Catalysts based on molybdenum oxide – alumina have found ever increasing uses in oxidation (1), hydrodesulphurization (2), hydrodenitrogenation (2), and other hydrocarbon reactions. It was observed that electron accepting centers of alumina increase when doped with metals (3) and of Mo–alumina when doped with promotor ions (4) like Co and Ni. In the present paper we report the effect of the variation in the concentration of electron accepting centers (Lewis acid sites) with the variation of molybdenum concentration and an attempt is made to correlate these centers with the denitrogenation and desulphurization activity. The effect of heating *in vacuo* at 320°C and the reversible behaviour of oxygen on the heated and evacuated catalyst is also reported.

Experimental

The technique for X-ray diffraction studies, infrared absorption spectra, and esr measurements, and the measurement of esr signal intensity are described elsewhere (5, 6). A solution of 0.05 *M* phenothiazine (TDPA) in benzene was used for phenothiazine cation radical formation on the surface of the catalyst. The catalysts used in this work were the same as used earlier by Parson and Ternan (2). The calcined pellets were ground and only 40–60 mesh size grains were used for the present study.

Results

The γ-alumina and pure MoO_3 powder did not give an esr signal under the experimental conditions. The esr spectra of the oxidised catalyst containing 30% MoO_3 on alumina is shown in Fig. 1, I (weak signal). The observed signal was due to Mo^{5+} (7). Catalysts containing less than 20% MoO_3 on alumina did not give an esr signal.

When alumina was treated with phenothiazine (TDPA) solution in benzene a very weak signal of TDPA cation radical was observed suggesting that γ-alumina has electron accepting centers (8, 9). The MoO_3 powder also gave a weak signal of TDPA cation when it was treated in a manner similar to that of alumina.

When 30% MoO_3–alumina was treated with a solution of TDPA, a new esr signal (strong) at $g = 2.003$ was observed in addition to the Mo^{5+} signal at $g = 1.923$ (Fig. 1, II). The new peak was due to the TDPA cation radical (10). The colour of the catalyst changed immediately (from white or yellow to red) on adding TDPA solution in benzene. Whereas in the case of pure alumina, the colour changed

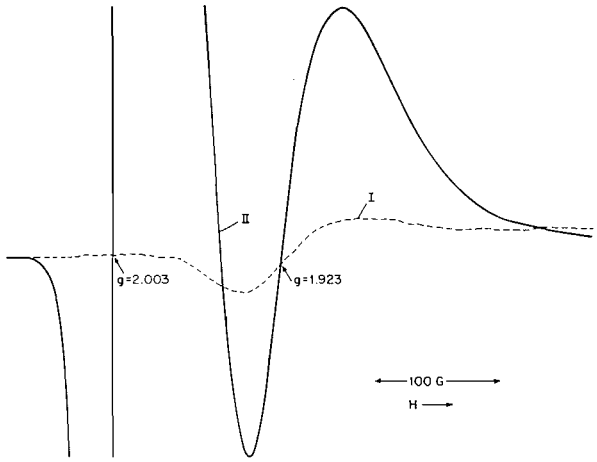

FIG. 1. I, esr spectra of 30 wt.% MoO_3–alumina; II, esr spectra of 30 wt.% MoO_3–alumina + TDPA.

from white to gray, the colour of Mo-doped alumina changed from white or yellow to red or dark red, depending on the concentration of Mo.

The electron acceptor site (Lewis site) is responsible for the oxidation of aromatic hydrocarbons to the corresponding cations (8, 9). The intensity of the esr signal of TDPA cation radicals increased linearly up to 18 wt.% MoO_3 on alumina and then decreased on further increases in Mo concentration (Fig. 2). It is suggested that the electron accepting property of the doped alumina increased with the increase in Mo concentration up to a certain limit and then decreased on further addition of Mo. It was observed (11) that the Mo^{5+} concentration increased linearly with the increase of MoO_3 concentration (up to ~30%).

When 18% MoO_3–alumina was degassed at room temperature for 72 h, a very weak signal of Mo^{5+} ion was obtained. However, when the sample was outgassed at 320°C for 2 h, its colour at room temperature became gray or black and a strong esr

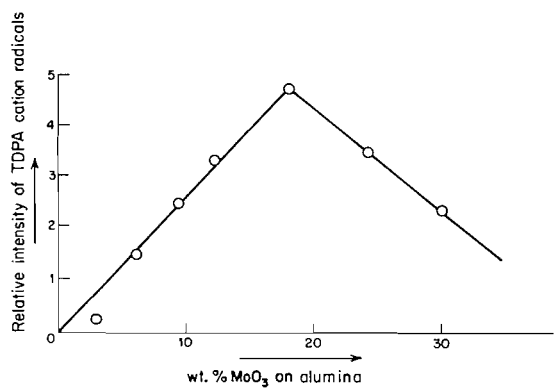

FIG. 2. Relative intensity of esr signals of TDPA cation radical vs. wt.% MoO_3–alumina.

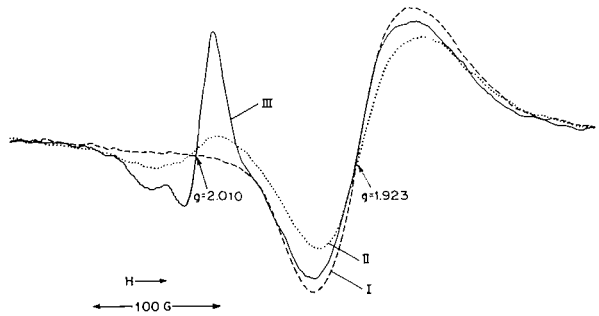

FIG. 3. I (---), esr spectra of 18 wt.% MoO_3–alumina degassed at 320°C for 2 h; II (...), esr spectra of degassed sample + O_2 (100 Torr); III (—), esr spectra of evacuated oxygen treated sample.

signal of Mo^{5+} was observed (Fig. 3, I). The intensity of the signal increased with the increase of Mo concentration. Similar results were obtained by Sheshadri *et al.* (12) on reduced catalysts.

When this black sample (degassed at 320°C, MoO_3–alumina catalyst) was treated with oxygen or air (100 Torr) at room temperature, the esr signal of Mo^{5+} slightly decreased (Fig. 3, II). However, when the adsorbed oxygen was evacuated at room temperature a new signal at g ~2.010 was observed, including the Mo^{5+} signal of almost original intensity as observed before admitting oxygen (Fig. 3, III). The intensity of this new signal depended on the concentration of Mo and the oxygen pressure. This new signal was assigned to the O_2^- species. This signal disappeared when the sample was treated with oxygen or heated. Thus, a reversible effect of oxygen was observed on this new signal. A similar effect was observed by Iyengar *et al.* (13) on TiO_2. Carbon monoxide and hydrogen did not affect this signal at room temperature indicating a negative test for the O^- ion species. The reversible behaviour of O_2 indicates that the signal at g = ~2.010 is associated with the surface oxygen and is subject to dipolar magnetic broadening by molecular O_2.

On heating the black sample at 400°C in the presence of air, the colour of the catalyst changed to white or yellow (original colour), which suggested a deficiency of O_2 in the degassed (at 320°C) MoO_3–alumina catalyst. X-ray and ir analyses did not reveal the existence of a detectable amount of free molybdenum or molybdenum oxide in the alumina supported molybdenum oxide samples (original and the black sample). It could be possible that either free MoO_3 or molybdenum was monodispersed. The blackness of the evacuated and heated alumina supported molybdenum oxides may be due to the presence of different valencies of molybdenum or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

lower oxides of molybdenum. However, other possibilities are not discarded.

Discussion

The Brønsted and Lewis acid sites (electron accepting centers) have always been looked upon as the active catalytic centers of alumina or alumina supported metal catalysts. Upon dehydration at increasing temperatures, the Brønsted acid sites, numerous at high water content, are gradually converted into Lewis acid sites. At high temperatures, the electron deficient character of alumina dominates.

X-ray analysis confirmed that the alumina was of the γ-type. The structure of γ-alumina is very complex. No detectable amount of free molybdenum or its oxides was found in alumina supported molybdenum (before and after evacuation and heating). Surface OH groups of alumina are not completely eliminated. Some of the OH groups of alumina are basic and are capable of forming a salt with the molybdic acid. Thus, with alumina as a carrier, practically all the metal is combined to form Mo—O—Al groups which are active centres for the generation of radicals. However, the possibility of other active centres could not be eliminated. The formation of aluminum molybdate has been discussed by several authors. Sonnemans and Mars (14) suggested that the catalyst prepared according to the normal impregnation method contains molybdenum in two forms, i.e. MoO_3 and aluminium molybdate. The molybdenum trioxide is present on the surface (aluminium molybdate) as a monolayer and has a heterogeneous character. A study by X-ray and ir analyses did not indicate the existence of free molybdenum or molybdenum oxides in the catalysts. It is our view that molybdenum exists in a 'combined form' in alumina. It is also reported that Mo^{6+} on a carrier of γ-alumina is present in tetrahedral coordination at low concentration and in octahedral coordination at high concentration of molybdenum (15). Molybdenum formed a compound with the carrier $Al_2(MoO_4)_3$. It seems that γ-alumina supported molybdenum oxides have a very complicated structure.

Molybdenum is an element with outermost structure $4d^5 4s^1$. It has oxidation states 2− to 6+; the lowest oxidation states (2−, 1−, 0, 1+) are exhibited only by organometallic compounds and compounds of π acceptor ligands. The higher oxidation states (4+, 5+, 6+) are the most stable. The true stability ranges of the various oxides will be very difficult to establish because of the slow reaction and the transformation rates, especially those occurring below about 600°C. There is a pronounced tendency for some of the phases to form and remain for long periods in a metastable state. It is possible that, depending on the method of preparation of the catalyst, molybdenum with different valencies can be present in alumina.

In the present investigation, it was observed that the concentration of electron accepting centers increased with increased Mo concentration up to a certain limit (18% MoO_3) and then decreased with further increase of Mo concentration (Fig. 2).

Parson and Ternan (2) studied hydrocracking, hydrodesulphurization, and hydrodenitrogenation of heavy oils over these catalysts. The activities in hydrocracking and hydrodesulphurization with MoO_3 concentration were quite high, up to 9 and 3% respectively, but the increases were more gradual at higher concentrations. On the other hand, the activity pattern for hydrodenitrogenation and the surface area of the catalyst were similar to that of Fig. 2. Thus, the number of electron accepting sites are directly related to the surface area of the catalysts and to the activity for hydrodenitrogenation. Parson and Ternan (2) also observed that the surface acidity of these catalysts increased linearly with increased concentration of Mo. The pattern for the electron accepting sites with Mo concentration was found to be different in the present study (Fig. 2). It was confirmed from our investigations that different types of acid centres are present on the surface as only the electron accepting centers could give the cation radical on the surface (8).

A comparison of Fig. 1, I with Fig. 1, II for Mo^{5+} concentrations would indicate that Mo^{5+} does not take part in the formation of cation radicals. The increase in Mo^{5+} concentration on the addition of TDPA could be understood by the reduction of Mo^{6+}.

$$Mo^{6+} + e^- \rightarrow Mo^{5+}$$

On evacuation at higher temperatures MoO_3 loses oxygen from the surface and produces the dissociation of Mo^{6+}.

$$Mo^{6+} \rightarrow Mo^{5+} + \text{hole}$$

Mo can exist in any of four valencies, 6+, 5+, 4+, and 3+, corresponding to d^0, d^1, d^2, and d^3 configurations. Hexavalent molybdenum is diamagnetic and therefore will not give an esr signal. Mo^{4+}, even if it were paramagnetic, would not give a spectrum except at a very low temperature. It would be expected that any observed resonance due to d^2 would have a large zero field splitting and would give a broad signal. The value of g for Mo^{3+} is 2.000 (7). It is thus concluded from the esr spectra obtained for Mo^{5+} that Mo^{5+} existed together with Mo^{6+}. How-

ever, from the colour of the catalyst, it can be presumed that some other species of molybdenum might also be present.

The new peak observed after degassing the adsorbed O_2 from the evacuated and heated Mo–alumina (Fig. 3, III) was due to the O_2^- species. A similar effect of O_2 was observed on rutile (13). The reversible behaviour of O_2 on the evacuated and heated Mo–alumina surface can be understood from the following mechanism:

Mo^{6+} dissociates to Mo^{5+}, and Mo^{5+} to Mo^{4+}

$$Mo^{6+} \rightarrow Mo^{5+} + \square_+$$

$$Mo^{5+} \rightarrow Mo^{4+} + \square_+$$

where $\square_+$ describes a hole with a positive charge and $\square_e$ the hole acting as electron.

It is also possible that an equilibrium exists between Mo^{5+} and Mo^{4+} ions as suggested by Ishii and Matsuura (16)

$$\square_+ + Mo^{4+} \leftrightarrows \square_e + Mo^{5+}$$

A weak signal of Mo^{5+} was observed when Mo–alumina catalyst was degassed at room temperature. It is possible that these Mo^{5+} ions could be different from Mo^{5+} ions formed after dissociation of Mo^{6+} as explained above. On treating with O_2, the original Mo^{5+} was converted into Mo^{6+} and thus reduced the concentration of Mo^{5+} slightly as follows:

[A] $$Mo^{5+} + O_2 \leftrightarrows Mo^{6+} + O_2^-$$

also

[B] $$Mo^{4+} + O_2 \leftrightarrows Mo^{5+} + O_2^-$$

The formation of Mo^{5+} in [B] could be less than Mo^{5+} consumed in [A] and [C]

[C] $$\square_e + O_2 \rightarrow O_2^-$$

On evacuating the adsorbed O_2, O_2^- ions remained behind and gave the esr spectra at $g = 2.010$. The disappearance of the O_2^- signal in the presence of O_2 may be due to dipolar magnetic broadening by molecular O_2.

When TDPA solution was added to the unheated and evacuated catalyst, the concentration of Mo^{5+} increased and TDPA cation radical formed. This suggests that Mo^{6+} ions behaved as electron accepting centers ($Mo^{6+} + e^- \rightarrow Mo^{5+}$). On heating and evacuating the catalyst, Mo^{6+} dissociates into Mo^{5+} as discussed above. On adding TDPA to the heated and evacuated catalyst, the intensity of the observed esr signal of the TDPA cation radical was less than the intensity of the TDPA radical when TDPA was added to the unheated catalyst. However, no appreciable change was observed in the Mo^{5+} signal. It seems from the foregoing observations that there are different types of electron accepting sites on the surface of the molybdenum–alumina catalyst.

The crystal structure of a dinuclear platinum(II) complex with a bent dihydroxy bridge, di-(μ-hydroxy)tetrakis(triethylphosphine)diplatinum(II).tetrafluoroborate

G. W. BUSHNELL

Chemistry Department, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received October 4, 1977

G. W. BUSHNELL. Can. J. Chem. **56**, 1773 (1978).

The crystal structure of di-(μ-hydroxo)tetrakis(triethylphosphine)diplatinum(II) fluoroborate has been determined and refined to an R value of 0.032. The space group is $P2_1/c$ and the cell dimensions are a = 1.604(1), b = 1.847(1), c = 1.336(1) nm, β = 101.6°, with 4 molecules per unit cell. The dimeric cation consists of two square planar Pt(II) centres bridged by a pair of hydroxo ligands. The angle between the mean plane normals is 36.4°. One of the BF_4^- groups, situated close to the dihydroxo bridge on the more open side, and having lower thermal parameters than the second fluoroborate anion, is hydrogen bonded to the oxygen atoms. The hydrogen atoms were not located. The interatomic distances (pm) are Pt—P = 223.5 (mean), Pt—O = 213.3 (mean), Pt(1)—Pt(2) = 312.1(1), O(1)—O(2) = 272(2), O(1)—F(1) = 288(2), O(2)—F(2) = 282(3). The mean bond angles (deg) are O—Pt—O = 79.4, P—Pt—P = 97.7, P—Pt—O = 91.5, and Pt—O—Pt = 94. One of the triethylphosphine groups is disordered or in thermal motion and was refined by constrained least squares using two superimposed partial structures. The results are discussed in relation to other known hydroxo bridged platinum species relevant to the field of platinum containing, cancer chemotherapeutic drugs.

G. W. BUSHNELL. Can. J. Chem. **56**, 1773 (1978).

On a déterminé la structure cristalline du fluoroborate du di-(μ-hydroxo)tétrakis(triéthylphosphine)diplatine(II) et on l'a affinée jusqu'à une valeur de R de 0.032. Le groupe d'espace est $P2_1/c$ et les dimensions de la maille sont a = 1.604(1), b = 1.847(1), c = 1.336(1) nm, β = 101.6° avec quatre molécules par maille. Le cation dimère comprend deux Pt(II) plan carré pontés par une paire de ligand hydroxo. L'angle entre les normales aux plans moyens est de 36.4°. Un des groupes BF_4^- situé près du pont dihydroxo du côté le plus dégagé et possédant des paramètres thermiques plus bas que ceux du second anion fluoroborate est lié par un pont hydrogène aux atomes d'oxygène. On n'a pas déterminé la position des atomes d'hydrogène. Les distances interatomiques (pm) sont Pt—P = 223.5 (moyen), Pt—O = 213.3 (moyen), Pt(1)—Pt(2) = 312.1(1), O(1)—O(2) = 272(2), O(1)—F(1) = 288(2), O(2)—F(2) = 282(3). Les angles de liaison moyens (degré) sont O—Pt—O = 79.4, P—Pt—P = 97.7, P—Pt—O = 91.5 et Pt—O—Pt = 94. Un des groupes triéthylphosphine est désordonné ou en mouvement thermique et on l'a affiné par la méthode des moindres carrés contraints utilisant deux structures partielles superposées. On discute des résultats en relation avec d'autres espèces connues de platine, pontées par des groupes hydroxo et reliées aux drogues contenant du platine utilisées dans la chémothérapie du cancer.

[Traduit par le journal]

Introduction

Previous work (1) on the hydroxy complexes of platinum(II) and palladium(II) established a preparative method and dimeric structure for compounds of the type $[M_2(OH)_2L_4](BF_4)_2$ where M = Pt and L = triethylphosphine, triphenylphosphine, or pyridine or where M = Pd and L = triphenylphosphine. These compounds are non-hygroscopic, air-stable solids, with nonlabile hydroxy protons. The hydroxy bridge resists cleavage by tertiary phosphines.

The cancer chemotherapeutic properties of *cis*-dichlorodiammineplatinum(II) and related compounds have excited a great deal of interest recently, and clinical trials on man have been undertaken (2). This compound is known (3) to undergo aquation at hydrogen ion concentrations similar to those found in living organisms, giving the ions $[Pt(NH_3)_2Cl(H_2O)]^+$ and $[Pt(NH_3)_2(H_2O)_2]^{2+}$. The acid dissociation constants of the diaquodiammineplatinum(II) cation are known, and neutralization of a solution of the complex with sodium hydroxide and the application of heat gives a solution containing the dimer $[(NH_3)_2Pt(OH)_2Pt(NH_3)_2]^{2+}$. Two groups of workers have determined the crystal structure of di-μ-hydroxotetramminediplatinum(II) nitrate (4, 5). Different triclinic unit cells have been assigned but the results agree on an approximately planar structure for the $Pt_2O_2N_4$ set of atoms in the cation. The important interatomic distances and bond angles are similar. Hydrogen bonding between the nitrate ions and the dimeric cations is important in this crystal structure.

A yellow hydroxy bridged trimer $[Pt_3(NH_3)_6(OH)_3](NO_3)_3$ was also obtained during the preparation of the above dimer (5). The crystal structure of

this compound (6) shows that each platinum atom has an approximately planar coordination, but that the cation as a whole has a three dimensional structure with a pseudo-twofold axis through a Pt atom and the O atom opposite to it in the nonplanar six-membered ring. Hydrogen bonding is prominent in this crystal structure just as it is in the dimer crystal.

The only other bridged hydroxy complexes of platinum(II) well characterized are a binuclear hydroxy bridged species prepared from the ethylenediamine diaquoplatinum(II) cation by Lim and Martin (7). Their work reports titrations of standard base into $[enPt(OH_2)_2]^{2+}$ and $[enPd(OH_2)_2]^{2+}$, and provides excellent evidence for rapid dimer formation in the palladium system, and good evidence of a slower dimerisation of $[enPt(OH_2)(OH)]^{+}$, with $K = 10^6\ M^{-1}$ estimated.

The crystal structure of the tetrameric hydroxytrimethylplatinum(IV) published by Spiro, Templeton, and Zalkin (8) contains $Pt_4O_4(Me)_{12}$ molecules, approximately described as a Pt_4O_4 cube consisting of interpenetrating Pt_4 and O_4 tetrahedra, with three methyl groups joined to each platinum atom, which thus attains octahedral coordination.

Hydroxo bridged species of platinum are currently of interest in connection with the formation of deep blue or purple compounds formed when *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ is neutralized and reacted with pyrimidines and purines. These compounds, commonly called 'platinum-blues', are water soluble, amorphous compounds which show promise as effective anti-tumour agents of comparatively low toxicity. Their structures are not yet known, but there are indications that mixed valence Pt(II)/Pt(IV) hydroxo bridged species may be involved and that the Pt—Pt distance may be important (5).

Our results show a type of di-μ-hydroxo bridge structure which is new in Pt chemistry and indicate that the anion may influence this bridge structure through hydrogen bonding.

Experimental

The preparation of the material has already been described (1). The colourless transparent crystals grew to 1 mm^3 in size. Photography using CuK_α radiation gave the space group and approximate unit cell dimensions. The crystal data are:

$C_{24}H_{62}B_2F_8O_2P_4Pt_2$ fw = 1070.4
Monoclinic, space group $P2_1/c$ (No. 14), unit cell a = 1.604(1), b = 1.847(1), c = 1.336(1) nm, β = 101.6(1)°; working cell a' = 1.869(1) nm, β′ = 122.8(1)°; cell volume 3.877 nm^3; crystal shape 0,1,1; 0,−1,−1; 0.129 mm; 0,1,−1; 0,−1,1; 0.097 mm; 6,3,−2; −6,3,2; 0.48 mm; density 1.821(5) (meas.), 1.834 (calcd.) g cm^{-3}; molecules per cell 4; absorption coefficient (MoK_α) 78.1 cm^{-1}.

A working unit cell, conveniently related to the morphology, was refined by least squares from diffractometer centering results for 24 pairs of reflections, used for data collection, and transformed to the conventional unit cell by the matrix 1,0,1;0,1,0;0,0,−1. The shape of the crystal used is specified by giving the indices in terms of the working cell and the perpendicular distance to the origin for each of the six crystal faces. The mounting direction was along a'. The intensity measurements were made with a Hilger four circle diffractometer using θ/2θ scans of 50 steps of 0.04° in 2θ, counting for 1 s at each step. Measurements were complete up to 2θ = 50° in one hemisphere using MoK_α radiation and a monochromator. Three standards were measured after every batch of 50 reflections. Absorption corrections were applied by numerical integration using an 8 × 8 × 8 Gaussian grid. To economize on computing time, reflections were rejected if $I < 5\sigma(I)$. Multiple measurements were averaged, the Lorentz and polarization corrections applied, and the indices transformed to match the conventional unit cell. A total of 17 133 measurements gave 5365 reflections in the final data set.

Structure Determination

The structure was solved from the three-dimensional Patterson function. The set of programs employed was that of the Chemical Crystallography Laboratory, Oxford (9). In the structure factor calculations the atomic scattering curves for Pt and P were those of Cromer and Waber (10), and the curves for F, C, and B were from the International Tables (11). All atoms were assumed to be uncharged and a correction was made for the anomalous dispersion of Pt (12). The model containing two Pt and four P atoms gave R = 0.22 initially. The model was refined by minimization of $\sum w(|F_o| - |F_c|)^2$ using the method of least squares. Light atoms were located and added to the model by means of Fourier maps. With further refinement, the R value decreased to 0.042 but at this stage it was clear that the triethylphosphine group containing P(1) was not appearing as clearly as the other three, and that the fluorine atoms F(5) to F(8) had large temperature factors. A structure factor calculation was done with the troublesome atoms removed, and the difference map based on this showed the fluorine atoms as before, but no resolution of the PEt_3 difficulty, since the map clearly showed more than six peaks near to the P(1) atom. The A and B parts of the partial structure factors corresponding to the reliably determined atoms were calculated for use while dealing with the first PEt_3 group and written on a peripheral device. The terminal methyl groups of the first PEt_3 group were temporarily neglected and the three carbon atoms bonded to P(1) were treated as six half atoms in two sets of three. The nomenclature C(51)–C(56) was used for the six extra labels required. Two least-square cycles were calculated using strict constraints (13) within each set to maintain reasonable bond lengths and angles, but allowing unhindered rotation about the Pt—P bond. This was followed by a difference map which showed three nonspherical

P(1)—C	0±100
C—C (1st PEt_3)	0±100

peaks attributable to three pairs of methyl carbon half atoms, which were added to the model and refined by two cycles of constrained least squares with the site occupation factors fixed at 0.5. The occupation factor was then refined giving 0.56 for C(11) to C(16) and 0.44 for C(51) to C(56). Finally the fixed atom file was dispensed with, and the whole structure refined by four cycles of least squares in which the constraints were loosened as far as possible. The final set of constraints is given in Table 1. A vibrational constraint limits the difference between two bonded atoms in the components of their mean square displacements along the bond direction. The full matrix was approximated using various blocking schemes throughout the refinement, but finally by blocks for (*i*) each PEt_3 group, (*ii*) the Pt and O atoms and the first BF_4 group, (*iii*) the second BF_4 group, and (*iv*) the scale and a dummy U (isotropic). A weighting scheme, devised to minimize systematic variations of $w\Delta^2$, took the form $w = 1/(1 + [|F_o| - A)/B]^2)$, with $A = 80$ and $B = 91$. The final R value was 0.032 and $R_w = 0.042$, where R_w is defined as $(\sum w\Delta^2/\sum w|F_o|^2)^{1/2}$. The final difference map gave no indication of any misplaced atom. The hydrogen atoms were not located. The structure factor table and tables containing some of the less interesting structural details are in the Depository for Unpublished Data.[1]

Results

Figure 1 shows the structure of the binuclear cation, consisting of two square-planar Pt(II) halves, joined by the bridging hydroxy groups at a substantial dihedral angle. Figure 1 also shows the juxtaposition of the cation and the first BF_4^- ion, the thermal vibration ellipsoids, and the atom labelling scheme. The atomic parameters are given in Tables 2 and 3. The complete unit cell is shown

[1]Copies may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

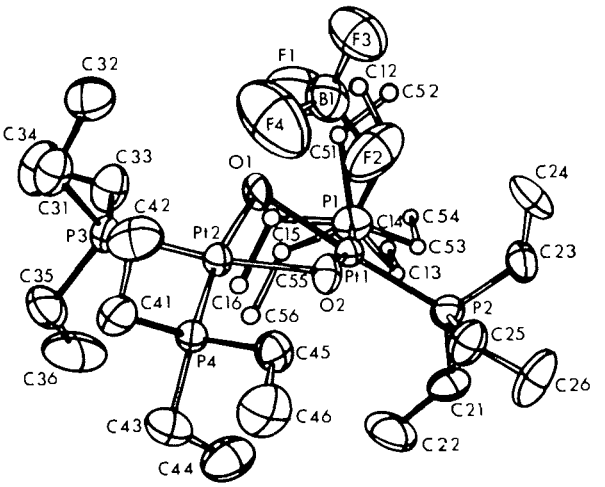

FIG. 1. The molecular structure of the $[(PEt_3)_2Pt(OH)_2Pt(PEt_3)_2]^{2+}$ cation with the first BF_4^- ion in juxtaposition.

in Fig. 2 which has its origin at the front lower right, with axes *a* right to left, *b* vertical, and *c* into the page. The second BF_4^- ion is situated near the right- and left-hand sides of the drawing in all its symmetry positions and is not close to the dihydroxy bridge.

Bond lengths are given in Table 4. The Pt—P lengths are all close to the mean value of 223.5 pm. The bond distances Pt—O(1) seem to differ slightly from the Pt—O(2) distances. It is not known whether this is a consequence of small errors in the structure determination or a real effect caused by differences in the hydrogen atom positions in the bridge. The Pt—O distances are slightly larger than the values 203(1) and 202(2) pm found in $[(NH_3)_2Pt(OH)_2Pt(NH_3)_2](NO_3)_2$ and $[Pt_3(NH_3)_6(OH)_3](NO_3)_3$ respectively, which is reasonable in view of the *trans*-influence of the phosphine ligand. The Pt(IV)—O distance in $(Me_3PtOH)_4$ is 222(1) pm. The Pt—O lengths and the bent nature of the bridge lead to a Pt—Pt distance of 312.1(1) in Table 4 compared to 308.5(1) in the above ammine dimer. In platinum metal, Pt—Pt = 277 pm. With the geometry of our complex and the d^8 electronic structure of Pt(II) it is difficult to imagine any bonding between the platinum atoms. The absence of Pt—Pt interaction is therefore assumed. The P—C lengths, mean = 183 pm, and the C—C lengths, mean = 154 pm, are normal. The mean B—F lengths are 135 and 127 pm in the first and second BF_4^- ions respectively. The shorter distance in the second ion is attributed to its greater thermal motion (14).

Selected bond angles are given in Table 5. The O—Pt—O and Pt—O—Pt angles are slightly smaller than the values of 81.3(4)° and 98.7(4)° found in

*x, y, and z values should be multiplied by 10^{-3} to obtain fractional crystal coordinates. Standard deviations are given in parentheses in units of the least significant decimal place.

$[(NH_3)_2Pt(OH)_2Pt(NH_3)_2](NO_3)_2$. The P—Pt—P angles agree closely with the values found in other *cis*-$[(PEt_3)_2PtXY]$ ions, such as X = Cl, Y = phenanthroline, 1,8-naphthyridine, phthalazine, wherein P—Pt—P = 99.5, 99.3, 98.9°, respectively (15). Excluding the first PEt_3 group, the mean values of angles are: Pt—P—C = 114°, C—P—C = 105°, P—C—C = 112°. The applied constraints (Table 1) which were derived from the crystal structure of

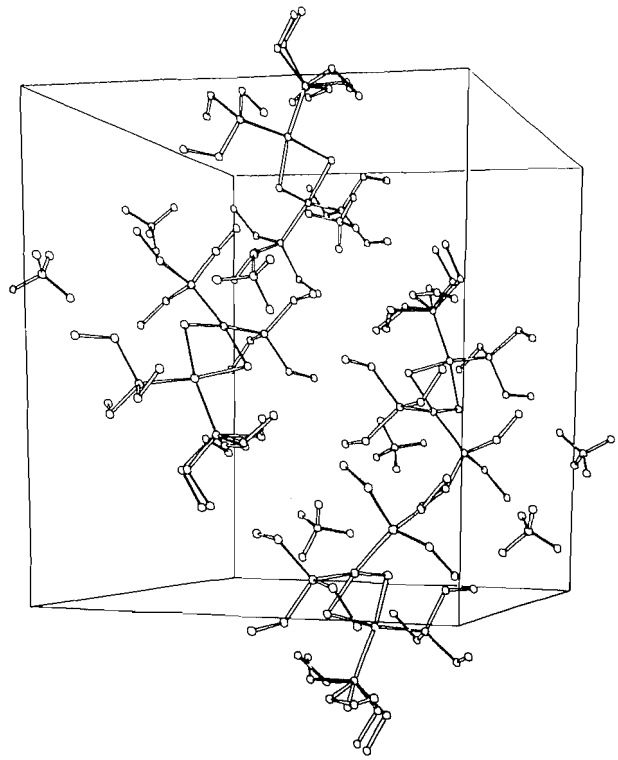

FIG. 2. The packing diagram for μ-dihydroxytetrakis(triethylphosphine)diplatinum(II) tetrafluoroborate.

$[(PEt_3)_2PtCl_2Pt(PEt_3)_2](BF_4)_2$ (16) are consistent with the lengths and angles subsequently found in the normal PEt_3 groups and the first BF_4^- ion.

The use of constraints was necessary to complete this structure determination with a chemically reasonable model. The constraints could not be removed at the end of the refinement, leaving a structure stable in a least-squares cycle based on the X-ray intensities alone. Therefore, the structure of the first PEt_3 group and the second BF_4^- ion has been partly imposed, partly determined. Fortunately the bent bridge structure and the position of the first BF_4^- ion can hardly be dependent on these details.

The conformation of the three normal PEt_3 groups is such that on each ligand the carbon atoms of two ethyl groups and the P atom form a W shape which runs perpendicular to the Pt coordination plane. The P atom and the two carbon atoms of the other ethyl lie approximately in the coordination plane and the direction of the P—C—C sequence is away from the other PEt_3 ligand of the *cis* pair. The P(1),C(51)–C(56) set of sites is similar except that the direction of the approximately in-plane P—C—C sequence is away from O(1). The P(1),C(11)–C(16) set is different in that it lacks the W shape: its conformation

*x, y, and z are fractional crystal coordinates. D = the perpendicular distance to the origin in pm.

resembles one of the PEt_3 ligands in the chloro bridged complex $[(PEt_3)_2PtCl_2Pt(PEt_3)_2](BF_4)_2$ (16).

A least-squares plane has been calculated for the coordination of each Pt atom and the results are given in Table 6. Each half of the binuclear complex is close to planarity. The angle of 36.4° between the plane normals is an interesting feature of the structure. An explanation in terms of the bond angles at the oxygen atoms does not work. Since the O—Pt—O angle is 79.4°, the angle Pt—O—Pt would be 100.6° if the complex were planar. The mean Pt—O—Pt angle is 94°. It can hardly be argued that the cation bends in order to reduce the Pt—O—Pt angle from 100.6° to 94° when the usual bond angle at oxygen is 104.5, as in water, or larger. The dihedral angle is most directly explained as a consequence of hydrogen bonding between the first BF_4^- ion and the bridging hydroxy groups. Evidence for the hydrogen bonding is as follows: (*i*) the temperature factors of the fluorine atoms are lower in the first than in the second fluoroborate ion (Table 3); (*ii*) the short interatomic distances O(1)—F(1) and O(2)—F(2) (Table 4); (*iii*) the suitable bond angles Pt—O(1)—F(1), Pt—O(2)—F(2), B(1)—F(1)—O(1), and B(1)—F(2)—O(2) (Table 5). A search of the literature for structural results giving evidence of hydrogen atom positions in the μ-dihydroxy bridges of binuclear complexes was not very rewarding, since the hydrogen atoms were usually undetected. Often

the M_2O_2 ring is planar, with a central inversion point. The most suggestive structure otherwise was that of *cis*-$[(PPr_3)ClPt(EtS)_2Pt(PPr_3)Cl]$ (17) which has a bent bridge with 50° between the normals. One ethyl group is axial, the S—C bond being approximately perpendicular to the mean plane through the entire heavy atom skeleton, whereas the other ethyl group is equatorial. On the basis of the above it seems that the hydrogen atoms of the μ-dihydroxy bridge are both axial, and equally involved in hydrogen bonding since distance O(1)—F(1) = O(2)—F(2) approximately.

The more clinically successful cancer chemotherapeutic drugs have amine instead of triethylphosphine groups. The inability of the triethylphosphine ligands to engage in hydrogen bonding is partly responsible for the difference in the structures of the μ-dihydroxy bridges of $[(NH_3)_2Pt(OH)_2Pt(NH_3)_2](NO_3)_2$ and $[(PEt_3)_2Pt(OH)_2Pt(PEt_3)_2](BF_4)_2$ in the crystalline state. In the former compound two nitrate ions on opposite sides of the complex are each involved in hydrogen bonding to a bridging hydroxy and a terminal ammine group. The hydrogen atoms were not located (4). In solutions of pyrimidine and purine bases a bending of the ammine complex due to hydrogen bonding from one side cannot be precluded.

The mainstream of chemical thought on the mechanism of action of *cis*-$[PtCl_2(NH_3)_2]$ has been that after passage through cell membranes in the nonionic form, the compound undergoes aquation in two stages and two steps of substitution with pyrimidine or purine bases, which produce cross linking of the DNA strands. The production of binuclear complexes which has now been clearly recognized (4, 5, 7) was initially neglected. Hydrogen bonding of the type discovered in this paper may be important in the mechanism. For example the N—C—O grouping of cytosine might hydrogen bond to a μ-dihydroxy bridge, thus holding the platinum complex in position until the more permanent formation of a Pt—N bond by guanine had been achieved. This would be followed by bridge cleavage and cross linking.

Acknowledgements

This work was carried out at the Chemical Crystallography Laboratory, Oxford, while the author was there on study leave in 1973–1974. Thanks are due to Professor H. M. Powell for generously making available the full facilities of the laboratory and to Drs. C. K. Prout, D. J. Watkin, and R. A. Forder. The versatile, fast, and elegant computer programming by Drs. J. R. Carruthers, J. S. Rollett, and E. White is gratefully acknowledged. Thanks are due to Dr. K. R. Dixon who provided the crystals, and to Mrs. K. Beveridge for Fig. 2. The study leave was supported by the University of Victoria and the National Research Council of Canada provided an operating grant.

Rupture du lien C—S lors de la réduction de sulfones par $LiAlH_4$

NORMAND DUFORT ET BERNARD JODOIN

Département de chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3J7

Reçu le 30 décembre 1977

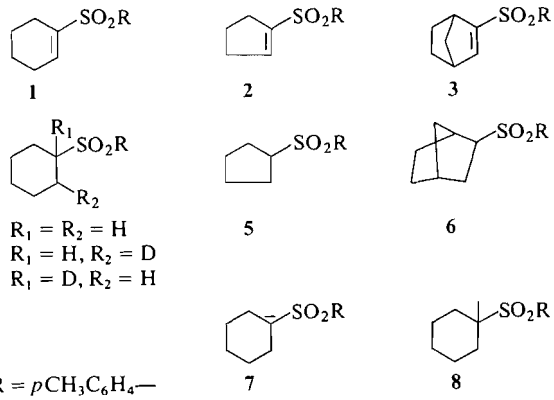
NORMAND DUFORT et BERNARD JODOIN. Can. J. Chem. **56**, 1779 (1978).

Différentes sulfones α,β-insaturées et saturées sont réduites par $LiAlH_4$. Il se produit une rupture du lien C—S dépendant de la nature de la sulfone.

NORMAND DUFORT and BERNARD JODOIN. Can. J. Chem. **56**, 1779 (1978).

Different α,β-unsaturated and saturated sulfones are reduced by $LiAlH_4$. A cleavage of the C—S bond occurs according to the kind of sulfones.

Dans le cadre de nos travaux, nous avons été appelés à étudier la réduction par $LiAlH_4$ de la cyclohexène-1 yl *p*-tolyl sulfone (**1**), de la cyclopentène-1 yl *p*-tolyl sulfone (**2**), de la norbornène-2 yl-2 *p*-tolyl sulfone (**3**) et des sulfones saturées correspondantes **4**, **5** et **6** et nous en rapportons les résultats.



1 **2** **3**

4 $R_1 = R_2 = H$
4*a* $R_1 = H, R_2 = D$
4*b* $R_1 = D, R_2 = H$

5 **6**

$R = pCH_3C_6H_4—$

7 **8**

Les sulfones insaturées **1**, **2** et **3** traitées par $LiAlH_4$ dans l'éther pendant 1 h, donnent les sulfones saturées correspondantes avec d'excellents rendements. Cette réduction chimique s'avère d'ailleurs plus efficace et plus rapide pour réduire la double liaison que la réduction catalytique. Un mécanisme plausible pour cette réduction serait le suivant: il y aurait tout d'abord attaque de l'hydrure sur le carbone en position β du groupe SO_2 pour conduire au carbanion **7** dont la charge négative est localisée sur le carbone en α du groupe sulfonyle (1–6). Le carbanion **7** conduirait ensuite à la sulfone saturée **4** lors de l'hydrolyse. Afin de vérifier ce mécanisme, le composé **1** a été réduit par $LiAlD_4$. Le spectre rmn du produit obtenu indique la disparition du proton oléfinique et la présence d'un hydrogène en α du groupe SO_2 et de neuf autres hydrogènes pour le groupe cyclohexyle confirmant ainsi la formation du composé **4***a* et le mécanisme proposé. Le spectre de masse indique que la deutération est complète puisque le produit monodeutéré **4***a* est pur à 98%. De plus, lorsque le composé **1** est réduit par $LiAlH_4$ suivi d'une hydrolyse par D_2O, on obtient le composé **4***b*.

Si le temps de réduction est prolongé, le produit obtenu n'est pas le sulfure comme on pourrait s'y attendre (7); mais il se produit une rupture du lien C—S pour donner l'acide *p*-toluènesulfinique qui est alors isolé sous forme de méthyl *p*-tolyl sulfone et l'hydrocarbure saturé correspondant (voir tableau 1). Cette réaction impliquerait d'abord la formation d'un carbanion en α du groupe SO_2. Ce dernier pourrait donner par rupture du lien C—S, l'anion *p*-tolyl sulfinate et un carbène par analogie avec la réduction des tosylhydrazones par $LiAlH_4$ (8). Le carbène par migration d'un hydrogène formerait une oléfine (9). Comme il s'est avéré impossible de détecter la présence d'oléfines par chromatographie en phase gazeuse et par résonance magnétique nucléaire, un tel mécanisme ne peut pas être retenu. La formation d'acide *p*-toluènesulfinique et d'hydrocarbure saturé s'expliquerait plutôt par le fait que le carbanion **7** pourrait être protoné par suite de la décomposition de l'éther en alcène (10), pour donner la sulfone saturée qui conduirait à la rupture du lien C—S.

En effet, lorsque les sulfones saturées **4**, **5** et **6** sont traitées par $LiAlH_4$ dans des conditions analogues aux sulfones insaturées, il se produit également une rupture du lien C—S pour donner de l'acide *p*-toluènesulfinique isolé sous forme de méthyl *p*-tolyl sulfone et les hydrocarbures saturés correspondants (voir tableau 1). Afin de s'assurer que la rupture des sulfones saturées n'impliquait pas un carbanion comme intermédiaire comme dans le cas des sulfones insaturées, il suffisait de choisir une sulfone n'ayant pas d'hydrogène en α du groupe SO_2. A cette fin, la méthyl-1 cyclohexyl *p*-tolyl sulfone **8** a été préparée en traitant la cyclohexyl *p*-tolyl sulfone **4** par le méthyl lithium, suivi d'une addition d'iodure de méthyle. Cette sulfone, traitée par $LiAlH_4$ dans les

mêmes conditions, donne également par rupture du lien C—S de l'acide *p*-toluènesulfinique et du méthyl cyclohexane avec un rendement de 33%.

Ce travail permet donc de déduire que la réduction de sulfones α,β-insaturées ou saturées et constituées d'une partie aromatique et non aromatique conduit à la rupture du lien C—S au lieu de donner le sulfure correspondant, tandis que les dialkyl ou les diaryl sulfones dans les mêmes conditions ne réagissent pas (voir tableau 1) à moins qu'il ne s'agisse d'hydroxybenzyl phényl sulfones (11).

Partie expérimentale

Préparation de la méthyl-1 cyclohexyl p-*tolyl sulfone (**8**)*

A 2.6 g de cyclohexyl *p*-tolyl sulfone **4** dissous dans 200 ml d'éther anhydre sous atmosphère d'azote et dans un bain de glace sèche et d'acétone, on ajoute 7.2 ml d'une solution de méthyl lithium 2.2 *M* dans l'éther. La solution se colore rapidement en jaune et on ajoute 10 ml d'iodure de méthyle. Le mélange agité durant une heure est ensuite hydrolysé par l'addition de quelques ml d'eau. Après extraction et évaporation du solvant, le résidu est cristallisé dans un mélange d'éther – éther de pétrole. Par cristallisation fractionnée, on sépare le produit qui n'a pas réagi (0.8 g) du produit méthylé **8** (1.4 g) qui fond à 78–79°C; spectre rmn: 7.60 (m, 4H, hydrogènes du noyau aromatique), 2.41 (s, 3H, méthyle du groupe tolyle), 1.28 ppm (s, 3H, méthyle en α de la sulfone). *Anal.* calc. pour $C_{14}H_{20}SO_2$: C 66.65, H 7.99; trouvé: C 66.92, H 7.78.

Méthode générale de réduction des sulfones α,β-insaturées en sulfones saturées

Une portion (0.002 mol) de sulfone insaturée est ajoutée à une suspension de 0.006 mol de $LiAlH_4$ dans 10 ml d'éther anhydre. Le mélange est porté à reflux durant 1 h. Après extraction et évaporation du solvant, le résidu recristallisé dans un mélange d'éther – éther de pétrole donne la sulfone saturée.

Méthode générale de réduction des sulfones α,β-insaturées avec récupération des produits de rupture

Une portion (0.002 mol) de sulfone est traitée par 0.012 mol de $LiAlH_4$ comme ci-dessus sauf que le temps de réaction est prolongé jusqu'à 144 h. Après extraction, l'éther est évaporé à travers une colonne de Widmer. Le résidu est alors chromatographié en phase gazeuse sur deux colonnes différentes afin d'identifier l'hydrocarbure formé (colonne de 12 pieds × ⅛ po. de diamètre, température 65°C et contenant 3% de JXR sur Chromosorb G AW DMCS et colonne de 20 pieds × ⅛ po. de diamètre, température 100°C et contenant 5% de QF-1 sur Chromosorb G AW DMCS). Par injections mixtes avec le produit authentique, on identifie l'hydrocarbure formé. De la phase organique, on récupère également de la sulfone saturée formée par réduction de la double liaison. A la phase aqueuse, on ajoute un large excès (5 ml) d'iodure de méthyle et quelques ml d'une solution de NaOH à 10%. Après un reflux de 24 h, le mélange est acidifié par une solution de HCl à 10%. Après extraction et évaporation du solvant, on recueille l'acide *p*-toluènesulfinique sous forme de méthyl *p*-tolyl sulfone.

Méthode générale de réduction des sulfones saturées avec récupération des produits de rupture

La même méthode de réduction est utilisée pour les sulfones saturées que pour les sulfones insaturées sauf que les quantités de sulfone et d'hydrure sont dans le rapport de 1 à 3 alors qu'il est de 1 à 6 pour les sulfones insaturées.

The reaction of 9,10-dimethylanthracene (**8**) with ferrocene (FcH) in the presence of $AlCl_3$–Al in decalin gave the stereospecifically hydrogenated product, η^6-*cis*-(*endo*-9,10-dihydro)-9,10-dimethylanthracene-η^5-cyclopentadienyliron cation (**10***a*), the hydrogenation at C-9,10 being *cis* and *endo* or on the same side as the cyclopentadienyliron (CpFe) moiety. When *cis*-9,10-dihydro-9,10-dimethylanthracene, generated from **10***a* by photolysis or pyrolytic sublimation, was used as the arene in the ligand exchange reaction, complexing with the CpFe group could occur from either side of the ring system, giving rise to a mixture of **10***a* and the η^6-*cis*-(*exo*-9,10-dihydro)-9,10-dimethylanthracene-η^5-cyclopentadienyliron cation (**10***b*). The η^6-*cis*-9,10-dihydro-9,10-dimethylanthracene-*trans*-bis-η^5-cyclopentadienyliron dication, with the two CpFe groups *trans*, was also prepared either from a stepwise ligand exchange using **10***a* or directly from reaction of **8** using an excess of FcH. A mechanism is proposed for the hydrogenation that has been found to accompany ligand exchange reactions between polycyclic arenes and FcH and possible applications are pointed out for the synthesis of partially hydrogenated polycyclic aromatic hydrocarbons.

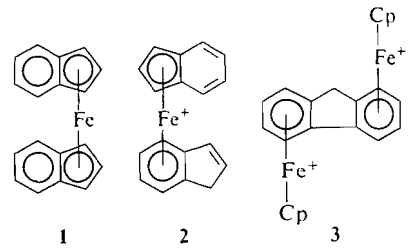
RONALD G. SUTHERLAND, W. JACK PANNEKOEK et CHOI CHUCK LEE. Can. J. Chem. **56**, 1782 (1978).

La réaction du diméthyl-9,10 anthracène (**8**) avec le ferrocène (FcH) en présence de $AlCl_3$–Al dans la décaline conduit à un produit hydrogéné stéréospécifiquement soit le cation η^6 (dihydro-9,10 *endo*) diméthyl-9,10 anthracène η^5 cyclopentadiénylfer *cis* (**10***a*), l'hydrogénation au niveau des atomes de carbone 9,10 se faisant *cis* et *endo*, soit sur le même côté que la portion cyclopentadiénylfer (CpFe). Lorsque l'on utilise du dihydro-9,10 diméthyl-9,10 anthracène *cis*, produit à partir de **10***a* par photolyse ou sublimation pyrolytique, comme arène dans la réaction d'échange de ligand, la complexation avec le groupe CpFe pourrait se produire de chaque côté du système cyclique et pourrait conduire à un mélange de **10***a* et du cation η^6 (dihydro-9,10 *exo*) diméthyl-9,10 anthracène η^5 cyclopentadiénylfer *cis* (**10***b*). On a aussi préparé le dication η^6 dihydro-9,10 diméthyl-9,10 anthracène *cis* bis-η^5 cyclopentadiénylfer *trans* avec les deux groupes CpFe *trans*; on a préparé ce composé soit par un échange par étape du ligand faisant appel à **10***a* soit directement par réaction de **8** avec un excès de FcH. On propose un mécanisme pour l'hydrogénation qui accompagne les réactions d'échange de ligand entre les arènes polycycliques et FcH et on indique des applications possibles pour la synthèse d'hydrocarbures aromatiques polycycliques partiellement hydrogénés.

[Traduit par le journal]

Introduction

In 1963, Nesmeyanov *et al.* (1, 2) first reported that η^6-arene-η^5-cyclopentadienyliron cations could be prepared by the reaction of benzene or substituted benzenes with ferrocene and $AlCl_3$, with Al powder also present in the reaction mixture to minimize the formation of ferricenium ions from ferrocene. Among the more intriguing early observations was the finding that the reaction with chloro- or bromobenzene was complicated by the loss of halogen to give the benzene complex and, in some instances, the biphenyl complex (3, 4). Apart from the synthesis of complexes from naphthalene and fluorene (3), early studies tended to neglect the reactions of polynuclear hydrocarbons with ferrocene. Our work in this area began with a successful attempt to prepare cations by an intramolecular ligand exchange process, whereby bisindenyliron (**1**) was converted to the corresponding η^6-arene-η^5-cyclopentadienyliron cation **2** by treatment with BF_3-etherate (5), a transformation which has since been confirmed by other workers (6).



1 2 3

The first successful synthesis of η^6-arene-*bis*-η^5-cyclopentadienyliron dications was reported from this laboratory in 1972 (7), using arenes such as biphenyl, diphenylmethane, and fluorene, and in the latter case, the two cyclopentadienyliron (CpFe)

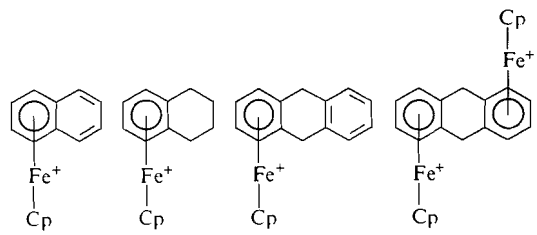
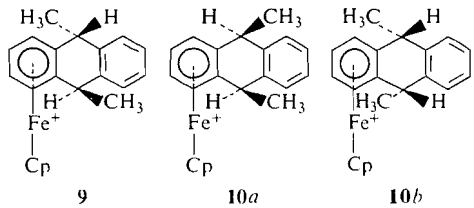
moieties were shown to be *trans* to each other (**3**). Subsequently, Hendrickson and co-workers (8) reported the synthesis of a number of such dications from a variety of aromatic polynuclear hydrocarbons. However, we have found that such reactions with aromatic polynuclear hydrocarbons resulted in a novel hydrogenation process. For example, reaction of naphthalene with ferrocene (FcH)–$AlCl_3$–Al gave rise to both the η^6-naphthalene-η^5-cyclopentadienyliron cation (**4**) and the η^6-tetralin-η^5-cyclopentadienyliron cation (**5**), whereas anthracene gave only the hydrogenated η^6-9,10-dihydroanthracene-η^5-cyclopentadienyliron cation (**6**) and the corresponding dication (**7**) (9). These observations as well as the early work in the field have recently been reviewed (10).



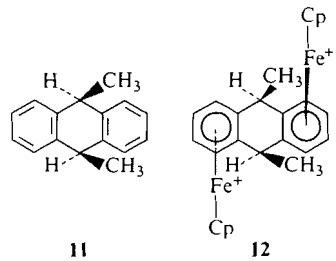
The ligand exchange reaction between FcH and a number of substituted naphthalenes has also been studied (11). It is of interest to note that with 1-bromonaphthalene, the reaction gave a mixture of the expected η^6-1-bromonaphthalene-η^5-cyclopentadienyliron cation, the debrominated cation **4**, and the debrominated-hydrogenated cation **5**. With added radical scavengers such as I_2 or diphenylpicrylhydrazyl (DPPH), the formation of **5** was suppressed, thus implicating radical ions in the hydrogenation process (11). In the present work, ligand exchange reactions between FcH and 9,10-dimethylanthracene, in the presence of $AlCl_3$–Al, were studied with the view of elucidating the stereochemical nature and hence the probable mechanism for the hydrogenation process observed in such reactions.

Results

9,10-Dimethylanthracene (**8**) can be readily prepared in a one-step reaction from vinyl acetate, $AlCl_3$, and benzene (12). By analogy with the ready formation of the 9,10-dihydroanthracene complex **6** from anthracene, it may be anticipated that if hydrogenation occurs in the ligand exchange reaction between FcH and **8**, the hydrogenation could be specifically *trans* to give ion **9**, specifically *cis* and *endo* to the CpFe group to give ion **10***a*, and specifically *cis* and *exo* to the CpFe group to give ion **10***b*,[1] or hydrogenation might take place randomly to give a mixture of these isomers.



Reaction of **8** with FcH in the presence of $AlCl_3$–Al (molar ratio of 1:1:2:1 for arene–FcH–$AlCl_3$–Al) required a minimum temperature of 130–140°C in decalin to give a single monocationic product, which upon photolysis (9) or pyrolytic sublimation gave the hydrogenated ligand, *cis*-9,10-dihydro-9,10-dimethylanthracene (**11**). The product, therefore, cannot be ion **9** but may be ion **10***a* or **10***b*. Subsequent observations (*vide infra*) showed that this product is **10***a*, the η^6-*cis*-(*endo*-9,10-dihydro)-9,10-dimethylanthracene-η^5-cyclopentadienyliron cation. The dication, **12**, can be prepared in a stepwise manner (7) from treatment of ion **10***a* with FcH, $AlCl_3$, and Al, or in a one-step process (8) from **8** with an excess of FcH (molar ratio of 1:5:10:1 for arene–FcH–$AlCl_3$–Al). When *cis*-9,10-dihydro-9,10-dimethylanthracene (**11**), derived from the photolysis or pyrolytic sublimation of **10***a*, was used as the arene, the ligand exchange reaction with FcH in the presence of $AlCl_3$–Al now gave a mixture of the *cis-endo*-dihydro cation **10***a* and the *cis-exo*-dihydro cation **10***b*, in a ratio of approximately 60:40. The ^1H and ^{13}C nmr spectral data and their assignments for hydrocarbon **11** and ions **10***a*, **10***b*, and **12** are summarized in Table 1 and, as illustrations, the ^{13}C nmr spectra of ions **10***a* and **12** are shown in Fig. 1.



Discussion

From Table 1, it is seen that in agreement with earlier observations (8, 9, 11), the aromatic ring, after complexing with the CpFe group, shows an upfield shift as was first reported by Hendrickson

[1]The *endo* and *exo* designations are used to indicate that the H atoms at C-9,10 and the CpFe group are on the same side and on opposite sides, respectively, of the ring system (13).

TABLE 1. ^1H and ^{13}C nmr data from *cis*-9,10-dihydro-9,10-dimethylanthracene (**11**), η^6-*cis*-(*endo*-9,10-dihydro)-9,10-dimethylanthracene-η^5-cyclopentadienyliron monocation (**10***a*), η^6-*cis*-(*exo*-9,10-dihydro)-9,10-dimethylanthracene-η^5-cyclopentadienyliron monocation (**10***b*), and η^6-*cis*-9,10-dihydro-9,10-dimethylanthracene-*trans*-bis-η^5-cyclopentadienyliron dication (**12**)

and co-workers (8). With regard to the stereochemistry of the hydrogenation, it is of interest to note that for ion **10***a*, in which the H atoms at C-9,10 are *endo* or on the same side of the ring system as the CpFe group, the CH_3 and C-9,10 absorptions are quite similar for **10***a* and the hydrogenated ligand **11**. On the other hand, for ion **10***b* in which the CH_3 groups at C-9,10 are *endo*, there is a steric downfield shift (14) for the CH_3 proton absorption at 2.00 ppm relative to that of **10***a* at 1.59 ppm. Similarly, the same steric effect that caused a loss of electron density for the CH_3 hydrogens gave rise to more shielding for the CH_3 carbons, resulting in an upfield shift (15, 16) for the CH_3 carbon absorption of **10***b* at 11.9 ppm relative to that of **10***a* at 27.2 ppm. Slightly more shielding for the C-9,10 carbons of **10***b* than **10***a* is also observed. Such results, therefore, establish the *cis*-(*endo*-9,10-dihydro) and *cis*-(*exo*-9,10-dihydro) structures for ions **10***a* and **10***b*, respectively.

The ^{13}C spectrum of dication **12** (Table 1, Fig. 1) shows two Cp resonances at 75.9 and 77.0 ppm and only one set of aliphatic peaks at 19.9 (CH_3) and at 35.4 ppm (C-9,10). These findings are consistent only with structure **12** in which the two CpFe groups are *trans*. If the two CpFe groups were *cis*, there would be only one equivalent Cp absorption, and if the two nonequivalent Cp peaks were due to a mixture in which the two CpFe groups were *cis* in one case and *trans* in the other, there would be two sets of resonances at the aliphatic region. Since in **12** the CH_3 groups are *endo* to one of the CpFe groups, the steric effect gave, relative to **10***a*, a downfield shift for the CH_3 proton absorption and an upfield shift for the CH_3 carbon absorption, quite similar to those observed for **10***b* relative to **10***a*, and, therefore, providing a further confirmation for structures **10***a* and **10***b*.

The present results thus indicate that the ligand exchange reaction between 9,10-dimethylanthracene (**8**) and FcH in the presence of $AlCl_3$–Al, as in the analogous reaction with anthracene (9), occurs with hydrogenation at the C-9,10 positions. However, a minimum temperature of 130–140°C is required in the reaction with **8**, in contrast with the reaction with anthracene which took place at about 80°C (9). The addition of the H atoms is stereospecifically *cis* and *endo* or on the same side as the CpFe group to give ion **10***a*. When *cis*-9,10-dihydro-9,10-dimethylanthracene (**11**) is used as the arene, there is no hydrogenation and the CpFe group can complex from either side of the ring system to give a mixture of ions **10***a* and **10***b*.

In our earlier work, it was shown that deuterium was not incorporated from D_2O during work up and that hydrogenation did occur during the ligand exchange reaction (9). The source of the hydrogen is probably the solvent since control experiments have shown that, instead of decalin, the use of hydrocarbons such as nonane, a poorer hydrogen donor, as solvent gave lesser extents of hydrogenation (17). With the naphthalene system, it was also found that

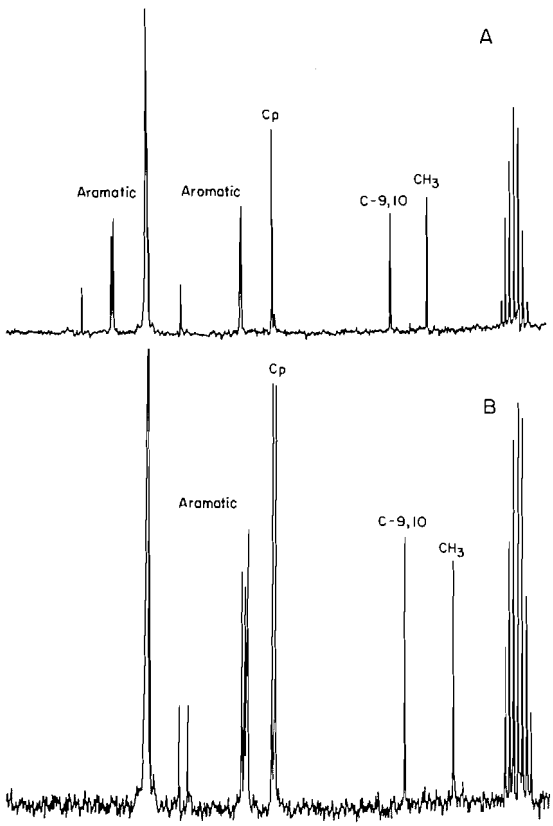

FIG. 1. ^{1}H-decoupled ^{13}C nmr spectra in CD_3CN of the η^6-*cis*-(*endo*-9,10-dihydro)-9,10-dimethylanthracene-η^5-cyclopentadienyliron cation **10***a* (*A*) and the η^6-*cis*-9,10-dihydro-9,10-dimethylanthracene-*trans*-bis-η^5-cyclopentadienyliron dication **12** (*B*).

the extent of hydrogenation was dependent on the concentration of $AlCl_3$ and that extensive scramblings occurred when perdeuteronaphthalene was used in the reaction (11). These observations strongly suggested that hydride abstraction by $AlCl_3$ likely played an important role. In the work with 1-halonaphthalenes (11), the relative ease of dehalogenation (Br > Cl ≫ F) again suggested the removal of halide by $AlCl_3$ as $AlCl_3X^-$ (X = Br, Cl). With 1-bromonaphthalene, the effect of radical scavengers in suppressing the hydrogenation, but not the dehalogenation, indicated that at least two steps were involved in the hydrogenation process, namely, the loss of $AlCl_3X^-$ followed by a radical reduction involving H atoms (11).

The present findings with **8** provided much additional information pertinent to the mechanism of the hydrogenation. The higher reaction temperature required by **8** in contrast to anthracene is consistent with hydride abstraction by $AlCl_3$, since a primary hydrogen has to be removed from **8** to initiate the hydrogenation. The stereospecificity observed in the addition of hydrogen to C-9,10, namely, *cis* and *endo* to the complexed iron, is of mechanistic significance. It suggests that the iron must have been complexed to the arene ligand before hydrogenation and that iron hydride intermediates are likely involved. Such stereospecific transfers of hydrogen via iron hydrides have been observed, for example, in the fragmentation of the complex, cyclohexadienylcyclopentadienyliron (18).

Considering all the information discussed above, a mechanism for the hydrogenation process is outlined in Scheme 1. This is a modification of the previously suggested radical-ion mechanism which was proposed as a working hypothesis (11). The mechanism in Scheme 1 can, of course, be readily adapted to account for the hydrogenation with other arenes such as the formation of **5** from naphthalene. Among the key steps in the mechanism is the intramolecular oxidation–reduction (11) in which an electron is

transferred from Fe(II) to give Fe(III) while a carbonium ion center is reduced to a free radical. This has a recent analogy in the work of Cais *et al.* (19) who found that a tertiary amine could transfer an electron to an α-ferrocenyl carbonium ion to give a radical, which subsequently could abstract H to form product.

Aside from the mechanistic aspects of the hydrogenation, the present and related work also indicate that there are synthetic applications. The reaction of **8** to give **10***a*, followed by pyrolytic sublimation to give **11** is the best synthetic route to this hydrocarbon. A number of reductive methods to give 9,10-dihydro-9,10-dimethylanthracene generally resulted in a mixture of the *cis* and *trans* isomers (20–22) while the synthesis of the pure *cis* isomer (**11**) required a sequence of stereospecific reactions (23, 24). Other related work (to be published) with polycyclic aromatics, such as acenaphthene, phenanthrene, chrysene and pyrene, show that hydrogenation occurs readily to give partially reduced polycyclics, which can then be obtained in a pure form by chromatographic separation of the complexes followed by either photolysis or pyrolytic sublimation to give the free ligand; for example, both 4,5-dihydropyrene and 4,5,9,10-tetrahydropyrene can be obtained in this manner from pyrene.

Experimental

η⁶-cis-(endo-*9,10-Dihydro*)-*9,10-dimethylanthracene*-η⁵-*cyclopentadienyliron cation (**10**a)*

A mixture of 5.15 g (25 mmol) of 9,10-dimethylanthracene (**8**) (12), 4.7 g (25 mmol) of ferrocene, 6.7 g (50 mmol) of $AlCl_3$, and 0.65 g (25 mmol) of Al powder in 50 ml of decalin were heated under reflux and under N_2 at 135°C for 12 h. The resulting material was cooled to room temperature and 50 ml of H_2O was added. The mixture was thoroughly shaken, the aqueous layer separated and washed with Skelly B (3 × 100 ml) and then filtered into a concentrated solution of ammonium hexafluorophosphate. The yellow hexafluorophosphate salt of **10***a* that precipitated (3.1 g, 25%) was dried under vacuum for 24 h. Recrystallization could be carried out in CH_3CN–tetrahydrofuran; however, on successive recrystallization, the melting point varied and the nmr spectra showed broadening of the peaks presumably owing to decomposition giving rise to paramagnetic impurities. It was noted that for the complex salts prepared in the present work, the best ^1H and ^{13}C nmr spectra were obtained with a minimum handling of the reaction products. The identification of ions such as **10***a* was, therefore, based on nmr spectroscopic data as summarized in Table 1 and exemplified in Fig. 1.

cis-*9,10-Dihydro-9,10-dimethylanthracene (**11**) from **10**a*

Photolysis

A solution of the hexafluorophosphate salt of **10***a* (2.5 g, 5.3 mmol) in tetrahydrofuran (50 ml) was irradiated under N_2 and with stirring for 16 h in a Rayonet reactor using 253.7 nm radiation. The resulting solution was poured into 200 ml of H_2O, extracted with CH_2Cl_2 (3 × 50 ml), and dried over $MgSO_4$. After removal of the solvent, the residue was subjected to column chromatography over neutral alumina with hexane as eluant. The eluate was concentrated to an oily residue and crystallized from CH_3OH giving 350 mg (30%) of **11**, mp 130-131°C (lit. (23) mp 130–131°C).

Pyrolytic Sublimation

The hexafluorophosphate salt of **10***a* was dissolved in a minimum of acetone or CH_2Cl_2 in a sublimator. The solvent was allowed to evaporate, leaving a thin coating of the material on the glass wall of the apparatus. After evacuation to about 0.1 Torr, heating was applied with a bunsen burner for 0.5 h or in an oil bath at about 180°C for 4 h. The solid sublimate that collected on the cold finger was dissolved in $CHCl_3$ and purified by passage through an alumina column using $CHCl_3$ as eluant. Recrystallization from CH_3OH gave **11** in yields of about 80%.

*Mixture of **10**a and **10**b from Reaction with **11***

A mixture of 940 mg (4.5 mmol) of **11**, 840 mg (4.5 mmol) of ferrocene, 1200 mg (9.0 mmol) of $AlCl_3$, and 120 mg (4.5 mmol) of Al powder in 18 ml of decalin was heated under reflux and under N_2 at 100°C for 16 h. The resulting material was worked up as described in the preparation of **10***a* from **8**. The product (400 mg, 20%) was a mixture of **10***a* and **10***b*, the nmr data for which are given in Table 1. From the ^1H nmr, the relative proportion of **10***a*:**10***b* was estimated to be 60:40.

η⁶-cis-*9,10-Dihydro-9,10-dimethylanthracene*-trans-*bis*-η⁵-*cyclopentadienyliron Dication (**12**)*

*From 9,10-Dimethylanthracene (**8**)*

A mixture of 1.25 g (6.0 mmol) of **8**, 5.58 g (30 mmol) of ferrocene, 8.0 g (60 mmol) of $AlCl_3$, and 0.16 g (6.0 mmol) of Al powder in 50 ml of decalin was heated under reflux and under N_2 at 140°C for 16 h. Work-up of the reaction mixture as described in the preparation of **10***a* from **8** gave 4.0 g (90%) of the hexafluorophosphate salt of **12**. The ^1H and ^{13}C nmr data are given in Table 1 and the ^{13}C nmr spectrum is shown in Fig. 1.

*From Ion **10**a*

A mixture of 1.0 g (0.21 mmol) of the hexafluorophosphate salt of **10***a*, 3.9 g (2.1 mmol) of ferrocene, 5.6 g (4.2 mmol) of $AlCl_3$, and 0.56 g (2.1 mmol) of Al powder in 50 ml of cyclohexane was refluxed (about 80°C) under N_2 for 16 h. Work-up as described above gave 300 mg (20%) of the hexafluorophosphate salt of **12**.

On the existence of *cis* and *trans* conformational isomers in 2-methylphenol and 4-chloro-2-methylphenol

TED SCHAEFER AND KALVIN CHUM

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received February 2, 1978

TED SCHAEFER and KALVIN CHUM. Can. J. Chem. **56**, 1788 (1978).

The analysis of the proton magnetic resonance spectra of 2-methylphenol and of 4-chloro-2-methylphenol in benzene-d_6 and CCl_4 solutions yields spin–spin coupling constants over five bonds between the hydroxyl proton and the *meta* ring protons. These coupling constants are related to the intramolecular equilibrium between conformers in which the hydroxyl group is oriented *cis* or *trans* to the methyl group. The free energy difference between the conformers is 0.4 ± 0.1 kcal/mol, with the *trans* form being the more stable. The concentration dependence of the hydroxyl proton chemical shift of the chloro compound in CCl_4 suggests that dimerization is relatively unimportant and yields rough values for the extent of self-association. It is argued that the derived free energy values refer to the intramolecular equilibrium for the monomers.

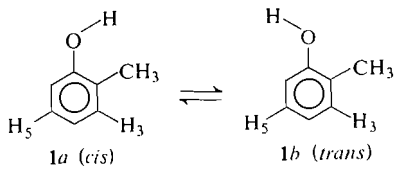
TED SCHAEFER et KALVIN CHUM. Can. J. Chem. **56**, 1788 (1978).

L'analyse des spectres de résonance magnétique nucléaire du proton du méthyl-2 phénol et du chloro-4 méthyl-2 phénol dans des solutions de benzène-d_6 et de CCl_4 conduisent aux constantes de couplage spin–spin à travers cinq liaisons entre le proton de l'hydroxyle et les protons du cycle en position *méta*. On a établi une relation entre ces constantes de couplage et l'équilibre intramoléculaire entre les conformères dans lesquels le groupe hydroxyle est orienté soit *cis* ou *trans* par rapport au groupe méthyle. La différence d'énergie libre entre les conformères est de 0.4 ± 0.1 kcal/mol, la forme *trans* étant la plus stable. La relation qui existe entre la concentration et le déplacement chimique du proton hydroxyle du composé chloré dans CCl_4 suggère que l'importance d'une dimérisation est faible et fournit des valeurs approximatives concernant le taux d'autoassociation. On présente des arguments à l'effet que les valeurs des énergies libres qui en sont dérivées se réfèrent à l'équilibre intramoléculaire des monomères.

[Traduit par le journal]

Introduction

A direct measurement of the *cis–trans* equilibrium for 2-methylphenol in solution is not available. The stretching frequency of the hydroxyl group in 2-methylphenol in CCl_4 solution at 300 K is not resolvable into two components, so that the free energy difference, ΔG, between the *cis* (**1***a*) and *trans* (**1***b*)



1*a* (*cis*) **1***b* (*trans*)

forms cannot be derived (1). An indirect estimate (1), based on the stretching band intensities in 2-*tert*-butylphenol and in 2-*tert*-butyl-5,6-dimethylphenol, yields $\Delta G = -0.5$ kcal/mol for the above equilibrium (**1***b* more stable) at 300 K in CCl_4.

The far infrared and low frequency Raman spectra in C_6H_{12} solution contain many bands, leading to ambiguous assignments of the torsional modes of the hydroxyl group (2, 3). A molecular mechanics calculation (4) suggests that **1***b* is more stable than **1***a* by 0.86 kcal/mol, the methyl group lying in a staggered conformation relative to the C—O bond.

When intermolecular proton exchange can be retarded sufficiently, it has been shown in this laboratory (5, 6) that ΔG can be deduced from the stereospecific long-range spin–spin coupling constants over five bonds between the hydroxyl proton and the protons or fluorine nuclei in positions *meta* to the hydroxyl site. In particular, it is very likely that ${}^5J_m^{OH,H_3} \equiv {}^5J_c$ is negligibly small in **1***a* and that ${}^5J_m^{OH,H_3} \equiv {}^5J_t$ can be as large as 0.7 Hz in molecules with conformations analogous to **1***b*. Corresponding remarks apply to ${}^5J_m^{OH,H_5}$ in **1***b* and in **1***a*, respectively.

In this paper a full analysis of the proton magnetic resonance spectra of 2-methylphenol (**1**) and of 4-chloro-2-methylphenol (**2**) in CCl_4 and C_6D_6 solutions yields information about the equilibrium between **1***a* and **1***b* and about the coplanarity of the O—H group with the benzene ring. The concentration dependence of the spectral parameters of **2** are also investigated.

Experimental

Solutions of 2-methylphenol, of 4-chloro-2-methylphenol, and of 4,6-dichloro-2-methylphenol at various concentrations (see below) in appropriate solvents, were degassed by the freeze–pump–thaw technique. They contained small amounts

of tetramethylsilane as an internal reference. Intermolecular hydroxyl proton exchange was retarded as previously described (7).

Proton magnetic resonance spectra were repeatedly calibrated at 5-Hz intervals in the frequency sweep mode at sweep rates of 0.01 and 0.02 Hz/s on an HA100 spectrometer. The probe temperature was 305 ± 1 K. Spectra were also calibrated while decoupling the hydroxyl proton. Consequently, the spectral parameters could be derived and compared for fully coupled (seven or eight spins) and partially decoupled (six and seven spins) conditions.

Results and Discussion

Spectral Analyses

These were performed by the computer program LAME (8, 9). In Table 1 the spectral parameters are entered for 2-methylphenol. Similar analyses yielded data for 4-chloro-2-methylphenol, the immediately relevant numbers being presented in Table 2. Figure 1 displays calculated and observed hydroxyl proton spectra for a 3.4 mol% solution of 4-chloro-2-methylphenol in CCl_4 solution. It illustrates the quality of spectra attainable for **2**.

The Cis–Trans Equilibrium in 1 and 2 2-Methylphenol

If ^5J_c in **1***a* and **1***b* is negligibly small,[1] then the free energy difference between **1***a* and **1***b* is $-RT \times \ln K = -RT \ln {}^5J_t/{}^5J_c = -RT \ln 0.484/0.215 = -490 \pm 50$ cal/mol for **1** in C_6D_6 solution and is -380 ± 40 cal/mol in CCl_4 solution (see Table 1). The estimated errors assume that the standard deviations in Table 1 are to be multiplied by 4.

It is tempting to suggest that the apparently greater stability of the *trans* form in C_6D_6 solution can be rationalized by invoking intermolecular hydrogen bonding to the π system of the solvent molecules, which might well be stronger for the *trans* form. Note that the OH and the H_6 protons of **1** display substantial

[1]A 10 mol% solution of 4,6-dichloro-2-methylphenol in C_6D_6 yielded no observable $^5J_m^{H_5,OH}$, nor was any line-narrowing observed for H_5 peaks when the hydroxyl proton was decoupled, strongly suggesting that ^5J_c is less than 0.03 Hz and that this compound exists predominantly as one conformer.

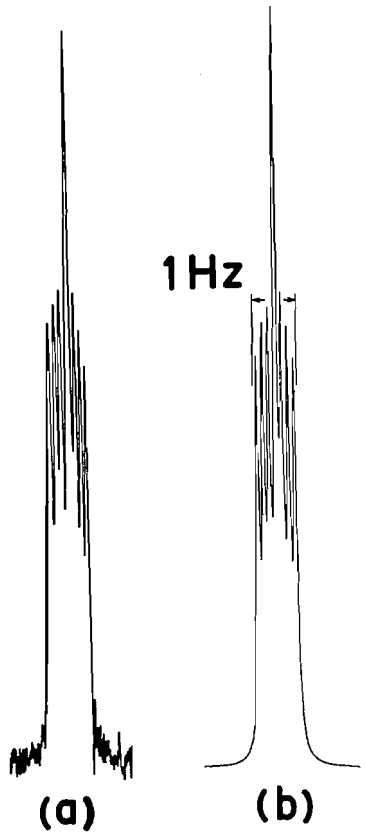

FIG. 1. The observed (*a*) and calculated (*b*) hydroxyl proton magnetic resonance spectra at 100 MHz of a 3.4 mol% solution of 4-chloro-2-methylphenol in CCl_4 at 305 K.

upfield shifts, relative to the CCl_4 solution (Table 1), compared to the other protons in **1**; this is expected if the magnetically anisotropic benzene solvent molecules pack preferentially about that region of the solute molecule. Yet this solvent effect on the *cis–trans* equilibrium must be small, if present at all.

The value of $^6J_p^{H_4,OH}$ is unobservably small in both solutions, as expected (10) if the barrier to rotation about the C—O bond is about 3.5 kcal/mol (11, 12). It is therefore reasonable to ignore any complications arising from an appreciable population of conformers in which the O—H bond lies out of the benzene plane.

Intermolecular hydrogen bonding between solute molecules must be present to some degree at these concentrations (5 mol%), but probably does not alter substantially the observed ^5J values (see discussion of **2** below). Hydrogen bonding to CCl_4 solvent molecules is apparently rather slight, having an *enthalpy* of only about 0.2 kcal/mol for phenol itself (13). Proton magnetic resonance measurements give no evidence for a specific phenol–CCl_4 complex (14).

4-Chloro-2-methylphenyl (2)

From the coupling data in Table 2, it follows that the average free energy difference between the *cis* and *trans* forms of **2** is -380 ± 60 cal/mol (*trans* more stable) in the various solutions. The values of $^5J_m^{H_3,OH}$ and $^5J_m^{H_5,OH}$ do not vary significantly between 2.5 and 8 mol% in CCl_4 and are apparently unchanged in C_6D_6 solution. Intermolecular hydroxyl proton exchange could not be stopped for a 10 mol% solution in CCl_4.

Intramolecular Hydrogen Bonding in 2

The purpose of the concentration studies was to ascertain whether increased intermolecular association could alter the intramolecular equilibrium. The *cis* and *trans* forms are present in appreciable amounts and the present approach should be sensitive to a change of 30% in the apparent intramolecular equilibrium constant, K (for $K \sim 2$). An estimate of the degree of association is necessary. One may argue as follows.

In general, the accurate determination of the type and concentration of the associated species of alcohols or phenols in solution from the hydroxyl proton chemical shift alone is probably impossible (15). For example, if at least two associated species are present; the two observables, total concentration and chemical shift, must be matched to two equilibrium constants and to the two chemical shifts for the associated species. Except in special cases (16), there may well exist more than two associated species. Indeed, infrared (17) and activity (18) data for phenol in CCl_4 can be most satisfactorily interpreted with a monomer – trimer sequential polymer model.

A plot vs. concentration in CCl_4 of the hydroxyl proton chemical shift of **2** implies a zero limiting slope at low concentrations, i.e., below 0.6 mol% or ca. 0.06 M (for **2** in CCl_4, $M \sim 0.1 \times$ mol%). As shown by Tucker *et al.* (15, 19), such is the behaviour expected for an association process in which the dimerization constant is very small and the first important association involves trimerization or a higher polymerization.

Dimerization is probably small; nevertheless, the degree of association of **2** can be only roughly approximated in the following manner. The chemical shift data (20) for phenol in CCl_4 clearly show that it is more highly associated than **2** in CCl_4. A fit of such data to a monomer–timer model (21, 22) overestimates the concentration of phenol monomer (18). A similar model for **2** will yield a small absolute error in the degree of association and will give a lower limit to the degree of association.

Between 0.15 and 8 mol% (ca. 0.15 and 0.8 M), the hydroxyl proton shift of **2** can be roughly fitted by a monomer–trimer model with $K_3 \sim 0.7$ molarity units, implying that about 10% of **2** is associated at 2.5 mol% and that 35% is associated at 8 mol%. The observed coupling constants are number averages for all extant species. It follows directly that, at 8 mol%, K for the intramolecular equilibrium could be as large as 5 in the trimer (compared to, say, 1.5 for the monomer) before an appreciable change ($\sim$0.02 Hz) occurs in the observed ^5J values. Consequently, a reasonable interpretation of the coupling data in Table 2 is that they are a measure of the intramolecular equilibrium in the monomer. Substantial changes in this equilibrium, caused by self-association, could only be measured reliably by this method if the extent of association were varied over a much larger range than is practical for **2**.

Conclusions

2-Methylphenol and 4-chloro-2-methylphenol exist in C_6D_6 and CCl_4 solutions as two conformers in which that conformer containing the O—H bond *trans* to the methyl group is 0.4 $\pm$ 0.1 kcal/mol lower in free energy than the *cis* conformer at 305 K. This result can be compared to 4-bromo-2-trifluoromethylphenol, 3.3 mol% in CCl_4 at 305 K, for which the *cis* conformer has a lower free energy of 0.5 kcal/mol (6). A concentration study of 4-chloro-2-methylphenol suggests that the calculated free energy differences refer to the intramolecular equilibrium for the monomers.

Kinetics and mechanism of the reaction of dimethyl acetylphosphonate with water. Expulsion of a phosphonate ester from a carbonyl hydrate

RONALD KLUGER, DAVID C. PIKE, AND JIK CHIN

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received January 2, 1978

RONALD KLUGER, DAVID C. PIKE, and JIK CHIN. Can. J. Chem. **56**, 1792 (1978).

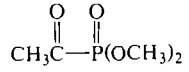
Dimethyl acetylphosphonate (DAP) is rapidly cleaved in water to acetate and dimethylphosphonic acid. The half time for reaction at p*H* 7, 25°C is estimated to be 3 s. The reaction is first order in hydroxide ion concentration and first order in DAP concentration. Rates of reaction were measured over the p*H* range 3.8 to 6.5 at 25°C, 6.5 and 7.0 at 5°C, 4.5 to 6.5 at 35°C, and 4.5 to 6.0 at 45°C. The average observed second-order rate constant at 25°C is $2.4 \times 10^6\ M^{-1}\ s^{-1}$. DAP is converted rapidly to a hydrated carbonyl adduct. The mechanism for the formation of the observed products is proposed to be analogous to cleavage reactions of other carbonyl hydrates, proceeding from a monoanion conjugate in this case. The estimated rate constant for the unimolecular cleavage of the carbonyl hydrate anion is $2 \times 10^3\ s^{-1}$. The rapid hydrolysis of DAP results from energetically favourable formation of a hydrate due to the electronic effect of the phosphonate diester. This effect also promotes ionization of the hydrate. The ionized hydrate readily expels the phosphonate diester to achieve the overall rapid hydrolysis.

RONALD KLUGER, DAVID C. PIKE et JIK CHIN. Can. J. Chem. **56**, 1792 (1978).

L'acétylphosphonate de diméthyle (APD) se coupe rapidement dans l'eau pour conduire à l'acétate et à l'acide diméthylphosphonique. Le demi-temps de la réaction à un p*H* = 7, à 25°C, est d'environ 3 s. La réaction est du premier ordre en hydroxyde est du premier ordre en APD. On a mesuré les vitesse de réaction à des p*H* allant de 3.8 à 6.5 à 25°C et 6.5 et 7.0 à 5°C, de 4.5 à 6.5 à 35°C et de 4.5 à 6.0 à 45°C. La valeur moyenne de la constante de vitesse du deuxième ordre à 25°C est de $2.4 \times 10^6\ M^{-1}\ s^{-1}$. Il y a une transformation rapide de APD en un adduit hydraté au niveau du carbonyle. Le mécanisme de formation des produits observés est proposé par analogie avec les réactions de clivage d'autres hydrates de groupements carbonylés qui procèdent, dans le cas actuel, à partir d'un monoanion conjugué. La constante de vitesse évaluée pour le clivage unimoléculaire de l'anion de l'hydrate du carbonyle est de $2 \times 10^3\ s^{-1}$. L'hydrolyse rapide de l'APD provient d'une formation d'un hydrate favorisé du point de vue énergétique à cause de l'effet électronique du diester de phosphonate. Cet effet accélère l'ionisation de l'hydrate. L'hydrate ionisé expulse facilement le diester de phosphonate pour conduire à une hydrolyse globale rapide.

[Traduit par le journal]

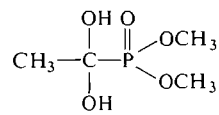
Esters of 1-keto phosphonates, such as dimethyl acetylphosphonate (DAP), **1**, were first reported



1

more than 30 years ago (1). These compounds are products of the Arbusov reaction between acyl chlorides and trialkyl phosphites. The original report by Kabachnik and Rossiiskaya (1) mentioned that dimethyl benzoylphosphonate reacted with alkali to give products resulting from cleavage of the bond between the carbonyl and phosphonyl groups. This tendency for internal bond cleavage to occur in preference to esterolytic cleavage made preparation of unesterified derivatives a problem (2). Monoesters and free acid derivatives have been prepared recently (3) by the methods first proposed by Zervas and Dilaris (4) for conversion of phosphate triesters to diesters and which were generalized to phosphonates by Kluger and Wasserstein (5).

We have prepared DAP and studied its rapid reaction in neutral aqueous solution. The reaction results in cleavage of the carbonyl-to-phosphonyl bond with attack of water occurring at the carbonyl carbon atom. The reaction is first order in hydroxide ion concentration and has an estimated half time at p*H* 7, 25°C, of 3 s. Nuclear magnetic resonance spectroscopy reveals that DAP reacts with water initially to form a hydrated carbonyl derivative **2**



2

which accounts for 90% of the total concentration of DAP added when a slightly acidic solution is utilized (to slow down the cleavage reaction).

The cleavage of hydrated carbonyl group compounds has been studied for a number of cases in which the leaving group is a carbanion (6). This type of intermediate is also invoked in the hydrolysis

reactions of esters (7) and amides (8) where the leaving group is an alkoxide ion or amine respectively. However, to our knowledge no previous study has dealt with the quantitative reactivity of a phosphorus anion leaving group departing from a carbonyl hydrate. The phosphorus anion that is expected to be generated is comparable in basicity to an alkoxide ion (9) and thus should decompose at a rate which may be comparable to hydrates derived from esters (7).

Experimental

Materials

All chemicals used for which preparations are not given were purchased from commercial suppliers. Liquids used for synthesis were distilled before use.

Dimethyl Acetylphosphonate (DAP)

This was prepared by the procedure of Kabachnik and Rossiiskaya (1). Trimethyl phosphite (110.1 g, 0.89 mol) was added dropwise with stirring to 67 g (0.89 mol) acetyl chloride under a nitrogenous atmosphere. The reaction mixture was occasionally cooled to maintain a temperature of less than 30°C. After the addition was complete, the mixture was distilled (product bp 42–45°C/0.01 Torr), yielding 101.7 g DAP (0.67 mol, 75%), a clear colourless mobile liquid. Spectroscopic data: ir(cm^{-1}): 3125, 1709, 1492, 1437, 1403, 1335, 1188, 1164, 1057, 1036; proton nmr spectrum 60 MHz, CCl_4 relative to internal TMS) δ: 2.41 (3H, d, $^3J_{PH}$ = 5.0 Hz, $CH_3C(O)$), 3.80 (6H, d, $^3J_{PH}$ = 10.1 Hz, P—O—CH_3), uv ($CHCl_3$) ε_{334}: 65. Proton nmr spectrum of DAP hydrate **2** (60 MHz, D_2O, p*D* 3 relative to internal DSS) δ: 1.32 (3H, d, $^3J_{PH}$ = 12.6 Hz, $CH_3C(OD)_2$), 3.86 (6H, d, $^3J_{PH}$ = 10.5 Hz, P—O—CH_3).

Methods

Product Analysis

The products of hydrolysis of DAP were analyzed by conducting the hydrolysis reaction in deuterium oxide and analyzing the resultant solution by proton nmr spectroscopy (Varian T60). The initial spectrum is due to DAP, **1**, and the deuterium-exchanged hydrate **2**; the latter accounts for approximately 90% of the total DAP concentration. This spectrum is rapidly converted to that of deuteriodimethyl phosphonate ($DP(O)(OCH_3)_2$), which is the predominant tautomer of dimethyl phosphite (9), and acetic acid. The product assignment was confirmed by addition of genuine samples of the two species and observation of appropriate peak enhancements. Furthermore, the hydrolysis of DAP produced a species which hydrolyzed further and at a rate identical to that of dimethyl phosphite. By integration of the original and product nmr spectra this analysis accounts for a quantitative yield of products from DAP.

Kinetics

The rate of conversion of DAP to acetic acid and dimethyl phosphonate was followed by two independent procedures. Since acetic acid dissociates to a significant extent under our reaction conditions, the rate of production of these materials could be followed by automatic p*H*-stat recording (using sodium hydroxide solution to maintain a constant reading on a p*H* meter). A Radiometer p*H* meter PHM 28 controlled by a Radiometer TTT1 automatic titrator was used with a Radiometer ABU12 burette (5). Recording of volume of added base was done with a Heath recorder connected to the ABU12 driveshaft with a 50-to-1 gear reduction potentiometer using a 1.5 V reference cell. The reaction vessel was jacketed and contained water circulated from a constant temperature bath maintained within ±0.1°C.

DAP (2 μl) was injected into 3 ml of a 0.1 *M* potassium chloride solution at a pre-set p*H* value. All DAP dissolved since observed rate *constants* were identical when 5 μl of DAP was used. The p*H*-stat method usually gave recorded plots that could be analyzed by first-order methods since the reactions were conducted under conditions which were pseudo first order in substrate ($[H^+]$, $[OH^-]$, and $[H_2O]$ remained constant and thus the reaction was pseudo-zero-order in those species at all times). However, the further hydrolysis reaction of dimethyl phosphite complicated observations and methods of separation of consecutive reactions had to be utilized (10). For reactions at p*H* 4.0 and 4.5 which were very slow, initial rate methods were used (11). Above p*H* 6.5, the reaction was too fast to measure.

The disappearance of DAP could also be followed spectrophotometrically. The carbonyl moiety of DAP has a local absorbance maximum in water at 320 nm (ε ~ 3). Since from proton nmr spectra it appears that ~90% of DAP is present as carbonyl hydrate, the actual ε_{320} (H_2O) for the carbonyl absorbance of DAP is probably 3 × 10 ≈ 30. The rate of formation of hydrate is too fast to measure by recording spectrophotometry with conventional mixing. However, the disappearance of DAP in equilibrium with hydrate could be followed. A Unicam SP1800A recording spectrophotometer was used to follow the disappearance of absorbance due to the carbonyl group of DAP. Unlike the p*H*-stat method, this disappearance is not complicated by further hydrolysis of dimethyl phosphite. Rate constants were obtained by plotting, by conventional first-order methods, absorbance at a particular time compared to final absorbance as a function of time. Acetic acid – sodium acetate buffer was used to maintain acidity at p*H* 3.80 and the observed rate constant coincided with that observed by p*H* stat in the absence of buffer. Therefore, the methods give comparable results and confirm the validity of the kinetic assumptions we have used.

Results

The observed rate constants for the hydrolysis of DAP to produce acetate and dimethyl phosphite are summarized in Table 1. The reaction appears to be first order in hydroxide ion concentration. A common rate constant was obtained with variation in p*H* when the observed rate constants were divided by hydroxide ion concentration. The rate constants obtained at each p*H* value by first-order plots of p*H*-stat results were averaged, divided by hydroxide concentration and these resultant second-order rate constants were averaged to obtain a mean second-order rate constant for a particular temperature. The data at 5, 25, 35, and 45°C were plotted according to the Arrhenius equation (correlation coefficient = 0.997) with E_a = 17.6 kcal/mol. Analysis by transition state theory (12) gives an activation enthalpy of 17.0 kcal/mol, an activation entropy of 10.3 entropy units and a free energy of activation of 14.0 kcal/mol (at 300 K). These values can be applied to a mechanistic analysis if appropriate equilibrium parameters for ionizations prior to the rate-determining step are incorporated.

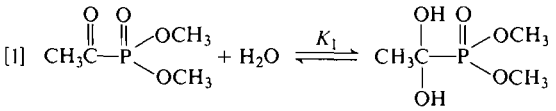
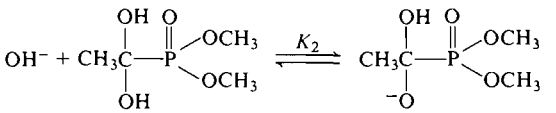
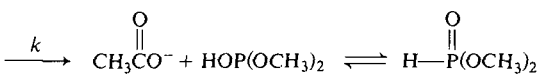
Discussion

The hydrolysis of DAP between p*H* 4 and 6.5 occurs by a mechanism involving specific base catalysis. The reaction is first order in hydroxide ion concentration and first order in DAP concentration. The hydrate of DAP forms rapidly and exists in equilibrium with the keto form. A mechanism consistent with other hydrolytic expulsions from carbonyl compounds and accommodating our data is given below.



1 **2**





This mechanism leads to the rate expression

[2] $v = kK_1K_2[\mathbf{1}]\,[OH^-] = k_{app}[DAP]\,[OH^-]$;

$$[DAP] = [\mathbf{1}] + [\mathbf{2}]$$

$$v = k_{app}(1 + K_1)\,[\mathbf{1}]\,[OH^-]$$

[3] $$k_{app} = kK_1K_2/(1 + K_1)$$

$$k = k_{app}(1 + K_1)/(K_1K_2)$$

We observe that K_1, the equilibrium constant for the hydration of **1** to give **2**, is approximately 9. The ionization constant, K_2, is the remaining parameter necessary to connect our observed rate constant to the rate constant k in the proposed mechanism [1]. This assumes that a carbonyl hydrate monoanion is the reactive species in the cleavage reaction.

Hine and Koser (6) have summarized mechanisms that have been observed for cleavage of a carbonyl hydrate when the leaving group is a carbanion. The intermediate hydrate ionizes to a monoanionic conjugate which cleaves only if the carbanion is a particularly good leaving group. For most leaving groups, reaction in alkaline solutions proceeds from the dianion of the hydrate; reaction via the monoanion is slow.

Hine and Koser (6) observed that the ionization of carbonyl hydrates conforms to a linear free energy relationship governed by substituent constants of the two substituents on the hydrated carbon atom. The pK_a of a hydroxyl group of a carbonyl hydrate is given by eq. [4].

[4] $$pK_a = 14.19 - 1.32(\sigma_{R_1}^* + \sigma_{R_2}^*)$$

For the hydrate **2**, $R_1 = CH_3$ and $R_2 = P(O)(OCH_3)_2$. The value of σ^* for a phosphonate diester group has been determined by Martin and Griffin (13) to be +2.18. That for a methyl group is zero, by definition (14). Therefore substituting into eq. [4], we estimate the pK_a of a hydroxyl group of **2** to be approximately 11. The equilibrium constant K_2 defined in [1] can be derived from the acid dissociation constant of **2** by dividing the latter by the autoionization constant of water. Therefore K_2 will have an approximate value given by [5].

[5] $$K_2 = (10^{-11}/10^{-14})\,M^{-1} = 10^3\,M^{-1}$$

Substituting K_2 into [3] and the approximate value of k_{app} at 25°C of $2 \times 10^6\ M^{-1}\ s^{-1}$;

[6] $$k \cong (2 \times 10^6)(10)(10^3)^{-1}(9)^{-1} \cong 2 \times 10^3\ s^{-1}$$

The factors controlling the hydrolytic reactivity of DAP are: the extent of hydration (measured by equilibrium constant K_1), the ease of ionization of hydrate **2** (measured by equilibrium constant K_2), and the facility with which the ionized hydrate is cleaved (measured by rate constant k). The hydration equilibrium is enhanced by the strongly electron withdrawing nature of the phosphonate diester sub-

stituent (13) and by the lack of resonance interactions between the phosphonate and carbonly groups. Similarly, the ionization equilibrium is assisted by the electronic nature of the phosphonate as a substituent (6). The magnitude of k is such that along with relatively favourable equilbria preceding the cleavage step, an overall large observed second-order rate constant (k_{app}) results.

Quantitative comparisons of the rate and equilibrium constants in the proposed mechanism to those in other carbonyl cleavage reactions involves assumptions about parallels in mechanism which probably require further study. Jencks (15) has summarized some of the problems which still remain in our understanding of these reactions. For example, the pK_a of the conjugate acid of the leaving group might be an adequate basis for a linear free energy analysis of the rate constant for expulsion of the leaving group. However, although carbanions and oxygen anions of comparable basicities can be expelled, catalysis by Brønsted acids only is observed for the oxygen anions. In this respect the phosphonate behaves like a carbanion.

If a comparison of the rate constant for expulsion of the phosphonate anion (k) is made with the rate constant for expulsion of a thiazolium conjugate base (16), we find that although thiazolium has a considerably higher pK_a than dimethyl phosphonic acid (9, 17), the rate constants are comparable. This suggests that the hydrate anion containing a phosphonate substituent may be relatively more stable than a similar compound with a carbon-based substituent. A complete analysis will therefore require a systematic study within the phosphonate series, including determinations of overall energetics. Such a study is in progress in our laboratory.

Pyrones. III. The alkylation of pyronones. Preferential formation of 2-alkoxy-4-pyrones[1]

TERRY DONALD CYR AND GERALD ARTHUR POULTON
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received December 5, 1977

TERRY DONALD CYR and GERALD ARTHUR POULTON. Can. J. Chem. **56**, 1796 (1978).

2-Alkoxy-4-pyrones and 2-alkoxychromones were prepared in high yield from 4-hydroxy-2-pyrones (2,4-pyronones) and 4-hydroxycoumarin, respectively. The products of diazomethane methylation of dehydroacetic acid (3-acetyl-4-hydroxy-6-methyl-2-pyrone) were identified.

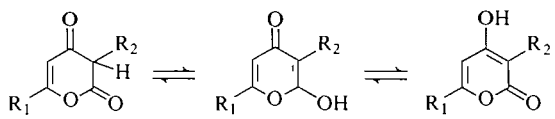
TERRY DONALD CYR et GERALD ARTHUR POULTON. Can. J. Chem. **56**, 1796 (1978).

Faisant respectivement appel aux hydroxy-4 pyrones-2 (pyronones-2,4) et à l'hydroxy-4 coumarine comme produits de départ, on a préparé, avec de bons rendements, des alkoxy-2 pyrones-4 et des alkoxy-2 chromones. On a identifié les produits obtenus en effectuant la méthylation de l'acide déhydroacétique (acétyl-3 hydroxy-4 méthyl-6 pyrone-2) avec le diazométhane.

[Traduit par le journal]

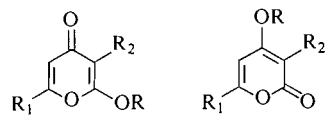
Introduction

Many investigations have been reported concerning the methylation of pyronones (2,4-pyrandiones) by various reagents; because of the tautomeric equilibrium which can exist between the diketo form **1***a* and enolic forms **1***b* and **1***c*, isomeric alkylated



1*a* **1***b* **1***c*

products may be formed. In methylations reported with diazomethane, triacetic acid lactone (6-methyl-2,4-pyrandione) (2, 3), 6-phenyl-2,4-pyrandione (2), 3,5-dialkylpyronones (4, 5), and the precursors to the natural products yangonin (6) and aureothin (7) afford separable mixtures of the 2-alkoxy-4-pyrone **2** and the 4-alkoxy-2-pyrone **3**. The 4-alkoxy-2-pyrone



2 **3**

is the major isomer in most of these alkylations; only in alkylations of 6-alkoxy- or 6-hydroxy-2,4-pyrandiones (5, 8) does the 2-alkoxy-4-pyrone sometimes predominate. Methylation of the silver salt of the pyrandione with methyl iodide has also been reported (9) to yield similar results. Methylation using base and dimethyl sulfate produces 4-alkoxy-2-pyrones quantitatively from 6-methyl- (10) and 6-phenyl-2,4-pyrandiones (9), as does the use of 10% methanolic HCl (9). Beak and Lee have recently reported (11) 2-alkylation of triacetic acid lactone with methyl fluorosulfonate. As we have been interested in an efficient route to 3-acyl-2-alkoxy-4-pyrones, we have investigated the alkylation of triacetic acid lactone (**1**, $R_1 = CH_3$, $R_2 = H$), dehydroacetic acid (**1**, $R_1 = CH_3$, $R_2 = CH_3CO$), and several related compounds.

Results and Discussion

Alkylation of dehydroacetic acid has been reported to yield only the 4-alkoxy-2-pyrone when carried out with either diazomethane (12, 13) or methyl or ethyl iodide and the silver salt (ref. 14 and references cited therein). Since recent experience has shown that both 2- and 4-pyrones are generally formed in the diazomethane methylations, we repeated the reaction with the intention of isolating the minor products of the reaction, in the hope of finding the desired 3-acetyl-2-methoxy-6-methyl-4-pyrone. Even using conditions designed (3) to produce increased 2-alkoxy-4-pyrone yields, no trace of the desired compound was detected. 3-Acetyl-4-methoxy-6-methyl-2-pyrone (**4**, Scheme 1) was indeed the major product under all conditions. Three minor products, 3-acetonyl-6-methyl-2,4-pyrandione (**5**), 3-acetonyl-4-methoxy-6-methyl-2-pyrone (**6**), and 3-acetonyl-2-methoxy-6-methyl-4-pyrone (**7**), arise from the initial addition of diazomethane to the acetyl group, followed by rearrangement (15): methylation of the tautomeric enols occurs yielding both possible isomers. We believe that both products can result when hydrogen bonding between the 4-hydroxyl and the 3-acyl substituent is removed. 4-Oxo-3,6-dimethyl-4*H*-furo[3,2-*c*]pyran (**8**) is a previously reported (12) product of this reaction, whereas 2,6-dimethyl-4-pyrone (**9**) is produced from dehydroacetic acid by hydrolysis and rearrangement (16).

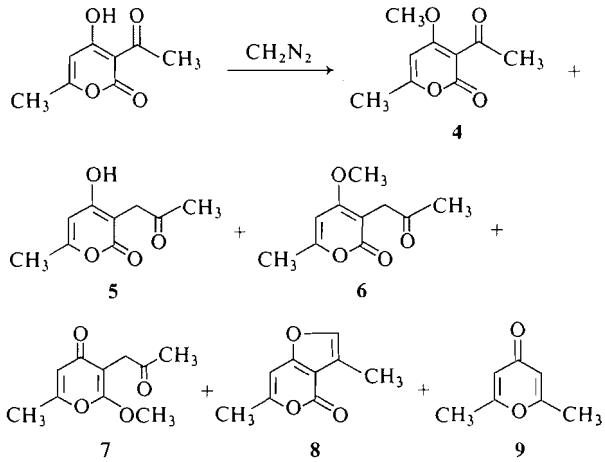
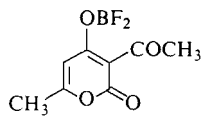


SCHEME 1

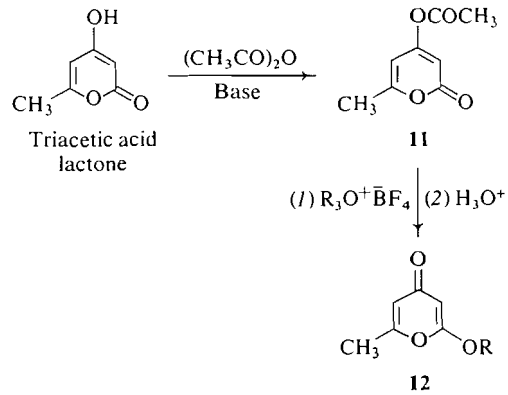
In a further attempt to produce the desired 2-alkylated products, the reaction of dehydroacetic acid and its sodium salt with Meerwein-type alkylating agents was investigated. Treatment of dehydroacetic acid with dimethoxycarbonium tetrafluoroborate gave a quantitative yield of 3-acetyl-6-methyl-2*H*-pyran-2-on-4-oxyboron difluoride (**10**). All attempts to force alkylation of this species by prolonged treatment with excess quantities of trimethyloxonium tetrafluoroborate, triethyloxonium tetrafluoroborate, or methyl fluorosulfonate failed. Similar treatment of sodium dehydroacetate (17) again yielded only **10**.



Our inability to produce an alkylated 4-pyrone in the dehydroacetic acid series led us then to triacetic acid lactone and its derivatives. We were successful in achieving virtually quantitative production of 2-ethoxy- or 2-methoxy-6-methyl-4-pyrone from triacetic acid lactone by the following simple procedure: careful base-catalyzed *O*-acylation with acetic anhydride (the absence of acid is essential to prevent the ready O → C Fries-type rearrangement which produces dehydroacetic acid (18)) yields 4-acetoxy-6-methyl-2-pyrone (**11**). Alkylation of this ester with triethyloxonium tetrafluoroborate yields, after mild acid hydrolysis, the desired 2-ethoxy-6-methyl-4-pyrone (**12**, R = Et) in 86% overall yield (Scheme 2). The reaction can also be carried out using trimethyloxonium tetrafluoroborate or dimethoxycarbonium tetrafluoroborate.

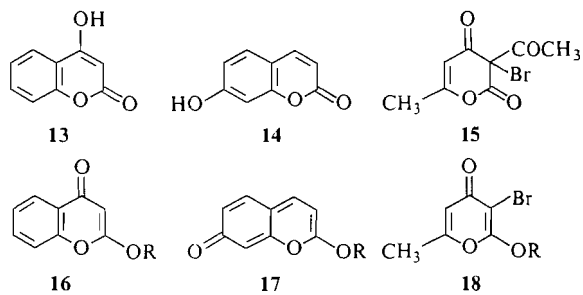
To test the applicability of the reaction, some other systems were alkylated. 4-Hydroxycoumarin (**13**) was readily acylated and subsequent alkylation as described above yielded 2-methoxy- or 2-ethoxychromone (**16**). 7-Hydroxycoumarin (**14**) acylated readily but alkylation produced only recovered hydroxy compound and did not give an alkylated product (i.e. **17**). 3-Acetyl-3-bromo-6-methyl-2,4-pyrandione (**15**) (19) was readily alkylated using Meerwein's reagent to yield 3-bromo-2-ethoxy-6-methyl-4-pyrone (**18**, R = Et, 80%).

The production of 2-alkoxy-4-pyrones from 2,4-pyrandiones and of 2-alkoxychromones from 4-hydroxycoumarins in high yields which we have described offers an excellent synthetic alternative to the previous procedures using diazomethane which involve a laborious separation of the two isomer pro-



SCHEME 2

ducts or to Beak's recently reported alkylation for which no experimental details have as yet been reported.



Experimental

Melting points were determined on a Bock Monoscop VS and are uncorrected. Mass spectra were obtained on an Hitachi-Perkin-Elmer RMU-7S double-focussing instrument. Nuclear magnetic resonance spectra were recorded in $CDCl_3$ solution with internal TMS reference on a Perkin-Elmer R12-A spectrometer at 60 MHz. Ultraviolet spectra were obtained using an Unicam SP-800 spectrophotometer.

Thin-layer chromatography was carried out using Merck silica gel GF254 precoated plates, column chromatography with 60–200 mesh silica gel (Davison Chemical) and preparative thin-layer with MN-Kieselgel G/UV 254 (Macherey, Nagel & Co.).

Compounds

Dehydroacetic acid was purchased from Aldrich Chemical Co. and recrystallized before use. Triacetic acid lactone (20) and 3-acetyl-3-bromo-6-methyl-2,4-pyrandione (19) were prepared by literature procedures. 4-Hydroxy- and 7-hydroxycoumarin were from Aldrich Chemicals.

Reaction of Dehydroacetic Acid with Diazomethane

(*A*) Dehydroacetic acid (1.00 g, 5.9 mmol) in dry ether (100 ml) was treated at 0°C with ethereal diazomethane (prepared (21) from *N,N'*-dimethyl-*N,N'*-dinitrosoterephthalamide, ca. 36 mmol). The reaction mixture was allowed to warm up to room temperature overnight, filtered, and evaporated to yield the crude product (1.014 g). Chromatography produced, as the major product, 3-acetyl-4-methoxy-6-methyl-2-pyrone (**4**, 705 mg, 65%), mp 90–91°C (lit. (13) mp 93–95°C); nmr δ: 6.11 (1H, s), 3.91 (3H, s), 2.47 (3H, s), and 2.31 ppm (3H, s). Minor products isolated by repeated column and thin-layer chromatography were identified as (*i*) 3-acetonyl-6-methyl-2,4-pyrandione (**5**, 145 mg, 13%), mp 179–180°C; nmr (in D_2O with external TMS reference) δ: 6.04 (1H, s), 3.48 (2H, s), 2.22 (3H, s), and 2.18 ppm (3H, s); *m/e* calcd. for $C_9H_{10}O_4$: 182.058; found: 182.053. (*ii*) 3-Acetonyl-4-methoxy-6-methyl-2-pyrone (**6**, 144 mg, 12%), mp 108.5–109.5°C; nmr δ: 6.04 (1H, s), 3.81 (3H, s), 3.48 (2H, s), 2.28 (3H, s), and 2.18 ppm (3H, s); *Anal.* calcd. for $C_{10}H_{12}O_4$: C 61.22, H 6.16; found: C 60.97, H 6.32. (*iii*) 3-Acetonyl-2-methoxy-6-methyl-4-pyrone (7, trace), nmr δ: 6.00 (1H, s), 3.91 (3H, s), 3.42 (2H, s), 2.26 (3H, s), and 2.18 ppm (3H, s); *m/e* (relative intensity): 196 (92), 168 (12), 154 (99), 153 (82), 139 (91), 113 (100), 85 (19), 69 (10), 59 (45), 43 (58), 39 (14); ir λ_{max}: 1733, 1686 cm^{-1}; (*iv*) 2,6-dimethyl-4-pyrone (**9**, 50 mg, 7%), mp 132°C (lit. (22) mp 132°C); nmr δ: 6.03 (2H, s) and 2.23 ppm (6H, s).

(*B*) From a similar experiment carried out in chloroform solution was isolated 3-acetyl-4-methoxy-6-methyl-2-pyrone (300 mg, 28%) and a second component, identified as 4-oxo-3,6-dimethyl-4*H*-furo[3,2-*c*]pyran (**8**, 120 mg, 12.5%), mp 129–130°C (lit. (12) mp 128–130°C); nmr δ: 7.24 (1H, s), 6.37 (1H, s), and 2.32 ppm (6H, s).

Reaction of Dehydroacetic Acid with Dimethoxycarbonium Tetrafluoroborate

Dehydroacetic acid (1.00 g, 5.9 mmol) in ethyl acetate (25 ml) was treated at room temperature with dimethoxycarbonium tetrafluoroborate (23) (1.70 g, 10.5 mmol) and stirred overnight. The ethyl acetate was evaporated *in vacuo*, the residues added to water (25 ml), and the product extracted with dichloromethane. Drying and evaporation of the solvent yielded 3-acetyl-6-methyl-2*H*-pyran-2-on-4-oxyboron difluoride (**10**, 1.285 g, 96%), mp 86–87°C; nmr δ: 6.14 (1H, s), 2.84 (3H, s), and 2.40 ppm (3H, s); ir λ_{max}: 1185 (B—O) and 1070 cm^{-1} (B—F); *m/e* (relative intensity): 216 (57, $M^{\ddagger}$), 201 (40, $M^{\ddagger} - CH_3$), 197 (17, $M^{\ddagger} - F$), 173 (29, $M^{\ddagger} - COCH_3$), 154 (34, *m/e* 173 − F), 69 (20), 43 (100); δ_{19_F} (relative to $CFCl_3$) 143 ppm; λ_{max} (MeOH) (log ε): 224 (3.98), 316 (4.09). *Anal.* calcd. for $C_8H_7BF_2O_4$: C 44.50, H 3.27; found: C 44.72, H 3.53.

Reaction of Sodium Dehydroacetate with Dimethoxycarbonium Tetrafluoroborate

Sodium dehydroacetate (17) (1.00 g, 5.26 mmol) suspended in ethyl acetate (25 ml) was treated with dimethoxycarbonium tetrafluoroborate (23) (1.51 g, 9.32 mmol) as described above. The same product was isolated in similar yield.

Alkylation of Triacetic Acid Lactone

Acylation

To triacetic acid lactone (4.0 g, 31.7 mmol) dissolved in 10% NaOH (15 ml) and ice (10 g) was added acetic anhydride (10 ml). The mixture was shaken for 10 min, then extracted with dichloromethane (3 × 100 ml), and the extracts dried (Na_2SO_4) and evaporated to yield pure 4-acetoxy-6-methyl-2-pyrone (4.87 g, 92%) (18). As this compound is prone to rearrangement, it was used immediately for the subsequent reaction.

Alkylation

To the above acetoxy compound (4.6 g, 27.4 mmol) was added triethyloxonium tetrafluoroborate (12 g, 63 mmol) and the mixture heated for 20 h under a nitrogen atmosphere. HCl (5%, 100 ml) was added and the product extracted with dichloromethane (3 × 100 ml). Drying and evaporating the extracts gave the crude product as a red oil (4.41 g) which was purified by chromatography to give 2-ethoxy-6-methyl-4-pyrone (**12**, R = Et, 3.77 g, 89%), mp 46–47°C (lit. (24) mp 44–46°C); nmr δ: 5.86 (1H, dd, J = 1.76, 0.84 Hz), 5.39 (1H, d, J = 1.76 Hz), 4.08 (2H, q, J = 7.22 Hz), 2.24 (3H, d, J = 0.88 Hz), 1.44 ppm (3H, t, J = 7.22 Hz); λ_{max} (EtOH): 240 (4.06); *m/e* (relative intensity): 154 (100), 126 (25), 98 (76), 97 (25), 69 (75), 58 (22), 54 (10).

Using similar procedures, the following products were prepared.

*2-Methoxy-6-methyl-4-pyrone (**12**, R = Me)*—from triacetic acid lactone (46%), mp 92–94°C (lit. (2) mp 94–94.5°C); nmr δ: 6.08 (1H, dd, J = 1.8 Hz, 0.8 Hz), 5.54 (1H, d, J = 1.8 Hz), 3.92 (3H, s), 2.28 ppm (3H, d, J = 0.8 Hz); λ_{max} (EtOH): 240 (4.10).

*2-Methoxychromone (**16**, R = Me)*—from 4-hydroxycoumarin (69%), mp 103–106°C (lit. (9) mp 106–107°C); nmr δ: 8.39 (1H, m), 7.9–7.4 (3H, m), 5.74 (1H, s), and 4.05 ppm (3H, s); λ_{max} (EtOH): 220 (4.26), 265 (3.98), 284 (3.90).

*2-Ethoxychromone (**16**, R = Et)*—from 4-hydroxycoumarin (91%), mp 99–102°C; nmr δ: 8.35 (1H, m), 7.9–7.4 (3H, m), 5.73 (1H, s), 4.35 (2H, q, J = 7.2 Hz), 1.52 (3H, t, J = 7.2 Hz); λ_{max} (EtOH): 220 (4.27), 267 (4.03), 285 (3.91); *m/e* 190 (48), 134 (11), 133 (10), 120 (24), 105 (13), 94 (100), 92 (29), 69 (33), 51 (16), 50 (16), 39 (17). *Anal.* calcd. for $C_{11}H_{10}O_3$: C 69.46, H 5.30; found: C 69.41, H 5.33.

Reaction of 3-Acetyl-3-bromo-6-methyl-2,4-pyrandione with Triethyloxonium Tetrafluoroborate

3-Acetyl-3-bromo-6-methyl-2,4-pyrandione (19) (**15**, 16.0 g, 65 mmol) in dichloromethane (150 ml) was treated with triethyloxonium tetrafluoroborate (13.3 g, 70 mmol), and the solution refluxed for 14 h. Most of the solvent was removed *in vacuo*, and HCl (5%, 150 ml) and ether (50 ml) added. The ether layer was removed and the aqueous layer extracted with dichloromethane (5 × 100 ml). From the dichloromethane layer was isolated 3-bromo-2-ethoxy-6-methyl-4-pyrone (**18**, R = Et, 12.1 g, 80%), mp 132–134°C (lit. (24) mp 131–132°C); nmr δ: 6.03 (1H, s), 4.42 (2H, q, J = 6.5 Hz), 2.27 (3H, s), 1.47 ppm (3H, t, J = 6.5 Hz); λ_{max} (EtOH): 200 (4.25), 264 (3.90); *m/e* (relative intensity): 234 (65), 232 (65), 206 (73), 204 (78), 166 (67), 164 (71), 151 (22), 124 (35), 66 (34), 45 (100), and 43 (40).

In a similar manner 2-methoxy-3-bromo-6-methyl-4-pyrone (**18**, R = Me) could be prepared; nmr δ: 6.09 (1H, s), 4.04 (3H, s), and 2.28 ppm (3H, s); λ_{max} (EtOH): 209.5 (4.27), 264 (3.91).

Activation energy for methoxy group relaxation

M. A. MAZID, J. P. SHUKLA, AND S. WALKER

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B-5E1

Received January 12, 1978

M. A. MAZID, J. P. SHUKLA, and S. WALKER. Can. J. Chem. **56**, 1800 (1978).

Dielectric absorption studies have been made on seven compounds which have methoxy groups attached to an aromatic ring and on some related rigid molecules. The solutes have been dispersed in a polystyrene matrix. In some cases, the absorptions due to the group and the molecular process have been separated completely, and this has permitted the estimation of more accurate Eyring enthalpies of activation for methoxy group relaxation. These values have been compared with those in the literature and, on the whole, it would seem likely that the energy barrier to group relaxation is small and of the order of 10 kJ mol^{-1} for cases where there is no mutual conjugation or steric effects.

M. A. MAZID, J. P. SHUKLA et S. WALKER. Can. J. Chem. **56**, 1800 (1978).

On a effectué des études d'absorption diélectrique sur sept composés possédant des groupes méthoxy attachés à un cycle aromatique et sur quelques molécules rigides qui leur sont apparentées. On a dispersé les solutés dans une matrice de polystyrène. Dans quelques cas, on a pu séparer complètement l'absorption due au groupe de celle du processus moléculaire et ceci a permis d'évaluer d'une façon plus précise les enthalpies d'activation de Eyring pour la relaxation du groupe méthoxy. On a comparé ces valeurs avec celles trouvées dans la littérature et, d'une façon générale, il semblerait que la barrière d'énergie à la relaxation du groupe est petite et de l'ordre de 10 kJ mol^{-1} pour les cas ou il n'y a pas de conjugaison mutuelle ou d'effet stérique.
[Traduit par le journal]

Introduction

Molecules which have a methoxy group attached to an aromatic ring have been widely studied by dielectric techniques (1–4). The molecules have been examined either as a pure liquid or as a solute in a dilute solution of a nonpolar solvent and the absorption has been observed in the microwave region. In all cases the molecular and group absorptions have overlapped and the relaxation time for the group had to be deduced from a Budó analysis (5). Such an analysis can sometimes be subject to appreciable errors which possibility in turn leads to serious errors in the enthalpy of activation for group relaxation.

In the dielectric study of flexible molecules it has been found possible in a number of cases studied by Davies *et al.* (6, 7) and Walker and co-workers (8–10) to separate completely the absorption due to the intramolecular and molecular processes by dispersing the solute in a polystyrene matrix. The enthalpies of activation for the intramolecular process have, on the whole, compared quite well with those from the other direct methods of nmr and ultrasonics (7, 10.).

It seemed appropriate to carry out such a dielectric study on a number of methoxy compounds in order to determine the energy barrier for group relaxation more accurately from dielectric data. Moreover, the study seems even more pertinent when it is borne in mind that there is no generally accepted value for methoxy group rotation when the group is attached to an aromatic ring. In fact, there are very serious deviations in the magnitude of the value as estimated theoretically and from vibrational spectra (see later).

Experimental Results

The dielectric measurements have been made on a General Radio 1615A capacitance bridge in the frequency range 50 to 10^5 Hz. The measuring cell was a three-terminal circular parallel plate capacitor mounted in a temperature-controlled chamber flushed with dry nitrogen gas. The cell may be operated from liquid nitrogen temperature to about 400 K. For one of the polystyrene matrix samples, additional measurements have been made using a Hewlett–Packard 4342A Q-meter with a temperature-controlled, two-terminal cell in the range 2.5×10^4 to 1.5×10^7 Hz. The apparatus and measurement techniques have been described previously by Walker and co-workers (8–10).

The polystyrene matrix was prepared in the way described by Davies and Swain (7) and we have adopted their procedures both experimentally and also in the evaluation of the relaxation time and distribution parameter, by means of the Fuoss–Kirkwood equation and the enthalpy of activation from the Eyring equation. The polystyrene used here had a weight average molecular weight, $\bar{M}_w$, of 230 000. The relaxation data and the results of Eyring equation analyses of these data are given in Table 1.

In the fitting of the data of relaxation time as a function of temperature to the Eyring equation,

standard statistical techniques have been employed to obtain the slope and intercept of the line and the variances of these two parameters. These data yielded values of the enthalpy (ΔH_E) and entropy (ΔS_E) of activation for the relaxation process along with confidence intervals for each of these two. The 95% confidence intervals on ΔH_E were typically $\pm 10\%$ of the nominal values, or less, in agreement with the work of Davies *et al.* (6, 7). For the ΔS_E term, these confidence intervals were of the order of $\pm 50\%$ of the nominal values in some cases, since this term is often a small part of the intercept, $(\ln (h/k_B) - \Delta S_E/R)$, of the $\ln (T\tau)$ vs. $(1/T)$ plot.

Discussion

2,6-Dimethoxynaphthalene

This is the simplest case of the molecules reported here since in this molecule the $C_{\overline{aromatic}}O$ bonds are collinear across the 2,6 positions of the naphthalene molecule. Since the energy barrier for the rotation of the methoxy group is low (see later), then stable *cis* and *trans* isomers are improbable and thence, a component of the dipole moment fixed with respect to the molecular skeleton (necessary to detect molecular relaxation) is improbable. In fact, only the dipole moments perpendicular to the long axis need to be considered and are the ones which relate to the rotation of the methoxy groups.

The relaxation data from 2,6-dimethoxynaphthalene are obtained from one set of absorption peaks in the temperature range, 91–108 K, characterized by an enthalpy of activation of 11 kJ mol^{-1}. This may be ascribed to the barrier opposing methoxy group relaxation.

1,7-Dimethoxynaphthalene

The dielectric absorption in this case was marked by two separate sets of absorption peaks in the temperature ranges 86–97 K and 275–301 K, respectively. The enthalpy of activation in the lower temperature range is found to be 14 kJ mol^{-1}, whereas the higher temperature process has a $\Delta H_E = 84$ kJ mol^{-1}.

The ΔH_E value observed for the lower temperature process is of the same order as that for the methoxy group relaxation in 2,6-dimethoxynaphthalene and its ΔG_{E150} of 14 kJ mol^{-1} and τ_{150} of 9.5×10^{-6} s also show good agreement with those of 14 kJ mol^{-1} and 1.5×10^{-5} s for 2,6-dimethoxynaphthalene.

For the other relaxation process for 1,7-dimethoxynaphthalene the ΔH_E of 84 kJ mol^{-1} is to be compared with that of 90 kJ mol^{-1} for the fairly similar sized, rigid molecule, 4-bromobiphenyl.[1] This is to be contrasted with the lower temperature process value

of 14 kJ mol^{-1} for 1,7-dimethoxynaphthalene. Thus, for this molecule the high temperature process may be ascribed to molecular relaxation and the lower temperature one to group relaxation. Support for this assignment may be gained from the entropy of activation data where for the high temperature process the value of $\Delta S_E \sim 150$ J K^{-1} mol^{-1} is appropriate for molecular relaxation of such a large molecule, whereas the ΔS_E values for methoxy group relaxation are much smaller and have negative values and for 1,7-dimethoxynaphthalene is -3 J K^{-1} mol^{-1}.

3,3'-Dimethoxybiphenyl

This solute has been found to give a set of absorption peaks in the temperature range 89–105 K in the frequency range of the GR bridge. From these data an enthalpy of activation (ΔH_E) of 10 kJ mol^{-1} was deduced. This value is much too small to be attributed to any form of molecular motion nor can it be ascribed to rotation about the C—C bond between the two rings since the barrier for such relaxation is appreciably higher than this (11). Thus, the most likely candidate for such a low barrier is the rotation of the methoxy group.

1,3-Dimethoxybenzene

This molecule yields a $\Delta H_E = 11$ kJ mol^{-1} and absorbs in the 86–119 K range. A rigid molecule of similar size and shape, 1,3-diiodobenzene, has a $\Delta H_E = 29$ kJ mol^{-1} (Table 1). Thus, the 1,3-dimethoxybenzene value cannot be ascribed to molecular relaxation, and its similarity to that obtained for methoxy group relaxation in 2,6-dimethoxynaphthalene would suggest that the relaxation process is, at least, predominantly methoxy group relaxation.

3,5-Dimethylanisole

3,5-Dimethylanisole exhibits two sets of absorption peaks in the temperature ranges 81–109 and 170–199 K, respectively. The enthalpies of activation corresponding to the above two processes are found to be 9.6 and 37 kJ mol^{-1}, respectively. The first process in the lower temperature region may be assigned to the group relaxation whereas the second process would correspond to the molecular reorientation. The ΔH_E of 9.6 kJ mol^{-1} is in good agreement with the ΔH_E of 10, 11, and 14 kJ mol^{-1} values for 3,3'-dimethoxybiphenyl, 1,3-dimethoxybenzene, and 1,7-dimethoxynaphthalene, respectively, and the differences are scarcely greater than the experimental errors involved in the measurements of such low ΔH_E values.

A comparison of the ΔG_{E150} (14 kJ mol^{-1}) with these systems (ΔG_E 14, 16, 14 kJ mol^{-1}) also shows a close agreement in the data, suggesting that the process is that of methoxy group relaxation and this is supported by the τ_{150} value of 8.3×10^{-6} s which is of the same order as the values for methoxy group relaxation values of 9.6×10^{-6} s, 6.0×10^{-5}, and 9.5×10^{-6} s for 3,3'-dimethoxybiphenyl, 1,3-dimethoxybenzene, and 1,7-dimethoxynaphthalene, respectively.

The higher temperature process yields a $\Delta H_E = 37$ kJ mol^{-1} and this may be assigned to molecular reorientation since it has a similar ΔH_E to that for 3,5-dichlorobenzonitrile, a slightly larger molecule, which has a value of 38 kJ mol^{-1} for the molecular relaxation process (see Table 1).

2,4,6-Tribromoanisole

This exhibits two sets of absorption peaks in the temperature ranges 115–150 and 178–217 K, giving rise to ΔH_E values of 16 and 33 kJ mol^{-1}, respectively.

The higher temperature process having a $\Delta H_E = 33$ kJ mol^{-1} would be expected to be attributed to molecular relaxation. It has also $\Delta G_{E150} = 31$ kJ mol^{-1}. These values are to be compared with the corresponding values for a slightly larger molecule, 3,5-dichlorobenzonitrile, which has $\Delta H_E = 38$ kJ mol^{-1}, $\Delta G_{E150} = 37$ kJ mol^{-1}, and also those for the molecular process of 3,5-dimethyanisole with $\Delta H_E = 37$ kJ mol^{-1} and $\Delta G_{E150} = 31$ kJ mol^{-1}. Thus, the higher temperature process for 2,4,6-tribromoanisole may be ascribed to molecular relaxation. The $\Delta H_E = 16$ kJ mol^{-1} for the low temperature process is to be allotted to methoxy relaxation and the increment in value of ~ 5 kJ mol^{-1} could be related to the presence of bromo atoms in the ring which may result in steric and additional conjugative effects.

Conclusions

As Grindley *et al.* (12) have pointed out, there is no generally accepted barrier for methoxy group relaxation in anisole. Dielectric relaxation studies (4) of anisole in a nonpolar solvent yield a value of ~ 6 kJ mol^{-1}. Theoretical calculations (13–15) yield values ranging between 0 and 7.5 kJ mol^{-1}. However, the vibrational spectrum (16) yields a much higher value of 25.1 kJ mol^{-1}. Grindley *et al.* (12) from a somewhat empirical approach, obtained a value of 11 kJ mol^{-1}. The values we have obtained for methoxy relaxation in 1,3-dimethoxybenzene and 3,5-dimethylanisole are 11 and 9.6 kJ mol^{-1}, respectively. These are the two molecules of those we have examined which should be closest to anisole in conjugative effects of the conjugated ring with the methoxy group. It is striking how near this value is to that estimated by Grindley *et al.* (12). In fact, even for 3,3'-dimethoxybiphenyl and 2,6-dimethoxynaphthalene the ΔH_E value is very similar. Only in

the case of 2,4,6-tribromoanisole, where there are appreciable steric effects and possibly increased conjugation involved, is the ΔH_E increased slightly to 16 kJ mol^{-1} for methoxy group relaxation.

It would seem reasonable to conclude that in the absence of appreciable steric or mutual conjugative effects the barrier to methoxy group relaxation, when attached to a conjugated system, is low and of the order of 10 kJ mol^{-1}.

Electrochemical reduction of pyridopyrazines

JOSEPH ARMAND, KHALED CHEKIR, AND JEAN PINSON

Laboratoire de Physicochimie des Solutions, Université Pierre et Marie Curie, Bâtiment F, 8 rue Cuvier, 75230 Paris, Cédex 05 France

Received October 13, 1977

JOSEPH ARMAND, KHALED CHEKIR, and JEAN PINSON. Can. J. Chem. **56**, 1804 (1978).

The electrochemical reduction of several pyrido[2,3-*b*]pyrazines in hydroorganic or aprotic media leads to 1,4-dihydro derivatives which can be isolated in some cases. Most of these derivatives isomerize into 1,2-, 3,4-, or 5,8-dihydro compounds. A molecule of alcohol is added to these last compounds in alkaline medium. The electrochemical reduction of 1,2- or 3,4-dihydro derivatives gives 1,2,3,4-tetrahydropyridopyrazines. In hydroorganic media, the 7-bromopyrido [2,3-*b*]pyrazines give a 1,4-dihydro compound which can either isomerize or debromhydrate. In an aprotic medium, the parent heterocycle is obtained. By electrochemical reduction of pyrido[3,4-*b*]pyrazines, 1,4-dihydro derivatives can be formed which isomerize. The 1,2- or 3,4-dihydro compounds thus obtained can be reduced at the electrode into 1,2,3,4-tetrahydro derivatives.

JOSEPH ARMAND, KHALED CHEKIR et JEAN PINSON. Can. J. Chem. **56**, 1804 (1978).

La reduction électrochimique de diverses pyrido[2,3-*b*]pyrazines en milieu hydroorganique et aprotique fournit des dérivés dihydro-1,4 isolés dans certains cas. Ces dérivés peuvent s'isomériser en solution en dérivés dihydro-1,2 ou -3,4 ou -5,8. Ces derniers additionnent une molécule d'alcool en milieu alcalin. La réduction des dérivés dihydro-1,2 ou -3,4 fournit des tétrahydro-1,2,3,4. Les dérivés 7-bromés conduisent en milieu hydroorganique à une dihydro-1,4 qui peut soit s'isomériser soit se débromhydrater, alors qu'en milieu aprotique il y a coupure de la liaison C—Br pour conduire à la pyrido[2,3-*b*]pyrazinè. La réduction électrochimique des pyrido[3,4-*b*]pyrazines fournit des dérivés dihydro-1,4 qui s'isomérisent uniquement en dérivés dihydro-1,2 ou -3,4 eux mêmes électroréductibles en tétrahydro-1,2,3,4.

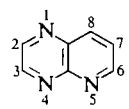
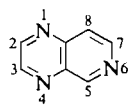
It has been shown in previous papers that by electrochemical reduction of compounds with the —N=C—C=N— group (1, 2), semihydrogenated derivatives can be prepared. We now present the results obtained in the case of pyridopyrazines, whose electrochemistry had never before been investigated in spite of their interesting pharmacological properties.



Pyrido[2,3-*b*]pyrazines



Pyrido[3,4-*b*]pyrazines

*Alkyl- and Arylpyrido[2,3-*b*]pyrazines*

Hydroorganic Media

In a water–methanol mixture (50:50 by volume) 2,3-diphenylpyrido[2,3-*b*]pyrazine (**1**) presents a single two-electron wave, with an $E_{1/2}$ which is pH dependent between pH 1 and 14: $E_{1/2} = -0.09 - 0.07$ pH. It is more easily reduced than the 2,3-diphenylpyrazine (2) for which $E_{1/2} = -0.38 - 0.079$ pH, owing to an increased conjugation with the pyridine ring. Electrolysis of a dilute solution of **1** in neutral or acidic media (Fig. 1) leads to a compound with an anodic wave whose $E_{1/2}$ value is near that of the cathodic wave of **1**. This reduced compound (**2**) precipitates during the electrolysis and is very easily oxidized. When dissolved in a non-deoxygenated solution, this compound is quickly and quantitatively reoxidized to **1**. In alkaline media (Fig. 2), the same primary reduction product is obtained but its anodic wave decreases with time and two cathodic waves appear; a preparative electrolysis

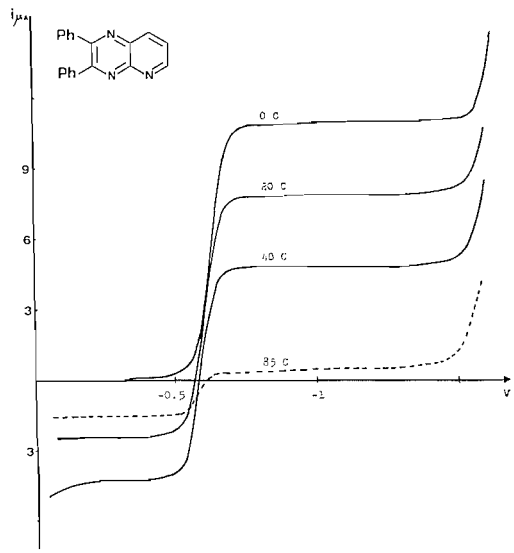


FIG. 1. Electrolysis of **1** in dilute solution: pH 7; $c = 2 \times 10^{-3}$ M, 50% CH_3OH, $E = -0.7$ V/sce, $V = 200$ ml. Polarograms recorded before (0 C), during (20 C, 40 C) and at the end of the electrolysis (85 C).

