distillation at 100°C under reduced pressure the product solidified on standing, and was obtained in 25% yield. The hydrochloride was prepared and recrystallized from absolute ethanol. It decomposed on heating above 255°C (lit. (24) mp 270–272°C); nmr (CF_3COOH) τ: 1.61 (m, 2, 2-*H* and 6-*H*), 2.43 (d, 2, 3-*H* and 5-*H*), 6.14 (s, 2, CH_2); ms (70 eV) *m/e* (relative intensity): 118 (100, M_r ($C_7H_6N_2$) = 118), 91(39), 78(27), 64(42), 51(54), 38(29), 36(83). *Anal.* calcd. for $C_7H_7N_2Cl$: C 54.35, N 18.13, H 4.56; found: C 54.48, N 18.31, H 4.55.

The methods for determining the pK values have been described (1).

The oxygen exchange from $O_2/C^{18}O_2$ with surfaces of vanadium pentoxide and alkali metal-promoted vanadium pentoxide catalysts

DAVID VICTOR FIKIS, KEITH WALTER HECKLEY, WILLIAM JOHN MURPHY,[1] AND ROBERT ANDERSON ROSS

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received July 7, 1978

DAVID VICTOR FIKIS, KEITH WALTER HECKLEY, WILLIAM JOHN MURPHY, and ROBERT ANDERSON ROSS. Can. J. Chem. **56**, 3078 (1978).

The oxygen exchange reaction between $O_2/C^{18}O_2$ and the surfaces of vanadium pentoxide and promoted vanadium pentoxide catalysts has been studied in a circulation system using a quartz differential reactor. Isotopic compositions were analysed with an in-line mass spectrometer. Alkali metal sulphates, Li to Cs, were added to the pentoxide as individual promoters at a concentration level of 9 mol% and the effect of variation of promoter concentration was examined with melts containing potassium sulphate at additional levels of 1, 2, and 5 mol%. The structures of the solids were studied by X-ray diffraction and by ATR and transmission infrared spectroscopy. The latter results have been used to explain the two activity series for the exchange rates: (*i*) V_2O_5 < Na < Li < K < Rb < Cs (melts) and (*ii*) V_2O_5 < 1 mol% < 2 mol% < 5 mol% < 9 mol% (K), in terms of additive effects on the relative abundance and strength of identified vanadium/oxygen linkages in the surfaces of the catalysts.

DAVID VICTOR FIKIS, KEITH WALTER HECKLEY, WILLIAM JOHN MURPHY et ROBERT ANDERSON ROSS. Can. J. Chem. **56**, 3078 (1978).

On a étudié dans un système à circulation muni d'un réacteur différentiel en quartz, les réactions d'échange d'oxygène entre $O_2/C^{18}O_2$ et les surfaces de catalyseurs de pentoxyde de vanadium et de pentoxyde de vanadium activé. Un spectromètre de masse en série analysait les compositions isotopiques. On a effectué des expériences en utilisant à titre de seul promoteur le sulfate d'un métal alcalin, de Li à Cs, qu'on ajoutait au pentoxyde à une concentration de 9 mol%. On a examiné l'influence d'une variation de la concentration du promoteur à l'aide d'autres échantillons contenant du sulfate de potassium à raison de 1, 2, et 5 mol%. On a étudié la structure des solides en utilisant la diffraction des rayons X, ainsi que la spectroscopie infrarouge par transmission et par RTA. Les vitesses d'échange ont conduit au classement de l'activité des systèmes selon les séries suivantes: (*i*) V_2O_5 < Na < Li < K < Rb < Cs et (*ii*) V_2O_5 < 1 mol% < 2 mol% < 5 mol% < 9 mol% (K). Les résultats des méthodes énumérées ci-dessus ont permis de relier ces deux séries aux effets conjugués de l'abondance et de la force relatives des liens vanadium/oxygène se trouvant sur la surface des catalyseurs.

[Traduit par le journal]

Introduction

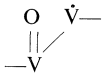
Vanadium pentoxide and vanadium pentoxide promoted with alkali metal sulphates have been used extensively as oxidation catalysts. The addition of these promoters has been shown to influence catalyst activity in oxygen exchange (1, 2), sulphuric acid production (3), and sulphur dioxide oxidation (4) in accord with the activity series:

$$V_2O_5\,(\text{none}) < (Li_2SO_4) < (Na_2SO_4) < (K_2SO_4) < (Rb_2SO_4) < (Cs_2SO_4)$$

A similar series has been reported for the reducibility of the catalysts by hydrogen (5). Catalyst activity increases also with increase in the concentration level of the additive up to 50 mol% (6).

These observations have been attributed to changes in the mobility of the catalyst oxygen (1, 2, 6, 7) which, in turn, has been related to the relative abundance of V^{4+} sites in the surface (2, 7, 8). This latter feature has also been reported to influence the activity of similar materials, vanadium bronzes, in the heterogeneous decomposition of 2-propanol (9).

Although relationships between activities and such properties as electrical conductivity have been explored (1, 9, 10), very few data are available, particularly for the promoted samples, regarding surface chemical factors which might influence catalyst activity. Infrared spectroscopic observations have shown that various changes occur in the spectra of vanadium pentoxide on mixing with alkali metal sulphates (11) and initiated the proposal that



species is the active centre for oxygen exchange on vanadium pentoxide (12).

These investigations have now been extended to

include a kinetic and mechanistic study of the oxygen exchange reaction between oxygen, carbon dioxide, and vanadium pentoxide as well as vanadium pentoxide modified by the addition of alkali metal sulphates. The solids have also been examined by ATR and transmission infrared spectroscopy in an attempt to identify active catalytic sites and any variation in site distribution which might be affected by addition of 1.01, 2.00, 4.98, and 9.09 mol% potassium sulphate and also by a change of the atomic number of the alkali metal additive at a fixed concentration, 9.09 mol%.

Experimental

Apparatus and Procedure

The kinetic measurements were carried out in an all-glass circulation apparatus described previously (13) using a quartz differential reactor. Total volume of the circulation loop of the apparatus was 507 ml. Analysis of the isotopic compositions of the gaseous mixture was obtained from a Vacuum Generator Micromass mass spectrometer, incorporating lanthanum hexaboride coated tungsten filaments. This unit was attached to the circulation loop via a capillary leak and operated at $\sim 3 \times 10^{-6}$ Torr.

Samples were pretreated at 500°C for 4 h in dry circulating oxygen at 10 Torr (1.33 kN m^{-2}) in order to remove adsorbed gases and to stabilise the oxygen content of the surface. Rubidium- and caesium-promoted samples were pretreated at 420°C. Experiments were performed primarily at partial pressures of 10 Torr oxygen and 2 Torr carbon dioxide. These pressures were varied between 2 and 3 Torr and 0.66 and 4.2 Torr, respectively, for rate order determinations. The catalyst charge was 10 g in all runs.

Materials

Vanadium pentoxide was >99.9% pure (Ventron, Boston). Samples containing alkali metal sulphates (Ventron, >99.9% pure) were prepared by mixing vanadium pentoxide powder and the corresponding weight of the appropriate additive in a ball mill for 2 h. This mixture was then heated at 700°C for 4 h in a quartz dish. The liquid melts were cooled rapidly, ground, and pelletized in a 1.27 cm die (ram pressure 3 tons) for 2 min. These pellets, and the pellets of pure vanadium pentoxide which were prepared in a similar manner, were calcined at 500°C for 10 h with the exception of the caesium and rubidium sulphate melts which were calcined at 430°C. The pellets were crushed and sieved to a particle diameter between 1 and 2 mm for the catalytic studies.

Oxygen (research purity grade, 99.995%) was supplied by Matheson Ltd., Toronto and the $C^{18}O_2$ (Lot 1876; >99%) was purchased from Stohler Isotope Chemicals, Montreal.

The surface areas of the catalysts (BET, krypton, σ = 21.1 Å^2) were 0.75, 0.58, 0.40, 0.86, 0.48, and 0.24 $m^2\ g^{-1}$ for the V_2O_5 and the catalysts containing 9.09 mol% Li_2SO_4, Na_2SO_4, K_2SO_4, Rb_2SO_4, and Cs_2SO_4, respectively. The surface areas of the 1.01, 2.00, and 4.98 mol% K_2SO_4-promoted catalysts were 0.52, 0.88, and 0.51 $m^2\ g^{-1}$, respectively. No change in surface area was observed after reaction. Chemical analyses of the various melts showed a maximum residual sulphate level of ~1 ppm prior to use in catalysis. This value was similar to that found with pure vanadium pentoxide samples, ~1 ppm in agreement with previous work (14).

The ir spectra reported were obtained by the KBr technique using a Beckman IR 12 IR spectrometer and X-ray analyses were conducted with Philips equipment.

Results

The exchange rates were studied from 400 to 500°C with the exception of samples promoted with Rb_2SO_4 and Cs_2SO_4 which were examined from 320 to 420°C. These latter catalysts evolved oxygen above 440°C.

Figure 1 shows a typical product distribution for the exchange reaction. All ^{18}O species exchanged with the surface or bulk oxygen of the catalysts in agreement with the literature (15, 16). No change in the ^{18}O content of molecular oxygen was observed during reaction and the reaction products were free of carbon monoxide.

The rates of exchange, R, at the various temperatures shown in Table 1 were determined from the expression (17)

$$[1] \qquad R = \frac{2.3 N_{O_2} N_{CO_2}}{S\tau(N_{O_2} + N_{CO_2})} \log (1 - F)$$

where S is the total surface area of the catalyst (in m^2); N_{O_2} is the amount of oxygen in the O_2 form (in g); N_{CO_2} is the amount of oxygen in CO_2 (in g); $F = (C_0 - C)/(C_0 - C_\infty)$ where C_0 is the initial concentration of ^{18}O (in %) in CO_2, C is the concentration of ^{18}O at the time of exchange, τ; and C_∞ is the equilibrium concentration of ^{18}O in the CO_2 (<2%). Applicability of eq. [1] to each exchange condition was demonstrated by plots of $-\log (1 - F)$ vs. τ. All gave straight lines with a typical correlation coefficient ~0.995.

The reaction rate was independent of both oxygen and carbon dioxide partial pressures in general agreement with current literature (15, 16) on similar systems.

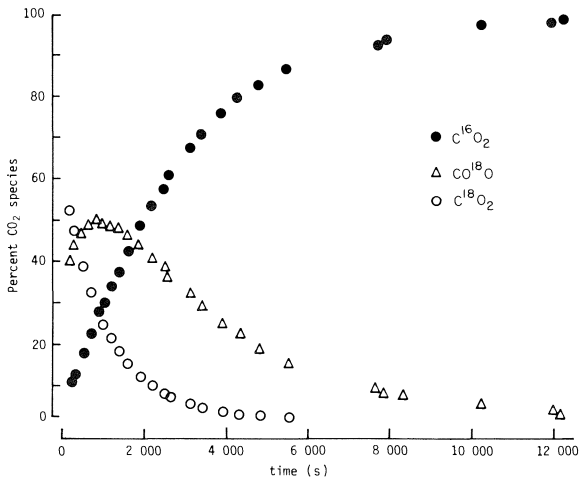

FIG. 1. Carbon dioxide product distribution at 500°C for the exchange of $^{16}O_2$, $C^{18}O_2$, and V_2O_5 promoted with 9.09 mol% Li_2SO_4.

Figure 2 shows the transmission infrared spectra of V_2O_5 and V_2O_5 promoted with alkali metal sulphates. Three major peaks are evident in the spectrum of V_2O_5 at 1020, 825, and 450 to 600 cm^{-1}. The first two have been identified respectively (12) as the V=O stretching vibration (1020 cm^{-1}) (18, 19) and the V—O—V stretching vibration (825 cm^{-1}). The nature of the vibration giving rise to the band at 450 to 600 cm^{-1} is uncertain but may be due to V—O—V rocking vibrations. Figure 2 further shows that with increase in the atomic number of the alkali metal additive, the V=O band splits into a multiplet. A similar but less marked effect is observed with the V—O—V stretch.

Figure 3 shows the infrared spectra of V_2O_5 and V_2O_5 promoted with the various levels of potassium sulphate. Again, the V=O peak splits and although the V—O—V band does not split, a destabilisation down scale is observed with increasing concentration level of the additive. Parallel experiments using

infrared ATR spectroscopy were performed and although the results showed similar behaviour, spectra were not so well defined.

Discussion

The solid solution of an alkali metal in vanadium pentoxide is known to modify the host lattice in a manner related to the atomic number and concentration of the added metal (20, 21). Thus, lithium, sodium, and potassium form a series of bronzes of general formula $M_xV_2O_5$ (9) which at low concentrations (Li, $0 < x \leq 0.13$; Na, $0 \leq x \leq 0.02$; K, $0 < x \leq 0.006$) are isostructural with orthorhombic vanadium pentoxide, α-bronzes. At higher concentrations of lithium ($0.22 \leq x \leq 0.62$) and sodium ($0.22 \leq x \leq 0.40$) the β-phase is formed with a monoclinic unit cell (9, 21). With the exception of the sodium promoted samples, all of the present catalysts gave X-ray diffraction patterns indistinguishable from that for vanadium pentoxide.

The catalysts containing sodium formed β-vanadium bronzes. In all of these solid solutions, the alkali metal atom occupies interstitial positions in tunnels or channels between V—O—V layers in the pentoxide lattice (21), as shown in Fig. 4.

The oxidation state of vanadium in vanadium pentoxide can influence catalyst activity (2, 7–9) and esr studies have indicated that the occurrence of the 4+ oxidation state is enhanced by alkali metal promotion (9). In some V_2O_5 glasses the V^{4+}/V^{5+} ratio can reach a level of 50% (22–24).

Table 1 shows two activity series for the exchange rates:

$$V_2O_5 < Na < Li < K < Rb < Cs \text{ (melts)}$$

and

$$V_2O_5 < 1.01 \text{ mol\%} < 2.00 \text{ mol\%} < 4.98 \text{ mol\%} < 9.09 \text{ mol\% (K)}$$

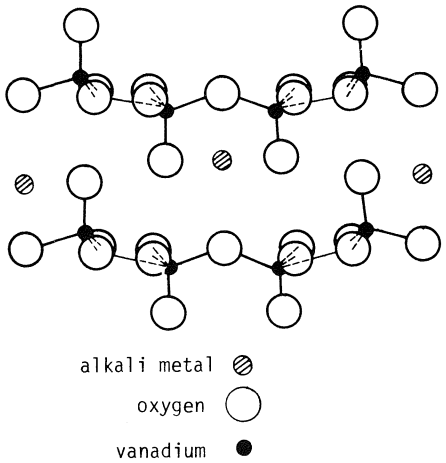

FIG. 4. Projection of the structure of V_2O_5 in the (001) plane.

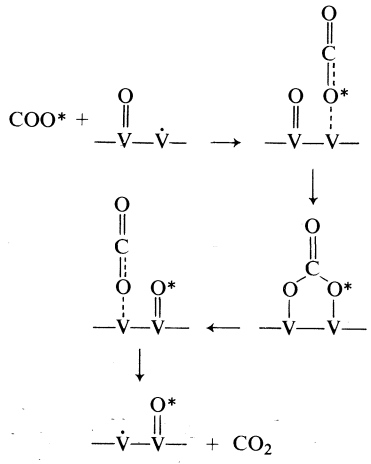
A comparison of these data with results recorded for similar catalysts in oxidation (4, 5) and oxygen-exchange studies (1, 2) shows that the second series is similar but the positions of Na and Li are reversed in the first. Earlier series have been related to both oxygen mobility and V^{4+} concentrations in the oxides (2, 7, 8). However, for β-vanadium bronzes it has also been reported that electron transfer reactions within the solid are more preponderant than for the other solid solutions. Specifically, a higher concentration of V^{4+} ions are formed (10, 25, 26). Thus the decrease in activity of the sodium-promoted catalyst in this study may somehow be inversely related to the preponderance of the 4+ oxidation state.

A mechanism of the type shown in Scheme 1 may



SCHEME 1

be applicable to the exchange reaction of O_2, CO_2, and V_2O_5, with carbon dioxide adsorbing to form a surface carbonate species. The scheme is similar to that of Hirota *et al.* (15) proposed for V_2O_5 alone but differs regarding the inclusion of the bidentate carbonate type intermediate.

The active sites are the adjacent $\begin{matrix}O\\\|\\-V-\dot{V}-\end{matrix}$ species and —V̇— represents V^{4+}. The V=O and the V—O—V stretching frequencies have been identified by transmission ir spectroscopy as occurring at 1020 cm^{-1} and 820 cm^{-1} (12).

Figure 2 shows that as the atomic number of the alkali metal promoter is increased the V=O stretching frequency band at 1020 cm^{-1} splits into a number of components with splitting increasing as the atomic number increases. This may be attributed to the destabilisation of V=O bands. A similar but less pronounced effect is observed with the V—O—V net stretch at 820 cm^{-1}. For the sodium-promoted catalyst although splitting and destabilisation of the V=O peak is observed, the population of such spe-

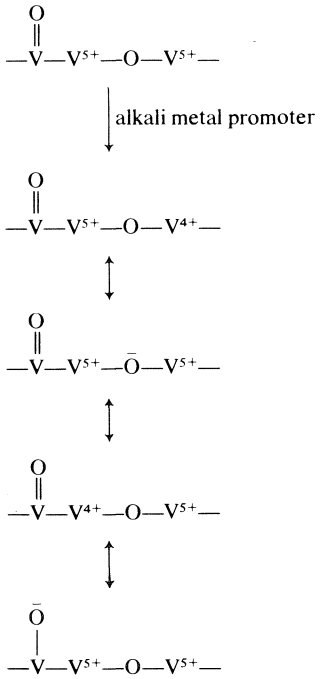
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

cies is very small when compared to the other members of the series. There is a corresponding destabilisation of the V—O—V stretching frequency from 820 to 750 cm^{-1}. Comparison of the relative populations of the V=O and destabilised V=O species with the activity series suggests that correlations may be possible.

Thus, the rates of reaction on the V_2O_5 and sodium-promoted catalysts may be dependent on two factors: (*a*) the population of all V=O species and (*b*) the percentage of the population of the weaker V=O species on the surface. And although the V=O species peak in the sodium-promoted catalyst is weaker than that in V_2O_5, the weaker V=O species in the sodium catalyst (1000 cm^{-1}), which is not present in the V_2O_5, may be contributing to catalyst activity.

Figure 3 provides information as to how the relative populations of the V=O and weakened V=O species might affect activity in the potassium series. As the additive percentage increases from 0 to 9.09 mol%, a gradual increase in the relative abundances of the weaker V=O species over the 'normal' V=O species may be noted in direct parallel with the trend in activities.

The zero order dependence of the reaction rate on carbon dioxide concentration indicates that the rate-determining step is invoked in the surface reaction and, acknowledging the data of Figs. 2 and 3, a mechanism may be proposed which recognises the influence of the polarity of the V=O species:

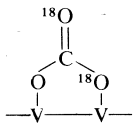


A measure of delocalisation may be expected through the interaction of the 3*d* orbital electron in V^{4+} with adjacent *p* orbitals of surface oxygen species. Since the added level of sodium caused a change in crystal structure from orthorhombic to monoclinic, the perturbation of the V—O—V network may be expected to modify in a direction which decreases the extent of delocalisation.

Since no change in the ^{18}O content of molecular oxygen was observed during reaction and since the exchange of oxygen between O_2 and the surface is slower (7) than that with CO_2, the formation of complexes by stepwise associative mechanisms involving CO_2 and O_2 would appear to be ruled out (16). Furthermore, no carbon monoxide was detected during the course of reaction which may indicate that a carbon–surface bond is likely to form before oxygen–carbon bond scission during the adsorption of carbon dioxide.

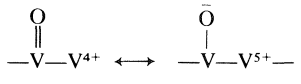
The activation energies are in good agreement with values reported for similar reactions (16, 17) and also exhibit a monotonic compensation effect with the rates. This latter feature provides some confirmation of the proposal regarding the location of rate control (27).

The increase in activation energy for the series Li < K < Rb < Cs may be related to the stability of the transient carbonate-type intermediate shown in Scheme 1 or in the following structure,



which would result from non-dissociative adsorption of CO_2. Both may occur since each may be regarded as a transient intermediate of the same basic adsorbed state and are indistinguishable in the present study.

Table 1 shows that the exchange rate over the sodium-promoted catalyst is lower than that for the lithium melt. This is consistent with a decrease in the population of V=O species while the faster rate measured for the same catalyst when compared with V_2O_5 may be related to a comparative decrease in electron delocalisation over the V—O—V network. The presence of some weakened V=O species, ~1000 cm^{-1}, indicates that some delocalisation does occur perhaps through modifications of surface forms, such as:



which could result in bond stabilisation during the formation of a carbonate-like intermediate. It could

be postulated that the latter would be more stable on vanadium pentoxide than on the samples containing Li or K, say, if the charge on the V^{4+} centre was of reduced range. Similarly, the higher activation energy for exchange on vanadium pentoxide may be a feature of effective delocalisation confined to limited areas of the surface.

The standard enthalpy of ionization of water at 298 K from calorimetric measurements on iodine pentoxide

PAUL J. CERUTTI, HON CHUNG KO, KEITH G. MCCURDY, AND LOREN G. HEPLER

Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4

Received July 7, 1978

PAUL J. CERUTTI, HON CHUNG KO, KEITH G. MCCURDY, and LOREN G. HEPLER. Can. J. Chem. **56**, 3084 (1978).

We have made calorimetric measurements of the enthalpies of reaction of I_2O_5(c) with water and with a small excess of OH^-(aq) and have combined the results to obtain $\Delta H^0 = 13.34_0$ kcal mol^{-1} for the standard enthalpy of ionization of water. It is suggested that this approach can be applied usefully to investigation of the enthalpy of ionization of D_2O for which there are still unresolved differences between reported values.

PAUL J. CERUTTI, HON CHUNG KO, KEITH G. MCCURDY et LOREN G. HEPLER. Can. J. Chem. **56**, 3084 (1978).

On a mesuré par calorimétrie l'enthalpie des réactions de I_2O_5(c) avec l'eau, d'une part, et avec un léger excès de OH^-(aq), d'autre part; à l'aide de ces résultats réunis, on a établi que l'enthalpie standard d'ionisation de l'eau est $\Delta H^0 = 13.34_0$ kcal mol^{-1}. On signale l'intérêt que peut présenter cette méthode pour l'étude de l'enthalpie d'ionisation de D_2O, enthalpie pour laquelle il existe entre les valeurs rapportées dans la littérature des écarts d'origine encore mal connue.

[Traduit par le journal]

Introduction

Reliable information about the self-ionization of water represented by

[1] $$H_2O(liq) \rightleftharpoons H^+(aq) + OH^-(aq)$$

is required for investigations of aqueous acids and bases, and also for other investigations that involve aqueous solutions. More specifically, we need to know the equilibrium constant K_ω and related thermodynamic quantities such as ΔG_ω^0, ΔH_ω^0, ΔS_ω^0, ΔC_p^0, ΔV^0, etc. It now appears that K_ω and ΔG_ω^0 are very well known at 25°C and 1 atm, and are pretty well known over a wide range of temperature and pressure (1–4). On the other hand, in spite of a considerable number of previous investigations, small but important uncertainties persist in the various other thermodynamic properties at 25°C and 1 atm, with generally larger uncertainties at other temperatures and pressures.

Because we are here concerned with ΔH_ω^0 at 25°C for the reaction represented by [1], we now focus our attention on some previous results that illustrate the need for still one more investigation of this old problem.

Our most reliable ΔH_ω^0 values for [1] appear to come from calorimetric investigations that are all of the same type in which the enthalpy of mixing a strong acid (usually HCl or $HClO_4$) with a strong base (usually NaOH) is measured at finite concentrations; results are either combined with enthalpies of dilution or extrapolated to zero concentration to obtain the desired standard state enthalpy represented by ΔH_ω^0. Procedures for using enthalpies of dilution (5, 6) and for extrapolation (7) have been published. The best results obtained this way (1–4) appear to range from $\Delta H_\omega^0 = 13.33$ to 13.36 kcal mol^{-1}, with $\Delta H_\omega^0 = 13.34$ kcal mol^{-1} commonly being selected for further use.

Another common way to obtain the desired ΔH_ω^0 is by application of d ln $K_\omega/dT = \Delta H_\omega^0/RT^2$ to K_ω values obtained at several temperatures. Possibly the most often quoted value obtained in this way is $\Delta H_\omega^0 = 13.526$ kcal mol^{-1} as calculated by Covington, Robinson, and Bates (8) from the earlier emf results of Harned and Robinson (9). Although the more recent thorough investigation by Covington and co-workers (10) indicates that small systematic errors in the emf results are the probable source of the discrepancy between ΔH_ω^0 values, we note that there is some calorimetric support (cited in refs. 1–4) for ΔH_ω^0 values at least 0.10 kcal mol^{-1} larger than the commonly selected value cited in the paragraph above.

