Our earlier examinations of bicyclooctanones in strongly basic media had shown that the [2.2.2] and [3.2.1] skeletons are interconvertible and that the rate of isomerization is enhanced significantly in the unsaturated derivatives (1). We had found that the α,α-dimethyl derivatives of bicyclo[2.2.2]octenone (**1**), bicyclo[3.2.1]oct-2-en-6-one (**2**), and its Δ^3 isomer **3** are equilibrated at 185°C in *tert*-butoxide – *tert*-butyl alcohol much more readily than their saturated analogs. From experiments in deuterated solvent it was found that hydrogen–deuterium exchange occurred at five carbon sites in **1–3** by examination of their ^{13}Cmr spectra (1*a*). These sites were C-2, -3, -4, -5, and the *exo*-methyl in **2** and **3**. Exchange at C-4 and the methyl site occur by β-enolization whereas that at C-2 (and C-4) involves an allylic carbanion and that at C-3 a vinyl anion presumably. For **1** exchange occurred at C-1, -5, -6, -7, and the *exo*-methyl sites. It was of interest to determine the relative rates of exchange at these sites and to examine the stereoselectivity at the methylene positions. A comparison of these data with the results of our examination of hydrogen–deuterium exchange in bicyclo[2.2.2]octene and bicyclo[3.2.1]oct-2-ene (2) would reveal an activating effect of the carbonyl group on the reactivity of the allylic and vinyl anions in these skeletons. To this end we have followed the progress of deuterium incorporation into ketones **1–3** as a function of time and determined the rates of isomerization using each of the three ketones as starting material. Experiments were carried out at 155 and 185°C. At the higher temperature, the data are directly comparable to the results obtained for a variety of ketonic substrates (3) but for some of the rate processes only lower limits could be estimated. Consequently a series of measurements at 155°C was performed to permit an improved assessment of the relative rates at the different sites in ketones **1–3**. Deuterium incorporation was monitored by examination of the ^{2}Hmr spectra of the deuterated products (4). Analysis of the proton spectra of **1–3** aided by the use of the Eu(fod)$_3$ shift reagent and spin decoupling allowed unambiguous assignments of the signals in the ^{2}H spectra. We wish to present the results of these experiments in this paper.

Experimental

The preparations of **1–3** have been described (1*a*, 5) as has the general procedure for the rearrangement and exchange

experiments (4). To a solution of the base, prepared *in situ* by dissolving potassium metal in dry *tert*-butyl alcohol under a nitrogen atmosphere, was added the ketone to give a solution containing ketone–*tert*-BuO$^-$–*tert*-BuOH in a molar ratio of 1:4:40. Aliquots were placed in glass tubes which were sealed after degassing and heated at the appropriate temperatures for various times. For the exchange experiments, *tert*-butyl alcohol-*O*-d_1 (99% deuterated and <0.005 *M* in water) was used. After cooling, the ketonic products were isolated by pentane extraction and the product mixtures analyzed by gas chromatography (gc). Preparative gc using either a 10% FFAP or 15% DEGS column was employed to isolate samples of each ketone. Their ^{2}H spectra, obtained as previously described (4), were recorded to determine the sites and extents of ^{2}H incorporation while the total ^{2}H content was determined by mass spectrometry using a Varian MAT-311A instrument. A Varian XL-100-15 system operating in the Fourier transform mode at 15.4 MHz was used for the ^{2}H spectra while proton spectra were recorded with a Varian HA-100 instrument. The effect of the shift reagent, Eu(fod)$_3$, was utilized to increase the proton shift dispersion to permit unambiguous assignments for specific protons by spin decoupling experiments. This information allowed definitive assignments in the ^{2}H spectra since ^{1}H and ^{2}H shieldings are essentially identical. These spectra were obtained for solutions in carbon tetrachloride containing 20% hexafluorobenzene (v/v) which was required for locking purposes for the ^{2}H spectra.

Results

A series of experiments using each of ketones **1–3** was carried out and the product compositions were determined as a function of time by analytical gc. Representative data from experiments with **1** are listed in Table 1. At 185°C the equilibrium composition was found to be 8:44:48 for **1**:**2**:**3** and equilibrium was established in less than 24 h. The half-life for the experiments with **1** as starting material was approximately 7 h corresponding to a rate constant for the disappearance of **1** of approximately 2.4×10^{-5} s^{-1}, the slow process being the skeletal rearrangement. With either **2** or **3** as starting material, the product is a nearly **1**:**1** mixture of **2** and **3** within several minutes with only trace quantities of **1** detectable by gc. At 155°C, the disappearance of **1** gave a rate constant of ca. 2.4×10^{-6} s^{-1}, i.e. a half-life of ca. 80 h. These rates indicate an activation energy

of approximately 30 kcal/mol for the skeletal isomerization.

A corresponding series of experiments was conducted using *tert*-butyl alcohol-*O*-d_1 as the solvent and the products after isolation were analyzed for total deuterium content by mass spectrometry while the extent of deuterium incorporation at the individual sites was determined from their ^{2}Hmr spectra. In each case the ^{2}H spectra contained six signals for the samples obtained after the longer reaction times. Two of these signals appeared at significantly lower field than the others and were readily assigned to the olefinic centres while the highest field signal could be ascribed to the methyl group. To assign these signals unambiguously, the proton spectra of **1–3** were recorded and the effects of added Eu(fod)$_3$ examined.

For **1**, the proton spectrum contained methyl singlets at 1.05 and 1.10 ppm, a complex multiplet at 1.2–2.2 ppm arising from four protons, as well as four multiplets, each corresponding to the absorption for a single proton centred at 2.56, 3.09, 6.10, and 6.52 ppm. The latter two patterns appeared as triplets of multiplets. Upon the addition of Eu(fod)$_3$, most of the patterns exhibit downfield shifts with the most pronounced effect apparent for the multiplet originally at 3.09 ppm which therefore arose from H-1. In the presence of 0.17 equiv. of Eu(fod)$_3$ the four lower field multiplets shifted to 3.04, 4.57, 6.60, and 6.99 ppm, respectively. Double irradiation centred at 6.60 ppm significantly narrowed the multiplet at 4.57 ppm while the absorption at 3.04 ppm was little affected. The opposite effects were found upon double irradiation at 6.99 ppm. These observations permitted assignment of these four multiplets to H-5, -6, -1, and -4 in order of increasing field. In this spectrum the methyl signals appeared at 1.96 and 1.99 ppm partially obscuring a multiplet which integrated for two protons. A second 2-proton pattern centred at 2.60 ppm was clearly resolved. The ^{2}H spectrum of **1**-d_x isolated from the product mixture after heating **1** at 185°C for 149 h contained six

signals which were assigned as follows: 6.5(D-5), 6.1(D-6), 3.0(D-1), 1.8, 1.5(D-7), and 1.05 ppm (*exo*-methyl-D). The three higher field assignments are based on the results obtained for **2**-d_x and **3**-d_x but, in any event, these are not crucial for any of the mechanistic conclusions drawn. The major concern is the assignment of the olefinic signals which was straightforward from the proton results.

Six signals also appeared in the ^{2}H spectra of most of the **2**-d_x samples. The positions and assignments are: 6.0(D-2), 5.5(D-3), 2.6(D-5), 2.4(*exo*-D-4), 2.1(*endo*-D-4), and 1.1 ppm (*exo*-methyl-D), based on the following observations. The proton spectrum contained one pattern at 5.96 ppm which was a triplet of multiplets and one at 5.50 ppm, a doublet of multiplets. These were readily assigned to the olefinic protons H-2 and -3, respectively, from their positions and multiplicities since the pattern for H-2 is expected to exhibit comparable spin coupling of 8–10 Hz to the vicinal bridgehead and olefinic protons while the pattern for H-3 would contain one of these interactions with smaller couplings to the allylic protons at C-4. An ill-defined multiplet at 2.55 ppm was ascribed to H-5 and verified upon finding that this pattern was most sensitive to the presence of Eu(fod)$_3$. The methyl protons were equivalent at 1.09 ppm but became nonequivalent in the presence of the shift reagent. A doublet, $J \sim 10$ Hz, at 1.85 ppm was assigned to the *anti*-8-proton and a 4-proton multiplet centred at 2.25 ppm contained the absorptions of the remaining protons. Upon the addition of Eu(fod)$_3$, each of the multiplets exhibited sufficiently different sensitivities such that with 0.3 equiv. of shift reagent each pattern could be unambiguously assigned to a specific proton. The broad multiplet originally at 2.55 ppm showed the largest shift to 9.14 ppm while the H-2 and -3 patterns shifted to 8.09 and 7.31 ppm, respectively. The methyl signals appeared at 5.61 and 4.77 ppm and the *anti*-8-proton absorbed at 4.30 ppm. A doublet at 7.02 ppm ($J \sim$ 18 Hz), each component of which was broad, could be assigned to the *endo*-4 proton, since it was essentially unaffected by double irradiation at H-5. Double irradiation at 7.02 ppm collapsed a pattern near 4.65 ppm thereby revealing the *exo*-4 proton, the lower field component of which coincided with the absorption for H-1 at 4.77 ppm. Finally, the absorption for the *syn*-8 proton appeared at 5.36 ppm. A number of multiple irradiation experiments confirmed these assignments. From similar experiments with solutions containing different amounts of shift reagent, plots of the individual proton shieldings vs. [Eu(fod)$_3$] showed that the *endo*- and *exo*-4-proton patterns crossed over with added reagent; thus, the assignments for each of the deuterium signals could be assigned in the ^{2}H spectrum recorded without added Eu(fod)$_3$. The spectrum of one of the heavily deuterated **2**-d_x samples was examined as a function of added shift reagent to confirm that the induced shifts agreed with those found from the ^{1}H results as a further confirmation of the assignments. As reported previously (1*a*), the methyl signals are readily assigned in the ^{13}C spectrum of **2** and the methyl absorption in the ^{2}H spectrum of **2**-d_x was shown to arise exclusively from the methyl nuclei more sensitive to Eu(fod)$_3$, i.e. exchange occurred only at the *exo*-methyl site in the limits of detection by ^{2}H spectra.

A similar approach was employed to unravel the ^{2}H spectra of the **3**-d_x samples, using initially those from the longer reaction times. In the absence of Eu(fod)$_3$, six signals were evident although the olefinic absorptions at 5.75 and 5.70 ppm were too close for precise integration or for specific assignments. In addition, signals appeared at 2.75, 2.45, 2.25, and 1.10 ppm. That at 2.75 ppm could be assigned to D-5 from its large relative shift upon the addition of Eu(fod)$_3$ while the highest field signal was the methyl absorption. In the proton spectrum of **3** the olefinic pattern is deceptively simple and it was essential to examine the effect of added Eu(fod)$_3$ to distinguish between the two olefinic protons. In the presence of Eu(fod)$_3$ patterns analogous to those described above for **2** emerged to permit unambiguous assignments. Also, as in the case of **2**, the methyl protons became nonequivalent with added shift reagent but, within our limits of detection, deuterium incorporation occurred only at the *exo*-methyl site. In contrast to **2**, it was more difficult to assign the patterns specifically for H-1 and -2, the more remote bridgehead and allylic methylene protons. However, in the ^{2}H spectra of **3**-d_x samples from short reaction times the signal at 2.45 was much more intense than that at 2.25 ppm leading to their assignments as the *exo*- and *endo*-2-deuterons, respectively. With added shift reagent these patterns cross over, behavior which is analogous to that of the 4-protons (deuterons) in **2**. The chemistry observed for the system also requires these assignments for **3**.

With the assignments for **1**–**3**, the ^{2}H spectra of each of the samples isolated after treatment in the deuterated medium were recorded and integrated using line-shape fitting as described previously (4) to determine the relative ^{2}H incorporation at each site. For this purpose the samples of **1**-d_x and **2**-d_x were examined without shift reagent since the individual signals are sufficiently separated. For the **3**-d_x samples, however, the relative amounts of deuterium at C-2, -5, and the methyl site were obtained without added Eu(fod)$_3$ and then the relative amounts at

C-3, -4, and -5 were determined for shifted spectra. In the latter the overlap in the higher field region precluded precise integration. From the two sets of ratios the relative amounts at each site could be derived. For each sample, the total deuterium content was determined by mass spectrometry. With these data the deuterium concentrations at each site were calculated and a summary of these results is tabulated in Tables 2 and 3 for the two temperatures studied.

Discussion

The first feature which is apparent from the present results is the enhanced rate of rearrangment relative to the behavior found for a variety of other bicyclic ketones (3). At 185°C, the temperature at which most of the earlier results were obtained, equilibrium was established in ca. 20 h. The rate of rearrangement for **1** is more than 100 times faster than that found for its saturated analog (*1b*) and deuterium incorporation at most of the sites of exchange in **1–3** was too fast to permit the extraction of even crude rate data. At 155°C approximate rate constants could be generated from the experimental results and it is interesting to compare these with earlier data for closely related systems. The decreased rearrangement rate for **1** corresponds to an activation energy of 30 kcal/mol which seems reasonable for this isomerization. The presence of the double bond in the bicyclo[2.2.2]octane skeleton also appears to bias the equilibrium more toward the [3.2.1] skeleton by comparison with the results for the saturated analogs (*1b*). Since the [3.2.1] system constitutes 92% of the mixture at equilibrium and the rate of **1** → **2**(**3**) is approximately 2.4×10^{-5} s^{-1} at 185°C, the rate of the slower interconversion **2** → **1** is $\sim 2 \times 10^{-6}$ s^{-1}. The corresponding values for 155°C are reduced by a factor of 10.

From the results for the **1**-d_x samples it is evident that exchange at C-6 is much more facile than at C-5; estimated first-order rate constants for ^{2}H incorporation at 155°C are 130×10^{-6} and 2.5×10^{-6} s^{-1}, respectively, i.e. a ratio of ~50. At 185°C, the rate constant for C-5 exchange is 30×10^{-6} s^{-1} while that at C-6 is $>400 \times 10^{-6}$ s^{-1}. These values may be compared to the value of 5.6×10^{-7} s^{-1} found for bicyclo[2.2.2]octene (2). Clearly, the carbonyl group has a pronounced activating effect on the vinyl exchange process in the ketone increasing the rate at C-5 by a factor of 50 and the rate at C-6 by perhaps 10^3. Conceivably, these rate enhancements could signal a change in mechanism but, without further information, it seems sufficient to attribute the enhancement to the polarity of the carbonyl bond either through an inductive or a field effect. At the higher temperature deuterium incorporation was also observed at C-1 and C-7 in the **1**-d_x samples but the rate of appearance was very much slower, $k \sim 2 \times 10^{-6}$ s^{-1}. Since this is comparable to the rate of rearrangement **2** → **1**, the incorporation probably occurred in the [3.2.1] skeleton rather than directly in **1**. This conclusion is supported by the fact that *endo* exchange at C-7 in the 10 h sample is greater than *exo* exchange. This carbon is the bridgehead carbon in **2** and **3** which undergoes rapid exchange at 185°C. Subsequent formation of the β-enolate **4**, followed by opening with inversion to **1** places the deuterium in

the *endo* orientation at C-7. From the results for other systems (2–4) and the data discussed below, it has been established that β-enolate opening with inversion is the preferred process.[3] Bridgehead exchange (C-1) in **1** also probably arises from exchange at the allylic methylene carbon in **2** which is very rapid at 185°C. Since the allylic site in **2** is essentially completely deuterated in the 2 h sample, conversion of **2** to **1** will account for deuterium at the bridgehead position in **1**. It may be noted that exchange was not observed at C-1 in the saturated analog of **1** under comparable reaction conditions (1*b*). The appearance of deuterium in the *exo*-methyl group of **1** after long reaction times may arise from slow direct exchange or via **2** and **3** but the available data do not permit a distinction. It may be noted that methyl exchange in the bicyclo[2.2.2]octanone case (1*b*) exhibited a rate constant of 5×10^{-8} s^{-1} and the corresponding process in **1** could be expected to be similarly slow.

A series of experiments was performed at 155°C using **3** as the starting material and isolating samples of **2**-d_x and **3**-d_x at various times (Table 2). Deuterium assay of these samples permitted assessment of the relative rates of exchange at C-2, -4, and -5 in each case. From the rate of change of the d_0 peak in the mass spectra of **3**-d_x a deprotonation rate of 8×10^{-5} s^{-1} was found. The fastest process is undoubtedly formation of the allylic anion **5** which can protonate at either C-2 reforming **3** or at C-4 generating **2**. The apparent rate of exchange at the *exo*-4 position in **2** is $\sim 18 \times 10^{-5}$ s^{-1} indicating some stabilization of the negative charge at C-4 by the carbonyl group. As expected the rate of formation of **2** from **3** is 2×10^{-4} s^{-1}, i.e. the same as the deuteration rate at C-4. The *exo*/*endo* ratio at C-4 in **2** is approximately 2 which is essentially the same as that found previously for bicyclo[3.2.1]oct-2-ene at 185°C (2) but the exchange rates in the ketone at the lower temperature are 250 times faster, suggesting a rate enhancement of ca. 10^3 for comparable temperatures. Of course, the anion can exist as **4** the cleavage of which is heavily biased to **5** rather than **1**. In contrast to **2**, the stereoselectivity of allylic exchange at C-2 in **3** is higher; the *exo*/*endo* rate ratio at this site is ca. 6. Conceivably this may arise from a steric effect of the *endo*-methyl at C-7 hindering approach of the deuterium donor. It is interesting that bridgehead exchange (C-5) appears to be approximately twice as fast in **2** as in **3** indicating that somewhat less strain is associated with α-enolization to form a noncon-

[3]A referee suggests that the intermediates from *exo* and *endo* proton abstraction from C-7 in **1** could differ in reactivity such that the intermediate from *exo* abstraction undergoes isomerization preferentially while that from *endo* abstraction is more rapidly reprotonated (deuterated).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

jugated enolate which can be pictured as **6**. It is apparent that methyl exchange and generation of a vinyl anion in **2** and **3** are much higher energy processes since no deuterium was detected at these sites in the experiments at 155°C. At 185°C, however, both processes were observable and the rate of exchange at the *exo*-methyl site is similar to that found for 7,7-dimethylbicyclo[3.2.1]octan-6-one (*1b*), namely 3×10^{-6} s^{-1}. It may be noted that this is a lower limit since the deuterium pool is appreciably diluted by the exchange processes at the other centres. In the saturated system it was possible to detect small amounts of deuterium at the *endo*-methyl position although the rate of *endo*-methyl exchange was 100 times slower than *exo*-methyl exchange. Presumably a similar difference exists for **2** and **3** but is unobservable because of more extensive dilution of the deuterium pool. As in the earlier cases, β-enolate formation of the *exo*-methyl group is implicated although, again, rearrangement to a ring-expanded skeleton was not detected. As noted previously, cyclopropoxides cleave in base to form the product from the more stable anion and the absence of ring expansion is not unexpected. The presence of the double bond in **2** and **3** apparently has no effect on the methyl exchange process. The appearance of deuterium at C-3 presumably via a vinyl anion was noted in our preliminary communication (*1b*) and we investigated deuterium exchange in the corresponding olefins (2). Both vinyl and allylic exchange occur in bicyclo[3.2.1]oct-2-ene and at similar rates. From the results for **2**-d_x and **3**-d_x, however, it is apparent that the rates differ by approximately an order of magnitude. Even so, the rates of vinyl exchange in the ketones, $\sim 8 \times 10^{-6}$ s^{-1}, are significantly faster than that found for the olefins, 2×10^{-7} s^{-1}. The factor of 40 relating the two processes is appreciably smaller than that found for the [2.2.2] system discussed above but it does indicate a significant enhancement by the carbonyl group, presumably through a field effect.

In summary, introduction of the double bond into the [2.2.2] system enhances its reactivity toward β-enolate formation and subsequent rearrangement to the [3.2.1] skeleton. Also, the double bond tends to increase the bias of the equilibrium toward the latter system. The carbonyl group accelerates both allylic and vinylic exchange in both skeletons but does not appear to affect the stereoselectivity of allylic exchange at C-4 in **2** relative to that found for the parent olefin. The effect of the double bond on β-enolization in this system suggests a number of extensions which are worthy of study to gain a better understanding of the utility of the process for synthetic purposes.

Ipso nitration. XVIII.[1] Nitration of 2-chloro-1,3,5-trimethylbenzene: nitration *ipso* to chlorine

ALFRED FISCHER AND SACHDEV SINGH SEYAN

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received November 28, 1977

ALFRED FISCHER and SACHDEV SINGH SEYAN. Can. J. Chem. **56**, 1348 (1978).

Nitration of 2-chloro-1,3,5-trimethylbenzene in acetic anhydride gives the *cis* and *trans* isomers of 4-chloro-1,3,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**1**, 21%), the *cis* and *trans* isomers of 3-chloro-2,4,6-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**2**, 6%), and 2-chloro-1,3,5-trimethyl-4-nitrobenzene (73%). Diene **1** reacts with acidified aqueous acetone to form the corresponding dienol, acidified methanol to form the methyl ether, and hydrogen chloride to form the corresponding chloride. In acetic acid a mixture of 4-chloro-3,5-dimethylbenzyl derivatives and 3-chloro-2,4,6-trimethylphenyl acetate are formed. In trifluoroacetic acid – trifluoroacetic anhydride and also in boron trifluoride etherate, 2-chloro-1,3,5-trimethyl-4-nitrobenzene is the predominant product. Diene **2** on reaction with acetic acid, acidified methanol, trifluoroacetic acid – trifluoroacetic anhydride, and boron trifluoride etherate gives 3-chloro-2,4,6-trimethylphenyl acetate. Some 2-chloro-4-nitromesitylene is obtained in trifluoromethanesulfonic acid. Diene **2** also gives the acetate on standing at ambient temperature or at −20°C, and on pyrolysis. Diene **1** gives 4-chloro-3,5-dimethylphenylnitromethane on standing at ambient temperature or at −20°C but a mixture of 2-chloro-1,3,5-trimethyl-4-nitrobenzene, chloromesitylene, and 3-chloro-2,4,6-trimethylphenyl acetate on pyrolysis.

ALFRED FISCHER et SACHDEV SINGH SEYAN. Can. J. Chem. **56**, 1348 (1978).

La nitration du chloro-2 triméthyl-1,3,5 benzène dans l'anhydride acétique conduit aux isomères *cis* et *trans* de l'acétate du chloro-4 triméthyl-1,3,5 nitro-4 cyclohexadiène-2,5 yle (**1**, 21%), aux isomères *cis* et *trans* de l'acétate du chloro-3 triméthyl-2,4,6 nitro-4 cyclohexadiène-2,5 yle (**2**, 6%) et au chloro-2 triméthyl-1,3,5 nitro-4 benzène (73%). Le diène **1** réagit avec de l'acétone en solution aqueuse acidulée pour conduire à la formation du diénol correspondant, avec du méthanol acidulé pour conduire à la formation de l'éther méthylique et avec du chlorure d'hydrogène pour conduire à la formation du chlorure correspondant. Dans l'acide acétique, il y a formation d'un mélange de dérivés du chloro-4 diméthyl-3,5 benzyle et de l'acétate du chloro-3 triméthyl-2,4,6 phényle. Dans un mélange d'acide trifluoroacétique et d'anhydride trifluoroacétique ainsi que dans l'éthérate du trifluorure de bore, le produit prédominant est le chloro-2 triméthyl-1,3,5 nitro-4 benzène. La réaction du diène **2** avec l'acide acétique, le méthanol acidulé, le mélange acide trifluoroacétique – anhydride trifluoroacétique et l'éthérate du trifluorure de bore conduit à l'acétate ou chloro-3 triméthyl-2,4,6 phényle. On obtient du chloro-2 nitro-4 mésithylène dans l'acide trifluorométhanesulfonique. Le diène **2** conduit aussi à l'acétate lorsqu'on le laisse à la température ambiante, à −20°C, ou lorsqu'on le pyrolyse. Le diène **1**, laissé à la température ambiante ou à −20°C, conduit au chloro-4 diméthyl-3,5 phénylnitrométhane; toutefois par pyrolyse on obtient un mélange de chloro-2 triméthyl-1,3,5 nitro-4 benzène, de chloromésithylène et d'acétate du chloro-3 triméthyl-2,4,6 phényle.

[Traduit par le journal]

Introduction

Addition of nitronium ion at an *ipso* position is an important reaction path in the nitration of aromatic derivatives (2–8). In acetic anhydride the *ipso*-nitrocyclohexadienyl cation so formed adds acetate to form the nitronium acetate (acetyl nitrate) adduct. In the benzene series adducts have been isolated in which the nitro group is *ipso* to methyl (9), methylene (10), and ethyl (7), and a cyclohexadienone has been obtained in which nitro is *ipso* to methoxyl (11). Nitration is known to occur *ipso* to other groups, such as isopropyl (12) or bromo (13), but in these cases the *ipso* group is lost and no adduct is obtained. In the naphthalene series an example of nitration *ipso* to bromine and to chlorine has long been known in the formation of 1-bromo-1-nitro-2(1*H*)-naphthalenone and 1-chloro-1-nitro-2(1*H*)-naphthalenone from 1-bromo-2-naphthol and 1-chloro-2-naphthol, respectively (14, 15).

In the present paper we report the isolation of a benzene series adduct with nitro *ipso* to chlorine.

Results and Discussion

Nitration and Formation of Adducts

Nitration of 2-chloro-1,3,5-trimethylbenzene (chloromesitylene) in acetic anhydride gave a mixture of diene adducts (30%) and 2-chloro-4-nitromesitylene (70%). The products were separated by low-tempera-

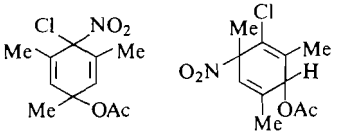
ture chromatography on alumina and, in addition to the nitro substitution product, the two diastereoisomers of 4-chloro-1,3,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate[2] (**1***a* and **1***b*) and one diastereo-



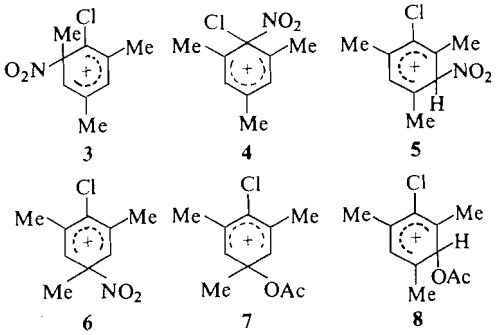
1 **2**

isomer of 3-chloro-2,4,6-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate[3] (**2***b*) were obtained. The second diastereoisomer of 3-chloro-2,4,6-trimethyl-4-nitro-1,4-dihydrophenyl acetate (**2***a*) was not isolated in a pure state but it was present as a major constituent in certain column fractions. Product recovery after chromatography represented a yield, based on the chloromesitylene of ca. 90%. Nuclear magnetic resonance analysis of the column fractions indicated that the ratio 2-chloro-4-nitromesitylene – (**1***a* + **1***b*) – (**2***a* + **2***b*) was 73:21:6. The amount of the adduct **2** varied from run to run but it was always less than the amount of adduct **1**. The variation is probably a reflection of the difficulty of measuring the small proportion of material rather than a variation of the portion of adduct **2** actually formed.

The ir and elemental analytical data confirm the presence of the acetate and nitro groups in the adducts. Adducts **1***a* and **1***b* have a plane of symmetry, as is evident from both the ^1H and ^{13}C nmr spectra. It follows that **1***a* and **1***b* must be 1,4 adducts and not 1,2 adducts which would have six chemically different ring carbon atoms with no chemically identical attached hydrogen atoms or methyl groups. Furthermore the symmetry requires the nitro group to be located at C-2 and the acetate at C-5 of the original 2-chloromesitylene, or vice versa. On addition of the shift reagent tris(1,1,1,2,2,3,3-heptafluoro-7,7-[$^2H_6$]dimethyl-4,6-[$^2H_3$]octanedionato)europium(III) (Eu([$^2H_9$]fod)$_3$) the peak attributed to the single methyl group (at C-5 of the original 2-chloromesitylene) moves downfield more rapidly (Table 1) than that of the two symmetrical methyl groups (at C-1 and C-3). The europium and thus the acetate group at which it is complexed must therefore be closer to C-5 than to C-1 and C-3. Thus the 5-acetoxy-2-nitro structure is correct and the alternative 2-acetoxy-5-nitro structure must be rejected. The latter structure is chemically unlikely since it contains a geminal chlorine and acetate. By analogy with the behaviour of related bromo compounds (16), the elements of acetyl chloride would be expected to be readily eliminated from such a structure to form a cyclohexadienone, i.e. 2,4,6-trimethyl-4-nitrocyclohexa-2,5-dienone is the expected product on addition of the nitronium ion at C-5 of 2-chloromesitylene.

The symmetry present in adducts **1***a* and **1***b* is not present in adduct **2***b*: ^1H nmr reveals the presence of four different methyl groups and two different ring protons and ^{13}C nmr shows that the six ring carbon atoms are chemically distinct. The absence of ultraviolet absorption around 255 nm shows that **2***b* is not a conjugated diene. It cannot be a 1,2 adduct and must therefore be a 1,4 adduct. The shift reagent studies (Table 1) show that one proton (relative slope 1.64) must be attached to the same site as acetate and the other (relative slope 0.22) is at least two carbon atoms away. Two of the methyl groups (relative slopes 0.51 and 0.53) must be equidistant from the acetate and closer than the third (relative slope 0.10). These observations can only be accommodated by the 4-acetoxy-1-nitro structure shown for **2***b* but not by any other structure. Diene **2***a* was identified as a diastereoisomer of **2***b* on the basis of its closely similar nmr spectrum. This is supported by the similar chromatographic behaviour: diene **2***a* was eluted in admixture with **2***b*.

2-Chloromesitylene has four chemically different ring carbon atoms at which the nitronium ion might be added and in so doing four different cyclohexadienyl cations, **3**–**6**, would be generated. There are



3 **4** **5**

6 **7** **8**

two (chemically identical) atoms at which nitronium ion can be added to form **3** and similarly for **5**. Thus, there is a statistical factor of 2 favouring the formation of these cations. The four cations are the key intermediates whose formation is the rate-determining step in the reaction paths potentially leading to adduct **2**, adduct **1**, 2-chloro-4-nitromesitylene and 2,4,6-trimethyl-4-nitro-cyclohexa-2,5-dienone, respectively. The relative energies of the transition states leading to these ions, and therefore the stabilities of the ions themselves, which are expected to parallel those of the transition states, should determine the relative yields of the products, due allowance being made for the statistical factors already mentioned. In cations

4 and **5** the methyl groups are similarly (favourably) located with respect to the positive charge: they are *ortho* and *para* with respect to the site of addition and attached to atoms bearing formal positive charges. The resonance (hyperconjugative) as well as the inductive effect of the methyl groups will be operative in stabilization of **4** and **5**. On the other hand the chlorine atoms in **4** and **5** are so located at formally neutral carbon atoms *ipso* and *meta* to the site of addition of nitronium ion that there is little or no opportunity for the stabilizing resonance effect to be called upon and, for this substituent, it is mainly the destabilizing electron-withdrawing inductive effect that is operative. In cations **3** and **6** the reverse situation exists: the chlorine is favourably located at a formally positive carbon (*ortho* or *para*) and its electron-donating resonance effect will be operative and will offset its electron-withdrawing inductive effect, whereas the methyl groups are less favourably located at the formally neutral carbons (*ipso* and *meta*) where the resonance effect of the substituent is reduced. In principle the relative yields of all four potential products are calculable from the appropriate substituent effects for the methyl and chloro groups. In practice, this cannot be done with useful accuracy for all four products, in part because the effect of the methyl groups is so disproportionate in favouring **4** and **5** over **3** and **6** that the relative effect of the methyl groups cannot be estimated reliably and cannot be measured directly from nitration of mesitylene. The relative effect of the methyl groups in directing the nitronium ion to the 1 or 2 position of mesitylene, estimated from the partial rate factors for methyl (17), is a factor of 5000:1 in favour of attack *ortho* and *para* to the three groups. (It is therefore not surprising that mesitylene gives only nitromesitylene on nitration and that the amount of adduct is too small to detect.) This very large factor is partially offset by the effect of the chlorine. From the data of Roberts *et al.* (18) for nitration of chlorobenzene the ratio of the *meta* to *ortho* partial rate factors, $m_f^{Cl}:o_f^{Cl}$, is 1:33 so that, e.g., the ratio of **5**:**3** and thus of chloronitromesitylene to adduct **2** is predicted to be 150:1 (5000:33). This ratio is much larger than the observed ratio of products from these ions, 12:1. In addition to the difficulty of estimating reliably the effects of the methyl groups the substituent effect of the chlorine is known to vary according to the system in which it is measured (2).[4] However, in spite of these difficulties the calculation does lead to the correct qualitative prediction: adduct **2** should be a minor product of the reaction. The relative amounts of adduct **1** and chloronitromesitylene can be calculated with more confidence, since the substituent effect of the methyl groups is the same in the intermediate cations **4** and **5** and thus the relative stability of **4** and **5** is determined only by the effect of the chlorine in the *ipso* and *meta* positions. The ratio[5] $i_f^{Cl}:m_f^{Cl}$ is 1:1.1 (2). Thus, allowing for the statistical factor the ratio of adduct **1** to chloronitromesitylene is predicted to be 1:2.2 whereas the observed ratio is 1:3.5. Likewise, in the comparison of cations **3** and **6** the effect of the methyl groups can be ignored and the amount of adduct **2** to diene should be determined only by the ratio $o_f^{Cl}:p_f^{Cl}$ = 1:4.7 and the statistical factor. The ratio of **2** to dienone is thus predicted to be 1:2.4. No dienone was detected although in one nitration reaction the appropriate absorptions in the ^1H nmr spectra of some column fractions suggested that 2,6-dimethyl-4-nitromethylphenol, the product of rearomatization of the dienone,[6] was present. It is unlikely that the amount of dienone formed, if any, could have exceeded the amount of adduct **2**. However, in spite of the absence of quantitative agreement between calculated and observed product yields both of these lead to the conclusion that the cations **4** and **5** with *ortho* and *para* methyl groups, and *ipso* and *meta* chlorine, respectively are of comparable stability and significantly more stable than cations **3** and **6**, with *meta* and *ipso* methyl groups, and *ortho* and *para* chlorine, respectively.

Reactions of the Adducts

The initial step in the solution reactions of diene adducts (4-nitro-2,5-cyclohexadienyl acetates) involves formation (or reformation) of cyclohexadienyl cations (3, 19). Two competititive pathways exist, one involving loss of nitro group as nitrite and formation of the substituted acetoxycyclohexadienyl cation, the other involving protonation of the acetate group and loss of acetic acid to form the substituted nitrocyclohexadienyl cation. Increased acidity of the reaction medium favours the formation of the nitrocyclohexadienyl cation and products derived from it. The cations that would be generated from adduct **1** by the two competititive paths are **7** and **4**, and from adduct **2**, **8** and **3**. Cations **7** and **8** are the acetoxy

[4]There is also some evidence for a variation in the partial rate factors of the methyl groups. Using partial rate factors more appropriate to polymethylbenzenes (17) the effect of the methyl groups is reduced to a factor of 1500:1 and the factor including the effect of the chlorine is 45:1. The change is in the correct direction but does not account for all of the discrepancy between calculation and observation.

[5]It can be shown that if the reason for the change of partial rate factors with substrate is because of the changes in the Hammett reaction constant for the reaction then partial rate factors of similar magnitude will be similarly affected i.e. a partial rate factor ratio which is close to unity in one system well not be significantly affected by change in the system.

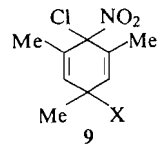
				5-H	0.22
				6-CH_3	0.53

analogs of cations **6** and **5**, respectively. Cation **7**, like **6**, has the methyl and chlorine substituents less favourably located for net stabilization than does **4**, whereas **8**, like **5**, has the substituents more favourably located for net stabilization than does **3**. It follows that ionization of **1** to give **7** should be less effective in competing with the acid-catalysed loss of acetate to give **4** than is ionization of **2** to give **8** in competition with protonation, and loss of acetate from **2** to give **3**. In fact the formation of cation **8** from adduct **2** is so favoured that 3-chloro-2,4,6-trimethylphenyl acetate, the product of deprotonation of **8**, was not only the sole product obtained in the weak acid, acetic acid, but it was also the only product obtained on treatment of **2** with sulfuric acid in methanol and in the much more strongly acidic conditions of trifluoroacetic acid – trifluoroacetic anhydride and boron trifluoride etherate. Only in the most extreme acidic conditions of neat trifluoromethanesulfonic acid was any product other than the aryl acetate obtained. 2-Chloro-4-nitromesitylene (17%) is clearly a product from cation **3**. From **3** a 1,2 shift of the nitro group would give cation **5**, which is in turn rapidly deprotonated to the chloronitromesitylene. Some 3-chloro-2,4,6-trimethylphenyl acetate (11%) was obtained indicating that even under conditions most conducive to reaction via the nitrocyclohexadienyl cation **3** the reaction via the acetoxycyclohexadienyl cation **8** is still competitive. The major product was 3-chloro-2,4,6-trimethylphenol (44%). This could be formed from the corresponding phenyl acetate by hydrolysis and thus indicative of the predominance of reaction via cation **8**. Alternatively its formation could involve solvolysis via cation **3** to form the nitrocyclohexadienol, which then undergoes ionization of the nitro group to form the hydroxycyclohexadienyl cation followed by deprotonation to the phenol. Although this latter pathway does not involve cation **8** itself it would point to the relative ease of formation of the hydroxy analog of cation **8**.

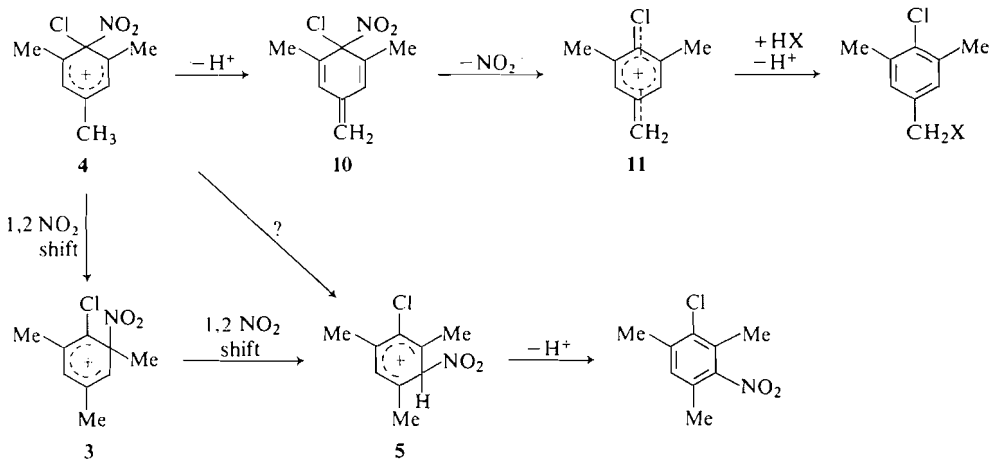
In contrast to the reactions of adduct **2** adduct **1** gave, almost exclusively, with the exception of the reactions carried out in the presence of silver salts, products derived from the nitrocyclohexadienyl cation, in this case **4**. The simplest reaction of cation **4** is combination with a nucleophile to form a pair of diastereoisomeric nitrocyclohexa-2,5-dienyl derivatives, the overall reaction from **1** being replacement of acetate by the S_N1 mechanism. Examples of this reaction are provided by the reactions of adduct **1** in acidified aqueous acetone (to give 4-chloro-1,3,5-trimethyl-4-nitrocyclohexa-2,5-dienol (**9***x*)), in acidified methanol (to give the corresponding methyl ether **9***y*), and with hydrogen chloride (to give the corresponding chloride **9***z*). In less strongly nucleophilic



9

x X = OH
y X = OMe
z X = Cl

conditions nitrocyclohexadienyl cations undergo rearomatization reactions. In the particular case, as in **4**, that the nitrocyclohexadienyl cation contains a methyl or primary or secondary alkyl group attached to the position *para* to the quaternary centre, i.e. attached to a formally positively charged carbon, then the methyl group can be deprotonated to form a triene (**10** from **4**) and eventually substituted by the sequence shown for **4** in Scheme 1. More generally, migration of the nitro group to an unsubstituted position followed by rapid deprotonation gives a nitro substitution product of the original aromatic compound. Both 1,2 and 1,3 nitro migrations have been observed (19, 20) and 2-chloro-4-nitromesitylene could conceivably be formed by either two successive 1,2 shifts or, less likely, by a direct 1,3 shift. The deprotonation of the methyl group to form the triene can apparently compete successfully with the nitro migration process when the solvent is of at least modest basicity. Reaction of **1** in acetic acid gave, as the major component of the product, a mixture of four side-chain derivatives. Some 3-chloro-2,4,6-trimethylphenyl acetate was also formed, presumably from the acetoxycyclohexadienyl cation **7**



SCHEME 1. Formation of side-chain derivatives and 2-chloro-4-nitromesitylene.

by 1,2 shift of the acetoxy group followed by deprotonation, but only trace amounts of 2-chloro-4-nitromesitylene could be detected. Of the four side-chain products 4-chloro-3,5-dimethylphenylnitromethane and 4-chloro-3,5-dimethylbenzyl acetate were identified by comparison (glc, nmr) with authentic samples. The compound with methylene peak at lowest field (δ 5.58 ppm) and which gave the corresponding benzaldehyde on standing is assigned as 4-chloro-3,5-dimethylbenzyl nitrite since this is an expected product of the reaction, the methylene peak of benzyl nitrite is at the corresponding position and also at lower field than that of phenylnitromethane and benzyl nitrate, and it would be expected to give the corresponding benzaldehyde on standing (21). The compound with methylene peak at highest field (δ 4.56 ppm) was always obtained in smallest amount and was most likely the corresponding alcohol. In the series benzyl nitrite, phenylnitromethane, benzyl acetate, and benzyl alcohol the methylene absorption of the alcohol is at highest field. In reactions carried out under varying conditions, neat acetic acid, acetic acid plus 10% acetic anhydride, acetic acid plus 10% water, the dominant side-chain product was, in turn, the nitromethane, nitrite, and acetate. However in all of these reactions the sum of the side-chain derivatives constituted the major proportion of the product. Formation of the different side-chain products involves combination of the chlorodimethylbenzyl cation with (*i*) nitrous acid, at oxygen, to generate, after deprotonation, the nitrite ester; (*ii*) nitrous acid, at nitrogen, to give the phenylnitromethane; (*iii*) acetic acid to give the benzyl acetate; (*iv*) water to give the benzyl alcohol. The nitrous acid required is from the nitrite released in forming the chlorodimethylbenzyl cation **11** and it is possible that cage recombination from a benzyl cation – nitrite anion ion pair could give rise to the nitrite ester and the nitromethane (22).

In more strongly acidic conditions (boron trifluoride etherate, trifluoroacetic acid – trifluoroacetic anhydride) 2-chloro-4-nitromesitylene was the major reaction product. The basicity of these media is lower than that of acetic acid and deprotonation of the cation **4** to form the triene **10** does not compete so effectively with the nitro shift process which results in the conversion of **4** to **5**. Deprotonation of **5** leads to the observed chloronitromesitylene.

In the rearomatization reactions of **1** discussed so far it is evident that the nitro group migrates or is eliminated in preference to chlorine. Perrin (15) has shown that the Cl^+ group is a poorer leaving group than NO_2^+. It is therefore to be expected (as has been assumed in the foregoing) that cation **4** would undergo preferential migration of the nitro group to give the chloronitromesitylene, although it is not possible to distinguish between this process and the similar migration of the chlorine, since both processes would lead to the same product. The nitro group is also preferentially lost as an anion, as in the reactions of adduct **1** in acetic acid. The unimolecular ionization of the nitro group (as nitrite) to give **7** as an intermediate in the formation of 3-chloro-2,4,6-trimethylphenyl acetate is doubtless a lower energy process than the unimolecular ionization of chloride because the latter leads to cation **12** which is much less stable than **7**. Similarly in the formation of

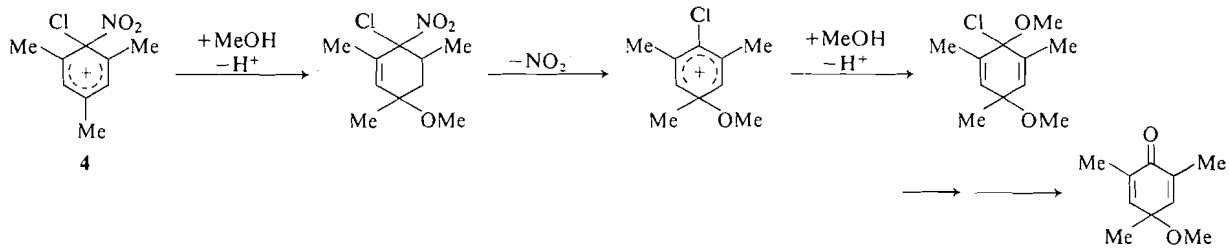
For personal use only.



SCHEME 2

the side-chain derivatives (Scheme 1) the chlorodimethylbenzyl cation **11** should be of lower energy than its nitro analog **13** and this accounts for the preferential loss of the nitro group rather than chlorine from triene **10**, as shown by the fact that the side-chain products retain the nuclear chlorine. The energy difference between the benzyl cations **11** and **13** should be smaller than that between the cyclohexadienyl cations **7** and **12** but even this smaller difference is apparently too large to be offset by the anionic leaving group ability of chlorine (presumably) being greater than that of nitro. In an attempt to bring about the loss of chloride some reactions were carried out in the presence of silver salts: silver nitrate in methanol, silver nitrite in methanol, and silver acetate in aqueous acetone. Although a minor amount of 2,4,6-trimethyl-3-nitro-phenyl acetate was obtained, in which the nitro was retained and the chlorine lost, the major component of the product in all of the reactions was 3-chloro-2,4,6-trimethylphenyl acetate. Presumably the formation of 2,4,6-trimethyl-3-nitrophenyl acetate involves silver-ion-catalysed loss of chloride to give cation **12** followed by the 1,2 shift of the acetate group and deprotonation. In the course of the reaction with silver nitrate in methanol a compound was formed with nmr peaks at δ 1.37, 1.92, and 6.47 ppm representing 3, 6, and 2 protons, respectively. It is likely that this compound was 4 - methoxy - 2,4,6 - trimethylcyclohexa - 2,5 - dienone, formed by the sequence shown in Scheme 2. The nmr spectrum of the compound is similar to that[6] of 2,4,6-trimethyl-4-nitrocyclohexa-2,5-dienone with the peaks of the 4-methyl and ring protons moved upfield. Formation of this compound could account for the component of mass 166 (169 from [$^2H_4$]methanol) observed by glc – mass spectrometry and attributed to 3-methoxy-2,4,6-trimethylphenol. A surprising feature of the reactions carried out in the presence of silver salts is the formation of 2-chloro-5-nitromesitylene. It is unlikely that cation **4** would survive long enough to allow the nitro shift process to occur. Even if some **4** was able to leak into a pathway other than recombination with methanol to give the methyl ether it should be deprotonated to form the triene **10**, and thus side-chain product, in preference to undergoing shift of the nitro group. It seems clear that some process other than that shown in the lower portion of Scheme 1 is required to account for the formation of the chloronitromesitylene under these conditions.

Dienes **1***a* and **1***b* decomposed on standing at ambient temperature and even at −20°C to give mainly 4-chloro-3,5-dimethylphenyl nitromethane. Diene **2***b* decomposed to 3-chloro-2,4,6-trimethylphenyl acetate. These reactions neatly illustrate the preference for **1** to react by initial loss of the acetate group and for **2** to undergo loss of the nitro group. On thermolysis **1** gave a mixture of chloromesitylene, 2-chloro-4-nitromesitylene, and 3-chloro-2,4,6-trimethylphenyl acetate and **2** gave 3-chloro-2,4,6-trimethylphenyl acetate.

Experimental

General experimental methods have been described previously (23). Chloromesitylene was obtained by chlorination of mesitylene in chloroform (24). It had bp 67°C/0.55 kPa and was pure by glc; ir (film): 3025 (w), 2975 (m), 2950 (m), 2920 (m), 2850 (w), 1460 (s), 1365 (w), 1173 (m), 1056 (s), 850 (s), 702 (m), 623 (w); ^{1}H nmr δ: 2.07 (s, 3, 5-CH_3) 2.18 (s, 6, 1-CH_3 and 3-CH_3) 6.57 ppm (s, 2, 4-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 20.5 (1-*C*H$_3$, 3-*C*H$_3$, and 5-*C*H$_3$), 129.2 (*C*-4 and *C*-6), 131.6 (*C*-2), 135.4 (*C*-5), 135.7 ppm (*C*-1 and *C*-3). The assignment of the C-5 and C-1,C-3 absorptions was made on the basis of the intensity difference of the peaks at 135.4 and 135.7 ppm. The 135.4 peak was only half as intense as that at 135.7 ppm.

Nitration of Chloromesitylene in Acetic Anhydride

Preliminary nmr scale experiments established the optimum conditions for the formation of adducts. A cold solution of nitric acid (28.5 g, 0.45 mol) in acetic anhydride (75 cm^3) was added slowly to a vigorously stirred slurry of chloromesitylene (23.3 g, 0.15 mol) in acetic anhydride (150 cm^3) at −78°C. The mixture was allowed to warm to −50°C, maintained at that temperature for 2 h, and cooled again to −78°C. Cold ether (1 dm^3) was added and the reaction mixture was worked up in the usual manner (23) to yield 34 g of pale yellow solid. Integration of the nmr spectrum of the crude product indicated that it was a mixture of diene adducts (30%) and 2-chloro-4-nitromesitylene (70%). Chromatography on alumina[7] at −40°C and elution with pentane and ether–pentane mixtures gave, in the 0–40% ether fractions, 2-chloro-4-nitromesitylene, which was recrystallized from ethanol and had mp 55–57°C (lit. (25) mp 56–57°C); ir (Nujol): 1530 cm^{-1} (NO_2); ^{1}H nmr (CCl_4) δ:

[7]Basic alumia, activity I (Camag) was deactivated with 3% (v/v) of 10% (v/v) aqueous acetic acid.

2.19 (s, 3, 5-CH_3), 2.26 (s, 3, 1-CH_3), 2.33 (s, 3, 3-CH_3), 6.98 ppm (s, 1, 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 15.7 (3-CH_3), 16.9 (5-CH_3), 20.8 (1-CH_3), 127.0 (*C*-5), 127.8 (*C*-3), 130.4 (*C*-6), 133.0 (*C*-2), 138.5 (*C*-1), 150.9 ppm (*C*-4); ms[8] (70 eV) *m/e* (relative intensity): 199* (87, M), 182* (100, *M* − OH), 154* (48), 127* (54), 115 (56), 91 (65). *Anal.* calcd. for $C_9H_{10}ClNO_2$: C 54.14, H 5.01, N 7.02; found: C 53.99, H 4.92, N 7.19.

The 45 and 50% ether fractions afforded one diastereomer of 4-chloro-1,3,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**1***a*). Crystallization from ether–pentane gave colourless crystals mp 46–49°C; ir (Nujol): 1740 and 1240 ($OCOCH_3$), 1560 cm^{-1} (NO_2); ^{1}H nmr (CCl_4) δ: 1.56 (s, 3, 1-CH_3), 1.87 (s, 6, 3-CH_3 and 5-CH_3), 1.94 (s, 3, $OCOCH_3$), 6.04 ppm (s, 2, 2-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 17.5 (3-CH_3 and 5-CH_3), 21.7 ($OCOCH_3$), 26.9 (1-CH_3), 74.0 (*C*-1), 104.7 (*C*-4), 129.8 (*C*-3 and *C*-5), 132.2 (*C*-2 and *C*-6), 170.0 ppm ($OCOCH_3$); ms (chemical ionization, methane) *m/e* (relative intensity): 213* (30, *M* − NO_2), 171* (100), 154* (71), 135 (30), 119 (22). *Anal.* calcd. for $C_{11}H_{14}ClNO_4$: C 50.86, H 5.39, N 5.39; found: C 50.58, H 5.33, N 4.91.

The 55% ether fraction contained as the major constituent the other diastereomer of 4-chloro-1,3,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**1***b*) together with some **1***a*. Diene **1***b* was crystallized from ether–pentane. The colourless crystals had mp 63.5–64.5°C; ir (Nujol): 1745 and 1235 ($OCOCH_3$), 1570 cm^{-1} (NO_2); ^{1}H nmr ($CDCl_3$) δ: 1.52 (s, 3, 1-CH_3), 1.85 (s, 6, 3-CH_3 and 5-CH_3), 2.00 (s, 3, $OCOCH_3$), 6.17 ppm (s, 2, 2-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 17.0 (3-CH_3 and 5-CH_3), 21.8 ($OCOCH_3$), 25.3 (1-CH_3), 74.9 (*C*-1), 103.0 (*C*-4), 129.7 (*C*-3 and *C*-5), 133.6 (*C*-2 and *C*-6), 169.8 ppm ($OCOCH_3$); ms (chemical ionization, methane) *m/e* (relative intensity): 224 (13, *M* − Cl), 213* (25, *M* − NO_2), 171* (100), 154* (62), 135 (13), 119 (10). *Anal.* calcd. for $C_{11}H_{14}ClNO_4$: C 50.86, H 5.39, N 5.39; found: C 50.67, H 5.51, N 5.67.

The 60% ether fractions contained two other dienes, **2***a* and **2***b*, as well as **1***b*. Diene **2***a*, one diastereoisomer of 3-chloro-2,4,6-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate was not isolated but its ^{1}H nmr could be determined from the mixture: (CCl_4) δ: 1.74 (s, 3, 6-CH_3), 1.82 (s, 3, 4-CH_3), 1.90 (s, 3, 2-CH_3), 2.10 (s, 3, $OCOCH_3$), 5.73 (s, 1, 5-*H*), 5.96 ppm (s, 1, 1-*H*).

The 65–100% ether fractions afforded the second diastereoisomer of 3-chloro-2,4,6-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**2***b*), obtained as colourless crystals from ether–pentane, mp 54–56°C; uv (CH_3OH): 217.5 nm (800 m^2 mol^{-1}); ir (Nujol): 1735 and 1225 ($OCOCH_3$), 1550 cm^{-1} (NO_2); ^{1}H nmr ($CDCl_3$) δ: 1.76 (s, 3, 6-CH_3), 1.86 (s, 3, 4-CH_3), 1.92 (s, 3, 2-CH_3), 2.18 (s, 3, $OCOCH_3$), 5.73 (s, 1, 5-*H*), 5.93 ppm (s, 1, 1-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 16.8 (2-CH_3), 19.1 (6-CH_3), 20.7 ($OCOCH_3$), 24.7 (4-CH_3), 69.8 (*C*-1), 89.3 (*C*-4), 125.0 (*C*-5), 128.5 (*C*-3), 134.0 (*C*-2), 136.4 (*C*-6), 170.1 ppm ($OCOCH_3$); ms (chemical ionization, methane) *m/e* (relative intensity): 213* (100, *M* − NO_2), 171* (25), 154* (35), 123 (82). *Anal.* calcd. for $C_{11}H_{14}ClNO_4$: C 50.86, H 5.39, N 5.39; found: C 50.84, H 5.53, N 5.61.

3-Chloro-2,4,6-trimethylphenol and 3-Chloro-2,4,6-trimethylphenyl Acetate

2-Chloro-4-nitromesitylene was reduced with stannous chloride in hydrochloric acid to 3-chloro-2,4,6-trimethylaniline; ir (film): 3460 and 3395 (m, NH_2), 2925 (m), 1627 (s), 1474 (s), 985 cm^{-1} (m); ^{1}H nmr (CCl_4) δ: 2.00 (s, 3, 6-CH_3), 2.13 (s, 3, 2-CH_3), 2.18 (s, 3, 4-CH_3), 3.25 (s, 2, NH_2), 6.60 ppm (s, 1, 5-*H*); the signal at 3.25 ppm disappeared on treatment with D_2O. Sodium nitrite (1.5 g, 22 mmol) in water (10 cm^3) was added slowly to a solution of the arylamine (3 g, 18 mmol) in sulfuric acid (30 cm^3) at 0°C. After 2 h the solution of the diazonium salt was slowly added to a solution of sulfuric acid (20 cm^3) in water at 50°C. After cooling and neutralization with aqueous sodium bicarbonate the phenol was extracted with ether and purified by chromatography, followed by crystallization from ethanol. 3-Chloro-2,4,6-trimethylphenol had mp 84–85°C; ir (Nujol): 3350 cm^{-1} (OH); ^{1}H nmr (CCl_4) δ: 2.17 (s, 3, 6-CH_3), 2.27 (s, 6, 2-CH_3 and 4-CH_3), 4.46 (s, 1, *OH*), 6.79 ppm (s, 1, 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 13.2 (2-CH_3), 15.7 (6-CH_3), 20.0 (4-CH_3), 121.2 (*C*-6), 121.9 (*C*-2), 127.7 (*C*-4), 129.5 (*C*-5), 132.4 (*C*-3), 150.6 ppm (*C*-1); ms (70 eV) *m/e* (relative intensity): 170* (73, M), 155* (24, *M* − CH_3), 135 (100, *M* − Cl), 105 (21), 91 (42), 77 (39). *Anal.* calcd. for $C_9H_{11}ClO$: C 63.53, H 6.47; found: C 63.42, H 6.58.

A solution of the chloromesitol (300 mg) in pyridine (1 cm^3) and acetic anhydride (4 cm^3) was heated under reflux for 30 min. Cooling in ice, dilution with water, and extraction with ether afforded 3-chloro-2,4,6-trimethylphenyl acetate, ir (film): 1770 and 1212 cm^{-1} ($OCOCH_3$); ^{1}H nmr ($CDCl_3$) δ: 2.07 (s, 3, 6-CH_3), 2.17 (s, 3, 2-CH_3), 2.31 (s, 6, 4-CH_3 and $OCOCH_3$), 6.93 ppm (s, 1, 5-*H*); (CCl_4) δ: 2.03 (s, 3, 6-CH_3), 2.13 (s, 3, 2-CH_3), 2.24 (s, 3, $OCOCH_3$), 2.29 (s, 3, 4-CH_3), 6.87 ppm (s, 1, 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 14.0 (2-CH_3), 16.0 (6-CH_3), 20.2 ($OCOCH_3$), 20.3 (4-CH_3), 128.2 (C-6), 128.5 (*C*-2), 129.8 (*C*-5), 132.4 (*C*-3), 133.6 (*C*-4), 146.5 (*C*-1), 169.2 ppm ($OCOCH_3$); ms (70 eV) *m/e* (relative intensity): 212* (10, M), 170* (100, *M* − CH_2CO), 135 (75, *M* − C_2H_2ClO), 91 (70).

2-Chloro-3,5-dimethylbenzyl Acetate and 4-Chloro-3,5-dimethylbenzyl Acetate

A solution of chloromesitylene (5 g, 32 mmol) and *N*-bromosuccinimide (6.4 g, 65 mmol) in carbon tetrachloride (100 cm^3) was heated under reflux and irradiated with uv light for 2 h. The succinimide was filtered, the solution washed with water, dried, and evaporated to give a mixture of side-chain bromides (8.3 g). The crude product (6.2 g, 20 mmol) was heated under reflux with potassium acetate (5.5 g, 50 mmol) in 95% ethanol (100 cm^3) for 2.3 h. After dilution with water and extraction with ether a mixture of side-chain acetates (5 g) was obtained. Chromatography on silica gel and elution with ether–pentane mixtures gave, in the 12.5% ether fraction, 4-chloro-3,5-dimethylbenzyl acetate, ir (film): 1735 and 1215 cm^{-1} ($OCOCH_3$); ^{1}H nmr (CCl_4) δ: 1.96 (s, 3, $OCOCH_3$), 2.27 (s, 6, 3-CH_3 and 5-CH_3), 4.83 (s, 2, CH_2), 6.94 ppm (s, 2, 2-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 20.6 (3-CH_3, 5-CH_3, $OCOCH_3$), 65.6 (CH_2), 128.3 (*C*-2 and *C*-6), 134.0 (*C*-1), 134.4 (*C*-4), 136.3 (*C*-3 and *C*-5), 170.4 ppm ($OCOCH_3$); ms (70 eV) *m/e* (relative intensity): 212* (53, M), 170* (100, *M* − CH_2CO), 153* (56, *M* − CH_3CO_2), 135 (74, *M* − C_2H_2ClO), 117 (47), 91 (22), 77 (20). The 22.5% ether fraction afforded 1,5-bisacetoxymethyl-2-chloro-3-methylbenzene (0.42 g), ir (film): 1740 and 1225 cm^{-1} ($OCOCH_3$); nmr (CCl_4) δ: 2.00 (s, 3, 5-CH_2OCOCH_3), 2.04 (s, 3, 1-CH_2OCOCH_3), 2.34 (s, 3, 3-CH_3), 4.90 (s, 2, 5-CH_2), 5.04 (s, 2, 1-CH_2), 7.12 ppm (s, 2, 4-*H* and 6-*H*).

The 10% ether fraction contained a mixture of monoacetates which were separated on a second column to give 2-chloro-3,5-dimethylbenzyl acetate, ir (film): 1740 and 1230 cm^{-1} ($OCOCH_3$); ^{1}H nmr (CCl_4) δ: 2.00 (s, 3, $OCOCH_3$), 2.23 (s, 3, 5-CH_3), 2.27 (s, 3, 3-CH_3), 5.00 (s, 2, CH_2), 6.92 (broad s, 2, 4-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 20.2 and 20.7 (3-CH_3

[8]Peaks containing ^{35}Cl are marked with an asterisk. Each such peak was accompanied by a ^{37}Cl peak of approximately one-third the intensity.

For personal use only.

and 5-CH_3), 20.7 ($OCOCH_3$), 64.1 (CH_2), 128.0 (*C*-6), 130.7 (*C*-2), 131.5 (*C*-4), 133.4 (*C*-1), 136.1 (*C*-5), 136.3 (*C*-3), 170.4 ppm ($OCOCH_3$); ms (70 eV) *m/e* (relative intensity): 212* (52, M), 177 (68, $M - Cl$), 170* (63, $M - CH_2CO$), 153* (58, $M - OCOCH_3$), 135 (100, $M - C_2H_2ClO$), 119 (79), 117 (83), 91 (38), 77 (44).

Decomposition of Dienes at Ambient Temperature. Pyrolysis

Rearomatization of the dienes occurred on prolonged storage even at −20°C. Dienes **1***a* and **1***b* gave mainly 4-chloro-3,5-dimethylphenylnitromethane which was recrystallised from ethanol, mp 92–93°C; ir (Nujol): 1545 cm^{-1} (NO_2); ^1H nmr ($CDCl_3$) δ: 2.37 (s, 6, 3-CH_3 and 5-CH_3), 5.29 (s, 2, CH_2), 7.12 ppm (s, 2, 2-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 20.7 (3-CH_3 and 5-CH_3), 79.4 (CH_2), 127.3 (*C*-4), 128.9 (*C*-1), 129.7 (*C*-2 and *C*-6), 137.2 (*C*-3 and *C*-5); ms (chemical ionization, methane) *m/e* (relative intensity): 199* (2, M), 181* (4, $M - H_2O$), 164 (1, $M - Cl$), 153* (100, $M - NO_2$); *Anal.* calcd. for $C_9H_{10}ClNO_2$: C 54.14, H 5.01, N 7.02; found: C 54.29, H 5.07, N 7.11.

On prolonged standing at room temperature the colourless solid diene **2***b* gave off brown fumes of nitrogen dioxide and formed a green liquid which contained essentially pure 3-chloro-2,4,6-trimethylphenyl acetate of identical ir, ^1H nmr, and ^{13}C nmr to that of the authentic acetate described above.

A sample of diene **1***a* in carbon tetrachloride was injected into the inlet of a gas chromatograph at 200°C. Analysis by glc and glc – mass spectrometry indicated the following product composition: chloromesitylene (22%) *m/e* (relative intensity): 154* (100, M), 119 (45, $M - Cl$); 2-chloro-4-nitromesitylene (27%), *m/e* (relative intensity): 199* (100, M), 182* (25, $M - OH$); 3-chloro-2,4,6-trimethylphenyl acetate (32%), *m/e*: 212* (37, M), 170* (100, $M - CH_2CO$); minor products 19%. A similar experiment with diene **1***b* gave chloromesitylene (56%), 2-chloro-4-nitromesitylene (14%), and 3-chloro-2,4,6-trimethylphenyl acetate (30%). Similar thermolysis of diene **2***b* gave 3-chloro-2,4,6-trimethylphenyl acetate (97%).

*Reaction of Diene **1** with Hydrogen Chloride*

Hydrogen chloride was bubbled through a solution of diene **1***a* (175 mg, 0.8 mmol) in ether (15 cm^3) at −12°C for 30 min. The reaction mixture was aspirated for 30 min and then neutralised with gaseous ammonia at −15°C. Excess NH_4Cl was filtered off and the solution dried and evaporated to give 3,6-dichloro-1,3,5-trimethyl-6-nitro-1,4-cyclohexadiene; ^1H nmr ($CDCl_3$) δ: 1.77 (s, 3, 3-CH_3), 1.86 (s, 3, 1-CH_3 and 5-CH_3), 6.06 ppm (s, 2, 2-*H* and 4-*H*), together with a smaller amount of aromatic compound, predominantly 2-chloro-4-nitromesitylene. A small peak at 1.72 ppm was likely the 3-CH_3 of the minor diastereoisomer.

Reaction of Diene 2b *with Trifluoromethanesulfonic Acid*

Trifluoromethanesulfonic acid (300 mm^3) at −78°C was added to a solution of diene **2***b* (56 mg, 0.2 mmol) in $CDCl_3$ (75 mm^3) also at −78°C. An immediate reaction occurred. After work-up[9] the products were identified by glc and glc – mass spectrometry (relative retention time, *m/e* of molecular ion, % composition) 1,3,5-trimethylbenzene-2,4-diol (3.5, 152, 12%), 3-chloro-2,4,6-trimethylphenol (4.5, 170*, 44%), 2-chloro-4-nitromesitylene (5.6, 199*, 17%), 3-chloro-2,4,6-trimethylphenyl acetate (6.8, 212*, 11%). Components at 2.5, 4%, and 13.7, 12%, were not identified.

[9]Small-scale reactions were worked up by addition of the solution to methylene chloride, neutralization with gaseous ammonia, drying over magnesium sulfate, followed by evaporation of the solvent.

Reaction of Dienes with Boron Trifluoride

$BF_3{\cdot}OEt_2$ (200 mm^3) was added to diene **1***a* (50 mg, 0.2 mmol) at −78°C. The ^1H nmr spectrum showed that 2-chloro-4-nitromesitylene and 4-chloro-3,5-dimethylphenylnitromethane were formed. When $BF_3{\cdot}OEt_2$ was added to a solution of diene **1***b* in $CDCl_3$ at 0°C only the 2-chloro-4-nitromesitylene was obtained on work-up, identified by nmr.

$BF_3{\cdot}OEt_2$ (300 mm^3) was added to a solution of diene **2***b* (57 mg) in $CDCl_3$ (50 mm^3) at −78°C and the solution allowed to warm to ambient temperature. Only 3-chloro-2,4,6-trimethylphenyl acetate was obtained on work-up (nmr).

Reaction of Dienes with Trifluoroacetic Acid – Trifluoroacetic Anhydride

A mixture of trifluoroacetic acid (150 mm^3) and its anhydride (150 mm^3) was added to diene **1***a* (107 mg, 0.4 mmol) in $CDCl_3$ (75 mm^3) at −78°C and the solution allowed to warm to ambient temperature. ^1H nmr showed that the major product was 2-chloro-4-nitromesitylene, confirmed after work-up by glc.

The same reaction carried out on diene **2***b* gave only 3-chloro-2,4,6-trimethylphenyl acetate, identified by ir, nmr, glc, and mass spectrometry, on work-up.

Reaction of Dienes in Acetic Acid

Diene **1***a* (86 mg, 0.3 mmol) was added to [$^2H_4$]acetic acid and the reaction monitored by ^1H nmr at 35°C. The diene slowly rearomatised ($t_{1/2} \sim 1$ h) to four side-chain derivatives with CH_2 peaks (and approximate composition) at δ: 5.58 (13%), 5.36 (30%, 4-chloro-3,5-dimethylphenylnitromethane), 4.98 (13%, 4-chloro-3,5-dimethylbenzyl acetate), 4.56 ppm (5%), and 3-chloro-2,4,6-trimethylphenyl acetate (38%). When the reaction was repeated using diene **1***b* in a solution of [$^2H_4$]acetic acid (180 mm^3) containing acetic anhydride (20 mm^3) the same products were obtained but the compound with δ 5.58 ppm was now the major product (~35%). The nitromethane and benzyl acetate derivatives were identified by addition of authentic samples and observing enhancement of the appropriate peaks in the nmr spectra. The CH_2 peak at δ 5.58 ppm disappeared on standing the reaction mixture for 3 months and new peaks appeared at 7.6, 7.8, and 9.88 ppm. Rearomatization of diene **1***b* was accompanied by partial isomerization to diene **1***a*. When the reaction was repeated using diene **1***a* in a solution of [$^2H_4$]acetic acid (270 mm^3) containing D_2O (30 mm^3) rearomatization occurred rapidly ($t_{1/2} \approx 20$ min) and the side-chain derivatives with CH_2 peaks at 5.58, 5.36, and 4.98 ppm were again formed as well as the phenyl acetate. The benzyl acetate was the major side-chain product. The CH_2 peak at 5.58 ppm again disappeared when the reaction mixture was allowed to stand for two months and new peaks appeared at 7.6, 7.8, and 9.8 ppm. Analysis of the worked-up reaction mixture by glc – mass spectrometry revealed a compound with $M = 168$, assigned as 4-chloro-3,5-dimethylbenzaldehyde, as well as the 3-chloro-2,4,6-trimethylphenyl acetate, 4-chloro-3,5-dimethylbenzyl acetate, and 4-chloro-3,5-dimethylphenylnitromethane. The last three compounds had the appropriate mass spectra and glc retention times were the same as those of authentic samples. The examination of the spectra of the initial reaction carried out in [$^2H_4$]acetic acid revealed that in this case too the compound with $\delta = 5.58$ disappeared on standing and the peaks attributed to the benzyaldehyde appeared. On work-up the compound with mass 168 was detected by glc – mass spectrometry. The characteristic methyl peaks of 3-chloro-2,4,6-trimethylphenyl acetate were recognised in the nmr spectrum of the worked-up product and the presence of this compound, 4-chloro-3,5-dimethylbenzyl acetate and 4-chloro-3,5-dimethylphenylnitromethane were confirmed by comparison

of glc retention times and glc – mass spectrometry. The benzyaldehyde and phenyl acetate were also detected by glc – mass spectrometry in the worked-up product of the reaction in [$^2H_4$]acetic acid containing acetic anhydride.

Diene **2***b* in [$^2H_4$]acetic acid at 35°C gave very rapidly ($t_{1/2}$ < 5 min) 3-chloro-2,4,6-trimethylphenyl acetate with identical ir, ^{1}H nmr, and glc retention time to an authentic sample.

Reaction with Aqueous Acid in [$^2H_6$]Acetone

A solution of diene **1***a* (53 mg, 0.2 mmol) in aqueous [$^2H_6$]acetone containing 10% (v/v) water and 0.1% sulfuric acid by volume was made up at 0°C and the reaction was observed by nmr at 35°C. After 1 h new absorptions, attributed to the hydroxydiene **9***x*, appeared at δ 1.27 and 1.36 (1-CH_3 of each diastereoisomer), 1.83 (3-CH_3 and 5-CH_3)$_3$, and 6.06 ppm (2-*H*- and 6-*H*). A new acetate peak (CH_3CO$_2$H) appeared at slightly higher field than that of the acetate peak of **1***a*. After 20 h the peak of **1***a* at 1.53 ppm (1-CH_3) had almost completely disappeared. The half-life of the original acetate was ~6 h. The diastereoisomer with 1-CH_3 at 1.27 was present to ca. 50% of that with 1-CH_3 at 1.36 ppm.

Reaction of Dienes with Acidified Methanol

Diene **1***a* (50 mg, 0.2 mmol) was added to a solution of sulfuric acid (6 μmol) in methanol (300 mm^3) at 0°C. Examination by nmr showed that no appreciable reaction occurred at this temperature but exchange was observed when the temperature was raised to 20°C and was more rapid at 30°C. The signal at δ 1.50 ppm associated with the 1-CH_3 of **1***a* decreased and disappeared and was replaced by two signals at 1.22 and 1.31 (1-CH_3 of the isomeric methoxy dienes). Simultaneously the sharp signal at 1.80 (3-CH_3 and 5-CH_3 of **1***a*) broadened (3-CH_3 and 5-CH_3 of isomeric methoxy dienes) the acetate signal at 1.95 was replaced by one at 1.97 (CH_3CO$_2$H) and the latter itself was gradually replaced by a new peak, attributed to methyl acetate formed by esterification of the liberated acetic acid; the signal at 6.07 (2-*H* and 6-*H* of **1***a*) was replaced by signals at 5.83 and 5.87 ppm (2-*H* and 6-*H* of isomeric methoxy dienes). After work-up a 1:1 mixture of the *cis* and *trans* isomers of 4-chloro-1,3,5-trimethyl-4-nitrocyclohexa-2,5-dienyl methyl ether (**9***y*) was obtained, ^{1}H nmr (CDCl$_3$) δ: 1.28 and 1.37 (s, 3 and 3, 1-CH_3), 1.87 (broad s, 6 and 6, 3-CH_3 and 5-CH_3), 3.03 and 3.15 (s, 3 and 3, OCH_3), 5.80 ppm (broad s, 2 and 2, 2-*H* and 6-*H*); ^{13}C nmr (CDCl$_3$) δ_C: 17.1 and 17.4 (3-*C*H$_3$ and 5-*C*H$_3$), 26.6 and 27.4 (1-*C*H$_3$), 52.4 and 52.8 (O*C*H$_3$), 71.9 (*C*-1), 132.3 and 132.6 (*C*-3 and *C*-5), 134.8 and 136.0 (*C*-2 and *C*-6). It was not possible to distinguish with certainty the peaks of *C*-4 (90.4?) from the background. These peaks are expected to be of low intensity.

Reaction of diene **2***b* under the same conditions gave only 3-chloro-2,4,6-trimethylphenyl acetate, identified by ir, nmr, glc, and mass spectrometry.

*Reaction of Diene **1** with Silver Nitrate in Methanol*

Diene **1***a* (79 mg, 0.3 mmol) was added to a solution of silver nitrate (98 mg, 0.6 mmol) in methanol (500 mm^3) at −78°C and the reaction was monitored by ^{1}H nmr at 35°C. Rearomatization occurred rapidly and was accompanied by the exchange of the acetate group for methoxyl as indicated by the development of signals at δ 1.23, 1.33, and 5.8 ppm characteristic of the diastereoisomer mixture of methoxy-nitro adducts. After work-up the nmr spectrum indicated the absence of methylene peaks and therefore of side-chain derivatives. Analysis by glc and glc – mass spectrometry gave major peaks whose structures were assigned from the mass spectra, on the assumption that the basic mesitylene structure was retained, as follows (relative retention time, *m/e* of molecular ion, % composition): 3-methoxy-2,4,6-trimethylphenol (1.5, 166, 15%), 2-chloro-4-nitromesitylene (5.6, 199, 24%), 3-chloro-2,4,6-trimethylphenyl acetate (6.8, 212, 52%), and 2,4,6-trimethyl-3-nitrophenyl acetate (10, 223, 8%). Authentic samples of 2-chloro-4-nitromesitylene and 3-chloro-2,4,6-trimethylphenyl acetate had the same retention time as the respective components assigned these structures.

The experiment was repeated in [$^2H_4$]methanol, which simplified ^{1}H nmr observation of the progress of the reaction. After 50 h aromatic products constituted ca. 80% of the reaction mixture which was worked up and examined by glc and glc – mass spectrometry which indicated the following composition: 3-[$^2H_3$]methoxy-2,4,6-trimethylphenol (1.5, 169, 20%), 2-chloro-4-nitromesitylene (5.3, 199, 21%), 3-chloro-2,4,6-trimethylphenyl acetate (6.5, 212, 45%), 3-nitro-2,4,6-trimethylphenyl acetate (10, 223, 8%), as well as other minor components. Examination of the nmr spectra taken as the reaction proceeded resulted in the following observations: within the first fifteen minutes a substantial amount of rearomatisation occurred, accompanied by the formation of the diastereoisomeric methoxy-nitro dienes (δ 1.23, 1.31, 5.85 ppm) and the disappearance of the acetoxy-nitro diene (δ 1.51, 6.10 ppm); a peak appeared at δ 1.46 ppm and appeared to be associated with a peak at 6.7 ppm since these disappeared again together over a 2 h period; as the peak at 6.7 ppm disappeared a new peak appeared at 6.58 ppm; the methoxy, nitro diene peaks (δ 1.23, 1.31, 5.85 ppm) disappeared over 50 h; the peak at 6.58 ppm is associated with peaks at 1.92 and 1.37 ppm since these peaks appeared together (the 1.92 ppm peak is also present in the acetoxy-nitro diene and the methoxy-nitro dienes and is the absorption of the six protons of the two identical methyl groups attached to the double bonds in these compounds; the peak remained but became sharper as the methoxy-nitro dienes disappeared; similarly, there is an overlap of the 1.31 ppm peak of one methoxy-nitro diene isomer and the 1.37 ppm peak); the last three peaks were also present at 6.47, 1.92, and 1.37 ppm in the worked-up reaction product and integrated for 2, 6, and 3 protons, respectively, appropriate for two ring protons, two methyl groups attached to double bonds, and one methyl group attached to saturated carbon; the diene component constituted 20% of the reaction mixture after work-up. Re-examination of the spectra of the reaction carried out in the nondeuterated methanol supported the foregoing observations.

*Reaction of Diene **1** with Silver Nitrite in Methanol*

Diene **1***a* (94 mg, 0.4 mmol) was added to a solution of silver nitrite (81 mg, 0.5 mmol) in [$^2H_4$]methanol (500 mm^3) at −78°C and the reaction monitored by nmr at 35°C. The changes that ensued parallelled those for the reaction with silver nitrate. After work-up, glc and glc – mass spectrometry gave the following product composition: 3-[$^2H_3$]methoxy-2,4,6-trimethylphenol (1.5, 169, 19%), 2-chloro-4-nitromesitylene (5.3, 199, 22%), 3-chloro-2,4,6-trimethylphenyl acetate (6.5, 212, 51%), 3-nitro-2,4,6-trimethylphenyl acetate (10, 223, 4%).

*Reaction of Diene **1** with Silver Acetate in Acetone*

Silver acetate (38 mg, 0.23 mmol) was added to a solution of diene **1***a* (97 mg, 0.4 mmol) in [$^2H_6$]acetone (500 mm^3) at 0°C and the reaction monitored at 35°C by ^{1}H nmr. The diene was largely rearomatized over 24 h. Work-up and analysis by glc and glc – mass spectrometry gave the following major components: 2-chloro-4-nitromesitylene (5.1, 199, 15%), 3-chloro-2,4,6-trimethylphenyl acetate (6.2, 212, 56%), 3-nitro-2,4,6-trimethylphenyl acetate (10, 223, 23%). The presence of nitro and acetate functions was confirmed by ir. The reaction was repeated with an excess of silver acetate (0.2 mmol of diene,

0.36 mmol of siver acetate) and similar results were obtained: 2-chloro-4-nitromesitylene (5.2, 199, 24%), 3-chloro-2,4,6-trimethylphenyl acetate (6.3, 212, 54%), 3-nitro-2,4,6-trimethylphenyl acetate (10, 223, 15%).

Conformational studies on cyclohexa-1,4-diene derivatives. The crystal and molecular structures of 1,2,4,5-tetraphenyl-3,6-dicarbomethoxycyclohexa-1,4-diene and 1,2-dicarbomethoxy-4,5-dimethylcyclohexa-1,4-diene

M. J. BENNETT AND J. T. PURDHAM[1]

Received July 29, 1977

M. J. BENNETT and J. T. PURDHAM. Can. J. Chem. **56**, 1358 (1978).

1,2,4,5-Tetraphenyl-3,6-dicarbomethoxycyclohexa-1,4-diene crystallizes in the monoclinic space group $I2/a$ (a non-standard setting of $C2/c$) with $a = 20.052(2)$, $b = 5.756(1)$, $c = 22.782(2)$ Å, $\beta = 95.73(1)°$, and $Z = 4$. 1,2-Dicarbomethoxy-4,5-dimethylcyclohexa-1,4-diene crystallizes in the orthorhombic space group *Pbca* with $a = 25.627(2)$, $b = 11.240(1)$, $c = 8.342(1)$ Å, and $Z = 8$. Both structures were solved by direct methods and refined by full matrix least-squares techniques to $R = 0.040$ and $R = 0.036$, respectively. Carbon–carbon double bond lengths are similar in the two compounds (1.326 and 1.333 Å, respectively), but the single bond lengths are significantly longer in 1,2,4,5-tetraphenyl-3,6-dicarbomethoxycyclohexa-1,4-diene (1.518 Å) compared with the 1.493 Å average found in 1,2-dicarbomethoxy-4,5-dimethylcyclohexa-1,4-diene. This and the fact that there are also small deviations from planarity in the former compound are thought to be due to the presence of substituents on the methylenic carbon atoms.

M. J. BENNETT et J. T. PURDHAM. Can. J. Chem. **56**, 1358 (1978).

Le tétraphényl-1,2,4,5 dicarbométhoxy-3,6 cyclohexadiène-1,4 cristallise dans le groupe d'espace $I2/a$ (un arrangement anormal de $C2/c$) avec $a = 20.052(2)$, $b = 5.756(1)$, $c = 22.782(2)$ Å, $\beta = 95.73(1)°$ et $Z = 4$. Le dicarbométhoxy-1,2 diméthyl-4,5 cyclohexadiène-1,4 cristallise dans le groupe d'espace orthorhombique *Pbca* avec $a = 25.627(2)$, $b = 11.240(1)$, $c = 8.342(1)$ Å et $Z = 8$. On a résolu les deux structures par les méthodes directes et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs finales respectives de $R = 0.040$ et $R = 0.036$. Les longueurs des liaisons doubles carbone–carbone sont semblables dans les deux composés (respectivement 1.326 et 1.333 Å) mais les longueurs des liaisons simples sont passablement plus longues dans le tétraphényl-1,2,4,5 dicarbométhoxy-3,6 cyclohexadiène-1,4 (1.518 Å) que dans le dicarbométhoxy-1,2 diméthyl-4,5 cyclohexadiène-1,4 (1.493 Å). Ce résultat et le fait qu'il y a aussi de petites déviations de planarité dans le premier composé seraient probablement dus à la présence de substituants sur les atomes de carbone méthyléniques.

[Traduit par le journal]

The conformation of cyclohexa-1,4-diene has been investigated by various techniques (1–14), with conflicting conclusions being reached as to the planarity of the six-membered ring.

In two independent and conflicting electron diffraction studies of cyclohexa-1,4-diene itself, Dallinga and Toneman (13) concluded that the molecule was essentially planar, but that small deviations leading to the chair form could not be precluded with certainty. The suggested deviations from the plane were less than 0.05 Å. Oberhammer and Bauer (14), on the other hand, obtained a structure with a boat conformation, with a significant deviation from the diene plane for the methylenic type carbon atoms.

Similar conflicting conclusions involving boat and planar conformations have resulted from nmr studies of cyclohexa-1,4-diene derivatives (9–12).

Three other cyclohexa-1,4-diene derivatives have been studied by single crystal X-ray diffraction. The conformations of 1,4-dicarbomethoxycyclohexa-1,4-diene (15, 16) and cyclohexa-1,4-diene-1-glycine (17) were found to be planar within experimental error, but standard deviations on the atomic parameters were such that small deviations from planarity could not be detected. The conformation of diethyl succinyl succinate (18) was also found to be essentially planar, small deviations from planarity being deemed insignificant.

In view of the contradictory conclusions arrived at, regarding the conformation of cyclohexa-1,4-diene and its derivatives, the molecular structures of 1,2,4,5-tetraphenyl-3,6-dicarbomethoxycyclohexa-1,4-diene (TDCD) and 1,2-dicarbomethoxy-4,5-dimethylcyclohexa-1,4-diene (DDCD) were undertaken in order to provide additional evidence concerning the planarity of the cyclohexa-1,4-diene ring system. The preparation and preliminary structure of TDCD have been reported earlier (19).

Experimental Section

1,2,4,5-Tetraphenyl-3,6-dicarbomethoxycyclohexa-1,4-diene

Crystal data:

$C_{34}H_{28}O_4$ fw = 500

Monoclinic, $a = 20.052(2)$, $b = 5.756(1)$, $c = 22.782(2)$ Å, $\beta = 95.73(1)°$, $V = 2616.24$ Å^3, $\rho_o = 1.26(1)$ g/ml, $Z = 4$, $\rho_c = 1.269$ g/ml (20°C; CuKα, $\lambda = 1.54182$ Å).

From film data, the space group was identified as either $I2/a$ or Ia with systematic absences occurring for hkl reflections when $h + k + l = 2n + 1$ and for $h0l$ reflections when $h = 2n + 1$. Since there are four molecules per unit cell, this required that each molecule occupied a special position in the space group $I2/a$ while there were no restrictions for the space group Ia. The successful refinement of the structure later confirmed that the space group was in fact $I2/a$. The standard cell C_2/c was not used because of its very obtuse β angle (134.57°). The equivalent positions for the I_2/a cell are: x,y,z; $\bar{x},\bar{y},\bar{z}$; $x,\bar{y},\frac{1}{2}+z$, $\bar{x},y,\frac{1}{2}-z$; $\frac{1}{2}+x,\frac{1}{2}+y,\frac{1}{2}+z$; $\frac{1}{2}-x,\frac{1}{2}-y,\frac{1}{2}+z$; $\frac{1}{2}+x,\frac{1}{2}-y,z$; $\frac{1}{2}-x,\frac{1}{2}+y,\bar{z}$.

Intensity data were collected on a Picker manual diffractometer. 1940 reflections were measured of which 1065 were considered to be significantly above background ($I > 3\sigma(I)$). These data were corrected for Lorentz and polarization effects. No attempt was made to correct for absorption, since this was considered to be negligible ($\mu = 6.67$ cm^{-1}, crystal dimensions 0.15 mm × 0.07 mm × 0.07 mm). However, a correction for the polarization term in the secondary extinction correction was applied (20). Structure factor amplitudes and standard deviations were then calculated.

The structure amplitudes were converted to normalized structure factors and the phases of 162 of the largest of these were determined by the symbolic addition procedure (21). In the E map calculated from these, a six-membered ring occupying a centre of symmetry at the cell origin was easily detected. Further inspection of this map revealed the positions of all 19 carbon and oxygen atoms.

The coordinates of these atoms were used as input to a structure factor calculation, which gave an R_1 value ($\Sigma(||F_o| - |F_c||)/\Sigma|F_o|$) of 0.273 that reduced to 0.097 after three cycles of full matrix least-squares refinement, in which each observation was assigned a weight equal to the reciprocal of its variance. The calculated phases were used to compute an electron density difference map from which the positions of all the hydrogen atoms in the asymmetric unit, other than the three methyl hydrogens, were determined.

These 11 hydrogen atoms were included in the least-squares refinement and R_1 fell to 0.082. The remaining three hydrogen atoms were located in an electron density difference map calculated using only data for which $\sin\theta/\lambda \leq 0.35$. These were included in all the remaining structure factor calculations.

In four more cycles of least-squares refinement, in which the carbon and oxygen atoms were allowed to refine anisotropically, R_1 fell to 0.043. At this point, the correction was made to the data for secondary extinction and the refinement converged in two more cycles to $R_1 = 0.040$ and R_2 ($[\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$) = 0.042. The largest peak in an electron density difference map computed at the end of the refinement was 0.17 electrons per Å^3.

1,2-Dicarbomethoxy-4,5-dimethylcyclohexa-1,4-diene

Crystal data:

$C_{12}H_{16}O_4$ fw = 224

Orthorhombic, $a = 25.627(2)$, $b = 11.240(1)$, $c = 8.342(1)$ Å, $V = 2405.64$ Å^3, $\rho_o = 1.23(1)$ g/ml, $Z = 8$, $\rho_c = 1.234$ g/ml (20°C; CuKα, $\lambda = 1.54182$ Å).

The compound was prepared by the Diels–Alder reaction betweeen 2,3-dimethyl-1,3-butadiene and dicarbomethoxyacetylene. The impure product was recrystallized from cyclohexane and found to crystallize in the orthorhombic space group $Pbca$, with systematic absences occurring in the $0kl$ data when $k = 2n + 1$, in the $h0l$ data when $l = 2n + 1$, and in the $hk0$ data when $h = 2n + 1$. Intensity data were collected on a Picker FACS I automatic diffractometer. Of the 1501 reflections measured, 1100 were considered to be significantly above background ($I > 2\sigma(I)$). These data were corrected for Lorentz and polarization effects and absorption and extinction were also corrected for ($\mu = 7.73$ cm^{-1}, crystal dimensions 0.35 mm × 0.18 mm × 0.12 mm). The results of these latter calculations indicated that correction for the polarization term in the extinction correction would have sufficed, the absorption term in the extinction correction and the absorption correction itself having little effect.

Structure factor amplitudes and standard deviations were calculated and, from the amplitudes, normalized structure factors were obtained. The phases of 147 of the largest of these were determined by the symbolic addition procedure (21), and in one of the E maps computed the positions of all 16 heavy atoms were located.

A structure factor calculation based upon these coordinates gave a $R_1 = 0.286$ which fell in four cycles of full matrix, least-squares refinement to 0.140. In the refinement, each observation was assigned a weight equal to the reciprocal of its variance. At this point the heavy atoms were allowed to refine anisotropically and two more cycles of refinement reduced R_1 to 0.094.

A difference electron density map was computed, from which the coordinates of all 16 hydrogen atoms were found. These were included in the refinement, but in order to reduce the number of variable parameters the hydrogens of the four methyl groups were included as hindered rotors (22). In four more cycles of refinement, R_1 fell to 0.041.

Absorption and extinction corrections were applied to the data at this stage and in two more cycles, the refinement converged at $R_1 = 0.036$ and $R_2 = 0.036$.[2]

For both compounds the scattering factors for the carbon and oxygen atoms were those of Cromer (23), while for hydrogen those of Mason and Robertson were used (24).

Tables of observed and calculated structure factor amplitudes (Tables 1 and 2) and tables of anisotropic temperature factors (Tables 4 and 6) are available.[3] Tables 3 and 5 give the atomic coordinates of the two compounds. Tables 7–10 give the various bond distances and angles within the two molecules. Table 11 gives the least-squares planes data for the two molecules.[3]

Discussion

The molecular structure of TDCD is shown in Fig. 1. The substance crystallizes with the cyclohexadiene ring occupying a crystallographic inver-

[2]For both structures, apart from certain local programs, the computer programs used were: a locally modified version of SFLS5 by C.T.P. Prewitt; FORDAP, by A. Zalkin, modified by B. Foxman; ORTEP by C. K. Johnson; MGEOM, by J. S. Wood; FAME and MAGIC by R. Dewar and A. Stone.

[3]Copies of the tables of observed and calculated structure factors (Tables 1, 2), anisotropic temperature factors (Tables 4, 6), and least-squares planes (Table 11) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

sion centre, with the plane of the ring almost perpendicular to the *b* axis. Because it occupies an inversion centre, the compound is necessarily in the *anti*-configuration and any deviations from planarity lead to a chair, not a boat form.

The structure of DDCD is illustrated in Fig. 2.

The carbon–carbon double bond lengths within the cyclohexadiene ring are similar in both compounds, as are all internal angles. In TDCD the C(sp^2)—C(sp^2) bond length is 1.326 Å, angles of the type C(sp^2)—C(sp^2)—C(sp^3) average 122.3° and the angle at the methylenic carbon is 115.4°. In DDCD these parameters are 1.333 Å, 122.0°, and 116.0° respectively.

The single bond lengths within the rings, however, are significantly different. In TDCD they average 1.518 Å longer than the 1.493 Å average found in DDCD and also longer than the 1.493 Å average of diethyl succinyl succinate (18) and 1.485 Å in cyclohexa-1,4-diene-1-glycine (17), all of which lack substituents attached to the methylenic carbon atoms.

The ester group in TDCD is attached to a sp^3 hybridized carbon atom, but is unable to attain the preferred conformation with the torsion angle Cβ—Cα—C=O equal or close to zero (25), be-

cause of steric interference by the phenyl rings. This steric interference causes the carbomethoxy group to rotate about the C4—C3 bond, giving a torsion angle of 45.9° for C1′—C3—C4 = O1.

The cyclohexadiene ring of TDCD has small but significant deviations from planarity (Table 11[3]),

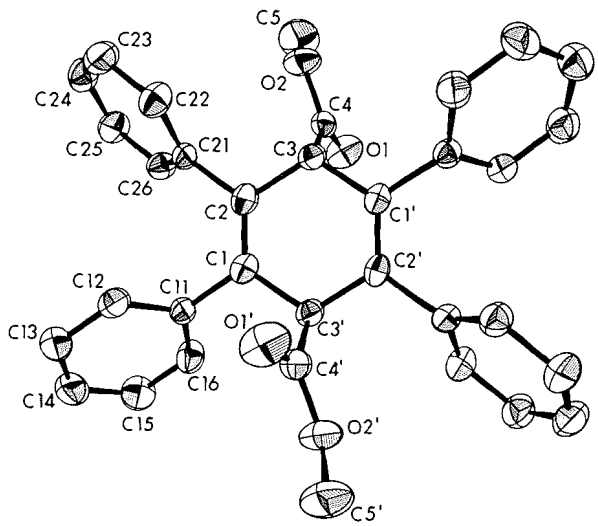

FIG. 1. The molecular structure of 1,2,4,5-tetraphenyl-3,6-dicarbomethoxycyclohexa-1,4-diene.

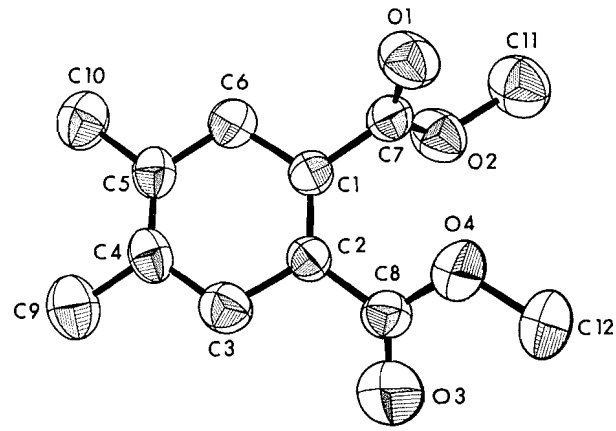

FIG. 2. The molecular structure of 1,2-dicarbomethoxy-4,5-dimethylcyclohexa-1,4-diene.

each of the six atoms lying 0.011 to 0.012 Å out of the least-squares plane. If we define the reference plane as the one containing the four olefinic carbon atoms, then the deviation of the methylenic carbon atom from this plane is 0.037 Å. The dihedral angle between the plane formed by C2C3C1′ and that by C1C2C1′C2′ is 177.4°. This agrees well with the electron diffraction work of Dallinga and Toneman (13), who refined a planar form of cyclohexa-1,4-diene to completion but could not rule out the possibility that other nearly planar conformations, especially the chair form, were present, with a maximum deviation from the plane of 0.05 Å. The results are, however, in disagreement with the electron diffraction study of Oberhammer and Bauer (14), who concluded that the cyclohexa-1,4-diene molecule had a pronounced boat conformation, the dihedral angle

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

between the two halves of the molecule being 159.3°, corresponding to deviations from the diene plane of 0.23 Å for the methylenic type carbon atoms.

However, one must always be cautious when extrapolating results obtained from solid state studies to molecules in the liquid or gaseous phase. While the cyclohexa-1,4-diene ring in this structure is not severely constrained, as it would be in a fused ring system, the question remains as to whether the slight chair conformation is a preferred conformation, or whether it is imposed upon the ring as a result of either intermolecular forces in the condensed phase or intramolecular forces due to the bulky substituents.

The intermolecular forces would appear not to be responsible. The closest C---C contacts occur between phenyl rings and are all greater than 3.74 Å. The closest carbon–hydrogen contacts are about 3.0 Å or more, and hydrogen–hydrogen contacts are 2.54 Å or greater. All these distances are greater than the sum of Van der Waals radii of the atoms concerned. The intermolecular interaction between the carbonyl oxygen and the methylenic carbon atom and its hydrogen atom in the molecule one unit cell away in the direction of the short *b* axis also is not important. The O1---H3 distance of 2.63 Å and the O1---C3 distance of 3.533 Å are both greater than the sum of the Van der Waals radii of the atoms involved, 2.6 Å and 3.1 Å respectively.

Intramolecular forces, on the other hand, are very important in this sterically overcrowded molecule. The phenyl–phenyl repulsions are reduced to some extent by the widening of the C_{phen}—C=C angle to 124.4° from the expected 120°. Of course, they would be further reduced by the adoption of a slight chair conformation by the molecule, since, normally, this would lead to a slightly staggered conformation of C11 and C21 with respect to the olefinic bond. It should be noted that this distortion would be expected to lead to a slight reduction in the π-bond overlap. However, an examination of the olefinic plane (Table 11[3]) indicates that this is not the case in this structure. The deviations of C11 and C21 from the least-squares olefinic plane are not what would be expected for the normal chair structure. The situation is shown, much exaggerated, in Fig. 3*a* and *b*. If we again use the plane defined by the four ethylenic carbon atoms as the reference plane, then C3 and C3′ lie 0.037 Å below and above this plane respectively. For the chair structure, one would expect deviations opposite in sign for C21 and C11 and of more or less the same magnitude as for C3 and C3′. Also, C21 should lie on the opposite side of the plane to C3, and C11 should lie on the opposite side of the plane to

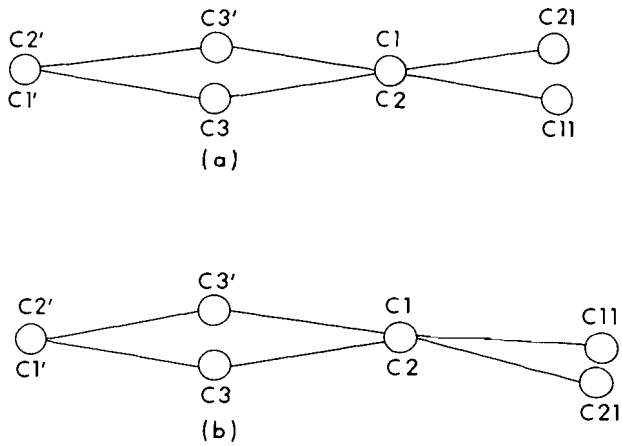

FIG. 3. 1,2,4,5-Tetraphenyl-3,6-dicarbomethoxycyclohexa-1,4-diene: exaggerated Newman projections. (*a*) Theoretical view down C2—C1 bond for chair conformation; (*b*) actual view down C2—C1.

C3′ (Fig. 3*a*). However, the deviations of these atoms from the plane (Table 11[3]) are 0.0015 Å for C11 which is smaller than expected, but in the right direction and 0.044 Å for C21 which is slightly larger than expected, and in the wrong direction (Fig. 3*b*). The atoms C11 and C21, therefore, have assumed positions closer to what one would expect for a completely planar or even boat form of the molecule. This situation lends itself to two possible interpretations; either the inter- and intramolecular forces are attempting to constrain the molecule in a planar or boat conformation and despite this the ring retains a slight chair conformation, or the preferred conformation is that assumed by the substituents and the inter- and intramolecular repulsive interactions are forcing the ring to take up a chair conformation.

Examination of the intramolecular contacts involving the carbomethoxy group greatly favours the latter interpretation. The C4---C21 and C4---C11′ distances are 2.916 and 2.993 Å respectively, while the C4---C2 and C4---C1′ are 2.445 and 2.474 Å, all significantly shorter than the Van der Waals contact of 3.4 Å and are therefore repulsive in nature. Since C4 lies below the plane of the four ethylinic carbon atoms and C11′ and C21, the effect of this repulsive interaction would be to force it even further below the plane, which in turn will cause C3 to move below this plane. The centrosymmetrically related C3′ will be correspondingly raised above the plane, thus leading to a chair conformation.

The lengthening of the single bonds in the cyclohexadiene ring over that found in cyclohexadienes without a methylenic carbon substituent is regarded as further evidence of this repulsive interaction as is

the C3—C4 bond length of 1.537 Å which is 0.02–0.03 Å longer than that commonly observed in the literature for this type of bond.

It is postulated then that for solid state cyclohexadiene derivatives the presence of substituents on the methylenic carbon atoms in the *anti*-configuration leads to a slight chair conformation. Conversely, it would be expected that substituents in the *syn*-configuration would lead to a slight boat conformation and that an absence of methylenic substituents would give a rigorously planar conformation.

It was precisely to test this latter hypothesis that the structure of DDCD was determined. Since this compound bears no methylenic substituents it would be expected to have a planar cyclohexadiene ring. Examination of the least-squares plane (Table 11[3]) shows that this is indeed so, the maximum deviation of any of the six atoms from the plane being 0.004 Å, and C3 and C6 lie 0.004 and 0.008 Å respectively out of the plane defined by the four olefinic carbon atoms.

The crystal and molecular structure of *anti*-1,2,4,5-tetraphenyl-3,6-dicarbomethoxytricyclo[3.1.0.0^{2,4}]hexane

M. J. BENNETT AND J. T. PURDHAM[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 29, 1977

M. J. BENNETT and J. T. PURDHAM. Can. J. Chem. **56**, 1364 (1978).

1,2,4,5-Tetraphenyl-3,6-dicarbomethoxytricyclo[3.1.0.0^{2,4}]hexane crystallizes in the monoclinic space group $P2_1/c$ with $a = 10.044(4)$, $b = 9.500(2)$, $c = 14.172(4)$ Å, $\beta = 104.38(2)°$, and $Z = 2$. Using 1032 unique reflections with $I > 3\sigma(I)$, the structural data were refined by full matrix least-squares techniques to $R = 0.038$. The molecule was found to be in the *anti*-configuration. All bond lengths within the highly strained central tricyclic framework were equal within experimental error and average 1.531 Å.

M. J. BENNETT et J. T. PURDHAM. Can. J. Chem. **56**, 1364 (1978).

Le tétraphényl-1,2,4,5 dicarbométhoxy-3,6 tricyclo[3.1.0.0^{2,4}] hexane cristallise dans le groupe d'espace monoclinique $P2_1/c$ avec $a = 10.044(4)$, $b = 9.500(2)$, $c = 14.172(4)$ Å, $\beta = 104.38(2)°$ et $Z = 2$. Faisant appel à 1032 réflexions uniques avec $I > 3\sigma(I)$, on a affiné les données structurales par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de $R = 0.038$. On a trouvé que la molécule existe dans une configuration *anti*. Toutes les longueurs de liaison à l'intérieur du tricycle central hautement tendu sont égales, à l'intérieur des erreurs expérimentales, à 1.531 Å.

The preparation and preliminary structure of 1,2,4,5-tetraphenyl-3,6-dicarbomethoxy [3.1.0.0^{2,4}]-tricyclohexane (TDTC) were described in an earlier report (1). Similar compounds have been prepared by other workers (2), but the stereochemistry of the product was either undetermined or the assignment uncertain. The X-ray crystal structure analysis of this photodimer of 3-carbomethoxy-1,2-diphenylcyclopropene was undertaken in order to unambiguously establish the stereochemistry of the product and to determine the exact geometry of the novel, strained tricyclic system, since it afforded the opportunity to observe the effect of ring fusion upon the geometry of the cyclopropane and cyclobutane rings.

Experimental

Crystal data:

$C_{34}H_{28}O_4$ fw = 500

Monoclinic, $a = 10.044(4)$, $b = 9.500(2)$, $c = 14.172(4)$ Å, $\beta = 104.38(2)°$, $V = 1309.90$ Å^3, $\rho_o = 1.28(1)$ g/ml, $Z = 2$, $\rho_c = 1.272$ g/ml (20°C; CuKα, $\lambda = 1.54182$ Å).

The molecule crystallized in the space group $P2_1/c$ with systematic absences for the $0k0$ reflections when $k = 2n + 1$ and for the $h0l$ reflections when $l = 2n + 1$. Since there were only two molecules in the unit cell, this required that each molecule occupied a crystallographic inversion centre.

Intensity data were collected on a Picker manual diffractometer. Of the 1958 reflections measured, 1032 were considered to be significantly above background ($I > 3\sigma(I)$). These data were corrected for Lorentz and polarization effects. No attempt was made to correct for absorption, since this was considered negligible ($\mu = 6.67$ cm^{-1}). However, a correction for the polarization term in the secondary extinction correction was applied (19). Structure factor amplitudes and standard deviations were then calculated.

The structure amplitudes were converted to normalized structure factors and the phases of 118 of the large E factors were determined by the symbolic addition procedure (3). All but four of the carbon atoms in the asymmetric unit were located in the E map calculated from these phases.

These 15 atom positions were used as input to a structure factor calculation, and the calculated phases were used to compute an electron density map which revealed the locations of the remaining four carbon atoms.

In the initial stages of the refinement, the phenyl rings were refined as rigid bodies with a C—C distance of 1.397 Å and C—C—C angle of 120°. The function being minimized in the refinement was $\Sigma w(|F_o| - |F_c|)^2$. The weight given to each observation was the reciprocal of its variance.

After three cycles of isotropic refinement by full matrix least squares the R_1 value ($\Sigma(||F_o| - |F_c||)/\Sigma|F_o|$) was 0.153, at which point the rigid body restriction was removed from the phenyl rings. One more cycle of refinement reduced R_1 to 0.136 and a difference electron density map calculated at this point showed clearly the positions of all the hydrogen atoms. These were included in the refinement and the heavy atoms allowed to refine anisotropically. The refinement converged at an $R_1 = 0.040$, R_2 ($[\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$) $= 0.048$. After the data had been corrected for the polarization part of the extinction correction, the refinement reconverged at $R_1 = 0.038$ and $R_2 = 0.038$.[2] The largest peak in

an electron density difference map computed at the end of the refinement was 0.13 electrons per Å^3.

A table of observed and calculated structure factor amplitudes is available (Table 1).[3]

The scattering factors for the carbon and oxygen atoms were those of Cromer (4), and for hydrogen, the scattering factors of Mason and Robertson were used (5).

Discussion

Table 2 gives the atomic coordinates and isotropic temperature factors while the anisotropic thermal parameters are available (Table 3).[3]

The molecule crystallizes on a crystallographic inversion centre and consequently is in the *anti*-configuration and has a planar cyclobutane ring. The carbomethoxy groups are in the *exo*-position. A diagram of the molecule is shown in Fig. 1 and bond lengths and angles are listed in Tables 4 and 5 respectively.

The most outstanding detailed structural feature of the molecule is that all bond lengths within the tricyclohexane framework are equal within experimental error and average 1.531 Å. The bond distances in the cyclopropane ring average 1.530 Å and the bond angles within the ring average 60.0°. The bond lengths in the cyclobutane ring average 1.534 Å and the ring is planar and square. The cyclopropane and cyclobutane rings meet at an angle of 109°.

The bond distances from the tricyclic system to the substituent phenyl and carbomethoxy groups are all about 0.02 Å shorter than is normally found in unstrained systems. This bond shortening to substituent groups is characteristic of highly strained systems and has been observed in many compounds (6–8). The phenyl ring attached to C2 is perpendicular to the plane of the cyclobutane ring while that attached to C1 is skewed. A similar situation is found in tetraphenyl cyclobutane (14).

The bond distances and angles within the carbomethoxy group are all normal, and the group is planar within experimental error. The torsion angle C2—C3—C4—O1 is 38.3°, which means that the carbomethoxy group has not taken up what has been described as the preferred conformation, with the carbonyl group *syn*-planar with the Cα—Cβ bond (9, 10). This may be entirely due to the intramolecular forces preventing the carbomethoxy group from taking up this preferred conformation, but Hoffman and Davidson (11) have pointed out that, for a carbomethoxy group attached to a cyclopropane ring, the *syn*-planar arrangement may not be the preferred conformation. They showed that the low lying Π* orbital of the carbonyl can interact with a pseudo-Π ring orbital, and that this interaction is greatest if the plane containing the carbomethoxy group is perpendicular to the plane of the cyclopropane ring and the C=O is *anti*-planar with respect to the ring C—H bond, that is, if the torsion angle O=C—C—H is 180°. This they termed the bisected conformation and is precisely the conformation found in this compound, the torsion angle O1—C4—C3—HB being 178°.

Fusion of the cyclopropane and cyclobutane rings affects the geometry of both. The bond lengths in the cyclopropane ring average 1.530(4) Å, longer than the 1.510 Å bond lengths found in cyclopropane itself (12), while the bond lengths in the cyclobutane ring average 1.534(4) Å, shorter than the 1.548 Å bond lengths found in cyclobutane itself (13).

In highly strained fused systems, there does seem to be a tendency towards the shortening of cyclobutane bonds and the lengthening of cyclopropane

bonds. In a tricyclo[2.1.0.0^{2,5}]pentane derivative (15), all the bond lengths except one average 1.53 Å. In bicyclo[2.1.0]pentane (16), the cyclopropane bonds average 1.517 Å and the cyclobutane bonds 1.534 Å, while in a bicyclo[3.2.0]heptene derivative, the cyclobutane ring has an average bond length of 1.532 Å (17).

The microwave structure of bicyclo[2.1.0]pentane is interesting from the point of view of comparison with TDTC, since it simply consists of one less cyclopropane ring in the fused system. Suenram and Harmony argue that since the rings have three and four centre Π-like orbitals, it is possible for them to relocate the total available electron density around the system, as needed to satisfy geometrical strain or other factors. The observed changes in bond length, a slight lengthening of the bonds in the cyclopropane ring and shortening of bonds in the cyclobutane ring, would then correspond to a small shift of electron density from the cyclopropane to the cyclobutane ring. The geometry observed in TDTC would certainly support this delocalization argument, especially if the effect of the substituents is taken into account. Hoffman pointed out that depending upon whether the substituents have electron donating or accepting groups, they can greatly affect the geometry of the cyclopropane ring (18). In a norcardiene derivative (6), the lengthening of two bonds in the cyclopropane ring is rationalized on the basis of a delocalization of electrons from the pseudo-Π orbital on the cyclopropane ring into the Π* orbitals of two geminally substituted cyanide groups. The carbomethoxy group in TDTC is in the correct position to maximize this type of pseudo Π–Π* interaction. This further delocalization would explain the even greater lengthening of the cyclopropane bond length in this compound compared with that found in bicyclo[2.1.0]pentane.

Synthesis of *trans*- and *cis*-α-damascone

HSING-JANG LIU, HING-KWOK HUNG,
GEORGE L. MHEHE, AND M. L. DUARTE WEINBERG
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 12, 1977

HSING-JANG LIU, HING-KWOK HUNG, GEORGE L. MHEHE, and M. L. DUARTE WEINBERG. Can. J. Chem. **56**, 1368 (1978).

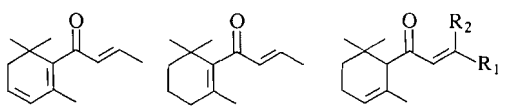
Selective thioketalization of a mixture of keto esters **5** and **6** resulted in the exclusive formation of thioketal **7** and complete recovery of keto ester **6**. Lithium aluminum hydride reduction of thioketal **7** followed by Moffatt oxidation of the resulting alcohol **8** gave aldehyde **10** which on treatment with a mixture of *cis*- and *trans*-1-propenyl magnesium bromide afforded *trans*-alcohol **11** and its *cis* isomer **12**. Manganese dioxide oxidation of alcohol **11** followed by desulfurization gave *trans*-α-damascone (**3**). Similarly, alcohol **12** was converted to *cis*-α-damascone (**4**).

HSING-JANG LIU, HING-KWOK HUNG, GEORGE L. MHEHE et M. L. DUARTE WEINBERG. Can. J. Chem. **56**, 1368 (1978).

La thiocétalisation sélective d'un mélange des céto esters **5** et **6** conduit à la formation exclusive du thiocétal **7** et une récupération complète du céto ester **6**. La réduction par $LiAlH_4$ du thiocétal **7**, suivie par une oxydation de Moffatt effectuée sur l'alcool **8**, fournit l'aldéhyde **10** qui, par traitement avec un mélange *cis* et *trans* des bromures de propène-1 yle magnésium, donne naissance à l'alcool *trans*-**11** et à son isomère *cis*-**12**. L'oxydation de l'alcool **11** par le dioxyde de manganèse, suivie par une désulfurisation, permet d'obtenir l'α-damascone *trans* (**3**). De la même manière, on peut transformer l'alcool **12** en α-damascone *cis* (**4**).

[Traduit par le journal]

β-Damascenone (**1**) (1-5) and β-damascone (**2**) (2, 6) are highly odoriferous compounds found in nature as trace components in the essential oils of several plant species. Because of their industrial importance and limited availability from natural sources, much attention (1, 7–15) has been drawn to the synthesis of these ketones as well as their structurally related compounds which are of equal industrial interest. Several syntheses of *trans*-α-damascone (**3**) and of *cis*-α-damascone (**4**) have previously been reported involving modifications of α-cyclocitral (1) or α-ionone (7, 11–13). In this paper we describe a full account of an efficient synthesis of **3** and **4** without relay (16).



1 **2** **3** $R_1 = CH_3$; $R_2 = H$
4 $R_1 = H$; $R_2 = CH_3$

Keto ester **5** was chosen as the starting compound since it possesses the three methyl groups of the target molecules **3** and **4** as well as suitable functionalities for subsequent transformations. Several methods are available for the preparation of **5** (17–20). The procedure of Rubinstein (17) was adapted for its simplicity. Although it was reported that a single isomer was obtained, the BF_3-catalysed condensation of acetone and ethyl acetoacetate under the described conditions gave, in our hand, a mixture of the desired keto ester **5** and its positional isomer **6** in a ratio of ca. 2:1. Attempts to separate these two isomers by distillation were fruitless. A similar mixture was also obtained previously by Surmatis *et al.* (20), using zinc chloride as a catalyst. They found that **6** could be selectively hydrolyzed by heating the mixture with zinc chloride in ethanol and water to facilitate the separation of **5**. Efforts made toward this end did not result in substantial change of the mixture composition. The desired compound **5** could however be separated from its isomer **6** by extensive column chromatography as noted (20) and its thioketalization gave rise to the thioketal **7** in quantitative yield. A more convenient procedure involves the treatment of the mixture of **5** and **6** with 1,2-ethanedithiol and boron trifluoride etherate at 0°C for 7 h. Under these reaction conditions, keto ester **5** underwent thioketal formation exclusively and quantitatively whereas **6** remained totally unchanged.

The conversion of thioketal **7** into ketones **3** and **4** requires the removal of the thioketal group and the modification of the ester substituent. The required side chain was first installed. Lithium aluminum hydride reduction of thioketal **7** afforded crystalline alcohol **8** in 82% yield. Moffatt oxidation of alcohol **8** using dicyclohexylcarbodiimide, dimethyl sulfoxide, trifluoroacetic acid, and pyridine (21) produced a substantial quantity of the dehydration product **9**.

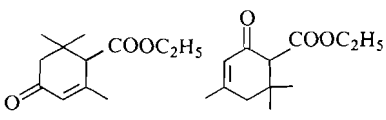
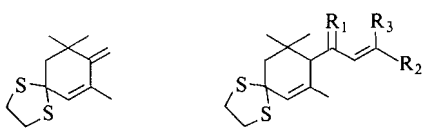
An 80% yield of the desired aldehyde **10** could however be obtained when phosphoric acid (22) was substituted for trifluoroacetic acid and pyridine. Subsequent treatment of aldehyde **10** with propenylmagnesium bromide (1) derived from a mixture of *cis*- and *trans*-1-bromopropene (ca. 1:1) gave a 93% yield of the isomeric alcohols **11** and **12** in approximately equal amounts. It is noted that, in principle, each of these isomers, if so desired, can be specifically prepared by the use of the stereochemically homogeneous reagent. Indeed, when aldehyde **10** was subjected to treatment with *trans*-1-propenyllithium (23), alcohol **11** was formed exclusively. This transformation also facilitated the differentiation of the isomeric pair **11** and **12** at this stage. Oxidation of alcohol **11** with a 30-fold (by weight) excess of manganese dioxide (24) in methylene chloride afforded an 85% yield of enone **13** whose nmr spectrum showed a large coupling constant of 15 Hz for the two vicinal vinylic protons at δ 6.80 and 6.21, confirming the *trans* nature of the conjugated double bond. Upon oxidation under the same conditions, alcohol **12** gave a 45% yield of the expected *cis*-enone **14** and a 31% yield of the *trans* isomer **13**.[1] Interestingly, when the oxidation of **12** was carried out using a lesser amount (12-fold excess) of manganese dioxide, it resulted in the exclusive formation of **14** in 91% yield.

The thioketal groups of **13** and **14** were removed by brief treatment with W-2 Raney nickel (25) which was deactivated in advance in refluxing acetone. Under these conditions, enone **13** gave exclusively



5 **6**

7 R = $COOC_2H_5$
8 R = CH_2OH
10 R = CHO



9

11 R_1 = H,OH; R_2 = CH_3; R_3 = H
12 R_1 = H,OH; R_2 = H; R_3 = CH_3
13 R_1 = O; R_2 = CH_3; R_3 = H
14 R_1 = O; R_2 = H; R_3 = CH_3

[1]The required isomerization most likely occurred before the oxidation since further treatment of *cis*-enone **14** with manganese dioxide under the same conditions did not produce any detectable amount of this compound.

trans-α-damascone (**3**) in 56% yield whereas enone **14** afforded equal amounts of *trans*- and *cis*-α-damascone (**3** and **4**)[2] in a total yield of 64%. The ir, nmr, and mass spectra of the two α-damascones thus obtained were in agreement with those reported in the literature (1, 7).

Experimental

General

Mass spectra were recorded on AEI MS-50, MS-9 and MS-2 mass spectrometers. Infrared spectra were obtained using Perkin-Elmer Models 457 and 337 spectrometers. Nuclear magnetic resonance spectra were recorded on Varian A-60 and HR-100 spectrometers, using tetramethylsilane as internal standard. Elemental analyses were performed by the microanalytical laboratory of this department. Melting points were determined on Kofler hot stage apparatus and are uncorrected.

4-Carbethoxy-3,5,5-trimethyl-2-cyclohexen-1-one (5) and 6-Carbethoxy-3,5,5-trimethyl-2-cyclohexen-1-one (6)

The procedure of Rubinstein (17) was used for the boron trifluoride catalysed condensation of ethyl acetoacetate and acetone. The product (55.9 g from 134 g of ethyl acetoacetate) was shown by the nmr spectrum to be a mixture of **5** and **6** in a ratio of ca. 2:1. A sample of the mixture (500 mg) was separated by column chromatography on silica gel. Elution with a solution of 10% ether in Skelly B gave 120 mg of **6** (faster moving) and 230 mg of **5** (20).

8-Carbethoxy-7,9,9-trimethyl-1,4-dithiospiro[4.5]dec-6-ene (7)

From Pure 5

At 0°C, to a solution of **5** (130 mg, 0.62 mmol) in 1,2-ethanedithiol (0.6 ml), was added boron trifluoride etherate (0.1 ml). The resulting solution, after stirring at room temperature for 16 h, was poured into ice-cold 2 *N* aqueous sodium hydroxide (25 ml) and extracted with chloroform. The chloroform solution was washed with water, dried ($MgSO_4$), filtered, and concentrated. Column chromatography of the residue on silica gel, using benzene as eluent, gave **7** (176 mg, 99%): ir (film): 1732 (ester) and 1665 cm^{-1} (double bond); nmr (CCl_4) δ: 5.63 (broad s, 1H, =CH—), 4.09 (q, 2H, J = 7 Hz, —OCH_2—), 3.28 (s, 4H, —SCH_2CH_2S—), 2.63 (d, 1H, J = 14 Hz, —C*H*(H)—), 2.52 (s, 1H, —CHCO—), 1.97 (d, 1H, J = 14 Hz, —C*H*(H)—), 1.66 (broad, s 3H, =CCH_3), 1.24 (t, 3H, J = 7 Hz, —OCH_2CH_3), 1.05 (s, 3H, —CH_3), and 0.95 (s, 3H, —CH_3); ms M^+ calcd. for $C_{14}H_{22}O_2S_2$: 286.10613; found: 286.10606.

From the Mixture of 5 and 6

At 0°C, a mixture of **5** and **6** (5 g, 23.8 mmol) obtained from the condensation reaction (*vide supra*) was dissolved in 1,2-ethanedithiol (20 ml) and boron trifluoride etherate (2 ml) was added. After stirring at the same temperature for 7 h, the reaction mixture was worked up according to the procedure described above to give an oily product which was purified by column chromatography on silica gel. Elution with benzene gave **7** (4.23 g, ~100% based on **5**). Further elution with benzene resulted in the recovery of **6** (1.45 g).

8-Hydroxymethyl-7,9,9-trimethyl-1,4-dithiospiro[4.5]-dec-6-ene (8)

Lithium aluminum hydride (990 mg, 26.05 mmol) was

[2]We have not been able to effect the desulfurization of **14** without partial isomerization of the double bond.

For personal use only.

slowly added to a well stirred solution of **7** (5 g, 17.48 mmol) in ether (60 ml) at −78°C. Stirring was continued under an atmosphere of nitrogen at room temperature overnight. Methanol was added dropwise until the evolution of hydrogen gas ceased. Water and saturated aqueous ammonium chloride (30 ml each) were added. The mixture was acidified with 1 *N* hydrochloric acid to ~p*H* 2 and extracted with chloroform. The extracts were washed with water and combined. Drying ($MgSO_4$), filtration, and concentration gave the crude product. Purification of the crude product by silica gel column chromatography using pentane–benzene (1:1) as eluent gave **8** (3.4 g, 82%): mp 46–47°C (ether); ir ($CHCl_3$): 3430 (alcohol) and 1650 cm^{-1} (double bond); nmr (CCl_4) δ: 5.64 (m, 1H, —CH=), 3.65 (m, 2H, —OCH_2—) 3.26 (s, 4H, —SCH_2CH_2S—), 1.79 (d, 3H, J = 2 Hz, =CCH_3), 1.05, and 1.08 (both s, 3H each, —$C(CH_3)_2$); ms M^+ calcd. for $C_{12}H_{20}OS_2$: 244.0955; found: 244.0952. *Anal.* calcd. for $C_{12}H_{20}OS_2$: C 58.97, H 8.25, S 26.24; found: C 59.15, H 8.16, S 26.07.

Alcohol **8** was found to be unstable, deteriorating when stored in chloroform over magnesium sulfate at room temperature overnight to give diene **9**: ir (film): 1670 and 1598 cm^{-1} (double bonds); nmr (CCl_4) δ: 5.63 (broad s, 1H, =CH—), 4.88 (broad s, 2H, =CH_2), 3.18 (s, 4H, —SCH_2CH_2S—), 2.17 (s, 2H, —CH_2—), 1.73 (d, 3H, J = 1.5 Hz, =CCH_3), 0.90 (s, 6H, —$C(CH_3)_2$); ms M^+ calcd. for $C_{12}H_{18}S_2$: 226.08519; found: 226.08496.

*8-Formyl-7,9,9-trimethyl-1,4-dithiospiro[4.5]dec-6-ene (**10**)*

To a solution of **8** (153 mg, 0.63 mmol) in dimethyl sulfoxide (0.7 ml), were added a solution of dicyclohexylcarbodiimide (400 mg, 1.94 mmol) in benzene (0.35 ml) and a solution of 85% phosphoric acid (4 μl) in dimethyl sulfoxide (0.4 ml). The reaction mixture was stirred at room temperature under a nitrogen atmosphere for 20 h. Ethyl acetate (1.5 ml) and a solution of oxalic acid (153 mg, 1.21 mmol) in methanol (3 ml) were added sequentially and the resulting mixture after stirring at room temperature for 30 min was filtered. The filtrate was added to water and extracted with chloroform. The chloroform solution after washing with saturated aqueous sodium bicarbonate, was dried over magnesium sulfate, filtered, and concentrated. The crude product thus obtained was subjected to preparative thin-layer chromatography using silica gel as adsorbant and a solution of 20% ether in petroleum ether as eluent to give **10** (122 mg, 80%): mp 62–63°C (ether); ir (film): 2730, 1715 (aldehyde), and 1648 cm^{-1} (double bond); nmr (CCl_4) δ: 9.39 (d, 1H, J = 5 Hz, —CHO), 5.79 (m, 1H, =CH), 2.39 (s, 4H, —SCH_2CH_2S—), 2.46, 2.19 (both d, 1H each, J = 15 Hz, —CH_2—), 2.28 (d, 1H, J = 5 Hz, —CHCHO), 1.67 (d, 3H, J = 1.5 Hz, =CCH_3), 1.07 and 1.04 (both s, 3H each, —$C(CH_3)_2$); ms M^+ calcd. for $C_{12}H_{18}OS_2$: 242.0799; found: 242.0799. *Anal.* calcd. for $C_{12}H_{18}OS_2$: C 59.46, H 7.48, S 26.45; found: C 59.52, H 7.50, S 26.09.

trans- *(**11**) and* cis-*1-(2,6,6-Trimethyl-4,4-ethylenedithio-2-cyclohexenyl)-2-buten-1-ol (**12**)*

Using trans- *and* cis-*1-Propenylmagnesium Bromide*

To a suspension of magnesium turnings (60 mg, 2.47 g-atom) in tetrahydrofuran (6 ml), was added a solution of *cis*- and *trans*-1-bromo-1-propene (ca. 1:1; obtained from Aldrich; 0.25 ml) in tetrahydrofuran (1 ml). The mixture was refluxed under a nitrogen atmosphere for 45 min and cooled to −10°C. A solution of **10** (418 mg, 1.73 mmol) in tetrahydrofuran (5 ml) was introduced. After stirring at −5°C for 2 h and at room temperature for an additional 2 h, the reaction mixture was filtered. The filtrate was poured into saturated aqueous ammonium chloride and extracted with chloroform. Work-up of the extracts in the usual manner gave an oil which was purified by silica gel preparative thin-layer chromatography. Elution with ether – petroleum ether (1:1) gave **11** (220 mg, 45%; faster moving) and **12** (234 mg, 48%). Alcohol **12**, mp 93–94°C (ether), showed the following spectral data: ir (CCl_4): 3540 (alcohol) and 1650 cm^{-1} (double bond); nmr (CCl_4) δ: 5.79 (d, 1H, J = 1.5 Hz, —C=CH), 5.38 (m, 2H, —CH=CH—), 4.68 (m, 1H, —CHOH), 3.24 (s, 4H, —SCH_2CH_2S—), 1.79 (d, 3H, J = 1.5 Hz, =CCH_3), 1.67 (d, 3H, J = 5 Hz, =$CHCH_3$), 1.11 and 1.01 (both s, 3H each, —$C(CH_3)_2$); ms M^+ calcd. for $C_{15}H_{24}OS_2$: 284.1269; found: 284.1251. *Anal.* calcd. for $C_{15}H_{24}OS_2$: C 63.33, H 8.50, S 22.54; found: C 63.25, H 8.38, S 22.39.

The following spectral data were obtained for **11**: ir (film): 3470 (alcohol) and 1645 cm^{-1} (double bonds); nmr (CCl_4) δ: 5.71 (broad s, 1H, —C=CH—), 5.52 (m, 2H, —CH=CH—), 4.36 (m, 1H, —CHOH), 3.27 (s, 4H, —SCH_2CH_2S—), 1.75 (d, 3H, J = 2 Hz, =CCH_3), 1.67 (m, 3H, =$CHCH_3$), 1.05 and 0.99 (both s, 3H each, —$C(CH_3)_2$); ms M^+ calcd. for $C_{15}H_{24}OS_2$: 284.1269; found: 284.1255.

Using trans-*1-Propenyllithium*

At −10°C, to a solution of **10** (90 mg; 0.37 mmol) in ether (10 ml), was added a 0.37 *N* solution of *trans*-1-propenyllithium (23) in ether (2 ml, 0.74 mmol). The resulting solution was stirred under an atmosphere of argon for 20 min. Methanol (2 ml) was added and the mixture was poured into saturated aqueous ammonium chloride solution and extracted with ether. The crude product obtained after the usual work-up of the extracts was purified by silica gel preparative thin-layer chromatography with ether – petroleum ether (1:1) elution to give **11** (70 mg, 67%).

*7,9,9-Trimethyl-8-(*trans-*1-oxo-2-butenyl)-1,4-dithiospiro[4.5]dec-6-ene (**13**)*

Alcohol **11** (600 mg, 2.11 mmol) was dissolved in methylene chloride (120 ml) and activated manganese dioxide (18 g) was added. The mixture was stirred at room temperature for 10 h and filtered. Concentration of the filtrate gave an oil. Preparative thin-layer chromatography (silica gel) of the oil eluted with a solution of 20% ether in *n*-pentane afforded **13** (501 mg, 85%): ir (film): 1685 (ketone), 1665 (double bond), and 1625 cm^{-1} (double bond); nmr (CCl_4) δ: 6.80 (qd, 1H, J = 15, J' = 6.5 Hz, =$CHCH_3$), 6.21 (qd, 1H, J = 15, J' = 1.5 Hz, —COCH=), 5.69 (broad s, 1H, —C=CH—), 3.29 (s, 4H, —SCH_2CH_2S—), 1.90 (dd, 3H, J = 6.5, J' = 1.5 Hz, =$CHCH_3$), 1.60 (d, 3H, J = 2 Hz, =CCH_3), 1.07 and 0.86 (both s, 3H each —$C(CH_3)_2$); ms M^+ calcd. for $C_{15}H_{22}OS_2$: 282.1113; found: 282.1113. *Anal.* calcd. for $C_{15}H_{22}OS_2$: C 63.78, H 7.85, S 22.70; found: C 63.83, H 7.72, S 22.51.

*Manganese Dioxide Oxidation of **12***

(*A*) Activated manganese dioxide (3.7 g) was added to a solution of **12** (300 mg, 1.06 mmol) in methylene chloride (80 ml). The reaction mixture was stirred at room temperature for 6 h. Filtration and concentration gave an oil which was purified by preparative thin-layer chromatography on silica gel. Elution with a solution of 20% ether in *n*-pentane afforded

For personal use only.

7,9,9-trimethyl-8-(*cis*-1-oxo-2-butenyl)-1,4-dithiospiro[4.5]-dec-6-ene (**14**) (273 mg, 91%); ir (film): 1680 (ketone), 1655 (double bond), and 1610 cm^{-1} (double bond); nmr (CCl_4) δ: 6.16 (m, 2H, —CH=CH—), 5.67 (broad s, 1H, =CH—), 3.26 (s, 4H, $-SCH_2CH_2S-$), 2.07 (m, 3H, $=CHCH_3$), 1.63 (d, 3H, J = 2 Hz, $=CCH_3$), 1.07 and 0.99 (both s, 3H each, $-C(CH_3)_2$); ms M^+ calcd. for $C_{15}H_{22}OS_2$: 282.1113; found: 282.1112. *Anal.* calcd. for $C_{15}H_{22}OS_2$: C 63.78, H 7.85, S 22.70; found: C 64.15, H 7.74, S 22.62.

(*B*) A mixture of **12** (900 mg, 3.17 mmol) and activated manganese dioxide (27 g) in methylene chloride (150 ml) was stirred at room temperature for 11 h. Work-up of the reaction in the usual manner followed by preparative thin-layer chromatography (silica gel; 20% ether in *n*-pentane elution) of the crude product gave 402 mg (45%) of **14** and 277 mg (31%) of **13**.

trans-α-*Damascone (3)*

A suspension of W-2 Raney Nickel (25) (2 ml) in acetone (5 ml) was refluxed for 8 min. After acetone was removed, a solution of **13** (52 mg, 0.18 mmol) in 98% ethanol (10 ml) was added and the resulting mixture was stirred at room temperature for 10 min. Filtration and concentration followed by preparative thin-layer chromatography of the crude product on silica gel with ether – petroleum ether (1:9) elution gave **3** (20 mg, 56%): ir (film): 1690 (ketone), 1662 (double bond), and 1628 cm^{-1} (double bond); nmr (CCl_4) δ: 6.77 (qd, 1H, J = 15.5, J' = 6.5 Hz, $=CHCH_3$), 6.18 (qd, 1H, J = 15.5, J' = 1.5 Hz, —COCH=), 5.52 (m, 1H, =CH—), 2.75 (broad s, 1H, —CHCO—), 1.88 (dd, 3H, J = 6.5, J' = 1.5 Hz, $=CHCH_3$), 1.55 (t, 3H, J = 1.5 Hz, $=CCH_3$), 0.92, and 0.83 (both s, 3H each), $-C(CH_3)_2$); ms M^+ calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1514.

cis-α-*Damascone (4)*

A solution of **14** (60 mg, 0.21 mmol) in 98% ethanol (10 ml) was added to the deactivated (by the same procedure described in the previous experiment) W-2 Raney nickel (2 ml) and the resulting mixture was stirred at room temperature for 1.5 h. The mixture was filtered and the filtrate concentrated. Preparative thin-layer chromatography of the oily product on silica gel using a solution of 10% ether in *n*-pentane as eluent gave **3** (faster moving; 13 mg, 32%) and **4** (13 mg, 32%). *cis*-α-Damascone (**4**) thus obtained showed the following spectral data: ir (film): 1685 (ketone), 1673 (double bond), and 1615 cm^{-1} (double bond); nmr (CCl_4) δ: 6.14 (m, 2H, —CH=CH—), 5.50 (m, 1H, =CH—), 2.67 (broad s, 1H, —CHCO—), 2.05 (d, 3H, J = 6 Hz, $=CHCH_3$), 1.55 (t, 3H, J = 1.5 Hz, $=CCH_3$), 0.91 and 0.85 (both s, 3H each $-C(CH_3)_2$); ms M^+ calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1512.

Field desorption mass spectrometry of carboxylic acids: characteristic spectra and analysis of mixtures and impure samples[1]

GORDON WALTER WOOD,[2] EMILY JANE OLDENBURG, PUI-YAN LAU, AND DONNA LEE WADE

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received November 28, 1977

GORDON WALTER WOOD, EMILY JANE OLDENBURG, PUI-YAN LAU, and DONNA LEE WADE. Can. J. Chem. **56**, 1372 (1978).

Field desorption mass spectra were obtained for a variety of saturated and unsaturated carboxylic acids containing 12 or more carbons. At best anode temperature molecular ions were dominant and small peaks representing $[M + 1]^+$, $[2M + 1]^+$, $[M - 17]^+$, and $[M - 44]^+$ were present in several compounds. At higher temperatures several novel ions were found, including one corresponding to $[2M + 1 - 18]^+$ which may represent anhydride formation. In a mixture of *cis*-5-eicosenoic and elaidic acids each molecular ion desorbed as expected but at higher temperatures the three possible anhydride ions appeared, with the cross product $[M_1 + M_2 + 1 - H_2O]^+$ as the base peak. Isomeric hydroxystearic acids (2-OH, 12-OH, 17-OH) gave predominantly ions in the molecular ion region with some differences in spectra which may relate to structure. Apparent polyester formation has been observed in 3-hydroxypropanoic acid where ions of the general formula $[xM - (x - 1)H_2O + H]^+$ with $x = 2, 3, \ldots 13$ were found. Several other hydroxyacids show dimer formation and lactic acid has ions up to $x = 5$ in the above formula. Two of four technical grade dicarboxylic acids tested were seriously contaminated by sodium ions and gave useful spectra only after extraction by dibenzo-18-crown-6 ether. After this treatment both adipic and azelaic acid have $[M + 1]^+$ as base peak, although adipic acid decarboxylates readily ($[M - 44]^+ = 74\%$). Other technical grade acids showed the presence of homologues and related structures as impurities.

GORDON WALTER WOOD, EMILY JANE OLDENBURG, PUI-YAN LAU et DONNA LEE WADE. Can. J. Chem. **56**, 1372 (1978).

On a obtenu les spectres de masse par désorption de champ pour un certain nombre d'acides carboxyliques saturés et insaturés contenant au moins 12 atomes de carbone. Dans les meilleures conditions de température d'anode, des ions moléculaires sont prédominants et des petits pics représentant $[M + 1]^+$, $[2M + 1]^+$, $[M - 17]^+$ et $[M - 44]^+$ sont présents dans plusieurs composés. A des températures plus élevées, on a trouvé plusieurs nouveaux ions y compris un ion correspondant à $[2M + 1 - 18]^+$ qui peut représenter la formation de l'anhydride. Dans un mélange d'acides eicosène-5 oïque *cis* et élaidique, il y a, tel que prévu, une désorption de chaque ion moléculaire; toutefois à des températures plus élevées, les ions des trois anhydrides possibles se forment avec le produit croisé $[M_1 + M_2 + 1 - H_2O]^+$ comme pic de base. Les acides hydroxystéariques isomères (OH-2, OH-12, OH-17) conduisent d'une façon prédominante à des ions dans la région de l'ion moléculaire avec quelques différences dans les spectres qui peuvent être dues à leurs structures. Dans le cas de l'acide hydroxy-3 propanoïque, on a observé une formation apparente de polyesters indiqués par la présence d'ions de formule générale $[xM - (x - 1)H_2O + H]^+$ où $x = 2, 3 \ldots 13$. Plusieurs autres hydroxyacides semblent conduire à la formation de dimères; dans le cas de l'acide lactique on a observé la présence d'ions allant jusqu'à $x = 5$ dans la formule mentionnée ci-dessus. Deux des quatres acides dicarboxyliques de pureté commerciale qui ont été examinés étaient sérieusement contaminés par des ions sodium et ne donnaient des spectres utiles qu'après extraction par l'éther dibenzo-18 couronne-6. Après ce traitement, l'acide adipique de même que l'acide azélaïque possèdent un pic de base de $[M + 1]^+$ alors que l'acide adipique se décarboxyle rapidement ($[M - 44]^+ = 74\%$). Dans le cas d'autres acides de pureté commerciale on a observé la présence d'impuretés correspondant aux homologues et à des composés de structures semblables.

Introduction

In recent years field desorption mass spectrometry (fdms) has been shown to be a useful technique for characterizing molecules of limited volatility and thermal stability (1, 2). One such class of compound is the higher molecular weight carboxylic acids, materials which are often sold and used as mixtures of moderate complexity. With the ultimate goal of evaluating fdms for analysis of such mixtures, we undertook a study of a range of pure acids containing varying degrees of unsaturation, hydroxyl or additional carboxylic acid groups, and related metal

Linoleic (18)	4	7	4		21	100		
Linolelaidic (t, 18)	4	7	12		28	100		
$CH_3(CH_2)_xCH{=}CHCH_2CH{=}CHCH_2CH{=}CH(CH_2)_yCOOH$								
Linolenic (18)	1	7	0[d]		28	100		

[a]Samples were deposited on the field anode from $CHCl_3$ solutions. For behenic acid, a mixture of $CHCl_3/CH_3OH$ was necessary. Spectra are reported as a set of intensities relative to base peak = 100.
[b]Compounds are identified by common name followed by carbon number (n). All olefinic bonds are *cis* except those marked (t) for *trans*.
[c]Lauric acid, $C_{11}H_{23}COOH$, is the lowest molecular weight carboxylic acid amenable to fdms. Caproic (n = 6), caprylic (n = 8), and capric (n = 10) when admitted to the ion source as gases gave spectra (field ionization) with M+ as base peak. The only other peaks of importance were found in the caproic acid spectrum: $[M + 1]^+ = 76\%$, $[M - 17]^+ = 9\%$.
[d]Spectra recorded at 0 mA are likely to contain a large component of ions produced in gas phase (fims).
[e]Palmitoleic acid showed a peak at $[2M + 1 - 18]^+ = 1\%$.
[f]At 8 mA the base peak for this acid becomes m/e 502 ($[2M + H - H_2O - COOH]^+$); at 15 mA, the base peak is 2M − H.
[g]At higher anode temperatures, the base peak for this acid shifted successively to $[2M - 17]^+$ (ahc = 14 mA), $[2M - 1]^+$ (16mA), and $[3M - 2H]^+$ (18 mA).

salts. The present paper reports the results for free acids, including some deductions about the behavior of these compounds under fd conditions and a comparison with the spectra obtained from representative samples of technical purity.

Experimental

Mass spectra were obtained on a Varian MAT Model CH5 DF instrument equipped with a fi/fd/ei source. Magnet scanning and data acquisition were under the control of an interfaced INCOS model 2000 data system. The field anode was a 10 μm tungsten wire activated by benzonitrile (3) in a modified Varian apparatus. For fd measurements an anode voltage of +3 kV and a cathode voltage of −7 to −8 kV were applied in an unheated source (70–100°C) at ca 10^{-6} Torr. The magnet was scanned quadratically from m/e 900 to 10 in 20 s with a nominal resolution of 1500 and the secondary electron multiplier at 1.75 kV.

A solution (ca. 5 mg/mL) of the sample was deposited on the activated anode by dipping (4). Initial focussing was done on acetone introduced via the batch inlet. During scanning the anode temperature was adjusted manually to achieve optimum desorption rate. After each sample the anode current was increased to its maximum value to clean the wire. Operation in fi mode differed only in that the sample was introduced via the batch inlet. Spectra are not corrected for ^{13}C content.

Myristoleic and 12-hydroxystearic acids were purchased from Sigma; all other monocarboxylic acids were obtained from Applied Science Laboratories. Azelaic, adipic, and isophthalic acids were obtained from Eastman and dibenzo-18-crown-6 ether from Aldrich. All solvents and other reagents were A.C.S. grade and were used without further purification. A series of technical grade fatty acids was kindly donated by Imperial Oil Enterprises Ltd., Sarnia.

The diacids were purified by twofold extraction of a 1% solution in water–methanol with equal volumes of 0.01 M dibenzo-18-crown-6 ether in CH_2Cl_2. The aqueous layer was evaporated *in vacuo* to recover the pure acid.

Results and Discussion

Carboxylic acids of high purity generally give fd mass spectra in which the molecular ion is dominant. As shown by the representative data in Table 1, several acids have significant $[M + 1]^+$ ions (after allowance for ^{13}C isotope) and these latter ions are accompanied by small amounts of complex ions ($[2M + 1]^+$) and/or fragments ($[M - 17]^+$, $[M - 44]^+$). These fragments are most reasonably assigned to loss from $[M + H]^+$ of H_2O and COOH, respectively. General structural correlations for the presence of the $[M + H]^+$ ion and these related species are thus far lacking, as is any explanation for the significant differences in anode temperature necessary for desorption. The most unusual behavior of elaidic and *cis*-5-eicosenoic acids with increasing anode temperature may reveal an increased tendency of these compounds to form dimer and higher complexes but comparisons with other acids must be made with caution. These results could equally well

TABLE 2. Comparison of isomeric hydroxystearic acids by fdms[a]

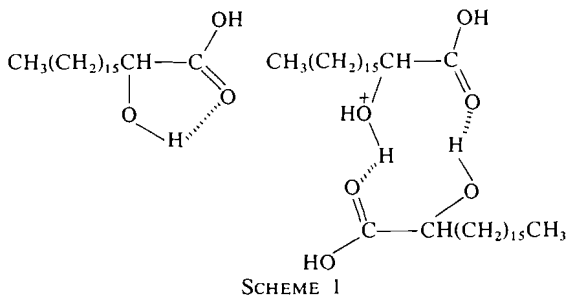
Acid	Anode heating current (mA)	Relative intensity (%) 2M + 1	M + 2	M + 1	M	M − 1	M − 17	M − 45	Others(%)
2-Hydroxystearic	12.5	16		49	100			10	2M − 45(6)
12-Hydroxystearic	10.5		14	100		2	21		
17-Hydroxystearic[b]	8		11	100	7		18		

[a]Spectra were obtained from $CHCl_3$ solutions, except for 17-OH where addition of CH_3OH was necessary. Intensities are reported relative to base peak = 100.
[b]Some scans showed ions in the region *m/e* 141–142 corresponding to $[M + H - H_2O]^{2+}$ and $[M - H_2O]^{2+}$.

arise from the higher temperature of desorption which in turn may reflect the physical state of the desorbed sample.

For several of the acids studied, desorption at higher anode temperatures produced peaks corresponding to $[2M + H - H_2O]^+$. In further study of this process which is at least formally equivalent to anhydride formation, we have observed the expected cross product from high temperature fdms of a mixture. For example, a 1:1 mixture of *cis*-5-eicosenoic acid (M_1) and elaidic acid (M_2) behaved normally at low temperatures, with desorption of elaidic acid occurring first as predicted from the behavior of the single compounds. At higher anode temperatures ions of the type $[2M + H - H_2O - COOH]^{\ddagger}$ become more prominent until at 15 mA both 'pure dimer' ions are present and the 'cross-product dimer' $[M_1 + M_2 + H - H_2O - COOH]^{\ddagger}$ is the base peak. At 18 mA the 'mixed anhydride' $[M_1 + M_2 + H - H_2O]^+$ is the base peak and protonated dimer $[M_1 + M_2 + H]^+$ has a relative intensity of 56%. This experiment may be added to earlier work showing that processes resembling known chemical reactions may occur on the field anode (5–8).

The results in Table 2 show that three isomeric hydroxystearic acids are readily field desorbed to give dominant peaks in the molecular ion region. The relative importance of molecular ion and $[2M + 1]^+$ ions for the 2-OH isomer may be related to the ease of formation of intra- and intermolecular hydrogen bonds as illustrated in Scheme 1.



SCHEME 1

Another notable difference between the 2-isomer and the others is the importance of COOH loss (from $M^{\ddagger}$ and $2M^{\ddagger}$) for the former and H_2O loss (from $[M + 1]^+$) for the latter two. At higher anode temperatures the intensity of $[2M + 1]^+$ and an accompanying $[2M + 1 - H_2O]^+$ becomes more important for the 2-isomer until at 15 mA the latter is the base peak.

There is no firm basis for differentiation of the 12- and 17-isomers, although the presence of a weak molecular ion peak for the 17-isomer suggests some tendency for intramolecular hydrogen bonding which may relate to a ring size effect or to differences in orientation in the condensed phase on the field anode.

The most dramatic difference among the dicarboxylic acids presented in Table 3 involves their ease of decarboxylation. The presence of strong $[M + 1]^+$ peaks along with lesser ions corresponding to $[2M + 1]^+$, $[M - 17]^+$, and $[M - 44]^{\ddagger}$ attests to the ease of desorption of these initially protonated species. Whether this behavior is related to ease of protonation or the relative difficulty in ionizing the neutral molecule is not clear (9). In any case, it is tempting to attribute the presence of $M^{\ddagger}$ for azelaic acid to intramolecular H-bonding. The 'self-protonated' species thus formed would involve a ring-size of 12, whereas the other members of the series would be required to form 9- or 15-membered rings to achieve comparable structures.

A number of technical grade carboxylic acids were submitted to fdms with the results summarized in Table 4. These results have been examined with two principal questions in mind. Perhaps most important is the ability of the technique to produce a recognizable mass spectrum of the main component in spite of the presence of contaminants. A secondary question involves the extent to which the major contaminants can be identified.

With the exception of two diacids heavily contaminated with sodium and potassium ions, the compounds tested gave the same base peak ($M^{\ddagger}$ or $[M + 1]^+$) as the pure sample previously discussed.

Isophthalic	13		1	8	100		2M + 23(1)

[a]Solutions were prepared in the same solvents used for the pure acid.
[b]Doubly-charged ions, $141.7 = 283^{2+}$; $142.2 = 284^{2+}$. See text.
[c]Spectra obtained after extraction with dibenzo-18-crown-6 ether, M = 360. Ion m/e 383 is $[M + Na]^+$.

Technical grade palmitic and stearic acids required a higher temperature for optimum desorption, perhaps as a result of the presence of minor impurities. Whatever the cause, a change from 0 to 6–7 mA involves two effects on the resulting spectra: any gas-phase (field ionization) component present at 0 mA will be removed and the higher temperature of desorption would be expected to increase the relative amount of complex ions and fragments. The latter effect is easily seen in the presence of $[3M + 1]^+$ and $[2M + 1]^+$ ions as well as fragments corresponding to loss of H_2O ($[M - 17]^+$) and loss of both H_2O and COOH (m/e 450 for palmitic acid).

Several ions were found which provide evidence for the presence of homologues and related compounds in these spectra. For instance, the ions at m/e 256 and 312 in the stearic acid sample probably represent contamination by saturated C_{16} and C_{20} homologues. Likewise, from peaks at m/e 280 and 254, the oleic acid sample appears to contain both a doubly unsaturated C_{18} (linoleic acid?) and a C_{16} homologue (palmitoleic acid?). Not surprisingly, 2-hydroxystearic acid shows important ions corresponding to stearic acid (m/e 284) and to an homologous hydroxypalmitic acid (m/e 272).

The significance of apparent $[M + 1 - H_2O]^{2+}$ and $[M - H_2O]^{2+}$ ions at m/e 142.7 and 142.2 for technical grade 12-hydroxystearic acid is not known. The authentic sample of this material did not show these ions although its spectrum was otherwise similar (Table 2). Careful examination of the spectrum of the authentic 17-hydroxy isomer revealed small amounts of these same ions.

As already noted, the technical grade samples of adipic and azelaic acids were contaminated with sodium and potassium ions to the point where no useful spectra could be obtained. The spectra reported in Table 4 were obtained after extraction of an aqueous solution of the sample with an organic solution of dibenzo-18-crown-6 ether. These spectra are comparable to those recorded for the standards (Table 3) with the important exception that decar-

[a]Extension of data presented in ref. 8.

boxylation is considerably less important for the samples purified by extraction. The presence of ions at *m/e* 360 and 383 representing ligand and ligand–sodium complex is not unexpected. From an analytical viewpoint, the most significant part of these results is the demonstration that the simple procedure of alkali metal extraction results in a dramatic improvement in the fd spectrum obtained.

Several hydroxyacids included in this study showed complex behavior. Some results for 3-hydroxypropanoic acid have been communicated (8). Other acids studied included glycolic, $HOCH_2COOH$; malic, $HOOCCHOHCH_2COOH$; lactic, $CH_3CHOHCOOH$; and glucuronic, $HOCH_2(CHOH)_4COOH$. The results obtained are rather complex and comparisons are rendered difficult by the wide differences in best anode temperature for these compounds. The often observed strong dependence of field desorption spectra on anode temperature has now been rationalized by increasing awareness that the desorption process is at least in large part thermal (10) and mechanisms for the desorption processes which take this fact into account have been proposed (9). The fact that three of the acids studied (3-hydroxypropanoic, glycolic, and lactic) desorbed at 0 mA while malic and glucuronic acids required 14 and 19.5 mA, respectively, no doubt has an important bearing on the results. In the discussion which follows, attention will be focussed on ions in the molecular region, complexes and peaks representing loss of water with or without apparent polymer formation.

At 0 mA glycolic acid ($M = 76$) had *m/e* 59 ($[M + 1 - H_2O]^+$) as base peak, major fragments at *m/e* 31 (70%) and 45 (54%), molecular ions (76 = 27%, 77 = 23%) and complex ions at *m/e* 153 (8%, $[2M + 1]^+$), 135 (15%, $[2M + 1 - H_2O]^+$), and 116 (5%, $[2M - 2H_2O]^{+\cdot}$). At 11 mA, *m/e* 59 was much less prominent, *m/e* 45 had become the base peak, and *m/e* 31 and 76 were next in importance.

Lactic acid also desorbed at 0 mA to produce a complex spectrum with ions up to *m/e* 398. This latter ion is assigned to $[5M + 2 - 3H_2O]^{+\cdot}$ and other 5M ions include *m/e* 380 ($[5M + 2 - 4H_2O]^{+\cdot}$), 365 ($[5M + 2 - 4H_2O - CH_3]^+$), 350 ($[5M + 2 - 4H_2O - 2CH_3]^+$), and *m/e* 335. This latter could be $[5M + 2 - 4H_2O - 3CH_3]^+$ or equally $[5M + 2 - 4H_2O - COOH]^+$. It should be noted here and later that all of these assignments have no backing other than their implicit reasonableness which arises largely from the observation that for such a molecule as lactic acid the number of protons associated with a given complex seems to be constant, and all the prominent ions can be 'explained' by loss of such likely fragments as H_2O, COOH, and CH_3.

Ions assigned to 4M species include *m/e* 326 ($[4M + 2 - 2H_2O]^{+\cdot}$), 308 ($[4M + 2 - 3H_2O]^{+\cdot}$), and 245 ($[4M + 2 - 4H_2O - COOH]^+$). With 3M we come for the first time to ions with different degrees of protonation. For example, *m/e* 254 could be $[3M + 2 - H_2O]^{+\cdot}$ whereas *m/e* 217 and 208 may be $[3M + 1 - 3H_2O]^+$ and $[3M + 1 - H_2O - COOH]^{+\cdot}$ and *m/e* 234, 216, and 189 correspond to $[3M - 2H_2O]^{+\cdot}$, $[3M - 3H_2O]^{+\cdot}$, and $[3M - 2H_2O - COOH]^+$, respectively. With 2M and below, the number of possible assignments increases but a major ion at *m/e* 162 appears to be the first member of the 'polyester series' for this molecule i.e. $[2M - H_2O]^{+\cdot}$. Other ions of note may represent loss of H_2O and COOH from dimers (*m/e* 117, 118, 119) and loss of H_2O from $M^{+\cdot}$ and $[M + 1]^+$ (*m/e* 91, 90, 73, 72 are all present). Finally, the base peak in this spectrum is *m/e* 45 which could represent either $[COOH]^+$ or $[M - COOH]^+$ but we favor the latter since $[COOH]^+$ is not ordinarily important.

Malic acid ($M = 134$) produces a relatively uncomplicated spectrum at 14 mA. $[M + 1]^+$ is the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

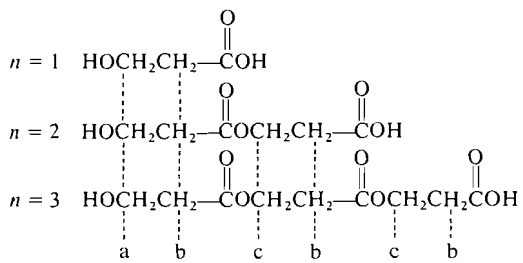
base peak and the most important fragments correspond to loss of COOH from that ion and from $M^{\ddagger}$. The only complex ions of significance are *m/e* 269 ($[2M + H]^+$) and 193 whose origin is uncertain.

Since glucuronic acid does not desorb below 16 mA and the best anode temperature is at 19.5 mA it is not surprising that it produces many ions whose structural significance is not obvious. Dimer ion at *m/e* 392 was the highest mass observed. Loss of 2, 3, and 4 H_2O from dimers in various degrees of protonation are seen. A monodehydration ion at *m/e* 179 (base at 16 mA) is the only peak near $M^{\ddagger}$. Among the fragments, *m/e* 31 is base and 61 is second in importance. These two latter ions dominate the spectrum at all values from 17–21 mA.

The apparent polymerization of 3-hydroxypropanoic acid has been shown to continue with increased anode temperature at least to 23 mA. As shown in Table 5, the base peak continues to increase in mass from 451 (degree of polymerization (dp) = 6) to 811 (dp = 11) over this temperature range.

Since the commercial product used in this work is known to contain some dimer and perhaps higher molecular weight oligomers, we have attempted to find out how much of the behavior observed here is related to species already present in the sample. Handling of the sample by fi gave no polymerization peaks. The base peak is *m/e* 72 and molecular ion is weak (3% or less). Attempts to remove all water from the sample before fd gives no spectrum at all. This may reflect the formation of a high polymer on the anode. Proton magnetic resonance spectra of the original sample showed three well separated signals which we assign as follows:



a = 4.8 ppm, 22% of intensity
b = 2.7 ppm, 49% of intensity
c = 4.4 ppm, 29% of intensity

That is, methylenes next to carbonyl are not distinguishable (δ 2.7) but terminal CH_2—O (δ 4.8) is separated from interior CH_2—O (δ 4.4). Integration of these signals and comparison with various compositions shows that an equimolar mixture of n = 1–4 agrees with the nmr intensities. Attempts to allow for higher polymers require the increase of monomer or dimer to maintain balance, e.g. 15% of hexamer with 60% dimer and 25% monomer also fits as does 30% hexamer and 70% monomer. Among the many solutions which can be considered for the nmr data, it appears that all of them must contain at least 50% of total monomer and dimer. Further, the higher polymers change the ratio more and thus less polymer can be mixed in. In summary, although it is not possible to exclude higher oligomers than dimer from the original sample, no combination of molecular species can give rise to the high intensities of high molecular weight ions found in fdms. Further, the fact that total ionization increases above 12 mA means that in general the intensities reported above tetramer represent more material than the ones at lower anode temperatures.

The synthesis of hypecorinine and bicucullinine

BALA C. NALLIAH AND DAVID B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 20, 1977

BALA C. NALLIAH and DAVID B. MACLEAN. Can. J. Chem. **56**, 1378 (1978).

The total synthesis of two isoquinoline alkaloids of unusual structure, hypecorinine **2** and bicucullinine **3**, from a common intermediate, dehydrobicuculline (**1**), is described.

BALA C. NALLIAH et DAVID B. MACLEAN. Can. J. Chem. **56**, 1378 (1978).

On décrit la synthèse totale de deux alcaloïdes de la série isoquinoléine possédant des structures inhabituelles soit l'hypécorinine **2** et la bicucullinine **3**; ces synthèses font intervenir un intermédiaire commun, la déhydrobicuculline **1**.

The synthesis of dehydrobicuculline (**1**) and its conversion to three spirobenzylisoquinoline and two phthalideisoquinoline alkaloids has been reported recently (1). Here we report the use of **1** in the synthesis of hypecorinine **2** and bicucullinine **3**, two alkaloids which have not been previously synthesised.

The isolation of hypecorinine was reported in 1972 from *Hypecoum erectum* and its structure and that of a companion alkaloid were established at that time (2). The same alkaloid was also found in *Corydalis incisa* Pers. and its structure established by spectral and chemical methods in 1975 (3); the name corydalispirone was given to the alkaloid. The latter work was apparently carried out without knowledge of the previous study. Since the name hypecorinine has precedence we have used this name for the alkaloid.[1]

We reported previously (1) that dehydrobicuculline **1** underwent reduction with diisobutylaluminum hydride to the keto aldehyde **5** which was converted in an aldol ring closure to sibiricine **6** and corydaine **7**. The reduction of intermediate **5** selectively to the keto alcohol **8** followed by oxidation of **8** with mercuric acetate would be expected to yield an immonium salt such as **4** which would then suffer ring closure to hypecorinine **2**. Previous experience with similar compounds led us to use lithium aluminum hydride as the preferred reducing agent (4) for the conversion of **1** into **8**. We found that when a solution of dehydrobicuculline in dry THF was treated with lithium aluminum hydride at 0°C the characteristic yellow colour of **1** disappeared and on work-up a product was obtained which by tlc was a mixture of two components, presumably **8** and **2**. When this product was dissolved in methanol and the solution was allowed to stand overnight, colorless prisms were deposited which were identical with an authentic sample of hypecorinine. We were unable to isolate **8** as a crystalline product presumably because of its ease of oxidation.

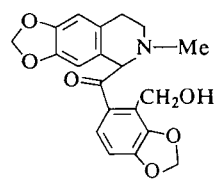
6 $R_1 = H$, $R_2 = OH$ (Sibiricine)
7 $R_1 = OH$, $R_2 = H$ (Corydaine)



8

We also found that the hydride reduction product was oxidized readily to **2** if it was dissolved in 5% aqueous acetic acid and stirred with mercuric acetate at room temperature for an hour (5). This is the pre-

[1]We thank a referee for drawing the work on hypecorinine to our attention.

For personal use only.

ferred procedure for synthesis of **2**. The perchlorate salt of our synthetic hypecorinine, prepared by the published procedure (3), was also identical with an authentic sample.

Bicucullinine (**3**) (6) is structurally related both to the phthalideisoquinoline alkaloid narceine (**9**) and to the alkaloid cryptopleurospermine (**10**). We anticipated that the quaternary salt **11** which contains all the carbon atoms of bicucullinine, might be converted into **3**, first by opening the lactone ring and then by allowing the ring-opened product to undergo aerial oxidation.

In practice **11** was prepared in good yield by treatment of **1** with methylfluorosulfonate in methylene chloride. When **11** was suspended in ethanol containing Triton B and potassium iodide it slowly dissolved upon stirring, presumably, through opening of the lactone ring, to give the zwitter ion **12**. The solution so obtained was allowed to stand at room temperature for one week and during this period compound **12** apparently reacted with atmospheric oxygen to form the hydroperoxide **13** which was then reduced to the carbinolamine **14** by the iodide ions present in the solution. Before or upon acidification with hydrochloric acid the carbinolamine **14** underwent ring opening and bicucullinine was isolated as its hydrochloride as yellow needles (mp 172–174°C), identical with an authentic sample. Analogous oxidations are reported in the literature (7). The hydrochloride was converted to bicucullinine and this too was identical with an authentic specimen.

13 **14**

These syntheses illustrate further the use of dehydrophthalides as synthetic intermediates in the synthesis of isoquinoline alkaloids.

Experimental

Preparation of Hypecorinine (2) from Dehydrobicuculline (1)

Lithium aluminum hydride (100 mg) was added to a stirred and ice-cooled solution of dehydrobicuculline (1) (100 mg) in dry THF (50 ml). After 1 h the reaction mixture was decomposed with a saturated solution of sodium sulfate and the precipitate removed by filtration. The filtrate was evaporated to dryness under reduced pressure and dissolved in 5% aqueous acetic acid (25 ml). Mercuric acetate (100 mg) was added and the solution stirred for 1 h at room temperature. The solution was basified (concentrated NH_4OH), extracted with CH_2Cl_2, and the extract evaporated to dryness. The residue was crystallized from methanol yielding colorless prisms, mp 196–198°C (51 mg), identical in mp, mixture mp, and spectroscopic properties (ir, nmr) with an authentic specimen; $\nu_{max}(CHCl_3)$: 1630 and 1692 cm^{-1}; δ ($CDCl_3$): 7.81 and 6.90 (q, 2H, J_{AB} = 8 Hz), 6.62 (s, 1H), 6.56 (s, 1H), 6.10 (s, 2H), 5.88 (s, 2H), 5.17 and 4.84 (q, 2H, J_{AB} = 15.5 Hz), 2.50–3.60 (m, 4H), 2.38 (s, 3H). *Anal.* calcd. for $C_{20}H_{17}O_6N$: C 65.39, H 4.67, N 3.81; found: C 65.53, H 4.80, N 3.64.

N-*Methyldehydrobicuculline (11)*

Freshly distilled methylfluorosulfonate (2 ml) was added to a solution of dehydrobicuculline (1 g) in dry CH_2Cl_2 and the solution stirred for 24 h at room temperature. The orange precipitate which separated was filtered and recrystallized from acetonitrile–MeOH (yield 950 mg). The perchlorate salt was obtained by adding a few drops of 60% perchloric acid to a warm concentrated solution of the salt in acetonitrile. It crystallized in yellow needles, mp 315–316°C (dec.); ν_{max}(Nujol): 1785 cm^{-1}; δ (DMSO): 7.37 (s, 1H), 7.17 (s, 1H), 7.33 and 7.03 (q, 2H, J_{AB} = 8.0 Hz), 6.37 (s, 2H), 6.13 (s, 2H), 3.63 (s, 6H), 3.4–3.7 (m, 2H), 2.9–3.2 (m, 2H). *Anal.* calcd. for $C_{21}H_{18}O_{10}NCl$: C 52.56, H 3.78, N 2.92, Cl 7.39; found: C 52.69, H 3.88, N 2.96, Cl 7.18.

Conversion of N-*Methyldehydrobicuculline (11) to Bicucullinine (3)*

Triton B (40% in MeOH) was added to a stirred suspension of the quaternary salt **11** (200 mg) in absolute ethanol until a clear solution was obtained. Potassium iodide (50 mg) was added, the solution stirred for another hour, and then let stand for a week. The solution was acidified with concentrated hydrochloric acid and left for another day. The residue obtained on evaporation of the solvent was dissolved in the minimum amount of 5% KOH and extracted with CH_2Cl_2 to remove both the iodine formed in the reaction and the excess Triton B. The aqueous solution was acidified with concentrated hydrochloric acid. Yellow needles separated on standing (86 mg), mp 172–174°C. The hydrochloride of the authentic bicucullinine was identical with the synthetic product, ν_{max}(Nujol): 1690, 1658, and 1595 cm^{-1}; δ (DMSO): 7.36 (s, 1H), 7.30 and 7.20 (q, 2H, J_{AB} = 8 Hz), 7.17 (s, 1H), 6.27 (s, 2H), 6.17 (s, 2H), 3.20 (br, s, 4H), 2.77 (s, 6H).

Bicucullinine hydrochloride was converted to bicucullinine in the following way. The hydrochloride was dissolved in aqueous base, this solution treated with freshly prepared silver hydroxide, filtered, and the filtrate acidified with acetic acid. The bicucullinine which crystallized from the aqueous mixture was identical with an authentic specimen.

Acknowledgments

We wish to thank Dr. G. Nonaka, Faculty of Pharmaceutical Sciences, Kyushu University, Fukuoka, Japan for providing us with a sample of corydalispirone (hypecorinine) and the National Research Council of Canada for financial support of this work.

Electron transport via metalloporphyrins

EUGENE C. JOHNSON, TONY NIEM,[1] AND DAVID DOLPHIN[2]

The Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 9, 1977

EUGENE C. JOHNSON, TONY NIEM, and DAVID DOLPHIN. Can. J. Chem. **56**, 1381 (1978).

The controlled potential electrolysis of Ni(II) *meso*-tetraphenylporphyrin (Ni(II)TPP) gives at room temperature the corresponding metalloporphyrin π-cation radical $[Ni(II)TPP]^{+\cdot}$. Upon freezing a solution of the π-cation radical to 77 K an internal electron transfer occurs to give $[Ni(III)TPP]^{+}$. A discussion of the routes of electron transport in heme proteins is given, and the roles of metalloporphyrin π-cation radicals in electron transport is evaluated.

EUGENE C. JOHNSON, TONY NIEM et DAVID DOLPHIN. Can. J. Chem. **56**, 1381 (1978).

L'électrolyse à potentiel contrôlé de la *méso*-tétraphénylporphyrine de Ni(II) (Ni(II)TPP) conduit, à température ambiante, au radical π cation métalloporphyrine correspondant $[Ni(II)TPP)^{+\cdot}$. Lorsque l'on congèle une solution du radical π cation à 77 K, un transfert interne d'électron se produit pour conduire au $[Ni(III)TPP]^{+}$. On discute des diverses routes de transport d'électron dans des protéines contenant de l'hème et on évalue le rôle des radicaux π cation métalloporphyrine dans le transport des électrons.

[Traduit par le journal]

Introduction

Redox reactions play critical roles in many biochemical transformations (1), and amongst the coenzymes and cofactors involved the iron porphyrins (hemes) play many varied and crucial functions. Hemes not only transport and store oxygen via hemoglobin and myoglobin, but in the form of cytochromes P-450 activate oxygen which, as monooxygenases bring about numerous biochemical oxidations (2). Other heme enzymes such as catalase and the peroxidases act as two electron reductants of hydrogen peroxide to hydroxide, and are concomitantly oxidized by two electrons to the so-called primary complexes of the enzymes. In the case of catalase the primary complex then acts as a two electron oxidant of hydrogen peroxide to oxygen, and is reduced to the resting ferrihemoprotein. Another group of heme-containing proteins, the cytochromes, function between Fe(II) $\rightleftharpoons$ Fe(III) couples, and by linking centres of different redox potentials couple the free energy change of the electron transport to covalent bond formation (e.g. oxidative phosphorylation (3)).

An insight into the modes of electron transport of metalloporphyrins was gained when it was shown that the initial, photochemically promoted, electron transport in photosynthesis involves the loss of an electron from one of the filled π-molecular orbitals of chlorophyll *a* to generate a chlorophyll (or bacteriochlorophyll) π-cation radical (4–6). Stable π-cation radicals of simpler metalloporphyrins had been reported earlier (7), and shortly after their occurrence in photosynthetic systems was elucidated it was found that similar π-cation radicals were the catalytically active forms of both the catalases and peroxidases (8, 9). Thus when either catalase or peroxidase is oxidized by hydrogen peroxide one electron is removed from the ferric iron and one from the π-cloud to give, in the primary complexes, an Fe(IV) π-cation radical electronic configuration. However, the ground states of these primary complexes differ in that in one the remaining unpaired electron is in an a_{2u}, and in the other in an a_{1u} orbital. The corresponding $^2A_{2u}$ and $^2A_{1u}$ ground states, as a result of their different electronic ground states, exhibit different optical and enzymic properties (8).

A change in the ground state from $^2A_{1u}$ to $^2A_{2u}$ can be demonstrated with the π-cation radical of cobaltic octaethylporphyrin (7). Thus in the presence of bromide ion the cobalt coordinates two ligands to give $[Co(III)OEP]^{2+\cdot}2Br^{-}$ which exhibits a $^2A_{1u}$ ground state. When the bromide ions are removed and replaced by perchlorate the ground state changes to that of $^2A_{2u}$. It is apparent that small changes in the environment about the metal (and at the porphyrin periphery) can bring about a change in the ground state, and this is consistent with calculations which suggest that the two ground states differ in energy by about 1500–2000 cm^{-1} or 4.3–5.7 kcal mol^{-1} (10).

We have been explicit in describing the electronic configuration of an oxidized metalloporphyrin and one might ask if it is possible to describe these configurations as resulting entirely from a metal or a ligand oxidation. Thus a cobaltic π-cation radical which has two electrons less than the Co(II) species

could formally be described as both a derivative of cobalt(IV) or a π-dication of cobalt(II). One might be inclined to conclude that each of these descriptions are extreme resonance forms of the same molecule and that the molecule should be described as some contribution of all of them. This is not, however, the case since the epr spectrum of $[Co(III)OEP]^{2+\cdot}$ shows that the unpaired electron spends less than 5% of its time on the metal (9). Since the unpaired electron is in a ligand based orbital it can be described as a π-cation radical of cobalt(III). Similarly the oxidation of ferric porphyrins removes electrons from the metal, not the ligand, since the optical spectra (which are dominated by π–π* transitions of the ligand) remain essentially unchanged upon oxidation whereas a dramatic change in the optical spectra would be observed if the ligand were oxidized (11).

The ground state electronic configuration of a metalloporphyrin can, from optical and epr measurements, be accurately determined; and the electronic configuration adopted will depend upon a variety of factors including the metal, the porphyrin and its peripheral substituents, and the axial ligands. Even in the 'simplest' metalloporphyrins small changes will influence the ground state. Thus the electrochemical one-electron oxidation of ruthenium(II) complexes of *meso*-tetraphenylporphyrin (TPP) gave a π-cation of [Ru(II)TPP](CO)(py) (viz. $[Ru(II)TPP]^{+\cdot}$(CO)(py)) but caused oxidation of the metal with $[Ru(II)TPP](py)_2$ to give $[Ru(III)TPP]^{+}(py)_2$ (12). Hence the substitution of the weakly backbonding ligand pyridine for the more strongly backbonding CO destabilized Ru(II) vs. Ru(III) and changed the electronic configuration of the one-electron oxidized species.

Even though the electronic configuration of a metalloporphyrin can now be readily determined, the mechanism, or route, of electron transfer by which such systems undergo redox chemistry is still a subject of much speculation with respect to even simple metalloporphyrins, which may be used as models of heme proteins; while the mechanisms by which heme proteins themselves transport electrons still remain, in general, largely unexplained (1).

As with other coordination complexes metalloporphyrins have been found to effect electron transfer via two well-characterized mechanisms; inner sphere (13), where electron transfer occurs through a bridging species between oxidant and reductant, and outer sphere, where a bridging species is absent and electron transfer must occur through the extended π-systems of the oxidant and reductant (14). While inner sphere mechanisms may operate with some model metalloporphyrins it is apparent, on spatial considerations alone, that for most heme proteins in general an inner sphere mechanism cannot obtain.

Wolberg and Manassen (15) have reported that the electrochemical oxidation of Ni(II)TPP in benzonitrile initially gives a $Ni(III)TPP^{+}$ species which decayed to a $Ni(II)TPP^{+\cdot}$ species. The presence of the two complexes was suggested by epr. In contrast we have recently reported that a similar oxidation in CH_2Cl_2 gives the $[Ni(II)TPP]^{+\cdot}$ species, which is in thermodynamic equilibrium with a $[Ni(III)TPP]^{+}$ species at 77 K, as shown by epr and electronic absorption spectra (16). We describe here a detailed study of these systems and suggest evidence of possible modes for outer sphere mechanisms of electron transfer in metalloenzymes.

Experimental

Materials

Dichloromethane (Fischer, reagent) was refluxed over calcium hydride and distilled and stored over 4 Å molecular sieves. Tetra-*n*-butylammonium hexafluorophosphate (TBAH) was prepared by treating an acetone solution of tetra-*n*-butylammonium iodide and ammonium hexafluorophosphate with water. The precipitated product was twice recrystallized from ethanol–water and dried in vacuum for 10 h at 100°C. Tetra-*n*-butylammonium perchlorate (TBAP) (Eastman) was twice recrystallized from ethanol–water and dried under vacuum for 10 h at 70°C. Tetraphenylporphyrinato nickel(II) was prepared from chlorin-free TPP since Ni(II)TPP is sparingly soluble and difficult to separate from chlorin impurity. ^{61}Ni(II)TPP was prepared similarly except that ^{61}Ni (99% enriched, Oakridge, TN) was initially dissolved in concentrated HCl, evaporated to dryness, and the resultant $^{61}NiCl_2$ used in place of $Ni(OAc)_2$.

Measurements

Ultraviolet–visible absorption spectra were recorded on a Cary 17 recording spectrophotometer. Room temperature spectra were recorded in CH_2Cl_2 using 1.0 cm cells. Spectra at 77 K were measured using a variation of the opal glass method (17). A Pyrex cell was made by flattening a tube (0.5 cm OD) until the pathlength was ~0.1 mm. A quantity of a methylene dichloride solution was transferred to the cell by syringe and the sample frozen, evacuated, and sealed. After warming the cell to room temperature a strip of thin Teflon tape was stretched over the flat face and the cell was then placed in a windowed quartz Dewar filled with liquid nitrogen and placed in the sample beam of the spectrometer. A piece of opal glass was placed in the reference beam and optical spectra were then recorded as usual. The epr measurements, at both room temperature and 77 K, were made on a Varian E-3 EPR spectrometer in degassed methylene dichloride solutions in evacuated quartz epr tubes (4 mm OD).

Electrochemical measurements were made at a Pt electrode in CH_2Cl_2 using 0.1 *M* TBAH or TBAP as supporting electrolyte. A Ag/AgCl couple was used as reference. Standard 3 electrode operational amplifier circuitry was utilized as described previously (6). Due to the sparing solubility of Ni(II)TPP, special care was taken to ensure that no solid material was present during electrochemical or epr measurements. Solutions were either filtered prior to use or, for coulometric measurements, accurately weighted samples of ~3 mg were stirred for 30 min in 30 ml of degassed CH_2Cl_2 prior to use to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ensure complete solution. Such solutions were then used without further treatment.

Results

Electrochemistry

The shape of the cyclic voltammograms varied significantly according to the supporting electrolyte used. Figure 1 shows cyclic voltammograms of Ni(II)TPP in CH_2Cl_2 using TBAH and TBAP. In the presence of TBAP the cyclic voltammogram, as previously reported (16), is consistent with two overlapping electrochemically reversible couples centered at 1.17 and 1.29 V, while the data for the TBAH system display two well-defined electrochemically reversible couples centred at 1.07 and 1.39 V. Exhaustive electrolysis at 1.24 V in either system produced a green solution which gave a cyclic voltammogram identical to the starting material. Controlled potential coulometry (at 1.24 V) gave *n*-values of 1.01 ± 0.05, consistent with a one-electron oxidation of the Ni(II)TPP. The green solution was stable for several days when protected from the light and the atmosphere, and upon electrolysis at 0.80 V the starting material was quantitatively regenerated ($n = 1$), such that the cycle was completely reversible. Further electrolysis of the green oxidation product at potentials anodic to the second couple gave a brown solution which decomposed over a period of a few hours. Immediate cathodic electrolysis of freshly prepared solutions of the second electrolysis product gave, by coulometry, $n = 0.92 \pm 0.05$, but the appearance of additional cycles indicated decomposition.

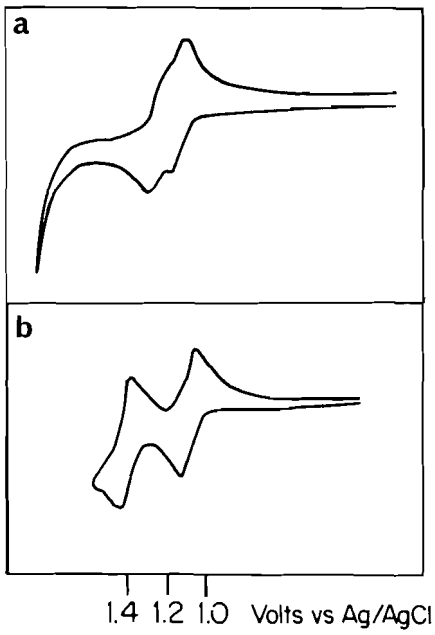

FIG. 1. Cyclic voltammogram of Ni(II)TPP in methylene dichloride using a Ag/AgCl couple as reference; (*a*) tetra-*n*-butylammonium perchlorate and (*b*) tetra-*n*-butylammonium hexafluorophosphate as supporting electrolytes at 0.1 *M*.

Spectra

Figure 2 follows the changes in the absorption spectra of Ni(II)TPP during electrolysis at 1.24 V to give the green one-electron oxidation product. The appearance of isosbestic points in the spectra indicates a clean conversion to the oxidized form. A comparison of the optical spectrum of the green oxidation product to that of the well characterized π-cation radical of Mg(II)OEP (Fig. 3) shows that the product is the π-cation radical $[Ni(II)TPP]^{+\bullet}$ and that further electrolysis generates the corresponding π-dication $[Ni(II)TPP]^{2+}$ (Fig. 3) which has an optical spectrum similar to other metalloporphyrin π-dications. This dication is a powerful electrophile reacting with a variety of nucleophiles such as methanol, or water, to give isoporphyrins (18).

Figure 4 shows the optical spectrum of $[Ni(II)TPP]^{+\bullet}PF_6^-$ at room temperature and after freezing to 77 K. The dramatic spectral changes are accompanied by a change from a green solution to an

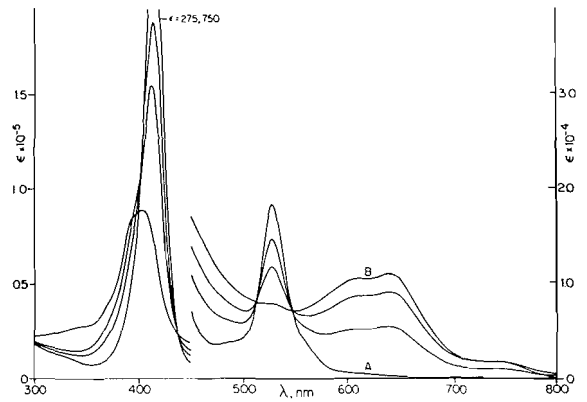

FIG. 2. Optical absorption spectra of Ni(II)TPP (*A*), during its electrochemical oxidation, in CH_2Cl_2, to the π-cation radical $[Ni(II)TPP]^{+\cdot}$ (*B*).

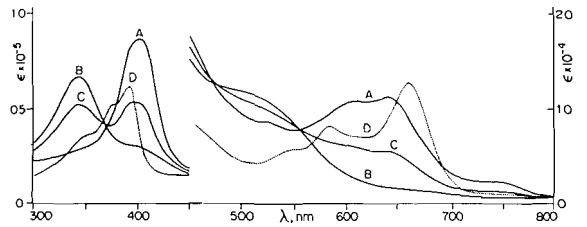

FIG. 3. Optical absorption spectra, in CH_2Cl_2, of the π-cation radical $[Ni(II)TPP]^{+\cdot}$ (*A*), the π-dication $[Ni(II)TPP]^{2+}$ (*B*). *C* is the optical spectrum during oxidation of *A* to *B* showing isosbestic points. *D* is the π-cation radical $[Mg(II)OEP]^{+}$.

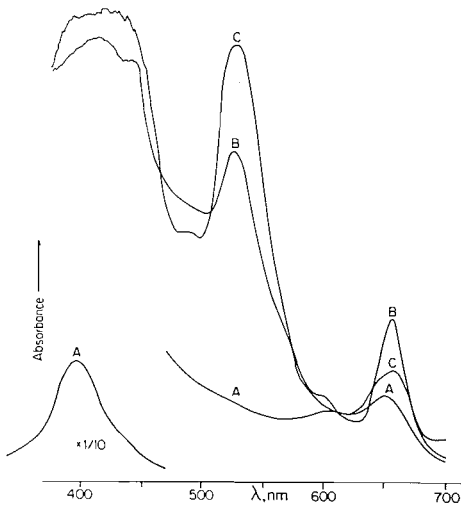

FIG. 4. Optical absorption spectra, in CH_2Cl_2, of [Ni(II)-TPP]$^{+\cdot}PF_6^-$ at room temperature (*A*), the same sample at 77 K showing spectrum of [Ni(III)TPP]$^+PF_6^-$ (*B*), and Ni(II)-TPP at 77 K (*C*).

orange-red frozen solid which has a strong band at 526 nm. The spectra of both Ni(II)TPP and [Ni(II)-TPP]$^{+\cdot}$ when measured in CH_2Cl_2 in the presence of both TBAH and TBAP at 77 K show a band centered at 654 nm (in the absence of TBAP or TBAH Ni(II)TPP does not exhibit this absorption). In addition Ni(II)TPP$^{+\cdot}$ at room temperature exhibits a broad absorption at 668 which moves to 656 at 77 K.

The optical spectra of methylene dichloride solutions of the π-cation radical [Ni(II)TPP]$^{+\cdot}$ [PF_6 or ClO_4]$^-$ showed no major changes upon cooling to 77 K when small amounts of water were present, nor were any changes observed with the bromide salt [Ni(II)TPP]$^{+\cdot}$ Br^-.

Electron Paramagnetic Resonance

The epr of the one-electron oxidation product were recorded at room temperature and at 77 K. At room temperature the green solution in the presence of PF_6^-, ClO_4^-, or Br^- exhibited a single signal, $g = 2.0041$ with a peak-to-peak separation of 47.2 G, indicative of a π-cation radical. At 77 K the orange-red solid showed signals at $g_\perp = 2.286$ and $g_\parallel = 2.086$, consistent with a low spin d^7 (Ni(III)) electronic configuration and in good agreement with spectra reported by Busch and co-workers (19) and by Wolberg and Manassen (15) for Ni(III) complexes. The epr signal of the Ni(III) species slowly decayed with time, being replaced after ~24 h by a weak isotropic signal which also decayed with time.

We have already noted above that upon cooling solutions of the PF_6^- or ClO_4^- salts, in the presence of small amounts of water, or the pure bromide salt no color change is observed. Similarly, these same solutions show no change in their epr spectra when cooled to 77 K, and only the isotropic signal at $g = 2.0041$ is present.

Discussion

From the physical studies described above we can conclude that when Ni(II)TPP is electrolyzed in methylene dichloride (with either TBAH, or TBAP as supporting electrolyte) at 1.24 V it undergoes a clean, reversible, one-electron oxidation to give the corresponding π-cation radical [Ni(II)TPP]$^{+\cdot}$. At room temperature this species shows all of the properties of other similar, and well characterized, metalloporphyrin π-cation radicals with a $^2A_{2u}$ ground state (5). The stability and ease of preparation of this π-cation radical is indicated by the clean electrochemistry and solution stability over long time periods. In addition this π-cation radical behaves like other metalloporphyrin π-cation radicals in that it can quantitatively be reduced back to Ni(II)TPP, and can be made to undergo a further one-electron oxidation to the π-dication [Ni(II)TPP]$^{2+}$.

In all of these respects [Ni(II)TPP]$^{+\cdot}$ is no different from other porphyrin π-cation radicals, which have been reported on in great detail, except for its quite exceptional thermal behavior. All of the above data are consistent with an internal electron transfer occurring as the temperature is lowered, with the hole jumping from the periphery to the metal. These redox reactions can be summarized as follows:

$$\text{Ni(II)TPP} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [\text{Ni(II)TPP}]^{+\cdot} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [\text{Ni(II)TPP}]^{2+}$$
$$\Big\downarrow\Big\uparrow \Delta$$
$$[\text{Ni(III)TPP}]^+$$

The strongest electronic transitions in metalloporphyrins (and their oxidized and reduced derivatives) are $\pi \rightarrow \pi^*$ in nature with molecular extinction coefficients of from 10 000 to 1 000 000 (20, 21). In such systems the weak *d–d* transitions of the metal are hidden. Except when charge transfer between metal and ligand occurs, the oxidation state of a specific metal makes only minor perturbation on the optical transitions of metalloporphyrins. The spectra of Ni(II)TPP and that of the orange frozen samples of the π-cation radical [Ni(II)TPP]$^{+\cdot}$ are quite similar (Fig. 4) which show that all of the bonding π-molecular orbitals are filled. Since the π-cation radical has lost an electron from its highest filled bonding π–MO, then upon cooling an electron must move from the metal to fill the π-system and generate Ni(III). The formation of a nickel(III) complex at low temperatures is confirmed by epr spectroscopy which shows two signals having *g* values comparable to

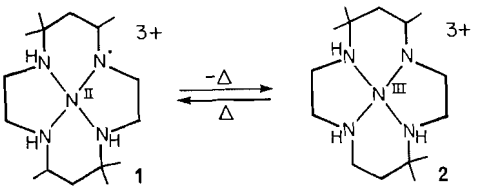
those of previously reported Ni(III) complexes (17, 22). When the same series of epr experiments were carried out using ^{61}Ni ($I = 3/2$) no change in the epr spectra of either the cation radical or the Ni(III) species was observed. However, ^{61}Ni has a small magnetic moment (-0.75) resulting in a small hyperfine interaction which is lost under the relatively broad signal.

Wolberg and Manassen (15) have reported that the initial one-electron oxidation product of Ni(II)-TPP in benzonitrile/TBAP is the metal oxidized $[Ni(III)TPP]^+$, and that upon standing at room temperature solutions of $[Ni(III)TPP]^+$ began to show a weak epr signal which was assigned to $[Ni(II)TPP]^{+\bullet}$. The epr signal which they assigned to $[Ni(III)TPP]^+$ was only observed at 77 K, and it is possible that these authors were observing a similar phenomenon to that reported here. However, the cyclic voltammogram reported for Ni(II)TPP in benzonitrile/TBAP and that reported here using methylene dichloride/TBAP exhibit features which are atypical of most metalloporphyrins (22–25). In the former case the cyclic voltammogram showed two overlapping successive one-electron oxidations which were separated by not more than 100 mV. In the latter case we can resolve the two peaks at 1.17 and 1.29 V which differ by 120 mV. In the numerous cases where it has been shown that the two oxidations occur at the porphyrin periphery (to give π-cation and π-dication) the difference between the two potentials is 290 ± 50 mV (23), and deviations from this value suggest that the metal, rather than the ring, is the redox reactive centre. When Ni(II)TPP is oxidized in CH_2Cl_2/TBAH the two oxidation waves are separated by 320 mV consistant with two ring oxidations, suggesting that the oxidations described above, which were carried out in the presence of perchlorate, involve an initial oxidation of the metal. In benzonitrile the $[Ni(III)TPP]^+$ is sufficiently stable to be observed at room temperature before it converts over to the $[Ni(II)TPP]^{+\bullet}$ whereas we find that at the end of a bulk electrolysis in methylene dichloride any $[Ni(III)TPP]^+$, if formed, has already converted to $[Ni(II)TPP]^{+\bullet}$.

Similar internal electron transfers have been reported previously (19, 26), and Barefield and Mocella (27) showed that a nickel Curtis-type macrocycle exhibited a similar temperature-dependent internal electron transfer, i.e. **1** ⇌ **2**. Although the total charge on these complexes is 3+ instead of the 1+ for the systems reported here, the same general physical behavior was noted. Barefield attributed this phenomenon to the phase change in going from solution to the solid state, and suggested that axial ligation might play an important role in the process. A similar situation obtains here, for when a frozen



sample is in thermal equilibrium with its solution the solid is orange while the solution is green, and only when the green solution freezes does it change color. It is not yet clear what happens, as the phase changes, to bring about the internal electron transfer and stabilize the hole on the metal rather than the periphery. One might anticipate that the higher oxidation state of the metal would be stabilized by the axial coordination of a donor ligand. The situation is not as clear cut as this, however, since in the presence of bromide or water only the π-cation radical is observed even at 77 K. Moreover, the fact that we have found no other prophyrin π-cation which exhibits this internal electron transfer (including the π-cation radical of Ni(II) octaethylporphyrin) suggests that the phenomenon must depend upon a number of closely balanced factors such that small perturbations can stabilize one or another of the two species undergoing the internal electron transfer. Nonetheless, the degree of axial ligation does play a role here since in addition to the intense band at 525 nm the nickel(III) complex shows a broad weak absorption around 650 nm. While the origin of this charge transfer band is unclear, a similar band also occurs in the Ni(II) complex, but only in the presence of ligands which would axially coordinate, and the appearance of a similar band in the spectrum of the Ni(III) complex suggests that at 77 K even PF_6^- and ClO_4^- are coordinating to the metal.

Other metalloporphyrins show similar internal electron transfers. Ferguson *et al.* (28) while studying octaethylporphyrinato Pb(II) (Pb(II)OEP) found two reversible oxidations on the cyclic voltammetric time scale (s) which they attributed to successive, and reversible, one-electron oxidations of the ring. The resulting π-dication decays, in rigorously purified solvents, with a half-life of ~5 min to a Pb(IV) complex (6), i.e.

$$\text{Pb(II)OEP} \overset{-e^-}{\rightleftharpoons} [\text{Pb(II)OEP}]^{+\bullet} \overset{-e^-}{\rightleftharpoons} [\text{Pb(II)OEP}]^{2+} \downarrow [\text{Pb(IV)OEP}]^{2+}$$

Having shown that a facile and reversible internal electron transfer can occur between a metal and the periphery of a coordinating porphyrin one can ask could such an internal transfer play any role in biochemical systems? Even though many cytochromes function via an Fe(II)–Fe(III) couple, and while it is

TABLE 1. Electron transfer rates for oxidation/reduction of cytochrome *c*

Reagent	Rate (M^{-1} s^{-1})	Reference
e_{aq}^-	1.3×10^{11}	29
$Fe(dipy)_2(CN)_2^+$	1.9×10^8	35
$Fe(CN)_6^{3-}$	8.0×10^6	35
Azurin	6.25×10^6	37
$Ru(NH_3)_6^{2+}$	3.8×10^4	32
$Fe(CN)_6^{4-}$	2.6×10^4	51
Fe(II) cyt *c*	2×10^4	52
Cr(II)	1.2×10^4	33
$Co(phen)_3^{3+}$	1.5×10^3	32

abundantly clear that the final oxidation states are indeed ferric and ferrous, how is ferrous cytochrome oxidized to its ferric state?

Much kinetic data have been gathered on the redox reactions of cytochromes, particularly the cytochromes *c*, using a variety of redox reagents ranging from hydrated electrons (e_{aq}^-) (29–31) through simple inner- and outer-sphere inorganic reagents (32–36) to those macromolecules which transfer electrons to and from cytochrome *c* in nature (37–41). Table 1 lists some of these redox reagents and observed rates of electron transfer, and while the rates vary they are generally in the range of 10^3–10^6 M^{-1} s^{-1}. Cytochrome *c* contains an axially coordinated methionine (42–43). Sutin has measured the rate of breaking the Fe—S bond, and of opening a heme crevice, which should be rate limiting for an inner sphere pathway (44). The measured value of 60 s^{-1} would appear to rule out an inner sphere process as a major route of electron transfer even with small inorganic redox reagents.

X-ray crystallography has shown that both the reduced and oxidized forms of cytochrome *c* have essentially the same structure (43). One striking feature of the crystal structure is the partially exposed edge of the heme porphyrin ring (a similar structural feature is observed with cytochrome b_5 (45), and we anticipate that other cytochromes in the respiratory chain will show similar exposed hemes). The tertiary structure of the protein will, of course, impose severe steric restraints upon the accessibility of the heme coordinated iron to even the smallest redox reagent, such that it is inconceivable that the iron atoms of two adjacent cytochromes could come close enough to transfer an electron via an inner sphere mechanism. How then do cytochromes transfer electrons amongst themselves? Kinetic studies have suggested three main routes.

(i) A remote transfer through aromatic residues in the protein—which can be seen in the crystal structure of cytochrome *c* to form a channel from the surface of the protein to the heme. Similar remote pathways with an electron tunneling through several Ångstroms of a hydrophobic protein channel have been proposed for some non-heme iron proteins, the ferredoxins (46). Thorough articulations of these arguments can be found elsewhere (47), but it should be noted such a pathway does not appear to be operative in cytochrome *c*.

(ii) A direct electron transfer through space—In addition to the classical inner- and outer-sphere modes of electron transfer the possibilities that direct electron transfer via quantum mechanical electron tunneling, or transfer to and transport through a solvent (as a hydrated electron (e_{aq}^-) in biochemical systems) must be considered. Even in redox reactions with simple inorganic ions the intermediacy, or lack thereof, of e_{aq}^- has yet to be satisfactorily demonstrated (48). The same situation applies to the more complex biochemical systems even though the reduction of ferricytochrome *c* by externally generated e_{aq}^- has been reported (49).

Quantum mechanical electron tunneling is, however, well documented, and tunneling through distances of tens of Ångstroms of inert solvents has been observed with non-biochemical systems (49). While application of the simple one-dimensional theory (49) to complex macromolecules is unwarranted, it does suggest that such mechanisms are possible in nature even though none has yet been documented.

(iii) Oxidation at the porphyrin periphery—A number of both kinetic and product isolation studies suggest that the oxidation of a coordinated metal can proceed through an outer-sphere mechanism, and studies with ferrocytochrome *c* and complexes of tris(1,10-phenantholine)cobalt(III) ions show that an outer sphere mechanism is operative and these studies have led Gray and co-workers (14) to suggest that the point of electron transfer is the partially exposed heme edge. But having concluded that electron transfer occurs via the porphyrin π-cloud how, in fact, is the ferrocytochrome *c* oxidized to the ferric state? We suggest that a process analogous to the oxidation of the Ni(II)TPP to the $Ni(III)TPP^+$ might be operative, that is via the intermediacy of a porphyrin π-cation radical, such that the oxidation of ferro- to ferricytochrome *c* could be described as:

$$\underset{\text{I}}{\text{Fe(II) cyt } c} \underset{+e}{\overset{-e^-}{\rightleftharpoons}} \underset{\text{II}}{[\text{Fe(II) cyt } c]^{+\cdot}} \rightleftharpoons \underset{\text{III}}{[\text{Fe(III) cyt } c]^+}$$

Since ferric and ferrous iron have different covalent

For personal use only.

radii there must be conformational changes around the iron and its ligands between ferro- and ferricytochrome *c* (I and III) and between the postulated ferrocytochrome *c* π-cation radical (II) and ferricytochrome *c* (III). Thus II and III would not be extreme resonance forms of the same species and an activation energy will be required to convert II to III. It has been suggested that the slow interconversion of $[Pb(II)OEP]^{2+}$ to $[Pb(IV)OEP]^{2+}$, discussed above, may be due to a Frank–Condon forbidden transition since the Pb(II) is out of plane and the Pb(IV) in plane (50); and that since there is no overlap between the empty a_{1u} porphyrin orbital and the $a_{2u}(6p_z)$ lead orbital the probability for charge transfer is small. In the case of the nickel complexes described here the system is more finely tuned and the electronic configurations are adjusted to a thermally controlled level. A similar situation might be anticipated in the cytochromes, and the rapid rate of electron transfer for self exchange in cytochromes *c* suggest that an intermediate such as II will be short lived ($<10^{-5}$ s), and as yet none have been detected.

A reformulation of the theory of unimolecular reactions

ANDREW W. YAU AND HUW O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received September 1, 1977

ANDREW W. YAU and HUW O. PRITCHARD. Can. J. Chem. **56**, 1389 (1978).

The theory of unimolecular reactions is reformulated in a way which makes no reference to the concepts of a transition state, a reaction coordinate, or of an activated complex: the present theory is based, instead, on a simple master-equation approach using the estimated positions and lifetimes of the rotation–vibration energy levels of the molecule. The fundamental basis of this reformulation is that the unimolecular rate is derived from the perturbation of the normal modes of internal relaxation of the reactant molecule by the microscopic reaction processes. The thermal decompositions of cyclobutane, cyclopropane, ethyl isocyanide, ethyl chloride, and methyl isocyanide are examined in detail, and it is shown that not only is the present theory much easier to use than is conventional RRKM theory, but also that it gives better results.

An Appendix provides a set of algorithms required for these calculations.

ANDREW W. YAU et HUW O. PRITCHARD. Can. J. Chem. **56**, 1389 (1978).

On propose une reformulation de la théorie des réactions unimoléculaires d'une façon telle que l'on ne fasse aucune référence aux concepts d'état de transition, de coordonnée de réaction ou de complexe activé: on base plutôt la nouvelle théorie sur une équation maîtresse simple utilisant des positions et des temps de vie évalués des niveaux énergétiques rotation–vibration de la molécule. Le concept fondamental de cette reformulation repose sur la notion que la vitesse unimoléculaire provient d'une perturbation des modes normaux de relaxation interne de la molécule réactive par des processus réactionnels microscopiques. On a examiné en détail les décompositions thermiques du cyclobutane, du cyclopropane, de l'isocyanure d'éthyle, du chlorure d'éthyle et d'isocyanure de méthyle et on a montré que la théorie est plus facile à utiliser que la théorie RRKM conventionnelle et qu'elle donne aussi de meilleurs résultats.

Un appendice fournit l'ensemble d'algorithmes requis pour ces calculs.

[Traduit par le journal]

I. Introduction

This examination of the theory of unimolecular reactions was undertaken principally out of a desire to see the theory cast in modern molecular-dynamic terms. We do not claim that the theory set out below satisfies this desire completely: in a purely formal sense it does, but in practice our estimates of the effective lifetimes of the reactive states with respect to predissociation are not, at present, derived by molecular-dynamic methods.

The most successful current theory of thermal unimolecular reactions is the RRKM theory (1–6), but despite its obvious success in describing reasonably well a very wide range of reaction processes, it suffers from some frustrating deficiencies. Most importantly, although much emphasis is placed upon the selection of a hypothetical reaction coordinate and the corresponding activated complex, it hardly matters what reaction coordinate is chosen (5, 7, 8) because the calculated fall-off behaviour is very insensitive to this choice. Less serious, but nevertheless unsettling, are the problems surrounding the assumed collisional deactivation efficiency: one is that markedly different collision efficiencies are often required to make the calculated and experimental fall-off curves coincide at different temperatures (5), or sometimes these efficiencies do not vary monotonically with temperature (9, 10); another is that collision efficiencies of the order of unity are often found, and yet it is reasonably well established that the vessel walls are more effective in transferring internal energy than are collisions with other molecules (11–13). These difficulties do not arise in the present reformulation: the concepts such as reaction coordinate do not appear, and it becomes evident in the later discussion (section XI*B*) that the puzzle surrounding collision efficiencies is part experimental in origin, and part a matter of theoretical interpretation.

II. List of Symbols

The nomenclature used in this presentation has been chosen to remain, as far as possible, in conformity with existing practices (5) where an identical or nearly identical concept is being represented; for the remainder, we have chosen the simplest nomenclature which appears possible.

- $\mathbf{A}$ internal relaxation matrix (s^{-1}); elements a_{ij}.
- A_∞ Arrhenius frequency factor at infinite pressure (s^{-1}).
- a_i coefficient in the numerator of the generalised Lindemann form, eqs. 46, 47; $\bar{a}_i$ is grouped value in graining procedure, and $\bar{\bar{a}}_i$ is scaled value used in the practical algorithm.

B symmetrised relaxation matrix (s^{-1}).
b_i ith coefficient in the denominator of the generalised Lindemann form, eqs. 46, 47; $\bar{b}_i$ and $\tilde{b}_i$ are respectively grouped and scaled quantities.
β inverse temperature (cm; $= 1/kT$).
D predissociation matrix; diagonal elements $d_i = -k_i$ (s^{-1}).
E equilibrium population matrix—non-dissipative system; diagonal elements $\tilde{n}_j$.
ε energy (cm^{-1} or kcal mol^{-1}).
ε_0 critical energy (cm^{-1} or kcal mol^{-1}; $= \varepsilon_\infty$ assuming eq. 34).
ε_∞ activation energy at infinite pressure for strict Arrhenius rate law.
ε_{act} activation energy at arbitrary pressure.
g_i degeneracy of state i.
$G(\varepsilon)$ state-sum up to energy ε.
Γ diagonalised reaction matrix; γ_j is jth eigenvalue.
k Boltzmann constant.
k_{il} predissociation rate constant from reactant in state i to product in state l (s^{-1}).
k_i decay rate constant from state i to all product channels (s^{-1}; $= \sum_l k_{il}$).
$k(\varepsilon)$ average decay rate constant over all states i at energy ε (s^{-1}).
k_{uni} unimolecular rate constant (s^{-1}; $= -\gamma_{n-1}$).
k_∞ infinite pressure rate constant (s^{-1}).
$\mathscr{L}$ Laplace transform.
Λ diagonalised relaxation matrix; λ_j is jth eigenvalue.
λ collisional efficiency in RRKM theory.
$\bar{\lambda}$ collisional efficiency or pressure-shift parameter.
[M] concentration of inert-gas molecules (molecules cm^{-3}).
n number of levels in relaxing system.
$\tilde{n}_i$ equilibrium (fractional) population of the ith state—non-dissipative system; $\sum_i \tilde{n}_i = 1$.
$\bar{n}_r$ total equilibrium (fractional) population within the rth reactive channel grain.
$\eta_i(t)$ population of the ith state at time t—dissipative system; $\sum_i \eta_i(0) = 1$.
p pressure (Torr).
p_{ij} transition probability per collision *from* state i *to* state j.
$P(\varepsilon)$ state-degeneracy at energy ε; $= \sum_i g_i$ over states at ε.
$\rho(\varepsilon)$ density of states at energy ε (cm).
q_{ij} transition rate constant *from* state i *to* state j (cm^3 $molecule^{-1}$ s^{-1}).
R symmetrised reaction matrix (s^{-1}).
S eigenvector matrix of relaxation matrix **B**; S_{ij} is ith element of jth eigenvector.
Ψ eigenvector matrix of reaction matrix **R**; ψ_{ij} is ith element of jth eigenvector.
s Kassel shape parameter for unimolecular fall-off curve.
σ collision diameter.
T temperature.
μ internal relaxation time constant of molecule (s^{-1}).
μ' internal relaxation rate constant (cm^3 $molecule^{-1}$ s^{-1}).
$\bar{\mu}$ internal relaxation rate constant ($Torr^{-1}$ s^{-1}; $= \mu' \times 9.88 \times 10^{18} T^{-1}$).
ν_i vibrational frequency of ith oscillator (cm^{-1}).
x_i anharmonicity factor of vibration, assumed to be a Morse oscillator.
$Z(T)$ collision number at temperature T (cm^3 $molecule^{-1}$ s^{-1}).
$\mathscr{Q}(\beta)$ partition function at inverse temperature β.

III. The Reaction Model

This treatment follows from an extension of the primitive master-equation model we described earlier this year (14). The reactant molecule X is considered to possess a denumerable set of rotation–vibration states X_i, and is diluted in a heat bath of structureless inert gas molecules M; transitions among the various internal states X_i are induced by collisions with M, and should a molecule X find itself in a state with energy greater than a critical amount ε_0, predissociation to products may occur with a set of characteristic time constants, in competition with collisional deactivation. The model then, is no more than a generalised Lindemann scheme (5, 6, 14)

$$X_i + M \underset{q_{ji}(T)}{\overset{q_{ij}(T)}{\rightleftharpoons}} X_j + M$$

$$X_i \xrightarrow{k_{il}} Y_l$$

where Y_l represents the product in the lth internal state; for the time being, we ignore the internal structure of the product molecules.

Implicit in the model are the following assumptions. The temperature of the heat bath remains unchanged during the reaction, and the heat-bath molecules maintain their translational equilibrium. The mutual interactions between the X molecules are neglected in order to preserve the linearity of the master equation. The model is also dissipative in the sense that the reverse reaction is excluded, a simplification justified by the fact that most unimolecular reactions are studied far away from equilibrium (14).

In this treatment, we have readopted the natural ordering of subscripts, so that $q_{ij}(T)$ is the *rate constant* for the transition of X *from* internal state i *to*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

internal state j upon collision with M at temperature T. This rate constant is related to the transition probability per collision $p_{ij}(T)$ *via* the collision number $Z(T)$, assumed to be independent of i, viz.

$$[1] \qquad q_{ij}(T) = Z(T) \cdot p_{ij}(T)$$

where

$$Z(T) = 2\sigma^2(2\pi/\beta m)^{1/2}$$

σ being the collision diameter and $\beta = 1/kT$, the inverse temperature, and m is the reduced mass of X and M. The quantities q_{ij} and q_{ji} are related by the principle of detailed balancing

$$[2] \qquad \tilde{n}_i q_{ij} = \tilde{n}_j q_{ji}$$

where $\tilde{n}_i$ is the equilibrium fractional population of the ith state in the *absence of reaction* (i.e. when $k_{il} = 0$ for all i); the internal-relaxation process is also Markovian, so that

$$[3] \qquad \sum_j p_{ij} = 1$$

The microscopic rate constant k_{il} for the conversion of the reactant in state i to the product in state l is assumed to be independent of both temperature and the concentrations of X and M. Thus, the master equation for the evolution of the population of the ith state of X is readily written as

$$[4] \qquad \frac{d\eta_i(t)}{dt} = \sum_j a_{ij}\eta_j(t) + d_i\eta_i(t)$$

where $\eta_i(t)$ is the fractional population of the ith state at time t, and

$$[5a] \quad a_{ij} = Z[M]\{(1 - \delta_{ij})p_{ji} - \delta_{ij}\sum_k (1 - \delta_{ik})p_{ik}\}$$

$$[5b] \quad d_i = -\sum_l k_{il}$$

Thus, d_i is zero for all unreactive states, and the summation in [5*b*] is understood to be over all accessible product channels; the quantity $-d_i$ will be redesignated as k_i later, in section V.

Since [4] is linear, it may be written in matrix notation

$$[6] \qquad \frac{d\boldsymbol{\eta}(t)}{dt} = (\mathbf{A} + \mathbf{D})\boldsymbol{\eta}(t)$$

where

$$d_{ij} = d_i\delta_{ij}$$

and the matrix sum $(\mathbf{A} + \mathbf{D})$ can be symmetrised in the usual way (15) using the equilibrium population vector, i.e.

$$[7] \qquad \mathbf{R} = \mathbf{E}^{-1/2}(\mathbf{A} + \mathbf{D})\mathbf{E}^{1/2}$$

where

$$e_{ij} = \tilde{n}_i\delta_{ij}$$

and $\mathbf{R}$ is now symmetric; under this transformation [6] becomes

$$[8a] \qquad \frac{d\boldsymbol{\chi}(t)}{dt} = \mathbf{R}\boldsymbol{\chi}(t)$$

with

$$[8b] \qquad \boldsymbol{\chi}(t) = \mathbf{E}^{-1/2}\boldsymbol{\eta}(t)$$

as the 'symmetrised population evolution vector'. Finally, if $\mathbf{R}$ is diagonalised using the matrices $\boldsymbol{\Psi}$ and $\boldsymbol{\Psi}^T$ to give

$$[9] \qquad \boldsymbol{\Gamma} = \boldsymbol{\Psi}^T\mathbf{R}\boldsymbol{\Psi}$$

$\boldsymbol{\Gamma}$ has the property that all the eigenvalues are real and negative, i.e.

$$0 > \gamma_{n-1} \gg \gamma_{n-2} \geq \gamma_{n-3} \geq \cdots \geq \gamma_0$$

since $\mathbf{R}$ is symmetric and negative definite. Because $\mathbf{R}$ and $(\mathbf{A} + \mathbf{D})$ are related by a similarity transformation, their eigenvalues are identical, and hence (14) we identify the experimentally observed unimolecular rate constant with the eigenvalue of largest algebraic magnitude, i.e.

$$[10] \qquad k_{uni} = -\gamma_{n-1}$$

It follows also that the evolution of the populations of the states of the molecule X is given by

$$[11] \quad \eta_i(t) = \tilde{n}_i^{1/2}\sum_j \exp(\gamma_j t)\psi_{ij}\sum_k \psi_{kj}\eta_k(0)\tilde{n}_k^{-1/2}$$

This equation has been used repeatedly in describing non-dissipative systems (16), but it is equally valid for dissipative systems.

The first aim of the master-equation formulation of unimolecular reactions is therefore the determination of the eigenvalue γ_{n-1}; subsequent aims will involve the determination of the eigenvector elements ψ_{ij}. However, whilst the formal solutions may be readily written, the explicit determination of the exact analytic solution for a general system, with a general set of transition probabilities p_{ij} and microscopic rate constants k_{il}, is a formidable task because of a general lack of theorems in this area; hence, our previous approach using numerical experiment (14). Consequently, we will attempt here to establish, as a first step in this direction, explicit relations between k_{uni} and the normal modes of internal relaxation (17), given a set of microscopic rate constants k_{il}. Note here that the term *internal relaxation* refers to changes between rotation–vibration states of X brought about by collision with M; thus, this avenue of attack is simply one way of trying to solve the generalised Lindemann scheme, as presented at the beginning of this section.

IV. The Relation Between k_{uni} and the Normal Modes of Relaxation

Following our earlier work on molecular relaxation (16, 17) we define, for the internal relaxation system, the symmetrised transition matrix **B** as

$$[12] \qquad \mathbf{B} = \mathbf{E}^{-1/2}\mathbf{A}\mathbf{E}^{1/2}$$

which has eigenvalues λ_j and eigenvectors $\boldsymbol{S}_j$;

$$[13] \qquad \mathbf{B} = \mathbf{S}\Lambda\mathbf{S}^T$$

Recalling briefly the properties of the conservative relaxation system, we have

$$[14] \quad n_i(t) = \tilde{n}_i^{1/2} \sum_j \exp(\gamma_j t) S_{ij} \sum_k S_{kj} n_k(0) \tilde{n}_k^{-1/2}$$

where $n_i(t)$ is the fractional population of state i in the absence of the reaction; notice the similarity with eq. 11. In the conservative case, however, the eigenvalue sequence is

$$0 = \lambda_{n-1} \gg \lambda_{n-2} \geq \lambda_{n-3} \geq \ldots \geq \lambda_0$$

with the zero eigenvalue ensuring conservation of particles, and the particular sequence of eigenvector elements

$$[15] \qquad S_{i,n-1} = \tilde{n}_i^{1/2}$$

ensuring the attainment of the Boltzmann equilibrium distribution as $t \to \infty$. Finally

$$[16] \qquad \lambda_i = \lambda_i'[\mathrm{M}]$$

where the λ_i' are constants, in other words, the relaxation time constants are proportional to [M].

We now rewrite the eigenvalue equation [9], i.e.

$$[17] \qquad \mathbf{R}\boldsymbol{\Psi}_i = \gamma_i \mathbf{I}\boldsymbol{\Psi}_i$$

in the iterative form (18)

$$[17a] \qquad \boldsymbol{\Psi}_i = (\gamma_i \mathbf{I} - \mathbf{B})^{-1}\mathbf{D}\boldsymbol{\Psi}_i$$

Then, using [13], we have

$$[18] \qquad (\gamma_i \mathbf{I} - \mathbf{B})^{-1} = \{\mathbf{S}(\gamma_i \mathbf{I} - \Lambda)\mathbf{S}^T\}^{-1} = \mathbf{S}(\gamma_i \mathbf{I} - \Lambda)^{-1}\mathbf{S}^T$$

whence

$$[19] \qquad \boldsymbol{\Psi}_i = \mathbf{S}(\gamma_i \mathbf{I} - \Lambda)^{-1}\mathbf{S}^T\mathbf{D}\boldsymbol{\Psi}_i$$

The perturbed eigenvector elements are then

$$[20] \qquad \psi_{ki} = \sum_l \left(\sum_m \frac{S_{km}S_{lm}}{\gamma_i - \lambda_m}\right)\left(\sum_j d_{lj}\psi_{ji}\right)$$

and since **D** is diagonal, this reduces to

$$[20a] \qquad \psi_{ki} = \sum_l \sum_m \frac{S_{km}S_{lm}}{\gamma_i - \lambda_m} \cdot d_l\psi_{li}$$

remembering that the summation over l refers to the predissociating states only. For a system with r predissociating states [20] leads to a system of r equations in r unknowns, γ_i and the $(r-1)$ ratios of ψ_{ki}. The utility of [20] follows from the particular spacings of the eigenvalues γ_i and λ_i, where, using a theorem of Courant and Hilbert (19), it may be shown that

$$[21] \quad 0 = \lambda_{n-1} < |\gamma_{n-1}| \ll |\lambda_{n-2}| \leq |\lambda_{n-3}| \leq \ldots \leq |\lambda_0|$$

whence, to an excellent degree of approximation

$$\psi_{k,n-1} = \sum_l \frac{S_{k,n-1}S_{l,n-1}}{\gamma_{n-1}} \cdot d_l\psi_{l,n-1} - \sum_l \sum_{m=0}^{n-2} \frac{S_{km}S_{lm}}{\lambda_m} \cdot d_l\psi_{l,n-1}$$

or, using [15]

$$[22] \quad \psi_{k,n-1} = \tilde{n}_k^{1/2}\gamma_{n-1}^{-1} \sum_l \tilde{n}_l^{1/2} d_l\psi_{l,n-1} - \sum_l \sum_{m=0}^{n-2} \frac{S_{km}S_{lm}}{\lambda_m} \cdot d_l\psi_{l,n-1}$$

Equation 22 lends itself to further development along two distinct lines. First, it provides a framework for the explicit examination of the dependence of k_{uni} on the normal modes of relaxation, at least for model systems, and will be used in this way in subsequent papers to treat other thermal reactions including dielectronic ionisation of hydrogen atoms, and shock wave dissociation of H_2 and D_2. Second, its linearity in γ_{n-1}^{-1} facilitates direct evaluation of k_{uni} for realistic systems of known microscopic rate constants k_{il} and normal modes of relaxation. We will pursue the first point insofar as it pertains to the theory of unimolecular reactions in the remainder of this section, and thereafter devote our attention to the second one.

Suppose there is only one predissociating state r, i.e.

$$d_i = d_r\delta_{ir}$$

Then, for the element $\psi_{r,n-1}$, [22] reduces to

$$[23] \quad \psi_{r,n-1} = \left\{\tilde{n}_r d_r \gamma_{n-1}^{-1} - \sum_{m=0}^{n-2} \frac{S_{rm}^2}{\lambda_m} \cdot d_r\right\}\psi_{r,n-1}$$

which, together with [10] and [16], leads to k_{uni} in the Lindemann form

$$[24] \qquad k_{uni} = -\gamma_{n-1} = \frac{-\tilde{n}_r d_r}{1 - d_r\kappa_{rr}/[\mathrm{M}]}$$

In this equation the term in the denominator

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[25] $$\kappa_{rr} = -\sum_{m=0}^{n-2} \frac{S_{rm}^{\ 2}}{\lambda_m'}$$

represents an average of all the normal modes of relaxation (S_{rm}^2) associated with the state r, *weighted* by their respective characteristic times $\tau_m = -\lambda_m^{-1}$; in fact, the quantity $\kappa_{rr}/[M] \simeq \tau$, the macroscopic relaxation time for the internal energy. Thus, for a system with only one predissociating state, the internal relaxation amongst its various states has the overall effect of grouping all the nonpredissociating states into one, and the fall-off of k_{uni} with pressure is determined principally by the internal energy relaxation rate and, to a lesser extent, by the fine structure of the relaxation, i.e. the detailed nature of the transition probabilities.

It is important to realise that [24] depends on the approximations made in [21], but since

$$|\gamma_{n-1}| \leq \tilde{n}_r|\lambda_{n-2}| \leq \ldots \leq \tilde{n}_r|\lambda_0|$$

and $\tilde{n}_r < 10^{-10}$ for systems of interest, the reason for our earlier numerical finding (14) that such a reaction obeyed Lindemann behaviour to better than one part in 10^6 becomes apparent. On the other hand, for a system with two predissociating states labelled r and s, we have, from [22]

[26] $$k_{uni} = \frac{(\tilde{n}_r\kappa_{rr} + \tilde{n}_s\kappa_{ss} - 2\tilde{n}_r^{1/2}\tilde{n}_s^{1/2}\kappa_{rs})d_rd_s[M]^{-1} - (\tilde{n}_rd_r + \tilde{n}_sd_s)}{1 + \{(\kappa_{rr}\kappa_{ss} - \kappa_{rs}^{\ 2})d_rd_s[M]^{-2} - (\kappa_{rr}d_r + \kappa_{ss}d_s)[M]^{-1}\}}$$

where, as before,

[26a] $$\kappa_{rs} = -\sum_{m=0}^{n-2} \frac{S_{rm}S_{sm}}{\lambda_m'}$$

Thus, with two predissociating channels open, k_{uni} no longer has the Lindemann form, as we found numerically earlier (14); moreover, it can be seen that, in general, k_{uni} cannot be written as a superposition of the Lindemann expressions for the respective channels. This latter observation, then, cuts away at one of the fundamental building blocks of conventional formulations, that k_{uni} can be expressed as the integral over all energy of the differential contribution, dk_{uni}, to the unimolecular rate constant, i.e.

[27] $$k_{uni} = \int_{\varepsilon_0}^{\infty} dk_{uni}$$

where the dk_{uni} are all in Lindemann form (5). The inadequacy of this integral formulation lies in its failure to take account of the perturbation of one predissociating state by all the other predissociating states: this mutual perturbation is of course implicit in the determination of γ_{n-1} through eq. 9. On the other hand, the failure of this integral representation is not catastrophic, for otherwise the development of theories of unimolecular reactions could not have progressed as far as they have done over the last 50 years; nevertheless, the abandonment of [27] is one of the factors contributing to the superiority of the present reformulation over existing theories.

V. The Choice of the k_i

The use of the master-equation formulation to describe chemically reacting systems presents us with a curious paradox. On the one hand, it would appear that, even for quite simple molecules, many millions or billions of state-to-state and state-to-product processes are taking place and therefore their rate constants need to be known. On the other hand, it has been found repeatedly for diatomic dissociation reactions that the rates of observable processes are either only weakly dependent on, or else totally independent of, the assumed state-to-state or state-to-product rate constants (20); we have elaborated on this point elsewhere already (14, 20). In this section, therefore, we will deduce an approximate choice for the numerical values of the k_i, in the following section we will suggest a logical choice for the numerical values of the a_{ij} and, thereafter, we will show that these two choices lead to an excellent representation of all the known unimolecular reaction characteristics for five reactions which have been subjected to extensive experimental scrutiny.

At infinite pressure, the rate constant k_{uni} becomes (14)

[28] $$k_\infty(\beta) = \sum \tilde{n}_i k_i$$

[28a] $$= \sum k_i g_i \exp(-\beta\varepsilon_i)/\mathcal{Q}(\beta)$$

where $\mathcal{Q}(\beta)$ is the molecular partition function of the reactant at the inverse temperature β. Thus, the sum of g_ik_i over all the states i at energy ε is the inverse Laplace transform of $k_\infty(\beta)\mathcal{Q}(\beta)$; i.e.

[29] $$\sum_{\varepsilon} k_i g_i = \mathcal{L}^{-1}\{k_\infty(\beta)\mathcal{Q}(\beta)\}$$

where the summation is over states at energy ε. We now define $k(\varepsilon)$ as the average of k_i over the states at ε, i.e.

[30] $$k(\varepsilon) = \sum_{\varepsilon} k_i g_i / P(\varepsilon); \quad P(\varepsilon) \neq 0$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where

$$[31] \qquad P(\varepsilon) = \sum_{\varepsilon} g_i$$

is the state-degeneracy at energy ε. Since $\mathscr{Q}(\beta)$ is just the Laplace transform of $P(\varepsilon)$, the product $k_\infty(\beta)\mathscr{Q}(\beta)$ in [29] is simply the Laplace transform of the convolution of $\mathscr{L}^{-1}\{k_\infty(\beta)\}$ and $P(\varepsilon)$; whence

$$[32] \qquad P(\varepsilon)k(\varepsilon) = \mathscr{L}^{-1}\{k_\infty(\beta)\} * P|_\varepsilon$$

where $f * g|_\varepsilon$ denotes the convolution of functions f and g from zero to ε. Thus, given $k_\infty(\beta)$ one may, at least in principle, obtain $k(\varepsilon)$, as was first done by Slater (21) in 1955. Over the years, considerable misgivings have been voiced about the validity of such procedures (22–26). However, it may be seen that the derivation of [32] from [28] is rigorous.[1] In particular, it may be shown that for a *discrete system* of predissociating levels, the $k(\varepsilon)$ function is given rigorously by

$$[33] \qquad k(\varepsilon) = A_\infty P(\varepsilon - \varepsilon_\infty)/P(\varepsilon); \quad P(\varepsilon) \neq 0$$

if *the rate law is strict Arrhenius in form*, i.e.

$$[34] \qquad k_\infty(T) \equiv k_\infty(\beta) = A_\infty \exp(-\varepsilon_\infty/kT) = A_\infty \exp(-\beta\varepsilon_\infty)$$

Similarly, it follows, again rigorously, that if the rate law is in modified Arrhenius form, viz.

$$[35] \qquad k_\infty(T) \equiv k_\infty(\beta) = B_\infty T \exp(-\varepsilon_\infty^*/kT) = B'\beta^{-1} \exp(-\beta\varepsilon_\infty^*)$$

where $B' = B_\infty/k$, then

$$[36] \qquad k(\varepsilon) = B'G(\varepsilon - \varepsilon_\infty^*)/\rho(\varepsilon)$$

where $G(\varepsilon)$ is the sum of states up to and including ε and $\rho(\varepsilon)$ is the state density at ε.

It is customary to present experimental data for the infinite-pressure rate constant k_∞ in Arrhenius form, eq. 34. Whether or not experimental rate data for thermal unimolecular reactions obey [34] *rigorously* is a matter which we will discuss further below, cf. Appendix 1; deviations from [34], on the other hand, are clearly small, so that we may write a generalised form of the Arrhenius equation, i.e.

$$[37] \qquad k_\infty = \sum_j A_{\infty j} \exp(-\beta\varepsilon_{\infty j}), \quad j = 1, 2, 3, \ldots$$

where obviously $\varepsilon_{\infty j} \simeq \varepsilon_{\infty 1}$ and $0 < A_{\infty j} \ll A_{\infty 1}$ for all $j \geq 2$, and of course, $\varepsilon_{\infty 1} \equiv \varepsilon_\infty$, $A_{\infty 1} \equiv A_\infty$. We then have, using [32],

$$[38] \qquad P(\varepsilon)k(\varepsilon) = \sum_j \mathscr{L}^{-1}\{A_{\infty j} \exp(-\beta\varepsilon_{\infty j})\} * P|_\varepsilon$$

$$[39] \qquad = \sum_j A_{\infty j} P(\varepsilon - \varepsilon_{\infty j})$$

$$[40] \qquad \simeq A_\infty P(\varepsilon - \varepsilon_\infty)$$

Thus, despite existing doubts, [37]–[40] demonstrate conclusively that the inverse transform of the experimental rate law *is* a good *approximation* to $P(\varepsilon)k(\varepsilon)$ in [33]. Equation 33 is not new, in the sense that it was first derived in the continuous form

$$[41] \qquad k(\varepsilon) = A_\infty \rho(\varepsilon - \varepsilon_\infty)/\rho(\varepsilon)$$

by Slater (21). Yet, the obvious conceptual difficulty, that of the density of states at zero energy, is not encountered in the present derivation of [33]. The two $k(\varepsilon)$ functions, [33] and [36], are quite different in form, as is shown for the example of cyclopropane in Fig. 1; however, they give rise to almost imperceptibly different rate laws given the present precision with which most thermal rate constants can be measured. In the present reformulation, we will adopt [33] for $k(\varepsilon)$, based on two arguments presented in Appendix 1: briefly, the use of [33] always gives a better representation of the shape of the fall-off curve than does the use of [36], as is shown, for example, for cyclopropane in Fig. 2, and there is no other overriding reason for preferring [36] over [33].