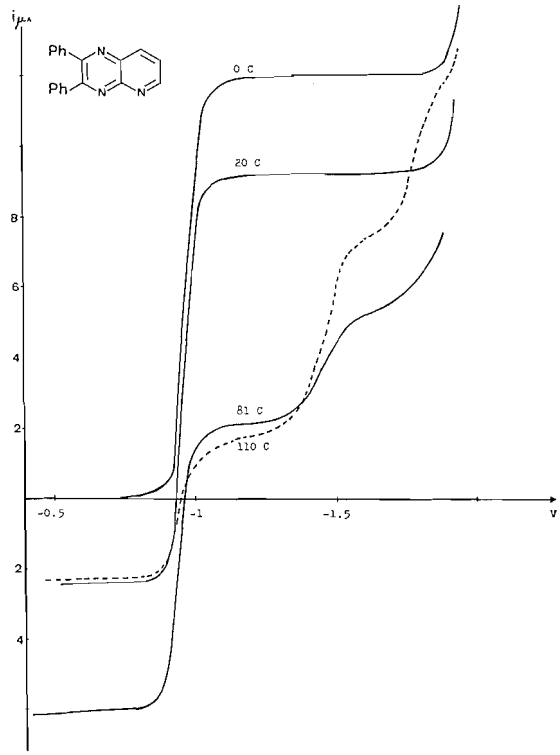

FIG. 2. Electrolysis of **1** in dilute solution: 0.1 *N* NaOH, $c = 2.10^{-3}$ *M*, 80% CH_3OH, $E = -1.1$ V/sce, $V = 200$ ml. Polarograms recorded before (0 C) and during the electrolysis (20 C, 81 C, 110 C).

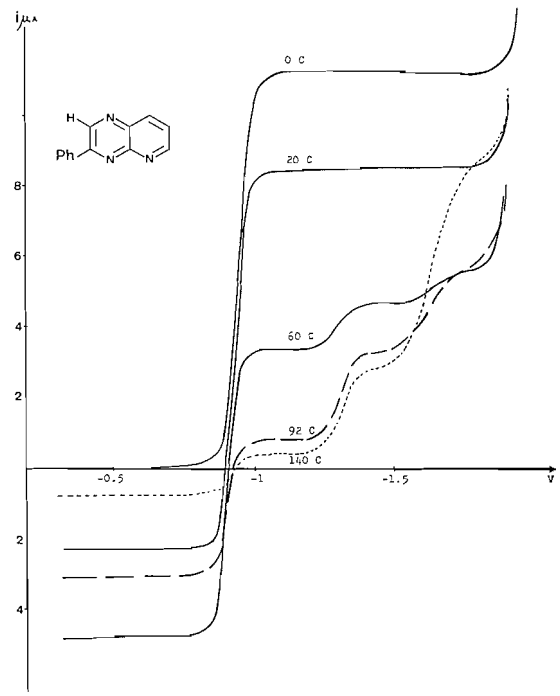

FIG. 3. Electrolysis of **5** in dilute solution: 0.1 *N* NaOH, $c = 2.10^{-3}$ *M*, 50% CH_3OH, $E = -1.05$ V/sce, $V = 200$ ml. Polarograms recorded before (0 C), during (20 C, 60 C, 92 C) and at the end of the electrolysis (140 C).

of **1** gives a mixture of two compounds which can be separated: 3,4-dihydro-2,3-diphenylpyrido[2,3-*b*]-pyrazine (**3**) and 5,6,7,8-tetrahydro-6-methoxy-2,3-diphenylpyrido[2,3-*b*]pyrazine (**4**). These two compounds give the same cathodic waves as those observed in Fig. 2.

*3-Phenylpyrido[2,3-*b*]pyrazine (**5**)*—The polarographic behaviour of **5** is similar to that of **1**; in a 50:50 water–methanol mixture, $E_{1/2}$ varies with p*H* according to the same equation. Electrolysis of dilute solutions also gives a highly oxidizable compound (**6**) which does not precipitate in the medium but is transformed slowly in an acidic or a neutral medium and more rapidly in an alkaline medium. This is shown on the polarograms recorded during the electrolysis (Fig. 3). In an alkaline water–methanol medium, a preparative electrolysis of **5** gives 5,6,7,8-tetrahydro-6-methoxy-3-phenylpyrido[2,3-*b*]pyrazine (**7**); by using C_2H_5OH instead of CH_3OH, one obtains 5,6,7,8-tetrahydro-6-ethoxy-3-phenylpyrido-[2,3-*b*]pyrazine (**8**).

*2,3-Dimethylpyrido[2,3-*b*]pyrazine (**9**)*—The polarograms are similar to those of **1**; $E_{1/2} = -0.15 - 0.07$ p*H* (50:50 water–methanol). During electrolysis in dilute solution, the polarograms show that the primary reduction product **10** is transformed at every p*H* (Fig. 4). A preparative electrolysis of **9** in an alkaline medium gives a 15:85 mixture (nmr titration) of 5,6,7,8-tetrahydro-6-methoxy-2,3-dimethylpyrido[2,3-*b*]pyrazine (**11**) and 1,2- (or 3,4-) dihydro-2,3-dimethylpyrido[2,3-*b*]pyrazine (**12**). This last compound can be purified by recrystallization.

The data in Scheme 1 account for our results. First of all, some of the dihydro and tetrahydro derivatives obtained by preparative electrolysis can be reduced at the dropping mercury electrode and produce a cathodic wave which is identical to that observed during the electrolyses of dilute solutions: the results of these electrolyses are thus in agreement with those of the preparative electrolyses. The primary reduction product shows an anodic wave with an $E_{1/2}$ value near that of the cathodic wave of the starting pyrido[2,3-*b*]pyrazine and it partially isomerizes into a 1,2- or 3,4-dihydro derivative; this behaviour is identical to that of pyrazines (2). Thus, the 1,4-dihydro structure can be assigned to compounds **2**, **6**, and **10** according to route *A*. In the case of **5**, 1,2- (or 3,4-) dihydro-3-phenylpyrido[2,3-*b*]pyrazine could not be isolated; this is indeed what is observed in Fig. 2 where a cathodic wave appears with an $E_{1/2}$ little different from that of **3**. This indicates that the 1,4-dihydro derivative **6** partially isomerizes into a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

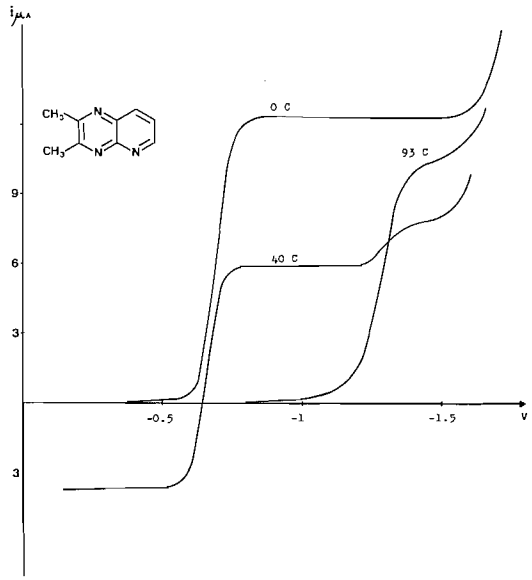

FIG. 4. Electrolysis of **9** in dilute solution: pH = 7.2, $c = 2.10^{-3}$ M; 50% CH_3OH, $E = -0.8$ V/sce, $V = 200$ ml. Polarograms recorded before (0 C), during (40 C) and at the end of the electrolysis (93 C).

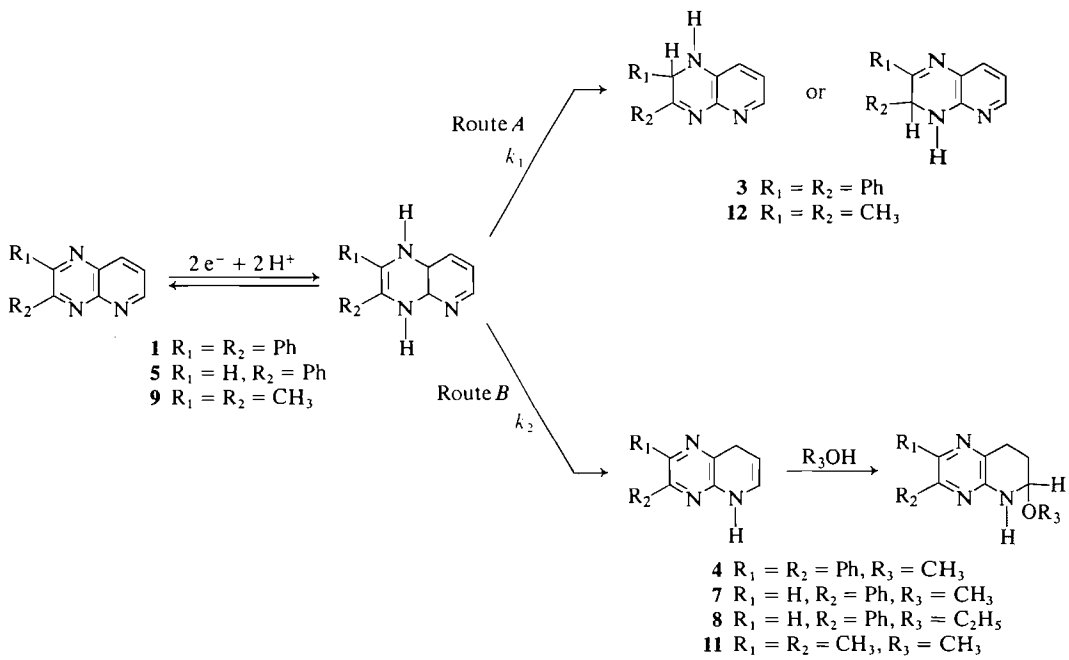
1,2- or 3,4-dihydro derivative which could not be isolated because of its low yield and high solubility.

To the best of our knowledge, route B is entirely new. The formation of the tetrahydro derivatives **4**, **7**, **8**, and **11** can be explained by covalent addition of alcohol to a dihydrogenated derivative. This type of addition, which is often observed with nitrogen heterocycles (3), generally takes place on a >C=N— bond. Thus, the most logical hypothesis is that the addition takes place on the 7,8-dihydro derivative. In a nonaqueous medium in the presence of phenol (see below), the electrolysis of the pyrido[2,3-*b*]pyrazines leads to the 5,8-dihydro derivative; this compound is rapidly and quantitatively transformed into the 5,6,7,8-tetrahydro derivative in an alkaline water–methanol mixture. These results indicate that the 1,4-dihydropyrido[2,3-*b*]pyrazine leads to the 5,8-dihydro compound which isomerizes in alkaline medium into the 7,8-dihydro derivative, with addition of a molecule of methanol (Scheme 1). The formation of a 5,8-dihydro compound can be explained either by an intramolecular rearrangement of the 1,4-dihydro compound or by the reduction on the 5,8 position of a molecule of pyrido[2,3-*b*]-pyrazine by a molecule of the 1,4-dihydro compound. The first hypothesis implies that the reaction is of first kinetic order in 1,4-dihydro derivative, whereas in the second hypothesis the reaction would be first order in 1,4-dihydro and first order in pyrido[2,3-*b*]-pyrazine. The isomerization reaction 1,4-dihydro → 1,2- or 3,4-dihydro is also first order in 1,4-dihydro. Thus, a fourfold increase of the initial concentration of **1** should not change the ratio of the number of moles of **4** to the number of moles of **3** if the first hypothesis is the right one, while this ratio should undergo a large increase in the second case. By changing the amount of **1** which is electrolyzed from



SCHEME 1. Reduction of pyrido[2,3-*b*]pyrazines in hydroorganic media: $1 <$ pH < 14.

For personal use only.

250 mg to 1 g (in the same volume), the above ratio remains constant; therefore, we can conclude that the 5,8-dihydro is obtained by intramolecular rearrangement of the 1,4-dihydro derivative.

Other cosolvents have been used: acetonitrile, dimethylformamide, and diglyme. In each case, the transformation rate of the 1,4-dihydro derivative is too slow to permit the isolation of isomerization products. The relative amounts of 1,2- or 3,4-dihydro and 5,6,7,8-tetrahydro derivatives obtained by routes *A* and *B* depend on the relative values of the rate constants k_1 and k_2. These depend not only on the nature of R_1 and R_2, as shown by the preparative electrolyses, but also on the reduction medium: the reduction of **1** leads to a 40% yield of **3** in an alkaline water – methanol mixture; this yield increases to 63% in dimethylformamide in the presence of phenol and decreases to 0% in acetonitrile in the presence of phenol.

In short, the primary reduction product of pyrido[2,3-*b*]pyrazines is the 1,4-dihydro derivative which isomerizes either to a 1,2- or 3,4-dihydro or to a 5,8-dihydro compound. The ratio of the different compounds depends on k_1, k_2, and the medium.

Nonaqueous Media

Electrochemical reductions in nonaqueous media were used to prepare 1,4-diacetyl-1,4-dihydro derivatives by operating in dimethylformamide (DMF) or acetonitrile (ACN) in the presence of acetic anhydride as shown by Lund and Simonet (4). In addition, nonaqueous media with phenol added as a proton donor were used to prevent the addition of alcohol. In DMF, the potentials are referred to the Ag,AgI/I^- 0.1 *M* electrode and in ACN to the Ag/Ag^+ 0.01 *M* electrode.

In DMF, **1** presents two one-electron waves (Fig. 5). By adding an excess of acetic anhydride, these two waves merge into a single two-electron wave with an $E_{1/2}$ which is slightly more positive than that of the first wave of **1**. A preparative electrolysis gives the 5,8-dihydro-5-acetyl-2,3-diphenylpyrido[2,3-*b*]-pyrazine (**13**). Similar polarographic behaviour is observed for **5**; however, preparative electrolyses led only to gummy products.

In ACN, the polarographic results are similar to that obtained in DMF for **1** and **5**. The electrolysis of **1** also gives **13** whereas with **5**, one obtains the 1,4-dihydro-1,4-diacetyl-3-phenylpyrido[2,3-*b*]pyrazine (**14**).

Upon addition of phenol, the second wave of the polarogram of **1** disappears progressively as the first one increases and becomes a two-electron wave, with an $E_{1/2}$ which is shifted to more positive potentials, both in ACN and DMF. In DMF, electrolysis of **1** gives **3** whereas in ACN, it leads to the 5,8-dihydro-

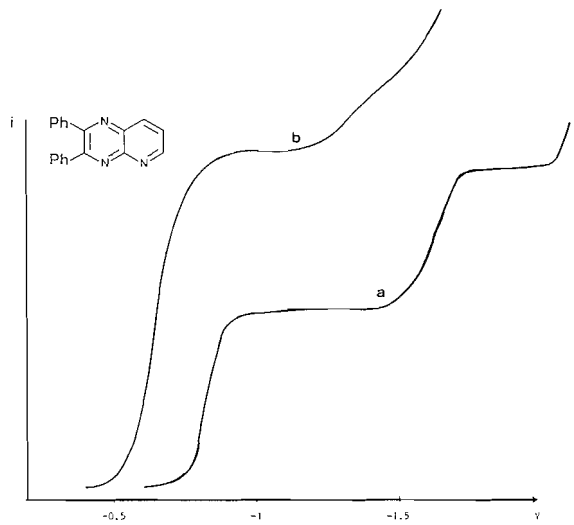

FIG. 5. Polarogram of (*a*) **1** in DMF: $c = 10^{-3}$ *M*, 0.15 *M* TBAI, $V = 50$ ml; and (*b*) after addition of 2 ml acetic anhydride (2.1×10^{-2} mol; mol ratio 10^3). Reference electrode Ag/AgI I^- 0.1 *M*.

2,3-diphenylpyrido[2,3-*b*]pyrazine (**15**). It should be noted that **15** does not acetylate in DMF in the presence of acetic anhydride.

In the case of **5**, polarograms are modified in the same way; electrolysis in DMF gives a mixture containing mostly the 1,4-dihydro-3-phenylpyrido-[2,3-*b*]pyrazine (**6**); in ACN, the 5,8-dihydro-3-phenylpyrido[2,3-*b*]pyrazine (**16**) is obtained.

In the absence of an electrophilic reagent or of a proton donor, the two monoelectronic waves can be assigned to the formation of an anion radical and of a dianion. The unusual stability of the dianion of **1** (Fig. 6) can be explained by its low basicity owing to a high degree of conjugation. It is recalled that the dianion of 2,3-diphenylpyrazine is unstable under the same conditions (Fig. 7).

In the presence of acetic anhydride, the reduction starting from **1** proceeds differently than that starting from **5** (Scheme 2). It should first be recalled that, as stated above, **13** can not be obtained through the acetylation of **15**. In the presence of an electrophile, the acetylation of nitrogen heterocycles can take place before or after the first electronic transfer (4). In the case of a preceding acetylation, which can be sketched as in Scheme 3, the most basic nitrogen in the molecule should be acetylated. In the case of pyridopyrazines, the most basic nitrogen is that of the pyridine ring (5). Thus a preceding acylation would seem to occur in the formation of **13**, whereas in the case of **14** the acetylation would take place after the first electronic transfer according to an ECEC mechanism.

In the presence of phenol, the solutions become

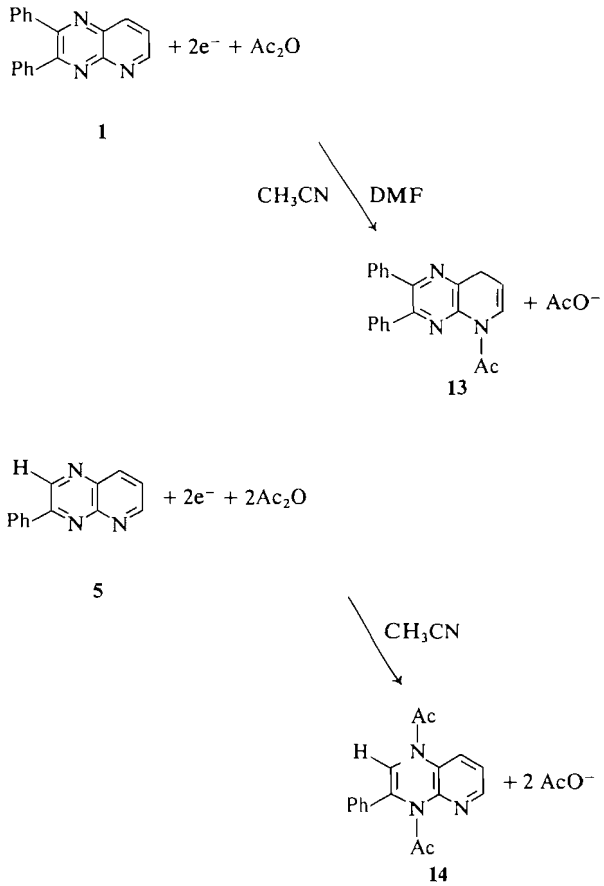
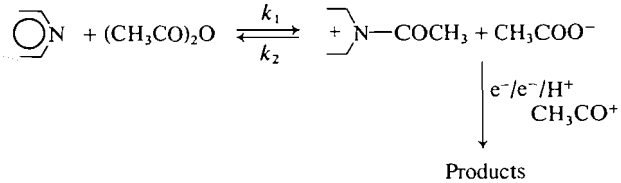


SCHEME 2. Reduction of pyrido[2,3-*b*]pyrazines in nonaqueous media.

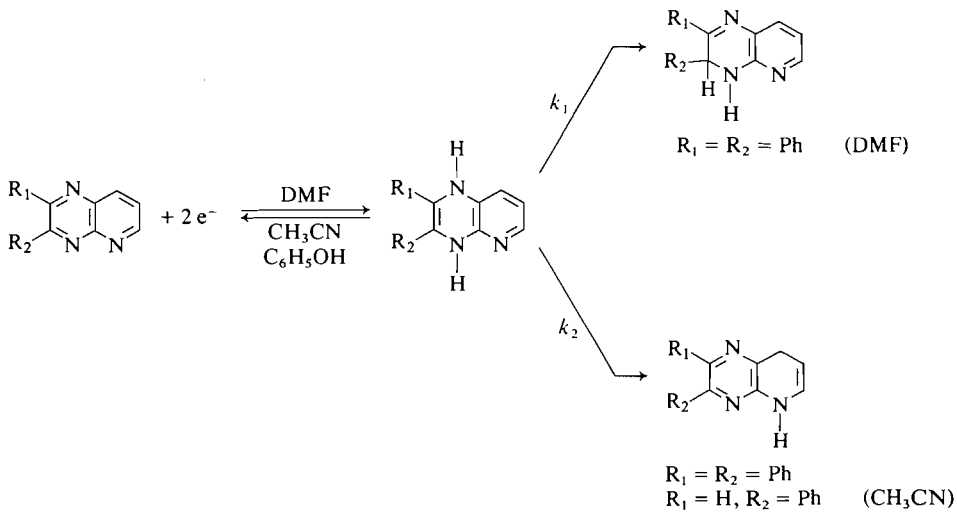
deep red during the electrolysis; this colour is stable in the case of **5** in DMF and is due to the 1,4-dihydro derivative as the primary reduction product which is stable in one case and which isomerizes in the three other cases. The rate and the orientation of this isomerization depend on R_1, R_2, and the medium as shown in Scheme 4.

*7-Bromopyrido[2,3-*b*]pyrazines*

These compounds were investigated to find out if their behaviour is similar to that of other aromatics (6, 7) where bromine is cleaved upon reduction, this cleavage being interesting for the synthesis of pyridopyrazines.



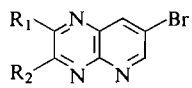
SCHEME 3. Mechanism of a preceding acetylation.



SCHEME 4. Reduction of pyrido[2,3-*b*]pyrazines in DMF and ACN with addition of phenol.

Hydroorganic Medium

In this medium, compounds **17**, **18**, and **19** present a single 2 F wave. The $E_{1/2}$ varies linearly with the pH: $E_{1/2} = -0.08 - 0.055$ pH for **17**, $E_{1/2} = -0.09 - 0.07$ pH for **18**, and $E_{1/2} = -0.15 - 0.068$ pH for **19**. The reductibility of pyrido[2,3-*b*]pyrazines is only slightly modified by the bromine atom as can be seen by comparing the above $E_{1/2}$ with those of the nonbrominated compounds.



17 $R_1 = R_2 = Ph$
18 $R_1 = H$, $R_2 = Ph$
19 $R_1 = R_2 = CH_3$

Electrolysis of dilute solutions of **17** and **18** in acidic or neutral media leads to a compound with an anodic wave, whose $E_{1/2}$ is near from that of the starting compound (Fig. 8). This compound can be reoxidized by air to give quantitatively the starting compound (nmr and polarograms). Thus, the primary reduction product is a 1,4-dihydro derivative which isomerizes very slowly. In alkaline media, the polarograms recorded during the electrolyses are similar to those obtained with the nonbrominated compounds. When **17** and **18** are electrolyzed under the conditions used for **1** and **5**, the same products are obtained (i.e. **3**, **7**, and **8**) with the same yields.

In alkaline media, the behaviour of **19** is similar to that of **17** and **18** but in acidic or neutral media, the 1,4-dihydro derivative is mainly transformed into a 1,2- (or 3,4-) dihydro derivative as shown by preparative electrolysis of **19** in a neutral medium

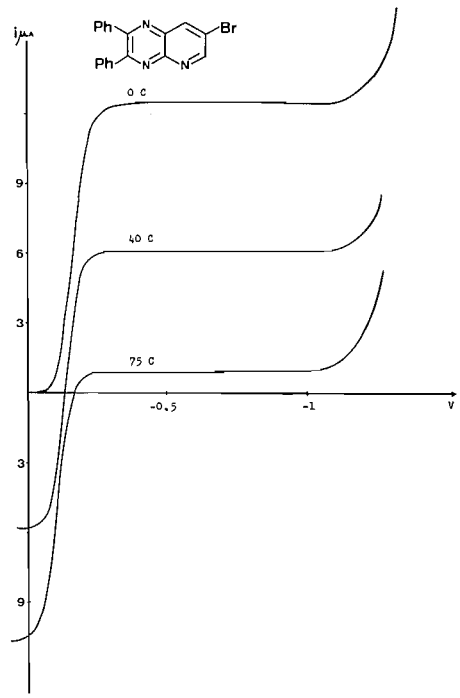


FIG. 8. Electrolysis of **17** in dilute solution: 0.1 N H_2SO_4, $c = 2 \times 10^{-3}$ M, 80% CH_3OH, $E = -0.25$ V/sce, $V = 200$ ml. Polarograms recorded before and during the electrolysis (40 C, 75 C).

where the 1,2- or 3,4-dihydro-2,3-dimethyl-7-bromopyrido[2,3-*b*]pyrazine (**20**) is formed.

These results indicate that in alkaline medium the cleavage of bromine from the 7-bromo compounds takes place at the level of the 1,4-dihydro derivative: the results are summarized in Scheme 5.

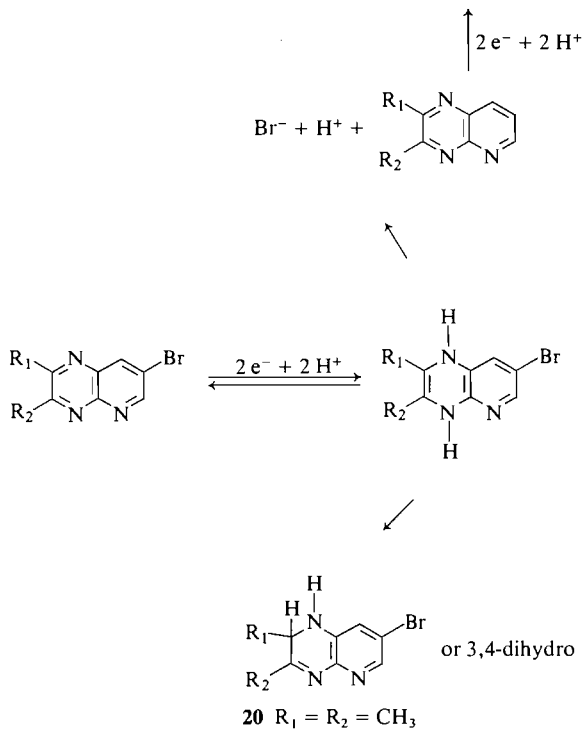
SCHEME I



20 $R_1 = R_2 = CH_3$

SCHEME 5. Reduction of 7-bromopyrido[2,3-*b*]pyrazines in hydroorganic media.

Nonaqueous Medium

In acetonitrile and DMF, the three bromo derivatives present a 1 F wave followed by the two waves of the parent heterocycle. The half wave potentials of these three compounds are not too different.

	17	18	19	Reference electrode
DMF	−0.63 V	−0.63 V	−0.80 V	Ag,AgI/I⁻ 0.1 *M*
ACN	−1.51 V	−1.51 V	−1.66 V	Ag/Ag⁺ 0.01 *M*

Voltammograms were recorded at different scan rates in the case of **17** in ACN (Fig. 9). At low scan rates, the first irreversible peak of **17** is followed by the two reversible peaks of **1** (Fig. 9*a*). At higher scan rates (Fig. 9*c*), the voltammogram shows two reversible peaks corresponding to the formation of the radical anion and the dianion of **17** and a small anodic peak of **1** ($\mathbf{1}^{\cdot-} \rightarrow \mathbf{1}$). This anodic peak is higher in Fig. 9*b* recorded at an intermediate sweep rate; therefore, the extent of bromine cleavage is greater than in Fig. 9*c* but is not complete as in Fig. 9*a*. Figure 9*d* is recorded at the same sweep rate as Fig. 9*b* but the cathodic scan is stopped before the second peak of **17**; it shows a single reversible peak which corresponds to the $\mathbf{17}/\mathbf{17}^{\cdot-}$ couple. In the case of **19** (in ACN) at a low scan rate (0.2 V s^{-1}), a single irreversible peak ($E_p = -1.76$ V) is observed, followed by the two peaks of **9** ($E_p = -1.96$ V reversible and $E_p = -2.32$ V irreversible). At a higher scan rate (200 V s^{-1}), the first peak becomes reversible and a new peak appears which corresponds to the formation of the dianion of **19**.

Coulometric experiments were also carried out: in the case of **17**, the electrolysis of a 10^{-3} *M* or 10^{-2} *M* solution consumes 1.5 F/mol and the main product is **1** in 53 and 70% yield, respectively; some by-products are evinced by thin-layer chromatography. The reduction of a 10^{-2} *M* solution of **19** consumes 1.5 F/mol and the yield of **9** is 50%.

The rate of decomposition of the radical anion obtained after the first electronic transfer can be measured by plotting E_p as a function of log v (v = sweep rate in V s^{-1}) (6). We found $k_1 = 18 \pm 6$ s^{-1} for **17** and 385 ± 100 s^{-1} for **19**. These rate constants are very small when compared to the rate constant for the decomposition of the radical anion of the 2,3-diphenyl-5-bromopyrazine (**21**). In the latter case, the first wave of the voltammogram remains irreversible up to 1200 V s^{-1}, indicating that k_1 is higher than 50 000 s^{-1} (Fig. 7).

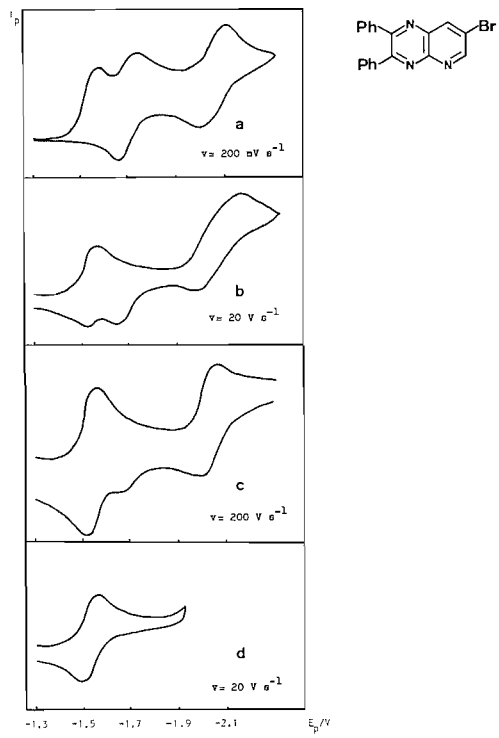


FIG. 9. Voltamograms of 7-bromo-2,3-diphenylpyrido[2,3-*b*]-pyrazine **17**. Solvent ACN; supporting electrolyte, tetraethylammonium perchlorate 0.1 *M*; reference electrode Ag/Ag⁺ 0.01 *M*.

If RBr represents the bromo heterocycle and RH the parent compound, the cleavage of bromine can take place at the level of the radical anion $RBr^{\cdot -}$ to give a neutral radical R· and a bromine anion. This neutral radical R· can enter into three competitive reactions: (*i*) hydrogen atom abstraction from the solvent; (*ii*) further reduction to R^- at the electrode; or (*iii*) electron exchange in solution. It has been shown (8) that when the rate constant k_1 is low, further electrode reduction is unlikely: the radical anion has enough time to diffuse from the electrode to the solution before it decomposes. Thus R· is obtained in the bulk of the solution and cannot be reduced at the electrode. Between the two last possibilities, the most probable reaction is a hydrogen atom abstraction from the solvent. Not only is it favoured by concentration effect but also the by-products evidenced by tlc can be explained by an attack of the solvent on R· (8)

$$R\cdot + SH \rightarrow RH + S\cdot \quad (SH = \text{solvent})$$

$$S\cdot + e \rightarrow S^-$$

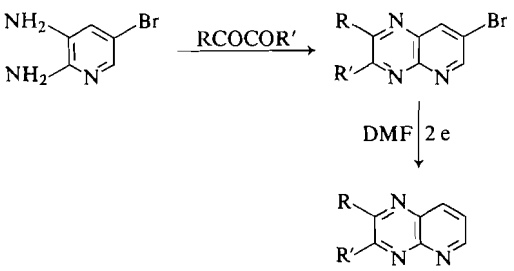
$$R\cdot + S^- \rightarrow RS^{\cdot -}$$

$$RS^{\cdot -} \rightarrow \text{By-products}$$

The reduction of S· to S^- would thus account for more than 1 electron being observed during the coulometric experiments.

An interesting and unusual feature of these compounds is the high stability of the dianion RBr^{2-}: a reversible peak corresponding to the $RBr^{\cdot -}RBr^{2-}$ couple is observed on the voltammogram of **17** even at relatively low scan rates (Fig. 9*b*). This dianion decomposes relatively slowly into R^- and a bromine anion; R^- is most likely protonated to RH by the residual water. At the potential where this reaction takes place, RH is reduced to $RH^{\cdot -}$ and the re-oxidation of this radical anion is seen on the anodic scan of the voltammogram (Fig. 9*b* and *c*).

It should be noted that the cleavage of Br^- from the 7-bromopyrido[2,3-*b*]pyrazines is useful for the synthesis of these series. To prepare pyrido[2,3-*b*]-pyrazines, one follows a synthetic route (9) where the



SCHEME 6. Electrochemical preparation of pyrido[2,3-*b*]-pyrazines.

most difficult step in the series of reactions is the chemical debromation of 2,3-diamino-5-bromo-pyridine. Through the sequence of reactions shown in Scheme 6, this chemical debromination step can be avoided. The debromation is carried out electrochemically on the pyrido[2,3-*b*]pyrazines which are easily prepared from 2,3-diamino-5-bromopyridine. For example, a preparative electrolysis of **17** carried out in DMF gives easily 51% of **1**.

*Chemical Preparation of the Reduced Derivatives of Pyrido[2,3-*b*]pyrazines*

Dihydro derivatives have been prepared by reaction of organomagnesium compounds with pyrido-[2,3-*b*]pyrazines (12); no 1,2- or 3,4-dihydropyrido-[2,3-*b*]pyrazines had been described before our preliminary communication (13). We have prepared the 1,4-dihydro derivative of **5** by reduction with sodium dithionite. Unlike compound **2** it cannot be prepared by electrolysis.

1,2,3,4-Tetrahydro derivatives have been obtained by reaction of organomagnesium compounds (12) or by reduction with $AlLiH_4$ (5, 10, 11). This last reagent does not give any result in the case of **5**; the tetrahydro derivative is prepared by hydrogenation with Pd–C. The 1,2,3,4-tetrahydro derivatives can also be obtained by electrolysis of 1,2- or 3,4-dihydro compounds: **3** leads to the *cis*-tetrahydro derivative whereas **2** gives a mixture of *cis* and *trans* isomers. 5,6,7,8-Tetrahydropyrido[2,3-*b*]pyrazines have been prepared by hydrogenation of 5,6-dihydro derivatives (11).

*Pyrido[3,4-*b*]pyrazines*

The electrochemical reduction of 2,3-diphenyl-pyrido[3,4-*b*]pyrazine (**22**) was investigated to assess the influence of the position of the pyridine nitrogen in comparison with the reduction pattern of **1**. This influence is indeed strong since the electrochemical reduction of **22** does not involve the pyridine ring.

Between p*H* 1 and 13 the polarogram of **22** presents a 2 F cathodic wave with an $E_{1/2}$ which varies with the p*H* as $E_{1/2} = 0.07 - 0.08\,pH$ between p*H* 1 and 7 and as $E_{1/2} = -0.07 - 0.069\,pH$ between p*H* 7 and 13 (CH_3OH, 50%). The reducibility of **22** is thus similar to that of **1**. An electrolysis of a dilute solution in a basic medium shows an anodic wave with an $E_{1/2}$ near that of the cathodic wave of **22**. This anodic wave decreases with time and a new cathodic wave appears (Fig. 10) whose half-wave potential is more negative than that of **22**. A preparative electrolysis in a basic medium gives the 1,2- or 3,4-dihydro-2,3-diphenylpyrido[3,4-*b*]pyrazine (**23**). In solution, this compound shows the same cathodic wave as that observed in Fig. 10. The reduction is outlined in Scheme 7.

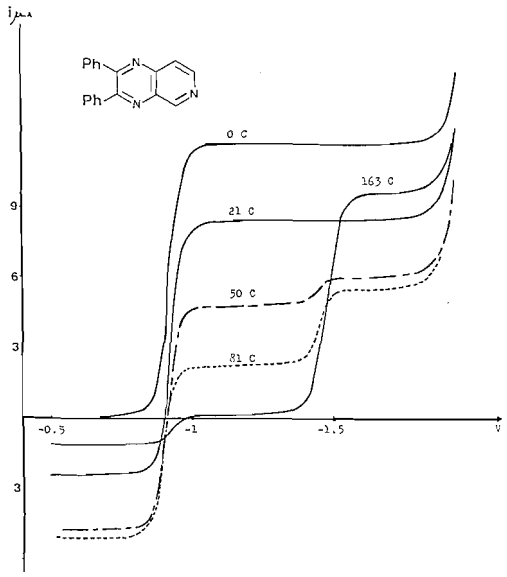


FIG. 10. Electrolysis of 2,3-diphenylpyrido[3,4-*b*]pyrazine **25** in dilute solution: 0.1 *N* NaOH, $c = 2.10^{-3}$ *M*; 75% CH_3OH, $V = 200$ ml. Polarograms recorded before (0 C), during (21 C, 50 C, 81 C), and at the end of the electrolysis (163 C).

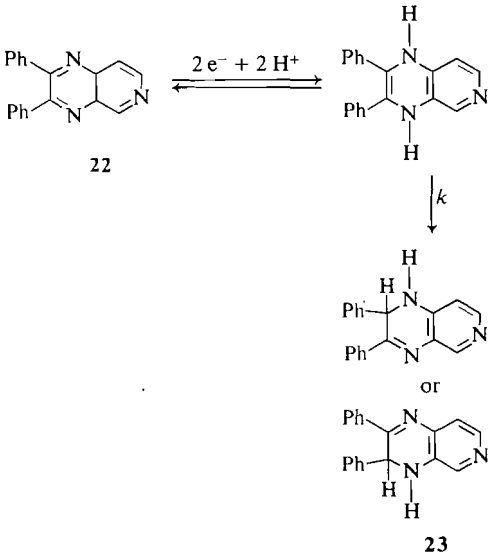
The 1,2- (or 3,4-) dihydro-2,3-diphenylpyrido[3,4-*b*]pyrazine (**23**) presents a 2 F cathodic wave $E_{1/2} = -1.47$ V in alkaline media (CH_3OH 75%; NaOH 0.1 *N*). An electrolysis at -1.6 V consumes 2 F/mol and the resulting solution does not present any polarographic wave. Preparative electrolysis yields 1,2,3,4-tetrahydro-2,3-diphenylpyrido[3,4-*b*]pyrazine.

Thus the polarographic behaviour of 2,3-diphenylpyrido[2,3-*b*]pyrazine (**1**) is analogous to that of



SCHEME 7. Reduction of pyrido[3,4-*b*]pyrazines in hydroorganic medium.

2,3-diphenylpyrido[3,4-*b*]pyrazine (**22**) but the rearrangement of the primary reduction product the 1,4-dihydro derivative does not involve the pyridine ring in the case of **22**. The relative position of the pyridine nitrogen is thus critical in the preparation of compounds containing hydrogenated pyridine rings.

In conclusion, the electrochemical reduction of pyridopyrazines in an aqueous or nonaqueous medium always yields a 1,4-dihydro derivative as the primary reduction product. This compound could be isolated as such or as its diacetyl derivative. This 1,4-dihydro compound usually rearranges rapidly: 1,2- or 3,4-dihydro as well as 5,8-dihydro and 5,6,7,8-tetrahydro derivatives can thus be obtained. The 1,2- or 3,4-dihydro compounds can be reduced into 1,2,3,4-tetrahydro derivatives. The correct choice of the reduction medium and of the potential permits a selective formation of one or the other of these compounds.

Experimental

Techniques

The apparatus and techniques used in hydroorganic medium have been described previously (1, 2). The reference electrode was a saturated calomel electrode. The p*H* values are measured with a Radiometer model 4 p*H* meter equipped with a combined glass–calomel electrode model GK2302B standardized in aqueous buffer. In nonaqueous media a three electrode polarograph Tacussel PRG3 was used to record the polarograms. The high scan rate voltammograms were recorded with the help of an apparatus composed of a Tacussel GSTP3 signal generator, a fast response wide bandpass potentiostat provided with an ohmic drop compensation device (14) and a memory oscilloscope Tektronix 7313. The stationary electrode was a mercury drop suspended on a gold disc 0.8 mm in diameter. The electrolyses were carried out either in the cell described previously or in a classical H cell with a 10 cm^2 mercury pool as a cathode; the potentiostat was a Tacussel ASA 100-1 and the integrator a Tacussel IG5-N. The supporting electrolyte was either 0.1 *M* tetrabutylammonium iodide or 0.1 *M* tetraethylammonium perchlorate. The reference electrodes were Ag/AgI/I^- 0.1 *M* in DMF (−0.51 V vs. sce) and Ag/Ag^+ 0.01 *M* in ACN (+0.29 V vs. sce). The microanalyses were performed by M. E. Dorme (University Pierre and Marie Curie). All the compounds described gave correct elemental analysis. The following abbreviations are used in reporting nmr results: s = singlet, d = doublet, t = triplet, q = quadruplet and m = multiplet.

Preparation of Pyrido[2,3-b]pyrazines

2,3-Diphenylpyrido[2,3-b]pyrazine (1) was prepared according to ref. 15 by reaction of 2,3-diaminopyridine with benzil in a 75:25 alcohol – acetic acid mixture; mp 144°C (alcohol); nmr ($CDCl_3$): 2-Ph + 3-Ph + 7-H, m centered at 7.5 ppm (11H); 8-H, q centered at 8.51 ppm (1H); 6-H, q centered at 9.16 ppm (1H); $J_{6-8} = 2$ Hz, $J_{7-8} = 8$ Hz, and $J_{6-7} = 5$ Hz.

3-Phenylpyrido[2,3-b]pyrazine (5) was prepared by condensation of 2,3-diaminopyridine with phenylglyoxal hydrate (11) in cold alcohol; mp 140°C; nmr ($CDCl_3$): Ph + 7-H + 8-H m centered at 7.6 and 8.3 ppm (7H); 6-H, q centered at 9.1 ppm (1H); 2-H, 9.36 ppm (1H).

2,3-Dimethylpyrido[2,3-b]pyrazine (9) was obtained by reaction of 2,3-diaminopyridine with diacetyl (15) in cold alcohol; mp 150°C (dec.) (benzene); nmr ($CDCl_3$): 2-CH_3, s, 2.7 ppm (3H); 3-CH_3, s, 2.81 ppm (3H); 7-H, q centered at 7.65 ppm (1H); 8-H, q centered at 8.38 ppm (1H); 6-H, q centered at 9.13 ppm (1H); and $J_{6-8} = 2$ Hz, $J_{7-8} = 8$ Hz, $J_{6-7} = 5$ Hz.

Electrochemical Reductions of Pyrido[2,3-b]pyrazines in Hydroorganic Media

The electrolyses in dilute solutions were carried out with 100 or 200 ml of solvent and the pyridopyrazine concentration was 2×10^{-3} *M*. The cosolvent was generally 50% methanol but the amount of methanol was increased to 75 or 80% in some cases to prevent the 1,4-dihydro derivative from precipitating.

Electrolysis of 2,3-Diphenylpyrido[2,3-b]pyrazine (1)

Preparation of 3 and 4—One gram of **1** was dissolved in 200 ml of 0.1 *N* NaOH solution (80% MeOH; $E = -1.1$ V). At the beginning of the electrolysis the solution was clear and the current 200 mA; after 720 C (682 C for 2 F/mol) the intensity fell to 5 mA. The solution with a solid in suspension was poured into 800 ml of water; the precipitate was filtered, washed with water, and dried (970 mg). An nmr spectrum showed that this solid was a 60:40 mixture of **3** and **4**. This solid was stirred in a 20:80 water–methanol mixture to give **4**; the filtrate was evaporated and yielded **3**. The analysis and the nmr spectrum of **3** showed that it was either a 1,2- or a 3,4-dihydro compound. As the nmr spectrum of the 1,2-dihydro-2,3-diphenylpyrido[2,3-*b*]pyrazine prepared by the method of ref. 12 was different from that of **3**, this compound must be the 3,4-dihydro-2,3-diphenylpyrido[2,3-*b*]pyrazine; mp 208°C (methanol); nmr ($CDCl_3 + D_2O$): 3-H, s, 5.9 ppm (1H); 7-H, q centered at 6.66 ppm (1H); 3-Ph + 2-Ph + 6-H, m centered at 7.35 and 7.9 ppm (11H); 8-H, q centered at 7.61 ppm (1H).

The analysis and the nmr spectrum showed that **4** was the 5,6,7,8-tetrahydro-6-methoxy-2,3-diphenylpyrido[2,3-*b*]pyrazine; mp 200°C (dec.) (methanol); nmr ($CDCl_3$): —CH_2—CH_2—, m centered at 2.15 and 3.15 ppm (4H); —O—CH_3, s, 3.28 ppm (3H); 6-H, m centered at 4.41 ppm (1H); $\rangle$N—*H*, s, 6.6 ppm disappears upon addition of D_2O (1H); 2-Ph + 3-Ph, m centered at 7.3 ppm (10H).

Acetyl derivative of 3—The product was dissolved in acetic anhydride (16) to give 4-acetyl-3,4-dihydro-2,3-diphenylpyrido[2,3-*b*]pyrazine (50% yield); mp 150°C (methanol); nmr ($CDCl_3$): —COCH_3, s, 2.48 ppm (3H); 2-Ph + 3-Ph + 3-H + 6-H + 7-H + 8-H, m between 7 and 8.3 ppm (14H).

Electrolysis of 3-Phenylpyrido[2,3-b]pyrazine (5)

Preparation of 7—The electrolysis of 1 g of **5** (70% CH_3OH, 0.1 *N* NaOH; $E = -1.1$ V) gave 600 mg of 5,6,7,8-tetrahydro-6-methoxy-3-phenylpyrido[2,3-*b*]pyrazine (**7**) (51% yield) after consumption of 2.06 F/mol; mp 183°C (methanol); nmr ($CDCl_3 + D_2O$): —CH_2—CH_2—, m centered at 2.15 and 3 ppm (4H); —O—CH_3, s, 3.3 ppm (3H); 6-H, m centered at 4.53 ppm (1H); Ph, m centered at 7.45 and 7.9 ppm (5H); 2-H, s, 8.3 ppm (1H).

Preparation of 8—Conditions were the same as above but ethanol instead of methanol was used; 1 g of **5** gave 730 mg of 5,6,7,8-tetrahydro-6-ethoxy-3-phenylpyrido[2,3-*b*]pyrazine (**8**) (59% yield); mp 165°C (ethanol); nmr ($CDCl_3$): —CH_2—CH_2— and —O—CH_2—, m centered at 2.15 and 3.3 ppm (6H); CH_3, t, 1.16 ppm (3H); 6-H, m centered at 7.45 and 7.9 ppm (5H); 2-H, s, 8.3 ppm (1H).

Electrolysis of 2,3-Dimethylpyrido[2,3-b]pyrazine (9)

Preparation of 12—One gram of **9** was electrolyzed (CH_3OH 80%; NaOH 0.2 *N*; $E = -1.2$ V; 2.16 F/mol) and the solution was extracted with five portions of 25 ml $CHCl_3$; the organic layer was dried and evaporated to give 350 mg of a solid containing **11** and **12** in 15:85 ratio as shown by nmr. This solid was dissolved in 2 ml of benzene and, upon addition of cyclohexane, 250 mg of a precipitate identified as 1,2- or 3,4-dihydro-2,3-dimethylpyrido[2,3-*b*]pyrazine (**12**) was obtained (25% yield); mp 106°C; nmr ($CDCl_3 + D_2O$): CH_3—$\underset{|}{C}$—H, d, 1.33 ppm (3H); CH_3—$\underset{|}{C}$=, s, 2.13 ppm (3H); CH_3—$\underset{|}{C}$—*H*, q, 4.3 ppm (1H); 7-H, 8-H, and 6-H, q centered at 6.6, 7.36, and 7.8 ppm (3H); $J_{CH_3-C-H} = 6$ Hz. The nmr of 5,6,7,8-tetrahydro-6-methoxy-2,3-dimethylpyrido[2,3-*b*]pyrazine (**11**) in $CDCl_3 + D_2O$: —O—CH_3, s, 3.3 ppm (3H); 2-CH_3 and 3-CH_3, s, 2.35 and 2.31 ppm (3H each); CH_3—O—$\underset{|}{C}$—*H*, m centered at 4.68 ppm (1H).

Electrochemical Reduction of Pyrido[2,3-b]pyrazines in Non-aqueous Media

The cathodic solution contained 60 ml of solvent, 1 g of substrate, and 8 ml of acetic anhydride or a quantity of phenol corresponding to about 10 times that of the substrate.

Electrolysis of (1) in DMF in the Presence of Acetic Anhydride

Electrolysis was carried out at $E = -1.1$ V; 2.06 F/mol; the electrolyzed solution was poured into 500 ml of water, the precipitate was filtered, washed with water, and dried. This product was dissolved in ether, hexane was added, and the brown precipitate was filtered. The filtrate was evaporated to dryness to give 300 mg of 5,8-dihydro-5-acetyl-2,3-diphenylpyrido[2,3-*b*]pyrazine (**13**) which was recrystallized from methanol (26% yield); mp 128°C; nmr ($CDCl_3$): CH_3—CO—, s, 2.77 ppm (3H); —CH_2—, q centered at 3.78 ppm (2H); 7-H, m centered at 7.41 ppm (1H); 2-Ph + 3-Ph + 6-H, m centered at 7.35 ppm (11H). When 100 mg of **13** was dissolved in 25 ml of alkaline solution (CH_3OH 80%; NaOH 0.1 *N*) a precipitate appeared after 10 min at room temperature. The solution was concentrated, the precipitate filtered, washed with water, and dried to give a quantitative yield of **4**.

Electrolysis of 5 in DMF in the Presence of Acetic Anhydride

Electrolysis was carried out at $E = -1.0$ V, 1.80 F/mol. The solution was treated in the usual way and gave a gummy mixture whose nmr spectrum indicated the presence of the starting pyridopyrazine among other unidentified products. Tentative purifications were unsuccessful.

Electrolysis of 1 in ACN in the Presence of Acetic Anhydride

Electrolysis was carried out at $E = -1.75$ V, 2.00 F/mol. The solution remained yellow during electrolysis; (the characteristic red colour of the 1,4-dihydro derivative did not appear). At the end of electrolysis, the solution was poured into 800 ml of water and a gummy compound precipitated which crystallized after 1 h. The precipitate was filtered, washed with water, and dried to give 1.05 g of **13** (91% yield).

Electrolysis of 5 in ACN in the Presence of Acetic Anhydride

Electrolysis was carried out at $E = -1.8$ V, 2.16 F/mol. During electrolysis the solution became red; at the end, the solution was poured into 1 ℓ of water. After 24 h the red-orange precipitate which formed was filtered, washed with water, and dried; thus, 270 mg of 1,4-dihydro-1,4-diacetyl-3-phenylpyrido[2,3-*b*]pyrazine (**14**) was obtained (19% yield); mp 206°C (methanol); nmr ($CDCl_3$): —CO—CH_3, s at 2.21 and 2.28 ppm (6H); 2-H, s, 6.66 ppm (2H); Ph + 6-H + 7-H + 8-H, m centered at 7.3 and 8.2 ppm (8H). In alkaline solution (CH_3OH 50%, NaOH 0.1 *N*) **14** desacetylated to give **5**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

*Electrolysis of **1** in DMF in the Presence of Phenol*

Electrolysis was carried out with 1 g of **1**, 1.66 g of phenol at $E = -1.0$ V, 1.80 F/mol. The solution became red during the electrolysis and at the end it was diluted with 500 ml of water; the precipitate was filtered, washed with water, and dried to give 900 mg of a product which, after recrystallization in MeOH, led to 640 mg of 3,4-dihydro-2,3-diphenylpyrido-[2,3-*b*]pyrazine (**3**) (63% yield).

*Electrolysis of **5** in DMF in the Presence of Phenol*

Electrolysis was carried out with 1 g of **5**, 2.3 g of phenol at $E = -1.0$ V, 1.82 F/mol. The solution became red and at the end of the electrolysis, it became yellow when exposed to air; (oxidation of the 1,4-dihydro derivative). An nmr spectrum in $CDCl_3$ showed that the compound which precipitated after dilution in deoxygenated water was a mixture containing mostly the starting pyridopyrazine. A polarogram of this product (MeOH 50%; NaOH 0.1 *N*) showed the anodic wave of **6**. A purification was attempted without results.

*Electrolysis of **1** in DMF in the Presence of Phenol*

Electrolysis was carried out with 1 g of **1**, 2 g of phenol at $E = -1.75$ V, 2.24 F/mol. The solution became red during the electrolysis and a precipitate appeared; it was filtered, washed with ACN, and dried to give 450 mg of 5,8-dihydro-2,3-diphenylpyrido[2,3-*b*]pyrazine (**15**) (45% yield). The filtrate was diluted with 800 ml of water to give a gummy product which was shown by nmr to be a mixture of **1**, **3**, and **15**. For **15**, mp 245°C (CH_3CN); nmr (DMSO-d_6): $-CH_2-$, q, 3.73 ppm (2H); 7-H, m centered at 4.66 ppm (1H); 6-H, m centered at 6.16 ppm (becoming a doublet upon addition of MeOD) (1H); 2-Ph + 3-Ph, m centered at 7.3 ppm (10H); $\rangle$N—H, d, 8.2 ppm (disappears on addition of MeOD) (1H); an irradiation of the $\rangle$NH signal transforms the 6-H signal into a doublet and irradiation of 6-H transforms the 7-H and $-CH_2-$ signals into a triplet and a doublet, respectively.

When 35 mg of **15** was dissolved in 30 ml of CH_3OH the reactant was recovered unchanged after 24 h at room temperature (nmr). Thus, methanol does not add to **15** under these conditions.

When 100 mg of **15** was dissolved in a DMF – acetic anhydride mixture, starting material was also recovered unchanged after 24 h at room temperature; thus **15** does not acetylate into **13** under these conditions.

When 100 mg of **15** was stirred for 24 h in an alkaline solution (80% CH_3OH; 0.1 *N* NaOH (i.e. conditions which allow the formation of **4** by electrolysis), filtered, washed with water, and dried 85 mg of **4** was obtained.

*Electrolysis of **5** in ACN in the Presence of Phenol*

Electrolysis was carried out with 1 g of **5**, 2.3 g of phenol at $E = -1.75$ V, 2.16 F/mol. As in the case of **1**, the solution became red during the electrolysis and a precipitate appeared which was filtered and washed with ACN to give 450 mg of 5,8-dihydro-3-phenylpyrido[2,3-*b*]pyrazine (**16**); by diluting the filtrate with water 150 mg of **16** was obtained (59% yield); mp 225°C (ACN); nmr (DMSO-d_6): $-CH_2-$, q, 3.71 ppm (2H); 7-H, m, 4.6 ppm (1H); 6-H, m centered at 6.2 ppm (becomes a doublet upon addition of MeOD) (1H); 3-Ph, m centered at 7.5 and 8.05 ppm (5H); 2-H + $\rangle$N—H, s, 8.5 ppm and a broad signal which disappears on addition of MeOD.

Preparation of 7-Bromopyrido[2,3-b]pyrazines

*7-Bromo-2,3-diphenylpyrido[2,3-b]pyrazine (**17**)* was obtained by condensation of 5-bromo-2,3-diaminopyridine (**9**) with benzil as (15) in a 25:75 acetic acid – alcohol mixture; mp 155°C (dec.) (alcohol); nmr ($CDCl_3$): 2-Ph + 3-Ph, m centered at 7.4 ppm (10H); 8-H, d, 8.6 ppm (1H); 6-H, d, 9.1 ppm (1H); $J_{6-8} = 2$ Hz.

*7-Bromo-3-phenylpyrido[2,3-b]pyrazine (**18**)* was obtained according to ref. 11 by condensation of 5-bromo-2,3-diaminopyridine with phenyl glyoxal hydrate in alcohol at room temperature; mp 168°C (alcohol); nmr ($CDCl_3$): 3-Ph, m centered at 7.6 and 8.3 ppm (10H); 8-H, d, 8.6 ppm (1H); 6-H, d, 9.16 ppm (1H); $J_{6-8} = 2$ Hz; 2-H, s, 9.43 ppm (1H).

*7-Bromo-2,3-dimethylpyrido[2,3-b]pyrazine (**19**)* was obtained by reaction of 5-bromo-2,3-diaminopyridine with diacetyl at room temperature (15); mp 150°C (dec.) (benzene); nmr ($CDCl_3$): 2-CH_3 and 3-CH_3, s, 2.78 and 2.80 ppm (6H); 8-H, d, 8.43 ppm (1H); 6-H, d, 9.03 ppm (1H); $J_{6-8} = 2$ Hz.

Reduction of 7-Bromopyrido[2,3-b]pyrazines in Hydroorganic Media

The electrolyses in dilute solutions were carried out in 100 or 200 ml of solution at a concentration of 2×10^{-3} *M* but owing to the insolubility of the bromopyridopyrazines, the amount of methanol was always 75–80%. In alkaline medium, the compounds obtained by reduction of **17**, **18**, and **19** are the same and in the same amounts as those obtained from their homologues **1**, **5**, and **9**: reduction of 1 g of **17**: CH_3OH 80%, NaOH 0.1 *N*, $E = -1.1$ V, 4.30 F/mol; reduction of 1 g of **18**: CH_3OH 70%, NaOH 0.1 *N*, $E = -1.1$ V, 4.30 F/mol; reduction of 1 g of **19**: CH_3OH 80%, NaOH 0.1 *N*, $E = -1.2$ V, 4.32 F/mol.

*Electrolysis of 7-Bromo-2,3-dimethylpyrido[2,3-b]pyrazine (**19**) in Neutral Medium*

As the ionic strength of a NaH_2PO_4–Na_2HPO_4 buffer is not high enough in an 80% methanol solution (the solubility of sodium phosphate is low in this medium) an acetic acid – ethylene diamine buffer was used. A solution was prepared from 10 g of acetic acid and 6 g of ethylenediamine in 190 ml CH_3OH; 160 ml of this solution was used to dissolve 2 g of **19** and water was added to 250 ml (p*H* 7.29; $E = -0.8$ V; 2.32 F/mol). At the end of the electrolysis, the solution was poured into 300 ml of water, filtered, and the filtrate extracted with six portions of 50 ml $CHCl_3$. The organic layer was dried and evaporated to give a gum which crystallized in cyclohexane to give 600 mg of **20** (30% yield); mp 160°C (dec.); nmr ($CDCl_3$ + D_2O): $CH_3-\underset{|}{\overset{|}{C}}-H$, d, 1.2 ppm (3H); $CH_3-\overset{|}{C}=$, s, 2.15 ppm (3H); $CH_3-\underset{|}{\overset{|}{C}}-H$, q centered at 4.32 ppm (1H); $J_{CH_3-C-H} = 6$ Hz; 6-H and 8-H, d at 7.48 (1H) and 7.83 ppm (1H), $J_{6-8} = 2$ Hz.

Reduction of 7-Bromopyrido[2,3-b]pyrazine in Aprotic Medium

The coulometric measurements were carried out in 50 ml of ACN at a concentration of 10^{-2} or 10^{-3} *M*. The final products were identified and titrated by polarography and glc (3% OV17 on Varaport 100–120, 1.5 m). An electrolysis of 7-bromo-2,3-diphenylpyrido[2,3-*b*]pyrazine (**17**) was carried out to prepare **1**: 1 g of **17** in DMF; $E = -0.7$ V. After completion of the electrolysis, the solution was poured into 500 ml of water and the precipitate was filtered, washed with methanol (in which **1** only is soluble) to obtain 400 mg of **1** (51% yield).

*Preparation of the 1,4-Dihydro-2,3-diphenylpyrido[2,3-b] pyrazine (**2**) by Electrochemical Reduction of **1***

Electrolysis of a 2×10^{-3} *M* solution of **1** (CH_3OH 50%, p*H* 7, $E = -0.7$ V) gave a red orange precipitate of **2** which was filtered under nitrogen, washed with deoxygenated water, and dried under nitrogen. In a deoxygenated alkaline solution (80% CH_3OH, 0.1 *N* NaOH) **2** presented an anodic wave the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$E_{1/2}$ of which was identical to that of the anodic wave observed during the electrolysis of **1**. When a solution of **2** was put in contact with air, the red colour disappeared and the polarogram showed only the cathodic wave of **1**.

Reduction of **5** *by Sodium Dithionite. Preparation of 1,4-Dihydro-3-phenylpyrido[2,3-*b*]pyrazine (6)*

The procedure of ref. 16 was used with some modifications: 4 g of sodium dithionite and 130 ml of alcohol were added to a solution of 4 g of sodium carbonate in 130 ml of water vigorously stirred and maintained under nitrogen. The solution was heated to 40°C and 867 mg of **5** in 10 ml of chloroform was added dropwise. The mixture is maintained 4 h at 40°C under nitrogen with continuous stirring: a brown solid appeared in the solution. After cooling, the precipitate was filtered under nitrogen, washed with deoxygenated water, and dried under nitrogen; 750 mg of 1,4-dihydro-3-phenylpyrido[2,3-*b*]pyrazine (**6**) was thus obtained. Compound **6** burned spontaneously in contact with air. In a deoxygenated basic solution (CH_3OH 50%, NaOH 0.1 *N*) **6** presented the same anodic wave as that shown in Fig. 3. In this solution **6** was instantaneously and quantitatively reoxidized to **5** when in contact with air. Tentative acetylations by the method of ref. 16 did not give any positive result.

*Preparation of Tetrahydropyrido[2,3-*b*]pyrazines. Catalytic Hydrogenation of* **5** *on 5% Pd/C*

A catalytic hydrogenation was carried out at room temperature with 300 mg of **5** in 100 ml ethanol in the presence of 75 mg of 5% Pd/C. After 12 h of stirring and consumption of 75 ml of hydrogen (theoretical: 65 ml of H_2 if 2 mol of H_2 are consumed per mole of **5**) the solution was filtered and evaporated to dryness to give a solid which was shown by nmr to be a mixture of 1,2,3,4-tetrahydro- and 5,6,7,8-tetrahydro-3-phenylpyrido[2,3-*b*]pyrazine in an 80:20 ratio. Recrystallization from alcohol afforded 100 mg of 1,2,3,4-tetrahydro derivative (33% yield); mp 181°C; nmr ($CDCl_3$ + D_2O): $-CH_2-$, m centered at 3.40 ppm (2H); Ph—$\underset{|}{C}$—*H*, q centered at 4.62 ppm (1H); 3-Ph + 6-H + 7-H + 8-H, m, 6.4–7.6 ppm (8H).

*Electrolysis of 3,4-dihydro-2,3-diphenylpyrido[2,3-*b*]pyrazine (***3***). Preparation of* cis*-1,2,3,4-Tetrahydro-2,3-diphenylpyrido[2,3-*b*]pyrazine*

Electrolysis was carried out using 100 mg of **3** in 100 ml of solution (60% CH_3OH, 0.1 *N* NaOH) at $E = -1.6$ V, 2.0 F/mol. At the end of electrolysis the methanol was evaporated, water added, and the precipitate was filtered. By recrystallization from alcohol, 85 mg of *cis*-1,2,3,4-tetrahydropyrido-[2,3-*b*]pyrazine was obtained; mp 206°C; nmr ($CDCl_3$): 2-H and 3-H, d, 4.70 and 4.80 ppm (after addition of D_2O) (2H); 2-Ph + 3-Ph + 6-H + 7-H + 8-H, m between 6.5 and 7.7 ppm (13H); $\rangle$N—H broad signals at 4.10 and 5.50 ppm (disappeared on addition of D_2O) (2H).

*Electrolysis of 1,2- (or 3,4-) Dihydro-2,3-dimethylpyrido-[2,3-*b*]pyrazine (***12***)*

Compound **12** was not electroreducible in alkaline medium; this compound was obtained by electrochemical reduction of **9** in a low yield. For this reason, electrolysis was carried out on 1 g of **9** (200 ml of solution; 50% CH_3OH, 0.1 *N* H_2SO_4) at a potential corresponding to the cathodic wave of **12** ($E = -1.1$ V, 3.84 F/mol). After completion of electrolysis, the solution was neutralized with 20 ml of 0.1 *N* NaOH and extracted six times with 25 ml of chloroform. The organic layer was dried and evaporated to give 733 mg (yield 71%) of a solid which was shown by nmr to be a mixture of *cis*- and *trans*-1,2,3,4-tetrahydro-2,3-dimethylpyrido[2,3-*b*]pyrazine; nmr ($CDCl_3$ + D_2O): $CH_3-\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}-CH_3$, m centered at 1.1 ppm (6H); $CH_3-\underset{|}{\overset{|}{C}}H-\underset{|}{\overset{|}{C}}H-CH_3$, m centered at 3.3 ppm (2H); 6-H, 7-H, and 8-H, m centered at 6.5 and 7.4 ppm (3H).

*Pyrido[3,4-*b*]pyrazine*

*Preparation of 2,3-Diphenylpyrido[3,4-*b*]pyrazine (***22***)*

This was obtained according to ref. 17 by condensation of the 3,4-diaminopyridine with benzil in alcohol; mp 177°C (alcohol); nmr ($CDCl_3$): 2-Ph + 3-Ph, m centered at 7.5 ppm (10H); 7-H and 8-H, d, 8.06 (1H) and 8.91 ppm (1H) (J_{7-8} = 6 Hz); 5-H, s, 9.71 ppm (1H).

Electrolysis of **22**

One gram of **22** was partially dissolved in 200 ml of 0.1 *N* NaOH solution containing 75% methanol. During the electrolysis (initial current, 150 mA), the solution became red (indicating the formation of the 1,4-dihydro derivative). After consumption of 2.06 F/mol the current falls to 5 mA and all the solid is dissolved. Electrolysis was continued for 2 h after which the red colour had disappeared and a new solid precipitated. This precipitate was filtered, washed with water, and dried (560 mg); more of this compound (360 mg) could be obtained by diluting the filtrate with water (total yield 91%). This product was shown to be 1,2- (or 3,4-) dihydro-2,3-diphenylpyrido[3,4-*b*]pyrazine (**23**); mp 247°C (alcohol); nmr (DMSO-d_6 + D_2O): Ph—$\underset{|}{C}$—*H*, s, 6.13 ppm (1H); 7-H or 8-H, d, 6.61 ppm (J_{7-8} = 6 Hz) (1H); 7-H or 8-H + 2-Ph + 3-Ph, m centered at 7.4 and 8.1 ppm (11H); 5-H, s, 8.36 ppm (1H).

Acetyl Derivative of **23**

Compound **23** was easily acetylated according to the method of ref. 16 to give 1,2- (or 3,4-) dihydro-1- (or 4-) acetyl-2,3-diphenylpyrido[3,4-*b*]pyrazine; mp 150°C (dec.; methanol); nmr ($CDCl_3$): $-CO-CH_3$, s, 2.41 ppm (3H); 2-Ph + 3-Ph, m, 6.9–7.6 ppm (10H); 7-H + 8-H + Ph—$\underset{|}{C}$—*H*, m centered at 8.1 ppm and d at 8.35 ppm (3H); 5-H, s, 8.96 ppm (1H).

Electrolysis of **23**

One gram of **22** was dissolved in 200 ml of solution (70% CH_3OH, 0.1 *N* NaOH) and the potential is set at the level of the cathodic wave of **23**: $E = -1.6$ V, 5.04 F/mol. At the end of the electrolysis, the methanol was evaporated and the solution diluted with 500 ml of water. The precipitate was filtered, washed with water, and dried to give 1 g (98% yield) of *cis*- or *trans*-1,2,3,4-tetrahydro-2,3-diphenylpyrido[3,4,*b*]-pyrazine; mp 110°C (dec.); nmr ($CDCl_3$ + D_2O): Ph—$\underset{|}{C}$*H*—$\underset{|}{C}$*H*—Ph, s, 4.66 ppm (2H); 7-H and 8-H, d, 6.40 and 7.73 ppm (J_{7-8} = 6 Hz) (2H); 2-Ph + 3-Ph, m, 6.6–7.23 ppm (10H); 5-H, s, 7.73 ppm (1H).

Theoretical and experimental behaviour of a thermal conductivity detector for the determination of the *ortho/para* hydrogen composition of gas mixtures in the temperature-jump region[1]

DAVID N. MITCHELL[2] AND DONALD J. LE ROY

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received December 13, 1977

DAVID N. MITCHELL and DONALD J. LE ROY. Can. J. Chem. **56**, 1817 (1978).

The theoretical characteristics of a thermistor type thermal conductivity detector were determined for gases in the range 1 to 30 Torr, and were tested experimentally for mixtures of *ortho*- and *para*-hydrogen in pure hydrogen and in dilute mixtures of hydrogen in helium. It was found that the detector could be treated as being spherically symmetric. For temperature-jumps of up to 100 K, the total heat transfer could be adequately explained by a simplified form of the Kennard temperature-jump theory, only two parameters being required, the radius of the thermistor and its accommodation coefficient. The differential behaviour, the sensitivity to changes in *ortho/para* composition, required an additional parameter, the apparent gas phase relaxation rate for rotational energy.

DAVID N. MITCHELL et DONALD J. LE ROY. Can. J. Chem. **56**, 1817 (1978).

On a déterminé les caractéristiques théoriques d'un détecteur de conductivité thermique de type thermistance pour les gaz à des pressions allant de 1 à 30 Torr et on les a vérifiées expérimentalement pour des mélanges d'hydrogène *ortho* et *para* dans de l'hydrogène pur et dans des mélanges dilués d'hydrogène dans l'hélium. On a trouvé que le détecteur peut être traité comme étant sphériquement symétrique. Pour des sauts de température allant jusqu'à 100 K, on peut expliquer adéquatement le transfert total de chaleur par une forme simplifiée de la théorie de Kennard concernant les sauts de température dans lesquels il ne faut que deux paramètres soit le rayon de la thermistance et son coefficient d'accommodation. Le comportement différentiel, la sensibilité à des changements dans des compositions *ortho/para*, nécessite un paramètre additionnel, le taux apparent de relaxation en phase gazeuse pour l'énergie rotationnelle.

[Traduit par le journal]

Introduction

The differing thermal conductivities of *ortho*-hydrogen (*o*-H_2) and *para*-hydrogen (*p*-H_2) have been used for many years for measuring the *ortho/para* composition of hydrogen (1–11). Following the development of gas chromatography, thermal conductivity cells were used in conjunction with chromatographic columns for separating and measuring *o*-H_2 and *p*-H_2, even in the presence of other gases (2, 3, 6–10). However, in gas phase reaction kinetic studies in flow systems at pressures less than 1 atm, the chromatographic method requires *off-line* collection, compression, and processing of the sample, generally at pressures of 1 atm or more. Recently the original, direct, thermal conductivity method was adapted to studies of the kinetics of hydrogen atom exchange in a flow system, by locating the thermal conductivity cells *on-line*, immediately following the reaction vessel, and operating them at the reactor pressure (4, 5, 11). This avoided the considerable time required for *off-line* processing using gas chromatography, as well as the possibility of *ortho/para* equilibration on the chromatographic column (6). A drawback of the *on-line* technique is that heat conduction is pressure dependent at the pressures (1 to 30 Torr) used in these experiments. This effect, attributed to the phenomenon of the "temperature-jump", has been recognized for many years (12–25). It can be avoided by internal calibration (11) or by using relative concentration measurements at fixed pressure (4, 5).

We have recently used the *on-line* method to measure the fraction of *p*-H_2 in hydrogen formed by gas phase three-body recombination in the presence of a large excess of helium (11). Because a wider range of pressures was needed to study the kinetics than had been used previously (4, 5), the pressure dependence of the signal was significant, and so it was decided to investigate the behaviour of the thermal conductivity detector in greater detail. In the paper we develop a theoretical model for the sensitivity of the detector and its pressure dependence, and show experimentally that the model is reasonable.

Experimental

Apparatus

The thermal conductivity detector used in these experiments

was similar to that described previously (4, 5), but incorporated several important modifications. The two thermal conductivity cells, *sample* and *reference*, were inserted via T joints in the flow line between the reaction vessel and the pressure control valve immediately before the pump; the former was upstream from the latter. Tungsten filaments, called equilibrators, were inserted between the thermal conductivity cells and the T joints. When heated to incandescence, these converted the hydrogen in the gas diffusing from the flow line to the thermal conductivity cells into *normal* hydrogen (n-H_2), containing a mole fraction of p-H_2 equal to 0.2500. The reference equilibrator was left *on* continuously to produce an n-H_2 reference, and the sample equilibrator was turned *on* in order to zero the bridge, and *off* to observe the difference in the fraction of p-H_2 in the sample gas.

The actual apparatus is shown in Fig. 1. The cylindrical thermal conductivity chambers (A), 3.3 cm deep by 1.9 cm in diameter, were drilled in a single, massive (3 kg) block of stainless steel, machined to fit into a 5 ℓ Dewar flask. Gases diffused from the reactant gas stream, through the equilibrators, to the thermal conductivity chambers via thin-walled stainless steel tubes (B), 4.8 cm in diameter and 18 cm long. The Dewar flask served as a temperature controlling bath and the thin-walled tubing reduced heat conduction from the room. Thus the walls of the thermal conductivity chambers could be maintained at a constant temperature.

The *hot* element of each thermal conductivity cell was a glass-coated bead thermistor (C) (Veco, Type 32A7, nominal resistance 2000 Ω at 25°C), soldered to electrical leads mounted in a long glass tube (D). These tubes were held rigidly in place by spring steel clips (E) at the bottom and O-ring seals (F) at the top of the stainless steel tubes. This arrangement allowed easy removal of the thermistor assembly for inspection or replacement.

The equilibrators (G) consisted of standard 500 W tungsten lamp filaments, stretched between supports to give a total length of 40 cm, and mounted in Pyrex tubes. The Pyrex tubes were jacketed and water was circulated from a thermostatted bath to keep the walls at a constant temperature of 25°C.

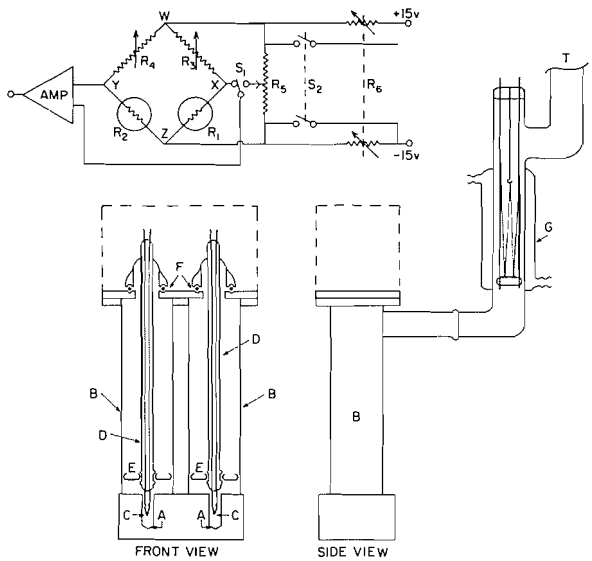

FIG. 1. Thermal conductivity detector. A, thermistor well; B, thin-walled stainless steel tube; C, bead thermistor; D, glass tube; E, spring steel clip; F, O-ring seal; G, equilibrator; T, T-joint connection. Bridge circuit is discussed in the text.

The thermistors comprised two arms of a conventional DC bridge circuit, also shown in Fig. 1. The thermistors R_1 and R_2 are designated as *sample* and *reference* thermistors respectively. The remaining arms of the bridge (R_3 and R_4) consisted of precision decade resistance boxes. The bridge output voltage V, between points X and Y was applied to a Burr Brown Instrumentation Amplifier, Type 3061/25, generally operated at unit gain; the amplifier output was read using a DC digital voltmeter with 10 μV sensitivity. The bridge voltage (E) between points W and Z was fixed at 30 V by applying the full output of a ±15 V stabilized DC power supply (Semiconductor Circuits Incorporated, Type LCD2.15.100A, ±0.001% stability). Consequently, the potential at points X and Y was near ground and saturation of the amplifier was avoided. Adjusting R_3 and R_4 allowed for slight differences in R_1 and R_2 (less than 0.5% at 25°C) and allowed both the temperature of the thermistors and the output voltage (V) to be adjusted simultaneously. The additional resistors (R_5 and R_6) and switches (S_1 and S_2) allowed E to be gradually increased to the final value of 30 V as the thermal conductivity chamber walls were cooled. This prevented the thermistors from either overheating or 'freezing'.

In operation, a change in the p-H_2 composition of the gas in the sample cell (by turning its equilibrator *off*) resulted in a change in thermal conductivity. This in turn caused the heat dissipated by R_1, and hence its resistance, to change, thereby causing a change in the voltage drop across R_1 which was detected as a change in the voltage V between X and Y.

Theory

The objective was to derive an expression for the sensitivity of the detector, defined as dV/dX_p, where X_p is the mole fraction of hydrogen in p-H_2 form in the hydrogen in a mixture of hydrogen and another gas, He in this case. Since n-H_2 is the reference, dV/dX_p is to be evaluated for $X_p = 0.25$. Accordingly, a model was developed for W_1, the power dissipated by the thermistor R_1. The general equation governing steady-state heat conduction from a thermistor through a gas at any pressure to a cylindrical wall, when the thermal conductivity of the gas, K, is dependent on temperature, is not readily solved. We therefore made a number of simplifying assumptions. Firstly, it was assumed that the thermistor bead is spherical. Secondly, it was assumed that the working pressures are sufficiently high that the conventional heat conduction equation (26), with temperature-jump boundary conditions (16), is valid. Finally, it was assumed that the wall radius is sufficiently large compared to the thermistor radius r_1, that the heat flow problem can be treated as that of a spherical heat source in an infinite medium, with the asymptotic gas temperature, as the radial distance tends to infinity, equal to the wall temperature, T_W. These assumptions were later tested experimentally.

For this model, the differential equation governing heat conduction is

$$[1] \qquad r^{-2}\, d[r^{-2}K(T)\, dT/dr]/dr = 0$$

After one integration we obtain

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[2] $$K(T)\,dT/dr = -W_1/4\pi r^2$$

where the form of the integration constant, $-W_1/4\pi$, follows from the observation that the power transmitted through any closed spherical surface of radius $r > r_1$ is equal to W_1, the power dissipated by the thermistor. On integrating [2] between the limits $r_1 < r < \infty$, we obtain the relation

[3] $$W_1 = 4\pi r_1 \int_{T_w}^{T_1'} K\,dT$$

where T_1' is, in general, less than the temperature of the thermistor, T_1, because of the temperature-jump phenomenon. The lower limit of the integration is taken to be the temperature of the wall T_w, i.e. the limit of $T(r)$ as $r \to \infty$.

It is found experimentally that the temperature-jump vanishes at sufficiently high pressures. Thus, for spherical symmetry,

[4] $$\lim_{p\to\infty} W_1 = W_1^{\infty} = 4\pi r_1 \int_{T_w}^{T_1} K\,dT$$

Hence [3] may be written

[5] $$W_1 = W_1^{\infty} - 4\pi r_1 \int_{T_1'}^{T_1} K\,dT$$

The term W_1^{∞} is normally evaluated empirically as the intercept of a plot of $1/W_1$ vs. $1/P$. Values of T_1' may also be evaluated empirically, most easily by using the explicit form[3] $K(T) = AT^B$ in the range $T_1' \leq T \leq T_1$. Thus

[6] $$T_1' = \left[T_1^{B+1} - \frac{(W_1^{\infty} - W_1)}{4\pi r_1}\frac{(B+1)}{A}\right]^{1/(B+1)}$$

where, in the present instance, r_1 is obtained from [4].

In theoretical considerations the temperature-jump is usually expressed (16) in the form

[7] $$T_1' = T_1 + g_1(dT/dr)_{r_1}$$

Thus, from [2] and [7],

[8] $$T_1' = T_1 - g_1 W_1/[4\pi r_1^2 K(T_1')]$$

According to the theory of Kennard (16), the temperature-jump distance, g_1, is given by

[9] $$g_1 = \left(\frac{2-a}{a}\right)(2\pi MRT)^{1/2}\frac{K}{C_P + C_V}\frac{1}{P}$$

where a is the accommodation coefficient, P is the pressure, and the other quantities have their usual significance. It has been pointed out (25) that the various quantities in [9] are to be taken at T_1'. If we use a kinetic theory expression for $K(T_1')$ developed to the same level of sophistication used in developing the temperature-jump theory, then [9] takes the form

[10] $$g_1 = \left(\frac{2-a}{a}\right)\frac{2}{3}\lambda(T_1')$$

in which $\lambda(T_1')$ is the appropriate mean free path. This is the same as the expression developed by Present (29). Thus from [3], [8], and [10],

[11] $$T_1' = T_1 - \left(\frac{2-a}{a}\right)\frac{2}{3}\frac{\lambda(T_1')}{r_1} \times \int_{T_w}^{T_1'} K\,dT/K(T_1')$$

Finally, since simple kinetic theory predicts that $\lambda(T_1')$ should be proportional to T_1' and inversely proportional to P, we may write

[12] $$T_1' = T_1 - \left(\frac{2}{3}\right)\frac{760}{273}\left(\frac{2-a}{a}\right)\frac{\lambda_0}{r_1}\frac{T_1'}{P} \times \int_{T_w}^{T_1'} K\,dT/K(T_1')$$

where λ_0 is the mean free path at 273 K and 760 Torr pressure.

In obtaining an expression for dV/dX_p we use the relation

[13] $$dV = -[R_3(R_1 + R_3)/E(R_1 - R_3)]\,dW_1$$

derived from the electrical properties of the circuit shown in Fig. 1. Also, dW_1 is related to dT_1 by the equation

[14] $$dW_1 = -\frac{(R_1 - R_3)}{(R_1 + R_3)^3}E^2\alpha_1 R_1\,dT_1$$

where the temperature coefficient of the thermistor at T_1 is defined as $\alpha_1 = d\ln R_1/dT_1$.

[3]The particular form $K(T) = AT^B$ is a useful functional form since the first order theory for monatomic gases obeys a similar law, and polyatomic gases follow this law approximately. Over the relatively narrow range of temperatures required in the present work (approximately 150 to 400 K) this function fits the data in refs. 27 and 28 with a precision of 1 to 2%. Using these data we obtain, for He, $K = 3.958 \times 10^{-5}T^{0.6369}$ and, for n-H_2, $K = 1.962 \times 10^{-5}T^{0.7915}$ (in units of W cm^{-1} K^{-1}).

Now it is evident that for a given mole fraction of total hydrogen, N_{H_2}, at constant pressure and T_W, W_1 will be a function of only two independent variables, T_1 and X_p. Thus, the total differential of W_1 is given by

$$[15] \qquad dW_1 = (\partial W_1/\partial T_1)_{X_p}\, dT_1 + (\partial W_1/\partial X_p)_{T_1}\, dX_p$$

By eliminating dT_1 between [14] and [15] and substituting for dW_1 using [13] we obtain the following equation for the sensitivity function:

$$[16] \qquad \frac{dV}{dX_p} = -\frac{[ER_1R_3/(R_1 + R_3)^2](\partial W_1/\partial X_p)_{T_1}}{E^2R_1(R_1 - R_3)/(R_1 + R_3)^3 + (\partial W_1/\partial T_1)_{X_p}/\alpha_1}$$

Expressions for the partial derivatives in [16] are obtained directly from [3]:

$$[17] \qquad (\partial W_1/\partial T_1)_{X_p} = 4\pi r_1 K(T_1')(\partial T_1'/\partial T_1)_{X_p}$$

$$[18] \qquad (\partial W_1/\partial X_p)_{T_1} = 4\pi r_1 \left\{ \int_{T_W}^{T_1'} (\partial K/\partial X_p)_T\, dT + K(T_1')(\partial T_1'/\partial X_p)_{T_1} \right\}$$

Substituting these expressions in [16] and noting that

$$[19] \qquad W_1 = E^2R_1/(R_1 + R_3)^2 = 4\pi r_1 \int_{T_W}^{T_1'} K\, dT$$

the expression for the sensitivity function becomes

$$[20] \qquad dV/dX_p = -\frac{[ER_1R_3/(R_1 + R_3)^2]\left\{ \int_{T_W}^{T_1'} (\partial K/\partial X_p)_T\, dT + K(T_1')(\partial T_1'/\partial X_p)_{T_1} \right\}}{[(R_1 - R_3)/(R_1 + R_3)] \int_{T_W}^{T_1'} K\, dT + K(T_1')(\partial T_1'/\partial T_1)_{X_p}/\alpha_1}$$

Although [20] is the ultimate form of the sensitivity function used, it is evident that the various quantities in it must be obtained either as observable parameters or by computation. Of these, the electrical quantities R_1, R_3, and E are known, as are T_1 and T_W, and α_1 is determined by separate calibration.

The quantities $K(T_1')$ and $\int_{T_W}^{T_1'} K\, dT$ can be evaluated from available data once the values of T_1' are known. These, in turn, can be evaluated in two ways: (*a*) purely empirically, using [6], or (*b*) by solving the theoretical expression of the modified Kennard theory eq. [12] by an iterative procedure; the possibility of using the latter method will be discussed below.

The partial derivative $(\partial T_1'/\partial T_1)_{X_p}$ in [20] can be evaluated by re-arranging [12] and differentiating logarithmically assuming that a is a weak function of T_1 and T_1'. Thus

$$[21] \qquad (\partial T_1'/\partial T_1)_{X_p} = \left\{ 1 + (T_1 - T_1') \left[1/T_1' + K(T_1') \Big/ \int_{T_W}^{T_1'} K\, dT - (\partial K/\partial T)_{X_p} \Big/ K(T_1') \right] \right\}^{-1}$$

where $(\partial K/\partial T)_{X_p}$ is to be evaluated for T_1' as well as $X_p = 0.25$. The partial derivative $(\partial T_1'/\partial X_p)_{T_1}$ can be evaluated in a similar way, and is most simply expressed as

$$[22] \qquad (\partial T_1'/\partial X_p)_{T_1} = (T_1 - T_1') \times \left[(\partial K/\partial X_p)_{T_1'} \Big/ K(T_1') - \int_{T_W}^{T_1'} (\partial K/\partial X_p)_T\, dT \Big/ \int_{T_W}^{T_1'} K\, dT \right] (\partial T_1'/\partial T_1)_{X_p}$$

To obtain an expression for the derivative $(\partial K/\partial X_p)_T$ appearing in [20] and [22] it was necessary to utilize a theoretical and semi-empirical approach since few relevant experimental data are available (30, 31). Using Hirschfelder's expression for non-polar gases (32), we write the following equation for a H_2–He mixture:

$$[23] \qquad K_{mix} = [K_{mix}]_{mono} + (K_{H_2} - [K_{H_2}]_{mono}) \left(1 - \frac{(1 - N_{H_2})D_{H_2H_2}}{N_{H_2}D_{H_2He}} \right)^{-1}$$

where $[K_{mix}]_{mono}$ and $[K_{H_2}]_{mono}$ are calculated by assuming no contribution from internal energy, and the diffusion coefficients $D_{H_2H_2}$ and D_{HeH_2} are assumed to be independent of the rotational state distribution of H_2.

Thus, for a fixed mole fraction of H_2,

$$[24] \qquad (\partial K/\partial X_p)_T = \frac{N_{H_2} D_{HeH_2}/D_{H_2H_2}}{1 - N_{H_2}(1 - D_{HeH_2}/D_{H_2H_2})} (\partial K_{H_2}/\partial X_p)_T$$

The theoretical value of K for a pure polyatomic gas is normally arrived at by multiplying K_{mono} by the Eucken factor. The latter has been generalized by Hirschfelder (32) in terms of a dimensionless parameter δ_f. In the present instance the theoretical value of K_{H_2} is given by

$$[25] \qquad K_{H_2} = [K_{H_2}]_{mono}\{1 + \delta_f[(2/5)(C_P/R) - 1]\}$$

where

$$[26] \qquad \delta_f = (5/2)P^0 D^0{}_{H_2H_2}/[K_{H_2}]_{mono}T$$

in which the superscript refers to a standard pressure. Since δ_f is independent of the rotational distribution we may write

$$[27] \qquad (\partial K_{H_2}/\partial X_p)_T = 0.1013(D^0{}_{H_2H_2}/T)[\partial(C_P/R)/\partial X_p]_T$$

where K_{H_2} has the units of W cm^{-1} K^{-1} and $D^0{}_{H_2H_2}$ is the self-diffusion coefficient of H_2 in cm^2 s^{-1} at 1 atm. Also, since the molar heat capacity of H_2 is a linear function of X_p,

$$[28] \qquad (\partial C_P/\partial X_p)_T = C_P(p) - C_P(o)$$

Thus from [24], [27], and [28],

$$[29] \qquad (\partial K/\partial X_p)_T = 0.1013 \frac{N_{H_2} D^0{}_{HeH_2}[C_P(p)/R - C_P(o)/R]/T}{1 - N_{H_2}(1 - D^0{}_{HeH_2}/D^0{}_{H_2H_2})}$$

Expressions for all of the quantities appearing in [20] have now been obtained.

Experimental Test of the Model

The assumption of spherical symmetry and the validity of the modified Kennard theory (eq. [12]) were tested experimentally using pure n-H_2 and pure He. Values of W_1 were measured electrically for T_W equal to 77, 195, and 273 K, for T_1 ranging from 277 to 373 K, and for P ranging from 1 to 30 Torr. These were corrected for heat losses through the thermistor leads and by radiation by measuring the power dissipated *in vacuo*.

The assumption of spherical symmetry implies that the 'cell constant' should be equal to $4\pi r_1$ as shown in [4]. To test this, values of $W_1{}^\infty$ were first obtained from plots to $1/W_1$ vs. $1/P$, as shown in Fig. 2. Although the curves for a given gas at fixed T_1 and T_W are not strictly linear, there is little error in extrapolating them to obtain $W_1{}^\infty$.

The values of the integral in [4] were evaluated numerically using the data tabulated by Liley (27, 28) for temperatures below 150 K and by using the form[3] $K(T) = AT^B$ for higher temperatures. Corresponding values of $W_1{}^\infty$ and $\int_{T_W}^{T_1} K\,dT$ are plotted in Fig. 3. It is evident that the data for He and n-H_2 lie on a common straight line through the origin. The value of r_1 derived from the slope is 0.0162 ± 0.0001 cm. The thermistor was actually somewhat ellipsoidal rather than spherical; its minor radius was 0.015 cm. Thus the assumption of spherical symmetry appears to be valid to a good approximation.

To test the validity of the modified Kennard theory we note that if, in [12], we set $K(T_1') = A(T_1')^B$ and if a does not vary appreciably over the range of temperature used, then a plot of $T_1 - T_1'$ vs. $(T_1')^{(1-B)} \int_{T_W}^{T_1'} K\,dT/P$ should give a single straight line for each gas, going through the origin, and having a slope of $(2 - a)/a \times 2/3 \times \lambda_0/r_1 \times 760/273 \times 1/A$. However, as shown in Fig. 4, the data for a given gas are best interpreted as lying on three separate lines, characterized by T_W but independent of T_1. Also, deviations from linearity occur at larger values of the abscissa. Examination of the latter phenomenon showed that in all cases the curves are linear through the origin for $P \geq$ ca. 4 Torr. We suggest that the deviations at lower pressures may arise either from the inadequacy of the Kennard expression for the temperature-jump, eq. [12], when $T_1 - T_1'$ is large or because of a temperature variation in the value of a.

By using published data on λ_0 for each gas the accommodation coefficients derived from the straight-line portions of the curves in Fig. 4 were calculated to be 0.25, 0.21, 0.20, and 0.22, 0.20, 0.17 for He and n-H_2 and T_W equal to 77, 195, and 273 K, respectively. Although the calculated values of a should not depend on T_W their magnitudes are not unreasonable.

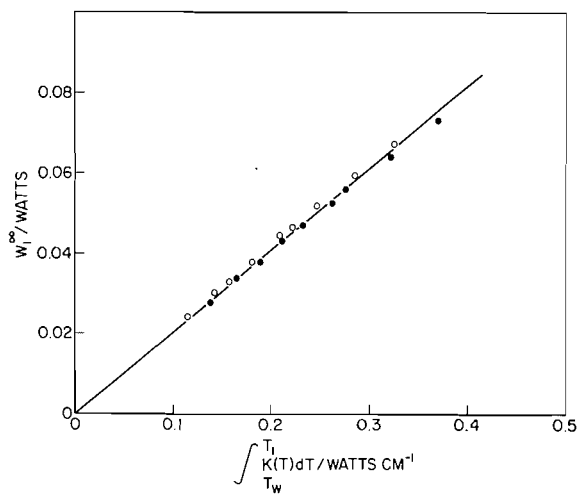

FIG. 3. Test of spherical symmetry at infinite pressure limit (eq. [4]). ●, n-H_2, ○, He.

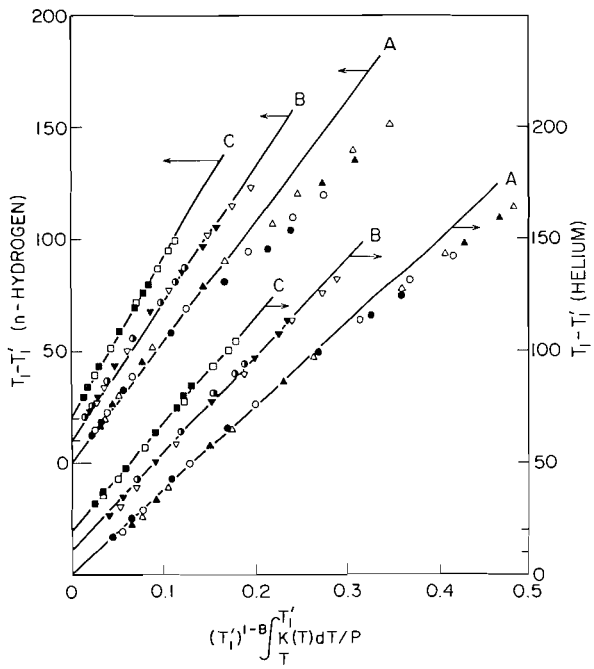

FIG. 4. Test of Kennard temperature-jump theory for He and n-H_2 and determination of accommodation coefficients (eq. [12]). (A) T_W = 77 K: ●, T_1 = 227 K, ○, T_1 = 302 K, ▲, T_1 = 327 K, △, T_1 = 352 K. (B) T_W = 195 K: ◑, T_1 = 302 K, ▼, T_1 = 327 K, ▽, T_1 = 352 K. (C) T_W = 273 K: ■, T_1 = 348 K, □, T_1 = 373 K.

The theoretical expression derived for the sensitivity dV/dX_p, given in [20], was tested experimentally for T_W = 77 K, for a number of different total pressures and values of T_1. This was done for pure H_2 and for dilute mixtures with $0.014 \leq N_{H_2} \leq 0.020$ in He. Various *ortho/para* compositions were obtained by subjecting known fractions of the gas mixture to passage through traps maintained at 77 K and containing a paramagnetic catalyst (Cr_2O_3 on alumina; Harshaw Chemical Company). It was found that H_2 in such portions was converted to the equilibrium composition, that is X_p = 0.5041.

In using pure H_2 the sensitivity was obtained by plotting ΔV, the change in V on equilibrating the sample, against ΔX_p, the corresponding change in X_p. For a fixed pressure these plots were linear through the origin except for $\Delta V > 0.5$ V. Deviations from linearity for larger values of ΔV were found to be due to appreciable changes in R_1, although the corresponding changes in T_1 were negligible. When the experimental values of ΔV were corrected for this purely electrical effect, the curves became linear throughout for all values of P from 1 to 30 Torr.

In the case of the dilute mixtures of H_2 in He the values of ΔV (and dV/dX_p) were, of course, much smaller, and to obtain a precision comparable to that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with pure hydrogen it was necessary to use samples with $X_p = 0.5041$.

In order to compare the values of the sensitivity for the various mole fractions, N_{H_2}, of hydrogen in the H_2–He mixtures, these were normalized by dividing by N_{H_2}. The validity of this procedure can be investigated by examination of [20]. The values of $K(T_1')$, $\int_{T_w}^{T_1'} K\,dT$, and $(\partial T_1'/\partial T_1)_{X_p}$ are very weak functions of N_{H_2} in the range used; in fact, using the values for pure He introduces very little error. On the other hand, the integrand $(\partial K/\partial X_p)_T$ and the term $(\partial T_1'/\partial X_p)_{T_1}$ in [20] are approximately proportional to N_{H_2}. This can be seen from [22] and [29] and noting that the ratio $D^0_{HeH_2}/D^0_{H_2H_2}$ ranged from 1.06 at 300 K to 1.11 at 77 K.

Experimental values of the sensitivity are shown as functions of pressure and for various values of T_1 in Figs. 5 and 6. The smooth curves labelled A are the theoretical ones given by [20], where the quantities in it are based on the modified Kennard theory of [12]. When $T_1 - T_1'$ was greater than 100 K a correction of up to 10% was used to compensate for the nonlinearity mentioned in connection with Fig. 4.

It can be seen from [12] that if we know λ_0 and

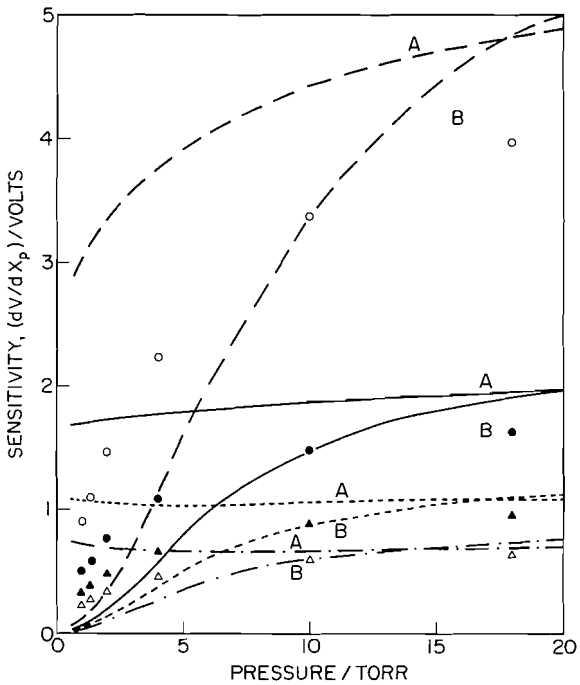

FIG. 5. Sensitivities for pure H_2 with $T_w = 77$ K. — — —, ○, $T_1 = 227$ K; ——, ●, $T_1 = 302$ K; ---, ▲, $T_1 = 327$ K; — · —, △, $T_1 = 352$ K. Points are measured values; smooth curves are theoretically constructed sensitivity functions. Curves A, eq. [20]; curves B, corrected for inefficient rotational accommodation, eq. [33].

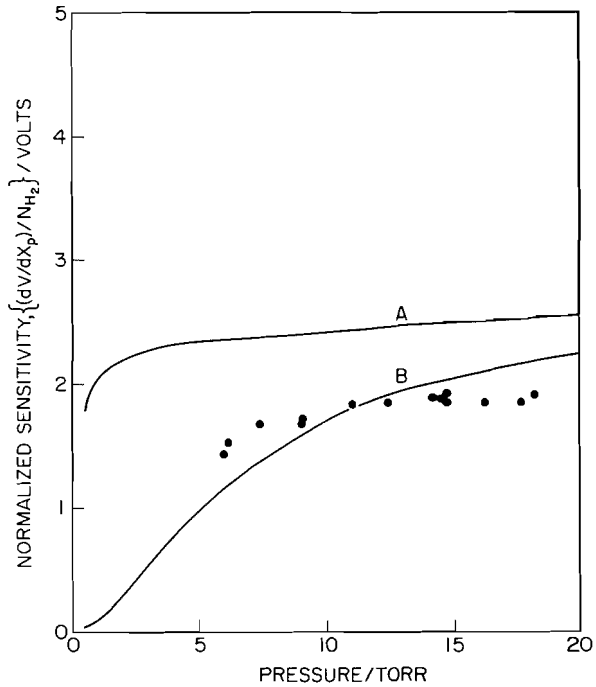

FIG. 6. Normalized sensitivity for He–H_2 mixtures (N_{H_2} = 0.014 to 0.020) with $T_w = 77$ K, $T_1 = 296.1$ K. Points are measured values; smooth curves are theoretically constructed sensitivity functions. Curve A, eq. [20]; curve B, corrected for inefficient rotational accommodation, eq. [33].

$K(T)$ then, once T_1, T_w, and P are chosen, the value of T_1' will be defined provided we know the values of a and r_1. These latter two can be considered to be semi-empirical quantities known from other measurements. In the present instance we set $r_1 = 0.0162$ cm and a at the values given for $T_w = 77$ K, viz. 0.22 for pure H_2 and 0.25 for the dilute mixtures in He. The values of T_1' were then determined by an iterative procedure. From these, all of the nonelectrical quantities in [20] were evaluated using [21], [22], and [29]. Values of C_P for H_2 were calculated directly from spectroscopic data (33) and diffusion coefficients were obtained from a recent literature survey (34). The integral $\int_{T_w}^{T_1'} (\partial K/\partial X_p)_T\,dT$ was evaluated numerically.

By choosing $E = 30.00$ V and obtaining $R_1(T_1)$ and $\alpha_1(T_1)$ from the calibration curve of the thermistor, the iteratively obtained values of T_1' also make it possible to calculate R_3. This follows by equating the electrical expression for W_1, $R_1E^2/(R_1 + R_3)^2$, to [3] after allowing for the heat losses by radiation and conduction through the leads, as described previously.

Discussion

The limiting high pressure behaviour of the de-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

tector (W_1^{∞}) is entirely in accord with the simple spherical model chosen. This agreement would be unlikely if significant convective heat transfer were present (12, 14), leading us to believe that convection is minimal under the experimental conditions used.

In the pressure range 1 to 30 Torr, the total heat transfer is in remarkably good agreement with the simplified form of the Kennard theory for temperature-jumps up to 100 K. The deviation found for larger values may arise from failure of the linear temperature gradient assumption in the Kennard theory. It could also result from the variation of a with T_1 and T_1'. Such variation has been found to occur (35), but in the present case it is not clear which interpretation of the deviation is correct. The other deviation from the theory, the apparent dependence of the accommodation coefficient on the wall temperature, is relatively minor, considering the wide range of wall temperatures used. This may be due to the assumption, in the Kennard theory, that the two surfaces act independently. The Knudsen theory (16, 23), which is valid at much lower pressures, considers the effects at both surfaces simultaneously. While our experimental conditions would be expected to lie outside the Knudsen range it is possible that the results could be better interpreted in terms of a theory covering the intermediate range.

On the basis of the modified Kennard theory it should be possible to predict the sensitivity of the detector to changes in *ortho/para* composition in pure H_2 and in dilute mixtures. Only two parameters should be required (in addition to physical data from other sources), the radius of the thermistor and its accommodation coefficient.

When the sensitivity is calculated in this way, agreement with experimental measurements is poor. Although this might be expected at low pressures (<4 Torr), the fact that the high pressure agreement is also poor leads us to question the way we applied the Eucken–Hirschfelder theory. If values of δ_f in [26] are calculated using the expression $[K_{H_2}]_{mono} = (15/4)(R/M)\eta$ (36), where the viscosity is obtained from a recent survey (37), we find they range from 0.86 at 100 K to 0.89 at 300 K. Thermal conductivity measurements (31), however, yield smaller values of δ_f. The effect of these differences in δ_f is to produce slight reductions (of from 1 to 5%) in the apparent thermal conductivity, which in the nondifferential measurements in this work would be virtually undetectable (although a reduction of K_{H_2} by the amount indicated would improve the already close agreement between the He and n-H_2 results in Fig. 2). The effect on the differential measurements (dV/dX_p), which depend on the internal energy contribution to thermal conductivity, would be very much larger. Various reasons for this effect have been proposed, including poor accommodation of internal energy at a surface, and rapid resonant energy exchange in the gas (31). The second reason is perhaps unlikely in the dilute H_2 in He case and we will therefore consider the first explanation only in this work.

Using a model outlined by Harris (31), we assume that from the thermistor surface out to a distance l, the gas behaves as a monatomic gas which only has translational energy, which it receives from the thermistor surface. The distance l represents the random walk distance through which the molecules go within the rotational relaxation time of H_2. Thus, on the average, the H_2 will convert its excess translational energy to rotational energy at a distance l from the thermistor surface and, from then on, will behave as a polyatomic gas.

A consequence of this is that the gas temperature at r_1, T_1', which was originally obtained from [3] using measured values of W_1, is incorrect, and should be replaced by a corrected temperature, T_1^c. The two are related by the integral equation

$$[30] \qquad \int_{T_1''}^{T_1^c} [K]_{mono}\, dT = \int_{T_1''}^{T_1'} K\, dT$$

obtained on integrating [2] and defining T_1'' as the gas temperature at $r_1 + l$, and $[K]_{mono}$ as the thermal conductivity in the absence of internal energy contributions.

For dilute mixtures of H_2 in He, we assumed that K is equal to K_{He}, so that the above definition means that $[K]_{mono} = K$, for the dilute H_2 in He and $T_1^c = T_1'$. In the case of pure H_2, however, $T_1^c \neq T_1'$. Within the temperature range $T_1'' \leq T \leq T_1^c$, K is independent of X_p, so that

$$[31] \qquad (\partial K/\partial X_p)_T = 0$$

and

$$[32] \qquad \int_{T_W}^{T_1^c} (\partial K/\partial X_p)_T\, dT = \int_{T_W}^{T_1''} (\partial K/\partial X_p)_T\, dT$$

Using these results, together with the relationship between $(\partial T_1^c/\partial X_p)_{T_1}$ and $(\partial T_1^c/\partial T_1)_{X_p}$ (cf. eq. [22]), we may write a corrected sensitivity analogous to [20],

$$[33] \quad (dV/dX_p)_c = -\frac{[ER_1R_3/(R_1+R_3)^2]\displaystyle\int_{T_W}^{T_1''} (\partial K/\partial X_p)_T\, dT \left\{1 - \frac{(T_1 - T_1^c)[K]_{mono}(\partial T_1^c/\partial T_1)_{X_p}}{W_1/4\pi r_1}\right\}}{[(R_1 - R_3)/(R_1 + R_3)]W_1/4\pi r_1 + [K]_{mono}(\partial T_1^c/\partial T_1)_{X_p}/\alpha_1}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where we use $W_1/4\pi r_1$ in place of $\int_{T_w}^{T_1'} K\,dT$.

By equating $(dV/dX_p)_c$ to the measured sensitivity at one mid-range pressure, it is possible to solve numerically the simultaneous nonlinear eqs. [30] and [33] for T_1^c and T_1''. The value of l is then obtained by integrating [2] between the limits $T_W \leq T \leq T_1''$ $(\infty \geq r \geq r_1 + l)$. For the dilute H_2 in He results, a pressure of 12 Torr was chosen and gave a distance $l = 0.006261$ cm, corresponding to a relaxation time of 2.5×10^{-9} atm s. For pure H_2, and a pressure of 10 Torr, the distance l was remarkably constant for the four values of T_1 used, with an average value of 0.01279 ± 0.00010 cm. This gave relaxation times ranging from 8.4×10^{-9} atm s, for $T_1 = 277$ K, to 6.0×10^{-9} atm s, for $T_1 = 352$ K. These results are comparable to those obtained by more direct measurement (38).

By assuming, further, that l depends only on pressure for a given gas, and setting $l = 0.07513/P$ cm for the dilute H_2 in He mixtures and $l = 0.1279/P$ cm for pure H_2 (where P is the pressure in Torr), we may calculate T_1'', T_1^c, and hence $(dV/dX_p)_c$ as a function of pressure. These corrected sensitivity functions are compared to experimental results in Figs. 5 and 6 (curves labelled B). The pressure dependence of the scaled curves is more realistic, although they appear to overestimate the effect of inefficient rotational accommodation. This is not surprising since it was assumed that the accommodation coefficient for internal energy is equal to zero (i.e. monatomic behaviour out to a distance of l), whereas it is likely that it is non-zero, although less than the observed values (39). In principle, the model could be further refined, but it is doubtful whether it would produce any useful additional information.

Conclusions

The thermal conductivity detector, based on a small bead thermistor, has been shown to be adequately described by simple heat transfer theory over a wide range of conditions, when the effects of surface accommodation are considered. Differential measurements (dV/dX_p), which depend on the effect of the small differences in rotational energy of o-H_2 and p-H_2 on the thermal conductivity, are not well described by the simple theory and it was necessary to take into account the efficiency of rotational relaxation, both on the thermistor surfaces and in the gas phase. By assuming negligible rotational relaxation on the thermistor surface, introduction of a single additional parameter, the apparent gas phase relaxation rate for rotational energy, produces theoretical sensitivity curves which are in closer agreement with experiment, and which may be useful in a predictive sense as well.

Acknowledgement

The authors would like to thank Dr. Simon Wauchop for his considerable contributions to the redesigning of the thermal conductivity detector used in this study and his initial work on explaining its operation.

Apparent molal heat capacities and volumes of amino acids in aqueous polyol solutions

GIUSEPPA DIPAOLA[1] AND BERNARD BELLEAU[2]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H2A 2K6

Received November 17, 1977

GIUSEPPA DIPAOLA and BERNARD BELLEAU. Can. J. Chem. **56**, 1827 (1978).

Densities (24°C) and volumetric specific heats (25°C) were measured for amino acids (0.05–0.5 *m*) containing apolar side chains in water, and in aqueous solutions of glycerol, mannitol, sorbitol, NaCl, urea, and Gu·HCl, with a flow densimeter and flow microcalorimeter respectively.

The derived apparent molal quantities and transfer functions of the amino acids in aqueous polyol solutions reveal no specificities which might explain the origin of the unique behavior of polyols in protein systems. However, the study did reveal a regular increase in the structure-making ability of the amino acid as the hydrophobicity of the side chains increased. This structure-making tendency was reduced significantly in dilute solutions of the higher polyols.

GIUSEPPA DIPAOLA et BERNARD BELLEAU. Can. J. Chem. **56**, 1827 (1978).

On a mesuré les densités (24°C) et les chaleurs spécifiques volumétriques (25°C) d'acides aminés (0.05–0.5 *m*) contenant des chaînes latérales non-polaires dans l'eau et dans des solutions aqueuses de glycérol, de mannitol, de sorbitol, de NaCl, d'urée et de Gu·HCl en faisant appel respectivement à un densimètre à écoulement et à un microcalorimètre à écoulement.

Les quantités molales apparentes que l'on peut en tirer et les fonctions de transfert des acides aminés dans les solutions de polyol aqueux ne révèlent aucune spécificité qui pourrait expliquer l'origine du comportement unique de polyols dans des systèmes de protéine. Toutefois, les études mettent en évidence qu'il existe une relation entre l'augmentation réguliére de l'habilité à produire des structures par des acides aminés et l'augmentation de l'hydrophobicité de la chaîne latérale. Il y a une réduction importante de cette tendance à former des structures lorsque l'on travaille dans des solutions diluées de polyols de poids moléculaires élevés.

[Traduit par le journal]

Introduction

Amino acids have been useful models for understanding the thermodynamic behavior of proteins, especially in determining apolar group contributions to the biopolymer's conformational stability. This is important because of the unique role played by hydrophobic hydration in the denaturation of proteins (1).

Standard free energies have been determined from solubility measurements of several amino acids in various solvents (2). Data on heats of transfer (3) and standard free energies of transfer from water to mixed aqueous solvents are also available (4). Until recently (3, 5–7), however, no reliable determination of partial molal heat capacities of amino acids in water existed.

The present work, which describes calorimetric and volumetric data on several α-amino acids (with apolar side chains) in a number of polyol–water systems, was undertaken in order to help elucidate possible correlations between structural interactions of amino acids in aqueous polyol solutions and the stabilizing effects of polyols on proteins. In previous publications we reported results of a similar study on other aqueous polyol systems (8, 9).

Experimental

Heat capacities were measured with a flow microcalorimeter capable of detecting differences between the volumetric specific heat of a solution and that of a reference solvent to $\pm 3 \times 10^{-5}$ J K^{-1} cm^{-3}. Densities were determined with a flow digital densimeter sensitive to $\pm 3 \times 10^{-6}$ g cm^{-3}. Details of the experimental procedure have been published previously (8). Apparent molal quantities (ϕ_c, ϕ_v) were calculated in the usual way (8).

Reagent grade polyhydric alcohols were used without further purification: glycerol (Fisher Certified Spectroanalyzed); ethylene glycol and 1,2-propanediol (Matheson, Coleman and Bell, Chromatoquality); 1,3-propanediol (Eastman Kodak Reagents); D-arabitol, D-xylitol, ribitol (Nutritional Biochemicals); D-mannitol, D-sorbitol, *myo*-inositol, sucrose (Fisher certified reagents), and *meso*-erythritol (Aldrich).

Reagent grade amino acids D-alanine, D- and L-valine, and

[2]Author to whom correspondence should be addressed.

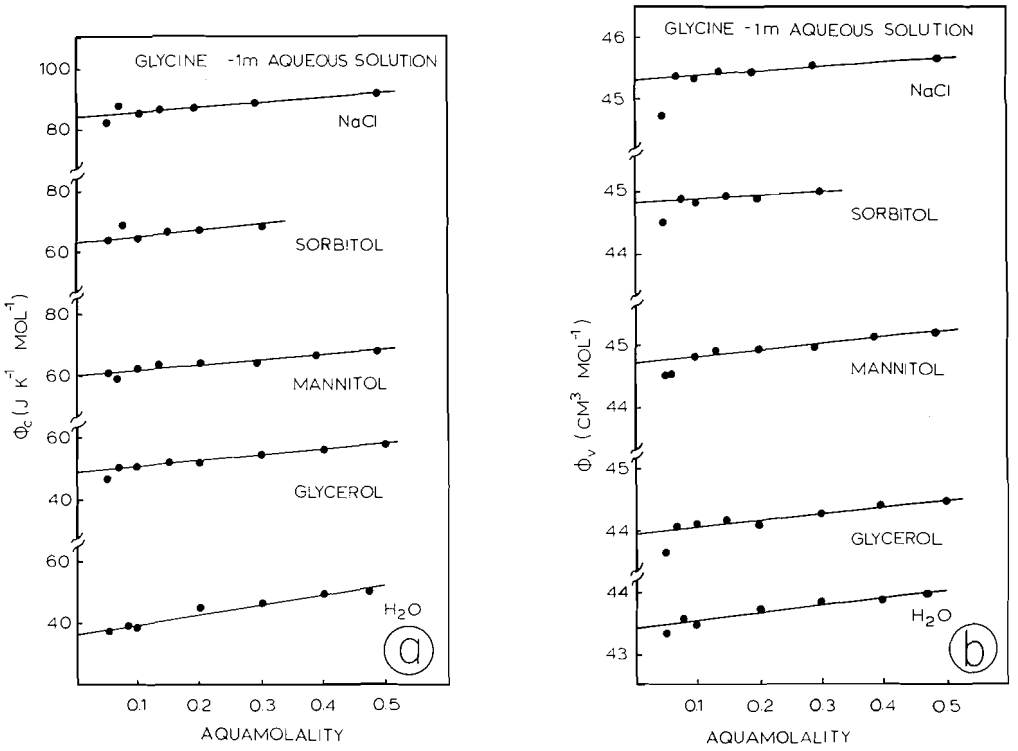

FIG. 1. Apparent molal quantities of glycine in 1 *m* aqueous solution. (*a*) ϕ_c at 25°C; (*b*) ϕ_v at 24°C.

L-leucine were obtained from Nutritional Biochemicals, L-alanine from Aldrich, DL-α-aminobutyric acid from Sigma, DL-norleucine and L-isoleucine from Eastman Kodak, glycine from Fisher Scientific, and DL-norvaline from BDH Chemicals Limited.

Urea (Schwarz-Mann, Ultra-Pure), guanidine·HCl (Sigma), and NaCl (Fisher certified reagents) were used without further purification.

Results

Apparent molal heat capacities (25°C) and volumes (24°C) were derived for several amino acids containing apolar side chains (glycine, D- and L-alanine, DL-α-aminobutyric acid, D- and L-valine, L-leucine, DL-norleucine, and DL-norvaline) in water, 1 *m* and 2 *m* glycerol, and 1 *m* mannitol, sorbitol, NaCl, urea, and Gu·HCl.[3]

The amino acids exhibit a linear dependence of ϕ_c and ϕ_v on concentration in the range of 0.05 to 0.5 *m*. Typical results (for glycine) are illustrated graphically in Fig. 1.[3] Results of a linear regression analysis of the data[4] for all the amino acids are summarized in Table 1; the standard apparent molal quantities and excess coefficients (B_v and B_c) are included.[5] The estimated uncertainties (based on duplicate measurements of 4–7 points) on the infinite dilution properties ϕ_c^0 and ϕ_v^0 are ± 1 J K^{-1} mol^{-1} and $\pm(0.05$–$0.1)$ cm^3 mol^{-1} respectively.

Table 2 compares the present results with data from the recent literature. The heat capacity data were taken from the work of Spink and Wadso (3) and Ahluwalia *et al.* (7); the volumetric data were taken from the papers of Gopal *et al.* (4), Ahluwalia *et al.* (7), and Ellerton *et al.* (10). References to other work in this area can be found in ref. 7. The present standard apparent molal quantities are in reasonable agreement with the previously determined values. Because of their low solubility in water, only a few experimental points at high dilution were obtained for leucine and norleucine. For this reason, the estimated uncertainty for these compounds is much higher than for the rest.

Results for heat capacities and volumes of the

[3]Complete sets of tabular data for d_0/d, σ/σ_0, ϕ_v, and ϕ_c are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[4]Data points outside experimental uncertainty were not considered in the analysis.

[5]Results were fitted by linear regression analysis to equations of the form:

$$[1] \qquad \phi_x = \phi_x^0 + B_x m$$

where m represents the aquamolal concentration of the amino acid and ϕ_x represents the appropriate apparent molal quantity. For most of the excess coefficients, B_x, only the magnitude is significant.

TABLE 1. Concentration dependence of amino acids in 1.0 *m* aqueous polyols

Amino acid	Solvent	ϕ_c^0 (J K^{-1} mol^{-1}) (25°C)	B_c	ϕ_v^0 (cm^3 mol^{-1}) (24°C)	B_v

amino acids in the mixed solvents could not be compared with literature values, since no such data exist. Any work that has been reported was carried out either at high concentrations (11) or is of dubious reliability (11, 12) because of the magnification of experimental error at low concentrations.

No significant differences are observed in the limiting thermodynamic behavior (ϕ_c^0, ϕ_v^0) of L- and D-configurations of amino acids in solution, e.g. compare D- and L-alanine, and D- and L-valine (Table 1).[6]

Apparent molal heat capacities and volumes of transfer of 0.1 *m* amino acids from water to the various aqueous solvents are summarized in Table 3.

[6]No difference is expected for mirror images; only for racemic, if solute–solute interactions exist, or if the asymmetric polyol interacts directly with the D- or L-form.

TABLE 3. Thermodynamic transfer functions of 0.1 *m* amino acids to 1 *m* aqueous solvent

Amino acid	Solvent	$\Delta\phi_{c\ tr}$[a] (J K^{-1} mol^{-1}) (25°C)	$\Delta\phi_{v\ tr}$[a] (cm^3 mol^{-1}) (24°C)

	NaCl	20.7	1.80

[a]The estimated uncertainties on $\Delta\phi_{c\ tr}$ and $\Delta\phi_{v\ tr}$ are approximately ±2 J K^{-1} mol^{-1} and ±(0.1–0.2) cm^3 mol^{-1} respectively. These uncertainties become respectively ±(4–8) J K^{-1} mol^{-1} and ±0.2 cm^3 mol^{-1} for leucine and norleucine.
[b]Transfer functions of 0.07 *m* amino acid.

Positive volumes of transfer are observed in all cases. The heat capacities of transfer are less systematic, however. Whereas negative values of $\Delta\phi_{c\ tr}$ values are observed for all amino acid transfers (except glycine) to glycerol solutions, the $\Delta\phi_{c\ tr}$ values are positive for all the amino acid transfers (except leucine and norleucine)[7] to the other solvent systems investigated.

[7]It must be noted that the uncertainties for leucine and norleucine are approximately double those for the other amino acids.

Discussion

Standard Apparent Molal Quantities

A consideration of the infinite dilution properties, ϕ_c^0 and ϕ_v^0, for the α-amino acids (Ala, Aba Norval, and Norleu) shows that the CH_2 contribution is similar to that found for aliphatic hydrocarbons (13), 86 J K^{-1} mol^{-1} and 15.8 cm^3 mol^{-1} respectively. The same conclusion was reached recently by Ahluwalia *et al.* (7). These results suggest that the electrostrictive effects of the zwitterion portion of the molecule do not seriously hinder the 'structure-enhancing' characteristics of the neighboring apolar groups. However, care must be exercised in predicting additivity relationships from group contribution data alone. The extrapolated values for ϕ_c^0 and ϕ_v^0 for glycine are significantly higher than the experimentally measured values.

The CH_2 group incremental contribution in mixed solvents (1 *m* glycerol and 1 *m* mannitol) is slightly lower than in water (85 and 80 J K^{-1} mol^{-1} respectively), suggesting a decrease in structural interactions in polyol–water as compared to pure water.

Data on amides, carboxylic acids, amines, and alcohols seem to indicate a negligible effect of branching from primary to secondary carbons (14). The data for leucine and norleucine show no effect within experimental error. However, the valine–norvaline data (Table 2) show an obvious branching effect (lower ϕ_c^0 and ϕ_v^0 for the branched isomer). One must keep in mind that a 1% impurity in the amino acid can probably cause an uncertainty of 5–10 J K^{-1} mol^{-1} in ϕ_c^0 (7).

Concentration Dependence

The concentration dependence (0.05–0.5 *m*) of ϕ_c ϕ_v for the amino acids in the various solvent systems is linear and small, and decreases slightly with increasing size of the aliphatic side chain. One would intuitively expect a greater concentration dependence as the hydrophobicity of the molecule increases, and also a nonlinear dependence, since the structure-making ability of the alkyl side chains should decrease with increasing amino acid concentration. However, this is not observed. Gucker and Allen (15) have also found that the partial molal heat capacity ($C_{p,2}$) for glycine and alanine is relatively insensitive to changes in concentration up to several molalities. A compensation mechanism between opposing electrostrictive and hydrophobic forces might provide a partial explanation.

Transfer Functions

There is an excellent correlation between the increase in hydrophobicity of the amino acid alkyl side chain and the trends in the apparent molal heat capacity of transfer to aqueous glycerol solutions

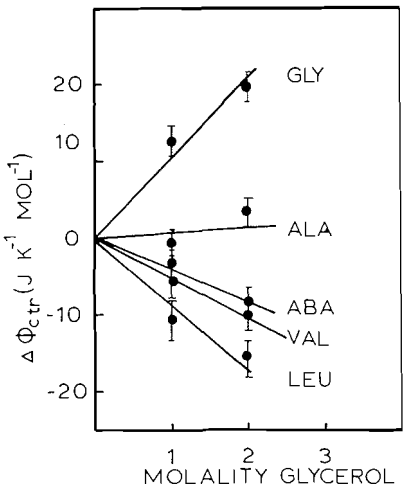

FIG. 2. Apparent molal heat capacities of transfer (25°C) of 0.1 *m* amino acids from water to aqueous glycerol solutions.

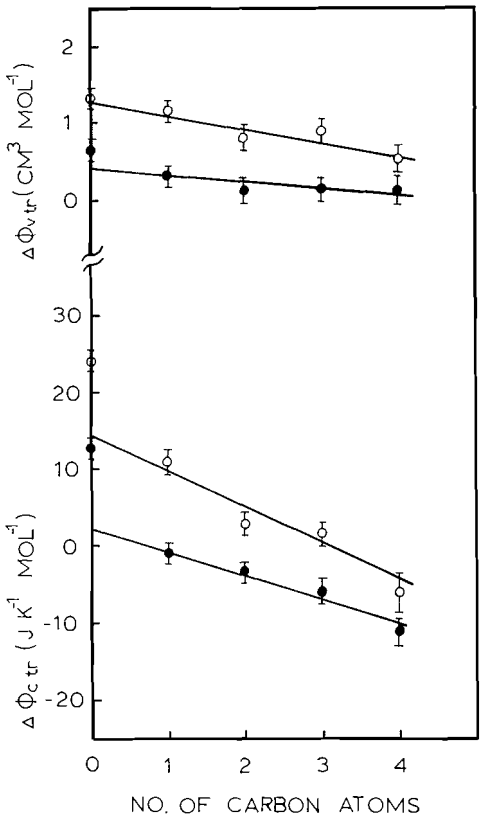

FIG. 3. Apparent molal volumes (24°C) and heat capacities of transfer of 0.1 *m* amino acids* to 1 *m* glycerol (●) and 1 *m* mannitol (○) solutions: *n = 0 ≡ Gly; 1 ≡ Ala; 2 ≡ Aba; 3 ≡ Val/Norval; 4 ≡ Leu/Norleu.

(Fig. 2), which suggests that the transfer functions are reflecting changes in structural interactions. The results can be explained in the manner already proposed for the transfer of the electrostrictive structure breaker, NaCl, and the hydrophobic probe, *n*-Bu_4NBr, to aqueous glycerol (8). Whereas glycine behaves as a typical structure breaker in glycerol–water (i.e. the solution behavior is dominated by the zwitterion portion), α-aminobutyric acid, valine, and leucine behave as typical hydrophobic structure makers (i.e. the solution behavior is dominated by the apolar portion). The structure-altering characteristics of alanine in aqueous glycerol are borderline.

Not only are the structure-altering characteristics of the amino acids differentiated by the transfer functions (Fig. 2), but the degree of structural order in different solvents is also differentiated (Fig. 3). Any differences that might occur in the transfer functions because of chain-branching effects, or differences between stereoisomers, are hidden within the experimental uncertainty. In general, the transfer parameters become increasingly more positive in the following order: glycerol–mannitol–sorbitol–urea–Gu·HCl–NaCl (Table 3). These results reflect the greater structure-breaking tendencies as one proceeds from glycerol to NaCl solutions, and the lowered structure-making ability of the apolar side chains as the degree of structural order in solution decreases. However, no definitive conclusions about changes in structural interactions in such solutions can be reached until more specific models for mixed aqueous solutions become available.

The density, electrical conductivity, freezing point, and viscosity of mixtures of trifluoromethanesulfonic acid and water

RONALD CORKUM AND JOHN MILNE

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received January 16, 1978

RONALD CORKUM and JOHN MILNE. Can. J. Chem. **56**, 1832 (1978).

Density, viscosity, specific conductivity, and freezing point measurements over the whole composition range of water – trifluoromethanesulfonic acid mixtures are reported. A maximum in viscosity and minimum in specific conductivity are observed at the composition corresponding to the monohydrate, $H_3O^+SO_3CF_3^-$, and a maximum deviation from the ideal density is found at the composition corresponding to $H_5O_2^+SO_3CF_3^-$. The freezing point curve gives evidence for four hydrates with 1:1, 2:1, 4:1, and 6:1 water/trifluoromethanesulfonic acid mole ratios. An incongruent melting hydrate, probably 2:1 acid to water mole ratio is also indicated.

RONALD CORKUM et JOHN MILNE. Can. J. Chem. **56**, 1832 (1978).

On rapporte des mesures de densité, de viscosité, de conductivité spécifique et de point de fusion à plusieurs compositions de mélanges d'eau et d'acide trifluorométhanesulfonique. On observe une viscosité maximum et une conductivité spécifique minimum à une composition correspondant au monohydrate, $H_3O^+SO_3CF_3^-$, et une déviation maximale de la densité idéale à une composition correspondant à $H_5O_2^+SO_3CF_3^-$. Les courbes de point de fusion donnent des indications à l'effet que quatre hydrates avec des rapports molaires de 1:1, 2:1, 4:1 et 6:1 eau/acide trifluorométhanesulfonique peuvent exister. Il y a aussi des indications à l'effet qu'un hydrate de point de fusion incongruent et de composition 2:1 d'acide par rapport à l'eau existe aussi.

Introduction

Physical measurements on trifluoromethanesulfonic acid (HTFMS) and its mixtures with some other solvents have been the subject of several studies. Haszeldine and co-workers (1, 2) have shown that the acid is completely dissociated in water and they have isolated the monohydrate, which may be formulated as $H_3O^+SO_3CF_3^-$, on the basis of its ir spectrum. Gramstad (3) has shown that HTFMS is stronger than perchloric acid in acetic acid medium and Russell and Senior (4) established that the acid is comparable in acid strength to chlorosulfuric acid but weaker than fluorosulfuric acid in 100% sulfuric acid as solvent. Fialkov and Ligus (5) have made density, viscosity, and electrical conductivity measurements on sulfuric acid – HTFMS mixtures and found evidence for a 1:1 compound which they formulate as $H_3SO_4^+SO_3CF_3^-$.

The kinetics of decomposition of HTFMS in aqueous solutions have been studied and the acid has been shown to be remarkably stable (6). No systematic studies have been made of the physical properties of aqueous HTFMS solutions over the complete composition range. This paper concerns the density, viscosity, electrical conductivity, and freezing point diagram of water–HTFMS mixtures.

Experimental

HTFMS (3M Company) was purified by double distillation with HTFMS anhydride added in the initial step. The fraction boiling at 162°C was collected. The anhydride was prepared by distillation of the acid from P_2O_5 (2). Distilled and deionized water were used throughout. For solutions at the acid rich end of the composition diagram, all transfers were made in a dry box.

Density Measurements

The density measurements were made at 25.0 ± 0.1°C in 25 ml volumetric flasks, which were recalibrated at the same temperature with distilled water. The average deviation in these density measurements is ±0.002 g/ml.

Viscosity Measurements

The viscosities were measured at 25.0 ± 0.1°C using an Ostwald viscometer. The viscometer was thoroughly cleaned before use and was calibrated with distilled water. The same volume of liquid was used in all runs. The viscosity was calculated from the average of from 2 to 5 runs. The average deviation of the measurements was ±0.0002 centipoise (cP). It should however be born in mind that a ±0.1°C change in temperature can cause a ±0.2% change in the viscosity of water.

Electrical Conductivity Measurements

Electrical conductivity was measured using an RC18 conductivity bridge from Industrial Instruments. The cell used has been described earlier (7). The measurements were made at 25.00 ± 0.01°C.

Freezing Point Measurements

Freezing points were measured in a vacuum jacketed cryoscope as described earlier (8). Temperature was measured with a chromel–alumel thermocouple with reference junction at 0°C. A Hewlett-Packard multimeter (Model 3465A) was used to measure potential. The thermocouple was calibrated at ice temperature and at the sublimation temperature of carbon dioxide. Freezing points were measured with temperature descending and in most instances, particularly where the

cooling curve of the solid–liquid mixture was steep, the freezing temperature was confirmed by remelting the mixture. The cryoscope was cooled with liquid air for all measurements except those above 5°C where ice was used. The initial cooling rate was set at 0.5°C/min, by adjusting the vacuum in the jacket of the cryoscope.

Results and Discussion

The experimental measurements of density, viscosity, electrical conductivity, and freezing points are all available as supplementary material.[1] Interpolated electrical conductivity values over the complete composition range are given in Table 1. Freezing point inflections are given in Table 2.

The results of the density measurements are shown in Fig. 1. Measurements could be made over the range of acid mole fraction 0.44 to 0.575 although solid monohydrate is the stable in this region. The densities in this range are, therefore, those of a supercooled mixture. The density found for the pure acid, 1.696 g/ml, is in excellent agreement with values reported earlier (5, 9). The mixtures show pronounced positive deviation from ideality and, thus, there is a strong interaction between water and HTFMS as expected. Maximum deviation from ideality occurs at 1:2 HSO_3CF_3/H_2O mole ratio.

The measurements of viscosity are plotted in Fig. 2. The viscosity of the pure acid was found to be 2.97 cP. This value is higher than that found by Fialkov and Ligus (5) (2.87 cP). It was not possible to measure the viscosity of the mixtures between acid mole fractions 0.44 and 0.58 at 25°C due to the formation of solid $H_3O^+SO_3CF_3^-$. The very large positive deviations from ideality indicate that the interaction is strong.

The electrical conductivity of dilute solutions of both HTFMS in water (1) and water in the acid (10) has been investigated. In both instances strong electrolyte behaviour has been observed as a result of the protonation reaction:

$$H_2O + HSO_3CF_3 \rightarrow H_3O^+ + SO_3CF_3^-$$

The trifluoromethanesulfonate anion ($TFMS^-$) in HTFMS conducts electricity by a proton transfer mechanism (10)[2] as does the hydronium cation in water. The specific conductivities of water – HTFMS acid mixtures at 25°C are given in Fig. 3. The monohydrate did not crystallize from the solutions with N_{HTFMS} between 0.44 and 0.575, unlike in the case of the viscosity measurements, and specific conductivities in this range are those of supercooled mixtures. The specific conductivity composition diagram exhibits 2 maxima at 0.063 and 0.855 and a minimum at 0.5 mole fraction of acid. As acid is added to water the conductivity increases to its maximum as the concentration of conducting species which conduct by proton transfer increases. In as much as trifluoromethanesulfonic acid is a sufficiently strong acid to protonate even the isolated water molecule (as opposed to bulk water), the ion concentration will in-

0.685	Peritectic	−17.5
1.000	Compound HTFMS	−43.53

[a]A peritectic and eutectic are indicated also near 0.85 mole fraction of acid.