Because of the possibility of small but important systematic errors (10) in K_ω values at different temperatures and thence in ΔH_ω^0 values obtained by application of d ln $K_\omega/dT = \Delta H_\omega^0/RT^2$ and also because of the less likely but still possible presence of systematic errors in the conventional calorimetric investigations, alternative approaches are desirable.

The first such alternative approach was originated by Larson (11), who calculated $\bar{S}^0 = -2.7_0$ cal K^{-1} mol^{-1} for OH^-(aq) from the thermodynamic properties of $NaOH \cdot H_2O$(c), NaCl(c), and solutions of these compounds. It is important to recognize that

this entropy is not based in any way on enthalpies of neutralization or on K_ω for water. Use of this entropy for $OH^-(aq)$ with $\bar{S}^0 = 0$ for $H^+(aq)$ and the well known entropy of $H_2O(liq)$ leads to $\Delta S_\omega^0 = -19.4_1$ cal K^{-1} mol^{-1} for the entropy of ionization of water as in [1]. Further combination of this ΔS_ω^0 with the well known ΔG_ω^0 of ionization leads to $\Delta H_\omega^0 = 13.31$ kcal mol^{-1} for the desired enthalpy of ionization.

Now, in this paper, we present results of our measurements on iodine pentoxide and our derived enthalpy of ionization of water.

Experimental

All calorimetric measurements were made with an LKB Precision Calorimetry System. The standard LKB 100 ml glass reaction vessel was used with solid samples contained in 1 ml glass ampoules. All calorimetric results apply to 25.00 ± 0.05°C and are reported in terms of the defined thermochemical calorie (1 cal = 4.184 J).

Several batches of $I_2O_5(c)$ were prepared according to the procedure first described by Lamb, Bray, and Geldard (12). For analysis, weighed samples were dissolved in water and then either titrated with standardized NaOH or reduced with excess I^- and then titrated with standardized thiosulfate; all titres were within 0.15% of values calculated on the basis of pure samples of $I_2O_5(c)$.

Results

We have measured enthalpies of reaction of $I_2O_5(c)$ with water and also with 0.0188 *m* aqueous sodium hydroxide (a small excess), as represented by the following equations:

[2] $\frac{1}{2}I_2O_5(c) + \frac{1}{2}H_2O(liq) = H^+(aq) + IO_3^-(aq)$ ΔH_2

[3] $\frac{1}{2}I_2O_5(c) + OH^-(aq) = IO_3^-(aq) + \frac{1}{2}H_2O(liq)$ ΔH_3

Results of our measurements, all expressed in terms of kcal mol^{-1} of iodate formed, are given in Tables 1 and 2.

We have combined our ΔH_2 values (Table 1) with calorimetrically measured (13) enthalpies of dilution of aqueous iodic acid solutions to obtain the corresponding standard state ΔH_2^0 values that are also listed in Table 1. Because of the electrical symmetry of the solutes in reaction [3], it is expected and observed that there is negligible dependence of ΔH_3 on concentration; we have therefore taken each ΔH_3 value to be the same as the desired ΔH_3^0. Average values of ΔH_2^0 and ΔH_3^0 are listed in Table 3 for each sample of $I_2O_5(c)$; the tabulated ± values are standard deviations.

Differences between ΔH_2^0 and ΔH_3^0 values for the various samples are larger than the reproducibilities indicated by the standard deviations. We suspect that these differences are due to the presence of different polymorphic forms of $I_2O_5(c)$. Whatever the cause, these differences are of little importance for our purposes because our analyses showed that all samples corresponded very closely to the com-

position represented by I_2O_5, which justifies use of equations [2] and [3] to represent the calorimetric reactions. We therefore limit our use of these results to combination of each ΔH_2^0 value with the ΔH_3^0 value for the same sample of I_2O_5(c) to obtain the desired enthalpy of ionization of water as

$$[4] \qquad \Delta H_\omega^0 = \Delta H_2^0 - \Delta H_3^0$$

The resulting ΔH_ω^0 values are given in Table 3, where the cited $\pm$ values are based on the standard deviations.

We had only small amounts of samples #1 and #2 left after completing the necessary analyses, hence the small number of calorimetric runs with these samples. Following completion of these runs we took extra care with subsequent preparations to make sure that each sample was well mixed and therefore homogeneous, and also made more calorimetric runs with each sample.

We obtain what we consider to be the best enthalpy of ionization of water from our results by assigning relative weights of one to the ΔH_ω^0 values (Table 3) from samples #1 and #2 and relative weights of three to ΔH_ω^0 values from samples #3, #4, and #5; the resulting weighted average is $\Delta H_\omega^0 = 13.34_0$ kcal mol^{-1}. We estimate the *total* uncertainty (chemicals, calorimetry, data treatment) to be ± 0.05 kcal mol^{-1}.

It is clear that the results of the present investigation, along with Larson's (11) derived ΔH_ω^0 cited earlier, all support the traditional calorimetric $\Delta H_\omega^0 = 13.34$ kcal mol^{-1} rather than some larger value as obtained from $\mathrm{d}\ln K_\omega/\mathrm{d}T = \Delta H_\omega^0/RT^2$ and from a few calorimetric investigations.

We now suggest that measurements of the enthalpies of ionization of I_2O_5(c) with D_2O(liq) and with excess OD^- (in D_2O) might help resolve present uncertainties in the thermodynamics of ionization of D_2O(liq).

It is interesting to note that the spread in reported values for the enthalpy of ionization of D_2O(liq) at 298 K is even larger than for H_2O(liq). The early measurements of Wynne-Jones (14) led to pK values at three temperatures, from which Goldberg and Hepler (6) calculated $\Delta H^0 = 14.49$ kcal mol^{-1}. Later more extensive measurements of pK at 10 temperatures from 5–50°C led Covington, Robinson, and Bates (8) to obtain $\Delta H^0 = 14.311$ kcal mol^{-1}. Calorimetric measurements of the enthalpy of reaction of DCl with NaOD in D_2O led Goldberg and Hepler (6) to obtain $\Delta H^0 = 14.488$ kcal mol^{-1}. Finally, measurements of pK at 10 temperatures from 25–225°C by Shoesmith and Lee (15) led to $\Delta H^0 = 14.548$ kcal mol^{-1}; in connection with this last value it should be noted that an alternative method of calculation also led Shoesmith and Lee (15) to obtain $\Delta H^0 = 14.18$ kcal mol^{-1}. We now suggest that the spread from 14.18 to 14.55 kcal mol^{-1} in all these results might best be resolved by further calorimetric measurements of enthalpies of reaction of strong acid with strong base in D_2O *and* measurements on I_2O_5(c) in D_2O and OD^- along the lines of the present investigation.

2,3-(1′-Pyrazolino-3′,4′) hexopyranosides and their products of decomposition[1]

HANS H. BAER, FRIEDRICH LINHART, AND HANNA R. HANNA

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received June 7, 1978

HANS H. BAER, FRIEDRICH LINHART, and HANNA R. HANNA. Can. J. Chem. **56**, 3087 (1978).

The methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitrohex-2-enopyranosides having the β-D-*erythro* (**1**), α-D-*erythro* (**2**), β-D-*threo* (**3**), and α-D-*threo* (**4**) configurations reacted with diazomethane to give high yields of 2,3-(1′-pyrazolino-3′,4′) derivatives (**5**–**8**). The pyrazolines **5** and **6** (from **1** and **2**) were deduced on the basis of nuclear magnetic resonance and optical rotatory dispersion data to possess the β- and α-D-*gluco* configurations, and **7** and **8** (from **3** and **4**), to have the β- and α-D-*ido* configurations, respectively. Thermolysis of **5**, **6**, and **8** led to the methyl-branched, nitroolefinic glycosides **9**, **10**, and **11** (the 2-*C*-methyl derivatives of **1**, **2**, and **4**), whereas **7** afforded the corresponding 2,3-*C*-methylene derivative **12**, a cyclopropano sugar. The α-anomeric cyclopropano derivative **13** was obtained from **8** by decomposition on silica gel.

HANS H. BAER, FRIEDRICH LINHART et HANNA R. HANNA. Can. J. Chem. **56**, 3087 (1978).

Par réaction avec le diazométhane les méthyl-4,6-*O*-benzylidène-2,3-didésoxy-3-nitrohex-2-énopyranosides ayant les configurations β-D-*érythro* (**1**), α-D-*érythro* (**2**), β-D-*thréo* (**3**) et α-D-*thréo* (**4**) ont donné avec de bons rendements les dérivés 2,3-(1′-pyrazolino-3′,4′) **5**–**8**. A l'aide de données de résonance magnétique nucléaire et de dispersion rotatoire on a déduit que les pyrazolines **5** et **6** (préparées à partir de **1** et **2**) possèdent, respectivement, les configurations β- et α-D-*gluco*, et **7** et **8** (préparées à partir de **3** et **4**) les configurations β- et α-D-*ido*. Par thermolyse de **5**, **6** et **8** on obtient les glycosides insaturés à branchement méthyle **9**, **10** et **11** (les dérivés 2-*C*-méthylés de **1**, **2** et **4**) alors que **7** donne un sucre cyclopropanique, le dérivé 2,3-*C*-méthylène **12**. Le dérivé cyclopropanique α-anomérique **13** a été obtenu par décomposition de **8** sur gel de silice.

The chemical literature contains a very large number of reports on the synthesis of carbohydrate derivatives that bear a nitrogen heterocycle fused to the sugar chain (3). The great variety of the fused-ring systems described and their manifold uses in synthetic work are matched by the number of different approaches to their preparation. However, it appears that few pyrazolines and pyrazoles derived from sugars are known, apart from some which originate from mono- and bis(phenylhydrazones) and no longer possess the structural feature of a pyranose or furanose ring. We now record the synthesis of some methyl hexopyranoside derivatives which carry a pyrazoline ring fused to the 2,3-position. The work was undertaken with the expectation that compounds of this type might be useful intermediates in the synthesis of branched-chain sugars.

One of the classical ways of pyrazoline synthesis is the 1,3-dipolar addition of diazoalkanes to olefins (4–6). Our special interest was focused on α-nitroalkenes as substrates which, by virtue of the nitro group, not only promised to be good dipolarophiles (5, 7) but also would lead to products having an additional functionality as a key to further transformations. It was therefore decided to study reactions between the four readily available, stereoisomeric methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitrohex-2-enopyranosides (**1**–**4**) and diazomethane. An extension of the work using methyl diazoacetate as a dipolar reagent will be described in a subsequent paper.

The nitroolefinic glycosides **1**–**4** reacted smoothly with a moderate excess of diazomethane in ether–tetrahydrofuran solution, giving high yields (80–95%) of the pyrazolines **5**–**8**. The reactions of the D-*erythro* glycosides **1** and **2** were performed at an initial temperature of 0°C for 1 h and went to completion at room temperature during an additional 30 min. The D-*threo* glycosides **3** and **4** (especially the latter) proved even more reactive and under the conditions just mentioned gave rise to by-products. However, good results were obtained by treating the β-glycoside **3** with diazomethane at −5°C for 20 min and the α-glycoside **4** at −20°C for 5 min. (Compound **4** can literally be titrated with diazomethane solution.) The products **5**, **6**, and **7** crystallized readily whereas **8** was obtained as a colorless, amorphous solid. They displayed limited stability and tended to decompose on storage but could be kept under refrigeration for some weeks or months. Although progress of the

[1]Part 41 in a series on reactions of nitro sugars. For part 40 see ref. 1. The essential results of this work were obtained in 1971 by F.L. during a sojourn as a postdoctorate fellow in this laboratory, and were communicated by us (2) in 1972. Publication of a full account was postponed until certain stereochemical details that awaited clarification were investigated by H.R.H. in the course of doctoral studies.

reactions and purification procedures could be monitored by tlc, **7** and **8** in particular exhibited a certain sensitivity towards silica gel which caused in some instances the appearance of a minor spot owing to a degradation product. This point will be referred to again in a subsequent paragraph.

The constitution of the pyrazolines was revealed by elemental analysis and spectral evidence. There was no infrared absorption above 3000 cm^{-1}, which indicated absence of N—H. Strong nitro bands were present at 1555–1560 cm^{-1}, and these showed shoulders around 1530–1540 cm^{-1} presumably owing to N=N vibrations of the 1-pyrazoline structure (8, 9). The typical benzylidene acetal bands occurred in the 700–800 cm^{-1} region. The compounds showed low-intensity ultraviolet absorption near 325 nm as do 1-pyrazolines generally (8, 9). The nmr spectrum of each product contained a 1-proton, highfield multiplet attributable to H-2 of the pyranose ring. The multiplet showed splittings owing to coupling with H-1 and the two methylene protons of the fused ring. These methylene protons were deshielded by the adjacent azo group, giving well-separated AB signals of an ABX system at medium field (δ 5–6 region). The spectral features thus established the heterocycles to be 1-pyrazolines as expected, rather than 2-pyrazolines as might have resulted from tautomerization, and indicated the orientation of ring fusion, i.e., attachment of the azomethylene bridge to C-2 and C-3 of the pyranose ring through CH_2 and N, respectively. This mode of 1,3-dipolar addition of diazomethane to α-nitroalkenes was in line with expectations based on previous findings and general considerations (4–7). All the remaining ^1H nmr signals could also be accounted for in terms of the constitution depicted (Table 1). The discussion of configuration is reserved for later paragraphs.

When **5**, **6**, and **8** were refluxed at 130°C in chlorobenzene, they underwent pyrolysis yielding mainly methyl 4,6-*O*-benzylidene-2,3-dideoxy-2-*C*-methyl-3-nitrohex-2-enopyranosides (**9**, **10**, and **11**, respectively), isolated crystalline in 51–67% yields. By contrast, the pyrazoline **7** on similar treatment afforded in 71% yield the crystalline cyclopropano sugar **12**. According to the nmr spectrum the crude **12** seemed to contain a minor proportion of what may have been the corresponding 2-*C*-methyl olefin (i.e., the β-anomer of **11**), but this could not be verified

by isolation. Conversely, in the pyrolysis of **8** the corresponding cyclopropane **13** apparently was a minor by-product. The cyclopropanes **12** and **13** were also formed slowly on exposure of **7** and **8**, respectively, to silica gel. This observation, first made during chromatographic tests, could be utilized to produce crystalline **13** on a preparative scale in high yield.

The structure of the unsaturated glycosides **9**–**11** was proved by their nmr spectra which contained a 3-proton signal near δ 2 owing to the 2-*C*-methyl group. In **9** and **10**, this signal was a narrow doublet because of long-range coupling with H-4 ($^5J_{4,Me}$ = 2 Hz). The H-4 signal occurred near δ 4.7 and, in the case of **9**, showed long-range coupling also with H-1 ($^5J_{1,4}$ = 2.5 Hz). No long-range coupling was evident in the corresponding signals of **11**. These findings were consistent with the geometry of the protons involved, in relation to the olefinic double bond (10). The three products gave infrared bands at 1530 cm^{-1} as expected for nitroalkenes.

The cyclopropano derivatives **12** and **13** were characterized by high-field signals (δ 1.7–2.5) for the two methylene protons of the cyclopropane ring and H-2 of the pyranose ring, in addition to well-separated signals at lower field that accounted for the remaining protons required of these structures. Assignment of configuration was possible on the basis of chemical shift and coupling parameters in comparison with the various, structurally analogous 2,3-anhydro-3-nitro glycoside stereoisomers obtained earlier in this laboratory (11) and with the 2,3-cyclopropano glycosides described by Horton and coworkers (12) and Radatus and Fraser-Reid (13). Thus, the H-4 signals of **12** and **13** were found at quite similar, conspicuously low field positions (δ 5.48 and 5.59, respectively). Considering that pyranose ring protons are noticeably deshielded by vicinal, *trans* oriented oxirane (11, 14) or cyclopropane (13) rings but shielded by such rings in *cis* orientation, one may conclude that **12** and **13** bear their cyclopropane rings on the same side, most likely *trans* to H-4. In the 2,3-anhydro-3-nitro glycoside of α-D-*talo* configuration (the analog of **13**), the H-4 resonance is at δ 5.63 whereas in all its stereoisomers studied (11) the range was δ 4.0–5.05. Furthermore, the H-1 signals of **12** and **13** also showed very similar chemical shifts (δ 4.76 and 4.90); the difference of only 0.14 ppm is unusually small for a pair of anomeric protons but is readily explained on the same basis. Thus, a cyclopropane ring located on the upper face of the pyranose will deshield the axial, β-anomeric proton situated *trans* to it but shield the equatorial, α-anomeric proton and thereby diminish the shift difference normally characteristic for the two. The configuration shown was strongly supported in the α-glycoside **13** by zero coupling between H-1 and H-2 as has previously been observed in analogous, benzylidenated 2,3-anhydro (11, 12, 15) and (non-nitro) cyclopropano (13) structures having an H-1,2 *trans* arrangement (i.e., the α-D-*talo* or α-D-*manno* configuration). In conformity with $J_{1,2}$ = 0 Hz, the H-2 signal of **13** was a quartet, split only by H-7_{exo} and H-7_{endo}. In the event of an opposite, downward orientation of the cyclopropane ring (H-1,2 *cis*) one would expect a large $J_{1,2}$ value as indeed was found (12, 13) for a non-nitro analog having the α-D-*allo* configuration ($J_{1,2}$ = 5–6 Hz). That the 3-*C*-nitro substituent does not have much influence can be seen from the value of 6.3 Hz observed in methyl 4,6-*O*-benzylidene-2,3-dideoxy-2,3-*C*-methylene-3-nitro-α-D-'allopyranoside,' a stereoisomer of our compounds recently obtained in a different way by Sakakibara and Sudoh (16).[2] Hence the designation of **13** as methyl 4,6-*O*-benzylidene-2,3-dideoxy-2,3-*C*-methylene-3-nitro-α-D-idopyranoside appears to be secure. The β-glycoside **12** showed $J_{1,2}$ = 2 Hz, and the H-2 signal at δ 2.54 was a septet reflecting that splitting. This coupling constant compares well with those in 2,3-anhydro and cyclopropano analogs having an H-1,2 *cis* structure as in the β-D-*manno* configuration, for which was found (11) 0.8 and (13) 3.5 Hz. For β-glycosidic 2,3-anhydro analogs possessing the D-*allo* and D-*gulo* configurations we found (11) $J_{1,2}$ = 0 Hz, and $J_{1,2}$ = 1 Hz was reported (13) for the β-D-*allo* cyclopropano analog. Despite some ambiguity present in these comparisons we believe the data to support the view that **12** is the anomer of **13**, i.e., it bears the ring in like disposition and is to be designated as a β-D-*ido* compound. As will be seen from the following discussion, the anomeric relationship is borne out by a consideration of the structure of the pyrazoline precursors from which **12** and **13** arose by extrusion of nitrogen, most certainly without inversion at C-2.

To begin with, some problems were encountered in the allocation of configurations to the pyrazolino derivatives **5**–**8**. From the origin of the compounds by 1,3-dipolar cycloaddition, *cis* fusion of the heterocycle to the pyranose ring could be inferred with

[2]The authors based their assignment, correctly no doubt, on the similarity of their $J_{1,2}$ value with that of the non-nitro analog (12, 13) having the α-D-*allo* configuration. However, their adoption of the same configurational prefix *allo* is unfortunate since substitution of H-3 by the nitro group implies, in terms of nomenclature, an inverted configuration so that the *gluco* designation should be applied. Compare the usage in other branched-chain sugars containing quaternary centers; see also footnotes 2 in refs. 17*a* and *b*.

TABLE 2. The ^{13}C chemical shifts (ppm from tetramethylsilane) for compounds **5–8** in chloroform[a]

Compound	C-1	C-2	C-3	C-4	C-5	C-6	C-7	Ph-CHO_2	O-CH_3
5	99.3	44.1	119.8	75.0	63.8	69.7	81.1	102.4	56.0
6	96.0	43.2	118.1	76.7	58.6	69.1	77.1	102.7	55.5

For personal use only.

certitude, but its upward or downward orientation in each individual case was difficult to establish. Although all the required ^1H nmr data were available (Table 1), they did not yield unambiguous information right away in this regard. This is so because, for each of the products, a reasonable conformation (distorted chair, half-chair, or skew form) that is consistent with the data can be constructed for *either* configuration. Nevertheless, some of the parameters were helpful in corroborating the configurations determined by other means, as will be mentioned below. Next, ^{13}C nmr spectra of **5–8** were evaluated. The ^{13}C chemical shifts obtained from proton-decoupled spectra (Table 2) clearly confirmed the constitution of the products and suggested at least a partial answer to the question of configuration. In the latter regard, inspection of the data reveals certain significant trends when the compounds are compared with each other, even though the over-all spectra are very similar. Thus, the normally expected increases in shielding of C-1 and C-5, and to a lesser degree of C-2 and C-4, are observed on going from a β-glycoside (**5** or **7**) to the respective α-glycoside (**6** or **8**). There are few conspicuous differences otherwise. It has been pointed out by Perlin and co-workers (18–20) that the sums of all ^{13}C chemical shifts occurring in each member of a set of diastereomers mirror the total steric interactions and should therefore bear relation to the overall configurations. For compounds **5** and **6** such summation (leaving out the phenyl group) gives $\sum_5 = 711.0$ and $\sum_6 = 697.9$ ppm, and the difference of 13.1 ppm is very nearly the same as that (13.6 ppm) derived from the reported (21) shifts of the anomeric methyl 4,6-*O*-benzylidene-D-glucopyranosides. This fact suggests that the steric influences exerted upon the molecules **5** and **6** by the structural features surrounding C-2 and C-3 must be quite similar, which in turn justifies the conclusion that the pyrazoline rings are attached in like orientations, causing the two compounds to be a pair of anomers. Similarly for **7** and **8**, the difference of the sums $\sum_7 = 701.4$ and $\sum_8 = 685.9$ ppm is 15.5 ppm. Although data of comparison for the corresponding methyl 4,6-*O*-benzylidene-D-galactopyranoside anomeric pair were unavailable, the difference is close to that (14.4 ppm) of the methyl β- and α-D-galactopyranosides (18), which supports the assumption of **7** and **8** being anomers also. This result fits the aforementioned indication that the degradation products **12** and **13** represent an anomeric pair. It should be noted, however, that the deductions based on the ^{13}C chemical shifts do not interrelate the pairs **5**/**6** and **7**/**8** configurationally; they merely advocate anomerism and leave open the C-2,3 configuration of either pair. Additional evidence was needed and this was provided by optical rotatory dispersion measurements.

It was found that the absorption band near 325 nm is associated with a negative Cotton effect in **5** and **6**, and with a positive one in **7** and **8**. To assess the significance of this, let us consider some analogies. It is known that the Cotton effect is determined largely by chirality in the immediate environment of the chromophore. Thus, in the structurally related methyl 2,3-anhydro-4,6-*O*-benzylidene-3-nitro-D-hexopyranosides, which also display an effect in that region (11), the sign is independent of the anomeric configuration and determined only by the configurations at C-3 and C-4. (The configuration of C-2, being by necessity linked to that of C-3, need not be considered separately here.) Figure 1 shows Newman projections of these nitroepoxides viewed along the C-3,4 bond.[3] The Cotton effect appears to obey the following empirical rule: when the C-3 nitro group is written at the top of the projection and O-4 then appears on its right-hand side, the sign is positive (cases A, B, and C); if O-4 appears on the left-hand side, the sign is negative (case D). The same was found to hold for the nitroalkenes **1–4** and **9–11**, although in these unsaturated sugars (λ_{max} 325–330 nm) C-3 is achiral and the sole determinant for the sign of the Cotton effect is C-4. The sign is negative in the α- and β-D-*erythro* compounds (Fig. 1, case E) and positive in the α- and β-D-*threo* compounds (case F). On the grounds of these observations the pyrazolino sugars **5** and **6**, if indeed they are anomers as indicated by the ^{13}C nmr data, may be ascribed the configuration represented by D (with

[3]Absence of perfect staggering is a consequence of the half-chair conformation in which these compounds must exist.