VI. The Choice of the a_{ij}

The evaluation of the detailed transition probability matrix elements is clearly a formidable task. Yet, it is now well recognised that the macroscopic behaviour of a relaxation system depends predominantly on the overall relaxation rate and much less so on the pattern of the transition probabilities; this is especially so when the internal relaxation rate is many orders of magnitude faster than the reaction rate, as is the case with most thermal unimolecular reactions. Given this degree of freedom, it is desirable that our choice of the a_{ij} shall satisfy two criteria, one, that it leads to an algebraically tractable solution and two, that its physical implications are clear, so that the limits of its usefulness can be well understood. Figure 3*a* shows in schematic form a set of unperturbed eigenvalues for the internal relaxation of a molecule as a function of [M], and Fig. 3*b* shows schematically the result of allowing this eigenvalue spectrum to be perturbed by a set of k_i elements. This is essentially the result obtained earlier in our numerical experiments (14) and foreseen a long

[1]It should be remembered, however, that $k_\infty(\beta)$ may not be defined in the form of eq. 28 if β is too small, but our treatment using the Laplace transform rather than a finite Laplace series implicitly assumes the validity of such definition. The precise effect of this assumption remains to be deduced although, fortunately, because of the inverse relationship between β and ε, any such effect should be most pronounced at infinitely high energy.

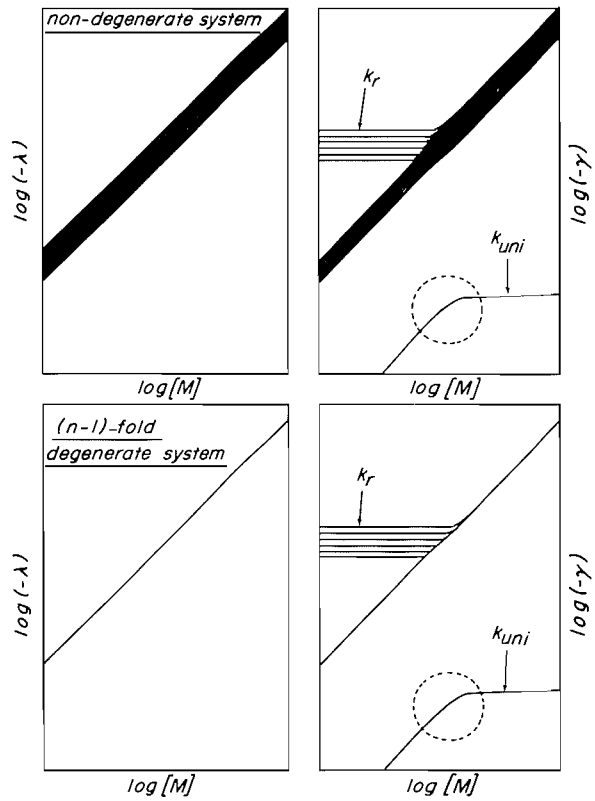

FIG. 3. Schematic representation of the eigenvalue behaviour of (*a*) a general relaxation matrix, (*b*) a general reaction matrix, (*c*) a relaxation matrix with $(n-1)$-fold degeneracy (eq. 42), and (*d*) a reaction matrix with relaxation behaviour of (*c*). Circles indicate pressure region of interest in unimolecular reaction studies.

time ago by Buff and Wilson (40): the important point for our argument is the wide separation between the bundle of eigenvalues representing the internal relaxations and the one representing the reaction rate. We propose, principally on the grounds of algebraic tractability, but also because no great injustice is done to the physical reality (as we shall argue below), to assume that the internal relaxations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

can be treated as being completely degenerate, Fig. 3*c*. The set of transition probabilities corresponding to this $(n-1)$-fold degeneracy of the eigenvalues is (16, 41)

$$[42] \quad a_{ij} = \bar{\lambda}Z[\mathrm{M}]\{(1-\delta_{ij})\tilde{n}_j - \delta_{ij}(1-\tilde{n}_i)\}$$

where $0 < \bar{\lambda} \leq 1$; for such a system, all the non-zero eigenvalues of the symmetrised transition matrix **B** will be degenerate, i.e.

$$\lambda_{n-2} = \lambda_{n-3} = \ldots = \lambda_0 = -\bar{\lambda}Z[\mathrm{M}] = -\mu < \lambda_{n-1} = 0$$

The quantity $\bar{\lambda}$ is therefore a (unknown) collisional efficiency parameter, analogous to the collisional deactivation efficiency (usually denoted by λ) in conventional theory (5, 6): it will be used here in a similar fashion, to effect a lateral shift in the calculated fall-off curve so as to obtain the optimum coincidence with the experimental observations; the quantity μ is of course the time constant for the internal relaxation.

It is important to understand clearly the implications of this approximation. Using [42], the unperturbed system relaxes in a purely exponential manner (16, 41), and it is this property which gives rise to a drastic simplification in the subsequent algebra. When the series of k_i elements is introduced, the behaviour of the perturbed eigenvalues changes to that depicted schematically in Fig. 3*d*, and the contention is that the encircled portion of the curve for k_{uni} in this diagram will be a good approximation to the encircled portion of the curve for k_{uni} in Fig. 3*b*; this is because the bundle of internal-relaxation eigenvalues is so well separated from the reaction-rate eigenvalue, and of course, as far as thermal unimolecular reactions are concerned, we are not interested in the eigenvalue behaviour elsewhere on these diagrams. In physical terms, the set of probabilities given by [42] will lead to a population evolution in which there are no fluctuations during the transient phase (42), but since we are interested only in the steady state in considering thermal unimolecular reactions, this artefact is unlikely to have serious consequences. On the other hand, examination of [42] reveals that the probability of an inelastic transition from state i to state j is proportional to the equilibrium population of the final state: this means that [42] will tend to overestimate the probabilities of transitions to states of high j, and we will return to a discussion of this problem later in the paper.

VII. The Unimolecular Rate Constant, k_{uni}

We are now interested in the way in which the presence of predissociation terms perturbs the solutions of [42]. In the absence of any perturbation, the behaviour of these solutions is very simple (16), namely that both the total energy $\xi(t)$ and each of the individual populations $n_i(t)$ evolve in a pure-exponential way, i.e.

$$[43] \quad \frac{\mathrm{d}\xi(t)}{\mathrm{d}t} = \mu[\xi(t) - \tilde{\xi}]$$

$$[44] \quad n_i(t) = \tilde{n}_i + [n_i(0) - \tilde{n}_i]\mathrm{e}^{-\mu t}$$

Making use of the orthogonality relations between the vectors, together with eq. 15, it then follows that if we have r decay channels present, eq. 22 for the perturbed eigenvector elements simplifies to

$$[45] \quad \psi_{k,n-1} = \tilde{n}_k^{1/2}\gamma_{n-1}^{-1}\sum_l \tilde{n}_l^{1/2} d_l \psi_{l,n-1} + \mu^{-1}\sum_l (\delta_{kl} - \tilde{n}_k^{1/2}\tilde{n}_l^{1/2}) d_l \psi_{l,n-1}$$

where the index l runs over only the predissociating states. Extracting k_{uni} (i.e. $-\gamma_{n-1}$) out of this set of r equations, we have

$$[46] \quad k_{\mathrm{uni}} = \frac{\sum_{i=1}^{r} a_i[\mu\mathrm{M}]^{1-i}}{1 + \sum_{i=1}^{r} b_i[\mu\mathrm{M}]^{-i}}$$

with

$$[47a] \quad a_i = \sum_{\{i\}}^{\{r\}} [(\sum \tilde{n}_j) \cdot (\prod k_j)]$$

$$[47b] \quad b_i = \sum_{\{i\}}^{\{r\}} [(1 - \sum \tilde{n}_j) \cdot (\prod k_j)]$$

where $\sum_{\{i\}}^{\{r\}}$ refers to summation over the $\left\{ {r \atop i} \right\}$ combinatorial terms and the summations and products are over the combinatorial elements.[2] Equation 46 can clearly be regarded as a generalised Lindemann equation, but not the conventional generalised form [27].

In a real system, where there are millions of either discrete or quasi-continuous decay channels, eqs. 46 and 47 would become hopelessly cumbersome. It is therefore necessary to group the decay channels into

[2]The combinatorial terms appearing in eqs. 47*a* and 47*b* are defined as follows, for example

$$a_2 = \sum_{\{2\}}^{\{r\}} \left[\left(\sum_j \tilde{n}_j \right) \cdot \left(\prod_j k_j \right) \right]$$
$$= k_1k_2(\tilde{n}_1 + \tilde{n}_2) + k_1k_3(\tilde{n}_1 + \tilde{n}_3) + \ldots + k_1k_r(\tilde{n}_1 + \tilde{n}_r) + k_2k_3(\tilde{n}_2 + \tilde{n}_3) + \ldots + k_2k_r(\tilde{n}_2 + \tilde{n}_r) + \ldots + k_{r-1}k_r(\tilde{n}_{r-1} + \tilde{n}_r)$$

pseudo-levels, much in the same way as has been done previously in earlier master-equation formulations (5, 6, 14). However, in previous formulations, the graining procedure has been considered to apply to all states of the molecule, both reactive and unreactive, whereas here, we only need to coarse-grain the reactive levels into pseudo-levels: this is because, *in this approximation*, the information relating to the internal relaxation of the unreactive states has been incorporated into [46] through the use of [45]. This graining procedure is depicted schematically in Fig. 4, which is drawn in such a way as to emphasise the fact that the grain sizes need not correspond to equal energy gaps; the grain widths can be chosen in any way which optimises the calculation with respect to truncation errors and computing costs. In practice, the choice of the number of grains required and the grain widths is straightforward, and is based on the following observations. The first is that for all the reactions considered, 99% of the total rate comes from states within 30 kcal mol^{-1} of the threshold, whatever the pressure, so that the summations in [46] can be terminated at about this energy. The second goes back to our earlier observation that if only one decay channel is present, the calculated fall-off curve is Lindemann in form, but as more decay channels are included in the calculation, the fall-off curve becomes more gradual (corresponding to a higher value of the Kassel shape parameter s) (14). This behaviour is shown in Fig. 5 for cyclopropane at 490°C with

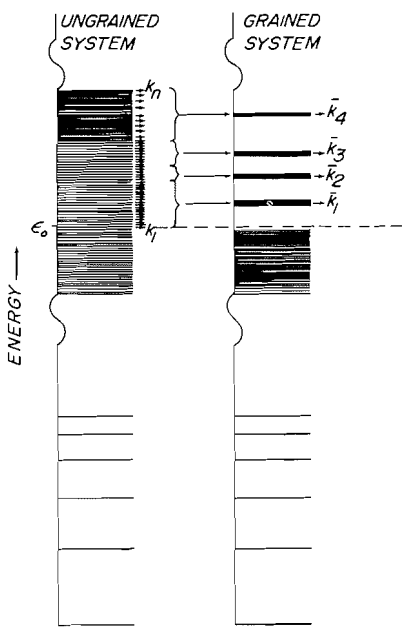

FIG. 4. Schematic representation of the graining procedure. Only the reactive states are grouped. The grain-widths need not be equal in energy.

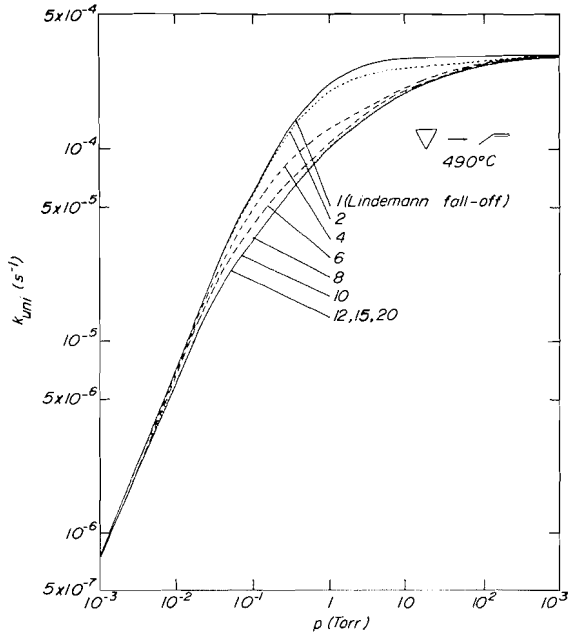

FIG. 5. Calculated fall-off curves for the isomerisation of cyclopropane at 490°C with r = 1, 2, 4, 6, 8, 10, 12, 15, and 20 pseudolevels. The last four curves are graphically indistinguishable. The first (r = 1) curve is exactly Lindemann in form. $A_\infty = 1.88 \times 10^{15}$ s^{-1}, ε_∞ = 65.6 kcal/mol.

r = 1, 2, 4, 6, 8, 10, 12, 15, and 20 decay channels: the calculated fall-off behaviour rapidly 'converges' as r increases, and in no case have we found it necessary to use more than 15 pseudo-levels to represent the spectrum of reactive states.

The use of this grouping procedure necessitates some redefinition of the meanings of terms used in eqs. 46 and 47 where the summations and products are over the individual predissociating states. For the ungrained system, the low-pressure and high-pressure limiting forms of the rate constant are

$$[48] \quad \lim_{[M]\to 0} k_{uni}(M) \equiv k_{bim}[M] = \mu \sum_r \tilde{n}_r/(1 - \sum_r \tilde{n}_r)$$

$$[49] \quad \lim_{[M]\to \infty} k_{uni}(M) \equiv k_\infty = \sum_r \tilde{n}_r k_r$$

If we let $\bar{n}_r$ and $\bar{k}_r$ be the *grouped* equilibrium population and decay constant respectively for the *grained* system, we require that

$$[50] \quad \lim_{[M]\to 0} k_{uni}(M) = \mu \sum_j \bar{n}_j/(1 - \sum_j \bar{n}_j)$$

$$[51] \quad \lim_{[M]\to \infty} k_{uni}(M) = \sum_j \bar{n}_j \bar{k}_j$$

where the summations are now over the *grained* 'pseudo-levels'. Equations 48–51 may be satisfied if

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

we have, for each grain

$$[52] \qquad \bar{n}_j = \sum_l \tilde{n}_l$$

$$[53] \qquad \bar{k}_j = \sum_l \tilde{n}_l k_l / \bar{n}_j$$

where the summations l in [52] and [53] are only over the levels within each grain. Explicitly,

$$[54] \qquad \bar{n}_j = [\mathcal{Q}(\beta)]^{-1} \sum_{\varepsilon_l = \varepsilon_j}^{\varepsilon_{j+1}} g_l \exp(-\beta\varepsilon_l)$$

$$[55] \qquad \bar{k}_j = A_\infty [\mathcal{Q}(\beta)\bar{n}_j]^{-1} \exp(-\beta\varepsilon_\infty) \times \sum_{\varepsilon_l = \varepsilon_j - \varepsilon_\infty}^{\varepsilon_{j+1} - \varepsilon_\infty} g_l \exp(-\beta\varepsilon_l)$$

However, as we will discuss further below, the mean width $\Delta\varepsilon$ of the predissociating levels (arising from the uncertainty principle) is several orders of magnitude greater than the mean spacing between the levels for the molecules considered here (i.e. $\rho(\varepsilon) \cdot \Delta\varepsilon \gg 1$), so that [54] may readily be written in integral form, viz.

$$[56] \qquad \bar{n}_j = [\mathcal{Q}(\beta)]^{-1} \int_{\varepsilon_j}^{\varepsilon_{j+1}} \rho(\varepsilon) \exp(-\beta\varepsilon)\, d\varepsilon$$

where we define

$$[57] \qquad \rho(\varepsilon) = \sum_i P(\varepsilon_i)\delta(\varepsilon - \varepsilon_i)$$

$\delta(\varepsilon)$ being the Dirac delta function and the summation goes over all states i. Similarly [55] may be written as

$$[58] \qquad \bar{k}_j = A_\infty [\mathcal{Q}(\beta)\bar{n}_j]^{-1} \exp(-\beta\varepsilon_\infty) \times \int_{\varepsilon_j - \varepsilon_\infty}^{\varepsilon_{j+1} - \varepsilon_\infty} \rho(\varepsilon) \exp(-\beta\varepsilon)\, d\varepsilon$$

Thus, the final expression for k_{uni} remains as eq. 46, but the expressions [56] and [58] for $\bar{n}_j$ and $\bar{k}_j$ are used in [47a] and [47b] instead of $\tilde{n}_j$ and k_j, and the index r is reinterpreted to be the number of pseudo-channels. For the remainder of this paper, for the reasons just mentioned above, the distinction between the discrete form for $k(\varepsilon)$, eq. 33, and the continuous form, eq. 41, will be relaxed, and [33] and [41] will be used interchangeably.

A major advantage of this computational scheme is that once the grain size and the number of grains (usually 15) have been chosen, the unimolecular rate constant k_{uni} at any pressure can be evaluated explicitly, and the calculation needs not be started anew, as is the case with RRKM (and RRK) procedures, for each pressure: this is one of the two reasons why our method is so much more economical in computer time than the pre-existing procedures; the other reason is that our new procedure for calculating densities and sums of states (43) can be up to two orders of magnitude faster than existing methods for complex molecules.

VIII. Which States to Count?

Our reformulation of unimolecular reaction theory is now complete, in a formal sense, the relevant equations being [46], [47a], [47b], [56], and [58]; however, the latter two equations contain the state-degeneracy of the molecule in the non-reactive region, and the density of states of the molecule in the reactive region. Tracing back the origins of this involvement of $P(\varepsilon)$ and $\rho(\varepsilon)$, it arises in our approach as part of a semi-empirical estimate (eq. 33) for the predissociation rate constants of the reactive states of the molecule, and our subsequent approximation using $\rho(\varepsilon)$ for $P(\varepsilon)$ in [57] which reduces [33] to the continuous form [41]. We have yet to consider in this context the problem of counting states, and to decide, for example, whether rotational or vibrational states can be regarded as making equal contributions to $k(\varepsilon)$. Consequently, we have to examine the interrelationship between the state density and the fall-off properties for a molecule.

It has been recognised since the early days of unimolecular reaction theory that both the position and curvature of the fall-off curve are related to the complexity of the molecule. Usually, the number of atoms in the molecule, or the number of vibrational degrees of freedom, is used as an indicator of this complexity, but in fact we are really dealing with a manifestation of the *distribution* of state density in the molecule; a more useful measure of the complexity would be the number of vibrational degrees of freedom weighted by the reciprocals of their respective fundamental frequencies. The more complex a molecule is, the more vibrational degrees of freedom (of lower average frequency) it has, and hence the more drastic its increase in state density with energy. This causes the fall-off in unimolecular reaction rate with decreasing pressure to be more gentle in two ways. First, there are relatively more reactive states accessible by collisional or intramolecular energy transfer, so that at low pressure there will be a relatively higher rate of reaction, and hence a less drastic fall-off. Second, the more complex the molecule, the smaller is the ratio $P(\varepsilon - \varepsilon_\infty)/P(\varepsilon)$ in eq. 33; thus, for fixed values of A_∞ and ε_∞, $k(\varepsilon)$ is smaller and the depletion of population by reaction at any particular pressure is not as severe.

It is of interest to note earlier attempts to characterise the fall-off behaviour of a unimolecular reaction in terms of the complexity of the reactant molecule, along such lines. These include the semi-empirical interpretation of the effective oscillator num-

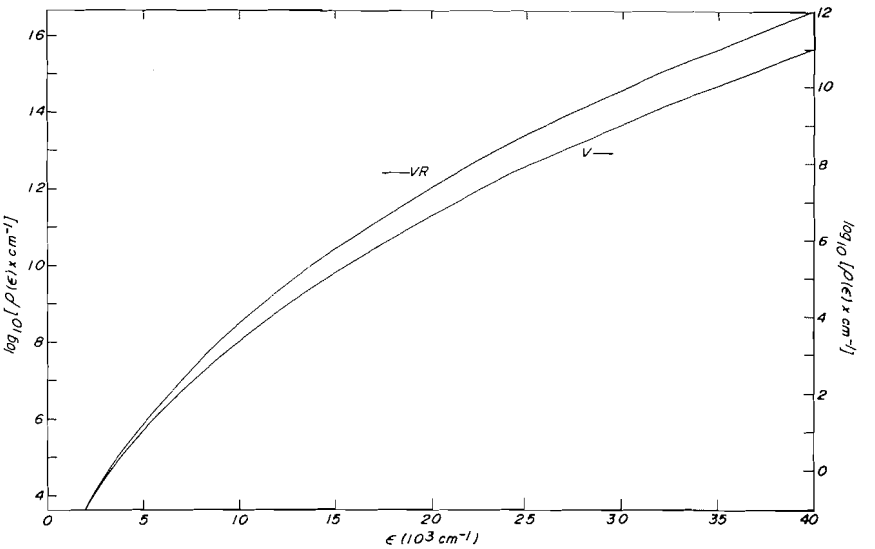

FIG. 6. Vibrational (V) and vibration–rotational (VR) state density of cyclopropane, using spectroscopic data in Appendix 3.

ber s in the Kassel integral in terms of the specific heat of the molecule (44), which is of course related to the distribution of energy levels (and the state density) in the molecule (43). The effective oscillator number s is no more than a fitting parameter (44, 45) whose role is essentially to calibrate the state density (albeit a classical and an inadequate one) of the reactant molecule. Yet the fact that most reactions consistently have a value of s equal to about half of the number of vibrational degrees of freedom tends to confirm the central role of state density in determining the fall-off behaviour, without the need to postulate additional parameters.

In conventional unimolecular rate theories, it has been customary to model a molecule as a collection of independent harmonic oscillators despite two longstanding difficulties. The first one is conceptual: a molecule consisting of pure harmonic oscillators can undergo neither dissociation nor internal energy randomisation. The second one is practical; until recently, fast, reliable methods for calculating state sums and state densities have been restricted to harmonic oscillators (46–48) and the apparent agreement between experiment and theory has certainly led to general acceptance of the harmonic oscillator model over the years, although this agreement has puzzled some authors (49). The actual distribution of states in a molecule is still very much unknown, especially at high energy. However, with the recent development of very efficient computational procedures for the calculation of state densities and state sums, both for harmonic and anharmonic oscillators (43, 50, 51), it is now possible to examine the consequences of assuming such models, with and without rotation, and for a wide range of reactions.

Certainly rotational effects are important in diatomic dissociation (20), and rotational predissociation of polyatomic molecules, although poorly documented, is believed to be a common process (52). Indeed, there are no arbitrary reasons to exclude rotation, in the sense that in the transition probability matrix [42], the a_{ij} elements can equally well be regarded to exclude or include rotational transitions, either alone or simultaneously with vibrational transfer. The density of states for cyclopropane in the interesting energy range is shown in Fig. 6, both with and without rotation. It can be seen that the inclusion of rotational degrees of freedom increases the state density at high energy, and also changes the shape of the state-density curve: this will lead to a shallower fall-off curve, and a shift in the position of the fall-off to lower pressure for a fixed value of $\bar{\lambda}$.[3]

The consequence of inclusion of anharmonicity in the model reactant molecule is less obvious. Yet, it is clear that a minimal description of any unimolecular reaction should treat the molecule, at the very least, as a collection of independent *anharmonic* oscillators. This certainly would be more realistic than the usual harmonic oscillator approximation,

[3]The fall-off behaviour is, however, insensitive to the rotational constants of the molecule: indeed, in the present treatment, using the classical approximation for the rotational partition function and the steepest-descent method (53), the rotational constants only appear as multiplicative factors in $\rho(\varepsilon)$ and $G(\varepsilon)$, and they drop out of the final expression for k_{uni}.

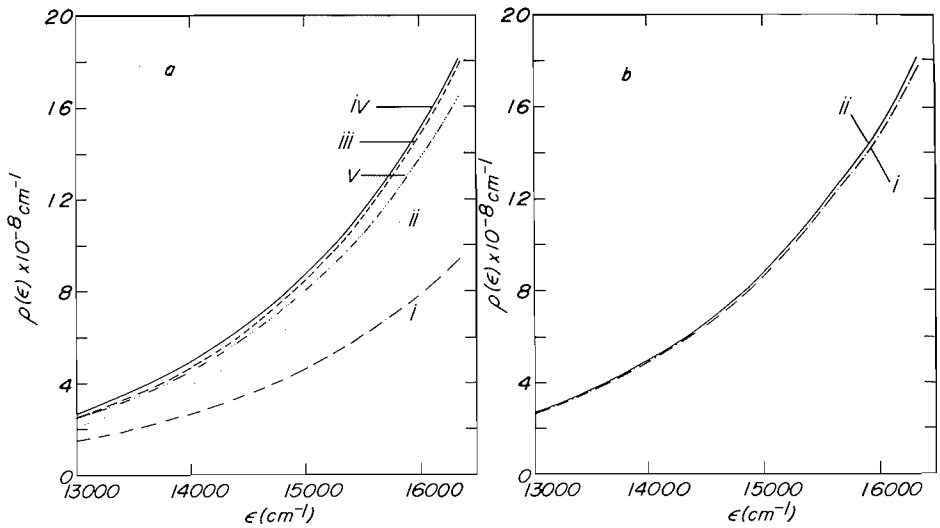

FIG. 7. (*a*) State density of methyl isocyanide in the reactive energy range, with the molecule modelled as (*i*) a set of harmonic oscillators and (*ii*)–(*v*) a set of independent Morse oscillators with $\nu_s = 263$ cm^{-1} and $x_s = 0, 0.01, 0.02$, and 0.03 respectively. All frequencies and anharmonicity factors are given in Appendix 3. All curves are essentially the same shape. (*b*) Variation of state density of methyl isocyanide in the reactive energy range with the anharmonicity factor of high-frequency vibrational mode $\nu_1 = 2966$ cm^{-1}; $x_1 = 0$ (*i*) and 0.08 (*ii*) respectively. All other frequencies and anharmonicity factors are given in Appendix 3. Curves for $0 < x_1 < 0.08$ fall in between (*i*) and (*ii*).

and would remove the conceptual difficulties noted above: on the other hand, the longstanding success of harmonic oscillator models would appear to suggest that the additional complexity might be unnecessary, either because the fall-off behaviour is too insensitive to the anharmonicity, or else because of some fortuitous cancellation of errors. Moreover, anharmonicity data are very limited (54) indeed for the complex molecules of interest here, and so it is necessary to undertake a thorough examination of the effects of anharmonicity before we can have any confidence in the theoretical predictions. The information on anharmonicities that is available comes from first-overtone measurements and/or approximate theoretical calculations (55), and it would appear that with few exceptions, regarding the vibrations as Morse oscillators of frequency ν_i, anharmonicity factors x_i lie in the range of 1–3%, i.e. $0.01 \leq x_i \leq 0.03$ (see Appendix 3 for definitions of ν_i and x_i). Qualitatively, the effect of introducing this anharmonicity is to increase the state density in the intermediate energy range, but to reduce it at high energies, since the set of energy levels now converges to a maximum value of the vibrational quantum number $v_{i,\max}$. Given the typical values of x_i, $v_{i,\max}$ will commonly be between 15 and 50. In order to focus our attention on the nature of the problem, we may subdivide the vibration frequencies of molecules roughly into three classes, those around 300, 1000, and 3000 cm^{-1}. We note that the interesting energy range for thermal unimolecular reactions is between 10 000 and 25 000 cm^{-1}: for example, the Arrhenius activation energy for the isomerisation of methyl isocyanide is about 13 360 cm^{-1}; states in this energy range could either have only very few high-frequency quanta, or at the other extreme, some tens of low-frequency quanta. It follows therefore that the calculated state density $\rho(\varepsilon)$ will not be very sensitive to variations in the anharmonicity factors for the high-frequency modes, but might be so for the low-frequency modes. No systematic study of this point has been reported in the literature, to our knowledge. We have therefore presented in Appendix 2 (and Figs. 7 and 8) such an analysis for methyl isocyanide and cyclopropane.

With the results displayed in Figs. 6–8, we can summarise the conclusions of this section as follows. The complexity of a reactant molecule can be identified with the distribution of energy states of the molecule, particularly at high energy, and this complexity property determines the shape of the fall-off curve, and also, more-or-less, its position. Through the operation of eqs. 46, 47, 56, and 58, the *shape* of the state-density function determines the *shape* of the fall-off curve, and the *magnitude* of the state density in the interesting energy range determines the *position* of the fall-off curve on the pressure axis, to within a factor of $\bar{\lambda}$. Clearly then, the position and shape of the fall-off curve are related, although not explicitly. Also, the calculated form of k_{uni} will depend upon whether $\rho(\varepsilon)$ is determined assuming harmonic or anharmonic oscillators, with or without rotation: as

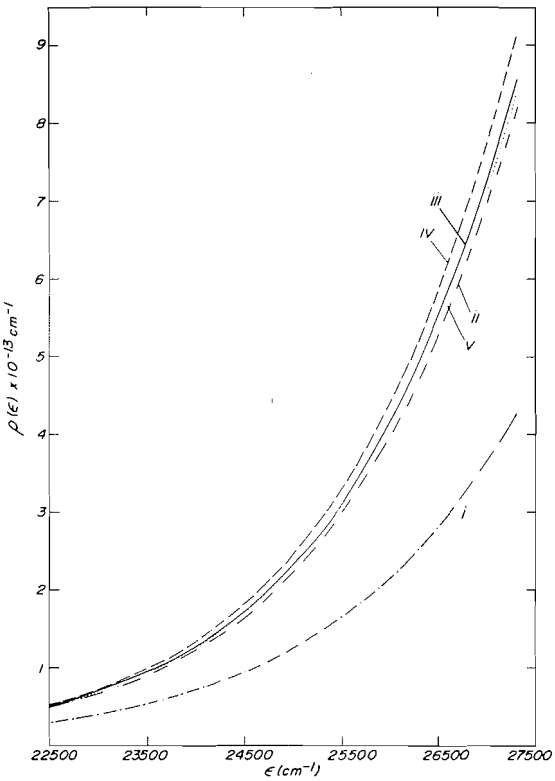

FIG. 8. Variation of state density of cyclopropane in the reactive energy range with the anharmonicity factor of the rocking mode (ν_8 = 854 cm^{-1}). (*i*) Harmonic-oscillator model (all modes); (*ii*)–(*v*) Morse-oscillator model (see Appendix 3), with x_8 = 0, 0.015, 0.03, and 0.09 respectively.

we shall find in the following sections, the best agreement between theory and experiment always results from the anharmonic oscillator model, with rotation. Fortunately, the sensitivity of the results to small imperfections in the assumed model is not great. Consequently, if the anharmonicity factors x_i can be estimated to within ± 0.01, the shape of the $\rho(\varepsilon)$ function will be of acceptable accuracy, and the absolute magnitude of the $\rho(\varepsilon)$ function in the interesting energy range (which determines the pressure shift $\bar{\lambda}$) will be correct to within about 30–50%. Similarly, imperfections in calculating the rotational contribution to $\rho(\varepsilon)$ will also be relatively unimportant: the model system of independent rotors and oscillators is an acceptable approximation.

IX. Comparison with Experiment

In most cases, experimental tests of the theory of unimolecular reactions have been confined to a comparison of the shapes of the experimental and theoretical fall-off curves; however, for some reactions, additional important information is available, namely the variation of the Arrhenius temperature coefficient and/or of the kinetic isotope effect with pressure. In this section we will show that our reformulation gives consistently better agreement with experiment than do any existing theories of unimolecular reactions for five important thermal unimolecular reactions. In fact, a thorough test of the theory is only possible for the isomerisation of cyclopropane, because this is the only molecule for which fairly complete anharmonicity data are available, and it is from the detailed examination of this reaction that we came to the conclusions of the preceding section: that our state count must refer to anharmonic oscillators and include all rotational degrees of freedom. Guided by the anharmonicity data for cyclopropane, we have deduced a set of rules for *estimating* anharmonicity factors for other molecules (see Appendix 3): with these estimated anharmonicity factors, our method gives virtually exact agreement with experiment for the thermal decompositions of cyclobutane and ethyl chloride, and it gives better agreement than exists at present for the isomerisations of methyl isocyanide and ethyl isocyanide (and in these two cases, we believe there may be valid reasons for the remaining discrepancies). The required molecular constants and other parameters are collected together in Appendix 3 and straightforward and efficient computer programs for the calculation of k_{uni} therefrom are described in Appendix 4. In this section, we will confine our attention to the description of the results of these calculations, and the comparison of the computed results with experiment; for the sake of brevity we will take as read earlier extensive comparisons of this nature, particularly those of Wieder and Marcus (3, 4), Lin and Laidler (56), and Robinson and Holbrook (5).

A. The Shape of the Fall-off Curve

Figure 9 shows the experimental results for the thermal isomerisation of cyclopropane at 490°C, obtained by Pritchard, Sowden, and Trotman-Dickenson (57, 58), compared with three model calculations for k_{uni}. The model calculations use the spectroscopic constants of Cyvin (55), the value of ε_∞ found by Falconer, Hunter, and Trotman-Dickenson (59), a value of k_∞ found by extrapolating k vs. $1/p$ (58), and A_∞ consistent with k_∞ and ε_∞ (see Appendix 3 for details). The dotted line shows a conventional RRKM calculation with these parameters (5), using harmonic oscillators and no rotation. The dashed curve shows the results of the present reformulation, again using harmonic oscillators with no rotation; the difference between these two curves stems, in part, from the difference between eq. 27 and eq. 46 and, in part, from the difference in the respective forms of the $k(\varepsilon)$ function (cf. Fig. 2). Thirdly, the

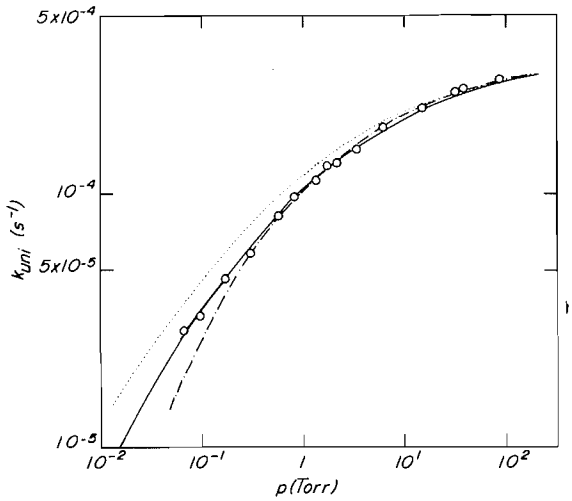

FIG. 9. Thermal isomerisation of cyclopropane at 490°C: ○ Experiment of Pritchard, Sowden, and Trotman-Dickenson (57, 58); ··· RRKM theory, with the antisymmetric CH stretch ($\nu = 3103$ cm^{-1}) mode isolated as reaction coordinate; -·-· this formulation, harmonic oscillator; — this formulation, rotating Morse oscillator.

FIG. 11. Thermal decomposition of ethyl chloride at 521°C: ○ Experiment of Holbrook and Marsh (64); — calculation, eq. 33.

solid line shows the results of the present reformulation using Morse oscillators and including rotation: other alternative choices, viz. Morse oscillators without rotation or harmonic oscillators with rotation are not as good, and are omitted for the sake of clarity. We remind the reader at this point that all three theoretical curves in Fig. 9 have been subjected to a lateral (pressure) shift in order to bring them into the best coincidence with the experimental data: the magnitudes of these shifts will be discussed separately below.

Figure 10 shows the experimental results for the thermal decomposition of cyclobutane to two ethylene molecules at 448°C, again obtained by Pritchard, Sowden, and Trotman-Dickenson (58, 60); other experimental data are very closely coincident (5, 61, 62) and are omitted for clarity. The solid line represents the form of k_{uni} calculated from the present reformulation, suitably shifted, and using the molecular constants and reaction-rate parameters given in Appendix 3.

Another reaction which has attracted much attention is the thermal decomposition of ethyl chloride to form ethylene and hydrogen chloride (5); the data are, however, much more scattered than the cyclopropane or cyclobutane data, and not always concordant (5, 63). Figure 11 shows the experimental data of Holbrook and Marsh (64) at 521°C, compared with our calculated form of k_{uni}; the agreement is equally satisfactory at other temperatures also, but unfortunately, because of the scatter inherent in the experimental measurements, does not provide a very stringent test of this reformulation.

The thermal isomerisation of methyl isocyanide to methyl cyanide represents, to date, the most thoroughly studied unimolecular reaction (5, 9, 34). The fall-off behaviour was first studied by Schneider and Rabinovitch (9) at 200, 230, and 260°C; they also derived the infinite-pressure Arrhenius parameters as $A_\infty = 10^{13.6}$ s^{-1} and $\varepsilon_\infty = 38.4$ kcal mol^{-1}. Unfortunately, the isomerisation is an exothermic reaction, and corrections had to be applied to the high-pressure data to allow for self-heating. Collister and Pritchard (34) have recently studied this reaction over the temperature range 120–320°C, in the rigorous absence of self-heating. The highest pressure they used in any of their experiments was 100 Torr and in the region of overlap of the two studies, i.e. $2 \leq p \leq 100$ Torr, $200 \leq T \leq 260$°C the agreement is excellent. Collister and Pritchard extrapolated their rate data (using an iterative RRKM procedure to find the most consistent set of ε_∞ and k_∞) to give $A_\infty = 10^{13.35\pm0.11}$ s^{-1} and $\varepsilon_\infty = 38.2 \pm 0.2$ kcal mol^{-1}, apparently in excellent agreement also with the values given by Schneider and Rabinovitch; however, Schneider and Rabinovitch's values of k_∞ are about 50% greater than those of Collister and Pritchard, which complicates the comparisons somewhat.

Schenider and Rabinovitch (9) examined a whole series of reaction models, but were never able to obtain consistent agreement between the theoretical and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

For personal use only.

experimental fall-off curves (cf. also ref. 5), nor were the pressure shifts monotonic (as they would be expected to be) at the three experimental temperatures. The shape of the fall-off at 230°C has been re-examined by Forst (23, 24) confirming that the experimental and theoretical shapes are not the same. Figure 12 shows the theoretical fall-off curve calculated by our new procedure, including anharmonicity and rotation, together with the experimental points of Schneider and Rabinovitch (9); again, the calculated and experimental curves do not have the same shape, and in the way we have adjusted the pressure shift, there seems to be a sudden rise in the rate constant above 300 Torr. We believe there could be a logical explanation of this observation. Schneider and Rabinovitch estimated the degree of self-heating in their high-pressure reactions on the basis of a ΔH of isomerisation of -15 kcal mol^{-1} and a thermal conductivity of 0.25 mW cm^{-1} deg^{-1}. We have recently remeasured both ΔH as -23.70 ± 0.14 kcal mol^{-1} (65) and the thermal conductivity, about 0.20 mW cm^{-1} deg^{-1} at 230°C (66), which implies that all of the correction factors for self-heating estimated by Schneider and Rabinovitch are *too small by about a factor of two*. It seems likely that if sufficient *raw* experimental data are still available to enable these self-heating corrections to be calculated properly, some of the present discrepancies might be eliminated. As will be shown below, our calculated curve for k_{uni} fits the data of Collister and Pritchard (34)

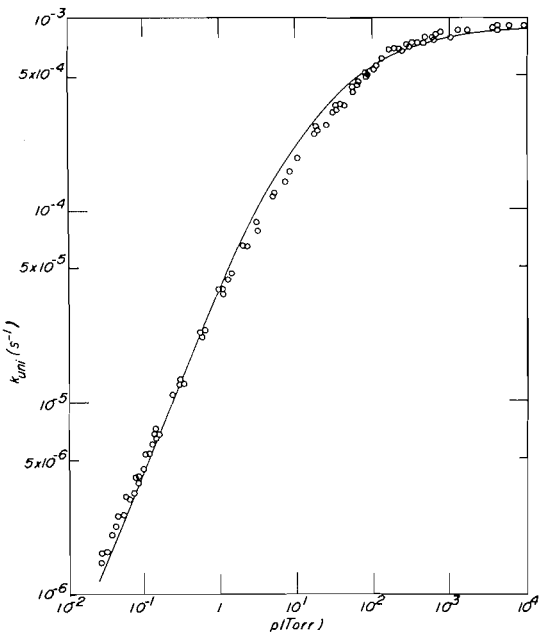

FIG. 12. Thermal isomerisation of methyl isocyanide at 230.4°C: ○ Experiment of Schneider and Rabinovitch (9);— calculation, eq. 33.

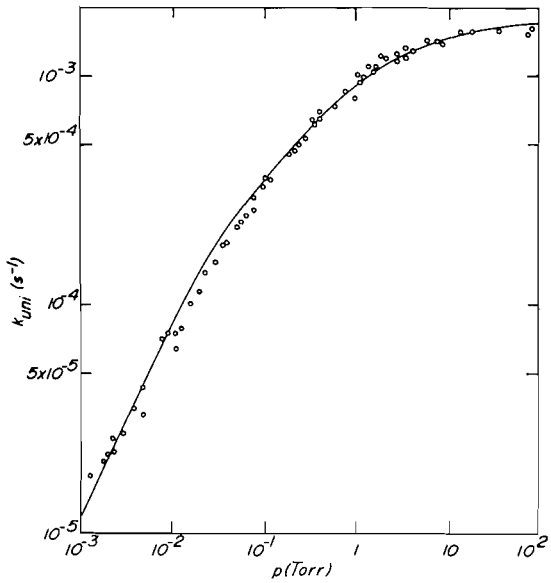

FIG. 13. Thermal isomerisation of ethyl isocyanide at 230.9°C: ○ Experiment of Maloney and Rabinovitch (10);— calculation, eq. 33.

very well, but in view of the short pressure range of this work ($2 \leq p \leq 100$ Torr), this again is not a very stringent test of the new theory.

Figure 13 shows the experimental data of Maloney and Rabinovitch (10) for the thermal isomerisation of ethyl isocyanide at 231°C, plotted together with the theoretical k_{uni} curve calculated from the present reformulation. There is a similar discrepancy to that shown for methyl isocyanide in Fig. 12, which again could be interpreted as an unexpected rise in the experimental rates above 1 Torr. As before, the self-heating corrections are suspect, and should be re-evaluated on the basis of the new value for ΔH (about -22 kcal mol^{-1}) (65) and a new estimate for the thermal conductivity; however, self-heating should not be important at pressures as low as 1 Torr, so there may be other, as yet undiscerned, reasons for this poor agreement.

B. The Position of the Fall-off Curve

As we noted earlier, and in common with other theories of unimolecular reactions, the calculation of k_{uni} does not establish the absolute position of the fall-off curve on the pressure axis. In conventional theory, a collisional deactivation efficiency parameter λ is used to move the calculated fall-off curve along the pressure axis to obtain the best fit with the experimental data. However, this collision efficiency parameter has two disconcerting properties.

The first is that it either varies widely with temperature, or does not vary in a monotonic fashion with temperature, and thus it does not appear to have the kind of properties required of an energy-

transfer probability. For example, for 1,1-dichlorocyclopropane (5), a value of $\lambda = 1.0$ would appear to be satisfactory near 360°C, whereas $\lambda = 0.4$ fits the data better at 425°C: in view of the common occurrence of values of λ of the order of unity, this large variation over such a short temperature range seems surprising. Better documented examples come from experiments on the methyl isocyanide and ethyl isocyanide isomerisations where the pressure correction factors (with the 'E-300' model) (9, 10) at three consecutive temperatures are CH_3NC: 0.91, 1.11, and 0.95; C_2H_5NC: 0.88, 1.37, and 1.25 respectively. It seems unlikely that energy-transfer collision efficiencies would vary in this random fashion, and it is not entirely clear to us whether recalculation of the self-heating corrections (alluded to above) would remove these anomalies altogether. That they are in fact anomalies is shown in Fig. 14 where we plot the data of Collister and Pritchard (34) for three different temperatures: the three lines which pass through the experimental data points all have the same value of the shift parameter $\bar{\lambda}$, and they all fit equally well. The representation of these agreements in this fashion does, however, require some amplification. We do not know how the relaxation time constant μ (cf. eqs. 42–44) for the internal relaxations varies with temperature: in the absence of more definite information, the least biased guess we can make is that $\mu = cT^{1/2}$ (note that $\mu = \bar{\lambda}Z[M]$), and it is this assumption that brings all the experimental data and the theoretical lines into coincidence with a single value of $\bar{\lambda}$. Clearly, if μ were assumed to be constant, the $\bar{\lambda}$ would be monotonic with temperature, unlike the earlier data (9, 10): thus, it seems that this particular difficulty may be mainly experimental in origin.

The second disconcerting property of the collision deactivation efficiency parameter λ is that it often seems to have a value very close to unity. The precise significance of λ is of course unclear because its numerical magnitude must depend upon the choice of the collision rate. It is well recognised that collision rates must be internal-state dependent, and that the 'structureless' collision numbers in common use represent nothing more than macroscopically averaged quantities. Clearly this averaging is very insensitive to the detailed distribution of collision efficiencies, and in the absence of more specific information, we can usually do no more than to use normal gas-kinetic collision diameters in calculating these collision rates (67). Given these difficulties, the occasional occurrence of values of λ slightly in excess of unity, by perhaps 10 or 20% (57, 60) is not alarming, and their observation has actually been interpreted as being supportive of the concept of unit deactivation probability (68). However, in very-low pressure experiments, where activation takes place predominantly at the wall rather than in gaseous collisions, molecule–wall collisions appear to be some 5–10 times as efficient as molecule–molecule collisions (11–13). Some doubts have been voiced about one of these experiments, and it was alleged (69) that the levelling off of the rate constant at low pressure, originally ascribed to wall activation, was really due to water vapour outgassing to a constant pressure from the vessel walls; the critics omitted to observe that a trap at −80°C was permanently in contact with the reaction vessel during each low-pressure run, in order to suppress unwanted pressures of both mercury and water vapours. Let us assume that accommodation coefficients for internal energy of complex molecules at the surface are of the order of 1 in a few collisions: to our knowledge, the only measurements which exist (70) relate to simple molecules at room temperature, but one can easily build an argument based

C_2H_5Cl	794.2	64.5	4.5	4.6	4.77	0.10_4

on the results of these measurements in favour of our assumption. Accepting that the low-pressure kinetic experiments (11–13) demonstrate molecule–wall collisions to be almost an order of magnitude more efficient than molecule–molecule collisions, then we might guess that λ would lie in the range $10^{-1.5}$ to 10^{-1} and that, certainly, λ would not be unity as it generally appears to be in RRKM treatments.

The use of the master-equation formulation enables us to shed some light on this problem, although in a cascading relaxation system the concept of a collision efficiency is not always a well-defined one, since the observed relaxation time depends upon the initial distribution (17). However, it takes on a theoretical meaning when, as in our reformulation, the internal relaxation can be described by a single relaxation time: in our case, cf. eq. 42, the 'sum rule' is obeyed (16) whence, unambiguously

$$[59] \qquad \mu = \bar{\lambda} Z[\mathrm{M}] \quad \text{or} \quad \bar{\lambda} = \mu/Z[\mathrm{M}]$$

where Z, the collision number, is defined as in eq. 1, or since (cf. ref. 5, p. 164) M is usually another molecule of the same kind,

$$[60] \qquad Z = 4\sigma^2(\pi kT/m)^{1/2}$$

where m is the mass of the molecule. It is also convenient to define a relaxation rate constant

$$[61] \qquad \mu' = \mu/[\mathrm{M}] = \bar{\lambda} Z$$

Given the fact that there is excellent coincidence between the experimental and theoretical fall-off curves for the five molecules considered in this paper, the determination of μ' is straightforward, and the results are shown in Table 1. It appears that all the collision efficiency parameters $\bar{\lambda}$ are of the order of 0.1, which is certainly more in line with modern ideas about energy transfer (11–13, 70) than is the unit efficiency of the RRKM theory.

This could, however, be an artefact (but we think not). The a_{ij} in eq. 42 overestimate the importance of large-energy transitions with respect to small-energy transitions, so that all cascading processes coalesce into a single process; however, experiments on these molecules have not yet resolved the cascading processes, so clearly this contraction is reasonably acceptable. The effect of overemphasising large-energy transitions is clearly shown in Fig. 15 which shows the population depletion in the reactive region at low-pressure, i.e. $\tilde{n}_i/\tilde{n}_i$, so that the equilibrium distribution is represented by $\tilde{n}_i/\tilde{n}_i = 1$. It can be seen that the populations of states begin to fall away below the threshold ε_0, and in a real system should continue to fall away to zero at very high energies (5, 14); in our case, however, somewhat above the topmost predissociating state, the values of $\tilde{n}_i/\tilde{n}_i$ return to the equilibrium value, because of the strength of the large-energy transitions implicit in using [42]. This presents no difficulty in our numerical formulation though, since we continue to include predissociating states up to a sufficiently high energy that there is no further contribution to the total rate, as shown in the shaded portion of the diagram. The only point we make here, then, is that the interpretation of the physical meaning of $\bar{\lambda}$ still requires a little circumspection.

C. The Pressure Dependence of the Activation Energy

The pressure dependence of the activation energy provides a sensitive test for unimolecular rate theories. At any pressure p and inverse temperature β, the formal expression for the activation energy

$$[62] \qquad \varepsilon_{\mathrm{act}}(\beta;p) = -\mathrm{d} \ln k_{\mathrm{uni}}(\beta;p)/\mathrm{d}\beta$$

may be obtained directly using the Hellman–Feynmann theorem,

$$[63] \qquad \varepsilon_{\mathrm{act}}(\beta;p) = (k_{\mathrm{uni}})^{-1} \psi_{n-1}{}^T (\partial \mathbf{B}/\partial\beta) \psi_{n-1}$$

The evaluation of [63] for a general system is clearly a formidable task, although some general properties regarding the pressure dependence of $\varepsilon_{\mathrm{act}}$ have been derived by various authors (6, 71, 72). It is simpler, in fact, to compute $\varepsilon_{\mathrm{act}}$ directly from the analytic expression for k_{uni}, if it is available. Indeed, in the present treatment, since $\varepsilon_{\mathrm{act}}$ is only weakly temperature-dependent at all pressures (and independent of temperature at infinite pressure by virtue of the strict

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

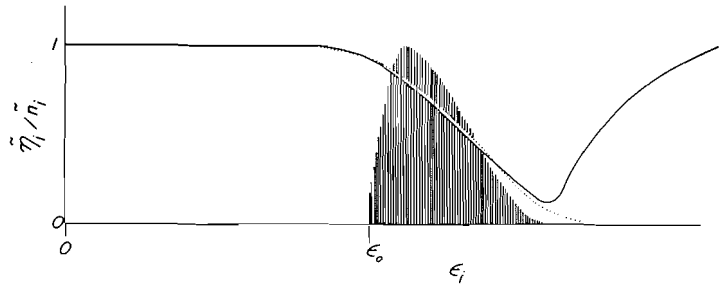

FIG. 15. Schematic representation of population depletion of states $\tilde{n}_i/\tilde{n}_i$ at low pressure as a function of reactant energy ϵ_i, in the $(n-1)$-fold degenerate system (solid line) and in a realistic system (dotted line). ϵ_0 is the critical energy. The shaded area is the distribution profile of reacting molecules.

Arrhenius behaviour), it may be computed from

$$[64] \quad \epsilon_{act}(\beta;p) = \frac{1}{\Delta\beta}\left\{1 - \frac{k_{uni}(\beta + \Delta\beta;p)}{k_{uni}(\beta;p)}\right\}$$

where $\Delta\beta$ is a small change in the inverse temperature β.

The most extensive data available on the pressure dependence of ϵ_{act} are for the thermal isomerisation of methyl isocyanide, from the work of Schneider and Rabinovitch (9) and of Collister and Pritchard (34); in the former work, the activation energy at low pressure was regarded as being temperature-independent, but in the latter work, ϵ_{act} was represented as being both pressure-dependent and temperature-dependent, as required by the present theoretical framework. Figure 16 compares the calculated values of ϵ_{act} from eq. 64 at 230°C with the experimental data of Collister and Pritchard (for that temperature) and of Schneider and Rabinovitch (mean values derived from Arrhenius plots over the range 200–260°C). The agreement between the present theory and experiment is excellent, and is superior to the RRKM description.

Figure 17 shows a similar comparison, using the experimental data of Maloney and Rabinovitch (10), for ethyl isocyanide: the solid line is the present theory, and the two dashed lines are those given by two RRKM models calculated by Maloney and Rabinovitch. The agreement here is not as good as it was for methyl isocyanide, but this is to be expected because the pressure shifts are more irregular for ethyl isocyanide (see preceding subsection). The present theory also gives a very good representation of $\Delta\epsilon_{act} = \epsilon_{act}(\infty) - \epsilon_{act}(0)$: Maloney and Rabinovitch estimated this to be about 4 kcal mol^{-1} compared with our calculated value of 4.5 kcal mol^{-1}.

Figure 18 compares theory and experiment for cyclobutane: the experimental data are deduced from the low-pressure rate constants of Vreeland and Swinehart (62) in the range 410–500°C and the high-pressure rate constants of Carr and Walters (73) between 419 and 460°C. The theoretical curve is calculated for 448°C, and the agreement is again excellent. However, the calculated value of $\Delta\epsilon_{act}$ cannot be compared satisfactorily with experiment because

of the abnormal levelling off of the rate data below 10^{-3} Torr.

Paradoxically, similar experiments have not been performed for cyclopropane: however, an approximation to $\Delta\varepsilon_{act}$ is available from the difference between the high-pressure (59) and low-pressure (11) activation energies, giving 8.4 ± 2 kcal mol^{-1} in the range 477–517°C compared with the theoretical value of $\Delta\varepsilon_{act}$ = 8.2 kcal mol^{-1}, at 490°C.

D. The Pressure Dependence of the Kinetic Isotope Effect

The kinetic isotope effect is an immediate consequence of any statistical rate theory based on molecular densities of states, such as the present formulation. The quantum-statistical effect at low pressure, from the RRKM point of view, has been described by Rabinovitch, Setser, and Schneider (74). Our reformulation, not unexpectedly, leads to a similar limiting form for the isotope ratio $\gamma = k_{uni,a}/k_{uni,b}$ (for isotopes a and b) at low pressure, except that the respective rates $k_{uni,a}(p \to 0)$ and $k_{uni,b}(p \to 0)$ are governed by the relaxation rate constants μ' rather than the collision numbers Z, whence

$$[65] \quad \gamma(p \to 0) = \frac{\mu_a' Z_b}{\mu_b' Z_a} \cdot \frac{\sum \bar{n}_{r,a}(1 - \sum \bar{n}_{r,b})}{\sum \bar{n}_{r,b}(1 - \sum \bar{n}_{r,a})}$$

Although Z_a and Z_b are simply related (via the square roots of the molecular masses), there is no need for μ_a' and μ_b' to be similarly related. However, since isotope-effect experiments are customarily performed by internal comparison, the required value of μ_a' would have to be that appropriate to the relaxation of species a by the mixture of isotopic molecules, and likewise for μ_b'; under these conditions, it seems likely that μ_a'/μ_b' would be close to unity, and with this simplifying assumption, the calculation of γ at all pressures is straightforward if the infinite-pressure Arrhenius parameters are known.

The isomerisation of trideuteriomethyl isocyanide has been studied by Schneider and Rabinovitch (75) at 230°C and over a range from 10^{-2} Torr to greater than 10^4 Torr; the isotope ratio γ varied from 0.28 at the low pressures to 1.07 at the highest pressures. The solid line in Fig. 19 shows the ratio $\gamma(p) = k_H(p)/k_D(p)$ calculated using eq. 65 and using the observed values of $\gamma(\infty)$ = 1.07 and $\varepsilon_{act,D}(\infty) - \varepsilon_{act,H}(\infty)$ = 0.1 kcal mol^{-1}. The dotted line is the 'E-300' RRKM model of Schneider and Rabinovitch (75) based on the same values of $\gamma(\infty)$ and $\Delta\varepsilon_{act}(\infty)$. The agreement with experiment of the reformulation, eq. 65 is again superior to that of the RRKM calculation, and considering the difficulties inherent in the experiments, may be regarded as, at least, satisfactory. Since the thermal conductivities and enthalpies of isomerisation will be very similar for the two isotopic species, the interpretation of these isotope-ratio experiments is probably not seriously jeopardised by possible errors in the self-heating corrections, to which we referred above.

X. Future Developments

This reformulation of the theory of unimolecular reactions removes the need to invoke such troublesome artefacts as the 'activated complex', the 'reaction coordinate', and the 'reaction path degeneracy'. One might ask why it is that RRKM theory, with all these hypothetical constructs, could have been so successful? Its use of the generalised Lindemann form [27] instead of the generalised Lindemann form [46] would obviously not be a major cause of error; likewise the use of a $k(\varepsilon)$ function rather like eq. 36 (based on the sum of states) rather than eq. 41 (based on the density of states) only has a minor effect, cf. Fig. 2. The basic reason why RRKM theory works so well is because, through the use of the entropy of activation to define the 'activated complex', the state

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sum of the latter is increased from the state density of the molecule given by the harmonic oscillator approximation to a form more nearly like that given by the rotating anharmonic oscillator approximation (cf. Fig. 7*a*): this is usually achieved in conventional calculations by reducing the frequencies of some of the oscillators in the molecule (5). The fall-off behaviour of a reaction is predominantly determined by the distribution of $\rho(\varepsilon)k(\varepsilon)$, which varies as $G_v^+(\varepsilon - \varepsilon_0)$, the vibrational state sum of the activated complex in the RRKM formulation. The vibrational state density ρ_v and state sum G_v of a molecule of v vibrations vary roughly as ε^s and ε^{s+1} respectively where s is related to the number of low-frequency modes (see section VIII in text). On the other hand, the vibration–rotational state density ρ_{vr} varies as $\varepsilon^{s+(3/2)}$. The lowering of some (typically a few) of the oscillator frequencies in the activated complex means that s for the complex will be greater than that of the molecule. Hence $(s_{\text{complex}} + 1) \simeq (s_{\text{molecule}} + \frac{3}{2})$ and the functional forms of G_v^+ and ρ_{vr} are comparable.

A major impediment, of course, to the application of this reformulation is the remarkable paucity of anharmonicity data for the vibrational motions of polyatomic molecules. It is obvious, then, that particularly in the consideration of the unimolecular break-up of photochemically excited states, of transient species, or of ionic species, the RRKM approach, which is here in its infancy (76), will not be rapidly superseded: the problem of estimating both vibration frequencies and their anharmonicities for such transient species will not readily be overcome.

In the immediate future, extension of this work can proceed in three well-defined directions. The first is towards the consideration of simpler molecules, where we expect that some of our cavalier assumptions will begin to break down. One can envisage at least four kinds of failure. For very simple molecules, e.g. H_2^+ or H_2, the lifetimes of quasibound states with respect to predissociation appear to be entirely random as a function of $(\varepsilon - \varepsilon_0)$ (77, 78), and so we can expect that for very simple molecules, eq. 33 for $k(\varepsilon)$ will become inadequate. Along with this, the density of states in such small molecules will be reduced, so that the states above threshold do not overlap, and therefore energy cannot be regarded as flowing freely throughout the molecule. For methyl isocyanide and cyclopropane, the predissociation widths of the states above ε_∞ implied by eq. 41 are respectively of the order 10^4 and 10^5 times the mean spacings between the levels, and the only qualm one needs to have about unlimited intramolecular energy exchange is the requirement to conserve angular momentum. Even below threshold, the density of states is such that collision broadening causes them to overlap significantly, dependent of course on the complexity of the molecule, the nature and duration of the collision, and the pressure. All this free intramolecular exchange of energy must die away as the molecule becomes too simple: we will do no more than mention a small selection of a growing literature related to this problem (79–82). Thirdly, there is the assumption, implicit in our use of eq. 33 that rotational and vibrational energy are equally effective in bringing about predissociation; while the actual effect of rotationally-induced predissociation remains to be documented, one may note the possible important implication of rotation in the 'anomalous' Arrhenius factors of some reactions (14). Fourthly, it may become impermissible to lump together, as does eq. 42, with a single relaxation time, the rotational and the vibrational relaxations of these small molecules. Obviously, it is some or all of these effects, in concert, that lie at the cause of the difference in shock-wave dissociation behaviour between very simple molecules and more complex molecules (83).

A second possible extension might be to the problems of multiphoton induced dissociation and of laser separation of isotopic molecules (84, 85). Many of the ideas implicit in this approach, including several outlined in the preceding paragraph, can be carried across to these new problems (85, 86). Unfortunately, until very recently (87), molecules which undergo well-characterised thermal unimolecular decompositions have not been studied by these new methods. It would be interesting to see laser isotope separation experiments undertaken for one of the five molecules discussed in this paper: ethyl chloride is the obvious candidate, despite the fact that the thermal rate constants are the least reproducible of the five sets of data we have analysed.

The third obvious extension is to the discussion of chemical activation. The problem is a little more difficult here, and to follow our present approach would require a set of matrix elements a_{ij} rather like those of eq. 42, but having two non-degenerate eigenvalues. This $(n - 2)$-fold degenerate formulation would also be useful for describing thermal reactions yielding two distinctly different products, and perhaps with distinctly different fall-off characteristics (88, 89).

Finally, there is the problem of completing the achievement of our original objective, that of putting the theory of thermal unimolecular reactions on a sound, modern molecular-dynamic footing. This requires us to understand why it is that the predissociation rate constants for individual states, i.e. the k_i, which almost certainly will have random values over

a small range of ε, can have a coarse-grain average which is reasonably well[4] approximated by eq. 33. A start on this problem was made by Polanyi and Wigner (90) in 1928, but we are still far from a complete understanding of this particular facet. In this year of his death, it seems entirely appropriate to us to dedicate this paper to the memory of Michael Polanyi (1892–1977) who, among his many feats of intellect, was the father of modern molecular dynamics.

[4]Very recently, Reddy and Berry (87) have studied the isomerisation of methyl isocyanide induced by intense laser radiation at 7265 Å: this corresponds to a value of $\varepsilon = 39.3$ kcal mol^{-1}, i.e. 1.1 kcal mol^{-1} above threshold (cf. Table 3). From the pressure dependence of the isomerisation rate, one can deduce that $k(\varepsilon)$ at this energy is $\sim 1 \times 10^7$ s^{-1}, whereas eq. 33 (or 41) gives $k(\varepsilon) = 1.0 \times 10^7$ s^{-1} for the same energy.

Appendix 1

Our choice of [33] for $k(\varepsilon)$ is based on two arguments, one theoretical and one experimental. Firstly, for every molecule considered in this paper, the use of [33] in this reformulation gives a better representation of the shape of the fall-off curve than does the use of [36]: the latter formula always leads to a slightly flatter fall-off curve; an example of this is shown in Fig. 2 for cyclopropane. However, we do not place excessive weight on this coincidence, since it could be an artefact of our particular choice for the a_{ij} elements, eq. 42. Secondly, we conclude from the analysis of experimental data in this appendix that there is no experimental justification for preferring modified Arrhenius [35] over strict Arrhenius [34] rate laws for thermal unimolecular reactions.

A survey of the literature would indicate wide acceptance for the view that experimental rate constants probably have a more complex temperature dependence than is given by eq. 34; common variants are the modified Arrhenius form [35], or more complicated forms in which both the activation energy and pre-exponential factor are temperature-dependent (27, 28). It is, of course, extraordinarily difficult to distinguish among these various forms for any particular set of experimental rate constants because this would require accurate measurements of the rates over very wide ranges of temperature (27), and to our knowledge, only three unimolecular reactions have been so studied. The thermal decomposition of di-*tert*-butylperoxide has been studied over a range of temperature from 363–677 K (29–31): over this range, the rate constant changes by about ten orders of magnitude, from about 10^{-7} s^{-1} to about 10^{3} s^{-1}, and there is no clear evidence that it cannot be represented by the strict Arrhenius form [34]. The

[e]$zpe = \frac{1}{2}(V - \nu)$ where V is the barrier height and ν is the torsional frequency; the rotational constant is then $B_r = \nu^2/V$ (99).
[f]Estimated from barrier for $C_2H_5CN = 1819\ cm^{-1}$ (100), i.e. $V(C_2H_5NC) \simeq V(C_2H_5CN) \times \nu(C_2H_5NC)/\nu(C_2H_5CN) \simeq 1819 \times 203/298\ cm^{-1}$.

thermal isomerisation of cycloheptatriene has been studied over the temperature range 600–1400 K (32, 33); again, the rate constant, ranging from about $10^{-4}\ s^{-1}$ to about $10^5\ s^{-1}$, is well represented by [34]. Likewise, the thermal isomerisation of methyl isocyanide has been studied over the range 393–593 K, with the rate constant changing by about seven orders of magnitude from about $10^{-8}\ s^{-1}$ to about $10^{-1}\ s^{-1}$ at the high pressures (34): in this case, the (extrapolated) infinite-pressure rate data were fitted by least squares to an equation of the form

$$[66] \qquad \ln k_\infty = A + BT^{-1} + CT^{-2}$$

and then the quadratic term was discarded as not being statistically significant (35). On the other hand, there have been some indications, backed by theoretical arguments (36), that the rates of decomposition of cyclopropane and cyclobutane fall markedly below those predicted by eq. 34 at very high temperatures, i.e. about 1100 K (37, 38); however, recent evidence suggests that these results are incorrect and that the rate constants for these reactions can be represented by eq. 34 at least up to 1500 K (39). On the basis of these observations, taken together with the fact that the observed fall-off behaviour is always more consistent with [33] and [34] than with [35] and [36], we propose, as far as *unimolecular* reactions are concerned, to proceed on the basis that until proved otherwise, infinite-pressure rate constants obey the strict Arrhenius form, eq. 34.

Appendix 2

The purpose of this appendix is to study the sensitivity of the state density of a molecule to variations in anharmonicity factor.

Figure 7 illustrates the sensitivity of the state density of methyl isocyanide for $\varepsilon \geq 13\,000\ cm^{-1}$ to variations in anharmonicity factor: Fig. 7*a* examines variations in the anharmonicity factor for $\nu_8 = 263\ cm^{-1}$ and Fig. 7*b* for $\nu_1 = 2966\ cm^{-1}$. Figure 7*a*, curve (*i*) shows the function $\rho(\varepsilon)$ calculated assuming that all the vibrations in the molecule are harmonic; curves (*ii*)–(*v*) are calculated assuming that all the oscillators are anharmonic (with the x_i as listed in Table 2) except for the bending mode ν_8, for which x_8 values of 0 (harmonic), 0.01, 0.02, and 0.03 respectively are assumed. Three conclusions can be drawn from Fig. 7*a*. One, that all the curves are essentially

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the same shape: for example $\rho(16\,000)/\rho(13\,000) \simeq 5.5$ for all curves, which implies that the calculated *shape* of the fall-off curve will be essentially the same for all five models; on the other hand, the absolute magnitude of $\rho(\varepsilon)$ for model (*i*) differs from the rest by as much as a factor of 2, which corresponds to a factor of two difference in the absolute pressure shift (i.e. the collisional efficiency factor λ, or $\bar{\lambda}$). Two, that as the anharmonicity factor increases from zero, the state density first increases to a maximum and then decreases, as is to be expected for low-frequency modes in the interesting energy range. Three, that $\rho(\varepsilon)$ only changes by about 10% for a change in x_8 from 0.01 to 0.03 (the estimated range), so that one can expect to derive reasonably meaningful results using estimated x_i values. In Fig. 7*b*, similar results are presented for the symmetric stretching mode $\nu_1 = 2966\ \text{cm}^{-1}$. Curves (*i*) and (*ii*) show the function $\rho(\varepsilon)$ for the anharmonic oscillator model (Table 2) but with $x_1 = 0$, and $x_1 = 0.08$ respectively; curves for $0 < x_1 < 0.08$ fall in between, and are omitted for clarity. Thus, for high-frequency modes, the state density is very insensitive indeed to the chosen values of x_i.

Finally, we examine in Fig. 8 the behaviour of $\rho(\varepsilon)$ as x_i changes from 0 to 0.09 for the rocking mode ($\nu_8 = 854\ \text{cm}^{-1}$) of cyclopropane to ensure that the conclusions just reached are equally valid at much higher energies; the $\rho(\varepsilon)$ curve for the harmonic oscillator model is also shown for comparison. Again, all the curves have essentially the same shape: for example $\rho(27\,400)/\rho(22\,500)$ is about 16 for Morse oscillators and about 14 for harmonic oscillators. Also, the absolute magnitude of $\rho(\varepsilon)$ changes by about 12% for a change in x_8 from 0 to 0.03, compared with a 10% change for methyl isocyanide as x_8 went from 0.01 to 0.03, despite the higher values of ε in this case: indeed, numerical examination shows that the sensitivity of $\rho(\varepsilon)$ to x_i varies roughly as the ratio of ε/ν.

Appendix 3. Molecular Constants and Reaction-rate Parameters

Reliable vibrational assignments, in the harmonic-oscillator approximation, are virtually complete for all the molecules considered in this paper: the only exceptions are for ethyl isocyanide where Maloney and Rabinovitch (10) estimated $\nu_{13} = 226\ \text{cm}^{-1}$ and $\nu_{20} = 270\ \text{cm}^{-1}$, and for the torsional oscillations of both ethyl chloride and ethyl isocyanide which we have treated as free internal rotations with the rotational constants derived from the torsional frequency and barrier height (99), cf. Table 2.

The calculation of anharmonic force constants, on the other hand, has been largely restricted to triatomic molecules, because of the enormous increase in the number of anharmonic terms in the potential function as the number of atoms increases (54). For unimolecular reaction systems, the most complete set of anharmonicity factors is that for cyclopropane, derived from approximate calculations by Cyvin (55). The anharmonicity factors x_i for the various modes are generally between 0.01 and 0.03, except for the stretching mode ($\nu_1 = 3038\ \text{cm}^{-1}$) for which $x_1 \simeq 0.08$; to our knowledge, no complete set of anharmonicity factors exists for any other large molecule of interest in thermal unimolecular reactions. To define our notation, we denote the standard frequency assignments for the molecule by ν_i and the anharmonicity factors x_i ($\equiv$ the x^* of Cyvin) such that

$$[67] \qquad \varepsilon_{v,i} = \frac{v}{1 - x_i}[\nu_i - v\nu_i x_i]$$

Since such data are unlikely to be available in the near future, and in view of the mild insensitivity of $\rho(\varepsilon)$ and the fall-off behaviour to the anharmonicity, we feel that, for the time being, it is a useful procedure to estimate values of x_i as follows, based on a comparison with Cyvin's (55) data for cyclopropane:

CH_3 rocking	$x_i \simeq 0.015$
CH_2 rocking	$x_i \simeq 0.015$
CH_2 twisting	$x_i \simeq 0.02$
CH_2 wagging	$x_i \simeq 0.02$
CH_2 deformation	$x_i \simeq 0.025$
CH antisymmetric stretch	$x_i \simeq 0.03$
CH degenerate stretch	$x_i \simeq 0.04$
CH symmetric stretch	$x_i \simeq 0.08$
C—C stretch	$x_i \simeq 0.02$
C—N stretch	$x_i \simeq 0.02$
Bending modes	$x_i \simeq 0.02$

Since the CH stretching modes have high frequencies, of the order of 3000 cm^{-1}, the state density is not sensitive to their larger values of x_i in the interesting energy range. All the lower-frequency modes, which make the largest contributions to $\rho(\varepsilon)$, appear to have values of x_i near 0.02, and in the absence of very refined calculations, this would appear to be about as close as one can get to the correct values. In the case of the isotopic pair of molecules CH_3NC and CD_3NC, we have assumed that the anharmonicity corrections are related by

$$[68] \qquad \frac{\nu_i x_i(\text{D})}{\nu_i x_i(\text{H})} = \left[\frac{\nu_i(\text{D})}{\nu_i(\text{H})}\right]^2$$

Table 2 lists all pertinent spectroscopic information, observed or estimated, for the six molecular species treated in this paper, i.e. vibration frequencies ν_i, anharmonicity factors, listed as $100x_i$, degen-

eracies g_i (where they are different from unity), and external rotational constants B_z, $B_{||}$. Table 3 gives a complete self-consistent set of kinetic parameters, with reference to the source of each key entry.

Appendix 4. Algorithm for Calculating k_{uni} and Computer Program

An annotated program of the algorithm for calculating k_{uni}, written in FORTRAN, together with detailed explanations of formulae, sample input data, and specimen output, is lodged with the Depository of Unpublished Data.[5]

The algorithm includes the following key steps:

(*i*) The vibrational state-degeneracy $g_v(\varepsilon)$ is computed from $\varepsilon = 0$ to ε_m by direct count. This procedure is similar to the Stein–Rabinovitch (51) method, but differs from it in some important respects. Counting is performed only at energies where an energy state is present which results in an appreciable saving in time when ε_m is not high (as in the case here where ε_m is a few thousand wave numbers). This is because there are only a few states near $\varepsilon = 0$, and one is therefore performing the counting and convolution only over these states, and not at all the energy grids, as in the Stein–Rabinovitch method. Also, the convolution is performed before round-off of the energy levels: this reduces to a minimum (with little additional programming effort) the propagation of round-off errors in the subsequent convolution with the rotational state-sum.

(*ii*) The rotational state-sum $G_r(\varepsilon)$ is calculated up to ε_m, and convoluted to obtain the vibration–rotation state-sum $G_{vr}(\varepsilon)$. Again, this is a conventional procedure, but the convolution is performed downwards towards $\varepsilon = 0$ (as opposed to the conventional scheme of starting upwards from $\varepsilon = 0$), resulting in a saving of half the required storage space.

(*iii*) If there are any internal rotational degrees of freedom, the state-deneracy $g_i(\varepsilon)$ of the internal rotation is convoluted with $G_{vr}(\varepsilon)$ to obtain the sum of internal states $G(\varepsilon)$ of the molecule. Again, this convolution procedure is performed downward.

(*iv*) The sum of states from $\varepsilon = \varepsilon_m + \Delta\varepsilon$ to $\varepsilon = \varepsilon_{max}$ is calculated at intervals of $\Delta\varepsilon$ using the non-iterative steepest-descent procedure (43).

(*v*) The density of states $\rho(\varepsilon)$ is calculated from ε_∞ to $\varepsilon_\infty + \varepsilon_{max}$ using the same procedure.

(*vi*) The reactive energy range (ε_∞ to $\varepsilon_\infty + \varepsilon_{max}$) is grained into r channels, with states between ε_l and ε_{l+1} being grouped into the lth channel: the channels are not necessarily equally spaced; the values of $\bar{n}_l$

[5]Complete set of material is available upon request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TABLE 3. Assumed values of the chemical kinetic rate parameters at infinite pressure: ε_∞ in kcal mol^{-1}, A_∞ and k_∞ in s^{-1}[a]

Molecule	C_3H_6	C_4H_8	CH_3NC[b]	CD_3NC	C_2H_5NC	C_2H_5Cl
Figure	9	10	12	19	13	11
ε_∞ (kcal/mol)	65.6 (59)	62.5 (73)	38.4 (9)	38.5 (75)	38.4 (10)	58.4 (64)
A_∞ (s^{-1})	1.88×10^{15}	3.66×10^{14}	3.98×10^{13} (9)	4.46×10^{13}	7.76×10^{13} (10)	1.07×10^{14} (64)
k_∞ (s^{-1})	3.07×10^{-4} (58)	4.26×10^{-5} (58)	8.57×10^{-4}	8.65×10^{-4} (75)	1.73×10^{-3}	8.88×10^{-3}
At T (K)	763.15	721.45	503.55	503.55	504.05	794.15

[a]Reference numbers in parentheses.
[b]The alternative set of values (34) used to construct Fig. 14 are $\varepsilon_\infty = 38.2$ kcal mol^{-1}; $A_\infty = 2.24\times10^{13}$ s^{-1}; $k_\infty = 4.81\times10^{-5}$ s^{-1} at 472.55 K, 5.89×10^{-4} s^{-1} at 503.55 K, and 4.83×10^{-3} s^{-1} at 532.95 K.

and $\bar{k}_l$ are calculated. The grouped decay rates $\bar{k}_l$ are scaled by the characteristic relaxation rate $\bar{\mu}$ (the relaxation rate at $p = 1$ Torr as defined in eq. 61) to avoid overflow or underflow difficulties in (*vii*) and (*viii*).

(*vii*) The scaled coefficients $\bar{\bar{a}}_i$ and $\bar{\bar{b}}_i$ for use in eq. 46 are computed using $\bar{n}_l$ and $\bar{\bar{k}}_l$; ($\bar{\bar{k}}_l = \bar{k}_l/\bar{\mu}$).

(*viii*) The unimolecular reaction rate constant k_{uni} may then be calculated for any value of the pressure p.

The FORTRAN program consists of the MAIN routine, which handles the flow of the program and the input data, and the following subroutines. (*1*) COUNT which makes a direct count of the vibrational energy level at low energy; (*2*) RINCNT which effects the convolution of any *internal* rotational degrees of freedom with the vibrational states; (*3*) EXTROT which brings about the convolution of the external rotational degrees of freedom; (*4*) DESENT which computes the state sum and state density of the molecule at higher energy by the non-iterative steepest-descent procedure (43); (*5*) GRAIN which divides the reactive energy region into grains and evaluates the quantities $\bar{n}_i$ and $\bar{k}_i$; (*6*) UNIRAT which computes the unimolecular rate constant at the desired values of the pressure p; (*7*) SETPLT (optional), which makes a Calcomp plot of the calculated rate constants as a function of pressure: this subroutine also reads in and plots specimen sets of experimental data, having determined the optimum value of the pressure-shift parameter $\bar{\lambda}$ required to effect the best coincidence between the calculated and experimental fall-off curves; (*8*) PFNCTN: a utility subroutine for calculating the molecular partition function; (*9*) FNPHI1 and FNPHI2: utility subroutines for the evaluation of the average internal energy and its first two derivatives, using exact and approximate (53) Morse partition functions respectively. All the desired options are specified in the input data set, and detailed descriptions of the input parameters and the structures of the respective subroutines are given as comments in the program listings.

The sample calculation evaluates k_{uni} for the methyl isocyanide isomerisation at about 50 values of p and matches the calculated curve with the experimental results of Collister and Pritchard (34) for the temperature $T = 230.4$°C, i.e. the middle curve of Fig. 14; the complete calculation took about 20 s on the York University IBM 370/158 Computer.

Calorimetric study of an electrochemical reduction

PETER J. TURNER AND HUW O. PRITCHARD
Chemistry Department, York University, Downsview, Ont., Canada M3J 1P3

Received December 13, 1977

PETER J. TURNER and HUW O. PRITCHARD. Can. J. Chem. **56**, 1415 (1978).

The aqueous trichloroacetate ion is reduced irreversibly and with unit current efficiency to the dichloroacetate ion. From the total energy release observed when this process is carried out inside a calorimeter, it is possible to deduce the enthalpy change for the reduction reaction.

PETER J. TURNER et HUW O. PRITCHARD. Can. J. Chem. **56**, 1415 (1978).

L'ion trichloroacétate en solution aqueuse se réduit d'une façon irréversible et avec une efficacité de courant égale à l'unité pour conduire à l'ion dichloroacétate. A partir de l'observation de l'énergie totale qui est dégagée lorsque ce processus est effectuée à l'intérieur d'un calorimètre, il est possible de déduire le changement d'enthalpie pour la réaction de réduction.

Introduction

In recent years, with the enormous growth in our knowledge of electrochemical synthesis, many electrochemical reactions having unit current efficiency have been discovered (1–4). Provided that there are no unwanted side reactions accompanying the reaction of interest, it would seem that the observation of such reactions taking place inside a calorimeter could, in principle at least, lead to valuable thermochemical data. For example, bromobenzene, neopentyl bromide, and 1-bromohexane all appear to be reduced with unit current efficiency in dimethylformamide solution using a mercury cathode: the first two yield the corresponding hydrocarbons in 100% yield, but the latter gives a mixture of hexane, hexene, and dihexylmercury (5); whereas the first two reactions might be suitable for calorimetric study, the latter clearly would not. If it is possible to establish such a calorimetric electrochemical route to enthalpy changes in chemical reactions, then improved enthalpy of formation data would be obtainable for many difficult molecules: these would include bromobenzene and various other aryl or alkyl halides as just mentioned or, for example, carbon tetrachloride, chloroform, etc. (6, 7).

Theory

The investigation of electrochemical reactions by calorimetry has received singularly little attention since Jahn's investigation of heats of cell reactions at the end of the last century (8, 9). For reversible electrochemical reactions, of course, it is both simpler and more accurate to obtain enthalpies of reaction from the temperature dependence of cell emf values (9); however, the electrode reactions to which we have referred above have associated with them, in general, large energy barriers and are irreversible.

The relationship between the electrical power input W_E, the energy release into the calorimeter $(-Q)$, and ΔH for the chemical reaction is simple and straightforward. Under the influence of the passage of an electric current, the contents of the calorimeter change from a defined initial state to a defined final state, at constant pressure and (in our diphenylether calorimeter, see Experimental section below) constant temperature. For the purposes of this argument, we regard the central part of the calorimeter, including the reaction vessel, as the thermodynamic system, and the diphenyl ether as the surroundings. Then

$$[1a] \qquad \Delta E = Q + W$$

$$[2a] \qquad = Q + W_E - P\Delta V$$

Therefore

$$[3] \qquad \Delta H = \Delta E + P\Delta V = W_E + Q$$

i.e., ΔH is the *numerical difference* between the total input power W_E and the energy release Q measured by the calorimeter, and in the limit, if the process could be carried out reversibly, Q would be identified with $T\Delta S$ and W_E with ΔG (9).

This simple thermodynamic argument is unsatisfactory in one respect, that it gives us no indication of the relative magnitudes of the quantities W_E, Q, and ΔH, which is especially important if $\Delta H \simeq 0$ as it turned out to be in the experiment described below. Consequently, we present an alternative derivation, based on electrokinetic considerations, which establishes this connection. For an electrochemical cell operating reversibly, there will be an energy input equal to ΔG from the external circuit, and an absorption of heat from the surroundings (i.e. the calorimeter) equivalent to $T\Delta S$, where ΔG and $T\Delta S$ refer to the total cell process (9). When the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

cell is operating irreversibly, however, we may argue simply that activation energy $E^{\neq}$ is supplied by the external power supply and is returned as heat evolved when the system (i.e. the cell) returns to equilibrium. Thus, the total electrical input is

$$[1b] \qquad W_E = \Delta G + E^{\neq}$$

and upon return to equilibrium, the total heat absorption from the surroundings is now

$$[2b] \qquad Q = T\Delta S - E^{\neq}$$

Thus

$$[3] \qquad W_E + Q = \Delta G + T\Delta S = \Delta H$$

and although $E^{\neq}$ cancels out, it is clear that the larger $E^{\neq}$, the greater will be the numerical magnitudes of W_E and Q compared with that of ΔH. We note in passing that there appears to have been a single exploratory investigation some years ago of this route to the measurement of ΔS, using an equation similar to [2*b*] and adjusting the overpotential to make Q zero (10); this approach, however, is not applicable to the reactions considered here since it is not possible to obtain reliable values for the open-circuit voltage, so that neither ΔG nor the overpotential is an accessible quantity.[1]

Experimental

One of the most thoroughly documented series of electrochemical reductions having unit current efficiency is the reduction of the haloacetic acids, particularly trichloro- and dichloro-acetic acids (11–13). These reactions have certain advantages for our exploratory study over the more exciting ones noted in the Introduction: in particular the simplifications arising from the fact that a completely aqueous system can be used, and that auxiliary thermochemical data are available, especially heats of dilution. Consequently, we chose to study the reduction of the trichloroacetate to the dichloroacetate ion. The reaction is irreversible (11), quantitative (14), and has been used (without 100% recovery of product) as a demonstration experiment in electro-organic chemistry (15); two reduction waves are observed with half-wave potentials of -0.73 and -1.65 V, corresponding to the consecutive removal of two chlorine atoms from the trichloroacetate ion (14).

The calorimetric measurements were made in our large diphenyl-ether isothermal calorimeter (16): this is not an ideal instrument for this investigation because the reaction-vessel space is severely restricted, being 10–15 cm in height but only 4 cm in diameter. Consequently, we decided to omit a third (reference) electrode (17) from the system. The reaction cell consisted of a cylindrical Pyrex vessel, using a pool of mercury on the floor as one electrode, and another pool held on an annular shelf as the other; each electrode consisted of about 10 ml of mercury, and a typical electrolyte volume was 40 ml. Since it is necessary to exclude oxygen from the reaction (14), the solution was deoxygenated using a stream of nitrogen and the reaction vessel was then isolated. Moreover, because of the small space available, and also because we were unable to achieve very high current densities (and therefore obtained rather small heats), we decided we would incur smaller errors by omitting a stirrer from this exploratory system as well.

Electrical input was from a Power Designs 2005 or Hewlett-Packard 2802A DC power supply operating in constant-voltage mode. The voltage across the cell and the current passing through it (the latter measured as the voltage across a Leeds and Northrup standard 1 ohm resistor in series) were displayed simultaneously on a Hewlett-Packard 7100 B two-channel recorder. Using the integrator facility of the recorder, the current was integrated to give the total number of coulombs passing: independent calibration showed this to be accurate to better than $\pm 0.3\%$. The power consumed was determined by graphical integration of the product of the voltage and the current: this integration was greatly simplified by the constancy of the voltage resulting from the characteristics of the power supply and from the approximately isothermal conditions obtaining in the cell; in addition, over the main period of the integration (i.e. after the initial transients had died out), voltage measurements made with a Hewlett-Packard 3465A digital multimeter were substituted for the graphically recorded values, thus improving the accuracy of the power measurement to about $\pm 0.4\%$.

Results

In our early experiments, we hoped to follow closely the work of Meites and Meites (14) using a chloride supporting electrolyte. With two mercury electrodes, the overall cell reaction is

$$[4] \quad 2Hg + Cl_3C{\cdot}CO_2^- + H^+ + Cl^- \rightarrow HCl_2C{\cdot}CO_2^- + Hg_2Cl_2$$

which according to the tabulated data (18) is exothermic to the extent of about $\Delta H = -22.6$ kcal mol^{-1}. However, the anode rapidly became coated with calomel and after about 2 min, the cell current became too small to yield useful calorimetric results. The use of nitric acid as the supporting electrolyte appeared to be more promising: at first, the products are (as expected) dichloroacetate and chloride ions at the cathode and mercurous ions (soluble in the nitrate electrolyte) at the anode. As the products diffuse together, calomel is precipitated, but recovery and subsequent analysis gave only 95% of the expected yield; this is because some of the calomel (inevitably) falls onto the cathode and is reduced. The measured values of ΔH, derived according to eq. 3, were in the region of -15 to -25 kcal mol^{-1} and were very irreproducible.

Our final technique, following Meites (17), was to introduce a membrane into the cell to prevent the mixing of the mercurous and chloride ions. Because of space limitations, we used dialysis tubing (Fisher) and a double layer of this material was found to be sufficient to keep the ions apart long enough for a satisfactory calorimetric determination. In the final

[1] NOTE ADDED IN PROOF: Dr. L. G. Hepler has called to our attention another attempt, about 20 years ago, to measure the heats of some electrochemical reactions in a calorimeter (20).

‡Errors are assigned to each individual measurement in columns 1, 2, and 4; errors in columns 3 and 5 follow from the normal rules for combining errors. The final value for ΔH of 1.92 ± 0.16 kcal mol^{-1} is obtained by taking the weighted mean of the entries in column 5.

arrangement, the dialysis tubing was folded in on itself to form a double-walled tube, then folded into a U-shape and supported away from the bottom of the cell: this 'bag' was filled with 10 ml of 1.0 *M* sodium nitrate and 10 ml of mercury. The remainder of the cell was filled with a mixture comprising 0.1 *M* trichloroacetic acid plus 1.0 *M* sodium nitrate, with 10 ml of mercury to act as the cathode. The solutions were deoxygenated with nitrogen and the reaction vessel was then isolated and placed in the calorimeter to establish a satisfactory fore-period.

Electrolysis was carried out for 1000 s using an applied potential of 2 V, giving a current of about 30 mA. Separate bench tests had established that it takes approximately 1 V to drive the anode, and therefore the cathode voltage is also about 1 V, thus falling well below the second wave for trichloroacetic acid. Both waves are rather broad, indicating a high degree of irreversibility: the first, corresponding to the removal of the first chlorine atom lies between −0.4 and −1.1 V and the second, corresponding to the reduction of the resulting dichloroacetate ion to monochloroacetate begins at about −1.3 V; the current density achieved under our conditions was very similar to that obtained by Meites and Meites (14, 17).

After the electrolysis was terminated, it took approximately 1 h for the calorimeter to achieve a linear after-period, which it sustained for about another 2 h, enabling us to estimate the total energy release satisfactorily (in most cases). Thereafter, an accelerated energy release into the calorimeter took place, due to diffusion of the catholyte and anolyte into each other with precipitation of calomel. We may write the overall cell reaction before this mixing occurs as

[5] $2Hg + Cl_3C{\cdot}CO_2^-(300H_2O) + H^+ \rightarrow \{HCl_2C{\cdot}CO_2^- + Cl^- + Hg_2^{2+}\}(9000H_2O)$

and ignoring small heats of mixing inherent in representing the cell reaction as [5], the estimated value of ΔH for this reaction is about +2 kcal mol^{-1} (18). The results listed in Table 1 show that the use of eq. 3 leads to a value of ΔH for reaction 5 of +1.9 ± 0.3 kcal mol^{-1}; this agreement has to be, to some extent, fortuitous since Cox and Pilcher (19) estimate uncertainties as large as ±2 kcal mol^{-1} in the recommended thermochemical data for both these acids.

Conclusions

The exploratory experiment described in this paper represents by no means an ideal thermochemical determination. The use of an isothermal calorimeter (both by Jahn (8) and ourselves) is, it seems, somewhat of an advantage in minimizing current and voltage changes during the experiment. On the other hand, our inability to achieve a homogeneous final solution renders this experiment far from perfect from a thermochemical point of view. Since most reactions of thermochemical interest will be halide reductions, this means that the use of mercury electrodes has to be abandoned in favour of some other metal with a high overpotential but with soluble halides, perhaps zinc. We think that such a change, together with the ability to stir the final solution, would remove most of the variability from the determination of Q found in column 2 of Table 1. Inspection of Table 1 reveals also that an improvement by an order of magnitude in the precision of the power-input measurement would be beneficial. Nevertheless, we believe that this experiment demonstrates that the calorimetric study of electrochemical reductions should be able, given careful experimental design and some ingenuity, to provide accurate enthalpy of formation data in many cases where combustion calorimetry or reaction calorimetry is difficult.

Complex fluoroanions in solution. VIII. Mixed anions containing fluoride and trifluoromethanesulfonate or fluorosulfate[1]

S. BROWNSTEIN, J. BORNAIS, AND G. LATREMOUILLE

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received December 7, 1977

S. BROWNSTEIN, J. BORNAIS, and G. LATREMOUILLE. Can. J. Chem. **56**, 1419 (1978).

Binary fluorides of groups III, IV, V, and VI of the periodic table form fluoroanions with the trifluoromethanesulfonate and fluorosulfate ions. The complexes are weaker and there is less disproportionation than with the trifluoroacetate ion. Fluorine exchange reactions in these anions are generally slow on the nmr time scale at −70°C.

S. BROWNSTEIN, J. BORNAIS et G. LATREMOUILLE. Can. J. Chem. **56**, 1419 (1978).

Les fluorures binaires des groupes III, IV, V et VI du tableau périodique forment des fluoroanions avec les ions trifluorométhanesulfonates et fluorosulfates. Les complexes sont plus faibles que ceux obtenus avec l'ion trifluoroacétate et il y a aussi moins de disproportionation. Les réactions d'échange du fluor dans ces anions sont généralement lentes à l'échelle de la rmn à −70°C.

[Traduit par le journal]

Introduction

The literature on trifluoromethanesulfonic acid and its derivatives has recently been reviewed (1). In addition to salts it forms the anionic species $[I(OSO_2CF_3)_4]^-$ and $[Sn(OSO_2CF_3)_6]^{2-}$ (2, 3). There do not appear to be any reports of mixed anionic species containing both fluoride and trifluoromethanesulfonate radicals. Fluorosulfates and mixed fluorosulfates of the form $M(FSO_3)_n$ (4–6) and $MF_n(FSO_3)_p$ (7, 8) have been reported as well as $M(FSO_3)_n^{p-}$ (9). From conductivity studies in fluorosulfonic acid the existence of the species $MF_n(FSO_3)_p^{q-}$ has been implied where M is Sb, As, and Bi (10). The ion $AsF_5SO_3F^-$ has been prepared and its Raman spectrum reported (11).

Both trifluoromethanesulfonic and fluorosulfonic acids are very strong acids, comparable in strength to the strongest mineral acids. In view of the extensive chemistry recently found with mixed anionic species containing fluoride and trifluoroacetate radicals (12) it is of interest to investigate the existence of similar species with the anions of the very strong acids trifluoromethanesulfonic and fluorosulfonic acid.

Experimental

Techniques for obtaining fluorine resonance spectra, vapor pressure measurements, and sample preparation were identical to those used for the corresponding trifluoroacetates (12). Tetramethylammonium trifluoromethanesulfonate and tetrabutylammonium trifluoromethanesulfonate were prepared by neutralization of an ice cold aqueous solution of the quaternary ammonium hydroxide with trifluoromethanesulfonic acid, and removal of the solvent under vacuum. The corresponding fluorosulfates were prepared in the same manner. Tetramethylammonium fluorosulfate was recrystallized from water; mp 349°C (dec.). *Anal.* calcd.: C 27.75, H 6.94, N 8.09, S 18.50; found: C 27.96, H 7.02, N 7.93, S 18.64.

Tetrabutylammonium fluorosulfate was recrystallized from methylene chloride – diethyl ether; mp 179°C. *Anal.* calcd.: C 56.30, H 10.56, N 4.11, S 9.38; found: C 56.46, H 10.45, N 4.04, S 9.47.

Tetramethylammonium trifluoromethanesulfonate was recrystallized from water; mp > 360°C. *Anal.* calcd.: C 26.91, H 5.38, N 6.28, S 14.35; found: C 26.92, H 5.48, N 6.31, S 14.51.

Tetrabutylammonium trifluoromethanesulfonate was recrystallized from methylene chloride – diethyl ether; mp 110°C. *Anal.* calcd.: C 52.17, H 9.21, N 3.58, S 8.18; found: C 52.28, H 9.11, N 3.63, S 8.29.

The fluorine resonance spectra showed no evidence of fluorine containing impurities. All spectra were of the tetramethylammonium salts in sulfur dioxide solution at −70°C except as specifically noted.

Results and Discussion

$(CH_3)_4NCF_3SO_3$ has a single, sharp fluorine resonance signal at −78.6 and $(CH_3)_4NFSO_3$ at 41.2 ppm. The complexes will be described in the order of their position in the periodic table.

Group III

Boron Trifluoride

Complexes of 1:1 stoichiometry are formed with both $(CH_3)_4NCF_3SO_3$ and $(CH_3)_4NFSO_3$. Their fluorine resonance parameters are listed in Table 1. Vapor pressure measurements give no indication of BF_3 complexing beyond 1:1 but the fluorine resonance spectra show rapid exchange between free and complexed BF_3 when an excess of BF_3 is present.

Group IV

Silicon Tetrafluoride

No complexes are formed with $(CH_3)_4NCF_3SO_3$ or $(CH_3)_4NFSO_3$.

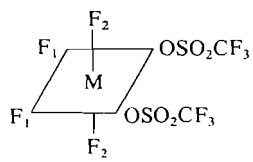
Germanium Tetrafluoride

The fluorine resonance spectra indicate that complex formation is occurring but are not amenable to simple interpretation.

Tin Tetrafluoride

A complex of structure **1** is formed with $(CH_3)_4NCF_3SO_3$ and there is also a single line which may arise from *trans*-$SnF_4(CF_3SO_3)_2^{2-}$. Similar results are found with $(CH_3)_4NFSO_3$ and the parameters are listed in Table 1. These results were obtained on freshly prepared samples at −20°C. Over a period of weeks at room temperature the spectra became more complicated. Group IV fluorides normally give *cis* complexes (13) but *trans* complexes have also been reported (14).



1

Titanium Tetrafluoride

There appear to be two complexes formed with $(CH_3)_4NCF_3SO_3$. One is probably *trans*-$TiF_4(CF_3SO_3)_2^{2-}$ and the other contains bridging and nonbridging fluorines but the spectrum could not be sufficiently resolved for a spectral analysis. The fluorine resonance spectrum of a freshly prepared sulfur dioxide solution with 2 equiv. of $(CH_3)_4NFSO_3$ per TiF_4 has a single line attributed to *trans*-$TiF_4(FSO_3)_2^{2-}$, an unresolved multiplet at 267 ppm, a broad signal from bridging fluorines at −19 ppm, and two other multiplets at low field. After a few weeks at room temperature the multiplet at 267 has disappeared and the spectrum of the other two multiplets is stronger and shown in Fig. 1. Irradiation of the higher field multiplet collapsed the other to a pair of doublets. A simulated spectrum for the case ABCXY is also shown in Fig. 1, where X and Y are bridging fluorines. Structure **2** and the fluorine resonance parameters shown fit these observations. Triple fluorine bridged titanium fluoroanions (15) and multidentate fluorosulfonate groups (6) have been reported. The existence of an ion of structure **2** must, however, be considered hypothetical until more and better evidence is accumulated.

2

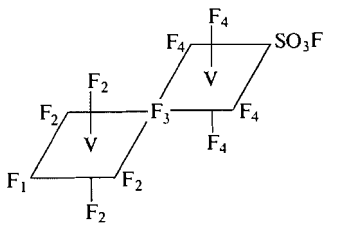
Group V

Phosphorus Pentafluoride and Arsenic Pentafluoride

Octahedral 1:1 complexes are completely formed. The parameters are listed in Table 1 with the axial fluorine as F_1. Tetrabutylammonium salts in methylene chloride as solvent at −90°C were employed with PF_5 in order to slow down axial–equatorial fluorine exchange and obtain well resolved spectra.

Vanadium Pentafluoride

The fluorine resonance spectrum of the complex with $CF_3SO_3^-$ is shown in Fig. 2 and interpreted as arising from structure **3**. The tetrabutylammonium



3

salt was employed in SO_2ClF as solvent since VF_5 reacts with SO_2. The single line at 345 arises from VF_6^-. The multiplet at 492 is assigned to F_1, which is spin coupled to F_2 and F_3. The triplet at 422.2 is assigned to F_2, almost equally coupled to F_1 and F_3. The doublet at 416.8 is assigned to F_4, which is spin coupled to F_3. No signal could be found for F_3, presumably because it is so broadened by spin coupling. This assignment cannot be considered as proven, but is consistent with the fact that only a bridged fluoroanion was found with trifluoroacetate as the other anion. Similar results were obtained with FSO_3^- and the fluorine resonance parameters are listed in Table 1.

Niobium Pentafluoride

Signals in the regions to be expected for axial and equatorial fluorines in a complex NbF_5L are found with both $CF_3SO_3^-$ and FSO_3^-. Their intensity ratios are appropriate but fluorine–fluorine spin coupling could not be resolved due to incomplete quadrupolar averaging of niobium–fluorine spin coupling.

Tantalum Pentafluoride

A sulfur dioxide solution with 2 equiv. of $CF_3SO_3^-$ for each TaF_5 has signals from $TaF_5CF_3SO_3^-$ and *cis*-$TaF_4(CF_3SO_3)_2^-$ of structure **1**. The fluorine resonance parameters are listed in Table 1. With a 1:1 solution additional broad lines are observed in the fluorine on tantalum region of the spectrum. They may arise from a condensed species. Only the 1:1 complex and perhaps some condensed species are found with FSO_3^- as the added anion. *Cis*-disubstituted fluoroanions of tantalum have been observed with trifluoroacetate (12) and ethoxide (16) as ligands, while both *cis* and *trans* complexes were observed with chloride and bromide ligands (17).

Group VI

Sulfur Tetrafluoride

Cis complexes of composition $SF_4L_2^{2-}$ are formed with both $CF_3SO_3^-$ and FSO_3^-. These complexes are the only example where there is a large chemical shift difference between the fluorines bonded to the central atom with different complexing anions. From a comparison with the trifluoroacetate complex (12) it would appear that the chemical shifts of $SF_4(CF_3SO_3)_2^{2-}$ are the unusual ones.

Molybdenum and Tungsten Hexafluorides

There is no significant complex formation with $CF_3SO_3^-$ or FSO_3^-. With a twofold excess of the anion a broad weak fluorine resonance peak was observed which might indicate a slight formation of a complex.

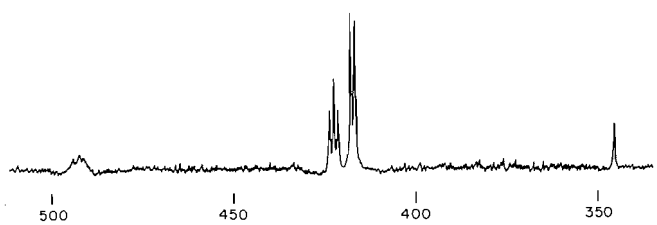


FIG. 2. Fluorine on vanadium region of the fluorine resonance spectrum of an SO_2ClF solution at −90°C with equivalent amounts of VF_5 and TBATFMS.

Group VII

Iodine Pentafluoride

No complex formation is found with $CF_3SO_3^-$ or FSO_3^-.

Conclusions

The two ions $CF_3SO_3^-$ and FSO_3^- behave very similarly in their reactions with binary fluorides. The chemical shifts of the corresponding fluorine atoms bonded to the central element in complexes with $CF_3SO_3^-$ are on average 1.5 ppm to lower field than in the complexes with FSO_3^-, except for the complexes with SF_4. There is no complex formation of these ions with several binary fluorides where trifluoroacetate ion does form complexes (12). There is also less disproportionation to yield more highly substituted fluoroanions with $CF_3SO_3^-$ and FSO_3^- than with trifluoroacetate ion. The weaker complexing can be correlated with the greater strength of the parent sulfonic acids or with the lesser steric requirements of the trifluoroacetate ion at the coordination site. Studies of other anions are needed to distinguish between these possibilities. The chemical shifts of the corresponding fluorine atoms bonded to the central element in complexes with trifluoroacetate ion are on average 14 ppm to lower field than in the complexes with $CF_3SO_3^-$. This is some indication of greater electron donation by $CF_3SO_3^-$ than trifluoroacetate ion, which is contrary to the acid strengths of the parent acids.

Phosphorus pentasulfide as a mild, selective reagent for the reduction of sulfoxides to sulfides[1]

IAN W. J. STILL,[2] S. KHAQAN HASAN,[3] AND KENNETH TURNBULL
Erindale College, University of Toronto, Mississauga, Ont., Canada L5L 1C6

Received December 28, 1977

IAN W. J. STILL, S. KHAQAN HASAN, and KENNETH TURNBULL. Can. J. Chem. **56**, 1423 (1978).

It has been shown that phosphorus pentasulfide (P_4S_{10}) is a mild, effective reagent for the reduction of sulfoxides to sulfides and that this conversion can be achieved selectively in the presence of other reactive groups such as ketone, ester, amide, nitro, and halogen. Phosphorus pentasulfide also appears to be a promising reagent for reducing selenoxides but is ineffective in reducing sulfones, sulfinates, or sulfites. The mechanistic evidence presented indicates a probable four-centre (Wittig-like) intermediate or transition state for the reduction of sulfoxides by P_4S_{10}.

IAN W. J. STILL, S. KHAQAN HASAN et KENNETH TURNBULL. Can. J. Chem. **56**, 1423 (1978).

On a montré que le pentasulfure de phosphore (P_4S_{10}) est un réactif doux et efficace permettant de transformer les sulfoxydes en sulfures et que cette réduction peut être effectuée d'une façon sélective en présence d'autres groupes réactifs comme des cétones, des esters, des amides, des dérivés nitrés et halogénés. Il semble aussi que le pentasulfure de phosphore soit un réactif qui offre beaucoup de promesses pour réduire les sélénoxydes; il serait toutefois inefficace pour réduire les sulfones, les sulfinates ou les sulfites. Les données mécanistiques présentées indiquent que la réaction de réduction des sulfoxydes par le P_4S_{10} se produit vraisemblablement par un intermédiaire à quatre centres (comme un Wittig).
[Traduit par le journal]

There has been a great deal of current interest in devising new reagents for both the mild, selective oxidation of sulfides to sulfoxides (1, 2) and, to an even greater extent, for the reverse process of reduction of sulfoxides to sulfides (3–6). The reduction of sulfoxides has also been the subject of a recent comprehensive review by Oae and co-workers (7).

It seemed to us that many of the published procedures suffered from one or more of the following disadvantages: expensive or difficultly accessible reagents, relatively severe reaction conditions, or lack of selectivity of the reducing agent. With this in mind we have examined the feasibility of using phosphorus pentasulfide (P_4S_{10}), a reagent which had briefly been reported as being successful for the reduction of sulfoxides in two very specific instances (8), and we would now like to present our findings; (for a preliminary account see ref. 9). As will be discussed later, we have not restricted our study to simple sulfoxides but have also investigated the reaction of P_4S_{10} with structurally related compounds such as sulfinates, sulfites, sulfones, and sulfilimines, as well as briefly examining the reaction of P_4S_{10} with selenoxides.

Results and Discussion

Synthetic Scope of the Reaction

Although the successful use of trivalent phosphorus compounds for the reduction of sulfoxides has been known for several years (10, 11) we believe that this is the first time that the readily available, inexpensive phosphorus pentasulfide has been employed generally for this reduction. As the results in Table 1 clearly illustrate, phosphorus pentasulfide is capable of reducing a wide variety of structural types of sulfoxide, under very mild reaction conditions, in yields ranging from fair to excellent. We are at present unable to satisfactorily explain the relatively poor yields obtained for the cyclic sulfoxides, thiolan 1-oxide and thian 1-oxide. A comparison of the three types of butyl sulfoxide reported in Table 1 was made to establish whether a significant steric hindrance factor exists in this reaction. From the results obtained it appears not, although examination of Dreiding models would suggest that the better conversion achieved in the di-*tert*-butyl sulfoxide case can be rationalized on steric grounds.

The final entry in Table 1 is of interest in that it clearly demonstrates that the reaction between the S=O group and P_4S_{10} is much faster than that between the C=O group and P_4S_{10}. In this case, as in many other examples in the literature, it is possible

to convert the carbonyl group to a thiocarbonyl group but only by using much higher-boiling solvents such as toluene or pyridine. Micetich (8) had earlier reported that in the deoxygenation of penicillin and cephalosporin sulfoxides there was no concomitant reaction of P_4S_{10} with ester or amide groups present in the sulfoxides. Further examples of functional groups which are not affected by the P_4S_{10} reagent are provided in Tables 1 and 2: they include aromatic nitro, chloro, and methoxy compounds, as well as a number of other sulfur-containing functional groups; (see below for a discussion of this). On the other hand, it is not likely that the reaction will be applicable to sulfoxides containing any kind of amino or hydroxyl group, or a cyano grouping, because reactions of P_4S_{10} with these functional groups have been well described (12–14).

TABLE 2. Effect of *para*-substituents on reduction of symmetrically substituted phenyl sulfoxides

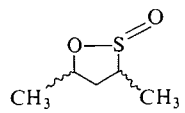
Cl	24
H	39
CH_3	81
OCH_3	100

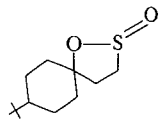
[a]All reactions were run for 4 h at 25°C in CH_2Cl_2 using the same concentrations of reagents.

Before taking up the discussion of a possible mechanism for the reduction of sulfoxides with phosphorus pentasulfide, its effect on a number of structurally related compounds will be considered. It was obviously of great interest, for example, to observe the behavior of sulfones with P_4S_{10} since there is a paucity of reliable methods for achieving the reduction of sulfones to sulfides, although reagents such as lithium aluminum hydride (15) and diisobutylaluminum hydride (16) have been used successfully in a number of instances. Unfortunately, both di-*n*-butyl sulfone and di-*p*-methoxyphenyl sulfone were recovered unchanged even after prolonged treatment (up to 72 h) with P_4S_{10} in refluxing dichloromethane or benzene. Acid catalysis of the reaction did not produce even a trace of sulfide. It should be noted that the sulfoxides analogous to these sulfones were among the most reactive of those reported in Table 1. Although disappointing from the synthetic standpoint, the lack of reactivity of phosphorus pentasulfide with sulfones can be rationalized in terms of our understanding of the mechanism of the sulfoxide reduction.

We have also examined the reaction of P_4S_{10} with the cyclic sulfinates **1** and **2**.[4] Again, perhaps more surprisingly, a lack of reactivity towards P_4S_{10} was evident. In the case of **1**, a 78% recovery of starting material was observed, while for **2**, starting material was recovered to the extent of only 50% but tlc analysis indicated that at least four products were being formed and accordingly the reaction was not pursued further.



1

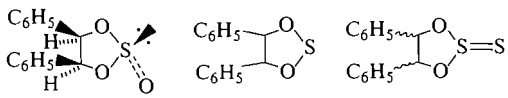


2

A similar situation prevailed when we attempted to extend the reaction with phosphorus pentasulfide to the cyclic sulfite **3**. This compound was readily obtained by the literature procedure (17) but, although only 50% of the starting sulfite survived the reaction with P_4S_{10} and a significant amount of stilbene was formed, we were unable to obtain any conclusive evidence for the formation of either the sulfoxylate ester **4** or a thioxosulfite **5** in this reaction.

One other reaction which was successfully

[4]Samples of these two compounds were generously provided by Professor T. Durst, University of Ottawa, Ottawa, Ont.

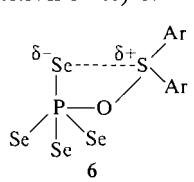


3 4 5

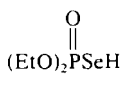
achieved with P_4S_{10} was the reduction of selenoxides to selenides. In fact, perhaps because of the longer Se—O bond, the reduction of diphenyl selenoxide (85% conversion in 3 h) was considerably faster than the diphenyl sulfoxide analogue (39% conversion in 4 h). Although we have not made a detailed study of a series of selenoxides, we also attempted the reduction of dibenzyl selenoxide to illustrate the generality of the procedure. In this case also the reaction proceeded even more smoothly than for the analogous sulfoxide, with an 83% isolated yield of dibenzyl selenide being obtained. Attempts to reduce selenoxides have not been widely reported in the literature to date, although the successful use of various phosphine selenides in halogenated solvents at 25°C for this purpose was very recently reported (18).

$$R_2SeO \xrightarrow[25°C]{P_4S_{10}} R_2Se$$

We were also interested in comparing the effectiveness of phosphorus pentaselenide with phosphorus pentasulfide in the reduction of sulfoxides. Phosphorus pentaselenide (P_4Se_{10}) is readily available and its use for the selenation of uracil derivatives by the reaction of P_4Se_{10} with the appropriate thiocarbonyl analogue has recently been reported (19). However, no reaction between diphenyl sulfoxide and P_4Se_{10} was observed after 6 h in dichloromethane at 40°C. In the light of our discussion of a possible mechanism for the sulfoxide reduction (see below) it is possible that this failure of P_4Se_{10} to react can be explained in terms of unfavorable S—Se bond polarization in the likely intermediate (or transition state) **6**.



6

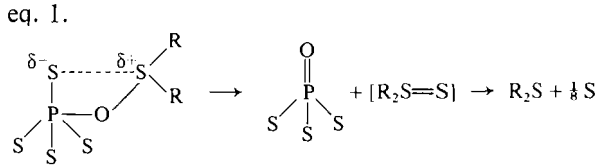


7

It is worth noting at this point that a more complex selenium-containing reagent, *O,O*-diethyl hydrogen phosphoroselenoate (**7**), has been successfully employed very recently for the reduction of sulfoxides to sulfides (20). Mikolajczyk (21, 22) had earlier reported the reduction of dimethyl sulfoxide by a series of related sulfur and selenium derivatives of phosphoric, phosphonic, and phosphinic acid, with concomitant replacement of the P=S (Se) functionality by P=O.

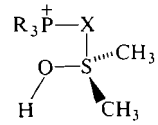
Mechanistic Aspects

There is a considerable difference in the ease with which aliphatic and aromatic sulfoxides react with phosphorus pentasulfide. With DMSO, for example, external cooling was required in the early stages of the reaction and reaction is essentially complete in a few minutes, whereas for diphenyl sulfoxide the conversion to sulfide is barely 40% complete after 4 h (Table 2). This led us to suspect that the electron density at the oxygen atom and hence a rate-determining nucleophilic attack of the oxygen in the $S^+—O^-$ bond at the phosphorus atom in P_4S_{10} are implicated in the reaction mechanism. Strong support for this view is provided by the results in Table 2 which show a clear-cut correlation between the rate of the reduction and increasing electron-donor capability of X in a series of sulfoxides $(p\text{-}XC_6H_4)_2SO$. Given the structure (in the solid state) of P_4S_{10} (23), with its adamantane-like skeleton and four equivalent P=S bonds, this result suggested a Wittig-like intermediate or transition state **8** reacting via the mechanism shown in eq. 1.



8

This suggestion is somewhat different from a mechanistic proposal by Mikolajczyk and Luczak (24) for the *strong-acid-catalyzed* reduction of dimethyl sulfoxide by a series of substituted phosphine sulfides and selenides. Under the acidic conditions, these authors propose initial protonation of the sulfoxide oxygen atom and the intermediacy of a tetracovalent sulfur species, **9**.



9
(X = S, Se)

A similar intermediate has been proposed by Oae and his co-workers (25) for the reduction of sulfoxides with *O,O*-dialkyl dithiophosphoric acids, $(RO)_2P(S)SH$, where the protonation step is presumably initiated by the phosphorus-containing reagent itself, since there is no strong acid catalyst present in their work.

On the other hand, Sakaki and Oae (18) have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

proposed an intermediate similar to our Wittig-like structure **8**, or a six-centre analogue involving two selenoxide molecules, for the reduction of selenoxides with phosphine selenides. In their case the argument for such an intermediate was strengthened by the isolation of the corresponding phosphine oxides in high yield, whereas in the reaction which we are investigating, the possibility of isolating the (unknown) by-product $P_4O_4S_6$ was explored without success. Indirect evidence in our case in favor of the four-centre intermediate or transition state was provided by the isolation of triphenylphosphine sulfide (17%) from the reaction between triphenylphosphine oxide and P_4S_{10}. No triphenylphosphine was detected in this reaction, and this should be contrasted with the finding of Oae *et al.* (25) that the reaction between triphenylphosphine oxide and his *O,O*-diethyl dithiophosphoric acid reagent gave, after prolonged reaction times, only a 'minute amount' of triphenylphosphine sulfide.

In terms of the stoichiometry required by [1] we have verified that elemental sulfur is indeed produced in the reaction in an amount almost 100% of that required by theory. We have obtained no direct evidence as yet for the existence of a thiosulfoxide intermediate en route to the sulfide but further experiments are planned with a view to resolving this question. Although a 4:1 molar ratio of sulfoxide to P_4S_{10} should suffice for the conversion to sulfide, we have found that the reaction is much slower under these conditions and that a 2:1 ratio works much better in practice.

Two mechanistic suggestions made by Micetich (8) have also been examined in the present work. Micetich had suggested that because no particular care had been taken to exclude moisture in his experiments the effective reagent might be thiophosphoric acids, rather than P_4S_{10} itself. However, we have run comparison experiments in carefully dried dichloromethane and can find no significant difference in reaction rate between these and experiments run in regular laboratory-grade solvent. We have also demonstrated that the presence of pyridine is not necessary for the success of the reaction, in contrast to Micetich's proposal. In connection with this, it is interesting that Weintraub (13) reports the ready formation of a 4:1 molecular complex between pyridine (but not some pyridine derivatives) and phosphorus pentasulfide.

To add further credence to our proposal for an intermediate such as **8** in the reaction of sulfoxides with phosphorus pentasulfide we carried out a comparison of the rates of reaction, as measured by the extent of reduction in a fixed time period, in solvents of differing polarity (Table 3). It might be

TABLE 3. Effect of solvent polarity on reduction of diphenyl sulfoxide

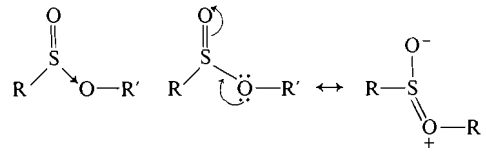
Solvent	Dielectric constant (ε)[a]	Conversion to sulfide (%)[b]
CS_2	2.64	65
CH_2Cl_2	8.93	41
CH_3COCH_3	20.70	55
CH_3CN[c]	37.50	20[c]
	43.30	0[d]

[a]Reference 35.
[b]All reactions were run for 5 h at 25°C, using identical concentrations of diphenyl sulfoxide.
[c]Control experiments revealed that there is a slow competing reaction of P_4S_{10} with the solvent to produce thioacetamide (see Experimental).
[d]Difficulty in removal of the solvent makes this result slightly suspect. No sulfide was detectable by tlc but the recovery of starting sulfoxide was far from quantitative.

expected, given the polarity of the P=S and S=O bonds, that the reactants would be highly solvated in polar media, in contrast to the four-centre intermediate **8**, and thus that there would be an inverse correlation of rate with the dielectric constant of the medium. Although the data in Table 3 are not conclusive, there is some evidence that this is indeed the case, as was noted by Sakaki and Oae (18) for the selenoxide – phosphine selenide reaction. The reactivity of phosphorus pentasulfide towards hydroxylic solvents already referred to, however, limited the number of the more polar solvents which could be used. Again, although it is not clear from the data in Table 3, which are based on conversions, dichloromethane emerged from this part of our study as the solvent of choice for synthetic purposes, since high yields could be obtained in this solvent even although the reaction times were longer than those in acetone or carbon disulfide.

Direct evidence in favor of the mechanism outlined in [1] is not yet available but it must be pointed out that the proposal of an initial attack of the sulfoxide oxygen at phosphorus in P_4S_{10} does help to explain not only the observed order of reactivity within the sulfoxide series but also the lack of reactivity observed for the sulfones and sulfinate esters. Dipole–dipole repulsion between the S—O bonds in a sulfone has been used to rationalize the much smaller difference in dipole moment between dimethyl sulfone and DMSO (0.35 D) than between the latter and dimethyl sulfide (2.45 D) (26) and would presumably account for a lesser activity of the sulfone oxygen atoms in a nucleophilic sense. The apparent lack of reactivity of the sulfinate derivatives strongly suggests that the inductive electron-withdrawal effect of the σ-bonded oxygen atom plays a greater role in determining the nucleophilic reactivity

of the sulfinyl oxygen than does a resonance contribution of the type shown below.



Finally, the greater reactivity of the selenoxides than their sulfoxide counterparts can be rationalized in terms of an intrinsically more polar Se—O bond in the selenoxide, although the greater bond length of this bond is probably also a factor.

The use of the readily available phosphorus pentasulfide affords an effective general method for converting sulfoxides to sulfides under mild conditions, and with a high degree of selectivity. Although the mechanism of this interesting reaction cannot be considered as established, there is a considerable weight of evidence in favor of an initial nucleophilic attack involving the oxygen atom of the sulfoxide at phosphorus, leading to the products via a relatively nonpolar intermediate or transition state. Further work to establish whether a thiosulfoxide intermediate is also formed is currently under way.

Experimental

Infrared spectra were recorded with a Perkin-Elmer 267 grating spectrophotometer, mass spectra with a Bell and Howell 21-490 spectrometer, and ^{1}H nmr spectra with a Varian EM-360 instrument. For the latter, solutions in deuteriochloroform containing tetramethylsilane as internal reference were used. Reactions were monitored by tlc on Merck DC-Alufolien Kieselgel 60F-254, with dichloromethane – hexane as solvent. Melting points were determined using an Electrothermal Mark II melting point apparatus and are corrected.

Sulfoxides

The sulfoxides used in this investigation were either commercially available or were prepared from the corresponding sulfides by one of two general procedures (27, 28). In the former case, the preliminary extraction of the crude reaction mixture with ether is best omitted.

Reduction of Sulfoxides with Phosphorus Pentasulfide

A representative procedure has already been described (9).

Attempted Reaction of Di-(p-methoxyphenyl) Sulfone with Phosphorus Pentasulfide

To a stirred solution of the sulfone (0.50 g, 1.80 mmol) in dichloromethane (10 ml) was added phosphorus pentasulfide (0.80 g, 1.80 mmol). The mixture was heated for 18 h under reflux. After cooling and dilution with water (20 ml) the organic layer was separated, dried ($MgSO_4$), and evaporated under reduced pressure to leave a colorless solid (0.42 g, 84%) identified (mp, mmp, ir) as unreacted starting material (29).

Attempted Reaction of 3,5-Dimethyl-1,2-oxathiolane-2-oxide (1) with Phosphorus Pentasulfide

The sulfinate (**1**) (1.00 mmol) was allowed to react with phosphorus pentasulfide (0.50mmol) in dichloromethane under the standard conditions. After the normal work-up procedure only starting material (78%) was recovered.

Preparation of 1β,2β-Diphenylethylene Sulfite

The title compound was prepared (17) as a 9:1 (*trans–cis*) mixture of isomers by the action of pyridine and thionyl chloride on *meso*-hydrobenzoin (30).

Reaction of 1β,2β-Diphenylethylene Sulfite with Phosphorus Pentasulfide

To a stirred mixture of the sulfite (**3**) (1.30 g, 5.00 mmol) in dichloromethane (15 ml) was added phosphorus pentasulfide (1.10 g, 2.50 mmol). After 12 h at room temperature the mixture was filtered and the solvent was removed under reduced pressure. The resultant yellow oil was chromatographed on silica gel; elution with hexane gave *trans*-stilbene (0.15 g, 17%) as colorless crystals, mp 122–124°C (lit. (31) mp 124°C). Further elution with a methylene chloride – hexane mixture (1:2, v/v) gave only the starting sulfite isomers (0.62 g, 48%),[5] mp 125–126°C (lit. (17) mp 122–126°C).

Reaction of Diphenyl Selenoxide with Phosphorus Pentasulfide

To a stirred solution of diphenyl selenoxide (32) (0.89 g, 3.57 mmol) in dichloromethane (12 ml) at 10°C was added phosphorus pentasulfide (0.79 g, 1.78 mmol). After 3 h, water (20 ml) was added and the organic layer was separated, dried ($MgSO_4$), and evaporated under reduced pressure to yield a pale yellow oil which was chromatographed on silica gel. Elution with a dichloromethane–hexane mixture (1:9, v/v) gave diphenyl selenide (0.71 g, 85%) as a colorless oil, spectroscopically identical (ir, nmr) with an authentic sample.[6]

Reaction of Dibenzyl Selenoxide with Phosphorus Pentasulfide

To a stirred solution of dibenzyl selenoxide (32) (0.12 g, 0.43 mmol) in dichloromethane (10 ml) was added phosphorus pentasulfide (0.098 g, 0.22 mmol). After 4 h at room temperature, water (20 ml) was added and the organic layer was separated, dried ($MgSO_4$), and evaporated under reduced pressure to yield a yellow oil which was chromatographed on silica gel. Elution with a dichloromethane–hexane mixture (1:9, v/v) gave dibenzyl selenide (0.094 g, 83%) as a pale yellow oil, spectroscopically identical (nmr, ms) with an authentic sample (33).

Attempted Reaction of Diphenyl Sulfoxide with Phosphorus Pentaselenide

To a stirred solution of diphenyl sulfoxide (1.01 g, 5.00 mmol) in dry (P_2O_5) dichloromethane (20 ml) was added phosphorus pentaselenide (2.31 g, 2.50 mmol) under an atmosphere of dry nitrogen. The mixture was heated 5 h under reflux, allowed to cool, and then filtered to remove insoluble inorganic material. Water (30 ml) was added and the organic layer was separated, dried ($MgSO_4$), and evaporated under reduced pressure to yield a colorless solid (0.90 g, 90%) spectroscopically identical (nmr, ms) with the starting sulfoxide.

Reaction of Triphenylphosphine Oxide with Phosphorus Pentasulfide

To a stirred solution of triphenylphosphine oxide (2.79 g, 10.00 mmol) in dichloromethane (30 ml) at 10°C was added phosphorus pentasulfide (2.22 g, 5.00 mmol). After 4 h the mixture was diluted with water (40 ml) and the organic layer was separated, dried ($MgSO_4$), and evaporated under reduced

[5]Although nmr evidence had indicated the presence of products other than the starting material in the crude reaction mixture, attempts to isolate these were unsuccessful.

pressure to yield a colorless solid which was chromatographed on silica gel. Elution with dichloromethane gave successively triphenylphosphine sulfide (0.50 g, 17%) as a colorless solid, mp 160–162°C (lit. (34) mp 157.5°C), spectroscopically identical (nmr, ms) with an authentic sample; and triphenylphosphine oxide (0.936 g, 34%), mp 151–153°C (lit. (31) mp 156°C), identical in all respects with authentic starting material.

*Reaction of Di-(*p*-tolyl) Sulfoxide with Phosphorus Pentasulfide (1 Equivalent)*

To a stirred solution of the sulfoxide (2.30 g, 10.00 mmol) in dichloromethane (30 ml) was added phosphorus pentasulfide (1.11 g, 2.50 mmol). After 4 h at room temperature the precipitated solid was removed by filtration. Soxhlet extraction (dichloromethane) for 6 h gave a yellow solid, mp 268–278°C, which could not be further purified. The filtrate was evaporated under reduced pressure and the residual oil was chromatographed on silica gel; elution with toluene gave successively, elemental sulfur (0.14 g, 98% of theory) and di-(*p*-tolyl) sulfide (0.96 g, 45%), mp 54–56°C (lit. (31) mp 57.3°C). Further elution with ethyl acetate gave the starting sulfoxide (0.78 g, 34%), mp 94–96°C (lit. (31) 94–96°C).

Reaction of Acetonitrile with Phosphorus Pentasulfide

A mixture of phosphorus pentasulfide (2.22 g, 5.00 mmol) in acetonitrile (10 ml) was stirred 12 h at room temperature and then diluted with water (100 ml). Evaporation of the dried ($MgSO_4$) dichloromethane extract (50 ml) under reduced pressure afforded a pale yellow oil which was chromatographed on silica gel. Elution with a dichloromethane–hexane mixture (2:1, v/v) gave thioacetamide (0.3 g, 20%), mp 114–116°C (lit. (31) mp 115–116°C), spectroscopically identical (nmr, ms) with an authentic sample.

Reçu le 11 octobre 1977

SAMRETH SOTH, MICHEL FARNIER et CLAUDE PAULMIER. Can. J. Chem. **56**, 1429 (1978).

L'action de l'azidoacétate d'éthyle sur les monoaldéhydes furanniques, thiophéniques et sélénophéniques permet l'accès aux furo-, thiéno- et sélénolo[2,3-*b*]- et -[3,2-*b*]pyrroles. Selon cette voie, seul le pyrrolo[2,3-*b*]pyrrole a pu être synthétisé en utilisant comme substrat le formyl-4 pyrrolecarboxylate-2 d'éthyle. Les thiéno et sélénolo[3,2-*b*]pyrroles peuvent aussi être obtenus par action du bromacétate d'éthyle sur un acétamido-3 thiophène ou sélénophène aldéhyde-2, puis cyclisation des acétamides *N*-substitués formés.

Pour les divers produits décrits, les caractéristiques observées en rmn, uv et spectrométrie de masse sont indiquées.

SAMRETH SOTH, MICHEL FARNIER, and CLAUDE PAULMIER. Can. J. Chem. **56**, 1429 (1978).

The reaction of ethyl azidoacetate with the monoaldehydes of furan, thiophene and selenophene yields furo-, thieno-, and selenolo[2,3-*b*]- and [3,2-*b*]pyrroles. Only pyrrolo[2,3-*b*]pyrrole could be prepared by this route using ethyl 4-formylpyrrole-2-carboxylate as the substrate. The thieno- and selenolo[3,2-*b*]pyrroles also could be obtained by the action of ethyl bromoacetate on 3-acetamidothiophene-2-aldehyde, or the corresponding selenolo compound, followed by cyclization of the *N*-substituted acetamide products.

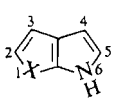
The nmr, uv, and mass spectra are recorded for the various products described.

[Journal translation]

Introduction

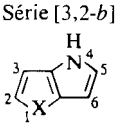
Les systèmes hétérocycliques contenant un cycle pyrrolique orthocondensé à un cycle thiophénique, furannique, sélénophénique ou pyrrolique sont encore assez mal connus. Or de tels composés revêtent, à priori, une importante pharmacologique en tant qu'isostères de l'indole. Dans ce travail, nous proposons des voies d'accès aux systèmes hétérocycliques fondamentaux en séries aréno[2,3-*b*]- et

Série [2,3-*b*]



5*b* X = S
5*c* X = Se
10 X = NH

Série [3,2-*b*]



17*a* X = O
17*b* X = S
17*c* X = Se

-[3,2-*b*]pyrroliques. Nous envisagerons successivement les résultats obtenus dans chacune de ces deux séries.

[1]Une partie de ce travail a fait l'objet d'une publication préliminaire (1).

Résultats

*Synthèses en série aréno[2,3-*b*]pyrrolique*

Antérieurement à nos travaux, aucun des hétérocycles de ce type n'avait été isolé. A priori, une méthode aisée pour accéder à de tels composés paraîssait être celle qui découle des travaux de Hemetsberger et Knittel (2), méthode utilisant la condensation de l'azidoacétate d'éthyle sur un aldéhyde hétérocyclique. C'est d'ailleurs cette voie qui a été mise en œuvre (3) pour obtenir selon le schéma 1 le thiéno[2,3-*b*]pyrrole **5***b*, le rendement global de la transformation **1***b* → **5***b* étant d'environ 35%.

Nous avons appliqué cette méthode en séries furannique et sélénophénique: les aldéhydes **1***a* et **1***c* se condensent avec l'azidoacétate d'éthyle avec de bons rendements. Par cyclisation, les acrylates substitués **2***a* et **2***c* donnent naissance aux esters **3***a* et **3***c*. Mais seule l'hydrolyse de l'ester **3***c* et la décarboxylation de l'acide **4***c* correspondant ont pu être réalisées, le sélénolo[2,3-*b*]pyrrole **5***c* étant isolé avec un rendement global de 20% par rapport à l'aldéhyde **1***c* de départ. A partir de l'ester **3***a*, il ne nous a pas été possible d'obtenir le système hétérocyclique fondamental correspondant, c'est-à-dire le furo[2,3-

SCHÉMA 1

b]pyrrole. Ce résultat est vraisemblablement dû à l'instabilité de ce dérivé; d'ailleurs le furo[3,2-*b*]pyrrole est également nettement moins stable que ses isostères thiophénique et sélénophénique.

En série pyrrolique, tous nos essais de condensation de l'azidoacétate d'éthyle sur le pyrrolecarbaldéhyde-3 se sont soldés par des échecs. Par contre cette condensation a pu être réalisée sur l'ester aldéhyde-2,4 **6** (voir schéma 2); la réaction doit alors être con-

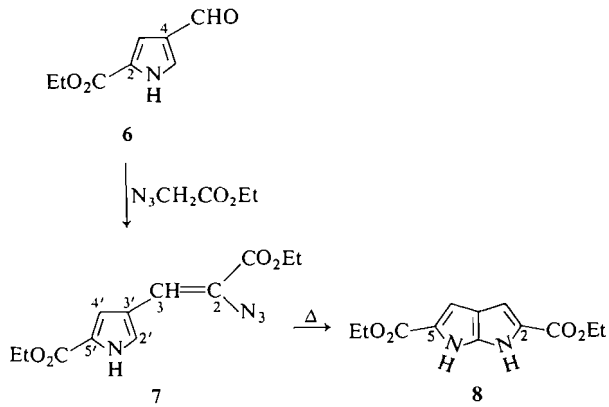

SCHÉMA 2

duite en utilisant l'azidoacétate d'éthyle comme solvant et en présence de pipéridine. Le produit de condensation **7** est isolé avec un rendement de 20%. Sa cyclisation conduit avec un bon rendement (80%) au diester pyrrolique **8** dont l'hydrolyse alcaline fournit le diacide **9**. La décarboxylation de ce dernier permet d'accéder au pyrrolo[2,3-*b*]pyrrole **10** mais seulement avec un rendement de 18%. A noter que ce pyrrolopyrrole est très instable: il doit être conservé à basse température et est très sensible à la moindre trace d'acidité.

*Synthèses en série aréno[3,2-*b*]pyrrolique*

Dans cette série, le thiéno[3,2-*b*]pyrrole est connu depuis les travaux de Snyder et coll. (4, 5). Beaucoup plus récemment Gronowitz *et al.* (6) ont obtenu ce même composé au départ de l'azido-3 thiophènecarbaldéhyde-2. Mais une méthode générale pour l'accès à ce même produit et à ses isostères sélénophénique et furannique paraîssait être celle envisagée en série [2,3-*b*]. Hemetsberger et Knittel (2) ont d'ailleurs condensé l'azidoacétate d'éthyle sur les aldéhydes-2 furannique **11***a* et thiophénique **11***b* et isolé les esters **13***a* et **13***b* (voir schéma 3). Nous avons étendu ces résultats à la série sélénophénique: par condensation de l'aldéhyde-2 **11***c* avec l'azidoacétate d'éthyle, on accède à l'acrylate substitué **12***c* dont la cyclisation fournit l'ester **13***c* (rendement global 45%).

Nous avons également cherché une autre voie d'accès aux esters **13** et nous avons opéré au départ des acétamido aldéhydes **14**. Les dérivés thiophénique **14***b* et sélénophénique **14***c* ont déjà été décrits (7). Quant à l'acétylamino-3 furannecarbaldéhyde-2 **14***a*, nous l'avons préparé comme ses homologues thiophénique et sélénophénique par formylation selon Vilsmeier et Haack du furyl-3 acétamide. Ce dernier composé a déjà été isolé (7) mais avec un faible rendement (20%): nous avons modifié le mode d'obtention préconisé et obtenu le furyl-3 acétamide avec un rendement de 70%. Sa formylation fournit l'aldéhyde **14***a* avec un rendement de 50%. La *N*-substitution des acétamides **14** par le bromacétate d'éthyle s'effectue dans l'acétone en présence de carbonate de potassium anhydre. Après chromatographie sur colonne de silicagel, les composés **15** ont pu être isolés mais avec un faible rendement (environ 30%) et non à l'état de pureté analytique. La cyclisation des composés thiophénique **15***b* et sélénophénique **15***c* s'effectue aisément et avec un excellent rendement (90%) et conduit aux esters **13***b* et **13***c*. Dans les mêmes conditions la réaction conduite à partir du dérivé furannique **15***a* se traduit par la formation de goudrons.

L'hydrolyse alcaline des esters **13** est quantitative et la décarboxylation des acides **16** obtenus conduit aux trois systèmes hétérocycliques fondamentaux **17***a* (rendement 30%), **17***b* (40%) et **17***c* (35%). Ainsi l'obtention des furo, thiéno et sélénolo[3,2-*b*]pyrroles à partir des aldéhydes-2 s'effectue globalement avec un rendement variant de 15 à 20%: la condensation de l'azidoacétate d'éthyle sur un aldéhyde hétérocyclique apparaît donc bien être la méthode de choix pour accéder à des aréno[3,2-*b*]pyrroles. Cependant cette condensation n'a pu être réalisée en série pyrrolique, ni au départ de l'aldéhyde-2, ni à partir de l'ester aldéhyde-2,5.

SCHÉMA 3

Spectres de résonance magnétique nucléaire

Les caractéristiques rmn des produits non cyclisés sont indiquées dans la partie expérimentale. Celles des furo, thiéno, sélénolo et pyrrolopyrroles substitués ou non sont groupées dans le tableau 1. Notons que nous avons reporté par ailleurs (3) les données relatives au thiéno[2,3-*b*]pyrrole **5***b*. Les valeurs indiquées au tableau 1 pour le thiéno[3,2-*b*]pyrrole **17***b* sont compatibles avec celles données par Gronowitz *et al.* (6) qui ont relevé ce spectre dans le tétrachlorure de carbone.

En dehors des couplages propres aux protons des cycles thiophénique, furannique, sélénophénique et pyrrolique, on note systématiquement la présence de couplages à longue distance: dans le cas des arénopyrroles de type [3,2-*b*], apparaissent un couplage $^5J_{36}$ de l'ordre de 0.7–0.9 Hz et un couplage $^6J_{25}$ de 1.1–1.2 Hz; pour les isomères de type [2,3-*b*], on relève un couplage $^6J_{25}$ de l'ordre de 0.8–1.0 Hz. Ces résultats sont tout à fait comparables à ceux observés (9) pour les thiénothiophènes.

Signalons enfin que l'ajout de D_2O se traduit normalement par l'élimination des couplages entre le proton lié à l'atome d'azote et ceux liés aux atomes de carbone du cycle pyrrolique. Ainsi, par exemple, le spectre du furo[3,2-*b*]pyrrole **17***a* relevé dans le DMSO-d_6 sans D_2O montre deux couplages supplémentaires: J_{45} = 2.9 et J_{46} = 1.7 Hz.

Spectres dans l'ultraviolet

Le tableau 2 regroupe les caractéristiques uv observées dans l'éthanol pour les arénopyrroles synthétisés. A noter que sur le spectre du furo[3,2-*b*]pyrrole **17***a* apparaît un épaulement vers 220 nm et sur celui du pyrrolo[2,3-*b*]pyrrole **10** une bande vers 190–200 nm difficilement analysable. A titre de comparaison, dans le même solvant, le pyrrole et le thiophène présentent respectivement des bandes à 207 nm (ε_{max} 7100) et 230 nm (ε_{max} 5400). Ainsi par rapport aux hétérocycles initiaux, on observe, et ce classiquement, un déplacement bathochrome. Si une certaine similitude se manifeste pour des systèmes appartenant à une même série [2,3-*b*] ou [3,2-*b*], par contre pour les séries [2,3-*b*] et [3,2-*b*], des différences apparaissent dans les valeurs des ε_{max} des deux bandes: la bande la plus intense se situe entre 210 et 220 nm pour la série [2,3-*b*] et entre 250 et 260 nm pour la série [3,2-*b*]. Enfin, signalons que les calculs théoriques de Klasinc et Trinajstic (10) concernant les spectres uv des thiénopyrroles ne prévoyaient pas cette différence entre les intensités relatives des bandes observées dans les deux séries étudiées.

Spectres de masse

Les spectres des deux sélénolopyrroles **5***c* et **17***c* ne diffèrent que par quelques variations dans les intensités relatives des pics observés. La présence du pic à 91 traduit la perte de l'atome de sélénium, la même fragmentation ayant d'ailleurs déjà été observée pour le sélénolo[3,2-*b*]sélénophène (11). De plus, le pic à 63 correspond à une perte de masse de 28 à partir de 91: c'est cette fois le cycle pyrrolique qui est fragmenté par perte de $CH_2N^{\bullet}$.

Si pour les sélénolopyrroles la perte initiale de l'atome de sélénium ne fait aucun doute, il est plus difficile pour les thiénopyrroles et pour le furopyrrole étudiés de préciser le cycle qui est fragmenté le premier: pour les thiéno[2,3-*b*]- et -[3,2-*b*]pyrroles dont les spectres sont très voisins, le pic moléculaire (*m/e* 123) est faible vis-à-vis du pic $M - H^{\bullet}$ et surtout du pic à 96. Celui-ci peut correspondre soit à la perte de C_2H_2 à partir du pic 122, coupure caractéristique du cycle thiophénique (réf. 12, p. 243), soit à la coupure du cycle pyrrolique (réf. 12, p. 325) par perte de HCN ou de $C_2H_3^{\bullet}$ à partir de 123. Pour le furo[3,2-*b*]pyrrole, le même problème se pose; cependant l'éventualité la plus probable semble être la coupure initiale du cycle furannique donnant le pic à 79

[a]Le spectre uv du thiéno[3,2-*b*]pyrrole a déjà été relevé par Matteson et Snyder (5).

correspondant à la perte de CO (réf. 12, p. 108), suivie des fragmentations spécifiques du cycle pyrrolique (réf. 12, p. 325).

Quant au pyrrolo[2,3-*b*]pyrrole, on observe successivement la coupure des deux cycles pyrroliques avec les pertes caractéristiques (réf. 12, p. 325) pour chaque cycle, des fragments C_2H_2, HCN, $C_2H_3^{\bullet}$ et $CH_2N^{\bullet}$.

Partie expérimentale

Les analyses élémentaires out été effectuées par le Laboratoire Central de Microanalyses du C.N.R.S. Les spectres rmn ont été relevés sur un appareil Jeol C 60 HL en utilisant le TMS comme référence interne (m, multiplet; M, massif). Les spectres de masse ont été obtenus à l'aide d'un appareil Finnigan 3300 (température de la source 90°C, tension d'accélération 70 eV) et les spectres uv sur un appareil Beckman DK 2.

Matières premières

Les aldéhydes non commerciaux ont été préparés selon les méthodes décrites dans la littérature: furannecarbaldéhyde-3 (13), sélénophènecarbaldéhyde-2 (14), sélénophènecarbaldéhyde-3 (15), formyl-4 pyrrolecarboxylate-2 d'éthyle (16), acétylamino-3 thiophènecarbaldéhyde-2 et acétylamino-3 sélénophènecarbaldéhyde-2 (7).

*Condensation de l'azidoacétate d'éthyle sur le sélénophènecarbaldéhyde-3 1*c

A une solution d'éthanolate de sodium (0.92 g (0.04 at. g) de Na dans 30 cm^3 d'éthanol absolu), on ajoute goutte à goutte et à 0°C une solution de 1.59 g (0.01 mol) d'aldéhyde **1***c* et 5.16 g (0.04 mol) d'azidoacétate d'éthyle dans 20 cm^3 d'éthanol absolu. L'addition terminée, l'agitation est maintenue 2 h à 0°C; puis on verse sur une solution glacée de chlorure d'ammonium et on extrait à l'éther. La phase éthérée est lavée à l'eau à neutralité, séchée ($MgSO_4$) et évaporée. Le résidu est élué sur colonne d'acide silicique par le mélange benzène–hexane (1:2). Après recristallisation dans le pentane, on isole 1.62 g (60%) d'azido-2 (séléniényl-3′)-3 acrylate d'éthyle (**2***c*), pf 27°C; rmn ($CDCl_3$) δ: 1.37 (t, 3H), 4.34 (q, 2H), 6.88 (s élargi, H_3), 7.72 (2d, $J_{2'4'} = 1.1$ et $J_{4'5'} = 5.1$ Hz, $H_{4'}$), 7.97 (2d, $J_{2'5'} = 2.3$ et $J_{4'5'} = 5.1$ Hz, $H_{5'}$), 8.60 (m, $J_{2'4'} = 1.1$, $J_{2'5'} = 2.3$ et $J_{2'3} = 0.6$ Hz, $H_{2'}$). *Anal.* calc. pour $C_9H_9N_3O_2Se$: C 40.01, N 15.55, Se 29.23; trouvé: C 40.30, N 15.45, Se 29.39.

*Condensation de l'azidoacétate d'éthyle sur le furannecarbaldéhyde-3 1*a

On opère comme décrit ci-dessus mais au départ de l'aldéhyde **1***a* (0.96 g, 0.01 mol). Après recristallisation dans l'éther de pétrole, on obtient 1.43 g (69%) d'azido-2 (furyl-3′)-3 acrylate d'éthyle (**2***a*), pf 24°C; rmn ($CDCl_3$) δ: 1.36 (t, 3H), 4.37 (q, 2H), 6.78 (M, H_4· et H_3), 7.39 (M, $H_{5'}$), 7.82 (M, $H_{2'}$). Ce composé a tendance à se cycliser spontanément et aucun résultat analytique satisfaisant n'a pu être obtenu.

*6H-Sélénolo[2,3-*b*]pyrrolecarboxylate-5 d'éthyle (3*c*)*

On chauffe 45 min à reflux le dérivé **2***c* (1.75 g) dans 100

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

cm^3 de xylène. Après évaporation du solvant puis recristallisation dans un mélange benzène–hexane (1:2), on recueille 1.35 g (86%) de l'ester **3***c*, pf 133°C. *Anal.* calc. pour $C_9H_9NO_2Se$: C 44.64, N 5.78, Se 32.61; trouvé: C 44.64, N 5.80, Se 32.56.

*6H-Furo[2,3-*b*]pyrrolecarboxylate-5 d'éthyle (3*a*)*

On porte 1 h à reflux le composé **2***a* (1 g) dans 40 cm^3 de xylène. Le résidu obtenu après élimination du solvant est élué sur acide silicique par le chloroforme. On obtient, après recristallisation dans l'éther de pétrôle, 430 mg (50%) de l'ester **3***a*, pf 94°C. *Anal.* calc. pour $C_9H_9NO_3$: C 60.33, H 5.06, N 7.81, O 26.79; trouvé: C 60.49, H 5.16, N 7.86, O 26.60.

Hydrolyse de l'ester **3**c

On chauffe 2 h à reflux l'ester **3***c* (1.21 g, 0.005 mol) et 0.56 g de potasse dans 10 cm^3 d'eau. On acidifie par une solution glacée d'acide chlorhydrique 5 *N*. Le précipité qui apparaît, essoré, lavé à l'eau glacée à neutralité et séché, fournit quantitativement l'acide 6*H*-sélénolo[2,3-*b*]pyrrolecarboxylique-5 (**4***c*), pf (déc.) 208°C.

*6H-Sélénolo[2,3-*b*]pyrrole (***5***c)*

On chauffe 30 min à 160°C, 1 g d'acide **4***c* et 300 mg de chromite de cuivre (activé par du baryum) dans 30 cm^3 de quinoléine. Puis on refroidit rapidement par un bain d'eau glacée et on verse dans de l'éther. Le sel de cuivre est éliminé par filtration; la phase éthérée est traitée par une solution d'acide chlorhydrique *N*, puis lavée à l'eau à neutralité et séchée; enfin le solvant est évaporé. Après recristallisation dans le pentane, on isole 300 mg (38%) de sélénolo[2,3-*b*]pyrrole **5***c*, pf 54°C; spectre de masse: M^+ 173 (11%), 171 (72), 169 (34), 168 (15), 167 (12), 91 (100), 64 (17), 63 (55). *Anal.* calc. pour C_6H_5NSe: C 42.37, H 2.97, N 8.24, Se 46.42; trouvé: C 42.60, H 2.97, N 7.99, Se 46.03.

Condensation de l'azidoacétate d'éthyle sur le formyl-4 pyrrolecarboxylate-2 d'éthyle **6**

On porte 6 h à 70°C l'ester aldéhyde **6** (16.7 g, 0.1 mol) dans 15 cm^3 de pipéridine et 80 cm^3 d'azidoacétate d'éthyle. Après retour à température ambiante, on verse dans 400 cm^3 d'éther, lave à l'acide chlorhydrique *N*, puis à l'eau jusqu'à neutralité. La phase éthérée est séchée et évaporée. L'excès d'azidoacétate d'éthyle est récupéré par distillation sous 0.05 Torr. L'huile résiduelle ainsi obtenue est éluée sur colonne d'acide silicique par le mélange chloroforme–acétone (10:1). Après recristallisation dans le benzène, on recueille 5.55 g (20%) d'azido-2 (éthoxycarbonyl-5′pyrrolyl-3′)-3 acrylate d'éthyle (7), pf 139°C; rmn ($CDCl_3$) δ: 1.37 (t, 6H), 4.37 (q, 2H), 4.40 (q, 2H), 6.94 (s, H_3), 7.34 (m, $H_{4'}$), 7.57 (m, $H_{2'}$). *Anal.* calc. pour $C_{12}H_{14}N_4O_4$: C 51.79, H 5.07, N 20.14, O 23.00; trouvé: C 51.95, H 5.00, N 20.01, O 22.86.

*1H,6H-Pyrrolo[2,3-*b*]pyrroledicarboxylate-2,5 de diéthyle (***8***)*

A 500 cm^3 de xylène portés à ébullition, on ajoute, par petites portions et en 15 min environ, 5 g du composé **7** fraîchement recristallisé. L'addition terminée, le reflux est maintenu durant 15 min, puis on refroidit rapidement par un bain d'eau glacée. Le précipité formé est essoré. Le filtrat est évaporé et le résidu, repris par de l'éther, abandonne également des cristaux de diester. Après recristallisation dans un mélange éthanol–eau (4:1) de l'ensemble des solides recueillis, on obtient 3.6 g (80%) du diester **8**, pf 216°C. *Anal.* calc. pour $C_{12}H_{14}N_2O_4$: C 57.59, H 5.64, N 11.20, O 25.58; trouvé: C 57.50, H 5.58, N 11.17, O 25.64.

*Acide 1H,6H-pyrrolo[2,3-*b*]pyrroledicarboxylique-2,5 (***9***)*

On chauffe 35 min à 75°C 3.5 g du diester **8** et 3.0 g de potasse dans 60 cm^3 d'eau. Après retour à température ambiante, une partie du diester qui n'a pas réagi est recueillie par filtration. Le filtrat est d'abord extrait au chloroforme pour récupérer le diester à l'état dissous, puis acidifié à 0°C par une solution d'acide chlorhydrique 5 *N*. Le précipité ainsi obtenu est essoré, lavé à l'eau glacée et séché. Au total, on obtient 1.45 g du diester **8** de départ et on isole 1.51 g (rendement 95% par rapport à la quantité de diester qui a réagi) du diacide **9**, pf (déc.) 255°C.

*1H,6H-Pyrrolo[2,3-*b*]pyrrole (***10***)*

A une suspension de 2 g de chromite de cuivre dans 40 cm^3 de quinoléine portés à 140°C, on ajoute, en une fois, le diacide **9** (5.82 g, 0.03 mol) et on maintient à 140°C pendant 45 min. Après avoir été refroidi rapidement, le mélange réactionnel est versé dans de l'éther (préalablement lavé par une solution de potasse). Le sel de cuivre est éliminé par filtration, le solvant évaporé et la quinoléine distillée sous 0.01 Torr. Le résidu est repris par de l'hexane (traité également par une solution de potasse) et le précipité qui apparaît est recristallisé dans le benzène. On obtient ainsi 570 mg (18%) de pyrrolo[2,3-*b*]pyrrole **10**, pf 153°C; spectre de masse: M^+ 106 (100%), 105 (27), 80 (5), 79 (60), 78 (16), 53 (14), 52 (48), 51 (25), 50 (14). *Anal.* calc. pour $C_6H_6N_2$: C 67.92, H 5.66, N 26.41; trouvé: C 67.86, H 5.87, N 26.44.

Condensation de l'azidoacétate d'éthyle sur le sélénophènecarbaldéhyde-2 **11**c

On opère comme décrit précédemment pour l'isomère **1***c*: au départ de l'aldéhyde **11***c* (1.59 g, 0.01 mol), après chromatographie sur acide silicique (éluant benzène–hexane (1:1)) et recristallisation dans l'éther de pétrole, on recueille 1.5 g (55%) d'azido-2 (séléniényl-2′)-3 acrylate d'éthyle **12***c*, pf 50°C; rmn ($CDCl_3$) δ: 1.38 (t, 3H), 4.34 (q, 2H), 7.21 (m, $J_{33'} = 0.7$ et $J_{35'} = 0.9$ Hz, H_3), 7.25 (2d, $J_{3'4'} = 3.9$ et $J_{4'5'} = 5.3$ Hz, $H_{4'}$), 7.44 (m, $J_{3'4'} = 3.9$, $J_{3'5'} = 1.3$ et $J_{33'} = 0.7$ Hz, $H_{3'}$), 8.23 (m, $J_{3'5'} = 1.3$, $J_{4'5'} = 5.3$ et $J_{35'} = 0.9$ Hz, H_5). *Anal.* calc. pour $C_9H_9N_3O_2Se$: C 40.01, H 3.36, N 15.55, Se 29.23; trouvé: C 40.07, H 3.49, N 15.54, Se 29.18.

*4H-Sélénolo[3,2-*b*]pyrrolecarboxylate-5 d'éthyle (***13***c)*

On chauffe 45 min à 110°C 4 g du composé **12***c* dans 200 cm^3 de xylène. Après évaporation du solvant et recristallisation dans un mélange benzène–hexane (1:1), on isole 2.95 g (82%) de l'ester **13***c*, pf 140°C. *Anal.* calc. pour $C_9H_9NO_2Se$: C 44.64, N 5.78, Se 32.61; trouvé: C 44.37, N 5.89, Se 32.40.

*4H-Furo[3,2-*b*]pyrrolecarboxylate-5 d'éthyle (***13***a)*

Cet ester a été préparé avec un rendement de 58% à partir du furfural selon le procédé décrit par Hemetsberger et Knittel (2); pf 121°C (litt. (2) pf 121.5°C).

*4H-Thiéno[3,2-*b*]pyrrolecarboxylate-5 d'éthyle (***13***b)*

Ce composé a été obtenu selon Hemetsberger et Knittel (2); pf 130°C (litt. (2) pf 131°C, litt. (8) pf 132.5–133°C).

N-*Furyl-3 acétamide*

A une solution refroidie à 0°C de 8 g d'acétyl-3 furanne dans 150 cm^3 de chloroforme, on ajoute 8 cm^3 d'acide sulfurique concentré en maintenant la température au dessous de 5°C. Puis on introduit, goutte à goutte et à 0°C, 80 cm^3 d'une solution chloroformique d'acide hydrazoïque préparée à partir de 35 g d'azoture de sodium et 200 cm^3 de chloroforme. L'addition terminée, l'agitation est maintenue 15 min puis on traite par 200 cm^3 d'eau. La phase organique est lavée à la soude, puis à l'eau à neutralité. Les phases aqueuses rassemblées sont rendues basiques puis extraites en continu par l'éther pendant plusieurs heures. Après évaporation de l'ensemble des phases organiques puis recristallisation dans un mélange chloroforme–hexane (1:1), on obtient 6.4 g (70%) de furyl-3 acétamide, pf 112°C (litt. (7) pf 112°C).

For personal use only.

*Acétylamino-3 furannecarbaldéhyde-2 (**14**a)*

A une solution de 2.4 g de furyl-3 acétamide dans 10 cm^3 de diméthylformamide, on ajoute goutte à goutte, à 0°C et sous agitation, 3.5 g d'oxychlorure de phosphore. Le mélange se solidifie et il est laissé 30 min à température ambiante. On verse alors dans 200 cm^3 d'eau contenant 12 g d'acétate de sodium. L'extraction en continu par l'éther fournit l'aldéhyde **14***a* que l'on recristallise (rendement 50%) dans un mélange chloroforme–éther de pétrole (1:9), pf 76°C; rmn ($CDCl_3$) δ: 2.15 (s, 3H), 7.46 (m, H_4 et H_5), 9.77 (s, 1H). *Anal.* calc. pour $C_7H_7NO_3$: C 54.90, H 4.58, N 9.15; trouvé: C 54.82, H 4.90, N 9.04.

*Condensation du bromacétate d'éthyle sur les acétamido aldéhydes **14***

Une solution de 5 mmol d'un acétamido aldéhyde **14** dans 25 cm^3 d'acétone est portée 3 jours à reflux en présence de 1.1 g de bromacétate d'éthyle et de 1.5 g de carbonate de potassium anhydre. Après refroidissement, filtration et concentration, on recueille un résidu qui est repris par l'eau. On extrait trois fois à l'éther. La solution éthérée est lavée à l'eau, séchée et évaporée. L'huile brune obtenue est éluée sur colonne de silicagel d'abord par le benzène pour séparer l'acétamido aldéhyde **14** de départ, puis par un mélange benzène–chloroforme (1:1) pour isoler l'ester **15**. On obtient ainsi les composés de structure **15** sous forme d'huiles avec un rendement voisin de 30%. Ils sont caractérisés par leurs spectres de rmn et n'ont pu être isolés à l'état de pureté analytique. Spectres rmn ($CDCl_3$) δ: **15***a*: 1.27 (t, 3H), 2.05 (s, 3H), 4.17 (q, 2H), 4.24 (s, 2H), 6.66 (d, J_{45} = 1.7 Hz, H_4), 7.65 (d, J_{45} = 1.7 Hz, H_5), 9.81 (s, H_a); **15***b*: 1.20 (t, 3H), 1.95 (s, 3H), 4.15 (q, 2H), 4.35 (s, 2H), 7.18 (d, J_{45} = 5.3 Hz, H_4), 7.79 (d, J_{45} = 5.3 Hz, H_5), 10.08 (s, H_a); **15***c*: 1.20 (t, 3H), 1.92 (s, 3H), 4.13 (q, 2H), 4.32 (s, 2H), 7.43 (d, J_{45} = 5.9 Hz, H_4), 8.47 (d, J_{45} = 5.9 Hz, H_5), 9.98 (s, H_a).

*Cyclisation des composés **15***

*Cyclisation de **15**b*

A une solution d'éthanolate de sodium (100 mg de Na dans 20 cm^3 d'éthanol absolu), on ajoute 1 mmol du composé **15***b* et on porte à reflux pendant 1 h. Après refroidissement on verse dans l'eau et on extrait à l'éther. La phase éthérée est lavée à l'eau, séchée et évaporée. Après recristallisation (solvant éther de pétrole–chloroforme (9:1)), on isole (90%) l'ester **13***b*, pf 130°C.

*Cyclisation de **15**c*

De même au départ de **15***c*, on obtient (90%) l'ester **13***c*, pf 140°C.

*Cyclisation de **15**a*

Par contre, dans les mêmes conditions, la réaction effectuée sur **15***a* ne fournit que des goudrons.

*Hydrolyse des esters **13***

Les acides **16** sont obtenus quantitativement par hydrolyse alcaline des esters **13** selon le mode opératoire décrit pour l'hydrolyse de l'ester **3***c*.

Acide 4*H*-furo[3,2-*b*]pyrrolecarboxylique-5 (**16***a*), pf (déc.) 237°C.

Acide 4*H*-thiéno[3,2-*b*]pyrrolecarboxylique-5 (**16***b*), pf (déc.) 239°C (solvant de recristallisation, eau), (litt. (4) pf 203–204°C).

Acide 4*H*-sélénolo[3,2-*b*]pyrrolecarboxylique-5 (**16***c*), pf (déc.) 220°C.

*Décarboxylation des acides **16***

La décarboxylation des acides **16** est réalisée comme décrit précédemment dans le cas de l'acide **4***c*, mais en ne dépassant pas 120–130°C pour le dérivé furannique **16***a*, en remplaçant le chromite de cuivre par de la poudre de cuivre dans le cas de l'acide thiophénique **16***b* et en acidifiant avec précaution avec de l'acide chlorhydrique 0.2 *N* pour les dérivés furannique et thiophénique.

4*H*-Furo[3,2-*b*]pyrrole (**17***a*), pf 39°C (solvant de recristallisation, pentane); spectre de masse: M^+ 107 (97%), 79 (26), 53 (53), 52 (100), 51 (19), 50 (14). *Anal.* calc. pour C_6H_5NO: C 67.28, H 4.70, N 13.07, O 14.94; trouvé: C 67.28, H 4.90, N 12.96, O 14.77.

4*H*-Thiéno[3,2-*b*]pyrrole (**17***b*), pf 29°C (solvant de recristallisation, hexane) (litt. (5) pf 25–28°C, (6) pf 24–26°C); spectre de masse: M^+ 123 (5%), 122 (25), 96 (100), 95 (15), 70 (25), 69 (19).

4*H*-Sélénolo[3,2-*b*]pyrrole (**17***c*), pf 38°C (solvant de recristallisation éther de pétrole); spectre de masse: M^+ 173 (5%), 171 (53), 169 (24), 168 (8), 167 (8), 91 (100), 64 (14), 63 (39). *Anal.* calc. pour C_6H_5NSe: C 42.37, N 8.24, Se 46.42; trouvé: C 42.14, N 8.26, Se 46.20.

Gas phase photolysis of 1-pentene and 1-pentene-d_{10} at 7.1 and 7.6 eV. Kinetic considerations

ANDRZEJ WIĘCKOWSKI[1] AND GUY J. COLLIN

Département des Sciences Pures, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Received December 13, 1977

ANDRZEJ WIĘCKOWSKI and GUY J. COLLIN. Can. J. Chem. **56**, 1435 (1978).

The gas phase photolysis of *n*-pentene was carried out in a static system using nitrogen resonance lines at 7.10–7.11 eV (≃ 174 nm) and the bromine line at 7.6 eV (≃ 163 nm). The mechanism for the photolysis was proposed and compared to what was concluded at 8.4 eV (147 nm, the xenon resonance line). The kinetics of the decomposition of the excited C_3H_5* radicals formed in the primary photochemical process and the C_5H_{11}* radicals formed by the addition of hydrogen atoms to the parent molecules were discussed. The investigations were extended to the *n*-C_5D_{10} photolytic system. The observed decomposition rate constants of the excited pentyl radicals as well as the secondary non-equilibrium isotope effects agree with the data published earlier. It is concluded from these experiments that, at least at 7.6 eV, hot hydrogen atoms are produced.

Only a small fraction of the C_3H_5* radicals decompose and yield allene. At the same time the combined primary–secondary non-equilibrium isotope effects are much less than those calculated for the 'pure' primary isotope effects. To account for these observations, it is assumed that the C_3H_5* radicals are formed with a wide spread in the internal energies. Since the threshold of the decomposition of the excited C_3H_5* radical lies above its mean excess energy (calculated on the statistical basis), an analogy in the energy-distribution functions on the radicals activated photochemically and thermally may be suggested. If so, an inverse secondary isotope effect may contribute to the gross effect involved in the C_3H_5* radical decomposition.

ANDRZEJ WIĘCKOWSKI et GUY. J. COLLIN. Can. J. Chem. **56**, 1435 (1978).

Nous avons étudié la photolyse du pentène normal en phase gazeuse en utilisant l'émission d'une lampe basse pression à azote (7.10–7.11 eV, ≃ 174 nm) et à brome (7.6 eV, ≃ 163 nm). La décomposition de la molécule photoexcitée a été observée et comparée à celle observée à 8.4 eV (147 nm) en utilisant une lampe de résonance à xénon. La cinétique de fragmentation des radicaux C_3H_5* formés dans les processus primaires de fragmentation et C_5H_{11}* formés par addition des atomes d'hydrogène sur la molécule parente a été discutée. La photolyse du pentène-d_{10} a aussi été faite à ces longueurs d'onde. Les constantes de vitesse de décomposition ainsi que l'effet isotopique secondaire "non à l'équilibre" observés des radicaux pentyls excités sont en bon accord avec les données publiées dans la littérature. De ces expériences, on conclue qu'au moins à 7.6 eV, des atomes d'hydrogène chauds sont impliqués dans le système.

Une fraction mineure des radicaux C_3H_5* se fragmentent en produisant l'allène. Dans ce cas un effet isotopique "non à l'équilibre" primaire et secondaire combiné est plus petit que celui prévu sur la base d'un seul effet primaire. Le fait que les radicaux C_3H_5* sont formés avec une distribution très large d'énergie, est utilisé pour réconcilier l'effet observé à celui prévu. Puisque le seuil de fragmentation des radicaux C_3H_5* est situé bien au-dessus de l'énergie moyenne contenu par ces radicaux (calculé sur une base statistique), on suggère que le présent système (photochemiquement activé) est analogue à un système thermiquement activé. S'il en est ainsi, un effet isotopique secondaire, inverse, peut contribuer à l'effet isotopique total mesuré pour la fragmentation des radicaux C_3H_5*–C_3D_5*.

Introduction

In recent work in our laboratory, the vacuum uv photolysis (for a review, see ref. 1) of *cis*- and *trans*-2-butene (2, 3) and normal and isobutene (4) at 7.1 eV (a nitrogen resonance lamp) has been studied. All the systems had major primary processes involving the elimination of methyl radicals and hydrogen atoms:

[1] $$C_4H_8^{**} \rightarrow C_3H_5^* + CH_3$$

$$\Delta H = 75.4 \text{ kcal mol}^{-1}$$

[2] $$C_4H_8^{**} \rightarrow C_4H_6 + 2H$$

The resulting C_3H_5* radicals decompose, yielding mainly allene (2), and the mode of the decomposition has been found of particular interest since it reflects the energy partitioning between the radical fragments formed in process [1]. The hydrogen atoms formed predominantly in process [2] added to the parent molecules producing a C_4H_9* species with excess internal energy capable of undergoing decomposition (except for isobutene):

[3] $$s\text{-}C_4H_9^* \rightarrow C_3H_6 + CH_3$$

The yield of propylene formed in this process was reported as a function of butene pressure, with the conclusion that hot hydrogen atoms were formed in

the system studied. The excess kinetic energy carried by the H atoms is probably different in each photolytic butene system (3).

The gas phase photolysis of *n*-pentene represents another possibility where photochemically initiated radicals possessing a certain excess energy are produced (5, 6)

[4] $$C_5H_{10}^{**} \rightarrow C_3H_5^{*} + C_2H_5$$
$$\Delta H = 71.4 \text{ kcal mol}^{-1}$$

and

[5] $$C_5H_{10} + H \rightarrow C_5H_{11}^{*}$$
$$\Delta H = -41.2 \text{ kcal mol}^{-1}$$

[6] $$C_5H_{11}^{*} \rightarrow C_3H_6 + C_2H_5$$
$$\Delta H = 24 \text{ kcal mol}^{-1}$$

Thus, the present report is a logical continuation of our earlier work. In order to investigate the primary photochemical processes of *n*-pentene as a function of photon energy, two resonance lamps have been applied (a nitrogen lamp, 7.1 eV, and a bromine lamp, 7.6 eV). For the purpose of comparison, the earlier data on this system obtained at 8.4 eV (a xenon resonance lamp) are included and discussed. Experiments with perdeuterated *n*-pentene have also been carried out. It is hoped that the presented rate constants of the decomposition of the excited radicals, as well as the observed non-equilibrium isotope effects, will be of some value from the viewpoint of the theory of unimolecular decomposition processes initiated by the absorption of a quantum of light by organic molecules (7).

Experimental

The spectral characteristics of the nitrogen lamp have been reported previously (2). The all-suprasil quartz bromine lamp (8) was filled with bromine (0.5 cm^3) and argon (0.3 Torr) and operated by electrodeless discharge from a Raytheon microwave power unit connected to a U-shaped microwave cavity. In the preparation of this lamp all measures recommended by Loucks and Cvetanović (8) were observed. The vapour pressure of bromine was controlled by placing a 'cold finger' of the lamp in a Dewar flask containing the Dry Ice – methanol bath (ca. −78°C). The emission spectrum was taken with a 0.5 m vacuum monochromator (235 GCA/McPherson instrument) with a 50 μm slit at a scanning speed of 5 nm/min. The spectrum is presented in Fig. 1. Substantial improvement in the performance (spectral purity) of the lamp as compared to the spectra previously reported was achieved (8). The output of the lamp was about 2×10^{14} quanta s^{-1} as determined by ethylene actinometry with $\Phi(C_2H_2) = 0.75$ (9).

The remaining details on the experimental and chromatographical procedure were essentially the same as described in previous studies of this laboratory (2, 6, 10). The results described below were corrected for the presence of small amounts of impurities (propylene, propane, 1,3-butadiene, less than 0.001%) in *n*-C_5H_{10} (NBS standard sample) and *n*-C_5D_{10} (Merck, Sharp and Dohme, Canada Ltd.) starting materials.

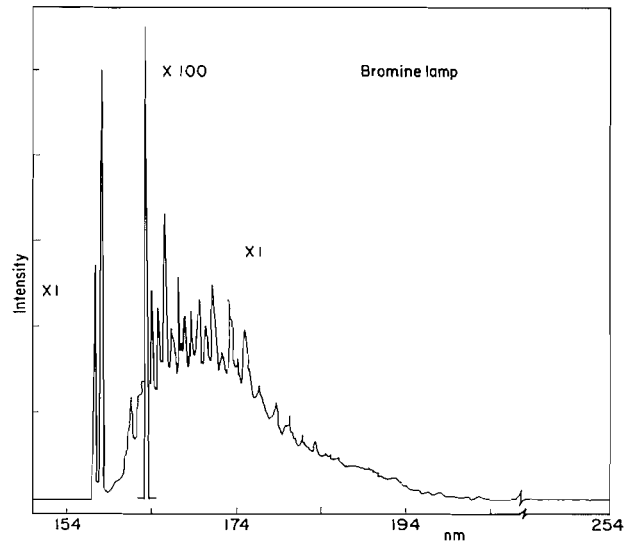

FIG. 1. Emission spectra from the bromine lamp between 150 and 260 nm. Note that the 163 nm (7.6 eV) line has been attenuated by a factor of 100.

Results

With ethylene as an actinometer, the quantum yields of the products at the 7.1 eV as well as the 7.6 eV photolysis of *n*-pentene were determined, and the results are shown in Table 1. The results of unscavenged experiments are given in the first columns of the table and NO and HI scavenged experiments are summarized in the second and the third columns, respectively. If not otherwise indicated it was found that a 10% addition of HI was sufficient to scavenge the radicals present. This observation appears to be of general validity for many organic photochemical systems, although some exceptions have been noted (11). Among the products given in Table 1 only propylene and allene quantum yields were strongly dependent on the *n*-pentene pressure and the pertinent results are summarized in Figs. 2 and 3. The experiments with the perdeuterated compound, C_5D_{10}, are also included in these figures. It should be noted that for each case a constant quantum yield value, no longer dependent on the total pressure, was attained at pressure above 20 Torr (Table 2). Assuming steady-state conditions for allene and propylene precursors, it is thus possible to construct a Stern–Volmer plot for the reciprocal of the product quantum yields, from which these constant values were subtracted, vs. total pressure, and such plots for propylene (H and D) and allene (H and D) for both photon energies are shown in Figs. 2 and 3, respectively.

Discussion

As shown in Table 1, the yields of acetylene, ethy-

lene, and 1,3-butadiene are virtually the same in unscavenged experiments and experiments scavenged by NO. Moreover, they were only slightly dependent on the total pressure. This suggests that they are formed in the primary processes and that their yields may be calculated directly from the actinometry. Allene and propylene, whose yields are no longer pressure dependent (the constant values determined at high pressure, Table 2), are also probably formed in the primary processes. The yields of radicals formed in the studied systems were obtained by subtracting the yields of the hydrocarbons found in the presence of NO from those obtained in the experiments with HI (Table 1). They represent the major products of the primary photodecomposition of *n*-pentene molecules at both photon energies. As seen in Tables 1 and 4, the C_3H_5, C_2H_5, and CH_3 radicals are formed in the prevalent amounts. The remaining products found in the unscavenged or the HI scavenged experiments are formed in secondary processes which are not discussed in the present report. The exceptions are the decomposition processes of the radicals which are propylene and allene precursors (see below).

Considering the material presented in Tables 1 and 2 and the above remarks, the mechanisms shown in Table 3 for 7.1 eV and 7.6 eV photolysis are proposed. For the purpose of comparison, this table also includes the data obtained at 8.4 eV (5, 6). The particular reactions are not discussed since it has been done for 8.4 eV photolysis in the earlier work in this laboratory (5, 6). The similar criteria of choice have been applied to the present interpretation. One may judge whether or not a good, consistent account has been made by comparing the experimental and mechanistic product quantum yields. For 7.6 eV photolysis, it is done in Table 4. If not otherwise indicated, the same features have been found for the 7.1 eV photolysis.

The constant values are taken from Table 2.

As seen from the data given in Table 4, the general agreement is good, remaining well within the experimental error. The calculated yield of the C_3H_5 radical is higher than that experimentally observed. This difference is outside of the experimental error and means that the experimental yield of this radical

C_3H_4	0.024	0.024
1,3-Butadiene	0.09	0.09

is probably underestimated (Table 1). This was also observed at 8.4 eV (6). It should be noted that much better agreement between calculated and measured $\Phi(C_3H_5)$ values (0.65 against 0.62) was obtained at 7.1 eV, suggesting that the difficulties in the quantitative titration of C_3H_5 radicals by HI may be due to their excess energy.

The total product quantum yield at 7.1 eV, less than one (Table 3), implies that some other minor processes are probably not accounted for.

The increase in the photon energy from 7.1 to 7.6 eV causes no substantial changes in the primary photochemical processes of *n*-pentene molecules (Table 3). However, some trends observed in this region are much more pronounced in the 7.6–8.4 eV region. As shown in Table 3 the importance of processes [7]–[9] increases with the photon energy and, at the same time, the yield of process [4] drops five times. Process [12] is also noteworthy since its quantum yield increases more than an order of magnitude

[a]Estimated error.

with the increase in photon energy in the studied region. The quantum yield of the C_2H_3 radical is much higher at 8.4 eV (5, 6) than at 7.1 and 7.6 eV (Table 1), explaining why process [17] (8.4 eV) is replaced by process [10] (this work).

Process [16] was virtually undetected at 7.1 eV as well as at 7.6 eV. The increase in the quantum yield of processes [7] and [12] with the increase in photon energy may not necessarily reflect a change in the primary photochemical processes since it may result from the increased decomposition of the higher energized C_3H_5 and C_2H_5 radicals formed in process [4]. However, on the basis of the Φ values of the remaining processes some substantial changes in the primary fragmentation pattern are concluded to occur along with the increase in photon energy in the 7.6–8.4 eV region.

Secondary Processes. Kinetic Considerations

As mentioned above, only the fate of the propylene and allene precursors will be followed. As to the former process no unambiguity exists (5, 12) regarding its formation process (processes [5] and [6]). On the other hand, allene may result from excited $C_3H_5^*$ radicals,

[18] $$C_3H_5^* \rightarrow C_3H_4 + H$$
$$\Delta H = 56.6 \text{ kcal mol}^{-1}$$

or from $C_4H_7^*$ radicals (11, 13)

[11] $$C_5H_{10}^{**} \rightarrow C_4H_7^* + CH_3$$
$$\Delta H = 85 \text{ kcal mol}^{-1}$$

[19] $$C_4H_7^* \rightarrow C_3H_4 + CH_3$$
$$\Delta H = 32.9 \text{ kcal mol}^{-1}$$

As indicated by HI scavenged experiments both C_3H_5 and C_4H_7 radicals are present in the system studied (Table 1). However, according to the earlier data the $CH_2CH_2CH{=}CH_2$ (1-buten-4-yl) radicals formed in process [11] either decompose to butadiene (14) or isomerize to the 1-buten-3-yl form (14, 15). It has recently been shown by Diaz and Doepker (11) that this 3-yl radical decomposes yielding 1,3-butadiene. The allene formation would demand the isomerization of the 4-yl radical involving 2,4 hydrogen atom shift but this mode of isomerization, which is less probable than the 3,1 shift due to the resonance energy of the 1-buten-3-yl radical, has not yet been reported. Therefore we conclude, as we did in our earlier works (2, 3), that the C_3H_5 (allylic) radical formed in process [4] is the only allene precursor.

The least-squares slopes and intercepts of the lines in Figs. 2 and 3 were used to determine the decomposition rate constants of the $C_5H_{11}^*$ and $C_3H_5^*$ radicals, and they are given in Table 5. The kinetic isotope effects are also included in this table. It is assumed that the deactivation of the excited radicals

[20] $$R^* + M \rightarrow R + M$$

([20]) occurs at each collision and the collision numbers were calculated in the normal way (16). The radical and molecular diameters used for the calculations are:

$$\sigma C_5H_{11} = 0.70 \text{ nm}$$
$$\sigma C_5H_{10} = 0.70 \text{ nm} \quad (12)$$

and

$$\sigma C_3H_5 = 0.467 \text{ nm} \quad (17)$$

Photon Energy Effect

More than a twofold increase in the decomposition rate constants of both radicals with the increase in photon energy is clearly demonstrated in Table 5. According to the theory of unimolecular reactions, this effect results from the increase in the internal energy of the radical species (18). Higher excess energy on the $C_3H_5^*$ radical at 7.6 eV than at 7.1 eV reflects the higher excitation energy gained in the primary photophysical process:

[21] $$C_5H_{10} + h\nu \rightarrow C_5H_{10}^{**}$$
$$\Delta H = 163 \text{ kcal mol}^{-1} \text{ (7.1 eV)}$$
$$\Delta H = 175 \text{ kcal mol}^{-1} \text{ (7.6 eV)}$$

The increase in the decomposition rate of the 2-$C_5H_{11}^*$ radical may result only from the increase in the exothermicity of process [5]. This proves that, at least in the 7.6 eV photolysis of 1-pentene, hot hydrogen atoms are produced.

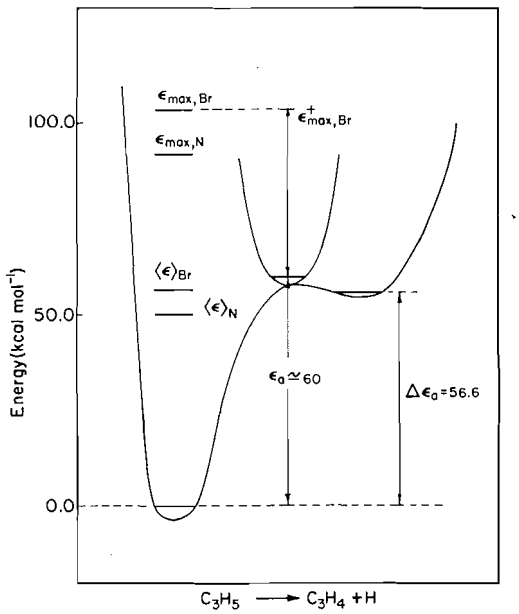

FIG. 4. Schematic potential energy diagram of the C_3H_5* radical decomposition process (see text). Subscripts N and Br refer to experiments done at 7.1 eV (nitrogen lamp) and 7.6 eV (bromine lamp). Activation energy of the process $H + C_3H_4 \rightarrow C_3H_5$ has been estimated from ref. 22.

The decomposition process of the chemically activated 2-pentyl radicals has previously been investigated by Pearson and Rabinovitch (12). Virtually thermal H-atoms were used for the activation. The average value of the rate constant of process [6] obtained by these authors between 0.5 and 2 Torr[2] was equal to 9.0×10^6 s^{-1} and this value is higher than the one found by us for 7.1 eV photolysis (Table 5). This means that a systematic error is probably involved between both studies. No conclusion on the energy of hydrogen atoms produced in the 7.1 eV system can thus be drawn. However, some evidence in favour of the presence of hot hydrogen atoms even at 7.1 eV comes from the isotope effect data (Table 5) which are discussed below.

The assumption has already been made that allene (whose yield is pressure dependent) results only from the C_3H_5* radical decomposition. The Φ(allene) value extrapolated to zero pressure equal to 0.03 ± 0.01 for both photon energies is very small as compared to the C_3H_5 radical quantum yield equal to 0.5 (process [4], Table 3). However, this result is consistent with our earlier observation of the *n*-butene photolysis at 7.1 eV (3), where the complete decomposition of the (C_3H_5)* radicals (formed in process [1]) was not attained either. Considering the thermochemical parameters of processes [1] and [4], and assuming the statistical distribution of energy among the internal degrees of freedom, one may calculate the average excess energies, $\langle\varepsilon\rangle$, on the C_3H_5* radicals formed from the photoexcited C_4H_8** and C_5H_{10}** molecules, respectively. At the photon energy of 7.1 eV these values are 66 kcal mol^{-1} (process [1]) and 50 kcal mol^{-1} (process [4], 56.5 kcal mol^{-1} at 7.6 eV) (19[3]). A schematic potential energy diagram for the decomposition of the allylic C_3H_5* radicals is shown in Fig. 4. It should be noted that the $\langle\varepsilon\rangle$ value (process [4]) estimated on the simple statistical basis lies below the critical energy for the reaction ($\varepsilon_0 = 60$ kcal/mol). Thus, if there is not any spread in the internal energies (2) of the (C_3H_5)* radicals (process [4]), no decomposition of these radicals should be expected. It may also be concluded that even if a single or multipeak energy distribution function is assumed (2), the maximum (maxima) for this function is (are) probably at energies well below the threshold energy for process [18]. As a result, only a minor fraction of the C_3H_5* radicals have sufficient energy to decompose, thus accounting for the small experimental allene quantum yield value.

Isotope Effects

Assuming the radical decomposition mechanisms discussed above, the observed isotope effects for the C_5H_{11}–C_5D_{11} and C_3H_5–C_3D_5 pairs may be classified as secondary and combined primary–secondary non-equilibrium kinetic isotope effects, respectively (7). In the low pressure region where the monoenergetic excitation (the 'δ' energy distribution function) may be assumed, both effects are mainly of the quantum statistical weight origin (due account being taken of the difference in zero point energies on isotope substitution in the case of the primary isotope effects).

For the secondary non-equilibrium isotope effect a large normal effect is predicted by theory and confirmed by experiments (7, 20). The magnitude of this effect depends on the number of isotopic substitutions in the molecules, on the average excess energy above the critical threshold ($\varepsilon^+ = \varepsilon - \varepsilon_0$), and on ε_0, the critical threshold of the reaction (7).

The isotope effects for the C_5H_{11}–C_5D_{11} system summarized in Table 5 may be compared with the secondary non-equilibrium isotope effects for the decomposition of *s*-butyl radicals investigated by Rabinovitch and co-workers (7, 21). The average value of the k_H^{dec}/k_D^{dec} ratio between 0.5 and 2 Torr found by the authors cited (21) were equal to 3.9 ± 0.3 (the external comparison experimental method)

[2]We were unable to detect the dependence of the $k^{dec}(2\text{-}C_5H_{11})$* on *n*-pentene pressure (11).

[3]The thermochemical data used in this work were taken from ref. 19.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and 3.95 ± 0.19 (the internal method). For the C_5H_{11}–C_5D_{11} system the isotope effects (assuming the same experimental conditions) might be expected to be higher, but it need not be so since the increase in the number of D atoms may be compensated for by the decrease in the critical energy (from 33 kcal mol^{-1} for *s*-C_4H_9 decomposition to 31.2 kcal mol^{-1}, process [6] (12)). The slightly smaller k_H^{dec}/k_D^{dec} ratio than that observed by Rabinovitch and co-workers for the C_4H_9–C_4D_9 system may be due to the higher excess energy on the 2-C_5H_{11}* radicals than on *s*-C_4H_9* obtained by the addition of thermal H atoms to the *cis*-2-butene double bond (21). This may suggest that hot hydrogen atoms are present even in 7.1 eV photolysis. However, the increase in the photon energy is not reflected by the diminishing of the secondary effect (Table 5). This discouraging observation is probably due to experimental error. The magnitude of the 'pure' primary non-equilibrium isotope effects declines with the increase in ε^+ and with the decrease in ε_0 (7). Assuming $\varepsilon_H = \varepsilon_D$ (the active energies of the molecules), which is a common case, the maximum value of this effect ($\varepsilon^+ \to 0$) varies from 6.1 to 6.96 at $\varepsilon_{0D} = 35$ kcal mol^{-1} and $\varepsilon_{0D} = 85$ kcal mol^{-1}, respectively (the results of the model calculations (7)). Since, as indicated above, a substantial excess energy on the (C_3H_5)* radicals cannot be expected, the result $k_H/k_D = 1.6 \pm 0.3$ (Table 5) is somewhat surprising. However, it should be recalled that: (*1*) the experimentally observed kinetic isotope effects for the C_3H_5–C_3D_5 pair should be treated in terms of a combined primary secondary effect, and (*2*) the energy distribution function at the (C_3H_5)* radicals, far from the δ function, should be taken into account.

Considering the above remarks and the preceding discussion, the low experimental isotope effects may be explained if we assume that an inverse secondary kinetic isotope effect contributes to the gross effect. The inverse non-equilibrium secondary effects are predicted by theory and experimentally observed in the low pressure region of thermally activated systems (7, 20). It is of interest to note that a close resemblance may be traced between the photochemically initiated C_3H_5* radicals and thermally activated species. As a result of the wide spread in the internal energies of the C_3H_5* radicals and due to the relationship $\langle\varepsilon\rangle < \varepsilon_0$, the unimolecular decomposition process involving these radicals probably amounts to averaging the energy-dependent unimolecular rate constant over the tail of the energy distribution function rather than over its entire energy range. This is a common feature of the thermally activated systems (18). This analogy indicates that the occurrence of the inverse secondary isotope effects is not, at least, improbable. Further study involving normal and perdeuterated *n*-butene is in preparation and it is hoped that it will throw more light on this interesting behaviour.

Acknowledgments

We would like to express our gratitude to the NRCC for its financial help throughout this work and to the Chemistry Division of the NRCC, Ottawa, who provided us with the quartz lamp (Dr. G. Paraskevopoulos and colleagues).

The viscosity of concentrated electrolyte solutions. II. Temperature dependence

DOUGLAS E. GOLDSACK AND RAYMOND C. FRANCHETTO

Department of Chemistry, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received April 4, 1977[1]

DOUGLAS E. GOLDSACK and RAYMOND C. FRANCHETTO. Can. J. Chem. **56**, 1442 (1978).

The temperature dependence of the viscosity of concentrated aqueous electrolyte solutions has been explained in terms of the temperature dependence of the E and V parameters of an equation previously developed for the viscosity of such solutions. Analysis of the V parameters for the alkali halide and ammonium halide salts leads to absolute ionic hydration numbers. The temperature dependence of these hydration numbers reveals two types of ionic behaviour: structure making ions and structure breaking ions. The Gourary–Adrian scale of ionic radii is found to be more consistent with these data and the temperature dependence than the Pauling ionic radii scale.

Analysis of the E parameters leads to the ionic free energy of activation parameters for viscous flow of the ions. The Furth model for hole formation in a liquid is found to correlate these ionic free energy values with the absolute ionic volume parameters obtained from the analysis of the V parameter for all salts. Again the ions are found to break into structure making and structure breaking groups in terms of the surface tension values for the water about the hydrated ions.

DOUGLAS E. GOLDSACK et RAYMOND C. FRANCHETTO. Can. J. Chem. **56**, 1442 (1978).

La relation qui existe entre la température et la viscosité de solutions électrolytiques aqueuses concentrées peut être expliquée en terme de la relation qui existe entre la température et les paramètres E et V d'une équation développée antérieurement pour la viscosité de telles solutions. L'analyse des paramètres V pour des sels d'halogénures alcalins ou d'ammonium conduit à des nombres absolus d'hydratation ionique. La relation qui existe entre la température et ces nombres d'hydratation révèle la présence de deux types de comportement ionique: les ions formant la structure et les ions brisant la structure. On a trouvé que l'échelle Gourary–Adrian des rayons ioniques est plus en accord avec ces données et les relations avec la température que l'échelle des rayons atomiques de Pauling.

L'analyse des paramètres E conduit aux paramètres de l'énergie libre d'activation ionique pour des écoulements visqueux des ions. On a trouvé que le modèle de Furth pour la formation de trous dans un liquide permet d'établir une corrélation entre ces valeurs d'énergie libre ionique et les paramètres absolus de volume ionique obtenus à partir d'une analyse du paramètre V de tous les sels. On a trouvé encore une fois que les ions se divisent en deux groupes les uns formant la structure et les autres brisant la structure de l'eau en terme des valeurs de la tension de surface de l'eau autour des ions hydratés.

[Traduit par le journal]

Introduction

In the first paper of this series (1) it was shown that a simple extension of the absolute rate theory of viscosity to include the contributions from all the particles in a concentrated electrolyte solution led to an equation which quantitatively accounted for the concentration dependence of the viscosity of electrolyte solutions in the 1–10 m range at fixed temperature. For a 1:1 electrolyte this equation is given by

$$[1] \qquad \eta = \frac{\eta_1 \, e^{XE}}{1 + XV}$$

where η is the viscosity of the electrolyte solution at a concentration m and temperature T, η_1 is the viscosity of the solvent at temperature T, X is the mole fraction of the cation or anion in solution, and the parameters E and V are defined as

$$[2] \qquad E = (\Delta G_c^* + \Delta G_a^* - 2\Delta G_1^*)/RT$$

$$[3] \qquad V = \left(\frac{V_c + V_a}{V_1}\right) - 2$$

where V_c = molar volume of the cation particle, V_a = molar volume of the anion particle, V_1 = molar volume of the solvent particle, ΔG_c^* = molar free energy of activation for viscous flow of the cation particle, ΔG_a^* = molar free energy of activation for viscous flow of the anion particle, ΔG_1^* = molar free energy of activation for viscous flow of the solvent particle, and $X = m/(55.5 + 2m)$, where m is the molality of the salt.

The previous paper dealt with a discussion of the concentration dependence of the viscosity of various 1:1 electrolyte solutions at 25°C. It is the purpose of this paper to show that eq. [1] also accounts for the

concentration dependence of the viscosity of 1:1 electrolyte solutions at various temperatures through the temperature dependence of the parameters V and E. The individual ionic components of the V parameter will be shown to be related to ionic solvation numbers, and the individual ionic free energy of activation components of the E parameters will be shown to be related to a surface free energy for formation of a hole in the liquid.

Experimental Results and Treatment of Data

The details of the experimental methods are given in the previous paper of this series (1). Viscosities of aqueous solutions of NaI, KI, NH_4Cl, NaBr, KBr, NH_4Br, NaF, and KF at several concentrations and at six temperatures between 5 and 55°C were determined. These data are presented in Table 1. Viscosities of other salts at several temperatures were obtained from the literature (2, 12, 16–30). All data were analyzed using [1] via a computerized iteration procedure as indicated in the previous paper (1). The $(V_c + V_a)/V_1$ and the E parameters for each salt as a function of temperature obtained by this method are given in Tables 2 and 3 respectively. The viscosity of water as a function of temperature was obtained from the Handbook of Physics and Chemistry (2). Figures 1 and 2 illustrate the reproducibility of the viscosity data for NH_4Br and NaBr as a function of concentration and temperature using the V and E parameters derived from [1].

Discussion

1. The Volume and Free Energy Parameters of the Solvent

The analysis of the concentration dependence of the viscosity of aqueous electrolyte solutions at fixed temperatures yields two parameters for any salt. These parameters, E and V, according to the theory outlined in the previous paper (1) are related to individual ionic parameters as given by [2] and [3]. However, in order to obtain these individual ionic parameters, it is first necessary to determine the molar volume, V_1, for the kinetic species which is involved in the viscous flow process for the solvent. The free energy of activation for viscous flow of the solvent, ΔG_1^*, can be determined from the following relationship for the viscosity of the solvent:

$$[4] \qquad \eta_1 = \frac{hN}{V_1} \exp(\Delta G_1^*/RT)$$

This relationship was one of the assumptions in the theoretical development of [1]. Thus, once V_1 is specified, then this activation free energy can be calculated at any temperature from

$$[5] \qquad \Delta G_1^* = RT \ln(\eta_1 V_1/hN)$$

Analysis of the temperature dependence of the self-diffusion coefficients and the dielectric relaxation times of water (3) has clearly shown that the kinetic species involved in both cases is a single water molecule at all temperatures. These methods allow a calculation of the radius of the kinetic entity involved in the diffusion and relaxation processes, and it was found that the radius so calculated was approximately the same as that of the radius of the water molecule as determined from X-ray analysis, i.e. 1.38 Å (4). For these reasons, V_1 was assumed to be independent of temperature and calculated to be 6.63 cm^3/mol. This implies that ΔG_1^* at any temperature, as given by [5], is solely dependent on the viscosity of water at that temperature. Combining $V_1 = 6.63$ cm^3/mol with [5] and [2], and the E parameters shown in Table 3, the total salt free energies of activation

$$\Delta G_{salt}^* = \Delta G_c^* + \Delta G_a^*$$

were then calculated for all salts at all temperatures studied. These data are displayed in Table 4.

2. Hydration Numbers and the V *Parameters of the Ions*

In the previous paper (1), it was shown that the Jones–Dole B viscosity parameter was related to the two parameters V and E of eq. [1] by the relation

$$B = (E - V)/55.51$$

Furthermore since B has been shown to be an additive parameter with contributions from all ions of a salt, and since E and V are composed of additive ionic parameters, then both the E and V parameters can be analyzed by arbitrarily assuming that the contributions of the potassium and chloride ions are equal at all temperatures, as is done in the analysis of B parameters for salts. Any subsequent conclusions from this arbitrary factoring method must bear this in mind.

Individual ionic V parameters based on V_{K^+} equal to V_{Cl^-} at all temperatures enabled average values of V_{ion} for each ion to be calculated from the total salt V parameters given in Table 2 and the assumed value of V_1 for the solvent. Assuming that these volumes reflect the degree of hydration of each ion, then it is possible to calculate average ionic hydration numbers for each ion as a function of temperature. By subtracting out the volume of the central cation (calculated using the Gourary and Adrian (9) radii scale), and including a dead space correction as given by Conway *et al.* (5), the remaining volume is assumed to be that of the hydration sphere. The hydration number at each temperature can then be obtained by dividing this volume by the volume V_1 =

6.63 cm^3/mol of a mole of water molecules. These resulting hydration numbers are shown in Table 5. As expected, these hydration numbers decrease with increasing temperature for each ion.

The temperature dependence of these numbers shows that these ions can be broken into two groups. The hydration numbers of Li^+, Na^+, and F^- ions are not as affected by an increase in temperature as are those of the K^+, Rb^+, Cs^+, Cl^-, Br^-, and I^- ions. This grouping of these ions has been previously characterized as "structure making ions" and "structure breaking ions" respectively based on a variety of physical properties of electrolyte solutions (6).

For instance, the ionic B coefficients of the Jones–Dole viscosity equation for electrolytes are negative

for structure breaking ions and positive for structure making ions at room temperatures. These differences are reduced at higher temperatures where the "structure" of water is destroyed (7).

One simple explanation of the temperature dependence of these hydration numbers, as well as the grouping of these cations into structure making and structure breaking ions, can be postulated as follows. For an ion to fit into a cavity formerly occupied by a water molecule, its radius must be less than or equal to that of a water molecule (1.38 Å). Thus, if one uses the Pauling ionic radii scale, then the Li^+,

[b]Estimate from trend with temperature.

Na^+, and K^+ ions should fit into such a cavity without disruption of the water structure (the primary and secondary hydration layers about this cavity) since their radii are respectively 0.60, 0.95, and 1.33 Å on this scale. On the other hand, the Rb^+, Cs^+, and NH_4^+ ions whose radii are 1.48, 1.69, and 1.44 Å respectively would be expected to disrupt the primary hydration layer, consisting of four water molecules tetrahedrally oriented about the cavity, by pushing these water molecules apart from each other. Furthermore, this would also result in a disruption of the secondary hydration layer consisting of eight water molecules (4). This disruption should lead to a weakening of the bonds holding these water molecules together in these hydration layers. Hence one would expect a similar temperature dependence of the hydration numbers for Li^+, Na^+, and K^+ ions and furthermore one would expect that the temperature dependence of the hydration numbers for Rb^+, Cs^+, and NH_4^+ ions should be larger than this first group because the water molecules in the primary and secondary hydration layers are not held as strongly in the latter group. However, the data of Table 5 show that the temperature dependence of the hydration numbers of the K^+ ion is not the same as that of the Li^+ and Na^+ ions, but in fact resembles that of the Rb^+, Cs^+, and NH_4^+ ions group. This anomaly is removed, however, if the ionic radii of these ions are re-examined.

The ionic radii scale of Pauling has recently been challenged by several groups of investigators (8, 10) as has been discussed by Desnoyers and Jolicoeur (11). In particular, the ionic radii scale of Gourary and Adrian (9) reveals that the Li^+ and Na^+ ions have radii of 0.94 and 1.17 Å respectively, whereas K^+, Rb^+, and Cs^+ are 1.49, 1.63, and 1.86 Å respectively. These new ionic radii are more consistent with the above explanation of the temperature dependence of the hydration numbers given in Table 5 than are the corresponding Pauling ionic radii. Hence, ionic

I^-	21	22	23	24	23	24	—	29	31	32	—	—	—

volumes were calculated using radii of 1.64 Å for Cl^-, 1.80 Å for Br^-, and 2.05 Å for I^- as given by Gourary and Adrian. The resulting hydration numbers calculated using this ionic radii scale, and including a dead space correction, are shown in Table 5.

Another indication that the Gourary and Adrian ionic radii scale is more consistent with this interpretation of the viscosity of electrolyte solutions is revealed in the behaviour of the fluoride salt solutions. For instance, from Table 1 one can observe that the concentration dependence of the viscosity of KF is that of a typical structure making salt (that is, a salt containing a structure making ion such as Li^+ or Na^+). The other fluoride salts show similar structure making characteristics (12). This implies then that the fluoride ion should be grouped with the Li^+ and Na^+ ions in the structure making group of ions. On the Pauling scale of ionic radii, F^- has a radius of 1.36 Å which is similar to that of the K^+ ion (1.33 Å). However, on the Gourary and Adrian scale the radius of the F^- ion is 1.16 Å, which is almost identical to that of the Na^+ ion (1.17 Å). Therefore the fluoride ion on the Gourary and Adrian ionic radii scale fits the pattern of a structure making ion in aqueous solutions with a radius much smaller than that of the water molecule.

Hence the Gourary and Adrian ionic radii scale allows a simple explanation of the different temperature dependences of the hydration numbers observed for both groups of ions. It also accounts for the individual grouping of these ions into the so-called 'structure making' and 'structure breaking' groups on the basis of ionic size relative to the water molecule. It should also be noted that this explanation does suggest why K^+, Rb^+, and Cs^+ ions can be properly labelled as structure breaking ions since their size alone causes disruption of the normal water structure. Any further calculations requiring the use of ionic radii will be done with the Gourary and Adrian scale.

3. A Model for the Ionic Free Energy of Activation Parameters for Viscous Flow

A simple model for calculating the size, distribution, and free energy of formation of holes in liquids, originally formulated by Furth (13), has been shown to be highly successful in explaining the temperature dependence of the viscosity and diffusion coefficients of molten salts (14). This model assumes that the kinetic species involved in the transport property moves into a cavity or hole of radius r and that the work involved in forming this hole in the liquid medium is given by the work required in forming the hole against the surface tension of the liquid. This work is equated with the free energy of activation for the flow property. In this case then it is assumed that the free energy of activation for viscous flow of an ion will be given by

$$\Delta G^* = 4\pi r^2\gamma \qquad [6]$$

where r is the radius of the hole in the liquid into which the ion moves and γ is the surface tension of the liquid surrounding the ion. Since the free energy of activation parameter for viscous flow of the salt, ΔG_{salt}^*, according to [2], is a linear addition of the contributions from the cation and anion, then combining [2] and [6] gives

$$\Delta G_s^* = \Delta G_{salt}^* = 4\pi r_c^2\gamma_c + 4\pi r_a^2\gamma_a \qquad [7]$$

where r_c is the radius of the cation kinetic species, γ_c is the surface tension of the water surrounding the cation, r_a is the radius of the anion kinetic species, and γ_a is the surface tension of the water surrounding the anion. Now the volume of this cavity into which the ion moves is assumed to be the volume of the kinetic species involved in the transport. This volume is given by the absolute ionic volume parameters V_{ion}. Hence, assuming these kinetic species are spherical in shape and the γ values are given in erg/cm^2, then including the appropriate conversion factor to yield ΔG_s^* values in calories, eq. [7] can be written as

[8] $$\Delta G_s^* = 9.76V_c^{2/3}\gamma_c + 9.76V_a^{2/3}\gamma_a$$

As in the case of the analysis of V parameters where V_{K^+} was equated to V_{Cl^-} at all temperatures based on the additivity of the Jones–Dole B parameter, so in like fashion one can assume $\Delta G_{K^+}^*$ is equal to $\Delta G_{Cl^-}^*$ at all temperatures. This enables a calculation of the surface tension for the solvent surrounding each ion as a function of temperature from the relation

[9] $$\gamma_{ion} = \Delta G_{ion}^*/9.76V_{ion}^{2/3}$$

where the ΔG_{ion}^* values for each ion at each temperature were obtained by averaging the ΔG^* values obtained for each ion from the total salt parameters of Table 4 and the assumed $\Delta G_{K^+}^* = \Delta G_{Cl^-}^*$ values. The average V_{ion} values were obtained from the analysis of Section 2 for the hydration numbers of each ion. The resultant ionic surface tension values are displayed in Table 6.

Again as noted for the hydration values of the ions, these ionic surface tension parameters show two major classes. The group of ions Li^+, Na^+, and F^- all show values of γ typical of structured solvents (e.g. water 72 erg/cm^2, glycerol 63 erg/cm^2, hydrazine 92 erg/cm^2), whereas the remaining ions K^+, Rb^+, Cs^+, NH_4^+, Cl^-, Br^-, and I^- show surface tension values characteristic of unstructured solvents (20–30 erg/cm^2). These values of the surface tension for each of these major groups fit in with the concept of structure making and structure breaking ions as discussed earlier since it would be expected that those ions which disrupt the liquid structure about them in solution should have some effect on the properties of the liquid about them. It is assumed that, according to the Frank–Wen model for ionic hydration (15), the property of water beyond the first hydration layer is roughly the same for all structure breaking ions. The parameters of Table 6 seem to agree with this assumption to a first approximation.

The temperature dependence of these ionic surface tension values is anomalous since the surface tension of normal liquids decreases with increase in temperature, whereas these calculated ionic surface tension parameters increase with an increase in temperature.

This anomaly may be due to the arbitrary assumption that the γ values of the potassium and chloride ion are the same at all temperatures. This may not be true in fact and until a method for obtaining absolute ionic viscosity parameters similar to those devised for absolute ionic molal volume parameters is devised only other arbitrary assumptions for obtaining a scale of ionic parameters can be explored. For instance since the ammonium ion seems to be minimally hydrated by this analysis one could assume the ammonium ion is unhydrated at all temperatures and that its energy of activation for viscous flow is the same as that of the solvent at all temperatures. These assumptions would yield another scale of ionic hydration and surface tension parameters.

Conclusions

The two-parameter equation for the viscosity of an electrolyte solution previously derived (eq. [1]) has been shown to account for the temperature dependence of the viscosity of concentrated electrolyte solutions. Analysis of the volume parameters has led to hydration numbers for each ion. The temperature dependence of these hydration numbers has indicated that the Gourary and Adrian ionic radii scale accounts for the grouping of the cations into structure making and structure breaking ions in a more consistent fashion than the Pauling ionic radii scale. Furthermore it gives a simple explanation of the basic differences between these two classes of ions.

A simple model previously used to account for the free energy of activation parameter for the viscosity of molten electrolytes has been shown to correlate the activation free energy parameters for viscous flow of salt ions in concentrated electrolyte solutions with the viscosity volume parameters for these same solutions. Analysis of these free energy of activation data leads to surface tension values for the water about structure making and structure breaking ions which are in agreement with surface tension data of structured and unstructured liquids respectively.

KAREL WIESNER, THOMAS Y. R. TSAI, and KRISHNAN P. NAMBIAR. Can. J. Chem. **56**, 1451 (1978).

A simple synthesis of the title compounds, which is more than 10 steps shorter and an order of magnitude more efficient than our recent photochemical synthesis of chasmanine, is described. The main feature of the new process is a stereo- and regiospecific addition of benzyl vinyl ether to an *o*-quinone intermediate masked by a spirolactone group according to the method of Deslongchamps.

KAREL WIESNER, THOMAS Y. R. TSAI et KRISHNAN P. NAMBIAR. Can. J. Chem. **56**, 1451 (1978).

On décrit une synthèse simple des composés mentionnés dans le titre; cette synthèse est 10 étapes plus courte et au moins 10 fois plus efficace que notre synthèse photochimique que nous avons récemment rapportée pour la chasmanine. La principale caractéristique du nouveau processus est une addition stéréo- et régiospécifique de l'éther vinylbenzylique à un intermédiaire *o*-quinone masqué par un groupe spirolactone faisant appel à la méthode de Deslongchamps.

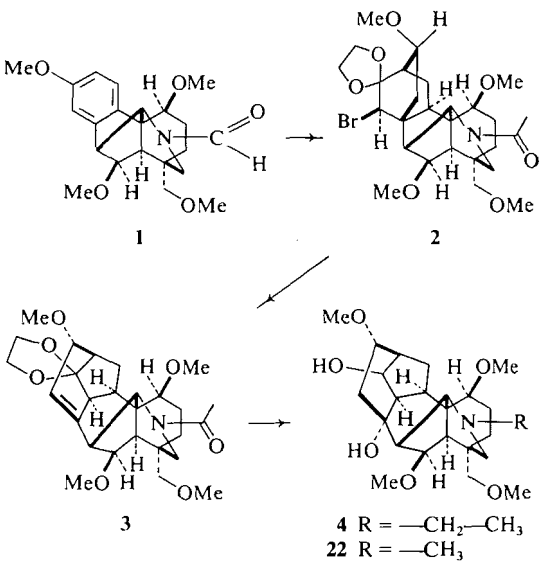
[Traduit par le journal]

We have described recently (1) the total synthesis of the alkaloid chasmanine (**4**) starting with the 'aromatic intermediate' **1** via the 'nordenudatine intermediate' **2** and the rearrangement product **3**. The construction of compound **2** was accomplished by a modification of our photochemical method.

In spite of the fact that the synthesis was stereospecific in all the steps and that all the substituents emerged in the correct positions simultaneously with the construction of the polycyclic skeleton, it turned out to be capable of considerable improvement. We have now developed a fundamentally different synthesis (see ref. 2 for model experiments) which is more than 10 steps shorter and an order of magnitude more efficient.

This new process represents the final generation of our effort to try out (with the aconite alkaloids) an 'engineering approach' (3) to the systematic development and simplification of synthetic strategy for polycyclic polysubstituted compounds.

In the present communication we wish to disclose the direct synthesis of racemic 13-desoxydelphonine and a formal synthesis of chasmanine by the new method. The starting material was the aromatic intermediate **5** (mp 163–164°C) which was prepared from vanillin by the aziridine rearrangement method (cf. ref. 3). The synthesis is fully stereo- and regiospecific and has been described in detail (4).



SCHEME 1

A more efficient route to the same compound starting from *o*-cresol has also been developed.[1]

The aromatic methoxyl in compound **5** was selectively cleaved with sodium thioethoxide in dimethylformamide at 120°C for 1.5 h. The phenol **6** (mp

For personal use only.

189–190°C) was obtained in a yield of 95%.[2] Phenol **6** was alkylated with methyl bromoacetate in dry acetone in the presence of potassium carbonate and 18-crown-6 ether at room temperature for 6 h. The oily ester **7** was obtained in a yield of 90%.

The methoxymethyl protecting group and the ester group of compound **7** were hydrolysed with hydrochloric acid in THF at 55°C and the resulting phenolic acid was immediately oxidized to the corresponding masked *o*-quinone according to the method of Berney and Deslongchamps (5). The oxidation was carried out by stirring the solution of the phenolic acid in methylene chloride with an aqueous solution of sodium acetate and *N*-bromosuccinimide for 30 min with ice cooling. The masked *o*-quinone thus obtained was treated with an excess of benzyl vinyl ether for 24 h at room temperature (cf. ref. 2). The adduct **8** was isolated by chromatography on silica gel in an overall yield of 70%. It was separated into the components **8***a* and **8***b* by preparative tlc (ptlc). The ratio of **8***a*:**8***b* was approximately 2:1 and we were unable to suppress the formation of **8***b*. Fortunately, this turned out to be not only unnecessary but to our advantage.

Compound **8***a* was crystalline and melted broadly at 164–176°C since it is a mixture of epimers at the spirolactone carbon. Compound **8***b* was oily and was purified by preparative tlc. It was practically identical in ir and nmr spectroscopy with compound **8***a* except for the nmr peak of the vinylic hydrogen which was in this case a singlet at τ 4.21. In **8***a* the vinylic proton appears as a doublet (J = 6 Hz) at τ 4.35.

The adduct **8***b* was reduced with zinc in glacial acetic acid in the presence of 18-crown-6 ether under reflux for 15 h. The oily product **9** was purified by ptlc and was obtained in a yield of 85%. The same result was also obtained with compound **8***a* and the mixture of **8***a* and **8***b*.[3]

The benzyl protecting group in compound **9** was removed by hydrogenolysis in absolute ethanol over palladium-on-charcoal. The mixture of epimeric alcohols **10** was obtained in a yield of 96% and was immediately acetylated with acetic anhydride in pyridine. The acetates **11** (90%) crystallized from ether–chloroform (mp 166–167°C). The partial epimerization of the hydroxyl in compound **10** was clearly due to a reverse aldol–aldol condensation reaction during the hydrogenolysis or work-up.

Compound **11** is fully analogous in structure to the corresponding intermediate of our photochemical synthesis, which was reached only after many more synthetic operations. The only difference in the two series from this point on is that the photochemical intermediates were *N*-acetyl tertiary amides.

The keto acetate **11** was converted to the saturated compound **12** by hydrogenation with 5% rhodium-on-alumina in methanol at 85 psi for 18 h, followed by oxidation with chromium trioxide – pyridine. The saturated keto acetate **12** was obtained stereospecifically in a yield of **88**% and it was crystallized from ether–chloroform (mp 198–199°C).

Compound **12** was transformed to the keto acetal **13** by the following three operations: (*i*) reflux with *p*-toluenesulfonic acid and ethylene glycol in benzene; (*ii*) hydrolysis with methanolic sodium hydroxide; (*iii*) oxidation with chromium trioxide in pyridine.

The intermediate **13** was obtained in an overall yield of 88% and recrystallized from ether–chloroform to a mp of 206–207°C; ir: 1720, 1620 cm^{-1} (ketone, lactam C=O); ^{1}Hmr τ: 6.05 (s, 4H, O—CH_2—CH_2—O), 6.63, 6.70 (s, 9H, 3 OCH_3), 7.08 (s, 3H, N—CH_3). Reduction of the keto acetal **13** with sodium borohydride in methanol yielded quantitatively the alcohol **14**, mp 271–272°C (ether–chloroform).

Methylation of **14** under our standard conditions (1, 2) with sodium hydride and methyl iodide in dioxane gave 97% of the methoxy derivative **15**, mp 178–179°C (chloroform–ether); ir: 1625 cm^{-1} (lactam C=O); ^{1}Hmr τ: 6.13 (bs, 4H, O—CH_2—CH_2—O), 6.62, 6.63, 6.69, 6.73 (s, 3H each, 4 OCH_3), 7.10 (s, 3H, N—CH_3).

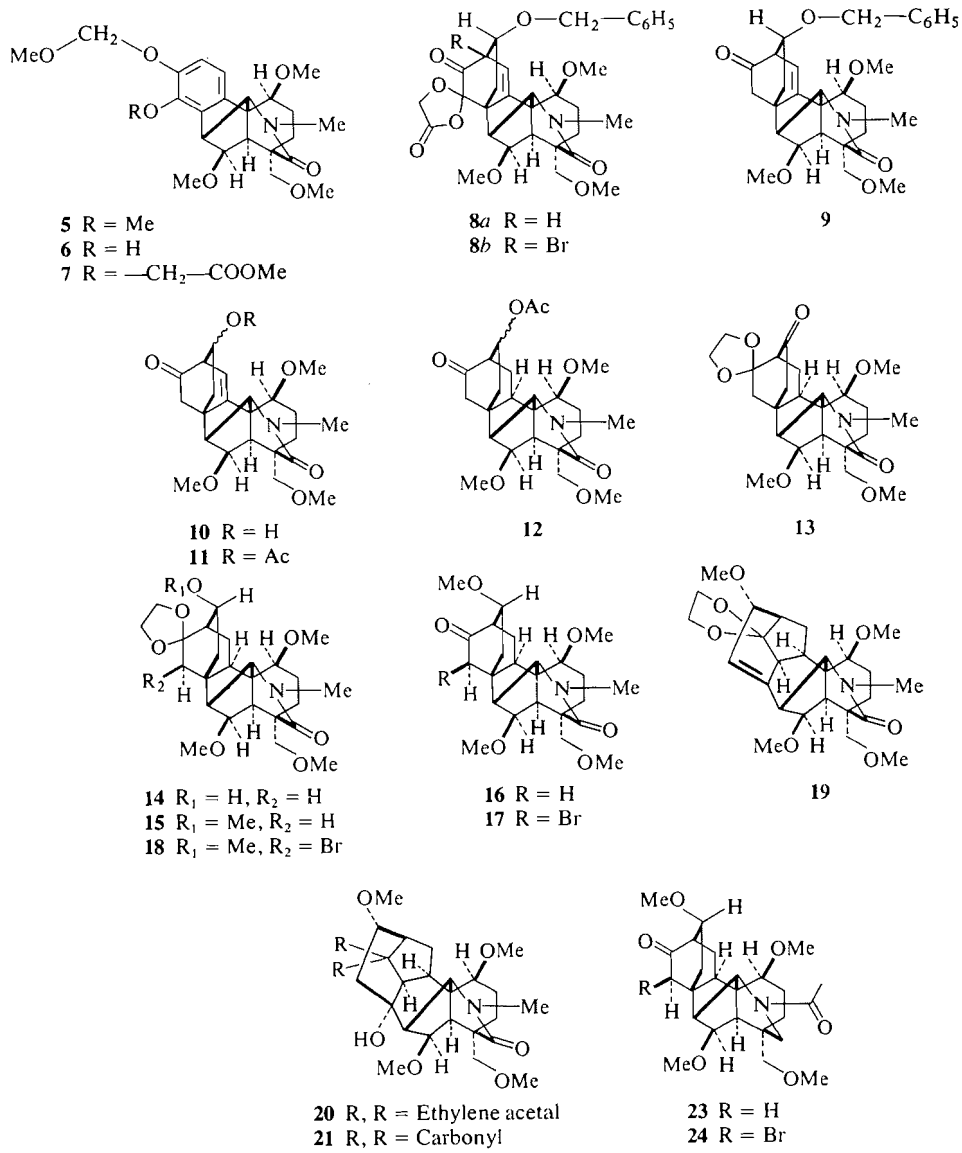
The acetal **15** was heated for 3 h in 80% acetic acid and the corresponding ketone **16** was obtained in a yield of 94% (mp 169–170°C, chloroform–ether); ir: 1720, 1625 cm^{-1} (ketone, lactam C=O).

Bromination of compound **16** with bromine in a mixture of ether and dioxane at room temperature for 4 h gave 90% of the bromo derivative **17** (mp 212–214°C, chloroform–hexane). The configuration of the bromine in formula **17** was assigned on the basis of the subsequent rearrangement, which requires antiplanarity of the leaving group and ring carbon–carbon bond. The bromo ketone **17** was transformed into the dioxolane **18** by reflux with an excess of ethylene glycol and an equimolar amount of *p*-toluenesulfonic acid in benzene for 24 h. Compound **18** (mp 150–152°C) was obtained in 80% yield.

The bromo derivative **18** was heated to 180°C for 6 h with an excess of DBN in a mixture (1:1) of

[2]All compounds gave correct molecular ions in mass spectrometry; all crystalline compounds gave satisfactory results in elemental analysis. The ir and nmr spectra are completely consistent with the assigned structures.

[3]Before this process was discovered the adduct **8***a* was converted to compound **9** via the diketone, dimethylketoacetal, dimethylhydroxyacetal, hydroxyketone, and mesyloxyketone (cf. ref. 2) which was finally reduced with zinc and acetic acid.



SCHEME 2

DMSO and *o*-xylene (cf. ref. 1). The oily rearranged compound **19** was the only product formed and was isolated by ptlc in a yield of 89%; ir: 1620 cm^{-1} (lactam C=O); ^{1}Hmr τ: 4.43 (d, J = 6 Hz, 1H, vinylic), 6.07 (m, 4H, O—CH_2—CH_2—O), 6.60, 6.67, 6.73, 6.77 (s, 3H each, 4 OCH_3), 7.10 (s, 3H, N—CH_3).

The pyro-oxo derivative **19** was subjected to oxymercuration followed by sodium borohydride reduction in THF (*1*). The oily alcohol **20** was isolated by ptlc in a yield of 65%; ir: 3550, 1622 cm^{-1} (OH, lactam C=O).

Compound **20** was heated in 80% acetic acid for 3 h to 85°C. The oily β-oxo-13-desoxy-14-ketodelphonine (**21**) was isolated by ptlc in quantitative yield; ir: 3560, 3440, 1745, 1622 cm^{-1} (OH, ketone, lactam C=O); ^{1}Hmr τ: 6.63, 6.68, 6.72 (s, 6H, 3H, 3H, 4 OCH_3), 7.04 (s, 3H, N—CH_3).

The keto lactam **21** was refluxed with lithium aluminum hydride in dioxane under nitrogen for 15 h. The *racemic totally synthetic 13-desoxydelphonine* (**22**) was recrystallized from hexane (64% yield). It melted constantly at 124–125.5°C and was identical by ir, nmr, mass spectrometry, and tlc in several systems with the optically active compound of the same structure, mp 92°C, prepared according to Marion and co-workers (6).

We have connected the new synthesis with our

For personal use only.

photochemical synthesis of chasmanine (1) as follows; the intermediate **15** was reduced with lithium aluminum hydride to the corresponding tertiary amine and this was oxidized with $KMnO_4$ in acetone in the presence of acetic acid at room temperature for 15 min. The crude *N*-formyl derivative which was thus obtained was hydrolyzed with 6 *N* HCl at reflux for 3 h and the product was acetylated with acetic anhydride and pyridine. The oily *N*-acetyl derivative **23** was isolated by ptlc in 20% yield. It was identical by ir, nmr, mass spectrometry, and tlc with the corresponding intermediate of our photochemical synthesis (1).

Compound **23** (obtained by the present route) was brominated by the described (1) procedure. The bromo derivative **24** melted after crystallization from ether–chloroform at 244–246°C alone and in mixture with our photochemical intermediate (1) of the same structure (mp 244–246°C). Both materials were indistinguishable by ir, nmr, mass spectrometry, and tlc. The present synthesis represents a completely stereo- and regiospecific construction without the use of a relay of a racemate *containing 13 chiral centres*. All the substituents emerged in the course of the synthesis at the correct positions simultaneously with the construction of the hexacyclic skeleton. This seems to be at the present time the record for chiral control in total synthesis.[4]

The chemistry of *N,N'*-dimethylformamidine. I. Formation from potassium methylamide and its thermal stability[1]

JAMES D. HALLIDAY, E. ALLAN SYMONS, AND J. DOUGLAS BONNETT

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ont., Canada K0J 1J0

Received October 12, 1977

JAMES D. HALLIDAY, E. ALLAN SYMONS, and J. DOUGLAS BONNETT. Can. J. Chem. **56**, 1455 (1978).

The thermal decomposition of methylamine solutions of potassium methylamide (PMA) to form the potassium salt (PDMFA) of *N,N'*-dimethylformamidine (DMFA) has been studied as a function of PMA concentration at 60°C. Although concentrated solutions yield normal pseudo-first-order plots (analysis by ultraviolet–visible spectrophotometry), dilute solutions (<0.05 mol L^{-1} PMA) show an increase to a new rate after about 20 h reaction.

The mechanism for this novel amidine salt synthesis is discussed in terms of rate-limiting β-hydride elimination from the PMA ion pair. The relatively sharp rate increase with time for the low concentration runs may arise from a slow buildup of one or more intermediates. The resulting inverse dependence of k_{obs} on PMA concentration is probably related to ion pair – dimer association phenomena.

Pure DMFA has been produced by this reaction, and its thermal stability examined. DMFA decomposes above 100°C to form bis-*N*-(*N'*-methylmethylenimine)methylamine and methylamine; the series of equilibria involved have been shown to be reversible.

JAMES D. HALLIDAY, E. ALLAN SYMONS et J. DOUGLAS BONNETT. Can. J. Chem. **56**, 1455 (1978).

On a étudié, en fonction de la concentration de la MAP à 60°C, la décomposition thermique de solutions de méthylamidure de potassium (MAP) dans la méthylamine conduisant à la formation du sel de potassium (DMFAP) de la *N,N'*-diméthylformamidine (DMFA). Alors que des solutions concentrées conduisent à des courbes normales de pseudo premier ordre (analyse par spectrophotométrie ultraviolet-visible), des solutions diluées (<0.05 mol L^{-1} MAP), indiquent une augmentation vers une nouvelle vitesse après environ 20 h de réaction.

On discute du mécanism pour cette nouvelle synthèse du sel d'amidine en terme d'une élimination β d'hydrure provenant d'une paire d'ions de MAP et déterminant la vitesse de réaction. L'augmentation relativement rapide de la vitesse en fonction du temps aux concentrations basses peut provenir d'une accumulation lente de l'un ou de plusieurs intermédiaires. La relation résultante inverse de k_{obs} avec la concentration de map est probablement due au phénomène d'association de paires d'ions dimères.

On a pu produire de la DMFA pure par cette réaction et on a évalué sa stabilité thermique. La DMFA se décompose au-dessus de 100°C pour conduire à de la bis-*N*-(*N'*-méthylméthylenimine) méthylamine et à de la méthylamine; on a montré que la série des équilibres impliqués est réversible.

of potassium methylamide (PMA) in methylamine (MA) was heated above ambient temperature (eq. [1]). Reported here are the results of an investigation into this interesting thermal decomposition reaction. Also discussed are DMFA recovery and purification procedures, and a brief study of the thermal stability of liquid DMFA.

[1] $2CH_3NH_2 + CH_3NHK \rightarrow 2H_2 + NH_3 + CH_3N{=}CHNKCH_3$

Experimental

Apparatus

The extremely reactive nature of PMA–MA solutions necessitated vacuum line and dry box techniques for preparation and handling. Details have been reported previously (5).

Ultraviolet–visible (uv–visible) spectra were run on Perkin Elmer 450 and Cary 17 spectrophotometers. Nuclear magnetic resonance spectra were recorded with a Bruker HX90 spectrometer, operating at 90 MHz for protons in a field of 2.114 T. Infrared spectra were obtained with a Perkin Elmer 467 instrument.

PMA Solution Preparation

The stock potassium methylamide solutions were prepared by reacting potassium (5 g ampoules, purity 99.95%, from Alfa Products, Ventron Corp.) with methylamine in 2.3 L stainless steel tanks. The water and ammonia in commercial methylamine (Matheson of Canada, Ltd.) had been removed by multiple treatments of the liquid with lithium metal (platinum black mesh catalyst), followed by vacuum distillation at each stage. In this way the ammonia level could be reduced to less than 8×10^{-3} mol L^{-1}, as determined by gas chromatography.

The stock solutions were stored at $-10°C$ to minimize thermal decomposition. The tanks had been fitted with stainless steel dip tubes for convenience in dispensing samples. The concentrations were determined by adding anhydrous ethanol to vacuum-dried sample residues and analyzing the resulting ethanol solutions of methylamine by gas chromatography. Nitrogen was used as carrier gas and the packing was 28% Pennwalt 223 plus 4% KOH on Gas Chrom R.

PMA Thermolysis Kinetic Runs

The thermal decomposition reaction was studied by monitoring the methylamide ion absorption spectrum by uv–visible spectrophotometry. Because of the elevated temperatures and resultant high methylamine vapour pressures involved, a stainless steel pressure cell assembly with thick quartz windows was used (variable path 0.01–0.1 cm). A sketch of the system is shown in Fig. 1. It was necessary to rinse the unit with dry methylamine at least twice to remove traces of water from the internal surfaces (6). Stock solution was then loaded under vacuum and the desired concentration obtained by dilution or concentration. Final solution volume was generally 40 mL.

Most kinetic runs were carried out at $60.0 \pm 0.1°C$ (oil bath). At appropriate times the reaction was quenched by cooling the tank to ambient temperature and the uv–visible spectrum run. Pseudo-first-order rate constants were obtained from least-squares plots of log absorbance at fixed λ (corrected for solvent baseline) vs. time. Tests had shown that Beer's Law was fairly well obeyed in this region.