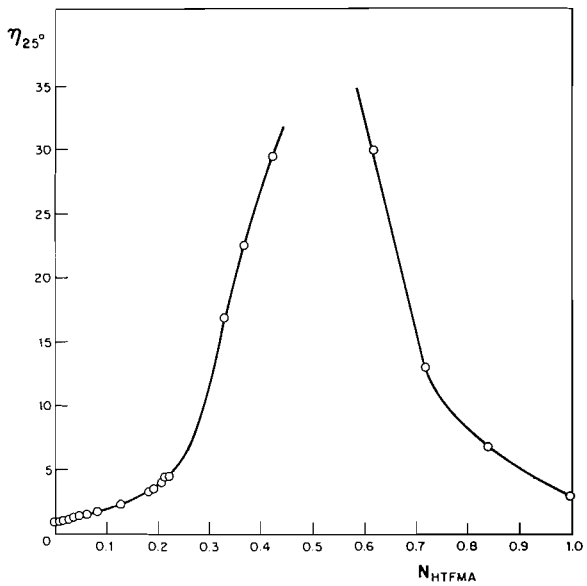

FIG. 2. The viscosity of H_2O–HTFMA mixtures at 25°C.

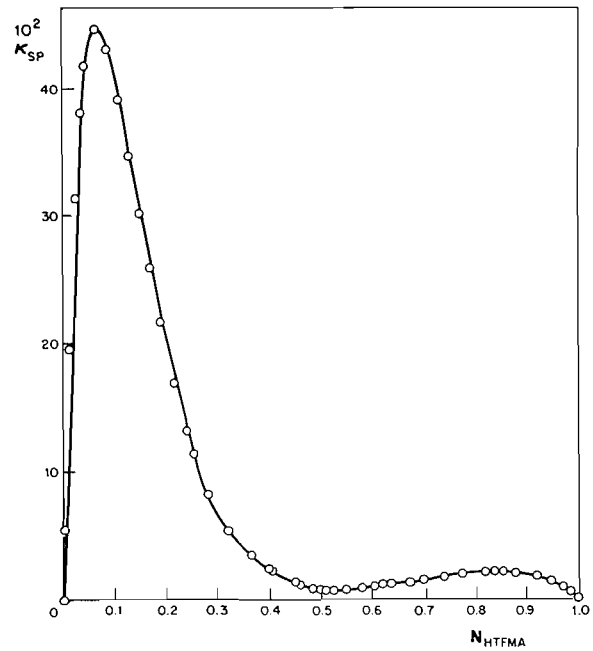

FIG. 3. The specific conductivity of H_2O–HTFMA mixtures at 25°C.

crease with increasing mole fraction of acid. Therefore, the decrease in specific conductivity after 0.063 mole fraction acid is not due to a decrease in the concentration of ions but is a result of increasing viscosity, electrophoretic and relaxation effects, if these are not offset by a change in dielectric constant, and, no doubt most importantly, the decreased efficiency of the proton transfer mechanism as the coordination of the hydronium ion changes from that of only water molecules, which are able to propagate the chain, to coordination with neighbouring $TFMS^-$ anions. The conductivity falls to a minimum at 1:1 HTFMS/water then, as the hydronium ions in the coordination shell of the $TFMS^-$ anion are replaced by HTFMS molecules with increasing acid mole fraction, the proton transfer mechanism, which can occur in bulk HTFMS via the solvent anion, becomes

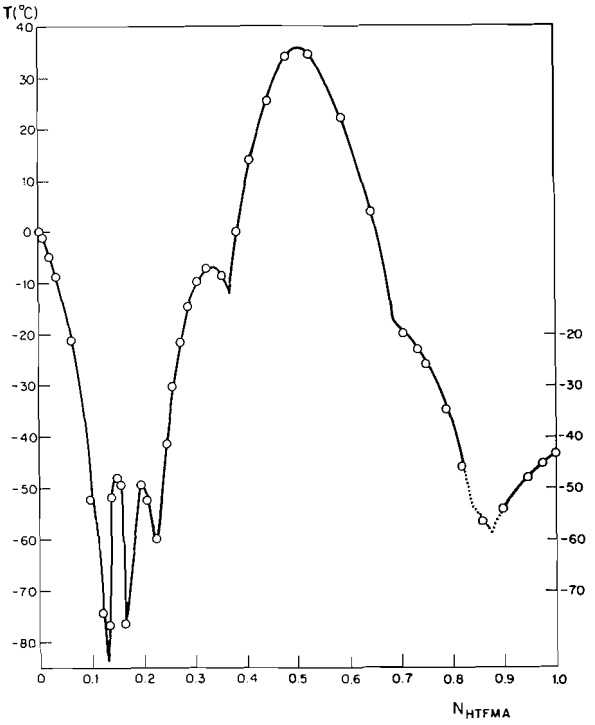

FIG. 4. The freezing point diagram for H_2O–HTFMA mixtures.

more important and the conductivity rises to a maximum. Decreasing viscosity, electrophoretic and relaxation effects will also play a role here. Finally, the conductivity begins to decrease again after 0.855 mole fraction of acid due to a decrease in ion concentration until the conductivity for pure acid is reached. Similar behaviour is observed for sulfuric acid – water mixtures (11).

The freezing point diagram for HTFMS–H_2O mixtures is shown in Fig. 4 and the freezing points of the eutectics, peritectics, and compounds formed are given in Table 2. The diagram gives evidence for trifluoromethanesulfonates of H_3O^+, $H_5O_2^+$, $H_9O_4^+$, and $H_{13}O_6^+$. These hydrates parallel those found in the H_2O–H_2SO_4 system (13) except that no evidence for a trihydrate is found in the H_2O–HTFMA system. The monohydrate is well established (2, 12) and its freezing point was reported by Gramstad and Haszeldine (2) at +34°C. The ir spectrum of the monohydrate confirms that the correct formulation is $H_3O^+SO_3CF_3^-$ (2, 12).

Evidence for a fifth hydrate is the peritectic point at 0.685 mole fraction of acid which indicates the existence of an incongruent melting compound, perhaps $H_2O{\cdot}2$HTFMA. Because of insufficient detail in the diagram near 0.85 mole fraction of acid, no definite conclusions can be drawn as to the exact location of the inflection points. Perchloric acid is known to form a hydrate of composition $H_2O{\cdot}4HClO_4$ (14) and a similar compound may be formed in the H_2O–HTFMA system.

A. GAVIN MCINNES, DONALD G. SMITH, JOHN A. WALTER, JEFFREY L. C. WRIGHT, LEO C. VINING, and GUY P. ARSENAULT. Can. J. Chem. **56**, 1836 (1978).

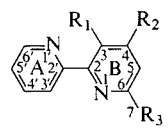
Analysis by ^1H and ^{13}C nmr spectrometry showed that caerulomycin D, a new metabolite isolated from *S. caeruleus*, possessed a novel ring system and had the structure (2*S*,3*R*,4*R*,4a*S*,10a*S*)-3,4,4a,10a-tetrahydro-4-hydroxy-3,4a-dimethoxy-2-methyl-9-(2-pyridyl)-2*H*-pyrano[3′,2′:5,6]-*p*-dioxino[2,3-*c*]pyridine-7-carboxaldehyde (*E*)-oxime.

A. GAVIN MCINNES, DONALD G. SMITH, JOHN A. WALTER, JEFFREY L. C. WRIGHT, LEO C. VINING et GUY P. ARSENAULT. Can. J. Chem. **56**, 1836 (1978).

L'analyse des spectres rmn du ^1H et du ^{13}C montre que la caerulomycine D, un nouveau métabolite isolé du *S. caeruleus*, possède un nouveau système cyclique et que sa structure correspond à l'oxime (*E*) du tétrahydro-3,4,4a,10a hydroxy-4 diméthoxy-3,4a méthyl-2 (pyridyl-2)-9 2*H*-pyrano[3′,2′:5,6]*p*-dioxino[2,3-*c*]pyridinecarboxaldéhyde-7 (2*S*, 3*R*, 4*R*, 4a*S*, 10a*S*).

[Traduit par le journal]

A previous paper (1) describes the isolation from cultures of *Streptomyces caeruleus* of several metabolites related to the antibiotic caerulomycin A for which the structure **1***a* has been established (2). Two



1*a* $R_1 = H, R_2 = OCH_3, R_3 = CH{=}NOH$
1*b* $R_1 = H, R_2 = OCH_3, R_3 = C{\equiv}N$
1*c* $R_1 = H, R_2 = OCH_3, R_3 = CH{=}NOAc$
2 $R_1 = OH, R_2 = OCH_3, R_3 = CH{\equiv}NOH$
3*a* $R_1 = OCH_3, R_2 = OCH_3, R_3 = CH{=}NOH$
3*b* $R_1 = OCH_3, R_2 = OCH_3, R_3 = C{\equiv}N$
3*c* $R_1 = OCH_3, R_2 = OCH_3, R_3 = CH{=}NOAc$

of the new compounds, caerulomycins B and C, were concluded from spectroscopic evidence to have structures **2** and **3***a*. The rationale for assigning resonances in the ^1H and ^{13}C nmr spectra of 2,2′-dipyridyl and the metabolites was explained and forms the basis for much of the additional work on the structure of the fourth metabolite, caerulomycin D, which is reported here.

Caerulomycin D, $C_{19}H_{21}N_3O_7$, displayed a characteristic red color with ferrous ions, and showed absorption maxima in the ultraviolet and infrared regions consistent with a 2,2′-dipyridyl structure (1). An increment of 2 mass units in the molecular ion after gas phase deuterium exchange indicated two active hydrogens in the molecule. Mild acetylation yielded a monoacetate which showed a carbonyl stretching absorption at 1785 cm^{-1} but retained a hydroxyl stretching absorption maximum at 3525 cm^{-1}; more vigorous conditions gave a nitrile (ν_{max} 2230 cm^{-1}) lacking these absorption maxima but showing a carbonyl stretching absorption at 1760 cm^{-1}. This behavior is accounted for if caerulomycin D possesses an aldoxime group and a less acidic hydroxyl function which is acetylated under vigorous conditions.

The structures of caerulomycin D (**4***a*), caerulomycinonitrile D monoacetate (**4***b*), and caerulomycin D monoacetate (**4***c*) have been elucidated mainly by ^1H and ^{13}C nmr studies. Earlier observations (1) on 2,2′-dipyridyl, caerulomycin C (**3***a*), its nitrile (**3***b*) and monoacetate (**3***c*), as well as comparisons with the model compounds 4-*tert*-butylcyclohexanone dimethylketal (**5**), 2,3-dimethoxyisopropylbenzene (**6**), and 1,4-benzodioxan (**7**) were particularly valuable. Proton assignments were confirmed by spin-decoupling experiments (3) and nuclear Overhauser enhancement (nOe) studies (4), while spectral simula-

b R_1 = Ac, R_2 = C≡N
c R_1 = H, R_2 = CH=NOAc

tion techniques (footnote to Table 1) were used to obtain relevant parameters from complex spectral sub-groups. The ^{13}C nmr data were obtained from proton-noise decoupled (pnd) and high resolution (hr) spectra, and assignments were aided by off-resonance (ord) and single ^1H frequency (sfd) decoupling experiments (5).

The ^1H nmr spectra of **4***a* (Table 1) and **3***a* (1) were virtually identical in the region δ 7.0–12.0, and nitrile formation caused similar spectral changes. Signals for the two methoxyl groups in **3***a* and **3***b* were replaced in the spectra of **4***a* and **4***b* by resonances for a methylated hexose residue, and it appeared that caerulomycins C and D differed only in this respect; a 3,4-dioxygenated 2,2′-dipyridyl-6-aldoxime structure being common to both compounds.

The ^{13}C nmr data (Tables 2 and 3) in **4***a* and **4***b* supported this conclusion. Resonances for the ring A, oxime, and nitrile carbons were readily identified (1). Five additional resonances in the spectra of both compounds were assigned to ring B carbons for reasons already given previously for **3***a* and **3***b* (1). Thus on going from **4***a* to **4***b*, C-7 was shielded and its coupling to H-12 removed, C-6 was deshielded and the coupling to H-6 increased, and the chemical shift of C-9 was only slightly affected. ^1H sfd experiments also showed that H-6 was coupled to C-9a of **4***a* and C-9a and C-5a of **4***b* in addition to the oxime and nitrile carbons. A similar change in the multiplicity of the C-5a, but not the C-9a, signal also accompanied the conversion of **3***a* to **3***b* (1).

The high-field portions of the ^1H nmr spectra of **4***a* and **4***b* (Table 1) each contained resonances for one methyl, two methoxyl, and four methine hydrogens; the spectrum of **4***a* also possessed a hydroxyl signal (δ 5.57; proton exchangeable with deuterium) which was replaced by one for an acetoxyl methyl group (δ 1.89) in the spectrum of **4***b*. In each compound one of the methine hydrogens gave a singlet resonance with a chemical shift (**4***a*, δ 5.68; **4***b*, δ 5.83) similar to that of the anomeric hydrogen of aryl glucopyranosides (6). From the absence of spin–spin coupling the adjacent carbon was not bonded to hydrogen. The chemical shifts of the three remaining methine hydro-

gens required that they were attached to carbons bearing oxygen (7), and the magnitudes of vicinal couplings (Table 1) indicated that they were axially orientated on adjacent sites of a six-membered ring (8). In addition, one (**4***a*, δ 3.90; **4***b*, δ 3.92) was vicinally coupled to hydrogens of the methyl group. These observations established that H-2, H-3, H-4, and the methyl group must be positioned as in structures **4***a* and **4***b*. In **4***a* H-4 was also coupled to a hydroxyl hydrogen. Acetylation to produce **4***b* removed the coupling and deshielded the signal from δ 3.74 to δ 5.00 as predicted (9) if the hydroxyl and acetoxyl substituents were bonded to C-4. The fragment $C_2H_6O_4$ still unaccounted for must include the two methoxyl groups evident in the ^1H nmr spectra. The methoxyl groups had chemical shifts characteristic of those in carbohydrate derivatives (10) and are plausibly located only at the 2 and 4 positions of a pyranose ring. On this evidence C-10a and C-4a must be linked to the 3 and 4 positions of the 2,2′-dipyridyl ring through oxygen atoms as shown in structures **4***a* and **4***b*.

The ^1H nmr nOe data in Table 1 support the above conclusions. Irradiating H-2 of **4***b* produced a significant nOe for H-4 but not H-10a, whereas irradiation of the low field (δ 3.46) methoxyl hydrogens showed a nOe for H-10a but no intensity change in the signal for H-4. No nOe was obtained for H-10a when the high field (δ 3.36) methoxyl hydrogens were irradiated. These observations confirm the 1,3-diaxial relationship of H-4 and H-2. They also establish that one methoxyl group (δ 3.46) is vicinal and *gauche* to H-10a as well as *trans* to H-4. As H-4 is axial, C-4a bears an axial methoxyl group and H-10a is equatorial. The second C—O bond at C-4a must be equatorially orientated, whereas the corresponding bond at C-10a must be axial. Because the nOe evidence excludes any possibility of the second methoxyl group (δ 3.36) being on C-4a, it has to be on C-3 since C-4 already bears a hydroxyl group. Nuclear Overhauser enhancement studies on **4***a* and **4***b* excluded the possibility of an aromatic hydrogen and a methoxyl group being on contiguous carbons (Table 1). The steric relationships of H-3 to the two methoxyl groups were inaccessible by nOe studies because of the proximity of all three resonances in the spectra of **4***a* and **4***b*.

^{13}C resonances were observed in the region δ_C 17.0–100.0 for all carbons associated with the sugar residue (Table 2). As expected (11) the anomeric carbon C-10a resonated at low field (**4***a* and **4***b*; δ_C 91.0), with a spin–spin coupling to H-10a (**4***a*, $^1J_{CH}$ = 178.1 Hz; **4***b*, $^1J_{CH}$ = 180.9 Hz) indicative of an equatorial orientation for this proton (12). The chemical shifts of the ketal carbon C-4a of **4***a* (δ_C 95.9) and **4***b* (δ_C 95.4) were similar to the value of δ_C 99.1 observed for C-1 of 4-*tert*-butylcyclohexanone dimethylketal (**5**). These carbons gave rise to singlet resonances broadened by long-range coupling to methoxyl and possibly other neighbouring hydrogens in the hr ^{13}C spectra. The chemical shifts of C-4 and C-2 are in the region expected for C-2 through C-5 of aldohexopyranosides which fall within a narrow range centered at about δ_C 70 and are not appreciably altered by acetylation (9). Replacement of a hydroxyl by a methoxyl group is known to deshield such carbons by ≈10 ppm (11) and the chemical shift of C-3 (**4***a*, δ_C 83.3; **4***b*, δ_C 80.5) is consistent with its bearing a methoxyl substituent. Moreover, one of the methoxyl carbons (**4***a*, δ_C 59.4; **4***b*, δ_C 59.9) was coupled ($^3J_{CH}$ ≈ 6.0 Hz) to the C-3 methine hydrogen. No long-range coupling of methoxyl carbons to aromatic hydrogens was observed in **1***a*, **1***b*, **3***a*, **3***b*, and **3***c* (1). Signals arising from the methoxyl group on C-4a (**4***a*, δ_C 50.3; **4***b*, δ_C 51.0) were assigned from proton ord studies. The methyl carbons had chemical shifts similar to the value of δ_C 17.9 observed for the methyl carbon of rhamnose (11). Two remaining resonances in the spectrum of **4***b* were due to the acetoxyl group (CH_3, δ_C 20.1; C=O, δ_C 169.2) attached to C-4.

In the ^{13}C spectrum of 4-*tert*-butylcyclohexanone dimethylketal (**5**) (Table 2) the axial and equatorial methoxyl carbons were almost chemically equivalent (δ_C 46.9 and 46.7), and were abnormally shielded (≈10 ppm) relative to the methoxyl carbons of *O*-methyl derivatives of inositols, monosaccharides, and methyl glycosides (11). Similar shielding was exhibited by the ketal methoxyl at C-4a of **4***a* (δ_C 50.3) and **4***b* (δ_C 51.0) when compared to the methoxyl at C-3 (**4***a*, δ_C 59.4; **4***b*, δ_C 59.9). The ring B carbon of **4***a* and **4***b* which is bonded via oxygen to C-4a should also be shielded by about 10 ppm whereas the one linked through oxygen to C-10a should be normally shielded. Deshielding contributions to C-9a and C-5a of **4***a* and C-3 and C-4 of **3***a* were estimated by comparing their chemical shifts with those of corresponding carbons in 2,2′-dipyridyl (1). Shielding effects of other substituents on ring B were ignored as they would be small compared to those of the directly bonded substituents. The results show that C-3 and C-4 of **3***a* are about equally deshielded (22.7 ± 0.5 ppm) by the directly bonded methoxyl groups (1), whereas C-9a and C-5a of **4***a* (Table 2) are deshielded by 16.1 and 5.6 ppm. The most reasonable explanation for the extra shielding of C-5a in **4***a* is that it is bonded through oxygen to C-4a, C-9a being similarly attached to C-10a. Examination of the data for **3***b* and **4***b* led to the same conclusion.

The chemical shifts of C-6, C-7, and C-9 in **4***a* or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

4*b* are quite similar to those for the corresponding carbons in **3***a* or **3***b* (1) but values for C-5a and C-9a are very different. Examination of the ^{13}C nmr spectrum of 2,3-dimethoxyisopropylbenzene (**6**) in DMSO-d_6 (Table 2) established that the methoxyl groups deshielded C-2 by ≈ 20 ppm and C-3 by ≈ 24 ppm relative to carbons at the same positions in cumene (13). The latter was examined in $CDCl_3$ but solvent effects should be small. The deshielding contributions were almost the same as those experienced by C-3 and C-4 in **3***a* or **3***b* (1). However, the aromatic carbons bonded to oxygen in benzo-1,4-dioxane (**7**) were deshielded by ≈ 15 ppm relative to the carbons of benzene suggesting that the methylene groups partially shield (≥ 5 ppm) these carbons. The same effect in **4***a* would be expected to result in C-5a and C-9a being deshielded by ≈ 15 ppm. The aromatic carbons bonded to oxygen in phenyl-α-D-glucopyranoside (δ_C 157.2), phenyl-β-D-glucopyranoside (δ_C 157.7), and anisole (δ_C 159.3) had almost the same chemical shifts so differences in the substitution at C-10a in **4***a* should not affect the deshielding contribution at C-9a. However, for C-5a the 'ketal' shielding contribution of ≈ 10 ppm must be taken into account and the net deshielding will be only about 5 ppm. From the ^{13}C data for 2,2′-dipyridyl (1) the chemical shifts of C-9a and C-5a in **4***a* are thus calculated to be ≈ 135 ppm (120 + 15 ppm) and 142 ppm (137 + 5 ppm), respectively, which is in reasonable agreement with the experimental values (Table 2).

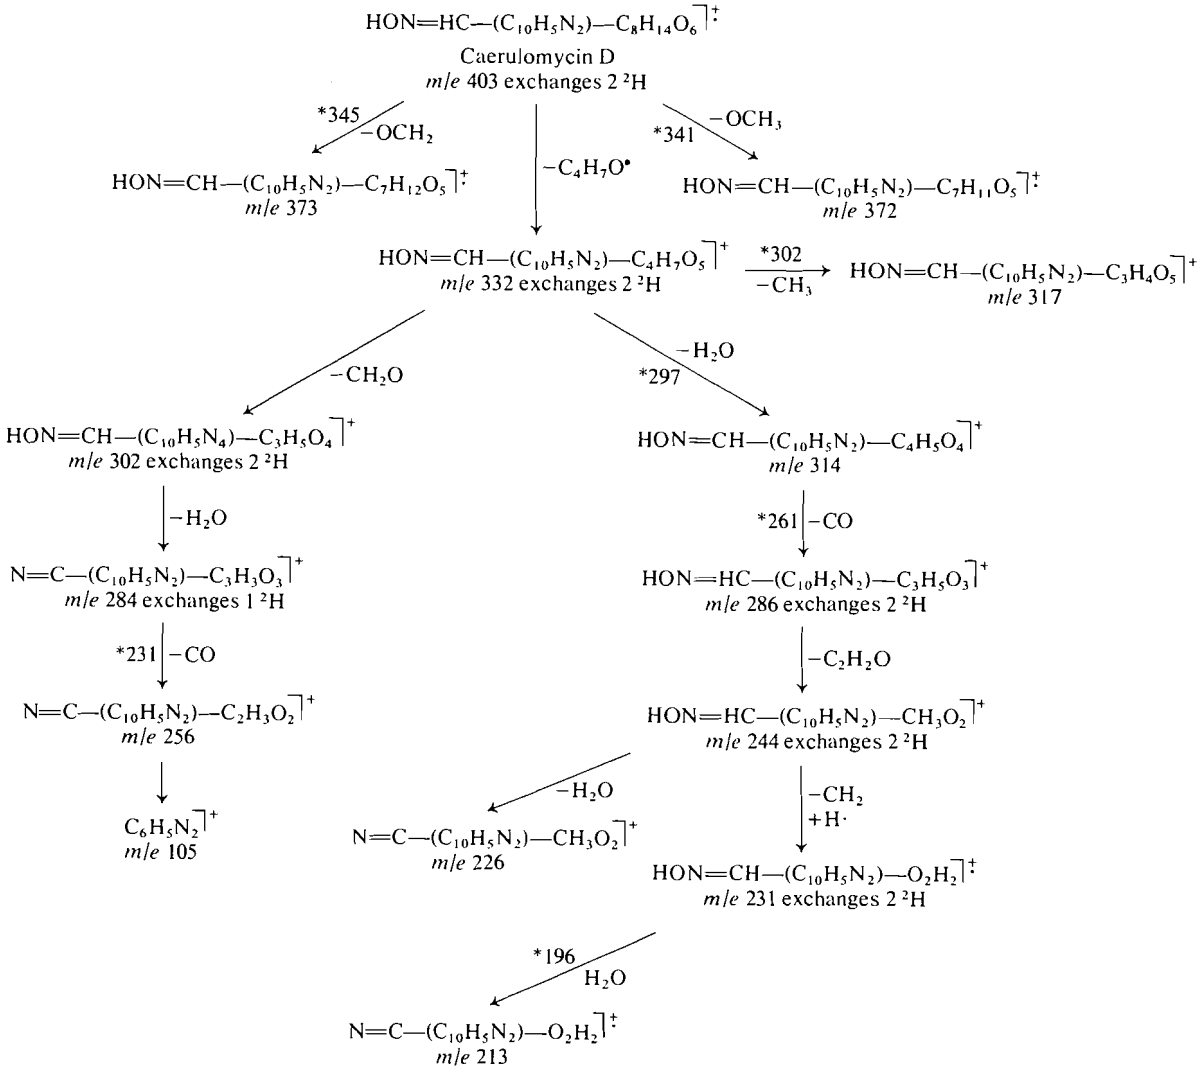
Chemical shifts of the ring B carbons show consistent trends on going from **1***a* to **1***b*, **3***a* to **3***b*, and **4***a* to **4***b*, except that values for C-5a in the latter pair differ by 5.5 ppm, whereas those for the corresponding carbon (C-4) in **1***a* and **1***b*, or **3***a* and **3***b*, are almost identical (1). Since deshielding of C-5a in **4***b* cannot be attributed to the oxime to nitrile conversion, replacement of the C-4 hydroxyl by an acetoxyl must be responsible. A space-filling molecular model revealed that methoxyl groups at C-3 and C-4a restrict the orientation of an acetoxyl group at C-4. In the most likely conformation of **4***b* the carbonyl group was positioned so that C-5a lay within its deshielding region, thus accounting for the downfield shift on going from **4***a* to **4***b*. Alternatively, but less likely, the chemical shift change might be due to differences of solvation.

No differences were observed between **3***a* and **4***a* in ^1Hmr and ^{13}C nmr data for the oxime group or in the chemical shifts of the ring B hydrogens, hence the oxime substituent in **4***a* must have the *E* configuration and orientation previously deduced for **3***a* (1). Also it was the oxime hydroxyl function of **4***a* which was acetylated under mild conditions to yield the monoacetate **4***c* because the ^1H nmr spectra of the two compounds were essentially indistinguishable except for the replacement of the oxime hydroxyl resonance (δ 11.55 ppm) of **4***a* by an acetyl methyl signal (δ 2.23 ppm) in the spectrum of **4***c*.

The mass spectrum of caerulomycin D showed a series of peaks corresponding to loss of 15 (CH_3), 18 (H_2O), and 30 (CH_2O) mass units, as observed for caerulomycins A and C (1). A strong peak corresponding to *m/e* 332 represented a loss of 71 mass units which did not occur in other dipyridyl compounds and can be accounted for by elimination of a C_4H_7O fragment from the sugar moiety. This initiated two major fragmentation pathways (Scheme 1), neither of which generated the ion at *m/e* 156 corresponding to unsubstituted dipyridyl that was observed in the spectra of caerulomycins B and C.

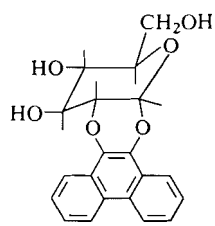
Information on the absolute configuration at C-2 of the sugar residue of **4***a* was provided by optical rotation measurements. α-D-Aldohexopyranoses and pyranosides, which exist solely in a *C*1 conformation, have positive molecular rotations (14, 15), and when the aglycone is phenyl the rotation increases. Thus phenyl-α-D-glucopyranoside has $[M]_D$ +463 (16). In the compound **8**, which possesses a 2,3-dihydro-1,4-dioxin ring system analogous to that in **4***a* and has $[M]_D$ +602 (17), attachment of the phenanthrene residue has made an even greater positive contribution. Converting the glucose residue of **8** to 6-deoxyglucose would decrease $[M]_D$ by only about 25 (15) and methylation of the C-4 hydroxyl would have little influence on the magnitude and no effect on the sign of rotation (18). Since an axial methoxyl at C-2 of **8** would have to make an improbable contribution of > -500 to the molecular rotation to change its sign the phenanthrene analogue of **4***a* would be expected to have a positive rotation if the sugar had a *C*1 conformation and belonged to the D-series and a negative one if it had a 1*C* conformation and belonged to the L-series. Thus the value of $[M]_D$ −216 found for **4***a* indicates that the sugar moiety has an L-configuration at C-2 and therefore an α-L-configuration at the anomeric center.

The combined evidence establishes caerulomycin D as (2*S*,3*R*,4*R*,4a*S*,10a*S*)-3,4,4a,10a-tetrahydro-4-hydroxy-3,4a-dimethoxy-2-methyl-9-(2-pyridyl)-2*H*-pyrano[3′,2′:5,6]-*p*-dioxino[2,3-*c*] pyridine-7-carboxaldehyde(*E*)-oxime. This structure is unique; the fundamental ring system 2*H*-pyran[3′,2′:5,6]-*p*-dioxino[2,3-*c*]pyridine has not been reported previously and the sugar portion is a derivative of 6-deoxy-L-*arabino*-hexos-2-ulose, a rare monosaccharide only recently synthesized from L-rhamnose (19). L sugars are widely distributed in natural products (20) and some which are constituents of anti-



SCHEME I

biotics possess unusual amino, deoxy, and branched-chain structures (21). However, we know of only one other example where a similar ring system was generated by glycosidic type linkages involving vicinal hydroxyl groups of an aglycone and the anomeric center and carbonyl group of a keto sugar. In actinospectacin, an antibiotic produced by *Streptomyces spectabilis*, a decahydro-2*H*-pyrano[2,3-*b*][1,4] benzodioxin ring system was formed from 1,3-dideoxy-1,3-bis(methylamino)-*myo*-inositol and a 4,6-dideoxy-2,3-diulose (22).



8

Experimental

^{1}H nmr spectra were taken on either a Varian Associates model HA-100D or XL-100-15 spectrometer operating in the continuous wave mode. ^{13}C nmr spectra were recorded at 25.16 MHz on the latter instrument in the pulse Fourier transform mode. Mass spectra were obtained with a Consolidated Electrodynamics Corporation model 110-B double-focusing spectrometer operated in the electrical mode.

Caerulomycin D (4a)

Procedures for the isolation of this compound are given in the previous paper (1). Repeated recrystallization from ethanol yielded fine colorless needles, mp 241–242°C; λ_{max} (MeOH) (log ε): 231 (4.14), 267 (4.00), and 305 nm (inflex.) (3.52);

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ν_{max} (KBr): 3450–3150 (br), 1580, 1570, 1560, 1250, 1125, 1060, 1040, 970, and 790 cm^{-1}; *m/e* (%): 403 (14), 388 (8), 332 (10), 314 (19), 302 (62), 286 (29), 284 (33), 231 (24), 213 (17), 105 (14), 78 (25), 72 (100). Deuterium exchange with D_2O from the heated inlet system of the mass spectrometer caused a shift in $M^{\ddagger}$ from *m/e* 403 to 405. Accurate mass measurement of selected ions (against a perfluorokerosene reference) gave *m/e* 403.1384 (calcd. for $C_{19}H_{21}O_7N_3$: 403.1379), 314.0776 (calcd. for $C_{15}H_{12}O_5N_3$: 314.0797), 302.0781 (calcd. for $C_{14}H_{12}O_5N_3$: 302.0777), 286.0826 (calcd. for $C_{14}H_{12}O_4N_3$: 286.0828) 284.0679 (calcd. for $C_{14}H_{10}O_4N_3$: 284.0671), 231.0656 (calcd. for $C_{11}H_9O_3N_3$: 231.0644), 213.0542 (calcd. for $C_{11}H_7O_2N_3$: 213.0538), and 105.0456 (calcd. for $C_6H_5N_2$: 105.0453). *Anal.* calcd. for $C_{19}H_{21}N_3O_7$: C 56.57, H 5.25, N 10.42; found: C 56.41, H 5.13, N 10.89. Caerulomycin D is relatively stable in acid and was recovered unchanged after 4 h heating under reflux in 2 *N* hydrochloric acid. Partial hydrolysis occurred with 6 *N* acid.

*Caerulomycin D Monoacetate (**4**c)*

Caerulomycin D (25 mg) suspended in acetic anhydride (4 ml) at room temperature dissolved slowly. After 24 h ice was added and the solution was evaporated at 45°C *in vacuo* to an almost colorless product (25 mg) which crystallized from ethanol as needles, mp 143–145°C; λ_{max} (MeOH) (log ε): 231 (4.15), 266 (3.97), and 305 nm (inflex.) (3.37); ν_{max} (CCl_4): 3525 and 1785 cm^{-1}; ν_{max} (KBr): 3600–3100 and 1780 cm^{-1}; $M^{\ddagger}$ at *m/e* 445 (<0.1%) and fragment ions at *m/e* (%): 427 (0.4), 385 (10), 370 (8), 314 (10), 298 (9), 284 (100), 270 (7), 254 (9), 226 (28), 213 (63), 197 (15), and 184 (11). Accurate mass measurement of *M* − 18: 427.1380 (calcd. for $C_{21}H_{21}N_3O_7$: 427.13795).

*Caerulomycinonitrile D Monoacetate (**4**b)*

Caerulomycin D (140 mg) was heated under reflux with acetic anhydride (15 ml) for 3 h. Addition of ice and evaporation of the solution *in vacuo* yielded a pale brown gum. This was purified by preparative thin-layer chromatography (silica gel HF_{254}; eluant 20% acetone–benzene: R_f 0.4) to give a gum which was rechromatographed (silica gel HF_{254}; 3% propanol–ether R_f 0.45) to yield leaflets, mp 63–65°C, λ_{max} (MeOH) (log ε): 229 (4.17), 257 (3.84), and 292 nm (3.50); ν_{max} (CCl_4): 2240 and 1760 cm^{-1}; ν_{max} (KBr): 2235 and 1756 cm^{-1}; $M^{\ddagger}$ at *m/e* 427 (17%) and fragment ions at *m/e* (%): 397 (44), 367 (11), 337 (22), 304 (10), 284 (14), 267 (17), 264 (18), 213 (100), 142 (55), and 127 (50). Accurate mass measurement of $M^{\ddagger}$: 427.1388 (calcd. for $C_{21}H_{21}N_3O_7$: 427.13795).

Assembly of the carbon skeletal framework of erythronolide A

STEPHEN HANESSIAN, GEORGES RANCOURT,[1] AND YVAN GUINDON[1]

Department of Chemistry, University of Montreal, Montreal, P.Q., Canada H3C 3V1

Received March 17, 1978

STEPHEN HANESSIAN, GEORGES RANCOURT, and YVAN GUINDON. Can. J. Chem. **56**, 1843 (1978).

The construction of the 15-carbon chiral framework of erythronolide A is described, based on a synthetic strategy that uses carbohydrate-derived 'chiral templates' as prefabricated segments of the target molecule.

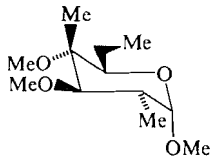
STEPHEN HANESSIAN, GEORGES RANCOURT et YVAN GUINDON. Can. J. Chem. **56**, 1843 (1978).

La construction du squelette carboné chiral de l'érythronolide A est décrite, basée sur une stratégie synthétique qui utilise des carbohydrates comme 'charpentes chirales.'

The construction of the chiral, polyfunctional carbon framework of macrolide aglycones (1–3) presently constitutes one of the more challenging synthetic endeavors in the chemistry of natural products. We have already described the synthesis of two functionalized chiral precursors I and II to erythronolide A, **1**, comprising 8 out of the 10 chiral centers of this formidable synthetic objective, and representing its C-1—C-6 and C-9—C-15 portions (4, 5).[2] We now describe the completion of a critical phase in the total synthesis of **1**,[3] namely, the bridging of appropriately modified precursors I and II, thus giving access to the entire functionalized carbon skeleton as a suitably protected derivative.

The synthetic plan for the construction of this derivative called for (*a*) the one-carbon homologation of precursors I (R = OMe) and II through C-6 and C-1, respectively, and their transformation, individually, into nucleophilic and electrophilic counterparts; (*b*) the efficient utilization of a C—C bond forming reaction for the union of two such segments; (*c*) introduction of a *C*-methyl group at C-8; and (*d*) elaboration of the tertiary center at C-6.

The nucleophilic component corresponding to C-1—C-6 of the erythronolides was prepared from



Precursor II

Precursor I R = OMe; Me

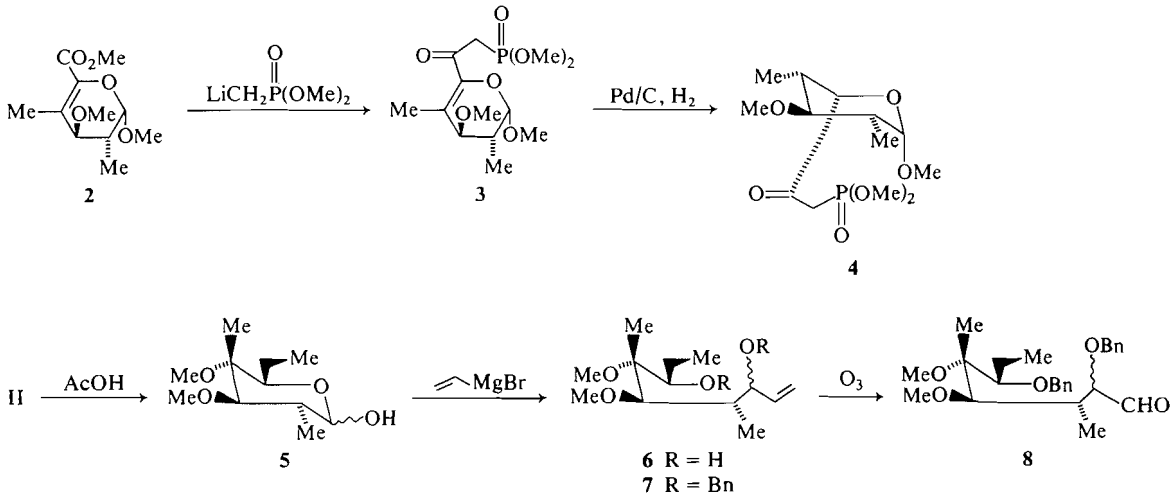
the α,β-unsaturated ester **2** (4, 5) (Scheme 1). Treatment of **2** with lithium dimethylphosphonoacetate (ether, 25°C) gave the corresponding ketophosphonate derivative **3** as a syrup (80% after chromatography); $[\alpha]_D$ +142.8°;[4] M^+ 322. Catalytic hydrogenation (5% Pd/C, H_2, MeOH), then gave the desired synthon **4** as a syrup (95%); $[\alpha]_D$ +130.1°; M^+ 324; δ (ppm): 2.93 (t, $J_{3,4}$ = 14 Hz, H-3), 4.38 (d, $J_{5,4}$ = 4 Hz, H-5), 4.73 (d, $J_{1,2}$ = 3.5 Hz, H-1), etc. The electrophilic component corresponding to C-9—C-15 of **1** was obtained from precursor II in the following manner. Acid hydrolysis (70% AcOH, 80°C) gave the free sugar **5** (Scheme 1) as a mixture of anomers (syrup, 74%), which was converted into a mixture of epimeric allylic alcohols **6** by reaction with vinylmagnesium bromide (7) in THF

[1]NRCC Predoctoral Fellow.

[2]Precursor I also represents the C-1—C-6 portion of erythronolide B.

[3]Expression **1** corresponds to one of several planar projections for the erythronolides, where the relative orientation of functional groups may vary according to the arbitrary choice of conformation (4, 5). The spatial disposition of each group in expression **1** is the same as that found in the solution conformation of erythronolide B (6). We therefore prefer the adoption of such an expression whenever the structures of these compounds are represented as plane projections; see also ref. 2.

[4]New compounds had spectroscopic (^{1}H nmr; ir) and mass spectral characteristics that were in accord with their structures. Optical rotations were measured at 25°C in chloroform at concentrations of 0.5–1%.



SCHEME 1

(25°C, 18 h, ~98%). Benzylation (BnBr, NaH, DME) then gave a mixture of epimeric compounds **7** as a syrup (73% overall from **6**) which was subjected to ozonolysis to give the desired aldehydo derivative **8** as a syrup (77%); ν_{max} 1725 cm^{-1} (C=O).

Coupling between intermediates **4** (slight excess) and **8** was accomplished in the presence of sodium hydride in THF (18 h, 25°C) to give **9** as a syrupy mixture of C-9 epimers which could be separated by chromatography (59%); $M^{\ddagger}$ 626.3809 ($C_{37}H_{54}O_8$) (Scheme 2). That the L-*ido* stereochemistry had remained intact during the coupling, as required for the C-1—C-6 portion in **1**, was ascertained chemically, by treatment of **9** with NaOMe (pH ~ 9) which led to virtually complete epimerization at C-5 within a few hours.[5]

Conjugate addition of lithium dimethylcuprate to **9** (ether, −5°C) gave the C-8 methyl derivative **10** as a mixture of syrupy diastereoisomers (approximately quantitative) without any detectable epimerization at C-5; δ (ppm): 4.25 ($J_{5,4}$ = 3 Hz, H-5). The tertiary center at C-6 was introduced by reaction of **10** with methyllithium in ether to give **11**, presumably as a mixture of diastereoisomers (syrup, 51%), $[\alpha]_D$ +35.2°. *Since C-9 is the site of the carbonyl group in* **1**, *and C-8* epi *derivatives can be epimerized* (*8*, *9*) *to give the desired configuration, the stereochemical purity at these centers in the mixture of diastereoisomers corresponding to* **11** *is unimportant at this stage of the synthesis.* The yet unknown stereochemistry at C-6 also offers some flexibility, since this center is introduced in the last step of the sequence (**10** → **11**) and the stereochemical control of the reaction could be further studied under a variety of conditions with no loss of chiral efficiency at other centers. In this context, we describe another approach for joining appropriately modified precursors I(R = Me) and II, in which I is used as a source of an electrophilic component, as exemplified in the following model study (Scheme 3). Treatment of precursor I (R = Me) with vinylmagnesium bromide gave a ~6:1 mixture of epimers (syrup > 90%) in which the preponderant product was assigned structure **12** based on literature precedents (10–12). Methylation (MeI, NaH, DMF) followed by oxidative cleavage (OsO_4–IO_4^-) gave the aldehydo derivative **13** (syrup, 65% from **12**) which was transformed via a Wittig or Horner–Emmons reaction into **14** (syrup, ~80% after chromatography); $[\alpha]_D$ +33°; *m/e* 325 ($M^{\ddagger}$ − MeO). Using this approach, the correct stereochemistry at C-6 would be secured early in the synthetic sequence, and subsequent introduction of the C-8 methyl group in the enone derived from **13** and the appropriate ketophosphonate derivative prepared from II, would involve a reductive alkylation process.

The synthetic conquest of only one macrolide aglycone has been achieved so far, in the landmark total synthesis of the 12-membered macrolide antibiotic methymycin (13). Other work in this area has involved lactonization of seco acids derived from 14- and 16-membered natural 'polyoxo' macrolide aglycones (9, 14). Two recent reports (15, 16) have dealt with the generation of aldol-type systems in the search for stereoselective methods that are potentially applicable to the stepwise construction of highly chiral and functional compounds such as **1**. In the Woodward route to **1** (17), a dithiadecalin ring system is ingeneously used as a framework for the systematic introduction of functionality corresponding to segments of the seco acid. Our approach for

[5]The D-*gluco* stereochemistry (C-1—C-6) of the resulting syrupy mixture of epimers at C-9 was clearly evident from nmr studies, $J_{4,5}$ = 11 Hz; *m/e* 594.3513 ($M^{\ddagger}$ − MeOH).

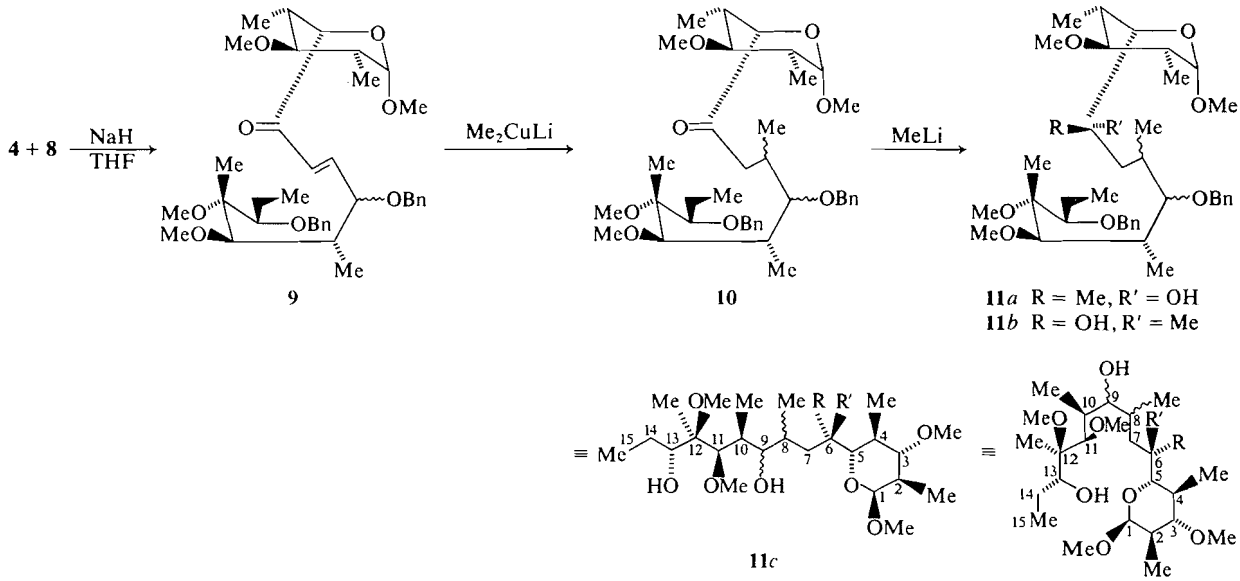

SCHEME 2

the assembly of the carbon skeletal framework of **1** and its 9-dihydro derivative (18), as exemplified by the 1,5-hemiacetal derivative **11***c*, has been based on the efficient utilization of prefabricated 'chiral templates' derived from carbohydrates (5, 7, 19, and references cited therein).[6] As a consequence, all the hydroxyl and methyl groups in **11** have been introduced regiospecifically and the correct absolute stereochemistry of at least eight chiral centers present in **1** has been secured.

The thermal desorption of surface species from sulfur dioxide adsorption on natural chrysotile asbestos and calorimetric sorption heats at 298, 323, 373, and 423 K

WILLIAM JOHN MURPHY AND ROBERT ANDERSON ROSS

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received January 4, 1978

WILLIAM JOHN MURPHY and ROBERT ANDERSON ROSS. Can. J. Chem. **56**, 1847 (1978).

Calorimetric heats of adsorption have been determined for sulfur dioxide adsorbed at 298, 323, 373, and 423 K on both Californian and Quebec chrysotiles. Adsorption isotherms have been measured and some differential molar entropies calculated. Thermal desorption of surface species resulting from the adsorption of sulfur dioxide on Californian chrysotile at 298 K have been studied from 25 to 450°C. Sulfurous and carbonic acids, in addition to sulfites and other trace species, have been shown to result from the adsorbent–adsorbate interactions. A mechanism for sulfur dioxide adsorption on chrysotile has been prepared which accounts for the observed high heats of adsorption measured at low surface coverages.

WILLIAM JOHN MURPHY et ROBERT ANDERSON ROSS. Can. J. Chem. **56**, 1847 (1978).

On a déterminé les chaleurs d'absorption calorimétriques de l'anhydride sulfureux adsorbé à 298, 323, 373 et 423 K sur des chrysotiles de la Californie et du Québec. On a mesuré les isothermes d'adsorption et on a calculé quelques entropies molaires différentielles. On a étudié, de 25 à 450°C, la désorption thermique d'entités de surface provenant d'une adsorption de l'anhydride sulfureux sur une chrysotile de la Californie à 298 K. On a démontré qu'il y a formation d'acides sulfureux et carbonique en plus de sulfites et de traces d'autres entités à partir d'interactions adsorbant–adsorbé. On a préparé un mécanisme pour expliquer l'adsorption de l'anhydride sulfureux sur la chrysotile qui tient compte des chaleurs d'adsorption élevées qui ont été observées et qui ont été mesurées à des valeurs faibles de recouvrement des surfaces.

[Traduit par le journal]

Introduction

Asbestos in its various forms is perhaps the most documented solid pollutant (1) of industrial societies and sulfur dioxide is recognized as one of the major gaseous pollutants (2, 3). Inhalation of the various asbestos types and its possible relationship to the initiation of respiratory disease has long been the subject of intensive research (4–6). It has been reported (7), however, "that neither pulmonary fibrosis (asbestosis) nor bronchogenic carcinoma (lung cancer), the two most common asbestos-related diseases, are peculiarly related to or caused solely by the inhalation of asbestos fibres". In this respect the reported synergetic relationship (8, 9) between cigarette smoke and asbestos with respect to lung cancer incidence is of major interest.

Through recent publications we have described thermodynamic studies of sulfur dioxide adsorption on a wide range of materials including γ-Al_2O_3 (10), charcoal (11), and chrysotile asbestos which had been subjected to various degrees of heat treatment (12). In an endeavour to typify the nature of the specific gas–solid interactions this work has now been extended to an examination of the adsorption of sulfur dioxide on chrysotile asbestos from 298 to 423 K using both thermodynamic and thermodesorption – mass spectrometric techniques. At the same time, these data could be of some value in health-related studies in determining whether synergism, with respect to respiratory diseases, is likely or possible with co-inhalation of the pollutants.

Experimental

Materials

Chrysotile ($Mg_3SiO_5(OH)_4$) samples were supplied by (*a*) Lake Asbestos, Black Lake, Quebec (sample 7T/5, Quebec chrysotile) and (*b*) Union Carbide Corporation (Calidria

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

asbestos sample HPO, Californian chrysotile). The major impurities were brucite ($Mg(OH)_2$), 10% in sample (*a*) and magnetite (Fe_3O_4), 3.75% in (*a*) and 0.75% in sample (*b*).

Sulfur dioxide (Matheson of Canada, anhydrous grade, >99.98% pure) was drawn directly from the cylinder, after line flushing, to a trap attached to the apparatus. It was then outgassed at 10^{-4} Torr and vacuum distilled over trays of phosphorus pentoxide. This purification procedure was repeated at least six times. Middle portions only were used and glc analyses showed these to be greater than 99.999% pure.

Surface areas of all samples were determined from nitrogen adsorption–desorption isotherms at 77 K (13) giving 60 and 40 $m^2 g^{-1}$ for Californian and Quebec chrysotiles, respectively.

The samples were pretreated at 423 K and 10^{-4} Torr for 24 h which results in a 0.5% weight decrease due to loss of physically adsorbed water from the surface (13, 19). The samples used in the thermal desorption experiments were initially pretreated as above and then exposed to sulfur dioxide at 600 Torr for 6 h at 298 K. The sulfur dioxide was then pumped off and the samples outgassed by pumping at 298 K for 24 h.

Apparatus and Procedure

Calorimetry

Calorimetric heats of adsorption were determined in a vessel similar to that described by Robinson and Ross (14). The calorimeter was operated in the adiabatic mode and the heat measurement conditions were adapted from those used by Smith and Ford (15) as recently reported (11). Entropies of adsorption were calculated from classical thermodynamic equations (16, 17).

Qualitative chemical tests for sulfite, sulfide, sulfate, and carbonate were performed on all samples from the calorimetric experiments, after desorption of sulfur dioxide and pumping overnight at 10^{-4} Torr.

Thermal Desorption

Thermal desorption of adsorbed species was carried out from 25 to 450°C at a heating rate of 3°C/min. Krypton (Matheson of Canada, Research Purity grade, >99.995% pure), at 1 Torr, was used as the carrier gas and as the internal pressure standard in an all-glass 'static' circulation apparatus similar to that of Boreskov and Popovskii (20), incorporating a differential reactor. The gas analyser was a Vacuum Generator Micromass Q7 mass spectrometer attached to the circulation loop via a capillary leak and operated at $\sim 3 \times 10^{-6}$ Torr.

Results

Adsorption and Calorimetry

Figures 1 and 3 show the adsorption isotherms for sulfur dioxide adsorption on Californian and Quebec chrysotiles, respectively, at substrate temperatures of 298, 323, 373, and 423 K. Californian chrysotile exhibited larger adsorption capacities than the Quebec material at corresponding substrate temperatures. Further, its capacity was more temperature dependent than that for Quebec chrysotile at a corresponding pressure of sulfur dioxide. For example, the adsorption capacity at 600 Torr for Californian chrysotile fell from 4.00 μmol m^{-2} at 298 K to 1.65 μmol m^{-2} at 423 K compared with 2.92 μmol m^{-2} at 298 K and 1.42 μmol m^{-2} at 423 K for the Quebec sample.

Figure 1 (inset) shows the results obtained in pretreatment experiments when Californian chrysotile was exposed to sulfur dioxide at 373 K for 6 h at 600 Torr. The gas was then pumped off and the chrysotile outgassed at 373 K by pumping at 10^{-4} Torr for a further 24 h. A reduction in adsorption capacity of between 25 and 30% over the entire equilibrium pressure range was observed when an isotherm was determined on this surface.

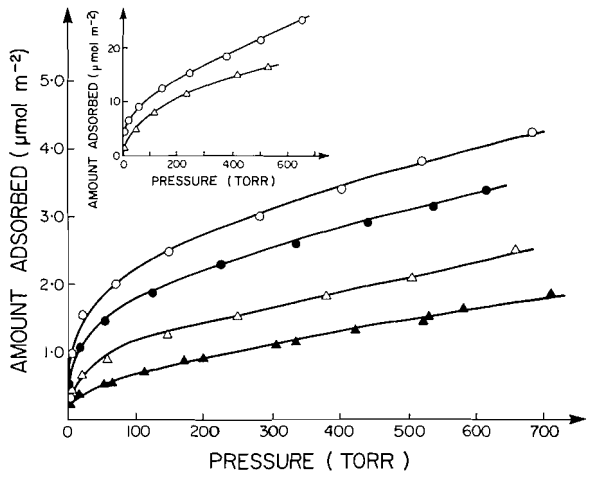

FIG. 1. Adsorption isotherms for sulfur dioxide on Californian chrysotile (HPO) at 298 K (○), 323 K (●), 373 K (△), and 423 K (▲). Inset: adsorption isotherms for sulfur dioxide at 373 K, after pretreatment with sulfur dioxide (○), and after standard pretreatment conditions (△).

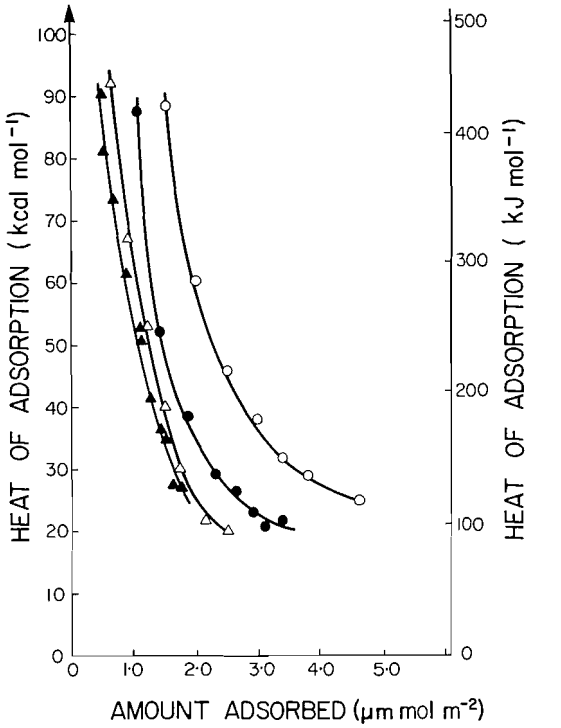

FIG. 2. Heat curves for the adsorption of sulfur dioxide on Californian chrysotile (HPO) at 298 K (○), 323 K (●), 373 K (△), and 423 K (▲).

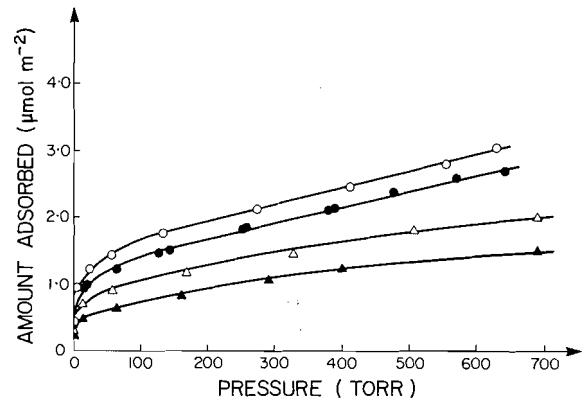

FIG. 3. Adsorption isotherms for sulfur dioxide on Quebec chrysotile (7T/5) at 298 K (○), 323 K (●), 373 K (△), and 423 K (▲).

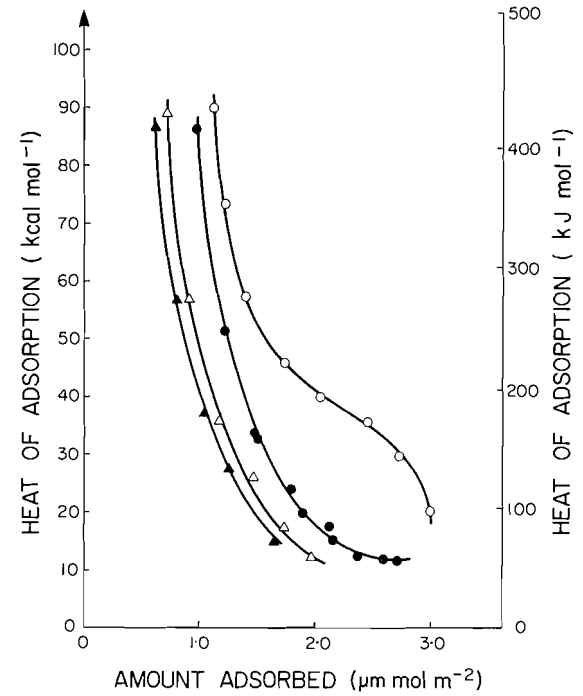

FIG. 4. Heat curves for the adsorption of sulfur dioxide on Quebec chrysotile (7T/5) at 298 K (○), 323 K (●), 373 K (△), and 423 K (▲).

Figures 2 and 4 show the heats of adsorption of sulfur dioxide on Californian and Quebec chrysotiles, respectively, at 298, 323, 373, and 423 K. Both adsorbents exhibited very high heats of adsorption at low coverages which fell sharply with increased coverage. The profile for Quebec chrysotile at 298 K was exceptional in that an inflexion point, which was reproducible, was observed, ~35 kcal mol^{-1} at 2.5 μmol m^{-2} coverage.

Thermal Desorption

Figure 5*a* shows the relative amounts of species

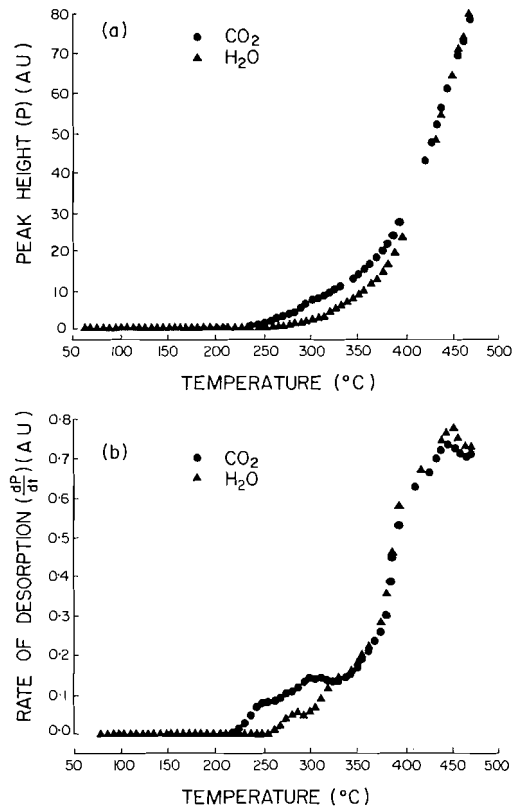

FIG. 5. Thermal desorption of adsorbed species on Californian chrysotile before pretreatment with sulfur dioxide.

which were desorbed from Californian chrysotile preheated under standard conditions, on increasing the temperature of the adsorbent from 50 to 450°C (au = arbitrary units). Figure 5*b* shows the rates of desorption of the species with respect to the substrate temperature. Only carbon dioxide and water were desorbed under these conditions. The figure indicates three distinct temperatures at which the rate of desorption of carbon dioxide maximizes, but there are only two such temperatures for the water component. The maximum at ~460°C in the carbon dioxide pattern coincides with the second maximum in the water desorption rate.

Figures 6*a* and *b* show the relative amounts of species desorbed and the rates of desorption, respectively, with temperature of substrate from Californian chrysotile after pretreatment with sulfur dioxide. In addition to sulfur dioxide, which exhibited four rate-of-desorption maxima, carbon dioxide and water were also desorbed (Fig. 6*b*). Comparison of Figs. 5 and 6 indicates that the desorption temperatures for carbon dioxide and water decrease considerably as a result of the pretreatment. Figure 6*b* further shows that, at a given temperature, more than one adsorbate can be desorbed. Thus,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

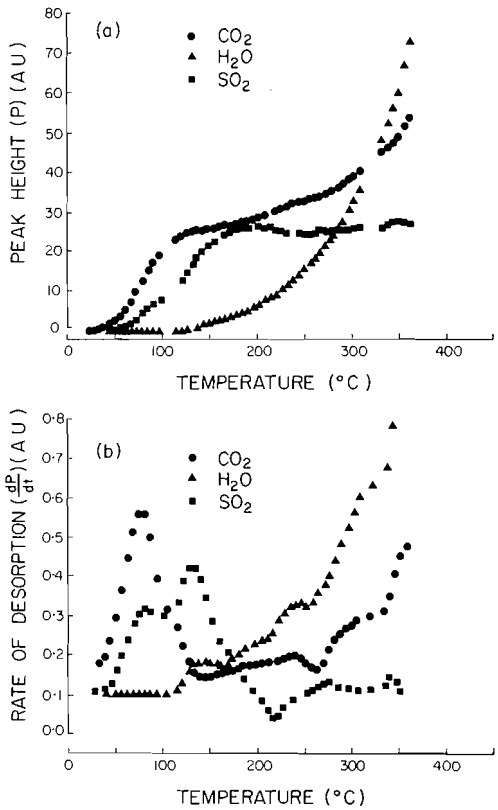

FIG. 6. Thermal desorption of adsorbed species on Californian chrysotile after pretreatment with sulfur dioxide.

for example, at 75°C both sulfur dioxide and carbon dioxide were desorbed, at 130°C both sulfur dioxide and water, and at 235°C both water and carbon dioxide.

These results suggest that co-desorbed sulfur dioxide and water and also carbon dioxide and water may exist as single species on the surface, perhaps as (H_2SO_3) and (H_2CO_3) respectively, or that the desorbed gases were attached to the surface in a very similar way. Cracking pattern studies tend to suggest that both phenomena occur. Thus sulfur dioxide and water desorbed at 135°C and the carbon dioxide and water desorbed at 235°C arise from (H_2SO_3) and (H_2CO_3), respectively, whereas all other species are desorbed as individual molecules from the surface.

Discussion

Previous work on magnesia (10), alumina (17), and silica (24) yielded values of 80, 20 to 50, and <10 kcal mol^{-1} for the heats of adsorption at surface coverages of 1 μmol m^{-2} in this temperature range. The alumina heat values were clearly related to the 'previous history' of the samples and the decrease in the heats over the oxide set was related to the decrease in ionicity of the oxides and to their ability to form compounds with sulfur dioxide.

The present results are generally consistent with these conclusions. Thus, Figs. 2 and 4 indicate that significant changes in the adsorbate–adsorbent interactions have occurred over the coverage range from chemisorption reactions, substantially exothermic, to a weaker chemisorption mode at 2–5 μmol m^{-2}.

These changes can be further emphasized by a comparison of the values of the calculated differential molar entropies. These were large and negative at low coverages (-80 to -40 cal deg^{-1} mol^{-1} at 100 Torr), increasing with increased coverage to values (4.0 cal deg^{-1} mol^{-1} at 600 Torr) close to the configurational entropy ($\sim$1.5 cal deg^{-1} mol^{-1}) in the case of Californian chrysotile and to values ($\sim$25 cal deg^{-1} mol^{-1} at 600 Torr) between the configurational entropy ($\sim$2.0 cal deg^{-1} mol^{-1}) and the entropy of a two dimensional 'mobile' film for the Quebec material.

The heat values for the highest coverages studied were still much higher than the heat of condensation of sulfur dioxide, $\sim$1.2 to 5 kcal mol^{-1}, at these temperatures, whence some form of hydrogen bond formation may be indicated (18).

The tendency of the heats of adsorption vs. coverage profiles to merge at higher substrate temperatures, Figs. 2 and 4, is consistent with the observation that above 100°C the sulfur dioxide which is most weakly bound to the surface, for example that desorbed at 75°C in Fig. 6, will not be retained and its contribution to the adsorption heats will be lost.

Figures 1 and 3 show that the chrysotiles exhibit similar isotherm patterns, with the Californian material having the larger adsorption capacity. The capacity differences shown by the lower temperature isotherms are almost directly proportional to the surface areas of the solids, 60 and 40 m^2 g^{-1} for the Californian and Quebec chrysotiles (13), respectively. At 373 and 423 K, the isotherms, as well as the adsorption heat profiles, for both materials show similar values suggesting that the extra capacity of the Californian asbestos at low temperatures is almost entirely achieved through the uptake of sulfur dioxide in a less strongly bound condition.

The thermal desorption results, Figs. 5*a* and *b*, may be usefully compared with De Vleesschauwer's (21) report that nesquehonite ($MgCO_3 \cdot 3H_2O$) under dynamic heating conditions similar to those used in the present study decomposes thus:

$$[1]\quad MgCO_3 \cdot 3H_2O \xrightarrow{\sim 150^\circ C} MgCO_3 \cdot H_2O \xrightarrow{\sim 400^\circ C} MgO + CO_2 + H_2O$$

Further it has been reported (21, 22) that in similar conditions nesquehonite yields some basic magnesium carbonate ($4MgO \cdot 3CO_2 \cdot 3H_2O$). These data suggest that perhaps a carbonate, similar to nesque-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

honite or the monohydrate dehydration product of nesquehonite, may be present as a trace impurity in Californian chrysotile.

This would also account for carbon dioxide and water desorption at 400°C and above. The remaining very minor carbon dioxide peaks could then be due to desorption of carbon dioxide with water or perhaps to the decomposition of a small amount of basic carbonate impurity.

Figure 6*b* shows that as the substrate temperature of the sulfur dioxide treated Californian chrysotile was increased both carbon dioxide and sulfur dioxide were desorbed simultaneously at approximately 75°C indicating that both were weakly chemisorbed to the surface perhaps by hydrogen bonding through mono- or bidentate complexes similar to those suggested for sulfur dioxide adsorbed on magnesia (23). With further increase in substrate temperature, sulfur dioxide and water were desorbed simultaneously. Sulfurous acid may have formed on the surface:

$$[2] \qquad 2SO_2 + Mg(OH)_2 \rightarrow MgSO_3 + H_2SO_3$$

$$\Delta H_{298} = -24 \text{ kcal mol}^{-1}$$

Sulfite ions were detected by chemical tests of the chrysotile even at temperatures >300°C. This sulfite was not present solely as sulfurous acid since this would not be present on the surface above 135°C. Further, analyses of the mass spectral cracking patterns in the temperature region where the sulfur dioxide and water were desorbed indicated that the sulfur dioxide was 'complexed' to the water and not in the 'free' state.

Raising the substrate temperature to 240°C resulted in the simultaneous desorption of carbon dioxide and water. Thus carbonic acid may also be a surface product:

$$[3] \qquad MgCO_3 \cdot xH_2O + SO_2 \rightarrow MgSO_3 + (CO_2 + xH_2O)$$

$$\Delta H_{298} \sim 0$$

$$MgCO_3 \cdot xH_2O + H_2SO_3 \rightarrow MgSO_3 + (CO_2 + yH_2O)$$

$$\Delta H_{298} \sim 0$$

Further increase to 275°C resulted solely in the desorption of sulfur dioxide. This may be explained by the decomposition of the surface sulfite complex already postulated as the product of a number of adsorbate–adsorbent interactions ([2] and [3]) in agreement with Goodsel *et al.* (23) who observed the decomposition of a bidentate sulfite complex of magnesium at ~300°C.

The remaining desorption products identified at higher temperatures would result from decomposition of unreacted carbonate residue and a more strongly bound surface sulfite. A comparison of the relative amounts of carbon dioxide and water desorbed above 300°C, Fig. 6*b*, from both untreated and treated chrysotiles, shows that the ratio $[CO_2]/[H_2O]$ is much smaller in the latter case in support of the hypothesis that all the carbon dioxide desorbed at 75 and 240°C originates from one source.

The adsorption of sulfur dioxide on Californian chrysotile tends to destabilise the residue of the carbonate impurity to thermal decomposition by as much as 50°C, Fig. 6*b*, again indicating that the carbonate is a surface species since a bulk carbonate impurity would be expected to show some residue of unreacted carbonate not affected by the adsorption of sulfur dioxide.

It now seems reasonable to suggest that sulfur dioxide may be adsorbed, perhaps by hydrogen bonding, on an adjacent site to the carbonate and that it can act to destabilise the carbonate to a greater or lesser extent. The former would be expected to result in carbon dioxide desorption while the simultaneous desorption of carbon and sulfur dioxides at 75°C, Fig. 6*b*, suggests that the decomposition of a surface complex involving the two species has occurred.

The high initial heats of adsorption, Figs. 2 and 4, may be related to surface heterogeneity but a scheme consistent with the observed surface dehydration reaction can also accommodate these features. It would result in the formation of magnesium sulfate and sulfur. Although the presence of trace quantities of elemental sulfur were indicated[1] by mass spectroscopy and electron microscopy, chemical tests for both materials were inconclusive. However, the presence of sulfate under very similar experimental conditions has previously been reported for sulfur dioxide on magnesia (10) where heats of adsorption were also in this region.

These various conclusions and hypotheses may be summarised (Scheme 1).

Thermodynamic analyses of possible contributing steps and a comparison with the measured heats of adsorption indicates that simple acid–base type reactions do not account for the high heats of adsorption measured at very low coverages. Summation of the heats of all of these possible steps, guided by the thermal desorption results, would account for only ~35 kcal mol^{-1} thus lending additional credibility to the postulate regarding sulfur formation at low surface coverages which would then yield overall heats of adsorption values ~90 kcal mol^{-1}.

The rapid decrease in the heats of adsorption with increased coverage indicates that the major continuing contribution to the heat values lies with interactions such as sulfite formation. However, in continuing these investigations we hope to clarify

Vapour pressures of $CaCl_2$–NaCl–H_2O and $MgCl_2$–NaCl–H_2O at 25°C. Prediction of the water activity of supersaturated NaCl solutions

DOAN THI AN, TJOON TOW TENG,[1] AND JAMES MALCOLM SANGSTER[2]

Département de Génie Chimique, Ecole Polytechnique, Campus de l'Université de Montréal, C.P. 6079, Succursale "A", Montréal (Qué.), Canada H3C 3A7

Received November 28, 1977

DOAN THI AN, TJOON TOW TENG, and JAMES MALCOLM SANGSTER. Can. J. Chem. **56**, 1853 (1978).

Vapour pressures of concentrated solutions (up to $I = 14$) of the systems $CaCl_2$ + NaCl + H_2O and $MgCl_2$ + NaCl + H_2O have been measured at 25°C by the static method. By means of reverse application of the Reilly–Wood–Robinson and Zdanovskii–Stokes–Robinson equations to these data, water activities of supersaturated NaCl solutions up to ~15 *m* have been deduced, and are represented in polynomial form.

DOAN THI AN, TJOON TOW TENG et JAMES MALCOLM SANGSTER. Can. J. Chem. **56**, 1853 (1978).

Les pressions de vapeur des solutions concentrées (jusqu'à $I = 14$) des systèmes $CaCl_2$ + NaCl + H_2O et $MgCl_2$ + NaCl + H_2O ont été mesurées à 25°C au moyen de la méthode statique. L'application à rebours des équations de Reilly–Wood–Robinson et de Zdanovskii–Stokes–Robinson à ces données a été effectuée pour calculer les valeurs de l'activité de l'eau de solution aqueuses sursaturées du NaCl jusqu'aux concentrations ~15 fois molales. Les résultats sont présentés en forme d'un polynome.

Introduction

In previous work (1, 2) the equations of Reilly–Wood–Robinson (RWR) and Zdanovskii–Stokes–Robinson (ZSR) have been used in reverse on water activity (a_w) data of mixed aqueous solutions to obtain supersaturated a_w's of single solutes. The calculations were done on existing data of various mixed solutions for certain electrolytes beyond their individual solubility limits.

Sodium chloride has been known to be salted-in by certain solutes in water (3), especially solutes with the common anion. In the present work, $MgCl_2$ and $CaCl_2$ have been chosen as partner solutes. Water activities of these systems have been measured by the static method to concentrations higher than those previously reported in the literature. The reverse calculation procedures introduced previously (1, 2) have been used here to extend supersaturated a_w values for NaCl up to ~15 *m*.

Experimental

Chemicals

NaCl (Anachemia, reagent) was dried at 100°C and used without further treatment. $MgCl_2.6H_2O$ (B.D.H Anala R) and $CaCl_2.2H_2O$ (Anachemia reagent) were treated (3*c*) to remove any superficial water. Distilled water was degassed by double distillation *in vacuo*.

Apparatus

The apparatus was similar to that described previously (4), except that the transducer and servo pressure controller were omitted.

Procedure

The salts were weighed into the sample flask through a capped side arm, after which water was distilled in through the vacuum manifold. The weight of water was determined by difference. A series of measurements were taken, starting with a dilute solution and concentrating it after a vapour pressure measurement by evaporating some solvent. Otherwise the manipulations were as previously described (4).

Results and Discussion

NaCl Alone

The apparatus and technique were first tested by measuring the vapour pressure of water and aqueous NaCl solutions at 25°C. The results for NaCl below saturation, expressed as osmotic coefficients, are shown in Fig. 1. This compares our measurements with those of Gibbard *et al.* (5), using as reference the standard data of Robinson and Stokes (taken from the equation parameters of Childs *et al.* (6)). Corrections for non-ideality of the vapour phase were not made in the present work, as these were usually less than the deviations shown in Fig. 1.

Mixed Electrolytes

Tables 1 and 2 present our experimental data of the mixed systems $CaCl_2$ + NaCl + H_2O and $MgCl_2$ + NaCl + H_2O at 25°C. Measurements were taken on both sides of the saturation limit of NaCl, at which $a_w = 0.75$ and $I = 6$. The solute mole fraction of NaCl was kept small for the special purposes of this work, i.e. to make I as large as possible (or a_w as small as possible) without precipitating the salts.

ZSR Equation

The application of this equation with corrections

for Zdanovskii non-ideality (1, 2) is valid for mixed solutions whose $a_w < 0.75$. In the present work we have calculated a ZSR deviation factor b_Z for solutions of $a_w > 0.75$ (3*b*, *c*, 7, 8) and for these systems it was found that b_Z could be represented empirically by the equation

$$[1] \qquad b_Z = b_0 + b_1 a_w + b_2/y_1 y_2$$

where the y's are solute molality fractions and b_0, b_1, and b_2 are constants. Equation [1] was assumed to be extrapolatable into the supersaturation region. Those pertinent data in Tables 1 and 2 were used to

calculate supersaturated a_w's as before (1, 2). The results appear in Tables 3 and 4 and are incorporated in Fig. 2.[3]

RWR Equation

The application of this equation, with corrections (2), is valid for mixed solutions whose $I > 6$. The corresponding RWR deviation factors (2) were found for solutions at $I < 6$ (3*b*, *c*, 7, 8) and could be represented as functions of a_w or I:

$$[2] \qquad b_{RWR} = c_0 + c_1 a_w$$

or

$$[3] \qquad b_{RWR} = d_0 + d_1 I$$

where the c's are independent of a_W and the d's inde-

Intermediates in the γ-radiolysis of divalent sulfur compounds in dilute glass matrices

FRANK CUTHBERT ADAM, GLENN EDWARD SMITH, AND ALLEN JOHN ELLIOT
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received September 7, 1977

FRANK CUTHBERT ADAM, GLENN EDWARD SMITH, and ALLEN JOHN ELLIOT. Can. J. Chem. **56**, 1856 (1978).

The optical spectra of the charged ions obtained from γ-irradiation of dilute alkyl mercaptans, sulfides, and disulfides in a variety of dilute rigid glasses are measured at 77 K. The photochemical stability of these ions is determined. A new photochromic species has been found. It is derived from a mercaptan dimer cation and is analogous to the photochromic anion produced from alkyl disulfides. The results of γ-radiation are compared to the uv photolysis of similar matrices, and it is found that the thiyl (RS·) and perthiyl radicals (RS_2·) are not generally in evidence in γ-irradiated matrices although they may be obtained by appropriate annealing or photobleaching of the irradiated matrix. The ions which have been characterized optically are RSH^+, RSH^-, $RSSR^+$ or their dimers, and RSS(H)R. The relative stabilities of these species in the low temperature glasses are determined.

FRANK CUTHBERT ADAM, GLENN EDWARD SMITH et ALLEN JOHN ELLIOTT. Can. J. Chem. **56**, 1856 (1978).

On a obtenu les spectres optiques d'ions portant des charges; ceux-ci ont été préparés par irradiation γ d'alkyl-mercaptans, de sulfures d'alkyle, de disulfures d'alkyle dilués dans un certain nombre de verres rigides à 77 K. On a déterminé la stabilité photochimique de ces ions. On a trouvé une nouvelle espèce photochromique. Elle dérive d'un cation dimère du mercaptan et elle est analogue à l'anion photochromique obtenu à partir des disulfures d'alkyle. On a comparé les résultats obtenus par irradiation γ à ceux obtenus par photolyse uv de matrices semblables et on a trouvé que les radicaux thiyl (RS·) et perthiyl (RS_2·) ne se retrouvent généralement pas dans les matrices ayant subit une irradiation γ quoiqu'elles peuvent être obtenues si l'on recuit ou si l'on fait subir une photodécoloration appropriée à la matrice irradiée. Les ions que l'on a caractérisés d'une façon optique sont RSH^+, RSH^-, $RSSR^+$ ou leurs dimères ainsi que RSS(H)R. On a déterminé les stabilités relatives de ces espèces dans des verres à basse température.

[Traduit par le journal]

Introduction

By currently held views in radiation biology, much of the damage caused by high energy radiation incident on living materials results not so much from primary effects but rather from secondary attack by ionized electrons and radicals produced in the surrounding medium, usually water (1). The target molecules themselves are usually present in a high state of dilution so that primary effects are minimal. It is also known that damage may eventually become localized within the target molecules at sites containing sulfur atoms (2). By way of example, disulfide linkages show a high cross-section for capture of mobile electrons, forming an anionic adduct (3) which may dissociate to give the thiyl radical RS·

$$e_m + RSSR \rightarrow RSSR^- \rightarrow RS^- + RS\cdot$$

Thiols act as efficient radical scavengers (4) also giving rise to the thiyl radical

$$RSH + X\cdot \rightarrow RS\cdot + HX$$

Depending upon the identity of R and X, the mercaptans may act to 'sensitize', 'protect against', or 'repair' damage to the substrate molecules. In any event, the transient common to most of these systems is the relatively unreactive thiyl radical and its presence is generally inferred by the detection of disulfides not present before irradiation and which result from the recombination of two such thiyl radical residues.

Earlier work done in this laboratory (5) has shown that in certain model systems which mimic the in vivo situation there were few similarities between the epr spectra of the γ-radiolysed and uv photolysed systems, both of which were purported to form the ubiquitous thiyl radical. This has resulted in much more detailed investigation of the uv photolysis of simple aliphatic mercaptans (6), sulfides, and disulfides (7), dissolved at low concentration in rigid organic glasses maintained at low temperatures. In such rigid media, diffusion controlled processes (such as thiyl recombination) can be retarded so that the metastable intermediates can be studied by conventional optical and epr techniques. The uv photolysed glasses have led to a characterization of the thiyl radical RS·, of the perthiyl radical RS_2·, and of other relevant species which may be of interest as possible intermediates in the γ-radiolysis of the same systems.

It is the aim of the present study to determine the nature of the metastable transients formed by γ-radiolysis and compare them, when possible, to those obtained by photolysis.

Three solvents are of particular utility in the present work in that each will form, at 77 K, a rigid transparent glass suitable for most optical studies, but will differ in the nature of the ionic transients that they will stabilize. These three solvents are MTHF (2-methyl tetrahydrofuran), 2-BuCl (2-chlorobutane), and 3MP (3-methyl-pentane) and because of their high concentration will sustain most of the radiation damage by the general reaction [1].

$$[1] \qquad MH \rightarrow MH^+ + e$$

In MTHF, the solvent cation rapidly disproportionates to give the solvent radical M· and a solvated proton. The ejected electron is either trapped in the matrix or adds to a suitable solute acceptor to give a stabilized anion species (8). On the other hand, 2-BuCl suffers dissociative electron capture to give immediately chloride ion and the corresponding butyl radical, while the cation in this case can oxidize a solute molecule to give a stabilized solute cation (9). The hydrocarbon glass 3MP stabilizes neither the free electron nor the MH^+ ion, so that both cationic and anionic solute species may be observed, along with any neutral radical entities which may result from ion recombinations and solvent decomposition (10).

Experimental

The general procedures have been described earlier (6, 7) and are analogous to those used in photolysis experiments. The solvents were purified by passage through activated silica gel columns and freshly distilled before use. The mercaptans were distilled under dry nitrogen gas at ambient pressure. The sulfides and disulfides were distilled at reduced pressure before use. All samples were prepared under high vacuum conditions with optical samples being in 15 mm id sealed suprasil ampoules while epr samples were in 3 mm id suprasil tubes. Both epr and optical samples were held within 2°C of the boiling point of liquid nitrogen and warmed by adjustment of the gas flow rate (epr) or liquid refrigerant level in a special optical Dewar. A Gates P-109 high pressure 100 W mercury lamp (for uv) or 500 W tungsten projection lamp (for visible light) were used for photobleaching experiments, although in some cases the Beckmann DU-2400 spectrophotometer provided sufficient intensity at the appropriate wavelength to effect the bleaching transformations. Otherwise the above sources were used in conjunction with those Corning Glass Co. filters required to isolate the spectral region of interest.

It was difficult with the large optical cells to produce clear glasses which did not shatter during the protracted times required to carry out some of the experiments. For this reason 20% by volume 3MP was added to all MTHF and 2-BuCl glasses. These modified glasses had all of the radiolytic properties associated with the pure matrices, so the mixtures will accordingly be referred to as 'MTHF' or '2-BuCl' in the following text.

The irradiation source was a ^{60}Co Gammacell 220 unit from Atomic Energy of Canada Ltd. and the dose rate was approximately 8×10^4 rad/h. It was necessary to irradiate the smaller samples used for epr study about 5–10 times longer than was required to obtain satisfactory spectra from the optical samples (i.e. with absorbancies in the 0.1 to 1.0 range).

Results

The optical spectra are described for the different substrates in Sections *A–C* dealing with the sulfides, disulfides, and mercaptans respectively. These are further subdivided according to the solvents used; first described are 2MTHF glasses which preferentially stabilize the ionized electrons, or substrate anions. Solute cations should not form in this glass except under very unusual circumstances. Secondly, the results for γ-irradiated 2BuCl glasses are described. In this matrix one expects absorptions from solvent or solute cations and nothing from the anionic species. Finally the spectra of irradiated 3MP glasses are considered. Absorptions due to both cationic and ionic substrate radical ions should be present, and each would be expected to tally (separately) with the absorptions observed in the other two solvents.

In each of the above glasses there will be, along with other non-absorbing species, solvent radicals resulting from the γ-irradiation.

A. Alkyl Sulfides

(1) 2MTHF Glasses

A γ-irradiation of a 0.1 *M* EtSEt/MTHF glass at 77 K produces only the blue coloration typical of the solvent trapped electron. This color may be bleached away with ir light giving rise to no new optical absorptions above 350 nm. The coloration fades on warming the matrix.

(2) 2BuCl Glasses

A γ-irradiated 0.1 *M* Et_2S/2BuCl glass gives an optical absorption at 475 nm, suggesting that this peak is due to a cation. An additional peak at 375 nm is also observed. Neither peak is affected by photobleaching and both disappear as the matrix is warmed to the melting point.

(3) 3MP Glasses

The corresponding 3MP glasses give an optical absorption at 475 nm, in addition to that observed in the MTHF glass. The latter transition is removed by an ir bleach or by thermal annealing of the matrix, during which the 475 nm peak is unaffected. The absorption at 375 nm of the BuCl glass is absent in 3MP, however.

The rose colored 0.1 *M* Et_2S/3MP glass is not readily altered by illumination at wavelengths longer than 254 nm, but fades irreversibly when warmed to 88 K to give pale yellow glass.

B. Alkyl Disulfides

(1) 2MTHF Glasses

As has been noted with other primary or secondary alkyl disulfides (11), EtSSEt exhibits photochromic behavior when γ-irradiated in MTHF glasses at 77 K. The absorption immediately following irradiation is at 420 nm and the glass is yellow. Bleaching with light in the 380–480 nm range gives the simultaneous diminution of the 420 nm peak and growth of a double peak in the near ir at 700 and 880 nm. Bleaching with 700–1000 nm light restores the original absorption at 420 nm. In the following text, the yellow form will be referred to as 'A' while its photochromic partner will be 'B'. All disulfides exhibit the initial 'A' absorption, but tertiary butyl disulfide cannot be converted to the 'B' form.

The photochromes 'A' and 'B' are bleached by near uv radiation to give weak absorptions near 400 nm and 520 nm.

(2) 2BuCl Glasses

All alkyl disulfides have absorptions near 720 nm in BuCl glasses (11) at 77 K. These glasses also have absorptions near 440 nm, as does the irradiated pure 2BuCl glass at 77 K. The 720 nm peak is stable to illumination at this wavelength, but photolysis of the 440 nm peak causes a reduction in its magnitude with concomitant growth of the 720 nm peak. This process is not reversible, and is not photochromic. It has been attributed (11) to the process

$$RSSR + BuCl^+ \xrightarrow{h\nu} BuCl + RSSR^+$$

wherein $BuCl^+$ absorbs at 440 nm and $RSSR^+$ absorbs at 720 nm.

(3) 3MP Glasses

Photochromism is observed in disulfide–3MP glasses; a 0.1 *M* Et_2S_2/3MP glass gives with γ-radiation one peak at 420 nm and a second peak at 720 nm as in Fig. 1*a*. The latter peak is stable to prolonged photolysis in the 720 nm region. On the other hand, photobleaching the 420 nm peak causes loss of this 'A' peak and growth of the 'B' peaks, superimposed on the cation absorption at 720 nm as in Fig. 1*b*. The 'A' ↔ 'B' transformations of Figs. 1*a* and *b* can be cycled several times without affecting the cation absorption intensity.

As far as the relative peak heights of the 420 and 720 nm absorptions are concerned, the spectrum of the 0.1 *M* Et_2S_2/3MP glasses in Fig. 1*a* is very similar to that obtained from irradiated pure *n*-amyl disulfide at 77 K (12). Since the latter compound scavenges both electrons and positive charges equally effectively, one must conclude that Et_2S_2 in 3MP does too. The ratio OD(anion)/OD(cation) is about 4 in each case. For 0.1 *M* t-Bu_2S_2/3MP glasses the

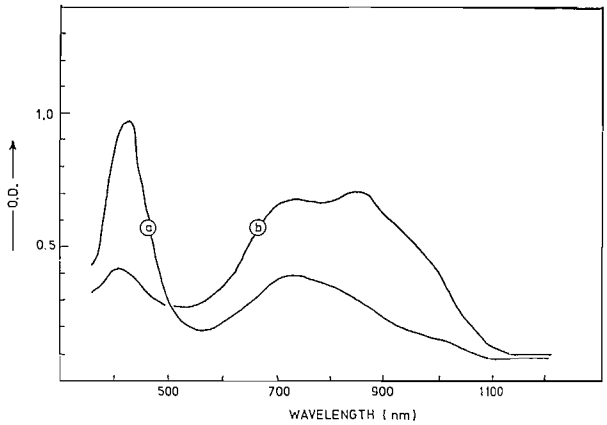

FIG. 1. Photochromic behavior of γ-radiolysed 0.1 *M* ℓ^{-1} Et_2S_2/3MP glass. (*a*) Initial spectrum, dose 1.6×10^{18} eV g^{-1} at 77 K and showing $Et_2S_2^-$ (420 nm) and $(Et_2S_2)_2^+$ at 720 nm. (*b*) Following 10 min 360–485 nm photobleach showing $(Et_2S_2)^+$ at 420 nm, EtSS(H)Et at 700–820 nm. A 800 nm photobleach will restore (*a*).

anion peak occurs at 430 nm and the cation peak occurs at 720 nm; the absorbance for the anion peak is roughly the same (at equivalent dose) for both the ethyl and *tert*-butyl derivatives, while the cation absorption is decreased by a factor of 6 for the *tert*-butyl disulfide. One can conclude from this that the efficiency of cation transfer from the solvent to the solute is much lower for *tert*-butyl derivatives than for the other alkyl disulfides. This is perhaps due to the 'shielding' of the disulfide linkage by the bulky tertiary alkyl groups.

As was also found for the pure *n*-amyl disulfide system (12) following γ-radiation, there was a gradual decay of the 'A' photochrome in the Et_2S_2/3MP system. Only a part of this decay can be accounted for by a slow 'A' → 'B' dark reaction. The decay can be accelerated by photobleaching with light in the 300–400 nm region, a result in accord with the work of Milliken *et al.* (13) who observed the effect in pure polycrystalline ethyl disulfide. In the 3MP matrix, the cation absorption at 720 nm is not materially affected by this photobleach (14).

C. Alkyl Mercaptans

(1) 2MTHF Glasses

When a 0.1 *M* EtSH/MTHF glass is irradiated, one obtains a greenish-blue glass which shows a solvent trapped electron absorption near 1150 nm, and a weak peak near 408 nm. An ir photobleach removes the former absorption while at the same time the 408 nm peak grows in intensity, with the result that the glass becomes yellow in color. A photobleach in the 400 nm region produces no immediate change (i.e. no photochromism) although prolonged bleaching causes the peak to shift to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

395 nm. The effect of a 300–400 nm bleach is similar. Clearly the original 408 nm absorption is due to an electron adduct to RSH, or is a product formed from RSH^- (15).

(2) 2BuCl Glasses

The γ-radiolysis of the 0.1 *M* EtSH/2-BuCl system produces a yellow glass. The peak located at 400 nm is not photochromic and there is no absorption in the 800 nm region. An identical absorption is obtained by 253.7 photolysis of the EtSH/BuCl glass (following slight warming) and can be attributed to the thiyl radical. It can arise in the γ-radiolysed system by a deprotonation reaction.

$$RSH^+ \rightarrow RS\cdot + H^+$$

$$H^+ + Cl^- \rightarrow HCl$$

(3) 3MP Glasses

The γ-irradiation of a 0.1 *M* EtSH/3MP glass produces a yellow–green coloration in the matrix at 77 K. This is due to an absorption at 420 nm and a double peak at 700 and 880 nm as in Fig. 2*a*. A short photobleach of the 420 nm peak produces no change, while a similar exposure to 800 nm radiation produces a marked increase in the absorption at 420 nm and total loss of absorption at 700 and 880 nm. This can be seen in curve *b* of Fig. 2. Illumination of this yellow matrix with 420 nm light restores the original spectrum of curve *a*. This photochromic behavior is also observed with isopropyl mercaptan/3MP glasses but not with the 0.1 *M* *tert*-butyl derivative, which gives a single nonphotochromic peak at 430 nm. There are quite apparently two species which may absorb in the 400 nm region, one of which is photochromic and the other of which is not. Furthermore the two photochromic species observed with EtSH appear identical in all ways to the corresponding 'A' and 'B' modifications observed with ethyl disulfide glasses.

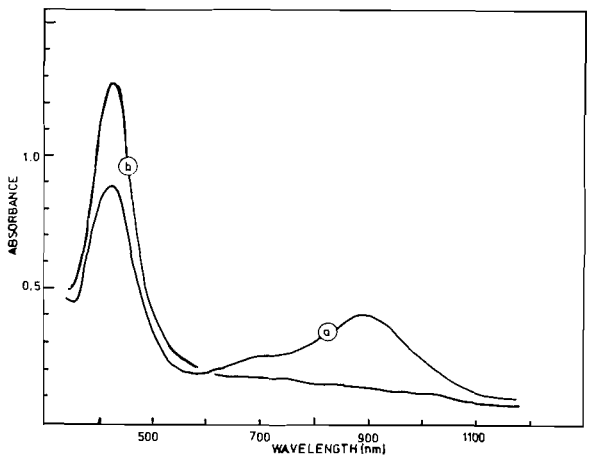

FIG. 2. Photochromic behavior of a γ-radiolysed 0.1 *M* ℓ^{-1} EtSH/3MP glass at 77 K. (*a*) Initial spectrum, dose 3.0×10^{18} eV gm^{-1} showing $(EtSH)_2^-$ at 420 nm, EtSS(H)Et at 700–820 nm. (*b*) Following 10 min >750 nm photobleach showing $Et_2S_2^-$ and $(EtSH)_2^-$ at 420 nm. A 420 nm photobleach will restore (*a*).

If the irradiated glass is stored overnight at 77 K, or subjected to a 300–400 nm photobleach, the 420 peak shifts to ~405 nm, and all absorptions in the 720–880 nm region are lost. The species produced may be the thiyl radical EtS· which is known to absorb at 405 nm in this particular matrix (6, 7). It is known that 300–400 nm light will not itself induce photolysis of the substrate RSH.

Discussion

There are complicating factors in the analysis and assignments in the optical spectra of irradiated and/or photolysed divalent sulfur compounds. For instance S_3 (16), S_8, RS·, RS_2·, and $RSSR^-$ are known to absorb in the spectral region between 380 and 425 nm as does, apparently, the electron adducts to mercaptans in nonpolar glasses. It would therefore be quite easy to make erroneous assignments to absorptions occurring in this region. Another difficulty arises because many of the radicals or radical ions of interest here can be produced by a variety of means under different experimental conditions. This has resulted in a number of entirely divergent assignments having been made to ostensibly the same species. We will try to reconcile some of these differences in the following discussion.

The particular advantage of working with low concentrations of sulfur substrates in rigid organic glasses is that the unstable transients can only react with their nearest neighbors, which are usually solvent molecules. Photolysis studies (7) have shown that sulfur atoms, for instance, do not migrate in 3MP at 77 K but only become mobilized as the temperature of the medium is warmed to ~85 K. As a result, species such as S_3 and S_8 can be logically eliminated as being present in the γ-radiolysed systems just described. Migration of smaller species such as protons are not ruled out however. Photolysis studies (7) have also shown that solute–solute interactions are not completely eliminated at the concentrations used here (0.1 mol dm^{-3}). These solutions are not sufficiently dilute to completely prevent association of the solute molecules as the liquids are frozen to the glassy state and some dimers are unquestionably present as the glasses finally harden. Once formed, however, no further changes in molecular distribution are possible. Dilute glasses are therefore intermediate between liquid phase studies where diffusion is unrestricted, and the solid crystalline state where there is no diffusion but where

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

short range solute–solute reactions may occur with ease.

(1) The Photochromic Process

Without a doubt the most intriguing aspect of the present radiolytic studies in the glassy phase is the photochromic transformation and the observation of this phenomenon with dilute mercaptans as well as with disulfides. It seems unlikely that such a close similarity in spectral properties in these two systems could result from 'accidental' coincidences between one-sulfur molecular species derived from a thiol and the two-sulfur species such as would be formed from a disulfide. We thought for some time that the photochromism could only result from the reversible 'pumping' an electron from a monomeric thiol negative ion to a thiocarbonyl molecule.

$$CH_3CH_2SH^- + CH_3CH{=}S \underset{h\nu'}{\overset{h\nu}{\rightleftharpoons}} CH_3CH_2SH + CH_3CH{-}S^-$$

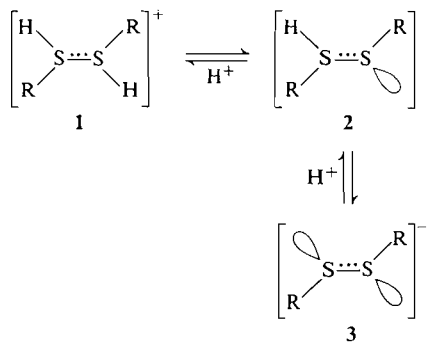
These particular species would have been anticipated to result from a tautomeric disproportionation of $Et_2S_2^-$. The thiocarbonyl, which absorbs weakly at 520 nm (7), has been observed to result from electronically excited RSH and RSSR. Dimeric species were not suspected at that time. Although this mechanism 'explains' why *tert*-butyl derivatives do not undergo photochromism (no α-hydrogen), the scheme suffers from a number of difficulties not the least of which is that aliphatic thioketyl anions have not been found to have optical absorptions in the 600–900 nm region and the proton hyperfine structure which might be expected for a species such as $CH_3\dot{C}HS^-$ is completely lacking in the epr spectrum (17).

On the other hand, the identification of the 'A' photochrome as the disulfide anion appears to be on firm ground. In the pulse radiolysis of aqueous disulfides, an absorption near 410 nm grows in at the same rate as the absorption of the hydrated electron disappears (18). Akasaka *et al.* (19) have also shown that single crystals of cystine hydrochloride turn yellow when γ-irradiated at low temperatures. The n–σ* absorption near 400 nm is associated with an anion with an epr signal containing the proton hyperfine structure characteristic of an intact C—S—S—C skeleton. This identification is consistent with our observation of an optical transition at 420 nm in irradiated Et_2S_2/MTHF and /3MP glasses. This assignment is presumed correct in the following discussion.

The most important feature of the mercaptan photochromism is that it is observed in 3MP but not in MTHF glasses, while disulfides exhibit the effect in both of these matrices. A second distinction is that it is the 'B' photochrome that is formed initially with thiols, while for disulfides it is the 'A' form which is produced during the radiolysis. These data are mutually compatible if the 'A' photochrome can be formed by an electron adduct to disulfide (i.e. $RSSR^-$) and if the 'B' form has a cationic thiol precursor. This precursor cannot be RSH^+ since the butyl chloride glasses give no indication of absorption in the 700–900 nm region and this ion does not meet the requirement of having two sulfur atoms in close proximity, so that $RSSR^-$ may be formed readily by a photochromic transformation. The same objection cannot be raised against a thiol dimer. Both 2-BuCl and 2-MTHF are considerably more polar than 3MP and may not support self-association of thiols to the extent that 3MP does. The presence of thiol dimers has already been established in the uv photolytic studies of the 3MP glass at the same solute concentration (7). In that instance, both the thiyl radical RS· (from the monomer) and the perthiyl radical RS_2· (from the dimer) are formed during the photolysis at 77 K. In the present case, if cationic dimers are indeed involved in the radiolysis then the most probable reaction to occur is the charge transfer process from the solvent cation;

$$(RSH)_2 + MH^+ \rightarrow (RSH)_2^+ + MH$$

The resulting dimer cation is in fact a fully protonated disulfide anion and may be converted to the latter by the successive deprotonations through a sulfenium radical intermediate, RSS(H)R. Thus,



The sulfenium radical **2** has been postulated as an intermediate in pulse radiolysis studies (18). We suggest that the ionized thiol dimer $(RSH)_2^+$ (i.e. **1**) spontaneously deprotonates to give the sulfenium species **2**, and that this is the species 'B' of both the irradiated mercaptan and disulfide systems. This molecule then undergoes photon-assisted deprotonation to give the 'A' modification **3**. The proton remains nearby in the medium because of the negative charge on **3**, but is readily available for the reverse photoinduced protonation 'A' → 'B'.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The foregoing scheme seems more plausible than that originally suggested (11) to explain the photochromism of the disulfide negative ion. It was thought to arise from photoinduced interchange between geometrical isomers (rotomers) of this ion. However it is difficult to see why mercaptans should give mostly the 'B' conformers while disulfides give the 'A' form. This is especially true for the *tert*-butyl derivatives which would be expected on steric grounds to give the 'B' or '*trans*' form for both thiol dimers and disulfides (11).

The reason that *tert*-butyl mercaptan does not undergo the photochromic reaction may now be ascribed to a lower association constant, to a lower probability of cationic exchange from the solvent radical ion (as was observed with the corresponding disulfide), or to an increased susceptibility for the sulfenium intermediate to decompose either by C—S cleavage, or by ejection of a thermal hydrogen atom. Thus, with the *tert*-butyl derivative

$$RSS(H)R \rightarrow RS_2\cdot + HR$$

or

$$\rightarrow RSSR + H\cdot_{th}$$

The last two reactions may also account for the fact that the sulfenium intermediate 'B' is not observed by photobleaching the 'A' species produced by electron attachment to *tert*-butyl disulfide. The bulky alkyl groups could also hinder any geometrical readjustments which the transformation might require.

(2) Nonphotochromic Anions

Since the photochromism model described above depends on the formation of thiol dimers in 3MP at 77 K, EtSH/3MP glasses have been studied at various EtSH concentrations (0.001 to 0.3 *M*) and different γ-radiolytic doses. The concentrations of the nonphotochromic yellow and photochromic blue species increase linearly with dose, but the relative proportions of each remain roughly the same in all determinations, so there is no systematic variation which will allow us to calculate an association constant. However, if the photochrome 'B' is indeed due to a dimer, then the constancy in relative absorptions between the two products suggests that the anionic species absorbing at 420 nm may also be a dimer ion. Thus,

$$(RSH)_2 + e \rightarrow (RSH)_2^-$$

We have obtained no evidence that the dissociative electron capture reaction

$$RSH + e \rightarrow R\cdot + SH^-$$

has occurred in 3MP matrices where alkyl radicals may be readily detected by epr at 77 K. This contrasts with more polar media (e.g. aqueous) where this reaction occurs readily (20). Although the optical absorptions in the near ir observed with RSH in both 3MP and 2MTHF are similar to those of the solvent trapped electron, we have been unable to get the singlet epr spectrum of this species under conditions where the signal is readily observed with the irradiated pure solvents. This suggests that the electrons are trapped near to mercaptan molecules in the glassy solutions and if indeed the molecular ion RSH^- is formed then it too absorbs in the near ir.

The disulfide negative ion has been discussed in the previous section. Sulfides do not apparently form negative ions, of either a monomeric or dimeric form.

(3) Nonphotochromic Cationic Species

Stable cations are expected to be formed only in BuCl or 3MP glasses.

(a) Sulfide Cations

Two absorptions can possibly be attributed to sulfide cations: that at 475 nm (which is observed in both 3MP and BuCl) and that at 375 nm (which is seen only in BuCl). One must compare these values to those obtained from irradiated single crystals of methionine (21) or *N*-acetylmethimine (22) which absorb in the 600–750 nm region. This absorption is photolabile and has been attributed to both the monomeric cation and to the dimeric cation (23), mostly on the basis of the epr proton hyperfine structure. This latter conclusion has, however, been contested (24). In aqueous sulfide solutions using hydroxyl radicals as oxidant (25) only dimeric cations, $(RSR)_2^+$, are observed, it being thought that the monomer ions are susceptible to deprotonation yielding the α-abstraction radical RSR-(—H). Pulse radiolysis studies (26) demonstrate in a very convincing manner that in aqueous solutions an absorption at 470 nm must be attributed to $(RSR)_2^+$. It has also been suggested that RSR^+ and $(RSR)_2^+$ both absorb at ~470 nm (27). A peak at 375 nm is obtained in pulse radiolysed sulfide aqueous solutions containing halide ion and assigned to the species R_2SCl (28). Since we observe a transition here in the Et_2S/BuCl system (but not in a 3MP glass) we suggest that rather than the formation of RSR^+ by charge transfer, in BuCl,

$$BuCl^+ + RSR \rightarrow R_2SCl + Bu^+$$

while in 3MP

$$MH^+ + RSR \rightarrow MH + RSR(—H) + H^+$$

We therefore assign the 470 nm peak to the dimer cation $(RSR)_2^+$ in agreement with the pulse radiolysis experiments.

TABLE 1. Absorption maxima of charged radicals of saturated divalent sulfur compounds and their photochemical stability. The *hν* refers to bleaching in the 300–400 nm region

	Transient	λ_{max}	Solvent	Remarks
Anions	$EtSSEt^-$	420	2MTHF, 3MP	Photochromic (to EtSS(H)Et)
	$EtSH^-$	~1150 nm	2MTHF, 3MP	Photolabile
	$(EtSH)_2^-$	408	2MTHF	H^+, $h\nu \rightarrow RS\cdot$
	$(EtSH)_2^-$	420	3MP	H^+, $h\nu \rightarrow RS_2\cdot$
Neutrals	$EtS\cdot$	395	2MTHF	Photostable
		400	BuCl	Photostable
		405	3MP	Reference 6
	$EtS_2\cdot$	395	3MP	Reference 6
	EtSS(H)Et	720–880	3MP	Photochromic (to $Et_2S_2^-$) $h\nu \rightarrow RS_2\cdot$
	$CH_3CH{=}S$	520	3MP, 2MTHF	Reference 6
Cations	$(EtSSEt)_2^+$	720	3MP, 2BuCl	Photostable
	$(EtSEt)_2^+$	475	3MP, 2BuCl	Photostable
	$EtSEt^+$	~430	3MP, 2BuCl	—
	$EtSEt^+$	>600(?)	3MP	Photolabile → EtSEt(—H)

(b) Disulfide Cations

There is likewise some question as to the assignment of the disulfide cation absorption. Aqueous pulse radiolysis studies (29) suggest it should lie at ~410 nm. No dimerization is observed. Single crystal studies of cystine (30) indicate a photolabile absorption at 550 nm should be attributed to the disulfide cation. It is likely that in this case the ion is held in a thermally metastable configuration by the crystal host and so the results cannot be compared directly to those obtained in less rigid matrices. As in the case of irradiated sulfide glasses, the formation of disulfide dimers cannot be precluded and the possibility that the absorption at 720 nm is in fact due to $(RSSR)_2^+$ must be considered. As can be seen, a small residual absorption at 420 nm occurs in Fig. 1*b*. This absorption may be due to $RSSR^+$ and it is normally concealed (as in Fig. 1*a*) by the more intense $RSSR^-$ absorption. In RSSR–BuCl glasses, where the latter species is absent, there is also absorption at 440 nm, but the pure irradiated glass also has an optical transition in this region (see Fig. 7 of ref. 11) so that no definitive conclusion can be reached. Until evidence is obtained to the contrary, the 720 nm peak in RSSR–3MP glasses is assigned to a disulfide dimer cation, while the monomeric ion is assumed to absorb near 430 nm.

(c) Mercaptan Cations

As noted in earlier sections, there has been no absorption directly attributable to mercaptan cations. The double peak at 700–820 nm in 3MP is due to sulfenium RSS(H)R and the single peak at 400 nm in BuCl is due to RS·. The precursors of these species are $(RSH)_2^+$ and $(RSH)^+$ respectively. RSH^+ should be stable in 3MP glasses, since this medium lacks strong proton acceptors such as Cl^- as found in BuCl glasses. It is possible that this species absorbs below 350 nm, the lower limit of our determinations. This would then agree with the pulse radiolysis results which place the absorption of aquated (or protonated) thiyl radical at 330 nm (20).

The ultimate assignments will have to await further experiments which are rather more sensitive to the dimer–monomer ratios of these glasses. It is for this reason that our epr experiments have not been particularly helpful. Apart from the many interfering resonances due to solvent radicals, etc., the smaller epr samples may well contain a different dimer–monomer balance due to the fact they freeze much more quickly than the large optical samples. This is especially unfortunate since it would have been a useful ancilliary to optical detection because, as has been mentioned, many irradiated sulfur compounds absorb in the same region of the spectrum. Since several of these compounds may be expected to occur in the same radiolysed system, great care should be taken when analysing the results of, say, pulse radiolysis experiments in nonpolar liquids where an optical method is the sole means used to discriminate between the reactive intermediates present. A summary appears in Table 1.

Photolyse de l'isoprène gazeux entre son seuil d'absorption (ca. 255 nm) et 147.0 nm

ROSAIRE DEMERS, GUY J. COLLIN[1] ET H. GAGNON-DESLAURIERS (MME)

Département des Sciences Pures, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Reçu le 21 octobre 1977

ROSAIRE DEMERS, GUY J. COLLIN et H. GAGNON-DESLAURIERS. Can. J. Chem. **56**, 1864 (1978).

La photolyse de l'isoprène a été étudiée entre son seuil d'absorption, ca. 255 nm, et 147.0 nm à des pressions variant entre 30 et 2660 N m^{-2}. Entre 230 et 255 nm, les produits légers formés ont des rendements qui suivent une loi de type Stern–Volmer. On en conclue que la molécule photoexcitée est stabilisée par collision dans cette région de pression. A 174 nm et à 163.3 nm, l'effet de pression est beaucoup moins important et la totalité des molécules photoexcitées se fragmentent. A 147 nm, aucun effet de pression n'est observable, et le produit majeur est le vinylacétylène ($\Phi = 0.66$). La formation de ce produit est expliquée par la scission de la liaison CH_3—C_4H_5 suivie de la fragmentation du radical C_4H_5* excité. A 174 nm, ce radical peut être stabilisé par collision. Enfin nous avons mesuré le rapport $k(CH_3 + H_2S)/k(CH_3 + \text{isoprène}) = k_1/k_{12}$ et ce rapport est de 41 ± 3.

ROSAIRE DEMERS, GUY J. COLLIN, and H. GAGNON-DESLAURIERS. Can. J. Chem. **56**, 1864 (1978).

We studied the photolysis of isoprene at wavelengths between the absorption threshold (ca. 255 nm) and 147.0 nm. The pressure effect was studied between 30 and 2660 N m^{-2}. At the lower energy, light products are formed and their yields decrease with an increase in the pressure. From Stern–Volmer plots, we have concluded that the photoexcited molecule is collision stabilized at high pressure. Less pressure dependence was observed at 174 and at 163.3 nm. At these energies, and at 147 nm, all of the photoexcited molecules decompose. At 147 nm, no pressure effect was observed, and the main product is vinylacetylene ($\Phi = 0.66$). The formation of this product was explained on the basis of the CH_3—C_4H_5 split followed by the fragmentation of the excited C_4H_5* radicals. At 174 nm, this last radical is collisionally stabilized. Finally we have measured the ratio $k(CH_3 + H_2S)/k(CH_3 + \text{isoprene}) = k_1/k_{12}$ and $k_1/k_{12} = 41 \pm 3$

Introduction

Lors de l'étude de la photolyse des butènes dans la région du l'ultra-violet sous vide, nous avons récemment étudié certains aspects de la chimie des divers radicaux C_3H_5 (1). Nous avons entrepris l'étude de l'isoprène, méthyl-2-butadiène-1,3, afin d'examiner si la scission de la liaison C—C centrale à partir de la molécule photoexcitée se fait avec une fréquence suffisante pour permettre l'étude des radicaux CH_3CCH_2. Nous sommes évidemment intéressés à connaître le comportement de la molécule photoexcitée en comparaison avec ce que nous connaissons des hydrocarbures insaturés (2).

Partie expérimentale

Produits chimiques

L'isoprène est un produit acheté de "Chem. Sample Co." de pureté moléculaire affichée de 99.5%. L'analyse de ce produit montre qu'il contient du méthyl-2-butène-2 (0.14%), du vinylacétylène (0.019%) et du méthyl-2-butène-1 (0.0061%). Un autre échantillon provenant de l' "American Petroleum Institute" de pureté moléculaire affichée à 99.96% a été utilisé à toutes longueurs d'onde. L'analyse n'a montré que la présence de méthyl-3-butène-1 (0.0026%). L'oxygène, 99.99% et l'oxyde nitrique, 99.0%, sont des produits "Matheson of Canada" et sont utilisés tels que reçus. L'iodure d'hydrogène ("anhydrous, Air liquide du Canada") de pureté 99.8% est utilisé après sublimation afin d'éliminer la présence d'iode qui s'accumule lentement dans le réservoir. On en mesure la pression, au moment de l'introduction dans le réacteur, à l'aide d'un manomètre à huile. L'hydrogène sulfuré (99.5%) est un produit de Matheson of Canada Ltd.

Préparation et analyses des échantillons

On a utilisé une rampe à vide munie de robinets en Téflon, de manomètres à membrane métallique, "Wallace et Tiernan", et maintenue à une pression de 5×10^{-6} Torr (6.6×10^{-4} N m^{-2}) ou moins à l'aide d'une pompe à diffusion à huile à deux étages.

Le réacteur est normalement un ballon de 0.5 ℓ en Pyrex attaché directement à la lampe au moyen d'un joint rodé scellé à la cire noire. Dans le cas des irradiations avec la lampe à mercure, on a utilisé un réacteur cylindrique en quartz de 0.75 ℓ situé à quelques cm de la lampe.

Les analyses ont été faites par introduction d'une fraction (5%) des échantillons photolysés dans un chromatographe à gaz équipé d'un double détecteur à flamme ionisante. On a utilisé une colonne de squalane (25%) de 8 m de longueur approximativement (3). Quelques analyses ont été faites avec une colonne d'alumine en programmation de température (30–150°C).

Lampes d'irradiations et actinométrie

La lampe à mercure utilisée est du type haute pression ("Hanovia 679A-36") et est utilisée soit avec un filtre en Vycor qui est complètement opaque en dessous de 229 nm, soit avec un filtre en Corex également opaque en dessous de 230 nm. La

lampe à azote a été préparée sur place (4) et produit des photons principalement autour de 174.5–174.3 nm. La lampe à brome a aussi été décrite et produit essentiellement l'émission du brome atomique à 163.3 nm (5). La lampe à xénon est essentiellement monochromatique (147 nm) (6). Tous les spectres des lampes, ainsi que l'absorption par l'isoprène des raies émises par le mercure ont été mesurées à l'aide d'un monochromateur "McPherson 235". On a ainsi observé que l'isoprène commence à absorber vers 255 nm. Par exemple 20 Torr (2660 N m^{-2}) d'isoprène absorbent ca. 10% de la raie située à 253.7 nm. L'absorption est complète vers 236 nm. L'actinométrie a été réalisée par comparaison. Dans le cas des lampes à azote et à brome on a admis que le rendement quantique $\Phi(C_2H_2)$ obtenu dans la photolyse de l'éthylène est de 0.75 (7). Dans le cas de la lampe à xénon, on a admis que le rendement quantique obtenu dans la photolyse du *cis*-butène-2 est de 0.30 (8). Aucune actinométrie n'a été faite avec la lampe à mercure, la difficulté majeure résidant dans le fait que la lampe est loin d'être monochromatique. Notons enfin que l'usage de HI n'est pas sans défaut puisque des traces d'air semblent catalyser l'addition de ce produit sur l'isoprène dans un mécanisme en chaîne (voir plus loin).

Résultats

La formation des produits est rapportée sous forme de rendements quantiques lorsqu'ils sont disponibles. L'incertitude expérimentale dans ce cas est de $\pm 10\%$. Par contre, les rendements des produits relativement les uns aux autres, sont valables à $\pm 5\%$, les analyses par chromatographie, sauf pour les produits de faibles rendements, étant le plus souvent reproductibles à $\pm 2\%$.

Photolyse vers 230–255 nm

On observe que la majorité des produits légers ont des rendements qui croissent entre 30 et 250 N m^{-2} et puis qui décroissent par la suite jusqu'à 2600 N m^{-2}. On trouve dans ce groupe, l'éthylène, l'acétylène, le propyne, l'allène et le pentadiène-1,4. Ces produits ne sont pas affectés par la présence de HI ou de NO. Afin d'alléger le texte on a représenté l'inverse du rendement des produits en fonction de la pression: figs 1 et 2. L'augmentation du rendement à basse pression est due au fait de l'absorption partielle de la lumière vers 230–245.5 nm. Dès que la pression atteint 150 N m^{-2}, l'échantillon absorbait plus de 90% de ce qu'il absorbait à une pression de 2660 N m^{-2}. Les points obtenus à 30, 70 et 150 N m^{-2} ont été corrigés relativement au rendement de l'éthylène en admettant que le rendement de ce produit qui suit une loi de type Stern–Volmer entre 280 et 2660 N m^{-2}, la suive aussi entre 30 et 280 N m^{-2}.

On trouve également dans ce groupe le vinylacétylène dont le rendement est fortement augmenté en présence de NO et de HI (tableau 1). L'addition de HI, augmente en outre les rendements en méthane, butadiène-1,3, méthyl-2-butène-1-yne-3, et fait apparaître d'importantes quantités de méthylbutènes. L'oxyde nitrique fait décroître légèrement le rendement en méthane, fait disparaître celui en éthane, et augmente le rendement en vinylacétylène. Enfin divers produits (figs 3 et 4) ont des rendements qui tantôt croissent, tantôt décroissent avec l'augmentation de la pression. Il faut dire que dans la région du chromatogramme où apparaissent la majorité de ces composés (méthyl-2-butène-2, cyclopentadiène, *trans*-pentadiène-1,4,... (certains se trouvant dans la queue de l'isoprène), l'identification des produits n'est pas absolument certaine. Ces produits ont été identifiés par une astérisque dans les figs 3 et 4. Une série d'expérience faite avec le filtre en Corex diminue l'intensité de la lampe d'un facteur ca. 5. Le maximum des rendements est obtenu vers une pression voisine de 800 N m^{-2}. Par contre la distribution et le comportement du rendement des produits avec la pression, en présence de NO ou de HI est très similaire à celui observé avec le filtre du Vycor. On ne rediscutera plus des résultats obtenus avec ce filtre.

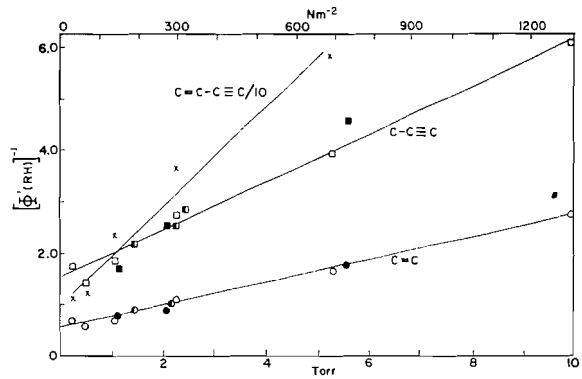

FIG. 1. Variations de l'inverse du rendement absolu (échelle arbitraire) de produits dans la photolyse de l'isoprène entre 230 et 255 nm: ×, ○, □: isoprène pur; ●, ■: isoprène + 10% NO; ◐, ◧: isoprène + 10% HI.

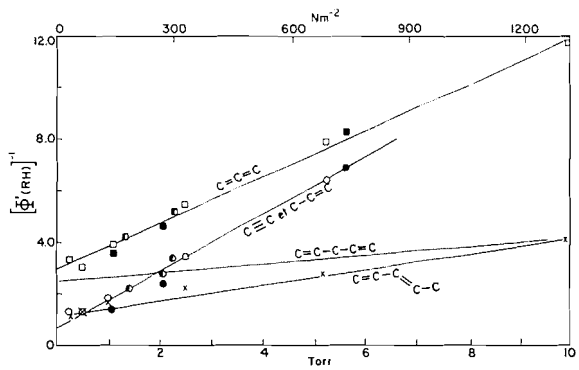

FIG. 2. Varaitions de l'inverse du rendement absolu (échelle arbitraire) de produits dans la photolyse de l'isoprène entre 230 et 255 nm: ×, ○, □: isoprène pur; ●, ■: isoprène + 10% NO; ◐, ◧: isoprène + 10% HI. Pour plus de clarté on n'a pas rapporté les points correspondants pour le pentadiène-1,4 (isoprène pur, en présence de HI).

[c]Identification incertaine.

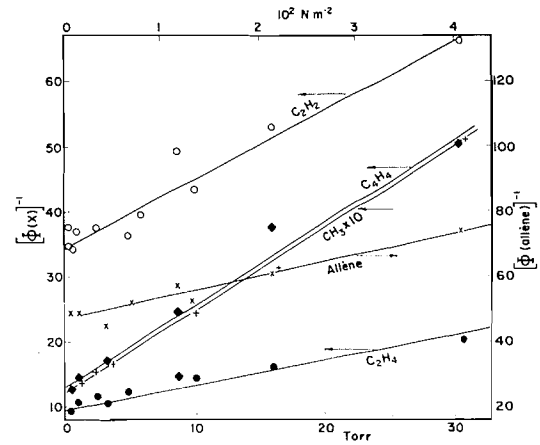

FIG. 5. Variations de l'inverse de rendements quantiques dans la photolyse de l'isoprène à 174 nm en fonction de la pression; ○: C_2H_2; ◆: C_4H_4; +: $CH_3/10$; ×: allène et ●: C_2H_4.

de HI augmente légèrement les rendements en méthane et butadiène-1,3 (fig. 5) et fait apparaître des quantités plus importantes de méthylbutènes. H_2S augmente de façon considérable le rendement en méthane (tableau 2).

Photolyse à 163.3 nm

Les résultats sont similaires à ceux obtenus à 174 nm, avec un effet de pression encore moindre. Les rendements sont indiqués dans le tableau 3, ainsi que l'effet de O_2, H_2S et de HI sur ceux-ci. L'oxygène diminue les rendements en méthane, éthane, vinylacétylène et butadiène-1,3. Au contraire, HI et H_2S augmentent les rendements en méthane, éthane, éthylène et butadiène-1,3.

Une série d'analyses a été faite pour rechercher les produits éventuels des réactions d'addition entre l'isoprène et les radicaux méthyles et les atomes

d'hydrogène d'une part, et l'isoprène et les atomes d'hydrogène et les radicaux méthyles d'autre part (tableau 4). Ces produits disparaissent en présence d'oxygène.

Photolyse à 147 nm

Les rendements des produits sont indiqués dans les tableaux 4 et 5. On note en plus l'absence d'effet de pression entre 90 et 2150 N m^{-2}. L'oxyde nitrique diminue les rendements en éthane, ainsi que de plusieurs composés en C_6. L'addition de HI ou de H_2S, augmente plusieurs des rendements dont celui du méthane $\Delta\phi(CH_4) = 0.75$, de l'éthylène $\Delta\phi(C_2H_4) = 0.12$, du propène $\Delta\phi(C_3H_6) = 0.09$, des C_3H_4 $\Delta\phi(C_3H_4) = 0.03$, ainsi que des méthylbutènes dans de plus importantes proportions.

Discussion

Bilans de matière et d'énergie

La comparaison des rendements quantiques obtenus à 174, 163.3 et 147 nm sous une pression de 133 N m^{-2} (tableaux 2, 3 et 5) montre une croissance

[a]Temps d'irradiation 30 min.
[b]Non mesuré.
[c]Rapport final C_4H_4/isoprène < 30×10^{-4} à une pression de 115 N m^{-2}.

des rendements avec l'énergie des photons incidents. A 174 nm, le produit "moléculaire", c'est-à-dire formé en présence d'un intercepteur radicalaire tel que l'oxygène ou l'oxyde nitrique, majeur est l'éthylène: $\Phi(C_2H_4) = 0.10$. A 163.3 nm, ce rendement est de 0.25. A 147 nm, le produit majeur est le vinylacétylène: $\Phi(C_4H_4) = 0.66$. Par contre l'usage d'intercepteur radicalaire comme l'hydrogène sulfuré, ou l'iodure d'hydrogène, montre un rendement appréciable en méthane: $\Phi(CH_4) \simeq 0.8$ à chaque cas. En présence de HI, de H_2S, cette formation est liée à la présence de radicaux méthyles (9):

[1] $CH_3 + HX \rightarrow CH_4 + HX$ (où X = HS, I)

Cette observation montre le rôle important de la liaison CH_3—C_4H_5 dans la fragmentation de la molécule photoexcitée.

Il est tentant de mettre en évidence la formation concurrente du radical C_4H_5, à travers une réaction similaire à la réaction [1]. L'augmentation marginale de butadiène-1,3 en présence de HI ou de H_2S, même s'il suggère la présence d'un tel radical est loin de montrer un accord quantitatif entre le rendement en radicaux CH_3 et C_4H_5 (10). Ce dernier radical, très insaturé, n'est probablement pas intercepté par H_2S, tout comme ne le sont pas les radicaux allyles (11). HI a cependant une meilleure efficacité bien qu'incomplète (10) (tableau 1). En outre la réactivité importante de l'isoprène envers les radicaux est un handicap sérieux à leur mesure.

[2] $C_5H_8 + h\nu \rightarrow C_5H_8^{**}$

[3] $C_5H_8^{**} \rightarrow CH_3 + C_4H_5$

$\Delta H = 439$ kJ mol^{-1}

Après scission de la liaison CH_3—C_4H_5, il reste un surplus de l'énergie du photon qu'il faut distribuer entre les deux fragments. Ce surplus est de 22–72 et

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

de 246 kJ mol^{-1} à 230–255 et 174 nm respectivement. On ne connaît rien de précis sur cette distribution. Si le radical méthyl emporte ce surplus, il est insuffisemment excité pour se fragmenter: $\Delta H(CH_3 \rightarrow CH_2 + H) = 468$ kJ mol^{-1}. Si le radical C_4H_5 emporte ce surplus, il est possible qu'il se fragmente: $\Delta H(C_4H_5 \rightarrow C_4H_4 + H) = 130$ kJ mol^{-1} à 174 nm. Une réaction globale du type

[4] $$C_5H_8^{**} \rightarrow C_4H_4 + CH_3 + H$$
$$\Delta H = 569 \text{ kJ mol}^{-1}$$

est donc thermiquement acceptable. La formation simultanée de méthane et de vinylacétylène est un processus mineur, puisqu'il y a toujours plus de C_4H_4 que de CH_4 moléculaires. Même vers 230–255 nm, le vinylacétylène formé en présence de NO est $\simeq 7$ fois plus important que le méthane.

A 163.3 et à 147 nm, le surplus d'énergie, après la réaction [3] est 290 et de 368 kJ mol^{-1}. L'augmentation du rendement en vinylacétylène avec l'augmentation d'énergie résiduelle est en faveur de ce mécanisme. Comme les réactions [3] et [4] sont les seules sources de radicaux méthyles (voir plus loin), et la réaction [4], la source de vinylacétylène, le rendement de ces deux produits permet la mesure des réactions [3] et [4].

Les réactions de formation de l'éthylène sont moins évidentes. En effet, il y a toujours moins de C_3H_4 que d'éthylène à être formé, et l'usage de H_2S, ou de HI, ne montre pas de façon évidente les fragments complémentaires de C_2H_4. On note cependant que le rapport C_3H_4/C_2H_4 est de 0.61 ± 0.04 entre 230 et 255 nm, 1.02 ± 0.06 à 174 nm, 0.60 ± 0.04 à 163.3 nm et de 1.5 ± 0.1 à 147 nm.

Dans la région de 230–255 nm, où l'énergie disponible par photon est de 511–461 kJ mol^{-1} une décomposition concertée peut être efficace.

[5] $$C_5H_8^{**} \rightarrow C_2H_4 + C_3H_4$$
$$\Delta H = 165 \text{ kJ mol}^{-1}$$

Cette réaction demande une modification importante de la molécule photoexcitée avec un déplacement de type [1]–[3] d'un atome d'hydrogène avant ou pendant la scission. La décomposition en deux fragments radicalaires, scission de la liaison C—C, avec formation de deux radicaux vinyles et $CH_3—C{=}CH_2$ suivie de la fragmentation du radical C_3H_5 est thermiquement inacceptable. Il en est de même de la fragmentation du radical vinyle.

[6] $$C_5H_8^{**} \rightarrow C_2H_3 + C_3H_4 + H$$
$$\Delta H = 602 \text{ kJ mol}^{-1}$$

[7] $$C_5H_8^{**} \rightarrow C_2H_2 + C_3H_5 + H$$
$$\Delta H = 610 \text{ kJ mol}^{-1}$$

Ces deux réactions ne sont donc acceptables qu'à 174 nm et en dessous. Le fragment C_3H_5 n'a pu être mis en évidence qu'à 147 nm (effet de HI ou de H_2S). Par contre on observe un léger rendement en radicaux vinyles: $\Phi(C_2H_3) = 0.03$ à 174 et à 163.3 nm et 0.11 à 147 nm rend crédible la réaction [6].

La rupture de la liaison centrale, réaction [6], produit le radical C_3H_5 de structure $CH_3—C{=}CH_2$ (en n'admettant aucune réorganisation dans la molécule photoexcitée avant ou pendant la dissociation). On sait que la fragmentation de ce radical lorsqu'il est excité peut conduire à l'allène et au propyne dans le rapport 1.5, en accord avec ce qui est observe à 147 nm (1, 12).

Enfin, un excès d'éthylène est formé. La réaction suivante est proposée pour tenir compte du bilan de matière mais la formation de radicaux C_3H_3 reste à faire (10):

[8] $$C_5H_8^{**} \rightarrow C_3H_3 + C_2H_4 + H$$

On observe à 230–255, 174 et 163.3 nm l'équivalence des rendements en propène et acétylène. Cela suggère la réaction concertée suivante:

[9] $$C_5H_8^{**} \rightarrow C_2H_2 + C_3H_6$$
$$\Delta H = 171.4 \text{ kJ mol}^{-1}$$

Cette réaction est précédée ou se fait de façon concurrente à un déplacement 4–2 d'un atome d'hydrogène dans la molécule photoexcitée. A 147 nm, le manque de propène comparativement à l'acétylène, si la réaction [9] est encore valide, est explicable par la fragmentation plus poussée du propène: l'excès d'énergie à cette longueur d'onde est de 636 kJ mol^{-1}.

Enfin, un dernier composé formé en quantités mineures est le méthyl-2-butène-1-yne-3.

[10] $$C_5H_8^{**} \rightarrow C_5H_6 + H_2 \text{ (2H)}$$
$$\Delta H = 60(540 \text{ kJ mol}^{-1})$$

Un certain nombre de composés en C_5 dont l'identification n'est pas définitive (figs 3 et 4) ont des rendements qui tantôt croissent, tantôt décroissent avec l'augmentation de pression à 230–255 nm et qui ont encore des rendements appréciables à 174 nm (produits formés en présence d'oxygène). Il faut noter ici que la photolyse sensibilisée au mercure ($^3P_1$) de l'isoprène fait apparaître les diméthyl-3,3- et 1,3-cyclopropènes qui ont un rendement dont le comportement est similaire à celui observé du méthyl-2-butène-2 (13). Ces deux composés dérivés du cyclopropène n'ont pas été identifiés, et l'absence de témoin ne permet pas d'éliminer leur formation. La présence de ces produits suggère cependant au moins à 230–255 nm, une réorganisation (isomérisation) de la molécule photoexcitée suivie d'une stabilisation par collision.

Effet de pression

Les courbes de type Stern-Volmer (figs 1, 2 et 5) illustrent la stabilisation par collision d'intermédiaires photoexcités: la molécule photoexcitée pouvant être l'un d'eux.

[11] $$C_5H_8^{**} + M \rightarrow C_5H_8^{*} + M$$

où $C_5H_8^*$ est une molécule qui ne donne plus lieu à la formation de produit léger. A 230–255 nm, l'augmentation des produits en C_5 est compatible avec la stabilisation de la molécule photoexcitée. A 174 et à 163.3 nm, la situation semble plus complexe. Le fait que les droites $\Phi(C_2H_2)^{-1}$ et $\Phi(C_3H_6)^{-1}$ en fonction de la pression sont confondues justifie la réaction [9]. Puisque le rendement en radicaux méthyles suit aussi une loi du même type, on est tenté d'admettre que même à 163.3 nm, la molécule photoexcitée a un temps de vie suffisemment long pour être stabilisée à haute pression. Cette observation est contraire avec ce qui est observé avec les butènes (1). Le spectre d'absorption de l'isoprène a été discuté (14, 15). Hormis la possibilité d'une absorption partielle par l'isomère *cis* de l'isoprène, les raies à 174 et à 163.3 nm se trouvent dans un région où existent des états Rydberg, états bien connus pour leur temps de vie relativement long.

En tenant compte de ces remarques et en utilisant les rendements obtenus à pression nulle (extrapolation des droites Stern–Volmer), on propose dans le tableau 6 le schémas de fragmentation de la molécule photoexcitée. Cette fragmentation est donc complète à pression nulle à 174 nm.

Réactions radicalaires

Le rendement en éthane, ainsi que celui de plusieurs composés en C_5 et C_6 disparaissent lors de l'addition d'oxygène ou d'oxyde nitrique confirmant ainsi leur origine radicalaire. Il faut tout d'abord noter la faible quantité d'éthane formé dans l'isoprène pur comparativement aux rendements $\Phi(CH_3)$ mesurés à l'aide de H_2S ou de HI_3 (tableaux 2 et 3). Dans ce système, les radicaux méthyles n'ont pas la chance de se recombiner entre eux mais disparaissent principalement par d'autres voies réactionnelles et l'addition directe du radical méthyle sur l'isoprène doit être envisagée. En fait on observe des produits provenant de l'addition successive du radical méthyle et d'un atome d'hydrogène, et l'inverse, sur l'isoprène (tableau 4).