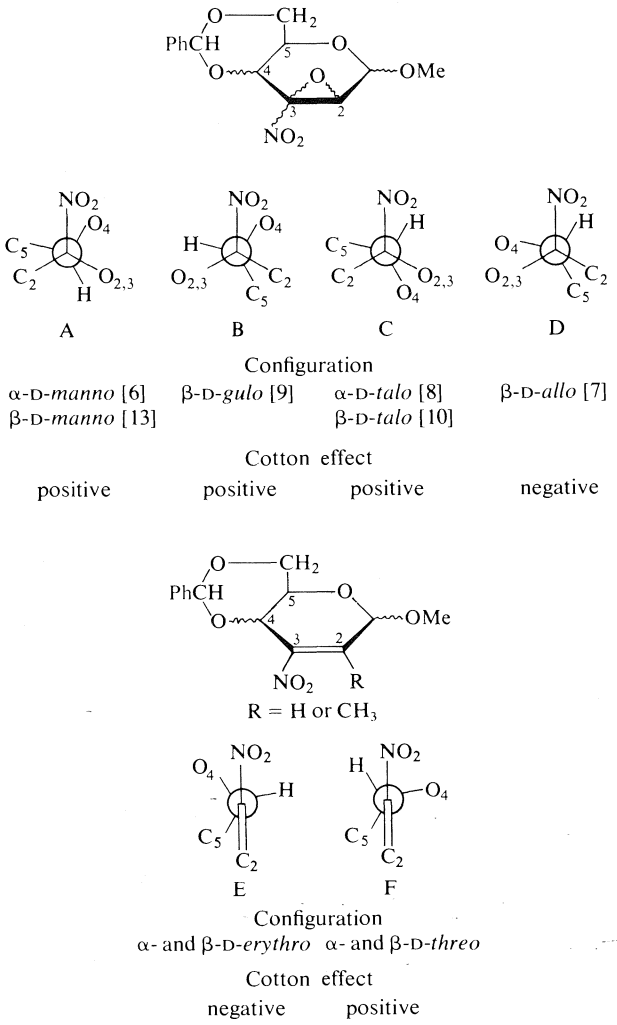

FIG. 1. Newman projections of methyl 2,3-anhydro-4,6-*O*-benzylidene-3-nitro-D-hexopyranosides (top) and methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-D-hex-2-enopyranosides and 2-*C*-methyl derivatives (bottom). The numbers in brackets are the compound numbers in ref. 11. The molecules are viewed along the C-3—C-4 bond.

CH_2—N=N— replacing $O_{2,3}$). The alternate possibility, corresponding to A, should be associated with a positive Cotton effect. We therefore designate **5** and **6** as β- and α-D-*gluco* isomers, respectively.[4] As for the isomers **7** and **8**, which would correspond to B or C (Fig. 1), their positive effect is in accord with the rule elaborated above but evidently cannot afford a distinction between these possibilities.[5] However, since the configuration of the cyclopropano derivative **13** is well supported by the nmr spectrum, the same α-D-*ido* configuration follows for its progenitor **8**, and with the additional evidence for an anomeric relationship, **7** can be accorded the β-D-*ido* configuration.

Given the configurations of **5**–**8** so assigned, one may now review the ^{1}H nmr data of Table 1 and be satisfied that these are consistent with a conformation close to the $_5H^4$ half-chair for **5**, and with distorted $_1C^4$ chair conformations for **6**, **7**, and **8**, as is best visualized with the aid of molecular models. It is worth noting, in particular, that the splitting values of 16.5–17.7 Hz for the geminally coupled pyrazoline protons at C-7 in **6**–**8**, and also the large vicinal couplings between both of these protons and H-2 in **7** and **8**, are in good agreement with corresponding data reported (9) for simple pyrazolines. The smaller $J_{2,7}$ couplings present in **5** and **6** likewise accord with the dihedral angles occurring in models of the conformations mentioned. The slightly increased $J_{7,7'}$ value (18.7 Hz) for **5** could be a consequence of change in the pyrazoline ring shape caused by its fusion to a pyranose half-chair. That **5** appears to stand apart conformationally from its three isomers is also suggested by the chemical shifts of the C-7 protons. These protons are influenced primarily by the anisotropy of the N=N double bond (9, 22). Thus, groups pseudoaxially oriented with respect to the plane of the double bond are placed in the shielding cone and are shifted to higher field (22). This applies to H_{7exo} in **6** and to H_{7endo} in **7** and **8**, which are shielded quite strongly relative to their geminal partners (Table 1). The difference is small in **5**, implying a more nearly equal space arrangement of the C-7 protons with respect to the double bond, and this accords with a more planar five-membered ring as would result from fusion to a half-chair. In the latter situation there is little puckering possible, contrary to the case of fusion to a (distorted) chair.

[4]The nitro group, as the substituent of highest configurational priority at the geminally disubstituted C-3, is thought of as replacing the hydroxyl group in the parent sugar, D-glucose. Note that the analogous epoxide having like orientations of the nitro group and fused hetero ring is termed a D-*allo* compound.

[5]The nitroepoxy and nitroolefinic glycosides just mentioned exhibit a second Cotton effect at shorter wavelengths (approximately 275 and 285–290 nm, respectively). The same appears to apply to **5**–**8** although technical difficulties prevented us from obtaining accurate determinations. At any rate, it has not yet been possible to correlate these second effects with configuration. Whether the rule for the first Cotton effect is in fact valid for the pyrazolino analogs as we are assuming in this discussion, and holds perhaps even more generally for any similar 2,3-fused systems, is of course a critical point that begs confirmation by other examples. Unfortunately, the cyclopropano sugars **12** and **13** cannot serve as such since they do not have an absorption maximum in the same region.

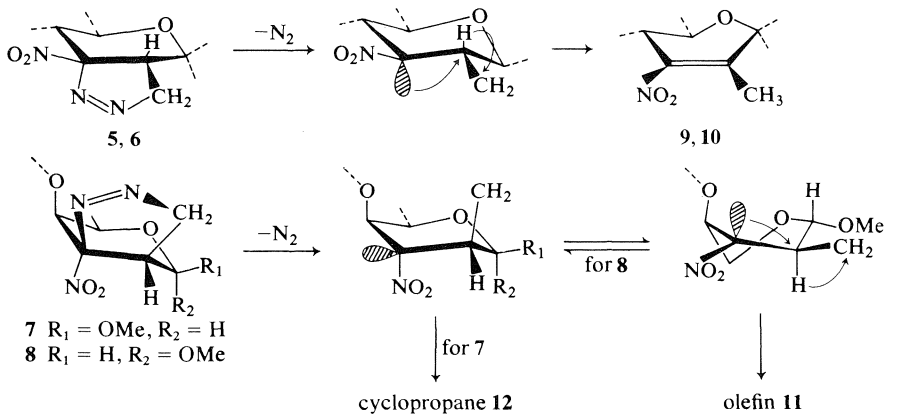

SCHEME 1

The highly stereoselective nature of diazomethane addition to each of the nitroolefins **1**–**4** invites comment. One might perhaps have anticipated at first sight that the orientation of the anomeric methoxyl group would influence the approach of the reagent to C-2; this is normally observed in kinetically controlled, nucleophilic additions (11, 17*b*, 23, 24). However, such is evidently not the case. Instead, a directing effect is associated with the orientation of O-4, and it seems possible that coordination of the diazomethane molecule precedes, and facilitates, addition which then produces the pyrazoline ring *cis* to this acetal oxygen. This might also explain why in **3** and **4**, wherein O-4 is in a better geometric position for this purpose, the reaction proceeds faster than in **1** and **2**.

Concerning the differential behavior of the pyrazolines in thermal decomposition, one may suggest that in **5** and **6** the geometry emerging concomitant with the loss of N_2 favors hydrogen migration from C-2 to C-7, leading exclusively to olefins as depicted in partial formulas in Scheme 1 (upper sequence). On the other hand, in **7** and **8** the same process may require, for a facile hydrogen shift, transition through a skew conformation. In the case of **8** such conformational change could be attained relatively easily; indeed, it would be promoted by relief of a severe 1,3-diaxial interaction between the nitro and methoxy group present in the normal chair. Hence, the olefin **11** is favored as the main product (Scheme 1, lower sequence). The same driving force for conformational change does not exist in **7**; moreover, attainment of the skew form would likely be opposed by the β-glycosidic methoxyl coming into interaction with O-4. Ring closure to give the cyclopropane **12** thus appears to be a reasonable alternative. Finally, it should be noted in this context that the decomposition of pyrazolines to cyclopropanes, a much-investigated subject (8, 22, 25–27, and further references cited therein), frequently involves configurational inversion at the carbon atoms adjacent to the azo bridge. However, the *central* pyrazoline carbon (C-2 in our derivatives) is not affected by this complication and consequently, the orientation of ring fusion in the cyclopropano sugars must remain the same as in the parent pyrazolines.

Experimental

For general procedures and instrumental techniques see preceding papers of this series (1, 11, 17). Optical rotations were determined at approximately 25°C in a Perkin-Elmer 141 automatic polarimeter. Cotton effects were measured with a Jasco ORD/UV-5 instrument. The ^{1}H nmr data were obtained from 100-MHz spectra of $CDCl_3$ solutions containing tetramethylsilane as internal standard, and signal assignments were confirmed, where feasible, by double irradiation. The ^{13}C nmr spectra, also of $CDCl_3$ solutions with TMS, were measured in a Varian CFT-20 instrument and assignments were aided by the SFORD technique. The methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitrohex-2-enopyranosides **1** (28, 29), **2** (29, 30), **3** (28, 31), and **4** (30, 32) were prepared as previously described. Diazomethane was generated from *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (Diazald®).

Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-methyleneazo-3-nitro-β-D-glucopyranoside (5)[6]

To a solution of potassium hydroxide (3 g) in water (5 ml) and 95% ethanol (15 ml), contained in a distillation flask immersed in a water bath of 65°C, was added dropwise a solution of Diazald (3 g) in ether (30 ml). The emerging mixture of diazomethane and ether vapor was passed through a condenser and the yellow condensate was allowed to react, in the receiver, with a solution of **1** (1.0 g) in dry tetrahydrofuran (10 ml, spectroscopy grade) and dry ether (17 ml) which was maintained at 0°C in an ice-water bath. After completion of the diazomethane production the reaction mixture was kept at 0°C (for a total of 1 h) and then at room temperature for

[6]Chemical Abstracts Service advises that **5** will be indexed as 3*H*-[1,3]dioxino[4′,5′:5,6]pyrano[4,3-*c*]pyrazole, 3a,4,5a,-6,9a,9b-hexahydro-4-methoxy-9b-nitro-8-phenyl-, [3a*R*-(3aα,-4α,5aβ,8β,9aα,9bα)]-.

another 0.5 h. The solution was evaporated *in vacuo* to give a yellow syrup which solidified upon trituration with a few drops of fresh, anhydrous ether. The material was chilled under ether (5 ml) for 3 h and then isolated as nearly colorless crystals (1.1 g), mp 115–116°C (with dec.). Recrystallized twice from anhydrous ether, the colorless product (0.81 g, 71%) showed an unchanged melting point; $[\alpha]_D$ −157.8°, $[\alpha]_{578}$ −163.9°, $[\alpha]_{546}$ −194.2°, $[\alpha]_{436}$ −429.6°, $[\alpha]_{365}$ −1307° (*c* 0.7, chloroform); ν_{max}(Nujol): 1563, with shoulder at 1535–1540 cm^{-1} (NO_2, N=N); λ_{max}(MeOH): 325 nm (ε 160); ord (*c* 0.4, methanol): $[\Phi]_{337}$ −8400°. *Anal.* calcd. for $C_{15}H_{17}N_3O_6$ (335.3): C 53.73, H 5.11, N 12.53; found: C 53.66, H 5.06, N 12.52.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-methyleneazo-3-nitro-α-D-glucopyranoside (**6**)*

The reaction was carried out as described above for **1**, on approximately 1/3 scale, using 300 mg of **2** dissolved in tetrahydrofuran (20 ml). Complete conversion of **2** into a single, faster-moving product was indicated by tlc with 1:2 ethyl acetate – petroleum ether (bp 30–60°C). Processing as described furnished colorless, crystalline **6** that was recrystallized once from ethyl acetate – anhydrous ether; yield 328 mg (95%), mp 179°C with dec.; $[\alpha]_D$ −2.2°, $[\alpha]_{578}$ −1.7°, $[\alpha]_{546}$ −5.8°, $[\alpha]_{436}$ −56°, $[\alpha]_{365}$ −400° (*c* 2.7, chloroform); ν_{max}(Nujol): 1560, with shoulders at about 1530 cm^{-1} (NO_2, N=N); ord (*c* 0.14, methanol): $[\Phi]_{352}$ −720°. *Anal.* calcd. for $C_{15}H_{17}N_3O_6$ (335.3): C 53.73, H 5.11, N 12.53; found: C 53.73, H 5.06, N 12.55.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-methyleneazo-3-nitro-β-D-idopyranoside (**7**)*

Diazomethane from 0.3 g of Diazald in ether (3 ml) was allowed to react with a solution of **3** (100 mg) in tetrahydrofuran (5 ml) maintained at —5°C. The reaction was complete within 20 min after the end of the diazomethane distillation, according to tlc (1:2 ethyl acetate – petroleum ether, bp 30–60°C). The solution was immediately evaporated to give a yellowish oil which solidified upon trituration with a little anhydrous ether. The crude product (92 mg, 81%) contained a very minor contaminant that moved slightly more slowly than the main product (tlc). Whereas recrystallization from ethyl acetate – petroleum ether or tetrahydrofuran–ether failed to remove the impurity, a pure sample of **7** was obtained by slow recrystallization from ethyl acetate – chlorocyclohexane at −15°C. The white needles had mp 115°C (with dec.); $[\alpha]_D$ +34.3°, $[\alpha]_{578}$ +40°, $[\alpha]_{546}$ +56.7°, $[\alpha]_{436}$ +265°, $[\alpha]_{365}$ +1548° (*c* 1.2, chloroform); ν_{max}(Nujol): 1563, with shoulder at 1540 cm^{-1} (NO_2, N=N); λ_{max}(MeOH): 323 nm (ε 260); ord (*c* 0.12, methanol): $[\Phi]_{333}$ +14000°. *Anal.* calcd. for $C_{15}H_{17}N_3O_6$ (335.3): C 53.73, H 5.11, N 12.53; found: C 53.65, H 5.20, N 12.39.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-methyleneazo-3-nitro-α-D-idopyranoside (**8**)*

A distilled, ethereal solution of diazomethane was prepared from Diazald (0.5 g) and ether (5 ml). This was added from a buret to a solution of **4** (100 mg) in tetrahydrofuran (5 ml), chilled by swirling in a bath of −20°C. The diazomethane was consumed rapidly and visibly. Within 5 min a yellow coloration began to persist in the reaction mixture, and the solvent was then immediately removed by evaporation at low temperature in an oil-pump vacuum. The residue was co-evaporated once with a portion of added ether, and the resulting, colorless foam was dried *in vacuo*; yield 114 mg. Attempts at crystallization from various common solvents failed; $[\alpha]_D$ +158.7°, $[\alpha]_{578}$ +168.2°, $[\alpha]_{546}$ +202.5°, $[\alpha]_{436}$ +516.6°, $[\alpha]_{365}$ +1820° (*c* 2.2, chloroform); ν_{max}(Nujol): 1560, with shoulder at about 1535 cm^{-1} (NO_2, N=N); λ_{max}(MeOH): 323 nm (ε 225); ord (*c* 0.2, methanol): $[\Phi]_{330}$ +15000°. To obtain a pure product it is important to observe the above reaction conditions carefully. Prolonged exposure of **4** to excess diazomethane, or a higher reaction temperature, tends to lead to side products whereas insufficient exposure may cause some **4** to remain unreacted as seen by the occurrence of minor nmr peaks due to its presence.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-C-methyl-3-nitro-β-D-erythro-hex-2-enopyranoside (**9**)*

The pyrazolino sugar **5** (582 mg) was boiled under reflux in chlorobenzene (15 ml) for 6 h, after which it was largely replaced by a faster-moving product (tlc). The solvent was evaporated and the residue chromatographed on a column of silica gel (20 g) by means of 4:1 carbon tetrachloride – ethyl acetate. The main fractions containing **9** together with some impurities were collected and evaporated to give 270 mg (51%) of **9**, mp 180–183°C, raised to 185–187°C by recrystallization from ether at low temperature. The colorless needles showed $[\alpha]_D$ −248.5° (*c* 1.06, chloroform); ν_{max}(Nujol): 1530 cm^{-1} (nitroalkene); cd: $[\theta]_{327}$ −16500 (0.0017 *M* in dioxane). *Anal.* calcd. for $C_{15}H_{17}NO_6$ (307.3): C 58.63, H 5.58, N 4.56; found: C 58.53, H 5.66, N 4.50.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-C-methyl-3-nitro-α-D-erythro-hex-2-enopyranoside (**10**)*

The pyrazolino sugar **6** (330 mg) was boiled under reflux in chlorobenzene (10 ml) for 6 h, after which time no **9** was left, according to tlc. The solvent was evaporated and the dry residue (304 mg) was recrystallized from ethyl acetate – petroleum ether to give 197 mg (65%) of colorless needles, mp 181–182°C, unchanged on a further recrystallization from ether at low temperature; $[\alpha]_D$ −117.8° (*c* 1.1, chloroform); ν_{max}(Nujol): 1525 cm^{-1} (nitroalkene); cd $[\theta]_{328}$ −18600 (0.0025 *M* in dioxane). *Anal.* calcd. for $C_{15}H_{17}NO_6$ (307.3): C 58.63, H 5.58, N 4.56; found: C 58.67, H 5.63, N 4.70.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-C-methyl-3-nitro-α-D-threo-hex-2-enopyranoside (**11**)*

A solution of the pyrazolino sugar **8** (122 mg) in chlorobenzene (5 ml) was boiled under reflux for 1 h and then evaporated to dryness. The tlc (1:2 ethyl acetate – petroleum ether) indicated that the residue contained a major product (**11**) together with a slightly faster migrating, minor product (the cyclopropano derivative **13**). The nmr spectrum of the crude product was also consistent with this. The material was recrystallized twice from ether and then weighed 75 mg (67%) and had mp 212–213°C but was not completely pure. It was further purified by chromatography on a column of silica gel (15 g) by use of 4:1 carbon tetrachloride – ethyl acetate as the eluent and by another recrystallization from ethyl acetate – ether, after which it showed mp 214–215°C; $[\alpha]_D$ +109° (*c* 1.04, chloroform); ν_{max}(Nujol): 1520 cm^{-1} (NO_2); cd: $[\theta]_{330}$ +11500 (0.0048 *M* in dioxane). *Anal.* calcd. for $C_{15}H_{17}NO_6$ (307.3): C 58.63, H 5.58, N 4.56; found: C 58.48, H 5.66, N 4.68.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-C-methylene-3-nitro-β-D-idopyranoside (**12**)*

A solution of the pyrazolino sugar **7** (200 mg) in toluene (10 ml) was refluxed for 16 h. Completion of the reaction was checked by tlc. The crystalline residue resulting from evaporation of the solvent was recrystallized from methylcyclohexane to yield 130 mg (71%) of **12**, mp 115–116°C; $[\alpha]_D$ −40°, $[\alpha]_{578}$ −43°, $[\alpha]_{546}$ −46.8°, $[\alpha]_{436}$ −43.6°, $[\alpha]_{365}$ −43.6° (*c* 2.3, chloroform); ν_{max}(Nujol): 1545 cm^{-1} (NO_2); mass spectrum: *m/e* 307. *Anal.* calcd. for $C_{15}H_{17}NO_6$ (307.3): C 58.63, H 5.58, N 4.56; found: C 58.50, H 5.46, N 4.46.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2,3-C-methylene-3-nitro-α-D-idopyranoside (**13**)*

In the preparation of **11** (see a preceding section), the formation of a minor by-product that moved slightly faster in tlc was noted. The same spot, attributed to **13**, was sometimes observed on tlc of the starting pyrazoline **8**. Its strength was variable and seemed to depend on incidental conditions of manipulation, one of which appeared to be the time elapsed between sample spotting and irrigation. This led us to consider that action of silica gel upon **8** was responsible for an accelerated formation of **13**, which was borne out by the following preparative experiment.

A sample of **8** (520 mg) dissolved in a small amount of 4:1 carbon tetrachloride – ethyl acetate was allowed to drain into the top of a column (diameter, 1 cm) of silica gel (20 g) moistened with the same solvent mixture. The sample was kept stationary in the top of the column overnight, during which period a slow evolution of gas took place. Trapped bubbles were released by careful stirring of the upper layer with a rod and elution of the column using the above solvent mixture was then commenced. The main fractions containing **13** were evaporated to give 348 mg (75%) of white crystals of **13** contaminated by a small proportion of **11** (tlc and nmr). The material was recrystallized twice from ether to give pure **13** as colorless needles, mp 169–171°C; $[\alpha]_D$ +87°, $[\alpha]_{578}$ +91°, $[\alpha]_{546}$ +104.5°, $[\alpha]_{436}$ +200°, $[\alpha]_{365}$ +395° (*c* 2.0, chloroform); ν_{max}(Nujol): doublet 1550–1530 cm^{-1}, ν_{max}($CHCl_3$): singlet 1540 cm^{-1}. *Anal.* calcd. for $C_{15}H_{17}NO_6$ (307.3): C 58.63, H 5.58, N 4.56; found: C 58.52, H 5.56, N 4.62.

*Circular Dichroism Data of Compounds **1–4***

Ellipticities are given for the first extremum in dioxane solution, with molar concentrations in parentheses: **1**, $[\theta]_{330}$ −11700 (0.0026); **2**, $[\theta]_{330}$ −12100 (0.0023); **3**, $[\theta]_{325}$ +2120 (0.0036); **4**, $[\theta]_{330}$ +3370 (0.005).

Studies on nucleation phenomena occurring in aqueous solutions supersaturated with calcium sulfate. II. The induction time

DOUGLAS MARTIN KELLER, RONALD E. MASSEY, AND O. E. HILEMAN, JR.

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 22, 1978

DOUGLAS MARTIN KELLER, RONALD E. MASSEY, and O. E. HILEMAN, JR. Can. J. Chem. **56**, 3096 (1978).

The results of a set of experiments designed to delineate the effects of changes in temperature and supersaturation levels on the length of the time interval between establishing those levels and the detection of a steady-state nucleation rate of $CaSO_4 \cdot 2H_2O$ from solution are reported. The data were obtained using the droplet technique coupled with *in situ* generation of SO_4^{2-} at such a rate that the system experienced a near step function change in the driving force with time. A theoretical model for the length of the time interval is derived and compared with the data. Empirical modeling studies led to a rather different functional relationship that is compared with a theoretical model discussed in the literature by Frisch and Carlier. The functional form of an equation relating together the lag time and the subsequent nucleation rate exhibited by a given system is proposed.

DOUGLAS MARTIN KELLER, RONALD E. MASSEY et O. E. HILEMAN, JR. Can. J. Chem. **56**, 3096 (1978).

On rapporte les résultats d'une série d'expériences ayant pour but de délimiter les effets de changements de température et de niveaux de sursaturation sur l'intervalle de temps qui existe entre le moment de l'établissement de ces niveaux et celui de la détection d'un état stationnaire pour la vitesse de nucléation du $CaSO_4 \cdot 2H_2O$ à partir d'une solution. On a obtenu ces résultats en faisant appel à la technique des gouttelettes de concert avec une génération *in situ* de SO_4^{2-} à une vitesse telle que le système subit, avec le temps, un changement de fonction incrémentielle de sa force motrice. On a déduit un modèle théorique pour la longueur de l'intervalle de temps et on l'a comparé avec ces dernières. Les études sur des modèles empiriques ont conduit à une relation fonctionnelle assez différente que l'on compare à un modèle théorique discuté dans la littérature par Frisch et Cartier. On propose la forme fonctionnelle d'une équation reliant le décalage de temps et la vitesse de nucléation subséquente d'un système donné.

Introduction

Equation [1], which summarizes the results of classical nucleation theory, does not lead one to expect the observed time gap between the establishment of a given supersaturation within a system and the attainment of the resultant time independent rate of appearance of particles of the new phase within it.

$$[1] \qquad J = A \exp\left[-\delta\sigma^3 v^2 (kT)^{-3} (\ln S)^{-2}\right]$$

where J is the rate of nucleation expressed as the number of new nuclei s^{-1} cm^{-3}; δ is a shape factor; σ is the surface energy in ergs cm^{-2}; v is the monomer volume in the newly forming phase in cm^3; S is the supersaturation defined as the $\{[Ca^{2+}][SO_4^{2-}]/K_{sp}\}^{1/2}$; A is some collection of constant and exponential terms assumed to be constant; and k and T have their usual meanings. These time gaps, variously called induction times or time lags, are quite long in the metastable region of the Ostwald diagram but shorten as the supersaturation approaches the metastable/labile boundary and then goes beyond into the labile region.