The loss of PMA could not be measured *in situ* by nmr, because of rapid amino proton exchange. However, confirmation of the uv–visible analytical approach to measuring the thermolysis rate was obtained by nmr, utilizing the fact that DMFA is stable in aqueous acid solution at ambient temperature (7). For several thermolysis runs, 2 mL samples of PMA reaction solution were removed from the vessel each time a uv–visible spectrum was run. After the solvent and volatiles were distilled off, the residue was reacted with 1–2 mL of 0.7 mol L^{-1} DCl in D_2O to produce a solution about 0.1 mol L^{-1} in dissolved salts. A comparison of the methyl group peak areas for DMFA·DCl and CH_3ND_2·DCl yielded a pseudo-first-order plot which gave rate constants for DMFA formation in agreement with the values for PMA loss from the uv–visible plots (e.g. 2.8×10^{-6} vs. 3.2×10^{-6} s^{-1}, respectively, at 0.15 mol L^{-1}). However, this nmr procedure was used only to confirm the other results, since sample preparation was more involved and the system sensitivity was not as good.

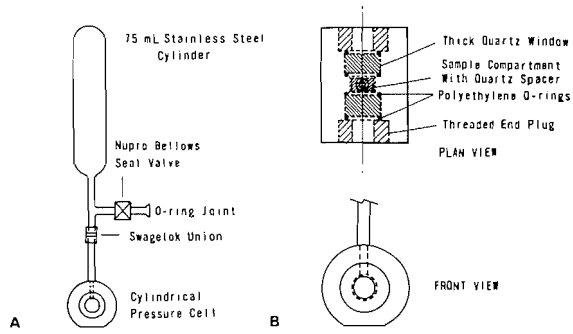

FIG. 1. (*A*) System used to study PMA thermolysis. (*B*) Detail of high pressure (to 6 MPa) uv–visible cell.

DMFA Synthesis

Potassium (13 g) and methylamine (210 g) were heated in a 1 L stainless steel tank at 100°C for 40 h, at which time the thermolysis reaction was complete. The hydrogen gas pressure was then released, the almost colourless solution transferred under vacuum to a Pyrex flask, residual methylamine and other volatiles distilled out, and *n*-dodecanol (300 g, Eastman technical) added to the potassium dimethylformamidide salt. The latter did not dissolve immediately but went into solution slowly as the alcohol was heated to 80°C and the generated DMFA was removed through a distillation column under

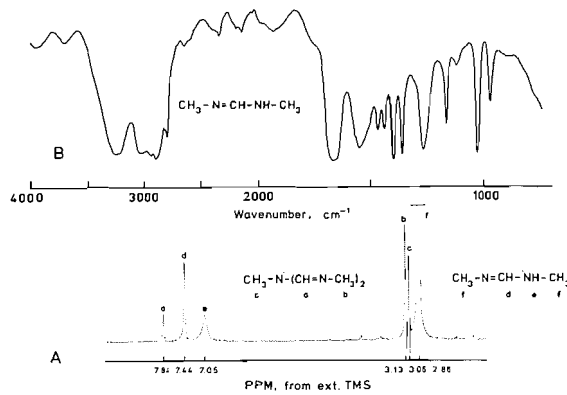

FIG. 2. (*A*) ^1H nuclear magnetic resonance spectrum of neat DMFA and its thermal decomposition product **12** (intentionally thermolyzed). (*B*) Infrared spectrum of neat DMFA, 0.025 mm IRTRAN 2 cell.

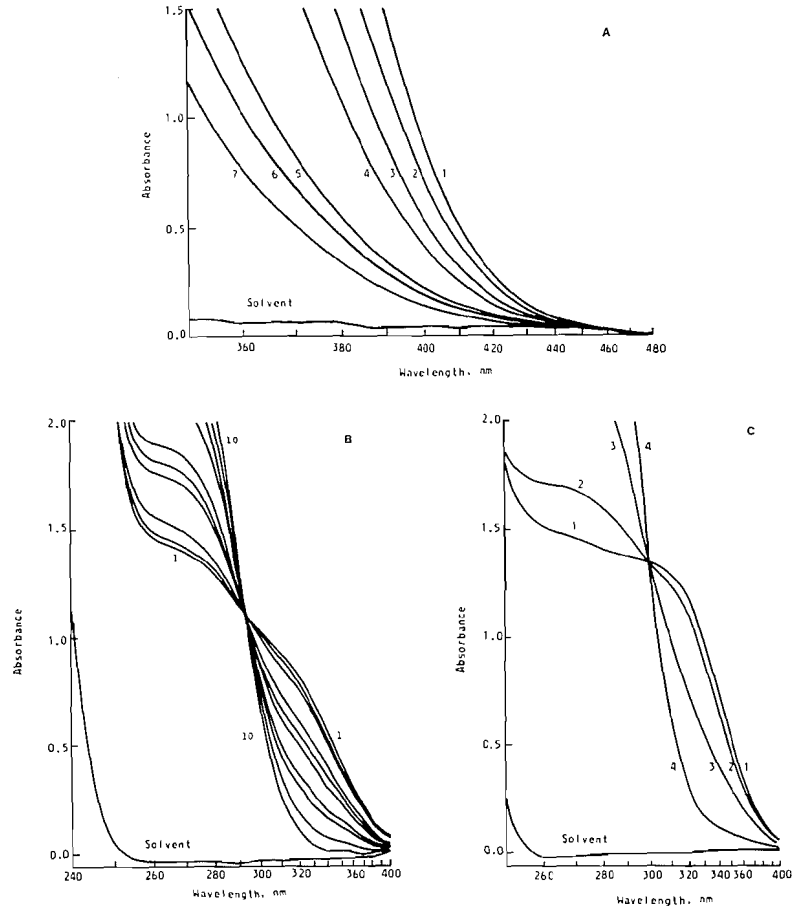

FIG. 3. (*A*) Change in uv–visible spectrum for 0.15 mol L^{-1} PMA at 60.0°C over time period 0–184 h. (*B*) Change for 0.035 mol L^{-1} PMA at 60.0°C, 0–74 h, final scan at 233 h. (*C*) Addition of neat DMFA to 0.085 mol L^{-1} PMA, in concentration ratios 0, 0.054, 0.46, and 1.2, at 23°C, 0.10 mm cell.

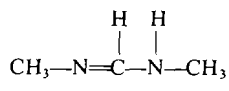
reduced pressure. This fraction contained several percent alcohol as determined by nmr. First stage yield was normally about 80%.

Final vacuum distillation through a packed 18 cm column (middle fraction 37.0–38.5°C at 0.5–0.7 kPa, uncorrected (lit. (1*a*) 59°C at 2.7 kPa, (1*c*) 50–53°C at 2.0 kPa) yielded a clear, colourless liquid whose spectral properties (infrared N—C=N stretch absorption at 1660–1680 cm^{-1} (8) (Fig. 2*B*) and ^1H nmr peaks at 7.44, 7.05, and 2.86 ppm (external TMS), ratios 1:1:6) and elemental analysis (*Anal.* calcd. for $C_3H_8N_2$: C 49.97, H 11.18, N 38.85; found: C 49.97, H 11.18, N 38.80) were in agreement with compound **1**. The nmr spectrum is shown in Fig. 2*A*, together with that of its thermal decomposition product (intentionally thermolyzed, see below). The purified DMFA was stored at −1°C to prevent decomposition.



1

The results of an ^1H nmr study of tautomeric exchange in DMFA and its solutions is reported in Part III of this series (9), while its hydrolysis is discussed in Part II (7).

DMFA Thermal Stability

The thermal decomposition of neat DMFA was studied by ^1H nmr spectrometry. Samples in 5 mm nmr tubes capped with Teflon plugs were heated to 143°C in an oven. Periodically they were cooled to ambient temperature and the nmr spectrum run. A capillary of TMS, inserted after the samples were cooled, served both as a lock material and an external reference.

Results and Discussion

Formation of DMFA

PMA Thermal Decomposition

Because the CTTS band (6) of the methylamide ion has a fairly large extinction coefficient (1.54×10^3 L mol^{-1} cm^{-1} at 300 nm), the absorbance decrease with time for the more concentrated solutions had to be measured on the steep shoulder, usually over the range 370–405 nm (Fig. 3*A*). For the dilute solutions more of the absorption band was visible and both growth of the DMFA anion peak and loss of the methylamide ion peak could be seen (Fig. 3*B*). The latter set of spectra compares favourably with that for a synthetic run derived by adding samples of

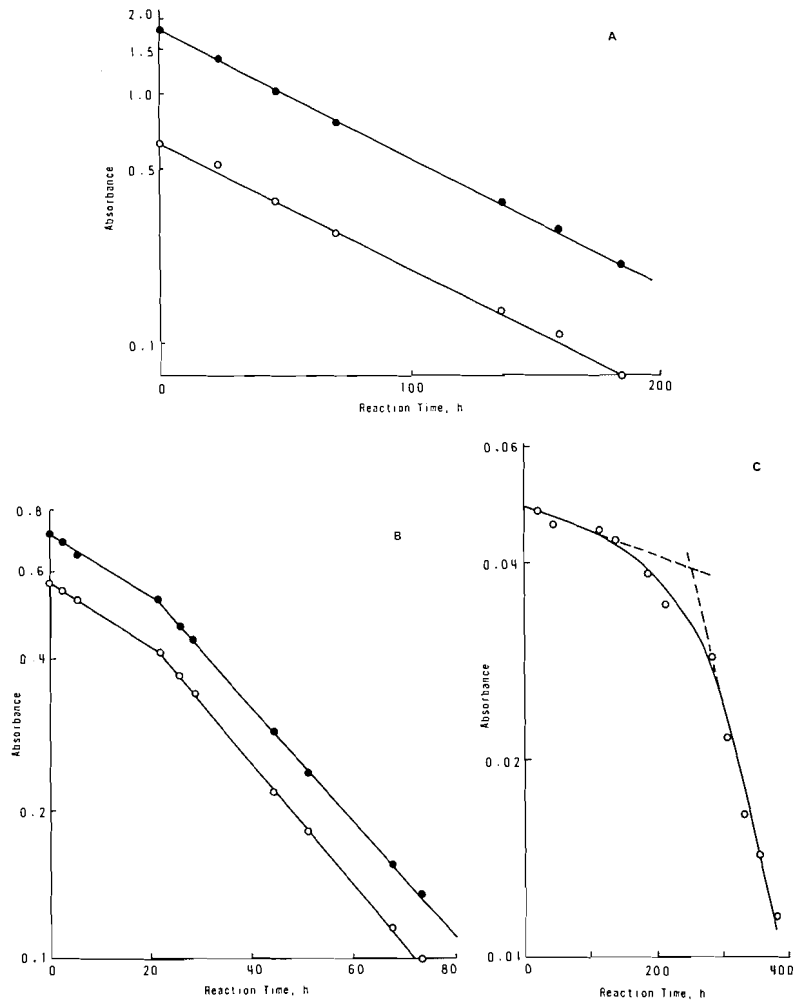

FIG. 4. (*A*) Pseudo-first-order plot of uv–visible data from Fig. 3*A*, half-life 59 h: ●, 386; ○, 405 nm. (*B*) Similar plot for data from Fig. 3*B*, initial half-life 47 h, final 26 h: ●, 330; ○, 340 nm. (*C*) Similar plot for data from run at 23°C with 6×10^{-6} mol L^{-1} PMA, 350 nm.

pure DMFA to a fresh potassium methylamide solution (Fig. 3*C*).

Plots of log absorbance vs. time for concentrated solutions were linear for 1 to 3 half-lives and showed negligible dependence on wavelength within the range 370–405 nm (Fig. 4*A*). On the other hand, for the more dilute solutions studied (below 0.05 mol L^{-1}) there was a distinct induction period of about 20 h before attainment of the final rate (Fig. 4*B*). There was no indication of a precipitate. Because of the lower absorbance for some of these solutions, measurements were occasionally made at somewhat shorter wavelengths (340–360 nm). However, the break in the curve was still evident for data at longer wavelength, although experimental error in the smaller absorbance values contributed to increased scatter. The results of a PMA decomposition run with a solution at very low concentration (6×10^{-6} mol L^{-1}, in all-glass apparatus equipped with a 100 mm optical cell) further support these observations (Fig. 4*C*). This run was carried out at 23°C since the apparatus could not safely withstand any higher internal pressure. Thus it is unlikely that the heating-for-reaction–cooling-for-analysis cycles are responsible for the rate change in the other runs.

Absorption by the potassium salt of DMFA does not interfere significantly with analysis of the decrease in methylamide ion spectrum with time (Fig. 3*C*). However, the contribution from initial product potassium amide (eqs. [8*a*] and [10*b*] below) was of concern. The amide ion is a strong enough base that it can react with solvent to regenerate some methylamide ion via equilibrium [2]. K_2 has not been measured directly but estimates range from 9 to 50

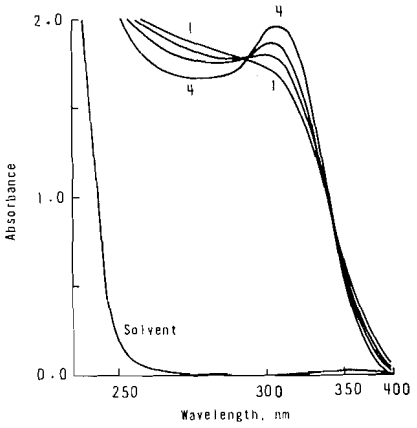

FIG. 5. Change in uv–visible spectrum upon addition of ammonia to 0.085 mol L^{-1} PMA at 23°C, concentration ratios 0, 0.46, 1.0, 2.2.

$$[2]\quad NH_3 + CH_3NH^-K^+ \overset{K_2}{\rightleftharpoons} NH_2^-K^+ + CH_3NH_2$$

(footnote 2 and ref. 10). The corresponding equilibrium for methylamine and the DMFA salt is known to lie well to the right, the dimethylformamidide ion being a much weaker base. Because of the excess CH_3NH_2 as solvent, early in the reaction the NH_2^- formed is all converted to NH_3. However, by the first half-life a small percentage will remain as NH_2^-, as shown for a test solution in Fig. 5. Since the spectra of the methylamide and amide salts are fairly similar, the result will have only a minor effect on the kinetic plots.

The pseudo-first-order rate constant data are presented in Table 1 and Fig. 6. The k_{obs} values calculated for both the initial and final phases of the kinetic plots for the low concentration runs are indicated. One such run, however, at about 0.05 mol L^{-1} PMA, did not exhibit any break in the kinetic plot.

Reaction Mechanism

The individual steps considered to be involved in moving from reactants to products are the following, based *in part* on reactions proposed by staff at Raylo Chemicals Limited,[2] L. G. Walker,[3] and W. J. Holtslander.[4]

Some general points can be made concerning relative stabilities of the various proposed intermediates. Both methylenimine (**2**) and *N*-methylmethylenimine (**5**) are known to be extremely reactive (11), often disappearing via polymerization reactions (3), and hence should be only transient species under the present strongly basic conditions.

[c]No slope change observed.

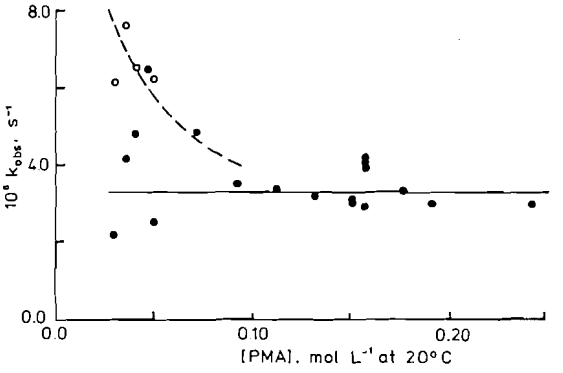

FIG. 6. Dependence of k_{obs} for PMA thermolysis at 60.0°C on PMA concentration. For dilute runs: ●, initial slope; ○, final slope.

A pungent, pyridine-like odour, probably arising from traces of cyclic nitrogen compounds, was often detected at the end of a run. Aminals (*gem*-diamines) are also unstable (3), so that their salts, such as **4**, **6**, and **8**, should have short lifetimes in these solutions, decomposing to amines, imines, and the corresponding salts (3). Evidence for the involvement of the *N*-methylmethylenimine (**5**) comes from the observation that when the thermolysis run is carried out with high hydrogen overpressure (7–30 MPa), dimethylamine is formed as a minor product.[4] This likely occurs through reaction of KH, produced to its solubility limit via equilibrium [13],[4] with **5** according to [14] and [15]. Methylenimine, *N*-methylmethylenimine, and hydrogen cyanide have been proposed as intermediates in the pyrolysis of methylamine (12). Step [13] has been shown to be rapid in the presence of freshly prepared, finely divided KH.[4] Thus, if proton transfer from one nitrogen atom to another is also considered to be rapid, then the main route steps given by eqs. [7], [8*a*], [9*a*], [9*b*], [10*b*], [11], [12], and [13] can all be expected to be fast.

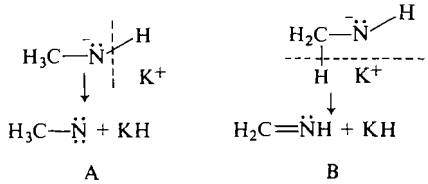
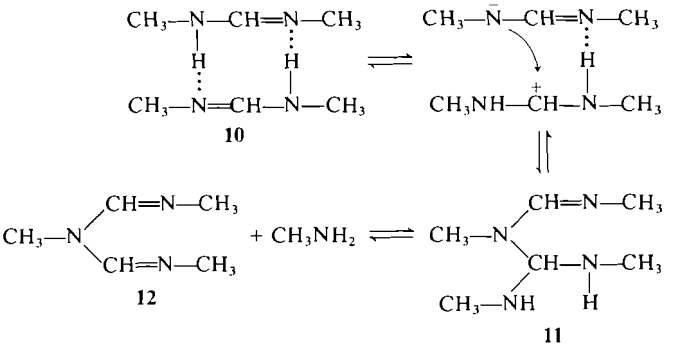
The rate-limiting steps are therefore believed to be those involving potassium hydride formation, i.e. [3], [8*b*], and/or [10*a*]. Similar metal hydride elimination reactions are known to occur in the decomposition of transition metal alkyl complexes when a β-hydrogen is available (13, 14). The stability of transition metal dialkylamides was ascribed to the absence of suitable β-hydrogen atoms in these compounds (15). Thermal decomposition of alkali metal alkyls leads to the formation of olefins and the alkali metal hydrides (16). Because methylamine has such a low dielectric constant (about 8.0 at 60°C), the dissociation of PMA ion pairs to free ions is slight ($K_d \simeq 10^{-7}$ mol L^{-1} at −25°C (17)). Thus the slow formation of KH probably occurs from the PMA ion pair, [4], via intramolecular elimination (13) either in the α-mode (A) or, more likely, the β-mode (B).



Lithium and sodium methylamides have been reported to yield the cyanides upon heating in methylamine solution or in a vacuum (18). Although this route does not appear to be an important one for the potassium case, there is evidence that the formation of cyanide is the *primary* route in the lithium case (see below). The cyanide must arise through a second hydride elimination step [5], from the methylenimide salt **3**. It is interesting that DMFA is a major product in the reaction between liquid methylamine and anhydrous hydrogen cyanide (1*a*).

The important role of the cation is clear from the more limited results of thermolysis studies with lithium methylamide (LMA). The rate of loss of LMA, as measured by uv–visible spectrophotometry, was roughly a factor of 10 slower than for the potassium salt at the same temperature. Two other runs were carried out in sealed, medium wall nmr tubes at 80°C; the nmr spectra were run at ambient temperature. The formation of lithium *N,N'*-dimethylformamidide was very slow relative to the rate of loss of LMA predicted from the uv–visible measurements but no new peaks appeared in the nmr spectrum. Because lithium cyanide would not be detected under these conditions, alternate tests were

[16]



made. The residue from one of these solutions was examined in a Nujol mull by ir and gave good evidence for the presence of cyanide ion, by comparison with the spectrum of potassium cyanide powder in Nujol. The residue from the other solution gave a positive response to a copper sulphide cyanide test (19).

Rate Constant Dependence on PMA Concentration

The high initial PMA concentration runs gave simple first order kinetic plots but for most of the dilute solution runs, below ca. 0.05 mol L^{-1}, an increase in rate was observed after a period of time (e.g. Figs. 4*B* and *C*). The question then arises as to which phase of these runs is comparable to the data for the high concentration runs. The simpler approach is to consider the initial rates as comparable, which yields the horizontal straight line in Fig. 6 (considerable scatter), and the straightforward conclusion that the reaction is indeed first order in PMA concentration. The rate acceleration measured for the dilute PMA runs is then assigned to an unknown side reaction, perhaps triggered by a change in degree of ion pairing, such as the cyanide scheme (eqs. [4] and [5]).

The alternative is to assume that the final rates are comparable, and that the low PMA concentration runs start slowly because of interference from some inhibitor which is gradually consumed. However, one is then left with the problem of explaining a decrease in k_{obs} with increasing PMA concentration, the dashed curve in Fig. 6. In either case, it is difficult to reconcile the fact that the very dilute PMA run behaves the same way (Fig. 4*C*). For this run, ion association will be much less extensive, yet interference from any inhibitor should be much more pronounced.

The effect of a slow buildup of some intermediate(s) must be considered, because of the complicated sequence of steps involved, eqs. [3]–[15]. It was possible, by assigning reasonable values to the various *k*'s (omitting steps 4, 5, 6, 8*b*–10*b*, 14, and 15), to simulate the shape of Fig. 4*B* by computer calculation.[5] Also, the curvature was reduced for higher PMA concentrations. However, as a result, the concentrations of intermediates **2** and **5** rose to levels approaching the initial PMA concentration and then remained constant, a situation which is unlikely in reality. Because of the number of variables involved, it was not feasible to examine all possible combinations of rate constants, but it is clear that a slow buildup of one or more intermediates could cause the behaviour seen in Figs. 4*B* and *C*.

If the last argument above is the correct one, then the problem of explaining the dashed curve in Fig. 6 returns. The phenomenon may arise from an increase in association of reactive ion pair monomers to form unreactive dimers and larger aggregates.

Thermal Stability of DMFA

During the most recent DMFA preparation, an efficient distillation from the *n*-dodecanol left negligible alcohol in the DMFA. However, after subsequent fractional vacuum distillation, a new impurity was discovered in the distillate by nmr; an additional distillation only raised the concentration of this impurity from about one to several percent. A sample of this DMFA, when heated in a sealed nmr tube for a period of 216 h at 143°C, slowly yielded about 15% conversion to the new compound.

The reaction sequence involved is postulated to have been the following (eq. [16]): autoprotolysis of one DMFA molecule by another via a dimeric structure,[6] transfer of the positive charge centre to carbon in the protonated molecule, attack by the anion on the cation of the pair, and finally elimination of methylamine from the unstable aminal **11** (3) to form bis-*N*-(*N'*-methylmethylenimine)methylamine (**12**). The ^{1}H nmr spectrum of **12** in DMFA, Fig. 2*A*, has peaks at 7.84, 3.13, and 3.06 ppm (external TMS) in the ratio 2:6:3.

This set of reactions was shown to be reversible. When a sample of DMFA containing a small percentage of **12** was treated with an excess of methylamine, relative to **12**, at ambient temperature for 18 h, the concentration of **12** was reduced to below 0.1%. The remaining methylamine was then quickly removed under vacuum below ambient temperature. It would appear that the forward reaction in [16] is inhibited by the presence of traces of protic species such as the alcohol, which would prevent the formation of DMFA anion initially.

Acknowledgements

The authors are grateful for discussions with Drs. J. H. Rolston and W. J. Holtslander at CRNL, and for the considerable assistance provided by Dr. Rolston in adapting the general computer simulation program[5] to the present problem. They also wish to thank Messrs. P. E. Bindner and J. P. Johnson for some assistance in the laboratory.

The chemistry of *N,N'*-dimethylformamidine. II. Hydrolysis. Kinetically controlled formation of *cis*-*N*-methylformamide[1]

JAMES D. HALLIDAY AND E. ALLAN SYMONS

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ont., Canada K0J 1J0

Received October 12, 1977

JAMES D. HALLIDAY and E. ALLAN SYMONS. Can. J. Chem. **56**, 1463 (1978).

The hydrolysis of *N,N'*-dimethylformamidine (DMFA) has been investigated in acid and alkaline aqueous media by ^{1}H nmr; only a narrow basic p*H* range could be extensively studied kinetically. The pseudo-first-order k_{obs} rose steadily from p*H* 11.5 to 13.0 (reaction approximately first order in OH^-), then became independent of p*H* above 13.5 (9.3×10^{-4} s^{-1} at 10°C). In contrast to many amidines, DMFA is quite stable in acid solution (estimated value of the pseudo-first-order hydrolysis rate constant is 1.4×10^{-11} s^{-1} at 10°C, p*H* 0.05, from measurements at 100 and 140°C). This stability is ascribed to the difficulty of eliminating the fairly strong base methylamine from the tetrahedral intermediate in acid solution.

N-Methylformamide (NMF), one of the products, is formed initially as the *cis* isomer. A somewhat slower conversion then occurs to the thermodynamically more stable *trans* isomer. This unusual result is explained in terms of Deslongchamps and co-workers' theory of stereoelectronic control for the orbital-assisted breakdown of tetrahedral intermediates.

JAMES D. HALLIDAY et E. ALLAN SYMONS. Can. J. Chem. **56**, 1463 (1978).

On a étudié l'hydrolyse de la *N,N'*-diméthylformamidine (DMFA) en milieu aqueux acide et alcalin en faisant appel à la rmn du ^{1}H; on n'a pu étudier d'une façon exhaustive la cinétique de cette réaction qu'à l'intérieur d'une région alcaline limitée de p*H*. La valeur k_{obs} pour une réaction du pseudo premier ordre augmente régulièrement lorsque le p*H* passe de 11.5 à 13.0 (la réaction est approximativement du premier ordre en OH^-) et elle devient alors indépendante du p*H* au dessus de 13.5 (9.3×10^{-4} s^{-1} à 10°C). Par opposition à plusieurs amidines, la DMFA est très stable en solution acide (on a évalué que la constante de vitesse hydrolyse du pseudo premier ordre est 1.4×10^{-11} s^{-1} à 10°C, pour un p*H* de 0.05; cette valeur a été évaluée à partir de mesures à 100 et 140°C). On attribue cette stabilité à la difficulté d'éliminer la méthylamine, qui est une base relativement forte, de l'intermédiaire tétraédrique en solution acide.

La *N*-méthylformamide (NMF), l'un des produits, se forme au départ sous la forme de l'isomère *cis*. Une conversion un peu plus lente se produit alors pour conduire à l'isomère *trans* qui est thermodynamiquement plus stable. On explique ce résultat inhabituel en terme de la théorie de Deslongchamps et de ses collaborateurs relative au contrôle stéréoélectronique de la décomposition assistée par les orbitales d'intermédiaires tétraédriques.

[Traduit par le journal]

When methylamine solutions of potassium methylamide are heated they decompose to form hydrogen, ammonia, and the potassium salt (PDMFA) of *N,N'*-dimethylformamidine (DMFA) (**1**) (1).[2] Al-

$$\underset{\mathbf{1}}{CH_3NKCH{=}NCH_3}$$

though a uv–visible spectrophotometric method was successfully applied to the measurement of the rate of this thermolysis reaction (1), an alternate confirmatory method was desirable which could also monitor the formation of products. Proton nmr was used but direct solution analysis was not practical; the technique is unable to distinguish the PMA methyl resonance in the presence of methylamine, because of rapid amino proton exchange. When the salts were isolated from reaction solution samples and dissolved in water to facilitate analysis, the DMFA, under these alkaline conditions, was fairly rapidly hydrolyzed. However, in acid solution, hydrolysis occurred very slowly and for analytical purposes at ambient temperature the rate was negligible. The p*H* dependence of the hydrolysis rate was examined in more detail and the results of this study are reported here.

The temperature dependence of tautomeric exchange in the neat liquid and in several solvents is discussed separately (2).

Experimental

The synthesis, identification, and purification of DMFA have been reported elsewhere in this series (1).

Most hydrolysis kinetic runs (0.21 mol L^{-1} DMFA) were carried out at constant ionic strength (0.50 mol L^{-1}), with HCl, KOH, and KCl being employed. The H_2O was triple distilled and the D_2O (99.7 at.% D, AECL) was used as received. Reaction solutions were prepared cold in 2 mL Pyrex tubes; samples were transferred immediately to nmr tubes.

Proton nmr spectra were recorded on a Bruker HX90 spectrometer equipped with a B-ST 100/700 variable temperature controlled probe (±0.5°C). The methyl region was scanned repeatedly as a function of time, using the H_2O signal as internal lock. For the runs with D_2O as solvent, a capillary of TMS was added as an external lock. Depending on the rate of reaction, from 20 to 50 kinetic points could be obtained per run over a period of 1 to 3 half-lives.

The chemical shifts of the species involved in the hydrolysis reaction are shown with the representative spectra in Fig. 1. In general, the DMFA methyl peak fell between the *cis*- and *trans*-*N*-methylformamide (NMF) peaks but their relative positions were dependent on p*H*. The methyl group of the second product of hydrolysis, methylamine (MA), was always to high field of the NMF and DMFA. When overlap of the DMFA and NMF peaks was too great to allow direct measurement of the DMFA integral, it was obtained by subtraction of the MA integral from the combined DMFA and NMF integrals.

Ultraviolet spectra were run on a Cary 17 spectrophotometer, and infrared spectra on a Perkin Elmer model 467 instrument.

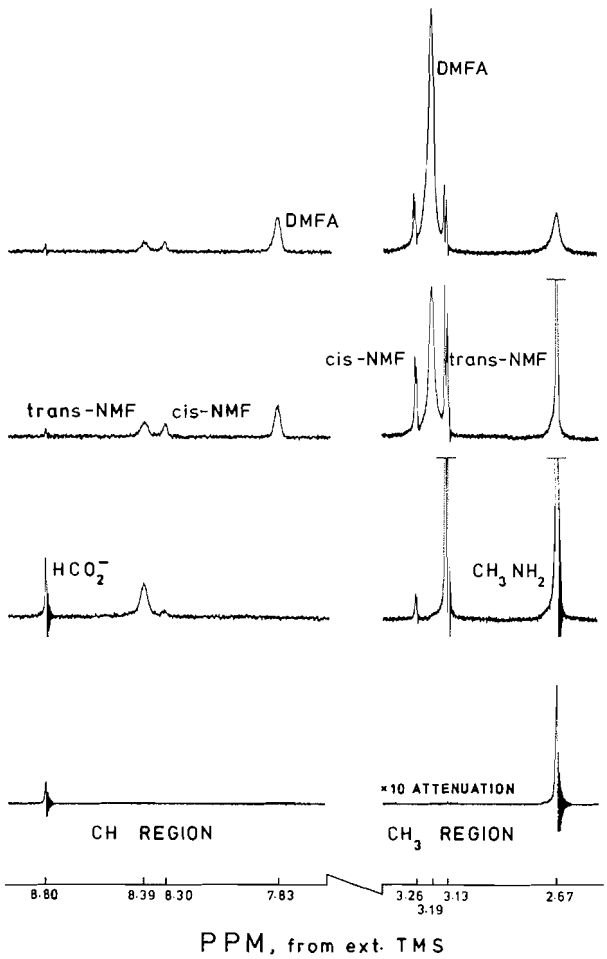

FIG. 1. Changes in the nmr spectrum during 0.21 mol L^{-1} DMFA hydrolysis. Top to bottom: 5 min at 0°C, 15 min at 0°C, 1 h at 23°C, 64 h at 23°C, p*H* 13.0.

Results

Hydrolysis Products

The general hydrolysis sequence, eqs. [1] and [2],

[1] $CH_3N{=}CHNHCH_3 + H_2O \xrightarrow{^-OH} CH_3NHCHO + CH_3NH_2$

[2] $CH_3NHCHO + H_2O \xrightarrow{^-OH} CH_3NH_2 + HCO_2H$

was confirmed by comparing the nmr and infrared spectra of reaction samples with those of aqueous solutions of authentic samples of *N*-methylformamide, methylamine, formic acid, and sodium formate.

Hydrolysis of the NMF, eq. [2], was found to occur at a rate at least a factor of 10 slower than for the DMFA over the p*H* range 11.5–14; however, at p*H* 1 the NMF reacted many orders of magnitude faster than the DMFA.

DMFA pK_a

For one hydrolysis run at 25°C with 0.21 mol L^{-1} DMFA and 0.50 mol L^{-1} KCl, a portion of the reaction sample was monitored with a p*H* meter to determine the extent of p*H* change during a run in the unbuffered system. It was found that the p*H* (glass and solid state electrodes) decreased slowly from 12.9 (extrapolated zero time value), levelling off at 12.2 over a period of 5 DMFA hydrolysis half-lives (as measured by nmr). From the zero time value, the pK_a of the DMFA conjugate acid was estimated to be 12.40 ± 0.10; this compares with the value of 12.40 for acetamidine at 25°C (3). *N,N'*-Diphenylformamidine is a much weaker base, with pK_a 6.15 (4). The p*H* of the various reaction solutions was then calculated via the equations provided by Kolthoff *et al.* (5), using the 12.40 estimate for the DMFA pK_a.

p*H Dependence of* k_{obs}

Least-squares treatment of linear plots of log DMFA integral vs. time yielded the pseudo-first-order rate constants for DMFA hydrolysis. One such plot is shown in Fig. 2. Above p*H* 13 such plots were linear for at least 2 half-lives ($R > 0.995$). Runs were reproducible to better than 10%. Below p*H* 13, the region of linearity for the plots decreased: 1 half-life at 12.5, less than 0.5 half-life at 12.0.

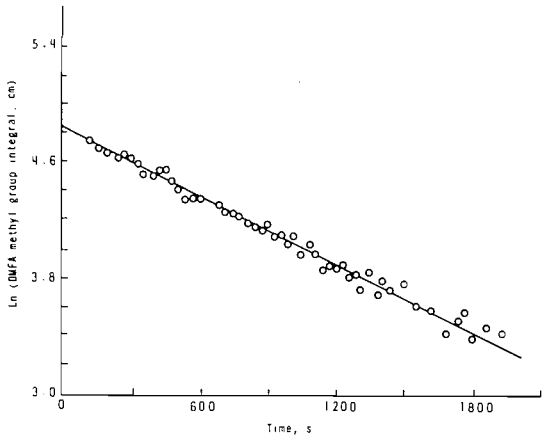

FIG. 2 Pseudo-first-order plot of nmr data for 0.21 mol L^{-1} DMFA hydrolysis at 10.8°C, p*H* 12.97.

The hydrolysis rate at 10.0°C was found to be practically independent of p*H* above 13.5 but it dropped rapidly as the starting p*H* was decreased below this value (Fig. 3). Because buffer solutions could not be used (see below), for the run at starting p*H* 11.5 the initial broad DMFA methyl group singlet changed slowly to a square-topped peak during the first 5% of reaction and then to a resolved doublet by 15% reaction, as the solution p*H* dropped and more extensive protonation of the remaining DMFA occurred. For this run, only the nmr data for the first 5% of reaction were used to calculate k_{obs}.

Accurate k_{obs} measurements could not be made in the p*H* range 2–11; because of sensitivity limitations, the DMFA concentration could not be lowered enough to permit proper buffering action by normal buffer solutions. As an alternate analytical technique the possibility of using uv–visible spectrophotometry was examined, since substrate concentrations in the range 10^{-2}–10^{-4} mol L^{-1} are ideal. Unfortunately, there is no strong chromophoric group in the DMFA molecule and tests showed that no suitable absorption peak was present in the aqueous solution spectrum. There was strong interference from the hydroxide and chloride ion absorption bands below about 240 nm, the region where DMFA begins to absorb.

At very low p*H* the acid hydrolysis of DMFA could be measured without buffers, although elevated temperatures (sealed nmr tubes) were required because of the much slower rates. For a solution at p*H* 0.05, the k_{obs} values at 100 and 140°C were 5.5×10^{-7} and 1.4×10^{-5} s^{-1}, respectively. Extrapolation via the Arrhenius activation energy, E_a, at this p*H* (Table 1) yields an approximate rate constant at 10°C of 1.4×10^{-11} s^{-1}, a value which is nearly 8 orders of magnitude slower than for the base-catalyzed reaction at p*H* 13. A direct extrapolation of the linear portion in Fig. 3 to p*H* 0 gives a value for k_{obs} of 2.4×10^{-17} s^{-1}, which suggests some catalytic effect in the strong acid.

Activation Parameters

Activation parameters were determined from rate constant data at several temperatures in the range −1 to 33°C for the high p*H* region and at 100 and 140°C for p*H* 0.05. The results for H_2O and D_2O are given in Table 1, together with the kinetic solvent isotope effect (KSIE) measured at p*H* 12.9. Figure 4

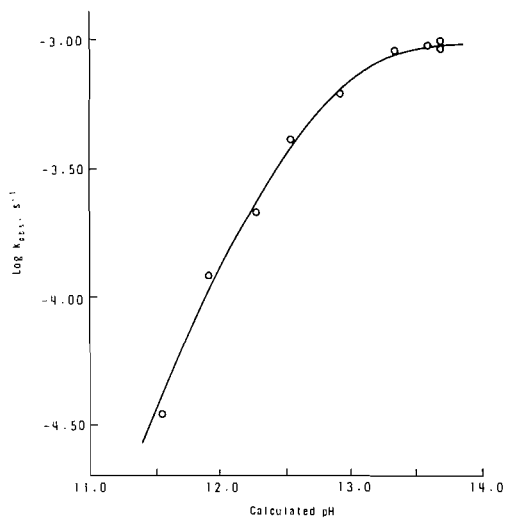

FIG. 3. Dependence of DMFA hydrolysis k_{obs} (0.21 mol L^{-1}) at 10.0°C on initial solution p*H*.

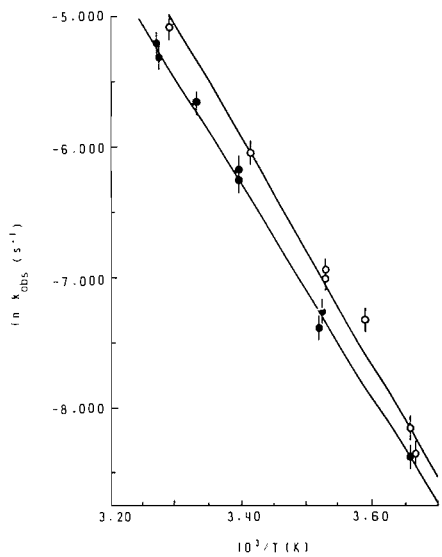

FIG. 4. Arrhenius activation energy plots for DMFA hydrolysis at p*H* 12.9 (●) and 13.7 (○). Bars indicate ±10%.

TABLE 1. Activation parameters and KSIE data for DMFA hydrolysis

Solvent	p*H*	Temperature (°C)	E_a (kJ mol^{-1})	$\Delta S^{\ddagger}$ (J deg^{-1} mol^{-1})	k_{D_2O}/k_{H_2O}
H_2O	12.9	0–33	68.1±1.6		
H_2O	13.7	0–33	70.0±2.9		
D_2O	12.9	0–33	70.2±1.7		
H_2O	0.05	100, 140	103		
H_2O	13.7	20		−65±10 (−15±3 eu)	
	12.9	0			0.85
	12.9	33			0.90

shows the good linearity of the Arrhenius plots over the range studied.

Discussion

DMFA Hydrolysis Mechanism

The following set of equations ([3] to [7]) should represent the overall reaction scheme for DMFA hydrolysis (6). Protonation occurs on the imino nitrogen (7). Jencks (6) states that the cationic imine **2** is likely to be the reactive form of DMFA, with the role of the free imine being insignificant. Nuclear magnetic resonance evidence points to the structure of **2** as more like $[N{=}{=}{=}C{=}{=}{=}N]^+$ than $N{-}{-}C{=}N^+$ (2, 8).

[3] $CH_3NHCH{=}NCH_3 + H_2O$ (DMFA) $\rightleftharpoons$ (K_b) $CH_3\underset{}{N}H\overset{+}{C}H\underset{}{N}HCH_3 + {}^-OH$ **2**

[4] **2** + $^-OH \rightleftharpoons CH_3NHCH(OH)NHCH_3$ **3**

[5] **3** + ^-OH (general base) $\rightleftharpoons CH_3NHCH(O^-)NHCH_3 + H_2O$ **4**

[6] **4** + H_2O (general acid) $\rightleftharpoons CH_3NHCH(O^-)\overset{+}{N}H_2CH_3 + {}^-OH$ **5**

[7] **5** $\longrightarrow CH_3NHCHO + NH_2CH_3$

Direct nucleophilic attack by the hydroxide ion on carbon in **2** is favoured over hyroxide-catalyzed attack of a water molecule (6), to give the tetrahedral intermediate **3**. Breakdown of the intermediate is assisted first by hydroxyl proton removal from **3** and then protonation of one nitrogen in **4** before or during formation of the observed products from **5**, a zwitterionic isomer of **3**.

The DMFA hydrolysis is approximately first order in hydroxide ion from p*H* 11.5 to 13.0 but the rate becomes independent of p*H* above 13.5 (Fig. 3). The same type of limiting behaviour was observed by Robinson (9) for hydrolysis of a cyclic formamidinium compound, 1,3-diphenyl-2-imidazolium chloride; at lower p*H* the hydroxide ion dependence approached second order. The levelling off of k_{obs} at high p*H* was attributed to complete conversion of the tetrahedral intermediate (e.g. **3**) to its conjugate base (e.g. **4**), with an estimated pK_a of 12.75 (9). In his system, Robinson (9) was able to detect the intermediate by ultraviolet spectrophotometry.

The rapid drop in hydrolysis rate with decreasing p*H* into the acid region is assigned to the difficulty of eliminating the relatively strong base, methylamine, from intermediate **3**. It is felt (6) that methylamine expulsion must occur from the conjugate base **4**, with the assistance of general acids, and the concentration of **4** is effectively suppressed at lower p*H*. This is not as severe a requirement for hydrolysis of substituted *N,N'*-diphenylformamidines (DPFA), where weaker amine bases, substituted anilines, are involved (6). DeWolfe found that these formamidines do undergo acid-catalyzed hydrolysis, at a rate only an order of magnitude slower than the base-catalyzed reaction (e.g. for DPFA itself, at 25°C and 1.0 mol L^{-1} HCl, k_{obs} is ca. 1.6×10^{-5} s^{-1} (4) and in 0.64 mol L^{-1} NaOH – 20% dioxane k_{obs} is 6.5×10^{-5} s^{-1} (10)). In contrast, the rate is faster in base but much slower in acid for DMFA relative to DPFA (in 0.50 mol L^{-1} KOH at 25°C k_{obs} is 3.8×10^{-3} s^{-1} but in 1.0 mol L^{-1} acid is calculated via E_a to be only ca. 1.3×10^{-10} s^{-1} at 25°C). For DPFA com-

For personal use only.

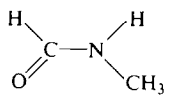
pounds with electron-withdrawing substituents, DeWolfe (10) observed a levelling off of the hydrolysis rate constant at high base concentration, over the range 0.2–0.6 mol L^{-1}. In this range for the other DPFA compounds, the rate constant was already independent of hydroxide concentration.

The results of Cegan *et al.* (11) for hydrolysis of *N'*-aryl-*N*,*N*-dimethylformamidines (ADMFA) are similar to those for the DMFA and substituted DPFA systems. The k_{obs} values for the ADMFA compounds increased with p*H* over the range 4 to 8–10 but were independent of p*H* above this point (buffered solutions); the individual limiting values of k_{obs} were dependent on the phenyl substituents. For the unsubstituted phenyl compound, k_{obs} at 60°C and p*H* 14 was 2.6×10^{-3} s^{-1}, which is about a factor of 10 slower than for DMFA. At p*H* 5 the value was 1.7×10^{-6} s^{-1}. The activation parameters measured at p*H* 13 and 60°C were $E_a = 67.8$ kJ mol^{-1} and $\Delta S^{\ddagger} = -100$ J deg^{-1} mol^{-1}. The corresponding data for DMFA at 20°C (Table 1) are comparable.

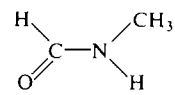
The KSIE data obtained in the present study (Table 1) are consistent with the small or inverse effects found for other general acid–base catalyzed reactions, including hydrolysis of formamidinium compounds (12).

cis-N-*Methylformamide Formation via Stereoelectronic Control*

There is an interesting aspect to the NMF formation at breakdown of the tetrahedral intermediate during DMFA hydrolysis. The *trans* isomer of NMF is known to be thermodynamically more stable than



trans-NMF



cis-NMF

the *cis* isomer, both neat and in aqueous solution (approximately 90% *trans* at equilibrium) (13). However, during the initial phase of the DMFA hydrolysis runs the *cis*-NMF peak was larger than the *trans* isomer, often by a factor of two or more depending on how soon the first spectral scans were taken. The *cis* peak soon reached a maximum value, then decreased to a fairly low steady state level, while the *trans* peak grew to its final intensity ratio of about 9:1 over the *cis*. The first spectrum in Fig. 1 shows the *cis* and *trans* peaks about equal in size. The NMF was itself hydrolyzed under these reaction conditions but at a considerably slower rate; data are available in the literature (14), so this stage was not studied in detail.

There was a remote possibility that the '*cis*' peak was in fact the tetrahedral intermediate (very few have ever been seen (9)) but the evidence presented below confirms that *cis*-NMF is the correct assignment. The nmr spectral peaks for reaction solutions were compared with those for a standard alkaline aqueous NMF solution. The CH_3 and CH peaks assigned in the reaction solutions to *cis*- and *trans*-NMF corresponded exactly with those in the standard solution, with final *cis*:*trans* peaks ratio of 1:9 as expected at equilibrium. The separation between the *cis*- and *trans*-methyl groups was 12 Hz, with the latter to higher field. The coupling constants, J_{H_3CNH}, were *cis*, 0.5_6 Hz and *trans*, 0.9_7 Hz for the standard solution, and *cis*, 0.5_5 Hz and *trans*, 0.9_5 Hz for one of the kinetic samples where the scans were made slowly enough to permit accurate measurement of the *J* values. Literature values reported for the coupling constants are (13): *trans*, 0.8 Hz (33% in water), 0.9 Hz (neat); *cis*, not measured; chemical shift difference, *cis*- and *trans*-methyl groups, 12 Hz.

The *cis–trans* conversion rate, which appeared to be only slightly slower than the rate of DMFA hydrolysis, could not be reliably obtained in the present study because of overlap of the NMF and DMFA nmr peaks in the methyl region and low sensitivity in the C—H region. However, a computer simulation of the system DMFA → *cis*-NMF ⇌ *trans*-NMF indicated that a *cis–trans* conversion rate constant in the range $5–10 \times 10^{-4}$ s^{-1} at 10°C gives the best fit to our data. This is reasonable, considering that a value of 6×10^{-5} s^{-1} at 10°C can be derived from the data of Neuman *et al.* (15) for C—N rotation in *neat* NMF. The corresponding k_{obs} values for DMFA hydrolysis at 10°C in the present study were in the range 3×10^{-5} to 1×10^{-3} s^{-1}.

It is clear from the experimental evidence that formation of the *cis* isomer of NMF is kinetically favoured during breakdown of the tetrahedral intermediate. Although a small amount of *trans*-NMF may be formed directly, most is produced through *cis*-NMF. The reason for this preferred reaction was not obvious from a preliminary examination of molecular models (Fisher–Hirschfelder–Taylor). However, the orientation of electron lone pairs on the hetero atoms (N and/or O) in hemiorthoesters and hemiorthoamides was considered by Deslongchamps *et al.* (16, 17) to be the governing factor in the base-catalyzed cleavage of these compounds to give the observed thermodynamically unfavoured products. It was required that *both* hetero atoms not involved in the leaving group must have an electron lone pair orbital oriented antiperiplanar to the leaving group for cleavage to occur. This proper orientation was believed to be a key factor in lowering the energy barrier.

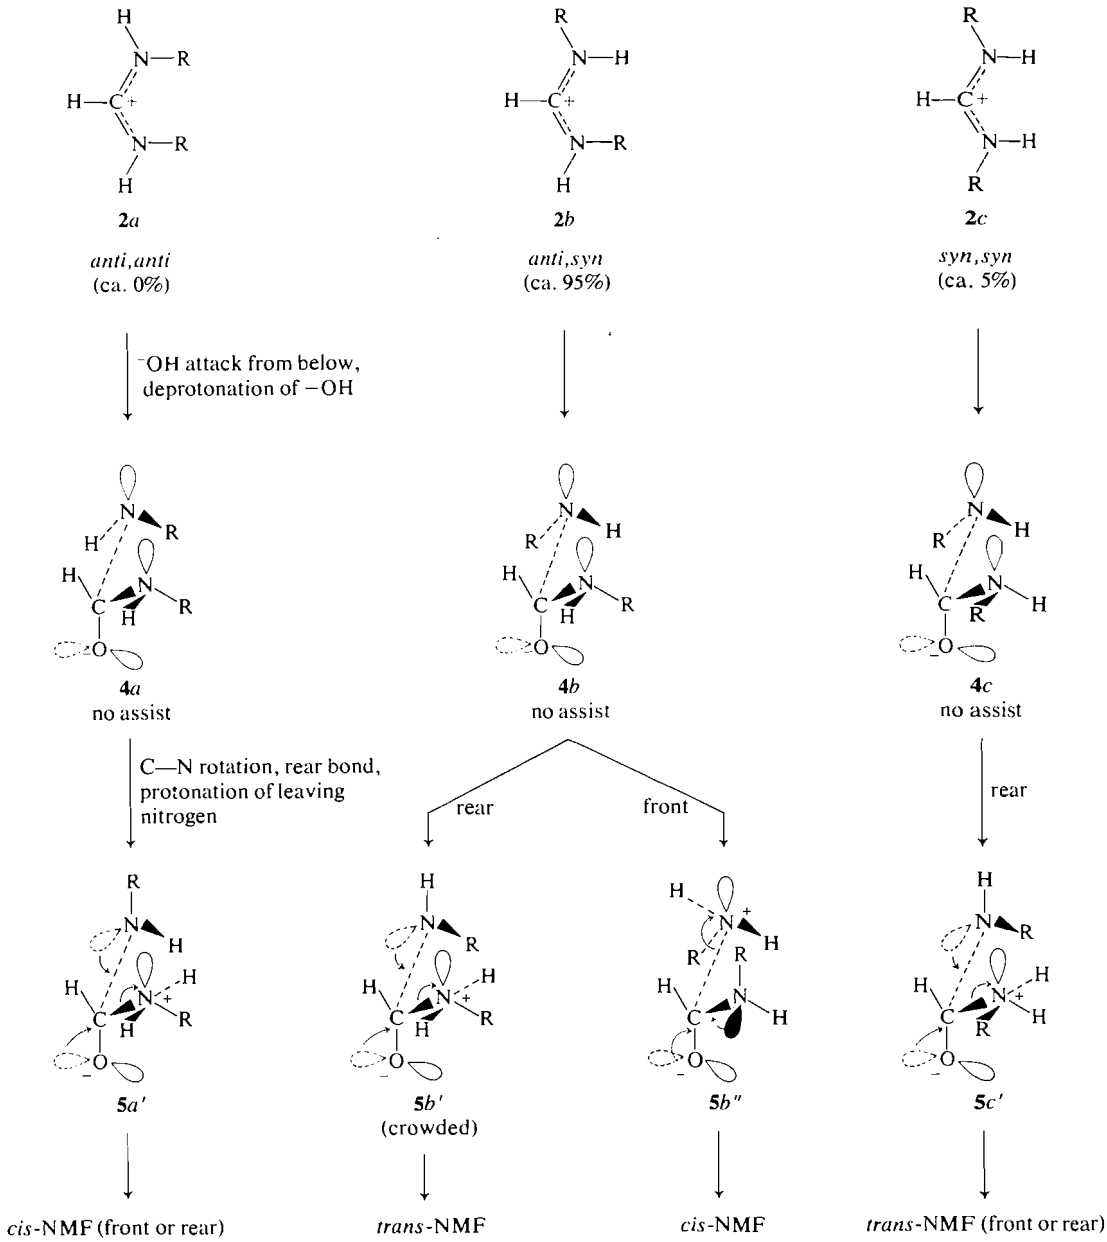
Their stereoelectronic control theory of orbital-assisted cleavage, which is supported by theoretical calculations (18), was applied to the breakdown of the DMFA hydrolysis intermediate, a hemiorthoformamidine. Benkovic and co-workers (19, 20) also had observed in some cases the formation of thermodynamically unfavoured products during hydrolysis or aminolysis of a series of acyclic and cyclic formamidinium compounds, and recently explained the hydrolysis results in terms of stereoelectronic control of the breakdown of the tetrahedral intermediates (20). For DMFA the two potential leaving groups are identical. The appropriate scheme (Scheme 1) is shown below, for attack by hydroxide ion perpendicular to the plane of each of the three possible conformers, **2***a*, **2***b*, and **2***c*, of the protonated DMFA. For this discussion R is substituted for the methyl groups.



SCHEME 1

When molecular models are examined for each step in this scheme, it becomes clear that steric crowding is a dominant factor in forcing formation of *cis*-NMF.

^{1}H nuclear magnetic resonance spectra of DMFA in dilute acid solution indicate that monoprotonated DMFA is present mostly as conformer **2***b*, with about 5% **2***c* and no detectable **2***a* (2). The last is quite sterically crowded because of the adjacent methyl groups. *cis*-NMF is formed via route *b* and intermediate **5***b*''; the structure required for *trans* formation (**5***b*') is so crowded that **5***b* should proceed predominantly to **5***b*''. Deslongchamps *et al.* (16) argue that *under conditions of proper orbital orientation* the energy barrier for elimination from the tetrahedral intermediate becomes lower than for conformational change. Thus **5***b*' does not occur in significant concentration, since it would immediately lead to *trans*-NMF, and the observed *initial* low concentration of *trans*-NMF must be formed via route *c* (which yields *only* the *trans* isomer, regardless of front or rear C—N bond rotation). It is concluded from the above discussion that the easiest route to *orbital-assisted* breakdown of the hydrolysis intermediate leads preferentially to the *cis* isomer of NMF, which then changes to the more stable *trans* isomer.

The chemistry of *N,N'*-dimethylformamidine. III. Tautomerism and hindered rotation[1]

JAMES D. HALLIDAY, E. ALLAN SYMONS, AND PATRICK E. BINDNER

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ont., Canada K0J 1J0

Received October 12, 1977

JAMES D. HALLIDAY, E. ALLAN SYMONS, and PATRICK E. BINDNER. Can. J. Chem. **56**, 1470 (1978).

Proton nmr and infrared studies of neat *N,N'*-dimethylformamidine (DMFA) have shown that the *cis* isomer **1** is present exclusively and that it undergoes tautomerism. At 25°C, $k_{taut} = 8.2 \times 10^2\ s^{-1}$, $E_a = 41.5 \pm 1.5\ kJ\ mol^{-1}$, $\Delta H^* = 39.1 \pm 1.5\ kJ\ mol^{-1}$, and $\Delta S^* = -57.5 \pm 5.0\ J\ mol^{-1}\ K^{-1}$. The tautomerism is proposed to occur through a hydrogen-bonded cyclic dimer. The effects of solvent on the tautomeric rate in DMFA have also been investigated for CD_3NH_2 and $CDCl_3$ solutions.

Potassium *N,N'*-dimethylformamidide (PDMFA) in CD_3NH_2 does not exhibit hindered rotation about the single C—N bond on the nmr time scale over the temperature range −56 to 25°C. However, protonated DMFA undergoes hindered rotation about this bond in highly acidic media (97 wt.% H_2SO_4 at 25°C, $k_{rot} = 0.16 \times 10^2\ s^{-1}$, $E_a = 35.4 \pm 0.8\ kJ\ mol^{-1}$). The acid catalysis is interpreted as occurring through formation of the diprotonated species. The two nitrogens in protonated DMFA have different base strengths.

JAMES D. HALLIDAY, E. ALLAN SYMONS et PATRICK E. BINDNER. Can. J. Chem. **56**, 1470 (1978).

Des études par rmn du proton et par infrarouge de la *N,N'*-diméthylformamidine (DMFA) à l'état pur ont montré que l'isomère *cis* **1** est le seul isomère présent et qu'il subit une réaction de tautomérie. A 25°C, $k_{taut} = 8.2 \times 10^2\ s^{-1}$, $E_a = 41.5 \pm 1.5\ kJ\ mol^{-1}$, $\Delta H^* = 39.1 \pm 1.5\ kJ\ mol^{-1}$ et $\Delta S^* = -57.5 \pm 5.0\ J\ mol^{-1}\ K^{-1}$. On suggère que la réaction de tautomérie se produit par l'intermédiaire d'un dimère cyclique comportant un pont hydrogène. On a aussi étudié les effets de solvant sur les vitesses de tautomérisation de la DMFA en solution dans CD_3NH_2 et $CDCl_3$.

La *N,N'*-diméthylformamididure de potassium (DMFAP) dans le CD_3NH_2 ne présente pas de rotation empêchée autour du lien simple C—N à l'échelle de temps de la rmn, à des températures allant de −56 à 25°C. Toutefois dans le cas de la DMFA protonée il existe une rotation empêchée autour de ce lien en milieu fortement acide (H_2SO_4 à 97% en poids à 25°C $k_{rot} = 0.16 \times 10^2\ s^{-1}$, $E_a = 35.4 \pm 0.8\ kJ\ mol^{-1}$). La catalyse acide suggèrerait la formation d'espèces diprotonées. Les deux azotes de la TMFA protonée ont des basicités différentes.

[Traduit par le journal]

In this series Part I (1) dealt with the thermal decomposition of both potassium methylamide in methylamine solutions (which yielded potassium *N,N'*-dimethylformamidide (PDMFA)) and the neat free base, *N,N'*-dimethylformamidine (DMFA). Part II (2) discussed the hydrolysis of the DMFA as a function of p*H*. In the course of these studies several unusual features associated with isomerism (geometrical, rotational) and tautomerism (3) in the structure of DMFA have been elucidated.

This paper describes an nmr study of tautomerism and hindered rotation in the title compound and its cationic and anionic forms as functions of solvent and temperature.

Experimental

All nmr samples were handled using dry box (He atmosphere) and vacuum line techniques to minimize moisture contamination. All nmr tubes were flame sealed.

PDMFA and DMFA were synthesized as described previously (1). DMFA·HCl was prepared by reacting DMFA with gaseous HCl at reduced temperature in the nmr tube. DMFA·H_2SO_4 was prepared by addition of DMFA directly to the precooled H_2SO_4 solution in the nmr tube. The acids used were (*a*) anhydrous HCl (Matheson), (*b*) aqueous HCl (Anachemia), and (*c*) H_2SO_4 (Baker). DCl (>99 at.% D) (Merck, Sharp, and Dohme), 38 wt.% in D_2O, was used to remove NH proton coupling in one sample of DMFA·H^+.

The solvents CD_3NH_2 (>98 at.% D) and $CDCl_3$ (>99.8 at.% D) (Merck, Sharp, and Dohme), the former dried over lithium metal, were distilled under vacuum before use. $CHCl_3$ (Fisher Spectranalyzed) was used for the infrared measurements.

Although there is a reaction between DMFA and CD_3NH_2, eq. [1] (4*a*), that produces the isotopically labeled mono- and di-CD_3 DMFA species, it is sufficiently slow that measurements of the tautomerism in DMFA can be made without appreciable deuterium isotope effects interfering.

Proton nmr spectra were recorded on a Bruker HX90 nmr spectrometer operating at 90 MHz in a field of 2.114 T. Variable temperature studies were performed using a Bruker variable temperature controller, B-ST 100/700 (±0.5°C). Probe temperatures were checked with a small calibrated Pt

resistance thermometer (Rosemount, model #146MA100F element, 1.5 mm diameter × 15 mm long). Infrared spectra of DMFA were run on a Perkin Elmer 467 spectrophotometer.

Results

DMFA

Temperature effects on the nmr spectra were studied for the neat material (ca. 14 *m*) and for solutions in CD_3NH_2 (1.4 *m*) and $CDCl_3$ (0.5–2.9 *m*). Rates for tautomeric exchange were obtained by complete lineshape analysis using the computer program DNMR3 (5). Coupling constants were corrected for peak overlap effects where necessary. Figure 1 shows the effect of solvent and Fig. 2 the variation with temperature of the measured exchange rate for tautomerism, τ^{-1} (s^{-1}), for DMFA. Representative nmr spectra for the system are illustrated in Fig. 3. No coupling owing to the NH protons could be observed in these solutions.

The infrared spectrum of DMFA as a function of concentration in $CHCl_3$ is shown in Fig. 4.

PDMFA

The salt PDMFA, a very strong base, has been studied in liquid CD_3NH_2 in which it is both soluble and stable. No significant change was observed in the methyl group nmr spectra for a 0.45 *m* sample over the temperature range −56 to 25°C. The spectra resembled those of DMFA in its high temperature limit, where the two methyl groups are equivalent. However J_{HCNCH} is smaller than in DMFA, 0.5_0 Hz instead of 0.7_8 Hz.

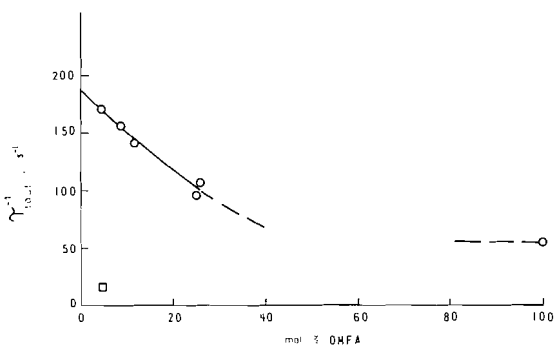

FIG. 1. Concentration effect on the rate (τ^{-1}) for DMFA tautomerism in $CDCl_3$ and CH_3ND_2 solutions at −16.2°C: ○, $CDCl_3$ solution; □, CD_3NH_2 solution.

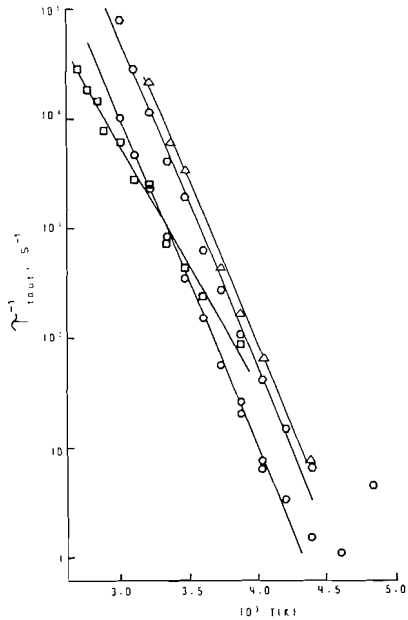

FIG. 2. Temperature dependence of the DMFA tautomerism rate (τ^{-1}): □, neat; ○, 1.4 *m* in CD_3NH_2; ⬡, 2.9 *m* in $CDCl_3$; △, 0.5 *m* in $CDCl_3$.

DMFA·H$^+$

It has been shown that aqueous acid solutions of DMFA·H^+ are very stable to hydrolysis (2).

DMFA·H^+ nmr spectra were run for a number of aqueous solutions with varying acid concentrations (0–97 wt.% H_2SO_4). Representative spectra are shown in Fig. 5.

Temperature dependence studies were done on the 6 mol L^{-1} HCl and 97 wt.% H_2SO_4 (0.2–1.0 *m* DMFA) solutions. In the former, except for effects associated with the change with temperature (−15 to 110°C) in quadrupolar relaxation owing to the ^{14}N, no exchange effects were observable. However, in the latter, two time-dependent processes could be seen occurring over this temperature range: first, increasing rates of exchange of NH protons, leading to collapse of the methyl doublets, and second, increasing rates of hindered rotation about the C—N bonds, leading to equivalent methyl groups. The rate constant and the Arrhenius activation energy measured for the latter process for both 0.2 and 1.0 *m* solutions at 40°C are 0.31×10^2 s^{-1} (0.16×10^2 s^{-1}, extrapolated to 25°C) and 35.4 ± 0.8 kJ mol^{-1}, respectively. Calculation of accurate exchange rates for the coalescence of the methyl groups is complicated by the NH proton – solvent exchange since it broadens the methyl lines during coalescence. The activation energy was taken from the higher temperature data where the effects of this latter exchange were minimal.

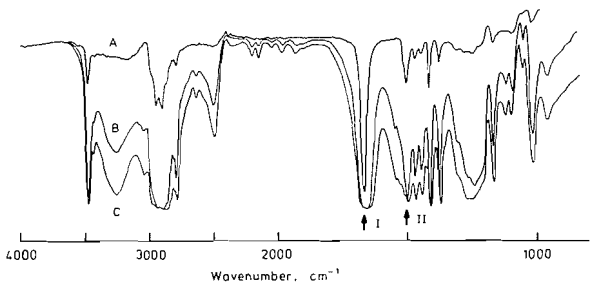

FIG. 4. Effect of concentration on the ir spectrum of DMFA in $CHCl_3$ at 25°C, 0.20 mm CaF_2 cells, $CHCl_3$ reference: (*A*) 0.04 *m*, (*B*) 0.4 *m*, (*C*) 0.8 *m*. The amidine I and II bands of DMFA are indicated.

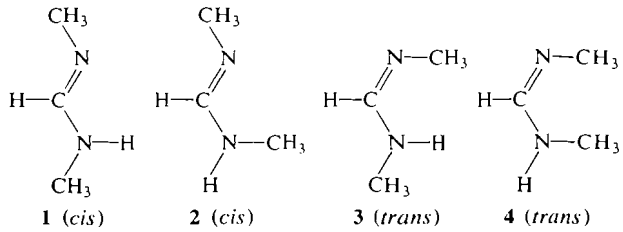
Discussion

DMFA

DMFA has four possible configurations, based on a planar N—C=N structure:



As with amides (6, 7), there is partial double bond character in the single C—N bond. The charge delocalization through the —N=C—N< structure will be indicated throughout this paper where it is appropriate to the discussion. The above isomers may interchange through (*i*) rotational isomerism (**1** and **2**, **3** and **4**), (*ii*) geometrical isomerism (**1** and **3**, **2** and **4**), and (*iii*) tautomerism. Tautomerism in **1** or **4** produces no effective change but in **2** yields **3** and vice versa. Owing to pronounced steric interactions (molecular models) the fraction of DMFA likely to be present as **4** is very small. To further complicate the analysis, a combination of geometric and rotational isomerism in **2** will also give **3**.

Based solely on the nmr spectral data, the

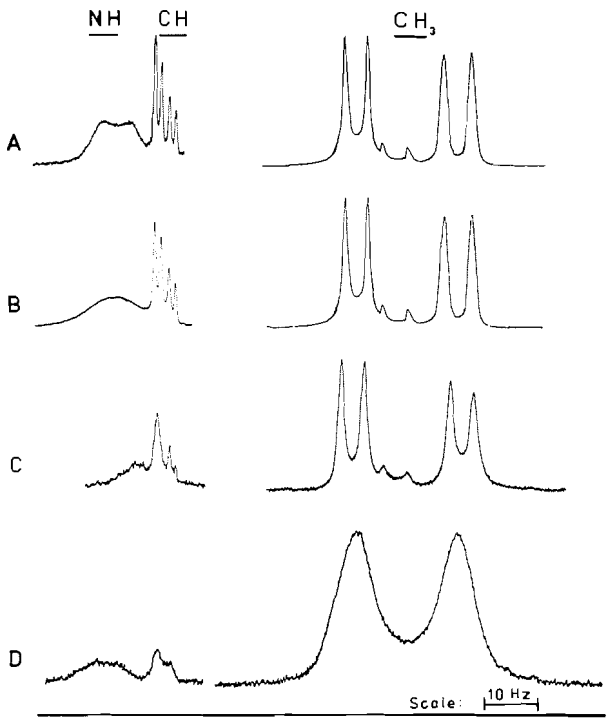


FIG. 5. Effect of acid concentration and temperature on the nmr spectrum of protonated DMFA: (*A*) −15°C, 6 mol L^{-1} HCl; (*B*) 25°C, 6 mol L^{-1} HCl; (*C*) 25°C, 66 wt.% H_2SO_4; (*D*) 25°C, 97 wt.% H_2SO_4.

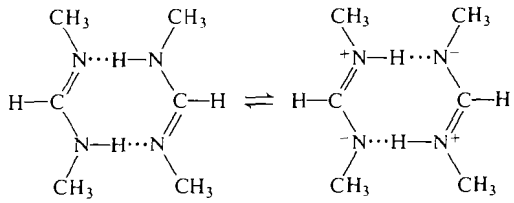
mechanism for the exchange occurring in this symmetrically *N,N'*-disubstituted amidine cannot be unambiguously assigned. However, with the addition of our infrared results and those of Prevorsek (3) we can show that the mechanism must be tautomerism in structure **1**.

Prevorsek (3) has studied a number of *N,N'*-ring substituted aryl amidines by infrared spectroscopy and concluded that they exhibit a tautomerism in solution, which leads at the same time to a geometrical isomerism with respect to both single and double CN bonds, i.e. corresponding to **2** ⇌ **3**. Evidence for his conclusion came from the observation of two ν(N—H) bands and two ν(C=N) bands for unsymmetrical *N,N'*-aryl-substituted acetamidines and even for the symmetrical *N,N'*-diphenylacetamidine. These duplicate bands indicated two isomers for each compound. In addition, the presence of a strong amidine II band at ca. 1500 cm^{-1} showed that there must be a *trans* isomer (3) in the acetamidines since this can only arise from that configuration (corresponding to **3** and/or **4**).

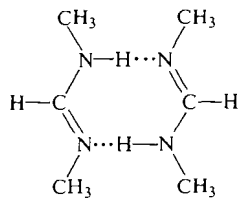
The ir spectra of DMFA in $CHCl_3$ solution (Fig. 4) show a major band (3480 cm^{-1}) and a very weak one (3435 cm^{-1}) in the ν(N—H) region and a single strong band (1670 cm^{-1}) in the ν(C=N) region. This suggests there is only one principal isomer in solution. Because the amidine II band (1505 cm^{-1}) is present at much reduced intensity, it appears there is very little *trans* configuration, i.e., **3** and/or **4** (3). Therefore DMFA in $CHCl_3$ solution must be present principally as **1** or **2**. Prevorsek (3) assigns the high frequency NH stretch to the *trans* configuration and the low frequency to the *cis* in the *N,N'*-diarylacetamidines. However, from our results for DMFA, it would appear that the high frequency band must be due to the *cis* configuration, since very little of the *trans*, **3** and/or **4**, is present.

From the nmr data obtained at reduced temperature for DMFA in CD_3NH_2, only one isomeric form predominates (Fig. 3*A*). At elevated temperature in this sample the methyl groups become equivalent. Rotational isomerism alone about the C—N bond, **1** to **2**, cannot produce equivalent methyl groups. Therefore the only mechanism that can be operative in the DMFA system is *tautomerism in 1*, since tautomerism in **2** would give **3**.

The ir data for DMFA in $CHCl_3$ (Fig. 4) and neat (1) illustrate the extent of molecular association via hydrogen bonding in these solutions. Dilution of DMFA from 0.8 to 0.04 *m* in $CHCl_3$ significantly reduces the broad band centred at 3260 cm^{-1} which arises from the hydrogen-bonded N—H stretch in the associated species in the neat and concentrated solutions. Effectively 100% association is shown for neat DMFA since the monomer band, which should be at 3480 cm^{-1}, is not present (1). The structure of these species can be determined from changes in the bands in the region 1900–2200 cm^{-1}, which are characteristic of imine salts (8). The most probable associated form is the cyclic dimer **5***a–c* (4). As White and Kilpatrick (4*b*) showed for *N,N'*-diphenylformamidine (K_{dimer} = 69), this should be a particularly stable dimer since it has an eight-membered ring structure, in which the two hydrogens (with presumably 180° valence bonds) reduce it in effect to a six-membered ring. The charge-separated structure (**5***b*) has been proposed as playing a role in



5*a* **5***b*



5*c*

the thermal breakdown of neat DMFA to produce bis-*N*-(*N'*-methylmethylenimine)methylamine (1). The dimer structures **5***a–c* are an example of Hunter's mesohydric tautomerism (9). The necessary transfer of a proton from one nitrogen to the other within the molecule to effect the tautomerism results directly from the H-bond association.

Activation Parameters for DMFA Tautomerism

The Arrhenius plot of the neat DMFA kinetic data is shown in Fig. 2 and the activation parameters calculated from it in Table 1. The error ranges

TABLE 1. Kinetic and thermodynamic parameters calculated from nmr data for DMFA tautomerism at 25°C

Solvent	k_{taut} (s^{-1})	$\Delta H^{\ddagger}$ (kJ mol^{-1})	$\Delta S^{\ddagger}$ (J mol^{-1} K^{-1})
Neat	8.2×10^{2}	39.1±1.5	−57.5±5.0
CD_3NH_2 (1.4 *m*)	7.4×10^{2}	55.7±0.4	1.2±2.7
$CDCl_3$ (0.5 *m*)	6.3×10^{3}	54.1±1.3	10.3±5.2
(2.9 *m*)	4.2×10^{3}	55.7±1.8	12.3±4.4

reported were determined by a least-squares analysis of the data.

The activation energies for hindered rotation about the C—N bond in amides and amidinium ions were studied by Neuman and Jonas (10*a*) and found to be in the range 84–100 kJ mol^{-1}, much higher than the 41 kJ mol^{-1} measured for tautomerism in DMFA. Since these amidinium compounds had no N—H protons and could not exhibit tautomerism, this is additional evidence that tautomerism, and not hindered rotation, is operating in DMFA.

Solvent Effects

Dilution of DMFA in $CDCl_3$ and CD_3NH_2 produces interesting changes in the observed rate of tautomerism (Fig. 1) and in the activation parameters calculated from the temperature dependence of τ^{-1} as a function of concentration (Table 1). The changes in τ^{-1} may be caused by changes in the monomer – hydrogen bonded dimer equilibrium with dilution (see ir spectra, Fig. 4) and/or solvent effects on the dimer structure itself. Changes in hydrogen-bond association between substrate and solvent can play an important role in determining the magnitude of the rate constant and activation energy in solution; e.g. for hindered rotation in neat *N,N*-dimethylformamide, $k_{rot} = 1.2 \times 10^{-2}$ s^{-1} with $E_a = 78$ kJ mol^{-1}, whereas for a 12 mol% solution in formamide $k_{rot} = 1.6 \times 10^{-4}$ s^{-1} with $E_a = 109$ kJ mol^{-1} (11).

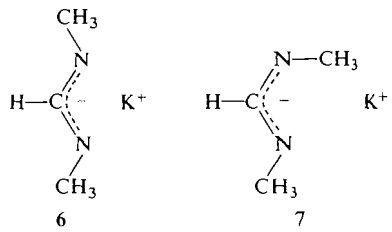
Our results for the hydrogen-bonding solvent CD_3NH_2 follow the same trend, a decrease in τ^{-1} with an increase in E_a relative to neat DMFA (Fig. 1). However, for the $CDCl_3$ solutions the τ^{-1} values show a marked increase. Defining the principal component responsible for these changes is difficult. If a constant for monomer–dimer equilibrium in the range 10–100 is used ($K = 69$ for *N,N'*-diphenylformamidine in benzene (4*b*)) then the percentage monomer can rise to ~10–15% (consistent with the ir spectra for DMFA–$CDCl_3$ solutions) for the most dilute solutions studied. This is probably not sufficient to have a pronounced effect on the results. We believe that it is small changes in the dimer structure with different solvents that produces the observed effects, since tautomerism in the dimer inherently should be easier than in the monomer. However, without further data on the extent of monomer and solvent participation in solutions of DMFA, our solution activation parameters must be considered qualitative, because the τ^{-1} cannot be related directly to a specific rate constant for tautomerism.

Nuclear Magnetic Resonance Spectral Assignments

Spectral assignments in the nmr results can be made on the basis of the chemical shifts and the coupling constants J_{HCNCH}. At 25°C the chemical shifts with respect to TMS for the CH_3, NH, and CH in neat DMFA are 2.85, 7.11, and 7.39 ppm, respectively. At low temperatures (Fig. 3*A*) the splitting of the high field methyl group ($J_{HCNCH} = 0.5_2$ Hz) originates from the amine nitrogen side and that for the low-field methyl group ($J_{HCNCH} = 0.9_8$ Hz) from the imino nitrogen side. The chemical shift difference between the methyl groups is 0.338 ppm. No coupling owing to the amino proton is observed. At elevated temperatures (Fig. 3*D*) magnetic equivalence of the methyl groups is shown by the doublet ($J_{HCNCH} = 0.7_8$ Hz) and septet ($J_{HCNCH} = 0.7_8$ Hz) in the CH_3 and CH positions, respectively. These lines exhibit some distortion due not to non-first-order effects but apparently to the presence of small quantities of isomers **2** and **3** which are formed at higher temperatures.

PDMFA

Removal of the DMFA amino proton forms the anion, PDMFA, whose structure can be **6** and/or **7**.



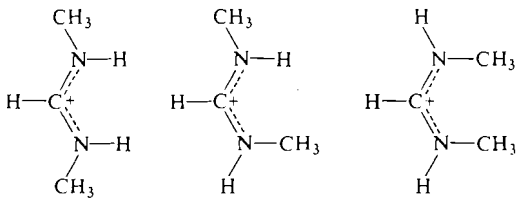
6 **7**

The third possible isomer, with both methyl groups *trans* to the CH, is ruled out on grounds of steric hindrance.

The nmr spectrum of PDMFA in CD_3NH_2 showed no significant change with temperature. Even at −56°C the methyl region resembled that of DMFA at high temperature with equivalent methyl groups. Although the only evidence for assigning a structure to PDMFA is the average coupling constant $J_{HCNCH} = 0.5_0$ Hz, which can be influenced by bond angles and charges in the molecule, it suggests that **6** is the only isomer in solution. The *trans* structure (**7**) would be expected to have a larger J value (see DMFA results) and hence an average J value greater than 0.5 Hz.

DMFA·H$^+$

In contrast, addition of a proton to the DMFA yields a much more interesting system. Structures **8**, **9**, and **10** are possible. Hammond and Neuman (12) studied *N,N'*-dimethylacetamidinium chloride (DMAA·HCl) in aqueous acid solutions and observed only one isomer, which was identified as that corresponding to **9**. Our spectrum of DMFA·HCl (Fig. 5) shows a predominance of **9** (methyl doublets at 3.70 and 3.49 ppm) and suggests a small quantity (ca. 5%) of the symmetrical isomer **8**



8 **9** **10**

(methyl doublet at 3.62 ppm). No evidence was seen for the third isomer (**10**). Since DMFA·HCl is less sterically hindered than DMAA·HCl the presence of a small amount of **8** is not surprising.

Spectral assignments can be made based on the lineshapes observed in protiated and deuterated solvents, and on a comparison with the assignments for DMAA·HCl (12). The high field methyl group doublet in Fig. 5 (3.49 ppm) is broadened by unresolved coupling to the CH proton and the lines deviate from Lorentzian shape accordingly. Since $J_{trans} > J_{cis}$ in amides (13) and other similar compounds (14), the high field broadened doublet can be attributed to the methyl group *trans* to the CH proton; the low field methyl doublet at 3.70 ppm then arises from the methyl group *cis* to the CH proton. These methyl doublets arise from coupling to the adjacent nitrogen protons, since they collapse to singlets in deuterated acid solution. The coupling constants observed for H—N—CH_3 in the different isomers are: **9**, high field 5.2 Hz, low field 4.4 Hz; **8**, 4.1 Hz.

The significantly distorted doublets at low field (Fig. 5, 8.50, 8.34 ppm) become one singlet in deuterated acid solution and belong to the CH proton coupled to the two nonequivalent nitrogen protons. The NH and CH protons comprise an ABC system, with the nitrogen proton portion of the spectrum (8.94 ppm) significantly broadened by quadrupolar relaxation. At lower temperatures (−15°C) the effect of this relaxation on the amino proton lines is reduced and they narrow sufficiently to show the broad outline of the BC component of the spectrum. Coupling constants extracted from simulation of this system using DNMR3 (5) gave J_{HNCH} of ca. 6 and 14 Hz.

This ABC subspectrum is further evidence for the nonequivalence of the two N—H protons and confirmation of structure **9** as the predominant species present.

Other than the above effects associated with the change in ^{14}N quadrupolar relaxation, no significant changes were observed in the spectrum of this sample over the temperature range −15 to 100°C. Partial coalescence of the methyl group signals through hindered rotation about the C—N bond had been expected, since this was observed for *N,N*-dimethylacetamidium chloride in DMSO-d_6 (10*a*).

The observed spectra are markedly affected by changes in the acid concentration. For an aqueous solution of DMFA·H^+ the spectrum is similar to that shown in Fig. 5*a*. However, as the acid concentration is raised (to achieve high acid concentrations, H_2SO_4 was used) the methyl doublets begin to collapse, as seen in the 66% H_2SO_4 spectrum, Fig. 5*c*. The high-field doublet shows the greater effect, indicating a difference in the basicity of the two nitrogens. At 97% H_2SO_4 the two methyl lines are beginning to coalesce. Thus two acid catalyzed exchange mechanisms would appear to be operating. First, there is exchange between the amino protons in the mono protonated cation and protons in the solvent, catalyzed through formation of the diprotonated species DMFA·H_2^{2+}. This exchange rate increases with added acid, and ultimately in media of high acidity becomes sufficiently fast to show loss of coupling to the N—CH_3 groups and collapse of the doublets. Second, the lifetimes of these diprotonated species become long enough to allow magnetic equivalence of the N—CH_3 groups by rotation about C—$\overset{+}{N}H_2CH_3$ bonds.

These results are in qualitative agreement with the more extensively studied DMAA·HCl system (12). However, there are differences in the relative rates of these reactions. In weakly acid solution DMAA·HCl shows only two singlets for the methyl groups when there is no added acid, and it is not until 14% H_2SO_4 is reached that the NH coupling is seen (12). For DMFA·HCl this inverse dependence of N—H proton exchange on acid concentration is not seen and the NH coupling is present even in very weakly acidic solutions, i.e., the residence time of the protons is long on the nmr time scale. At the other extreme, in strongly acid solution DMAA·HCl shows coalescence of the two methyl groups in 90.7% H_2SO_4 (12) but even at 97% H_2SO_4, the DMFA salt still has two broad but resolved singlets.

The pK_a of DMAA is estimated at ca. 13 (12) and that of DMFA was found to be 12.4 (2). DMAA, being slightly more basic, would be expected to diprotonate faster in acid and therefore show the effects of this second protonation sooner than DMFA·H^+, i.e., a lower acid concentration is required to coalesce the methyl group signals in DMAA·H^+. The behaviour at low acid concentrations, where the DMFA·H^+ does not show the inverse dependence of the NH proton exchange rate while DMAA·H^+ does, may result from dimer formation in the DMFA·H^+, forcing an initial longer residence time for the protons.

The mechanism for these exchange reactions with DMAA·HCl at higher acid concentrations, proposed by Neuman and Hammond (12), applies equally well to DMFA·H^+ (Scheme 1).

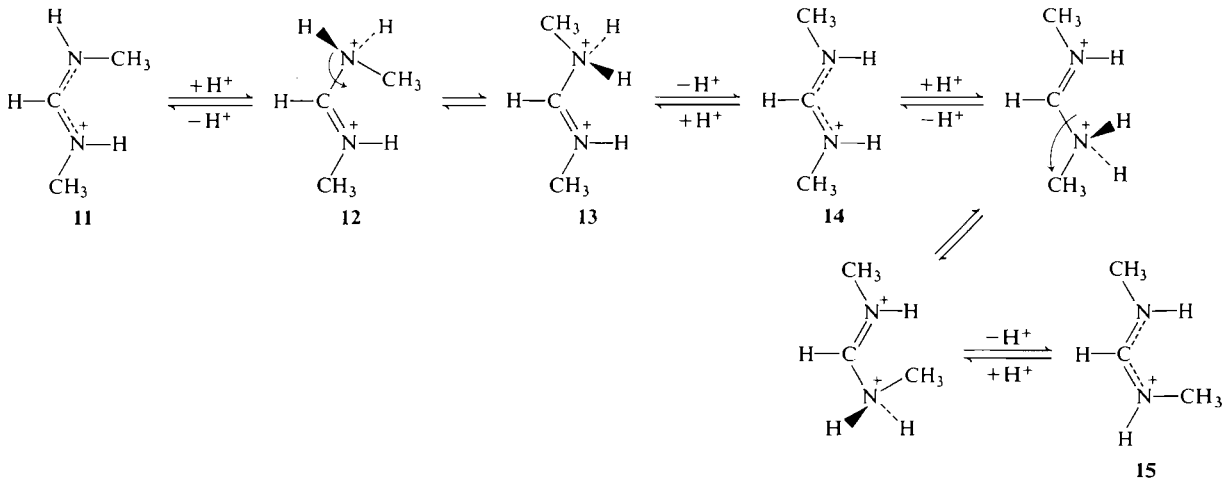

SCHEME 1

The exchange reactions with the solvent occur via protonation of **11** to form **12**. Equivalence of the two methyl groups of **11** requires that each CN bond must undergo hindered rotation, and that the higher energy symmetrical formamidinium ions **8** and **10** must be intermediates. This would be consistent with the observation that methyl equivalence is slower than NH exchange with the solvent.

The activation energy of 35 kJ mol^{-1} is very much less than that measured for hindered rotation about the C—N bond in *N*,*N*-dimethylacetamidinium cations in DMSO-d_6 (10*a*) or *N*,*N*,*N*′,*N*′-tetramethylformamidinium perchlorate in $CDCl_3$ (10*b*). This can be explained by assuming that the double bond character of the C—N single bond in the diprotonated species is significantly reduced from that in the monoprotonated amidinium ion, since the C=N double bond is more effectively frozen in these strongly acid solutions.

Arene–chromium complexes: Photochemical substitution of phosphine and phosphite ligands by olefin

G. Paul Donnini and Alan Shaver[1]

Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal, P.Q., Canada H3A 2K6

Received October 26, 1977

G. Paul Donnini and Alan Shaver. Can. J. Chem. **56**, 1477 (1978).

Complexes of the type (η^6-$C_6H_5XCH_2CH{=}CH_2$)$Cr(CO)_2L$, where X = O, CH_2 and L = $P(C_6H_5)_3$, $P(OC_6H_5)_3$, $P(OC_2H_5)_3$, and $P(CH_3)_2(C_6H_5)$ are photochemically labile. Ultraviolet irradiation leads to rapid displacement of L and coordination of the pendent olefin. [1,3,5-$(CH_3)_3C_6H_3$]$Cr(CO)_2P(C_6H_5)_3$ undergoes the same reaction in the presence of *cis*-cyclooctene. These observations are related to the general inability to substitute a second carbonyl ligand in (arene)$Cr(CO)_2Y$ by photochemical methods. Two new complexes (η^6-$C_6H_5XCH_2CH{=}CH_2$)$Cr(CO)_2CS$ are reported but these decompose under ultraviolet irradiation.

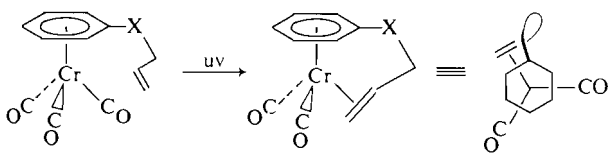
G. Paul Donnini et Alan Shaver. Can. J. Chem. **56**, 1477 (1978).

Les complexes du type (η^6-$C_6H_5XCH_2CH{=}CH_2$)$Cr(CO)_2L$, où X = O, CH_2 et L = $P(C_6H_5)_3$, $P(OC_6H_5)_3$, $P(OC_2H_5)_3$ et $P(CH_3)_2(C_6H_5)$ sont photochimiquement labiles. Par irradiation ultraviolette, on obtient un déplacement rapide du groupe L et une coordination de l'oléfine pendante. Le [1,3,5-$(CH_3)_3C_6H_3$]$Cr(CO)_2P(C_6H_5)_3$ subit la même réaction en présence de cyclooctène-*cis*. Ces observations sont reliées au fait qu'il est généralement impossible de substituer un second ligand carbonyle dans l'arène$Cr(CO)_2Y$ par des méthodes photochimiques. On rapporte la préparation de deux nouveaux complexes (η^6-$C_6H_5XCH_2CH{=}CH_2$)$Cr(CO)_2CS$ mais ceux-ci se décomposent sous l'influence d'une irradiation ultraviolette.

[Traduit par le journal]

Introduction

The stereochemistry of chiral organometallic complexes has been receiving increased attention (1). In particular arene–chromium carbonyl complexes have been the subject of a number of studies. The first examples of resolved enantiomeric complexes of this type have already been reported (2). The chromium tricarbonyl unit can also be used to 'label' one side of organic molecules containing an arene ring. With the plane of symmetry so removed, intricate asymmetric reactions may be carried out on the organic moiety (3).



1
a X = O
b X = CH_2

2
a X = O
b X = CH_2

Complexes of type **1** are interesting since stable olefin complexes **2** are obtained upon irradiation (4). Complexes of type **2** are chiral owing to the link between the olefin and the arene (i.e. the olefin is prochiral (5)). Racemization can only occur by dissociation of the olefin and recoordination of its other 'face'. Diastereoisomerism in **2** has been generated by the use of an asymmetrically substituted arene ring (6). However, the same thing may be achieved if one of the remaining carbonyls could be effectively replaced by a different ligand, thus creating a second chiral center. During our studies on these complexes, we have discovered that uv irradiation of arenechromiumdicarbonylphosphine or -phosphite complexes in the presence of an olefin (free or attached to the arene) causes facile replacement of the phosphine or phosphite by the olefin.

Experimental

All operations were carried out in a nitrogen atmosphere; all evaporations were performed *in vacuo*. All solvents were distilled in a nitrogen atmosphere before use. Hexane was distilled from sodium wire. Benzene and tetrahydrofuran (THF) were distilled from sodium–benzophenone. The ultraviolet irradiation source was a 100 W Hanovia high-pressure quartz mercury vapor immersion lamp in a water-cooled Pyrex photochemical immersion cell (Ace Glass Inc., catalogue numbers 6515-30 and 6517, respectively). The major ultraviolet band is at 366 nm (1.4 W); other lines in the visible and their radiated energy (W) are 4045(0.75), 4350(1.08), 5461(1.35), and 5780(1.55) as quoted by Ace Glass Inc., Vineland, NJ. (Pyrex glass seriously absorbs at wavelengths shorter than 330 nm (7).) The sample chamber had a capacity of 70 ml. Agitation of the reaction solution was achieved by continuously bubbling nitrogen from an inlet at the bottom of the chamber. Nuclear magnetic resonance (^{1}H nmr) spectra were obtained on a Varian T-60 instrument, using tetramethylsilane (TMS) as internal standard, unless otherwise noted. Infrared (ir) spectra were taken on a Perkin-Elmer 257 grating spectrophotometer. Mass spectra were obtained at 70 eV using a direct inser-

tion probe at the Mass Spectroscopy Unit, McGill University, and at the Department of Chemistry, University of Alberta. Melting points were determined in open capillaries in a Thomas Hoover Uni-Melt apparatus and are uncorrected. Chromatographic separations were carried out with neutral activated alumina. Compounds **1***a* and *b* and **2***a* and *b* were prepared via published techniques [4, 8].

*Preparation of Phosphine and Phosphite Complexes (***3***a–e)*

These yellow-orange adducts were prepared by irradiation of tricarbonyl **1** (2–3 mmol) in benzene (THF for **3***a*) until it was converted to olefin adduct **2**. The progress of the reaction was followed by monitoring the carbonyl stretching bands in the infrared and generally took 1.5 h. The red solution was transferred by means of a syringe to a 100 ml, three-neck flask equipped with a N_2 inlet. A slight excess of the appropriate ligand was added, and the solution was heated (50–55°C) with stirring overnight (15 h). Evaporation to dryness and chromatographic purification on alumina, eluting with CH_2Cl_2–hexane (1:2), afforded fairly pure adducts. Purer products, but lower overall yields (based on **1***b*), could be obtained by reacting recrystallized (hexane) **2***b* with the appropriate ligand in benzene.

The preparation of **3***a* was slightly different from the above procedure and is described in greater detail below. Infrared data are given in Table 1.

*(η⁶-Allyl phenyl ether)(triphenylphosphine)dicarbonylchromium (***3***a)*

A solution of 575 mg (2.2 mmol) of tricarbonyl **1***a* in 70 ml THF was irradiated for 1.5 h. The solution was transferred to a 100-ml three-neck flask and evaporated to dryness. The residue was extracted with 3 × 15 ml hexane and the combined extracts were filtered. Then 600 mg (2.3 mmol) of triphenylphosphine was added and the solution was heated to 45°C overnight. Evaporation to dryness and chromatography afforded a 50% overall yield of crude orange solid, which was recrystallized from CH_2Cl_2–hexane, mp 112–113°C; nmr (acetone-d_6, external TMS) δ: 4.27–4.67 (m's, 5H, 3ArH and CH_2O), 4.75–5.58 (m's, 4H, 2ArH and CH_2=CH), 5.65–6.38 (m, 1H, CH=CH_2), 7.2–7.80 ppm (m, 15H, $P(C_6H_5)_3$); ms *m/e*: 504 (M^+), 448 ($M^+ - 2CO$), 407 ($M^+ - 2CO - C_3H_5$), 314 ($CrP(C_6H_5)_3$), 262, 183, 108. *Anal.* calcd. for $C_{29}H_{25}CrO_3P$: C 69.04, H 5.00; found: C 68.96, H 5.09.

*(η⁶-4-Phenyl-1-butene)(triphenyl phosphite)dicarbonylchromium (***3***b)*

Compound **3***b* was obtained in 75% yield, mp (hexane) 100–101°C; nmr ($CDCl_3$) δ: 2.12 (d, 4H, CH_2—CH_2), 4.00 (m, 1H, *p*-ArH), 4.25–4.50 (m, 2H, ArH), 4.6–4.95 (m, 3H), 5.05 (bs, 1H), 5.3–6.0 (bm, 1H, CH=CH_2), 7.0–7.4 ppm (m, 15H, $P(OC_6H_5)_3$); ms *m/e*: 550 (M^+), 494 ($M^+ - 2CO$), 362 ($CrP(OC_6H_5)_3$). *Anal.* calcd. for $C_{30}H_{27}CrO_5P$: C 65.45, H 4.94; found: C 65.48, H 4.76.

*(η⁶-4-Phenyl-1-butene)(triethyl phosphite)dicarbonylchromium (***3***c)*

Compound **3***c* was obtained in 65% yield (oil); nmr ($CDCl_3$) δ: 1.27 (t, 9H, 3 × CH_3), 2.43 (m, 4H, CH_2—CH_2), 3.91 (quintet, 6H, 3 × CH_2OP), 4.7–5.3 (m, 7H, 5ArH and CH_2=CH), 5.3–6.2 ppm (bm, 1H, CH=CH_2); ms *m/e*: 406 (M^+), 361 (M^+ – OEt), 350 ($M^+ - 2CO$), 218 ($CrP(OEt)_3$), 184 ($CrC_6H_5CH_2CH_2CH$=CH_2). *Anal.* calcd. for $C_{18}H_{27}CrO_5P$: C 53.20, H 6.70; found (average of two analyses): C 53.64, H 6.72.

*(η⁶-4-Phenyl-1-butene)(triphenylphosphine)dicarbonylchromium (***3***d)*

Compound **3***d* was obtained in 60% yield, mp (hexane) 101–102°C; nmr ($CDCl_3$) δ: 2.37 (m, 4H, CH_2—CH_2), 4.4–5.2 (m's, 7H, 5ArH and CH_2=CH), 5.45–6.1 (bm, 1H, CH=CH_2), 7.15–7.70 ppm (m, 15H, $P(C_6H_5)_3$); ms *m/e*: 502 (M^+), 446 ($M^+ - 2CO$), 314 ($CrP(C_6H_5)_3$), 262 ($P(C_6H_5)_3$). *Anal.* calcd. for $C_{30}H_{27}CrO_2P$: C 71.71, H 5.42; found: C 71.38, H 5.69.

*(η⁶-4-Phenyl-1-butene)(dimethylphenylphosphine)dicarbonylchromium (***3***e)*

Compound **3***e* was obtained in 60% yield (oil); nmr ($CDCl_3$) δ: 1.57 (d, 6H, $P(CH_3)_2$, J_{PCH} = 8 Hz), 2.25 (m, 4H, CH_2—CH_2), 4.3–5.15 (m's, 7H, 5ArH and CH_2=CH), 5.4–6.15 (bm, 1H, CH=CH_2), 7.15–7.75 ppm (bm, 5H, C_6H_5—P); ms *m/e*: 378 (M^+), 322 ($M^+ - 2CO$), 190 ($CrP(C_6H_5)Me_2$), 184 ($CrC_6H_5CH_2CH_2CH$=CH_2). *Anal.* calcd. for $C_{20}H_{23}CrO_2P$: C 63.49, H 6.13; found: C 62.52, H 6.24.

Irradiation of Phosphine and Phosphite Complexes

The concentration, solvent, and reaction time are given in Table 2. The progress of the reaction was followed by monitoring the carbonyl stretching bands. Once the production of **2***a* or *b* was complete, a 30-ml portion of the reaction mixture was transferred to a 100-ml three-neck flask and evaporated to dryness. Nuclear magnetic resonance analysis of the residue confirmed the presence of **2** and the disappearance of **3**. The remaining portion of the reaction mixture was heated to 50°C; a clean regeneration of **3** was noted in all cases.

*(η⁶-Allyl phenyl ether)dicarbonylthiocarbonylchromium (***7***a)*

A solution of 300 mg (1.1 mmol) of tricarbonyl **1***a* in 70 ml benzene was irradiated for 1.5 h, then filtered. The filtrate was evaporated to 30 ml and 5 ml dry CS_2 was added. The solution was heated to 40–45°C in the dark for several hours and the reaction was monitored by ir spectroscopy. The resulting dark mixture was cooled, filtered, and the filtrate was evaporated to dryness. The residue was chromatographed on alumina, eluting with hexane–CH_2Cl_2 (3:2). A 20% yield of yellow oily product was recovered. This was crystallized from hexane, mp 61–62°C (dec.); ir (hexane): 1970, 1927 cm^{-1}; nmr (benzene-d_6, external TMS) δ: 3.90 (m, 2H, CH_2O), 4.20 (m, 1H, *p*-ArH), 4.36–5.35 (m's, 6H, 4ArH and CH_2=CH), 5.40–6.20 ppm (m, 1H, CH=CH_2); ms *m/e*: 286 (M^+), 230 ($M^+ - 2CO$), 186 ($M^+ - 2CO - CS$), 145 ($M^+ - 2CO - CS - C_3H_5$). *Anal.* calcd. for $C_{12}H_{10}CrO_3S$: C 50.35, H 3.52; found: C 50.91, H 4.70.

*(η⁶-4-Phenyl-1-butene)dicarbonylthiocarbonylchromium (***7***b)*

One millimole (240 mg) of olefin adduct **2***b* was dissolved in 30 ml benzene and a solution of 265 mg (1 mmol) of triphenylphosphine in 5 ml dry CS_2 was added. The mixture was heated to 50°C in the dark and the reaction was monitored by ir spectroscopy. After 4 h, the mixture was allowed to cool to room temperature. One hour later, the solvents were stripped off and the dark residue was chromatographed on alumina, eluting with CH_2Cl_2–hexane (1:2). Careful elution afforded 153 mg (60% yield) of a yellow oil. This could be further purified by crystallization from hexane at low temperature but the yellow solid melted below room temperature; ir (hexane): 1973, 1931 cm^{-1}; nmr ($CDCl_3$) δ: 2.45 (m, 4H, CH_2—CH_2), 4.95 (m, 1H, CHH=CH), 5.15 (m, 1H, CHH=CH), 5.3–6.2 ppm (m's, 6H, 5ArH and CH=CH_2); ms *m/e*: 284 (M^+), 228 ($M^+ - 2CO$), 184 ($M^+ - 2CO - CS$), 91, 52.

Irradiation of Thiocarbonyl Adducts **7***a and* b

When either adduct **7***a* or *b* (0.2–0.7 mmol) was irradiated in either benzene or hexane, a brownish precipitate formed almost immediately. Continued irradiation (20–30 min) caused the gradual disappearance of the ir carbonyl absorptions of **7***a* and *b* and other, much weaker bands appeared.

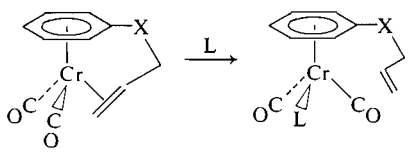
Results and Discussion

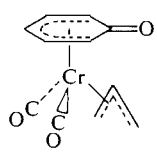
The yellow complexes **3** were prepared by reacting **2** with the appropriate ligand in warm benzene or hexane. These reactions proceed very smoothly and in good yield. The general preparation of (arene)Cr-$(CO)_2$L complexes often consists of irradiation of (arene)$Cr(CO)_3$ in a donor solvent such as THF, whereby (arene)$Cr(CO)_2$THF is presumably produced. The THF is replaced by the desired ligand after the irradiation. In **2** the coordinated pendent olefin plays the same role as THF, stabilizing the dicarbonyl. The chelate nature of the arene–olefin ligand is undoubtedly the reason (4) for the greatly increased stability of **2** over unchelated (arene)Cr-$(CO)_2$olefin complexes, which are seldom isolated. The progress of the reactions can be followed by monitoring the infrared spectrum in the carbonyl stretching region. The two bands due to **2** are gradually replaced by two others which are lower in energy (Table 1). The reaction is accompanied by a red to yellow colour change.



2 *a* and *b* 3

a X = O, L = $P\phi_3$
b X = CH_2, L = $P(O\phi)_3$
c X = CH_2, L = $P(OEt)_3$
d X = CH_2, L = $P\phi_3$
e X = CH_2, L = $PMe_2\phi$

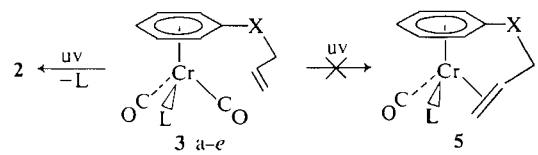
The preparation of **3***a* is of note because of the recent report of the production of **4** by stirring **2***a* in benzene with or without $P(C_6H_5)_3$ for 93 h (9).



4

In contrast, we observed that the same reaction in warm hexane gave **3***a* in over 50% yield. Some minor bands in the infrared spectrum of the reaction mixture might be due to **4** but only **3***a* was isolated after chromatography. We found that refluxing the reaction in benzene resulted in extensive decomposition. Stirring in benzene at room temperature gave **4** as reported (9). This reaction provides a striking example of solvent effects on the path of organometallic reactions.

The complexes **3***a–e* were irradiated in an attempt to generate **5**, which would have two centers of optical activity and thus be diastereotopic. Although substitution of the second carbonyl is rare (10), it was hoped that the presence of the pendent olefin might trap out any monocarbonyl produced. However,



irradiation of **3***a–e* in benzene or hexane rapidly regenerated **2**. The irradiations were accompanied by a colour change from yellow to the characteristic red of **2**. The reactions are quite rapid, being up to three times faster than the photosubstitution of a carbonyl in **1** to produce **2** (Table 2). If the uv lamp is shut off and the reaction solution is stirred, **3** is gradually regenerated. This process can be speeded by warming. The reactions are quite clean and irradiation–heating cycles can be repeated several times. After work-up, the presence of **2** was confirmed by nmr spectroscopy. Within the limits of our detection (ca. 7%), no monocarbonyl **5** was produced, although continued irradiation of **2***a* causes a gradual decrease in intensity of its carbonyl stretching bands. Eventually no **2***a* remains and a pale yellow solid (mp 147–148°C dec.) having a band in the infrared at 1888 cm^{-1} (benzene or THF) is isolated in low yield. This is not **5**, since it does not have any arene ligand but

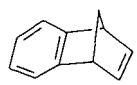
does contain triphenylphosphine. We have been unable to characterize it further.

Similar photosubstitutions of ligands by an olefin have been reported for complexes containing η^6-benzonorbornadiene (11). This may be regarded as a special case, since the olefin is held close to the metal by the rigid, multicyclic nature of the ligand. The substitution of another ligand by the olefin might be



Benzonorbornadiene

accelerated in this case, in order to reduce steric crowding at the chromium. The olefins used in our study are attached to the arene ring by only one connection. The olefin is free to swing away from the metal. Therefore, we assume that the olefin does not promote phosphine loss; rather, that the Cr—P bond is particularly photosensitive under the reaction conditions. To test this idea, $[1,3,5\text{-}(CH_3)_3C_6H_3]Cr(CO)_2P(C_6H_5)_3$, **6**, a complex with no pendent olefin, was prepared (12) and irradiated in the presence of excess *cis*-cyclooctene. The irradiation in benzene was accompanied by a yellow to red colour change, characteristic of the generation of the olefin complex. As the reaction progressed, the two infrared bands at 1896 and 1848 cm^{-1} (hexane) due to **6** were replaced by two bands at 1904 and 1855 cm^{-1}. The latter bands were assigned to $[1,3,5\text{-}(CH_3)_3C_6H_3]Cr(CO)_2[cis\text{-}C_8H_{14}]$, since they appeared when $[1,3,5\text{-}(CH_3)_3C_6H_3]Cr(CO)_3$ was irradiated in the presence of *cis*-cyclooctene during our preparation of **6**. Lack of a pendent olefin requires use of excess free olefin and also results in reduced yields of the olefin complex.

These observations are relevant to an understanding of the reactivity of (arene)$Cr(CO)_2L$ complexes. The lack of monocarbonyl derivatives has been attributed to the stabilizing effect (10) which the initial loss of CO from (arene)$Cr(CO)_3$ has on the remaining carbonyls. We propose an alternative explanation. Irradiation of the tricarbonyl with uv light leads to the loss of the only two electron donor that can be displaced, namely CO. However, in **3** there is a choice of two such ligands. Apparently the Cr—P bond is very labile when the molecule is photoexcited, as has been predicted (13). This seems to be general for all (arene)$Cr(CO)_2L$ studied so far (11, 13). Loss of L is due to the photolability of the Cr—L bond and not necessarily due to any increased stability of the Cr—CO bond in the dicarbonyl complex.

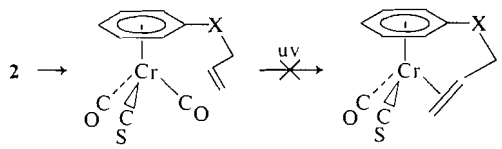
The one reported example (14*a*) of substitution of a carbonyl ligand is the irradiation (290–370 nm) of $(C_6H_5CO_2Me)Cr(CO)_2P(OEt)_3$ in the presence of $P(OMe)_3$. The complexes isolated are $(C_6H_5CO_2Me)Cr(CO)L_1L_2$ where $L_1 = CO$, $L_2 = P(OMe)_3$ (20%); $L_1 = L_2 = P(OMe)_3$ (10%); and $L_1 = P(OEt)_3$, $L_2 = P(OMe)_3$ (15%). Disubstitution occurs but ligand exchange, $P(OMe)_3$ for $P(OEt)_3$, is very evident. The disubstitution was attributed to the π acidity of the $P(OEt)_3$ and CO_2Me groups, which weakened the Cr—CO bond as reflected in infrared and pK_a studies. This may be so, but the exchange of phosphite ligands is probably due to the photolability of the Cr—P bond. Moreover, irradiation of $(C_6H_5CO_2Me)Cr(CO)_2L$, where L = $P(OMe)_3$, $P(OEt)_3$, and $P(C_6H_5)_3$, in the presence of $P(C_6H_5)_3$ and $P(OEt)_3$, results in the displacement of L by the new ligand (14*a*).

The factors that affect the photoreactivity of (arene)$Cr(CO)_2L$ complexes are not understood. Although correlations of photoreactivity with metal carbonyl stretching frequencies are attractive, they are not necessarily relevant to the molecules in excited states. The photoreactivity of these complexes is likely to be very dependent on the wavelength of irradiation, as has already been observed when L = *trans*-4-styrylpyridine (13). This may be the explanation of why, under our reaction conditions, the Cr–olefin bond is less photolabile than the Cr—P

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

bond. Wavelength dependence studies on the photochemistry of (arene)$Cr(CO)_2L$ complexes are needed.

In contrast to the cases where L = phosphine and other ligands, CO is displaced when L = CS, as in (arene)$Cr(CO)_2CS$ [2, 14*b*]. Accordingly, we prepared the new complexes **7** according to slightly modified published techniques [14]. They were characterized by their infrared, nmr, and mass spectra. Both complexes decomposed when exposed to fluorescent lighting. When they were irradiated in an attempt to synthesize **8**, they rapidly decomposed



7 **8**

a X = O
b X = CH_2

under a variety of reaction conditions, including the presence of $P(C_6H_5)_3$. A dark, high-melting precipitate formed in all cases.

Conclusions

The failure to photosynthesize monocarbonyl **5** is due to the photolability of the Cr—P bond and not due to increased stability of the dicarbonyl precursor. The prediction (13) of the general photolability of the Cr—L bond in (arene)$Cr(CO)_2L$ is thus substantiated for L = phosphines and phosphites. Under our reaction conditions, the Cr–olefin bond is less photolabile than the Cr—P bond.

Aminoglycoside antibiotics: Chemical conversion of neomycin B, paromomycin, and lividomycin B into bioactive pseudosaccharides[1,2]

STEPHEN HANESSIAN, TETSUYOSHI TAKAMOTO,[3] ROBERT MASSÉ, AND GHANSHYAM PATIL

Department of Chemistry, University of Montreal, Montreal, P.Q., Canada H3C 3V1

Received October 28, 1977

STEPHEN HANESSIAN, TETSUYOSHI TAKAMOTO, ROBERT MASSÉ, and GHANSHYAM PATIL. Can. J. Chem. **56**, 1482 (1978).

Pseudosaccharides containing various natural combinations of rings present in aminoglycoside antibiotics were prepared from the parent antibiotics, neomycin B, paromomycin, and lividomycin B, by oxidation of available vicinal diols and β-elimination. Pseudotrisaccharides comprising rings A, B, and C of paromomycin and lividomycin B, a pseudotrisaccharide comprising rings B, C, and D of the three antibiotics, and a 'core' pseudotrisaccharide containing rings B and C were thus prepared. These are valuable biological probes and intermediates for semisynthetic work in this series.

STEPHEN HANESSIAN, TETSUYOSHI TAKAMOTO, ROBERT MASSÉ et GHANSHYAM PATIL. Can. J. Chem. **56**, 1482 (1978).

Des pseudosaccharides qui contiennent des combinaisons naturelles de noyaux présents chez les antibiotiques aminoglycosidiques, néomycine B, paromomycine et lividomycine B, ont été préparés par une séquence impliquant l'oxydation des diols vicinaux chez les substances parentes, suivie d'une β-élimination. Ainsi les pseudotrisaccharides contenant les noyeaux A, B et C des antibiotiques néomycine et paromomycine, ceux qui portent les noyeaux B, C et D des trois antibiotiques, et un pseudodisaccharide 'core' contenant les noyeaux B et C ont été préparés. Ces substances peuvent être utilisées en tant qu'intermédiaires en synthèse dans cette série et aussi comme outils biologiques.

The aminoglycoside (aminocyclitol) antibiotics are a group of naturally occurring substances that exhibit powerful antibacterial effects on a wide variety of bacteria, by interfering with their normal process of protein biosynthesis at the ribosomal level (for recent reviews see refs. 2 and 3). A better understanding of their modes of action, as well as of other physiological properties necessitates a knowledge of structural, functional, conformational, and related parameters associated with these molecules. Correlations between structure and biological functions have been somewhat hampered by the unavailability of suitable model substrates that bear structural resemblance to the parent antibiotics. Only recently has it been possible to compile data (4) relating structural and functional features within a given series of aminoglycoside antibiotics to their biological activities, their susceptibilities to bacterial inactivating enzymes (see ref. 5 for recent reviews) and to their potential toxicity (6).

Despite the commercial availability of a number of aminoglycoside antibiotics and their extensive use in the treatment of pathogenic infections there is, at the present time, an ever-increasing interest in discovering novel types or analogs that have broader antibacterial spectra, with much lower degrees of toxicity and susceptibility to inactivating enzymes. Extensive research programs are currently in progress, particularly in the industrial sector, involving chemical modification and semisynthetic analogs (2) starting from the readily available, bioactive antibiotics and, whenever possible, from suitable fragments derived from these substances.

In the 4,6-*O*-glycosylated 2-deoxystreptamine group of antibiotics, such as neomycin B (**1**) and paromomycin (**2**) (Scheme 1), it has been known, since their discovery, that the corresponding pseudodisaccharides neamine and paromamine, isolated by methanolysis of the parent antibiotics, were only weakly antibacterial when tested in vitro. With the discovery of ribostamycin (**6**), a 5-*O*-β-D-ribofuranosylneamine (7), it became evident that the presence of the 2,6-diamino-2,6-dideoxyhexosyl unit attached to the ribofuranosyl portion in neomycin and paromomycin was not mandatory for biological activity as ribostamycin is more active than neamine but still less active than neomycin.[4]

At the inception of this study, there remained at least two other natural combinations of glycosidically-linked pseudosaccharides in molecules such as neomycin B and paromomycin that were unavailable either chemically or from other sources. It was there-

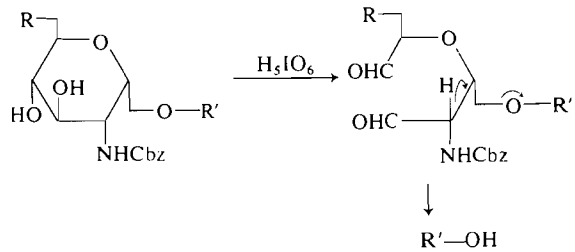
fore of paramount importance to devise practical and efficient means of obtaining such pseudosaccharides and to assess their utility in a general program concerned with the chemistry and biochemistry of aminoglycoside antibiotics. An examination of the structure of paromomycin reveals that there are three such pseudosaccharides in its skeletal framework. These constitute the two pseudotrisaccharides having rings A, B, C and rings B, C, D, and the 'core' pseudodisaccharide containing rings B, C. The latter two subunits are also common to the neomycins, lividomycin B (**3**) (8), ribostamycin, and related antibiotics.

In previous communications (1, 9), we have reported on the oxidative degradations of derivatives of neomycin B and paromomycin. In this paper, we report details of these conversions, as well as other pertinent transformations in this series.

Access to the pseudotrisaccharide comprising rings A, B, and C was considered first because of the inherent biological properties of such aminoglycosides. The basic strategy involved the use of the readily available neomycin B and paromomycin as starting materials and to effect, through suitably protected derivatives, periodate oxidation of the vicinally situated diol at C-3‴—C-4‴ of the diamino sugar unit D, followed by a base-catalyzed elimination of the resulting dialdehyde to release the aglycone, as illustrated in Scheme 2.

Paromomycin was chosen as the starting substrate because it should lend itself to preferential functionalization in ring A via the formation of a 4′,6′-*O*-benzylidene acetal. In such a derivative, the only vicinal diol is situated in ring D and the oxidative degradation discussed above should prove feasible. The classical procedure for the preparation of *O*-benzylidene acetals in the carbohydrate series involves the use of benzaldehyde in the presence of anhydrous zinc chloride (10). Under these conditions, and particularly in the presence of excess zinc chloride and benzaldehyde, penta-*N*-benzyloxycarbonylparomomycin (**5**) led to the corresponding 4′,6′-*O*;4‴,6‴-*O*,*N*-dibenzylidene derivative (11). However, treatment of **5** with benzaldehyde in the presence of 98% formic acid, as described in the case of methyl α-D-mannopyranoside (12), gave the desired 4′,6′-*O*-acetal **7** in high yield (Scheme 3). Periodate oxidation of **7** was found to proceed efficiently with a moderate excess of periodic acid in tetrahydrofuran in the presence of 4-Å molecular sieves. The resulting dialdehyde derivative[5] was isolated as an amorphous solid that exhibited the expected color tests for aldehydes (see Experimental). Treatment of the dialdehyde in methanol solution with triethylamine effected the desired β-elimination to give a crystalline product



SCHEME 2

[5]For convenience the dialdehyde derivatives are represented in their acyclic forms rather than as internal acetals.

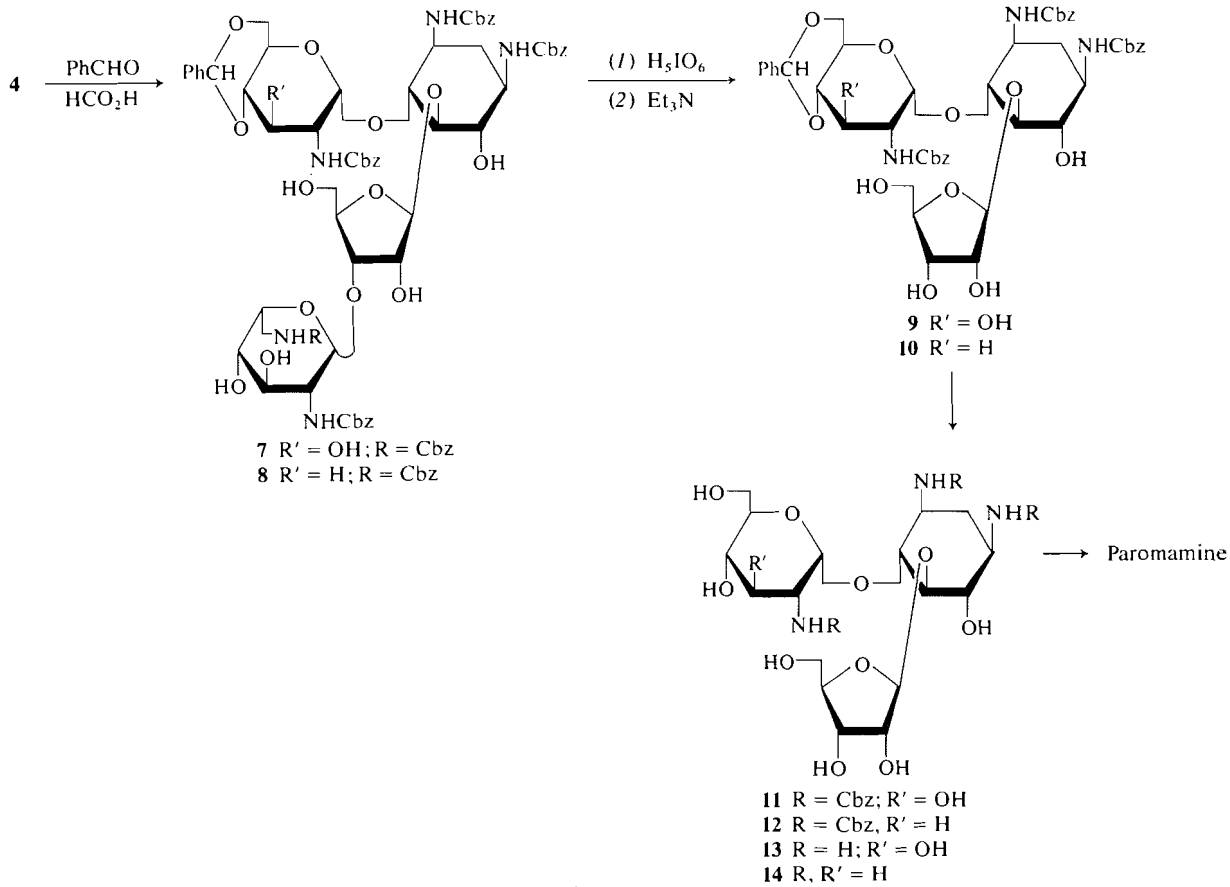

SCHEME 3

that was assigned the expected pseudotrisaccharide structure **9**, based on chemical and spectroscopic data. This product gave an amorphous tetraacetate derivative. Cleavage of the acetal function in the presence of dilute acetic acid in the usual manner led to the crystalline product **11** in high yield. Finally, removal of the benzyloxycarbonyl groups by hydrogenolysis gave the desired pseudotrisaccharide **13**, isolated as the amorphous free base. The structure of the pseudotrisaccharide was substantiated by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

high resolution mass spectral data (9), by ^{13}Cmr data (Table 1), as well as by chemical means. Thus, by virtue of the presence of the vicinal, *cis*-diol group in the ribose moiety of **9**, it was possible to effect periodate oxidation of **9** to the corresponding dialdehyde. Reduction of the latter with sodium borohydride led to the corresponding diol, which upon acid hydrolysis, hydrogenolysis, and cleavage of the labile glycosidic linkage comprising the ring-C-opened ribose unit, led to paromamine as the sole product.

Pseudotrisaccharide **13** is structurally closely related to ribostamycin **6**, the only difference being a peripheral, functional replacement of an amino group at C-6′ in the latter by an alcohol group in the former. It was, therefore, of interest that the antibacterial spectrum of **13** was comparable to that of ribostamycin (7) but weaker than that of neomycin B or paromomycin. It was also not altogether unexpected that the pseudotrisaccharide **13**, like its parent antibiotic and related analogs, was an effective substrate for phosphotransferases I and II,[6] which are known to inactivate the neomycin–kanamycin group of antibiotics by phosphorylation at the C-3′ hydroxyl group (5).

The pseudotrisaccharide related to **13** has been recently obtained from an alkaline hydrolysis of an aminoglycoside antibiotic, isolated from *Bacillus circulans* and designated Bu-1709E$_2$ (13). This substance differs from **13** in that it contains an *N*-1 (*S*)-(−)-4-amino-2-hydroxybutyryl unit, as in the butirosin group of aminoglycosides (14). ^{13}C magnetic resonance data on **13** at p$D \geq 11$ and p$D \simeq 1$ are listed in Table 1 and are in accord with the structure and in good agreement with data published for the closely related ribostamycin (15).

Since ribostamycin was the only naturally occurring pseudotrisaccharide related to the neomycins at the inception of this study, it was of interest to extend the oxidative degradation described for paromomycin, to its 3′-deoxy analog, lividomycin B (**3**).

Application of the sequential periodic acid oxidation and β-elimination reaction to the lividomycin B (**3**) series was possible with the 4′,6′-benzylidene derivative **8** (16),[7] which was prepared from the corresponding *N*-benzyloxycarbonyl derivative **4**. The pseudotrisaccharide derivative **10** was obtained in good yield and was subsequently treated with dilute acid to give the crystalline derivative **12**. Removal of the benzyloxycarbonyl groups by hydrogenolysis led to the pseudotrisaccharide **14** (desneosaminyllividomycin B), isolated as the amorphous sulfate salt. As lividomycin B lacks the C-3′ hydroxyl group, its antibacterial activity is somewhat broader than that of paromomycin, particularly against strains capable of producing phosphotransferases. The antibacterial activity of **14** was found to be disappointingly weak against strains of *E. coli* that were known to be resistant to kanamycin and was generally marginal against a limited number of other susceptible strains. It appears therefore that the diaminosugar (neosamine B) portion of lividomycin B plays an integral part in dictating its overall biological activity, unlike the case of paromomycin and neomycin whose corresponding A, B, C pseudotrisaccharides maintain substantial intrinsic activities. The 6′-amino derivative of **14** (3′-deoxyribostamycin) possesses superior antibacterial activity compared to ribostamycin itself (17). These findings demonstrate the profound influence of subtle functional changes in seemingly identical molecules on their biological properties and provide valuable information concerning functional requirements. The readily obtained pseudotrisaccharides **13** and **14**, and their respective derivatized precursors, can be regarded as useful intermediates to bioactive analogs in the ribostamycin and butirosin series, since methods of selective functionalization at C-6′ are now available (18). It should also be mentioned that our originally published procedure (9) for the conversion of paromomycin into **13** has been recently adapted to the oxidative degradation of penta-*N*-acetyllividomycin B (19) and should prove useful in other cases also.

In their elegant studies on the neomycins, Rinehart *et al.* (20) had observed that *N*-acylated derivatives of neosamine B (2,6-diamino-2,6-dideoxy-L-idose, corresponding to ring D in **1**–**2**) were resistant to periodate oxidation and they had invoked conformational arguments to explain this behavior, particularly that the C-5 epimeric neosamine C derivatives were susceptible to oxidation. On the basis of these observations and related studies in our laboratory, it was anticipated that a preferential cleavage of ring A might be possible in derivatives of neomycin B and paromomycin, leading eventually to a pseudotrisaccharide comprising rings B, C, and D. Indeed, treatment of hexa-*N*-benzyloxycarbonylneomycin B (**15**) (1) (Scheme 4) with a slight excess of periodic acid in tetrahydrofuran led to a dialdehyde **19** (Scheme 5), which when treated with triethylamine in methanol underwent β-elimination to give the crystalline pseudotrisaccharide derivative **16** in 63% yield. Hydrogenolysis in the presence of 20% palladium-hydroxide-on-charcoal (21) gave the pseudotrisaccharide **17** as an amorphous solid, whose structure was confirmed by mass spectral analysis of the

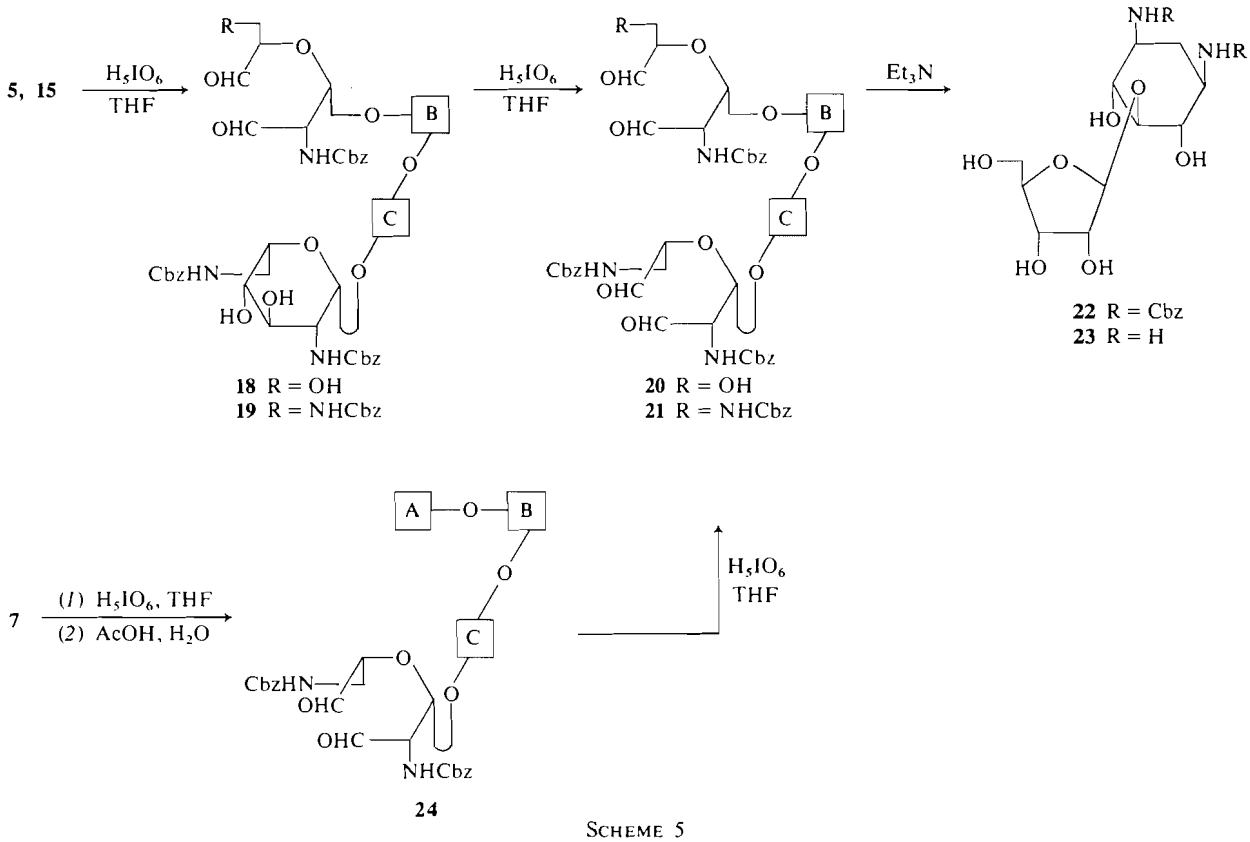
SCHEME 4

corresponding *N*-acetylated, *O*-trimethylsilyl derivative in accord with previous studies (22). The same product **17** could also be obtained from penta-*N*-benzyloxycarbonylparomomycin (**5**). It should be noted that a pseudotrisaccharide found as a minor component in commercial samples of neomycin (23) had been assigned a gross structure as in **17**. This had led to the suggestion (23) that it may be a biosynthetic precursor to the antibiotic (24). It appears that the neobiosamine portion (rings C, D) is formed at a relatively early stage in the biosynthesis of the neomycins (24) but it is as yet uncertain whether the remaining steps of the biosynthetic process involve the stepwise assembly of the 2-deoxystreptamine (ring B) and ultimately the neosamine C (ring A) portion, or a direct glycosylation of a preformed neamine. In a recent study, Pearce *et al.* (25) have shown that neamine is converted into neomycin (30%) by *Streptomyces rimosus* which was deoxystreptamine-negative. It still remains to be seen, however, if the pseudotrisaccharide **17**, which is found in commercial samples of neomycin, contributes to the biosynthetic pathway and, if so, to what extent. With the availability of the pseudotrisaccharide **17**, it will now be possible to provide conclusive evidence for the existence of an alternate biosynthetic pathway.[8] Surprisingly, the pseudotrisaccharide **17** was found to have some antibacterial activity, being 4–10 times less active than neamine.

In connection with these oxidative degradations of the neomycins and related antibiotics, it might be of interest to comment on ^{13}Cmr data which corroborate the difference in ground state conformations of rings A and D in these compounds. The ^{13}Cmr spectrum of neomycin B was recorded at $pD \geq 11$ in order to eliminate effects associated with the protonated or partially protonated amino groups. The assignments are in accord with data published on related aminoglycosides (26). Although the ground state conformation of the 2,6-diamino-2,6-dideoxy-α-D-glucopyranosyl portion (ring A, neosamine C) in neomycin B is most likely one that approximates a *C*1(D) form, that of the 5-epimeric 2,6-diamino-2,6-dideoxy-β-L-idopyranosyl portion (ring D, neosamine B) cannot be defined with certainty. Extensive ^{13}Cmr studies have shown that the conformations of the idopyranosides can vary considerably between the extreme *C*1 and 1*C* forms, depending on the configuration of the anomeric carbon, the oxidation state at C-6, the solvent, and the temperature (27). Examination of the ^{13}Cmr data in Table 1 reveals that the chemical shifts of the anomeric carbon atoms C-1′ and C-1‴ of rings A and D, respectively, are essentially identical. There is, however, a notable upfield shift of the signals associated with C-2‴, C-3‴, and C-4‴, compared to their counterparts in the ring A portion. As in the case of paromomycin and its analogs (11), this is most likely due to a distortion of the *C*1(L) conformation in the plane of at least three carbon atoms. A 1*C* conformation, as is known for idopyranosides, would place the aglycone in an equatorial orientation. The coincidence of chemical shifts of C-1′ and C-1‴ could, in this case, be due to the presence of different aglycones in rings A and D. Proton magnetic resonance data (20) in connection with the coupling constants of the anomeric hydrogen atoms in the neomycins reveal a much smaller dihedral angle (J_{12} = 1.6 Hz) in the β-L-*ido* portion (ring D), compared to the α-D-*gluco* portion (J_{12} = 2.7 Hz) indicating a departure from the idealized equatorial, axial (*C*1 form) or axial, equatorial (1*C* form) orientations of hydrogen atoms

[8]In collaboration with Prof. K. L. Rinehart, Jr.



SCHEME 5

in the former case. Unfortunately the ^{1}Hmr spectra of the neomycins are not amenable to analysis in the region of other ring protons which would shed light on the solution conformations of the respective rings. In this regard, a study of proton-coupled ^{13}Cmr spectra might be informative, particularly in conjunction with appropriate model compounds.

^{13}C magnetic resonance data on hexa-*N*-acetylneomycin B (28) show that the signals associated with C-3′′′—C-4′′′ (ring D) are also at higher field compared to those of C-3′—C-4′ (ring A), with a maximum shift of +2.9 Hz for C-4′′′. While H-bonding effects might indeed contribute to the preponderance of certain conformations in solution, it appears that *N*-acylation does not change the solution conformation drastically. In a derivative such as **15**, the angles subtended by the C-3′′′—C-4′′′ hydroxyl groups in ring D will depart considerably from that in the D-gluco counterpart ($\simeq$60°) (20), hence a preferential periodate oxidation of the latter under controlled conditions would be a reasonable expectation.

To obtain the core pseudodisaccharide comprising rings B and C, advantage was taken of the presence of the vicinal diol function in ring D of **7**. Thus, treatment of **7** with a moderate excess periodic acid ($\cong$3 equiv.) gave the dialdehyde derivative which was subjected to mild acid hydrolysis to cleave the acetal function. The resulting dialdehyde derivative **24** was isolated as an amorphous solid in good yield (Scheme 5). A second periodic acid oxidation with only 1.5 equiv. of oxidant led to the tetraaldehyde **20** which, after β-elimination as previously described, gave the crystalline pseudodisaccharide derivative **22** in 18.8% overall yield. The latter could also be obtained in fewer steps from the oxidative degradation of **5** or **15** using a large excess of periodic acid. Hydrogenolysis then gave the pseudodisaccharide **23** as an amorphous solid which was found to be inactive in the standard antibacterial test. It is of interest that a recent synthesis of ribostamycin **6** utilizes the pseudodisaccharide derivative **22** obtained by glycosylation procedures, followed by chromatographic separation of positional isomers (29).

In addition to their potential antibacterial activities, the pseudodisaccharides described in this work could be of interest in other contexts as well. As already discussed above, they can be regarded as versatile, readily available intermediates for semisynthetic work, particularly that their modes of formation lead to *N*-acylated, preferentially *O*-substituted derivatives suitable for various transformations in-

For personal use only.

cluding the all important glycosylation reactions. In addition, some of these pseudosaccharides can be regarded as ideal biochemical probes to study a variety of functions at the molecular level, since they encompass some of the structural and functional units present in the parent antibiotics. They could therefore be useful in bridging the last gap in relating structure–activity relationship in this series. Finally, they constitute potentially useful biosynthetic building blocks for the biotransformation of aminoglycosides (see, for example, ref. 30) and they could provide the 'missing link' in the biosynthetic pathway of the neomycin–paromomycin group of antibiotics.

Experimental

Melting points are uncorrected. Optical rotations were measured on a Perkin-Elmer automatic spectropolarimeter, model 141. Proton magnetic resonance spectra were recorded on a JEOL instrument at 60 MHz unless otherwise stated, with tetramethylsilane as internal standard, in deuteriochloroform as solvent. ^{13}C magnetic resonance spectra were recorded on a Bruker WH-90 instrument at 22.6 MHz. Mass spectra were recorded on an AEI-902 mass spectrometer at low and high resolution. Column chromatography was done using silica gel G254, with application of moderate suction.

Penta-N-*benzyloxycarbonylparomomycin (5)*

Benzyloxycarbonyl chloride (4.8 ml) was added dropwise and with vigorous stirring to a mixture of paromomycin **2** (4.8 g), sodium carbonate (8.64 g) in water (4.8 ml), and methanol (120 ml). After stirring at 5°C for 2 h, the mixture was stirred at room temperature for 17 h. Methanol (150 ml) was added, the inorganic precipitate was removed by filtration, and the filtrate was evaporated to dryness. Trituration of the residue with water (300 ml, total), filtration, and washing the solid with petroleum ether, gave the title compound; yield 7.37 g (92%). The colorless amorphous solid was suitable for further manipulations, although tlc indicated the presence of a trace amount of a second product (EtOAc–$CHCl_3$–MeOH, 25:40:9); a portion was purified by chromatography over silica gel; mp 139–141°C; $[\alpha]_D^{20}$ +22.6° (*c* 0.4, MeOH). *Anal.* calcd. for $C_{63}H_{75}N_5O_{24}\cdot 1.5H_2O$: C 57.62, H 5.95, N 5.34; found: C 57.25, H 5.87, N 5.40.

4′,6′-O-*Benzylidenepenta*-N-*benzyloxycarbonylparomomycin (7)*

Formic acid (1 ml) was added at 0°C to a mixture of **5** (0.73 g) in 7 ml of freshly distilled benzaldehyde and the clear solution was allowed to stand at 0°C for 25 h. The solution was added dropwise to a stirred solution of aqueous sodium bicarbonate with occasional addition of petroleum ether. The resulting amorphous solid was filtered, washed with water and petroleum ether, the solid was dissolved in methanol, and refiltered to remove a trace of insoluble material. Evaporation of the filtrate gave a syrup that solidified when triturated with petroleum ether to give the title compound as an essentially chromatographically homogeneous, amorphous solid; yield 0.775 g (95%); this material was suitable for utilization in the next step. Purification of a small quantity by preparative tlc ($CHCl_3$–EtOAc–MeOH, 10:2:1) gave material having mp 142–144°C (sinters ~135°C); $[\alpha]_D^{20}$ +17.8° (*c* 0.6, MeOH). This material gave a green colored spot when sprayed with acidic ammonium molybdate spray (31). *Anal.* calcd. for $C_{70}H_{79}N_5O_{24}\cdot 1.5H_2O$: C 60.00, H 5.86, N 5.00; found: C 59.71, H 5.82, N 5.12.

Acetylation of a portion (103 mg) in pyridine containing acetic anhydride (0.5 ml) during 5 days at 25°C, followed by evaporation of the solution gave the corresponding hexaacetyl derivative as a chromatographically homogeneous syrup; 75 mg (62%). An nmr spectrum of the product showed the correct ratio of protons in the integrated areas corresponding to acetyl methyl groups.

Periodic Acid Oxidation of 7

A mixture containing **7** (2.27 g, 1.59 mmol), periodic acid (545 mg, 2.39 mmol), and 4-Å molecular sieves (1.5 g) in 60 ml of redistilled tetrahydrofuran was allowed to stand at 0°C for 24 h. It was then poured into aqueous sodium bicarbonate with stirring and the solution was extracted with chloroform (4 × 50 ml). The organic phase was washed with water, dried over anhydrous sodium sulfate, and processed as usual to give a colorless syrup. Trituration with ether gave the dialdehyde derivative resulting from **7**, as an amorphous solid, which was suitable for use in the next step; yield 2.12 g (93%). The product showed one major spot on tlc (R_f 0.6, $CHCl_3$–EtOAc–MeOH, 20:4:3) and gave an orange color with the aniline hydrogen phthalate spray and a blue color with the ammonium molybdate spray; this is characteristic of aldehydes and hemiacetals (compare with green color in case of **7**, **9**, etc.).

4-O-*(4,6*-O-*Benzylidene-2-benzyloxycarbonylamino-2-deoxy*-α-D-*glucopyranosyl)-5*-O-*(*β-D-*ribofuranosyl)-1,3-di*-N-*benzyloxycarbonyl-2-deoxystreptamine (9)*

A solution containing the above-described dialdehyde derivative (2.13 g) and triethylamine (1 ml) in 70 ml of methanol was stirred at room temperature for 4 h. Evaporation of the solution gave a solid residue which was triturated with ether and filtered. Crystallization from ethanol gave the title compound (0.89 g, 63%) which was essentially pure by tlc ($CHCl_3$–EtOAc–MeOH, 20:5:3) and gave a characteristic greenish color when sprayed with acidified ammonium molybdate. Recrystallization from ethanol, or purification by preparative thick-layer chromatography gave an analytical sample; mp 221–222°C; $[\alpha]_D^{20}$ +35.4° (*c* 0.7, acetone). *Anal.* calcd. for $C_{48}H_{57}N_3O_{18}\cdot H_2O$: C 59.81, H 5.92, N 4.36; found: C 59.61, H 5.80, N 4.27.

Acetylation of a portion (50 mg) as described for **7** gave the peracetate as a chromatographically homogeneous foam (96%); $[\alpha]_D^{20}$ +12° (*c* 1, acetone).

4-O-*(2-Benzyloxycarbonylamino-2-deoxy*-α-D-*glucopyranosyl)-5*-O-*(*β-D-*ribofuranosyl)-1,3-di*-N-*benzyloxycarbonyl-2-deoxystreptamine (11)*

A suspension of **9** (450 mg) in 80% acetic acid was stirred at room temperature. After 30 h the clear solution was evaporated to dryness and the residue was washed with ether by decantation to give the crystalline title compound; yield 410 mg (quantitative). Purification by a sample (50 mg) preparative tlc ($CHCl_3$–EtOAc–MeOH, 4:1:1), followed by recrystallization from methanol gave an analytical sample (41 mg); mp 213–215°C; $[\alpha]_D^{20}$ +31.7° (*c* 0.88, dioxane). *Anal.* calcd. for $C_{41}H_{51}N_3O_{17}\cdot H_2O$: C 54.55, H 6.21, N 4.66; found: C 54.87, H 5.95, N 4.72.

The corresponding peracetate was obtained as a foam which exhibited the expected ^1Hmr spectral characteristics.

4-O-*(2-Amino-2-deoxy*-α-D-*glucopyranosyl)-5*-O-*(*β-D-*ribofuranosyl)-2-deoxystreptamine (13)*

A solution containing **11** (150 mg) in a mixture of methanol (20 ml) and dioxane (10 ml) was hydrogenated in the presence of 20% palladium-hydroxide-on-charcoal (21) (100 mg) and 0.64 ml of *N* hydrochloric acid. After 2.5 h, 10 ml of water was added and the hydrogenation was continued for 1.5 h. The suspension was filtered, the neutral filtrate was treated with

For personal use only.

Rexyn (OH^-), and the filtered solution was evaporated to dryness below 40°C to give a cream-colored solid; yield 75 mg (94%). The product was dissolved in the minimum volume of water and reprecipitated by addition of ethanol to give 31 mg of the chromatographically homogenous pseudotrisaccharide. Processing of the mother liquors gave an additional 35 mg of material; mp 160–175°C with decomposition at ~200°C; $[\alpha]_D^{20}$ +21° (*c* 1, H_2O); tlc (MeOH – $CHCl_3$ – 28% NH_4OH, 3:1:2) R_f 0.42, $R_{paromamine}$ 0.85; paper chromatography (1-PrOH–pyridine–H_2O–AcOH, 15:10:12:3) $R_{paromamine}$ 1.25 (pseudotrisaccharide **13** lit. (13) mp 168–170°C (for the carbonate salt); $[\alpha]_D$ +42° (H_2O)).

Mass spectral data on the *N*-acetyl *O*-trimethylsilyl derivative (22): *m/e* calcd. for $C_{31}H_{64}N_3O_{11}Si_4$ fragment: 766.3617; found: 766.3612; *m/e* calcd. for a $C_{28}H_{59}N_2O_{10}Si_4$ fragment: 695.3246; found: 695.3249. The ^{1}Hmr spectrum (D_2O, 100 MHz) of the pseudotrisaccharide **10** showed the two anomeric protons at −0.52 and −0.54 ppm relative to the HOD signal. ^{13}C magnetic resonance data are listed in Table 1.

Oxidative Degradation of ***9****: Isolation of Paromamine*

A solution containing **9** (300 mg) in 50 ml of methanol was treated with an aqueous solution of sodium metaperiodate (150 mg, 6 ml). After standing at room temperature overnight the solution was treated with 0.5 ml of ethylene glycol and the solvent was evaporated. The residue consisting essentially of the corresponding dialdehyde derivative was dissolved in methanol (15 ml) and 0.5 *N* HCl (5 ml) was added. After stirring for 24 h, the solution was evaporated partially and the resulting insoluble solid was filtered, washed with water, and dried; yield 250 mg. This product was dissolved in a 1:1 mixture of methanol and tetrahydrofuran, and 45 mg (4 equiv.) of sodium borohydride in 1 ml of water was added. After stirring the solution for 5 h, tlc ($CHCl_3$–EtOAc–MeOH, 20:5:4) indicated the complete conversion of the dialdehyde into the corresponding triol derivative, R_f 0.26. Evaporation of the solution and chromatographic separation, gave 140 mg of the triol. This material was dissolved in 30 ml of methanol and subjected to hydrogenolysis in the presence of 20% palladium-on-charcoal (50 mg) and 25 ml of *N* HCl. After 1 h, 10 ml of water was added to the mixture and the hydrogenation was continued for another 2 h. The mixture was filtered, the filtrate was neutralized with Rexyn 203 (OH^-) and processed as usual to give the triol derivative as a colorless solid (72 mg, quantitative); mp ~180°C (dec.); $[\alpha]_D$ +18.5° (*c* 0.34, H_2O); $R_{paromamine}$ 1.18 (MeOH – $CHCl_3$ – 28% NH_4OH, 3:1:2).

Treatment of the above product in 6 *N* HCl (18 h, 25°C) gave paromamine hydrochloride (53 mg) identical in all respects to an authentic sample (32).

*4-O-(4,6-O-Benzylidene-2-benzyloxycarbonylamino-2,3-dideoxy-α-D-ribo-hexopyranosyl)-5-O-(β-D-ribofuranosyl)-1,3-di-N-benzyloxycarbonyl-2-deoxystreptamine (****10****)*

To a solution containing 4′,6′-*O*-benzylidenepenta-*N*-benzyloxycarbonyllividomycin B (**8**) (16) (200 mg) in 10 ml of tetrahydrofuran was added 187 mg (5.5 equiv.) of periodic acid and 1 g of 4-Å molecular sieves at 0°C. The mixture was stirred gently at 0–5°C for 20 h after which time tlc ($CHCl_3$–EtOAc–MeOH, 20:5:3) indicated the complete consumption of **8** and the formation of a new, less polar product. The mixture was poured into aqueous sodium bicarbonate, the solution was extracted with chloroform, and the latter was processed as usual to give the dialdehyde resulting from **8** as a syrup (180 mg). This material gave the characteristic blue color for aldehydes with the ammonium molybdate spray. The syrup was dissolved in methanol (30 ml), traces of insoluble salts were filtered, and the filtrate was treated with 0.5 ml of triethylamine. After stirring overnight, the mixture was evaporated to dryness, the residue was triturated with ether and filtered to give the title compound as an amorphous, chromatographically homogenous solid; yield 125 mg. This material gave a green color when sprayed with acidified ammonium molybdate. It was used as such in the following step.

*4-O-(5-Benzyloxycarbonylamino-2,3-dideoxy-α-D-ribo-hexopyranosyl)-5-O-(β-D-ribofuranosyl)-1,3-di-N-benzyloxycarbonyl-2-deoxystreptamine (****12****)*

The above obtained product (125 mg) was dissolved in 8 ml 80% aqueous acetic acid and the solution was stirred at room temperature overnight. The solution was evaporated to dryness, the residue was triturated with water, and the resulting solid was filtered, washed with petroleum ether, and dried. The crude product, consisting of one major component (tlc, $CHCl_3$–EtOAc–MeOH, 4:1:1) was purified by preparative thick-layer chromatography to give the title compound as a crystalline solid (76 mg, 61% overall from **8**). Recrystallization of a portion of ethanol, gave fine colorless crystals; mp 228–229°C; $[\alpha]_D^{25}$ +27.7° (*c* 1, dioxane). *Anal.* calcd. for $C_{41}H_{51}N_3O_{16}$: C 58.50, H 6.06, N 5.00; found: C 58.92, H 6.18, N 4.87.

*4-O-(2-Amino-2,3-dideoxy-α-D-ribo-hexopyranosyl)-5-O-(β-D-ribofuranosyl)-2-deoxystreptamine (Deneosaminyllividomycin B) (****14****)*

The preceding compound (60 mg) was dissolved in 20 ml containing 0.34 ml of *N* hydrochloric acid, 60 mg of 20% palladium-hydroxide-on-charcoal and the mixture was hydrogenated for 3 h. Filtration, treatment of the filtrate with Rexyn (OH^-), and usual manipulation gave a syrup that was chromatographed on Amberlite CG-50 (NH_4^+) using *N* ammonia as developer the fractions containing the product were combined to give 15 mg (~45%) of a syrup that solidified upon trituration with ethanol. The corresponding sulfate salt was obtained as an amorphous solid by adding the required volume of aqueous sulfuric acid and evaporation in the presence of ethanol; mp 170–175°C (dec.); $[\alpha]_D^{25}$ +28° (*c* 0.8, H_2O) (lit. (19) mp 170–174°C (dec.); $[\alpha]_D^{25}$ +30° (H_2O)).

Treatment of **14** (10 mg) with 2,4-dinitrofluorobenzene (15 mg) in aqueous sodium bicarbonate – ethanol, followed by diluting with water and stirring overnight, gave a yellow precipitate that was purified by preparative thick-layer chromatography ($CHCl_3$–EtOAc–MeOH, 3:2:1), to give the corresponding tri-*N*-dinitrophenyl derivative as an amorphous, yellow powder (10 mg, 43%); mp 215–220°C (gradual dec.).

*Hexa-N-benzyloxycarbonylneomycin B (****15****)*

A solution containing neomycin sulfate (11.44 g) in 150 ml of water containing 25 g of sodium carbonate was diluted with 200 ml of methanol. The solution was cooled to 0°C and treated dropwise and with stirring, with 25 ml of benzyloxycarbonyl chloride. After 4 h, the mixture was diluted with 500 ml of cold water, and the whole was poured into 1 ℓ of ice-water with vigorous stirring. The resulting oily residue was separated from the supernatant by decantation and it was repeated by trituration with petroleum ether, then with water. The resulting paste was dissolved in a mixture of chloroform and methanol (1:1), the solution was filtered to separate traces of insoluble material, and the filtrate was evaporated to a colorless foam. Trituration with water gave a solid that was filtered and air dried. It was then suspended in petroleum ether and the mixture was vigorously stirred to give a fine colorless powder; yield 16.06 g (89%). Thin-layer chromatography ($CHCl_3$–EtOAc–MeOH, 20:5:3) indicated the presence of a major component and two minor components corresponding to the title product, the neomycin C analog, and a partially *O*-esterified derivative, respectively. The latter could be trans-

For personal use only.

formed into the neomycin derivative by treatment with sodium methoxide.

A portion of the above product (4.76 g) was dissolved in refluxing chloroform (50 ml), the solution was cooled and added to a column containing 250 mg of silica gel. Elution with chloroform (100 ml), then with the solvent mixture $CHCl_3$–EtOAc–MeOH, 20:5:2, gave successively, the *O*-benzyloxycarbonyl derivative (0.26 g), the title compound (3.67 g), and hexa-*N*-benzyloxycarbonylneomycin C (0.5 g). A second chromatographic treatment of the title compound (which contained traces of the C isomer) gave 3.03 of chromatographically homogenous material; mp 116–120°C; $[\alpha]_D^{25}$ +32.9° (*c* 0.54, $CHCl_3$).

5-O-[3-O-(2,6-Dibenzyloxycarbonylamino-2,6-dideoxy-α-L-idopyranosyl)-β-D-ribofuranosyl]-1,3-di-N-benzyloxycarbonyl-2-deoxystreptamine (16)

The preceding product **15** (1 g, 0.78 mmol) was dissolved in 60 ml of anhydrous tetrahydrofuran, the solution was cooled to 0°C, and treated with 10 g of 4-Å molecular sieves and 210 mg (0.92 mmol) of periodic acid. The mixture was left at 0–2 C for 20 h after which tlc indicated the disappearance of **15** and the formation of a less polar product (the dialdehyde **19**) which gave a positive test when chromatoplates were sprayed with aniline hydrogen phthalate. The mixture was treated with Rexyn 203 (OH^-), and the neutral supernatant was separated and combined with washings. The solution was evaporated to dryness, the syrupy residue (0.942 g) was dissolved in methanol (30 ml) containing triethylamine (1 ml), and the solution was heated at 55°C for 2 days. Evaporation of the solution gave a solid residue that was triturated with ether. The residue was chromatographed on silica gel ($CHCl_3$–EtOAc–MeOH, 20:5:2) to give the crystalline title compound (370 mg, 46%) and starting material (160 mg). Based on recovered **15**, the yield of **16** was 56%. Recrystallization from hot 2-propanol gave an analytical sample; mp 228–230°C; $[\alpha]_D^{25}$ +22.9° (*c* 0.9, dioxane). *Anal.* calcd. for $C_{49}H_{58}N_4O_{18}$: C 59.38, H 5.89, N 5.15; found: C 59.29, H 5.80, N 5.61.

5-O-[3-O-(2,6-Diamino-2,6-dideoxy-α-L-idopyranosyl)-β-D-ribofuranosyl]-2-deoxystreptamine (17)

A solution containing **16** (470 mg, 0.47 mmol) in 60 ml of methanol and 2.9 ml of *N* hydrochloric acid was treated with 20% palladium-hydroxide-on-charcoal (250 mg) and the mixture was hydrogenated. After 3 h, the mixture was processed in the usual manner to give a syrup which was redissolved in water (5 ml) and the solution was treated with Rexyn 203 (OH^-) until the p*H* became neutral. Filtration and evaporation of the filtrate gave a residue which solidified by trituration with ethanol, to give the title compound as an amorphous colorless solid (179 mg, 83%); mp 210–212°C (dec.); $[\alpha]_D^{25}$ +22.5° (*c* 0.25, H_2O); R_f 0.38 ($CHCl_3$ – MeOH – 28% NH_4OH, 1:3:2); paromamine had R_f 0.48; neomycin, R_f 0.21 in the same solvent system; mass spectral data for the *N*-acetylated, *O*-trimethylsilyl derivative: *m/e* calcd. for a fragment $C_{16}H_{33}N_2O_4Si_2$: 373.1977; found: 373.1987; *m/e* calcd. for $C_{16}H_{33}N_2O_5Si_2$: 388.1928; found: 389.1947.

This product could also be prepared from penta-*N*-benzyloxycarbonylparomomycin (**5**), essentially by the same procedure as described in the sequence **15** → **16** → **17**.

5-O-(β-D-Ribofuranosyl)-1,3-di-N-benzyloxycarbonyl-2-deoxystreptamine (22)

From 7

A sample of **7** (820 mg, previously dehydrated by dissolving in pyridine and distillation of the solvent) was oxidized with periodic acid (430 mg, 3.16 equiv.) in tetrahydrofuran (30 ml) in the presence of 4-Å molecular sieves. After 24 h at 0–5°C the mixture was poured in aqueous sodium bicarbonate solution and was processed as previously described to give the corresponding dialdehyde as a syrup (720 mg). The latter was dissolved in 80% aqueous acetic acid and, after 2 days, the solution was evaporated to dryness. The residue was triturated with water and then dried to give the dialdehyde derivative **24** as an amorphous solid (670 mg).

A second periodic acid oxidation (178 mg, 1.5 equiv.) in 30 ml of tetrahydrofuran as described above gave the tetraaldehyde derivative **20** (614 mg), which was dissolved in 20 ml of methanol containing 0.5 ml of triethylamine and the solution was stirred at 50°C for 2 days. Evaporation to dryness and trituration of the residue with ether gave a solid which was purified by preparative thick-layer chromatography ($CHCl_3$–EtOAc–MeOH, 4:1:1) to give the title compound in the form of colorless needles (63 mg, 18.8% overall). Recrystallization from ethanol gave an analytical sample; mp 235–237°C (sintering); $[\alpha]_D^{25}$ −44° (*c* 1, MeOH); mass spectral data for the *O*-TMS derivative: *m/e* 675 for a fragment containing the 2-deoxystreptamine portion and a $O—CH=\overset{+}{O}TMS$ substituent (arising from C-1 of the ribose unit with $\overset{+}{O}TMS$ migration). *Anal.* calcd. for $C_{27}H_{34}N_2O_{11}$: C 57.65, H 6.05, N 4.98; found: C 57.42, H 5.92, N 4.91.

From 5

Penta-*N*-benzyloxycarbonylparomomycin **5** (1 g) was oxidized with periodic acid (1.42 g, 8 equiv.) in 70 ml of tetrahydrofuran containing 4-Å molecular sieves. After standing at 0°C for 20 h, the mixture was poured into aqueous sodium bicarbonate and processed as usual to give 890 mg of the tetraaldehyde intermediate **20**. Treatment of the latter in methanol (70 ml) containing triethylamine (1 ml) for 15 h at room temperature and processing as described above gave the crude, chromatographically homogenous title compound (170 mg, 39–40% overall). Recrystallization from ethanol gave the crystalline product (70 mg, 16%) identical to that obtained above.

The same results were obtained starting from the neomycin derivative **15** and proceeding via the corresponding tetraaldehyde derivative **21**.

5-O-(β-D-Ribofuranosyl)-2-deoxystreptamine (23)

A solution containing 210 mg of the preceding compound in 50 ml of methanol containing 1.3 ml of *N* hydrochloric acid was hydrogenated in the presence of 20% palladium-hydroxide-on-charcoal (100 mg). After 4 h, the catalyst was filtered and the filtrate was processed in the usual manner to give a syrup (104 mg, 98%) which solidified from ethanol. The chromatographically homogenous product showed R_f 0.56 in $CHCl_3$ – MeOH – 28% NH_4OH, 1:3:2, $R_{paromamine}$ 1.12, and $R_{deoxystreptamine}$ 1.36; mp ~135°C (with foaming); $[\alpha]_D^{25}$ −24.6°C (*c* 0.22, H_2O).

Aminoglycoside antibiotics: The formation and characterization of dihydrooxazine derivatives in the paromomycin series[1]

STEPHEN HANESSIAN, ROBERT MASSÉ, AND (IN PART) GORAN EKBORG[2]

Department of Chemistry, University of Montreal, Montreal, P.Q., Canada H3C 3V1

Received October 28 1977

STEPHEN HANESSIAN, ROBERT MASSÉ, and GORAN EKBORG. Can. J. Chem. **56**, 1492 (1978).

Treatment of penta-*N*-benzyloxycarbonylparomomycin with benzaldehyde and excess zinc chloride gives a dibenzylidene derivative in high yield. This consists of the 4′,6′-*O*-benzylidene 4‴,6‴-*N*,*O*-benzylidene (dihydrooxazine) derivative of penta-*N*-benzyloxycarbonylparomomycin. Chemical evidence is presented to support this structure and model studies are reported for the formation of dihydrooxazine and oxazolidine derivatives of benzyloxycarbonylamino sugars containing suitably situated hydroxyl groups. The easily obtained dihydrooxazine derivative of paromomycin constitutes an interesting, preferentially blocked derivative, that is useful for the chemical modification of the parent antibiotic.

STEPHEN HANESSIAN, ROBERT MASSÉ et GORAN EKBORG. Can. J. Chem. **56**, 1492 (1978).

Le traitement de la penta-*N*-benzyloxycarbonylparomomycine par la benzaldehyde et un excès de chlorure de zinc donne un dérivé dibenzylidenique avec des hauts rendements. Ce dérivé implique les cycles 4′,6′-*O*-benzylidenique et 4‴,6‴-*N*,*O*-benzylidenique (dihydrooxazinique) de la penta-*N*-benzyloxycarbonylparomomycine. La structure de ce produit a été élucidée par des méthodes chimiques. Des transformations sur des subtrats modèles sont effectuées en vue d'obtenir des dérivés dihydrooxaziniques et oxazolidiniques. Les dérivés ainsi obtenue dans la série de la paromomycine sont des intermédiaires utiles, amenable à des transformations chimiques.

The knowledge that certain enzymes elaborated by bacterial strains carrying resistance transfer factors are capable of inactivating a group of aminoglycoside antibiotics (1) has been an important stimulus for intensive research work directed at the synthesis (2) and chemical modification of these substances (1*c*, 3). The planning of a synthetic sequence aimed at the selective chemical modification at a specific site in these molecules is sometimes hampered by their multifunctional character. There exists, therefore, a crucial need for the development of methods leading to preferentially blocked derivatives within a given series, by which critical portions of a given molecule are temporarily masked by appropriate functionalities, thus exposing other regions for various manipulations. The problem becomes all the more difficult if one considers that, in a large number of aminoglycosides that contain one or more sugars anchored around a 2-deoxystreptamine unit for example, the orientations and relative dispositions of amino and hydroxyl groups are, for the most part, very similar. One may be faced, for example, with the need to effect selective reactions at one vicinal *trans*-diol group in a hexopyranose unit, but not at another, located on a different sugar unit in a given aminoglycoside.

We were interested in probing the chemical reactivities of pairs of amide and alcohol functions having a 1,2- or a 1,3 disposition, in an aminoglycoside antibiotic such as paromomycin (**1**) (4) (Scheme 1) toward aldehydes and ketones, with the object of preparing oxazolidine and dihydrooxazine derivatives. Such derivatives would constitute interesting synthetic intermediates for further chemical modification work. Paromomycin (**1**) contains four sets of amine alcohol functions, two of which are situated on different rings, whereas the other two are in the 2,6-diamino sugar unit (paromose) (5). Previous work (6) has shown that it is possible to prepare a 4′,6′-*O*-benzylidene derivative in high yield by the treatment of *N*-benzyloxycarbonylparomomycin (**2**)

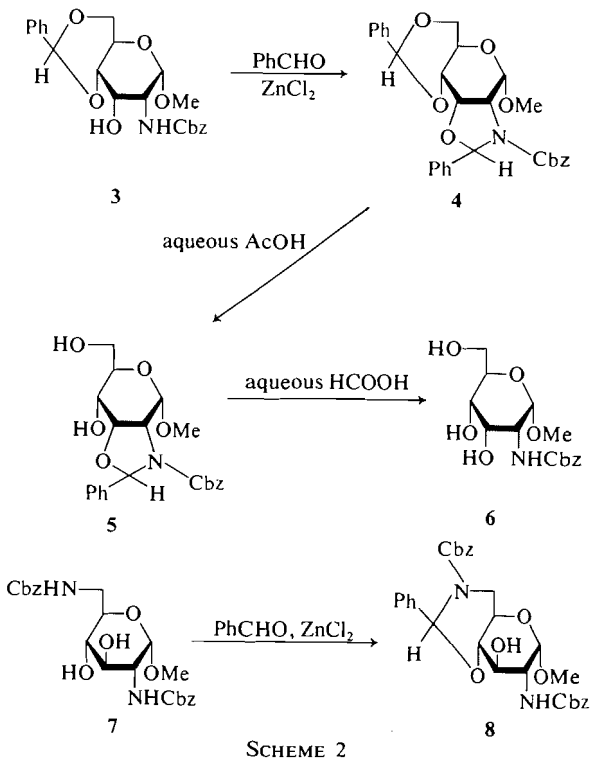
with benzaldehyde in the presence of formic acid. Using excess zinc chloride as catalyst, **2** was transformed into a product that contained two benzylidene groups. This compound isolated in over 80% yield was not oxidized by periodic acid in tetrahydrofuran. An acetal spanning a *trans*-diol group in the diamino sugar portion was excluded because of the relative acid stability of the new compound (see below). The possibility of the formation of an oxazolidine of dihydrooxazine ring, spanning favorably situated amide and hydroxyl functions, was therefore contemplated. In view of the existence of several possibilities involving such rings, we deemed it necessary to study the reaction with some model compounds which encompass some of the structural and functional features present in the various units of paromomycin.

Treatment of methyl 4,6-*O*-benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside (7) with benzaldehyde and excess zinc chloride gave back unchanged starting material, indicating the reluctance of the *trans* amide–alcohol system to form an oxazolidine derivative. It was apparent, therefore, that the newly introduced 'acetal' function in **2** did not involve any of the three sets of vicinal *trans*-oriented amide hydroxyl units. On the other hand, treatment of methyl 4,6-*O*-benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-D-allopyranoside (**3**) (8) (Scheme 2) with benzaldehyde and excess zinc chloride gave the corresponding crystalline oxazolidine derivative **4**. It was of interest to study the relative stabilities of the acetal and oxazolidine rings in **4**, as it would be expected that the acetal group would be preferentially cleaved under controlled conditions. Indeed, treatment of **4** with 80% aqueous acetic acid at room temperature effected complete cleavage of the acetal function to give the oxazolidine derivative **5** in high yield. When treated with 50% aqueous formic acid, the latter compound was transformed into methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-allopyranoside (**6**) (8).

Attention was next turned to the formation of *N,O*-benzylidene derivatives of the dihydrooxazine type, spanning three carbon atoms. Methyl 2,6-dibenzyloxycarbonylamino-2,6-dideoxy-α-D-glucopyranoside (**7**), which contains an unreactive *trans*-vicinal amide hydroxyl unit and a potentially reactive unit having a 1,3-disposition at C-4 and C-6, was treated with benzaldehyde and excess zinc chloride (Scheme 2). As anticipated, the corresponding *N,O*-benzylidene derivative **8** was indeed formed, although there remained some unchanged starting material. Treatment of the product with 50% aqueous formic acid gave, as in the previous case, starting compound **7** in good yield.

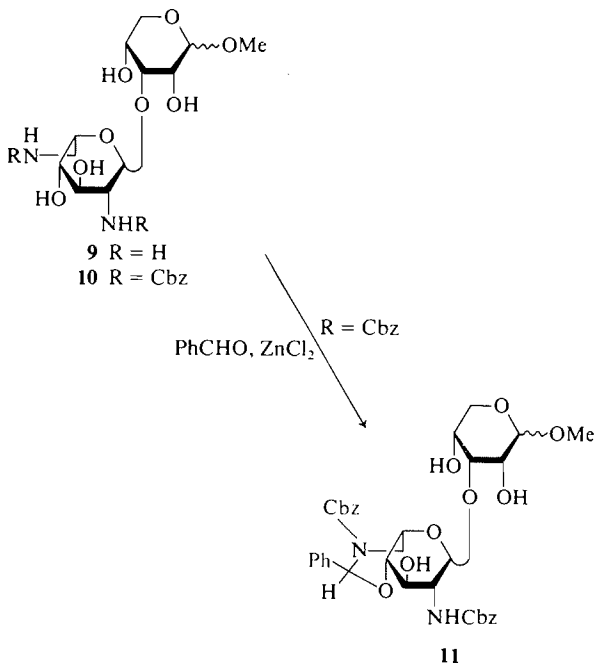


SCHEME 2

Finally, in an effort to simulate the structural and configurational requirements of the diamino sugar unit in paromomycin toward an *N,O*-benzylidenation reaction, a suitable degradation product of the antibiotic was sought as a model. Methanolysis of paromomycin gives, in addition to paromamine (9), the disaccharide glycoside, methyl paromobiosaminide **9** (10) (Scheme 3) in which the D-ribose portion has undergone ring expansion. Aside from this structural variation, however, the diamino sugar unit remains unchanged and should be an excellent model to simulate, as closely as possible, the dihydrooxazine ring forming reaction in the parent antibiotic derivative. Treatment of the *N*-benzyloxycarbonyl derivative of methyl paromobiosaminide (**10**) with benzaldehyde and zinc chloride gave a high yield of a new product to which the structure **11** can be assigned. This product was not oxidized with sodium metaperiodate and upon treatment with aqueous formic acid gave **10** in 70% yield.

Based on the results obtained with the model compounds, it was reasonable to assume that the new product formed in the reaction of **2** or **12** with benzaldehyde and excess zinc chloride was actually the dibenzylidene derivative **14** (Scheme 4). We then proceeded to seek direct chemical proof of this structure and to study some of its properties.

The dihydrooxazine ring formation was dependent on the concentration of zinc chloride, as a minimum



SCHEME 3

of 4 equiv. of the Lewis' acid was needed for complete reaction. With 1 or 2 equiv., the major product was the acetal derivative **12**. Treatment of **12** with benzaldehyde and zinc chloride gave the product **14** which was identical to that obtained from the direct treatment of **2**. *N,O*-Benzylidenation also took place with 4′,6′-*O*-cyclohexylidene-*N*-benzyloxycarbonylparomomycin (**13**) to give **15**. Treatment of **14** and **15** individually with aqueous acetic acid effected selective cleavage of the 4′,6′-acetal group to give the preferentially blocked paromomycin derivative **16**. Treatment with aqueous formic acid at 50°C resulted in the formation of the parent **2** but the reaction was accompanied by extensive degradation, no doubt owing to the presence of the relatively acid-labile *O*-β-D-ribofuranosyl residue. The regeneration of the parent antibiotic, paromomycin, was possible however, under conditions of hydrogenolysis, where the only detectable side product was paromamine.

Unlike their respective precursors, compounds **14** and **15** were not susceptible to periodate oxidation owing to the lack of vicinal diol groups. In previous papers (6, 11), we described a method for the controlled degradation of amino glycoside antibiotics, based on the cleavage, with periodate, of vicinal diol groups situated on C-3,C-4 on amino sugar units, followed by treatment with mild base. This sequence provides not only useful, selectively blocked predisposed amino glycoside fragments for semisynthetic work but with the proper choice of substrates it can lead to pseudodisaccharide and pseudotrisaccharide fragments that can be used as biological probes. Treatment of **16** with 1 equiv. of periodic acid in dry tetrahydrofuran gave a dialdehyde derivative **17**, which was subjected to β-elimination in the presence of triethylamine. Based on its physical characteristics and mode of formation, the product, formed in high yield from the sequence shown in Scheme 5, was assigned structure **18**. Acid hydrolysis with 50% aqueous formic acid gave several products, among which *N*-benzyloxycarbonyl-2-deoxystreptamine and D-ribose were identified by chromatography. Hydrogenolysis in the presence of palladium-hydroxide-on-charcoal (12) gave the known (11) pseudotrisaccharide **19**.

The formation of oxazolidine derivatives in the aminoglycoside series has been demonstrated in the gentamicin group (13), and has been used as supporting evidence for the *cis* disposition of the vicinal methylamino and tertiary hydroxyl groups in the garosamine moiety (14). Thus, on gentle warming in the presence of various aromatic aldehydes in ethanol, gentamicin C_2 is converted into the corresponding oxazolidine Schiff base derivative. The benzylidene analog has been used as an intermediate in the preparation of *N*-benzyl (13) and deoxygenated derivatives (15).

An oxazolidine derivative has also been reported to arise as a by-product in the treatment of penta-*N*-ethoxycarbonylribostamycin with 2,2-dimethoxypropane and *p*-toluenesulfonic acid in DMF at 70°C (16). It is of interest that in this case the oxazolidine ring encompasses the vicinally situated C-1 ethoxycarbonylamino and C-6 hydroxyl groups in the central 2-deoxystreptamine ring, and that these groups bear a *trans* relationship to each other. The instability of such a strained ring is evident from its hydrolytic behavior in the presence of an *O*-isopropylidene group.

Finally, an oxazolidine derivative of *N*-acetylepiinosamine-1 has been prepared in the course of ketal forming reactions, also under forcing conditions (2,2-dimethoxypropane, DMF, TsOH, at 80°C) (17). Because of the *cis* arrangement of the vicinal acetamido and hydroxyl groups, it was possible to selectively hydrolyze an *O*-isopropylidene group in the *O,O*:*N,O*-diisopropylidene derivative of *N*-acetylepiinosamine-1.

To the best of our knowledge, we are not aware of the formation of stable dihydrooxazine derivatives in the aminoglycoside series. Preliminary results have shown that the mild treatment of other aminoglycosides containing benzyloxycarbonylamino and alcohol functions in a 1,3 orientation with benzaldehyde and zinc chloride leads to the formation of the corresponding dihydrooxazine (*N,O*-benzylidene)

SCHEME 4

derivatives. In the paromomycin series, the reaction leads in high yield to a derivative in which the 2,6-diamino-2,6-dideoxy-L-idopyranosyl (paromose) moiety is effectively protected as the O^4,N^6-benzylidene derivative, thus paving the way for modifications at the other rings, particularly the 2-amino-2-deoxy-α-D-glucopyranosyl moiety, which is the site of enzymatic inactivation (1). By treatment with benzaldehyde and excess zinc chloride, it is thus possible to preferentially protect sets of amino alcohol groups in the multifunctional aminoglycosides, depending on their relative dispositions (1,2 or 1,3) and spatial orientations.

Finally, it may be of interest to recall the relative tendencies for the formation of oxazolidine and dihydrooxazine rings from the respective benzyloxy-

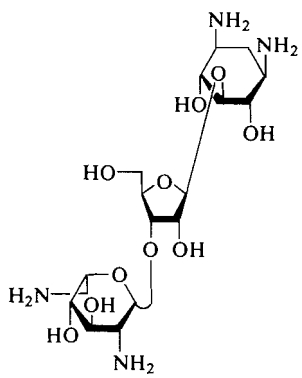
TABLE 1. ^{13}C magnetic resonance spectra of paromomycin (**1**), neamine, and methyl nebiosaminide (**9**) (ppm from TMS)[a]

Compound	Ring	Carbon atoms[b] 1	2	3	4	5	6
Paromomycin[c]	A	100.2	56.3	74.4	70.8	73.8	61.6
$pD \geq 11$	B	50.1	36.5	50.1	84.4	82.5	78.3
	C	109.1	74.4	77.0	84.9	62.3	—
	D	100.3	53.6	71.5	69.3	77.0	42.0
Neamine	A	101.9	56.4	74.7	72.5	74.3	42.9
$pD \geq 11$	B	51.5	36.8	50.5	88.5	77.1	78.6
Methyl	C	102.0	69.5	75.3	68.6	64.2	—
neobiosaminide[d]	D	99.5	53.9	71.7	69.5	76.9	42.0
$pD \geq 11$							

[a]Chemical shifts corrected to TMS scale taking δ dioxane as 67.4 ppm.
[b]For simplicity and space conservation, the carbon atoms are not primed; ring A atoms should be singly primed; ring C, doubly primed; and ring D, triply primed, as in the text.
[c]Assignments corroborated by appropriate β-shifts at acid p*D*, and by correlation with model compounds (E. Wenkert and E. W. Hagaman. Private communcation).
[d]The anomeric methoxyl group showed a signal at 56.6 ppm, corresponding to the carbon nucleus of the major α-anomer in the sample.

carbonyl amino and alcohol functions (e.g. **3** → **4**, **7** → **8**, and **10** → **11**).

The moderate yield (34%) and the recovery of unreacted starting material in the conversion of **3** → **4** can be attributed to the high energy of the conformationally biased pyranose ring, as the attachment of a five-membered oxazolidine ring is expected to introduce considerable ring strain. Molecular models show that the hexopyranose ring in **4** is forced into a half-chair conformation as a result of the presence of the oxazolidine ring. The



19

exceptionally facile formation of the dihydrooxazine ring in the disaccharide derivative **11** (89%) and in the paromomycin derivatives **14** and **15** (84%) compared to the model compound **8** (54%) is somewhat unexpected. Recent ^{13}Cmr spectroscopic studies (18) have shown that the conformations of methyl D-idopyranosides can depart significantly from the ground state *C*1(D) or 1*C*(D) forms. If the reasonable assumption is made that the 2-amino-2-deoxy-α-D-glucopyranosyl moiety in paromomycin adopts the *C*1(D) conformation, the conclusions derived from ^{13}Cmr data on paromomycin (Table 1) are that the 2,6-diamino-2,6-dideoxy-β-L-idopyranosyl portion adopts a time-averaged conformation that is substantially different than *C*1(L), particularly in the environment of C-2‴—C-4‴. Thus, we find that the chemical shifts of C-1′ and C-1‴ corresponding to the anomeric carbon atoms of the α-D-*gluco* and β-L-*ido* units, respectively, are coincident at $pD \geq 11$, while the signals due to C-2‴, C-3‴, and C-4‴ are at higher field (Δ 2.7, 2.9, and 1.5 Hz, respectively), compared to their C-2′—C-4′ counterparts, indicating quasi-axial orientations approaching a 1*C* form. Comparison of the ^{13}Cmr assignments of the carbon atoms of the diamino sugar portion in methyl neobiosaminide **9** and in neamine (19), respectively, reveal a similar upfield shift for signals associated with C-3—C-4 in the former case, indicating a different conformation (Table 1). It is of interest to recall the ^{1}Hmr studies on penta-*N*-acetylparomomycin by Rinehart *et al.* (20) who found a smaller H-1‴—H-2‴ coupling constant ($J_{1,2}$ = 1.8 Hz) in the 2,6-diamino-2,6-diamino-β-L-idopyranosyl moiety compared to that in the 2-amino-2-deoxy-α-D-glucopyranosyl moiety ($J_{1,2}$ = 3.5 Hz), reflecting a smaller dihedral angle for the vicinally disposed hydrogen atoms in the former sugar. A departure from a *C*1(L) conformation is also evident from periodate oxidation studies (refs. 11, 21, and 10*c*, pp. 29–31), as was originally proposed by Rinehart *et al.* (refs. 21 and 10*c*, pp. 29–31). Assuming that the conformation of the 2,6-diamino sugar moiety in paromomycin and methyl neobiosaminide does not change significantly in the derivatives **2** and **10**, it is not clear why the formation of the corresponding *N*,*O*-benzylidene derivatives is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

more favored compared to a D-*gluco* structure (as in **9**). It is possible that in such a conformation the nucleophilicity of the C-4‴ hydroxyl group toward the benzaldehyde–$ZnCl_2$ complex is enhanced through H-bonding with the carbonyl group of the 2-benzyloxycarbonylamino group. Such an enhancement cannot be envisaged for **7** in its ground state.

Experimental

Melting points are uncorrected. Optical rotations were measured on a Perkin-Elmer automatic spectropolarimeter, model 141. ^1H magnetic resonance spectra were recorded on a JEOL instrument at 60 MHz unless otherwise stated, with tetramethylsilane as internal standard, in deuteriochloroform as solvent. Spectra were not well resolved except in certain regions but were consistent with the structures. ^{13}C magnetic resonance spectra were recorded on a Bruker WH-90 instrument at 22.6 MHz. Mass spectra were recorded on an AEI-902 mass spectrometer at low resolution. Column chromatography was done using silica gel G254, with application of moderate suction.

*Methyl 4,6-*O*-Benzylidene-2,3-*N,O*-benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-*D*-allopyranoside (**4**)*

A mixture containing **3** (340 mg, 0.9 mmol) and anhydrous zinc chloride (408 mg, 3 mmol) in 3 ml of benzaldehyde was stirred at room temperature overnight. The solution was poured into aqueous 10% sodium bicarbonate (200 ml) and extracted with chloroform (2 × 50 ml). The organic phase was processed in the usual manner to give an oily residue, from which excess benzaldehyde was removed by distillation at 50°C under vacuum. The viscous residue solidified after trituration with petroleum ether to give a product that contained the title compound (tlc $CHCl_3$–EtOAc, 10:1), in addition to an appreciable amount of starting material. Separation by thick-layer chromatography gave **3** (115 mg) and the title compound (120 mg). Recrystallization of the latter from 2-propanol – petroleum ether gave 110 mg (34%) of an analytical sample; mp 180–181°C; $[\alpha]_D^{21}$ +117.5° (*c* 0.3, $CHCl_3$); ν_{max} (KBr): 1725 cm^{-1} (C=O). *Anal.* calcd. for $C_{29}H_{29}O_7N$: C 69.17, H 5.80, N 2.78; found: C 69.43, H 6.07, N 2.95.

*Methyl 2,3-*N,O*-Benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-*D*-allopyranoside (**5**)*

The preceding compound (40 mg) was dissolved in 5 ml of 80% aqueous acetic acid and the solution was stirred 12 h at room temperature. Evaporation of the solvent gave a syrupy residue that was triturated with aqueous sodium bicarbonate then with water and finally with petroleum ether. The residual syrup was dissolved in 2-propanol and the solution was diluted with petroleum ether to give the title compound as a colorless amorphous solid that was homogeneous by tlc ($CHCl_3$–EtOAc–MeOH, 25:15:3); yield 28 mg (82%); mp 110–115°C; $[\alpha]_D^{25}$ +189.3° (*c* 0.14, $CHCl_3$); ν_{max} (film): 3450 cm^{-1} (C=O).

Heating a solution of the product (10 mg) in 1.5 ml of 50% formic acid at 50°C for 20 h followed by conventional work-up gave 5.5 mg of methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-allopyranoside (8); mp 79–81°C; $[\alpha]_D^{25}$ +70° (*c* 0.1, MeOH), identical with an authentic sample.

*Methyl 2,6-Dibenzyloxycarbonylamino-2,6-dideoxy-α-*D*-glucopyranoside (**7**)*

A solution containing methyl 6-azido-2-benzyloxycarbonylamino-2,6-dideoxy-α-D-glucopyranoside (**22**) (235 mg, 0.67 mmol) in 40 ml of methanol and 5 ml of water was hydrogenated in the presence of 200 mg of 20% palladium-hydroxide-on-charcoal (12). After 2 h, the catalyst was filtered, the filtrate was evaporated to dryness, and the residue was dissolved in 15 ml of 3:1 aqueous methanol. The solution was treated with 1 ml of benzyloxycarbonyl chloride, 0.5 g of sodium bicarbonate, and the suspension was stirred at 0°C for 10 h. Dilution with a mixture of chloroform and petroleum ether resulted in the precipation of the product, which was filtered and dried; yield 171 mg of an amorphous colorless solid; mp 158–160°C; $[\alpha]_D^{25}$ +37.5° (*c* 0.12, $CHCl_3$).

*Methyl 4,6-*N,O*-Benzylidene-2,6-dibenzyloxycarbonylamino-2,6-dideoxy-α-*D*-glucopyranoside (**8**)*

Anhydrous zinc chloride (150 mg, 1.1 mmol) was added to a solution containing **7** (130 mg, 0.28 mmol) in 2 ml of freshly distilled benzaldehyde and the mixture was stirred at room temperature for 24 h. The solution was poured into 10% aqueous sodium bicarbonate with vigorous stirring and the resulting precipitate was collected by filtration. The filtrate was diluted with petroleum ether to give a sticky solid that was washed with the same solvent by decantation. The remaining solid consisted of a major product, contaminated with a small amount of unreacted starting material (tlc $CHCl_3$–EtOAc, 10:1). Separation by preparative thick-layer chromatography gave the title compound (61 mg, 52% based on recovered starting material). Recrystallization from 2-propanol gave an analytical product; mp 111–112°C; $[\alpha]_D^{27}$ +33° (*c* 0.10, $CHCl_3$). *Anal.* calcd. for $C_{30}H_{32}N_2O_8$: C 65.68, H 5.81, N 5.10; found: C 65.55, H 5.97, N 4.92.

Treatment of the above obtained derivative (15 mg) with 50% aqueous formic acid (50%, 20 h), followed by neutralization with Rexyn 203 (OH^-) and processing as usual, gave methyl 2,6-dibenzyloxycarbonylamino-2,6-dideoxy-α-D-glucopyranoside (7) (10 mg); mp 157–160°C; $[\alpha]_D^{27}$ +36.8° (*c* 0.1, $CHCl_3$).

*Methyl Di-*N*-benzyloxycarbonylparomobiosaminide (**10**)*

Methyl paramobiosaminide dihydrochloride (**9**) (1.2 g), obtained by methanolysis of paromomycin **1** (10), was dissolved in a mixture of water (25 ml) and methanol 10 ml, containing 2.3 g of sodium carbonate. The solution was cooled to 0°C and treated dropwise and with vigorous stirring with 1.41 g of benzyloxycarbonyl chloride. After 30 min, the mixture was left at 0°C for 10 h. Addition of cold water (200 ml) gave a sticky solid that was washed with cold water by decantation. Trituration with petroleum ether gave an amorphous solid that was dissolved in 50 ml of chloroform and the solution was filtered to eliminate a small amount of insoluble material. Evaporation of the solvent and purification by chromatography ($CHCl_3$–EtOAc–MeOH, 20:5:3) gave the title compound as a colorless solid. It was dissolved in chloroform and reprecipitated with petroleum ether; yield 490 mg; mp 230–235°C (foams with dec.); $[\alpha]_D^{27}$ +29.2° (*c* 0.51, $CHCl_3$); this chromatographically homogeneous product was used as such in the next step.

*Methyl 3-*O*-(4,6-*N,O*-Benzylidene-2,6-dibenzyloxycarbonylamino-2,6-dideoxy-β-*L*-idopyranosyl)α,β-*D*-ribopyranoside (**11**)*

A solution containing 200 mg (0.33 mmol) of the preceding compound in 5 ml of freshly distilled benzaldehyde was treated with 328 mg (2.41 mmol) of zinc chloride. After vigorous stirring for 4 h, the solution was added dropwise into 10% aqueous sodium bicarbonate and the resulting colorless precipitate was washed with water, dried, and dissolved in chloroform. The solution was dried with sodium sulfate, filtered, and the filtrate was evaporated to give a syrup that solidified from a mixture of chloroform and petroleum ether;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

yield 205 mg (89%). This product was chromatographically homogeneous (benzene–EtOAc, 1:1). An analytical sample was obtained by preparative thick-layer chromatography; the colorless amorphous product softened at 95–98°C and melted at 105–110°C; $[\alpha]_D^{27}$ +29.7° (*c* 0.16, $CHCl_3$); ^{1}Hmr: 3.36 (s, OCH_3), 6.78 ppm (b, PhCH<N,O>), etc. The product was unaffected by periodic acid in tetrahydrofuran (0°C, 24 h). *Anal.* calcd. for $C_{35}H_{40}O_{12}N_2$: C 61.76, H 5.92, N 4.11; found: C 61.88, H 6.10, N 3.88.

Acetylation of the dihydrooxazine derivative **11** (94 mg) in pyridine and acetic anhydride gave 97 mg (87%) of an amorphous triacetate derivative; mp ~ 112–115°C; $[\alpha]_D^{27}$ +30.9° (*c* 0.41, $CHCl_3$). Nuclear magnetic resonance data indicated the incorporation of three *O*-acetyl groups, as judged from the relative integration of appropriate areas in the spectrum.

Acid Stability of the Dihydrooxazine Derivative ***11***

Acetic Acid

The dihydrooxazine derivative **11** (10 mg) was dissolved in 80% aqueous acetic acid and the solution was left overnight at room temperature. Thin-layer chromatographic examination indicated no change. Heating the solution at 50°C for 24 h also showed unchanged starting material.

Formic Acid

An amount of the dihydrooxazine derivative **11** (35 mg) in 5 ml of 50% aqueous formic acid was heated at 50°C for 19 h, the solution was then treated with Rexyn 203 (OH^-), and processed in the usual manner to give methyl di-*N*-benzyloxycarbonylparomobiosaminide (**10**) 21 mg (70%); $[\alpha]_D^{27}$ +30° (*c* 0.29, $CHCl_3$).

*4′,6′-*O*-Benzylidene-4‴,6‴-*N,O*-benzylidenepenta-*N*-benzyloxycarbonylparomomycin (**14**)*

To a suspension containing 420 mg (0.32 mmol) of penta-*N*-benzyloxycarbonylparomomycin (**2**) (6) in 10 ml of freshly distilled benzaldehyde, was added anhydrous zinc chloride (620 mg, 4.52 mmol) and the mixture was stirred overnight. The mixture was then poured into 100 ml of cold 2% aqueous sodium bicarbonate and the resulting precipitate containing zinc salts was filtered and thoroughly washed with petroleum ether (200 ml), then with methanol. The filtrate, now containing an amorphous precipitate,[3] was diluted with a further 100 ml of petroleum ether. Filtration and washing with the same solvent gave a solid that was dissolved in 100 ml of chloroform containing 3 drops of triethylamine; the solution was concentrated to about 5 ml, then it was diluted with petroleum ether. The resulting colorless precipitate was transformed into a fine powder by vigorous stirring of the mixture. The crude product 370–445 mg (87–98%) consisted of a major component when analysed by tlc ($CHCl_3$–EtOAc–MeOH, 20:5:3). Purification by chromatography on a silica gel (80 g; developed with chloroform, 100 ml, then the above stated tlc solvent) gave 385 mg (84%) of a chromatographically homogeneous solid. The product could be reprecipitated several times from chloroform – petroleum ether, with minimal loss in weight; mp 139–142°C; $[\alpha]_D^{27}$ +31.3° (*c* 4.78, $CHCl_3$). *Anal.* calcd. for $C_{77}H_{83}N_5O_{23}\cdot 1.5H_2O$: C 62.51, H 5.68, N 4.84; found: C 62.76, H 5.68, N 4.75.

The product could also be obtained from 4′,6′-*O*-benzylidenepenta-*N*-benzyloxycarbonylparomomycin (**12**) (6), using essentially the same conditions but only half the volume of benzaldehyde; yield 76%; mp 141–143°C; $[\alpha]_D^{27}$ +30.9° (*c* 3.74, $CHCl_3$).

The product **14** was unaffected when treated with periodic acid in tetrahydrofuran (0°C, 48 h) and it was recovered unchanged (98%).

Treatment with 50% aqueous formic acid (55%, 48 h), followed by neutralization with Rexyn 203 (OH^-) and tlc examination revealed the presence of **2** as the major product. Also present were traces of more polar components resulting from further degradation of the molecule. The parent penta-*N*-benzyloxycarbonylparomomycin (**2**) was subsequently recovered by preparative thick-layer chromatography; $[\alpha]_D^{27}$ +21° (*c* 0.1, $CHCl_3$) (lit. (11) $[\alpha]_D^{27}$ +22.6° ($CHCl_3$)).

*Penta-*N*-benzyloxycarbonyl-4′,6′-*O*-cyclohexylideneparomomycin (**13**)*

A solution containing 616 mg (0.48 mmol) of penta-*N*-benzyloxycarbonylparomomycin (**2**), 21 mg of *p*-toluenesulfonic acid, and 2 ml of 1,1-dimethoxycyclohexane in 20 ml of anhydrous DMF was heated at 45°C under reduced pressure (~20 Torr) for 1 h. The cooled solution was neutralized with Rexyn 253 (OH^-) and the solvent was removed by co-distillation with 1-butanol. The residue was triturated with petroleum ether to give 650 mg (~quantitative) of an amorphous solid, that consisted of a major component (tlc, $CHCl_3$–EtOAc–MeOH, 20:5:3). Purification by chromatography on silica gel, as described in the previous preparation, gave the title compound as a colorless amorphous solid. It was dissolved in chloroform and reprecipitated with hexane; yield 450 mg (68%); mp 124°C (softens), ~145°C (foams); $[\alpha]_D^{27}$ +38.1° (*c* 0.32, $CHCl_3$). *Anal.* calcd. for $C_{69}H_{83}N_5O_{24}$: C 60.65, H 6.12, N 5.12; found: C 60.18, H 6.24, N 5.48.

*4‴,6‴-N,O-Benzylidenepenta-N-benzyloxycarbonyl-4′,6′-O-cyclohexylideneparomomycin (**15**)*

A solution containing 120 mg (0.088 mmol) of **13** in 50 ml of freshly distilled benzaldehyde was treated with anhydrous zinc chloride (435 mg, 3.20 mmol) and the resulting suspension was stirred and processed as described in the preparation of **14**. Chromatography of the crude product (110 mg) gave 95 mg (80%) of the title dihydrooxazine derivative **15**; mp 142–145°C; $[\alpha]_D^{27}$ +30.6° (*c* 3.94, $CHCl_3$). *Anal.* calcd. for $C_{76}H_{87}N_5O_{24}\cdot 0.5H_2O$: C 62.37, H 5.99, N 4.78; found: C 62.44, H 5.54, N 4.58.

The product was not affected by treatment with periodic acid in tetrahydrofuran (0°C, 48 h), whereas the parent **13** was transformed to the corresponding dialdehyde derivative under the same conditions.

Treatment of the product (10 mg) with 50% aqueous formic acid (50°C, 48 h) resulted in the formation of the parent **13** in addition to several degradation products (tlc).

*4‴,6‴-N,O-Benzylidenepenta-N-benzyloxycarbonylparomomycin (**16**)*

*From **14***

A solution containing 198 mg of the dihydrooxazine derivative **14** in 10 ml of 80% acetic acid was stirred at room temperature for 30 h. Evaporation of the solvent gave a colorless syrup that solidified when triturated with cold 1% aqueous sodium bicarbonate. The solid was filtered, washed with water, dried, and redissolved in 20 ml of chloroform. Drying over sodium sulfate, filtration, and evaporation of the solvent gave an amorphous solid that showed a major spot on tlc ($CHCl_3$–EtOAc–MeOH, 20:5:3), yield 165 mg (94%). Purification by thick-layer chromatography gave the title compound as an amorphous colorless solid (from chloroform – petroleum ether); yield 138 mg (79%); mp 143–146°C; $[\alpha]_D^{27}$ +24.7° (*c* 1.04, $CHCl_3$). *Anal.* calcd. for $C_{70}H_{79}N_5O_{24}\cdot 2H_2O$: C 59.60, H 5.64, N 4.96; found: C 59.81, H 5.54, N 5.00.

[3]If a syrup is formed, it is stirred under petroleum ether until it solidifies. Decantation and trituration with cold water will also cause solidification.

From 15

The dihydrooxazine derivative **15** (77 mg) was dissolved in 4 ml of 80% acetic acid, and the solution was stirred at room temperature for 30 h. The product was isolated as described in the preceding section; yield 60 mg (81%); mp 142–146°C; $[\alpha]_D^{27}$ +25° (*c* 0.71, MeOH).

Acid hydrolysis of the product (50 mg) in 50% formic acid (50°C, 24 h), followed by neutralization with Rexyn 203 (OH^-) and chromatography gave penta-*N*-benzyloxycarbonylparomomycin (**2**) (15 mg, 32%); $[\alpha]_D^{27}$ +21° (*c* 0.15, $CHCl_3$), in addition to several degradation products (tlc).

5-O-[3-O-(4,6-N,O-Benzylidene-2,6-dibenzyloxycarbonylamino-2,6-dideoxy-α-L-idopyranosyl)-β-D-ribofuranosyl]-1,3-di-N-benzyloxycarbonyl-2-deoxystreptamine (18)

Periodic acid (5 mg, 2.9 mmol) was added to a solution of the dihydrooxazine derivative **16** (63 mg) in 5 ml of dry tetrahydrofuran. After 24 h at 0°C and 6 h at room temperature, tlc examination indicated the absence of starting material (benzene–EtOAc, 1:1) and the conversion into the dialdehyde derivative **17**; this could be detected as a major component and gave a positive test with the aniline hydrogen phthalate test for aldehydes. The solution was then neutralized with Rexyn 203 (OH^-) and was processed in the usual manner to give a syrup. The latter was dissolved in 2 ml of methanol, 1 ml of triethylamine was added, and the solution was heated at 60°C overnight. Evaporation of the solvent gave a syrup that was purified by chromatography on silica gel ($CHCl_3$, 50 ml, then $CHCl_3$–EtOAc–MeOH, 20:5:3), to give the title compound as an amorphous solid the latter was dissolved in chloroform and reprecipitated with petroleum ether; yield 42 mg (80%); mp 114–116°C; $[\alpha]_D^{27}$ +20.1° (*c* 0.42, $CHCl_3$). *Anal.* calcd. for $C_{56}H_{62}N_4O_{18}$: C 62.32, H 5.79, N 5.19; found: C 62.07, H 5.91, N 5.21.

A portion of the above product (11 mg) was subjected to acid hydrolysis in 50% formic acid (50°C, 24 h); tlc examination revealed the presence of 1,3-di-*N*-benzyloxycarbonyl-2-deoxystreptamine, ribose, and two other unidentified components.

Hydrogenolysis in the presence of 20% palladium-hydroxide-on-charcoal (13) in 1:1 aqueous methanol gave the known (12) pseudotrisaccharide **19**, in addition to a small amount (5–10%, estimated from tlc) of paromamine.

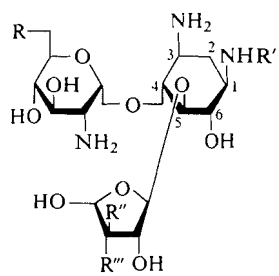
Pseudotrisaccharides of paromamine having a 6-*O*-(β-D-ribofuranosyl) and 6-*O*-(α-D-arabinofuranosyl) moieties were prepared from appropriately *N,O*-substituted derivatives of paromamine by glycosylation reactions. Selective functionalization at C-6′ in 6-*O*-(β-D-ribofuranosyl)paromamine led to the corresponding neamine-containing pseudotrisaccharide. None of these semisynthetic aminoglycosides possessed antibacterial activity, although at least one of them has been shown to be a substrate for the phosphotransferases I and II. The unnatural attachment of a pentofuranosyl moiety at C-6 of the 2-deoxystreptamine unit in these pseudotrisaccharides is, therefore, detrimental to their antibacterial action, unlike amino sugar containing analogs at the same position.

STEPHEN HANESSIAN, TOMOYA OGAWA et TETSUYOSHI TAKAMOTO. Can. J. Chem. **56**, 1500 (1978).

Des pseudotrisaccharides de la paromamine contenant les unités 6-*O*-(β-D-ribofuranosyl) et 6-*O*-(α-D-arabinofuranosyl) ont été préparés à partir des dérivés de la paromamine, par des réactions de glycosylation. Des transformations sélectives ont été effectuées sur la position C-6′ dans la 6-*O*-(β-D-ribofuranosyl)paromamine, menant à un analogue contenant un résidu néamine. Aucun de ses dérivés semisynthétiques s'est avéré avoir des propriétés antibactériennes, quoique au moins un pseudotrisaccharide s'est montré comme substrat à l'action des phosphotransférases I et II. L'attachement nonnaturel d'une unité pentofuranosyl sur C-6 de la 2-deoxystreptamine est au détriment de l'action antibactérienne, contrairement aux analogues qui contiennent un sucre aminé à la même position.

In spite of the large variation in the nature of the sugar units in aminoglycoside antibiotics of the 2-deoxystreptamine type, a unique feature exists in this group of potent antibacterial agents in that the pattern of substitution of the sugar residues is invariably at positions 4,5 and 4,6 of the central cyclitol ring; (see ref. 1 for recent reviews). In the former case, all the known, microbially-derived pseudotrisaccharides have been found to contain a β-D-pentofuranosyl moiety attached at C-5 of the 2-deoxystreptamine ring, the other sugar being, without exception, of the aminodeoxy type. To date, the β-D-*ribo* and β-D-*xylo* configurations have been found, as in the case of ribostamycin (**1**) (2), butirosin B (**3**) (3), antibiotic Bu-1709E$_1$ (**5**) (4), and butirosin A (**2**) (3), and xylostatin (**4**) (5), respectively (Scheme 1). It should be noted that with the exception of the butirosin types, in which the *N*-1 group is acylated with (*S*)-(−)-4-amino-2-hydroxybutyric acid, all these compounds have a common three-ring pseudotrisaccharide structure with only minor variations in the configuration of an isolated hydroxyl group, e.g. C-3 in the β-D-pentofuranosyl unit. It is also important to note that other peripheral modifications involving the exchange of an amino group for hydroxyl or the deoxygenation at a specific site, such as in Bu-1975C$_1$ and C$_2$ (6), may have important consequences at the molecular level. For example, it is known that neamine is more active than paromamine, while ribostamycin **1**, its 6′-hydroxy analog, **6** (7) and xylostatin **4**, its C-3′′ epimer, are of comparable biological activity in an in vitro test, which emphasizes the role of the β-D-pentofuranosyl moiety in these pseudotrisaccharides (8).

In a general program directed toward the synthesis



1 (Ribostamycin) R = NH$_2$; R′, R″ = H; R‴ = OH
2 (Butirosin A) R = NH$_2$; R″ = OH; R‴ = H; R′ = L-HABA
3 (Butirosin B) R = NH$_2$; R″ = H; R‴ = OH; R′ = L-HABA
4 (Xylostatin) R = NH$_2$; R′, R‴ = H; R″ = OH
5 (Bu-1709E$_2$) R, R‴ = OH; R″ = H; R′ = L-HABA
6 R,R‴ = OH; R′, R″ = H

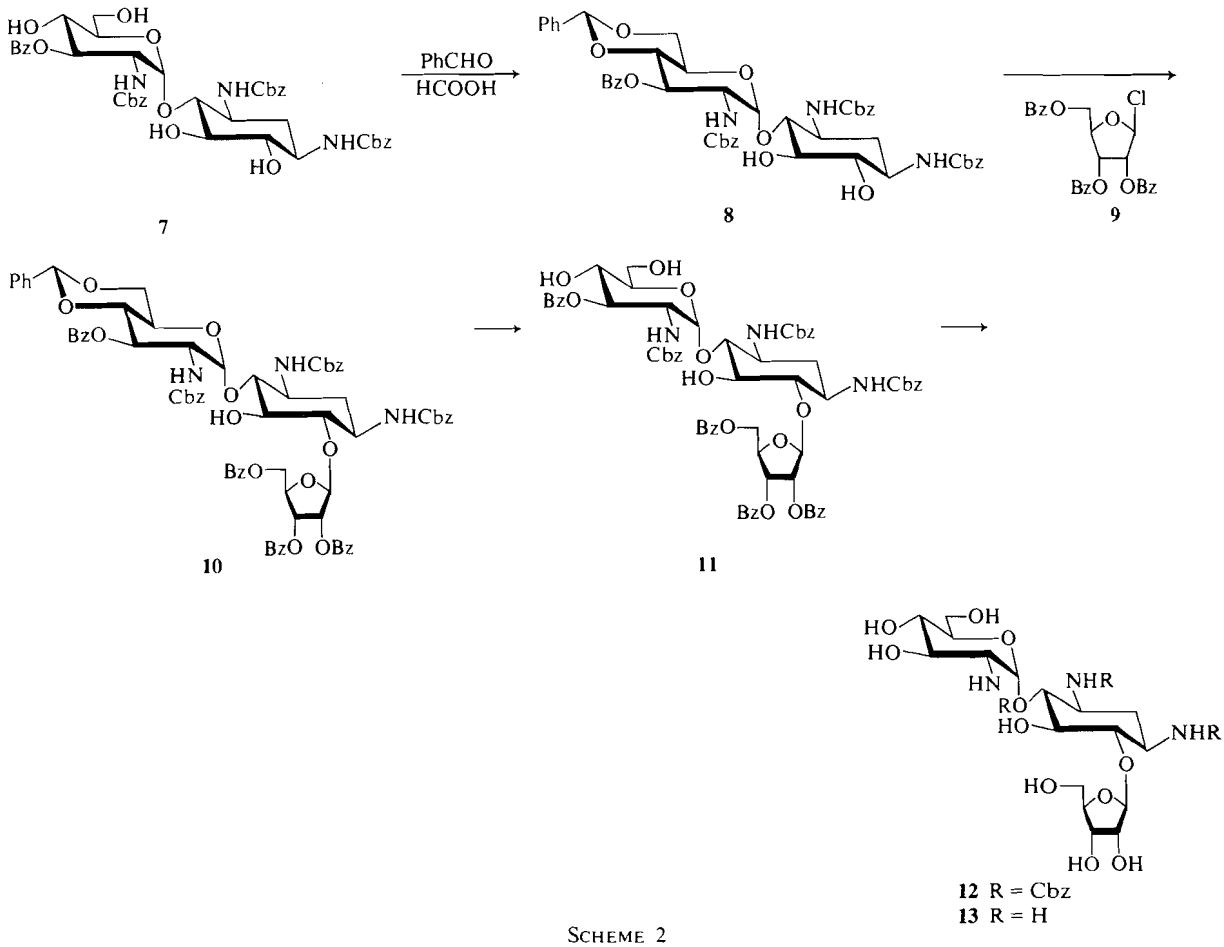

SCHEME 2

and chemical modification of aminoglycoside antibiotics, it was of interest to prepare pseudotrisaccharides derived from paromamine and neamine containing a β-D-ribofuranosyl unit glycosidically attached to the 'unnatural' C-6 position of the 2-deoxystreptamine ring. In this respect, the target compounds would be positional isomers of the naturally occurring ribostamycin and of its bioactive 6-hydroxy analog (7). In a preliminary communication (9), we described the preparation of 6-*O*-(β-D-ribofuranosyl)paromamine, which was also reported by the Farmitalia group (10). We now disclose details of this and related syntheses in this series.

The pseudosaccharides neamine and paromamine, which are readily available from the methanolysis of the respective antibiotics (11, 12), constitute ideal starting materials for semisynthetic work. In this work, paromamine was chosen as the substrate for glycosylation reactions because it lends itself to preferential functionalization in the 2-amino-2-deoxy-D-glucopyranosyl moiety, thus allowing transformations in the 2-deoxystreptamine portion. Furthermore, it was anticipated that pseudotrisaccharides derived from paromamine, could be easily converted into their neamine counterparts by selective transformations at the C-6′ position (13).

The readily available di-*O*-isopropylidene derivative of tri-*N*-benzyloxycarbonylparomamine (14) was benzoylated in the usual manner and the acetal groups were preferentially hydrolyzed to give crystalline 3′-*O*-benzoyl-tri-*N*-benzyloxycarbonylparomamine (**7**) in high yield (Scheme 2). The latter was then transformed into the corresponding 4′,6′-*O*-benzylidene derivative **8** by an adaptation of a procedure used for methyl α-D-mannopyranoside (15). The crystalline derivative **8**, was ideally suited for glycosylation reactions at C-5 and/or C-6 of the 2-deoxystreptamine unit. The readily available 2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl chloride (**9**) (16) was an obvious derivative for such a reaction as it encompasses the configurational as well as structural features to be found in the target compound. Furthermore, there were ample precedents in the literature for the formation of 1,2-*trans* glycosidic

linkages using this glycosyl halide derivative; (see for example, ref. 17). Although the site of *O*-glycosylation was not as predictable, it was anticipated that reaction might occur preponderantly at the C-6 hydroxyl group of the 2-deoxystreptamine moiety of **8**, based mainly on steric considerations. Previous glycosylation reactions of 2-deoxystreptamine had shown that the newly introduced sugar units were attached to the hydroxyl groups situated at C-4 and C-6 (18). Treatment of **8** with the glycosyl halide derivative **9** in the presence of mercuric cyanide as catalyst led to a major product in high yield, which, after chromatographic separation gave the pseudotrisaccharide derivative **10** as an amorphous colorless solid. Proof of homogeneity was secured by further transformations and by comparative reactions with the isomeric pseudotrisaccharide derivative in which the β-D-ribofuranosyl unit was at C-5 of the 2-deoxystreptamine (7).

Preferential hydrolysis of the acetal function of **10** gave the pseudotrisaccharide derivative **11** which had distinctly different chromatographic properties compared to its positional isomer, prepared by oxidative degradation of paromomycin (7). Furthermore, when **10** was subjected to debenzoylation and the resulting product was acetylated, only a derivative corresponding to **10** could be obtained, in which the C-5 hydroxyl group remained free. On the other hand, parallel reactions of the positional isomer corresponding to structure **6**, resulted in complete *O*-acetylation. This behavior can be rationalized on steric grounds as models show that the C-5 hydroxyl group is severely hindered and not readily accessible in derivatives of type **11**. In fact, total di-*O*-acetylation and benzoylation of derivatives such as **8** required unusually severe conditions, compared to analogous acylations of other polyhydroxy compounds (Scheme 3). Monoacetylation of **8**, occurred under very mild conditions to give the corresponding 6-acetate **15**, whereas acetylation under the same conditions of 4′,6′-*O*-benzylidenetri-*N*-benzyloxycarbonylparomamine (**14**) led to the corresponding 3′,6-diacetate derivative **18**. Acylation of **14**, **15**, or **18** under forcing conditions gave the fully *O*-acylated crystalline derivatives **16**, **17**, and **19**. The partially acylated derivatives **15** and **18** could be considered as preferentially protected synthetic intermediates for further reactions at the C-5 hydroxyl group (e.g. glycosylation) although as seen, this position is not too readily accessible.

Preferential hydrolysis of the benzoyl groups in **11** led to the pseudotrisaccharide derivative **12** in good yield. Subsequent removal of the benzyloxycarbonyl groups by hydrogenolysis gave the free pseudotrisaccharide **13** which was isolated as the free base and was found to be different from its positional isomer **6** by chromatography and identical to the product obtained by the Farmitalia group (10). The gross structural features of **13** were established by high resolution mass spectrometry on the corresponding *N*-acetylated *O*-trimethylsilyl derivative (19). The fragmentation patterns of this derivative and those derived from its positional isomer **6** were too similar to allow a differentiation between them. The same observation was made with the corresponding *N*-acetylated *N*,*O*-permethylated derivatives; however the peak at *m/e* 530 corresponding to the loss of a 2,3,5-tri-*O*-methyl-D-ribofuranosyloxy unit from the pseudotrisaccharide derivative was much more prominent in the spectrum of the product derived from **6** compared to that from **13**. Recent studies along these lines on kanamycin analogs allow a distinction to be made regarding the pattern of substitution on the 2-deoxystreptamine ring (20). Unlike its positional isomer **6**, pseudotrisaccharide **13** was found to be inactive against a variety of gram-positive and gram-negative strains in a standard antibacterial assay.[2] Interestingly it was also found to be a good substrate for phosphotransferases I and II, enzymes which are known to inactivate aminoglycoside antibiotics by phosphorylation at the C-3′-hydroxyl group (21).[3]

As previously mentioned, seemingly minor peripheral modifications in the basic molecular architecture of the aminoglycoside molecule may have profound effects on their biological properties. Since neamine was known to be a more effective inhibitor of the in vitro growth of bacteria than its 6′-hydroxy

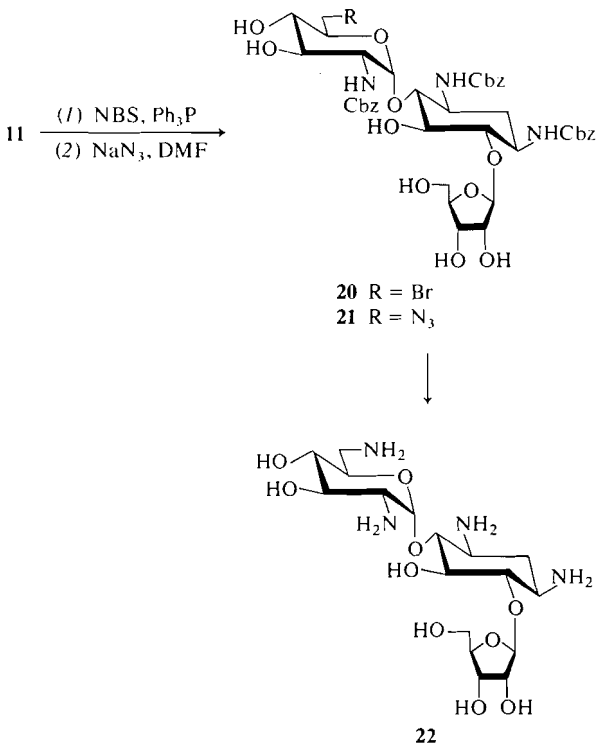

SCHEME 4

analog paromamine, it was of interest to convert the pseudotrisaccharide **13** into its neamine counterpart, i.e. 6-*O*-(β-D-ribofuranosyl)neamine. The *N*,*O*-protected intermediate **11** appeared to be ideally suited as a precursor for such a transformation, which necessitated a selective functionalization of one of two primary hydroxyl groups in the molecules, namely at C-6′. Thus, treatment of **11** with the reagent pair *N*-bromosuccinimide and triphenylphosphine in DMF gave, as previously shown for other polyfunctional molecules (13), including aminoglycosides (22), the selectively brominated derivative **20** in 85% yield (Scheme 4). The potential amino group at C-6′ was introduced via a displacement reaction with sodium azide in DMF in the usual way (83%) and hydrogenolysis of the resulting 6′-azido derivative **21** gave the pseudotrisaccharide **22** as an amorphous solid. The latter had distinctly different chromatographic mobilities compared to its positional isomer, ribostamycin (**1**). Unfortunately, like its precursor **13**, pseudotrisaccharide **22** was devoid of antibacterial activity when tested in the standard in vitro assay. At the time of the completion of this part of our program, the same compound was reported by the Farmitalia group (10), based essentially on the same sequence, namely, preferential glycosylation of a suitable *N*,*O*-protected paromamine derivative at C-6, followed by chemical conversion to the neamine analog via selective sulfonylation and amination. More recently, Suami *et al.* (23), based on our initial observation (9) that 6-*O*-(β-D-ribofuranosyl)paromamine (**13**) was much less active than its isomer **6** (14), have also prepared the neamine containing pseudotrisaccharide **22** by a sequence involving indirect acetylation of *N*,*O*-substituted neamine derivatives at the C-5 and C-6 hydroxyl groups, via several steps from tetra-*N*-ethoxycarbonylneamine and glycosylation of the derived isomer, essentially as previously described for **10**. At this point, it should be mentioned that Ito *et al.* (25) have effected a similar glycosylation reaction between the halide **9** and 3′,4′-di-*O*-benzyl-tri-*N*-benzyloxycarbonylneamine, and have reported the isolation of a major product in moderate yield in which the D-ribofuranosyl moiety was attached to the 5-position of the 2-deoxystreptamine unit. In our studies and those of the Farmitalia group (10), the major products in similar glycosylations were, as already discussed, the 6-*O*-substituted glycosides, with only trace amounts of the isomeric glycosides being found in the crude reaction mixtures. Except for the presence of a 4′,6′-acetal in the 2-amino-2-deoxy-α-D-glucopyranosyl portion of our substrates (e.g. **8**), the remaining structural and functional features are very similar to the neamine derived substrate (25) and it is difficult to rationalize the divergence in the sites of glycosylation. An assessment of these results, particularly in the light of the antibacterial assays, revealed to us that there exists a critical positional requirement with regard to the site of attachment of the pentofuranosyl ring in these pseudosaccharides. It was also evident that the role of functional parameters, such as the presence of a neamine rather than a paromamine containing unit in these compounds was not critical enough at the molecular level to compensate for the adverse effects associated with unnatural attachment of the third ring.

In contrast to cases such as **1**–**6**, where the pentofuranosyl moiety is at position-5 of the pseudodisaccharide, the sugar residue which occurs at position-6 in antibiotics such as kanamycin, are all *cis*-1,2 linked pyranosides. Therefore, it was of interest to find out if the adverse effect of the attachment of a 6-*O*-β-D-pentofuranosyl unit was due to its intrinsic structure or to the presence of the 'unnatural' anomeric configuration. To separate these effects, the synthesis of an 6-*O*-(α-D-pentofuranosyl)paromamine was planned. The D-*arabino* configuration was chosen because of the ready availability of *O*-esterified glycosyl halides in this series which, by virtue of

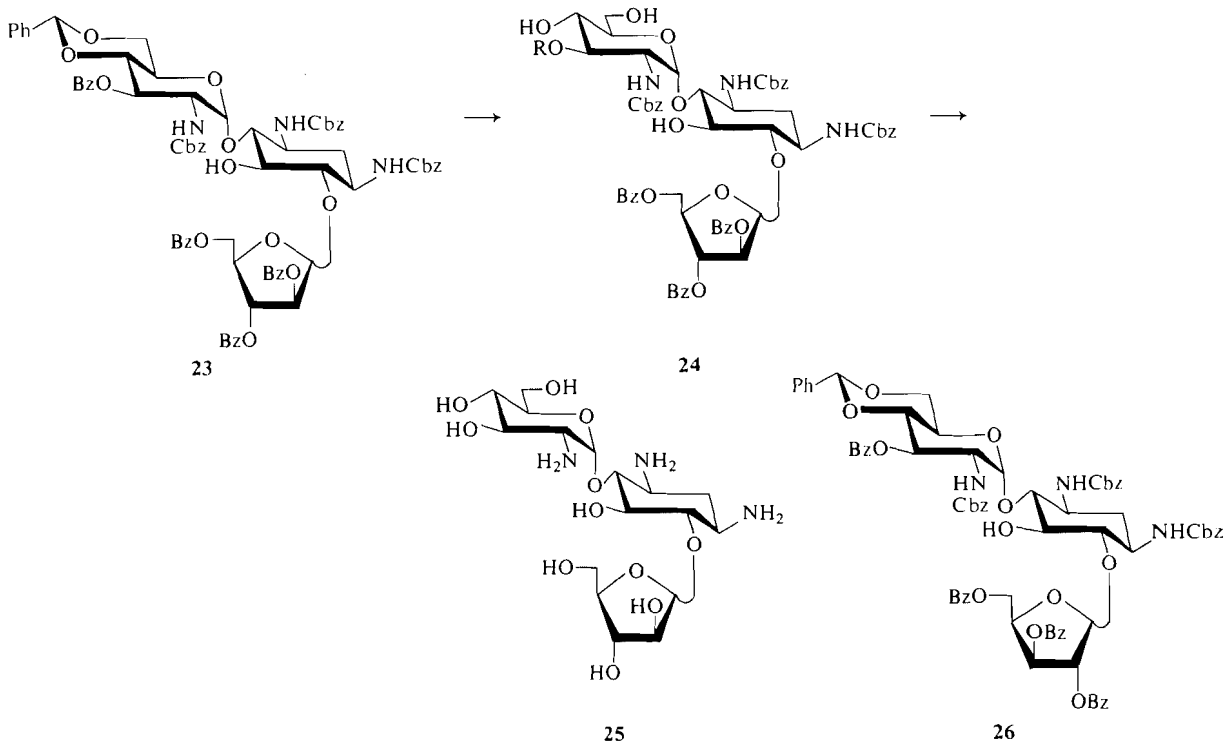

SCHEME 5

neighboring group participation during the glycosylation reaction, would be expected to lead to the desired α-D linkage. Thus, treatment of **8** with 2,3,5-tri-*O*-benzoyl-α-D-arabinofuranosyl bromide in the presence of mercuric cyanide as catalyst, gave the corresponding glycoside **23** in 50% yield (Scheme 5). Once again acylation reactions were found to be extremely slow, as in the D-*ribo* analog **10**. Removal of the 4′,6′-acetal group led to the derivative **24**, isolated as a chromatographically homogeneous solid. Debenzoylation followed by hydrogenolysis gave the desired 6-*O*-(α-D-arabinofuranosyl)paromamine (**25**) as an amorphous solid. Its gross structural features were estabilshed by mass spectral analysis of the corresponding *N*-acetylated *O*-trimethysilyl derivative. The pseudosaccharide **25** was found to be devoid of antibacterial activity. In this context, it is of interest that Suami *et al.* (23) have extended their glycosylations to include 6-*O*-α- and -β-D-glucopyranosyl and galactopyranosyl derivatives of neamine. As expected, only the α-D series showed activity, which emphasizes the role of *ring size and anomeric configuration* in conjunction with sites of attachment of sugars to 2-deoxystreptamine. Finally, the synthesis of a pseudotrisaccharide derivative **26**, containing the β-D-xylofuranosyl moiety at C-6 was also accomplished. However, in view of the results of biological testing on the analogs **13**, **22**, and **27**, it was not converted into the free pseudotrisaccharide, which would be a positional isomer of xylostatin (5).

In conclusion, it is evident, that the presence of at least one amino group in the sugar moiety at C-6 in neamine–paromamine type aminoglycosides is an important functional prerequisite for attaining acceptable thresholds of antibacterial activity as is the case with the naturally occurring kanamycins, gentamicins, and related aminoglycosides.

Experimental

Melting points are uncorrected. Optical rotations were measured on a Perkin-Elmer automatic spectropolarimeter, model 141. ^{1}H magnetic resonance spectra were recorded on a Jeol instrument at 60 MHz, unless otherwise mentioned, with tetramethylsilane as internal standard in deuteriochloroform as solvent. Mass spectra were recorded on an AEI-902 mass spectrometer, at low and high resolution. Reference material in peak matching experiments was tris(pentadecafluoroheptyl)-*s*-triazine, the exact mass of the $C_{13}F_{23}N_2$ ion being taken as *m/e* 620.9693. Column chromatography was done using silica gel G254, with application of moderate suction.

*4′,6′-O-Benzylidenetri-N-benzyloxycarbonylparomamine (**14**)*

To a suspension containing tri-*N*-benzyloxycarbonylparomamine (**7**) (9) (0.5 g) in 4.2 ml of freshly distilled benzaldehyde, was added 98% formic acid (1.7 ml). After 30 min the mixture was transformed into a gelatinous mass which was kept at room temperature for 24 h, after which time it was poured into aqueous sodium bicarbonate. Addition of petroleum ether with vigorous stirring resulted in the precipitation of the product, which was filtered and washed successively with aqueous bicarbonate, water, and finally with

petroleum ether. Recrystallization from a mixture of tetrahydrofuran and methanol gave the title compound, 427 mg (76%); mp 299–300°C (dec.); $[\alpha]_D^{20}$ +52.8° (*c* 0.1, dioxane); R_f 0.29 (tlc, $CHCl_3$–EtOAc–MeOH, 20:50:1). *Anal.* calcd. for $C_{43}H_{47}N_3O_{13}$: C 63.46, H 5.82, N 5.16; found: C 63.22, H 5.68, N 5.02.

3′,5,6-Tri-O-*acetyl-4′,6′*-O-*benzylidenetri*-N-*benzyloxycarbonylparomamine* (**19**)

A mixture containing **14** (100 mg) in pyridine (2 ml) and acetic anhydride (0.1 ml) was heated at 100–105°C for 4 h, and the solution was concentrated under reduced pressure. The residue was recrystallized from a mixture of chloroform, ethanol, and petroleum ether, to give the title compound (99 mg, 86%); mp 270–272°C; $[\alpha]_D^{25}$ +36.1° (*c* 1.0, dioxane); R_f 0.71 (tlc, $CHCl_3$–EtOAc–MeOH, 20:5:1). *Anal.* calcd. for $C_{49}H_{53}N_3O_{16}$: C 62.62, H 5.64, N 4.50; found: C 62.46, H 5.69, N 4.34.

3′,5,6-Tri-O-*benzoyl-4′,6′*-O-*benzylidenetri*-N-*benzyloxycarbonylparomamine* (**17**)

A solution containing 1 g of **7** in 20 ml of dry pyridine was treated with benzoyl chloride (3 ml) at 0°C. The solution was stirred at room temperature for 2 h, and then at 45–50°C for 3 days, when tlc examination indicated that esterification was complete. Water (0.5 ml) was added and after standing for 1 h, the solution was poured into ice-water. Extraction with dichloromethane and processing of the organic phase as usual, gave a syrup (1.6 g) which crystallized from a mixture of toluene and pyridine. Recrystallization from chloroform and ether gave the title compound (1.2 g, 87%); mp 227–230°C; $[\alpha]_D^{20}$ +22.4° (*c* 0.5, $CHCl_3$). *Anal.* calcd. for $C_{64}H_{59}N_3O_{16}$: C 68.28, H 5.28, N 3.73; found: C 68.12, H 5.14, N 3.50.

Selective hydrolysis of the acetal function was affected in a 4:1 acetic acid–water solution, at 80–85°C for 5.5 h. Chromatographic separation (toluene – ethyl acetate, 4:1) gave 3′,5,6-tri-*O*-benzoyltri-*N*-benzyloxycarbonylparomamine as a syrup, ~90%.

3′,6-Di-O-*acetyl-4′,6′*-O-*benzylidenetri*-N-*benzyloxycarbonylparomamine* (**18**)

A mixture of **14** (80 mg), acetic anhydride (0.1 ml), and pyridine (2 ml) was left at 5°C overnight; the solvent was co-distilled with toluene and the residue was triturated with a mixture of tetrahydrofuran and acetone to give the title compound as an amorphous, chromatographically homogenous solid (75 mg, 85%); mp 269–275°C (dec.); $[\alpha]_D^{25}$ +36.0° (*c* 1, dioxane); R_f 0.51 (tlc, $CHCl_3$–EtOAc–MeOH, 20:5:1). Acetylation of this product under forcing conditions (100°C, 4 h) gave the crystalline triacetate **19** (quantitative).

3′-O-*Benzoyltri*-N-*benzyloxycarbonylparomamine* (**7**)

To a solution containing tribenzyloxycarbonyl-4′,6′:5,6-di-*O*-isopropylideneparomamine (**14**) (2.65 g) in 14 ml of dry pyridine was added benzoyl chloride (1.1 ml) with cooling and stirring. The reaction mixture was diluted with chloroform after standing at room temperature overnight and the solution was washed with aqueous bicarbonate, then with water. Drying the organic phase and evaporation gave a syrup that solidified when triturated with petroleum ether. The benzoylated intermediate was dissolved in 75 ml of 80% acetic acid and after stirring at room temperature for 27 h, water was added to give the title compound; yield 2.4 g. Recrystallization from ethanol gave an analytical sample (2.3 g, 95%); mp 247–248°C; $[\alpha]_D^{20}$ +91.6° (*c* 1, DMF). *Anal.* calcd. for $C_{37}H_{43}N_3O_{13}$: C 60.23, H 5.87, N 5.7; found: C 60.05, H 5.87, N 5.62.