TABLEAU 6. Fragmentation de la molécule isoprène photoexcitée

N°	$C_5H_8^{**} \rightarrow$	Rendements quantiques 174 nm	163.3 nm	147 nm
10	$C_5H_6 + 2H\ (H_2)$	0.02	0.05	0.09
3	$C_4H_5 + CH_3$	0.70	0.60	0.16
4	$C_4H_4 + CH_3 + H$	0.07	0.15	0.50
9	$C_3H_6 + C_2H_2$	0.03	0.095	0.04
7	$C_3H_5 + C_2H_2 + H$	—	—	0.09
5	$C_3H_4 + C_2H_4$	0.03	0.135	0.03
6	$C_3H_4 + C_2H_3 + H$	0.03	0.03	0.12
8	$C_3H_3 + C_2H_4 + H$	0.07	0.105	0.03
	Isomérisation (?)	0.06	<0.01	$\simeq 0.00$
Total:		1.01	1.165	1.06

L'addition d'un atome d'hydrogène sur l'isoprène n'est pas empêchée même par la présence d'oxygène (16). Une fraction des radicaux méthyles se combinent donc aux radicaux C_5H_9 qui en résultent. La somme des rendements en C_6 donne une limite inférieure du rendement en atome d'hydrogène puisqu'il faut tenir compte de la recombinaison des radicaux C_5H_9 entre eux. Le rendement de cette réaction peut être grossièrement évaluée sur la base de la loi statistique habituelle (17):

$$\frac{\Phi(CH_3 + C_5H_9)}{\Phi(CH_3 + CH_3)^{1/2} \cdot \Phi(C_5H_9 + C_5H_9)^{1/2}} = 2$$

Ainsi à 163.3 nm et sous 560 N m^{-2}, le rendement $\Phi(C_5H_9 + C_5H_9)$ peut être estimé à 0.07 et cette valeur atteint 0.3 à 147 nm. Le rendement en atome d'hydrogène est alors tel que $\Phi(H) = 2\Phi(C_5H_9 + C_5H_9) + \Phi(C_6)$. On obtient $\Phi(H) = 0.3 \pm 0.1$ et 0.9 ± 0.2 à 163.3 et à 147 nm respectivement. En outre le rendement en radicaux méthyles peut aussi être évalué de la même façon: $\Phi(CH_3) = 2\Phi(C_2H_6) + \Phi(C_6) + 2\Phi(C_7)$ (le terme $\Phi(C_7)$ tient compte de l'addition successive de deux radicaux méthyles sur l'isoprène). On obtient ainsi $\Phi(CH_3) = 0.68$ et 0.43 à 163.3 et à 147 nm respectivement. Ces valeurs sont sous estimées puisque la mesure systématique des produits en C_7 n'a pas été faite. On note donc une diminution des rendements en atomes d'hydrogène avec une diminution de l'énergie des photons en accord avec la fragmentation proposée de la molécule photoexcitée (tableau 6).

A 174 nm, seul le rendement en éthane intéressant cette cinétique radicalaire a été mesuré et son rendement est relativement bas. Cette observation est probablement reliée au fait que l'intensité de la lampe est plus faible que les deux autres. Il en résulte que les radicaux méthyles disparaissent du réacteur principalement par addition sur l'isoprène. Nous avons tiré avantage de ces conditions expérimentales pour mesurer le rapport des constantes de vitesse des réactions entre le radical méthyle et l'hydrogène sulfuré d'une part, et l'isoprène d'autre part.

[12] $$CH_3 + C_5H_8 \rightarrow C_6H_{11}$$

Les réactions [1] et [12] conduisent à une cinétique

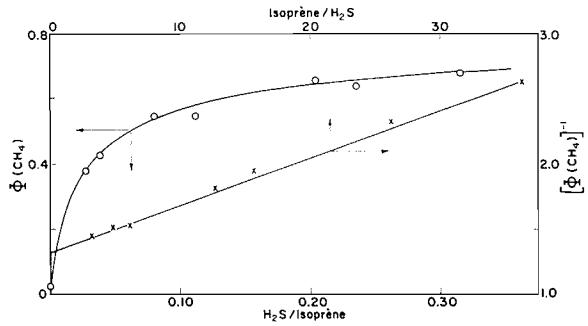

FIG. 6. Variation du rendement en méthane et de son inverse dans la photolyse à 174 nm des mélanges isoprène (5.0 Torr – 665 N m^{-2}): hydrogène sulfuré.

simple:

$$[\Phi(CH_4)]^{-1} = [\Phi(CH_3)]^{-1} + [\Phi(CH_3)]^{-1} \cdot k_{12}/k_1 \cdot [\text{isoprène}]/[H_2S]$$

La fig. 6 montre la linéarité obtenue entre l'inverse du rendement en méthane et la variation du rapport [isoprène]/[H_2S]. D'après la pente de la droite, on a estimé le rapport k_1/k_{12} à 41 $\pm$ 3. Ce rapport est sans doute légèrement sous-estimé puisque l'on a ignoré les réactions du type $CH_3 + CH_3$ et $CH_3 + C_6H_{11}$.

Nota

Dans ce système, l'usage de HI comme intercepteur radicalaire, n'est pas sans défaut. Dans chacun des cas on a noté une augmentation importante du rendement des méthyl-2-butène-2 et, en moindres quantités, méthyl-3-butène-1 (les rendements quantiques pouvaient atteindre 10) (voir aussi tableau 1). On sait que HI s'additionne facilement sur l'isoprène en position 1,4 et qu'il donne lieu à la formation des C_5H_{10} dans un mécanisme en chaîne probablement entretenu par les atomes d'iode (18). Ainsi à 174 nm, on a été incapable de mesurer convenablement le rendement en radicaux méthyles par cette méthode.

Remerciements

Nous voulons exprimer notre gratitude au CNR ainsi qu'au MEQ (programme FCAC) pour l'aide qu'ils nous ont généreusement accordé tout au long de ce travail.

INGER V. OLOFSSON, JAN J. SPITZER, and LOREN G. HEPLER. Can. J. Chem. **56**, 1871 (1978).

We have made heat capacity and density measurements leading to apparent molar heat capacities and volumes for dilute aqueous solutions of Na_2SO_4, K_2SO_4, $Na_2S_2O_3$, $Na_2S_2O_8$, $K_2S_2O_8$, K_2CrO_4, Na_2MoO_4, and Na_2WO_4. We have used these apparent molar quantities to extrapolate to infinite dilution to obtain the corresponding standard state apparent and partial molar quantities. These latter values have been used in calculation of conventional ionic heat capacities and volumes.

INGER V. OLOFSSON, JAN J. SPITZER et LOREN G. HEPLER. Can. J. Chem. **56**, 1871 (1978).

On a effectué des mesures de capacité calorifique et de densité conduisant aux capacités calorifiques et aux volumes molaires apparents de solutions aqueuses diluées de Na_2SO_4, K_2SO_4, $Na_2S_2O_3$, $Na_2S_2O_8$, $K_2S_2O_8$, K_2CrO_4, Na_2MoO_4 et Na_2WO_4. On a utilisé ces quantités molaires apparentes pour effectuer une extrapolation vers une dilution infinie afin d'en tirer les quantités molaires partielles apparentes des états standard correspondants. On a utilisé ces dernières valeurs pour calculer les capacités calorifiques et les volumes ioniques conventionnels.

[Traduit par le journal]

Introduction

As part of our continuing program of measurements leading to thermal and volumetric properties of aqueous solutions, we have made calorimetric measurements leading to apparent molar heat capacities and density measurements leading to apparent molar volumes of eight $(M^+)_2(X^{2-})$ electrolytes at 25°C. Results of these measurements and our thermodynamic calculations are reported in this paper.

Experimental

Our heat capacity measurements have been made with two different Picker flow calorimeters of the same type, as described previously (1). A small systematic error in the measurements with the first calorimeter has been identified and corrected as recently described (2, 3). Tests by Picker and our various comparisons (4–10)[2] of results obtained with several calorimeters have confirmed that the earlier small error is negligible with the new calorimeter.

Densities of solutions have been measured with a flow densimeter that has been described previously (11).

Results of all calorimetric and density measurements refer to 25.00 ± 0.05°C.

Samples of analytical reagent grade Na_2SO_4, K_2SO_4, and K_2CrO_4 were dried to constant mass at 110°C. Solutions were then prepared from dried samples and distilled water by mass.

Reagent grade $Na_2S_2O_8$ and $K_2S_2O_8$ were recrystallized from solutions that were saturated at about 50°C and then cooled to 0°C. Resulting crystals were dried to constant mass over P_2O_5. All solutions for subsequent measurements were prepared by mass of salt and distilled water.

Reagent grade Na_2MoO_4 and Na_2WO_4 were recrystallized from slightly alkaline solutions and dried by heating to constant mass. Solutions for subsequent measurements were prepared by mass of salt and distilled water.

Stock solutions of sodium thiosulfate were prepared from analytical grade $Na_2S_2O_3 \cdot 5H_2O$ and then analyzed by adding excess iodide and titrating with standard KIO_3 solution. Other solutions were prepared by dilution of these stock solutions.

Results and Calculations

Results of measurements with the Picker flow calorimeter are heat capacities per unit volume, which we express in terms of J K^{-1} cm^{-3}. Combination of these heat capacities with the densities and the already known heat capacity of pure water permits calculation and heat capacities of solutions expressed in terms of J K^{-1} (g of solution)$^{-1}$. These latter heat capacities are then used in obtaining the desired apparent molar heat capacities of solutes that we represent by ϕ_C and express in terms of J K^{-1} mol^{-1}. Similarly, densities of the solutions lead to the apparent molar volumes of the solutes that we represent by ϕ_V and express in terms of cm^3 mol^{-1}. For these calculations of apparent molar quantities we have used equations based on

$$[1] \qquad \phi_Y = [Y(\text{solution}) - n_1 Y_1^0]/n_2$$

in which the symbols have the following meanings: Y is the extensive property (heat capacity or volume here) of a specified quantity of solution, n_1 is the number of moles of solvent in this specified quantity of solution, Y_1^0 is the property (heat capacity or volume) of 1 mol of pure solvent, and n_2 is the number of moles of solute in the specified quantity of solution.

TABLE 1. Parameters for eq. [2]

Solute	ϕ_C^0 (J K^{-1} mol^{-1})	B_C (J K^{-1} mol^{-2} kg)	ϕ_V^0 (cm^3 mol^{-1})	B_V (cm^3 mol^{-2} kg)
Na_2SO_4	−190.1	133.0	11.4	0.8
K_2SO_4	−251.0	73.6	32.8	2.4
$Na_2S_2O_3$	−163.6	106.0	26.3	3.0
$Na_2S_2O_8$	−29.3	50.9	76.1	−2.4
$K_2S_2O_8$	−84.0	160.0	97.6	−6.9
K_2CrO_4	−235.0	36.6	38.2	0.2
Na_2MoO_4	−122.8	31.1	28.0	−0.5
Na_2WO_4	−110.4	7.8	30.0	−2.8

Our experimental results are finally tabulated in terms of ϕ_C and ϕ_V values at specified molalities.[3] Concentrations of solutions ranged from 0.015 to 0.29 molal.

Apparent molar properties of dilute solutions of strong electrolytes are accurately described by equations of the form

$$[2] \qquad \phi_Y = \phi_Y^0 + A_Y(d_1^0 m)^{1/2} + B_Y m$$

in which ϕ_Y^0 is the value of ϕ_Y at infinite dilution, A_Y is the limiting slope derived from the Debye–Hückel theory, m is the molality, and B_Y is an adjustable parameter. Our principal interest has been in determining the ϕ_Y^0 values that are identical with the corresponding partial molar properties at infinite dilution ($\bar{Y}_2^0$). For calculations leading to these values we have used $A_C(d_1^0)^{1/2} = 150.4$ J K^{-1} mol$^{-3/2}$ kg$^{1/2}$ and $A_V(d_1^0)^{1/2} = 9.72$ cm^3 mol$^{-3/2}$ kg$^{1/2}$. Our ϕ_C^0, B_C, ϕ_V^0, and B_V values based on least-squares fitting of our experimental results to equations of the form of [2] are given in Table 1. Total uncertainties due to chemicals, measurements, and data treatment amount to about ±3 J K^{-1} mol^{-1} in ϕ_C^0 and about ±0.5 cm^3 mol^{-1} in ϕ_V^0.

Results of our work as summarized in Table 1 can be compared with results of earlier investigators as follows. We also present calculations with ionic heat capacities and volumes, based on the common and useful convention that $H^+(aq)$ has $\phi_C^0 = 0$ and $\phi_V^0 = 0$. For these latter calculations we also use $\phi_C^0(Na^+) = 43$ J K^{-1} mol^{-1} and $\phi_C^0(K^+) = 13$ J K^{-1} mol^{-1} from Desnoyers, de Visser, Perron, and Picker (3) along with $\phi_V^0(Na^+) = -1.21$ cm^3 mol^{-1} and $\phi_V^0(K^+) = 9.02$ cm^3 mol^{-1} from Millero (12).

Our $\phi_C^0 = -190.1$ J K^{-1} mol^{-1} for aqueous Na_2SO_4 is in excellent agreement with $\phi_C^0 = -191.7$ J K^{-1} mol^{-1} from the Université de Sherbrooke (3), also obtained by flow calorimetry. Earlier enthalpy of solution measurements at several temperatures in combination with $d\Delta H^0/dT = \Delta C_p^0$ led Gardner, Jekel, and Cobble (13) to $\bar{C}_p^0$ ($= \phi_C^0$) $= -195$ J K^{-1} mol^{-1} for aqueous Na_2SO_4. For aqueous K_2SO_4 we have $\phi_C^0 = -251.0$ J K^{-1} mol^{-1} and also $\phi_C^0 = -254.5$ J K^{-1} mol^{-1} from the Université de Sherbrooke (3). Our ϕ_C^0 values for these two electrolytes in combination with ϕ_C^0 values for $Na^+(aq)$ cited in the paragraph above lead to $\phi_C^0 = -276$ and -277 J K^{-1} mol^{-1} for $SO_4^{2-}(aq)$, while the other ϕ_C^0 values lead to $\phi_C^0 = -278$, -281, and -280 J K^{-1} mol^{-1} for $SO_4^{2-}(aq)$. We now choose an average $\phi_C^0 = -278$ J K^{-1} mol^{-1} (std. dev. = 2) for $SO_4^{2-}(aq)$ and list this value in Table 2.

We do not know of any earlier results leading to ϕ_C^0 values for the other salts we have investigated so we proceed to use our ϕ_C^0 values from Table 1 for calculation of ionic heat capacities.

The ϕ_C^0 for aqueous $Na_2S_2O_3$ leads to $\phi_C^0 = -250$ J K^{-1} mol^{-1} for $S_2O_3^{2-}(aq)$. For $S_2O_8^{2-}(aq)$ we obtain $\phi_C^0 = -115$ J K^{-1} mol^{-1} from the ϕ_C^0 for aqueous $Na_2S_2O_8$, while the ϕ_C^0 for aqueous $K_2S_2O_8$ leads to $\phi_C^0 = -110$ J K^{-1} mol^{-1} for $S_2O_8^{2-}(aq)$. Because we believe that the samples of $K_2S_2O_8$ were purer than the samples of $Na_2S_2O_8$, we choose this latter $\phi_C^0 = -110$ J K^{-1} mol^{-1} as best for $S_2O_8^{2-}(aq)$. The ϕ_C^0 values for aqueous K_2CrO_4, Na_2MoO_4, and Na_2WO_4 lead to the following: $\phi_C^0 = -261$ J K^{-1} mol^{-1} for $CrO_4^{2-}(aq)$, $\phi_C^0 = -209$ J K^{-1} mol^{-1} for $MoO_4^{2-}(aq)$, and $\phi_C^0 = -196$ J K^{-1} mol^{-1} for $WO_4^{2-}(aq)$.

TABLE 2. Conventional [$\phi_Y^0(H^+) = 0$] apparent molar heat capacities and volumes for aqueous ions at 298.15 K

Ion	ϕ_C^0 (J K^{-1} mol^{-1})	ϕ_V^0 (cm^3 mol^{-1})
SO_4^{2-}	−278	13.98[a]
$S_2O_3^{2-}$	−250	28.7
$S_2O_8^{2-}$	−110[b]	79.6[b]
CrO_4^{2-}	−261	20.2
MoO_4^{2-}	−209	30.4
WO_4^{2-}	−196	32.4

[a]From ref. 12.
[b]Based on our results for the potassium salt.

[3]A complete set of the experimental results is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Millero (12) has listed ϕ_V^0 values for aqueous Na_2SO_4 and K_2SO_4 that are almost certainly more accurate than our values for these electrolytes, although the agreement is satisfactory. On the other hand, our ϕ_V^0 values for the other electrolytes we have investigated are probably more accurate than the corresponding values cited by Millero (12). We therefore adopt $\phi_V^0 = 13.98$ cm^3 mol^{-1} for SO_4^{2-}(aq) from Millero (12) and calculate the following ionic volumes from our results. Our ϕ_V^0 values for aqueous $Na_2S_2O_3$, K_2CrO_4, Na_2MoO_4, and Na_2WO_4 lead to $\phi_V^0 = 28.7$ cm^3 mol^{-1} for $S_2O_3^{2-}$(aq), $\phi_V^0 = 20.2$ cm^3 mol^{-1} for CrO_4^{2-}(aq), $\phi_V^0 = 30.4$ cm^3 mol^{-1} for MoO_4^{2-}(aq), and $\phi_V^0 = 32.4$ cm^3 mol^{-1} for WO_4^{2-}(aq). Our ϕ_V^0 values for aqueous $Na_2S_2O_8$ and $K_2S_2O_8$ lead to $\phi_V^0 = 78.5$ and 79.6 cm^3 mol^{-1} for $S_2O_8^{2-}$(aq). As before we select the result from the potassium salt as the most accurate. All of these ionic ϕ_V^0 values are collected in Table 2.

Acknowledgments

We all thank the National Research Council of Canada for support of this research. I.V.O. also thanks the Canada Council for a scholarship.

Reçu le 30 septembre 1977

PHILIPPE JOUBERT, ROLAND BOUGON et BERNARD GAUDREAU. Can. J. Chem. **56**, 1874 (1978).

Les oxypentafluorouranates(VI) $MUOF_5$ (M = NH_4, K, Rb, Cs) ont été préparés dans SO_2 liquide par action sur UOF_4 du fluorure d'ammonium ou du fluorure alcalin correspondant. Leur étude par diffraction des rayons-X, par spectroscopie infra-rouge et Raman et une isotypie avec les hexafluorouranates(V) MUF_6 correspondants a permis de mettre en évidence deux types d'environnement de l'uranium: l'environnement pseudooctaédrique constitué des 5 atomes de fluor et de l'oxygène dans $CsUOF_5$ et dodécaédrique pour les autres complexes (M = NH_4, K, Rb). Dans ce dernier cas les dodécaèdres pontés par des fluors forment des chaines infinies.

L'ion UOF_5^- a été caractérisé à l'état solide par spectroscopie vibrationnelle. L'indexation des spectres faite dans l'hypothèse d'une symétrie C_{4v} a été confirmée par un calcul de constantes de force. Selon ces données et contrairement aux valeurs connues pour d'autres oxypentafluoroanions, le fluor axial est moins ionique que les fluors équatoriaux.

PHILIPPE JOUBERT, ROLAND BOUGON, and BERNARD GAUDREAU. Can. J. Chem. **56**, 1874 (1978).

The oxypentafluorouranates(VI) $MUOF_5$, where M = NH_4, K, Rb, Cs, have been synthetized from reaction of UOF_4 with the ammonium or corresponding alkali metal fluoride in liquid SO_2. According to X-ray diffraction, Raman and infrared spectroscopy, and from an isomorphism with the corresponding hexafluorouranates(V) MUF_6, two different environments around the uranium atom are observed. In $CsUOF_5$ the five fluorine atoms and the oxygen around the uranium result in a pseudo-octahedral surrounding whereas for the other complexes (M = NH_4, K, Rb) each uranium is surrounded by eight light atoms forming a dodecahedron. In this structure the dodecahedra are linked together by fluorine atoms to form infinite chains. The UOF_5^- ion has been characterized by vibrational spectroscopy in the solid state. The proposed assignment, which was made with the assumption of a C_{4v} symmetry of the UOF_5^- ion, was confirmed by a force constant calculation. From these data and contrary to the values reported for comparable oxypentafluoroanions, the axial fluorine is found to be less ionic than the equatorial ones.

Introduction

L'étude des oxypentafluorouranates(VI) $MUOF_5$ (M = NO, NH_4, K) que nous avions abordée précédemment (1, 2) a été approfondie avec les composés où M désigne NH_4, K, Rb, Cs.

Partie expérimentale

Réactions

Les mélanges et les broyages des produits solides sont effectués sous atmosphère d'azote sec. Les transferts des produits volatils s'effectuent à l'aide d'une rampe en monel équipée de vannes F.W. Les réactions ont lieu dans des pots en KelF (polymère de monochlorotrifluoréthylène) munis de vannes d'isolement également en KelF.

Produits de départ: préparations

$UOF_4\alpha$ est obtenu par hydrolyse ménagée d'UF_6 (Comurhex) en milieu fluorhydrique (3). KF, RbF (Merck) et CsF (British Drug House) sont déshydratés à 300°C sous vide. NH_4F est obtenu par synthèse à partir de HF (Comurhex), bidistillé sous fluor (Comurhex) et d'ammoniac (Air Liquide) bidistillé sur P_4O_{10}. L'anhydride sulfureux (Matheson) est déshydraté par bidistillation sur P_4O_{10}. SO_2 liquide est condensé sur un mélange équimolaire de $UOF_4\alpha$ et de MF dans un réacteur refroidi à −196°C. Lors du retour à la température ambiante le réacteur est agité, puis SO_2 est évacué par vaporisation et pompage. Dans une précédente publication (1) nous signalions l'utilisation de HF comme milieu réactionnel, mais la présence fréquente d'impureté HMF_2 nous a fait préférer SO_2 liquide. En effet les fluorosulfinates sont thermodynamiquement moins stables que les hydrogénofluorures correspondants (4, 5).

Les résultats des analyses chimiques des produits ainsi obtenus sont reproduits dans le tableau 1. Ils indiquent qu'on a bien formé les composés 1/1 correspondant au mélange initial, et qu'il n'y a pas eu de départ de composé volatil (O_2, UF_6).

Les pentafluorouranates préparés se présentent sous la forme de poudres jaune à jaune-orangé. Ces poudres sont très hygroscopiques et donnent par hydrolyse des composés d'uranyle.

Mesures physiques

Diffractions des rayons-X

Le diagramme Debye–Scherrer des poudres contenues dans des capillaires de Lindemann est réalisé en utilisant la raie Kα du cuivre. Une chambre a été modifiée afin d'enregistrer les spectres entre 77 et 300 K.

Spectres infra-rouges

La poudre est maintenue entre deux fenêtres de AgBr ou de AgCl. Les spectres sont réalisés avec les spectrophotomètres Perkin-Elmer 457 et 225 et Beckman IR9. Un dispositif mis au point au laboratoire permet d'enregistrer les spectres à 90 K.

Spectres Raman

Les échantillons sont contenus dans des capillaires scellés en Pyrex de 2 mm de diamètre. Les spectres sont enregistrés à l'aide d'un spectrophotomètre Coderg T800 équipé d'un laser Spectra-Physics 165-02 à argon–krypton ionisé. La raie utilisée est à 647.1 nm. Un cryostat Coderg à température variable (77–300 K) permet d'enregistrer les spectres Raman à basse température.

Résultats et discussion

Cristallographie

L'existence de grandes analogies entre les spectres de diffraction des rayons-X (RX) des complexes de l'U(V) de formule MUF_6 (M = NH_4, K, Rb, Cs) (6, 7) et les $MUOF_5$ correspondants nous a permis d'indexer ces derniers par isotypie (tableau 2), et de mettre en évidence deux types d'oxypentafluorouranates: orthorhombique si M = NH_4, K, Rb, et rhomboédrique pour $CsUOF_5$. Aucune transformation allotropique n'a pu être observée pour les deux types ($RbUOF_5$ et $CsUOF_5$) entre 300 et 77 K.

$MUOF_5$: M = NH_4, K, Rb

Ces phases sont isotypes des MUF_6 correspondants (6, 7), donc de $RbPaF_6$ (8). La structure de $RbPaF_6$ comprend des piles de dodécaèdres liés par des arêtes le long de l'axe *a*. La formule structurale s'écrit:

$$[Rb(PaF_{4/2}{}^{**}F_4{}^{*})]$$

où *F sont les fluor terminaux appartenant à la même sphère de coordination Pa—F* = 2.09 Å et **F les fluors pontés appartenant à deux sphères de coordination adjacentes le long de l'axe *a* (Pa—F** = 2.34 Å).

En l'absence de monocristal nous ne pouvons déterminer le groupe d'espace dans lequel les composés étudiés cristallisent. A ce stade un désordre oxygène–fluor peut être envisagé sur tous les sites anioniques.

$CsUOF_5$

Ce composé présente un diagramme RX voisin de celui de $CsUF_6$ (6) dont la maille cristalline est rhomboédrique de groupe spatial $R\bar{3}$ (9). Elle se décrit comme un empilement CsCl d'ions Cs^+ et UF_6^-. Par analogie, $CsUOF_5$ serait donc constitué d'ions Cs^+ et UOF_5^-, les 5 atomes de fluor et celui d'oxygène étant distribués statistiquement sur les 6 sites équivalents de groupe $R\bar{3}$.

Spectroscopie vibrationnelle

La différence structurale mise en évidence par RX apparaît aussi dans les spectres vibrationnels (tableau 3) les figs 1 et 2 représentent les spectres ir et Raman obtenus pour $RbUOF_5$ et $CsUOF_5$. Les spectres vibrationnels des sels de potassium et d'ammonium présentent le même aspect que ceux de rubidium exepté pour les vibrations du cation NH_4^+. Par contre $CsUOF_5$ se distingue des autres complexes et les différences les plus sensibles apparaissent pour les vibrations attribuables à l'extension des liaisons U—O et U—F terminale. Un abaissement régulier de ces fréquences est prévisible lorsque l'on passe du sel de potassium à celui du césium comme pour $M_3U^{VI}O_2F_5$ (10), $MU^{VI}F_7$, $M_2U^{VI}F_8$ (11). Cet abaissement se manifeste bien lors du passage du potassium au rubidium mais la fréquence de vibration U—O du sel de césium est supérieure de 10 cm^{-1} à celle de l'oxypentafluorouranate de rubidium. Cette anomalie s'explique par la différence d'environnement de l'uranium mise en évidence par l'étude cristallographique.

Pour le sel d'ammonium on constate une augmentation de la fréquence de vibration U—O. Ce phénomène déjà mis en évidence pour $(NH_4)_3UO_2F_5$ (10) s'interprète par la formation préférentielle de liaison hydrogène avec les atomes de fluor avec en corollaire un renforcement de la liaison U—O.

Les vibrations situées dans le domaine 800–850 cm^{-1} sont attribuées à l'extension de la liaison uranium–oxygène (11), et celles situées dans le domaine 500–600 cm^{-1} correspondent aux vibrations

des fluors terminaux (11, 12). Les différentes études faites sur $UOF_4\alpha$ (11) et sur $UF_5\alpha$ et β (13) ont montré que les fréquences imputables aux vibrations des fluors pontés sont situées aux environs de 380 cm^{-1} ($UOF_4\alpha$ 375 cm^{-1}, $UF_5\alpha$ 388 cm^{-1}, $UF_5\beta$ 390 cm^{-1}).

Pour les phases $MUOF_5$ autres que $CsUOF_5$ il existe plusieurs vibrations dans la zone des 380 cm^{-1} qu'on peut raisonablement attribuer à des fluors pontés. Par contre les oxygènes ne sont certainement pas pontés, en effet la vibration située à 800–830 cm^{-1} correspond à l'extension d'une liaison U—O terminale (11) et l'existence de ponts U—O—U entraînerait la présence d'une bande ir large et intense entre 400 et 600 cm^{-1} (14–16) qui n'est pas observée dans les spectres $MUOF_5$. Les bandes ir vues dans cette région sont selon toute vraisemblance uniquement attribuables aux liaisons U—F. Nous concluons donc que seuls des ponts fluors existent dans les phases $MUOF_5$ pour M = NH_4, K, Rb, et celles-ci doivent s'écrire [$M(UF_{4/2}{**}O, 3F*)$], les astérisques ayant les mêmes définitions que précédemment.

Dans le cas de $CsUOF_5$ il n'y a pas de vibration aux environs de 380 cm^{-1}, donc ni les fluors ni les oxygènes (voir discussion précédente) ne sont pontés. L'existence de l'ion UOF_5^- dans $CsUOF_5$ inférée par les résultats de diffraction X se trouve donc confirmée.

Les spectres vibrationnels obtenus aux environs de 90 K sont identiques à ceux obtenus à température

TABLEAU 4. Constantes de force calculées pour l'ion UOF_5^- et comparées à celles obtenues pour des espèces homologues (millidynes par Å)

Constante de force	UOF_5^-	IOF_5 (21)	UF_6 gaz (31)	UF_6^- (32)	UOF_5^- (27)	$UO_2F_5^{3-}$ (33)
f_S	5.90	6.99			5.87	5.892
f_R	3.68	4.60				
f_r	2.67	4.42	3.80	2.70		
f_{rr}	0.46	0.18	0.302	0.363		
f'_{rr}	0.47	0.00	−0.202	−0.258		
f_α/r^2	0.22	0.20	0.134	0.115		
f_β/r_R	0.18	0.55				
f_γ/r_S	0.29	0.44				
$f_{\beta\gamma}/r_{RS}^{1/2}$	0.07	0.06				

U—O=S=1.80 Å; U—F_{eq}=r=UF_{ax}=R=2.09 Å

α=F—U—F=90°

β=F—U—F′=90°

γ=F—U—O=90°

ambiante. Ceci implique une conservation de la symétrie des motifs optiques et corrobore les résultats cristallographiques obtenus aux mêmes températures.

Spectres vibrationnels de l'ion UOF_5^- et attribution

La complexité des spectres vibrationnels des phases $MUOF_5$ avec M = NH_4, K, Rb due à la faible symétrie du motif optique (vraisemblablement C_1) n'a pas permis d'approfondir l'analyse vibrationnelle de ces composés. En ce qui concerne $CsUOF_5$, l'indexation des spectres vibrationnels de l'ion UOF_5^- a été faite dans l'hypothèse d'une symétrie C_{4v} à partir de comparaisons avec les spectres des espèces MOF_5^{2-} et MOF_5^-, M = Ta (17), Te (18), Mo, W (2, 19), Re (20) et IOF_5 (21) et à partir des résultats de résonance magnétique nucléaires du ^{19}F (22). Cette dernière a montré que pour $CsUOF_5$ il existait à la température ambiante deux types de fluors dans la proportion 1/4. La raie la plus intense est située vers les hauts champs par rapport à l'autre soit respectivement −285 et −405 ppm par rapport à $CFCl_3$ pris comme référence externe. Dans l'hypothèse d'une symétrie C_{4v} et suivant des observations faites sur des composés semblables (23), le fluor axial serait donc moins ionique que les fluors équatoriaux, contrairement à ce qui a été observé en solution pour les ions $MoOF_5^-$ et WOF_5^- (2). Par contre un ordre identique à celui que nous trouvons pour UOF_5^- a déjà été observé dans le cas de IOF_5 (24).

Il faut noter que cette symétrie C_{4v} n'est qu'une approximation: en effet de par les structures cristallines trouvées pour K_2MoOF_5, H_2O (25) (monoclinique), $AMOF_5$ (A = K, Rb, Cs et M = Mo, W (26)) et $CsUOF_5$ (rhomboédrique) l'atome central est dans un site de symétrie plus basse que C_{4v}. Nous indexons cependant les spectres vibrationnels avec cette symétrie qui est par ailleurs justifiée en première approximation par les résultats de rmn (22) et par le nombre de raies Raman et ir observées,

Pour cette symétrie la théorie des groupes prévoit 11 modes normaux de vibrations soit $4A_1 + 2B_1 + B_2 + 4E$, tous les modes sont actifs en Raman, seuls les modes A_1 et E le sont en ir.

Les indexations ont été faites en considérant les formes et les intensités respectives des différentes bandes des spectres ir et Raman. Pour comparaison, on a fait figurer dans le tableau 3 les fréquences attribuées (27) à l'anion dans le composé $[Ph_4P]UOF_5$.

D'une façon générale, on a observé pour tous les composés une largeur importante des raies du spectre Raman de ces solides même aux environs de 90 K. Ainsi la raie du mode $\nu_1(a_1)$ a une largeur à mi-hauteur $\Delta\bar{\nu}$ de 13 cm^{-1} à 90 K. Cela peut probablement s'interpréter par l'existence d'un désordre cristallin entraînant des élargissements des niveaux vibrationnels (28).

Détermination des constantes de force

Les attributions précédentes ont été confirmées par une analyse en coordonnées normales. Les notations et le champ de force définis par Smith et Begun (21) dans le cas de l'étude de la molécule IOF_5 ont été utilisés. Les calculs de constantes de forces ont été effectués sur un ordinateur IBM 360/91 à l'aide de programmes mis au point par Rousson et coll. (29).

Les angles sont pris égaux à 90° et les distances interatomiques choisies sont déduites des calculs faits à partir des spectres de diffraction de neutrons soit U—O = S = 1.80 Å, U—F_{eq} = r = UF_{ax} = R = 2.09 Å (22). Le fait de prendre des liaisons

For personal use only.

UF_{eq} et UF_{ax} égales entre elles peut se justifier par le faible écart correspondant de 0.04 Å trouvé (30) par diffraction électronique pour IOF_5.

Sur les 11 fréquences prévues par la théorie des groupes 9 ont été observées; ce qui ne permet pas de calculer tous les termes de la matrice **F**. Il a été admis que tous les termes d'interaction pliage-extension étaient nuls, de même que les interactions entre angles α opposés ($f_{\alpha\alpha}$) et adjacents β et γ ($f_{\beta\beta}$, $f_{\gamma\gamma}$) ainsi que les interactions entre liaisons à 90° sauf la constante f_{rr}'. De même que Smith, un terme non diagonal a été calculé afin d'obtenir des solutions physiquement acceptables et donnant un bon accord entre fréquences observées et calculées (21).

Le calcul de la distribution d'énergie potentielle a montré par ailleurs que les modes ν_9, ν_{10} et ν_{11} de symétrie E étaient fortement couplés.

Les valeurs des constantes de force calculées sont consignées au tableau 4 où figurent à titre de comparaison les valeurs des constantes de forces de UF_6 gaz (31) UF_6^- (32), UOF_5^-(f_{U-O}) (27), $UO_2F_5^{3-}$ (F_{U-O}) (33) et IOF_5 (21): la liaison U—O possède dans UOF_5^- un caractère certain de double liaison, puisque la constante de force correspondante est proche de celle connue pour l'ion $UO_2F_5^{3-}$ (33). Par ailleurs la liaison U—F_{ax} a un caractère de covalence inférieur ou proche de celui de UF_6 (31) tandis que les quatres liaisons du plan équatorial ont un caractère ionique proche de celui trouvé pour l'ion UF_6^- (32). On identifie bien, deux types de liaisons pour UOF_5^- avec une liaison axiale plus covalente que l'équatoriale. Ces résultats sont à rapprocher de ceux trouvés pour IOF_5 d'après les spectres vibrationnels (21) et la rmn du ^{19}F (24). L'ion UOF_5^- dans $CsUOF_5$ solide a une répartition du nuage électronique différente de celle trouvée pour les ions analogues tels que $TeOF_5^-$ (18), $MoOF_5^-$ et WOF_5^- (2, 19, 20), la charge formelle négative serait donc essentiellement répartie dans l'ion UOF_5^-, sur les quatre fluors du plan équatorial. Ces différences de répartition sont peut être attribuables aux effets des orbitales de l'uranium.

Conclusion

Par réaction dans SO_2 liquide entre UOF_4 et des bases de Lewis telles que NH_4F, KF, RbF et CsF, les pentafluorouranates ont été obtenus exempts de composés de composition différente. La connaissance de l'ensemble des spectres de diffraction X, infrarouge et Raman nous permet de dire que les phases $MUOF_5$ s'écrivent $M(UF_{4/2}(O, 3F))$ avec M = NH_4, K, Rb et Cs^+ UOF_5^-. Pour l'ion UOF_5^- les spectres vibrationnels et leur analyse en coordonnées normales qui sont en accord avec une symétrie C_{4v} montrent que le fluor axial possède un caractère plus covalent que les fluors équatoriaux.

Ion association in solutions of HCl in DMSO–water mixtures: ultrasonic absorption studies

PEETER KRUUS AND M. JACQUELINE MCGUIRE

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received January 5, 1978

PEETER KRUUS and M. JACQUELINE MCGUIRE. Can. J. Chem. **56**, 1881 (1978).

Ultrasonic absorption measurements are reported for the system HCl – dimethylsulfoxide (DMSO) – water in the frequency range 3.5 to 140 MHz. For all solutions studied, the excess absorption due to the presence of HCl can be fitted well with a single relaxation equation. For 0.10 mol ℓ^{-1} solutions of HCl in DMSO–water mixtures, no further relaxations at higher frequencies are likely. Reasonable results are obtained when the ultrasonic results are analyzed assuming the process responsible for the excess absorption to be the dissociation–association equilibrium of HCl, and using equilibrium constants determined from conductivity (C. Cooke *et al.* Electrochim. Acta, **20**, 591 (1975)). The value of $|\Delta V_{eff}|$ is 20–25 cm^3 mol^{-1} and k_{ass} is approximately 3×10^9 ℓ mol^{-1} s^{-1}, as compared to a value of 10×10^9 ℓ mol^{-1} s^{-1} calculated from limiting conductivities assuming diffusion-controlled rate theory.

PEETER KRUUS et M. JACQUELINE MCGUIRE. Can. J. Chem. **56**, 1881 (1978).

On rapporte des mesures d'absorption d'ultrasons par le système HCl – diméthylsulfoxyde (DMSO) – eau à des fréquences allant de 3.5 à 140 MHz. Pour toutes les solutions étudiées, l'absorption en excès due à la présence de HCl peut être bien exprimée par une seule équation de relaxation. Pour des solutions de 0.10 mol ℓ^{-1} de HCl dans des mélanges de DMSO – H_2O, il ne semble pas y avoir d'autres relaxations à des fréquences plus élevées. On obtient des résultats raisonnables lorsqu'on analyse les résultats d'ultrasons en faisant l'hypothèse que le processus responsable pour l'absorption en excès est dû à l'équilibre association/dissociation de HCl et en faisant appel aux constantes d'équilibre déterminées par la conductivité (C. Cooke *et al.* Electrochim. Acta, **20**, 591 (1975)). La valeur de $|\Delta V_{eff}|$ est 20–25 cm^3 mol^{-1} et k_{ass} est environ 3×10^9 ℓ mol^{-1} s^{-1}; on doit comparer cette valeur à celle de 10×10^9 ℓ mol^{-1} s^{-1}, calculée à partir des conductivités limites en faisant appel à la théorie de la vitesse contrôlée par la diffusion.

[Traduit par le journal]

Introduction

The detailed mechanism of ion pairing has been elucidated to a considerable extent through ultrasonic absorption studies (1). In nearly every case, ultrasonic absorption results suggest that ion pairing occurs through a process involving at least two steps. This is the case for multivalent electrolytes in water (2) and for univalent electrolytes in organic solvents (3, 4).

Results for aqueous solutions of medium strong acids can be explained by a single-step mechanism (5), but the acid dissociation constant obtained in such an analysis is somewhat different from that obtained by other methods, e.g. conductivity. Data on solutions of HCl in dimethylformamide have also been analysed by a single-relaxation mechanism (6).

An ultrasonic study of HCl in dimethylsulfoxide (DMSO) – water solutions was undertaken in order to see if the ion pairing in this system occurs by a single-step mechanism. A thorough conductivity study of this system is available (7), giving the association constants, the limiting conductivities, and the dielectric constants. It is thus also possible to determine whether it is valid to describe the ultrasonic results in terms of simple basic models such as diffusion controlled kinetics.

DMSO is of considerable medical and industrial importance (8), especially in the form of a water–DMSO solvent system. Because of the strong hygroscopic nature of DMSO, it seldom can be used in a completely non-aqueous state (3, 7).

Experimental

Stock solutions of HCl in DMSO were made up by bubbling HCl gas diluted with N_2 through liquid DMSO in a flask swirled in an icebath. The heat of solution is sufficient so that without cooling and dilution of the gas, decomposition of DMSO resulted, as evidenced by the smell of mercaptans. The concentrations of the stock solutions were measured through titration with standardized sodium hydroxide of samples diluted considerably with water; these were at most 0.6 mol ℓ^{-1}. Aliquots of these standard solutions were diluted with DMSO and/or water to make up the solutions used in the study. It was found to be most convenient to express the composition in terms of mole fraction X of DMSO and molarity c of HCl.

Solutions with $X < 0.92$ and $c < 0.3$ were also made up by mixing concentrated aqueous hydrochloric acid with DMSO. The results for solutions made up this way were consistent with results for solutions made up from the stock.

The chemicals used were: Matheson anhydrous HCl, Baker Analyzed Reagent or Fisher Certified DMSO, Linde N_2, and Baker Analyzed Reagent hydrochloric acid. In making up some samples of stock solution, the gas was bubbled through two DMSO samples in series, with only the second sample used. This was to remove any DMSO-soluble impurities in the

*B fixed at values shown except where for * values which were obtained by a 3-parameter fit.
†Only these values were determined experimentally; other values were obtained by interpolation.
‡Braces denote data combined for analysis in Table 3.
§Final results rejected as solutions probably picked up water during transfer from high to medium frequency apparatus.

gas. Results obtained using these solutions were consistent with results from solutions where this precaution was not taken.

Dry-box conditions were not used, but it was attempted to minimize the time of contact of the solutions with the atmosphere. Other steps were taken to minimize water content: the gas mixture was passed through a drying agent before bubbling through DMSO; the DMSO used was taken from freshly opened bottles or decanted from bottles where the DMSO had been standing over molecular sieves. Even though the water content in the Baker DMSO is quoted as $<0.05\%$, previous work (3) suggests that the initial "nonaqueous" DMSO solutions may have had a water content of up to 0.2% by volume, corresponding to $X \simeq 0.99$ or a concentration of water in the order of 0.1 mol ℓ^{-1}. Exposure to the atmosphere would increase the water content even more, as at 20°C, DMSO has an equilibrium moisture content of 10% water (9).

Ultrasonic absorption was measured for all the solutions in the frequency range 10.6 to 52 MHz with the medium frequency apparatus described in ref. 10. Velocities were also measured on this apparatus by the method described in ref. 10, and viscosities with a Cannon–Fenske viscometer.

Absorption at 20, 60, 100, and 140 MHz was measured with apparatus B as described in ref. 10. The signal from the receiving transducer was fed directly into an HP10514 mixer, where it was mixed with a CW signal from an HP VHF signal generator to give a difference frequency of 20 MHz. This signal was then passed through a preamplifier and displayed on an oscilloscope. The absorption was measured by noting the size of the signal on the oscilloscope as the distance travelled by the ultrasound was varied. Any non-linearities in the amplification were corrected for by calibrating the apparatus with liquids of known absorption (carbon tetrachloride, toluene, DMSO, and water).

Analysis of Results by Single Relaxation Equations

Table 1 summarizes the ultrasonic absorption, velocity, and viscosity results obtained.

The absorption data (α/ν^2 as a function of ν) were analyzed in terms of a single relaxation equation, [1]:

$$[1] \qquad \frac{\alpha}{\nu^2} = \frac{A}{1 + (\nu/\nu_r)^2} + B$$

For the cases where high frequency data were available, the data were fitted by eq. [1] with A, B, and ν_r all being adjusted to give a minimum in the standard deviation σ. Examples of two such fits are given in Fig. 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

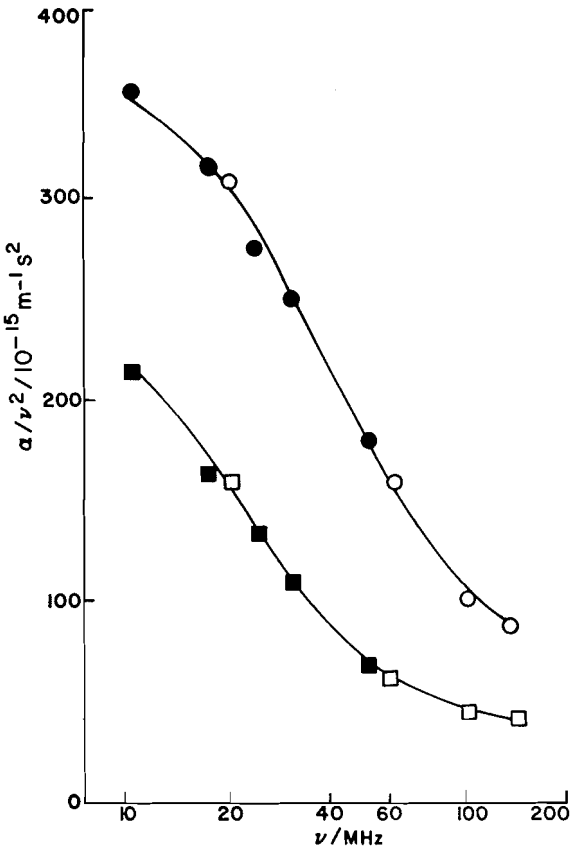

FIG. 1. Single-relaxation curve fitting (A, B, ν_r variable) of experimental data: ●, ○, $c = 0.30$, $X = 0.80$; ■, □, $c = 0.10$, $X = 1.00$. The filled points represent data taken with the medium-frequency apparatus, the empty with the high-frequency.

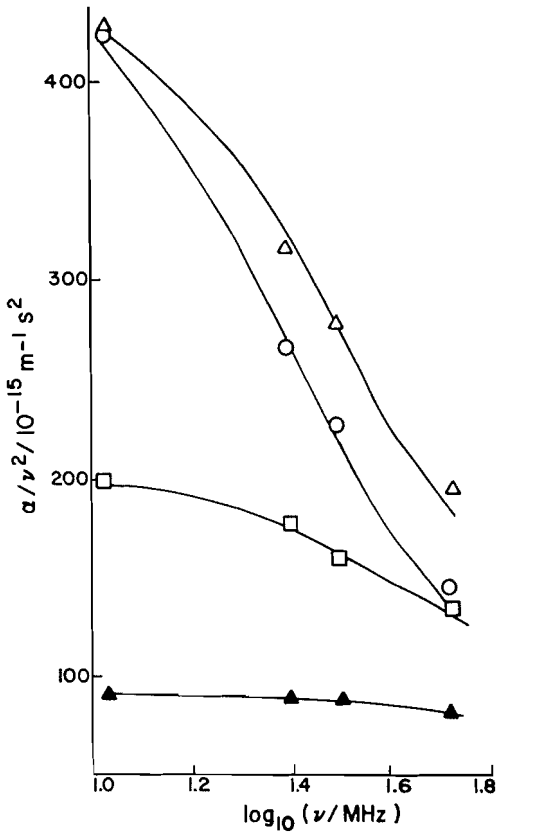

FIG. 2. Single-relaxation curve fitting (A, ν_r variable, B fixed) of experimental data, $c = 0.30$; ○, $X = 0.97$; △, $X = 0.85$; □, $X = 0.65$; ▽, $X = 0.48$.

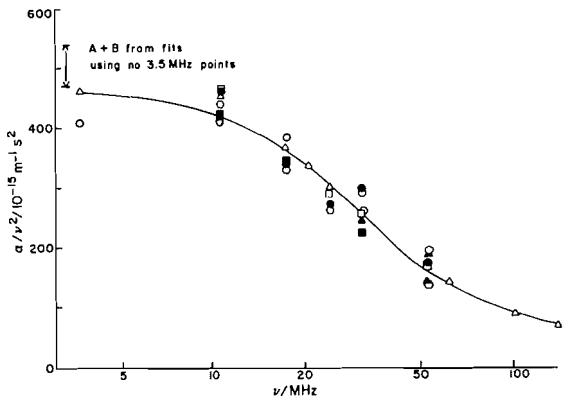

FIG. 3. Single-relaxation curve fitting of data from 7 different runs, $c = 0.3$, $X = 0.92 \pm 0.01$.

In order to obtain a complete frequency range from 10.6 to 140 MHz, two apparatuses had to be used. This involved transfer of the solution and readjustment of the electronic equipment. The majority of the solutions were therefore investigated only in the 10.6 to 52 MHz range. These data were fitted also by eq. [1], but only A and ν_r were adjusted. The value of B was chosen by interpolation from B-values obtained from 3-parameter fits. Figure 2 shows examples of fits where only A and ν_r were varied.

Figure 2 also shows how at lower X values, the relaxation frequency ν_r becomes so great that a meaningful fit of the data in the 10.6 to 52 MHz range by [1] becomes meaningless. In such cases, ν_r cannot be obtained, but the low frequency data can be used to obtain $A + B$ directly ($\nu \ll \nu_r$).

It was in principle possible to make absorption measurements also at 3.5 MHz with the apparatus used. However, the precision of these results was very poor. Even when α/ν^2 is relatively high (of the order of $400 \times 10^{-15}\ m^{-1}\ s^2$), at 3.5 MHz the value of α is so small ($\simeq 4\ m^{-1}$) that meaningful absorption measurements are difficult. Thus the 3.5 MHz values are reported here only for the solution where absorption was highest (Fig. 3). The low α values at 3.5 MHz and the flatness of the α/ν^2 vs. ν graphs at low X values are signs that there are no additional relaxation processes present in these systems with a ν_r in the low MHz range.

Table 1 contains data on the ultrasonic velocity v and the kinematic viscosity η/ρ for some solutions. The data for other solutions was obtained by interpolation. Data for the pure solvent system DMSO–water is not listed as it was found to be in good agreement (within 1%) of those in ref. 7. These data are needed to calculate the classical absorption α_c, due primarily to viscosity (1):

$$[2] \qquad \frac{\alpha_c}{\nu^2} = \frac{8}{3}\pi^2 \frac{\eta}{\rho} \frac{1}{v^3}$$

Reference 3 contains the (α_c/ν^2) data for the solvent system.

The B values obtained for solutions with $c = 0.10$ are within 1 or 2 units of the values obtained by correcting the absorption of the pure solvent system with changes in (α_c/ν^2) due to changes in v and η/ρ, i.e., setting

$$[3] \quad (B)_{\text{solution}} = (B)_{\text{solvent}} + \left(\frac{\alpha_c}{\nu^2}\right)_{\text{solution}} - \left(\frac{\alpha_c}{\nu^2}\right)_{\text{solvent}}$$

This suggests that in these solutions there are no additional relaxation processes due to the presence of the HCl at higher frequencies; unless, of course, there is a process which has $\Delta V_{eff} = 0$ (see eq. [7]).

The $c = 0.30$ solutions have B values slightly in excess of those predicted from eq. [3], suggesting the presence of another process relaxing at higher frequencies. Such a process could conceivably be the formation of a complex ion HCl_2^-. The Cl^- ion is poorly solvated in DMSO (3, 11) and HCl_2^- has been noted (12). In addition, $AgCl_2^-$ forms readily in DMSO solutions (13). Since the relaxation strength of the process responsible for the high frequency absorption excess is small, further ultrasonic studies (i.e., by variation of c) would be quite imprecise.

Single-relaxation equations fit the experimental data quite well. The relative standard deviations for the $c = 0.10$ data are all below 3% when σ is taken relative to $A/2$. In the case of the $c = 0.30$ solutions, the highest value of $2\sigma/A$ is 15% with typical values more of the order of 5%. The variation of the A and ν_r values obtained by the analysis are presented in Fig. 4.

The validity of the curve-fitting techniques used was tested on a set of data at the experimental frequencies which describe a single-relaxation curve exactly. Table 2 shows that an error of 10% in the choice of B already introduces a relative error of 2.5%. For the type of data obtained in this experiment, the curve-fitting is seen from Table 2 to give more scatter in the ν_r values than in the A values. This may be one cause for the scatter in the ν_r vs. X data in Fig. 4.

An estimate of the variability in the A and ν_r values due to experimental uncertainty is also made in Table 2. The least accurate experimental data used regularly are the α/ν^2 for 10.6 MHz, which may have an uncertainty of 5 to 10%, depending on its absolute value. An error of 5% in the 10.6 MHz data would cause an error of 12% in A and 7% in ν_r, while one of 10% would cause an error of 23% in A and 15% in ν_r. Such uncertainties are consistent with the scatter in Fig. 4.

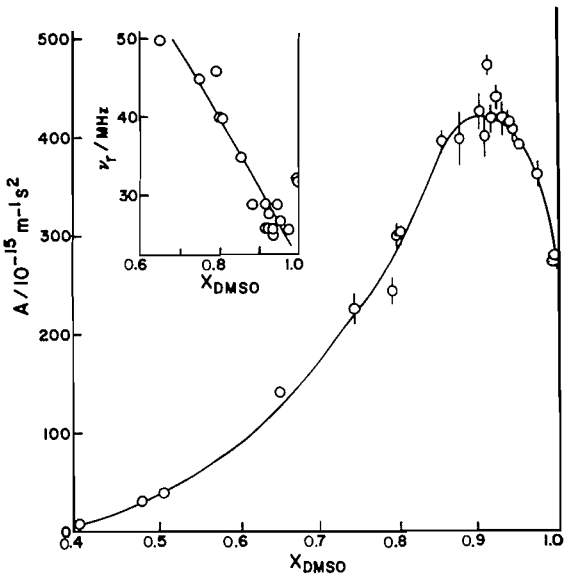

FIG. 4. A vs. X and ν_r vs. X for solutions 0.30 mol ℓ^{-1} in HCl.

Correlation of Ultrasonic and Conductivity Results

HCl is not fully dissociated in DMSO. However, when sufficient water is added, the dissociation becomes in effect complete. As the excess ultrasonic absorption disappears as $X < 0.4$, the process most likely to be responsible for the absorption is:

$$[4] \qquad H^+ + Cl^- \underset{k_{diss}}{\overset{k_{ass}}{\rightleftharpoons}} HCl$$

The activity equilibrium constants K_a for process [4] in DMSO–water mixtures have been measured by conductivity (7). In the range $0.74 < X \leq 1.0$, the measured values of K_a follow the Bjerrum equation quite well, with critical distances of $q = e^2/2\varepsilon kT$ of the order of 0.12 nm.

Analysis of the A and ν_r values from ultrasonics requires a knowledge of the concentration equilibrium constant $K_c = K_a y_\pm^2 / y_{HCl} = K_a y_\pm^2$ assuming $y_{HCl} = 1$. The activity coefficients are available for HCl in DMSO, but only up to 0.05 molal. The Debye–Hückel relation describes the $y_\pm$ well up to 0.01 molal (14). Here the $y_\pm$ was assumed to be

*Fixed values of B. Points used are at 10 experimental frequencies 3.5, 10.6, 17.6, 20.9, 24.6, 31.6, 51.6, 61.0, 101.0, 141.0 MHz for an exact single-relaxation equation with $A = 200$, $B = 100$, $\nu_r = 25$.

given by the Davies form (15):

$$[5]\quad \log_{10} y_{\pm} = \frac{-1.825 \times 10^6 \times (\varepsilon T)^{-3/2} \times \mu^{1/2}}{1 + (50.3 \times 10^8 \times (\varepsilon T)^{-1/2} \times 3.04 \times 10^{-8} \times \mu^{1/2})} + 0.1\mu$$

This assumes the distance of closest approach parameter to be 0.30 nm. The sensitivity of the results of the analysis to the form of the $y_{\pm}$ equation assumed has been investigated previously, although not for cases where concentrations are as high as 0.3 molar (5).

The K_c values can be obtained by an iteration in which K_c is initially assumed equal to K_a. Next the degree of dissociation α can be obtained, and hence the ionic strength $\mu = \alpha c$ for a 1:1 electrolyte. The $y_{\pm}$ is next calculated from [5] and a new value $K_c = y_{\pm}^2 K_a$ is obtained. This iteration is continued until K_c is constant to within 0.1%. Values of $y_{\pm}$, K_c, and α obtained this way are shown in Table 3 together with the K_a and ε values from ref. 7 used in the analysis. It is of interest to note that $y_{\pm}$ varies relatively little with the value of K_a due to counterbalancing effects in [5]. The μ used and the $y_{\pm}$ calculated here do not assume complete dissociation as some listings do. If incomplete dissociations are included in the $y_{\pm}$ value, then the $y_{\pm} = \alpha \times$ the $y_{\pm}$ calculated here.

The quantity A in Table 1 for a process such as that described by [4] is given by (5):

$$[6]\quad A = \frac{\pi(\Delta V_{eff})^2 \rho v}{RT} \left\{ \frac{(2-\alpha)}{\alpha(1-\alpha)c} + \frac{\partial \ln y_{\pm}}{\partial \alpha} \right\}^{-1} \cdot \frac{1}{\nu_r}$$

Here ΔV_{eff} is the effective volume change of [4],

$$[7]\quad \Delta V_{eff} = \Delta V^0 - \frac{\alpha \Delta H^0}{\rho C_p}$$

In [7] α refers to the thermal expansivity. Values of $|\Delta V_{eff}|$ can be calculated from [6] as all other quantities are available. The results are shown in Table 3. Neither the sign of ΔV_{eff} can be determined, nor can the relative contributions to it from ΔV^0 and ΔH^0 (eq. [7]).

The rate constant k_{ass} for the process in [4] can be obtained from values of ν_r through the relation (5):

$$[8]\quad \frac{1}{\tau} = 2\pi\nu_r = k_{diss} + k_{ass}(c_{H^+} + c_{Cl^-}) = k_{ass,\infty} \left\{ \frac{1}{K_a} + (\alpha c)^2 y_{\pm}^2 \left(\frac{2}{\alpha c} + 2\frac{\partial \ln y_{\pm}}{\partial \alpha} \right) \right\}$$

The $k_{ass,\infty}$ calculated in this way is the limiting value at infinite dilution, i.e., as $\mu \to 0$. The values obtained are listed in Table 3. No corrections to k_{ass} have been made due to change in ε with c (15).

The sensitivity of the $|\Delta V_{eff}|$ and k_{ass} values listed in Table 3 to variations is such that if one of ρ, v, or A is changed by 10%, then $|\Delta V_{eff}|$ is altered only by 5% while k_{ass} remains the same. A 10% change in K_a changes $|\Delta V_{eff}|$ by 1% and k_{ass} by 5%, while a 10% change in ν_r changes $|\Delta V_{eff}|$ by 5% and k_{ass} by 10%. Taking account of all possible errors, experimental as well as from analysis, the values of $|\Delta V_{eff}|$ and k_{ass} listed are probably correct to better than 20%. The largest uncertainty is probably the evaluation of activity coefficients, i.e., the use of eq. [5]. Values of $y_{\pm}$ (really $\alpha y_{\pm}$) can in principle be determined experimentally from cell emf values.

Table 3 also shows the results of application of simple diffusion control theory to estimate $k_{ass,\infty}$.

The diffusion controlled rate constants k_{diff} are calculated from the relation (5):

$$[9] \quad k_{diff} = \frac{4\pi(D_+ + D_-)}{1000} Lw(\exp[w/a] - 1)^{-1}$$

Here L is Avogadro's number, and $w = -e^2/\varepsilon kT$ for [+1], [−1] reactions. The sum of diffusion constants can be obtained from conductivity as $D = \Lambda_\infty RT/F^2$ for infinite dilution. A correction for an increased viscosity for $c > 0$ was made, but no correction for any effect of dissolved electrolyte on ε.

A reaction distance a of 0.72 nm was used in applying eq. [9]. This is the distance between a solvent separated ion pair, i.e., (+)DMSO(−). If a = 0.42 nm were used, then the values of k_{diff} would be 85% of those in Table 3, and for a = 0.12 nm, the Bjerrum distance from conductivity (7), 80%. A value 0.72 nm was chosen as it is unreasonable to use a continuum theory for distances less than molecular dimensions.

Discussion

In most ultrasonic studies of ion pairing, the results cannot be fitted by a single relaxation equation in a satisfactory manner. For HCl in DMSO–water, however, the data can be fitted very well by a single-relaxation equation.

The variation of A with X as shown in Fig. 4 shows the relaxation strength to peak at $X \simeq 0.92$. At this solvent composition, $K_a \simeq 65$, giving an optimal degree of dissociation for ultrasonic absorption (eq. [6]). For $X > 0.92$, equilibrium [4] is shifted too far towards products (associated ions), and for $X < 0.92$, too far towards reactants (free ions). In the case of alkali metal halides, the optimal degree of association is never reached, so that any addition of water to a solution of alkali halides in DMSO causes a decrease in ultrasonic absorption (3).

The variation of v_r with X is also shown in Fig. 4. There is definitely an increase in v_r as more water is present. However, the higher v_r values at $X = 1.0$ are not clearly outside the limits of experimental uncertainty. An anomaly might be expected where $c_{H_2O} \simeq c_{Cl^-}$ as Cl^- is poorly solvated by DMSO (11) and might therefore be expected to have strong preferential solvation by H_2O. For solutions 0.3 molar in HCl this condition ($c_{H_2O} = c_{Cl^-} \simeq 0.24 \times 0.3$) would occur already at $X_{DMSO} = 0.995$ (0.13% by volume H_2O) as [DMSO] is 14 mol ℓ^{-1}. Thus even in 'pure' DMSO the mole ratio of H_2O to Cl^- is probably appreciable. No anomalous behaviour of Λ_∞ vs. X or Λ vs. c is apparent in the conductivity data (7), but the concentrations of HCl used in conductivity studies are smaller by more than a factor of 10.

Equation [8] suggests that v_r should increase with c. However, the data in Table 1 show v_r to be about the same for $c = 0.3$ and $c = 0.1$. This is due to the greater degree of dissociation at lower c values, together with a larger value of k_{ass} at lower c values. The $k_{ass,\infty}$ values calculated from the v_r (Table 3) show them to be somewhat greater for $c = 0.1$. It may be that formation of complex ions is non-negligible at $c = 0.30$. Since activity coefficient corrections are more likely to be valid for $c = 0.10$, the values of $|\Delta V_{eff}|$ and $k_{ass,\infty}$ in Table 3 for $c = 0.10$ are more likely to be correct.

The results of an ultrasonic study of HCl in dimethylformamide (6) give $|\Delta V_{eff}|$ and k_{ass} values close to those in Table 3. A distance of closest approach of 1.0 nm is calculated from k_{ass} using diffusion-controlled theory in ref. 6. However $-e^2$ instead of e^2 should have been used in the equation corresponding to [9]. With this correction, the results in ref. 6 are similar to those found here: $k_{ass,\infty}$ is too low to give a physically real value of reaction distance a from eq. [9].

Ultrasonic studies of acids in water give a much larger value of a (5). This is possible because of the possibility of hydrogen-bond jumping in reactions in water involving H^+. The value of $|\Delta V_{eff}|$ ($\simeq |\Delta V^0|$ in aqueous solutions) is about 20 cm^3 mol^{-1}, similar to the values in Table 3. Diffusion-controlled rate theory should be more realistic for the case of the aqueous acid studies (5), as it is used for distances well in excess of a molecular diameter for the solvent H_2O.

Studies of ultrasonic absorption in solutions of 1:1 salts in nonaqueous solvents suggest that a two-step model is more appropriate. Both in the case of DMSO (3) and 2-propanol (4) solutions, experimental data suggested a second relaxation at higher frequencies. A second step may also be possible in the HCl–DMSO–water system when $c = 0.30$. In ref. 4, the high frequency absorption is postulated to be due to a modification of the structure of the solvent by the ions, instead of one of the steps in the 2-step ion pair mechanism proposed. In ref. 3, the insensitivity of the lower v_r ($\simeq$ 5 MHz) with ionic species suggests it to be characteristic of a reaction involving primarily solvent motion, e.g. reaction to form a contact ion pair from a solvent separated ion pair. In the case of a small ion like H^+, the ion may essentially "belong" to only one solvent molecule (16), making it more easily accessible for anions. For larger cations a more structured primary solvent sheath is formed which prevents the anion from immediately contacting the cation, making the solvent-separated ion pair a meaningful entity.

Conclusions

The results of the study strongly suggest that the excess ultrasonic absorption observed in this system is due to a single-relaxation process. The process responsible seems quite certainly to be the association–dissociation equilibrium of HCl.

Analysis of the ultrasonic results using the equilibrium constant from conductivity gives $|\Delta V_{eff}|$ values of the order of 20–25 $cm^3\ mol^{-1}$, typical of the ΔV's of ion pairing reactions when hydrogen ions are involved. Moreover, the $|\Delta V_{eff}|$ values obtained are quite consistent with variation in the mole fraction of DMSO even though the relaxation strength and the equilibrium constant vary considerably.

Values of the rate constant for ionic association are of the order of $3 \times 10^9\ \ell\ mol^{-1}\ s^{-1}$, as compared to $10 \times 10^9\ \ell\ mol^{-1}\ s^{-1}$ calculated from diffusion-controlled theory. Such a large discrepancy is not unexpected since k_{diff} is calculated assuming the solvent to be a continuum. Such a model is especially inappropriate in cases where the solvent molecules are large (DMSO has a diameter of approximately 7 Å), as then the distances considered are more likely to be of the order of molecular dimensions. Approximations made in the calculation of $k_{ass,\infty}$ from experimental data may also contribute to the discrepancy. The estimation of activity coefficient effects is especially open to error.

The results for this study differ from results of most other studies of ion-pairing phenomena in that the phenomenon can be explained in a satisfactory manner by a single relaxation process, and in that when the available conductivity equilibrium constant data are used in analysis, the results are very reasonable. For ion pairing processes involving larger cations, at least two equilibria affect the ultrasonic absorption.

This may be because larger cations (e.g. alkali metal or earth ions) may have primary solvation sheaths which contain several quite rigidly held solvent molecules, preventing a contact ion pair from forming readily. Thus a distinct solvent-separated ion pair species exists, and at least two distinct equilibria exist in the process free ions → contact ion pair. In a primarily nonaqueous solution, a smaller ion has fewer molecules in its primary solvation shell (11). The crude model of the solvation of a proton in such solutions may be obtained by considering it as a very small ion. It would then possibly be solvated most strongly by only a single solvent molecule. Thus it is not well shielded geometrically, and direct formation of the contact ion pair is easier.

Pulse radiolysis of deuterated aqueous LiCl glasses. Dependence of the yields and rates of reaction of visible and infrared absorbing trapped electrons on LiCl concentration[1]

HUGH A. GILLIS AND GEORGE G. TEATHER

Division of Physics, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

HUGH A. GILLIS, GEORGE G. TEATHER, and GEORGE V. BUXTON. Can. J. Chem. **56**, 1889 (1978).

The yields and reactions of trapped electrons which absorb in the visible (e_{vis}^-) and infrared (e_{ir}^-) have been studied by pulse radiolysis in deuterated aqueous 6–15 *M* LiCl glasses at low temperatures. At 76 K $G(e_{vis}^-)$ increases and $G(e_{ir}^-)$ decreases as the concentration of LiCl is increased, but $[G(e_{vis}^-) + G(e_{ir}^-)] \simeq 1.8$ over the whole concentration range. Because the hydration number of Li^+ is 4, $G(e_{ir}^-)/G(e_{vis}^-)$ was plotted against [free D_2O]/[$LiCl \cdot 4D_2O$] and found to give a straight line passing through the origin, for $[D_2O]/[LiCl] > 4$. From this proportionality it is concluded that e_{ir}^- is an electron trapped in a purely amorphous water environment and e_{vis}^- is mainly associated with water bound to Li^+.

The reactions of e_{ir}^- and e_{vis}^- with Cu(II) and SeO_4^{2-} have been investigated. At 138 K the rate of reaction of e_{vis}^- with SeO_4^{2-} increases with decreasing [LiCl] whereas its rate of reaction with Cu(II) is slower and independent of [LiCl]. At 76 K, where the rates of reaction of e_{ir}^- with the scavengers can also be measured, it is found that in each case e_{vis}^- and e_{ir}^- react more slowly in 12 *M* LiCl glass than in 6 *M* LiCl glass, the difference being more marked for SeO_4^{2-}. In the absence of scavenger the electron in the smaller yield decays faster. These observations can be rationalized on the basis that electrons can tunnel in either direction between visible and infrared traps before being scavenged, and it seems they cannot be rationalized in terms of direct tunnelling only.

$G(Cl_2^-)$ is found to be proportional to the electron fraction of $Cl^- \cdot 3D_2O$ in the glass and its extrapolated value for pure $Cl^- \cdot 3D_2O$ is 3.4. It is inferred that Cl_2^- arises mainly from ionization of the D_2O bound to Cl^-.

HUGH A. GILLIS, GEORGE G. TEATHER et GEORGE V. BUXTON. Can. J. Chem. **56**, 1889 (1978).

Les rendements et les réactions d'électrons piégés qui absorbent dans le visible (e_{vis}^-) et dans l'infrarouge (e_{ir}^-) ont pu être étudiés par radiolyse pulsée dans des verres aqueux deutérés de 6 à 15 *M* de LiCl à basse température. A 76 K, $G(e_{vis}^-)$ augmente et $G(e_{ir}^-)$ diminue à mesure que la concentration de LiCl augmente; toutefois $[G(e_{vis}^-) + G(e_{ir}^-)] \simeq 1.8$ à toutes les concentrations. Dû au fait que le nombre d'hydration de Li^+ est 4, on a porté en graphique $G(e_{ir}^-)/G(e_{vis}^-)$ en fonction de [D_2O libre]/[$LiCl \cdot 4D_2O$] et on a trouvé que cette ligne est droite et qu'elle passe à l'origine pour $[D_2O]/[LiCl] > 4$. En se basant sur cette proportionalité, on peut conclure que e_{ir}^- est dû à un électron piégé dans un environnement d'eau purement amorphe alors que e_{vis}^- est associé principalement avec de l'eau liée à Li^+.

On a étudié les réactions de e_{ir}^- et de e_{vis}^- avec Cu(II) et SeO_4^{2-}. A 138 K, la vitesse de la réaction de e_{vis}^- avec SeO_4^{2-} augmente lorsque la concentration de [LiCl] diminue alors que sa vitesse de réaction avec Cu(II) est plus faible et ne dépend pas de la concentration de [LiCl]. A 76 K, température à laquelle les vitesses de réaction de e_{ir}^- avec des piégeurs ont pu aussi être mesurées, on a trouvé que dans chaque cas e_{vis}^- et e_{ir}^- réagissent plus lentement dans des verres de 12 *M* LiCl que dans des verres de 6 *M* LiCl; la différence est la plus marquée avec SeO_4^{2-}. Lorsqu'il n'y a pas de piégeurs, l'électron dans un champ plus faible disparaît plus rapidement. On peut rationaliser ces observations en se basant sur l'hypothèse que les électrons peuvent réagir par une réaction tunnel dans chaque direction entre les pièges du visible et de l'infrarouge avant d'être piégé et il semble que l'on ne peut pas rationaliser les observations en terme uniquement de tunnel direct.

On a trouvé que $G(Cl_2^-)$ est proportionnel à la fraction électronique de $Cl^- \cdot 3D_2O$ dans le verre et sa valeur extrapolée pour $Cl^- \cdot 3D_2O$ pure est de 3.4. On a déduit que Cl_2^- provient principalement de l'ionisation de D_2O lié à Cl^-.

[Traduit par le journal]

Introduction

Trapped electrons which absorb in the infrared, e_{ir}^-, have been observed in a few aqueous glasses, but not in several others (1). These trapped electrons can be produced directly by ionizing radiation (1), or indirectly by photoionization of trapped electrons

which absorb in the visible, e_{vis}^- (2). The intensities of the infrared and visible absorption bands vary from one glass to another, e.g. the infrared band is much more prominent in 2.5 *M* $MgCl_2$ than in 9.5 *M* LiCl, while the opposite is true for the visible band. We have also observed a similar infrared band in single crystals of ice which we have tentatively assigned to electrons trapped in naturally occurring cavities in the ice structure (3).

These observations suggest that the infrared band in the glasses might also be due to electrons trapped in a purely water environment, and that the higher yields of e_{ir}^- found in particular glasses (1) could be due to these glasses having smaller fractions of their water content involved in hydration, so that the probability of electrons being trapped in a purely water environment would be greater.

To test this idea we chose to investigate the variation in intensity of the infrared and visible bands with composition in the LiCl system because (*a*) it forms good glasses over a wide range of LiCl concentration (4), (*b*) we have already studied this glass extensively for 9.5 *M* LiCl (1, 5, 6), and (*c*) the total hydration number of LiCl has been estimated as 6–8 in one report (4), while more recent work (7) indicates that the hydration number of Li^+ is 4. Thus in glasses containing the lower concentrations of LiCl significant amounts of the water will not be involved in hydration of the ions.

It has also been shown (6) that the rate at which e_{vis}^- reacts with scavengers in 9.5 *M* LiCl glass is consistent with its being transformed into e_{ir}^- before reaction, and in a very recent study (2*b*) strong evidence for the reverse transformation has been obtained. Therefore with the hope of obtaining more information about these conversions, we have also investigated in the present study the effect of the composition of the LiCl glasses on the reactions of e_{vis}^- and e_{ir}^- with chosen solutes.

Experimental

The experiments at 76 K were carried out at the National Research Council of Canada, Ottawa and those at 138 K at the University of Leeds. Details of the pulse radiolysis facilities and techniques used in this work were as described before (1, 5, 6). All optical densities (OD) reported in this paper have been corrected for small absorptions in the Suprasil cells. All samples were prepared in D_2O (99.7 atom% D, from Merck, Sharp and Dohme, or 99.8 atom% D, from Norsk Hydro) which was used as received. Solutes were analytical reagent grade and were also used without further purification.

Results

(1) Spectrum of Trapped Electrons (e_t^-) at 76 K: Dependence on LiCl Concentration

The spectrum of e_t^- was measured at 76 K at the end of a 40 ns pulse in a number of LiCl/D_2O glasses of different compositions. As before (1), the spectrum consists of a band in the visible region with $\lambda_{max} \sim 650$ nm and a second band in the infrared with $\lambda_{max} > 2350$ nm, but the intensities of the two bands depend strongly on the concentration of LiCl in the glass, as can be seen in Fig. 1. However, no effect of LiCl concentration on the positions or shapes of the two bands is seen.

We have shown before (1) that the absorption at 650 nm is due solely to e_{vis}^- and absorption at 2350 nm is similarly due only to e_{ir}^-. The data in Table 1 show how the yields of these species vary with the composition of the LiCl/D_2O glass. The striking feature of these data is the way in which $G(e_{ir}^-)$ increases and $G(e_{vis}^-)$ decreases as the water content of the glass increases, while the sum of the yields remains practically constant.

The values of $G(e_{vis}^-)$ and $G(e_{ir}^-)$ in 9.5 *M* LiCl glass are respectively 29% and 18% lower than the values which were reported before (1). We believe that the discrepancy is associated with dosimetry problems in the earlier work. The values in Table 1 have been confirmed in repeat experiments and are therefore considered to be correct.

(2) Decay of e_t^- at 76 K

The decay of e_{vis}^- and e_{ir}^- at 76 K after a 40 ns pulse was monitored at 650 nm and 2350 nm respectively. The decays are kinetically complex and depend on the composition of the glass. Examples are given in Fig. 2 and Table 2 which show that the rate at which a given band decays increases as the intensity of the band decreases.

12	1.321	3.38	1.46	0.39	1.85
15	1.359	2.41	1.65	0.10	1.75

[a] ε_{650} taken as $2 \times 10^4\ M^{-1}\ cm^{-1}$ (1).
[b] ε_{2350} taken as $3.05 \times 10^4\ M^{-1}\ cm^{-1}$ (1).
[c] Corrections have been made for the electron densities of the glasses at 76 K. The yields were measured 100 ns after the start of a 40 ns pulse.

(3) Effect of the Electron Scavengers Cu(II) and SeO_4^{2-}

To investigate further the idea that the reaction of e_{vis}^- with certain solutes proceeds via transformation of e_{vis}^- into e_{ir}^- (6), we have measured the rate at which e_t^- reacts with cupric ion and selenate ion. These solutes were chosen because (*a*) SeO_4^{2-} is a very efficient scavenger of 'dry' electrons, e_{dry}^-, whereas Cu(II) is a very inefficient one (6), (*b*) the opposite holds for e_{vis}^-, and (*c*) there are indications (1, 6) that the reactivity of e_{ir}^- may be similar to that of e_{dry}^-.

(a) Reaction at 138 K

At 138 K no e_{ir}^- are observed (1) and so reaction of e_{vis}^- with Cu(II) and SeO_4^{2-} was followed at 600 nm. The decays of e_{vis}^- following a 10 ns pulse are presented in Figs. 3 and 4 and have been corrected for the decay of e_{vis}^- in the absence of scavenger by dividing $OD/OD_{17\ ns}$ in the presence of scavenger by $OD/OD_{17\ ns}$ in the absence of scavenger. This procedure, used earlier by Miller (8), is valid if the change in OD due to e_t^- is of the form

$$\frac{-d(OD)}{dt} = (k'(t) + k''(t))(OD)$$

where $k'(t)$ and $k''(t)$ are time-dependent first-order rate constants which refer to the decay of e_t^- in the absence of scavengers and reaction of e_t^- with scavengers respectively. In the presence of scavenger the optical density OD_s at time t is given by

$$\ln OD_s = -\int_0^t k'(t)\,dt - \int_0^t k''(t)\,dt$$

when the initial OD_s is taken as unity. Similarly in the absence of scavenger the optical density OD_B at time t is given by

$$\ln OD_B = -\int_0^t k'(t)\,dt$$

Hence

$$\ln (OD_s/OD_B) = -\int_0^t k''(t)\,dt$$

which on differentiation gives

$$\frac{-d(OD_s/OD_B)}{dt} = k''(t)(OD_s/OD_B)$$

Therefore from plots of OD_s/OD_B vs. time as in Figs. 3–6, which have been normalised to unity at the first observation time (17 ns or 100 ns), $k''(t)$ can be calculated at any time.

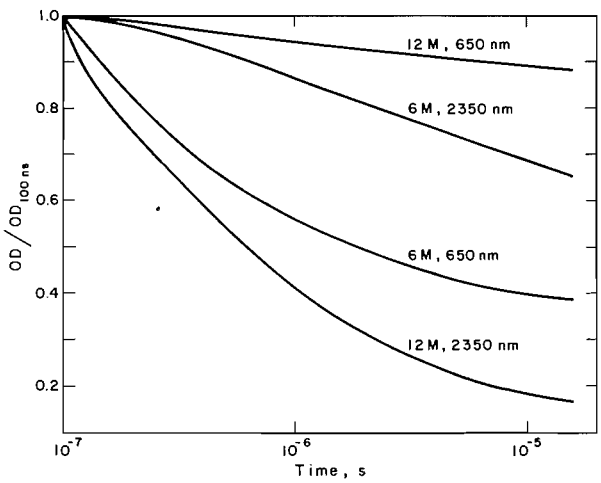

FIG. 2. Decay of e_t^- at 650 nm and 2350 nm at 76 K in 6 M and 12 M LiCl glass, without scavenger. Time is measured from the start of a 40 ns pulse.

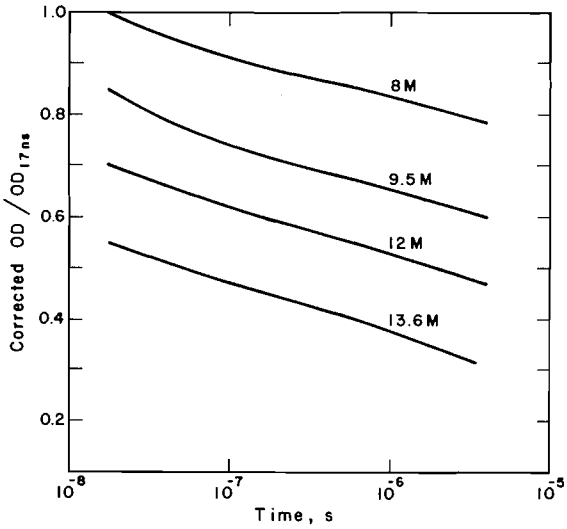

FIG. 3. Effect of [LiCl] on the decay of e_{vis}^- at 600 nm at 138 K in LiCl glass containing 5 m*M* Cu(II). Time is measured from the start of a 10 ns pulse. Each curve has been corrected for the decay of e_{vis}^- in the glass containing no scavenger as described in the text. The lower curves are displaced vertically.

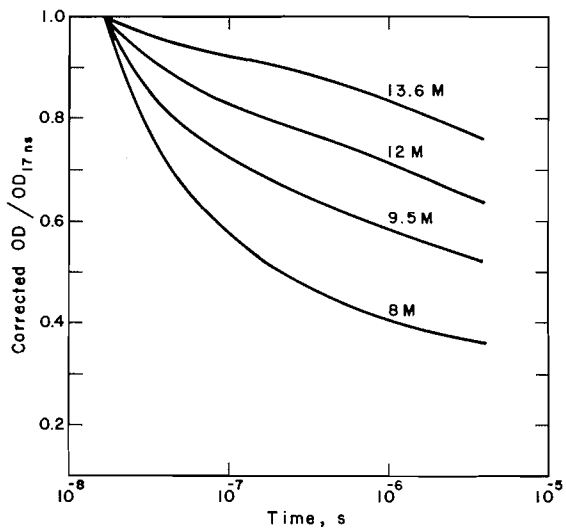

FIG. 4. Effect of [LiCl] on the decay of e_{vis}^- at 600 nm and 138 K in LiCl glass containing 5 m*M* SeO_4^{2-}. Time is measured from the start of a 10 ns pulse. Each curve has been corrected for the decay of e_{vis}^- in the glass containing no scavenger as described in the text.

Noteworthy features of the data in Figs. 3 and 4 are the increase in the rate of reaction of e_{vis}^- with SeO_4^{2-}, and its constant and slower rate of reaction with Cu(II), with decreasing [LiCl].

(b) Reaction at 76 K

At 76 K the decays of e_{vis}^- and e_{ir}^- were followed at 650 nm and 2350 nm respectively. Data for 6 *M* and 12 *M* LiCl glasses containing SeO_4^{2-} or Cu(II) are presented in Figs. 5 and 6. The pulse length was

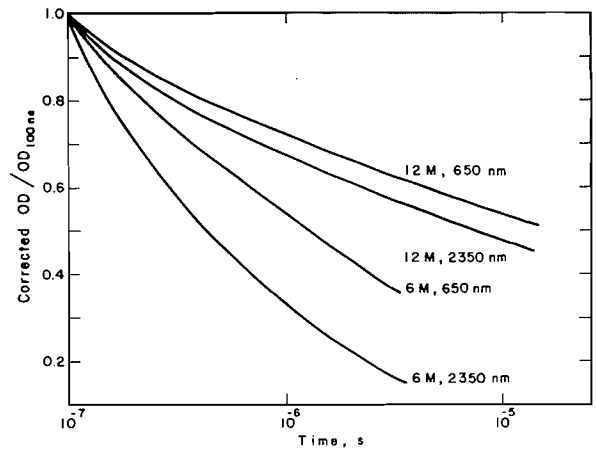

FIG. 5. Effect of [LiCl] on the decay of e_{vis}^- at 650 nm and e_{ir}^- at 2350 nm at 76 K in LiCl glass containing 20 m*M* Cu(II). Time is measured from the start of a 40 ns pulse. Each curve has been corrected for the decay of e_{vis}^- or e_{ir}^- in the glass containing no scavenger as described in the text.

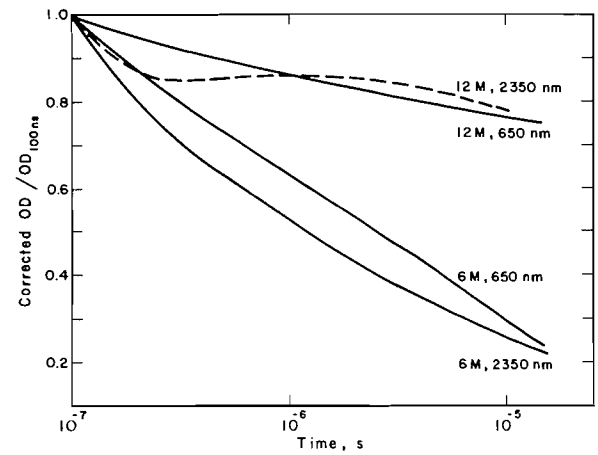

FIG. 6. Effect of [LiCl] on the decay of e_{vis}^- at 650 nm and e_{ir}^- at 2350 nm at 76 K in LiCl glass containing 5 m*M* SeO_4^{2-}. Time is measured from the start of a 40 ns pulse. Each curve has been corrected for the decay of e_{vis}^- or e_{ir}^- in the glass containing no scavenger as described in the text. The data for the 12 *M* glass at 2350 nm are rather uncertain.

40 ns and the decays have been corrected for the decay in the absence of scavenger (see Fig. 2) as described above.

(4) Effect of Scavengers on the Yields of e_{vis}^- and e_{ir}^-

The data in Table 3 show how G/G_0, the ratio of the yields in the presence and absence respectively of Cu(II) or SeO_4^{2-}, measured at the end of the pulse, varied with [LiCl]. At 138 K where only $G(e_{vis}^-)$ could be measured, 5 m*M* Cu(II) scarcely affected G/G_0 in any LiCl glass whereas 5 m*M* SeO_4^{2-} decreased G/G_0 to a larger extent at the lower concentrations of LiCl. At 76 K SeO_4^{2-} was again more effective than Cu(II) in decreasing $G(e_{vis}^-)$ and

$G(e_{ir}^-)$. However, at this temperature G/G_0 for e_{vis}^- was essentially independent of [LiCl].

(5) Yields of Cl_2^-

The maximum in the spectrum of Cl_2^- at 76 K was confirmed as 350 nm for 7 M LiCl glass. The measured yields of Cl_2^- for several different LiCl concentrations are listed in Table 4. We have corrected these yields for the contribution of e_{vis}^- (which cannot be measured) to the total absorption at 350 nm by assuming that the absorption spectra of e_{vis}^- in LiCl glasses and 50% ethylene glycol/D_2O glass, which have virtually identical shapes when $\lambda > 450$ nm (1), are also similar at $\lambda < 450$ nm.

Discussion

(1) Correlation between Glass Composition and Trapped Electron Yields

The dependence of $G(e_{vis}^-)$ and $G(e_{ir}^-)$ on [LiCl] in the glass (see Table 1) strongly suggests that they are correlated. The quantum yields for production of e_{ir}^- by laser bleaching of e_{vis}^- show the same trend with varying [LiCl] as that shown in Table 1; quantum yields for 6.5 and 15 M glasses were measured as 0.018 and 0.004, respectively (2*b*). Conclusions reached about the structure of these glasses from recent nmr studies (7) are that the lithium ion is coordinated to the oxygen atoms of four water molecules in a tetrahedral structure. Three of these are shared with six separate chloride ions in an octahedral arrangement, and the fourth water molecule is unshared. The basic unit is therefore $(Li{\cdot}4H_2O)^+Cl^-$ and the basic structure is believed to be a distorted face-centred cube with the Li^+ and Cl^- arranged octahedrally round one another. Water in excess of that required to form $(Li{\cdot}4H_2O)^+$ does not form further coordination shells and is regarded as being essentially free (7). The structure of this free water is not established but it appears to be amorphous rather than ice-like (7). Angell and Sare (4) similarly concluded that concentrated LiCl solutions around the glass transition temperature consist of two coexisting liquid phases: amorphous water (or very dilute solution) and a salt-rich hydrated ionic liquid. The more dilute of the LiCl solutions which can form glasses show a tendency to phase separate (4). Substitution of D_2O for H_2O is unlikely to change these structures.

On this basis we might expect a correlation of $G(e_{vis}^-)$ and $G(e_{ir}^-)$ with the relative amounts of $LiCl{\cdot}4D_2O$ and free water in the glass. This is borne out by Fig. 7 which shows that $G(e_{ir}^-)/G(e_{vis}^-)$ is proportional to [free D_2O]/[$LiCl{\cdot}4D_2O$]. Such a relationship is expected to hold if pre-existing trapping sites for e_{ir}^- and e_{vis}^- are in competition for mobile electrons which would otherwise recombine with the geminate positive holes (reactions [1]–[3]),

[1] $e^- + \text{positive hole} \rightarrow \text{no } e_t^-$

[2] $e^- + \text{infrared trap} \rightarrow e_{ir}^-$

[3] $e^- + \text{visible trap} \rightarrow e_{vis}^-$

These processes are analogous to the competitive scavenging of electrons by two solutes in hydrocarbons (10). The appropriate equations are (10) [4] and [5]

$$[4] \qquad \frac{G(e_{ir}^-)}{G(e_{vis}^-)} = \frac{\alpha_2[\text{ir trap}]}{\alpha_3[\text{vis trap}]}$$

$$[5] \quad G(e_{ir}^-) + G(e_{vis}^-) = G_i \frac{\{\alpha_2[\text{ir trap}] + \alpha_3[\text{vis trap}]\}^{1/2}}{1 + \{\alpha_2[\text{ir trap}] + \alpha_3[\text{vis trap}]\}^{1/2}}$$

where G_i is the initial yield of mobile electrons and α is the reactivity of the electron with the trapping site. Here we assume, by analogy with the situation in liquid hydrocarbons (10), that all the mobile electrons in the glass can be treated as geminate ions. This is reasonable since only the high frequency dielectric constant will apply at this stage. The data in Fig. 7 satisfy eq. [4] if [ir trap] = x[free D_2O] and [vis trap] = y[$LiCl{\cdot}4D_2O$] when the ratio [D_2O]:[LiCl] > 4. Correspondingly the requirement for eq. [5] to be valid is that $\{[\text{free } D_2O] + LiCl{\cdot}4D_2O]\}^{1/2}$ be constant since $[G(e_{ir}^-) + G(e_{vis}^-)]$ is approximately constant (see Table 1) and $x\alpha_2 = y\alpha_3$ (see Fig. 7). In fact $\{[\text{free } D_2O] + [LiCl{\cdot}4D_2O]\}^{1/2}$ decreases by only 29% from 5.45 for 6 *M* LiCl to 3.84 for 9.5 *M* LiCl. The latter concentration corresponds to the lowest nonzero value of [free D_2O]/[$LiCl{\cdot}4D_2O$] in Fig. 7. The lack of any decrease in $[G(e_{ir}^-) + G(e_{vis}^-)]$ between 6 and 9.5 *M* LiCl may be due to a lower yield of unscavenged holes that can undergo reaction [1] at higher $[Cl^-]$ (see section (4) below).

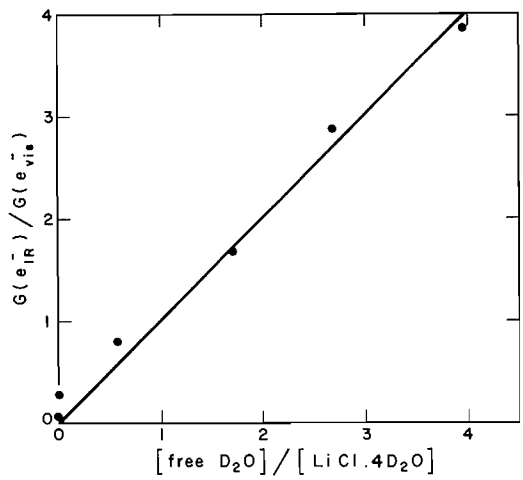

FIG. 7. Dependence of $G(e_{ir}^-)/G(e_{vis}^-)$ on [free D_2O]/[$LiCl{\cdot}4D_2O$] in LiCl glass at 76 K.

So far the simple model of e_{ir}^- and e_{vis}^- being electrons trapped in free water and $LiCl{\cdot}4D_2O$ structures respectively seems to be a reasonable one. However, it is clear from Table 1 and Fig. 7 that $G(e_{ir}^-)$ is still significant at LiCl concentrations of 12 or 15 *M* where little or no free water is expected to be present in the glass. This leads us to conclude that either traps for e_{ir}^- are not exclusively confined to purely water structures, or such structures are by chance still formed when [D_2O]:[LiCl] < 4.

(2) Reaction of e_t^-

Reaction of e_t^- with solutes in rigid glasses is generally accepted to proceed via a tunnelling mechanism. Before discussing the reactions observed in this study it will be helpful to summarise the pertinent features of the two types of tunnelling mechanism which have been postulated, viz. direct tunnelling (11) and trap-to-trap tunnelling (12). The basis of the direct tunnelling model is that the electron tunnels from its trap to the acceptor so that the reaction rate depends upon the concentration of the acceptor but not on the presence of other (empty) traps. In the trap-to-trap tunnelling model it is postulated that the electron tunnels from one trap to another until it finds itself in a trap which is within the reaction distance of the acceptor. In this case the reaction rate depends upon the concentration of traps as well as of acceptor.

Miller's (11) formulation of the direct tunnelling model is as follows: If every trapped electron within the distance a of randomly distributed acceptor S is captured, the probability P that it will have reacted in time t is

$$[6] \qquad P = 1 - \exp(-2.52 \times 10^{-3} a^3[S])$$

where a is the width of the barrier through which the electron tunnels and is given by (8)

$$[7] \qquad a = a_0 + 2.26B^{-1/2}(15 + \log Ft)$$

B is the binding energy of the trapped electron and F is an "inefficiency factor" included by Miller (8) to take account of the observation that tunnelling rates differ from one kind of acceptor to another. Thus, according to the model, the parameters affecting the tunnelling rate are B, F, and [S]. Values of B are not known with any certainty (2*b*) but are probably within a factor of two of 1 eV for aqueous glasses. For 6 *M* NaOH glass Miller (8) assumed B = 1.2 eV and found that F ranged from 10^4 to 10^{-15} depending on the acceptor. The factor F is thought (8) to be associated with Franck–Condon restrictions to the transfer of an electron to the acceptor.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In the trap-to-trap tunnelling model proposed by Buxton and Kemsley (12), it is assumed that the probability that an electron will have reacted in time t is $P_t \times P_s$, where P_t is the probability that the electron will tunnel to another trap and is given by eq. [6] with [S] replaced by [trap], and P_s is the probability that the electron will be scavenged and is given by eq. [6] with a replaced by r. In this case the tunnelling rate of the electron should depend on [trap], [S], a, and r. For a number of different aqueous glasses, the parameter r varies with acceptor, ranging from 6 Å to 20 Å (12), but for a given acceptor it has about the same value as the reaction distance for solvated electrons obtained from diffusion kinetics measurements in the corresponding aqueous liquid (12). In general these values of r do not change very much from one aqueous liquid to another (6, 12). In this case the variation in r is, presumably, also a reflection of Franck–Condon restrictions to the electron transfer process.

The striking features of the data shown in Figs. 5 and 6 are (*a*) for a particular glass at 76 K e_{vis}^- and e_{ir}^- react at rather similar rates with either SeO_4^{2-} or Cu(II), (*b*) changing [LiCl] markedly affects the reaction rates, and (*c*) SeO_4^{2-} is a very efficient acceptor of e_{vis}^- in the more dilute LiCl glasses (see also Fig. 4) although it is a very poor acceptor in other aqueous glasses (8, 12).

On the face of it these results seem to be the opposite of what one would expect to observe if the direct tunnelling model outlined above was operative. Thus one might anticipate that e_{ir}^- would react much faster than e_{vis}^- since e_{ir}^- would be expected to be much less strongly bound than e_{vis}^-, the respective transition energies at λ_{max} being 0.34 eV and 1.94 eV (1). It could be argued, perhaps, that changes in B are counterbalanced by changes in F, and we have no information about F other than as an adjustable parameter. The effects of [LiCl] on the tunnelling rate are also unexpected since they imply that values of F for both e_{vis}^- and e_{ir}^- change very considerably when [LiCl] is increased from 6 M to 12 M. Such large changes in F appear to be at variance with the spectral data in Fig. 1 which show that the positions and shapes of the bands assigned to e_{vis}^- and e_{ir}^- are independent of [LiCl], which suggests that B for each type of electron does not change very much either. We have no information on the effect of [LiCl] on the energy states of the acceptors, but feel that any changes should be rather small, especially in view of the insensitivity of r for solvated electron reactions to the composition of the aqueous liquid noted above.

A factor which does change with [LiCl] is the trap concentration, as revealed by the values of $G(e_{vis}^-)$ and $G(e_{ir}^-)$ in Table 1 which we have already discussed. Therefore it does appear that there is some sort of influence of trap concentration on tunnelling rates in LiCl glasses and this suggests that trap-to-trap tunnelling may occur. If this is the case can these unusual tunnelling kinetic data be rationalized? As noted above, SeO_4^{2-} is a very poor acceptor of e_{vis}^- although it scavenges e_{dry}^- very efficiently (5, 8), and yet both e_{vis}^- and e_{ir}^- react rapidly with SeO_4^{2-} when the ratio visible traps:infrared traps is low, and they both react slowly when this ratio is high (see Fig. 6 and Table 1). Let us assume that electrons can tunnel between any two traps, and donor and acceptor traps can be either visible or infrared. Then, in 6 M LiCl glass an electron on average would be more likely to tunnel to an infrared trap and conversely, in 12 M LiCl glass tunnelling to a visible trap would be more likely. Thus if SeO_4^{2-} is a better acceptor of e_{ir}^- than e_{vis}^- (i.e. the reaction distance r is larger for e_{ir}^-; see also section 3 below) both e_{ir}^- and e_{vis}^- would appear to react more rapidly in 6 M LiCl glass and less rapidly in 12 M LiCl glass. The same considerations apply to the data in Fig. 4 for 138 K. The less marked effects of [LiCl] in the case of Cu(II) (see Figs. 3 and 5) would then suggest that this acceptor reacts with more nearly the same efficiency with both e_{vis}^- and e_{ir}^-. In other systems Cu(II) reacts much more efficiently than SeO_4^{2-} with e_{vis}^- (6, 11).

Objections which have been raised by the referees to the idea of trap-to-trap tunnelling are that the occupied traps would be deeper than the unoccupied traps, and that infrared traps would be shallower than visible traps. We have observed no signs of trap deepening in this work and we emphasize the fact that e_{ir}^- exists quite separately from e_{vis}^- and there is no evidence that it transforms into e_{vis}^- by deepening its trap. However, if we make the reasonable assumption that tunnelling cannot be endothermic by much more than kT, then the trap-to-trap interpretation requires that a fairly high concentration of visible traps have a ground state energy that is very similar to that of a high concentration of infrared traps, and such a near-coincidence is unexpected in view of quite different energies at λ_{max} of the optical transitions in e_{vis}^- and e_{ir}^-. In terms of e_t^- as a particle in a cubic box, which is undoubtedly a gross over-simplification of the real situation, the near-coincidence in ground state energies would imply that the infrared traps must be $\sqrt{5.7}$ times wider than the visible traps.

In our opinion the present data are more in line with a trap-to-trap tunnelling model than with current direct tunnelling models. However, each model is undoubtedly a very simplified representa-

tion of the actual processes occurring and further experimental and theoretical work is needed to unravel their complexities. In particular attention should be focussed on the effects of the glass composition and structure on tunnelling kinetics.

(3) Effect of Cu(II) and SeO_4^{2-} on the Yields of e_{vis}^- and e_{ir}^-

It is difficult to evaluate the data in Table 3 quantitatively because of the problem of estimating the amount of decay which occurs during the pulse. However, a number of features deserve comment. First, Cu(II) reduces $G(e_t^-)$ much less effectively than SeO_4^{2-} in agreement with previous conclusions that SeO_4^{2-} is a good dry electron scavenger and Cu(II) is not (6, 12). As proposed before (6), the effect of Cu(II) on $G(e_{vis}^-)$ at 76 K is attributed mainly to formation of encounter pairs. Secondly, $G(e_{ir}^-)$ is decreased more than $G(e_{vis}^-)$, indicating a higher probability of encounter pair formation by e_{ir}^- (1), i.e. a larger value of r. The effect is more marked for SeO_4^{2-}, and supports the conclusions already drawn from the kinetic data about the reactivity of e_{ir}^-. Thirdly, the G/G_0 values for SeO_4^{2-} at 138 K vary much more with [LiCl] than those at 76 K for SeO_4^{2-} or Cu(II). A possible explanation for this is that at 138 K thermal detrapping of e_{ir}^- and efficient scavenging of the resulting mobilised electron by SeO_4^{2-} plays a significant role in the decay of e_{vis}^- at low [LiCl].

(4) Yields of Cl_2^-

Whereas $[G(e_{vis}^-) + G(e_{ir}^-)]$ is independent of [LiCl], $G(Cl_2^-)$ appears to be proportional to [LiCl]. Cl_2^- is likely to be produced by the reaction sequence

$$[8] \qquad (D_2O^+ \ldots Cl^-) \rightarrow D_2O + Cl$$

$$[9] \qquad Cl + Cl^- \rightarrow Cl_2^-$$

where $(D_2O^+ \ldots Cl^-)$ represents ionization of D_2O bound to Cl^-.

If as proposed (7) each Cl^- is bound to six water molecules, each of which is shared with another Cl^-, then $G(Cl_2^-)$ should be proportional to the electron fraction of $Cl^-\cdot 3D_2O$ if ionization of the free D_2O and the D_2O bound only to Li^+ does not contribute significantly to $G(Cl_2^-)$. A plot of $G(Cl_2^-)$ against the electron fraction of $Cl^-\cdot 3D_2O$ is shown in Fig. 8 and implies that $G(Cl_2^-)$ from this entity is 3.4.

The larger yields of Cl_2^- at higher $[Cl^-]$ imply a lower yield of unscavenged holes that can undergo reaction [1], and hence a higher yield of e_t^- through reactions [2] and [3]. This effect could compensate for the lower concentration of electron traps (decrease in $\{[\text{free } D_2O] + [LiCl\cdot 4D_2O]\}^{1/2}$) and account for the observation that $[G(e_{vis}^-) + G(e_{ir}^-)]$ does not decrease at the higher concentrations of LiCl.

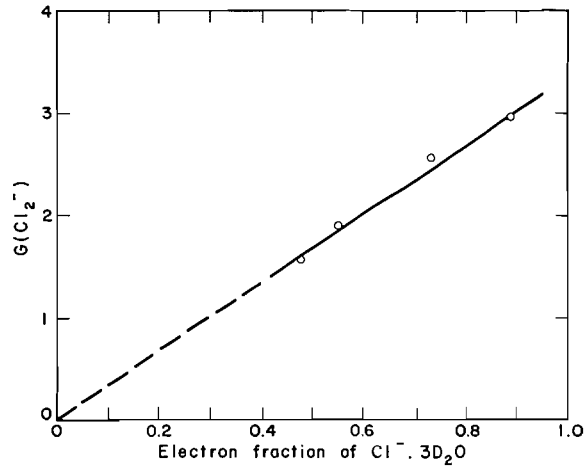

FIG. 8. Dependence of $G(Cl_2^-)$ on the electron fraction of $Cl^-\cdot 3D_2O$ in LiCl glasses at 76 K.

It is perhaps worth noting that in a pulse radiolysis (13) study of aqueous lithium chloride solutions at room temperature it was found that $G(Cl_2^-)$ passes through a maximum at a Cl^- concentration of about 9 *M*. However, there is no evidence that structures such as $Cl^-\cdot 3H_2O$ exist at room temperature, so that similarities with results found in the present work are not expected.

(5) Conclusions

The major conclusions drawn from this work are the following: (*a*) The infrared absorbing trapped electron is mainly associated with a purely water environment, which is in agreement with conclusions from luminescence studies on mixed-solute aqueous glasses (14), and e_{vis}^- is mainly associated with water bound to Li^+. (*b*) The unusual tunnelling kinetics observed in LiCl glasses seem to be associated with the relative concentrations of infrared and visible traps which change with [LiCl].

^{13}C nuclear magnetic resonance spectra of diastereomeric C-24 alkyl sterols have been assigned. Differences in the chemical shifts of side-chain carbons permitted the determination of the absolute configuration at C-24 in several sterols since these chemical shifts are insensitive to structural changes remote from the asymmetric centre. An unknown sterol from *Tetraselmis suecica* has been identified as (24*R*)-24-methylcholest-5-en-3β-ol and the configuration assigned from ^1H nmr data to the sterol from *Phaeodactylum tricornutum* has been confirmed. The utility and potential of this method in characterising new sterols and their biological precursors is discussed.

On a attribué les spectres rmn du ^{13}C de stérols diastéréoisomères en position C-24 de la chaîne alkyle. Les différences dans les déplacements chimiques des carbones de la chaîne latérale permettent de déterminer la configuration absolue au niveau C-24 dans plusieurs stérols puisque ces déplacements chimiques ne sont pas sensibles à des changements structuraux éloignés du centre asymétrique. Un stérol inconnu provenant du *Tetraselmis suecica* a pu être identifié comme étant le méthyl-24 cholesten-5 ol-3β (24*R*) et on a pu confirmer la configuration attribuée à partir de la rmn du ^1H au stérol provenant du *Phaeodactylum tricornutum*. On discute de l'utilité et des potentialités de cette méthode dans la caractérisation de nouveaux stérols et de leurs précurseurs biologiques.

[Traduit par le journal]

Introduction

Many sterols of plants and microorganisms contain a methyl or ethyl group at C-24, and both C-24 diastereoisomers have been found to occur naturally. From the cases that have been examined it appears that the alkyl group is derived biosynthetically by a transalkylation process involving *S*-adenosylmethionine (1). Sterols are vital membrane components of many organisms and presumably their stereochemical features are important in this respect (2–4). Indeed, there appears to be some phylogenetic significance to the configuration at C-24, since, in general, algae and fungi produce sterols with the 24β configuration (24*S* if a saturated side chain, 24*R* if the Δ^{22} derivative) whereas sterols in most vascular plants possess the 24α configuration (1).

In the identification of stereoisomers ordinary X-ray diffraction analysis yields only the relative configurations of chiral centers, although the absolute configurations become accessible if one is already known. Anomalous X-ray scattering is the only method which characterises configurations directly. In contrast indirect methods always involve comparisons with model compounds of known configuration. Those which measure a general property of a molecule, e.g. optical rotation, melting point, retention time in gas–liquid chromatography, are necessarily restricted to the recognition of previously identified compounds, whereas others like nuclear magnetic resonance spectrometry, which provide information on specific sites in a molecule, can be used to identify structural units in unknown compounds.

During the course of our investigations of marine algal products, it occurred to us that the efficacy of ^{13}C nmr spectroscopy to probe stereochemical features (5, 6) might result in a more versatile approach to the identification of C-24 alkyl sterols. Thus chemical shift data obtained for the side-chain carbons of diastereoisomeric model steroids epimeric at C-24 should provide the basis for defining the configuration at this position in unknown steroids with the same side chain, provided changes in molecular structure are remote from the chiral center. Also, as the spin–lattice relaxation times of corresponding carbons in the two epimeric side chains would be

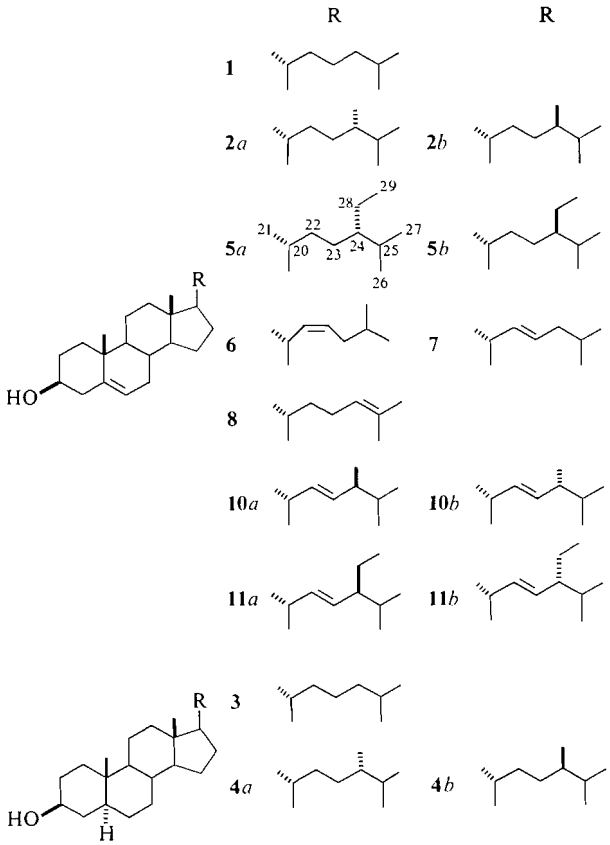
very similar, the composition of mixtures of stereoisomers can be obtained from the relative intensities of corresponding carbon signals.

Experimental

(24*R*)-24-Methylcholesta-4,22-dien-3-one (**14**) was purchased from Steraloids Inc., Wilton, NH, listed as 4,22-cholestadien-24-methyl-3-one, catalogue No. C2952. 'Campesterol' (**2***b*), from soybean, was obtained from Nutrional Biochemicals, Cleveland, OH, and contained approximately one-third 22,23-dihydrobrassicosterol (**2***a*). Stigmasterol (**11***a*) was purchased from Applied Science Laboratories, State College, PA, and purified by chromatography on alumina and crystallisation.



Ergostanol (**4***a*) and 22,23-dihydrobrassicasterol (**2***a*) were obtained by selective reduction (7) of ergosterol (**9**). 24-Methylcholesterol (**2***b*) from *Tetraselmis suecica*, clionasterol (**5***a*) from *Nitella*, poriferasterol (**11***b*) from *Spirogyra*, and 22-dehydrocampesterol (**10***a*) from *Phaeodactylum tricornutum* were obtained from Dr. G. Patterson. The sample of 22-*cis*-dehydrochalesterol was a gift from Dr. J. A. Svoboda. Except as noted elsewhere in the text the remaining sterols were isolated from scallop or prepared from these sterols (8, 9).

^{13}C nuclear magnetic resonance spectra were recorded with a Varian XL-100/15 Fourier transform spectrometer under the following conditions: frequency 25.16 MHz, acquisition time 1.6 s (data accuracy ± 0.3 Hz), spectral width 2560, 4002, or 5120 Hz, flip angle ca. 57°, internal pulse lock to ^2H in C^2HCl_3 (solvent), temperature 30°C, concentration 5–30 mg/ml. For off-resonance decoupling, protons were irradiated at δ_H ca. 6.25 ppm ($\gamma H_2/2\pi$ ca. 1800 or 3800 Hz). Broadband ^1H decoupling was obtained by phase modulation of the decoupling field from 0 to 180° at 150 Hz, with $\gamma H_2/2\pi$ 3800 Hz.

Proportions of diastereoisomers in mixtures were determined by averaging the relative intensity of each pair of ^{13}C resonances for which the chemical shift differed appreciably between epimers (error is standard deviation).

Results

Assignment of Resonances

Sterol Ring System

The original assignments of the resonances in the ^{13}C nmr spectrum of cholesterol (**1**) were made by Reich *et al.* (10) and were later confirmed by Mantsch and Smith (11), although those for C-12, C-16, C-20, C-26, and C-27 were tentative. Subsequent work (12, 13) showed that the assignments for C-12 and C-16 should be interchanged but final confirmation of the assignments arose from an elegant study by Popják and co-workers (14) on cholesterol biosynthesis using singly and doubly ^{13}C-labeled mevalonate. They were also able to establish for the first time that the *pro*-(*S*)-methyl carbon C-27 (derived from C-3′ of mevalonate) resonated at lower field than the *pro*-(*R*)-methyl carbon C-26 (originating from C-2 of mevalonate). Thus all the sterols listed in Table 1 possessing the cholesterol ring system produce easily identifiable signals in their ^1H broadband-decoupled, off-resonance decoupled, and high resolution ^{13}C spectra. Similarly the resonances for C-1 through C-19 in **4***a* and **4***b* were assigned with the aid of recent chemical shift data (15, 16) on 5α-cholestan-3β-ol (**3**) which differed from initial assignments (10) by interchanging those for C-12 and C-16, and C-18 and C-19.

Saturated Side Chain

Resonances for the alkyl side-chain carbons (C-20 through C-28 or C-29) of **2***a*, **2***b*, **4***a*, **4***b*, **5***a*, and **5***b* (see Table 1) were assigned by direct comparison with published spectral data on model alkanes (17), combined with calculations using an improved set of ^{13}C chemical shift additive substituent parameters (18). Space-filling molecular models indicated restricted rotation about the C-24, C-25 bond in these steroids, with H-24 and H-25 antiperiplanar in the most stable conformation, and this conclusion is supported by the X-ray crystallographic data for several ergostane derivatives (19). If this conformation predominates in **2***a* and **4***a*, which have a 24*S*-configuration, it follows that the *pro*-(*R*)-methyl carbon (C-26, δ_C 17.7) attached to C-25 will be synclinal to the C-28 methyl group, and therefore chemically shielded (20) relative to the *pro*-(*S*)-methyl carbon (C-27, δ_C 20.5), whereas the reverse can be expected for **2***b* and **4***b* with a 24*R* configuration (C-26, δ_C 20.2; C-27, δ_C

18.3). The numbering of these methyl carbons conforms with that used for the corresponding carbons in cholesterol (14).

Previously reported (17) chemical shift data for 2,3-dimethyl- (**12**) and 2-methyl-3-ethylpentane (**13**) were used to assign resonances for C-26 and C-27 of **5***a* and **5***b*. Two methyl carbons attached to C-2 in **12** resonated at δ_C 20.0 and δ_C 17.7, whereas similar carbons in **13** were fortuitously chemically equivalent at δ_C 19.0. Thus replacement of the methyl group bonded to C-3 of **13** with an ethyl group deshields one methyl carbon (δ_C 17.7) by 1.3 ppm and shields the other (δ_C 20.0) by 1.0 ppm. The same substituent change at C-24 on going from **2***a* (**2***b*) or **4***a* (**4***b*) to **5***a* (**5***b*) produces a similar shift in resonances, permitting the C-26 (*pro-*(*R*)-methyl) and C-27 (*pro-*(*S*)-methyl) signals for **5***a* and **5***b* to be assigned as shown in Table 1.

10*a* and **10***b* was based on chemical shift data from a recent study by Cushley and co-workers (21) on ergosterol (**9**) labeled from [1-^{13}C]acetate. Their results led to the interchange of previous assignments (10) for the pairs of carbons C-5,C-8; C-12,C-16; C-22,C23, and left only the assignments for C-21, C-26, and C-27 in doubt. The latter were identified as follows. Comparison with published data (22) for (*E*)-(C-6, δ_C 22.36) and (*Z*)-5-methylhex-22-ene (C-6, δ_C 22.42) enabled the resonances of C-26 (δ_C 22.41, 22.31) and C-27, (δ_C 22.64, 22.31), and therefore C-21 (δ_C 20.73, 20.87), to be identified in **6** and **7**. Although the C-21 methyl resonance is insensitive to the stereochemistry of the Δ^{22} double bond the data for desmosterol (**8**) indicates that this carbon, as well as C-26 and C-27, is influenced by the position of the bond. In **9**, **10***a*, and **10***b* the methyl substituent at C-24 would be expected to shield both C-26 and C-27, but not C-21, which would still resonate at ca. δ_C 21.0. Resonances were assigned to C-26 and C-27 on the basis that the most shielded methyl carbon is synclinal to C-28 in the most stable conformation. The chemical shifts of C-26 and C-27 in **9**, **10***a*, and **10***b* are in good agreement with the shift of the fortuitously chemically-equivalent terminal methyl carbons (δ_C 19.78) of 3,4-dimethylpent-1-ene (22). For **11***a* and **11***b*, the assignments for C-20 through C-25, C-28, and C-29 followed from the expected changes in chemical shift due to replacement of the C-24 methyl group of **9**, **10***a*, and **10***b* by an ethyl group. The signals from C-26 and C-27 were assigned as for **5***a* and **5***b*.

Discussion

The absolute configuration at C-20 and C-24 has been deduced for several C-24 alkyl sterols, as a result of chemical (23) and X-ray crystallographic studies (19).

The original ^{1}H nmr study (24) at 60 and 100 MHz showed slight chemical shift differences between the methyl hydrogens of several C-24 alkyl sterols but later studies at 220 MHz (25–29) and 270 MHz (30) permitted a rough quantitative analysis of an epimeric mixture. However it was still difficult to differentiate the epimers of C-24 ethyl sterols and the problem was magnified by the introduction of a *trans* double bond at C-22 (28, 29).

*(24*R*)-24-Methylcholest-5-en-3*β*-ol (**2**b) and (24*S*)-24-Methylcholest-5-en-3*β*-ol (**2**a)*

Four samples were available including authentic 24*R* and 24*S* material, the former from Applied Science Laboratories and the latter obtained by catalytic reduction of ergosterol (**9**). The remaining two were epimeric mixtures, one from soybean and the other from scallop. For these sterols characteristic chemical shifts induced by the C-28 methyl group on other side-chain carbons provide a basis for assigning the configuration at C-24. Thus C-26 has δ_C 17.6 in the 24*S* epimer **2***a* and C-27 has δ_C 18.3 in the 24*R* epimer **2***b*. C-26 and C-27 in the 24*S* diastereoisomer have a chemical shift difference of 2.8 ppm in contrast to a difference of only 1.8 ppm for the 24*R* epimer, although in both cases the average chemical shift of the two carbons is δ_C 19.2 $\pm$ 0.1 ppm. Also C-25 is 1 ppm more shielded in the 24*S* than the 24*R* diastereoisomer. Configurational effects on other side-chain carbons are less pronounced, with C-17 slightly more shielded and C-20, C-21, C-23, and C-24 more deshielded in the 24*S* isomer. This information allowed a 24-methyl cholesterol derivative of unknown configuration from *Tetraselmis suecica* to be identified as campesterol (**2***b*). Intensity measurements established that the soybean mixture contained 34% **2***a* and 66% **2***b*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(±5%) in contrast to the scallop sample which contained 52% **2***a* and 48% **2***b* (±6%).

*(24*R*)-24-Methyl-5α-cholestan-3β-ol (4*b*) and (24*S*)-24-Methyl-5α-cholestan-3β-ol (4*a*)*

This mixture of diastereoisomers was obtained by catalytic reduction of 24-methyl-22-dehydrocholesterol isolated from scallop. Reduction of the cholesterol nucleus has no effect on the side-chain resonances which display shifts almost identical with those for dihydrobrassicasterol (**2***a*) and campesterol (**2***b*) (Table 1). Analysis of the mixture showed 33% **4***a* and 67% **4***b* (±3%).

*(24*R*)-24-Ethylcholest-5-en-3β-ol (5*b*) and (24*S*)-24-Ethylcholest-5-en-3β-ol (5*a*)*

Three samples were examined: sitosterol (**5***b*) isolated and purified from soybean, clionasterol (**5***a*) obtained from *Nitella* as the acetate (31), and a mixture isolated from scallop.

As discussed in the ^{1}H nmr studies (28, 29), it becomes more difficult to differentiate the C-24 diastereoisomers of C_{29} sterols. With ^{13}C nmr they are more readily distinguishable although the differences are small and it is advisable to have spectra of both epimers for comparison.

For **5***a* and **5***b*, the most substantial chemical shift differences as a result of configuration changes at C-24 occur for C-26 (0.77 ppm more shielded in the *S* isomer), C-27 (0.55 ppm less shielded), C-23 (0.30 ppm less shielded), C-25 (0.20 ppm more shielded), C-24 (0.22 ppm less shielded), and C-20 (0.12 ppm less shielded).

Good quantitative analysis of a mixture is possible: the diastereomeric mixture from scallop shows 33% **5***a* and 67% **5***b* (±2%). Interestingly the sample of 24*S* isomer, clionasterol (**5***a*), isolated from *Nitella* (31) appears to contain a slight amount (~10–15%) of the diastereoisomer, perhaps reflecting a lack of stereochemical control during the biogenesis or epimerisation of a labile biogenetic intermediate.

*(22*E*,24*R*)-24-Methylcholesta-5,22-dien-3β-ol (10*b*) and (22*E*,24*S*)-24-Methylcholesta-5,22-dien-3β-ol (10*a*)*

Two samples were examined: a mixture of C-24 diastereoisomers from scallop and a sample from the diatom *Phaeodactylum tricornutum* reported to be the 24*S* isomer, 22-dehydrocampesterol (**10***a*). Since no authentic sample of the 24*R* isomer was available to us, ergosterol acetate (21) was used as a model compound for the chemical shifts of the side-chain carbons C-20 through C-28 (Table 1).

Differences between the ^{13}C nmr spectra of the epimers were apparent from a comparison of 22-dehydrocampesterol (**10***a*) and the scallop mixture, the most useful for analysis being the resonances of C-28 and C-16, respectively 0.4 and 0.28 ppm more shielded in the 24*R* isomer. Specifically, the resonance for the C-28 methyl carbon appears at a characteristic value of δ_C 17.6 ± 0.1 in the 24*R* epimer. The C-26 resonance in the 24*S* isomer overlaps with that for C-27 in the *R* isomer but δ_C for C-27 (*S*) and C-26 (*R*) differ by 0.17 ppm. Integration of resonances from the scallop mixture indicated that it contained 72% of **10***a* and 28% **10***b* (±2%).

The ^{13}C nmr spectrum of the sterol from *P. tricornutum* was in complete accord with the assignment of the 24*S* configuration by Rubinstein and Goad (27), based on ^{1}H nmr data.

*(22*E*,24*R*)-24-Ethylcholesta-5,22-dien-3β-ol (11*b*) and (22*E*,24*S*)-24-Ethylcholesta-5,22-dien-3β-ol (11*a*)*

Three samples were examined: the two pure diastereoisomers and a mixture from scallop that contained predominantly one epimer.

The ^{13}C chemical shift differences between these diastereoisomers are so small that it is preferable to have the other isomer, or a mixture, for comparison under identical conditions before the configuration of an unknown sterol of this type can be established. From our data (Table 1) the largest chemical shift difference between epimers is at the C-16 resonance (0.14 ppm) and the C-29 resonance (0.16 ppm). Quantitative analysis is still possible, and this mixture from scallop contains 33% **11***a* and 67% **11***b* (±8%).

To improve analysis by ^{1}H nmr Rubinstein *et al.* (28) suggested the unsaturated side chain should be reduced. Although this would assist in the ^{13}C nmr analysis it is not essential. Chiral solvents may help, but shift reagents are unlikely to be useful as they cause negligible shifts in the side-chain resonances (15, 33).

Using our data, it should be possible to identify the configuration of unknown sterols with a side chain common to any of the cases we have analysed in this study. The effect of changing the concentration of various steroid derivatives is small (16) and from the data available it appears that many structural changes in rings A, B, and C of the sterol also have little or no effect on the chemical shift of the side-chain resonances. For example, compare data for **2***a*,**2***b*; **4***a*,**4***b*; **10***a*,**10***b* (Table 1).

The C-28 methyl resonance at δ_C 17.6, characteristic of a 24*R* configuration in sterols possessing an unsaturated side chain, is also found in the cholestadienone derivative **14** (Table 1) and in a variety of ergosterol derivatives (34) despite structural modifications of ring C. Similarly we can assign an *S*

configuration at C-24 of cyclolaudanol (**15**) (35) in spite of the major structural differences between the cholesterol and cycloartenol skeletons. These examples illustrate the potential of this approach in characterising unknown sterols and their biological precursors.

The X-ray crystal structure of (±)-flavipucine

PETER S. WHITE, JOHN A. FINDLAY, AND WAH HUNG JOHN TAM
Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received February 6, 1978

PETER S. WHITE, JOHN A. FINDLAY, and WAH HUNG JOHN TAM. Can. J. Chem. **56**, 1904 (1978).

Synthetic (±)-flavipucine ($C_{12}H_{15}O_4N$) is monoclinic, space group $P2_1/c$, with $a = 11.506(5)$, $b = 8.765(5)$, $c = 11.981(7)$ Å, $\beta = 91.09(2)°$, $Z = 4$. X-ray analysis confirms its structure as **1**, 3′-isovaleryl-6-methyl pyridine-3-spiro-2′-oxiran-2(1*H*),4(3*H*)-dione and reveals the configuration of the oxirane to be *Z*.

PETER S. WHITE, JOHN A. FINDLAY et WAH HUNG JOHN TAM. Can. J. Chem. **56**, 1904 (1978).

La (±)-flavipucine ($C_{12}H_{15}O_4N$) obtenue par synthèse est monoclinique, groupe d'espace $P2_1/c$ avec $a = 11.506(5)$, $b = 8.765(5)$, $c = 11.981(7)$ Å, $\beta = 91.09(2)°$, $Z = 4$. L'analyse par rayons-X confirme que sa structure est celle de **1**, soit l'isovaléryl-3′ méthyl-6 pyridine spiro-3 oxiranne-2′ dione-2(1*H*), -4(3*H*) et révèle que la configuration de l'oxiranne est *Z*.

[Traduit par le journal]

Some time ago on the basis of chemical and spectroscopic data we proposed (1) structure **1**, 3′-isovaleryl-6-methyl pyridine-3-spiro-2′-oxiran-2(1*H*),-4(3*H*)-dione, for flavipucine an antibiotic factor isolated from a strain of *Aspergillus flavipes*. Recently, we developed an efficient two-step synthesis of racemic (±)-flavipucine starting with 4-hydroxy-6-methyl-2-pyridone and isobutyl glyoxal (2). Despite this latter development the relative configuration of the oxirane bridge remained unsolved. Furthermore, direct chemical or spectroscopic evidence for the existence of the epoxide feature was scant. Attempts to solve the structure of natural (−)-flavipucine by X-ray techniques by two different groups failed.[1] Noting that our synthetic racemic (±)-flavipucine had a different melting point (153–155°C) from natural (−)-flavipucine (130–131°C) we considered that its crystals might be more amenable to scrutiny by X-ray methods. Accordingly a sample of synthetic (±)-flavipucine recrystallized from benzene was studied with the following results.

Experimental

A preliminary photographic investigation indicated the space group to be $P2_1/c$. Unit cell dimensions were obtained by a least squares fit of 12 well-centered reflections on a Picker FACS-I diffractometer using graphite monochromated Mo K_α radiation. The relevant crystallographic data are:

$C_{12}H_{15}O_4N$ fw = 237.2
Monoclinic, $P2_1/c$, $a = 11.506(5)$, $b = 8.765(5)$, $c = 11.981(7)$ Å. $\beta = 91.09(2)°$, $V = 1208.0$ Å^3, $D_c = 1.30$, $Z = 4$ (20°C; Mo K_α, $\lambda = 0.71069$ Å), crystal size 0.60 × 0.35 × 0.45 mm.

Intensities were measured on the diffractometer using an $\omega - 2\theta$ scan at a rate of 1° 2θ min^{-1} over a range of 2° 2θ corrected for dispersion of the K_α doublet. A stationary background count of 10 s was made on both sides of each reflection. A standard reflection monitored every 20 reflections throughout data collection showed no systematic change in intensity. After correction for background, reflections with a net intensity of less than 20 counts were classified as unobserved. Data were collected to $2\theta = 50°$ which resulted in 2128 unique reflections of which 1160 were considered observed and used in the refinement of the structure.

Structure Determination and Refinement

The structure was solved by multiple solution direct methods using the computer program MULTAN (3). The set of phases with the highest 'combined figure of merit' was used to produce an *E*-map which was searched for peaks. The program FRAGMENT (4) was used to locate sets of connected peaks consistent with expected bond lengths and angles. The resulting fragment consisted of all the nonhydrogen atoms; the oxygen and nitrogen positions were assigned from a chemical knowledge of the structure (1).

Data reduction and refinement of the structure was performed using the XRAY-76 program package of Stewart (5). The structure was refined by least-squares methods, minimizing the quantity $\sum w(|F_o| - |F_c|)^2$. The weighting scheme was of the form $w = 1/\sigma^2(F)$, with σ estimated from the measured intensity (6). Initial refinement of the nonhydrogen atomic positions with isotropic thermal parameters resulted in an agreement index $R = 0.15$, at this point a difference synthesis was used to locate the hydrogen positions. Inclusion of hydrogens with isotropic thermal parameters and use of anisotropic thermal parameters for all other atoms yielded a final agreement index of $R = 0.062$. Table 1 contains the final atomic positional parameters.[2]

Discussion

The structure of the molecule and the numbering scheme are shown in Fig. 1, hydrogens being numbered after the atom to which they are bonded; bond distances and angles are given in Table 2. The six membered ring is essentially planar with an expected shortening of the bond lengths caused by partial

delocalization of the π bonds, C3 however, lies 0.23 Å out of the plane (Table 3) on the same side as C3′. The plane of the epoxide ring (C3, O1′, C3′) is inclined at 89.4° to that of the six-membered ring. There are no other unusual features observed in the bond lengths and angles, neither are there any short intramolecular contacts. The shortest intermolecular contact is N1—H1---O1′, N1---O1′ being 3.05 Å. The H1---O1′ distance of 2.10 Å is significantly shorter than the sum of van der Waals' radii of 2.4 Å (7) and may be the result of weak hydrogen bonding.

The clarification of the stereochemistry of flavipucine, showing the oxirane bridge to have a *Z* configuration, sheds light on the question of the mechanism of the flavipucine to (optically inactive) isoflavipucine (9) **4** transformation which we observed to take place when the crystalline material is heated to its melting point or alternatively when heated in non-

anhydrous xylene (139°C). Recently we have found that application of synthetic racemic flavipucine to alumina tlc plates and development with benzene – ethyl acetate (7:3) also effects a substantial (35%)

transformation to isoflavipucine **4**. Earlier we had outlined possible mechanisms for this novel reaction, one of which required an *E* configuration for the oxirane bridge. We have now found that synthetic racemic epiflavipucine **2** is transformed (on alumina) into isoflavipucine **4** with equal facility as is flavipucine **1** itself. To accommodate these findings we propose the mechanism portrayed in Scheme 1 in which either **1** or **2** is first transformed into the common achiral intermediate **3**.

A new route to 5-bromo-5′-bromomethylpyrromethenes[1]

AREND ROWOLD AND S. FERGUSON MACDONALD

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received February 16, 1978

AREND ROWOLD and S. FERGUSON MACDONALD. Can. J. Chem. **56**, 1907 (1978).

Esters of hitherto inaccessible 5-bromo-5′-bromomethylpyrromethenes, with alternating acetic acid (or methyl) and propionic acid groups in the β positions, are obtained by brominating the appropriate 5-acetoxymethylpyrrole-2-carboxylic acids in ethanol-free chloroform at ≤10°C. The bromomethylpyrromethenes give the corresponding methoxymethylpyrromethenes in methanol at room temperature.

AREND ROWOLD et S. FERGUSON MACDONALD. Can. J. Chem. **56**, 1907 (1978).

On a pu obtenir des esters des bromo-5 bromo-5′ méthylpyrrométhènes qui étaient jusqu'à présent inacessible et qui possèdent en alternance en position β, des groupes acide acétique (ou méthyle) et des groupes d'acide propionique; on a réalisé cette préparation en faisant la bromuration des acides acétoxyméthyl-5 pyrrolecarboxyliques-2 appropriés dans du chloroforme sans éthanol à une température ≤10°C. Les bromométhylpyrrométhènes conduisent au méthoxyméthylpyrrométhènes correspondants par réaction avec le méthanol à la température ambiante.

[Traduit par le journal]

The unavailability of some 5-bromo-5′-bromomethylpyrromethenes has limited the generality of Johnson and co-workers (1) synthesis of porphyrins from 1′-bromo-8′-methylbiladienes-a,c (cf. refs. 2 and 3). We were particularly interested in esters of **4***a* and its isomers, which were also promising intermediates for the synthesis of polypyrranes related to the uroporphinogens (4, 5). A preliminary communication (5) covers the work described below.

2-Methylpyrroles, and their 5-carboxy- (ref. 6*a*) or 5-*tert*-butoxycarbonyl derivatives (7), are brominated to 5-bromo-5′-methylpyrromethenes with alternating β substituents, e.g. **3***a*. 5-Bromo-5′-bromomethylpyrromethenes are obtained in the same way or, with greater formal generality, by brominating 5-bromo-5′-methylpyrromethenes. However, both of these are uncertain routes to the bromomethylpyrromethenes when there are propionic acid groups in the β positions. In particular, the brominations of **3***d*, **3***e* (4), and of **3***j* (8) had failed, although unstable preparations of 5-bromo-5′-bromomethylpyrromethenes had been obtained by brominating the 5′-methylpyrromethenes **7** (9) and **8** (2), and the *tert*-butyl ester **1***l* (10) (see below). In the brominations of **7** and **8**, the 5-bromo-5′-methylpyrromethenes were identified intermediates.

To study the formally more general of the two methods, the bromination of four 5-bromo-5′-methylpyrromethenes under various conditions was followed by the ^{1}Hmr signals of the CH_2Br (or CH_2OMe) and bridge CH groups. The best results were obtained in acetic acid after 45 min on the steam bath, using 2 mol of bromine with **3***h* and **3***k*, and 4 mol with **3***b* and **3***e*. Complete bromination could not be forced because of the instability of the bromomethyl derivatives. The crude products, containing 5′-methyl- and 5′-bromomethylpyrromethenes, were treated with methanol to convert the latter into more stable 5′-methoxymethylpyrromethenes, and those from **3***b* and **3***e* were then dissolved in chloroform–methanol (9:1) and filtered through alumina to remove by-products. The ^{1}Hmr spectra of the products from **3***b*, **3***e*, **3***h*, and **3***k* then indicated conversions of <30, <30, 65, and 85%, respectively. Only the methoxymethylpyrromethene **5***k* (<60%) was obtained crystalline, and this is much more readily obtained otherwise (see below). Other routes to **4***a* and **4***d* or their esters were obviously required, but the ester **3***k* was evidently more readily brominated than the above mentioned free acid **3***j*.