The observed induction time, τ', is usually considered to be comprised of one or more of the following: t_d, the time required for development of a steady-state embryo distribution; t_n, the time required for the attainment of a steady-state nucleation rate; and t_g, the growth time required to bring the critical nuclei to some detectable size (see eq. [2]).

$$[2] \qquad \tau' = f(t_d, t_n, t_g)$$

In literature reports of laboratory studies on nucleation phenomena, authors have suggested the use of either the first detection of the new phase or the attainment of a steady-state rate of appearance of discrete units of the new phase as suitable signals of the end of the induction period. Examples of each are illustrated by the schematic plots of Fig. 1 where both n_t, the observed number of new particles and J_e', the rate of particle nucleation calculated from it, are plotted as a function of t, the lapsed time after a time independent driving force has been established in the system.

In Fig. 1, Λ denotes the time of first detection of the new phase and τ the attainment of the time independent rate of its formation. A conclusion one

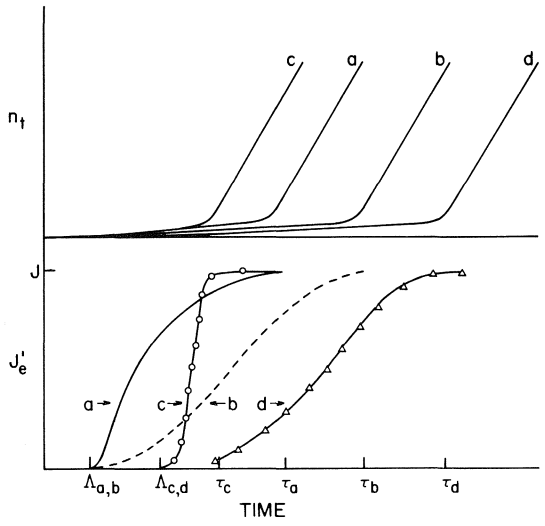

FIG. 1. Schematic representation of n_t and J_e' as functions of time during a nucleation from solution experiment.

can draw from a study of Fig. 1 is that it is rather difficult to sort out the relative impacts of t_d, t_n, and t_g on τ' using the data supplied by use of either Λ or τ alone or in concert.

Time dependent rates of nucleation have been considered from a theoretical point of view by several authors (1–14). Most start with the Zeldovich–Frenkel equation and attempt a solution of that equation under specific boundary conditions and approximations that give an overall time to the point where the rate is no longer a function of t. This, of course, ignores the additional time contribution to the experimentally observed τ that is required to bring the initially formed nuclei to crystals of detectable size. Thus, experimental verification of any theoretical model is difficult unless one assumes that the growth time is some negligible fraction of the observed time lag. Since values of both of these are non-linear functions of the supersaturation the validity of such an assumption may be suspect.

In this paper we report the results of some of our studies on the influence of variations in temperature and supersaturation levels on the observed time gap between the establishment of a given $CaSO_4 \cdot 2H_2O$ supersaturation level and the subsequent attainment of a steady-state nucleation rate of that compound from aqueous solution. Starting from the Zeldovich (1) modification of the Becker–Döring (18) equation and following the methods used by Frisch (8) we develop a theoretical model showing the expected dependency and this is compared with that experimentally observed. Several empirical models are also considered. Additionally a relationship is shown between the observed lag time and nucleation rate.

Experimental Details

Vonnegut's droplet technique coupled with *in situ* generation of the sparingly soluble $CaSO_4 \cdot 2H_2O$ from very soluble precursors (DTiGS) and photomicroscopy were used as experimental tools in the study (15, 16). A DTiGS experiment can be divided into a sequential series of steps, namely: preparation of an aqueous solution containing the precursors for generation of the supersaturation, dispersion of a small known amount of this solution in an immiscible oil, selection and subsequent preparation of a population of droplets for microscopic observation, generation of the supersaturation, notation of 'number–time' data, and then data analysis and interpretation. Additionally, the rate of formation of the supersaturation and the equilibrium solubility of the crystalline product in aqueous medium must be measured.

The reaction between $S_2O_8^{2-}$ and I^- was used to generate SO_4^{2-} *in situ*, in the presence of Ca^{2+}. Initial conditions used are shown in Table 1. Supersaturation data for a droplet population were inferred from results of 'beaker' experiments carried out in parallel. The appearance of crystals within the droplet population was recorded photomicrographically. For subsequent analysis, the 'number–time' data were separated on the basis of narrow droplet volume ranges. For explicit details of the procedure see ref. 17. A summary of the results pertinent to this paper is shown in Table 2 and as a contour plot of τ vs. T and S in Fig. 2.

Discussion

The Zeldovich (1) modification of the Becker–Döring (18) theory of nucleation may be used to develop equations describing solid formation within a supersaturated mother liquor.

The concentration of embryos composed of n monomers at time t is denoted by the function $f(n,t)$. The fundamental kinetic equation of the new phase formation is (18)

$$[3] \qquad \partial f_n/\partial_t = I_n - I_{n+1}$$

I_n is the net number of embryos of size n formed per unit time from embryos of size $n-1$, often labelled the 'flux of embryos', and is given by

$$[4] \qquad I_n = f_{n-1} a_{n-1} \beta_{n-1} - f_n a_n \alpha_n$$

where a_n is the surface area of an embryo composed of n monomers, β_n is the rate of addition per unit area of monomers to an embryo composed of n monomers, and α_n is the rate of departure per unit area of monomers from an embryo of size n.

From these equations Frenkel (2) obtains

$$[5] \qquad \frac{\partial f}{\partial t} = \frac{\partial}{\partial n}\left(D \frac{\partial f}{\partial n}\right) + \frac{1}{kT} \frac{\partial}{\partial n}\left(Df \frac{\partial \Delta G}{\partial n}\right)$$

where ΔG is the free energy change accompanying the embryo formation and D is given by $D = a\beta$ in the Becker–Döring theory.

The definition of lag time used in this paper is that introduced by Daynes (19) in diffusion theory: the intersection with the time axis of the asymptote to

μ_f	1.23	1.23	1.23	1.23	1.37	1.37	1.37	1.37	1.52	1.52	1.52	1.52

*$[SO_4^{2-}]_f$ = final sulfate concentration, μ = final ionic strength, pH = 3.23, NH_4I = 0.350 M, $[Ca^{2+}]/[SO_4^{2-}]$ = 1.00.

the function $Q(t)$. This function is defined as the number of embryos of the new phase of size N formed to time t where N is greater than n^* (the critical embryo size defined by the extremum of ΔG, i.e., $((d\Delta G/dn)_{n=n^*} = 0)$ such that the probability of decomposition for these embryos is virtually zero (2).

To solve [5] requires the specification of the initial distribution of f. This was often taken to be the steady distribution introduced by Becker and Döring (16)

$$f(n) = \text{constant for } n = 0$$

$$f(n) = 0 \text{ for } n > 0$$

If the $\Delta G(n)$ function possesses a narrow enough extremus peak a more realistic distribution which does not ignore the local fluctuations of monomer density is given in ref. 8 as

$$f_s(n) - f(n, 0) \simeq 0 \text{ for } 0 < n < n^* - \left(\frac{kT}{\gamma}\right)^{1/2}$$

$$\simeq f_s(n^*) \text{ for } n^* - \left(\frac{kT}{\gamma}\right)^{1/2} < n < n^* + \left(\frac{kT}{\gamma}\right)^{1/2}$$

$$\simeq 0 \text{ for } n^* < n < N$$

where the subscript s indicates steady-state, $\gamma = -(\partial^2 \Delta G(n)/\partial n^2)_{n=n^*}$, and $(kT/\gamma)^{1/2}$ is a measure of the width of the peak of $\Delta G(n)$.

Following the methods used by Frisch and Carlier (14) and Courtney (9) in their treatment of the equation resulting from the Zeldovich–Becker–Döring theory (eqs. [3] through [5]) and using the latter distribution results in the following expression for the lag time

$$[6] \qquad L \simeq \frac{(2\pi)^{1/2} kT}{D(n^*)\gamma}$$

Recalling that $D = a\beta$ and $\gamma = -(\partial^2 \Delta G(n)/\partial n^2)_{n=n^*}$ expressions for a, β, and ΔG appropriate to our system are required. The embryo will be assumed to be of spherical shape, hence

$$a = 4\pi r_n^2$$

where r_n is the radius of an embryo composed of n monomers and

$$\Delta G(n) = n(\mu_n - \mu_m) + a\sigma$$

$$= n(\mu_n - \mu_m) + (4\pi)^{1/3}(3v)^{2/3} n^{2/3}\sigma$$

where μ_n is the chemical potential of a monomer within the embryo, μ_m is the chemical potential of a monomer in the mother phase, and σ is the surface

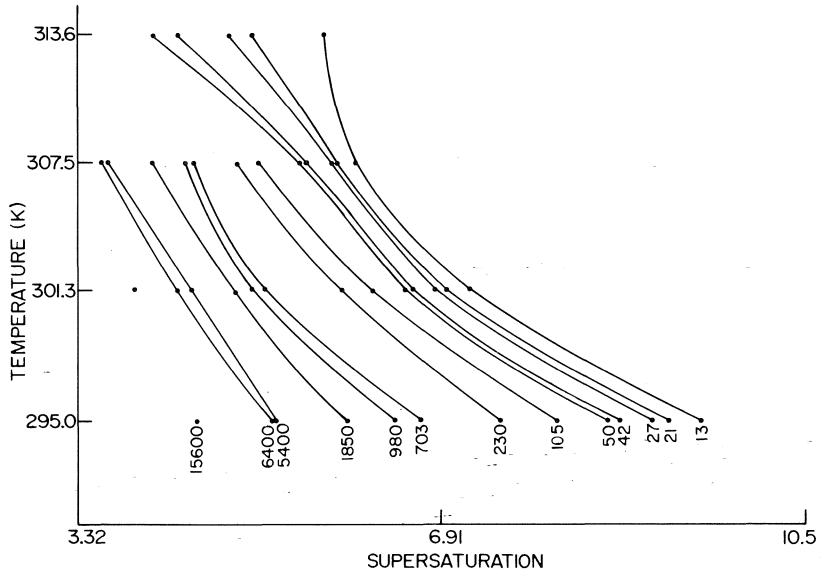

FIG. 2. A contour map of τ vs. T and S for the nucleation of $CaSO_4{\cdot}2H_2O$ from solution.

tension between the mother liquor and the embryo. This gives

$$\left(\frac{\partial^2 \Delta G}{\partial n^2}\right)_{n=n^*} = \frac{\mu_n - \mu_m}{3n^*}$$

For liquid solutions (2)

$$\beta = c_m \left(\frac{kT}{2\pi m}\right)^{1/2} \exp\left(\frac{-\Delta G_D}{kT}\right)$$

$$= sSN_0{}^{3/2} \left(\frac{kT}{2\pi m}\right)^{1/2} \exp\left(\frac{-\Delta G_D}{kT}\right)$$

where c_m is the concentration of free monomers, m is the monomeric mass, ΔG_D is the free energy of activation of diffusion (2), s is the equilibrium solubility of the solid phase in mol cm^{-3}, S is the supersaturation ratio, N_0 is Avogadro's number, and M is the molecular weight of the monomer in g mol^{-1}. Equation [7], resulting from the above expressions substituted into eq. [6], expresses L in terms of physical observables.

$$[7] \qquad L = \frac{4\pi\sigma M^{1/2} \exp\left(\frac{\Delta G_D}{kT}\right)}{(N_0 kT)^{3/2} sS \ln^2 S}$$

A contour plot of L values, generated with eq. [7] and the data of Table 3, as a function of T and S levels available in our laboratory studies is shown as Fig. 3. Contour lines of various equal L values have been drawn in Fig. 3 to facilitate comparison with Fig. 2, a similar contour plot showing the data obtained from the experimental program. Although the surface shapes are similar: a dished, tilted surface of sharply rising gradient that tends to ∞ at the

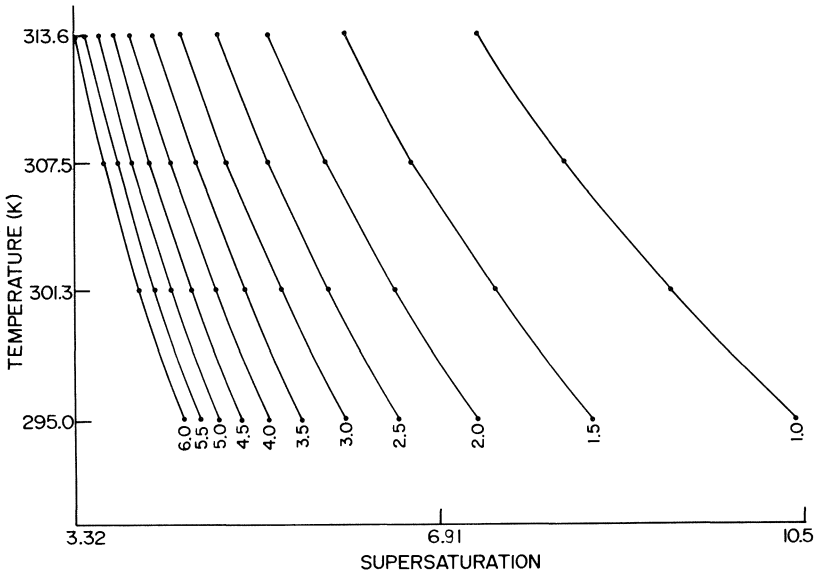

FIG. 3. A contour map of $L \times 10^6$ vs. T and S generated by use of eq. [7].

stable limit of the Ostwald diagram and to zero at high values of S, a comparison of the τ and L values shows that the generated surface lies much below the experimental surface reaching L levels approaching the reported τ levels only at values of S near to one (1.0001). Also, the extent of variation across the L values is much less than that for the experimental data. That is, the generated surface is rather like a rising plateau of low gradient whereas the experimental surface exhibits a much larger gradient. Taken together, these qualitative observations lead one to suspect the validity of the functional relationships suggested by the theoretical model. Thus, we turned to empirical modeling to search out the best functional relationship between τ, S, and T.

The search program was comprised of a selection of several equations from each of the following six general functional relationships: (*1*) $\tau = f(S,T)$; (*2*) $\tau = f(S) + g(T)$; (*3*) $\tau = f(S,T) + g(S)$, $\tau = f(S,T) + g(T)$, $\tau = f(S,T) + g(S,T)$; (*4*) $\ln \tau = f(S,T)$; (*5*) $\ln \tau = f(S) + g(T)$; (*6*) $\ln \tau = f(S,T) + g(S)$, $\ln \tau = f(S,T) + g(T)$, $\ln \tau = f(S,T) + g(S,T)$. Those equations screened representing groups

*Calculated from $\sigma = 26.64 - 0.125t$, where t is temperature in °C.

(*1*) through (*4*) exhibited values of the square of the multiple correlation coefficient (r^2) less than 0.71, those from group (*5*) had r^2 values less than 0.97 while representatives from group (*6*) showed r^2 values greater than 0.97. Thus further attention was focussed on the latter functional relationship as being the most promising for describing the observed lag times in our studies on $CaSO_4 \cdot 2H_2O$.

Shown in Table 4 is a listing of the set of equations [8]–[18] from group (*6*) screened along with the best values of the adjustable parameters and r^2 for each. r^2 is not a measure of goodness of fit although it is frequently used in this manner. A true goodness of fit parameter, Mallow's CP statistic, indicates that a significant difference exists between the various members of the listing. They are presented in Table 4 in descending order of goodness of fit. Values for r^2 are quoted rather than Mallow's CP statistic since the r^2 statistic is much more familiar and in this case directly parallels the level of goodness of fit.

Figure 4 shows a contour map of calculated $\ln \tau$ values as a function of S and T resulting from use of the uppermost tabular equation. For comparison the experimental $\ln \tau$ values are also shown in Fig. 4. The sum of the square of the residuals is 1.90 and is a further indication that the model fits the data rather well. We suggest, then, that reasonable estimates of the lag time for $CaSO_4 \cdot 2H_2O$ nucleation from solution can be obtained by use of eq. [19].

$$[19] \quad \ln \tau = \frac{-871.5}{\ln S} + \frac{5.115 \times 10^3}{\ln T \ln S} - 0.8346$$

Note that [18] of Table 4 has the form of eq.

TABLE 4. Equations representing group (*6*) used in the multiple regression screening program

[18]	$\ln \tau = \frac{a}{T^3 \ln^2 S} + \frac{b}{T} + c$	5.222×10^8	2.290×10^4	-76.52	0.9701
*		1.140×10^9	-1.974×10^3	-20.66	
†	$L = \frac{a \exp \frac{b}{T}}{T^{3/2} S \ln^2 S} + c$	5.712×10^5	2.200×10^3	-8992	0.6600

[III.6] of ref. 14; i.e.,

$$[20] \quad \ln L_1 \cong \frac{16\pi\sigma^3 v^2}{3k^3 T^3 \ln^2 S} - \frac{(4\pi)^{1/3}(3v)^{2/3}\sigma}{kT} + \ln\left[\left(\frac{\pi d}{4\sigma v}\right)^{1/2} \frac{1}{N_0 s}\right]$$

Using averaged values for $CaSO_4 \cdot 2H_2O$ of σ (22.75 ergs cm^{-2}) and s (3.972×10^{-5} mol cm^{-3}) across the temperature range the 'constant' terms in eq. [20] were calculated. The results are listed in Table 4 (entry *) below the corresponding parameter estimates for the empirical equation. The most significant distinction between the two sets of results is the sign difference on b. The first two terms of the fitted equation work in concert to decrease τ as T increases; whereas in eq. [20] the second term provides a small negative correction to τ as T increases. Equation [20], using a least-squares criterion, appears as a poorly optimized version of that particular functional relationship but it could provide insight into the physical significance of the parameters in the analogous empirical equation.

Historically, the results of the application of fluctuation theory to the problem of the lag time in nucleation phenomena have led to expressions that have the form of eq. [7] (entry † in Table 4). Our attempts to fit equations of that form and of the forms represented in groups (*1*) through (*3*) to the data obtained from studies on $CaSO_4 \cdot 2H_2O$ nucleation failed. Surprisingly, empirical equations analogous in form to that examined by Frisch and Carlier (ref. 14, eq. [III.6]), but discarded by them, lead to data fits that are far superior; these were discarded because they represented an unrealistic initial boundary condition for vapour–liquid nucleation experiments under the usual experimental conditions. The results of our modeling program indicate that future efforts in the derivation of models of lag times in nucleation from solution should be concentrated on relationships of the form of group (*6*).

A term by term comparison of eqs. [1] and [20] leads to the suggestion that there could be a functional relationship between J and L_1 of the form shown as eq. [21]. Equations of this form were tested

$$[21] \quad \ln J \cong \ln L_1^{-1} + \ln T - \frac{(4\pi)^{1/3}(3Md)^{2/3}\sigma}{N^{2/3}kT} + \ln\left\{\frac{Akd}{2K_{sp}}\left[\frac{\pi N_0}{\sigma M}\right]^{1/2}\right\}$$

TABLE 5. Various functional relationships between J, L, and T evaluated with the multiple regression program

	Equation number and form	a	b	c	d	r^2
[23]	$\ln J = a \ln L^{-1} + bT + cT^{-1} + d$	1.827	-3.110	-2.654×10^5	1.845×10^3	0.8998
[24]	$\ln J = a \ln L^{-1} + b \ln T^{-1} + cT^{-1} + d$	1.827	1.874×10^3	-5.478×10^5	1.254×10^3	0.8997
[25]	$\ln J = a \ln L^{-1} + b \ln T^{-1} + cT + d$	1.827	-1.738×10^3	-5.953	-8.098×10^3	0.8997
[26]	$\ln J = a \ln L^{-1} + bT + c$	1.820	-0.2379	9.827×10^1	—	0.8862

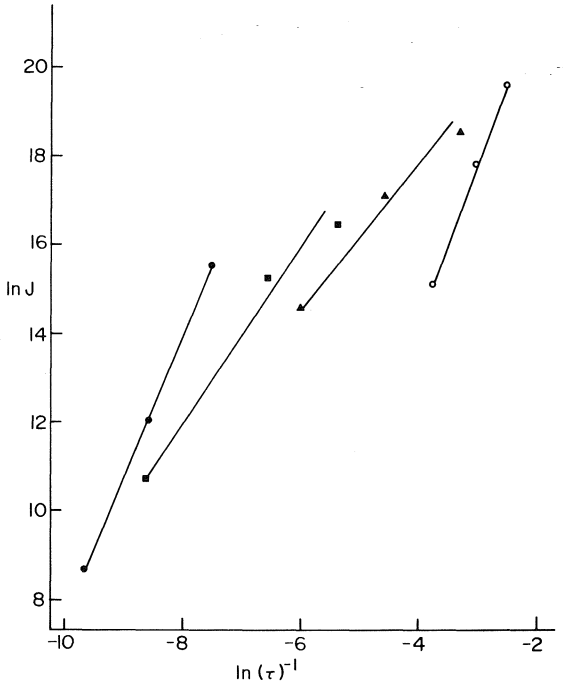

FIG. 5. Plots of ln J vs. ln τ^{-1} for twelve levels of supersaturation distributed over four temperatures. ●, 295.0 K; ■, 301.3 K; ▲, 307.5 K; ○, 313.6 K.

by comparison with the experimentally determined J, τ, and T values using a multiple regression screening program. The results are shown in Table 5 and plots of ln J vs. ln τ^{-1} at various temperatures are included as Fig. 5. Each result suggests that a relationship between the rate, lag time, and temperature can be represented by eq. [22].

$$[22]\quad \ln J = 1.827 \ln \tau^{-1} - 1.874 \times 10^3 \ln T - 5.478 \times 10^5 T^{-1} + 1.254 \times 10^4$$

This linear relationship between ln J and ln τ^{-1} at constant temperature is very important in that it demonstrates that the lag time, as defined, is a real nucleation response. Thus, measurements of it can be used to estimate σ, A, and S^* for systems in which measurements of J are difficult or impossible to obtain.

Nuclear magnetic resonance studies of the solution chemistry of metal complexes. XV. Trimethyllead complexes of inorganic ligands

EMIKO K. MILLAR, CHRISTOPHER A. EVANS, AND DALLAS L. RABENSTEIN[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 8, 1978

EMIKO K. MILLAR, CHRISTOPHER A. EVANS, and DALLAS L. RABENSTEIN. Can. J. Chem. **56**, 3104 (1978).

The formation constants of the trimethyllead(IV) complexes of SO_3^{2-}, SeO_3^{2-}, $S_2O_3^{2-}$, SCN^-, HPO_4^{2-}, CO_3^{2-}, Cl^-, Br^-, and I^- have been determined in aqueous solution by ^1H nuclear magnetic resonance spectroscopy. The formation constants are in general fairly small and the extent to which complexes form is strongly dependent on pH. At high pH $(CH_3)_3PbOH$ forms while at low pH protonation of those ligands which are the conjugate bases of weak acids competes with complex formation. There is no indication of high selectivity in the binding of trimethyllead(IV) by a particular ligand type, and calculations indicate that trimethyllead(IV) is likely to be distributed among a variety of ligands in biological fluids, including chloride which forms uncharged and presumably lipid soluble $(CH_3)_3PbCl$.

EMIKO K. MILLAR, CHRISTOPHER A. EVANS et DALLAS L. RABENSTEIN. Can. J. Chem. **56**, 3104 (1978).

Faisant appel à la spectroscopie rmn ^1H, on a déterminé les constantes de formation des complexes du triméthylplomb(IV) avec SO_3^{2-}, SeO_3^{2-}, $S_2O_3^{2-}$, SCN^-, HPO_4^{2-}, CO_3^{2-}, Cl^-, Br^- et I^- en solution aqueuse. Les constantes de formation sont généralement assez faibles et le degré de formation des complexes est fortement influencé par le pH. A des pH élevés, il y a formation de $(CH_3)_3PbOH$ alors qu'à des pH faibles, la protonation des ligands qui sont des bases conjuguées d'acides faibles sont en compétition avec la formation du complexe, On n'a relevé aucune indication concernant une grande sélectivité pour la liaison du triméthylplomb(IV) avec un type particulier de ligand; les calculs indiquent que le triméthylplomb(IV) est vraisemblablement distribué entre une variété de ligands dans les fluides biologiques, y compris le chlorure qui forme du $(CH_3)_3PbCl$ qui ne porte pas de charge et qui est vraisemblablement soluble dans les lipides.

Introduction

Even though the organometallic chemistry of trialkyllead(IV) compounds has been the subject of much study, little is known about their coordination chemistry in aqueous solution. In this paper, we report the results of a study of the complexation of trimethyllead by sulfite, selenite, thiocyanate, thiosulfate, phosphate, carbonate, and the halides. Some results are also presented for the complexation of trimethyllead by sulfide. The complexation was studied by ^1H nuclear magnetic resonance spectroscopy. Previous studies have shown that the chemical shift of trimethyllead provides a sensitive probe of complex formation (1).