6-O-*Acetyl-3′*-O-*benzoyl-4′,6′*-O-*benzylidenetri*-N-*benzyloxycarbonylparomamine* (**15**)

Acetylation of **8** (50 mg) as described above gave the title compound as a chromatographically homogenous solid; mp 257–264°C; $[\alpha]_D^{25}$ +34.6° (*c* 1, dioxane); R_f 0.53 (tlc, $CHCl_3$–EtOAc–MeOH, 20:5:1). Acetylation of this product under forcing conditions gave the crystalline diacetate derivative **16** (quantitative).

5,6-Di-O-*acetyl-3′*-O-*benzoyl-4′,6′*-O-*benzylidenetri*-N-*benzyloxycarbonylparomamine* (**16**)

A mixture containing **8** (28 mg), acetic anhydride (0.05 ml), and pyridine (1 ml) was heated at 100–110°C for 5 h with stirring. Co-distillation of the solvent with toluene gave a residue which was triturated with ethanol and the solution evaporated to give a solid. Recrystallization from a mixture of chloroform and ethanol, gave the title compound (21 mg, 64%) as needles; mp 289–291°C (dec.); $[\alpha]_D^{20}$ +21.6° (*c* 1, dioxane); R_f 0.33 (tlc, benzene–2-butanone, 3:1); R_f 0.81 ($CHCl_3$–EtOAc–MeOH, 20:5:1). *Anal.* calcd. for $C_{54}H_{55}N_3O_{16}$: C 67.74, H 5.49, N 4.20; found: C 64.84, H 5.56, N 4.00.

3′-O-*Benzoyl-4′,6′*-O-*benzylidenetri*-N-*benzyloxycarbonylparomamine* (**8**)

A suspension of **7** (2.5 g) in freshly distilled benzaldehyde (20 ml), was treated with 4 ml of 98% formic acid, after which the solution became clear and homogenous. After stirring for 1 h, a gelatinous mass was obtained and was left at room temperature for 27 h. Pouring into aqueous bicarbonate and dilution with petroleum ether gave the title compound as a solid (2.36 g), which was filtered and washed as previously described. Dissolution of the product in tetrahydrofuran followed by addition of acetone gave the title compound as a chromatographically homogenous colorless solid; yield 2.2 g (81%); $[\alpha]_D^{2}$ +44.3° (*c* 1, dioxane); R_f 0.4 (tlc, $CHCl_3$–EtOAc–MeOH, 15:5:1). This material was suitable for use in subsequent transformations.

6-O-*(2,3,4-Tri*-O-*benzoyl*-β-D-*ribofuranosyl)-3′*-O-*benzoyl-4′,6*-O-*benzylidenetri*-N-*benzyloxycarbonylparomamine* (**10**)

Mercuric cyanide (2 g) and calcium sulfate (5 g) were added to a solution of **8** (1 g, previously dried by azeotropic removal of traces of water with DMF) in a mixture of DMF (10 ml) and 1,2-dichloroethane (30 ml). To the stirred suspension was added a solution of 2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl chloride (**9**), prepared from 2 g of the corresponding 1-acetate derivative (**26**), in 5 ml of 1,2-dichloroethane. After stirring the mixture at 50°C for 18 h, it was filtered through a bed of Celite (this latter having been well washed with dichloromethane) and the pooled filtrates and washings were extracted with aqueous bicarbonate, then with water. Processing of the organic phase as usual gave a syrup which solidified upon trituration with di-2-propyl ether. Filtration of the solid and washing with the same solvent gave the title compound; yield 1.35 g (91%). The product exhibited one major spot on tlc (toluene – ethyl acetate, 3:2, R_f ~0.65). A portion of the product was dissolved in a 4:1 mixture of carbon tetrachloride and acetone, and the solution was poured through a short column of silica gel. Elution with a 3:1 mixture of the same solvents, followed by isolation and reprecipitation from a mixture of dichloromethane and di-2-propyl ether gave an analytical sample; mp 278–279°C; $[\alpha]_D^{20}$ +26.8° (*c* 1, dioxane). *Anal.* calcd. for $C_{76}H_{71}N_3O_{21}$: C 67.00, H 5.25, N 3.09; found: C 66.77, H 5.02, N 3.15.

Attempts to acylate the above product were not successful, and starting material was recovered without loss; e.g. acetic anhydride in pyridine, 25°C, 5 days; benzoyl chloride in pyridine, 25°C, 65 h. A portion of the product (100 mg) was treated with sodium methoxide in a mixture of methanol and

For personal use only.

dichloromethane. After standing overnight, acetic acid was added to p*H* ~ 5 and the solution was evaporated to dryness to give a chromatographically homogenous product, mp > 250°C, corresponding to the debenzoylated analog of **10**. This product had the same chromatographic mobility as its positional isomer derived from **6** (24); tlc, $CHCl_3$–EtOAc–MeOH, 15:5:4. Acetylation of the two products, individually (acetic anhydride, pyridine, 25°C, 5 days) gave distinctly different acetylated products owing to a total *O*-acetylation in the case of the 5-*O*-(β-D-ribofuranosyl) derivative and only partial acetylation in the case of the positional isomer because of the sterically hindered C-5 hydroxyl group in the latter. Benzoylation (25°C, 65 h) led to the same results.

*6-O-(2,3,5-Tri-*O*-benzoyl-*β*-D-ribofuranosyl)-3′-O-benzoyltri-*N*-benzyloxycarbonylparomamine (**11**)*

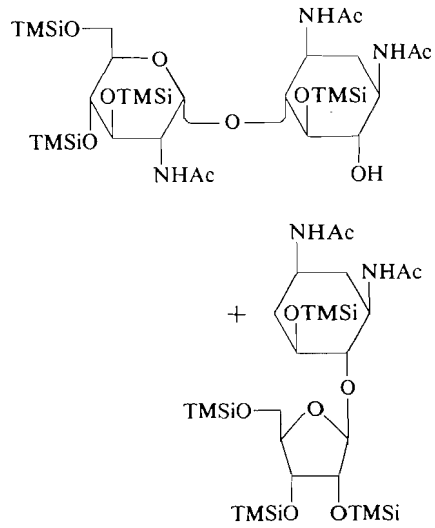
Compound **10** (1.34 g) was dissolved in a mixture of acetic acid (40 ml), dioxane (20 ml), and water (10 ml), and the solution was stirred at 50–55°C for 4 days. Evaporation gave a syrup, that was chromatographed on short silica gel column ($CHCl_3$). The fractions containing the major component were combined and evaporated to a syrup. Trituration with dichloromethane – di-2-propyl ether gave the title compounds as a chromatographically homogenous solid; yield 760 mg (64%); mp 242–243°C; $[\alpha]_D^{20}$ +52.8° (*c* 0.75, dioxane); tlc (toluene–EtOAc–MeOH, 15:10:3), R_f ~ 0.55. The product was suitable for transformations without further purification. A portion was subsequently purified by preparative thick-layer chromatography. *Anal.* calcd. for $C_{69}H_{67}N_3O_{21}$: C 65.03, H 5.30, N 3.30; found: C 64.68, H 5.23, N 3.13.

*6-O-(β-D-ribofuranosyl)tri-*N*-benzyloxycarbonylparomamine (**12**)*

A solution containing 300 mg of the preceding compound in 5 ml of dichloromethane was treated with a 0.1 solution of sodium methoxide in methanol (12 ml). After standing at room temperature overnight, the solution was treated with aqueous acetic acid to p*H* 5 and the solvents were removed under reduced pressure. Trituration of the residue with aqueous methanol gave the title compound as a chromatographically homogenous solid; yield 200 mg (98%); mp 260–265°C (dec.); $[\alpha]_D^{20}$ +41.4° (*c* 0.5, DMF). *Anal.* calcd. for $C_{41}H_{51}N_3O_{17}$: C 57.40, H 5.99, N 4.90; found: C 57.44, H 5.95, N 4.77.

*6-O-(β-ribofuranosyl)paromamine (**13**)*

A mixture containing 135 mg of **12** and 100 mg of 20% palladium-hydroxide-on-charcoal (27) in 30 ml of methanol–dioxane (2:1) was hydrogenated in the presence of 0.48 ml of *N* HCl. After 1 h, mixture was diluted with 10 ml of water and hydrogenation was continued for an additional 2 h. The suspension was filtered, the filtrate was treated with Rexyn 203 (OH^-), and the neutralized solution was processed as usual to give a colorless solid; yield 55 mg (77%). The product was chromatographically homogenous in several solvent systems; R_f 0.47; tlc, ($CHCl_3$ – MeOH – 28% NH_4OH, 1:3:2); $R_{paromamine}$ 1.00; paper chromatography (1-PrOH–pyridine–H_2O–AcOH, 15:10:12:3) $R_{paromamine}$ 1.24. The product could be precipitated from aqueous solution (minimum volume) by the addition of methanol or ethanol; mp 174–175°C (sintering at 145°C); $[\alpha]_D^{20}$ +34.2° (*c* 1, H_2O). As the free base, the product had a tendency to absorb variable amounts of carbonic acid depending on the periods of exposure to air. Its chromatographic properties were not altered however. For further characterization, a sample (2 mg) of the free base was acetylated (acetic anhydride in pyridine, 25%, 6 days), the product was treated with sodium methoxide, and the resulting *N*-acetyl derivative was *O*-silylated according to a previously described standard procedure (19), to give the *N*-acetyl *O*-trimethylsilyl derivative which was analyzed by high resolution mass spectrometry; *m/e* calcd. for a $C_{30}H_{63}N_3O_{10}Si_4$ fragment (containing the deoxystreptamine and D-glucosamine portions): 737.3590; found: 737.3586; *m/e* calcd. for a $C_{27}H_{57}N_2O_8Si_4$ fragment (deoxystreptamine, ribose): 649.3192; found: 649.3198, corresponding to the following fragments.



The mass spectral data of the corresponding tri-*N*-acetyl-*N*,*O*-permethyl derivative was also in accord with the gross structure, *m/e* 260 (D-glucosaminyl portion); *m/e* 175 (D-ribofuranosyl portion); *m/e* 530 (paromamine portion with loss of D-ribofuranosyloxy moiety), etc.

*6-O-(2,3,5-Tri-*O*-benzoyl-*β*-D-ribofuranosyl)-3′-O-benzoyl-6′-bromo-6′-deoxytri-*N*-benzyloxycarbonylparomamine (**20**)*

A solution containing 500 mg (0.4 mmol) of **20** (previously dried by azeotropic removal of traces of moisture with DMF at 110°C) and 330 mg (1.25 mmol) of triphenylphosphine in 15 ml of dry DMF was treated at 0°C and with stirring, with 125 mg (1.2 mmol) of *N*-bromosuccinimide. The solution was heated at 50°C for 3 days. After cooling, methanol (2 ml) was added to destroy excess halogenating reagent and the solution was evaporated under reduced pressure by co-distillation with 1-butanol. The residue was triturated with ether several times, until the remaining solid contained no more triphenylphosphine oxide. This solid (460 mg) was dissolved in 30 ml of chloroform and the solution was added to a short column (1.5 × 2.5 cm) containing silica gel. Elution with chloroform gave the title compound as a chromatographically homogenous colorless solid; yield 427 mg (85%); mp 215–218°C; $[\alpha]_D^{20}$ +64.0° (*c* 0.5, DMF). *Anal.* calcd. for $C_{69}H_{60}N_3O_{20}Br$: C 61.98, H 4.98, N 3.14; found: C 61.77, H 5.45, N 2.96.

*6-O-(β-D-Ribofuranosyl)-6′-azido-6′-deoxytri-*N*-benzyloxycarbonylparomamine (**21**)*

The preceding compound (370 mg) was dissolved in dry DMF (10 ml), sodium azide (200 mg) was added, and the mixture was heated at 100°C overnight. Evaporation of the solvent to a small volume, followed by a pouring in the water, gave a solid (300 mg, 83%); mp 213–215°C; this corresponded to the 6′-azido analog of **21**, which was suitable for use in the next step. Debenzoylation of this product in the presence of 0.5 *N* sodium methoxide in methanol (20 ml), followed by neutralization with aqueous acetic acid, evaporation, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

trituration of the residue with water, gave a colorless solid; yield 170 mg (83%). The product was chromatographically homogenous; tlc ($CHCl_3$–EtOAc–MeOH, 15:5:3) R_f 0.5; mp 233–237°C (dec.); $[\alpha]_D^{20}$ +48.4° (*c* 0.62, DMF); ν_{max} (KBr): 2100 cm^{-1}, N_3. *Anal.* calcd. for $C_{41}H_{50}N_6O_{16}$: C 39.41, H 4.03, N 6.72; found: C 39.22, H 4.15, N 6.42.

6-O-(β-D-Ribofuranosyl)neamine (22)

The preceding compound (128 mg) was hydrogenated in a 1:2 dioxane–methanol (30 ml) containing 0.7 ml of *N* HCl in the presence of 20% palladium-hydroxide-on-charcoal (100 mg). After 1 h, water (10 ml) was added and the hydrogenation was continued for 2.5 h. After filtration and processing of the filtrate as described for **13**, there was obtained a chromatographically homogeneous colorless solid (68 mg). The product was dissolved in a small volume of methanol and precipitated with ethanol to give the amorphous title compound; mp ~ 140°C (dec.); $[\alpha]_D^{20}$ +27.0° (*c* 0.5, H_2O); R_f 0.41 (tlc, $CHCl_3$–MeOH–NH_4OH, 1:3:2); R_f of ribostamycin, 0.35; R_f of **13**, 0.47 (lit. (23) mp 140°C (dec.); $[\alpha]_D^{20}$ +33.0° (H_2O); lit. (10) mp 175°C; $[\alpha]_D^{20}$ +33.0° (H_2O)). The corresponding *N*-dinitrophenyl derivative was obtained as follows. The product (50 mg) in 2.5 ml of water was treated with 50 mg of sodium bicarbonate followed by 20 mg of 2,4-dinitrofluorobenzene dissolved in 1.5 ml of ethanol. After stirring for 22 h, water (10 ml) was added and the resulting yellow solid was collected by filtration. The product was dissolved in dioxane and reprecipitated by the addition of ethanol and water; yield 65 mg; mp 195–198°C (dec.); $[\alpha]_D^{20}$ +186.6° (*c* 0.5, DMF); R_f 0.63 (tlc, $CHCl_3$–EtOAc–MeOH, 3:2:1).

6-O-(2,3,5-Tri-O-benzoyl-α-D-arabinofuranosyl)-3′-O-benzoyl-4′,6′-O-benzylidenetri-N-benzyloxycarbonylparomamine (23)

To a suspension containing **8** (1 g), mercuric cyanide (2 g) calcium sulfate (5 g) in 10 ml of DMF, and 30 ml of 1,2-dichloroethane was added a solution of 2,3,5-tri-*O*-benzoyl-α-D-arabinofuranosyl bromide (prepared from 2 g of the corresponding methyl glycoside by treatment with 10:1 acetic acid – acetic anhydride saturated with hydrogen bromide) in 10 ml of 1,2-dichloroethane. The mixture was stirred at 55°C for 18 h; it was then diluted with dichloromethane and the suspension was filtered through a layer of Celite. The filtrate was washed with aqueous bicarbonate, then with water. Processing of the organic phase in the usual manner gave a solid (1.15 g) which showed a major spot on tlc (toluene–EtOAc, 3:2). Further purification was achieved by chromatography on silica gel with chloroform as eluent. The title compound was thus obtained as a colorless amorphous solid. It was dissolved in dichloromethane and precipitated with di-2-propyl ether; yield 740 mg (50%); mp 238–241°C; $[\alpha]_D^{20}$ +28.3° (*c* 1, dioxane). *Anal.* calcd. for $C_{76}H_{71}N_3O_{21}$: C 67.00, H 5.25, N 3.09; found: C 66.96, H 5.25, N 3.22.

6-O-(α-D-Arabinofuranosyl)paromamine (25)

A solution containing **23** (130 mg) was dissolved in a mixture of acetic acid (4 ml), dioxane (2 ml), and water (1 ml), and the solution was stirred at 50°C for 4 days. Processing as described for **11** gave an amorphous solid that was homogenous by tlc, except for the presence of trace amounts of **7** (yield, 80 mg); purification by preparative tlc and debenzoylation as described for **12**, gave a product which was subjected to hydrogenation as in the case of **12**, to give the title pseudotrisaccharide (25 mg), as a colorless amorphous solid; mp foams ~120°C, decomposes ~140°; $[\alpha]_D$ +77.3° (*c* 1.01, H_2O); R_f 0.47 (tlc $CHCl_3$ – MeOH – 28% NH_4OH, 1:3:2); ms data on the corresponding *N*-acetyl-*O*-trimethylsilyl derivative *m/e*: 737 (4%), 649 (2%), see data under the preparation of **13**.

6-O-(2,3,5-Tri-O-benzoyl-β-D-xylofuranosyl)-3′-O-benzoyl-4′,6′-O-benzylidenetri-N-benzyloxycarbonylparomamine (26)

A suspension containing **8** (200 mg), mercuric cyanide (400 mg), and calcium sulfate (1 g) in a mixture of DMF (2 ml) and 1,2-dichloroethane (6 ml) was treated with 2,3,5-tri-*O*-benzoyl-D-xylofuranosyl bromide (2 ml; obtained from 0.7 g of the corresponding methyl glycoside derivative by treatment with a mixture of acetic acid saturated with hydrogen bromide and acetic anhydride (0.25 ml in 2 ml of 1,2-dichloroethane)). The mixture was stirred at 50°C for 3 days and processed as described for **10** to give a solid residue (from chloroform – di-2-propyl ether; yield 188 mg; 70%) which showed essentially one major spot on tlc. A portion was purified by preparative tlc (toluene–EtOAc, 3:2, R_f ~ 0.65) to give the title compound as a colorless amorphous solid; mp 251–256°C; $[\alpha]_D^{25}$ +11.0 (*c* 0.5, dioxane). *Anal.* calcd. for $C_{76}H_{71}N_3O_{21}$: C 67.00, H 5.25, N 3.09; found: C 66.47, H 5.30, N 3.09.

Aminoglycoside antibiotics: Studies directed toward the selective modification of hydroxyl groups: Synthesis of 3′-epiparomamine and 3′-epineamine[1,2]

STEPHEN HANESSIAN, ROBERT MASSÉ, AND TOSHIO NAKAGAWA[3]
Department of Chemistry, University of Montreal, Montreal, P.Q., Canada H3C 3V1

Received October 28, 1977

STEPHEN HANESSIAN, ROBERT MASSÉ, and TOSHIO NAKAGAWA. Can. J. Chem. **56**, 1509 (1978).

Based on the knowledge that certain bacterial strains can produce enzymes that are capable of phosphorylating the 3′-hydroxyl group of a series of aminoglycoside antibiotics, the pseudodisaccharide 3′-epiparomamine was prepared through a series of high yielding steps, starting from paromamine. Application of selective halogenation and subsequent amination reactions allowed the efficient transformation of 3′-epiparomamine to 3′-epineamine. The two compounds were not substrates for the inactivating enzymes, however, they are also much weaker antibiotics compared to the parent compounds paromamine and neamine. Model synthetic studies in the 2-amino-2-deoxy-D-glucose series are also reported.

STEPHEN HANESSIAN, ROBERT MASSÉ et TOSHIO NAKAGAWA. Can. J. Chem. **56**, 1509 (1978).

La synthèse de la 3′-epiparomamine et la 3′-epineamine fut réalisée à partir de la paromamine par des transformations chimiques, basée sur la connaissance que des enzymes dans certaines souches bactériennes sont capables d'inactiver une série d'antibiotiques aminoglycosidiques par phosphorylation sur la fonction 3′-hydroxyle. Les nouveaux pseudodisaccharides ne sont pas des substrats pour ces enzymes, pourtant leur pouvoir antibactérien est beaucoup plus faible comparé aux molécules parentes. Des réactions modèles dans la série D-glucosamine furent aussi réalisées.

Because of their therapeutic importance in the control of certain infections caused by gram-negative bacteria, the aminoglycoside antibiotics have recently been the target of extensive research work on several fronts (1–4). Experience has shown that even minor structural variations, induced chemically or enzymatically, can result in dramatic changes in the biological profile of a given aminoglycoside antibiotic (5–7). A delicate balance exists, therefore, between functional, structural, configurational, and conformational factors that is reflected in the biological roles of these substances at the molecular level. In view of the highly multifunctional, polar nature of these molecules, progress in the selective chemical modification at strategic positions has been relatively slow. For these and other reasons, we have been interested in exploring chemical methods for selective transformations involving hydroxyl groups, with the objective of ultimately applying them to the aminoglycosides.

One of the principal modes of enzymatic inactivation (3–5) of this group of antibiotics of the 2-deoxystreptamine type, that bear a C-3′ hydroxyl group, is via phosphorylation, mediated by a phosphotransferase, such as NPT_I.[4] The resulting 3′-phosphate esters of these aminoglycosides are devoid of biological activity. The presence of the entire molecule is not necessary for such enzymatic reactions, since pseudodisaccharides and pseudotrisaccharides in the same series are also substrates for these enzymes. The need for functional modifications specifically at C-3′ (and C-4′), based on the preceding biochemical rationales is, therefore, evident in a continuing quest for aminoglycosides that are less susceptible to the action of the phosphotransferases yet maintain, if not improve, their biological potency. Since enzyme–substrate interactions are particularly sensitive to configurational and conformational changes, chemical modifications of the paromamine and neamine pseudodisaccharides were envisaged, that should, in principle, result in an aberrant recognition by the phosphorylating enzymes. Epimerization, chain branching, and deoxygenation reactions at C-3′ were thus explored with model compounds, the premise being that promising results would encourage extension of these modifications to the parent antibiotics containing the above mentioned pseudodisaccharide units.

Peripheral transformations, as in the passage from a primary hydroxyl group to an amino group, were also studied in this context.

Model Substrates

A suitable, readily available model substrate for three of the above mentioned modifications was methyl 4,6-*O*-benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside (**1**) (8), in which the desired C-3 hydroxyl group is unsubstituted and can

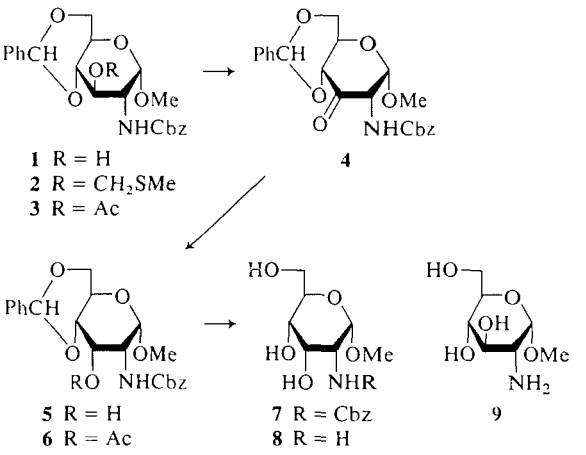
Δδ	+2.9	+4.8	+5.9	+3.1	+5.0	—	+0.4

be effectively modified. Moreover, the parent sugar, its analogs, and its positional isomers, constitute one of the amino sugar units in several aminoglycosides that are susceptible to the action of the phosphotransferases. The choice of the *N*-protecting benzyloxycarbonyl group was important, since, in addition to its anticipated compatibility with various conditions of reactions that were planned, it could be cleaved under mild hydrogenolytic conditions.

Oxidation of **1** with acetic anhydride in dimethyl sulfoxide (9) gave a 76% yield of the crystalline 3-uloside **4** and a small amount of the methylthiomethyl ether derivative **2**. Formation of the latter was avoided when the oxidation was done using dimethyl sulfoxide – *N*,*N*-dicyclohexylcarbodiimide (10) and the yield of crystalline material remained essentially unchanged. Based on a literature precedent involving the corresponding 2-benzamido derivative (11), it was anticipated that reduction of **4** with sodium borohydride would lead preponderantly to the D-*allo* analog **5**. Indeed, reduction of **4** gave a quantitative yield of **5**, which had discernibly different chromatographic properties compared to the epimeric **1**. Further confirmation of the structure of **5** was obtained from comparison of the nmr spectral characteristics of the acetate derivatives **3** and **6**, and the ^{13}C magnetic resonance spectra of the *N*,*O*-deblocked methyl glycosides **8** and **9**. Thus, selective cleavage of the acetal function in **5** gave methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-allopyranoside (**7**), which was subjected to hydrogenolysis to give methyl 2-amino-2-deoxy-α-D-allopyranoside (**8**), isolated as the amorphous hydrochloride salt. Similar treatment of **1** gave the epimeric methyl 2-amino-2-deoxy-α-D-glucopyranoside (**9**), isolated as the hydrochloride. These reactions are summarized in Scheme 1.

The ^{13}C spectral characteristics for the epimeric compounds **8** and **9** are recorded in Table 1. Except for the resonances of the hydroxymethyl and methoxyl carbon atoms, all other resonances undergo an upfield shift in the D-*allo* isomer. The most significant shift is observed for C-3 and agrees with data in the monosaccharide series (12) for upfield shifts associated with ^{13}C nuclei bearing axial hydroxyl groups. The large shielding effect observed for C-5 in compound **8** can be explained in the terms expressed by Perlin *et al.* (12), as there could exist a strong H_5–O_3 *syn*-diaxial interaction. Since the exact conformation of **8** relative to that of **9** is not known, some of the shielding effects could also presumably result from subtle conformational changes, thus enhancing the initial effect experienced by the ^{13}C nuclei adjacent to the one bearing the axial hydroxyl group.



SCHEME 1

It was next decided to explore the feasibility of a chain branching reaction at C-3 with the uloside derivative **4** as a model. Treatment of the latter with methylmagnesium iodide in tetrahydrofuran gave a high yield of the 3-*C*-methyl derivative **10** (Scheme 2). Mechanistic arguments and literature precedents (13) strongly favored the D-*allo* configuration for this product. A second objective in this series was to attempt a ring opening of the benzylidene acetal function in **10**, with *N*-bromosuccinimide (NBS) (14), as a means of functionalizing the terminal primary carbon atom. Treatment of **10** with NBS gave a 57% yield of the expected product **11**, thus encouraging

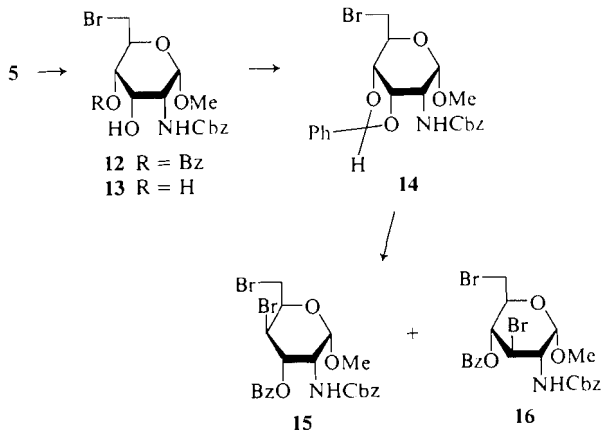
applications of the same sequence in the aminoglycoside series. Unfortunately, when the Grignard reaction was extended to a suitably protected paromamine derivative, no reaction occurred, presumably owing to the formation of an insoluble complex. Further work on chain branching reactions in this series was therefore abandoned.

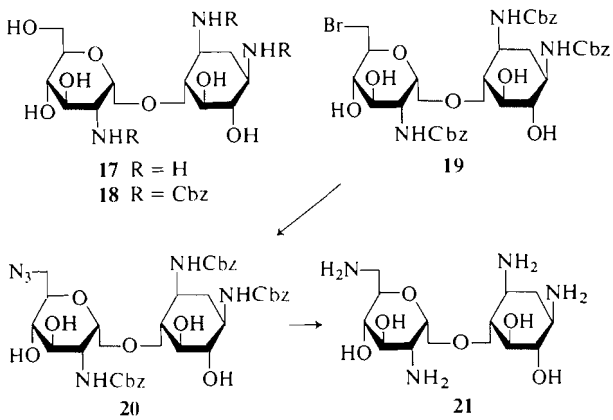
It was of interest next to study newer methods for the introduction of deoxy functions at C-3 and/or C-4 using a D-glucosamine derivative as a model. In previous work, we had shown that the reaction of methyl 2-azido-3,4-*O*-benzylidene-6-bromo-2,6-dideoxy-α-D-altropyranoside with NBS was highly stereoselective, since the preponderant product was the corresponding 3,6-dibromo derivative (15). The presence of a *cis*-diol group in **7** prompted us to prepare the corresponding *O*-benzylidene acetal and to study its reaction with NBS (Scheme 3). To avoid multiple blocking and deblocking steps, it was decided to first convert **5** into the corresponding 6-bromo derivative **12** via an NBS reaction. Sequential debenzoylation to **13** and acetal formation gave the 3,4-*O*-benzylidene derivative **14**. Treatment of the latter with NBS gave a mixture of two products **15** and **16** in a ratio of 1:1. The isomeric relationship between the two products was indicated by mass spectral data of the individual compounds. ^{1}H magnetic resonance spectral data allowed a tentative assignment of the D-*gulo* structure to the crystalline isomer **15**. In view of the moderate yield of the NBS reaction (42%) and the nonregiospecific distribution of products in the model studies, this approach to deoxygenation of aminoglycosides was not pursued further.

Finally, a practical method was sought to replace a primary hydroxyl group by an amino group, that could be adapted to the aminoglycoside series. Such a transformation is the basis of a well known and now classical procedure that consists in the nucleophilic displacement of primary sulfonic acid esters by a nitrogen nucleophile such as ammonia or azide ion; (see for example ref. 16).



SCHEME 3

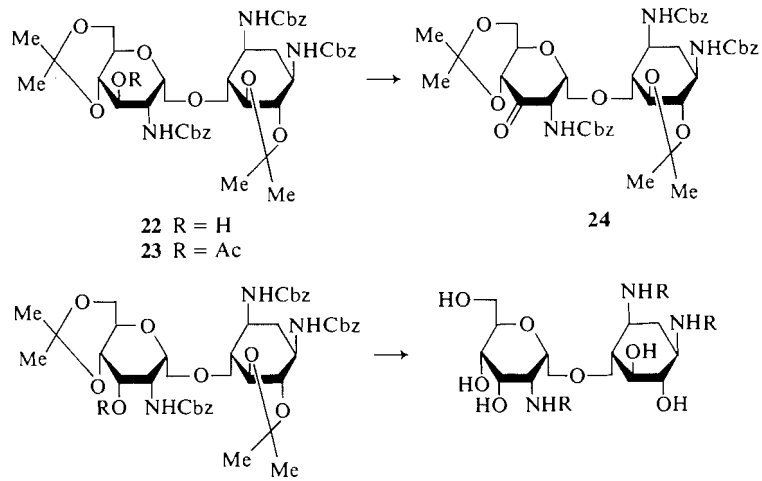
Although this procedure has been extensively used in monosaccharide chemistry, its applications in the area of aminoglycosides have been few and the yields have been moderate or low in most cases (17–19), except where selectivity was of little concern because of prior protection of many of the existing hydroxyl groups (20). In previous papers (21) we reported on the selective halogenation of primary hydroxyl groups in polyhydroxy compounds, containing a variety of substituents, with triphenylphosphine and the appropriate *N*-halosuccinimide. The reaction has been found to be remarkably suitable in the case of the polyfunctional *N*-substituted aminoglycosides as exemplified by the transformation of tri-*N*-benzyloxycarbonylparomamine (**18**) into neamine **21** in high overall yield via the corresponding 6′-bromo **19** and 6′-azido **20** derivatives (Scheme 4).



SCHEME 4

3′-Epiparomamine (28) and 3′-Epineamine (31)

The virtually stereospecific reduction of the 3-uloside derivative **4** paved the way to a similar reaction sequence in the paromamine series (**17**) with the objective of preparing 3′-epiparomamine (**28**) (22). The disposition of the hydroxyl groups in tri-*N*-benzyloxycarbonylparomamine (**18**) is such that acetal formation can take place, under somewhat forcing conditions, to the corresponding diisopropylidene derivative **22** (23) (Scheme 5). Oxidation of the latter with dimethyl sulfoxide and acetic anhydride gave the desired 3′-uloside derivative **24** in over 80% yield, after chromatographic purification. Reduction of **24** with sodium borohydride in a mixture of methanol and DMF, or with tri-*tert*-butylaluminium hydride in tetrahydrofuran, gave in each case the corresponding 3′-epiparomamine derivative **25** in high yield. This product has a significantly different chromatographic mobility compared to its



SCHEME 5

epimer **22**. Confirmation of the D-*allo* stereochemistry of the amino sugar portion was secured by chemical and spectroscopic means. Thus, acetylation of **22** and **25** individually, gave the respective 3′-acetates **23** and **26**, in which the signals for the acetyl methyl resonances were distinctly different, as would be expected from the presence of equatorial and axial acetate groups, respectively (24). This was further confirmed in the ^{1}Hmr spectrum of a sample of **26**, to which progressively increasing amounts of **23** were added. Treatment of **25** with 80% aqueous acetic acid effected cleavage of the acetal groups to give crystalline tri-*N*-benzyloxycarbonyl-3′-epiparomamine (**27**), which had discernibly different chromatographic properties compared to **17**. Finally, reductive cleavage of the *N*-protecting groups gave 3′-epiparomamine, isolated as the amorphous trihydrochloride salt **28**. Acid hydrolysis of **27** and chromatographic examination of the mixture revealed the presence of 2-deoxystreptamine and 2-amino-2-deoxy-D-allose. Ninhydrin degradation of this amino sugar gave rise to a neutral sugar that was identified as ribose by chromatography in several solvent systems. An identical degradation of 2-amino-2-deoxy-D-glucose gave arabinose as expected. The gross structural features of 3′-epiparomamine were also confirmed by high resolution mass spectral data, obtained on the corresponding *N*-benzyloxycarbonyl and *N*-acetyl *O*-trimethylsilyl derivatives (25). It is of interest that such *N*-benzyloxycarbonyl derivatives are amenable to mass spectral analysis, and give fragmentation patterns similar to those already known (25) in the *N*-acetyl series, with the exception that the fragments containing the amino sugar and 2-deoxystreptamine components give rise to peaks that have much lower relative intensities compared to the *N*-acetyl series.

Extension of the bromination reaction with the reagent pair Ph_3P–NBS to **27** was also successful and led to the formation of tri-*N*-benzyloxycarbonyl-6′-bromo-6′-deoxy-3′-epiparomamine (**29**) in high yield. In this case, the selective bromination was done at room temperature in HMPT as solvent, which illustrates the preparative utility of this reaction in this series (Scheme 6). Displacement of the bromine atom in **29** with azide ion in the usual manner led to the corresponding 6′-azido derivative **30** in high yield. Previous studies in this laboratory have in fact shown that it is possible to effect a sequential bromination and azide displacement reaction in one flask, which simplifies the manipulative part of these reactions, while maintaining the elements of practicality and efficacy. Finally, catalytic reduction of **30** caused a simultaneous hydrogenolysis of the benzyloxycarbonyl groups to give 3′-epineamine (**31**) isolated as the amorphous tetrahydrochloride salt. Its structural and functional features were confirmed by high resolution mass spectrometry and by ^{13}C spectral data. Like in the monosaccharide series, the effect of an inversion of configuration at C-3 in 3′-epiparomamine and 3′-epineamine, compared to the naturally occurring pseudodisaccharides (26, 27), is manifested by an upfield shift in the absorption of the ^{13}C nuclei corresponding to C-2′,C-5′ of the amino sugar moiety. Shielding of C-5′, however, was much less pronounced compared to **8**, possibly owing to orientational (rotamer) effects (28, 29) associated with the presence of a larger aglycone in the pseudodisaccharides. Upon acidification to $pH \simeq 1$, the expected β-shifts were observed in both

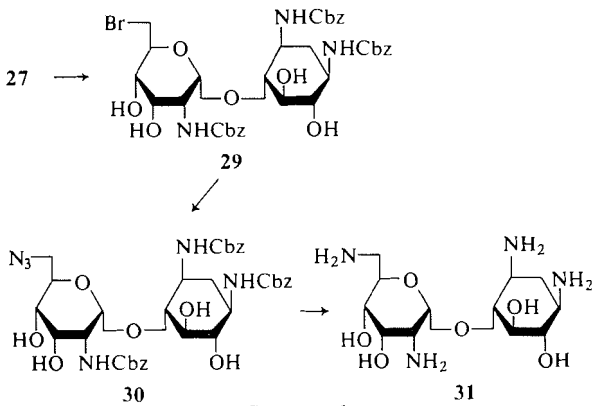
[a]Primed numbers refer to the carbon atoms of the amino sugar portion.
[b]Numbers with asterisks denote carbon atoms susceptible to β-shifts at acid p*H* values.



SCHEME 6

series, as can be seen in Table 2. An interesting feature in the spectrum of 3′-epineamine is the apparent large upfield shift of the C-4′ signal compared to that found in 3′-epiparomamine. This could be due to increasing 1,3-*syn* interactions with H-4–O-5, or more likely, to the presence of different rotamer populations (28, 29) associated with the $—CH_2NH_2$ group in 3′-epineamine. Such a γ effect (30) would be reflected in the spectrum of 3′-epineamine, upon changing the p*H*, but not as much in the case of the 3′-epimeric pseudodisaccharide **28**.

As anticipated at the outset of this study, 3′-epiparomamine was not a substrate[5] for the phosphotransferases that normally attack neomycin, paromomycin, and kanamycin among other related aminoglycosides (3, 4). Unfortunately, the antibacterial spectra of 3′-epiparomamine and 3′-epineamine were disappointing, compared to their respective parent pseudodisaccharides, although as expected, 3′-epineamine showed a better relative activity. Thus, while the effects of inactivating enzymes could be curtailed by inversion at C-3′ in paromamine and neamine, the subtle prerequisites for effective penetration into bacterial cells, and for binding to the ribosomes appear not to be fulfilled in the modified analogs.

[5]We are grateful to Professor J. Davies, University of Wisconsin, for these studies.

Experimental

Melting points are uncorrected. Optical rotations were measured on a Perkin-Elmer automatic spectropolarimeter, model 141. ^1H magnetic resonance spectra were recorded on a JEOL instrument at 60 MHz unless otherwise mentioned, with tetramethylsilane as internal standard and deuteriochloroform as solvent. ^{13}C spectra were recorded on a Bruker WH-90 instrument at 22.6 MHz, utilizing a frequency decoupler at 90 MHz. Samples (50–200 mg) were dissolved in deuterium oxide (0.8–1.2 ml) which was previously degassed. Dioxane or methanol were used as internal standards and showed signals at 67.4 and 49.8 ppm, respectively, downfield from tetramethylsilane (TMS). Spectra were measured at neutral p*H*, at p*H* ≃ 11, and p*H* ≃ 1, with appropriate p*H* adjustment with an anion exchange resin (Rexyn 203 OH^- form) and sulfuric acid, respectively. Sweeping frequencies varied from 10 000–90 000 scans depending on the concentration of the sample. Mass spectra were recorded on an AEI-902 mass spectrometer, at low and high resolutions. Column chromatography was done using silica gel G254, with application of moderate suction.

Methyl 4,6-O-Benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-D-ribo-hexopyranosid-3-ulose (4)

Oxidation with DMSO–Ac_2O

A solution containing 846 mg (2.05 mmol) of methyl 4,6-*O*-benzylidene-2-benzyloxycarbonyl-amino-2-deoxy-α-D-glucopyranoside (**1**) (8) in 16 ml of a 1:1 mixture of dimethyl sulfoxide and acetic anhydride was left at room temperature overnight. The solution was poured into 200 ml of ice-water with vigorous stirring, and the resulting precipitate was recovered by filtration and washing with cold water. The colorless solid (710 mg) consisted of the desired product, contaminated by a small amount of the corresponding methylthiomethyl ether derivative **2**. Recrystallization from 2-propanol gave 480 mg

(58%) of the ketone **4**. Additional material was obtained from the mother liquors by preparative thick-layer chromatography (benzene–EtOAc, 1:1); total yield, 640 mg (76%); mp 201–202°C; $[\alpha]_D^{27}$ +89.3° (*c* 2.45, $CHCl_3$); ν_{max} (KBr): 3295 (NH), 1745, 1685 cm^{-1} (C=O). *Anal.* calcd. for $C_{22}H_{23}NO_7$: C 63.91, H 5.60, N 3.38; found: C 64.19, H 5.45, N 3.40.

The methylthiomethyl ether derivative **2** was isolated from the above preparative thick-layer chromatographic separations; mp 188–189°C (2-propanol); $[\alpha]_D^{27}$ +154.5° (*c* 2.48, $CHCl_3$); nmr: 1.97 (s, CH_3S—), 3.35 (s, CH_3O—), 4.80 ppm (s, O—CH_2—S), etc. *Anal.* calcd. for $C_{24}H_{29}O_7NS$: C 60.61, H 6.14, N 2.94; found: C 60.69, H 6.09, N 2.88.

Oxidation with DMSO–DCC

A solution containing 1.49 g (3.91 mmol) of **1** in 25 ml of dimethyl sulfoxide was treated with 2.92 g (14.15 mmol) of dicyclohexylcarbodiimide and 1 g of phosphoric acid at 0°C. After 50 h at room temperature, the suspension was filtered and the filtrate was partitioned between chloroform (400 ml) and aqueous sodium bicarbonate (75 ml). Processing of the organic phase, evaporation to a small volume (~40 ml), and pouring into ice-water (500 ml) gave a colorless precipitate which was isolated by filtration. Drying under vacuum and recrystallization from 2-propanol gave the title compound (1.15 g, 77%); mp 201–202°C.

*Methyl 4,6-O-Benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-D-allopyranoside (**5**)*

To a solution containing 477 mg (1.15 mmol) of **4** in 5 ml of DMF and 15 ml of methanol was added 411 mg of sodium borohydride, in small portions and with external cooling. After 1 h at room temperature, the solution was evaporated to a small volume, diluted with chloroform (100 ml), and the solution was washed with water. Processing of the organic phase in the usual manner gave 480 mg of colorless chromatographically homogeneous solid. Recrystallization from a mixture of ethyl acetate and hexane gave the title compound (465 mg, 97%); mp 103–104°C; $[\alpha]_D^{27}$ +56.2° (*c* 3.15, $CHCl_3$); ν_{max} (KBr): 3420 (OH), 3330 (NH), 1685 cm^{-1} (NHCO). Compounds **1** and **5** had discernibly different chromatographic mobilities (tlc, $CHCl_3$–EtOAc, 5:1) showing R_f 0.42 and 0.55, respectively. *Anal.* calcd. for $C_{22}H_{25}NO_7$: C 63.60, H 6.06, N 3.37; found: C 63.42, H 6.12, N 3.49.

The 3-*O*-acetyl derivative **6**, prepared by acetylation of **5** with pyridine and acetic anhydride, was obtained as a colorless foam; $[\alpha]_D^{27}$ +28° (*c* 0.21, $CHCl_3$); ^{1}Hmr: 2.08 ppm (OAc). The epimeric acetate **3**, prepared from **1**, showed mp 188–189°C; $[\alpha]_D^{27}$ +154.4° (*c* 2.48, $CHCl_3$); ^{1}Hmr: 1.82 ppm (OAc).

*Methyl 2-Benzyloxycarbonylamino-2-deoxy-α-D-allopyranoside (**7**)*

A solution containing 211 mg of **5** in 80% aqueous acetic acid was left at room temperature for 12 h. Evaporation of the solvent gave a syrup that solidified from a mixture of 2-propanol and petroleum ether (bp 30–60°C); yield, 145 mg (87%); mp 82–83°C; $[\alpha]_D^{27}$ +69.4° (*c* 0.37, MeOH); ν_{max} (KBr): 1700 cm^{-1} (NHCO); R_f 0.24 (tlc, $CHCl_3$–EtOAc–MeOH, 25:15:3).

*Methyl 2-Amino-2-deoxy-α-D-allopyranoside Hydrochloride (**8**)*

A solution containing 250 mg of the preceding compound **7**, in 25 ml of methanol, was hydrogenated, in the presence of 100 mg of 20% palladium-hydroxide-on-charcoal (31). After 2 h, the suspension was filtered, the filtrate was evaporated to a syrup that was dissolved in 20 ml of methanol containing 1 ml of *N* hydrochloric acid. The yellow solution was decolorized with charcoal and processed in the usual way to give a colorless syrup that solidified under vacuum; yield 140 mg (90%); mp 80–85°C (softening); 112–115°C (foaming and decomposition); $[\alpha]_D^{27}$ +82.4° (*c* 0.21, MeOH). The product was chromatographically homogeneous, R_f 0.59 (tlc, $CHCl_3$ – MeOH – 28% NH_4OH, 1:3:1). The ^{13}C spectral parameters are listed in Table 1.

*Methyl 2-Amino-2-deoxy-α-D-glycopyranoside Hydrochloride (**9**)*

Catalytic hydrogenation of **1** (310 mg) in 20 ml of methanol as described above gave a syrup that solidified from aqueous ethanol to give 161 mg (88.5%) of the title compound; mp 118–120°C; $[\alpha]_D^{27}$ +126.5° (*c* 0.39, H_2O) (lit. (32) mp 119°C; $[\alpha]_D^{27}$ +129° (H_2O)); R_f 0.73 (tlc, $CHCl_3$ – MeOH – 28% NH_4OH, 1:3:1). The ^{13}C spectral parameters are listed in Table 1.

*Methyl 4,6-O-Benzylidene-2-benzyloxycarbonylamino-2-deoxy-3-C-methyl-α-D-allopyranoside (**10**)*

To a cooled solution of methylmagnesium iodide (prepared from 1.5 g (61.7 mmol) of magnesium turnings and 4 ml of methyl iodide in 30 ml of ether) was added the ketone **4** (811 mg, 1.96 mmol) in 40 ml of tetrahydrofuran, dropwise and with stirring. The mixture was heated at reflux for 5 h, excess reagent was destroyed with a 20% solution of ammonium chloride (50 ml), and the solution was extracted with chloroform. Processing of this solution in the usual manner gave a crystalline product that showed a major component on tlc ($CHCl_3$–EtOAc, 5:1). Recrystallization from ethanol gave the title compound; yield 673 mg, 80%; mp 138.5–140°C. A second recrystallization gave an analytical sample; mp 142–143°C; $[\alpha]_D^{27}$ +50.5° (*c* 4.69, $CHCl_3$); ^{1}Hmr: 1.30 (s, C—CH_3), 3.02 (bs, OH), 3.34 (s, OCH_3), 4.70 (d, H-1, $J_{1,2}$ = 3.7 Hz), 5.12 (s, $PhCH_2O$—), 5.52 (s, PhCH<O>O), 7.35 ppm (m, Ph), etc. *Anal.* calcd. for $C_{23}H_{27}NO_9$: C 64.32, H 6.33, N 3.26; found: 64.51, H 6.36, N 3.36.

*Methyl 4-O-Benzoyl-2-benzyloxycarbonylamino-6-bromo-2,6-dideoxy-3-C-methyl-α-D-allopyranoside (**15**)*

To a solution containing 468 mg (1.08 mmol) of **14** and 207 mg (1.16 mmol) of *N*-bromosuccinimide in 50 ml of carbon tetrachloride was added 2 g of barium carbonate and the mixture was heated at reflux for 20 min. Processing the mixture in the usual manner gave a pale yellow syrup that was purified by chromatography ($CHCl_3$–EtOAc, 25:2). The title compound was thus obtained as colorless crystals (316 mg, 57%); recrystallization was effected from a mixture of 2-propanol and petroleum ether; mp 89.5–90.5°C; $[\alpha]_D^{27}$ +58° (*c* 1.52, $CHCl_3$); ^{1}Hmr: 1.18 (s, C—CH_3), 3.48 (s, OCH_3), 4.83 ppm (d, H-1, $J_{1,2}$ = 3.7 Hz), etc. *Anal.* calcd. for $C_{23}H_{26}NO_7Br$: C 54.34, H 5.16, N 2.75; found: C 53.94, H 5.95, N 2.38.

*Methyl 4-O-Benzoyl-2-benzyloxycarbonylamino-6-bromo-2,6-dideoxy-α-D-allopyranoside (**12**)*

To a solution of **5** (323 mg, 0.87 mmol) in 50 ml of carbon tetrachloride was added 196 mg (1.1 mmol) of *N*-bromosuccinimide, followed by 1.3 g of barium carbonate. The suspension was heated at reflux for 30 min, the inorganic solids were filtered, and the filtrate was washed with water (20 ml) and dried. Evaporation gave a colorless syrup that crystallized from a mixture of 2-propanol and petroleum ether at 0°C; yield 231 mg, 60%; mp 151–151.5°C; $[\alpha]_D^{27}$ +74° (*c* 2.56, $CHCl_3$). *Anal.* calcd. for $C_{22}H_{24}NO_7Br$: C 53.44, H 4.85, N 2.8, Br 16.17; found: C 53.18, H 4.59, N 2.88, Br 16.05.

*Methyl 2-Benzyloxycarbonylamino-6-bromo-2,6-dideoxy-α-D-allopyranoside (**13**)*

Debenzoylation of compound **12** (312 mg) in the usual manner (sodium methoxide, methanol, 25°C, 30 min) followed by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

treatment of the solution with a small amount of Dowex-50 (H^+) and processing the solution gave the title compound as a syrup. Crystallization was effected from a mixture of 2-propanol and petroleum ether; yield, 240 mg, 93%; mp 114–115.5°C; $[\alpha]_D^{27}$ +66.8° (*c* 0.15, $CHCl_3$). *Anal.* calcd. for $C_{15}H_{20}NO_6Br$: C 46.16, H 4.16, N 3.51; found: C 46.22, H 4.45, N 3.32.

*Methyl 3,4-O-Benzylidene-2-benzyloxycarbonylamino-6-bromo-2,6-dideoxy-α-D-allopyranoside (**14**)*

Zinc chloride (1.5 g) was added to a solution containing **13** (250 mg, 0.64 mmol) in 5 ml of benzaldehyde and the resulting suspension was stirred at room temperature for 36 h. The mixture was poured into ice-water containing 10 g of sodium bicarbonate, the solids were filtered, and the filtrate was extracted with chloroform. Processing as usual gave a syrup that was purified by chromatography (benzene–EtOAc, 5:1) to give the title compound as a homogeneous syrup, yield 182 mg, 60%; $[\alpha]_D^{27}$ +15.8° (*c* 2.21, $CHCl_3$). ^1H magnetic resonance spectral analysis indicated the presence of a 4:1 mixture of diastereoisomers: 3.49 (bs, 2H, $PhCH_2O$—), 5.95 and 6.27 ppm (s, PhCH<O/O>), etc. This compound was used as such for subsequent transformations.

*Reaction of Acetal **14** with* N-*Bromosuccinimide*

A suspension containing **14** (170 mg, 0.35 mmol), *N*-bromosuccinimide (71 mg, 0.39 mmol), and 800 mg of barium carbonate in 25 ml of carbon tetrachloride was heated at reflux for 2 h. Filtration and evaporation of the filtrate gave a colorless syrup (107 mg) which showed the presence of two major products by tlc (benzene–EtOAc, 5:1). Separation by preparative thick-layer chromatography gave 41 mg of a product having R_f 0.71, and 42 mg of a product having R_f 0.84 (total yield, 42%).

The former product is tentatively assumed to be *methyl 4-O-benzoyl-2-benzyloxycarbonylamino-3,6-dibromo-2,3,6-trideoxy-α-D-glycopyranoside* (**16**); $[\alpha]_D^{27}$ +40.6° (*c* 1.04, $CHCl_3$). The product having R_f 0.84 crystallized from 2-propanol and was assigned the isomeric structure *methyl 3-O-benzoyl-2-benzyloxycarbonylamino-4,6-dibromo-2,4,6-trideoxy-α-D-glucopyranoside* (**15**); mp 101–102°C; $[\alpha]_D^{27}$ +41.7° (*c* 0.12, $CHCl_3$); nmr: 3.60 (s, 3H, OCH_3), 4.22 (dd, H-4, $J_{4,3}$ = 1.5 Hz, $J_{4,5}$ = 6.7 Hz), 4.48 (dd, H-2, $J_{2,1}$ = 3.7 Hz, $J_{2,3}$ = 3.3 Hz), 5.16 (s, $PhCH_2O$—), 5.60 (t, H-3, $J_{3,2}$ = 3.3 Hz, $J_{3,4}$ = 1.5 Hz), 7.60, 7.80 ppm (m, Ph), etc. *Anal.* calcd. for $C_{22}H_{23}NO_6Br_2$: C 47.42, H 4.16, N 2.51; found: C 47.97, H 4.59, N 2.24.

*Selective Bromination of Tri-*N*-benzyloxycarbonylparomamine. Synthesis of Tri-*N*-benzyloxycarbonyl-6′-bromo-6′-deoxyparomamine (**19**)*

A 349 mg (0.48 mmol) sample of tri-*N*-benzyloxycarbonylparomamine (**18**) (23), previously freed from traces of moisture by azeotropic removal of water with pyridine, was added to 258 mg (0.98 mmol) of triphenylphosphine in 15 ml of dry hexamethylphosphoramide (HMPT). To the stirred and cooled solution was added 158 mg (0.89 mmol) of NBS, in portions, over a period of 5 min. The pale yellow solution was stirred at 55°C for 10 h, excess reagent was destroyed by addition of methanol (5 ml), and the solvents were removed *in vacuo* at 70°C. The syrupy dark yellow residue solidified when triturated with cold water. A major portion of triphenylphosphine oxide was removed by successive trituration with hot petroleum ether. The residual solid was recrystallized from ethanol to give 341 mg (82%) of the title compound; mp 241–243°C; $[\alpha]_D^{27}$ +49.3° (*c* 0.80, DMF). *Anal.* calcd. for $C_{36}N_{42}N_3O_{12}Br$: C 54.82, H 5.36, N 5.32; found: C 54.60, H 5.40, N 5.21.

A slightly lower yield (76%) was obtained in DMF but longer times were required to effect complete reaction (72 h) and there was considerable discoloration of the mixture.

Acetylation of **19** gave the crystalline tetraacetate derivative; mp 211.5–212.5°C; $[\alpha]_D^{27}$ +79.5° (*c* 0.22, $CHCl_3$).

*6′-Azidotri-*N*-benzyloxycarbonyl-6′-deoxyparomamine (**20**)*

A mixture containing 210 mg (0.36 mmol) of the preceding bromo derivative and 215 mg of sodium azide in 6 ml of dry HMPT was heated at 55°C for 5 h. The solution was poured dropwise and with vigorous stirring into ice-water (200 ml) and the resulting precipitate was filtered, washed well with water, and dried. The desired product was reprecipitated from hot ethanol; yield 163 mg (81.5%); mp 240–242°C; $[\alpha]_D^{27}$ +68° (*c* 0.75, DMF); ν_{max} (KBr): 3400–3350 (OH, NH), 2100 (N_3), 1665 cm^{-1} (C=O). The product was chromatographically homogeneous and was used as such in the following step.

The yield was essentially the same when the reaction was done in DMF (90°C, 20 h).

The amorphous tetraacetate derivative of **20** (mp 123–125°C; $[\alpha]_D^{27}$ +66° (*c* 0.29, $CHCl_3$)) was obtained in the usual manner.

*Neamine (**21**)*

The preceding compound (139 mg, 0.18 mmol) was hydrogenated in the presence of 20% palladium-hydroxide-on-charcoal (31) in a mixture of methanol (2 ml) and dioxane (12 ml) containing 5 ml of 0.1 *N* hydrochloric acid. After 2.5 h, the catalyst was filtered and washed with water. Processing the filtrate gave a colorless syrup that was dissolved in a few drops of water; addition of ethanol gave the title compound as the hydrochloride salt; yield 71.5 mg (83%); mp 220–225°C (dec.); $[\alpha]_D^{27}$ +82.9° (*c* 0.66, H_2O) (lit. (18) mp 233°C (dec); $[\alpha]_D^{27}$ +86.8° (H_2O)).

The product was identical to authentic neamine in two solvent systems. ^{13}C spectral data are provided in Table 2.

*4-O-(3-O-Acetyl-2-benzyloxycarbonylamino-2-deoxy-4,6-O-isopropylidene-α-D-glycopyranosyl)-1,3-di-*N*-benzyloxycarbonyl-5,6-O-isopropylidene-2-deoxystreptamine (**23**)*

A solution containing 400 mg (0.49 mmol) of tri-*N*-benzyloxycarbonyl-di-*O*-isopropylideneparomamine (**22**) (23) in 2 ml of dry pyridine as treated with acetic anhydride (0.4 ml). After 18 h, the solvent was co-distilled with toluene at 30–35°C and the residual syrup was triturated from a mixture of dioxane and cyclohexane. The resulting colorless solid was filtered and dried; yield 358 mg (85%). That product was chromatographically homogeneous; mp 123–135°C; $[\alpha]_D^{27}$ +46.1° (*c* 1.0, $CHCl_3$); ^1Hmr: 1.93 ppm (s, CH_3COO), etc. *Anal.* calcd. for $C_{44}H_{53}N_3O_{14}\cdot H_2O$: C 61.03, H 6.40, N 4.96; found: C 61.30, H 6.25, N 4.88.

*4-O-(2-Benzyloxycarbonylamino-2-deoxy-4,6-O-isopropylidene-α-D-ribohexopyranose-3-ulosyl)-1,3-di-*N*-benzyloxycarbonyl-5,6-O-isopropylidene-2-deoxystreptamine (**24**)*

A solution containing **22** (1.83 g, 2.27 mmol) in a mixture of dimethyl sulfoxide (20 ml) and acetic anhydride (20 ml) was kept in the dark at room temperature for 3 days. Evaporation of the solvent gave a residue that was dissolved in dichloromethane (60 ml) and the solution was washed with aqueous sodium bicarbonate and then with water. Processing of the organic phase gave a solid residue that was purified by chromatography (CH_2Cl_2–ether, 1:1). The product was isolated as an amorphous solid and reprecipitated from dioxane – cyclohexane (containing a drop of triethylamine); yield 1.51 g (82.5%); mp 152–154°C; $[\alpha]_D^{27}$ +39° (*c* 0.40, $CHCl_3$). *Anal.* calcd. for $C_{42}H_{49}N_3O_{19}$: C 62.75, H 6.14, N 5.25; found: C 62.43, H 6.12, N 5.28.

4-O-(2-Benzyloxycarbonylamino-2-deoxy-4,6-O-isopropylidene-α-D-allopyranosyl)-1,3-di-N-benzyloxycarbonyl-5,6-O-isopropylidene-2-deoxystreptamine (25)

To a cooled solution of the ketone **24** (713 mg, 0.89 mmol) in 1.5 ml of DMF and 30 ml of methanol was added, in portions and with stirring, 299 mg (7.94 mmol) of sodium borohydride. After 18 h at room temperature, the solution was diluted with cold water (50 ml) and the resulting precipitate was collected by filtration, washed, and dried. Recrystallization from a mixture of ethanol and petroleum ether in the presence of a drop of triethylamine gave 565 mg (80%) of the title compound; mp 174–176°C; $[\alpha]_D^{27}$ +26° (*c* 0.50, $CHCl_3$). The product was discernibly different on tlc (benzene–EtOAc, 1:1) showing R_f 0.55, compared to the epimeric **22**, which showed R_f 0.32. *Anal.* calcd. for $C_{42}H_{51}N_3O_{13}$: C 62.60, H 6.38, N 5.21; found: C 62.00, H 6.43, N 5.38.

Reduction in the presence of lithium tri-*tert*-butylaluminium hydride (0°C, then 12 h at 25°C, in THF) gave the same product, in essentially the same yield as above. The mother liquors did not contain detectable amounts of the epimeric alcohol **22**, as evidenced by tlc, but consisted of more of the same product.

4-O-(3-O-Acetyl-2-benzyloxycarbonylamino-2-deoxy-4,6-O-isopropylidene-α-D-allopyranosyl)-1,3-di-N-benzyloxycarbonyl-5,6-O-isopropylidene-2-deoxystreptamine (26)

The preceding compound (100 mg) was acetylated in a mixture of pyridine (1 ml) and acetic anhydride (0.5 ml). After 24 h, the solvent was removed by co-distillation with toluene and the syrupy residue was heated with a mixture of dioxane and cyclohexane to give a colorless solid (95 mg, 90%) that was chromatographically homogeneous; mp 106–108°C; $[\alpha]_D^{27}$ +35° (*c* 0.54, $CHCl_3$); ^{1}Hmr: 2.13 ppm (s, CH_3COO), etc.; compare with 1.93 ppm for the equatorial acetate group in the epimeric **21**. *Anal.* calcd. for $C_{44}H_{53}N_3O_{14}\cdot H_2O$: C 61.03, H 6.40, N 4.96; found: C 61.30, H 6.25, N 4.88.

4-O-(2-Benzyloxycarbonylamino-2-deoxy-α-D-allopyranosyl)-1,3-di-N-benzyloxycarbonyl-2-deoxystreptamine (Tri-N-benzyloxycarbonyl-3′-epiparomamine) (27)

A solution of **25** (300 mg) in 10 ml of 80% acetic acid was heated at 65–70°C for 1 h. The solvent was evaporated under reduced pressure and the residual crystalline solid was triturated with 50 ml of cold water. Filtration, washing with water, and drying gave the title compound which was recrystallized from methanol; yield 227 mg (84%); mp 243–245°C; $[\alpha]_D^{27}$ +42.8° (*c* 2.12, DMF); $[\alpha]_D^{27}$ +40° (*c* 2.10, dioxane); R_f 0.47 (tlc, $CHCl_3$–EtOAc–MeOH, 20:5:3). The C-3′ epimeric paromamine analog **18** showed R_f 0.40. *Anal.* calcd. for $C_{36}H_{43}N_3O_{13}$: C 59.58, H 5.97, N 5.79; found: C 59.15, H 6.26, N 5.59.

4-O-(2-Amino-2-deoxy-α-D-allopyranosyl)-2-deoxystreptamine (3′-Epiparomamine Trihydrochloride) (28) (23)

A mixture containing 467 mg of the preceding compound and 311 mg of palladium-hydroxide-on-charcoal (31) in 20 ml of methanol and 25 ml of dioxane containing 10 ml of 0.1 *N* hydrochloric acid was hydrogenated for 5 h. The catalyst was filtered on a layer of Celite, washed with 10 ml of water, and the filtrate was evaporated to dryness. The resulting yellow syrup was dissolved in water, the solution was decolorized with charcoal and processed as usual to give a colorless syrup that solidified from a mixture of water and ethanol. The colorless amorphous solid was dried at 50°C for 24 h; yield 254 mg (91%) of 3′-epiparomamine trihydrochloride (**28**); mp > 240°C (dec.); $[\alpha]_D^{27}$ +72.5° (*c* 0.60, H_2O); R_f 0.44 (tlc, $CHCl_3$–MeOH–28% NH_4OH, 1:3:2). On paper chromatograms (1-propanol – pyridine – acetic acid – water, 15:10:3:12) the product showed $R_{glucosamine}$ 0.19 and $R_{paromamine}$ 0.23 (21 h elution); high resolution mass spectral data for the tri-*N*-acetylper-*O*-trimethylsilyl derivative: *m/e* calcd. for fragment $C_{17}H_{38}NO_5Si_3$: 420.2058; found: 420.2072; calcd. for fragment $C_{16}H_{33}N_2O_4Si_2$: 373.1979; found: 373.1984; ^{13}C spectral data for 3′-epiparomamine are shown in Table 2.

Chemical characterization of 3′-epiparomamine was effected by hydrolytic studies. Acid hydrolysis (acetic acid – water – hydrochloric acid – 2-methoxymethanol, 10:3:2:5) (23) of tri-*N*-benzyloxycarbonyl-3′-epiparomamine at 100–110°C for 15 h, followed by paper chromatographic examination of the mixture, revealed the presence of two components, corresponding to 2-amino-2-deoxyallose (R_f 0.46) and 2-deoxystreptamine (R_f 0.20 (1-butanol – pyridine – water – acetic acid, 5:5:3:1) (33). In the same system, 2-amino-2-deoxy-D-glucose showed R_f 0.49 and the two amino sugars were easily separated, when analyzed individually or as a mixture.

4-O-(2-Benzyloxycarbonylamino-6-bromo-2,6-dideoxy-α-D-allopyranosyl)-1,3-di-N-benzyloxycarbonyl-2-deoxystreptamine (29)

Tri-*N*-benzyloxycarbonyl-3′-epiparomamine (**27**) (303 mg, 0.41 mmol) was dissolved in 20 ml of HMPT and the solution was reduced to half its volume by distillation under reduced pressure at 90°C to remove traces of moisture. The solution was diluted with 10 ml of dry HMPT, 227 mg (0.86 mmol) of triphenylphosphine was added, the solution was cooled to 0°C then treated with *N*-bromosuccinimide (146 mg, 0.82 mmol) as previously described. After stirring at room temperature for 10 h, tlc analysis revealed that the starting material had been transformed to a less polar product. Excess reagent was destroyed with methanol and the solvents were removed at 70°C *in vacuo*. The resulting syrup was dissolved in 3 ml of chloroform and the solution was diluted with ether to give a solid. This treatment eliminated a major portion of the triphenylphosphine oxide which remained in solution. The residual solid was isolated by decantation of the supernatant solution. It was then triturated with water, filtered, and air dried. Thin-layer chromatographic examination of the solid revealed the presence of a major product and traces of triphenylphosphine oxide and polar impurities. These were removed by trituration with chloroform, to leave a chromatographically homogeneous solid (200 mg). The filtrate was concentrated and applied to thick-layer plates ($CHCl_3$–EtOAc–MeOH, 20:5:2) to give 60 mg of the expected bromo derivative; total yield 260 mg (79%). Recrystallization was effected from ethanol; mp 209–211°C; $[\alpha]_D^{27}$ +25.9° (*c* 0.7, EtOH); *m/e*: 502 (corresponding to the glycosyl cation), 412, 315, etc; *m/e* 557 (corresponding to the 2-deoxystreptamine cation, with loss of a glycosyloxy portion from M^+), etc.

4-O-(6-Azido-2-benzyloxycarbonylamino-2,6-dideoxy-α-D-allopyranosyl)-1,3-di-N-benzyloxycarbonyl-2-deoxystreptamine (30)

A solution containing 217 mg (0.27 mmol) of the preceding compound and 225 mg of sodium azide in 7 ml of HMPT was heated at 55°C with stirring for 4 h. The solution was then cooled and added dropwise to 100 ml of ice-water, and the resulting precipitate was collected by filtration. The solid was dissolved in methanol, traces of insoluble material were removed by filtration, the filtrate was evaporated to dryness, and the residue was recrystallized from ethanol to give the title compound; yield 115 mg (56%); mp 195–197°C; $[\alpha]_D^{27}$ +36° (*c* 0.80, MeOH); ν_{max} (KBr): 2100 cm^{-1} (N_3). *Anal.* calcd. for $C_{36}H_{42}N_6O_{12}\cdot H_2O$: C 56.24, H 5.50, N 10.93; found: C 56.27, H 5.17, N 10.76.

4-O-(2,6-Diamino-2,6-dideoxy-α-D-allopyranosyl)-2-deoxystreptamine Tetrahydrochloride (3′-Epineamine Tetrahydrochloride) (31)

A suspension containing the preceding compound (104 mg,

0.13 mmol), 105 mg of palladium-hydroxide-on-charcoal catalyst in a 1:1 mixture of dioxane (10 ml), and 0.5 *N* hydrochloric acid (10 ml) was hydrogenated for 5 h. After filtration and evaporation of the filtrate, a pale yellow syrup was obtained. Treatment of an aqueous solution with decolorizing carbon and processing in the usual manner gave a colorless solid that was dissolved in the minimum volume of water containing 0.5 ml of methanol and was reprecipitated by addition of ethanol. The title compound was thus obtained as a chromatographically homogeneous solid; yield 60 mg (93%); mp 200–205°C (dec.); $[\alpha]_D^{27}$ +62.1° (*c* 0.66, H_2O); R_f 0.37 in $CHCl_3$ – MeOH – 28% NH_4OH, 1:3:2. Neamine showed R_f 0.45 in the same solvent system; high resolution mass spectral data for the tetra-*N*-acetylper-*O*-trimethylsilyl derivative: *m/e* calcd. for fragment $C_{16}H_{33}N_2O_5Si_2$: 389.1928; found: 389.1949; calcd. for fragment $C_{16}H_{33}N_2O_4Si_2$: 373.1979; found: 373.1990; ^{13}C spectral data for 3′-epineamine are shown in Table 2.

The dissociation constant for potassium methylamide ion pairs in methylamine[1]

E. ALLAN SYMONS AND J. DOUGLAS BONNETT

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ont., Canada K0J 1J0

Received November 24, 1977

E. ALLAN SYMONS and J. DOUGLAS BONNETT. Can. J. Chem. **56**, 1518 (1978).

The limiting equivalent conductance (Λ_0) and ion pair dissociation constant (K_d) have been obtained for potassium methylamide in methylamine from conductance data measured over the temperature range -55 to $+25$°C. The value of K_d increases from 6.3×10^{-8} mol L^{-1} at the highest temperature to 9.4×10^{-7} mol L^{-1} at the lower limit. The results show good agreement with literature data for potassium amide in ammonia after corrections for differences in solvent viscosity and dielectric constant. The heat of dissociation is -26 kJ mol^{-1} above -15°C, but decreases gradually at progressively lower temperatures as a shift occurs from tight to loose ion pair structures.

E. ALLAN SYMONS et J. DOUGLAS BONNETT. Can. J. Chem. **56**, 1518 (1978).

On a déterminé la conductivité équivalente limite (Λ_0) et la constante de dissociation des paires d'ions (K_d) pour le méthylamidure de potassium dans la méthylamine à partir de données de conductivité mesurées à des température allant de -55 à $+25$°C. La valeur de K_d augmente de 6.3×10^{-8} mol L^{-1} jusqu'à 9.4×10^{-7} mol L^{-1} lorsque l'on passe de la température la plus élevée à la limite inférieure. Les résultats montrent une bonne concordance avec les données de la littérature pour l'amidure de potassium dans l'ammoniac après corrections pour les différences de viscosité de solvant et de constante diélectrique. La chaleur de dissociation est de -26 kJ mol^{-1} au dessus de -15°C mais cette valeur diminue graduellement à mesure que la température diminue; ce résultat est le reflet d'un déplacement qui se produit dans les structures des paires d'ions qui passent d'une nature intime vers une structure plus lâche.

[Traduit par le journal]

Introduction

A chemical process based on isotopic exchange between molecular hydrogen and methylamine has been considered (1) as an alternative to the hydrogen sulphide – water exchange process currently used in Canada for the production of heavy water. Unlike the latter process, the methylamine system requires an added catalyst (eq. [1]) to accelerate the deuterium isotope exchange rate to a useful level. The compounds examined as potential catalysts have been the alkali metal salts of methylamine, with potassium methylamide (PMA) receiving the most study.

$$[1] \qquad HD + CH_3NH_2 \xrightarrow{PMA} H_2 + CH_3NHD$$

In spite of the extensive body of kinetic data now available from Holtslander,[2] Kalra and Otto (2), and Rochard and Ravoire (3) for isotope exchange in concentrated solution, the mechanism of reaction [1] has yet to be clarified. A major problem has been the lack of information concerning the degree of dissociation of the catalyst PMA into free ions, eq. [2]. Since methylamine has a fairly low dielectric constant (about 9.4 at 25°C), concentrated PMA solutions should consist of a mixture of free ions, ion pairs, triple ions, and larger ion aggregates. Rochard has reported the values 3×10^{-7} mol L^{-1} at -90°C and 4×10^{-7} mol L^{-1} at -62°C for the ion pair dissociation constant, K_d, in dilute solution (3, 4).

$$[2] \qquad CH_3NH^-K^+ \overset{K_d}{\rightleftharpoons} CH_3NH^- + K^+$$

The results of an electrical conductivity study of K_d for PMA as a function of temperature over the range -55 to $+25$°C are now presented.

Experimental

Reagents

Water and most of the ammonia were removed from commercial methylamine (Matheson) by at least one treatment of the liquid with lithium metal. The precipitated mixture of lithium hydroxide and amide was left behind during subsequent fractional vacuum distillation onto fresh lithium. Ammonia analysis was by gas chromatography: TC detector, He at 30 mL min^{-1}, 2 m × 6 mm column packed with 28% Pennwalt 223 – 4% KOH on 80–100 mesh Gas Chrom R. Liquid amine samples were diluted 1:3 with absolute ethanol, 100 μL of the resultant solutions being injected at 65°C isothermal. Purified methylamine was found to contain between 3×10^{-3} and 2×10^{-2} mol L^{-1} NH_3.

Stock PMA solutions were prepared as described previously (5). Standard KCl solutions were made up with J. T. Baker Ultrex grade KCl and quadruple-distilled water (acidic dichromate and alkaline permanganate treatments).

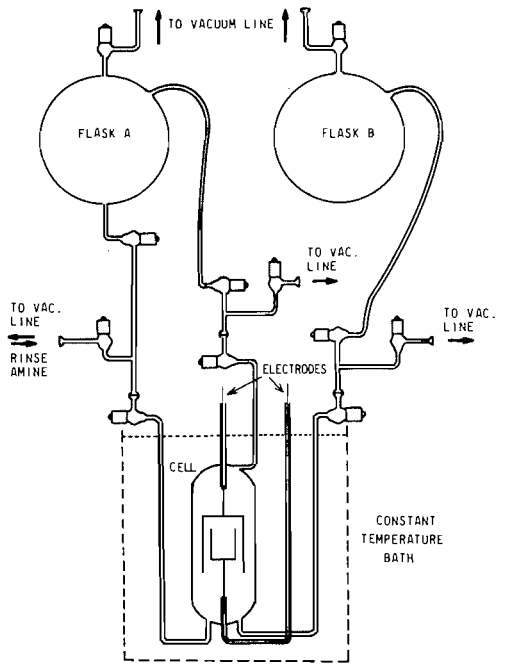

FIG. 1. Apparatus used to study electrical conductivity of methylamine solutions.

Apparatus

The constant temperature bath was a Neslab model LTV 40 low temperature type with a side window. Absolute ethanol was used as bath fluid over the range −60 to +25°C; control was better than ±0.02°C. Temperatures were measured with a Stolab 911 PL electronic thermometer that had been calibrated against a standard platinum resistance thermometer; accuracy was ±0.02°C.

Conductivity cell resistance was measured with a Beckman RC-18A bridge, with a specified accuracy of ±0.05% over the range 500 to 50 000 Ω. The design of the electrode system was based on the recommendations of Nichol and Fuoss (6). The pair of concentric platinum cylinders (1 cm diameter × 2 cm long and 2 cm diameter × 3 cm long) was mounted vertically in the conductivity cell (see Fig. 1). The cell was calibrated at 25.0°C with KCl solutions. The cell constant, an average of 0.0351 ± 0.0012 cm^{-1} for three determinations, was obtained by using the equation of Fuoss and co-workers (7).

Conductivity Measurements

The solution handling and conductivity cell systems are illustrated in Fig. 1. The vessels were constructed of Pyrex glass, with liquid feedthrough tubes ring-sealed at the vertical O-ring joint connection points to prevent solution contact with the ethylene–propylene rubber O-rings. The latter had been pretreated with concentrated PMA solution. The standard Teflon–glass stems in the J. Young Co. greaseless valves were replaced with chemically more resistant low density polyethylene stems.

To remove water still on the vessel walls after normal vacuum drying (8), the system was rinsed with concentrated PMA solution and then dry methylamine. The temperature of the bath was lowered or raised from ambient to facilitate liquid transfer into the cell from flask A or out of the cell to waste storage flask B, respectively.

The conductance solutions were prepared in flask A by successive dilution with dry methylamine (vacuum transfer), starting from a stock concentrated PMA solution of known concentration. The first portion of each such solution was used to rinse the cell again. The concentrations of the diluted solutions were calculated from the measured weight of added methylamine at each stage.

A series of resistance readings was made at 1000 and 3000 Hz as a function of temperature for each concentration. The readings normally stabilized within 15 to 20 min after a change in temperature. For values above about 90 kΩ, a 10 kΩ precision resistor (0.01%) was placed in parallel with the cell (9). A correction (usually less than 0.1%) was made for the effects of electrode polarization, using the procedure of Robinson and Stokes (10).

Equivalent conductance values (Λ) were calculated from the resistance data in the normal manner. The correction for the specific conductance of the solvent ranged from two percent for the concentrated solutions to ten percent for the most dilute ones. The Λ data are believed to be accurate within ±10% for these highly reactive solutions, based on likely errors in resistance and concentration values.

Results

Plots of Λ at constant temperature versus the square root of the stoichiometric concentration produced the curves normally expected for an ion-paired electrolyte in a solvent of moderately low dielectric constant (11) (see Fig. 2). However, when some data obtained by Holtslander[2] at higher concentrations up to 0.4 mol L^{-1} were included, there was no indication of the shallow minimum usually seen at the onset of formation of triple ions (10).

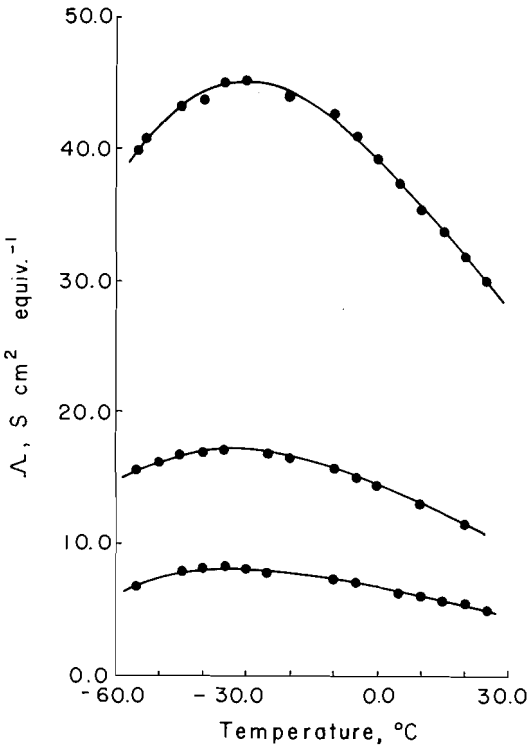

FIG. 3. Dependence of potassium methylamide solution equivalent conductance on temperature at (top to bottom) 9.04×10^{-6}, 5.01×10^{-5}, and 2.84×10^{-4} mol L^{-1} (25°C).

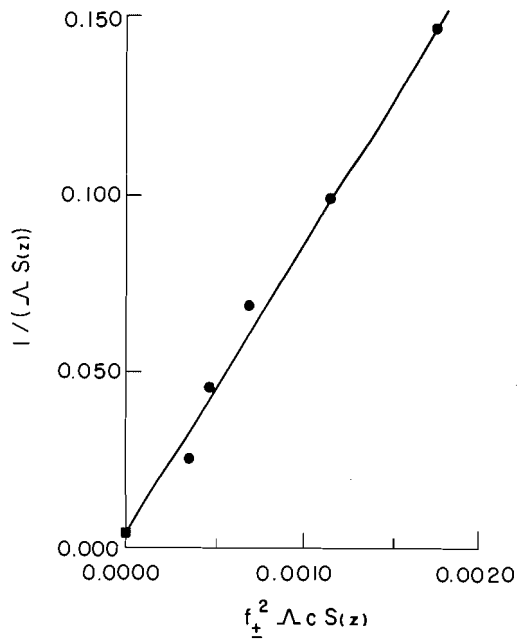

FIG. 4. Fuoss plot (11–13) for potassium methylamide in methylamine at 0.0°C (a = 3 Å, $\Lambda_0\eta$ = 66 mPa s S cm² equiv.$^{-1}$).

The dependence of Λ on temperature for three representative concentrations is shown in Fig. 3. An explanation for the distinct maximum seen in each case at about −30°C is considered in the Discussion section.

The limiting equivalent conductance, Λ_o, and the ion pair dissociation constant, K_d, were determined by the procedure of Fuoss and co-workers (12–14), as outlined below. Only conductivity data measured at stoichiometric concentrations (c) below 5×10^{-4} mol L^{-1} were used; above this concentration, calculated from the equation $c = 1.19 \times 10^{-14} D^3T^3$ (14) (where D is solvent dielectric constant and T the absolute temperature), triple ion formation becomes important.

There are two similar equations which may be employed to obtain Λ_o and K_d, both of which give identical results when K_d is less than 10^{-3} mol L^{-1} (12, 14). The one chosen for the present study was:

$$[3] \qquad 1/(\Lambda S(z)) = 1/\Lambda_0 + c\Lambda f_{\pm}^2 S(z)/(K_d\Lambda_0^2)$$

The function $S(z)$ is defined in ref. 14. The equation used to calculate $\log f_{\pm}^2$ (mean activity coefficient $f_{\pm}$) was that given by Robinson and Stokes (ref. 10, p. 229).

A computer program was used to evaluate and plot the terms in eq. [3], starting with an estimate for Λ_0 (based on an extrapolation of the Λ data to zero concentration at each temperature) and assigning the value 3 Å to the ion pair size parameter "a" in the log $f_{\pm}^2$ equation.[3] A Fuoss plot of $1/(\Lambda S(z))$ vs. $c\Lambda f_{\pm}^2 S(z)$ for each set of data gave a line of slope $1/(K_d\Lambda_0^2)$ and intercept $1/\Lambda_0$, from which K_d and Λ_0 could be determined. This value of Λ_0 was fed back into eq. [3] on an iterative basis until new and old values agreed within 1.0 S cm² equiv.$^{-1}$.

A typical Fuoss plot is shown in Fig. 4. Included is a refinement brought about by the observation of a random scatter in the final computer Λ_0 data as a function of temperature (see Table 1). To smooth out the data Walden's Rule (15) was applied, the product of the computer Λ_0 and the solvent viscosity, η, being averaged for the temperature range −45 to +15°C. A refined value of the limiting equivalent conductance, Λ_0', was then calculated from this average $\eta\Lambda_0$ (66 mPa S cm² equiv.$^{-1}$) and the η at each temperature. Finally, the Λ_0' values were run through the computer program to obtain the set of X, Y coordinates for the final Fuoss plot (no optimization). A least-squares line was drawn through these coordinates, including the $X = 0$, $Y = 1/\Lambda_0'$ point (shown as a square point in Fig. 4), to permit a calculation of K_d.

[3]A change from 3 to 4 to 5 Å for "a" had no significant effect on the values of Λ_0 and K_d obtained.

The resultant K_d data as a function of temperature are given in Table 2, while Fig. 5 shows a Van't Hoff plot of the results (16). Because of the procedure used to obtain Λ_0 and K_d, the uncertainty in their values may be as high as 20% for Λ_0 and 30% for K_d, although relative agreement appears to be better than this.

Discussion

Potassium Methylamide or Amide?

Some ammonia is always present in methylamine solutions of methylamide salts, either from the solvent itself or from slow thermal decomposition of the salts (5). Ammonia can react with potassium methylamide to form potassium amide, eq. [4]. K_{eq}

$$[4] \qquad KNHCH_3 + NH_3 \overset{K_{eq}}{\rightleftharpoons} CH_3NH_2 + KNH_2$$

has not been measured directly but estimates reported are 9 and 50 (footnote 4 and ref. 17, respectively). The question therefore arose as to whether the conductivity data, obtained at low PMA concentrations, were in fact applicable to PMA or to KNH_2.

Although $K_{eq} > 1$, the high concentration of the methylamine as solvent (ca. 21 mol L^{-1}) will suppress the formation of KNH_2 at least for reasonably low concentrations of NH_3. In the present work, the NH_3 concentration was generally in the range 3×10^{-3} to 1×10^{-2} mol L^{-1}, which would convert no more than 0.4% of the PMA, assuming a value of $K_{eq} = 10$. For Rochard's work with methylamine containing up to 0.1 mol L^{-1} NH_3 (3, 4), the conversion would have been closer to 5%.

Some success was later achieved in substantially lowering the concentration of ammonia in the methylamine by using a low-temperature fractional distillation technique.[5] A 1 m long vacuum-jacketed column, based on a design in the literature (18), was operated under reflux with cooling fluid pumped through the central condenser tube at about −21°C (bp NH_3 −33.4°C, CH_3NH_2 −6.5°C). By removing up to eight 2 ml condensed vapour samples from the top of the column over a period of 48 h, it was possible to decrease the NH_3 content of the methyl-

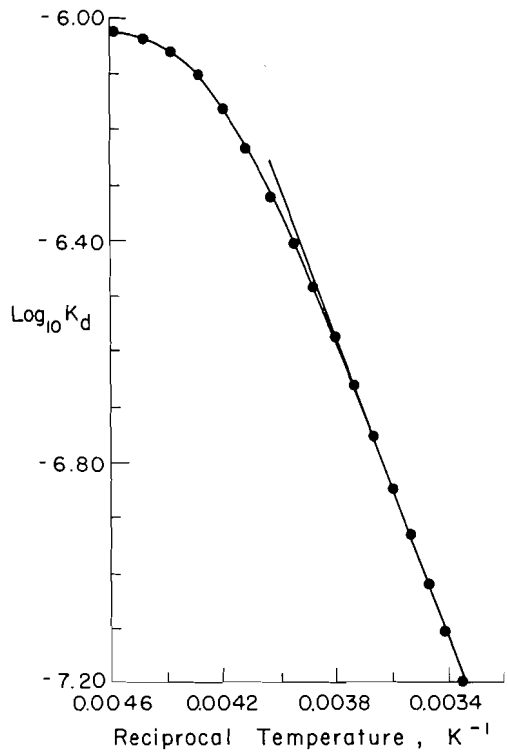

FIG. 5. Van't Hoff plot for potassium methylamide ion pair dissociation in methylamine. ΔH_d from linear portion is -26 kJ mol^{-1}.

amine in the 2 L pot (initially 4×10^{-3} mol L^{-1} NH_3) to below 1×10^{-5} mol L^{-1}.

In spite of this ability to obtain methylamine *initially* very low in NH_3, it was found impossible to maintain a low level for any useful period of time. The thermal decomposition of methylamide salts in methylamine solutions that occurs at higher temperatures and concentrations to produce ammonia (5) still proceeds at a significant rate under the conditions of conductivity measurement. In addition, the reaction of potassium with low-NH_3 methylamine to make moderately dilute $KNHCH_3$ solutions for study tended to generate NH_3 at concentrations up to 5×10^{-4} mol L^{-1}.

Theoretical Value of K_d *for* $KNHCH_3$

Fuoss has derived a relation between the ion *association* constant, K_a, and the solvent dielectric constant (D) for 1:1 electrolytes (19). In eq. [5], e is the electronic charge and k the Boltzmann constant. No allowance is made for specific ions or solute–solvent interactions.

$$[5] \quad K_a = 1/K_d = 2.524 \times 10^{-3}\, a^3 e(e^2/akDT)$$

The values calculated at several temperatures for a 1:1 electrolyte in methylamine are compared in Table 3 with the data measured for $KNHCH_3$. The agreement between theoretical and experimental K_d is best for a value of "a" (in eq. [5]) just greater than 3 Å. Delmas (20) chose 3 Å for KNH_2 in ammonia, based on the sum of the ionic radii for this salt. The K_d derived from Rochard's conductivity data at -90°C is smaller than expected by at least a factor of 10 (Table 3) but the reason is not known.

TABLE 3. Dependence of theoretical K_d for $KNHCH_3$ in methylamine on value of "a" and comparison with experimental results

Temperature Dependence of K_d *for* $KNHCH_3$

A Van't Hoff plot of log K_d vs. $1/T$ provides the heat of dissociation, ΔH_d, for the ion pairs (16). The plot for $KNHCH_3$ in methylamine, Fig. 5, yields a value of -26 kJ mol^{-1} for the linear region above about -15°C. This result is comparable to those found for other ion pairing equilibria (16).

The marked curvature seen in this plot below -15°C has also been observed in other systems (21, 22). It has been explained on the basis of an equilibrium between two types of ion pairs, 'tight' and 'loose', with the latter containing one or more solvent molecules sandwiched between the anion and cation (21). The tight ion pair, with a larger heat of dissociation, is favoured at higher temperature, while the other, with a smaller ΔH_d, is favoured at low temperature (21).

The above results help to explain the shape of the Λ–temperature plots in Fig. 3. The distinct maximum, seen also by Holtslander[2] at much higher PMA concentrations up to the solubility limit of 0.4 mol L^{-1}, can arise from a combination of two factors (23). The solution conductance is dependent on both the number of ions and their mobilities. When the temperature is raised, from e.g. -60°C, the ion mobilities will increase because the solvent viscosity decreases, but at the same time K_d decreases (Fig. 5), thereby lowering the total number of ions. Thus the viscosity effect dominates at temperatures below the conductance maximum, while the

decrease in K_d becomes dominant at higher temperatures.

A Comparison of $KNHCH_3$ in CH_3NH_2 with KNH_2 in NH_3

The present results for $KNHCH_3$ in methylamine can be compared with the data of Delmas *et al.* (20, 24) for KNH_2 in ammonia. First, the Λ_0 of a salt at a given temperature should only differ, to a first approximation, by the ratio of the solvent viscosities (Walden's Rule (15)). At $-33.4°C$ $\eta_{NH_3} = 0.255$ and $\eta_{CH_3NH_2} = 0.384$ mPa s. Delmas gives $\Lambda_{0(KNH_2-NH_3)} = 308$ S cm^2 equiv.$^{-1}$ at this temperature, so that $\Lambda_{0(KNH_2-CH_3NH_2)}$ is predicted to be 205 S cm^2 equiv.$^{-1}$. The experimental value for $\Lambda_{0(KNHCH_3-CH_3NH_2)}$, based on the assumption of constant $\Lambda_0\eta$ in methylamine (as discussed earlier), is somewhat lower at about 172 S cm^2 equiv.$^{-1}$, which is consistent with $^-NHCH_3$ being a slightly larger ion than $^-NH_2$.

The K_d values for the salts in the two solvents should be related by the respective dielectric constants through eq. [5]. The conversion factor $\exp [(e^2/akT)(1/D_{CH_3NH_2} - 1/D_{NH_3})]$ was used. At $-33.4°C$, $D_{NH_3} = 22.4$, $D_{CH_3NH_2} = 13.1$, and $K_{d(KNH_2-NH_3)} = 1.0 \times 10^{-4}$ mol L^{-1} (20). The value thus predicted for $K_{d(KNH_2-CH_3NH_2)}$ is 1.2×10^{-6} mol L^{-1} for $a = 3$ Å and 3.9×10^{-7} mol L^{-1} for $a = 4$ Å. These compare favourably with the experimental $K_{d(KNHCH_3-CH_3NH_2)}$ at this temperature, 6.5×10^{-7} mol L^{-1}, and suggest again that "a" for $KNHCH_3$ lies between 3 and 4 Å.

Reduction of cyclic anhydrides. II. Factors affecting regioselectivity of attack on the carbonyl group by metal hydrides

MARGARET M. KAYSER AND PETER MORAND

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received November 21, 1977

MARGARET M. KAYSER and PETER MORAND. Can. J. Chem. **56**, 1524 (1978).

The reduction of unsymmetrically substituted cyclic anhydrides with metal hydrides often leads to the preferential formation of one of the two possible lactones. In the light of recent experimental findings and theories concerning metal hydride addition to the carbonyl function, the electronic and steric factors influencing regioselectivity of cyclic anhydride reductions are discussed and an explanation for the observed patterns is proffered. Similar considerations may be extended to predict the major lactonic products in the reductions of various other unsymmetrical cyclic anhydrides.

MARGARET M. KAYSER et PETER MORAND. Can. J. Chem. **56**, 1524 (1978).

La réduction par les hydrures métalliques d'anhydrides cycliques substitués d'une façon non-symétrique conduit souvent à la formation préférentielle d'une des deux lactones possibles. A la lumière de résultats expérimentaux récents et des théories concernant l'addition des hydrures métalliques sur les fonctions carbonyles, on discute des facteurs électroniques et stériques influençant la régiosélectivité des réductions d'anhydrides cycliques et on présente une explication pour les tendances observées. On peut étendre des considérations similaires pour prédire la nature des produits lactoniques principaux formés lors de la réduction de divers autres anhydrides cycliques non-symétriques.

[Traduit par le journal]

The direct conversion of a cyclic anhydride into the corresponding lactone is of general interest to chemists, as it is well established that lactones are important intermediates in the synthesis of a variety of compounds, particularly natural products; see, for example, ref. 1*a*. Several methods have been used to accomplish this conversion (1*b* and *c*) but the simplest and most effective are reductions with metal hydrides. Unsymmetrically substituted anhydrides can potentially yield two lactones. Catalytic hydrogenations generally produce lactones resulting from the reduction of the less hindered carbonyl function (1*b*). Reductions with metal hydrides, often but not always, take place selectively at the more hindered carbonyl group (2, 3). In this paper, an attempt is made to identify the factors which appear to govern regioselectivity in metal hydride reductions.

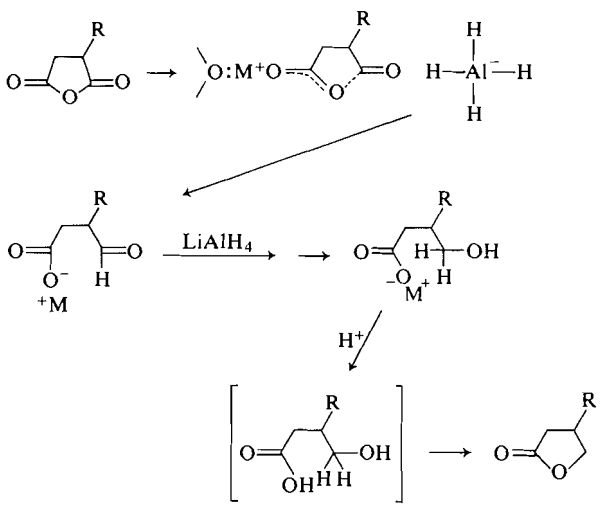

FIG. 1. Mechanism for anhydride reductions with metal hydrides proposed by Bloomfield and Lee (2*b*).

Selective reduction of the more sterically encumbered carbonyl group with metal hydrides has been explained by a mechanism involving initial attack of a metal cation on the less hindered carbonyl function, followed by the transfer of a hydride ion to the more hindered carbonyl group (2*a* and *b*).[1] The intermediate aldehyde is then rapidly reduced to yield an alcohol function and cyclization occurs upon acidification (Fig. 1). Although never challenged, the mechanism of Bloomfield and Lee (2*b*) fails to explain known cases of preferential reduction of the less hindered carbonyl group (3*c* and *d*).

In the course of our work on reductions of cyclic anhydrides, we have encountered other cases of

[1]Such selectivity has been reported in the reactions of steroidal cyclic anhydrides (3*a* and *b*) with lithium aluminum hydride and lithium tri-*tert*-butoxyaluminum hydride. With the latter reagent, lactols (hemiacylals) are formed by closure of the intermediate carboxyaldehyde. The authors explained the regioselectivity observed in terms of inter- or intramolecular complex formation similar to that invoked by Bloomfield and Lee (2*b*). We have examined the Dreiding model of **19** and concluded that it is the slightly more accessible carbonyl group which undergoes reduction. However, in view of the very similar steric environment around the carbonyl groups the perception of which one is more hindered remains disputable.

selective nucleophilic additions to the less hindered carbonyl group (**10** and **11**), as well as examples of reduction of the more sterically congested carbonyl function (**1**, **3**, **5**, **16**). Reductions of two anhydrides (**12** and **15**) lead to a mixture of lactones, a result of diminished preference for the more hindered carbonyl group.

To explain the observed patterns of regioselectivity in these reactions, we would like to propose an alternative approach, based on the following assumptions: (*i*) the mechanism of cyclic anhydride reductions bears a fundamental resemblance to the mechanism of hydride ion addition to the carbonyl group of cyclic ketones; (*ii*) the attack of the cation and hydride ion occurs on the *same* carbonyl function; (*iii*) the site of the attack is controlled by electronic factors, when the two carbonyl functions are electronically different.

Metal Hydride Reductions of the Carbonyl Function

Reductions of ketones with simple metal hydrides have been studied and used extensively for over three decades (4). Although the mechanism of the reaction and the factors determining its stereochemistry remain an area of speculation and controversy, the results of recent investigations and quantum mechanical calculations provide guidelines for a working mechanistic model.

Molecular Orbital Picture of Electrophilic and Nucleophilic Addition to the Carbonyl Group

The most favourable mechanism in terms of MO theory for electrophilic and nucleophilic additions to the carbonyl function is generally accepted to occur in the following manner: the electrophile attacks the frontier HOMO orbital, the so-called nonbonding orbital of the carbonyl oxygen. The product has a plane of symmetry, i.e., the five atoms involved remain in one plane, whereas the π bond of the carbonyl group is orthogonal to this plane. The association of a cation with the oxygen atom of the carbonyl function enhances the addition of a nucleophile to the LUMO π orbital and specifically, to the carbon atom of the carbonyl group (5). The maximum overlap (in the transition state) would suggest an initial approach perpendicular to the molecular plane but the polarity of the molecule favours a greater separation between nucleophile and the oxygen atom. The above conclusion is derived from the work of Bürgi *et al.* (6), who calculated the minimum energy path for addition of hydride ion to formaldehyde. At a distance of 2 Å the line of approach of the nucleophile is not perpendicular, but forms an angle of about 110° with the C=O bond (Fig. 2).

Baldwin (7) extended these results into a simple method of assessing the stereochemical restraints in hydride reductions of other carbonyl functions. Using Baldwin's approximation, the approach vector of H^- (representing the most favourable reaction coordinate) on an ester or anhydride function is shifted (angle β) from the symmetric position, as in a ketone (Fig. 3*a*), to a position in space away from the oxygen atom (Fig. 3*b*) and directed at the molecular plane at an angle (α) of approximately 110° (Fig. 3*c*).

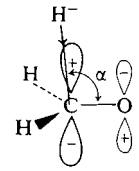

FIG. 2. The attack of hydride ion on the molecular plane of formaldehyde.

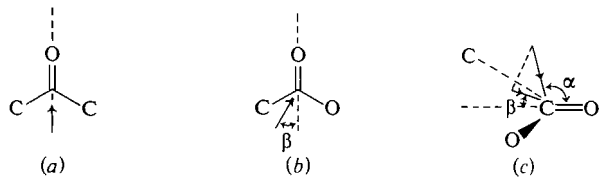

FIG. 3. The projections of H^- attack on the molecular plane.

The term 'steric hindrance' needs to be revised in view of the above considerations (8). The steric congestion in the vicinity of the carbonyl function with respect to the perpendicular approach of a nucleophile is not the same as when the angle of approach is wider (8, 9). However, for reasons of simplicity, theoretical calculations generally assume a perpendicular approach (10).

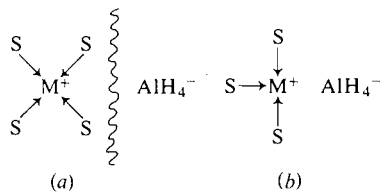
Kinetics of Metal Hydride Reductions and Catalytic Activity of Li^+ Cation

Kinetic studies (11) have shown that the reaction of mesityl phenyl ketone with $LiAlH_4$ in THF is first order in both ketone and metal hydride.[2]

The reaction of metal hydrides with ketones depends on the nature of the cation (11). The effects of the cation on the reactivity of the ketone is not entirely clear. However, it has been demonstrated (15) that upon removal of the Li^+ cation with the appropriate crown ether, no reaction (within a reasonable reaction time)[3] took place before hydroly-

[2]The same kinetics apparently apply to reductions with sodium borohydride (12). Wiegers and Smith (13) studied the reduction of 2,4,6-trimethoxy benzophenone in diethylether solution and found the reaction first order in ketone, but 0.5–0.6 order in $LiAlH_4$. This, according to the authors, indicates participation of both monomeric and dimeric lithium aluminum hydride. Ashby (14) suggests that the difference between $LiAlH_4$ in THF and $LiAlH_4$ in diethyl ether is due to the difference in solvation of $Li^+AlH_4^-$ in those two solvents.

[3]It is possible that the role of cation, especially Li^+ cation, is catalytic and in its absence, reactions are very slow. Apparently, Li^+ cation is not necessary for reductions with aluminum hydrides, since $NaAlH_4$ and NR_4AlH_4 reduce ketones, although at a considerably slower rate (14).



(*a*) (*b*)

FIG. 4. Solvent separated (*a*) and contact (*b*) ion pairs.

sis. Concurrent or prior association of the carbonyl oxygen with Li^+ cation, followed by hydride transfer has been suggested by Ashby *et al.* (16). Pierre and Handel (17) have proposed that a cation intervenes in a catalytic fashion and that stereoselection is fixed from the first step in the mechanism, namely the association of the cation with the carbonyl oxygen atom.

Solvent Effects

Conductance experiments indicate that $LiAlH_4$ in THF exists predominantly as solvent-separated ion pairs (Fig. 4*a*) whereas $NaAlH_4$ appears to be a mixture of solvent-separated (Fig. 4*a*) and contact ion pairs (Fig. 4*b*) (11). Thus, solvation offers a partial explanation for superior reactivity (11) and selectivity (3*b*, 16) of Li^+ cation with respect to Na^+ cation.

Mechanism of $LiAlH_4$ Reduction of the Carbonyl Group

In summary, the mechanism of this reaction is generally accepted to involve the following steps: (*i*) association of the cation with the oxygen atom of the carbonyl group (a fast process in which the solvent separated ion pair falls apart); (*ii*) approach of the AlH_4^- nucleophile[4] from above or below the molecular plane to the carbon end of the carbonyl group,[5] at an angle wider than 90 and as close as possible to 110°; (*iii*) passage through the transition state; (*iv*) formation of the products.

Metal Hydride Reductions of Cyclic Anhydrides

We assume as a working hypothesis that the same principal steps apply to the reduction of anhydrides. However, in the case of unsymmetrically substituted cyclic anhydrides, there are two different carbonyl groups which may undergo reduction. In the majority of cases studied (Table 1), there is a definite preference for reduction to occur at the more electron rich carbonyl function. The preferential association of the Li^+ cation with the carbonyl group bearing the most basic, most isolated, nonbonding electrons on its oxygen atom, is followed by the addition of the hydride ion to the carbon end of the *activated* carbonyl function. The stereochemistry of nucleophilic approach is illustrated in Fig. 3*b* and *c*.

Several anhydrides (**1**, **6**, **8**, **10**, **11**, and **16**) were reduced with both $LiAlH_4$ and $NaBH_4$. The site of reduction was consistently the same and the yields of lactones comparable.[6]

A survey of the data presented in Table 1 reveals that the course of reaction must be governed by electronic effects which induce differences in electron availability on the two carbonyl groups: (*i*) conjugation with aromatic systems; (*ii*) presence of a tertiary carbon atom α to one of the carbonyl functions; (*iii*) presence of electron-withdrawing (phenyl or nitro) or electron-releasing (alkyl) groups on the carbon atom α to the carbonyl function.

Conjugation with aromatic systems results in delocalization of electrons which weakens the carbonyl dipole. This effect is illustrated by the reduction of homophthalic anhydride **13**. The only product isolated, lactone **13***b*, results from reduction of the carbonyl function *not* conjugated with the benzene ring.

The attack of Li^+ cation occurs preferentially on the oxygen atom having the most basic, nonbonding electrons. Not surprisingly, greater reactivity is exhibited by the carbonyl group adjacent to a tertiary carbon atom.[7] Inasmuch as the addition of nucleophile to the carbonyl group is enhanced by the interaction of the cation with the oxygen atom, the transfer of hydride ion to the activated carbonyl group follows. Such a sequence of events adequately describes the results obtained in the reduction of anhydrides **1**, **3**, **5**, **16**, and **17**, as well as compounds **6**, **7**, **8**, and **9**, reported in the literature. The steric hindrance about the carbonyl group in these compounds does not deter hydride transfer where simple metal hydrides (AlH_4^- and BH_4^-) are used. It

[4]In the case of $LiBH_4$ reductions (18) hydride addition was found to be the rate-determining step.

[5]The variety of steric and/or electronic effects will determine the direction of hydride approach. Obvious steric congestion, and in cases of nonhindered carbonyls, the torsional interactions (19) and unequal distortion of electron density about the carbonyl group (20, 21) are examples of such effects.

[6]Since the Na^+ cation is a poor catalyst, the mechanism of $NaBH_4$ reduction differs from $LiAlH_4$ reduction in the first step, i.e., association with the cation. It is generally believed (ref. 2*a* pp. 51, 52) that $NaBH_4$ reductions are catalyzed by protic solvent or, in cases of reductions carried out in anhydrous alcohol free solvents, the reaction may actually occur only during the isolation procedure when water, acid or alcohol is added. From the practical point of view, it is simpler to reduce an anhydride to a lactone, using $NaBH_4$, rather than $LiAlH_4$. The products obtained in the majority of cases studied are the same. The only example, to our knowledge, where the reductions with $NaBH_4$ and $LiAlH_4$ yielded significantly different ratios of lactones has been reported for the Inhoffen adduct (**19**, ref. 3*b*).

[7]The greater reactivity of the carbonyl function next to the most highly substituted carbon atom has also been manifested in esterification reactions of cyclic anhydrides to half-acid esters (22).

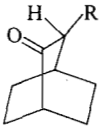

FIG. 5. Example of ketone having Cram's model conformation built in.

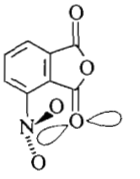

FIG. 6. Nitro group is twisted from the plane of the molecule.

should be pointed out that under conditions of overpowering steric crowding, the course of the reaction might be reversed, but at present, there are no known examples in the cyclic anhydride series. A somewhat analogous situation, encountered in the reduction of ketones, has been recently discussed by Chérest *et al.* (21). A number of 3-alkyl bicyclo[2.2.2]octan-2-ones (example, Fig. 5) undergo reduction with $LiAlH_4$ from the more hindered side leading to *trans* alcohols,[8] when R is methyl, ethyl or isopropyl. However, when R is *tert*-butyl, the *cis* alcohol is obtained as the major product. The authors attribute these results to the anisotropic inductive effects of the alkyl groups which lead to differences in electron density on the two faces of the plane containing the trigonal carbon atom.[9] When the R group becomes large enough to block completely the path of nucleophilic attack, the reaction becomes subject to steric control.

The subtle differences engendered by the presence of electron-releasing and electron-withdrawing groups are illustrated by the following examples from Table 1. 2-Methylsuccinic anhydride (**2**) is preferentially reduced on the more sterically crowded side of the molecule. According to the mechanism proposed by Bloomfield and Lee (2*b*) (Fig. 1), 2-phenylsuccinic anhydride (**4**) should lead to a higher ratio in favour of the lactone formed by reduction on the more hindered side, since a phenyl group is more important sterically than a methyl group (24). However, the experimental results show that **4** is reduced to a lesser extent at the more hindered carbonyl function. It is obvious that the electron-withdrawing phenyl group weakens the neighbouring carbonyl function, thus slightly promoting reduction of the less hindered carbonyl group, (40% reduction on the less hindered side in **4**, *vs.* 30% in **2**).

Electronic factors operating in these reactions may be complicated by other effects not obvious at first glance. The case which illustrates well the danger of hasty predictions, is exemplified in the reduction of 3-nitrophthalic anhydride **15**. Considering the electron-withdrawing effects of the nitro group, we might have expected 7-nitrophthalide (**15***a*) as the major product but, in fact, the isomeric 4-nitrophthalide (**15***b*) is produced preferentially. In this case, the nitro group, twisted from the molecular plane, owing to the proximity of the neighbouring carbonyl group, cannot undergo electron delocalization and therefore does not deactivate the carbonyl group in the *ortho* position. On the other hand, the cation will be attracted to this highly oxygenated end of the molecule (Fig. 6) and consequently, will preferentially activate the *ortho* carbonyl function.

The ring system to which the anhydride is attached greatly influences the site of metal hydride reduction. A case in point is the complete reversal in regioselectivity observed in the reduction of the anhydrides **10** and **11**, compared to anhydride **6**. The former two compounds differ from **6** only by having a methylene or ethylene bridge respectively. Since it is known that the formation of enolate anion greatly inhibits the reduction of carbonyl groups (25, 26), one is tempted to explain the above results[10] by evoking the relative ease of enolization of the carbonyl group in **6**, as opposed to resistance to enolization in the bridgehead compounds **10** and **11**. The enolate anion of succinic anhydride has been generated (27) but it appears that under the reduction conditions employed, enolization does not occur to any significant extent.[11]

The difference in reactivity between the two carbonyl functions of cyclic anhydrides may be ascribed to hyperconjugative effects (28, 29). The carbonyl group for which one or more no-bond resonance canonical forms can be written should be a weaker dipole due to electron delocalization. The two bridged anhydrides **10** and **11** have folded structures and are not able to flatten out. Consequently, neither enolization nor hyperconjugation can contribute to the delocalization of electrons and the two carbonyl groups are essentially equivalent. An approach (by nucleophile) from the concave side is

[8]With $LiAl(tOBu)_3H$ more sensitive to steric hindrance, reduction always occurs selectively from the less hindered side of the molecule (21).

[9]Klein (23) evokes this effect to explain and predict addition to trigonal carbon, sulfur and pyramidal nitrogen atoms.

[10]It is equally tempting to use enolization to justify the results of reductions for all the anhydrides possessing one carbonyl group α to the tertiary carbon atom, while the other one is α to the primary or secondary carbon atom.

[11]No incorporation of deuterium is observed when the reaction is quenched with DCl–D_2O. Also, no significant amount of H_2 gas is evolved during the reductions of cyclic anhydrides.

prevented by the electrons of the π bond. The hydride ion therefore must approach from the convex face. Here, the cation may associate itself with one or the other carbonyl group but this step is fast and reversible and the nucleophile will be transferred to the less crowded group.

Camphoric anhydride **12** presents another case where subtle electronic effects influence the selectivity of the reaction. By analogy to the stereoselectivity observed in the reduction of camphor (10), the nucleophile should add from the *endo*, more 'overt' side. There is little difference in steric environment between the two carbonyl groups when the approach is from the *endo* side. We would have expected a mixture of two lactones in a 1:1 ratio. The slight preference shown for the 'more' hindered carbonyl may be due to the inductive effect of the angular methyl group.

The results of the metal hydride reductions of 19 cyclic anhydrides presented in Table 1 clearly show that these reactions cannot be governed by steric factors alone. The observed pattern may be rationalized by evoking a different electronic character for the two carbonyl groups,[12] when applicable. Obviously, in the absence of electronic differences, the reduction is subject to steric factors. It is yet to be established at what point steric factors begin to dominate the course of the reaction when electronic differences exist. It should be emphasized that the above considerations may not be valid for reduction of cyclic anhydrides with bulky metal hydrides (e.g. $LiAl(tOBu)_3H$) which are more sensitive to steric hindrance.

Experimental

Melting points were determined on a Thomas–Hoover capillary melting point apparatus and are uncorrected. Infrared spectra were obtained on a Beckman IR-20 spectrophotometer and proton nmr spectra in $CDCl_3$, with TMS as internal standard, on a Varian T-60 or HA-100 instrument. Tetrahydrofuran was distilled under argon from lithium aluminum hydride into oven-dried and argon-flushed flasks containing the lithium aluminum hydride. The transfer of tetrahydrofuran, when necessary, was accomplished with an argon-swept syringe. Gas–liquid chromatographic analyses were carried out with an Autoprep Model A-700 gas chromatograph.

The general procedure for the reductions was as follows. Lithium aluminum hydride (0.005–0.01 mol) was placed in an oven-dried, argon-swept, three-neck flask into which 25–50 ml of tetrahydrofuran was subsequently distilled. The flask was fitted with an inlet port for syringes, a magnetic stirrer, a thermometer, and a gas outlet tube. The flask, swept with a slow stream of nitrogen, was cooled in a Dry Ice – acetone bath. The gas tube was then connected to the gas measuring system and anhydride (0.01 mol) dissolved in a small quantity of distilled tetrahydrofuran (20–30 ml) was injected into the flask. The hydrogen evolved was noted. The temperature of the reaction mixture was maintained below −55°C, throughout the addition process. The stirred solution was slowly warmed to 0°C over a period of 2 h. The flask was then cooled again to −20°C and 5 ml of 6 *N* HCl was added slowly. The reaction mixture was left overnight. The layers were separated and the acidic aqueous layer was extracted with ether. The combined organic layers were dried, concentrated, and analyzed by glc. Reductions with sodium borohydride were carried out according to the procedure of Belleau and Puranen (1*a*).

2,2-Dimethylsuccinic anhydride (**1**) was prepared from 2,2-dimethylsuccinic acid by dehydration with acetyl chloride and was reduced according to the procedure described above (31). Yields of lactones ranged from 50–75% and 10–15% of diacid was recovered. Gas–liquid chromatographic analysis (6 ft, 10% carbowax, 120°C), showed the ratio of the two lactones to be 19:1. The major product *β,β-dimethyl-γ-butyrolactone* (**1***a*) was purified by distillation under reduced pressure (*2c*,32); ν_{max}: 1720 cm^{-1} (lactone C=O); δ:1.20 (s, 6H, 2 × CH_3), 2.34 (s, 2H, CH—C=O), 3.98 (s, 2H, CH_2—O). This lactone was compared with α,α-dimethyl-γ-butyrolactone (1*b*) prepared by $RuCl_2(Ph_3P)_3$ catalyzed hydrogenation of the anhydride **1** (31); δ:1.28 (s, 6H, 2 × CH_3), 2.12 (t, 2H, CH_2—C=O), 4.26 (t, 2H, CH_2—O).

2,2-Dimethylglutaric anhydride (**5**), upon reduction with $LiAlH_4$, yielded lactone **5***a* as a major product. Gas–liquid chromatographic analysis (6 ft, 10% carbowax, 135°C) indicated the ratio **5***a*:**5***b* to be 9:1. γ,γ-Dimethyl-δ-valerolactone (**5***a*): ν_{max}: 1730 cm^{-1} (lactone C=O) (lit.(33)); δ:0.98 (s, 6H, 2 × CH_3), 1.62 (t, 2H), 3.90 (s, 2H, CH_2—O). This lactone was compared with α,α-dimethyl-δ-valerolactone (**5***b*) which was obtained as a major product of catalytic hydrogenation ($RuCl_2(Ph_3P)_3$) of the anhydride **5**: δ:4.22 (t, 2H, CH_2—O).

2,2-Diphenylsuccinic acid was prepared according to the method of Makosza (34*a*) by condensing, under phase transfer conditions, diphenylacetonitrile with methyl bromoacetate. The product *3,3-diphenyl-3-cyanopropionic acid* was obtained in 76% yield; mp 178–181°C; *m/e* (70 eV): 251 (M^+); ν_{max}: 2220 cm^{-1} (C≡N; δ:3.5 (s, 2H), 7.3 (s, 10H). 3,3-Diphenyl-3-cyanopropionic acid was hydrolyzed by refluxing for 12 h in a mixture of concentrated H_2SO_4 and glacial acetic acid (1:1). 2,2-Diphenylsuccinic acid was obtained in 60% yield; mp 179–180°C (lit. (34*a*) mp 175°C); *m/e*: 252 ($M - H_2O$); ν_{max}: 1710 cm^{-1}; δ: 3.6 (s, 2H), 7.33 (s, 10H). 2,2-Diphenylsuccinic acid was heated to melting and it solidified to give needle-like crystals of *2,2-diphenylsuccinic anhydride* (**3**); mp 89–91°C (lit. (34*b*) mp 90.5–90°C); ν_{max}: 1700 and 1770 cm^{-1} (C=O anhydride); δ:3.66 (s, 2H), 7.36 (s, 10H).

Reduction of 2,2-Diphenylsuccinic Anhydride

The anhydride **3**, 1.26 g (0.005 mol) was dissolved in isopropyl alcohol (350 ml). The stirred solution was cooled to 0°C and $NaBH_4$ 0.185 g (0.005 mol) added in small portions over a period of 2 h. The solution was then allowed to warm to room temperature and was stirred for an additional 2 h. The isopropyl alcohol was distilled under reduced pressure and excess 3 *N* HCl was added, followed by 150 ml of chloroform. The reaction mixture was stirred for a few hours and the layers separated. The aqueous layer was extracted twice with chloroform and the combined organic layers were dried and evaporated. The residue was chromatographed on silica gel. Lactone **3***a* was eluted first with benzene, yield 67%; mp 109–110°C (lit. (35) mp 109–110°C); ν_{max}: 1780 cm^{-1} (C=O); δ:3.19 (s, 2H), 4.73 (s, 2H), 7.40 (10H). The anhydrides **10** and

[12]It is quite likely that the same mechanism could explain the results of the reductions of unsymmetrical succinimides (30*b*).

11 were prepared by Diels–Alder addition (36) of citraconic anhydride to cyclopentadiene and 1,3-cyclohexadiene, respectively. exo-*2-Methylnorborn-5-ene*-endo-*2,3-dicarboxylic acid anhydride* (**10**); mp 139–141°C; ν_{max}: 1770 and 1850 cm^{-1} (anhydride C=O); δ: 1.6 (s, 3H, Me), 1.86 (m, 2H), 3.08 (m, 1H). *Anal.* calcd. for $C_{10}H_{10}O_3$: C 67.42, H 5.62; found: C 67.71, H 5.76. exo-*2-Methylbicyclo[2.2.2]oct-5-ene-2,3*-endo-*dicarboxylic acid anhydride* (**11**); mp 182–184°C; ν_{max}: 1775 and 1850 cm^{-1} (anhydride C=O); δ: 1.41. *Anal.* calcd. for $C_{11}H_{12}O_3$: C 68.73, H 6.17; found: C 68.92, H 6.29.

Reduction of the anhydride **10** with $LiAlH_4$ according to the general procedure as well as with $NaBH_4$ in dimethylformamide gave the crystalline lactone, *exo*-2-methylnorborn-5-ene-*endo*-(3-methyl-2-carbo-3a)-lactone (**10***b*; yield 84%; mp 137–139°C; ν_{max}: 1745 cm^{-1} (lactone C=O); δ: 1.52 (s, 3H, CH_3), 4.02 (m, 2H, CH_2—O), 6.33 (m, 2H); δ (0.5 *N* NaOD): 3.60 (d, 2H, CH_2—O). *Anal.* calcd. for $C_{10}H_{12}O_2$: C 73.17, H 7.31; found: C 73.01, H 7.54). A trace of the lactone resulting from the reduction on the more hindered side could be detected by glc.

Reduction of the anhydride **11** with $LiAlH_4$ or with $NaBH_4$ gave the crystalline lactone **11***b*; yield 86%; mp 184–185°C; ν_{max}: 1755 cm^{-1} (lactone C=O); δ: 1.37 (s, 3H, Me), 4.05 (m, 2H, CH_2—O), 6.30 (m, 2H). *Anal.* calcd. for $C_{11}H_{14}O_2$: C 74.15, H 7.86; found: C 74.75, H 7.91.

Reduction of *camphoric anhydride* (**12**) with $LiAlH_4$ produced 70–78% yields of the mixture of **12***a* and **12***b* in the ratio 3:2 determined by glc analysis. The unreacted anhydride 20–25% was recovered. The two lactones were separated on base-washed alumina, crystallized from low boiling petroleum ether, and sublimed. β-*Campholide* (**12***a*) mp 214–216°C (lit. (37, 38) mp 213–216°C); ν_{max}: 1735 cm^{-1} (lactone C=O); δ: 0.90 (d, 6H, CH_3), 1.08 (s, 3H, CH_3), 4.05 (m, 2H, CH_2—O). α-*Campholide* (**12***b*) mp 210–211°C (lit. (41) mp 210–211°C); ν_{max}: 1730 cm^{-1} (lactone C=O); δ: 0.95 (s, 3H, CH_3), 1.10 (s, 3H, CH_3), 1.20 (s, 3H, CH_3), 4.35 (m, 2H, CH_2—O). Unequivocal proof of structure for the two lactones was obtained by direct comparison of the lactone **12***b* with α-campholide obtained by the Baeyer–Villiger oxidation of camphor (39).

Reduction of *3-nitrophthalic anhydride* (**15**) was carried out according to the general procedure. The reduction product, a yellow crystalline substance was isolated in 80% yield. The proton nmr analysis showed the presence of two lactones in the ratio 2:1, where *4-nitrophthalide* (**15***b*) is a major product. Chromatography on silica gel yielded pure **15***b*; mp 135–136°C (lit. (40) mp 136°C); ν_{max}: 1780 (lactone C=O), 1550, and 1370 cm^{-1} (NO_2); δ: 5.75 (s, 2H, CH_2—O). *7-Nitrophthalide* (**15***a*) showed proton resonance δ 5.40 (s, CH_2—O).

The anhydride **16** (41), upon reduction with sodium borohydride in DMF, gave lactone **16***a*. Yields ranged from 80–90%; mp 175–176°C; analysis, ir, and proton nmr spectra were consistent with assigned structure.

Reduction with ½ mol of $NaBH_4$ to 1 mol of the anhydride (16) yielded corresponding hemiacylal which was further reduced with $NaBH_4$ to give the lactone **16***a*. The anhydride **17** reduced under similar conditions yielded a mixture of the lactone **17***a* and hemiacylal. The hemiacylal could be reduced with excess $NaBH_4$ to give **17***a*. Lactone **17***a*, mp 159–160°C; hemiacylal, mp 178–179°C; analysis, ir, and proton nmr spectra were consistent with assigned structures.

Mechanism of L-ascorbic acid oxidation on a mercury electrode. II. Basic medium

JUAN JOSÉ RUIZ,[1] ANTONIO ALDAZ,[2] AND MANUEL DOMINGUEZ

Departamento de Química Física, Facultad de Ciencias, Universidad de Sevilla, Spain

Received June 16, 1977

JUAN JOSÉ RUIZ, ANTONIO ALDAZ, and MANUEL DOMINGUEZ. Can. J. Chem. **56**, 1533 (1978).

A polarographic study of the oxidation mechanism of L-ascorbic acid is carried out in a basic medium and two oxidation waves are observed.

An analysis of these waves shows that the limiting current is governed by diffusion and that in each reaction a two electron transfer takes place. On the rising portion of the waves, the oxidation process consists of two consecutive one electron transfers. In the first wave, the second transfer is the rate determining step, whilst in the second wave, a chemical stage subsequent to the second electron transfer is the rate determining step. The reaction orders, together with the Tafel slopes, are calculated.

The oxidation mechanism of this acid in basic media is different from that in acid media.

JUAN JOSÉ RUIZ, ANTONIO ALDAZ et MANUEL DOMINGUEZ. Can. J. Chem. **56**, 1533 (1978).

On a effectué une étude polarographique du mécanisme d'oxydation de l'acide L-ascorbique en milieu acide et on a observé deux vagues d'oxydation.

Une analyse de ces vagues montre que le courant limite est gouverné par la diffusion et que dans chacune d'elle il se produit un transfert de deux électrons. Sur la portion montante des vagues, le processus d'oxydation comporte deux transferts consécutifs d'un électron. Dans la première vague, le deuxième transfert détermine la vitesse alors que dans la deuxième vague l'étape déterminante se trouve dans une étape chimique subséquente au deuxième transfert d'électron. On a calculé les ordres des réactions de même que les pentes de Tafel.

Le mécanisme d'oxydation de cet acide en milieu basique diffère de celui obtenu en milieu acide.

[Traduit par le journal]

Introduction

In a previous paper (1), we studied the polarographic behaviour of L-ascorbic acid and dehydro-L-ascorbic acid in an acid medium. A study was also made of the *i–E* curves in the rising portion of the polarographic wave. These data, together with those obtained from the microcoulometric study from electron spin resonance and from electrolysis with the identification of products by paper chromatography, led us to propose a reaction mechanism that fully agrees with the experimental results.

The polarographic behaviour of L-ascorbic acid differs with acid and basic media. This paper describes a study of the oxidation mechanism of this acid in a basic medium.

Experimental

All apparatus, cells, electrodes, solutions, and measurements are identical to those described in our previous paper (1).

Results

General Behaviour

The L-ascorbic acid, in a basic medium, oxidizes over the drop mercury electrode (DME), producing two polarographic waves. The second wave is only completely defined from p*H* 8 onwards (Fig. 1).

Microcoulometric Measurements

It is not possible to determine the number of electrons taking part in the oxidation waves of L-ascorbic acid in a basic medium from the decrease of the limiting current with the time of electrolysis.

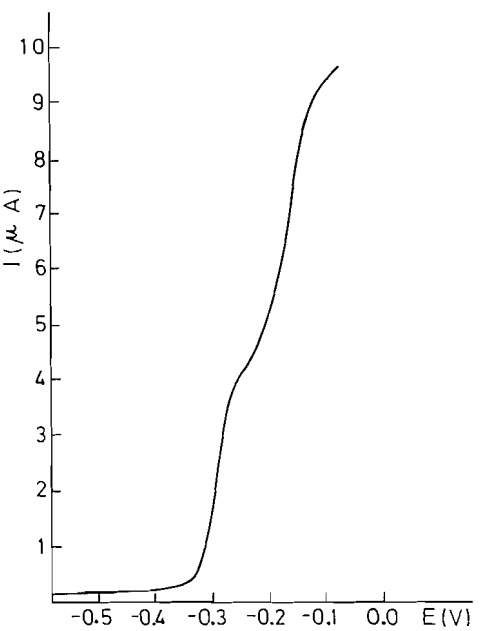

FIG. 1. Oxidation waves of L-ascorbic acid; p*H* = 8.20, $c = 5 \times 10^{-4}$ *M*.

This is due to the fact that L-ascorbic acid is unstable in this medium and therefore the decrease of the current is not only caused by the electrochemical oxidation of the acid but also by its homogeneous decomposition in solution.

If we consider, however, that the limiting current of the first wave is the same for both acid and basic media, that the second wave has practically the same height as the first, and that the compounds originating these waves must have, as will be seen later, similar diffusion coefficients, it can be concluded that the number of electrons transferred in both waves is equal to that of the first wave in an acid medium, i.e. two.

Polarographic Behaviour

For the first oxidation wave, the limiting current is independent of the p*H* whilst $E_{1/2}$ varies linearly with the p*H*. The value of the slope of the plot $E_{1/2}$ vs. p*H* is -68 mV/p*H* unit. This variation corresponds to the ultimate linear portion of Fig. 2. The two previous linear portions demonstrate the behaviour of $E_{1/2}$ vs. p*H* in acid and neutral media (1) (p*H* between 2.5–8).

$E_{1/2}$ is independent of the concentration of L-ascorbic acid. The logarithmic analysis of the wave gave a straight line with a slope of 30 mV per decade that is practically independent of the p*H*.

The limiting current is governed by diffusion as $\log i_{lim}$ vs. $\log h$ (corrected for the back pressure) is linear with a slope of 0.50. The limiting current has a temperature coefficient of 1.1% per °C and is proportional to the L-ascorbic acid concentration in the bulk of the solution.

The second oxidation wave appears at p*H* 7, although it is not completely defined until p*H* 8. The limiting current is independent of the p*H* whilst $E_{1/2}$ varies linearly with the p*H*. The slope of the plot of $E_{1/2}$ vs. p*H* is -79 mV/p*H* unit (Fig. 3).

With a decrease in the L-ascorbic acid concentration, $E_{1/2}$ shifts to more anodic values, whilst i_{lim} varies linearly. The limiting current is governed by diffusion the plot $\log i_{lim}$ vs. $\log h$ being linear with a slope of 0.51.

Tafel Curves and Reaction Orders

(a) Influence of pH

In the case of the first oxidation wave, the Tafel curves are independent of the p*H* and their slopes have an average value of 42 mV per decade (Fig. 4).

The reaction orders with respect to the H^+ con-

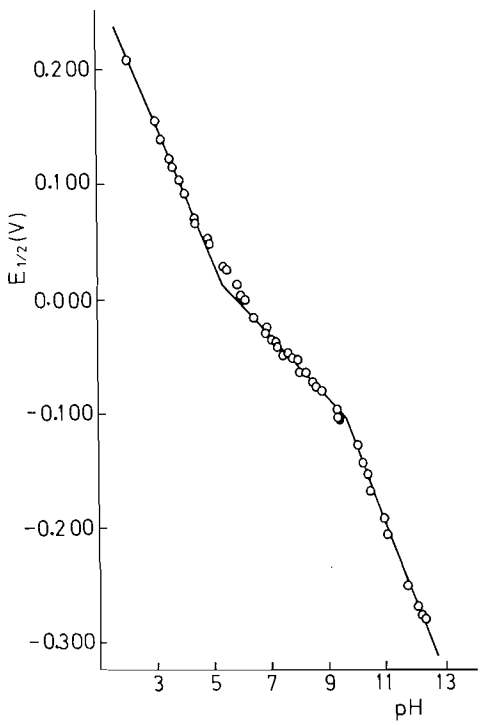

FIG. 2. First wave: variation of $E_{1/2}$ with p*H*.

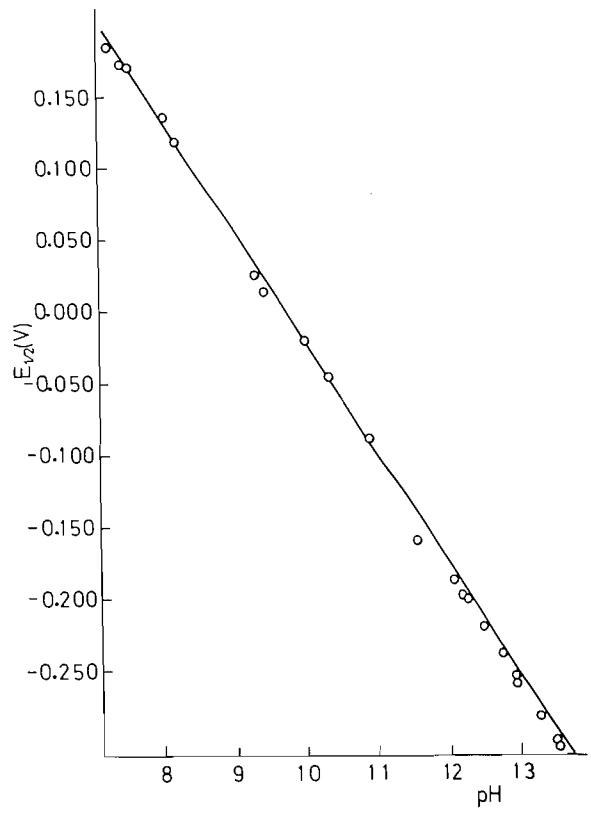

FIG. 3. Second wave: variation of $E_{1/2}$ with p*H*.

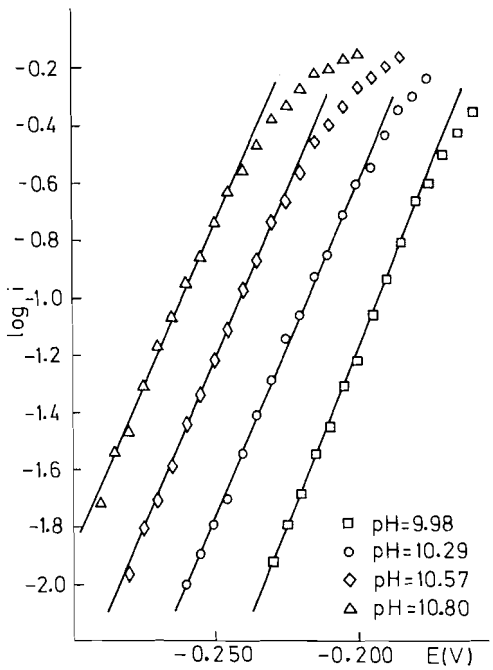

Fig. 4. Representation of Tafel curves, first wave.

centration are:

$$\left[\frac{\partial \log i}{\partial \log \mathrm{H}^+}\right]_{E,T,c_{i\neq j}} = -2.0 \quad \text{at } pH = 10\text{–}11$$
$$= -1.1 \quad \text{at } pH = 12\text{–}13$$

The order is independent of the potential in the zone where Tafel's law is obeyed (Fig. 5).

In the case of the second oxidation wave, the Tafel slopes are equally independent of the H^+ concentration, and the slopes have an average value of 30 mV per decade. The reaction order with respect to the H^+ concentration in the pH range 7–9 is -2.0.

(b) Influence of L-*Ascorbic Acid Concentration*

For both oxidation waves, the order with respect to the concentration was 1 in all cases and was independent of the potential in the zone where Tafel's law is obeyed.

Identification of Intermediate Products

It has already been established (1) that the first product from the L-ascorbic acid oxidation is dehydro-L-ascorbic acid. This acid or any of its derivatives could therefore be responsible for the electron transfer that originates the second oxidation wave.

Using the Mapson and Partridge technique (2) the first product of oxidation in an acid medium was identified as dehydro-L-ascorbic acid from its R_F characteristics (0.07 weak and 0.49 strong). As the position of the weak spot (0.07) corresponds approximately with that assigned to 2,3-diketogulonic acid, it can be assumed that there is a rupture of the lactone ring of dehydro-L-ascorbic acid. This fact was confirmed when the chromatography was carried out in a basic medium (pH 10) and the spot was accentuated. It can therefore be supposed that, in a basic medium, L-ascorbic acid, or its first oxidation product, undergoes hydrolysis with rupture of the lactone ring.

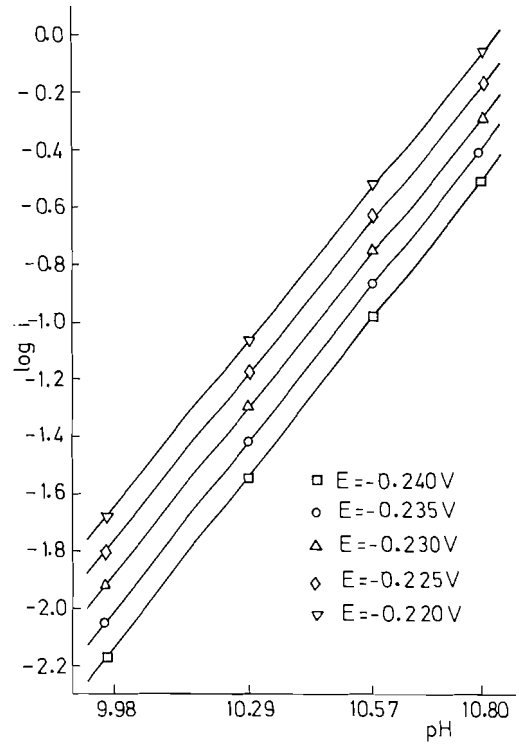

FIG. 5. Reaction orders.

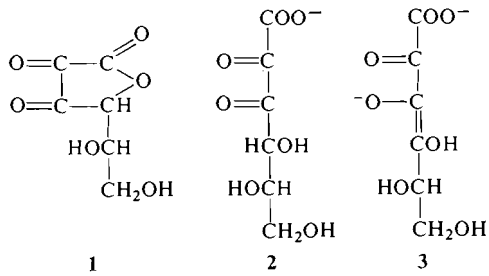
On the other hand, Euler and Hasselquist (3) detected the formation of an enediol type compound during the decomposition of dehydro-L-ascorbic acid in a basic medium. In the present study, we have obtained the corresponding disodium salt by using the technique described by Kenyon and Munro (4). The structure of this salt was confirmed by infrared spectroscopy where it was observed that the C—O band (1160 cm^{-1}), characteristic of γ-lactones, had disappeared and that a band of double bonding existed (1640 cm^{-1}).

Therefore, from these results, one can assume that dehydro-L-ascorbic acid undergoes, in a basic medium, the **1**, **2**, **3** sequence.

The final products of the reaction form an extremely complex mixture in which L-treonic and oxalic acids are found, together with fructose and



1 2 3

other sugars. These products are identified by paper chromatography on a concentrated solution which has undergone electrolysis.

Discussion and Conclusions

(a) First Oxidation Wave

In a previous paper (1) the oxidation mechanism of L-ascorbic acid in an acid medium was established. The reaction orders with respect to the H^+ concentration were -2 and -1 depending on whether the acid was nondissociated or in its monodissociated form. The potentials varied as predicted with the pH, i.e. the plot of $E_{1/2}$ vs. pH gave two linear segments with slopes of -59 and -27 mV/pH unit which correspond to a process in which a two proton and a one proton transfer takes place respectively.

If this oxidation mechanism were also true for basic media, the reaction orders would be -1 and 0 depending on whether the acid was in its monodissociated form or was completely dissociated. The plot of $E_{1/2}$ vs. pH should give two linear segments with slopes of -27 and 0 mV/pH unit, respectively.

However, the reaction orders were found to be -2.0 for pH 10–11 and -1.1 for pH 12–13, whilst the plot of $E_{1/2}$ vs. pH is linear with a slope of -68 mV/pH unit.

The fact that, with respect to the H^+ concentration, the reaction order increases from -1 (in neutral medium) to -2 and that the slope of the plot $E_{1/2}$ vs. pH increases from -27 mV/pH unit (neutral medium) to -68 mV/pH unit indicates the existence of a chemical step, with the participation of an H^+ ion, before the rate determining step (r.d.s.).

On the other hand, from data obtained from the identification of products, 2,3-diketogulonic acid in solution is converted to the enolate shown in structures **1**, **2**, **3**.

From the above conclusions, the oxidation mechanism in a basic medium can be represented by Scheme 1, where reaction 1 represents hydrolysis with rupture of the lactone ring, reactions 2 and 3 represent the one electron transfers, and reaction 4 represents dissociation (enolate formation) of 2,3-diketogulonic acid.

Assuming reaction 3 to be the r.d.s. and applying the approximation of equilibrium state, the value of the intensity in the rising portion of the wave could be expressed as

$$[1] \qquad i = 2FK_1K_2k_3 \frac{c_T}{K_1c_H + c_H^2} \exp(2-\beta)FE/RT$$

where c_T is the total concentration of L-ascorbic acid in the bulk of the solution, c_H the concentration of H^+ ions, K_1 and K_2 the equilibrium constants of reactions 1 and 2, and k_1 the rate constant of the rate determining step.

Table 1 gives a comparison of the theoretical results from the aforementioned mechanism and the experimental results.

As is logical, when pK_2 is less than the pH of the medium, reaction 1 of Scheme 1 should be ignored.

The close agreement between the experimental and theoretical results indicates that the oxidation process probably takes place as shown in Scheme 1.

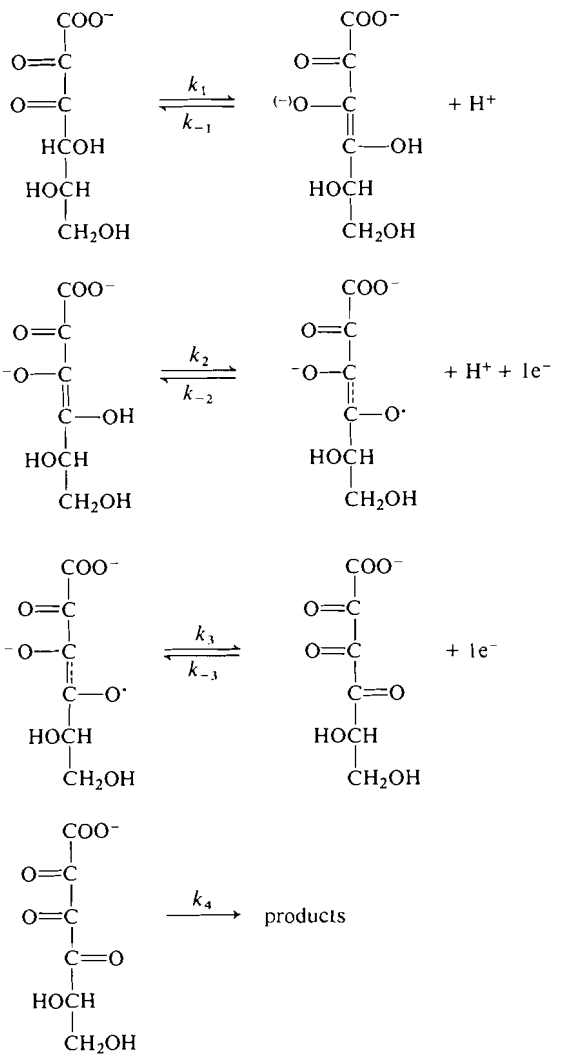
TABLE 1. Comparison between theoretical and experimental results for first wave

Parameter	Value: Theoretical ($\beta = 0.5$)	Value: Experimental
Tafel slope	39 mV	42 mV
Order with respect to L-ascorbic acid concentration	1	1
Order with respect to H^+ ion	-2 for $K_1 \ll c_H$ -1 for $K_1 \gg c_H$	-2.0 (pH 10–11) -1.1 (pH 12–13)

(b) Second Oxidation Wave

The fact that this wave has practically the same intensity as the first seems to indicate that the wave is caused by the product of the first oxidation of L-ascorbic acid in a basic medium, i.e. 2,3-diketo-



SCHEME 2. Reaction kinetic pathways of L-ascorbic acid (second wave).

TABLE 2. Comparison between theoretical and experimental results for second wave

Parameter	Value: Theoretical	Value: Experimental
Tafel slope	29.5 mV	29.7 mV
Order with respect to L-ascorbic acid concentration	1	1
Order with respect to H^+ ion	-2 for $(1 + K_1)c_H \gg K_1K_2$ -1 for $K_1K_2 \gg (1 + K_1)c_H$	-2 —

gulonic acid. As this compound undergoes, in a basic solution, a series of consecutive chemical reactions, these can perhaps be considered as being the primary stages of oxidation, that is, enolization and dissociation (reaction 1 of Scheme 2).

Following the formation of the enolate, oxidation can take place by means of two one electron transfers forming 2,3,4-triketogulonic acid (reactions 2 and 3 of Scheme 2). This acid is believed to be highly unstable owing to the presence of four adjoining carbonyl groups and decomposition follows giving substances with a shorter carbon chain (reaction 4 of Scheme 2), as observed in the results from the chromatography.

Considering reaction 4 to be the r.d.s. and applying the approximation of equilibrium state, the value of the current in the rising portion of the wave can be expressed by

$$[2]\quad i = 2FK_1K_2K_3k_4 \frac{c_T}{K_1K_2c_H + (1 + K_1)c_H^2} \times \exp(2FE/RT)$$

where c_T is the total concentration of L-ascorbic acid in the bulk of the solution, K_1, K_2, and K_3 are the equilibrium constants of the reactions 1, 2, and 3, and k_4 is the rate constant of the rate determining step.

Table 2 gives a comparison between theoretical values deduced from the above mechanism and the experimental results.

The close agreement between the theoretical and experimental results clearly indicates that the oxidation process probably takes place as shown in Scheme 2.

Received August 3, 1977

DAVID J. CANE, WILLIAM A. G. GRAHAM, and LIVIU VANCEA. Can. J. Chem. **56**, 1538 (1978).

A series of (1,3-dithiane)$Fe(CO)_4$ complexes, (2-X-1,3-dithiane)$Fe(CO)_4$, X = H, Me, $SiMe_3$, $GeMe_3$, $SnMe_3$, $PbMe_3$, has been prepared and characterized, and both the complexes and the free ligands studied by ^1H and ^{13}C nmr spectroscopy. The energy barrier to ring inversion in (1,3-dithiane)$Fe(CO)_4$, ΔG_{298}†, is 14.7 ± 0.2 kcal mol^{-1}, some 4.4 kcal mol^{-1} higher than in free 1,3-dithiane. ^{13}C nmr spectra showed that within the $Fe(CO)_4$ moiety, rapid averaging of carbonyl groups occurs down to at least −80°C.

DAVID J. CANE, WILLIAM A. G. GRAHAM et LIVIU VANCEA. Can. J. Chem. **56**, 1538 (1978).

On a préparé et caractérisé une série de complexes (dithiane-1,3)$Fe(CO)_4$, (2-X-1,3-dithiane)$Fe(CO)_4$, X = H, Me, $SiMe_3$, $GeMe_3$, $SnMe_3$ et $PbMe_3$ et on a étudié aussi bien les complexes que les ligands libres par spectroscopie rmn ^1H et ^{13}C. La barrière d'énergie à l'inversion du cycle dans le (dithiane-1,3)$Fe(CO)_4$, ΔG_{298}†, est 14.7 ± 0.2 kcal mol^{-1}, soit une valeur qui est 4.4 kcal mol^{-1} plus élevée que dans le dithiane-1,3 libre. Les spectres rmn du ^{13}C montrent qu'à l'intérieur de la fraction $Fe(CO)_4$ il se produit des transpositions rapides des groupes carbonyles jusqu'à une température d'au moins −80°C.

[Traduit par le journal]

Introduction

Over the past few years, the six-membered heterocycle 1,3-dithiane and its derivatives have been the subject of many investigations. Initially, the interest arose because of their structural similarity to cyclohexane and 1,3-dioxane. Most efforts were directed at understanding the conformational preferences in these heterocycles, and this was tackled using the equilibrium method (1, 2), ^1H (3–7) and ^{13}C (3, 8) nmr spectroscopy, dipole moment measurements (6), and X-ray structural determinations (9). Recently, 1,3-dithianes have become increasingly important reagents in organic (10) and organometallic synthesis (11, 12).

Transition metal complexes of 1,3-dithianes have been comparatively little studied. In 1975, the synthesis and crystal structure of the first metal carbonyl complex of this type, (1,3-dithiane)$Fe(CO)_4$, was reported (13). In the solid state structure of this compound the dithiane ring adopts a chair conformation in which one of the sulphur atoms occupies an axial site in the trigonal bipyramidal arrangement around iron. Some mercury (14), niobium (15), tantalum (15), and copper (16) complexes of 1,3-dithiane have also been described.

In the course of a study of transition metal derivatives of 1,3-dithiane, we have prepared a series of 2-substituted dithianes, together with the corresponding iron tetracarbonyl complexes, (2-X-1,3-dithiane)$Fe(CO)_4$, X = Me, $SiMe_3$, $GeMe_3$, $SnMe_3$, $PbMe_3$. We report here full characterization of the previously unknown members of this series, together with the results of ^1H and ^{13}C nmr studies on all the compounds, and on (1,3-dithiane)$Fe(CO)_4$.

Results and Discussion

Reaction of diiron nonacarbonyl with 1,3-dithiane (13) or its derivatives proceeds smoothly in THF (17) at room temperature according to reaction 1:

[1] 
X = H, Me, $SiMe_3$, $GeMe_3$, $SnMe_3$, $PbMe_3$

The (dithiane)$Fe(CO)_4$ complexes are yellow or red–brown crystalline solids, which are reasonably stable in air. For example, infrared spectroscopy of (2-Me_3Si-1,3-dithiane)$Fe(CO)_4$ showed no appreciable decomposition after the crystals were exposed to the atmosphere for 4 days. However, solutions of the complexes are sensitive to air and light.

The (dithiane)$Fe(CO)_4$ complexes were fully characterized by analysis, mass spectrometry (low and high resolution), infrared, ^1H and ^{13}C nmr spectroscopy.

Infrared Spectra

Assuming that the solid-state structure (13) of (1,3-dithiane)$Fe(CO)_4$ is preserved in solution, idealized C_{3v} symmetry at iron would predict three infrared-active carbonyl stretching bands ($2A_1 + E$).

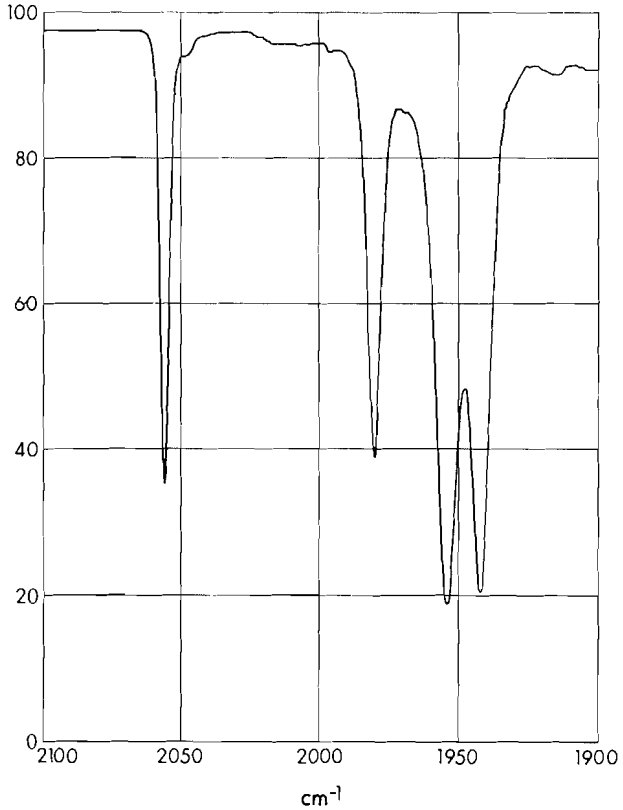

FIG. 1. Carbonyl stretching region of the infrared spectrum of (1,3-dithiane)$Fe(CO)_4$ in *n*-hexane solution.

The infrared spectrum of this compound in fact showed four terminal carbonyl bands[1] (Fig. 1), which may be understood in terms of the asymmetry introduced by the dithiane ligand (C_s symmetry, $3A' + A''$ modes (19)).

The carbonyl stretching frequencies observed for the series of complexes prepared here differ very little (Table 1), although there is a general trend to lower frequencies upon substitution.

[1]The previously reported (13) infrared spectrum of (1,3-dithiane)$Fe(CO)_4$ is now agreed to be in error (18).

^1H *Nuclear Magnetic Resonance Spectra*

In the absence of ring inversion, the ^1H nmr spectrum of 1,3-dithiane can be roughly described (see below) as consisting of both AB and AA'BB'CD spin systems. Coordination of one of the sulfur atoms to iron reduces the symmetry of the molecule, and AB and ABCDEF spin systems are obtained. The following discussion will deal mainly with the H-2 resonances. The numbering scheme adopted is shown in reaction 1.

At $-30°C$, the ^1H nmr spectrum of (1,3-dithiane)-$Fe(CO)_4$ in toluene-d_8 showed an AB pattern with calculated chemical shifts at 3.12 and 2.58 ppm, and three sets of multiplets with estimated positions at 1.9, 1.7, and 1.1 ppm (Fig. 2). The upfield part of the AB pattern was considerably broader (width at half-height 4 Hz) than the lower field part (width 1.5 Hz). Selective decoupling confirmed that this differential broadening is due to coupling to the multiplets centered at 1.7 and 1.9 ppm. The resonance at 2.58 ppm is assigned to H-2_{eq} and the one at 3.12 ppm to H-2_{ax}. H-2_{eq} can couple via a planar W-pathway to H-4_{eq} and H-6_{eq} and this broadens its signal relative to that of H-2_{ax} for which no such couplings exist. Analysis of the AB system (20) afforded $^2J(\text{H-}2_{ax} - \text{H-}2_{eq}) = 13.5$ Hz and $\delta(\text{H-}2_{ax}) - \delta(\text{H-}2_{eq}) = 54.2$ Hz.

The three multiplets at higher field in the spectrum are tentatively assigned to H-4, H-6, and H-5, on the basis of their upfield shifts on complex formation.

On warming, the AB pattern broadens, coalesces, and at 35°C becomes a single resonance (Fig. 2). At this temperature, ring inversion occurs rapidly on the nmr time scale. The coalescence temperature is 25°C and this gives a value for the free energy of activation for ring inversion ($\Delta G_{298}\dagger$) of 14.7 ± 0.2 kcal mol^{-1}. It therefore appears that coordination of a ring sulfur atom to iron results in a considerable increase in the free energy barrier for ring inversion over that in free 1,3-dithiane ($\Delta G_{213}\dagger = 10.3$ kcal mol^{-1}) (21).

^1H nmr data for the other (dithiane)$Fe(CO)_4$ com-

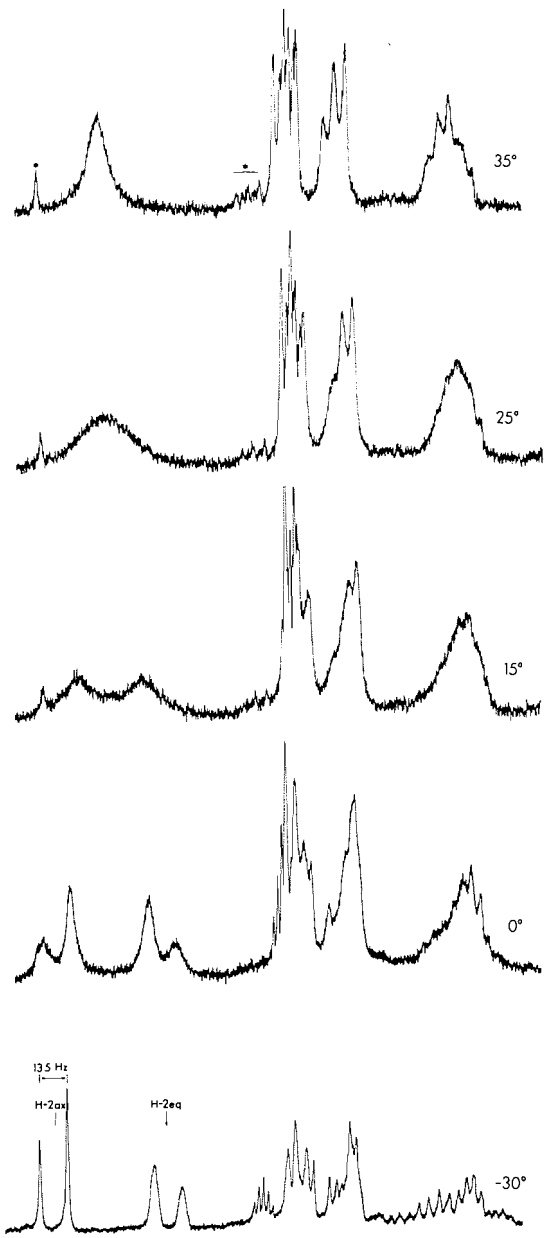

FIG. 2. Proton nmr spectra of (1,3-dithiane)$Fe(CO)_4$ in toluene-d_8 at a series of temperatures. Peaks marked with asterisks are due to free 1,3-dithiane. Quintet visible at centre of −30°C spectrum is due to residual toluene-d_7.

plexes are given in Table 2. The corresponding parameters for the free ligands are listed in Table 3. The ^1H nmr of 1,3-dithiane and 2-Me-1,3-dithiane in CS_2 have been previously reported, but not analyzed (22). The analysis of such AA'BB'CD systems has been described (23), and the 220 MHz spectrum of 2-Ph-1,3-dithiane has been interpreted using iterative methods (23, 24).

Generally speaking, the H-2 resonance in the free ligands is deshielded on going from silicon to lead derivatives. Complexation to iron results in a general upfield shift of the ring proton resonances, H-2 being most affected. The methyl protons attached to the group IV substituent atom, on the other hand, frequently shift to lower field.

Considerable difficulty was encountered in obtaining the ^1H nmr spectra of (dithiane)$Fe(CO)_4$ complexes. Although samples were prepared in the dark using dry, oxygen-free solvents, rapid decomposition of the lower members of the series frustrated many attempts at spectral determination. However, it was found that spectra of high quality could be obtained by sealing the samples in cyclohexane-d_{12} or toluene-d_8 under 1 atm of carbon monoxide.[2]

^{13}C *Nuclear Magnetic Resonance Spectra*

The ^{13}C nmr spectrum of 1,3-dithiane is expected to show three resonances, due to C-2, C-4,6, and C-5. The presence of a substituent in the 2-position makes the assignment unambiguous: C-2 can be differentiated from C-5 by off-resonance decoupling, and C-4,6 has twice the intensity of C-2 or C-5. Coordination of 1,3-dithiane to iron removes the plane of symmetry and four signals of equal intensity are expected for the ring carbons of (1,3-dithiane)$Fe(CO)_4$. Unambiguous assignment is possible using model compounds such as (2-Me_3E-1,3-dithiane)-$Fe(CO)_4$ where E has an isotope with spin of 1/2 in sufficient abundance, for example $^{117,119}Sn$ or ^{207}Pb.

^{13}C nmr data for the (dithiane)$Fe(CO)_4$ complexes and for the free ligands are given in Tables 4 and 5, respectively. The ^{13}C nmr spectra of 1,3-dithiane and 2-Me-1,3-dithiane in $CDCl_3$ have been reported previously (8).

Complexation of dithianes to iron results in a downfield shift for C-2, C-5, C-6, and for the methyl carbons. As expected, C-2 and C-6 are the most affected; the downfield shift for C-2 is between 9.9 and 12.5 ppm, and the corresponding shift for C-6 between 13.6 and 15.9 ppm. The downfield shift of the methyl carbons is only 1.6–4.0 ppm and C-5 is even less affected: downfield shift 0.5–2.4 ppm. In contrast, C-4, the ring carbon most distant from iron, is shifted upfield by 0.3 to 1.3 ppm.

The carbonyl chemical shifts differ little on changing the group IV substituent on the dithiane ligand.

The ^{13}C–$^{117,119}Sn$ or ^{13}C–^{207}Pb coupling constants for the ring carbons decrease on complexation, the most affected being the one-bond coupling to C-2.

[2]On one occasion, an nmr tube containing (1,3-dithiane)-$Fe(CO)_4$ in toluene-d_8 under carbon monoxide shattered as the spectrum was being run, damaging the probe.

	4.22 (s) [31]	2.4 (m)	1.8 (m)	0.91 (s) [64]

[a]In ppm from TMS; multiplicities in parentheses; ambient temperature. Values in square brackets are ^{1}H–^{117,119}Sn or ^{1}H–^{207}Pb coupling constants in Hz. Solvent: cyclohexane-d_{12} (top entry) or toluene-d_8 (bottom entry).
[b]^3J(H—CH$_3$) = 7 Hz.

The similar coupling to the methyl carbons increases on complexation. No coupling was observed to the carbonyl carbons.

Although the solid state structure of (1,3-dithiane)-Fe(CO)$_4$ indicates nonequivalent carbonyl groups, in solution at room temperature the carbonyl carbon resonances of this and of all the other (dithiane)Fe-(CO)$_4$ complexes appear as a sharp singlet. This indicates a rapid carbonyl rearrangement on the nmr time scale.

Spectra at lower temperatures were recorded in the hope of slowing down the carbonyl scrambling process. However, the carbonyl signals of all complexes investigated here remained sharp to the lowest accessible temperatures (−80°C for (1,3-dithiane)Fe(CO)$_4$, (2-Me-1,3-dithiane)Fe(CO)$_4$, and (2-Me$_3$Ge-1,3-dithiane)Fe(CO)$_4$ and −90°C for the others). This perhaps is not too surprising in view of the extremely low barrier for carbonyl scrambling in Fe(CO)$_5$ (25, 26) and its derivatives, such as Fe(CO)$_4$L (L = C_5H_5N (27), PF_3 (28)) and Fe(CO)$_3$(L—L) (L—L = $Me_2PCH_2CH_2PMe_2$ (29), $Ph_2PCH_2PPh_2$ (30), to mention but a few).

The ring carbons of the (dithiane)Fe(CO)$_4$ complexes showed fairly sharp resonances in the room temperature spectra. As the temperature was decreased, these resonances broadened and at −80 or −90°C, the ring signals had in many cases disappeared into the baseline. The methyl carbons exhibited sharp resonances throughout this temperature range.

The temperature dependence of the ^{13}C nmr spectra described above is presumably due to nonrigidity in the dithiane ring. For (1,3-dithiane)Fe-

[d]Coupling constant too small to observe.

$(CO)_4$ it is likely that we are observing the same ring inversion process in both ^1H and ^{13}C spectra. Ring inversion has also been observed in the compounds cyclohexyltrimethyltin and cyclohexyltrimethyllead (31). The exact nature of the processes involved in the 2-substituted dithiane complexes is open to speculation.

Experimental Section

All experiments were carried out under an atmosphere of dry, oxygen-free argon or nitrogen. Solvents were distilled from lithium aluminum hydride or calcium hydride and saturated with argon or nitrogen before use. Nuclear magnetic resonance solvents were dried over type 4A Molecular Sieves. In general, starting materials were commercially available and were used as received. Me_3PbBr was prepared by a literature method (32).

^1H nmr spectra were recorded on Varian A-56/60A or HA-100 instruments. Spectra were referenced vs. internal tetramethylsilane (TMS) or the residual proton from deuterated solvents (cyclohexane-d_{12} 1.38 ppm, toluene-d_8 6.98 ppm (33). Our own measurements confirm these values). Nuclear magnetic resonance tubes containing (dithiane)$Fe(CO)_4$ complexes in toluene-d_8 or cyclohexane-d_{12} (previously degassed by several freeze–thaw cycles) were sealed off under 1 atm of carbon monoxide,[2] and were stored at liquid nitrogen temperature in the dark. The free energy of activation for ring inversion in (1,3-dithiane)$Fe(CO)_4$ was calculated from the chemical shift separation at slow exchange and the coalescence temperature (34, 35). The chemical shift difference between the axial and equatorial H-2 resonances below the region of coalescence (243–273 K) was temperature dependent. A least-squares analysis of the chemical shift difference ($\Delta\delta$) in toluene-d_8 against temperature (T, K) suggested the following relationship:

$$\Delta\delta = -0.1445T + 89.35$$

From this relationship, $\Delta\delta$ at coalescence could be calculated.

^{13}C nmr spectra were recorded in the pulse Fourier transform mode of operation on a Bruker HFX-90-Nicolet 1085 spectrometer operating at 22.6 MHz. Spectra were obtained using proton broad-band decoupling conditions and with quadrature detection. Assignment of resonances was carried out using the off-resonance decoupling technique, as well as $^{117,119}Sn$ or ^{207}Pb satellites. The number of data points (channels) was usually 8000 and the sweep width 6000 Hz (for the (dithiane)$Fe(CO)_4$ complexes) or 5000 Hz (for the free ligands). This afforded a digital resolution of approximately 0.03 ppm. Other operating conditions were as given elsewhere (36). Toluene-d_8 served as nmr solvent and lock and TMS was employed as internal standard. For most spectra, tris(acetylacetonato)chromium(III) was used as a relaxation agent (37). Most sample tubes, especially for the lower members of the (dithiane)$Fe(CO)_4$ series, were sealed off under vacuum. Chemical shifts downfield from TMS are taken as positive.

Infrared spectra were recorded using a Perkin-Elmer 337 grating spectrometer with scale expansion, operating at a speed of 39 cm^{-1} min^{-1} and calibrated with carbon monoxide gas. Reported infrared stretching frequencies are considered accurate to ± 1 cm^{-1}.

[a]Yields quoted are of pure material.
[b]Determined by mass spectrometer. Values quoted refer to the most intense peak of the isotopic multiplet due to the parent ion.

Routine mass spectra were obtained using AEI MS-12 or modified MS-2 instruments. Exact mass measurements were performed on MS-9 and MS-50 spectrometers. Samples were introduced by direct evaporation or sublimation, with the inlet systems of the mass spectrometers at room temperature. Computer-calculated isotope combination patterns were in excellent agreement with those observed for the parent ions of the new compounds.

Microanalyses were carried out by the Microanalytical Laboratory of this Department. Melting points were determined in sealed tubes on a Gallenkamp apparatus, and are uncorrected.

Preparation of 2-Substituted 1,3-Dithianes

Preparations of 2-Me-1,3-dithiane (38), 2-*tert*-Bu-1,3-dithiane (39), and 2-Me_3Si-1,3-dithiane (12) were carried out according to published procedures. Compounds 2-Me_3E-1,3-dithiane (E = Ge, Sn, Pb) were prepared from Me_3GeBr, Me_3SnCl, and Me_3PbBr using the method quoted above for 2-Me_3Si-1,3-dithiane. Yields, analytical data, and physical properties of new compounds are given in Table 6.

Preparation of (Dithiane)$Fe(CO)_4$ Complexes

The synthesis of (1,3-dithiane)$Fe(CO)_4$ (in 28% yield) has been described (13). We prepared the compounds (2-Me-1,3-dithiane)$Fe(CO)_4$ and (2-Me_3E-1,3-dithiane)$Fe(CO)_4$ (E = Si, Ge, Sn, Pb) using a similar procedure, although we found that purification by low-temperature crystallization gave improved yields over chromatographic work up. Yields, analytical data, and physical properties are given in Table 6. In attempted preparations of (2-*tert*-Bu-1,3-dithiane)$Fe(CO)_4$, infrared spectra suggested that the compound was formed, but the crystals obtained decomposed on reaching room temperature.

Synthesis of (1,3-Dithiane)$Fe(CO)_4$

All operations were carried out with precautions to exclude light. To $Fe_2(CO)_9$ (3.8 g, 10.5 mmol) was added a solution of 1,3-dithiane (1.26 g, 10.5 mmol) in 75 ml THF. The mixture was stirred under a static argon atmosphere for 4 h, and then solvent and $Fe(CO)_5$ were removed at room temperature under vacuum. The dark brown, oily residue was extracted with petroleum-ether (bp 50–80°C, 50 ml) and after filtration the yellow–brown solution was cooled to −20°C overnight to give (1,3-dithiane)$Fe(CO)_4$ as long, red–brown crystals (1.3 g, 43%). Further cooling of the mother liquor to −78°C gave a secondary yield of 0.9 g of slightly less-pure material.

Hydrolysis of $(Et_4N)[TaF_6]$ with Et_4NOH in organic medium gives $(Et_4N)_2[Ta_2OF_{10}]$. The Ta—O—Ta infrared and Raman frequencies reflect the linearity of the bridge, in agreement with a previous X-ray study. The ^{19}F nmr spectrum is of the type $AA'E_4E_4'$. Chemical shifts are compared with other pseudo-octahedral species of tantalum with formula $[TaF_5L]$.

J. SALA-PALA, J. Y. CALVES, J. E. GUERCHAIS, S. BROWNSTEIN, J. C. DEWAN et A. J. EDWARDS. Can. J. Chem. **56**, 1545 (1978).

Le composé $(Et_4N)_2[Ta_2OF_{10}]$ a été obtenu lors de l'hydrolyse d'une solution organique de $(Et_4N)[TaF_6]$ par de l'hydroxyde de tétraéthylammonium. Les fréquences caractéristiques du groupement Ta—O—Ta (ν_{as} = 880 cm^{-1}, ν_s = 270 cm^{-1}) sont en accord avec la linéarité du pont décelée lors d'une étude antérieure par diffraction de rayons-X. Le spectre rmn (^{19}F) est de type $AA'E_4E_4'$ avec δ_A = 13.0 et δ_E = 32.0 ppm ($CFCl_3$); $J_{A-A'}$ = 9.2, J_{A-E} = 33.4, $J_{A-E'}$ = 0.6 et $J_{E-E'}$ = 0 Hz. Les valeurs des déplacements chimiques des fluors sont comparées à celles d'autres espèces pseudo-octaédriques du tantale de type $[TaF_5L]$.

Introduction

Several tantalum fluoride species, $[TaF_6]^-$, $[TaF_7]^{2-}$, $[TaF_8]^{3-}$, and $[TaF_9]^{4-}$, have been reported in hydrofluoric acid solution (1, 2). The first three species have been well characterized by X-ray crystallography (3), while the last has been inferred by a study in solution (1). The hydrolysis of these species has excited little interest except for two articles. The solid $K_4[Ta_2OF_{12}]$ was obtained by the reaction of $K_2[TaF_7]$ with KOH (4). The hydrolysis of $[TaF_6]^-$ in aqueous solution was studied by fluorine magnetic resonance (5). There are some ambiguities in the latter article, e.g. a fluorine resonance doublet attributed to the equatorial fluorines of a pseudo-octahedral species $[TaF_5L]^{n-}$ could be due to $[TaF_5(OH_2)]$, $[TaF_5OH]^-$, $[TaOF_5]^{2-}$, or a polymeric species.

An attempt to isolate, as solids, the various species produced in the hydrolysis of $[TaF_6]^-$ was made to fill the gaps in the previous studies. Such a procedure, although slower and more difficult than solution studies alone, is probably the only certain means of identifying the species produced and their degree of polymerization.

[1]NRCC No. 16542.

Experimental

$Et_4N[TaF_6]$ was prepared by the addition of Et_4NF to a hydrofluoric acid solution of $TaCl_5$(Et_4N/Ta = 1). Upon concentrating the solution the product precipitated. It was filtered, dried under vacuum (60°C and 15 Torr) for several days, and recrystallized from anhydrous CH_3CN.

$(Et_4N)_2[Ta_2OF_{10}]$

To an anhydrous methanol solution of $Et_4N[TaF_6]$ was added an aqueous methanolic solution of 20% Et_4NOH (Et_4N/Ta = 1.05). After shaking for several minutes the solution was slowly evaporated under vacuum until a precipitate was formed. This was filtered, washed with ether, and stored over P_4O_{10}. Its infrared spectrum and X-ray powder pattern were identical with those obtained for single crystal material of formula $(Et_4N)_2[Ta_2OF_{10}]$ used for the X-ray structure determination of that compound (6). *Anal.* calcd. for $C_{16}H_{40}F_{10}N_2OTa_2$: C 23.20, H 4.87, F 22.93, N 3.38; found: C 23.45, 23.60, H 4.89, 4.95, F 22.51, 22.51, N 3.25, 3.35.

Infrared and Raman Spectroscopy

Infrared spectra were obtained on a 1% KBr pellet with a 'Perkin-Elmer 225' apparatus. The infrared spectrum is shown in Fig. 1, with principal bands (cm^{-1}):

Fluorine Resonance Spectroscopy

Spectra were obtained at 94.1 MHz on a 'Varian Associates XL-100A-12' (at −70°C in liquid SO_2), at 250 MHz on a 'CAMECA' (from −30 to +20°C in CH_2ClCN), and at 56.4 MHz on a 'JEOL C-60HL' (from −30 to +60°C in CH_2ClCN). Chemical shifts are relative to internal $CFCl_3$ with positive shifts to low field.

Results and Discussion

Preparation

The slow evaporation of a solution of $Et_4N[TaF_6]$ in hydrogen peroxide gives a mixture of $Et_4N[TaF_6]$, $(Et_4N)_2[Ta(O–O)F_5]$, $Et_4N[Ta(O–O)F_4(H_2O)]$, and a fourth compound (7). The presence of an infrared band at 880 cm^{-1} in the latter compound was tentatively assigned to ν(O–O). However an X-ray diffraction study has shown that in fact it is an oxo compound of formula $(Et_4N)_2[Ta_2OF_{10}]$ in which the dimerisation is effected by a linear Ta—O—Ta bridge as in Fig. 3 (6). The origin of the 880 cm^{-1} band is described below.

In order to confirm, by a chemical path, the absence of a peroxo group we attempted a synthesis in a medium containing no peroxide. The precipitate obtained by addition of an Et_4NOH solution to an alcoholic solution of $Et_4N[TaF_6]$ had identical infrared spectra and Debye–Scherrer powder patterns with the previously obtained crystals of $(Et_4N)_2[Ta_2OF_{10}]$ (6). The formation of this anion, the first of the type $[M_2OF_{10}]^{2-}$ with a transition metal, might arise via an intermediate hydroxy compound (eq. [1]) followed by a condensation (eqs. [2] or [2′]).

Infrared and Raman Studies

For an anion $[M_2OX_{10}]^{n-}$ of symmetry D_{4h}, group theory predicts 33 normal modes ($4a_{1g}$, a_{1u}, $4a_{2u}$, $2b_{1g}$, b_{1u}, b_{2g}, $2b_{2u}$, $4e_g$, $5e_u$) of which 14 are infrared active (a_{2u} and e_u modes) and 15 are Raman active (g modes) (8).

In the present case the assignment of all these modes is not possible because of the intense bands arising from the organic cation. Nevertheless by comparison with studies of the anions $[M_2OX_{10}]^{n-}$ where M = Ru, Os, W; X = Cl and n = 4 (8–10) the following assignments are made. A very strong and wide infrared absorption at 880 cm^{-1} is attributed to the valence vibration ν_{as}(Ta—O—Ta).

Two strong infrared bands at 530 and 575 cm^{-1}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

are assigned to the valence vibrations ν_{as}(Ta—F_{axial}) and ν_{as}(Ta—$F_{equatorial}$).

In the Raman spectrum the most intense bands at 270 and 669 cm^{-1} are assigned to ν_s(Ta—O—Ta) and ν_s(Ta—F) respectively. The frequencies of ν_{as} and ν_s(Ta—O—Ta) (at 880 and 270 cm^{-1} respectively) are close to those of the bridge in the ion $[Os_2OCl_{10}]^{4-}$ (ν_{as} = 852 cm^{-1}, ν_s = 225 cm^{-1}; ∠Os—O—Os = 180°) (11) and quite different from those of the ion $[\{WO(O_2)_2(H_2O)\}_2O]^{2-}$ (ν_{as} = 790 cm^{-1}, ν_s = 556 cm^{-1}; ∠W—O—W = 139°) (12). This difference in the frequency separation of ν_{as} and ν_s is attributable to the difference in the angle ∠M—O—M in the anion. The high value of ν_{as} and the low value of ν_s found for the anions of tantalum and osmium arise from the linearity of the M—O—M bridge, a linearity which implies the existence of multiple-oxygen bonding because of overlap of the empty d_{xy} and d_{yz} orbitals of Ta(V) with the filled orbitals p_x and p_z of oxygen (see Fig. 3 for notations).

Fluorine Magnetic Resonance Studies

The fluorine resonance spectrum of $[Ta_2OF_{10}]^{2-}$, a doublet at 32 ppm and a quintuplet at 13 ppm with relative intensities of 4/1, is consistent with the structure found in the solid state. Fine structure in the quintuplet is particularly marked at −70°C in liquid sulfur dioxide (Fig. 4*b*). The origin of this fine structure was shown to be magnetic, rather than chemical, non-equivalence by a double irradiation experiment. When the doublet (equatorial fluorines) is irradiated only a single collapsed line is observed for the axial fluorines (Fig. 4*c*). A theoretical spectrum for the system $AA'E_4E_4'$ with $J_{A-A'}$ = 9.2, J_{A-E} = 33.4, $J_{A-E'}$ = 0.6, and $J_{E-E'}$ = 0 Hz is shown in Fig. 4*d*. It was calculated by the program NUMARIT[2].

Spectra in CH_2ClCN solution at −30°C and 250 MHz are very similar to those shown in Fig. 4 except for somewhat poorer resolution of the fine structure of the quintuplet. This fine structure disappears with increasing temperature such that at room temperature only a simple moderately resolved quintuplet is found.

In Table 1 are listed the fluorine resonance parameters for several species (TaF_5L) with a pseudo-octahedral structure about tantalum. They can be divided into two groups. One group has an axial–equatorial fluorine coupling constant of about 25 Hz, has the axial fluorine resonance at lower field than the equatorial fluorine resonance, and has both of them at lower field than the signal of $[TaF_6]^-$. The second group has a coupling constant of about 35 Hz, the axial fluorine at higher field than the equatorial fluorine, and both often at higher field than the signal of $[TaF_6]^-$. The species $[Ta_2OF_{10}]^{2-}$ clearly belongs to the second group.

[a]Species $[F_5Ta—Y—TaF_5]^{2-}$ with Y = O (see Fig. 3).
[b]Species $[F_5Ta—Y—TaF_5]^-$ with Y = F (see Fig. 3). δ_Y = 80.8, J_{A-Y} = 165, J_{E-Y} = 48.
[c]Species $[TaF_6]^-$ with all fluorines equivalent.
[d]Measured by the present authors.

The main group V elements, where there are no free *d* electrons, have the chemical shifts of axial fluorines at higher field than equatorial fluorines in their complexes while the reverse is found for the transition group V elements in those complexes where bonding via the *d* electrons is not possible (14). Therefore those complexes of TaF_5 which have the axial fluorine resonance at higher field than the equatorial may have multiple bonding between the tantalum and the ligand, employing the *d* orbitals of tantalum.

Conclusions

The hydrolysis of $[TaF_6]^-$ with Et_4NOH yields initially the dinuclear species $[Ta_2OF_{10}]^{2-}$. Further hydrolysis of $[TaF_6]^-$ or $[Ta_2OF_{10}]^{2-}$ yields compounds less rich in fluorine which are presently being studied by the same experimental techniques used in this work. The contribution of infrared, Raman, fluorine magnetic resonance, and X-ray structure determination on the same material provides a solid base for the study of further compounds in this series.

Equilibrium decomposition pressures of the compounds K_2ZrCl_6 and K_2HfCl_6

G. J. KIPOUROS AND S. N. FLENGAS

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received October 3, 1977

G. J. KIPOUROS and S. N. FLENGAS. Can. J. Chem. **56**, 1549 (1978).

The chemical equilibria representing the reactions

$$K_2ZrCl_{6(S\text{ or }L)} \geq 2KCl_{(S\text{ or }L)} + ZrCl_{4(vap,P,T)}$$

and

$$K_2HfCl_{6(S\text{ or }L)} \geq 2KCl_{(S\text{ or }L)} + HfCl_{4(vap,P,T)}$$

were investigated by direct vapour pressure measurements. The thermodynamic data for these reactions, such as free energies and enthalpies of reaction, have been calculated. With reference to the separation of Hf from Zr by a recently developed process based on the selective reactivity of $ZrCl_4$ and $HfCl_4$ vapours with alkali chlorides, it is shown that KCl is a better separating agent than LiCl.

G. J. KIPOUROS et S. N. FLENGAS. Can. J. Chem. **56**, 1549 (1978)

On a étudié, par des mesures directes de pression de vapeur, l'équilibre chimique représentant les réactions

$$K_2ZrCl_{6(S\text{ ou }L)} \geq 2KCl_{(S\text{ ou }L)} + ZrCl_{4(vap,P,T)}$$

et

$$K_2HfCl_{6(S\text{ ou }L)} \geq 2KCl_{(S\text{ ou }L)} + HfCl_{4(vap,P,T)}$$

Pour ces réactions on a calculé les données thermodynamiques telles que les énergies libres et les enthalpies de la réaction. Dans l'optique d'une séparation du Hf du Zr à l'aide d'un processus développé récemment, basé sur une réactivité sélective des vapeurs de $ZrCl_4$ et $HfCl_4$ avec des chlorures alcalins, on a montré que le KCl est un meilleur agent pour la séparation que le LiCl.

[Traduit par le journal]

Introduction

In previous publications from this laboratory (1–4) the vapour pressures of $ZrCl_4$ in equilibrium with its solutions containing alkali chlorides such as LiCl, NaCl, KCl, and CsCl, and of $HfCl_4$ in equilibrium with its solutions containing alkali chlorides such as LiCl and CsCl, have been determined by direct experimental techniques involving the use of a spoon type Bourdon gauge (1, 2) or a molten tin isoteniscope (3, 4).

In the present investigation, a quartz spiral type Bourdon gauge has been applied to the determination of the vapour pressures of $ZrCl_4$ and of $HfCl_4$ in equilibrium with the two pure compounds K_2ZrCl_6 and K_2HfCl_6 respectively, over a temperature range extending below and above their melting points.

In addition, part of the phase diagram of the system K_2ZrCl_6–K_2HfCl_6 has been determined by cryoscopy.

From the results of this study, the equilibrium dissociation constants, free energies, and enthalpies for the reactions

$$[1] \qquad K_2MCl_{6(S)} \rightleftarrows 2KCl_{(S)} + MCl_{4(vap)}$$

where M represents Zr or Hf, have been calculated.

The equilibrium constant for the exchange reaction

$$[2] \qquad K_2ZrCl_6\ (\text{in solid solution}) + HfCl_4\ (\text{vapour}) \geq K_2HfCl_6\ (\text{in solid solution}) + ZrCl_4\ (\text{vapour})$$

was also calculated

From the above data, the theoretical efficiency for the separation of hafnium from zirconium by a previously developed process based on the selective reactivity of $ZrCl_4$ and $HfCl_4$ vapours with alkali halides (5, 6) has been calculated. The results indicate that KCl should be more efficient for separating those two elements than LiCl.

Experimental

At specific partial pressure and temperature, pure $ZrCl_4$ and $HfCl_4$ vapours react with solid KCl to form the stoichiometric solid complex compounds K_2ZrCl_6 and K_2HfCl_6 respectively. The corresponding reactions may be written as:

$$[3] \qquad 2KCl\ (\text{solid}) + ZrCl_4\ (\text{vapour})\ \text{at } P,T \rightarrow K_2ZrCl_6\ (\text{solid})\ P,T$$

and

$$[4] \qquad 2KCl\ (\text{solid}) + HfCl_4\ (\text{vapour})\ \text{at } P,T \rightarrow K_2HfCl_6\ (\text{solid})\ P,T$$

The KCl–K_2ZrCl_6 (1) and KCl–K_2HfCl_6 (7) binary systems are related by simple eutectic type phase diagrams which clearly indicate the stability of these congruently melting complex compounds.

For personal use only.

The general method applied for the preparation of the pure stoichiometric compounds was developed in this laboratory earlier (1, 2) and involves the reaction of finely ground KCl, having a particle size of less than 325 mesh, with $ZrCl_4$ or $HfCl_4$ vapours at 1 atm pressure.

The optimum reaction temperature for both K_2ZrCl_6 and K_2HfCl_6 has been found to be 485°C. Reaction time was of the order of 80 to 100 h.

When the formation of the complex compounds has been completed, the weight gain of KCl, which is converted to either K_2ZrCl_6 or K_2HfCl_6, remains constant with time and it indicates mole ratios of KCl/ZCl_4 or $KCl/HfCl_4$ respectively equal to 2.

The $ZrCl_4$ and $HfCl_4$ salts were purchased from the Wah Chang Corporation of America, Albany, New York. As they were always received in a partially hydrolyzed condition, they were purified by repeated sublimations in vacuum through a molten tin plug, as reported earlier (3).

The KCl used in the present investigation was reagent grade containing less than 0.01% total impurities, and supplied by Fisher Scientific. It was dehydrated under vacuum, at 500°C.

Handling of materials, preparation of samples, and transfer to the reaction cells were conducted in a dry box filled with argon gas.

The apparatus for measuring the equilibrium vapour pressures of $ZrCl_4$ and $HfCl_4$ over the pure complex compounds K_2ZrCl_6 and K_2HfCl_6 respectively is shown in Fig. 1. It consisted of a hollow fused quartz spiral Bourdon type gauge, made by Worden Quartz Products, Houston, Texas. The gauge was connected to the quartz reaction cell as shown in Fig. 1.

The gauge serves only as a null point detector, while the pressure is read directly on the attached closed end mercury manometer. After connecting the gauge to the apparatus, the gauge was checked for distortion using two closed end mercury manometers and comparing the two readings. The null point of the quartz spiral was determined with the aid of a telescope to the nearest 0.2 mm, while the mercury levels in the manometers were measured by a cathetometer.

Heat was supplied by a nichrome resistance furnace containing independent heating zones. The lower zone heated the sample to the desired reaction temperature, while the upper zone was controlled at a constant temperature, higher than the sublimation point of the corresponding tetrachloride. By inserting part of the two furnace windings into each other, the temperature profile within the entire system was such that condensation of the volatile vapours was prevented in all regions. The temperature was measured by means of a 22-gauge chromel–alumel thermocouple contained in a glass tube immersed in the salt sample. The thermocouple had been calibrated against a certified platinum 13% rhodium vs. platinum standard. The temperature variation within the zone occupied by the sample was ±0.4 K.

The quartz spiral type gauge was used recently in this laboratory (8) and was found to be superior to both the spoon type Bourdon gauges (1, 2) and the molten tin isoteniscopes (3, 4) used previously, because of its ability to sustain large and sudden pressure changes of an order of 1 atm without shattering. This eliminated the need for close supervision of the apparatus. In addition, because the gauge is connected directly to the sample container, and because of its small volume, the initial composition of the sample is not altered during an experiment. Furthermore, the salt sample and its vapour are contained in a closed system, thus preventing material losses and creating truly equilibrium conditions.

In a typical experiment, the sample container was loaded with the appropriate amount of salt through the tube A (Fig. 1), quickly sealed, heated to about 200°C, and periodically evacuated through the tube B to remove any gaseous hydrolysis products which might have been formed during the glass blowing operations, as well as any gas which may have been absorbed by the finely ground salt. The cell was then sealed under vacuum at the constriction C, placed in the furnace, and subjected to repeated heating and cooling cycles over the entire temperature range of interest. Experiments lasted usually a period of 30 days, and during this period the quartz cells were not visibly attacked by any of the salts. Pressure measurements during heating were in excellent agreement with those obtained during cooling.

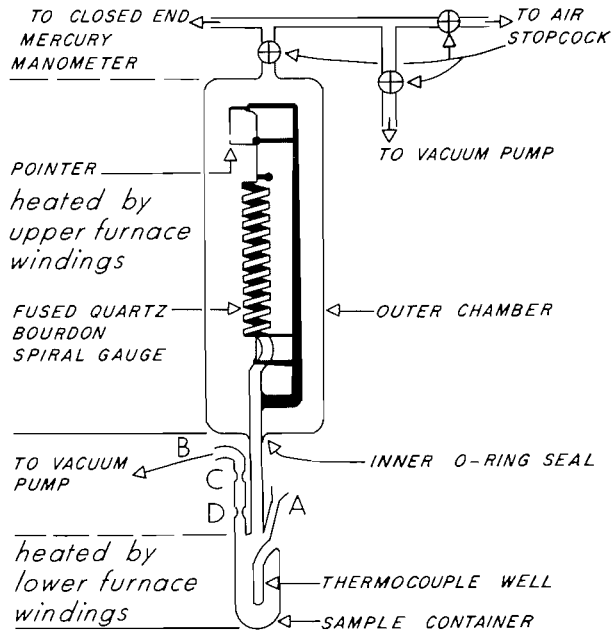

FIG. 1. Apparatus for measurement of the vapour pressures.

The apparatus for determining the phase diagram for the system K_2ZrCl_6–K_2HfCl_6 has been described elsewhere (1, 3). The containers for the mixtures to be measured were heart-shaped quartz cells having the thermocouple well at the centre of the charge, and were sealed under vacuum. Applied cooling rates were ¼°C to 1°C per min. The measurements are obtained under the pressure of $ZrCl_4$ or $HfCl_4$, respectively, in equilibrium with the two compounds or their solutions.

Experimental Results

Determination of the K_2ZrCl_6–K_2HfCl_6 Phase Diagram

The characteristic data for this diagram are given in Table 1. The liquidus tie line, when drawn, is continuous and linear and indicates a continuous series of ideal solid–liquid solutions between the two compounds. This type of behaviour, which is typical of zirconium–hafnium compounds, was also found in the systems Li_2ZrCl_6–Li_2HfCl_6 (3) and $ZrCl_4$–$HfCl_4$ (9).

The melting point for pure K_2ZrCl_6, given in Table 1, is in good agreement with that reported by Lister and Flengas (1). The melting point for pure K_2HfCl_6 determined in this work is higher than that reported by Morozov and Sun-In-Chzhu (7) by about

67.0	805
100.0	808

6°C. The disagreement may be attributed to the presence of impurities in the K_2HfCl_6, probably in the form of hydrated zirconium oxychlorides, used by those workers. Their method of preparing K_2HfCl_6 consisted of intimately mixing the stoichiometric amounts of $HfCl_4$ and KCl, and the hydrated oxychlorides which are always present in 'pure' zirconium tetrachloride would be expected to remain in the mixture.

Vapour Pressure Measurements

The vapour pressures of $ZrCl_4$ and $HfCl_4$, in equilibrium with the pure compounds K_2ZrCl_6 and K_2HfCl_6 respectively, have been determined. Pressures were measured in mm Hg, and corrections were made for mercury expansion and for gravity effects (10, 11) to convert to standard conditions, i.e., at 273.15 K and an acceleration of free fall of 9.80665 m/s^2. These corrected pressures are given in Table 2. Temperatures reported herein are based on the IPTS-68 (12). In Fig. 2 these data are plotted as $\ln P_{MCl_4}$ vs. $1/T$, and the lines shown on the graphs are calculated by the least-squares method, while the points are experimental.

Some experimental points for the equilibrium decomposition pressures of K_2ZrCl_6 obtained previously in the laboratory (1) using the fragile quartz spoon type gauges are also shown in Fig. 2 and are in good agreement with the present work. These previous data were obtained only at higher temperatures near the melting temperature of K_2ZrCl_6, as at lower temperatures the measurements became irreversible due to gases absorbed by the sample.

It should be noted that in the present work, due to the ability of the spiral type gauge to withstand large pressure gradients, the samples could be degassed extensively prior to measurement, thus making possible accurate low pressure readings.

The corresponding equations for the temperature dependence at the equilibrium pressures within the characteristic temperature ranges were calculated and are given in Table 3. Reaction 1 in Table 3 defines the equilibrium pressure of $ZrCl_4$ over pure solid K_2ZrCl_6 and solid KCl at temperatures lower than the eutectic temperature shown in Fig. 2.

Reaction 2 in Table 3 represents the equilibrium pressure of $ZrCl_4$ over pure solid K_2ZrCl_6 at temperatures higher than the eutectic temperature and in the presence of a solution of KCl and K_2ZrCl_6 of liquidus composition, as predicted by the phase diagram (1). Due to the temperature and composition dependence of the activity of KCl in this region, the $\ln P_{ZrCl_4}$ vs. $1/T$ plot exhibits a curvature (nonlinear part in Fig. 2).

Reaction 3 in Table 3 represents the equilibrium pressure of $ZrCl_4$ over pure molten K_2ZrCl_6 at temperatures higher than its melting point.

Similar considerations apply to reactions 4, 5, and 6 for K_2HfCl_6 given in Table 3. It should be noted that the nonlinear and upper linear portions of the pressure curves for K_2ZrCl_6 and K_2HfCl_6 in Fig. 2 intercept at temperatures which are in agreement with the melting points of the compounds K_2ZrCl_6 and K_2HfCl_6 respectively.

Discussion

Below the corresponding eutectic temperatures of

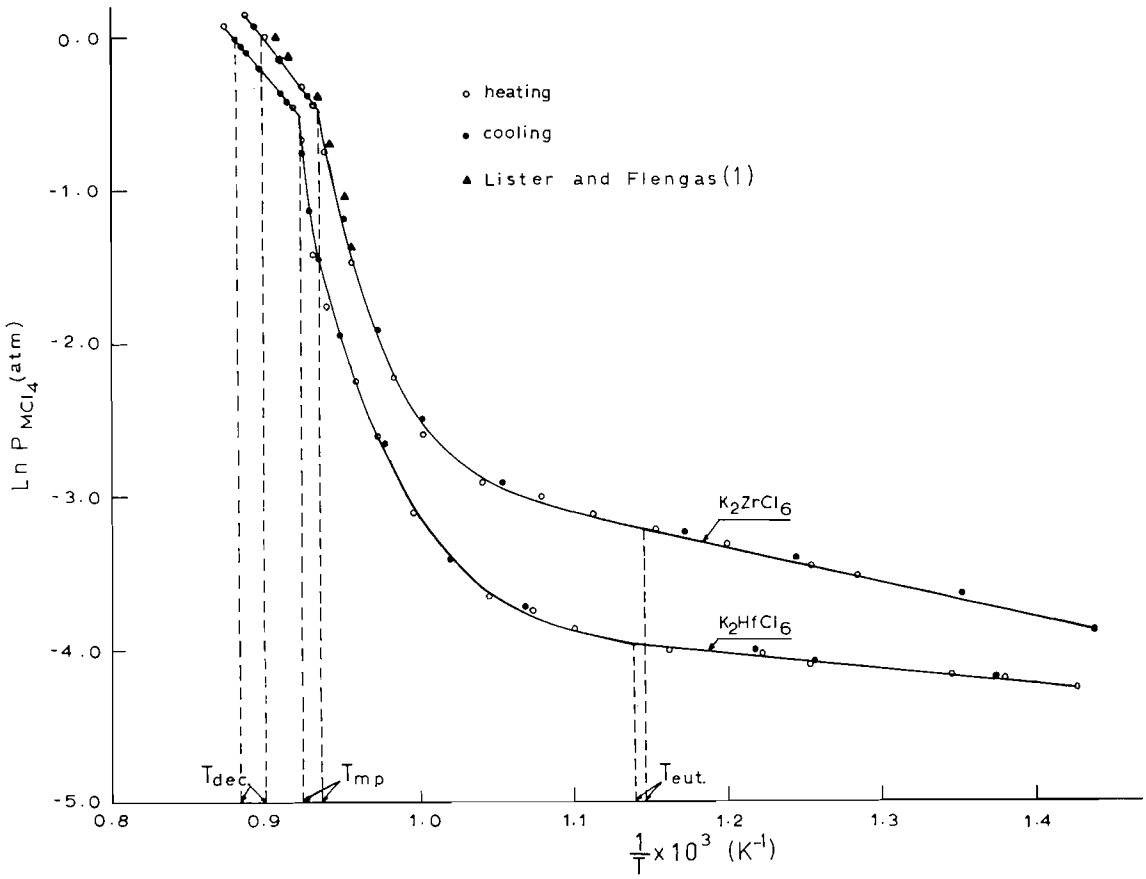

FIG. 2. Diagram of ln P_{MCl_4} vs. $1/T$ for the pure complex compounds K_2ZrCl_6 and K_2HfCl_6.

the pseudo-binary systems KCl–K_2ZrCl_6 and KCl–K_2HfCl_6 respectively, the thermal decomposition of the chlorozirconate and chlorohafnate complex compounds are described by the reactions:

[5] $$K_2ZrCl_{6(s)} \rightleftarrows 2KCl_{(s)} + ZrCl_{4(vap)}$$

[6] $$K_2HfCl_{6(s)} \rightleftarrows 2KCl_{(s)} + HfCl_{4(vap)}$$

If the standard states for the condensed phases are chosen as the pure solids at all temperatures and for the vapour phases, the pure vapours at 1 atm, the thermodynamic equilibrium constants for the decomposition reactions [5] and [6] can be written as:

[7] $$K_5 = P_{ZrCl_4(vap)}$$

[8] $$K_6 = P_{HfCl_4(vap)}$$

In these equations, actual pressures have been used instead of fugacities, as the zirconium tetrachloride vapour has been shown to be unimolecular and ideal (13, 14), and hafnium tetrachloride vapour should be expected to be quite similar.

The standard heat for the decomposition reactions ΔH_R^0 may be obtained from the van't Hoff equation, written as:

[9] $$\frac{d \ln k}{dT} = -\frac{\Delta H_R^0}{RT^2}$$

while the standard free energy and the average standard entropy can be determined from the well-known equations:

[10] $$\Delta G^0 = -RT \ln k$$

[11] $$\Delta G_R^0 = \Delta H_R^0 - T\Delta S_R^0$$

The results of these calculations for pure K_2ZrCl_6 and K_2HfCl_6 are given in Table 4. From these data, the equilibrium constant of the exchange reaction:

[12] $HfCl_4$ (vapour) + K_2ZrCl_6 (as a solid solution of K_2ZrCl_6 in K_2HfCl_6) = $ZrCl_4$ (vapour) + K_2HfCl_6 (as a solid solution of K_2HfCl_6 in K_2ZrCl_6)

is calculated as:

[13] $$K_{ex} = (P_{ZrCl_4}/P_{HfCl_4})_{vapour} \times (X_{K_2HfCl_6}/X_{K_2ZrCl_6})_{in\ solid\ solution}$$

In this equation, mole fractions (X's) have been

substituted for activities, because of the suggested ideal behaviour of the solid solutions.

Since [12] was derived by subtracting [5] from [6], given in Table 3, the temperature dependence on the equilibrium constant given by [13] may be calculated by combining [7] and [8] as:

$$[14] \quad \ln K_{ex} = 1.799 - (951/T) \qquad \text{st. dev.} = 0.1097$$

A plot of K_{ex} vs. T (in °C) is shown in Fig. 3.

It has been shown in a previous publication (6) that impure $ZrCl_4$ containing $HfCl_4$ may be purified in a closed two-compartment reaction cell in which the impure $Zr(Hf)Cl_4$ mixture is placed in the first compartment, which is kept at a temperature T_1, while an alkali chloride ACl is placed in the second compartment, which is kept at a temperature T_2.

The separation is based on the formation of the complex compounds A_2ZrCl_6 and A_2HfCl_6, which appear in the second compartment as a solid solution. The efficiency of the separation process depends upon the magnitude of the equilibrium constant for the exchange reaction [12].

The efficiency of separation η is defined as:

$$[15] \quad \eta = \frac{(\text{wt.\% } HfCl_4)_{\text{initial}} - (\text{wt.\% } HfCl_4)_{\text{final}}}{(\text{wt.\% } HfCl_4)_{\text{initial}}} \times 100$$

and may be calculated from the previously derived relationship

$$[16] \quad K_{ex} = \frac{2(X^1_{ZrCl_4})a - b + 2Z}{2(X^1_{HfCl_4})a - 2Z} \times \left(\frac{P^0_{ZrCl_4}}{P^0_{HfCl_4}}\right)_{T_1} \frac{2Z}{b - 2Z}$$

where $X^1_{ZrCl_4}$ and $X^1_{HfCl_4}$ are the mole fractions of $ZrCl_4$ and $HfCl_4$ respectively in the $Zr(Hf)Cl_4$ mixture initially present in the first compartment of the separation cell prior to reaction; a represents the

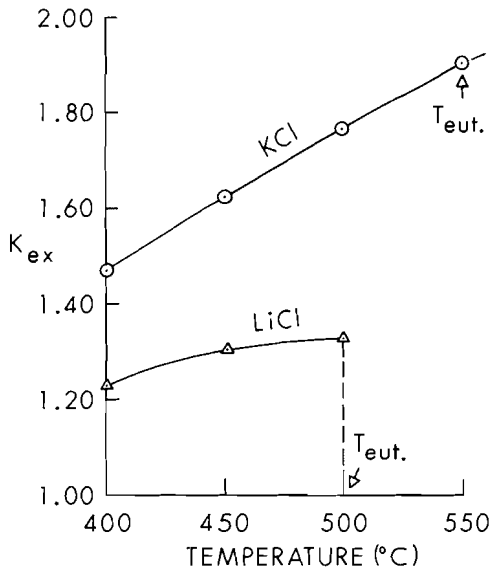

FIG. 3. Temperature dependence of the equilibrium constants K_{ex} for the exchange reactions:

$$HfCl_4 \text{ (vapour)} + K_2ZrCl_6 \text{ (solid solution)} \rightleftharpoons K_2HfCl_6 \text{ (solid solution)} + ZrCl_4 \text{ (vapour)}$$

and

$$HfCl_4 \text{ (vapour)} + Li_2ZrCl_6 \text{ (solid solution)} \rightleftharpoons Li_2HfCl_6 \text{ (solid solution)} + ZrCl_4 \text{ (vapour)}$$

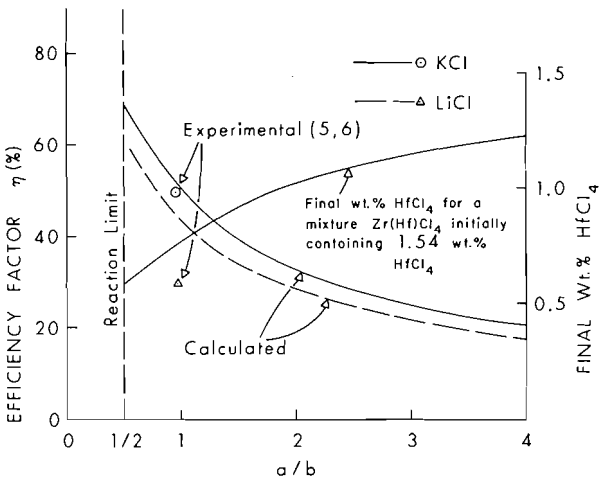

FIG. 4. Variation of the separation efficiency factor η with the molar ratio a/b of $Zr(Hf)Cl_4$ to LiCl or KCl respectively. Calculations are based on $Zr(Hf)Cl_4$ initially containing 1.54 wt.% $HfCl_4$. T_1 and T_2 temperatures are respectively 330 and 450°C.

total number of moles of $Zr(Hf)Cl_4$ present in the first compartment of this reactor, prior to separation; b represents the number of moles of ACl present in the second compartment of the reactor; Z is the number of moles of $HfCl_4$ which have reacted with ACl and are retained in the second compartment of the reactor after equilibrium has been reached; $P^0_{ZrCl_4}$ and $P^0_{HfCl_4}$ are the sublimation pressures (15) of pure $ZrCl_4$ and $HfCl_4$ respectively, at the temperature T_1.

Considering a reactor containing KCl and T_1 and T_2 temperatures of 330 and 450°C respectively, the separation efficiency factor η may be calculated from the determined values of K_{ex} and for various ratios of a/b.

Figure 4 illustrates the variation of η with the a/b ratio for LiCl and KCl. As is seen, η increases as the a/b ratio decreases. Hence the separation becomes more efficient when the amount of the $Zr(Hf)Cl_4$ mixture placed in compartment I is close to that required by the stoichiometry for the formation of K_2ZrCl_6 and K_2HfCl_6. The reaction limit is reached at $a/b = 0.5$, at which point all the added tetrachloride vapours react with the KCl. On the other hand, as the a/b ratio approaches the value of 0.5, most of the $Zr(Hf)Cl_4$ ends up as a K_2ZrCl_6–K_2HfCl_6 solid solution in compartment II. Hence for practical purposes, the a/b ratio must be larger than 0.5, and a value of about 0.8 to 1.0 appears optimum. At $a/b = 0.8$ the calculated separation efficiency is about 56%.

By comparing LiCl and KCl as separating agents for Hf, it is also evident that at 450°C KCl is more efficient than LiCl. In addition, potassium chloride is a more readily available chemical, and does not require the very elaborate dehydration procedure which is necessary for producing anhydrous lithium chloride.

In Fig. 3, it is seen that the K_{ex} for the reaction with KCl increases significantly with temperature and the separation process may be conducted at temperatures as high as 594°C, which is the eutectic temperature for the binary system K_2ZrCl_6–KCl. At this temperature the complexes K_2ZrCl_6 and K_2HfCl_6 would not decompose, since their decomposition temperatures have been found to be 840 and 863°C, respectively.

On the contrary, in the LiCl system the temperature range for a gas–solid reaction extends only up to 496°C, which is the corresponding eutectic temperature for the system Li_2ZrCl_6–LiCl, and at this temperature the pure Li_2ZrCl_6 and Li_2HfCl_6 compounds also decompose thermally (3).

Considering the reaction with KCl at a temperature of 550°C, for which $K_{ex} = 1.92$, and for $a/b = 1$, the separation efficiency factor is calculated to be 56.49%. This should be compared with η = 43% for the LiCl reaction at 450°C.

Therefore, it should be possible to reduce the $HfCl_4$ content from an initial level of 1500 ppm to less than 50 ppm in only four successive separation steps.

Received November 29, 1977

JAMES PEELING, FRANK E. HRUSKA, and N. STEWART MCINTYRE. Can. J. Chem. **56**, 1555 (1978).

A series of pyrimidine and purine bases has been studied experimentally by electron spectroscopy for chemical analysis. Individual component peaks in the spectra were assigned on the basis of known substituent effects on core electron binding energies. Binding energies for all the core levels in the molecules provide sufficient data to determine the molecular charge distributions. The results compare favourably with atomic charges determined theoretically in the CNDO/2 molecular orbital formalism.

JAMES PEELING, FRANK E. HRUSKA et N. STEWART MCINTYRE. Can. J. Chem. **56**, 1555 (1978).

On a étudié expérimentalement, en faisant appel à la spectroscopie d'émission photoélectronique induite par rayons-X (ESCA), une série de bases purine et pyrimidine. On a attribué les composantes individuelles des spectres en se basant sur des effets connus des substituants sur les énergies de liaison des électrons des couches internes. Les énergies de liaison pour tous les niveaux internes des molécules fournissent des données suffisantes pour déterminer les distributions des charges moléculaires. Les résultats se comparent favorablement avec les charges atomiques déterminées d'une façon théorique par un formalisme d'orbitale moléculaire du type CNDO/2.

[Traduit par le journal]

Introduction

Electron spectroscopy for chemical analysis (ESCA) or X-ray photoelectron spectroscopy (XPS) has proven to be a valuable tool in studies of structure and chemical bonding. The binding energies and relative intensities of core photoelectron peaks provide a direct elemental analysis of a sample. At a finer level of observation, chemical shifts in core electron binding energies relate directly to the charge distributions in molecular solids, in cases where lattice effects on the binding energies are of secondary importance. In the realm of biologically important molecules, although a number of studies of amino acids (1–4) and proteins (3, 5–8) have been reported, relatively few investigations have been directed towards the area of nucleic acids and their components. The ESCA spectra of tRNA and a few of its components were described briefly (9), and studies on metal complexes of DNA (10), AMP (11), and some thiouracils (12) have appeared. Detailed studies of the ESCA spectra of the purine and pyrimidine bases themselves appear to be limited to the early investigations of Barber and Clark on adenine (13), cytosine and thymine (14), in spite of the interest which this work created (15–18). Clark has also recently published the spectra of 5- and 6-azauracil (19).

In this paper we describe the core electron spectra of common purine and pyrimidine bases, some of their aza analogs, and one fluorinated analog (Fig. 1). These analogs have chemotherapeutic value (20), which ultimately must be due to the electronic perturbations elicited by the chemical modifications to the base. The measured binding energies are used to derive experimental charge distributions in the molecules. These are compared with the results of

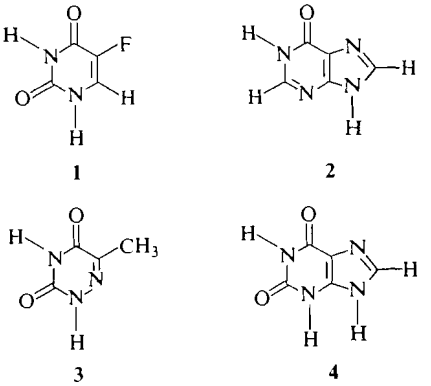

FIG. 1. Chemical formulae for several of the purine and pyrimidine bases studied here: 5-fluorouracil (**1**), 6-azathymine (**2**), hypoxanthine (**3**), and xanthine (**4**).

CNDO (21) molecular orbital theory calculations. Although extensive theoretical studies have been directed towards the elucidation of charge distributions in nucleic acid bases (22–25), a limited quantity of independent experimental data are available.

Experimental

The bases were all commercial samples (Sigma Chemical Company) and were examined, without further purification, as powders mounted on the spectrometer probe either using double-sided tape or by pressing into finely grooved copper flats fixed to the probe. Spectra of the C_{1s}, N_{1s}, O_{1s}, and F_{1s} core levels were obtained on a McPherson ESCA-36, calibrated as described previously (26), using $MgK_{\alpha_{1,2}}$ radiation (1253.6 eV). Several of the samples were run over extended periods of time, and all were examined visually, to check for radiation damage. The constancy of the ratios of the core level peak intensities and their positions were taken as evidence that no substantial radiation damage occurred.

Peak positions in incompletely resolved bands were determined by computer deconvolution using the peak fitting routine described by Bancroft *et al.* (27). The bands used in fitting a peak envelope are defined according to their centroid position, half-width, shape (an equal combination of Gaussian and Lorentzian distributions), and intensity. These parameters are then varied to obtain a minimum in the error sum of squares between the values for the experimental curve and the trial combination of bands. An important feature of this program is its ability to constrain certain parameters of selected bands within set limits, while allowing the others to vary freely. Peak parameters for the intensity of a given core line were constrained to give peak areas proportional to those required by the molecular formula. C_{1s} peak widths were constrained to half-widths (FWHM) between 1.4 and 1.6 eV, since preliminary studies showed that peak widths for all carbon sites investigated fell in this range. N_{1s} half-widths were constrained between 1.3 and 1.4 eV. Figure 2 shows some examples of envelopes deconvoluted in this manner. Binding energies were determined relative to the C_{1s} peak ascribed to hydrocarbon contamination, which was assigned a value of 285.0 eV (28). This peak gradually increased in intensity with time as residual hydrocarbons deposited on the sample surface.

Results and Discussion

ESCA Spectra

Table 1 gives the experimental binding energies for the bases examined, with corresponding sites in the purines and pyrimidines listed in the same column. In Fig. 2 are some representative examples of deconvoluted C_{1s} bands. The reproducibility of the deconvolution procedure, and of the spectra themselves, was checked for several of the compounds by processing spectra obtained in repeated measurements on a number of different samples. For the pyrimidines the absolute binding energies determined in this fashion generally agreed to better than ± 0.15 eV (2σ), while the relative binding energies for peaks under any one envelope were reproducible to better than ± 0.10 eV. In the case of the purine bases, the generally greater number of peaks under a given spectral envelope, combined with a smaller spread in binding energies, resulted in increased uncertainties

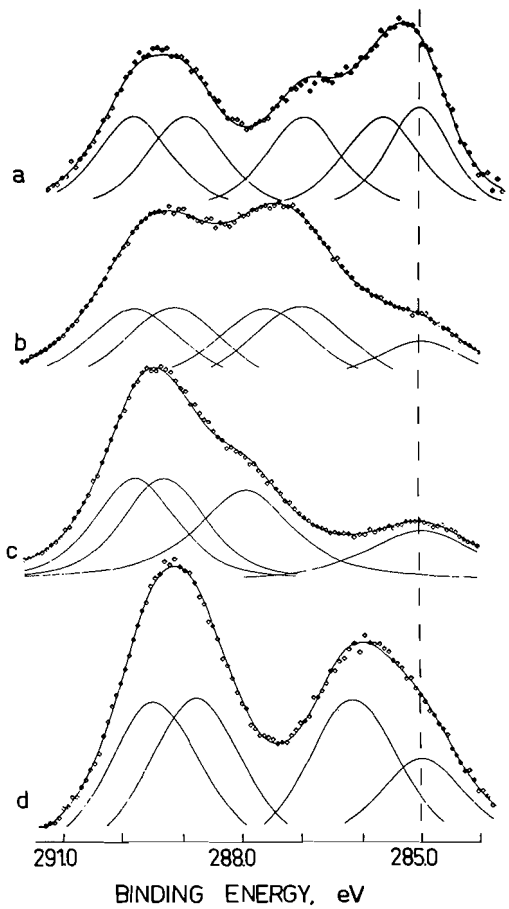

FIG. 2. Computer deconvoluted C_{1s} bonds for (*a*) uracil, (*b*) 5-fluorouracil, (*c*) 5-azauracil, and (*d*) 6-azauracil. The hydrocarbon contamination peak used for reference is the peak at the lowest binding energy. For clarity, the full extent of each Gaussian–Lorentzian band has been truncated in the fitted spectra.

in peak positions, the standard deviations being about ± 0.2 eV for the C_{1s} bands. The poorly resolved N_{1s} bands of the purines presented some difficulties. For xanthine, visual inspection of the N_{1s} spectral region showed that it consisted of two poorly resolved peaks of relative intensities 3:1. Computer deconvolution based on this assumption gave a good fit to the experimental spectrum, the peaks being of equal width. The linewidth was about the same as that for N_{1s} peaks in the pyrimidines, so the reported binding energies are probably accurate to better than ± 0.3 eV. A similar approach to the hypoxanthine N_{1s} band showed that it could be fitted well by two peaks of equal intensity. However, for 8-azaxanthine, guanine, and 8-azaguanine, the N_{1s} envelopes consisted of featureless bands, and the deconvolution procedure consisted of a random fitting under the broad spectral envelopes of the number of peaks of equal intensity required by the molecular formulae.

The N_{1s} binding energies listed in Table 1 for these latter compounds give a satisfactory but not necessarily unique fit to the experimental spectra. It is difficult to assess quantitatively the accuracy of these data but a reasonable uncertainty in the binding energy of any one component peak is ± 0.4 eV.

The N_{1s} peaks for uracil, 5-fluorouracil, and thymine consisted of single peaks with linewidths indistinguishable from those found for chemically unique N_{1s} peaks. The same is true in the case of the O_{1s} bands; the peaks observed for the single oxygen in hypoxanthine, guanine, and 8-azaguanine were not sharper than those of the other bases which contain two chemically distinct oxygen species.

The lack of resolution in the ESCA technique which becomes apparent in the above discussion is likely to be the limiting factor in carrying out detailed structural studies of the type reported here. The number of incompletely resolved peaks under a given core level band that can be determined uniquely is generally quite small, so even moderately complex molecules like the purine bases are often not amenable to a thorough analysis. Although improved resolution, for instance using monochromatic X-ray sources (29), undoubtedly helps to some extent, the limited resolution is inherent in the method and the complexity of the molecules that can be studied is thus restricted.

Assignment of C_{1s} Spectra

The assignments of the deconvoluted C_{1s} spectral peaks can be carried out using known substituent effects on core electron binding energies (29). The factors giving rise to ESCA chemical shifts in molecular solids are generally short range in nature. Although in the case of the nucleic acid bases, intermolecular effects, such as hydrogen bonding, may not be insignificant, they are likely to be of secondary importance in comparing similar molecular sites. That they are of secondary importance becomes clear on considering the binding energy data in Table 1. Where the immediate environment of the C(2) carbon is unchanged through the series of compounds, the binding energy remains fairly constant. Replacing the 2-keto oxygen of xanthine and 8-azaxanthine with the less electronegative $-NH_2$ group results in a decrease in the binding energy of this carbon. A further decrease in binding energy occurs on removing the $-NH_2$ group to form hypoxanthine. Similarly C(4) shows a significant change in binding energy only for 5-azauracil and 5-fluorouracil, where the substitution of the nearby electronegative group induces an increase in binding energy at this site. As expected, the fluorine substitution also gives rise to an increase in the binding energy of C(6), and to a much more substantial

† Square brackets contain experimental charges for uracil obtained from *L*-shell STO scattering factors (ref. 36).

increase in that of C(5). Similarly, C(5) and C(6) in the 6- and 5-azapyrimidines, respectively, show higher binding energies, a consequence of replacing a ring carbon with a more electronegative nitrogen. However, in the purine bases, the influence of the imidazole nitrogens on the binding energies of the analogous carbons (C(5) and C(4)) is considerably smaller.

Assignment of N_{1s} Spectra

In spite of the difficulties discussed above in determining the N_{1s} binding energies, a qualitative analysis of substituent effects can be used in assigning the peaks. The data in Table 1 show that the binding energies of N(3) in the pyrimidine bases and N(1) of the purines, being isolated from major structural changes, are constant to within ±0.15 eV. An increase to 401.20 eV for 5-fluorouracil is the largest change. For the 6-azapyrimidines, N(1) is closer to the structural change and an increase in binding energy is apparent here as well as for 5-fluorouracil. In the purines hypoxanthine, guanine, and 8-azaguanine, the binding energy of N(3) decreases by ~1.2 eV relative to xanthine. The lower binding energy for the $\diagdown\!\!=\!\!\diagup$N compared to the $\diagdown\!\!-\!\!\diagup$NH structural feature has been noted before (1) and is also evident in the case of N(5) and N(6) in the azapyrimidines. Similarly, N(7) in xanthine, hypoxanthine, and guanine has a binding energy of ~399.6 eV, while N(9), whose immediate environment is similar to that of N(1), is assigned to a component at ~400.9 eV. (An X-ray crystallographic study of guanine (30) has shown that only the tautomeric form having N(9) protonated is formed in the crystals; we assume that this is also the case for xanthine and hypoxanthine.) In 8-azaxanthine N(8) is protonated and N(9) is unprotonated (31). The immediate environments of N(7) and N(9) are thus similar and they are assigned identical binding energies, which, because of the influence of N(8), are greater than those of other $\diagdown\!\!=\!\!\diagup$N structural features. The N(8) nitrogen, being adjacent to two other nitrogen atoms, is assigned to the N_{1s} peak at highest binding energy. The structure of 8-azaguanine (32) on the other hand shows that N(9) is protonated instead of N(8), so N(7) remains lower in binding energy than N(9). The limited resolution does not permit a distinction in the binding energies of N(8) and N(9). The —NH_2 nitrogen in guanine and 8-azaguanine is assigned to the peaks at 399.5 and 399.6 eV, respectively. Barber and Clark (13) previously have assigned a peak at 399.5 eV to an —NH_2 group in the structurally similar adenine molecule.

In 5-azauracil the assignment of the N_{1s} peaks at 401.20 and 400.60 eV to N(1) and N(3), respectively, is not obvious from substituent effects. Therefore, CNDO/2 calculations were carried out for this molecule, and the calculated atomic charges were used to determine the relative binding energies through application of the charge potential model (see below). The order of the N_{1s} binding energies in Table 1 was confirmed. Further support for this ordering is found in the results of detailed *ab initio* molecular orbital theory studies (25, 33), which also show the 1s binding energy of N(1) to be greater than that of N(3).

Tautomeric Forms

The binding energy data in Table 1 also provide information on the tautomeric forms of the bases. In general, the diketo forms of uracil and its derivatives predominate in the crystal (as well as solution) state (24, 34), and the N_{1s} binding energies and the C_{1s} binding energies for C(2) and C(4) are in accord with this structure for each of our pyrimidines. Thus, experimental and theoretical studies on model com-

pounds have shown that the C_{1s} binding energy of an alcoholic carbon is about 1 eV lower than that of a ketonic carbon (35). Furthermore, in the enol form either N(1) or N(3) (or both) assumes the $\diagdown\!\!=\!\!\text{N}$ structure, the N_{1s} binding energy of which is substantially lower ($\sim$1.5 eV) than in the $\diagdown\!\text{NH}$ unit. No crystal structure of 5-azauracil has appeared as yet. Our C_{1s} and N_{1s} binding energies show no evidence of the enol form, the only significant change compared to uracil being an increase in the binding energy of C(4) owing to the influence of N(5). Therefore, it is apparent that this base also exists in the diketo form. Similar arguments utilizing the binding energy data for the purine bases indicate that xanthine and 8-azaxanthine exist in the diketo structure, while in hypoxanthine, guanine, and 8-azaguanine the keto form is assumed at C(6). This is consistent with crystallographic studies on 8-azaxanthine (31), guanine (30), and 8-azaguanine (32). A study of selectively-methylated bases is planned in order to examine more thoroughly the influence of tautomeric forms on the ESCA spectra.

Charge Distributions

In the electrostatic potential model (36) core electron binding energies E_i for a molecular solid are related to the molecular charge distribution by

$$[1] \qquad E_i = E_i^0 + k_i q_i + \sum_{j \neq i} \frac{q_j}{r_{ij}}$$

where E_i^0 is a reference level, q_i is the charge on atom i, q_j is the charge on atom j situated at a distance r_{ij} from i, and k_i is a constant. The determination of molecular charge distributions from experimental binding energies using eq. [1] requires knowledge of the parameters k_i and E_i^0 for the different core levels. Clark and Thomas (36) used the CNDO/2 molecular orbital formalism to determine charge distributions in a number of model carbon and oxygen compounds. These charges were used with the experimental binding energies and molecular geometries to yield values of k_i and E_i^0 for the C_{1s} and O_{1s} levels via eq. [1]. We used a similar approach with published N_{1s} binding energies for a number of simple compounds examined in the solid phase and values of $k_N = 18.5 \pm 2.5$ and $E_N^0 = 399.7 \pm 0.5$ eV were found.

In a system composed of C, N, and O, for which the geometry and all the core level binding energies are known, the potential model eq. [1] are sufficient to determine all the atomic charges q_i, and the neutrality requirement gives one additional equation. However, the nucleic acid bases all contain several hydrogen atoms in addition to C, N, and O, so it is necessary to make some approximations. Experience with CNDO/2 calculations on a variety of molecular systems has shown that in neutral molecules the charge on a hydrogen atom bonded to a carbon is small, whereas hydrogen in an N—H bond has a deficiency of about 0.10 to 0.15 electrons. For all the bases reported here we have therefore set $q_H = 0.0$ for C—H and $q_H = 0.13$ for N—H hydrogens. With these approximations there are enough equations for 5-fluorouracil to determine the charges on the C, N, O, and F atoms, while for the other bases there is one equation more than required to find the charge distributions.

The internuclear distances, r_{ij}, required in eq. [1], were determined from geometries obtained in X-ray crystallographic studies of uracil (37), 5-fluorouracil (38), 6-azauracil (39), thymine (40), 6-azathymine (39), guanine (31), 8-azaguanine (32), and 8-azaxanthine (31). The geometries of 5-azauracil, xanthine, and hypoxanthine were estimated by comparison with the experimental geometries of the other bases.

The experimentally determined charges are given in Table 2. Uncertainties in the values originate to some extent from uncertainties in the binding energies but mainly from uncertainties in the values for k_i and E_i^0. The experimental N_{1s} and O_{1s} binding energies used to determine the constants appropriate to these core levels spanned rather limited ranges, so these constants are less certain than those for the C_{1s} levels. Based on the precision of the experimental binding energies and the constants, uncertainties in the experimental charges are estimated to be: N_{1s}, 0.08; O_{1s}, 0.06; and C_{1s}, 0.03 electrons.

The values of k_i in eq. [1] depend on the definition of atomic charge and, when determined using a molecular orbital theory treatment, on the basis set used. The values used in this work were derived from CNDO/2 molecular orbital calculations, so it is appropriate to compare our experimental charges to charges calculated within this theoretical framework. Using the molecular geometries described above, atomic charges were calculated by the CNDO/2 molecular orbital method, and the results are included in Table 2 (in parentheses), Using X-ray scattering factors, Stewart (41) has also obtained an experimental estimate of the charge distribution in uracil, and his data, obtained from *L* shell Slater type orbitals (STO's) are included in Table 2.

The CNDO/2 charges refer to free molecules while the ESCA data refer to the solid phase, where such effects as intermolecular hydrogen bonding may be expected to affect the molecular charge distributions. However, the agreement evident in Table 2 between the experimental and theoretical charges is very good and lends support to the original ESCA peak assignments. For some of the bases, different assignments were assumed and the charges recalculated. In all instances this yielded charges further removed from the theoretical results and in most cases the calculated changes were strongly changed by the alternative assignment.

For uracil, and the pyrimidines in general, some consistent trends in the experimental and theoretical results for the relative atomic charges are evident. The larger uncertainties in the experimental data for the purines possibly mask some of the more subtle differences but the major trends in variations in the charge distributions are reproduced.

The chemical and biochemical implications of differences in the electron distributions in the nucleic acid bases have been discussed extensively (22–25) and comments here are restricted to a brief mention of inconsistencies between the experimental and theoretical numbers. In the pyrimidines the most notable difference is at the 5 and 6 positions of uracil, 5-azauracil, and thymine. The theoretically calculated electron excess at the 5 position is greater than that indicated by the ESCA results, and the corresponding electron deficiency at C(6) is also greater. It has been noted that use of [1] with CNDO/2 charges predicts the wrong ordering of the C_{1s} levels in 5-azauracil (25, 33), a consequence of the apparent over-polarization of the 5—6 bond suggested by the CNDO/2 calculations. In the purines the magnitudes of the calculated charges at C(5) and C(4) also exceed those determined by the ESCA procedure. At N(7) the molecular orbital theory calculations show the negative charge to be greater than the ESCA-derived value. Finally, major disagreement is apparent between the theoretical and experimental charge at the $-NH_2$ nitrogen of guanine and 8-azaguanine.

Some of these discrepancies could result from effects such as hydrogen bonding or from the hydrogen charge approximations made in the CNDO/2 calculations. However, a more likely reason for the discrepancies resides in the CNDO/2 method itself which, using Koopmans' theorem, does not take account of core hole relaxation energy differences in differing sites in the molecule. Clark and co-workers (25) have made *ab initio* calculations of the neutral and core hole states in 5-azauracil and have shown that the C_{1s} and N_{1s} relaxation energies in this molecule differ with the chemical environment. They have suggested that specific group relaxation energy shifts can be used to refine charge calculations which are based on the charge potential model. We intend to apply such procedures to determine if the discrepancies observed in this work can be completely accounted for by relaxation effects.

Conclusions

This study has shown that in favourable cases application of the charge potential model (eq. [1]) with experimental core electron binding energies can yield atomic charges in the pyrimidine and purine bases. The accuracy of the results for small molecules is sufficient to study differences in electron distributions originating in structural modifications. Difficulties in assigning the ESCA spectra, and in the subsequent derivation of charges, arise from the somewhat low resolution of the technique, and apparently limit the complexity of the systems amenable to this sort of analysis. The pyrimidine bases are readily analyzed, while the purines appear to be close to the limit of complexity for thorough analysis.

The solid phase synthesis of monoester monoamides and monoester monoalcohols from symmetrical diacid chlorides[1,2,3]

JUDAH M. GOLDWASSER AND CLIFFORD C. LEZNOFF

Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3

Received January 18, 1978

JUDAH M. GOLDWASSER and CLIFFORD C. LEZNOFF. Can. J. Chem. **56**, 1562 (1978).