Routes to **4***a* and **4***d* or their esters based on the bromination of 2-methylpyrroles were then considered, although these would be inapplicable to isomers. The familiar mechanism for such halogenations (11) appeared to be an uncertain guide here. Its failure to explain the chlorination of a 2-methylpyrrole to a 5-free-5′-methylpyrromethene (4) is a fundamental defect, and it is not relevant to the threat of more complex reactions (11). However, it had suggested that 5′-bromomethylpyrromethenes would be favoured if 2-methylpyrroles were more completely converted to 2-bromomethylpyrroles before condensing to pyrromethenes; thus 2-methyl-5-*tert*-butoxycarbonylpyrroles were brominated to 5-bromo-5′-bromomethylpyrromethenes (12). With this in mind, we brominated 5-acetoxymethylpyrrole-

1 **2** **3** X = Me; **4** X = CH_2Br; **5** X = CH_2OMe **6**

R^1,R^2 = (*a*) P,A; (*b*) P^{Me},A^{Me}; (*c*) P^{Et},A^{Et}; (*d*) A,P; (*e*) A^{Me},P^{Me}; (*f*) A^{Et},P^{Et}; (*g*) P,Me; (*h*) P^{Me},Me; (*i*) P^{Et},Me; (*j*) Me,P; (*k*) Me,P^{Me}; (*l*) Me,P^{Et}

7 **8** X = H; **9** X = COO*t*Bu

A = CH_2COOH, A^{Me} = CH_2COOMe, A^{Et} = CH_2COOEt,
P = CH_2CH_2COOH, P^{Me} = CH_2CH_2COOMe, P^{Et} = CH_2CH_2COOEt

2-carboxylic acids **2**, for both a hydroxymethylpyrrole (13) and an ethoxymethylpyrromethene (6*b*) had been converted into their bromomethyl derivatives by hydrogen bromide in acetic acid. This was not considered too promising because the acetoxymethyl groups might well be displaced by bromine before they were locked on as bromomethyl, a process requiring hydrogen bromide formed by the brominative displacement of the carboxyl group.

However, bromine in ethanol-free chloroform at $\leq 10°C$ converted the 2-acetoxymethylpyrrole-5-carboxylic acids **2***c*, **2***f*, **2***i*, and **2***l* into the pure crystalline 5-bromo-5′-bromomethylpyrromethene hydrobromides **4***c*, **4***f*, **4***i*, and **4***l* (55–70%). At room temperature, although this was not at first realized, methanol converted these into the 5-bromo-5′-methoxymethylpyrromethene hydrobromides **5***c*, **5***f*, **5***i*, and **5***l* (80–90%). The methyl ester **4***b* corresponding to the ethyl ester **4***c* was obtained analogously from **2***b*. Some of these bromomethylpyrromethenes do not keep well unless thoroughly purified. Particularly in the case of **4***c*, they are better stored as their methoxymethyl derivatives which appear to be equivalent synthetically. Analyses of 5-methoxymethylpyrromethenes were regarded as more significant than those of 5-bromomethylpyrromethenes, which might not be distinguished by analysis from mixtures of 5-methylpyrromethenes with their perbromides.

The 5-bromomethylpyrromethenes **4***k* and **4***l* are exceptional among those discussed here because they are available, and more easily so, by an earlier method. This is because the *tert*-butyl esters **1***k* and **1***l* not only are obtained directly by ring synthesis, but also give **4***k* and **4***l* on bromination. The two-stage bromination which had converted **1***l* to **4***l* (10) failed with **1***k*, and its bromination in chloroform gave only **3***k*. However, bromine in hot acetic acid converted **1***k* to **4***k* which was isolated as the methoxy methyl derivative **5***k*. In other but related situations *tert*-butyl esters appeared less useful than carboxylic acids or carboxyl-free derivatives. Thus, although 5-bromomethylpyrromethenes were obtained by brominating **8** and **2***l* (see above), we failed to obtain such by brominating the related *tert*-butyl esters **9** and the known **6***k* (14).

It may be noted that all the 5-bromo-5′-methylpyrromethene hydrobromides **3***a*–**3***l* are now known, except **3***f* and **3***l*: **3***a* (4), **3***d* (15), **3***e* (4), **3***g* (6*c*), **3***j* (6*d*), **3***k* (free base (6*d*)); see Experimental for **3***b*, **3***c*, **3***g* (a better preparation), **3***h*, **3***i*, **3***k* (hydrobromide).

Experimental

Preparations are ordered according to the parent pyrrole: **2***b*, **3***b*, **4***b* then **2***c*, **3***c*, **4***c*, **5***c*, etc. Ethanol-free chloroform was used in preparing 5′-bromomethylpyrromethenes: chloroform was washed three times with concentrated H_2SO_4, filtered, stirred with NaOH pellets, filtered, stabilized by adding 5% (v/v) of dry ether, and stored indefinitely in brown bottles. The ^{1}Hmr spectra (in $CDCl_3$, tetramethylsilane as internal standard) were determined on a Varian EM360 (60 MHz) spectrometer; chemical shifts are expressed as ppm (δ).

*5-Acetoxymethyl-3-(2-methoxycarbonylethyl)-4-methoxycarbonylmethylpyrrole-2-carboxylic Acid (***2***b)*

Benzyl 5-acetoxymethyl-3-(2-methoxycarbonylethyl)-4-methoxycarbonylmethylpyrrole-2-carboxylate (16) (6.5 g) was hydrogenated in 250 ml of methanol over 400 mg of 5% Pd–C. The filtrate and washings (hot chloroform) were evaporated and the residue was twice recystallized from chloroform–hexane to give a colourless product (56%), mp 153–157°C. *Anal.* calcd. for $C_{15}H_{19}O_8N$: C 52.78, H 5.61, N 4.10; found: C 53.02, H 5.56, N 3.97.

*5-Bromo-4,3′-bis(2-methoxycarbonylethyl)-3,4′-bismethoxycarbonylmethyl-5′-methylpyrromethene Hydrobromide (***3***b)*

The corresponding tetracarboxylic acid **3***a* (4) (4.69 g) was warmed to solution in 50 ml of methanol containing 2.5 ml of acetyl bromide. After 24 h at 20°C the solution was seeded, left 2 h at 0°C, and the product was separated. After washing with cold methanol it formed brown rods (82%), mp 149–

152°C. *Anal.* calcd. for $C_{24}H_{30}O_8N_2Br_2$: C 45.44, H 4.77, N 4.42, Br 25.20; found: C 45.61, H 4.90, N 4.41, Br 25.03.

*5-Bromo-5′-bromomethyl-4,3′-bis(2-methoxycarbonylethyl)-3,4′-bismethoxycarbonylmethylpyrromethene Hydrobromide (**4**b)*

Powdered 5-acetoxymethyl-3-(2-methoxycarbonylethyl)-4-methoxycarbonylmethylpyrrole-2-carboxylic acid (**2***b*, 2.23 g) slurred in 60 ml of ethanol-free chloroform was stirred for 20 min at 10°C after 0.52 ml of bromine had been added at that temperature. The solvent was removed (rotary, then at 0.1 Torr for ½ h), and the residue was stirred with dry ether to give the product (67%) as red needles, mp 124–126°C (dec.); ^{1}Hmr: 2.4–3.3 (8H, m, 2 CH_2CH_2CO), 3.45, 4.00 (4H, 2s, $2CH_2CO$), 3.68, 3.70, 3.77 (12H, 3s, $4CH_3O$), 5.00 (2H, s, CH_2Br), 7.74 (1H, s, bridge CH). *Anal.* calcd. for $C_{24}H_{29}N_2O_8Br_3$: C 40.41, H 4.10, N 3.93, Br 33.61; found: C 40.69, H 4.17, N 3.95, Br 33.12.

In later runs this (unlike the corresponding ethyl ester) did not crystallise readily unless the crude product was swirled mechanically with ether and glass beads.

Benzyl 5-Acetoxymethyl-3-(2-ethoxycarbonylethyl)-4-ethoxycarbonylmethylpyrrole-2-carboxylate

Benzyl 5-methyl-3-(2-ethoxycarbonylethyl)-4-ethoxycarbonylmethylpyrrole-2-carboxylate (17) (12 g) and 15.4 g of lead tetraacetate in 360 ml of acetic acid were stirred at 38°C for 16 h, then for 3 h more after adding 2 g of lead tetraacetate. The solvent was removed below 50°C and 200 ml of water were added to the residue. The mixture was neutralized with sodium bicarbonate, then extracted several times with chloroform. The chloroform (800 ml) was washed with water until the latter was clear and colourless. Evaporating the chloroform left the product which was crystallized from benzene–*n*-hexane as tiny colourless needles (76%), mp 108–110°C (lit. (18) mp 105–106°C). *Anal.* calcd. for $C_{24}H_{29}O_8N$: C 62.73, H 6.36, N 3.05; found: C 63.04, H 6.40, N 2.93.

*5-Acetoxymethyl-3-(2-ethoxycarbonylethyl)-4-ethoxycarbonylmethylpyrrole-2-carboxylic Acid (**2**c)*

The preparation of this from the above 2-benzyl ester followed that of its isomer **2***f* (below) exactly, except that it could be done on a larger (5 g) scale because it was more stable. The recrystallized product (95%) formed colourless needles, mp 148–152°C (dec.). *Anal.* calcd. for $C_{17}H_{23}O_8N$: C 55.28, H 6.28, N 3.79; found: C 55.52, H 6.35, N 3.76.

*5-Bromo-4,3′-bis(2-ethoxycarbonylethyl)-3,4′-bisethoxycarbonylmethyl-5-methylpyrromethene Hydrobromide (**3**c)*

The corresponding tetracarboxylic acid **3***a* (recrystallized (4), 400 mg) was heated to solution in 5 ml of 10% ethanolic HBr (prepared using HBr gas). The solution was kept at 50°C for 5 h, seeded, then 18 h at 20°C, then 2 h at 0°C. After washing with ether the product formed red-brown plates (63%), mp ca. 105°C, changing to needles, mp ca. 113°C. *Anal.* calcd. for $C_{28}H_{38}O_8N_2Br_2$: C 48.71, H 5.55, N 4.06, Br 23.15; found: C 48.74, H 5.57, N 4.01, Br 23.03.

*5-Bromo-5′-bromomethyl-4,3′-bis(2-ethoxycarbonylethyl)-3,4′-bisethoxycarbonylmethylpyrromethene Hydrobromide (**4**c)*

The pyrrole **2***c* (1.4 g) was heated to solution in 35 ml of ethanol-free chloroform. Bromine (0.44 cm^3 in four portions) was added to the stirred solution at 10°C. The solvent was removed (rotary, then 1 h at 0.1 Torr) after 10 min, and the residue was stirred 1 h with 30 ml dry ether. The crystalline product was separated, washed with dry ether, and recrystallized from ethanol-free chloroform–*n*-pentane as red needles (69%), mp 114–115°C (capillary); ^{1}Hmr: 1.10–1.40 (12H, m, 4 CH_2CH_3), 2.5–3.3 (8H, m, 2 CH_2CH_2CO), 3.68 and 4.00 (each 2H, s, CH_2CO at 4′ and 3 respectively), 4.00–4.45 (8H, m, 4 CH_2CH_3), 5.05 (2H, s, CH_2Br), 7.83 (1H, s, bridge CH). *Anal.* calcd. for $C_{28}H_{37}O_8N_2Br_3$: C 43.71, H 4.85, N 3.64, Br 31.16; found: C 43.80, H 4.92, N 3.59, Br 31.02. Store at 0°C as the more stable methoxymethyl derivative.

*5-Bromo-5′-methoxymethyl-4,3′-bis(2-ethoxycarbonylethyl)-3,4′-bisethoxycarbonylmethylpyrromethene Hydrobromide (**5**c)*

The above bromomethyl derivative **4***c* was dissolved in methanol which was then evaporated, all at room temperature. The residue crystallized when ether was added to it. It was recrystallized as orange needles (90%) from chloroform–*n*-pentane, mp 112–113°C (capillary); ^{1}Hmr: 1.08–1.39 (12H, m, 4 CH_2CH_3), 2.5–3.2 (8H, m, 2 CH_2CH_2CO), 3.46 (3H, s, OCH_3), 3.66 and 3.95 (each 2H, s, CH_2CO at 4′ and 3, respectively), 3.85–4.40 (8H, 4q, 4 CH_2CH_3), 5.03 (2H, s, CH_2OCH_3), 7.76 (1H, s, bridge CH). *Anal.* calcd. for $C_{29}H_{40}O_9N_2Br_2$: C 48.34, H 5.60, N 3.89, Br 22.18; found: C 48.18, H 5.59, N 4.12, Br 22.32.

Benzyl 5-Acetoxymethyl-4-(2-ethoxycarbonylethyl)-3-ethoxycarbonylmethylpyrrole-2-carboxylate

The preparation of this from benzyl 5-methyl-4-(2-ethoxycarbonylethyl)-3-ethoxycarbonylmethylpyrrole-2-carboxylate (17) (12 g) followed exactly that of its isomer (β substituents reversed) above. The recrystallized product (74%) formed fine colourless hairs, mp 128–130°C. *Anal.* calcd. for $C_{24}H_{29}O_8N$: C 62.73, H 6.36, N 3.05; found: C 62.94, H 6.47, N 2.95.

*5-Acetoxymethyl-4-(2-ethoxycarbonylethyl)-3-ethoxycarbonylmethylpyrrole-2-carboxylic Acid (**2**f)*

The above benzyl ester (1.58 g) was hydrogenated in 80 ml of ethanol with 120 mg of 5% Pd–C for ½ hr only (uptake 106% theory). The filtrate from the catalyst was evaporated (rotary) and the residue was crystallized three times from chloroform–*n*-hexane (finally at 0°C) to give the cream coloured dimorphic product (80%) as rods, mp ca. 85°C, fine needles, mp 114–117°C. Two further recrystallizations gave the colourless analytical specimen. *Anal.* calcd. for $C_{17}H_{23}NO_8$: C 55.28, H 6.28, N 3.79; found: C 55.09, H 6.35, N 3.69. Larger runs were less successful because the product is rather unstable.

*5-Bromo-5′-bromomethyl-3,4′-bis(2-ethoxycarbonylethyl)-4,3′-bisethoxycarbonylmethylpyrromethene Hydrobromide (**4**f)*

Bromine (0.2 ml) was added over 2 min to a stirred solution of 5-acetoxymethyl-4-(2-ethoxycarbonylethyl)-3-ethoxycarbonylmethylpyrrole-2-carboxylic acid (**2***f*, 700 mg) in 15 ml of ethanol-free chloroform cooled in ice. After 10 min the solvent was removed at 20°C (rotary, then 0.1 Torr for 1 h). The residue was stirred with 15 ml of dry ether and the product filtered off and washed with 5 ml of dry ether. It formed tiny orange-red needles, (62%) as recrystallized from ethanol-free chloroform–*n*-pentane, mp 133–134°C (capillary); ^{1}Hmr: 1.27 (12H, t partly overlapped, 4 CH_2CH_3), 2.67–3.13 or broader (8H, m, 2 CH_2CH_2CO), 3.57 and 3.85 (each 2H, s, CH_2CO at 3′ and 4), 3.94–4.38 (8H, 4q, 4 CH_2CH_3), 5.02 (2H, s, CH_2Br), 7.78 (1H, s, bridge CH). *Anal.* calcd. for $C_{28}H_{37}O_8N_2Br_3$: C 43.71, H 4.85, N 3.64, Br 31.16; found: C 43.81, H 4.98, N 3.67, Br 31.28.

*5-Bromo-5′-methoxymethyl-3,4′-bis(2-ethoxycarbonylethyl)-4,3′-bisethoxycarbonylmethylpyrromethene Hydrobromide (**5**f)*

The preparation of this from **4***f* followed that of its isomer **5***c* above exactly. The recrystallized product (87%) formed orange-brown needles, mp 126–127°C (capillary); ^{1}Hmr: 1.1–1.4 (12H, 4t overlapping, 4 CH_2CH_3), 2.4–3.2 (8H, m, 2

For personal use only.

CH_2CH_2CO), 3.50 (3H, s, OCH_3), 3.56 and 3.87 (each 2H, s, CH_2CO at 3′ and 4, respectively), 4–4.4 (8H, 4q overlapping, 4 CH_2CH_3), 4.98 (2H, s, CH_2OCH_3) 7.72 (1H, s, bridge CH). *Anal.* calcd. for $C_{29}H_{40}O_9N_2Br_2$: C 48.34, H 5.60, N 3.89, Br 22.18; found: C 48.48, H 5.59, N 3.91, Br 21.90.

Ethyl 3-(2-Ethoxycarbonylethyl)-4,5-dimethylpyrrole-2-carboxylate

A solution of ethyl 3-(2-ethoxycarbonylethyl)-5-methylpyrrole-2-carboxylate (20) (40 g) in 200 ml of 67% hydriodic acid, 200 ml of acetic anhydride and 60 ml of 50% hypophosphorous acid was stirred at 25°C while 9 g paraformaldehyde were added in portions. After ¼ h additional stirring at 45°C, 10 ml of hypophosphorous acid were added then, after 1 h, 400 ml of ice water. The precipitate was separated after standing at 0°C and washed with water. More was obtained by concentrating the filtrate to 250 ml (rotary, 30°C) then diluting with 250 ml of water. The dried precipitate was heated to boiling in 100 ml of 10% ethanolic HCl. After 4 h at 20°C and 2 days at 0°C, the product was separated and washed with water; more was obtained by concentrating the ethanolic filtrate. Recrystallization from 400 ml *n*-pentane (thimble) gave colourless prisms (85%), mp 91–91.5° (lit. (19) mp 90.5–91.5°C).

3-(2-Carboxyethyl)-4,5-dimethylpyrrole-2-carboxylic Acid

Ethyl 3-(2-ethoxycarbonylethyl)-4,5-dimethylpyrrole-2-carboxylate (12.5 g) in 40 ml of ethanol was boiled on the steam bath while aqueous NaOH (60 ml of 10% w/v) was added in portions. Boiling was continued ½ h then the ethanol was removed (rotary, 30°C). The residue was made up to 75 ml with water then heated 1 h *in* the steam bath under reflux. The product was precipitated at 0°C by SO_2 (congo red), scratching to ensure a filterable product. It was separated and washed by stirring in 50 ml of ice water, mp 128–131°C (80%). *Anal.* calcd. for $C_{10}H_{13}O_4N$: C 56.86, H 6.20, N 6.63; found: C 56.98, H 6.20, N 6.65.

5-Bromo-4,3′-bis(2-carboxyethyl)-3,4′,5′-trimethylpyrromethene Hydrobromide (3g) (6c)

Powdered 3-(2-carboxyethyl)-4,5-dimethylpyrrole-2-carboxylic acid (1 g) suspended in 3 ml of acetic acid was stirred while 2.5 ml of bromine in acetic acid (15 g of bromine made up to 25 ml) was added in three portions. The solution was seeded then allowed to stand 2 h while protected from moisture before the product was filtered off. After washing with acetic acid then acetic acid – ether it formed red-brown prisms (51%), mp ca. 200°C (dec.). It analysed badly: *Anal.* calcd. for $C_{18}H_{22}O_4N_2Br_2$: C 44.10, H 4.52, N 5.72; found: C 41.03, H 4.59, N 5.46.

5-Bromo-4,3′-bis(2-methoxycarbonylethyl)-3,4′,5′-trimethylpyrromethene Hydrobromide (3h)

This was prepared, like the corresponding ethyl ester **3*i*** below, from **3*g*** and MeOH–AcBr. It formed orange rods (78%), mp ca. 185°C when rapidly heated. *Anal.* calcd. for $C_{20}H_{26}O_4N_2Br_2$: C 46.35, H 5.06, N 5.41, Br 30.84; found: C 46.16, H 5.12, N 5.29, Br 30.66.

Benzyl 3-(2-Ethoxycarbonylethyl)-4,5-dimethylpyrrole-2-carboxylate

Ethyl 3-(2-ethoxycarbonylethyl)-4,5-dimethylpyrrole-2-carboxylate (above, 16 g) was heated 3 h on the steam-bath under a water-pump vacuum with a solution of 2.91 g of sodium in 450 ml of reagent grade benzyl alcohol. The benzyl alcohol was then evaporated (rotary) and the residue was dissolved in 400 ml of water. After the solution was twice washed with ether, it was acidified to congo red at 15°C. The precipitate was recrystallized from aqueous dioxan as fine needles of the monobenzyl ester (free propionic acid), mp 170–173°C. This was esterified in 450 ml of 5% HCl in ethanol to give the product (15.2 g, 77%) as colourless needles, mp 84–85.5°C after recrystallization from hexane (thimble).

Benzyl 5-Acetoxymethyl-3-(2-ethoxycarbonylethyl)-4-methylpyrrole-2-carboxylate

A solution of 5 g of benzyl 3-(2-ethoxycarbonylethyl)-4,5-dimethylpyrrole-2-carboxylate and 7.25 g of lead tetraacetate in 125 ml of acetic acid was stirred 18 h at 41°C while protected from moisture; 1 g more lead tetraacetate was then added and stirring continued for 4 h. Water (250 ml) was added and the mixture was left 2½ h in ice. The precipitate was separated and dissolved in chloroform. The chloroform solution was washed with water, concentrated to 20 ml, diluted with 400 ml of warm *n*-hexane, then left at 0°C. The crystals which separated were recrystallized from benzene–*n*-hexane then from hexane giving colourless needles (75%), mp 94–96°C. For analysis, it was recrystallized from benzene–*n*-hexane, mp 95–96°C. *Anal.* calcd. for $C_{21}H_{25}O_6N$: C 65.10, H 6.50, N 3.62; found: C 65.28, H 6.51, N 3.58. Under other conditions the product obtained was contaminated with the starting material or the aldehyde (^{1}Hmr).

5-Acetoxymethyl-3-(2-ethoxycarbonylethyl)-4-methylpyrrole-2-carboxylic Acid (2i)

The above benzyl ester (1.935 g) was hydrogenated for 3 h in 50 ml of dioxan with 200 mg 5% Pd–C. The filtered solution was concentrated to 10 ml, 10 ml of ether were added, and the solution was left at 0°C overnight. The product separated as colourless prisms (40%), mp 124–130°C. *Anal.* calcd. for $C_{14}H_{19}O_6N$: C 56.56, H 6.44, N 4.71; found: C 56.80, H 6.39, N 4.79. Much more of the product was recovered from the mother liquor.

5-Bromo-4,3′-bis(2-ethoxycarbonylethyl)-3,4′,5′-trimethylpyrromethene Hydrobromide (3i)

The dicarboxylic acid **3*g*** (above) was heated to boiling in 20 ml of ethanolic HBr (prepared from 25 ml ethanol and 1.25 ml of acetyl bromide) then left overnight at 20°C. The mixture was then cooled to 0°C and the product (77%) was separated and washed with cold ethanol, mp 161–162°C. *Anal.* calcd. for $C_{22}H_{30}N_2O_4Br_2$: C 48.36, H 5.54, N 5.13, Br 29.26; found: C 48.50, H 5.57, N 4.98, Br 29.12.

5-Bromo-5′-bromomethyl-4,3′-bis(2-ethoxycarbonylethyl)-3,4′-dimethylpyrromethene Hydrobromide (4i)

This was prepared like **4*f*** using 564 mg of **2*i***, 15 ml of ethanol-free chloroform and 0.2 ml of bromine. After recrystallizing from chloroform–*n*-hexane it formed tiny red needles (70%), dec. >160°C; ^{1}Hmr: 1.23, 1.28 (6H, 2t, 2 $COOCH_2CH_3$), 2.17, 2.50 (6H, 2s, CH_3's at 3 and 4′), 2.5–3.1 (8H, m, 2 CH_2CH_2CO), 4.12, 4.18 (4H, 2q, 2 $COOCH_2CH_3$), 4.94 (2H, s, CH_2Br), 7.56 (1H, s, bridge CH). *Anal.* calcd. for $C_{22}H_{29}O_4N_2Br_3$: C 42.26, H 4.68, N 4.48, Br 38.35; found: C 42.28, H 4.74, N 4.49, Br 38.33.

5-Bromo-5′-methoxymethyl-4,3′-bis(2-ethoxycarbonylethyl)-3,4′-dimethylpyrromethene Hydrobromide (5i)

The preparation of this from **4*i*** was analogous to that of **5*c*** but it was recrystallized from chloroform–*n*-hexane, finally at 0°C. It formed purple needles (82%), mp 125–126°C (capillary); ^{1}Hmr: 1.20, 1.26 (6H, 2t, 2 $COOCH_2CH_3$), 2.16, 2.50 (6H, 2s, CH_3's at 3 and 4′), 2.5–2.9 (8H, m, 2 CH_2CH_2CO), 3.51 (3H, s, CH_2OCH_3), 4.15, 4.20 (4H, 2q, 2 $COOCH_2CH_3$), 4.97 (2H, s, CH_2OCH_3), 7.55 (1H, s, bridge CH). *Anal.* calcd. for $C_{23}H_{32}O_5N_2Br_2$: C 47.93, H 5.60, N 4.86, Br 27.73; found: C 47.60, H 5.69, N 4.94, Br 27.89.

5-Bromo-3,4′-bis(2-methoxycarbonylethyl)-4,3′,5′-trimethylpyrromethene Hydrobromide (3k)

Bromine (4 ml) in 20 ml of chloroform was added over 10 min to *tert*-butyl 4-(methoxycarbonylethyl)-3,5-dimethylpyr-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

role-2-carboxylate **1***k* (7) (10.34 g) in 100 ml of chloroform while stirring at 20°C. Stirring was continued 1 h, the solvent was removed *in vacuo* and the residue was crystallized as red plates (64%) from chloroform–ether, mp >160°C (dec.); ^{1}Hmr: 2.05, 2.43, 2.73 (each 3H, s, CH_3's at 4, 3′ and 5′, respectively), 2.5–3.3 (8H, m, 2 CH_2CH_2CO), 3.62, 3.68 (each 3H, 2s, $2OCH_3$), 7.41 (1H, s, bridge CH). *Anal.* calcd. for $C_{20}H_{26}O_4N_2Br_2$: C 46.35, H 5.06, N 5.41, Br 30.84; found: C 46.47, H 5.16, N 5.40, Br 30.79. The free base has been described (6*d*).

Ni Complex of the Free Base

Red-brown prisms, mp 152–153°C from methanol. *Anal.* calcd. for $C_{40}H_{48}O_8N_4Br_2Ni$: C 51.58, H 5.19, N 6.02, Br 17.16; found: C 51.82, H 5.23, N 6.15, Br 17.17.

*5-Bromo-5′-methoxymethyl-3,4′-bis(2-methoxycarbonylethyl)-4,3′-dimethylpyrromethene Hydrobromide (***5***k)*

A solution of 2.07 g of *tert*-butyl 4-(2-methoxycarbonylethyl)-3,5-dimethylpyrrole-2-carboxylate **1***k* (7) and 1.6 ml of bromine in 6 ml of acetic acid was heated ½ h on the steam bath. The solvent was evaporated and the residue was stirred for a few minutes with warm methanol. The residue left on removing the methanol *in vacuo* crystallized on stirring with 10 ml of ether. Recrystallization from chloroform–ether gave small orange needles (55%), decomposes above 150°C; ^{1}Hmr: 2.10 and 2.43 (each 3H, s, probably 4- and 3′- CH_3, respectively), 2.6–3.1 (8H, m, 2 CH_2CH_2CO), 3.52 (3H, s, CH_2OCH_3), 3.66 and 3.71 (each 3H, s, 2 $COOCH_3$), 4.97 (2H, s, CH_2OCH_3), 7.51 (1H, s, bridge CH). *Anal.* calcd. for $C_{21}H_{28}O_5N_2Br_2$: C 46.00, H 5.15, N 5.11, Br 29.15; found: C 45.94, H 5.21, N 5.09, Br 29.24.

Free Base of the Above

A chloroform solution of the hydrobromide **5***k* was shaken with 5% aqueous NaOH. The chloroform was evaporated and the residue was crystallized from methanol as red-brown plates (75%), mp 90–93°C; ^{1}Hmr: 2.00 and 2.21 (each 3H, s, probably 4- and 3′- CH_3, respectively), 2.3–3.1 (8H, m, 2 CH_2CH_2CO), 3.43 (3H, s, CH_2OCH_3), 3.69 (6H, s, 2 $COOCH_3$), 4.51 (2H, s, CH_2OCH_3), 6.84 (1H, s, bridge CH). *Anal.* calcd. for $C_{21}H_{27}O_5N_2Br$: C 53.97, H 5.82, N 5.99, Br 17.10; found: C 54.02, H 5.77, N 5.93, Br 17.28.

*5-Acetoxymethyl-4-(2-ethoxycarbonylethyl)-3-methylpyrrole-2-carboxylic Acid (***2***l)*

Benzyl 5-acetoxymethyl-4-(2-ethoxycarbonylethyl)-3-methylpyrrole-2-carboxylate (21) (3.87 g) was hydrogenated in 120 ml of dioxan over 500 mg of 5% Pd–C for 1.5 h. The filtrate was concentrated (rotary, 20°C) to 20 ml and 20 ml of ether was added. The colourless needles (71%), mp 117–125°, could not be recrystallized without decomposition and analysed badly. *Anal.* calcd. for $C_{14}H_{19}O_6N$: C 56.56, H 6.44, N 4.71; found: C 58.45, H 6.54, N 4.37.

*5-Bromo-5′-bromomethyl-3,4′-bis(2-ethoxycarbonylethyl)-4,3′-dimethylpyrromethene Hydrobromide (***4***l)*

This was prepared like **4***f* using 564 mg of 5-acetoxymethyl-4-(2-ethoxycarbonylethyl)-3-methylpyrrole-2-carboxylic acid **2***l*, 15 ml of ethanol-free chloroform, and 0.2 ml of bromine. After recrystallization from ethanol-free chloroform–*n*-pentane, it formed small red needles (56%), mp 180–181°C (capillary, dec.) (lit. (10) mp 155°C). *Anal.* calcd. for $C_{22}H_{29}O_4N_2Br_3$: C 42.26, H 4.68, N 4.48, Br 38.35; found: C 42.28, H 4.88, N 4.44, Br 38.51.

*5-Bromo-5′-methoxymethyl-3,4′-bis(2-ethoxycarbonylethyl)-4,3′-dimethylpyrromethene Hydrobromide (***5***l)*

The preparation of this from **4***l* was analogous to that of **5***c* but it was recrystallized from chloroform–ether as orange needles (81%), mp 129–130°C (capillary); ^{1}Hmr: 1.23, 1.28 (6H, 2t, 2 $COOCH_2CH_3$), 2.13, 2.47 (6H, 2s, CH_3's at 4 and 3′), 2.61–3.14 (8H, m, 2 CH_2CH_2CO), 3.54 (3H, s, CH_2OCH_3), 4.16, 4.20 (4H, 2q, 2 $COOCH_2CH_3$), 5.02 (2H, s, CH_2OCH_3), 7.55 (1H, s, bridge CH). *Anal.* calcd. for $C_{23}H_{32}O_5N_2Br_2$: C 47.93, H 5.60, N 4.86, Br 27.73; found: C 47.85, H 5.80, N 4.73, Br 27.93.

tert-*Butyl 5-Formyl-4-methoxycarbonylethyl-3-methylpyrrole-2-carboxylate*

The corresponding 5-methylpyrrole **1***k* (7) (2.81 g) and 4.43 g of lead tetraacetate in 70 ml of acetic acid was stirred vigorously for 1 h at 20–25°C. More lead tetraacetate (4.43 g) was then added and the mixture was heated 1 h on the steam-bath. The solvent was removed *in vacuo* and the residue was extracted several times with chloroform. The extract was well washed with water, dried, and evaporated. When the residue was dissolved in very little methanol, the product crystallized as colourless rods (75%), mp 89–93°C, raised to 94.5–95.5°C (lit. (2) mp 91–94°C) after two recrystallizations from chloroform–*n*-hexane. *Anal.* calcd. for $C_{15}H_{21}O_5N$: C 61.00, H 7.17, N 4.74; found: C 61.16, H 7.21, N 4.69.

tert-*Butyl 3,3′-bis(2-Methoxycarbonylethyl)-4′-methoxycarbonylmethyl-4,5′-dimethylpyrromethene-5-carboxylate Hydrobromide (***9***)*

tert-Butyl 5-formyl-4-(2-methoxycarbonylethyl)-4-methylpyrrole-2-carboxylate (295 mg) and the dimethyl ester of hemopyrroledicarboxylic acid (19), (239 mg) in 10 ml of methanol were treated with six drops of 47% hydrobromic acid. After 1 h the solvent was evaporated and the residue was rubbed with ether to give the product (420 mg). For analysis it was twice recrystallized from chloroform–*n*-hexane, mp 125–128°C; ^{1}Hmr: 1.74 (9H, s, CMe_3), 2.33 (3H, s, CH_3 at 4), 2.6–3.2 (8H, m, 2 CH_2CH_2CO), 2.86 (3H, s, CH_3 at 5′), 3.59 (2H, s, CH_2COOCH_3), 3.68–3.78 (9H, 3 partially overlapping s, 3 OCH_3), 7.00 (1H, s, bridge CH). *Anal.* calcd. for $C_{27}H_{37}O_8N_2Br$: C 54.27, H 6.24, N 4.69, Br 13.38; found: C 54.33, H 6.29, N 4.58, Br 13.21.

Received January 10, 1978

THEODORE A. ONDRUS, FRANK M. PASUTTO, EDWARD E. KNAUS, and C. S. GIAM. Can. J. Chem. **56**, 1913 (1978).

Reaction of the ambident 1-lithio-1,2-dihydropyridines (**1**) and related dienamines (**2**) with several electrophiles has been investigtaed. Reaction of **1** with aliphatic isocyanates occurs predominantly or exclusively at nitrogen, whereas similar reactions employing **2** do not proceed and a dimeric product **8** resulting from self condensation of **2** is obtained. In contrast, reaction of **2***a* with the more electrophilic phenyl isocyanate (**3***c*) gave both *N*-phenylaminocarbonyl-2-*n*-butyl-1,2-dihydropyridine (**4***d*) and 2-*n*-butyl-5-phenylaminocarbonylpyridine (**6***d*) whereas a similar reaction with **1***a* afforded **4***d*, **5***d*, and **6***d*, as well as the stable *N*-unsubstituted-1,2-dihydropyridine **7***d*. Novel 2-*n*-butyl-5-(2-,3-,4-pyridylcarbonyl)-1,2-dihydropyridines **13***a–c* are obtained from reaction of **1***a* with pyridyl esters **12***a–c*. Reaction of **1***a* with diethyl chlorophosphate and ethyl acetate occurs exclusively at nitrogen to afford high yields of **16***a* and **16***b*, respectively. The mechanism for the formation of the 1,5-disubstituted-1,2-dihydropyridines **5** is described.

THEODORE A. ONDRUS, FRANK M. PASUTTO, EDWARD E. KNAUS et C. S. GIAM. Can. J. Chem. **56**, 1913 (1978).

On a étudié la réaction entre divers électrophiles et des lithio-1 dihydro-1,2 pyridines (**1**) et des diénamines (**2**) qui leur sont reliées et qui possèdent deux sites réactifs. La réaction de **1** avec les isocyanates aliphatiques se produit principalement ou exclusivement au niveau de l'azote; des réactions semblables faisant appel à **2** ne se produisent pas et l'on obtient que le dimère **8** résultant de l'autocondensation de **2**. Par opposition, la réaction de **2***a* avec l'isocyanate de phényle qui est plus électrophile (**3***c*) conduit à la *N*-phénylaminocarbonyl *n*-butyl-2 dihydro-1,2 pyridine (**4***d*) ainsi qu'à de la *n*-butyl-2 phénylaminocarbonyl-5 pyridine (**6***d*); une réaction semblable avec la **1***a* fournit **4***d*, **5***d*, **6***d* ainsi que **7***d*, la dihydro-1,2 pyridine non-substituée sur l'azote qui est stable. On a obtenu les nouvelles *n*-butyl-2(pyridylcarbonyl-2 ou -3,-4)-5 dihydro-1,2 pyridines **13***a–c* par réaction de **1***a* avec les esters de pyridyl **12***a–c*. La réaction de **1***a* avec le chlorophosphate de diéthyle et l'acétate d'éthyle se produit exclusivement au niveau de l'azote pour conduire, avec de bons rendements, à **16***a* et **16***b* respectivement. On décrit le mécanisme conduisant à la formation des dihydro-1,2 pyridines disubstituées en 1,5 (**5**).

[Traduit par le journal]

The reaction of the ambident *N*-lithio-1,2-dihydropyridines (**1**), obtained from the reaction of organolithium reagents and pyridines (1), with suitable electrophiles is a versatile procedure for the synthesis of *N*-substituted 1,2-dihydropyridines and/or 3-substituted pyridines which are otherwise difficult to prepare (2). In this way direct methods for the preparation of *N*-acyl(aroyl)-1,2-dihydropyridines (3) and introduction of alkyl, aminoalkyl, arylalkyl, hydroxyalkyl, acyl, amino, halo, and 3-pyridyl substituents into the β position of pyridine were conveniently effected (2–4). The ratio of *N*/*C*-substitution dropped significantly in going from the less reactive to more reactive electrophiles (3). The mesomeric structures of the structurally related dienamines (**2**), obtained from reaction of **1** with 3 equiv. of water (5), strongly suggest that electrophilic attack may also occur either at carbon or nitrogen or both. We now wish to describe the reactions of **1** and **2** with isocyanates, pyridyl esters, and diethyl chlorophosphate.

Reaction of *N*-lithio-2-*n*-butyl-1,2-dihydropyridine

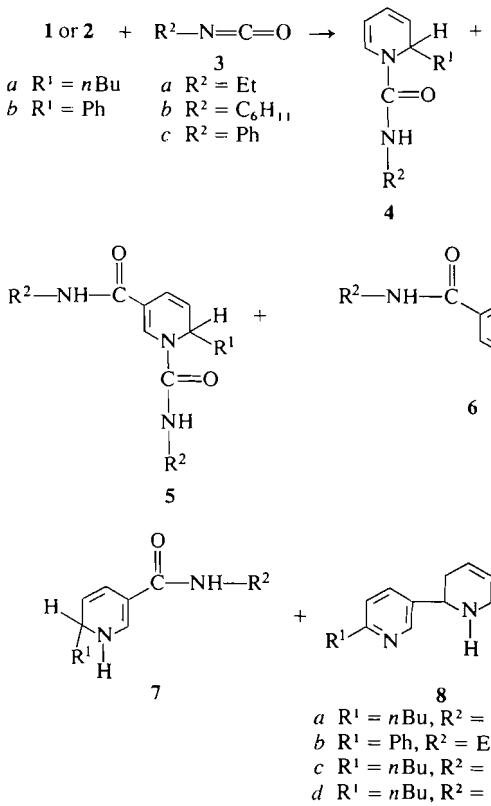
(**1***a*) with ethyl isocyanate (**3***a*) afforded 1-ethylaminocarbonyl-2-*n*-butyl-1,2-dihydropyridine (**4***a*, 51.6%), the 1,5-disubstituted-1,2-dihydropyridine **5***a* (11.8%), and the *C*-substitution product 2-*n*-butyl-5-ethylaminocarbonylpyridine (**6***a*, 14.6%). On the other hand, reaction of **1***b* with **3***a* resulted in exclusive *N*-substitution to yield **4***b* (61%) as the sole product. The reaction of **2***b*, in comparison to **1***b*, with **3***a* was

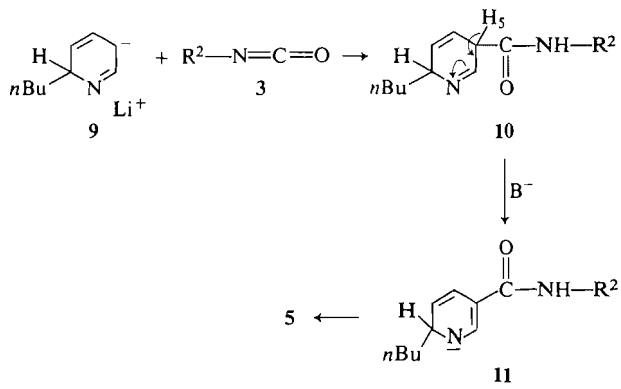


almost negligible since a near quantitative yield of 2-phenylpyridine was obtained together with a trace of **4***b*. Treatment of **2***a* (lithium hydroxide free) with **3***a* afforded **8** (R^1 = Bu, 35.4%) as the only isolable product. The dimeric product **8** (R^1 = Bu) most likely arises from self condensation of **2***a* since repetition of the reaction in the absence of **3***a* gave **8** (R^1 = Bu, 37.3%) and 2-butylpyridine (10.4%). In a related study it was found that 10% of the lithium hydroxide produced upon addition of 1 equiv. water to **1***a* remained in solution.[1] It is essential that solutions of **2** be free of lithium hydroxide which would also be expected to react with isocyanates **3** leading to urea derivatives (6). Lithium hydroxide free solutions of **2***a* are prepared by adding 3 equiv. of water to **1** and drying the ethereal solution with anhydrous sodium sulfate. Reaction of **1***a* with cyclohexyl isocyanate (**3***b*) afforded **4***c* (17%) and **6***c* (14%) whereas the reaction of **2***a* with **3***b* gave rise to **8** (R^1 = Bu, 27.2%) as the only isolable product.

The reaction of **2***a* with phenyl isocyanate (**3***c*) was investigated since an electron-attracting substituent is known to enhance the reactivity of the isocyanate group to a nucleophilic reagent (6). Thus, treatment of **2***a* with the more electrophilic **3***c* afforded the *N*-substituted product **4***d* (30.2%) and the *C*-substitution product **6***d* (15%). The 1,5-disubstituted product **5***d* was not detected. In a similar experiment (see Table 1) reaction of **1***a* with **3***c* gave rise to **4***d* (9.0%), **5***d* (14.8%), **6***d* (29.9%), and the stable *N*-unsubstituted 1,2-dihydropyridine **7***d* (42.8%). The structures assigned to **4**–**8** were assigned on the basis of their ir, ^{1}H nmr, and ms data which is consistent with the spectroscopic data previously reported for reaction of the ambident **1** with other electrophiles (1–3).

One possible pathway for the formation of the 1,5-disubstituted compounds **5***a* and **5***d* could involve reaction of the isocyanate **3** with **9** to give the dihydro intermediate **10**. Proton abstraction of the active C-5 proton by base such as 2-butylpyridine (some of which is always obtained) could give rise to **11** which on further reaction with **3** would afford **5**. It is unlikely that **5** arises from reaction of **4** with **3** since treatment of **4***a* with **3***a* and then 2-butylpyridine failed to yield any of the disubstituted product **5***a*, an observation which is consistent with a previous study (3).

The reaction of *N*-lithio-2-*n*-butyl-1,2-dihydropyridine (**1***a*) with pyridyl esters **12** was examined since it could be a useful procedure to prepare novel diheterocyclic ketones which would be useful medicinal intermediates. Treatment of **1***a* with ethyl



nicotinate (**12***a*) resulted in exclusive *C*-acylation to give **13***a* (39.6%), **14***a* (2.7%) along with some 2-butylpyridine (**15**, 8%). Similar reactions of **1***a* with **12***b* gave **13***b* (47.4%), **14***b* (8.6%), and **15** (4.8%) and with **12***c* afforded **13***c* (47.5%), **14***c* (4%), and **15**

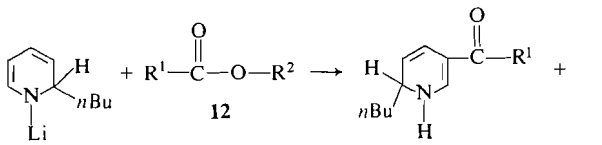
TABLE 1. Reactions of 1,2-dihydropyridines with isocyanates

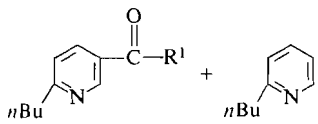
1,2-Dihydropyridine	Isocyanate 3 R^2	Yield (%) 4	5	6	7	8
1*a*	Et	51.6	11.8	14.6		
1*b*	Et	61.0				
2*a*	Et					35.4[a]
1*a*	C_6H_{11}	17.0		14.0		
2*a*	C_6H_{11}					27.2[a]
1*a*	Ph	9.0	14.8	29.9	42.8	
2*a*	Ph	30.2[a]		15.0[a]		

[a]The solution of the dienamine **2***a* is lithium hydroxide free.

(15.1%). It is expected that **14***a–c* arise from **13***a–c* during tlc purification since the presence of **14** was not evident in the reaction mixture before purification and solutions of **13** in deuteriochloroform



1*a* **12** **13**

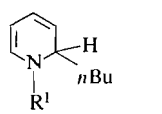


14 **15**

a R^1 = 3-pyridyl, R^2 = Et
b R^1 = 4-pyridyl, R^2 = Me
c R^1 = 2-pyridyl, R^2 = Et

undergo oxidation slowly at 25°C on exposure to air as indicated by ^{1}H nmr. The stability of the 1,2-dihydropyridines **13***a–c* is likely due to the stabilizing effect of the 5-(2-,3-,4-pyridylcarbonyl) substituents (7).

Treatment of **1***a* with diethyl chlorophosphate and ethyl acetate afforded **16***a* (68.3%) and **16***b* (99%), respectively. Further studies involving the chemistry of dienamines **1** and **2** are now in progress in these laboratories.



16

a $R^1 = (EtO)_2P(O)$—
b $R^1 = CH_3CO$—

Experimental

Melting points are determined with a Büchi capillary apparatus and are uncorrected. ^{1}H nmr spectra were determined for solutions in deuteriochloroform unless otherwise noted with TMS as internal standard with a Varian EM-360A or A-60 A spectrometer. Infrared spectra were recorded on a Perkin Elmer 267 spectrometer. Mass spectra were measured with an AEI-MS-9 or MS-50 mass spectrometer and these exact mass measurements are used in lieu of elemental analysis.

*1-Lithio-2-*n*-butyl-1,2-dihydropyridine (***1***a) and 2-*n*-Butyl-1,2-dihydropyridine (***2***a)*

General Procedure A

To an ice-cold solution of *n*-butyllithium (1.28 g, 0.02 mol) in 50 ml anhydrous ether, under a nitrogen atmosphere, pyridine (1.58 g, 0.02 mol) was added dropwise with stirring. The resulting dark brown solution containing **1***a* (0.02 mol) was allowed to stir for 35 min at 0°C before use in subsequent reactions.

To the solution of **1***a* (0.02 mol) in 50 ml anhydrous ether described above, under a nitrogen atmosphere, water (1.33 g, 0.074 mol) was added dropwise with stirring at 0°C. The reaction was allowed to proceed for 10 min, anhydrous sodium sulfate (16 g) was added, and the mixture stirred for an additional 15 min at 0°C. The solution was allowed to stand without agitation for 5 min after which an aliquot of the supernatant containing the required amount of **2***a* (lithium hydroxide free) was removed using a syringe under a nitrogen atmosphere.

*1-Lithio-2-phenyl-1,2-dihydropyridine (***1***b)*

General Procedure B

To an ice-cold solution of phenyllithium (1.68 g, 0.02 mol) in 100 ml anhydrous ether, under a nitrogen atmosphere, pyridine (1.58 g, 0.02 mol) was added dropwise with shaking. The resulting yellow precipitate was redissolved by repeated shaking. Upon cooling to 0°C the adduct **1***b* was obtained as a yellow crystalline solid which was washed with 30 ml dry ether and taken up in 100 ml dry tetrahydrofuran. A 2 ml aliquot of the above solution was hydrolyzed with 10 ml water and the concentration determined by titration with hydrochloric acid (8).

*N-Ethylaminocarbonyl-2-*n*-butyl-1,2-dihydropyridine (***4***a), 1,5-Di(ethylaminocarbonyl)-2-*n*-butyl-1,2-dihydropyridine (***5***a), and 2-*n*-Butyl-5-ethylaminocarbonylpyridine (***6***a)*

To a solution of **1***a* (1.53 g, 10.67 mmol) in 125 ml anhydrous ether, under a nitrogen atmosphere at −65°C, a solution of ethyl isocyanate (0.758 g, 10.67 mmol) in 2 ml anhydrous ether was added dropwise with stirring. The reaction was stirred at −65°C for 1.5 h and allowed to return to 25°C over a 0.5 h period after which 50 ml water was added. Extraction with chloroform (3 × 50 ml), drying (sodium sulfate) and removal of the solvent *in vacuo* gave a yellow oil. Preparative tlc was effected on eight 8 × 8 in. silica gel DF-5 plates, 0.75 mm in thicknesss, using benzene–ether (1:3 v/v) as development

solvent. Extraction of the band having R_f 0.86 with 100 ml warm methanol afforded **4***a* (1.145 g, 51.6%); ir (neat): 3360 (s, NH), 1642 (s, CO) cm^{-1}; ^1H nmr δ: 0.76–1.82 (m, 12H, $—CH_3$, C_4H_9) 3.33 (m, 2H, $—CH_2—$), 4.72 (m, 1H, H-2), 5.26 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,5}$ = 5 Hz of d, $J_{3,5}$ = 1.5 Hz, 1H, H-5), 5.41–5.82 (m, 2H, H-3, NH, exchanges with deuterium oxide), 5.91 (d, $J_{3,4}$ = 9.5 Hz of d, $J_{4,5}$ = 5 Hz, 1H, H-4), 6.66 (d, $J_{5,6}$ = 8 Hz, 1H, H-6). Exact mass calcd. for $C_{12}H_{20}N_2O$: 208.1571; found (high resolution ms): 208.1581. Similar extraction of the band having R_f 0.2 afforded a yellow oil which was rechromatographed on two 8 × 8 in. silica gel DF-5 plates, 0.75 mm in thickness, using ether–methanol (16:1 v/v) as development solvent. Extraction of the band having R_f 0.78 with 100 ml warm methanol afforded **5***a* (0.175 g, 11.8%); ir (KBr): 3360 (m, NH), 1665 (s, CO), 1655 (s, CO) cm^{-1}; ^1H nmr δ: 0.7–1.81 (m, 9H, C_4H_9), 1.18 (t, J = 7 Hz, 6H, $—CH_3$), 3.38 (m, 4H, $—CH_2—$), 4.79 (m, 1H, H-2), 5.62 (d, $J_{3,4}$ = 9.2 Hz of d, $J_{2,3}$ = 6 Hz, 1H, H-3 and m, 1H, NH, exchanges with deuterium oxide), 6.0 (t, J_{NH-CH_2} = 5 Hz, 1H, NH, exchanges with deuterium oxide), 6.3 (d, $J_{3,4}$ = 9.2 Hz, 1H, H-4), 7.58 (s, 1H, H-6). Exact mass calcd. for $C_{15}H_{25}N_3O_2$: 279.1941; found (high resolution ms): 279.1947. Similar extraction of the band having R_f 0.73 afforded **6***a* (0.322 g, 14.6%); ir (neat): 3340 (m, NH), 1650 (s, CO) cm^{-1}; ^1H nmr δ: 0.79–1.93 (m, 7H, $—CH_2CH_2CH_2CH_3$), 1.2 (t, J = 7 Hz, 3H, $—CH_2CH_3$), 2.79 (t, J = 7 Hz, $—CH_2CH_2CH_2CH_3$), 3.45 (m, 2H, $—CH_2CH_3$), 6.32 (s, 1H, NH, exchanges with deuterium oxide), 7.18 (d, $J_{3,4}$ = 8 Hz, 1H, H-3), 8.01 (d, $J_{3,4}$ = 8 Hz of d, $J_{4,6}$ = 2.5 Hz, 1H, H-4), 8.89 (d, $J_{4,6}$ = 2.5 Hz, 1H, H-6). Exact mass calcd. for $C_{12}H_{18}N_2O$: 206.1415; found (high resolution ms): 206.1412.

*N-Ethylaminocarbonyl-2-phenyl-1,2-dihydropyridine (**4**b)*

To a solution of **1***b* (4.1 mmol) in 20 ml anhydrous tetrahydrofuran, under an atmosphere of nitrogen at −65°C, a solution of ethyl isocyanate (0.291 g, 4.1 mmol) in 2 ml dry tetrahydrofuran was added dropwise with stirring. The reaction was immediately allowed to return to 25°C and stand for 1 h after which 10 ml water was added. Extraction with chloroform (3 × 20 ml), drying (sodium sulfate) and removal of the solvent *in vacuo* gave an orange viscous semisolid. This semisolid was washed with 10 ml cold ether (to remove 2-phenylpyridine) leaving **4***b* (0.551 g, 61%) as a white solid; mp 108–110°C; ir (KBr): 3310 (s, NH), 1640 (s, CO) cm^{-1}; ^1H nmr δ: 1.01 (t, J = 7 Hz, 3H, $—CH_3$), 3.2 (q, J = 7 Hz, 2H, $—CH_2—$), 4.81 (broad s, 1H, NH, exchanges with deuterium oxide), 5.22 (d, $J_{5,6}$ = 7.5 Hz, of d, $J_{4,5}$ = 5.75 Hz, 1H, H-5), 5.4–5.85 (m, 2H, H-2, H-3), 5.96 (d, $J_{3,4}$ = 8.75 Hz, of d, $J_{4,5}$ = 5.75 Hz, 1H, H-4), 6.86 (d, $J_{5,6}$ = 7.5 Hz, 1H, H-6), 7.3 (m, 5H, phenyl). Exact mass calcd. for $C_{14}H_{16}N_2O$: 228.1263; found (high resolution ms); 228.1252.

*6,6′-Di-n-butyl-1,2,3,6-tetrahydro-2,3′-dipyridyl (**8**, R_1 = Bu)*

To a solution of **2***a* (1.462 g, 10.67 mmol) in 80 ml anhydrous ether, under a nitrogen atmosphere at −65°C, a solution of ethyl isocyanate (0.758 g, 10.67 mmol) in 2 ml anhydrous ether was added dropwise with stirring. The reaction was stirred at −65°C for 0.5 h, allowed to return to 25°C and stir for 1.5 h after which 50 ml water was added. Extraction with chloroform (3 × 40 ml), drying (sodium sulfate), and removal of the solvent *in vacuo* gave a viscous yellow oil. Preparative tlc was effected on eight 8 × 8 in. silica gel DF-5 plates, 0.75 mm in thickness, using benzene–ether (1:1 v/v) as development solvent. Extraction of the band having R_f 0.46 with 200 ml warm methanol afforded **8**, R′ = Bu (0.515 g, 35.4%). Identification was based on the spectral properties which were identical to those of an authentic sample (4).

*N-Cyclohexylaminocarbonyl-2-n-butyl-1,2-dihydropyridine (**4**c) and 2-n-Butyl-5-cyclohexylaminocarbonylpyridine (**6**c)*

To a solution of **1***a* (2.72 g, 19 mmol), in 50 ml dry ether, under a nitrogen atmosphere at −65°C, cyclohexyl isocyanate (2.42 g, 19 mmol) was added dropwise with stirring. The resulting solution was allowed to stir at −65°C for 20 min and after warming to 25°C, 20 ml water was added. Extraction with chloroform (3 × 20 ml), drying (sodium sulfate), and removal of the solvent *in vacuo* gave a brown oil. Preparative tlc was effected on six 8 × 8 in. silica gel GFP 254 plates, 0.75 mm in thickness, using benzene – ethyl acetate (1:3 v/v) as development solvent. Extraction of the fraction having R_f 0.95 with 50 ml warm methanol afforded **4***c* (0.846 g, 17%); ir (neat): 3340 (m, NH), 1630 (s, CO), cm^{-1}; ^1H nmr δ: 0.8–2.05 (m, 21H, C_4H_9, C_6H_{11}, NH, exchanges with deuterium oxide), 4.66 (m, 1H, H-2), 5.34 (m, 1H, H-5), 5.64 (m, 1H, H-3), 5.98 (m, 1H, H-4), 6.4 (m, 1H, H-6). Exact mass calcd. for $C_{16}H_{26}N_2O$: 262.2045; found (high resolution ms): 262.2045. Similar extraction of the band having R_f 0.65 gave **6***c* (0.692 g, 14%), mp 103–104°C; ir (chloroform): 3435 (m, NH), 1650 (s, CO), cm^{-1}; ^1H nmr δ: 0.94 (t, J = 7 Hz, 3H, $—CH_3$), 1.1–2.1 (m, 15H, C_6H_{11}, $—CH_2CH_2CH_2CH_3$), 2.29 (broad s, 1H, NH, exchanges with deuterium oxide), 2.82 (t, J = 7 Hz, 2H, $—CH_2CH_2CH_2CH_3$), 7.22 (d, $H_{3,4}$ = 7.5 Hz, 1H, H-3), 8.0 (d, $J_{3,4}$ = 7.5 Hz of d, $J_{4,6}$ = 2.5 Hz, 1H, H-4), 8.84 (d, $J_{4,6}$ = 2.5 Hz, 1H, H-6). Exact mass calcd. for $C_{16}H_{24}N_2O$: 260.1888; found (high resolution ms): 260.1892.

*N-Phenylaminocarbonyl-2-n-butyl-1,2-dihydropyridine (**4**d), 1,5-Di(phenylaminocarbonyl)-2-n-butyl-1,2-dihydropyridine (**5**d), 2-n-Butyl-5-phenylaminocarbonylpyridine (**6**d), and 2-n-Butyl-5-phenylaminocarbonyl-1,2-dihydropyridine (**7**)*

To a solution of **1***a* (1.462 g, 10.67 mmol) in 125 ml anhydrous ether under a nitrogen atmosphere at −65°C, a solution of phenyl isocyanate (1.509 g, 12.67 mmol) in 3 ml anhydrous ether was added dropwise with stirring. The reaction was stirred at −65°C for 0.5 h, allowed to return to 25°C and stir for 1.5 h after which 100 ml water was added. Extraction with chloroform (4 × 50 ml), drying (sodium sulfate), and removal of the solvent *in vacuo* gave an orange semisolid. This semisolid was triturated with 30 ml ether leaving **7** (1.158 g, 42.8%) as a light yellow solid; mp 140–141°C; ir (KBr): 3400 (w, NH), 3280 (w, NH), 1650 (s, CO) cm^{-1}; ^1H nmr (DMSO-d_6) δ: 0.67–1.65 (m, 9H, C_4H_9), 4.18 (m, 1H, H-2), 4.99 (d, $J_{3,4}$ = 10 Hz of d, $J_{2,3}$ = 4 Hz, 1H, H-3), 6.49 (d, $J_{3,4}$ = 10 Hz, 1H, H-4), 6.82–7.83 (m, 7H, H-6, phenyl, NH, exchanges with deuterium oxide), 8.95 (s, 1H, NH, exchanges with deuterium oxide). Exact mass calcd. for $C_{16}H_{20}N_2O$: 256.1571; found (high resolution ms): 256.1573. The ethereal filtrate was evaporated *in vacuo* to give a viscous yellow oil. Preparative tlc was effected on eleven 8 × 8 in. silica gel DF-5 plates, 0.75 mm in thickness using benzene–ether (2:1 v/v) as development solvent. Extraction of the band having R_f 0.98 with 100 ml warm methanol afforded **4***d* (0.246 g, 9.0%) whose spectral properties were identical to those of **4***d* described in the reaction below. Similar extraction of the band having R_f 0.82 afforded **5***d* as a white solid (0.591 g, 14.8%): mp 70°C; ir (KBr): 3330 (m, NH), 1652 (s, CO) cm^{-1}; ^1H nmr δ: 0.63–1.91 (m, 9H, C_4H_9), 4.75 (m, 1H, H-2), 5.6 (d, $J_{3,4}$ = 10 Hz of d, $J_{2,3}$ = 6 Hz, 1H, H-3) 6.39 (d, $J_{3,4}$ = 10 Hz, 1H, H-4), 6.93–7.6 (m, 10H, phenyl), 7.7 (s, 1H, H-6), 8.15 (s, 1H, NH, exchanges with deuterium oxide), 8.22 (s, 1H, NH, exchanges with deuterium oxide). *Anal.* calcd. for $C_{23}H_{25}N_3O_2$: C 73.57, H 6.71, N 11.19; found: C 72.47, H 6.85, N 10.48. Repeated attempts to obtain analytically pure **5***d* were not successful. Similar extraction of the band

having R_f 0.3 afforded **6***d* (0.81 g, 29.9%) whose spectral properties were identical to those of **6***d* described in the reaction below.

*N-Phenylaminocarbonyl-2-*n*-butyl-1,2-dihydropyridine (**4**d) and 2-*n*-Butyl-5-phenylaminocarbonylpyridine (**6**d)*

To a solution of **2***a* (1.462 g, 10.67 mmol) in 80 ml anhydrous ether, under a nitrogen atmosphere at −65°C, a solution of phenyl isocyanate (1.271 g, 10.67 mmol) in 3 ml anhydrous ether was added dropwise with stirring. The reaction was stirred at −65°C for 0.5 h, allowed to return to 25°C and stir for 1.5 h after which 50 ml water was added. Extraction with chloroform (3 × 40 ml), drying (sodium sulfate), and removal of the solvent *in vacuo* gave a viscous yellow oil. Preparative tlc was effected on 11 silica gel DF-5 plates, 8 × 8 in., 0.75 mm in thickness using benzene–ether (1:1 v/v) as development solvent. Extraction of the band having R_f 0.98 with 100 ml warm methanol afforded **4***d* (0.824 g, 30.2%); ir (neat): 3330 (m, NH), 1655 (s, CO) cm^{-1}; ^1H nmr δ: 0.75–2 (m, 9H, C_4H_9), 4.88 (m, 1H, H-2), 5.49 (d, $J_{5,6}$ = 7.5 Hz of d, $J_{4,5}$ = 5 Hz of d, $J_{3,5}$ = 1.5 Hz, 1H, H-5), 5.8 (m, 1H, H-3), 6.05 (d, $J_{3,4}$ = 9.25 Hz of d, $J_{4,5}$ = 5 Hz, 1H, H-4), 6.61 (d, $J_{5,6}$ = 7.5 Hz, 1H, H-6), 6.78 (s, 1H, NH, exchanges with deuterium oxide), 7.04–7.6 (m, 5H, phenyl). Exact mass calcd. for $C_{16}H_{20}N_2O$: 256.1571; found (high resolution ms): 256.1577. Similar extraction of the band having R_f 0.41 afforded **6***d* (0.405 g, 15.0%); ir (KBr): 3352 (m, NH), 1660 (s, CO) cm^{-1}; ^1H nmr δ: 0.7–1.99 (m, 7H, $—CH_2CH_2CH_2CH_3$), 2.85 (t, J = 7 Hz, 2H, $—CH_2CH_2CH_2CH_3$), 6.9–7.8 (m, 6H, H-3, phenyl), 8.14 (d, $J_{3,4}$ = 8 Hz of d, $J_{4,6}$ = 2.5 Hz, 1H, H-4), 8.56 (s, 1H, NH, exchanges with deuterium oxide), 9.01 (d, $J_{4,6}$ = 2.5 Hz, 1H, H-6). Exact mass calcd. for $C_{16}H_{18}N_2O$: 254.1415; found (high resolution ms): 254.1427.

*2-*n*-Butyl-5-(3′-pyridylcarbonyl)-1,2-dihydropyridine (**13**a) and 2-*n*-Butyl-5-(3′-pyridylcarbonyl)pyridine (**14**a)*

To a solution of **1***a* (1.43 g, 10 mmol) in 60 ml anhydrous ether, under a nitrogen atmosphere at 25°C, a solution of 3-ethoxycarbonylpyridine (1.51 g, 10 mmol) in 5 ml anhydrous ether was added dropwise with stirring. The reaction was stirred at 25°C for 1 h after which 90 ml water was added. Extraction with ether (6 × 30 ml), drying (sodium sulfate), and removal of the solvent *in vacuo* gave a red oil. Preparative tlc was effected on three 8 × 16 in. silica gel DF-5 plates, 0.75 mm in thickness using ether–methanol (9:1 v/v) as development solvent. Extraction of the band having R_f 0.42 with 100 ml warm methanol afforded **13***a* (0.957 g, 39.6%); ir (neat): 3260 (m, NH), 1652 (s, CO) cm^{-1}; ^1H nmr δ: 0.66–1.77 (m, 9H, C_4H_9), 4.29 (m, 1H, H-2), 5.15 (d, $J_{3,4}$ = 10 Hz, 1H, H-3), 6.54 (d, $J_{3,4}$ = 10 Hz, 1H, H-4), 6.94–7.4 (m, 3H, H-5′, H-6, NH, exchanges with deuterium oxide), 7.72 (d, $J_{4',5'}$ = 8.5 Hz of d, $J_{4',6'}$ = 2 Hz of d, $J_{2',4'}$ = 2 Hz, 1H, H-4′), 8.53 (d, $J_{5',6'}$ = 5 Hz of d, $J_{4',6'}$ = 2 Hz, 1H, H-6′), 8.58 (d, $J_{2',4'}$ = 2 Hz, 1H, H-2′). Exact mass calcd. for $C_{15}H_{18}N_2O$: 242.1415; found (high resolution ms): 242.1414. Similar extraction of the band having R_f 1 afforded a dark yellow oil which was rechromatographed on one 8 × 16 in. silica gel DF-5 plate, 0.75 mm in thickness using ether–methanol (20:1 v/v) as development solvent. Extraction of the band having R_f 1 with 100 ml warm methanol afforded 2-*n*-butylpyridine (0.108 g, 8.0%). Similar extraction of the band having R_f 0.95 afforded 3-ethoxycarbonylpyridine (0.408 g, 27.0%). Similar extraction of the band having R_f 0.76 afforded **14***a* (0.064 g, 2.7%); ir (neat): 1670 (s, CO) cm^{-1}; ^1H nmr δ: 0.73–2.17 (m, 7H, $—CH_2CH_2CH_2CH_3$), 2.89 (t, J = 7 Hz, 2H, $—CH_2CH_2CH_2CH_3$), 7.2—7.59 (m, 2H, H-5′, H-3), 7.92–8.24 (m, 2H, H-4′, H-4), 8.7–9.05 (m, 3H, H-2′, H-6′, H-6). Exact mass calcd. for $C_{15}H_{16}N_2O$: 240.1259; found (high resolution ms): 240.1257.

*2-*n*-Butyl-5-(4′-pyridylcarbonyl)-1,2-dihydropyridine (**13**b) and 2-*n*-Butyl-5-(4′-pyridylcarbonyl)pyridine (**14**b)*

To a solution of **1***a* (2.86 g, 20 mmol) in 60 ml anhydrous ether, under a nitrogen atmosphere at 25°C, a solution of 4-methoxycarbonylpyridine (2.74 g, 20 mmol) in 10 ml anhydrous ether was added dropwise with stirring. The reaction was stirred at 25°C for 0.5 h after which 100 ml water was added. Extraction with ether (6 × 100 ml), drying (sodium sulfate), and removal of the solvent *in vacuo* gave a red oil. Preparative tlc was effected on six 8 × 16 in. silica gel DF-5 plates, 0.75 mm in thickness using ether–methanol (15:1 v/v) as development solvent. Extraction of the band having R_f 0.21 with 100 ml warm methanol afforded **13***b* (2.29 g, 47.4%); ir (neat): 3240 (m, NH), 1650 (s, CO) cm^{-1}; ^1H nmr δ: 0.65–1.7 (m, 9H, C_4H_9), 4.27 (m, 1H, H-2), 5.13 (d, $J_{3,4}$ = 10 Hz of d, $J_{2,3}$ = 3.5 Hz, 1H, H-3), 6.49 (d, $J_{3,4}$ = 10 Hz, 1H, H-4), 6.88–7.28 (m, 3H, H-3′, H-5′, H-6), 7.93 (m, 1H, NH, exchanges with deuterium oxide), 8.4–8.62 (m, 2H, H-2′, H-6′). Exact mass calcd. for $C_{15}H_{18}N_2O$: 242.1415; found (high resolution ms): 242.1417. Similar extraction of the band having R_f 0.67 afforded **14***b* (0.41 g, 8.6%); ir (neat): 1670 (s, CO) cm^{-1}; ^1H nmr δ: 0.72–2.07 (m, 7H, $—CH_2CH_2CH_2CH_3$), 2.9 (t, J = 7 Hz, 2H, $—CH_2CH_2CH_2CH_3$), 7.29 (d, $J_{3,4}$ = 8 Hz, 1H, H-3), 7.48–7.65 (m, 2H, H-3′, H-5′), 8.04 (d, $J_{3,4}$ = 8 Hz of d, $J_{4,6}$ = 2.5 Hz, 1H, H-4), 8.72–8.95 (m, 3H, H-2′, H-6′, H-6). Exact mass calcd. for $C_{15}H_{16}N_2O$: 240.1259; found (high resolution ms): 240.1256. Similar extraction of the band having R_f 0.85 afforded 4-methoxycarbonylpyridine (0.449 g, 16.4%). Similar extraction of the band having R_f 0.94 afforded 2-*n*-butylpyridine (0.128 g, 4.8%).

*2-*n*-Butyl-5-(2′-pyridylcarbonyl)-1,2-dihydropyridine (**13**c) and 2-*n*-Butyl-5-(2′-pyridylcarbonyl)pyridine (**14**c)*

To a solution of **1***a* (1.45 g, 10.1 mmol) in 60 ml anhydrous ether, under a nitrogen atmosphere at 25°C, a solution of 2-ethoxycarbonylpyridine (1.53 g, 10.1 mmol) in 5 ml anhydrous ether was added dropwise with stirring. The reaction was stirred at 25°C for 1 h after which 100 ml water was added. Extraction with chloroform (5 × 50 ml), drying (sodium sulfate), and removal of the solvent *in vacuo* gave a red oil. Preparative tlc was effected on eight 8 × 8 in. silica gel DF-5 plates, 0.75 mm in thickness, using ether–methanol (15:1 v/v) as development solvent. Extraction of the band having R_f 0.54 with 100 ml warm methanol afforded **13***c* (1.162 g, 47.5%); ir (neat): 3250 (s, NH), 1648 (s, CO) cm^{-1}; ^1H nmr δ: 0.7–1.95 (m, 9H, C_4H_9), 4.3 (m, 1H, H-2), 5.14 (d, $J_{3,4}$ = 10 Hz, 1H, H-3), 6.7 (d, $J_{3,4}$ = 10 Hz, 1H, H-4), 7.03–8.25 (m, 5H, H-6, H-3′, H-4′, H-5′, NH, exchanges with deuterium oxide), 8.52 (m, 1H, H-6′). Exact mass calcd. for $C_{15}H_{18}N_2O$: 242.1415; found (high resolution ms): 242.1412. Similar extraction of the band having R_f 0.81 afforded **14***c* (0.097 g, 4%); ir (neat): 1670 (s, CO) cm^{-1}; ^1H nmr δ: 0.68–2.24 (m, 7H, $—CH_2CH_2CH_2CH_3$), 2.88 (t, J = 7 Hz, 2H, $—CH_2CH_2CH_2CH_3$), 7.3 (d, $J_{3,4}$ = 8 Hz, 1H, H-3), 7.46–8.22 (m, 3H, H-4′, H-3′, H-5′), 8.4 (d, $J_{3,4}$ = 8 Hz of d, $J_{4,6}$ = 2.5 Hz, 1H, H-4), 8.75 (d, $J_{5',6'}$ = 5 Hz of d, $J_{4',6'}$ = 2 Hz, of d, $J_{3',6'}$ = 1 Hz, 1H, H-6′), 9.36 (d, $J_{4,6}$ = 2.5 Hz, 1H, H-6). Exact mass calcd. for $C_{15}H_{16}N_2O$: 240.1259; found (high resolution ms): 240.1247. Similar extraction of the band having R_f 0.95 afforded 2-ethoxycarbonylpyridine (0.236 g, 15.5%). Similar extraction of the band having R_f 1 afforded 2-*n*-butylpyridine (0.206 g, 15.1%).

*N-Diethylphosphoryl-2-*n*-butyl-1,2-dihydropyridine (**16**a)*

To a solution of **1***a* (2.72 g, 19 mmol) in 50 ml anhydrous

ether, under a nitrogen atmosphere at −65°C, a solution of diethyl chlorophosphate (3.28 g, 19 mmol) in 5 ml dry ether was added dropwise with stirring. The resulting solution was maintained at −65°C for 20 min and after warming to 25°C, 20 ml water was added. Extraction with chloroform (3 × 20 ml) drying (sodium sulfate) and removal of the solvent *in vacuo* afforded a brown oil which was subjected to preparative tlc on six 8 × 8 in. silica gel GFP 254 plates, 0.75 mm in thickness, with benzene–ether (1:1 v/v) as development solvent. Extraction of the band having R_f 0.7 with 50 ml methanol gave **16***a* (3.54 g, 68.3%), ir (neat): 1265 (s, PO) cm^{-1}; ^1H nmr δ: 0.9 (t, J = 7 Hz, 3H, $—CH_2CH_2CH_2CH_3$), 1.0–1.8 (m, 12H, $—CH_2CH_2CH_2CH_3$, $—OCH_2CH_3$), 4.0 (m, 5H, H-2, $—OCH_2CH_3$), 5.25 (m, 1H, H-5), 5.5 (m, 1H, H-3), 5.85 (m, 1H, H-4), 6.1 (m, 1H, H-6). Exact mass calcd. for $C_{13}H_{24}NO_3P$: 273.1494; found (high resolution ms): 273.1494.

N-*Acetyl-2*-n-*butyl-1,2-dihydropyridine* (**16**b)

To a solution of **1***a* (1.36 g, 9.5 mmol) in 50 ml dry ether, under an atmosphere of nitrogen at −65°C, ethyl acetate (0.84 g, 9.5 mmol) was added dropwise with stirring. The resulting solution was maintained at −65°C for 20 min and after warming to room temperature water (25 ml) was added. Extraction with chloroform (3 × 20 ml), drying (sodium sulfate) and removal of the solvent yielded a light yellow oil. Quantitative vpc analysis using a ⅛ × 20 in. column packed with 10% UCW-98 on WAW-DMCS (80–100 mesh) with a helium flow rate of 25 ml/min and a column temperature of 125°C afforded 2-*n*-butylpyridine (0.011 g, 0.8%), retention time of 1.2 min, which showed ir and ^1H nmr spectra identical to those of an authentic sample; and **16***b* (1.74 g, 99%), retention time of 6.1 min; ir (neat): 1655 (s, CO) cm^{-1}; ^1H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.0–1.95 (m, 6H, $CH_2CH_2CH_2CH_3$), 2.19 (s, 3H, $COCH_3$), 5.07 (m, 1H, H-2), 5.33 (m, 1H, H-5), 5.67 (m, 1H, H-3), 5.82 (m, 1H, H-4), 6.5 (m, 1H, H-6). Exact mass calcd. for $C_{11}H_{17}NO$: 179.1310; found (high resolution ms): 179.1310.

Analyse des malates de cuivre et d'uranyle par potentiométrie, polarimétrie et spectrophotométrie

ILHAM KHALIL,[1] MICHELLE M. PETIT-RAMEL ET CLAUDETTE CHAPELET-BARBIER[2]

Laboratoire de Chimie Minérale I, Université Claude Bernard, Lyon I, 43 Boulevard du 11 novembre 1918, 69621, Villeurbanne, France

Reçu 5 août 1977

ILHAM KHALIL, MICHELLE M. PETIT-RAMEL et CLAUDETTE CHAPELET-BARBIER. Can. J. Chem. **56**, 1919 (1978).

Les constantes de stabilité et constantes optiques des malates de cuivre $[CuH_2Mal]^+$, $[CuHMal]$, $[CuH_2Mal_2]^{2-}$, $[CuMal]^-$, $[Cu_2Mal_2]^{2-}$ et $[CuH_{-1}Mal]^{2-}$ ont été affinées par une méthode de "pit-mapping", qui donne aussi leurs limites de confiance, à partir des mesures potentiométriques, spectrophotométriques visibles et polarimétriques.

Dans le cas des malates d'uranyle, la présence d'espèces polynucléaires, perceptible par potentiométrie, a été confirmée par spectrométrie rmn. Les constantes des espèces $[UO_2HMal]$, $[UO_2Mal]^-$, $[(UO_2)_2Mal_2]^{2-}$, $[(UO_2)_3Mal_5]^{9-}$ et $[(UO_2)_3H_{-2}Mal_5]^{11-}$ ont été calculées d'abord par "pit-mapping", puis par la méthode graphique de Lefebvre. Toute les valeurs sont données à 25°C pour une force ionique de 0.5 en $NaNO_3$.

ILHAM KHALIL, MICHELLE M. PETIT-RAMEL, and CLAUDETTE CHAPELET-BARBIER. Can. J. Chem. **56**, 1919 (1978).

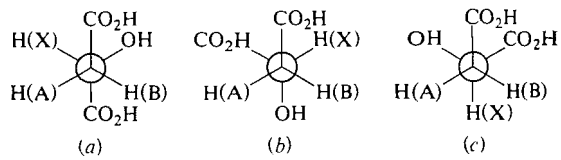
The stability and optical constants of the copper malates $[CuH_2Mal]^+$, $[CuHMal]$, $[CuH_2Mal_2]^{2-}$, $[CuMal]^-$, $[Cu_2Mal_2]^{2-}$, and $[CuH_{-1}Mal]^{2-}$ have been fitted by a pit-mapping method, which also gives their confidence limits, from potentiometric, visible spectroscopic and polarimetric measurements.

In the case of the uranyle malates, the presence of polynuclear species, detectable in the potentiometric study, have been confirmed by nmr spectrocopy. The constants of $[UO_2HMal]$, $[UO_2Mal]^-$, $[(UO_2)_2Mal_2]^{2-}$, $[(UO_2)_3Mal_5]^{9-}$, and $[(UO_2)_3H_{-2}Mal_5]^{11-}$ have been determined, first by a pit-mapping method, then, by the graphical method of Lefebvre. All the values are given at 25°C for an ionic strength of 0.5 in $NaNO_3$.

Bien que, dès 1844 Peligot (1) puis Itzig (2) et Courtois (3) aient décrit la préparation des malates d'uranyle à l'état solide, nous constatons que les malates occupent une place beaucoup moins importante que les complexes d'autres acides-alcools tels les acides tartrique, lactique ou citrique (4–6).

Pour notre part, nous avons utilisé la potentiométrie pour l'interprétation des phénomènes et surtout le calcul des constantes de stabilité, la spectrophotométrie et la polarimétrie pour la confirmation de certains de nos résultats. Enfin la résonance magnétique du proton devrait nous permettre d'élucider les phénomènes d'association métal-coordinat, tout particulièrement dans le cas de l'uranyle.

En ce qui concerne l'acide malique, dont nous ne rappellerons que les résultats définitifs (6), la rmn a permis de mettre en évidence, comme l'avait montré Pachler (23) les variations du déplacement chimique et des constantes de couplage jusqu'au point d'équivalence. Selon le domaine de pH envisagé, l'acide malique existe essentiellement sous deux formes rotamères (*a*) et (*c*), la forme (*a*) devenant prédominante avec l'augmentation de l'alcalinité du milieu (7, 8).



I. Malates d'uranyle

Feldman et coll. (9, 10) ont montré que l'acide malique formait vers pH 2.4, des chélates à prédominance binucléaire par l'intermédiaire de liaisons tridentées. Ces liaisons se produisant par des ponts OH entre les ions uranyle, la formation de ces dimères est suivie à p$H > 4$ de leur hydrolyse et de leur polymérisation, puis de l'apparition du trimère. Rajan et Martell (11) puis Campi et Ginnaro (12) en ont déjà calculé les constantes de stabilité, mais la structure de ces complexes ayant donné lieu à des interprétations diverses nous les discuterons et les comparerons à l'ensemble de nos résultats.

I.1. Mise en évidence des espèces et calcul des constantes

La démarche que nous suivrons découle directement de l'examen des courbes de formation (fig.

[1]Boursière du Centre National de la Recherche Scientifique du Liban.

[2]Laboratoire de Chimie Physique Moléculaire, Université Claude Bernard, Lyon I, 43 Boulevard du 11 novembre 1918, 69621, Villeurbanne.

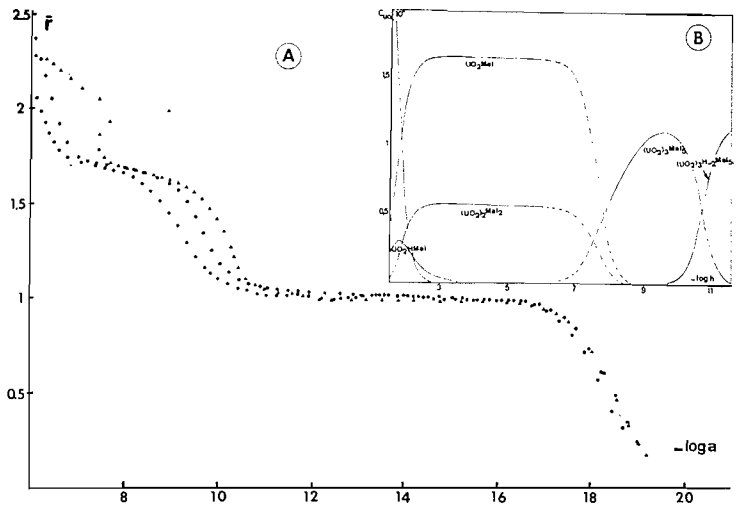

FIG. 1. Uranyl – acide malique. (*a*) Courbes de formation, [Mal] = 6×10^{-2} *M*. ● $[UO_2] = 10^2$ *M*; * $[UO_2] = 2 \times 10^{-2}$ *M*; ▲ $[UO_2] = 3 \times 10^{-2}$ *M*. (*b*) Courbes de répartition. [Mal] = 6×10^{-2} *M*; $[UO_2] = 3.2 \times 10^{-2}$ *M*.

1*a*) sur lesquelles on distingue trois zones bien différenciées:

p*H* < 5 formation de l'espèce UO_2Mal en même temps que des espèces protonées pour des $-\log a > 12$.

6 < p*H* < 10 présence de l'espèce polynucléaire $(UO_2)_3Mal_5$ pour des $-\log a$ compris entre 11 et 7.5. Les courbes sont équidistantes et l'écartement séparant deux courbes est proportionnel à Δm (21).

p*H* > 10 formation d'espèces hydroxydées pour des $-\log a < 7.5$.

Les complexes du milieu acide p*H* < 5 ont pu être abordés facilement par la méthode du "pit-mapping" (13). Pour les p*H* > 5 les espèces ont été mises en évidence spectrophotométriquement par la méthode trichrome (14) et les constantes de stabilité déterminées par la méthode de Lefebvre (4). La polarimétrie sera dans tous les cas un moyen commode de délimiter les zones de formation et même de confirmer certains de nos résultats.

I.1.1. Méthode du "pit-mapping": La comparaison des courbes de titrage normalisées $\bar{q}_{cal}$, $\bar{q}_{exp} = f(pH)$ (fig. 2) pour des p*H* < 5 a permis de calculer les constantes de stabilité des espèces et l'écart-type correspondant. Les valeurs définitives sont rassemblées dans le tableau 2.

I.1.2. Méthode spectrophotométrique: La complexation de l'uranyle par l'acide malique se traduit sur la fig. 3 par un léger déplacement vers les fortes longueurs d'onde. Ce phénomène se reproduit d'ailleurs pour un grand nombre de composés de l'uranyle, en particulier les citrates (15–17) et peut être rapproché de l'effet néphélauxétique observé dans les complexes lanthanidiques colorés (18).

Entre p*H* 2.8 et 5.0 la densité optique ne varie plus

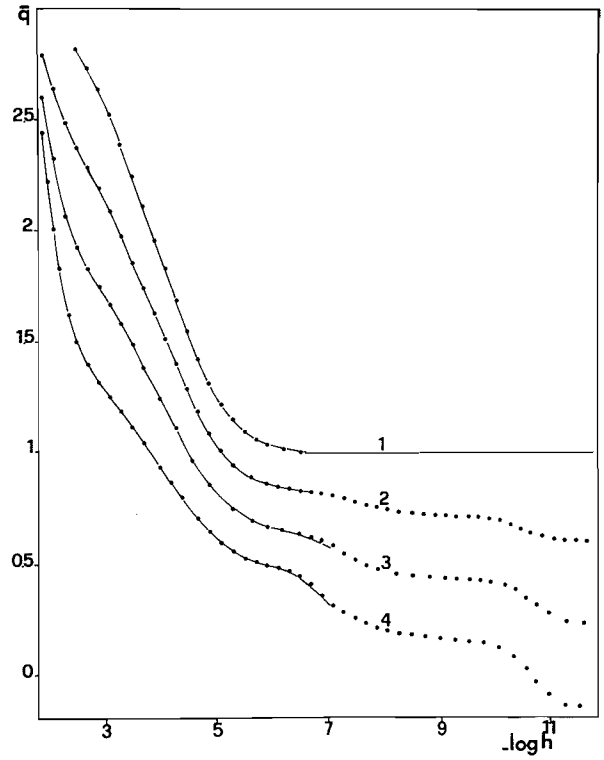

FIG. 2. Uranyle – acide malique. Courbes normalisées $\bar{q} = f(pH)$ [Mal] = 6×10^{-2} *M*. (*1*) $[UO_2] = 0$; (*2*) $[UO_2] = 10^{-2}$ *M*; (*3*) $[UO_2] = 2 \times 10^{-2}$ *M*; (*4*) $[UO_2] = 3 \times 10^{-2}$ *M*.

et les spectres sont confondus. Le ou les complexes formés ont atteint leur maximum de concentration. Au fur et à mesure que le p*H* augmente, une autre espèce apparait et on observe son maximum de formation dans le domaine étroit de p*H* compris entre 9.4 et 10.3. Un léger déplacement a lieu ensuite

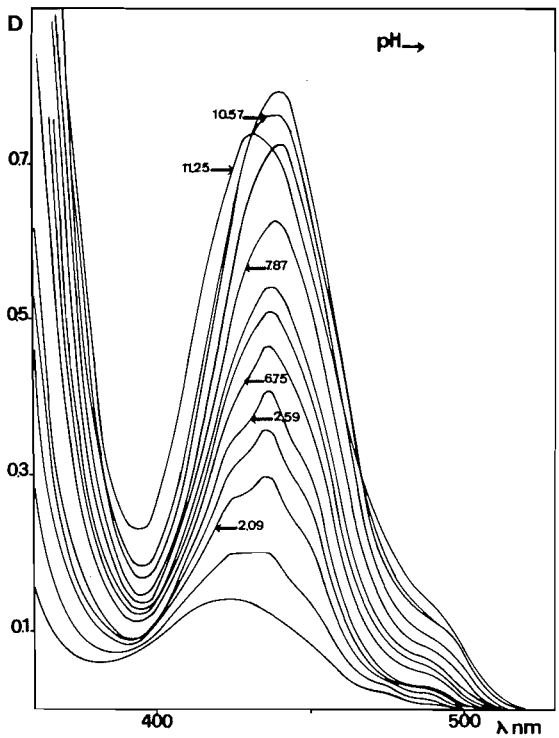

FIG. 3. Uranyle – acide malique. Spectres d'absorption en fonction du pH. [Mal] = 6×10^{-2} M. [UO_2] = 10^{-2} M.

vers les faibles longueurs d'onde et le coefficient d'absorption diminue. L'apparition d'un point isosbestique à 430 nm suppose la présence d'un équilibre entre deux espèces absorbant à cette même longueur d'onde.

L'application de la méthode trichrome (14) aux faisceaux de spectres de la fig. 3 révèle l'existence de plus d'une espèce jusqu'à pH 2.8 (fig. 4). Puis les courbes deviennent parallèles à l'axe des pH et dans le meilleur des cas il y a présence d'une seule espèce absorbant dans ce domaine. Ce parallélisme se retrouve dans un domaine de pH restreint $8.8 < pH < 10.2$ et aux environs de pH 11.7.

L'existence des complexes étant pressentie, nous avons déterminé la formule par application de la méthode des variations continues à pH 9. L'absorption maximum est obtenue pour 37.5% d'uranyle et 62.5% d'acide malique. Ceci exclut, par conséquent le rapport 1:1 acide malique:uranyle au pH envisagé. Ajoutons que si nous mesurons l'écart entre chaque courbe de neutralisation du complexe et celle de l'acide malique et si nous nous reportons aux courbes de formation, nous constatons qu'il correspond à la consommation de 5/3 d'ion OH par atome d'uranyle lorsque $8.8 < pH < 10.2$ et 7/3 d'ion OH dans le domaine $11 < pH < 12$. Cela conduit, en première approximation aux formules $(UO_2)_3Mal_5$

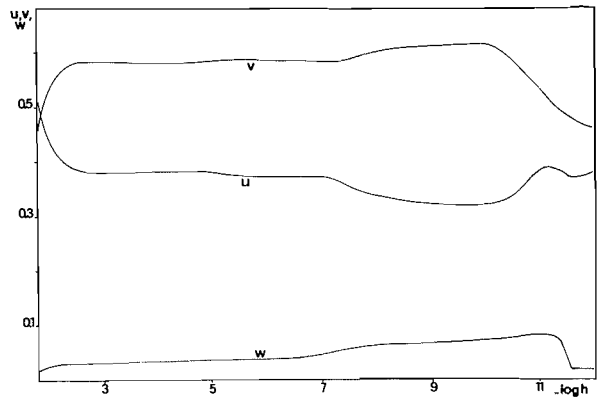

FIG. 4. Uranyle – acide malique. Méthode trichrome.

et $(UO_2)_3H_{-2}Mal_5$ avec

$$3(UO_2)^{2+} + 5(HMal)^{2-} \rightleftarrows ((UO_2)_3Mal_5)^{9-} + 5H^+$$

$$3(UO_2)^{2+} + 5(HMal)^{2-} + 2H_{-1}H^+ \rightleftarrows ((UO_2)_3H_{-2}Mal_5)^{11-} + 7H^+$$

si $H_{-1}H^+ = OH^-H^+$.

I.1.3. Méthode de Lefebvre: Les complexes ci-dessus sont caractérisés successivement par les constantes β_{305} et β_{3-25}, définies par:

$$\beta_{305} = \frac{[(UO_2)_3(Mal)_5]}{[UO_2]^3[Mal]^5}$$

$$\beta_{3-25} = \frac{[(UO_2)_3H_{-2}(Mal)_5]}{[UO_2]^3[H]^{-2}[Mal]^5}$$

et dont la détermination nécessite la connaissance préalable des concentrations de toutes les espèces présentes en solution.

La concentration en ions uranyle est calculée par application de la méthode de Lefebvre (4) puisque $-\log m$ ne nous est pas accessible par mesure directe à l'aide d'une électrode réversible. La méthode consiste à relever, à partir du faisceau de courbes de neutralisation pour différentes valeurs de pH, les volumes de soude correspondants et ceci pour tous les rapports envisagés. On effectue alors le tracé des droites:

$$V_{ml} = f(C_{UO_2}) \quad \text{à différents pH} \qquad \text{(fig. 5}a\text{)}$$

On mesure la pente de chacune de ces droites et on trace:

$$\delta n_{H-1}/\delta n_{UO_2} = f(-\log h) \qquad \text{(fig. 5}b\text{)}$$

Nous remarquons sur la fig. 5*b* un palier, situé entre les pH 8.8 et 10.2 correspondant à une consommation en uranyle proportionnelle au nombre de ml versés. En d'autres termes, nous nous trouvons dans la zone du saut de potentiel coïncidant avec la formation du complexe $(UO_2)_3Mal_5$. La surface

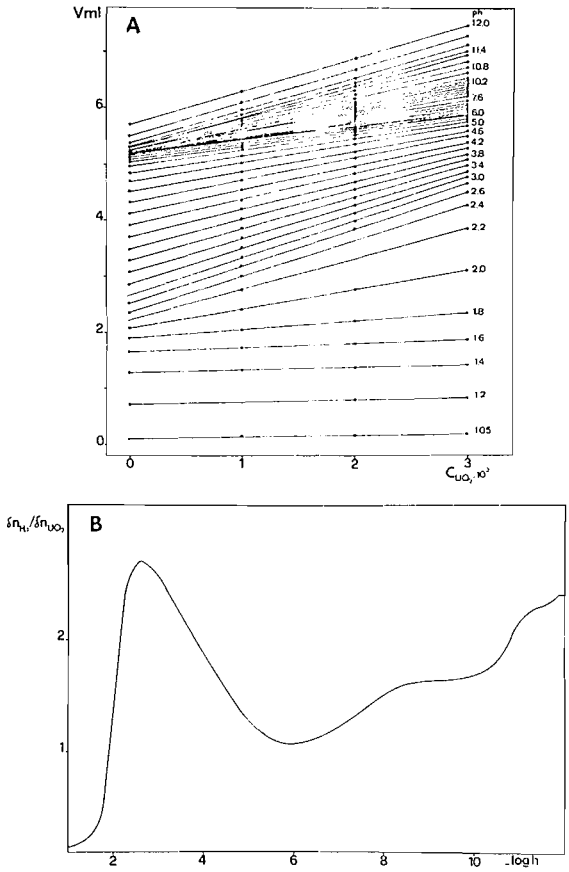

FIG. 5. Uranyle – acide malique. Méthode de Lefebvre.

comprise entre cette dernière courbe et l'axe des pH, ajoutée à $-\log [UO_2]_{initial}$ connu, permet d'obtenir $-\log [UO_2]_{final}$ tout au long de la courbe. Notons que $-\log [UO_2]_{initial}$ est facilement calculé, à partir de la concentration initiale en uranyle, puisque le pH de départ, atteint après addition d'une quantité d'acide nitrique suffisante pour rétrograder l'ionisation de l'acide malique, ne permet pratiquement pas la complexation de l'ion métallique. Ceci se traduit par des courbes de neutralisation relativement confondues au point de départ vers pH = 1.

En ce qui concerne la concentration en ions malates libres, elle est calculée par différence entre la concentration totale en acide malique et la concentration du complexe supposé être entièrement formé dans tout le domaine d'existence précédemment déterminé.

Le même raisonnement est valable pour le domaine des pH, situé aux environs de 11.7.

Nos essais expérimentaux ont été réalisés sur des solutions de compositions suivantes:

Solution n°	1	2	3	4
C_{H_3Mal}	6×10^{-2}	6×10^{-2}	6×10^{-2}	6×10^{-2}
C_{UO_2}	0	10^{-2}	2×10^{-2}	3×10^{-2}

Les valeurs rassemblées dans le tableau 1 permettent le calcul des constantes de stabilité du complexe polynucléaire $(UO_2)_3Mal_5$ puis du complexe $(UO_2)_3H_{-2}Mal_5$. Sur le même tableau nous avons représenté la variation de chacune des constantes des espèces $(UO_2)_3Mal_5$, $(UO_2)_2Mal_3$ et $(UO_2)_3H_{-2}Mal_3$. Pour les premières, la calcul a été fait en écrivant l'acide malique sous la forme H_3Mal alors que pour la dernière, nous nous sommes placés dans les conditions de Rajan et Martell et nous avions considéré l'acide malique comme un diacide. La comparaison de ces valeurs montre bien une constance plus importante pour l'espèce $(UO_2)_3Mal_5$. Ce qui permet, encore une fois, de recouper notre hypothèse.

En procédant de la même façon pour $(UO_2)_3H_{-2}Mal_5$ et $(UO_2)_3H_{-1}Mal_5$, nous sommes amenés à admettre, en définitif, dans chacune des deux zones, les espèces $(UO_2)_3Mal_5$ et $(UO_2)_3H_{-2}Mal_5$ respectivement.

Les constantes calculées pour les espèces précédentes sont obtenues en faisant la moyenne des valeurs du tableau 1

$(UO_2)_3Mal_5$ $8.8 < pH < 10.3$

$$\log \beta_{305} = 79.50 \pm 0.07$$

$(UO_2)_3H_{-2}Mal_5$ $pH > 11$

$$\log \beta_{3-25} = 57.70 \pm 0.10$$

I.1.4. Courbes de répartition: Elles représentent globalement les résultats du "pit-mapping" et de la méthode de Lefebvre (fig. 1*b*). Comme les courbes de répartition, les courbes polarimétriques $\alpha = f(pH)$ (fig. 6) montrent une nette séparation des domaines de formation des espèces. Les constantes optiques ainsi que les constantes de stabilité sont rassemblées dans les tableaux 2 et 3.

I.2. Etude par résonance magnétique du proton

Les premiers travaux de rmn sur le malate d'uranyle ont été effectués par Mariano et Gil (7, 8) sur une solution équimoléculaire 0.2 *M* d'acide malique et d'ion uranyle à pH 3. Nous avons exploré le domaine de pH allant de 3 à 5.6 avec des solutions contenant les mêmes proportions molaires d'acide malique et d'uranyle (0.16 et 0.2 *M*). Tous les spectres observés présentent un caractère commun à savoir la présence de deux parties X distinctes, l'une résolue, l'autre non résolue tandis qu'il n'apparait qu'une seule partie AB. La séparation ainsi que le rapport d'intensité des

deux massifs de la partie X varient avec les conditions de pH et de température. Sur l'un des deux massifs situé du côté des champs faibles, à température ordinaire, (fig. 7) apparait la structure qui nous a servi (avec la partie AB) à évaluer les constantes de couplage. On constate que les paramètres de couplage ainsi que le déplacement chimique entre les noyaux A et B varient peu avec le pH; seule varie de façon appréciable la position relative des deux groupes de raies de la partie X. A pH 5.6 leur séparation de 0.24 ppm devient suffisante pour mesurer le

$(UO_2)_3H_{-2}Mal_5$	57.70(0.10)	69	−1355

*Seules les valeurs notées d'un astérisque peuvent être comparées à celles de nos références bibliographiques. Nous les avons recalculées sans tenir compte de la dissociation alcoolique de l'acide malique (tableau 3).

rapport des intensités ($<1/1.6$), le massif le plus intense se situant du côté des champs forts. Nous donnerons les valeurs des paramètres indépendants du pH et de la concentration (à la précision de nos mesures).

$$J_{AX} = 12.5 \text{ Hz} \qquad J_{BX} = 0.1 \text{ Hz}$$

$$J_{AB} = (-)17.2 \text{ Hz} \qquad \delta_{AB} = 0.07 \text{ ppm}$$

L'influence de la température a été étudiée sur la solution équimoléculaire 0.173 M à pH 5.6. On constate qu'à 10°C, la résolution de la partie X est moins bonne qu'à 30°C, la partie X la mieux résolue se trouvant encore du côté des champs faibles. Tandis qu'à 60°C, les raies X et AB sont nettement plus fines, le massif X non résolu se trouvant cette fois du côté des champs faibles, contrairement aux deux premiers cas.

Il faut admettre, d'après ces observations qu'il existe plusieurs espèces différentes en solution. Aux pH inférieurs à 7, l'existence d'un couplage à longue distance du deuterium alcoolique avec le proton X dans l'une des formes étant exclu on peut avancer l'hypothèse de la présence simultanée de trois espèces: le monomère $(UO_2)Mal$ et deux dimères $(UO_2)_2Mal_2$ de structures différentes **1** et **2**.

Ces trois complexes sont très voisins par leurs systèmes AB, mais l'un d'eux se différencie plus nettement par ses noyaux X. D'après les structures **1** et **2**, on peut en effet attendre des spectres très voisins pour le monomère et le dimère **1**, tandis que la partie X du dimère **2** serait plus affectée par la présence de deux groupements uranyle, les parties AB étant moins sensibles à la différence de structure.

II. Malates de cuivre

Delsal (20), Lefebvre (4), Rajan et Martell (5) ont mis en évidence la formation d'un complexe très stable de formule $CuMal$ ou Cu_2Mal_2. La neutralisation progressive de mélanges acide malique–cuivre fait bien apparaître un saut de pH très net après addition de un OH par ion cuivrique. Puis, la précipitation de l'hydroxyde rend les mesures impossibles et l'on ne retrouve pas le deuxième point d'équivalence mis en évidence par Lefebvre, car il est uniquement perceptible en présence d'un grand excès d'acide malique. De plus, l'addition d'ions cuivriques à la solution d'acide malique, modifie très nettement le pouvoir rotatoire, ce qui indique que la complexation a lieu dès le début de la neutralisation. Les variations du pouvoir rotatoire en fonction du pH

(fig. 8) laissent prévoir la formation d'au moins quatre espèces.

II.1. Mise en évidence des espèces

L'examen des courbes de formation (fig. 9*a*) montre, pour $10 < -\log a < 15$ (soit $3.3 <$ p$H <$ 7), un déplacement net des $-\log a$ pour des valeurs croissantes en Δm, ce qui suppose, comme dans le cas précédent, la présence d'espèces polynucléaires. En outre $\bar{r}$, tend vers l, deux hypothèses sont possibles: soit formation de la seule espèce Cu_nMal_n, soit présence simultanée du monomère CuMal et du polymère Cu_nMal_n. De part et d'autre de la zone de formation de l'espèce polynucléaire, la présence d'espèces protonées en milieu acide ($-\log a > 15$; p$H < 3.3$) et d'espèces hydroxydées en milieu alcalin ($-\log a < 9$; p$H > 8$) est tout à fait probable.

II.2. Calcul des constantes de stabilité et des constantes optiques

La comparaison des courbes de neutralisation normalisées $\bar{q}$, et par suite la convergence du processus d'affinement conduit aux valeurs des constantes de stabilité rassemblées dans le tableau 2. Pour pouvoir comparer nos résultats aux données bibliographiques, nous représenterons les valeurs calculées avec les constantes d'ionisation carboxyliques seules (22). Les courbes de répartition des malates de cuivre en fonction du pH sont représentées sur la fig. 9*b*.

Le tracé des spectres d'absorption (fig. 10) pour toutes les valeurs de pH dans le domaine des longueurs d'onde 500–900 nm, montre la formation graduelle d'espèces relativement stables qui déplacent le maximum vers les faibles longueurs d'onde. Le point isosbestique vers 780 nm indique la présence de deux espèces en équilibre, CuHMal et CuMal; la contribution de l'espèce $Cu(HMal)_2$ n'intervenant pratiquement pas.

A partir des données précédentes nous avons pu calculer à l'aide du programme ACREF 5A, les pouvoirs rotatoires et les coefficients d'absorbance de

chacune des espèces à la longueur d'onde de 700 nm (tableau 2).

II.3. Résonance magnétique du proton

Le paramagnétisme électronique des ions Cu^{2+} ne nous a pas permis d'envisager une étude quantitative des spectres rmn et nous n'avons pu que suivre l'interaction coordinat – ion métallique en observant l'élargissement progressif des raies de résonance de l'acide malique après addition de cuivre.

Conclusions

Jusqu'à p*H* 5, les malates d'uranyle ont été traités par "pit-mapping". Pour des p*H* plus élevés, la présence d'espèces polynucléaires perceptible sur les courbes de formation, dont le décalage $\Delta(-\log a)$ est proportionnel à l'augmentation de la concentration du métal Δm (6) a été confirmée par spectrophotométrie. Ces constantes de stabilité de ces polymères ont du être calculées par la méthode graphique de Lefebvre. Parmi les trois métaux étudiés, Cu, Y (19) et UO_2, c'est bien l'ion UO_2(VI) qui présente la plus forte tendance à former des complexes polynucléaires. Bien que la plupart des auteurs aient négligé la présence du monomère (UO_2)Mal (10, 11, 24), les études potentiométriques et polarimétriques révèlent la présence simultanée d'un monomère et d'un dimère. En outre, les spectres rmn nous ont permis de visualiser le dédoublement de la partie X correspondant à l'équilibre monomère ⇄ dimère, ce dernier pouvant présenter deux structures différentes.

Au delà de p*H* 6, la rmn se révèle inopérante car les rapports UO_2 : Mal utilisés, voisins de 1, favorisent la précipitation d'hydroxyde insoluble.

En ce qui concerne les malates de cuivre, le décalage $\Delta(-\log a)$ des courbes de formation traduit l'apparition de l'espèce dimérisée Cu_2Mal_2 en concentration faible par rapport au monomère.

Partie expérimentale

Les mesures conjointes de p*H*, de pouvoir rotatoire ou d'absorption ont été réalisées à l'aide d'un compensateur Metrohm E 388 couplé, soit à un spectrophotomètre Beckman DK 2A soit à un polarimètre photoélectrique Perkin-Elmer M141.

Les spectres rmn ont été effectués à 100 MHz sur spectrophotomètres Varian HA 100 et XL 100 en présence d'alcool isobutylique tertiaire comme référence interne. Les échantillons ont été préparés par mise en solution directe dans l'eau lourde, d'acide malique et de nitrate d'uranyle en proportions égales. La recristallisation du malate d'uranyle pour la préparation de l'échantillon, ne modifiant pas le spectre rmn a été abandonnée. Le p*H* a été ajusté et corrigé par addition d'une solution concentrée de NaOD en très faible quantité.

Remerciements

The reactions of metal acetylacetonates with acids

A. J. C. NIXON AND D. R. EATON

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received January 24, 1978

A. J. C. NIXON and D. R. EATON. Can. J. Chem. **56**, 1928 (1978).

The reactions of a number of metal acetylacetonates with trifluoroacetic acid have been investigated using nmr. The initial reaction involves protonation on the carbon atom of the ligand. In the case of the aluminum compound in coordinating solvents there is further reaction to give cationic complexes. The results are used to reinterpret the kinetics of ligand exchange for this compound. It is argued that, contrary to previous suggestions, the slow step is the breaking of the first metal oxygen bond to form a dangling ligand intermediate. A consequence of this conclusion is that intramolecular rearrangements of Al(III) β diketonates must proceed by twisting rather than by bond rupture mechanisms.

A. J. C. NIXON et D. R. EATON. Can. J. Chem. **56**, 1928 (1978).

Faisant appel à la rmn, on a étudié les réactions d'un certain nombre d'acétylacétonates de métaux avec l'acide trifluoroacétique. La réaction initiale implique la protonation de l'atome de carbone du ligand. Dans le cas du composé de l'aluminium, dans des solvants permettant la coordination, il y a une réaction subséquente conduisant à des complexes cationiques. On a utilisé ces résultats pour réinterpréter la cinétique de l'échange de ligand de ce composé. On présente des arguments qui, contrairement aux suggestions antérieures, suggéreraient que l'étape déterminante correspond aux bris du premier lien métal oxygène pour former un intermédiaire comportant un ligand en suspens. Une conséquence de cette conclusion implique que les réarrangements intramoléculaires de β-dicétonates de Al(III) doivent procéder par des torsions plutôt que par un mécanisme de rupture des liaisons.

[Traduit par le journal]

Introduction

A number of ligand exchange reactions of β diketonate complexes of metal ions have been shown to be catalyzed by acids. In particular the case of aluminum acetylacetonate has been investigated in some detail by Saito and Masuda (1, 2). These authors suggested that protonation occurs on the oxygen of the ligand and results in the formation of a dangling ligand intermediate of "considerably long lifetime". Their interpretation of the data leads to the conclusion that the rate determining step for ligand exchange was the breaking of the second metal–ligand bond. This conclusion has been quoted (3) to support the possibility of bond rupture mechanisms for the intramolecular rearrangement reactions of this and similar chelates. We have recently investigated (4) both the ligand exchange and isomerization reactions of vanadium(III) β diketonates with somewhat similar results. Saito and Masuda's mechanism implies that nmr spectra should provide evidence for the suggested intermediate. Such evidence could take the form of either additional lines in the spectra or of broadening or shifting of the $Al(acac)_3$ resonances due to rapid exchange with another species. The present paper reports nmr studies of the reactions of acids with a number of metal acetylacetonates which were undertaken with the objective of clarifying the ligand exchange mechanisms.[1]

Results

Trifluoroacetic acid has been used in most of these studies. It is a relatively strong acid (pK_a 0.25) which is miscible with most organic solvents. The trifluoroacetic anion is a poor ligand and side reactions such as oxidation are minimal. Sulphuric acid was used in some experiments and gave generally similar results but some charring of the solutions was evident at temperatures greater than 0°C. The reactions with $Al(acac)_3$ (acac = acetylacetonate) have been studied in most detail but results with V, Pd, Pt, Rh, and Co acetylacetonates will also be briefly reported.

The nature of the nmr spectra obtained by adding trifluoroacetic acid to $Al(acac)_3$ depends very markedly on the solvent used. However all the results can be fitted to the following scheme:

$$[1]\quad Al(acac)_3 + CF_3COOH \underset{}{\overset{\text{fast}}{\rightleftharpoons}} Al(acac)_2(acHac)^+ + CF_3COO^-$$

[1] A preliminary account of some of these results has appeared. See ref. 19.

[2] $Al(acac)_2(acHac)^+ + S \underset{}{\overset{slow}{\rightleftharpoons}} Al(acac)_2(acacH)S^+$

[3] $Al(acac)_2(acacH)S^+ + S \underset{fast}{\rightleftharpoons} Al(acac)_2S_2^+ + acacH$

In this scheme (acHac) represents the keto form of acetylacetone and (acacH) the enol form. S is a solvent molecule which may in some cases be water which is always present in small amounts. $Al(acac)_2(acacH)S^+$ is a dangling ligand intermediate (2).

In solvents such as dimethyl formamide (DMF) dimethyl sulphoxide (DMSO) and acetone, there are four sets of resonances. One set belongs to $Al(acac)_3$ and two other sets are assigned to the enol and keto isomers of acetylacetone. This assignment is confirmed by adding acetylacetone. All of these lines are sharp and are not shifted from the positions found in the absence of acid. The fourth set is assigned to $Al(acac)_2S_2^+$. The nmr spectrum for this complex (S = DMF) has been reported by Movius and Matwiyoff (5) and the observed chemical shifts are in good agreement with this report. The ionic nature of the product was confirmed by conductivity measurements (in acetone). The addition of $Al(acac)_3$ produced a large increase in the conductivity of trifluoroacetic acid. The ^{19}F nmr spectrum showed only a single line in the position expected for trifluoroacetic acid. A mixture of $Al(acac)_3$ and $Al(CF_3COO)_3$ (in acetone) showed two additional sets of lines, one corresponding to $Al(acac)_2S_2^+$, in good agreement with the additional lines obtained by adding CF_3COOH to $Al(acac)_3$ in acetone, and one corresponding to the complex $Al(acac)S_4^{2+}$ reported by Movius and Matwiyoff (5).

In these solvents, therefore, equilibrium [1] is to the left and equilibrium [3] is to the right. As a result the intermediate species of eqs. [1]–[3] are present only in very low concentrations and the nmr spectra show only the initial reactant ($Al(acac)_3$) and the final products $Al(acac)_2S_2^+$ and acacH.

The situation in non-coordinating solvents such as benzene-d_6 or nitromethane-d_3 is different. The initial effect of adding CF_3COOH is to broaden the CH protons of $Al(acac)_3$. In a solution in benzene 0.5 *M* in CF_3COOH the C—H resonance is ~30 Hz broad (at 100 MHz). At the same time, weak resonances corresponding to acacH appear. The chemical shifts of $Al(acac)_3$ are entirely unaffected by CF_3COOH but those of acacH are significantly changed. In these cases since S is a poor ligand equilibria [2] and [3] are displaced to the left. As a result there is a sufficient concentration of $Al(acac)_2(acHac)$ to cause significant broadening of the C—H resonances. Protonation has occurred on the carbon at a rate moderately fast on the nmr time scale. Only a small amount of acacH has been formed and this appears at an average chemical shift due to equilibrium [3]. Since benzene is unlikely to function even as a poor ligand it is possible that S may represent trace amounts of water in the above case.

Chloroform and methylene chloride show behaviour as solvents which is intermediate between DMF and benzene. There is some broadening of the C—H resonance and new lines attributable to $Al(acac)_2S_2^+$ have appeared. Figure 1 shows a 220 MHz spectrum of the methyl region of $Al(acac)_3$ + CF_3COOH in $CDCl_3$. A small splitting of the resonance assigned to $Al(acac)_2S_2^+$ is apparent with one component being rather broader than the other. By analogy with the results of Movius and Matwiyoff (5) the two lines are assigned as *cis*- and *trans*-$Al(acac)_2S_2^+$ with the *cis* line being broadened by exchange between the two non-equivalent methyl environments. In contrast to the results in DMF and DMSO the free ligand lines show small shifts from their usual positions. These shifts cannot be accounted for by the effect of CF_3COOH alone. In these cases the equilibria [2] and [3] are sufficiently far to the right to give significant amounts of $Al(acac)_2S_2^+$ but the concentrations of intermediates remaining are sufficiently high to give line broadening and shift effects. The observed chemical shifts of the various species in different solvents are summarized in Table 1.

The results for other metal acetylacetonates may be summarized briefly. $Co(acac)_3$ and $Rh(acac)_3$ in $CDCl_3$ showed marked broadening of the C—H resonance but no new lines appeared. We deduce that reaction [1] occurs but that the stability of the complexes is too great to allow reactions [2] and [3] to proceed. With $Pt(acac)_2$ only a small broadening

*Shifts in ppm from TMS, 100 MHz, $T = 27°C$.

of the C—H resonance was observed. This complex is apparently difficult to protonate. The paramagnetic $V(acac)_3$ showed a decrease in the intensity of the CH_3 and C—H resonances with concurrent appearance of free ligand lines. At least one new, but extremely broad, resonance appeared downfield from the CH_3 line, i.e. in a position corresponding to complexed acetylacetone. Superficially at least $V(acac)_3$ behaves similarly to $Al(acac)_3$. The reaction of CF_3COOH with $Pd(acac)_2$ leads to the appearance of a number of new lines, some, but not all, of which can be assigned to free ligand. The ^{19}F spectrum of a solution of $Pd(acac)_2$ with CF_3COOH in $CDCl_3$ shows new resonances 0.71 and 1.44 ppm downfield from CF_3COOH. It appears that CF_3COO^- can replace acac on $Pd(acac)_2$ in a manner analogous to that observed for other anionic ligands (6). A side reaction was also noted which led to loss of the TMS calibrant and the appearance of a new line 0.21 ppm downfield from TMS. At the same time metallic Pd is deposited. This reaction may be analogous to the reaction between lead tetraacetate and TMS in trifluoroacetic acid (7).

Discussion

The above results are not consistent with the mechanism of Saito and Masuda (1, 2) for ligand exchange in $Al(acac)_3$.

The three reactions [1]–[3] provide a pathway for ligand exchange. Modifications are possible, e.g. reaction [2] could occur without transferring the proton from carbon to oxygen. However the three basic steps of (*a*) protonation, (*b*) breaking and reforming the first metal–oxygen bond, and (*c*) breaking and reforming the second metal–oxygen bond must be present. Since the overall reaction is slow at least one of these steps must be slow.

Contrary to the suggestion of Saito and Masuda protonation occurs on the carbon. Brouwer (8) has investigated the protonation of a number of 1,3-dicarbonyl compounds. In some cases the initial protonation is on oxygen and in others it occurs on carbon. Acetylacetone protonates initially on oxygen but substitution of CH_3 by a more electron withdrawing group, e.g. OC_2H_5, leads to carbon protonation. Since the aluminum ion will withdraw electrons from the oxygen, carbon protonation is perhaps not surprising. Protonation is clearly not the slow step.

The following argument shows that reaction [3], the breaking of the second Al—O bond, cannot be slow as was suggested by Saito and Masuda. In THF (the solvent used in ref. 1.) equilibrium [3] is clearly to the right since the nmr spectra show only $Al(acac)_2S_2^+$ and free ligand rather than $Al(acac)_2(acacH)S^+$. If the rate constant for the forward reaction were small, that for the backward reaction would have to be even smaller to give a large equilibrium constant. If this were the case the overall rate

of ligand exchange would be determined by the backward reaction and would be proportional to ligand concentration. Saito and Masuda found the rate to be independent of ligand concentration. The nmr results support this conclusion since they indicate that in less strongly coordinating solvents the free ligand is in rapid exchange with another species. Only a reaction involving breaking of the second bond can lead to exchange with free ligand. Breaking of the first Al—O bond (reaction [2] or a modification thereof) must therefore be the slow step.

This conclusion does not represent any disagreement with the experimental results of Saito and Masuda. Their argument in favour of the slow step being the breaking of the second bond was based on the observation that the activation energies were the same for the acid catalyzed and uncatalyzed reactions. They considered that this observation was inconsistent with the breaking of the first bond being the rate determining step. However an examination of Fig. 5 of ref. 2 suggests that their rate constant for acid catalysis also contains a term for water catalysis which may be dominant. In this case the reported activation energies refer to the same reaction. The remainder of their data is entirely consistent with the present interpretation.

The above discussion applies to acid catalyzed ligand exchange reactions. Similar arguments are relevant to the uncatalyzed and water catalyzed pathways. If the rate of breaking the first bond is slow for the protonated complex it will be even slower in the neutral complex. Data in the literature allow an estimate of this rate for some acetylacetonate complexes. Thus Pearson and Anderson (9) have studied the kinetics of the formation of $Cu(acac)^+$ and concluded that the rate determining step is ring closure to form the second M—O bond and the six membered chelate ring. This conclusion is consistent with a great deal of other data on the formation of six membered chelates (10, 11). Since for most acac complexes the equilibrium constant clearly favours the chelate over the dangling ligand isomer it follows that if the formation reaction is slow the dissociation to the dangling ligand must be very slow. The postulation of rapid dangling ligand formation for $Al(acac)_3$ is therefore anomalous. The rate for $Cu(acac)^+$ may be estimated. The formation constant for the complex (14) is $\sim 10^{10}$. For a model monodentate ligand, e.g. propionic acid (14) $K \sim 10^2$. The overall rate of formation (9) is 2×10^4 s^{-1} M^{-1}. Hence the rate for dangling ligand to chelate is $\sim 10^2$ s^{-1} and the equilibrium constant for this reaction is $\sim 10^8$. This gives a rate for the chelate to dangling ligand intermediate of 10^{-6} s^{-1}. Fortuitously this agrees exactly with the rate 6×10^{-5} min^{-1} given by Saito and Masuda for the uncatalyzed ligand exchange of $Al(acac)_3$. Clearly, though, the observed rates are consistent with the rate determining step being the breaking of the first M—O bond. Catalysis by water increases this rate by taking up the sixth coordination position and stabilizing the dangling ligand intermediate. Acid catalysis operates by weakening the M—O bond by protonating either the carbon or the oxygen (indirectly). Evidence for such increased lability is provided by the studies of Cramer and Chudyk (12) and of van Leeuwen and Praat (13) on metal complexes of neutral acetylacetone.

The above conclusion has important consequences in the area of intramolecular rearrangements of Al(III) β diketonates (3). A number of authors (14–16) have discussed such mechanisms in detail but have been unable to reach a definite decision as to whether they involve a bond rupture or a twisting process. The above result eliminates all bond rupture mechanisms. The rate for such a mechanism cannot be faster than ligand exchange which is much slower than rearrangement. By analogy a similar argument may hold for Ga and In β diketonates but cannot be applied directly to V, Zr, and Hf complexes (4, 17) since the rates of ligand exchange reactions of these compounds are not determined by the rates of breaking M—O bonds. However, for the case of $V(acac)_3$ it is interesting to note that there is no acid catalysis of the rearrangement reactions but the ligand exchange is strongly acid catalyzed (4). The present results suggest that $V(acac)_3$ reacts with acids in a manner similar to $Al(acac)_3$. If this is the case, acid catalysis of the rearrangement reactions of V(III) β diketonate complexes would be predicted if they involve metal–oxygen bond breaking. The fact that catalysis is not observed therefore argues against a bond breaking mechanism. Catalysis of ligand exchange in cases where there is a term in the rate equation dependent on ligand concentration can be rationalized by noting that the rate determining step involves reaction of free ligand with $M(acac)_2(acacH)S^+$ or with $M(acac)_2S_2^+$ which require protons for their formation. The above results are therefore also consistent with the reported acid catalysis of ligand exchange of $Pd(acac)_2$ (18).

Experimental

Metal acetylacetonates were obtained from Research Organic/Inorganic Chemical Co. Nuclear magnetic resonance spectra were obtained with a Varian HA 100 spectrometer (probe temperature 27°C) using tetramethyl silane as an internal calibrant. A few samples were examined on a Varian 220 MHz spectrometer to obtain optimum resolution. All solvents were deuterated except DMF.

The third-order rate constants of the reaction between tetraphenylphosphonium chloride and sodium hydroxide in binary tetrahydrofuran–water systems have been determined as a function of temperature. Increasing the THF content of the reaction medium up to 70% (v/v) results in a ca. 10^6-fold rate acceleration at 25°C. This is explained as due to increased desolvation of reactants as well as an opposite effect on the transition-state solvation in THF-rich media. The rate in deuterium oxide is higher than in water and the kinetic isotope factor k'_{DO^-}/k'_{HO^-} depends strongly on temperature. The inverse proportionality of rate to the water concentration of medium showed that a large number of water molecules (about 13) is to be removed from the solvation sheaths of reactants before formation of the activated complex. The thermodynamic activation parameters have been derived and expressed as functions of the composition of the medium. It is found that $\Delta H^{\ddagger}$ decreases by about 17 kcal/mol over the range 0–70% THF, while $\Delta S^{\ddagger}$ decreases by about 29 cal mol^{-1} deg^{-1} over the same range. As a result, $\Delta G^{\ddagger}$ shows a net decrease of 8 kcal/mol indicating partial compensation between $\Delta H^{\ddagger}$ and $T\Delta S^{\ddagger}$.

FAYEZ Y. KHALIL et GUNNAR AKSNES. Can. J. Chem. **56**, 1933 (1978).

On a déterminé, en fonction de la température, les constantes de vitesse du troisième ordre de la réaction entre le chlorure de tétraphénylphosphonium et l'hydroxyde de sodium dans un système binaire tétrahydrofuranne–eau. Une augmentation de la quantité de THF dans le milieu réactionnel jusqu'à environ 70% (v/v) conduit à une augmentation de vitesse, à 25°C, d'environ 10^6. On explique ce résultat sur la base d'une augmentation de la désolvatation de réactifs ainsi que par un effet opposé sur la solvatation de l'état de transition dans un milieu riche en THF. La vitesse dans l'eau lourde est plus grande que dans l'eau et l'effet isotopique k'_{DO^-}/k'_{HO^-} varie d'une façon importante avec la température. Le fait que les vitesses varient d'une façon proportionellement inverse à la concentration d'eau dans le milieu montre qu'un grand nombre de molécules d'eau (environ 13) doivent être enlevées des couches de solvatation des réactifs avant la formation du complexe activé. On a évalué les paramètres d'activation thermodynamique et on les a exprimés en fonction de la composition du solvant. On a trouvé que le $\Delta H^{\ddagger}$ diminue par environ 17 kcal/mol lorsque la quantité de THF varie de 0–70% alors que le $\Delta S^{\ddagger}$ diminue d'environ 29 cal mol^{-1} deg^{-1} aux mêmes concentrations. Il en résulte que le $\Delta G^{\ddagger}$ présente une diminution nette de 8 kcal/mol indiquant une compensation partielle entre le $\Delta H^{\ddagger}$ et le $T\Delta S^{\ddagger}$.

[Traduit par le journal]

Introduction

The solvent effects on the alkaline decomposition of quaternary phosphonium salts have been the subject of our interest in recent years (1–4). Different studies of these reactions have been made before (5); but treatment of the problem from the viewpoint of medium effects is, however, far less exhaustive; it is the aim of our present work to examine these effects. As a representative of this type of reaction we have chosen tetraphenylphosphonium chloride which reacts with sodium hydroxide to give tetraphenylphosphine oxide and benzene. We have studied the reaction both kinetically and thermodynamically in a series of binary organic solvent–water mixtures. The solvents taken were nonpolar as well as dipolar aprotic ones, namely, dioxane–water (2), acetone–water (3), and dimethyl sulphoxide–water (1) mixtures. Because the reaction takes place between two ions, the changes of solvation that reactants exhibit upon transfer from the protic solvent water to a dipolar aprotic solvent such as acetone or dimethyl sulphoxide will have a remarkable effect on rate. Our previous work (1–3) has established that tremendous rate acceleration can be obtained, giving rise to rate factors as large as 9 powers of 10 upon addition of a dipolar aprotic

solvent to the reaction medium (1). Such an observation has also been reported for many organic reactions involving anions (ref. 6 and references cited therein and ref. 7) and has often been attributed to changes in solvation of reactant anion as well as the transition state (1, 8–10).

Tetrahydrofuran (THF) is a solvent of low ionising power (11) with a dielectric constant of 7.4 at 25°C, a dipole moment of 1.7 D (12), and a certain hydrogen-bonding ability (13). It is classified as structure making when it is a cosolvent in water (14) and it possesses a suitable range of miscibility with water which allows for preparing binary solvent mixtures varying widely in composition. The present paper deals with a kinetic investigation of the alkaline decomposition of tetraphenylphosphonium chloride in a series of THF–water mixtures at different temperatures in order to accumulate kinetic, thermodynamic, and mechanistic data for confirming the reaction behaviour in protic – dipolar aprotic media. The major effect of THF on rate will be a consequence of the modifying effect on the water structure (15, 16) and hence on the hydrogen-bonding ability of the mixed solvent. The reaction was also studied in a THF–D_2O mixture at several temperatures in conjunction with kinetic solvent isotope effect as well as changes in thermodynamic parameters of activation.

Experimental

Tetraphenylphosphonium chloride (Fluka) was obtained in an adequately pure form and was used without further purification. Tetrahydrofuran (Fluka) was freed of peroxides by treatment with ferrous sulphate and sodium bisulphate, then solid potassium hydroxide, followed by drying and fractional distillation from sodium metal. The pure solvent boiled at 65.2°C (17). The heavy water (Norsk Hydro) used was 99.8% D_2O.

The kinetic procedure for measurement of the reaction rate was based on determination of the amount of sodium hydroxide consumed during the course of the reaction. The reaction mixtures were prepared so as to contain 0.02 mol/ℓ of NaOH in a series of THF–H_2O mixtures. In addition, a solution containing 0.02 mol/ℓ NaOD (prepared by dissolving Na metal in D_2O) in 70% THF–D_2O mixture was prepared. Thermally equilibrated quantities of each solvent mixture were mixed with 0.02 mol/ℓ amounts of the phosphonium salt previously weighed in volumetric flasks. The solutions were thoroughly shaken and immediately placed in a thermostat adjusted to within ±0.05°C. At time intervals accurate samples were taken and rapidly poured into an excess of standard HCl. The resulting solutions were analysed by back titration against standard NaOH to the phenolphthalein end point. Several runs were made in duplicate and the results were concordant within ±2%. The values of the dielectric constant of the mixed THF–water solvents were interpolated from the data reported by Heydtmann and Steiger (18).

Results and Discussion

The rates of the reaction were determined in binary solvent mixtures of THF and water covering the range 0–70% (v/v) in steps of 10%. The temperatures at which the reaction was studied depended on the rates in different media and varied from 20 to 55°C, where each run was carried out at six temperatures. Rate measurements were also made in a medium consisting of 70% THF (v/v) and 30% D_2O using DO^- as the attacking anion. In all cases the reaction was found to obey third-order kinetics in which the rate was first order in the phosphonium cation and second order in the hydroxide or deuteroxide anions, respectively. The specific rate constants were obtained from slopes of the graphical plots, represented in Fig. 1, of $(1/(a-x)^2) - 1/(a^2)$ vs. time in the range below 30% completion in H_2O-rich solvents and 75% completion in THF-rich solvents. The reason for this discrepancy is that in more aqueous media the produced phosphonium oxide precipitated and had a catalysing effect on the reaction causing a marked deviation of the linear third-order plots towards higher rate. In less aqueous media, however, no precipitation of tetraphenylphosphonium oxide took place and the reaction could be followed accurately up to 75% completion. The activation energies were determined from the appropriate Arrhenius plots of log k' vs. $1/T$. The results are set forth in Table 1. The thermodynamic parameters of activation $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$, as well as the preexponential factor log A were obtained from the expressions (19) $k' = (kT/h) \exp(-\Delta G^{\ddagger}/RT)$, $\Delta H^{\ddagger} = E - RT$, $\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\Delta S^{\ddagger}$, and $k' = A \exp(E/RT)$, respectively.

$k'_{70\%THF}/k'_{water}$		1.2×10^{6}		4.8×10^{5}	3.2×10^{5}

[a]Equal concentrations of phosphonium and hydroxide or deuteroxide ions (0.02 M) were taken throughout.
[b]Total ionic strength amounts to 0.04. No corrections for zero ionic strength or thermal expansion were made.

Effect of THF Content of the Medium

The gradual addition of THF to water causes a large increase in the rate. Thus, in 70% THF–water (v/v) at 25°C the rate is higher by a factor of 6 powers of 10 than that in water at the same temperature. The plot of log k' vs. the concentration of THF, expressed, in moles per litre of the mixed solvent, shows a relatively slow increase in rate in the water-rich solvents followed by a rapid increase when the THF content exceeds about 30% (v/v) or 4 mol/ℓ (Fig. 2). It is well known that water has an extensive tendency to solvate ions strongly and to form hydrogen bonds with hydroxide anions (20, 21). This is favoured by the high dielectric constant of water which, in turn, is due to the polar nature of this solvent and to the fact that the dimensions of the water molecule favour a tetrahedrally coordinated structure (21). Diluting water with a dipolar aprotic solvent, the solvating power of the medium will decrease progressively until it reaches a minimum in slightly aqueous or nonaqueous solvents. Consequently, the retarding effect of the solvation sheath around the anion will drop causing a large enhancement in the reaction rate. The rate-retarding role of water can be shown; for example, in the alkaline decomposition of some tetraalkylphosphonium ions (22) it was found that the anhydrous compound decomposed within 30 min at 25°C, whereas its aqueous solution was refluxed for 40 h without any appreciable change. It is to be concluded, therefore, that the increase in rate of the present reaction with increasing THF content of the medium is, at least partly, attributable to desolvation of the hydroxide ion. The latter, being the strongest base that can exist in water, and its catalytic activity greatly inhibited by its extensive hydration, will gradually loose its solvation sheath, particularly in high THF contents, and thus will be much more reactive. The effect is, of course, relatively slight at high water concentrations in which there is enough water to hydrate the HO^- anions as well as to form hydrogen bonds with the cosolvent. This explains the initial slow rise in the curves of Fig. 2 followed by a steep increase.[1]

It may be assumed that the inverse proportionality of the reaction rate to the water concentration of the medium can be included in the kinetic equation, shown below, since the removal of the hydration sheaths of reactants is an important process prior to formation of the activated complex:

$$[1] \qquad \frac{dx}{dt} = \frac{k_1}{[H_2O]^n}(a - x)(b - x)^2$$

in which dx/dt, the reaction rate, is assumed to be inversely proportional to the nth power of the molar concentration of water, k_1 being the proportionality constant, $(a - x)$ the concentration of the phosphonium cation, and $(b - x)$ that of the hydroxide anion. Practically, the concentration of water remains constant during the reaction course, and therefore the value $k_1/[H_2O]^n$ will be equal to the specific

[1]Under the conditions of the present experimental technique it was quite difficult to follow the reaction with sufficient accuracy up to more than 70% THF (v/v). The question, therefore, whether the plot of log k' vs. amount of THF added would be expected to level off at higher organic solvent compositions, remains without answer.

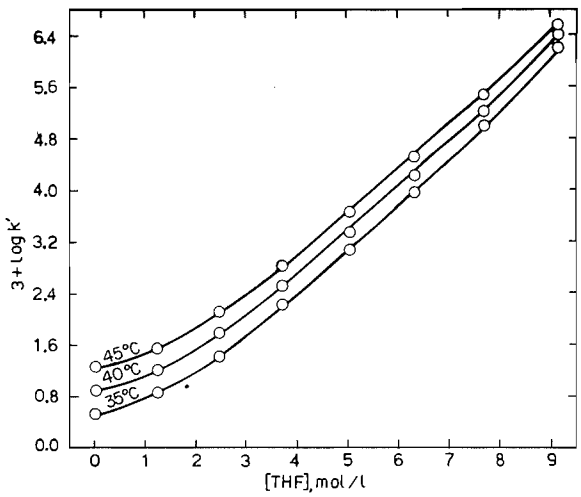

FIG. 2. Plots of the rate constant (log k') for the reaction under investigation vs. the concentration of THF in the medium.

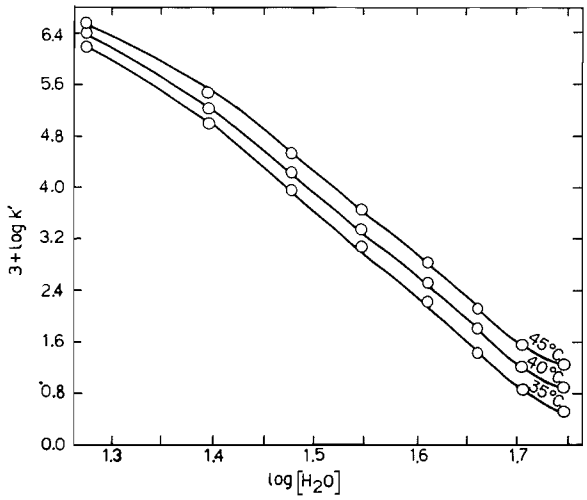

FIG. 3. Variation of the rate constant (log k') for the reaction studied with the concentration of water (log [H_2O]) in the medium at different temperatures.

third-order rate constant k', i.e.,

$$[2] \qquad k' = k_1/([H_2O]^n)$$

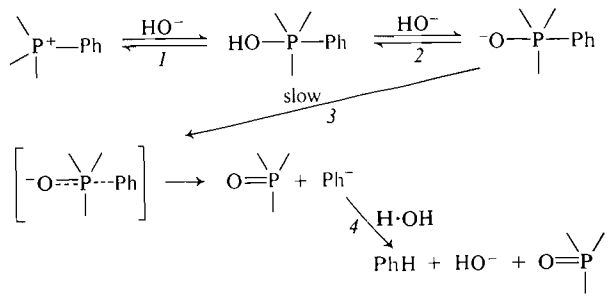
and

$$[3] \qquad \log k' = k_2 - n \log [H_2O]$$

where k_2 is another constant. Consequently, the plot of log k' against log [H_2O] should be linear with a negative slope of n. Such plots, illustrated in Fig. 3, gave a linear relationship in the range 10–60% (v/v) THF or 51–25 mol/ℓ of water. The value of n estimated in this way amounts to about 13, confirming our assumption (2) that a large number of water molecules are involved in the activation process. This argument may find further support if one calculates $k'[H_2O]^n$ according to eq. [2], putting, for example, n = 1–12. The resulting values show the same remarkable variation with solvent composition, though decreasing dependence is exerted as n approaches 13. On the other hand, the value $k'[H_2O]^{13}$ was found to be almost constant and independent of the water content or the solvent composition of the medium. Nevertheless, this large value of n is not surprising if one considers that the HO^- anion is, at least, trihydrated in water (23) and that the solvation sheaths around two hydroxide anions and one phosphonium cation have to be disrupted before the formation of the activated complex can take place.