At the present time, there is considerable interest in the behavior of lead and its compounds in the environment, and in the toxicology of these compounds. Of the various organometallic forms, the trialkyllead(IV) species are of particular importance. For example, it has long been recognized that inhalation or absorption of tetraalkyllead compounds results in the presence of trialkyllead(IV) salts in the fluids and tissues of the body (2). More recently, interest has focussed on the trimethyllead(IV) species as a result of reports on the methylation of lead by microorganisms (3–5). It seems likely that the behavior of trialkyllead(IV) compounds in the environment and in biological systems will depend to some extent on their coordination chemistry. The research described in this paper forms the second part (1) of a continuing program directed towards characterizing the aqueous solution chemistry of trimethyllead and its complexes.

[1]To whom all correspondence should be addressed.

Experimental

Chemicals

Trimethyllead acetate (Alfa Inorganics) was used as the source of trimethyllead. Because acetate forms a complex with $(CH_3)_3Pb^+$ in aqueous solution, it was converted to a stock solution of trimethyllead perchlorate by an ion exchange procedure described previously (1). The stock solution was standardized by potentiometric titration (1).

Sodium selenite (Alfa Inorganics) was purified by first filtering an aqueous solution and then recrystallization. Stock solutions prepared from the purified solid were standardized by adding an excess of $HClO_4$ and then titration with NaOH. The selenite concentration was determined from the volume of NaOH between the first and second endpoints. Disodium hydrogen phosphate (B.D.H.) solutions were standardized by a similar titration procedure. Sodium hydrogen sulfite and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sodium sulfide (J. T. Baker) solutions were standardized by literature procedures (6). The other ligands were obtained as reagent grade sodium salts, and were used as received.

pH Measurements and Nuclear Magnetic Resonance Measurements

pH measurements and nmr measurements were made as described previously (1). Spectra were recorded at a probe temperature of 25 ± 1°C. Chemical shifts were measured relative to the *tert*-butyl resonance of *tert*-butanol (TBA), but are reported relative to the methyl resonance of sodium 2,2-dimethyl-2-silapentane-5-sulphonic acid (DSS). Positive shifts correspond to resonances of protons less shielded than the methyl protons of DSS. The TBA resonance is 1.243 ppm downfield from the methyl resonance of DSS. The ^1H nmr spectrum of trimethyllead consists of a singlet flanked symmetrically by two small satellites due to those methyl groups bonded to the ^{207}Pb isotope ($I = \frac{1}{2}$, natural abundance = 21.1%). Previous studies have shown the magnitude of $J_{^{207}Pb-^1H}$ to be relatively insensitive to complex formation (1).

Solution Preparation

The experiments were of two types: (*a*) measurement of the chemical shift of trimethyllead in solutions having a constant $[ligand]_{total}/[(CH_3)_3Pb]_{total}$ ratio as a function of pH and (*b*), measurement of the chemical shift of trimethyllead in solutions having a range of $[ligand]_{total}/[(CH_3)_3Pb]_{total}$ ratios at constant pH. In experiments of the first type, a solution was prepared from trimethyllead stock solution, either solid ligand or ligand stock solution, and enough solid $NaClO_4$ to give a constant ionic strength of 0.30 *M*. The pH was then adjusted with concentrated $HClO_4$ or carbonate-free NaOH, and ~0.4 ml samples withdrawn at the appropriate pH values. Samples were taken at closely spaced pH intervals (typically every 0.3–0.5 pH unit), generally over the pH range 2–12. Nuclear magnetic resonance spectra were recorded immediately after sample preparation. Solutions of those ligands which are easily oxidized were prepared in an argon atmosphere.

In experiments of the second type, individual solutions were prepared at each of the desired $[ligand]_{total}/[(CH_3)_3Pb]_{total}$ ratios from the stock trimethyllead solution, the solid ligand, and $NaClO_4$. In all experiments except those involving NaSCN, the ionic strength was kept constant at 0.30 *M* by adding $NaClO_4$. In studying the $(CH_3)_3Pb$–SCN system, an ionic strength of 1.5 *M* was used to permit a wider range of $[NaSCN]_{total}/[(CH_3)_3Pb]_{total}$ ratios to be used at constant ionic strength.

Trimethyllead concentrations of $2 \times 10^{-3} - 5 \times 10^{-3}$ *M* were used.

Results

The formation constants listed in Table 1 were calculated from the chemical shift of the methyl protons of $(CH_3)_3Pb(IV)$ in solutions containing known amounts of $(CH_3)_3Pb(IV)$ and ligand. For example, Fig. 1 shows the chemical shift as a function of pH for an aqueous solution of trimethyllead perchlorate and for an aqueous solution containing trimethyllead perchlorate and disodium hydrogen phosphate. Figure 2 shows chemical shift data as a function of the $[NaX]_{total}/[(CH_3)_3Pb]_{total}$ ratio for the NaI, NaBr, and NaCl systems. In both Figs. 1 and 2, the presence of ligand causes the chemical shift to change, indicating the formation of trimethyllead complexes.

TABLE 1. Acid dissociation constants and formation constants of the trimethyllead complexes of selected inorganic ligands, and the ^1H chemical shifts of the trimethyllead complexes

Ligand	pK_a[a]	$\delta_{complex}$[b]	K_f[a] $(CH_3)_3PbX$
HPO_4^{2-}	6.71	1.435	75 ± 3

I^-		1.867	1.89 ± 0.13
Br^-		1.692	1.95 ± 0.19
Cl^-		1.595	1.22 ± 0.39

[a]At 25°C and 0.30 *M* ionic strength (with $NaClO_4$) unless otherwise noted.
[b]In ppm vs. DSS.
[c]1.50 *M* ionic strength ($NaClO_4$).

Formation constants for the phosphate, sulfite, selenite, thiosulfate, and carbonate complexes were calculated from data of the type shown in Fig. 1. For each of these systems, exchange averaged resonances were observed for the trimethyllead, indicating exchange of trimethyllead among its various species to be rapid on the nmr time scale. Consequently, separate resonances were not observed for the complexed $(CH_3)_3Pb(IV)$ and it was necessary to calculate the formation constants by curve fitting procedures. The general procedure will be described with reference to the phosphate complex.

The pH dependence of the chemical shift of $(CH_3)_3Pb(IV)$ in aqueous solution is due to the following pH-dependent equilibria (1):

[1] $$(CH_3)_3Pb^+ + OH^- \rightleftarrows (CH_3)_3PbOH$$

$$K_1 = \frac{[(CH_3)_3PbOH]}{[(CH_3)_3Pb^+][OH^-]} = 7.34 \times 10^4\ M^{-1}$$

[2] $$(CH_3)_3Pb^+ + (CH_3)_3PbOH \rightleftarrows ((CH_3)_3Pb)_2OH^+$$

$$K_2 = \frac{[((CH_3)_3Pb)_2OH^+]}{[(CH_3)_3Pb^+][(CH_3)_3PbOH]} = 3.12 \times 10\ M^{-1}$$

where waters of hydration are omitted. In the solution containing phosphate, some $(CH_3)_3Pb(IV)$ also is present in complexed form. Of the various models tested for the complexation equilibria, the best fit was obtained for one in which the $(CH_3)_3Pb(IV)$ and HPO_4^{2-} form a simple one-to-one complex.

[3] $$(CH_3)_3Pb^+ + HPO_4^{2-} \rightleftarrows (CH_3)_3Pb(HPO_4)^-$$

$$K_f = \frac{[(CH_3)_3Pb(HPO_4)^-]}{[(CH_3)_3Pb^+][HPO_4^{2-}]}$$

Because exchange is rapid, the observed chemical

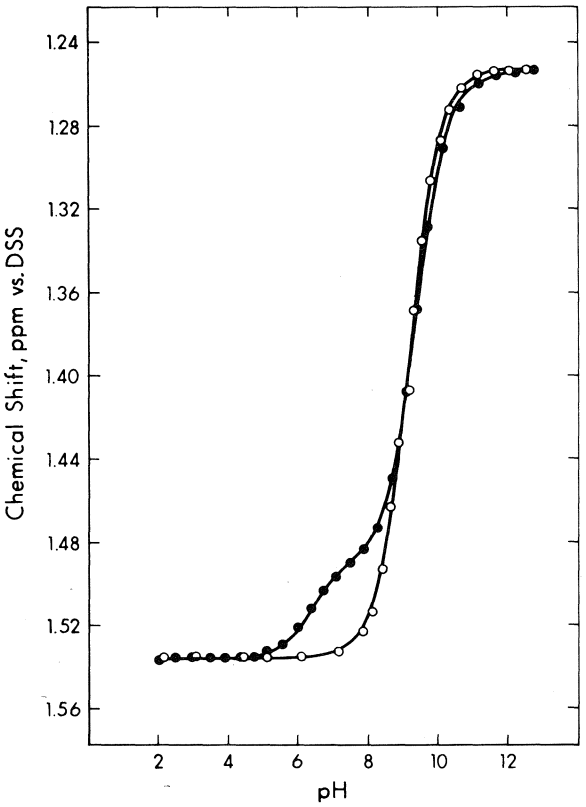

FIG. 1. pH dependence of the chemical shift of the methyl protons of trimethyllead(IV) in aqueous solutions containing 5.00×10^{-3} M $(CH_3)_3Pb(ClO_4)$ (open points) and containing 5.00×10^{-3} M $(CH_3)_3Pb(ClO_4)$ and 1.35×10^{-2} M Na_2HPO_4 (solid points). The ionic strength was 0.30 M ($NaClO_4$ as required).

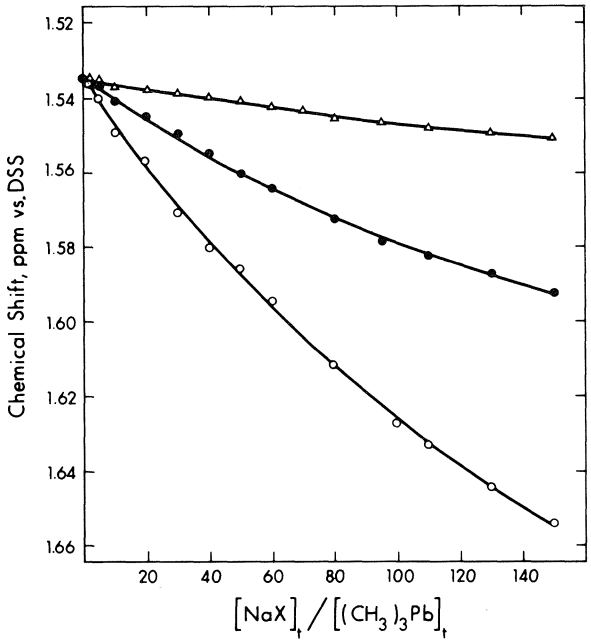

FIG. 2. The chemical shift of the methyl protons of trimethyllead(IV) in aqueous solutions containing 2.00×10^{-3} M $(CH_3)_3Pb(ClO_4)$ and sodium halide as a function of the ligand-to-trimethyllead ratio at pH 4.00. Sodium chloride (△), sodium bromide (●), and sodium iodide (○). The ionic strength was 0.30 M ($NaClO_4$ as required).

shift, δ_{obs}, is the weighted average of the chemical shifts of the various species present.

$$[4] \quad \delta_{obs} = P_{TML}\delta_{TML} + P_{(TML)_2OH}\delta_{(TML)_2OH} + P_{TMLOH}\delta_{TMLOH} + P_C\delta_C$$

where P represents the fractional concentration of trimethyllead in the form indicated by the subscript, δ the chemical shift of that form, and TML represents $(CH_3)_3Pb^+$.

K_f for $(CH_3)_3Pb(HPO_4)^-$ was obtained by curve fitting chemical shift data to eq. [4]. The procedure involved (*i*) estimating initial values for K_f and δ_C, (*ii*) calculating the fractional concentration of each species at the pH of the given data point using this estimate for K_f, the values for K_1 and K_2 given above, and the total $(CH_3)_3Pb(IV)$ and ligand concentrations, (*iii*) predicting a value for the averaged chemical shift ($\delta_{i,pred}$) at the particular pH from these fractional concentrations, the initial estimate for δ_C, and the known values (1) for δ_{TML}, $\delta_{(TML)_2OH}$, and δ_{TMLOH}. Steps (*i*)–(*iii*) are then repeated for each data point using the initial estimates for K_f and δ_C. In step (*iv*), the nonlinear least-squares program KINET (7) compares the set of predicted chemical shifts with the observed values by calculating the sum of the squares of the residuals (SSR) and then (*v*), KINET adjusts K_f and δ_C to minimize the SSR. Steps (*i*)–(*v*) are then repeated until the best values for K_f and δ_C are obtained from the particular experimental data as indicated by a minimum in the SSR.

The K_f value obtained for $(CH_3)_3Pb(HPO_4)^-$ by this procedure using data in the pH region 2 to 13 is 75.1 ± 3, where the uncertainty is a linear estimate of the standard deviation (7). The solid curve through the experimental points in Fig. 1 for the trimethyllead–phosphate system is predicted from the values obtained for K_f and δ_C. There was no indication of complexes formed with other phosphate species; at high pH where PO_4^{3-} forms, hydroxide ion competes with the phosphate ligand and $(CH_3)_3PbOH$ forms while at low pH there is a competitive equilibrium between protonation and complexation of HPO_4^{2-}. The data in Fig. 1 indicate no complexation by $H_2PO_4^-$, which also is weak as a conjugate base. The pH dependence of the formation of $(CH_3)_3Pb(HPO_4)^-$ is shown in Fig. 3.

The formation constants in Table 1 for the sulfite, selenite, thiosulfate, and carbonate complexes were determined by the same procedure. For the sulfite

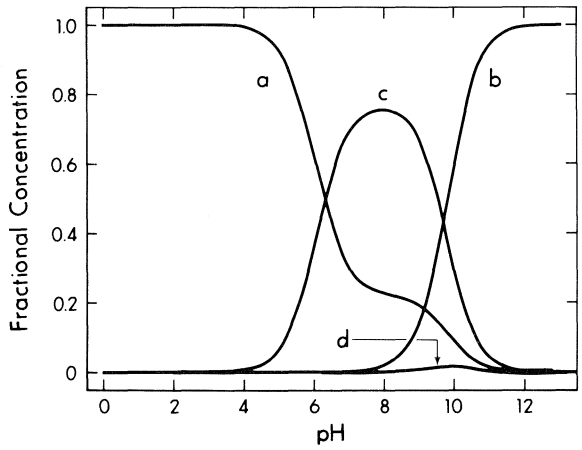

FIG. 3. pH dependence of the distribution of trimethyllead among its various forms in a solution containing 5.00×10^{-3} *M* $(CH_3)_3Pb(ClO_4)$ and 1.35×10^{-2} *M* Na_2HPO_4. $(CH_3)_3Pb^+$ (*a*), $(CH_3)_3PbOH$ (*b*), $(CH_3)_3Pb(HPO_4)^-$ (*c*), and $((CH_3)_3Pb)_2OH^+$ (*d*).

and selenite systems, chemical shift data in the pH ranges 7 to 12.7 and 8 to 12.7 respectively were fit to models in which $(CH_3)_3Pb(SO_3)^-$ and $(CH_3)_3Pb(SeO_3)^-$ are the only complexes. Attempts to fit data at pH < 7 to these models were unsuccessful. At pH < 7, both ligands are protonated, suggesting the formation of other complexes; however, it has not been possible to determine the nature of the complexes. The simple model in Table 1 for thiosulfate describes its complexation equilibria with $(CH_3)_3Pb(IV)$ over the pH range 2 to 13, and that for carbonate over the range 9 to 13.

Formation constants for the chloride, bromide, iodide, and thiocyanate complexes were obtained from data of the type shown in Fig. 2 by similar curve fitting procedures. The results are given in Table 1. A constant pH of 4 was used in the halide studies and 5 in the thiocyanate studies to minimize competition from OH^- for the $(CH_3)_3Pb^+$. Even though ligand-to-metal ratios as high as 150 and 300 were used in the halide and thiocyanate studies, respectively, all of the data for each system could be fit with good precision to a model involving a simple one-to-one $(CH_3)_3PbX$ complex.

Similar data were taken for fluoride; however, precipitation precluded a determination of the formation constant for the fluoride complex.

Data of the type shown in Fig. 1 were taken for solutions containing $(CH_3)_3Pb(IV)$ and sodium sulfide over the pH range 7–13. The data indicate formation of strong complexes, apparently with both S^{2-} and HS^-; however, it has not been possible to obtain reliable values for the formation constants. This may be related to the apparent decomposition of trialkyllead compounds in the presence of sulfide (4).

Discussion

The coordination geometry around the lead atom of $(CH_3)_3Pb(IV)$ in aqueous solution is thought to be trigonal bipyramidal, with the three methyl groups and the lead atom in the planar trigonal unit and the two water molecules in axial positions (8, 9)[2]. The trimethyllead complexes studied in this work probably form from $(CH_3)_3Pb^+$ by substitution of one H_2O ligand. Their formation constants are small, indicating the affinity of the trimethyllead moiety for these ligands not to be large relative to that for water. There is no evidence of complexes having a ligand-to-metal ratio greater than 1:1 with these ligands, indicating an even smaller tendency to replace the second water molecule. This is expected since the formation constants for the stepwise formation of complexes generally decrease as the ligand-to-metal ratio increases.

The only literature result available for comparison with the formation constants determined in this work is the value of 630 obtained by Bertazzi by anion exchange techniques for the $(CH_3)_3PbSCN$ complex (10). This value is considerably larger than that determined in this work, and much too large to be compatible with the chemical shift data.

The results in Table 1 together with other results from our studies on the coordination chemistry of trimethyllead (1) suggest that trimethyllead does not show a strong preference for any particular type of donor group.[3] The largest formation constants appear to be with the deprotonated sulfhydryl groups of organic thiol ligands.[3] For example, with mercaptoethanol the formation constants of the complexes formed are[3]

[5] $$(CH_3)_3Pb^+ + RS^- \rightleftarrows (CH_3)_3PbSR$$
$$K_{f1} = 9.1 \times 10^5$$

[6] $$(CH_3)_3Pb^+ + (CH_3)_3PbSR \rightleftarrows ((CH_3)_3Pb)_2SR^+$$
$$K_{f2} = 14.0$$

This is of particular interest with respect to the chemistry of trimethyllead in biological fluids, where there is an abundance of potential ligands, including carboxylate groups, carbonate, inorganic and organic phosphate, chloride, and the sulfhydryl groups of peptides and proteins. Because of the different pH dependence of the extent to which the various complexes form and the relative abundances of the different ligands, the formation constants predict that, at physiological pH, there will be a significant fraction of $(CH_3)_3Pb(IV)$ complexed even by those ligands having small formation constants.

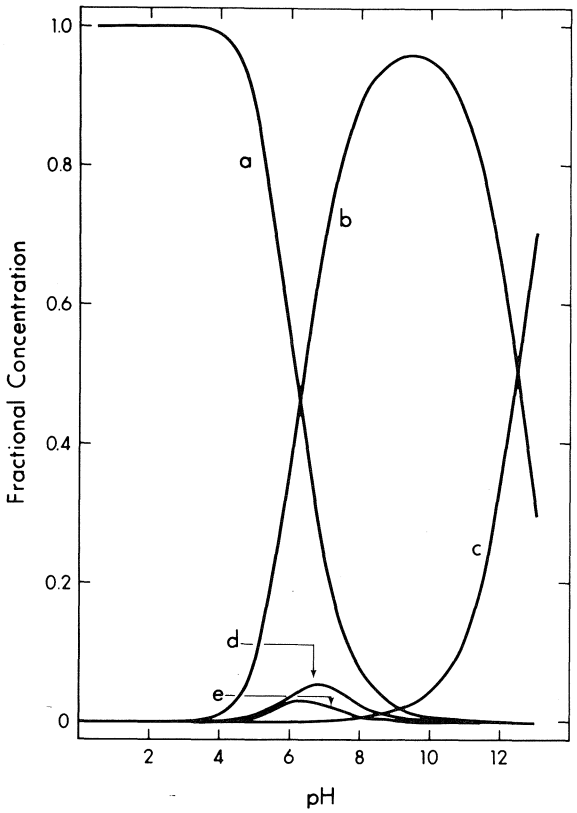

FIG. 4. pH dependence of the distribution of trimethyllead among its various forms in an aqueous solution containing $(CH_3)_3PbClO_4$, 2-mercaptoethanol, and sodium phosphate, each at a total concentration of 5.00×10^{-3} *M*. $(CH_3)_3Pb^+$ (*a*), $(CH_3)_3Pb(SCH_2CH_2OH)$ (*b*), $(CH_3)_3PbOH$ (*c*), $(CH_3)_3Pb(HPO_4)^-$ (*d*), $((CH_3)_3Pb)_2SCH_2CH_2OH^+$ (*e*).

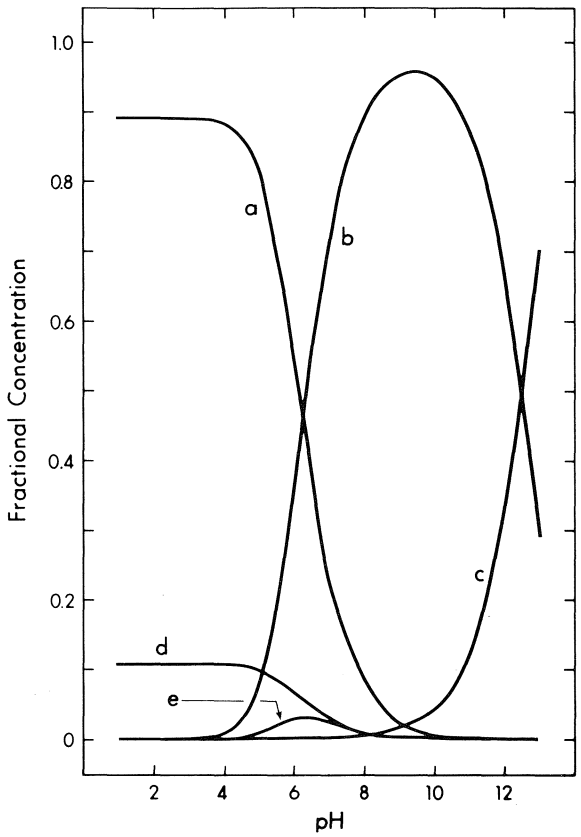

FIG. 5. pH dependence of the distribution of trimethyllead among its various forms in an aqueous solution containing 5.00×10^{-3} *M* $(CH_3)_3PbClO_4$ and 2-mercaptoethanol and 0.10 *M* NaCl. $(CH_3)_3Pb^+$ (*a*), $(CH_3)_3Pb(SCH_2CH_2OH)$ (*b*), $(CH_3)_3PbOH$ (*c*), $(CH_3)_3PbCl$ (*d*), and $((CH_3)_3Pb)_2SCH_2CH_2OH^+$ (*e*).

To illustrate, the pH dependence calculated for the fractional concentrations of the various trimethyllead species in solutions containing 2-mercaptoethanol and phosphate and in solutions containing 2-mercaptoethanol and chloride are shown in Figs. 4 and 5. Even though K_f for the $(CH_3)_3Pb(HPO_4)^-$ and $(CH_3)_3PbCl$ complexes are several orders of magnitude less than that for the 2-mercaptoethanol complex, some $(CH_3)_3Pb(HPO_4)^-$ and $(CH_3)_3PbCl$ form because of the competitive protonation of the sulfhydryl ligand. This situation is in marked contrast to that for $CH_3Hg(II)$, which shows such an extreme affinity for sulfhydryl ligands that, in biological systems, essentially all of the $CH_3Hg(II)$ is assumed to be complexed by the sulfhydryl groups of peptides and proteins (11). The presence of even a small fraction of $(CH_3)_3Pb(IV)$ as $(CH_3)_3PbCl$ is of particular interest because this complex has electroneutrality and most likely is lipid soluble. $(CH_3)_3Pb^+$ complexes of HPO_4^{2-}, Cl^-, and CO_3^{2-} are probably even more important in the environment where the concentration of sulfhydryl ligands can be expected to be low.