A 2% crosslinked divinylbenzene–styrene copolymer, incorporating benzyl alcohol groups, was used to monoprotect the symmetrical diacid chlorides, $ClOC(CH_2)_nCOCl$ (where $n = 2, 3, 4$, and 8), terephthaloyl chloride and isophthaloyl chloride. Subsequent reaction of the resulting polymer-bound monoester monoacid chloride with aniline, benzylamine, dimethylamine, *tert*-butylamine, or ammonia yielded polymer-bound monoester monoamides, which on base cleavage and esterification gave monoester monoamides in high yield. Borohydride reduction of polymer-bound sebacoyl chloride, terephthaloyl chloride, and isophthaloyl chloride gave their respective polymer-bound monoester monoalcohols, which on base cleavage from the polymer and esterification yielded the monoester monoalcohols in good yield along with some recovered dimethyl esters of the respective starting diacid chlorides.

JUDAH M. GOLDWASSER et CLIFFORD C. LEZNOFF. Can. J. Chem. **56**, 1562 (1978).

On a utilisé un copolymère divinylbenzène–styrène reticulé à 2% et incorporant de l'alcool benzylique pour effectuer la monoprotection des chlorures de diacides symétriques $ClOC(CH_2)_nCOCl$ (où $n = 2, 3, 4$ et 8) de téréphtaloyle et d'isophtaloyle. Une réaction ultérieure, du chlorure de monoacide monoester lié au polymère qui en résulte, avec de l'aniline, de la benzylamine de la diméthylamine, de la *tert*-butylamine ou de l'ammoniac fournit des monoamides monoesters liés au polymère qui, par clivage basique et estérification, conduisent à des monoamides monoesters avec de bons rendements. Une réduction au borohydrure des chlorures de sébacoyle, de téréphtaloyle et d'isophtaloyle liés au polymère conduit aux monoalcools monoesters correspondants liés au polymère qui, par clivage basique du polymère et estérification, fournissent des monoesters monoalcools avec de bons rendements aux côtés des esters diméthyliques récupérés de leurs chlorures de diacides de départs respectifs.

[Traduit par le journal]

Introduction

Monoester monoamides have invariably been prepared by treatment of a monoester monoacid chloride with an amine. This method was used by Wohl (1) in 1910 in the preparation of methyl *N*-methylisophthalamate and more recently by Johnson (2) to prepare a number of ethyl adipamates in low yield. Furthermore, the monoester monoacid precursors are prepared from the symmetrical diesters or diacids in less than 50% yield as base hydrolysis of symmetrical diesters (3, 4) or esterification of symmetrical diacids (4, 5) leads to a 1:2:1 ratio of diester, desired monoester monoacid, and diacid. Only in the preparation of monoamides of diacids such as succinic acid, where the anhydride can be used as the precursor, are the yields as high as 70% and even for this example (6) the solid phase synthesis gives higher yields (see below).

ω-Hydroxyaliphatic acids and hydroxymethylbenzoic acids have been prepared by several different routes but *rarely* from the readily available symmetrical diacids or diesters (7). Ruzicka and Stoll (8) prepared long chain ω-hydroxyacids in low yield by the Baeyer–Villiger oxidation on poorly accessible macrocyclic ketones. Ozonolysis of naturally occurring olefinic acids followed by reduction with $NaBH_4$ gives ω-hydroxyaliphatic acids in high yield as shown by Diaper and Mitchell (9) and Lyncan and Adams (10) provided an inexpensive long chain olefinic acid is available. Hydroxymethylbenzoic acids have been usually made from unsymmetrical precursors such as *p*-toluic acid chloride (11), bromobenzyl bromide (12), or *p*-cyanotoluene (13).

We have previously shown how insoluble polymer supports can be used as monoblocking agents of symmetrical diols (14, 15), dihydric phenols (16), dials (17, 18), and diamines (19) and that the free functional group is available for elaboration to insect sex attractants (20, 21) and unsymmetrical carotenoids (22). In a preliminary report of this article (23) we showed how solid phases can be used to monoblock symmetrical aliphatic diacid chlorides, which can be elaborated to aliphatic monoester monoamides in high yield. In this paper we present the details of the solid phase preparation of a variety

of aliphatic and aromatic monoester monoamides and monoester monoalcohols.

Results and Discussion

Monoester Monoamides

A large excess of succinyl (**1**), glutaryl (**2**), adipoyl (**3**), or sebacoyl chloride (**4**) was added to a suspension of a 2% crosslinked divinylbenzene–styrene copolymer, containing benzyl alcohol groups, (**5**) (24), in tetrahydrofuran (THF) and the mixture stirred overnight under argon. Filtration of the polymers under anhydrous conditions (15) gave their respective polymer-bound monoester monoacid chlorides (**6–9**) as shown in Scheme 1. The infrared (ir) spectra of **6–9**, exhibited strong absorptions at 1740 cm^{-1} indicative of the monoester group, a shoulder at 1760 cm^{-1} and an enhancement of an absorption peak at 1812 cm^{-1}, normally associated with the polystyrene resin but also indicative of an acid chloride. The loading capacities of polymer **5** for their respective acid chlorides were determined by hydrolysis of **6–9** in aqueous dioxane to give polymer-bound monoester monoacids **10–13**, respectively. The ir spectra of **10–13** exhibited strong absorptions at 1740 and 1710 cm^{-1} indicative of the ester and acid groups, respectively. The absorption peak at 1710 cm^{-1} was absent in **6–9**, indicating that the free acid chloride groups in **6–9** had not hydrolysed in the work-up or in the preparation of the KBr pellets, used to take the ir of **6–9**. Cleavage of **10–13** with either tetra-*n*-butylammonium hydroxide in THF at room temperature for 48 h or with potassium carbonate (K_2CO_3) in methanol at the reflux temperature for 12 h, gave the diacids derived from **1–4**. The diacids liberated from **10–13** were treated with diazomethane in ether to give dimethyl succinate (**14**), dimethyl glutarate (**15**), dimethyl adipate (**16**), and dimethyl sebacate (**17**), respectively. In some instances sebacic acid was isolated directly from cleavage of **13** and not esterified. Thus, the loading capacities of polymer **5** for **1–4** were determined by isolation of their respective diesters **14–17** and are recorded in Table 1. Treatment of the polymer-bound acid chlorides (**6–9**) with aniline (**18**) and **9** with benzylamine (**19**), dimethylamine (**20**), and ammonia (**21**), respectively, gave the polymer-bound monoester monoamides **22–28**, respectively. The ir spectra of **22–28** all exhibited intense absorptions at 1740 cm^{-1} and between 1650–1700 cm^{-1} indicative of the ester and amide functional groups, respectively. In addition, the secondary amides **22–26** exhibited peaks at 1510–1550 cm^{-1} indicative of amide II absorptions of secondary amides. Cleavage of **22–28** with K_2CO_3 in methanol followed by esterification with diazomethane yielded methyl *N*-phenylsuccinamate (**29**) (6), methyl *N*-phenylglutaramate (**30**), methyl *N*-phenyladipamate (**31**), methyl *N*-phenylsebacamate (**32**) (3), methyl *N*-benzylsebacamate (**33**), methyl *N*,*N*-dimethylsebacamate (**34**), and methyl sebacamate (**35**) (4) in high yield (Table 1). In some preparations a small amount of the symmetrical diesters **14–17** were recovered (Table 1)

along with **29–35** and were separated from **29–35** by preparative thin-layer chromatography (tlc). The spectral and physical data for **29–35** are consistent with the assigned structures (see Experimental). *It should be emphasized that in almost all cases the crystalline monoester monoamides can be cleanly separated from the oily symmetrical dimethyl esters by crystallization* and that preparative tlc was done simply to obtain the accurate yield data recorded in Table 1.

Similarly, treatment of the symmetrical aromatic diacid chlorides, terephthaloyl chloride (**36**), and isophthaloyl chloride (**37**) yielded the polymer-bound monoester monoacid chlorides **38** and **39**, respectively, as shown in Scheme 2. The ir spectra of **38** and **39** showed absorption peaks at 1730 and 1770–1785 cm^{-1} indicative of aromatic esters and aromatic acid chlorides respectively. Hydrolysis of **38** with aqueous dioxane gave the polymer-bound monoester monoacid (**40**), which exhibited absorptions in its ir spectrum at 1730 and 1700 cm^{-1} typical of aromatic esters and aromatic acids, respectively, but similar hydrolysis of **39** resulted in substantial cleavage from the polymer to liberate isophthalic acid. Polymer **40** could be cleaved as before but this time the resulting terephthalic acid was esterified with HCl in methanol to give dimethyl terephthalate (**41**) as the intermediate acid is insoluble in ether making esterification with diazomethane inefficient. Treatment of **38** and **39** with *tert*-butylamine led to the polymer-bound monoester monoamides **42** and **43**, respectively, which exhibited absorption peaks at 1730, 1650–1680, and 1520–1560 cm^{-1}, in their ir spectra, indicative of ester, amide I, and amide II absorptions,

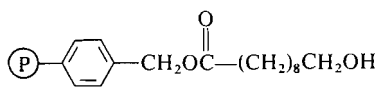
respectively. Cleavage of **42** and **43** and esterification of the product with HCl in methanol gave methyl *N-tert*-butylterephthalamate (**44**) and methyl *N-tert*-butylisophthalamate (**45**), respectively (Table 1). A small amount of **41** was recovered in the preparation of **44**. No dimethyl isophthalate was found in the preparation of **45** but this was expected as any unreacted **39** would probably have been cleaved in the work-up of **43**. The spectral and physical data for **44** and **45** are consistent with the assigned structures (Experimental). It may be noted in Table 1 that the use of freshly prepared **5** yielded the monoester monoamides exclusively while recycled **5** yielded the monoester monoamides in high yield but this time accompanied by some diester. Whether the formation of the diester results from some initial double-binding of **1**–**4** and **36**–**37** with recycled **5** or is due to subsequent incomplete reaction of the polymer-bound monoester monoacid chlorides with the appropriate amine is still conjecture.

Monoester Monoalcohols

The successful monoprotection of symmetrical diacid chlorides as represented by the polymer-bound monoester monoacid chloride **9** allows for the possibility of reducing **9** to the polymer-bound ω-hydroxymonoester **46** shown below. Sodium borohydride ($NaBH_4$) is known to reduce acid chlorides but not esters (25). Hence reduction of **9** with $NaBH_4$ in THF under argon for 12 h gave **46**, which on cleavage with K_2CO_3 in methanol and esterification with diazomethane yielded methyl 10-hydroxydecanoate (**47**) (10) in 67% yield (Table 2), the



46

remaining material being **17**, derived from unreacted **9**. As some **17** was recovered from the reduction of **9** some attempts were made to optimize the yield of **47** by changing the reaction conditions. These variations and their results are recorded in Table 2. Similar results were obtained with new or recycled polymer **5**. Since $NaBH_4$ is not very soluble in THF or dioxane, other reducing agents selective for reducing acid chlorides or acids but not esters were sought. Borane in THF, known to selectively reduce acids in the presence of esters (26), when added to polymer-bound monoester monoacid **13** caused cleavage of the ester linkage to the polymer and hence was unsuitable. Zinc borohydride [$Zn(BH_4)_2$] (27) caused partial cleavage of the ester linkage of polymer **9** and still did not result in complete reduction of **9** to **47** (Table 2). We also perceived that incomplete reduction of **9** might be due to increased crosslinking of the intermediate borate esters due to the fact that the borane reagents have multiple hydrides. Thus, as the reduction of **9** proceeds, crosslinking increases and the reaction eventually stops as further reducing agent cannot penetrate to the interior of the polymer beads. We did attempt to reduce **9** with the *monohydride* sodium monohydridotris(2-methoxyethoxo)-borate, $NaBH(OCH_2CH_2OCH_3)_3$ (28) but this reagent is more reactive than $NaBH_4$ causing partial reduction of **9** to 1,10-decanediol.[4] Sodium cyanoborohydride, $NaBH_3CN$ (29), is less reactive than $NaBH_4$ and is soluble in THF. Reduction of **9** with $NaBH_3CN$ gave **46** and hence **47** in a yield comparable but no better than that using $NaBH_4$ (Table 2).

Similarly, reduction of the polymer-bound aromatic monoester monoacid chlorides **38** and **39** with

[4]Experiment done by V. Yedidia.

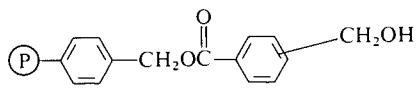
$NaBH_4$ gave the polymer-bound monoester monoalcohols **48** and **49** shown below. Cleavage of **48** and **49** as before and esterification with HCl in methanol yielded methyl *p*-hydroxymethylbenzoate (**50**) (11) and methyl *m*-hydroxymethylbenzoate (**51**), respectively (Table 2). Some dimethylterephthalate (**41**) was recovered from the cleavage of **48**.



48 *p*-CH_2OH
49 *m*-CH_2OH

Conclusions

It has been shown that monoester monoamides can be prepared, often in quantitative yield, from a variety of inexpensive symmetrical aliphatic and aromatic diacid chlorides using a readily available functionalized solid phase. Polymer-bound symmetrical aliphatic and aromatic diacid chlorides can also be selectively reduced to monoester monoalcohols in good yield.

Experimental

A chloromethylated 2% divinylbenzene (DVB) – styrene copolymer, containing 1.16 mequiv. Cl/g of resin,[5] obtained from Sigma Chemical Company was used as the starting resin in all resin transformations. Filtration was done under vacuum using sintered glass Büchner funnels. Suspensions and solutions were stirred using magnetic stirrers. Matheson high purity argon was used to maintain inert atmosphere conditions. Filtration under an inert atmosphere was accomplished under positive pressure in a modified fritted Schlenk tube apparatus (15). Infrared (ir) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs for solids or as neat films between NaCl discs. Nuclear magnetic resonance (nmr) spectra were recorded on a Varian EM 360 spectrometer using deuterochloroform as solvent and tetramethylsilane as the internal standard. The positions of the signals are reported in δ units. The splittings of the signals are described as singlets (s), doublets (d), triplets (t), quartets (q), or multiplets (m). Mass spectra (ms) were recorded at 70 eV on a Hitachi Perkin Elmer RMU 6E mass spectrometer. The number in parentheses after the indicated ion shows the percentage of the base peak represented by that ion. Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed using silica gel G as the adsorbent and benzene–ether (7:3) as eluant unless otherwise stated. Microanalyses were done by G. Gygli of Toronto and Dr. C. Daesslé of Montreal. Spectral and analytical data are given for all new compounds and for known compounds where data are unreported.

Preparation of Polymer-bound Acid Chlorides ***6–9, 38, and 39***

Thirteen millimoles of the symmetrical diacid chloride (**1–4**, **36**, or **37**) was added to 3 g (containing a maximum of 3.48 mequiv. of benzyl alcohol groups) of **5** suspended in 50 ml of dry THF in a modified Schlenk tube apparatus (15) and stirred under an inert atmosphere for 12 h at room temperature. The suspensions were filtered under argon and washed with dry THF in a modified Schlenk tube apparatus and stirred under argon for 12 h at room temperature to give the polymer-bound monoester monoacid chlorides (**6–9**, **38**, and **39**); ir (KBr): 1812–1760 (COCl), 1740–1730 (CO_2R), and 1180–1150 cm^{-1} (C—O).

Preparation of Polymer-bound Monoester Monoacids ***10–13 and 40***

Polymer **6–9** or **38** (1 g) was suspended in 50 ml of aqueous THF and stirred at the reflux temperature for 5 h. The resultant polymer was then filtered, washed once with THF, three times with methanol, and twice with ether to give the polymer-bound monoacid **10–13** or **40**; ir (KBr): 1740–1730 (CO_2R), 1710–1700 (CO_2H), and 1180–1150 cm^{-1} (C—O).

Cleavage of the Polymer-bound Monoester Monoacids ***10–13 and 40 with*** K_2CO_3

A polymer-bound acid **10–13** or **40** (1.1 g) and 0.75 g of K_2CO_3 were suspended in 50 ml of methanol and stirred at the reflux temperature for 12 h. Regenerated polymer **5** was filtered, washed four times with methanol, once with benzene, three times with methanol, and twice with ether. An ir spectra of **5** exhibited no absorption peaks at 1740–1730 and 1710–1700 cm^{-1} due to uncleaved acid. The filtrate was evaporated almost to dryness, acidified with HCl, and esterified with diazomethane in ether. The product was then extracted with ether three times. The ether layer was then washed once with dilute H_2SO_4, once with dilute NaOH, and once with water. The ether layer was dried over $MgSO_4$ and evaporated to dryness to give pure dimethyl succinate (**14**), dimethyl glutarate (**15**), dimethyl adipate (**16**), dimethyl sebacate (**17**), and dimethyl terephthalate (**41**), identical to the commercially available diesters. The cleavage product from **13** was sometimes acidified with HCl and isolated directly as sebacic acid by extraction with ether. The cleavage product from **40** was esterified with HCl in methanol to give **41**. The amount of recovered **5** was determined. The loading capacities of the diesters **14–17** and **41** for polymer **5** are recorded in Tables 1 and 2. Thus, approximately one-half to one-third of the benzyl alcohol groups of **5** are available for reaction with the symmetrical acid chloride.

Preparation of the Polymer-bound Monoester Monoamides ***22–28, 42, and 43***

A suspension of 1.1 g of polymer **6–9** in dry THF was treated with 5 mmol of aniline (**18**) and the mixture stirred under argon for 5 h at room temperature. The polymer was subsequently filtered and washed once with THF, three times with methanol, once with benzene, three times with methanol and twice with ether to give the polymer-bound monoester monoamide **22**, **23**, **24**, or **25**; ir (KBr): 3450–3300 (broad) (N—H), 1740 (CO_2R), 1700–1670 (amide I), and 1550–1510 cm^{-1} (amide II).

Similarly, **9** reacted with benzylamine (**19**) to give polymer-bound monoester monoamide **26**; ir (KBr): 3450–3300 (broad) (NH), 1740 (CO_2R), 1690–1660 (amide I), and 1550–1510 cm^{-1} (weak) (amide II).

Similarly, **9** reacted with dimethyl amine (**20**) to give the polymer-bound monoester monoamide **27**; ir (KBr): 1740 (CO_2R) and 1660–1650 cm^{-1} (amide I).

Similarly, **9** reacted with ammonia to give the polymer-bound monoester monoamide **28**; ir (KBr): 3500–3350 (broad) and 3200 (weak, NH), 1740 (CO_2R), and 1690–1670 cm^{-1} (amide I).

Similarly, **38** or **39** reacted with *tert*-butylamine to give the

[5]Thus, it can be calculated (30) that approximately one in eight of the benzene rings is chloromethylated.

polymer-bound monoester monoamide **42** or **43**; in (KBr): 3600–3350 (broad) (NH), 1730 (CO_2R), 1680–1660 (amide I), and 1540–1510 cm^{-1} (amide II).

*Preparation of the Monoester Monoamides **29–35**, **44**, and **45***

A suspension of 1.1 g of **22** was cleaved with K_2CO_3 in methanol, esterified, and extracted with ether as described above for the cleavage of **10**. The amount of recovered **5** was determined. The product was purified by preparative tlc to give as the sole product (Table 1) 66 mg of methyl *N*-phenylsuccinamate (**29**); mp 94–94.5°C (lit. (6), mp 97–99°C); ir (KBr): 3320 (NH), 1742 (CO_2R), 1670 (amide I), 1550 (amide II), 1600 (phenyl), and 1165 cm^{-1} (C—O); nmr δ: 8.1 (s, 1, N*H*), 7.7–7.2 (m, 5, aromatic *H*), 3.8 (s, 3, CH_3O), and 2.8 (s, 4, $CH_2C{=}O$); ms: 207 (53) (M^+), 176 (36), 93 (100).

Similarly, **23** yielded methyl *N*-phenylglutaramate (**30**); mp 72–72.5°C; ir (KBr): 3370 (NH), 1730 (CO_2R), 1690 (amide I), 1605 (phenyl), 1540 (amide II), and 1165 cm^{-1} (C—O); nmr δ: 8.1 (s, 1, N*H*), 7.7–7.1 (m, 5, aromatic *H*), 3.7 (s, 3, CH_3O), 2.5 (m, 4, $CH_2C{=}O$), and 2.1 (m, 2, CH_2); ms: 221 (82) (M^+), 129 (65), 93 (100). *Anal.* calcd. for $C_{12}H_{15}NO_3$: C 65.14, H 6.83, N 6.33; found: C 65.43, H 6.88, N 6.37.

Similarly, **24** gave methyl *N*-phenyladipamate (**31**); mp 43°C; ir (KBr): 3430 (NH), 1740 (CO_2R), 1670 (amide I), 1605 (phenyl), 1550 (amide II), and 1180 cm^{-1} (C—O); nmr δ: 7.9 (s, 1, N*H*), 7.7–7.1 (m, 5, aromatic *H*), 3.8 (s, 3, CH_3O), 2.5 (m, 4, $CH_2C{=}O$), and 1.8 (m, 4, CH_2); ms: 235 (8) (M^+), 93 (100). *Anal.* calcd. for $C_{13}H_{17}NO_3$: C 66.36, H 7.28, N 5.95; found: C 66.28, H 7.37, N 6.02.

Similarly, **25** gave methyl *N*-phenylsebacamate (**32**); mp 68°C (lit. (3) mp 68°C); ir (KBr): 3370 (NH), 1720 (CO_2R), 1690 (amide I), 1605 (phenyl), 1550 (amide II), and 1170 cm^{-1} (C—O); nmr δ: 8.3 (s, 1, N*H*), 7.7–7.1 (m, 5, aromatic *H*), 3.8 (s, 3, CH_3O), 2.4 (m, 4, $CH_2C{=}O$), and 1.9–1.1 (m, 12, CH_2).

Similarly, **26** yielded methyl *N*-benzylsebacamate (**33**); mp 70–71°C; ir (KBr): 3390 (NH), 1742 (CO_2R), 1635 (amide I), 1555 (amide II), and 1175 cm^{-1} (C—O); nmr δ: 7.4 (s, 5, aromatic *H*), 6.3 (s, 1, N*H*), 5.6 (d, 2, J = 6 Hz, NCH_2Ph), 3.7 (s, 3, CH_3O), 2.4 (m, 4, $CH_2C{=}O$), and 1.9–1.1 (m, 12, CH_2). *Anal.* calcd. for $C_{18}H_{27}NO_3$: C 70.79, H 8.91, N 4.59; found: C 70.63, H 8.54, N 4.59.

Similarly, **27** yielded methyl *N*,*N*-dimethylsebacamate (**34**) as an oil; ir (neat): 1742 (CO_2R), 1645 (amide I), and 1165 cm^{-1} (C—O); nmr δ: 3.8 (s, 3, CH_3O), 3.1, 3.05 (d, 6, CH_3N), 2.4 (m, 4, $CH_2C{=}O$), and 1.9–1.2 (m, 12, CH_2). *Anal.* calcd. for $C_{13}H_{26}NO_3$: C 64.16, H 10.36, N 5.76; found: C 63.99, H 10.26, N 5.64.

Similarly, **28** gave methyl sebacamate (**35**); mp 74–76°C (lit. (4) mp 74–76°C); ir (KBr): 3400, 3200 (NH_2), 1738 (CO_2R), 1650 (amide I), and 1175 cm^{-1} (C—O); nmr δ: 5.7 (s, 2, NH_2), 3.7 (s, 3, CH_3O), 2.2 (m, 4, $CH_2C{=}O$), and 1.9–1.2 (m, 12, CH_2).

Similarly, **42** gave methyl *N-tert*-butylterephthalamate (**44**); mp 124.5–125°C; ir (KBr): 3310 (NH), 1725 (CO_2R), 1640 (amide I), 1550 (amide II), and 1290, 1110 cm^{-1} (C—O); nmr δ: 8.3–7.7 (m, 4, aromatic *H*), 6.2 (s, 1, N*H*), 4.1 (s, 3, CH_3O), and 1.6 (s, 9, CH_3C); ms: (235) (88) (M^+), 220 (77) ($M^+ - CH_3$), 180 (90), 163 (100) ($M^+ - NHC(CH_3)_3$). *Anal.* calcd. for $C_{13}H_{17}NO_3$: C 66.36, H 7.28, N 5.95; found: C 66.73, H 7.74, N 5.52.

Similarly, **43** yielded methyl N-*tert*-butylisophthalamate (**45**); mp 77.5°C; ir (KBr) 3350 (NH), 1730 (CO_2R), 1640 (amide I), 1550 (amide II), and 1270, 1150 cm^{-1} (C—O); nmr δ: 8.4–7.4 (m, 4, aromatic *H*), 6.2 (s, 1, N*H*), 4.0 (s, 3, CH_3O), and 1.5 (s, 9, CH_3C); ms: (235) (25) (M^+), 220 (23) ($M^+ - CH_3$), 182 (38), 163 (100) ($M^+ - NHC(CH_3)_3$). *Anal.* calcd. for $C_{13}H_{17}NO_3$: C 66.36, H 7.28, N 5.95; found: C 66.33, H 7.29, N 5.84.

In the isolation of **31–34** and **44**, some of the corresponding dimethyl esters **16**, **17**, and **41** were detected and separated from the monoamide monoesters by preparative tlc (see Table 1).

*Preparation of Polymer-bound Monoester Monoalcohols **46**, **48**, and **49***

To a suspension of 1.0 g of **9**, was added 4 mmol of $NaBH_4$, $NaBH_3CN$ or $Zn(BH_4)_2$ in 40 ml of dry THF. The mixture was stirred under argon at room temperature for 12 h. The excess borohydride was decomposed with water and dilute HCl. The resultant polymer was filtered and washed four times with methanol, once with benzene, three times with methanol, and twice with ether to give the polymer-bound monoester monoalcohol (**46**); ir (KBr): 3600–3400 (O—H), 1740 (CO_2R), 1600 (phenyl), and 1160 cm^{-1} (C—O).

Similarly, reduction of **38** yielded the polymer-bound monoester monoalcohol (**48**); ir (KBr): 3600–3400 (O—H), 1730 (CO_2R), 1602 (phenyl), and 1170 cm^{-1} (C—O).

Similarly, reduction of **39** gave the polymer-bound monoester monoalcohol (**49**): ir (KBr): 3600–3400 (OH), 1730 (CO_2R), 1602 (phenyl), and 1180 cm^{-1} (C—O).

*Preparation of the Monoester Monoalcohols **47**, **50**, and **51***

A suspension of 1.1 g of **46** was cleaved with K_2CO_3 in methanol, esterified, and extracted with ether as described above for the cleavage of **10**. The amount of recovered **5** was determined. The product was purified by preparative tlc to yield (Table 2) some recovered **9** and methyl 10-hydroxydecanoate (**47**) as an oil (10); ir (neat): 3500–3300 (OH), 1743 (CO_2R), and 1175 cm^{-1} (C—O); nmr δ: 3.72 (s, 3, CH_3O), 3.65 (t, 2, J = 6 Hz, CH_2O), 2.0 (s, 1, O*H*), 2.35 (t, 2, J = 7 Hz, $CH_2C{=}O$), and 1.8–1.2 (m, 14, CH_2).

Similarly, **48** yielded (Table 2) some recovered **41** and methyl 4-hydroxymethylbenzoate (**50**); mp 49.5–50°C (lit. (11) bp 155–157°C/4–5 Torr); ir (KBr): 3340–3200 (OH), 1730 (CO_2R), 1620 (phenyl), and 1290, 1175 cm^{-1} (C—O); nmr δ: 8.2–7.3 (m, 4, aromatic *H*), 4.7 (s, 2, CH_2O), 4.0 (s, 3, CH_3O), and 2.5 (s, 1, O*H*); ms: 166 (88) (M^+), 135 (97) ($M^+ - OCH_3$ or CH_2OH), 107 (100) ($M^+ - CO_2CH_3$). *Anal.* calcd. for $C_9H_{10}O_3$: C 65.07, H 6.07; found: C 65.64, H 6.25.

Similarly, **49** gave methyl 3-hydroxymethylbenzoate (**51**) as an oil; ir (neat): 3550–3300 (OH), 1730 (CO_2R), 1600 (phenyl), and 1290, 1200 cm^{-1} (C—O); nmr δ: 8.2–7.3 (m, 4, aromatic *H*), 4.7 (s, 2, CH_2O), 4.0 (s, 3, CH_3O), and 2.8 (s, 1, O*H*); ms: 166 (84) (M^+), 135 (98) ($M^+ - OCH_3$ or CH_2OH), 107 (100) ($M^+ - CO_2CH_3$). *Anal.* calcd. for $C_9H_{10}O_3$: C 65.07, H 6.07; found: C 64.94, H 6.20.

*Attempted Preparation of **46** by the Borane Reduction of **13***

To a suspension of 1.0 g of **13** in 30 ml of dry THF cooled in ice, was added borane (two mmol) in THF. The mixture was allowed to warm to room temperature and was stirred under argon for 12 h. Excess hydride was decomposed with water and dilute HCl. The resultant polymer was filtered and washed once with THF, four times with methanol, twice with benzene, three times with methanol, and twice with ether. The ir spectrum of the resultant polymer showed complete loss of absorption at 1740 cm^{-1}, indicating that total cleavage of the ester linkage had taken place.

Propriétés hydrodynamiques des conformations ordonnées et desordonnées du poly(γ-L-glutamate de benzyle): dimensions et flexibilité de la chaîne

NGA HO-DUC

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A Montréal (Qué.), Canada H3C 3V1

Reçu le 13 octobre 1977

NGA HO-DUC. Can. J. Chem. **56**, 1569 (1978).

Théoriquement, on peut déterminer la structure désordonnée ou ordonnée des polypeptides en solution, ainsi que leurs dimensions à partir des propriétés hydrodynamiques. Nous avons un certain nombre suffisant de théories pour interpréter les résultats expérimentaux. En ce qui concerne la conformation ordonnée hélicoidale, ces théories se basent sur des modèles physiques d'un ellipsoide de révolution allongé, d'une chaîne vermiforme plus ou moins flexible, d'une chaîne cylindrique rigide ou semi-flexible.

Les données expérimentales de viscosité des sept échantillons de poly(γ-L-glutamate de benzyle) dans le dichloro-1,2 éthane à 25°C ont été étudiées. La longueur d'un résidu h a été calculée selon le modèle ellipsoidal. Le degré de flexibilité est caractérisée par le nombre de monomères par segment rigide (N_S). La valeur de N_S a été déterminée selon l'équation de Yamakawa et Fujii réarrangée par Vitovskaya et Tsvetkov. Nous obtenons pour h, en supposant que la chaîne est rigide, des valeurs se situant entre 1.3 et 2 Å. Nous constatons pour les échantillons de poids moléculaires suivants: 1.8×10^5, 1.7×10^5, 1.5×10^5, que la valeur de h est voisine de 1.5 Å. Ce sont, précisément, des échantillons dont la longueur de chaîne est du même ordre de grandeur que celle d'un segment rigide.

L'analyse des données de la viscosité du poly(γ-L-glutamate de benzyle) dans l'acide dichloroacétique indique qu'à part de la formation de liaisons hydrogène entre le polypeptide et le solvant, d'autres interactions sont présentes.

Bref, nous constatons que, si l'étude de la transition conformationnelle est jugée satisfaisante à partir des données hydrodynamiques, la détermination des dimensions caractéristiques permettant de décrire la conformation reste ambigue. Un des problèmes est la flexibilité de la chaîne. Pour contourner cette difficulté, nous proposons une méthode qui consiste à déterminer le nombre de monomères par segment rigide à partir des différentes valeurs obtenues pour h pour les différents poids moléculaires et ensuite les dimensions à partir des échantillons dont la longueur des chaînes est en bon accord avec celle du segment rigide ainsi déterminée.

NGA HO-DUC. Can. J. Chem. **56**, 1569 (1978).

Theoretically we can determine the disordered or ordered structure of polypeptides and their dimensions in dilute solutions from hydrodynamic properties. We have presently a wealth of theories for random coil chains and a limited but sufficient number of theories for ordered chains for interpreting experimental results.

Viscosity data for seven poly(γ-benzyl-L-glutamate) samples in 1,2-dichloroethane at 25 C are analyzed and the length per monomeric residue (h) is calculated according to the equivalent ellipsoid approach. The degree of flexibility or rigidity is characterized by calculating N_S, the number of monomer units in a rigid segment or a Kuhn statistical segment; the determination of N_S is made by applying Yamakawa and Fujii's equation modified by Vitovskaya and Tsvetkov.

Values obtained for h assuming the solute molecule to be a rigid, stiff chain, range between 1.3 to 2 Å. One notices that the h value close to 1.5 Å is found for the three following molecular weights: 1.8×10^5, 1.7×10^5, and 1.5×10^5. They are, in fact, the samples having a length in good quantitative agreement with that of the rigid segment determined by the method of Vitovskaya and Tsvetkov. This rigid segment corresponds to a sample of 700 ± 100 monomer units.

The analysis of the experimental data of poly(γ-benzyl-L-glutamate) in dichloroacetic acid indicates that, in addition to the formation of hydrogen bonds, other interactions between the polypeptide and the solvent are present.

In summary, we may conclude that the study of the helix–coil transition using hydrodynamic measurements is judged satisfactory but the determination of characteristic dimensions used to describe exactly the conformation of the macromolecule is somewhat ambiguous. One major problem is the degree of flexibility encountered with high molecular weight chains. However, to get around this difficulty, we propose, according to our results, a method which consists in determining the number of monomer units within a rigid segment from the different values found for h and then the dimensions from the samples for which the chain length is in good agreement with that of a rigid segment thus determined.

Introduction

L'étude des conformations ordonnée et désordonnée des polypeptides synthétiques a donné naissance ces 15 dernières années à un certain nombre de théories thermodynamiques. Au point de vue hydrodynamique, nous constatons que l'effort se développe d'une façon remarquable depuis 1970. Il existe actuellement quelques théories raffinées (1–6) dont les différences fondamentales proviennent des simplifications apportées aux modèles physiques décrivant le phénomène concerné. Cependant, il faut noter que l'information correspondant à la conformation ordonnée est limitée théoriquement par plusieurs facteurs.

Comme ces propriétés hydrodynamiques se déduisent du coefficient de frottement de la macromolécule en solution et que ce coefficient dépend de la forme et de la grandeur du soluté, nous essayons de calculer ces quantités à partir de la viscosité intrinsèque et plus tard du coefficient de sédimentation en se basant sur les théories ayant pour modèles physiques un ellipsoide de révolution allongé, un batonnet rigide ou semi-flexible ou la chaîne vermiforme.

A partir des données expérimentales de la viscosité intrinsèque des échantillons de poly(γ-L-glutamate de benzyle) dans le dichloro-1,2 éthane et dans l'acide dichloroacétique nous calculons les dimensions de la chaîne et la longueur statistique de Kuhn. Nous étudions ensuite l'effet de la flexibilité de la chaîne sur les dimensions et proposons un moyen permettant de faire un choix convenable parmi les différentes valeurs obtenues.

Considérations théoriques

L'interprétation des données hydrodynamiques d'une macromolécule en solution peut se faire à l'aide des relations théoriques entre la viscosité intrinsèque $[\eta]$ et les dimensions de la chaîne ainsi que son poids moléculaire et certains paramètres d'interaction. Les relations théoriques exactes sont bien connues pour les particules sphériques ou d'équivalence hydrodynamique sphérique (7) et pour les particules d'ellipsoïde de révolution (8); les expressions de $[\eta]$ pour la structure hélicoïdale assimilé à un ellipsoïde de révolution allongé, à une chaîne cylindrique ou semi-flexible ou une chaîne vermiforme sont encore discutables. Nous résumons sommairement ces approximations couramment utilisées pour élucider ce problème.

L'approximation qui consiste à assimiler l'hélice à un ellipsoïde de révolution discutée par plusieurs auteurs (9, 10) a pour base les équations de Simha (11) avec l'hypothèse que le grand axe a de l'ellipsoïde est proportionnel au poids moléculaire du soluté, a étant égal à la longueur de contour de la chaîne (L).

Le petit axe b est relié au diamètre d de l'hélice par la relation suivante:

$$b = (3/2)^{0.5} d$$

Dans le cas où $(L/d) \gg 1$, la viscosité intrinsèque d'une particule d'ellipsoïde allongé peut s'écrire:

$$[1] \quad [\eta] = \frac{\pi N_A M^2}{4 M_L^3} \left\{ \frac{14}{15} \left(\frac{d}{L}\right)^2 + \frac{2}{45[\ln (2L/d) - 1.70]} + \frac{2}{15[\ln (2L/d) - 0.7]} \right\}$$

où $M_L = M/L$ ou sous la forme qui la relie directement à h, la longueur d'un résidu ou d'un motif de base

$$[2] \qquad hM = 6.86 M_0 ([\eta]/M)^{1/3} [p/\Lambda(p)]^{1/3}$$

où M_0 le poids moléculaire du motif de base et p le rapport axial. Notons que pour une chaîne rigide $h = M_0/M_L$ et

$$\Lambda(p) = \frac{14}{15} + \frac{p^2}{15(\ln 2p - 1.5)} + \frac{p^2}{5(\ln 2p - 0.5)}$$

Notons que dans l'éq. [2] h est exprimé en Å et $[\eta]$ en dl/g.

Hearst et Tagami (13) ont dérivé une équation pour la viscosité d'une chaîne vermiforme en appliquant la théorie générale de Kirkwood en tenant compte de la distribution à symétrie cylindrique du modèle. Quelques années plus tard Hearst *et al.* (14) ont repris ce modèle continu en ajoutant une force de flexion permettant de calculer la viscosité d'une chaîne vermiforme à un certain degré de flexibilité. Le résultat théorique de Hearst peut s'écrire selon la relation linéaire suivante entre $M/[\eta]$ et $M^{1/2}$

$$[3] \quad \frac{M}{[\eta]} = \frac{(\lambda M_L)^{3/2}}{\phi} \left[K \left(\frac{M_L}{\lambda}\right)^{1/2} + M^{1/2} \right]$$

où ϕ est une constante, λ^{-1} la longueur statistique de Kuhn, le paramètre K, une constante pour un polypeptide donné, est donné par la relation suivante: $K = -K_2 [K_3 + \ln(\lambda d)]$; K_2, K_3 sont des constantes numériques. Il faut noter que l'éq. [3] et celle donnée par Noda (15) en tenant compte du volume exclu ne sont valides que pour des chaînes ayant une flexibilité relativement grande. Nous verrons plus tard, dans la partie des résultats, que ce modèle ne peut s'appliquer à la chaîne de poly(γ-benzyl-L-glutamate), cette dernière étant "trop"

rigide. Plus récemment Yamakawa et Fujii (6) ont évalué la viscosité intrinsèque des chaînes rigides ou faiblement flexibles en appliquant les procédés de calculs hydrodynamiques d'Oseen Burgers au modèle de chaîne vermiforme cylindrique. L'approche de Yamakawa et Fujii (6) conduit à l'expression analytique semi-empirique suivante pour $[\eta]$

$$[4]\quad [\eta] = \frac{\pi N_A L^3}{24M \ln\left(\frac{L}{d}\right)} \frac{f(L)}{1 + \sum_{i=1}^{4} A_i \left[\ln\left(\frac{d}{L}\right)\right]^{-1}}$$

où A_i sont des grandeurs numériques indépendantes de L et d

$$f(L) = \frac{3}{2L^4}(e^{-2L} - 1 + 2L - 2L^2 + -\tfrac{3}{4}L^3)$$

Toutefois il faut noter que cette équation n'est qu'approximative pour $L/d < 100$. Selon les calculs des auteurs si $L = 10$, $d = 0.1$ l'erreur est de l'ordre de 0.5%, si $L = 10$ et $d = 0.25$ l'erreur passe à 3%.

Récemment Vitovskaya et Tsvetkov (16) ont réarrangé l'équation de Yamakawa et Fujii sous une forme plus pratique permettant de mesurer la rigidité ou la flexibilité de la chaîne. Ils substituent $f(L)$ par $f(x)$

$$f(x) = \frac{24}{x^4}\left(e^{-x} - 1 + x - \frac{x^2}{2} + \frac{x^3}{6}\right)$$

où $x = 2\,L\lambda$. A partir de l'éq. [4] ils obtiennent facilement avec ce changement de variable l'expression suivante:

$$[5]\quad y = h^3 f(x) = \frac{[\eta]}{M^2}\frac{24}{\pi N_A} M_0{}^3 \left[\ln\frac{L}{d} - 1.839 + \frac{8.24}{\ln\frac{L}{d}} - \frac{32.85}{\ln^2\frac{L}{d}} + \frac{41.10}{\ln^3\frac{L}{d}}\right]$$

ou

$$[6]\quad y = h^3\left(1 - \frac{2}{5}\frac{1}{M_0 N_S} M + \frac{2}{15}\frac{1}{M_0{}^2 N_S{}^2} M^2 - \ldots\right)$$

où N_S = nombre de monomères ou de résidus par segment rigide. Nous calculons à partir de N_S le poids correspondant M_{NS}. Cette quantité sera utilisée comme l'intermédiaire valable pour faire un choix judicieux parmi les différentes valeurs obtenues pour les dimensions de la chaîne déterminées à l'aide des données viscosimétriques.

Partie expérimentale

Les échantillons de poly(γ-benzyl-L-glutamate) ont été fournis par la compagnie Sigma. Les poids moléculaires ont été déterminés par viscosimétrie selon les calibrations de Doty *et al.* (17) et de Fujita *et al.* (18). Les solvants utilisés, l'acide dichloroacétique et dichloro-1,2 ethane, ont été purifiés par distillation sous vide. Toutes les mesures de viscosité ont été effectuées à l'aide d'un viscosimètre semi-micro Cannon Ubbelhode en utilisant le montage automatique de Hewlett Packard modèle 5901 B. Pour éviter la dégradation du polypeptide dans l'acide dichloroacétique, la mise en solution et les mesures ont été faites dans le minimum de temps possible. La température est maintenue à 25.00 ± 0.02°C; la concentration varie entre 1 à 0.2% p/v.

Résultats et discussions

Les résultats viscosimétriques des systèmes étudiés $[Glu(OBzl)]_n$-Cl_2AcOH et $[Glu(OBzl)]_n$-Cl_2Et et $[Glu(OBzl)]_n$-Cl_2AcOH/Cl_2Et sont groupés dans le tableau 1.

Mentionnons, en passant, qu'à partir de ces données nous traçons les graphiques de $[\eta]$ en fonction de M (fig. 1) et nous avons trouvé les relations suivantes respectivement pour Cl_2AcOH et Cl_2Et.

$$[7]\quad [\eta]\ \mathrm{dl/g} = 1.12 \times 10^{-4} M^{0.75}$$

$$[8]\quad [\eta]\ \mathrm{dl/g} = 1.2 \times 10^{-7} M^{1.40}$$

L'exposant pour le système $[Glu(OBzl)]_n$-Cl_2AcOH est inférieur à celui de Doty *et al.* (17).

Notons également le point d'isoviscosité intrinsèque (i.e. le point où la viscosité intrinsèque est indépendante du changement de conformation) est aux environs de 0.35 ce qui correspond à un poids moléculaire approximativement de 5×10^4. Le volume hydrodynamique moyen d'un tel poids moléculaire ne change pas lors de la transition hélice–pelote.

Dimensions et flexibilité de la chaîne dans Cl_2Et: conformation hélicoïdale

Nous avons déterminé h à partir de l'éq. [2] en posant pour le $[Glu(OBzl)]_n$, $p = 3.8 \times 10^{-4}$ M. La constante de proportionnalité 3.8×10^{-4} correspond à une hélice α rigide de 15 Å de diamètre. L'erreur sur p affecte peu la détermination de h à cause du

terme $[p^2/\Lambda(p)]^{1/3}$. Nous trouvons les valeurs de h ainsi calculées dans le tableau 2.

Notons en passant que la valeur de h peut être évaluée graphiquement à partir de l'éq. [1]. En effet lorsque $\ln L/d > 1.5$, i.e. dans le cas d'une hélice α, une chaîne d'au moins cinquante motifs de base, l'éq. [1] peut être remplacée approximativement par la relation [1*a*]

$$[1a] \qquad \frac{N_A M^2}{[\eta]} = \frac{45}{2\pi}\left[\ln\frac{L}{d} - \text{cte}\right] M_L{}^3$$

Le graphique $N_A M^2/[\eta]$ en fonction de ln M (fig. 2) nous permet de calculer M_L et ensuite h. La valeur de h calculée de cette façon est de 1.3 Å qui est plutôt une valeur caractéristique de l'hélice π que de l'hélice α, i.e. 1.5 Å. Cette faible valeur est due à la flexibilité de la chaîne et à l'approximation apportée à l'équation. Examinons plutôt les valeurs de h obtenues par l'éq. [2] pour chaque échantillon; les points à noter dans ces résultats sont les valeurs de h trop élevées pour des échantillons de faible masse, légèrement faibles pour le poids moléculaire 3×10^5 et égales, aux erreurs expérimentales près, à celle attendue pour les échantillons de poids moléculaire s'étalant de 1 à 2×10^5.

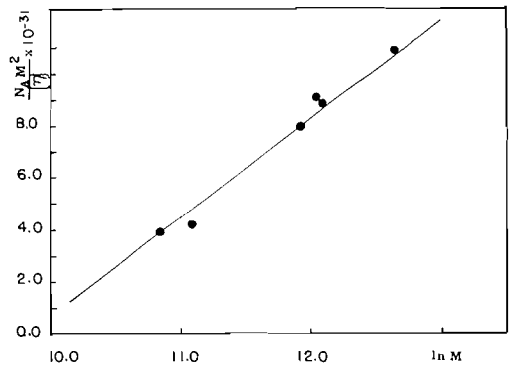

FIG. 2. Courbe permettant le calcul de h pour l'équivalence hydrodynamique ellipsoïdale allongée (système cgs).

Passons maintenant au degré de flexibilité de la chaîne. Ce degré peut être caractérisé par la longueur de persistance ou par la longueur du segment de Kuhn ou par N_S le nombre de monomère par segment rigide. Ce dernier peut être déterminé à partir de l'éq. [6] qui est représentée graphiquement, à partir de résultats expérimentaux, sur la fig. 3. En effet l'ordonnée à l'origine nous donne la valeur numérique de h, elle est égale à 1.6 Å et la pente initiale de la courbe nous permet de calculer N_S. La valeur de N_S ainsi déterminée est égale à 700 ± 100 ce qui correspond à un poids moléculaire M_{NS} d'environ 1.5×10^5 pour le $[Glu(OBzl)]_n$, autrement dit hélice α dont la longueur dépasse 1200 Å n'est plus rigide, elle devient plus ou moins flexible. Cet ordre de grandeur de poids moléculaire se compare favorablement avec celui des échantillons dont h est égal à 1.5 Å, i.e. les trois échantillons suivants: 1.8×10^5, 1.7×10^5 et 1.5×10^5. La valeur un peu faible 1.4 Å s'explique facilement par une légère flexibilité de la chaîne. Les valeurs 1.7 et 2 Å pour des chaînes courtes pourraient être expliquées par l'approximation de l'équivalence hydrodynamique d'un ellipsoïde de révolution pour la chaîne héli-

coïdale. Elle donne des valeurs élevées à cause probablement des effets des bouts effilés de l'ellipsoïde. D'après nos résultats expérimentaux, au moins pour le $[Glu(OBzl)]_n$ le modèle d'équivalence hydrodynamique ellipsoïdale est valable pour des chaînes ayant une longueur supérieure à 650 Å; par contre lorsque la chaîne devient très longue le facteur de flexibilité intervient.

Enfin nous essayons d'étudier la flexibilité de la chaîne avec l'éq. [3] de Hearst *et al.* La fig. 4 dont la pente du graphique $M/[\eta]$ en fonction de $M^{1/2}$ est négative, nous indique que le $[Glu(OBzl)]_n$ est "trop" rigide, il n'a pas la conformation vermiforme statistique, i.e. un long batonnet cylindrique très peu rigide. Notons que la pente reste encore négative pour un solvant mixte de Cl_2Et et de Cl_2AcOH à 60% d'acide, sûrement nous constatons que la rigidité diminue. C'est une façon d'illustrer qualitativement la variation de la rigidité de la chaîne.

Dimensions de la chaîne dans Cl_2AcOH:conformation pelote statistique

La viscosité intrinsèque d'une chaîne de conformation pelote statistique est reliée à la masse et au rayon quadratique moyen $\langle\overline{R^2}\rangle^{1/2}$ par la relation simple et bien connue

$$[9] \qquad [\eta] = \phi_0 \frac{\langle\overline{R^2}\rangle^{3/2}}{M}$$

ou ϕ_0 est la constante de Flory, elle est égale à 1.9×10^{21} pour le $[Glu(OBzl)]_n$ à 100% désordonnée (19).

Les valeurs de $\langle\overline{R^2}\rangle^{1/2}$ calculées à partir de l'expression [9] sont groupées dans le tableau 3. Les valeurs de $\langle\overline{R_0^2}\rangle^{1/2}$ données dans le même tableau, sont calculées à partir du graphique $[\eta]/M^{0.5}$ en fonction de $M^{0.5}$ selon la méthode de Stockmayer–Fixman. Elles sont du même ordre de grandeur que celles calculées à partir des données de Brant et

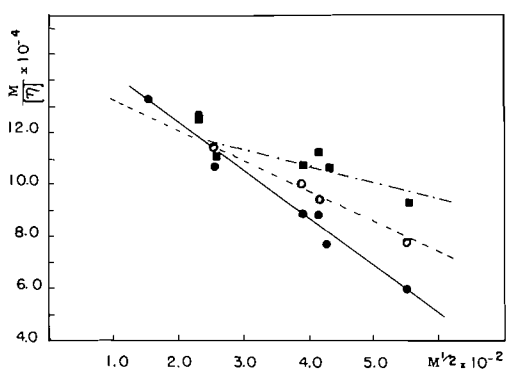

FIG. 4. Flexibilité de la chaîne en fonction de la composition des solvants (système cgs): (●) 100% Cl_2Et; (○) 60% Cl_2Et + 40% Cl_2AcOH; (■) 40% Cl_2Et + 60% Cl_2AcOH.

TABLEAU 3. Valeurs numériques de $\langle\overline{R_0^2}\rangle^{1/2}$ et $\langle\overline{R^2}\rangle^{1/2}$ du système $[Glu(OBzl)]_n$–Cl_2AcOH

		$\langle\overline{R_0^2}\rangle^{1/2}$(Å)		
M	$\langle\overline{R^2}\rangle^{1/2}$(Å)	Réference 20	Ce travail	α
300 000	625	417	418	1.50
180 000	444	323	324	1.38
170 000	433	314	315	1.38
150 000	408	295	296	1.38
65 000	243	194	195	1.25
52 000	214	174	174	1.23
24 000	140	118	118	1.19

Flory (20). Notons que Norisuye (19) a trouvé la même valeur pour le rapport $\overline{R_0^2}/nl_p^2$ où l_p est la difference entre deux α-C successifs.

Le volume exclu est calculé à partir de l'équation suivante:

$$[10] \qquad u = 2(\alpha^5 - \alpha^3)\frac{4\pi}{3}(\overline{R_G^2})_0^{3/2}F(x)$$

ou

$$\langle R_G^2\rangle = \frac{1}{6}\langle\overline{R^2}\rangle$$

et

$$F(x) = 1 - \frac{x}{2^{3/2}2!} + \frac{x^2}{3^{3/2}3!} - \cdots$$

$$x = 2(\alpha^2 - 1)$$

Nous avons calculé les volumes V_{SF} et V_{BL} théoriquement d'une façon très approximative selon la méthode de Kopp, d'une chaîne solvatée selon le mécanisme proposé par Sayama *et al.* (21) et selon celui de Bixon et Lifson (22). Nous avons discuté ces mécanismes dans une publication antérieure (23).

La fig. 5 représente seulement l'allure de variation de u et des V_{YF}, V_{BL} en fonction du poids molécu-

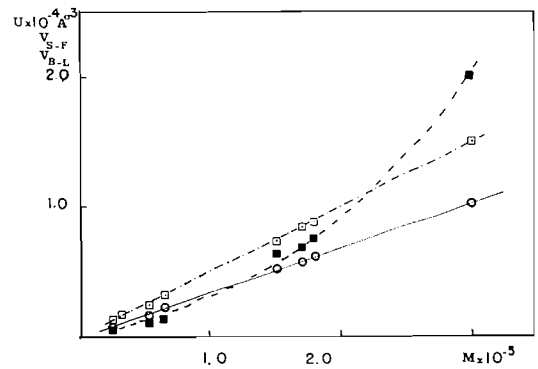

FIG. 5. Relation entre le volume exclu ou le volume occupé par une chaîne solvatée et le poids moléculaire: (■) volume exclu (u) calculé à partir des données viscosimétrique; (○) V_{SF} volume occupé par une chaîne solvatée selon le mécanisme de Sayama *et al.* (21); (□) V_{BF} volume occupé par une chaîne solvatée selon le mécanisme de Bixon et Lifson (22).

laire. Il faut noter que les valeurs absolues de V_{SF} et de V_{BL} n'ont aucun sens, ce qui nous intéresse c'est l'allure de la variation. En comparant la variation de u avec celle de V_{YF} et de V_{BL} nous devrions conclure, à titre d'indication, qu'à part de la formation des liaisons hydrogène entre le polypeptide et le solvant, l'interaction polymère–solvant, d'ordre différent du cas précédent, est loin d'être négligeable.

Conclusions

Théoriquement on peut déterminer la conformation, les dimensions des polypeptides en solution à partir des propriétés hydrodynamiques. En effet, nous avons un certain nombre limité mais suffisante de théories pour interpréter les résultats expérimentaux, mais nous constatons que, si l'étude de la transition conformationnelle est jugée satisfaisante, la détermination des dimensions caractéristiques permettant de définir d'une façon précise la conformation de la chaîne en hélice est fortement influencée par plusieurs facteurs. Un des problèmes majeurs qui se pose est le degré de flexibilité de la chaîne. Cependant nous pensons, d'après nos résultats, qu'on peut contourner ce problème, dans une certaine mesure, en déterminant le nombre de monomères par segment rigide selon l'équation de Yamakawa–Fujii réarrangée par Vitovskaya et Tsvetkov, à partir des différentes valeurs de h trouvées pour différents échantillons, puis ensuite les dimensions à partir des échantillons dont la longueur des chaînes est en bon accord avec celle du "segment rigide" ainsi déterminée. En effet pour un polypeptide donné on pourrait classer les valeurs de h calculées à partir de l'équation de Simha en trois catégories selon le schéma suivant:

$$M_x \text{ (chaîne courte)} \ll M_{NS} \qquad h_x > h_{réel}$$

$$M_x \leq M_{NS} \qquad h_x \approx h_{réel}$$

$$M_x \gg M_{NS} \qquad h_x < h_{réel}$$

En utilisant une valeur de h trouvée à partir d'un échantillon de poids moléculaire M_h pour déterminer N_S ou M_{NS} trois cas pourraient se présenter: (*i*) $M_{NS} \gg M_h$; (*ii*) $M_{NS} \approx M_h$; (*iii*) $M_{NS} \ll M_h$. La valeur la plus proche de la valeur réelle de h devrait être celle qui satisfait le cas (*ii*). Nous remarquons également que l'effet des bouts effilés de l'équivalence hydrodynamique ellipsoïdale ne semble négligeable que pour des chaînes moyennement longues. Le modèle n'est valable, pour le cas de poly(γ-L-glutamate de benzyle), que pour des chaînes ayant plus de 200 motifs de base. Nous pensons qu'on pourrait vérifier l'existence de cet effet en comparant les résultats viscosimétriques avec ceux de la sédimentation. En effet les théories traitant la viscosité et la sédimentation des polymères sont basées sur le même modèle physique, mais il y a une différence fondamentale entre ces deux phénomènes. Pour la viscosité, la molécule de soluté se déplace en même temps que le solvant et la force de frottement est due au mouvement de rotation de la molécule tandis que dans la sédimentation, la molécule de soluté se déplace toute seule et la force de frottement est due surtout au mouvement de translation de la molécule, les bouts effilés ont un effet plus accentué dans ce dernier cas. Nous effectuons actuellement des mesures de sédimentation sur ces mêmes échantillons dans les mêmes conditions.

Remerciement

Received December 21, 1977

R. A. BACK, C. WILLIS, and D. A. RAMSAY. Can. J. Chem. **56**, 1575 (1978).

The absorption spectra of N_2H_2 and N_2D_2 in the region 3000–4300 Å have been re-examined with somewhat higher resolution than was used in earlier work. The vibrational assignments of the principal progressions are unchanged except for the revision of the vibrational numbering suggested by the calculations of Perić, Buenker, and Peyerimhoff in 1977. The transition is electronically forbidden ($^1B_g - {}^1A_g$) but is made vibronically allowed by excitation of one quantum of the antisymmetric stretching vibration $\nu_5'(b_u)$. Weaker progressions are induced by the torsional vibration $\nu_4'(a_u)$ and the antisymmetric H—N—N bending vibration $\nu_6'(b_u)$. Agreement between experiment and theory is generally satisfactory though some significant discrepancies in Franck–Condon factors have been noted.

R. A. BACK, C. WILLIS et D. A. RAMSAY. Can. J. Chem. **56**, 1575 (1978).

On a redéterminé les spectres d'absorption du N_2H_2 et du N_2D_2 dans la région de 3000–4300 Å avec une résolution meilleure que celle utilisée dans un travail antérieur. Les attributions vibrationnelles des principales progressions sont inchangées excepté pour la revision de la numérotation vibrationnelle suggérée par les calculs de Perić, Buenker et Peyerimhoff en 1977. La transition est électroniquement défendue ($^1B_g - {}^1A_g$) mais est rendue vibroniquement permise par excitation d'un quantum de la vibration de valence antisymétrique $\nu_5'(b_u)$. Des progressions plus faibles sont induites par la vibration de pivotement $\nu_4'(a_u)$ et la vibration de déformation angulaire H—N—N antisymétrique $\nu_6'(b_u)$. L'accord entre l'expérience et la théorie est généralement satisfaisante quoique quelques disparités importantes ont pu être notées dans les facteurs Franck–Condon.

[Traduit par le journal]

Introduction

The near-ultraviolet spectra of N_2H_2 and N_2D_2 in the region 3000–4300 Å have been studied recently by the present authors (1). Vibrational analyses of the weak diffuse bands indicated that there are three long progressions in ν_2', the symmetric H—N—N bending frequency, corresponding to the excitation of 0, 1, and 2 quanta of ν_3', the N—N stretching frequency. The system was assigned to the symmetry-forbidden $^1B_g - {}^1A_g(\pi^* \leftarrow n_+)$ transition, probably made allowed by vibronic interaction. The long progressions in ν_2' indicated a large change in the H—N—N angle between the ground and excited states, estimated by simple Franck–Condon calculations to be 25 ± 2°. Since the inducing mode was not known, the vibrational numberings could not be determined unambiguously and there was some uncertainty in this estimate.

In 1975, Vasudevan *et al.* (2) reported *ab initio* calculations for the ground and first excited state of *trans*-diimide which predicted a difference of only 15° in the H—N—N angle. They suggested a reinterpretation of the near-ultraviolet absorption spectrum, assigning the long progressions to excitation of the antisymmetric bending frequency, $\nu_6'(b_u)$, which is clearly contrary to the Herzberg–Teller selection rules. More recently, Perić, Buenker, and Peyerimhoff (3) have published detailed calculations of Franck–Condon factors and of the relative activities of the three possible inducing modes, ν_4', ν_5', and ν_6'. Their results indicate that the antisymmetric N—H stretching frequency $\nu_5'(b_u)$ is the most active in making the transition vibronically allowed and that the original identification of the progressions is correct but the values for v_2' were incorrect and should be reduced by 3. A few bands at the long wavelength end of the spectrum were reassigned to similar though weaker progressions made allowed by the excitation of one quantum of the torsional frequency, $\nu_4'(a_u)$.

In view of these interesting results, we have undertaken a re-examination of the spectra of N_2H_2 and N_2D_2 using somewhat higher resolution than in the earlier work, especially at the longer wavelengths.

Experimental

Most of the experimental conditions were the same as described previously (1). However, spectra were obtained using

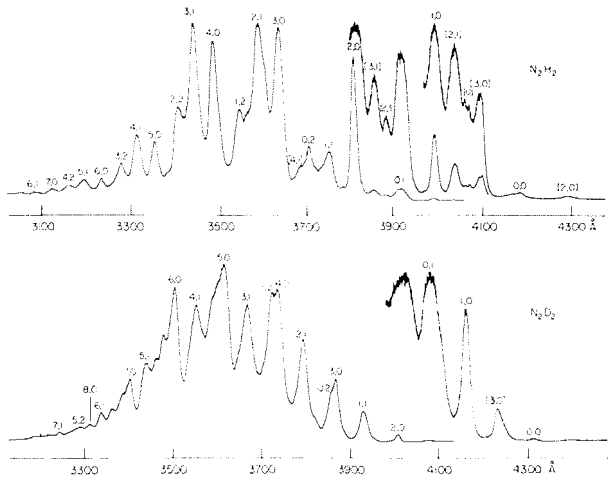

FIG. 1. Microphotometer curves of the absorption spectra of N_2H_2 and N_2D_2. Assignments refer to the values of $v_2'v_3'$. Assignments without brackets refer to ν_5'-induced progressions; [ ] denotes ν_4'-induced progressions and { } indicates ν_6'-induced bands.

a 7.3 m vacuum Ebert spectrograph in the first order with a reciprocal dispersion of 4.5 Å/mm. This spectrograph has from 4 to 10 times the dispersion of the medium Hilger spectrograph used in the earlier work and is adequate in view of the diffuse nature of most of the bands. Some of the bands at longer wavelengths ($\lambda > 3800$ Å)[2] show coarse rotational structure; for example, the band of N_2H_2 near 4184 Å shows at least six head-like features which are presumably caused by *K*-structure. Microphotometer curves of the complete spectra of N_2H_2 and N_2D_2 are shown in Fig. 1. New measurements of the frequencies of the bands of both isotopic species were made and usually agreed with the earlier measurements to within 10 or 20 cm^{-1} except for weak bands which are heavily overlapped. Several new bands were found for N_2H_2 and the frequencies and assignments for all the bands are given in Table 1. For N_2D_2, fewer new bands were found and these are discussed in the text.

Discussion

The three vibrational modes which can make the $^1B_g - {}^1A_g$ transition vibronically allowed are $\nu_4(a_u)$, $\nu_5(b_u)$, and $\nu_6(b_u)$. The torsional vibration ν_4 gives rise to bands with vibronic species $^1B_u - {}^1A_g$ for which the transition moment lies in the molecular plane.[3] The bands therefore consist of sub-bands with $\Delta K_a = 0$ (*a*-type) and $\Delta K_a = \pm 1$ (*b*-type), the relative intensities depending on the direction of the transition moment with respect to the inertial axes. Bands which are induced by ν_5 or ν_6 have vibronic species $^1A_u - {}^1A_g$ and give rise to *c*-type structures with only $\Delta K_a = \pm 1$. The rotational constants for the ground state of N_2H_2 are well known from the infrared studies of Carlotti, Johns, and Trombetti (5) ($A'' = 10.000$, $B'' = 1.304$, and $C'' = 1.150$ cm^{-1}) and constants for the excited state can be estimated from the calculated structures of Perić *et al.* (3) ($A' = 13.0$, $B' = 1.12$, $C' = 1.07$ cm^{-1}). The *K*-structures of the bands are therefore expected to be violet-degraded and the *J*-structures red-degraded. For *a*-type bands the origin is expected to

[2]The diffuseness of the spectrum has been attributed to rapid intersystem crossing to the ground state at large torsional displacements (4). The rather abrupt loss of rotational structure below 3800 Å suggests the onset of a more efficient intersystem crossing at this energy, about 75 kcal/mol.

[3]Throughout this discussion we treat the excited state as though it were planar. The calculations of Perić *et al.* (3) indicate a twisted structure but the essential arguments are unchanged.

lie close to the low frequency edge; for *b*-type and *c*-type bands the *K*-structure forms a 'head of heads' estimated to lie about 30 cm^{-1} below the band origin. The measurements in Table 1 reflect these considerations. As noted above, a few bands at the long wavelength end of the spectrum show evidence of *K*-structure although it is not sufficiently well developed to permit an unambiguous assignment of the *K*-numbering.

The calculations of Perić *et al.* (3) indicate that the relative activities of the three inducing modes for N_2H_2 are $\nu_4:\nu_5:\nu_6::\frac{1}{3}:1:\frac{1}{40}$. The strongest progressions should therefore be ν_5'-induced. The revision of the vibrational numberings of the principal progressions for N_2H_2 and N_2D_2 appears reasonable in view of the Franck–Condon calculations and also the irregularities of the vibrational intervals for low v_2' (<3) in the original assignments. For N_2H_2, the strongest bands are the (3,1), (2,1), (3,0), (4,0), and (2,0) bands with respect to (v_2', v_3') (Fig. 1). The unassigned bands are readily accommodated into ν_4'-induced progressions and weaker ν_6'-induced progressions with similar values of (v_2', v_3'). The validity of the assignments is supported by the consistency of the values which are obtained for the vibrational differences ($\nu_5' - \nu_4'$) and ($\nu_5' - \nu_6'$) (Table 2). Apart from a weak feature[4] at 26 444 cm^{-1} all the N_2H_2 bands are now assigned, including some weak bands unassigned in the earlier work and some weak additional bands found in the present work.

For N_2D_2 the strongest bands in the ν_5'-induced progressions are the (5,0), (6,0), (4,0), (3,1), and (4,1) bands (Fig. 1). The band at 23 601 cm^{-1}, originally assigned as the (2,1) band, is reasonably reassigned as the (3,0) band of the ν_4'-induced progression, giving ($\nu_5' - \nu_4'$) = 2278 cm^{-1} (Table 2). Unfortunately, all the higher members of this progression and of the progression with $v_3' = 1$ are overlapped by stronger ν_5'-induced bands so that it is not possible to obtain a satisfactory confirmation of this vibrational interval. Five new weak bands were found at 24 413 (overlapped), 25 292, 26 199, 25 762, and 26 626 cm^{-1}.[5] It is tempting to assign these bands as the (3,0), (4,0), (5,0), (3,1), and (4,1) bands induced by ν_6'. However, the first three bands give values for ($\nu_5' - \nu_6'$) ranging from 1437–1444 cm^{-1} and the latter two give values of 1500 and 1538 cm^{-1}. These discrepancies are larger than the experimental errors and it is possible that the latter two bands are the (5,0) and (6,0) bands induced by $3\nu_4'$. One of the problems in the earlier work was an apparent doubling of the higher members of the third principal progression with $v_3' = 2$, which was tentatively ascribed to Fermi resonance. The bands appear with the same relative intensities in the present work (see Fig. 1) and hence are presumably not caused by an impurity, e.g., N_2HD. The frequencies of the bands are too high for ν_4'- or ν_6'-induced bands and the Fermi resonance interpretation involving levels (1, v_2', 0) and (0, $v_2' + 1$, 1) still seems the most reasonable.

[a]Perić *et al.* (3).
[b]Numbers in parentheses are less certain.
[c]See Discussion.

The calculations of Perić *et al.* account for the relative activities of the inducing modes in a very satisfactory manner. However, the calculations of Franck–Condon factors are less satisfactory. The strongest bands in the observed progressions occur at slightly higher values of v_2' than in the calculated. The observed intensity distributions are noticeably different in some of the progressions indicating a breakdown of the zero-order Born–Oppenheimer approximation; for example, the (3,0) and (4,0) bands of N_2H_2 are comparable in intensity, whereas the (3,1) band is much stronger than the (4,1) band (Fig. 1). A more dramatic difference between the observed and calculated intensities occurs for the lowest values of v_2', where the band intensities decrease much more rapidly with increasing wavelength than predicted. For example, the calculated value for the ratio of the intensities of the (0,0) and (2,0) bands of N_2H_2 is 0.64 but the experimental value is certainly less than 0.1; similar differences exist for N_2D_2. The reason for these differences is not clear but may be associated with the low barrier for the torsional vibration

[4]This feature may be the (3,1) or possibly the (4,0) band induced by $3\nu_4'$; the calculations of Perić *et al.* (3) predict that these bands should have $\frac{1}{23}$ of the intensities of the corresponding ν_5'-induced bands.

[5]Weak unassigned shoulders have also been seen near 27 435 and 28 622 cm^{-1}.

in the excited state and the sensitivity of this barrier to the excitation of other vibrations. Finally, the agreement between the observed and calculated frequency differences ($\nu_5' - \nu_4'$) and ($\nu_5' - \nu_6'$) for the excited state lies within 10% (Table 2); however, the calculated anharmonicities for the N—N stretching frequency ν_3' (81 cm^{-1} for N_2H_2, 75 cm^{-1} for N_2D_2) are much larger than the experimental and seem unreasonably high. The overall agreement between theory and experiment is most encouraging though some differences need to be resolved.

Quelques aspects du spectre d'absorption infrarouge de complexes par liaison hydrogène

WILLIE A. BUENO[1] ET NEUSA M. MAZZARO[2]

Depto Química da F.F.C.L.R.P.-U.S.P. 14100, Ribeirão Prêto, SP, Brésil

Reçu le 21 septembre 1977

WILLIE A. BUENO et NEUSA M. MAZZARO. Can. J. Chem. **56**, 1579 (1978).

Les spectres infrarouges, dans la région de 4000 à 1600 cm^{-1}, de 24 complexes par liaison hydrogène des oxydes d'amines aliphatiques avec certains dérivés du phénol sont discutés.

WILLIE A. BUENO and NEUSA M. MAZZARO. Can. J. Chem. **56**, 1579 (1978).

A discussion is given of the infrared spectra in the region 4000 to 1600 cm^{-1} of 24 hydrogen-bonded complexes between aliphatic amine oxides and a number of phenol derivatives.

[Traduit par le journal]

Introduction

Le caractère semipolaire de la liaison N—O dans les oxydes d'amines aliphatiques en fait d'excellents accepteurs de proton pour la formation de liaisons hydrogène (1, 2). Toutefois, la liaison hydrogène entre des dérivés du phénol et des oxydes d'amines aliphatiques est peu connue, que ce soit du point de vue de sa nature, de la structure des bandes d'absorption infrarouge ou de l'influence des substituants à l'état liquide pur. Ce travail étudie la formation de tels complexes et discute les caractéristiques des bandes d'absorption du spectre infrarouge, dans la région de 4000 à 1600 cm^{-1}.

Conditions expérimentales

Les oxydes d'amine ont été préparés à partir de l'amine et d'eau oxygénée. On obtient un liquide visqueux qui cristallise en aiguilles aprés quelques jours sous vide en présence de P_2O_5 (3).[3] Les phénols commerciaux ont été purifiés suivant les méthodes usuelles de recristallisation ou de sublimation et déséchage. Les complexes sont obtenus par mélange du donneur et de l'accepteur de proton dans la proportion 1:1, malaxage en atmosphère sèche et chauffage jusqu'à la température de fusion. Ils sont ensuite sèchés sous vide. Aucun des complexes obtenus n'a cristallisé. Les spectres infrarouges ont été obtenus avec un spectromètre Perkin-Elmer, modèle 457, en film entre des faces de NaCl, à la température moyenne de 30°C. Les intensités des bandes ont été mesurées relativement à celle de la bande qui apparait aux environs de 1585 cm^{-1} vu qu'elle est pratiquement constante dans tous les cas étudiés.

Résultats et discussion

L'observation des spectres infrarouges montre que la vibration de valence de la liaison N—O (ν(NO)) se situe autour de 945 cm^{-1} pour l'oxyde de triméthylamine (TMAO) et pour l'oxyde de triéthylamine (TENO) et autour de 965 cm^{-1} pour l'oxyde de tripropylamine (TPNO). La vibration δ(ONC) n'a pas été analisée vu qu'elle ne se presente pas comme une bande d'absorption "pure" (4). La formation des complexes ne déplace pas la ν(NO), mais diminue son intensité. Cette diminution peut être expliquée, qualitativement, par le modèle de Orville-Thomas (5), étant donné que la formation de la liaison hydrogène B—O···H—OR induit une polarization de la paire d'electrons de la base provocant ainsi une augmentation de l'intensité de la ν(OH···). Les spectres montrent aussi qu'il y a déplacement de la fréquence d'absorption ν(OH) vers des valeurs plus basses. Cette absorption se présente sous la forme de bandes larges et relativement intenses. Ces faits sont causés par la liaison hydrogène qui se forme entre l'hydrogène du groupe O—H phénolique et l'oxygène d'amines.

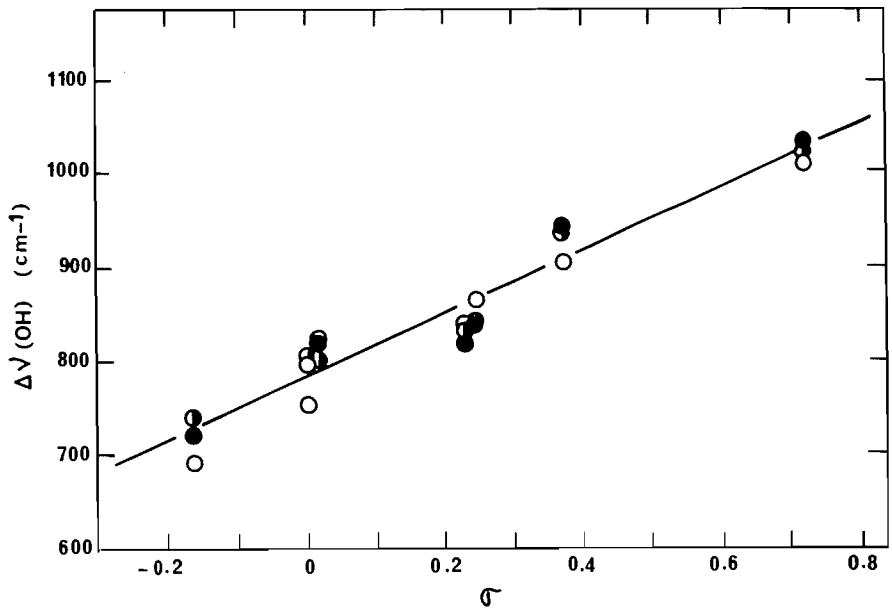

FIG. 2. Déplacement de la fréquence de valence de la liaison O—H vs. le sigma de Hammett. ○ = TMAO, ● = TENO et ◑ = TPNO.

L'analyse des spectres, dans la région de 4000 à 1600 cm^{-1}, montre qu'il existe une large bande dont l'intensité croit du *p*-nitrophénol au *p*-méthylphénol et qui présente plusieurs épaulements (Fig. 1) dont on a essayé d'expliquer la nature de diversès manières (6). On a tenté de trouver des modes de combinaisons ou harmoniques faisant intervenir les frequences fondamentales se situant entre 1650 à 1150 cm^{-1}. Il apparait que la large bande vers 3000 cm^{-1} contient plusieurs bandes dues à des résonances de Fermi qui s'ajoutent à l'absorption ν(OH) qui, à cause de la liaison hydrogène, se déplace vers des fréquences plus basses. Aprés élimination des absorptions dues aux bandes de combinaison (de la même manière que Hall et Wood (10)) et aux vibrations ν(CH) il est possible de préciser la fréquence de la vibration ν(OH) des complexes, en utilisant le méthode de Nelson et coll. (1), et donc Δν(OH) (tableau 1). Cette valeur est aussi fondée sur l'obtention d'une relation entre Δν(OH) et σ (discutée dans la littérature (7, 8), pour les dimères d'acides organiques), avec un coefficient de corrélation satisfaisant[4] ($r = 0.961$, sauf pour le *p*-nitrophénol). La relation obtenue entre la constante du substituant donné par Hammett (11) (σ) et les Δν(OH), fig. 2, est donnée par

$$\Delta\nu(OH)\ (\text{en cm}^{-1}) = 334\sigma + 785$$

[4]Les valeurs statistiques de la correlation entre Δν(OH) et les constants du substituant ont été calculées à partir de Jaffè (9) ($r = 0.961$; $s = 27.02$; $s_\rho = 21.95$; $n = 21$).

La valeur positive de la pente de la droite obtenue (désignée par Hammett comme ρ) indique que la constante d'equilibre de formation du complexe augmente avec l'affinité du substituant des noyaux phénoliques pour les electrons. Toutefois, cela n'explique pas les intensités des bandes d'absorption dans la région vers 3000 cm^{-1}.

Dans les spectres du type *i*, décrits par Hadzi (12), comme cela a déjà été indiqué, on distingue trois larges bandes d'absorption: la bande *A* (ν(OH) > 2800 cm^{-1}), la bande *B* (~2550 cm^{-1}) et la bande *C* (~1900 cm^{-1}). Le tableau 2 donne les fréquences des trois types de bandes observées. Les bandes dues aux ν(CH) et aux vibrations harmoniques du noyau aromatique se superposent aux bandes *A*.

TABLEAU 1. Déplacement de la fréquence des vibrations de valence O—H de divers phénols dans les complexes avec oxyde d'amines aliphatiques*

Substituant du phénol	σ (11)	ν(OH) (8)	Δν(OH)† TMAO	TENO	TPNO
m-NO_2	0.710	3604	1014	1034	1024
m-Cl	0.373	3607	907	947	947
p-Br	0.232	3609	859	839	839

p-Br	2750	2570	1870	2775	2560	1815	2775	2570	1830
p-Cl	2780	2560	1870	2790	2560	1820	2780	2570	1820
p-ϕ	2790	2570	1875	2790	2570	1820	2790	2570	1815
H	2860	2580	1870	2810	2590	1825	2810	2560	1810
p-CH_3	2920	2500	1875	2780	2550	—	2810	2560	—

En accord avec les observations de Hadzi et coll. (12, 13) l'intensité des bandes *A* et *B* diminue quand la force de l'acide augmente (fig. 1). Quand le pK_a de l'acide décroit (c'est-à-dire, quand la forçe de l'acide augmente) l'intensité des bandes *A*, *B* et *C* diminue mais l'intensité de la bande *C* ne diminue pas dans la même proportion. Ceci est contraire aux observations de Hadzi (12) qui, en utilisant différents dérivés de l'acide acétique, a observé que *C* augmente avec la forçe de l'acide. On observe aussi que, dans les complexes les plus faibles, la bande *A* est du type ν(OH) alors que c'est la bande *B* qui possède ce caractère dans les complexes les plus forts. Cependant, la deutération déplace les bandes *A* et *B* vers des fréquences plus basses et toutes les bandes de cette region sont dues aux interactions entre ν(OH) avec des bandes de combinaisons (10). Dans les cas du *m*-chlorophénol et du *m*-nitrophénol, le maximum d'absorption, qui probablement n'est pas une bande de résonance de Fermi, apparaît déjà à des fréquences inférieures à celles de la bande *A*, ce qui semble indiquer que la force de ces complexes se situe entre celle des autres. Quand l'acide est le *p*-nitrophénol, la bande *A* a la plus faible intensité, et il y a une forte et large bande d'absorption au – dessous de 1600 cm^{-1} (13). Cette large bande au – dessous de 1600 cm^{-1} est peut-être due à l'apparition d'autres bandes d'absorption dues aux formes $AH^+\cdots B$ et $BH^+\cdots B$ (2). De cette manière, il pourrait être faux que les spectres des complexes entre le *p*-nitrophénol et les récepteurs de protons suivent la tendance observée dans les spectres des complexes avec les phénols moins acides (fig. 1) étant donné qu'il est difficile de situer le bande d'absorption de la vibration ν(OH) parce que ces composés absorbent fortement entre 2000 et 300 cm^{-1} (2).

Remerciements

Les fonctions de Hartree–Fock–Slater comme base pour des calculs de perturbation à un électron pour molécules. III. Le calcul de la première hyperpolarisabilité

M. TRSIC ET W. G. LAIDLAW

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Reçu le 19 octobre 1977

M. TRSIC et W. G. LAIDLAW. Can. J. Chem. **56**, 1582 (1978).

On a calculé les premières hyperpolarisabilités des molécules CO, CH_4, HCHO et CN^- par une méthode Hartree–Fock–Slater non couplé. Différentes fonctions de base ont été essayées.

M. TRSIC and W. G. LAIDLAW. Can. J. Chem. **56**, 1582 (1978).

Uncoupled Hartree–Fock–Slater first hyperpolarizabilities have been calculated for CO, CH_4, HCHO, and CN^-. Different basis sets have been tested for CH_4 and CO.

Introduction

Etant donné qu'une méthode Hartree–Fock–Slater (HFS) non couplée a produit des résultats satisfaisants pour des polarisabilités moléculaires (1), on a entrepris le calcul des premières hyperpolarisabilités β par la même technique. On rapporte ici les valeurs obtenues pour les cas de CO, CN^-, CH_4 et HCHO quand on maintien les orbitaux 1*s* de C, N et O "congelés". Dans les cas de CO et HCHO on peut comparer avec des autres méthodes et dans le cas de CH_4 on a des résultats de calcul et aussi un résultat expérimental approché pour comparaison.

La méthode de perturbation

Pour une molécule dans un champ électrique uniforme F, la théorie des perturbations donne l'expression suivante pour le tenseur β (2, 3):

$$[1]\quad -\tfrac{1}{6}\sum_{\nu,\mu,\omega}\beta_{\nu\mu\omega}F_\nu F_\mu F_\omega = \sum_{m,n\neq 0}\frac{\langle 0|H^{(1)}|m\rangle\langle m|H^{(1)}|n\rangle\langle n|H^{(1)}|0\rangle}{(W_0-W_m)(W_0-W_n)} - \sum_{m\neq 0}\frac{\langle 0|H^{(1)}|m\rangle\langle 0|H^{(1)}|0\rangle\langle m|H^{(1)}|0\rangle}{(W_0-W_m)^2}$$

avec

$$[2]\qquad H^{(1)} = -\sum_\nu\sum_i q_i r_\nu^{(i)}F_\nu$$

$H^{(1)}$ étant la perturbation produite par le champ. W_m est l'énergie de l'état non perturbé $|m\rangle$ et q_i est la charge de la particule *i*.

Si l'on exprime la formule 1 à l'aide des orbitaux moléculaires (OM), on obtient pour l'élément tensoriel $\beta_{\nu\mu\omega}$

$$[3]\quad \beta_{\nu\mu\omega} = S\left\{2\sum_{k,a,b}\frac{\langle k|er_\nu|a\rangle\langle a|er_\mu|b\rangle\langle b|er_\omega|k\rangle}{(\varepsilon_a-\varepsilon_k)(\varepsilon_b-\varepsilon_k)} + 2\sum_{k,l,a}\frac{\langle k|er_\nu|a\rangle\langle k|er_\mu|l\rangle\langle a|er_\omega|l\rangle}{(\varepsilon_a-\varepsilon_k)(\varepsilon_a-\varepsilon_l)} - 4\sum_{k,a}\frac{\langle k|er_\nu|a\rangle\langle k|er_\mu|k\rangle\langle a|er_\omega|k\rangle}{(\varepsilon_a-\varepsilon_k)^2}\right\}$$

Les integrals $\langle k|er_\nu|a\rangle$, $\langle a|er_\mu|b\rangle$, etc. sont mono-électroniques et construites sur les OM–HFS, k, l sont des orbitaux occupés dans l'état fondamental et a, b sont des orbitaux virtuels, e est le charge électronique et r_ν, r_μ et r_ω sont des coordonnés des électrons. La lettre S indique une somme sur toutes les permutations des coordonnés r_ν, r_μ et r_ω et ε_a et ε_k sont des énergies HFS mono-électroniques.

L'expression 3 est le résultat de l'interaction de l'état fondamental non perturbé avec des états mono-excités et les interactions entre les différents états mono-excités, la dernière somme étant originé par "l'auto-interaction" de l'état fondamental. Les éléments matricielles avec des états doublement et poli-excités sont tous zéro. Dans le cas des molécules avec un moment dipolaire on peut s'attendre que les termes diagonaux en [3] auront beaucoup d'importance dans la somme totale.

La partie nucléaire de l'éq. 1, originé par l'opérateur [2], est annulé quand on utilise l'approximation de Born et Oppenheimer et, par conséquence, n'apparaît pas dans l'éq. 3.

La qualité des fonctions d'onde de HFS

La qualité des fonctions de base employés pour constuire les OM–HFS est un des facteurs qui détermine la qualité des résultats obtenus par la méthode de perturbation. Pour illustrer cet effet, on rapporte les résultats obtenus pour CO et CH_4 quand on utilise les bases optimisées pour les atomes (4), une fonction pour chaque orbitale atomique (BS) et deux fonctions pour chaque orbitale atomique (BD) et aussi, les bases étendues et optimisées pour la molécule (BM) de CH_4 par Baerends et Ros (5) et pour la molécule de CO par McLean et Yoshimine (6). Les aspects plus spécifiques de la méthode utilisé pour obtenir les fonctions de HFS (7), c'est à dire, l'effet de l'intégration numérique et la façon de rapprocher la densité électronique (ressemblable aux techniques LEDO (8) et PDDO (9)) ne seront pas rapportés en détail. Il suffit de dire (on utilise CO comme example) que le nombre de points pour l'intégration numérique

choisir le signe de β n'est pas uniforme dans la littérature et on a choisi celle décrite par Buckingham et Orr (2) pour les résultats de ce calcul. Dans les cas où on a pu clairement établir l'emploi d'une convention pour le signe opposé à celle de Buckingham et Orr, on montre aussi, dans la deuxième colonne dessous chaque élément de β, le valeur prise en utilisant cette dernière convention. C'est le cas pour deux des résultats pour CO de O'Hare et Hurst (la convention utilisé est décrite en bas du tableau VII de la réf. 10). Aussi, Liebmann et Moskowitz comparent leurs résultats avec ceux de O'Hare et Hurst au même temps qu'ils rapportent le résultat de Buckingham et Stephen (3) avec le signe changé (voir le tableau VIII de la réf. 11). En conséquence, on montre les résultats de Liebmann et Moskowitz (11) avec le signe changé. La convention utilisé par McLean et Yoshimine (13) semble être la même que la notre. La convention utilisé par les autres auteurs n'est pas aussi simple pour nous de retrouver. On peut seulement dire qu'on trouve le même signe que Hush et Williams (12) avec un calcul semi-empirique à "champ fini" pour CH_4 et CO et le signe contraire que Lazzeretti et Zanasi (14) et Arrighini *et al.* (15) pour CH_4. Aussi pour CH_4, on a le même signe que le calcul semi-empirique de type Unsold de Buckingham et Stephen (3).

On voit que nos résultats pour β montrent l'effet de la base utilisée pour obtenir les fonctions HFS; néanmoins, cette influence n'est pas très prononcée (on trouve des effets plutôt drastiques, comme dans le travail d'O'Hare et Hurst où même un changement de signe est produit par un changement de base). Pour le CO, le changement de β (BS) à β (BD) est plus prononcé que le changement de β (BD) à β (BM); cependant, le calcul BD ne paraît pas capable d'apporter une relative stabilité dans le cas du CH_4. Ceci paraît raisonable si on s'aperçoit que la base BD n'améliore pas l'espace variationel dans la région des atomes de H du CH_4 tandis qu'elle représente une amélioration pour les deux atomes du CO. Il faut la base BM pour introduire une flexibilité suffisante dans la région des H du CH_4.

Les variations des valeurs de β pour CH_4 et CO publiées sont d'un ordre de grandeur, les valeurs pouvant être positives ou negatives (la convention pour le signe n'est pas, malheureusement, à l'origine de toutes les différences de signe). Pour CH_4, en principe, on devrait donner préférence aux résultats de Lazzeretti et Zanasi et d'Arrighini *et al.* obtenus par une méthode HF *ab initio* couplée; de façon similaire, pour CO on choisirait les résultats de McLean et Yoshimine obtenus à l'aide d'une technique de "champ fini" (méthode qui est essentiellement de caractère couplée). On est, toutefois, mal à l'aise pour choisir la valeur HF couplée correcte du CH_4 etant donné que les valeurs proposées par Lazzeretti et Zanasi et Arrighini *et al.* diffèrent par un ordre de grandeur et, même, révèlent une tendance divergente avec l'amélioration de la base atomique. La valeur expérimentale $\beta = |0.1|$ proposée par Maker (2) ne paraît pas suffisamment concluante pour résoudre cette différence. Si l'on considère que les résultats d'Arrighini *et al.* (16) pour la polarisabilité sont toujours bas par rapport à l'expérience, on peut s'attendre à une situation pareille pour β.

Ce que la comparaison des différents résultats semble révéler c'est que les valeurs HFS non couplées de ce travail pour CO sont ressemblables aux celles d'O'Hare et Hurst obtenues par une méthode HF non couplée et double perturbation et des ensembles de base comparables ($\beta_{zzz} = 13.8$ avec 10.1 et 9.8). La comparaison avec le calcul HF non couplé avec double perturbation de Liebmann et Moskowitz qui utilisent une base de qualité à peu près BD permet la même conclusion ($\beta_{zzz} = 14.2$ avec 12.1). Tous ces résultats non couplés montrent le même signe et un ordre de grandeur en dessus des résultats HF "à champ fini" de McLean et Yoshimine ($\beta \simeq 1$).

Dans le cas du CH_4 on obtient le même ordre de grandeur et le même signe que Liebmann et Moskowitz ($\beta_{xyz} = -5.3$ avec -1.9). Comme on a remarqué en haut, la comparaison avec le résultat HF couplé correct n'est pas facile, il est seulement évident que les valeurs non couplées se trouvent en dessus des valeurs couplées.

On peut conclure que la méthode HFS non couplée rends des résultats ressemblables aux calculs HF du type non couplé quand on utilise des bases de qualité comparable. Aussi, une base BD paraît suffisante pour se rapprocher à la limits HFS non couplée, l'atome de H faisant exemption. On peut alors considérer la valeur obtenue pour l'ion CN^- comme suffisamment proche de la limite HFS non couplée, tandis qu'on est moins rassuré sur la signification du résultat pour la molécule de HCHO. Finalement, il faudra attendre des nouveaux résultats expérimentaux pour décider le degré de crédit dû aux résultats non couplés par rapport des résultats couplés.

Remerciements

On remercie le soutien du Conseil national de recherches du Canada. On remercie messieurs E. Baerends et T. Ziegler pour l'emploi de quelques fonctions d'onde. Aussi, on a profité des commentaires de M. le Professeur A. D. Buckingham.

Enthalpies of formation of crystalline selenium(IV) chloride and bromide

ALAN D. WESTLAND AND RAMESH MAKHIJA

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received January 16, 1978

ALAN D. WESTLAND and RAMESH MAKHIJA. Can. J. Chem. **56**, 1586 (1978).

Standard enthalpies of formation of crystalline selenium(IV) halides were determined by solution calorimetry relative to that of selenium(IV) oxide. The values obtained were: $\Delta H^{\ominus}_{f,298}$ $SeCl_4$(c), -42.7 ± 0.4 and $\Delta H^{\ominus}_{f,298}$ $SeBr_4$(c), -17.9 ± 0.5 kcal mol^{-1}.

ALAN D. WESTLAND et RAMESH MAKHIJA. Can. J. Chem. **56**, 1586 (1978).

On a déterminé les enthalpies standard de formation des halogénures cristallins du selenium(IV) en faisant appel à la calorimétrie en solution relative aux propriétés de l'oxyde de selenium(IV). On a obtenu les valeurs suivantes: $\Delta H^{\ominus}_{f,298}$ $SeCl_4$(c), -42.7 ± 0.4 et $\Delta H^{\ominus}_{f,298}$ $SeBr_4$(c), -17.9 ± 0.5 kcal mol^{-1}.

[Traduit par le journal]

In a study of the enthalpies of reaction of selenium(IV) halides with the corresponding alkali halides, it was useful to know the standard enthalpies of formation of $SeCl_4$(c) and $SeBr_4$(c). The value -43.8 kcal mol^{-1} is given for the chloride in the most recent tabulation published by the National Bureau of Standards, Washington (1). This value appears to derive from the measurements made by Thompsen (2) in the last century. His original value has undergone revision because it is now realized that the hexagonal form of selenium is the most stable state (3), whereas Thompsen chose glassy selenium as the standard state. It appeared desirable to repeat the determination by means of an alternative method. There is no reported value of the enthalpy of formation of $SeBr_4$.

We have measured both of these enthalpies by solution calorimetry. Thus, a determination of the enthalpy of the process

[1] $$SeO_2(c) + 4HCl(g) = SeCl_4(c) + 2H_2O(l)$$

enables us to obtain $\Delta H_f^{\ominus}$ for $SeCl_4$ from the tabulated enthalpies of formation for the other compounds in the equation. The partial processes, the enthalpies for which were either measured or evaluated from published data, are as follows:

[2] $$SeCl_4(c) + \{316HCl + 4029H_2O\} = \{SeCl_4 + 316HCl + 4029H_2O\}$$

[3] $$SeO_2(c) + \{320HCl + 4027H_2O\} = \{SeCl_4 + 316HCl + 4029H_2O\}$$

[4] $$4HCl(g) + \{316HCl + 4029H_2O\} = \{320HCl + 4029H_2O\}$$

[5] $$2H_2O(l) + \{320HCl + 4027H_2O\} = \{320HCl + 4029H_2O\}$$

The braces indicate solutions. It is seen that $\Delta H_1 = -\Delta H_2 + \Delta H_3 + \Delta H_4 - \Delta H_5$ where the subscripts correspond to the numbers of the equations.

The foregoing represents the typical case in which 1 g of SeO_2 is dissolved in 200 cm^3 of 4.0 *M* hydrochloric acid. The enthalpies of reactions [2] and [3] were measured and ΔH_4 and ΔH_5 were evaluated from published data (1).

In order for the method to give a correct result, it is necessary that the selenium species in solution be labile. We were unable to discover from the literature what period of time is required for the oxyhalo species to reach equilibrium but the shape of our temperature–time plots for the dissolution of selenium(IV) halides suggested that all enthalpic processes were complete within 2–6 min. Raman spectra indicate that identical solutions result from dissolving either $SeCl_4$ or SeO_2 in hydrochloric acid.[1]

The relevant equations for the study of $SeBr_4$ are as follows:

[6] $$SeO_2(c) + 4HBr(g) = SeBr_4(c) + 2H_2O(l)$$

[7] $$SeBr_4(c) + \{320HCl + 4029H_2O\} = \{SeBr_4 + 320HCl + 4029H_2O\}$$

[8] $$SeO_2(c) + \{4HBr + 320HCl + 4027H_2O\} = \{SeBr_4 + 320HCl + 4029H_2O\}$$

[9] $$4HBr(g) + 18.7H_2O = \{4HBr + 18.7H_2O\}$$

[10] $$\{4HBr + 18.7H_2O\} + \{320HCl + 4008.3H_2O\} = \{4HBr + 320HCl + 4027H_2O\}$$

[11] $$20.7H_2O + \{320HCl + 4008.3H_2O\} = \{320HCl + 4029H_2O\}$$

We see that $\Delta H_6 = -\Delta H_7 + \Delta H_8 + \Delta H_9 + \Delta H_{10} - \Delta H_{11}$. Equation [9] represents the formation of

TABLE 1. Enthalpies of solution of $SeCl_4$, $SeBr_4$, SeO_2, and HBr*

Compound	Range of sample weight (g)	No. of determinations	Mean molar enthalpy of solution (kcal mol^{-1})	Reaction enthalpy
$SeCl_4$	0.249–0.487	6	-24.22 ± 0.13	ΔH_2
$SeBr_4$	0.517–0.998	7	-7.18 ± 0.11	ΔH_7
SeO_2	0.399–0.988	4	$+1.69 \pm 0.03$	ΔH_3
SeO_2*	0.510–1.258	7	$+1.04 \pm 0.05$	ΔH_8
HBr (48.97% solution)	1.901–3.062	4	-1.10 ± 0.02	$\Delta H_{10}/4$

*The solvent was 4.02 *M* hydrochloric acid for all cases except for ΔH_8. In this case, the solvent was 4.02 *M* hydrochloric acid containing the stoichiometric amount of HBr.

49% w/w hydrobromic acid from HBr gas. The enthalpy for this process was interpolated from literature data (1). The enthalpy of mixing the two acids was measured calorimetrically. The enthalpies of the other partial processes were obtained as in the $SeCl_4$ case.

Experimental

Preparation of $SeCl_4$

Selenium pearls (99.999%) were treated with chlorine in a Pyrex tube according to the procedure given by Brauer (5). The product was sublimed in chlorine and stored in sealed ampoules under nitrogen. *Anal.* calcd. for $SeCl_4$: Se 35.8, Cl 64.2; found: preparation 1: Se 35.7, Cl 63.6; preparation 2: Se 35.7, Cl 64.5.

Preparation of $SeBr_4$

Selenium pearls were placed in a Pyrex tube which was evacuated and sealed. A supply of excess purified bromine was attached to this tube via a break-seal. After breaking the seal, bromine entered the reaction space and combination of the elements proceeded spontaneously. The excess bromine was removed by condensing it in the original bromine reservoir and the product was removed in the inert atmosphere box and stored in N_2-filled ampoules. *Anal.* calcd. for $SeBr_4$: Se 19.8, Br 80.2; found: preparation 1: Se 20.1, Br 79.7; preparation 2: Se 19.6, Br 80.2.

Selenium(IV) Oxide

Two commercial samples of SeO_2 (Ventron, 99.9%) were used. One of these was used as received, the other was sublimed in a slow stream of oxygen. The samples were kept in a closed system during handling operations in order to avoid contamination by hydrolysis.

Hydrochloric and hydrobromic acids were reagent grade and were analyzed by titration with 1.0 *N* sodium hydroxide solution.

Analyses

Selenium was determined iodometrically according to a procedure described by Vogel (method *C*) (6). Halogen was determined by potentiometric or Volhard titration.

Calorimetric Measurements

The calorimeter has been described previously (7). The data were treated by the method of Kubaschewski to correct for heat loss or gain (8). The accuracy of the calorimeter was checked by measuring the heat of neutralization of tris(hydroxymethyl)aminomethane with excess 0.1 *N* HCl at 298 K (found: 29.6, 29.7; lit. (9) 29.72 kJ mol^{-1}).

Results

Table 1 contains the results of our calorimetric measurements of enthalpies of solution. Two preparations of each of the tetrahalides were used to obtain the results shown. The mean values for the independent preparations differed in both cases by much less than the overall standard deviations given in the table. The enthalpy of solution of SeO_2 was slightly less endothermic when the calorimeter liquid contained 4 mol of HBr per mole of SeO_2.

Commercial hydrobromic acid was titrated with 1.0 *M* NaOH and found to have a concentration of 48.97% w/w. The glassware used in this analysis was carefully standardized by weighing deliveries of distilled water. Samples of the acid were mixed in the calorimeter with 4.02 *M* hydrochloric acid. The entry in the table refers to the enthalpy of mixing expressed per mole of HBr. The enthalpy of equation [10] is thus four times this quantity.

ΔH_f° of $SeCl_4$

We obtained -24.22 ± 0.13 and 1.69 ± 0.03 kcal mol^{-1} respectively for ΔH_2 and ΔH_3. The enthalpy of reaction [4] was taken to be -63.3 ± 0.3 kcal. This was obtained by graphical interpolation of literature data (1) and is the difference in the integral heats of solution of HCl(g) to form the solutions $\{316HCl + 4029H_2O\}$ and $\{320HCl + 4029H_2O\}$. The data are very precise: the uncertainty limits here reflect chiefly the assumed error in the interpolation procedure while assuming that the literature data provide correct first order differences. The heat of dilution ΔH_5 was found in a similar way to be -0.16 kcal when 2 mol of water dissolve in the solution $\{320HCl + 4027H_2O\}$. These data give -37.2 ± 0.6 kcal as the enthalpy of reaction [1]. For the literature values (1) of standard enthalpies of formation we have: SeO_2(c), -53.86, HCl(g), -22.062, and H_2O(l), -68.315 kcal mol^{-1}. The value for SeO_2(c) is that recorded by Gattow (3) for the hexagonal modification. Previously reported values for

SeO_2 were obtained in most cases with glassy or poorly defined selenium. The data lead to $\Delta H^{\ominus}_{f,298}$ $SeCl_4(c) = -42.7 \pm 0.4$ kcal mol^{-1}. The standard deviation given here is the root mean square value of those for the partial processes.

The value obtained is 1.1 kcal mol^{-1} less negative than that cited in ref. 1. However, the uncertainty on Thompsen's value has been estimated to be ± 1.5 kcal mol^{-1} (4) which overlaps with our value. In order to decide upon the best value, the following points should be considered. The present method of determination is indirect while Thompsen measured the enthalpy of the process $Se_2Cl_2(l) + 3Cl_2(g) = 2SeCl_4(c)$. This was combined with the result for the process $2Se(glass) + Cl_2(g) = Se_2Cl_2(l)$. However, Thompsen failed to give experimental details so that a proper assessment of his work is not possible.

The indirectness of our method does not appear to introduce an appreciable cumulative error as the precision of the quantities used in the calculations is very good. The literature data for HCl and H_2O are especially precise. One must consider the purity of the SeO_2 and the $SeCl_4$. Sublimation of the former had no effect on its enthalpy of solution. The chloride is subject to hydrolysis and possible contamination with Se_2Cl_2. We measured the enthalpies of solution of H_2SeO_3 and Se_2Cl_2 in 4.02 *M* hydrochloric acid and obtained +4.5 and −5.1 kcal mol^{-1} respectively. It follows that an error of 0.1 kcal mol^{-1} in the heat of solution of $SeCl_4$ would be caused by 0.5 mol% of either one of these impurities. Such a mixture of $SeCl_4$ and Se_2Cl_2 was prepared and it was found to have a distinct yellow colour. As the $SeCl_4$ used was almost pure white it was evident that there was no appreciable contamination with Se_2Cl_2. As Se—O bands in the infrared spectrum are normally weak, we were unable to devise a method to specifically detect hydrolysis. The chlorine analyses lead us to believe that no more than 1 mol% hydrolysis had occurred.

$\Delta H_f^{\ominus}$ of $SeBr_4$

We obtained -7.18 ± 0.11, $1.04 + \pm 0.05$, and -4.40 ± 0.08 kcal for ΔH_7, ΔH_8, and ΔH_{10} respectively. ΔH_9 and ΔH_{11} were interpolated graphically from literature data (1) and were taken to be -71.24 ± 0.2 and -1.58 ± 0.05 kcal respectively. The literature data appear to be highly reliable: the uncertainty in ΔH_9, the integral heat of solution of 4 mol of HBr, reflects the uncertainties in the published data combined with that of our analysis of the concentrated acid. The data yielded -65.8 ± 0.3 kcal for the enthalpy of reaction [6].

In order to calculate the standard enthalpy of formation of $SeBr_4$, ΔH_6, $\Delta H_f^{\ominus} SeO_2$, $\Delta H_f^{\ominus} H_2O$ and $\Delta H_f^{\ominus} HBr$ were used. This last was taken to be -8.70 kcal mol^{-1} (1). These data give $\Delta H^{\ominus}_{f,298}$ $SeBr_4(c) = -17.9 \pm 0.3$ kcal mol^{-1}.

As before with $SeCl_4$, the limiting factor in the accuracy of the determination was held to be the purity of the $SeBr_4$ in respect of both the initial stoichiometry and possible subsequent hydrolysis during handling. Because of its colour, it was not possible to assess the purity of the $SeBr_4$ by its appearance alone; however, the analytical purity was very good. Separate preparations of $SeBr_4$ gave good agreement in heats of solution.

Received December 20, 1977

R. JOHN KOMINAR, MICHAEL J. KRECH, and STANLEY JAMES W. PRICE. Can. J. Chem. **56**, 1589 (1978).

The pyrolysis of C_6H_5Br has been studied by the toluene carrier technique over the temperature range 1018 to 1126 K using contact times of 1.18 to 2.85 s and total pressures of 3.8 to 4.4 kPa. Percent decomposition based on analyses of residual C_6H_5Br ranged from 4 to 89%. When HBr was trapped out and quantitatively determined it accounted for more than 95% of the bromine expected. Within the limits of the experimental method the decomposition was found to be homogeneous and first order.

[1] $$C_6H_5Br \rightarrow C_6H_5 + Br$$

The Arrhenius equation for reaction [1] is

$$\log k_1 (s^{-1}) = (14.6 \pm 0.26) - \frac{317\ 000 \pm 5400}{19.15T}$$

Making an approximate correction of the activation energy to 298 K then gives $D(C_6H_5—Br) = 313 \pm 5.4$ kJ mol^{-1}.

R. JOHN KOMINAR, MICHAEL J. KRECH et STANLEY JAMES W. PRICE. Can. J. Chem. **56**, 1589 (1978).

On a étudié la pyrolyse du C_6H_5Br à l'aide de la technique de l'entraînement par le toluène à des températures allant de 1018 à 1126 K, utilisant des temps de contact de 1.18 à 2.85 s et des pressions totales allant de 3.8 à 4.4 kPa. Les pourcentages de décomposition, basés sur l'analyse du C_6H_5Br résiduel, vont de 4 à 89%. Lorsque l'on piège le HBr et qu'on le détermine quantitativement, on récupère ainsi plus de 95% du brome attendu. A l'intérieur des limites de la méthode expérimentale, on a trouvé que la décomposition est homogène et du premier ordre.

[1] $$C_6H_5Br \rightarrow C_6H_5 + Br$$

L'équation d'Arrhénius pour la réaction [1] est

$$\log k_1 (s^{-1}) = (14.6 \pm 0.26) - \frac{317\ 000 \pm 5400}{19.15T}$$

Si l'on fait une correction approximative de l'énergie d'activation à 298 K, on obtient alors $D(C_6H_5—Br) = 313 \pm 5.4$ kJ mol^{-1}.

[Traduit par le journal]

Introduction

In an earlier toluene carrier study of C_6H_5Br a value of the order of 297 kJ mol^{-1} was reported for $D(C_6H_5—Br)$ (1). This is considerably lower than the value suggested by Benson and O'Neal (2) of 339 kJ mol^{-1} based on thermochemical kinetic evidence. In a recent paper by two of the present authors (3) comparing values of $D(C_6H_5—X)$ and $D(C_6F_5—X)$ the bromo analogs were not included. A recent thermochemical study gives a value of 436 kJ mol^{-1} for $D(C_6F_5—Br)$ (4). The present study was undertaken in an attempt to resolve the discrepancy between the earlier toluene carrier study and the more recent thermochemical suggestion of $D(C_6H_5—Br)$, and to extend the $D(C_6H_5—X)$, $D(C_6F_5—X)$ comparison to include the bromo analogs.

Experimental

Materials

(a) Bromobenzene

The bromobenzene used was obtained from Eastman Organic Chemicals #43. Prior to use, the bromobenzene was distilled and head and tail fractions were discarded. Analysis by gas chromatography (6 ft × 0.125 in. 15% Apiezon L on chromosorb W, N_2 carrier, 30 cm^3/min, isothermal for 4 min at 100°C and temperature programmed from 100–160°C at 32°C/min) showed only minor impurities estimated at a maximum of 0.01% of the sample.

(b) Benzene

Analar grade benzene from British Drug House was simi-

larly tested by gas chromatography and the minor impurities were estimated at a maximum of 0.01% of the sample.

(c) Toluene

Toluene from sulfonic acid (Eastman Organic X325) was prepared for use by refluxing over sodium under vacuum and then degassing by bulb-to-bulb distillation.

(d) n-*Undecane*

n-Undecane was obtained from Polyscience Corporation and used as received.

(e) Diethyl Mercury

Diethyl mercury was obtained from Alpha Inorganics and used as received.

Apparatus and Procedure

The basic toluene carrier system has been previously described (5). The quantity of C_6H_5Br required for a run was injected via a gas-tight syringe through a silicone rubber septum. It was then subjected to controlled evaporation into the toluene carrier stream. Total pressures were taken by a differential manometer after the C_6H_5Br had been removed from the system while only toluene was flowing. The reaction vessel was treated with hot fuming nitric acid prior to use. Residual acid was baked out under vacuum after the vessel was installed in the system.

Toluene, unreacted C_6H_5Br, HBr, and other condensibles were trapped at −80°C. After the run, in experiments where the amount of HBr produced was quantitatively determined, the liquid products were isolated, the cold bath removed, and 25 ml of standardized NaOH introduced into the flask. The entire contents were stirred for 10–15 min with a magnetic stirrer, while still under vacuum. The contents of the trap were quantitatively transferred to a separatory funnel, the aqueous layer separated, and titrated with standard HCl. The organic layer was transferred to an amber sample bottle with a Teflon lined top, weighed, and a weighed amount of internal standard *n*-undecane added. In experiments where HBr analyses were not carried out the collected liquid products were transferred directly to the amber bottles, weighed, and a weighed amount of internal standard introduced. The samples were analyzed on a P.E. Model 3600 Gas Chromatograph for residual C_6H_5Br, toluene, and benzene by an internal standard technique. The areas were determined using a Columbia Scientific Industries Model CSI38 digital electronic integrator. The integrator was acquired half-way through the course of this work and the quantitative gc analysis showed a marked increase in precision when the integrator was put into use.

Results and Discussion

Selected experimental results are given in Table 1 and the Arrhenius plot for the decomposition of C_6H_5Br is shown in Fig. 1. The results may be discussed in terms of the following mechanism.

[1] $C_6H_5Br \rightarrow C_6H_5 + Br$

[2] $Br + C_6H_5CH_3 \rightarrow C_6H_5CH_2 + HBr$

[3] $C_6H_5 + C_6H_5CH_3 \rightarrow C_6H_6 + C_6H_5CH_2$

[4] $C_6H_5 + C_6H_5CH_2 \rightarrow C_6H_5CH_2C_6H_5$

[5] $2C_6H_5CH_2 \rightarrow (C_6H_5CH_2)_2$

[6] $2C_6H_5 \rightarrow (C_6H_5)_2$

The products of reactions [3] through [6] were identified qualitatively by gas chromatography.

1018	4.04	2.26	5.8	103	0.0263

* P denotes runs in packed reaction vessel, surface-to-volume ratio 17 times that in unpacked vessel.

Over the temperature range 1018 to 1126 K the C_6H_5Br decomposition ranged from 4 to 89%. Over this same temperature range it is estimated (6) that 0.08 to 4.4% of the toluene carrier decomposed. Since the toluene to phenyl bromide ratio was usually about 100:1 it is therefore also necessary to consider the following additional reactions.

[7] $C_6H_5CH_3 \rightarrow C_6H_5CH_2 + H$

[8] $H + C_6H_5CH_3 \rightarrow H_2 + C_6H_5CH_2$

[9] $H + C_6H_5CH_3 \rightarrow CH_3 + C_6H_6$

[10] $H + C_6H_5Br \rightarrow C_6H_5 + HBr$

The major concern here is the possible occurrence of reaction [10] to a significant extent. Reaction [8] should be approximately 40 kJ more exothermic than reaction [10] and should have an added statistical advantage (three H on CH_3 available for abstraction versus one Br). It, therefore, seems likely that k_8 should be somewhat larger than k_{10}. Given this, and the fact that the toluene–C_6H_5Br ratio was generally in the range 80:1 to 120:1, it seems unlikely that reaction [10] would be significant.

As an experimental check on this conclusion three experiments were carried out using approximately equimolar amounts of C_6H_5Br and $Hg(C_2H_5)_2$. At the temperatures used reactions [11] and [12] occurred extremely rapidly producing an effective increase in the rate of H atom production of at least a

[11] $Hg(C_2H_5)_2 \rightarrow 2C_2H_5 + Hg$

[12] $C_2H_5 \rightarrow C_2H_4 + H$

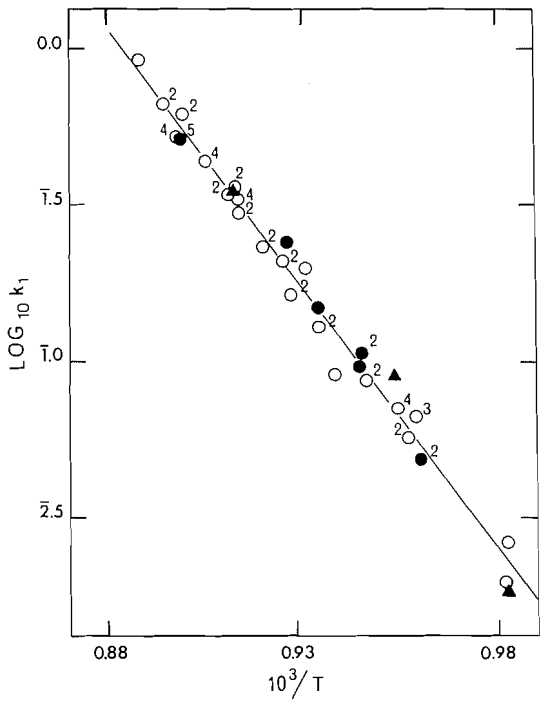

FIG. 1. Arrhenius plot for the decomposition of bromobenzene. Open circles, ○, represent unpacked vessel runs. Full circles, ●, represent packed vessel runs. Full triangles, ▲, represent addition of $Hg(C_2H_5)_2$ in selected runs. Numbers beside points indicate the number of experiments averaged to obtain the plotted point.

factor of 10 at the lowest temperature and a factor of 2 at the highest temperature used. The results of these runs are shown in Table 2. No significant increase in the decomposition of C_6H_5—Br was observed. It therefore seems unlikely that reaction [10] plays any significant role in the proposed mechanism.

The rate constants given in Table 1 have been calculated from the amount of undecomposed C_6H_5Br. As a check, the quantity of HBr produced was measured in a number of runs and was found to be 94–99% of the expected value.

TABLE 2. Effect of $Hg(C_2H_5)_2$ on C_6H_5—Br decomposition

T (K)	Decomposition (%)	k_1 (s^{-1})
1018*	3.8	0.0179
1018	4.2	0.0193
1049*	16.7	0.0862
1049	14.3	0.0714
1075*	52.4	0.3499
1075	51.2	0.3355

*Denotes the addition of $Hg(C_2H_5)_2$ to C_6H_5Br.

It is also possible that small quantities of CH_3Br were formed; however, no CH_3Br was observed when analyzed for by gas chromatography.

Benzene analyses were carried out on the liquid samples but the amount of benzene cannot be quantitatively related to the primary reaction because of the benzene coming from the toluene carrier decomposition.

Approximately one quarter of the experiments were carried out using a packed reaction vessel, with surface to volume ratio 17 times that in the unpacked vessel. No detectable surface effects were observed (Fig. 1).

Values of k_1 have been calculated from the usual first-order expression. The data in Table 3 indicate that values of k_1 determined in this way show no significant variation when the C_6H_5Br concentration is varied over a range of up to a factor of 7.4. Within experimental limits the decomposition is first order in C_6H_5Br.

The linear regression line for all the data points in Fig. 1 may be represented by (stated error limits are $\pm\sigma$)

$$\log k_1\,(s^{-1}) = (14.63 \pm 0.26) - \frac{317\ 000 \pm 5400}{19.15T}$$

Approximate correction of the activation energy to 298 K then gives $D(C_6H_5—Br) = 313.0 \pm 5.4$ kJ mol^{-1}. Using $\Delta H^0_{f298}(C_6H_5, g) = 325.1$ kJ mol^{-1} (7) to revise Benson and O'Neal's (2) value for the C_6H_5Br decomposition gives

$$\log k = 14.8 - 328/19.15T$$

in reasonable agreement with the present results.

In Fig. 2 a comparison is made of $D(C_6F_5—X)$ and $D(C_6H_5—X)$ bond dissociation energies (3, 4). In general the enhanced electron density on the carbon attached to X in C_6F_5X leads to stronger C—X bonds. In C_6F_6 all of the carbon atoms are positive but the p-orbital overlap is optimum.

TABLE 3. Test of the effect of C_6H_5Br concentration on k_1

T (K)	Bromobenzene concentration (mol cm^{-3} × 10^9)	k_1 (s^{-1})
1095	28.9	0.3377
	21.3	0.2941
	14.1	0.3092
	12.2	0.3522
	10.1	0.3506
	9.0	0.3465
	8.6	0.3207
	3.9	0.3280

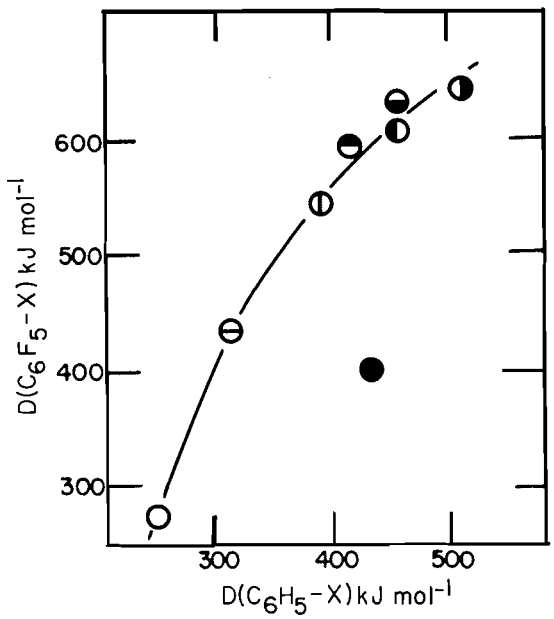

FIG. 2. Comparison of $D(C_6F_5—X)$ and $D(C_6H_5—X)$ bond dissociation energies for X = I (○), Br (⊖), Cl (◑), CH_3 (◓), H (◒), OH (◐), F (◑), and CF_3 (●).

The marked exception to the correlation shown is for X = CF_3. In this and in similar groups where the carbon in X is bonded to highly electronegative atoms the sp^3 hybrid orbitals on this carbon will be distorted to such an extent that overlap with the ring carbon orbitals is drastically reduced. The low value for $D(C_6F_5—CF_3)$ is therefore not unexpected.

Received March 6, 1978

ITSUO KUROBANE, LEO C. VINING, A. GAVIN MCINNES, and DONALD G. SMITH. Can. J. Chem. **56**, 1593 (1978).

In alkaline cultures of *Fusarium solani* fusarubin is formed by nonenzymic oxidation of two previously unknown dihydrofusarubins, *rel*-(3*R*,4a*R*,10a*R*)- and *rel*-(3*R*,4a*R*,10a*S*)-5,10-dioxo-3,4,4a,5,10,10a-hexahydro-7-methoxy-3-methyl-3,6,9-trihydroxy-1*H*-naphtho[2,3-*c*]pyran.

ITSUO KUROBANE, LEO C. VINING, A. GAVIN MCINNES et DONALD G. SMITH. Can. J. Chem. **56**, 1593 (1978).

Dans des cultures alcalines de *Fusarium solani*, il y a formation de fusarubine par l'oxydation non-enzymatique de deux dihydrofusarubines inconnues jusqu'à maintenant soit les *rel*-(3*R*,4a*R*,10a*R*) et *rel*-(3*R*,4a*R*,10a*S*) dioxo-5,10 hexahydro-3,4,4a,5,10,10a méthoxy-7 méthyl-3 trihydroxy-3,6,9 1*H* naphto[2,3-*c*] pyrannes.

[Traduit par le journal]

Fusarubin (oxyjavanicin (1)), which has structure **1** (2–5), has been regarded as a metabolite of *F. solani* and *F. javanicum* for over 30 years. Fusarubinogen, an ammonium sulfate ester of a reduced form of **1**, has been reported as a possible progenitor metabolite in one strain of *F. solani* (3) but more probably is an artifact produced by the isolation procedure. We now report the isolation of two diastereoisomeric dihydrofusarubins (**2** and **3**) from *F. solani* cultures, and present evidence that air oxidizes them under alkaline conditions to yield **1**.

Cultures of *F. solani* grown on a maltose (2%) – ammonium tartrate (0.46%) – salts medium were harvested at 2 days when the p*H* had dropped to 3 from an initial value of 5. An ethyl acetate extract of the filtrate was taken to dryness and the residue chromatographed on silicic acid. Elution with a 5:1 benzene – ethyl acetate mixture gave **2**, $[\alpha]_D^{20}$ +145.4° (*c* 0.31, acetone); mp 153–154°C (reddish-orange needles from CH_2Cl_2); $M^{\ddagger}$ at *m/e* 308.0905 (calcd. for $C_{15}H_{16}O_7$: 308.08961); λ_{max} (95% EtOH): 213, 243, 273, 300, and 391 nm (log ε: 4.17, 4.30, 3.87, 3.71, and 3.94). Decreasing the benzene – ethyl acetate ratio to 3:1 gave **3**, $[\alpha]_D^{20}$ +23.3° (*c* 0.31, acetone); mp 117–118°C (pale-yellow needles from methanol); $M^{\ddagger}$ peak too small for mass measurement, $M - 18$ (also observed in the mass spectrum of **2**) at *m/e* 290.0784 (calcd. for $C_{15}H_{14}O_6$: 290.07904; λ_{max} (95% EtOH): 213, 243, 273, 300, and 391 nm (log ε: 4.15, 4.31, 3.89, 3.70, and 3.96).

*Compound 2 in $C_5{}^2H_5N$ at 0°C and compound 3 in $C^2H_2Cl_2$ at 28°C. Chemical shifts in ppm relative to TMS. Coupling constants $J_{p,q}$ in Hz. The protons H-1ax through H-4ax form a coupled six-spin system which was analyzed with the Varian spin simulation program on a 620L data system.

Conversion of **2** and **3** to **1** occurs rapidly at room temperature in 0.1 *N* NaOH solution and when *F. solani* cultures are basified at 2 days with NaOH. The conversions also take place in pyridine although **2** is stable at solution temperatures <0°C. The uv data are consistent with **2** and **3** containing a 5,8-dihydroxy-1,4-dioxo-1,2,3,4-tetrahydronaphthalene ring system (6) whereas the chemical evidence requires that they be isomeric dihydrofusarubins.

The signals for the methyl and methoxy groups in the ^{1}H nmr spectra of **2** and **3** (see Table 1) were readily assigned. Resonances for the ketal and intramolecularly hydrogen-bonded phenolic hydroxyl groups were temperature dependent and removed by exchange with ^2H_2O. H-8 was deshielded relative to its counterpart (δ 6.36) in **1** (5) and was, therefore, present in a phenolic rather than a quinone ring (5, 7). From the chemical shifts and spin–spin coupling constants (e.g., ref. 8) the ketal ring systems giving rise to the coupled six-spin systems had the conformations shown, with H-4a and H-10a antiperiplanar in **2** and synclinal in **3**. Conformational free energy calculations (9) indicate that the hydroxyl group at C-3 in both **2** and **3** is axially orientated, assuming a methyl group has a stronger 1,3-diaxial interaction with hydrogen (0.9 kcal mol^{-1}) than a hydroxyl group and the 'anomeric effect' favours the epimer with an axial hyroxyl group (0.55 kcal mol^{-1}). Thus the combined evidence establishes **2** and **3** as *rel*-(3*R*,4a*R*,10a*R*)- and *rel*-(3*R*,4a*R*,10a*S*)-5,10-dioxo-3,4,4a,5,10,10a-hexahydro-7-methoxy-3-methyl-3,6,9-trihyroxy-1*H*-naphtho[2,3-*c*]pyran.

The total weight of crude extract (347 mg ℓ^{-1}) from *F. solani* cultures changed little after 2 days but the amount of **2** and **3** rapidly decreased after 3 days. This loss was accompanied by a rapid increase in the p*H* of the medium from 3 to 8, and an increasing proportion of **1** in the product. Maintaining the p*H* of the culture at about 3 by adding acetic acid prevented this conversion. We presume that enolization involving H-4a, H-10a, and the carbonyl groups of **2** and **3** is promoted by alkaline conditions, and the hydroquinones thus obtained are oxidized by air to quinones. The tautomeric form of fusarubin initially formed subsequently rearranges to **1**.

Deactivation of singlet oxygen and triplet pentacene by transition metal complexes

HIROSHI FURUE AND KENNETH E. RUSSELL

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received October 4, 1977

HIROSHI FURUE and KENNETH E. RUSSELL. Can. J. Chem. **56**, 1595 (1978).

Rate constants, k_Q, have been determined for the deactivation of singlet oxygen in carbon tetrachloride by a range of transition metal complexes. The singlet oxygen was produced by flash photolysis of air-saturated carbon tetrachloride solutions with methylene blue as sensitizer, and the decay followed by observing the concentration of the acceptor 1,3-diphenylisobenzofuran at 435 nm. The high rate constants of certain diamagnetic nickel complexes are accounted for by a spin-allowed transfer of electronic energy from singlet oxygen to the complex. Rate constants have also been determined for the deactivation of triplet pentacene by a number of these metal complexes. The triplet pentacene was produced by flash photolysis of dilute solutions of pentacene in benzene and the decay monitored at 492 nm. The rate constants for quenching of triplet pentacene are generally lower than those for quenching of singlet oxygen but there is a good correlation between the two sets of results. Both processes appear to proceed by way of electronic energy transfer without the intervention of complex formation between donor and acceptor.

HIROSHI FURUE et KENNETH E. RUSSELL. Can. J. Chem. **56**, 1595 (1978).

On a déterminé les constantes de vitesse, k_Q, des réactions de désactivation de l'oxygène singulet dans le tétrachlorure de carbone par un certain nombre de complexes de métaux de transition. On a produit l'oxygène à l'état singulet par la photolyse éclair de solutions d'air saturées de tétrachlorure de carbone en utilisant le bleu de méthylène comme sensibilisateur et on a suivie la décroissance en observant la concentration de l'accepteur diphényl-1,3 isobenzofuranne à 435 nm. On explique les constantes de vitesse élevées, observées avec certains complexes diamagnétiques du nickel, par un transfert d'énergie électronique permise par le spin de l'état singulet de l'oxygène vers le complexe. On a aussi déterminé les constantes de vitesse de la réaction de désactivation de l'état triplet du pentacène par un certain nombre de ces complexes métalliques. On a produit l'état triplet du pentacène par photolyse éclair de solutions diluées de pentacène dans le benzène et on a contrôlé la décroissance à 492 nm. Les constantes de vitesse de la réaction de piégeage de l'état triplet du pentacène sont généralement plus faibles que celles observées pour le piégeage de l'état singulet de l'oxygène mais il existe une bonne corrélation entre les deux séries de données. Les deux processus semblent se produire par l'intermédiaire d'un transfert d'énergie électronique sans l'intervention de la formation d'un complexe entre le donneur et l'accepteur.

[Traduit par le journal]

Introduction

Deactivation of singlet oxygen ($^1\Delta_g$) by transition metal complexes has attracted attention because of its possible involvement in the stabilization of polyolefins against photodegradation (1). The effectiveness of such complexes in deactivating singlet oxygen in solution has been studied by various groups, usually by determining the rate of consumption of rubrene in the presence of a steady state concentration of $^1\Delta$ O_2 (2–4). Adams and Wilkinson (5) and Merkel and Kearns (6) demonstrated some years ago that laser photolysis can be used to study directly the decay of singlet oxygen in solution. We have shown that the decay in carbon disulfide can equally well be studied by flash photolysis (7) and that quenching rate constants, k_Q, of transition metal complexes can be obtained from rates of decay of $^1\Delta$ O_2 in the presence and absence of the quencher. In our earlier study, the $^1\Delta$ O_2 was produced by flash photolysis of oxygen-saturated carbon disulfide solu-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tions containing methylene blue as sensitizer; the decay was observed by monitoring the disappearance of the acceptor 1,3-diphenylisobenzofuran (DPBF) at 435 nm. $^1\Delta$ O_2 has an even longer lifetime in the solvent carbon tetrachloride (6) and the original study has now been extended to yield k_Q values for a wide range of metal complexes in carbon tetrachloride solution.

The quenching of $^1\Delta$ O_2 may occur by a number of different routes. Water and alcohols appear to deactivate by an electronic–vibrational energy transfer mechanism (6). The intermediate quenching ability of amines is associated with the formation of charge transfer complexes between the amines and the $^1\Delta$ O_2, with its high electron affinity; the required 'spin-flip' may be assisted by spin–orbit interactions in the complex (8). β-Carotene is an extremely efficient quencher of $^1\Delta$ O_2 and the quenching proceeds by spin-allowed energy transfer with the formation of triplet β-carotene (9).

$$^1\Delta\ O_2 + {}^1C \rightarrow {}^3\Sigma\ O_2 + {}^3C$$

The rapid transfer of electronic energy is possible because the triplet energy of β-carotene is less than that of singlet oxygen. The very high quenching constants of some transition metal complexes may also be associated with their possessing low energy excited states (cf. ref. 10). Since it was not possible to obtain direct information on these energies, e.g. by phosphorescence studies, a study of the quenching of triplet pentacene by transition metal complexes was made. Triplet pentacene has an excitation energy of the order of 7000 cm^{-1} (11, 12), compared with 7882 cm^{-1} for $^1\Delta$ O_2, and it was anticipated that the ease of quenching of triplet pentacene by a metal complex would parallel its ability to deactivate singlet oxygen if a spin-allowed energy transfer mechanism were operative.

Experimental

Materials

Carbon tetrachloride, methanol, benzene, and pyridine were of certified A.C.S. grade. Methylene blue, 1,3-diphenylisobenzofuran, and pentacene were used as supplied (Aldrich Chemical Corp.). 2-Hydroxy-4-dodecyloxybenzophenone, octadecyl 3-(3′,5′-di-*tert*-butyl-4′-hydroxyphenyl)-propionate, bis(di-*n*-butyldithiocarbamato)nickel(II), Ni(di-*n*-butyl-dtc)$_3$, and bis(di-*n*-butyldithiocarbamato)zinc(II), recrystallized from a chloroform–acetone mixture, were gifts from Drs. D. J. Carlsson and D. M. Wiles. Bis(di-*i*-propyldithiophosphato)nickel(II), Ni(di-*i*-propyl-dtp)$_2$, bis(2,4-pentanedionato)diaquonickel(II), Ni(acac)$_2$aq$_2$, were used as supplied and 2,2′-thiobis-4-(*tert*-octyl)phenolato[*n*-butylamine]nickel(II) was recrystallized from a chloroform–ethanol mixture. Bis(di-*n*-butyldithiocarbamato)copper(II), bis(diethyldithiocarbamato)nickel(II), and tris(di-*n*-butyldithiocarbamato)cobalt(III) were prepared in water from copper(II) sulfate, nickel(II) chloride, and cobalt(II) nitrate respectively and the appropriate potassium dialkyldithiocarbamate (13, 14). Bis(di-*i*-propyldithiophosphato)bis[pyridine]nickel(II) was prepared by adding pyridine dropwise to a benzene solution of bis(di-*i*-propyldithiophosphato)nickel(II). Bis(diethyldithiophosphato)palladium(II) was prepared from potassium tetrachloropalladate(II) and ammonium diethyldithiophosphate (14). Bis(dithiobenzil)nickel(II) was prepared from benzoin, phosphorus pentasulfide, and nickel(II) chloride (15). Tris(2,2′-bipyridine)ruthenium(II) chloride pentahydrate, Ru(bipy)$_3$Cl$_2$, was a gift from Dr. M. C. Baird.

Apparatus

The flash photolysis apparatus was similar to that used in an earlier investigation (7). For the singlet oxygen study, the monitoring light source (435 nm) consisted of a 200 W high pressure mercury lamp and a grating monochromator. Filters of red photographic film (Diazochrome Red KRD Tecnifax) were installed between the flash tubes and the reaction cell to cut off radiation below 600 nm, in order to prevent bleaching of DPBF by light from the flash. In the pentacene study, the monitoring light source (492 nm) was a 55 W, 12 V quartz–iodine tungsten lamp. Plates of window glass (4 mm) were installed between the flash tubes and the reaction cell to reduce decomposition of the pentacene by ultraviolet radiation from the flash.

Procedure

For the singlet oxygen investigation, the sensitizer methylene blue was dissolved in methanol, and the DPBF and the quencher in carbon tetrachloride. The solvent normally consisted of carbon tetrachloride containing 2 vol% methanol, although 1 vol% methanol was adequate to solubilize the methylene blue. The solvent was saturated with air and the oxygen concentration was about 2.5×10^{-3} *M* (16). Some results were obtained using the solvent mixture saturated with oxygen at 1 atm in order to determine the effect of oxygen concentration on the decay. A typical reaction mixture contained methylene blue (5×10^{-6} *M*), DPBF (2.94×10^{-6} *M*), oxygen (2.5×10^{-3} *M*), and quencher, e.g. bis(di-*i*-propyl-dithiophosphato)nickel(II) (1.0×10^{-6} *M*). DPBF fades slowly even in the monitoring light and the initial settings of the apparatus were made with a reaction mixture containing no DPBF. The cell was then filled with a normal reaction mixture containing DPBF and the final adjustments made. Finally a fresh reaction mixture was placed in the cell and flashed (2×20 μF, 4 kV) and the decay curve on the oscilloscope screen photographed by means of a Polaroid camera.

The cell for the triplet pentacene study had a path length of 42.6 cm. A weighed amount (ca. 0.5 mg) of pentacene was placed in the degassing ampoule attached to the cell and benzene (70 ml), or a benzene solution of the quencher, added. The mixture was carefully degassed three times on the vacuum line and left overnight to allow complete solution of the pentacene. The reaction mixture was then transferred to the cell compartment, the condenser banks (10 μF) charged to 6 kV, and the decay curve recorded in the usual manner.

Results and Discussion

Decay of Singlet Oxygen in Carbon Tetrachloride – Methanol Mixtures

The decay of singlet oxygen was first studied in the absence of added quencher. The rate of decay was determined by monitoring the bleaching of the acceptor DPBF photometrically. The $^1\Delta$ O_2 is formed by energy transfer from triplet methylene blue, ^{3}MB,

[I] $$^3\text{MB} + {}^3\Sigma\ O_2 \rightarrow {}^1\text{MB} + {}^1\Delta\ O_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and it decays to ground state oxygen either by physical deactivation

[2] $$^1\Delta\, O_2 \rightarrow {}^3\Sigma\, O_2$$

with rate constant $1/\tau$, or by reaction with DPBF (A) to give the peroxide AO_2

[3] $$^1\Delta\, O_2 + A \rightarrow AO_2$$

with rate constant k_A. The decay is observable over a period of about 1 ms with carbon tetrachloride + 2% methanol as solvent. If $[AO_2]$ and $[AO_2]_\infty$ are the concentrations respectively of AO_2 at time t and after the decay of $^1\Delta\, O_2$ is complete, and $[^1\Delta]_0$ is the concentration of $^1\Delta\, O_2$ at the start of the decay, it can be shown (10) that

[4] $$[AO_2]_\infty - [AO_2] = \frac{k_A[A][^1\Delta]_0}{1/\tau + k_A[A]} \times \exp -(1/\tau + k_A[A])t$$

[5] $$2.30 \log ([A] - [A]_\infty) = -(1/\tau + k_A[A])t + \text{constant}$$

If OD, OD_∞ represent optical densities of DPBF at time t and after complete decay of $^1\Delta\, O_2$,

[6] $$2.30 \log (OD - OD_\infty) = -(1/\tau + k_A[A])t + \text{constant}$$

Plots of log $(OD - OD_\infty)$ vs. t yield lines of slope $-(1/\tau + k_A[A])/2.30$. Typical first order decay plots for initial DPBF concentrations of 1.47×10^{-6} and 6.12×10^{-6} M are shown in Fig. 1. The plots show slight curvature due to the change in [A], and hence of $k_A[A]$, during the course of an experiment. A summary of the experimental conditions used and the derived $1/\tau + k_A[A]$ values is given in Table 1. Following the suggestion of Young *et al.* (17), the results have been analyzed using the average acceptor concentration $[A]_{AV}$. A plot of $1/\tau + k_A[A]$ vs. $[A]_{AV}$ is linear and values of $\tau = 310 \pm 50$ μs and $k_A = (5.3 \pm 1.7) \times 10^8\ M^{-1}\ s^{-1}$ were derived for the solvent carbon tetrachloride + 2 vol% methanol.

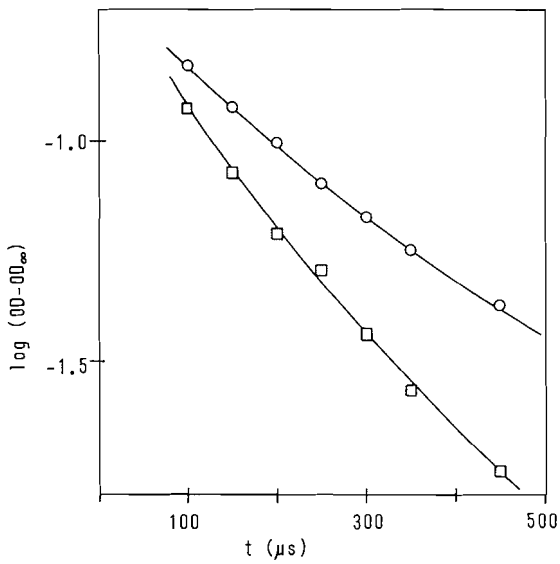

FIG. 1. First order decay plots for singlet oxygen. □, $[A]_0 = 6.12 \times 10^{-6}$ M, 5 cm cell; ○, $[A]_0 = 1.47 \times 10^{-6}$ M, 20 cm cell.

The effect of changing the methanol content from 1 to 5 vol% was examined. The first order decay constants, $1/\tau$, are plotted against methanol content of the solvent in Fig. 2. Linear extrapolation yields a value of $1/\tau = (1.42 \pm 0.40) \times 10^3\ s^{-1}$ for pure carbon tetrachloride, corresponding to a lifetime of 700^{+280}_{-150} μs in this solvent (cf. Merkel and Kearns (6), 700 ± 200 μs). It was not expected that quenching by methylene blue and oxygen would contribute significantly to $1/\tau$, and, in agreement with this, changing the concentration of methylene blue and of oxygen by factors of 2 and 5 respectively did not affect the decay rates of $^1\Delta\, O_2$ in carbon tetrachloride containing 2 vol% methanol.

The rate constants, k_A, for the reaction of singlet oxygen with DPBF are respectively 7.3, 4.8, 5.4, 5.2, and $6.0 \times 10^8\ M^{-1}\ s^{-1}$ at 25°C for methanol contents of 1, 2, 3, 4, and 5 vol%. There may be some change with methanol content but the results are all in the range $4.8–7.3 \times 10^8\ M^{-1}\ s^{-1}$ and they are the same within the margin of experimental error. These values compare with k_A values of $3 \times 10^8\ M^{-1}\ s^{-1}$ for carbon disulfide containing 2 vol% methanol as solvent (7) and $2 \times 10^9\ M^{-1}\ s^{-1}$ for pyridine (17).

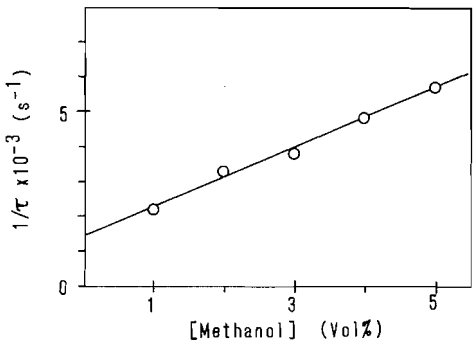

FIG. 2. Effect of methanol on $1/\tau$ for singlet oxygen ($^1\Delta$) in carbon tetrachloride.

Quenching of Singlet Oxygen by Polyolefin Stabilizers

Addition of a polyolefin stabilizer, Q, such as bis(di-*i*-propyldithiophosphato)nickel(II) to the solution provides an additional mode of decay of $^1\Delta\ O_2$

$$[7] \qquad {}^1\Delta\ O_2 + Q \rightarrow {}^3\Sigma\ O_2 + Q$$

If k_Q is the rate constant for deactivation via reaction [7] the dependence of $[AO_2]$ on time is given by

$$[8] \quad 2.3 \log \{[AO_2]_\infty - [AO_2]\} = -(1/\tau + k_A[A] + k_Q[Q])t + \text{constant}$$

so that

$$[9] \quad 2.3 \log (OD - OD_\infty) = -(1/\tau + k_A[A] + k_Q[Q])t + \text{constant}$$

Thus values of k_Q may be obtained from plots of log $(OD - OD_\infty)$ vs. t in the absence and in the presence of quencher. A relatively high quencher concentration results in only slight bleaching of the DPBF so that the useful range of quencher concentrations is generally only two- or threefold. It was confirmed, however, that over this range the slopes of log $(OD - OD_\infty)$ vs. t plots increase linearly with [Q] for all nickel and cobalt chelates investigated. For example, the magnitudes of these slopes for concentrations of $Ni(acac)_2aq_2$ of 0, 4.4×10^{-5}, and 8.8×10^{-5} M were found to be 10.1×10^3, 16.8×10^3, and 23.7×10^3 s^{-1}; the slopes are reproducible to better than $\pm 4\%$.

The rate constants, k_Q, for the quenching of $^1\Delta\ O_2$ by a range of polyolefin stabilizers and related compounds are given in Table 2. In some instances the k_Q values quoted are upper limits. At concentrations of 2-hydroxy-4-dodecycloxybenzophenone up to 10^{-2} M, no increase in slope of the decay plot was observed. The highest concentrations of Cu(di-*n*-butyl-dtc)$_2$ and $Ru(bipy)_3Cl_2$ which could be used were 5×10^{-6} and 1×10^{-6} M respectively because these complexes absorb significantly at the wavelength of the monitoring light. At these concentrations, the copper and ruthenium complexes had no effect on the decay of singlet oxygen.

[a]Values obtained in carbon tetrachloride containing 2 vol% methanol.
[b]Values obtained in benzene at room temperature.
[c]Values obtained by Flood *et al.* (7) in carbon disulfide containing 2 vol% methanol.
[d]Value revised as a tetramer (3).
[e]Value estimated from reported datum (4) assuming that the quenching rate constant for β-carotene is 2×10^{10} M^{-1} s^{-1} in toluene.

As has been noted in earlier studies (2–4), nickel complexes containing sulfur ligands are efficient quenchers of singlet oxygen. A change in the metal in the complex may result in a considerable reduction in k_Q. For example Ni(di-*n*-butyl-dtc)$_2$ has a k_Q of 4.1×10^9 M^{-1} s^{-1} whereas Zn(di-*n*-butyl-dtc)$_2$ has a k_Q of only 2×10^7 M^{-1} s^{-1}. This wide variation indicates that enhancement of intersystem crossing by heavy atoms is not a major factor with these quenchers. There is also no correlation between k_Q and the paramagnetism of the complexes. The rate constants for the diamagnetic complexes investigated range from 2×10^7 M^{-1} s^{-1} (Zn(di-*n*-butyl-dtc)$_2$) to 7.6×10^9 M^{-1} s^{-1} (Ni(di-*i*-propyl-dtp)$_2$). Paramagnetic complexes include $Ni(acac)_2aq_2$ for which $k_Q = 6.6 \times 10^7$ M^{-1} s^{-1}, Cu(di-*n*-butyl-dtc)$_2$ ($k_Q < 5 \times 10^8$ M^{-1} s^{-1}), and probably 2,2′-thiobis-4-(*tert*-octyl)phenolato[*n*-butylamine]nickel(II) (18) for which $k_Q = 6.0 \times 10^8$ M^{-1} s^{-1}.

The high rate constants for the diamagnetic nickel

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

complexes can be accounted for by a spin-allowed transfer of electronic energy from singlet oxygen to the metal complex

[10] $$^1\Delta O_2 + {}^1Q \rightarrow {}^3\Sigma O_2 + {}^3Q$$

For efficient transfer, the energy of the lowest triplet state of the complex must be lower than or near to the excitation energy of $^1\Delta O_2$ (9). Experimental data on triplet energies of the diamagnetic d^8 nickel dialkyldithiocarbamates and dialkyldithiophosphates are not available since these substances do not phosphoresce. However, their lowest singlet–singlet absorptions, which are due to metal *d–d* transitions, are observed and they can be used to make rough estimates of the required triplet energies. It is found that the energy differences between singlet–singlet absorption maxima and estimated triplet (0–0) energies for complexes of first and second transition metals (e.g. ruthenocene)[1] are of the order of 8000 cm^{-1}. If the same difference applies to Ni(diethyl-dtc)$_2$ and Ni(diethyl-dtp)$_2$, their respective triplet energies are close to 8000 and 7000 cm^{-1}. These estimates are only approximate but they indicate that low lying triplet levels are available to permit deactivation of singlet oxygen via reaction [10]. A low triplet energy of ~8000 cm^{-1} is also estimated for diamagnetic d^6 Co(di-*n*-butyl-dtc)$_3$ for which a k_Q of 1.2×10^9 M^{-1} s^{-1} is observed. On the other hand Ru(bipy)$_3$Cl$_2$ phosphoresces with a maximum at 15 700 cm^{-1} (20) and the lowest singlet–singlet absorption in d^{10} Zn(di-*n*-butyl-dtc)$_2$, an internal ligand transition, is about 36 000 cm^{-1} (14). These complexes do not possess triplet energies close to the excitation energy of $^1\Delta O_2$ and their k_Q values are correspondingly low ($<1 \times 10^9$ M^{-1} s^{-1} for the ruthenium complex and 2×10^7 M^{-1} s^{-1} for the zinc complex).

Decay of Triplet Pentacene in Benzene

The decay of triplet pentacene in benzene solution was first studied in the absence of added quenchers. In these experiments, the concentration of pentacene is very low ($<3 \times 10^{-5}$ *M*) so that quenching by ground state pentacene is small (11). Triplet–triplet quenching may be observable with flash times of 4 μs (11), but it is not important under the conditions used in this work. The decay can therefore be analysed assuming a simple first order process,

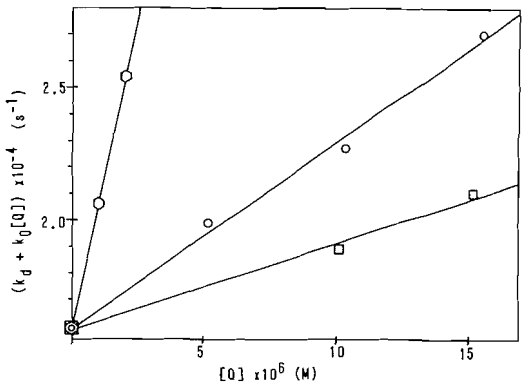

FIG. 3. Effect of quenchers on the decay of triplet pentacene. ⬡, Bis(dithiobenzil)nickel(II); ○, nickel(diethyl-dtc)$_2$; □, Co(di-*n*-butyl-dtc)$_3$.

[11] $$2.3 \log OD = -k_d t + \text{constant}$$

where OD represents the optical density of triplet pentacene at time *t* and k_d is the first order decay constant. Plots of log OD vs. *t* are linear;[2] the value of k_d obtained from results with a number of initial solutions was $(1.59 \pm 0.06) \times 10^4$ s^{-1}. This compares with a value of $(1.43 \pm 0.07) \times 10^4$ s^{-1} recorded by Hellner *et al.* (11). The result was unaffected when the pentacene concentration was lowered by a factor of three. The same k_d was obtained when a given solution was flashed a dozen times suggesting that the residual concentration of oxygen is sufficiently low to have no measurable effect on the rate of decay (cf. ref. 24). The effect of adding 1 vol% pyridine was determined because it was necessary to have pyridine present in the quenching study of Ni(di-*i*-propyl-dtp)$_2$py$_2$. The k_d value for benzene containing 1 vol% pyridine was $1.45 \pm 0.05 \times 10^4$ s^{-1}.

Quenching of Triplet Pentacene by Transition Metal Complexes

Addition of a quencher, Q, provides a further route for the decay of triplet pentacene,

[12] $$^3P + Q \rightarrow {}^1P + Q$$

If the rate constant for this process is k_Q, the dependence of log OD on time in the presence of quencher is given by [13]

[13] $$2.3 \log OD = -(k_d + k_Q[Q])t + \text{constant}$$

k_Q values can thus be derived from the slopes of plots

[1]Ruthenocene has its lowest singlet–singlet and singlet–triplet absorptions (19) and phosphorescence maximum (20, 21) at 29 500, 26 000, and 17 000 cm^{-1} respectively. The triplet (0–0) energy was assumed to be midway between the absorption and phosphorescence maxima, i.e. 21 500 cm^{-1}, yielding an energy difference between the singlet–singlet absorption maximum and triplet (0–0) energy of ruthenocene of 8000 cm^{-1}. Similar treatment of Rh(dimethyl-dtc)$_3$ (22) and ferrocene (19, 23) gives differences of 7700 and 7800 cm^{-1} respectively.

[2]Copies of a typical decay curve and a plot of log OD vs. *t* are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

of log OD vs. time. For the quenchers bis(dithiobenzil)nickel(II), Ni(diethyl-dtc)$_2$, and Co(di-*n*-butyl-dtc)$_3$, the concentration of quencher was varied; the decay rate constants, $k_d + k_Q[Q]$, are plotted against [Q] in Fig. 3. The results for all the quenchers investigated are summarized in Table 2. The k_Q values for Pd(diethyl-dtp)$_2$ and Pt(diethyl-dtp)$_2$ are merely upper limits; no quenching was observed at the highest quencher concentrations (respectively 1×10^{-4} and 9×10^{-4} M) which could be used without serious absorption by the quencher at the monitoring wavelength (492 nm). Quenching by Zn(di-*n*-butyl-dtc)$_2$ was small even at a concentration of 10^{-2} M.

The measured k_Q's range from 1.8×10^5 M^{-1} s^{-1} for Zn(di-*n*-butyl-dtc)$_2$ to a maximum of 4.7×10^9 M^{-1} s^{-1} for bis(dithiobenzil)nickel(II). As with the deactivation of singlet oxygen, there is no correlation between k_Q and the paramagnetism of the metal complex. The quenching rate constants for the paramagnetic complexes investigated range from 2.3×10^7 to 3.4×10^8 M^{-1} s^{-1} whereas those for diamagnetic complexes range from 1.8×10^5 to 4.7×10^9 M^{-1} s^{-1}. Square planar complexes appear to be slightly more efficient than the roughly corresponding octahedral complexes. For example, the k_Q for square planar Ni(diethyl-dtc)$_2$ is 7×10^8 M^{-1} s^{-1} whereas that for octahedral Co(di-*n*-butyl-dtc)$_3$ is 3.3×10^8 M^{-1} s^{-1}. Addition of two molecules of pyridine to square planar Ni(di-*i*-propyl-dtp)$_2$ to form the octahedral bis[pyridine] complex reduces k_Q from 7.8×10^8 to 3.6×10^8 M^{-1} s^{-1}.

The quenching of triplet pentacene by transition metal complexes can best be interpreted in terms of an electronic energy transfer mechanism (25–27). Farmilo and Wilkinson determined rate constants for quenching of the triplet states of 16 organic compounds by tris(acetylacetonato)iron(III), -ruthenium(III), and -aluminum(III). They established energy transfer as the mechanism of quenching by relating quenching ability to the energies of the triplet states being quenched and the spectroscopically determined energy levels of the complexes. In the present study the highest k_Q value, 4.7×10^9 M^{-1} s^{-1}, was observed for quenching by diamagnetic bis(dithiobenzil)nickel(II). This is close to the maximum value of about 6×10^9 M^{-1} s^{-1} associated with quenching of triplet states in benzene at room temperature (23, 28). The lowest singlet–singlet electronic transition observed for the dithiobenzil complex has an energy of 11 500 cm^{-1} (15), and a rough estimate of the lowest triplet energy is 5500 cm^{-1}. Since this is almost certainly lower than the triplet energy of pentacene, it is not surprising that the quenching ability of the complex is high. The electronic transition involved is a ligand π–π^* transition so that steric factors are likely to be unimportant.

Ni(diethyl-dtc)$_2$ possesses a *d–d* transition whose triplet energy is estimated to be approximately 8000 cm^{-1}; this is perhaps slightly higher than the triplet energy of pentacene. Its quenching ability would be expected to be lower than that of the benzil complex and in fact its k_Q value is 7.0×10^8 M^{-1} s^{-1}. On the other hand, Ni(diethyl-dtc)$_2$ is approximately 4000 times more efficient than Zn(di-*n*-butyl-dtc)$_2$ in quenching triplet pentacene. The zinc complex has a d^{10} structure and does not possess any low energy triplet levels; it is therefore impossible for it to quench triplet pentacene by an efficient energy transfer process. Furthermore, the replacement of Ni(II) in dialkyldithiophosphato complexes by Pd(II) or Pt(II) increases significantly the energy of the *d–d* transition (rough estimates of the triplet energies are respectively 14 000 and 15 000 cm^{-1}). The k_Q values of these complexes are low because their triplet energies are too large to allow significant energy transfer.

Comparison of Results for Singlet Oxygen and Triplet Pentacene

The rate constants, k_Q, for the quenching of singlet oxygen and triplet pentacene by a number of metal complexes are given in Table 2. There is a good correlation between the two sets of results, although in many cases the k_Q for singlet oxygen is an order of magnitude greater than the k_Q for triplet pentacene. These results add support to the conclusion that the quenching of singlet oxygen and of triplet pentacene both proceed by way of electronic energy transfer. The involvement of similar chemical factors, in e.g. complex formation, is unlikely in view of the dissimilar natures of singlet oxygen and triplet pentacene.

The diffusion controlled rate constants for the quenching of singlet oxygen (6, 29) and triplet pentacene (28) in benzene are about 2×10^{10} and 6×10^9 M^{-1} s^{-1} respectively. The rate constants for bis(dithiobenzil)nickel(II) are about 3/4 of these values; the difference between the rate constants for this highly efficient quencher may have its origin in differing diffusion rates of singlet oxygen and triplet pentacene in solution. The rate constants also depend on the relative magnitudes of the excitation energies of singlet oxygen and triplet pentacene. The value for singlet oxygen is known to be 7882 cm^{-1} but the calculated values for triplet pentacene vary from 6400 to 8500 cm^{-1}, and an experimental value, obtained from phosphorescence studies of pentacene in tetracene (12), is as low as 6500 cm^{-1}. The triplet energy of pentacene is thus probably slightly lower

For personal use only.

than the excitation energy of $^1\Delta$ O_2, and this could lead to a more rapid fall-off of k_Q with triplet pentacene as donor, as opposed to singlet oxygen, as the lowest triplet energy of the acceptor is increased. A steric factor may also affect rate constants in solution, particularly if k_Q is considerably less than that expected for the diffusion controlled reaction (26). Large triplet pentacene molecules are likely to be subject to greater steric hindrance in the process of exchanging energy than small singlet oxygen molecules. This may be of particular significance when the acceptor is a square planar complex with the appropriate orbitals localized on the central metal atom.

The crystal and molecular structure of *trans*-chloro(3-hydroxypropyl-*N*,*N*-dimethylaminocarbene)-bis(dimethylphenylphosphine)platinum(II) hexafluorophosphate

ROBERT F. STEPANIAK AND NICHOLAS C. PAYNE[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 4, 1977

ROBERT F. STEPANIAK and NICHOLAS C. PAYNE. Can. J. Chem. **56**, 1602 (1978).

The crystal and molecular structure of *trans*-chloro(3-hydroxypropyl-*N*,*N*-dimethylaminocarbene)bis(dimethylphenylphosphine)platinum(II) hexafluorophosphate has been determined from three-dimensional X-ray data collected on an automated four circle diffractometer using CuKα radiation. The compound crystallizes in the orthorhombic space group $Pna2_1$, with $Z = 4$, and cell dimensions $a = 14.403(2)$, $b = 12.631(2)$, and $c = 16.151(2)$ Å. Full matrix least-squares refinement on F gave a final conventional R factor of 0.047 for 3442 observations with $I > 3\sigma(I)$. The cation coordination geometry is square planar, with the carbene ligand lying approximately perpendicular to the plane. The Pt—Cl bond length is 2.356(4) Å and the Pt—C(carbene) distance is 1.978(12) Å. The C(carbene)—N bond length is 1.293(16) Å. These dimensions are discussed in terms of the *trans* influences of the carbene and chloride ligands and the bonding in the carbene species.

ROBERT F. STEPANIAK et NICHOLAS C. PAYNE. Can. J. Chem. **56**, 1602 (1978).

On a déterminé la structure cristalline et moléculaire de l'hexafluorophosphate du chloro-(hydroxy-3-propyl-*N*,*N*-diméthylaminocarbène)bis(diméthylphénylphosphine) platine(II) *trans* à partir de données de rayon-X tridimensionnelles recueillies sur un diffractomètre automatique à quatre cercles utilisant la radiation CuKα. Le composé cristallise dans le groupe d'espace orthorhombique $Pna2_1$, avec $Z = 4$, et des dimensions de mailles $a = 14.403(2)$, $b = 12.631(2)$ et $c = 16.151(2)$ Å. On a affiné la structure par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.047 pour 3442 observations avec $I > 3\sigma(I)$. La géométrie de coordination du cation est plan carrée alors que le ligand carbène se trouve approximativement perpendiculaire au plan. La longueur de la liaison Pt—Cl est 2.356(4) Å et la distance Pt—C(carbène) est 1.978(12) Å. La longueur de la liaison C(carbène)—N est 1.293(16) Å. On discute de ces dimensions en terme des influences *trans* des ligands carbène et chlorure et de la nature des liaisons dans les espèces carbène.

[Traduit par le journal]

Introduction

The investigation of the structure, bonding, and geometry of carbene ligands has been the focus of much research. Square planar complexes of Pt(II) containing tertiary carbene ligands have been studied using X-ray crystallographic techniques (1–6). The carbene ligands in these compounds can conveniently be divided into two categories:

A *B*

X, Y = OR, NR′R″, SR
R = alkyl, aryl
R′R″ = H, alkyl, aryl

Several structures of complexes containing ligands of type *A* have been reported (4–6). In general it has been concluded that virtually all the stabilization of the C(carbene) atom is by electron donation from the nucleophilic substituents X and Y. Metal–ligand $d\pi$–$p\pi$ interaction has been shown to be at best very weak by both structural (4, 5)[2] and spectroscopic (8) studies. Pt—Cl bond lengths in complexes where the Cl^- is *trans* to type *A* carbene ligands show that these carbenes exert a very strong *trans* influence (5, 6).

We have determined the structures of several square planar cationic complexes of Pt(II) containing carbene ligands of type *B* (1–3) in order to study the bonding and *trans* influence of these entities. All complexes studied contain a methyl ligand in the coordination site *trans* to the carbene. The Pt—C(methyl) bond lengths observed have proved to be poor indicators of the *trans* influence of the carbene ligands.

Recent successes in estimating the *trans* influence of carbon donor ligands from Pt—Cl bond lengths (9) prompted us to determine the structure of a complex where a chloride ion replaced the methyl ligand opposite a carbene ligand of type *B*. The complex selected was the product of ring cleavage of

a cyclic alkoxycarbene ligand (10), which was prepared by the method of Chisholm and Clark (11). Treatment with dimethylamine opened the ring, and the *trans* methyl ligand was subsequently replaced by Cl^- by reaction with HCl. Detailed preparative, spectral, and physical data for the salt are presented elsewhere (12).

In addition to examining the *trans* influence of the carbene, we are also interested in the effect of ligands of varying *trans* influence on the Pt—C(carbene) bond, and in the structure and geometry of the type *B* carbene ligand as compared to carbenes of type *A*.

Experimental

Irregular octahedral blocks of **1**, *trans*-[PtCl{HO$(CH_2)_3$-C=NMe_2}$(PMe_2Ph)_2$]PF_6, were obtained by recrystallization from a mixture of dichloromethane and ether. Preliminary Weissenberg and precession photographs indicated the orthorhombic system. The observed systematic absences, $0kl$; $k + l$ odd, and $h0l$; h odd, are consistent with the centrosymmetric space group *Pnam*, an alternate setting of *Pnma* (D_{16}^{2h} No. 32) and the acentric space group $Pna2_1$ (C_{2v}^9 No. 33) (13).

The density of the crystals, determined by flotation in CH_2BrCH_2Br and CCl_4, and the cell volume indicate a Z value of 4. For *Pnam* the ions must occupy special positions of site symmetry m, while no symmetry restrictions are imposed upon the ions in space group $Pna2_1$. The presence of the long alcoholic group bonded to C(carbene) minimizes the possibility of the presence of a mirror plane through Cl, Pt, and the carbene ligand, so m site symmetry was considered unlikely. The structure solution was therefore initiated in $Pna2_1$, and successfully completed.

A crystal with well developed faces and of dimensions $0.22 \times 0.17 \times 0.18$ mm[3] was selected. Optical goniometry was used to identify the 15 crystal faces, the forms {111}, {11$\bar{1}$}, and {01$\bar{1}$}, and the faces (001), (0$\bar{1}$1), ($\bar{1}\bar{1}$0), (110), and (1$\bar{1}$0). The crystal was mounted on a Picker FACS-1 computer controlled diffractometer taking care that symmetry axes were not coincident with the spindle axis to avoid multiple reflections (14). Twenty-five reflections in the range $34° < 2\theta < 72°$ (CuKα, $\lambda = 1.54056$ Å) were centered. Least-squares refinement of the setting angles[3] was carried out to obtain an orientation matrix, the unit cell constants, and their estimated standard deviations (esd). These and other crystal data are given in Table 1. The ω scans of several intense, low angle reflections were recorded to check crystal mosaicity. The mean width at half height was 0.06°. The conditions for data collection are also given in Table 1. 5296 hkl and $hk\bar{l}$ intensities were recorded out to a 2θ maximum of 125°. The five standard reflections showed a mean increase of 10(1)% over the period of the experiment, and a slight deterioration in peak quality was observed. No correction was applied to the data for this increase in intensity, which is attributed to an increase in crystal mosaicity. All data were corrected for background, Lorentz, and polarization effects, and a standard deviation σ assigned to each value as previously described (15). p was taken as 0.03. 3442 observations were found to have $I > 3\sigma$. The structure solution was based on these reflections only. All data with $I > 0$ were corrected for absorption[3]. The maximum and minimum transmission coefficients are 0.407 and 0.261 respectively.

[3]The computer programs used include local modifications of the following: cell refinement and orientation matrix, PICKTT, from W. C. Hamilton's MODE1; full matrix least-squares, J. A. Ibers' NUCLS; Patterson and Fourier syntheses, A. Zalkin's FORDAP; function and errors, W. R. Busing, K. O. Martin, and H. A. Levy's ORFFE; crystal structure illustrations, C. K. Johnson's ORTEP; absorption correction by the analytical method of de Meulenaer and Tompa in the program AGNOST as modified by Cahen and Ibers (7).

Structure Solution and Refinement

From a three-dimensional Patterson function the positional parameters of the Pt atom were obtained. These values, together with an overall scale factor, were varied in the cycles of least-squares refinement. Agreement factors were obtained of

$$R_1 = \frac{\sum(||F_o| - |F_c||)}{\sum |F_o|} = 0.232$$

and

$$R_2 = \left[\frac{\sum w(|F_o| - |F_c|)^2}{\sum w(F_o)^2}\right]^{1/2} = 0.293$$

where F_o and F_c are the observed and calculated structure factor amplitudes. w is the weighting factor given by $4F_o^2/\sigma^2$. The function minimized in all least-squares calculations was $\sum w(|F_o| - |F_c|)^2$. The scattering factors for Pt, P, Cl, F, O, N, and C were those of Cromer and Waber (16) and those for the H atom were taken from Stewart, Davidson, and Simpson (17). Corrections for the anomalous dispersion of Pt, P, and Cl atoms were those calculated by Cromer and Liberman (18).

Remaining non-hydrogen atom positions were determined from successive least-squares refinements and difference Fourier syntheses. The orientation of the cations in the unit cell was found to be such as to preclude m symmetry as required by space group *Pnam*, so the choice of $Pna2_1$ as the correct space group was confirmed. As a further test for the presence of a centre of symmetry, the distribution of E values was compared to theoretical calculations for centric and acentric crystals. However, the results were inconclusive.

The phosphine phenyl rings were refined as rigid groups (19) with D_{6h} symmetry, and a rigid group of O_h symmetry described the six F atoms of the anion. During refinement with isotropic non-group atom temperature factors and overall group thermal parameters being varied, together with positional parameters and an overall scale factor, the temperature factor of the F6 rigid group increased to about 26 Å^2. An examination of a difference Fourier synthesis suggested either excessive thermal motion of the anion, or the presence of disorder. Two models were proposed to account for this. Refinement of F atoms with anisotropic thermal parameters resulted in unacceptable anion geometry, and large amplitudes of vibration. A better description was obtained by re-

[a]Thermal parameters are given as $U_{ij} \times 10^4$ (Å^2). The form of the ellipsoid is given by $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* \cos\gamma^* + 2U_{13}hla^*c^* \cos\beta^* + 2U_{23}klb^*c^* \cos\alpha^*)]$.
[b]Numbers in parentheses given here and in other tables are estimated standard deviations in the least significant digits.
[c]Isotropic thermal parameters are given as U (Å^2).

taining the group constraints upon the F6 entities, and introducing a second rigid group. A multiplicity parameter was refined, and the appropriate constraints were applied to the derivatives (2). The P atom of the anion, P(3), was assigned an isotropic thermal parameter, and refined as an individual atom.

$Pna2_1$ is a polar space group, so the presence of polar dispersion error must be entertained (20). Each enantiomorphic structure was refined, varying the same parameters in each case. All non-group atoms of the cation were allowed to vibrate anisotropically. Individual isotropic thermal parameters were varied for phenyl ring rigid groups and overall group temperature factors were calculated for the F6 rigid groups. Values of R_1 and R_2 for the original structure were 0.051 and 0.060 respectively. The second model converged at $R_1 = 0.060$ and $R_2 = 0.074$. Application of Hamilton's R factor significance test to the R_2 values showed that the second could be rejected at the 0.005 significance level.

[a] Ring C atoms are numbered sequentially. 1C(1) is bonded to P(1).
[b] Overall isotropic thermal parameters were applied to each atom in the F6 groups.

The contributions to F_c of 34 H atoms were included in the final least-squares cycles. Ten phenyl H atom positions were obtained using a C—H distance of 0.95 Å. Positional parameters for the 6 methylene H atoms and the 18 methyl H atoms were calculated from an ideal tetrahedral geometry. A C—H distance of 1.00 Å was assumed. The H atom thermal parameters were 1.0 Å^2 greater than those of the atoms to which they are bonded. Definite evidence for the H atom bonded to O was not observed in the electron density maps, so structure factors were not calculated for this atom. However, all others were present in a difference Fourier synthesis.

The final two cycles of full matrix least-squares refinement employed 3421 observations with $I > 3\sigma$. 187 parameters were varied. Final agreement parameters of $R_1 = 0.047$ and $R_2 = 0.054$ were obtained. The largest parameter shift was associated with the disorder model for the anion, 1.81σ, in the final cycle. Other shifts were all less than 0.2 esd. The error on an observation of unit weight is 1.75 electrons. The largest peak in a total difference Fourier synthesis is associated with the disordered PF_6 at (0.269, 0.229, −0.0358), and has an electron density of 1.38(13) e Å^{-3}. The disorder multiplicity parameter was 0.51(2). A statistical examination of the structure factors in terms of Miller indices, magnitudes of F_o, λ^{-1} sin θ, and diffractometer setting angles showed no unusual trends. Examination of F_o and F_c for intense reflections showed no evidence for secondary extinction.

Final positional and thermal parameters of the non-group atoms are presented in Table 2. Rigid group positional and orientation parameters are

given in Table 3, and derived positional and thermal parameters of rigid group atoms are given in Table 4. Calculated H atom positional and thermal parameters are shown in Table 5, and a list of $10|F_o|$ and $10|F_c|$ in electrons, together with the weight $w \times 10^4$, is presented in Table 6.[4]

Description of the Structure

Crystals of the salt result from the packing of discrete ions. The nearest anion-cation approach is 2.93 Å, between O and 1F(2). Disorder of the anion is observed with each possible orientation being equally populated. The cation with the atom labelling scheme is presented in Fig. 1, and an overall stereoview of the cation is shown in Fig. 2. Intraionic bond distances and angles together with their estimated standard deviations are listed in Table 7.

The square plane of the metal atom is slightly distorted, since the P(1)—Pt—P(2) angle is 174.3(2)°.

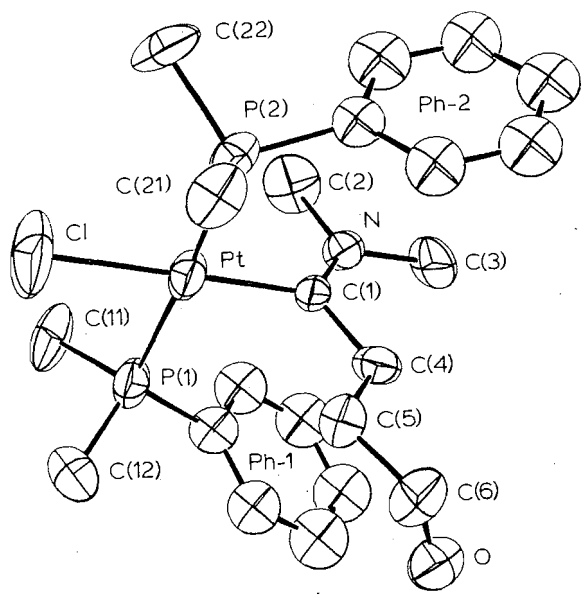

FIG. 1. A view of the cation, showing the atom numbering scheme. Thermal ellipsoids are drawn at the 50% probability level.

[4]Tables 5 and 6 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

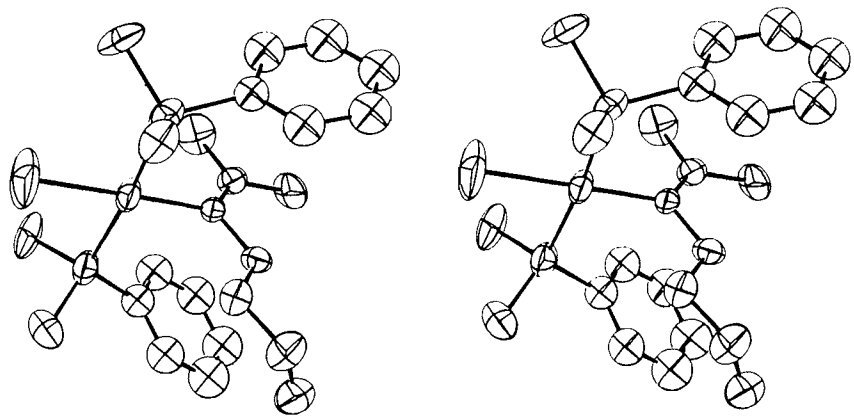

FIG. 2. A stereoview of the cation. Atoms are drawn at the 50% probability level.

The phosphine ligands are bent back away from the carbene ligand. The mean C(1)—Pt—P angle is 92.9(2)° and the average Cl—Pt—P angle is 87.2(3)°. A weighted least-squares plane calculated through Pt, Cl, P(1), P(2), and C(1) is given in Table 8. P(1) lies 0.020(6) Å above this plane and is farthest from it. None of the other atoms deviate significantly from the plane. The Cl—Pt—C(1) angle is 179.4(4)°.

The dimethylphenylphosphine ligand orientations and geometries are similar to those observed in other structures (2, 3). Thus the phenyl rings lie on the carbene side of the square plane and virtually perpendicular to it. The angles between the normals to the planes are 94° and 92° for Ph-1 and Ph-2 respectively. The phosphine P atoms are equidistant from the metal atom at 2.312(4) Å.

The weighted least-squares plane of the carbene ligand (Table 8), defined by C(sp^2), N, and the atoms C(4), C(2), and C(3) to which they are bonded, lies at an angle of 90.2° to the coordination plane of the metal atom. The N atom is farthest from the plane and lies 0.016(12) Å above it. The carbene ligand can be written as $RCH_2C{=}NMe_2$, where R is an ethanolic substituent. Of the atoms making up this group, C(5) and C(6) lie only slightly below the carbene plane, and O is 1.15 Å above it.

TABLE 8. Weighted least-squares planes

Atom	Deviation from plane (Å)
Atoms included: Pt, Cl, P(1), P(2), C(1)	
Equation of plane: $6.763x + 7.207y - 10.88z = -1.641$	
Pt	−0.0002(4)
Cl	0.000(7)
P(1)	0.020(6)
P(2)	0.008(4)
C(1)	0.020(14)
Atoms included: C(1), N, C(2), C(3), C(4)	
Equation of plane: $10.31x - 8.759y - 1.355z = 0.3068$	
C(1)	−0.008(12)
N	0.016(12)
C(2)	−0.008(16)
C(3)	−0.014(18)
C(4)	0.003(13)
C(5)	−0.067
C(6)	−0.039
O	1.15

The Pt—C(sp^2) bond distance is 1.978(12) Å and is shorter by 5.6σ than that of 2.079(13) Å observed for complex **2**, $[Pt(MeC{=}NMe_2)Me(PMe_2Ph)_2]PF_6$ (2). Within the carbene ligand, the C(sp^2)—N bond length is 1.293(16) Å. This is not significantly longer than that of 1.266(15) Å observed in **2**, for the bond lengths differ by 1.2σ. The mean N—C(methyl) distance is 1.465(15) Å and the C(sp^2)—C(4) bond length is 1.505(20) Å. These values too are equivalent to those obtained for **2**. The angles about the C(carbene) atom have a mean value of 120(2)°. The mean C(1)—N—C(methyl) angle is 122(1)° and the C(2)—N—C(3) angle is 116(1)°. Coplanarity of C(1), N, C(2), C(3), and C(4), as well as the magnitude of the angles about C(1) and N, are indicative of sp^2 hybridization. The C(sp^3)—N—C(sp^3) angle for the dimethylamino substituent in **2** is 113(1)°. The mean C(sp^3)—C(sp^3) bond length in the alcoholic substituent is 1.511(7) Å, and the mean angle at the C(sp^3) atoms of this group is 114(3)°.

The Cl ligand is located *trans* to the carbene and a Pt—Cl bond of 2.356(4) Å is observed. This value is of comparable magnitude to those of 2.362(3) and 2.361(5) Å obtained for **3**, *cis*-$PtCl_2\{C(NPhCH_2)_2\}PEt_3$ (5) and **4**, *cis*-$PtCl_2\{C(OEt)NHPh\}PEt_3$ (6) respectively. In these complexes carbene ligands also lie opposite a Cl ligand.

The disorder model for the anion is satisfactory, in that the mean P—F bond length is 1.58(2) Å, and the mean F—P—F angles are 89.9(6) and 174.2(7)° for *cis* and *trans* F atoms, respectively.

[a]Secondary carbene ligand.

Discussion

Pt—Cl bond lengths are useful for determining the *trans* influence of the ligand in the opposite coordination site (9). For example, the Pt—Cl bond length of 2.276(1) Å in *cis*-$PtCl_2(CO)PPh_3$ (20) is shorter than that of 2.371(3) in *trans*-$PtMeCl(PPh_2Me)_2$ (21) by 31.7σ. In the former complex the Cl ligand lies opposite CO, a ligand of very weak *trans* influence, whereas in the latter Cl is opposite methyl, a strong *trans* influence ligand. In this study, the Pt—Cl bond length is 2.356(4) Å. This is 3.0σ shorter than that where Cl is *trans* to a methyl ligand and 20.0σ longer than that where Cl is *trans* to CO. The type *B* carbene ligand displays a *trans* influence approximately as large as that of the methyl ligand. Comparable Pt—Cl bond lengths of 2.362(3) and 2.361(5) Å have been obtained for the complexes **3** and **4** respectively, where type *A* tertiary carbene ligands lie opposite Cl. Thus the *trans* influences of the different types of tertiary carbene ligands are similar, suggesting that the nature of the Pt—C(sp^2) bonds is also similar.

In Table 9 are presented some Pt—C(carbene) bond length data for square-planar platinum(II) systems. The Pt—C(sp^2) bond lengths in the three complexes where Cl lies opposite carbene ligands are not significantly different. The mean bond length is 1.983(14) Å, shorter by 4.7σ than the bond distance where a carbene lies *trans* to another carbene, and 6.0σ shorter than that where a methyl ligand lies opposite a carbene. The above bond length differences can be attributed to the weak *trans* influence of Cl and to the strong *trans* influences of the methyl and carbene ligands. However, in the complex *trans*-[Pt(CH_2C—OCH_2CH_2)Me$(PMe_2Ph)_2$]PF_6 (3) the Pt—C(carbene) bond of 2.00(2) Å is shorter than expected when methyl is present in the *trans* coordination site, but in this alkoxycarbene compound the high electronegativity of the oxygen atom may result in a greater metal–ligand π interaction (25).

Also shown in Table 9 is a summary of C—N distances for carbene ligands of types *A* and *B*. Values are included for the secondary carbene ligands in RuI_2{HC—N(Me)-*p*-C_6H_4Me}CO(C≡N-*p*-C_6H_4Me)(PPh_3) (23) and $RhCl_3(HC$—$NMe_2)$-$(PEt_3)_2$ (24), where the C—N bonding is expected to be similar to that in the type *B* ligands. The single nucleophilic substituent in type *B* and secondary carbene ligands must contribute more electron density to stabilize the C(sp^2) atom than either of the two substituents in a type *A* ligand. This is apparently reflected in the C—N bond lengths. The majority of type *A* ligands have values around 1.33 Å, whereas the type *B* ligands all have distances less than 1.30 Å.

Interaction fluorure d'hydrogène – acide perchlorique: Reactivité du nitromethane dans le milieu

CLAUDE BELIN ET JACQUELINE POTIER

Laboratoire des Acides Minéraux (associé au C.N.R.S. N° 79), Université des Sciences et Techniques du Languedoc, Place Eugène Bataillon, 34060 Montpellier Cédex, France

Reçu le 20 septembre 1977

CLAUDE BELIN et JACQUELINE POTIER. Can. J. Chem. **56**, 1610 (1978).

Le fluorure d'hydrogène donne, avec l'acide perchlorique, un composé à fusion non congruente (−117°C); par spectroscopie infrarouge, on montre que $HClO_4$ est fixé sur un polymère $(HF)_n$ par liaison faible. Le liquide de même composition contient encore une faible proportion de ce complexe; HF est bien une base vis-à-vis de $HClO_4$. La réactivité du nitrométhane a été étudiée dans ce milieu liquide acide, on montre que $MeNO_2$ y est une base légèrement plus forte que HF.

CLAUDE BELIN and JACQUELINE POTIER. Can. J. Chem. **56**, 1610 (1978).

Hydrogen fluoride reacts with perchloric acid yielding an incongruently melting compound (−117°C); by ir spectroscopy, we demonstrate that $HClO_4$ is linked to a $(HF)_n$ polymer through a weak hydrogen bond. The liquid of the same composition still contains a small amount of the complex; HF is really a base for $HClO_4$. The reactivity of $MeNO_2$ was studied in this liquid acidic medium and the nitromethane is found to be somewhat stronger than HF.

Introduction

Les solutions anhydres des acides HF et $HClO_4$ doivent être des milieux extrèmement acides; logiquement, leur acidité de Hammett doit varier de −10.8 pour HF (1) à la valeur estimée, −16, pour $HClO_4$ (2). En fait, on ne sait pratiquement rien sur ces solutions à l'exception des conclusions contradictoires de Hantzsch (3) (composé cristallisé $H_2F^+ClO_4^-F$ 57°C) et de Brauer et Distler (4) (inexistence de ce composé).

Dans ce mémoire, on étudie successivement: (*i*) le diagramme des équilibres liquide–solide entre HF et $HClO_4$ où est mis en évidence le composé cristallisé HF–$HClO_4$ en fait très différent de celui envisagé par Hantzsch; (*ii*) la nature des interactions entre les deux acides dans ce composé cristallisé (par spectroscopie de vibration infrarouge); (*iii*) la nature des composés présents dans le liquide de même composition et (*iiii*) la compétition, vis-à-vis de l'acide $HClO_4$, des bases très faibles HF et CH_3NO_2.

Méthodes expérimentales

Le fluorure d'hydrogène est un produit Matheson (pureté 99.9%) bidistillé. Le fluorure de deutérium est obtenu par action, à haute température, de l'acide deutérosulfurique anhydre sur du fluorure de calcium (Merck, 99.95%). D_2SO_4 est préparé par hydratation à l'eau lourde (99.9% en deutérium), de SO_3 synthétisé suivant la méthode de Bernard (5) (pureté 99.98%). Les mélanges sont réalisés à l'abri de toute trace d'humidité et analysés thermiquement dans un tube laboratoire en polytrifluorochloroéthylène (Kel-F). Le nitrométhane CD_3NO_2 est un produit Merck Uvasol titrant au moins 99% en deutérium. L'acide perchlorique anhydre est préparé au laboratoire selon la méthode mise au point par Mascherpa (15) et titre au minimum 99.96 mol%.

Equilibres liquide–solide dans le binaire $HClO_4$–HF

Le diagramme des équilibres liquide–solide a été établi par atd à l'échauffement. La fig. 1 reproduit les résultats obtenus. On relève essentiellement deux paliers d'invariance. Le premier à −117°C entre 0 et 55 mol% de $HClO_4$. Le diagramme des effets thermiques est, dans ce cas, maximum à 50%, ce qui permet de conclure à l'existence dans l'état solide du composé 1·1 HF–$HClO_4$.

Le second palier d'invariance à −118.8°C s'étend sur toutes les concentrations et son diagramme de Tamman[1] présente deux maxima à 50 et 67%; ce palier d'invariance est donc lié à deux phénomènes physiques différents.

La forme du liquidus entre 55 et 67 mol% de $HClO_4$ amène à attribuer ce palier à l'eutectique entre le composé 1·1 et $HClO_4$ cristallisé, ceci rend compte du maximum à 67%. On peut penser que le second maximum est lié à l'existence d'une deuxième forme du composé 1·1 dont la température de transformation serait très voisine de celle de l'eutectique.

Le tableau suivant rend compte des principales

[1]Diagramme de Tamman: il donne en unité arbitraire l'évolution de l'effet thermique corrigé en fonction de la concentration relative des constituants, mais non corrigé en fonction des chaleurs spécifiques:

$$T = sm/(M_1X_1 + M_2X_2);$$

s, surface de l'effet thermique sur la courbe d'enregistrement; *m*, masse de l'échantillon; M_1 et M_2, masses molaires des constituants; X_1 et X_2, fractions molaires des constituants.

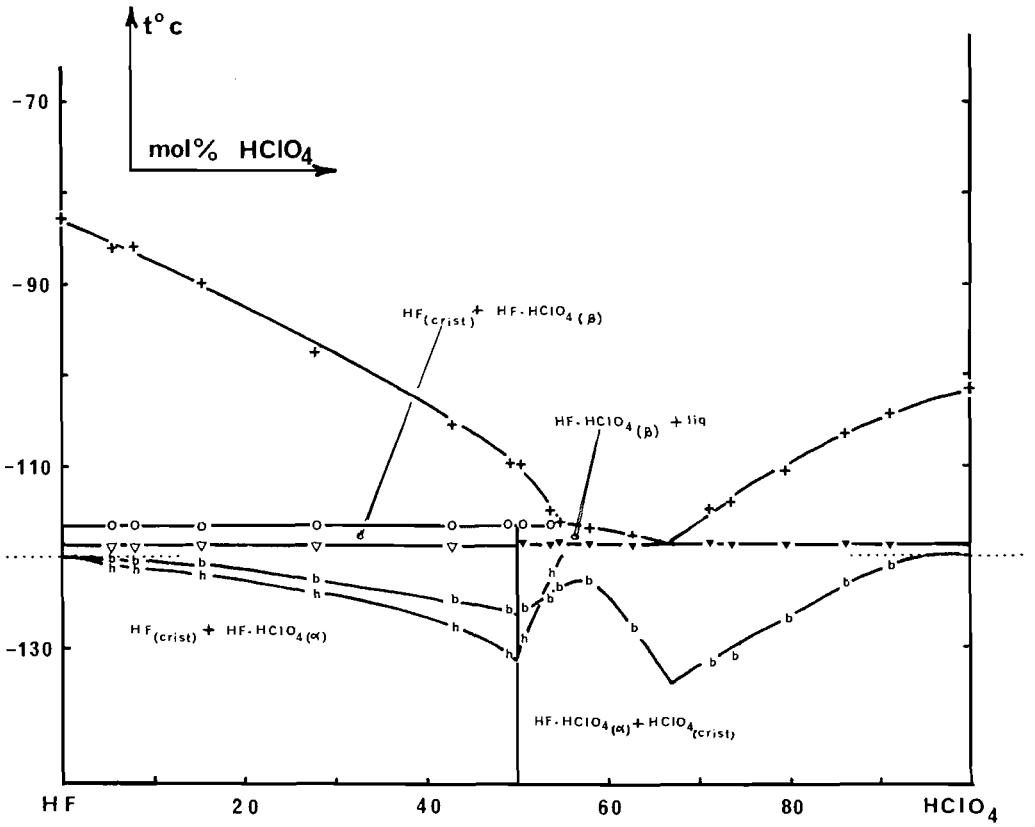

FIG. 1. Diagramme des équilibres liquide–solide du système $HClO_4$–HF; +, fin de fusion; O, invariant de transition; ▼, invariant d'eutexie; ▽, invariant de transformation dans l'état solide; h, effet thermique de l'invariant de transition; b, effet thermique global des invariants d'eutexie et de transformation dans l'état solide.

caractéristiques de ce binaire; α et β représentent les

$$HF_{(crist)} \leftrightarrow HF_{(liq)} \qquad F = -83.6°C$$

$$(HClO_4{\cdot}HF)_{(\beta)} \leftrightarrow HF_{(crist)} + \text{liquide eutectique} \quad \begin{cases} T = -117°C, \\ \text{mol\% } HClO_4 = 55 \end{cases}$$

$$(HClO_4{\cdot}HF)_{(\alpha)} \leftrightarrow (HClO_4{\cdot}HF)_{(\beta)} \quad \begin{cases} T = -118.8°C, \\ \text{mol\% } HClO_4 = 50 \end{cases}$$

$$(HClO_4{\cdot}HF)_{(\beta)} + HClO_{4(crist)} \leftrightarrow \text{liquide eutectique} \quad \begin{cases} T = -118.8°C, \\ \text{mol\% } HClO_4 = 67 \end{cases}$$

deux formes allotropiques cristallisées du composé.

Le composé $HF{\cdot}HClO_4$ se forme bien, mais avec des caractéristiques très différentes de celles indiquées par Hantzsch. Le bas point de fusion observé (fusion non congruente) conduit à penser à une association faible plutôt qu'à une réaction $HClO_4 + HF \leftrightarrow H_2F^+ClO_4^-$. Par ailleurs, le système est totalement miscible au-dessus de −60°C.

Spectroscopie de vibration du composé 1·1 cristallisé

Les spectres ir du composé 1·1 hydrogéné et partiellement deutérié (dans la suite de ce travail, par raison de simplicité on adopte la notation "deutérié"), ont été enregistrés à −150°C, ils sont reproduits sur la fig. 2. On y relève essentiellement deux domaines: entre 4000 et 2000 cm^{-1}, celui des vibrations de valence ν_{XH} et ν_{XD} (X = F ou O) et entre 1400 et 400 cm^{-1}, celui des vibrations de valence de ClO_3, Cl—OH, des déformations δ ClO et évidemment des déformations δ_{XH} et δ_{XD}. L'absence de bandes entre 1000 et 1100 cm^{-1} dues à l'ion perchlorate permet de rejeter définitivement la structure ionique de Hantzsch.

Domaine 4000–2000 cm^{-1}

Trois bandes apparaissent à 3415, 3230 et 3060 cm^{-1}, elles glissent par deutériation (50% en deutérium) respectivement à 2510, 2403 et 2300 cm^{-1} (rapports isotopiques 1.36, 1.34 et 1.33). Ces trois bandes sont retrouvées par dilution isotopique à 3415, 3250 et 3080 cm^{-1}, elles sont donc attribuables à des vibrations fondamentales et correspondent aux vibrations de valence ν_{FH} et ν_{OH}. Cependant pour un échantillon ne contenant que 14% de deutérium,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

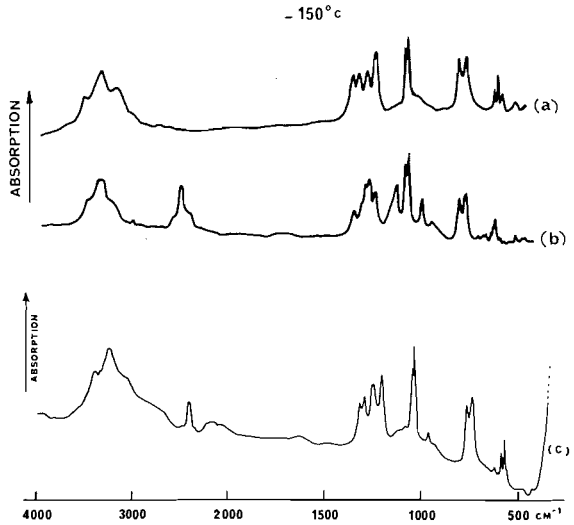

FIG. 2. Spectres infrarouges à $-150°C$ du composé cristallisé $HF{\cdot}HClO_4$: (*a*) hydrogéné; (*b*) partiellement deutérié (50%); (*c*) partiellement deutérié (14%).

on observe dans le domaine ν_{XD} une bande fine à 2410 cm^{-1} et une bande plus large centrée à 2160 cm^{-1}.

Dans ce domaine le spectre de HF cristallisé présente deux bandes à 3401 et 3056 cm^{-1}, l'intensité de la deuxième étant nettement plus importante que celle de la première; ces observations sont en accord avec celles de Kittelberger et Hornig (6), Sastri et Hornig (7), Giguère et Zengin (8). Par ailleurs, Pavia au laboratoire (9) ainsi que Karelin et Grigorovich (10) ont montré que pour $HClO_4$ cristallisé, ν_{OH} apparaît, pour l'un à 3350 cm^{-1}, pour les autres à 3355 cm^{-1}. Manifestement, le spectre obtenu, ici, n'est pas la somme des spectres des composés de départ; il y a donc interaction, probablement par liaison hydrogène.

La formation d'un complexe moléculaire simple par liaison hydrogène de type $HF\cdots HOClO_3$ ou de type $HO—ClO_2—O\cdots HF$ entraînerait l'existence de deux vibrations de valence XH seulement. La présence des trois bandes à 3415, 3230 et 3060 cm^{-1} ne peut s'expliquer que par l'existence d'un polymère pour l'une des molécules d'acide. Or, on sait (9), que $HClO_4$ est toujours monomère, tandis que Atoji et Lipscomb (11) ont montré, par radiocristallographie, que HF est un polymère en chaîne. Dans ces conditions, il semble logique de penser que l'interaction des deux acides est en réalité celle de $HClO_4$ monomère sur HF polymère.

On attend alors, dans ce domaine, au moins trois bandes: deux pour les mouvements en phase et en opposition de phase du polymère $(HF)_x$ et une pour le monomère $HClO_4$ fixé sur le polymère $(HF)_x$ en F comme sur le schéma 1 suivant. Dans ce cas, on admet que les couplages entre les différentes molécules de $HClO_4$ ne peuvent être détectés mais sont responsables de la largeur du massif.

Le spectre du composé à grande dilution isotopique (14%) doit être le plus simple à analyser; en effet on élimine ainsi certains modes de couplage et on doit attendre dans le domaine des ν_{XD} seulement deux bandes correspondant à ν_{FD} et ν_{OD}. La bande fine à 2410 cm^{-1} est à associer à la bande intense à 3230 cm^{-1} sur le spectre du composé totalement hydrogéné ($\rho = 1.34$) et à la bande également intense observée à 2403 cm^{-1} sur le spectre du composé partiellement deutérié (50%); signalons à ce sujet que dans un mélange DF,HF à 99% en HF (7), la bande unique ν_{FD} est observée à 2403 cm^{-1}. Il apparaît donc très logique d'attribuer cette bande à ν_{FD} de l'acide fluorhydrique et par conséquent la bande large de plus basse fréquence (2160 cm^{-1}) à ν_{OD} de l'acide perchlorique; quant à l'épaulement à 2080 cm^{-1}, on pourrait y voir, avec plus de réserves, la trace d'une harmonique (2×1085) vraisemblablement exaltée par résonance de Fermi; l'attribution de la bande à 1085 cm^{-1} est donnée ultérieurement.

Sur le spectre du composé totalement hydrogéné, l'attribution spécifique du triplet à 3415, 3230 et 3060 cm^{-1} est plus difficile. Les deux plus hautes fréquences doivent probablement être reliées aux deux modes ν_{FH} en phase et en opposition de phase du polymère HF_x; la bande à 3060 cm^{-1} est trop haute pour être attribuée purement à ν_{OH} de $HClO_4$ ($\rho = 1.41$ avec ν_{OD}) et on doit penser à un couplage avec ν_{FH}.

Domaine 1400–400 cm^{-1}

A priori, les vibrations de valence du groupe ClO_3 doivent être peu affectées par cette association. La comparaison des spectres de $HClO_4$ anhydre et du composé $HClO_4{\cdot}FH$ cristallisé le confirme (fig. 3).

Les principales différences sont: l'existence d'une nouvelle bande relativement intense à 1315 cm^{-1} et d'un doublet au niveau de 750 cm^{-1}, le déplacement

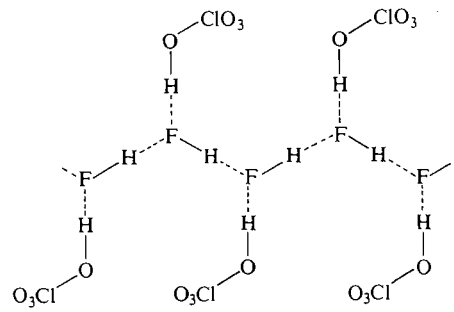

SCHÉMA 1

For personal use only.

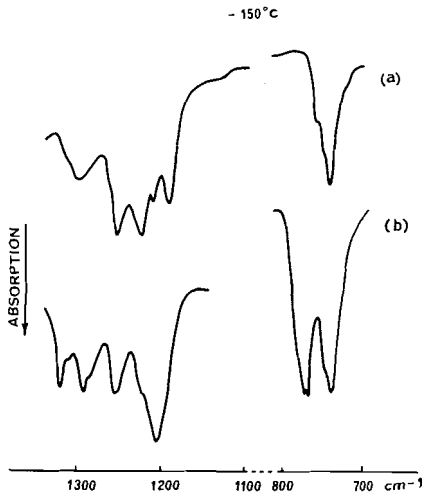

FIG. 3. Spectres ir à −150°C entre 1350 et 700 cm^{-1}; (*a*) $HClO_4$ anhydre cristallisé; (*b*) $HClO_4$·HF cristallisé.

de +15 cm^{-1} de la bande à 1185 cm^{-1} et l'augmentation de son intensité.

Sur le spectre du composé "deutérié" apparaissent (fig. 2), trois nouvelles bandes à 1085, 960 et 595 cm^{-1}. Simultanément, les bandes à 1315, 765 et 565 cm^{-1} diminuent d'intensité tandis que la bande à 1200 cm^{-1} se déplace de +5 cm^{-1} et diminue aussi d'intensité. Les trois nouvelles bandes sont, sans problème, attribuées à des déformations δ_{XD}. Quatre déformations sont attendues, les déformations dans le plan δ_{FH} et δ_{OH} et les déformations hors du plan correspondantes.

Pour $HClO_4$ cristallisé, on observe δ_{OH} à 1190 cm^{-1} et γ_{OH} à 480 cm^{-1}, tandis que, dans CH_3NO_2·$HClO_4$, δ_{OH} est pointé à 1230 cm^{-1} et γ_{OH} à 755 cm^{-1}. Pour $(HF)_x$ cristallisé, selon les auteurs, δ_{FH} est observé à 1200 cm^{-1} (8) ou à 1025 cm^{-1} (6). Il semble que la faiblesse de la liaison hydrogène F···$HOClO_3$ qui se traduit par un abaissement de fréquence ν_{OH} trois fois plus faible que dans CH_3NO_2·$HClO_4$ ne permette pas d'attribuer la bande à 1315 cm^{-1} à δ_{OH}. Le couple 1200 ↔ 960 cm^{-1} pour $\delta_{OH} \leftrightarrow \delta_{OD}$ est beaucoup plus compatible avec la force de la liaison hydrogène observée ici. Le déplacement de δ_{OH} (+10 cm^{-1}), par rapport à δ_{OH} de $HClO_4$, est tout à fait logique, il est cinq fois plus faible que celui observé pour CH_3NO_2·$HClO_4$.

La bande à 1315 cm^{-1} (1085 cm^{-1} dans le composé "deutérié") doit être attribuée à la déformation dans le plan du polymère $(HF)_x$. Le déplacement de fréquence est important, il traduit sans aucun doute la rigidisation du polymère $(HF)_x$ par addition des molécules d'acide perchlorique et aussi le fait que le fluor est tricoordiné dans le composé.

Les déformations hors du plan γ_{XH}, sont toujours attendues à des fréquences inférieures; un raisonnement analogue à celui suivi pour les déformations dans le plan conduit à attribuer à γ_{OH} la bande à 565 cm^{-1} qui diminue d'intensité lors de la deutériation partielle. Le couple 765 ↔ 595 cm^{-1} est dû à $\gamma_{FH} \leftrightarrow \gamma_{FD}$. Il convient de rappeler qu'on relève ces vibrations à des fréquences particulièrement élevées dans les ions H_2F^+, *n*HF (12). En conclusion, le composé HF·$HClO_4$ est dans l'état solide un composé moléculaire dans lequel subsiste le polymère $(HF)_x$ sur lequel des molécules de $HClO_4$ sont liées par de faibles liaisons hydrogènes aux atomes de fluor.

Présence du composé 1·1 dans l'état liquide

Le spectre d'un mélange de composition 1·1 est reproduit sur la fig. 4. Il est différent de celui du composé cristallisé, particulièrement dans le domaine des ν_{XH}. Le massif avec trois maxima est centré autour de 3600, 3360 et 2600 cm^{-1}. Dans une solution partiellement deutériée de stoechiométrie identique, ces maximums ont glissé à 2650, 2500 et 1950 cm^{-1}; les rapports ρ = 1.36, 1.37 et 1.33 sont corrects pour des maxima aussi mal résolus. Il faut noter sa largeur qui passe de 600 cm^{-1} dans le solide à 1700 cm^{-1} dans le liquide.

Pour HF liquide, ν_{FH} se présente sous forme d'une bande unique centrée à 3450 cm^{-1} alors que pour $HClO_4$ liquide, ν_{OH} ne donne qu'une bande à 3340 cm^{-1}. On est obligé d'admettre que dans l'état liquide, il n'y a pas que coexistence des deux bandes mais, interaction entre HF et $HClO_4$; cette déduction est confirmée par la présence de la bande à 1314 cm^{-1} caractéristique de la libration du polymère $(HF)_x$-$(HClO_4)_x$. Puisque pour le composé 1·1 dans l'état solide, les interactions sont faibles, elles le seront *a priori* plus encore dans l'état liquide.

L'évolution du massif ν_{XH} en fonction de la température entre 0, −100 et −150°C où le complexe est cristallisé peut être suivie sur la fig. 5. Il semble que très progressivement, la bande à 3600 glisse à 3400 cm^{-1} tandis que corrélativement celle à 3360 glisse à 3230 cm^{-1}. Cette évolution de fréquence en fonction de la température est normale, elle conduit à proposer d'attribuer la bande à 3600 cm^{-1} à ν_{FH} et celle à 3360 cm^{-1} à ν_{OH}. Sur cette dernière figure, on

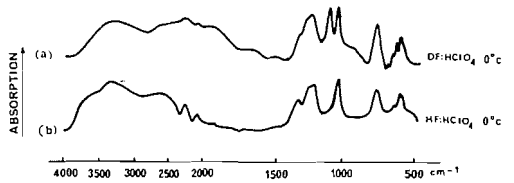

FIG. 4. Spectres ir à 0°C des composés 1·1 dans l'état liquide; (*a*) DF·$HClO_4$; (*b*) HF·$HClO_4$.

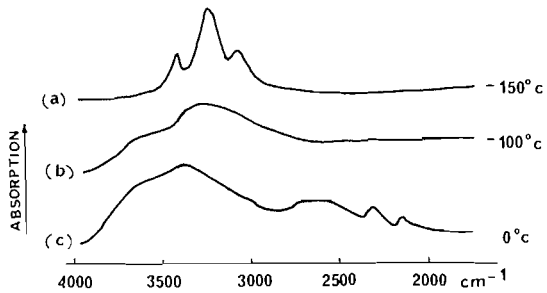

FIG. 5. Evolution du massif XH pour le composé $HF{\cdot}HClO_4$ en fonction de la température; (*a*) −150°C; (*b*) −100°C; (*c*) 0°C.

remarquera la disparition de la bande à 2600 cm^{-1} en fonction de la diminution de la température qui conduit à penser que cette bande est de type A, B, C dans la nomenclature de Hadzi (13). On peut penser qu'elle est liée à l'harmonique de la libration $(FH)_x$ en résonance de Fermi avec la bande large $\nu_{OH} + \nu_{FH}$, comme on l'observe toujours en pareil cas (14). Pour le composé partiellement deutérié, on retrouve cette même forme A, B, C mais avec une intensité moindre; à la bande à 2600 cm^{-1}, on doit associer la bande diffuse autour de 1680 cm^{-1} (fig. 4), qui diminue d'intensité quand la température décroit, pour disparaître presque totalement à −100°C.

La présence de la bande à 1315 cm^{-1} (1050 dans le complexe deutérié) caractéristique du complexe $HF{\cdot}HClO_4$ et l'évolution du massif ν_{XH}, prouve que l'association subsiste dans l'état liquide. Cependant, la largeur du massif entre 4000 et 2000 cm^{-1} ne peut s'expliquer que par la coexistence, à côté du composé 1·1, des molecules $(HF)_x$ et $HClO_4$ libres. Cette conclusion est logique puisque le composé 1·1 ne peut s'autodissocier dans l'état liquide que selon l'équilibre:

$$(HF{\cdot}HClO_4)_x \rightleftarrows (HF)_x + xHClO_4$$

Il est bien évident que dans HF et dans le complexe, les polymères $(HF)_x$ sont d'ordres différents et que, certainement, dans le liquide à la composition du complexe, des polymères de degrés d'association différents peuvent coexister. En conclusion, il y a, dans l'état liquide, interaction entre $(HF)_x$ et $HClO_4$ par liaison hydrogène entre l'atome de fluor et le groupe OH de l'acide perchlorique, mais coexistent simultanément des molécules d'acide perchlorique et de fluorure d'hydrogène.

Etude du mélange liquide CD_3NO_2–HF–$HClO_4$. Basicité relative de HF

Après avoir mis en évidence les propriétés basiques de $(HF)_x$ vis-à-vis de $HClO_4$, il était intéressant d'étudier la compétition vis-à-vis de $HClO_4$ entre cette base et une autre base faible. La base choisie est

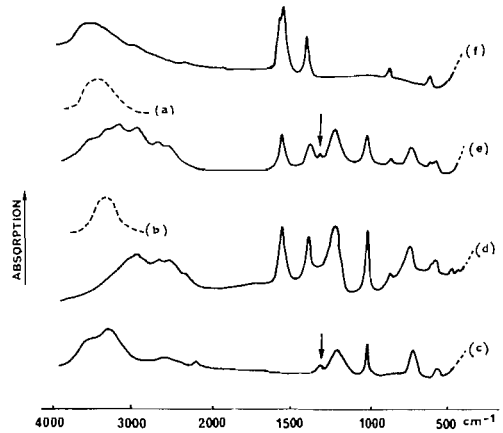

FIG. 6. Spectres ir à +25°C dans l'état liquide; (*a*) HF; (*b*) $HClO_4$; (*c*) $HF{\cdot}HClO_4$; (*d*) $CD_3NO_2{\cdot}HClO_4$; (*e*) CD_3NO_2, $HF,HClO_4$; (*f*) CD_3NO_2,HF; ↓ 1315 cm^{-1}.

le nitrométhane. On a enregistré un spectre d'un mélange de composition molaire: 1 HF, 1 $HClO_4$, 1 CD_3NO_2 (on a utilisé le nitrométhane deutérié pour éviter toute interférence, tant dans le domaine des ν_{XH} que des ν_{ClO_3}). Sur la fig. 6, au spectre obtenu, on a joint, à titre de comparaison, les spectres des différents mélanges binaires correspondants à des composés susceptibles de se former, c'est-à-dire, $HClO_4{\cdot}CD_3NO_2$, $(HF{\cdot}HClO_4)_x$ cristallisé et dans l'état liquide HF,CD_3NO_2, dans le rapport moléculaire 1·1.

On note, tout d'abord, sur le spectre du mélange ternaire HF–$HClO_4$–CD_3NO_2, la présence d'une bande faible à 1315 cm^{-1}: dans ce mélange, existe donc le composé $(HF{\cdot}HClO_4)_x$.

A côté de cette bande, on retrouve un très large massif qui s'étend de 4000 à 2000 cm^{-1}, caractérisé par un maximum vers 3200 cm^{-1} associé à des sous-maxima à 3500 et 2750 cm^{-1}. La comparaison du spectre de $(HF{\cdot}HClO_4)_x$ dans l'état liquide (spectre fig. 7*c*) de $CD_3NO_2{\cdot}HClO_4$ (fig. 7*d*) et de celui du mélange ternaire (fig. 7*e*) montre que ce massif est la somme des différents constituants $(HF{\cdot}HClO_4)_x$, $CD_3NO_2{\cdot}HClO_4$; en particulier, c'est à ce dernier composé que sont associés les sous-maxima à 3200 et 2750 cm^{-1}.

Par ailleurs, il semble que, dans ce milieu, le polymère $(HF)_x$ est moins polymérisé qu'il ne l'est dans le fluorure d'hydrogène liquide, on note en effet, un glissement de +150 cm^{-1} vers les hautes fréquences, déplacement analogue à celui observé aussi bien dans le composé $(HF{\cdot}HClO_4)_x$ que dans le mélange binaire $HF{\cdot}CD_3NO_2$.

En conclusion, dans ce mélange ternaire, existe $(HF{\cdot}HClO_4)_x$, $CD_3NO_2{\cdot}HClO_4$ et $(HF)_x$ largement dépolymérisé. Le nitrométhane n'a donc pas rompu totalement la liaison $HF\cdots HOClO_3$; en conséquence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

vis-à-vis de l'acide perchlorique, les basicités de HF et de CD_3NO_2 doivent être du même ordre de grandeur quoique le nitrométhane soit certainement moins faible, comme le révèlent les glissements de fréquences ν_{OH} et δ_{OH} de $HClO_4$ respectivement $\Delta\nu_{OH}$ de -130 et $-600\ cm^{-1}$ et $\Delta\delta_{OH}$ $+10$ et $+50\ cm^{-1}$.

Conclusion generale

Au cours de ce travail, on a pu montrer que contrairement aux conclusions de Brauer et Distler (4), $HClO_4$ réagit sur la base HF pour former un autre composé $1\cdot1$ dans l'état solide. La force de l'acide $HClO_4$ n'est cependant pas suffisante pour former un complexe moléculaire simple $HF\cdots HO—ClO_3$ même dans l'état solide et, a fortiori, pour protoner HF et donner le composé $H_2F^+ClO_4^-$ annoncé par Hantzsch (3). Le composé formé est dans l'état solide, un polymère $(HF)_x$ fixé à $HClO_4$ par une liaison hydrogène sur l'atome de fluor, beaucoup plus faible que celle existant dans $CD_3NO_2\cdot HClO_4$. Dans le liquide de stoechiométrie $HF:HClO_4$, ce complexe $(HF\cdot HClO_4)_x$ subsiste en équilibre avec $(HF)_x$ et $HClO_4$ libre. Enfin, on a montré que dans une solution ternaire $HF:HClO_4:CD_3NO_2$ coexistent les composés $(HF\cdot HClO_4)_x$ et $HClO_4\cdot CD_3NO_2$ (en grande proportion), et bien entendu $(HF)_x$ et $HClO_4$. L'ensemble de ces faits permet de parler de la basicité de HF dans ces milieux, basicité plus faible que celle de CD_3NO_2.

Anthraniloylanthranilamide (*o*-amino-*N*-(*o*-carbamoylphenyl)benzamide): Preparation and use as a synthetic precursor for quinazolino[1,2,3]benzotriazinones

FITZROY D. EDDY AND KEITH VAUGHAN

Department of Chemistry, Saint Mary's University, Halifax, N.S., Canada B3H 3C3

AND

MALCOLM F. G. STEVENS

Department of Pharmacy, University of Aston in Birmingham, Gosta Green, Birmingham, England B4 7ET

Received October 6, 1977

FITZROY D. EDDY, KEITH VAUGHAN, and MALCOLM F. G. STEVENS. Can. J. Chem. **56**, 1616 (1978).

Several synthetic routes to anthraniloylanthranilamide (**6**) are described; the problems involved in *o*-aminobenzoylation reactions are explored. Reduction of *N*-(*o*-nitrobenzoyl)-anthranilamide by stannous chloride gave a low yield of **6**, which was also obtained in low yield by reaction of isatoic anhydride with *o*-aminobenzamide. The possible use of *O*-(*o*-amino-benzoyl)hydroxylamines for *o*-aminobenzoylation was investigated but proved impractical. Diazotisation of **6** affords 3-(*o*-carbamoylphenyl)-1,2,3-benzotriazin-4(3*H*)-one (**2**), which undergoes base-catalysed cyclisation to the quinazolino[3,2-*c*]benzotriazine (**4**). The conversion **2** → **4** probably involves the isomeric quinazolino[1,2-*c*]benzotriazine (**3**), which could not be isolated.

FITZROY D. EDDY, KEITH VAUGHAN et MALCOLM F. G. STEVENS. Can. J. Chem. **56**, 1616 (1978).

On décrit plusieurs chemins de synthèse conduisant à l'anthraniloylanthranilamide (**6**); on explore les problèmes impliqués dans les réactions d'*o*-aminobenzoylation. La réduction de la *N*-(*o*-nitrobenzoyl)anthranilamide par le chlorure stanneux conduit à **6** avec un mauvais rendement; on peut aussi obtenir **6** avec un mauvais rendement par la réaction de l'anhydride isatoïque avec l'*o*-aminobenzamide. On a étudié la possibilité d'utiliser de l'*O*-(*o*-aminobenzoyl) hydroxylamine pour effectuer l'*o*-aminobenzoylation; cette réaction ne s'avère toutefois pas pratique. La diazotisation de **6** conduit à la *o*-carbamoylphényl-3 benzotriazine-1,2,3 (3*H*) one-4 (**2**) qui subit une cyclisation catalysée par les bases pour conduire à la quinazolino-[3,2-*c*]benzotriazine (**4**). La transformation de **2** → **4** implique probablement la quinazolino-[1,2-*c*]benzotriazine (**3**) isomère qui n'a pu être isolé.

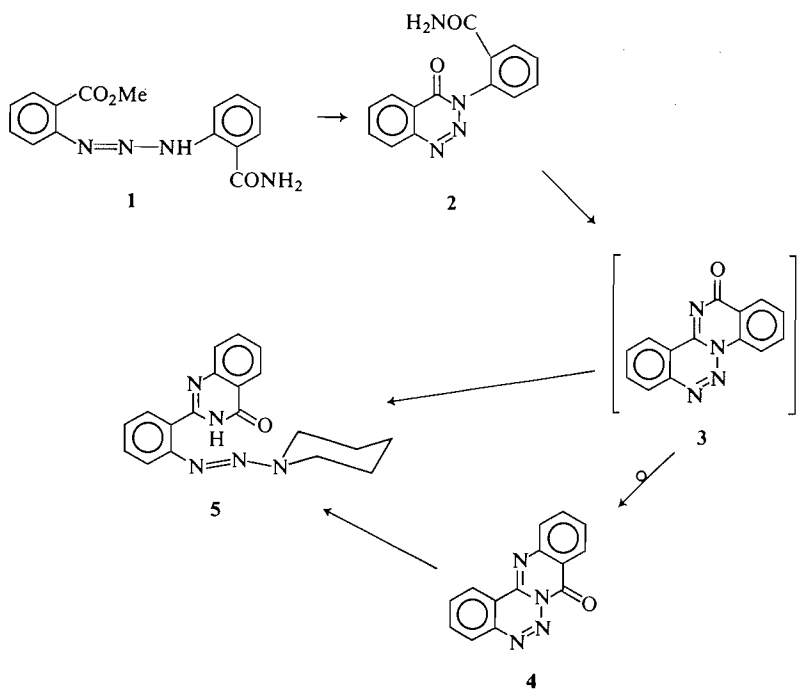
[Traduit par le journal]

In a previous report (1), the reactions of the diaryltriazene (**1**) were investigated as a possible synthetic entry to the quinazolinobenzotriazine ring system, i.e. **3** or **4**. Compound **1** was observed to undergo conversion to the triazenophenylquinazolone (**5**) by reaction with piperidine in ethanol at moderate temperatures. The initial step in the conversion **1** → **5** must be cyclisation to the triazinone (**2**), followed by further ring closure to afford the quinazolino[1,2-*c*]benzotriazine (**3**). Interaction of piperidine with the triazine ring of **3** leads to the observed product **5** directly, although the possibility of rearrangement of **3** to the isomer **4**, before interaction with piperidine, could not be ruled out. Indeed, the conversion of **4** (a known compound) to **5** was shown to occur under the same conditions as **1** → **5**. However the intermediate species **2**, **3**, and **4** could not be isolated during the reaction of **1** with piperidine.

Although the triazinone (**2**) does not appear to be stable during cyclisation involving formation of the N3—C4 bond, synthesis via formation of the N2—N3 bond offers more hope for isolation and study of **2**. Diazotization of *o*-aminobenzamides (2) affords triazinones by N2—N3 bond formation; the necessary precursor for this approach to **2** would be anthraniloylanthranilamide (**6**), which surprisingly has been reported in the literature only once (3). The published synthesis involves reduction of the nitro group in *N*-(*o*-nitrobenzoyl)anthranilamide in very low yield (11%). This method has been repeated by us and, although on some occasions the yield improved slightly, lower yields were recorded just as frequently.

An improved method of synthesis of **6** would obviously be useful; a feasible alternative could be direct *o*-aminobenzoylation of anthranilamide. However, methods for the direct introduction of the *o*-aminobenzoyl group are scarce and, whenever possible, the preferred method is *o*-nitrobenzoylation, followed by reduction, as used by Butler and Partridge (3). Perhaps the most frequently used reagent for *o*-aminobenzoylation is isatoic anhydride (**7**), which reacts readily with amines and several

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



other nucleophiles to afford anthranilamides and other anthraniloyl derivatives (4). A disadvantage of **7** for this application is the competing reactivities of the C2 and C4 carbonyl groups, and reaction with amines often gives rise to ureides, as a result of steric interaction at C4 (5). Nevertheless isatoic anhydride reacts with anthranilic acid in basic solution to afford anthraniloyl anthranilic acid (the parent acid of **6**) (6); however the analogous reaction of **7** with anthranilamide was unsuccessful. Reaction did occur (as evidenced by CO_2 evolution) when **7** and anthranilamide were heated in dimethylformamide at 124°C but the yield of **6** obtained in this way was only 6%.

3-(*o*-Aminobenzoyloxy)-1,2,3-benzotriazin-4(3*H*)-one (**8**) has recently been shown to be a potentially useful reagent for *o*-aminobenzoylation (7). Although the versatility of this reaction has not been thoroughly demonstrated, **8** does react with primary alkylamines to afford anthranilamides (7). When a mixture of **8** and excess anthranilamide was refluxed in nitromethane, formation of anthraniloylanthranilamide (**6**) was quickly evident as adduced by tlc analysis, which also showed the presence of both the starting materials and the expected by-product, *N*-hydroxybenzotriazinone (**9***a*). Because of the tendency of **9***a* to undergo thermolytic conversion to **8** (7), a twofold excess of anthranilamide was used to effect a stoichiometric conversion of **8** → **6**. However, after prolonged refluxing, it was evident (from tlc) that the amount of the required product (**6**) in the reaction mixture was not increasing significantly and that other reactions, e.g. polymerisation (7) of **8**, were interfering. The resulting reaction mixture was somewhat intractable and it was not possible to separate the anthraniloylanthranilamide from the

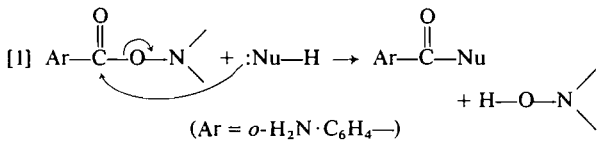
other products and unreacted anthranilamide. Nevertheless, the fact that **6** is formed from **8** in this reaction is further evidence of the synthetic use of this novel triazine, and suggests that further studies of the reactions of *N*-(*o*-aminobenzoyloxy) derivatives with nucleophiles (reaction [1]) are worthwhile.



[1] $Ar{-}C(=O){-}O{-}N< + :Nu{-}H \rightarrow Ar{-}C(=O){-}Nu + H{-}O{-}N<$

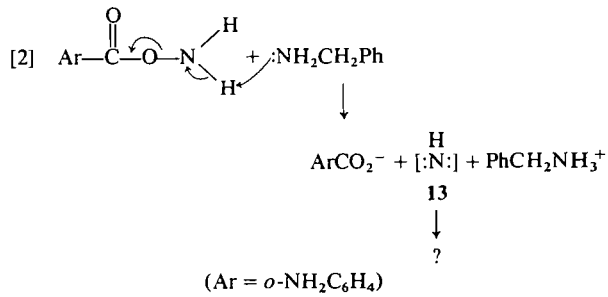
(Ar = *o*-$H_2N{\cdot}C_6H_4$—)

Indeed, the reaction of isatoic anhydride (**7**) with hydroxylamine in basic solution is reported to afford the *O*-(*o*-aminobenzoyl)hydroxylamine (**10***a*) (8). The structure of **10***a* appears to be unequivocal, especially since it is clearly a different compound from the *N*-(*o*-aminobenzoyl) isomer (**11***a*), which can be obtained by reaction of methyl *o*-aminobenzoate with hydroxylamine (8). This *O*-aroylation of hydroxylamine by isatoic anhydride evidently involves nucleophilic attack by the hydroxyl group, although formation and rearrangement of an *N*-oxide, via nucleophilic attack by the amino group, is feasible (9). However if the latter mechanism was operative during the reaction of **7** with hydroxylamine, the stable *N*-aroyl derivative (**11***a*) would arise and not the observed product **10***a*.

Further evidence for *O*-aroylation is provided by the reaction of isatoic anhydride with *N*-blocked hydroxylamines. Thus, reaction of **7** with *N*,*N*-diethylhydroxylamine affords a single product, which has analytical and spectroscopic data fully consistent with the expected *O*-aroyl structure (**10***b*). Likewise, **7** reacted with *N*-methylhydroxylamine, but gave a lower yield of the *N*-methyl derivative (**10***c*). The *O*-aroylhydroxylamines (**10***a–c*) display carbonyl absorption at 1680–1700 cm^{-1} in the ir spectra and the mass spectra all show an abundant molecular ion, together with a pronounced fragment at *m/e* 137, evidently arising from O—N bond cleavage. The diethyl derivative (**10***b*) is light-sensitive but appears to be stable in the dark unlike the *O*-amino derivative (**10***a*), which often decomposes within a day of preparation.

As previously reported by Kohl and Wolf (10), the reaction of **7** with *O*-benzylhydroxylamine affords the *N*-(*o*-aminobenzoyl)hydroxylamine (**11***b*). Evidently the *O*-blocked hydroxylamine can react as a nucleophile via the N atom with equal reactivity to the *N*-substituted hydroxylamines. The reaction of **7** with *O*-alkylhydroxylamines is a useful step in the synthesis of 3-alkyloxybenzotriazinones; diazotization of **11***b* affords the 3-benzyloxytriazinone (**9***b*), which was also synthesised by direct benzylation of the 3-hydroxytriazinone (**9***a*) (7).

The reaction of the *O*-aroylhydroxylamine (**10***a*) with benzylamine does not follow the predicted pathway (reaction [1]). When **10***a* is treated with neat benzylamine, a vigorous exothermic reaction occurs, after a short induction period, and copious effervescence is observed. The solid product obtained from this reaction was not *N*-benzylanthranilamide but, surprisingly, was found to be the benzylammonium salt of anthranilic acid (**12**). The same salt was obtained when **10***a* and benzylamine reacted in acetonitrile solution. A possible mechanism to explain the formation of this salt involves a base-induced α-elimination from the hydroxylamine (reaction [2]); an analogous intramolecular process



[2] $Ar{-}C(=O){-}O{-}N(H){-}H + :NH_2CH_2Ph \rightarrow ArCO_2^- + [:\overset{H}{N}:] + PhCH_2NH_3^+$

13 → ?

(Ar = *o*-$NH_2C_6H_4$)

could be responsible for the spontaneous slow decomposition of **10***a* previously discussed.

The eventual fate of the nitrogen fragment (**13**) is uncertain but it is quite likely the source of the unidentified gas evolved during the reaction. Also the mass spectrum of **10***a* exhibits a strong peak at *m/e* 137, corresponding to loss of the fragment NH. Further evidence for the proposed mechanism (reaction [2]) is the fact that the diethyl derivative **10***b* does not react in this way, nor does it appear to react by the nucleophilic displacement mechanism (reaction [1]). Reaction of **10***b* with benzylamine did not produce effervescence and gave only an intractable, ether-soluble red oil. Although **10***a* showed the same vigorous reaction with alkylamines, e.g. methyl- and propylamines, no such reaction was seen with other nucleophilic reagents, e.g. ethanol and aniline.

Thus, although the *O*-aroylhydroxylamine (**10***a*) is a reactive species, it clearly behaves differently from the *N*-(*o*-aminobenzoyloxy)triazinone (**8**) in reaction with nucleophiles and, consequently, is not a potential precursor of anthraniloylanthranilamide. The reactivity of **8** towards nucleophilic attack at the aroyl group may be due to the presence of the electron-withdrawing carbonyl group bonded to the N atom of the N—O-aroyl system; this structural feature is not present in **10***a*. In further studies, it is hoped that the structural requirement for a more useful *o*-aminobenzoylating agent will be elaborated.

Diazotization of anthraniloylanthranilamide (**6**) proceeded without complication and afforded a good

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

yield of 3-(*o*-carbamoylphenyl)-1,2,3-benzotriazin-4(3*H*)-one (**2**), which is a stable, colourless, crystalline solid. **2** reacted with piperidine in ethanol at 60°C to afford the same triazene (**5**) which had previously been obtained from the amide ester (**1**) under identical conditions (1). This observation confirms the previous hypothesis that **2** is an intermediate in the conversion **1** → **5**. Whereas no intermediate species in the conversion **1** → **5** could be isolated, the reaction of **2** with piperidine in ethanol at room temperature afforded a good yield of the quinazolinobenzotriazinone (**4**), in addition to the triazene (**5**) as a minor product. Compound **2** is evidently much more reactive than the precursor **1**, which required elevated temperatures to react with piperidine, and it is therefore likely that the rate-determining step in the conversion **1** → **5** is the initial reaction **1** → **2**.

Several modifications to these reaction conditions have been attempted in order to isolate the unknown isomeric quinazolinobenzotriazinone (**3**), the presumed intermediate in the conversion **2** → **4**. Compound **2** was recovered quantitatively unchanged after prolonged reflux in ethanol; evidently piperidine, or a similar catalyst, is essential for cyclisation of **2** to occur. Reaction of **2** with DABCO (1,4-diaza[2,2,2]bicyclooctane), which is a base catalyst more sterically hindered as a nucleophile than piperidine, in acetonitrile was much slower than reaction with piperidine; however the only product observed, both at room temperature and under reflux, was the same quinazolinobenzotriazinone (**4**). Compound **2** was found to be stable to solution thermolysis at 160°C and no evidence of cyclisation under these conditions could be found. Attempts to dehydrate the triazinone (**2**) using dicyclohexylcarbodiimide were unsuccessful.

In conclusion, it is evident that the quinazolino-[1,2-*c*]benzotriazinone (**3**) is a very elusive species. Certainly **3** does not appear to be stable under the reaction conditions necessary for the cyclisation of **2** and the rearrangement **3** → **4** must be a very facile process. This rearrangement of **3**, which is a fused 1,4-dihydroquinazoline, is analogous to the well known tautomerisation of 1,4-dihydroquinazolines to 3,4-dihydroquinazolines (11).

Experimental

Anthraniloylanthranilamide (**6**)

(*a*) A solution of *o*-nitrobenzoyl chloride (50 g) in anhydrous benzene (200 ml) was added to a vigorously stirred solution of anthranilamide (33 g) and pyridine (50 ml) in anhydrous benzene (120 ml). After stirring 1 h at room temperature, the benzene was removed under vacuum and the residue treated with water (1 ℓ) to afford *o*-(*o'*-nitrobenzamido)benzamide (80 g), mp 194–196°C (ethanol) (lit. (3) mp 195–196°C).