Rate in Deuterium Oxide

The kinetic deuterium isotope effect constitutes an important tool which has found wide application, both kinetically and mechanistically (24). The simple use of such effect involves the determination of whether a bond to a hydrogen or deuterium is broken in the rate-determining step of the reaction, and hence mechanistic information can firmly be established. In the present work, the kinetic solvent deuterium isotope effect was investigated under the same experimental conditions by measuring the rate in 70% THF – D_2O mixture at six different temperatures. In these experiments deuteroxide ion furnished the attacking nucleophile instead of hydroxide ion. The results are included in Table 1, where it is evident that the rate in D_2O is always higher than that in H_2O. The observation confirms that the reaction mechanism does not involve the breaking of any bonds to H or D in the rate-determining step, as shown below.



in which preequilibrium *1* is a rapid addition of the HO^- ion to the phosphorus atom of the quaternary salt, whereas preequilibrium *2* involves a rapid formation of the conjugate base of the pentacovalent phosphorus intermediate. This is followed by step *3* which is a slow rate-determining formation of tetraphenylphosphine oxide and the phenyl carbanion. The latter finally takes up a proton in the

TABLE 2. Comparison of the kinetic isotope effects for the reaction in different solvent systems

Solvent mixture	$D_{25°C}$ (organic solvent)	k'_{DO^-}/k'_{HO^-} (at 25°C)	ΔE $E_{HO^-} - E_{DO^-}$ (kcal mol^{-1})	$t(k'_{DO^-}/k'_{HO^-} = 1)$ (°C)
70% dioxane–D_2O	2.1	2.32	3.83	69
70% THF–D_2O	7.4	3.80	4.80	77
70% acetone–D_2O	20.4	2.19	5.63	52
60% DMSO–D_2O	46.4	1.50	9.89	35

rapid step *4* to give benzene. The formation of a pentacovalent rather than a hexacovalent intermediate, which is formed during the alkoxide-promoted decomposition of phosphonium salts (4), takes place since the ionised phosphorane is sufficiently energetic to expel the phenyl carbanion.[2]

The present isotope effect is, therefore, shown to be a secondary rather than a primary one. This effect, expressed in the kinetic factor k'_{DO^-}/k'_{HO^-}, exhibits a strong dependence on temperature. It amounts to 4.5 at 20°C and drops to 2.3 at 40°C (Table 1). The temperature at which this factor becomes unity, i.e. when the rate in 70% THF – H_2O becomes equal to that in 70% THF–D_2O mixture, is extrapolated to be 77°C. The value of this temperature was found to be 69°C for dioxane–water (2), 52°C for acetone–water (3), and 35°C for dimethyl sulphoxide – water systems (cf. Table 2). Furthermore, although the value of ΔE, which is the difference in activation energies between the hydroxide- and deuteroxide-promoted reactions for the different solvent systems runs parallel to the increase in polarity of the medium, yet the change in the kinetic isotope factor does not follow the same sequence. The anomaly is exhibited by THF–D_2O medium which should have given a value of k'_{DO^-}/k'_{HO^-} between that of dioxane–D_2O and acetone–D_2O mixtures. This variation shows clearly that specific solvent effects play an important role in determining the relative rates in D_2O when mixed with different organic solvents, as compared to the rates in H_2O when mixed with the same solvents. The lower activation energy and the higher reaction rate in the THF–D_2O mixture as compared to those in the corresponding THF–H_2O mixture (Table 1) are attributed partly to the higher basicity of DO^- in D_2O than HO^- in H_2O (25), and partly due to a difference in the stabilities of the internal solvent structure of the two media towards rise in temperature (1, 3). The latter effect, which directly influences the solvating power of the reaction medium as well as the structural stabilities of the solvation shells of initial and transition states, predominates at temperatures higher than 77°C, causing a lower rate in D_2O than in water.

The Role of Changing Dielectric Constant

According to Born's theory (26) the rate of reaction between two ions of opposite sign should show inverse proportionality to the dielectric constant of the medium, where the plot of log k' vs. $1/D$ should be linear with a negative slope. Applying this to the reaction under investigation in the present solvent mixtures gave a straight line only in the high dielectric constant range (Fig. 4). Deviation from linearity towards lower rates starts beyond 40% (v/v) THF and may be attributed to differential solvation effects (19). The slope of the linear portion of the plot gives a value of 0.55 Å for $r^{\neq}$, the radius of the activated complex, which is far below the calculated value (5–6 Å) (2). Treating the solvent as one with a uniform dielectric constant and a zero ionic strength, which is not the case, causes discrepancy and renders the rates of ionic reactions poorly correlatable to the dielectric constant of the medium (27, 28). In other words, the specific solvent effects encountered here add further evidence to the fact that the type of solvent is more important than its polar character, as estimated by the dielectric constant. This furnishes another example violating the

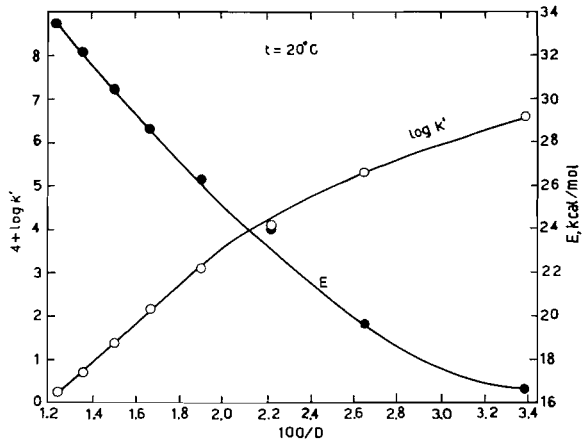

FIG. 4. Dependence of the rate constant (log k') and activation energy E for the present reaction upon the dielectric constant ($1/D$) of the binary solvent mixture.

[2]Further evidence for the pentacovalent intermediate can be found in ref. 38.

Hughes–Ingold theory (29) which simply relates the reaction rate to the polarity of the solvent.

It has been pointed out frequently (8–10) that separation of solvent effects into ground and transition-state contributions in bimolecular reactions involving anions revealed that higher rates and lower activation energies in dipolar aprotic solvents are due also to the increased solvation of transition states in those solvents. Decreasing the polarity, and hence the dielectric constant, leads to more solvation of the transition state, where there is charge dispersal, as the solvent changes from protic to dipolar aprotic (6, 20). As a result, the potential energy of the transition state will decrease (19) and hence the activation energy will drop more and more as the medium is enriched in THF. The drastic lowering (about 17 kcal/mol) of E over the whole range of solvent composition is thus rationalised in terms of some combination of these two factors, namely reactant desolvation and increased transition-state solvation. The latter effect, however, becomes more evident at sufficiently low dielectric constants where the organic cosolvent prevails. In this range of solvent composition there is not enough water to solvate the transition state efficiently and therefore solvation of the latter will take place mainly with the dipolar aprotic solvent. No doubt such a large decrease in E (cf. Fig. 4) manifests the internal structural changes, and hence the alterations in hydrogen-bonding ability, of the solvent mixture as the latter is varied in dielectric constant.

Thermodynamic Activation Terms

Table 3 lists the thermodynamic data of activation ($\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$) together with the preexponential factor log A. All parameters show considerable dependence on solvent composition. Thus, the increase in reaction rate is associated with a decrease in activation enthalpy ($\Delta H^{\ddagger}$) by about 17 kcal/mol, which is partially compensated (30–32) through the decrease of $\Delta S^{\ddagger}$ by about 29 cal mol^{-1} deg^{-1} over the whole range of medium composition, thus causing $\Delta G^{\ddagger}$ to decrease only by 8 kcal/mol. The considerable changes in these functions imply that the contributions from relative changes in solvation shells of reactants and transition state during the course of the reaction are very important factors in the rate process. Theoretical calculations and interpretations of such contributions (33, 34) expected of microscopic solvent changes are complicated by the involvement of several steps in the reaction mechanism. However, it is possible to correlate the trend in each of these parameters with the ionising power or hydrogen bonding ability of the solvent system. Thus, the decrease in $\Delta G^{\ddagger}$ with successive addition of THF is a direct consequence of the decrease in the free energy involved in breaking the hydrogen bonds associated with the ground state. The latter energy will definitely decrease as the mixed solvent is made less hydrogen bonding by decreasing its water content. The large decrease in the value of $\Delta H^{\ddagger}$ depicted in Table 3 as the medium composition passes from 0 to 33 mol% THF indicates that in water-rich solvents more energy has to be overcome before the transition state can be formed. The substantial diminution of $\Delta S^{\ddagger}$ values with addition of THF is also indicative of remarkable changes in solvation effects. A solvent-sorting phenomenon is evident in the nonlinear drop of $\Delta S^{\ddagger}$ with changes in solvent composition (35). Opposing the decrease in E, the preexponential factor log A decreases progressively along the same range of solvent composition. However, it is the enormous decrease in E that controls the reaction rate rather than the drop in A.

It is noteworthy that although the trends in the thermodynamic parameters of the reaction in different solvent systems (1–3) appear, at the first glance, to be more or less similar, complications arise upon comparison of the absolute values of these parameters. Such comparison is, however,

rendered easier if enough data are available concerning the exact specific effects of each binary solvent system as well as the relative hydrogen-bonding energies and other relevant thermodynamic properties of its components (36, 37).

Received July 25, 1977[2]

PATRICK GENESTE, ROBERT DURAND, JEAN-MARC KAMENKA, HELMUT BEIERBECK, ROBERT MARTINO, and JOHN K. SAUNDERS. Can. J. Chem. **56**, 1940 (1978).

The carbon-13 chemical shifts for a number of relatively rigid ketoximes are presented. It is shown that the chemical shift difference, $\Delta\delta$ (*syn–anti*), for the carbons α to the oxime carbon depends on the dihedral angle between the C=N and C_α—H bonds. This stereochemical dependence is then used to determine the preferred conformation of substituted cyclohexanone oximes.

PATRICK GENESTE, ROBERT DURAND, JEAN-MARC KAMENKA, HELMUT BEIERBECK, ROBERT MARTINO et JOHN K. SAUNDERS. Can. J. Chem. **56**, 1940 (1978).

On rapporte les déplacements chimiques du carbone-13 d'un certain nombre de cétoximes relativement rigides. On démontre que la différence des déplacements chimiques, $\Delta\delta$(*syn–anti*), pour les carbones en α du carbone de l'oxime dépend de l'angle dièdre entre les liens C=N et C_α—H. On utilise ensuite cette corrélation stéréochimique pour déterminer la conformation privilégié des oximes de cyclohexanone substitués.

[Traduit par le journal]

Currently, carbon-13 nuclear magnetic resonance spectroscopy (^{13}Cmr) is an informative and important technique for conformational analysis. The shielding parameters have been shown to be very sensitive to environment (1) such that relatively small conformational changes lead to significant chemical shift variations. During a study of the reactivity of ketones and ketoximes, it was necessary to have increased knowledge of their conformations in solution. From earlier reports (2, 3), it appeared that ^{13}Cmr may furnish such information since $\Delta\delta$(*syn–anti*) values for the carbons α to the oxime carbon are significant and hence we undertook a study of the ^{13}Cmr chemical shifts of a number of relatively rigid ketoximes. In this paper we present the results of this study and their subsequent use in the conformational analysis of substituted cyclohexanone oximes.

Results

The ^{13}Cmr spectral data for the ketoximes studied are given in Table 1. The chemical shifts for compounds **1**, **3**, **12**, **13**, **16**, **17**, and **18** have been given elsewhere (3). The two sets of values agree within 0.3 ppm, with the exception of **17** and **18** where slight assignment modifications have been made. The assignments for the remaining compounds were made with the aid of single frequency off-resonance decoupled (sford) spectra, from the chemical shifts for the corresponding ketones (4), and the observation (2, 3) that for carbons α to the C=N bond, the carbon *syn* to the OH group is shielded relative to the *anti* position. Also, for oximes whose corresponding ketones do not have two-fold symmetry, distinguishable isomers exist, which were generally present in unequal amounts. For compound **2**, carbons 1, 2, 4, 6, 7 (the quaternary carbon), and 8 (the CH_3 carbons) were readily assigned from the sford spectrum. The protons on carbon 2 have a chemical shift difference of 1 ppm (5) and thus this carbon appeared in the sford spectrum as the X part of an ABX system, whereas the other methylenes appeared as the normal triplets. The remaining resonances were assigned to carbons 3 and 5 on the basis of the different shifts induced by $Pr(fod)_3$. The signals for **3** could then be assigned using the data for **2** together with the effect of a tertiary butyl group (6). The sford spectra for **4**, **5**, and **6** led to straightforward assignments of carbons 1, 3, and 5 in each compound and for carbon 2 in **4** and **5**. The only ambiguity is the distinction between (*i*) the pairs of carbons β and γ to the oxime and (*ii*) carbons 4 and 8 of compound **4**. The latter were assigned from the corresponding ketone data (4). In **1**, **2**, and **3**, $\Delta\delta$(*syn–anti*) for the β carbon is approximately -1.3 ppm and thus in **4**, **5**, and **6**, the

[c]Could be interchanged.

more shielded β or γ carbon was assigned as the *syn*. The carbon resonances for **7** were assigned in a similar manner.

The twistane isomers were present in unequal amounts. The spectrum of the major isomer, **8**, was assigned from the sford spectrum and by comparison with the corresponding ketone (7). The only carbons of the minor isomer that could be assigned were those corresponding to carbons 3 and 4. For compounds **10–13** use of the sford spectra together with the reported values for the corresponding ketones (4, 8) led to the assignments given in Table 1. The ketone corresponding to **14** gave the following spectrum: 217.1 (C-2), 45.6 (C-1,3), 44.0 (C-4,9), 31.5 (C-5,8), and 26.4 ppm (C-6,7). The spectrum of **14** was then assigned using these values together with the sford spectrum as was the spectrum of **15**.

The two oximes, **17** and **18**, were present in unequal amounts with the major isomer having the CH_3 and the OH groups *anti* (3). From the sford spectrum, carbons 1, 2, and 7 (the CH_3 carbon) of **17** could readily be assigned as could carbon 6 since it appeared as the X part of an ABX system. Carbons 4 and 5 should be little changed from their position in **3** and thus the remaining resonances were assigned. In **18**, the methyl group is axial as evidenced by the chemical shift at 20.6 ppm which can only be assigned to carbon 4. The sford spectrum led to the assignments of carbons 1, 2, and 7 and since C-5 is δ to the CH_3 group it should have about the same chemical shift in **2**, **17**, and **18**. Also C-6 should be shielded by about 4.0 ppm in **18** relative to **2** owing to the axial CH_3 group at C-2. Thus, C-5 absorbs at 26.9, C-6 at 28.4, and C-3 at 31.7 ppm in **18**. These assignments differ from the earlier values (3); for **17**, C-5 and C-6 have been interchanged whereas for **18**, C-3, C-5, and C-6 have been changed.

The assignments of the resonances for compounds **19–25** were straightforward with the aid of sford spectra, and assuming that the $\Delta\delta(syn\text{–}anti)$ for β and γ carbons are negative. In the case of the tetramethyl, trimethylphenyl, and the di-*tert*-butyl compounds, the CH_3 absorptions could not be unambigously assigned.

Discussion

In Fig. 1, the chemical shift difference $\Delta\delta(syn\text{–}anti)$ for the carbons α to the C=N bond is plotted as a function of the dihedral angle (θ)[3] between the C=N and C—H bonds. The plot demonstrates a marked dependence on the value of θ with a maximum

[3]Values of θ were obtained from the literature. The references for the individual compounds are found in ref. 5. Only C—H bonds with θ < 90° are considered.

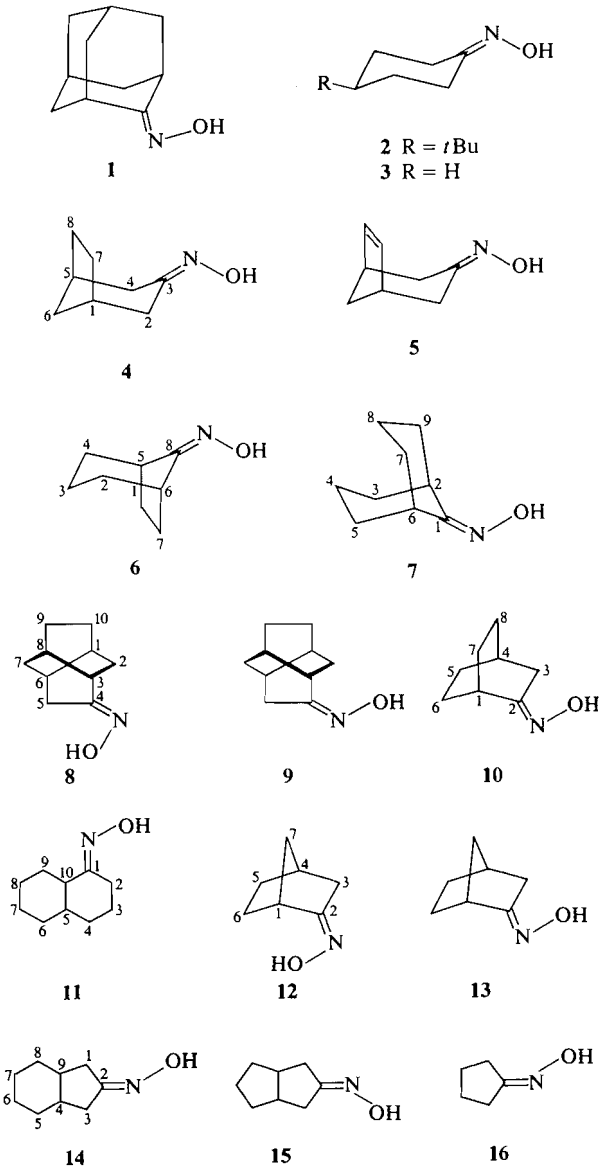

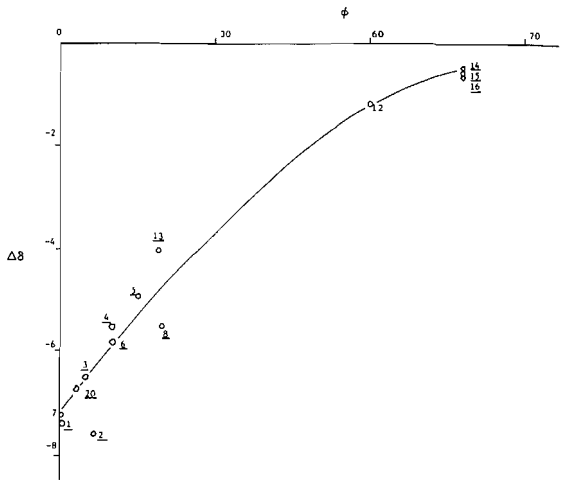

FIG. 1. Plot of $\Delta\delta$(*syn–anti*) vs. dihedral angle for the α carbons of ketoximes.

occurring when θ is 0° and decreasing with increasing angle. The shape of the curve resembles that obtained from the ^{1}Hmr spectra of ketoximes (5). However, the signs of the shift difference are opposite, i.e. whereas in the ^{13}Cmr spectra $\Delta\delta$(*syn–anti*) = −7.5 ppm at 0°, in the ^{1}Hmr spectra $\Delta\delta$ is +1.0 ppm. Such a correlation is also obtained from $\Delta\delta$(*syn–anti*) for the carbon β to the C=N although the variation with angle is much smaller. It is thus apparent from these curves that both the ^{13}Cmr and the ^{1}Hmr $\Delta\delta$ values for the α carbons are sensitive probes for stereochemical information.

The chemical shifts for C-4 of **18** and **19** are identical, and since in **19** the CH_3 group *syn* to OH is axial (5), we can conclude that **18** has the CH_3 axial as was proposed earlier (3).

For compound **20**, $\Delta\delta_\alpha$(*syn–anti*) is −6.5 ppm indicating a dihedral angle of about 10° between the C=N and C_α—H bonds. Also C-4 absorbs at 16.4 ppm, that is, it is shielded by 4.2 ppm relative to C-4 in **19**. This can only be explained by a conformation in which the two methyl groups are axial as was proposed earlier from ^{1}Hmr spectra (5). More recently Fraser and Grindley (9) demonstrated that the two methyl groups in *N*-nitroso-*trans*,*trans*-2,6-dimethyl-4-phenylpiperidine are also axial. Compounds **21**–**24** all have $\Delta\delta_\alpha$ values between −6.7 and −7.2 ppm indicating that these compounds exist in chair conformations since the dihedral angle is close to 0°. This result confirms the most widely held view of the conformations of the starting ketones (5). Finally, compound **25** has a $\Delta\delta_\alpha$(*syn–anti*) value of −3.5 ppm indicating that θ is of the order to 40°. Thus this molecule must exist in a twist boat conformation with the *tert*-butyl groups occupying pseudoequatorial positions in accordance with the twist conformation of the ketone (10).

It has been shown (11) that the effect of methyl group substitution can be ascertained using eq. [1]

$$[1] \qquad \Delta\delta = \eta_{HC}(HC) + \eta_{CC}(CC) + \gamma$$

where HC corresponds to the *gauche* interaction CH_3—C,C—H; CC corresponds to the *gauche* interaction CH_3—C,C—C; γ corresponds to the shielding effect on the carbon γ to the substituted carbon; and η is the number of interactions. The numerical values attributed to each of these is HC = 4.7 ppm, CC = +1.7 ppm, γ = −4.5 ppm when the introduction of the CH_3 group removes a 1,3 diaxial hydrogen–

25

hydrogen interaction and γ = 0 when introduction of the CH_3 group does not remove such an interaction (12). These values were derived from cyclohexane derivatives. In the case of the substituted carbons, α shifts of +5.8 ppm (equatorial) and 1.2 ppm (axial) can be used (13). The chemical shifts for compounds **17–25** can then be predicted using eq. [1], α shifts where necessary, and the data for compound **3** to verify that compounds **17–21** exist in essentially the same conformation as **3** and that **25** is in a different conformation. Compound **19** can be used as an example to illustrate the method of predicting shifts; δ(C-2) = 25.4 + 1.2(α) = 26.6; δ(C-3) = 25.7 + 4.7(HC) + 1.7(CC) = 32.1; δ(C-4) = 24.4 − 4.5(γ) = 19.9; δ(C-5) = 26.7 + 2 × 4.7 (2 × HC) = 36.1; δ(C-6) = 31.9 + 5.8(α) − 4.5(γ) = 33.2. The results given in Table 2 indicate that for compounds **17–21**, the chemical shifts are predicted reasonably well using methyl parameters deduced from cyclohexane derivatives and thus these compounds exist essentially in chair forms. The small discrepancies between the predicted and experimental values are probably due to small distortions which alleviate the axial CH_3,CH_3 interactions. For compound **25**, the lack of correlation between predicted and observed values is confirmation that the compound exists in a conformation other than a chair.

From Table 1, the chemical shifts for the oxime carbons exhibit a consistent behaviour for six-membered rings. The oxime carbon for compounds **2**, **3**, **4**, **21**, **23**, and **24** all absorb at 160 ± 1 ppm. Substitution of one CH_3 group at the α carbon causes a 3 ppm downfield shift as seen for compounds **17** and **18**, whereas with substituents at both α carbons this absorption appears at 167 ± 1 ppm as observed for **1**, **6**, **7**, **19** and **20**. These results imply an additive β effect. However, the oxime carbon in cyclopentanone oxime absorbs at 164.9 ppm whereas in cyclohexanone oxime it absorbs at 160.4 ppm. Grover *et al.* (14) suggested that eclipsing between an α CH and the CO bonds for ketones has an important influence on the shielding of the carbonyl carbon and that the closer the CH and CO bonds are to being eclipsed, the more shielded is the carbonyl carbon. The results presented here for oximes are similar, provided a 3.0 ppm deshielding effect for an axial CH_3 (or CH_2) is included, i.e. the deshielding effect of an axial CH_3 (or CH_2) group appears to be a β effect, whereas the introduction of an equatorial group in six-membered rings can be interpreted in terms of a β effect, removal of an eclipsing C—H bond, or a combination of both. The comparison of the shifts for five- and six-membered rings indicates that the eclipsing interaction has a role in the shielding of the oxime carbon. In fact, with the exception of **5**, the larger the value of $\Delta\delta_\alpha$(*syn–anti*) the more shielded the oxime carbon, after allowing for the effect of axial CH_3 or CH_2 groups. A good example can be seen by comparing **2** and **25** since **2** exists in the chair conformation whereas **25** has been shown to exist as a twist boat. The oxime

[a]Positive numbers indicate deshielding.
[b]Reference for ketones.

carbon of **25** is deshielded by 2.5 ppm relative to that in **2**. Also the carbonyl carbon of the ketone analog of **25** is deshielded by 3.3 ppm relative to that observed in **2**. The anomalous high field shift of **5** is due to an interaction between the double bond and the oxime carbon, an interaction shown to shield the carbonyl carbon of the corresponding ketone (4). Thus, as was found in the case of ketones (14), it appears that the eclipsing of the C_α—H and C=N bonds shields the oxime carbon.

Inspection of Table 3, in which the chemical shift differences between the ketoximes and their corresponding ketones are given, permits a number of interesting observations. First of all, the chemical shift differences for the substituted carbons are relatively constant with the exception of **6**, **7**, **18**, and **20**. In the latter two compounds, the preferred conformations of the oximes are different from those observed for the ketones. Methyl groups which were equatorial in the ketone are axial in the oximes. For **6** and **7**, the chemical shift of the substituted carbon is similar to that observed for similar structural units (e.g. ref. 1) whereas in the corresponding ketones, the carbonyl carbon is deshielded by 4 to 5 ppm relative to adamantanone. These results suggest that the parent ketones of **6** and **7** exist in distorted conformations which differ from the conformations of the ketoximes. Secondly, the variation of $\Delta\delta_\alpha$(*syn–anti*) is due to a variation in the shielding of both the *syn* and *anti* carbons. The $\Delta\delta_\alpha$(ketone oxime) for **6** is quite different from values observed in other six-membered ring compounds which supports the proposed conformational change suggested above. Finally, the effect of the oxime group is also transmitted to the β carbons in that both Δδ(ketone oxime) and Δδ(*syn–anti*) differ from zero with the *syn* carbon generally more shielded than the *anti* carbon.

One of the most useful diagnostic tools in ^{13}Cmr is the so called γ effect as has been mentioned and applied earlier. This effect was originally ascribed in the case of axial methylcyclohexane derivatives to a hydrogen–hydrogen steric compression causing electron density to move from the hydrogen to the carbon resulting in a shielding of the carbon and a concomitant deshielding of the hydrogen (16). Recently, other interpretations of the origin of this

120	−0.89	1.46	−0.57	1.03	0.97	0.06

effect have been suggested (12, 17). Calculations using equations similar to those derived by Grant and Cheney (16) show that although the steric compression model predicts the trend of the chemical shift difference as a function of dihedral angle for the α carbons, it is not quantitative. Also it does not explain the $\Delta\delta_\beta$(*syn–anti*) values.

Another factor that has been invoked to explain shieldings is the electric field effect (18–20). Using the simplified point dipole approximation and the equation derived by Buckingham (21) calculations of the chemical shifts due to the electric field effect at the α carbons of oximes as a function of dihedral angle are given in Table 4. The calculated stereochemical dependence is similar to that observed experimentally. No attempt was made to obtain a quantitative correlation between predicted and observed shifts since the representation of the electric field as a point dipole is an approximation which should only be employed to show qualitative trends. Also the shift difference for a given angle in ^{13}Cmr should be about 20 times that observed in ^1Hmr since shieldings of about 180 ppm/electron in the former and 8 ppm/electron in the latter have been observed (22). Hence other factors must also be involved in the shieldings. In the *N*-nitroso derivative of piperidine where the dihedral angle between the N—N and the α C—H bonds is 0°, a value of Δδ(*syn–anti*) = −11.0 ppm was observed in ^{13}Cmr whereas in ^1Hmr this difference was only 0.03 ppm (9). In this type of compound both the steric compression model (9) and the electric field effect (20) have been invoked to explain the ^{13}C shifts.

Thus even though both the electric field effect and the steric compression model can explain the observed $\Delta\delta_\alpha$ trends, it is evident that other factors must be taken into account to explain the absolute shifts observed in both ^{13}Cmr and ^1Hmr.

Conclusions

The results presented here demonstrate the dependence, the origin of which is not yet clear, of the chemical shift difference Δδ(*syn–anti*) on the dihedral angle between the C=N and C—H bonds. The observed values of Δδ can be used to estimate this angle and thus to determine the preferred conformation of oximes in solution. It appears that the chemical shift of the oxime carbon depends on the number of C=N, C_α—H eclipsing interactions as well as on the number of axial CH_3 or CH_2 groups. From the observed Δδ(*syn–anti*) values, it has been shown that *cis*-2,6-dimethylcyclohexanone oxime exists in a slightly distorted chair form with the 2-CH_3 group axial, that 3,3,5,5-tetramethyl and 3-phenyl-3,5,5-trimethylcyclohexanone oxime exist in chair conformations whereas the *trans*-3,5-di-*tert*-butyl derivative exists in a twist boat.

Experimental

All compounds were synthesized using methods described in the literature (5). The ^{13}Cmr spectra were recorded on a Bruker HX-90 spectrometer equipped with a Nicolet 1083 computer (8K memory for data) operating in the Fourier transform mode. Sweep widths of 5000 Hz were used with a line broadening factor of 0.5 Hz. The compounds were studied as approximately 0.7 *M* solutions in $CDCl_3$ with internal TMS as reference.

Application of water nuclear magnetic resonance relaxation times to study of metal complexes of the soluble soil organic fraction fulvic acid[1]

KATALIN DECZKY AND COOPER H. LANGFORD[2]

Metal Ions Group, Chemistry Department, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received August 30, 1977

KATALIN DECZKY and COOPER H. LANGFORD. Can. J. Chem. **56**, 1947 (1978).

The binding of the paramagnetic metal ions Mn^{2+}, Cu^{2+}, and Fe^{3+} to the acid soluble organic fraction of soils, fulvic acid, has been examined. The measurements use effects on paramagnetic ion induced longitudinal (T_1) and transverse (T_2) relaxation in the proton magnetic resonance signal of solvent water. The effects of the fulvic acid sample are compared to model ligand effects. Evidence is developed to suggest that Mn^{2+} forms outer sphere complexes with fulvic acid. On the contrary, Cu^{2+} and Fe^{3+} appear to form inner sphere complexes.

KATALIN DECZKY et COOPER H. LANGFORD. Can. J. Chem. **56**, 1947 (1978).

On a étudié l'adsorption des ions métalliques paramagnétiques Mn^{2+}, Cu^{2+} et Fe^{3+} par l'acide fulvique, la fraction acide organique des sols qui est soluble en acide. Les mesures font appel à la relaxation longitudinale (T_1) et transversale (T_2) induite par l'ion paramagnétique sur le signal de résonance magnétique du proton de la molécule de solvant. On compare les effects de l'échantillon d'acide fulvique avec les effets de ligands modèles. On a observé des données suggérant que le Mn^{2+} forme des complexes périphériques avec l'acide fulvique. Par ailleurs le Cu^{2+} et le Fe^{3+} semblent former des complexes au niveau des sphères intérieures.

[Traduit par le journal]

Introduction

The soil organic fractions, humic acid and fulvic acid, are probably important in a variety of processes in which metals are mobilized in aquatic and soil systems and may play a central role in supplying nutrients to plants. A well characterized sample of a fulvic acid isolated at the Soil Research Institute, Agriculture Canada has received serious attention by titrimetric and ion exchange technique which characterizes its thermodynamics as a ligand (1). (It binds metals in even quite acid media.) Structural modification has provided some evidence of the structure of such complexes (1). The present report is devoted to attempt to come to additional structural conclusions by looking at the effects of fulvic acid on the nmr relaxation times of solvent protons on water molecules which may exchange into the sites in the coordination sphere of dissolved metal ions. In studying fulvic acid complexing, we are driven to means such as solvent nmr by the generally very unfavourable spectroscopic situation which fulvic acids impose. Broad and featureless bands from this structurally complicated material obscure most of the regions of the visible, uv, ir, and Raman spectra which might offer structural guidance. Solvent nmr is a way past this serious barrier. We have chosen to work at acid pH, such as that generated by modest amounts of the relatively strong acid, fulvic acid, in order to minimize extraneous electrolytes in the fulvic acid solutions. (That complexing is sufficient in such media is indicated by the effects of ligands on the interactions between paramagnetic ions and H_2O that we monitor by nmr.)

Some time ago, Mildvan and Cohn (2) demonstrated the utility of solvent nmr relaxation times in the presence of paramagnetic ions for study of the binding of these ions to enzymes. Paramagnetic ions shorten relaxation times of coordinated water molecules. When there is fast chemical exchange of nuclei (protons) of coordinated water molecules with water molecules in the bulk of the solution, the nmr signal is an average between the two environments and the paramagnetic effect is seen in the nmr signal for bulk solvent protons averaged in according to McConnell's fast exchange equation. This is a limiting case of the general treatment of chemical exchange (3):

$$[1] \qquad 1/T_{1,2(\mathrm{obs})} = P_{\mathrm{A}}/T_{1,2\mathrm{A}} + P_{\mathrm{M}}/T_{1,2\mathrm{M}}$$

where $T_{1,2(\mathrm{obs})}$ designates the *observed* relaxation time (T_1 or T_2) for either longitudinal (T_1) or transverse (T_2) relaxation in the proton nmr signal. The subscript A designates the relaxation times characteristic for protons in the bulk solvent environment. The subscript M designates protons in the paramagnetic ion solvation shell. P_{A} is the probability that a proton is in the bulk solvent environment. P_{M} is the probability that a proton is in the coordination sphere of the paramagnetic ion. In a dilute solution, P_{A} is equal to unity to a good approximation. P_{M}

may be expressed in terms of C_M, the concentration of paramagnetic ions and q, the number of water molecules coordinated to the paramagnetic ion. Thus a proportionality may be written:

$$[2] \qquad (1/T_{1,2(obs)} - 1/T_{1,2A}) \propto qC_M/T_{1,2M}$$

If a paramagnetic ion is coordinated only to water, q will be equal to 4–6. (In the case of the present metal ions, the number is 6.) The coordination of the metal ion to a non-solvent ligand must change q to a smaller value but it may simultaneously lead to an alteration of $T_{1,2M}$. As a result, there are three cases. Coordination of a paramagnetic ion to a non-solvent ligand may lead to an increase in observed relaxation rates (of $1/T_{1,2}$) because of a reduction of $T_{1,2M}$. Second, a decrease in observed relaxation rates can be a consequence of reduction of q. The third possibility is decrease of observed relaxation rate because of an increase of $T_{1,2M}$. In studies of interaction of Mn^{2+} with enzymes (2), the most important case is the first where a reduction of $T_{1,2M}$ is observed. Since the simplest measurement is that of T_2 from absorption signal line width ($\pi\Delta\nu = 1/T_{2(obs)}$ where $\Delta\nu$ is the width at half height of the Lorentzian absorption line), the reduction of T_{2M} is associated with *enhanced* line broadening (increased $\Delta\nu$).

The factors which control T_{1M} or T_{2M} are described by the Solomon–Bloembergen equation (3,4). The relaxation of a nucleus is determined by one of the various possible sources of a fluctuating magnetic field which can influence the magnetic state of the nucleus under observation. These are described by τ_R, the rotational correlation time, τ_S, the paramagnetic electron relaxation correlation time, and τ_M, the chemical exchange correlation time. (τ_M cannot control in the fast exchange case of eq. [1], it is included here for completeness.) A simple physical picture of effects on observed T_1 or T_2 depends upon the recognition that both τ_S, the paramagnetic electron relaxation correlation time, and τ_R, the rotational correlation time of the molecule containing the nucleus, are short times compared to the reciprocal of the nmr frequency. They tend to average out the fluctuation of local field to zero. The result is that observed relaxation processes are 'maximally inefficient', governed by the *fastest* correlation time. This curious situation means that as a correlation time shortens, it becomes determining and reduces efficiency of relaxations.

In situations where τ_R is most important, rotation of a metal ion is slowed by complexation to a large molecule (protein or fulvic acid) and the consequence for $1/T$ is increase in relaxation efficiency. For the case of $1/T_2$ enhanced line broadening is observed (2). In situations where τ_S is important, long times are usually associated with high spins and electron configurations in high symmetry environments. These times are reduced by removal of symmetry and the result is less efficient relaxation (line narrowing in the T_2 case).

Two preliminary points remain to be recorded. First, frequently $T_1 \neq T_2$. This can only arise in the fast exchange when τ_S is the important factor and *scalar* coupling is important between the paramagnetic electron and the nucleus (4, 5). As long as magnetic dipolar coupling dominates interactions between the paramagnetic electron and the nucleus under observation, $T_1 = T_2$. (τ_M control also leads to $T_1 = T_2$ but τ_M is not important in fast exchange.) Second, the basic reference point for study of complexes of metal ions with macromolecular ligands is the behaviour of the hexaaquometal ions $M(OH_2)_6^{n+}$ ($n = 2$ or 3). The factors important to water proton relaxation times in the hexaaquometal ions are collected in Table 1.

Experimental

Materials

The fulvic acid sample used in these studies was a generous gift of Dr. D. S. Gamble of The Soil Research Institute, Agriculture Canada. It is an unusually well characterized sample of this poorly understood material which is derived from a Bh horizon podzol from Prince Edward Island. The characteristics of this sample have been reviewed (1). For our purposes, its most important characteristics are 3.3 milliequivalents of phenolic functional groups and 7.7 milliequivalents of carboxylate functional groups per gram of FA (1). This and studies of blocking group inhibitions of the metal complexing functions (1) imply that strong metal complexes are formed with salicylic acid type functionality. All experiments used fulvic acid concentration of 1 mg/ml.

Model ligands were Fisher or Eastman Organic Chemicals of good grades used without purification. Metal ion stock solutions were prepared from suitable reagent grade sulfate or perchlorate salts and standardized by well known titrimetric techniques (11). Fulvic acid solutions at final desired concentrations were brought to pH = 2 with $HClO_4$. Some model ligand studies were carried out in solutions near neutral pH. There were no qualitative differences. In the case of Mn^{2+}, an experiment was also run by neutralization to pH = 4.00 which corresponds to extensive deprotonation of the FA (1).

Equipment

All nmr spectra were those of protons on water (the solvent). Transverse relaxation times were estimated from the width at half height ($\Delta\nu$) of continuous wave absorption signals of Lorentzian shape recorded on Varian T-60, EM360, and HA100 spectrometers. Special attention was directed to signal phasing and operating at low RF power because these are the main sources of line shape distortion. $1/T_{2(obs)}$ was calculated from the relation $\pi\Delta\nu = 1/T_{2(obs)}$. Temperature dependence studies in the 5–40°C range were performed on the Varian EM360 using a Varian temperature control device capable of maintaining constant, known sample temperature of ±1°C. Locking signals were obtained from external D_2O or CH_3CN.

Longitudinal relaxation times were obtained on a Varian XL-100 system with a Nicolet Fourier transform computer. T_1

TABLE 1. Factors important to water proton relaxation times in hexaaquometal ions

Paramagnetic ion	Number of unpaired electrons	τ_S	τ_R	τ_M	Dominating τ	Reference
Mn^{2+}	5	1×10^{-8}	3×10^{-11}	2.5×10^{-7}	τ_R	1, 5, 6
Cu^{2+}	1	10^{-9}	3×10^{-11}	10^{-9}	τ_R	6, 7
Fe^{3+}	3	$\sim 10^{-11}$ to $\sim 10^{-12}$	$\sim 10^{-11}$	10^{-9}	τ_S	8, 9, 10

values were calculated from free induction decay records. The lock was external D_2O and temperature control was similar to that on the EMS60. Pulses ranged from 0.001 to 8 s.

Procedure

Solutions were prepared at constant ligand concentrations and variable metal ion concentration. A pH of 2.00 was used throughout, except in an Mn^{2+} series. It was adjusted with perchloric acid. The model organic ligands were in excess or in a 1:1 relationship to the most concentrated metal ion solutions. As noted above, fulvic acid concentrations were 1 mg/ml. This implies (1) 3.3 milliequivalents dm^{-3} of functionality analogous to salicylic acid. Metal ions were added to FA solutions up to 3.3×10^{-3} M except in the case of Cu^{2+}. In this case, studies of transverse relaxation rates were made using 5×10^{-3} M Cu^{2+} and 5 mg/ml of FA. In this case, dependence of T_2 on model ligand concentration was not followed because of the small values of line widths.

Results and Discussion

Manganese Experiments

The experiments on Mn^{2+} are an extension of those on T_2 reported in a previous publication (12). We reported there that formation of inner sphere complexes between Mn^{2+} and either ethylenediaminetetraacetic acid (EDTA) or bipyridine (bipy) led to a substantial reduction in water line widths, hence $1/T_2$. Line-width changes at 10^{-3} M Mn^{2+} where a factor of 2 with bipy and a factor near 10 for EDTA. This could be attributed to occupation of exchangeable water sites by the ligand and reduction of q of eq. [2]. However, it is also possible that conversion of the essentially octahedral aquo ion Mn^{2+} to a complex of lower symmetry can reduce paramagnetic electron relaxation times (τ_S). (Frequency dependence confirms a role for τ_S.)

In either case, there was a sharp contrast between the effect of these ligands and the effect of sulphosalicylic acid (SSA) which has complexing functionality very similar to that expected to be effective in fulvic acid. SSA had no effect on T_2 values in solutions containing Mn^{2+}. Since SSA is reported to complex divalent metal ions (13), we concluded (12) that the complex was outer sphere with almost no perturbations of q or τ_S. The results with FA are similar to those with SSA but *not* equivalent. At the time of our earlier report, we suggested that the FA complexes of Mn^{2+} which when clearly shown to be present by ion exchange measurements reported in ref. 12 were outer sphere like those of SSA but we were unable to interpret the small decrease in line widths ($1/T_2$) in the presence of FA.

Figure 1 shows water line widths in FA solutions as a function of Mn^{2+} concentrations at two frequencies. The dashed line shows the behaviour in the absence of FA. There is a definite decrease due to FA. The frequency dependence implicates τ_S but the temperature dependence indicated by curves A and G in Fig. 2 indicates that the relaxation mechanism is only slightly different from that in the absence of FA. The situation is clarified in Fig. 3 where $1/T_1$ values are reported. We see that FA has a nearly zero effect on T_1. T_1 is controlled by τ_R (2, 6, 7). Thus, τ_S is more sensitive than τ_R to complexing the large FA molecule.

Although FA does modify water T_2, it is possible that Mn^{2+} complexing is very small at pH = 2.0. Consequently, the experiments were also run at pH = 4.0 where ion exchange experiments (12) have shown extensive Mn^{2+} binding to FA. The Mn^{2+} dependence of relaxation is entirely parallel to the results at pH = 2.0. The only difference is that FA alone causes a little water relaxation itself at pH = 4.0. Some free radical character of FA's has been noted (1).

There is only one straightforward explanation of this combination of circumstances. An outer sphere

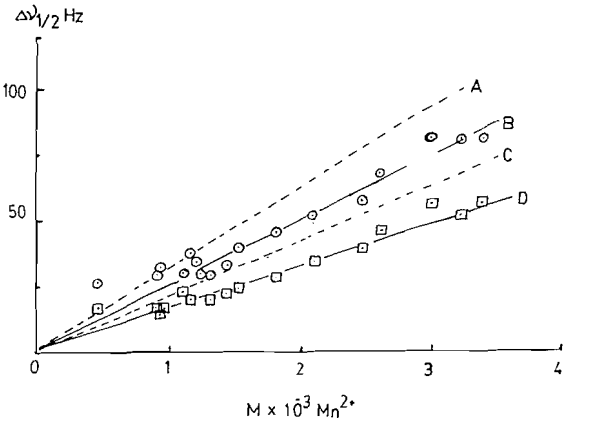

FIG. 1. Concentration dependence of transverse relaxation rates of Mn^{2+}-aquo and FA complexes, at 60 and 100 MHz. Concentration of FA = 1 mg/ml, A = Mn^{2+}-aquo at 100 MHz. B = Mn^{2+}-FA at 100 MHz. C = Mn^{2+}-aquo at 60 MHz. D = Mn-FA at 60 MHz.

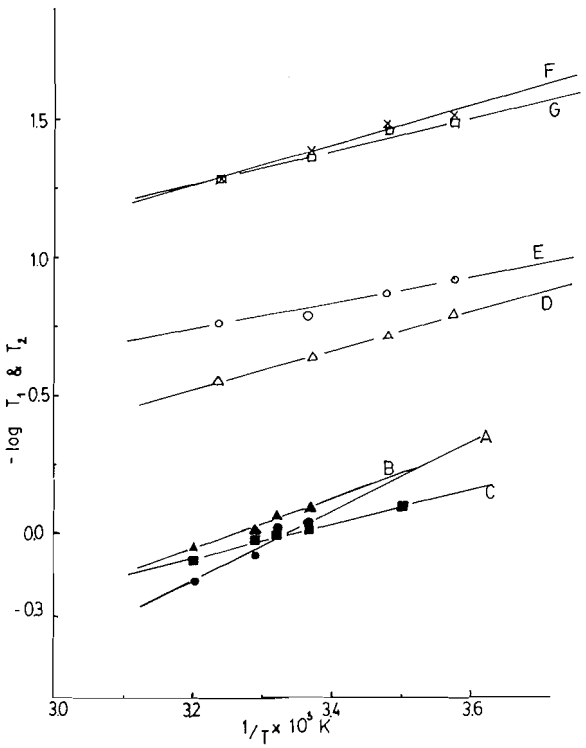

FIG. 2. Temperature dependence of transverse and longitudinal relaxation times of Mn^{2+} and Cu^{2+} complexes. A = longitudinal relaxation times of 1×10^{-4} Mn^{2+} + 1 mg/ml FA solution at pH = 2. B = longitudinal relaxation times of 1×10^{-3} M of Cu^{2+}-aquo complex. C = longitudinal relaxation times of 1×10^{-3} M Cu^{2+} + 1 mg/ml FA solution. D = transverse relaxation times of 5×10^{-3} M Cu^{2+} + 5 mg/ml FA solution. E = transverse relaxation times of 5×10^{-3} M Cu^{2+}-aquo complex. F = transverse relaxation times of 1×10^{-3} M Mn^{2+}-aquo complex. G = transverse relaxation times of 1×10^{-3} M Mn^{2+} + 1 mg/ml FA.

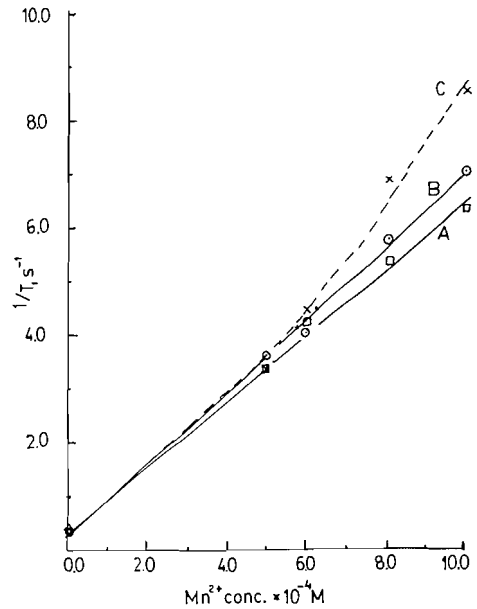

FIG. 3. Longitudinal relaxation rate dependence on the concentration of the Mn^{2+} ion at room temperature. Concentration of FA = 1 mg/ml, of bipy = 6×10^{-3} M. A = Mn–aquo. B = Mn–FA. C = Mn–bipy.

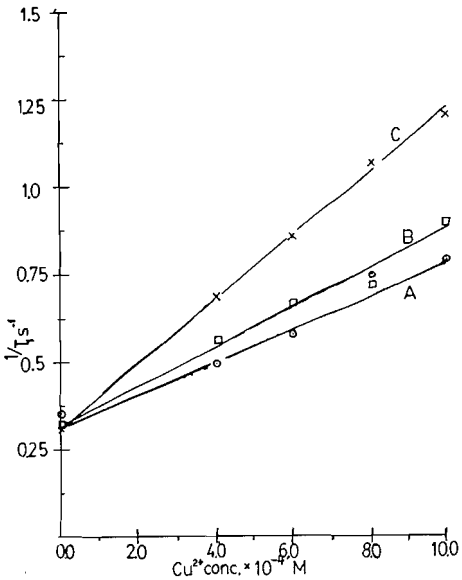

FIG. 4. Longitudinal relaxation rate dependence on the Cu^{2+} ion concentration at room temperature. Concentration of FA = 1 mg/ml of bipy = 1×10^{-3} M. A = Cu^{2+}–bipy. B = Cu^{2+}–aquo. C = Cu^{2+}–FA.

complex forms between the fully hydrated $Mn(OH_2)_6^{2+}$ and FA which can rotate nearly as freely as in water, probably because coordinated water protons H-bond to FA ligand sites more or less as they do to solvent water. (In ref. 12, thermodynamic analyses of Mn^{2+} binding suggested dominance by simple electrostatic interaction.) On the other hand, the $Mn(OH_2)_6^{2+}$ ion does not see a fully symmetric environment and this alters τ_S, and consequently T_2, moderately. (An alternate and structurally similar possibility is H-bonding to FA slowing proton exchanges, but this should initially cause broadening.) This gives us a picture of an ion, fully hydrated, tumbling around on electrostatic binding sites of the ligand. The picture suggests a "caged" ion which is consistent with the Schnitzer–Gamble (1) picture of FA as a three dimensional entity with H-bonding crucial to overall structure.

Copper Experiments

It has been suggested that Cu^{2+} forms an inner sphere bidentate chelate complex with adjacent —COOH and phenolic functional groups of FA (1). The temperature dependence data in Fig. 2 indicate that addition of FA to a Cu^{2+} solution does change the mechanism of proton relaxation significantly. Cu^{2+} concentration dependence of $1/T_1$ is shown in

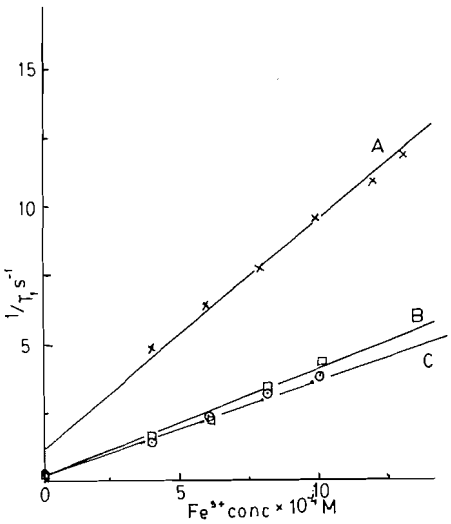

FIG. 5. Longitudinal relaxation rate dependence on the Fe^{3+} ion concentration at room temperature. Concentration of FA = 1 mg/ml, concentration of SSA = concentration of Fe^{3+}. *A* = Fe^{3+}–aquo. *B* = Fe^{3+}–FA. *C* = Fe^{3+}–SSA.

Fig. 4. Data for the complexation of Cu^{2+} by bipy is included for comparison.

Bipy, which is a small molecule, causes a slight decrease in the relaxation rate, $1/T_1$. This is consistent with a reduction in q under circumstances where τ_R is the important relaxation time as it is in the aquo complex in water (7, 8). FA, in contrast, enhances relaxation. This is consistent with τ_R remaining important for an inner sphere complex of Cu^{2+} where rotation requires tumbling of the entire large FA entity. Relaxation enhancement here is very similar to that seen in studies of Mn^{2+} binding to proteins (2) and arises similarly. The contrast to Mn^{2+}–FA behaviour clearly supports assignment of an inner sphere structure to the Cu^{2+} complex and an outer sphere structure to the Mn^{2+} complex. We see clear evidence of real effects in both cases but one is opposite to the other. The implication clearly follows from earlier theory (2).

Iron Experiments

Combination of Fe^{3+} with either FA or the related model SSA causes similar and large reduction of both relaxation rates, $1/T_1$ and $1/T_2$. The T_1 data are shown in Fig. 5. A 'titration' experiment with SSA showed that the largest part of the effect could be produced with one equivalent of SSA per Fe^{3+} and that a second and third SSA had a small effect. Since the 1:1 stoichemistry *requires at least four of the six water molecules coordinated to* Fe^{3+} *to remain. The effect is not on q.* It is only plausible to attribute the effect to a change in τ_S consequent on reduction of the symmetry of the high spin d^5 centre. The case parallels the aquo ion, Fe^{3+} where τ_S (9, 10) was considered dominant. Our earlier paper noted a frequency dependence in T_2 for iron complexes (12). Since the effect is large here, it implies inner sphere complexation.

Concluding Remark

The most useful result of this study may prove to be the recognition of $Mn(OH_2)_6^{2+}$ outer sphere complexes of FA. If such interactions are general in acid solution, the ion may prove to be a useful probe for FA conformational changes.

Synthèse et propriétés chimiques du phényl-5-octahydro-1,2,3,4,6,7,8,9-dibenzophosphole

FRANÇOIS MATHEY ET DANIEL THAVARD

Equipe IRCHA-CNRS, 2 à 8 rue Henry Dunant, 94320 Thiais, France

Reçu 2 novembre 1977

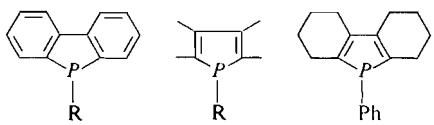
FRANÇOIS MATHEY et DANIEL THAVARD. Can. J. Chem. **56**, 1952 (1978).

Le phényl-5-octahydro-1,2,3,4,6,7,8,9-dibenzophosphole (L) a été synthétisé en faisant réagir le DBU sur le composé d'addition $PhPBr_2$-bicyclohexenyl-1,1′. Les propriétés chimiques ont été comparées avec celles des phospholes plus classiques. Son oxyde et son sulfure sont monomères. Une double réaction d'expansion de cycle est observée avec le chlorure de benzoyle comme dans le cas des phospholes simples. Au contraire les rendements de la coupure de la liaison P—Ph par K dans le THF sont faibles et l'échange P—Ph → P—*t*Bu par réaction avec *t*BuLi, ne donne aucun résultat. Le phosphacymantrène correspondant est obtenu par réaction avec $Mn_2(CO)_{10}$. Les complexes $\sigma LFe(CO)_4$, $\sigma,\eta LFe_2(CO)_7$ et $\eta LOFe(CO)_3$ ont été préparés par réaction de L ou LO avec $Fe_3(CO)_{12}$.

FRANÇOIS MATHEY and DANIEL THAVARD. Can. J. Chem. **56**, 1952 (1978).

5-Phenyl-1,2,3,4,6,7,8,9-octahydrodibenzophosphole (L) has been synthesized by reacting DBU with the $PhPBr_2$-1,1′-bicyclohexenyl cycloadduct. Its chemical properties have been compared with those of more classical phospholes. Its P-oxide and P-sulfide are monomeric. A double ring-expansion reaction is observed with benzoyl chloride as with simple phospholes. On the contrary we met a limited success with the P—Ph bond cleavage by K in THF and we did not succeed at all when attempting a P—Ph → P—*t*Bu exchange by reaction with *t*BuLi. The corresponding phosphacymantrene has been obtained with $Mn_2(CO)_{10}$. $\sigma LFe(CO)_4$, $\sigma,\eta LFe_2(CO)_7$, and $\eta LOFe(CO)_3$ complexes have been obtained from the reactions of L or its P-oxide with $Fe_3(CO)_{12}$.

Les dibenzophospholes **1** sont probablement les phosphines cycliques les plus utilisées comme coordinats des métaux de transition (voir réf. 1). Leur géométrie rigide et leur demande stérique relativement faible, entraînent la stabilisation de degrés de coordination peu courants (par exemple la coordinance 5 du nickel). D'autre part, de puissants catalyseurs d'hydrogénation, à base de rhodium et de phényl-5-dibenzophosphole, ont été décrits (2). Ces phosphines présentent donc un intérêt tout particulier pour la chimie des métaux de transition. Or, par

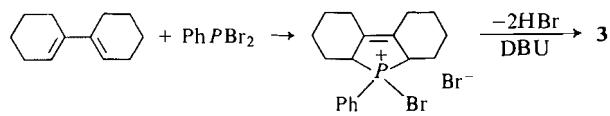


1 **2** **3**

rapport aux phospholes simples du type **2**, les dibenzophospholes se caractérisent essentiellement par deux faits: (*a*) l'intéraction doublet libre du phosphore – système diénique a pratiquement disparu dans **1** (voir les données comparées sur **1** et **2** concernant l'oxydation (3), la déquaternarisation (4) et l'inversion du P (5)). (*b*) Il n'y a pas dans **1** de système diénique "libre" disponible pour fournir des complexes η avec les métaux de transition au contraire de **2** (voir réf. 1).

Pour rétablir l'intéraction doublet libre – système diénique dans **1** et pour "libérer" le motif diénique, tout en conservant une géométrie à peu près équivalente, nous nous sommes donc intéressés au phényl-5-octahydro-1,2,3,4,6,7,8,9-dibenzophosphole **3**. Le phosphole **3** doit a priori fournir des P-complexes plus labiles que ceux de **1** (rétablissement de la délocalisation partielle du doublet libre) et que ceux de **2** (cône d'encombrement plus ouvert selon Tolman (6)) ce qui doit présenter un intérêt particulier pour les catalyseurs d'hydrogénation du type Wilkinson. Par contre, il doit fournir des complexes diéniques plus stables que ceux dérivés de **2** (la tétrasubstitution enrichit en électrons le système diénique). Nous verrons ci-après, que ces conclusions semblent partiellement vérifiées par l'expérience. Nous décrivons ci-contre la synthèse de **3**, l'étude de sa chimie "classique" et quelques-uns de ses complexes avec le fer et le manganèse.

Le composé d'addition de la phényldibromophosphine et du bicyclohexényl-1,1′ a été préparé en s'inspirant du travail de Campbell et coll. (7). Ce produit a été ensuite déshydrohalogéné directement par le DBU suivant la méthode générale que nous avons décrite pour la préparation des phospholes (8).



DBU = diaza-1,5-bicyclo[5,4,0]undécène-5

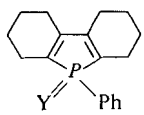
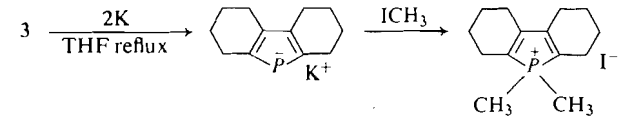
Le rendement global de cette séquence peut atteindre 38%. Le phosphole **3** se présente sous la forme d'un liquide visqueux ayant une certaine tendance à la cristallisation à température ambiante. Sa faible volatilité (Eb ~165–170°C/0.1 mm Hg) et probablement aussi l'encombrement du phosphore lui confèrent une assez bonne résistance à l'oxydation par l'air. Son spectre de rmn du proton ($CDCl_3$, TMS interne) se compose d'un pseudo-doublet asymétrique assez fin à 7.26 et 7.19 ppm (Ph) et de deux massifs élargis d'importance égale à 2.28 et 1.67 ppm (CH_2). Le phosphore (δ positif à champ fort, P_4O_6 externe) présente le déblindage caractéristique des phospholes: $\delta^{31}P$ (**3**) = 104.9 ppm. La valeur trouvée est pratiquement identique à celle du phényl-1-phosphole (9). A noter que l'on ne retrouve pas ici le blindage relatif dû à la substitution dialkyl-3,4 dans la famille des phospholes. Le spectre de rmn ^{13}C est évidemment complexe mais il est facile de détecter les trois types de carbones secs. L'interprétation que nous proposons est la suivante: P—*C*(Ph) δ = 133.9 ppm $^1J_{(P-C)}$ = 13.3 Hz; P—*C*(cycle) δ = 138.5 ppm $^1J_{(P-C)} \leq 1$ Hz; P—C—*C*(cycle) δ = 144 ppm $^2J_{(P-C)}$ = 8.9 Hz. Ces valeurs sont compatibles avec les données de la littérature (10, 11). Le couplage $^1J_{(P-C)}$ dans le cycle est cependant exceptionnellement faible, la valeur la plus basse observée précédemment étant celle du phényl-1-diméthyl-3,4-phosphole: $^1J_{(P-C)}$ = 2.8 Hz.

L'oxyde **4**, dérivé de **3**, est préparé classiquement par oxydation de **3** par H_2O_2 dans l'acétone à −30°C; ir: ν(P=O) = 1195 cm^{-1} (KBr). Il est monomère comme l'atteste la rmn du phosphore: $\delta^{31}P$ (**4**) = 66.8 ppm. Il est intéressant de remarquer que c'est le premier oxyde de phosphole monomère ne comportant pas de substituants aryles sur les carbones du noyau. L'absence de dimérisation selon Diels–Alder est probablement due à l'encombrement du système diénique. Le sulfure **5** est également monomère: $\delta^{31}P$ (**5**) = 61.6 ppm.



Y = O **4**
Y = S **5**

Nous avons ensuite étudié la coupure de la liaison P—Ph par deux équivalents de potassium dans le THF au reflux, selon la méthode de Braye (12). En méthylant le produit de la réaction par ICH_3, nous avons obtenu le sel de phospholium **6** avec un rendement très modeste toutefois (~15%). Ce sel a été parfaitement caractérisé par une analyse élémentaire complète et par rmn en solution dans $CDCl_3$: ^1H: absence de phényle, doublet $CH_3\overset{+}{P}$ à 2.35 ppm, $^2J_{(H-P)}$ = 14 Hz. ^{13}C: $CH_3\overset{+}{P}$ à 6.6 ppm, $^1J_{(P-C)}$ = 48.4 Hz; Cα à 122.9 ppm, $^1J_{(P-C)}$ = 79.2 Hz; Cβ à 157.1 ppm, $^2J_{(P-C)}$ = 22 Hz. ^{31}P: $\delta^{31}P$ (**6**) = 78.5 ppm.

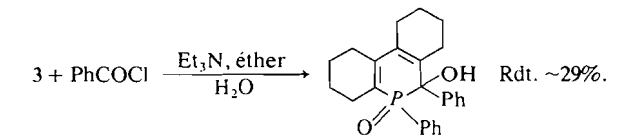


6

Comme le suggère Braye (12), il semble bien que les substituants aryles sur les carbones du noyau jouent un rôle non négligeable dans la stabilisation des anions phospholyles, d'où les rendements élevés des réactions qu'il décrit.

D'autre part, l'échange P—Ph → P—Bu^t par réaction de **3** avec le tertiobutyl-lithium dans l'hexane à température ambiante par analogie avec la réaction du phényl-1-diméthyl-3,4-phosphole (13) a échoué; on obtient un mélange complexe de produits difficilement séparables. L'encombrement stérique du phosphore joue peut être un rôle important dans l'échec de cette réaction.

Au contraire la réaction d'extension de cycle des phospholes par le chlorure de benzoyle (14) est transposable avec **3** mais le rendement reste modeste:

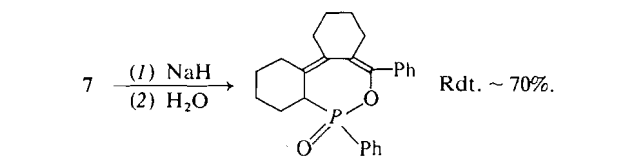


7

Le composé **7** a été caractérisé sans ambiguïté par ir (ν en cm^{-1}, KBr): OH 3160, C=C 1623, 1600, 1580, P=O 1150 et rmn ^1H (DMSO) δ OH 5.73 ppm $J_{(H-P)}$ 14 Hz (voir réf. 14) et ^{13}C ($CDCl_3$, TMS) δ (P—*C*—OH) 45.4 ppm $^1J_{(P-C)}$ 69.9 Hz; δ (P—*C*=C) 76.9 ppm $^1J_{(P-C)}$ 83 Hz.

Il est intéressant de noter que, tout récemment, la même réaction a été appliquée avec succès aux dibenzophospholes (15, 16). A la différence des dibenzophospholes toutefois (16) et de la même façon que les phospholes simples (14) il est également possible de convertir l'hydroxydihydrophosphorine **7** en oxa-1-phospha-2-cycloheptadiène-4,6 **8**.

La disparition du OH dans le composé **8** est visible sur le spectre ir (KBr) qui est comparable à celui des



8

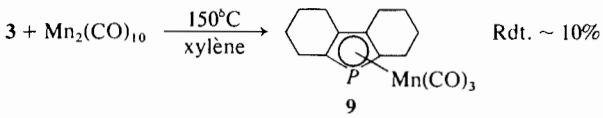
For personal use only.

cycles à 7 chaînons analogues (voir réf. 14): C=C 1630, 1599, 1590, P=O 1240, 1230, P—O—C 1048. La rmn ^{13}C ($CDCl_3$) confirme la présence d'un groupe P—CH dans le cycle: δ (P—*C*H) 38.9 ppm $^1J_{(P-C)}$ 84.4 Hz $^1J_{(C-H)}$ 124.4 Hz et la rmn du phosphore ($CDCl_3$, P_4O_6 externe) est compatible avec une structure de phosphinate: $\delta^{31}P$(**8**) = 49.7 ppm.

Nous avons ensuite complété cette étude chimique "classique" de **3** par une étude de quelques-uns de ses complexes.

A 150°C dans le xylène avec une quantité équimoléculaire de $Mn_2(CO)_{10}$, **3** fournit le phosphacymantrène correspondant **9** après coupure de la liaison P—Ph de la même façon que les P-phénylphospholes plus simples (17). Le rendement reste toutefois très modeste et la réaction est peu reproductible.

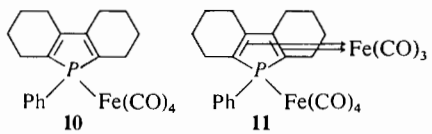


9

Le spectre ir de **9** (décaline) est particulièrement intéressant: ν(CO) = 2018, 1943 et 1930 cm^{-1}. Ces données sont à comparer avec celles du phosphacymantrène lui-même: ν(CO) = 2032, 1958 et 1954 cm^{-1} et celles de son dérivé diméthylé en 3,4: ν (CO) = 2025, 1953 et 1941 cm^{-1}. Elles mettent bien en évidence le caractère η-donneur très accentué du noyau phospholyle de **9**. Le phosphore de **9** est très blindé comme dans tous les produits de cette série (travaux sous presse): $\delta^{31}P$(**9**) = 165.1 ppm (P_4O_6 externe).

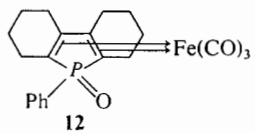
Enfin le spectre de masse (70 eV) comprend le moléculaire de *m/e* 330 (*I* = 16%), le pic M-2CO de *m/e* 274 (*I* = 16%) et le pic de base M-3CO de *m/e* 246 ce qui confirme définitivement la formule proposée.

La réaction de **3** avec $Fe_3(CO)_{12}$ nous a fourni, d'autre part, 3 complexes que nous décrivons par ordre de Rf décroissants (gel de silice).



10

11



12

Le premier de ces complexes est le classique complexe σLFe$(CO)_4$ **10**. L'analyse ne permet pas de le distinguer du complexe ηLFe$(CO)_3$ (complexation du diène) mais la formule **10** est établie sans ambiguïté par ir: ν(CO) (décaline) = 2053, 1977, 1945 et 1938 cm^{-1}. Ces données sont à comparer avec celles du complexe LFe$(CO)_4$ où L = phényl-1-diméthyl-3,4-phosphole: ν(CO) = 2051, 1979, 1948 et 1939 cm^{-1} (18). Il semble donc que le phosphore de **3** ait un pouvoir donneur–accepteur très voisin de celui du phényl-1-diméthyl-3,4-phosphole ce qui est, somme toute, assez logique. Le complexe LFe$(CO)_4$ dérivé de **1** étant inconnu, nous ne pouvons toutefois pas contrôler nos hypothèses de départ sur ce point. Le spectre de masse de **10** comprend le moléculaire de *m/e* 436 (*I* = 6%), le pic M-2CO de *m/e* 380 (*I* = 16%), le pic M-3CO de *m/e* 352 (*I* = 35%), le pic M-4CO de *m/e* 324 (*I* = 100%) et le pic M-4CO-Fe de *m/e* 268 (*I* = 100%) ce qui parachève l'identification de **10**. Le phosphore apparaît à 37.8 ppm (P_4O_6) ce qui confirme la complexation de P (même déblindage que dans le cas du phényl-1-diméthyl-3,4-phosphole (18)).

Le deuxième complexe est le complexe σ,ηLFe_2-$(CO)_7$ **11** analogue à celui obtenu avec le phényl-1-diméthyl-3,4-phosphole (18). Sa formule est essentiellement établie sur la base du spectre de masse: moléculaire de *m/e* 576 (*I* = 0.6%); présence de tous les pics M-CO, M-2CO, ..., M-7CO, ce dernier assez intense (*I* = 69%); pic de base à *m/e* 268 (M-7CO-2Fe). L'analyse élémentaire C,H,Fe est en bon accord avec la formule proposée et le déplacement chimique du P est compatible avec les données existantes (18): $\delta^{31}P$ (**11**) = 0 ppm (P_4O_6). Le spectre ir est évidemment assez compliqué dans la région des CO: bandes à 2061, 2046, 2023, 2020, 1997, 1988, 1978, 1949 et 1937 cm^{-1} dans la décaline.

Le dernier complexe est le complexe η dérivé de l'oxyde **12**. Il a été authentifié par comparaison avec un complexe préparé directement à partir de **4**. Son spectre ir est caractéristique des systèmes diène–Fe$(CO)_3$: ν(CO) = 2063, 2000 et 1973 cm^{-1} (décaline) et le phosphore est peu affecté par la complexation: $\delta^{31}P$ (**12**) = 59.1 ppm (P_4O_6); ir: ν(P=O) = 1205 cm^{-1} (KBr).

Partie expérimentale

Toutes les chromatographies ont été effectuées sur colonnes de gel de silice 70–230 mesh Merck. Le travail expérimental a été réalisé avec la collaboration de M. M. Longeau. Les auteurs remercient Mme R. Mankowski-Favelier pour les spectres rmn ^{31}P et ^{13}C (Jeol PS 100 F.T.).

I. Synthèse du phényl-5-octahydro-1,2,3,4,6,7,8,9-dibenzophosphole **3**

On laisse réagir à l'abri de la lumière, sous argon et à température ambiante, pendant dix jours, un mélange de bicyclohexenyl-1,1′: 17.8 g (0.1 mol + 10%) et de phényldibromophosphine: 26.8 g (0.1 mol).

L'adduit formé est alors recouvert par 200 cm^3 de benzène sec, refroidi par un bain de glace et traité par une solution de 30.5 g de DBU dans 200 cm^3 de chlorure de méthylène sec. Lorsque tout l'adduit a réagi, on hydrolyse par HCl 0.5 *N*. La

For personal use only.

couche organique est décantée, lavée par une solution de CO_3K_2 et séchée. Les solvants sont évaporés et le phosphole distillé sous pression réduite. Eb 165–170°C/0.1 mm Hg. Rendement maximum obtenu: 38%. *Anal.* calc. pour $C_{18}H_{21}P$: C 80.56, H 7.88; trouvé: C 80.34, H 7.84.

II. Oxyde **4**

A une solution de 5.7 g (0.02 mol) de **3** dans 50 cm³ d'acétone à −30°C, on ajoute 2 cm³ (0.02 mol) de H_2O_2 à 112 vol. On ajoute une pincée de trioxyméthylène et laisse revenir à température ambiante. L'excès de trioxyméthylène est filtré, l'acétone est évaporée. L'oxyde est chromatographié (éluant: AcOEt), puis recristallisé dans l'éther. pf: 141°C; rdt: 44%. *Anal.* calc. pour $C_{18}H_{21}OP$: C 76.03, H 7.44; trouvé: C 75.26, H 7.54.

III. Sulfure **5**

Préparé par action du soufre en excès dans le benzène à l'ébullition pendant 3 h. Le soufre en excès est ensuite filtré. Le benzène est évaporé et le sulfure est recristallisé dans l'hexane. rdt: 70%; pf: 89°C. *Anal.* calc. pour $C_{18}H_{21}PS$: C 71.97, H 7.05; trouvé: C 71.83, H 7.16.

IV. Iodure de diméthyl phospholium **6**

On chauffe à reflux pendant 4 h sous argon: 5.4 g de **3** (0.02 mol), 1.70 g de K (0.04 at.) dans 100 cm³ de THF anhydre. On ajoute alors 5.6 g de ICH_3 (0.04 mol). Au bout de 2 h, on hydrolyse par 10 cm³ d'eau dans 20 cm³ de THF. On évapore à sec; le résidu est repris par un mélange eau–chloroforme. La couche chloroformique est séchée, concentrée. Le produit ainsi obtenu est repris au benzène, l'insoluble est filtré et séché; c'est le sel **6**. rdt: 1 g (15%); pf: 243°C. *Anal.* calc. pour $C_{14}H_{22}IP$: C 48.29, H 6.36, I 36.44, P 8.89; trouvé: C 48.36, H 6.46, I 36.21, P 8.76.

V. Essai d'échange P—Ph → P—tBu dans **3**

A 3.6 g (0.0135 mol) de **3** dans 60 cm³ d'hexane sec, sous argon et à température ambiante, on ajoute 22.5 cm³ de *t*BuLi 0.6 *M*. On laisse agiter pendant 6 h, puis on hydrolyse par 25 cm³ d'eau et neutralise par HCl 2 *N*. La couche organique est séparée, la couche aqueuse est extraite à l'hexane. Les fractions d'hexane réunies sont séchées sur SO_4Na_2 puis distillées. On obtient une fraction $Eb_{0.1}$ = 125–140°C qui est un mélange de **3** et d'autres produits que nous n'avons pu séparer.

VI. Hydroxy-2-dihydro-1,2-phosphorine **7**

Un mélange de 8.1 g de phosphole (0.03 mol) et 30 cm³ de Et_3N dans 170 cm³ d'éther anhydre, on ajoute 9 cm³ (0.06 mol) de chlorure de benzoyle. On chauffe à reflux pendant 4 h, puis on hydrolyse par 100 cm³ d'eau. La couche organique est évaporée à sec. Le résidu est purifié par chromatographie (éluant AcOEt puis AcOEt/MeOH – 90/10). Poids: 3.4 g; rdt: 29%; pf: 181°C. *Anal.* calc. pour $C_{25}H_{27}O_2P$: C 76.90, H 6.97; trouvé: C 76.88, H 6.93.

VII. Oxa-1-phospha-2-cycloheptadiene-4,6 **8**

On agite pendant 48 h à température ambiante, 2 g de **7** dans 50 cm³ de DMF auquels on a ajouté une pincée de NaH. On hydrolyse ensuite par 5 cm³ d'eau, neutralise par HCl 2 *N*, évapore sous vide mécanique et reprend le résidu par un mélange eau–chloroforme. On concentre la couche chloroformique et purifie le produit par chromatographie (éluant AcOEt). Poids: 1.4 g; rdt: 70%; pf: 158°C. *Anal.* calc. pour $C_{25}H_{27}O_2P$: C 76.90, H 6.97; trouvé: C 76.68, H 6.82.

VIII. Phosphacymantrène **9**

On chauffe à reflux pendant 4 h un mélange de 2.7 g (0.01 mol) de **3** et 4 g de $Mn_2(CO)_{10}$ dans 50 cm³ de xylène. On filtre, concentre le filtrat. Le résidu est repris à l'hexane, refiltré, concentré à nouveau et purifié par deux chromatographies successives (la première à l'hexane, la seconde au pentane). Poids: 0.5 g; pf: 61°C. *Anal.* calc. pour $C_{15}H_{16}MnO_3P$: C 54.56, H 4.88; trouvé: C 55.56, H 4.92.

IX. Complexes **10**, **11** *et* **12**

On chauffe à 80°C pendant 3 h 5.4 g (0.02 mol) de **3** et 11 g de $Fe_3(CO)_{12}$. On filtre l'insoluble, concentre le filtrat et chromatographie le résidu. En utilisant d'abord le benzène, on élue ensemble les complexes **10** et **11**; en continuant avec l'acétate d'éthyle on obtient ensuite le complexe **12**. pf: 182°C; rdt: ~15%. *Anal.* calc. pour $C_{21}H_{21}FeO_4P$: C 59.45, H 4.98, Fe 13.16; trouvé: C 60.24, H 5.0, Fe 12.92.

Les complexes **10** et **11** sont ensuite séparés par une nouvelle chromatographie: **10** est élué à l'aide d'un mélange pentane/hexane 50/50 et **11** à l'aide d'un mélange hexane/benzène 70/30. **10**: pf: 84°C; rdt: ~10%. *Anal.* calc. pour $C_{22}H_{21}FeO_4P$: C 60.57, H 4.85, Fe 12.8; trouvé: C 61.28, H 4.95, Fe 13.4. **11**: pf: 135°C (déc.); rdt: ~12%. *Anal.* calc. pour $C_{25}H_{21}Fe_2O_7P$: C 52.12, H 3.67, Fe 19.39; trouvé: C 52.12, H 3.69, Fe 19.68.

Le complexe **12** a été également préparé directement par action du $Fe_3(CO)_{12}$ sur l'oxyde **4** dans les mêmes conditions qu'à partir de **3**: 3 h à reflux dans le benzène et chromatographie (éluant AcOEt). rdt ~50%.

Molecular activation analysis for methylmercury

J.-P. SCHMIT[1] AND D. R. WILES

Chemistry Department, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received January 20, 1978

J.-P. SCHMIT and D. R. WILES. Can. J. Chem. **56**, 1956 (1978).

The principle of molecular activation analysis is described, as well as its unsuccessful application to the species specific determination of methylmercury in fish. The reasons for the failure of the method were determined and are found to be of significance to hot atom chemistry and to possible future use of this principle. The reasons are: (*i*) a matrix dilution of the species sought, (*ii*) a scavenging, probably of methyl groups, by serine or related components of fish powder, and (*iii*) a methylation by some unidentified component associated with the fish fats.

J.-P. SCHMIT et D. R. WILES. Can. J. Chem. **56**, 1956 (1978).

On décrit le principe de l'analyse moléculaire par activation neutronique appliquée au dosage spécifique du méthylmercure dans les poissons. Bien que cette nouvelle méthode n'ait pas réussi dans cette application, les raisons de son insuccès ont été trouvées très significatives dans l'étude de la chemie des atomes chauds et dans son application éventuelle à d'autres problèmes. Ces raisons sont les suivantes: (*i*) la dilution par la matrice de l'espèce étudiée, (*ii*) la reaction de groupes libres methyle avec la serine ou d'autres composés similaires présents dans la chair des poissons, (*iii*) la méthylation du mercure par un composé inconnu associé avec les tissus adipeux des poissons.

Introduction

Recent publications from this laboratory (1–3) have described the principle of "molecular activation analysis", a form of neutron activation analysis in which the specific chemical form of an element can be determined as well as its total quantity. Stemming from developments in the field of hot atom chemistry (4) this method recognizes that a fraction, R, of the molecules will retain their original molecular identity following neutron activation. If the value of R is reliably known, then chemical isolation of the desired compound, with known chemical recovery, q, makes possible the measurement of its radioactivity, so that the usual equation for activation analysis becomes:

$$W_x = \frac{A_x}{qR}\frac{W_r}{A_r}\cdot \phi(t, T)$$

where W and A are respectively the weight and radioactivity of the element present in the compound and a reference sample (denoted by x and r) respectively. The function $\phi(t,T)$ accounts for possible differences in irradiation time t, and decay time T, and can usually be made sensibly equal to 1.00.

In applying this method to the determination of methylmercury in fish, blood, and other materials we first determined the retention, R, of methylmercury in pure crystalline CH_3HgCl:

$$CH_3HgCl(n,\gamma)\ {}^{197}Hg \begin{cases} \nearrow CH_3{}^{197}HgCl \\ \searrow \text{other forms} \end{cases}$$

Results from this experiment were quite satisfactory, as is shown in Table 1. Corresponding determination (2, 3) of the retention in CH_3Hg-doped fish protein concentrate (FPC) led unfortunately to values which were both very low and dependent on the origin of the protein. Values of R ranged from 3% for cod and haddock through 6–8% for tuna and swordfish to 11.8% for seal, as is seen in Table 2. While we were able to develop (3) an alternative method of neutron activation analysis specific for CH_3Hg—, the variability of R clearly means that the intended method is unreliable without a great deal of further work.

In seeking an explanation for the inconsistency of the retention, R, in protein and the wide disparity between these values and that for pure CH_3HgCl, we find several possibilities, any or all of which could be contributing:

(*1*) A matrix effect in the protein concentrate itself. This could result from the wide physical separation of the methylmercury groups from one another, which would make momentum transfer from the activated atom less effective and would cause a reduction of the retention (e.g. from 82% to 12% or to 3%).

TABLE 1. Yields of radioactive mercury from neutron irradiation of crystalline CH_3HgCl

Product isolated	^{197}Hg yield (%)
$(CH_3)_2Hg$	0.1 (ref. 3)
CH_3HgCl	82.0 (ref. 3)
Hg^{2+}	18 (by difference)

TABLE 2. Retention of ^{197}Hg as CH_3Hg in fish tissue, each value given is the average of several determinations

Sample	Retention	Reference
Cod, haddock	3.4±0.3	3
Swordfish, tuna	6.6±0.9	3
Seal	11.8	3
Soya flour doped with CH_3HgCl	10.2	This work
Soya flour doped with $HgCl_2$	2.7	This work

(*2*) A 'foreign' compound in the protein causing a further *decrease* in retention (e.g., from 12% to 3%). This could be, for example, a mercury atom scavenger or a methyl radical scavenger.

(*3*) A 'foreign' compound in the protein causing an *increase* in retention (e.g. from 3% to 12%). To judge from the data in Table 2, this would plausibly be related to the fat content. For example, the effectiveness of a typical methylating agent in this case was demonstrated (2) by the substantial increase in retention (from 7% to 22%) on irradiation of a sample of CH_3Hg-doped swordfish protein moistened with 2,2,4-trimethylpentane.

It was with a view to elucidating the cause of this apparent inconsistency in the effect that we undertook the present study, in the hope that even if this method might not be applicable to fish, it might be more reliable when applied to other substrates.

Experimental

Materials and Reagents

Fish samples were obtained from the retail trade as fresh cod filets. Methylmercury chloride was obtained from Strem Chemicals, Inc., and was purified by recrystallization from chloroform. It was kept dry and stored under refrigeration. All other reagents used were Reagent Grade. Solvents were kept air-free and dry by the use of molecular sieves. Soya flour (SF) was obtained as commercial product and washed twice with 25% isopropyl alcohol (IPA) in water, twice with pure IPA, twice with acetone, and once with petroleum ether before being dried and stored at room temperature.

Preparation of Doped Soya Flour

To study the radiochemical retention of methylmercury in the SF 'matrix' we prepared a doped SF by treating purified SF with a solution of methylmercury chloride in chloroform, as was described earlier (2). That the methylmercury is chemically bound to the matrix is shown (5) by the fact that it is completely removed from a chloroform solution on passage of the solution through a 3–5 cm column of soya flour, and is not removed from the column by washing with further chloroform. The nature of this bonding is not known, and we can only surmise that binding is similar to that in other protein-containing substances (6, 7).

Preparation of Fat and the Water Soluble Extract

Fat and other components were extracted from fresh cod filets according to published procedures (8) by means of IPA. After IPA was removed water was added to the residue and the fat extracted with diethyl ether.

(a) Preparation of the fat. After being dried over $CaCl_2$, the crude fat was obtained by removing the ether. A part of the crude product obtained was dissolved in petroleum ether (PE) washed three times with 0.1 *N* HCl to remove the amines and finally with water. The organic layer was then dried and the petroleum ether removed. The crude and the purified fats were kept under refrigeration. The fat was applied to the doped SF as a solution in petroleum ether which was subsequently evaporated.

(b) Preparation of the water soluble extract (WS). The aqueous fraction obtained during the crude fat preparation was separated into two fractions by precipitation with methanol. The precipitate was discarded. The methanol-soluble fraction was evaporated to dryness and the residue (WS) dissolved in 25 ml of a 25% mixture of isopropyl alcohol in water.

Separation Methods

Separation of methylmercury from the SF was done using a modification of the method of Uthe, Solomon, and Grift (9). A few milligrams of nonradioactive methylmercury chloride was added to the aqueous medium to act as a carrier for the radioactive molecules. This method entails the following steps: (*i*) add the neutron-irradiated doped SF to a mixture of 15 ml aqueous solution of 0.1 *M* $CuSO_4$ plus 10 ml of 3 *M* NaBr – 2 *M* H_2SO_4 solution, add about 5 mg CH_3HgCl carrier in 15 ml toluene, shake vigorously for 45 min, let the layers separate, (*ii*) carefully remove the toluene and backwash 3 times by shaking with distilled water, (*iii*) count an aliquot of the toluene solution in a NaI scintillation counter under reproducible geometry.

Radioactivation and Measurements

Neutron irradiations were done using the SLOWPOKE reactor of the Atomic Energy of Canada Ltd., Ottawa, which gave a flux of thermal neutrons of 1.0×10^{12} cm^{-2} s^{-1} and a γ-ray intensity of about 1×10^6 rad h^{-1}. Irradiations were normally of 10 min duration. The reactor temperature at the point of irradiation was about 30–40°C.

Radioactivity measurements were made using a 3 × 3 in. Na(Tl)I scintillation detector coupled to a 512-channel pulse height spectrometer. The 77 keV peak of ^{197}Hg stood out quite clearly above the background. Decay of ^{197}Hg in the samples was corrected for by extrapolating the activities of both the reference sample and the extracted methylmercury sample back to the same time. Counting rates were sufficiently high that statistical errors were small.

We have found that, although pure methylmercury chloride escaped quite readily from polyethylene vials during neutron irradiation (10), methylmercury bound to SF by the doping procedure outlined above did not (3).

Results and Discussion

Among the factors which may perturb the methylmercury retention, the most complex are possible fish protein 'matrix' effects. However, this source of uncertainty can be eliminated by using instead a matrix of soya flour (SF), a similar but more reproducible protein-containing substrate. In fact, on the one hand, soya flour gives retentions comparable to those obtained in protein concentrates and, on the other hand, it is easily obtained pure and does not contain much sodium (whose induced radioactivity interferes with γ-ray measurements). Thus, we have used that new substrate to undertake a systematic study of the factors which may modify the methylmercury retention.

(a) Influence of Fish Fat

Regarding the influence of fat as a factor expected to increase the methylmercury retention, two principal features deserve consideration. First, previously cited experiments with 2,2,4-trimethylpentane as a methylating agent gave positive results. Second, the retention seems strongly dependent on the normal fat content of the fishes under study, as is seen from the data in Table 2. According to Dambergs, cod protein is produced essentially free of fat, while in other fish, notably herring, the extraction is less effective (8).

In order to understand this anomaly, we prepared a sample of soya flour doped with 158 μg CH_3HgCl per g of SF. To a series of aliquots we added selected amounts of crude fish fat. These samples were then irradiated with neutrons and the retention was measured as described above. The results are shown in Fig. 1. Although, as was expected, the presence of fat increases the retention, it is noteworthy that extrapolation of the observed retention vs. percentage of fat does not lead to the normal 'zero-fat' value of 10.2% for the retention of SF doped only with pure methylmercury. On the other hand, a similar experiment done with fat washed with dilute HCl does lead by extrapolation to the expected value. Moreover, in this experiment the effect of the acid-washed 'pure' fat is strikingly higher than that of the crude product.

A second series of experiments was then undertaken, using SF doped with $HgCl_2$ (172 μg/g SF) instead of methylmercury. The results, shown in Fig. 2, indicate that here again methylmercury is found, in amounts which increase with increasing fat concentration. Since none was present initially, it is clear that in this case the methylmercury has been formed rather than retained. The CH_3 comes presumably from the protein. Moreover, it is noteworthy that with $HgCl_2$-doped SF, both curves, with crude as well as with HCl-washed fat, lead by extrapolation to the expected methylmercury retention of 2.8% for the pure $HgCl_2$-doped SF. As with the methylmercury study, the influence of the HCl-washed fat is stronger than that of the crude fat.

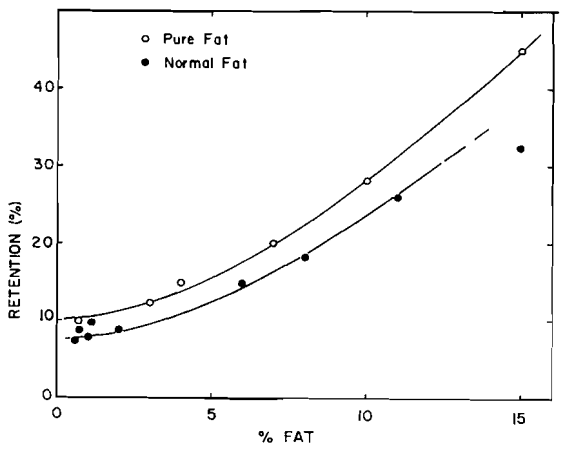

FIG. 1. Variation of retention with fat (CH_3HgCl).

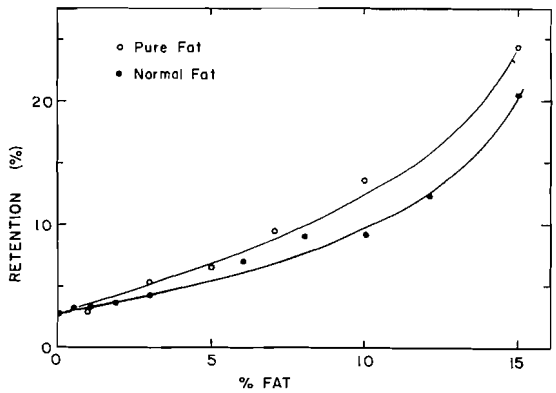

FIG. 2. Variation of retention with fat ($HgCl_2$).

From these observations several features should be noted. First, comparison of the two series of experiments strongly suggests that the phenomenon involves primarily the availability of a reactive methyl group. Indeed, both the 2,2,4-trimethylpentane (2) and the fat can be considered as methylating agents. Thus, these two compounds are able to increase the local concentration of methyl groups and, as a consequence, there is a higher probability for methyl-mercury recombination. Further, the same methylating effect can be observed in the second series of experiments ($HgCl_2$-doped SF) in the absence of initial methylmercury. In this latter case, the only sources of methyl groups are the soya protein, which can be considered constant, and the fat. Thus, it seems that the fundamental mechanism of the variation of retention is more a problem of availability of methyl groups for the recoiling mercury atom than of some inherent properties of that latter. Secondly, the observation that the methylmercury retentions do not extrapolate to the zero-fat value could result from the presence in the fat of another compound which decreases the retention. Thus, one can wonder whether the retention differences in the three classes of fish proteins may be the results of a varying *decrease* (from ~13%) rather than a varying *increase* (from 3%). If this hypothesis is true, then this decreasing factor must act mostly as a methyl radical trap. Moreover, it must be only partly extracted by Damberg's method for FPC preparation, and then must be in higher concentration in the water soluble (acid) fraction. Finally, it must be able

	7.6	9.9			
	10.0	14.3			

to influence the retention even at very low concentration and with very little concentration dependence. This is shown below to be the case.

(b) Retention Decreasing Product (RDP)

Since the very nature of the RDP is unknown, its concentration is also unknown. In a first series of experiments we added different volumes of the methanol fraction of the water soluble extract (WS) to the CH_3HgCl-doped SF. From the results given in Table 3, one can see that: (*i*) the retention is strikingly decreased, even with little volume of WS; (*ii*) the presence of WS delays the increasing effect of fat. On the other hand, irradiation of methylmercury-doped SF fat, followed by separations of fat and SF shows the relative contributions of the two components to the retention, as is seen in Table 4. It is noteworthy that the fat contribution to the total retention and the specific methylmercury retention in fat are not directly related. Moreover, we found that the methylmercury retention in the fat reaches its maximum value at about 15% of fat in the sample, although it is true that for more fat than 15% the results become highly unreliable. The preparation method for doped SF allows the introduction of CH_3HgCl into the protein matrix, while one can expect the fat to be only on the surface, so that beyond a certain fraction (e.g. 1%), addition of fat does not increase the extent of coverage but only the less important depth of coverage. Thus, it is plausible to represent the reaction mixture as a set of CH_3HgCl-doped particles of soya flour coated by layers of fat of various thickness (10–15 monolayers). In that model the role of the fat would be to trap the escaping hot mercury atoms, while the RDP acts as an efficient scavenger for the free methyl radical formed in the soya flour particle. We have no evidence to support this conjecture.

Finally, we conducted a series of experiments in order to elucidate the nature of RDP, if not to determine its exact identity. Of many possible methyl-scavenging compounds, four types are common in fish: amino acids, triglycerides (both saturated and unsaturated), and phospholipids. Of these, the amino acid seemed the most likely to us, because of the demonstrated extractibility of RDP in aqueous HCl. We chose to use serine because of its importance in muscle tissue, along with lecithin (a phospholipid) and triolein and trilaurin (unsaturated and saturated triglycerides, respectively). The results of this experiment are given in Table 5, where it is evident that only the serine has any effect on the retention. The others seemingly have little or no influence on the retention (which also eliminates them as significant methylating agents). The serine gives an immediate distinct reduction in the retention which does not change with a further 1000-fold increase in the serine concentration. This latter behaviour is in keeping

TABLE 4. Distribution of radioactive CH_3Hg— between the soya flour and the fat

with its being a scavenging reaction. The fact that the addition of larger amounts of fat increases the retention after the initial decrease (Fig. 1) suggests that only the original $—CH_3$ is being scavenged while the further methylation does not occur by a scavengeable mechanism.

The slow increase in retention evidently caused by small amounts of the triglycerides, triolein and trilaurin, suggests that one of these compounds (more likely triolein) is responsible for the methylation by added fat.

Conclusions

It now seems that the dependence of the retention on the species of fish is not a matter of a fat-induced increase, as we had initially surmised, but is caused rather by a decrease in retention resulting from the presence of species such as serine and related compounds.

Thus, the main features of the problem can now be explained. The retention of ^{197}Hg in pure crystalline CH_3HgCl is found to be 82.0%, while with methylmercury bound in a protein matrix it is much less: about 11–12%. This marked decrease is doubtless due to a combination of the dilution (by a factor of about 10^4) and the fact that the protein lattice is composed of lighter atoms (C, H, O, N rather than C, H, Hg, and Cl). The latter provides a slightly looser cage for a recoiling mercury atom, so that the atom can somewhat more readily escape from its original ligands. The former ensures that the escaped atom will not be able to react, by exchange, hot reaction or whatever, with a nearby methylmercury, since the nearest one is some 25 molecules away.

This 'standard' protein retention value is then further decreased by the presence, in fish protein concentrate, of methyl scavengers which reduce the probability that the hot mercury atom will remain bound to its original methyl. The identity of these scavenger compounds is not known, although it seems clear from the data in Table 5 that they may be similar to serine. The absence of a concentration dependence shows that the retention difference between one species and another (Table 2) is not a matter of variations of the scavenger concentration among fish species but must rather be a difference in the compound itself.

These experiments show further that the high radiochemical retention in CH_3HgCl must be largely the result of interactions of recoil atoms with neighbouring molecules and does not represent the truest form of retention, in which the original molecule remains intact.

The overall radiochemical reaction involved in the neutron irradiation of CH_3HgCl can now be sketched in terms of three different reactions: (*i*) survival of the molecule intact ('true' retention), 3%; (*ii*) reformation of the original $CH_3—Hg$ bond (scavengeable), 8–9%; (*iii*) formation of CH_3HgCl by reaction with other molecules, 70%; total retention, 82%. Step (*i*) may well include breaking and rapid reformation of the Hg—Cl bond, while step (*iii*) likely includes both hot, epithermal, and thermal reactions.

Clearly, step (*iii*) is not available in pure fish or other protein matrices and step (*ii*) is evidently quenched by acid-extractable compounds such as serine.

Nitroform is the major radiation induced species observed after the pulse radiolysis of acidic oxygen saturated solutions of tetranitromethane (TNM) and formic acid. It is formed in three stages, of which a major component at pH < 3 is first order with $t_{1/2} = 49$ s, independent of [TNM] and pH. Evidence is provided for the reactions

$$HO_2 + NO_2 \underset{k_{14}}{\overset{k_3}{\rightleftharpoons}} HO_2NO_2$$

in which $k_{14} = 0.014 \pm 0.002\ s^{-1}$. The data support similar conclusions reached previously in rapid mixing experiments (1) from which it was concluded that $k_3 = 4 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$.

Analysis of the fastest component of nitroform production over the pH range 1–4 shows that the COOH radical reduces TNM to nitroform with a rate constant about four times greater than that for its reaction with oxygen to produce HO_2.

HARRY CALLENDER SUTTON, WILLIAM ARTHUR SEDDON et FRED CHARLES SOPCHYSHYN. Can. J. Chem. **56**, 1961 (1978).

Lorsque l'on effectue la radiolyse de solutions d'acide formique et de tétranitrométhane (TNM) saturées d'oxygène, le nitroforme est l'espèce la plus importante que l'on observe. Ce composé se forme en trois étapes; la plus importante, qui se produit à un pH < 3, est du premier ordre avec $t_{1/2} = 49$ s et elle est indépendante de [TNM] et du pH. On présente des données concernant les réactions indiquées

$$HO_2 + NO_2 \underset{k_{14}}{\overset{k_3}{\rightleftharpoons}} HO_2NO_2$$

dans lesquelles $k_{14} = 0.014 \pm 0.002\ s^{-1}$. Les données sont en accord avec des conclusions semblables qui ont été obtenues antérieurement lors d'expériences de mélanges rapides à partir desquelles on a conclu que $k_3 = 4 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$.

L'analyse de la réaction la plus rapide lors de la formation du nitroforme à des pH allant de 1 à 4 montre que le radical COOH réduit le TNM en nitroforme avec une constante de vitesse qui est environ quatre fois plus grande que celle de sa réaction avec de l'oxygène pour fournir du HO_2.

[Traduit par le journal]

Introduction

In a recent study using rapid mixing techniques in a flow system (1), it was concluded that HO_2 produced by the radiolysis of aerated formic acid solution reacts with acid solutions of tetranitromethane (TNM) as follows:

[1] $$HO_2 \rightleftharpoons O_2^- + H^+$$

[2] $$C(NO_2)_4 + O_2^- \rightarrow C(NO_2)_3^- + O_2 + NO_2 \qquad k_2 = 2 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$$

[3] $$HO_2 + NO_2 \rightarrow HO_2NO_2 \qquad k_3 = 4 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$$

[4] $$2NO_2 \rightarrow N_2O_4 \qquad k_4 = 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$$

[5] $$N_2O_4 + H_2O \rightarrow HNO_2 + HNO_3$$

[6] $$HO_2NO_2 + C(NO_2)_4 \rightarrow \cdots \rightarrow C(NO_2)_3^-$$

The major feature of this mechanism is that the rapidly formed species HO_2NO_2 (termed peroxynitric acid) reacts slowly with TNM to produce the coloured nitroform anion in [6], in a reaction time which exceeds several seconds but is less than 10 min. In contrast, the nitroform resulting from [2] was produced in less than a second under the conditions studied. Potassium thiocyanate (KCNS) was found to suppress [6] (presumably by decomposing HO_2NO_2) but not [2].

We report here studies of the pulse radiolysis of oxygen saturated solutions of formic acid and TNM with results which confirm and extend these conclusions.

Experimental

The basic pulse radiolysis techniques (2) and methods of chemical preparation and analysis (1) have been described previously. Solutions were irradiated in 2 cm cells using 0.5 μs electron pulses from a 2.5 MeV Van de Graaff accelerator. Doses per pulse ranged from 500–900 rads (5–9 Gy).

Slow reactions were recorded on a Tektronix 556 oscilloscope by connecting the external horizontal input to a Wavetek Model 162 function generator and extending the sweep speeds to 24 or 60 s cm^{-1}. In such experiments, photomultiplier fatigue was eliminated using a manually operated light shutter permitting intermittent measurement of the analysing light level at 5–20 s intervals. The pH of solutions was adjusted with H_2SO_4 or KOH, and read on a Fisher Accumet model 320 pH meter.

Results

After pulsing oxygen saturated solutions of 0.01 mol dm^{-3} formic acid containing 155 μmol dm^{-3} TNM at pH 1.85, nitroform was produced in three stages: (i) immediate (complete in 5 μs); (r) rapid, produced in a first order build-up with $k_r = 840\ s^{-1}$ ($t_{1/2} = 0.82$ ms), and (d) delayed, in a first order build-up with $k_d = 0.0144\ s^{-1}$ ($t_{1/2} = 48$ s). Figure 1 shows reproductions of oscilloscope traces which illustrate this behavior. Nitrofrom was, at all stages, the major radiation induced species detectable by light absorption and its spectrum, measured from 270–400 nm, precluded the observation of any other minor species.

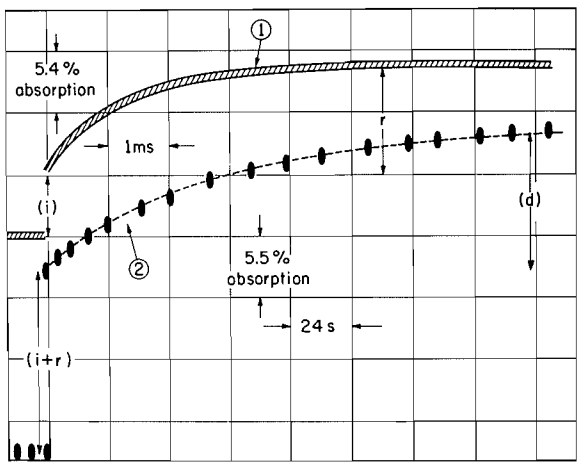

FIG. 1. Reproductions of oscilloscope traces, monitored at 350 nm, showing the formation of nitroform in oxygen saturated solutions of 0.01 mol dm^{-3} HCOOH containing TNM. Concentrations are as given for experiment 8 in Table 1. Dose per pulse, *1* = 810 rads, *2* = 945 rads. The dotted line in trace *2* corresponds to a first order fit with $k_d = 0.0148\ s^{-1}$.

Table 1 summarizes the nitroform yields and kinetic data taking the extinction coefficient at the nitroform band maximim (350 nm) $\varepsilon_{350} = 14\ 400$ $dm^3\ mol^{-1}\ cm^{-1}$ (1). Nitroform yields at each stage (i), (2–5 μs), (r), (4–20 ms), and (d) (300 s) are denoted as G_i, G_r, and G_d respectively, whilst their total is expressed as G_t.

Discussion

The immediate yield of nitroform is partially due to the rapid reaction

[7] $$e_{aq}^- + C(NO_2)_4 \rightarrow C(NO_2)_3^- + NO_2 \qquad k_7 = 4.6 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$$

which competes with

[8] $$e_{aq}^- + O_2 \rightarrow O_2^- \qquad k_8 = 1.9 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$$

and

[9] $$e_{aq}^- + H^+ \rightarrow H \qquad k_9 = 2.3 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$$

for solvated electrons, e_{aq}^-, with $G_{e_{aq}^-} = 2.9$ molecule/100 eV (3). The known rate constants of these reactions (4, 5) imply that about 10% of the immediate yield observed in experiment 11 at pH 1.82 with 582 μmol dm^{-3} TNM ($G_i = 2.28$) is due to reaction [7], and this fraction decreases with decreasing pH.

We attribute the remainder (i.e., most) of the immediate yield to the reactions

[10] $$OH + HCOOH \rightarrow COOH + H_2O$$

[11] $$COOH + C(NO_2)_4 \rightarrow C(NO_2)_3^- + CO_2 + NO_2 + H^+$$

and

[12] $$COOH + O_2 \rightarrow CO_2 + HO_2$$

Reactions analogous to [11] and [12] must be considered in conjunction with the ionised form of the COOH radical, for example

[13] $$CO_2^- + O_2 \rightarrow CO_2 + O_2^-$$

Consequently the apparent rate constants of these reactions are expressed in total radical concentrations as k_{11}^{ap} and k_{12}^{ap}, respectively. Thus, for example, $d([HO_2] + [O_2^-])/dt = k_{12}^{ap}([COOH] + [CO_2^-]) \times [O_2]$ where $k_{12}^{ap} = xk_{13} + (1 - x)k_{12}$ and $x = [CO_2^-]/([CO_2^-] + [COOH])$. Assuming $G_{OH} = 2.7$ (3), independent of pH, then our data conform with this interpretation if $k_{12}^{ap}/k_{11}^{ap} = 0.24 \pm 0.1$. The data do not show any consistent variation of k_{12}^{ap}/k_{11}^{ap} with pH from 1.08 to 4, the values obtained being 0.26 at pH 1.08; 0.26 at 1.32; 0.35 at 1.55; 0.12, 0.14, and 0.27 at 1.82; 0.21 at 1.85; 0.31 at 2.1; 0.27 at 2.85; 0.18 at 3.5; and 0.22 at pH 4.

[e]Not determined.

Measurements of the pK of the COOH radical have been reported from 1.4 (6, 7) to 3.9 (8), with recent evidence favouring 1.4 (6). Thus the fraction x defined above cannot exceed 0.32 at pH 1.08 and must increase at least three-fold over the pH range we studied. Fojtik *et al.* (8) report that $k_{11}^{ap} = (4 \pm 1) \times 10^9$ dm^3 mol^{-1} s^{-1}, independent of pH from pH 2 to 7. We conclude, firstly, that $k_{12}^{ap} = (1^{+1}_{-0.5}) \times 10^9$ dm^3 mol^{-1} s^{-1} at $1 < pH \leq 4$, and secondly, that k_{12} must be comparable with k_{13} and probably within the range 10^8 to 10^9 dm^3 mol^{-1} s^{-1}. We are not aware of other measurements of k_{12} but values of k_{13} have been reported as 2.4×10^9 (9) and 2.0×10^9 dm^3 mol^{-1} s^{-1} (10), in reasonable agreement with these conclusions.

The rapid stage, (r), of nitroform production corresponds in rate with that observed after irradiating oxygen saturated TNM solutions (4). It is due to reduction of TNM by O_2^- in [2] at a rate which is approximately expressed by a pseudo first order rate constant of fk_2[TNM] where $k_2 = 2 \times 10^9$ dm^3 mol^{-1} s^{-1} (4), $f = [O_2^-]/([O_2^-] + [HO_2])$, and the p$K$ of the HO_2 radical is 4.88 (11). The observed build-up of nitroform was approximately first order with values of k_r which agree with those calculated as fk_2[TNM] at pH 6 where $f = 1$, but exceed these to an extent increasing with decrease of pH to about three-fold at pH 1.8 and four-fold at pH 1.08.

The mechanism we propose requires that reactions [3] and [4] should compete with [2] for HO_2 and NO_2 in the rapid stage and influence the observed build-up. Computerised calculations of this effect have been made with the rate constants reported previously for k_3 and k_4 (1), taking somewhat uncertain values for $[HO_2]^0$ and $[NO_2]^0$ at the beginning of the rapid stage which are explained and discussed later. On this basis the build-up of nitroform in the rapid stage is calculated to be approximately exponential with a rate constant which exceeds fk_2[TNM] by a factor increasing from 1 to approximately 2 as the pH is lowered from 6 to 1, which is in reasonable agreement with our observations. It seems likely that the effect we describe may have occurred to a smaller extent in the experiments of Rabani *et al.* (4), as these authors also noted a slow build-up of nitroform over some minutes in the pulse radiolysis of oxygen saturated TNM solutions, probably attributable to HO_2NO_2. If so, this would introduce a small error in the estimate of the pK of the HO_2 radical (4.45 ± 0.25) which they deduced from their observations.

The rate of the delayed stage, (d), of nitroform production corresponds with that attributed to [6] (i.e., to peroxynitric acid) in the rapid mixing experiments (1). Delayed yields are also of the same magnitude as in these experiments, amounting to about half the total yield at pH 1.6 and zero at pH 6. Addition of KCNS completely suppressed the delayed reaction both in the rapid mixing experiments and in those reported here. We also found that KCNS partially reduced the immediate and rapid components (G_i and G_r), owing to its competition with [10] for OH radicals (12). However, the delayed formation of nitroform cannot be due to direct re-

action of HO_2NO_2 with TNM since the observed build-up is first order with k_d nearly independent of [TNM] and pH.

A possible explanation is that the species HO_2NO_2 slowly decomposes as follows:

[14] $$HO_2NO_2 \rightarrow HO_2 + NO_2$$

so that the NO_2 and HO_2 so evolved at low concentration react nearly quantitatively in [1], [2], [4], and [5]. On this view HO_2NO_2 might be regarded as somewhat analogous to the species H_2O_3 which is formed by reaction of HO_2 with OH (13), but differs from HO_2NO_2 in that it slowly decomposes to unreactive products at a rate which varies with pH. This interpretation implies that the observed $k_d = k_{14} = 0.014 \pm 0.002\ s^{-1}$ and that HO_2NO_2 itself does not react with TNM but is decomposed by KCNS. It also requires that the total or final yield of nitroform (G_t) should be independent of the formation of HO_2NO_2, and therefore constant in all these experiments except for variations of $G_{e_{aq}^-}$ and G_{OH} with pH. In fact, G_t agrees fairly well in most cases with $G(O_2^-) = 6$ at pH ≥ 6 (14), but occasional discrepancies occur in which G_t is smaller by amounts up to 0.7 G units. In the rapid mixing experiments the final yields observed in acid solutions generally exceeded those at pH 7 by about 8% (1).

It is not possible to make reliable kinetic analyses of these yields along the lines given previously (1) because $[HO_2]^0$ at the beginning of the rapid stage (r) can only be inferred indirectly from our observations as the difference between the total and immediate yields of nitroform. This concentration is consistent with the mechanism proposed above and gives calculated values for $[HO_2]^0$ which are typically 3 μmol dm^{-3} at pH ≤ 4. Actual values of $[HO_2]^0$ may exceed those calculated by 0.5 mol dm^{-3} in some cases for reasons given in the preceding paragraph.

Values for $[NO_2]^0$ at the beginning of the rapid stage (resulting from reactions [7] and [11]) may be estimated with less uncertainty as equal to the immediate yield of nitroform, and range from 0.6 to 1.5 μmol dm^{-3} in our experiments. In the rapid mixing experiments, however, $[HO_2]^0$ could be measured directly as typically 7 μmol dm^{-3}, whilst $[NO_2]^0 = 0$. The rapid and delayed yields of nitroform in experiment 9 were $G_r = 2.45$ and $G_d = 2.89$, respectively. These may be compared with those calculated for reactions [2] and [3] (since we assume all the HO_2NO_2 formed in the rapid stage ultimately yields nitroform in a delayed reaction) in competition with reaction [4] as $G[2]_{calcd} = 2.69$ and $G[3]_{calcd} = 2.67$, respectively, adopting the rate constants previously quoted (1) for k_3 (4×10^9 dm^3 mol^{-1} s^{-1}) and k_4 (10^{10} dm^3 mol^{-1} s^{-1}). In this case the apparent mass balance is reasonable, i.e., $G_t = 5.89$, which is close to 6. In experiment 14, $G_t = 5.22$, probably implying that the actual $[HO_2]^0$ considerably exceeds its calculated value. For this experiment $G_r = 1.73$ as compared with $G[2]_{calcd} = 1.94$, and $G_d = 2.60$ as compared with $G[3]_{calcd} = 2.37$, i.e., the calculated yield of HO_2NO_2. In most cases the agreement between observed and calculated yields was within 0.3 G units, and in all cases within 0.6 G units. This appears reasonable in view of the uncertainties in estimating $[HO_2]^0$.

There can be no doubt that a long-lived species such as HO_2NO_2 occurs under the conditions we described, but since we have not observed its absorption spectrum its concentration and properties can be inferred only indirectly. Both the data reported here and previously are consistent with the reaction mechanism discussed in this paper.

Received February 7, 1978

WILLIAM R. CULLEN, BRIAN R. JAMES, and GIORGIO STRUKUL. Can. J. Chem. **56**, 1965 (1978).

The reactions of the title complexes $Rh_4Cl_4(CO)_4(O_2)_2P_2$ (where P is a tertiary phosphine type ligand, in particular diphenylisobutylphosphinite) with both dihydrogen and carbon monoxide were studied in solution in the absence and presence of excess P. The reaction stoichiometries, particularly a measured carbon dioxide evolution, confirm the formulation of the reactant tetranuclear complexes. The complexes are effective for catalytic hydrogenation and hydroformylation of olefinic substrates, and the nature of the active catalysts is considered.

WILLIAM R. CULLEN, BRIAN R. JAMES et GIORGIO STRUKUL. Can. J. Chem. **56**, 1965 (1978).

On a étudié les réactions, en solution, des complexes mentionnés dans le titre, $Rh_4Cl_4(CO)_4(O_2)_2P_2$ (où P est un ligand de type phosphine tertiaire en particulier la diphénylisobutylphosphinite), avec l'hydrogène et le monoxyde de carbone en présence et en l'absence d'un excès de P. Les stoechiométries de la réaction, en particulier des mesures d'évolution du dioxyde de carbone, confirment la formule des complexes tétranucléaires réactifs. Les complexes sont efficaces pour effectuer l'hydrogénation et l'hydroformylation d'oléfines et on considère la nature des catalyseurs actifs.

[Traduit par le journal]

Introduction

We recently reported (1) on the synthesis of polynuclear oxygenated rhodium complexes of the type $Rh_4Cl_4(CO)_4(O_2)_2P_2$ (**1**) via O_2 oxidation of the corresponding *trans*-$RhCl(CO)P_2$ complexes (P = PPh_3, PPh_2OBu^i, $PPhEt_2$, PEt_3, and poly-$OPPh_2$ (diphenyl-polymethallylphosphinite)). Their interest stems from their potential as oxygenation catalysts (1). The dioxygen moieties were considered to be present as bridged superoxides. Because of the difficulty in unequivocally demonstrating the oxygen content of such oxidized complexes, we have investigated further the chemistry of **1** (P = $PPh_2(OBu^i)$), especially its reactivity in solution toward H_2 and toward CO, with and without added P; the overall stoichiometries of these reactions confirm the formulation of the oxidized complexes and are of interest in terms of the reactivity of coordinated dioxygen moieties.

In view of the known catalytic activity for some related oxidized rhodium complexes (2), some preliminary studies were then carried out to investigate the catalytic potential of our Rh_4 complexes. The species formed from the H_2 reaction were found effective for the catalytic hydrogenation of olefinic substrates, and those formed from the CO reaction were effective as hydroformylation catalysts.

Experimental Section

Many of the materials and methods used were described in the earlier paper (1). $[RhCl(C_2H_4)_2]_2$, prepared according to the literature (3), was used to synthesize $[RhCl(PPh_2OBu^i)_2]_2$. The ethylene complex (0.3 g) was refluxed with PPh_2OBu^i (0.8 g) in toluene (15 ml) under N_2 for 3 h; after cooling and filtering, the filtrate was concentrated to ~3 ml, and 15 ml of N_2-saturated petroleum ether were then added. The yellow precipitate was collected, washed with petroleum ether, and dried *in vacuo*. Elemental analysis was correct for a chlorobisphosphinite and, on comparison with $[RhCl(PPh_3)_2]_2$, a dimer formulation is assumed (4).

CO_2 and H_2O were identified by glc using a Hewlett Packard 5750 with Porapak N and 15% FFAP/Chromosorb W columns, respectively.

Olefinic substrates were commercial products, which were passed through alumina to remove peroxides (readily detected by Fe^{2+}/SCN^-) and then distilled under N_2. Hydrogenation procedures have been described elsewhere (5). Hydroformylation reactions were carried out in a stainless steel Parr high pressure bomb (150 ml), thermostatted in an oil-bath; external magnetic stirring was employed. The composition of the final solution was determined by glc or combined glc/mass spectrometry.

Results and Discussion

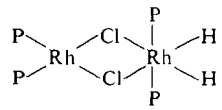
Reactions of $Rh_4Cl_4(CO)_4(O_2)_2P_2$ with H_2; $P = PPh_3$, PPh_2OBu^i, $PPhEt_2$, PEt_3

The Rh_4 complexes in CH_2Cl_2, chlorobenzene, or *N,N*-dimethylacetamide (DMA) solution, and even in the solid state, decompose quite readily under 1 atm H_2 at 25°C to give metal. We favored the O_2 moiety being bound as bridging superoxide between Rh(I) and Rh(II) centers (1), but in any case treatment with H_2 will lead to formation of Rh(I) (6) and, due to the relatively low number of π-acceptor ligands present per rhodium, hydrogen reduction (or disproportionation) of Rh(I) to metal occurs (7). In the presence of excess P, however, the solution reaction, which takes a few hours at 30°C, results in a color change from deep red to yellow, and no metal is formed; these yellow solutions (CH_2Cl_2) showed single ν(CO) ir bands for P = PPh_3, PPh_2OBu^i, $PhEt_2$, and PEt_3, at 1960, 1980, 1955, and 1950 cm^{-1}, respectively, which correspond to those we measured for the *trans*-$RhCl(CO)P_2$ complexes. Gas liquid chromatographic analysis of the yellow solutions showed the presence of H_2O, and similar analysis of the gas phase above the solution showed CO_2 to be present.

A quantitative study of the H_2 reaction in the presence of excess P proved convenient for the PPh_2OBu^i complex in chlorobenzene solution, and the data are consistent with the overall stoichiometry of reaction [1].

$$[1]\quad Rh_4Cl_4(CO)_4(O_2)_2P_2 + 6P + 3H_2 \rightarrow \underset{\mathbf{1}}{H_2(RhClP_2)_2} + 2RhCl(CO)P_2 + 2H_2O + 2CO_2$$

Solutions of **1** (10^{-2} *M*) containing a six-fold excess of P, when subjected to 1 atm H_2 at 30°C, slowly absorb H_2, and after 8 h the absorption corresponds to 1.0 ± 0.1 mol/mol **1**; in the presence of a sodalime tube, which absorbs the CO_2, the stoichiometry reaches a 3:1 ratio; 2.1 ± 0.2 mol H_2O were also formed per mol of **1**. No phosphine oxide is formed. The $RhCl(CO)P_2$ was detected essentially quantitatively by using the ν(CO) ir band, and was isolated from the yellow solution. The stoichiometry on oxygen can thus be fully accounted for. A small amount of a white solid was also isolated. This solid showed an ir band at 2065 cm^{-1} (Nujol), and in CD_2Cl_2 gave a quartet in the high-field ^1H nmr centered at τ26.6; the same ^1H nmr spectrum was obtained from an authentic sample of $[RhCl(PPh_2OBu^i)_2]_2$ in the presence of H_2, and is attributed to $H_2[RhCl(PPh_2OBu^i)_2]_2$. Such dimer hydrides have been studied by Tolman *et al.* (4) and shown to have structure **2** by the high-field ^1H nmr



2

which consists of a pair of triplets. However, the coupling of the H to Rh is similar to that of coupling to a *cis*-P, e.g. for the P(*p*-tolyl)$_3$ complex (4) τ26.7, J(Rh–H) = 22 and J(P–H) = 17 Hz, and the quartet observed for our phosphinite complex is accounted for if J(Rh–H) = 21 Hz = J(P–H).

The dimer hydride was not recovered quantitatively and this would be difficult in view of the ready loss of hydrogen from such complexes (4). Nevertheless, taken together with further data below on H_2 uptake, and with data for some CO reactions (following section), the stoichiometry of reaction [1] is considered to be established.

In the presence of a ten-fold excess of P, chlorobenzene solutions of **1** showed a net absorption of ~1.7 mol gas/mol **1**; this is entirely consistent with the expected formation of a tris(phosphinite) complex and its dihydride H_2RhClP_3. The net gas stoichiometry will be governed by equilibria [2]–[4]

$$[2]\quad 2RhClP_3 \rightleftharpoons [RhClP_2]_2 + 2P$$

$$[3]\quad H_2 + RhClP_3 \rightleftharpoons H_2RhClP_3$$

$$[4]\quad H_2 + [RhClP_2]_2 \rightleftharpoons H_2[RhClP_2]_2$$

Data given for the P(*p*-tolyl)$_3$ system (4) indicate that the H_2RhClP_3 complex would not be fully formed for the conditions of our gas uptake experiments (complete formation of $H_2RhCl(PPh_2OBu^i)_3$ requires a net gas absorption of 2.0 mol per mol **1**). H_2 absorption in the presence of less than a five-fold excess of P led to some metal production.

Reaction [1] seemed of interest mechanistically especially in view of the CO_2 production often considered to occur via oxygen atom transfer to coordinated CO (8). Unfortunately, a kinetic investigation by following the gas absorption was thwarted by a lack of reproducibility (typically factors of 2 or 3 for identical runs). Nevertheless, based on some work from this laboratory (9) which showed CO_2 production from reaction of carbonylchlororhodate(I) species with peroxy radicals, and especially a

report by Harvie and McQuillin (10) on formation of CO_2 and $[RhCl(PPh_3)_2]_2$ from reaction of $RhCl(CO)(PPh_3)_2$ with *tert*-butylhydroperoxide, reactions [4], [5], and [6] seem reasonable for the overall reaction shown in reaction [1].

[5] $Rh_4Cl_4(CO)_4(O_2)_2P_2 + 6P + 2H_2 \rightarrow 4RhCl(CO)P_2 + 2\text{“}H_2O_2\text{”}$

[6] $2RhCl(CO)P_2 + 2\text{“}H_2O_2\text{”} \rightarrow [RhClP_2]_2 + 2H_2O + 2CO_2$

Sen and Halpern (11) have recently demonstrated the existence of H_2O_2 in some related systems using Pt(0) phosphine complexes for catalytic O_2-oxidation of the phosphine. In our system, H_2O_2 was not detected directly, and the possibility of a rhodium-hydroperoxide intermediate without formation of free H_2O_2 is equally plausible. Nucleophilic attack by free phosphine on coordinated dioxygen can generate peroxide which subsequently oxidizes the phosphine to phosphine oxide (11), and of interest in this respect, addition of excess phosphine to the $Rh_4Cl_4(CO)_4(O_2)_2P_2$ complexes in the *absence of* H_2 leads very slowly (~1 week) to only $RhCl(CO)P_2$ and phosphine oxide, presumably via reaction [7].

[7] $Rh_4Cl_4(CO)_4(O_2)_2P_2 + 10P \rightarrow 4RhCl(CO)P_2 + 4PO$

However, there can be no contribution of such a pathway to reaction [1], the detailed paths of which remain to be elucidated.

Solutions of **1**, especially in DMA where the complexes exist as dinuclear species (1), catalyze the hydrogenation of terminal olefins at 1 atm H_2 and 30°C. With the P = PPh_2OBu^i system, hexene-1, octene-1, and styrene (0.2 *M*) were hydrogenated at maximum rates of $\sim 3 \times 10^{-5}$ *M* s^{-1} using 6.5×10^{-4} *M* **1**. There was no accompanying isomerization. Towards completion of the hydrogenations, metal precipitated and this must result from a lowering of concentration of the olefin which is necessary to coordinate and stabilize rhodium(I). Indeed with more weakly binding substrates such as internal olefins and ketones, metal is formed immediately on exposing the system to H_2. Similar solutions of **1** in the presence of a six-fold excess of P (reaction [1]) effect catalytic hydrogenation of terminal and internal olefins (octene-1, styrene, cyclohexene, diethylmaleate, and acrylamide).

The catalysis could proceed via the $[RhClP_2]_2$ dimer which is known to be a hydrogenation catalyst (4), since the $RhCl(CO)P_2$ systems are ineffective under these conditions (ref. 12, p. 257). In the strongly coordinating DMA solvent, however, solvated $RhClP_2$ monomers will almost certainly be present (cf. reaction [9] below), and the catalysis likely proceeds via such species. Addition of greater than a six-fold excess of P inhibited the hydrogenations which is consistent with mechanistic schemes established for the Wilkinson-type catalysts (4, 13). Augustine and co-workers (2) have used oxidized Rh complexes obtained from $RhCl(PPh_3)_3$ for catalyzing hydrogenation of olefins, but the nature of the catalysts was uncertain.

Reactions of $Rh_4Cl_4(CO)_4(O_2)_2P_2$ with CO

Deep red solutions of the Rh_4 complexes slowly absorb CO at 1 atm and 35°C and become orange; CO_2 is formed. Quantitative gasometric studies in chlorobenzene for the PPh_2OBu^i system show 3.0 mol gas are finally absorbed per mole of **1**, and this ratio becomes 7:1 in the presence of a sodalime tube. Infrared data on the final solutions are given in Table 1, together with data for some $[Rh(CO)_2Cl]_2$ systems; DMA was sometimes used because of the limited solubility of the Rh_4 complexes, although CO absorption studies in this solvent were complicated by an accompanying very slow carbonylation reaction which we have not been able to account for.

The overall process of reaction [8] accounts for the gas stoichiometries and the ir data in CH_2Cl_2:

[8] $Rh_4Cl_4(CO)_4(O_2)_2P_2 + 7CO \xrightarrow{CH_2Cl_2}$  +  + $\frac{1}{2}[Rh(CO)_2Cl]_2 + 4CO_2$

3

When $[Rh(CO)_2Cl]_2$ and PPh_2OBu^i are mixed in a 1:1 ratio under CO, the ir spectrum is identical to that measured after carbonylation of $Rh_4Cl_4(CO)_4(O_2)_2(PPh_2OBu^i)_2$. Poilblanc and co-workers (14) reported for the $[Rh(CO)_2Cl]_2/PPh_3$ system under CO in octane a very similar spectrum with major ir bands at 2103, 2090, 2032, 2020, and 2000 cm^{-1} and these were due to a mixture of $[Rh(CO)_2Cl]_2$, *cis*-$RhCl(CO)_2P$, and $Rh_2Cl_2(CO)_3P$. We thus formulate reaction [8] as shown; once the coordinated O_2 moieties are converted to CO_2, the system essentially becomes like that of Poilblanc and co-workers, the starting tetranuclear formulation requiring 0.5 mol of $[Rh(CO)_2Cl]_2$ dimer product to balance the reaction.

The simpler spectra measured in DMA are readily accounted for, considering that this coordinating solvent can cleave chloride bridges (1). All the $Rh_4Cl_4(CO)_4(O_2)_2P_2$ complexes after carbonylation give the same two bands as $[Rh(CO)_2Cl]_2$ in DMA;

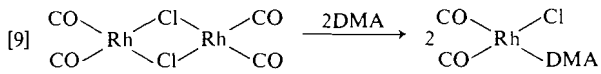
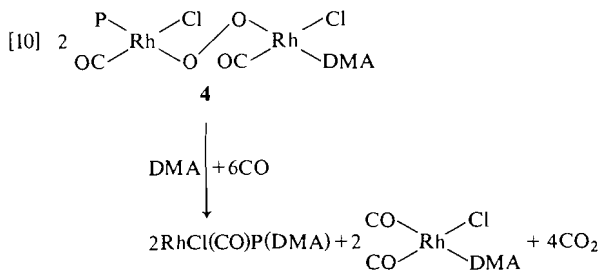
[a]A band at 2340 cm^{-1} due to dissolved CO_2 was observed, unless a sodalime tube was present.

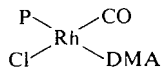
these must be due to a *cis*-$Rh(CO)_2Cl(DMA)$ species formed from the dimer according to reaction [9].



The other product formed in the carbonylation reactions shows a ν(CO) that varies from 2045–2035 cm^{-1} and this must be due to a carbonyl containing the appropriate phosphine. Again the $[Rh(CO)_2Cl]_2/PPh_2OBu^i$ system under CO gives the same spectrum as the $Rh_4Cl_4(CO)_4(O_2)_2(PPh_2OBu^i)_2$/CO solution. We believe that the carbonylphosphine species must be RhCl(CO)P(DMA). The Rh_4 complexes in DMA are known to be dimers (1) of possible configuration **4**, and thus the carbonylation of **1** in DMA may be written as



Unfortunately, as mentioned above, we were not able to confirm the net gas absorption in DMA. However, reaction [10] follows rationally from a consideration of reaction [8]: **3** would cleave to give *cis*-$Rh(CO)_2Cl(DMA)$ and RhCl(CO)P(DMA); the $\frac{1}{2}$ mol $[Rh(CO)_2Cl]_2$ would yield *cis*-$Rh(CO)_2Cl(DMA)$; and the *cis*-$RhCl(CO)_2P$ would evolve 1 mol CO in DMA to yield RhCl(CO)P(DMA) (addition of 2 mol of phosphine to 1 mol of $[Rh(CO)_2Cl]_2$ in DMA was found to evolve 2 mol CO). Formation of RhCl(CO)P(DMA) from **3**, **4**, or *cis*-$RhCl(CO)_2P$ could readily yield initially the configuration shown in **5**.



5

The small variation in ν(CO) is certainly consistent with CO being *cis* to P. As with phosphine oxidation, carbonyl oxidation clearly occurs more readily by attack of free rather than ligand CO on the coordinated O_2.

DMA solutions of the Rh_4 complexes catalyzed hydroformylation of terminal olefins under moderate conditions. Data for the PPh_2OBu^i system are given in Table 2. Heptene-1 gave only octanal, 2-methylheptanal, and small amounts of heptane, and the product distribution at 90°C was insensitive to the H_2/CO composition over the range noted at a total pressure of 1000 psi. Diminished activity resulted at lower temperatures but there was little change in the ratio of linear:branched aldehydes (~1.5). Reducing the total pressure increases the selectivity somewhat for linear aldehydes. A similar observation has been reported for rhodium carbonyl catalysts containing phosphites (ref. 12, pp. 262–269, refs. 15, 16) (although the opposite has been observed with phosphines (ref. 12, pp. 262–269, ref. 16)), and this coupled with the relatively high activity of the system indicates that the catalyst contains a PPh_2OBu^i ligand. Better selectivity is also observed on addition of more phosphinite, again typical of rhodium carbonyl systems (ref. 12, pp. 262–269, ref. 16), and in view of the absence of accompanying olefin isomerization, this can be rationalized in terms of more sterically crowded hydridocarbonylphosphine species favoring anti-Markownikov addition of the metal-hydride across the olefinic bond (ref. 12, pp. 262–269, ref. 16). As expected, a $[Rh(CO)_2Cl]_2/PPh_2OBu^i$

The photochemical reactivity of some benzoylthiophenes. IV. The effect of an adjacent methyl group on the excited state reactivity of 3-benzoylthiophene[1]

D. R. ARNOLD AND C. P. HADJIANTONIOU[2]

Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 16, 1977

D. R. ARNOLD and C. P. HADJIANTONIOU. Can. J. Chem. **56**, 1970 (1978).

The electronic absorption and phosphorescence emission spectra and the photochemical reactivity of several methyl-3-benzoylthiophenes (2- and 4-methyl-3-benzoylthiophene (**1**, **2**), 2,5-dimethyl-3-benzoylthiophene (**3**), and 3-(2-methylbenzoyl)thiophene (**4**)) have been studied. Partial state diagrams have been constructed. The lowest energy absorption in hexane solution in every case is the carbonyl $n \rightarrow \pi^*$ transition. The two lowest triplet states of these ketones are close in energy and, in fact, the nature of the emitting triplet (n,π^* or π,π^*) depends upon the position of methyl substitution and upon the solvent. The photochemical reactions studied include intramolecular hydrogen abstraction (revealed by deuterium exchange in the adjacent methyl group upon irradiation in perdeuteriomethanol solution), photocycloaddition of dimethyl acetylenedicarboxylate to the thiophene ring, and photocycloaddition of isobutylene to the carbonyl group. Generalizations, potentially useful for predicting photochemical reactivity of these and other aromatic ketones are summarized.

D. R. ARNOLD et C. P. HADJIANTONIOU. Can J. Chem. **56**, 1970 (1978).

On a étudié les spectres électroniques, les spectres d'émission de phosphorescence ainsi que la réactivité photochimique de plusieurs benzoyl-3 thiophènes méthylés (méthyl-2 et -4 benzoyl-3 thiophène (**1**, **2**), diméthyl-2,5 benzoyl-3 thiophène (**3**) et (méthyl-2 benzoyl)-3 thiophène (**4**)). On a pu élaborer des diagrammes partiels des états d'énergie. L'absorption d'énergie la plus basse en solution dans l'hexane correspond, dans tous les cas, à la transition $n \rightarrow \pi^*$ du carbonyle. Les deux états triplets les plus bas de ces cétones ont des énergies semblables et de fait la nature du triplet qui émet (n,π^* ou π,π^*) dépend de la position du substituant méthyle ainsi que du solvant. Les réactions photochimiques étudiées comprennent des réactions d'enlèvement d'hydrogène (mises en évidence par un échange de deutérium dans le groupe méthyle adjacent lorsque l'on effectue une irradiation dans une solution de perdeutériométhanol), une réaction de photocycloaddition de l'acétylène dicarboxylate de diméthyle sur le thiophène et une photocycloaddition de l'isobutylène sur le groupement carbonyle. On donne un résumé des généralisations qui peuvent être utiles pour prédire la réactivité photochimique de ces cétones ainsi que d'autres cétones aromatiques.

[Traduit par le journal]

Introduction

This continuing research program has had two major objectives.[3] The first has been to define generalizations which would be potentially useful for predicting the photochemical reactivity of carbonyl compounds. Such generalizations would ideally be based upon structural considerations and knowledge of the reactivity of model systems alone. Additional knowledge of the electronic configuration of the excited states obtained from absorption and emission studies may be useful and, finally, extrapolation from one type of characteristic excited-state reactivity to another may be required. Predictions have been tested with a series of benzoylthiophenes where the vast knowledge of the photochemical reactivity of alkyl aromatic ketones and benzophenone derivatives serves as the model. In this paper, we focus on the photochemical reactivity of 2- and 4-methyl-3-benzoylthiophene (**1**, **2**), 2,5-dimethyl-3-benzoylthiophene (**3**), and 3-(2-methylbenzoyl)thiophene (**4**); *o*-methylbenzophenone has been extensively studied and is, of course, structurally analogous.