Methyl β-cellobioside (**2**) has been deuterated at positions C-2, -3, -3′, -4, -6, and -6′ by ^1H–^2H exchange with deuterium oxide in the presence of Raney nickel catalyst. The resulting simplification in the ^{13}C nmr spectrum of this isotopically-labelled compound has facilitated the measurement of interresidue ^{13}C–^1H coupling, as a means of determining the orientation of the glycosidic linkage in **2**. Three-bond coupling across the linkage between ^{13}C-1 and H-4′ is found to be 4.3 Hz and that between ^{13}C-4′ and H-1, 4.2 Hz. By reference to other ^{13}C–^1H coupling data, which exhibit a Karplus type of relationship between the magnitude of $^3J_{C-H}$ and dihedral angle in $^{13}C—O—C—^1H$ arrays of bonded atoms, it appears that torsion angles ϕ and ψ of the disaccharide in aqueous solution are in the region of 25–30°, i.e., close to the angles of crystalline **2**. Corresponding data for the hepta-*O*-acetyl derivative indicate that ψ is smaller by ~10° and ϕ is unchanged. An analysis of the ^1H-coupled ^{13}C spectrum of cyclohexaamylose-2,3,6,6′-d_4 is presented in relation to these findings. Computer simulations of the observed spectra have been used to determine coupling constants and to assess the importance of second-order effects on the measurement of J_{C-H}.

GORDON K. HAMER, FELIPE BALZA, NATSUKO CYR et ARTHUR S. PERLIN. Can. J. Chem. **56**, 3109 (1978).

On a deutéré le β-cellobioside de méthyle (**2**) aux positions C-2, -3, -3′, -4, -6 et -6′ par échange ^1H–^2H avec l'oxyde de deutérium en présence de catalyseur de nickel de Raney. Ce produit du marquage isotopique possède un spectre rmn de ^{13}C simplifié qui facilite la mesure du couplage ^{13}C–^1H entre les résidus, ce qui permet de déterminer l'orientation du lien glycosidique dans **2**. On trouve pour le couplage sur trois liaisons dans le lien glycosidique, des valeurs de 4.3 Hz entre ^{13}C-1 et H-4′ et de 4.2 Hz entre ^{13}C-4′ et H-1. Si l'on se reporte à d'autres mesures de couplage ^{13}C-^1H, qui manifestent une relation du type Karplus entre la valeur de $^3J_{C-H}$ et l'angle dièdre dans la séquence $^{13}C—O—C—^1H$ d'atomes liés, on déduit que les angles de torsion ϕ et ψ du disaccharide en solution aqueuse se situent aux environs de 25–30°C, soit tout près des angles observés dans le composé **2** cristallin. Les données correspondantes pour le dérivé hepta-*O*-acétylé n'indique aucun changement sur ϕ et une diminution de ~10° sur ψ. On présente, en rapport avec ces nouveaux résultats, une analyse du spectre de ^{13}C avec couplage ^1H pour la cyclohexaamylose-2,3,6,6′-d_4. On a utilisé la reconstitution des spectres par ordinateur pour déterminer les constantes de couplage et évaluer l'importance des effets de second ordre sur les mesures de J_{C-H}.

Introduction

As an aid in studying conformations of disaccharides and oligosaccharides in solution, measurements of interresidue spin–spin coupling (^3J) between a ^{13}C nucleus of one residue and the nearest ^1H of the adjacent residue (**1**) are being made from natural abundance, ^1H-coupled ^{13}C nmr spectra (1–3). That is, the conformation of the glycosidic region represented by **1** should be reflected in the magnitude of ^3J between the ^{13}C and ^1H nuclei, inasmuch as ^3J is dependent upon the dihedral angle relating these nuclei in space (4–6). A number of α-D-glucopyranosides have been examined in this way, including maltose and cyclohexaamylose (1–3). For the latter compounds, the observed interresidue coupling of ^{13}C-1 with H-4′ (or H-4) and of ^{13}C-4′ (or C-4) with H-1 is interpreted (2) as evidence that torsion (dihedral) angles ϕ (C′—O—C—H) and ψ (C—O—C′—H′) (**1**) of their glycosidic bonds, correspond to conformations in solution that are somewhat more staggered than in the solid state.

Here, we deal with the orientation of the glycosidic bond in methyl β-cellobioside (**2**). Cellobiose itself was examined initially (1), although strong overlap between the α- and β-anomeric pairs of C-1 and C-4′ signals interfered with measurements of their line widths. Judging from the results to be presented, our estimates (1) of interresidue coupling in cellobiose are low. By choosing a single glycosidic form (**2**), this source of difficulty has now been avoided. In addition, however, the present measurements of interresidue coupling in **2** have been greatly facilitated by the availability of an octa-*C*-deuterio analog of the glycoside, i.e., **3**, because of a marked

simplification in the ^{1}H-coupled ^{13}C nmr spectrum of **3** as compared with that of **2**.

Results and Discussion

^{13}C Nuclear Magnetic Resonance Spectra of Methyl β-Cellobioside-d_8

Compound **3** was prepared (7) by treating methyl β-cellobioside with deuterium oxide at 100°C for 24 h in the presence of Raney nickel catalyst, a procedure shown (8) to extensively *C*-deuterate simpler glycosides. Deuterium was incorporated into all positions except 1, 5, 1′, 2′, 4′, and 5′, as shown by a comparison of the ^{13}C nmr spectra of **2** and **3** (Figs. 1*A* and 1*B*). This ^{2}H distribution is consistent with general observations (7, 8) on glycosides under these conditions, in that only protons α to a free hydroxyl group undergo appreciable ^{1}H–^{2}H exchange. Most of the signal assignments for **2** and **3** in Fig. 1 are based on the reports of earlier workers (9, 10), although our results call (7) for a reversal of their designations for C-3 and C-5 and also C-3′ and C-5′ (see Experimental). The resistance of H-2′ in glycoside **2** to exchange is analogous to the relatively low reactivity found for H-2 of methyl β-D-glucopyranoside, which appears to be even greater in the disaccharide owing, presumably, to the presence nearby of the linkage at position-4′.

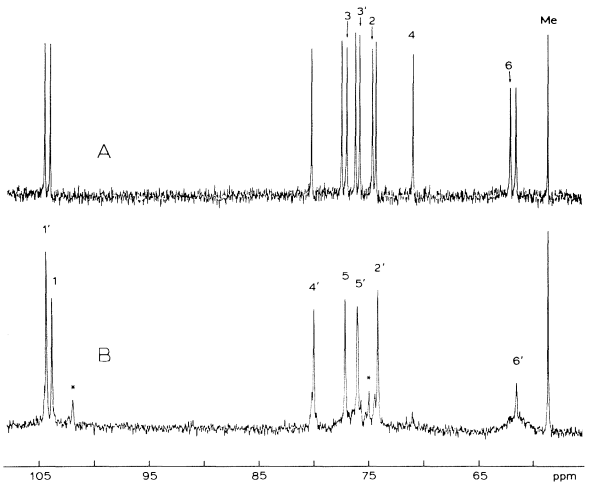

FIG. 1. 22.63 MHz ^{1}H-decoupled ^{13}C nmr spectrum of (*A*) methyl β-cellobioside (**2**) and (*B*) methyl β-cellobioside-d_8 (**3**); recorded in D_2O solution at 35°C. Signals indicated by asterisks are due to isomerization product(s) formed during ^{1}H–^{2}H exchange (see Experimental).

Of particular significance is the fact that in the preparation of **3**, positions-1 and -4′ remain intact; hence also, the 1- and 4′-carbon signals essential for a study of ^{13}C–^{1}H coupling across the glycosidic bond, remain among those readily observable in Fig. 1*B*.

The substantial simplification of spectrum 1*A*, achieved in 1*B* through the introduction of deuterium is magnified in the ^{1}H-coupled spectra of **2** and **3**. An example of this is found in examining the signals of the two anomeric carbons. The C-1 and C-1′ signals of **2** overlap extensively (Fig. 2*A*), whereas with the deuterated compound (**3**) the individual signals are clearly visible (Fig. 2*B*); reasons for this are considered later (see footnote 2). It is to be noted that Figs. 2*A* and *B* represents only half of these signals, the other half being separated by the magnitude of one-bond coupling with H-1 or H-1′.[1] This type of presentation emphasizes fine structure due to two- and three-bond couplings and is used below as well in dealing with other signals.

If there were *no* appreciable interresidue coupling in **2** between C-1 and H-4′, the C-1 signal should exhibit a splitting pattern similar to that of C-1 of β-D-glucose. The latter has the appearance of a doublet of doublets ($^1J_{C\text{-}1\text{–}H\text{-}1}$ = 161 Hz, $^2J_{C\text{-}1\text{–}H\text{-}2}$ = −5.7 Hz (1, 11, 12)). As seen in Fig. 2*D*, a 2 Hz coupling (^3J) with H-5 (6) is not resolved but introduces some line broadening; this becomes more evident (Fig. 2*E*) when H-5 of β-D-glucose is replaced (1) by deuterium (the effect of long-range coupling

[1] $^1J_{C\text{–}H}$ is approximately 160 Hz in each instance, in accord with (4, 6) the β-D-*gluco* configuration of each residue in **2** (Table 1).

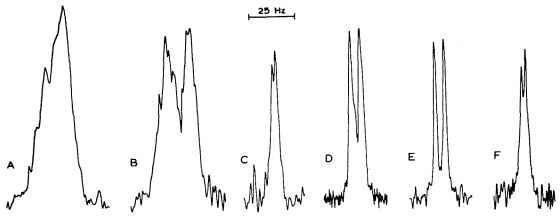

FIG. 2. One-half of the 22.63 MHz ^{1}H-coupled ^{13}C nmr spectrum of (*A*) C-1 of methyl β-cellobioside (**2**), (*B*) C-1 of methyl β-cellobioside-d_8 (**3**), (*C*) C-1 of β-D-glucose-2,3,4,6,6′-d_5 (**6***b*) formed by enzymic hydrolysis of **3**, (*D*) C-1 of β-D-glucose, (*E*) C-1 of β-D-glucose-5,6,6′-d_3, (*F*) C-1 of β-D-glucose-2,3,4,6,6′-d_5 (**4**) prepared by acid hydrolysis of methyl α-D-glucopyranoside-2,3,4,6,6′-d_5. Spectra recorded in D_2O solution at 35°C.

with H-3 and -4 is small). With the deuterated cellobioside (**3**), the fact that H-2 (as well as -3 and -4) has been exchanged[2] should give a C-1 signal in which only the couplings with H-1 and H-5 are evident (although slight broadening is to be expected owing to coupling with ^{2}H-2[3]), *again assuming that interresidue coupling is negligible*. A model for this is the C-1 signal of β-D-glucose-2,3,4,6,6′-d_5 (**4**) (Fig. 2*F*) (prepared by acid hydrolysis of the corresponding methyl α-D-glycoside (7, 8)), which exhibits a splitting of 2.2 Hz, due to the H-5 remaining.

It is clear from the C-1 signal of **3**, however, that in addition to the expected spacing of ~2 Hz associated with H-5, an additional spacing of ~4 Hz is present (Fig. 2*B*). The latter is attributed to interresidue coupling with H-4′. This has been demonstrated by treatment of **3** with a β-glucosidase from *Aspergillus phoenicis*, an enzyme shown by Reese and co-workers (14) to be highly selective in liberating the nonreducing end residue of methyl β-cellobioside. Hydrolysis of **3** proceeded almost quantitatively to give a mixture of two products, characterized by ^{13}C nmr spectroscopy as methyl β-D-glucopyranoside-3,6,6′-d_3 (**5**) and α,β-D-glucose-2,3,4,6,6′-d_5 (**6**). As seen in Fig. 2*C*, $^3J_{C\text{-}1-H\text{-}5}$ of the β-anomer of **6** is 2.0 Hz, which is close to that found (Fig. 2*F*) in **4**. Since the C-1 signal no longer exhibits the ~4 Hz spacing evident before hydrolysis, interresidue coupling of C-1 with H-4′ in the intact glycoside must have accounted for this splitting. By computer simulation, the value of $^3J_{C\text{-}1-H\text{-}4'}$ was determined to be 4.3 Hz and $^3J_{C\text{-}1-H\text{-}5}$, 2.2 Hz (Table 1).

[2]An accompanying decrease in line width undoubtedly contributes to the greater signal separation for C-1 and C-1′ in spectrum 2*B* as compared with 2*A*. Another probable factor is an upfield β-isotope displacement (13 and references cited therein) of the C-1 signal relative to that of C-1′ (−0.04 ppm) due to the deuterium at position-2.

[3] ^{13}C–^{2}H coupling was not resolved in any of the spectra examined here. Undoubtedly, however, ^{2}H-decoupling would be an advantage by giving more sharply resolved signals.

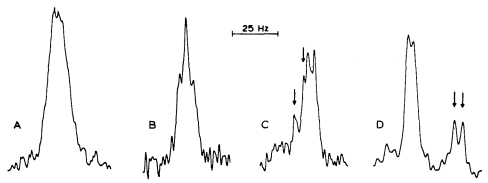

FIG. 3. One-half of the 22.63 MHz ^{1}H-coupled ^{13}C nmr spectrum of (*A*) C-4′ of methyl β-cellobioside (**2**), (*B*) C-4′ of methyl β-cellobioside-d_8 (**3**), (*C*) C-4 of methyl β-D-glucoside-3,6,6′-d_3 (**5**) formed by enzymic hydrolysis of **3**, (*D*) C-4 of **5** recorded in 70% C_5D_5N–D_2O solution (see Experimental); except for (*D*), spectra recorded in D_2O solution at 35°C. Signals indicated by arrows ((*C*) and (*D*)) arise from the aglycon CH_3 of **5**.

The C-4′ signal of **2** is a multiplet (Fig. 3A) comprised in part of splittings owing to two-bond coupling with H-3′ and H-5′, which are expected (12) to be 3–4 Hz. However, these and other possible spacings are not discernible. Through removal of the coupling with H-3′ (4.5 Hz in β-D-glucose (12)) by deuteration, the C-4′ signal of **3** (Fig. 3B) becomes a broad triplet comprised of spacings of about 4 Hz each. One of these splittings must be due to H-5′. Since the contribution of H-2′ should be small ($^3J < 1$ Hz), because it is *gauche* with respect to C-4′ (6), the only other possible source of the ~4 Hz spacing is interresidue coupling with H-1. Now, during the enzymic hydrolysis of **3** described above, the C-4′ signal virtually disappeared, to be replaced by the C-4 resonance of newly-liberated methyl β-D-glucoside-3,6,6′-d_3 (**5**). This latter signal is essentially a doublet with a spacing of 3.5 Hz (Fig. 3*C*); computer simulation gave $^2J_{C\text{-}4-H\text{-}5} = -3.0$ Hz.[4] Thus, it is clear that the extra splitting of about 4 Hz in Fig. 3*B* is due to coupling between C-4′ and H-1 of the nonreducing end residue of **3**. Based on a computer simulation of the C-4′ signal, the interresidue coupling amounts to 4.2 Hz, whereas $^2J_{C\text{-}4'-H\text{-}5'}$ is −3.0 Hz (Table 1).

A recent study of octa-*O*-acetyl-β-cellobiose-1-^{13}C by ^{1}H nmr spectroscopy has shown (15) that C-1 engages in coupling with H-4′ to the extent of 5.5 Hz, which is appreciably larger than the corresponding value now found for the unsubstituted methyl β-cellobioside (**3**). *O*-Acetyl derivatives are of general interest in the context of comparing solution geometries with those of crystalline materials, because they eliminate the possible role of interresidue hydrogen bonding that characterizes these molecules in the solid state (16, 17), as well as in methyl sulfoxide solution (18). Accordingly, measurements have been made on the heptaacetate of **3**

[4]Note that because of second order effects, the magnitude of ^2J is not equal to the observed spacing. By analogy with other measurements of two-bond coupling in pyranose sugars (6, 11, 12), the sign of ^2J is taken to be negative.

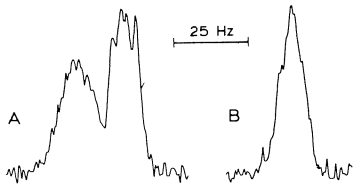

FIG. 4. One-half of the 22.63 MHz ^{1}H-coupled ^{13}C nmr spectrum of (*A*) C-1 of methyl hepta-*O*-acetyl-β-cellobioside-d_8 (**7**), (*B*) C-4′ of **7**; recorded in $CDCl_3$ solution at 35°C.

(**7**), for comparison with **3** itself, and also to see how closely analogous its C-1–H-4′ coupling is with that of β-cellobiose octaacetate (coupling between C-4′ and H-1 in the latter compound has not previously been examined).

As found in comparing the spectrum of **3** with that of **2**, the C-1 and C-4′ signals of **7** exhibited a much clearer splitting pattern than the corresponding signals before ^{1}H–^{2}H exchange. The coupling constants determined for the C-1 signal (Fig. 4*A*) by computer simulation, are 5.2 and 3.0 Hz (Table 1). Since the latter must be due to coupling with H-5, a value for $^3J_{C\text{-}1\text{–}H\text{-}4'}$ of 5.2 Hz is obtained; this is close to the 5.5 Hz interresidue coupling reported (15) for the β-octaacetate. Although the resolution of the C-4′ signal of **7** (Fig. 4*B*) is relatively poorer than that of C-4′ in **3**, the signals are virtually superimposable ($\Delta\nu^{1/2}$ is 9 Hz in both cases). Assuming that $^2J_{C\text{-}4'\text{–}H\text{-}5'}$ is the same in both compounds, then $^3J_{C\text{-}4'\text{–}H\text{-}1}$ for **7** is estimated to be 4.2 Hz.

Dihedral Angle Dependence of $^3J_{C-H}$*, and the Conformation of Methyl* β*-Cellobioside*

X-ray crystallographic data for methyl β-cellobioside show (16) that φ and ψ are 25 and −38°, respectively. For β-cellobiose, the corresponding angles are noticeably different (17, 19, 20), i.e., 44.6 and −13.7°.[5] According to optical rotatory studies (21, 22), these latter angles closely describe the orientation of the glycosidic bond of β-cellobiose, as well as of the β-glycoside (**2**), in aqueous solution.

To compare the results of the present measurements with these others, reference may be made to ^{13}C–^{1}H coupling in model compounds of known conformation. Although there is ample experimental (4–6) and theoretical (23, 24) evidence that a 'Karplus-type' of relationship exists between $^3J_{C-H}$ and torsional angle, values reported (6) for sp^3 carbons in carbohydrate molecules exhibit a considerable scatter. However, *interresidue* coupling involves sp^3 carbons contained in a specific sequence of nuclei, namely ^{13}C—O—C—^{1}H. Data obtained from monosaccharides for this type of array are plotted in Fig. 5, and although a relatively small number of points are represented, the well-known Karplus curve shape is evident in the solid line shown. Unfortunately, experimental values for the 0 to 60° range are difficult to find, because there can be few model compounds containing fixed ^{13}C—O—C—^{1}H angles of the appropriate size. Yet, as shown by the experimental findings and theoretical calculations (26, 27) on the conformation of cellobiose and its derivatives, it is in terms of this region that the present results need to be evaluated.

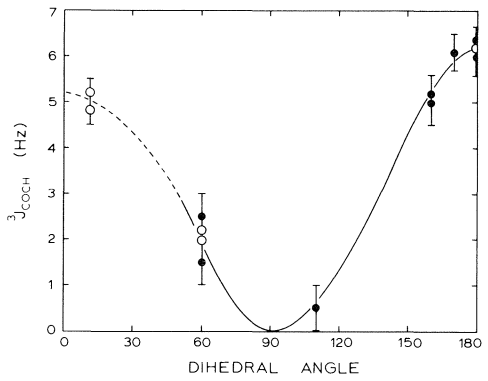

FIG. 5. Relationship between $^3J_{C-O-C-H}$ and the ^{13}C—O—C—^{1}H dihedral angle. Data represented by filled circles taken from refs. 6, 7, and 25; data represented by open circles, this work.

To help complete the curve in Fig. 5, data for cyclohexaamylose (**8**) may be considered. X-ray studies (28) of several complexes of this cyclic oligosaccharide show that φ and ψ are close to ±10°, on the average, and angles of the same magnitude are predicted by theoretical studies (29). Slightly larger values, i.e., ±20°, have been reported (22) for aqueous solutions of **8** on the basis of optical rotatory measurements.[6] We have estimated recently (2) that the interresidue couplings in **8** between ^{13}C-1 and H-4 and between ^{13}C-4 and H-1 are in the region of 4–5 Hz. These couplings have now been remeasured in the spectrum of the compound (**9**) after ^{1}H–^{2}H exchange (at carbons 2, 3, and 6) because the C-1 and C-4 signals (Fig. 6) exhibit more clearly defined splittings than could be observed (2) in the spectrum before deuteration. Analysis of the C-1 signal, with the aid of computer simulation, has afforded a ^3J value of 4.8 Hz for interresidue coupling between C-1 and H-4. Similarly, simulation of the C-4

[5]Its conformation appears to change little when the compound is dissolved in methyl sulfoxide, inasmuch as the hydrogen bond that occurs between OH-3′ and O-5 in the crystal is retained in solution (18).

[6]Alternatively, it is possible that instead of the conformation being symmetrical, one of the glycosyl residues is substantially folded away from the axis of the ring (21), as is found (29) in crystalline cyclohexaamylose hexahydrate. Such a distinction would not be apparent in the time-averaged nmr measurements.

TABLE 1. ^{13}C–^{1}H coupling data for methyl β-D-cellobioside-d_8, cyclohexaamylose-d_4, and related compounds[a]

Compound	Signal observed	^{1}J (Hz)[b]	^{2}J (Hz)[b]	^{3}J (Hz)[b]
Methyl β-cellobioside-d_8 (**3**)	C-1	162.1(H-1)		4.3(H-4′) 2.2(H-5)
	C-4′	147.4(H-4′)	−3.0(H-5′)	4.2(H-1)
	C-5′	143.5(H-5′)	−3.5(H-4′)	
Methyl β-cellobioside-d_8 heptaacetate (**7**)	C-1	161.8(H-1)		5.2(H-4′) 3.0(H-5)
	C-4′	148.4(H-4′)	−3.0(H-5′)	4.2(H-1)
Methyl β-glucoside-d_3 (**5**)	C-4	146(H-4)[c]	−3.0(H-5)[d]	
β-D-Glucose-d_5 (**4**)	C-1	161.9(H-1)		2.2(H-5)
(**6***b*)	C-1	161(H-1)[e]		2.0(H-5)
Cyclohexaamylose-d_4 (**9**)	C-1	169.1(H-1)		4.8(H-4)
	C-4	145.8(H-4)	−3.5(H-5)	5.2(H-1)
	C-5	146.5(H-5)	−2.9(H-4)	6.2(H-1)

[a]Determined by computer simulation. The sign of ^{2}J is assumed to be negative by analogy with ^{2}J in related compounds (6, 11, 12).
[b]The coupled proton is indicated in parentheses.
[c]Approximate value, owing to partial overlap with C-5.
[d]In 70% C_5D_5N–D_2O, $^{2}J = -2.8$ Hz (see Experimental).
[e]Approximate value, owing to partial overlap with C-1 of **5**.

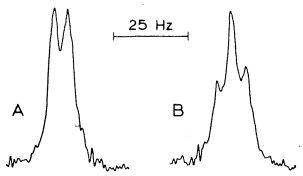

FIG. 6. One-half of the 22.63 MHz ^{1}H-coupled ^{13}C nmr spectrum of (*A*) C-1 of cyclohexaamylose-d_4 (**9**), (*B*) C-4 of **9**; recorded in D_2O solution at 50°C.

signal gives a value of −3.5 Hz for $^{2}J_{C\text{-}4\text{–}H\text{-}5}$, i.e., close to that of **5**, and a value of 5.2 Hz for the interresidue coupling with H-1 (Table 1).

Using this information, the plot in Fig. 5 has been extended (broken line) so as to permit an approximation of torsional angles in the cellobioside (**3**) in aqueous solution. Accordingly, the observed values for interresidue ^{13}C–^{1}H couplings of 4.3 and 4.2 Hz (in **3**) correspond to torsional angles of about 25–30°. Although these values reflect a thermodynamically-averaged conformation, they suggest that both φ and ψ are of the same order as their values in the solid state. By contrast, on the basis of optical rotations (21, 22) it has been suggested that the solution and crystalline conformations differ appreciably. We cannot account for this discrepancy between the results of the optical measurements, and our own results; perhaps it is a reflection of uncertainties in both sets of data.

An examination of **7**, the heptaacetate of **3**, in chloroform shows that interresidue coupling between C-1 and H-4′ increases by ~1 Hz, whereas that between C-4′ and H-1 remains the same as for the nonesterified compound. On this basis, the orientation of the glycosidic bond in **7** (in chloroform) may be represented by a geometry in which ψ is 10–20° smaller than in **3** (in water).[7] It is noteworthy in this context that acetylation may have a substantial effect on ψ in the solid state: X-ray data show (20) that ψ changes from −13.7° in β-cellobiose to +15.7° in its octaacetate, whereas φ remains constant. This variation has been attributed (20) to the loss of a hydrogen bond between O-5 and OH-3′ through acetylation. However, it is possible that the difference between **3** and **7** in *solution* is related not so much to changes in interresidue hydrogen bonding, as in solvation patterns and substituent size. Conceivably, these latter changes could be compatible with a major conformational variation. Theoretical calculations (26) predict a subsidiary minimum for cellobiose, in which ψ is ~180. Since the C-1,H-4′ coupling of 5.2 Hz in **7** is not inconsistent with a large value of ψ (Fig. 5), there remains the possibility that **7** represents a conformation related to this alternate energy minimum.