The nitro amide (20 g) was reduced with stannous chloride (60 g) in glacial acetic acid (150 g) and concentrated HCl (60 ml) at room temperature for 2 h. The product was isolated as the oxalate and tin compounds were precipitated by bubbling H_2S through a suspension of the crude product in 0.5 *N* H_2SO_4. Filtration of the hot suspension and cooling the filtrate afforded pure anthraniloylanthranilamide (yield 7–18%), mp 206–208°C (lit. (3) mp 207.5–208°C); ν_{max}: 3450, 3340, 3200 (broad), and 1650 (broad) cm^{-1}.

(*b*) Isatoic anhydride (1.63 g) and anthranilamide (1.39 g) were heated in dimethylformamide (10 ml) at 124°C for 2.2 h, when effervescence had ceased. After cooling, the reaction mixture was treated with water (42 ml) and the p*H* adjusted to 9.4. After standing for 24 h, the resulting precipitate was filtered to afford the aminoamide (**6**) (0.16 g, 6%), which had identical ir spectrum to that obtained in (*a*).

(*c*) 3-(*o*-Aminobenzoyloxy)-1,2,3-benzotriazin-4(3*H*)-one (**8**) (0.5 g) and anthranilamide (0.5 g) were refluxed in nitromethane (20 ml) for 125 h. The progress of the reaction was followed by tlc analysis on Kieselgel 60 F254 (Merck) using chloroform as solvent. Thin-layer chromatography indicated the presence of the expected reaction products, **6** and **9***a*, in addition to both starting materials, in the reaction mixture after only 1 h reflux. The same four components were still present after 50 h reflux. After 125 h, tlc analysis indicated the presence of the required product (**6**), and only trace amount of **9***a*; in addition, the mixture contained considerable amounts of unreacted anthranilamide and unidentified products. Fractional crystallisation of the reaction mixture eventually afforded a solid (12 mg), but tlc analysis showed that it was a mixture of **6**, anthranilamide, and one other component.

O-*(o-Aminobenzoyl)hydroxylamine* (**10**a)

Hydroxylamine hydrochloride (13.8 g) was dissolved in water (250 ml) and added to a solution of sodium carbonate (21.2 g) in water (250 ml). The mixture was stirred while isatoic anhydride (16.3 g) was added over 10 min with vigorous effervescence. After stirring for 1 h, the solid was filtered and dried in air to afford *O*-(*o*-aminobenzoyl)hydroxylamine (9.8 g), mp 79–81°C; ν_{max}: 3420, 3300, 3200, and 1700 cm^{-1}; M^+ 152 (17%), *m/e*: 137 (23%) (*M* − NH), 120 (100%) ($H_2N{\cdot}C_6H_4CO$), and 92 (58%).

Reaction of isatoic anhydride with *O*- and *N*-substituted hydroxylamines by the above procedure afforded the following compounds.

N-*Methyl*-O-*(o-aminobenzoyl)hydroxylamine* (**10**c)

Yield 45%, mp 48–50°C; ν_{max}: 3430, 3300, 3230, 3160, and 1680 cm^{-1}; M^+ 166 (40%), *m/e*: 137 (91%) (*M* − CH_3N), 120 (100%)($H_2NC_6H_4CO$), and 92 (100%). *Anal.* calcd. for $C_8H_{10}N_2O_2$: C 57.83, H 6.02, N 16.87; found: C 57.28, H 6.08, N 16.62.

N,N-*Diethyl*-O-*(o-aminobenzoyl)hydroxylamine* (**10**b)

Yield 84%, mp 70–72°C, ν_{max}: 3450, 3340, and 1695 cm^{-1}; M^+ 208 (7%), *m/e*: 174 (2%), 161 (3%), 146 (6%), 137 (25%) (*M* − C_4H_9N), 120 (100%); δ ($CDCl_3$): 1.15 (t, *J* = 7 Hz, 6H, Me), 3.03 (q, *J* = 7 Hz, 4H, CH_2), 5.8 (broad s, 2H, NH_2), and 6.5–7.9 ppm (m, 4H, aromatic). *Anal.* calcd. for $C_{11}H_{16}N_2O_2$: C 63.46, H 7.69, N 13.46; found: C 63.23, H 7.58, N 13.90.

O-*Benzyl*-N-*(o-aminobenzoyl)hydroxylamine* (**11**b)

Yield 48%, mp 101–102°C (lit. (10) mp 104–106°C), ν_{max}: 3420, 3350, 3150, 1740(w), 1655, and 1640 cm^{-1}; δ ($CDCl_3$): 4.93 (s, 2H, CH_2), 5.3 (br s, 2H, NH_2), and 6.5–7.4 (m, 9H, aromatic). *Anal.* calcd. for $C_{14}H_{14}N_2O_2$: C 69.42, H 5.79, N 11.57; found: C 69.09, H 6.05, N 11.79.

*3-Benzyloxy-1,2,3-benzotriazin-4(3*H*)-one* (**9**b)

(*a*) *O*-Benzyl-*N*-(*o*-aminobenzoyl)hydroxylamine (486 mg) was dissolved in 2 *M* HCl (5 ml), diluted with water (40 ml), and diazotised at 0°C with sodium nitrite (140 mg) in water.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

After stirring for 3 h at 0°C, the precipitate was filtered and recrystallised from ethanol to afford the triazinone (**9***b*) (400 mg, 78%), mp 151–153°C (ethanol); ν_{max}: 1720 cm^{-1}. *Anal.* calcd. for $C_{14}H_{11}N_3O_2$: C 66.40, H 4.35, N 17.87; found: C 66.52, H 4.56, N 17.68.

(*b*) 3-Hydroxy-1,2,3-benzotriazin-4(3*H*)-one (420 mg) was dissolved in 10% aqueous NaOH (1 ml) and the yellow solution diluted with water (5 ml) and ethanol (2 ml). Benzyl bromide (425 mg) was added and the mixture stirred for 12 h at room temperature. The suspended oil slowly dissolved and was replaced by a white precipitate. The solid was filtered, washed with cold aqueous ethanol and dried to afford the benzyloxybenzotriazinone (**9***b*) (400 mg, 62%), which was identical (ir spectrum, mp and mixture mp 151–153°C) with a sample from above.

Benzylammonium o-*Aminobenzoate* (**12**)

(*a*) *O*-(*o*-Aminobenzoyl)hydroxylamine (**10***a*) (1 g) was treated with benzylamine (1 ml). No immediate reaction took place but within approximately 1 min, a vigorous reaction set in with copious effervescence. The resulting oil solidified on cooling and was triturated with ether, filtered and recrystallised from benzene to afford the anthranilate salt (**12**) (1.25 g), mp 114°C (benzene); ν_{max}: 3450, 3350, 2700 (br), and 1610 cm^{-1}. *Anal.* calcd. for $C_{14}H_{16}N_2O_2$: C 68.85, H 6.56, N 11.48; found: C 67.95, H 6.52, N 11.27. This salt was identical (ir and mixture mp) with a sample prepared from benzylamine and anthranilic acid.

(*b*) *O*-(*o*-Aminobenzoyl)hydroxylamine (0.5 g) was dissolved in acetonitrile (5 ml) and benzylamine (0.5 ml) was added. The mixture was warmed on a steam bath under reflux for 0.5 h, during which slight effervescence was evident. The acetonitrile was removed under vacuum and the residue was dissolved in hot benzene and left to crystallise. Filtration afforded the same benzylammonium salt (**12**) (0.64 g, 67%) as in (*a*).

*3-(*o*-Carbamoylphenyl)-1,2,3-benzotriazin-4(3*H*)-one* (**2**)

Anthraniloylanthranilamide (**6**) (0.5 g) was dissolved in 2 *M* HCl (3 ml), diluted with water (15 ml), and diazotised at 0°C with sodium nitrite (0.14 g) in water. The solution went clear briefly before a white precipitate formed. The reaction mixture was allowed to warm slowly to room temperature and then filtered to afford the triazinone (0.44 g, 85%), mp 201–204°C (dec.) (ethanol); ν_{max}: 3400, 3250, 3150, 1680, and 1650 cm^{-1}. *Anal.* calcd. for $C_{14}H_{10}N_4O_2$: C 63.15, H 3.76, N 21.05; found: C 63.11, H 3.90, N 21.07.

Reactions of the Amide (**2**)

(*a*) Compound **2** (0.1 g) was refluxed in ethanol (5 ml) for 24 h. The cooled solution afforded a crystalline precipitate; both the precipitate and the residue in the filtrate, were identical with the starting material (quantitative recovery).

(*b*) Compound **2** (0.1 g) was suspended in cold ethanol (10 ml) and piperidine (0.03 g) was added. The suspension was stirred at room temperature for 13 days and the residual precipitate was filtered to afford quinazolino[3,2-*c*][1,2,3]-benzotriazin-8-one (**4**) (50 mg, 54%), mp 216–218°C, which was identical (mixture mp 216–218°C and ir spectrum) with an authentic sample (12). The ethanolic filtrate was evaporated and the residue recrystallised from aqueous ethanol to afford the triazene (**5**) (20 mg, 16%), which was identical with the sample prepared as follows (*c*).

(*c*) Compound **2** (0.1 g) was dissolved in ethanol (10 ml) containing piperidine (0.03 g) at 60°C. The clear solution was maintained at 60–70°C for 5 h. The ethanol was removed under vacuum and the oily residue was triturated with 60–80°C petroleum ether – benzene. The insoluble solid was filtered to afford unchanged starting material (0.04 g). Evaporation of the filtrate gave an oil, which solidified on standing and recrystallised from aqueous ethanol to afford 2-[2-(piperidin-1-ylazo)phenyl]quinazolin-4(3*H*)-one (**5**) (0.05 g) (40%), mp 143–145°C, which was identical (ir spectrum and mixture mp 143–145°C) with an authentic sample (1).

(*d*) Compound **2** (0.1 g) was refluxed in anhydrous diglyme (2 ml) for 5 h. Dilution with petroleum ether (60–80°) caused precipitation; filtration afforded unchanged starting material (66 mg).

(*e*) *with DABCO*

(*i*) Compound **2** (0.1 g) was suspended in a solution of DABCO (50 mg) in acetonitrile (10 ml) and the mixture was refluxed for 24 h. Thin-layer chromatographic analysis of the solution showed a mixture of two components, the principle one being the starting material (**2**); the second component, which had the greater R_f value, was the quinazolinobenzotriazinone (**4**). Evaporation of the reaction mixture, trituration with benzene and filtration gave a solid mixture of the two components **2** and **4**. Recrystallisation of this solid from ethanol–acetonitrile afforded the pure quinazolinobenzotriazinone (**4**) (10 mg), which was identical with an authentic sample (12).

(*ii*) The above procedure was repeated at room temperature for 7 days. Thin-layer chromatographic analysis of the solution showed only the presence of the same two components, **2** and **4**.

(*f*) Compound **2** (0.1 g) and dicyclohexylcarbodiimide (0.2 g) were dissolved in acetonitrile (10 ml) with slight warming and the mixture stirred at room temperature for 140 h. (Occasional warming was necessary to maintain a clear solution.) Thin-layer chromatographic analysis showed that no reaction had occurred.

Indole *N*-alkylation of tryptamines via dianion and phthalimido intermediates. New potential indolealkylamine haptens

S. OSMUND DE SILVA AND VICTOR SNIECKUS

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo Campus, Waterloo, Ont., Canada N2L 3G1

Received December 22, 1978

S. OSMUND DE SILVA and VICTOR SNIECKUS. Can. J. Chem. **56**, 1621 (1978).

Tryptamine derivatives **3***a–c* and **4***a*, **4***b*, **4***d* have been converted into the indole *N-p*-carbomethoxybenzyl derivatives **1***a*, **1***b*, **1***g*, and **2***a*, **2***b*, **2***c*, respectively, using dianion and phase-transfer catalytic methodologies. Treatment of these compounds with lithium iodide and sodium cyanide in refluxing dimethylformamide gave the corresponding carboxylic acids **1***d*, **1***e*, **1***h*, and **2***d*, **2***e*, **2***f*. The serotonin analogue **1***f* was obtained by catalytic debenzylation of **1***h*. These products may be useful haptens for eliciting specific antibodies to indolealkylamines.

S. OSMUND DE SILVA et VICTOR SNIECKUS. Can. J. Chem. **56**, 1621 (1978).

Faisant appel à des méthodes impliquant des dianions et une catalyse par transfert de phase, on a pu transformer les dérivés de la tryptamine **3***a–c*, **4***a*, **4***b* et **4***d* en leurs dérivés respectifs *N-p*-carbométhoxybenzyle indoles (**1***a*, **1***b*, **1***g* et **2***a*, **2***b*, **2***c*). La réaction de ces composés avec l'iodure de lithium et le cyanure de sodium dans la diméthylformamide à reflux conduit aux acides carboxyliques correspondants **1***d*, **1***e*, **1***h* et **2***d*, **2***e* et **2***f*. On a obtenu l'analogue de la sérotonine **1***f* par une débenzylation catalytique de **1***h*. Ces composés peuvent être des haptènes utiles pour découvrir des anticorps spécifiques aux indolealkylamines.

Introduction

In connection with a problem concerning production of antibodies to tryptamines (1), it was of interest to prepare a series of indole *N*-substituted compounds of the types **1** and **2**. These compounds would possess a free carboxylic acid function (R^2 = H) which would serve as a handle for coupling to protein to afford potential antigens which in turn would be used directly (**1**) or after suitable demasking of the side-chain amino group (**2**) in attempts to elicit specific antibodies (2).

It may be envisaged that compounds **1** and **2** would be most conveniently available by N_a-*p*-carboalkoxybenzylation of either commercially or synthetically (3) available tryptamine derivatives. Although a number of excellent methods have been developed (4), particularly in recent years (5), for *N*-alkylation of simple indole derivatives, this reaction appears not to have been extensively explored (4) for tryptamines. This situation may be explained in part by the observation that relatively few complex indole alkaloids possess N_a-substitution (6) and, since tryptamines are common building blocks for these natural products, a general synthetic need for N_a-alkylated tryptamines has not arisen.

Herein we report on (*i*) the regioselective N_a-*p*-carbomethoxybenzylation of dianions from N_b-acyl tryptamines **3** generated using sodium hydride in DMF (7) or phase-transfer conditions (8) to give **1**, R^2 = Me; (*ii*) similar N_a-benzylation of monoanions of N_b-phthaloyl tryptamines **4**, available using

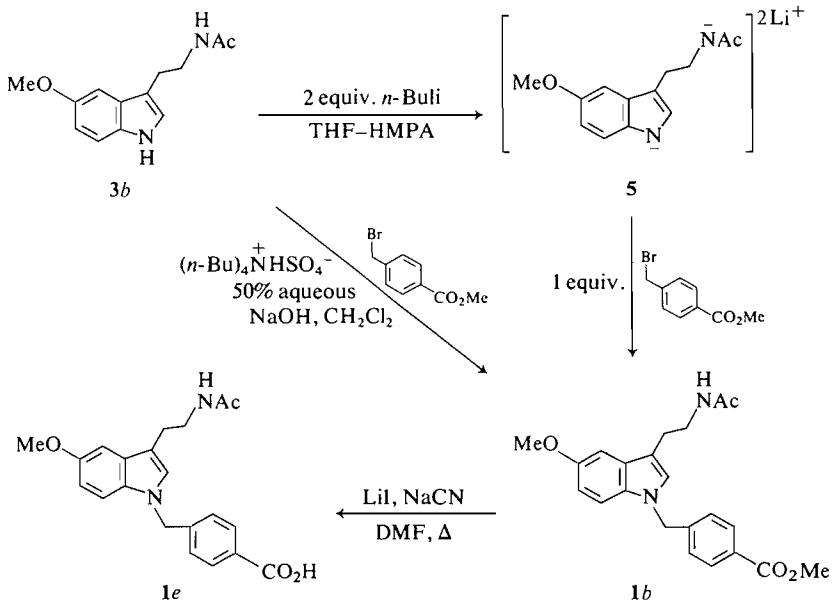

SCHEME 1

Nefkens' reagent **6** (9), to give **2**, R^2 = Me; and (*iii*) selective ester hydrolysis of **1** and **2** (R^2 = Me) to the carboxylic acids, **1** and **2** (R^2 = H) by the nonaqueous procedure of McMurry and Wong (10).

Results and Discussion

It was anticipated that treatment of melatonin (**3***b*) with 2 equiv. of base would generate the dianion **5** which upon reaction with 1 equiv. of *p*-carbomethoxybenzyl bromide would undergo alkylation at the more reactive N_a-anion to provide, after work-up, compound **1***b*.[1] In the event, when this reaction was conducted in a THF–HMPA mixture using *n*-butyllithium as base, the desired product (**1***b*) was formed in 60% yield (Scheme 1). When the N_a-alkylation was carried out in a two-phase system (8) consisting of methylene chloride and concentrated aqueous sodium hydroxide with a phase-transfer catalyst (tetra-*n*-butylammonium hydrogen sulfate), a significant improvement in efficiency and yield was noticed with the added advantage of avoiding the anhydrous conditions that are essential for the procedure using *n*-butyllithium. That the alkylation had occurred in the indole rather than the side-chain nitrogen was ascertained from examination of the ir and nmr spectra which showed absence of characteristic indole NH absorption and presence of a two-proton singlet at τ 4.83 typical of benzylic protons of 1-benzylindole (*vide infra*). For the final stage of the synthesis, **1***b* → **1***e*, it was necessary to use conditions which would selectively hydrolyze the ester without affecting the amide function. The nonaqueous procedure of McMurry and Wong (10) proved suitable for this purpose and provided **1***e* in 50% yield.

Following the route delineated in Scheme 1, compounds **1***d*, **1***f*, and **1***h* were also synthesized (see Tables 1 and 2). In the case of the serotonin analogue **1***f*, the protected *O*-benzylacetylserotonin **3***c* was alkylated with *p*-carbomethoxybenzyl bromide. The resulting product **1***c* underwent deesterification when subjected to reaction with lithium iodide and sodium cyanide in refluxing DMF to give **1***h*. Debenzylation of the blocked phenol to obtain **1***f* was achieved by catalytic hydrogenation.

The N_b-phthaloyl derivatives **2***d–f* were prepared by adaptation of N_a-alkylation conditions extensively used previously in our laboratories (7). The general route is shown in Scheme 2 for the preparation of **2***e* and the results are summarized in Tables 1 and 2. The starting phthaloyl derivatives **4***a–c* were readily prepared from commercially available tryptamines by treatment with phthalic anhydride or, preferably, by application of Nefkens' excellent *N*-carbethoxyphthalimide (**6**) reagent (9) which enjoys moderate use in peptide synthesis (13) but which appears not to be widely employed by organic chemists, e.g., in the Gabriel synthesis. Alkylations were carried out at room temperature using sodium hydride in DMF; as in the case of **3***c*, the protected *O*-acetyl phthaloylserotonin (**4***d*) was used for the base-catalyzed alkylation reaction. The phase transfer method applied to **4***a* gave only low yields of **2***a* and was

[1]For indole *N*-alkylation of tryptophan dianion, see ref. 11; for other synthetic work with indole compounds using dianion intermediates, see ref. 12.

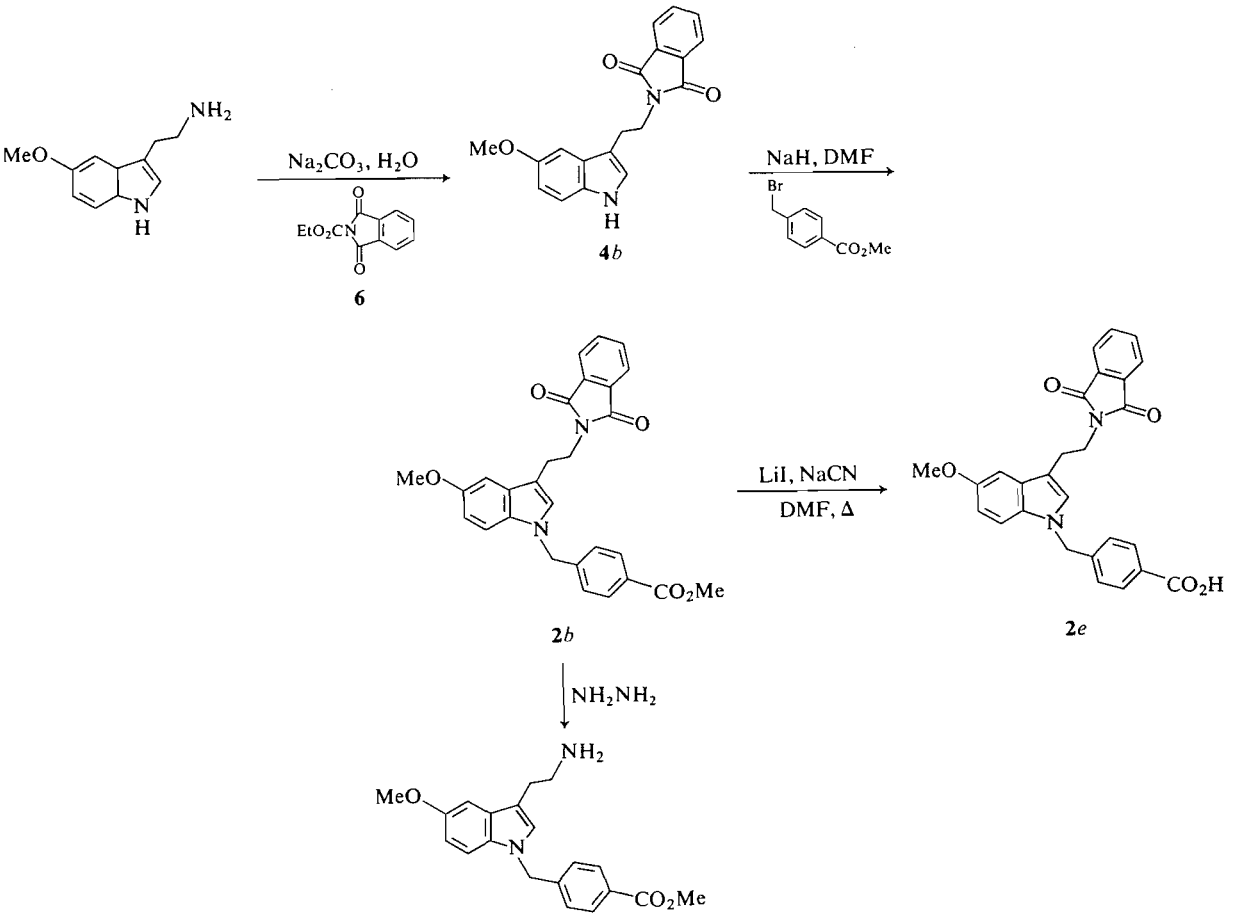

SCHEME 2

therefore not pursued. The nmr spectra of the alkylated products **2***a–c* all showed a two-proton singlet at $\tau \sim 4.8$ which can be unambiguously assigned to the N_a-benzylic hydrogens by analogy with the data obtained in the N_b-acetyl series (**1***a–c*). Finally, deesterifications of **2***a–c* were effected using the LiI–NaCN reagent to give compounds **2***d–f*. The LiI–NaCN reaction on **2***c* gave directly the deesterified-deacetylated product **2***f*. Deacetylation occurs owing to the basic conditions that prevail during aqueous work-up of the reaction mixture.

To test the dephthaloylation step[2] required for antibody generation studies after coupling to protein (1), compound **2***b* was subjected to the standard conditions of hydrazinolysis at room temperature (13). The expected product, **7**, was obtained in good yield.

In conclusion, this work provides ready access to N_a-*p*-carboxybenzyl tryptamine derivatives **1***d–f* and **2***d–f*. These may be useful in radioimmunoassay, immunohistochemical and related studies which are in progress elsewhere.[3]

Experimental

Melting points were measured on a Mel-Temp apparatus and are uncorrected. Microanalyses were performed by A. B. Gygli, Toronto. Infrared spectra were determined with a Beckman IR-5A instrument. Nuclear magnetic resonance spectra were obtained on Varian T-60 and Perkin-Elmer R-12 spectrometers. Thin-layer chromatography was carried out with Merck silica gel GF 254 and column chromatography with Merck silica gel (0.05–0.2 mm) obtained from Brinkmann (Canada) Ltd. THF was dried by refluxing over sodium and benzophenone until a deep blue color persisted in solution. Dry DMF was prepared by refluxing over calcium hydride followed by distillation. HMPA was dried by allowing it to stand over Linde molecular sieves (Type 4A) followed by distillation.

n-Butyllithium was purchased as a solution in *n*-hexane from Alfa Ventron Crop. Tryptamine hydrochloride, 5-methoxytryptamine hydrochloride, and 5-benzyloxytryptamine

[2]For an example of its application in penicillin synthesis see the recent work of Kukolja and Lammert (13).

[f]Yield improved to 96% if **6** is added portionwise to an aqueous mixture of serotonin salt and Na_2CO_3.
[g]Starting material (30–50%) was recovered.

hydrochloride were purchased from Aldrich Chemical Co. Melatonin and serotonin–creatinine sulfate were procured from Sigma Chemical Co. All of these compounds were used without further purification.

*1-(*p*-Carbomethoxy)benzylmelatonin (**1**b)*

Method A

To a solution of melatonin (**3***b*) (0.116 g, 0.5 mmol) in a mixture of dry THF (30 ml) – HMPA[4] (0.5 ml) maintained under an atmosphere of dry nitrogen and cooled in an ice-bath was added via a syringe through a septum cap a solution of *n*-butyllithium (2.4 *M*, 0.42 ml (1 mmol)) in *n*-hexane. Over a period of 4 h stirring at room temperature there accumulated a colorless, gelatinous precipitate. A solution of methyl α-bromo-*p*-toluate (ref. 14 and footnote 5) (0.114 g, 0.5 mmol) in dry THF (5 ml) was introduced dropwise and stirring was continued for a further 4 h. The clear yellow solution was treated with 0.1 *N* hydrochloric acid solution (5 ml) and the resulting mixture was evaporated to dryness *in vacuo*. The residue was suspended in water (50 ml) and extracted with methylene chloride (2 × 50 ml). The organic extract was dried (sodium sulfate) and evaporated to dryness. The residue on chromatography (silica gel, benzene–acetone–methanol eluent, 8:1:1) gave a yellow gum (0.115 g, 60%) which was crystallized from a 1:3 mixture of benzene – petroleum ether (60–80°C) to give **1***b* as a colorless solid.

Method B

A solution of melatonin (**3***b*) (0.232 g, 1 mmol) in methylene chloride (30 ml) was mixed with an aqueous solution (20 ml 50% w/v) of sodium hydroxide. Solid methyl α-bromo-*p*-toluate (0.250 g, 1.09 mmol) and a solution of tetra-*n*-butylammonium hydroxide (a few drops of 40% aqueous solution) were successively introduced and the mixture was stirred at 30–33°C for 3 h. Heating was discontinued and the mixture was stirred at room temperature overnight (~14 h). The reaction mixture was cooled in ice and carefully acidified (litmus paper) with a dilute solution of hydrochloric acid. The organic layer was separated, washed with a saturated solution of sodium carbonate and then with water. Drying (sodium sulfate) of the organic extract followed by evaporation to dryness *in vacuo* gave a gummy material which was purified by column chromatography as in method *A*. Crystallization of the purified product (0.37 g, 98%) from a mixture of benzene–*n*-hexane (1:1) gave a colorless solid. This compound was found to be identical with a sample of **1***b* prepared by method *A*.

*1-(*p*-Carboxy)benzylmelatonin (**1**e)*

Method C

A mixture of 1-(*p*-carbomethoxy)benzylmelatonin (**1***b*) (0.223 g, 0.587 mmol), anhydrous lithium iodide (0.804 g, 6 mmol), and sodium cyanide (0.050 g, 1 mmol) in dry DMF (50 ml) under a blanket of dry nitrogen was heated in an oil bath at 140–145°C (external temperature) for 50 h. Most of the solvent was removed *in vacuo* and the residual gum was suspended in water (25 ml) and extracted with chloroform (2 × 20 ml). The organic extract was dried (Na_2SO_4) and evaporated to dryness to give 0.062 g (28%) of recovered starting material (**1***b*). The aqueous layer was acidified with concentrated hydrochloric acid. Cooling in ice resulted in formation of a gum. The water layer was decanted, ethanol was added and the whole was evaporated to dryness. There was obtained 0.142 g (66%) of **1***e* as a yellow solid.

[4]Dictated by solubility problems. In all other cases of method *A*, DMF was used as the sole solvent.

[5]This compound was prepared by the method of Julia and Chastrette (14).

*1-(*p*-Carboxy)benzyl-*N*-acetylserotonin (**1***f*)*

Method D

A solution of **1***h* (0.161 g, 0.36 mmol) in absolute ethanol (150 ml) containing a suspension of 10% palladium-on-charcoal (0.175 g) was hydrogenated in a Parr apparatus at 45 psi for 18 h. Filtration of the reaction mixture followed by evaporation to dryness and recrystallization gave **1***f* as an off-white crystalline solid (0.123 g, 96%).

*Phthaloyltryptamine (**4**a)*

Method E

Nefkens' method (9) was adapted. Tryptamine hydrochloride (1.967 g, 1 mmol) and *N*-carbethoxyphthalimide (2.41 g, 1.1 mmol) were suspended in water (50 ml) and sodium carbonate decahydrate (5.72 g, 2 mmol) was added with stirring. After 0.5 h at room temperature, an additional amount of *N*-carbethoxyphthalimide (0.48 g, 0.2 mmol) was added and stirring was continued for another 0.5 h. The yellowish-white solid was collected by filtration and recrystallized to give yellow crystals of **4***a* in three crops, 2.74 g (94%).

Method F

A mixture of tryptamine hydrochloride (0.393 g, 2 mmol), phthalic anhydride (0.312 g, 2.02 mmol), anhydrous sodium carbonate (0.110 g, 1.02 mmol) and dry benzene (50 ml) was refluxed under a Dean–Stark water separator. After 20 h, the solvent was removed *in vacuo* and then the residue was pyrolyzed for 15 min in an oil bath preheated to 210°C. The brownish solid residue was allowed to cool to about 80°C and hot water (200 ml) was added with vigorous trituration. The mixture was extracted with methylene chloride (200 ml) and the organic extract was successively washed with a 5% aqueous solution of sodium hydroxide (100 ml) and water (200 ml). The organic layer was treated with decolorizing carbon, filtered, dried (sodium sulfate), and evaporated to dryness. The residual solid was recrystallized from ethanol to give **4***a* (0.523 g, 90%), identical with a sample obtained by method *E*.

*Phthaloyl-5-hydroxytryptamine (**4**c)*

Method G

A mixture of serotonin–creatinine sulfate (0.388 g, 1 mmol), phthalic anhydride (0.5 g, 3.37 mmol), and anhydrous pyridine (20 ml) was heated in an oil bath at 100°C for 20 h. Evaporation to dryness followed by azeotropic distillation with absolute ethanol gave a residual solid which was pyrolyzed in a preheated oil bath at 200°C. The melt was allowed to cool and was then triturated with hot ethanol (30 ml). The mixture was cooled to 0°C. The resulting solid was collected by filtration and was washed successively with water (40 ml), a saturated aqueous solution of sodium carbonate (50 ml), and water (40 ml). The solid was air dried and recrystallized to give a yellow crystalline material (0.210 g, 69%), shown to be identical with a sample of **4***c* prepared by method *E*.

O-*Acetylphthaloylserotonin (**4**d)*

Method H

A stirred solution of **4***c* (0.306 g, 1 mmol) in dry THF (75 ml) maintained at room temperature under an atmosphere of dry nitrogen was treated with sodium hydride (0.060 g, 1.2 mmol, 50% dispersion in mineral oil). Over a period of 0.5 h, a reddish-brown color developed. Acetic anhydride (0.3 ml, 3 mmol) was added to the mixture and stirring was continued for 12 h. The mixture was treated with aqueous hydrochloric acid (0.1 *N*, 5 ml) and most of the THF was removed *in vacuo*. The aqueous solution was diluted with water (200 ml) and the resulting brownish gum was retained by decanting the supernatant aqueous layer. The gummy material was suspended in absolute ethanol and the whole was taken to dryness *in vacuo*. This process was repeated several times. The gum was washed with hot petroleum ether (60–80°C, 50 ml) and dried *in vacuo* to give **4***d* as a cream-colored foam, 0.342 g (99%) which was used without further purification for the preparation of **2***c*.

For personal use only.

N-*Acetyltryptamine (3a)*

Tryptamine hydrochloride (0.200 g, 1.02 mmol) suspended in a mixture of dry pyridine (10 ml), benzene (20 ml), and acetic anhydride (3 ml) was stirred at room temperature for 6 h. The mixture was evaporated to dryness *in vacuo* and the residue was suspended in water (200 ml) and extracted with methylene chloride (2 × 100 ml). Successive washing of the organic extract with 10% aqueous sodium carbonate solution, water, 10% hydrochloric acid, and water followed by drying (sodium sulfate) and removal of solvent *in vacuo* gave a colorless gummy material. This compound was crystallized from a mixture of ether – benzene – petroleum ether (60–80°C) (10:10:1) to give **3***a* as a white crystalline solid (0.192 g, 93%), mp 75°C (lit. (15) mp 75–76°C).

5-Benzyloxy-N-*acetyltryptamine (3c)*

The procedure described for the preparation of **3***a* was employed. From 0.950 g (3.14 mmol) of 5-benzyloxytryptamine hydrochloride and 10 ml of acetic anhydride in a mixture of dry pyridine (40 ml) and benzene (5 ml) there was obtained a gummy product which was crystallized from a mixture of benzene–*n*-hexane (10:1) to give **3***c* as a cream-colored solid (0.943 g, 97%), mp 123°C (lit. (16) mp not recorded); ir ν_{max} (KBr): 1645 cm^{-1}; nmr ($CDCl_3$) τ: 1.30 (br s, 1H, indole NH), 2.3–3.2 (m, 9H, aromatic H), 4.10 (br s, 1H, amide NH), 4.86 (s, 2H, $PhCH_2$), 6.45 (two overlapping triplets, J = 7 Hz, 2H, $N—CH_2$), 7.12 (t, 2H, J = 7 Hz, $—CH_2$), 7.85 (s, 3H, $COCH_3$). *Anal.* calcd for $C_{19}H_{20}N_2O_2$: C 74.00, H 6.54, N 9.08; found: C 73.78, H 6.31, N 8.89.

N-*Carbethoxyphthalimide (6)*

Nefkens' method (9) for the preparation of this compound was modified. A solution of phthalimide (14.7 g, 100 mmol) in dry DMF (100 ml) was added dropwise into a stirred suspension of sodium hydride (5.0 g, 105 mmol, a 50% dispersion in mineral oil, oil removed by washing with dry petroleum ether) kept at room temperature. After 3 h, the evolution of hydrogen had ceased. The mixture was cooled to 5°C and freshly distilled ethyl chloroformate (10 ml, 130 mmol) was added dropwise keeping the temperature below 40°C. The mixture was stirred at 35°C for 3 h and then poured into ice-cold water (1 L) with vigorous stirring. The resulting white solid was collected by filtration and recrystallized from ethanol to give 20 g (91%) of product, mp 80°C (lit. (9) mp 80°C).

Synthesis of the spirosesquiterpene (−)-acorenone and related cyclopentanoid monoterpenes[1]

GORDON L. LANGE, ELI E. NEIDERT, WILL J. ORROM, AND DAVID J. WALLACE

Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received January 30, 1978

GORDON L. LANGE, ELI E. NEIDERT, WILL J. ORROM, and DAVID J. WALLACE. Can. J. Chem. **56**, 1628 (1978).

The first total synthesis of the spirosesquiterpene (−)-acorenone (**1**) is described. The critical step involves a spiroannelation of the enamine of aldehyde **11** with 1-methoxy-3-buten-2-one (**16**) in the presence of acetic acid to give ketone **17**. Reaction of **17** with methylmagnesium iodide followed by treatment of the resultant alcohol **18** with *p*-toluenesulfonic acid in refluxing benzene leads directly to **1** in good overall yield. As the starting material for the preparation of the cyclopentanoid aldehyde **11** was (+)-limonene the final product is optically active and thus the absolute configuration of naturally occurring (−)-acorenone (**1**) is established. The preparation of a number of other optically active cyclopentanoid monoterpenes (**4** and **13**) is also described.

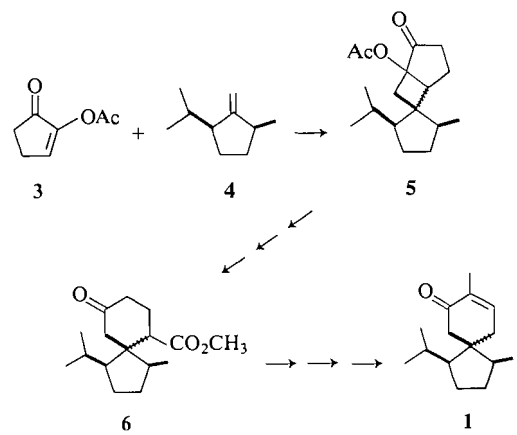
GORDON L. LANGE, ELI E. NEIDERT, WILL J. ORROM et DAVID J. WALLACE. Can. J. Chem. **56**, 1628 (1978).

On décrit la première synthèse totale du spirosesquiterpène (−)-acorénone (**1**). L'étape critique implique une spiroannélation de l'énamine de l'aldéhyde **11** avec la méthoxy-1 butène-3 one-2 (**16**) en présence d'acide acétique pour donner la cétone **17**. La réaction de **17** avec l'iodure de méthylmagnésium, suivie par un traitement de l'alcool **18** qui en résulte avec de l'acide *p*-toluènesulfonique dans le benzène au reflux, conduit directement à **1** avec un rendement global qui est bon. Comme le produit de départ pour la préparation de l'aldéhyde cyclopentanique **11** est le (+)-limonène, le produit final est optiquement actif et on a donc établi ainsi la configuration absolue de la (−)-acorénone (**1**) que l'on retrouve dans la nature. On décrit aussi la préparation d'un certain nombre d'autres monoterpènes cyclopentaniques optiquement actifs (**4** et **13**).

[Traduit par le journal]

The spirosesquiterpene (−)-acorenone (**1**) was isolated from sweet flag oil (*Acorus calamus* L.) by Sorm and co-workers (2) and its structure determined by degradation (3) and by comparison with acorenone-B (**2**) (4), which differs only in its configuration at the spiro carbon. Syntheses of **2** were reported by several groups (5) and the conversion of (±)-**2** to (±)-**1** was recently effected (6). In this report we outline the first synthesis of (−)-**1** and also describe the preparation of a number of optically active cyclopentanoid monoterpenes which were synthons in our proposed routes to **1**.

Our initial approach to the synthesis of **1** (Scheme 1) involved as the first and critical step a photocycloaddition of **3** to **4**. Previous investigation of a model system employing methylenecyclopentane as the alkene component had given the desired adduct, which in two additional steps was converted to the spiro[4.5]decan-7-one system in moderate overall yield (7). It was first necessary to prepare a sample of **4** and as we chose (+)-limonene (**7**) as our starting material all subsequent products were optically active. Catalytic hydrogenation of **7** yielded (+)-*p*-menth-1-ene, which was converted by performic acid to a mixture of *trans*-*p*-menthane-1,2-diols (**8**) (8). Cleavage of **8** with periodic acid in aqueous pyridine gave (−)-3-isopropyl-6-oxoheptanal (**9**) (9) which was cyclized using acetic acid and piperidine[2] to the



SCHEME 1

[1]A preliminary communication on a portion of this work has appeared (1).

[2]This procedure was used previously for the cyclization of 3-isopropenyl-6-oxoheptanal (10).

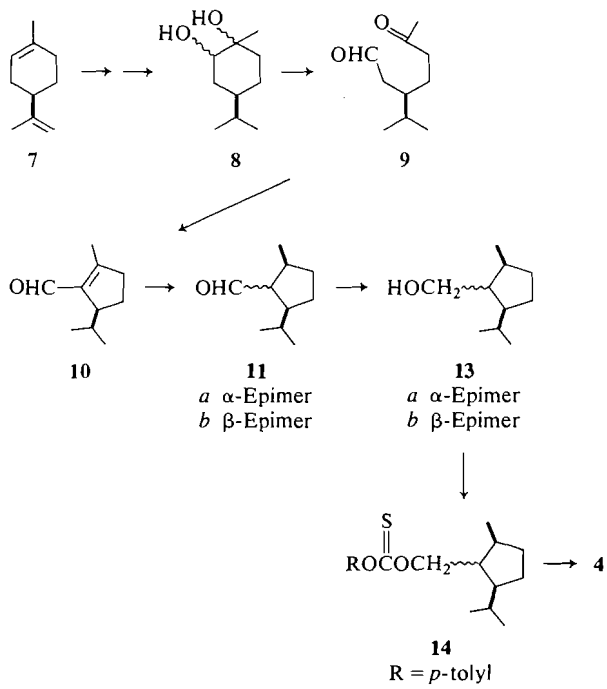


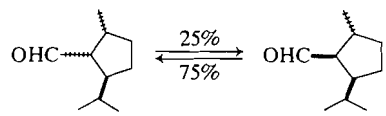
SCHEME 2

(−)-aldehyde **10**. **10** was reported previously (11) but herein we give experimental details for its preparation and complete spectral data.

Reduction of the carbon–carbon double bond in the unsaturated aldehyde **10** was the critical step in establishing the *cis*-orientation of the substituents at the 1 and 3 positions. It was anticipated that the large isopropyl group would block the approach of the reagent to the β-face of **10** and thus attack on the α-face would give the desired *cis* geometry. In the fact, catalytic hydrogenation of **10** with 5% palladium-on-charcoal in absolute ethanol gave an epimeric mixture of the desired aldehydes (**11**) in which the all *cis* product (**11***b*) predominated.[3] To prove the *cis* geometry of the 1 and 3 substituents, pure samples of the two epimers were collected by gc and each was treated with methanolic sodium methoxide to effect epimerization. Gas chromatographic analysis of the products showed a mixture of 90% of **11***a* and 10% of **11***b* in both instances. In a previous investigation, Buchi and Wuest (12) prepared similar aldehydes in which the 1 and 3 substituents were *trans* (**12**) and found that the equilibrium mixture consisted of 75% of **12***a* and 25% of **12***b*. In the case of aldehydes **11**, an even greater preference for one of the aldehydes, namely **11***a*, would be expected as the considerable steric strain in the all *cis* isomer, **11***b*, would be relieved. The physical data for both epimers are recorded in the Experimental section but in subsequent preparative reactions the mixture was used.

Lithium aluminum hydride reduction of aldehyde **11** gave a mixture of alcohols (**13**) with the ratio depending on the ratio of epimeric aldehydes present in the starting material. Gas chromatographic samples of pure **11***a* and **11***b* were reduced separately to confirm the conversions to **13***a* and **13***b*, respectively. Physical data for both alcohols are reported but normally the mixture was used in subsequent steps.

The last step in the preparation of **4** was the dehydration of **13**. Pyrolysis of the xanthate of **13** gave consistently low yields of **4** (<10%) as the favoured pathway appeared to be conversion to the dithiolcarbonate. This side reaction has been noted previously in the case of xanthates of primary alcohols (13). A recently reported pyrolysis method (14), which is particularly effective in the case of hindered alcohols, was attempted next. The thiocarbonate *O*-ester **14** was prepared by reaction of **13** with *O*-4-methylphenyl chlorothioformate (15) in pyridine. Pyrolysis of crude **14** at 230°C with distillation of the product as formed, yielded (−)-*cis*-1-methyl-2-methylene-3-isopropylcyclopentane (**4**)[4] in 68% yield from alcohol **13**. Gas chromatographic analysis on



12*a* **12***b*

two columns indicated **4** to be >95% pure and ir, nmr, mass spectral, and elemental analyses were all consistent with the structure proposed. Pyrolysis of **14** prepared from an alcohol mixture which was predominantly either **13***a*[5] or **13***b* gave similar yields of **4** showing that both alcohols were effective precursors of the alkene.

The above sequence describes the synthesis of a variety of derivatives with the 1,2-dimethyl-3-isopropylcyclopentane carbon skeleton which is present in several classes of natural products: the iridoids (17*a*), the insect monoterpenoids (17*b*), and the monoterpene alkaloids (17*c*). In almost all these compounds the methyl and isopropyl moieties at the 1 and 3 positions bear a *trans* relationship to each other and consequently most synthetic investigations have been directed towards the preparation of compounds with this particular stereochemistry (18). This study provides entry not only into optically active cyclopentanoid derivatives with less common

[3]The ratio of the two epimers varied from run to run and longer exposure to the catalyst resulted in epimerization of **11***b* to **11***a*.

[4]Racemic **4**, **13***a* and **13***b* were previously obtained as minor components of a complex reaction mixture but none was isolated or characterized (16).

[5]Prepared by epimerization of **11** before reduction.

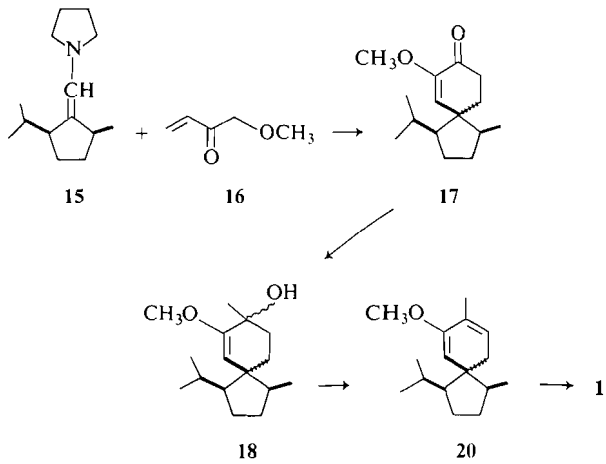
cis orientation of the 1 and 3 substituents but also yields compounds which are potential synthons for the preparation of more complex natural products.

Now that the desired alkene **4** was available, we were able to investigate the approach to **1** as outlined in Scheme 1. Irradiation of **3** and **4** in benzene using conditions previously described for the model system (7) gave a complex mixture of adducts from which **5** was isolated in low yield. Conversion of **5** to **6** was effected using the procedures previously reported (7) but the overall yield was low and the separation of the products was difficult. Therefore, this approach was abandoned in favour of a shorter and more efficient route to **1** in which it was still possible to use aldehyde **11** (Scheme 2).

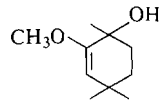
In our second approach, the spiro system was formed by an annelation reaction of an enamine with a vinyl ketone. Reaction of **11** with pyrrolidine gave enamine **15** (Scheme 3) as a 4:1 mixture of double bond isomers. When **15** was stirred at room temperature with an excess of 1-methoxy-3-buten-2-one (**16**) (19) and 1 equiv. of acetic acid (in the absence of solvent) a 35% yield of (+)-**17** was isolated. Compound **17** was the spiroannelation product expected from an initial Michael reaction of **16** with the less hindered α-face of **15** followed by cycloaldolization. If acetic acid was not present in the initial stages of the reaction of **15** and **16** a different C_{15} product of undetermined structure, which could not be converted to either **1** or **2**, was formed. The use of less than an equivalent of acetic acid resulted in mixtures of **17** and the unknown compound. Presumably the acetic acid effectively catalyzes the cycloaldolization step without destroying the reactivity of the enamine by protonation. Enone **16** has been used by Wenkert and others (19) in annelation reactions but this is the first report of its use in the preparation of spiro systems. Spiroannelation reactions employing methyl vinyl ketone and enamines of cyclic aldehydes have been reported (20), but the use of solvents resulted in long reaction times. When these procedures were employed with reactants **15** and **16** none of the desired product was isolated. The use of this enamine – enone – acetic acid system in other annelation reactions is presently under investigation.

The successful preparation of **17** gave an ideal synthon for introduction of a methyl group at C(8), a double bond between C(8) and C(9), and a carbonyl group at C(7) as required to complete the synthesis of **1**. Treatment of **17** with methylmagnesium iodide gave alcohol **18** and introduced the desired methyl group. Hydrolysis of the enol ether moiety in **18** with a two-phase ether – aqueous sulfuric acid mixture proceeded much more slowly and in lower yield than



SCHEME 3

was the case with the model system **19**[6] because of steric hindrance in the region of the C(6)—C(7) double bond of **18**. This result provided additional support for the configuration assigned to the spiro carbon in **17**. Finally it was discovered that merely



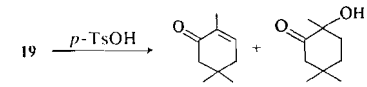
19

by refluxing a solution of **18** in benzene containing a catalytic amount of *p*-toluenesulfonic acid both the dehydration and the hydrolysis steps could be accomplished in one operation to yield (−)-acorenone (**1**) in 74% yield.[7] If the reflux period was halved, diene **20** could be isolated in significant yield. This result indicated that the dehydration step took place first and the water formed then effected hydrolysis of the enol ether. Conversion of **17** → **1** constitutes a new alkylative carbonyl transposition[8] and its utility in the synthesis of other natural products will be reported in a separate publication.

The synthetic sample of (−)-**1** was compared with

[6]Prepared by reaction of methylmagnesium iodide with 2-methoxy-4,4-dimethyl-2-cyclohexenone (19).

[7]Similar treatment of model compound **19** gave a 40:60 mixture of enone and ketol, respectively, indicating that the dehydration and hydrolysis reactions proceeded at about the same rate in this unhindered system. It was not possible to dehydrate the ketol using these conditions and thus our clean conversion of **18** → **1** was dependent on steric hindrance enabling the dehydration to be effected before the hydrolysis step.



[8]For an extensive list of other carbonyl transposition reactions see ref. 1 in a recent paper by Trost *et al.* (21).

a natural sample which was isolated as previously described (2) from European calamus oil.[9] The two samples were identical in every respect including the magnitude and sign of the optical rotation (see Experimental).[10] This synthesis of (−)-**1** from a compound of known absolute configuration, (+)-limonene (**7**), establishes for the first time the absolute configuration of the natural product and also represents the first total synthesis of (−)-acorenone.

Experimental

Infrared spectra were recorded on a Beckman Model IR 12 spectrophotometer, nmr spectra on a Varian A-60A spectrometer using TMS (τ 10.0) as internal standard, uv spectra on a Cary 118 spectrophotometer and optical rotations were determined on a Bendix NPL Automatic Polarimeter, Type 143 at 25°C using a 1-cm cell and carbon tetrachloride as solvent. Mass spectra were obtained on a Varian MAT CH7 spectrometer operating at 70 eV while accurate mass determinations were obtained on a VG Micromass 7070F unit. Gas chromatoraphic analyses and collections were performed on an Aerograph Autoprep Model A-700 with either of the following: column *A*, 20% Carbowax 20 M on Chromosorb W, 6 ft × 0.25 in; column *B*, 15% benzyl cyanide – $AgNO_3$ on Chromosorb W, 9 ft × 0.19 in; column *C*, 20% Carbowax 20 M on Chromosorb W, 9 ft × 0.25 in. Thin-layer chromatographic separations and analyses were accomplished on silica gel GF 254 with thickness of 0.50 and 0.25 mm, respectively. Elemental analyses were performed by H. S. McKinnon, University of Guelph or A. B. Gygli, Microanalysis Lab, Toronto.

*(−)-3-Isopropyl-6-oxoheptanal (**9**)*

Freshly distilled limonene (**7**), $[\alpha]_D$ +125°, was hydrogenated using 5% platinum-on-charcoal without solvent (8). The resultant *p*-menth-1-ene was oxidized to the *trans-p*-menthane-1,2-diols (**8**) using performic acid followed by ethanolic potassium hydroxide (8). The viscous mixture of distilled diols was oxidized with periodic acid in pyridine to give **9** after distillation in 78% yield (9).

*(−)-1-Methyl-2-formyl-3-isopropylcyclopentene (**10**)*

A solution of 42.4 g (0.25 mol) of **9**, 3 ml of glacial acetic acid, 3 ml of piperidine in 300 ml of dry benzene was heated to reflux for 2.5 h during which time the water produced (4.5 ml) was removed by use of a Dean–Stark trap. The benzene solution was cooled and extracted with dilute hydrochloric acid, with saturated sodium bicarbonate solution and finally with saturated brine solution. The organic phase was dried ($MgSO_4$), the solvent was removed under vacuum and the residue distilled to give 29.0 g (76%) of **10**, which exhibited only one peak on gc analysis using column *A* at 200°C: bp 68–74°C/1.4 Torr; $[\alpha]_D$ −7.9°; ir (neat): 2970, 2870, 2820, 2710, 1670, 1635 cm^{-1}; uv_{max} (EtOH): 250 nm (ε 12 000); nmr ($CDCl_3$) τ: 0.01 (1H, s), 7.84 (3H, t, J = 1.4 Hz), 7.4–8.5 (6H, m), 9.12 (3H, d, J = 6.8 Hz), 9.35 (3H, d, J = 6.8 Hz).

*1-Methyl-2-formyl-3-isopropylcyclopentane (**11**)*

A sample of 15.6 g (0.103 mol) of freshly distilled **10** in 190 ml of absolute ethanol was placed in a 500 ml hydrogenation flask and 1.0 g of 5% Pd-on-charcoal was added. The suspension was hydrogenated for 45 min at room temperature in a Parr Series 3910 low pressure apparatus (initial pressure 14 psi, final pressure 6 psi). The catalyst was filtered and the solvent was carefully removed at reduced pressure. Fractional distillation of the residue at 80–88°C/4.5 Torr gave 10.3 g (65%) of product which on gc analysis on column *A* at 132°C indicated two major peaks in a ratio of 1:2 in order of elution from the column. The two peaks, **11***a* and **11***b* respectively, were collected as oils by preparative gc and the following physical properties were determined. Aldehyde **11***a*: $[\alpha]_D$ −17.8°; ir (CCl_4): 2968, 2880, 2820, 2714, 1728, 1473, 1390, 1373, 1115 cm^{-1}; nmr (CCl_4) τ: 0.45 (1H, d, J = 3.0 Hz), 7.8–9.0 (8H, m), 9.00 (3H, d, J = 6.5 Hz), 9.11 (3H, d, J = 6.0 Hz), 9.14 (3H, d, J = 6.0 Hz); ms *m/e* (relative intensity): 154 (M^+, 1), 152 (16), 127 (100), 110 (42), 109 (40), 87 (52), 81 (87), 69 (75). *Anal.* calcd. for $C_{10}H_{18}O$: C 77.87, H 11.76; found: C 77.72, H 11.56. Aldehyde **11***b*: $[\alpha]_D$ +16.4°; ir (CCl_4): 2968 2890, 2836, 2728, 1727, 1474, 1390, 1372, 1120 cm^{-1}; nmr (CCl_4) τ: 0.23 (1H, d, J = 5.5 Hz), 7.7–8.6 (8H, m), 8.8–9.2 (9H, three d); ms *m/e* (relative intensity): 154 (M^+, 1), 152 (17), 127 (34), 115 (39), 110 (46), 109 (34), 87 (76), 81 (60), 69 (75). *Anal.* calcd. for $C_{10}H_{18}O$: C 77.87, H 11.76; found: C 77.58, H 11.76.

*Epimerization of **11***

A solution of 75 mg of **11***a* and 75 mg sodium methoxide in one ml of methanol was left under nitrogen at room temperature for 18 h. Water (5 ml) was added to the reaction solution and the product was extracted with ether to yield 67 mg of a colorless residue. Gas chromatographic analysis (column *A*, 132°C) indicated an equilibrium mixture of 90% of **11***a* and 10% of **11***b*. Similarly, treatment of 23 mg of **11***b* as described above gave a mixture of 90% of **11***a* and 10% of **11***b*.

*1-Methyl-2-hydroxymethyl-3-isopropylcyclopentane (**13**)*

A solution of 20 g (0.13 mol) of crude **11** in 20 ml of anhydrous ether was added dropwise over 1 h to a stirred suspension of 5.0 g (0.13 mol) of lithium aluminum hydride in 200 ml of anhydrous ether. The reaction mixture was then heated to reflux for an additional 0.5 h, cooled, and the excess hydride reagent destroyed by successive additions of 5 ml of ether, 5 ml of 4 *M* sodium hydroxide solution, and 15 ml of water. The resultant granular precipitate was removed by filtration and the ether solution was dried with anhydrous $MgSO_4$. The solvent was removed and the residue distilled to give 14 g (70%) of alcohol **13**, bp 65–70°C/1.2 Torr. Gas chromatographic analysis (column *A*, 172°C) of **13** showed the two major peaks at 11 min and 13.5 min were present in a ratio of 1:4, respectively.[11] Pure samples of aldehydes **11***a* and **11***b* were reduced separately and it was shown that **11***a* was converted to the earlier gc peak, alcohol **13***a* and **11***b* was converted to the second gc peak, alcohol **13***b*. Pure samples of alcohols **13***a* and **13***b* were collected by preparative gc and their spectral properties determined. Alcohol **13***a*: $[\alpha]_D$ −15.6°; ir (CCl_4): 3640, 2975, 2895, 1045 cm^{-1}; nmr (CCl_4) τ: 5.90 (1H, s, disappeared on addition of D_2O), 6.48 (2H, m), 7.9–9.1 (8H, m), 8.98 (3H, d, J = 6.5 Hz), 9.08 (3H, d, J = 5.5 Hz), 9.13 (3H, d, J = 5.5 Hz); ms *m/e* (relative intensity): 156 (M^+, 2), 138 (14), 123 (36), 95 (100), 81 (39), 69 (43), 55 (36). *Anal.* calcd. for $C_{10}H_{20}O$: C 76.86, H 12.90; found: C 76.86, H 12.97. Alcohol **13***b*: $[\alpha]_D$ +0.28°; ir (CCl_4): 3640, 2970, 2890, 1473, 1389,

[9]We wish to thank Fritzsche Ltd., Toronto, for a generous sample of this oil.

[10]We thank Professor V. Herout, Czechoslovak Academy of Science, for an ir spectrum of **1** and Professor J. D. White, Oregon State University, for a sample of (−)-**2**.

[11]The ratio in **13** is different than in **11** as the aldehyde undergoes partial epimerization upon distillation.

1371, 1039 cm^{-1}; nmr (CCl_4) τ: 6.47 (2H, d, J = 4.5 Hz), 7.8–9.0 (8H, m), 8.15 (1H, s, disappeared on addition of D_2O), 8.93 (3H, d, J = 6.5 Hz), 9.10 (6H, m); ms *m/e* (relative intensity): 156 (M^+, 2), 141 (10), 138 (7), 123 (41), 95 (100), 81 (59), 69 (81). *Anal.* calcd. for $C_{10}H_{20}O$: C 76.86, H 12.90; found: C 77.11, H 12.75.

O-4-Methylphenyl Thiocarbonate **14**

To a solution of 6.5 g (42 mmol) of distilled alcohol **13** in 175 ml of pyridine at room temperature was added with stirring 8.2 g (44 mmol) of *O*-4-methylphenyl chlorothioformate (15). The viscous precipitate which formed initially dissolved after one h and stirring was continued an additional 4 h. The reaction solution was poured into water (500 ml) and extracted with chloroform (4 × 100 ml). The combined organic layers were washed with cold 6 *N* HCl (2 × 100 ml), with a saturated solution of sodium bicarbonate, with a saturated brine solution and dried with anhydrous $MgSO_4$. The solvent was removed completely using a rotary evaporator and then a vacuum pump to leave 13.5 g of crude thiocarbonate **14** as a dark amber oil: ir (neat): 2910, 2830, 1540, 1495, 1450, 1270, 1210, 1190 cm^{-1}. Complete removal of the solvent at this stage facilitated the isolation in the next step of alkene product which was not contaminated with chloroform.

*(−)-*cis*-1-Methyl-2-methylene-3-isopropylcyclopentane (4)*

A micro distillation apparatus was assembled with a dropping funnel placed in one neck of the distillation flask. Four millilitres of triethylene glycol in the flask were heated to 230°C and then the 13.5 g of crude thiocarbonate **14** were added dropwise at a rate (addition time about one h) which maintained slow distillation of the alkene product. The pot temperature was then slowly raised to 250°C over an additional hour. The resultant 8.8 g of crude yellow distillate, which contained *p*-cresol as the major impurity, was chromatographed on 75 g of silica gel (60–200 mesh) and the product was eluted with pentane to give 3.9 g (68% from alcohol **13**) of alkene **4** as a colorless liquid with a pinene-type odor. Gas chromatographic analysis on columns *A* (72°C) and *B* (60°C) showed the alkene to be >95% pure: $[\alpha]_D$ −28.5°; ir (neat): 3030, 2940, 2850, 1645, 1470, 1390, 1370, 880 cm^{-1}; nmr (neat) τ: 5.16 (2H, m), 7.4–9.0 (7H, m), 9.00 (3H, d, J = 6.5 Hz), 9.07 (3H, d, J = 6.5 Hz), 9.23 (3H, d, J = 6.5 Hz); ms *m/e* (relative intensity) 138 (M^+, 9), 123 (17), 95 (100), 81 (61), 67 (50). *Anal.* calcd. for $C_{10}H_{18}$: C 86.88, H 13.12; found: C 86.58, H 13.42.

Pyrrolidine Enamine **15**

A solution of 20.4 g (0.132 mol) of **11** and 19.4 g (0.273 mol) pyrrolidine in 50 ml of benzene was refluxed under nitrogen for 6 h. During the reflux period 2.4 ml water was formed and collected in a Dean–Stark water separator. The solvent was removed at reduced pressure and the residue distilled to yield 22.0 g (80%) of **15**. Gas chromatographic analysis on column *C* at 179°C showed the distillate to be a 1:4 mixture of isomers. Compound **15** had bp 80–90°C 0.25 Torr; $[\alpha]_D$ +34.2°; ir (neat): 2950, 1655, 1465, 1455 cm^{-1}; nmr (CCl_4) τ: 4.39 (1H, m), 7.07 (4H, m), 8.1–8.6 (11H, m), 8.9–9.3 (9H, m); ms *m/e* (relative intensity): 207 (M^+, 18), 192 (6), 165 (33), 164 (100), 148 (7), 120 (7), 95 (10), 93 (11), 70 (18). *Mol. wt.* calcd. for $C_{14}H_{25}N$: 207.1987; found: 207.1967.

(+)-1-Isopropyl-7-methoxy-4-methylspiro[4.5]dec-6-en-8-one (17)

To 3.0 g (14 mmol) of **15** was added with stirring under nitrogen through a serum cap 1.7 g (17 mmol) of 1-methoxy-3-buten-2-one (**16**). The yellow solution was cooled in an ice bath and 0.84 g (14 mmol) acetic acid was added dropwise with stirring. After 10 min the ice bath was removed and the stirring was continued for 6 h at which time the reaction mixture was a dark brown viscous liquid. The mixture was dissolved in 100 ml chloroform and extracted three times with water, once with 5% HCl, once with saturated $NaHCO_3$ solution, once with brine and dried with anhydrous $MgSO_4$. Removal of the solvent and short path distillation (bath 80–100°C) gave 1.18 g (35%) of **17**. Analysis by gc (column *C* at 225°C) or tlc ($CHCl_3$) indicated the distillate was >90% pure. An analytical sample was prepared by preparative tlc: $[\alpha]_D$ +34.5°; ir (neat): 2960, 1695, 1625, 1210, 1140 cm^{-1}; uv_{max} (EtOH): 266 nm (ε 8000); nmr (CCl_4) τ: 4.5 (1H, s), 6.44 (3H, s), 7.56 (2H, d, J = 6.5 Hz), 7.8–8.5 (9H, m), 8.9–9.2 (9H, m); ms *m/e* (relative intensity): 236 (M^+, 33), 193 (32), 180 (22), 165 (86), 152 (100), 137 (42), 123 (47). *Mol. wt.* calcd. for $C_{15}H_{24}O_2$: 236.1776; found: 236.1779.

(+)-1-Isopropyl-7-methoxy-4,8-dimethylspiro[4.5]dec-6-en-8-ol (18)

A solution of 0.86 g (3.6 mmol) of **17** in 15 ml anhydrous ether was added dropwise over 15 min to 8.4 ml of a 0.5 *M* (4.2 mmol) solution of methylmagnesium iodide in ether under an atmosphere of nitrogen. The reaction was heated to reflux for 1 h, cooled, and poured into an NH_4Cl solution. The aqueous phase was extracted twice with ether and the combined organic phases were extracted with saturated $NaHCO_3$ solution, with brine, and dried ($MgSO_4$). Removal of the solvent gave 0.89 g (98%) of crude **18** which tlc (50% ether–petrol) showed to be a 40:60 mixture of isomers at R_f's 0.55 and 0.50, respectively. An analytical sample of the mixture of **18** was separated by preparative tlc: $[\alpha]_D$ +33°; ir (neat): 3470, 2970, 1665, 1215, 1140 cm^{-1}; nmr (CCl_4) τ: 5.75 (1H, s), 6.47 (3H, s), 7.83 (1H, s, disappears on addition of D_2O), 8.0–8.6 (11H, m), 8.73 (3H, s), 8.9–9.2 (9H, m); ms *m/e* (relative intensity): 252 (M^+, 36), 237 (11), 196 (32), 168 (100), 149 (91), 136 (67), 109 (86). *Mol. wt.* calcd. for $C_{16}H_{28}O_2$: 252.2089; found: 252.2087.

(−)-Acorenone (1)

A solution of 0.11 g (0.44 mmol) of tlc purified **18** and 0.02 g of *p*-toluenesulfonic acid in 10 ml benzene was heated to reflux under nitrogen for 4 h. The solution was cooled, 30 ml benzene was added, and the solution was extracted with saturated $NaHCO_3$ solution, with brine, and dried ($MgSO_4$). Removal of the solvent gave 94 mg of crude product which was purified by preparative tlc (20% ether–petrol) to yield 71 mg (74%) of pure (−)-acorenone (**1**): $[\alpha]_D$ −28°; ir (CCl_4): 2965, 1677, 1380, 1365, 1190 cm^{-1}; uv_{max} (EtOH): 238 nm (ε 8200); nmr was identical to that previously reported (6). A sample of natural **1** isolated from European calamus oil as previously described (2) and purified by preparative gc had spectral properties identical to the synthetic **1** and $[\alpha]_D$ −27°. The gc retention times of the two samples were also coincident.

Etude structurale du fluorure de chloryle en phase solide

GEORGES TANTOT, PHILIPPE JOUBERT ET ROLAND BOUGON[1]

Division de chimie, Département de Génie Isotopique, Centre d'Etudes Nucléaires de Saclay, Boîte Postale No 2, 91190 Gif/Yvette, France

Reçu le 26 juillet 1977

GEORGES TANTOT, PHILIPPE JOUBERT et ROLAND BOUGON. Can. J. Chem. **56**, 1634 (1978).

Le fluorure de chloryle ClO_2F est étudié en phase solide par diffraction des rayons X et des neutrons ainsi que par la spectroscopie vibrationnelle.

Les diagrammes de diffraction ont été indexés en corrélation avec la structure connue de ClF_3. A 77 K, la maille élémentaire de ClO_2F a les paramètres suivants: $a = 8.85 \pm 0.02$ Å, $b = 6.17 \pm 0.02$ Å, $c = 4.62 \pm 0.01$ Å; $\beta = 95.0 \pm 0.1°$; $Z = 4$. Cette maille, qui peut être considérée comme résultant d'une légère déformation monoclinique de la maille orthorhombique de ClF_3, est compatible avec les mesures de densité réalisées sur ClO_2F et ClF_3.

Le groupe d'espace C_{2h}^1 ($P2/m$) permet le mieux de rendre compte des résultats de la spectroscopie vibrationnelle et des raies observées dans les diagrammes de diffraction de ClO_2F poly-cristallin.

GEORGES TANTOT, PHILIPPE JOUBERT, and ROLAND BOUGON. Can. J. Chem. **56**, 1634 (1978).

Chloryl fluoride, ClO_2F was studied in its solid phase by X-ray and neutron diffraction techniques and by vibrational spectroscopy.

The powder diffraction patterns of ClO_2F were indexed by comparison with ClF_3. At 77 K, the parameters of the monoclinic cell of ClO_2F are as follows: $a = 8.85 \pm 0.02$ Å, $b = 6.17 \pm 0.02$ Å, $c = 4.62 \pm 0.01$ Å, $\beta = 95.0 \pm 0.1°$, $Z = 4$. This cell, which can be thought as arising from a slight monoclinic deformation of the orthorhombic cell of ClF_3, is consistent with the density measurements also performed on ClO_2F and ClF_3.

The space group C_{2h}^1 ($P2/m$) was found to be the best compatible with both the vibrational data and the lines observed in the powder diffraction patterns for ClO_2F in the polycrystalline state.

Introduction

Peu de résultats structuraux sont disponibles sur le fluorure de chloryle ClO_2F, composé particulièrement réactif (1). La spectroscopie vibrationnelle infrarouge et Raman (2, 3), puis la spectroscopie de micro ondes (4, 5) ont permis de déterminer la forme de la molécule. Celle-ci a une structure pyramidale de symétrie ponctuelle C_s avec l'atome de chlore au sommet, en accord avec la théorie de la répulsion des paires électroniques de valence (6). La molécule possède six modes fondamentaux de vibration, pour lesquels nous adoptons la dénomination usuelle (3). Quatre sont de type a' parfaitement symétrique et deux de type a'', tous sont actifs en absorption infrarouge et en diffusion Raman.

Il nous a paru intéressant de poursuivre ces études dans la phase solide, pour laquelle aucun résultat n'est connu. En effet, le fluorure de chloryle possède des propriétés relativement voisines du trifluorure de chlore ClF_3, dont la structure cristalline à basse température a été déterminée (7) et qui fait l'objet d'une étude spectroscopique (8). Nous avons employé à la fois la cristallographie et la spectroscopie vibrationnelle, méthodes dont les résultats se complètent souvent (9). Nous avons étudié en phase solide les spectres de diffusion Raman en fonction de la température, et le spectre infrarouge du composé pur et dilué par le chlore. Les résultats structuraux acquis sont complétés par les données déduites du diagramme de poudre et permettent de proposer un groupe d'espace pour ClO_2F.

Partie expérimentale

Le fluorure de chloryle (98%) est fourni par la Société Comurhex (Pierrelatte, France). Il est traité par le fluorure de sodium anhydre, distillé entre −78°C et 0°C. La pureté est vérifiée par spectroscopie infrarouge et par microsublimation (10).

Les spectres infrarouges sont enregistrés de 4000 à 400 cm^{-1} sur un spectromètre Beckman IR 9. Les appareils sont étalonnés en fréquence à l'aide d'un film de polystyrène et de composés gazeux. Pour les spectres de contrôle en phase gazeuse, nous avons utilisé une cellule de dix centimètres en monel, préalablement passivée par ClO_2F, à fenêtres de chlorure d'argent. Le spectre Raman de ClO_2F gazeux a été étudié, sous une pression de 1200 Torr dans une cuve à fenêtres de corindon orientées et des mesures de polarisation ont été faites. A basse température, nous avons employé un cryostat à azote liquide mis au point au laboratoire, à fenêtres de chlorure d'argent. Nous obtenons par conduction une température fixe de 90 K, ce qui explique le choix du chlore comme diluant dans l'étude en matrice au lieu des habituels gaz nobles. Les spectres de diffusion Raman sont enregistrés sur un spectromètre Coderg T 800. La source d'excitation est un laser Spectra-physics modèle 164 à argon ionisé (raies bleue à 488.0 nm et verte à 514.5 nm) dont les raies de plasma sont éliminées par des filtres interférentiels. L'étalonnage est réalisé avec une

[1]A qui toute demande concernant ce travail peut être demandée

lampe au néon (11). Nous avons utilisé principalement un cryostat à hélium liquide de la Société l'Air Liquide, employant un bain de gaz refroidi. Nous avons réalisé les diagrammes de diffraction de poudre à 77 K à l'aide de neutrons thermiques ($\lambda = 1.140$ Å) et de rayons X (raie CuK_α). Une chambre Debye-Scherrer a été spécialement modifiée pour enregistrer ce dernier (12). Les deux spectres sont semblables et, dans les deux cas, les cristallites sont trop gros pour pouvoir considérer les intensités comme fiables. Les échantillons sont contenus dans des tubes de KelF ou de quartz de 6 à 14 mm de diamètre, ou des capillaires de 0.4 mm de diamètre (RX).

La densité de la phase liquide a été mesurée à 24.7°C par pesée d'un même volume de ClF_3, de densité connue (13), et de ClO_2F, soit 1.581 ± 0.006. Nous avons observé la variation de la densité avec la température dans un tube calibré. Nous avons vérifié le bon calibrage du tube et sa dilatation thermique à l'aide d'un composé de référence, l'oxyde d'éthyle (14). Entre 150 et 300 K, la densité de ClO_2F liquide obéit à l'équation

$$d = 1.649 - 2.631.10^{-3}t\,(°C)$$

avec un intervalle de confiance à 95% égal à 0.007.

La densité apparente du solide au point de fusion (150 K) est égale à 2.18. Nous avons corrélé dans les phases liquides et solide la variation de la densité avec la température et le déplacement des raies de diffusion Raman. Ce calcul donne par extrapolation la densité apparente à 77 K (température d'obtention des spectres de diffraction), soit 2.21 ± 0.03.

Le composé ClF_3 servira de comparaison en cristallographie et nous avons obtenu de la même façon à 77 K une densité apparente de 2.47 pour une valeur calculée de 2.53 (7).

Resultats et discussion

Etude spectroscopique

Nous avons enregistré les spectres vibrationnels du fluorure de chloryle (donnés à 90 K en fig. 1). On remarque dans ces spectres la séparation de certaines raies en plusieurs composantes. L'origine de ces éclatements qui peut a priori provenir de couplage intermoléculaires, d'effets isotopiques ou d'effets de site sera considérée plus loin.

Si l'on considère les intensités relatives des raies Raman des modes internes: les bandes ν_3 et ν_4 ont des intensités voisines, et supérieures d'un ordre de grandeur à celles des bandes ν_5 et ν_6. De même en corrigeant l'intensité de ν_1 de la perte de sensibilité du détecteur dans ce domaine on obtiendrait pour cette bande une intensité comparable à celle de ν_3 et ν_4. Les mêmes résultats ont été obtenus en phase gazeuse, où de plus la mesure des taux de polarisation a montré que seules les raies ν_5 et ν_6 étaient dépolarisées (15).

Ceci indique le caractère symétrique du mode ν_4, qui est le mode critique (si la molécule devient plane, il perd le caractère de parfaite symétrie), et résultat important pour cette étude, que la molécule reste probablement, pyramidale en phase solide.

Des mesures calorimétriques[2] ont montré l'existence d'une phase solide unique entre 78 et 150 K.

[2]P. Barberi. Communication personelle.

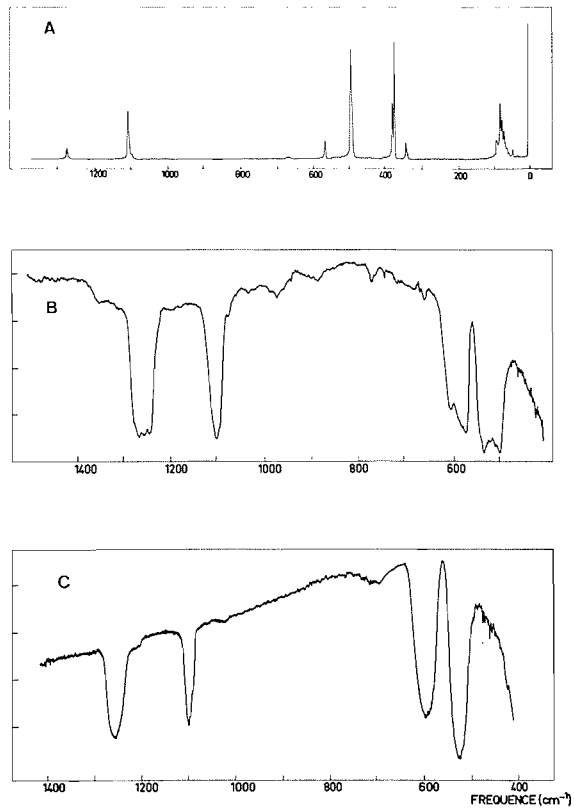

FIG. 1. Spectres vibrationnels de ClO_2F solide (90 K): (A) spectre Raman du solide; (B) spectre infrarouge du solide; (C) spectre infrarouge du composé dilué dans le chlore solide (4.3%).

Par l'étude des spectres Raman en fonction de la température, nous concluons à l'absence de transition jusqu'à 10 K pour les raisons suivantes: (*i*) la conservation de l'allure du spectre (et des intensités relatives), (*ii*) une même analogie dans la zone des modes externes, (*iii*) un déplacement continu et monotone des bandes de diffusion. Le rapport des intensités entre les composantes du mode ν_4 ne varie pas, alors qu'il serait vraisemblablement sensible à une modification du réseau cristallin. L'apparent changement d'allure de certains modes externes entre 140 et 10 K tient à une meilleure résolution à basse température (la largeur moyenne de ces modes passe de 3.4 à 1.6 cm^{-1}), les modes supplémentaires étant masqués par les ailes des modes intenses.

Si l'on considère à présent le spectre infrarouge (fig. 1) du composé à l'état pur ou dilué. Les bandes sont larges et mal résolues, ce phénomènes est fréquent parmi les composés interhalogènes. Dans le solide pur, les bandes comportent de une à quatre composantes. Dans le spectre réalisé en matrice de chlore (4.3% molaire en ClO_2F); les composantes supplémentaires ou toutes disparues et les raies se

sont affinées. Les raies infrarouges supplémentaires du solide pur ne sont donc pas attribuables à l'effet isotopique du chlore, et ceci est en accord avec les observations et calculs de Begun *et al.* (3). Les éclatements de raies sont donc dûs uniquement à des couplages intermoléculaires et/ou des effets de site.

On peut faire aussi une remarque d'incidence importante concernant les intensités relatives: on constate que même si les raies a' et a'' sont actives en infrarouge et en Raman, il existe cependant une certaine exclusion en intensité entre les deux phénomènes. Ainsi par exemple la branche du mode ν_4 à 378 cm^{-1} doit posséder un caractère antisymétrique.

Les attributions des vibrations internes présentées dans le tableau 1 ont été faites en tenant compte de ces remarques. L'examen de ce tableau montre d'importants écarts de fréquence entre les contreparties infrarouge et Raman d'un même mode, tel ν_2. Pour ν_3 cela est moins apparent à cause de la variation d'absorption des fenêtres en AgCl dans ce domaine. En l'absence d'un centre de symétrie, la coïncidence infrarouge Raman doit être observée pour toutes les bandes. Les exclusions observées indiquent donc la présence d'un centre d'inversion dans le motif observé en spectroscopie (9), et ce centre est propre au motif puisque la molécule isolée est de symétrie C_s.

Les modes externes, qu'on observe au nombre de douze à 10 K (15) permettent de préciser le nombre de molécules du motif optique, puisque ce nombre correspond à un couplage, entre au moins trois molécules (16). Par ailleurs la présence du centre d'inversion indique un nombre pair de molécules, la motif optique doit donc comporter quatre éléments.

Etude structurale

Nous avons complété le travail précédent par une étude cristallographique. Le motif optique comporte quatre molécules d'après nos conclusions, et nous avons recherché une maille cristallographique compatible. Des tentatives d'indexation automatique, fondées sur la minimisation du volume de la maille (17), montrent l'absence de solution dans les systèmes autres que monoclinique ou triclinique. Nous avons envisagé la possibilité d'une maille orthorhombique à huit molécules. Le nombre de réflexions absentes, déjà important dans une maille moitié, devient alors prohibitif. De plus, la meilleure solution obtenue dans ce cas est une maille contenant 7.1 molécules, qui n'apparaît pas physiquement acceptable. Les molécules ClF_3 et ClO_2F présentent des propriétés assez voisines (7, 8), dont l'encombrement: la densité obtenue en plaçant quatre molécules de ClO_2F dans la maille de ClF_3 (−120°C) est 2.36. Leurs diagrammes de diffraction sont représentés en fig. 2. Il apparaît des analogies structurelles, en particulier en ce qui concerne les positions de certaines raies. Cette similitude pourrait cependant n'être que fortuite puisque aussi bien en phase gazeuse que condensée, les molécules sont, du moins en ce qui concerne l'arrangement spatial des atomes, de symétries différentes. Nous avons cependant examiné la possibilité, pour la maille de ClO_2F, de dériver de celle de ClF_3 par déformation monoclinique. Remarquons que les raies de ClF_3 d'indexation $hk0$ ou $0kl$ ne se déplacent que très peu, ce qui implique l'absence de permutation d'axes. Un spectre de ClO_2F à 77 K s'indexe en totalité avec les paramètres suivants: $a = 8.85 \pm 0.02$ Å; $b = 6.17 \pm 0.02$ Å; $c = 4.62 \pm 0.01$ Å; $\beta = 95.0 \pm 0.1°$. Les résultats de l'indexation figurent dans le tableau 2. La densité calculée est de 2.29 et 2.23 si l'on adopte un défaut de remplissage analogue à celui de ClF_3, soit un excellent accord avec la valeur expérimentale.

tinction qu'elles impliquent (18), nous avons retenu les groupes d'espace suivant (avec les notations de la réf. 9): C_2^1, C_2^2, C_s^1, C_s^2, C_{2h}^1, C_{2h}^2. Seuls les groupes d'espace $C_{2h}^1(P2/m)$ et $C_{2h}^2(P2_1/m)$ sont compatibles avec le centre d'inversion mis en evidence par spectroscopie vibrationnelle.

L'analyse du groupe facteur (16) correspondant à ces groupes montre que les spectres obtenus sont en accord avec cette analyse. En particulier, le nombre de modes externes observés en diffusion Raman correspond à ceux de ces modes qui doivent être actifs ($6a_g + 6b_g$). Le diagramme de corrélation indique que le groupe de site est C_1 ou C_s. Mais par ailleurs si l'on reprend les données cristallographiques des deux groupes retenus, on constate qu'en site C_1, deux molécules se trouvent superposées à une distance $b/2a$, ce qui n'est pas possible d'un point de vue stérique. Le groupe de site des molécules est donc C_s. Des deux groupes $C_{2h}^1(P2/m)$ et $C_{2h}(P2_1/m)$ sélectionnés, seul (18) le premier permet de placer 4 molécules sur des sites C_s, et ceci par une occupation des deux ensembles de sites C_s à 2 équiv. par ensemble. Cette dernière conclusion permet aussi de dire que les séparation de raies observées peuvent avoir pour origine les effets de site aussi bien que les couplages intermoléculaires.

Pour résumer l'ensemble de l'étude, une similitude des diagrammes de diffraction de ClF_3 et de ClO_2F a facilité l'indexation de celui de ClO_2F. La spectroscopie vibrationnelle a permis de compléter les données de diffraction et de proposer le groupe $C_{2h}^1(P2/m)$ pour ClO_2F en phase solide. Cette proposition serait bien entendu à valider par une étude cristallographique plus approfondie.

Remerciements

Nous tenons à remercier M. Meriel de son aide précieuse pour l'obtention des spectres de diffraction de neutrons et Mme Charpin de ses avis expérimentés et de son constant intérêt pour ce travail.

B. WYNCKE, F. BREHAT, A. HADNI, J. SERRIER et M. BAVEREZ. Can. J. Chem. **56**, 1638 (1978).

Spectres d'absorption dans l'infrarouge lointain et spectres de diffusion Raman (15–250 cm^{-1}) des dérivés *ortho* et *méta* disubstitués du benzène ClC_6H_4Cl, ClC_6H_4Br et BrC_6H_4Br ont été enregistrés pour des températures comprises entre 80 et 300 K. Ils permettent de découvrir que les *o*- et *m*-dichlorobenzène présentent une transition de phase à 200 et 220 K respectivement, et que l'*o*-chlorobromobenzène présente deux transitions de phase à 185 et 222 K.

B. WYNCKE, F. BREHAT, A. HADNI, J. SERRIER, and M. BAVEREZ. Can. J. Chem. **56**, 1638 (1978).

Far infrared absorption and Raman spectra were recorded for *ortho*- and *meta*-disubstituted benzene ClC_6H_4Cl, ClC_6H_4Br, and BrC_6H_4Br from 15 to 250 cm^{-1} at different temperatures (80–300 K). From spectroscopic evidence, one phase transition is found for both the *o*- (200 K) and the *m*-dichlorobenzene (220 K), and two for the *o*-chlorobromobenzene (185 and 222 K).

Introduction

Lors d'une étude précédente (1, 2) nous avons enregistré le spectre dans l'infrarouge lointain de composés dihalogénés du benzène substitués en position para. Afin de compléter cette étude, nous examinons les composés ClC_6H_4Cl, ClC_6H_4Br et BrC_6H_4Br substitués en position ortho et méta. Contrairement aux dérivés *para* disubstitués les dérivés *ortho* et *méta* disubstitués sont liquides à température ambiante. Les spectres d'absorption infrarouge et de diffusion Raman à basse température permettent d'étudier l'évolution des modes de réseau de ces dérivés dihalogénés du benzène en fonction de la température. Des changements de phase sont mis en évidence pour la première fois.

Partie expérimentale

Les liquides que nous avons utilisés sont de qualité Purum fournis par les établissement Fluka. Nous ne les avons pas purifiés davantage. Les spectres d'absorption infrarouge sont enregistrés sur un spectromètre Cameca SI 36. Les liquides sont introduits dans une cuve cylindrique d'épaisseur variable, à fenêtres de quartz ou de TPX. Le diamètre du faisceau lumineux est de 18 mm; il existe donc une différence de température entre les bords de la cuve porte-échantillon et le centre de l'échantillon. Dans certains cas le centre, n'atteint qu'une température de 110 K alors que les bords de la cuve sont beaucoup plus froids (78 K). La température de la carotte de cuivre qui supporte la cuve porte-échantillon est régulée et peut être maintenue à toute valeur comprise entre 78 et 320 K. Un étalonnage a été nécessaire pour connaître la température au centre de l'échantillon; c'est cette dernière qui est indiquée sur les courbes et diagrammes.

Les spectres de diffusion Raman ont été enregistrés sur un spectromètre Coderg T 800. La raie excitatrice a une longueur d'onde de 4880 Å, correspondant à la lumière bleue émise par un laser Spectra Physics à argon.

Les liquides sont introduits dans un capillaire de 1 mm de diamètre et sont refroidis dans un cryostat à circulation d'air liquide dont le débit permet de réguler la température entre 85 et 300 K. Le rayonnement diffusé est observé à 90° du rayonnement incident.

Spectres infrarouge et Raman

Les dihalogénobenzènes que nous avons étudiés sont liquides à température ambiante. Les fréquences des maximums d'absorption observés sont rassemblées dans le tableau 1. Le refroidissement de ces liquides donne des solides polycristallins pour lesquels il n'est pas possible de connaître la polarisation des modes infrarouge et Raman.

Sur la fig. 1 nous présentons les spectres d'absorption infrarouge (ir) et de diffusion Raman (R) des dérivés disubstitués du benzène à l'état solide pour quelques températures.

La résolution obtenue avec le spectromètre infrarouge est de 1 cm^{-1} pour les fréquences spatiales $\dot{\nu}$ inférieures à 100 cm^{-1} et de 2 cm^{-1} pour les fréquences supérieures. Le spectrophotomètre Raman utilisé a une résolution de 1 cm^{-1} pour les fréquences spatiales comprises entre 5 et 250 cm^{-1}. L'absorption dans l'infrarouge lointain (15–100 cm^{-1}) est représentée par la variation de l'indice d'absorption $k = K/4\pi\dot{\nu}$ calculé à partir des spectres de transmission. L'intensité I des raies de diffusion Raman est exprimée en unités arbitraires.

Nous avons constaté expérimentalement que le spectre infrarouge lointain de l'orthobromochlorobenzène est différent suivant que le liquide est refroidi lentement ou rapidement. Ce composé doit donc présenter des modifications structurales lors du refroidissement. L'analyse thermique différentielle nous a permis de déceler deux transitions de phase à 185 et 222 K. Dans le cas de l'*o*- et du *m*-dichlorobenzène une transition de phase se produit à 200 et 220 K respectivement. Les autres composés ne présentent pas de transition de phase dans le domaine de température étudié.

L'évolution des fréquences des modes de réseau en fonction de la température est représentée sur les figs 2–7. Les fréquences observées vers 240 K sont désignées par ν_i ($i = 1, 2 \ldots n$) dans l'ordre des fréquences croissantes. Sur les figs 2–7 nous avons également représenté la variation de la fréquence

d'absorption infrarouge du liquide entre la température du point de fusion et 300 K. Dans les liquides polaires la bande d'absorption de basse fréquence est très large et nous avons représenté sur les figures la largeur de la raie à mi-hauteur par une zone hachurée. L'ensemble des résultats obtenus est rassemblé dans le tableau 2.

Discussion

Liquides

Les raies dont les fréquences sont inférieures à 100 cm^{-1} sont dues à l'absorption des liquides polaires. Nos résultats sont en bon accord avec ceux de Mansingh (3). La fréquence du maximum d'absorption et l'intensité de la bande peuvent s'expliquer à l'aide des modèles choisis par Benson *et al.* (4) et Larkin (5). La valeur moyenne du maximum de l'indice d'absorption k est de l'ordre de 4.77×10^{-2} pour les dérivés disubstitués que nous avons étudiés alors qu'il est égal à 0.53×10^{-2} dans le cas du benzène à 300 K (6). Ceci montre le caractère fortement dipolaire de ces liquides.

Les fréquences que nous avons observées au dessus de 100 cm^{-1} sont dues à des mouvements de déformation des molécules. Nos résultats sont en général identiques à ceux que Green (7) a publiés pour les dérivés benzèniques dichlorés et chlorobromés en position *ortho* et *méta*. Nous rappelons dans la colonne 7 du tableau 1 l'attribution proposée par cet auteur. Pour les *o*- et *m*-dibromobenzène seules les fréquences 131, 133 et 157 cm^{-1} sont comparables à celles que Green a observées et attribuées à ν_{11}, ν_{20} et ν_{11} respectivement. Dans l'*o*-dibromobenzène l'absorption observée à 149 cm^{-1} est d'intensité faible et peut être due à un mode de combinaison. La raie intense à 218 cm^{-1} pourrait être attribuée à ν_{20} bien que Green (7) ne l'ait pas observée. Shurvell *et al.* (8) situent un mode b_1 à 220 cm^{-1} qui correspond à l'absorption que nous avons observée à 218 cm^{-1} et confirme l'attribution à ν_{20}. L'absorption observée à 196 cm^{-1} dans le spectre du *m*-dibromobenzène correspond d'après Shurvell à un mode de type a_2 inactif en absorption infrarouge, ce qui pourrait expliquer sa faible intensité comparée à celle des modes situés à 133 et 157 cm^{-1} de type b_1 et a_1 respectivement.

Solides

Dérivés dihalogénés présentant des transitions de phase

L'*o*-dichlorobenzène (fig. 2*a* et *b*) présente une transition de phase à 200 K confirmée par analyse thermique différentielle. C'est au voisinage de 200 K que se produisent les modifications des spectres. Au dessus de 200 K nous observons huit modes de réseau, trois sont actifs en absorption infrarouge et

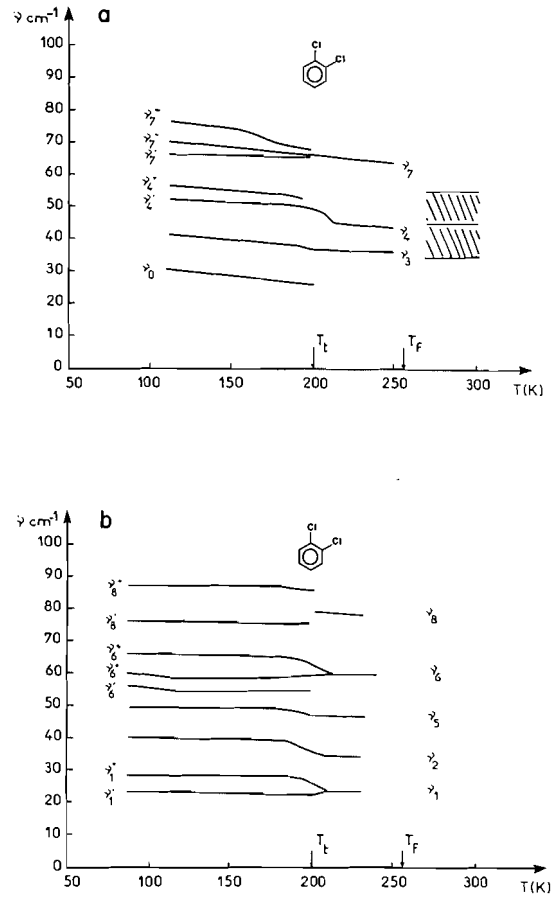

FIG. 2. Variation en fonction de la température des fréquences spatiales ($\tilde{\nu}$) des modes de vibration du réseau: (*a*) actifs en infrarouge et (*b*) actifs en diffusion Raman de l'*o*-dichlorobenzène.

les cinq autres en diffusion Raman. Lorsqu'on abaisse la température et que le changement de phase s'est produit on constate que seul le mode ν_3 conserve une variation linéaire de fréquence en fonction de la température contrairement à ν_2 et ν_5. Les autres modes ν_1, ν_4, ν_6 et ν_7 donnent plusieurs composantes et il apparait dans le spectre infrarouge un mode nouveau ν_0. Au voisinage de la température de transition ν_8 disparaît par affaiblissement d'intensité alors qu'apparaissent deux composantes ν_8' et ν_8'' dont l'intensité se renforce avec l'abaissement de la température.

Le *m*-dichlorobenzène (fig. 3*a* et *b*) présente une transition de phase à 220 K qui produit peu de modifications des spectres. L'*o*-chlorobromobenzène (fig. 4*a* et *b*) présente deux transitions de phase à 185 et 222 K. Ces températures de transition sont confirmées par analyse thermique différentielle, l'aire du pic de la seconde transition est 2.6 fois supérieure à celle de la première, cette différence est attribuée à la disparition brutale du mode ν_7' à 210 K.

D'une manière générale les fréquences observées en diffusion Raman et en absorption infrarouge ne coïncident pas et ne sont pas dues au même mode de vibration. Dans le cas où les fréquences observées en absorption et en diffusion sont voisines comme par exemple les fréquences 34–36 cm^{-1} et 43–46.5 cm^{-1} de l'*o*-dichlorobenzène à 240 K on constate (fig. 1*a*) que la différence de fréquence des modes infrarouges est de 43–36 = 7 cm^{-1} et celle des modes Ramans de 46.5–34 = 12.5 cm^{-1}. Cette différence n'est pas due à une erreur expérimentale et montre bien que les fréquences 34 et 36 cm^{-1} n'ont pas pour origine le même mode normal de vibration. Il en est de même pour les fréquences 43–46.5 cm^{-1}. Le mode 63 cm^{-1} observé à 250 K a une largeur de bande à mi-hauteur qui est de l'ordre de 25 cm^{-1} et s'étend

de 50 à 75 cm^{-1}. Il recouvre entièrement les modes observés en diffusion à 59 et 78 cm^{-1}. La largeur de bande et l'intensité de ce mode permet de penser qu'il comporte plusieurs composantes dont celles situées à 59 et 78 cm^{-1}. Le changement de phase et l'abaissement de la température nous montrent que ce mode donne naissance à trois composantes en absorption (67.5–71.5 et 76 cm^{-1}) et à deux en diffusion (66 et 76.5 cm^{-1}). La coïncidence des fréquences ne peut alors être admise que pour 67.5–66 cm^{-1} et 76–76.5 cm^{-1}. L'aspect complémentaire des spectres d'absorption et de diffusion nous permet de penser que le groupe facteur du cristal pourrait être C_{2h} ou D_{2h} en supposant que ces composés cristallisent dans le système monoclinique ou orthorhombique. La distinction entre ces deux groupes ne peut se faire que par l'étude de monocristaux en lumière polarisée.

A 240 K les spectres d'absorption des *o*-dichloro- et *o*-chlorobromobenzène présentent trois maximums d'absorption ce qui permet de penser que la cellule de Bravais ne comporte pas plus de deux molécules. Les molécules des composés étudiés ici sont dépourvues de centre de symétrie et le site occupé par celles-ci ne peut être un centre d'inversion de telle sorte que les vibrations de pivotement et de translation ont même type de symétrie. La vibration fondamentale réelle observée est la superposition de ces mouvements de telle sorte qu'il est difficile d'attribuer les fréquences que nous avons observées. Nous pouvons dire seulement que la vibration faisant intervenir le pivotement de la molécule autour de l'axe porteur du moment dipolaire permanent sera peu intense en absorption.

Dérivés dihalogénés ne présentant pas de transition de phase

Les variations en fonction de la température des fréquences des modes de réseau du *m*-chlorobromo-

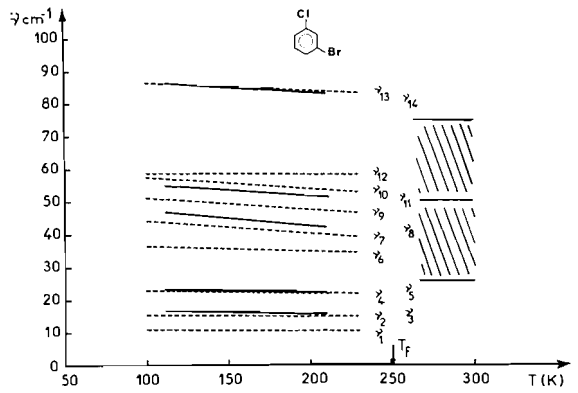

FIG. 5. Variation en fonction de la température des fréquences spatiales ($\dot{\nu}$) des modes de vibration du réseau: — actifs en infrarouge et ---- en diffusion Raman du *m*-chlorobromobenzène.

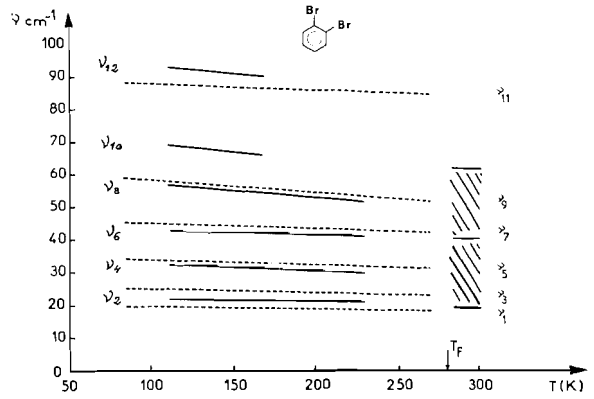

FIG. 6. Variation en fonction de la température des fréquences spatiales ($\dot{\nu}$) des modes de vibration du réseau: — actifs en infrarouge et ---- en diffusion Raman de l'*o*-dibromobenzène.

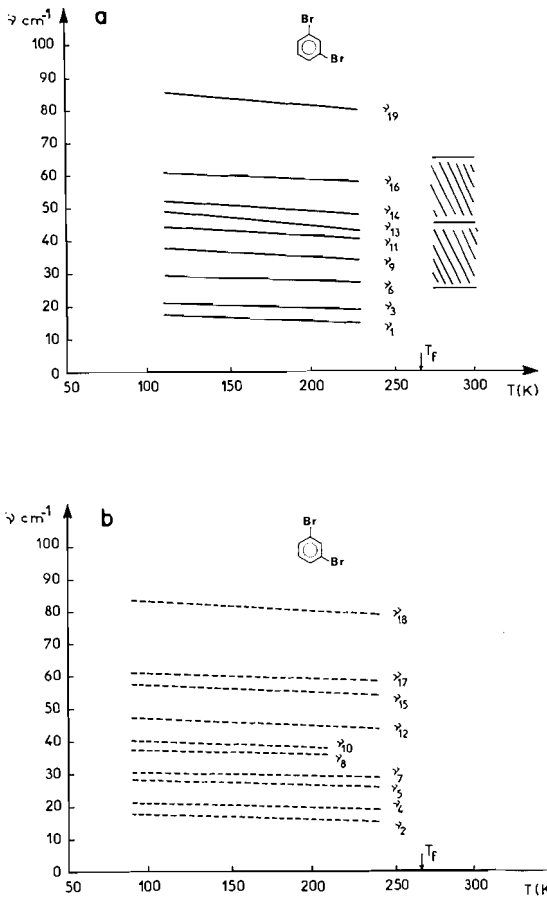

FIG. 7. Variation en fonction de la température des fréquences spatiales ($\dot{\nu}$) des modes de vibration du réseau: (*a*) actifs en infrarouge et (*b*) actifs en diffusion Raman du *m*-dibromobenzène.

benzène et des *o*- et *m*-dibromobenzène sont représentées sur les figs 5, 6 et 7. Ces variations sont linéaires et ces dérivés dihalogénés ne présentent pas de transition de phase dans le domaine de température étudié.

Contrairement aux dérivés présentant des transitions de phase les fréquences de vibration observées en absorption et en diffusion coïncident, à la précision des mesures près, pour ces trois composés. A 112 K les fréquences de vibration du *m*-dibromobenzène peuvent s'associer de la manière suivante: $17.5(\nu_1)$–$18(\nu_2)$, $21(\nu_3)$–$21(\nu_4)$, $38(\nu_9)$–$37.5(\nu_8)$, $48(\nu_{13})$–$47.5(\nu_{12})$, $61(\nu_{16})$–$61.5(\nu_{17})$ et $85(\nu_{19})$–$83(\nu_{18})$ cm^{-1}. Le maximum d'absorption observé à 27 cm^{-1} (ν_6) apparait résolu en deux composantes $26(\nu_5)$ et $29(\nu_7)$ cm^{-1} en diffusion alors que ν_{10}, ν_{11}, ν_{14}, ν_{15} situés respectivement à 40, 45, 53 et 57 cm^{-1} n'apparaissent que dans un seul des deux spectres.

Ces remarques vérifiées dans le cas de l'*o*-dibromobenzène et du *m*-chlorobromobenzène permettent de proposer comme groupe facteur un des groupes C_s, C_2, D_2 ou C_{2v} dans le cas où ces cristaux appartiennent au système monoclinique ou orthorhombique. La cellule de Bravais peut comporter quatre molécules.

Conclusion

Les spectres d'absorption dans l'infrarouge lointain de six dérivés dihalogénés du benzène, étudiés à l'état liquide à 300 K, présentent tous un maximum d'absorption au voisinage de 45 cm^{-1}.

La solidification de ces liquides par refroidissement permet d'observer les modes de réseau par absorption dans l'infrarouge lointain et par diffusion Raman. L'étude de la variation des fréquences en fonction de la température nous a permis de déceler des transitions de phase dans les *o*- et *m*-dichlorobenzène, ainsi que dans l'*o*-chlorobromobenzène. L'attribution définitive des modes de réseau ne pourra être faite que lorsque les structures seront connues.

Approaches to the synthesis of triterpenoids. III. Some *cis*-decalins corresponding to rings D and E of some pentacyclic triterpenes[1]

JOHN W. APSIMON,[2] SATYANAND BADRIPERSAUD, TUNG T. T. NGUYEN, AND RICHARD PIKE

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received August 3, 1977

JOHN W. APSIMON, SATYANAND BADRIPERSAUD, TUNG T. T. NGUYEN, and RICHARD PIKE. Can. J. Chem. **56**, 1646 (1978).

The synthesis of 10-methoxycarbonyl-1,7,7-trimethyl-*cis*-2-decalone (**6***c*) is described as well as that of the corresponding *trans* isomer. The stereochemistry of catalytic hydrogenation of the carbon–carbon double bond of $\Delta^{1,9}$-2-octalones is shown to be controlled by the angular substituent at position 10.

The *cis*-decalin system is considered as a synthon for the DE ring system of certain pentacyclic triterpenes.

JOHN W. APSIMON, SATYANAND BADRIPERSAUD, TUNG T. T. NGUYEN et RICHARD PIKE. Can. J. Chem. **56**, 1646 (1978).

On décrit la synthèse de la méthoxycarbonyl-10 triméthyl-1,7,7 décalone-2 *cis* (**6***c*) de même que celle de l'isomère *trans* correspondant. On a montré que la stéréochimie de l'hydrogénation catalytique de la double liaison carbone–carbone des $\Delta^{1,9}$ octalones-2 est contrôlée par le substituant angulaire en position 10.

On considère le système de la décaline *cis* comme un synthon pour le système des cycles DE de certains triterpènes pentacycliques.

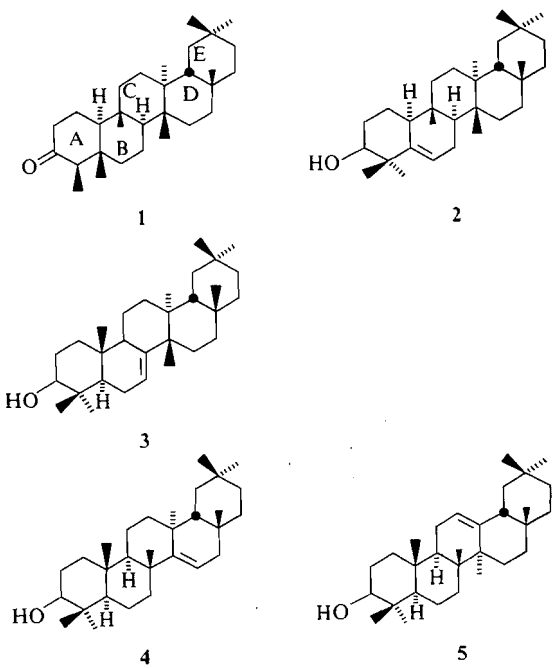
For some years our laboratory has been occupied with research directed towards the total synthesis of triterpenes, particularly the biogenetically related pentacyclic species represented by friedelin (**1**), alnusenol (**2**), multiflorenol (**3**), taraxerol (**4**), and β-amyrin (**5**) (2). The pentacyclic triterpenes display a great number of structural variations and complexities, yet in contrast to reports concerning the synthesis of lower terpenes and steroids (3), relatively little attention has been directed towards the laboratory construction of this class of compound (4) until recently when the outstanding researches of a number of groups have provided syntheses of lupeol (5), alnusenone (6), shionone (7), friedelin (8), germanicol (9) serratenediol (10), tetrahymanol (11), δ-amyrin, β-amyrin, and germanicol (12). Heathcock and coworkers (13, 14) have reported the synthesis of several synthons suitable for incorporation in a triterpene synthetic sequence.

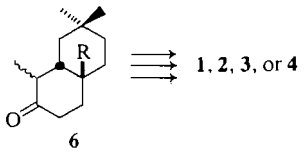
In a series of closely related triterpenoids two or more rings present possess the same structural and stereochemical features. For example compounds **1**–**5** all possess a *cis*-fused decalin system as the DE rings (see **1** for ring designations) and only in β-amyrin (**5**) is the C-13 α-methyl group absent. In one of the synthetic routes being investigated in our laboratory we considered a unit represented by **6** as an obvious synthon[3] for triterpenoids of types **1**–**4** and this paper describes some of our experiments directed towards the synthesis of such a species.



[1]This work is described in the M.Sc. Thesis of T.T.T.N. (Carleton University, Ottawa, Ont., 1971) and the Ph.D. Thesis of S.B. (Carleton University, Ottawa, Ont., 1976). For Part II see ref. 1.

[2]To whom inquiries should be directed.

[3]Except for structures **1**–**5** which represent natural products, all structures used in this paper represent racemates. Only that enantiomer bearing a direct relationship to the natural series is shown for convenience.



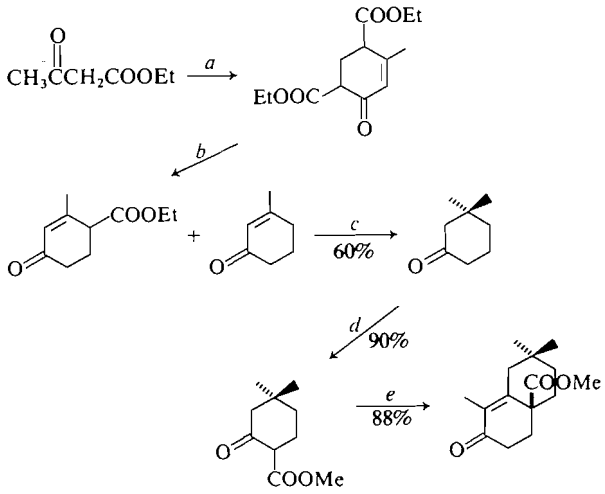
6

a R = CH_3
b R = COOMe
c R = CH_2OH

Similar work has been described by Halsall and Thomas (15) and recently by Heathcock and co-workers (14).

For two reasons, our work was centred on the use of a substrate in which the future C-28 methyl group of the triterpenoids is functionalised. Firstly, we anticipated the activating effect of the methyl ester to be of use in the synthesis of **8** and secondly the synthons **6***b* or **6***c* could conceivably be used for the elaboration of pentacyclic triterpenes in which one or more methyl groups have been oxidised (2).

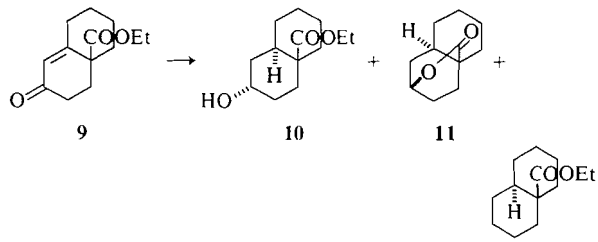
As a precursor for our studies we chose 10-carbomethoxy-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalone (**8**) the synthesis of which is outlined in Scheme 1. Thus,



SCHEME 1. Reagents: (*a*) HCHO, piperidine; (*b*) H_2SO_4; (*c*) MeMgI, CuI; (*d*) $CO(OMe)_2$, NaH; (*e*) $CH_3CH_2COCH{=}CH_2$, NaOMe.

carboxymethylation of 3,3-dimethylcyclohexanone (16) by refluxing in dimethylcarbonate containing sodium hydride provided 6-carbomethoxy-3,3-dimethylcyclohexanone (**7**) in excellent yield. A Robinson annelation of this keto ester with ethyl vinyl ketone furnished the octalone **8** in an overall yield of 35% from ethyl acetoacetate.

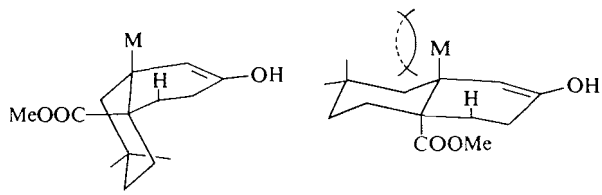
Next, our work turned to a study of the catalytic hydrogenation of **8**. Literature precedent would suggest either of two routes for this reduction. Thus, the reports of Heathcock and co-workers (14) and Halsall and Thomas (15) suggest reduction should proceed to yield a *cis*-fused decalone, whereas Dauben and Rogan (17) have noted that ester **9** is catalytically hydrogenated to a mixture of the *trans*-decalone **10**, lactone **11**, and hydrogenolysis product **12**. Other reports confirm that the angular substituent has a major role in directing the course of reduction (14, 15, 18) as does the p*H* of the reaction medium (19, 20) and substituents at other positions in the



9 **10** **11** **12**

molecule (17, 18*b*). Based on the arguments of Augustine (19) concerning the 1,4 addition of hydrogen to α,β-unsaturated ketones in acidic medium we considered the intermediate **13** leading to a *cis*-decalone more likely than **14** in which the axial C-7 methyl group would incur a severe steric interaction with the metal surface and which would lead to a *trans*-decalone.

In the event, catalytic hydrogenation of **8** provided a variety of products[4] depending on the conditions used. These are summarised in Scheme 2. Thus, hydrogenation in acetic acid at room temperature using platinum provided a 2:1 ratio of alcohol **15** and lactone **16** whilst reduction of the amount of catalyst increased reduction time but reduced the amount of lactone formed.[5] Hydroxy ester **15** on



13 **14**

M = Metal

[4]In the majority of cases described in this paper, the spectral and analytical properties of the compounds prepared are unexceptional and lead unequivocally to the structures proposed. In the interests of brevity no extended discussion has been included on the structural elucidation for these materials but all relevant data is reported in the experimental section. The correlation of the various compounds discussed with keto ester **17** whose structure has been demonstrated by a single crystal X-ray analysis leaves no doubt as to the structures proposed.

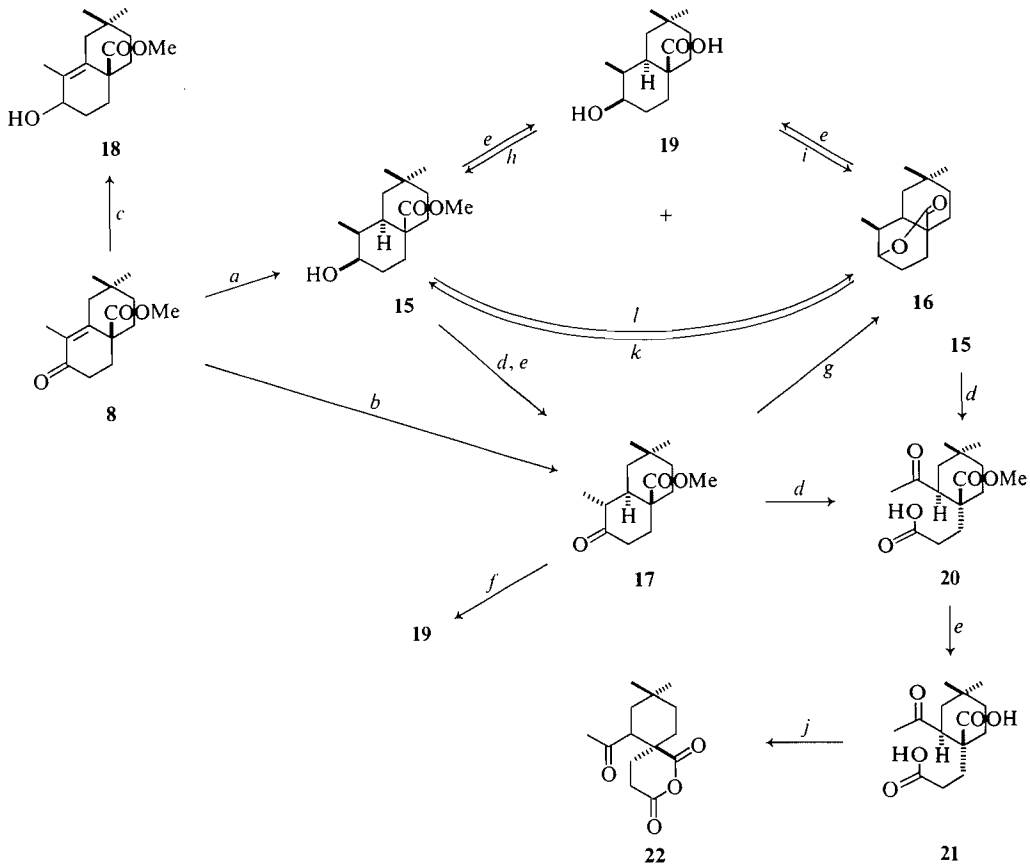

SCHEME 2. Reagents: (*a*) Pt, H_2, CH_3COOH; (*b*) EtOH, 3% 3*N* HCl, 10% Pd–C, H_2; (*c*) Pt, H_2, EtOH, CH_3COOH; (*d*) CrO_3, Me_2CO; (*e*) NaOH; (*f*) Na, isopropanol; (*g*) $NaBH_4$; (*h*) CH_2N_2, Et_2O; (*i*) *p*-toluene sulphonic acid; (*j*) distil; (*k*) NaOMe; (*l*) CH_3COOH.

hydrolysis provided the acid **19** which in turn, on acid treatment yielded lactone **16**, also available directly from **15**. Cleavage of **16** by methoxide furnished **15** and by sodium hydroxide followed by neutralisation gave **19**. Oxidation of **15** by Jones' reagent provided a liquid ketone that yielded crystalline **17** on base treatment. Assuming that this transformation involves equilibration at the C-1 methyl group together with the observation of lactone formation and the X-ray structure data for **17** (22), then stereostructures **15**, **16**, and **19** emerge. Presumably **15** arises by the net *cis*-addition of hydrogen to all four positions of the enone system of **8**. From the Jones' oxidation of **15** we also detected substantial amounts of the ring-cleaved keto acid ester **20** (33), the structure of which was confirmed by hydrolysis to the diacid **21** followed by pyrolytic distillation to the substituted glutaric anhydride **22**.

Reduction of **8** in ethanol with a trace of acetic acid over prereduced platinum oxide furnished allylic alcohol **18**, oxidation of which yielded **8**. The use of 10% palladium-on-charcoal as a catalyst in ethanol acidified with hydrochloric acid yielded the saturated ketone **17** (22) in 60% yield. Although at this stage of our studies we were unsure of the *trans* stereochemistry depicted for **17**, the formation of **15** and **16** were reminiscent of Daubens' report (17, 18*b*). Attempts to prepare **17** by a Birch reduction (12) of **8** were unsuccessful. A single crystal X-ray analysis of **17** was carried out by Huber and Gabe (22) revealing the stereochemistry shown and indicating that in this case the angular carbomethoxyl group possesses a directing effect (18*a*) over any steric effects (19).

Our next tactic was to reverse the stereochemistry of the double bond hydrogenation in **8** by catalytic reduction of 10-hydroxymethyl-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalone (**23**) (17, 18*b*, 23) utilising the haptophilic properties of the hydroxymethyl group. Octalone **23** was obtained from octalone **8** by two routes (Scheme 3). Thus, reduction of **8** with lithium aluminum hydride provided **24** (60%) and **25** (15%), both as mixtures of C-2 epimers. Allylic oxidation of **24** with activated manganese dioxide provided the required keto alcohol **23** in 71% yield. However, the

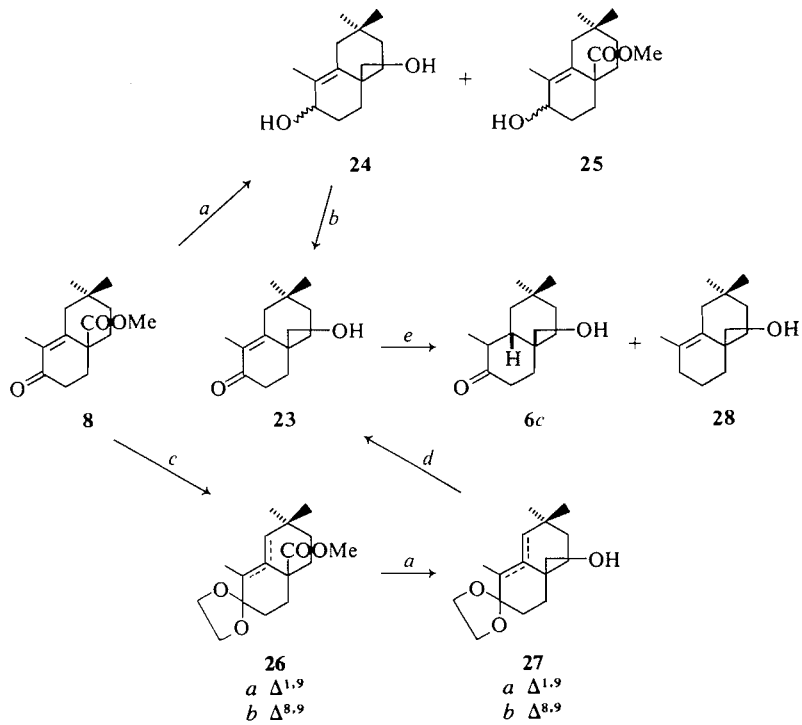
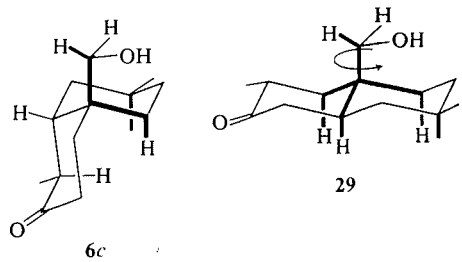


SCHEME 3. Reagents: (*a*) $LiAlH_4$; (*b*) MnO_2; (*c*) $HOCH_2CH_2OH$, *p*-toluene sulphonic acid, benzene azeotrope; (*d*) 10% HCl; (*e*) 10% Pd–C, H_2.

use of large amounts of manganese dioxide (10-fold) required for the oxidation step was not amenable to larger scale preparations; thus **23** was prepared by the alternate route involving ketalisation of **8** to the mixture of double bond isomers **26** reduction to **27** and deketalisation.

Hydrogenation of **23** proceeded over 10% palladium-on-charcoal to yield decalone **6***c* (68%) and hydrogenolysis product **28** (10%). The *cis*-ring junction stereochemistry was assigned on the basis of a comparison of its physical properties with those of 10-hydroxymethyl-1,7,7-trimethyl-*trans*-2-decalone (**29**) obtained by lithium aluminum hydride reduction of the ester group of *trans*-decalone **17** after protection of the keto group as its ethylene ketal, followed by deprotection. Table 1 outlines the major differences in these properties including the gas chromatographic characteristics of their trimethylsilyl derivatives. A similar comparison of the physical properties of esters **6***b* and **17** (see Table 2) emphasises these differences.

Of particular use in the assignment of stereochemistry was the observation that the signals corresponding to the C-10 hydroxymethyl protons (C(10)-CH_2OH) in the *trans*-decalone **29** appearing at δ 3.72 and 4.08 as a pair of doublets have a half-height width of 3 Hz as opposed to the same signals for the *cis*-decalone **6***c* where the pair of doublets at δ 3.77 and 3.95 have a half-height width of only 1 Hz. This observation can be attributed to long range W coupling (**24**) of the hydroxymethyl group protons **29** with three axial protons whereas in **6***c* only one proton is capable of attaining a suitable W arrangement with the angular hydroxymethyl group protons as shown (25).



The mass spectra of the pairs of *cis* and *trans* isomers **6***c* and **29**, their corresponding ethylene ketals, and **6***b* and **17**, displayed some striking differences especially in the case of the ketals.[6] Thus the ethylene ketal **30** (C,9H-β) had the molecular ion (M^+ 268) as its parent ion with the expected ketal directed fragmentation (26) to **31** being observed with a relative abundance of 50%, on the other hand

[6]We have, as yet, been unable to observe any regularities in the fragmentation of these parallel series of stereoisomers but hopefully, continuing work in these laboratories will provide more data (27).

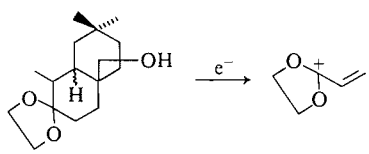
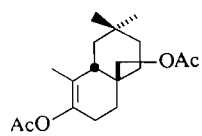
in the case of the ketal **30** (C,9H-α) the molecular ion showed only a relative abundance of 10% with the fragment *m/e* 99 (i.e. **31**) being the parent ion.

With compound **6***c* in our hands, we next turned our attention to alkylation at C-1, arguing for β-face

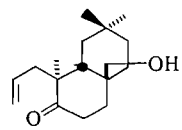


30 **31** (*m/e* 99)

alkylation from the open face of the hinge-like *cis*-fused decalin. Such an event would then lead to the stereochemistry desired for friedelin (**1**). These studies were disappointing although in one experiment we observed that alkylation of the enol acetate **32** with allyl bromide provided a low yield of a product tentatively assigned structure **33**. It is interesting to note that enol acetylation of **6***c* with acetic anhydride, perchloric acid in carbon tetrachloride (28) yielded the expected regioisomer **32** (29). At this stage of our studies we postponed further work on this problem in favour of other more promising synthetic routes to the triterpenoids.



32



33

Experimental

All melting points were obtained on a Kofler hot stage and are uncorrected. Boiling points are uncorrected. Thin-layer chromatography was carried out on precoated silica gel plates obtained from E.M. reagents (silica gel F-254, 0.25 mm or 2.0 mm); the plates were developed either by exposure to iodine vapour or by spraying with a solution of ceric sulphate and heating. The nuclear magnetic resonance spectra were obtained on a Varian Model T-60 or Varian H-A 100 spectro-

meter with tetramethylsilane as internal standard. Chemical shifts are expressed in the δ scale and the following abbreviations apply: s, singlet; d, doublet; t, triplet; m, multiplet. Infrared spectra were determined on a Perkin-Elmer Model 237B Grating Infrared spectrometer and Beckman AccuLab 2 infrared spectrometer. The ultraviolet spectra were run on a Cary recording spectrometer Model 14 or Perkin-Elmer 202 ultraviolet–visible spectrophotometer. Gas chromatographic analyses were carried out on a Hewlett-Packard F & M Scientific 402 high efficiency gas chromatograph. Mass spectra were obtained on an AEI MS12 instrument at Trent University, Peterborough. Combustion analyses were performed by Spang Microanalytical Laboratory, Ann Arbor, Michigan. The term 'dry benzene' refers to benzene which has been distilled and stored over sodium wire. The term 'dry tetrahydrofuran' refers to tetrahydrofuran which has been distilled from lithium aluminum hydride under anhydrous conditions. Petroleum ether refers to the fraction boiling at 30–60°C. Boron trifluoride etherate was obtained from Eastman Kodak Company and was purified by distillation from calcium hydride.

3-Methyl-2-cyclohexenone

This compound was prepared by a modification of the method of Smith and Rouault (30). Piperidine (20 ml) was added to a mixture of ethyl acetoacetate (500 g, 3.85 mol) and paraformaldehyde (57.6 g, 1.92 mol). The mixture was warmed to 50°C to initiate the reaction. The solution became yellow and the temperature rose quickly to 70°C. The reaction flask was cooled in an ice bath and the temperature maintained at about 50°C for 15 min and the reaction mixture was left stirring overnight at room temperature. The yellow viscous oil was poured into 1.ℓ of 20% sulphuric acid and refluxed for 24 h. After cooling, the organic material was extracted with methylene chloride (250 ml × 4) and dried over anhydrous sodium sulphate. Removal of the solvent under reduced pressure gave an oil which was vacuum distilled to afford 3-methyl-2-cyclohexenone (124 g; 58%); bp 85–90°C/15 Torr (lit. (30) bp 75–77°C/10 Torr); ir (neat): 1660 (C=O) and 1625 cm^{-1} (C=C); nmr ($CDCl_3$) δ: 1.97 (s, 3, C-3 CH_3) and 5.83 (s, 1, C-2 H).

3,3-Dimethylcyclohexanone

Magnesium turnings (33.6 g, 1.38 mol) were placed in a three-necked round-bottomed flask fitted with a condenser, equilibrating dropping funnel and a nitrogen inlet. The magnesium turnings were covered with anhydrous ether and 1 ml of methyl iodide was added through the dropping funnel. The mixture was stirred until the reaction started and then 200 g (1.4 mol) of methyl iodide diluted with anhydrous ether (300 ml) was added dropwise such that reflux was maintained. After addition was completed the mixture was cooled (ice-bath) and copper iodide (10.8 g, 0.057 mol) was added and stirred. Still at 0°C, 3-methyl-2-cyclohexenone (124 g, 1.12 mol) in an equal volume of anhydrous ether was added slowly and stirring was continued for an additional 15 min. The mixture was poured into 1 ℓ of cold 3 *N* H_2SO_4 and mechanically stirred. The ether layer was separated and washed with sodium thiosulphate solution and dried over anhydrous sodium sulphate. After removal of solvent, the residue was distilled *in vacuo* to yield 86 g (66%) of 3,3-dimethylcyclohexanone as an oil; bp 50–60°C/10 Torr (lit. (16) bp 62–65°C/13 Torr, 71–71.5°C/19 Torr); ir (neat): 1700 cm^{-1} (C=O); nmr ($CDCl_3$) δ: 0.98 (s, 6, *gem*-dimethyl).

6-Methoxycarbonyl-3,3-dimethylcyclohexanone (7)

Sodium hydride (53.5 g, 2.23 mol) and dimethyl carbonate (250.5 g 2.78 mol) were placed in a three-necked round-bottomed flask under a nitrogen sweep and the mixture was stirred vigorously and heated to reflux. While refluxing, 3,3-dimethylcyclohexanone (71.1 g, 0.56 mol) was added dropwise. After addition was completed, the mixture was stirred and refluxed for another 30 min, then cooled and acidified with acetic acid. The organic material was extracted with ether, washed with saturated sodium bicarbonate solution followed by saturated sodium chloride solution and was dried over anhydrous sodium sulphate. After filtration, solvent was evaporated to yield an oil which on distillation furnished 69 g (70%) of the keto ester **7**; bp 60–65°C/10.5 Torr; ir (neat): 1710 (C=O) and 1745 cm^{-1} (ester); nmr ($CDCl_3$) δ: 0.97 (s, 6, *gem*-dimethyl), and 3.77 (s, 3, OCH_3). *Anal.* calcd. for $C_{10}H_{16}O_3$: C 65.19, H 8.75; found: C 64.97, H 8.53.

10-Methoxycarbonyl-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalone (8)

To dry, distilled methanol (200 ml) was added 0.6 g (0.026 mol) of sodium. After all of the sodium had reacted, the solution was cooled to 0°C and 6-methoxycarbonyl-3,3-dimethylcyclohexanone (**7**) (50 g, 0.27 mol) was added dropwise to the stirred solution at 0°C. The solution was stirred for an additional 15 min then ethyl vinyl ketone (22.2 g, 0.26 mol) in 30 ml of methanol was added dropwise, the solution still being at 0°C. An excess of base (2 g (0.087 mol) of Na in 30 ml of MeOH) was added and the mixture was stirred at room temperature overnight. Water was added and the mixture was acidified with 3 *N* H_2SO_4. The organic material was extracted with ether, washed twice with water, saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. After removal of the solvent, the oil obtained was distilled to give 69 g (88%) of the octalone **8**, bp 99–104°C/0.1 Torr. This material solidified on refrigeration but melted after a few hours at room temperature; ir (neat) 1675 (C=O), and 1715 cm^{-1} (ester); nmr ($CDCl_3$) δ: 0.87 (s, 3, C-7 CH_3), 1.03 (s, 3, C-7 CH_3), 1.83 (s, 3, C-1 CH_3), and 3.75 (s, 3, $COOCH_3$). *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 71.68, H 8.62. M^+ (ms) 250.

10-Methoxycarbonyl-1,7,7-trimethyl-trans-*2-decalone (17)*

A mixture of 10% palladium-on-charcoal (1 g), ethanol (100 ml), and 5 ml 3 *N* HCl was hydrogenated at 1 atm pressure of hydrogen at room temperature for 4 h. 10-Methoxycarbonyl-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalone (10 g) was added and the resulting mixture was hydrogenated for 4 h (uptake of 950 ml H_2). The mixture was filtered, the filtrate was diluted with water and extracted with chloroform (3 × 30 ml). The chloroform layer was washed with saturated sodium bicarbonate solution, saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. Removal of the solvent at reduced pressure gave an oil which crystallized from hexane to give 6.0 g (60%) of the decalone **17**. Recrystallization from hexane produced colorless needles; mp 103–106°C; ir (Nujol): 1715 (ketone), 1730 (ester), and 1360, 1380 cm^{-1} (*gem*-dimethyl); nmr ($CDCl_3$) δ: 0.91, 0.95 (two s, 3 each, *gem*-dimethyl), 1.01 (d, 3, J = 6 Hz, C-1 CH_3), and 3.74 (s, 3, $COOCH_3$); ms *m/e* (relative intensity): 252 (100), 237 (5), 220 (15), 192 (31), 175 (58). *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.47, H 9.77.

Hydrogenation of 10-Methoxycarbonyl-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalone (8)

(*a*) A mixture of 2.00 g. of platinum oxide and 100 ml of acetic acid was hydrogenated at 1 atm pressure for 4 h. The α,β-unsaturated ketone **8** (5.01 g) was added and the resulting mixture was hydrogenated at atmospheric pressure and at room temperature overnight. After filtration, the solution was diluted with water and extracted with chloroform. The chloro-

For personal use only.

form solution was washed with saturated sodium bicarbonate solution, dried over anhydrous sodium sulphate and evaporated to give 4.77 g. of a colorless oil. Thin-layer chromatography showed the presence of two compounds. The crude product was chromatographed on 141 g of Woelm neutral alumina (grade 1). Elution with chloroform gave 2.19 g (66%) of **15** as a colorless oil; ir 3400 (OH), 1725 cm^{-1} ($COOCH_3$); nmr ($CDCl_3$) δ:0.85, 0.98 (s, 3H each, *gem*-dimethyl), 0.93 (d, 3H, CH_3—CH—), 3.68 (s, 3H, $COOCH_3$). Further elution with 25% ether in chloroform gave 1.49 g (34%) of **16** as colorless crystals. Recrystallization from hexane gave an analytical sample; colorless long needles, mp 68–69°C; ir ($CHCl_3$):1736 cm^{-1} (CO of a six-membered ring lactone); nmr ($CDCl_3$) δ: 0.88, 1.06 (s, 3H each, *gem*-dimethyl), 0.93 (d, 3H, CH_3—CH—), 4.33 (m, 1H, —*CH*—O—); ms *m/e*:222 (molecular ion). *Anal.* calcd. for $C_{14}H_{22}O_2$: C 75.67, H 9.91; found: C 75.70, H 9.84.

(*b*) A mixture of 200 mg of platinum oxide, absolute ethanol (20 ml) and acetic acid (1 ml) was hydrogenated at 1 atm for 2 h. The α,β-unsaturated ketone **8** (100 mg) was added and the resulting mixture was hydrogenated at ambient temperature and at atmospheric pressure for 30 min. After filtration, the solution was diluted with water and extracted with chloroform. After washing with sodium bicarbonate solution, and water, the solution was dried and evaporated to provide a colorless oil (0.98 g) that crystallized on standing. Recrystallization twice from aqueous methanol provided an analytical sample of **18**; mp 102–103°C; ir 3200 (OH), 1725 cm^{-1} ($COOCH_3$); nmr ($CDCl_3$) δ: 0.8, 0.9 (s, 3H each, *gem*-dimethyl), 1.8 (s, 3H, *CH*—C=C), 3.64 (s, 3H, $COOCH_3$) and 4.0 (m, 1H, C*H*—OH). *Anal.* calcd. for $C_{15}H_{24}O_3$ (M^+ 252): C 71.39, H 9.59; found (M^+ 252): C 71.53, H 9.84.

Preparation of Lactone ***16***

(a) Stepwise Approach

To a solution of 0.906 g of the crude hydroxy ester **15** in 15 ml methanol was added 12 ml of 2 *N* sodium hydroxide and 10 ml of benzene. The resulting mixture was heated at reflux for 5 h then cooled to room temperature. The reaction mixture was diluted with water and extracted with chloroform. After washing the organic layer with saturated sodium bicarbonate solution and drying over anhydrous sodium sulphate, evaporation gave a yellow oil (0.426 g) which was shown to be the starting material **15** by nmr. The aqueous layer was acidified with hydrochloric acid and extracted thoroughly with chloroform. The chloroform solution was washed with saturated sodium chloride solution, dried over anhydrous sodium sulphate, and evaporated giving a colorless amorphous powder **19** (0.336 g, 94% yield based on recovered starting material); mp 102–105°C; tlc (30:70 ethyl acetate – benzene, iodine development) showed one spot R_f 0.22; nmr ($CDCl_3$) δ: 0.76, 0.93 (s, 3H each, *gem*-dimethyl), 1.00 (d, 3H, CH_3—CH), 3.80 (m, 1H, —*CH*—OH), 6.50 (s, 2H, *OH* and CC*OH*).

A solution of 0.336 g of the hydroxy acid **19** and 0.121 g of *p*-toluenesulfonic acid monohydrate in 25 ml of benzene was heated at reflux overnight using a Dean–Stark trap to collect water. The reaction mixture was cooled and extracted with benzene. The organic layer was washed with saturated sodium bicarbonate solution, dried over anhydrous sodium sulphate, and evaporated to give a yellowish oil (0.236 g, 76% yield) which crystallized from hexane and was shown to be identical in all respects (ir, nmr, tlc) with lactone **16**.

(b) Direct Approach

A solution of 0.103 g of the hydroxy ester **15** in 10 ml of acetic acid was stirred at room temperature overnight. The mixture was poured into water and extracted with chloroform. The organic layer was washed with saturated sodium bicarbonate solution and dried over anhydrous sodium sulphate. Evaporation afforded a yellowish oil (0.077 g, 85% yield) which after crystallization from hexane was shown to be identical with the lactone **16** by tlc, ir, and nmr.

Preparation of Hydroxy Acid ***19*** *from Lactone* ***16***

A mixture of 0.124 g of the lactone **16**, 2 ml of 2 *N* sodium hydroxide, and 10 ml of benzene was refluxed overnight. The resulting solution was cooled and extracted with chloroform. The organic layer was washed with 5% hydrochloric acid solution, dried over anhydrous sodium sulphate, and evaporated to give a colorless amorphous powder (0.098 g, 73% yield) which was shown to be identical in all respects (ir, nmr, and tlc) with the hydroxy acid **19**.

*Collins' Oxidation of 10-Methoxycarbonyl-1α,7,7-trimethyl-*trans*-2β-decalol (**15**)*

Chromium trioxide 0.472 g (0.0047 mol) was added to a solution of 0.770 g (0.0094 mol) of pyridine in 15 ml of methylene chloride under nitrogen. The deep burgundy solution was stirred for 15 min then 0.209 g (0.0008 mol) of the crude hydroxy ester **15** in 5 ml of methylene chloride was added in one portion. A black precipitate appeared and the mixture was stirred for half an hour. Methylene chloride was decanted from the residue which was washed three times with ether. Solvent was removed under vacuum, ether was added, and the solution filtered, washed with saturated sodium bicarbonate solution, saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. Removal of the solvent left a yellowish oil (0.180 g) which showed no trace of starting material. The crude product was chromatographed on 104 g of Woelm neutral alumina (grade 1). Elution with 75% chloroform in benzene gave colorless crystals (0.120 g, 58%). Recrystallization from hexane gave the pure saturated ketone **17** as colorless prismatic needles; mp 84–85°C; ir: 1725 ($COOCH_3$), 1710 cm^{-1} (CO); nmr ($CDCl_3$) δ: 0.88, 1.03 (s, 3H each, *gem*-dimethyl), 0.92 (d, 3H, CH_3—CH—), 3.74 (s, 3H, $COOCH_3$); nmr (C_6D_6) δ: 1.17 (d, 3H, CH_3—CH—). *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.07, H 9.47.

*Sodium Borohydride Reduction of 10-Methoxycarbonyl-1α,7,7-trimethyl-*trans*-2-decalone (**17**)*

To a solution of 0.104 g (0.0004 mol) of the ketone **17** in 5 ml of methanol was added 0.313 g (0.0008 mol) of sodium borohydride in 1 ml of water. The resulting mixture was refluxed overnight. The solution was cooled, acidified with hydrochloric acid, and extracted with chloroform. After washing the organic layer with saturated sodium bicarbonate solution and drying over anhydrous sodium sulphate, evaporation gave colorless crystals in a yellowish oil (0.107 g). Thin-layer chromatography showed two spots, one of which was the starting material. The crude product was chromatographed on 3 g of Woelm neutral alumina (grade 1).

Elution with benzene afforded colorless needles mp 68–70°C after evaporation of solvent (0.041 g, 88% yield based on recovered starting material), shown to be identical with the lactone **16** by infrared and nmr.

*Jones' Oxidation of 10-Methoxycarbonyl-1α,7,7-trimethyl-*trans*-2β-decalol (**15**)*

Jones' reagent was added dropwise to a solution of 0.190 g of the crude hydroxy ester **15** in 5 ml of acetone until the orange color of the reagent persisted while stirring vigorously. The reaction mixture was allowed to stir at room temperature for an additional 15 min and acetone was then evaporated. Water was added, the mixture was shaken vigorously, and additional aliquots of water were added until the green chro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

mium salts dissolved. The aqueous layer was extracted thoroughly with ether. The combined extracts were washed with saturated sodium bicarbonate solution, water, and dried over anhydrous sodium sulphate. Removal of the solvent left a yellowish oil (0.097 g, 53%), which could not be induced to crystallize; however, after treatment of an alcoholic solution with 2 *N* NaOH solution and reisolation, pure **17** was obtained.

The combined washing layer was acidified with hydrochloric acid and extracted with chloroform. After washing the organic layer with saturated sodium chloride solution, it was dried over anhydrous sodium sulphate, before evaporation to give colorless crystals (0.089 g, 47%). Recrystallization from carbon tetrachloride afforded the pure acid ester **20** as a colorless amorphous powder; mp 112–113°C; ir ($CHCl_3$): 3600–2500 (COOH), 1710 cm^{-1} (CO); nmr ($CDCl_3$) δ: 0.87, 0.94 (s, 3H each, *gem*-dimethyl), 2.18 (s, 3H, CH_3—CO—), 3.70 (s, 3H, $COOCH_3$), 5.77 (m, 1H, *OH*); nmr (C_6D_6) δ: 1.80 (s, 3H, CH_3—CO—); ms *m/e*: 284 (molecular ion), base peak at *m/e* 43 (CH_3CO^+). *Anal.* calcd. for $C_{15}H_{24}O_5$: C 63.36, H 8.51; found: C 63.09, H 8.28.

*Jones' Oxidation of 10-Methoxycarbonyl-1α,7,7-trimethyl-*trans*-2-decalone (17)*

To a solution of 0.300 g of the ketone **17** in 5 ml of acetone, sufficient Jones' reagent was added to maintain an orange coloration. The reaction mixture was stirred at room temperature for 15 min then acetone was removed under reduced pressure. Water was added and the mixture was extracted with chloroform. The organic layer was washed with saturated sodium bicarbonate solution and water, then dried over anhydrous sodium sulphate. Evaporation after filtration gave yellow needle-like crystals (0.053 g) which were shown to be the starting material **17**. The aqueous layer was acidified with hydrochloric acid and extracted with chloroform. The chloroform solution was washed with saturated sodium chloride solution, dried over anhydrous sodium sulphate, and evaporated to give yellowish crystals (0.205 g, 77% yield based on recovered starting material). Sublimation at 180°C under vacuum afforded the diacid **21** as colorless prismatic needles; mp 193–194°C; ir: 3500–2300 (COOH), 1720 (CO of COOH), 1700 cm^{-1} (CO); nmr ($CDCl_3$) δ: 0.95, 0.99 (s, 3H each, *gem*-dimethyl), 2.18 (s, 3H CH_3—CO—). *Anal.* calcd. for $C_{14}H_{22}O_5$: C 62.20, H 8.20; found (M^+ (ms) 270): C 62.37, H 8.41.

*Sodium Reduction of 10-Methoxycarbonyl-1α,7,7-trimethyl-*trans*-2-decalone (17)*

To a solution of 0.44 g (0.0002 mol) of the ketone **17** in 5 ml of isopropanol was added 0.080 g (0.0035 mol) of sodium. The resulting mixture was refluxed under nitrogen overnight. The solution was cooled, acidified with hydrochloric acid, and extracted with chloroform. After washing the organic layer with saturated sodium chloride solution and drying over anhydrous sodium sulphate, evaporation gave a yellowish amorphous powder (0.026 g, 61% yield) which was shown to be identical with the hydroxy acid **19** (tlc, ir, nmr).

Preparation of Anhydride 22 from Acid Ester 20

A solution of 0.200 g of acid ester **20** in 20 ml of methanol was added to 15 ml of 2 *N* sodium hydroxide. The resulting solution was refluxed overnight. The reaction mixture was cooled, acidified with hydrochloric acid, and extracted with chloroform. The organic layer was washed with saturated sodium chloride solution, dried over anhydrous sodium sulphate and evaporated giving colorless needle-shaped crystals (0.148 g, 78% yield). This product was identical in all respects (ir, nmr, tlc) with diacid **21**. This was sublimed at 180°C under vacuum to give a yellowish oil (0.110 g) which showed carbonyl absorptions in its ir spectrum at 1770 and 1720 cm^{-1} for the anhydride **22**. M^+ calcd. for $C_{14}H_{20}O_4$: 252; found (ms): 252.

10-Hydroxymethyl-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalol (24)

A solution of octalone **8** (2.5 g, 0.01 mol) in anhydrous ether (100 ml) was stirred with 0.38 g (0.01 mol) of lithium aluminum hydride at reflux temperature for 2 h. The mixture was cooled in an ice bath and excess of lithium aluminum hydride was decomposed by adding dropwise a saturated solution of Rochelle salt. The ether layer was separated and the aqueous layer extracted with ether (3 × 20 ml). After drying the combined ether extracts over anhydrous magnesium sulphate, the solvent was removed to give an oil. Column chromatography on silica gel eluting with petroleum ether containing increasing amounts of benzene gave two fractions.

Fraction 1

10-Methoxycarbonyl-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalol (**25**) (12%); mp 102–103°C; ir (Nujol): 3400 (OH) and 1730 cm^{-1} (ester); nmr ($CDCl_3$) δ: 0.83, 0.95 (2 s, 3 each, *gem*-dimethyl), 1.80 (s, 3, C-1 CH_3), 3.70 (s, 3, $COOCH_3$), and 4.00 (broad, 1, $W_{h/2}$ = 8 Hz, C-2 H); ms *m/e* (relative intensity): 252 (trace), 238 (26), 191 (45), 175 (100). *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.41, H 9.52.

Fraction 2

10-Hydroxymethyl-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalol (**24**) (60%); ir (neat): 3350 (OH) and 1360, 1380, cm^{-1} (*gem*-dimethyl), nmr ($CDCl_3$) δ: 0.93, 0.97 (2 s, 3 each, *gem*-dimethyl), 1.77 (s, 3, C-1 CH_3), 3.47 (m, 2, CH_2OH), and 4.10 (broad, 1, C-2 H); ms *m/e* (relative intensity): 224 (trace), 206 (8), 176 (100). *Anal.* calcd. for $C_{14}H_{24}O_2$: C 74.95, H 10.78; found (M^+ (ms) 272): C 74.77, H 10.48.

10-Hydroxymethyl-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalone (23)

10-Hydroxymethyl-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalol (**24**) (2.7 g, 12 mmol) and manganese dioxide (31) (7 g, 80 mmol) in 50 ml chloroform were vigorously stirred for 72 h at room temperature. The mixture was filtered under suction and the residue washed with chloroform. The combined chloroform solutions were washed with saturated brine and dried ($MgSO_4$). Evaporation of the solvent gave an oil which was chromatographed on 90 g alumina. Elution with benzene and then benzene containing increasing amounts of ethyl acetate furnished 1.91 g (71%) octalone **23** and further elution gave 0.2 g of starting octalol **24**. Bulb-to-bulb distillation of the octalone **23** at 140°C/0.2 Torr furnished an analytical sample; uv_{max} (95% C_2H_5OH): 251 nm (ε 17 500); ir (neat): 3400 (OH), 1650 (C=O), and 1600 cm^{-1} (C=C); nmr ($CDCl_3$) δ: 0.87, 1.07 (2 s, 3 each, *gem*-dimethyl), 1.78 (s, 3, C-1 CH_3), and 3.75 (s, 2, CH_2OH); ms *m/e* (relative intensity): 222 (50), 193(100), 192 (100), 149 (50). *Anal.* calcd. for $C_{14}H_{22}O_2$: C 75.63, H 9.97; found: C 75.70, H 10.03.

Hydrogenation of 10-Hydroxymethyl-1,7,7-trimethyl-$\Delta^{1,9}$-2-octalone (23)

Run 1

The octalone **23** (525 mg, 2.1 mmol) in ethanol (5 ml) was added to 100 mg prehydrogenated 10% palladium-on-charcoal in 40 ml ethanol. Hydrogenation was carried out for 48 h during which time 60 ml hydrogen was absorbed. The mixture was filtered and the filtrate was diluted with water and extracted with ether (30 ml × 3). The ether extract was washed with water, saturated brine and dried (Na_2SO_4). Removal of the ether gave an oil which was chromatographed on a silica gel plate (2 mm). Development of the plate twice with benzene – ethyl acetate (1 : 1) gave two main products.

Fraction 1—(R_f 0.59, 19%) was identified as 10-hydroxymethyl-1,7,7-trimethyl-$\Delta^{1,9}$-octalin (**28**): ir (neat): 3300 and 1030 cm^{-1} (primary alcohol), no carbonyl absorption; nmr ($CDCl_3$) δ: 0.82, 0.97 (2 s, 3 each, *gem*-dimethyl), 1.65 (s, 3, C-1 CH_3), and 3.42, 3.65 (2 d, 2, J = 4 Hz, AB quartet,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

—CH_2—OH); ms *m/e*: 208 (M^+). *Anal.* calcd. for $C_{14}H_{24}O$: C 80.66, H 11.57; found: C 80.71, H 11.61.

Fraction 2—(R_f 0.43, 19%) was the decalone **6***c*. Two recrystallizations from methanol–water gave an analytical sample: ir (Nujol): 3200 (OH) and 1700 cm^{-1} (C=O); nmr ($CDCl_3$) δ: 0.86, 0.90 (2 s, 3 each, *gem*-dimethyl), 0.93 (d, 3, J = 6 Hz, C-1 CH_3), 3.77, 3.95 (2 d, 2, J = 10 Hz, AB quartet $W_{h/2} - W_{h/2}$ (TMS) = 1.5 Hz, CH_2—OH), and 2.85 (m, 1, C-1 H). Decoupling of the C-1 CH_3 (0.93 caused the signal at 2.85 to collapse to a doublet J = 5 Hz; ms *m/e* (relative intensity): 224 (10), 193 (20), 175 (10). *Anal.* calcd. for $C_{14}H_{24}O_2$: C 74.95, H 10.78; found: C 74.88, H 10.76.

Run 2

The octalone **23** (2.2 g) in 15 ml ethanol was added to 1.1 g of prehydrogenated 10% Pd–C in 75 ml ethanol and 3 ml 3 *N* HCl. Hydrogenation was carried out and in 4 h 305 ml of hydrogen was absorbed. Work-up as above gave an oil which was crystallized directly from hexane to give the decalone **6***c* in 68% yield. Thin-layer chromatography on silica gel plates (0.25 mm) of the mother liquor showed the presence of starting material and hydrogenolysis product **28**.

2-Ethylenedioxy-10-methoxycarbonyl-1,7,7-trimethyl-$\Delta^{1,9}$*-octalin (***26***a) and 3-Ethylenedioxy-10-methoxycarbonyl-1,7,7-trimethyl-*$\Delta^{8,9}$*-octalin (***26***b)*

A mixture of octalone **8** (5 g), *p*-toluenesulfonic acid (375 mg), and excess ethylene glycol (10 ml) in 300 ml benzene was stirred and refluxed for 24 h using a Dean–Stark water separator. The mixture was cooled, washed with 5% sodium bicarbonate solution, water, saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. Distillation of the solvent *in vacuo* yielded a clear oil (5.8 g, 98%) which was indicated by nmr to be a mixture of $\Delta^{1,9}$-ethylene ketal **26***a* (60%) and $\Delta^{8,9}$-ethylene ketal **26***b* (40%). Column chromatography of a sample over alumina (grade III) eluted with petroleum ether and petroleum ether containing increasing amounts of benzene gave pure samples of the two isomers. Evaporative distillation of each isomer at 130–140°C/0.1 Torr afforded analytical samples.

2-Ethylenedioxy-10-methoxycarbonyl-1,7,7-trimethyl-$\Delta^{1,9}$*-octalin (***26***a)*: ir (neat): 1720 (ester), and 1030, 1060, 1130, 1150, 1190 cm^{-1} (ketal); nmr ($CDCl_3$) δ: 0.83, 0.97 (2 s, 3 each, *gem*-dimethyl), 1.67 (s, 3, C-1 CH_3), 3.70 (s, 3, $COOCH_3$), and 4.02 (broad s, 4, —O—CH_2—CH_2—O—); ms *m/e* (relative intensity): 294 (32), 279 (37), 235 (40), 99 (100). *Anal.* calcd. for $C_{17}H_{26}O_4$: C 69.36, H 8.90; found: C 69.28, H 8.92.

3-Ethylenedioxy-10-methoxycarbonyl-1,7,7-trimethyl-$\Delta^{8,9}$*-octalin (***26***b)*: ir (neat): 1720 (ester), and 1020, 1060, 1110, 1130, 1150 cm^{-1} (ketal); nmr ($CDCl_3$) δ: 1.00, 1.03 (2 s, 3 each, *gem*-dimethyl), 1.01 (d, 3, J = 6 Hz, C-1 CH_3), 3.70 (s, 3, $COOCH_3$), 3.93 (broad s, 4, —O—CH_2—CH_2—O—), and 5.37 (d, 1, J = 2 Hz, C-8 H); ms *m/e* (relative intensity): 294 (4), 297 (3), 235 (7), 99 (100). *Anal.* calcd. for $C_{17}H_{26}O_4$: C 69.36, H 8.90; found: C 69.36, H 8.78.

2-Ethylenedioxy-10-hydroxymethyl-1,7,7-trimethyl-$\Delta^{1,9}$*-octalin (***27***a) and 2-Ethylenedioxy-10-hydroxymethyl-1,7,7-trimethyl-*$\Delta^{8,9}$*-octalin (***27***b)*

To a stirred suspension of lithium aluminum hydride (700 mg, 0.018 mol) was added through a dropping funnel 5 g (0.017 mol) of a mixture of $\Delta^{1,9}$- and $\Delta^{8,9}$-ketal esters **26***a* and **26***b*. On completion of addition the mixture was refluxed for 2 h, the reaction mixture was then cooled in an ice bath and the excess lithium aluminum hydride decomposed by careful addition of a saturated solution of Rochelle salt. The ether layer was separated, washed with water, saturated aqueous sodium chloride solution and dried over anhydrous magnesium sulphate. Evaporation of the solvent gave 3.98 g (88%) of the hydroxy ketals as an oil. The two ketal esters **26***a* and **26***b* were reduced separately by above procedure to give samples of the hydroxy ketals **27***a* and **27***b*. Recrystallization twice from methanol afforded analytical samples of each isomer.

Hydroxy ketal ***27***a: mp 81–83°C; ir (Nujol): 3475 (OH), 1040, 1050, 1060, 1145 cm^{-1} (ketal); nmr ($CDCl_3$) δ: 0.83, 0.98 (2 s, 3 each *gem*-dimethyl), 1.62 (s, 3, C-1 CH_3), 3.57 (broad s, 2, CH_2—OH); and 3.98 (s, 4, —O—CH_2—CH_2—O—); ms *m/e* (relative intensity): 266 (5), 222 (35), 193 (80), 192 (75), 99 (100). *Anal.* calcd. for $C_{16}H_{26}O_3$: C 72.14, H 9.84; found: C 72.32, H 9.92.

Hydroxy ketal ***27***b: mp 87–90°C; ir (neat): 3450 (OH), and 1020, 1060, 1110, 1165, 1190 cm^{-1} (ketal); nmr ($CDCl_3$) δ: 1.00 (s, 6, *gem*-dimethyl), 1.00 (d, 3, J = 6 Hz, C-1 CH_3), 3.58 (s, 2, CH_2OH), 3.92 (s, 4, —O—CH_2—CH_2—O—), and 5.28 (broad s, 1, C-8 H); ms *m/e* (relative intensity): 266 (3), 236 (1), 99 (100). *Anal.* calcd. for $C_{16}H_{26}O_3$: C 72.14, H 9.84; found: C 72.23, H 9.83.

10-Hydroxymethyl-1,7,7-trimethyl-$\Delta^{1,9}$*-2-octalone (***23***) from the Ketals* ***27***a *and* ***27***b

A mixture of $\Delta^{1,9}$- and $\Delta^{8,9}$-hydroxymethyl ketal **27***a* and **27***b* (1 g) was dissolved in acetone (15 ml). Aqueous oxalic acid solution (5%) was added until the solution became cloudy and the mixture was refluxed for 1 h. The acetone was evaporated under reduced pressure and the organic material extracted with ether, washed with saturated sodium bicarbonate solution, saturated sodium chloride solution and dried over magnesium sulphate. Rotary evaporation of the solvent gave an oil which was chromatographed on grade III alumina (elution with benzene – ethyl acetate 70:30) to give octalone **23** (484 mg). A short column distillation provided an analytical sample: bp 140–145°C/0.2 Torr; ir (neat): 3400 (OH), 1650 (C=O), and 1600 cm^{-1} (C=C); nmr ($CDCl_3$) δ: 0.87, 1.07 (2 s, 3 each, *gem*-dimethyl), 1.78 (s, 3, C-1 CH_3), and 3.75 (s, 2, CH_2OH); ms *m/e* (relative intensity): 222 (50), 192 (100), 191 (100), 149 (50). *Anal.* calcd. for $C_{14}H_{22}O_2$: C 75.63, H 9.97; found: C 75.42, H 9.84.

*10-Trimethylsilyloxymethyl-1,7,7-trimethyl-*cis*-2-decalone*

This derivative was prepared according to the procedure of Zinkel (32). To a small pear-shaped flask containing a solution of (5 mg) alcohol **6***c* in 5 ml petroleum ether was added 1 ml of hexamethyldisilazine followed by 1 ml trimethylchlorosilane. The flask was gently heated over a steam bath for 1 h. The solvent was removed by rotary evaporation and the trimethylsilyl ether was extracted with petroleum ether, filtered and concentrated. A 1-μL sample of this concentrated solution was injected into a 6 ft × 0.25 in. column of OV-225 (stationary phase: 5% cyanopropylmethyl phenylmethylsilicone fluid on Chromosorb G, 100–80 mesh) at 160°C. A single peak was observed: retention time 30.8 min.

*2-Ethylenedioxy-10-methoxycarbonyl-1,7,7-trimethyl-*trans*-decalin*

A mixture of 500 mg (1.98 mmol) of *trans*-decalone **17**, *p*-toluenesulfonic acid (37 mg), and ethylene glycol 2 ml in 100 ml benzene was stirred and refluxed overnight, water being removed by azeotropic distillation with benzene. The mixture was cooled and saturated aqueous sodium bicarbonate solution was added. The resulting neutral solution was washed twice with water, then with saturated sodium chloride solution and dried over anhydrous magnesium sulphate. Evaporation of the solvent gave a solid in quantitative yield. Recrystallization thrice from methanol/water furnished an analytical sample: mp 85–87°C; ir (Nujol): 1700 cm^{-1} (ester); nmr δ: 0.80 (d, 3, J = 6Hz, C-1 CH_3), 0.97 (s, 6, *gem*-dimethyl), 3.63 (s, 3, $COOCH_3$), and 3.91 (s, 4, —O—CH_2—CH_2—O—); ms *m/e* (relative intensity): 296 (60), 237 (24), 167 (34), 100 (85),

86 (100). *Anal.* calcd for $C_{17}H_{28}O_4$: C 68.89, H 9.52; found: C 68.85, H 9.43.

2-Ethylenedioxy-10-hydroxymethyl-1,7,7-trimethyl-trans-*decalin*

A solution of ketal ester 1.025 g (3.5 mmol) in dry ether 25 ml was added dropwise to a stirred suspension of lithium aluminum hydride (10 mmol) in dry ether 75 ml. The mixture was stirred for 5 h at room temperature, then cooled in an ice bath, and excess lithium aluminum hydride was destroyed by the careful addition of a saturated solution of Rochelle salt. The ether layer was separated and the aqueous layer extracted two more times with 20 ml each of ether. The combined ether extracts were washed with water, a saturated solution of sodium chloride and dried over anhydrous magnesium sulphate. Evaporation of the solvent gave an oil (99%) which solidified on standing. Recrystallization from methanol yielded 770 mg (83%). Two recrystallizations from methanol afforded an analytical sample: mp 133–135°C; ir (Nujol): 3480 cm^{-1} (OH), no carbonyl absorption; nmr ($CDCl_3$) δ: 0.73 (d, 3, J = 6 Hz, C-1 CH_3), 0.97 (s, 6, *gem*-dimethyl), 3.70 (s, 2, CH_2—OH), and 3.92 (s, 4, —O—CH_2—CH_2—O—); ms *m/e* (relative intensity): 268 (10), 99 (100), 86 (10). *Anal.* calcd. for $C_{16}H_{28}O_3$: C 71.60, H 10.52; found: C 71.63, H 10.62.

10-Hydroxymethyl-1,7,7-trimethyl-trans-*2-decalone (29)*

The hydroxy ketal (770 mg) was dissolved in 50 ml acetone containing 2 ml of 6 *N* HCl and refluxed for 2 h. Water was added to the mixture and the acetone evaporated. The aqueous residue was extracted with ether (3 × 20 ml). The ether extract was washed with water, saturated sodium chloride solution and dried over magnesium sulphate (anhydrous). Evaporation of the ether at reduced pressure gave a solid which was recrystallized from hexane 555 mg (86%) to yield decalone **29** (555 mg, 86%) as colorless needles. Another recrystallization gave an analytical sample: mp 103–104°C; ir (Nujol): 3450 (OH) and 1715 cm^{-1} (C=O); nmr ($CDCl_3$) δ: 0.90, 0.97 (2 s, 3 each, *gem*-dimethyl), 1.00 (d, 3, J = 4 Hz, C-1 CH_3), and 3.72, 4.08 (2 d, 1 each, J = 10 Hz, $W_{h/2} - W_{h/2}$(TMS) = 4 Hz, AB quartet CH_2—OH); ms *m/e* (relative intensity): 224 (22), 193 (16), 176 (35), 165 (34). *Anal.* calcd. for $C_{14}H_{24}O_2$: C 74.94, H 10.78; found: C 74.88, H 10.66.

10-Trimethylsilyloxymethyl-1,7,7-trimethyl-trans-*2-decalone.*

Prepared by the procedure of Zinkel (32) as described above using the alcohol **31** (10 mg). Injection of 1 μL of a concentrated petroleum ether solution of this silyl ether into a 6 ft × 0.25 in. OV-225 column at 160°C (see above) gave a single peak, retention time 27.4 min. Coinjection of a mixture of the *cis* and *trans* silyl ethers indicated two compounds of retention times 27.4 and 30.8 min, respectively.

10-Carboxyl-1,7,7-trimethyl-cis-*2-decalone*

The hydroxy ketone **6***c* (200 mg) was dissolved in 15 ml acetone and cooled in an ice bath. To the stirred solution, Jones' reagent was added dropwise until a permanent orange colour remained. Stirring was continued for a further 30 min at 0°C. The mixture was poured into a separatory funnel, water was added and the organic material was extracted with ether. The ether layer was washed with saturated $NaHCO_3$ solution, then water until clear and then dried over anhydrous magnesium sulphate. Evaporation of the ether under reduced pressure gave a solid, mp 187–192°C; ir (Nujol): 1685 (COOH) and 1710 cm^{-1} (C=O); nmr ($CDCl_3$) δ: 10.87 (COO*H*); no CH_2--OH absorption. This material was esterified without further purification.

10-Methoxycarbonyl-1,7,7-trimethyl-cis-*2-decalone (6*b*)*

To a stirred solution of the acid obtained from 200 mg alcohol **6***c* in 20 ml ether was added an ether solution of diazomethane until there was a permanent yellow colour. The reaction was allowed to stand for 3 h at room temperature when evaporation of the ether and excess diazomethane gave an oil (257 mg). Gas chromatographic analysis on a 6 ft × 0.25 in. OV-225 column at 160°C showed a single peak (43 min retention time). Several attempts to induce crystallization failed. Bulb-to-bulb distillation at 120°C/0.5 Torr provided an analytical sample of ester **6***b*; ir (neat): 1712 (ketone) and 1725 cm^{-1} (ester); nmr ($CDCl_3$) δ: 0.95 (s, 6, *gem*-dimethyl), 0.97 (d, 3, J = 6 Hz, C-1 CH_3), and 3.80 (s, 3, COOCH_3); ms *m/e* (relative intensity): 252 (16), 137 (2), 220 (4), 192 (100), 177 (13), 175 (11). *Anal.* calcd. for $C_{25}H_{24}O_3$: C 71.41, H 9.58; found: C 71.34, H 9.62.

2-Acetoxy-10-acetoxymethyl-1,7,7-trimethyl-$\Delta^{1,9}$-cis-*octalin (32)*

A mixture of 200 mg of ketol **6***c*, acetic anhydride (1 ml) and 1 drop of perchloric acid in carbon tetrachloride (10 ml) was stirred at room temperature for 1 h. The reaction mixture was diluted with water and the carbon tetrachloride layer was separated. The aqueous layer was extracted with (10 ml × 2) chloroform and the combined chloroform and carbon tetrachloride extracts were washed with saturated sodium bicarbonate solution, water and saturated sodium chloride solution and dried over magnesium sulphate (anhydrous). Evaporation of the solvents gave an oil which on bulb to bulb distillation at oil pump pressure furnished a colorless oil which was homogeneous by tlc; ir (neat): 1745 cm^{-1} (acetate); nmr ($CDCl_3$) δ: 0.92 (s, 6, *gem*-dimethyl), 1.50 (s, 3, C-1 CH_3), 2.05, 2.10 (2 s, 3 each, C-CH_3), and 3.90, 4.13 (2 d, 1 each, J = 11 Hz, CH_2—OAc); ms: M^+ 276. *Anal.* calcd. for $C_{18}H_{28}O_2$: C 78.21, H 10.21; found: C 79.88, H 9.95.

Decomposition of tetramethyl-2-tetrazene under acidic conditions

LEON J. MADGZINSKI, K. SOMASEKHAREN PILLAY, HERVÉ RICHARD, AND YUAN L. CHOW
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received December 12, 1977

LEON J. MADGZINSKI, K. SOMASEKHAREN PILLAY, HERVÉ RICHARD, and YUAN L. CHOW. Can. J. Chem. **56**, 1657 (1978).

Decompositions of tetramethyl-2-tetrazene (TMT) under acidic conditions were investigated by product analysis and by nmr and esr spectroscopic monitors. Photolysis in acetonitrile containing trifluoroacetic acid generated the dimethylaminium radical which added efficiently to an olefinic double bond. Some adducts contained a $(CH_3)_2NCH_2$— moiety, the immediate precursor of which could be $CH_2{=}N(CH_3)_2^+$ species. Photolytic addition of TMT to norbornenes generated 2-norbornyl radicals that underwent coupling through the *exo* or *endo* side to give the dimers. Thermal decomposition in sulfuric acid in the presence of toluene gave *N*,*N*-dimethyltoluidines, *N*-methylphenethylamine, benzyltoluenes, and a plethora of other minor products in addition to a large amount of formylidene methylamine. The last compound was the major product when thermal decomposition of TMT was carried out in trifluoroacetic acid in the presence of toluene or anisol; amination products of aromatic substrates were low and contained only *ortho* and *para* isomers. TMT dissolved in these solvents exhibited the esr signal of the stable $TMT^{\ddagger}$ (the tetrazene cation radical) which did not react with cyclohexene. In concentrated sulfuric acid, TMT was decomposed in less than 15 min giving formylidene methylamine and dimethylamine as shown by nmr. In trifluoroacetic acid, the esr signal of tetramethylhydrazine cation radical ($TMH^{\ddagger}$) emerged after the TMT solution was irradiated; no dimethylaminium radical signal could be detected. The relationship of $TMT^{\ddagger}$ and $TMH^{\ddagger}$ with formation of the observed products remains unclear.

LEON J. MADGZINSKI, K. SOMASEKHAREN PILLAY, HERVÉ RICHARD et YUAN L. CHOW. Can. J. Chem. **56**, 1657 (1978).

On a étudié, à l'aide de l'analyse des produits et par études spectroscopiques rmn et rpe la décomposition de la tétraméthyltétrazène-2 (TMT) dans des conditions acides. La photolyse dans l'acétonitrile contenant de l'acide trifluoroacétique conduit à la formation de radical diméthylaminium qui s'additionne d'une façon efficace à la double liaison oléfinique. Quelques produits contenaient une portion $(CH_3)_2NCH_2$— dont le précurseur immédiat serait l'espèce $CH_2N(CH_3)_2^+$. L'addition photolytique du TMT aux norbornènes conduit à des radicaux norbornyl-2 qui subissent des couplages par les faces *exo* ou *endo* pour conduire à des dimères. La décomposition thermique dans l'acide sulfurique en présence de toluène conduit aux *N*,*N*-diméthyltoluidines, à la *N*-méthylphénéthylamine, aux benzyltoluènes et à toute une série d'autres produits mineurs en plus d'une grande quantité de formylidène méthylamine. Ce dernier composé est le produit majeur lorsque la décomposition thermique du TMT est effectuée dans l'acide trifluoroacétique en présence du toluène ou d'anisol; les produits d'amination des substrats aromatiques sont faibles et contiennent uniquement les isomères *ortho* et *para*. Lorsque le TMT est dissous dans ces solvants, il présente un signal rpe correspondant à l'entité $TMT^{\ddagger}$ (le radical cation tétrazène) qui ne réagit pas avec le cyclohexène. Dans l'acide sulfurique concentré, le TMT se décompose en moins de 15 minutes pour conduire à la formylidène méthylamine et à la diméthylamine tel que montré par le spectre rmn. Dans l'acide trifluoroacétique, le signal rpe du radical cation tétraméthylhydrazine ($TMH^{\ddagger}$) peut être observé lorsque l'on irradie la solution de TMT; on n'a pu détecter aucun signal correspondant au radical diméthylaminium. La relation qui existe entre la nature des produits observés et la formation de $TMT^{\ddagger}$ et le $TMH^{\ddagger}$ demeure confuse.

[Traduit par le journal]

Introduction

The presence of the thermally (1, 2) and photolytically (2–4) labile azo linkage has attracted many workers to investigate decomposition of tetraalkyl-2-tetrazene in expectation to observe reactive intermediates centered at the amine nitrogen. Most of the investigations were carried out with tetramethyl-2-tetrazene (TMT) from which formylidene methylamine ($CH_2{=}NCH_3$) or its derivatives (e.g., the trimer **1**, *N*,*N*′,*N*″-trimethylhexahydrotriazine, or the hydrolysis products, methylamines and formaldehyde) are invariably the major products isolated (5–8). A number of mechanisms proposed so far may be summarized as shown in eqs. [1–3] (6, 8–10).

Thermolysis or photolysis of TMT to generate the dimethylamine radical (eq. [1]) has been proven by the recording of the esr signal of the radical (3, 4). TMT decomposition in dilute acidic solution produces equimolar yields of nitrogen, formaldehyde, and methylamine from which $TMT{-}H^+$ is proposed

to decompose by an ionic process giving the nitrenium ion as in eq. [2] (or its ion pairs with the existing anions) (8, 9). However, other investigators also suggest an intramolecular cyclic proton transfer to account for the decomposition (10). In concentrated sulfuric acid the diprotonated tetraphenyl-2-tetrazene is suggested to homolytically decompose to yield diphenylaminum radicals (11). This leads to speculation that TMT might be homolytically decomposed to the two aminium radicals in concentrated sulfuric acid as shown in eq. [3]. As the observed products could be rationalized equally satisfactorily with aminium radical or nitrenium ion, mechanisms of TMT decomposition remain an open question.

Investigations utilizing esr spectroscopy show that treatments of TMT with alkylating or acylating agent in acidic conditions give the fairly persistent radical cations $TMT^{\ddagger}$ and $TMH^{\ddagger}$ (tetramethylhydrazine), the formations of which have been suggested to involve an electron transfer (oxidation) to aminium radicals (6, 7). Whether these two radicals participate in the subsequent reactions is obscure. The complex reaction patterns of TMT decomposition are further shown by isolation or detection (by esr) of various by-products that are not readily explained by the straightforward mechanisms of eqs. [1–3] (1,

$$[1]\quad (CH_3)_2NN{=}NN(CH_3)_2 \xrightarrow[\Delta]{h\nu \text{ or}} 2(CH_3)_2N\cdot + N_2$$

$$[2]\quad \underset{(TMT\text{–}H^+)}{(CH_3)_2NN{=}\overset{+}{N}NH(CH_3)_2} \xrightarrow{\text{dil. } H^+} (CH_3)_2N^+ + (CH_3)_2NH_2{}^+ + N_2$$

$$[3]\quad TMT\text{–}2H^+ \xrightarrow{\text{conc. } H_2SO_4} 2(CH_3)_2NH^{\ddagger} + N_2$$

6). It appears that heterolysis or homolysis are not the only possible TMT reactions but electron transfer reactions might also occur either as a part of or independently from the reaction.

Provided conditions can be found, acidic decomposition of TMT may be regarded as a clean way to generate two entities of the dimethylaminium radical (eq. 3). Reactivities of aminium radicals have been established to undergo highly specific inter- and intramolecular (the Hofmann–Löeffler type) H-abstraction, addition to olefinic bonds, electrophilic substitution on activated aromatic rings, and α-hydrogen elimination (12–15). It is envisaged that such reactions might give us a clue to the nature of the reactive intermediates in TMT decompositions. We wish to report here the photochemical and thermal decompositions of TMT under acidic conditions.

Photolysis of TMT in Trifluoroacetic Acid – Acetonitrile Solution

Decompositions of TMT in dilute acidic solutions, e.g., 1 *M* hydrochloric acid or trifluoroacetic acid in methanol or acetonitrile, at 0°C was very slow but became faster at room temperatures and higher. In these thermal decompositions, high yields of the trimer of formylidene methylamine **1** were obtained either in the absence or presence of an olefin; basic products incorporating the olefinic molecule were not detected.

When an acetonitrile solution of TMT containing trifluoroacetic acid and cyclohexene was photolysed under an inert atmosphere, a complex mixture was obtained from the basic extract. By direct matching of the vpc peaks with authentic samples, dimethylaminocyclohexane (**4**, 17%),[1] dimethylaminocyclo-

7 R = Cl

hexene (**3**, 8.5%), *trans*-1,2-bisdimethylaminocyclohexane (**6**, 1.2%), bis-2-dimethylaminobicyclohexyl (**2**, 1.4%), and *trans*-2-dimethylaminomethyl-1-dimethylaminocyclohexane (**5**, 16%) and the corresponding *cis*-isomer of **5** (4.1%) were identified. In the presence of hydrochloric acid, instead of trifluoroacetic acid, the TMT photolysis afforded, in addition to the above products, unstable *cis*- and *trans*-1-dimethylamino-2-chlorocyclohexanes **7**. In this case, **2** and **7** were isolated by column chromatography and *trans*-**5** by preparative vpc. In both experiments, trimer **1** was also isolated as the major product.

The reasonably good yields of dimethylaminocyclohexyl derivatives indicate that the dimethylaminium radical is generated as the reactive intermediate and attacks cyclohexene fairly efficiently in agreement with the photoadditions of *N*-nitrosamines (12), *N*-chloramines (13, 15), and *N*-nitroamines (16) to olefins. In the present case, the photolabile species presumably is the monoprotonate TMT ($TMT\text{–}H^+$,

[1]All the percentage yields were calculated on the basis of 1 mol of TMT to yield 1 mol equiv. of the products.

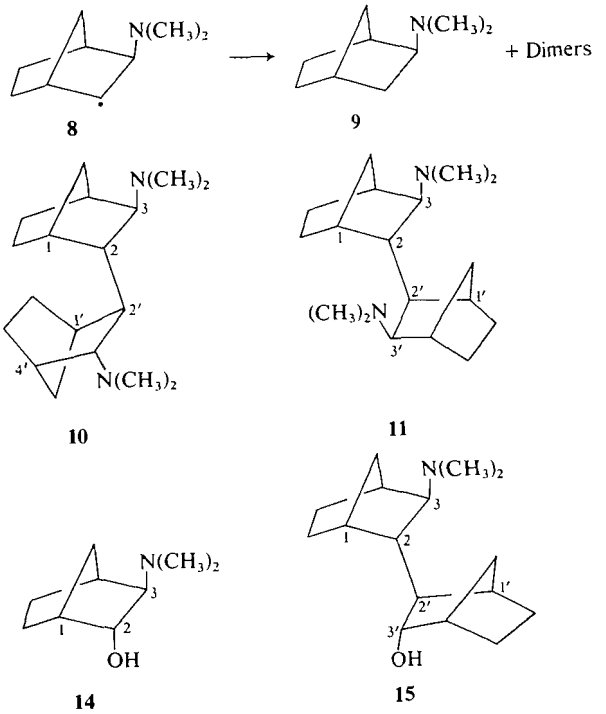
For personal use only.

pK_a 3.9) which has λ_{max} 239 nm (6, 8) and is dissociated to give two dimethylaminium radicals and nitrogen. In contrast, thermolysis of TMT under similar conditions does not yield the addition products indicating that the aminium radical is not generated.

The complexity of the product patterns might arise from the lack of a good counter radical donor or from low concentrations of radicals to react with the dimethylaminocyclohexyl radical intermediate which may undergo dimerization or disproportionation to yield **2**, **3**, and **4**. TMT and other nitrogen containing bases are protonated under the experimental conditions, and are expected to be poor hydrogen atom donors owing to electrostatic repulsion of cationic charges. The $CH_2N(CH_3)_2$ moiety of **5** and chlorine of **7** could be derived from $CH_2{=}N(CH_3)_2$ or $(CH_3)_2NCH_2\overset{+}{N}H(CH_3)_2$ (1) and hydrogen chloride, respectively, but their incorporations by radical mechanisms find no precedence. It is suspected that electron transfer reactions also intervene in the radical processes leading to incorporation of these ionic species into the overall reaction (*vide infra*). In view of the formation of both *cis* and *trans* isomers for **5** and **7**, a purely ionic route, e.g., a nitrenium ion attack to give the aziridinium intermediate, can hardly be a rational alternative. It follows that the observed complexity of products might be avoided if the cyclohexyl radical intermediate is captured with a good radical donor; indeed under oxygen the cyclohexyl radical is efficiently scavenged to give good yields of the 1-dimethylamino-2-hydroperoxycyclohexane (17). Although TMT photoaddition to cyclohexene under nitrogen is not a synthetically useful reaction, those to other olefins, such as norbornene and 1,5-cyclooctadiene, give more amenable results.

In the presence of norbornene, similar TMT photolysis in acetonitrile–TFA gave monomer and dimeric adducts in a ratio of 1:10; the former was assigned as *exo*-2-dimethylaminobicyclo[2.2.1]heptane **9** by comparisons of the ir and nmr data with those published (18). The four dimers were adducts of 1 molecule of TMT to 2 molecules of norbornene less N_2 as shown by gc–ms analysis.[2] Two major components were isolated in the pure state and were shown to be 2-*endo*-(3′-*exo*-dimethylaminobicyclo[2.2.1]hept-2′-*endo*-yl)-3-*exo*-dimethylaminobicyclo[2.2.1]heptane (**10**, 16%) and 2-*endo*-(3′-*exo*-dimethylaminobicyclo-



[2.2.1]hept-2′-*exo*-yl)-3-*exo*-dimethylaminobicyclo-[2.2.1]heptane (**11**, 22%). The former is readily proven by the eight ^{13}C nmr signals[2] owing to the presence of the plane of symmetry; the alternative all *exo*-configuration was unlikely since aminium radical initiated addition to norbornene generally gave *trans* configuration as the major product (19). The highly symmetrical structure of **10**, and therefore a low dipole moment, was suggested by its insolubility in methanol and solubility in hexane in contrast to the solubility behavior of **11**. The ^{13}C nmr data obtained by the off-center decouplings were particularly useful in assignments of the stereochemistry. Some assignments of the proton and ^{13}C nmr were ascertained by comparisons with the reported chemical shifts of substituted norbornanes (20) and by single frequency irradiation of proton signals in relation to the ^{13}C spectral changes;[2] for comparisons, two norbornyl derivatives **14** and **15** (17) are also included in Table 1. The relatively low field of the C-7 at 37.3 ppm and the high field of the C-6 at 23.2 ppm indicated an *endo* and *exo* substitution at the C-2 and C-3 in **10** (20). If the $(CH_3)_2N$— groups were *endo*, the shift at C-5 would be in the order of 20 ppm instead of the observed 28.5 ppm. Dimer **11** exhibited a one-proton double doublet at τ 7.56 with the coupling constants of 8.5 and 1.5 Hz assignable to the C-3 *endo*-proton geminal to the $N(CH_3)_2$ group. The coupling pattern clearly indicated a 2,3-*cis* configura-

[2]These and other spectra and decoupling techniques are given in the Thesis by L. J. Madgzinski (ref. 17). The conditions and operation of vpc analyses are also described in the same reference.

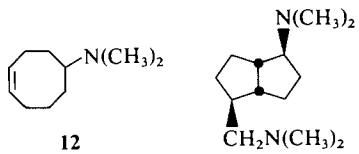
tion of the substitutions on the norbornene system. The other C-3 proton appeared at τ 7.43 as a multiplet. Since the ^{13}C nmr spectrum showed all 16 signals indicating the molecular dissymmetry, structure **11** was assigned. Comparisons of ^{13}C nmr chemical shifts as shown in Table 1 also supported the assignments of structure **10** and **11**. It was noteworthy that for **11** the C-5′ and C-6′ resonated at relatively low fields in comparison to the C-5 and C-6 chemical shifts in agreement with the assignment of the *cis-exo* configuration to one-half of the molecule (20). Two other dimers resisted various efforts of purification methods. In this photolysis, trimer **1** was also obtained in a 40% yield.

In the presence of 1,5-cyclooctadiene (COD), TMT photolysis under similar conditions yielded two compounds which were identified as 5-dimethylaminocyclooctene (**12**, 32%) and 2-*exo*-dimethylamino-6-*exo*-dimethylaminomethyl-*cis*-bicyclo[3.3.0]octane (**13**, 12%). No material was extracted from the acidified photolysate. The structural assignments of **12** and **13** followed readily from their spectral properties and the elemental analyses. The *exo* configuration of the 2-dimethylamino group in **13** was indicated by the double triplet signal at τ 6.40 in the nmr spectrum of the dimethiodide of **13**; this proton must have one *cis*-vicinal interaction (J = 8.5 Hz) and two *trans*-vicinal interactions (J = 6 Hz) in a cyclopentane ring (21). The *cis*-ring fusion as well as the *exo* configuration of the $(CH_3)_2NCH_2$— group were derived from the favored stereochemical course of a radical addition to a COD ring (22).



12 13

The relatively simple product pattern in the photoaddition to COD may indicate that COD is a better hydrogen donor than cyclohexene as shown by the higher yield of **12**. The transannular ring closure immediately after the aminium radical attack on COD has ample analogies (22–24) in radical addition reactions but the precursor of the $CH_2N(CH_3)_2$ moiety in **13** poses the same question as mentioned above.

The extensive formation of dimeric compounds (>75%) in contrast to the low yield of **9** in the TMT photoaddition to norbornene under nitrogen is surprising. The stereochemistry of the major dimers **10** and **11** suggests that the dimers are formed by coupling of the norbornyl radicals **8** rather than by a stepwise addition of **8** to norbornene followed by a combination with a dimethylaminium radical. For if the latter occurs, an *endo-endo* connection and an *exo-exo*-dimethylamino orientation to norbornene rings, such as in **10**, would not constitute the major products (19). This has led us to conclude that the norbornyl radical **8** has reasonable concentration, and therefore a reasonable life-time in the reaction system presumably owing to the fact that there is no good H-atom donor in the system. It is known that 2-norbornyl radicals do not have a resonance stabilization similar to that of 2-norbornyl cation (25). In theory, the *endo-endo* coupling of **8** would give a *dl* pair and *meso* isomers and the *endo-exo* coupling two *dl* pairs. From the ^{13}C nmr spectrum, dimer **10** is the *endo-endo meso* isomer. The dimer **11** and two unidentified dimers might be the *dl* pairs.

TMT photoaddition to dicyclopentadiene **16** and 5-vinylnorbornene **17** were also investigated. In methanol solution containing TFA, the photoaddition to **16** gave two monomeric adducts **18** (35%) and a mixture of dimeric adducts **19** (40%) in addition to five minor components. These two groups of closely related isomers showed overlapped peaks in attempted vpc separation and were isolated and identi-

For personal use only.

fied as mixtures. The relatively high yields of monomeric adducts **18** obviously arises from the better hydrogen atom donating solvent, methanol, to intercept the C-radical intermediate. Despite careful analysis of the products, compounds derived from cyclization were not detected in the basic products. TMT photoaddition to **17** in acetonitrile gave at least four dimeric adducts similar to **19** as the major product in 70% yield in addition to many monomeric adducts as shown by gc–ms analysis. The initial attack of the dimethylaminium radical occurred nearly exclusively at the norbornyl double bond as indicated by the strong vinyl proton signal in the nmr spectrum of the crude products. The nmr analysis of the same chromatographic fractions containing the minor products show that tricyclic adducts resulting from cyclization might be formed in small quantities; attempts to isolate these minor products were unsuccessful.

Photoaddition of TMT to 1,6-heptadiene yielded cyclized diamine **20** as the major product which could not be easily extracted due to the solubility in water. The cyclization to a five-membered ring system was inferred in analogy to the radical addition of C_3F_7I to the olefin (26) and the structure was supported by ^{13}C nmr and mass spectra; in both cases the incorporation of an extra methylene group was clearly indicated. In view of the clean ^{13}C nmr spectrum, this sample must contain only one geometric isomer of **20** though the *cis* or *trans* stereochemistry could not be determined.

Spectroscopic Studies of TMT Decomposition

To gain insight on the TMT decomposition under acidic conditions, the decomposition processes were monitored with nmr and esr spectroscopy. While some of these results supported the published reports, there were other observations that could not be conclusively related to the proposed mechanism.

Controlled dissolution of TMT in concentrated sulfuric acid at 0°C caused immediate evolution of nitrogen giving rise to $(CH_3)_2NH_2^+$ (at τ 7.10) and $CH_3NH{=}CH_2^+$ (at τ 6.27 and 1.93) in an equimolar ratio with a small signal of TMH–$2H^+$ at τ 6.40. The nmr signals for TMH–$2H^+$ decayed slowly at 20°C but rapidly at 100°C to be replaced by the signals of the former two species. Although no nmr signal of TMT–H^+ could be detected, this solution exhibited a weak esr signal for $TMT^{\ddagger}$ (6, 7, 27) which decayed slowly over several days giving no new signal.

Solutions of TMT in TFA or in 1 *M* TFA-acetonitrile-d_3 showed the nmr singlets for TMT–H^+ at τ 6.62, 6.82, and 6.92 with the ratio of 1:1:2 at −15°C in analogy to those of the hydrochloride salt of TMT (27). The signals were broadened at 10°C and at 30°C coalesced to the singlet at τ 6.78 which decayed to be replaced by the signals of $(CH_3)_2NH_2^+$ and $CH_3NH{=}CH_2^+$ in an equimolar amount. Irradiation of the TMT–H^+ solution in TFA at 0°C gave the nmr signals of these two species in addition to a weak TMH–H^+ signal at τ 7.14 and other unidentified signals. However irradiation in the TFA–acetonitrile solution gave a complex nmr spectrum.

A TMT solution in TFA–acetonitrile exhibited a strong esr signal for the $TMT^{\ddagger}$ (6, 7) at room temperature or lower with *g*-factor 2.0040 ± 0.0005, a_N = 1.15 (2N), a_N = 10.85 (2N), a_H = 10.40 (6H) and a_H = 10.60 G (6H). This signal persisted for days at −45°C but decayed rapidly in 2 h at room temperature with no appearance of new signals. This solution was irradiated at 25°C without a filter; on interruption of irradiation an esr signal for $TMH^{\ddagger}$ (a_N = 13.2, a_H = 12.7 G and *g*-factor = 2.0039 ± 0.0006) (6) built up rapidly in 5 min and decayed slowly in 1 h. The interruption of irradiation at −45°C generated the persistent esr signals of $TMH^{\ddagger}$ superimposed with a weaker signal of $TMT^{\ddagger}$. Addition of cyclohexene to this solution at −45°C caused immediate disappearance of the $TMH^{\ddagger}$ signal but the $TMT^{\ddagger}$ remained unchanged.

Ubiquitous presence of the persistent $TMT^{\ddagger}$ signal in these experiments indicates that this radical is unreactive even to an olefin. TMH has been proposed to be formed by dimerization of the dimethylamino radicals in the treatment of TMT with acylation or alkylation agents (6, 7). The corresponding $TMT^{\ddagger}$ and $TMH^{\ddagger}$ radicals are suggested to be formed by oxidation using the aminium radicals as the electron acceptor (7). Under the present photolytic conditions, the $TMH^{\ddagger}$ might be formed as shown in eqs. [4–7]. However, neither in the reported (6, 7) nor in the present experiments, the esr signals of the aminium radicals could be detected presumably due to fast reactions of eqs. [5–7]. The lack of

$$\text{TMT–H}^+ \xrightarrow[\text{H}^+]{h\nu} 2(\text{CH}_3)_2\text{NH}^{\ddagger} + \text{N}_2 \quad [4]$$

$$2(\text{CH}_3)_2\text{NH}^{\ddagger} \rightarrow \text{TMH–H}^+ + \text{H}^+ \quad [5]$$

$$\text{TMH–H}^+ + (\text{CH}_3)_2\text{NH}^{\ddagger} \rightarrow \text{TMH}^{\ddagger} + (\text{CH}_3)_2\text{NH}_2^+ \quad [6]$$

$$\text{TMT–H}^+ + (\text{CH}_3)_2\text{NH}^{\ddagger} \rightarrow \text{TMT}^{\ddagger} + (\text{CH}_3)_2\text{NH}_2^+ \quad [7]$$

the $TMH^{\ddagger}$ esr signal during irradiation might arise from photolability of this radical which is consumed as it is formed. The appearance of $TMH^{\ddagger}$ esr signal after interruption of photolysis suggests that a precursor decomposes thermally to generate the dimethylaminium radicals which undergo reactions [5] and [6]. Such a precursor could be the *cis* form of the TMT–H^+ in analogy to the thermally unstable *cis*-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

tetraisopropyl-2-tetrazene reported previously (4). If so, the photoexcitation serves to isomerize the *trans* form to the *cis* form of TMT–H^+. The formation of TMH in the decomposition in sulfuric acid might also indicate the intermediacy of the dimethylaminium radical under the conditions.

While the $TMH^{\ddagger}$ was demonstrably reactive toward cyclohexene, its role in the observed photoaddition could not be ascertained since photolysis of TMH under the same conditions as those used in the TMT photoaddition to cyclohexene did not give addition products. The quantity of $TMT^{\ddagger}$ and $TMH^{\ddagger}$ generated in the decomposition is reported (6) to be very low; the reaction of eqs. [4–7] are probably not the major reaction pathway.

When TMT was added to a 1:1 mixture of cyclohexene–acetonitrile containing TFA, two layers developed: the top cyclohexene layer exhibited a poorly resolved $TMT^{\ddagger}$ esr signal which decayed in 45 min to be replaced by a signal at $g = 2.0024 \pm 0.0004$ with 17 major bands. This signal is tentatively assigned to *N,N,N'*-trimethyldiaminomethyl radical, $(CH_3)_2\dot{N}CHNHCH_3$, on the basis of a computer simulated spectrum using the coupling constants of known α-aminoalkyl radicals (28, 29). The sequence of the spectral formation suggests that $TMT^{\ddagger}$ decomposition is related to the formation of the radical. However, the mechanism remains to be clarified.

Thermal Decomposition of TMT in Concentrated H_2SO_4

N-Chlorodimethylamine has been decomposed in concentrated sulfuric acid thermally, photolytically or catalysed with ferrous, cuprous, or titanous ion in the presence of toluene (15, 30). *N,N*-Dimethyltoluidines are obtained in these reactions in which unusually high yields (5 ~ 54%) of the *meta* isomers are interpreted by a radical mechanism involving dimethylaminium radical as the reactive species (15). Since the aminium radicals generated from *N*-nitrosamine photolysis in 0.1 *M* HCl in methanol fail to give toluidine derivatives (12), high acidity media, such as concentrated H_2SO_4 or mixtures with AcOH, appear to be necessary to stabilize the dimethylaminium radical so that it has a sufficiently long lifetime to successfully attack toluene. As shown above, TMT decomposition in H_2SO_4 also suggests dimethylaminium radical intermediacy; the decomposition in the presence of toluene was therefore investigated.

At the beginning, the reaction of *N*-chlorodimethylamine with toluene in sulfuric acid was repeated according to the procedure of Bock and Kompa (30) from which 35% of toluidines **21** with an *ortho*:*meta*:*para* ratio of 9:61:30 was obtained; previously unisolated *o*- and *p*-benzyltoluenes (**22**) were also isolated in 8% yield from the neutral fraction. These samples were used to establish an efficient analytical procedure by vpc and gc–ms methods as described in the Experimental section. A heterogeneous mixture of TMT, toluene, and concentrated sulfuric acid was allowed to react at room temperature or lower with vigorous stirring from which large amounts of polymeric material containing aromatic rings and dimethylamino groups were obtained. The yields of toluidines **21** ranged 5 ~ 23% with a typical *ortho*:*meta*:*para* ratio of 15:10:75; the ratio however fluctuated considerably and could not be reproduced. The yields were ca. 5% for several hours reaction but increased significantly after 20 h. From the neutral fractions, about 10% of *o*- and *p*-benzyltoluenes (**22**) with a ratio of 4:6 and a trace amount of bibenzyl were also identified.

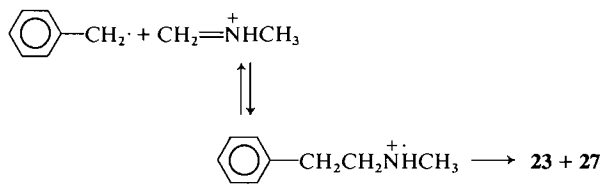
In the basic fractions, in addition to toluidines **21** and the trimer **1**, minor amounts of *N*-methylphenethylamine (**23**), *N,N*-dimethylbenzylamine (**24**), *N*-methylindoline (**27**), *N,N*-dimethylphenethylamine (**25**), and *p-N*-methyltoluidine (**26**) were also detected by the peak matching method with authentic samples (31). The identity of these compounds were further supported by gc–ms analyses. However, when the reaction was carried out at 80°C for 15 min, the yields of toluidines **21** decreased to 1–2% and those of phenethylamines **23** and **25** increased to 30 and 8%; *o*- and *p*-benzyltoluenes **22** were also formed in 10% in this reaction.

Since the above nmr results indicate that TMT on dissolution in concentrated sulfuric acid decomposes within several minutes, the phenethylamines **23** and **25** and benzyltoluenes **22**, but not toluidine **21**, appear to be formed within this time scale. In a prolonged decomposition, phenethylamines **23** and **25** are presumably decomposed to the polymers and toluidines **21** are formed from a slow reaction of an aminating species attacking on toluene. Assumption that TMH—$2H^+$ in sulfuric acid reversibly generates the dimethylaminium radical in a slow dissociation could not be substantiated since TMH under the same conditions does not react with toluene: the identity of the aminating species remains obscure.

At the present stage, mechanistic interpretations of other basic product formation involve many uncertainties and not warranted. However, lack of *m*-benzyltoluene in the TMT as well as *N*-chlorodimethylamine reaction products implies that the *ortho* and *para* isomers are formed by an electrophilic attack of the benzyl cation on toluene. As the benzyl radical intermediacy is also suggested by the small amounts of bibenzyl in the products, both radical and ionic processes are suspected to operate in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the decomposition. Both phenethylamine **23** and **25** are expected to be formed from a benzyl moiety reacting with $CH_2{=}NHCH_3^+$ and $CH_2{=}N(CH_3)_2^+$. An analogy to such a reaction is the reverse pathway of the fragmentation of the N-methylphenethylaminium radical (31) which also serves as the precursor to indoline **27** (15).



Decompositions of TMT in toluene–TFA (ratio of 0.7:7:4) were also carried out under similar conditions as above to give the trimer **1** as the major product; toluidine **21** was obtained in only *ca.* 2% yields with the *ortho*:*para* ratio of 60:40 but the *m*-toluidine **21** was not obtained. Neither the basic products **23**–**27** nor benzyltoluenes **22** were obtained. The decomposition pattern in TFA is thus much simpler and probably does not involve a dimethylaminium radical. In view of the high ratio of the *o*- to *p*-toluidine and lack of the *m*-toluidine, it is tempting to suggest an electrophilic attack of the nitrenium ion on toluene: similar products patterns have been reported in the nitronium and isopropyl carbonium ion attacks on toluene (32, 33). Decomposition of TMT in a mixture of anisole and TFA gave ca. 10% of *N*,*N*-dimethylanisidine with an *ortho* and *para* isomeric ratio of 2:1. The low yield of the amination product might arise from a rapid proton migration of nitrenium ion to $CH_2{=}NHCH_3$ which could account for the clean formation of the trimer **1** in the TFA decomposition. Such a reaction finds analogies in the rapid rearrangement of methylnitrene (34) and deprotonation of isopropylcarbonium ion (35). However, attempts to intercept the dimethylnitrenium ion with cyclohexene did not give the expected addition products.

The decompositions of TMT discussed above display complex patterns probably owing to concurrence of many side reactions. With the exception of photolysis of TMT—H^+ to generate the dimethylaminium radical, no clear mechanistic conclusion can be made on the thermolysis of TMT in acidic conditions.

Experimental

Unless otherwise specified, the following conditions were used. The ir spectra were recorded with a Perkin-Elmer 457 spectrophotometer as liquid films or Nujol mulls, uv spectra with a Unicam SP 8000 spectrophotometer, mass spectra with a Hitachi-Perkin-Elmer RMU-6E instrument at 80 eV (peak intensity was given as a percentage of the most intense peak), esr spectra with a Varian E-4 EPR spectrometer using a flat quartz Varian E-248 aqueous solution sample cell and diphenylpicrylhydrazyl radical as the external standard, and the nmr spectra with either a Varian A 56/60 or a Varian XL-100 instrument equipped with a Nicolet 1080 computer in CCl_4 or $CDCl_3$ using TMS as internal standard or in H_2SO_4 or CF_3COOH using the dimethylammonium ion signal (τ 7.10) as the internal standard. The gas chromatographic (vpc) analyses were obtained on an F & M Model 810-19 dual flame analytical instrument using a Varian Aerograph Model 20 strip chart recorder equipped with a Model 224 disc chart integrator with a 10% Carbowax 20M on Chromosorb W 100/120 (10 ft × $\frac{1}{16}$ in.) stainless steel column. Preparative vpc separations were performed on a Varian Aerograph Series 1700 thermal conductivity instrument with a 25% Carbowax 20M on Chromosorb W 60/80 (10 ft × $\frac{1}{4}$ in.) stainless steel column and the gc–ms were done on a 5% Carbowax 20M on Chromosorb W 100/120 (6 ft × $\frac{1}{8}$ in.) glass column in a Varian 1400 instrument which was directly coupled to the mass spectrometer.

Preparation of Tetramethyl-2-tetrazene (TMT) and Tetramethylhydrazine (TMH)

The procedure of Watson (1) was slightly modified to give better yields. HgO (158 g, 0.74 mol) was added slowly over 2 h to a stirred solution of dimethylhydrazine (50 ml, 0.66 mol) in ether (400 ml) at −5°C. Solid K_2CO_3 (10 g) was then added and the mixture stirred for 2 h more at −5°C, then 2 h at room temperature. The mixture was filtered, the ether was removed, and the resulting yellow liquid (34.2 g) was distilled to give TMT as a pale yellow liquid (29.5 g, 78%); bp 42°C/28 Torr; uv λ_{max} (ethanol): 277 nm (ε, 8 × 10^3); nmr τ:7.19 (s). The mercury was collected, washed with water, and dried (107 g, 82%).

TMH was prepared as described by Watson (1): nmr τ:7.14 (s) for TMH—H^+ in CF_3CO_2H and 6.40 for TMH—$2H^+$ in H_2SO_4.

Photolysis of TMT under Nitrogen

In the Presence of Cyclohexene

A solution of TMT (4.8 g), cyclohexene (17 g), trifluoroacetic acid (32 g), and acetonitrile (320 ml) was made up in a photocell under a nitrogen atmosphere and was irradiated with a low pressure mercury lamp (Ultraviolet Products Inc.)[3] for 6 h. The residue from the photolysate was acidified with aqueous HCl and extracted to afford a small amount of the neutral fraction. The aqueous phase was basified with Na_2CO_3 and heated over a steam bath for 2 h. Ether extraction afforded the basic fraction (2.87 g).

The major products of the basic fraction were identified by gc analysis (20% Dowfax 9N9 – 10% TEP on Chromosorb) as dimethylaminocyclohexane (**4**, 13 min, 17%), 3-dimethylaminocyclohexene (**3**, 14.5 min, 8.5%), *trans*-diamine **6** (26 min, 1.2%), *trans*-**5** (29 min, 16%), *cis*-**5** (32 min, 4.1%), and **2** (40 min, 1.4%, *vide infra*).

In a separate experiment, the basified aqueous solution was not heated but was extracted to give the basic fraction from which imine trimer **1** was obtained in a 60% yield in addition to the above compounds. In this experiment, a portion of the zero hour sample was kept in the dark at 0 ~ 5°C for 3 days after which time the TMT uv absorption had disappeared. The usual work-up afforded a basic oil which was shown to contain

[3]In all other photolyses, except this case, a Hanovia lamp was used. In all experiments, the zero hour samples kept in the dark at 0°C were examined by uv spectroscopy at the end of the reaction showing no decrease of the intensity at 239 nm.

For personal use only.

only the trimer **1** and showed no nmr signals due to a cyclohexane ring.

In the Presence of Norbornene

A solution containing TMT (3 g), norbornene (6.85 g), trifluoroacetic acid (23 g), and acetonitrile (200 ml) was prepared at 0°C and was photolysed under nitrogen for 2 h at 0°C. The solution turned to deep yellow within 15 min of irradiation but the color faded by the end of the photolysis. The basified aqueous solution was extracted to give the first basic fraction (2.68 g) and further continuously extracted to give the second basic fraction (300 mg). The latter contained only the imine trimer **1** as shown by the nmr signal at τ 6.78 and 7.79.

A part of the first basic fraction was chromatographed on basic alumina. Methylene chloride eluted 2-*endo*-(3′-*exo*-dimethylaminobicyclo[2.2.1]hept-2′-*endo*-yl)-3-*exo*-dimethylaminobicyclo[2.2.1]heptane (**10**) which was recrystallized, as white prisms; mp 165–171°C (sealed tube); ir: 2870, 2775, 1290, 1268, 1179, 1169, 1060, 1042, 1013, 850, and 714 cm^{-1}; ^1H nmr τ: 7.75 (s, 12H), 7.7–7.9 (m, 2H), 8.06 (m, $W_{\frac{1}{2}}$ = 4 Hz, 2H), 8.2–9.2 (m, 16H); ^{13}C nmr: 74.9(d), 46.9(d), 42.4(q), 40.0(d), 37.3(t), 35.3(d), 28.5(t), and 23.2(t); ms (80°C): 276.2561 (M^+, 10, calcd. for $C_{18}H_{32}N_2$: 276.2565), 261(100), 232(10), 218(10), 192.1749 (51, calcd. for $C_{10}H_{22}N$: 192.1753), 150(9), 138.1279 (9, calcd. for $C_9H_{16}N$: 138.1282). *Anal.* calcd. for $C_{18}H_{32}N_2$: C 78.20, H 11.67, N 10.13; found: C 78.25, H 11.58, N 10.13.

Elution with 1% MeOH in CH_2Cl_2 gave a mixture. Elution with 2% MeOH in CH_2Cl_2 gave a solid which was sublimed to give 2-*endo*-(3′-*exo*-dimethylaminobicyclo[2.2.1]hept-2′-*exo*-yl)-3-*exo*-dimethylaminobicyclo[2.2.1]heptane (**11**) as white needles; mp 67–72°C (sealed tube); ir: 2878, 2777, 1680, 1292, 1270, 1260, 1174, 1091, 1056, 1025, 1012, 942, 888, 848, and 760 cm^{-1}; ^1H nmr τ: 7.42 (m, $W_{\frac{1}{2}}$ = 10 Hz, 1H), 7.56 (d, J = 8 Hz, 1H), 7.65–7.85 (m, 2H), 7.76 (s, 12H), 8.16–8.22 (m, 16H); ^{13}C nmr: 76.6(d), 71.9(d), 53.2(d), 45.5(d), 44.8(q), 43.0(q), 40.0(d), 39.0(d), 37.2(t), 35.0(d and t), 34.2(d), 30.3(t), 29.2(t), 28.4(t), 23.0(t); ms: (80°C) 276 (M^+, 8), 261(100), 232(17), 218(17), 192(53), 152(26), 98(22), 84(53), and 58(43). Addition of 20% Europium(III) 2,2,6,6-tetramethylheptanedioate (Ventron Corp., Montreal) separated the low field protons showing at τ 7.43 (m) and 7.55 (dd, J = 8.5 and 1.4 Hz) and also two N—CH_3 singlets with 3 Hz spacing. *Anal.* calcd. for $C_{18}H_{32}N_2$: C 78.20, H 11.67, N 10.13; found: C 78.54, H 11.72, N 10.65.

The crude basic fraction showed five major vpc peaks with retention times (20% Dowfax 9N9 – 19% TEP on chromosorb P 60/80) of 25, 134, 143, 150, and 158 min in a ratio of 8:43:11:31:16. The first peak was isolated from the vpc analysis as oily dimethylaminobicyclo[2.2.1]heptane (**9**); *m/e*(%): 139 (M^+, 38), 124(8), 110(46), 98(38), 84(29), 71(33), and 58(100); ir: 2862(s), 2759(s), 1454(s), 1159, 1147(b), 1072(s), 1040(s), 1021(s), 930, 897, and 819 cm^{-1} (18). The other four peaks were due to the dimeric compounds and the 150 and 134 min peaks were shown to correspond to compounds **10** and **11**.

In a separate experiment under the similar conditions, 2.5 g of the basic fraction was obtained. Analysis by vpc showed the monomer to dimers ratio was 1:10 and the four dimers had a ratio of 40:10; 28:15 in the order of the retention times.

In the Presence of 1,5-Cyclooctadiene

A solution of TMT (4 g), 1.5-cyclooctadiene (4 g), trifluoroacetic acid (25 g), and acetonitrile (100 ml) was prepared in a photovessel at 0°C and was photolysed for 2 hs. Half of the photolysate was worked up to give a basic fraction (1.64 g) but no acidic fraction. The basic fraction gave two vpc peaks at 6.8 and 14.3 min in the ratio of 1.9:1. The mixture (1.48 g) was chromatographed on neutral alumina (75 g); elution with a 1:1 mixture of petroleum ether and ether gave a colorless oil (565 mg) which was distilled to 5-dimethylaminocyclooctene (**12**); ir: 3020, 2828, 2779, 1688(w), 1458, and 727 cm^{-1}; ms: 153 (M^+, 25), 138(5), 136(5), 125(18), 124(18), 110(25), 84(66), 71(100); nmr τ: 4.48 (m, 2H), 7.92 (s, 6H), 7.8–8.1 (m, 11H), 8.15–9.05 (bm, 6H). *Anal.* calcd. for $C_{10}H_{19}N$: C 78.37, H 12.50, N 9.14; found: C 78.15, H 12.36, N 9.49.

The picrate was recrystallized from ethanol: mp 153–167°C (dec.). *Anal.* calcd. for $C_{16}H_{22}N_4O_7$: C 50.26, H 5.80, N 14.65; found: C 50.76, H 5.97, N 14.70.

Further elution gave a mixture (122 mg). Elution with ether gave a colorless oil (266 mg) which was distilled (20°C/0.05 Torr) to give 2-*exo*-dimethylamino-6-*exo*-dimethylaminomethyl-*cis*-bicyclo[3.3.0]octane (**13**); ir: 2818, 2770(s), 1458(s), and 1040(s) cm^{-1}; ms: 210 (M^+, 30), 195(2), 166(22), 165(15) 152(10), 150(6), 137(7), 136(6), 126(23), 124(18), 110(11), 84(49), 71(32), and 58(100); nmr τ 7.74(s), 7.78(s). *Anal.* calcd. for $C_{13}H_{26}N_2$: C 74.23, H 12.46, N 13.36; found: C 74.18, H 12.43, N 13.42.

The dipicrate was recrystallized from ethanol; mp 217–221°C (dec.). *Anal.* calcd. for $C_{25}H_{32}N_8O_{14}$: C 44.91, H 4.82, N 16.76; found: C 44.78, H 4.84, N 16.60.

The dimethiodide was recrystallized from ethanol; mp 155 190°C (dec.): ms: (70°C) 210(4), 142(59), 127(18), 84(17), and 58(100); nmr τ 6.40 (dt, J = 8.5, 6.5, and 6 Hz, 1H), 6.64 and 6.75 (the AB part of a ABX, J_{AB} = 13.5, J_{AX} = 8.9, J_{BX} = 3.9 Hz), 6.99 (s, 9H), 7.04 (s, 9H), 7.32 (bm, 7H), 7.75–8.25 (bm, 7H), 8.30–8.83 (m, 3H). Irradiation at τ 7.93 collapsed the signals at 6.64 and 6.75 to an AB quartet ($\Delta\delta$ = 19 Hz, J = 13.5 Hz). Irradiation at τ 7.32 collapsed the dt at τ 6.40 signal to a double doublet (J = 8.5 and 6 Hz) and at 8.05 the same signal to a double doublet (J = 6.5 and 6 Hz). *Anal.* calcd. for $C_{15}H_{32}N_2I_2$: C 36.45, H 6.53, N 5.67; found: C 36.48, H 6.64, N 5.58.

In the Presence of Cyclohexene

A solution of TMT (3 g), cyclohexene (16 g), concentrated hydrochloric acid (15 ml), and acetonitrile (200 ml) was photolysed as above under nitrogen. The photolysate was worked up as usual to give neutral (22 mg) and basic (2.52 g) fractions. The crude basic fraction was analysed by vpc peak matching method on a 10% Carbowax 20M column to give the peaks of the imine trimer **1** (1.1 min) as the major component and minor peaks of 3-dimethylaminocyclohexene (**3**, 2.2 min), dimethylaminocyclohexane (**4**, 6.1 min), *trans*-chloroamine **7** (8.0 min), and *cis*-chloroamine **7** (9.0 min) (*vide infra*).

The basic fraction (2.5 g) was chromatographed on a silica gel column. With ether as the eluent, it gave what appeared to be a *bis*-dimethylaminodicyclohexane (**2**, 10 mg); ir: 2930(s), 2860, 2780, 1450, 1261, 1185, 1042(s), 805 cm^{-1}; ms: 252.2541 (M^+, 8, calcd. for $C_{16}H_{32}N_2$: 252.2565), 237.2307 (12, calcd. for $C_{15}H_{29}N_2$: 237.2330), 207.1966 (22, calcd. for $C_{14}N_{25}N$; 207.1987), 192.1724 (12, calcd. for $C_{13}H_{22}N$: 192.1752), 167(20), 149(24), 140(24), 125.1201 (36, calcd. for $C_8H_{15}N$: 125.1206), 84(100), and 71(46).

Continued elution with ether gave unstable *trans*-2-chlorodimethylaminocyclohexane (**7**, 285 mg, 7.1%) which was distilled to a pale yellow oil; nmr τ: 6.11 (dt, J = 4 and 10 Hz, 1H), 7.67 (s, 6H), and 7.65 (m, 1H); ms: 163.1011 (calcd. for $C_8H_{16}NCl$: 163.0942), 161.0944 (calcd. for $C_8H_{16}NCl$: 161.0972), 126.1280 (calcd. for $C_8H_{16}N$: 126.1282).

Elution with 10% CH_2Cl_2 in ether gave the *cis*-chloroamine 7 (59 mg, 1.5%); nmr τ: 5.43 (m, $W_{\frac{1}{2}}$ = 7 Hz, 1H), 7.67 (s, 6H), 7.75 (m, 1H); the mass spectrum was very similar to that of the *trans* isomer. With 20% CH_2Cl_2 in ether the imine trimer **1** was obtained.

The column was washed with 1 *N* HCl in methanol and the basic material (725 mg) was recovered. This material was ana-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

lysed by vpc on a 20% Dowfax 9N9/10% TEP column by the peak matching method to give the following peaks: *trans*-diamine **6** (26 min, 2.4%), *trans*-**5** (28 min, 12%), and *cis*-**5** (33 min, 1%).

In the Presence of Dicyclopentadiene

A solution of TMT (3.48 g), *endo*-dicyclopentadiene (3.96 g, bp 38–39°C), and TFA (17.1 g) in methanol (170 ml) was photolysed through a Corex filter under nitrogen for 1 h. The photolysate was worked up to give neutral (217 mg, dicyclopentadiene) and basic fractions (5.18 g); the latter showed an nmr signal at τ 3.80 for a norbornene olefinic proton and τ 4.42 for a cyclopentene olefinic proton in a ratio of 1:14 and the major singlets at τ 7.75 and 7.85 for dimethylamino groups. The ratio of the olefinic and dimethylamino protons is 4:13 indicating no major cyclization products.

The vpc analysis of the basic fraction showed two major clusters of peaks at 8.2 min (**18**, two peaks, 35%) and 21.5 min (**19**, four peaks, 40%), and five sharp minor peaks at 7.7, 9.1, 11.7, 12.5, and 12.8 min. A portion of the basic fraction (1 g) treated with methanol gave a white solid (185 mg) which was recrystallized to give a dimer **19** as colorless needles; mp 181–183°C; ir: 3040, 2820(s), 2760(s), 1610(w), 1278, 1024(s), 942, 740, and 692(s) cm^{-1}; ^1H nmr τ 4.39 (m, 2H), 4.51 (m, 2H), 7.75 (s, 6H), 7.76 (s, 6H), and 8.32–8.36 (AB quartet with further splitting) and other multiplets; ^{13}C nmr 23 peaks; ms (%): at 110°C: 352.2883 (M^+, 50, calcd. for $C_{24}H_{36}N_2$: 352.2878), 337.2636 (70, calcd. for $C_{23}H_{33}N_2$: 337.2644), 308.2383 (15, calcd. for $C_{22}H_{30}N$: 308.2378), 189(30), 149(60), 110(45), 84.0813 (100, calcd. for $C_5H_{10}N$: 84.0813) and 58(85). *Anal.* calcd. for $C_{24}H_{36}N_2$: C 81.76, H 10.29, N 7.95; found: C 81.61, H 10.17, N 7.77.

The basic fraction (1.5 g) was chromatographed on neutral alumina using ether and petroleum ether as eluent. Elution with 30 ~ 40% ether in petroleum ether gave mixtures of monomeric and dimeric compounds. Elution with 45% ether in petroleum ether gave an oil (320 mg) which was distilled at 20°/0.5 Torr to give colorless oil of **18**; ir: 3045, 2950(s), 2860(s), 2820(s), 2770(s), 1610(w), 1050(s), 1040(s), and 700(s) cm^{-1}; nmr τ 4.42 (m, 2H), 6.95 (m, 1H), 7.85 (s, 6H), and other multiplets; ms (%) at 80°C: 177 (M^+, 46), 162(6), 148(5), 136(17), 122(19), 109(100), 84(60), 71(57), and 58(48). *Anal.* calcd. for $C_{12}H_{19}N$: C 81.30, H 10.80, N 7.90; found: C 81.47, H 10.81, N 7.98.

In the Presence of 5-Vinyl-2-norbornene

An acetonitrile (170 ml) solution containing TMT (4.64 g), *endo*-5-vinyl-2-norbornene (4.2 g), and TFA (28.5 g) was photolysed under nitrogen at 0°C until the 235 nm absorption disappeared. The photolysate was worked up in the usual manner to afford a neutral (275 mg) and basic fraction (3.9 g). The basic fraction exhibited nmr signals at τ 4.4 and 5.0 for the vinyl olefinic protons and a weak one at τ 4.0 for the norbornene olefinic protons.

The vpc of the basic fraction showed peaks at 4.5 min (two peaks, 7%), 8.3 min (three peaks, 1%), 10 min (three peaks, 13%), and a cluster of four peaks at 16.4, 17.0, 17.2, and 18.1 min (40%). The gc–ms analysis showed that the first fraction exhibited *m/e* (%) at 165 (M^+, 51), 150(20), 136(22), 110(42), 98(39), 84(52), 71(84), and 58(100) and the peaks of the last fraction showed strong *m/e* at 328 (M^+), 313, 284, 244, 110, 84, 71, and 58. The first fraction was isolated by preparative vpc to give a colorless oil; ir: 3070, 29.40(s), 2860(s), 2810(s), 2760(s), 1635(m), 1035, and 902(s) cm^{-1}; nmr τ 4.34 (m, 1H), 5.14 (m, 2HO, 7.93(s), 7.97(s), and other multiplets.

In the Presence of 1,6-Heptadiene

A solution of TMT (3.3 g, 0.0287 mol), 1,6-heptadiene (2.1 g, 0.0221 mol), and TFA (25 g) in acetonitrile (200 ml) was photolysed under nitrogen in the usual manner. The photolysate was worked up in the usual manner to give only a small amount of neutral and basic fractions. The basic aqueous solution was continuously extracted with ether to afford an oil (450 mg) which showed one major spot on tlc. The basic fraction was chromatographed on alumina using 1% methanol in methylene chloride to give 1-(2′-dimethylaminoethyl)-2-dimethylaminomethylcyclopentane (**20**) as a volatile oil (163 mg); ir: 2820(s), 2760(s), 1265(m), 1040(m), 1030(m), and 845(w) cm^{-1}; ^1H nmr τ 7.75(s), 7.78(s), and other multiplets; ^{13}C nmr (ppm from TMS): 59.8 (t, CH_2N), 58.7 (t, CH_2N), 45.5 (q, CH_3N), 45.2 (q, CH_3N), 39.6 (d, —CH—), 30.1(t), 28.8(t), 27.0(t), and 22.1(t); *m/e* (%): 198(4), 154(22), 153(19), 138(17), 110(19), 84(44), 71(22), 59(27), and 58(100). *Anal.* calcd. for $C_{12}H_{26}N_2$: C 72.66, H 13.12, N 14.12; found: C 72.84, H 13.17, N 14.17.

Synthesis of Authentic Samples

trans-*1,2-Bisdimethylaminocyclohexane (6)*

The procedure of Swift (36) was used to prepare *trans*-1,2-diaminocyclohexane and the methylation was carried out according to Winterwitz *et al.* (37). The crude product was purified by preparative vpc on a 20% Dowfax 9N9/10% TEP column to give **1** as an oil; ir: 2928(s), 2862(s), 2830(s), 2781(s), 1452, 1172, 1047, 1026; nmr τ: 7.71(s); ms: 170 (M^+, 100), 155(6), 125(27), 124(29), 110(25), 97(53), 84(100), 71(84) and 58(65). The picrate (ethanol) was yellow plates; mp 209–211°C (lit. mp (37) 204°C. *Anal.* calcd. for $C_{22}H_{28}N_8O_{14}$: C 42.04, H 4.49, N 17.83; found: C 42.16, H 4.47, N 17.97.

cis- *and* trans-*2-Dimethylaminomethyl-1-dimethylaminocyclohexane (5)*

The oxime of 2-dimethylaminomethylcyclohexanone was prepared according to the known method as white needles; mp 113–116°C (lit. (38) mp 110–120°C). This oxime was reduced with $LiAlH_4$ in ether and was methylated with a mixture of formic acid – formaldehyde to give a mixture of *cis*- and *trans*-**5**. The mixture was separated by preparative vpc on a 20% Dowfax – 10% TEP column in which the *trans* isomer had retention time of 41 min (59%) and the *cis* isomer 57 min (41%). The *trans* isomer had properties as follows: ir: 2925, 2855, 2818, 2763, 1451, 1036 cm^{-1}; ^1H nmr τ 7.81 (s, 6H), 7.87 (s, 6H), 7.58 (dt, J = 3 and 12 Hz, 1H), 7.9–9.2 (m, 9H); ^{13}C nmr in ppm: 17.3, 21.3, 21.7, 30.6 (for C(3), C(4), C(5), and C(6)), 37.9 (C(2)), 39.9 (N—CH_3), 46.0 (N—CH_3), 62.8 (CH_2—N), and 66.2 (C(1)); ms *m/e* (%): 184 (M^+, 27), 140(34), 139(66), 138(21), 126(14), 124(34), 111(36), 110(57), 84(59), 71(48), and 58(100). *Anal.* calcd. for $C_{11}H_{24}N_2$: C 71.68, H 13.12, N 15.20; found: C 71.34, H 13.22, N 15.35.

The dipicrate was recrystallized from ethanol; mp 176–179°C (dec.). *Anal.* calcd. for $C_{23}H_{30}N_8O_{14}$: C 42.99, H 4.71, N 17.44; found: C 42.80, H 4.71, N 17.34.

The *cis*-isomer was isolated as an oil; ir: 2930, 2860, 2818, 2764, 1465, 1452, 1035 cm^{-1}; the ms is identical to that of the *trans* isomer.

Thermal Decomposition of TMT in the Presence of Olefins Under Acidic Conditions

In the Presence of Cyclohexene

A solution of TMT (3 g), concentrated hydrochloric acid (15 ml), cyclohexene (16 g), and methanol (200 ml) kept at 4°C under nitrogen in the dark showed ca. ⅓ of TMT disappearance after 120 h. The remaining TMT decomposed completely at room temperature after 20 h. The solution was worked up in the usual manner to give no neutral fraction but a basic fraction by CH_2Cl_2 extraction (1.13 g) which was almost pure imine trimer **1**; nmr (in H_2SO_4) ppm from H_2SO_4: −7.57 (dt, J = 6 and 1.5 Hz, 3H), −3.38 (m, 1H), −3.15 (m, 1H), and −3.70 (bs, 1H); ir: 2945(s), 2780(s), 2638, 1675(w), 1470, 1445, 1388, 1263(s), 1236(s), 1160, 1115(s), 1004, 915(s), 860 cm^{-1}; ms: 43(62) and 42(100). The yield is quantitative.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

In a separate experiment, a solution of TMT (1 g) and cyclohexene (7.25 g) was added dropwise to trifluoroacetic acid (8 g) under continuous purging of carbon monoxide at room temperature with vigorous stirring. A purple color developed in the lower phase and vigorous evolution of nitrogen was observed. After 30 min, the lower phase turned to pale yellow and nitrogen evolution stopped. In another 90 min, the solution was worked up to give no neutral fraction. The basic fraction was obtained by continuous extraction and gave imine trimer **1** (180 mg, 47%) as the only product.

In the Presence of Norbornene

A solution of TMT (1 g) and norbornene (8.3 g) in acetonitrile (10 ml) was added dropwise to trifluoroacetic acid (8 g) in 2 min under nitrogen with stirring. After 5 h the solution was worked up to give a basic fraction (250 mg) which showed nmr singlets at τ 6.78 and 7.70 (in the 2:3 ratio for **1**) and weak signals at τ 6.15 and 8.0–9.1 regions. The yield of the imine trimer **1** was 30% as determined by vpc.

Nuclear Magnetic Resonance Studies of TMT Decomposition

TMT in H_2SO_4

TMT (0.5 ml) was added dropwise to a 25 ml flask containing H_2SO_4 (5 ml) cooled to -10°C with vigorous stirring. The solution turned to bright yellow and expelled gases. The solution was transferred to a precooled nmr tube and the spectra were recorded at -20°C in 15 min after mixing and at 20°C in 30 min. TMH (100 mg) was dissolved in H_2SO_4 (3 ml) as above and the nmr spectrum was recorded at 20°C. The signal at τ 6.40 for TMH–$2H^+$ persisted for 2 weeks at 20°C but was replaced by the signals at τ 1.93, 6.27 and 7.10 on warming in a water bath.

TMT in TFA

TMT (100 mg) was added to TFA (0.5 ml) at -10°C with stirring. The solution kept at -15°C showed singlets at τ 6.62, 6.82, and 6.92 in a ratio of 1:1:2. The signals showed no change at -15°C for 1 h but broadened at 10°C and coalesced to a singlet at τ 6.78 at 30°C. At 30°C, the singlet decayed with a half-life of ca. 20 min to give the new set of signals at 1.90 (m), 6.25 (m, 2H), and 7.10 (t, 3H).

A solution prepared from TMT (50 mg), CD_3CN (0.5 ml), and TFA (100 mg) at -10°C showed singlets at τ 6.58, 6.88, and 6.96 in a ratio of 1:2:1. Both this and the above solutions were irradiated through a Corex filter. The resulting solution exhibited signals at τ 6.25, 7.10, and 7.14 in addition to other unidentified signals.