The second objective has been to exploit the unusual reactivity of the excited state of these ketones for synthetic purposes. Utilization of the thiophene ketones should provide not only thiophene derivatives and other sulfur containing products which are difficult to prepare by other methods but also, the reactivity of the thiophene ring in the photoproduct should provide a means of further molecular modification followed perhaps by eventual desulfurization.

Several photochemical reactions have been considered: (*i*) photochemically induced positional isomerization of the thiophene: (*ii*) photoenolization, which might lead to incorporation of deuterium in the adjacent methyl group upon irradiation in deuteriomethanol or to thienocyclobutene systems. Alter-

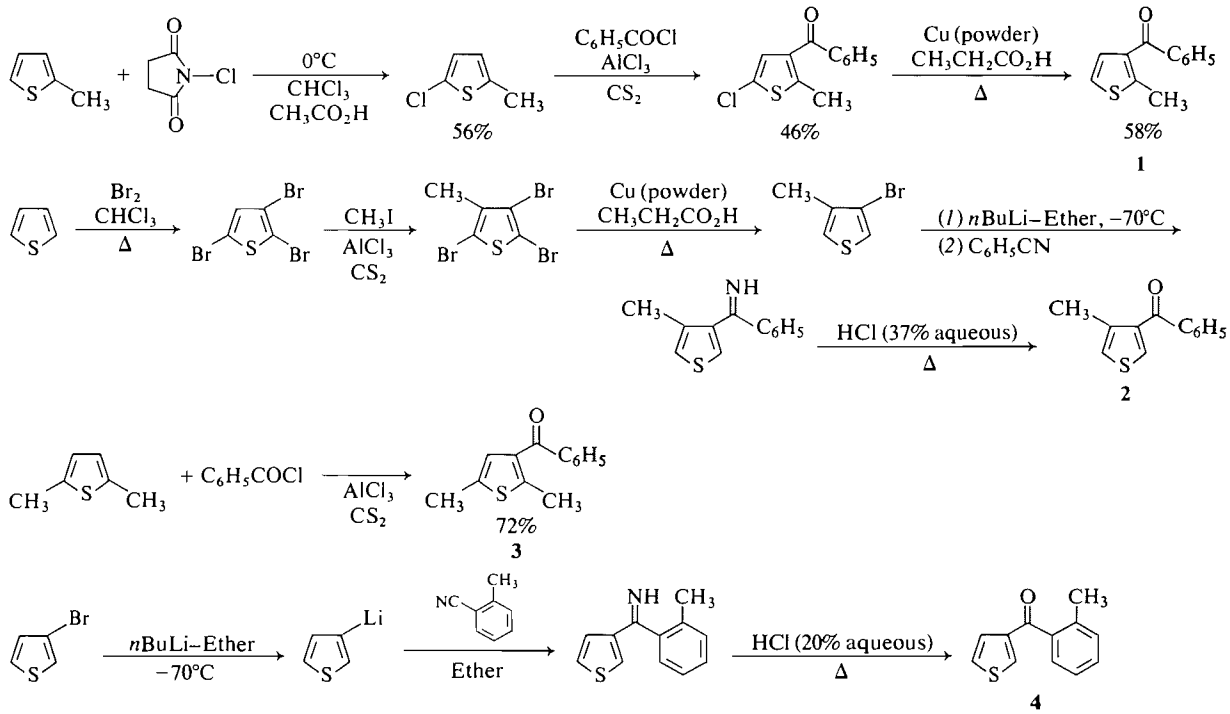

SCHEME 1

natively, the photoenol might be trapped by reaction with dienophiles to afford a useful synthesis of fused bicyclic molecules; (*iii*) photocycloaddition of olefins or acetylenes to the carbonyl group or to the thiophene ring might occur.

The results of these photochemical studies of **1–4** are discussed in connection with the partial state-diagrams for these ketones and for 3-benzoylthiophene (**5**), which can be drawn following the analysis of the absorption and phosphorescence emission spectra.

Results

The procedures used for the preparation of the ketones **1–4** required for this study are summarized in Scheme 1; **1**, **2**, and **4** are new compounds. In our initial attempts to prepare **1**, we used *N*-bromosuccinimide, instead of the *N*-chloro derivative, for the first step. The major brominated product obtained was carried through the Friedel–Crafts benzoylation and debromination and gave 2-benzoyl-5-methylthiophene instead of the desired **1**. In fact, it is known that 2-bromo-5-methylthiophene rearranges to the 4- and 3-bromo-2-methyl derivatives under remarkably mild conditions and the bromo ketone was therefore 5-methyl-4 (or 3) -bromo-2-benzoylthiophene instead of the desired isomer (2). The chloro derivative is much less susceptible to rearrangement. Details are reported in the Experimental.

The ultraviolet absorption spectra of **1–4** and 3-benzoylthiophene (**5**) in hexane and in methanol solution are shown in Figs. 1 and 2. The phosphorescence emission spectra of **1–5** were obtained in several solvents, ethanol–methanol (4:1) (EtOH–MeOH), methylcyclohexane (MCH), ethylene glycol (EG), methylcyclohexane – silica gel (MCH – SG), and diethyl ether – isopentane – ethanol (5:5:2) (EPA), at liquid nitrogen temperature. The triplet energies obtained from the emission spectra are given in Table 1. The shape of the phosphorescence emission varied depending upon the position of the methyl substituent and upon the solvent. Isomers **2**, **4**, and **5** have very similar emission in the same solvent; the variation with solvent for **5** is shown in Fig. 3. No distinct vibrational structure was observed in the emission from either **1** or **3** in any solvent. Except for a significant shift to longer wavelengths (Table 1) for **3**, the spectra were similar to those from **1** as illustrated in Fig. 4.

The rate of phosphorescence decay of ketones **1–5** was briefly studied. It was apparent that, in most solvents, the rate of decay was not a simple exponential function and no attempt was made to determine accurate rate constants. We estimate the lifetimes to be between 10^{-3} – 10^{-1} s in every case.

Irradiations were carried out in Pyrex (100% absorption < 280 nm) tubes kept at 10°C. The source was a 1 kW medium-pressure mercury vapour lamp

in a quartz, water-cooled immersion well. Ketones **1–4** were irradiated in perdeuteriomethanol solution. The progress of the reaction was followed by proton nuclear magnetic resonance spectroscopy (^{1}Hmr). During the irradiation the mixture turned dark yellow; however, after 40 h, the starting ketone was largely recovered and purified by column chromatography. There was no evidence of positional isomerization of substituents on the thiophene ring. The extent of deuterium incorporation was determined by mass spectroscopy and in some cases nmr (^{1}H and ^{2}H).

In every case, deuterium (8–20% D_1) was incorporated. The greatest exchange was observed in the case of **3** where the deuterium nmr spectrum indicates deuterium was incorporated in *both* methyl groups. The methyl group which appears at lower field (2.55 ppm) had slightly more exchange than the other methyl group (2.39 ppm): 27% more in a sample which had incorporated 13% of one deuterium. The assignment of the lower field signal to the methyl in the 2 position is consistent with the chemical shift (2.63 ppm) of the methyl in **1**. Furthermore, the higher field methyl signal is broadened as a result of coupling with the proton in the 4 position. No attempt was made to determine the absolute efficiency of these deuterium exchange reactions. A relative estimate of the efficiency was obtained by comparing the extent of deuterium incorporated in *o*-methylbenzophenone under identical conditions. Tubes of *o*-methylbenzophenone and **3**, in perdeuteriomethanol were simultaneously irradiated. After 1 h, the methyl peak of *o*-methylbenzophenone had decreased in area by 25%, after 2 h by 50%; meantime, the peaks due to the methyls in **3** remained essentially unchanged.

The ketones **1–4** were irradiated for 7 h in benzene solution containing an excess of dimethyl acetylenedicarboxylate. Evaporation of the solvent gave a dark oily residue; the ^{1}Hmr spectra indicated considerable starting materials remained and a complex mixture of products had formed. Column chromatography partially separated these mixtures; starting materials were recovered, elemental sulfur was eluted, and in each case a fraction containing major products of the reactions, judging from the correspondence of the ^{1}Hmr spectra with those of the crude reaction mixtures, was obtained.

In each case the ^{1}Hmr and vapour phase chromatography (vpc) indicated this fraction contained at least three compounds. We believe these are positional isomers of benzoyl, methyl, dimethyl phthalates and terephthalates, based upon the ^{1}Hmr, ir, mass spectra, and combustion analysis of the mixtures. Because of the complexity of these mixtures and the large number of possible isomers, no attempts were made to separate and further characterize the products.

When the signals from these keto diesters were subtracted from the ^{1}Hmr spectra of the crude reaction mixtures, another major product was obviously present in each case. These products were not eluted from the column and were unstable in the crude reaction mixtures. Structures consistent with the ^{1}Hmr spectra are the bicyclic adducts (**6–9**) which would result from $2\pi e + 2\pi e$ cycloaddition of the dimethyl acetylenedicarboxylate to the thiophene ring across the 2—3 bond. We found no evidence for any other type of adduct being formed. These irradiations are summarized in Scheme 2.

Obviously the methyl group, present on **1–4**, should not be required for this type of photocycloaddition. To decrease the number of possible isomeric products and provide an analogy for the formation of the keto diesters we studied the irradiation of **5** under these conditions in more detail.

The ^{1}Hmr spectrum of the crude photolysate from

SCHEME 2

5 and dimethyl acetylenedicarboxylate in benzene had absorptions attributable to the one-to-one adduct, **10**, and three keto diesters (Scheme 3). In this case also, the adduct was not stable; however, a rapid column chromatography provided a fraction, free from starting materials, which contained the adduct and the keto diesters. The analysis of the ^{1}Hmr spectrum of **10**, in comparison with those for the methyl derivatives **6–9**, supports the structural assignments of these compounds. These spectra are summarized in the Experimental. The mass spectrum of the mixture had a peak (*m/e*) equivalent to the molecular weight (exact mass) of adduct **10**. All attempts to obtain the adduct pure led to formation of the keto diester(s). Three keto diesters were separated by column and vapour phase chromatography and their structures established by comparison (ir) with authentic samples obtained by the independent synthesis outlined in Scheme 4.

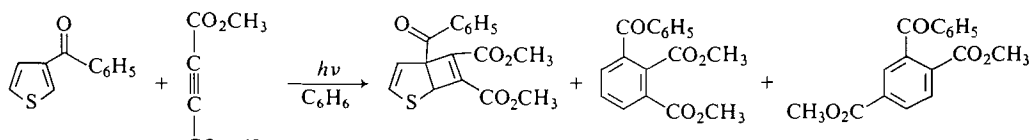
The thermal Diels–Alder reaction (aluminium trichloride catalyzed (3)) of 2-benzoylthiophene with dimethyl acetylenedicarboxylate was attempted as an alternative approach for the synthesis of **11**; however, the ketone was recovered unchanged and no phthalate could be detected. This reaction was tried for the preparation of the phthalate from ketone **1** and phthalate **12**, also without success.

The ketones **1–4** were irradiated for 1 week in a benzene solution in which isobutylene (30% by weight) was dissolved. Evaporation of the solvent and excess isobutylene left a dark residue. The ^{1}Hmr and vpc of this residue indicated considerable starting ketone remained in every case and several (more than 15) products. There was no evidence in the ^{1}Hmr for the oxetanes. The residues were chromatographed on alumina columns and in every case the first compound to be eluted was the olefin (**14–17**). There was no evidence for the formation of the other possible olefin (i.e., the 1,1-disubstituted ethylene). The ketones **1–4** (60–70%) were eluted after the olefins. We found no indication of positional isomerization of the ketones. None of the other products was identified. These results are summarized in Scheme 5.

The structures of the olefins were firmly established by alternative synthesis: acid-catalyzed dehydration of the alcohol obtained from the Grignard reaction of isopropyl bromide on the ketones **1–4**. The olefin **16** and the alcohol precursor (obtained by the Grignard reaction of phenyl magnesium bromide with 3-isobutyroyl-2,5-dimethylthiophene) have been described previously (4); the olefins **14**, **15**, **17** are new compounds.

Discussion

We have previously reported the ultraviolet absorption and phosphorescence emission spectra of 3-benzoylthiophene (**5**), and constructed a partial state-diagram for this ketone (1*a*). We concluded



5 **10** **11** (46%) **13** (11.5%)

12 (34%)

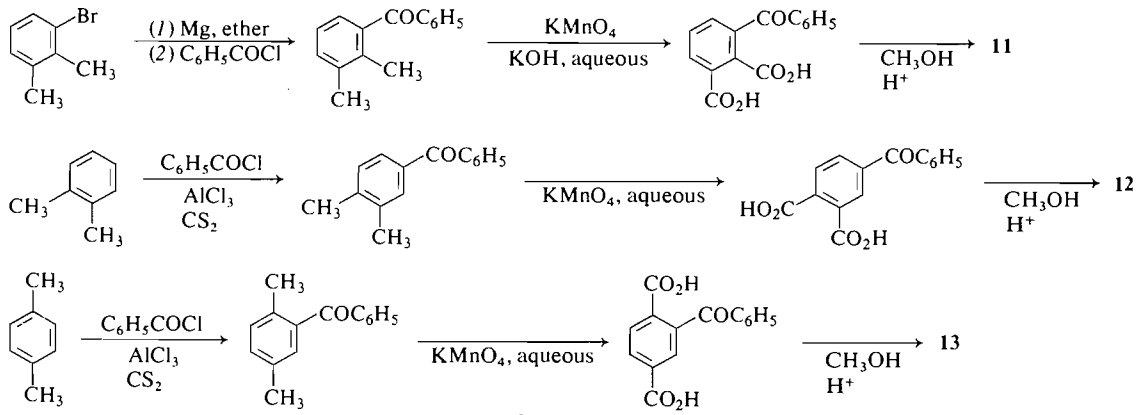
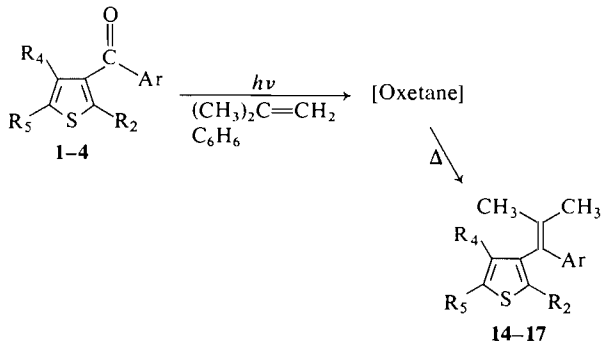


SCHEME 4

that since the lowest energy triplet (in EPA) had n,π* character, **5** would have photochemical reactivity similar to that of benzophenone. What seemed to be a valid extrapolation led to the further prediction (1*c*) that 3-benzoylthiophenes with an adjacent methyl group would react similarly to *o*-methylbenzophenone. We therefore expected that



1–4

1 and **14** $R_2 = CH_3$, $R_4 = R_5 = H$, $Ar = C_6H_5$
2 and **15** $R_4 = CH_3$, $R_2 = R_5 = H$, $Ar = C_6H_5$
3 and **16** $R_2 = R_5 = CH_3$, $R_4 = H$, $Ar = C_6H_5$
4 and **17** $R_2 = R_4 = R_5 = H$, $Ar = C_6H_4(o\text{-}CH_3)$

SCHEME 5

ketones **1–4** would undergo efficient intramolecular hydrogen abstraction evidenced by incorporation of deuterium in the adjacent methyl group, upon irradiation in perdeuteriomethanol, and further, that the photoenol might be trapped with a reactive dienophile such as dimethyl acetylenedicarboxylate.[4] These photochemical reactions are well known for *o*-methylbenzophenone (5). Such was not the case; ketones **1–4** do not react photochemically in the expected way. We therefore studied the absorption and phosphorescence emission spectra of **1–5** in more detail in search of an explanation. Since the photochemical reactivity is best discussed in terms of the excited states available to these ketones, we will take up the absorption and emission studies first, construct the partial energy diagrams, and then discuss the photochemical reactivity in light of these results.

The ultraviolet absorption spectra of ketones **1–5** in hexane and in methanol solution are shown in Figs. 1 and 2. The long wavelength (> 320 nm) region of the spectra in hexane solution shows the weak carbonyl n → π* absorptions. This transition is shifted to shorter wavelengths and the shoulder of the adjacent π → π* absorption is shifted to longer wavelengths in methanol solution, so the n → π* absorption is partially obscured in this polar, hydrogen-bonding solvent.

In the spectrum of **5** in hexane, the thienyl, benzoyl, and 3-thienoyl chromophores all contribute to the strong absorption at 252 nm. These bands undergo a bathochromic shift (ca. 10 nm) in methanol as expected for π → π* transitions (1*a*). This region of the spectra of **2** and **4** is similar to that of **5**. There is no evidence for a shift to longer wavelengths of any of the π → π* transitions which could be attributed to an interaction of the methyl substituent.

In contrast, the absorption spectra of **1** has the shoulder at longer wavelengths (275 nm in hexane) indicative of a significant bathochromic shift of a π → π* transition. This shift is even more pronounced (ca. 300 nm in hexane) in the spectrum of **3** (6). The shifts to longer wavelengths of a π → π* transition in the spectra of **1** and **3** gave the first indication of a marked difference between the excited states of these ketones and **2**, **4**, and **5**.

The similarity of the energies of the corresponding singlet states for **2**, **4**, and **5**, reflected in the absorption spectra, extends also to the triplet states. The phosphorescence emission from **2**, **4**, and **5** are similar to one another and behave similarly as a function of solvent. Our interpretation is that the methyl group in the 4 position of thiophene and in the

[4]For a recent review on photoenolization see ref. 5*a*.

o-benzoyl position has little effect on either the singlets or the triplets in these compounds. On the other hand, the methyl in the 2 position of **1** and in the 2 and 5 positions of **3** have a pronounced effect on both the singlet and the triplet of these compounds.

The triplet energies, taken from the phosphorescence emission spectra in several solvents, are summarized in Table 1 and typical spectra are shown in Figs. 3 and 4.

In Fig. 3, the phosphorescence emission from **5** in EPA has the vibrational structure characteristic of n,π* carbonyl triplet emission. The separation of the O—O and O—1 bands is 1664 cm^{-1} indicative of the carbonyl bond stretching mode. This 'five fingered' vibrational structure is also observed from **2** and **4** in this medium. The O—O – O—1 band separation is 1654 cm^{-1} for **2** and 1658 cm^{-1} for **4**. The nature of the emissions from **2**, **4**, and **5** changes when MCH is the medium. Still n,π* character is dominant; however, an additional broad structureless emission becomes obvious at longer wavelengths. When the medium is MCH–SG or EG all trace of the structured emission disappears and broad structureless emission is observed from **2**, **4**, and **5**. We assign the structureless emission to a π,π* triplet. This inversion in the order of the n,π* and π,π* triplet of ketones upon changing the solvent from hydrocarbon to polar, hydrogen-bonding solvents is not common but has adequate precedent (7).

The phosphorescence emission from **1** is shown in Fig. 4; **3** behaves similarly except that the emission is at considerably longer wavelengths (Table 1). There is no structured emission from these ketones in any solvents; a regular shift to longer wavelengths, as the solvent polarity is increased, is observed. These features are consistent with the assignment of a π,π* triplet for the lowest triplet of both **1** and **3**.

In their review (7*a*) Nicholls and Leermakers suggest a classification for carbonyl compounds based upon their emissive behaviour as a function of solvent: (I) those ketones with emitting n,π* triplet states in both polar and nonpolar media; (II) those compounds which emit from an n,π* triplet in low polarity solvents but invert to a π,π* state in high polarity media; and (III) ketones for which the lowest-lying triplet is π,π* in all solvents. Using this classification, ketones **2**, **4**, and **5** would be in Group II, whereas **1** and **3** are in Group III. Some acetophenone and benzaldehyde derivatives are also known to be in Group II (7*b*,*d*).

The significant difference in triplet energy and the inversion of the order of triplet state as a function of position of methyl substitution was not anticipated at the onset of this work. In retrospect, the bathochromic shift of a π → π* transition in the absorption spectra of **1** and **3** could have provided insight.

The fact that the methyl group in the 5 position of **3** has a rather large effect, decreasing the π,π* triplet energy by >4 kcal mol^{-1}, while the methyl group in the 4 position of **2** has very little effect, was at first surprising. However, there is a significant effect of a methyl group in the 4 position on the triplet energy (π,π*) of 2-benzoylthiophene where the position of the two groups is interchanged. The triplet energy of 2-benzoylthiophene and 4-methyl-2-benzoylthiophene are 63.5 and 61.5 kcal mol^{-1} (ethanol–methanol (4:1)) (1*c*).

It now seems reasonable that the effect of the methyl(s) lowering the π,π* singlet state in **1** and **3** also affects the corresponding triplet which presumably is associated with the 3-thienoylchromophore.

The partial state-diagrams shown in Fig. 5, are based on the absorption and phosphorescence emission spectra and indicate the energy and order of states in hydrocarbon media. The π,π* singlet energy levels are taken from the maxima or shoulders of the absorption spectra and are therefore maximum values, useful only for comparison. The n,π* singlet energy levels are from the O—O band of the n → π* transitions. The energy of the lowest triplet levels are taken from the O—O band, or high energy onset, of the emission spectra. When the n,π* triplet is the T_2 state (**1** and **3**), its energy has been estimated by assuming the normal ca 2000 cm^{-1} singlet–triplet separation. Obviously, in the case of **2**, **4**, and **5**, where the T_2 state is π,π* (in nonpolar media), the energy gap must be very small (<ca. 4 kcal mol^{-1}) and we estimate a value less than 74 kcal mol^{-1} from the known π,π* triplet energy of the benzoyl chromophore.

It should be pointed out that the triplet energies in Table 1 and Fig. 5 were obtained in rigid media at liquid nitrogen temperatures. The energy, and in fact the order of triplet states, may be different in fluid solutions at the temperature of the irradiations (10°C). What little is known about the effect of these environmental changes on triplet energy indicates the n,π* triplet may be as much as 2 kcal mol^{-1} less in the fluid media at room temperature than that determined in rigid media at −196°C, whereas the π,π* triplet associated with the benzoyl chromophore has virtually the same triplet energy in rigid and nonrigid media (8*a*).

The phosphorescence emission was intense and no fluorescence was observed from **1** – **5** in any solvent. In view of the ordering of states shown in the partial energy-diagrams (Fig. 5), with a lowest n,π* singlet and a lower or near-by π,π* triplet, it seems likely that intersystem crossing will be a rapid process, as it is for most benzophenone derivatives (9).

The first observation regarding the photochemical reactivity of the ketones **1**–**5** is the lack of positional

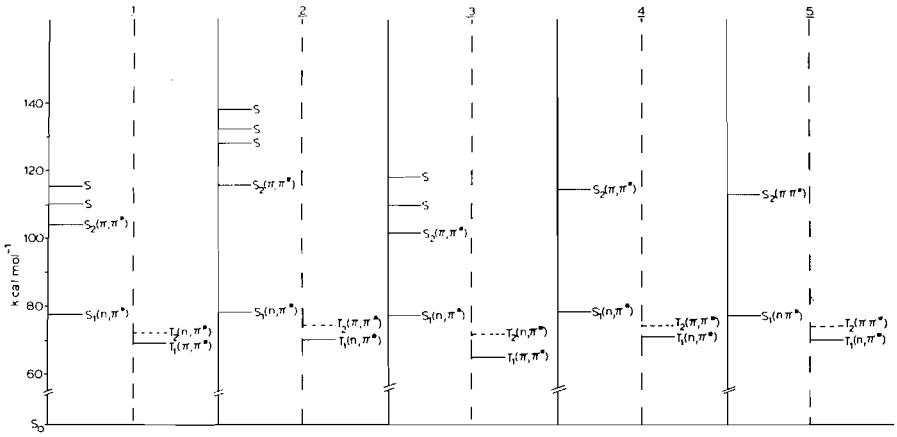

FIG. 5. Partial energy diagrams of 3-benzoylthiophenes **1** – **5**.

isomerization. The interchange of the thiophene carbons 2 and 3 occurs via the intermediate cyclopropenyl thioketone or thioaldehyde and is a fairly general reaction for alkyl- and aryl-substituted thiophenes. This rearrangement appears to involve the lowest singlet π,π^* state and has never been observed when the thiophene is substituted with a carbonyl group; thiophene aldehyde and acetylthiophene also do not rearrange (10). To our knowledge there are no exceptions to this generalization which may, therefore, be useful for predicting photochemical reactivity of other substituted thiophenes.

It is now generally accepted that carbonyl compounds with π,π^* lowest triplets are appreciably less reactive toward both intermolecular and intramolecular (eg. Norrish type II process) hydrogen abstraction (8*a*,*b*). The photoenolization reaction is usually considered as a special intramolecular example of these hydrogen abstractions and, in view of the fact that a 1,4-biradical is known or postulated to be an intermediate, the analogy is justified. An alternative orbital symmetry allowed sigmatropic 1,5-hydrogen shift in the excited state requires an antarafacial hydrogen migration, which seems unlikely, or a sign inversion at one of the incipient double bonds. The latter possibility could lead directly to the formation of the photoenol having the (*E*)-dienol configuration. Since this configuration is frequently the only isomer trapped with dienophiles (5*e*) perhaps the concerted reaction should not be discounted.

In any event, it is certain that an n,π^* state, singlet or triplet, is *not* required for photoenolization. The most convincing evidence for this is the observed photochemical reactivity of the corresponding alkene. Deuterium exchanges between the vinyl and the methyl position of 1,1-dideuterio-2-phenyl-2-(*o*-tolyl)ethylene (11) and the *o*-xylylene has been trapped in a Diels–Alder reaction with cyclohexene (12). Unfortunately, the efficiency (or more to the point, the rate constant) of this reaction has not been measured.

Although it is difficult to estimate the efficiency of the photochemical deuterium incorporation in ketones **1**–**4**, particularly since light absorbing by-products are gradually produced, the comparatively rapid exchange observed with *o*-methylbenzophenone under identical conditions indicates the efficiency of exchange with **1**–**4** is several orders of magnitude *less* than that of the benzophenone derivative.

We are unable to attribute what reactivity does occur to any particular state; the n,π^* singlet and π,π^* and n,π^* triplets are all possibilities. In the case of alkyl phenyl ketones the photochemical reactivity in the Norrish type II reaction (indicated by the rate constant for the hydrogen abstraction step) of those ketones having a lowest π,π^* triplet was attributed to thermal equilibration with the upper reactive n,π^* triplet. The reactivity decreased as the separation between the lowest π,π^* triplet and the upper n,π^* triplet increased (8). Although there is no direct relationship between the efficiency of a photochemical reaction and the reactivity as reflected by the rate constant, we can point out that the most efficient deuterium exchange was observed with **3** where the energy difference between $T_1(\pi,\pi^*)$ and $T_2(n,\pi^*)$ is the largest. However, the observation that deuterium was incorporated in the methyl group in the 5 position of **3** requires that some mechanism in addition to, or perhaps instead of, photoenolization occurs.

There are some features associated with some of the deuterium exchange processes which are worthy of special note. In the case of **2** a simple photoenol intermediate is impossible. The photoenol would have a tetracovalent sulfur structure which would be analogous to the *o*-xylylene intermediate discussed previously in connection with the thermal rearrange-

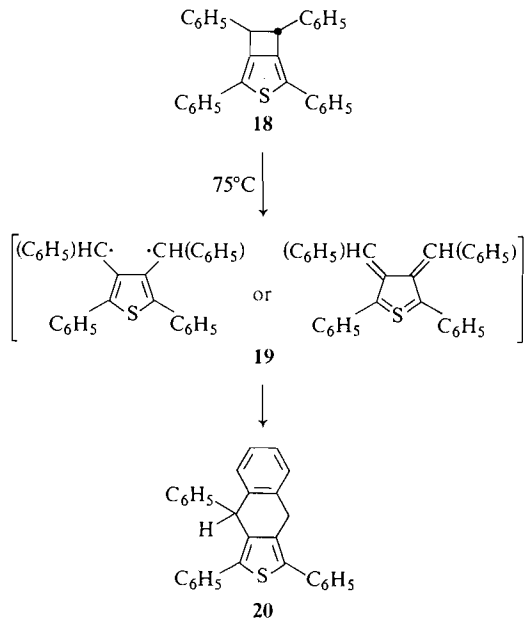

SCHEME 6

ment of thieno[*c*]cyclobutene derivatives (13). For example, **18** rearranges at 75°C to the dihydronaphtho[*c*]thiophene derivative **20** (Scheme 6) (13). We thought it might be possible that irradiation of **2** would yield the thieno[*c*]cyclobuteneol, dihydronaphtho[*c*]thiophene, or other product which would attest to formation of an intermediate similar to **20**; such was not the case. We must, therefore, leave open the question regarding the structure of the intermediate(s) in the deuterium exchange of **2**.

The inefficiency in the exchange process with **4** is significant since the hydrogen being abstracted in this case is benzylic, not thiophenylic, and the photoenol would be an *o*-xylylene analogous to that formed from *o*-methylbenzophenone. The implication is that the inefficiency results from the inherent reactivity of the excited state of the 3-benzoylthiophene chromophore and not the inability to abstract hydrogen from the methyl group on the thiophene.

The question regarding possible conformers of **1–4** should be raised. It has recently been shown that *o*-methylacetophenone has two conformationally related triplets, i.e. where the *o*-methyl group and the carbonyl oxygen are on the same (*syn*) or opposite (*anti*) sides of an approximately planar molecule. These two triplets decay with rates 5×10^9 and 3×10^7 s^{-1} in benzene at room temperature. The longer lived triplet is believed to be the *anti* conformer where the rate of decay is determined by rotation to the *syn* conformer which is then followed by rapid hydrogen abstraction (14). We do not know the preferred conformation of the ground state of **1–4** nor do we know the rate of interconversion of these conformers around the thiophene–carbonyl carbon bond in the excited state. It is, however, unlikely that the preferred orientation or the rate of interconversion is very different from that of *o*-methylacetophenone. This is certainly true for **4** where rotation around the phenyl–carbonyl carbon bond would be involved in an excited state which, from the emission spectrum, appears to be localized predominantly on the 3-thienoyl moiety.

The irradiations of **1–4** in the presence of dimethyl acetylenedicarboxylate were carried out in an attempt to trap the photoenol. The complexity of the reaction mixtures makes it impossible for us to rule out a small amount of this type of reaction; however, we found no evidence for adducts of this type. The products that were characterized indicate the predominant reaction was photocycloaddition to the 2,3 bond of the thiophene. The photocycloaddition of electron-deficient olefins and acetylenes to the excited state of thiophenes and benzothiophenes has been observed previously (15).

A typical known example of this reaction is illustrated in Scheme 7 with 2,5-dimethylthiophene and dimethyl acetylenedicarboxylate (15*a*). These reactions are complicated by the photochemical and thermal instability of the bicyclic adducts. Studies using triplet–triplet transfer sensitizers indicated the cycloaddition reaction can occur with the thiophene triplet. The energy threshold (≥ 62.4 kcal mol^{-1} in benzene solution at room temperature) required to cause reaction with 2,5-dimethylthiophene is somewhat lower than the observed triplet energy of **3** (ca. 65 kcal mol^{-1}, Table 1). It seems improbable that 2,5-dimethylthiophene has a lower triplet energy than **3**; the results more likely indicate the energy transfer process can be endothermic to a small ex-

For personal use only.

tent. These workers also estimate the triplet energy of thiophene to be ≥ 70 kcal mol^{-1}. This was the first indication of the pronounced effect of the 2,5-methyl groups toward lowering the triplet energy (15*a*).

The formation of adducts **6–10** and the subsequent decomposition of these adducts to diesters, therefore, has adequate precedent and is consistent with a reaction involving the π,π^* triplet of the ketones **1–5**.

The purpose behind the experiments, irradiatngi **1–4** in the presence of isobutylene (Scheme 6), was to test the ability of the excited states of these ketones to undergo photocycloaddition of the olefin to the carbonyl group. It was known that **5** yields the oxetane under these conditions; if intramolecular hydrogen abstraction competes with photocycloaddition, **1–4** would be less prone to yield the oxetanes. The analogous photocycloaddition of *o*-methylbenzophenone is strongly quenched (16). However, *o*-methylbenzaldehyde forms the oxetane with 2,3-dimethyl-2-butene with high efficiency (17).

Following the irradiations, the crude reaction mixtures were quite complex. The oxetanes were not detected; however, the olefins **14–17**, presumably derived from the oxetanes, were separated from the other products and were positively identified. The instability of the oxetanes is not surprising (1*b*,*c*) and the formation of the olefins attests to the fact that **1–4** do indeed undergo photocycloaddition of isobutylene to the carbonyl group. The other products were not identified.

Not too many years ago, it was thought that the first step toward photocycloaddition of the carbonyl group required attack by the nonbonding electron on the oxygen of the carbonyl n,π^* state on the double bond of an electron-rich olefin much like an alkoxy radical would add to an olefin (16). This simple picture no longer adequately explains the results and it is now generally recognized that the first step toward oxetane usually is formation of a complex (or exciplex) between the excited state (n,π^* or π,π^*) of the carbonyl compound and the olefin. The complex then reacts further to give the oxetane, perhaps with the intervention of a diradical intermediate, or deactivates. When the two molecules involved have molecular orbitals which differ in size and shape there may be more than one energy minima on the surface describing the structure of the complex. Whether the product from the excited state of benzoylthiophenes **1–4** with an olefin occurs at the carbonyl group or to the triophene (oxetene or bicyclic adduct upon reaction with dimethyl acetylenedicarboxylate) will then depend upon: (*i*) where complexing occurs, over the carbonyl group or over the thiophene ring; (*ii*) the relative reactivity going on to product vs. the various deactivation pathways for each of the possible orientations of the complex and any other intervening intermediate(s). Stated in this more realistic way it is obvious that predicting the photocycloaddition reactivity of a complex molecule will remain a difficult problem for some time to come.

Conclusions

(*i*) The analysis of the ultraviolet absorption and phosphorescence emission spectra of the 3-benzoylthiophenes **1–5** reveals a pronounced influence of position of methyl substitution and solvent on the energies and relative order of the singlet and triplet states. These data are summarized in Table 1 and in the energy diagrams shown in Fig. 5.

(*ii*) Ketones **1–4** incorporate deuterium in the adjacent methyl group upon irradiation in perdeuterio methanol. Deuterium is also incorporated in the methyl group in the 5 position of **3**. This exchange is much less efficient than that observed for the analogous *o*-methylbenzophenone. A mechanism other than photoenolization may be involved.

(*iii*) Bicyclic[3.2.0] adducts were obtained from the irradiation of ketones **1–5** in the presence of dimethyl acetylenedicarboxylate. These adducts were unstable and decomposed thermally with loss of sulfur to the phthalates and terephthalates. There was no evidence of adducts of the Diels–Alder type involving the photoenol of **1–4**.

(*iv*) The ketones **1–4** undergo photocycloaddition at the carbonyl group with isobutylene. The oxetanes were not characterized; the olefines, formed by loss of formaldehyde from the oxetane, attest to their formation.

(*v*) We found no evidence for photorearrangement of the ketones **1–5**.

(*vi*) The photolysis mixtures were generally complex owing to the photochemical and/or thermal instability of the products. The material balance was therefore poor. The reactions were comparatively inefficient. These factors tend to complicate photophysical and mechanistic studies required to attribute reactivity to a particular excited state. It is clear, however, that these ketones (**1–4**) do not show the expected efficient reactivity of an n,π^* triplet. The available evidence indicates either the π,π^* triplet, or an upper n,π^* triplet, possibly in thermal equilibrium with the π,π^* triplet, is reacting.

Experimental

General

The apparatus and instrumentation for ultraviolet absorption spectra, phosphorescence emission spectra, and life-time measurements were reported in Part I (1*a*). Ultraviolet absorption spectra were obtained in *n*-hexane (BDH, spectral grade)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and in methanol, which was purified by distillation from magnesium metal, using 1-cm quartz cells. The emission spectra were measured in five different solvents at 77 K after degassing the solutions by three freeze–pump–thaw cycles. Ethanol was purified the same way as methanol, the methylcyclohexane was Eastman Kodak spectro grade, ethylene glycol was from Fisher Scientific, and EPA was from American Instrument Co. All the above solvents showed no emission when irradiated at the wavelength used to obtain the spectra.

Samples used for spectroscopic studies, combustion analyses, and photochemical reactions were purified by semipreparative vpc (Varian, model 920, 10% DEGS Chrom.w, nonacid washed (NAW), 60–80 mesh and 30% SE-30, Chrom.w; NAW, 60–80 mesh).

All irradiations were carried out using a General Electric Co. 1 kW medium-pressure mercury vapour lamp, through a Pyrex filter at 10°C. Samples were not degassed unless stated otherwise. The progress of the reaction was followed by ^{1}Hmr and/or vpc. ^{1}H nuclear magnetic resonance spectra were run in deuteriochloroform solution using tetramethylsilane as internal standard with a Varian HA-100 spectrometer. The chemical shifts are taken as the center of multiplets and the reported coupling constants are the result of a first-order analysis; coupling was confirmed by double irradiation experiments.

The deuterium nmr spectrum of 2,5-dimethyl-3-benzoylthiophene was obtained at 15.4 MHz with a Varian XL-100-15 system in the Fourier transform mode.

Infrared spectra were recorded on a Beckman IR-5A or IR-20A spectrometer and mass spectra on a Varian M-66 or Mat 311A mass spectrometer. Calibration of the ir spectra was done using the 1601.8 cm^{-1} absorption band of polystyrene. The combustion analyses were performed by Chemalytics, Inc., Tempe, Arizona.

3-Methylthiophene, 2,5-dimethylthiophene, 3-bromothiophene, and 3-bromo-*o*-xylene were obtained from Aldrich Chemical Co.

All reported yields are based on isolated products.

Synthesis of Starting Materials

Synthesis of 2-Methyl-3-benzoylthiophene (1)

Preparation of 2-chloro-5-methylthiophene (18)—*N*-Chlorosuccinimide (19) (14.6 g, 10% excess) was added to a solution of 2-methylthiophene (9.8 g, 0.1 *M*) in benzene (60 ml) – acetic acid (60 ml) and stirred for 30 min, refluxed for 1 h, and poured into water. The organic layer was separated, washed with sodium hydroxide (200 ml, 2 *N*) and water and then dried over magnesium sulfate. After three consecutive distillations pure 2-chloro-5-methylthiophene (7.6 g, 58%, bp 155–156°C/760 Torr) was obtained.

Preparation of 5-chloro-2-methyl-3-benzoylthiophene—2-Chloro-5-methylthiophene (4.6 g) and benzoylchloride (4.9 g) were dissolved in carbon disulfide (35 ml) and the solution was cooled in an ice-bath. Aluminum chloride (4.6 g) was added in portions. A slightly exothermic reaction occurred giving a deep red solution which was stirred for 1 h at room temperature and then poured into cold water (200 ml) and extracted with ether. The ether layers were washed with aqueous potassium hydroxide (10%), water (2 × 200 ml), and dried over magnesium sulfate (anhydrous). Evaporation of the solvent and distillation gave 5-chloro-2-methyl-3-benzoylthiophene (3.7 g, 46%, bp 166–167°C/0.15 Torr).

Dechlorination (20) of 5-chloro-2-methyl-3-benzoylthiophene—5-Chloro-2-methyl-3-benzoylthiophene (3.6 g) and activated copper powder (4 g) in propionic acid (10 ml) were refluxed under an argon atmosphere for 24 h. The resulting mixture was poured into water, filtered from solids, neutralized with solid sodium bicarbonate, and extracted with ether. The ether layer was washed with water and dried over anhydrous magnesium sulfate. Removal of ether gave crude product (2.3 g, 73%) which, after distillation, yielded pure 2-methyl-3-benzoylthiophene (1.8 g, 58%, bp 150°C/0.3 Torr); ir (neat) ν: 1660, 1452, 1278, 854, 696, 665 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (TMS): 7.07 (H-4), 6.95 (H-5), 2.62 ppm (methyl); $J_{4,5}$ = 5.2 Hz; ms (70 eV) *m/e* (relative intensity): 202 (100, M^+), 201 (90), 124 (50), 105 (15), 77 (28). *Anal.* calcd. for $C_{12}H_{10}OS$ (1): C 71.28, H 4.99; found: C 71.09, H 5.08.

Initial attempts to prepare the above thiophene used *N*-bromosuccinimide instead of *N*-chlorosuccinimide. Friedel–Crafts reaction of 2-bromo-5-methylthiophene gave a bromo ketone (mp 93–94°C, recrystallization from hexane); ir (Nujol) ν: 1664, 877, 860, 788, 720, 699, 640 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (TMS): 7.72 (m), 7.42 (m), 2.40 ppm (s, methyl); ms (70 eV) *m/e* (relative intensity): 282 (8, M^+), 280 (9, M^+), 205 (17), 203 (18), 201 (10), 145 (17), 105 (26), 77 (42), 32 (100), 28 (90). *Anal.* calcd. for $C_{12}H_9BrOS$: C 51.27, H 3.23, Br 28.42; found: C 51.02, H 2.93, Br 28.62.

Debromination of this ketone with activated copper powder yielded 2-benzoyl-5-methylthiophene identified by comparison with the known ir spectrum. Obviously, the 2-bromo-5-methylthiophene underwent isomerization to 4 (or 3) -bromo-2-methylthiophene during the Friedel–Crafts benzoylation and the above bromo ketone (mp 93–94°C) consequently has to be 4-bromo-5-methyl-2-benzoylthiophene or 3-bromo-5-methyl-2-benzoylthiophene instead of the desired 5-bromo-2-methyl-3-benzoylthiophene.

Activated Copper Powder (21)

Oxide free zinc was added to an excess of slightly acidified aqueous cupric sulfate keeping the temperature below 40°C. The precipitated copper was collected, washed with water to remove the remaining cupric sulfate and acid, and finally washed twice with dry acetone and dried for 30 min at 100°C.

Synthesis of 4-Methyl-3-benzoylthiophene (2)

4-Methyl-3-benzoylthiophene was prepared by an adaptation of Gronowitz's method (22), using 3-bromo-4-methylthiophene and benzonitrile.

3-Bromo-4-methylthiophene (23)—2,3,5-Tribromo-3-methylthiophene (24) (12.3 g, 0.037 *M*) was added portionwise to a stirred refluxing mixture of water (75 ml), zinc powder (10.5 g), and acetic acid (7 ml). After addition was complete the mixture was refluxed for 30 h and then distilled from the reaction flask. The aqueous layer of the distillate was separated from time to time from the organic phase and returned to the reaction vessel. The organic phase was washed with sodium carbonate solution then water, dried, and distilled. A crude product (5.5 g, 84%, bp 59–65°C/11 Torr) was obtained. Redistillation gave pure 3-bromo-4-methylthiophene (4.4 g, 68%, bp 179–183°C/760 Torr).

4-Methyl-3-benzoylthiophene (2)—A well dried three-necked round bottom flask with stopper, magnetic stirrer, serum cap, and gas inlet tube was purged with argon for ½ h and cooled in a Dry Ice – acetone bath. The flask was then charged with 3-bromo-4-methylthiophene (1.77 g) and anhydrous ether (4 ml). The etherial solution was stirred for 15 min and then *n*-butyllithium (3.6 ml, 2.77 *M*, in hexanes) was added via a dry syringe, through the serum cap during about 5 min. The light yellow solution was stirred for ½ h and a solution of benzonitrile (1.03 g) in anhydrous ether (2.0 ml) which had been purged with argon and cooled to −78°C, was quickly added to the solution. The resulting orange solution was stirred for 2 h at −78°C and allowed to warm up slowly to −10°C. Then hydrochloric acid (20%, 15 ml) was added via the syringe. The colour changed to brown and then to light yellow while a pre-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

cipitate appeared and redissolved. After 30 min stirring, the organic layer was separated, the ether was evaporated, and the remaining brown oil added to the aqueous layer which was then refluxed with hydrochloric acid (20%, 10 ml) for 10 h. This mixture was extracted with ether (2 × 20 ml), washed with water, saturated aqueous sodium bicarbonate, and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave a dark oil, which was a mixture of the imine and the ketone. These were separated by fractional distillation. The first fraction (bp 170°C/0.05 Torr) yielded 4-methyl-3-benzoylthiophene (1.25 g, 62%); ir (neat) ν: 1645, 1445, 1265, 1180, 895, 870, 816, 790, 747, 730, 712, 693, 668 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (TMS); 7.58 (H-2, m), 6.98 (H-5, m), 2.42 ppm (CH_3); $J_{2,5}$ = 3.2, J_{5,CH_3} = 1.2 Hz; ms (70 eV) *m/e* (relative intensity): 202 (92, M^+), 201 (100), 124 (38), 105 (9), 77 (15). *Anal.* calcd. for $C_{12}H_{10}OS$ (**2**): C 71.28, H 4.99; found: C 71.28, H 5.10.

Synthesis of 2,5-Dimethyl-3-benzoylthiophene (3)

2,5-Dimethyl-3-benzoylthiophene was prepared (25) by the Friedel–Crafts reaction of 2,5-dimethylthiophene (2.02 g, 0.018 *M*) and benzoyl chloride (2.38 g, 0.017 *M*) in carbon disulfide (25 ml). Anhydrous aluminum chloride (4.53 g, 0.044 *M*) was added in portions and the mixture, after 1 h refluxing, was poured into cold water (1 ℓ) and stirred for 30 min. The organic layer was separated and the aqueous layer was further extracted with carbon disulfide. The combined extract was first washed with aqueous sodium hydroxide (10%, 1 × 200 ml) and then water (3 × 200 ml) and dried over anhydrous magnesium sulfate. Removal of solvent gave a brown viscous oil, which after distillation yielded a clear oil (2.85 g, 72%, bp 185–187°C/10 Torr) that crystallized upon cooling. Recrystallization from methanol gave colourless crystals (mp 44.5–45°C (lit. (4) mp 44°C)).

Synthesis of 3-(2-Methylbenzoyl)thiophene (4)

3-(2-Methylbenzoyl)thiophene was also prepared by an adaptation of Gronowitz's method (22). From 3-bromothiophene (4.06 g) in anhydrous ether (5 ml), *n*-butyllithium (1.25 ml, 2.04 *M*, in hexanes), and *o*-methylbenzonitrile (1.75 g) in anhydrous ether (5 ml), a brown oil (4.62 g crude product, 92%) was obtained. Distillation of the above oil gave two fractions. The first fraction (2.3 g, 46%, bp 114°C/0.03 Torr) was the desired ketone (**4**) and the second fraction (1.8 g, bp 194°C/0.03 Torr) the unhydrolized imine (ir ν: NH 3300, C=N 1602 cm^{-1}) which, upon further refluxing with hydrochloric acid (20%) gave again a mixture of imine and ketone. Isolation of the ketone from the mixture can be achieved by fractional distillation; ir (neat) ν: 1655, 1510, 1417, 1402, 1235, 1150, 970, 862, 825, 738, 662 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (TMS) 7.76 (H-2), 7.56 (H-4), 7.31 (H-5), 2.39 ppm (methyl); $J_{2,4}$ = 1.4, $J_{2,5}$ = 3.0, $J_{4,5}$ = 5.2 Hz; ms (70 eV) *m/e* (relative intensity): 202 (80, M^+), 201 (40), 185 (17), 169 (100), 157 (9), 141 (72), 119 (19), 111 (56), 91 (52), 83 (25). *Anal.* calcd. for $C_{12}H_{10}OS$ (**4**): C 71.28, H 4.99; found: C 71.48, H 5.07.

Synthesis of 3-Benzoylthiophene (5)

3-Benzoylthiophene was prepared by the method of Hornfeldt and Gronowitz (22) as described in detail in Part I (1*a*).

Irradiation Experiments in Perdeuteriomethanol

A Pyrex ^{1}Hmr tube, containing the 3-benzoylthiophene (100 mg) (**1**–**4**) in perdeuteriomethanol (3 ml) was purged with argon for 10 min, sealed with a serum cap, and irradiated for 40 h. The integrated area and the heights of the ^{1}Hmr peaks due to the methyl group and aromatic protons before and after irradiation indicate a small amount of deuterium incorporation in the methyl group. Evaporation of the solvent in each case gave yellow oils. The mass spectra of samples purified by vpc show ratios of $(M + 1)^+/M^+$ peaks higher than in the corresponding starting materials, evidence indicating deuterium incorporation. The extent of deuteration was calculated using a computer program, and data (peak heights M − 1, M, M + 1, M + 2, M + 3) taken from the mass spectra (14 eV) of the starting and the deuterated compound.

Irradiation of 2-Methyl-3-benzoylthiopene in CD_3OD

Starting material $(M + 1)^+/M^+$ = 0.158; deuterated compound $(M + 1)^+/M^+$ = 0.249 (8.2% mono-D, 0.6% di-D).

Irradiation of 4-Methyl-3-benzoylthiophene in CD_3OD

Starting material $(M + 1)^+/M^+$ = 0.158; deuterated compound $(M + 1)^+/M^+$ = 0.248 (8.2% mono-D, 0.2% di-D).

Irradiation of 2,5-Dimethyl-3-benzoylthiophene in CD_3OD

Starting material $(M + 1)^+/M^+$ = 0.163; deuterated compound $(M + 1)^+/M^+$ = 0.413 (19.3% mono-D, 2.3% di-D).

Irradiation of 2,5-Dimethyl-3-benzoylthiophene in CH_3OD

Starting material $(M + 1)^+/M^+$ = 0.172; deuterated compound $(M + 1)^+/M^+$ = 0.309 (13% mono-D, 0.9% di-D). For the ^{2}H nmr spectrum a mixture of $CHCl_3$ and C_6F_6 (4 : 1, v/v) was used and the instrument locked to the ^{19}F signal with noise modulated proton decoupling at 100 MHz. The shift reagent $Pr(fod)_3$ was used to obtain better dispersion of the ^{2}H resonances but line broadening accompanies the increased dispersion. Line-shape fitting was employed to obtain the relative areas of the individual absorption signals. Shift reagent studies of the proton spectrum of 2,5-dimethyl-3-benzoylthiophene using a Varian XL-100 instrument were also carried out to confirm the assignment of ^{2}H nmr spectrum. With the total deuterium content (13%) as measured by mass spectroscopy deuterium analysis, the relative concentrations of deuterium at individual centers were found 7.3% of D in the methyl group of position 2 (lower field methyl) and 5.7% of D at methyl group of position 5 of the thienyl ring.

Irradiation of 3-(2-Methylbenzoyl)thiophene in CD_3OD

Starting material $(M + 1)^+/M^+$ = 0.160; deuterated compound $(M + 1)^+/M^+$ = 0.320 (14% mono-D, 0.6% di-D).

Irradiation of 3-(2-Methylbenzoyl)thiophene in CH_3OD

Starting material $(M + 1)^+/M^+$ = 0.135; deuterated compound $(M + 1)^+/M^+$ = 0.379 (18% mono-D, 1.9% di-D). The deuterium was clearly in the (2-methylbenzoyl) fragment. Starting material $(119 + 1)^+/(119)^+$ = 0.078; deuterated compound $(119 + 1)^+/(119)^+$ = 0.25 (15% mono-D, 1.1% di-D).

Irradiation Experiments in the Presence of Dimethyl Acetylenedicarboxylate

Irradiation of 3-Benzoylthiophene (5) in the Presence of Dimethyl Acetylenedicarboxylate

Dimethyl acetylenedicarboxylate (376 mg, 0.004 *M*), 3-benzoylthiophene (568 mg, 0.002 *M*), and benzene (6 ml) were placed in a Pyrex irradiation vessel, purged with argon for 15 min, and irradiated for 8 h. The resulting dark brown solution, a complex mixture, was partially separated by column chromatography on silica gel.

3-Benzoylthiophene (283 mg) was isolated from the first fractions eluting with hexane and a mixture of products (145 mg of an orange oil) was obtained from later fractions eluting with 10% benzene in hexane. The ^{1}Hmr and mass spectra of this mixture provided evidence for the formation of a one-to-one adduct. Structure **10** (5-benzoyl-6,7-dicarbomethoxy-2-thiabicyclo[2.3.0]hepta-3,6-diene) was assigned to this adduct; ^{1}Hmr ($CDCl_3$) δ (TMS): 3.85 (s, 3H, methyl), 3.81 (s, 3H, methyl), 4.70 (d, 1H, H-1), 5.93 (d, 1H, H-4), 6.39 (doublet of doublets, 1H, for H_3), 7.68 ppm (complex, 5H, aromatics); $J_{3,4}$ = 6.5, $J_{1,3}$ = 1.5 Hz; ms (70 eV): M^+ 300 (on the mixture). In an attempt to isolate the adduct from this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

mixture by a second column chromatography on silica gel, a mixture containing only aromatic and methyl protons was obtained; no trace of the adduct was eluted. Further separation of this mixture was carried out by semipreparative vpc (10% SE-30, column temperature 210°C). The three major peaks in the vpc were due to isomeric keto diesters. The peak with the shortest retention time corresponds to dimethyl-3-benzoylphthalate (**11**) (48 mg, 46%, mp 125–126°C): ir (neat) ν: 1720, 1660, 1455, 1430, 1300, 1270, 1250, 1145, 1105, 1067, 1002, 932, 830, 822, 795, 787, 772, 750, 723, 702, 697, 652 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (TMS): 7.74 (complex, 8H, aromatics), 3.91 (s, 3H, methyl), 3.70 ppm (s, 3H, methyl); ms (70 eV) *m/e* (relative intensity): 298 (38, M^+), 267 (56), 239 (18), 221 (100), 207 (8), 105 (82), 77 (33). *Anal.* calcd. for $C_{17}H_{14}O_5$ (**11**): C 68.45, H 4.73; found: C 68.33, H 4.78.

The second peak was dimethyl-2-benzoylterephthalate (**13**) (12 mg, 12%, mp 101–102°C).

Dimethyl-4-benzoylphthalate was the third isomer (36 mg, 34%, mp 82.5–83°C); ir (Nujol) ν: 2940, 1730, 1660, 1600, 1575, 1450, 1290, 1260, 1195, 1158, 1142, 1128, 1065, 982, 948, 926, 868, 840, 825, 800, 792, 785, 768, 745, 722, 700, 674, 662 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (TMS): 3.92 (s, 3H, methyl), 3.95 (s, 3H, methyl), 7.82 ppm (complex, 8H, aromatics); ms (70 eV) *m/e* (relative intensity): 298 (23, M^+), 267 (35), 239 (7.5), 221 (38), 105 (100), 77 (65). *Anal.* calcd. for $C_{17}H_{14}O_5$ (**12**): C 68.45, H 4.73; found: C 68.34, H 4.82.

The ^{1}Hmr spectra and especially the ir spectra of the keto-diesters (**11–13**) were identical to those of authentic samples obtained by independent synthesis.

Irradiation of 2-Methyl-3-benzoylthiophene (1) in the Presence of Dimethyl Acetylenedicarboxylate

A solution of 2-methyl-3-benzoylthiophene (101 mg, 0.5×10^{-3} *M*) and dimethyl acetylenedicarboxylate (142 mg, 10^{-3} *M*) in benzene (3 ml) was purged with argon for 15 min and irradiated for 8 h; 60% of the starting ketone remained unreacted. Analysis of the ^{1}Hmr spectrum of the crude reaction mixture provided evidence for a one-to-one adduct assigned structure **6**; ^{1}Hmr ($CDCl_3$) δ (TMS): 1.56 (s, 3H, methyl), 6.03 (d, 1H, H-4), 6.45 ppm (d, 1H, H-3); $J_{3,4} = 6$ Hz. The signals for the methyl groups of the carbomethoxyls appear together with other methyl groups in the mixture. Column chromatography on silica gel allowed recovery of the starting materials and a mixture of dimethyl benzoylphthalates (11 mg, 17.5%), showing only aromatic and methyl protons in the ^{1}Hmr spectrum and carbonyl absorption at 1730 and 1670 cm^{-1} in the ir spectrum. *Anal.* calcd. for $C_{18}H_{16}O_5$: C 69.22, H 5.16; found (on the mixture of isomers): C 68.83, H 5.09.

Irradiation of 4-Methyl-3-benzoylthiophene (2) in the Presence of Dimethyl Acetylenedicarboxylate

4-Methyl-3-benzoylthiophene (101 mg, 0.5×10^{-3} *M*) and dimethyl acetylenedicarboxylate (142 mg, 10^{-3} *M*) in benzene (3 ml) solution was purged with argon for 15 min and irradiated for 8 h; 55% of the starting ketone remained unreacted. Structure **7** was assigned to the unstable adduct (4-methyl-5-benzoyl-6,7-dicarbomethoxy-2-thiabicyclo[2.3.0]hepta-3,6-diene) based on the ^{1}Hmr spectrum of the crude reaction mixture. For adduct **7**: ^{1}Hmr ($CDCl_3$) δ (TMS): 3.88 (s, 3H, methyl), 3.80 (s, 3H, methyl), 4.68 (d, 1H, H-1), 1.80 (d, 3H, methyl in position 4), 5.96 ppm (m, 1H, H_3); $J_{3,CH_3} = 1.4$, $J_{1,3} = 1.6$ Hz.

Column chromatography on silica gel gave fractions containing a mixture of dimethyl benzoylphthalates (10 mg, 14%). In the ^{1}Hmr spectrum only aromatic and methyl protons appear and in the ir spectrum carbonyl absorptions at ν 1730 and 1670 cm^{-1} are observed. *Anal.* calcd. for $C_{18}H_{16}O_5$: C 69.22, H 5.16; found (on the mixture of isomers): C 69.40, H 5.15.

Irradiation of 2,5-Dimethyl-3-benzoylthiophene (3) in the Presence of Dimethyl Acetylenedicarboxylate

2,5-Dimethyl-3-benzoylthiophene (**3**) (216 mg, 10^{-3} *M*) and dimethyl acetylenedicarboxylate (284 mg, 2×10^{-3} *M*) in benzene (3 ml) solution were purged with argon for 15 min and irradiated for 8 h; 45% of the starting ketone was recovered. Structure **8** was assigned to the adduct (1,3-dimethyl-5-benzoyl-6,7-dicarbomethoxy-2-thiabicyclo[2.3.0]hepta-3,6-diene); ^{1}Hmr ($CDCl_3$) δ (TMS): 1.56 (s, 3H, methyl), 1.95 (d, 3H, methyl), 5.73 ppm (m, 1H, H-4); $J_{CH_3,4} = 1.5$ Hz. The chemical shifts of methyls in the carbomethoxy groups appear together with other methyl groups present in the reaction mixture. Column chromatography on silica gel gave a mixture of dimethyl benzoylphthalates (32 mg, 18%), showing only aromatic and methyl protons in the ^{1}Hmr spectrum and carbonyl absorptions at 1740 and 1670 cm^{-1} in the ir spectrum. *Anal.* calcd. for $C_{19}H_{18}O_5$: C 69.92, H 5.56; found (on the mixture of isomers): C 70.13, H 5.59.

Irradiation of 3-(2-Methylbenzoyl)thiophene (4) in the Presence of Dimethyl Acetylenedicarboxylate

3-(2-Methylbenzoyl)thiophene (**4**) (101 mg, 0.5×10^{-3} *M*) and dimethyl acetylenedicarboxylate (142 mg, 10^{-3} *M*) in benzene (3 ml) were purged with argon for 15 min and irradiated for 8 h; 50% of the starting ketone remained unreacted. Structure **9** was assigned to the one-to-one adduct (5-(2-methylbenzoyl)-6,7-dicarbomethoxy-2-thiabicyclo[2.3.0]hepta-3,6-diene), based on ^{1}Hmr and double irradiation experiments on the crude reaction mixture; for **9** ^{1}Hmr ($CDCl_3$) δ (TMS): 2.40 (s, 3H, methyl), 4.60 (d, 1H, H-1), 5.66 (d, 1H, H-4), 6.16 (doublet of doublets, 1H, H-3), 7.20 ppm (complex, 4H, aromatics), $J_{1,3} = 1.5$, $J_{3,4} = 6$ Hz. The signals for the methyls of the carbomethoxy groups cannot be assigned as they appear together with other methyl groups present in the mixture. Column chromatography on silica gel gave a mixture of dimethyl- (*o*-methylbenzoyl)phthalates (14 mg, 18%), which was further purified for combustion analysis by vpc. *Anal.* calcd. for $C_{18}H_{16}O_5$: C 69.22, H 5.16; found (on the mixture of isomers): C 69.22, H 5.25. The ir spectrum shows carbonyl absorption at 1730 and 1655 cm^{-1} and in the ^{1}Hmr spectrum only methyl and aromatic protons appear.

The yields in each case were based on the amount of ketone consumed.

Preparation of Dimethyl 3-Benzoylphthalate (11)

2,3-Dimethylbenzophenone (26) (Grignard Reaction)

Magnesium metal (480 mg), 3-bromo-*o*-xylene (500 mg), and anhydrous ether (20 ml) were placed in a dry apparatus and a crystal of iodine was added. An exothermic reaction started and the mixture was gently refluxed. The mixture was stirred and additional 3-bromo-*o*-xylene (totally 3.7 g) in anhydrous ether (20 ml) was added at a rate such that the reflux was maintained (~1 h).

After the addition, the mixture was heated under reflux for ½ h and allowed to cool to room temperature. Then benzoylchloride (2.8 g) in dry ether (10 ml) was added to this solution and the mixture refluxed for 10 h. The resulting mixture was cooled in an ice bath and acetic acid (20 ml, 10%) was slowly added. Water (200 ml) was added and the mixture was extracted (3 × 100 ml) with ether. Evaporation of the solvent and then distillation gave 2,3-dimethylbenzophenone (2.6 g, 62%).

3-Benzoylphthalic Acid

2,3-Dimethylbenzophenone (1 g) and sodium hydroxide (600 mg) in water (100 ml) was heated on a water bath. Potassium permanganate (6 g) was added in four equal portions at 30 min intervals. After 19 h heating, the solution was decolourized with methanol, filtered, and the filtrate acidified

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with concentrated hydrochloric acid. The colourless crystals were recrystallized from water and were 3-benzoylphthalic acid (840 mg, 65%, mp, decomposes giving the anhydride (27)).

*Dimethyl 3-Benzoylphthalate (**11**)*

3-Benzoylphthalic acid (840 mg) in methanol (15 ml) and concentrated sulfuric acid (1 ml) were refluxed overnight. After the work-up and recrystallization of the crude product from chloroform, dimethyl 3-benzoylphthalate (600 mg, 65%, mp 125–126°C) was obtained.

*Preparation of Dimethyl 2-Benzoylterephthalate (**13**)*

2,5-Dimethylbenzophenone (Friedel–Crafts Reaction)

m-Xylene (21.2 g, 0.2 *M*), benzoylchloride (14.0 g, 0.1 *M*), aluminum trichloride (16.0 g, 1.2 *M*), and nitromethane (60 ml) were used. The product 2,5-dimethylbenzophenone (16 g, 40%), was a viscous yellow oil (bp 320°C/760 Torr (lit. (28) bp 317°C/744 Torr).

2-Benzoylterephthalic Acid (29)

2,5-Dimethylbenzophenone (10 g) and potassium permanganate (37 g) in water (250 ml) were refluxed overnight. The resulting diacid (2 g, 42%, based on the consumed ketone) was obtained as colourless crystals (mp 285–286°C, recrystallized from ethanol).

*Dimethyl 2-Benzoylterephthalate (**13**)*

2-Benzoylterephthalic acid (2 g), methanol (30 ml), and concentrated sulfuric acid (2 ml) were refluxed overnight. After the work-up, colourless crystals of dimethyl 2-benzoylterephthalate were obtained (1.4 g, 64%, mp 101–102°C (lit. (30) mp 100-101°C).

*Preparation of Dimethyl 4-Benzoylphthalate (**12**)*

3,4-Dimethylbenzophenone (31) (Friedel–Crafts Reaction)

From *o*-xylene (2.23 g, 0.2 *M*), benzoylchloride (14.05 g, 0.1 *M*), aluminum trichloride (16 g, 1.2 *M*) in nitromethane (60 ml), 3,4-dimethylbenzophenone was obtained (mp 46–48°C (from ethanol), bp 58–60°C/2 Torr).

4-Benzoylphthalic Acid (32)

2,3-Dimethylbenzophenone (10 g) and potassium permanganate (37 g) in water (25 ml) were stirred overnight. The 4-benzoylphthalic acid (150 mg, 23% based on the consumed ketone, mp 173–176°C) was obtained.

*Dimethyl 4-Benzoylphthalate (**12**)*

4-Benzoylphthalic acid (150 mg), methanol (4 ml), and concentrated sulfuric acid (0.5 ml) were refluxed overnight; after the usual work-up, dimethyl 4-benzoylphthalate (99 mg, 60%, mp 82.5–83°C) was obtained.

Irradiation Experiments in the Presence of Isobutylene

A Pyrex irradiation vessel containing the thiophene (**1**–**4**) in benzene was cooled and purged with isobutylene until the maximum amount of isobutylene was dissolved (ca. 25% by volume, 30% by weight). The tube was sealed with a rubber serum cap and irradiated for 190 h. The reaction mixture, after removing the excess isobutylene and the solvent gave a brown oil, which was a complex mixture of products. No ^{1}Hmr absorption was apparent in the region expected for the oxetane methylene protons. The crude reaction mixture was chromatographed on neutral alumina (Fisher, activity 1, 60–200 mesh). Elution with hexanes gave 1-phenyl-1-thienyl-2-methylpropenes (olefins **14**–**17**), with ir spectra identical to those of authentic olefins prepared by a Grignard method given below. Further elution with hexanes–benzene separated unreacted starting ketone. All yields are based on the consumed ketone.

*Irradiation of **1** in the Presence of Isobutylene*

Irradiation of thiophene **1** (100 mg) in a solution of isobutylene in benzene (20 ml) gives a complex mixture. The ^{1}Hmr spectrum has a complex absorption between 2.53–1.33 ppm including singlets at 2.36, 1.83, and 1.63 ppm characteristic of the olefin and at 2.53 for the starting ketone (**1**). After column chromatography, the olefin **14** (6 mg, 11.5%) and the starting thiophene **1** (38 mg), were separated.

*Irradiation of **2** in the Presence of Isobutylene*

Thiophene **2** (60 mg) in a solution of isobutylene in benzene (15 ml) was irradiated. From the resulting mixture, olefin **15** (4 mg, 10.5%) and thiophene **2** (35 mg) were separated.

*Irradiation of **3** in the Presence of Isobutylene*

Thiophene **3** (800 mg) in a solution of isobutylene in benzene (40 ml) was irradiated and a mixture of products was obtained which had complex ^{1}Hmr absorption between 2.5–0.9 ppm, including singlets at 2.00, 1.93, 1.75, 1.60 ppm indicative of the olefin **16** and two singlets at 2.5 and 2.3 ppm for the starting ketone. Chromatography of the crude reaction mixture gave olefin **16** (44 mg, 9%) and starting ketone **3** (428 mg).

*Irradiation of **4** in the Presence of Isobutylene*

Thiophene **4** (160 mg) in a solution of isobutylene in benzene (30 ml) was irradiated. Sharp singlets in the ^{1}Hmr spectrum at 2.01, 1.30, and 1.42 ppm indicated the presence of the olefin **17**. From the crude reaction mixture, olefin **17** (12 mg, 12%) and starting thiophene (72 mg), were separated by column chromatography.

*Synthesis of 1-Phenyl-1-thienyl-2-methylpropenes (Olefins **14–17**)*

Garbish's procedure (33) was followed for the preparation of the olefins **14**–**17**. To a dry flask containing magnesium metal and anhydrous ether, 2-bromopropane in anhydrous ether was slowly added. A crystal of iodine initiated the reaction and the ether was allowed to boil gently until all the magnesium had dissolved. The reaction mixture was heated for 30 min under reflux and was cooled to room temperature. Then thiophene (**1**–**4**) in anhydrous ether was slowly added with stirring. The reaction mixture was stirred overnight and then poured into aqueous ammonium chloride (10%). The resulting layers were separated and the aqueous layer extracted with ether. The combined ether extracts were dried over anhydrous magnesium sulfate and evaporation of the solvent gave a yellow oil, presumably the alcohol, which was not characterized but was taken up in benzene and refluxed for 30 h in the presence of 4-toluenesulfonic acid (trace). The resulting mixture was washed with sodium bicarbonate (10%, aqueous) and dried over magnesium sulfate (anhydrous). Evaporation of the solvent yielded a dark brown oil which was chromatographed on neutral alumina (Fisher, activity 1, 60–200 mesh) to give the olefin (**14**–**17**) upon elution with hexanes.

*Preparation of 1-Phenyl-1-[3-(2-methylthienyl)]-2-methylpropene (**14**)*

Following the above procedure from 2-bromopropane (280 mg) in anhydrous ether (20 ml), magnesium metal (56 mg), and 2-methyl-3-benzoylthiophene (470 mg) olefin **14** (62 mg, 12%) was obtained; ir (neat) ν: 3070, 1520, 1475, 1425, 1340, 1225, 1210, 1050, 930, 977, 848, 750, 666 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (TMS): 1.69 (s, 3H, methyl), 1.82 (s, 3H, methyl), 2.25 (s, 3H, methyl), 6.65 ppm (d, H-4 of thienyl group; $J_{3,4}$ = 5.5 Hz; ms (70 eV) *m/e* (relative intensity): 228 (100, M^+), 213 (21), 185 (65), 129 (20), 115 (15), 97 (7), 91 (12), 77 (6), 59 (7), 45 (6), 37 (5). *Anal.* calcd. for $C_{15}H_{16}S$ (**14**): C 78.92, H 7.06; found: C 78.91, H 7.11.

*Preparation of 1-Phenyl-1-[3-(4-methylthienyl)]-2-methylpropene (**15**)*

Following the above procedure, from 2-bromopropane (28 mg), magnesium metal (5.6 mg) in anhydrous ether (5 ml) and thiophene **4** (47 mg), olefin **15** (9 mg, 17%) was obtained; ir (neat) ν: 3065, 2960, 1515, 1425, 1224, 1208, 1043, 1030, 928,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

860, 845, 782, 728, 713, 699, 668 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (TMS): 1.68 (s, 3H, methyl), 1.83 (s, 3H, methyl), 2.66 (s, 3H, methyl), 7.26 – 6.70 ppm (7H, thienyl and aromatic); ms (70 eV) *m/e* (relative intensity): 228 (100, M^+), 213 (30), 185 (78), 165 (36), 129 (39), 115 (54), 91 (15), 77 (19). *Anal.* calcd. for $C_{15}H_{16}S$ (**15**): C 78.92, H 7.06; found C 78.86, H 6.79.

*Preparation of 1-Phenyl-1-[3-(2,5-dimethylthienyl)]-2-methylpropene (**16**)*

Following the above procedure, olefin **16** (71 mg, 12%) was obtained by using 2-bromopropane (280 mg) and magnesium metal (56 mg) in anhydrous ether (20 ml) and 2,5-dimethyl-3-benzoylthiophene (540 mg) also in anhydrous ether (20 ml). This compound was previously prepared (4) by a different route; ir (neat) ν: 3040, 2920, 1615, 1500, 1452, 1380, 1210 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (TMS): 1.70 (s, 3H, methyl), 1.78 (s, 3H, methyl), 2.18 (s, 3H, methyl), 2.30 (s, 3H, methyl), 6.27 (broad, 1H, H-4) 7.34 – 6.90 ppm (complex, 5H, aromatic); $J_{4,5} < 1$ Hz; ms (70 eV) *m/e* (relative intensity): 242 (100, M^+), 227 (38), 199 (68), 184 (29), 165 (22), 129 (56), 115 (28), 202 (91), 59 (30).

*Preparation of 1-(2-Methylphenyl)-1-(3-thienyl)-2-methylpropene (**17**)*

Olefin **17** (49 mg, 9%) was also prepared by the Garbish procedure (280 mg 2-bromopropene, 56 mg magnesium metal in 20 ml anhydrous ether, and 470 mg of 3-(2-methylbenzoyl)-thiophene (4) in 20 ml anhydrous ether); ir (neat) ν: 3070, 2950, 2870, 1450, 1380, 848, 786, 775, 747, 726, 686, 678 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (TMS): 1.58 (s, 3H, methyl), 1.98 (s, 3H, methyl), 2.11 (s, 3H, methyl), 7.33 – 6.83 ppm (complex, 7H, aromatic and thienyl); ms (70 eV) *m/e* (relative intensity): 228 (100, M^+), 185 (97), 165 (29), 152 (19), 129 (71), 115 (21), 97 (27), 91 (15), 77 (16). *Anal.* calcd. for $C_{15}H_{16}S$ (**17**): C 78.92, H 7.06; found: C 79.14, H 7.03.

Polarized fluorescence study of retinals at room temperature

SURAT HOTCHANDANI, PAUL PAQUIN, AND ROGER M. LEBLANC

Groupe de Recherche en Biophysique, Département de Chimie–Biologie, Université du Québec à Trois-Rivières, Trois-Rivières (Qué.), Canada G9A 5H7

Received January 2, 1978

SURAT HOTCHANDANI, PAUL PAQUIN, and ROGER M. LEBLANC. Can. J. Chem. **56**, 1985 (1978).

The solid films of all-*trans*, 9-*cis*, and 13-*cis* retinals have been found to be fluorescent at room temperature. Their polarization study with the aim of understanding the nature of their fluorescent state has also been carried out at room temperature. The high positive polarization of fluorescence with respect to the excitation carried out in the main $^1B_u \leftarrow {}^1A_g$ absorption transition of retinals suggests that their fluorescent state possesses a large amount of ^1B_u character. A vibronic coupling mechanism that suggests the $^1A_g^-$ (a weakly allowed π,π^*) state or $^1n,\pi^*$ state being the lowest singlet state in retinals has also been considered.

SURAT HOTCHANDANI, PAUL PAQUIN et ROGER M. LEBLANC. Can. J. Chem. **56**, 1985 (1978).

A température ambiante, nous observons la fluorescence des isomères de retinal (tout-*trans* 9-*cis* et 13-*cis*) à l'état de film solide. Afin de connaître la nature des états fluorescents, nous avons examiné la polarisation de la fluorescence. La valeur positive de polarisation des retinals lorsque l'excitation est faite dans la transition d'absorption $^1B_u \leftarrow {}^1A_g$ suggère que leur fluorescence possède un fort caractère ^1B_u. La possibilité d'un mécanisme de couplage vibronique a aussi été considérée.

Introduction

During the past couple of years increasing interest in understanding the ordering of the electronic states of retinyl polyenes, the chromophores of the visual pigments, has manifested itself in recent literature (1–10). The phenomenon of electronic relaxation of the singlet states of the polyenes has been, in particular, the topic of active research. The recent discovery (6–8) of a very weakly allowed excited state $^1A_g^-$ (π–π^*) and its contribution to the radiative (fluorescence) properties has also been discussed. The $^1A_g^-$ state, it has been shown, arises due to the inclusion of doubly excited configurations in the calculations of configuration interaction (8), and is considered to be the lowest excited singlet state responsible for fluorescence of polyenes (6, 7, 10). This is in contrast with the usual ^1B_u (π,π^*) assignment of the lowest singlet state for polyenes (11).

The presence of the weakly allowed state $^1A_g^-$ does, however, explain very successfully many discrepancies in fluorescence characteristics of polyenes, for example, (*a*) the radiative fluorescence lifetimes (τ_0) measured experimentally (4, 5, 10) are anomalously longer than those calculated from their respective integrated absorption intensities using Strickler–Berg equation (12), (*b*) the dependence of τ_0 on temperature (5, 10), and (*c*) the different solvent effect on absorption and fluorescence spectra (6).

In retinals (polyene aldehydes) the presence of n,Π^* states (introduced due to nonbonded electrons of heteroatom oxygen) should also be considered in determining their radiative and nonradiative properties. For instance, Abrahamson and Ostroy (1) reported that the retinals but not retinols or retinal Schiff bases have an efficient pathway into the triplet manifold. This unique pathway (channel) by which retinal triplet state is populated has been attributed to the presence of n,π^* singlet states which increase intersystem crossing. This preferential $^1n,\pi \leftrightarrow {}^3\pi$–$\pi^*$ intersystem crossing has also been shown to be responsible for marked dependence of the retinals fluorescence quantum yield, ϕ_f, upon excitation wavelength (2). Although Hochstrasser *et al.* (13) are of the opinion that the triplet precursor lives for about 36 ps and the intersystem crossing process probably involves mixing of σ,π^* and π,π^* states.

In order to characterize the nature of the emitting state, polarization experiments are usually good techniques to look forward to. Moore and Song (*9a*) thus carried out the polarization fluorescence study of all-*trans* retinal in ether at 77 K. Their results did not give any indication of the presence of weakly allowed $^1A_g^-$ (π,π^*) or $^1n,\pi^*$ in the fluorescence state of retinal, and also other isomers were not studied. Since most of the published work on retinals has been carried out at 77 K except for the recent work of Becker *et al.* (2*d*) on all-*trans* retinal, and also since the visual events occur at physiological temperature (which is closer to the room temperature) we have carried out the fluorescence experiments of retinals at room temperature. As an extension of our interest in these molecules (14), we present here the polarized fluorescence study of all-*trans*, 9-*cis*, and 13-*cis* retinals in solid films and at room temperature using photoselection techniques as described by Albrecht (15).

Experimental

Materials

The isomeric retinals, namely all-*trans*, 9-*cis*, and 13-*cis* (anhydrous quality), were purchased from Sigma Co., St. Louis, MO, and were stored in the dark at 0°C. The solutions of retinals were made in ether ("ARISTAR" grade, ethanol content 200 ppm, water content 500 ppm) obtained from B.D.H. Chemicals, Montreal. The retinals and solvent ether were used without further purification, and the films were prepared as described elsewhere (14*b*).

Methods and Techniques

Ultraviolet–visible spectra of the films were recorded on Perkin-Elmer 124 spectrophotometer with a HTV R136 photomultiplier. Fluorescence excitation and emission spectra of the films at room temperature were recorded on Perkin-Elmer MPF-2A spectrofluorimeter fitted with excitation and emission monochromators and RCA-136 photomultiplier. The detection of the fluorescence of the films was made by the method as outlined by Leblanc *et al.* (16) and the polarization experiments were carried out as described by Hotchandani and Testa (17). The concentration of the solutions for preparation of the films for recording their fluorescence excitation and emission was $\sim 10^{-5}$ *M*. However, a higher concentration $\sim 10^{-4}$ *M* was used for polarization experiments. All experiments were carried out at room temperature in red light and in nitrogen atmosphere.

Results and Discussion

The solid films of all-*trans*, 9-*cis*, and 13-*cis* retinals have been found to be fluorescent at room temperature. Their absorption, fluorescence excitation, and emission spectra recorded at room temperature are shown in Figs. 1, 2, and 3, respectively. Their polarization curves also recorded at room temperature are shown in the figures. The broad shape, the absence of 0–0 band, and large Stokes shift (3000–3500 cm^{-1}) indicate that the absorption and fluorescence bands of the retinals are severely Franck–Condon forbidden. The broad spectra of retinals are probably due to close lying n,π^* and π–π^* states. Such spectral broadness has also been observed with other polyene aldehydes (18) and many nitrogen heterocyclics (19), and has been attributed to the presence of n,π^* states lying close to π,π^* states.

The fluorescence maxima and other spectral features of the films are presented in Table 1. For comparison the fluorescence maxima of all-*trans* retinal at room temperature (2*d*) and at 77 K (2) are also included. As noted from the table our results for fluorescence maxima of the solid films at room temperature (RT) are at longer wavelengths than those reported at 77 K (2). Judging from the fluorescence maximum of all-*trans* retinal solution (2*d*) at room temperature ($\lambda_{fl} \simeq 600$ nm which is even further displaced to longer wavelengths than the films), one would expect that the fluorescence of

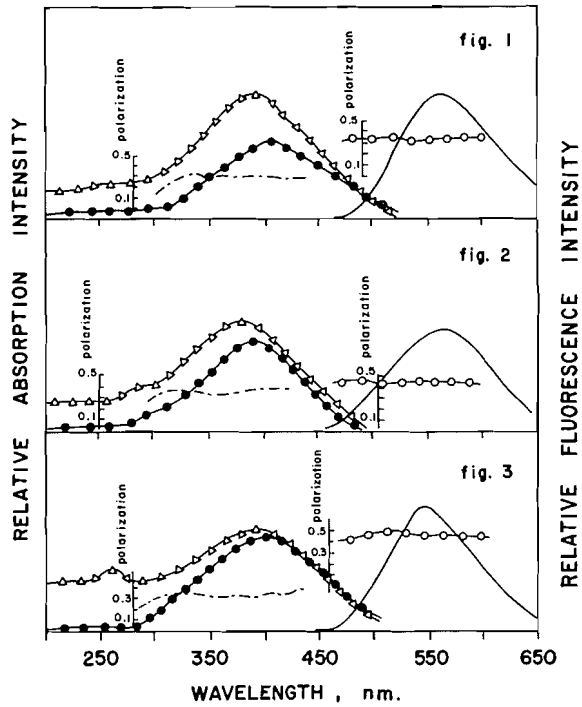

FIG. 1. Absorption spectrum (△), excitation spectrum (●), corrected fluorescence spectrum (—), excitation polarization (·····), and emission polarization (○) of films of all-*trans* retinal at room temperature. The films for excitation and emission were prepared from 500 μl of 3.403×10^{-5} *M* solution in ether. For polarization experiments the films were prepared from 500 μl of 3.403×10^{-4} *M* solution. Monitoring wavelengths for excitation and emission polarization were 550 and 410 nm, respectively.

FIG. 2. Spectra for 9-*cis* retinal films. The films for excitation and emission were prepared from 500 μl of 5.62×10^{-5} *M* solution in ether. For polarization experiments the films were prepared from 500 μl of 5.62×10^{-4} *M* solution. Monitoring wavelengths for excitation and emission polarization were, respectively, 560 and 385 nm. Please refer to Fig. 1 caption for details.

FIG. 3. Spectra of 13-*cis* retinal films. The films for excitation and emission were prepared from 500 μl of 1.258×10^{-5} *M* solution in ether while those for polarization studies were prepared from 500 μl of 1.258×10^{-4} *M* solution. Monitoring wavelengths for excitation and emission, respectively, were 540 and 400 nm. For details, please refer to Fig. 1 caption.

retinals follows the pattern

$$\lambda_{fl}\text{ (Solution at RT, non-rigid system)} > \lambda_{fl}\text{ (Film, rigid system at RT)} > \lambda_{fl}\text{ (Rigid system at 77 K)}$$

such trend has also been observed with other retinyl polyenes (3–5). This shows us that the observed film fluorescence in the present work is due to the retinals and not due to the impurities.

TABLE 1. Fluorescence characteristics of retinals

Compound	Solid films at room temperature (present work)						
	λ_{max} (nm) absorption maximum	λ_{max} (nm) uncorrected excitation	λ_{max} (nm) corrected fluorescence maximum	Fluorescence polarization when excited into the main absorption $^1B_u \leftarrow {}^1A_g$ band	Excitation polarization in the region 320–450 nm	λ_{max} (nm) corrected fluorescence at room temperature	λ_{max} (nm) corrected fluorescence at 77 K (±10 nm)
All-*trans* retinal	395	405	545±10	+0.30–+0.38	+0.25–+0.30	600±25‖ (EPA)	510 (3MP)*†‡ 520 (3MP)§ 540 (EPA)§
9-*cis* retinal	380	390	555±10	~+0.40	+0.30–+0.35		520–525 (3MP)*†‡
13-*cis* retinal	390	400	535±10	~+0.40	+0.30–+0.35		505 (3MP)*†‡

*The values reported are for ordinary retinals in ordinary 3MP where H-bonding is occurring.
†Reference 2*b*.
‡Reference 2*c*.
§Reference 2*e*.
‖Reference 2*d*.

We have also checked qualitatively the excitation wavelength dependence of fluorescence quantum yield of retinals by carrying out excitation at wavelengths (400–450 nm) longer than their respective $^1B_u \leftarrow {}^1A_g$ absorption bands. We definitely have seen an augmentation in the fluorescence intensities as has been reported by others (2) though, of course, the quantitative study was not carried out.

Recently (2 *d*, *e*), it has been shown that the dry retinals in dry hydrocarbon solvents (3MP) or in dry non-hydrogen-bonding polar solvents (dichloromethane) do not fluoresce ($\phi_f < 10^{-4}$) whereas ordinary retinals, in ordinary 3MP (containing trace amounts of water) and in hydrogen-bonding solvents like ethanol, EPA, have been found to fluoresce. This fluorescence was interpreted as due to the hydrogen-bonded retinal species, and that there existed an equilibrium mixture of non-hydrogen-bonded and hydrogen-bonded retinals in hydroxylic solvents explaining the excitation wavelength dependence of ϕ_f of retinals. It is possible that, in the present work, the observed fluorescence of solid films of retinals (prepared from solvent ether containing trace amounts of ethanol and water) is also due to the hydrogen-bonded retinal species, which would then explain the dependence of the fluorescence intensity (or ϕ_f) on excitation wavelength as observed in the present work.

The high positive polarization ($P = +0.40$) for the fluorescence of the isomeric retinals (Table 1) as obtained with the excitation carried out at wavelengths corresponding to the maxima of their respective highly allowed $^1B_u \leftarrow {}^1A_g$ absorption suggests that the absorption and fluorescence correspond to transitions to and from ^1B_u (π,π^*) state or the fluorescent state has large amount of B_u character incorporated in it. The positive polarization for excitation in the wavelength region 320–450 nm further supports it. The declining tendency of the excitation polarization in the wavelength region shorter than 300 nm, as seen from the figures, is possibly due to the onset of second electronic transition of higher energy.

It has been, however, proposed that the $^1A_g^-$ (π,π^*) a very weakly allowed state is the lowest in polyenes, in general, including retinals (6, 7, 10); while others suggest that the $^1n,\pi^*$ is the lowest or is essentially degenerate with the lowest $^1A_g^-$ (π,π^*) state. For example, Song *et al.* (9*b*), in view of their heavy-atom effect results on retinals, suggested that $^1n,\pi^*$ state was above the fluorescing $^1\pi,\pi^*$ state. They, however, did not assign the symmetry (i.e. $^1A_g^-$ or ^1B_u) to this π,π^* fluorescent state of retinals. Becker *et al.* (2 *d*, *e*), on the other hand, while studying the fluorescence of all-*trans* and 13-*cis* retinals in various solvents concluded that the $^1n,\pi^*$ is the lowest excited singlet state in dry alkane nonhydrogen-bonding solvents whereas in hydrogen-bonding solvents $^1\pi,\pi^*$ is the emitting (lowest) state in retinals. The recent two-photon excitation studies of Fang *et al.* (20) on diphenyl octatetraene (DPO) have, however, shown conclusively that $^1A_g^-$ is the emitting state of DPO.

Our results for the positive fluorescence polarization ($P \simeq +0.35–+0.40$) of the solid films of the isomeric retinals at room temperature (when excited into their $^1B_u \leftarrow {}^1A_g$ absorption band), unfortunately, do not seem to be compatible with either $^1\pi,\pi^*$ ($^1A_g^-$), or $^1n,\pi^*$ assignment of the lowest singlet state responsible for retinals fluorescence, but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

on the contrary seem to support that the fluorescent state possesses a large amount of B_u character. A negative or even low positive (+0.00–+0.05) polarization values would have indicated the presence of $^1n,\pi^*$ or $^1A_g^-$ state.

Of course, for hydrogen-bonded retinals as is the case in the present work, the possibility of n,π^*state as the lowest excited singlet state is ruled out. Though, our polarized experiments do not reveal directly the presence of the weakly allowed $^1A_g^-$ state, yet the positive polarization results are in full agreement with the $^1A_g^-$ (π,π^*) assignment of the lowest excited state of retinals. This is due to the fact that $^1A_g^-$ (principally a doubly excited state) has virtually no transition moment of its own to the ground state, and steals all of its intensity from the strongly allowed $^1B_u \leftarrow {}^1A_g$ transition and thus acquires B_u radiative and polarization characteristics. This could occur if the state ^1B_u (π,π^*), $^1A_g^-$ (π,π^*) and, even $^1n,\pi^*$ are energetically very close and are in reality highly mixed due to vibronic interactions.

Kinetics and mechanism for the formation of oxygenated products from the photolysis of hexafluoroacetone–methane system

E-CHUNG WU, ROBERT RICHMOND CLARK, AND YI-NOO TANG
Department of Chemistry, Texas A&M University, College Station, TX 77843, U.S.A.

Received October 19, 1977

E-CHUNG WU, ROBERT RICHMOND CLARK, and YI-NOO TANG. Can. J. Chem. **56**, 1989 (1978).

In addition to CF_3H and C_2F_6, four oxygenated products were identified in the photolysis of hexafluoroacetone–methane system: CH_3COCF_3, $(CF_3)_3COH$, $(CF_3)_2(CH_3)COH$, and $(CF_3)_2(CH_3)COCF_3$. The mechanism for the formation of these compounds is discussed, and the activation energies of several of the reactions involved are evaluated from detailed temperature and composition studies.

E-CHUNG WU, ROBERT RICHMOND CLARK et YI-NOO TANG. Can. J. Chem. **56**, 1989 (1978).

Lors de la photolyse du système hexafluoroacétone–méthane, on a identifié quatre produits oxygénés en plus du CF_3H et du C_2F_6; il s'agit de CH_3COCF_3, $(CF_3)_3COH$, $(CF_3)_2(CH_3)COH$ et $(CF_3)_2(CH_3)COCF_3$. On discute du mécanisme de formation de ces composés et on évalue les énergies d'activation de plusieurs réactions impliquées en faisant appel à des études détaillées de température et de composition.

Introduction

During the past twenty years, the various chemical and physical processes associated with the photolysis of hexafluoroacetone (HFA) have been extensively studied (1–7). Although the mechanism of photolysis is quite complicated, the only significant products observed by most of the investigators over a wide range of pressure and temperature were CO and C_2F_6, with the latter being formed from the recombination of CF_3 radicals. Because of the apparent simplicity of the photodecomposition, and the ease of measuring the dissociation yields, HFA has been used as a major source of CF_3 radicals to study their chemical interactions (8).

Hydrogen abstraction of CF_3 in a $(CF_3)_2CO$–CH_4 system has been studied by Ayscough, Polanyi, and Steacie (9), Carmichael and Johnston (10), and Whittle and co-workers (11). An activation energy for this process has been obtained in the range of 10.3–11.5 kcal mol^{-1}. Ayscough (12) has also used this system to estabish the recombination rate of CF_3 radicals. The corresponding reactions with deuterated and partially deuterated methane have been the backbone of the studies of isotopic effects in free radical abstractive interactions (11, 13, 14).

In the pure HFA system, Gordon (7) has also detected an ether as a product which is attributable to the addition of CF_3 to the C=O double bonds of the ketone. He has also evaluated the activation energies for both the addition and reverse decomposition processes. We have performed a detailed study on the interactions of CF_3 radicals with HFA in the presence of methane, and have detected four oxygenated products. The energetics and mechanism for the formation of these four species will be discussed in detail.

Experimental

Hexafluoroacetone obtained from PCR, Inc. was purified by vacuum distillation. Ultra pure grade methane from Matheson with a purity of 99.99% was used directly without further purification. Those compounds used for the purpose of identification, such as CF_3H, C_2F_6 (from Matheson), CF_3COCH_3, $(CF_3)_2CH_3COH$, and $(CF_3)_3COH$ (from PCR, Inc.), were used directly without purification.

The experimental set-up consists of a greaseless vacuum line with two Validyne pressure transducers, a 45 mm × 150 mm long quartz reaction cell in a cylindrical aluminum oven which was regulated by a proportional temperature controller with a temperature fluctuation of ±1.0°C at 300°C, and a Bausch and Lomb monochromator which isolated 313 nm light from an Osram Super-pressure Hg lamp.

HFA was condensed into the reaction cell while CH_4 was transferred by expansion. The reactants were equilibrated at the required temperature for half an hour prior to photolysis. A blank test has shown no dark reaction taking place. Four oxygenated products were observed. Three of them, CF_3COCH_3, $(CF_3)_3COH$, and $(CF_3)_2(CH_3)COH$ were identified by mass spectrometry and further confirmed gas chromatographically using authentic samples. The fourth compound exhibited the following major peaks in its mass spectrum: 181, $(CF_3)_2(CH_3)CO^+$; 145, $(CF_3)_2(CH_3)C^+$; 97, CF_3CO^+; 69, CF_3^+; and 43, CH_3CO^+; no molecular ion is observed. This evidence, coupled with mechanistic expectations, led to the identification of this fourth compound as $(CF_3)_2(CH_3)COCF_3$.

After photolysis, samples were separated into three portions of known ratios which then were analyzed gas chromatographically using three sets of columns: (*1*) a 10 ft × ¼ in. dimethylsulfolane column (23°C) + a 10 ft × ¼ in. molecular seive 5A column (40°C) were used for the analysis of CO and C_2F_6; (*2*) a 50 ft × ¼ in. PCA column (propylene carbonate

For personal use only.

on alumina) at 0°C was used for the analysis of CF_3H and C_2F_6; (*3*) a 30 ft × ¼ in. silicon fluids #96 column (23°C) was used to analyze oxygenated compounds. The peak was measured by (*1*) the product of peak height and half-peak width; and (*2*) the "cut and weigh" method. The results obtained from both methods are in good agreement. Relative thermal conductivities of most of the product compounds were precisely calibrated with authentic samples. The thermal conductivity of $(CF_3)_2(CH_3)COCF_3$ was estimated from those of other oxygenated compounds.

Results and Discussion

Mechanism for Product Formation

The photolysis of HFA in the presence of methane at 313 nm has been studied over a wide pressure and composition range at various temperatures from 298 to 443 K. In most of the samples, the HFA pressure employed is 40 Torr, but the CH_4 pressure varies from 10 to 400 Torr. The products formed are: CO, C_2F_6, CF_3H, $(CF_3)_3COH$, CF_3COCH_3, $(CF_3)_2(CH_3)COH$, and $(CF_3)_2(CH_3)COCF_3$. The yields of CF_3H and CF_3COCH_3 increase, while those of $(CF_3)_3COH$, $(CF_3)_2(CH_3)COH$, and $(CF_3)_2(CH_3)COCF_3$ decrease as the reaction temperature increases. The latter two have a very sensitive temperature dependence. An overall mechanism for the formation of products is proposed as follows:

[1] $(CF_3)_2CO \xrightarrow{h\nu} 2CF_3 + CO$

[2] $2CF_3 \rightarrow C_2F_6$

[3] $CF_3 + CH_4 \rightarrow CF_3H + CH_3$

[4], [−4] $CF_3 + (CF_3)_2CO \rightleftarrows (CF_3)_3CO$

[5] $(CF_3)_3CO + CH_4 \rightarrow (CF_3)_3COH + CH_3$

[6] $CH_3 + (CF_3)_2CO \rightarrow (CF_3)_2(CH_3)CO$

[7] $(CF_3)_2(CH_3)CO \rightarrow CF_3COCH_3 + CF_3$

[8] $(CF_3)_2(CH_3)CO + CH_4 \rightarrow (CF_3)_2(CH_3)COH + CH_3$

[9] $(CF_3)_2(CH_3)CO + CF_3 \rightarrow (CF_3)_2(CH_3)COCF_3$

Another plausible reaction for the mechanism, $(CF_3)_3CO + CF_3 \rightarrow (CF_3)_3COCF_3$, is omitted because the expected ether is not observed as a significant product in the present experiments.

The product, $(CF_3)_3COH$, has never been observed in previous studies. In some earlier work related to the formation and decomposition of $(CF_3)_2(CH_3)CO$ as shown in [6] and [7], Smith and Calvert (15) formed the same radical through reaction [10]

[10] $CF_3 + CH_3COCF_3 \rightarrow (CF_3)_2(CH_3)CO$

by photolyzing a mixture of $CF_3COC_6H_5$ and CF_3COCH_3, but they failed to observe $(CF_3)_2CO$ as a reaction product. This indicated that reaction [−6], the reverse of [6], is not an important decomposition route for this radical. Later, Gile and Whittle (16) studied the photolysis of a mixture of CF_3COCF_3 and CH_3COCH_3, and observed the formation of CF_3COCH_3. With this combined evidence, we have omitted the reverse process [−6] from the mechanism and accepted process [7] as the sole path for the decomposition of $(CF_3)_2(CH_3)CO$. The reason for the domination of process [7] may be attributed to the stronger repulsion between the CF_3 groups and the stabilization of the CH_3 group by hydrogen bonding between H and O atoms in the radical. Besides undergoing decomposition, this radical can either abstract a hydrogen to give an alcohol as in [8], or combine with a CF_3 radical to give an ether as in [9].

Recently, Gordon and co-workers (17) studied the photolysis of a $(CF_3)_2CO$–C_2H_6 mixture and observed $(CF_3)_2(C_2H_5)COH$ as a product. They proposed a mechanism for the formation of this alcohol which involved the H-abstraction from C_2H_6 by electronically excited HFA molecules. This was based on their observations that the CO produced was at the most a few percent of that which would be produced from the unquenched photolysis of HFA, and that considerably more C_2F_6 was observed than would correspond to the observed CO. However, such a chemical quenching mechanism is not significant in the present HFA–CH_4 system because of the following observations. (*i*) The yield of CO from the HFA–CH_4 system is very close to that of the pure HFA system. (*ii*) The product ratio, C_2F_6/CO, is always less than unity. (*iii*) The mass balance between CF_3 and CO for most of the HFA–CH_4 samples (except for those of very high $[CH_4]$) shows a $[C_2F_6 + \frac{1}{2}CF_3H + \frac{1}{2}(CF_3)_3COH - \frac{1}{2}CH_3COCF_3]/CO$ ratio which is around unity.

Evaluation of Activation Energies

From the mechanism postulated above, four quantitative relationships can be obtained as follows:

[11] $k_3/k_2^{1/2} = R_3/R_2^{1/2}[CH_4]$

[12] $R_8/R_7 = (k_8/k_7)\,[CH_4]$

[13] $R_9/R_7 = (k_9/k_7k_2^{1/2})R_2^{1/2}$

[14] $R_3\,[HFA]/R_5 = (k_3/k_4)\,[CH_4] + (k_3/k_4)\,(k_{-4}/k_5)$

where R_i = reaction rate of process i, and [X] = concentration of compound X. The values of $k_3/k_2^{1/2}$ calculated from the right-hand side of eq. [11] are listed in Table 1. At 383 K, a constant value of $R_3/R_2^{1/2}[CH_4]$ was obtained with excellent precision for a thirty-fold variation of the $[CH_4]/[HFA]$ ratio. At 363 K, the data show a slightly larger fluctuation for a ten-fold variation in the $[CH_4]/[HFA]$ ratio due mainly to the smaller yield of CF_3H at this lower

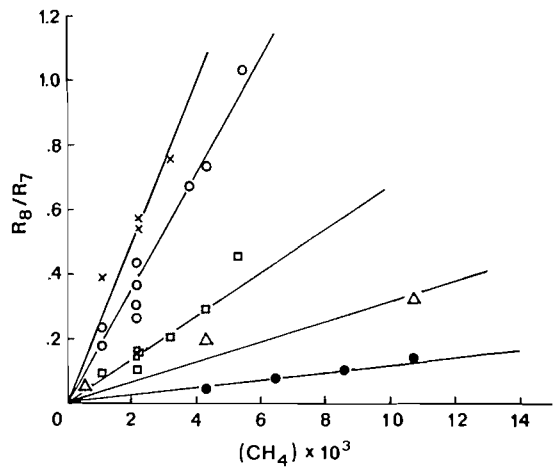

FIG. 1. A plot of R_8/R_7 vs. the concentration of methane at various temperatures. ×, 303 K; ○, 308 K; □, 323 K; △, 343 K; and ●, 363 K.

temperature. Several runs were also carried out at higher temperatures, i.e., 403, 423, and 443 K. An Arrhenius plot for these data gave a value for $E_3 - \frac{1}{2}E_2 = 9.90 \pm 0.34$ kcal mol^{-1}. If we assume $E_2 = 0$, E_3 therefore equals 9.90 kcal mol^{-1}, which is consistent with the value 10.3 kcal mol^{-1} evaluated by Ayscough, Polanyi, and Steacie (9), and the value 9.5 kcal mol^{-1} evaluated by Pritchard, Pritchard, and Trotman-Dickenson (18). Whittle and co-workers (11) have obtained larger values, 11.3, 11.5, while Carmichael and Johnston (10) obtained a value of 11.0 kcal mol^{-1} for E_3. From the Arrhenius plot, a value for log $(A_3/A_2^{1/2}) = 3.05 \pm 0.18$ is obtained where $A_3/A_2^{1/2}$ is in units of $\ell^{1/2}$ mol$^{-1/2}$ s$^{-1/2}$. The corresponding value from ref. 9 is 3.49 and that from ref. 10 is 3.80.

Results related to eqs. [12], [13], and [14] have been calculated. Plots of the ratios R_8/R_7 vs. $[CH_4]$ at various temperatures are shown in Fig. 1 and are linear as required by eq. [12]. The least-squares values of the slopes are 250.3, 177.9, 68.2, 23.44, and 8.44 ℓ mol^{-1} at reaction temperatures of 303, 308, 323, 343, and 363 K, respectively. An Arrhenius plot, shown in Fig. 2(*A*), gave a least-squares value of 12.29 ± 0.09 kcal mol^{-1} for the difference of activation energies, $E_7 - E_8$, and a value of -6.47 ± 0.06 for log (A_8/A_7) where A_8/A_7 is in units of ℓ mol^{-1}.

A plot of R_9/R_7 vs. the square root of R_2 yields the ratio of rate constants, $k_9/k_7k_2^{1/2}$. From Fig. 3 these slopes are 0.495, 0.292, and 0.107 $\ell^{1/2}$ s$^{1/2}$ mol$^{-1/2}$ at 303, 308, and 323 K, respectively. From the Arrhenius plot of these slopes, shown in Fig. 2(*B*), we obtained a least-squares value of -14.53 ± 1.32 kcal mol^{-1} for $E_9 - E_7 - \frac{1}{2}E_2$ and a value of -10.81 ± 0.92 for log $(A_9/A_7A_2^{1/2})$ with the A term in the unit of $\ell^{1/2}$ s$^{1/2}$ mol$^{-1/2}$. If we assume $E_9 = E_2 = 0$ for the radical–radical recombination processes, $E_7 = 14.53$ kcal mol^{-1}. By combining this E_7 value with that of $E_7 - E_8$ determined above, we obtain 2.24 ± 1.32 kcal mol^{-1} for E_8.

The appropriate plot for eq. [14], shown in Fig. 4, yielded least square values of k_3/k_4 from the slopes, 0.094, 0.151, and 0.189 at temperatures 343, 353, and

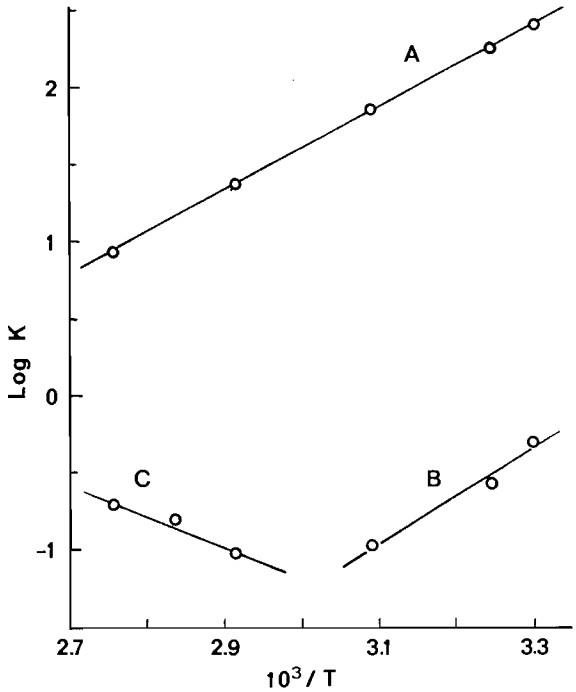

FIG. 2. An Arrhenius plot of log K vs. $1/T$. (A), $K = k_8/k_7$; (B) $K = k_9/k_7k_2^{1/2}$; (C) $K = k_3/k_4$.

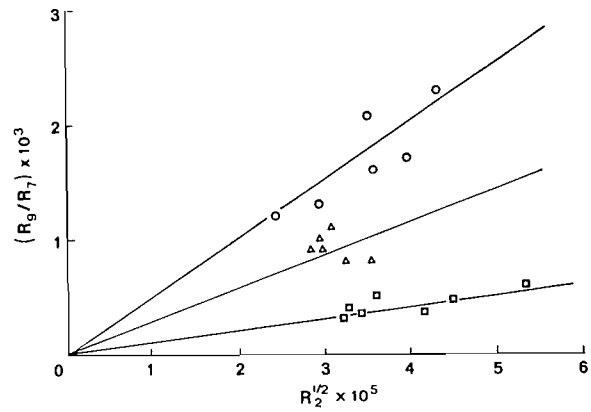

FIG. 3. A plot of R_9/R_7 vs. $R_2^{1/2}$ at various temperatures. O, 303 K; △, 308 K; and □, 323 K.

363 K, respectively; the corresponding values of $k_3k_4/k_{-4}k_5$ from the intercepts are 0.0014, 0.0041, and 0.0054 mol ℓ^{-1} at these three temperatures. The difference of activation energies, $E_3 - E_4$, can thus be obtained as 8.70 ± 1.9 kcal mol^{-1} from the Arrhenius plot shown in Fig. 2(C). The log (A_3/A_4) value is 4.54 ± 1.19. Since E_3 is 9.9 kcal mol^{-1} we can estimate a value of 1.2 kcal mol^{-1} for E_4. The values of k_{-4}/k_5 can also be obtained from the ratios of intercept/slope in Fig. 4 but with higher uncertainties. A least-squares value for $E_{-4} - E_5$ can be estimated as 8.17 ± 3.55 kcal mol^{-1}.

These results are summarized in Table 2.

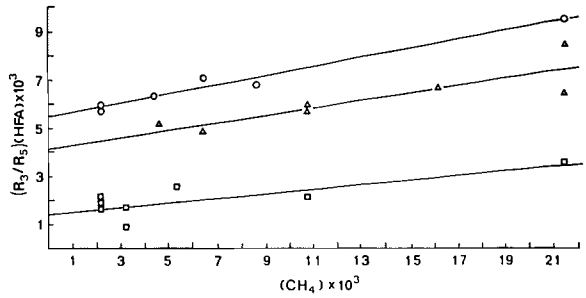

FIG. 4. A plot of R_3[HFA]$/R_5$ vs. the concentration of methane at various temperatures. □, 343 K; △, 353 K; and ○, 363 K.

The CF_3 Addition Process to C=O Bond in HFA

In 1962, Gordon (7) studied the photolysis of HFA at various temperatures and observed the formation of a perfluoro-ether, $(CF_3)_3COCF_3$, as a major product. He proposed that CF_3 radicals formed from the photolysis added to the oxygen end of the C=O bond to give $(CF_3)_2COCF_3$ as shown in [15], which then combined with another CF_3 radical to form the ether as shown in [16].

[15] $$CF_3 + (CF_3)_2CO \rightleftarrows (CF_3)_2COCF_3$$

[16] $$CF_3 + (CF_3)_2COCF_3 \rightarrow (CF_3)_3COCF_3$$

He obtained a value of 9.67 kcal mol^{-1} for E_{15} and a value of 30.6 kcal mol^{-1} for E_{-15}. However, the formation of $(CF_3)_3COH$ and $(CF_3)_2(CH_3)COH$ as major products in our reaction system indicates clearly that the addition should take place at the carbon end of the C=O bond. Therefore, E_{15} obtained by Gordon (7) should be identical to E_4 in our mechanism. We obtained a value of 1.2 kcal mol^{-1} for E_4, which is much smaller than his E_{15} value. We are in favor of this low value because the present experimental results indicate that the rate of formation of $(CF_3)_3COH$ at room temperature is very much higher than that of CF_3H. This indicates that the overall activation energy of processes [4] and [5] should be much less than that of process [3] which is about 10 kcal mol^{-1}. Since the E_a value for [5], the H-abstraction reaction from CH_4 by $(CF_3)_3CO$ radical, should be significant, it renders a 1.2 kcal mol^{-1} E_a value for [4] to be more likely than the 9.67 kcal mol^{-1} value.

Other Kinetic Considerations[1]

As we have discussed above, the values of 8.17 and

[1]Table 3, the dependence of R_8/R_7 on the pressure of methane at various temperatures, and Table 4, composition and temperature dependence of R_2 and R_9/R_7, are both lodged with the Depository of Unpublished Data. Copies of these may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TABLE 2. A summary of the evaluated activation energies of various processes in the mechanism

Processes	Activation energies (kcal mol^{-1})
$CF_3 + CH_4 \xrightarrow{3} CF_3H + CH_3$	$E_3 = 9.90 \pm 0.34$
$CF_3 + (CF_3)_2CO \xrightarrow{4} (CF_3)_3CO$	$E_4 \simeq 1.2$
$(CF_3)_3CO \xrightarrow{-4} (CF_3)_2CO + CF_3$	$E_{-4} - E_5 = 8.17 \pm 3.55$
$CH_4 + (CF_3)_3CO \xrightarrow{5} (CF_3)_3COH + CH_3$	
$(CF_3)_2(CH_3)CO \xrightarrow{7} CF_3COCH_3 + CF_3$	$E_7 = 14.53 \pm 1.32$
$CH_4 + (CF_3)_2(CH_3)CO \xrightarrow{8} (CF_3)_2(CH_3)COH + CH_3$	$E_8 = 2.24 \pm 1.32$

12.29 kcal mol^{-1} have been obtained for $E_{-4} - E_5$ and $E_7 - E_8$, respectively, and we have calculated the value of E_8 from the known value of E_7. If we assume E_5 has a value similar to that of E_8, we are able to estimate a value of 10.4 kcal mol^{-1} for E_{-4}. This value is slightly less than that of E_7. If we compare this estimated E_{-4} value with that of E_{-15} obtained by Gordon (7), again his value is much higher than ours. Our experimental results indicated that in the temperature range of 300–350 K, the stability of these fluorinated *tert*-butoxyl radicals decreases rapidly as temperature increases. Because the stability of these radicals is sensitive to such low temperatures, the activation energies for their decomposition are likely to be rather low. In fact, the decomposition of *tert*-butoxyl radicals has been studied (19, 20): the activation energy is in the range between 11 to 13 kcal mol^{-1} which is consistent with our finding.

There are no values for the Arrhenius parameters of H-abstraction by fluorinated *tert*-butoxyl radical available in the literature. However, it is well known that the *tert*-butoxyl radical needs a much lower activation energy for H-abstraction than does a methyl radical (21). Our low value of E_8, 2.24 kcal mol^{-1}, is therefore consistent with these observations.

By employing the activation energies of eqs. [4] and [−4], we can also evaluate the heat of formation for the $(CF_3)_3CO$ radical. Since we know that $\Delta H_f^0(CF_3,\ 298\ K) = -112.5$ kcal mol^{-1} (22) and $\Delta H_f^0[(CF_3)_2CO,\ 600\ K] = -325.2$ kcal mol^{-1} (23), with the help of the group additivity rule (22) to calculate the required C_p values, we are able to roughly estimate the heat of formation for $(CF_3)_3CO$ as −448 kcal mol^{-1}.

Dehydrogenation of Δ^3-carene over chromia and chromia–alumina catalysts

V. KRISHNASAMY

Alagappa Chettiar College of Technology, University of Madras, Guindy, Madras 600 025, India

Received December 20, 1977

V. KRISHNASAMY. Can. J. Chem. **56**, 1994 (1978).

3-Carene is dehydrogenated over oxidized and reduced chromia and chromia–alumina catalysts at 340 to 500°C, without and with pyridine. Dehydrogenation is found to be more effective over reduced than oxidized catalysts; in either state, however, chromia–alumina is more active than chromia. Pyridine brings down the dehydrogenation ability of chromia and chromia–alumina in both reduced and oxidized states, more markedly in the reduced state. The ratio of *p*-cymene to *m*-cymene at 360 to 425°C is higher over chromia than over chromia–alumina. Increase of temperature from 360°C to higher values decreases the ratio of cymenes over chromia but does not affect the ratio over chromia–alumina. Pyridine has no effect on the ratio of cymenes over chromia; over chromia–alumina, neither, pyridine nor the pretreatment of the catalyst with oxygen or hydrogen has any effect on the ratio.

V. KRISHNASAMY. Can. J. Chem. **56**, 1994 (1978).

Il y a déshydrogénation du carène-3 sur des catalyseurs oxydés et réduits de sesquioxyde de chrome et de sesquioxyde de chrome–alumine à des températures allant de 340 à 500°C avec ou sans addition de pyridine. On a trouvé que la déshydrogénation est plus efficace sur des catalyseurs réduits plutôt qu'oxydés; toutefois, dans chacun des états, le catalyseur sesquioxyde de chrome–alumine est plus actif que le sesquioxyde de chrome. La pyridine abaisse l'habilité à déshydrogéner du sesquioxyde de chrome et du sesquioxyde de chrome–alumine aux états soit réduits ou oxydés; toutefois cet effet est plus marqué dans l'état réduit. Le rapport de *p*-cymène à *m*-cymène à des températures allant de 360 à 425°C est plus élevé lorsque l'on opère sur du sesquioxyde de chrome que dans le cas du sesquioxyde de chrome–alumine. Une augmentation de la température de 360°C vers des valeurs plus élevées provoque une diminution du rapport des cymènes sur le sesquioxyde de chrome mais n'affecte pas le rapport sur le sesquioxyde de chrome–alumine. La pyridine n'a aucun effet sur les rapports de cymènes sur du sesquioxyde de chrome; sur le sesquioxyde de chrome–alumine, ni la pyridine ni un prétraitement du catalyseur avec de l'oxygène ou de l'hydrogène n'affecte ce rapport.

Introduction

3-Carene is the major constituent (about 60%) of Indian turpentine oil (1). The oil cannot be stored, as 3-carene readily undergoes aerial oxidation (2, 3) forming resins. Attempts are being made to convert this unstable compound into stable useful intermediates. With this object, chromia and chromia–alumina catalysts which are employed for important industrial reactions (4) have been used in the present investigation for the vapour phase conversion of 3-carene. The observed results are explained in terms of the acidity of the catalyst, the dispersion and oxidation states of chromium ions on the surface of the catalysts, and the poisoning influence of pyridine.

Experimental

Preparation of Materials

Alumina

Alumina was prepared by hydrolysing aluminium isopropoxide with distilled water (5). The precipitated aluminium hydroxide was filtered, washed thoroughly with water, dried at 120°C for 24 h. It was then activated at 500°C in dry air for 24 h, crushed into powder, sieved (100–120 mesh) and used as support for chromia.

Chromia Gel

Chromia gel was prepared and activated according to the procedure described elsewhere (6, 7). The activated material was powdered and pelletized (4 × 4 mm cylindrical size).

Chromia–Alumina

Chromia–alumina (4 × 4 mm cylindrical pellets) was prepared according to the methods of Selwood and Eischens (8) and Yeddanapalli *et al.* (9). The percentage of chromium was estimated to be 5.78.

The surface area measurements of chromia and chromia–alumina were made according to BET method (10) by the adsorption of nitrogen at liquid nitrogen temperature. The experimental procedure and calculations were the same as described by Shoemaker and Garland (11). The values for chromia and chromia–alumina are found to be 14 and 116 m^2/g, respectively.

Prior to each run, the catalyst was reactivated by heating for 8 h in a current of dry air at 500°C until no oxides of carbon were detected in the exit gas; it was then reduced by passing pure dry hydrogen for 6 h at the same temperatures and then brought to the requisite experimental temperature. For conducting runs in the oxidized state, the catalyst was not reduced.

3-Carene

First-quality Indian turpentine oil (Government Turpentine and Rosin Company, Bareilly, India) was used. It contained about 60% 3-carene, the rest being α-pinene and small amounts of β-pinene. 3-Carene was obtained from this oil by fractiona-

For personal use only.

tion at 10 mm, using a 152 cm glass column packed with stainless steel helices, equivalent to 22 theoretical plates. The purity was found to be better than 99% by gas chromatography.

Pyridine

Analar pyridine (E. Merck) was refluxed over KOH pellets and fractionally distilled with exclusion of moisture, the material distilling at 115.5°/760 mm being collected. Its purity was found to be better than 99% by gas chromatography.

Hydrogen

Hydrogen (Indian Oxygen Co.) was purified by passing successively through a silica gel drying tower, a tube containing freshly reduced copper turnings at 400°C, another silica gel tower, and finally through a trap cooled in liquid oxygen.

Apparatus and Procedure

The reactions were carried out at atmospheric pressure in a fixed bed flow-type reactor. The catalyst (5 g) was placed in a Pyrex reactor tube, 25 cm long and 3 cm internal diameter. Above the catalyst bed, Pyrex glass beads (4 mm diameter) were placed to a height of 5 cm. The tube was inserted into the furnace, a cylindrical steel tube of internal diameter 4 cm, coated with a thin layer of asbestos and wound uniformly with nichrome wire, and heated electrically to the requisite temperature. 3-Carene was passed at a constant rate of 2 cm^3 per gram of catalyst per hour over the catalyst using a constant feed rate syringe pump that could be operated at different feed rates. This procedure was repeated for carene–pyridine mixture also. The hydrogen supply was controlled through precision 'Hoke' valves.

The liquid products collected for the first 15 min of each run, which normally covers an hour, was discarded and analysis was made only of the products collected after this time. This was done to ensure the attainment of a steady state for the reaction over the catalyst and also to eliminate temperature fluctuations, if any, due to the starting of the reaction. After the reaction, the catalyst was regenerated and reduced as described earlier.

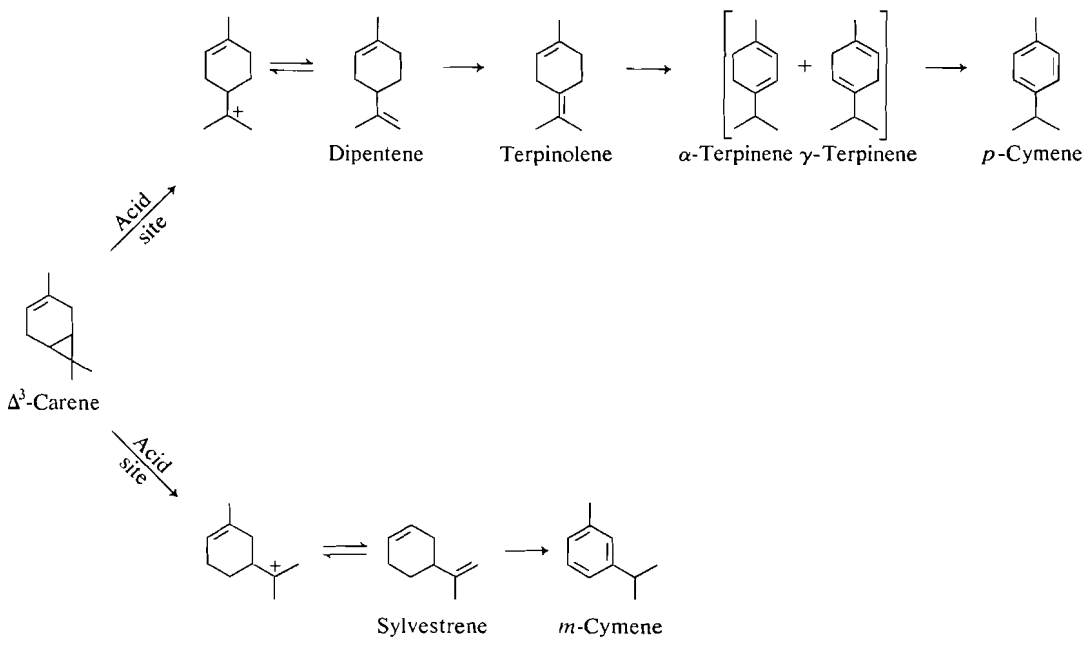
The liquid products of dehydrogenation were identified and estimated using a Perkin-Elmer Infracord Model-137 and a Perkin-Elmer Vapour Fractometer Model 154-D. Products other than cymenes were quantitatively estimated by a Perkin-Elmer Column K, consisting of a 2-m column of carbowax on chromosorb. The column temperature for the best resolution within a reasonable time was found to be 115°C with hydrogen inlet pressure of 15 psi. *para* and *meta*-cymenes were separated and estimated in a specially prepared 2-m column filled with 40–60 mesh acid washed kieselguhr, coated with the stationary liquid, consisting by weight of 9% Bentone-34 and 4% Apiezon-L, heated at 108°C with hydrogen passed at a pressure of 28 psi.

For the identification of different peaks in a chromatogram retention times for the different compounds were found by introducing pure substances donated by Hercules Powder Company, U.S.A. For quantitative analysis, synthetic mixtures containing the different compounds in varying proportions were introduced and calibration curves relating the concentration with the peak heights were drawn. Since the peaks obtained were sharp and symmetrical, peak heights were used as a measure of concentration. Initial experiments, in which both peak heights and the total areas were compared using mixtures of known concentrations, gave identical results. Therefore, in subsequent work all analyses were based on comparison of peak heights.

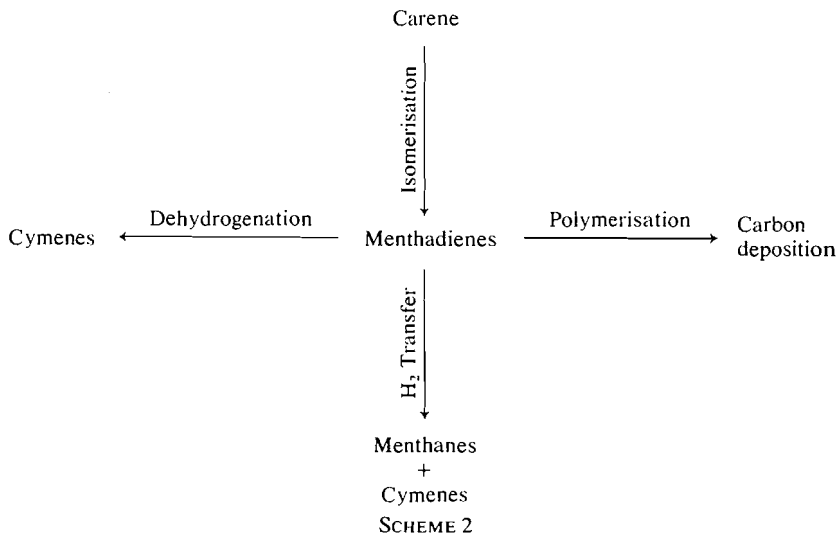
The reaction sequence pertaining to the isomerization of 3-carene to *p*- and *m*-menthadienes and their further dehydrogenation to *p*- and *m*-cymenes is outlined in Scheme 1. The various possible transformations of menthadienes following the isomerization of 3-carene are illustrated in Scheme 2.

Results and Discussion

The results obtained over reduced and oxidized chromia, without and with pyridine, are given in Figs. 1 and 2, respectively. Figures 3 and 4 illustrate



SCHEME 1



SCHEME 2

the corresponding results over chromia–alumina. The ratios of *p*-cymene to *m*-cymene obtained over chromia and chromia–alumina in both reduced and oxidized states are presented in Fig. 5.

Acidity and Disperison of Chromium Ions

Chromia–alumina in either state is more active than chromia (Figs. 1 to 4). This observation is explained in terms of the acidity of the catalysts and the dispersion of chromium ions. The conversion of 3-carene to cymenes involves two steps (cf. Scheme 1). First, the isomerization of 3-carene to menthadienes and the dehydrogenation of menthadienes to cymenes. The first step requires acid sites and the second step dehydrogenation centres.

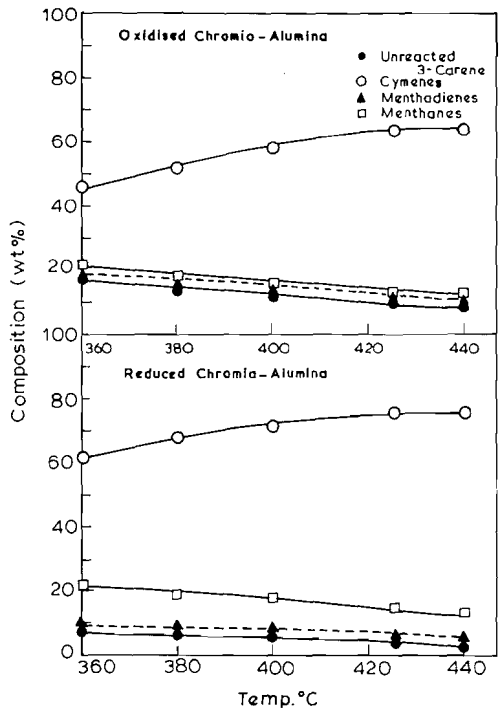

FIG. 3. Dehydrogenation of Δ^3-carene over oxidized and reduced chromia–alumina at different temperatures. LHSV = 2.

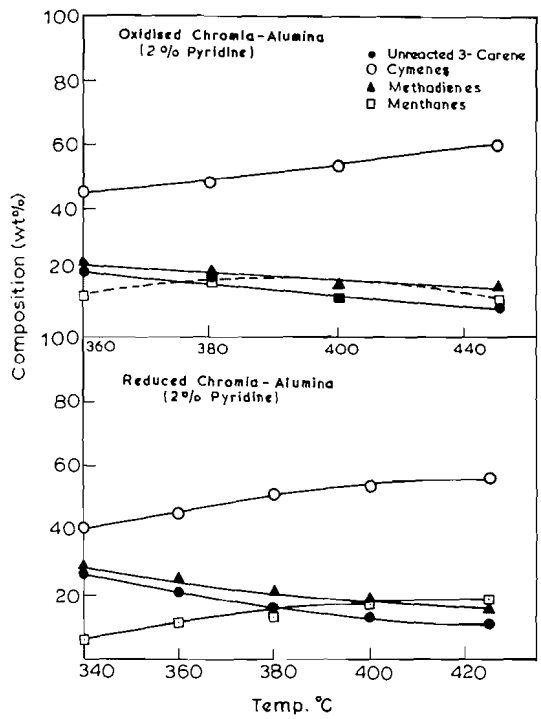

FIG. 4. Dehydrogenation of Δ^3-carene in the presence of 2% pyridine over oxidized and reduced chromia–alumina at different temperatures. LHSV = 2.

The total acidity (12) of chromia–alumina and chromia are 0.64 and 0.14 milliequivalent of *n*-butylamine/g, respectively. The alumina used as a support for chromia in this investigation is found to contain a spectrum of strong, medium, and weak acid sites (13). The acid sites over chromia–alumina are stronger and also more numerous than that over chromia and these decyclise the cyclopropane ring in carene to menthadienes which subsequently get dehydrogenated to cymenes. Such a facile conversion of 3-carene to menthadienes may not be possible over chromia and hence the observed low activity.

The chromia–alumina catalyst employed in this work is an impregnated type, containing less than 6% chromium. The higher dehydrogenation activity of such a catalyst, according to Selwood and Eischens (8) is due to the better dispersion of chromium ions over alumina. It may be mentioned here that in pure chromia the chromium ions occur in the form of isolated clusters, which are not as reactive as the chromium ions dispersed over alumina. When chromia–alumina is used, the menthadienes formed by the isomerization of 3-carene over the acidic sites on alumina also get dehydrogenated over the chromium ions, with the result the menthadienes do not accumulate in the products.

It is of interest to note that chromia–alumina in both reduced and oxidized states favour formation of menthanes, while chromia does not favour their formation (cf. Figs. 1 to 4). This shows that hydrogen is adsorbed strongly over chromia–alumina and hydrogenates the menthadienes adsorbed on the adjacent sites to form menthanes. This observation has also been confirmed by our earlier study (14) of partial pressure of hydrogen over these two catalysts. We have found that an increase of partial pressure of hydrogen increases directly the formation of menthanes over chromia–alumina, but not over chromia. A strong adsorption of hydrogen over chromia–alumina has also been reported by Selwood (15).

Oxidation States of Chromium Ions

Chromia–alumina and chromia are more active in their reduced states than in their oxidized states. It has been reported that chromium in both chromia and chromia–alumina exists as Cr(VI), Cr(V), Cr(III), and, in some cases, Cr(II) states, depending upon the pretreatment (16–21). When the catalyst is treated in an atmosphere of oxygen, it is likely that chromium may be in the Cr(VI), Cr(V), and Cr(III) states. Out of these, only Cr(III) is associated with dehydrogenation activity. On reduction of the catalyst in an atmosphere of hydrogen, all the higher valent chromium ions are reduced to Cr(III) ions and a few may be reduced even further to Cr(II) state,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

both these states being catalytically active. Further, oxidized chromia contains more Cr(VI) ions than oxidized chromia–alumina as found by Soxhlet extraction and hydrogen peroxide decomposition (22). If the higher valent chromium ions other than Cr(III) and Cr(II) are associated with dehydrogenation activity, oxidized chromia and not oxidized chromia–alumina would be more active. Since oxidized chromia is less reactive than oxidized chromia–alumina, the higher valent chromium ions may not be active for the dehydrogenation reactions. Reduction of the catalysts in an atmosphere of hydrogen prior to catalytic reaction creates more chromium ions possessing dehydrogenation activity and, therefore, under reduced catalyst conditions they are more reactive.

Inhibition by Pyridine

Pyridine inhibits the dehydrogenation activity of both oxidized and reduced chromia and chromia–alumina, the poisoning influence being more over reduced catalysts. According to Voltz *et al.* (23), the higher valent chromium ions are more acidic than the lower valent chromium ions. Pyridine being a strong base gets preferentially adsorbed over the strong Lewis acid sites. Since the higher valent chromium ions as explained above are not active for the dehydrogenation of 3-carene, the dehydrogenation activity of oxidized catalysts are less affected.

In the absence of higher valent chromium ions over the reduced catalysts, pyridine may be assumed to be coordinated with lower valent chromium ions; as a result, there is a marked reduction in their activity. This assumption is further supported by a study of heat of adsorption of pyridine over oxidized and reduced chromia by gas chromatography following the methods of Eberly (24). Values obtained are 16.7 and 15.5 kcal/mol for oxidized and reduced chromia (25), respectively. The almost similar values cannot be explained by acidity alone, as a large difference between the oxidized and reduced samples would be expected. The high heat over reduced chromia may be explained if we assume that the exposed Cr(II) ions, being d^4 systems, favour Jahn–Teller distortion of their surroundings so that there are empty coordination sites on which strong adsorption of pyridine can take place. Similar reduction in the activity of reduced chromia by carbon monoxide is also reported (12).

Ratio of p- *to* m-*Cymene*

The ratios of *p*-cymene to *m*-cymene (cf. Fig. 5) over reduced and oxidized chromia at 360°C are 2.6 and 2.0, respectively, which decrease to 0.6 and 1.0 at 500°C. The values for reduced and oxidized chromia with 2% pyridine are about 1.8 and 1.2, respectively, in the temperature range 425 to 500°C. In the case of chromia–alumina, the relative proportion of cymenes is found to be independent of pretreatment of the catalysts and also of the presence of pyridine.

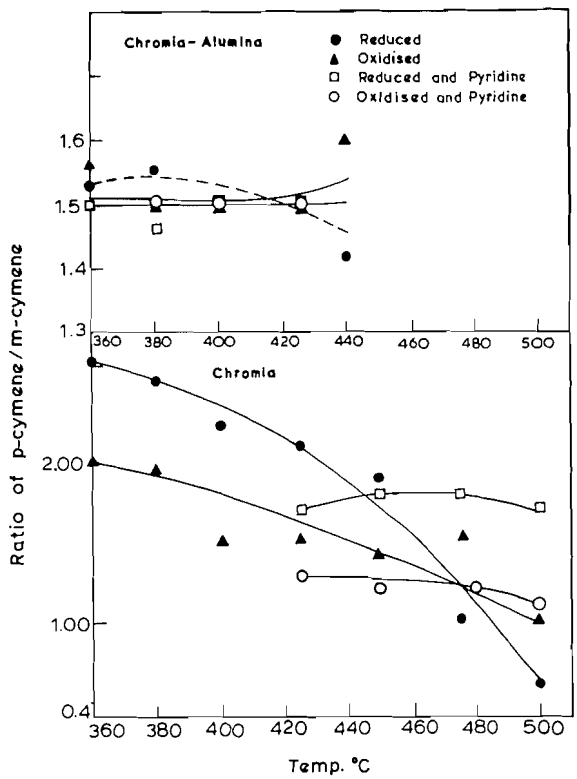

FIG. 5. Ratio of *p*-cymene to *m*-cymene over reduced chromia, oxidized chromia, and in the presence of 2% pyridine; reduced chromia–alumina, oxidized chromia–alumina, and in the presence of 2% pyridine. LHSV = 2.

The decrease in the cymene ratio with increase of temperature is not clearly understood. The possibility of *p*-cymene being converted to *m*-cymene at higher temperatures is ruled out, since separate experiments with pure *p*-cymene fail to isomerize to *m*-cymene. At elevated temperatures, new sites may probably be created which favour the formation of more *m*-menthadienes which are subsequently dehydrogenated to *m*-cymene. When 3-carene mixed with 2% pyridine and passed over these catalysts, the ratio of cymenes remains constant and unaffected by temperature. The new sites assumed to be created as explained above may get deactivated by the presence of pyridine molecules, thereby keeping the cymene ratio constant.

The lower values of *p*-cymene to *m*-cymene over oxidized chromia may be associated with strong acidic sites present in some form over the surface. The higher valent Lewis sites, assumed in an earlier

discussion, may get reduced during the reaction in the presence of 3-carene and their contribution for the lower values of cymene ratio may be insignificant.

The oxygen present initially over the catalyst may oxidize the hydrocarbon to CO which may be coordinated to chromium, giving rise to carboxylate ions, which will increase the surface acidity and hence reduce the cymene ratio. Reduced chromia when pretreated with CO, and also when CO is passed along with 3-carene simultaneously, the cymene ratio is found to be reduced (12). Clark *et al.* (26) has also reported the formation of carboxylate ions over reduced chromia in the presence of CO.