Further Comments on the Measurement of ^{13}C–^{1}H Coupling Constants. Second-order Effects

It was pointed out above that the observed splitting patterns have been reproduced by computer simulation. This procedure was adopted primarily because some second order effects were to be expected (30). For example, the C-4′ signal of **3** has

[7]This parallels the results of our earlier comparison (2) of the conformation of methyl β-maltoside and its heptaacetate.

the general appearance (Fig. 2*B*) of a symmetrical triplet comprised of spacings of ~4 Hz each. However C-4′ is part of an ABMX spin system also containing H-4′ (A) and H-5′ (B), which are strongly coupled ($^3J_{H\text{-}4'\text{–}H\text{-}5'}$ = 9.5 Hz). A simple first-order treatment, therefore, could give rise (30) to substantial disagreement between observed and calculated ^{13}C–^1H coupling involving C-4′. In fact, computer calculation of the spectrum shows that the C-4′–H-5′ coupling is smaller than the observed spacing by ~1 Hz, i.e., $^2J_{C\text{-}4'\text{–}H\text{-}5'} = -3.0$ Hz. As shown by the simulated spectrum (Fig. 7*B*), use of the latter value together with $^3J_{C\text{-}4'\text{–}H\text{-}1}$ = 4.2 Hz closely reproduces the experimentally observed C-4′ signal.

Second-order effects arise also in dealing with interresidue coupling between C-1 and H-4′ of **3**. Although C-1 is not coupled to H-5′, the latter couples strongly with H-4′ ($^3J_{H\text{-}4'\text{–}H\text{-}5'}$ = 9.5 Hz), and $\Delta\nu_{4',5'}$ is small (3 Hz). Treating C-1 as the X part of an ABMRX spin system in which J_{BX} ($J_{C\text{-}1\text{–}H\text{-}5'}$) = 0, gives the complex multiplet shown in Fig. 7*A*, which closely reproduces the experimentally observed signal. Similar considerations apply to C-1 of **7** and **9**, although the second order effects are not as apparent because, here, $\Delta\nu_{4',5'}$ is larger (16.7 and 21.2 Hz, respectively).

Among other signals examined were those of C-5′ of **3** and C-5 of cyclohexaamylose-d_4 (**9**); these signals were of particular interest because ^2J values involving C-5 and H-4 of pyranose sugars could not be measured in earlier studies (6, 11, 12). The C-5 signal of the oligosaccharide (**9**) (Fig. 7*C*) is a doublet of doublets in which the larger spacing is attributable to three-bond coupling with antiperiplanar H-1. As with C-4′ of **3** above, however, a large value of $^3J_{H\text{-}4\text{–}H\text{-}5}$ introduces a second order correction (30) for $^2J_{C\text{-}5\text{–}H\text{-}4}$, giving a value of −2.9 Hz (whereas the spacing observed is 3.7 Hz). The calculation also affords a value of 6.2 Hz for $^3J_{C\text{-}5\text{–}H\text{-}1}$, as compared with the observed coupling of 6.3 Hz (7) for the analogous pathway in methyl α-D-glucopyranoside-2,3,4,6,6′-d_5. Similarly, $^2J_{C\text{-}5'\text{–}H\text{-}4'}$ in methyl β-cellobioside-d_8 was calculated to be −3.5 Hz (Table 1).

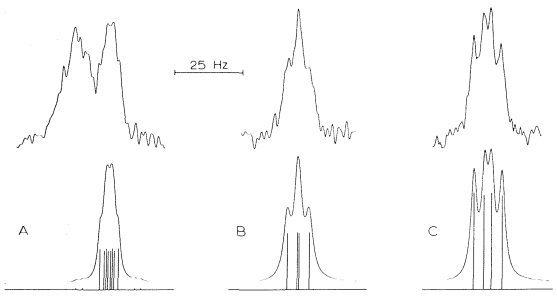

FIG. 7. One-half of the observed (upper) and theoretical (lower) ^1H-coupled ^{13}C nmr spectra of (*A*) C-1 of methyl β-cellobioside-d_8 (**3**), (*B*) C-4′ of **3**, (*C*) C-5 of cyclohexaamylose-d_4 (**9**). Theoretical spectra calculated from the parameters given in Tables 1 and 2.

Experimental

^{13}C Nuclear Magnetic Resonance Spectra

^{13}C nmr spectra were recorded on a Bruker WH-90 Ft spectrometer operating at 22.63 MHz. Except for methyl β-cellobioside-d_8 heptaacetate (**7**), samples were prepared in D_2O (200–400 mg/ml) containing several drops of CH_3OH as an internal standard; chemical shifts referenced to CH_3OH are expressed relative to external TMS ($\delta_C(CH_3OH)$ = 50.4 ppm). The heptaacetate **7** was run in $CDCl_3$ with TMS as an internal reference. In the ^1H-coupled spectrum of the enzyme hydrolysate (mixture of **5** and **6**), the C-4 signal of **5** is partially overlapped by the lowest field signal of the methyl quartet (Fig. 3*C*). By recording the spectrum in 70% C_5D_5N–D_2O, the CH_3 resonance was shifted 1.4 ppm to higher field (Fig. 3*D*) thus permitting clear observation of the C-4 doublet. Unless stated otherwise, the nmr probe temperature was 35 ± 1°C. Owing to its lower solubility, cyclohexaamylose-d_4 (**9**) was run at 50°C.

Proton-coupled ^{13}C spectra were recorded with gated ^1H-irradiation essentially as previously described (2). Spectral widths of 1000–1500 Hz were used, giving a digital resolution of 0.24–0.37 Hz after Fourier transformation (4K real data points). For **7**, a spectral width of 2000 Hz was required (resolution, 0.49 Hz).

Analysis of ^1H-coupled Spectra

Spectra were analyzed by computer simulation using the ITRCAL program (31) run on a Nicolet B-NC 12 model computer interfaced to the WH-90 spectrometer. First-order AMX analyses were made for the C-1 spectra of **4** and **6***b*. Second-order analyses (ABMRX, ABMX, or ABX) were carried out for C-1 (**3**, **7**, **9**), C-4 (**5**, **9**), C-4′ (**3**, **7**), C-5 (**9**), and C-5′ (**3**) signals. The required ^1H nmr parameters (J_{AB} and $\Delta\nu_{AB}$) were taken from the literature (**5**) or calculated from spectra (**3**, **7**, **9**) recorded on the WH-90 at 90.0 MHz (Table 2). In each case the analysis involved a systematic variation of the appropriate $J_{C\text{–}H}$ values together with the line-width to obtain the best visual fit between simulated and observed spectra. Where the multiplet structure was well resolved (e.g., C-5 of **9**), the ITRCAL program was run in iterative mode (31). It is estimated that the error in the values of ^2J and ^3J listed in Table 1 is ±0.2–0.4 Hz.

Preparation of Deuterated Compounds

Methyl β-Cellobioside-d_8 (3)

A solution of methyl β-cellobioside (**2**) (0.40 g) in D_2O (99.5%, 25 ml) containing Raney nickel (7, 33) (3.9 g wet weight, preexchanged with D_2O) was heated under reflux for 24 h. The solution was filtered through Celite, passed through a short column of Chelex-100 ion-exchange resin (Na^+ form) to ensure removal of paramagnetic ions and concentrated to a volume of 1.0 ml. ^{13}C nmr analysis of the solution (Fig. 1*B*) showed seven major signals attributable to **3** (the product was characterized as its heptaacetate, **7** (see below)) and several minor signals from an unidentified product, most probably an isomer of **3** arising from epimerization(s) of the nonreducing glucose residue (7, 8). ^{13}C nmr data for **2**: δ_C 104.4 (C-1′), 103.9 (C-1), 80.1 (C-4′), 77.3 (C-5), 76.9 (C-3), 76.1 (C-5′), 75.7 (C-3′), 74.5 (C-2), 74.2 (C-2′), 70.8 (C-4), 62.0 (C-6), 61.5 (C-6′), 58.5 (CH_3); ^{13}C nmr data for **3**: δ_C 104.4 (C-1′), 103.8 (C-1), 80.0 (C-4′), 77.1 (C-5), 76.0 (C-5′), 74.1

TABLE 2. ^{1}H nuclear magnetic resonance data used in ABMRX, ABMX, and ABX spectrum simulations[a]

Compound	X	A	B	M	R	J_{AB}(Hz)	$\lvert\Delta\nu_{AB}\rvert$(Hz)[b]
3	C-1	H-4′	H-5′[c]	H-1	H-5	9.5	3.0
	C-4′	H-4′	H-5′	H-1	—	9.5	3.0
	C-5′	H-4′	H-5′	—	—	9.5	3.0
5[d]	C-4	H-4	H-5	—	—	9.4	7.7
7	C-1	H-4′	H-5′[c]	H-1	H-5	9.9	16.7

[d] Reference 32.

(C-2′), 61.5 (undeuterated C-6′, residual signal), 58.5 (CH_3). Signal assignments are based on the work of Dorman and Roberts (9) and Usui *et al.* (10); however, a comparison of the data for **2** and **3** (specifically, the absence in **3** of signals at 76.9 and 75.7 ppm) requires the reversal of their assignments (9, 10) for C-3 and C-5 and also C-3′ and C-5′. The small upfield displacement of most signals of **3** relative to those of **2** reflects the β-isotope effect (13) due to deuteration of adjacent carbons. In the case of C-5, which is flanked by deuterium at both C-4 and C-6, the shift is particularly large (−0.24 ppm).

Methyl Hepta-O-acetyl-β-Cellobioside-d_8 *(7)*

The solution of **3** (above) was concentrated and the residue was acetylated by heating with acetic anhydride and anhydrous sodium acetate. The product, methyl hepta-*O*-acetyl-β-cellobioside-d_8 (**7**) was recrystallized from ethanol; mp 183–185°C (lit. (34) mp for undeuterated **7**, 187°C); ^{13}C nmr δ_C: 170.5, 170.3, 170.2, 169.8, 169.7, 169.3, 169.0 ($COCH_3$); 101.5 (C-1′); 100.8 (C-1); 76.5 (C-4′); 72.7 (C-5′); 71.8 (C-5); 71.6 (C-2′); 62.0 (C-6′, residual signal); 57.0 (CH_3); 20.8 (1C), 20.7 (1C), 20.5 (5C) ($COCH_3$).

Enzymic Hydrolysis of Methyl β-*Cellobioside-*d_8

A solution of **3** (0.30 g) in 1.0 ml of H_2O–D_2O (3:1) was prepared in a 10-mm nmr tube and 1–2 mg of *A. phoenicis* β-glucosidase (14) added. The progress of the hydrolytic reaction was monitored at 20 min intervals by ^{13}C nmr spectroscopy (probe temperature, 50°C). When the intensity of the C-4 signal of the liberated methyl β-D-glucoside-d_3 (**5**) became essentially constant, the solution was heated at 100°C for 10 min, centrifuged, and filtered. ^{13}C nmr analysis showed that the hydrolysate consisted of methyl β-D-glucoside-3,6,6′-d_3 (**5**) and α,β-D-glucose-2,3,4,6,6′-d_5 (**6**) together with a small amount of unreacted disaccharide; ^{13}C nmr data for **5**: δ_C 104.7 (C-1), 77.2 (C-5), 74.5 (C-2), 71.1 (C-4), 58.6 (CH_3); ^{13}C nmr data for **6**: δ_C 97.4 (C-1β), 93.6 (C-1α), 77.2 (C-5β), 72.7 (C-5α).

A sample of β-D-glucose-2,3,4,6,6′-d_5 (**4**) was also prepared chemically by acid hydrolysis of methyl α-D-glucoside-2,3,4,6,6′-d_5 (7, 8); ^{13}C nmr data for **4**: δ_C 97.3 (C-1), 77.2 (C-5).

Cyclohexaamylose-2,3,6,6′-d_4 *(9)*

Cyclohexaamylose (**8**) (0.50 g) was dissolved in D_2O (25 ml), Raney nickel (5.0 g wet weight, preexchanged with D_2O) introduced, and the suspension refluxed for 72 h. After filtration and treatment with Chelex-100 resin ^{13}C nmr analysis of the product showed >95% ^{2}H–^{1}H exchange at C-2, C-3, and C-6 (note that after 24 h, H-3 is only ~50% exchanged (7)); ^{13}C nmr data for **8**: δ_C 102.9 (C-1), 82.7 (C-4), 74.8 (C-3), 73.5 (C-5), 73.2 (C-2), 61.9 (C-6); ^{13}C nmr data for **9**: δ_C 102.8 (C-1), 82.6 (C-4), 73.4 (C-5). These results confirm the cyclohexaamylose signal assignments given by Colson *et al.* (35); thus, the earlier assignments of Usui *et al.* (10) for C-2 and C-5 should be reversed.

Acknowledgments

The authors express their gratitude to the Pulp and Paper Research Institute of Canada and the National Research Council of Canada for generous support. They also acknowledge the assistance of A. Parfondry and helpful discussions with H. J. Koch and R. S. Stuart. E. T. Reese kindly furnished the sample of *A. phoenicis* β-glucosidase, and W. R. Grace and Co., samples of Raney nickel catalyst.

^{13}C-nuclear magnetic resonance spectra of oxiranes. Configuration of 1,2-epoxypropyl side chains in fungal metabolites

SUZANNE LESAGE AND ARTHUR S. PERLIN

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7

Received June 20, 1978

SUZANNE LESAGE and ARTHUR S. PERLIN. Can. J. Chem. **56**, 3117 (1978).

^{13}C nmr data indicate that the epoxypropyl side chain of 'asperlin' (**1**) has a *trans* configuration. This assignment follows from associated measurements on model compounds, showing that the ^{13}C chemical shift of an epoxypropyl CH_3 group is close to either 17 ppm (*trans* isomers) or 13 ppm (*cis* isomers). Synthesized as oxirane derivatives related to **1** are diastereomeric pairs of 8-deoxy-6,7-*cis*- and -*trans*-epoxy-1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-octopyranoses.

SUZANNE LESAGE et ARTHUR S. PERLIN. Can. J. Chem. **56**, 3117 (1978).

Les résultats de la rmn du ^{13}C indiquent que la chaîne latérale époxypropyle de l'"asperlin" (**1**) possède une configuration *trans*. Cette attribution fait suite à des mesures connexes effectuées sur des composés modèles, qui montrent le déplacement chimique du ^{13}C pour le groupe CH_3 de l'époxypropyle se situe soit vers 17 ppm (isomère *trans*), soit vers 13 ppm (isomère *cis*). On a synthétisé des dérivés oxirannes reliés à **1**, soit les paires diastéréomériques des désoxy-8 *cis*- et désoxy-8 *trans*-époxy-6,7 di-*O*-isopropylidène-1,2:3,4 α-D-*galacto*-octopyrannoses.

Introduction

The oxirane ring is found in a variety of natural products (1). This article is concerned with the configuration of the oxirane moiety in asperlin (**1**), an antibiotic and antitumor compound produced by *Aspergillus nidulans* (2–4).

^{13}C nmr spectra of *cis*- and *trans*-2,3-epoxybutane and higher homologs indicate (5) that geometric isomers are distinguishable, by the fact that the ring carbons of *cis* oxiranes generally resonate upfield of those of the corresponding *trans* isomers. In attempting to utilize these observations to determine the configuration of the epoxypropyl side chain of asperlin, compounds more closely akin in structure to **1** than the simpler epoxides cited above, have been synthesized as reference molecules and their ^{13}C nmr spectra have been obtained for comparison with that of **1**.

Results and Discussion

The compounds synthesized, represented by **2**, are 8-carbon sugar derivatives containing a pyranose ring moiety and an epoxypropyl side chain. 1,2:5,6-Di-*O*-isopropylidene-α-D-galactopyranose (**3**) was oxidized with pyridinium chlorochromate (6) in dichloromethane, affording syrupy dialdose **4**[1] in 75% yield. A Wittig reaction between **4** and ethylidene triphenylphosphorane in the presence of *n*-butyllithium produced 6,7,8-trideoxy-1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-oct-6-*cis*-enopyranose (**5**) (9, 10).[2] From the latter, a 3:1 mixture of diastereomeric *cis* epoxides (**6**, **7**) was obtained in the form of an analytically pure mixed crystal, by oxidation with *m*-chloroperbenzoic acid.

Although the corresponding *trans* isomers also were required for this study, none of the *trans* olefin (**8**) appeared to have been formed together with **5**, nor had it been detected (9, 10) under the conditions of the earlier syntheses of **5**. Modifications of the Wittig reaction that have been known to alter *cis* to *trans* ratios, also failed to yield product **8**: i.e., acid isomerization of the intermediate betaine (11) was tried, as well as the use of a crown ether (12). However, isomerization of the isolated *cis* olefin (**5**), proved to be successful: uv irradiation of **5** in cyclohexane resulted in its conversion into **8** to the extent of about 75%.[3] Then, oxidation of **8** with *m*-chloroperbenzoic acid afforded a 2:1 mixture of the diastereomeric *trans* oxiranes (**9**, **10**).

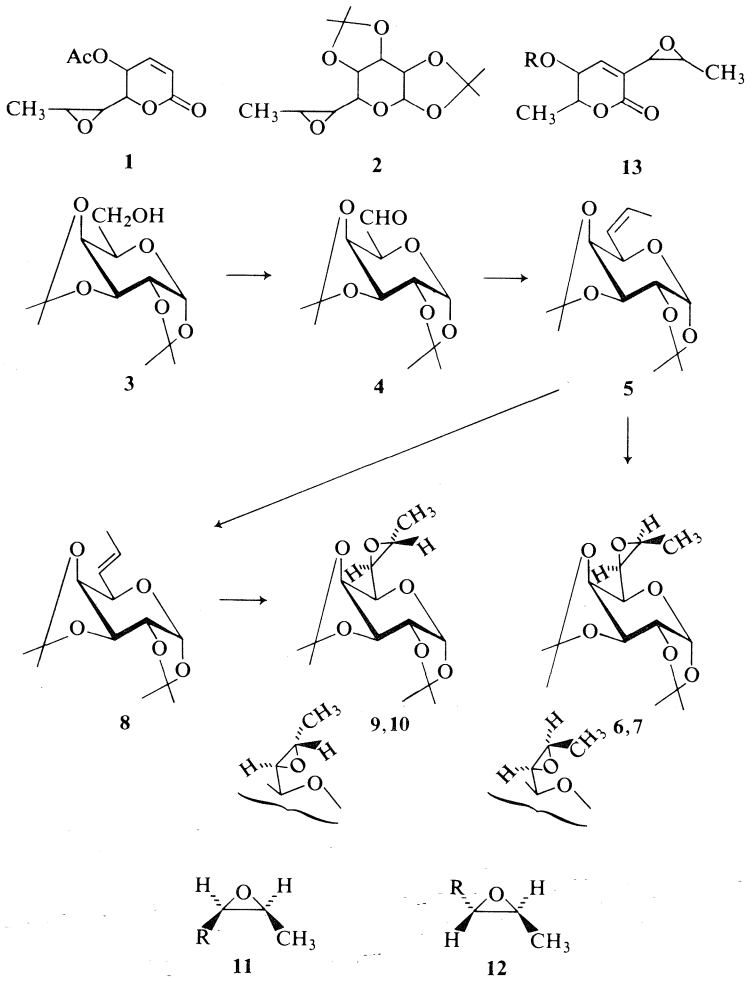
Paulson *et al.* (5) have shown that chemical shifts for the ring carbons of isomeric oxiranes are generally predictable, because in the *cis* isomers (**11**) these nuclei are more strongly shielded than in the *trans* isomers (**12**). This difference appears to be analogous to the 'steric compression' effect that has been

[1]Dialdose **4** is available also by methylsulfoxide oxidation of **3** (7, 8) but its isolation from that reaction is less convenient.

[2]Sodamide was employed in these earlier syntheses of **5**, whereas *n*-butyllithium proved to be more satisfactory in the present instance.

[3]Another isomerization procedure tried, i.e., thermally in the presence of triphenylphosphine (13), had virtually no effect on **5**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



observed with a wide variety of stereoisomeric compounds (14, 15). Similarly, the C-6 and C-7 signals[4] of the synthetic *cis* oxiranes (**6**, **7**) are upfield (on the average) of those of their *trans* isomers (**9**, **10**) (Table 1). Shielding influences (16, 17) owing to substituents appended to an epoxide ring have been evaluated by Paulson *et al.* (5) but the number of substituent parameters obtained is insufficient for calculating the C-7, C-8 chemical shifts of **1** and the model epoxides synthesized. Furthermore, shielding contributions of the pyrone ring of **1** are such that the chemical shifts of C-6 and C-7 overlap the range of values for the corresponding carbons in **6**, **7**, **9**, and **10** (Table 1). This precludes using these data from the model compounds, as well as from the simpler epoxides, for determining the configuration of the oxirane ring of asperlin.

By contrast, the methyl groups of these various compounds show a large, and consistent, difference in chemical shift. Among the data of Paulson *et al.* (5) are values for several pairs of geometric isomers containing an epoxypropyl grouping. For these, and also for the pairs **6**, **7** and **9**, **10**, the CH_3 signals of all *cis* isomers appear at 13–14 ppm, whereas those of *trans* isomers are found substantially downfield, at 17–18 ppm (Table 1).[5] Consequently, the observed value of 16.9 ppm for C-8 of asperlin shows that the epoxypropyl side chain of the metabolite has a *trans* configuration.

It is well known (20, 21) that *cis* and *trans* oxiranes may be differentiated by ^1H nmr spectroscopy, because vicinal coupling between the ring protons of *cis* isomers is usually larger than that for *trans*. How-

[4]Owing to differences in the system of numbering, C-6 and C-7 of the reference compounds correspond to C-7 and C-8 of **1**.

[5]A similar configurational difference is exhibited (14, 15) in the alkene series: e.g., the allylic methyl groups in the series 2-butene to 2-decene have chemical shifts of 11.4–12.8 ppm (*cis* isomers) or 16.8–18.0 (*trans* isomers) (18). It is noteworthy that corresponding values for olefins **5** and **8** are 13.6 and 17.8 ppm, respectively.

13	54.6	59.1	17.5
13 (acetate)	54.3	58.7	17.5

[a]In ppm relative to TMS; solvent, $CDCl_3$.
[b]Assignments for **1** and **13** are taken from ref. 19*a* and *b*, respectively. The other signal assignments are given by analogy with those of **1**; carbons-6 and -7 of **6**, **7**, **9**, **10** correspond to C-7 and C-8 of **1**.
[c]Data from ref. 5.

ever, the ranges of $^3J_{cis}$ and $^3J_{trans}$ overlap in the 2.2–2.5 Hz region, so that a coupling of this magnitude could be ambiguous, particularly if both isomers are not available and/or coupling with other protons introduces second-order effects. With deuteriochloroform as solvent, the H-6 and H-7 signals of asperlin overlap (4). In deuteriobenzene, however, good separation has been obtained (δ 2.87 and 2.67, respectively) and, measured from a 220 MHz spectrum, the observed spacing is 1.7 Hz. Since this value is appreciably *less* than 2.2 Hz, the result is consistent with the *trans* configuration assigned above. It is in agreement also with results obtained through synthesis (22) of an enantiomeric form of asperlin.

A pyrone metabolite related to asperlin, i.e., **13** (R = H), contains a 1,2-epoxypropyl side chain at position-2 (23, 24). The terminal methyl group of this compound has a chemical shift of 17.6 ppm and that of its acetate (**13**, R = Ac) 17.5 ppm, showing that the oxirane moiety of this class of metabolite also possesses a *trans* configuration. Earlier (22), **13** had been designated a *trans* isomer on the basis of a coupling of 2.0 Hz between the two epoxide protons. Although this value is in the region of overlap for geometric isomers, the present ^{13}C data serve to substantiate the original conclusions.

It is seen, therefore, that the 1,2-epoxypropyl side chains of both metabolites (**1** and **13**), although located at different positions of the pyrone ring, have the same (*trans*) configuration. The present data also serve as a further illustration of the usefulness of ^{13}C nmr spectroscopy for the characterization of oxiranes.