Electron Spin Resonance Studies of TMT Decompositions

A solution of TMT in desired solvent was prepared by slow addition and stirring at 0°C or lower. The solution was transferred to an aqueous esr cell and purged with nitrogen for 2 min. The acetonitrile–TFA solution showed the esr spectrum at room temperature of $TMT^{\ddagger}$: a_N (2N) = 1.15, a_N(2N) = 10.85, a_H(6H) = 10.40, a_H(6H) = 11.60 G, and g = 2.0040 ± 0.0005 (lit. (6) a_N = 1.20, a_N = 10.96, a_H = 10.40, a_H = 11.52 G, and g = 2.0036). This solution was irradiated with an Osram 200 W lamp in the esr cavity at room temperature for 5 min. Five minutes after switching off the lamp a strong esr signal of $TMH^{\ddagger}$ was observed: a_N(2N) = 13.5, a_H(12H) = 12.7 G, and g = 2.0034 ± 0.0004) (lit. (39) a_N = 13.5, a_H = 12.7 G, and g = 2.0035). Although $TMT^{\ddagger}$ esr signal persisted for several hours, the $TMH^{\ddagger}$ signal decayed within 1 h at room temperature.

An acetonitrile solution containing TMT (0.17 *M*) and TFA (1.1 *M*) showed a strong $TMT^{\ddagger}$ signal at -45°C. Photolysis of the solution in the cavity caused no change in the esr signal. When the light was shut off, the $TMH^{\ddagger}$ signal started to build up reaching a maximum after 10 min. The $TMH^{\ddagger}$ signal remained unchanged for several hours at -45°C but decayed in 30 min at 30°C. To a solution showing $TMH^{\ddagger}$ and weak $TMT^{\ddagger}$ signals, a drop of cyclohexene was added at -45°C. On rescanning, the $TMH^{\ddagger}$ signal decreased rapidly leaving behind the $TMT^{\ddagger}$ signal. The $TMT^{\ddagger}$ signal persisted even when this solution was warmed to room temperature.

A solution of TMT in cyclohexene (0.5 *M*, 2 ml) was added to TFA in acetonitrile (1.3 *M*, 2 ml) at 20°C to give a binary phase system. The upper phase exhibited a $TMT^{\ddagger}$ signal which disappeared in 45 min to be replaced by a 17 band signal at g = 2.0024 ± 0.004. This signal is very similar to the simulated (EPRCAL) spectrum of the $(CH_3)_2\dot{N}CHNHCH_3$ using a_N = 8, a_N = 6, a_H(N—H) = 8, a_H(α-H) = 15.5, and $a_H(CH_3)$ = 4 G (28).

Decomposition of TMT in H_2SO_4 in the Presence of Toluene

Generally, a solution of TMT in toluene was added to a mixture of toluene and H_2SO_4 at a particular temperature ranging from -10 to 80°C. The reaction was terminated by the addition of ice and extracted with ether. The ether and toluene were removed by distillation at 110°C to provide the 'neutral' fraction. At this point the polymeric material which had separated was collected by scraping it off the sides of the flask. It was washed with 10% aqueous KOH followed by water and then ether. The washings were combined with the major aqueous portion. This was basified with aqueous KOH and extracted with ether. After the ether was removed, the residual oil was analyzed for products. A typical experiment is described below.

A solution of TMT (0.9 g) in toluene (4.1 ml) was added dropwise to a vigorously stirred mixture of toluene (4.0 ml) and concentrated sulfuric acid (2.5 ml) at -5°C; the addition speed was adjusted so that the temperature did not rise above 0°C. Gases were evolved and the mixture turned a deep purple color. The reaction was continued at -5°C for 20 h to give a dark brown mixture.

The neutral oil (142 mg) could not be separated by preparative vpc and exhibited *m/e* peaks at 182 (M^+, 92), 167(100), 165(38), 152(15), 141(4), 128(6), 104(36), 91(19), and 77(10) and ir peaks at 3028, 1604, 1516, 1031, 791(w), 769(w), 746, 729(s), 698(s), and 600 cm^{-1}. The nmr spectrum showed two sets of singlets at τ 6.05 and 7.79 for *o*-benzyltoluene **22** and at τ 6.10 and 7.71 for *p*-benzyltoluene in a ratio of 37:63. A weak singlet at τ 7.15 was tentatively assigned to bibenzyl (40).

The basic fraction (238 mg) was taken up in 5 ml of carbon tetrachloride containing 0.197 *M* chlorobenzene as the internal standard. The solution was analysed on a 10% Carbowax 20 *M* chromosorb W 100/200 column (10 ft × $\frac{1}{16}$ in. stainless steel column, N_2 gas at 30 psi, temperature programmed at 2°/min. from 100 to 200°C) to give the following retention times: 4.6, 6.0, 9.2, 10.2, 15.0, 18.6, 19.4, 20.2, 23.0, and 26.0 for **1**, chlorobenzene, **24**, *o*-**21**, **25**, **23**, *p*-**21**, *m*-**21**, **27**, and **26**, respectively. The percentage yields were calculated based on the technique described in the literature (2). The major peaks were identified by the peak matching with the authentic samples and were further supported by gc–ms patterns.

Decomposition of *N*-chlorodimethylamine in toluene–sulfuric acid mixture was carried out according to Bock and Kampa (30) to give neutral and basic fractions. The latter, in 35% yield, served as reference sample for analysis and was shown to contain *N,N*-dimethyltoluidine with a *o*:*m*:*p* ratio of 9:61:30 by the same analysis. The neutral fraction was shown to contain *o*- and *p*-benzyltoluene in an 8% yield.

TMT Decomposition in TFA in the Presence of Toluene

A solution of TMT (0.9 g) in toluene (4 ml) was added dropwise at a controlled temperature with rapid stirring to a solution of TFA (5.25 g) in toluene (4 ml). During the addition

gases were evolved and two phases were formed. The reaction was terminated by addition of ice and worked up as above. No purple color was observed, nor polymeric material obtained.

In one experiment, *o-N,N*-dimethyltoluidine (**21**) was isolated by preparative vpc as an oil; ir: 2940(s), 2870, 2835(s), 2780, 1600(s), 1494(s), 945(s), 805, 762(s), and 725(s) cm^{-1}.

A theoretical study of the energies of solution, association, and migration for univalent substitutional anion impurities in alkali metal chloride crystals

JOHN CORISH AND BRENDA M. C. PARKER
Department of Chemistry, University College, Dublin 4, Ireland
AND
PATRICK W. M. JACOBS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 31, 1977

JOHN CORISH, BRENDA M. C. PARKER, and PATRICK W. M. JACOBS. Can. J. Chem. **56**, 1668 (1978).

Theoretical calculations have been made of the energy change accompanying the substitution of a univalent anion, F^-, Br^-, or I^-, into crystals of the alkali metal chlorides LiCl, NaCl, KCl, and RbCl. Association energies for the formation of nearest neighbour (nn) or next nn complexes with a vacancy in the anion sub-lattice and the activation energies for the four basic kinds of single vacancy jumps have also been calculated. The results of these calculations are discussed with respect to ion size and polarization effects and their relation to the activation energy (E') for the diffusion of a univalent impurity in the host crystals. The availability of experimental values of E' for some systems permits an assessment of the contribution to E' from the temperature dependence of the correlation factor and from vacancy pair diffusion.

JOHN CORISH, BRENDA M. C. PARKER et PATRICK W. M. JACOBS. Can. J. Chem. **56**, 1668 (1978).

On a effectué des calculs théoriques sur les changements d'énergie qui accompagnent la substitution par un anion univalent F^-, Br^- ou I^-, dans des cristaux des chlorures de métaux alcalins LiCl, NaCl, KCl et RbCl. On a calculé les énergies d'association correspondant à la formation de complexes entre une lacune du sous-réseau des anions et ses premiers ou deuxièmes voisins; on a aussi calculé les énergies d'activation qui accompagnent les quatre types fondamentaux de sauts d'une monolacune. On discute de ces résultats en termes de la grosseur des ions et d'effets de polarisation et de leur relation avec l'énergie d'activation (E') pour la diffusion d'une impureté monovalente dans les cristaux hôtes. La disponibilité de valeurs expérimentales de E' pour quelques systèmes permet d'évaluer la contribution à E' à partir de la relation température-facteur de corrélation et de la diffusion de bilacunes.

Introduction

In a recent paper (1) Catlow, Diller, and Norgett (CDN) derived two alternative self-consistent sets of two-body potentials for the alkali halides with the rock salt structure. The availability of these new potentials makes it possible to perform new calculations on the properties of defects in these crystals. Results communicated hitherto include calculations on vacancy and interstitial defects in NaCl, KCl, and KBr (2), a systematic study of vacancy defects in the 16 alkali halides with the rock salt structure (3), calculations of the equilibrium location and energy of the univalent substitutional impurities Li^+ and F^- in several host crystals (19), and calculations on association and migration energies for seven cation and six anion univalent impurity-host systems (4). In these last calculations we employed the earlier Set I CDN potentials (1) and we also utilized the geometric mean approximation to evaluate the three unknown parameters A_{ij}, ρ_{ij}, C_{ij}, in the short-range Buckingham potential

$$[1] \qquad \phi_{ij} = A_{ij} \exp(-R_{ij}/\rho_{ij}) - C_{ij}/R_{ij}^6$$

for the impurity-host second neighbour interaction. In eq. [1], ϕ_{ij} is the potential energy due to the interaction of ions of types i and j, A_{ij} and ρ_{ij} are the repulsive and hardness parameters in the repulsive interaction, and C_{ij} is the van der Waals coefficient in the attractive dipole–dipole interaction; R_{ij} is the distance between ions i and j.

In this paper we investigate the 12 univalent anion impurity systems obtained by incorporating F^-, Br^-, I^- in the alkali metal chlorides LiCl, NaCl, KCl, RbCl. Two of these systems namely KCl:F^- and KCl:Br^- were investigated previously (19) but are included here for completeness and because we have now, whenever possible, used the CDN Set II (spline) potentials.

Calculations

The calculations were performed using the HADES computer program (5, 6). The ions in the crystal are divided into two sets. One set called

region I comprises the defect (that is the impurity plus, in some instances, a vacancy) together with the immediately surrounding ions. The relaxations of the ions in region I are calculated explicitly as the crystal adopts its configuration of minimum energy. Full advantage is taken of symmetry but nevertheless the size of region I is limited by the capacity of the available computers to handle the large numbers of variables required to specify the ion positions. Of the six defect energies evaluated four were calculated with 81 ions in region I; for the remaining two defects the maximum size of region I obtainable was 48 ions because of their lower symmetry. Consequently for one system, namely $LiCl:Br^-$, calculations were performed with a smaller region I as well as for the 81-ion region I to check for any variations due to the size of the explicitly relaxed region. The remainder of the crystal is treated as a dielectric continuum matched to region I at the boundary.

Both the Set I and Set II potentials (1) of CDN are based on the shell model with ion shell charges and spring constants chosen to reproduce the anion polarizabilities and the static and high-frequency permittivities and the frequencies of the transverse optic mode of the crystals. The second neighbour interaction in Set I was of the Buckingham form (eq. [1]) with repulsive parameter A_{ii} and hardness parameter ρ_{ii} determined from calculations based on the electron gas approximation (7). The total attractive component of the second neighbour potential was arbitrarily partitioned equally between anion and cation interactions ($C_{ii} = C_{jj}$). The nearest neighbour (nn) repulsive parameters were fitted to bulk properties. In order to reduce the number of potential constants to be fitted the repulsive parameters were assumed to have the form

$$[2] \qquad A_{ij} = b \exp [(a_i + a_j)/\rho_{ij}]$$

with $a_i + a_j = a$, the nn anion–cation distance, and b a constant for all the 16 halides. The van der Waals interaction between nearest neighbours was assumed to be completely quenched ($C_{ij} = 0, i \neq j$). Potential parameters b, a_i, a_j, ρ_{ij}, and C_{ii} were adjusted to fit the stability condition, cohesive energy, and elastic constants of all the 16 alkali halides. In this procedure a separate C_{ii} is required for each substance.

The potentials of Set II differ from Set I in having separate values of the second neighbour van der Waals coefficients C_{ii}, C_{jj} specific to each interaction. The second neighbour potential is of a more complex form, the repulsive wall and attractive tail being joined to the potential minimum by fifth-order and third-order polynomials respectively, at adjustable spline knots. Both sets give excellent representations of the equilibrium, elastic, and dielectric properties of the crystals.

For the calculations involving an impurity ion (k) the potential describing the nn (ik) interaction should clearly be taken to be the same as for the corresponding pure crystal (ik). However, new second neighbour (kj) potentials are needed. For the calculations based on Set II, the repulsive parameters A_{kj}, ρ_{kj} were calculated using the electron gas approximation, C_{kj} was obtained from the geometric mean $(C_{kk}C_{jj})^{1/2}$, and the spline knots were arithmetic means of the knots for the corresponding kk, jj interactions. The calculations are not in fact sensitive to the precise location of the spline knots.

There are some difficulties concerning calculations for LiCl. There is no splined potential for the Li–I interaction because of insufficient elastic data for LiI (1). It was therefore necessary to use Set I for $LiCl:I^-$. For $LiCl:Br^-$ calculations were also performed with Set I so that the sensitivity of the results to details of the potential could be evaluated.

Defect Energies

The energy change accompanying the process

$$[3] \qquad M^+X^- + X'^- = M^+X'^- + X^-$$

is given by

$$[4] \qquad \Delta u(X') = u(X') - u_c(MX') + u_c(MX)$$

where $u(X')$ is the defect energy calculated for a crystal containing a single X'^- ion at its normal substitutional position in the crystal and u_c denotes the cohesive energy. The energy change accompanying the formation of a complex, with the vacancy on the nn anion site, from an isolated X'^- ion and an anion vacancy $\boxminus$,

$$[5] \qquad X'^- + \boxminus = X'^-\boxminus$$

is

$$[6] \qquad \Delta u_{a1} = u_{a1} - u_-^{\infty} - u(X')$$

where u_{a1} is the energy of the crystal containing one complex and u_-^{∞} is the energy required to remove an anion X^- from a normal lattice site to a point well outside the crystal. Δu_{a2}, the energy to form a complex with the vacancy in the next nn site in the anion sub-lattice, is given by an analogous expression to [6]. Thus in addition to the energies of the various defect configurations u_c and u_-^{∞} had to be calculated in order to obtain $u(X')$ and Δu_{a1}. This information is given in Table 1. The symbols u_1, u_2, $u_{3,4}$ denote the saddle point energies for anion vacancies executing jumps of types w_1, w_2, w_3, or w_4 (Fig. 1); Δu_1, Δu_2, Δu_3, Δu_4 are the corresponding activation energies for these jumps. The defect energies $u(X')$,

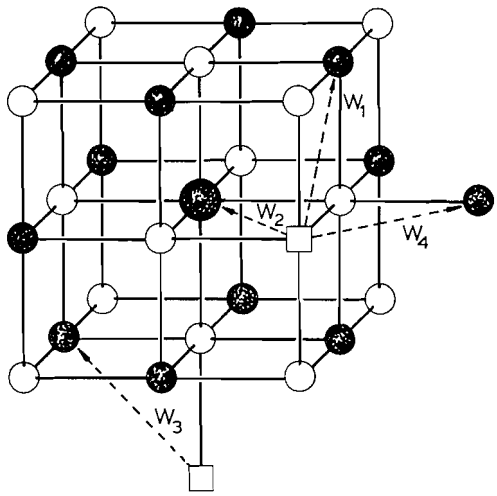

FIG. 1. Definition of the anion vacancy jumps w_1, w_2, w_3, w_4 associated with an anion impurity. The large filled circle denotes the impurity, smaller filled circles denote anions of the host crystal, open circles denote cations, and squares denote anion vacancies. The symbol w_n is used to denote both the type of jump and the corresponding jump frequency.

u_{a1}, u_{a2}, u_1, u_2, and $u_{3,4}$ are given in Table 2, and the substitutional energies, association energies, and activation energies appear in Table 3.

In calculating $u(X')$ the origin was fixed at the lattice site for which the impurity ion is the basis atom, but the impurity was allowed to move off this site to its most stable position. This motion was constrained by symmetry to ⟨110⟩ directions, since experimental work has shown that the F^- ion occupies an off-centre position along ⟨110⟩ in NaBr:F^-, KI:F^-, and RbI:F^- (8, 9). In every system investigated here, with the exception of LiCl:F^-, the impurity relaxed to the lattice site. The choices of origin for the calculation of u_{a1}, u_{a2}, u_1, u_2, $u_{3,4}$ are shown in Figs. 2*a–e*. All the calculations were performed with 81 ions in region I except those of u_1 and $u_{3,4}$ for which 48 ions were used. To test whether this would introduce any untoward effects, the defect energies for LiCl:Br^- were recalculated with a smaller region I. In each case this was chosen to be as close as possible to 48 ions provided that if one ion in a particular symmetry-related set was included, then so were all the ions in that set. The results of these test calculations are shown in Table 4. They show that although minor quantitative differences arise from the choice of a smaller region I, defect energies are little affected and reasonably satisfactory convergence with respect to the size of region I has been achieved. However, the substitutional, association, and activation energies involve taking differences of these defect energies and so uncertainties of a 2–3 hundreths of an eV in those energies that involve $u_{3,4}$ and u_1 can be expected. Table 4*b* compares the above energies calculated from the consistently smaller region I (~48 ions) with those values obtained previously using the 81-ion region I whenever possible. Even though only minor differences arise these could be important if the energy parameter is close to zero. For example Δu_{a1} is +0.011 eV for the small region I but −0.017 eV for the 81-ion region, implying that, although association energies are small for univalent impurity ions, the nn position for the vacancy is marginally favoured for Br^- in LiCl.

The effect of the choice of potential may be judged from Table 5 where we compare Set I and Set II results for LiCl:Br^- and KCl:Br^-. The results clearly show the same trends although some quantitative differences are apparent. For LiCl:Br^- the jump activation energies are lower by about 0.1 eV when calculated from Set I instead of from Set II. For KCl:Br^- the results are very comparable throughout except for the small association energy for the nn vacancy which was expected from ion size considerations. In general, Set II potentials are preferable because of the greater flexibility of the potential function and the specific van der Waals coefficient for each interaction.

Ion Displacements

The calculations for substitutional impurities were done by giving the impurity ion an initial ⟨110⟩ displacement. During the calculation the crystal adopts its minimum energy configuration and in every

system, except for LiCl:F^-, this resulted in the impurity ion going back onto the lattice site. The maximum displacement, that for RbCl:I^-, was 0.00026, 0.00026, 0. Such small displacements are considered insignificant. The locations of near neighbour ions up to the fourth neighbours (initially at 2,0,0) are given in Table 6 for the 11 systems which have full cubic symmetry. We notice the importance of ion-size effects. If the substitutional impurity is smaller than the host anion then the first, second, and fourth neighbours move in towards the impurity but if the impurity is larger than the host-crystal anion then these neighbouring ions are displaced outwards. The displacement of the third neighbours from their sites with coordinates $\pm 1, \pm 1, \pm 1$ are very small ($\leq 0.002a$). The displacements of the fourth neighbour ions are significant and are the most important after the nn ions, a fact which seems to be generally true and for which there is experimental evidence from Raman scattering measurements, for example.

In LiCl:F^- the F^- ion does not go on-centre; the displacement is constrained by symmetry to the ⟨110⟩ direction which is known to be the preferred direction for F^- impurity ions. The coordinates of the F^- impurity ion and its near neighbours, up to the fourth neighbours, are given in Table 7 for LiCl:F^-. The coordinates of the ions not given in the table can be worked out by using the fact that the final configuration has a ⟨110⟩ axis of symmetry. Since polarization effects must be important when small impurity ions adopt an off-centre configuration simple ion-size effects alone are unlikely to account for the calculated displacements. However, the fourth neighbours are again seen to undergo significant outward displacements when the adjacent nn ion suffers a large outward displacement (cf. the displacements at the 2,0,0 and 1,0,0 lattice sites).

Discussion

There have been no previous calculations of the energy parameters presented in this paper except the substitutional energies which can be extracted from Fancher and Barsch's (10) results of calculations of the energy of formation of several alkali halide solid

Δu_4	0.951	0.975

solutions as functions of composition. Our calculated values should be compared with the limiting slope at infinite dilution of $U(x)$ for X′ in MX, where $U(x)$ is the energy of mixing at mole fraction x, and this was done by estimating this slope as $U(x = 0.01)/0.01$. Fancher and Barsch used the model of Dick and Das (14, 15) which takes account of repulsive interactions for nn only and neglects van der Waals forces entirely. Despite the simpler potential employed by these authors the two sets of results parallel one another quite closely and the same conclusions may be drawn from either set. The first factor is ion size. I^- and Br^- are larger than Cl^- and so the replacement energies are positive with the I^- values being larger than the Br^- energies. Also for a given impurity ion the replacement energy decreases as the cation radius, and therefore deformability increases. The F^- results show that ion size is not the only consideration and the large replacement energies obtained for F^- point to the importance of ion polarization effects. $U(x)$ has been measured experimentally for only two of the systems examined here and these results, which are in reasonable agreement with both calculated values, are also given in Table 8. Again the quoted values are the limiting

partial molar energies for $x \to 0$, obtained from $U(x = 0.01)$.

There are no experimental data yet for association energies or for the activation energies for type w_1, w_2, w_3, or w_4 jumps. The major factor causing association between vacancies and aliovalent impurity ions is electrostatic interaction (16) but ion size also plays a part particularly in determining whether nn or next nn sites (in the same sub-lattice) are favoured. These calculations are for univalent impurities and therefore enable one to assess ion-size factors. Br^- and I^- impurity ions are larger than Cl^- and we should therefore expect the nn sites for the vacancy to be favoured. Table 3 shows that this is so; Δu_{a1} is negative in every case, and more so for I^- than Br^-. An anion vacancy in the next nn anion site, however, does not relieve the local strain and so this site is not favoured, $\Delta u_{a2} > 0$. On size arguments alone one should not expect $\Delta u_{a1} < 0$ for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

substitutional F^- ions. For RbCl it is slightly positive, for KCl it is approximately zero, for NaCl it is slightly negative, and for LiCl it is definitely positive. In all these cases the sign of Δu_{a2} is opposite to that of Δu_{a1}, that is, if the nn position is unstable the next nn position is stable. These more complicated results with F^- are due to polarization effects.

The calculated values (3) of the activation energy (Δu_0) for the motion of a single isolated vacancy in the four host crystals are 0.69 eV for LiCl, 0.72 eV for NaCl, 0.69 eV for KCl, and 0.63 eV for RbCl. We should expect Δu_2, the activation energy for the impurity–vacancy interchange, to be roughly the same as Δu_0 if the anion impurity is not very different in size to the host anion. This is certainly true for Br^- in NaCl, KCl, RbCl for which Δu_2 differs from Δu_0 by $\sim$0.01 eV. For the larger I^- ion larger repulsive interactions will be offset by a greater polarization contribution and it is not possible to predict in advance which will be the more important effect. The results for I^- in NaCl, KCl, RbCl show that Δu_2 is less than Δu_0 by 0.04 to 0.06 eV, so that polarization effects slightly outweigh the increased repulsive energy. For F^- the interchange energy Δu_2 is much less than Δu_0 and this is due not only to its smaller size but also to polarization effects.

The results presented here for the w_2, w_3, w_4 jumps are of some help in predicting activation energies for impurity diffusion by a single vacancy mechanism. The ratio of the impurity diffusion coefficient D' to the self-diffusion coefficient D for the pure crystal is (17)

$$[7] \qquad D'/D = w_2 f_i'/w_0 f_0$$

where w_0 is the jump frequency for the motion of a single vacancy in the pure crystal,

$$[8] \qquad f_i' = f_i w_3/w_4$$

and the correlation factor for the impurity is

$$[9] \qquad f_i = \frac{w_1 + Fw_4}{w_2 + w_1 - Fw_4}$$

with F a slowly varying function of w_3/w_0 in the range 1 to $\frac{7}{2}$. f_0 is the correlation factor for self-diffusion in the pure crystal. From eqs. [7]–[9] we have

$$[10] \quad -k[\mathrm{d}\ln(D'/D)/\mathrm{d}T^{-1}] = E_v' - E_v = \Delta u_2 - \Delta u_0 + \Delta u_3 - \Delta u_4 - k[\mathrm{d}\ln f_i/\mathrm{d}T^{-1}]$$

where E_v, E_v' are the activation energies for the diffusion of host ions and impurity ions, respectively, by single vacancy jumps. We have calculated the first four terms on the right side of [10] but an accurate prediction of $E_v' - E_v$ would require a knowledge of the dependence of the correlation factor f_i on temperature, and hence of the entropies of activation and effective vibrational frequencies as well as of the energies of activation. We may obtain a first approximation to E_v', called $\tilde{E}_v'$, by simply omitting the correlation term in [10] so that

$$[11] \qquad \tilde{E}_v' = \tfrac{1}{2}u_S + \Delta u_2 + \Delta u_3 - \Delta u_4$$

where u_S is the energy to form a Schottky defect. Values of $\tilde{E}_v'$ calculated from [11], using u_S values from ref. 3, are given in Table 9, together with the only currently available values (18) for E', the experimental activation energy for vacancy diffusion. Apart from the neglect of the correlation term in $\tilde{E}_v'$, experimentally measured diffusion coefficients include contributions from both vacancy pair diffusion and the diffusion of single vacancies. Thus a comparison of E' with $\tilde{E}_v'$ gives a measure of the contribution to E' of the combined effects of the temperature dependence of the correlation factor and that from the vacancy pair contribution to D'. Table 9 suggests that these two effects provide a net correction to $\tilde{E}_v'$ which is positive and of the order of a few tenths of an eV.

TABLE 9. Calculated values of the activation energy for diffusion by single vacancies of a univalent anion impurity ($\tilde{E}_v'$) in alkali metal chloride crystals, neglecting the temperature dependence of the correlation factor, compared with experimental values of the activation energy E' for impurity diffusion. All numerical values are in eV

Host crystal	$\tilde{E}_v'$ for: F^-	Br^-	I^-
LiCl	1.57	2.13	1.98

Received December 12, 1977

STEVEN J. RETTIG, JAMES TROTTER, W. KLIEGEL, and D. NANNINGA. Can. J. Chem. **56**, 1676 (1978).

Crystals of diphenylboron *N*-methylacethydroxamate are orthorhombic, $a = 12.5478(8)$, $b = 7.8735(3)$, $c = 13.6809(5)$ Å, $Z = 4$, space group *Pnam*. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.037$ and $R_w = 0.054$ for 1265 reflections with $I \geq 3\sigma(I)$. The molecule features a five-membered BO_2CN ring which lies in the crystallographic mirror plane. The carbon and nitrogen atoms of the heterocyclic ring are positionally disordered. Mean bond lengths (corrected for libration) are: O—B, 1.550(2), B—C, 1.609(2), O—C/N, 1.340(3), C—N, 1.300(2), C/N—CH, 1.470(2), and C—C(phenyl), 1.394(8) Å.

STEVEN J. RETTIG, JAMES TROTTER, W. KLIEGEL et D. NANNINGA. Can. J. Chem. **56**, 1676 (1978).

Les cristaux du *N*-méthylacéthydroxamate de diphénylbore sont orthorhombiques, $a = 12.5478(8)$, $b = 7.8735(3)$, $c = 13.6809(5)$ Å, $Z = 4$, groupe d'espace *Pnam*. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R = 0.037$ et $R_w = 0.054$ pour 1265 réflexions avec $I \geq 3\sigma(I)$. La molécule comporte un cycle BO_2CN à cinq chaînons qui se trouve dans un plan mirroir cristallographique. Les atomes de carbone et d'azote de l'hétérocycle sont disposés d'une façon désordonnée. Les longueurs moyennes des liaisons (corrigées pour la libration) sont: O—B, 1.550(2), B—C, 1.609(2), O—C/N, 1.340(3), C—N, 1.300(2), C/N—CH, 1.470(2) et C—C(phényle), 1.394(8) Å.

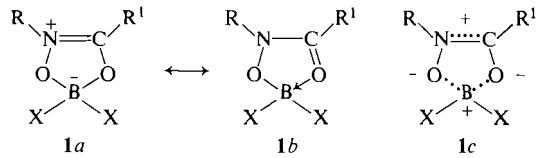
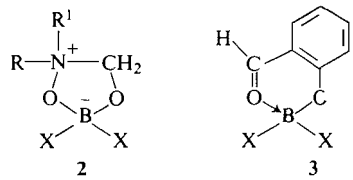
Introduction

The search for the best formal description of the boron chelates of *N*-substituted hydroxamic acids led us to the investigation of the difluoroboron derivative of *N*-methylacethydroxamic acid (**1**, R = R^1 = Me, X = F). An X-ray crystallographic analysis of this compound (1) gave evidence for a predominant contribution of the zwitterionic form **1***a* to the resonance structure of the compound. In addition to establishing the boron–nitrogen betaine formulation (**1***a*), a remarkable molecular symmetry was observed. In spite of the chemically different functions (C=O and N—O) in the ligand, the O—B distances in the difluoroboron chelate are equal within experimental error and a comparatively short amide C—N bond indicates **1***a* or **1***c*. In view of these findings it is of great interest to examine the molecular dimensions of an analogous chelate compound in which the extremely electron-deficient difluoroborenium ion (in **1***c*, X = F) is replaced by a less electrophilic diphenylborenium ion (X = Ph).

Other diphenylboron chelates with bidentate oxygen ligands having chemically different oxygen



1*a* **1***b* **1***c*



2 **3**

atoms, such as **2** (X = Ph) (2), which can be regarded as a formal reduction product of **1**, and the salicylaldehyde derivative **3** (X = Ph) (3), have significantly different O—B distances. In a B,N-betaine structure **1***a* or **1***c*, two nearly identical O—B bond lengths could also be expected in the case of X = Ph. The main structural difference between the difluoro and diphenyl derivatives should be in the intra-annular bond lengths to boron, expected to be longer for X = Ph.

Experimental

4,5-Dimethyl-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopent-4-ene[1]

N-Methylacethydroxamic acid (2 mmol) (4) and oxybisdiphenylborane (1 mmol) (diphenylborinic acid anhydride) were dissolved in 15 ml of absolute ethanol. Crystals began precipitating after a few minutes at room temperature. The mixture was heated to boiling to complete the reaction. After cooling, 0.44 g (1.74 mmol, 87%) of colorless crystals were isolated and were recrystallized from acetone–chloroform, mp 214°C. *Anal.* calcd. for $C_{15}H_{16}BNO_2$: C 71.18, H 6.37, N 5.53, B 4.27; found: C 71.16, H 6.44, N 5.42, B 4.27; ir (1/300 KBr): 1650 cm^{-1} (C=N/O); ^1H nmr (60 MHz, DMSO-d_6/TMS) δ (ppm): 2.37 (s, 3, C—CH_3), 3.57 (s, 3, N—CH_3), 7.1–7.8 (m, 10, Ph).

X-ray Crystallographic Analysis

The crystal chosen for study was mounted with *b* parallel to the goniostat axis and had dimensions of ca. 0.2 × 0.6 × 0.8 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by least squares on 2 sin θ/λ values for 27 reflections measured on a diffractometer with Cu K_α radiation (λ = 1.540562 and 1.544390 Å for α_1 and α_2). Crystal data (at 22°C) are:

$C_{15}H_{16}BNO_2$ fw = 253.11

Orthorhombic, a = 12.5478(8), b = 7.8735(3), c = 13.6809(5) Å, V = 1351.6(1) $Å^3$, ρ_m = 1.22 (flotation in aqueous KI), Z = 4, ρ_c = 1.244 g cm^{-3}, $F(000)$ = 536, μ(Cu K_α) = 6.6 cm^{-1}. Absent reflections: $0kl$, $k + l \neq 2n$, and $h0l$, $h \neq 2n$. Space group *Pnam* (non-standard setting of *Pnma*, D_{2h}^{16}, No. 62) from structure analysis.

Intensities were measured with nickel-filtered Cu K_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 4° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. Background counts of 10 s were measured at each end of the scan. Data were measured to 2θ = 160°. The intensities of the check reflections, measured every 50 reflections throughout the data collection, remained constant to within ±1.7%. After data reduction, an absorption correction was applied using the Gaussian integration method (5, 6). Transmission factors ranged from 0.722 to 0.905. Of the 1534 independent reflections measured, 1271 (83%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time-averaged background count.

The systematic absences allow space groups $Pna2_1$ or *Pnam*, the latter being indicated by the *E*-statistics. The structure was solved in the centrosymmetric space group by direct methods (7). The positions of the 13 non-hydrogen atoms were given by the 13 highest peaks on an *E*-map calculated from the best set of signs. Full-matrix least-squares refinement of the non-hydrogen atoms with isotropic, then with anisotropic thermal parameters, gave R = 0.088. A difference map revealed the positions of the phenyl hydrogen atoms and indicated a twofold disorder of both sets of methyl hydrogen atoms. In order to determine the location of the nitrogen atom in the heterocyclic ring, parallel refinements were carried out with the nitrogen atom in positions X(1) and X(2). Both refinements gave R = 0.066 with inconsistent anisotropic thermal parameters, indicating probable disordering. The positions X(1) and X(2) were then refined as 50% nitrogen and 50% carbon, giving an R value of 0.060 and reasonable thermal parameters. The occupancies of the disordered hydrogen atoms were set at 0.5 and were not refined.

The scattering factors of ref. 8 were used for non-hydrogen atoms and those of ref. 9 for hydrogen atoms. Anomalous scattering factors from ref. 10 were used for the non-hydrogen atoms. The weighting scheme, $w = 1.0$ if $|F_o| < 8.0$, $w = (8.0/|F_o|)^2$ if $|F_o| \geq 8.0$, and $w = 0.137$ for the unobserved planes, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. A correction for secondary extinction was approximated by basing the least-squares refinement on the minimization of $\Sigma w[|F_o| - |F_c/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was 8.3×10^{-8}. Convergence was reached at R = 0.037 and R_w = 0.054 for 1265 reflections with $I \geq 3\sigma(I)$ (6 reflections with $||F_o| - |F_c|| > 3\sigma(F)$ were treated as unobserved in the final stages of refinement; instrumental error was suspected, but it seemed unwise to bias the data by remeasurement; the discrepancies were not large). For all 1534 reflections R = 0.048 and R_w = 0.059.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.03 and 0.30σ respectively. The mean error in an observation of unit weight was 0.3406. A final difference map showed maximum fluctuations of ±0.25 e $Å^{-3}$. Final thermal parameters of the disordered hydrogen atoms indicate that for the C(2) methyl group occupancies of 0.5 are correct but for the C(3) group the unprimed positions

C(ar)—H,	0.98–1.00(2), mean 0.99(1) Å

appear to be favored by a factor of about 3:1 over the primed positions. The final positional and thermal parameters appear in Tables 1 and 2[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (11) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0008 Å^2. Analyses of the phenyl ring plus the boron atom and the seven atom group consisting of the non-hydrogen atoms lying in the mirror plane (rms ΔU_{ij} = 0.0015 and 0.0006 Å^2, respectively) gave physically reasonable rigid-body parameters. The appropriate bond distances have been corrected for libration (12) using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values. Bond angles are not significantly different from the uncorrected values listed in Table 4.

Results and Discussion

Figure 1 shows a general view of the molecule with the crystallographic numbering scheme and the disordered methyl hydrogen atoms. The packing arrangement viewed along *b* is shown in Fig. 2.

The crystal structure consists of discrete molecules of diphenylboron *N*-methylacethydroxamate. All intermolecular distances correspond to normal van der Waals interactions with the exception of a possible weak hydrogen bond involving a disordered methyl hydrogen atom (C(3)—H(3a')...O(2)[$x - \frac{1}{2}$, $\frac{3}{2} - y$, $\frac{1}{2} - z$]: C...O = 3.275(3), H...O = 2.42(11) Å, and ∠C—H...O = 154(8)°).

The **1***a* molecule with X = F was found to have an essentially planar BO_2CN ring and geometrical symmetry remarkably close to C_{2v} (2/*m*). The diphenyl derivative has crystallographic *m* symmetry, the five-membered ring lying on the mirror plane and therefore exactly planar. The geometrical C_{2v} symmetry of the molecule is again present as expected but in this case the C and N atoms are indistinguishable. The geometry of the *N*-methylacethydroxamate moiety is the same as that found in the difluoro derivative within the limits of experimental error. The symmetrical disposition of the two phenyl rings is unique among diphenylboron chelates (2, 3, 13–16).

[2]Copies of the structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

*Primed atom at $x, y, \frac{1}{2} - z$.

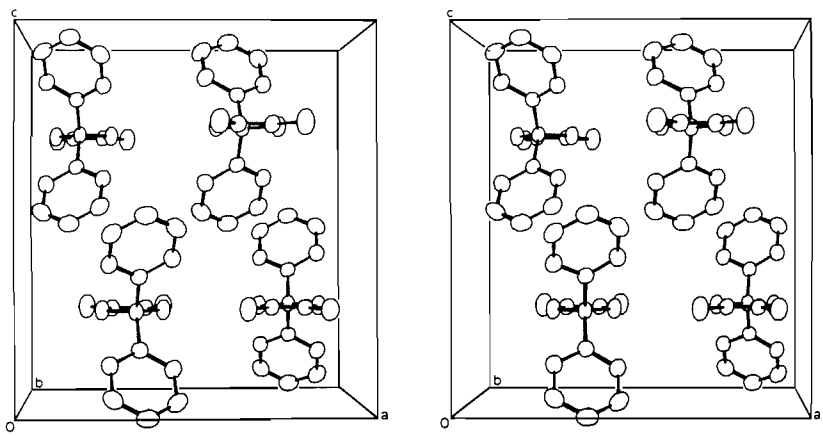

FIG. 2. Stereo view of the packing arrangement of diphenylboron *N*-methylacethydroxamate viewed along *b*.

The O—B distances (1.548(2) and 1.552(2) Å) are, as expected, significantly longer than those in the difluoro analogue (1.496(3) and 1.497(3) Å); they are close to the (N)O—B distance of 1.556(8) Å in **2** (2) but are considerably longer than the true O—B single bonds in the ethanolamine esters of diarylborinic acids (13–15) (mean[3] 1.477(5) Å) and the weakened single bonds in L-prolinatodiphenylboron (16) (1.529(3) Å), **3** (1.500(4) Å), and **2** (1.506(7) Å). The dative O—B bond in **3**, 1.574(4) Å, is significantly longer than the O—B bonds in the present structure. This evidence further supports the earlier contention (1) that the overall structure of **1** is best described as a 3:1 hybrid of resonance forms **1***a* and **1***b*.

The B—C distance of 1.609(2) Å lies near the short end of the range of B—C distances observed in diphenylboron chelates (2, 3, 13–16), 1.603(4) in **3** to 1.639(8) Å in **2** with a mean value of 1.617(8) Å. The mean C—C(phenyl) distance of 1.394(8) Å is normal, but individual bond lengths and angles in the ring differ significantly. This substituent-induced distortion of the phenyl ring is essentially identical to that found in related compounds (15, 16).

[3]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

Anesthesia and hydrogen bonding. A semi-quantitative infrared study at room temperature

GINETTE TRUDEAU, K. C. COLE, RACHEL MASSUDA, AND C. SANDORFY
Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received December 22, 1977

GINETTE TRUDEAU, K. C. COLE, RACHEL MASSUDA, and C. SANDORFY. Can. J. Chem. **56**, 1681 (1978).

It has been shown previously that certain anesthetics hinder the formation of hydrogen bonds of the O—H---O, N—H---N, N—H---O=C$\diagdown$ types. An attempt has now been made to correlate this hydrogen bond 'breaking' property with anesthetic potency. As a measure of the former, relative intensities of infrared bands related to 'free' and hydrogen bonded species were used. The band which was chosen for this purpose is the OH or NH stretching + in-plane bending combination band. This made it possible to carry out the measurements at room temperature. A semi-quantitative relationship has been found. Its significance for the theories of anesthesia is discussed.

GINETTE TRUDEAU, K. C. COLE, RACHEL MASSUDA et C. SANDORFY. Can. J. Chem. **56**, 1681 (1978).

Il a été démontré dans notre laboratoire que les anesthésiques halogénés entravent la formation des liaisons hydrogène de types O—H---O, N—H---N et N—H---O=C$\diagdown$. Nous avons effectué une étude par spectroscopie infrarouge afin de voir s'il existe une relation entre cette propriété et le pouvoir anesthésique de ces composés. A cette fin nous nous sommes servis des intensités relatives des bandes infrarouges libres et associées (par liaison hydrogène) de systèmes-modèle mesurées en présence et en absence d'anesthésiques. La bande qui nous a permis d'exécuter ce travail est une combinaison de la vibration de valence et de la vibration de déformation du groupement OH ou NH. Cette bande possède, en effet, un rapport libre–associé favorable à des mesures à la température ambiante. Une relation semi-quantitative a été trouvée. On discute son importance pour les théories de l'anesthésie.

Introduction

It has been observed in our laboratory that fluorocarbon type anesthetics containing higher halogens hinder the formation of hydrogen bonds (HB). The HB's were of the O—H---O, N—H---N, N—H---O=C$\diagdown$, or S—H---S types (1–5). When compounds like $CF_3CHClBr$ (halothane), CF_3-$CHCl_2$, or C_3F_7Br, for example, are added to solutions containing alcohols, phenols, amines, amides, thiols engaged in such HB's, the intensity ratio of the free and associated infrared X—H (X = O or N or S) stretching bands is modified in favor of the free (or less associated) species. This effect often takes spectacular proportions at low temperatures. Instead of the expected increase of the intensity of the associated band on lowering the temperature we observe its decrease and the accompanying reappearance of the free band. Therefore, in order to magnify the effect much (but not all) of our previous work was carried out at low temperatures (down to −190°C).

Subsequently we (6) were able to show that similar observations can be made on HB's involving water (for example, water bonded to an ether). Another series of infrared measurements (7) yielded the result that anesthetics like chloroform, halothane, methoxyflurane, enflurane, which contain an acidic hydrogen atom, can form HB's as proton donors whereby hindering the formation of N—H---N, O—H---O, and N—H---O=C$\diagdown$ HB's. Brown and Chaloner (8), Koehler *et al.* (9), and Davies *et al.* (10, 11) using different methods also arrived at the conclusion that HB formation by this acidic hydrogen might play a role in the mechanism of anesthesia.

The mechanism whereby anesthetics perturb or dissociate HB's might involve hydrophobic or polar interactions or the formation of another HB. As to the latter possibility, since available proton acceptor sites in the organism are quite certainly already engaged in HB's, it is clear that competitive HB cannot occur without perturbing or dissociating existing ones.

Present time theories of anesthesia are based on the 'unitary hypothesis' and the 'hydrophobic site theory' which state that the mechanism of action of all inhalation anesthetics is essentially the same and it implies only interactions at hydrophobic sites of the membrane (cf. refs. 12–15). The above-mentioned observations seem to indicate the need for a more

balanced theory of anesthesia taking into account, in addition to hydrophobic interactions, the possibility of polar ones including hydrogen bonding.

Most of our previous infrared spectroscopic studies were carried out at low temperatures. This had two drawbacks: the difficulty of making measurements quantitative due to problems inherent with the low temperature solution technique and the remoteness from in vivo conditions. In order to transpose our work to room temperature and to make it at least semi-quantitative we had to use an infrared band other than the X—H stretching fundamental (X = O, N, or S). To understand this we have to remark that at room temperature and at concentrations which have to be used the free band is often too weak and too highly overlapped by the associated band to be amenable to quantitative measurements. Fortunately, the free–associated ratio is different for overtones and combination tones. It generally favors the free band (16–19). The region of the first X—H overtone in the spectrum is usually complicated, however. No freestanding bands are found and, in some cases, we encounter the opposite difficulty: it is the associated band which is too weak (1). Thus we have to look for combination bands. Alcohols and phenols possess bands in the near infrared centered at about 5200–5300 cm^{-1} (or 1.92–1.88 μm) for which the free and associated bands overlap relatively little and the free–associated intensity ratio is moderate. This band is the combination of the O—H stretching and the O—H in-plane bending mode. Luck and Ditter (20) and Bonner and Choi (21) have applied these bands to hydrogen bond studies several years ago. Secondary amides have a band near 5000–4900 cm^{-1} (or 2.00–2.04 μm), also a combination of the N—H stretching mode and the N—H in-plane bending mode. These bands make it possible to carry out quantitative studies at room temperature. The assignment of the bands to the free and associated species respectively has been verified by varying the concentrations and comparison with the related NH or OH fundamentals.

Three model systems were chosen: water and dioxane (O—H---O<), self-associated *N*-methyl and *N*-ethylacetamide (the two gave practically the same results) (N—H---O=C<), and self-associated tertiary butanol. The intensities of the free and associated bands have been determined for a series of anesthetics: $CFCl_3$, CF_2BrCF_2Br, CH_2Cl_2, CF_3CHCl_2, $CHCl_3$, $CF_3CHClBr$ (halothane), and CH_3OCF_2-$CHCl_2$ (methoxyflurane). The concentrations of the solutions were the same in all cases.

The spectra were subjected to a curve analysis described in the Experimental section. Then correlations were sought between the band areas representing the intensities of the vibrational transitions and the anesthetic potencies.

Experimental

A. Purification of Samples and Solvents

Dioxane (from Anachemia) was refluxed on sodium wires for 4 h, then distilled under nitrogen atmosphere. It was kept on molecular sieves (4X) in a dry box and protected from light. We used deionized water obtained by passage through an ion-exchanger resin. *N*-Ethylacetamide (from Eastman Organic Chemicals) was dried on molecular sieves and distilled under vacuum. It was kept in a dry box and protected from light. *Tert*-butanol (Fisher Scientific, spectro grade) was dried on $MgSO_4$ and purified by fractional distillation. Methylcyclohexane (Matheson, Coleman and Bell) was passed through a silica gel column which had been dried at 350°C for 10 h, then dried over P_2O_5 and distilled under nitrogen atmosphere. Chloroform (Fisher Scientific, spectranalyzed) was washed several times with water, dried on $CaCl_2$, and distilled. It was stored in a dry box under nitrogen atmosphere and protected from light. Methylenechloride (Fisher Scientific, spectranalyzed) was dried on P_2O_5 and distilled. $CFCl_3$ (Freon 11), CF_3CHCl_2 (Freon 123), and CF_2BrCF_2Br (Freon 114-B-2), all from the E. I. DuPont de Nemours Company, were treated in the same way. Halothane, from Hoechst Pharmaceuticals of Canada, and methoxyflurane, from Abbott Laboratories of Canada, were used without further purification. The absence of any significant impurity was checked by gas chromatography. The samples were kept over molecular sieves in a refrigerator. The solutions were prepared in a dry box and the spectra recorded forthwith.

B. Preparation of Solutions

For the water–dioxane system first a 5 g/ℓ solution of water in dioxane was prepared (0.277 *M*). Then 0.05 mol of the (liquid) anesthetic was added to 5 ml of the water–dioxane solution and methylcyclohexane was added to the mixture to make the total volume of the solution 13 ml. For example, when $CFCl_3$ was the 'anesthetic', the solution contained 5 ml of the (5 g/ℓ) water–dioxane solution + 5.6 ml (0.05 mol) of $CFCl_3$ + 2.4 ml of methylcyclohexane. In this way the molar concentration of both water (0.107 *M*) and the anesthetic was the same for all anesthetics. In the case of *N*-ethylacetamide we first prepared a 0.594 *M* solution in carbon tetrachloride since the amide was not sufficiently soluble in methylcyclohexane. To 5 ml of this solution we added 0.04 mol of the anesthetic. Then we completed the volume with CCl_4 to 11 ml so that the amide had the same concentration in all solutions (0.270 *M*) as did the anesthetics. For *tert*-butanol we added 0.05 mol of the anesthetic to 5 ml of an initial solution of 2.98 *M* in CCl_4. Then CCl_4 was added to the solution to make the concentration of *tert*-butanol 1.24 *M* in every case. Carbon tetrachloride is, of course, not entirely 'inert' but this does not seriously affect the additional effects exerted by the other compounds.

C. Instrumental

The near-infrared spectra were measured with a Cary-17 spectrometer using silica cells. Both normal and differential spectroscopic methods were used. For the latter the reference cell contained the same amount of dioxane, anesthetic, and methylcyclohexane as the sample cell plus CCl_4 to compensate for water contained in the latter in the case of the water–dioxane system and similarly for the other systems.

D. Curve Analysis

The computer programs we used have been developed by Jones and co-workers (22–26). They consist of four parts.

CONVERT (Canadian NRC Program II)

This converts the experimental spectra obtained in units of absorbance vs. wavelength to units of transmittance vs. wavenumbers.

CURFIT (CNRC Program X)

This is the basic band fitting program. The experimental band envelope is approximated by Cauchy–Gauss product functions while the 'baseline constant' is also allowed to vary. The program varies and refines the (four) input parameters characteristic of the Cauchy–Gauss functions.

CURCOM (CNRC Program XIV)

With the parameters obtained from CURFIT this program calculates the composite curve and compares it with the experimental curve.

LWIDTH

A program written by one of us (K.C.C.) then computes the half-width, integrated intensity, and the Cauchy–Gauss ratio for each band obtained through the preceding programs.

The computations were carried out using the CYBER-173 (CDC) computer of the Université de Montréal.

A typical example of band decomposition is shown in Fig. 1. The numerical results are given in Table 1. In Figs. 3, 5, and 6, the band areas are given on a relative scale. This scale is different for the different systems since the actual concentrations of the free and associated species are not known and no molar extinction coefficients can be computed. Thus the numerical values should not be compared among different figures.

Results

A. The Water–Dioxane System

The maximum of the free ($\nu_2 + \nu_3$) band of water is at 5288 $\pm$ 6 cm^{-1} in the series of anesthetics which were studied. Two broader, associated bands are found centered at 5223 $\pm$ 9 and 5120 cm^{-1} (shoulder) respectively. Since dioxane is present in great excess the self-association of water can be disregarded as well as complexes which would be formed by one dioxane and more than one water molecule. Thus the most probable associated species are those in which one water molecule connects two dioxane molecules (>O---H—O—H---O<) or the one to one complex with one bonded and one 'free' OH group. The former probably correlates to the band at 5223 cm^{-1}. This is, however, not essential from the point of view of our problem. A qualitative picture of what occurs is given in Fig. 2. As we add to the water–dioxane system equal amounts of CF_2BrCF_2Br, CF_3CHCl_2, $CHCl_3$, or $CH_3OCF_2CHCl_2$, the free band's intensity obviously increases to the detriment of those of the associated bands. The computed band areas of the free band in the presence of different anesthetics appear in Table 1. We did not seek correlations with the associated bands in this case since we do not know the relative intrinsic intensities of the two bands and thus could not make a weighted sum of them.

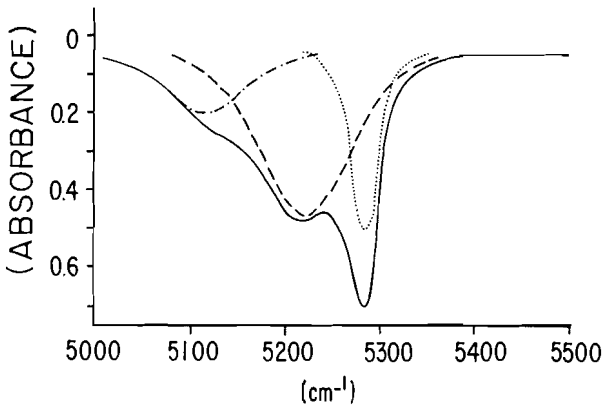

FIG. 1. Curve analysis (band fitting) of the OH stretching + OH in-plane bending region of the near infrared spectrum of the water–dioxane system (see Experimental section).

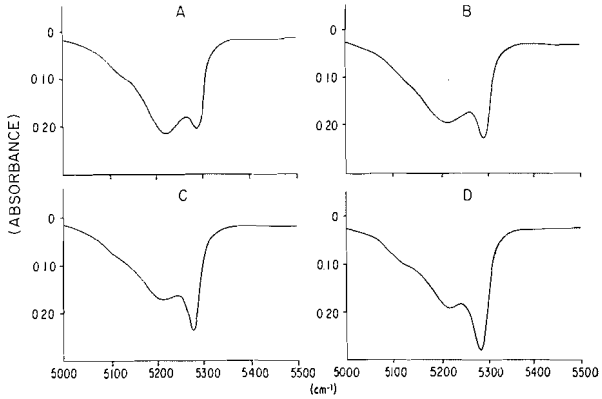

FIG. 2. Changes in the relative intensities of the free and associated ($\nu_2 + \nu_3$) combination band in the water–dioxane system for solutions containing equimolar amounts of one of the following anesthetics: *A*, CF_2BrCF_2Br; *B*, CF_3CHCl_2; *C*, $CHCl_3$; *D*, $CH_3OCF_2CHCl_2$.

In Table 1 and Fig. 3 the band area under the free band is compared to the anesthetic potency represented by log $1/p$ where p is the effective anesthetic pressure in atmospheres (ATA) required to suppress the righting reflex of mice in half of the experimental animals. The p values are those used by Miller and Smith (12), Hansch *et al.* (27), and Di Paolo *et al.* (28) in their critical investigation of the Meyer–Overton relationship. As can be seen a reasonably good correlation is obtained except that CH_2Cl_2 lies off the line by an amount which seems to exceed experimental error. For CF_2BrCF_2Br we found no p value in the literature but a MAC[1] value was given by Suckling (29). From this MAC value we estimated a p value lying between 0.9 and 1.3. The location of this point

[1]Minimum alveolar concentration needed to cause anesthesia.

TABLE 1. Computed relative band areas for the OH or NH stretching + in-plane bending combination. The band areas are on different relative scales for each system and should only be compared within a given column

Anesthetic	Log 1/*p*	Band area water–dioxane free OH	Band area self-associated *N*-ethylacetamide free NH	Band area self-associated *N*-ethylacetamide associated NH	Band area self-associated *tert*-butanol free OH
C_7H_{14}	~0	3.01	37.78	46.68	3.50
$CFCl_3$	0.82	3.88	37.89	45.42	6.11
CF_2BrCF_2Br	0.90–1.30 (estimated)	3.73	—	—	7.30
CH_2Cl_2	1.52	5.35	39.19	42.15	13.10
CF_3CHCl_2	1.57	4.80	40.90	—	—
$CHCl_3$	2.08	5.27	41.73	33.60	14.41
$CF_3CHClBr$	2.11	5.40	42.95	30.75	14.30
$CH_3OCF_2CHCl_2$	2.66	6.49	44.70	29.20	14.81

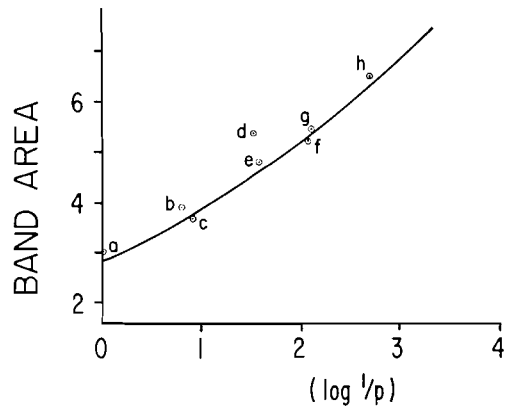

FIG. 3. The relationship between the logarithm of the inverse of the effective anesthetic pressure and the computed relative band area of the free ($\nu_2 + \nu_3$) band of the water–dioxane system in the presence of different anesthetics: *a*, C_7H_{14}; *b*, $CFCl_3$; *c*, CF_2BrCF_2Br; *d*, CH_2Cl_2; *e*, CF_3CHCl_2; *f*, $CHCl_3$; *g*, $CF_3CHClBr$; *h*, $CH_3OCF_2CHCl_2$.

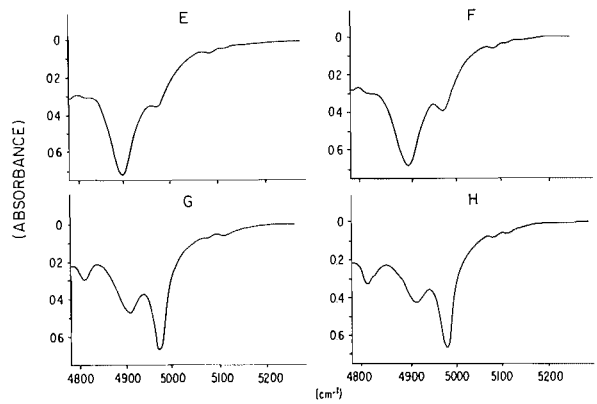

FIG. 4. Changes in the relative intensities of the free and associated NH stretching + NH in-plane bending combination band of self-associated *N*-ethylacetamide. The solutions contained equimolar amounts of one of the following anesthetics: *E*, C_7H_{14}; *F*, $CFCl_3$; *G*, CH_2Cl_2; *H*, $CHCl_3$.

is uncertain but it is clearly located near the point related to $CFCl_3$ and much lower than those related to anesthetics containing an acidic hydrogen.

The case of CH_2Cl_2 presents a special problem which is discussed to some extent below.

B. Self-associated N-*Ethylacetamide*

The free band we used has its maximum at 4978 ± 5 cm^{-1} and the associated band at 4905 ± 10 cm^{-1} in all cases. On the basis of the previous work by Fillaux and DeLozé (30) we can consider these as the NH stretching + NH in-plane bending combinations. *N*-Ethylacetamide might have *cis* and *trans* forms but we cannot distinguish separate bands due to these. They must be contained in the fairly broad bands which we observed.

Figure 4 shows the qualitative aspect; again we see that when anesthetics are added to the amide solution the free band increases and the associated band decreases in intensity in a way parallelling anesthetic potency. Figure 5 and Table 1 give the relation between the integrated intensities of the free band and log 1/*p* as defined above. This time we obtain a smooth relationship which is about equally good for all the anesthetics we used. With the associated band we obtain a relationship which is roughly the inverse of what was found with the free band (Fig. 6).

Similar correlations were obtained when we used absorbances instead of the band areas. This is in keeping with the fact that, in this case, the band widths do not vary widely.

C. Self-associated tert-*Butanol*

Only the free band could be used for reasons similar to those which we encountered in the case of the water–dioxane system. It is located at 4938 ± 5 cm^{-1} (see Asselin and Sandorfy (31)). The results are similar to those for the two other systems and are included in Table 1. $CFCl_3$ and CF_2BrCF_2Br clearly behave differently from the others. CH_2Cl_2 seems to be less irregular in this case.

Discussion and Conclusions

The following observations can be made.

(*1*) In all three systems we have studied, the most potent anesthetics are also the most efficient hydrogen bond breakers. These are chloroform, halothane, and methoxyflurane, the latter being the most potent everywhere. The general trend is that halogenated anesthetics containing no acidic hydrogen are less potent and those which contain one are more potent.

(*2*) While this applies to all three of our model systems there are significant differences among the correlations obtained. This shows that the pattern of associations of the different anesthetics with the O—H---O<, O—H---O—H---, and N—H---O=C< systems is to some extent different.

(*3*) A few detailed comments are needed on those anesthetics which do not contain the acidic hydrogen. $CFCl_3$ which we considered as an inert solvent in some of our previous work does have a moderate anesthetic potency. As to its HB breaking ability, in the case of the amide system, it seems to be just slightly greater than that of methylcyclohexane. We have found no data on the anesthetic potency of the latter but it is likely to be somewhat less than that of $CFCl_3$. The same applies to the *tert*-butanol system. In the case of the water–dioxane system, $CFCl_3$ is found to be a more efficient HB breaker. On the whole these are all weak effects, however.

CF_2BrCF_2Br seems to be a somewhat stronger HB breaker for the amide and *tert*-butanol but weaker for the water–dioxane system. As has been shown earlier (1–5) this molecule can be made a powerful HB breaker at low temperatures. Possibly $CFCl_3$ acts mainly by its permanent dipole moment (0.45 D) while CF_2BrCF_2Br through its higher polarisability.

CH_2Cl_2 is a rather intriguing case. While it falls in line for the amide and for *tert*-butanol it is anomalous for water–dioxane. It breaks many more HB's than would be expected from its known log $1/p$ value. According to Oi and Coetzee (32) and Green (33), this molecule can form HB's as a proton donor. Curiously, however, this does not seem to affect its C—H stretching frequencies. It does affect the C—Cl stretching modes. Clearly, this is a complicated case and requires a detailed study. We are examining the problem through low temperature measurements in order to magnify the effect of association. The results will be reported later.

Chloroform, halothane, CF_3CHCl_2, and methoxyflurane behave similarly for all three systems. There is no doubt about the importance of the acidic hydrogen. There are, however, other associative sites in these molecules. These are the chlorine atoms in all of them, the bromine in halothane, and the ether linkage in methoxyflurane. They probably help, to a variable extent.

The correlations we have obtained are far from being perfect. They could not be expected to be so. It is clear, however, that there is a definite parallelism between hydrogen bond breaking power and anesthetic potency. This has been indicated already in our previous, low temperature work. It has now been obtained through a room temperature study, closer to biological conditions and in a semi-quantitative fashion. Observations *1* and *2* lend weight to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

supposition that the perturbation of hydrogen bonds plays a role in the mechanism of inhalation anesthesia and that this perturbation varies in strength and nature according to the HB system which is perturbed. What we observe under in vivo conditions is probably an integral of many such effects. It is believed that these perturbations are additional to other hydrophobic and polar interactions. On the molecular level, the mechanism of anesthesia is likely to be pluralistic involving a number of different interactions.

Acknowledgments

We are indebted to Dr. R. N. Jones for letting us have the benefit of his programs and his experience on infrared curve analysis. Our thanks are due to Dr. R. Denis and Dr. D. D. Denson for supplying us with samples and for stimulating conversations and correspondence and to Mr. Paul Sauvageau for helping us with the experimental aspects of our work. Financial support from the National Research Council of Canada and le Ministère de l'Education du Québec is gratefully acknowledged.

Synthesis of triquinacene and some of its derivatives

PIERRE DESLONGCHAMPS, UKKEN OUSEPH CHERIYAN, YVON LAMBERT, JEAN-CLAUDE MERCIER, LUC RUEST, ROBERT RUSSO, AND PIERRE SOUCY

Laboratoire de synthèse organique, Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received December 13, 1977

PIERRE DESLONGCHAMPS, UKKEN OUSEPH CHERIYAN, YVON LAMBERT, JEAN-CLAUDE MERCIER, LUC RUEST, ROBERT RUSSO, and PIERRE SOUCY. Can. J. Chem. **56**, 1687 (1978).

Several routes for the synthesis of triquinacene (**1**) and 2,3-dihydrotriquinacen-2-one (**3**) are described using Thiele's acid as starting material.

PIERRE DESLONGCHAMPS, UKKEN OUSEPH CHERIYAN, YVON LAMBERT, JEAN-CLAUDE MERCIER, LUC RUEST, ROBERT RUSSO et PIERRE SOUCY. Can. J. Chem. **56**, 1687 (1978).

Les synthèses du triquinacène (**1**) et du dihydro-2,3-triquinacénone-2 (**3**) sont décrites à partir de l'acide de Thiele en utilisant plusieurs voies différentes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Tricyclo[5.2.1.$0^{4,10}$]decatriene-2,5,8 (**1**) usually called triquinacene (Scheme 1) was first synthesized by Woodward and his collaborators (1). Since then, several syntheses of triquinacene and some derivatives thereof have appeared in the literature (2–11). Some of these compounds can be considered potential starting materials for the synthesis of dodecahedrane (**2**) (12–16) which is the equivalent of dimeric triquinacene (**1**).

We have reported in preliminary communications (7, 8) syntheses of triquinacene (**1**) and 2,3-dihydrotriquinacen-2-one (**3**). We wish now to report these syntheses in detail as well as the preparation of several other related derivatives.

Strategy

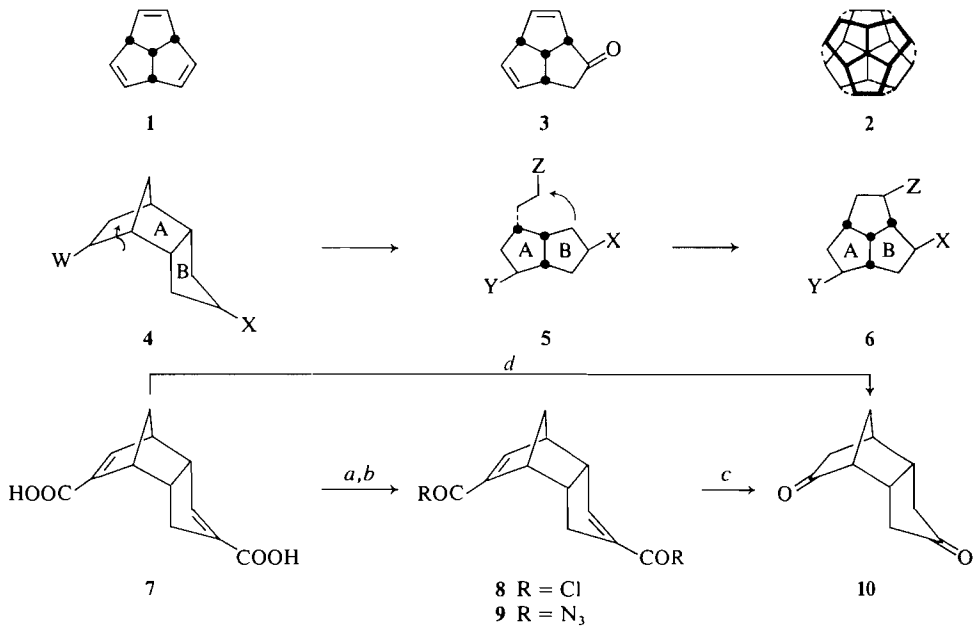
In our preliminary planning, it appeared to us that a good synthetic strategy would be to use a tetrahydrodicyclopentadiene derivative containing two functional groups such as **4** and to convert it into triquinacene via the intermediates **5** and **6**.

Our plan was therefore based on the recognition that (*a*) the tetrahydrodicyclopentadiene skeleton is a tricyclic isomer of hexahydrotriquinacene with which it has two identical five-membered rings (rings A and B); (*b*) the desired starting material **4** should be easily available because dicyclopentadiene chemistry is well known; (*c*) the specific carbon–carbon cleavage on **4** where the functional group W is converted into two new functional groups Y and Z in intermediate **5** should be possible; (*d*) the bicyclic intermediate **5** contains three functional groups, two of which (X and Z) can be used to make a new carbon–carbon bond to generate the hexahydrotriquinacene skeleton **6** having three functional groups conveniently disposed in specific positions, so that triquinacene can be obtained by further appropriate transformations, (*e*) the intermediate **5** also possesses the correct configuration at three asymmetric carbons, so that the right configuration for the four asymmetric carbons of the skeleton of **6** is assured; (*f*) the three external tertiary hydrogen atoms of the skeleton of **6** should behave like bridgehead hydrogens. In such a case, the regiospecific transformation of X, Y, and Z into the desired disubstituted double bonds which are present in triquinacene should be easy.

It is also interesting to point out that the functional groups in intermediate **5** are in such a position that they cannot alter the configuration of the three asymmetric carbons of the skeleton by epimerization. There was also almost no possibility that two of these three functional groups could interact together to generate either new unwanted functional groups or undesired skeleton fragmentations. Such possibilities existed in intermediates of type **6** only. The functional groups X and Z are in a 1,3 relationship in **6** and they could prefer to always react together so that they could not easily be converted into two of the three isolated double bonds of triquinacene. We felt however that this difficulty could be overcome by appropriate protection of one of the functional groups if the tertiary hydrogen between these two functional groups would not behave like a bridgehead hydrogen as previously suggested.

Starting Material

The tricyclic diketone **10** (Scheme 1) was chosen as our first key intermediate since we were convinced that the two carbonyl groups could be easily differentiated. The readily available Thiele's acid (**7**) (17), the structure of which is well established (ref. 18 and references cited therein), was selected as our starting material. The tricyclic diketone **10** was first obtained (7) from **7** in three steps via the diacid chloride **8** (19) and the diazide **9**. We subsequently succeeded in a direct conversion of Thiele's acid (**7**) into the diketone **10** in 35–40% yield using sodium azide in a mixture of sulfuric and trifluoroacetic acid (8). This one-step



SCHEME 1. (*a*) Oxalyl chloride, CH_2Cl_2; (*b*) NaN_3; (*c*) heat, DME, H_2O; (*d*) NaN_3, CF_3COOH, H_2SO_4.

procedure was preferred because of its simplicity of operation.

The Baeyer–Villiger Route

In our first route to triquinacene derivatives which is described in Scheme 2, we have selected the Baeyer–Villiger reaction to effectuate the desired cleavage **4** → **5**. The diketone **10** was first converted into the monoketal **11**. 3,3-Dimethylpropane-1,3-diol was chosen because the monoketal **11** is highly crystalline and is therefore easily obtained pure by crystallization. Treatment of the monoketal **11** with *m*-chloroperbenzoic acid gave a high yield of a mixture of the lactones **12** (73%) and **13** (27%). The desired lactone **12** was obtained pure by specific basic hydrolysis of the other lactone **13**.[1] The ketal lactone **12** was characterized further by its transformation into the bicyclic methyl ester benzoate **14**.

The conversion of the ketal lactone **12** into the ketal aldehyde acetate **18**, which has the appropriate functional groups to build the hexahydrotriquinacene skeleton (**5** → **6**), was carried out in four steps. The ketal lactone **12** was reduced to the diol **15** which was converted into the diacetate **16**. Basic hydrolysis under mild conditions gave the acetate alcohol **17** as the major product which was oxidized to the ketal aldehyde acetate **18**. Treatment of **18** under acidic conditions gave directly an ≃1:1 mixture of the aldol condensation products, the *cis* and the *trans* tricyclic ketone alcohol acetates **19** and **20** which were separated by chromatography. Oxidation of **19** and **20** gave the same β-diketone acetate **21**. This result shows that **19** and **20** are epimeric alcohols having the same skeleton. The assignment of the *cis* and the *trans* configuration to **19** and **20**, respectively, will be confirmed below. The epimeric alcohols **19** and **20** were further characterized by acetylation which gave the *cis* and *trans* ketone diacetates **22** and **23**, respectively.

The *trans* tricyclic ketone alcohol acetate **20** was then transformed into the ketal alcohol acetate **24** which was hydrolysed under basic conditions to give the ketal diol **25**. The ketal diol **25** was converted into the ketal dimesylate **26** which on treatment with potassium *tert*-butoxide gave a mixture of ketal dienes **27** (10%) and **28** (90%). Mild acid hydrolysis of the mixture of **27** and **28** gave a mixture of dienones **29** (10%) and **3** (90%) which were separated by vapor phase chromatography. The dienone **29** was found to be extremely unstable and it was characterized by its infrared spectrum only. The dienone **3** (2,3-dihydrotriquinacen-2-one) had the expected spectroscopic properties and was characterized by the preparation of a crystalline dinitrophenyl hydrazone derivative. The dienone **3** was shown to be identical with an authentic sample of 2,3-dihydrotriquinacen-2-one which was prepared by the oxidation of 2-*exo*-2,3-dihydrotriquinacenol (**30**) (16).[2]

[1]For a discussion concerning the large difference in the rates of the basic hydrolysis of this type of lactone, see page 2476 of ref. 20.

[2]We are grateful to Professor R. B. Woodward for his generous gift of 2-*exo*-2,3-dihydrotriquinacenol (**30**).

The preceding results show that we had developed a valuable approach for the synthesis of triquinacene derivatives. It involved however many operations (13 steps, **7** → **10** → **11** → **12** → **15** → **16** → **17** → **18** → **20** → **24** → **25** → **26** → **28** → **3**) and a mixture of **19** and **20** which could not be easily separated. The next task was to develop a shorter route within that scheme.

Reduction of the ketal lactone **12** with diisobutyl aluminium hydride (Scheme 3) gave directly the ketal aldehyde alcohol **31** in excellent yield. Molecular distillation of **31** gave the crystalline tricyclic ketal

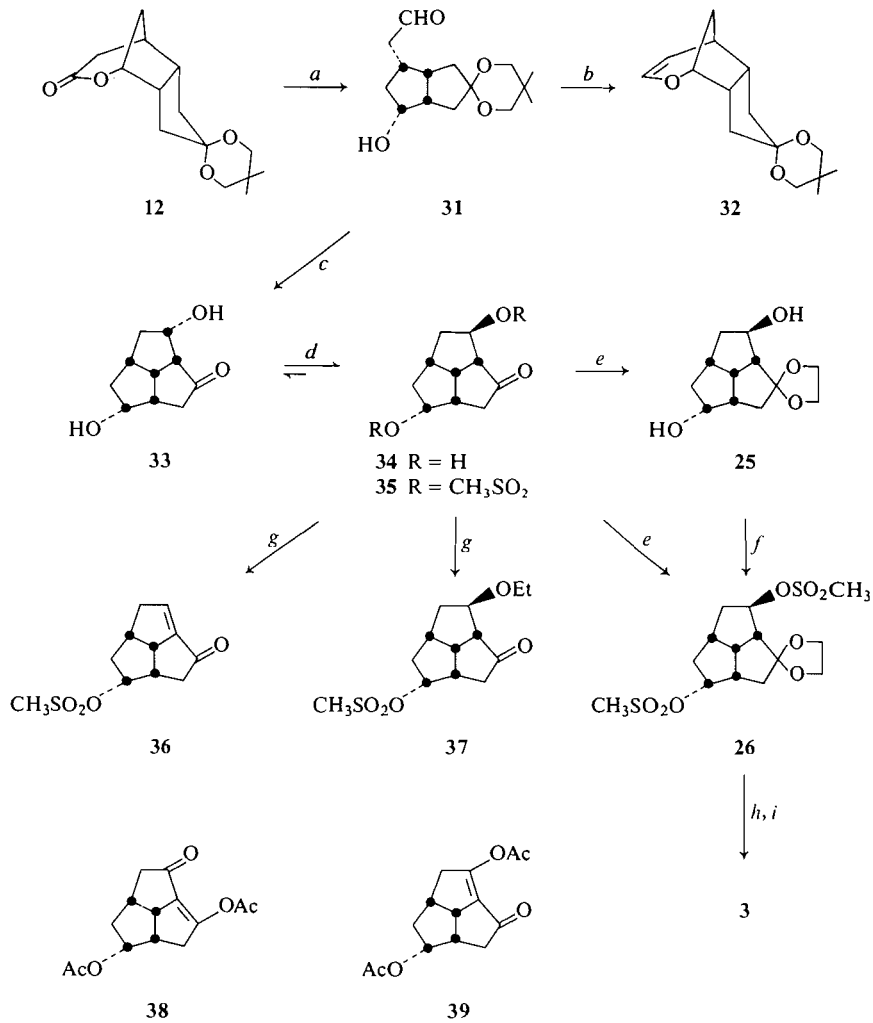

SCHEME 3. (*a*) Diisobutyl aluminium hydride; (*b*) heat; (*c*) HCl 2*N*, acetone; (*d*) EtONa, EtOH; (*e*) ethylene glycol, benzene, *p*-toluenesulfonic acid; (*f*) CH_3SO_2Cl, pyridine, CH_2Cl_2; (*g*) NaOH, EtOH, CH_2Cl_2; (*h*) *t*BuOK, DMSO; (*i*) HCl 2*N*, THF.

enol ether **32** and, upon acetylation, **31** gave the ketal aldehyde acetate **18** which we have previously obtained by a longer procedure described in Scheme 2. Treatment of the ketal aldehyde alcohol **31** under acidic conditions gave an $\simeq 1:1$ mixture (thin-layer chromatography) of the epimeric aldol products, the *cis* and the *trans* ketone diols **33** and **34** which were not separated. Upon treatment with a catalytic amount of sodium ethoxide in ethanol, equilibration occurred to give mainly one product, which was isolated directly by crystallization in $\simeq 63\%$ yield. We have assigned the *trans* diol structure **34** to this product. This assignment is based on the fact that structure **34** has one secondary hydroxyl group in the *exo* configuration. It must therefore be more stable than the *cis* diol structure **33** which has that same hydroxyl group oriented in the less sterically favored *endo* orientation. This can be clearly seen on examination of a molecular model.

Acetylation of the *trans* ketone diol **34** gave the *trans* ketone diacetate **23** which we have described in Scheme 2. The assignment of configuration for the *trans* tricyclic ketone alcohol acetate **20** is thus established. Since, compounds **19** and **20** have been shown to be epimers by their respective transformation into the β-diketone acetate **21**, the configuration of the *cis* tricyclic ketone alcohol acetate **19** is also established.

Ketalization of *trans* ketone diacetate **22** with ethylene glycol followed by basic hydrolysis gave the *trans* ketal diol **25**. We have already described the conversion of compound **25** into the *trans* ketal dimesylate **26**. The same *trans* ketal dimesylate **26** can also be obtained by a simple two-step procedure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

from the *trans* ketone diol **34**. The *trans* ketone diol **34** upon mesylation gave the ketone dimesylate **35** which could also be converted under carefully controlled conditions into the same *trans* ketal dimesylate **26** in an excellent yield. Since compound **26** gives 2,3-dihydrotriquinacenone (**3**) in two steps, this new route represents a nine-step synthesis of compound **3** (**7** → **10** → **11** → **12** → **31** → **34** → **35** → **26** → **28** → **3**).

It is interesting to note that the ketone dimesylate **35** is a stable compound which can even be transformed into the *trans* ketal dimesylate **26**. This result suggests that the tertiary hydrogen in α-position to the carbonyl group behaves like a bridgehead hydrogen or at least is not easily removed under mild basic (during the mesylation reaction) or acidic (during the ketalization reaction) conditions.

We have found however that in the presence of sodium hydroxide, this tertiary hydrogen α to the carbonyl group can be removed. When the *trans* ketone dimesylate **35** was treated with slightly less than 1 equiv. of sodium hydroxide in ethanol at 0°C, it gave the crystalline conjugated enone mesylate **36** which was well characterized. When the same reaction was carried out at room temperature with an excess of sodium hydroxide, a new compound was isolated to which we have assigned the structure **37** with an ethoxy group in the *exo* position.

These results show that the tertiary hydrogen is not in a completely bridgehead position but the high reactivity of enone mesylate **36** suggests that the trisubstituted double bond must be strained. The preparation of compound **36** and the comparison of its infrared spectrum with that of compound **29** confirmed the structure assignment previously made for **29**.

The infrared spectrum of the β-diketone acetate **21** shows that this compound exists in the β-diketone form only (21). However, on treatment with acetic anhydride and pyridine, compound **21** gave, in high yield, a crystalline ketone enol diacetate which can have structure **38** or **39**. Although, we have not established the exact structure for that compound, it is interesting to note that only one of the two possible enol acetates was observed. This result shows also that it is possible to have triquinacene derivatives with a double bond at one of the bridgehead positions.

The above nine-step sequence represents a convenient method for the preparation of 2,3-dihydrotriquinacen-2-one (**3**). It is still however a lengthy procedure because there are some steps which can be considered unnecessary. In principle, these extra steps are the following: (*a*) the diketone **10** needs to be protected in the form of the ketal ketone **11** before the Baeyer–Villiger reaction; (*b*) the ketal lactone **12** obtained from the Baeyer–Villiger reaction needs a readjustment of its functionality to the ketal aldehyde **31** so that the aldol condensation can take place; (*c*) the carbonyl group in the *trans* ketone diol **34** needs to be protected in the form of a ketal group (→**26**) before the elimination reaction can proceed; (*d*) the alcohol groups need to be activated as mesylates to facilitate the formation of the double bonds; and (*e*) the ketal group must then be removed. Clearly, an ideal synthesis should avoid all these steps! In the following approaches, we have tried to eliminate a good majority of these 'unnecessary' steps.

The Photochemical Route

In our second approach to triquinacene and its derivatives, we have chosen the well-known photochemical fragmentation of ketones (22) to effectuate the cleavage **4** → **5**. Upon ultraviolet irradiation, the ketal ketone **11** (Scheme 4) is transformed into the bicyclic ketal olefin aldehyde **40** in good yield. Upon acidic treatment, compound **40** gave mainly the aldol condensation product, the tricyclic *exo* ketone alcohol **41**. Acetylation of this crude product gave after chromatography the pure *exo* ketone acetate **42** in 75% yield. The *exo* ketone acetate **42** was shown to be identical with an authentic sample obtained from the acid hydrolysis of the *exo* ketal acetate **47** (*vide infra*).

This method represents a four-step synthesis (**7** → **10** → **11**, **40** → **41**) of the triquinacene derivative **41** in which only one step (**10** → **11**) can be considered extra. We have therefore tried to eliminate this unnecessary step and we have found that it is indeed possible to photolyse the diketone **10** directly to give the ketone aldehyde **43** in good yield. The successful specific cleavage of the diketone **10** is presumably due to the fact that the norbornanone carbonyl group is more strained.

The ketone aldehyde **43** was then treated under acidic conditions to effectuate the aldol condensation reaction. This crude product was acetylated and it was shown by vapor phase chromatography to contain ≃80% of the *exo* ketone acetate **42**, ≃15% of the *endo* ketone acetate **51**, and ≃5% of an unidentified product. The *endo* ketone acetate **51** was shown to be identical with an authentic sample obtained from the acid hydrolysis of the *endo* ketal acetate **48** (*vide infra*).

Treatment of the crude aldol condensation product with sodium ethoxide in ethanol followed by acetylation gave a mixture of *exo* ketone acetate **42** (94.5%), *endo* ketone acetate **51** (1.5%), and an unidentified product (4%). Equilibration of **41** and **50** had thus occurred since the crude product obtained from this

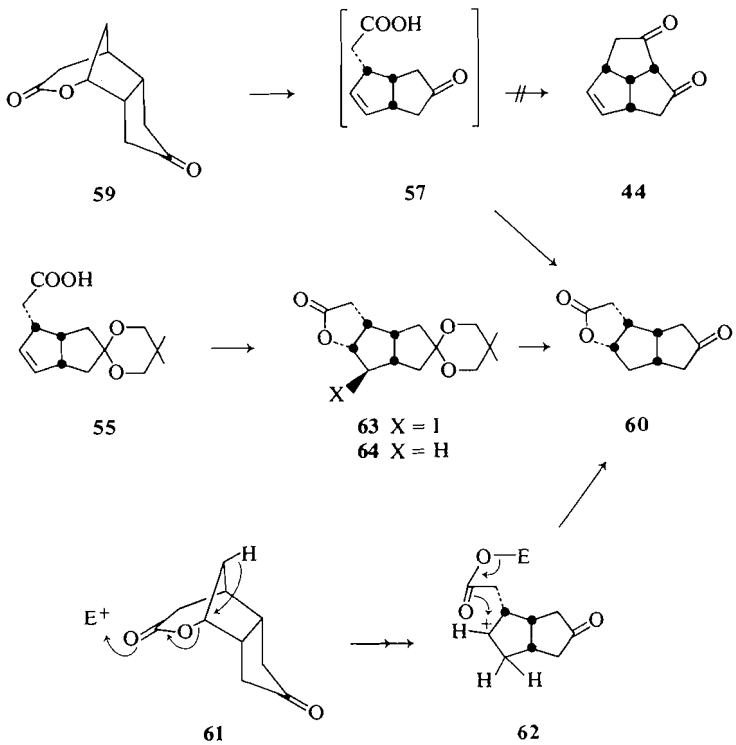


SCHEME 5

basic treatment contains mainly the *exo* ketone alcohol **41**. This crude product was used directly without further purification.

The assignment of the *exo* and *endo* configuration for the hydroxyl group in **41** and **50** comes from the basic equilibration studies. This assignment was also confirmed by the following experiments. The unpurified *exo* ketone alcohol **41** was oxidized to give the highly crystalline β-diketone **44**. Selective ketalization of **44** to give the crystalline ketal ketone **45** was achieved with 3,3-dimethylpropane-1,3-diol. Reduction of the ketal ketone **45** with lithium tri-*tert*-butoxyaluminium hydride gave the *endo* ketal alcohol **46**. The *endo* configuration was assigned because the alcohol product must be the result of an attack by hydride ion on the least hindered *exo* face of the ketal ketone **45**. This conclusion was further confirmed by a chemical reduction of **45**. Treatment of **45** with sodium in ethanol gave a mixture of the epimeric ketal alcohols **46** (13%) and **47** (87%). The *exo* ketal alcohol **47** was obtained pure by crystallization. The *endo* and the *exo* ketal alcohols **46** and **47** were transformed into their corresponding ketal acetates, **48** and **49**, respectively. The ketal acetates **48** and **49** were then hydrolysed under acid conditions to give, respectively, the *endo* and the *exo* tricyclic ketone acetates **51** and **42**. The *exo* configuration of the tricyclic alcohol **41** is thus established.

The *endo* tricyclic ketal alcohol **46** was converted into the *endo* mesylate **52** which on treatment with potassium *tert*-butoxide followed by acid hydrolysis gave the 2,3-dihydrotriquinacen-2-one (**3**) in nine steps (**7** → **10** → **43** → **41** → **44** → **45** → **46** → **52** ⇉ **3**) from Thiele's acid.

A shorter synthesis of **3** was devised by using the *exo* ketone alcohol **41**. Compound **41** was converted into the ketal **47** which, after mesylation (→**53**) followed by dehydromesylation and acid hydrolysis, gave 2,3-dihydrotriquinacen-2-one (**3**) in seven steps (**7** → **10** → **43** → **41** → **47** → **53** ⇉ **3**) from Thiele's acid. This is the shortest and most convenient method for the preparation of the dienone **3**.

The tricyclic β-diketone **44** could also be prepared by an internal acylation reaction. The ketal aldehyde **40** was oxidized to the ketal carboxylic acid **55** which was analysed as its corresponding methyl ester **56**. Acid hydrolysis of the ketal methyl ester **56** gave the ketone methyl ester **58** which was converted into the ketone carboxylic acid **57** by hydrolysis under basic conditions. Upon heating in benzene in the presence of *p*-toluenesulfonic acid, compound **57** gave a good yield of the β-diketone **44**. Upon treatment with acetic anhydride and pyridine, the β-diketone **44** was converted into the ketone enol acetate **54**.

The very facile acylation reaction (**57** → **44**) suggests that there is a possibility to transform directly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the ketone lactone **59** (Scheme 5) into the β-diketone **44** by using anhydrous acidic conditions. Under such conditions, it is reasonable to envisage that the lactone **59** would dehydrate to give the olefin ketone carboxylic acid **57** or its equivalent as an intermediate which would then give the β-diketone **44**. The ketone lactone **59** was obtained by acid hydrolysis of the ketal lactone **12**. On treatment with polyphosphoric acid, the ketone lactone **59** did not yield the anticipated β-diketone **44**; instead, the γ-lactone **60** was produced in good yield. This result suggests that, in strong acidic conditions, the lactonization is faster than the acylation reaction or that **59** gives **60** via a process which is expressed in formulas **61** and **62**.

The structure of the γ-lactone **60** was proven chemically: iodolactonization of ketal carboxylic acid **55** gave the ketal iodolactone **63** which was hydrogenolysed to the ketal γ-lactone **64**. Acid hydrolysis of the ketal γ-lactone **64** gave a γ-lactone which was found identical with the tricyclic γ-lactone ketone **60** obtained from the polyphosphoric acid treatment of **59**.

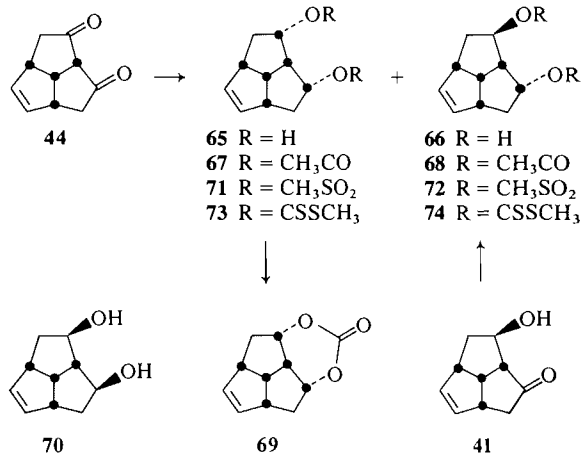
Synthesis of Triquinacene

The tricyclic *exo* ketone alcohol **41** and the highly crystalline β-diketone **44** (Scheme 6), which can be obtained in three and four steps, respectively, from Thiele's acid, appeared as ideal intermediates for a convenient synthesis of triquinacene (**1**).

Reduction of the β-diketone **44** with lithium aluminium hydride gave a 5:1 mixture of the *cis* and the *trans* diols **65** and **66** which were separated by chromatography. Both diols were converted into their corresponding diacetates **67** and **68**.

We have assigned the *endo-cis* structure **65** for the major diol because (*a*) the simplicity of nmr spectra of **65** and its diacetate **67** shows that these products must have a plane of symmetry; (*b*) the major diol can be converted into a cyclic carbonate derivative **69** by reaction with phosgene. Examination of molecular models show clearly that the *cis-endo* diol structure **65** can easily form a cyclic carbonate whereas the *cis-exo* diol structure **70** cannot. In structure **70**, the direction in space of the two *exo* alcohol groups is such that they cannot form a cyclic six-membered ring carbonate. This assignment was further strengthened by the fact that on reduction with a bulkier hydride such as lithium tri-*tert*-butoxy aluminium hydride, the β-diketone **44** gave almost exclusively the diol assigned as structure **65**.

The assignment of the *trans* (*endo-exo*) configuration to the minor diol follows from the examination of the nmr spectra of **66** and its diacetate **68** which indicates a complete lack of symmetry in these compounds. This assignment is further confirmed by the



SCHEME 6

fact that the reduction of the *exo* ketone alcohol **41** with lithium tri-*tert*-butoxy aluminium hydride gave almost exclusively the diol **66**.

The *cis* and the *trans* diols **65** and **66** can be transformed into their respective *cis* and *trans* dimesylates **71** and **72** and into their respective *cis* and *trans* dixanthates **73** and **74**. Triquinacene can be prepared in approximately 50% yield from each of these four intermediates. No attempt was made to improve this yield or to develop an alternative higher yielding procedure. Both dimesylates **71** and **72** on treatment with basic alumina (23) give triquinacene **1**. Similarly, pyrolysis of the *cis* and the *trans* dixanthates **73** and **74** give also triquinacene (**1**). A synthesis of triquinacene can therefore be realized in six steps (**7** → **10** → **43** → **41** → **66** → **72** (or **74**) → **1**) or in seven steps (**7** → **10** → **43** → **41** → **44** → **65** → **71** (or **73**) → **1**). The six-step sequence via the *trans* dimesylate **72** appears to be the method of choice.

Experimental

The ir spectra were taken on a Perkin-Elmer 257 spectrophotometer. The ultraviolet (uv) spectra were registered on a Varian Techtron 635 spectrophotometer. Vapor phase chromatographic (vpc) analysis were carried out on a Varian aerograph instrument model 90-P. Proton nmr spectra were recorded on a Varian A-60 instrument. Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard. The mass spectra were taken on a Hitachi-Perkin-Elmer RMU-6 mass spectrometer by Mr. J. R. Martin, Université de Sherbrooke. Microanalyses were carried out by Mr. J. Tamas, Laboratoire de Microanalyse, Université de Sherbrooke, and by Dr. C. Daesslé, Organic Microanalyses, Montreal. Thiele's acid (**1**) was prepared by the method described in reference 24. Anhydrous magnesium sulfate was used as the drying agent in working up reactions. Low boiling petroleum ether (bp 30–60°C) was used.

Diacid Chloride **8**

Oxalyl chloride (63.5 g, 42.6 ml, 0.5 mol) was added with stirring to a suspension of powdered Thiele's acid **7** (50 g, 0.23 mol) in anhydrous methylene chloride (800 ml) under an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

atmosphere of nitrogen. After the addition was complete, the stirring was continued at room temperature for 5 days. The unreacted acid was then filtered off and the filtrate was evaporated to dryness under vacuum. The brown oil obtained was triturated with petroleum ether (10 × 125 ml) and the solution was cooled to yield white crystals (40 g, 73%); mp 61–62°C (lit. (19) mp 62°C); ir (CH_2Cl_2): 1750, 1617, and 1587 cm^{-1}; nmr ($CDCl_3$) δ: 6.93 (1H, quadruplet, J = 2 Hz) and 7.18 (1H, quadruplet, J = 1 and 2 Hz) (two olefinic hydrogens).

*Diazide **9** (2)*

A solution of the diacid chloride **8** (32.3 g, 0.126 mol) in acetone (100 ml) was added dropwise with stirring to a solution of sodium azide (17.9 g, 0.275 mol) in water (100 ml) at 0°C. After the addition was complete the reaction mixture was stirred for 10 min at 0°C. The white precipitate of the diazide obtained was collected by filtration. Owing to the explosive nature of the product, it was immediately converted into the diketone **10** without further purification. An analytical sample was prepared from an aliquot by recrystallization from petroleum ether (white crystals); mp 75–77°C; ir (CH_2Cl_2): 2150, 1683, 1674, 1618, and 1586 cm^{-1}; nmr ($CDCl_3$) δ: 6.60 (1H, quadruplet, J = 2 and 4 Hz) and 6.93 (1H, doublet, J = 3 Hz) (two olefinic hydrogens); ms *m/e*: 149, 107, 79, and 52. *Anal.* calcd. for $C_{12}H_{10}O_2N_6$: C 53.31, H 3.73; found: C 53.95, H 3.86.

*Diketone **10***

*(a) From Diazide **9***

The moist diazide obtained as above was heated in a mixture of dimethoxyethane (170 ml) and water (60 ml) with stirring at 80°C for 2 h under an atmosphere of nitrogen. The reaction mixture was then cooled to 10°C and treated with dilute hydrochloric acid (3 *N*, 50 ml) and stirring continued at room temperature for 1 h. It was then continuously extracted with ether (1 ℓ) for 20 h. Evaporation of the ether extract yielded a white syrup (16 g, 77%). An analytical sample of the diketone **10** was prepared by the hydrolysis of the monoketal **11** as follows. The monoketal **11** (84 mg, 0.34 mmol) was stirred in a mixture of tetrahydrofuran (2 ml) and hydrochloric acid (1 *N*, 1 ml) for 5 h at room temperature. Dichloromethane (50 ml) was then added to the reaction mixture, the organic layer was separated, washed with saturated sodium bicarbonate and sodium chloride solution, and dried. The white syrup (56 mg, 100%) obtained on distilling off the solvent was sublimed under vacuum (80°C/0.1 Torr); mp 113–115°C; ir (CH_2Cl_2): 1750 cm^{-1}; nmr ($CDCl_3$) δ: 6.80–8.50 (12 H, multiplets); ms *m/e*: 164 (M^+). *Anal.* calcd. for $C_{10}H_{12}O_2$: C 73.14, H 7.37; found: C 73.02, H 7.24.

(b) From Thiele's Acid

Thiele's acid (50 g, 0.225 mol) was dissolved in a mixture of sulfuric acid (concentrated, 250 ml) and trifluoroacetic acid (150 ml). Sodium azide (30.5 g, 0.47 mol) was then added in small portions. After the addition was completed, the mixture was heated at 45–50°C (oil bath temperature) for 5 h. After cooling to 0°C, water (1.5 ℓ) was slowly added and the mixture was extracted with dichloromethane (continuous extraction for 4 days). The organic extract was washed with saturated bicarbonate solution, dried with sodium sulfate, and evaporated to dryness. The crude diketone was then purified by column chromatography on Florisil using successively pentane, benzene, and ether. The diketone **10** (≃13.0 g, ≃35%) was obtained in the ether solution as a waxy product which can be used directly for the next operation.

*Monoketal **11***

The crude diketone **10** (23.4 g, 0.142 mol) was dissolved in anhydrous benzene (600 ml) and mixed with 2,2-dimethyl-1,3-propanediol (15.6 g, 0.15 mol) and *p*-toluenesulfonic acid (50 mg). The mixture was refluxed for 20 h using a Dean–Stark water separator. The resulting brown solution was washed successively with saturated sodium carbonate and sodium chloride solution, dried, and concentrated under vacuum to yield a pale yellow solid. The above solid was recrystallized from benzene–ether to give white crystals (24.5 g, 69%); mp 125–126°C; ir ($CHCl_3$): 1740, 1360, 1350, and 1110 cm^{-1}; nmr ($CDCl_3$) δ: 0.87 (3H, singlet, CH_3), 0.98 (3H, singlet, CH_3), 7.00–9.00 (12 H, multiplet), 3.42 (2H, singlet, CH_2O), and 3.48 (2H, singlet, CH_2O); ms *m/e*: 250 (M^+). *Anal.* calcd. for $C_{15}H_{12}O_3$: C 71.97, H 8.86; found: C 71.99, H 9.03.

*Lactone **12***

Anhydrous sodium bicarbonate (33.6 g, 0.4 mol) and *m*-chloroperbenzoic acid (85%, 19.5 g, 96.4 mmol) were added to a solution of the monoketal **11** (20.0 g, 80.0 mmol) in dry carbon tetrachloride and stirred for 45 h. The reaction mixture was then diluted with dichloromethane (1500 ml) and washed thoroughly with a solution of sodium thiosulfate (10%, 2 × 100 ml), water (200 ml), a solution of sodium hydroxide (1 *N*, 2 × 200 ml), and again water (4 × 100 ml). The organic phase was then dried and evaporated to dryness under vacuum to give a white solid (21.1 g) containing the two lactones **12** and **13** in the ratio 73:27; ir (CH_2Cl_2): 1735, 1215, and 1100 cm^{-1}; nmr ($CDCl_3$) δ: 0.90 (singlet), 1.02 (singlet), 1.50–3.00 (multiplets), 3.47 and 3.50 (4H, OCH_2 of the acetal), 4.32 (27% of 2H, CH_2OCO, broad multiplet), and 4.70 (73% of 1H, CHOCO, broad multiplet).

The purification of the lactone **12** was carried out by selective basic hydrolysis of the isomeric lactone **13**. The crude mixture of the isomeric lactones **12** and **13** (21.19 g, 80 mmol) in the ratio 73:27 was dissolved in dimethoxyethane (700 ml) and cooled (5°C). This was treated with a solution of sodium hydroxide (1 *N*, 22 ml, 22 mmol) diluted with water (230 ml) and the reaction mixture was kept at room temperature for 17 h. A further amount of sodium hydroxide solution was then added (1 *N*, 17 ml, 17 mmol) and the disappearance of the lactone was followed by analyzing aliquots of the reaction mixture by nmr (disappearance of the signal at δ 4.32). The hydrolysis was complete in 9 h 30 min. The dimethoxyethane was then distilled off under vacuum and the residue was taken up in dichloromethane (600 ml). The organic phase was separated and washed with sodium hydroxide solution (1 *N*, 100 ml). The aqueous phase was reextracted with dichloromethane (150 ml) and the combined extracts were washed with water (2 × 150 ml), dried, and the solvent evaporated off under vacuum to yield only the lactone **12** as a white solid (13.8 g, 90%). The analytical sample was prepared by recrystallization from dichloromethane–ether; mp 158–159°C; ir (CH_2Cl_2): 1735, 1215, 1120, and 1110 cm^{-1}; nmr ($CDCl_3$) δ: 0.88 (3H, singlet, CH_3), 1.00 (3H, singlet, CH_3), 1.30–3.00 (11 H, multiplet), 3.42 (2H, singlet, CH_2O), 3.47 (2H, singlet, CH_2O), and 4.63 (1H, multiplet, CHOCO); ms *m/e*: 266 (M^+). *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.64, H 8.33; found: C 67.80, H 8.58.

*Methyl Ester Benzoate **14***

A solution of sodium methoxide in methanol was prepared by adding sodium (430 mg, 18.7 mmol) to anhydrous methanol (10 ml) with the exclusion of moisture. The lactone **12** (1.00 g, 3.76 mmol) dissolved in dry methanol was added to the above solution and stirred at room temperature for 12 h. The methanol was then evaporated off under reduced pressure and the residue dissolved in dichloromethane (250 ml). The organic phase was washed with water (1 × 100 ml and 2 × 50 ml),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dried, and the solvent distilled off under vacuum to give the corresponding hydroxy methyl ester as an oil (1.07 g, 95%); ir (CH_2Cl_2): 3600, 3460, 1735, 1080, 1062, and 1025 cm^{-1}; nmr ($CDCl_3$) δ: 0.95 (6H, singlet, $(CH_3)_2C$), 7.20–8.80 (11 H, multiplet), 3.42 (4H, singlet, two OCH_2), 3.62 (3H, singlet, OCH_3), and 4.2 (1H, multiplet, CHOH).

The above crude hydroxy methyl ester (690 mg, 2.31 mmol) was dissolved in dichloromethane (10 ml) and pyridine (2 ml). Benzoyl chloride (358 mg, 2.56 mmol) was added to the above solution and stirred at room temperature for 11 h. The reaction mixture was then diluted with water (200 ml) and extracted with dichloromethane (200 ml). The extract was stirred with very dilute hydrochloric acid (100 ml, p*H* 3). The organic phase was separated, washed with sodium bicarbonate solution (5%, 50 ml), and water (50 ml). It was then dried and the solvent was removed by distillation under vacuum to give an oil (896 mg) which was purified by thick-layer chromatography on silica gel using benzene–ether (3:2). This resulted in a white crystalline product (624 mg, 67%). An analytical sample was prepared by recrystallization from ether; mp 86–87°C; ir (CCl_4): 3070, 1741, 1720, 1601, 1580, 1110, and 1000 cm^{-1}; nmr (CCl_4) δ: 0.88 (3H, singlet, CH_3), 0.94 (3H, singlet, CH_3), 1.00–3.10 (11 H, multiplet), 3.39 (4H, multiplet, two OCH_2), 3.65 (3H, singlet, OCH_3), 5.20 (1H, multiplet, CHOCO), 7.45 (3H, multiplet, aromatic hydrogens), and 8.04 (2H, multiplet, aromatic hydrogens); ms *m/e*: 402 (M^+). *Anal.* calcd. for $C_{23}H_{30}O_6$: C 68.63, H 7.51; found: C 68.30, H 7.79.

Diol ***15***

A solution of the lactone **12** (15.4 g, 0.058 mol) in anhydrous tetrahydrofuran (200 ml) was added dropwise with stirring during a period of 60 min to a suspension of lithium aluminium hydride (4.5 g, 0.12 mol) in dry ether (350 ml) at 0°C. The reaction mixture was then stirred at room temperature for 2 h and refluxed for 60 min. It was then cooled and diluted with dichloromethane (500 ml). The complex formed was decomposed by the slow addition of saturated Rochelle salt solution (35 ml). The excess of water was removed by stirring with anhydrous magnesium sulfate. The inorganic salts were filtered off and the filtrate was evaporated to give a colorless oil (14.6 g, 94%) which could not be distilled; ir (CH_2Cl_2): 3610, 3460, 1360, 1350, and 1115 cm^{-1}; nmr ($CDCl_3$) δ: 0.96 (6H, singlet, $(CH_3)_2C$), 3.32 (2H, singlet, CHO*H* and CH_2OH), 3.52 (4H, singlet, two OCH_2), 3.60 (2H, triplet, J = 7 Hz, CH_2OH), and 4.20 (1H, multiplet, CHOH); ms *m/e*: 270 (M^+).

Diacetate ***16***

The ketal diol **15** (14.4 g, 0.053 mol) was dissolved in a mixture of pyridine (100 ml) and acetic anhydride (50 ml) and kept at room temperature in the dark for 13 h. It was then evaporated to dryness under vacuum. The last traces of the solvent were removed by repeated codistillation with benzene to give an oil (18.9 g, 100%). An analytical sample was prepared by molecular distillation; bp 155°C/0.05 Torr; ir (CH_2Cl_2): 1730, 1243, and 1115 cm^{-1}; nmr ($CDCl_3$) δ: 0.97 (3H, singlet, CH_3), 0.94 (3H, singlet, CH_3), 2.00 (6H, singlet, two CH_3CO), 3.46 (4H, singlet, two OCH_2), 4.05 (2H, triplet, J = 7 Hz, CH_2OCO), and 4.95 (1H, multiplet, CHOCO); ms *m/e*: 354 (M^+). *Anal.* calcd. for $C_{19}H_{30}O_6$: C 64.38, H 8.53; found: C 64.45, H 8.54.

Acetate Alcohol ***17***

A solution of potassium carbonate (7.3 g, 0.053 mol) in water (150 ml) was added dropwise with stirring during a period of 50 min to a solution of the ketal diacetate **16** (18.6 g, 0.052 mol) in methanol (850 ml) at 0°C. After the addition was complete the stirring was continued for 30 min. It was then treated with saturated sodium chloride solution (400 ml) and the reaction mixture was extracted several times with dichloromethane. The residue obtained upon distilling off the solvent was again dissolved in dichloromethane (500 ml), dried, and evaporated under vacuum to give a colorless oil (15 g) which was a mixture of the diol **15**, the acetate alcohol **17**, and the starting material **16**. The monoacetate **17** was obtained pure by column chromatography on Florisil (elutions with petroleum ether – benzene) as a colorless oil (8.8 g, 53.7%) which could not be distilled: ir (CH_2Cl_2): 3600, 3500, 1726, 1240, and 1112 cm^{-1}; nmr ($CDCl_3$) δ: 0.93 (3H, singlet, CH_3), 0.98 (3H, singlet, CH_3), 2.02 (3H, singlet, CH_3CO), 2.37 (1H, singlet, CH_2OH), 3.50 (4H, singlet, two OCH_2), 3.64 (2H, triplet, J = 7 Hz, CH_2OH), and 4.95 (1H, multiplet, CHOCO); ms *m/e*: 252 ($M^+ - CH_3COOH$).

Ketal Acetate Aldehyde ***18***

(*a*) *From Acetate Alcohol* ***17***

The acetate alcohol **17** (2.5 g, 8 mmol) dissolved in dichloromethane (100 ml) was added to a solution of chromium trioxide pyridine complex (25) (12.4 g, 48 mmol) in the same solvent (300 ml) at 0°C. The reaction mixture was then stirred at room temperature for 20 min and poured into water (500 ml). The organic layer was separated and the aqueous layer was extracted three times with dichloromethane. The extracts were combined and washed with saturated copper sulfate solution followed by saturated sodium chloride solution. It was then dried and the solvent was distilled off under vacuum to give crude ketal acetate aldehyde **18** as a yellow oil (2.4 g, 97%); ir (CH_2Cl_2): 2730, 1735, 1245, 1060, and 1030 cm^{-1}; nmr ($CDCl_3$) δ: 0.95 (6H, singlet, $(CH_3)_2C$), 3.43 (4H, singlet, two OCH_2), 4.93 (1H, multiplet, CHOCO), and 9.70 (1H, multiplet, CHO).

(*b*) *From Ketal Aldehyde Alcohol* ***31***

The ketal aldehyde alcohol **31** (649 mg, 2.42 mmol) was dissolved in a mixture of pyridine (5 ml) and acetic anhydride (2.5 ml) and kept in the dark at room temperature for 10 h. The residue obtained on removing the solvent under vacuum was dissolved in dichloromethane (200 ml) and washed with water (2 × 30 ml). The organic phase was dried, filtered, and the solvent evaporated off under reduced pressure to yield an oil (608 mg). It was purified by treatment with active charcoal and chromatography on Florisil. Elution with ether–benzene gave the pure ketal acetate aldehyde **18** (209 mg, 28%) identical with the product obtained in the above procedure.

Cis *and* Trans *Ketone Alcohol Acetates* ***19*** *and* ***20*** *(26)*

The ketal aldehyde alcohol **31** (1.994 g, 7.45 mmol) was acetylated by the method described above to yield the crude ketal acetate aldehyde **18** (2.109 g) which was dissolved in a mixture of acetone (800 ml) and hydrochloric acid solution (3 *N*, 16 ml). After 2 h at room temperature, excess solid sodium bicarbonate was added. After filtration, the solvent was evaporated and dichloromethane was added. The resulting solution was dried with sodium sulfate, filtered, and evaporated to dryness. Thick-layer chromatography with silica gel in two successive elutions with ether gave the *cis* and the *trans* ketone alcohol acetates **19** and **20**. The *cis* ketone alcohol acetate **19** was obtained pure by crystallization with ether – petroleum ether (R_f 0.45, 516 mg, 31%); mp 73–74°C; ir (CH_2Cl_2): 3600, 3500, 1730, and 1245 cm^{-1}; nmr ($CDCl_3$) δ: 2.05 (3H, singlet, CH_3CO), 3.64 (1H, broad singlet, OH), 4.58 (1H, quadruplet, J = 7 Hz, CHOH), and 5.30 (1H, multiplet, CHOCO); ms *m/e*: 224 (M^+). *Anal.* calcd. for $C_{12}H_{16}O_4$: C 64.27, H 7.19; found: C 64.17, H 7.37.

The *trans* ketone alcohol acetate **20** was obtained pure as an oil (R_f 0.3, 434 mg, 25%); ir (CH_2Cl_2): 3600, 3450, 1735, and 1245 cm^{-1}; nmr ($CDCl_3$) δ: 2.02 (3H, singlet, CH_3CO), 4.58

For personal use only.

(1H, multiplet, C*H*OH), and 5.31 (1H, multiplet, CHOCO); ms *m/e*: 224 (M^+).

β-*Diketone Acetate* ***21***

(*a*) *From* Cis *Ketone Alcohol Acetate* ***19***

The *cis* alcohol acetate **19** (64 mg, 0.28 mmol) was dissolved in acetone (50 ml) and cooled to 0°C. A slight excess of a solution of chromium trioxide in sulfuric acid (27), was added from a burette to this solution with vigorous stirring. After 10 min the excess oxidizing agent was destroyed by the addition of isopropanol and the reaction mixture was neutralized with solid sodium bicarbonate. It was then filtered and the residue was washed with acetone. The filtrate was evaporated to dryness under reduced pressure to give a solid which was dissolved in dichloromethane. The above solution was dried over sodium sulfate, filtered, and the solvent was distilled off under vacuum to yield a solid (62 mg, quantitative). An analytical sample was prepared by recrystallization from ether – petroleum ether; mp 124–126°C; ir (CH_2Cl_2): 1768, 1741, 1721, and 1230 cm^{-1}; nmr ($CDCl_3$) δ: 1.90 (3H, singlet, CH_3CO), 1.70–4.00 (10 H, multiplet), and 5.47 (1H, multiplet, CHOCO); ms *m/e*: 222 (M^+). *Anal.* calcd. for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 64.87, H 6.30.

(*b*) *From* Trans *Ketone Alcohol Acetate* ***20***

Using the experimental procedure described above, the *trans* alcohol acetate **20** was also converted into the same β-diketone acetate **21** in essentially quantitative yield.

Cis *Ketone Diacetate* ***22***

A solution of the *cis* alcohol acetate **19** (205 mg, 0.83 mmol) in a mixture of pyridine (3 ml) and acetic anhydride (1.5 ml) was kept in the dark at room temperature for 24 h. It was then cooled (5°C) and methanol (2 ml) was added with stirring. The reaction mixture was then shaken with dichloromethane (200 ml) and the organic phase was washed with hydrochloric acid (1 *N*, 100 ml) followed by water (100 ml). The solution was then dried and the solvent was evaporated off under reduced pressure to give an oil (249 mg) which was purified by preparative thick-layer chromatography on silica gel with benzene–ether (70 mg, quantitative); bp 140°C/5 × 10^{-6} Torr, dec.; ir (CH_2Cl_2): 1740 and 1240 cm^{-1}; nmr ($CDCl_3$) δ: 2.08 (6H, singlet, two CH_3CO) and 5.35 (2H, multiplet, two OCHCO); ms *m/e*: 266 (M^+).

Trans *Ketone Diacetate* ***23***

(*a*) *From* Trans *Ketone Alcohol Acetate* ***20***

The *trans* acetate alcohol **20** (86 mg, 0.38 mmol) was dissolved in a mixture of pyridine (1.5 ml) and acetic anhydride (0.8 ml) and kept in the dark for 24 h. The reaction mixture was then cooled (5°C), mixed with methanol (1.5 ml) and stirred at room temperature for 30 min. It was then diluted with ether (200 ml), washed successively with dilute hydrochloric acid (1 *N*, 2 × 50 ml), saturated sodium bicarbonate solution (50 ml), and water (2 × 50 ml). Removal of the dried solvent under vacuum gave an oil (93 mg, 92%) which crystallized from ether – petroleum ether; mp 78–79°C; ir ($CHCl_3$): 1740, 1245, and 1210 cm^{-1}; nmr ($CDCl_3$) δ: 2.02 (6H, singlet, two CH_3COO) and 5.37 (2H, multiplet, two OCHCO); ms *m/e*: 266 (M^+). *Anal.* calcd. for $C_{14}H_{18}O_5$: C 63.15, H 6.81; found: C 63.14, H 6.91.

(*b*) *From* Trans *Ketone Diol* ***34***

The *trans* ketone diol **34** (511 mg, 2.8 mmol) was dissolved in pyridine (15 ml) and acetic anhydride (7.5 ml) and stirred. The above solution was kept at room temperature in the dark for 75 h. It was then evaporated to dryness under reduced pressure. The resulting oil (830 mg) was purified by column chromatography on Florisil. Elution with benzene–ether gave the pure ketone diacetate **23** (628 mg, 84%). Recrystallization from ether – petroleum ether gave white crystals whose physical and spectral properties were identical to the product **23** obtained above.

Ketal Alcohol Acetate ***24***

The ketone alcohol acetate **20** (277 mg, 1.2 mmol) was dissolved in benzene (50 ml) and mixed with ethylene glycol (0.3 ml, 5 mmol) and *p*-toluenesulfonic acid (15 mg). The reaction mixture was refluxed for 8 h using a Dean–Stark water separator. The cooled reaction mixture was diluted with dichloromethane (100 ml) and washed with saturated sodium carbonate and saturated sodium chloride. The dried solution was evaporated to give a yellow oil. Thick-layer chromatography on silica gel using ether as the solvent gave the pure ketal alcohol acetate **24** (205 mg, 64%). It was recrystallized from ether – petroleum ether; mp 73–74°C; ir (CH_2Cl_2): 3600, 3500, 1740, 1245, and 1115 cm^{-1}; nmr ($CDCl_3$) δ: 1.97 (3H, singlet, CH_3CO), 2.32 (1H, singlet, OH), 3.90 (4H, singlet, two OCH_2), 4.27 (1H, multiplet, C*H*OH), and 4.93 (1H, multiplet, CHOCO); ms *m/e*: 268 (M^+). *Anal.* calcd. for $C_{14}H_{20}O_5$: C 62.67, H 7.51; found: C 62.52, H 7.56.

Trans *Ketal Diol* ***25***

(*a*) *From Ketal Alcohol Acetate* ***24***

A solution of ketal alcohol acetate **24** (135 mg, 0.5 mmol) in methanol was mixed with potassium carbonate (345 mg, 2.5 mmol) in water (5 ml). The mixture was left at room temperature for 4 h. Most of the methanol was removed by evaporation and the resulting aqueous mixture was continuously extracted with dichloromethane during 24 h. Drying and evaporation of the solvent gave a yellow crystalline residue (102 mg, 90%) which was recrystallized from ethyl acetate; mp 150–151°C; ir (CH_2Cl_2): 3600 and 3470 cm^{-1}; nmr ($CDCl_3$) δ: 3.50 (2H, broad singlet, two OH), 3.98 (4H, singlet, two OCH_2), and 4.27 (2H, multiplet, two C*H*OH); ms *m/e*: 266 (M^+). *Anal.* calcd. for $C_{12}H_{18}O_4$: C 63.70, H 8.02; found: C 63.80, H 7.92.

(*b*) *From* Trans *Ketone Diacetate* ***23***

A solution of *trans* ketone diacetate **23** (127 mg, 0.48 mmol) in benzene (55 ml) was mixed with ethylene glycol (574 mg, 9.25 mmol) and *p*-toluenesulfonic acid (15 mg). The mixture was heated to reflux during 11 h using a Dean–Stark water separator. Ether (200 ml) was then added and the organic phase washed with saturated sodium bicarbonate (100 ml) and water (100 ml). The dried solution was evaporated to dryness to give the corresponding *trans* ketal diacetate which crystallized from petroleum ether (118 mg, 80%); mp 57–59°C; ir (CH_2Cl_2): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 2.01 and 2.03 (6H, two singlets, two CH_3CO), 3.96 (4H, broad singlet, two CH_2O), and 5.17 (2H, multiplet, two CHOCO); ms *m/e*: 310 (M^+). *Anal.* calcd. for $C_{16}H_{22}O_6$: C 61.92, H 7.15; found: C 62.01, H 7.24.

The above *trans* ketal diacetate (628 mg, 2.03 mmol) was dissolved in methanol (50 ml) and mixed with water (23 ml) and triethylamine (6 ml). This mixture was heated at 70°C for 16 h. The solvent was then removed *in vacuo* and the residue was dissolved in methanol (15 ml) and dichloromethane (500 ml). The solution was dried and the solvent was evaporated. The residual oil was purified by column chromatography on Florisil. The ketal diol **25** (347 mg, 76%) was obtained pure by elution with methanol–ether (1:19). Recrystallization from ethyl acetate gave a product which was found identical with the *trans* ketal diol **25** obtained by the above procedure.

Trans *Ketal Dimesylate* ***26***

(*a*) *From* Trans *Ketal Diol* ***25***

The ketal diol **25** (328 mg, 1.43 mmol) was dissolved in a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mixture of dichloromethane (60 ml) and pyridine (3.4 ml) at 0°C. Methane sulfonyl chloride (822 mg, 7.7 mmol) was added to the above solution and the reaction mixture was kept in the cold (5°C) for 4½ days. It was then diluted with dichloromethane (500 ml) and washed with hydrochloric acid (1 *N*, 100 ml), sodium carbonate solution (10%, 100 ml), and water (2 × 75 ml). The organic phase was dried and the solvent was distilled off under reduced pressure. The residue was recrystallized from dichloromethane–ether to give the pure dimesylate **26** (384 mg, 70%); mp 122.5–123.5°C; ir (CH_2Cl_2): 1360, 1340, 1180, 1100, and 1000 cm^{-1}; nmr ($CDCl_3$) δ: 3.03 (3H, singlet, CH_3SO_2), 3.10 (3H, singlet, CH_3SO_2), 4.00 (4H, singlet, two OCH_2), and 5.00 (2H, multiplet, two $CHOSO_2$); ms *m/e*: 286 ($M^+ - CH_3SO_2OH$). *Anal.* calcd. for $C_{14}H_{22}O_8S_2$: C 43.96, H 5.80; found: C 43.99, H 5.78.

(b) From Ketone Dimesylate 35

A solution of *p*-toluenesulfonic acid (8 mg) and ethylene glycol (284 mg, 4.6 mmol) in benzene (50 ml) was refluxed for 1 h with a water separator. The ketone dimesylate **35** (142 mg, 0.41 mmol) was then added to the above solution and the reaction mixture was refluxed for 2 h. The solution was cooled and treated with ice cold water (100 ml). The organic phase was separated and the aqueous phase was extracted with dichloromethane (300 ml). The combined extracts were washed with ice cold water (100 ml), dried and the solvent evaporated off under reduced pressure to give the ketal dimesylate **26** (157 mg, quantitative) as an oil. It was crystallized from dichloromethane:ether. The product obtained was found identical with the *trans* ketal dimesylate **26** obtained by the procedure above.

*Dienone **29** and 2,3-Dihydrotriquinacen-2-one (3)*

Potassium *tert*-butoxide purified by sublimation (224 mg, 2 mmol) was added to a solution of the dimesylate **26** (204 mg, 0.53 mmol) in anhydrous dimethyl sulfoxide (20 ml) under an atmosphere of nitrogen and stirred at 30°C for 6 h. The yellow reaction mixture was poured into ice cold water (150 ml) containing sodium chloride and the mixture was extracted with ether. The ether extract was washed with water, dried, and evaporated to give an oil (95 mg, 94%). The oil was distilled (60–70°C/0.5 Torr; 69 mg, 68%) and analyzed by vapor phase chromatography (5 ft × ¼ in., 15% OS-138 on Chromosorb W, 200°C). It was found to contain three products with retention times 10, 11, and 14 min, respectively, in the ratio 71:25:4. The above mixture was separated into two fractions by preparative thick-layer chromatography on silica gel. One of the fractions (20 mg, R_f 0.50) contained the three products and the other (45 mg, R_f 0.39) showed the presence of only two products with retention times 10 and 11 min in the ratio 76:24. It could be shown by hydrolysis that they were the ketals **27** and **28**; ir (CH_2Cl_2): 3040, 1120, and 1102 cm^{-1}; nmr ($CDCl_3$) δ: 1.20–3.9 (multiplets), 3.92 (singlet), and 5.35–5.85 (multiplet).

Hydrochloric acid (2 *N*, 1 ml) was added to a mixture of the ketal dienes **27** and **28** (42 mg, 0.22 mmol) in the ratio 87:13 in tetrahydrofuran (2 ml) and stirred at room temperature for 7 h. The mixture was diluted with saturated sodium chloride solution and extracted with ether. The organic phase was washed with saturated sodium bicarbonate solution, water, and dried. Evaporation of the solvent gave a yellow oil (33 mg), the vapor phase chromatographic analysis of which revealed the presence of two compounds (5 ft × ¼ in., 15% OS-138 on Chromosorb W, 200°C) with retention times 6 and 9 min in the ratio 86:14. They were separated by preparative thick-layer chromatography on silica gel with benzene. The conjugated ketone **29** was obtained as a colorless oil (6 mg, 19%, R_f 0.40). The above compound showed only one peak with retention time 9 min by vapor phase chromatography. It was found to be unstable at room temperature; ir (CH_2Cl_2): 1707 and 1615 cm^{-1}.

The ketone **3** (15 mg, 47%, R_f 0.20) isolated as a yellow oil was pure by vapor phase chromatography with retention time 6 min. It was further purified by molecular distillation (45°C/0.9 Torr); ir (CH_2Cl_2): 3040, 1740, 1614, and 1604 cm^{-1}; nmr ($CDCl_3$) δ: 1.00–4.00 (6H, multiplet) and 5.78 (4H, multiplet, four olefinic hydrogens); ms *m/e*: 146 (M^+).

The 2,4-dinitrophenylhydrazone derivative was prepared by reacting the ketone with a solution of the 2,4-dinitrophenylhydrazine in ethanol containing traces of sulfuric acid. The product was recrystallized from ethyl acetate; mp 155°C. *Anal.* calcd. for $C_{16}H_{14}O_4N_4$: C 58.89, H 4.32; found: C 58.79, H 4.47.

2,3-Dihydrotriquinacen-2-one (3)

*(a) From 2-*exo*-2,3-Dihydrotriquinacenol (30)*

A solution of 2-*exo*-2,3-dihydrotriquinacenol (**30**) (27.2 mg, 0.18 mmol) in dry dichloromethane (3 ml) was added to a solution of Collins' reagent (25) (284 mg, 1.1 mmol) in the same solvent (10 ml) and stirred for 30 min. The reaction mixture was then poured into water (30 ml) and extracted with dichloromethane (3 × 35 ml). The organic phase was washed with dilute hydrochloric acid (1 *N*, 15 ml) saturated sodium bicarbonate solution (25 ml), and saturated sodium chloride solution (25 ml). It was dried and the solvent was distilled off under reduced pressure to give an oil (21 mg) which was purified by filtration through a column of silica gel (3 g). 2,3-Dihydrotriquinacen-2-one (**3**) was obtained pure (15 mg, 54%) as a colorless oil with ether – petroleum ether (1:1).

(b) From Exo *Ketal Mesylate 53*

The *exo* ketal mesylate **53** (100 mg, 0.30 mmol) was dissolved in dry benzene (25 ml) in a flask equipped with a water separator under an atmosphere of nitrogen. Benzene was distilled off (20 ml) and a large excess of 1,5-diazabicyclo[3.4.0]nonene-5 (DBN) (1.00 g, 8 mmol) was added. The temperature of the bath was raised to 160–165°C and the reaction was completed in 3 h (tlc). The reaction mixture was then cooled to room temperature and diluted with benzene (60 ml). The solution was washed with ice cold dilute hydrochloric acid (0.1 *N*), sodium bicarbonate solution (10%), and brine. It was dried over sodium sulfate and the solvent was distilled off to give the crude ketal diene (64 mg, 90%); nmr ($CDCl_3$) δ: 0.95 (3H, singlet, CH_3), 0.97 (3H, singlet, CH_3), 1.36 (1H, quartet), 2.30 (1H, multiplet), 2.91 (1H, multiplet), 3.50 (7H, multiplets, two CH_2O and three allylic hydrogens), and 5.58 (4H, multiplets, four olefinic hydrogens). A solution of the ketal diene (58 mg, 0.25 mmol) in tetrahydrofuran (2 ml) and dilute hydrochloric acid (1 *N*, 1 ml) was stirred for 6 h under nitrogen. Excess solid sodium bicarbonate was added and the reaction mixture was diluted with dichloromethane (50 ml). The organic phase was washed with brine, dried over sodium sulfate, and filtered through a column of silica gel (20 g). The filtrate was concentrated under vacuum to give a product (25 mg, 70%) which was found identical with 2,3-dihydrotriquinacen-2-one (**3**).

(c) From Endo *Ketal Mesylate 52*

A solution of the ketal mesylate **52** (215 mg, 0.65 mmol) in anhydrous dimethyl sulfoxide (12 ml) was heated to 65°C under an atmosphere of nitrogen. Freshly sublimed potassium *tert*-butoxide (145 mg, 1.3 mmol) was added to the above reaction mixture in two equal portions with an interval of 3 h. At the end of 6 h the reaction mixture was poured into water (50 ml) containing sodium chloride and the solution was worked up as already described to give the corresponding ketal diene (140 mg).

The above ketal diene was converted into 2,3-dihydro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

triquinacen-2-one (**3**) by treatment with dilute hydrochloric acid as described in the above procedure *b*.

*Ketal Aldehyde Alcohol **31** (28)*

A solution of the lactone **12** (1.34 g, 5.04 mmol) in dry benzene (45 ml) was mixed with anhydrous ether (25 ml) and cooled (−5°C) in an atmosphere of nitrogen. Diisobutylaluminium hydride solution (10.3 ml, 5.52 mmol, 11.4% in hexane) was added to the above solution rapidly by means of a syringe. After 35 min it was decomposed by the careful addition of water (2.7 ml) and was allowed to warm up slowly to room temperature. The reaction mixture was then diluted with dichloromethane (500 ml), dried over sodium sulfate, and the solvent was evaporated off under reduced pressure to give an oil (1.45 g, quantitative). This product was directly used for subsequent reactions. A small amount of the product was purified by chromatography on Florisil using ether–benzene and ether; ir (CH_2Cl_2): 3600, 3480, 2730, 1730, 1065, and 1030 cm^{-1}; nmr ($CDCl_3$) δ: 0.97 (6H, singlet, $(CH_3)_2C$), 3.55 (4H, singlet, two OCH_2), 4.27 (1H, multiplet, C*H*OH), and 9.88 (1H, multiplet, CHO); ms *m/e*: 268 (M^+).

*Ketal Enol Ether **32***

The aldehyde alcohol **31** (294 mg, 1.10 mmol) was subjected to microdistillation. Formation of a white solid was observed in the distillate. The distillate was purified by preparative thick layer chromatography with benzene. Two products were isolated: the aldehyde alcohol **31** (183 mg) and the enol ether **32** as a solid (73 mg). An analytical sample of the ketal enol ether **32** was prepared by recrystallization from petroleum ether; mp 94–96°C; ir (CH_2Cl_2): 3080, 1640, 1100, and 1000 cm^{-1}; nmr ($CDCl_3$) δ: 0.95 (3H, singlet, CH_3), 0.98 (3H, singlet, CH_3), 3.50 (4H, singlet, two OCH_2), 4.45 (1H, multiplet, CHO), 4.82 (1H, triplet, J = 6.5 Hz, C*H*=CHO), and 6.20 (1H, doublet, J = 5.5 Hz, C=C*H*O); ms *m/e*: 250 (M^+). *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 71.61, H 9.06.

Cis *and* Trans *Ketone Diols **33** and **34** (26)*

The aldehyde alcohol **31** (5.49 g, 20.4 mmol) was dissolved in acetone (2.2 ℓ) and treated with dilute hydrochloric acid (2 *N*, 50 ml, 100 mmol). The reaction mixture was stirred at room temperature for 2 h and 15 min. Afterwards, it was neutralized with solid sodium bicarbonate and the stirring was continued for another 45 min. It was filtered and the solvent was evaporated under reduced pressure. The residue obtained was taken up in dichloromethane (1.5 ℓ) and dried over anhydrous sodium sulfate for 30 min. Removal of solvent under vacuum yielded an oil which was purified by chromatography on a column of Florisil (225 g) using ether–methanol. An oil (3.67 g, 98.5%) containing the two isomers in the ratio 1:1 was recovered. Thin-layer chromatography of the mixture on silica gel by double elution with methanol–ether showed two spots of equal intensity corresponding to the *cis* diol **33** (R_f 0.25) and the *trans* diol **34** (R_f 0.20).

The epimerisation of *cis* **33** and *trans* **34** ketone diols was carried out in the following way: the above mixture of the ketone diols **33** and **34** (2.18 g, 11.9 mmol) was dissolved in anhydrous ethanol (220 ml). Nitrogen was bubbled through the solution for 15 min and a solution of sodium ethoxide in ethanol (0.174 *M*, 3.42 ml, 0.56 mmol) was added and the mixture was stirred at room temperature for 21 h. Hydrochloric acid was then added (1 *N*, 0.58 ml) and stirred again for 15 min. The solvent was distilled off under reduced pressure and the residue was taken up in dichloromethane (800 ml). The above solution was dried over anhydrous sodium sulfate and evaporated under reduced pressure to give an oil (2.20 g) containing mainly the *trans* diol **34** with a small quantity of the *cis* diol **33**. The *trans* **34** isomer was isolated in the pure state (866 mg) by crystallization from ethyl acetate. The residue was subjected to dry column chromatography on silica gel. Elution with methanol–ether (3:97 and 1:24) yielded another crop of the *trans* diol **34** (498 mg) (total yield 62.5%); mp 97–99°C; ir (KBr): 3300 and 1720 cm^{-1}; nmr (acetone-d_6) δ: 1.10–4.20 (10H, multiplets) and 4.5 (2H, multiplet, two C*H*OH); ms *m/e*: 182 (M^+). *Anal.* calcd. for $C_{10}H_{14}O_3$: C 65.92, C 7.74; found: C 65.62, H 7.77.

*Ketone Dimesylate **35***

The *trans* ketone diol **34** (626 mg, 3.43 mmol) was dissolved in a warm mixture of dichloromethane (70 ml) and pyridine. The solution was then cooled (−5°C) and methane sulfonyl chloride (1.97 g, 17.2 mmol) was added and the reaction mixture was kept in the cold (5°C) for 4½ days. It was afterwards diluted with ice cold dichloromethane (700 ml). The organic phase was washed with ice cold water (100 ml), cold dilute hydrochloric acid (1 *N*, 200 ml), ice cold saturated sodium bicarbonate solution (100 ml), and again ice cold water (100 ml). The solution was then dried and evaporated under reduced pressure to give an oil which was recrystallized from dichloromethane – ether – petroleum ether (1.10 g, 95%); mp 114–116°C; ir (CH_2Cl_2): 1741, 1360, 1335, and 1170 cm^{-1}; nmr ($CDCl_3$) δ: 1.70–3.70 (10H, multiplet, 3.08 (3H, singlet, CH_3SO_2), 3.10 (3H, singlet, CH_3SO_2), and 5.37 (2H, multiplet, two $CHOSO_2$); ms *m/e*: 338 (M^+). *Anal.* calcd. for $C_{12}H_{18}O_7S_2$: C 42.59, H 5.36; found: C 42.38, H 5.37.

*Enone Mesylate **36***

A solution of sodium hydroxide in ethanol (0.105 *N*, 5.56 ml, 0.58 mmol) was added during a period of 25 min to a solution of the ketone dimesylate **35** (198 mg, 0.58 mmol) in dichloromethane (15 ml) at 0°C. After the addition was complete the reaction mixture was stirred for 10 min, diluted with ice cold water (150 ml), and extracted with dichloromethane (300 ml). The extract was washed with water (50 ml), dried, and the solvent was distilled off under vacuum to yield the enone mesylate **36** (140 mg, quantitative). An analytical sample was prepared by recrystallization from dichloromethane–ether; mp 83–84.5°C; ir (CH_2Cl_2): 3050, 1717, 1626, 1355, 1330, and 1170 cm^{-1}; uv ($CHCl_3$) λ_{max}: 243 nm (ε 9400); nmr ($CDCl_3$) δ: 2.00–3.50 (8H, multiplet), 2.93 (3H, singlet, CH_3SO_2), 3.78 (1H, multiplet), 5.18 (1H, multiplet, $CHOSO_2$), and 6.38 (1H, multiplet, olefinic hydrogen); ms *m/e*: 242 (M^+). *Anal.* calcd. for $C_{11}H_{14}O_4S$: C 54.53, H 5.82; found: C 54.45, H 5.84.

*Ethoxy Ketone Mesylate **37***

The ketone dimesylate **35** (200 mg, 0.59 mmol) was dissolved in a mixture of dichloromethane (10 ml) and ethanol (10 ml). A solution of sodium hydroxide in ethanol (0.1 *N*, 6.2 ml, 0.65 mmol) was added to the above solution with stirring during a period of 20 min at room temperature. After the addition was complete, the stirring was continued for another 40 min. The reaction mixture was then diluted with water (100 ml), the organic phase was separated, and the aqueous phase was extracted with dichloromethane (300 ml). The extracts were combined, washed with water (100 ml), and dried. The removal of solvent under vacuum yielded a yellow oil which was purified by chromatography on Florisil (10 g) with dichloromethane–ether to give the ethoxy ketone mesylate **37** (134 mg, 79%) as an oil; ir (CH_2Cl_2): 1735, 1360, 1340, and 1180 cm^{-1}; nmr ($CDCl_3$) δ: 1.18 (3H, triplet, J = 7 Hz, CH_3CH_2), 3.02 (3H, singlet, CH_3SO_2), 3.50 (2H, quadruplet, J = 7 Hz, CH_3CH_2), 4.13 (1H, multiplet, $CHOCH_2CH_3$), and 5.18 (1H, multiplet, $CHOSO_2$); ms *m/e*: 288 (M^+).

*Ketone Enol Diacetate **38** or **39***

The β-diketone acetate **21** (50 mg, 0.22 mmol) was dissolved

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in a mixture of pyridine (2 ml) and acetic anhydride (1 ml) and kept in the dark at room temperature for 22 h. The reaction mixture was then evaporated to dryness under reduced pressure to give a solid residue (61 mg, quantitative). An analytical sample was prepared by recrystallization from a mixture of dichloromethane – ether – petroleum ether; mp 146–147.5°C; ir (CH_2Cl_2): 1769, 1744, 1722, 1702, 1236, and 1225 cm^{-1}; uv ($CHCl_3$) λ_{max}: 284 (ε 590) and 241 nm (ε 870); nmr ($CDCl_3$) δ: 1.90 (3H, singlet, CH_3COOCH), 2.47 (3H, singlet, CH_3 of enol acetate), 4.37 (1H, multiplet), and 5.43 (1H, multiplet, CHOCO); ms *m/e*: 264 (M^+). *Anal.* calcd. for $C_{14}H_{16}O_5$: C 63.03, H 6.10; found: C 63.55, H 6.07.

Ketal Olefin Aldehyde ***40***

The mono ketal **11** (4 g, 16 mmol) was dissolved in anhydrous tertiary butanol (1 ℓ) and irradiated with a mercury lamp (450 W) equipped with a quartz filter in an atmosphere of nitrogen (22). The entire system was cooled by circulating cold water during the irradiation. The reaction was complete in 90 min. The solvent was distilled off under vacuum to give an oil which was purified by column chromatography on Florisil by eluting successively with pentane, benzene, and ether. About 2.4 g (60–65%) of the aldehyde **40** and 200 mg (5%) of the starting material were recovered. The product was found unstable and therefore should be kept in the cold or used up immediately for the subsequent reaction; ir (CH_2Cl_2): 2720 and 1730 cm^{-1}; nmr ($CDCl_3$) δ: 0.94 (6H, singlet, $(CH_3)_2C$), 3.42 (2H, singlet, CH_2O), 3.48 (2H, singlet, CH_2O), 5.50 (2H, multiplet, two olefinic hydrogens), and 9.55 (1H, triplet, J = 1 Hz, CHO); ms *m/e*: 250 (M^+).

Exo *and* Endo *Ketone Alcohols* ***41*** *and* ***50*** *(26)*

(a) From Ketal Olefin Aldehyde ***40***

A solution of the ketal olefin aldehyde **40** (4.0 g, 16 mmol) in acetone (500 ml) was stirred with hydrochloric acid (3 *N*, 35 ml) at room temperature for 2 h. Sodium bicarbonate (25 g) was then added and stirred for another 15 min. The reaction mixture was filtered and the filtrate was concentrated to remove the acetone. The aqueous solution was then thoroughly extracted with dichloromethane. The extract was dried and the solvent was distilled off under vacuum to give crude *exo* ketone alcohol **41**; ir (CH_2Cl_2): 3585, 3410, and 1730 cm^{-1}; nmr ($CDCl_3$) δ: 4.32 (1H, multiplet, CHOH) and 5.56 (2H, quadruplet, J = 6 Hz, two olefinic hydrogens); ms *m/e*: 164 (M^+). A portion of this crude product (700 mg) was acetylated with pyridine and acetic anhydride. Preparative thin-layer chromatography on Florisil with ether as solvent gave pure *exo* ketone acetate **42** (660 mg, 75%).

(b) From Ketone Olefin Aldehyde ***43***

A solution of the ketone olefin aldehyde **43** (600 mg, 3.66 mmol) in acetone (80 ml) was stirred with hydrochloric acid (3 *N*, 6.4 ml) at room temperature for 1 h. Sodium bicarbonate (2 g) was added, the mixture was filtered, and concentrated. The resulting solution was extracted with dichloromethane. The organic extract was dried, filtered, and evaporated to give a crude product (600 mg). An aliquot (18 mg) of this crude product was acetylated with pyridine and acetic anhydride. Vapor phase chromatography showed that the product obtained was a mixture of *exo* ketone acetate **42** (≃80%), *endo* ketone acetate **51** (≃15%), and an unidentified product (≃5%). The remaining crude aldol condensation product was mixed with ethanol (50 ml) containing a small quantity of sodium ethoxide (4 mg) and the mixture was left at room temperature for 1.5 h under nitrogen. Most of the ethanol was evaporated, dilute hydrochloric acid was added, and the aqueous phase was extracted with dichloromethane (3 × 20 ml). The dried organic phase was evaporated to dryness to give an oil which consisted mainly of *exo* ketone alcohol **41** (580 mg). Acetylation of an aliquot gave *exo* ketone acetate **42** (94.5%), *endo* ketone acetate **51** (1.5%), and an unidentified product (4%).

Exo *Ketone Acetate* ***42***

The *exo* ketal acetate **49** (80 mg, 0.3 mmol) was dissolved in acetone containing a few drops of water and *p*-toluenesulfonic acid (12 mg). After 18 h at room temperature, the solvent was evaporated and dichloromethane (30 ml) was added. The organic solution was washed with water (2 × 5 ml), dried with sodium sulfate, and evaporated to dryness. The resulting oil was purified by preparative thin-layer chromatography on silica gel with ether to give pure *exo* ketone acetate **42** (50 mg, 80%) as a liquid; ir (CH_2Cl_2): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 2.04 (3H, singlet, CH_3CO), 5.24 (1H, quadruplet, J = 6 Hz, CHOCO), and 5.64 (2H, quadruplet (unsymmetric), olefinic hydrogens); ms *m/e*: 206 (M^+); vpc: one peak at 8.24 min (5 ft × ¼ in.; 5% SE-30 on Chromosorb W, 140°C). *Anal.* calcd. for $C_{12}H_{14}O_3$: C 69.89, H 6.84; found: C 69.63, H 7.04.

Ketone Aldehyde ***43***

The diketone **10** (4 g, 24.4 mmol) was dissolved in anhydrous methanol (1 ℓ). The solution was irradiated with a mercury lamp (450 W) in quartz with cooling under an atmosphere of nitrogen (22). After 30 min, analysis by gas chromatography (5 ft × ¼ in., 5% SE-30 on Chromosorb W, 135°C) indicated the presence of a major peak corresponding to the ketone aldehyde (retention time: 3 min) and a minor peak, the starting material (5%, retention time: 5 min). The solvent was then evaporated off under reduced pressure to give an oil (4 g) which was used without purification; ir (CH_2Cl_2): 2710 and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 5.68 (2H, quartet, J = 6 Hz, olefinic hydrogens) and 9.49 (1H, triplet, J = 1 Hz, CHO); ms *m/e*: 164 (M^+).

β-*Diketone* ***44***

(a) From Exo *Ketone Alcohol* ***41***

To a solution of the crude alcohol **41** (2 g, 12.2 mmol) in acetone (100 ml) cooled to 0°C, Jones' reagent (26) was added dropwise until an orange color persisted. After 60 min the solvent was removed and the residue was diluted with water and extracted with dichloromethane. The organic phase was washed with water, dried, filtered through Celite, and evaporated under vacuum. The solid product obtained was recrystallized from ethyl acetate to give colorless needles (600 mg, 30%) of the β-diketone **44**; mp 115°C; ir (CH_2Cl_2): 1760 and 1710 cm^{-1}; nmr ($CDCl_3$) δ: 5.6 (2H, singlet, olefinic hydrogens); ms *m/e*: 162 (M^+); vpc: one peak at 8 min (5 ft × ¼ in., 5% SE-30 on Chromosorb, 140°C). *Anal.* calcd. for $C_{10}H_{10}O_2$: C 74.06, H 6.21; found: C 73.80, H 6.19.

(b) From Ketone Carboxylic Acid ***57***

The crude ketone carboxylic acid **57** (135 mg, 0.75 mmol) was dissolved in anhydrous benzene, *p*-toluenesulfonic acid was added (≃20 mg) and the mixture was refluxed for 17 h in a flask equipped with a Dean–Stark water separator. The solvent was then evaporated off and the residue was dissolved in dichloromethane. It was washed twice with water, dried, and the solvent was distilled off under vacuum to give a yellow solid which was recrystallized from ethyl acetate to give a product (98 mg, 83%) identical with the β-diketone **44** obtained by the above procedure.

Ketal Ketone ***45***

A solution of the β-diketone **44** (1 g, 6.2 mmol) in benzene (150 ml) was mixed with 2,2-dimethyl-1,3-propanediol (744 mg, 7 mmol) and *p*-toluenesulfonic acid (20 mg). The reaction mixture was refluxed for 24 h in a flask equipped with a Dean–Stark water separator. It was then washed with sodium

For personal use only.

bicarbonate solution (5%, 20 ml) and saturated sodium chloride solution (2 × 20 ml). The organic phase was dried and the solvent was distilled off under vacuum to give a mixture containing mainly the ketone ketal **45**. The product was purified by column chromatography on Florisil with benzene–methanol (99:1), followed by crystallization from petroleum ether (850 mg, 55%), mp 64–65°C; ir (CH_2Cl_2): 1730, 1200, and 1000 cm^{-1}; nmr ($CDCl_3$) δ: 0.90 (3H, singlet, CH_3), 0.98 (3H, singlet, CH_3), 3.48 (4H, multiplet, two CH_2O), and 5.70 (2H, singlet, two olefinic hydrogens); ms *m/e*: 248 (M^+). *Anal.* calcd. for $C_{15}H_{20}O_3$: C 72.55, H 8.12; found: C 72.34, H 7.84.

Endo *Ketal Alcohol* ***46***

The ketone ketal **45** (1.2 g, 4.8 mmol) dissolved in dry tetrahydrofuran (20 ml) was added to a suspension of lithium tri-*tert*-butoxyaluminium hydride (2.4 g, 9.6 mmol) in the same solvent (150 ml). The reaction mixture was then refluxed for 40 h and treated with aqueous sodium bicarbonate solution (5%, 1 ml), just enough to destroy the excess hydride. The organic phase was then dried over anhydrous sodium sulfate, filtered, and evaporated. The crude product obtained was purified by crystallization from ether (1 g, 80%); mp 94–95°C; ir (CH_2Cl_2): 3500 cm^{-1}; nmr ($CDCl_3$) δ: 0.95 (3H, singlet, CH_3), 0.98 (3H, singlet, CH_3), 3.51 (2H, singlet, CH_2O), 3.55 (2H, singlet, CH_2O), 4.4 (1H, multiplet, C*H*OH), and 5.60 (2H, quadruplet, J = 6 Hz, two olefinic hydrogens); ms *m/e*: 250 (M^+).

Exo *and* Endo *Ketal Alcohols* ***46*** *and* ***47***

The ketal ketone **45** (154 mg, 0.62 mmol) was dissolved in absolute ethanol (15 ml) and refluxed. Small pieces of sodium were added until a faint precipitate began to appear in the reaction medium. The stirring was continued for another 2 h. The reaction mixture was then cooled in an ice bath and poured into a saturated sodium chloride solution (20 ml). It was extracted with ether (5 × 50 ml), dried, and the solvent was evaporated to give an epimeric mixture of *exo* (87%) and *endo* (13%) ketal alcohols **47** and **46** as an oil. The relative proportion of the two isomers was determined by nmr spectroscopy. Crystallization with ether gave the pure *exo* ketal alcohol **47** (120 mg, 80%). An analytical sample was prepared by recrystallization from ether–pentane; mp 109–110°C; ir (CH_2Cl_2): 3500 cm^{-1}; nmr ($CDCl_3$) δ: 0.83 (3H, singlet, CH_3), 1.06 (3H, singlet, CH_3), 3.48 (4H, multiplet, two CH_2O), 3.95 (1H, multiplet, C*H*OH), and 5.55 (2H, quadruplet, J = 6 Hz, two olefinic hydrogens); ms *m/e*: 250 (M^+). *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 72.00, H 8.95.

Exo *Ketal Alcohol* ***47***

A solution of the crude *exo* ketone alcohol **41** (587.7 mg, 3.58 mmol) in benzene (70 ml) containing 2,2-dimethyl-1,3-propanediol (0.374 g, 3.58 mmol) and *p*-toluenesulfonic acid was refluxed for 3.3 h with a system equipped with a Dean–Stark water separator. Most of the solvent was removed by evaporation and dichloromethane was added. The organic phase was washed with solutions of saturated sodium carbonate and sodium chloride. The organic phase was dried with sodium sulfate, filtered, and evaporated to dryness. The resulting product can be crystallized with a mixture of ether–pentane. It can also be purified by column chromatography on Florisil using benzene–ether (25:2) as eluent. A yield of approximately 50–55% is obtained. This yield is based on the starting diketone **10**; mp 109–110°C. This product was found identical with the *exo* ketal alcohol **47** obtained from the chemical reduction of the ketal ketone **45**.

Endo *Ketal Acetate* ***48***

The ketal alcohol **46** (350 mg, 1.4 mmol) was dissolved in acetic anhydride (15 ml) containing sodium acetate (250 mg, 2.8 mmol). The reaction mixture was heated at 70°C for 72 h with stirring. The solution was then filtered and the filtrate was concentrated under reduced pressure to give a crystalline residue which was recrystallized from ether (390 mg, 95%). An analytical sample was prepared by recrystallization from ether – petroleum ether; mp 134°C; ir (CH_2Cl_2): 1730 and 1255 cm^{-1}; nmr ($CDCl_3$) δ: 0.84 (3H, singlet, CH_3), 1.05 (3H, singlet, CH_3), 1.94 (3H, singlet, C*H*$_3$CO), 3.40 (2H, singlet, CH_2O), 3.55 (2H, singlet, CH_2O), 5.50 (1H, multiplet, CHOCO), and 5.55 (2H, singlet, two olefinic hydrogens); ms *m/e*: 292 (M^+). *Anal.* calcd. for $C_{17}H_{24}O_4$: C 69.84, H 8.27; found: C 69.91, H 8.82.

Exo *Ketal Acetate* ***49***

The *exo* ketal alcohol **47** (74 mg, 0.3 mmol) was dissolved in a mixture of pyridine (2 ml) and acetic anhydride (1 ml) and left in the dark for 48 h at room temperature. The solvent was distilled off under reduced pressure and the last traces were removed by repeated evaporation with benzene. The product obtained was purified by preparative thick-layer chromatography on silica gel using ether as the eluent to give the *exo* ketal acetate **49** as a solid; mp 131–132°C; ir (CH_2Cl_2): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 0.86 (3H, singlet, CH_3), 1.05 (3H, singlet, CH_3), 2.03 (3H, singlet, CH_3CO), 3.52 (4H, multiplet, two CH_2O), 5.00 (1H, multiplet, CHOCO), and 5.60 (2H, quadruplet, olefinic hydrogens); ms *m/e*: 292 (M^+). *Anal.* calcd. for $C_{17}H_{24}O_4$: C 69.84, H 8.27; found: C 69.94, H 8.22.

Endo *Ketone Acetate* ***51***

A solution of the ketal acetate **48** (390 mg, 1.3 mmol) in wet acetone (50 ml) was treated with *p*-toluenesulfonic acid (40 mg, 10% by weight) and stirred at room temperature for 18 h. The solvent was then evaporated off and the residue was dissolved in dichloromethane (100 ml), washed with water (2 × 15 ml), and dried. The oil obtained on removing the solvent was purified by column chromatography on silica gel using benzene–ether (25:1) as the eluent to give the *endo* ketone acetate **51** as an oil (220 mg, 80%). An analytical sample was prepared by preparative thick-layer chromatography on silica gel with ether; ir (CH_2Cl_2): 1735 cm^{-1}; nmr ($CDCl_3$) δ: 1.93 (3H, singlet, CH_3CO), 5.42 (1H, multiplet, CHOCO), and 5.65 (2H, quadruplet, J = 6 Hz, olefinic hydrogens); ms *m/e*: 206 (M^+); vpc: one peak at 7.48 min (5 ft × $\frac{1}{4}$ in., 5% SE-30 on Chromosorb W, 140°C). *Anal.* calcd. for $C_{12}H_{14}O_3$: C 69.89, H 6.84; found: C 70.20, H 6.97.

Endo *Ketal Mesylate* ***52***

Methane sulfonyl chloride (0.42 ml, 5.4 mmol) was added to a solution of the ketone alcohol **46** (238 mg, 0.95 mmol) in dichloromethane (35 ml) and pyridine (4 ml) and kept in the dark for 5 days at room temperature. The reaction mixture was then diluted with dichloromethane (100 ml), washed with water (2 × 25 ml), and dried. The solvent was evaporated off under reduced pressure and the last traces of pyridine were removed with the aid of benzene. The yellow oil obtained was purified by chromatography on a column of Florisil by eluting successively with petroleum ether (30–60°C), benzene, and ether to give white crystals. An analytical sample was prepared by recrystallization from ether; mp 90°C; ir (CH_2Cl_2): 1360, 1340, 1180, 1100, and 1000 cm^{-1}; nmr ($CDCl_3$) δ: 0.95 (6H, singlet, $(CH_3)_2C$), 2.92 (3H, singlet, CH_3SO_2), 3.44 (2H, singlet, CH_2O), 3.54 (2H, singlet, CH_2O), 5.12 (1H, multiplet, $CHOSO_2$), and 5.58 (2H, singlet, two olefinic hydrogens); ms *m/e*: 328 (M^+). *Anal.* calcd. for $C_{16}H_{24}O_5S$: C 58.51, H 7.37; found: C 58.68, C 7.46.

Exo *Ketal Mesylate* ***53***

Methane sulfonyl chloride was added (0.62 ml, 7.94 mmol) to a solution of the ketal alcohol **41** (350 mg, 1.4 mmol) in dichloromethane (50 ml) and pyridine (5.9 ml) and the reaction mixture was kept at room temperature for 16 h with the exclusion of light. It was then diluted with dichloromethane (100 ml) and washed with water (2 × 25 ml). The organic phase was dried and concentrated. The last traces of pyridine were removed by codistillation with benzene. The product obtained was recrystallized from ether–pentane (368 mg, 80%); mp 103–104°C; ir ($CHCl_3$): 1345, 1325, 1155, 1100, and 1000 cm^{-1}; nmr ($CDCl_3$) δ: 0.98 (3H, singlet, CH_3), 0.93 (3H, singlet, CH_3), 2.96 (3H, singlet, CH_3SO_2), 3.48 (4H, multiplet, $(CH_2O)_2$), 3.30 (2H, multiplet), 4.67 (1H, quartet, $CHOSO_2$), and 5.51 (2H, quartet, J = 5.5 Hz, two olefinic hydrogens); ms *m/e*: 328 (M^+). *Anal.* calcd. for $C_{16}H_{24}O_5S$: C 58.51, H 7.37; found: C 58.72, H 7.53.

Ketone Enol Acetate ***54***

The β-diketone **44** (175 mg, 1.08 mmol) was dissolved in a mixture of acetic anhydride (1 ml) and pyridine (2 ml) and kept in the dark for 12 h at room temperature. The solvent was then distilled off under reduced pressure. The last traces of pyridine were removed by codistillation with benzene. The yellow solid obtained was recrystallized from benzene–ether (175 mg, 80%); mp 123.5–124°C; ir (CH_2Cl_2): 1765 and 1705 cm^{-1}; uv ($CHCl_3$) λ_{max}: 292 (ε 278) and 244 nm (ε 516); uv (EtOH) λ_{max}: 293 (ε 250) and 212 nm (ε 2750); nmr ($CDCl_3$) δ: 2.38 (3H, singlet, CH_3CO), 3.58 (2H, multiplet, $CH_2C{=}C$), 4.44 (1H, triplet, J = 9 Hz, H_{10}), and 5.68 (2H, singlet, two olefinic hydrogens); ms *m/e*: 204 (M^+). *Anal.* calcd. for $C_{12}H_{12}O_3$: C 70.58, H 5.92; found: C 70.36, H 5.81.

Ketal Carboxylic Acid ***55*** *and its Methyl Ester* ***56***

A solution of silver nitrate (5.77 g, 0.34 mol) in water (32 ml) was added to a solution of the ketal olefin aldehyde **40** (4 g, 0.016 mol) in ethanol (42 ml). A solution of sodium hydroxide (2.62 g, 0.065 mol) in water (90 ml) was added during a period of 15 min. It was then stirred at room temperature for 3 h. The reaction mixture was filtered through Celite, concentrated, diluted with water, and extracted several times with ether. The aqueous phase was then acidified with dilute hydrochloric acid to p*H* 6 and extracted exhaustively with ether. It was dried and the solvent evaporated off to give the crude ketal carboxylic acid **55** as an oil (3.3 g, 75%) which was not further purified.

An excess of diazomethane in ether was added to a solution of the crude acid **55** (3.3 g, 0.012 mol) in ether (20 ml) at room temperature and stirred for 30 min. The evaporation of the solvent at reduced pressure yielded the ketal carboxylic acid methyl ester **56** as an oil which was purified by microdistillation (3.36 g, 100%, 120–130°C/5 Torr); ir ($CHCl_3$): 1730 and 1105 cm^{-1}; nmr ($CDCl_3$) δ: 0.96 (3H, singlet, CH_3), 0.92 (3H, singlet, CH_3), 3.43 (2H, singlet, CH_2O), 3.48 (2H, singlet, CH_2O), 3.67 (3H, singlet, CH_3O), and 5.54 (2H, multiplet, two olefinic hydrogens); ms *m/e*: 280 (M^+). *Anal.* calcd. for $C_{16}H_{24}O_4$: C 68.55, H 8.63; found: C 68.60, H 8.69.

Ketone Carboxylic Acid ***57*** *and its Methyl Ester* ***58***

The ketal ester **56** (1.1 g, 3 mmol) was dissolved in a solution of aqueous acetic acid (70%, 20 ml) and heated at 70°C for 12 h. The reaction mixture was concentrated under reduced pressure and extracted with dichloromethane. The organic phase was washed with water, dried, and the solvent distilled off under vacuum. The remaining acetic acid was removed by distillation with benzene. The oil obtained was dissolved in ether (20 ml) and treated with an excess solution of diazomethane in ether. The above solution was stirred at room temperature for 30 min and the solvent was evaporated off to give the ketone carboxylic acid methyl ester **58** as an oil which was purified by preparative thick-layer chromatography on Florisil to give 20% of the starting ketal carboxylic acid methyl ester **56** and **58** (490 mg, 72%); ir ($CHCl_3$): 1735 cm^{-1}; nmr ($CDCl_3$) δ: 2.00–3.65 (9H, multiplet), 3.70 (3H, singlet, CH_3O), and 5.68 (2H, singlet, two olefinic hydrogens); ms *m/e*: 194 (M^+). *Anal.* calcd. for $C_{11}H_{14}O_3$: C 68.02, H 7.27; found: C 68.23, H 7.28.

A solution of the ketone ester **58** (222 mg, 1.2 mmol) in water (15 ml) was mixed with aqueous sodium hydroxide (1 *N*, 1.8 ml) and allowed to react for 2 h at room temperature. The neutral material was then removed by extraction with ether. The aqueous solution was acidified with dilute hydrochloric acid and was extracted several times with dichloromethane. The extracts were combined, dried, and evaporated under reduced pressure to give the ketone carboxylic acid **57** as an oil (180 mg, 90%) which was not purified further. This crude acid was then used directly for the preparation of the β-diketone **44**.

Ketone δ-Lactone ***59***

The ketal lactone **12** (3.0 g, 0.0113 mol) was dissolved in acetone (300 ml) and treated with dilute hydrochloric acid (3 *N*, 24 ml, 0.072 mol). The reaction mixture was stirred at room temperature for 5 h and then was concentrated and extracted several times with dichloromethane. The organic phase was washed with saturated sodium bicarbonate solution and water. It was dried and the solvent was evaporated off under vacuum to yield white crystals of ketone δ-lactone **59** that were purified by recrystallization from dichloromethane–ether (1.58 g, 80%); mp 148–150°C; ir ($CHCl_3$): 1745 cm^{-1}; nmr ($CDCl_3$) δ: 1.78–3.50 (11H, multiplet) and 4.83 (1H, multiplet, CHOC); ms *m/e*: 180 (M^+). *Anal.* calcd. for $C_{10}H_{12}O_3$: C 66.65, H 6.71; found: C 66.46, H 6.54.

Ketone γ-Lactone ***60***

(a) From Ketone Lactone ***59***

The ketone lactone **59** (2 g, 11 mmol) was added in small portions to polyphosphoric acid (30 g, 92 mmol). The reaction mixture was homogenized and heated on a water bath at 80–90°C for 15 min. The above solution was then poured over crushed ice and extracted several times with dichloromethane. The organic phase was washed several times with saturated sodium carbonate solution and with water. It was then dried and the solvent was removed to give a yellow solid which was recrystallized from dichloromethane–ether (1.67 g, 84%); mp 105–106.5°C; ir ($CHCl_3$): 1780 and 1740 cm^{-1}; nmr ($CDCl_3$) δ: 1.42–3.57 (11H, multiplet) and 5.10 (1H, multiplet, CHOCO); ms *m/e*: 180 (M^+). *Anal.* calcd. for $C_{10}H_{12}O_3$: C 66.65, H 6.71; found: C 66.61, H 6.60.

(b) From Ketal γ-Lactone ***64***

A solution of ketal γ-lactone **64** (119 mg, 0.44 mmol) in acetone (15 ml) containing dilute hydrochloric acid (3 *N*, 2 ml was left at room temperature for 7 h. Most of the acetone was then removed by evaporation, water was added, and the aqueous phase was extracted with dichloromethane. The organic extract was washed with a solution of saturated sodium bicarbonate and water. The dried solution was evaporated to yield the ketone γ-lactone **60** which was recrystallized from dichloromethane–ether (63 mg, 80%). The product obtained was found identical with the ketone γ-lactone **60** obtained in the above procedure.

Ketal Iodolactone ***63*** *(29)*

The crude ketal acid **55** (1.00 g, 3.7 mmol) was stirred in a solution of sodium hydroxide (1 *N*, 3.7 ml, 3.7 mmol) for 20 min and was then saturated with sodium bicarbonate. To the above mixture, an aqueous solution of iodine (1.52 g, 5.9

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mmol) and potassium iodide (1.41 g, 8.5 mmol) was added and stirred at room temperature for 4 h. The excess of iodine was then destroyed by the addition of sodium thiosulfate solution. The reaction mixture was extracted several times with dichloromethane. The extracts were combined, dried and the solvent was distilled off to give crude ketal iodolactone **63** as an oil (1.25 g, 84%) which was not purified further; ir ($CHCl_3$): 1775 cm^{-1}; nmr δ ($CDCl_3$): 0.92 (3H, singlet, CH_3), 0.99 (3H, singlet, CH_3), 3.45 (4H, singlet, two CH_2O), 4.09 (1H, triplet, CHI), and 5.16 (1H, triplet, CHOCO); ms *m/e*: 392 (M^+).

Ketone γ-Lactone ***64***

A solution of the crude iodolactone **63** (62 mg, 1.5 mmol) in anhydrous ethanol (420 ml) was treated with Raney nickel (1.8 g) in the presence of pyridine (0.36 ml). The reaction mixture was stirred under hydrogen at atmospheric pressure and room temperature for 7 h. The solution was filtered through Celite and evaporated to dryness to give the ketal γ-lactone **64** as a crystalline product which was recrystallized from dichloromethane–pentane (360 mg, 86%); mp 85–87°C; ir ($CHCl_3$): 1765 cm^{-1}; nmr ($CDCl_3$) δ: 0.95 (6H, singlet, $(CH_3)_2C$), 1.37–3.27 (11H, multiplet), 3.46 (4H, singlet, two CH_2O), and 4.97 (1H, multiplet, CHOCO); ms *m/e*: 266 (M^+). *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.65, H 8.33; found: C 67.29, H 8.20.

Cis *and* Trans *Diols* ***65*** *and* ***66***

A solution of the β-diketone **44** (200 mg, 1.2 mmol) in dry tetrahydrofuran (10 ml) was added slowly to a suspension of lithium aluminium hydride (280 mg, 7.0 mmol) in the same solvent (10 ml). The reaction mixture was refluxed for 5 h, cooled, and hydrolysed slowly with water. It was then extracted with dichloromethane. The organic phase was dried and evaporated to give an oil containing the two diols which were separated by preparative thick-layer chromatography on silica gel. The *cis* diol **65** (R_f 0.54, 134 mg) and the *trans* diol **66** (R_f 0.19, 25 mg) were found to be identical with their respective authentic samples obtained as described below.

Cis *Diol* ***65***

A solution of the β-diketone **44** (100 mg, 0.6 mmol) in tetrahydrofuran (10 ml) was added slowly to a suspension of lithium tri-*tert*-butoxy aluminium hydride (1.08 g, 4.2 mmol) in the same solvent (10 ml). The reaction mixture was then refluxed for 40 h. It was cooled, hydrolysed slowly with water, and extracted with dichloromethane. The organic phase was dried and the solvent was distilled off to yield an oil which was purified by thick-layer chromatography on silica gel to give pure *cis* diol **65** (70 mg, 70%) which was recrystallized from ether – petroleum ether; mp 129–130°C; ir ($CHCl_3$): 3520 and 3400 cm^{-1}; nmr ($CDCl_3$) δ: 1.47–3.58 (10H), 4.49 (2H, quadruplet, J = 6.0 Hz, two C*H*OH), and 5.70 (2H, singlet, two olefinic hydrogens); ms *m/e*: 166 (M^+). *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49; found: C 71.99, H 8.30.

Trans *Diol* ***66***

A solution of the crude *exo* ketone alcohol **41** (1.5 g, 9 mmol) in ether (30 ml) was added to a suspension of lithium aluminium hydride (1.71 g, 45 mmol) in the same solvent (20 ml) and refluxed for 3 h. The reaction mixture was then cooled, decomposed slowly with water, and extracted with ether. The extract was dried and evaporated. The crystalline *trans* diol **66** obtained was recrystallized from dichloromethane–ether (825 mg, 55%); mp 97.5–98°C; ir ($CHCl_3$): 3580 (weak) and 3390 cm^{-1} (strong); nmr ($CDCl_3$) δ: 1.00–3.47 (8H, multiplet), 4.30 (2H, multiplet, two CHOH), and 5.53 (2H, quadruplet, two olefinic hydrogens); ms *m/e*: 166 (M^+). *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49; found: C 72.15, H 8.31.

Cis *Diacetate* ***67***

The *cis* diol **67** (70 mg, 0.4 mmol) was dissolved in a mixture of pyridine (2 ml) and acetic anhydride (2 ml) and stirred at room temperature for 12 h with the exclusion of light. The pyridine and acetic anhydride were distilled off under reduced pressure and the last traces were removed by codistillation with benzene. The product obtained was purified by preparative thick-layer chromatography on silica gel to give the *cis* diacetate **66** as a liquid (70 mg, 70%); ir ($CHCl_3$): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 1.97 (6H, singlet, two CH_3CO), 4.66 (2H, quadruplet, two CHOCO), and 5.57 (2H, singlet, two olefinic hydrogens); ms *m/e*: 250 (M^+); vpc one peak at 4.12 min (5 ft × ¼ in.; 5% SE-30 on Chromosorb W, 165°C).

Trans *Diacetate* ***68***

A solution of the *trans* diol **66** (70 mg, 0.4 mmol) in pyridine (2 ml) and acetic anhydride (2 ml) was stirred at room temperature for 12 h with exclusion of light. The reaction mixture was then worked up and purified as described for the *cis* acetate **67** (80 mg, 80%); mp 53.5–55°C; ir ($CHCl_3$): 1725 cm^{-1}; nmr ($CDCl_3$) δ: 1.96 (3H, singlet, CH_3CO), 2.00 (3H, singlet, CH_3CO), 5.13 (1H, quadruplet, CHOCO), 5.29 (1H, quadruplet, CHOCO), and 5.62 (2H, quadruplet, two olefinic hydrogens); ms *m/e*: 250 (M^+); vpc: one peak at 7.62 min (5 ft × ¼ in., 5% SE-30 on Chromosorb W, 165°C).

Cyclic Carbonate ***69***

A solution of phosgene in dry benzene (1.6 ml, 2.36 g/30 ml, 1.28 mmol) was added to a solution of the *cis* diol **65** (53 mg, 0.32 mmol) in the same solvent (10 ml) containing pyridine (0.1 ml, 1.28 mmol) during a period of 5 min. The reaction mixture was then stirred for 30 min at room temperature. The excess phosgene was destroyed by the slow addition of water and the mixture was extracted several times with dichlorome thane. The extracts were combined, washed with dilute hydrochloric acid (6%), water, and dried. The product obtained on removal of the solvent was recrystallized from dichloromethane–ether (54 mg, 90%); mp 143–153°C; ir ($CHCl_3$): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 1.82–3.80 (8H, multiplet), 4.96 (2H, multiplet, two CHOCO), and 5.60 (2H, singlet, two olefinic hydrogens); ms *m/e*: 192 (M^+). *Anal.* calcd. for $C_{11}H_{12}O_3$: C 68.74, H 6.29; found: C 68.43, H 6.46.

Cis *Dimesylate* ***71***

Methane sulfonyl chloride (0.07 ml, 0.9 mmol) was added to a solution of the *cis* diol **65** (45 mg, 0.3 mmol) in dichloromethane (2 ml) and pyridine (1 ml) in the cold (−20 to −30°C). The reaction mixture was then left in the refrigerator at 0°C for 24 h in the dark. The reaction mixture was then poured into water and extracted several times with dichloromethane. The organic phase was washed with dilute hydrochloric acid (6%), saturated sodium chloride solution, and water. It was dried and the solvent was distilled off under vacuum to yield a crystalline product which was recrystallized from dichloromethane – petroleum ether (80 mg, 92%); mp 151–152°C; ir ($CHCl_3$): 1350, 1335, and 1170 cm^{-1}; nmr ($CDCl_3$) δ: 2.07–3.52 (8H, multiplet), 3.03 (6H, singlet, two CH_3SO_2), 5.26 (2H, quadruplet, two CHO), and 5.65 (2H, singlet, two olefinic hydrogens); ms *m/e*: 322 (M^+). *Anal.* calcd. for $C_{12}H_{18}O_6S_2$: C 44.70, H 5.48; found: C 45.02, H 5.57.

Trans *Dimesylate* ***72***

Methane sulfonyl chloride (3 ml, 38.7 mmol) was added to a cold (−20 to −30°C) solution of the *trans* diol **66** (2.15 g 12.9 mmol) in dichloromethane (126 ml) and pyridine (42 ml) and kept at 0°C in the dark for 60 h. It was then left at room temperature for 24 h. The reaction mixture was worked up as described for the *cis* dimesylate **71**. The product obtained was recrystallized from dichloromethane–ether–pentane (4.52 g,

For personal use only.

84%); mp 111.5–112°C; ir ($CHCl_3$): 1360, 1340, and 1175 cm^{-1}; nmr ($CDCl_3$) δ: 1.50–3.50 (8H, multiplet), 3.04 (6H, singlet, two CH_3SO_2), 5.06 (2H, multiplet, two CHO), and 5.60 (2H, quadruplet, two olefinic hydrogens); ms *m/e*: 226 ($M^+ - CH_3—SO_2OH$). *Anal.* calcd. for $C_{12}H_{18}O_6S_2$: C 44.70, H 5.48; found: C 43.68, H 5.66.

Cis *and* Trans *Dixanthates* ***73*** *and* ***74*** *(30)*

Sodium hydride (192 mg, 8.0 mmol) was added to an equimolar mixture of the *cis* and *trans* diols **65** and **66** (250 mg, 1.5 mmol) dissolved in tetrahydrofuran (20 ml). The reaction mixture was refluxed for 1 h, cooled to room temperature, treated with carbon disulfide (5.0 ml, 12.0 mol), and refluxed again for 1½ h. The reaction mixture was cooled to room temperature, methyl iodide was added (5 ml, 12.4 mmol), and it was refluxed for another 1 h. It was then cooled, concentrated under reduced pressure, and poured into benzene. The organic phase was washed with water, dried, and the solvent was evaporated off. The oil obtained was purified by chromatography on Florisil to give the pure *cis* xanthate **73** (208 mg) and the *trans* xanthate **74** (203 mg) (total yield: 80%).

Cis *xanthate* ***73***: ir ($CHCl_3$): 1240, 1222, 1218, and 1157 cm^{-1}; nmr ($CDCl_3$) δ: 3.49 (6H, singlet, two CH_3S), 6.06 (2H, quadruplet, two CHOC), and 5.60 (2H, singlet, two olefinic hydrogens); ms *m/e*: 346 (M^+). *Anal.* calcd. for $C_{14}H_{18}O_2S_4$: C 48.58, H 5.20; found: C 49.22, H 5.55.

Trans *xanthate* ***74***: mp 69.5–70.5°C; ir ($CHCl_3$): 1225, 1190, 1070, and 1050 cm^{-1}; nmr ($CDCl_3$) δ: 3.47 (3H, singlet, CH_3S), 3.49 (3H, singlet, CH_3S), 5.94 (2H, multiplet, two CHOC), and 5.63 (2H, multiplet, two olefinic hydrogens); ms *m/e*: 346 (M^+). *Anal.* calcd. for $C_{14}H_{18}O_2S_4$: C 48.58, H 5.20; found: C 49.02, H 5.66.

In another experiment, the pure *trans* diol **66** (336 mg, 2.0 mmol) was converted into the *trans* dixanthate **74** as described above (680 mg, 96%).

*Triquinacene (****1****)*

(a) From Cis *Dimesylate* ***71*** *(22)*

Neutral alumina (Woelm, activity I, 5 g) was added to a solution of the *cis* dimesylate **71** (240 mg, 0.12 mmol) in dichloromethane (8 ml). The mixture was magnetically stirred at room temperature during 23 h. The mixture was then filtered and the dichloromethane was removed by distillation at atmospheric pressure to yield crude triquinacene which was distilled at 80–85°C (30–35 min) (40 mg, 42%); ir (CH_2Cl_2): 3040, 2460, 2380, 1605, and 1348 cm^{-1}; nmr ($CDCl_3$) δ: 3.70 (4H, singlet) and 5.63 (6H, singlet, six olefinic hydrogens); ms *m/e*: 130 (M^+), 129 ($M^+ - 1$), 115 ($M^+ - 15$), 78 ($M^+ - 52$), and 77 ($M^+ - 53$); vpc one peak at 2.87 min (5 ft × ¼ in., 5% SE-30 Chromosorb W, 152°C). *Anal.* calcd. for $C_{10}H_{10}$: C 92.26, H 7.74; found: C 91.92, H 7.91.

(b) From Trans *Dimesylate* ***72*** *(22)*

Using an experimental procedure similar to the one described above, the *trans* dimesylate **72** (2 g, 3.1 mmol) gave pure triquinacene (460 mg, 57%).

(c) From Cis *Dixanthate* ***73***

The *cis* dixanthate **73** (90 mg, 0.26 mmol) was heated at 210°C in a sealed tube (under vacuum) during a period of 6 h. The resulting product was dissolved in pentane and purified by chromatography on Florisil. The pentane solution was removed and distillation gave pure triquinacene (17 mg, 50%).

(d) From Trans *Dixanthate* ***74***

Using an experimental procedure similar to one described above, the *trans* dixanthate **74** (470 mg, 1.35 mmol) gave pure triquinacene (**1**) (89 mg, 50%). No special effort was made to improve the yield of triquinacene in these four different experimental procedures.

Received December 13, 1977

ARIS TERZIS, J. BRIAN FAUGHT, and T. BRUCE GRINDLEY. Can. J. Chem. **56**, 1705 (1978).

The crystal structure of *cis-anti-cis*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane (**2**) has been determined by X-ray diffraction. The crystals are monoclinic, $a = 11.120(1)$, $b = 8.127(1)$, $c = 7.990(1)$ Å, $\beta = 110.01(1)°$, $P2_1/c$, with $Z = 2$. The structure was solved by the application of symbolic addition procedures and refined to a final R value of 0.031 (R_w 0.040) for 989 reflections with $I > 2.0\sigma(I)$.

This structural determination confirms a previous tentative assignment of the relative configuration of **2**. In the crystal, the two *cis*-substituted cyclohexane rings adopt chair conformations in which the equatorial oxygens on different rings are linked through methylene groups to axial oxygens on the other rings. The central 10-membered tetraoxecane ring adopts the boat–chair–boat conformation, the most stable conformation for cyclodecane.

ARIS TERZIS, J. BRIAN FAUGHT et T. BRUCE GRINDLEY. Can. J. Chem. **56**, 1705 (1978).

On a déterminé, par diffraction des rayons-X, la structure cristalline du biscyclohexano-4,5:9,10 tétraoxécanne-1,3,6,8 *cis-anti-cis* (**2**). Les cristaux sont monocliniques $a = 11.120(1)$, $b = 8.127(1)$, $c = 7.990(1)$ Å, $\beta = 110.01(1)°$, $P2_1/c$ avec $Z = 2$. On a résolu la structure par l'application du processus d'addition symbolique et on l'a affinée jusqu'à une valeur finale de R de 0.031 (R_w 0.040) pour 989 réflexions avec $I > 2.0\sigma(I)$.

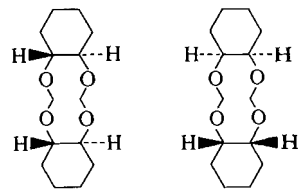
Cette détermination de structure confirme une attribution antérieure non définitive de la configuration relative de **2**. Dans le cristal, les deux cycles cyclohexaniques substitués *cis* adoptent des conformations chaises dans lesquelles les oxygènes équatoriaux sur les différents cycles sont liés par l'intermédiaire de groupes méthylènes à des oxygènes axiaux sur les autres cycles. Le cycle tétraoxécanne à dix chaînons que l'on retrouve au centre de la molécule adopte une conformation bateau–chaise–bateau; cette conformation est la plus stable pour le cyclodécane.

[Traduit par le journal]

Introduction

Medium rings are one of the few systems where nonbonded interactions are very important in the determination of molecular geometry and therefore there is considerable interest in the properties of these systems (1). The crystal structures of only few medium rings containing hetero atoms have been determined and, in particular, only two crystals containing 10-membered rings with more than one oxygen atom in the ring have been examined. The most stable cyclodecane conformation (1, 2) in the solid state appears to be the boat–chair–boat (BCB) (1,2) and this conformation was observed for the 10-membered ring in *trans-syn-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane (**1**) (3). In this publication, we report the structure of a 4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane (**2**) obtained as a minor product from the base catalysed reaction of *cis*-1,2-cyclohexanediol and methylene chloride.

This product (**2**) had previously been tentatively assigned the *cis-anti-cis* configuration on symmetry arguments based on its nmr spectra (4). At low temperatures in solution, inversion of the two *cis*-disubstituted cyclohexane rings slows and two conformational possibilities arise, a C_i symmetric form (**2***a*) with equatorial bonds linked to axial and a C_2 symmetric form (**2***b*) with axial bonds linked to axial and equatorial to equatorial (see Fig. 1). Preliminary low temperature nmr results strongly suggest that the latter C_2 symmetric form (**2***b*) is favoured in solution (ref. 5 and footnote 2).



1 **2**

Experimental

Compound **2** was prepared according to the procedure of Brimacombe *et al.* (6). Crystals suitable for study were obtained by recrystallization from ethanol and had mp 143–144°C

FIG. 1. The two possible relative orientations of the cyclohexane rings in *cis-anti-cis*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane (**2**).

(lit (6) mp 142–143°C). Crystal data:

$C_{14}H_{24}O_4$ fw = 256.34
Monoclinic, a = 11.120(1), b = 8.127(1), c = 7.990(1) Å, β = 110.01°(1), V = 678.49 Å^3, ρ_{obs} = 1.26 g cm^{-3}, Z = 2, ρ_{calcd} = 1.255 g cm^{-3} (18°C, CuK$_\alpha$, λ = 1.54051 Å).

Preliminary precession and Weissenberg photographs showed the following systematic absences: $h0l$, $l = 2n + 1$; $0k0$, $k = 2n + 1$. These absences uniquely identify the space group as $P2_{1/c}$. The unit cell dimensions were obtained from a least-squares refinement of the diffractometer angular settings of 12 independent reflections.

A crystal (0.21 × 0.21 × 0.18 mm) was mounted with the a axis nearly parallel to the ϕ axis of a Picker FACS-1 automated diffractometer with a graphite monochromator. Data were collected by the $\theta - 2\theta$ scan technique from a point 0.95° below the calculated 2σ position for CuK$_{\alpha 1}$ to 0.95° above the calculated position for CuK$_{\alpha 2}$, at a rate of 1° min^{-1}. Stationary background counts were taken for 20 s at either end of the scan range. During the course of the data collection, three standard reflections were measured at a period of 30 reflections. Their variations were less than 4.5% of their respective mean values.

A total of 1452 intensity measurements, including standards, were made for h, k, $\pm l$ in the region of $2\theta < 127°$ and reduced to a set of 1096 independent reflections after averaging equivalent reflections whose intensities were within 2σ of each other. The integrated intensity was calculated as

$$I(\text{net}) = I(\text{scan}) - 0.5t_T/t_B(B_1 + B_2)$$

where I(scan) is the number of counts over the scan range, t_T is the scan time, and t_B is the time for each background count B_1 and B_2. The standard deviations were calculated according to the expression

$$\sigma(I) = [N_T + 0.25(t_T/t_B)^2(B_1 + B_2) + cI^2 + 0.04^2(I - I_c)^2]^{\frac{1}{2}}$$

where N_T is the total integrated scan count obtained in time t_T, c is the factor to account for instrument instability during data collection (for this structure, c was 0.035), I is the net intensity, and I_c is I corrected for absorption. The last term in brackets is a factor accounting for errors in the absorption correction. Only data for which $I > 2.0\sigma(I)$ were used which left 989 reflections to be entered in the least-squares refinement.

An absorption correction was applied[3] to the data and calculated transmission coefficients based on a linear absorption coefficient of 7.44 cm^{-1} for CuK$_\alpha$ radiation ranged from 0.850 to 0.887. Finally, Lorentz and polarization corrections were applied.

The structure was determined by the application of symbolic addition procedures (10). All the nonhydrogen atoms were found in the first E-map. A structure factor calculation based

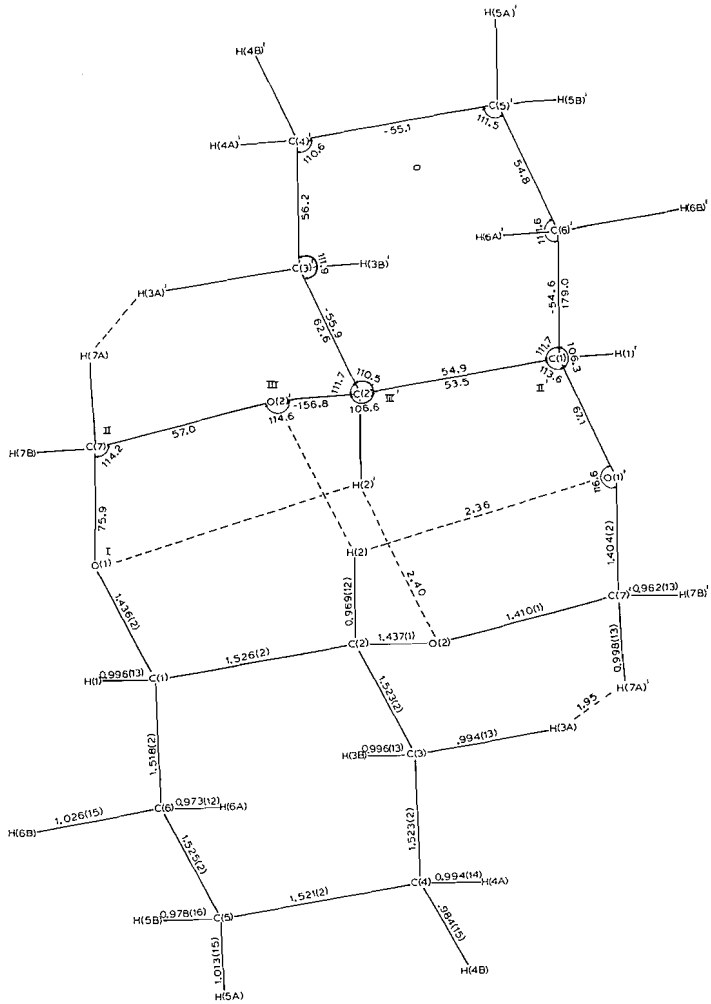

FIG. 2. Numbering and structural parameters for *cis-anti-cis*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane. Bond lengths (Å) with their errors in parentheses (10^3Å), and the more significant calculated short intramolecular distances (---) are shown on the bottom half of the diagram. Bond angles (deg) and torsional angles (deg) between heavy atoms are shown on the top half. All errors in angles were 0.1°. Roman numerals indicate the positions of the three different types of BCB positions on the structure.

on these atoms led to a conventional R factor of 0.287 where $R = \Sigma||F_o| - |F_c||/\Sigma F_o$. Temperature and scale factors were taken from the Wilson plot. Four cycles of block diagonal least-squares refinement (with unit weights) varying atomic positional and isotropic thermal parameters gave $R = 0.117$. All the hydrogen positions were determined from a difference Fourier map calculated at this point. Refinement continued, varying atomic positional and anisotropic thermal parameters for the nonhydrogen atoms, and positional and isotropic thermal parameters for the hydrogen atoms. Inclusion of a secondary extinction correction (11) as well as a weighting scheme ($w = 1/(\sigma F_o)^2$) led to a final $R = 0.031$ (observed data) and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{\frac{1}{2}}$ of 0.040 after seven cycles of refinement. Maximum shifts in the final least-squares refinement were 0.3σ. The 'goodness of fit,' defined as $[\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{\frac{1}{2}}$ was 1.70, where m = number of observations and n = number of refined parameters. The final difference map was featureless and there were no trends in the quantity $\Sigma w(|F_o| - |F_c|)^2$ as a function of $|F_o|$, sin 2θ, or $|h|$ (slowest varying index during data collection). The scattering factors for all atoms were taken from Cromer and Mann (12) and the anomalous dispersion components for carbon and oxygen were taken from Cromer and Lieberman (13).

Results and Discussion

Atomic positions and thermal parameters for **2** are given in Table 1. The structure factor table and Table 2, which contains the bond angles involving hydrogen, were put on deposit.[4] Numbering, bond lengths, bond angles, torsional angles, and short intramolecular distances of interest are shown in Fig. 2. To facilitate comparison with the results from

[4]A complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa Ont., Canada K1A 0S2.

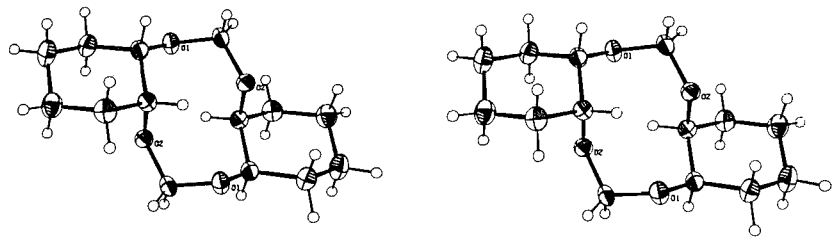

FIG. 3. Stereoscopic view of the solid state structure of *cis-anti-cis*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane.

molecular mechanics calculations, the short intramolecular distances were recalculated using a C—H bond length of 1.1 Å. Figure 3 is an ORTEP diagram of the crystal structure of **2**.

This crystal structure determination confirmed the previous (4) tentative assignment of the *cis-anti-cis* configuration to **2**. In the solid state, **2** adopted the C_i symmetric form **2***a*, in contrast to its preference at low temperature in solution (ref. 5 and footnote 2) and the 10-membered ring was in a BCB conformation. Only **2***a* can adopt a BCB conformation; the particular combination of torsional angles required by the relative orientations of the two cyclohexane rings in **2***b* cannot be accommodated in this type of conformation. Since only the BCB conformation has been observed for unhindered cyclodecane derivatives in the solid state (2) it is not surprising that the crystal structure of **2** contains **2***a*.

The BCB conformation observed for the 10-membered ring of **2** is very similar to that of **1** (see Fig. 4 and Table 3). In particular, this BCB conformation is narrower than those in cyclodecane derivatives because of relief of transannular nonbonded interactions. In cyclodecane the BCB conformation has C_{2h} symmetry which results in three different types of carbon positions termed I, II, and III and the locations of these positions for **1** and **2** are shown in Fig. 4 and Fig. 2, respectively. For **2**, the cyclohexane ring is fused in equatorial orientations at BCB positions type II and III whereas for **1**, the ring fusion differs only in that the orientation at the type II position is axial. Since substituents at either axial or equatorial type II BCB positions have similar steric interactions, this similarity of geometry is expected although it does support the contention (3) that the conformation of **1** was not much affected by intermolecular interactions.

The few differences in geometry between the tetraoxecane rings in **1** and **2** arise from the change in nonbonded interactions when the cyclohexane carbon at the type II positions changes from being an axial carbon on C(1). Removal of this interaction in **2** allowed the bond angle C(1)—O(1)—C(7) to decrease from 118.2 to 116.6° and by reducing the torque on the $C(7)H_2$ group considerably reduced the rocking and particularly twisting distortion of this group from local C_{2v} symmetry (see Tables 3 and 4 and ref. 3).

One extraannular bond angle, C(6)—C(1)—O(1), is markedly smaller in **2** (106.3°) than in **1** (112.8° for the comparable angle). This angle is smaller in **2** because the ethyl methyl ether fragment C(6)—C(1)—O(1)—C(7) is now *anti* rather than *gauche* as in **1**. This decrease in bond angles on changing from *gauche* to *anti* in similar CCOC fragments has been observed in macrocyclic polyethers (14) and has been attributed to relief of the *gauche* interactions. In **2**, additional effects cause the angle under discussion to be particularly small; decreasing this angle decreases the distance between the $C(3)'H_2$ group and the $C(7)H_2$ group and particularly between H(7A) and H(3A)'.

TABLE 3. Comparison of bond angles and torsional angles in **1** and **2**

BCB position type	Atoms involved	Angle (deg) Compound **1**	Compound **2**	Difference
Bond angles				
I	COC	118.2	116.6	−1.6
II	OCO	113.7	114.2	+0.5
III	COC	115.3	114.6	−0.7
III′	OCC	106.9	106.6	−0.3
II′	CCO	114.3	113.6	−0.7
Torsional angles				
I and II	COCO	73.0	75.9	+2.9
II and III	OCOC	60.9	57.0	−3.9
III and III′	COCC	−158.2	−156.8	+1.4
III′ and II′	OCCO	52.6	53.5	+0.9
II′ and I′	CCOC	65.4	67.1	+1.7

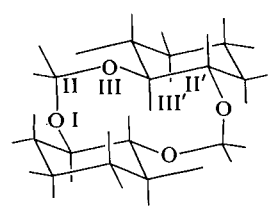

FIG. 4. Approximate representation of the structure of *trans-syn-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane with BCB positions indicated by roman numerals.

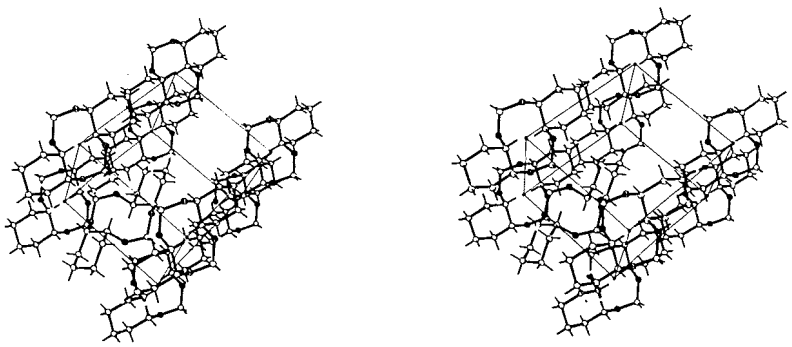

FIG. 5. Stereoscopic view of the molecular packing.

TABLE 4. Comparison of the distortion of the OCH_2O group from local C_{2v} symmetry

Compound	Mean angle size*	Distortion		
		Wag*	Rock*	Twist*
1	108.4	2.0	−3.4	−8.6
2	107.5	−1.7	−1.6	−4.9

*These terms are defined as in ref. 3 and were calculated using bond angles in Tables 2 and 3.

The packing diagram is shown in Fig. 5. There is one H–H intermolecular nonbonded interaction at a distance closer than 2.5 Å, between H(2) and an H(7A) of 2.341 Å. This distance is sufficiently large so as not to significantly influence the conformation of the 10-membered ring.

Synthesis of covalently-linked dimeric porphyrins

JOHN B. PAINE III AND DAVID DOLPHIN

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received March 28, 1978

JOHN B. PAINE III and DAVID DOLPHIN. Can. J. Chem. **56**, 1710 (1978).

Dimeric porphyrins covalently linked directly at their periphery (β,β′-biporphyrins) or via a hydrocarbon chain $(CH_2)_n$, where n = 1–8, have been synthesized from the corresponding β,β′-linked bispyrroles.

JOHN B. PAINE III et DAVID DOLPHIN. Can. J. Chem. **56**, 1710 (1978).

Utilisant les bispyrroles correspondants liés en β,β′ comme produits de départ, on a synthétisé les porphyrines dimères liées d'une façon covalente directement à leur périphérie (β,β′ biporphyrines) ou par l'intermédiaire d'une chaîne hydrocarbonée $(CH_2)_n$ où n = 1–8.

[Traduit par le journal]

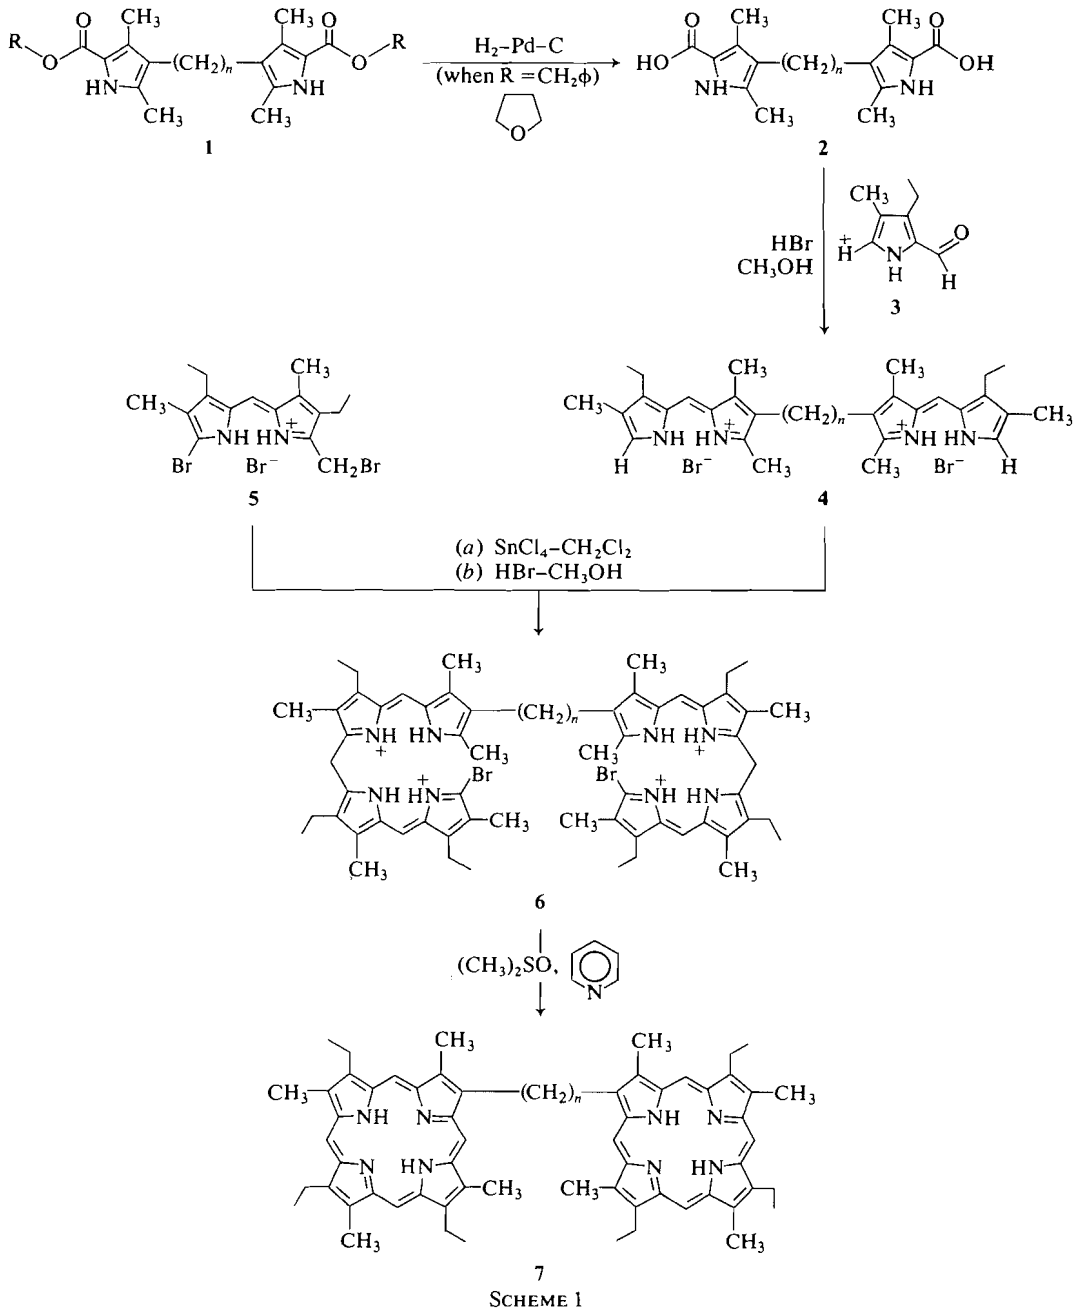
Since our first report (1) of covalently-linked dimeric porphyrins, joined by amide linkages, a number of similar dimeric porphyrins with amide, ester, or ether linkages have been reported (2–10). That all of these systems employed the coupling of porphyrins, through these functional groups, results from the 'ready' availability of the porphyrin precursors and the ease of formation of amide, ester, and ether linkages. However, once formed, such linkages have numerous disadvantages in that they generally lower the solubility (of systems which naturally have low solubilities), and increase the reactivity, and thereby decrease the stability. In addition the presence of extraneous functional groups complicates mechanistic and spectral studies on such systems.

Whereas all previous syntheses of dimeric porphyrins consist of joining two preformed porphyrin entities in the final steps, our approach consists of constructing the covalent link *first*, and then building a porphyrin onto either end. To avoid the disadvantages of the linkages discussed above a synthesis has been developed where hydrocarbon chain-linked bispyrroles **1** are converted into the corresponding dimer porphyrins **7** where the hydrocarbon chain plays a passive role both chemically and electronically.

Experimentally, the sequence depicted in Scheme 1 is facile to perform. The preparation of the bispyrroles **1** depends upon the length of the linking chain. When n = 0 the β,β′-bipyrrole was prepared by Ullmann coupling (11) of the corresponding β-iodopyrrole **8** (R = I). For n = 1 the β,β′-dipyrromethane was prepared from **9** (R = H) and acidified methanolic formaldehyde. For $n > 5$ acylation of **8** (R = H) or **9** (R = H) with a diacid chloride (in methylene chloride – nitromethane at 0°C with excess stannic chloride) gave the diketo bispyrroles **13** which were reduced to **1** with an excess of diborane. The diacid chlorides of succinic and glutaric acids could only be mono substituted, presumably owing to the propensity of the intermediate pyrrolyl keto acid chlorides **10***c* to cyclise to the five- and six-membered enol lactones, which upon work up gave the pyrrolyl keto acids **10***a*. These after esterification to the ethyl esters **10***b* were reduced by diborane in ethyl acetate – tetrahydrofuran to **11***a*, which were selectively saponified (carboxylalkyl side-chain esters saponify much faster than nuclear carboxylate esters which are vinylogous carbamates) to **11***b*. These two carboxylic acids along with the pyrrolylpropionic acid **11***b* (n = 3) prepared similarly from the readily available ester (Knorr synthesis with methyl 4-acetyl-5-oxohexanoate and ethyl oximinoacetoacetate) were treated with oxalyl chloride, followed by **8** (R = H) and reduction of the keto bispyrrole with diborane gave **1** (n = 3, 4, and 5) in high yields.

So far the ethane-linked bispyrrole **1** (n = 2) has not been prepared by the above routes owing to the insolubility of the acid **11***b* (n = 2) prepared by reductive alkylation of **8** (R = H) with glyoxylic acid, and the instability of its acid chloride **11***c* (n = 2) under the reaction conditions.

Most of the above pyrrolic intermediates were prepared as the ethyl esters and then transesterified to their benzyl esters, ready for hydrogenolysis to the diacid **2**. Condensation of **2** with the formyl-



SCHEME 1

pyrrole **3** gave ~90% yields of the bisdipyrromethenes **4** for the cases studied (n = 0–8). Condensation of **4** with an excess of the bromomethyldipyrromethene **5** gave the bisbiladienes-*a*,*c* which were converted, under conditions of the Johnson porphyrin synthesis (12), into the covalently linked dimeric porphyrins[1] **7** in yields of 55–70% for n = 3–8 and in the sterically hindered systems ca. 30% yields based upon **4**.

These systems, and doubly linked cyclophane porphyrins which are available by modifications of

[1]All of the porphyrins and their precursors give elemental analyses, electronic, ^{1}H and ^{13}C nmr, and mass spectra consistent with their proposed structures. All of the sequences leading up to the porphyrins are notable for their excellent yields. The Friedel–Crafts acylations and diborane reductions proceeded in 80–90% yields; the dimeric dipyrromethenes were all isolated in 85–95% yields based upon the preceding dibenzyl esters, and the transbenzylations, where employed, gave 90–95%. The selective saponifications give 95% recovery of the desired product.

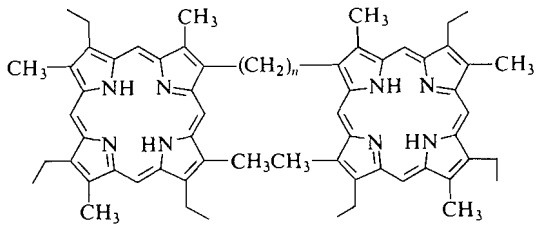
Faisant appel à la spectroscopie d'absorption électronique et de rmn du ^{13}C, on a mesuré les interactions entre des porphyrines dimères liées d'une façon covalente à leur périphérie.
[Traduit par le journal]

A number of dimeric porphyrins has recently been reported (1–9) covalently joined via amide or ester linkages in a manner similar to the systems which we initially prepared (10). The electronic absorption spectra of these various dimers show a variety of changes in their electronic transitions, compared to the corresponding monomeric species, which are related to small changes in their conformations.

Thus a blue shift in the Soret band of cofacial porphyrin dimers has been observed by Chang *et al.* (1) and Collman *et al.* (2) whereas Kagan *et al.* (7) saw no change in the Soret region but a considerable red shift in the visible region.

We (11) have recently prepared dimeric porphyrins covalently linked directly at their periphery (β,β′-bisporphins), or via a hydrocarbon chain, i.e., **1**



1

where n = 1–8. Figure 1 shows the electronic spectra for the free bases n = 0, 1, and 8, and for monomeric etioporphyrin I.[1] Figure 2 shows the spectra of the same four species in their protonated forms (each porphyrin ring is an *N,N*-diprotonated dication). Recently an extensive discussion of exciton coupling in the μ-oxo dimer of Sc porphyrins has been given (12). The considerations there can be applied with some extension to the present case. In general the exciton coupling parameter between identical units for a dimer electronic band depends on

$$V = (\mu^2/R^3)f$$

Here μ^2 is the transition dipole strength of the monomer and depends on the molar extinction coefficients of the band; R is the distance between centers; and f is a factor depending on the vector relations among the transition dipoles on each unit and the vector direction between centers, with $-2 \leq f \leq 1$. For the visible bands where μ^2 is small, V is comparable to the solution line-width, so the only effect of dimer formation is a slight broadening of the lines and a very small bathochromic shift. For the Soret band, V is substantially larger and more apparent effects are expected.

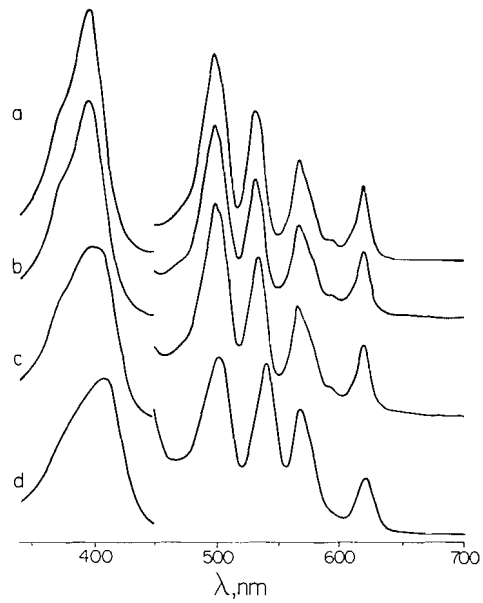


FIG. 1. Electronic spectra of free base porphyrins in CH_2Cl_2: *a* = etioporphyrin I, *b* = **1**, n = 8; *c* = **1**, n = 1, *d* = **1**, n = 0.

For the dimer **1** (n = 8) no changes are observed between its spectra, of both the free base and protonated cations, and those of etioporphyrin I, suggesting that the two porphyrin rings in this dimer (whose centres could be greater than 15 Å apart) do not interact. But in the n = 1 and n = 0 dimers, a significant effect on the Soret band is observed, including the appearance of two resolved bands in the dication case. To understand this it should be recalled that the Soret band of each dication monomer arises from doubly degenerate excited states X_1, Y_1 on one unit and X_2, Y_2 on the other. The

[1]Etioporphyrin I is 2,7,12,17-tetraethyl-3,8,13,18-tetramethylporphyrin and has the same substitution pattern as the dimers **7**, except that the bridging group in the dimer is replaced by an ethyl group.

*Degenerate peaks; superscript indicates probable number of carbons in coincidence. For $n \geq 3$, the amount of degeneracy of a given peak is not always ascertainable.
†Unique carbons for odd numbered carbon linkage.

exact interaction among the four excited states depends on the detailed geometry, which is not as yet known. But for a variety of geometries, to a first approximation the four states interact pairwise. Thus the four resulting dimer excited states are roughly of form $(X_1 \pm X_2)(2)^{-1/2}$ and $Y_1 \pm Y_2)(2)^{-1/2}$. The expected geometry for $n = 0$ would have the transition dipoles of one pair of states, call these X_1 and X_2, parallel to the vector $\boldsymbol{R}$ between centers; the allowed exciton state then is the one at lower energy. The transition dipoles for the other pair, call these Y_1 and Y_2, would be perpendicular to $\boldsymbol{R}$; here the allowed exciton state may be unshifted or blue shifted depending on the detailed orientation. This may account for the well-resolved doublet observed in the Soret band for the dication with $n = 0$. However, in the free base, the Soret states X_1, Y_1 are nondegenerate in the monomer, and the interaction with X_2, Y_2 will be far more complicated. Thus, only an unresolved, highly broadened Soret band is observed. Similar, though less well resolved transitions are observed for the dimer $n = 1$.

The electronic interaction between the two porphyrin rings in the dimers is also evident when examining their ^{13}C magnetic resonance spectra. The spectra were obtained from deuteriochloroform solutions containing an excess of trifluoracetic acid, to increase the solubility and allow the observation of α carbons by eliminating NH tautomerization (13).

For chain length ≥ 3, the porphyrin nucleii are largely pseudosymmetrical, as the charge-repulsion entailed by diprotonation of each macrocycle should tend to minimize the interaction. The 16 α and β carbons (of each porphyrin) which are in fact entirely nonequivalent, give 7 signals of varying degeneracy for $n = 4$, 5, 7, and 8, 9 signals for $n = 6$, 8 for $n = 3$ but 13 each for $n = 0$ or 1 (Table 1).

The *meso* carbons give only a single broad peak for all *n greater* than 2, but resolve into four well-defined peaks for *n less* than 2.

The substituent ethyl groups give single peaks at δ 16 and 20, and the methyls produce a singlet near 11.7 δ, when *n* greater than 2, with the anomalous exception of $n = 6$, which gives an additional methyl

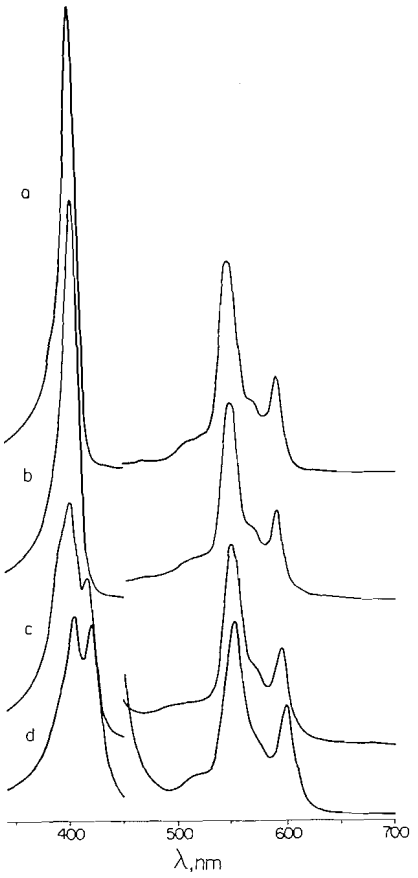

FIG. 2. Electronic spectra of *N,N*-diprotonated porphyrins in CH_2Cl_2–TFA: *a* = etioporphyrin I; *b* = **1**, *n* = 8; *c* = **1**, *n* = 1; *d* = **1**, *n* = 0.

peak at δ = 11.53. The cases *n* = 0 and 1 show an extra ethyl peak near 16, and three (*n* = 0) or four (*n* = 1) methyl peaks.

Thus only when the porphyrins are constrained to be proximate, are the interactions sufficiently strong to reduce the pseudodegeneracy. The *n* = 2 example is clearly of interest as the boundary point of these interactions but is as yet unavailable.

The linking chain itself is of interest: the termini, linked to the porphyrin, are shielded relative to the other carbons, and occur in the range 26.5–27 ppm, except for the *n* = 1 case, which appears even further upfield, at 25. The penultimate carbon is the farthest downfield, typically at 32–32.2 δ, except for the *n* = 3 case, where this carbon has a doubled relationship and is down to 34.1. Interior carbons occur in the 29.3–30.4 range. We anticipate that a more detailed analysis of these and other data on metallo-derivatives of the dimers reported here will give a greater insight into the conformation that these species can adopt, and upon the relationship between the distance and orientation of porphyrin chromophores, and the effect upon energy transfer between porphyrins as a function of the orientation and distance between the chromophores.

Long-range ^1H, ^{19}F spin–spin coupling constants in benzenesulfonyl fluoride and some of its derivatives. Insensitivity of ^{19}F shifts to *ortho* substituents

TED SCHAEFER AND WILLIAM J. E. PARR[1]

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 6, 1978

TED SCHAEFER and WILLIAM J. E. PARR. Can. J. Chem. **56**, 1717 (1978).

The proton and ^{19}F high resolution nuclear magnetic resonance spectra of benzenesulfonyl fluoride and of some derivatives are analyzed to yield spin–spin coupling constants between ^{19}F and the ring protons. These parameters display a marked dependence on the ring substituents and it is not clear how their conformational behaviour can be distinguished from intrinsic substituent perturbations. The large magnitudes of the couplings over six bonds to the *para* protons, relative to those in benzoyl fluoride, strongly indicate the importance of conformations in which the S—F bond does not lie in the benzene plane. The methyl group replacement technique suggests that the six-bond coupling contains contributions in addition to that from a σ–π mechanism. The chemical shift of the *para* proton yields a π electron density at the contiguous carbon atom which is considerably smaller than in nitrobenzene, for example. The ^{19}F shifts are much less sensitive to *ortho* substituents than are the ^{19}F shifts in benzoyl fluoride derivatives, implying much smaller intramolecular van der Waals interactions in the sulfonyl compounds.

TED SCHAEFER et WILLIAM J. E. PARR. Can. J. Chem. **56**, 1717 (1978).

On a analysé les spectres de résonance magnétique nucléaire à haute résolution du proton et du ^{19}F du fluorure de benzènesulfonyle et de quelques-uns de ses dérivés pour obtenir les constantes de couplage spin–spin entre le ^{19}F et les protons du cycle. Ces paramètres présentent une dépendance marquée sur les substituants du cycle et il n'est pas clair comment leur comportement conformationnel peut être distingué des perturbations intrinsèques dues aux substituants. Les très grandes valeurs des constantes de couplage à travers six liens avec les protons en *para*, relatives à celles obtenues dans le fluorure de benzoyle, indiquent d'une façon bien marquée l'importance des conformations dans lesquelles le lien S—F ne se trouve pas dans le plan du benzène. La technique du remplacement du groupe méthyle suggère que le couplage à travers six liaisons contient des contributions supplémentaires par rapport à celles du mécanisme σ–π. Le déplacement chimique du proton *para* indique la présence d'une densité électronique π au niveau de l'atome de carbone contigu qui est beaucoup plus faible que celle présente, par exemple, dans le nitrobenzène. Les déplacements chimiques du ^{19}F sont beaucoup moins sensibles aux substituants *ortho* que les déplacements chimiques du ^{19}F dans les dérivés du fluorure de benzoyle; ce résultat implique que des interactions de van der Waals intramoléculaires sont beaucoup plus faibles dans le cas des dérivés sulfonyles.

Introduction

The long-range couplings between protons or ^{19}F nuclei on the side chain and protons or ^{19}F nuclei on the benzene ring are of interest in the elucidation of spin–spin coupling mechanisms (1), can often be used in the deduction of conformational preferences (ref. 2 and references therein) and even of small barriers to internal rotation (0–3 kcal/mol) about the bonds connecting the side chains to the benzene ring (3). Detailed measurements, frequently accompanied by semiempirical calculations, of the long-range couplings have been made for CH_3 (ref. 4 and references therein), CH_2X, where X = OH, F, Cl, Br, I, CH_3, etc.; cyclo-C_3H_5, CHX_2, SiH_3, SiH_2X,

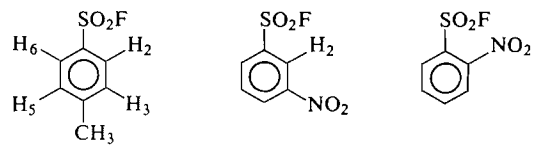
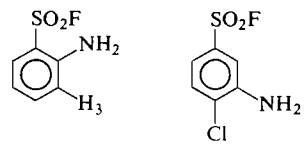
$SiHX_2$; CF_3, SiF_3; CHO, COF; OH, SH, SeH; and other side chains (2–11).

The couplings involving ^{19}F in the SO_2F moiety are available for three benzenesulfonyl fluoride derivatives, $C_6F_5SO_2F$ (12), 2,4,6-tri$(CH_3)C_6H_2$-SO_2F and 2,5-di$(F)C_6H_3SO_2F$ (13). In this paper we report full analyses of the proton and ^{19}F magnetic resonance spectra for benzenesulfonyl fluoride, **1**, and five of its derivatives, **2–6**.



2 **3** **4**



5 **6**

Experimental

Compound **1** was prepared from the sulfonyl chloride by treatment with aqueous KF, as was the *m*-nitro derivative. The other compounds were of commercial origin.

The ^{1}Hmr spectra of 5–10 mol% degassed solutions in $CDCl_3$ (but see Table 2) were recorded in the frequency sweep mode at 100.001 MHz on an HA100 spectrometer at 305 K. Repeated calibrations involved the reading of sweep and of lock oscillator frequencies at approximately 5 Hz intervals. The ^{19}F magnetic resonance spectra were similarly calibrated at 56.443 MHz on a DA60I spectrometer at 302 K. The samples contained tetramethylsilane and $CFCl_3$ as internal lock sources.

The relative signs of the $^1H,^{19}F$ coupling constants were determined by double resonance experiments (14) and have been related to $^1H,^{19}F$ couplings within the ring of the 2,5-difluoro compound (13), so that their absolute signs are fairly certain.

Results and Discussion

Spectral Analyses

These proceeded in a straightforward manner according to the computer program LAME (15, 16). In Table 1, the spectral parameters for 3-nitrobenzenesulfonyl fluoride are tabulated, giving an idea of the precision of the analyses. Rather than tabulate all parameters for the other compounds (the ring proton shifts for **1** being available in Table 1), the coupling constants to ^{19}F and its shift relative to internal $CFCl_3$ are presented in Table 2. These data are most pertinent to the following discussion.

Ring Proton Parameters

The shift of the *para* proton, δ_4, of 8.01 ppm downfield of TMS for **1**, is considerably larger than that for nitrobenzene, 7.65 ppm (17), or benzoyl fluoride, 7.64 ppm (18) in CCl_4. These data suggest that the SO_2F group withdraws π electron density from C4 to a significantly greater degree than do the NO_2 or COF groups. The shift of C_6H_6 can be taken as 7.25 ppm, so that SO_2F is a somewhat stronger π electron withdrawer than NH_2 is a donor, δ_4 being 6.62 ppm is aniline (17). A proton chemical shift of about 11 ppm/π electron at the contiguous carbon (19) indicates an increase in electron density of about 0.13 electrons in going from **1** to aniline. Recent *ab initio* calculations yield a difference of 0.087 electron at C4 in aniline and nitrobenzene (20), in decent agreement with the above considerations (a proportionality factor of 12 ppm/π electron gives almost exact agreement with the observed shift difference of 1.03 ppm but may be fortuitous). In any event, it appears that the SO_2F group reduces the π electron density at the *para* position by 0.06–0.07 electrons when allowance is made for slight differential solvent shifts between CCl_4 and $CDCl_3$ (21).

The plethora of ring proton shifts and coupling

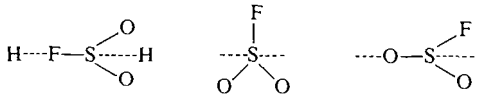
constants within the ring will not be further discussed. The data will be forwarded on request.

Substituent and Conformational Dependence of Coupling Constants to ^{19}F

The couplings to *ortho* and *meta* protons in **1**, of −0.56 and 1.04 Hz, respectively, are similar to those in benzoyl fluoride, viz., −0.60 and 1.33 Hz (5). Both couplings are strongly dependent on the presence of ring substituents, e.g., $^5J_m^{H,SF}$ sinks to 0.38 Hz in the presence of an *ortho*-nitro group (Table 2) in both C_6D_6 and $CDCl_3$ solutions. Apparently it would be difficult to separate the substituent from the conformational dependence of these coupling constants.

Part of the complexity arises from our ignorance of the conformational preferences of the SO_2F group. An STO-3G calculation (22), using a regular geometry for the benzene ring and the SO_2F geometry previously described (13), gave **8** as 3.2 kcal/mol higher in energy than **9**; **10** was of intermediate



8 **9** **10**

energy. These calculations suggest that $^6J_p^{H,SF}$ should be finite and negative if it arises via a σ–π mechanism (4, 23); just as $^6J_p^{H,CF}$ should vanish in benzoyl fluoride, as it does (5), because the C—F bond prefers the benzene plane by some 4 kcal/mol (24). The σ–π coupling increases in magnitude as $\sin^2\theta$, where θ is the angle by which the S—F bond twists out of the benzene plane.

The observed $^6J_p^{H,SF}$ in **1** is −0.67 Hz (Table 2). However, the σ–π mechanism also implies that replacement of the *para* proton by a methyl group should entail (25–27) $-^6J_p^{H,SF} \simeq {}^7J_p^{CH_3,SF}$. Yet the latter is +1.01 Hz in **2**, of the correct sign but much too large (assuming a *para*-methyl group does not alter the SO_2F conformational preferences). As ^7J does presumably measure the σ–π contribution to ^6J (11, 25–27), it follows that ^6J contains a positive σ electron contribution[2] of about 0.34 Hz. Its angle dependence is not known. Consequently, any hope of using ^6J in the determination of barriers to internal rotation (3, 28) in **1** or its derivatives is probably a forlorn one.

Furthermore, $^6J_p^{H,SF}$ becomes −1.1 Hz in the presence of an *ortho*-nitro group, whereas it remains unchanged in the presence of an *ortho*-amino substituent and changes only slightly on introduction of an *ortho*-fluorine atom (Table 2). Because of the σ electron contribution, it is not possible to decide whether the nitro group exerts an intrinsic substituent effect on this component of ^6J or on the σ–π component, or if it indeed forces the S—F bond farther towards a plane perpendicular to the benzene ring. These complexities stand in sharp contrast to the behaviour of $^6J_p^{H,CH}$ in toluene derivatives (3, 4, 7), which displays only a $\sin^2\theta$ dependence and a minimal dependence on the electronic properties of the ring substituent.

It does appear that the S—F bond spends considerable time away from the benzene plane but the present coupling data cannot confirm the STO-3G predictions of relatively strong conformational preferences. The coupling data are also consistent with weak conformational preferences of the SO_2F group.

The ^{19}F Chemical Shifts

These occur some 40 ppm to low field of the shifts in benzoyl fluoride derivatives (29). The range of

[2]If couplings over six bonds between ^{19}F on a side chain and a ring proton contain σ electron contributions, then previous assumptions about such couplings in benzyl fluoride (28) are incorrect. These problems are under investigation.

For personal use only.

2.3 ppm in the shifts (Table 2) contrasts sharply with the lowfield shift of up to 35 ppm experienced by ^{19}F in *ortho*-substituted benzoyl fluoride derivatives (30). The latter are very likely caused by strong intramolecular van der Waals interactions between the fluorine atom in the COF group and the *ortho* substituents. Such interactions are highly sensitive to interatomic distances. The preferred planar conformation of benzoyl fluoride (24) favors small distances between the fluorine atom and the *ortho* substituents.

Accordingly, the relative insensitivity to *ortho* substituents of the ^{19}F shifts in the sulfonyl fluorides suggests that the S—F bond can easily avoid the *ortho* groups; although, as indicated by $^{6}J_{p}^{H,SF}$, the S—F bond is not forced into conformations analogous to **8**.

The internal barriers to rotation about the carbon–carbon bond in 3,5-dichlorobenzyl alcohol and selenol by the *J* method

TED SCHAEFER, WERNER DANCHURA, WALTER NIEMCZURA, AND WILLIAM J. E. PARR

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 17, 1978

TED SCHAEFER, WERNER DANCHURA, WALTER NIEMCZURA, and WILLIAM J. E. PARR. Can. J. Chem. **56**, 1721 (1978).

The *J* method, depending on a comparison between observed spin–spin coupling constants over six bonds between protons on a side chain and *para* ring protons and those calculated by a hindered rotor treatment, is applied to the determination of the twofold barrier to internal rotation about the carbon–carbon bonds in 3,5-dichlorobenzyl alcohol and selenol. In the alcohol, the C—O bond prefers the benzene plane by 0.3 ± 0.2 kcal/mol whereas, in the selenol, the C—Se bond prefers a plane perpendicular to the benzene ring by 3.8 ± 0.7 kcal/mol. Comparison with the thiol suggests that a major component of the barrier arises from repulsive interactions, increasing as the size of the XH (X = O, S, Se) group increases.

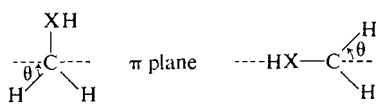
TED SCHAEFER, WERNER DANCHURA, WALTER NIEMCZURA et WILLIAM J. E. PARR. Can. J. Chem. **56**, 1721 (1978).

On a appliqué la méthode *J*, qui dépend d'une comparaison entre les constantes de couplage spin–spin observées à travers six liaisons entre des protons d'une chaîne latérale et les protons du cycle en position *para* et les constantes calculées par un traitement de rotor empêché, à la détermination de la barrière binaire à la rotation interne autour des liens carbone–carbone des alcool et sélénol du dichloro-3,5 benzyle. Dans l'alcool, le lien C—O préfère la conformation dans le plan du benzène par 0.3 ± 0.2 kcal/mol alors que dans le sélénol le lien C—Se préfère une conformation perpendiculaire au plan du cycle benzénique par 3.8 ± 0.7 kcal/mol. Une comparaison de ces données avec celles obtenues avec les thiols suggère qu'une composante importante à la barrière à la rotation provient d'interactions de répulsion dont l'importance croît à mesure que la grosseur du groupe XH (X = O, S, Se) augmente.

[Traduit par le journal]

Introduction

In a recent application of the *J* method, a value of 1.8 ± 0.2 kcal/mol was estimated for the twofold barrier to internal rotation about the carbon–carbon bond in 3,5-dichlorobenzyl mercaptan (1). Conformation **1** was demonstrated to be the reasonable low-energy form, with **2** as the conformation of high energy.



θ = 30° **1** θ = 60° **2**

The *J* method for the determination of small twofold barriers depends on the experimental (2, 3) and theoretical (4) knowledge that $^6J_p^{H,CH}$, the spin–spin coupling constant over six formal bonds between the side-chain proton and the *para* ring proton, is proportional to $\langle \sin^2\theta \rangle$, the average or expectation value of $\sin^2\theta$. The angle θ measures the out-of-plane twist of the C—H bond containing the coupled proton. Application of a hindered rotor formalism (5) leads (6) to a value of $\langle \sin^2\theta \rangle$ as a function of internal barrier, temperature, and the reduced moment of inertia about the bond around which rotation occurs; being quite insensitive to the last parameter. A knowledge of $^6J_{90}$, the six-bond coupling for a conformation in which the side-chain C—H bond lies in a plane perpendicular to the benzene plane, is also required.

The presence of the chlorine atoms at the *meta* positions does not perturb $^6J_p^{H,CH}$ (7, 8) and allows a more accurate determination of this quantity; benzyl systems normally giving rise to very tightly coupled phenyl ring ^{1}H nmr spectra at 100 MHz.

If the barrier in 3,5-dichlorobenzyl mercaptan is determined mainly by steric interactions in **2**, it follows that in the benzyl alcohol the barrier should be considerably reduced and that in the benzyl selenol a higher barrier should exist. Indeed, *ab initio* molecular orbital calculations at the STO3G level (9) suggest that the C—O bond in benzyl alcohol prefers the benzene plane to the extent of 0.22 kcal/mol, perhaps because C—O hyperconjugation is less effective in lowering the energy than is C—H hyperconjugation.

In this paper, the *J* method is applied to the determination of the internal barrier in the alcohol and the selenol. It turns out that the barriers lie at the low and high extremes at which the *J* method becomes insensitive to the actual barrier. Nevertheless, useful

conclusions about conformational energetics can be made.

Experimental

The 3,5-dichlorobenzyl alcohol was prepared from the commercial benzoic acid by reduction with $LiAlH_4$. The bromide followed by treatment with PBr_3. The 3,5-dichlorobenzyl selenol was synthesized from the bromide via the Grignard reagent, exactly following the procedure given for the preparation of phenyl selenol (10). The ^1H nmr spectra left no doubt about the identity of the alcohol and selenol.

^1H nmr spectra of the benzyl alcohol were recorded for a 5 mol% solution in C_6D_6 and for a 1 mol% solution in CS_2, whereas, for reasons of spectral dispersion, the selenol had its spectrum recorded as a 10 mol% solution in C_6D_6. All solutions were degassed by the freeze–pump–thaw technique and contained a small amount of internal TMS. Spectra were repeatedly calibrated by interpolation between markers placed at 5 Hz intervals in the frequency sweep mode of an HA100 spectrometer at a probe temperature of 305 K. At sweep rates of 0.02 and 0.01 Hz/s and a dispersion of 1 Hz/cm, this procedure yielded peak positions with a standard deviation comparable to that between calculated and observed spectra in the spectral analyses.

Results and Discussion

Spectral Analyses

Performed by means of the computer program LAME (11, 12), the analyses gave the spectral parameters in Table 1. The standard deviations of well below 0.01 Hz suggest an accuracy of at least 0.02 Hz in the parameters of greatest interest, viz. $^6J_p^{H,CH}$. It may be noted that $^6J_p^{H,CH_2}$ was -0.59 Hz for the alcohol in both CS_2 and C_6D_6 solutions. Because the OH and SeH protons do not couple to the ring protons the spectra are easily assigned as AB_2X_2R spin systems.

The Barriers and Conformations

3,5-Dichlorobenzyl Alcohol

The value of $^6J_p^{H,CH}$ is -0.59 Hz in both CS_2 and C_6D_6 solutions, at concentrations differing by a factor of 5, suggesting that intermolecular association is ineffective at altering this coupling constant. This is not to say that the barrier in the liquid state must be the same as in the gaseous state.

In previous work it was argued that the substituent in the methyl group reduces the magnitude of $^6J_{90}^{H,CH}$ if it is much more electronegative than hydrogen (8). The reduction can occur because the localization of the π type molecular orbitals of the CH_2OH group is greater than in the CH_3 group (13). A value of -1.14 Hz for CH_2Cl led to a reasonable barrier in benzyl chloride, and was estimated on the basis of a monotonic relationship between $^6J_{90}^{H,CH}$ and electronegativity. A linear extrapolation (E_H = 2.1, E_{Cl} = 3.0, E_{OH} = 3.5) yields $^6J_{90}^{H,CH}$ as -1.08_5 Hz for CH_2OH. In that situation, $\langle \sin^2 \theta \rangle$ becomes 0.54 ($0.59/1.08_5$) and the internal barrier is 0.4 ± 0.2 kcal, where an error of 0.02 is assumed in $\langle \sin^2 \theta \rangle$.

An alternative approach to $^6J_{90}^{H,CH}$ for CH_2OH takes the value of -1.09 Hz for CH_2F calculated (6) by INDO–MO–FPT (14). These calculations are successful in finding reasonable values for the β-proton hyperfine coupling constants in the β-fluoroethyl radical; such couplings are also transmitted via a σ-π mechanism (15). Furthermore, the calculations exactly reproduce the magnitude and $\langle \sin^2 \theta \rangle$ dependence of $^6J_p^{H,CH_3}$ in toluene (4). In this situation, $^6J_{90}^{H,CH}$ is -1.13 Hz, $\langle \sin^2 \theta \rangle$ becomes 0.52 and the internal barrier is 0.1 ± 0.2 kcal/mol.

In both instances, the stable form is **2**. If the stable form were **1**, $\langle \sin^2 \theta \rangle$ would be <0.5. Such a situation could be achieved if $^6J_{90}^{H,CH}$ for CH_2OH had a magnitude of greater than 1.18 Hz, i.e., $>0.59/0.5$ Hz. If, in fact, $^6J_{90}^{H,CH}$ were unchanged from its value of -1.24 Hz in toluene,[1] then $\langle \sin^2 \theta \rangle$ would be 0.47_6 and the internal barrier would be 0.2 ± 0.2 kcal/mol, with **1** most stable.

Abraham and Bakke (16, 17) show that the hydroxyl proton chemical shift and the geminal proton coupling constant in benzyl alcohol itself are consistent either with free rotation about the C—C bond or with a conformation in which the C—O bond is rotated by 60° out of the benzene plane. Such a conformation implies that $\langle \sin^2 \theta \rangle$ varies between 0.37_5 for a very large barrier (>3 kcal/mol) and 0.50 for a vanishing barrier. If $^6J_{90}$ is in fact equal to -1.24 Hz, then this conformation as the ground state, but with a barrier to rotation of about 0.5 kcal/mol, is compatible with our coupling data.

In our opinion, the coupling data are best fitted by 0.3 ± 0.2 kcal/mol for the twofold barrier to internal rotation in 3,5-dichlorobenzyl alcohol, **2** being the most stable conformation, in perhaps accidental agreement with STO-3G calculations on benzyl alcohol.

3,5-Dichlorobenzyl Selenol

The value of $^6J_p^{H,CH}$ is -0.37 Hz, yielding $\langle \sin^2 \theta \rangle$ as 0.29_7 if $^6J_{90}^{H,CH}$ is -1.24 Hz; or, if the electronegativity of the SeH· group is taken as 2.4, then $^6J_{90}^{H,CH}$ is -1.21 Hz according to the discussion given for CH_2OH and $\langle \sin^2 \theta \rangle$ is 0.30_4. For a very large barrier, $\langle \sin^2 \theta \rangle$ would be 0.25 for **1** as the ground state conformation. In other words, the barrier is substantial and in a region where the J method is rather insensitive to the barrier. The plot of $\langle \sin^2 \theta \rangle$ vs. barrier yields 3.8 ± 0.7 kcal/mol for

[1]Coupling constant data for compounds of known conformation indicate that the estimated $^6J_{90}$ values are reasonably good (S. Sternhell and C. Fallick. Private communication).

TABLE 1. Proton chemical shifts[a] and coupling constants for 3,5-dichlorobenzyl alcohol and selenol at 305 K

Parameter	Value OH[b]	Value SeH[c]	Parameter	Value OH	Value SeH
ν_{XH}	195.020(5)[d]	−40.299(3)[e]	$^4J_{24}{}^{H,H}$	1.917(5)	1.894(3)
ν_{CH_2}	456.130(6)	298.829(4)	$^4J_o{}^{H,CH_2}$	−0.775(6)	−0.487(4)
ν_2	712.593(5)	674.949(3)	$^6J_p{}^{H,CH_2}$	−0.588(7)[f]	−0.368(3)
ν_4	714.956(5)	694.668(2)	Root mean square		
$^3J^{XH,CH_2}$	5.951(6)	6.804(3)	deviation	0.019	0.012

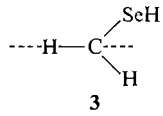
[c]For a 10 mol% solution in C_6D_6.
[d]The numbers in parentheses give the standard deviations in the last place.
[e]To high field of internal TMS.
[f]$^6J_p{}^{H,CH_2}$ for a 5 mol% solution in C_6D_6 was −0.585(7) Hz.

an error of 0.02 in $\langle \sin^2 \theta \rangle$. It seems certain that the barrier is larger than 3 kcal/mol.

An alternative ground state conformation might have been **3**, for which $\langle \sin^2 \theta \rangle$ would have varied



3

between 0.5 for zero barrier and 0.375 for a very large barrier, i.e., the observed $^6J_p{}^{H,CH}$ would have fallen between −0.62 and -0.46_5 Hz. Therefore **3** need not be considered because the observed $^6J_p{}^{H,CH}$ is −0.37 Hz.

The derived barriers for the series OH, SH, and SeH are 0.3 ± 0.2, 1.8 ± 0.2, and 3.8 ± 0.7 kcal/mol, respectively, the value for SH having the lowest percentage error because the J method is most accurate for barriers between about 0.8 and 2.2 kcal/mol when **1** is the low energy conformation. It appears that the sizes of the substituent and, therefore, repulsive forces, play a major role in these barriers. Furthermore, the barriers for the corresponding CH_2F (6), CH_2Cl, and CH_2Br (8) compounds display a similar gradation.

A novel acid-catalyzed isomerization of the adducts of 1,4-dimethyl-2,3-diphenylcyclopentadiene and dialkyl azodicarboxylates

LÊ H. DAO[1] AND DONALD MACKAY

The Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received October 7, 1977

LÊ H. DAO and DONALD MACKAY. Can. J. Chem. **56**, 1724 (1978).

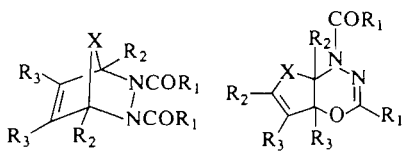
The adduct (**4***a*) of 1,4-dimethyl-2,3-diphenylcyclopentadiene with dimethyl azodicarboxylate is isomerized by one or more equivalents of trifluoroacetic acid to the exocyclic alkene **5***a*. The di-*tert*-butyl analogue **4***b* is isomerized by limited amounts of trifluoroacetic acid to a mixture of **5***b* and the oxadiazine **10**, the latter being the only product with 1 equiv. of acid; **5***b* can be made more efficiently from **4***b* by the action of pyridine or triethylamine. Excess acid converts **4***b*, **5***b*, or **10** to the oxadiazinone **7**. A protonated intermediate derived from **4***b* is postulated as the precursor to both **5***b* and **7** in acid, a view supported by deuterium labelling studies.

LÊ H. DAO et DONALD MACKAY. Can. J. Chem. **56**, 1724 (1978).

L'adduit (**4***a*) du diméthyl-1,4 diphényl-2,3 cyclopentadiène avec l'azodicarboxylate de diméthyle peut être isomérisé par un ou plusieurs équivalents d'acide trifluoroacétique pour conduire à l'alcène exocyclique **5***a*. L'analogue di-*tert*-butyle **4***b* peut être isomérisé par des quantités faibles d'acide trifluoroacétique pour conduire à un mélange de **5***b* et d'oxadiazine **10**; ce dernier composé est le seul produit lorsque l'on traite **4***b* par un équivalent acide. On peut obtenir **5***b* d'une façon plus efficace à partir de **4***b* par l'action de la pyridine ou de la triéthyl amine. Le traitement de **4***b*, **5***b* ou **10** par de l'acide en excès conduit à l'oxadiazinone **7**. On fait l'hypothèse qu'un intermédiaire protoné dérivé de **4***b* serait le précurseur aussi bien de **5***b* que de **7** en milieu acide; cette hypothèse est supportée par des études de marquages au deutérium.

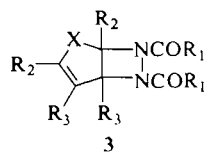
[Traduit par le journal]

The role of the substituents X, R_1, R_2, and R_3 in the thermal and acid-catalyzed isomerizations of **1** has been discussed in some detail (1). In particular the rate enhancement trends X = CO > X = CH_2 and R_1 = alkyl or aryl > R_1 = alkoxy or aryloxy have been clearly established (1*e*). Thus *N*-acyloxy groups, unlike their *N*-acyl counterparts, were thermally unreactive in the adducts of cyclopentadiene (**1**, X = CH_2, R_2 = R_3 = H) but participated readily in the thermal or acid-catalyzed isomerization of the adducts of 2,5-dimethyl-3,4-diphenylcyclopentadienone (**1**, X = CO, R_2 = Me, R_3 = Ph) to give both the oxadiazines **2** and the diazetidines **3** (1*c*).



1

2



3

We now wish to describe briefly the intermediate case, with the methyl and phenyl substituents but with CH_2 rather than CO in the bridge (**1**, X = CH_2, R_2 = Me, R_3 = Ph). Specifically we have studied the dimethyl and di-*tert*-butyl esters **4***a* and *b* which show that yet another isomerization pathway is available to bridged pyridazine systems like **1**.

The expected Diels–Alder reaction between 1,4-dimethyl-2,3-diphenylcyclopentadiene and dimethyl or di-*tert*-butyl azodicarboxylate occurred readily (the former reaction is extremely fast) in benzene, or in carefully purified chloroform or carbon tetrachloride.[2] The spectroscopic properties of the adducts **4***a* (mp 162–163°C) and **4***b* (mp 157.5–159°C), fully supported the assigned structures, in particular the *C*- and *O*-methyl singlets in the ^{1}Hmr spectra.

In the absence of traces of acid or base, the adducts **4** were thermally much more stable than their carbonyl bridged counterparts. Thus when heated in hydrocarbon solvents at reflux they showed little reaction in toluene but were decomposed slowly in xylene and rapidly in decalin.

Heating **4***a* in benzene containing 1 equiv. or more of trifluoroacetic acid (TFA) resulted in the formation of a glassy isomer (90% yield by ^{1}Hmr analysis).

[1]Present address: Department of Chemistry, York University, Downsview, Ont.

[2]Stock reagents caused isomerization of the adducts, very rapidly in the case of **4***a*, perhaps owing to traces of acid in the solvents.

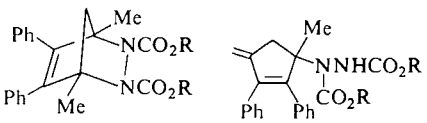
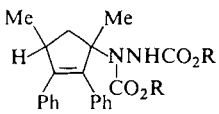
Its ir spectrum (CCl_4) had NH absorptions at 3420 and two ester carbonyl absorptions at 1768 and 1732 cm^{-1}. Of note in its ^{1}Hmr spectrum ($CDCl_3$) were two methoxy singlets at 6.32 and 6.26, a *tert*-methyl singlet at 8.45, a widely separated methylene AB pair, the low field proton obscured by the ester groups, the high field one at 7.18, and two broad absorptions for one proton each at 5.05 and 5.15 τ. The latter absorptions were strongly indicative of a double bond exocyclic to methylene. The most reasonable structure for this isomer is **5***a*, supported by its ready hydrogenation (Pd–C) to a dihydro derivative **6***a*, whose ^{1}Hmr spectrum showed a distorted methyl doublet (second order), a complex tertiary proton absorption, and the absence of vinylic absorptions.



4 **5**

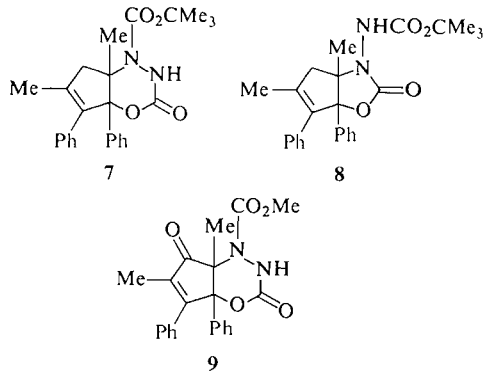


6

a R = Me
b R = CMe_3

The reaction of **4***b* in the presence of TFA was more complex. A solution at room temperature in neat TFA, or in carbon tetrachloride containing more than 1 equiv. of TFA, gave rapidly and quantitatively a compound $C_{25}H_{28}N_2O_4$ of mp 153.5–154.5°C, corresponding to the loss of C_4H_8. Structure **7** could be confidently assigned to this product, both by analogy with the product (**9**) of acid dealkylation of the three isomeric adducts from 2,5-dimethyl-3,4-diphenylcyclopentadienone and dimethyl azodicarboxylate (1*d*), and by its spectra. The ^{1}Hmr pattern derived from the carbocyclic ring resembled that observed in earlier work (1*d*, and *e*) with this ring system. The ir spectrum had, as well as NH absorption, two carbonyl bands at 1784 and 1763 cm^{-1}, attributable to the exo- and endocyclic ester groups, respectively; the value for the latter is more consistent with the six- than with a five-membered ring alternative (2), as in isomer **8**.

The formation of **7** from **4***b* parallels exactly that of **9** from **1** (R_1 = OMe, R_2 = Me, R_3 = Ph, X = CO) with excess TFA; in that case, if limited amounts of TFA were used, isomerization to the 1,3,4-oxadiazine and 1,2-diazetidine was observed to compete with solvolysis (1*d*). Examination by ^{1}Hmr spectroscopy of the reaction of **4***b* in scrupulously



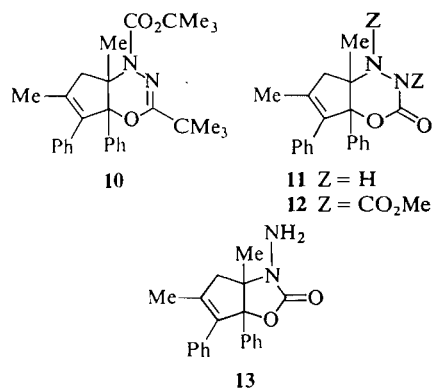
7 **8**

9

dry benzene-d_6 with limited amounts (0.05–1 equiv.) of TFA showed the formation of two isomers. One of these, in amounts never exceeding 25% of product, was readily recognized as the diene **5***b* by the exo- and endocyclic methylene ^{1}Hmr pattern characteristic of **5***a*; as more acid was added these peaks disappeared. The major isomer, whose formation was quantitative after 1 equiv. of acid had been added,[3] had two *tert*-butoxy singlets and otherwise absorptions very similar to those of **7**. Precipitation of the TFA as its pyridinium salt gave a benzene solution of the isomer, obtained on evaporation as an oil to which the structure **10** was assigned on the basis of its ir and ^{1}Hmr spectra.

Efforts to crystallize **10** failed. It proved to be extraordinarily labile to solvolysis, water, alcohols, or acids giving immediately the dealkylated product **7**.

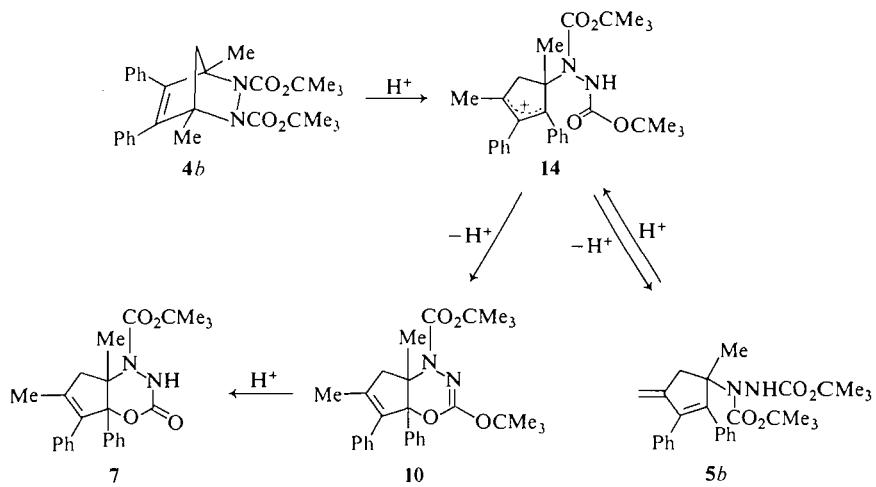
The isomerization reaction of **4***b*, described above, clearly shows that **5***b*, unlike **5***a*, is unstable towards high concentrations of TFA. Compound **5***b* could, however, be obtained as a solid (mp 155–155.5°C), in nearly quantitative yield, by heating **4***b* in carbon tetrachloride containing an excess of pyridine or triethylamine. It had spectra completely in line with



10 **11** Z = H
12 Z = CO_2Me

13

[3]If the equivalent of acid was added all at once the formation of **5***b* was not observed.



SCHEME 1

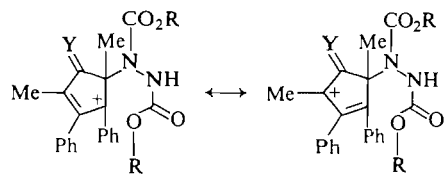
those of **5***a* and it too gave a dihydro derivative **6***b*, involving reduction of the exocyclic double bond. Treatment of **5***b* with excess of TFA resulted, as expected, in the quantitative formation of **7**.

Solvolysis of both *tert*-butyl groups could be achieved readily when either **4***b* or **5***b* was refluxed with dilute hydrochloric or sulfuric acid in methanol, or heated neat in TFA; (presumably **10** is an intermediate). The product **11** (M^+ 320) was an oil which resisted crystallization. It was recognized by the methyl and methylene patterns of its ^{1}Hmr spectrum and a weak NH and intense lactone absorption in its ir spectrum. An oily dicarbomethoxy derivative **12** (M^+ 436) was obtained by treatment with 2 equiv. of sodium hydride and methyl chloroformate in pyridine. The nonequivalence of the methoxy singlets in the ^{1}Hmr spectrum (benzene-d_6) of this product permitted rejection of **13** as an alternative isomer of the acid hydrolysis.

The isomerization and solvolysis reactions in acid and base described above are outlined in Scheme 1 for the *tert*-butyl case. The mechanistic relationship suggested between them involves as the key intermediate in acidic conditions the allylic cation **14**, which can be neutralized either by loss of a methyl H to give the diene **5***b* or by loss of amide H in cyclization to **10**. No ready explanation is apparent for the stability of **4***a* to excess of TFA.

The conversion of **14** to **5***b* as a major pathway is in contrast with the behaviour of the analogous protonated intermediates derived from the adducts of cyclones and azo esters, in which only cyclization to the oxadiazine is observed. The intermediate in the latter case is in fact an α-keto allylic cation, **15**. Its degree of positive character at the methyl substituted carbon is expected to be small (contrast the resonance contributions expected of **15***b* and **16***b*) and loss of a methyl H is correspondingly inhibited.

Some support for Scheme 1 is provided by deuterium studies using trifluoroacetic acid-*d*. When **4***b* was treated with excess of the labelled acid in benzene-d_6 the formation of **7** with an unlabelled vinylic methyl peak was observed in the ^{1}Hmr spectrum. Under identical conditions **5***b* gave **7** in which deuterium incorporation in the vinylic methyl group was almost complete. These results are consistent with the intermediacy of **14** to both **5***b* and **7**. They also show that in excess of acid the formation of **5***b* from **4***b* is negligible (a result already implied in footnote 3) and that **5***b* is not an intermediate to **7**.



a *b*

15 Y = O
16 Y = H,H

The possibility that acid could catalyze the synthesis of **4**, as well as its isomerization, was examined. Thus in the Diels–Alder reaction protonation of either the 1,4-dimethyl-2,3-diphenylcyclopentadiene or the azo ester could lead to a $4^+ + 2$ (3) or a $4 + 2^+$ reaction (4, 5). It was found (^{1}Hmr analysis) that an equimolar solution of diene and di-*tert*-butyl azodicarboxylate reacted in the presence of 0.5 mol equiv. of TFA in benzene-d_6 faster than without the catalyst but no **4***b* could be detected. The products were a mixture of **5***b* and (mainly) **7**. When **4***b* itself was treated with TFA under identical conditions it formed **5***b* and **7**[4] seven times faster than the previous reaction. This rate factor does not allow

[4]The failure to observe **10** in these reactions is probably because the solvent was not rigorously dried.

a decision to be made about the occurrence or otherwise of the acid-catalyzed Diels–Alder reaction.

Experimental

The following spectrometers were used: for ir a Beckman IR10; for uv a Coleman EPS-3T Hitachi; for ms an AEI MS-30; for ^{1}Hmr a Varian T-60.

*2,3-Dialkoxycarbonyl-1,4-dimethyl-5,6-diphenyl-2,3-diazabicyclo[2.2.1]hept-5-enes (**4**)*

The Dimethoxycarbonyl Compound (4a)

The reaction of 1,4-dimethyl-2,3-diphenylcyclopentadiene (246 mg, 1 mmol) and dimethyl azodicarboxylate (146 mg, 1 mmol) in benzene solution (2 ml) at room temperature was rapid and exothermic; nmr analysis of a portion of the solution showed only the formation of the adduct **4***a*, which was complete within a few minutes. Evaporation of the solution and addition of pentane caused crystallization of the product (370 mg, 95%). Recrystallisation from benzene–hexane gave prisms, mp 162–163°C; ν (CCl_4): 1745, 1715 cm^{-1} (C=O); τ (CCl_4): 2.6–3.3 (10H, phenyl), 6.53 (s, 6H, OMe), 7.99 (s, 2H, methylene), 8.17 ppm (s, 6H, *tert*-Me); τ (C_6H_6): 8.29, 8.35 ppm (ABq, 2H, methylene, J = 9 Hz). *Anal.* calcd. for $C_{23}H_{24}N_2O_4$: C 70.39, H 6.16, N 7.14; found: C 70.31, H 6.09, N 6.85.

*The Di-*tert*-butoxycarbonyl Compound (**4**b)*

Under the same conditions the diene and the di-*tert*-butyl azodicarboxylate reacted in about 12 h to give **4***b* quantitatively (^{1}Hmr control experiment). Evaporation and crystallization of the residue by addition of pentane gave the adduct (80%) which was twice crystallized from hexane–cyclohexane as large prisms, mp 157.5–159°C; ν (CCl_4): 1730, 1702 cm^{-1}; τ (CCl_4–$CDCl_3$): 2.86 (broad s, 10H, phenyl), 7.97 (s, 2H, methylene), 8.13 (s, 6H, *tert*-Me), 8.65 ppm (s, 18H, *tert*-BuO); in C_6H_6 the methylene hydrogens are separated, $\Delta\tau$ = 0.23 ppm (J = 9.5 Hz). *Anal.* calcd. for $C_{29}H_{36}N_2O_4$: C 73.08, H 7.61, N 5.88; found: C 73.35, H 7.53, N 6.16.

*Thermal Stability of **4**a and* b

Solutions of the adducts (ca. 05 *M*) were refluxed in appropriate solvents and monitored at intervals by evaporating samples and subjecting the residues to ^{1}Hmr analysis. The results were: **4***a* and *b*, 4 h in toluene, <10%, <5% decomposition; **4***a* and *b*, 3 h in xylene, 30%, 50% decomposition; **4***a*, 3 h in decalin, complete decomposition.

*1,2-Dialkoxycarbonyl-1-(1-methyl-2,3-diphenyl-4-methylidene-2-cyclopentenyl)hydrazines (**5**)*

The Dimethoxycarbonyl Compound (5a)

A solution of **4***a* (100 mg, 0.26 mmol) in benzene (10 ml) containing TFA (29 mg, 0.26 mmol) was kept at room temperature for 1 h. Pyridine (21 mg, 0.27 mmol) was added, followed by *n*-hexane (20 ml) to precipitate the pyridinium salt. The filtered solution was evaporated to a glassy residue which resisted crystallization. Purification by column chromatography (silica gel – methylene chloride) gave **5***a* (70 mg, 70%) as a hard glass which softened between 175–178°C; ν (CCl_4): 3420 (NH), 1768, 1732 cm^{-1} (C=O); τ ($CDCl_3$): 2.8–3.1 (10H, phenyl), 3.36 (s, 1 NH), 5.05 (b, 1H, vinyl), 5.15 (b, 1H, vinyl), 6.32 (s, 3H, OMe), 6.36 (s, 3H, OMe), ~6.4 (1H, methylene, concealed by OMe), 7.18 (d, 1H, methylene, J = 16 Hz), 8.45 ppm (broad s, 3H, *tert*-Me, sharpens >100°C); *m/e* 364 (M^+ – CO, 15%), 246 ($C_{19}H_{18}^+$, 100%).

*The Di-*tert*-butoxycarbonyl Compound (**5**b)*

A solution of **4***b* (100 mg, 0.21 mmol) was refluxed in a mixture of carbon tetrachloride (1 ml) and either pyridine or triethylamine (0.5 ml) for 16 h. Evaporation, followed by crystallization of the residue twice from hexane–cyclohexane gave **5***b* as prisms (80 mg, 80%), mp 155–155.5°C; ν (CCl_4): 3415 (NH), 1752, 1715 cm^{-1} (C=O); τ (CCl_4–$CDCl_3$): 2.6–3.0 (10H, phenyl), 3.80 (1NH), 5.00 (b, 1H, vinyl), 5.10 (b, 1H, vinyl), 6.31 (d, 1H, methylene, J = 17 Hz), 7.13 (d, 1H, methylene), ca. 8.5 (3H, *tert*-Me, concealed by *tert*-BuO), 8.51 (s, 9H, *tert*-BuO), 8.60 ppm (s, 9H, *tert*-BuO). *Anal.* calcd. for $C_{29}H_{36}N_2O_4$: C 73.08, H 7.61, N 5.88; found: C 73.24, H 7.69, N 5.81.

*Alternative Synthesis of **5**b*

A solution of **4***b* (208 mg, 0.44 mmol) in dry benzene (3 ml) containing TFA (29 mg, 0.25 mmol) was kept at room temperature for 30 min. The solvent was evaporated and the residue taken up in chloroform and the product then purified by chromatography on silica gel. This reaction was monitored by ^{1}Hmr analysis using a solution of **4***b* and TFA in benzene-d_6 (dried over molecular sieves) at the same concentration as in the preparative scale experiment. The formation of both **5***b* (52 mg, 25%) and **10** (156 mg, 75%) was observed. Addition of further TFA up to 1 equiv. caused complete formation of **10**.

*1,2-Dialkoxycarbonyl-1-(1,4-dimethyl-2,3-diphenyl-2-cyclopentenyl)hydrazines (**6**)*

The Dimethoxycarbonyl Compound (6a)

Compound **5***a* (79 mg, 0.20 mmol) in dioxane (10 ml) took up hydrogen (0.20 mmol) in 10 h on shaking over palladium–charcoal. Filtration, evaporation, and treatment with hexane gave **6***a* (40%) as a glassy solid, softening between 70–75°C; ν (CCl_4): 3432 (NH), 1765, 1730 cm^{-1} (C=O); τ ($CDCl_3$): 2.6–3.0 (10H, phenyl), 3.60 (1NH), 6.20 (s, 3H, OMe), 6.30 (s, 3H, OMe), 7.50 (m, 2H, methylene), 7.95 (m, 1H, *tert*-H) 8.70 (s, 3H, *tert*-Me), 8.80 ppm (distorted d, 3H, *sec*-Me); *m/e* 394 (M^+, 0.3%), 247 ($C_{19}H_{19}^+$, 100%).

*The Di-*tert*-butoxycarbonyl Compound (**6**b)*

Hydrogenation of **5***b* was carried out under identical conditions on the same scale but the reaction was complete after 2 h. Filtration and evaporation gave **6***b* (94%), which was crystallized from benzene–hexane, mp 129–130°C; ν (CCl_4): 3428 (NH), 1760, 1722 cm^{-1} (C=O); τ ($CDCl_3$): 2.7–3.0 (10H, phenyl), 3.90 (1NH), 7.60 (m, 2H, methylene), 8.46 (s, 9H, *O-tert*-Bu), 8.66 (s, 9H, *O-tert*-Bu), 8.72 (s, 3H, *tert*-Me), 8.90 ppm (distorted d, 3H, *sec*-Me); *m/e* 247 ($C_{19}H_{19}^+$, 100%). *Anal.* calcd. for $C_{29}H_{38}N_2O_4$: C 72.77, H 8.00, N 5.86; found: C 72.50, H 7.82, N 5.76.

Cis-*4*-tert-*Butoxycarbonyl-4a,6-dimethyl-7,7a-diphenyl-2,3,4,4a,5,7a-hexahydrocyclopenta-1,3,4-oxadiazin-2-one (**7**)*

*From **4**b*

The adduct **4***b* (202 mg, 0.4 mmol) was dissolved in carbon tetrachloride (5 ml) containing TFA (0.2 ml). After 4 h at room temperature the solution was evaporated and the residue was dissolved in ether and washed with aqueous sodium hydrogen carbonate. The ether layer afforded an almost quantitative yield of 7 which crystallized as prisms, mp 153.5–154.5°C from carbon tetrachloride – hexane; ν (CCl_4): 3385, 3260 (free and H-bonded NH), 1784, 1763 cm^{-1} (C=O); τ (CCl_4): 2.53 (1NH), 2.75, 2.85 (s, s, 10H, phenyl), 7.06 (d, 1H, methylene, J = 16.5 Hz), 7.57 (d, 1H, methylene), 8.07 (s, 3H, vinyl-Me), 8.53 (s, 9H, *tert*-BuO), 9.12 ppm (s, 3H, *tert*-Me). *Anal.* calcd. for $C_{25}H_{28}N_2O_4$: C 71.41, H 6.71, N 6.66; found: C 71.12, H 6.75, N 6.70.

In a variant on this experiment **4***b* (0.2 mmol) was dissolved in neat TFA (0.3 ml) in an ^{1}Hmr tube. An intense blue-green color developed immediately. The spectrum obtained in less than 1 min was that of the final product (no further change

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with time) and had the absorptions described above in addition to the *tert*-BuO signal of *tert*-butyl alcohol. Evaporation and work-up as before gave a nearly quantitative yield of 7.

From **5**b

The blue-green colour was again observed when **5***b* (0.2 mmol) was dissolved in TFA (1 ml); ^{1}Hmr analysis at this point showed that the formation of 7 was quantitative. The work-up was carried out as before.

cis-*2*-tert-*Butoxy-4*-tert-*butoxycarbonyl-4a,6-dimethyl-7,7a-diphenyl-4,4a,5,7a-tetrahydrocyclopenta-1,3,4-oxadiazine (**10**)*

A solution of **4***b* (238 mg, 0.50 mmol) in benzene (5 ml, dried over molecular sieves) was kept with TFA (57 mg, 0.50 mmol) at room temperature for 30 min. Dry pyridine (41 mg, 0.52 mmol) was added and, after stirring for 5 min, pyridinium trifluoroacetate was precipitated by the addition of excess of *n*-hexane (Na dried) and removed by filtration. The filtrate was finally evaporated in a stream of dry nitrogen to the viscous **10**, which resisted crystallization and decomposed immediately and quantitatively to **7** on contact with hydroxylic solvents. It had ν (CCl_4): 1785, 1760 (C=O), 1670 cm^{-1} (C=N); τ (CCl_4): 2.5–3.2 (10H, phenyl), 7.12 (d, 1H, methylene, J = 17 Hz), 7.76 (d, 1H, methylene), 8.22 (s, 3H, vinyl Me), 8.55 (s, 9H, *tert*-BuO), 8.80 (s, 9H, *tert*-BuO), 9.12 ppm (s, 3H, *tert*-Me); *m/e* 448, 421, 364, 320, 275, 246 ($C_{19}H_{18}^+$).

cis-*4a,6-Dimethyl-7,7a-diphenyl-2,3,4,4a,5,7a-hexahydrocyclopenta-1,3,4-oxadiazin-2-one (**11**)*

A solution of either **4***b* or **5***b* (100 mg, 0.26 mmol) in methanol (15 ml) was stirred for 12 h with 2 *N* HCl or H_2SO_4 (5 ml); alternatively a solution of **4***b* (100 mg) was refluxed for 2 h in TFA (2 ml). The solvent was evaporated and the residue, dissolved in chloroform, was washed with aqueous sodium hydrogen carbonate. The chloroform solution gave **11** (57 mg, 70%) as a glassy product resisting crystallization: ν (CCl_4): 3355 (NH), 1765 cm^{-1} (C=O); τ (CCl_4): 2.74 (s, 5H, phenyl), 2.87 (s, 5H, phenyl), 6.23 (b, 2NH), 7.10 (d, 1H, methylene, J = 18 Hz), 7.52 (d, 1H, methylene), 8.08 (s, 3H, vinyl Me), 9.12 ppm (s, 3H, *tert*-Me); *m/e* 320 (M^+, 30%), 305 (30%), 275 (90%), 246 ($C_{19}H_{18}^+$, 100%).

cis-*3,4-Dimethoxycarbonyl-4a,6-dimethyl-7,7a-diphenyl-2,3,4,4a,5,7a-hexahydrocyclopenta-1,3,4-oxadiazin-2-one (**12**)*

Addition of **11** (80 mg, 0.25 mmol) in tetrahydrofuran (2 ml) to a suspension of 50% sodium hydride – mineral oil (33 mg, 0.69 mmol NaH) in tetrahydrofuran (5 ml) caused vigorous effervescence of hydrogen. Methyl chloroformate (78.5 μl, 1 mmol) was then introduced. After 5 h at room temperature ether and water were added, and the ether layer was shaken out several times with water, dried, and evaporated. The residue was purified by column chromatography on silica gel with elution by benzene. The bisurethane **11** was obtained as a glassy solid: ν (CCl_4): 1760, 1740 cm^{-1} (C=O); τ (CCl_4): 2.64 (m, 5H, phenyl), 2.80 (s, 5H, phenyl), 6.06 (s, 6H, OMe), 7.70 (m, 2H, methylene), 8.04 (s, 3H, vinyl Me), 9.01 ppm (s, 3H, *tert*-Me); τ (C_6D_6): 6.00 (s, 3H, OMe), 6.10 ppm (s, 3H, OMe); *m/e* 436 (M^+, 5%), 392 ($M^+ - CO_2$, 20%), 334 (43%), 319 (7%), 260 (34%), 244 ($C_{19}H_{16}^+$, 100%).

Deuterium Incorporation Studies on **4**b *and* **5**b

A solution of **4***b* (24 mg, 0.05 mmol) in chloroform-*d* (0.3 ml) saturated with D_2O was treated with 1 drop of trifluoroacetic anhydride and the ensuing reaction monitored by ^{1}Hmr analysis. When the conversion to 7 was complete the vinylic methyl peak was found by integration to be lacking in deuterium.

The experiment was repeated under identical conditions with **5***b*. Integration of the peaks for the product **7** showed the vinylic methyl to be exactly two thirds the intensity of the *tert*-methyl peak.

Kinetics Procedures

(a) Acid Catalysis of Diels–Alder Reaction

A solution of 1,5-dimethyl-2,3-diphenylcyclopentadiene and di-*tert*-butyl azodicarboxylate (13 mg each, 0.05 mmol) in benzene-d_6 (0.3 ml, undried stock solvent) was treated with TFA (2 μl, 0.025 mmol) and monitored by ^{1}Hmr analysis. The rate of formation of **7** (major product) and **5***b* (minor) was determined from the concentrations measured by integration of the methyl peaks. The adduct **4***b* was not detected.

(b) Acid Catalysis of Reaction of **4**b

A solution of **4***b* and TFA in benzene-d_6 at exactly the concentrations used in *a* was similarly analyzed. The formation of **7** and **5***b* occurred at a rate seven times greater than that observed in *a*.

A new extraction–spectrophotometric method for the determination of phosphate

KUNNATH S. SUBRAMANIAN AND ALFIO CORSINI

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 2, 1977

KUNNATH S. SUBRAMANIAN and ALFIO CORSINI. Can. J. Chem. **56**, 1729 (1978).

A new extraction–spectrophotometric method has been developed for the determination of trace amounts of phosphorus as orthophosphate. The method is based on the chemistry of 12-tungstophosphoric acid, $H_3PW_{12}O_{40}$ (TPA). In the procedure, orthophosphate is converted quantitatively to TPA in aqueous solution at a tungstate–phosphate molar ratio ≥ 24, in the p*H* range 1.2 to 1.9 and in the temperature range 60 to 100°C. The TPA is subsequently extracted into *n*-amyl alcohol and its absorbance measured at 267 nm. Beer's law is followed up to at least 25 μg/ml P. The method is less prone to solution conditions and species interference (especially As(V) and Si(IV)) than the widely used molybdenum-blue methods and is competitive in terms of sensitivity, precision, and accuracy. The TPA method was applied successfully to the determination of phosphate in a variety of phosphorus-containing specimens including natural waters, ores, and alloys.

Based on potentiometric and spectrophotometric studies, a scheme which accounts for the observed heptaproticity of TPA is proposed.

KUNNATH S. SUBRAMANIAN et ALFIO CORSINI. Can. J. Chem. **56**, 1729 (1978).

On a développé une nouvelle méthode d'extraction liée à la spectrophotométrie pour la détermination de phosphore à l'état de trace sous forme d'orthophosphate. La méthode est basée sur la chimie de l'acide tungstophosphorique-12 $H_3PW_{12}O_{40}$ (TPA). Dans cette méthode, on transforme quantitativement l'orthophosphate en TPA en solution aqueuse à un rapport molaire de tungstate–phosphate ≥ 24, à des p*H* allant de 1.2 à 1.9 et à des températures allant de 60 à 100°C. On extrait par la suite le TPA par l'alcool amylique et on mesure son absorption à 267 nm. La loi de Beer peut être appliquée jusqu'à au moins 25 μg/ml P. Cette méthode est moins susceptible aux conditions de solution et d'interférence par diverses substances (spécialement As(V) et Si(IV)) que la méthode plus utilisée du bleu de molybdène; de plus elle est compétitive en terme de sensibilité, de précision et d'exactitude. On a appliqué avec succès la méthode TPA pour la détermination du phosphate dans un grand nombre de spécimens contenant du phosphore comme des eaux naturelles, des minerais et des alliages.

En se basant sur des études potentiométrique et spectrophotométrique, on propose un schéma qui permet de tenir compte de l'heptaproticité observée dans le TPA.

[Traduit par le journal]

Introduction

Phosphorus is usually determined in such matrices as natural waters, minerals, steels, agricultural products, and foodstuffs by spectrophotometric procedures based on the formation of 12-molybdophosphoric acid (MPA) and its reduction to molybdenum-blue (1). The molybdenum-blue method and its various modifications have been thoroughly reviewed (1–3). In spite of its popularity, the molybdenum-blue method has a number of drawbacks, the most important of which are: (*i*) the method is based on empirical grounds (4) and the fundamental steps involved in the chemistry are not fully understood (4, 5); for example, the chemical nature of the 'blue' species is still uncertain and 'blues' have been proposed in which Mo is in some combination of either +4 and +5 or +5 and +6 oxidation states (e.g., ref. 6); (*ii*) serious interferences result from As(V), Cr(VI), Cu(II), Ge(IV), Hg(II), NO_2^-, Si(IV), and V(V) (7–9); and (*iii*) the intensity and stability of the colour, the position of peak maxima, and the extent of interference are all sensitive to the choice and concentration of the reductant, the concentration of molybdate and acid, standing time, and temperature (2, 8). Thus, with each reductant used (e.g., stannous chloride, ascorbic acid, 1-amino-2-naphthol-4-sulphonic acid) conditions must be found in which maximum sensitivity in the presence of phosphate is combined with minimum sensitivity in its absence (10). These difficulties clearly show the need for an alternative method which allows wider flexibility of experimental conditions and greater freedom from interferences and for which the chemistry is understood.

In regard to the above considerations, the analytical potential of 12-tungstophosphoric acid, $H_3PW_{12}O_{40}$ (TPA), for the determination of phosphorus has received scant attention (11) even though TPA is reported to be more stable than MPA to both acid and reducing agents (12) and has a higher molar absorptivity ($\varepsilon_{267} = 4.7 \times 10^4\ \ell\ mol^{-1}\ cm^{-1}$ (13) vs. $\varepsilon_{825} = 2.7 \times 10^4\ \ell\ mol^{-1}\ cm^{-1}$ (14)). Pre-

sumably, the complicated aqueous solution chemistry of TPA and tungstate ion (WO_4^{2-}) has discouraged serious analytical study of TPA. For example, the p*H* region in which TPA exists as the undissociated (or ion-associated) acid is still uncertain (15). Furthermore, TPA is reported to be both triprotic and heptaprotic in aqueous solution (e.g., refs. 12, 15). With regard to tungstate ion, its solution chemistry is very complex, involving the formation of isopolytungstate species through condensation reactions (12).

The present paper describes an extraction–spectrophotometric method for the determination of trace amounts of phosphorus, based on the quantitative formation of TPA from tungstate, phosphate, and acid under appropriate conditions. The method has been tested on a number of standard reference materials and applied to natural water samples. In addition, the hydrolytic stability of TPA has been studied and although it was found that TPA is intrinsically triprotic, a scheme that accounts for its observed heptaproticity in water is advanced.

Experimental

Apparatus

Spectra in the uv region were recorded with a Bausch and Lomb Spectronic 600 double-beam spectrophotometer, equipped with a Sargent Model SRL strip-chart recorder. Quartz cells (Hellma) with path lengths ranging from 50 to 0.1 mm were used, depending on sample concentration.

Potentiometric titrations of TPA in aqueous and nonaqueous media were done with a Radiometer Model p*H* M4 meter equipped with a fibre-type saturated calomel electrode and a low sodium-ion error glass electrode.

A Gilmont ultra-precision digital micrometer syringe burette was used for dispensing volumes of phosphate and arsenate solutions.

Reagents and Solutions

Stock solutions of tungstate (0.1 *M*), phosphate (155.5 μg P/ml), and TPA (1.0×10^{-3} *M*) were prepared respectively, from $Na_2WO_4 \cdot 2H_2O$ ('Baker Analyzed' reagent), KH_2PO_4 (primary standard, Analar, B.D.H.), and anhydrous $H_3PW_{12}O_{40}$ (obtained by heating to 280–300°C for 10 h hydrated TPA (Alfa) after purification by extraction into ether). The solutions were stored in polyethylene bottles. Suitable aliquots of the tungstate and phosphate solutions were taken to obtain solutions of lower concentration. Standard solutions (1.0 and 0.1 *M*) of perchloric acid and sodium hydroxide were stored in polyethylene bottles. *n*-Amyl alcohol and 2-butanone were dried over K_2CO_3, distilled at atmospheric pressure, and stored over type 4A Linde molecular sieves (16). (The *n*-amyl alcohol was collected at 138.0–138.2°C and 2-butanone at 79.6–80.2°C.) All other reagents were of suitable purity for the purpose intended.

Procedure

(a) Hydrolytic Stability of TPA

The stability of TPA in aqueous solutions of varying p*H* was studied both spectrophotometrically and potentiometrically. Solutions of TPA (3.21×10^{-5} *M*) with acidities ranging from 4 *M* $HClO_4$ to p*H* 12 were prepared. For solutions of p*H* > 0, the ionic strength was adjusted to unity with $NaClO_4$. Spectra were recorded in the range 200–400 nm (5 cm cells, corresponding reference solutions without TPA) at zero time (i.e., immediately after preparation of each solution) and at 1, 5, 10, 24, and 120 h intervals. Titrations in aqueous medium (50 ml of 10^{-3} *M* TPA) were made with 2.01×10^{-2} and 9.90×10^{-2} *M* solutions of NaOH in the p*H* range 2–7 and 7–12, respectively. The ionic strength was maintained at ~1 by addition of $NaClO_4$. For titrations in nonaqueous media, 0.153 and 0.144 g of anhydrous TPA were dissolved in 50 ml of *n*-amyl alcohol and 2-butanone, respectively, and the solutions titrated with a 0.101 *M* tetra-*n*-butylammonium hydroxide which was standardized as described by Fritz and Gainer (17).

(b) Formation of TPA from Phosphate, Tungstate, and Acid

Experiments to establish conditions for the quantitative conversion of phosphate to TPA in aqueous solution and for the subsequent quantitative extraction of the TPA into *n*-amyl alcohol were carried out. Several solutions were prepared in the p*H* range 0 to 5.4, each solution having final phosphate and tungstate concentrations of 4.0×10^{-5} and 4.8×10^{-4} *M*, respectively (W/P molar ratio = 12). Spectra were recorded at zero time, 0.5, 1, and 5 h and at 1, 5, 10, and 15 days, with cells of appropriate path length and corresponding reference solutions without phosphate. The extent of formation of TPA and of interference from isopolytungstate species was obtained by reference to spectra of standard solutions of TPA and of appropriate isopolytungstate species. In a further experiment, a series of solutions was prepared in the p*H* region 0–3, each solution (10 ml) having final phosphate and tungstate concentrations of 5.0×10^{-5} and 6.0×10^{-4} *M* (W/P ratio = 12, phosphate concentration equivalent to 1.55 μg P/ml). The solutions were then extracted for 2 min with *n*-amyl alcohol (25 ml) under the following conditions; after standing for 0, 0.5, and 24 h at 25°C; and after newly prepared solutions were heated momentarily to 45, 60, or 100°C and cooled to 25°C. The spectrum of the alcohol phase was recorded in the range 200–400 nm. The *n*-amyl alcohol extract of the corresponding blank was used as a reference solution. These experiments were repeated at W/P molar ratios of 24, 48, 96, 144, and 240. For each ratio, the phosphate concentration was kept constant at 1.55 μg/ml P. Similar experiments were performed at 15.5 μg P/ml at the above W/P molar ratios and also at 0.155 μg P/ml at W/P ratios of 24, 48, 144, 240, 480, 960, 1440, and 2400. The extent of formation–extraction of TPA was estimated by comparison to spectra of standard solutions of TPA in *n*-amyl alcohol.

Conformity to Beer's law of the TPA formed in aqueous solution and extracted into the alcohol phase was tested by taking suitable aliquots of phosphate ranging from 0 to 25 μg P/ml. The solution conditions were: W/P molar ratio ≥ 24; p*H* 1.2–1.9; the solution brought momentarily to a boil and cooled to 25°C and extracted as before. The absorbance of the alcohol phase was measured at 267 nm.

(c) Effect of Foreign Ions

The solution conditions for the study of foreign-ion effects were: phosphate concentration, 1.55 μg P/ml; W/P molar ratio, 96; p*H* range, 0–2; initial concentration of foreign ion, $(1.0–5.0) \times 10^3$ μg/ml, depending on the ion, and progressively lowered until the response corresponded to 100% phosphate recovery. The solutions containing tungstate, phosphate, acid, and the foreign ion were boiled, cooled, extracted, and the absorbance of the alcohol phase measured at 267 nm. The foreign ions tested are listed later. Since arsenic, silicon, and germanium form corresponding heteropolytungstates (15) and tungstate ion condenses to isopolytungstates, some of which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

absorb in the region of 270 nm (18), the effect of these species was studied in detail as described below.

(i) Effect of arsenic—The formation and extraction of 12-tungstoarsenic acid (TAA) was studied under the same conditions as described for TPA in section (*b*). The concentrations of arsenate (Na_2HAsO_4) corresponded to 0.75, 1.50, 2.30, and 3.80 and 15.00 μg As/ml. The W/As ratio was ~96. Studies on the recovery of phosphate in the presence of arsenate were done at phosphate concentrations of 0.0155, 0.155, 1.55, and 15.5 μg P/ml. For each P concentration, arsenate concentrations of 0.75, 1.50, 3.80, and 15.0 μg As/ml were used. In each case, the tungstate concentration was 0.01 *M* and the p*H* was 1.5–1.9.

(ii) Effect of silicon and germanium—Solutions (2.0×10^{-5} *M*) of 12-tungstosilicic and -germanic acids ranging in acidity from 4 *M* $HClO_4$ to p*H* 12 were extracted with *n*-amyl alcohol (25°C). Spectra of the aqueous phase before extraction and of the alcohol phase after extraction were taken over the range 200–350 nm.

(iii) Effect of isopolytungstates—Tungstate solutions (10^{-1}–10^{-3} *M*) were adjusted to p*H* 0–2, heated to 60 and 100°C, cooled to 25°C, and extracted with *n*-amyl alcohol. Spectra of the aqueous and final organic phases were recorded over the range 220–400 nm. Similar tests were made on solutions of metatungstate, $H_2W_{12}O_{40}^{6-}$ (2.0×10^{-5} *M*), and paratungstate, $H_2W_{12}O_{42}^{10-}$ ($3.2 \times 10^{-5} - 1.28 \times 10^{-4}$ *M*).

(d) Analytical Application to Phosphorus-containing Materials

(i) Determination of total soluble phosphate in water samples—The following procedure was used for natural water and sewage water samples and is suitable in general for the determination of total soluble phosphate. Pipet an aliquot (25 ml for concentrations < 0.1 μg P/ml; ≤ 10 ml for concentrations ≥ 0.1 μg P/ml) into a 125 ml conical flask, add 1 ml of 5 *M* H_2SO_4, 0.4 g of $(NH_4)_2S_2O_8$, dilute to 50 ml with deionized water, and digest until the volume is reduced to 10–15 ml (~1 h). Allow the solution to cool, transfer to a 50 ml beaker (use 5–10 ml of deionized water to rinse the flask), and adjust the p*H* to >7 with 5 *M* NaOH (dropwise). Add a volume of tungstate solution so that the final analytical concentration $\geq 10^{-3}$ *M*. (For samples containing ≤ 10 μg P/ml, 1–3 ml of 0.1 *M* tungstate is adequate.) Re-adjust the p*H* (potentiometrically) to 1.2–1.9 (1.5–1.9 if As(V) is present) with 1 *M* $HClO_4$. Bring the solution to a boil (heating to 60°C for 2–3 min is also adequate), cool to 25°C in a water bath, and transfer to a separatory funnel, using a few ml of 0.03 *M* $HClO_4$ to rinse the beaker. Then add exactly 10 ml of *n*-amyl alcohol, extract for 2 min, and measure the absorbance of the alcohol phase at 267 nm against the corresponding *n*-amyl alcohol extract of the reagent blank, using cells of suitable path length (e.g., 2 or 5 cm cells for 0 to 0.1 μg P/ml). Between measurements, the cell should be rinsed with the next sample and not with solvents (e.g., acetone) that absorb in the 200–300 nm range. Also, excessive water in the alcohol phase causes cloudiness; in such cases, a period of ~40 min is required for the water to settle. Obtain the concentration of P by reference to a calibration curve prepared from standard phosphate solutions.

Filter sewage-water samples through a 0.45 μ Millipore filter to remove suspended and particulate matter, prior to the determination.

(ii) Application to an organophosphorus compound (triphenyl phosphate, NBS standard, 1071 a)—Between 2–3 mg of the sample (dried over P_2O_5 for 2 h) was quickly weighed and treated with distilled water (50 ml), 6 *M* H_2SO_4 (1.5 ml), and $(NH_4)_2S_2O_8$ (1 g). After digestion as above, the volume was adjusted to 100 ml and a 5 ml aliquot taken for analysis. The aliquot was diluted to 10–15 ml and then processed exactly as in section (*i*).

(iii) Application to alloys. Steel samples (NBS)—To weighed amounts (0.05–0.1 g) in 100 ml beakers were added 5 ml of 1:1 HNO_3 and after the oxides of nitrogen were expelled by gentle boiling, 10 ml of 2% $(NH_4)_2S_2O_8$. The solution was reboiled for 5 min, 4 ml of concentrated HCl added, and the solution evaporated to dryness. The residue was dissolved in 40 ml of 0.01 *M* HCl and the solution passed through an ion-exchange column (Amberlite, CG-120, type $RSO_3^-Na^+$) to remove Fe(III). The phosphate was eluted with 60–80 ml of a 0.2 *M* HCl (3 ml/min flow rate) and collected in a 250 ml beaker. The solution was evaporated to 10–15 ml, cooled, and diluted exactly to 100 ml. A suitable aliquot was taken and processed exactly as in section (*i*) above.

(a) Phosphor-bronze samples (Canada Centre for Mineral and Energy Technology)—To weighed samples (0.05–0.08 g) were added 0.5 ml of concentrated HNO_3 and 1 ml of concentrated HCl. After the vigorous reaction had subsided, 10 ml of distilled water was added and the mixture heated until dissolution was complete. The solution was diluted exactly to 50 ml and a suitable aliquot taken for processing as above.

(iv) Application to ores and a mineral. Nickel–copper–cobalt ore, SU-1 (standard reference material, Canada Centre for Mineral and Energy Technology)—A sample (0.05–0.06 g) of the dried ore (2 h at 110°C) was treated with 5 ml of concentrated HNO_3 and after evaporation, 2 ml of concentrated HCl. After re-evaporation and addition of 10 ml of water, the silica was removed by filtration and the filtrate passed through an ion-exchange column as described for steel samples. The eluate (~100 ml) was evaporated to 25–30 ml, diluted to 50 ml, and a 10-ml aliquot processed in the usual way.

(a) Manganese ore (NBS, 25c)—Ten millilitres of 0.05 *M* HNO_3 was added to a dried sample (~0.07 g), followed by 30–32% (w/w) H_2O_2 (dropwise) until all vigorous action ceased. After heating and dilution to ~25 ml, the solution was filtered to remove silica and the filtrate diluted to 50 ml. A suitable aliquot was processed.

(b) Feldspar (NBS, 99a)—A dried sample (0.1–0.2 g) was fused with $K_2S_2O_7$ (0.8–1.6 g) for 90 min, the crucible was transferred to a 150 ml beaker containing 40–50 ml distilled water, and the mixture boiled until only the silica remained undissolved. After the silica was removed, the filtrate was diluted to 100 ml and a 10 ml aliquot taken for analysis.

Results and Discussion

(a) Hydrolytic Stability of TPA

The isolation of the Ag(I) and guanidine hepta salts led early workers to formulate TPA as $H_7PW_{12}O_{42}$. An element of uncertainty with regard to the proposed heptaproticity in water was introduced after Keggin, on the basis of X-ray studies, formulated the heteropoly anion as $PW_{12}O_{40}^{3-}$, although there followed several physicochemical measurements the results of which again suggested TPA to be heptaprotic (19). Finally, in a heat of neutralization study, Spitsyn and Kosmodemyanskaya (20) concluded that in aqueous solution TPA is triprotic and that its apparent high proticity is due to degradation to a species of higher charge, such as $PW_{11}O_{39}^{7-}$.

In the present study, the intrinsic triprotic nature of TPA was confirmed by titration in *n*-amyl alcohol and in 2-butanone. Each titration curve showed a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

single sharp potentiometric step, with the end-point corresponding to the consumption of precisely 3 mol of base per mole of TPA, based on the formula $H_3PW_{12}O_{40}$. In aqueous solution, however, and as found by others, the titration curve revealed two steps, the first corresponding to 7 mol of NaOH per mole of TPA and the second to an additional 19 mol. The buffer regions occurred in the pH ranges 2–4 and 6–9, respectively.

Based on TPA as $H_3PW_{12}O_{40}$, the overall titration reaction is:

$$[1]\quad H_3PW_{12}O_{40} + 26OH^- \rightleftharpoons 12WO_4^{2-} + HPO_4^{2-} + 14H_2O$$

An empirical scheme that reasonably accounts for the overall stoichiometry is:

$$[2]\quad H_3PW_{12}O_{40} + 3OH^- \rightleftharpoons PW_{12}O_{40}^{3-} + 3H_2O$$

$$[3]\quad PW_{12}O_{40}^{3-} + 4OH^- \rightleftharpoons PW_{11}O_{39}^{7-} + WO_3{\cdot}H_2O + H_2O$$

$$[4]\quad WO_3{\cdot}H_2O + 2OH^- \rightleftharpoons WO_4^{2-} + 2H_2O$$

$$[5]\quad PW_{11}O_{39}^{7-} + 17OH^- \rightleftharpoons 11WO_4^{2-} + HPO_4^{2-} + 8H_2O$$

The reaction scheme is consistent with the titration curve. Reactions [2] and [3] are postulated to occur over the pH range 2–4 without step-wise differentiation. These reactions together could have led earlier workers to conclude that TPA is heptaprotic. Similarly, reactions [4] and [5] are postulated to occur mainly over the pH range 6–9. The unit $PW_{11}O_{39}^{7-}$ has been previously proposed (21) and the degradation of heteropolytungstates to WO_4^{2-} in alkaline solution is well-known (12, 15).

The absorption spectra of solutions of TPA in the range 4 M $HClO_4$ to pH 12 further support the scheme (Fig. 1). The constant absorbance at 267 nm ($\varepsilon_{267} = 5.1 \times 10^4\ \ell\ mol^{-1}\ cm^{-1}$) in the range p$H$ 0.3–1.9 (curve *2*) suggests that TPA exists either as the undissociated acid or as an ion-associated species (e.g., $3H_3O^+$, $PW_{12}O_{40}^{3-}$) below pH 2. (The greater absorbance in 4 M $HClO_4$ (curve *1*) is attributable to strong secondary medium effects in concentrated electrolyte solutions (22).) The progressive decrease in absorbance and shift of peak maximum from 267 to 248 nm (curves *3–6*) and the ultimate disappearance of the 248 nm maximum (curves *7–9*) are indicative of the decomposition of TPA with increasing pH. Curve *9* is identical to the spectrum of simple tungstate ion. The absence of an isosbestic point in the pH range 0.3–5.0 (curves *2–6*) is suggestive of complex behaviour, i.e., a simple acid–base protonic dissociation is not the sole process taking place. Indeed, the time dependence of the absorbance at 248 nm (curves *4–6*) attests to complicated processes. Since each mole of TPA consumed 7 mol of NaOH up to ~pH 4 (3 mol for neutralization, 4 mol for a first-stage decomposition to a species postulated to be $PW_{11}O_{39}^{7-}$), the assignment of the 248 nm band to the $PW_{11}O_{39}^{7-}$ species seems reasonable.

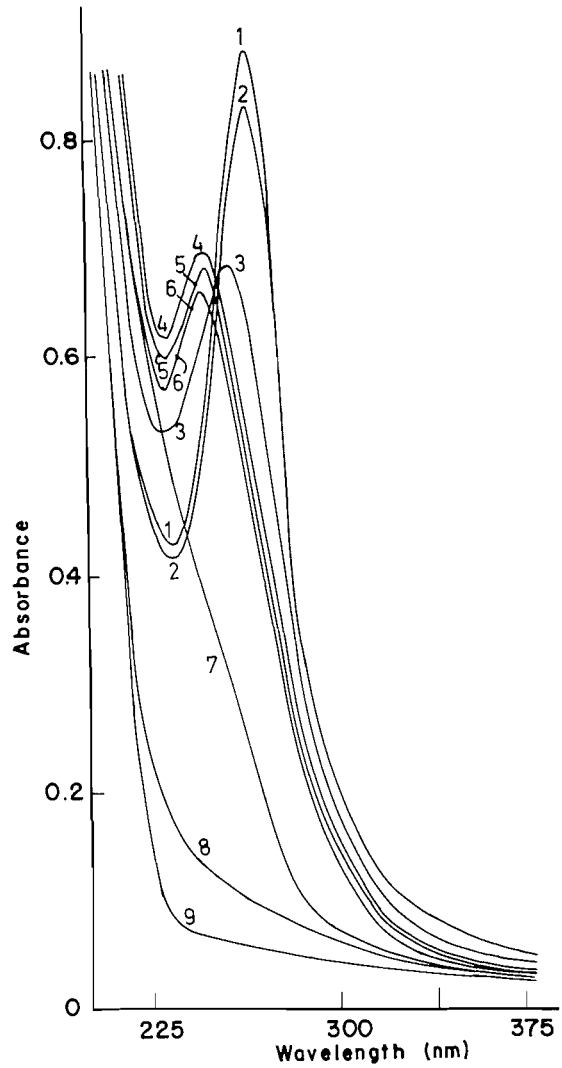

FIG. 1. Absorption spectra of TPA in aqueous solution as a function of pH ($C_{TPA} = 3.21 \times 10^{-5}$ M, $\mu = 1$, 25°C, 5 mm cells, corresponding solution without TPA as reference). (*1*) 4 M $HClO_4$; (*2*) pH 0.3–1.9; (*3*) pH 2.4; (*4*) pH 3.7; (*5*) pH 4.1; (*6*) pH 5.0; (*7*) pH 7.7; (*8*) pH 8.4; (*9*) pH 11.9.

The hydrolytic instability of TPA above pH 2 was further confirmed when the extraction of an aqueous solution of TPA (2.00×10^{-5} M) into *n*-amyl alcohol was found to be quantitative only at p$H \leq 2$; also, Beer's law was valid for aqueous solutions of TPA and the *n*-amyl alcohol extracts of the aqueous solutions only below pH 2.

For personal use only.

The above studies clearly show that any development of a quantitative method for phosphate based on the formation of TPA from phosphate, tungstate, and acid would have to be done at $pH \leq 2$.

(b) Formation of TPA in Solution from Phosphate, Tungstate, and Acid

Preliminary studies in aqueous solution at a W/P ratio of 12 and at 25°C showed that the formation of TPA was not quantitative even after 15 days at $pH < 2$, and that serious interference occurred from the simultaneous formation of isopolytungstates. Therefore, the development of a useful analytical method would require not only optimization of experimental parameters (e.g., temperature, tungstate concentration) for quantitative formation of TPA in solution, but also reduction of interference from the isopolytungstates. Since detailed studies with tungstate ion, paratungstate ($H_2W_{12}O_{42}^{10-}$), and metatungstate ($H_2W_{12}O_{40}^{6-}$) in acid medium showed that isopolytungstates are not extracted into *n*-amyl alcohol at $pH > 1$, and since TPA is quantitatively extracted up to pH 2, subsequent measurements of the formation of TPA were carried out after alcohol extraction of the aqueous phase set at pH 0–3, with particular interest in the pH range 1–2.

These measurements showed that the formation of TPA at 25°C was indeed quantitative (in the pH range 1.2–1.9) at a W/P ratio ≥ 24; however, under these conditions, the aqueous phase reaction required 24 h to be quantitative, even at W/P = 240, and as such is unsuitable for analytical use. Figure 2 (for W/P = 48) is typical of the data obtained. Figure 3 shows that quantitative formation of TPA was instant (in the pH range 1.2–1.9) when the aqueous phase (W/P $\geq$ 24) was brought to a boil. Instant quantitative formation was also achieved at 60°C, but only 90% formation occurred at 45°C. In Fig. 3, the decrease in absorbance above pH 2 is due to the decomposition of TPA; the decrease below pH 1 is due to precipitation of tungstic oxide and to the formation and extraction of isopoly compounds. These processes reduce the effective analytical concentration of tungstate available for reaction with phosphate. Also, the extraction of isopoly species occurs to a greater extent in the reference than in the test solution, resulting in a decrease in absorbance.

For the above studies, the phosphate concentration was 1.55 μg P/ml in the aqueous phase. Similar results were obtained at 15.5 μg P/ml. At 0.155 μg P/ml, however, instant quantitative formation of TPA was achieved only at W/P ratios $\geq$240. At a W/P ratio of 24, for example, the extent of TPA formation was only 33%. The higher W/P ratio required for low concentrations of phosphorus is accommodated in the analytical procedure for water samples by the directive to add 1–3 ml of 0.1 *M* tungstate solution.

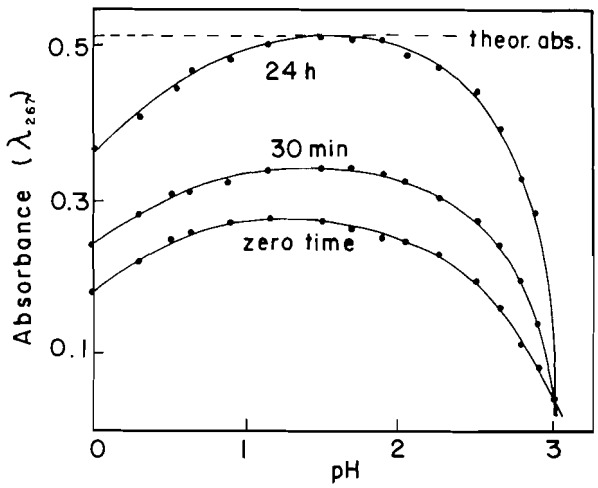

FIG. 2. Formation–extraction of TPA as a function of pH ($C_{WO_4^{2-}} = 2.4 \times 10^{-3}$ *M*, $C_{H_2PO_4^-} = 5.0 \times 10^{-5}$ *M*, W/P = 48, 25°C, 5 mm cells, corresponding *n*-amyl alcohol extract of blank as reference).

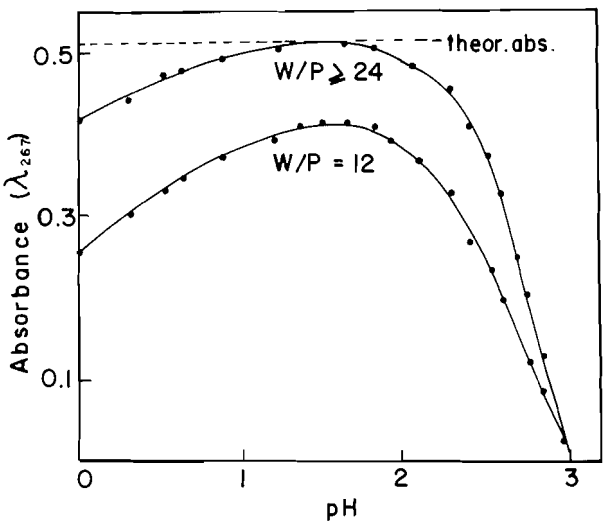

FIG. 3. Instant (zero time) formation–extraction of TPA as a function of pH ($C_{H_2PO_4^-} = 5.0 \times 10^{-5}$ *M*, 100°C, 5 mm cells, corresponding *n*-amyl alcohol extract of blank as reference).

A test of the conditions under which phosphate is converted quantitatively to TPA showed that Beer's law is obeyed for phosphate concentrations at least up to 25 μg P/ml. Furthermore, the absorbance values of TPA in the alcohol phase remained constant for at least 48 h. This stability is a decided advantage over both the popular molybdenum-blue and the molybdovanadophosphate methods (23).

To ensure that the species formed and extracted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

into the alcohol phase under the conditions described above was indeed TPA, the extracted compound was isolated, dried at 275–300°C for 1 h, and an X-ray powder pattern taken. The excellent agreement in *d*-spacings between the isolated compound and a sample of anhydrous TPA obtained by drying commercially available TPA, together with the exact coincidence of spectra in *n*-amyl alcohol, confirmed the matter.

In the course of this work, some observations were made that are of interest with regard to the mechanism of formation of $H_3PW_{12}O_{40}$ in aqueous solution. (*i*) When a small amount of freshly precipitated white tungstic oxide is heated in the presence of phosphate at ca. p*H* 1, the oxide dissolves and TPA is formed and extracted into *n*-amyl alcohol. TPA is not formed from aged oxide. (*ii*) TPA is not formed from metatungstate ($H_2W_{12}O_{40}^{6-}$) and phosphate in the range p*H* 2 to 4 *M* $HClO_4$. In this range, metatungstate is stable. In 7 *M* $HClO_4$, however, decomposition to tungstic oxide is instant. On addition of phosphate to this solution and heating, TPA is formed. (*iii*) An acid solution of paratungstate (p*H* < 2) in the absence of phosphate precipitates the white oxide. In the presence of phosphate, the oxide is not precipitated but, rather, TPA is formed. From these observations, it is almost certain that TPA is not formed by direct reaction of phosphate with a dodecameric species but from smaller isopoly species formed in the degradation of the dodecameric species.

(*c*) *Effect of Foreign Ions*

Studies at 1.55 μg P/ml showed no interference from: K^+, Na^+, Cl^-, NO_3^-, and SO_4^{2-} up to 5000 μg/ml; Mg(II), Ca(II), Mn(II), Co(II), Ni(II), Cr(VI), Mo(VI), and F^- up to 1000 μg/ml; Hg(II), Al(III), Si(IV), Br^-, I^-, CN^-, NO_2^-, S^{2-}, SO_3^{2-}, Si(IV), and SeO_3^{2-} in the range 400–700 μg/ml; Ag(I), Ba(II), Cd(II), As(III), and U(VI) in the range 150–300 μg/ml; Be(II), Cu(II), Zn(II), Pb(II), Sn(IV), and Ge(IV) in the range 50–100 μg/ml; and Ti(IV) and Zn(IV) in the range 20–50 μg/ml.

Serious interference occurred from As(V), Fe(III) (≥3 μg/ml), Sn(II) (≥2 μg/ml), Th(IV) (≥2 μg/ml), and V(V) (≥2 μg/ml). Respectively, these interferences may be due to the formation of $AsW_{12}O_{40}^{3-}$, $FePO_4$ ($K_{sp} = 10^{-21.9}$ at 25°C (24)), tungsten-blue from reduction of TPA by Sn(II), $Th_3(PO_4)_4$ ($K_{sp} = 10^{-78.6}$ at 25°C (24)), and $PVW_{11}O_{40}^{4-}$ (15). Since the effects of Fe(III), Sn(II), Th(IV), and V(V) have not been fully examined in the molybdenum-blue method, valid comparisons with the TPA method could not be made.

Since As(V) interferes seriously in the molybdenum-blue procedure with $SnCl_2$ as the reductant (As is returned as its equivalent of P (8, 25)) and with ascorbic acid – Sb(III) as the reductant (only 0.01 μg As/ml can be tolerated for 1.0 μg P/ml (26)), a

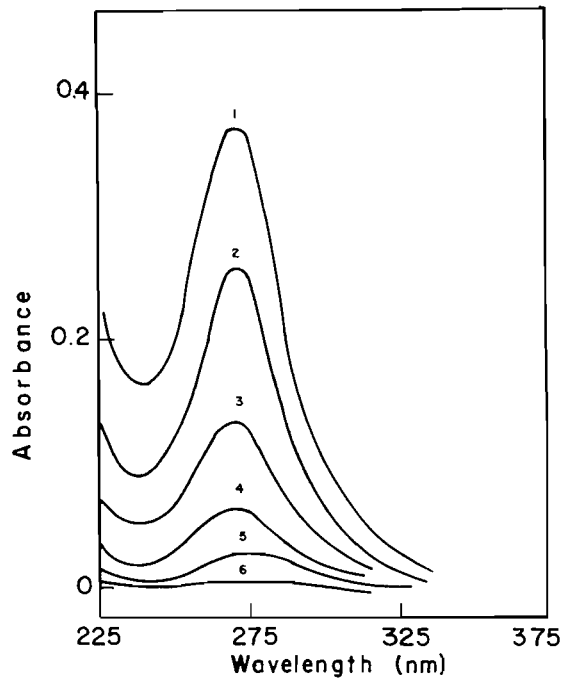

FIG. 4. Absorption spectra for the formation-extraction of $H_3AsW_{12}O_{40}$ ($C_{WO_4^{2-}} = 4.8 \times 10^{-3}$ *M*, $C_{HAsO_4^{2-}} = 5.0 \times 10^{-5}$ *M* (3.75 μg/ml As), 100°C, 5 mm cells, corresponding *n*-amyl alcohol extract of blank as reference). (*1*) p*H* 0.0; (*2*) p*H* 0.7; (*3*) p*H* 1.2; (*4*) p*H* 1.4; (*5*) p*H* 1.7; (*6*) p*H* 1.8.

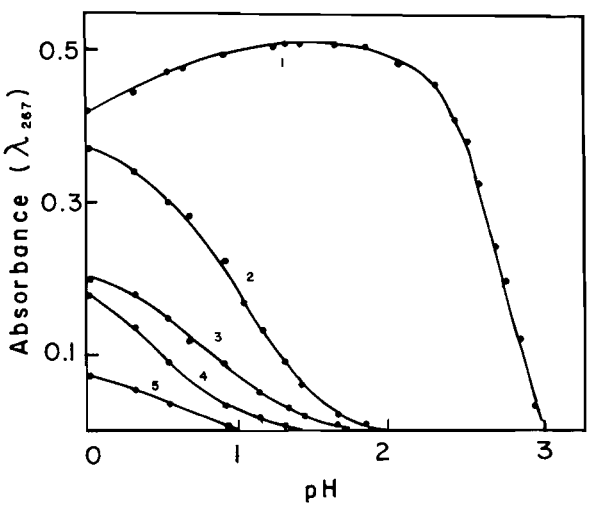

FIG. 5. Formation–extraction of $H_3AsW_{12}O_{40}$ and comparison to TPA (W/As ≥ 24, W/P ≥ 24, 100°C, 5 mm cells, corresponding *n*-amyl alcohol extract of blank as reference). (*1*) 1.55 μg P/ml; curves (*2*)–(*5*), 15.0, 3.75, 1.50, and 0.75 μg As/ml.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

detailed study of the effect of As(V) was made in the present work. The formation of $H_3AsW_{12}O_{40}$ (TAA) in acid solution has been reported recently (27). Figure 4 shows typical absorption spectra in *n*-amyl alcohol of TAA extracted from aqueous solution in the p*H* range 0–2. It is evident that the interference from As(V) arises from the intense absorption at 267 nm. In Fig. 5, the formation–extraction of TAA at concentrations ranging from 0.75 to 15 μg As/ml is shown. Superimposed is the curve for the formation–extraction of TPA (equivalent to 1.55 μg P/ml). Obviously, if the p*H* is set between 1.5–1.9, interference from As is minimized. The data of Table 1 clearly show that even for rather high As/P ratios, the recovery of P is satisfactory in the p*H* range 1.5–1.9. This relative freedom from interference of As(V) represents a significant advantage over the phosphate methods now in routine use.

The high tolerance of the TPA procedure to Si(IV) and Ge(IV) (at 1.55 μg P/ml) arises from the fact that extraction of 12-tungstosilicic and -germanic acids into *n*-amyl alcohol is negligible at acidities lower than 0.3 *M* $HClO_4$. In the molybdenum-blue method, no more than 3.0 μg Si/ml ($SnCl_2$ reduction (2)) and 10 μg/ml (ascorbic acid – Sb(III) reduction (8)) can be tolerated at 10 μg P/ml. No quantitative information is available on the extent of Ge(IV) interference.

As already discussed, the isopoly species do not interfere under the conditions of the TPA method.

(d) Analytical Applications

(i) Water Samples

The water samples, which had been preserved by addition of H_2SO_4 to a p*H* ~ 1, were obtained from the Upper Lakes Pollution Group (Windsor, Ontario) (ULPG) and the Canada Centre for Inland Waters (Burlington, Ontario). A concentrated nutrient reference sample was provided by the Environmental Protection Agency (Cincinnati, Ohio). The analytical results are presented in Table 2. The values by the molybdenum-blue method were obtained by other laboratories. The ULPG values (samples 42, 44, 46) for total soluble phosphate represent the average result of several laboratories which participated in a round-robin analysis. These laboratories used the molybdenum-blue method but a variety of reductants such as $SnCl_2$, 1-amino-2-naphthol-4-sulphonic acid, ascorbic acid, or a combination of ascorbic acid and Sb(III). On the whole, the agreement between the TPA and molybdenum-blue values is good. A comparison of the precision values is not valid since some data represent several different analysts and other data represent only a single determination. The molybdenum-blue method, however, requires much stricter control over the experimental conditions. This disadvantage is somewhat offset by the more tedious TPA procedure.

The literature contains several methods for the determination of phosphorus in natural waters but few for its determination in wastewater (8, 28). According to Heinke (28), many analysts are using methods developed for natural waters for the determination of phosphorus in wastewaters without proof that materials in sewage do not interfere. In this regard, the TPA method was tested by application to raw-sewage influent and effluent from a municipal sewage-treatment plant. The standard-addition technique was used to ascertain the effect of possible interferences. Excellent agreement was obtained between the found and added values for the spike (Table 3).

TABLE 1. Recovery of phosphorus (as phosphate) in the presence of arsenic (as arsenate)[a]

Taken (μg/ml)		
P	As[b]	P found (μg/ml)[c]
0.0155	3.75	0.023 ±0.002
	1.50	0.017 ±0.002
	0.75	0.0153±0.0002
0.155	15.0	0.212 ±0.003
	3.75	0.180 ±0.001
	1.50,0.75	0.156 ±0.002
1.55	15.0	1.75 ±0.02
	3.75,1.50,0.75	1.54 ±0.002
15.50	15.0	16.10 ±0.02
	3.75,1.50,0.75	15.53 ±0.02

[a]T = 100°C, p*H* 1.5–1.9.
[b]For the range 0.01–0.02 μg P/ml, an As/P ratio (μg/ml) of at least 50 is tolerable. For the ranges 0.1–0.2 and 1–2 μg P/ml, ratios of at least 10 and 2, respectively, are tolerable.
[c]Average of two determinations. Precision measure is the average deviation.

(ii) Alloys, Ores, a Mineral, and an Organophosphorus Compound

The results for %P in steel samples (NBS) and phosphor–bronze samples (Canada Centre for Mineral and Energy Technology) and in an organophosphorus compound (NBS) are presented in Table 4. Also reported are the results (as $\%P_2O_5$) for ores and a mineral.

A separation was not required in the analysis of the phosphor–bronze samples since Fe was present at <3 μg/ml and the other metals present (Cu, Sn, Pb, Zn, Ni, and Al) did not interfere. Separation of Fe was, however, necessary in the analysis of the steel samples.

(e) Reliability of the TPA Method

The reliability of a method is characterized by its accuracy, precision, and sensitivity. These properties are discussed in turn with respect to the TPA method.

14e	3	0.008	0.001	0.008 ±0.003	0.008 ±0.006

[a]The confidence interval is based on the equation: $\mu = \bar{x} \pm ts/\sqrt{\eta}$.

(i) Accuracy

Both the 95% and 99% confidence intervals (Table 5) are satisfactory for the small number of replicate determinations done. Although the testing is by no means exhaustive, the data show that the TPA method is capable of yielding acceptably accurate results.

(ii) Precision

Based on the 95% confidence limit, the percentage coefficient of variation was found to be 4.8% for 0.0062 ppm P; 2.3% for 0.062 ppm; 1.6% for 0.62 ppm; and 0.65% for 6.2 ppm. The percentage coefficient of variation values reported for the molybdenum-blue methods (8) are: 19% at 0.16 ppm P and 8.5% at 3.2 ppm with stannous chloride as the reductant; 4% at 0.05–0.10 ppm P, 11% at 0.027 ppm, and 100% at 0.81 ppm with ascorbic acid as the reductant. The superior precision of the TPA method is primarily the result of the greater range in experimental conditions which the TPA method allows. A detailed discussion of this topic is given elsewhere (29).

(iii) Sensitivity

If, following Sandell (30), the minimum detectable value of absorbance is taken as 0.001, the use of a 1 cm cell would give for TPA ($\varepsilon_{267} = 5.1 \times 10^4$) a limit of detection corresponding to 0.62 ppb P. This sensitivity, however, is not attainable in practice since it is limited by the accuracy of the apparatus and the magnitude of the blank value. The blank value in the present work corresponded to 0.005 ± 0.002 absorbance units on a total of 20 measurements. If a signal could be considered to be different from the blank value when it is at least as great as the mean blank value plus three standard deviations of the blank value (31), the practical limit of absorbance would be ~0.011, and consequently the practical limit of sensitivity of the TPA method would be ~6 to 7 ppb P for a 1 cm cell. Comparisons are not possible with the molybdenum-blue methods since standard deviations of the blank values do not appear to have been reported.

Conclusions

The TPA method is at least competitive with the molybdenum-blue methods in terms of accuracy, precision, and sensitivity. In addition, it is less prone to interferences, especially from As(V), and it allows greater freedom in the adjustment of experimental conditions. Because of the number and nature of steps required by the TPA procedure, however, it is difficult to automate and, at the present time, is best suited to the analysis of non-routine samples and as a reference method.

TPA is intrinsically triprotic; its apparent heptaproticity in aqueous solution is due to its instability in aqueous solution above p*H* 2.

The volume of activation for benzyl chloride hydrolysis and its pressure dependence

R. LOHMÜLLER, D. D. MACDONALD, M. MACKINNON, AND J. B. HYNE[1]

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received September 15, 1977

R. LOHMÜLLER, D. D. MACDONALD, M. MACKINNON, and J. B. HYNE. Can. J. Chem. **56**, 1739 (1978).

Various equations which have been proposed to provide the 'best' functional form for the dependence of rate upon pressure for reactions in solution have been tested for the extraction of ΔV^* and $d\Delta V^*/dp$ for the hydrolysis of benzyl chloride at 30°C and at pressures over the range 1 to 6895 bar. One hundred individual rate constants were determined for this reaction at pressure increments of 345 bar and provide a sufficiently large body of data to permit application of statistical methods for testing the various rate–pressure functions with little risk of bias.

R. LOHMÜLLER, D. D. MACDONALD, M. MACKINNON et J. B. HYNE. Can. J. Chem. **56**, 1739 (1978).

On a vérifié diverses équations qui ont été proposées pour fournir la "meilleure" forme fonctionnelle exprimant la relation entre la vitesse de réaction et la pression afin d'en tirer le ΔV^* et le $d\Delta V^*/dp$ de réactions d'hydrolyse en solution du chlorure de benzyle à 30°C et à des pressions allant de 1 à 6895 bar. On a déterminé 100 constantes de vitesse individuelle pour cette réaction avec des augmentations de pression de 345 bar et ces données fournissent un ensemble suffisamment étendu pour permettre l'application de méthodes statistiques pour vérifier les diverses fonctions vitesse–pression en impliquant un minimum de risque de polarisation.

[Traduit par le journal]

Introduction

In recent years there has been considerable discussion and controversy as to the best method for determining the activation volume, ΔV^*, and its pressure dependence $(\partial\Delta V^*/\partial p)_T$ from rate vs. pressure data for reactions in solution (1–11). Various methods have been suggested, including the use of polynomial $\ln k$ vs. p functions (6), incremental extrapolation (7), and by assuming that the volume of activation has a functional dependence upon pressure approximated by the empirical Tait equation (8, 9), which has been found to represent satisfactorily the PVT properties of many real substances.

The first two methods rely upon the differentiation of an empirical expression for the pressure dependence of $\ln k$ to evaluate ΔV^* according to [1].

$$[1] \qquad \Delta V^* = -RT\left(\frac{\partial \ln k}{\partial p}\right)_T$$

However, the Tait equation method is, in principle, one of integration, in that ΔV^* is assumed to have some a priori pressure dependence. The function form of the pressure dependence of $\ln k$ is then

$$[2] \qquad \ln (k_p/k_0) = -\frac{1}{RT}\int_{p_0}^{p} \Delta V^*(p)\, dp$$

A previous statistical analysis by Golinkin *et al.* (4) using relatively sparse experimental $\ln k$ vs. pressure data for benzyl chloride solvolysis in aqueous alcohol systems indicated that the second order polynomial function provided the best method for extracting ΔV^* and $(\partial\Delta V^*/\partial p)$ from rate–pressure data. This finding has been questioned frequently (see review by Eckert (10)) and the problem of selecting the best method for evaluating these pseudo-thermodynamic parameters of activation remains. This is of particular importance in the extraction of higher derivative activation parameters such as $d\Delta V^*/dp$. Part of the problem lies in the paucity of good experimental $\ln k$ vs. pressure data for most reactions studied. Furthermore, the data available have seldom been treated by rigorous statistical methods, and the choice of the $\ln k$ vs. pressure function has frequently been subject to bias.

In this paper we re-examine the problem of selecting the best functional dependence of $\ln k$ upon pressure for obtaining ΔV^* and $d\Delta V^*/dp$ values. The reaction chosen as the test case is the hydrolysis of benzyl chloride at 30°C over a pressure range of 1 to nearly 7000 bar. This reaction has been studied previously (11–14) and is particularly suitable in that no reactions (e.g. elimination) have been shown to occur other than the simple hydrolysis, i.e.

$$C_6H_5CH_2Cl + H_2O \rightarrow C_6H_5CH_2OH + HCl$$

In the present study we have made some 100 individual rate determinations at pressure increments of 345 bar. This number of independent data points is larger than has hitherto been available for any single

reaction in solution at a given temperature under hydrostatic pressure and, for the first time, permits a statistical analysis to be performed with little risk of bias.

Experimental

Materials

House distilled water was passed through a deionizing resin and exhibited a specific conductance of less than 8×10^{-7} S cm^{-1} at 25°C. Benzyl chloride was distilled twice under reduced pressure and the middle fraction collected. Analysis by gas–liquid chromatography showed less than 0.02% impurity.

Rate Measurements

Rate measurements at atmospheric pressure and at pressure increments of 345 bar up to 6895 bar were carried out as previously described (11, 15). The pressure vessel was submerged in a 40 gal thermostat which was controlled to better than ±0.01°C. An automatic pressure control device permitted pressures to be held constant to within ±14 bar over the entire pressure range employed. Approximately 1 h was allowed for temperature and pressure equilibration before rate data were collected.

The rate of production of HCl resulting from the hydrolysis of the benzyl chloride was followed by an *in situ* conductimetric method thereby avoiding uncertainties introduced by aliquot sampling techniques. The type of cells used has been described previously (15). The conductance measurement was carried out with an automatic conductance bridge General Radio Type 1680-A (1 kHz) which printed the results in 4 to 5 digit integers with an average change of 1000 integer units per half-life measured. The reproducibility of the conductance bridge is quoted to better than ±1 in the last digit. The time required for a conductivity reading was less than 1.1 s, according to the manufacturer's specifications. Therefore, a standard deviation of ±2 s in the independent variable (time) in the conductance–time relationship was assumed.

Systematic errors in the rate determinations could occur by contamination of the sample (especially with compression oil through uneven pressurization) and through aquisition of data before thermal equilibrium was achieved. Special procedures were adopted, as described below, in the reaction rate analysis to eliminate experimental results containing systematic errors.

Results and Discussion

The Rate Constant and its Errors

It has been established in earlier work (11) that the hydrolysis of benzyl chloride in dilute aqueous solution follows a strictly pseudo-first order rate expression. The Guggenheim (16) rate analysis technique (eq. [3]) is therefore a convenient way of extracting the rate constant, k, from conductance–time data.

$$[3] \quad \ln(\lambda_{t+\Delta t} - \lambda_t) = kt + \ln(\lambda_\infty - \lambda_0)(1 - e^{k\Delta t})$$

Other methods (17, 18) have been tried and yield identical results, but do not have the advantage of being amenable to linear regression analysis. Furthermore, they are not as sensitive to deviations of the experimental data from a first order rate relationship.

The regression analysis, i.e. the evaluation of the slope k and the intercept of a linear regression, was carried out by computer to reduce the possibility of bias. This statistical treatment also provides several criteria for the final selection of acceptable conductance–time data, i.e. for the exclusion of sets of conductance–time data which carry systematic errors or features that can be ascribed to experimental artifact. No sets of conductance–time data were employed in the final analysis if the correlation coefficient was smaller than 0.99990. Further, if the 95% confidence limit of the slope indicated an error limit in the rate (k) in excess of 1% the data were rejected. This test is sensitive to the number of conductance–time data points taken in each run and used in the regression analysis. This number normally exceeded 20.

Finally a graphical representation of the deviation of the experimental data points from the least-squares regression line was constructed, together with a double-sided test of significance, to detect any systematic deviation of the data from a straight line. In this double-sided test the slope obtained by regression on the first two-thirds of the conductance–time data was compared with the slope calculated from the last two-thirds of data. The 95% confidence limit of the Student's t function was used as the criterion for acceptance. The selected rate constants, k, are presented in Table 1.

Determination of the Error in k

Since the rate constant, k, is not a directly measured quantity, the determination of its error requires elaboration. Excluding systematic errors, the *major* reasons for the deviation of the computed value, k, from κ (the true value of the rate constant) are uncertainties in p, T, λ (conductance), and t, and their mutual dependency (i.e. correlations).

The error in k due to temperature variation can be predicted using the Arrhenius relationship between the reaction rate and temperature.

$$[4] \quad k = A \exp(-E_a/RT)$$

where E_a is the energy of activation and A is a constant. The standard error (SE) of a function $y = f(x)$ is defined as

$$[5] \quad \mathrm{SE}(X) = |\partial y/\partial x|\sigma$$

in which σ is the standard deviation of the parent population. The standard error in k at a given temperature, δk_T, therefore can be evaluated using [6].

$$[6] \quad \delta k_T = \left[\frac{AE_a}{RT^2}\exp(-E_a/RT)\right]\delta T$$

Substitution of values for A and E_a from the work of Dickson and Hyne (15) on benzyl chloride hydrolysis at atmospheric pressure yields $\delta k_T = 2.6 \times 10^{-8}\ s^{-1}$ at 30°C for an assumed error in temperature of

±0.01°C. This represents an uncertainty of ~0.1% of the mean value of k (2.478×10^{-5} s^{-1}) at this temperature.

The relationship between the rate constant, k, and pressure is given by [1], in which terms due to the pressure dependencies of the activity coefficients have been neglected. Since the pressure dependence of $\Delta V^{\neq}$ is generally unknown, the differential has to be solved by approximation. Without further justification at this point we assume that a quadratic relationship between ln k and p is sufficient for the purpose of evaluating the error in k due to uncertainty in pressure. Accordingly, differentiation of [7],

$$[7] \qquad \ln k = A_0 + A_1 p + A_2 p^2$$

yields the error function as

$$[8] \qquad \delta k_p = [k(A_1 + 2A_2 p)]\delta p$$

where the empirical constants A_1 and A_2 were obtained from the quadratic fit (see later discussion). For $\delta p = 14$ bar (i.e. the uncertainty in pressure control), the error in k for $T = 30$°C amounts to 2.12×10^{-7} s^{-1} at 3447 bar ($k = 6.627 \times 10^{-5}$ s^{-1}) and 2.10×10^{-7} s^{-1} at 6895 bar ($k = 1.215 \times 10^{-4}$ s^{-1}). These errors represent uncertainties of 0.32% and 0.17% in the mean values for k at 3447 and 6895 bar, respectively. It appears, therefore, that the error due to uncertainty in pressure is significantly greater than that due to uncertainty in temperature, at least for the data used here.

The rate constant, k, is related to the conductance, λ, by [3] which was used for the Guggenheim rate analysis. After rearranging, and substituting D for the constant term and $\Delta\lambda$ for the conductance difference ($\lambda_{t+\Delta t} - \lambda_t$), eq. [3] reduced to the following expression.

$$[9] \qquad k = \frac{\ln \Delta\lambda}{t} - \frac{D}{t}$$

Since t and λ are both subject to error, and are strongly correlated, the estimation of the δk has to be made (19) using [10].

$$[10] \quad \delta k_{\lambda,t} = \left[\left(\frac{\partial k}{\partial t}\right)^2 \delta^2(t) + \left(\frac{\partial k}{\partial \Delta\lambda}\right)^2 \delta^2(\Delta\lambda) + 2\left(\frac{\partial k}{\partial t}\frac{\partial k}{\partial \Delta\lambda}\right)\delta(t)\delta(\Delta\lambda)\rho(t, \Delta\lambda) \right]^{1/2}$$

where $\rho(t,\Delta\lambda)$ is the correlation coefficient for t and $\Delta\lambda$.

As an illustration of the numerical evaluation of $\delta k_{\lambda,t}$ we consider a run at 3447 bar and 30°C with a rate constant of 6.625×10^{-5} s^{-1}. The error was calculated using the experimental values of λ_t = 10 101 S and $\lambda_{t+\Delta t}$ = 13 253 S at t = 17 100 s. The actual correlation coefficient of 0.999813 for this run was substituted by the minimal correlation coefficient of 0.9999. An error δt = 2.0 s (i.e. the uncertainty in the time of reading) and a relative error of $\delta\lambda$ = 2 S in the combined conductance readings (i.e. ±1 in each conductance reading) yielded an error in k of $\pm 5.1 \times 10^{-8}$ s^{-1}. This represents an uncertainty of 0.08% in the mean value for the rate constant.

Although temperature, pressure, and conductance are not independent, the errors in these reaction parameters can be considered independent for the present purpose since, in the error range considered, a change in one parameter would not significantly affect the other parameters. The total error δk, therefore, can be calculated from [11].

$$\delta k = \delta k_T + \delta k_p + \delta k_\lambda \qquad [11]$$

This analysis yields values for δk of 1.0×10^{-7} s^{-1} and 3.0×10^{-7} s^{-1} for pressures of 1 and 3447 bar, respectively. The percentage errors in k corresponding to these pressures are ±0.4% (1 bar) and ±0.5% (3447 bar), which we consider to be entirely realistic for the error sources considered.

Error propagation provides a reasonable means for the evaluation of the lower error limit, of the quality of the experiments, and of the magnitude and importance of error parameters when an improvement in the experimental method is planned. For instance, the calculations carried out in the previous section indicate that the greatest source of error in k arises from the uncertainty in pressure. Thus, the total error in k could be markedly reduced by an improvement in the method of pressure control. However, for the evaluation of an *experimental* error the experiments have to be carried out, and whenever experimental findings disagree with computed results the former must take priority. The reason for this, of course, is that a host of possible statistical error sources exist which are not covered by [6], [8], and [10]. Furthermore, the confidence limit for the *mean value* of k (i.e. $\bar{k}$) is sensitive to the number of values from which it was calculated. Therefore, in order to obtain statistically meaningful estimates of $\bar{k}$, and the associated errors, the rate data listed in Table 1 were subjected to detailed statistical analysis. In addition to the previously discussed experimental k values, the mean $\bar{k}$ values for each pressure, their standard deviations, and 95% confidence limits are listed in Table 1. The distribution to the values was found to be close enough to normality, even in their logarithmic form, to justify this statistical treatment.

The observation that the error remains small with rising pressure seems to hold if a sufficient number of experiments are carried out. However, the difficulty of carrying out a successful experiment increases with pressure. Therefore, the number of experiments performed, and hence the precision in determining the mean value of k, usually also decreases with p. The relative sensitivity of the standard deviation and the confidence limit to the number of individual rate determinations at a given pressure is well illustrated by the values at 3447 and 3792 bar (Table 1). Both the standard deviations are quite low (0.040 and 0.048) and it might be concluded that the $\bar{k}$ values are equally precise. However, the 95% confidence limit for the 3792 value (0.431) with only two rate determinations available is an order of magnitude different from that at 3447 (0.033) where eight rate values were used in the determination of the mean. Accordingly, it seems important to cite *both* the overall standard deviation and the overall error limit for 95% confidence when reporting rate constants at elevated pressures.

The Rate–Pressure Functions

In the previous section considerable effort was expended in establishing the reliability of rate constants for the hydrolysis of benzyl chloride as a function of pressure. These data are now used to evaluate various empirical methods for extracting the volume of activation, $\Delta V^{\ddagger}$, and its pressure dependence, $(\partial\Delta V^{\ddagger}/\partial p)_T$ for this reaction. No a priori assumptions are made regarding the quality of any given empirical function in representing the pressure dependence of the rate constant k. The various empirical functions chosen for analysis are described below.

Polynomial Function

The simplest functional dependence of ln k upon pressure is given by the polynomial equation [12*a*]

$$\ln k = \sum_{i=0}^{n} A_i p^i \qquad [12a]$$

where n is the degree of the polynomial with coefficients (A_0, A_1, ..., A_n). Differentiation of [12*a*] with respect to pressure yields the following expressions for $\Delta V^{\ddagger}$ and $(\partial\Delta V^{\ddagger}/\partial p)$ at zero pressure

$$\Delta V_0^{\ddagger} = -RTA_1 \qquad [12b]$$

$$(\partial\Delta V^{\ddagger}/\partial p)_{p=0} = -2RTA_2 \qquad [12c]$$

It should be noted that when n = 1 the resulting linear rate–pressure relationship is the classical van't Hoff equation.

For personal use only.

Incremental Function

Whalley and co-worker (2, 7) proposed that reliable values for the activation volume can be derived graphically using the incremental expression eq. [13]

$$[13a] \quad \ln [k(p_{i+1})/k(p_i)]/(p_{i+1} - p_i) = A_1 + A_2\left[\frac{p_{i+1} + p_i}{2}\right]$$

where

$$[13b] \quad \Delta V_0^{\ddagger} = -RTA_1$$

$$[13c] \quad (\partial \Delta V^{\ddagger}/\partial p)_{p=0} = -2RTA_2$$

It should be noted that the incremental method represents, in mathematical terms, a reduced quadratic equation. Although the incremental method is basically a graphical technique for analysing rate–pressure data, it is treated in this study by computer to obtain statistical data for comparison with the other functions chosen for study.

Benson–Berson Function

Benson and Berson (8) expressed the pressure dependence of $\Delta V^{\ddagger}$ in terms of the empirical Tait equation and, upon integration (eq. [2]), derived the following expression for the dependence of rate upon pressure

$$[14a] \quad [\ln (k_i/k_o)]/p_i = A_1 + A_2 p^{0.523}$$

where

$$[14b] \quad \Delta V_0^{\ddagger} = -RTA_1$$

$$[14c] \quad (\partial \Delta V^{\ddagger}/\partial p)_{p=1} = -0.797RTA_2$$

The exponent 0.523 is strictly valid only for organic solvents, although it has been used for aqueous systems. The Benson–Berson function as written above is included here for reasons of comparison only.

Reduced Quadratic Function

The incremental and Benson–Berson functions described above can be treated as linear regressions after transformation of the variables. This transformation clearly involves a rather drastic change in scale of the dependent variable. In order to assess the effect of transforming an inherently nonlinear function to a linear one, we have carried out a similar transformation on the quadratic function, thereby deriving the following expressions for the pressure dependence of ln k and the corresponding parameters of activation.

$$[15a] \quad [\ln (k_i/k_0)]/p_i = A_1 + A_2 p_i$$

$$[15b] \quad \Delta V_0^{\ddagger} = -RTA_1$$

$$[15c] \quad (\partial \Delta V^{\ddagger}/\partial p)_{p=0} = -2RTA_2$$

Note that in [15] the regression is forced through the initial point (k_0) and the function, therefore, contains one less regression coefficient than the corresponding polynomial of degree 2.

The Regression Analysis

Regression analyses (19–23) were performed with each of the functions discussed above using the rate data unweighted and weighted. In the weighted data cases standard deviation (SD) or the 95% confidence limits (CL) as listed in Table 1 were used separately to calculate statistical weights (21) for each rate–pressure point.

Because of the variety of types of weighted and unweighted data treatment more than 80 regression coefficients and their associated variances were yielded by this analysis. Only the coefficients for the unweighted data treatment are presented here (Table 2). Other values are available on request.

In order to determine the point at which higher order terms in the polynomial expression no longer represents a statistically significant improvement of fit, Student's t-test has been applied. Table 3 lists various t values calculated from the three types of weighted and unweighted regression analyses; t_u unweighted, t_{SD} standard deviation weighted, and t_{CL} confidence limit weighted. Values in each of these categories are shown for various orders of the polynomial. These values can then be compared with t values taken from statistical tables for various levels of confidence. When t_u, t_{SD}, or t_{CL} values for a given polynomial become smaller than the corresponding t value for a given confidence level the highest order term in the polynomial is no longer statistically significant.

Accordingly for a 99% confidence limit the unweighted regression (t_u) indicates that third and higher order terms are not significant, hence the quadratic expression should be used. When the data are weighted by either method (t_{SD}, t_{CL}), however, the third order term is significant, indicating a cubic polynomial is appropriate. Reducing the confidence limit to 95% does not change the cut-off for the weighted data cases.

In extracting the $\Delta V^{\ddagger}$ and $d\Delta V^{\ddagger}/dp$ parameters, therefore, no polynomials above third order have been employed. The nontriviality of the third power pressure term implies the existence of pressure dependence of $d\Delta V^{\ddagger}/dp$. This should be compared with the pressure dependence of the compressibility of real substances and with the temperature dependence of the enthalpy of activation (i.e. $\Delta C_p^{\ddagger}$).

The Pseudo-thermodynamic Parameters

The essential purpose of this detailed and statistically rigorous analysis is to extract the pseudo-

thermodynamic activation parameters $\Delta V^{\ddagger}$ and $d\Delta V^{\ddagger}/dp$ and to obtain estimates of their reliability depending upon the function used to express the pressure dependence of the rate. The values calculated from the regression coefficients of the various functions are shown together with their standard errors (square root of variance) in Table 4. Three values of each parameter are shown for each function corresponding to the method of data treatment, i.e. weighted by standard deviation, by confidence limit, or unweighted. It will be recalled that the confidence limit weighting is more sensitive to the number of rate determinations made than is the standard deviation weighting.

The values in Table 4 clearly illustrate the inadequacy of the linear or van't Hoff type function. This has been demonstrated previously by several workers but it is important to note that it is not only the standard error that is unacceptably large but the $\Delta V^{\ddagger}$ value itself is significantly different from those obtained using higher power expressions. Such differences could be of considerable significance in mechanistic arguments based on the value of meaured volumes of activation.

There appears to be relatively little difference in $\Delta V^{\ddagger}$ values extracted by the various higher degree functions, whether the data are weighted or unweighted. An overall average value of 8.6 ± 0.4 ml/mol includes all values irrespective of the method of calculation. Bearing in mind the very extensive data base and the rigour with which the analysis was performed it is clear that few, if any, $\Delta V^{\ddagger}$ values currently available on any system can be considered to be more precise than ± 0.5 ml/mol. This is of special significance when considering *differences* between $\Delta V^{\ddagger}$ values as a criterion of reaction mechanism changes.

The Table 4 data also permit some comment to be made on the relative merits of the various nonlinear functional forms. All are clearly adequate in that they all provide a consistent value for $\Delta V^{\ddagger}$. Considering the size of the data base that each expression

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

was fitted to, however, the standard error associated with each value is informative. The quadratic, reduced quadratic, and Benson–Berson equations yield very small $\Delta V^{\ddagger}$ standard errors under all circumstances (<0.1 ml/mol). The cubic function has a somewhat higher value when applied to unweighted or standard deviation weighted data but it will be recalled that the Student *t*-test examination of the polynomial forms (Table 3) indicated that the cubic term was not significant with unweighted data. The large standard error in the $\Delta V^{\ddagger}$ value extracted by the incremental method suggests that when applied to a much more limited rate data set this functional form could yield $\Delta V^{\ddagger}$ values that were somewhat imprecise.

The mere fact that nonlinear functional forms provide a better fit of the rate–pressure data establishes the fact that the pressure dependence of $\Delta V^{\ddagger}$ is nontrivial. The feasibility of quantitative measurement of this important pseudo-thermodynamic activation parameter has, however, been questioned. As in the case of other second order derivatives there is no doubt that good data are essential for meaningful $d\Delta V^{\ddagger}/dp$ values to be obtained. The data in Table 4 illustrate the kind of precision that can be obtained using extensive and high quality rate–pressure data.

Again for the large data set used here there appears to be little difference between values obtained by weighting or not weighting the input data. The Benson–Berson and incremental functions, however, yield values that are significantly higher than the various nonlinear polynomials. The standard error associated with the incremental value is also larger, but that for the Benson–Berson is similar to that for the much lower $\Delta V^{\ddagger}$ values of the polynomials. It may be that the high value of the Benson–Berson $d\Delta V^{\ddagger}/dp$ is a reflection of forcing the data to a 0.523 power term which, as noted previously, is strictly valid only for organic solvents. Such a restriction would be expected to have a more noticeable effect on the second order derivative than on the $\Delta V^{\ddagger}$ term, as is the case.

The $d\Delta V^{\ddagger}/dp$ data would suggest that with extensive high quality rate–pressure data values of this activation parameter can be measured with a precision of $\pm 10\%$. Since even the sign of $d\Delta V^{\ddagger}/dp$ can be a useful piece of information in attempting to unravel the details of reaction mechanism, this level of precision is more than adequate for useful $d\Delta V^{\ddagger}/dp$ parameters.

A Mössbauer study of organotellurium compounds. Part III. Tellurium heterocycles and related compounds

NIGEL S. DANCE AND COLIN H. W. JONES

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received October 20, 1977

NIGEL S. DANCE and COLIN H. W. JONES. Can. J. Chem. **56**, 1746 (1978).

Mössbauer data are reported for a number of heterocyclic compounds containing tellurium. The influence on the Mössbauer parameters of the constraints imposed by accommodating tellurium in these ring systems are discussed. The influence of the bulky aryl ligand 2-biphenylyl, $C_{12}H_9$—, on the Mössbauer parameters of diaryltellurium dihalides and aryltellurium trihalides has also been investigated.

NIGEL S. DANCE et COLIN H. W. JONES. Can. J. Chem. **56**, 1746 (1978).

On rapporte des données de Mössbauer pour un certain nombre de composés hétérocycliques contenant du tellure. On discute de l'influence, sur les paramètres de Mössbauer, des contraintes imposées par l'accommodation d'un tellure dans ces systèmes cycliques. On a aussi étudié l'influence du ligand aryle volumineux biphénylyl-2, $C_{12}H_9$—, sur les paramètres de Mössbauer des dihalogénures de diaryltellure et des trihalogénures d'aryltellure.

Introduction

In previous papers (1–4) we have reported the ^{125}Te Mössbauer spectra of a wide range of organotellurium compounds and in the present paper the study is extended to include a number of tellurium heterocycles and related derivatives. Thus, in addition to forming diaryl and dialkyl tellurides, tellurium is also found in five- and six-membered heterocycles (5). In such compounds the bond lengths and bond angles are largely determined by the constraint of accommodating the tellurium atom in the ring and it was of interest to determine what effects this might have on the ^{125}Te Mössbauer parameters. Similarly, the effect of steric hindrance due to bulky aryl groups was also of interest, particularly for the trihalide derivatives.

It is relevant to briefly review here the important general features of the interpretation of ^{125}Te Mössbauer parameters. The ^{125}Te quadrupole splittings are determined predominantly by the imbalance in the 5*p* orbital populations, while the isomer shifts are influenced by the population of both the 5*s* and 5*p* orbitals. Removal of 5*s* electron density from the tellurium decreases the nuclear *s*-electron density $|\Psi_s(0)|^2$ and results in a more negative isomer shift, while removal of 5*p* electrons increases $|\Psi_s(0)|^2$ through deshielding and leads to a more positive isomer shift. It has been found that an additivity model satisfactorily explains the main features of the quadrupole splitting data for Te II and Te IV organotellurium derivatives (1, 2), this despite the fact that Te II possesses two lone pairs of electrons and Te IV one lone pair. The ^{125}Te isomer shifts span only a small range from -1.2 to $+1.8$ mm s^{-1} and as such are not a particularly useful probe to changes in chemical environment.

Results and Discussion

The computed Mössbauer parameters are reported in Table 1 and structural formulae for some of the compounds studied are presented in Table 2.

The Cyclic Tellurides

Of immediate interest in Table 1 are the Mössbauer parameters for dibenzotellurophene, $C_{12}H_8Te$ (**3**), phenoxtellurine, $C_{12}H_8OTe$ (**5**), and tellurium acetylacetonate, $C_5H_6O_2Te$ (**6**). The crystal structure data for these compounds are compared with that for $(p\text{-}MeC_6H_4)_2Te$ in Table 3. In these relatively simple molecules the C—Te—C bond angles vary from 101 to 81.7° and some variation is also observed in the bond lengths. The quadrupole splittings, and possibly the isomer shifts, show small differences from one compound to another. In the Townes and Dailey theory the quadrupole coupling constants for the compounds R_2Te can be related to the unit coupling constant, e^2q_0Q, the C—Te—C bond angle, θ, and the C—Te bond orbital population, *a*, through the expressions (10)

$$\frac{e^2qQ}{e^2q_0Q}\left(1+\frac{\eta}{3}\right) = 2 - a; \quad \eta = -3\cos\theta$$

for $90° < \theta < 109°$.

These expressions relate e^2qQ to the relative *s* and *p* character of the bonding orbitals and the two lone pairs. When $\theta = 90°$ the bonding would be pure *p* in character. It can be seen that changes in *a* and θ will influence the observed quadrupole splitting, $\frac{1}{2}e^2qQ(1 + \eta^2/3)^{1/2}$. Since the C—Te bond lengths,

* δ with respect to I/Cu, source, and absorbers at 4.2 K.
†With the exception of those compounds noted, all measurements were made in this work.

and hence the tellurium bond orbital populations, vary, a simple dependence of Δ on θ is not to be expected. Moreover the C—Te—C bond angles may not accurately reflect the directed valencies on the tellurium. However, both $C_{12}H_8OTe$ and $C_5H_6O_2Te$, for which $\theta \simeq 90°$, exhibit relatively larger Δ and δ values in comparison with Ph_2Te, for example, and this is consistent with a greater *p* character in the Te—C bonds and hence a greater lone-pair character for the tellurium 5*s* electrons.

The inductive effect of the oxygen atom in $C_{12}H_8OTe$ and of the carbonyl group in $C_5H_6O_2Te$ may be a factor in influencing Δ for these compounds, although the ditelluride $(TeCH_2CO_2H)_2$ (**10**) has very similar parameters to those of Ph_2Te_2 (Table 1).

In $C_{12}H_8Te$ the C—Te—C bond angle (9) is 81.7° and a simple combination of *s* and *p* orbitals cannot be used to rationalise the bonding about the tellurium. The quadrupole splitting for $C_{12}H_8Te$ is significantly smaller than that of the other cyclic tellurides. A contributing factor may be π-delocalisation around the five-membered ring, which is essentially planar.

An adduct of $C_{12}H_8Te$ with picric acid, $C_{12}H_8Te{\cdot}C_6H_3N_3O_7$ (**4**) can be isolated by recrystallizing dibenzotellurophene from ethanol in the presence of picric acid (11). The Mössbauer parameters for this adduct are identical to those obtained for the parent molecule and there is no evidence for any coordination of the molecule of picric acid to the tellurium. The adduct presumably involves a charge-transfer interaction between the two aromatic molecules.

The Cyclic Telluronium Cation, $C_{12}H_8OTeMe^+$

The compound $C_{12}H_8OTeMe^+I^-$ (**15**) contains the telluronium cation $C_{12}H_8OTeMe^+$ in which the tellurium is accommodated in a heterocyclic ring. We have previously reported Mössbauer data for two telluronium salts, Ph_2CH_3TeI and $Ph(CH_3)_2TeI$ (3), and for completeness we report here measurements on $(p\text{-}MeOC_6H_4)_2TeMe^+I$ (**11**) and $Ph_3Te^+Cl^-$ (**13**). The Mössbauer parameters for all the telluronium salts, regardless of anion and the precise nature of the organic groups attached to the tellurium, are very similar (Δ = 5.4 to 6.2 mm s^{-1}). This is consistent

with the presence of an essentially pyramidal telluronium cation in which the electric field gradient at the tellurium arises predominantly from some small stereochemical activity of the lone pair and is not influenced by secondary contacts to the tellurium (12). The fact that $C_{12}H_8OTeMeI$ has a Δ which is similar to the other telluronium salts suggests that even in this complex cation the tellurium finds itself in an essentially pyramidal environment very similar to that of the other telluronium salts, with C—Te—C bond angles approaching 90°.

Another aspect of the chemistry of telluronium salts is the evidence from ir data for ion pairing in solutions of DMSO.[1] Mössbauer spectra of frozen solutions of $(p\text{-}MeOC_6H_4)_2TeMe^+I^-$ in $CDCl_3$ and $Ph_3Te^+Cl^-$ in DMSO gave parameters (Table 1) very similar to those of solid samples, again suggesting that the immediate environment at the tellurium site determines the Mössbauer parameters.

The Cyclic Dichlorides

The dichlorides $C_{12}H_8TeCl_2$ (**17**), $C_{12}H_8OTeCl_2$ (**18**), and $C_5H_6O_2TeCl_2$ (**19**) were studied to allow a comparison with simple diaryltellurium dichlorides. The dichlorides were chosen for investigation, rather than the bromides or iodides, because they exhibit the largest quadrupole splittings. The crystal structures of $C_{12}H_8OTeI_2$ (14) and $C_5H_6O_2TeCl_2$ (8) show the tellurium to be in a Ψ-trigonal bipyramidal geometry with the halogen ligands in *trans*-axial positions. The dihalides exhibit more positive isomer shifts than the parent tellurides, the halogen ligands removing predominantly *p*-electron density from the tellurium. Compounds **17**, **18**, and **19** exhibit isomer shifts comparable with those of $(p\text{-}MeOC_6H_4)_2TeCl_2$. However, the quadrupole splittings of the cyclic dichlorides are all significantly smaller (ca 8.1 mm s^{-1}) than that of $(p\text{-}MeOC_6H_4)_2TeCl_2$ (9.1 mm s^{-1}).

TABLE 3. Crystallographic data for the tellurides

Compound	C—Te—C bond angle (deg)	C—Te bond length (Å)	Ref.
$(p\text{-}MeC_6H_4)_2Te$	101	2.05(5)	6
$C_{12}H_8OTe$	89.4(3)	2.10(9)	7
$C_5H_6O_2Te$	89.5(4)	2.17(1)	8
$C_{12}H_8Te$	81.7(2)	2.087(5)	9

These differences in Δ may arise in part from differences in asymmetry parameter, η, in the two cases.

Alternatively, the smaller quadrupole splittings for the cyclic dichlorides may be understood in terms of the additivity model. Given the larger splittings of the parent cyclic tellurides, the cyclic dihalides would be expected to have a smaller splitting. This follows from the interpretation of the splittings in tellurides and organotellurium dihalides presented in earlier papers (1–3). It should be noted that the $C_{12}H_8OTe$ moiety in $C_{12}H_8OTeI_2$ is essentially identical (14) with that in the parent telluride (7) and this also holds for $C_5H_6O_2TeCl_2$ and $C_5H_6O_2Te$ (8).

For $C_{12}H_8TeCl_2$ (**17**) the splitting is again relatively small in comparison with $(p\text{-}MeOC_6H_4)_2TeCl_2$. However, the splitting of $C_{12}H_8Te$ was itself relatively small. The crystal structures of $C_{12}H_8Te$ (9) and $C_{12}H_8TeI_2$ (15) show that while the C—Te—C bond angles are the same (ca. 81°), the Te—C bond length is shorter in the former case than the latter. This would be consistent with delocalization around the five-membered ring in $C_{12}H_8Te$, such delocalization being eliminated in the diiodide. The Mössbauer parameters for $C_{12}H_8TeCl_2$ are comparable with those of $C_{12}H_8OTeCl_2$ and $C_5H_6O_2TeCl_2$.

The Cyclic Dinitrate, $C_{12}H_8OTe(NO_3)_2$, and Related Compounds

In addition to the dichlorides discussed above we have recorded the spectra of the dinitrates $C_{12}H_8OTe(NO_3)_2$ (**20**) and $Ph_2Te(NO_3)_2$ (**21**). These compounds exhibit large quadrupole splittings (9.3 and 8.9 mm s^{-1} respectively) comparable with those of dichlorides. This is consistent with the crystal structure of $C_{12}H_8OTe(NO_3)_2$ (16), which shows the tellurium to be in a Ψ-trigonal bipyramidal environment with the nitrate groups in *trans*-axial positions, and with interpretations of the ir data for $Ph_2Te(NO_3)_2$, which suggest a similar structure (17).

While $C_{12}H_8OTeCl_2$ has a smaller splitting than Ph_2TeCl_2, $C_{12}H_8OTe(NO_3)_2$ has a very similar splitting to $Ph_2Te(NO_3)_2$. It is interesting that the crystal structure data for $C_{12}H_8OTe$ (7) and $C_{12}H_8OTe(NO_3)_2$ (16) show that there is a very significant difference in the angle of fold in the heterocyclic ring containing the O and Te atoms in these two molecules. The Mössbauer data suggest that the tellurium environments in $C_{12}H_8OTe(NO_3)_2$ and $Ph_2Te(NO_3)_2$ are very similar.

The compound $(C_{12}H_8OTeNO_3)_2O$ (**22**) has the structure shown in Table 2, the $C_{12}H_8OTeNO_3$ units being linked through an oxygen bridge (18). The isomer shift and quadrupole splitting of this compound are significantly smaller than those of $C_{12}H_8OTe(NO_3)_2$ or $Ph_2Te(NO_3)_2$. The compound Ph_2TeO (**23**) exhibits an even smaller quadrupole splitting (Table 1). The structure of Ph_2TeO has not been determined. It is reasonable to assume that the tellurium finds itself in an essentially trigonal pyramidal environment, possibly with distant contacts *trans* to the oxygen and phenyl groups.

In $(C_{12}H_8OTeNO_3)_2O$ the tellurium may be viewed as being in a distorted trigonal bipyramidal environment with the C—Te—C bonds and the assumed lone pair in the equatorial plane and the Te—O and Te—ONO_2 bonds in *trans*-axial positions, the O—Te—ONO_2 angle being 172°. The heterocyclic ring in $(C_{12}H_8OTeNO_3)_2O$ is intermediate in terms of planarity between that found in $C_{12}H_8OTe$ (7) and $C_{12}H_8OTe(NO_3)_2$ (16). The quadrupole splitting for $(C_{12}H_8OTeNO_3)_2O$, 7.6 mm s^{-1}, lies between that of Ph_2TeO, 5.0 mm s^{-1}, and $C_{12}H_8OTe(NO_3)_2$, 9.3 mm s^{-1}, again suggesting a simple additivity of the components to the electric field gradient.

Aryltellurium Trihalides and Diaryltellurium Dihalides with Bulky Organic Ligands

While full crystal structures on several diaryltellurium dihalides were reported some years ago, similar data have only recently become available for the aryltellurium trihalides. Kobelt and Paulus found that in $ClCH_2CH_2TeCl_3$ the tellurium is present in a square-based pyramidal geometry with the organic ligand in the axial position and four chlorines, two bridging, in the plane (19). Infrared and Raman data have suggested a similar structure for the phenyltellurium trihalides (20, 21). However, recent crystal structures (22, 23) of the α and β forms of 2-biphenylyltellurium triiodide, which are very similar, and of the bromide (24), $C_{12}H_9TeBr_3$, have revealed a Ψ-trigonal bipyramidal geometry about the tellurium with the $C_{12}H_9$ ligand, one halogen and the assumed lone pair in the equatorial plane, and two halogens in *trans*-axial positions.

In previous Mössbauer studies we have measured the spectra of a number of aryltellurium dihalides and trihalides (1–3). Given the recent structural work on the 2-biphenylyl derivatives, and the very bulky nature of this ligand, it was of interest to measure the Mössbauer spectra of the compounds $(C_{12}H_9)_2TeX_2$ and $C_{12}H_9TeX_3$ (X = Cl, Br, I), and to compare their parameters with those of the previously studied halide derivatives. It may also be noted that it was relevant to investigate these compounds in the present study in as much as the trihalides may be used as intermediates in the preparation of $C_{12}H_8Te$.

Whereas aryltellurium trichlorides, tribromides, and triiodides have previously been found to yield Δ values of 9.3, 7.9, and 5.2 mm s^{-1} respectively, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

2-biphenylyl derivatives gave values of $C_{12}H_9TeCl_3$, 8.0; $C_{12}H_9TeBr_3$, 7.1; and $C_{12}H_9TeI_3$, 7.8 mm s^{-1}. These two sets of values are significantly different and raise some question as to whether the $C_{12}H_9TeX_3$ compounds may be viewed as 'typical' organotellurium trihalides or whether, as a result of steric hindrance arising from the bulkiness of the 2-biphenyl group, the structures of the $C_{12}H_9$ derivatives are significantly different from those of other aryl derivatives. It will be of interest to determine the crystal structure of a phenyltellurium trihalide to see whether it has a distorted trigonal bipryamidal structure or a square-based pyramidal structure as previously proposed. It should be noted that $(C_{12}H_9)_2Te$ (**7**) and $(C_{12}H_9Te)_2$ (**9**) have Mössbauer parameters very similar to those of other tellurides and ditellurides and that the 2-biphenylyl ligand is similar to other aryl ligands in those compounds. It is interesting that $C_{12}H_9TeI_3$ has an unusually large quadrupole splitting for a triiodide, while $C_{12}H_9TeCl_3$ and $C_{12}H_9TeBr_3$ are both smaller than would have been expected. In both the α and β forms of $C_{12}H_9TeI_3$ the three iodine atoms are inequivalent (22, 23), while in $C_{12}H_9TeBr_3$ the *trans*-axial bromine atoms are equivalent (24). In the triiodide the larger Δ value may be explained by the presence of an appreciable asymmetry parameter, η.

In the light of the apparently anomalous quadrupole splittings of the 2-biphenylyltellurium trihalides, it was of interest to measure the Mössbauer spectra of the bis(2-biphenylyl)tellurium dihalides. The data of Table 1 clearly show that, while these dihalides had isomer shifts comparable with other dihalides, the quadrupole splittings were again relatively smaller. Thus, diaryltellurium dichlorides generally exhibit Δ values of ca. 9.2 mm s^{-1}, whereas the bis(2-biphenylyl) derivative had a splitting of only 8.2 mm s^{-1}. The difference in the splittings for the diaryltellurium (8.0 mm s^{-1}) and bis(2-biphenylyl)tellurium dibromide (7.6 mm s^{-1}), however, was much smaller, while the bis(2-biphenylyl)tellurium diiodide appeared similar to other diaryltellurium diiodides (Δ = 6.3 mm s^{-1}). For the chlorides, and possibly the bromides, there is again evidence that the 2-biphenylyl derivatives may have structures which are significantly different from those of the phenyltellurium dihalides.

Experimental

Mössbauer spectra were recorded on compounds naturally abundant in tellurium. The source used was a 20 mCi ^{125}Sb/Cu source provided by New England Nuclear. The absorbers, containing 5–10 mg cm^{-2} of ^{125}Te, and the source were immersed in liquid helium in a Harwell Instruments Dewar. The constant acceleration drive, operating on a ramp which generates single spectra, was a Harwell Instruments MV 200 transducer driven by a MWG 200 wave-form generator and an MSA 200 attenuator. The spectra were accumulated in 256 channels in a Nuclear Data 2200 series multichannel analyser. During the experiments a Xe/CO_2 (Reuter Stokes) proportional counter and a thin NaI/Tl scintillation counter were used, the two giving comparable spectra. The detectors were gated on the Xe or I escape peak and a copper absorber was used to reduce the background under the escape peak. The compounds studied gave percent resonance absorptions in the peak minima of 6–10%. Spectra were routinely accumulated to 1 to 2 × 10^5 counts per channel. The spectra were computer fitted to independent Lorentzians using a program first described in ref. 25. The spectrometer was routinely calibrated using a ^{57}Co/Pd source and an iron foil absorber at room temperature.

Most of the compounds described were prepared following literature procedures (13, 26–28), and were identified by elemental analyses, melting points, mass spectroscopy, infrared, and ^1H nmr spectroscopy. Elemental analyses were not obtained where compounds were shown to be identical to previously prepared samples.

The following new compounds were prepared.

Bis(2-biphenylyl)telluride. 2-Biphenylylmercury chloride (7.75 g, 20 mmol) and tellurium tetrachloride (2.70 g, 10 mmol) were dissolved in 20 ml of dioxane and refluxed for 4 h. The solution was cooled, and the precipitated mercuric chloride – dioxane complex filtered under vacuum. The filtrate was evaporated to an oil, and diethyl ether added to precipitate crude bis(2-biphenylyl)tellurium dichloride. This was dissolved in hot ethanol, and hydrazine added dropwise until evolution of nitrogen ceased. The resulting turbid solution was evaporated to dryness and extracted with light petroleum ether, which on evaporation yielded 3.2 g of red oil. This was added to 2 g of freshly prepared copper powder in 25 ml of dry dioxane and refluxed for 6 h. After this time the initially red solution had become light green, and a heavy black precipitate formed. The solution was filtered and evaporated to dryness. Recrystallization from ethanol produced 0.85 g (19% of theoretical yield) of bis(2-biphenylyl)telluride.

Bis(2-biphenylyl)tellurium dichloride. Chlorine gas was passed into a solution of bis(2-biphenylyl)telluride (0.3 g) in 20 ml of carbon tetrachloride. After a few minutes a small amount of precipitate formed. Evaporation produced a quantitative yield of bis(2-biphenylyl)tellurium dichloride.

Bis(2-biphenylyl)tellurium dibromide and *bis(2-biphenylyl)-tellurium diiodide.* These compounds were similarly prepared in quantitative yields by mixing carbon tetrachloride solutions of equimolar amounts of bis(2-biphenylyl)telluride and the appropriate halogen.

Oxidation of methyl glycopyranosides by *Acetobacter suboxydans*

G. Wayne Schnarr and Walter A. Szarek

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received December 19, 1977

G. Wayne Schnarr and Walter A. Szarek. Can. J. Chem. **56**, 1752 (1978).

A synthesis of methyl pentopyranosid-4-uloses has been achieved by microbiological oxidation by *Acetobacter suboxydans* of some methyl pentopyranosides. The oxidation products were isolated as their *O*-methyloxime derivatives, and the assignment of the configuration of the oximes was made on the basis of the carbon-13 magnetic resonance spectra. An analysis of the oxidative specificity of *A. suboxydans* towards methyl glycopyranosides is presented.

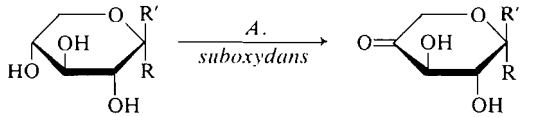
G. Wayne Schnarr et Walter A. Szarek. Can. J. Chem. **56**, 1752 (1978).

On a effectué une synthèse des pentopyrannosiduloses-4 de méthyle par une oxydation microbiologique à l'aide d'*Acétobacter suboxydans* de quelques pentopyrannosides de méthyle. On a isolé les produits d'oxydation sous forme de dérivés *O*-méthyloximes et l'attribution de la configuration des oximes a été effectuée en se basant sur les spectres de résonance magnétique nucléaire du carbone 13. On présente une analyse de la spécificité de l'oxydation des glycopyrannosides de méthyle par l'*Acétobacter suboxydans*.

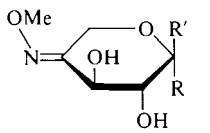
[Traduit par le journal]

Introduction

In a preliminary communication (1), we reported the successful oxidation of methyl α- and β-D-xylopyranosides (**1**, **2**) by the acetic acid bacterium (2) *Acetobacter suboxydans* to give the corresponding glycosid-4-uloses (**3**, **4**) as the major products, with



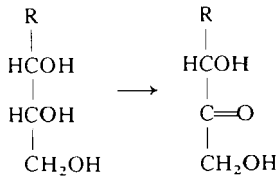
1 R = OMe, R′ = H
2 R = H, R′ = OMe
3 R = OMe, R′ = H
4 R = H, R′ = OMe



5 R = OMe, R′ = H
6 R = H, R′ = OMe

traces of the glycosid-3-uloses also being present. Chemical procedures were used to determine the site of the oxidation, and the oxidation products were further characterized as their *O*-methyloxime derivatives (**5**, **6**). We now report the results with a series of methyl pento- and hexopyranosides and also present an analysis of the oxidative specificity of *A. suboxydans* towards methyl glycopyranosides in terms of the specificity of the previously known dehydrogenase systems.

Acetobacter suboxydans apparently contains two enzyme systems which are responsible for the oxidation of the alditols. The predominant system oxidizes a polyhydric alcohol containing the structural unit **7**



7 **8**

R = H,—(CHOH)$_n$—CH$_2$OH (n = 0–5)

to the ketose **8**, and this oxidative specificity has been formulated as the Bertrand–Hudson rule (3). A more recently recognized system (4), designated as a D-*galacto* dehydrogenase, is responsible for the oxidation of D-galactose diethyl dithioacetal (**9**), to give the corresponding 5-keto compound (**10**), and also for the oxidation of other compounds possessing the D-*galacto* configuration (5).

Acetobacter suboxydans was also found to oxidize the cyclitols and some of their derivatives in a stereospecific manner. Magasanik *et al.* (6) proposed that the oxidative specificity could be defined by two

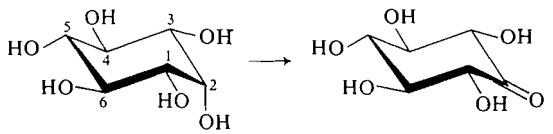
rules, with the possibility of a third rule also being applicable. Anderson *et al.* (7) proposed a modification of rule 3 to give the following set of rules: (*1*) only axial hydroxyl groups will be oxidized; (*2*) if an axial hydroxyl group is to be oxidized, there must be an equatorial hydroxyl group in the *meta* position, in a clockwise direction if the molecule is oriented so that the axial hydroxyl group projects downwards; (*3*) if there is an equatorial hydroxyl group in the *para* position, the oxidation will proceed at a faster rate and, if there is a choice, the axial hydroxyl group satisfying this rule will be preferentially oxidized. These rules can be represented by C-2, C-6, and C-5, respectively, in the oxidation of 1,2,3,5/4,6-cyclohexanhexol (**11**, *myo*-inositol) to 2,4,6/3,5-pentahydroxycyclohexanone (**12**).



11 **12**

Results and Discussion

Since *A. suboxydans* probably does not contain a glycoside-specific dehydrogenase, the procedure normally used for the oxidation of polyhydric alcohols (8) was modified. Instead of using a proliferating culture in which the glycoside would replace the polyhydric alcohol, cells isolated from cultures grown on D-sorbitol broths were used. Paper chromatography, in which several spray reagents could be used to detect the products, and uv spectroscopy, in which λ_{max} (H_2O) ~ 265 nm changed to λ_{max} ~ 310 nm in 1 *N* sodium hydroxide, were used to determine whether oxidation was occurring. When a sample was treated, successively, with sodium borohydride and sulfuric acid, and the products were examined by paper chromatography, two aldoses, epimeric at the site of microbial oxidation, were revealed.

Since it was also necessary to determine the extent of the oxidation, the *O*-methyloxime derivatives of the oxidation products were prepared and isolated by column chromatography. In some cases, treatment of the oxidation mixture with methoxylamine hydrochloride also resulted in the formation of the bis(*O*-methyloxime) derivative; however, attempts to prepare the bis(*O*-methyloxime) from the *O*-methyloxime **6** by treatment with an excess of methoxylamine hydrochloride were unsuccessful.

The presence of only one geometrical isomer of each oxime (**5**, **6**, and **13**) was indicated by both the ^{1}Hmr and ^{13}Cmr spectra. When some simple, *N*-substituted ketimines were examined by ^{13}Cmr spectroscopy (9), it was found that the shielding of the *syn*-carbon was greater than that of the *anti*-carbon, a phenomenon attributable mainly to differences in steric compression. It was on this basis that the signals for compounds **5**, **6**, and **13** were assigned (see Table 1); the *E*-configuration can also be assigned to the *O*-methyloximes on the basis of the ^{13}Cmr chemical-shift data. The bis(*O*-methyloxime) was shown by hplc to be a mixture of two isomers; the major isomer was assigned the 3*E*,4*E*-configuration on the basis of the ^{13}Cmr chemical-shift data.

The results of the attempted oxidations in a series of methyl glycopyranosides are summarized in Table 2. The yields are based on the combined, isolated yields of the *O*-methyloxime and bis(*O*-methyloxime) derivatives, except for methyl α-D-xylopyranoside (**1**) in which case the quantitative oxidation is based on the absence of starting material after the reaction with methoxylamine hydrochloride. Although there are insufficient examples to allow complete analysis of the oxidative specificity of *A. suboxydans* towards methyl glycopyranosides, there are certain patterns which can be recognized.

The quantitative oxidation of methyl α-D-xylopyranoside (**1**) within 4 days, a time comparable to that required for oxidation of the alditols and cyclitols, makes this an ideal model for comparison with previously known dehydrogenase systems. The likelihood that *A. suboxydans* possesses an enzyme system specific for glycopyranosides is remote and is not considered here. Based strictly on the cyclic nature of the glycopyranosides, the enzyme or enzymes responsible for the oxidation of the cyclitols would have to be considered. However, none of the three requirements for oxidation (see Introduction) are satisfied by methyl α-D-xylopyranoside. There are also the enzymes responsible for oxidation of the cyclic diols and triols (10) but insufficient information is known about these systems to allow a comparison.

The configurational requirements for the two systems responsible for oxidation of the alditols, shown

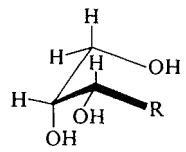
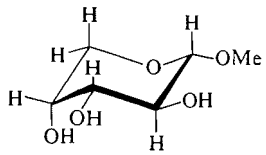
by **26**, representing the Bertrand-Hudson system, and **27**, representing the more recently recognized D-*galacto* system, can be compared to the configurational state in methyl α-D-xylopyranoside (**1**). Assuming the three hydroxyl groups to be the necessary contact points for binding to the enzymes and considering the topographic similarity of **1** and **27**, it is not surprising that oxidation of **1** occurred at C-4. When the model compound is altered, the extent of the oxidation is diminished in a predictable manner. Thus, when the glycopyranosides which are epimeric at C-1 (**2**) and C-2 (**19**) are oxidized, the yields are reduced to 41 and 43%, respectively; also, when an equatorial hydroxymethyl group is introduced at C-5 in any of the three pentopyranosides mentioned above (that is, **22**, **23**, and **24**), there is no oxidation observed. Although this pattern indicates that the D-*galacto*-specific enzyme is responsible for these three oxidations, this suggestion cannot be proven until the oxidations are attempted with the purified enzyme.

A complex pattern is presented by the other four positive oxidations. The enzyme responsible for oxidizing the alditols according to the Bertrand-Hudson rule could be assumed to be responsible for the oxidation of methyl α-D-arabinopyranoside (**15**) when the topographic similarities of **15** and **28** are considered. Structures **26** and **28** possess the same configura-



28



15

tional but different conformational requirements. The oxidation of methyl α-L-arabinopyranoside (**17**) by either of these enzymes cannot be rationalized; however, comparison of **11** and **17** shows that both rule *1* and rule *2* for oxidation of the cyclitols (see Introduction) are satisfied by **17**. Therefore, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

enzyme, or one of the enzymes, responsible for oxidation of the cyclitols is apparently responsible for the oxidation of methyl α-L-arabinopyranoside. The oxidations which occurred at C-2, for which the products could not be isolated or characterized, may have been caused by the enzyme or enzymes which oxidized some aldonic acids to the corresponding 2-keto compounds (11).

It is apparent from these results that the oxidation of methyl glycopyranosides by *A. suboxydans* is complicated by the presence of at least four active enzymes. The resolution of this problem will not be forthcoming until the enzymes have been purified. Nevertheless, the microbiological synthesis of some methyl pentopyranosid-4-uloses has been achieved, and a large number of cyclic, carbohydrate derivatives are now potential substrates for oxidation by this microorganism.

Experimental

Melting points were determined with a Fisher–Johns melting point apparatus and are uncorrected. The infrared (ir) spectra were recorded on a Perkin–Elmer 180 spectrophotometer. Ultraviolet (uv) spectra were recorded on a Unicam SP800 B spectrophotometer. Proton magnetic resonance (^{1}Hmr) spectra were recorded at 60 MHz on a Varian EM-360 spectrometer in chloroform-*d* with tetramethylsilane (TMS, δ = 0.00) as the internal standard, unless otherwise indicated. Carbon-13 magnetic resonance (^{13}Cmr) spectra were recorded in chloroform-*d* or methyl sulfoxide-d_6 solutions on a Bruker HX-60 spectrometer equipped with a FT60M Fourier transform accessory at 15.09 MHz; chemical shifts are given in ppm downfield from TMS. Thin-layer chromatography (tlc) was performed with Silica Gel G as the adsorbent in the following solvent systems (v/v): (*A*) ethyl acetate – ethanol, 5:1; (*B*) ethyl acetate; (*C*) petroleum ether (bp 60–80°C) – ethyl acetate, 1:3. The developed plates were air-dried and exposed to uv light and/or sprayed with a solution of cerium sulfate (1.0%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at ~150°C. Column chromatography was performed on Brinkmann silica gel (70-325 mesh). Paper chromatography (pc) was performed on Whatman No. 1 chromatography paper using the descending technique. The following solvent systems were used (v/v): (*I*) *n*- propanol – ethyl acetate – water, 7:1:2; (*II*) 0.55% benzeneboronic acid in ethyl acetate – acetic acid – water, 9:2:2 (12); (*III*) *n*-butanol–ethanol–water, 3:1:1. The following spray reagents were used to detect the carbohydrates on the paper chromatograms: (*i*) 2,5-diphenyl-3-(*p*-styrylphenyl)tetrazolium chloride (TSTZ) (13); (*ii*) aniline hydrogen phthalate (14); (*iii*) *p*-anisidine hydrochloride (15); (*iv*) triphenyltetrazolium chloride (TTC) (16); (*v*) *o*-phenylenediamine (17). High performance liquid chromatography (hplc) was performed using a Waters Model ALC-GPC-244 liquid chromatograph with Model 440 Absorbance Detector (254 nm). A μPorasil column was used with hexane – ethyl acetate (1:1, v/v) as the solvent. Solvents were evaporated under reduced pressure below 50°C.

Acetobacter suboxydans (ATCC 621H) was grown as previously described (18). All of the microbiological oxidations were performed in the following manner. *Acetobacter suboxydans* cells were isolated from D-sorbitol broths by centrifugation (~10 000 rpm, ~12 000 g) using an International Refrigerated Centrifuge Model B-20. The substrate was dissolved in distilled water (1–2%, w/v), the isolated cells were added, and the suspension was swirled mechanically. For the oxidation of 2 g of substrate, the cells isolated from 150 ml of standard sorbitol broth were used.

Oxidation of Methyl α-D-Xylopyranoside (1)

(*a*) An aqueous solution of **1** was oxidized by *A. suboxydans* cells. The oxidation was shown to be complete after 4 days, at which time tlc (solvent *A*) showed that no starting material remained when a sample was treated with methoxylamine hydrochloride (see part *b*). Examination of the oxidation mixture by pc (solvent *III*) revealed a streak ($R_{SORBOSE}$ 2.4–3.3) using both spray *i* (purple) and spray *ii* (yellow, faded quickly). When an oxidation sample was examined using uv spectroscopy, the sample showed λ_{max} 262 nm and a sample in ~1 *N* sodium hydroxide showed λ_{max} 308 nm. After 4 days, the cells were removed by centrifugation. When a sample was treated, successively, with sodium borohydride and ~1 *N* sulfuric acid (~70°C, 3 h), and the products were examined by pc (solvents *II* and *III*, spray *iii*), the presence of xylose, arabinose, and a trace of ribose was revealed.

(*b*) Methoxylamine hydrochloride (5.0 g) was added to an oxidation sample containing 4.0 g of oxidized **1**. The solution was adjusted to p*H* 4 and heated at ~70°C for 3 h. Thin-layer chromatography (solvent *A*) revealed the presence of only one major product (R_F 0.71) and traces of two minor components (R_F 0.79, 0.90). The solution was neutralized and concentrated to a syrup which was extracted with hot dichloromethane. The organic solution was dried (magnesium sulfate), concentrated to a syrup, and the major product was isolated by column chromatography (solvent *B*). The major product was identified as methyl β-L-*threo*-pentopyranosid-4-ulose (*E*)-*O*-methyloxime (**5**) and was isolated as a syrup (3.90 g, 84%); $[\alpha]_D$ +133° (*c* 1.50, water) and +174° (*c* 1.37, chloroform); ν_{max} (neat): 1640 (weak, C=N), 3430 cm^{-1} (strong, OH); ^{1}Hmr data δ: 3.46 (s, 3H, OMe), 3.89 (s, 3H, NOMe), 3.5–5.0 (m, 7H, H-1, H-2, H-3, 2H-5's, OH-2, OH-3); ^{13}Cmr data: see Table 1. *Anal.* calcd. for $C_7H_{13}O_5N$: C 44.0, H 6.8, N 7.3; found: C 43.8, H 6.8, N 7.3.

(*c*) A solution of **5** (3.90 g) in distilled water (125 ml) was shaken with Rexyn 101 resin (H^+) until tlc (solvent *A*) indicated that no starting material remained and that a single product (R_F 0.47) had been formed. Paper chromatography (solvent *I*) showed that this product migrated at the same rate as the product formed in the original oxidation. The resin was removed by filtration and the aqueous solution was concentrated to give methyl β-L-*threo*-pentopyranosid-4-ulose (**3**) as a syrup (2.65 g, 81%); $[\alpha]_D$ + 170° (*c* 1.60, water); ν_{max} (neat): 1730 cm^{-1}(strong, C=O), 3350 cm^{-1}(strong, OH); λ_{max}(H_2O) 260 nm (ε 931); λ_{max} (0.1 *N* NaOH): 317 nm (ε 1750), and λ_{sh} 341 nm; ^{1}Hmr data (in deuterium oxide relative to DSS) δ: 3.38 (s, 3H, OMe), 3.4–4.8 (m, 5H, H-1, H-2, H-3, 2H-5's); ^{13}Cmr data: see ref. 1. *Anal.* calcd. for $C_6H_{10}O_5$: C 44.4, H 6.2; found: C 43.9, H 6.1.

Oxidation of Methyl β-D-Xylopyranoside (2)

(*a*) An aqueous solution of **2** was oxidized for a period of 30 days. Paper chromatography (solvent *III*) revealed a streak ($R_{SORBOSE}$ 2.3–3.6) using both spray *i* (purple) and spray *ii*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(yellow). When a broth sample was examined using uv spectroscopy, the sample showed λ_{max} 268 nm and a sample in ~1 *N* sodium hydroxide showed λ_{max} 313 nm and λ_{sh} 337 nm. After 30 days, the cells were removed by centrifugation. When a sample was treated, successively, with sodium borohydride and ~1 *N* sulfuric acid (~70°C, 3 h) and the products were examined by paper chromatography (solvent *III*, spray *iii*), the presence of xylose, arabinose, and a trace of ribose was revealed.

(*b*) An oxidation sample containing 2.0 g of **2**, both oxidized and unoxidized, was treated with methoxylamine hydrochloride. Thin-layer chromatography (solvent *B*) revealed the presence of one major product (R_F 0.54), one minor product (R_F 0.68) which was visible under uv light, and the unoxidized starting material (R_F 0.09). The reaction mixture was processed as before and the two products were separated using column chromatography (solvent *B*). The slower-moving component was identified as methyl α-L-*threo*-pentopyranosid-4-ulose (*E*)-*O*-methyloxime (**6**) and was obtained as white flakes (700 mg, 30%) having mp 69–70°C (recrystallized from dichloromethane – petroleum ether (30–60°C)); $[\alpha]_D$ −135° (*c* 1.03, water); ν_{max} (KBr): 1645 (weak, C=N), 3380 cm^{-1} (strong, OH); ^{1}Hmr data δ: 3.61 (s, 3H, OMe), 4.06 (s, 3H, NOMe), 3.5–5.0 (m, 7H, H-1, H-2, H-3, 2H-5's, OH-2, OH-3); ^{13}Cmr data: see Table 1. *Anal.* calcd. for $C_7H_{13}O_5N$: C 44.0, H 6.8, N 7.3; found: C 43.9, H 7.0, N 7.3.

The faster-moving component was isolated as a syrup (294 mg), $[\alpha]_D$ −4° (*c* 2.10, chloroform); ν_{max} (neat): 1620, 1725 (conjugated C=N's), 3450 cm^{-1} (OH); λ_{max} (CH_2Cl_2): 265 nm. High performance liquid chromatography revealed that the syrup was a mixture of two isomers in a ratio of ~20:1. The major component was identified as methyl β-D-*glycero*-pentopyranosid-3,4-diulose (3*E*,4*E*)-bis(*O*-methyloxime) (**14**); ^{1}Hmr data δ: 3.20 (s, 1H, OH-2), 3.47 (s, 3H, OMe), 4.02 and 4.07 (s, 3H each, 2 NOMe's), 4.5–4.8 (m, 4H, H-1, H-2, 2H-5's); ^{13}Cmr data: see Table 1. *Anal.* calcd. for $C_8H_{14}N_2O_5$: C 44.0, H 6.5, N 12.8; found: C 44.2, H 6.5, N 12.8.

(*c*) A solution of **6** (650 mg) in distilled water (50 ml) was shaken with Rexyn 101 resin (H^+) until tlc (solvent *B*) indicated that no starting material remained and that a single product (R_F 0.09) had been formed. The hydrolysis mixture was processed to give methyl α-L-*threo*-pentopyranosid-4-ulose (**2**) as a syrup (470 mg, 85%); $[\alpha]_D$ −38° (*c* 1.56, water); ν_{max} (neat): 1730 (C=O), 3390 cm^{-1} (OH); λ_{max} (H_2O): 269 nm (ε 120); λ_{max} (1.0 *N* NaOH): 311 nm (ε 365); ^{1}Hmr data (in deuterium oxide relative to DSS) δ: 3.58 (s, 3H, OMe), 3.2–4.7 (m, 5H, H-1, H-2, H-3, 2H-5's); ^{13}Cmr data: see ref. 1. This product was shown by paper chromatography (solvent *I*) to be identical to that formed in the original oxidation. An accurate elemental analysis could not be obtained as the compound started to decompose as soon as it was concentrated to a syrup.

Oxidation of Methyl α-D-Lyxopyranoside (19)

(*a*) An aqueous solution of **19** was oxidized for a period of 30 days. Paper chromatographic analysis (solvent *I*) revealed a product ($R_{SORBOSE}$ 2.17) when both spray *i* (purple) and spray *iv* (red) were used. When an oxidation sample was examined using uv spectroscopy, the sample showed λ_{max} 294 nm and a sample in 1 *N* sodium hydroxide showed λ_{max} 311 nm and λ_{sh} 347 nm. When a sample was treated, successively, with sodium borohydride and 2 *N* sulfuric acid (~80°C, 3h), paper chromatography (solvent *III*, spray *iii*) revealed the presence of lyxose and a small amount of ribose.

(*b*) An oxidation sample containing 1.5 g of **19**, both oxidized and unoxidized, was treated with methoxylamine hydrochloride and tlc (solvent *A*) showed the presence of a major product (R_F 0.81), a minor product (R_F 0.87) which could be seen under uv light, and unreacted starting material (R_F 0.56). The reaction mixture was processed as before and the two products were separated by column chromatography (solvent *C*). The slower-moving component was isolated as a syrup (455 mg, 26%) and identified as methyl β-L-*erythro*-pentopyranosid-4-ulose (*E*)-*O*-methyloxime (**13**); $[\alpha]_D$ +109° (*c* 2.10, dichloromethane); ν_{max} (neat): 1650 (weak, C=N), 3430 cm^{-1} (strong, OH); ^{1}Hmr data δ: 3.46 (s, 3H, OMe), 3.89 (s, 3H, NOMe), 3.8–4.9 (m, 7H, H-1, H-2, H-3, 2H-5's, OH-2, OH-3); ^{13}Cmr data: see Table 1. *Anal.* calcd. for $C_7H_{13}O_5N$: C 44.0, H 6.8, N 7.3; found: C 44.0, H 6.8, N 7.2.

The faster-moving component was isolated as a syrup (295 mg), $[\alpha]_D$ +5° (*c* 2.10, chloroform); ν_{max} (neat): 1620, 1725 (conjugated C=N's), 3450 cm^{-1} (OH); λ_{max} (CH_2Cl_2): 265 nm. High performance liquid chromatography revealed the syrup to be a mixture of two isomers in an approximate ratio of 20:1. Based on the ^{1}Hmr and ^{13}Cmr data, which were identical to those of **14** from the oxidation of methyl β-D-xylopyranoside, the major isomer was identified as methyl β-L-*glycero*-pentopyranosid-3,4-diulose (3*E*,4*E*)-bis(*O*-methyloxime).

(*c*) When **13** was hydrolyzed with Rexyn 101 resin (H^+) and the reaction mixture was processed as in the previous two cases, the product decomposed before it could be characterized.

Oxidation of Methyl α-D-Arabinopyranoside (15)

(*a*) An aqueous solution of **15** was oxidized for a period of 30 days. Paper chromatography (solvent *I*) revealed a product ($R_{SORBOSE}$ 1.92) when both spray *iv* (red) and spray *i* (purple) were used. When a broth sample was examined using uv spectroscopy, the sample showed λ_{max} 260 nm and a sample in ~1 *N* sodium hydroxide showed λ_{max} 310 nm and λ_{sh} 343 nm. A sample was treated, successively, with sodium borohydride and ~2 *N* sulfuric acid (~85°C, 6 h), and paper chromatography (solvents *II* and *III*, spray *iii*) revealed the presence of arabinose and xylose.

(*b*) An oxidation sample containing 4.0 g of **15**, both oxidized and unoxidized, was treated with methoxylamine hydrochloride and tlc (solvent *B*) revealed the presence of one major product (R_F 0.67), one minor product (R_F 0.83) which could be seen under uv light, and unreacted starting material (R_F 0.06). The reaction mixture was processed as before and the two components were isolated by column chromatography (solvent *B*). The major component was identified as methyl α-D-*threo*-pentopyranosid-4-ulose (*E*)-*O*-methyloxime and was isolated as white flakes (1.30 g, 28%) having mp 64–65°C; $[\alpha]_D$ +132° (*c* 1.21, water). The ir, ^{1}Hmr, and ^{13}Cmr spectra were identical to those of **6** isolated from the oxidation of methyl β-D-xylopyranoside. The faster-moving component was isolated as a syrup (294 mg), $[\alpha]_D$ +5° (*c* 1.33, chloroform); ν_{max} (neat): 1620, 1735 (conjugated C=N's), 3430 cm^{-1} (OH); λ_{max} (CH_2Cl_2): 264 nm. High performance liquid chromatography revealed that the syrup was a mixture of two isomers in an approximate ratio of 11:1. On the basis of hplc retention times, and ^{1}Hmr and ^{13}Cmr spectral data, the major isomer was identified as methyl β-L-*glycero*-pentopyranosid-3,4-diulose (3*E*,4*E*)-bis(*O*-methyloxime).

Oxidation of Methyl α-L-Arabinopyranoside (17)

(*a*) An aqueous solution of **17** was oxidized for 30 days. Paper chromatography (solvent *I*) revealed a product ($R_{SORBOSE}$ 1.95) when both spray *iv* (red) and spray *i* (purple) were used. When an oxidation sample was examined using uv spectroscopy, the sample showed λ_{max} 260 nm and a sample in ~1 *N* sodium hydroxide showed λ_{max} 314 nm and λ_{sh} 341 nm. When a sample was treated, successively, with sodium borohydride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and 2 *N* sulfuric acid (~85°C, 7 h), paper chromatography (solvents *II* and *III*, spray *iii*) revealed the presence of arabinose and xylose.

(*b*) An oxidation sample containing 4.0 g of **17**, both oxidized and unoxidized, was treated with methoxylamine hydrochloride and tlc (solvent *B*) showed the presence of two products (R_F 0.53, 0.72) and a large amount of unreacted starting material (R_F 0.04). The reaction mixture was processed as before and the two products were isolated by column chromatography. The products were identical in all respects to those obtained from the oxidation of methyl β-D-xylopyranoside; the *O*-methyloxime **6** was isolated in 11% yield (509 mg), and 253 mg of a syrupy mixture of the isomeric bis(*O*-methyloximes) were also isolated.

Oxidation of a Mixture of Methyl D-*Ribosides*

An aqueous solution of a mixture of methyl D-ribosides, prepared by a Fischer glycosidation, was oxidized by a suspension of *A. suboxydans* cells. Examination of the oxidation mixture after 5 days by paper chromatography (solvent *I*) showed the presence of one major product ($R_{SORBOSE}$ 2.2–2.3) and one minor product ($R_{SORBOSE}$ 1.4). With sprays *i* (purple), *ii* (yellow), and *v* (visible using uv light), both products gave in each case the same color reaction, whereas with spray *iii* the major and minor products gave a yellow and a red color, respectively. When an oxidation sample was examined using uv spectroscopy, the sample showed λ_{max} 267 nm, whereas a sample in ~1 *N* sodium hydroxide showed λ_{max} 320 nm and λ_{sh} ~345 nm. An oxidation sample was treated successively, with sodium borohydride and ~2 *N* sulfuric acid (~80°C, 4 h), and paper chromatography (solvents *I* and *III*, spray *iii*) showed the presence of ribose and a trace of arabinose. Attempts to prepare oxime, *O*-methyloxime, and phenylhydrazone derivatives of the oxidation products were unsuccessful.

Oxidation of Methyl β-L-*Arabinopyranoside (18)*

An aqueous solution of **18** was oxidized for 30 days. Examination of an oxidation sample by paper chromatography (solvent *I*) revealed the presence of one product ($R_{SORBOSE}$ 2.03) using spray *iii* (purple). When an oxidation sample was treated, successively, with sodium borohydride and ~2 *N* sulfuric acid (~85°C, 6 h), paper chromatography (solvent *III*, spray *iii*) revealed the presence of arabinose and a small amount of ribose. Attempts to prepare an *O*-methyloxime derivative were unsuccessful.

Oxidation of Methyl β-D-*Glucopyranoside (23)*

An aqueous solution of **23** was oxidized for 30 days. Paper chromatographic analysis of the oxidation mixture revealed a product, having $R_{SORBOSE}$ 1.53 (solvent *I*), which gave a positive reaction with spray *i* (purple) and spray *v* (gray-brown). Paper chromatographic examination (solvent *III*, spray *iii*) of a sample treated, successively, with sodium borohydride and ~2 *N* sulfuric acid (~80°C, 4 h) revealed only the presence of glucose. Attempts to prepare an *O*-methyloxime derivative were unsuccessful.

Oxidation of Methyl α-D-*Mannopyranoside (24)*

An aqueous solution of **24** was oxidized for 30 days. Paper chromatographic analysis of the oxidation mixture revealed a product, having $R_{SORBOSE}$ 1.77 (solvent *I*), which gave positive reactions with both spray *i* (purple) and spray *v* (gray-brown). Paper chromatographic examination of a sample treated, successively, with sodium borohydride and ~2 *N* sulfuric acid (~85°C, 6 h) gave inconclusive results. Attempts to prepare an *O*-methyloxime resulted in the formation of a trace of a product which could not be isolated.

Other Attempted Oxidations

Aqueous solutions of the following methyl aldopyranosides were oxidized for 30 days, and paper chromatographic analysis showed that no oxidation had occurred in each case: methyl α-L-lyxopyranoside (**20**), methyl β-D-arabinopyranoside (**16**), methyl α-D-glucopyranoside (**22**), and methyl β-D-galactopyranoside (**25**).

Ipso nitration. XX.[1] Nitration of 5-*tert*-butyl-1,2,3-trimethylbenzene in acetic anhydride. Formation and rearomatization of adducts

ALFRED FISCHER AND KHAY CHUAN TEO

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received January 5, 1978

ALFRED FISCHER and KHAY CHUAN TEO. Can. J. Chem. **56**, 1758 (1978).

Nitration of 5-*tert*-butyl-1,2,3-trimethylbenzene in acetic anhydride gives both diastereomers of the adduct 1-*tert*-butyl-3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate and one diastereomer of 1-*tert*-butyl-3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienol, in 91% yield, together with 5-*tert*-butyl-1,2,3-trimethyl-4-nitrobenzene. Solvolysis of the dienyl acetate in acidified aqueous acetone and acidified methanol affords the diastereomers of the dienols and the dienyl methyl ethers, respectively. The dienyl methyl ethers are also formed from the dienyl acetate in neutral methanol and again on reaction with methanolic sodium methoxide. The dienols isomerize (epimerize) in acidified aqueous acetone. Reaction of the dienyl methyl ethers in aqueous methanol, or prolonged reaction in methanol, results in the formation of methyl-1,2,3-trimethylphenyl ether. Similar cleavage of the *tert*-butyl group is the main reaction on solvolysis of the dienyl acetate in aqueous acetic acid. Under more acidic conditions the dienyl acetate gives 5-*tert*-butyl-2,3-dimethylbenzyl nitrite and lesser amounts of 5-*tert*-butyl-2,3-dimethylphenylnitromethane and 5-*tert*-butyl-2,3-dimethylbenzyl acetate. In trifluoromethanesulfonic and fluorosulfonic acids 5-*tert*-butyl-1,2,3-trimethyl-4-nitrobenzene is the major product.

ALFRED FISCHER et KHAY CHUAN TEO. Can. J. Chem. **56**, 1758 (1978).

La nitration du *tert*-butyl-5 triméthyl-1,2,3 benzène dans l'anhydride acétique conduit aux deux diastéréoisomères de l'adduit, acétate de *tert*-butyl-1 triméthyl-3,4,5 nitro-4 cyclohexadiène-2,5 yle, et à un diastéréoisomère du *tert*-butyl-1 triméthyl-3,4,5 nitro-4 cyclohexadiène-2,5 ol avec un rendement de 91% aux côtés du *tert*-butyl-5 triméthyl-1,2,3 nitro-4 benzène. La solvolyse de l'acétate de diényle dans de l'acétone aqueuse acidulée et dans du méthanol acidulé conduit respectivement aux diastéréoisomères des diénols et des éthers méthyliques de diényle. Les éthers méthyliques de diényle se forment aussi à partir de l'acétate de diényle dans le méthanol neutre et aussi par réaction du méthylate de sodium en milieu méthanolique. Les diénols s'isomérisent (épimérisent) en solution dans l'acétone aqueuse acidulée. La réaction des éthers méthyliques de diényle avec le méthanol aqueux ou par action prolongée du méthanol conduit à la formation de l'éther méthylique du triméthyl-1,2,3 phényle. Un clivage semblable du groupe *tert*-butyle correspond à la réaction principale observée lors de la solvolyse de l'acétate de diényle dans l'acide acétique aqueux. Utilisant des conditions plus acides, l'acétate de diényle conduit au nitrite du *tert*-butyl-5 diméthyl-2,3 benzyle et à des quantités plus faibles de *tert*-butyl-5 diméthyl-2,3 phénylnitrométhane et d'acétate du *tert*-butyl-5 diméthyl-2,3 benzyle. Dans les acides trifluorométhanesulfonique et fluorosulfonique, le *tert*-butyl-5 triméthyl-1,2,3 nitro-4 benzène est le produit principal.

[Traduit par le journal]

Nitration of *p*-*tert*-butyltoluene in acetic anhydride results in predominant *ipso* (1) attack by the nitronium ion at the methyl-substituted position and the formation of 1,2 and, to a lesser extent, 1,4 nitronium acetate adducts (2). Nitration of 4-*tert*-butyl-*o*-xylene gives 1,4 adduct (3) although a small amount of 1,2 adduct is also formed. The present investigation of 5-*tert*-butyl-1,2,3-trimethylbenzene (**1**) continues our study of the nitration of the series of *tert*-butylmethylbenzenes. The unusual formation of 1,2 adducts is of specific interest in this series. A related study is the nitration of 1,2,3,5-tetramethylbenzene (4).

[1]For Part XIX see ref. 10.

Results and Discussion

Nitration and Formation of Adducts

Nitration of 5-*tert*-butyl-1,2,3-trimethylbenzene (**1**) in a mixture of acetic anhydride and methylene chloride at −55°C gave a product mixture containing ca. 91% of diene adducts. One diastereoisomer[2] of 1-*tert*-butyl-3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate[3] (**2***a*) was crystallized from the product mixture. Low temperature chromatography of the residue after concentration of the mother liquor gave 5-*tert*-butyl-2,3-dimethylbenzyl nitrite (**5**)

[2]Individual members of a pair of diastereoisomeric adducts are designated as *a* and *b*.

[3]1-*tert*-Butyl-3,4,5-trimethyl-4-nitro-1,4-dihydrophenyl acetate.

5-*tert*-butyl-1,2,3-trimethyl-4-nitrobenzene (**9**), a second diastereoisomer of 1-*tert*-butyl-3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**2***b*), and 1-*tert*-butyl-3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienol (**3***a*), with stereochemistry corresponding to that of the acetate **2***a*. The correspondence of the stereochemistry was demonstrated by the reduction with aluminum hydride of acetate **2***a* to an alcohol identical to **3***a*. The nitrite **5** was eluted in the early column fractions and was followed by the nitroarene **9**. More nitrite **5** together with acetic acid was obtained in the fractions immediately following **9**. It is clear that these fractions must have contained a diene which decomposed to **5** and acetic acid (and a small amount of other benzylic derivatives, **6** and **7**) subsequent to elution from the column. Probably this diene was **2***a* since it was the major component of the immediately following fraction (0.11 g) which contained a mixture of dienes and it is highly unlikely that all of the **2***a* initially formed could have cleanly crystallized from the reaction mixture before chromatography, without leaving a significant fraction remaining in solution. Diene **2***a* was shown to decompose to **5** and acetic acid, together with variable amounts of the nitromethane **6** and acetate **7**, on standing in solution at ambient temperature and the solid diene decomposed similarly. It is clear that diene **2** is very labile. This was confirmed by allowing a nitration reaction mixture to warm to 0°C before work-up. Under these conditions the nitromethane **6** and nitrite **5** were the predominant reaction products and no dienes were obtained.

The symmetry evident from the ^1H and ^{13}C nmr spectra of **2***a*, **2***b*, and **3***a* shows that these are 2,5 or 5,2 adducts of the original 5-*tert*-butyl-1,2,3-trimethylbenzene. The nitro group must be attached to the C-2 position since the position *ipso* to *tert*-butyl is very hindered and, moreover, addition of the nitronium ion at this position (C-5) would lead to de-*tert*-butylation (5). Addition of nitronium ion *ipso* to *tert*-butyl does not occur to either *p-tert*-butyltoluene (2) or 4-*tert*-butyl-*o*-xylene (3) and is even less likely in 5-*tert*-butyl-1,2,3-trimethylbenzene (*vide infra*). A very small amount of another diene(s) (δ 6.02, 6.08, 6.21 ppm) appeared in one column fraction. It is possible that this was a conjugated diene, such as a 1-acetoxy-2-nitro adduct of the original arene, or a 1-nitro-4-acetoxy adduct. Since the amount was ~0.2% of the total product it was not further investigated. No significant amount of dienes other than those isolated was apparent in the reaction mixture prior to chromatography. Thus it appears that the predominant formation of 1,2 adducts in the case of *p-tert*-butyltoluene is unique.

From the relative extents of attack by the nitronium ion at the nuclear positions of 1,2,3-trimethylbenzene (6, 7) and *tert*-butylbenzene (8) the relative amounts of attack at the nuclear positions of **1** may be calculated on the assumption of additivity (7). Attack at the 2 *ipso* position is predicted to occur to the extent of 95%, with only 1% at the 1 *ipso* position and 5% at the 4 position. Little or no attack is expected at the highly hindered 5 position, *ipso* to *tert*-butyl (2, 5). Although the results of such calculations should be treated with some caution (6, 9) it is clear that, in the case of **1**, calculation is in accord with experiment. The 91% of dienes formed (by nmr), or 91% of diene and benzylic (diene derived) products isolated, reflects that extent of attack at the 2 position. No 5-nitro-1,2,3-trimethylbenzene, the expected product of attack at the 5 position, was detected.

The dienol **3***a* is not a primary reaction product and must have been formed by solvolysis of the dienyl acetate **2**, or other adduct, during work-up.

Reactions of the Adducts

Reactions of diene adducts proceed via cyclohexa-

dienyl cations. Ionization of the nitro group as nitrite anion gives an acetoxycyclohexadienyl cation. Loss of acetate as acetic acid (acid-catalysed) gives a nitrocyclohexadienyl cation. The competition between the two pathways is controlled by: (*i*) the acidity of the solution, more acid solutions favouring the catalysed loss of acetate to form the nitrocyclohexadienyl cation; (*ii*) the ionizing power of the solvent, increased ionizing power favouring the formation of acetoxycyclohexadienyl cation and nitrite anion; and (*iii*) the other substituents present in the diene. In the case of **2** the nitrocyclohexadienyl cation **10** has two methyl and one *tert*-butyl groups attached to centres bearing a formal positive charge, whereas the acetoxy-cyclohexadienyl cation **11** has only one methyl group attached to such a centre. Thus formation of the nitrocyclohexadienyl cation **10** is greatly favoured by the substituents. The ease of formation of **10** is shown by the facility in which the acetate group of **2** is replaced by other nucleophiles in substitution reactions.

Substitution and Isomerization Reactions of Dienes ('Exchange Reactions')

Reactions in which the acetate group of **2** is exchanged for other nucleophiles occur readily, apparently by the S_N1 mechanism.[4] Similarly the diastereoisomeric dienols **3***a* and **3***b* and ethers **4***a* and **4***b* readily undergo isomerization (epimerization) reactions, again by the S_N1 mechanism. All of these reactions presumably involve the intermediate formation of cation **10**. Thus reaction of acetate **2***a* with [$^2H_4$]acetic acid containing 10% acetic anhydride and sulfuric acid led to rapid exchange of the [$^2H_3$]acetate for acetate. Similarly reaction of both **2***a* and **2***b* with aqueous sulfuric acid in acetone gave the dienols **3***a* and **3***b* (Table 1) and with acidified methanol the ethers **4***a* and **4***b*. The facts that both diastereomers of the product were produced from a single diastereomer of the reactant, that both diastereomers of the reactant gave the same initial ratio of products and that the diastereomers of the product subsequently equilibrated provide strong support for the suggested formation of an intermediate nitrocyclohexadienyl cation in which one of the two original chiral centres has become achiral. The substitution and isomerization reactions were conveniently followed by the changes in the *tert*-butyl region of the ^1H nmr spectra. The reactions provide a potentially excellent route to the preparation of both diastereoisomers of **3** and **4**. Dienol **3***b*, which, unlike **3***a*, was not obtained from the nitration reaction mixture, was isolated from the mixture of diastereomers prepared in this manner. The mixture of the ethers **4***a* and **4***b* was prepared similarly and **4***b* isolated by chromatography. An interesting feature of the exchange reactions is that the isomer formed more rapidly, **3***a* and **4***a*, with the *tert*-butyl peak at lower field, is not the most stable isomer. Prolonged reaction led to the predominant formation of **3***b* and **4***b*, with the higher field *tert*-butyl group. The acid-catalysed methanolysis of **2** was carried out under conditions such that the replacement of acetate by methoxyl and the subsequent equilibration was very fast. Both **2***a* and **2***b* gave the same ratio of **4***a*:**4***b*, 29:71. However, formation of the nitrocyclohexadienyl cation is so facile that it was possible to observe methanolysis in the absence of added acid (Tables 2 and 3). It was then possible to observe the disappearance of **2***a* and the initial formation of an approximately 1:1 mixture of **4***a* and **4***b*, which subsequently equilibrated to a mixture containing ca. 70% of **4***b*, and then slowly rearomatized forming, as the major product, methyl 3,4,5-trimethylphenyl ether (**14**). Epimerization of the dienols **3***a* and **3***b* in acetone containing aqueous sulfuric acid was readily followed (Table 4).

4000[b]		46	46	8[c]

[a]Amounts in mol% from integrals of *tert*-butyl peaks at δ 1.02 (2*a*), 0.99 (3*a*), 0.92 (3*b*), and 1.22 ppm (aromatic product and/or *tert*-butyl alcohol equivalent to aromatic cleavage product).
[b]Reaction mixture allowed to stand at lower temperature for 2 days and then worked-up.
[c]From *tert*-butyl peak at δ 1.30 and also from the aromatic peak at 7.12 ppm.

Acetate **2***a* and dienol **3***a* have the same stereochemistry and hence **2***b* and **3***b* must have the same stereochemistry. The *tert*-butyl and 4-methyl ^1H nmr peaks of **2***b* are at higher field than **2***a* and similarly for **3***b* with respect to **3***a*. In the case of the dienyl methyl ethers the ^1H nmr peaks of *tert*-butyl and 4-methyl protons are at higher field in **4***b* than in **4***a*. On the basis of these parallels it seems reasonable to propose that **4***a* has the same stereochemistry as **2***a* and **3***a* and that **4***b* has the same stereochemistry as **2***b* and **3***b*.

Solvolysis of acetate **2***a* in aqueous methanol gave both the dienols **3***a* and **3***b* and the dienyl methyl

[4]In the acid-catalysed reactions it is the conjugate acid of the diene which undergoes the S_N1 reaction.

ethers **4***a* and **4***b*, the products arising from reaction of cation **10** with both solvent species. Since the ratio of **4***b* to **4***a* was close to the equilibrium value (~70% **4***b*) whereas **3***a* appeared to be present in greater amount than **3***b* it would seem that the dienyl ethers epimerize more rapidly than the dienols. This reaction clearly illustrates the preference for formation of cation **10**, from **2**, over cation **11**. Solvolysis in aqueous alcohols normally leads to loss of the nitro group as nitrite (6, 10) and the preferred loss of

acetate in the present instance is a reflection of the degree to which the alkyl substituents preferentially stabilize cation **10** compared with **11**.

Reaction of acetate **2***a* with sodium methoxide in methanol gave as the major product the ethers **4***a* and **4***b* and a small amount of dienol **3**. Reaction of the adducts of *p*-xylene (**11**), *p*-cymene (**12**), and the 1,4 adduct of *p*-*tert*-butyltoluene (**2**) with sodium methoxide leads to the initial formation of the corresponding dienols, by cleavage of the acetate at the acetyl group ($B_{AC}2$ transesterification), followed by rearrangement to the 3,4-dialkylphenol, in the cases of the adducts of *p*-xylene[5] and *p*-cymene, and cleavage of the *tert*-butyl group, in the case of the adduct of *p*-*tert*-butyltoluene. For **2** only a small amount of the reaction, at most, proceeds along this pathway. The main reaction is ionization of the acetate group to form cation **10** which combines with methoxide to form the ether **4**. Two factors presumably contribute to the dominance of the $B_{AL}1$ over the normal $B_{AC}2$ pathway for reaction of the acetate ester. The ease of formation of cation **10** is one. The other is that the bulky *tert*-butyl group shields, to at least some degree, the neighbouring acetyl group from attack by methoxide. It is striking that ionization of acetate dominates ionization of the nitro group as nitrite, even under conditions such that no acid is available for catalysis, not even the acid normally released in the solvolysis.

In the substitution and epimerization reactions which were followed over extended periods of time, and in the rearomatization reactions discussed below, dienes other than those already mentioned appeared to be formed, as shown by the appearance of other peaks in the δ 5.7–6.3 ppm (vinyl hydrogen) and/or 1.5–2.0 ppm (allylic methyl and methyl

For personal use only.

bonded to saturated carbon) and/or ~1.1 ppm ('saturated' *tert*-butyl) regions. It is possible that these absorptions arose from the presence of conjugated dienes. However, such absorptions never represented more than a minor amount of the product and the conclusion (*vide supra*) that the special factors which result in the preferential formation of 1,2 adduct (conjugated diene) from *tert*-butyltoluene do not exist in the 5-*tert*-butyl-1,2,3-trimethylbenzene system is reinforced.

Rearomatization Reactions

Rearomatization products of diene adducts are formed via the nitrocyclohexadienyl cation (13) or the acetoxycyclohexadienyl cation (6). Acetate **2** gives the nitrocyclohexadienyl cation **10** much more rapidly than the acetoxycyclohexadienyl cation **11** under all conditions investigated. However this does not result in all of the rearomatization reactions proceeding via **10**, as the transition state barrier between **10** and its aromatic product may be, and in the relevant instances presumably is, higher than that between **2**, **11** and its aromatic product (cf. 14).

As discussed above methanolysis of acetate **2***a* gave the dienyl ethers **4***a* and **4***b*, which subsequently equilibrated (Tables 2 and 3). On prolonged reaction the dienyl ethers rearomatized and the major aromatic product was methyl 3,4,5-trimethylphenyl ether (**14**). Formation of **14** occurs via the methoxycyclohexadienyl cation **12**, which undergoes loss of the *tert*-butyl cation. The ether **14** was formed in close to quantitative yield when the dienyl ethers **4***a* and **4***b* were first prepared and then solvolysed in aqueous methanol, conditions most favourable to the ionization of the nitro group (6). The methoxyl group is a poorer leaving group than acetoxyl and a possible explanation for the formation of the rearomatization product via the methoxycyclohexadienyl cation **12** might be that ionization of the nitro group as nitrite from **4** is faster than loss of methoxide (although slower than loss of acetate from **2**). However, since **4** epimerizes before rearomatization (Tables 2 and 3) formation of **10** would seem to be *faster* than formation of **12**. Thus the barrier for loss of the *tert*-butyl cation from **12** is lower than that (those) for rearomatization of **10**.

Solvolysis of acetate **2***a* in moist [$^2H_4$]acetic acid resulted in rapid exchange of the acetate group prior to rearomatization and epimerization accompanying rearomatization (Table 5). Formation of the nitrocyclohexadienyl cation **10** is evidently faster than formation of the acetoxycyclohexadienyl cation **11**. However the predominant rearomatization products, the [$^2H_3$]acetate **15** and the phenol **16**, are not derived from cation **10** but from **11** (or the hydroxy analog **13**), which ejects the *tert*-butyl cation. Conceivably, the phenol **16** could have been formed by hydrolysis of the aryl acetate **15**. It seems more likely that some dienol **3** was formed from **2***a* by partial exchange of acetate with solvent water, via **10**, and that the phenol was in turn formed from the dienol via ionization to cation **13** followed by loss of the *tert*-butyl cation. A compound of relative molecular mass 192 was also a significant product from the solvolysis of acetate **2***a*. No significant amounts of benzylic derivatives were detectable by nmr hence this product is probably a phenol. Reaction pathways which would lead to both unrearranged phenol, i.e. 6-*tert*-butyl-2,3,4-trimethylphenol, and to rearranged phenol, i.e. 2-*tert*-butyl-3,4,5-trimethylphenol, have been observed in other systems (3, 12), and may apply here. Loss of the *tert*-butyl group also occurred in the solvolysis of the 1,4 adducts of *p*-*tert*-butyltoluene and 4-*tert*-butyl-*o*-xylene, although in the latter case this was a minor reaction, the major reaction being the normal 1,2 acetate shift leading to the aryl acetate.

It is evident that in the solvolytic rearomatization reactions in aqueous acetic acid, aqueous methanol and methanol one mole of *tert*-butyl derivative, viz. *tert*-butyl acetate, alcohol, or methyl ether, as appropriate, must have been formed per mole of aromatic de-*tert*-butylation product. Although the *tert*-butyl cleavage products were not identified as such ^1H nmr peaks were observed at the appropriate positions in the spectra of the reaction mixtures, e.g. at δ 1.30 (*tert*-butyl alcohol (15)) and 1.43 ppm (*tert*-butyl acetate (15)) in the products of solvolysis of **2***a* in moist acetic acid. The formation of these peaks provides a measure of the extent of rearomatization even

TABLE 5. Solvolysis of acetate **2***a* in moist acetic acid[a]

Time (min)	Amount (mol %)		
	2*a*	**2***b*	ArH
0	100		
10	44	26	12
15	35	24	20
20	26	20	30
25	21	16	39
30	16	13	44
35	12	11	48

[a]Reaction carried out in [$^2H_4$]acetic acid containing 2% water. Amounts determined from integrals of *tert*-butyl peaks at δ 0.92 ('2*b*'), 0.99 ('2*a*'), and 1.25 plus 1.29 ('ArH') expressed as a fraction of the total integral from 0.85 to 1.35 ppm. Other (smaller) peaks appeared at 1.07 and 1.14 ppm. '2*a*' may include a contribution from dienol 3*a* and likewise for '2*b*' and 3*b*. 'ArH' may include a contribution from *tert*-butyl alcohol and *tert*-butyl acetate, the expected cleavage products.

though the compounds exhibiting the absorption peaks are not themselves aromatic.

As the acidity of the reaction medium is increased the rate of formation of the nitrocyclohexadienyl cation **10** and its steady-state concentration will increase relative to the acetoxycyclohexadienyl cation **11**, because the loss of acetate group from **2** is acid catalysed but the loss of the nitro group is not. The rate of rearomatization from **10** will also increase and will eventually become faster than the rate of rearomatization via **11**. Addition of 0.05% sulfuric acid and 10% acetic anhydride to acetic acid brings about this transition and the aromatic products formed are derived from the nitrocyclohexadienyl cation **10** (Table 6).[6] Deprotonation of **10** at either of the symmetrical methyl groups leads to the triene **17** which in turn undergoes ionization of the nitro group to form the benzyl carbonium ion **18** and nitrite anion. Combination of **18** and nitrite anion, at oxygen, would give the benzyl nitrite **5** and, at nitrogen, would give the aryl nitromethane **6**. Combination of the benzyl cation with acetate would give the benzyl acetate **7**.[7] Inspection of Table 6 reveals that the aldehyde **19** is not a primary reaction product but is formed from the nitrite **5** in the more strongly acidic solutions and also during work-up. In fact it was possible to follow the conversion of **5** into **19** in the reaction mixtures to which the 5% and 50% sulfuric acid solutions were added. Thus it is clear that the nitrite **5** is the major primary aromatic product over the complete acidity range investigated. Benzyl nitrite itself is known to undergo autodecomposition to benzaldehyde (16) and benzaldehydes often accompany benzylic products obtained from rearomatization of diene adducts (3, 4, 11, 17). The benzyl alcohol **8** which was obtained on work-up of the reaction to which 0.05% sulfuric acid had been added also appears to have been formed from **5**. A small amount of the nitroarene **9** also appeared to have been formed in the reaction to which 50% sulfuric acid was added.

Reaction of acetate **2***a* in deuteriochloroform with 2% aqueous sulfuric acid led to initial partial conversion into dienol **3**. However, rapid rearomatization ensued and the final product was the nitrite **5** and acetic acid. Reaction of acetate **2***a* in ether with hydrogen chloride (in an unsuccessful attempt to prepare the nitrocyclohexadienyl chloride) also gave nitrite **5** as the major product and some nitromethane **6**. The conversion of **5** to benzaldehyde **19**, on standing in the acid solution was again demonstrated. Reaction of **2***a* with boron trifluoride in ether also gave a mixture of the side-chain products **5**, **6**, **7**, and **8** and, on one occasion, the benzaldehyde **19**.

TABLE 6. Yields of products of rearomatization of diene **2***a* with sulfuric acid and 10% acetic anhydride in [$^2H_4$]acetic acid[a]

	Yield immediately before work-up					Yield after work-up				
%H_2SO_4[c]	**19**	**5**	**6**	**7**	X[b]	**19**	**5**	**6**	**7**	X[b]
0.05[d]		47	13	12	14	12	18	33	16	5

[a]Yields in mol% determined by integration of the methylene, vinyl, and aromatic regions of the ^1H nmr spectrum.
[b]Unidentified compound δ 7.00 ppm in both reaction mixture and $CDCl_3$, possibly **1**.
[c]Amount of sulfuric acid by weight in the acetic anhydride – [$^2H_4$]acetic acid solution before addition of 250 mm^3 to a solution of **2***a* (120 mg) in $CDCl_3$ (200 mm^3).
[d]Before work-up peaks between δ 6.0 and 6.5 ppm integrated for ~14% of the products. After work-up 16% of **8** was obtained in addition to the products listed.
[e]Because of phase separation the product distribution prior to work-up could not be measured quantitatively. Qualitatively, **19** increased relatively during the reaction to become the major product, **5** was present initially but disappeared prior to work-up as **19** was formed and **6** and **7** were minor products. Peaks attributed to a minor amount of nitroarene **9** were also present in the ^1H nmr spectrum of the worked-up product.

At very high levels of acidity the opportunity for cation **10** to be deprotonated to the triene **17** is reduced. The life-time of **10** is therefore increased and the opportunity for migration of the nitro group to occur is enhanced. Migration of the nitro group to the unsubstituted position gives cation **20**, the precursor to the nitroarene **9**. When acetate **2***a* was reacted with fluorosulfonic acid and with trifluoromethane sulfonic acid the nitroarene **9** was the major reaction product, although benzylic derivatives, mainly the aldehyde **19**, itself presumably formed from the nitrite **5**, and some nitromethane **6** were also formed. A small amount of **9** was also detected in the reaction with 50% sulfuric acid in acetic acid – acetic anhydride, as mentioned above.

Adduct **2** has a marked preference for the formation of benzylic derivatives. On reaction with sulfuric acid in acetic acid – acetic anhydride the adduct of 4-*tert*-butyl-*o*-xylene gave only modest amounts of benzylic product. The nitroarene was formed at the lowest acidities and became the major product at higher acidities. In trifluoroacetic acid and/or boron trifluoride etherate the adducts of *p*-xylene, *tert*-butyltoluene, and 4-*tert*-butyl-*o*-xylene all gave the nitroarene. Under these conditions, as mentioned, **2** gave benzylic derivatives and only gave the nitro-

[6]These reactions were carried out in a medium which contained 44% deuteriochloroform. The presence of the chloroform and the absence of water would make for a poorly ionizing solution and this factor would contribute to a decreased ease of formation of **11** and hence a reduced extent of rearomatization by this pathway.

[7]These reactions can also be formulated as occurring between the benzyl cation and nitrous and acetic acids, followed by deprotonation.

arene under more highly acidic conditions and even then appreciable amounts of benzylic derivatives were still formed. This preference may be attributed to the stability of cation **10** and the fact that the nitro group has to migrate across an interposed *ipso* position to form cation **20** the precursor to nitroarene. If the migration involves successive 1,2 shifts then cation **21** is formed as an intermediate. Cation **21** is much less stable than **10** and it will preferentially reform **10** rather than **20**. Thus the existence of **21** in the sequence **10** → **21** → **20** effectively increases the lifetime of **10** and allows more opportunity for deprotonation to the triene **17** to occur. In addition, there is, of course, a statistical factor of 2 favouring deprotonation of **10** as compared with the 4-*tert*-butyl-1,2-dimethylbenzene case.

Thermolysis of acetates **2***a* and **2***b* gave the parent hydrocarbon **1** and benzylic derivatives as the major products. Thermolysis of the dienol **3***a* gave the phenol **16**, formally the product of the elimination of the elements of *tert*-butyl nitrite, and the benzyl alcohol **8** as the major products.

Experimental

General experimental methods have been described previously (3).

*5-*tert*-Butyl-1,2,3-trimethylbenzene (**1**)*

Alkylation of *m*-xylene (2.5 mol) with *tert*-butyl alcohol and aluminum chloride catalyst (18) gave 5-*tert*-butyl-1,3-dimethylbenzene (73% after distillation at 41°C/55 Pa); ir (film): 1600, 1475, 1360, 845, 701 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.26 (s, 9, $C(CH_3)_3$), 2.24 (s, 6, 1-CH_3 and 3-CH_3), 6.75 (s, 1, 2-*H*), 6.95 ppm (s, 2, 4-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 21.5 (1-CH_3 and 3-CH_3), 31.4 ($C(CH_3)_3$), 34.4 ($C(CH_3)_3$), 123.1 (*C*-4 and *C*-6), 127.1 (*C*-2), 137.3 (*C*-1 and *C*-3), 151.0 ppm (*C*-5); ms (70 eV) *m/e* (relative intensity): 162 (30, M), 148 (18), 147 (100, $M - CH_3$), 119 (30, $M - C_3H_7$), 107 (33), 91 (18).

Chloromethylation of the 5-*tert*-butyl-1,3-dimethylbenzene (1 mol) gave 5-*tert*-butyl-2-chloromethyl-1,3-dimethylbenzene (83% after two recrystallizations from pentane); mp 26–27°C (lit. (19) 25.6–25.9°C); ir (melt): 1610, 1480, 1450, 1360, 1270, 1243, 933, 870, 726, 675 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.24 (s, 9, $C(CH_3)_3$), 2.34 (s, 6, 1-CH_3 and 3-CH_3), 4.53 (s, 2, CH_2), 7.01 ppm (s, 2, 4-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 19.4 (1-CH_3 and 3-CH_3), 31.2 ($C(CH_3)_3$), 34.3 ($C(CH_3)_3$), 41.0 (CH_2Cl), 125.4 (*C*-4 and *C*-6), 131.0 (*C*-2), 136.9 (*C*-1 and *C*-3), 151.3 ppm (*C*-5); ms (70 eV) *m/e* (relative intensity): 212 (8) and 210 (24, M), 197 (33) and 195 (100, $M - CH_3$), 175 ($M - Cl$).

Reduction of the 5-*tert*-butyl-2-chloromethyl-1,3-dimethylbenzene (0.72 mol) with lithium aluminum hydride gave 5-*tert*-butyl-1,2,3-trimethylbenzene (**1**, 99%); mp (sealed tube) 34–35°C (lit. (19) 30–32°C); ir (Nujol): 1470, 1350, 1309, 1240, 1205, 998, 929, 865, 711 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.27 (s, 9, $C(CH_3)_3$), 2.10 (s, 3, 2-CH_3), 2.24 (s, 6, 1-CH_3 and 3-CH_3), 7.00 ppm (s, 2, 4-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 14.9 (2-CH_3), 20.8 (1-CH_3 and 3-CH_3), 31.4 ($C(CH_3)_3$), 34.1 ($C(CH_3)_3$), 124.6 (*C*-4 and *C*-6), 131.9 (*C*-2), 135.8 (*C*-1 and *C*-3), 147.9 ppm (C-5); ms (70 eV) *m/e* (relative intensity): 176 (29, M), 161 (100, $M - CH_3$), 145 (9), 133 (30), 121 (46), 119 (15), 105 (20), 91 (20).

*5-*tert*-Butyl-2,3-dimethylbenzyl Acetate (**7**) and 5-*tert*-Butyl-2,3-dimethylbenzyl Alcohol (**8**)*

Chloromethylation (19) of 4-*tert*-butyl-1,2-dimethylbenzene gave 5-*tert*-butyl-1-chloromethyl-2,3-dimethylbenzene; ir (Nujol) 1470, 1350, 1278, 1262, 1242, 1208, 879, 737, 688, 625 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.26 (s, 9, $C(CH_3)_3$), 2.21 (s, 6, 2-CH_3 and 3-CH_3), 4.51 (s, 2, CH_2), 7.12 ppm (s, 2, 4-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 14.4 (2-CH_3), 20.6 (3-CH_3), 31.3 ($C(CH_3)_3$), 34.1 ($C(CH_3)_3$), 45.9 (CH_2Cl), 124.6 (*C*-6), 127.6 (*C*-4), 132.6 (*C*-2), 135.0 (*C*-1), 136.9 (*C*-3), 148.3 ppm (*C*-5); ms (70 eV) *m/e* (relative intensity): 212 (9) and 210.124 (27, M_r calcd. for $^{12}C_{13}{}^1H_{19}{}^{35}Cl$): 210.118), 197 (40) and 195 (100, $M - 15$), 175 (13, $M - Cl$), 169 (5) and 167 (13, $M - C_3H_7$), 161 (18), 159 (36), 119 (33), 91 (13).

The chloride (1.5 g, 7 mmol) was heated under reflux with silver acetate (1.4 g, 8 mmol) in acetic acid (20 cm^3) for 1 h. After work-up 5-*tert*-butyl-2,3-dimethylbenzyl acetate (**7**, 1.7 g, 7 mmol was obtained); ir (film) 1730 and 1238 ($OCOCH_3$), 1470, 1370, 1350, 1021, 870 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.30 (s, 9, $C(CH_3)_3$), 2.00 (s, 3, $OCOCH_3$), 2.16 (s, 3, 2-CH_3), 2.25 (s, 3, 3-CH_3), 5.07 (s, 2, CH_2), 7.15 ppm (s, 2, 4-*H* and 6-H); ms *m/e* 234.161 (M_r($^{12}C_{15}{}^1H_{22}{}^{16}O_2$): 234.162).

Reduction of the acetate 7 with lithium aluminum hydride gave 5-*tert*-butyl-2,3-dimethylbenzyl alcohol (**8**); ir (CCl_4) 3630, 3500–3250 (broad) 1470, 1350, 1240, 1018, 1000, 874 cm^{-1}; ^1H nmr: 1.30 (s, $C(CH_3)_3$), 1.22 (s, 2-CH_3), 1.29 (s, 3-CH_3), 4.70 (s, CH_2), 7.20 ppm (m, 4-*H* and 6-*H*); ms (70 eV) *m/e* (relative intensity): 192.153 (41, M_r calcd. for $^{13}C_{13}{}^1H_{20}{}^{16}O$: 192.151), 175 (100, $M - OH$), 159 (81), 119 (34).

*Nitration of 5-*tert*-Butyl-1,2,3-trimethylbenzene (**1**)*

A solution of freshly distilled nitric acid (18.9 g, 0.30 mol) in acetic anhydride (60 cm^3) was added to **1** (17.6 g, 0.10 mol) in a mixture of acetic anhydride (40 cm^3) and dry methylene chloride (30 cm^3) at a rate such that the temperature of the mixture (cooled in solid carbon dioxide – acetone) did not rise above −55°C. The pale yellow mixture was allowed to stand at −75°C for 1 h and after work-up in the usual manner (3) yielded a yellow crystalline solid (30.7 g) consisting of (by ^1H nmr) ca. 91% of dienes. Recrystallization at low temperature from ether–pentane gave white prismatic crystals of 1-*tert*-butyl-3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**2***a*, 17.0 g, 61 mmol); mp 80.5–81.5°C (dec.); uv (CH_3OH): 225 nm (ε 160 m^2 mol^{-1});[8] ir (CCl_4): 1735, 1250 and 1222 ($OCOCH_3$), 1540 and 1355 (NO_2), 1154, 1085, 995, 950, 897 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.01 (s, 9, $C(CH_3)_3$), 1.75 (d, 6, $J \simeq 0.8$ Hz, 3-CH_3 and 5-CH_3), 1.79 (s, 3, 4-CH_3), 1.93 (s, 3, $OCOCH_3$), 5.75 ppm (d, 2, $J \simeq 0.8$ Hz, 2-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 18.0 (3-CH_3 and 5-CH_3), 19.0 (4-CH_3), 22.0 ($OCOCH_3$), 25.3 ($C(CH_3)_3$), 39.1 ($C(CH_3)_3$), 80.5 (*C*-1), 92.5 (*C*-4), 125.8 (*C*-2 and *C*-6), 135.1 (*C*-3 and *C*-5), 169.5 ppm ($OCOCH_3$). *Anal.* calcd. for $C_{15}H_{23}NO_4$: C 64.04, H 8.24, N 4.98; found: C 64.27, H 8.29, N 5.00.

The residue (11.9 g) after evaporation of the solvent was subjected to chromatography on alumina (700 g) at −40°C. Elution with pentane and ether–pentane mixtures (250 cm^3 per fraction) gave, in the pentane and 5% ether fractions, 5-*tert*-butyl-2,3-dimethylbenzyl nitrite (**5**, 0.5 g, 2 mmol); ir ($CDCl_3$): 1660 and 1610 cm^{-1} (ONO); nmr ($CDCl_3$) δ: 1.29 (s, $C(CH_3)_3$), 2.17 (s, 3, 2-CH_3), 2.27 (s, 3, 3-CH_3), 5.65 (s, 2, CH_2) 7.15 ppm (broad s, 2, 4-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 14.5 (2-CH_3), 20.6 (3-CH_3), 31.3 ($C(CH_3)_3$), 34.2 ($C(CH_3)_3$), 69.4 (CH_2), 124.5 (*C*-6), 127.6 (*C*-4), 132.7 (*C*-1 and *C*-2), 136.8 (*C*-3), 148.5 ppm (*C*-5).

[8]The limit of measurement under the conditions used was 225 nm, where only end absorption was observed.

For personal use only.

5-*tert*-Butyl-1,2,3-trimethyl-4-nitrobenzene (**9**, 1.9 g, 9 mmol) was eluted in the second 5% and first 10% ether fractions. After recrystallization from pentane it had mp 89–91°C; ir (CCl_4): 1520 and 1365 cm^{-1} (NO_2); ^1H nmr ($CDCl_3$) δ: 1.34 (s, 9, $C(CH_3)_3$), 2.08 (s, 3, 2-CH_3), 2.16 (s, 3, 1-CH_3), 2.28 (s, 3, 3-CH_3), 7.13 ppm (s, 1, 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 14.8 (2-CH_3), 15.7 (3-CH_3), 21.0 (1-CH_3), 30.9 ($C(CH_3)_3$), 35.2 ($C(CH_3)_3$), 126.8 (*C*-6), 127.5 (*C*-3), 134.4 (*C*-2), 136.5 (*C*-1), 137.6 (*C*-5), 149.8 ppm (*C*-4); ms (70 eV) *m/e* (relative intensity): 221.143 (39, M_r calcd. for $^{12}C_{13}{}^1H_{19}{}^{14}N^{16}O_2$: 221.142), 207 (17), 206 (100, $M - CH_3$), 175 (22, $M - NO_2$).

The second 10% and the 20% ether fractions probably contained more diene **2***a* (4.3 g, 15 mmol), however the nmr spectra showed only the rearomatization product, the nitrite **5**, and an equivalent amount of acetic acid. Minor amounts of the nitromethane derivative **6** and the acetate **7** were also present. The second diastereoisomer of 1-*tert*-butyl-3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**2***b*, 2.2 g, 8 mmol) was obtained in the 30–60% ether fractions. After low temperature recrystallization from ether–pentane **2***b* had mp 82.0–83.0°C (dec.); uv (CH_3OH): 225 nm (ε 130 m^2 mol^{-1});[8] ir (Nujol): 1740, 1247 and 1220 ($OCOCH_3$), 1540 (NO_2), 1155, 1075, 1002, 963, 890, 848, 792 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.93 (s, 9, $C(CH_3)_3$), 1.72 (s, 3, 4-CH_3), 1.77 (d, 6, $J \simeq 1$ Hz, 3- and 5-CH_3), 1.99 (s, 3, $OCOCH_3$), 5.80 ppm (d, 2, $J \simeq 1$ Hz, 2- and 6-H); ^{13}C nmr ($CDCl_3$) δ_C: 17.8 (3-CH_3 and 5-CH_3), 21.3 (4-CH_3), 21.6 ($OCOCH_3$), 25.0 ($C(CH_3)_3$), 39.6 ($C(CH_3)_3$), 80.7 (*C*-1), 90.9 (*C*-4), 127.1 (*C*-2 and *C*-6), 133.3 (*C*-3 and *C*-5), 169.2 ppm ($OCOCH_3$). *Anal.* calcd. for $C_{15}H_{23}NO_4$: C 64.04, H 8.24, N 4.98; found: C 64.37, H 8.19, N 4.28.

1-*tert*-Butyl-3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienol (**3***a*, 1.33 g, 5.6 mmol) was obtained in the 90–100% ether fractions. It was recrystallized at low temperature from ether–pentane and had mp 78.5–79.0°C (dec.); uv (CH_3OH): 225 nm (ε 140 m^2 mol^{-1});[8] ir (CCl_4): 3620 (OH), 1530 and 1340 (NO_2), 1218, 1152, 1075, 1059, 1029, 980, 652 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.99 (s, 9, $C(CH_3)_3$), 1.39 (s, 1, OH), 1.74 (s, 3, 4-CH_3), 1.77 (d, 6, $J \simeq 0.8$ Hz, 3-CH_3 and 5-CH_3), 5.95 ppm (d, 2, $J \simeq 0.8$ Hz, 2- and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 18.3 (3-CH_3 and 5-CH_3), 22.1 (4-CH_3), 25.3 ($C(CH_3)_3$), 38.1 ($C(CH_3)_3$), 72.0 (*C*-1), 90.7 (*C*-4), 130.5 (*C*-2 and *C*-6), 132.9 ppm (*C*-3 and *C*-5).

When the above reaction was repeated at a temperature of 0°C no diene adduct was obtained and the major products apparent (nmr) in the reaction mixture after work-up were the nitromethane **6** and the nitrite **5**. Crystallization of the crude product from pentane gave 5-*tert*-butyl-2,3-dimethylphenylnitromethane (**6**); mp 77–78°C: ir (CCl_4) 1545 and 1355 (NO_2), 1256, 1210, 1000, 975 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.28 (s, 9, $C(CH_3)_3$), 2.20 (s, 3, 2-CH_3), 2.28 (s, 3, 3-CH_3), 5.45 (s, 2, CH_2), 7.12 and 7.26 ppm (q, 2, $J \simeq 2$ Hz, 4-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 14.8 (2-CH_3), 20.7 (3-CH_3), 31.2 ($C(CH_3)_3$), 34.2 ($C(CH_3)_3$), 78.5 (CH_2), 126.3 (*C*-6), 128.1 (*C*-1), 128.9 (*C*-4), 133.6 (*C*-2), 137.2 (*C*-3), 148.8 ppm (*C*-5); ms (70 eV) *m/e* (relative intensity): 221 (5, M), 176 (22), 175 (100, $M - NO_2$), 160 (25), 145 (23), 133 (13). *Anal.* calcd. for $C_{13}H_{19}NO_2$: C 70.56, H 8.65, N 6.33; found: C 70.81, H 8.74, N 6.33.

Diene **2***a* rearomatized rapidly in $CDCl_3$ solution at ambient temperature to form the nitrite **5** (76%; ^1H nmr δ: 1.28, 2.15, 2.26, 5.65, 7.16 ppm), the nitromethane **6** (16%; δ 5.45 ppm), the acetate **7** (4%; δ 5.12 ppm) and acetic acid (δ 2.03 ppm). On another occasion the nitrite **5** was formed in 90% yield. At 0°C rearomatization occurred within 24 h and the benzylic products were formed in the amounts: **5** (58%), **6** (36%), **7** (6%), together with acetic acid. A sample of **2***a* which had rearomatized at ambient temperature and was then worked-up gave (^1H nmr) the aldehyde **19** (8%; δ: 7.39, 7.66, 10.28 ppm), **5** (25%), **6** (34%), **7** (11%), and **8** (16%). Formation of **19**, **6**, **7**, and **8** was confirmed by glc–mass spectrometry. Dienol **3***a* also rearomatized rapidly in $CDCl_3$ solution at ambient temperature to give the nitrite **5**, identified by ^1H and ^{13}C nmr, and small amounts of **6** (14%; δ 5.45 ppm) and **8** (14%; δ 4.68 ppm).

Aluminum Hydride Reduction of Diene Acetate **2**a

Diene **2***a* (120 mg, 0.40 mmol) in dry tetrahydrofuran (THF) (1 cm^3) was stirred with a solution of excess AlH_3 (2.7 mmol) in THF (15 cm^3) at 0°C for 15 min. After work-up a pale yellow oil (95 mg) was obtained, and the major component (ca. 80%) was identified as the dienol **3***a*; (ir (CCl_4): 3620, 1530, 1340, 1252, 1155, 1075, 1058, 1029, 980, 652 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.99, 1.40, 1.73, 1.76, 5.93 ppm).

Hydrolysis of Acetate **2** *in Acidified Aqueous Acetone. 1-tert-Butyl-3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienol (3b)*

The dienyl acetate **2***a* (100 mg) was dissolved in aqueous [$^2H_6$]acetone (400 mm^3; 10:90, v/v) containing sulfuric acid (0.02% w/v) and the disappearance of **2***a* and formation of the diastereoisomeric dienols **3***a* and **3***b*, at 35°C, was followed by integration of the *tert*-butyl peaks at δ 0.92 (**3***b*), 0.99 (**3***a*), and 1.02 (**2***a*). Data are shown in Table 1. A small amount of aromatic compound was also formed as indicated by the appearance of peaks at δ 1.2 ppm ($C(CH_3)_3$) and at 7.2 ppm (Ar*H*). The reaction was worked-up after standing two days at lower temperature.[9] At this time equal amounts of **3***a* and **3***b* were present. Peaks characteristic of both **3***a* and **3***b* were clearly distinct in the nmr spectrum of the worked-up product; **3***a*: ^1H nmr ($CDCl_3$) δ: 0.99, 1.76, 1.78, 5.96 ppm; **3***b*: ^1H nmr ($CDCl_3$) δ: 0.93, 1.69, 1.73, 5.92 ppm. A similar experiment starting with acetate **2***b* likewise gave an initial mixture of dienols in which **3***a* predominated and in which **3***b* increased with time to become eventually larger than **3***a* in the ratio of 1.4:1.

On a preparative scale acetate **2***a* (700 mg) was dissolved in acidified aqueous acetone (3 cm^3) at 31°C. After 95 min, at which time ^1H nmr indicated that 40% yield of dienol **3***b* had been obtained, the mixture was worked-up to yield a yellow oil (660 mg) containing dienols (92%) and aromatic compound(s) (8%). Chromatography on alumina at −30°C and elution with pentane–ether gave dienol **3***a*. Elution with ether gave dienol **3***b* (180 mg); mp 91–95°C (dec.); ^1H nmr ($CDCl_3$) δ: 0.93 (s, 9, $C(CH_3)_3$), 1.69 (s, 3, 4-CH_3) 1.73 (d, 6, $J = 0.7$ Hz, 3-CH_3 and 5-CH_3) 2.20 (s, 1, *OH*), 5.91 ppm (broad s, 2, 2-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 17.7 (3-CH_3 and 5-CH_3), 21.2 (4-CH_3), 25.0 ($C(CH_3)_3$), 37.8 ($C(CH_3)_3$), 72.5 (*C*-1), 91.2 (*C*-4), 130.5 (*C*-2 and *C*-6), 132.1 ppm (*C*-3 and *C*-5).

Reaction of Acetate **2** *with Acidified Methanol*

Diene **2***a* (100 mg, 0.36 mmol) was added to methanol (400 mm^3) containing sulfuric acid (0.2% w/v). Although acetate **2***a* is not very soluble in methanol it dissolved readily in the acidified methanol, indicative of reaction on solution and, indeed, before the ^1H nmr spectrum of the mixture could be examined (< 4 min) diene **2***a* had been completely converted into a mixture of the ethers **4***a* and **4***b* and the two diastereoisomers had been equilibrated. The ratio of **4***a*:**4***b* as determined by the ratio of the integrals of the *tert*-butyl peaks at 0.96 and 0.89 ppm was 29:71. In a similar experiment with diene **2***b* the exchange and equilibration was complete in less than 2 min and the same ratio of **4***a*:**4***b* was found. In both

[9]Small-scale reactions were worked-up by adding the solution to methylene chloride (5 cm^3) followed by neutralization with gaseous ammonia (for reactions in acid) or ammonium chloride (for reactions in base), drying over magnesium sulfate, and removal of the solvent under reduced pressure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

cases rearomatization was negligible, less than 2% occurring in 16 min.

On preparation scale acetate **2***a* (0.5 g) was reacted with methanol (3 cm^3) containing sulfuric acid (0.2% w/v) at 0°C for 15 min. After work-up a clean mixture of the ethers **4***a* (36%) and **4***b* (64%) was obtained.

Methanolysis of Acetate **2**a

A suspension of diene **2***a* (100 mg) in methanol (400 mm^3) was prepared in an nmr tube. After treatment in an ultrasonic bath at 21°C for 22 min the solution became homogeneous and the reaction was then followed by ^1H nmr at a probe temperature of 35°C. The relative amounts of reactant and products were determined by integration of the *tert*-butyl peaks and results are summarized in Table 2. Initially a mixture of the dienyl ethers **4***a* and **4***b* was formed and after some time the amount of **4***b* became significantly greater than **4***a*. Eventually rearomatization occurred giving as the main product methyl 3,4,5-trimethylphenyl ether (**14**). Similar results were obtained for a reaction carried out in [$^2H_4$]methanol and followed by ^1H nmr.

The reaction was repeated using a solution of acetate **2***a* (550 mg) in methanol (800 mm^3) and $CDCl_3$ (300 mm^3). After treatment in the ultrasonic bath at 25°C for 25 min, the reaction was followed by ^{13}C nmr at a probe temperature of 27°C. Decoupled spectra (2000 scans) were accumulated at the indicated time intervals (Table 3). The disappearance of the peaks characteristic of acetate **2***a* and the appearance of peaks characteristic of acetic acid (20.9 and 175 ppm) and of the cyclohexadienyl methyl ethers **4***a* and **4***b* were readily observed. No rearomatization was detected by ^{13}C nmr. However, when the reaction mixture was examined by ^1H nmr after 2700 min it was evident that aromatic products, δ 7.1 (12%) and 6.52 ppm (11%, methyl 3,4,5-trimethylphenyl ether (**14**)) had been formed. The 2.08, 2.22, and 3.68 ppm peaks of **14** were also evident. A component with δ 5.9 ppm (10%) was also present. *tert*-Butyl peaks at δ 1.14, 1.16 and 1.18 were also apparent and each was ca. 13% of the total *tert*-butyl peak intensity. The aryl ether (11%) could be clearly discerned in the worked-up product, the *tert*-butyl intensity at 1.15 and 1.18 ppm was reduced to half the amount before work-up and there were aromatic peaks at 7.10 (5%) and 6.95 ppm (7%).

Chromatography of the product on alumina at −50°C and elution with pentane and ether–pentane mixtures gave, in the 5% ether fraction, methyl 3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienyl ether (**4***b*); ^1H nmr ($CDCl_3$) δ: 0.89 (s, $C(CH_3)_3$), 1.70 (s, 4-CH_3), 1.76 (broad s, 3-CH_3 and 5-CH_3) 3.12 (s, OCH_3), 5.72 ppm (s, 2-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 17.6 (3-CH_3 and 5-CH_3), 21.3 (4-CH_3), 25.3 ($C(CH_3)_3$) 38.4 ($C(CH_3)_3$), 52.0 (OCH_3), 78.3 (*C*-1), 91.2 (*C*-4), 129.4 (*C*-2 and *C*-6), 135.5 ppm (*C*-3 and *C*-5). Methyl 3,4,5-trimethylphenyl ether (**14**) was present as a contaminant. Its isolation and characterisation is described below. The dienyl ether **4***a* was not separately isolated. It was eluted with its diastereoisomer **4***b* (60%) in the 10% ether fraction and had ^1H nmr ($CDCl_3$) δ: 0.97 (s, $C(CH_3)_3$), 1.71 (s, 4-CH_3), 1.80 (broad s, 3-CH_3 and 5-CH_3), 2.90 (s, OCH_3), 5.72 ppm (s, 2-*H* and 6-*H*); ^{13}C nmr δ_C 18.0 (3-CH_3 and 5-CH_3), 22.2 (4-CH_3), 25.6 ($C(CH_3)_3$), 38.6 ($C(CH_3)_3$), 51.4 (OCH_3), 78.3 (*C*-1), 91.2 (*C*-4), 129.1 (*C*-2 and *C*-6), 136.2 ppm (*C*-3 and *C*-5).

Isomerization (Epimerization) of the Dienols **3**a *and* **3**b

The dienol **3***a* was dissolved in aqueous acetone (400 mm^3; 10:90, v/v) containing sulfuric acid (0.05% w/v) and isomerization at 35°C was followed by integration of the *tert*-butyl peaks of the ^1H nmr spectrum at δ 0.98 (**3***a*) and 0.92 ppm (**3***b*). A similar experiment was carried out starting from **3***b*. Peaks characteristic of the isomers were distinct in the aqueous acetone solution; **3***a*: 0.98, 1.75 (s, 3-CH_3, 4-CH_3 and 5-CH_3), 5.99; **3***b*: 0.92, 1.70 (s), 5.99 ppm and the formation of the mixture of isomers from each single isomer was readily discerned. In the course of both reactions small peaks also developed at δ 1.05, 1.12, 1.14, 1.20, 1.28, 6.47, and 7.12 ppm. Results are shown in Table 4.

Solvolysis of Diene **2** *in Aqueous Methanol*

A suspension of acetate **2***a* (100 mg) in CD_3OD–D_2O (80% w/v, 300 mm^3) was agitated in an ultrasonic bath at ca. 20°C for 25 min. After work-up ^1H nmr indicated that a mixture of the ether **4** (δ 5.72, 59%) dienol **3** (δ 5.92, 25%) and aromatic compounds (δ 6.5, 6%; δ 7.1 ppm, 10%) had been formed. The ratio of **4***b* to **4***c* was ~3:1 but **3***a* appeared to be present in greater amount than **3***b*.

Reaction of Diene **2** *with Sodium Methoxide*

A solution of sodium methoxide (2 mmol) in methanol (2 cm^3) was added to a solution of **2***a* (160 mg, 0.6 mmol) in methanol (1 cm^3) at −78°C. The mixture was stirred at 0°C for 60 min. After work-up ^1H nmr showed that the product consisted of 10% aromatic compounds (δ ~ 7.1 and ~7.3 ppm), 7% dienols **3***a* and **3***b* (δ ~ 5.9 ppm), and 83% dienyl ethers **4***a* and **4***b* (δ ~ 5.7 ppm). The ratio of **4***a* to **4***b* was ~1:4, determined from the relative heights of the methoxy peaks at δ 2.90 and 3.12 and qualitatively supported by the relative heights of the *tert*-butyl peaks at 0.97 and 0.89 ppm. It was not possible to establish the ratio of dienol **3***b* to **3***a* because of the overlap of the dienol *tert*-butyl peaks (δ 0.93 and 0.99 ppm) with those of the ether.

Solvolysis of Diene **2**a *in Moist* [$^2H_4$]*Acetic Acid*

A solution of diene **2***a* (160 mg, 0.64 mmol) in a mixture of water (8 mm^3) and [$^2H_4$]acetic acid (400 mm^3) was observed by nmr at 35°C. The diene exchanged acetate rapidly with the solvent since in the first observed spectrum, after 2 min, the only acetate peak was that of acetic acid at 2.03 ppm. Furthermore, in the course of the reaction a higher field *tert*-butyl (δ 0.92 ppm) appeared and disappeared more slowly than the original *tert*-butyl peak as the diene(s) rearomatized over a period of 40 min (Table 5). The formation of brown fumes of NO_2 indicated that the dominant rearomatization reaction involved loss of the nitro group. Aromatic peaks appeared at δ 6.50, 6.64, and 6.69 and a (diene?) peak at 6.28 ppm. The mixture stood at 40°C for a further 30 min. After work-up the δ 5.5–7 ppm region exhibited peaks at δ 5.87 (7%), 6.16 (15%), 6.43 (37%), 6.58 (24%), and 6.70 ppm (15%). Major *tert*-butyl peaks appeared at δ 1.30 (*tert*-butyl alcohol) and 1.43 ppm (*tert*-butyl acetate). Gas–liquid chromatography and glc–mass spectrometry established the products to be a phenol (17%, M^+ 192), the phenol **16** (22%, M^+ 136), the deuterated acetate **15** (32%, M^+ 181), two unidentified components (4% and 3%), the aldehyde **17** (8%), alcohol **8** (5%), acetate **7** (4%), and nitroarene **9** (M^+ 221, 8%). The mass spectra of the peaks identified as **17**, **8**, and **7** were not determined and the identification is based solely on retention time.

Solvolysis of the Dienyl Methyl Ethers **4** *in Aqueous Methanol*

A mixture of the dienyl ethers **4***a* and **4***b* (0.2 g) was reacted with a solution of water (2 cm^3) and methanol (8 cm^3) at 50–55°C for 90 min. After work-up essentially pure (96% by glc) methyl 3,4,5-trimethylphenyl ether (**14**) was obtained; ^1H nmr ($CDCl_3$) δ: 2.01 (s, 3, 4-CH_3), 2.16 (s, 6, 3-CH_3 and 5-CH_3), 3.60 (s, 3, OCH_3), 6.47 ppm (s, 2, 2-*H* and 6-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 14.5 (4-CH_3), 20.8 (3-CH_3 and 5-CH_3), 55.0 (OCH_3), 113.1 (*C*-2 and *C*-6), 127.0 (*C*-4), 137.5 (*C*-3 and *C*-5), 157.0 (*C*-1); ms *m/e* 150 (M). When the reaction was repeated at 25°C 12% of the dienyl ethers **4** was converted into the aryl ether **14** in 90 min.

Reaction of Diene **2** *with Sulfuric Acid in Acetic Anhydride – [$^2H_4$]Acetic Acid*

In separate experiments solutions of 0.05, 0.5, 5, and 50% H_2SO_4 (by weight) in 10% acetic anhydride – [$^2H_4$]acetic acid (250 mm^3) were added to a solution of diene **2***a* (120 mg, 0.4 mmol) in $CDCl_3$ (200 mm^3) and the ensuing reactions followed by ^{1}H nmr as the temperature was raised from −20°C. In the most dilute sulfuric acid solution exchange of the [$^2H_3$]acetate for the unlabelled acetate in the diene could be followed at −20°C and was substantially complete after 6 min. When, after 16 min, the temperature was raised to −5°C development of rearomatization product, nitrite **5** (δ 1.28, 2.15, 2.26, 5.65, and 7.15 ppm) could be observed. After 42 min and at +15°C 50% of the diene had rearomatized and the minor products, the nitromethane **6** (δ 5.49) and acetate **7** (δ 5.10), were clearly evident. At +15°C/48 min new diene peaks (whose initial formation was just apparent at +5°C/32 min) at 6.13 (major) and 6.08 (minor) integrated for ca. 20% of the mixture, approximately equal to the amount of diene **2**, and a significant amount of diene **2***b* (δ 0.95) was present as well as the original **2***a*. The *tert*-butyl peak of the new diene(s) overlapped with that of the original diene at δ 1.03. However, the diene methyl region, which had initially exhibited only a singlet at δ 1.74 ppm, now had peaks at δ 1.69, 1.75, 1.78, and 1.81 ppm. As the temperature was raised to +35°C (85 min) diene **2** disappeared more rapidly than the new diene and some new peaks appeared at δ 1.06, 6.43 ppm. Before work-up (after 90 min) all of the original diene had disappeared and the new diene(s) constituted ~10% of the mixture. The distribution of the benzylic products was 67% **5**, 18% **6**, 18% **7**. After work-up no diene was present and the product composition was 5-*tert*-butyl-2,3-dimethylbenzaldehyde (**19**); nmr ($CDCl_3$) δ: 1.31 (s, C(CH_3)$_3$), 2.30 (s, CH_3), 2.50 (s, CH_3), 7.39 (d, J = 2 Hz, 1, 4-*H*), 7.66, (d, J = 2 Hz, 1, 6-*H*), 10.28 ppm (s, 1, C*H*O), 12%; **5**, 18%; **6**, 33%; **7**, 16%; **8**, 16%. An unidentified component (δ 7.00 ppm) whose formation had been observed in the course of the variable temperature study, was present to the extent of ~5%. The presence of **19**, **6**, **7**, and **8** in the reaction product was confirmed by glc and glc – mass spectrometry.

In the reaction to which 0.5% sulfuric acid had been added rearomatization occurred at a lower temperature (+5°C) and in the reactions with 5 and 50% acid rearomatization was complete before nmr observation. Aldehyde **19** appeared in the reactions before work-up and in the cases of the reaction with 5 and 50% sulfuric acid the (complete) conversion of **5** to **19** before work-up could be followed. Results are shown in Table 6.

Reaction with added 0.05% sulfuric acid at +7°C and with added 0.5% sulfuric acid at +12°C were also followed by ^{13}C nmr. In the more dilute acid solution, the exchange of the [$^2H_3$]acetate in **2***a* could be followed by the reduction in the intensity of the peak at 171.0 ppm ($OCOCH_3$). In the more concentrated acid solution rearomatization was essentially complete when the spectrum was initially observed and the methylene carbons of **5** (69.7), **6** (78.7), and **7** (66.5) were apparent in the spectrum.

Reaction of Diene **2** *in Acidified Aqueous Chloroform*

Aqueous sulfuric acid (2% w/v, 20 mm^3) was added to a solution of diene **2***a* (100 mg) in [^{2}H]chloroform (400 mm^3) and the ensuing reaction followed by ^{1}H nmr at 35°C. Within 4 min, the peak of the dienol **3***a* at δ 5.92 had appeared and was 25% of the height of the diene **2***a* peak at 5.72 ppm. However the nitrite **5** then formed very rapidly and was detected by a sharp signal at 5.64 ppm which, after 12 min, was the largest peak in this region of the spectrum. Peaks also appeared at 5.83 and 6.07 ppm but all except the 5.65 ppm peak disappeared after 40 min and the spectrum was that of nitrite **5** (1.30, 2.18, 2.28, 5.65, and 7.15 ppm) and acetic acid (2.06 ppm).

TABLE 7. Yields of products from the thermolysis at 260°C of diene adducts[a]

	% yield of product								
Diene	A	**1**	**15**	**16**	**19**	**8**	**7**	**6**	B
2*a*	3	28	5		5	21	26	14	
2*b*	4	38	4	4		14	19	11	
3*a*	7			35		51			7

[a]Yields determined from the gas chromatogram. Compounds are listed from left to right in order of increasing retention time on a 3% SE 30 column at 160°C. A and B are unidentified compounds. The appropriate *m/e* value for the molecular ion was observed in the chemical ionization (methane) mass spectrum of each of the identified compounds.

Reaction of Diene **2** *with Hydrogen Chloride*

Reactions of **2***a* (500 mg) in ether (25 cm^3) at −70 and −78°C with hydrogen chloride, added as the gas and, in other experiments, in ether solution, were carried out in an attempt to prepare the nitrocyclohexadienyl chloride. All of these reactions were unsuccessful, only benzylic products being obtained. The major product was nitrite **5** with a lesser amount (15–25%) of the nitromethane **6**. A reaction which was allowed to stand at room temperature before work-up gave mainly aldehyde **19** and no **5**.

Reaction of Diene **2**a *with Boron Trifluoride*

Boron trifluoride etherate (200 mm^3) was added to a solution of diene **2***a* (120 mg) in dry ether (1 cm^3). After 5 min the reaction was worked-up and the product examined by nmr and glc – mass spectrometry. Reactions were carried out at both −78 and 0°C and essentially similar results were obtained. The side-chain derivatives **5** (22%), **6** (26%), **7** (31%), and **8** (20%) were formed in the typical yields indicated and were identified by the characteristic methylene region absorption of each compound. On glc – mass spectral analysis major peaks with appropriate retention times and *m/e* values for the molecular ions of **6**, **7**, and **8** were obtained and, in addition, a peak with molecular ion *m/e* 190, attributed to 5-*tert*-butyl-2,3-dimethylbenzaldehyde (**19**). A small amount (2%) of **1** (M$^+$ 176) was also observed. On one occasion peaks typical of the aldehyde were apparent in the nmr spectrum of a mixture of side-chain products containing some of the nitrite **5**. Presumably the aldehyde is also formed from the nitrite under the glc conditions.

Reaction of Diene **2** *with Fluorosulfonic Acid and with Trifluoromethanesulfonic Acid*

Fluorosulfonic acid (250 mm^3) was added to a solution of **2***a* (130 mg) in $CDCl_3$ (200 mm^3) at −78°C. The mixture, which separated into two phases, was warmed to ambient temperature and worked-up. ^{1}H nmr showed that the product contained nitroarene **9** (50%), the nitromethane **6** (16%), and the aldehyde **19** (34%).

A solution of diene **2***a* (200 mg) in methylene chloride (1 cm^3) was added to a solution of trifluoromethanesulfonic acid (0.5 cm^3) in methylene chloride (5 cm^3) at −78°C. After warming to ambient temperature and work-up the product was shown to be the nitroarene **9** (81%) and the aldehyde **19** (12%) by ^{1}H nmr and glc – mass spectrometry. Two other unidentified components were detected by glc and ^{1}H nmr also showed the presence of a small amount of the nitromethane **6** (δ 5.46 ppm).

Thermolysis of the Dienyl Acetates 2a *and* 2b *and the Dienol* 3a

Ethereal solutions of the diene acetates 2*a* and 2*b* and of the alcohol 3*a* were injected into the inlet of the gas chromatograph set at 260°C. Thermolysis took place smoothly and well-resolved peaks were observed. Product identification was carried out by comparison of retention times with those of authentic samples, and by glc – mass spectrometry. The results are shown in Table 7.

Electron spin resonance studies of the surface chemistry of molybdenum–alumina catalysts

K. C. KHULBE, R. S. MANN, AND M. TERNAN[1]

Department of Chemical Engineering, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received December 22, 1977

K. C. KHULBE, R. S. MANN, and M. TERNAN. Can. J. Chem. **56**, 1769 (1978).

When alumina was doped with molybdenum oxide, the concentration of the electron accepting sites increased linearly up to 18 wt.% MoO_3, and then decreased. The colour of the Mo–alumina changed from whitish yellow to grayish black when degassed at 320°C for 2 h. This depended on the concentration of Mo. A strong signal for Mo^{5+} was observed. Oxygen species were formed when the degassed sample was treated with oxygen or air. A reversible behaviour of oxygen on these species was observed. A possible mechanism has been discussed for the formation of O_2^- species and the reversible behaviour of oxygen. The concentration of electron accepting centers has been correlated with the activity for the hydrodenitrogenation of heavy oils over MoO_3–alumina catalysts.

K. C. KHULBE, R. S. MANN et M. TERNAN. Can. J. Chem. **56**, 1769 (1978).

Lorsque l'on additionne de l'oxyde de molybdène à de l'alumine, la concentration des sites acceptant des électrons augmente d'une façon linéaire jusqu'à 18% en poids de MoO_3; par la suite cette valeur diminue. La couleur du mélange alumine–molybdène change d'une jaune blanchâtre à un noir grisatre lorsque l'on enlève les gaz à 320°C pendant deux heures. Cette couleur dépend de la concentration de molybdène. On a observé un signal puissant correspondant à du Mo^{5+}. Il se forme des espèces oxygénées lorsque l'on traite un échantillon dans lequel on a enlevé les gaz avec de l'oxygène ou avec de l'air. Le comportement réversible de l'oxygène sur ces espèces a pu être observé. On discute d'un mécanisme possible pour la formation d'espèces de O_2^- et pour le comportement réversible de l'oxygène. On a établi une corrélation entre la concentration des centres accepteurs d'électrons et l'activité lors de l'hydrogènation accompagnée de l'enlèvement d'azote présent dans des huiles lourdes sous l'influence de catalyseurs de MoO_3–alumine.