Experimental

Evaporations were carried out under reduced pressure at or below 60°C. The adsorbent for column chromatography was silica gel, 0.02–0.05 mm particle size (Macherey Nagel and Co., Germany). Microanalyses were performed by Dr. C. Daessle (Montreal). Carbon-13 magnetic resonance spectra were obtained with a Bruker WH-90 spectrometer; proton spectra were obtained with a Varian HA-100 spectrometer, those at 220 MHz being furnished by Dr. A. A. Grey (220 MHz Centre, Toronto, Ont.).

1,2:3,4-Di-O-*isopropylidene*-α-D-galacto-*hexodialdo-1,5-pyranose* (*4*)

To a solution of 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (**3**) (prepared according to Singh *et al.* (25)) (12 g, 0.05 mol) in dichloromethane (100 ml) was added pyridinium chlorochromate reagent (21.5 g, 0.01 mol) prepared as described by Corey and Suggs (6). The reaction mixture was stirred at room temperature for 4–5 h, ether (500 ml) was added, and the solution was filtered through Silica Gel, then concentrated. After column chromatography with methylene chloride as eluant, aldehyde **4** (8 g, 75%) was obtained as a pale yellow syrup, which had spectroscopic properties indistinguishable from those described by Horton *et al.* (7).

6,7,8-Trideoxy-1,2:3,4-di-O-*isopropylidene*-α-D-galacto-*oct-6*-cis-*enopyranose* (*5*)

(*a*) *n*-Butyllithium (5 ml, 15% in hexane) was added to ether (150 ml) under N_2, followed by ethyltriphenylphosphonium bromide (3 g), and the orange solution was refluxed (0.5 h). Aldehyde **4** (1.9 g) in ether (10 ml) was then added dropwise; the reaction mixture became colourless and a white precipitate separated. After refluxing (0.5 h), the precipitate was filtered off and rinsed with ether (50 ml); the organic layer was washed with 5% H_2SO_4 (2 × 50 ml), and water, dried over sodium sulfate, and concentrated to an oil (**5**) (1.5 g, 75%) which had physical and ^1Hmr spectroscopic properties similar to those described by Lance and Szarek (9); ^{13}Cmr data for **5**: δ: 13.6 (C-8); 24.5, 25.0, 26.1 (×2) (CH_3-isopropylidene); 63.7 (C-5); 70.4, 71.1 (C-2, C-3); 73.4 (C-4); 96.7 (C-1); 108.3, 109.1 (C-isopropylidene); 126.5 (C-6); 128.4 (C-7).

(*b*) The same olefin (**5**) was obtained by heating under reflux for 3–4 h a methylene chloride (50 ml) solution of aldehyde **4** (6 g) and ethyltriphenylphosphonium bromide (11 g), to which potassium *tert*-butoxide (3 g) and crown ether (18-crown-6, 0.5 g) (12) were added. The solvent was evaporated off and the residue extracted with cyclohexane (5 × 100 ml), the extract was concentrated, and the syrup obtained was then chromatographed with CH_2Cl_2 as eluant to yield olefin **5** as a colourless oil (4.5 g), indistinguishable from the product obtained in *a*.

(*c*) Since the latter method has been known to yield different ratios of *cis* and *trans* isomers in different solvents, the reaction was repeated using tetrahydrofuran as solvent (12) but only the *cis* olefin (**5**) was detected.

8-Deoxy-6,7-cis-*epoxy-1,2:3,4-di*-O-*isopropylidene*-α-D-galacto-*octopyranoses* (*6*, *7*)

A solution of the *cis* olefin (**5**) (0.43 g, 1.58 mmol) and *m*-chloroperbenzoic acid (0.30 g, 1.75 mmol) in methylene chloride (15 ml) was stirred at room temperature for 24 h. On work-up, as described by Lewis (26), a colourless syrup (0.43 g) was obtained, which proved to be a 3:1 mixture of diastereomers **6** and **7** (^{13}Cmr evidence). It crystallized and was recrystallized from ethanol–water, mp 76–77°C; $[\alpha]_D^{25}$ −79°C (c 1.58, $CHCl_3$); ^1Hmr data for **6**,**7**: δ: 1.32, 1.46 (12H, s, isopropylidene), 1.5 (3H, H-8, 8′, 8″); 3.0–3.3 (2H, m, H-6, H-7); 3.50 (1H, q); 4.2–4.7 (3H, m); 5.48 (1-H, d, H-1, J = 5 Hz); ^{13}Cmr data, major component: δ: 13.3 (C-8); 24.4, 24.8, 26.0 (×2), (CH_3-isopropylidene); 52.6 (C-7); 53.7

(C-6); 65.6 (C-5); 70.6, 70.7, 71.6 (C-2,3,4); 96.4 (C-1); 108.4, 109.4 (*C*-isopropylidene); minor component: δ: 14.2 (C-8); 24.4, 24.8, 26.0 (×2), (CH_3-isopropylidene); 51.2 (C-7); 55.5 (C-6); 67.9 (C-7); 70.3, 70.8, (C-2,3,4); 96.9 (C-1); 108.7, 109.9 (*C*-isopropylidene). *Anal.* calcd. for $C_{14}H_{22}O_6$: C 58.72, H 7.75; found: C 58.5, H 7.5.

6,7,8-Trideoxy-1,2:3,4-di-O-*isopropylidene*-α-D-galacto-*oct-6*-trans-*enopyranose* (***8***)

A cyclohexane solution (300 ml) of the *cis* olefin (**5**) (4.5 g) was irradiated in a water-cooled quartz cell with unfiltered uv light (450 W Hanovia Type of mercury-arc lamp, Model 679A) under a stream of N_2 for five periods of 2 h. After each treatment polymeric material in suspension was filtered off. The final solution was concentrated to a yellow syrup which was chromatographed (eluant, CH_2Cl_2) to yield a colourless syrup (4.0 g) consisting of a mixture (3:1, from ^{1}Hmr spectra) of the *trans* (**8**) and *cis* (**5**) olefins; ^{1}Hmr data for **8**: δ: 1.40 (6H, s, CH_3-isopropylidene); 1.54 (3H, s, CH_3 isopropylidene); 1.54 (3H, s, CH_3-isopropylidene); 1.80 (3H, d, H-8, 8′, 8″. J = 5 Hz); 4.1–4.4, 4.6–4.8 (4H, overlapping m); 5.60 (1H, d, H-1, J = 5 Hz); 5.68–5.90 (2H, m, H-6, H-7); ^{13}Cmr data: δ: 17.8, (C-8); 24.3, 24.8, 25.9, 26.8 (CH_3-isopropylidene); 69.0 (C-5); 70.4, 70.9, 73.2 (C-2,3,4); 96.5 (C-1); 108.2, 109.0 (C-isopropylidene); 126.8, (C-6); 129.7 (C-7).

8-Deoxy-6,7-trans-*epoxy-1,2:3,4-di*-O-*isopropylidene*-α-D-galacto-*octopyranoses* (***9***, ***10***)

A sample of syrupy oxiranes **9** and **10** was obtained by subjecting olefin **8** (0.15 g) to the conditions described above for olefin **5**; ^{1}Hmr data for **9**,**10**: δ: 1.45, 1.49, 1.61 (12H, s, CH_3-isopropylidene): ~1.5 (3H, H-8, 8′, 8″); 5.0–5.5 (2H, m, H-6, H-7); 5.5–5.65 (1H; m); 4.3–4.8 (3H, m); 5.65 (1H, br d, H-1); ^{13}Cmr data, major component: δ: 17.3 (C-8); 24.4, 24.9, 26.0 (CH_3-isopropylidene); 54.7 (C-7); 56.8 (C-6); 68.8 (C-5); 70.6, 70.7, 71.4 (C-2,3,4); 96.2 (C-1); 108.7, 109.6 (*C*-isopropylidene); minor component (some peaks were poorly resolved and/or lost in the noise): δ: 17.3 (C-8); 51.2 (C-6); 55.5 (C-7); 69.7 (C-5); 70.8, 71.0, 71.6 (C-2,3,4); 96.4 (C-1).

Acknowledgments

The authors express their gratitude to the National Research Council of Canada for generous support. They also acknowledge with thanks the kind assistance of Dr. N. Cyr and Dr. P. G. Farrell, and the gift of a sample of 'asperlin' from the Upjohn Co.

^{13}C nuclear magnetic resonance spectra of some C-19-hydroxy, C-5,6 epoxy, C-24 ethyl, and C-19-norsteroids

HERBERT L. HOLLAND, PETER R. P. DIAKOW, AND GREGG J. TAYLOR

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received April 17, 1978

HERBERT L. HOLLAND, PETER R. P. DIAKOW, and GREGG J. TAYLOR. Can. J. Chem. **56**, 3121 (1978).

The carbon magnetic resonance spectra of a series of C-19 hydroxy, C-5β,6β epoxy, C-5α,6α epoxy, and C-24 ethyl steroids have been assigned. Shift parameters for the C-19 hydroxyl function are listed. The data presented has led to a reassignment of the published spectra of several C5α,6α epoxy steroids. In addition, ^{13}Cmr spectral data for several bicyclic enones and a $\Delta^{5(10)}$-3-estrone are presented.

HERBERT L. HOLLAND, PETER R. P. DIAKOW et GREGG J. TAYLOR. Can. J. Chem. **56**, 3121 (1978).

On a fait l'attribution des signaux des spectres de résonnance magnétique nucléaire de ^{13}C pour une série de stéroides portant un hydroxyle en C-19, un époxyde en C-(5,6)β, un époxyde en C-(5,6)α ou un éthyle en C-24. On donne une liste de paramètres de déplacement pour la fonction hydroxyle en C-19. A la lumière des présents résultats, on a repris les attributions dans le cas de spectres déjà publiés pour plusieurs époxystéroides-C(5,6)α. On présente en outre des résultats de spectres rmn du ^{13}C pour certaines énones bicycliques et pour la $\Delta^{5(10)}$-estrone-3.

In spite of continuing interest in the carbon magnetic resonance of steroids, culminating in the recent publication of the first truly comprehensive review of the subject (1), several important groups of steroids remain to be examined by this technique. In this study, we have used standard methods of ^{13}C magnetic resonance spectroscopy to assign the carbon resonances of a series of C-19 hydroxy ,C-5,6 epoxy, and C-24 ethyl steroids, as well as those of $\Delta^{5,10}$-3-estrone and several bicyclic model compounds.

Our study began with the bicyclic enone **1***a* (Table 1). Resonances at C-1, -2, and -8a were readily assignable by comparison with the ^{13}C spectra of Δ^4-3-keto steroids (1); the remaining resonances were assigned as follows. Comparison of the ^{13}Cmr spectra of 19-nor-Δ^4-3-keto steroids and corresponding steroids carrying the C-10 methyl substituent (1) enabled us to calculate a substituent effect for the removal of the C-19 methyl on the resonances of carbons 1–10 of the steroid system. Average values from a series of such comparisons are listed under 'Δppm' in Table 1. Application of these parameters to the spectrum of **1***b* (2) now allowed unambiguous assignment of the resonances of carbons 4, 6, and 7 of **1***a*.

The remaining resonances were assigned following the synthesis of the deuterium labelled compounds **1***d* and **1***e*. Base-catalysed deuterium exchange of Δ^4-3-keto steroids is known to occur principally at the C-2 position (3). Application of a similar procedure to **1***a* led to the isolation of a labelled enone

1*d* in which the resonance at 36.6 ppm was apparently absent. Mass spectral analysis indicated that the principal component was a dideuterated species, although substantial amounts of d_4, d_3, and d_1 species were also present. In confirmation of this, a reduction in the intensity of peaks at 35.5 and 37.9 ppm in **1***d* of ca. 30% with respect to the corresponding peaks in the spectrum of **1***a* was observed.

The above data confirm the assignment of C-3 at 36.6 ppm and suggest that the other enolic carbons, C-4a and -8, resonate at 37.9 and 35.5 ppm. The latter was confirmed following the synthesis of **1***e* in which exchange has occurred at all the enolic carbons (3). The spectrum of **1***e* shows only four signals in

[a]To aid comparison, the numbering of the bicyclic enones is also included in parentheses. Chemical shifts marked with asterisks may be interchanged.

the aliphatic region of the spectrum, those of C-4, -5, -6, and -7.

With the assignments of C-4a at 37.9 ppm (calcd. 40.1 ppm) and C-8 at 35.5 ppm (calcd. 36.3 ppm) now secure, assignment of the remaining resonance at 34.6 ppm to C-5 is unambiguous.

The β,γ-unsaturated ketone **2** was next examined as a model for rings A and B of estr-5(10)-ene-3,17-dione (**3**) but only the resonances at C-1, -2, and -3 were uniquely assignable (Table 1): the chemical shift of C-2 is analogous to those of similar β,γ-unsaturated carbonyl carbons (4). The corresponding steroid **3** is significant in that it contains the $\Delta^{5(10)}$-3-keto functionality present in commercial birth control hormones (5). The resonances of carbons 11–18 of **3** (Table 1) were readily assigned by comparison with the published spectra of estr-4-ene-3,17-dione (1, 6) and those of C-2, -3, -4, -5, -8, -9, and -10 by analysis of the off-resonance spectrum and comparison with the spectrum of **2**. Assignment of C-10 to the lower field olefinic resonance at 130.8 ppm follows from the presence of a β substituent (C-11) not present in **2**. The resonances of C-6 and -7 were assigned by the aid of parameters derived from a comparison of the spectrum of **1***a* with that of the corresponding steroid estr-4-ene-3,17-dione (1, 6) (C-6, +0.1; C-7, +4.9) and the remaining resonance of **3** at 24.9 assigned to C-1.

An interesting comparison with **3** is provided by the C-5β,19-cyclopropyl steroid **4**. Resonances of carbons 2–4, 7, 9, and 11–18 of **4** were assigned by comparison with other 3,17-diketosteroids (1), whereas those of C-5, -10, and -19 follow from their presence in a cyclopropyl ring. Of the two remaining methylene resonances (26.6 and 31.8 ppm), the former has been tentatively assigned to C-6 and the latter to C-1. Although close comparison of **4** with other 5β steroids may not be fully justified, since the geometry of the AB ring junction is different (*vide infra*), it is nevertheless interesting to note that both C-4 and -6 resonate at lower field than the corresponding carbons of other 5β-androstan-3-ones (1), an effect which may be due to the presence of the extra β-C substituent at C-5. That the resonance of C-1 at 31.8 ppm, is upfield from the corresponding value of C-1 in 5β-androstan-3-ones (1) may be attributed to the removal of the C-5β hydrogen (7). The resonance of C-9 of **4** at 48.3 ppm is well downfield from that characteristic of 5β steroids (1, 8–10), owing to a distortion of **4** from normal 5β steroid geometry by the cyclopropyl system. Such a distortion would be expected to reduce the steric interactions between the C-9 hydrogen and the C-2α and -4α hydrogens which are responsible for the shift of C-9 to higher field in 5β steroids (9).

Before commencing an analysis of the ^{13}Cmr spectra of the C-19 alcohols **5***b–d*, and **6***b* and **6***c*, we recorded the spectra of the corresponding C-19 unsubstituted steroids **5***a*, **6***a*, and **6***d* in the solvent ($CDCl_3$) used for the subsequent study (Table 2). Assignments were straightforward and were made by comparison with literature values for related steroids and solvents (1).

Examination of the C-19 alcohols began with the

[a]The numbering of the bicyclic enones is in parentheses. Chemical shifts marked with asterisks may be interchanged.
[b]Solvent $CDCl_3$–DMSO-d_6.

model compound **1***c*, the assignments for which followed directly from a consideration of the α, β, and γ oxygen substituent effects of primary alcohols (11) and the spectrum of **1***b* (Table 1), and are shown in Table 2. The spectra of 19-hydroxyandrost-4-ene-3,17-dione (**5***b*) and the related Δ^4-3-ketones **5***c* and **5***d* are also assigned in Table 2: carbons 3–5, 7, 8, and 11–18 were assigned by comparison with C-19 unsubstituted steroids (**5***a* and refs. 1 and 6). Carbons 9, 10, and 19 were assigned from off-resonance data and 1, 2, and 6 on the basis of parameters derived by a comparison of the spectra of the model compounds **1***b* and **1***c*. With the assignments for **5***b–d* secure, the spectra of the Δ^5-3β,19-diols **6***b* and **6***c* could be assigned by comparison with the data for **6***a* and **6***d*.

The shift parameters for carbons 1–11 and 19 observed for the introduction of an hydroxyl function at C-19 of the steroids are presented in Table 3. In the series **5***b–d*, C-4 is deshielded and C-5 shielded whereas for **6***b* and **6***c*, C-6 is deshielded, C-5 shielded, and C-4 unaffected. These shifts may be ascribed to a polarization of the π electrons by the oxygen atom at C-19; this effect also caused a slight downfield shift at C-3 in **5***b–d*.

As a basis for the examination of the ^{13}Cmr spectra of C-5α,6α and C-5β,6β epoxy steroids **8** and **9**, respectively, we have used the corresponding Δ^5 olefins. The assignments for the latter are presented here (**6***a*, Table 2, **7***a–c*, Table 4) for those examples not available in the literature (1). The assignments for **6***a* have been discussed (*vide supra*) and those for **7***c* follow directly from related steroids (1). The spectrum of testosterone ethylene ketal (**7***a*) was readily interpreted by comparison with the spectra of testosterone (1, 6) and **6***a* (Table 2); only carbons 1 and 12 have not been uniquely assigned. Similarly, the resonances of **7***b* were assigned by comparison with the spectrum of **6***a*.

The spectra of the β-epoxides **9***a* and **9***b* were assigned by comparison with the corresponding olefins **6***a* and **7***a*, respectively. Carbon 8 of **9***a* and **9***b* was unambiguously assignable in the off-resonance

spectra, whereas the assignment of C-6 of **9***a* was confirmed following specific decoupling from the C-6α hydrogen at δ 3.2. The chemical shift differences (with the exception of those for C-5 and C-6) between the Δ^5 olefin and the corresponding β epoxide are small, being greatest at the γ carbons 3, 8, and 19 (ca. −2 ppm, see Table 4). In particular, the lack of an appreciably shift difference between carbons 1–4 and 9 in **9***a* and **9***b* vs. **6***a* and **7***b*, may be indicative of little change of relative geometry of the A/B ring junction in the two systems. The values observed in the epoxides are much different from those of the corresponding A and B ring carbons of normal 5β steroids (1), especially at C-9 (8–10). The lack of an appreciable upfield γ shift at C-1, such as that observed in the C-5α,6α epoxides (*vide infra*) may be attributed to a fixed C-1—C-5 oxygen dihedral angle of close to 180°.

Carbons 8–19 of the C-5α,6α epoxy steroids **8***a–f* (and C-20 and -21 of **8***c*) were assigned by analysis of the off-resonance spectra and comparison with the spectra of the corresponding olefins (1) (Tables 4 and 5). Of the remaining carbons, carbons 3–6 were readily assignable. Carbons 1, 2, and 7 were then assigned as follows. Carbon 7 should not vary appreciably across the series **8***a–f*, whereas carbons 1 and 2 of **8***b–f* should show shifts consistent with the substitution (OH or OAc) at C-3β (1). In addition the resonance of C-2 would be expected to correspond closely with that of the corresponding olefin

and other C-5α steroids (1). The assignments which follow from this approach are given in Table 5. They differ in the assignments of C-2 and -7 from the published data on related C-5α,6α epoxy steroids (12); the latter were however derived from a consideration of the small effect of a C-11α-hydroxyl group on the shift of C-1 and C-2, and without the more definitive data arising from acetylation at C-3 available to us.

A striking feature of the spectra of **8***a–f* relative to the corresponding olefins is the upfield γ shifts of C-1 and C-9 absent for the corresponding β epoxides: models reveal fixed C-1–C-5 oxygen and C-1–C-9 oxygen dihedral angles of $<90°$. Similar downfield shifts at C-1 and -9 occur in C-5α hydroxy steroids (1).

The last group of steroids to be examined in the present study comprises the 24-ethyl steroids stigmasterol (**10***a*), β-sitosterol (**11***a*), and the corresponding acetates **10***b* and **11***b* (Table 6). Carbons 1–19 of this series correspond closely with the same carbon resonances of cholesterol (1) and cholesteryl acetate (**6***d*, Table 2). Carbons 20–22 of **10***a* and **10***b* were assigned by comparison with ergosterol (1), while the chemical shifts of carbons 23–28 were calculated from a consideration of the effect of addition of a methyl group (C-29) to C-28 of ergosterol (calcd. C-23, 129.3; C-24, 51.2; C-25, 31.5; C-26, 19.7; C-27, 20.0; C-28, 26.7 ppm). Carbons 20 and 21 of **11***a* and **11***b* exhibit chemical shifts very similar to those of the corresponding carbons of cholesterol (1) and cholesteryl acetate (**6***d*): the chemical shifts of carbons 22–27 were calculated by considering the effect of ethyl substitution (C-28 + C-29) at C-24 of cholesterol (calcd. C-22, 33.7; C-23, 28.3; C-24, 48.5; C-25, 25.4; C-26, 19.0; C-27, 19.2). The remaining resonances are then assignable to C-28 and -29. With the exception of C-18 and -29 of **10***a* and **10***b*, all the assignments of this series are unambiguous.

TABLE 6. ^{13}C chemical shifts of stigmasterol (**10***a*) stigmasteryl acetate (**10***b*), β-sitosterol (**11***a*), and β-sitosteryl acetate (**11***b*)[a]

Experimental

Apparatus, Methods, and Materials

Natural abundance ^{13}C nuclear magnetic resonance spectra were recorded on a Bruker WP-60 Fourier transform spectrometer at 15.08 MHz. Samples were 0.15–0.3 *M* in $CDCl_3$; TMS was used as internal reference. 8K FID's were collected, yielding transformed spectra of 4096 data points giving an accuracy of 0.92 Hz per point. The following compounds were prepared in this laboratory by established procedures and gave satisfactory spectral and analytical data: 4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (**1***a*) (13), 4a-hydroxymethyl-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (**1***c*) (13, 14), 3,4,5,6,7,8-hexahydro-2(1*H*)-naphthalenone (**2**) (15), 3,3-ethylenedioxy-17β-hydroxyandrost-5-ene (**7***a*) (16), 17,17-ethylenedioxy-3β-hydroxyandrost-5-ene (**7***b*) (17), (5,6)α-epoxy-3,3-ethylenedioxy-17β-hydroxy-5α-androstane (**8***a*) (16), (5,6)α-epoxy-17,17-ethylenedioxy-3β-hydroxy-5α-androstane (**8***b*) (18), 3β-acetyloxy-(5,6)α-epoxy-5α-pregnan-20-one (**8***c*) (19), (5,6)α-epoxy-3β-hydroxy-5α-androstan-17-one (**8***d*) (20), 3β-acetyloxy-(5,6)α-epoxy-5α-androstan-17-one (**8***e*) (21), 3β,17β-diacetyloxy-(5,6)α-epoxy-5α-androstane (**8***f*) (22), (5,6)β-epoxy-3β-hydroxyandrostan-17-one (**9***a*) (20), (5,6)β-epoxy-3,3-ethylenedioxy-17β-hydroxy-5β-androstane (**9***b*) (16), 3β-hydroxystigmast-5-ene (β-sitosterol (**11***a*)) (23), and 3β-acetyloxystigmast-5-ene (**11***b*) (23).

(5β,19)-Cycloandrostan-3,17-dione (**4**) was kindly supplied by Dr. M. Gut of the Worcester Foundation for Experimental Biology. The other steroids used in this study were commercial samples.

*4,4a,5,6,7,8-Hexahydro-2(3*H*)-naphthalenone*-3,3-d_2 (*1*d)

Sodium (0.7 g) was dissolved in dioxan (50 ml) containing deuterium oxide (12 ml) and the enone **1***a* (2 g) added to this solution. The resulting mixture was stirred at room temperature for 72 h and then poured onto phosphate buffer (pH 7, 50 ml). The mixture was extracted with ether and the extract dried and evaporated. The residue was distilled at 70–75°C/0.7 Torr, to give **1***d* (0.6 g). Mass spectral analysis indicated the isotopic composition to be d_4, 17%; d_3, 26%; d_2, 35%; d_1, 15%; d_0, 5%.

*4,4a,5,6,7,8-Hexahydro-2(3*H*)-naphthalenone*-1,3,3,4a,8,8-d_6 (*1*e)

The enone **1***a* (2 g) was dissolved in dioxan (20 ml) containing deuterium oxide (10 ml). *p*-Toluenesulphonic acid (0.5 g) was then added and the mixture heated under reflux for 4 days. The product **1***e* (1.7 g) was isolated as described above; ms: isotopic composition d_6, 54%; d_5, 30%; d_4, 10%; d_3, 5%.