The cymene ratio over chromia–alumina is not affected either by pretreatment of the catalyst or by the presence of 2% pyridine with 3-carene. This shows that the intrinsic acidity of alumina, not affected by the above mentioned factors, decides the cymene ratio. The intrinsic acidity of alumina and chromia–alumina is found to be altered by the incorporation of either alkali metal ions or halide ions (10, 11) and in these cases the cymene ratio is also altered.

Chelates of nickel(II) and copper(II) with tridentate Schiff base formed by the condensation of *S*-benzyldithiocarbazate with benzoin

M. T. H. TARAFDER AND M. AKBAR ALI

Rajshahi University, Rajshahi, Bangladesh

Received August 3, 1977

M. T. H. TARAFDER and M. AKBAR ALI. Can. J. Chem. **56**, 2000 (1978).

New complexes with the Schiff base ligand derived from *S*-benzyldithiocarbazate (NH_2—NH—$CSSCH_2C_6H_5$) have been prepared and characterized by elemental analyses, magnetic, conductometric, ir, and electronic spectral studies. The tridentate ONS Schiff base *S*-benzyl-β-*N*-(phenyl,phenylhydroxymethyl)methylenedithiocarbazate gave mono-ligand complexes with Ni(II) and Cu(II) having the general formula [MligandX] (M = Ni(II) and Cu(II); X = NO_3, Cl, Br, NCS). A proposed square-planar structure for the nickel complexes is supported by magnetic and spectral data. A square-planar structure is also suggested for Cu(II) complexes. The ir results give evidence of the different bondings present in the complexes.

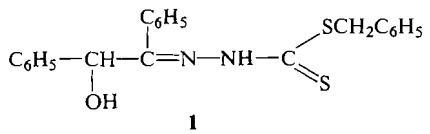
M. T. H. TARAFDER et M. AKBAR ALI. Can. J. Chem. **56**, 2000 (1978).

On a préparé de nouveaux complexes utilisant un ligand comportant une base de Schiff provenant du *S*-benzyldithiocarbazate (NH_2—NH—$CSSCH_2C_6H_5$) et on les a caractérisés par des analyses élémentaires, magnétiques et conductimétriques et par des études de spectres ir et électroniques. La base de Schiff ONS tridentate *S*-benzyl-β-*N*-(phényl,phényl-hydroxyméthyl)méthylènedithiocarbazate réagit avec le Ni(II) et le Cu(II) pour conduire à des complexes ne comportant qu'un ligand ayant des formules générales [MligandX] (M = Ni(II) et Cu(II); X = NO_3, Cl, Br, NCS). La structure plan carré proposée pour les complexes du nickel est en accord avec les données magnétiques et spectrales. On suggère aussi l'existence d'une structure plan carré pour les complexes du Cu(II). L'infrarouge indique les différents types de liaisons qui sont présents dans ces complexes.

[Traduit par le journal]

Introduction

Numerous metal complexes of Schiff base derivatives having nitrogen and sulphur as donors have been investigated extensively (1). However detailed studies of Schiff bases derived from *S*-benzyldithiocarbazate having nitrogen, oxygen, and sulphur as donors are lacking. We present a magnetic and spectroscopic study of Ni(II) and Cu(II) complexes of a ONS Schiff base, i.e., *S*-benzyl-β-*N*-(phenyl,-phenylhydroxymethyl)methylenedithiocarbazate



1

derived from *S*-benzyldithiocarbazate.

Experimental

All the chemicals used were reagent grade and were used without further purification. Preparation of the Schiff base, *S*-benzyl-β-*N*-(phenyl,phenylhydroxymethyl)methylenedithiocarbazate (**1**): this compound deposited as yellow crystals after solutions containing *S*-benzyldithiocarbazate (0.1 mol) in 50 ml hot absolute alcohol and benzoin (0.1 mol) in hot alcohol (50 ml) had been heated on the steam bath for a few minutes, mp 205°C. *Anal.* calcd. for $C_{22}H_{20}ON_2S_2$: C 67.33, H 5.1, N 7.1, S 16.3; found: C 67.1, H 5.0, N 6.8, S 15.8. Preparation of complexes: the ONS ligand (0.01 mol) in hot absolute alcohol (300 ml) was mixed with metal (Ni(II) and Cu(II)) salt solution (0.01 mol) in hot absolute alcohol (20 ml). The resulting mixture was kept under reflux for 3 h. The precipitate which settled was filtered, washed several times with hot absolute alcohol so as to remove unreacted Schiff base, and dried *in vacuo* over P_2O_5. The Schiff base yielded complexes having a stoichiometry of 1:1 metal to ligand. The complexes isolated were analyzed as follows. *1. Anal.* calcd. for [Ni(ONS)NO_3]: C 51.58, H 3.7, N 8.2, M 11.47, S 12.5; found: C 51.3, H 3.4, N 8.0, M 11.3, S 12.1. *2. Anal.* calcd. for [Ni(ONS)Cl]: C 54.4, H 3.9, N 5.77, M 12.09, S 13.18; found: C 54.2, H 3.6, N 5.62, M 12.1, S 12.7. *3. Anal.* calcd. for [Ni(ONS)Br]: C 49.8, H 3.58, N 5.28, M 11.08, S 12.08; found: C 49.7, H 3.3, N 5.1, M 11.0, S 11.7. *4. Anal.* calcd. for [Ni(ONS)NCS]: C 54.3, H 3.7, N 8.08, M 11.5, S 18.9; found: C 54.1, H 3.4, N 7.7, M 11.38, S 18.5. *5. Anal.* calcd. for [Cu(ONS)NO_3]: C 51.1, H 3.67, N 8.1, M 12.2, S 12.3; found: C 50.8, H 3.5, N 7.9, M 12.1, S 11.9. *6. Anal.* calcd. for [Cu(ONS)Cl]: C 58.87, H 3.8, N 5.7, M 12.96, S 13.05; found: C 53.65, H 3.5, N 5.35, M 12.8, S 12.7. *7. Anal.* calcd. for [Cu(ONS)Br]: C 49.39, H 3.5, N 5.2, M 11.8, S 11.97; found: C 49.1, H 3.3, N 5.01, M 11.75, S 11.45. The preparation of [Cu(ONS)NCS] was unsuccessful.

Spectra

The solid-state electronic spectra of the complexes were obtained in a Carl Zeiss PMQ II spectrophotometer with a solid-reflectance attachment using MgO as the calibrant. The ir spectral data have been recorded in the range 4000–200 cm^{-1}, with Perkin-Elmer 457 and 225 spectrophotometers, as Nujol mulls between KBr or as KBr discs. The far ir spectra (400–200 cm^{-1}) were recorded as Nujol mulls between polyethylene sheets. The electrical conductance measurements were made at room temperature with a conductivity bridge type E 7566/3 of the M.E.L. Equipment Company Limited,

*S = strong.

Sussex, using a Griffin and George NO-S75-915/010 conductivity cell with platinum black electrode. Millimolar solutions of the metal-chelates were used. Magnetic susceptibility measurements were made on solid samples at room temperature by the Faraday method. All the values were corrected for diamagnetism according to the method of Selwood (2).

Analysis

Metal analyses were made by means of EDTA titration after decomposing the complexes with a mixture of nitric, sulphuric, and perchloric acids. Carbon–hydrogen–nitrogen analyses were made using microanalytical techniques. The sulphur analysis was carried out according to the method described by Vogel (3).

Results and Discussion

The Schiff base ONS (**1**) was formed by the condensation of *S*-benzyldithiocarbazate with benzoin. With Ni(II) and Cu(II) mono-ligand nitrate, chloride, bromide, and thiocyanate complexes have been assigned the structures [MligandX] on the basis of molecular conductivities and ir absorptions (Table 1). The conductance measurements were done in nitrobenzene medium in which the metal chelates behaved as non-electrolytes because they have very low conductance values, 0–2.5 and 0–2.1 Ω^{-1} cm^2 mol^{-1} for the nickel and copper complexes, respectively, suggesting anion coordination to the metal ion which is also supported by the ir absorptions of the complexes.

The ONS Schiff base *S*-benzyl-β-*N*-(phenyl,phenylhydroxymethyl)methylenedithiocarbazate acts as a tridentate ligand coordinating the metal ion via the β-nitrogen atom, thioketo sulphur, and the oxygen of the hydroxyl group as evident from ir spectral data (Table 1). The C=N stretching vibration in the free ONS Schiff base occurs at ca. 1535 cm^{-1} (4) but on complexation the bands in all the complexes are shifted towards the lower frequency regions (Table 1). This lowering of C=N stretching mode on complexation may tentatively be attributed to a lowering of the C=N bond order as a result of M—N bond formation (5) as evident from the appearance of ν(Ni—N) and ν(Cu—N) bonds at 510–570 (6) and 480–500 cm^{-1} (7) respectively (Table 1). The α-nitrogen atom is not bonded with the metal as ν(N—H) band (ca. 3080 cm^{-1} (8)) of the free ligand does not suffer any shift in the complexes. The ir spectrum of the uncomplexed ligand shows ν(C=S) at ca. 1000 cm^{-1}; it undergoes considerable shift towards lower frequencies in the metal complexes (Table 1). This negative shift of ν(C=S) bands may be taken as an indication of coordination by the thioketo sulphur. This shifting may be due to a lowering of C=S bond order as a result of M—S bond formation.

The far ir spectra of the metal complexes were measured in order to locate metal–sulphur stretching frequencies. The appearance of ν(Ni—S) and ν(Cu—S) bands at ca. 395 cm^{-1} and 360–370 cm^{-1} is indicative of the presence of Ni—S (9) and Cu—S (10) bonds in the nickel and copper complexes. Ali and Livingstone (1) have established in the cases of *S*-methyldithiocarbazate and its various Schiff bases that the thioether sulphur does not coordinate to the metal ion. The disappearance of ν(O—H) observed in the free ligand around 3300 cm^{-1} (11) clearly indicates the loss of the proton from O—H on coordination and formation of a new bond between metal and oxygen as evident from ir spectral data. The absorptions in the region 540–550 and 470–490 cm^{-1} (Table 1) may be due to Ni—O (12) and Cu—O (7) linkages in the nickel and copper complexes respectively. Complex 1 gives ir bands at 1485 and 1260 cm^{-1} indicative that NO_3 occupies one of the stereochemical sites of Ni(II) (13). The complexes [Ni(ONS)X](X = Cl,Br) show ir bands at ca. 260 and 200 cm^{-1} corresponding to ν(Ni—Cl) and ν(Ni—Br) vibrations respectively. The complex [Ni(ONS)NCS] has thiocyanate ν(C—N) absorption at 2105 cm^{-1} suggesting the presence of terminal N-bonded thiocyanate (14). [Cu(ONS)NO_3] gives ir bands at 1480 and 1255 cm^{-1} characteristic of coordinated NO_3. The complexes 6 and 7 display ν(Cu—Cl) and ν(Cu—Br) at 320 and 220 cm^{-1} respectively.

The brown [Ni(ONS)X] complexes are low-spin type (diamagnetic) suggesting square-planar structure. The three coordination positions are occupied

For personal use only.

by the ONS sequence and the fourth coordination site of the Ni(II) ion is occupied by either NO_3, Cl, Br, or NCS. The electronic spectra of the metal complexes provide evidence regarding their structures. The spectra of the nickel complexes give an envelope with a shoulder at 20 000 – 20 100 cm^{-1} which corresponds to $^1A_{2g} \leftarrow {}^1A_{1g}$ transition (15). The other two *d–d* transitions, $^1B_{1g} \leftarrow {}^1A_{1g}$ and $^1E_g \leftarrow {}^1A_{1g}$ (15), in the present cases were not observed but probably were hidden by the charge transfer band. The green paramagnetic copper complexes [Cu(ONS)X] yield magnetic moment (1.8–1.87 BM) corresponding to one unpaired electron. The copper complexes are said to possess square-planar stereochemistry since the copper ion has been found to be reluctant to take up a regular tetrahedral geometry (16). The electronic spectra of the complexes give the two bands at 16 000 – 16 100 cm^{-1} ($^2A_{1g} \leftarrow {}^2B_{1g}$) and 19 000 – 19 600 cm^{-1} ($^2E_{1g} \leftarrow {}^2B_{1g}$) which corresponds to the square-planar stereochemistry (17, 18).

pK_a values of protonated α,β-unsaturated cyclic carboxylic acids. Effect of ring size on acidities

S. N. BHAT, RAMA RAO, AND K. RANGANAYAKULU[1]

Department of Chemistry, Banaras Hindu University, Varanasi 221 005, U.P., India

Received December 15, 1977

S. N. BHAT, RAMA RAO, and K. RANGANAYAKULU. Can. J. Chem. **56**, 2003 (1978).

The pK_a values of protonated α,β-unsaturated acids, namely tiglic, cyclopentene carboxylic, cyclohexene carboxylic, and cycloheptene carboxylic acids have been determined spectrophotometrically and the values are −4.08, −4.05, −3.88, and −3.84, respectively. The conjugate acid of tiglic acid is a stronger acid than that of crotonic acid (pK_a −3.94) and the difference in acid strength is explained on the basis of steric inhibition of resonance by the α-methyl group. All the protonated cyclic acids are shown to be somewhat weaker than the corresponding acyclic ones. Several factors have been considered to explain the acid strength of these cyclic α,β-unsaturated acids. It has been shown that the ease of placing the double bond *exo* to the ring system is responsible for the changes in acidity of the above cyclic systems.

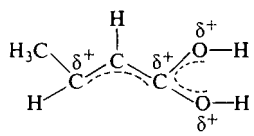
S. N. BHAT, RAMA RAO et K. RANGANAYAKULU. Can. J. Chem. **56**, 2003 (1978).

On a déterminé spectrophotométriquement les valeurs de pK_a des acides α,β non saturés protonés suivants: l'acide tiglique et les acides cyclopentène, cyclohexène et cycloheptènecarboxyliques; les valeurs des pK_a sont respectivement de −4.08, −4.05, −3.88 et −3.84. L'acide conjugué de l'acide tiglique est un acide plus fort que l'acide crotonique (pK_a −3.94) et on explique la différence dans la force de l'acide en se basant sur une inhibition stérique à la rèsonance provenant de la présence du groupe méthyle α. On a montré que tous les acides cycliques protonés sont un peu plus faibles que les acides acycliques correspondants. On a considéré plusieurs facteurs pour expliquer la force de l'acide de ces acides α,β non saturés cycliques. On a montré que la facilité de placer la double liaison *exo* dans un système cyclique est responsable des changements d'acidité dans les systèmes cycliques mentionnés ci-dessus.

[Traduit par le journal]

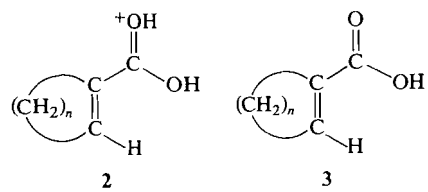
Introduction

The study of the pK_a values of protonated carboxylic acids has attracted many workers lately. Electronic, steric and solvent effects were the most widely studied aspects (1–5). Sorensen (6) considered structure **1** for the protonated crotonic acid on the basis of the symmetrical structure proposed by earlier workers (3, 7) for the protonated carboxyl group. The fact that alkyl substituents at the 3 position remarkably influence the acid strength supports the allylic cation structure **1**. Since resonance



1

participation is more important in the ionic species (**2**) than in the neutral molecule (**3**), the pK_a value is a measure of the stability of the protonated form relative to the unprotonated one. In spite of the large amount of data that are available in the literature on the pK_a values of protonated carboxylic acids (1, 2), there is not much information available so far regarding the acid strength of the cyclic α,β-unsaturated carboxylic acids. We have studied the acid strength of protonated α,β-unsaturated cyclic carboxylic acids **2** (n = 3, 4, 5).[2] Also, the study of the influence of alkyl substitution at the 2 position on the acid strength of protonated crotonic acid was thought to be important since it serves as a model compound for the α,β-unsaturated cyclic carboxylic acids.



2 **3**

Experimental

Materials and Methods

Cyclopentene, cyclohexene, cycloheptene carboxylic acids, and tiglic acid were prepared according to known methods reported in the literature. Cyclopentene carboxylic acid (8) (mp 123–124°C) was purified by recrystallisation from *n*-hexane – ethyl acetate, and cyclohexene carboxylic acid (9) (bp 103°C/1 Torr), and cycloheptene carboxylic acid (10) (bp 107°C/1 Torr) were purified by distillation. Tiglic acid (11) (mp 63–64°C) was

[1]Author to whom correspondence may be addressed.

[2]We could not determine the pK_a values of other cyclic acids namely, cyclobutene carboxylic acid, cyclopentylidene carboxylic acid, and cyclohexylidene carboxylic acid as these acids are found to be not stable in acidic media.

purified by recrystallisation from water. Aqueous sulphuric acid solutions were titrated against standard base. The Hammett acidity functions H_0 and H_A for a given percentage (w/w) of sulphuric acid were available from the literature (12). Although the saturated carboxylic acids act like well behaved Hammett bases in indicator studies (13) and fit the H_0 function, many α,β-unsaturated carbonyl compounds are shown to follow the H_A function (14).[3] We have therefore plotted log Q, i.e. [B]/[BH$^+$], vs. H_A as well as H_0 for the series of α-β-unsaturated carboxylic acids used in the present study and the slopes for both scales are given in Table 1. The actual plot for one of the acids, namely cyclopentene carboxylic acid, is given in Fig. 1. It is clear from the slopes that α,β-unsaturated carboxylic acids have slopes close to unity using the H_A function and we have calculated the data accordingly. The pK_a values of the protonated α,β-unsaturated carboxylic acids using the H_0 function where the slopes of log Q vs. H_0 are not unity, do not represent the true pK_a values. Rather, they are the values at half protonation. However, the order of acidities remains the same in any scale and the same reasoning can be applied to correlate structural effects with acidity.

Various methods, for example potentiometric titrations, conductometric methods, and spectrophotometry, were used earlier to find the dissociation constants or the pK_a values of protonated organic acids in acidic solution. We preferred spectrophotometry for the determination of the pK_a values, since this procedure is reasonably accurate for the determination of the dissociation constants, as long as the different species have different absorptions (15, 16).

Solutions for spectral measurements were made by weighing 0.2–1.0 mg of the organic acid in a small glass boat using a microbalance. The boat was added to the solvent, previously made up to the mark in a standard volumetric flask at 25 ± 0.5°C. A known volume of the solution was further diluted to 10 ml so that the concentration of final solution is $\sim 10^{-5}$ mol/ℓ.

The spectra of the solutions were recorded using a Cary 14-R uv spectrophotometer with a solvent blank as the reference. The temperature did not vary more than 0.5°C during the measurements. Every time a base line correction was made since the absorbance was sometimes very small. The samples were quite stable during the measurements and no irreversible new products were formed.

The dissociation of an acid BH$^+$ in water may be written as

$$BH^+ \rightleftharpoons B + H^+$$

Thus, the pK_a values which are equal to H_A, the Hammett acidity constant, when [BH$^+$]/[B] is equal to unity, were determined.

Results and Discussion

The three cyclic acids, namely cyclopentene (**4**), cyclohexene (**5**), and cycloheptene (**6**) carboxylic acids absorb at 224, 219, and 222 nm, respectively, in water and are in good agreement with the literature data (17). However, the molar extinction coefficients differ slightly. Tiglic acid (**7**) absorbs at 216.5 nm. The transition energies and intensities (oscillator strengths) of these acids show that these are the π–π* transition bands. Our attempts to determine the dissociation constants using n–π* transition bands were not successful as the latter are very weak.

[3]The authors are thankful to one of the referees, who suggested to use the H_A function rather than the H_0 function for the α,β-unsaturated carboxylic acids.

TABLE 1. pK_a values of α,β-unsaturated carboxylic acids using H_A and H_0 functions

Acid	−pK_a*		Slope	
	H_A	H_0	H_A	H_0
Cyclopentene carboxylic acid	4.05	6.47	0.98	0.46
Cyclohexene carboxylic acid	3.88	6.27	0.95	0.48
Cycloheptene carboxylic acid	3.84	6.13	0.96	0.45
Tiglic acid	4.08	6.52	0.94	0.48

*Error limit ±0.10.

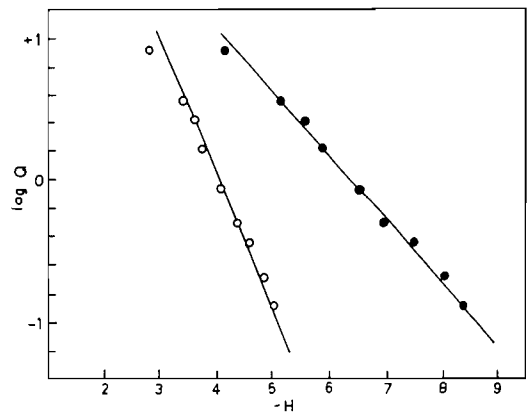

FIG. 1. Plot of log Q, i.e. [B]/[BH$^+$], vs. H for cyclopentene carboxylic acid: (○) using H_A function; (●) using H_0 function.

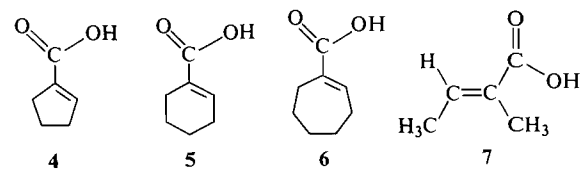
For the sake of brevity, the variation and the intensity of the band position with the strength of sulphuric acid is given only for cyclopentene carboxylic acid (Table 2). The extent of protonation is determined simply by the decrease in the absorption



4 **5** **6** **7**

maxima of the free base and the increase in the absorption of the protonated base, the fully protonated base having negligible absorption in the region of maxima. It can be seen from Table 2 that as the concentration of sulphuric acid decreases, that of the protonated species also decreases. The absorption maxima of cyclopentene carboxylic acid shifts from 262.5 to 224 nm, when the medium is altered from 95.32% sulphuric acid to water. Similarly, for the acids **5**, **6**, and **7** the band maxima positions shift

62.55	236.0	2193	7416	−5223
59.58	234.0	1724	7722	−5998
56.20	232.5	957	7898	−6941
52.13	231.5	707	8274	−7567
39.93	228.5	160	9080	−8920
0.00	224.0	207	7858	−7651

from 256, 256, and 249.5 to 219, 222, and 216.5 nm, respectively. The bands are relatively sharper in pure solvents and then become broad as we approach 50% protonation. The band has its maximum width at this point. The bathochromic shift may be partly due to the effect of change in the dielectric constant of the medium on the π–π* transition of the unprotonated species and partly due to the increased conjugation in the ionic species. The change in half-width of the absorption band also goes in parallel with the above observation. The changes in transition energies when the medium is changed is minimum in case of cyclopentene carboxylic acid and maximum in cyclohexene carboxylic acid.

It was assumed, in general, that displacement of the maximum does not occur as the concentration of sulphuric acid changes when both the forms show clear absorption maxima sufficiently far apart. The superimposed spectra over a range of ionisation ratios should show a clear isobestic point. However, the failure to observe the isobestic points in the present cases shows the 'medium shift' which may be due to the progressive nonavailability of water as the acid strength of the solution is increased. The data are analysed by following the procedure of Davis and Geissman (18). But, as it can be seen from Fig. 2, it is not easy to determine the midpoint of the sigmoid curve, which corresponds to the pK_a value. Therefore, we have used the derivative curve; i.e. dε/dH was plotted against the average H value to get better pK_a values. The values thus obtained are given in Table 1. As the error limit is ±0.10, the above values reported in Table 1 represent the order of acidities rather than the absolute values.

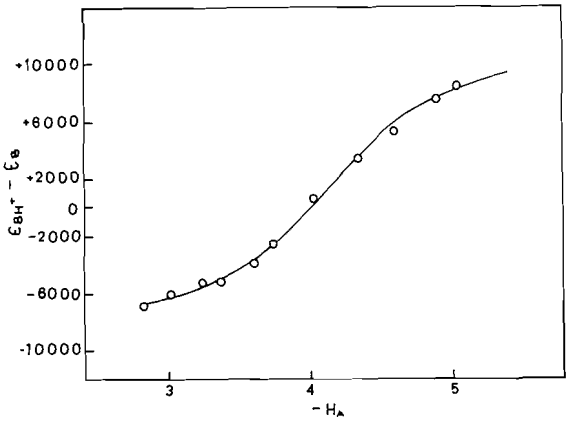

FIG. 2. pK_a calculation using the procedure of Davis and Geissman (18) for cyclopentene carboxylic acid.

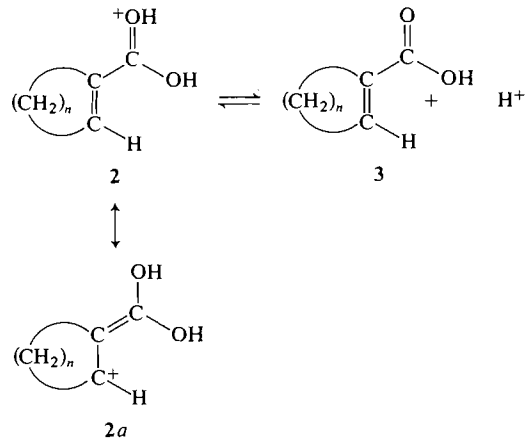
Origin of the Differences in pK_a Values

From the data it is clear that the conjugate acid of tiglic acid, with a pK_a value of −4.08 is a stronger acid than crotonic acid (pK_a −3.94), and β,β-dimethylacrylic acid (pK_a −3.55), which were also determined by a similar procedure (ref. 6 and footnote 3). This is in line with the *o*-substituted benzoic acids, where it has been shown that the steric inhibition of resonance by an *ortho* substituent raises the acidity of the conjugated acids (3). Similar trends have also been observed in the dissociation constants of a series of *cis*- and *trans*-methylacrylic acids (19).

In the five-, six-, and seven-membered ring system series, there is a regular decrease in acidity with an increase in ring size. At first glance, the differences in the magnitude of the pK_a values in the cyclic systems may look smaller; however, it is noteworthy that in the benzoic acid series the change in the pK_a value is only 0.18 when the system is changed from benzoic acid to *p*-methylbenzoic acid.[4] All the protonated cyclic acids are weaker than the protonated tiglic acid showing that the protonated species of cyclic systems are stabilized better than that of the open-chain system, presumably due to the absence of the *ortho* effect. As pointed out earlier, resonance interactions are more important in the protonated species (**2**), compared with those of neutral species (**3**), the differences in pK_a in a given series of compounds being a measure of the stability of the protonated form relative to the neutral molecules. Comparison of the acidities in the cyclic system will, therefore, give a measure of the stabilities of the protonated form **2** (n = 3, 4, 5) relative to each other in this series.

Since the difference in these systems is only the

[4]All literature pK_a values are corrected by using the H_A scale of ref. 12.



2 3

2a

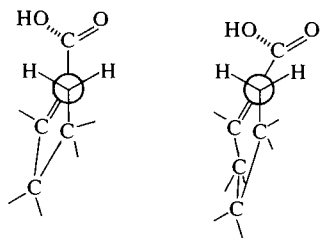
size of the ring, the following factors could be considered to explain the difference in their acidity.

Solvation

Since smaller ions are solvated better, one would expect the solvation to decrease progressively as the ring size increases, which results in an increase in acidity with increase in the ring size.

Twisting of the Carboxyl Group Out of the Olefinic Plane

In the five-membered ring system the carboxylic group and the double bond are in a single plane, resulting in only small interaction with the C5 hydrogens, whereas in the six-membered ring system, the hydrogens at C6 would push the carboxyl group out of the olefinic plane owing to greater steric interaction, and this results in a weaker conjugative effect in this system. Therefore one would expect considerable increase in the acid strength in the case of six-membered ring system.



Stabilisation of the Endo *Double Bond vs.* Exo *Double Bond*

One has to consider the resonance forms of the protonated species (structures **2** ↔ **2***a*), which involves placing the double bond *exo* to the ring system.

The first two factors predict the reversal of the order of acidities to those observed. Therefore, we presume that it is the third factor, namely the ease of placing the double bond *exo* to the ring system, which is responsible for changes in acidity in this series. A study of molecular models reveals that in the five-membered ring system, placing a double bond *exo* to the ring leads to a considerable amount of strain and therefore conjugation effects here are less than in the case of six- and seven-membered ring systems, leading to more negative pK_a values. Our observations are parallel to those made by Turner and Garner (20) using the heat of isomerisation values of cycloalkylidene compounds to cycloalkenes. Their studies indicate that an *endo* double bond is more stable in both the five- and six-membered ring systems. But there is a greater difference in the *exo–endo* stability in the five-membered ring system (−3.9 cal/mol) compared to the six-membered case (−2.4 cal/mol). The trend is similar with the seven-membered ring system (−2.32 cal/mol).

The values of the dissociation constants of cyclopentene (0.78), cyclohexene (0.38), and cycloheptene (0.23) carboxylic acids in an ethanol–water system have been determined (21). The larger dissociation constant for cyclopentene carboxylic acid has been attributed to an electron withdrawing effect in the strained five-membered system, which would facilitate the ionisation process and lead to higher acid strength. In the light of our present investigation the differences in the dissociation constants can be attributed to the greater stabilisation of the six- and seven-membered cyclic carboxylic acids by conjugation compared to the five-membered carboxylic acid.

In conclusion, the data presented here on the pK_a measurement of protonated cyclic α,β-unsaturated acids is a direct proof of the greater stability of the *endo* double bond over the *exo* in a five-membered ring system compared to the six-membered one.

Acknowledgements

GABRIEL LLABRES, MARCEL BAIWIR, LÉON CHRISTIAENS, JOSÉ DENOEL, LÉOPOLD LAITEM et JEAN-LOUIS PIETTE. Can. J. Chem. **56**, 2008 (1978).

On rapporte les résultats d'une étude par résonance magnétique du proton et du carbone 13 sur l'anisole, le thioanisole, le sélénoanisole et le telluroanisole, ainsi que sur certains de leurs dérivés *para* substitués. Considérés comme des méthyles substitués, ces composés ont un comportement analogue à celui des halogénures de méthyle. On a pu mettre en évidence une relation linéaire entre le déplacement chimique des protons et celui du carbone du méthyle dans la série de l'anisole et dans les halogénures de méthyle à la fois. Si ces résultats s'interprètent le plus souvent à partir d'effets électroniques, un "effet d'atome lourd" doit être invoqué dans le cas des composés tellurés. Les résultats expérimentaux ne sont pas en désaccord avec l'hypothèse d'une configuration plane des composés étudiés.

GABRIEL LLABRES, MARCEL BAIWIR, LÉON CHRISTIAENS, JOSÉ DENOEL, LÉOPOLD LAITEM, and JEAN-LOUIS PIETTE. Can. J. Chem. **56**, 2008 (1978).

Results are reported of a study by ^{1}H and ^{13}C nuclear magnetic resonance of anisole, thioanisole, selenoanisole and telluroanisole as well as of several of their *para*-substituted derivatives. If these compounds are considered as substituted methyl groups, they display a behaviour analogous to that of the methyl halides. It is possible to demonstrate that a linear relation exists between the proton and the carbon chemical shifts in the anisole series as well as in the methyl halides. Although these results most frequently are interpreted in terms of electronic effects, a 'heavy atom effect' must be invoked for the tellurium compounds. The experimental results do not contradict the hypothesis that the compounds studied have a planar configuration [Journal translation]

Introduction

Tant l'anisole que le thioanisole et, dans une mesure moindre, le sénénoanisole ont fait l'objet de nombreux travaux au cours des dernières années (1–4), le problème essentiellement abordé étant celui de la conformation de ces composés et de leurs dérivés substitués. Par contre, aucun travail consacré à la conformation du telluroanisole n'a été publié à ce jour.

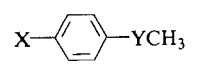
Il est généralement admis que les facteurs les plus importants dans ce problème conformationnel sont, d'une part, une éventuelle interaction d'une paire libre de l'hétéroatome avec le système π du cycle et, d'autre part, une interaction stérique entre le groupement méthyle et les hydrogènes aromatiques situés en *ortho*, deux facteurs pouvant influencer de manière assez considérable le spectre rmn de ces composés. En outre, si on admet généralement que la faculté, qu'ont les ponts —O—, —S—, —Se— et —Te— de transmettre des effets électroniques entre deux groupements organiques, aliphatiques ou aromatiques, substitués ou non, décroît dans l'ordre S > Se ≃ — > O (où — désigne le cas où il n'y a pas d'atome liant), ce sujet est malgré tout controversé (5).

Ce sont ces problèmes qui nous ont notamment conduits à entreprendre l'étude par rmn de l'anisole et de ses analogues chalcogénés (fig. 1).

Résultats et discussions

Résonance magnétiques du proton

Le tableau 1 compare les paramètres rmn dans les familles de l'anisole Ph—Y—Me et de l'éther de diméthyle Me—Y—Me, les composés étant considérés comme des méthanes substitués dans les deux cas. L'augmentation des deux paramètres lorsqu'on passe de Me à Ph montre que l'électronégativité de —YPH est supérieure à celle de —YMe quel que soit Y.



X = H, CH_3, Cl, Br
Y = O, S, Se, Te

FIG. 1. Composés étudiés au cours de ce travail.

Si on applique les relations empiriques [1] (6) et [2] (7), établies, dans le cas des méthanes substitués, entre les paramètres rmn du méthyle et, d'une part, l'électronégativité E_X du substituant et, d'autre part, la longueur de la liaison r_{C-X}, on obtient le même résultat (tableau 2).

$$[1] \qquad J_{C-H} = 22.6E_X + 40.1r_{C-X} + 5.5$$

$$[2] \qquad \delta_H = 1.667E_X - 2.30$$

L'écart entre les électronégativités calculées dans les deux familles de composés est plus important quand on utilise la relation [2]. Si dans le cas des constantes de couplage [1], les effets électroniques sont de loin les plus influents, dans le cas des déplacements chimiques [2], l'effet de champ, les effets stériques et les effets d'anisotropie magnétique peuvent jouer un rôle important. La mesure des moments dipolaires de Ph_2S et Me_2S (11), d'une part, et l'examen d'un simple modèle géométrique, d'autre part, permettent cependant de négliger pratiquement les deux premiers effets dans la comparaison des deux familles de composés. De fait, le calcul de l'effet de l'anisotropie magnétique à l'aide des tables de Haigh et Mallion (12) permet de rendre compte de façon satisfaisante des différences observées. Il faut signaler que, lors de ce calcul, le meilleur accord a été obtenu en attribuant une configuration plane aux composés. Ce résultat est en accord avec l'étude en température des spectres rmn qui ne montrent aucune variation notoire entre -80 et $+150$°C (tableau 3).

Le tableau 4 montre que les effets sont qualitativement les mêmes dans les halogénures et les chalcogénures de méthyle. Pour les premiers, il existe une relation linéaire ($R = 0.99$) entre l'électronégativité du substituant et le déplacement chimique des protons. Si on interpole les valeurs relatives aux composés chalcogénés sur cette droite, on obtient pour les groupements PhO—, PhS—, PhSe— et PhTe— les électronégativités 3.6, 2.65, 2.55 et 2.45 respectivement (fig. 2), valeurs en bon accord avec celles du tableau 2 et avec celles qu'on attribue généralement aux atomes O, S, Se et Te (10). On peut en conclure que, dans la série de l'anisole, il n'y a pas de changement d'hybridation quand on passe d'un hétéroatome à l'autre.

Le tableau 5 montre que le parallélisme entre les monohalogénures de phényle et les composés étudiés ici est également remarquable tant en ce qui concerne les constantes de couplage que les déplacements chimiques.

La variation des déplacements chimiques en *para*, quand on passe de O à Te (0.3 ppm) et de F à I (0.2 ppm) peut s'interpréter en termes de densité électronique π du carbone lié au proton. L'effet mésomère du substituant diminue quand on passe de F à I et de O à Te. On notera par ailleurs que la délocalisation d'une paire libre du substituant sera maximum dans le cas d'une configuration plane de la molécule. Dans le cas des halogénobenzènes, cette interprétation est corroborée par l'excellente corrélation existant entre le déplacement chimique du proton en *para* et la constante de Taft du substituant (19).

Contrairement à la plupart des benzènes substitués, il n'existe pas de corrélation entre les dé-

*On a également mesuré $^2J_{Se-H} = 11.8$ Hz et $^2J_{Te-H} = 22.5$ Hz.

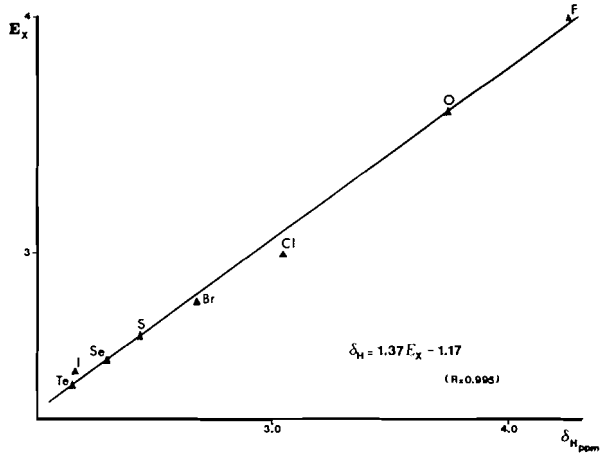

FIG. 2. Corrélation entre le déplacement chimique des protons du méthyle dans les halogénures de méthyle et l'électronégativité du substituant.

placements chimiques des protons en *ortho* et ceux des protons en *para* tant dans les halogénobenzènes que dans nos composés. Dans les deux cas, il s'agit probablement d'une manifestation de l' "effet *ortho*" (20), effet dont la nature n'est pas encore bien définie, mais dans lequel la taille du substituant doit jouer un rôle important.

Notons encore que les constantes de couplage du telluroanisole sont voisines de celles du benzène ($J_o = 7.56$ Hz, $J_m = 1.38$, $J_p = 0.68$ Hz), ce qui peut indiquer que le tellure ne perturberait que faiblement le système électronique du phényle.

Les tableaux 6 et 7 montrent que la substitution d'un chlore ou d'un brome en *para* n'affecte guère que le groupement —TeMe: cette singularité de comportement du tellure est probablement une manifestation d'un "effet d'atome lourd" (21).

Résonance magnétique du carbone 13

Tant dans la série de l'anisole que dans les halogénures de méthyle, le déblindage du carbone du méthyle augmente avec l'électronégativité du substituant (tableau 8). Ce parallélisme se traduit par une

TABLEAU 6. Déplacements chimiques des protons des dérivés *para* substitués dans la série de l'anisole

X	Y	δ_{ortho}	$\delta_{méta}$	δ_{CH_3}(YMe)	δ_{CH_3}
CH_3	O	6.688	6.976	3.72	2.26
CH_3	S	7.083	7.005	2.40	2.295
CH_3	Se	7.258	6.993	2.27	2.305

Br	Te	7.426	7.235		2.194

excellente relation linéaire: $\delta_C{}^X = 1.34\delta_C{}^Y + 2.08$ ($R = 0.999$).

Il faut aussi remarquer que l'effet devient blindant dans les cas du tellure et de l'iode: on retrouve ici l'"effet d'atome lourd" invoqué plus haut (21).

En ce qui concerne les carbones aromatiques, on note à nouveau un parallélisme entre les halogénobenzènes et la famille de l'anisole (tableau 9). Pour C_1 et C_o notamment, il existe des excellentes relations linéaires ($R = 0.999$). L'effet global sur C_1 quand on passe de O à Te est cependant moins marqué que pour le carbone du méthyle (47.4 ppm de variation au lieu de 71.8 ppm). Un carbone aromatique est moins sensible au substituant qu'un carbone aliphatique. Dans le cas de Te, C_1 est blindé par rapport au benzène.

La variation de C_{para} montre une certaine délocalisation de la paire libre du substituant vers le système π du cycle, délocalisation diminuant lorsque la taille de l'hétéroatome augmente.

Quant à C_{ortho}, blindé par rapport au benzène pour O et S, il est déblindé pour Se et Te: l'"effet *ortho*" devrait à nouveau jouer un rôle important.

En résumé, l'effet de substitution des chalcogènes varie de manière importante quand on passe de O à Te. Il dépend grossièrement d'un effet capteur qui

s'estompe au profit d'un effet blindant en carbone 13 (déblindant en proton) de nature mal définie que l'on serait tenté d'appeler "effet d'atome lourd", par analogie avec le comportement des halogénobenzènes.

Si, on considère le carbone et les protons du méthyle à la fois dans la série de l'anisole et dans les halogénures de méthyle, on note une relation linéaire ($R = 0.97$) entre les déplacements chimiques des deux types de noyaux. On est ainsi amené à penser que les mêmes effets agissent sur les deux noyaux, essentiellement effets électroniques et effet d'atome lourd.

Partie expérimentale

Les composés étudiés au cours de ce travail ont été synthétisés dans nos laboratoires, à l'exception des anisoles disponibles commercialement (Aldrich).

Les dérivés séléniés et sulfurés (22) ont été préparés à partir des sélénophénols et thiophénols, eux-mêmes obtenus par réaction entre les magnésiens et le sélénium ou le soufre.

Les dérivés tellurés (23) ont été préparés par réduction des ditellurures et condensation avec l'iodure de méthyle. Ces ditellurures sont obtenus par réaction entre le lithique aromatique et le tellure élémentaire.

Les spectres de résonance magnétique du proton ont été obtenus sur un spectromètre HA100 de Varian. Les paramètres ont été calculés selon la méthode itérative de Johannesen *et al.* (24) à l'aide du programme n° 188 du "Quantum Chemistry Program Exchange." Les déplacements chimiques (référence: TMS) ont été extrapolés pour une dilution infinie. Le solvant utilisé est le tétrachlorure de carbone. Sauf mention contraire, les déplacements chimiques sont exprimés en ppm (±0.003 ppm) et les constantes de couplage en Hz (±0.02 Hz).

Les spectres de résonance magnétique du carbone 13 ont été obtenus sur spectromètre HFX90 de Bruker. Ils ont été enregistrés en transformée de Fourier avec et sans découplage de bruit des protons. Les mesures (à ±0.1 ppm) ont été effectuées à température ordinaire sur des échantillons contenant 1 g de substance pour 2 ml de deutériochloroforme ou à partir de solutions saturées dans le même solvant (référence: TMS).

Remerciements

Nous tenons à remercier Messieurs les Professeurs J. Toussaint et M. Renson pour l'intérêt suivi qu'ils accordent à nos travaux. Nous remercions également le Centre de Résonance Magnétique Nucléaire de l'Université de Liège qui a mis son matériel à notre disposition. L'un de nous (Léopold Laitem) remercie le Fonds National de la Recherche Scientifique de Belgique pour l'octroi d'un mandat d'aspirant.

The synthesis and properties of the hexachloroniobates and hexachlorotantalates of Na, K, Rb, and Cs

DONALD R. SADOWAY[1] AND S. N. FLENGAS

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received January 16, 1978

DONALD R. SADOWAY and S. N. FLENGAS. Can. J. Chem. **56**, 2013 (1978).

The compounds $NaNbCl_6$, $NaTaCl_6$, $KNbCl_6$, $KTaCl_6$, $RbNbCl_6$, $RbTaCl_6$, $CsNbCl_6$, and $CsTaCl_6$ were synthesized in a closed system by the reaction of $NbCl_5$ or $TaCl_5$ vapour with solid alkali-metal chloride as follows

$$MCl_5(g) + ACl(s) = AMCl_6(l)$$

where M is Nb or Ta, and A is Na, K, Rb, or Cs. The X-ray powder diffraction patterns of these compounds were obtained. Temperatures of various phase transformations were determined cryoscopically.

DONALD R. SADOWAY et S. N. FLENGAS. Can. J. Chem. **56**, 2013 (1978).

On a synthétisé les composés $NaNbCl_6$, $NaTaCl_6$, $KNbCl_6$, $KTaCl_6$, $RbNbCl_6$, $RbTaCl_6$, $CsNbCl_6$ et $CsTaCl_6$ dans un système fermé en faisant réagir du $NbCl_5$ ou du $TaCl_5$ à l'état vapeur avec un chlorure de métal alcalin solide d'après la réaction

$$MCl_5(g) + ACl(s) = AMCl_6(l)$$

où M est soit Nb ou Ta et A est Na, K, Rb ou Cs. On a pu obtenir les spectres de diffraction de rayon-X des poudres de ces composés. On a déterminé les températures de diverses transformations de phase par une méthode cryoscopique.

[Traduit par le journal]

Introduction

The pentachlorides of niobium and tantalum are known to react with alkali-metal chlorides to produce hexachloroniobate(V) and hexachlorotantalate(V) compounds of the general formula, $AMCl_6$, where A is an alkali metal and M is either Nb or Ta. These compounds contain thermodynamically stable forms of the volatile covalently bonded pentachlorides and, as such, are of interest in the extractive metallurgy of niobium and tantalum. Although these compounds have been the subjects of earlier investigations, the results of different studies vary considerably and, in some cases, are contradictory.

In the present investigation the compounds $NaNbCl_6$, $NaTaCl_6$, $KNbCl_6$, $KTaCl_6$, $RbNbCl_6$, $RbTaCl_6$, $CsNbCl_6$, and $CsTaCl_6$ have been synthesized by a method different from those previously employed, as well as, by a conventional technique. The X-ray powder diffraction patterns of these compounds have been obtained. The temperatures of various phase transformations have been determined by cryoscopy.

Experimental

The principal method of compound preparation in this study was the reaction of MCl_5 vapour with ACl powder at a temperature above the melting point of the $AMCl_6$ compound under synthesis. The reaction may be represented as follows:

$$MCl_5(g) + ACl(s) = AMCl_6(l)$$

This was a batch operation conducted in a closed non-isothermal system and was actually a modification of a method used previously in this laboratory to prepare chlorotitanates, chlorozirconates, and chlorohafnates of alkali-metal chlorides and alkaline-earth chlorides (1–3). A variation of this method in which molten $KNbCl_6$ and $KTaCl_6$ are produced in a continuous operation has been reported (4).

The compounds $NbCl_5$ or $TaCl_5$ were obtained from Research Organic/Inorganic Chemical Corporation, Belleville, NJ, U.S.A., and were certified to be of purity 99.99 and 99.9% respectively. Although they were supplied sealed in bottles under a dry nitrogen atmosphere hydrolysis occurred and oxychlorides were present. To purify the salts either of two methods was used. The first method was to sublime the salt in a stream of helium saturated with thionyl chloride as described by Keneshea *et al.* (5). Oxychloride and water reacted according to

$$MOCl_3(g) + SOCl_2(g) \rightarrow MCl_5(g) + SO_2$$

and

$$H_2O(g) + SOCl_2(g) \rightarrow 2HCl + SO_2$$

where M represents Nb or Ta. The purified compounds were sublimed into glass ampoules and sealed under vacuum for storage. The second method, described by Brown (6), was to dissolve the pentachloride compound in freshly distilled thionyl chloride, allow the mixture to digest for 24 h, and filter the solution through a fritted disc having a nominal pore size of 5 μm. The $SOCl_2$ was evaporated from the filtrate and the remaining salt was sublimed in a sealed tube. Reagent grade alkali-metal chlorides were ground to a particle size of −200 mesh. They were dehydrated by exposure to a mixture of chlorine and HCl gases for several hours at 500°C.

To prepare the compound, $AMCl_6$, equimolar amounts of ACl and MCl_5 were placed in a borosilicate glass reaction tube, which is shown in Fig. 1. To minimize hydrolysis of the reagents this operation was performed in a glove box filled with anhydrous helium. With its ends stoppered the reaction tube was removed from the glove box and the end nearer the ACl was flame sealed. Next, the reaction tube was evacuated and the ACl was heated to 400°C. During this time the reaction tube was being evacuated to exhaust the gas which was desorbing off the surface of the ACl powder. After 12 h the reaction tube was flame sealed under vacuum. It was placed in a furnace with two independently controlled elements. The MCl_5 was heated to the temperature at which its pressure was approximately 1.5 atm, i.e. 266°C for $NbCl_5$ and 257°C for $TaCl_5$ (7). Except in the case of the NaCl the other alkali chlorides were heated to approximately 10°C above the melting point of the corresponding $AMCl_6$ compound. Reaction times were of the order of several hours. Power to both furnace elements was then disconnected simultaneously and the reaction tube was furnace-cooled. The high pressures over the molten compounds, $NaNbCl_6$ and $NaTaCl_6$, necessitated their preparation in the solid state. Time of reaction was 3 days.

Despite all precautions, a small amount of fibrous white substance remained behind in the MCl_5 part of the reaction tube. This was probably hydrolysed MCl_5. The reaction tube was opened in the glove box and the glass boat was weighed to determine the amount of MCl_5 which had reacted with the ACl and, therefore, the composition of the material in the boat.

For the sake of comparison, some of the compounds were synthesized by precipitation from solutions of $SOCl_2$–ICl (6, 8). Attempts were made to prepare all $AMCl_6$ compounds by this method; however, only $CsNbCl_6$, $CsTaCl_6$, and $RbTaCl_6$ could be produced in quantity.

Other investigators (9–13) have made these compounds by mixing the appropriate quantities of $NbCl_5$ or $TaCl_5$ with ACl and slowly heating the mixture to its melting temperature. The melt is then cooled and the solid product is ground in a dry atmosphere. This method was not used in the present study because it was felt that gas–solid reaction reduces the contamination of the product.

$KNbCl_6$ and $KTaCl_6$ have also been prepared by two other methods. In one, the reaction of a mixture of K_2O and Nb_2O_5 or Ta_2O_5 with CCl_4 is conducted in a sealed ampoule at 400°C (14). In the other, specified amounts of KCl and $NbCl_5$ or $TaCl_5$ dissolved in $SOCl_2$ are heated, excess KCl is removed by filtration, and $SOCl_2$ is evaporated from the filtrate (15). These methods, however, have low yields and are used mainly for the preparation of spectral samples of small mass.

At room temperature the hexachloroniobates are green. Upon heating they turn yellow–orange, and their melts are red. On exposure to moisture for several minutes the solids turn blue, they are white when completely hydrolysed.

The solid hexachlorotantalates and all their hydrolysis products are white. The molten hexachlorotantalates are transparent and have a faint lemon–yellow colour.

Results

X-ray Powder Patterns

The X-ray powder patterns were obtained with a Debye–Scherrer 114.8 mm camera, exposed for 1 h to CuK_α radiation ($\lambda = 1.5418$ Å) filtered through nickel. In a glove box filled with helium the specimens were ground and screened to -200 mesh and hermetically sealed in 0.3 mm quartz glass capillaries.

The results for $NbCl_5$ and $TaCl_5$ which had been purified by precipitation from $SOCl_2$, as described above, agree well with earlier work by Douglass and Staritzky (16) for $NbCl_5$ and Rolsten (17) for $TaCl_5$.

The X-ray patterns of the eight compounds $AMCl_6$, where A is Na, K, Rb, or Cs, and M is Nb or Ta have been obtained. Despite the fact that in some cases the specimens did not consist of exactly equimolar amounts of ACl and MCl_5 extraneous lines which could be attributed to these small variations in composition were not found. Furthermore, in the case of $RbTaCl_6$, $CsNbCl_6$, and $CsTaCl_6$, which were successfully synthesized both by the reaction of MCl_5 vapour with ACl powder and by precipitation from $SOCl_2$–ICl solutions, the two patterns obtained were identical.

Only three X-ray studies of $AMCl_6$ compounds have been reported. Kozhina *et al.* (13) studied $KNbCl_6$ and $KTaCl_6$, Smirnova and Tsintsius (18), $RbNbCl_6$ and $CsNbCl_6$, and Bagnall and Brown (8), $CsNbCl_6$ and $CsTaCl_6$.

There is excellent agreement between the results of this work and that reported by Kozhina *et al.* (13) for $KNbCl_6$ and $KTaCl_6$ respectively.

The results of this work are also in agreement with the main lines obtained by Smirnova and Tsintsius (18) for $RbNbCl_6$.

The results of this study for $CsTaCl_6$ agree with those of Bagnall and Brown (8). The latter prepared their samples by precipitation from $SOCl_2$–ICl solutions; in this study samples were prepared both by that method and by the reaction of CsCl with $TaCl_5$ vapour. Although the pattern by Bagnall and Brown has more lines, both patterns agree on lines of greater intensity. Samples prepared herein by precipitation and by solid–vapour reaction were irradiated; all gave the same results. Furthermore, this powder pattern was successfully indexed. No explanation is given for the extra lines reported by Bagnall and Brown.

The X-ray diffraction patterns for the alkali hexachloroniobate and alkali hexachlorotantalate compounds which have been obtained in this laboratory may be found in the Depository of Unpublished Data, CISTI, at the National Research Council of Canada.[2]

The X-ray diffraction pattern for the compound $CsNbCl_6$ was also obtained. Previous data by Smirnova and Tsintsius (18) and by Bagnall and Brown (8) are contradictory. As seen in Table 1, the present work is in better agreement with the results by Bagnall and Brown (8) who prepared the compound by

[2]Copies of these data are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

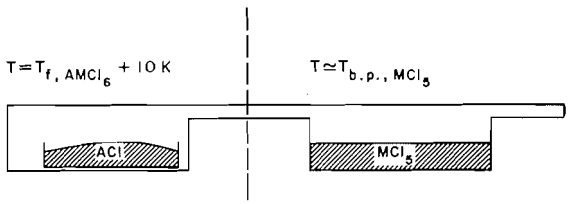

FIG. 1. Reaction apparatus for the synthesis of alkali hexachloroniobate(V) and hexachlorotantalate(V) compounds.

the $SOCl_2$–ICl method as compared to the method of co-melting equimolar amounts of $NbCl_5$ and CsCl used by Smirnova and Tsintsius.

In this study samples which had been prepared both by precipitation from $SOCl_2$–ICl solutions and by the reaction of CsCl with $NbCl_5$ vapour were irradiated. In all cases, the pattern given in Table 1 was obtained. To determine the effect of CsCl on the pattern, a sample of composition $X_{CsNbCl_6} = 0.535$, balance CsCl, was irradiated. The powder pattern was identical with the exception of the reflection at 2.91 Å, the intensity of which had increased with the presence of CsCl. In other experiments with $CsNbCl_6$ two allotropic modifications were detected. Perhaps different investigators have seen different allotropic forms. Nevertheless, five different samples of $CsNbCl_6$ were irradiated in this study, and all five gave the powder pattern in Table 1.

X-ray diffraction patterns for the compounds $NaNbCl_6$, $NaTaCl_6$, and $RbTaCl_6$ also obtained in this laboratory are given in Table 2.

As this study was the first to identify these compounds no comparison can be made with existing data.

Attempts were made to determine the crystal structures of the hexachloroniobate and hexachlorotantalate compounds. Although the data were those of polycrystalline samples, it was possible to test whether the structures were cubic, tetragonal, or hexagonal by means of nomographs. A summary of the results of these calculations is given in Table 3 and the complete indexed X-ray powder patterns and the calculated and experimentally obtained *d*-spacings for $NaNbCl_6$, $KNbCl_6$, $KTaCl_6$, $RbTaCl_6$, and $CsTaCl_6$ may be found at the Depository of Unpublished Data.[2]

Good agreement with the measured pattern of $NaNbCl_6$ was obtained by assuming this compound to have a tetragonal structure.

The measured powder pattern of $KNbCl_6$ is compared with that generated on the assumption that its crystal structure is cubic with a cell dimension $a = 9.80$ Å. The agreement between observed and calculated *d*-spacings is excellent. This confirms a similar conclusion made previously by Kozhina *et al.* (13).

The measured powder patterns of $RbNbCl_6$, $CsNbCl_6$, and $NaTaCl_6$ could not be correlated

TABLE 3. Cell dimensions and crystal structures of alkali hexachloroniobate and hexachlorotantalate compounds

Compound	Structure	a (Å)	c (Å)
$NaNbCl_6$	Tetragonal	11.20	10.57
$KNbCl_6$	Cubic	9.80	—
$KTaCl_6$	Hexagonal	11.62	10.97
$RbTaCl_6$	Hexagonal	11.92	14.00
$CsTaCl_6$	Hexagonal	12.60	19.52

without ambiguity to any of the structures considered. This is in contrast with claims by previous investigators that $RbNbCl_6$ and $CsNbCl_6$ are both tetragonal (18). However, these compounds are known to have more than one allotropic modification, and it is possible that the samples prepared herein had different crystal structures.

The measured X-ray powder patterns of $KTaCl_6$, $RbTaCl_6$, and $CsTaCl_6$ corresponded well with those generated by assuming each to possess a hexagonal crystal structure. Previously, Kozhina *et al.* (13) on the basis of their measurements suggested that $KTaCl_6$ was hexagonal. The cell dimensions were given as $a = 11.87$ Å and $c = 10.79$ Å and agree well with estimates of this work, which are, $a = 11.62$ Å and $c = 10.97$ Å. There are no structural data reported in the literature for either $RbTaCl_6$ or $CsTaCl_6$.

Figure 2 shows that the cube root of the volume of the unit cell varies linearly with the radius of the alkali-metal cation, indicating that these three compounds are isostructural.

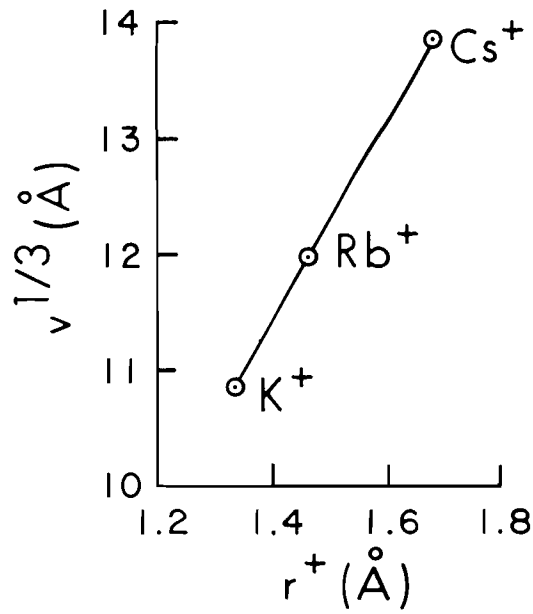

FIG. 2. Variation of cell size with alkali-metal cation radius for the compounds $KTaCl_6$, $RbTaCl_6$, and $CsTaCl_6$.

Cryoscopy

The approximate melting points and temperatures of the solid transformations were found by cryoscopy. Each sample weighed approximately 20 g and was contained in an evacuated fused quartz ampoule. The ampoule contained a glass well which allowed a thermocouple to be placed at the heart of the salt sample. For immersion into a vertical tube furnace the ampoule was contained in a grounded metal sheath which served to prevent induction of spurious voltages in the thermocouple by the ac field of the furnace windings. Furnace temperature was controlled by a variable autotransformer. To maintain a fixed cooling rate an electric motor drove down the variable autotransformer through a variable-ratio gear reductor. Each sample was cooled several times at different rates ranging from 0.5 K/min to 2.5 K/min to obtain data which were free from the effects of undercooling. The thermocouple, 22 gauge, Chromel-P vs. Alumel, ASTM type K, was certified by the Hoskins Manufacturing Co., Detroit, MI, U.S.A., and was checked in this laboratory against a platinum – 13% rhodium vs. platinum standard, manufactured by Egelhard Industries, Carteret, NJ, U.S.A.

The output from the thermocouple was recorded on a multirange chart recorder, Honeywell ElectroniK 193, after compensation by a Sargent zero

NOTE: (i) denotes that the compound melts incongruently.
*The eutectic temperature is that of the ACl–$AMCl_6$ subsystem.

displacement recorder accessory. The results are summarized in Table 4. The most striking feature is that all the $AMCl_6$ compounds proved to be polymorphic in the solid state.

The results of this work for $NaNbCl_6$ and $NaTaCl_6$ agree well with the findings of Palkin and Chikanov (19). Attempts were made to measure the melting points of the incongruently melting compounds. However, the dissociation vapour pressures are so high at this temperature that the fused quartz cells explode. Aside from the well defined solid–solid transformation at 245°C, which occurs with an estimated large enthalpy of transition, $NaNbCl_6$ showed signs of a solid–solid transformation at 299°C, which has not been reported in the literature. It occurs with an estimated very small enthalpy of transition.

$KNbCl_6$ is the most thoroughly studied of all the $AMCl_6$ compounds. Investigators seem to agree that it melts at approximately 395–400°C and that the $KNbCl_6$–KCl eutectic temperature is in the vicinity of 370°C. The solid–solid transformation temperatures vary greatly. Palkin and Chikanov (19) claim two transformations, one at 321°C and another at 160°C, the latter occurring with a large enthalpy of transition. In this investigation, none of the samples of $KNbCl_6$ or $KNbCl_6$–KCl showed any evidence of the latter. Indeed, the transformation reported herein to occur at 299°C is elusive and was observed only in samples whose composition was almost pure $KNbCl_6$.

The results for $KTaCl_6$ agree well with those of Palkin and Chikanov (20) for the $KTaCl_6$–KCl eutectic temperature and the temperature of the $\alpha \rightarrow \beta$ transformation. The latter occurs with an estimated small enthalpy change. Although this study quotes the temperature of the $\beta \rightarrow \gamma$ transformation to be 138°C in contrast to 160°C reported by Palkin and Chikanov (20), both studies estimate the enthalpy change which accompanies this transition to be extremely large. The melting point of $KTaCl_6$, determined herein as 401°C, was a rather elusive quantity to measure because the liquidus from pure $KTaCl_6$ to the $KTaCl_6$–KCl eutectic at 48 m/o $TaCl_5$ is very steep, varying 40–50 K in a composition range of 2 m/o.

Only Huber *et al.* (11) have studied the phase

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

changes of $RbNbCl_6$ and $RbTaCl_6$. $RbNbCl_6$ reportedly melts incongruently at 360°C. In this study the liquidus was identified at 380°C; however, there was no thermal arrest at 360°C. The $\alpha \rightarrow \beta$ transformation, which occurs at 305°C with an estimated large enthalpy change, has been discovered in this investigation. Huber *et al.* and this study report effectively identical values for the melting point of $RbTaCl_6$. It appears that this study is the first to discover the $\alpha \rightarrow \beta$ transformation of $RbTaCl_6$. This occurs at 313°C with an estimated large enthalpy change. The cooling curves suggested that there may be still another phase change occurring at 261°C with an estimated small enthalpy change.

The melting point of $CsNbCl_6$ was measured herein to be 535°C, in good agreement with previous estimates (11, 21). The $\alpha \rightarrow \beta$ transition at 290°C with a large enthalpy change has been identified. Morozov in his book (21) reports the existence of a solid–solid transformation at 300°C. Unfortunately, there is no reference to the original study. The measured melting point and temperature of the solid–solid transformation of $CsTaCl_6$ agree well with those determined by Morozov and Simonich (22).

Trimethylene sulfite conformations: Effects of sterically demanding substituents at C-4,6 on ring geometry as assessed by ^1H and ^{13}C nuclear magnetic resonance

GERALD W. BUCHANAN, CATHERINE M. E. COUSINEAU, AND THOMAS C. MUNDELL

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received February 16, 1978

GERALD W. BUCHANAN, CATHERINE M. E. COUSINEAU, and THOMAS C. MUNDELL. Can. J. Chem. **56**, 2019 (1978).

^1H and ^{13}C nmr data for eight phenyl, diphenyl- and di-*tert*-butyl-2-oxo-1,3,2-dioxathianes, substituted at C-4 and/or C-6 are presented. Vicinal couplings obtained from ^1H spectra by iterative computer analysis indicate chair geometries for all materials except *trans*-4,6-disubstituted compounds. ^{13}C chemical shifts are corroborative.

GERALD W. BUCHANAN, CATHERINE M. E. COUSINEAU et THOMAS C. MUNDELL. Can. J. Chem. **56**, 2019 (1978).

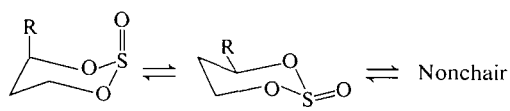
On rapporte des données de rmn du ^1H et du ^{13}C relatives à huit phényl-, diphényl- ou di-*tert*-butyl-oxo-2 dioxathianes-1,3,2 substitués en positions 4 et/ou 6. Les valeurs obtenues pour les constantes de couplage vicinales obtenues à partir des spectres du proton par une analyse itérative à l'aide d'un ordinateur indiquent que tous les composés existent dans des conformations chaises à l'exception des composés disubstitués en 4,6 *trans*. Les déplacements chimiques du ^{13}C corroborent ces conclusions.

[Traduit par le journal]

Introduction

For over 15 years, conformational analysis of trimethylene sulfite and its alkyl derivatives has posed an interesting problem in stereochemistry. The literature includes studies by dipole moment measurement (1–3), ultrasonic absorption (4, 5), infrared spectroscopy (1, 6–11), chemical equilibration (12, 13), electron diffraction (14), and ^1H and ^{13}C nmr spectroscopy (6–11), (15–21).

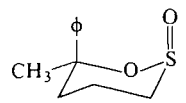
The predominance of an axial S=O function in trimethylene sulfite itself is well established, $-\Delta G^0$ being ca. 2.1 kcal/mol (3). For compounds in which a single substituent can be potentially *syn*-axial to the exocyclic oxygen i.e., *a* (below), the question arises as to whether the ring will change its geometry. If so, does it ring invert to a chair with equatorial S=O or is a twist conformation adopted?



a *b* *c*

On the basis of dipole moments (1–3), ^1H nmr (6–11, 19), and ^{13}C nmr (21) it has been suggested that twist forms are populated appreciably when the possibility of *syn*-axial interaction between the S=O and a single CH_3 group at C-4 or C-6 exists. Recently these interpretations have been questioned by Pihlaja and co-workers (22) who conclude that energy considerations preclude significant contributions from twist forms at least in the case of a single axial CH_3 and an axial S=O group. Their argument is based on rigorous analysis of ^1H spectra and calculations which indicate that the twist chair form of 1,3,2-dioxathiane is ca. 8 kcal/mol less stable than the chair conformer (23, 24).

If the conclusions of Pihlaja and co-workers (22) are valid, then the question arises as to how large a single axial substituent at C-4,6 must be, in order to induce conformational change in sulfites. For 1,2-oxathian-2-oxides we have recently found that even a sterically bulky moiety such as phenyl is insufficient to alter the conformation from a chair with axial S=O (25) i.e.,



In the case of trimethylene sulfites, no systematic study of compounds having axial functions larger than CH_3 has been reported. Accordingly we have synthesized a series of trimethylene sulfites having potentially axial phenyl and *tert*-butyl functions at C-4,6. These materials have been subjected to ^1H and ^{13}C nmr analysis in order to detect their preferred geometries in solution.

Results and Discussion

^1H Spectra

Table 1 contains the chemical shifts and Table 2 the coupling constants for **1**–**8**. Spectra were analyzed by means of the LAOCN3 program (34) and fitted to an rms error of ± 0.1. In the cases of **4** and **5**, the corresponding 6,6-dideuterio compounds were synthesized, and their spectra employed as a starting

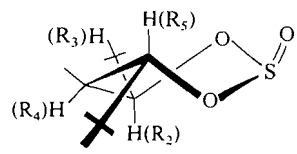
point for the spectral analysis. For **5**, the protons at C-6 are accidentally isochronous in 0.1 *M* $CDCl_3$ solution, but the spectra recorded in acetone-d_6 show a substantial chemical shift difference between these nuclei. Parenthesized values denote the centre of the phenyl regions which were not analyzed.

The large vicinal couplings observed in **1** and **2** are indicative of chair conformers in which nearly 180° dihedral angles are present between *trans*-diaxial protons. Also in **1**, where the sulfinyl group is *syn*-axial to axial H's on C-4,6 (R_1 and R_5), a pronounced deshielding (0.58 ppm) of these protons is apparent relative to **2** in which the sulfinyl group is equatorial. This difference is close to that found for the corresponding dimethyl compounds (19) and the analogous diphenyl systems **6** and **7** (0.55 ppm). The similarity in the vicinal couplings for **6** and **7** compared to **1** and **2** indicates similar geometries, namely chair forms with axial S=O in **6** and equatorial S=O in **7**.

The ^{1}H spectrum of **3** recorded in CCl_4 and CH_3CN solutions has been analyzed by Cazaux *et al.* (26). Based on Eu(fod)$_3$ experiments and consideration of Karplus curves they concluded that the molecule adopts a twist conformation as shown below.



3

Our data for **3** in $CDCl_3$ are in close accord with those reported by the French group. The intermediate couplings of ca. 10 Hz between R_2R_3 and R_4R_5 could arise from dihedral angles near 150° in each case. For couplings involving R_2R_4 and R_3R_5, dihedral angles of ca. 30° may be present, resulting in the smaller couplings of ca. 6 Hz.

The other situation which could lead to intermediate J values is a chair–chair equilibrium. If this were the case, the shift difference between R_2 and R_5 of **3** would be considerably less than that between the C-4,6 protons of **1** and **2** (0.58 ppm), since the S=O would be *syn*-axial to R_5 only part of the time. But the observed shift difference between R_2 and R_5 of **3** is large (0.68 ppm), indicating a preference for a conformation such as the twist form above in which the S=O deshields R_5 considerably relative to R_2. Further support for this conclusion comes from the ^{13}C data (*vide infra*). Also, we have carried out low temperature studies (to $-120°C$) on **3** and no spectral changes were found. Although this is not rigorous proof for a twist form, it does mitigate against a chair $\rightleftharpoons$ chair equilibrium with a barrier >10 kcal/mol and appreciable contributions from two chairs.

With regard to the monophenyl systems **4** and **5**, the only previous work published was on a material proposed to be '4-phenyltrimethylene sulfite' by Albriktsen (18). This liquid compound was characterized only by its boiling point. No elemental analysis data were presented. Furthermore *only one isomer* was described. We have now synthesized two isomers of this material, one liquid (**4**) and one solid (**5**) and our nmr results are drastically different from those of Albriktsen *for both isomers*. A further problem with the earlier work was that the spectrum of the neat liquid was analyzed, although it has been clearly demonstrated (27) that sulfites experience strong self association and are likely to be dimers at high solute concentration. In an attempt to determine if the previous liquid (18) was a polymer of our liquid isomer **4**, we have recorded a 60 MHz spectrum of neat **4** and compared it to the 60 MHz spectrum published earlier. The spectra are grossly different and we are forced to conclude that Albriktsen's material was *not* in fact a 4-phenyltrimethylene sulfite at all.

In contrast to Albriktsen's postulate of a twist conformation, the ^1H data clearly show that *both* **4** and **5** are chair forms, with axial and equatorial sulfinyl groups respectively. The large vicinal couplings between potentially diaxial protons suggest chairs, so do the small J's between axial–equatorial and equatorial–equatorial nuclei. The large negative geminal J's are normal, with $J_{5,6}$ being more positive due to the influence of the adjacent electronegative oxygen atom (28).

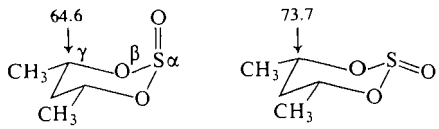
The substantial deshielding of the axial proton of **4** (i.e. R_5) relative to R_6, is evidence for the axial S=O, whereas in **5**, with the equatorial S=O, R_5 and R_6 have only slightly different chemical shifts (in acetone-d_6).

For the *cis*-diphenyl compounds **6** and **7**, the couplings are remarkably similar to those for the *cis*-di-*tert*-butyl materials **1** and **2**, respectively. Accordingly, we suggest that **6** is a chair conformer with axial S=O, whereas **7** is a chair with an equatorial S=O moiety. The *trans*-diphenyl isomer **8** shows intermediate magnitude for vicinal H–H couplings. We have examined its spectrum to $-120°C$ with no observable changes and therefore conclude that it also most likely adopts a nonchair geometry, with the same provisos re: a possible chair $\rightleftharpoons$ chair equilibrium as stated earlier for **3**.

^{13}C Spectra

Carbon shifts for **1–8** are collected in Table 3. Assignments were straightforward and were verified by selective ^1H irradiation for carbons bearing protons. Aromatic resonances are designated as quaternary, *ortho*, *meta*, and *para*. Peak overlap was evident for *meta* and *para* positions in most materials.

The primary diagnostic tool for ring geometry is the γ effect of the exocyclic oxygen on the C-4,6 resonances. When the S=O is axial in a chair, the *gauche*-γ effect results in a substantial upfield shift at C-4,6 in sulfites (21) relative to instances where the S=O is equatorial in a chair. Analogous findings for isomeric sulfoxides (thiane oxides) have also been published (29). For the 4,6-dimethyl trimethylene sulfites studied earlier (21), results are presented below (9.1 ppm *gauche*-γ effect).



Findings for **1** vs. **2** and **6** vs. **7** are very similar to those for the dimethyl isomers. In **1**, the existence of an axial S=O in the chair shields C-4,6 by 9.6 ppm relative to **2**, whereas in **6** the *gauche*-γ shielding is 8.7 ppm compared to **7**.

For the *trans*-di-*tert*-butyl compound **3** the shift at C-6 is 1 ppm upfield from that found in **1**. This result mitigates against a substantial amount of a chair conformer with equatorial S=O since this would deshield C-6. On the other hand, if **3** was in a chair form with axial S=O, the presence of the axial *tert*-butyl group at C-4 should shield C-6 more than 1 ppm (relative to **1**) owing to the extra *gauche*-γ interaction. We feel the data are best accommodated by the twist boat form of **3** depicted earlier. In this conformation C-6 still experiences a large γ-effect owing to the *pseudo*-axial S=O but the *syn*-axial interaction between the bulky *tert*-butyl group and the exocyclic oxygen is removed.

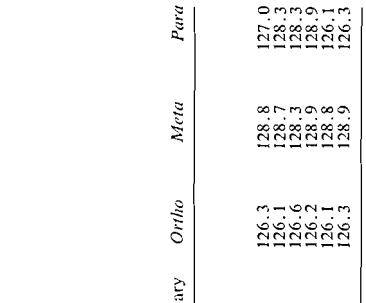
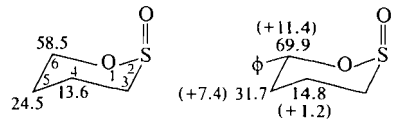
TABLE 3. ^{13}C chemical shifts ($\delta_c \pm 0.1$ from TMS) for **1–8** (0.1 *M* in $CDCl_3$)

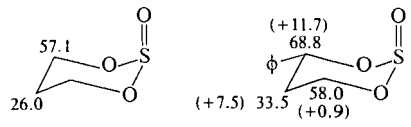


Compound	Substituent	Conformation	C-4	C-5	C-6	R_1	R_2	R_3	R_4	R_5	R_6	$(*CH_3)_3C$	Quaternary	*Ortho*	*Meta*	*Para*
1	$R_2 = R_6 = C(CH_3)_3$	*a*	75.4	26.7	75.4		34.0				34.0	25.3				
2	$R_1 = R_5 = C(CH_3)_3$	*b*	85.0	24.9	85.0	34.7				34.7		25.6				
3	$R_1 = R_6 = C(CH_3)_3$	*c*	80.0	27.7	74.4	34.2					33.7	25.3				
4	$R_2 = \phi$	*a*	68.8	33.5	58.0								138.7	126.3	128.8	127.0
5	$R_1 = \phi$	*b*	78.7	31.8	64.6								138.3	126.1	128.7	128.3
6	$R_2 = R_6 = \phi$	*a*	70.0	41.0	70.0								138.7	126.6	128.3	128.3
7	$R_1 = R_5 = \phi$	*b*	78.7	39.4	78.7								138.0	126.2	128.9	128.9
8	$R_1 = R_6 = \phi$	*c*	74.6	38.8	69.5								138.8	126.1	128.8	126.1
													138.7	126.3	128.9	126.3

In the case of compound **4**, it is instructive to compare the shifts induced by phenyl substitution with those caused by equatorial phenyl substitution at C-6 in 1,2-oxathiane-2-oxides (sultines), which are deemed to be in chair conformations having axial S=O groups (25).



For the above sultines, the α effect is +11.4 ppm, the β effect is +7.4 ppm, and the *trans*-γ shift at C-4 is +1.2 ppm. In the sulfite **4** the α, β, and *trans*-γ effects are +11.7, +7.5, and +0.9 ppm, respectively. The striking correspondence between these substituent parameters suggest that these sultines and sulfites have similar geometries.



4

The marked downfield shifts at C-4 (10.7 ppm) and C-6 (6.6 ppm) compared to **4** indicate the absence of any substantial amount of axial S=O in **5**, since the *gauche*-γ shieldings are essentially lost. We therefore assign a chair form to **5** with equatorial S=O, although the fact that the changes at C-4 are ca. 4 ppm larger than at C-6 may indicate a minor amount of twist conformer.

For the *trans*-diphenyl material **8**, the ^{13}C shifts at C-4,6, compared with those for the *cis* isomers **6** and **7**, are remarkably similar to the case of the *trans*-di-*tert*-butyl system **3**, when viewed relative to **1** and **2**. Therefore a similar twist geometry is proposed for **8** and **3**.

To conclude, our results show clearly that the introduction of a phenyl or *tert*-butyl group in a potentially *syn*-axial orientation to the S=O of a trimethylene sulfite, causes the ring to invert to a chair with both the S=O and the bulky substituent equatorial. The only cases in which twist geometries are present are in *trans*-4,6-disubstituted systems in which there appears to be a reluctance for the heterocycle to adopt a chair conformation with a purely axial phenyl or *tert*-butyl function at C-4 or C-6.

Experimental

Spectra

The ^1H nmr spectra were obtained as 0.1 *M* solutions in $CDCl_3$ with TMS as internal standard, using a Varian HA-100 nmr spectrometer.

The ^{13}C nmr spectra were recorded as 0.1 *M* solutions in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$CDCl_3$ with TMS as internal standard, using a Varian XL-100-12 nmr spectrometer equipped with a Nicolet BNC-12 computer (20K memory). The pulsed Fourier transform method was employed at 25.16 MHz with complete proton noise decoupling. The free induction decays were transformed after a sufficient number had been accumulated. Commonly 8192 data points were used in the interferogram. Spectra widths of 5000 Hz were routinely used.

Materials

cis-*4,6-Di*-tert-*butyltrimethylene Sulfites (**1** and **2**)*

To 1.0 g *meso*-2,2,4,4-tetramethyl-3,5-heptanediol (30) in 20 ml dry pyridine and 75 ml dry benzene was added 1.5 ml $SOCl_2$ in 25 ml of benzene, dropwise with stirring and external cooling. The reaction was allowed to run overnight. The organic layer was then filtered to remove the pyridinium hydrochloride and treated with 10% sodium carbonate, washed with water, and dried over sodium sulphate.

After filtration the excess solvent was removed on a rotary evaporator yielding a viscous liquid which solidified immediately. Fractional crystallization from 50:50 pentane–benzene yielded 550 mg of **2**, mp 133–135°C, (lit. (26) 138°C) and 130 mg of **1**, mp 102–103°C. Both compounds gave satisfactory ir spectra, with sulfinyl stretching bands at 1200 cm^{-1} (**1**) and 1220 cm^{-1} (**2**) *Anal.* calcd. for **1**: C 56.37, H 9.47, O 20.48, S 13.68; found: C 56.39, H 9.49, S 13.60.

trans-*4,6-Di*-tert-*butyltrimethylene Sulfite (**3**)*

To 1.0 g racemic 2,2,4,4-tetramethyl-3,5-heptanediol (30) in 100 ml dry benzene and 12 ml dry pyridine was added 1.0 ml $SOCl_2$ in 20 ml benzene, dropwise with external cooling. The reaction was allowed to continue overnight at room temperature. The solution was then filtered and washed in turn with 10% sodium carbonate, 0.1 *N* HCl, and water. Concentration on the rotary evaporator gave 1.0 g viscous yellow liquid which solidified on cooling. Recrystallization from toluene yielded 630 mg of **3**, mp 45–46°C (lit. (26) 46°C). The ir showed S=O stretch at 1215 cm^{-1}.

*4-Phenyltrimethylene Sulfites (**4** and **5**)*

To 2.0 g of 1-phenyl-1,3-propanediol (31) in 50 ml anhydrous ether and 8 ml pyridine was added dropwise with stirring and external cooling, 1.5 ml $SOCl_2$ in 20 ml dry ether. The reaction was allowed to run at room temperature overnight.

After filtering off the pyridine HCl, the organic layer was washed with 5% $NaHCO_3$, 0.1 *N* HCl, and water and dried over sodium sulphate. The solvent was then evaporated and the mixture chromatographed on 50 g of silica gel with benzene as eluent to yield 450 mg of **4** as a clear liquid n_D^{25} 1.5458 and 800 mg of **5** as a white solid, mp 60–61°C. The ir showed characteristic sulfinyl stretching vibrations at 1190 cm^{-1} for **4** and 1220 cm^{-1} for **5** with no OH. *Anal.* calcd. for **4**: C 54.52, H 5.08, S 16.17, O 24.22; Found: C 54.61, H 5.00, S 16.21.

cis-*4,6-Diphenyltrimethylene Sulfites (**6** and **7**)*

To 400 mg of the *meso*-1,3-diphenyl-1,3-propanediol (32) in 10 ml dry benzene and 2 ml dry pyridine was added dropwise with stirring and external cooling 0.5 ml $SOCl_2$ in 5 ml benzene. The reaction was allowed to run at room temperature for 3 h. The hydrochloride salt was then filtered off and the mother liquor washed in turn with sodium carbonate, 10% HCl, and water and dried over magnesium sulphate.

Evaporation of the solvent yielded a white solid which recrystallized from toluene as fibers. This initial product proved to be **7** almost exclusively. It was impossible, however, to completely separate the two isomers by fractional crystallization so it was necessary to chromatograph the products on 50 g of silica gel with benzene as eluent. This gave a total of 120 mg **6**, mp 83–84°C, and 155 mg **7**, mp 123–124°C. The ir contained S=O stretching peaks at 1190 cm^{-1} for **6** and 1220 cm^{-1} for **7** and no OH absorption. *Anal.* calcd. C 65.67, H 5.14, S 11.69, O 17.50; found for **6**: C 65.70, H 5.21, S 11.67; found for **7**: C 67.81, H 5.09, S 11.72.

trans-*4,6-Diphenyltrimethylene Sulfite (**8**)*

To 2.0 g of the racemic 1,3-diphenyl-1,3-propanediol (30) with 10 ml pyridine in 200 ml dry benzene was added dropwise with external cooling 1.6 ml thionyl chloride in 6.5 ml benzene. After 3 h the salt was removed by filtration and the solvent evaporated. Sulfite **8** crystallized directly from the residual pyridine as plates, mp 54–55°C. The ir spectrum contained a characteristic S=O stretching absorption at 1225 cm^{-1} but no OH band. A total of 1.7 g product was obtained. *Anal.* calcd. for **8**: C 65.67, H 5.14, S 11.69, O 17.50; found: C 65.64, H 5.11, S 11.75.

*6,6-Dideuterio-4-phenyltrimethylene Sulfites (**4**-d_2 and **5**-d_2)*

Preparation was identical to that described for **4** and **5**. The required 3,3-dideuterio-1-phenyl-1,3-propanediol was prepared by $LiAlD_4$ reduction of the product of the Reformatsky reaction between benzaldehyde and ethyl bromo acetate (33). Mass spectra (low resolution) of dideuterio-**4**-d_2 and **5**-d_2 gave the following *m/e* values (relative intensities in parentheses), **4**-d_2: parent ion 200(9.0), 136(11.0), 119(4.1), 104(100), 77(30.0), 51(22.0), 43(13.4), and 28(89.0); **5**-d_2: 200(9.8), 136(25.6), 119(5.0), 104(100), 77(26.0), 51(22.0), 43(11.0), and 28(89.0).

The clathrate hydrate of 2-methylpropanal: dielectric evidence[1]

S. R. GOUGH

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received March 6, 1978

S. R. GOUGH. Can. J. Chem. **56**, 2025 (1978).

Dielectric relaxation evidence is presented of the encageability of 2-methylpropanal in the structure II clathrate hydrate lattice. The hydrate composition is inferred to be $(CH_3)_2CHCHO \cdot 17H_2O$ and, for the 2-methylpropanal/THF mixed hydrate studied in detail, the activation energy for aldehyde reorientation is shown to be 2.0 kcal/mol. The results suggest that the guest–host interactions may be somewhat different for the two guest species.

S. R. GOUGH. Can. J. Chem. **56**, 2025 (1978).

On présente des données de relaxation diélectrique concernant la possibilité de mettre en cage le méthyl-2 propanal dans un réseau d'hydrate clathratique ayant la structure II. On déduit que la composition de l'hydrate est $(CH_3)_2CHCHO \cdot 17H_2O$ et dans le cas de l'hydrate mixte du méthyl-2 propanal/THF qui a été étudié en détail, l'énergie d'activation de la réorientation de l'aldéhyde est de 2.0 kcal/mol. Les résultats suggèrent que les interactions entre le réseau et les molécules encagées sont quelque peu différentes pour les deux espèces emprisonnées.

[Traduit par le journal]

Recently the properties of aldehyde–water systems have been under scrutiny from a variety of angles (1–4). Phase diagrams have been published for such systems for ethanal (CH_3CHO) (1), propanal (CH_3CH_2CHO) (3), butanal ($CH_3CH_2CH_2CHO$) (2), and 2-methylpropanal ($(CH_3)_2CHCHO$) (2) which indicate the formation of various hydrates for all except butanal. Of these hydrates, X-ray examination (2, 3) showed those of propanal and 2-methylpropanal to be clathrate hydrates of structure II. Elsewhere, concurrent dielectric and nmr experiments (4) showed ethanal and propanal to form unstable clathrate hydrates most probably of structure II. In this note are presented similar dielectric results which demonstrate the encageability of 2-methylpropanal in the structure II lattice and which allow the composition of the hydrate to be estimated. 2-Methylpropanal is a large molecule ($\simeq$6.9 Å) and is enclathrated only with some difficulty as is evidenced below.

Sample Preparation

Initial attempts to prepare the hydrate by dropwise addition of water at 0°C to freshly distilled aldehyde held at temperatures near −25°C (the method of Cohen and van der Horst (4, 5) for "ice VIII") met with only limited success, but nevertheless, sufficient hydrate ($\simeq$8% of the dielectric sample) was obtained to demonstrate its clathrate nature. However, several samples prepared as before (4) by rapidly mixing the precooled liquids, immediately freezing the mixture in liquid nitrogen, and then conditioning at various temperatures for varying periods, showed, by the absence of any low temperature dielectric absorption, the absence of hydrate of the clathrate type. Similarly, attempts to prepare nmr samples in sealed tubes in the absence of air by methods which have previously met with considerable success for other hydrates, proved futile.[2] Probably the 2-methylpropanal hydrate requires the incorporation of a considerable quantity of air as a "Hilfsgas" (7) to ensure its stability relative to ice. Practically quantitative enclathration of the 2-methylpropanal (RCHO) was achieved finally, by promoting formation of the structure II lattice by including a quantity of the well known (8, 9) hydrate former, tetrahydrofuran (THF), in the reaction mixture. Two samples, containing 0.48 and 0.25 mol of THF respectively per $\simeq$ 17 mol of water, were prepared as follows. The appropriate quantities of THF and aldehyde were cooled, mixed with precooled water at 0°C, and shaken using a Vortex mixer to form an emulsion which was then frozen quickly to a solid mass. This was warmed until partially melted and the resultant slurry, after further shaking, was pipetted into the precooled dielectric cell (10) where it was refrozen and then conditioned at $\simeq -10$°C for half an hour before cooling to the required temperature. The stoichiometric composition of the system was $0.52RCHO \cdot 0.48THF \cdot 13.5H_2O$ in the first case and $0.75RCHO \cdot 0.25THF \cdot 16.0H_2O$ in the second, excess of the hydrate formers with respect to the ideal $M \cdot 17H_2O$ requirement being taken in order to suppress the formation of ice. The mixed hydrates proved to be stable over periods of several days (at temperatures as high as −5°C for the 0.52:0.48 sample) with no sign of conversion of the hydrated aldehyde to *gem*-diol and ice. This is in contrast to the results obtained for the hydrates of other aldehydes previously examined (4), which, in the dielectric samples studied, showed considerable rates of decomposition, even at −80°C in one instance.

Results

The dielectric properties of the 2-methylpropanal/THF mixed hydrate of 52:48 mol% guest ratio are illustrated in Fig. 1 for the temperature range where the enclathrated molecules show dielectric relaxation effects at frequencies of 1 MHz and below. At each

TABLE 1. Dielectric relaxation data for hydrates of 2-methylpropanal and tetrahydrofuran

	Permittivity			Temperature (K) of 10 kHz loss max.		Activation energy (kcal/mol)	
	$\varepsilon_{\infty 2}$ at 7 K	ε_{02} at 168 K		$T_{\varepsilon_m''}$ (THF)	$T_{\varepsilon_m''}$ (RCHO)	ΔE (THF)	ΔE (RCHO)
RCHO hydrate	—	—	(8.10)*	—	54.5	—	—
Mixed hydrate (25% THF)	—	—	—	24.0	52.5	—	—
Mixed hydrate (48% THF)	3.35±0.05	6.5±0.1	(6.55)*	24.5	51.1	0.87	2.0_1
THF hydrate	—	—	—	24.2†	—	0.91†	—

*Calculated value, see text.
†Data taken from ref. 8.

frequency two regions of dispersion–absorption are apparent corresponding to the reorientation of the two types of guest molecule present. For the lower temperature region the usual Arrhenius plot yields an activation energy of 0.87 kcal/mol for the THF reorientation process. This value, together with the temperatures at which the loss exhibits maxima, is in agreement with previously published data (8) for the pure THF–water structure II clathrate system. For the higher temperature relaxation region, which can only arise from the molecular reorientation of encaged aldehyde molecules,[3] the corresponding energy is 2.0_1 kcal/mol, a value in accord with those of other molecules of similar size enclathrated in the type II lattice (11). The results, summarized in Table 1, demonstrate the considerably greater reorientational mobility in the clathrate cage of the smaller (≃5.9 Å) THF molecules over the larger (≃6.9 Å), more hindered, aldehyde molecules. This is strikingly illustrated in Fig. 1, where, near 32 K, reorientation of THF may be seen to correspond to frequencies near 1 MHz whereas that for aldehyde corresponds to frequencies near 1 Hz, indicating a difference of $\simeq 10^6$ in reorientation rate for the two guest species at this temperature.

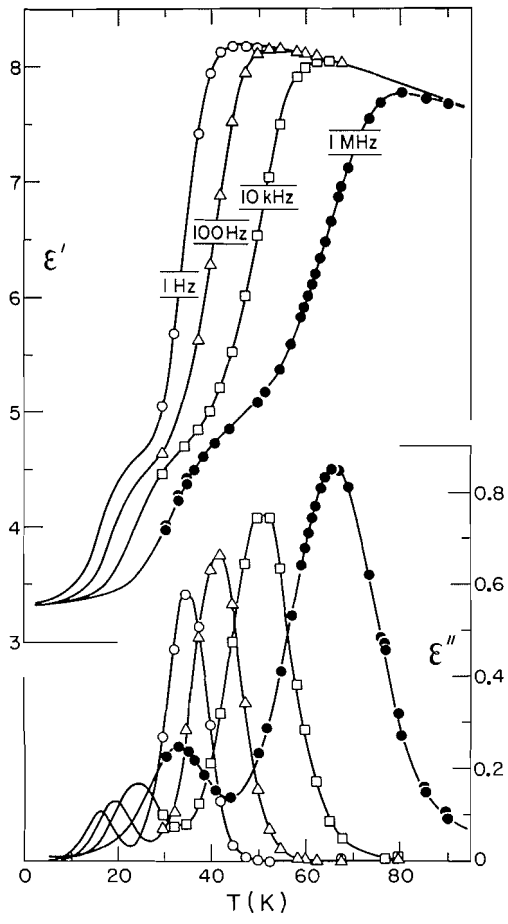

FIG. 1. Guest molecule dispersion–absorption curves for the mixed hydrate of THF and 2-methylpropanal. Data points below 30 K are omitted for greater clarity. Composition is $0.52RCHO{\cdot}0.48THF{\cdot}13.5H_2O$.

Discussion

(a) Permittivity

Previous dielectric studies (8) of clathrate hydrates of type II have shown that the contribution to the permittivity arising from near isotropic reorientation of the guest molecules is well represented by the Onsager spherical cavity model, which in this case may be applied in the form

$$\frac{(\varepsilon_{02}-1)(2\varepsilon_{02}+1)}{3\varepsilon_{02}} = \frac{(\varepsilon_{\infty 2}-1)(2\varepsilon_{\infty 2}+1)}{3\varepsilon_{\infty 2}} + \frac{4\pi N_M}{3kT}\left[\frac{x\mu_{THF}^2}{(1-f_M\alpha_{THF})^2} + \frac{(1-x)\mu_{RCHO}^2}{(1-f_M\alpha_{RCHO})^2}\right]$$

where x and $(1-x)$ represent the relative amounts of THF and RCHO respectively. ε_{02} is the permittivity which includes contributions from reorientation of both guest molecules but not from water

[3]The candidacy of an intramolecular reorientation process for this absorption is eliminated (*a*) by the absence of a third relaxation region at still higher temperatures corresponding to relaxation of the remaining aldehyde dipole component, and (*b*) by the fact that the dielectric increment observed at higher temperatures corresponds (see Discussion) to isotropic reorientation of the total aldehyde dipole.

molecules and $\varepsilon_{\infty 2}$ is the limiting low temperature permittivity containing no orientational component. N_M is the number density of the guest molecules, μ their dipole moment, and α their polarisability derived from the molar refraction of the respective liquids. The reaction field factor f_M is given by $2(\varepsilon_{02} - 1)/[a^3(2\varepsilon_{02} + 1)]$ where a is the mean free radius (3.2 Å) of the almost spherical clathrate cage. For the sample of 52:48 mol% ratio, $\varepsilon_{\infty 2} = 3.35$ at 7 K, and with $N_M = 1.545 \times 10^{21}$ molecules cm^{-3} (derived from the structure II lattice parameter of 17.3 Å at 168 K) and $\mu_{RCHO} = 2.7$ D (a value typical (12) of similar molecules), ε_{02} is calculated to be 6.5_5 at 168 K, a value which compares well with the experimentally observed one of 6.5 ± 0.1. (For the pure aldehyde hydrate, containing no THF and of composition $RCHO \cdot 17H_2O$, the model predicts ε_{02} at 168 K to be 8.1.) Thus, in agreement with the previously reported X-ray observation (2), it may be concluded from the above and from the observation of rapid molecular motion at low temperatures that molecules of 2-methylpropanal can be incorporated into the large cage of the structure II hydrate lattice, albeit with some difficulty.

(b) Relaxation Times

The apparent variation of guest molecule relaxation time with hydrate composition, as is evidenced by the temperatures at which ε'' shows maxima (Table 1), offers an opportunity to comment on the influence of compositional change on the reorientation of the guest species. The trends, illustrated in Fig. 2, may be rationalized in terms of changes in guest–host interaction as the guest concentration ratio varies. The temperatures of maximum loss are reproducible, and are considered to be accurate, to within 0.1° and are *inversely* related[4] to the reorientation rates of the guest molecules. For RCHO, the increase in relaxation time with increasing aldehyde concentration evident from the figure, points to increasing restriction of the already highly hindered aldehyde molecules. This must arise as a consequence of the increase in net dipole moment per unit volume as THF ($\mu = 1.63$ D) is replaced by RCHO ($\mu \simeq 2.7$ D). At the same time the lattice must expand[5] as more of the larger guest is enclathrated at the expense of the smaller. This expansion apparently dominates the situation in the case of the THF, where, as is reflected in the upper curve of the figure, faster relaxation of the already relatively unhindered THF molecules is seen for the sample of higher aldehyde content.

In the case of the mixed hydrate considered here the interesting possibility arises for the occurrence of some expansion of the cages containing aldehyde at the expense of compression of the adjacent cages containing THF, the overall lattice parameter being little affected at low aldehyde concentrations. The data (Fig. 2) offer some support for this concept in that the THF reorientation is slightly slower for the 50% sample, than for the pure THF hydrate itself. At concentrations of aldehyde greater than $\simeq 50\%$ the effect of the lattice expansion predominates and so the THF relaxation again becomes faster.

The opposite effects observed for the two guest species, as the guest concentration ratio changes, supports the speculation that their guest–host interactions are essentially different in some respects. The extremely rapid THF reorientation probably is controlled predominantly by the small electrostatic fields arising, at the cage centre, from the dipoles of the water molecules forming the cage walls. The much slower (by a factor of $\simeq 10^6$) reorientation of the larger, more restricted, aldehyde molecules, on the other hand, may well be controlled predominantly by forces arising from extensive van der Waals contact with the cage walls and by somewhat shielded interactions with neighbouring guest molecules.

(c) Composition

The composition of structure II clathrate hydrates has been examined in detail twice previously. In the first instance (9) for fifteen type II hydrates it was shown that no statistical evidence of any departure from the ideal $M \cdot 17H_2O$ stoichiometry could be

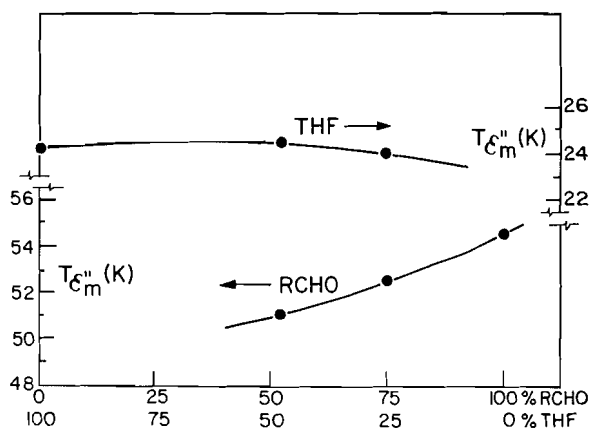

FIG. 2. Dependence of guest molecule reorientation (see text) on relative guest concentration. The datum for THF hydrate is taken from ref. 8.

[4]The inverse relationship between temperature and rate arises simply as a consequence of the method of measurement, i.e., fixed frequency and variable temperature. At constant frequency, relaxation observed at lower temperatures arises from intrinsically faster reorientation processes. The extreme widths of the low temperature absorptions precluded adoption of the more conventional variable frequency, fixed temperature, technique.

[5]Lattice expansion as a function of lattice occupancy factor (6) and of guest size (11) has been well documented previously.

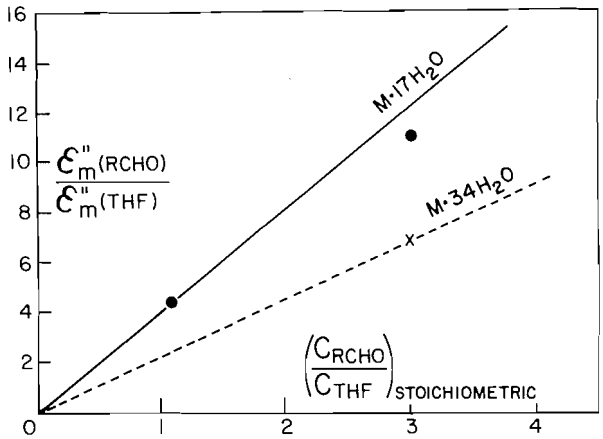

FIG. 3. Dependence of dielectric loss ratio on concentration ratio for the two guest species considered. The lines, drawn for illustrative purposes, refer to hydrate compositions as indicated. The data point at concentration ratio 3:1 falls short of the solid line as a consequence of incomplete conversion to hydrate of the initial components. Point X is derived by simple proportion from the magnitudes of the experimentally observed loss maxima.

demonstrated. The more recent publication (11) discussed (in some detail for the case of 1,3-dioxane hydrate) the evidence against the proposals of Rosso and Carbonnel (refs. 7 and 12 of ref. 11), based on thermal measurements, that the composition of certain hydrates is $M{\cdot}34H_2O$. Those arguments are extended to the hydrates discussed here by means of Fig. 3, in which are compared the relative magnitudes of the 10 kHz loss peaks for aldehyde and THF for the samples studied. The ε_{max}'' ratio shows the proportionality with stoichiometric concentration ratio expected for hydrate compositions near $M{\cdot}17H_2O$, where here M refers to the sum of the RCHO and THF components. Furthermore, for the sample of 75:25 mol% guest ratio the figure clearly demonstrates an aldehyde occupancy factor considerably greater than that required by an $M{\cdot}34H_2O$ composition as indicated by X. It is inferred from these considerations that the composition of the less stable hydrate of 2-methylpropanal itself, containing no other dipolar hydrate former, is also $M{\cdot}17H_2O$ rather than the $M{\cdot}34H_2O$ value, deduced from thermal measurements, which has already been questioned (11).

Catalyst modification by metal deposition: the deposition of silver on platinum at underpotential and overpotential

REMIGIO GERMANO BARRADAS, STEPHEN FLETCHER, AND SANDOR SZABO[1]

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received January 1, 1978

REMIGIO GERMANO BARRADAS, STEPHEN FLETCHER, and SANDOR SZABO. Can. J. Chem. **56**, 2029 (1978).

It is demonstrated that platinum catalysts can be modified by electrochemical means. The deposition of silver is described at both underpotential and overpotential. Although the deposition reactions can be quantified, the electrode kinetics cannot be investigated because of the simultaneous formation and reduction of platinum oxides.

REMIGIO GERMANO BARRADAS, STEPHEN FLETCHER et SANDOR SZABO. Can. J. Chem. **56**, 2029 (1978).

On a démontré que les catalyseurs de platine peuvent être modifiés par des méthodes électrochimiques. On décrit la déposition de l'argent à sous-tension et sur-tension. Quoique les réactions de déposition peuvent être quantifiées, on ne peut pas étudier la cinétique à l'électrode à cause de la formation et de la réduction simultanées des oxydes de platine.

Introduction

The deposition of silver on polycrystalline platinum has been studied by several workers (1–8). They have shown that silver may be deposited in two fundamentally different forms. One form is deposited in monolayer quantities at potentials positive to the reversible equilibrium potential (1–6), which is the so-called underpotential deposition. The other form is bulk silver which is deposited at overpotential (7, 8). The processes involved in these depositions are not only of fundamental theoretical interest (9–12), but are also of great practical importance in the modification of the properties of finely dispersed catalytic surfaces (see, for example, refs. 6 and 13). The present study was therefore undertaken with a view to characterizing some of these processes.

According to Stucki (1), measurement of the rate of change of the number of adsorbed hydrogen atoms compared to the number of deposited silver atoms at underpotential indicated that after the deposition of two monolayers the Pt electrode had assumed the properties of bulk silver. Also the stripping curve of the Ag layers showed two peaks, one at +0.73 V and the other at 0.80 V vs. SCE. This compared with the bulk value of 0.35 V.

Hammond and Winograd (14) recently studied X-ray photoelectron spectroscopic evidence of distinctive underpotential deposition states of Ag on Pt substrates. They noted that the formation of "islands" was minimized and that a bulk silver species was formed only after the completion of the first monolayer. The deposit appeared more metallic than ionic in nature and existed as a smooth two-dimensional atomic array in submonolayer quantities.

Some measurements of the charge associated with underpotential deposition were reported by Cadle and Bruckenstein (4). The effect on the adsorption of hydrogen at platinum by the deposition process was also studied. Submonolayer and monolayer amounts of Ag were deposited at +300 mV (vs. SCE) and then the electrode was scanned into the hydrogen adsorption region. It was found that the weakly adsorbed hydrogen was inhibited more than the strongly adsorbed species provided that the surface coverage of Ag was $< 50\%$. A maximum of 368 $\mu C\ cm^{-2}$ was deposited before hydrogen adsorption was completely inhibited. One monolayer of close-packed silver atoms corresponded to 268 $\mu C\ cm^{-2}$ at their electrode.

The deposition of bulk silver has been studied by Pangarov and Velinov (8). They studied the crystal orientation of three-dimensional electrodeposited silver as a function of overpotential, and then correlated their results with work function data. It is clear from the data described above that their work was not so much on a platinum substrate but rather on a substrate considerably modified by underpotentially deposited silver.

In the present work we utilize the linear potential sweep technique, the potential step technique, and rotating disc electrodes in order to investigate this manifestly complex system. The underpotential deposition is considered first.

Experimental

The smooth (polycrystalline) platinum electrodes used in the present work were in the form of small cylinders sealed in Araldite and machined into rotating discs of conventional

[1] On leave from The Central Research Institute for Chemistry of the Hungarian Academy of Sciences, H-1525/17, Budapest, Hungary.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

design (apparent surface area = 0.41 cm^2). Before use the electrodes were rinsed in nitric acid then washed for several hours in triply-distilled water. Electrical contact was made between the electrodes and the instrumentation via Vibrometer mercury slip-ringless transmitters (Rohrbach System). These transmitters succeeded in eliminating almost completely the numerous disadvantages of the usual solid contact transmitters, e.g. variations in insulation and contact resistances and parasitic thermal emf. Contact resistance was $\ll 0.2$ mΩ. Solution resistance was minimized by the incorporation into the cell design of an adjustable luggin reference probe which was connected to a hydrogen electrode in the same solution. The use of the identical solution in the reference and cell compartments of the apparatus hence obviated the need for a frit or liquid junction. All potentials are therefore quoted on the ϕ-potential scale.

The plating solutions consisted of various quantities of ARISTAR silver perchlorate in 1.00 *M* ARISTAR perchloric acid. The cell was cleaned before the commencement of experiments by immersion for several hours in boiling nitric acid. After this treatment the cell was then flushed with boiling triply-distilled water in order to desorb any residual impurities on the surface of the Pyrex glass.

The constant potential source was a PAR 170 potentiostat and appropriate potential waveforms were generated on the same instrument. On short time-scales data were recorded photographically via a Tektronix oscilloscope (type 503).

Deoxygenation was achieved by flushing the apparatus with purified nitrogen from which any residual traces of oxygen were removed by washing with vanadous chloride solutions. The gas was further cleaned by incorporating strongly alkaline (KOH) solutions into the delivery system to eliminate the possibility of contamination of the cell by microtraces of grease from within the nitrogen cylinders and regulation valves. The gas was finally passed through an identical solution to that in the cell to remove any small water droplets carried through from the other purification stages.

Some measurements were also performed on large platinum foils (apparent surface area 4.86 cm^2, 99.999% purity, Koch-Light laboratories) which were sealed into Pyrex glass holders. Where comparison was possible these electrodes produced identical results to the rotating disc electrodes. Hence there was no possibility of contamination from the Araldite mounting in the case of the rotating disc electrodes, which in a separate experiment were found to be stable in perchloric acid media for a period of several months.

Results

(1) The Deposition of Ag at Underpotential on Pt

The effect of cycling the electrode potential linearly over the range +1400 to +50 mV until a pseudo-steady state is reached is shown in Fig. 1. The scan rate is 20 mV s^{-1} at a stationary platinum electrode in 10^{-4} *M* $AgClO_4$. It is immediately apparent that a number of separate processes are occurring. (A) is the bulk deposition of silver in the region of three-dimensional nucleation and growth (8), for which deposition begins at circa +450 mV. The peak marked (B) in the figure is the reverse process of that indicated by (A), namely the dissolution of bulk silver back into solution. At point (C) there is some small indication of the possible oxidation of a weakly adsorbed silver species, and this is followed by the oxidation of the

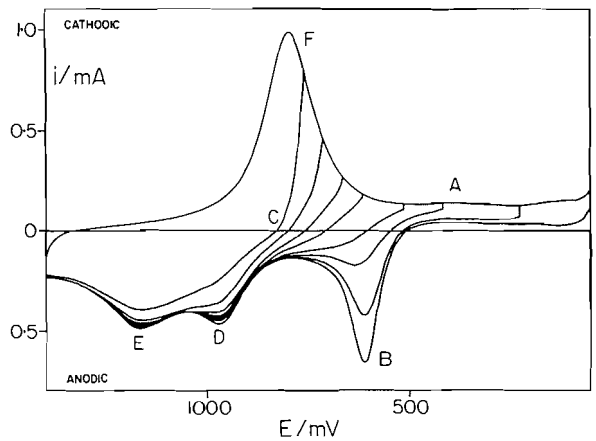

FIG. 1. Effect of linearly scanning the electrode potential at a stationary Pt electrode. v = 20 mV s^{-1}, $[Ag^+] = 10^{-4}$ *M*.

two strongly adsorbed species labelled (D) and (E) at +970 and +1160 mV respectively. Upon reversing the direction of the potential scan the underpotential deposition of Ag can be seen to occur in one broad, unresolved peak (F) at +800 mV. This is a potential region which coincides with the reduction of platinum oxides in the pure base electrolyte. The deposited silver completely inhibits hydrogen adsorption in this case.

By comparing the cyclic voltammogram of Fig. 1 with that of the same electrode in the base electrolyte alone, it is possible to estimate the amount of charge (corresponding to a monolayer) from the charge of the hydrogen adsorption reaction (1). This is shown as the shaded area in the stripping curve (Fig. 2). Unfortunately further quantification does not appear to be possible because some platinum oxides may be formed in the same region at the same time as the silver desorption.

According to the data of Stucki (1) the two strongly adsorbed silver species (our E and D, his I and II) should occur at +450 and +380 mV anodic to the bulk dissolution respectively. In our case, these underpotential values are +560 and +370 mV. We can only conjecture that the differences arise because of the different electrolytes used in the two studies (i.e. 1.0 *M* H_2SO_4 in ref. 1 and 1.0 *M* $HClO_4$ in the present work).

Attempts to locate a very weakly adsorbed species with an underpotential of 80 mV, as reported by Szabo and Nagy (6), proved futile. There are several possible explanations for this discrepancy. The first is that the time-scale of the present work (s) did not allow sufficient resolution of the phenomenon. The second explanation is that the arrest observed on the charging curves of ref. 1 is an artifact produced by the complex diffusion problems nor-

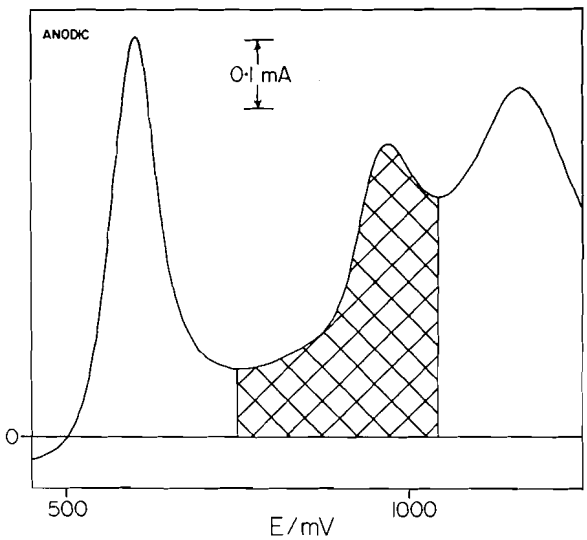

FIG. 2. Typical stripping curve showing bulk silver and two major underpotentially deposited species. The shaded area corresponds to one monolayer of charge at our electrode.

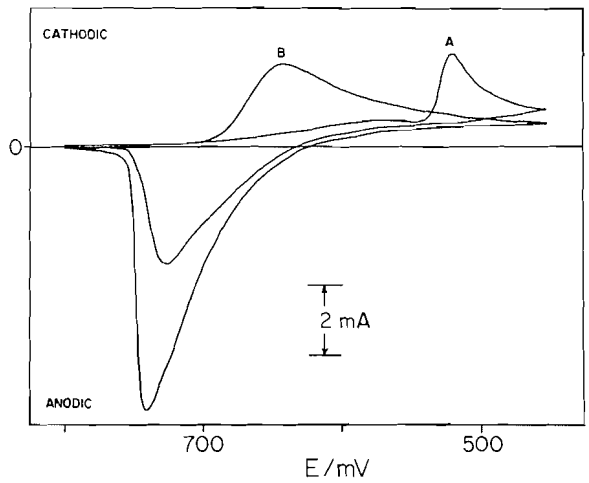

FIG. 3. Continuous cycling of electrode potential following preanodization. Deposition and stripping of bulk silver. v = 50 mV s^{-1}, $[Ag^+] = 10^{-2}$ *M*. (*A*) First cycle, (*B*) pseudo-steady state.

mally associated with finely dispersed surfaces (i.e. platinized platinum). A third possible explanation is the existence of two peaks in the voltammogram corresponding to bulk silver dissolution. Such a phenomenon has been observed, in fact, in the present work (see below).

(II) The Deposition of Ag at Overpotential on Pt

At potentials cathodic to the reversible Nernst potential, silver is deposited in the form of three-dimensional nuclei on the Pt/Ag substrate (8). However it was found that the reaction was not at all straightforward, since the *i–E* and *i–t* curves recorded showed a strong time dependence following surface pretreatment. A good example is shown in Fig. 3. In this case, the electrode was strongly anodized ($E > +1000$ mV) so that all silver deposited on the electrode dissolved into the bulk of solution, leaving the electrode covered with a thick film of platinum oxide. Having rotated the electrode to bring the bulk concentration of electrolyte to the electrode surface, the electrode potential was then continuously cycled (50 mV s^{-1}) between +800 and +450 mV. It was found that the deposition potential slowly shifted by about 300 mV in the anodic direction until a pseudo-steady state had been established. The reason for this must be that the bulk deposition will not proceed in the absence of underpotentially adsorbed silver. Indeed, on the first cycle a broad prepeak may be observed which we attribute to the underpotential deposition reaction. The other reason for the slow attainment of the pseudo-equilibrium is the relaxation of the diffusion regime into which the deposit is growing. Obviously the bulk concentration of Ag^+ close to the electrode surface becomes depleted as the surface deposit grows. The nature of the diffusion zone was therefore the next phenomenon investigated. This was best observed by the use of rotating electrodes.

The result is shown in Fig. 4*a* for a bulk concentration of Ag^+ of 1.0×10^{-2} *M*, using a linear potential scan rate of 50 mV s^{-1}. It is clear that the current rises very rapidly indeed and that eventually a limiting current condition is reached. The limiting currents are plotted as a function of rotation speed in Fig. 4*b*, which are in accordance with the Levich equation

$$[1] \qquad i_{lim} = 0.62nFC_b D_0^{2/3} \nu_k^{-1/6} \omega^{1/2}$$

where i_{lim} is the limiting current density (mA cm^{-2}), n is the number of electrons, F is the Faraday constant, C_b is the bulk concentration (mol ml^{-1}), D_0 is the diffusion coefficient (cm^2 s^{-1}), ν_k is the kinematic viscosity (cm^2 s^{-1}), and ω is the rotation speed. We may therefore apply the Nernst diffusion zone hypothesis and suppose that a semi-infinite *linear* diffusion zone exists at the electrode surface. This contradicts the intuitive notion that each individual (crudely hemispherical) silver nucleus grows into a hemispherical diffusion zone. It is obvious, therefore, that the diffusion zones surrounding each individual nucleus must have overlapped on the time scale of the experiment.

The data of Fig. 4*a* were obtained without a preanodisation, which accounts for the absence of the prepeak so evident in Fig. 3. When a strong anodisation precedes the evaluation of the rotation speed

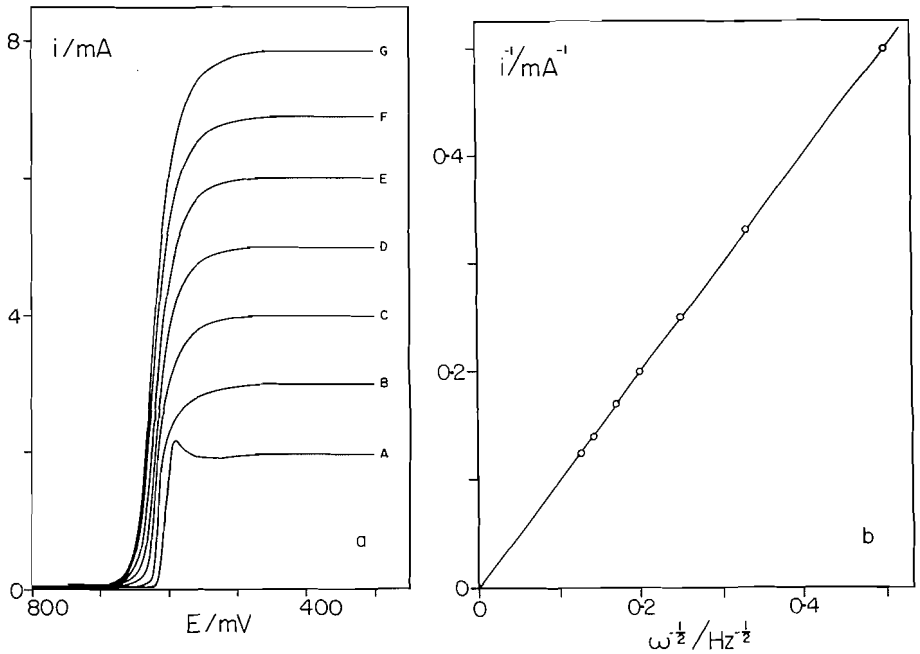

FIG. 4. (*a*) Rotation speed dependence of the bulk deposition reaction, showing attainment of steady state. $v = 50$ mV s^{-1}, $\omega = (A)$ 4, (B) 9, (C) 16, (D) 25, (E) 36, (F) 49, (G) 64 Hz. $[Ag^+] = 10^{-2}$ *M*. (*b*) Test of the Levich equation with the data of Fig. 4*a*.

dependence, the prepeak of course reappears, although this in no way affects the value of the limiting currents. This is because the value of the limiting current is determined purely by the bulk concentration of Ag^+ and the other constants described by [1].

The extraordinary sharp increase in current at short times in Fig. 4*a* arises because of the large dependence of the nucleation and growth parameters on potential. Quantitative estimation of these parameters is usually best obtained by potential step measurements at stationary laminar electrodes. Some of these are illustrated in Fig. 5. Once again it is clear that the rate of growth of the deposit depends very strongly on the residual quantity of platinum oxide from the preanodization. However the approximately linear-rising transient clearly indicates the nucleation and growth nature of the deposition process.

Finally we report a rather novel result. At high ($>10^{-3}$ *M*) bulk concentrations of Ag^+ the amount of underpotentially adsorbed silver becomes negligible compared to the bulk deposit (Fig. 6). The most striking consequence of this increase is that the dissolution peak of bulk silver splits into two peaks. This duplication does not appear if the cycling takes place over the potential ranges +1400 to +400 mV or +1000 to +40 mV, but it appears on the first cycle even over the potential range +800 to +40 mV if the electrode has been anodized before the first

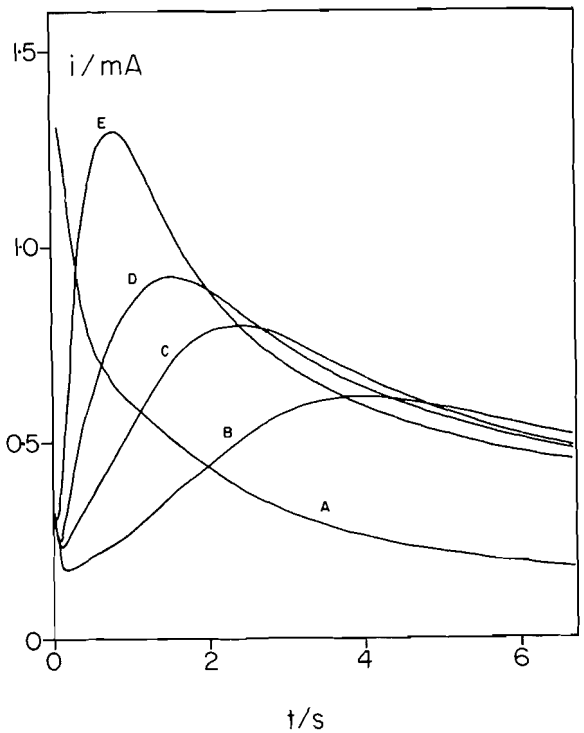

FIG. 5. Repetitive pulses from +800 to +575 mV following a strong anodization. $[Ag^+] = 10^{-2}$ *M*, $\omega = 0$ (A) 1st pulse, (B) 5th pulse, (C) 6th pulse, (D) 7th pulse, (E) 8th pulse.

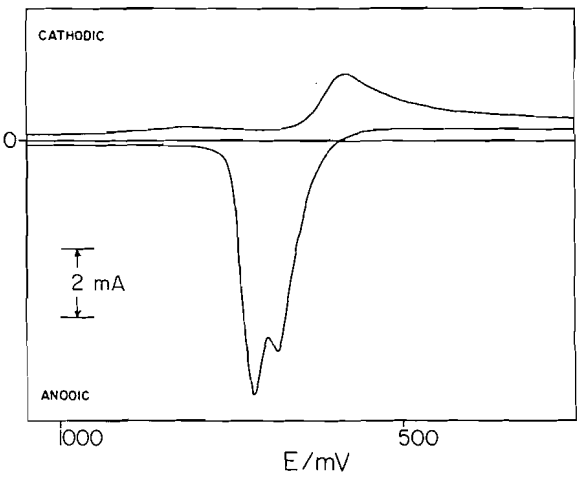

FIG. 6. Splitting of silver bulk dissolution peak under conditions of continuous cycling of electrode potential. Scan from +1250 to +40 mV, $[Ag^+] = 5 \times 10^{-3}$ *M*, $v = 200$ mV s^{-1}, $\omega = 0$.

scan. These experimental observations clearly indicate that the doublet is connected with the reduction of the surface oxides of the platinum. The phenomenon could be best investigated between 10^{-3} and 10^{-2} *M* $AgClO_4$ concentration limits.

We suppose that there are two types of surface oxide on the platinum. These may be adsorbed, for instance, on the 100 and 110 crystal faces of the polycrystalline material, in a similar manner to adsorbed hydrogen (15). If the rate of reduction of surface oxides is different, it follows that after the reduction of the first oxide silver begins to deposit on the free surface and later the reduction of the second oxide provides the silver deposition process with new free surface. The deposition on two 'different' surfaces might then result in two structurally different deposits, which would then dissolve at different potentials.

An alternative explanation is that bulk silver may be deposited in more than one orientation or morphology (as indicated by Pangarov and Velinov (8)) independent of the rate of reduction of the platinum oxides. However, whether such a phenomenon might fully explain the 'splitting' of the dissolution peaks of Fig. 6 is not at present known.

Conclusions

It has been demonstrated that platinum catalysts can easily be modified by electrochemical means. In this instance, various quantities of silver have been deposited and stripped from a (formally) laminar surface. The processes involved have been identified and compared to literature data. A completely quantitative analysis, involving the solution of the electrode kinetics, could not be performed because of the polycrystalline nature of the electrode surface and because of the concurrent formation of platinum oxides in the potential region of interest. Further advances must obviously await parallel investigations on platinum single crystal electrodes (11, 12).

An HF generator based on the dissociation pressure of an alkali bifluoride is described. Sodium bifluoride salt was found to yield HF pressures of the order of 0.001 to 0.3 mm in the temperature range 60 to 135°C due to the equilibrium $NaHF_2 \rightleftarrows HF + NaF$. The HF generator allows a dry carrier gas (typically N_2) to pass through a thermoregulated chamber filled with the crystalline bifluoride and furnishes HF concentrations from 5 to 1000 ppm at flowrates up to 5 ℓ/min for periods up to one year. The HF concentrations thus generated were stable to within 1% after a 40 min warm up period. Described also is the associated control system which allows the operator to send alternately dry carrier gas with or without trace HF concentration to an external cell or analyser.

FRANK M. KIMMERLE, A. ARCHAMBAULT et GHYSLAIN DUBE. Can. J. Chem. **56**, 2034 (1978).

On décrit un générateur de HF qui est basé sur la pression de dissociation d'un bifluorure alcalin. On a trouvé qu'un sel de bifluorure de sodium fournit des pressions de HF de l'ordre de 0.001 à 0.3 mm à des températures allant de 60 à 135°C dues à l'équilibre $NaHF \rightleftarrows HF + NaF$. Le générateur de HF permet à un gaz porteur sec (N_2) de passer à travers une chambre à température constante remplie de bifluorure cristallin et fournit des concentration de HF de 5 à 1000 ppm à des vitesses d'écoulement allant jusqu'à 5 ℓ/min pour des périodes allant jusqu'à une année. Les concentrations de HF générées de cette manière sont stables à 1% après une période de réchauffement de 40 minutes. On décrit aussi un système de contrôle associé qui permet à l'opérateur d'envoyer d'une façon alternative un gaz porteur sec avec ou sans trace de concentration de HF vers une cellule extérieure ou un analyseur.

[Traduit par le journal]

Introduction

In the course of our research program on the adsorption of HF on alumina powders, we needed a reliable, precise, and inexpensive source of dilute hydrogen fluoride in an appropriate carrier gas. Although dilute gas mixtures were available at relatively low pressures on special order from commercial suppliers of compressed gases, their composition was variable and their cost prohibitive for our purposes. We have succeeded in building a simple generator based on the temperature dependent dissociation of sodium bifluoride

[1] $$NaF \cdot HF \rightleftarrows NaF + HF$$

At HF/NaF mole ratios <1, where no other stoichiometric compounds except $NaHF_2$ and NaF have been reported, the equilibrium vapour pressure of HF should be independent of the quantity of the bifluoride or fluoride present and can be calculated from the equilibrium constant of eq. [1] as

[2] $$\ln P_{HF}\,(\text{atm}) = \ln K_{diss} = \frac{\Delta \bar{G}_{diss}}{RT}$$

This system has been studied by Fisher (1), Froning *et al.* (2), and Miller (3) using, respectively, direct pressure measurements, a transpiration method (both at higher temperatures), and a room temperature effusion method. They calculated K_{diss} and hence P_{HF}, the partial pressure of HF as a function of temperature and their results can be expressed respectively as

At 430–542 K

[3] $$\log P_{HF}\,(\text{atm}) = 6.594 - 3521/T\,(T \text{ in K})$$

At 473–548 K

[4] $$\log P_{HF}\,(\text{atm}) = 5.821 - 3196/T\,(T \text{ in K})$$

At 310–371 K

[5] $$\log P_{HF}\,(\text{atm}) = 6.677 - 3940/T\,(T \text{ in K})$$

At 273 K, eqs. [3], [4], and [5] predict equilibrium values of 5.0×10^{-7}, 1.3×10^{-6}, and 1.8×10^{-8} atm. Extrapolation to 373 K also gives rise to the contradictory values 1.4×10^{-3}, 1.8×10^{-3}, 1.3×10^{-4} atm. Although it is difficult to comment on the validity of the different experimental techniques employed, it has been noted by Miller (3) that the discrepancy may be due in part to the different temperature regions investigated.

Results reported in this study are based on concentration, not pressure measurements. In the presence of an inert carrier gas of molecular weight M_{CG}, and a total pressure P_T atm, the HF concentration may be conveniently expressed as a weight fraction:

$$[6] \quad [\text{HF}] \text{ in ppm} \simeq \frac{M_{HF}P_{HF} \times 10^6}{M_{HF}P_{HF} + M_{CG}(P_T - P_{HF})}$$

While the apparent molecular weight of hydrogen fluoride gas approaches that of H_6F_6 at very high pressures (4), a value of 20.01 g/mol was used at the low partial pressures prevailing in this present work. On the basis of eqs. [3] to [5] it could therefore be expected that HF/N_2 mixtures (5 ppm to 10%) of fixed compositions should result by passing dry nitrogen gas through a bed of $NaHF_2$ crystals at temperatures in the range 0 to 200°C. A prototype generator based on these thermodynamic predictions was built and, incidentally, numerical results in close agreement with Miller's work were obtained.

Experimental

(1) Reagents

Sodium bifluoride was prepared from Analar hydrofluoric acid 48% and Baker Analyzed Reagent sodium fluoride. HF (230 ml 48%) was added to 235 g NaF dissolved in 3 ℓ of boiling doubly distilled water. The solution was allowed to digest overnight on a steam bath, allowed to cool slowly to 0°C, and then rapidly filtered. The precipitate was recrystallized from doubly distilled water in a similar manner, dried in a dry air stream and finally in a vacuum oven for 12 h at 110°C at 10 mm Hg. All manipulations were carried out using new Nalgene Labware cleaned with live steam and boiling hot distilled water.

A hexamethylenetetraamine (Baker Grade), HMTA, solution was used to absorb HF. This buffer solution was prepared by neutralizing a 1% HMTA aqueous solution to p*H* 5.6 with 6 *M* HCl and adding 2 ml of the surfactant Triton X-100 0.2% in order to lower its surface tension.

(2) Instrumentation

The HF generator consists of the bifluoride reactor, a temperature control system, and a control system for the switching of gas streams. It is designed to be used with an external cell where HF can react or be adsorbed and an external HF analyser where the original or the residual HF concentration can be measured. The entire generating system is constructed from commercially available hardware, SWAGELOK connections, WHITEY and NUPRO valves and metering valves, 1/4 in. and 1/8 in. copper tubing. For the sake of economy all metal parts in contact with the gas stream are copper or brass rather than more resistant metals such as monel. However, after three months of continuous use at temperatures up to 135°C no deterioration due to HF attack was noticeable.

$NaHF_2$ Reactor

The reactor consists of a slightly modified PICKER type 449 TP 11 *M* heat exchanger. Its 48 inner copper tubes were filled with crystalline sodium bifluoride salt. The finely divided salt retained by two copper screens and thin Teflon membranes was compacted by mechanically vibrating the entire structure. One charge of the reactor, about 850 g $NaHF_2$, is theoretically sufficient to furnish over two million litres of HF at a concentration of 100 ppm. Connections to the external system are achieved by two B-14BKM4S4 WHITEY valves which can also be closed to isolate the reactor for repairs or exchange.

Temperature Control

The temperature of the $NaHF_2$ reactor is controlled by circulating oil in the outer jacket of the reactor in a countercurrent direction to the gas flow in the inner tubes. The oil is heated by a 800 W element which is controlled by a Yellow Springs Instrument type 406 thermistor located at the entrance to the reactor. The temperature of the circulating oil is thus controlled to better than 0.1°C at the lower end of the reactor, i.e. the exit of the HF/N_2 gas. The thermistor constitutes part of an electrical bridge and its resistance is continuously compared with one of five reference resistances. The out-of-balance signal controls the heating element whose power can be further adjusted with a variable transformer to yield about 50% utilisation time.

Reactant Controls

The control logic governing the gas flow is schematized in Fig. 1. A stream of carrier gas sent through the network (1 + 2) or a stream passing through the network 3 can be directed to an external cell by means of a fourway valve (S-Reactor). Subsequently either stream can be sent to the external HF analyser or to waste by means of a fourway valve (S-Analyser).

HF Analyser

The gas stream containing concentrations of the order of 10 to 500 ppm HF is contacted in an absorption tower, Fig. 2, with the HMTA absorbing solution. After degassing, the buffered solution is analysed using an Orion fluoride electrode 94-09-A in a manner not unlike that described previously (5). The 4 ml free gas volume of the tower provides a contact time of more than 0.5 s (at flow rates up to 0.5 ℓ/min) with about 0.3 ml of liquid hold up. The volume of the capillary tubing between the tower and the electrodes was kept to 0.2 ml, and the dead space of the electrode compartment to 0.1 ml in order to obtain a response time of less than 30 s.

Results and Discussion

HF Analyser

The electrode response of the analyser was calibrated using NaF solutions 10^{-6} to 10^{-1} *M* F^- in the 0.05 *M* HMTA buffer. These standard solutions were drawn through the electrode compartment by a Technicon Pump at the same rate as the sample solutions, i.e. 1.52 to 1.54 ml min^{-1}. A Nernstian electrode response with a slope −58.5 mV/log $[F^-]$ was observed over the concentration range 10^{-1} to 10^{-4} *M* but slight deviations from linearity became notice-

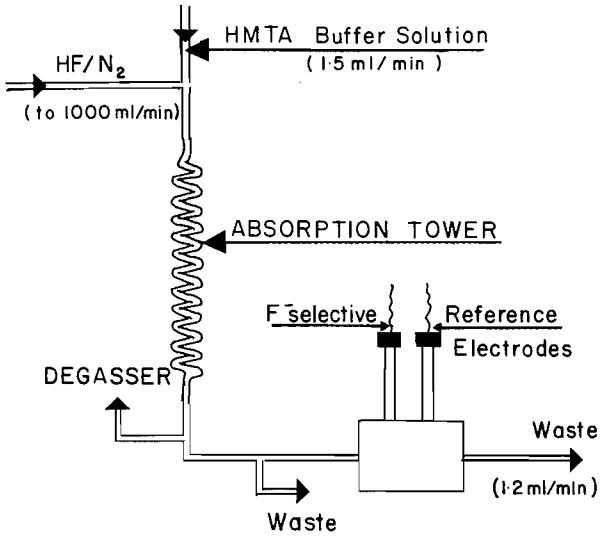

FIG. 2. HF adsorption tower and electrode compartment.

able below 5×10^{-5} *M* F^-. Measurements of HF concentrations in the sample solutions were confined to the range 5×10^{-2} to 10^{-4} *M* F^-.

Evaluation of the efficiency of the scrubbing or absorption tower ideally requires a steady source of a fixed HF concentration in an inert carrier gas and the purpose of this project was precisely to construct such a generator. By allowing the scrubbed nitrogen carrier gas to bubble through a second absorption solution for extended periods of time it was evident that over 99% of the HF was absorbed in the tower for nitrogen flow ranges below 500 ml/min. As the gas flow rate increased further and the residence time in the absorption tower was reduced to less than 0.5 s, the scrubbing efficiency decreased slightly to about 95%. The scrubbing efficiency did not depend on the F^- concentrations except under conditions where the F^- concentration in the absorbing solution exceeded the concentration of the HMTA buffer, i.e., 0.05 *M*.

The HF analyser (i.e. the absorption tower and electrode response) can be evaluated by varying the flow rate of the buffer solution, the flow rate of the HF/N_2 gas, or the concentration of the HF in the carrier gas. The fluoride concentration in the buffer solution should vary as

$$[F^-] = \frac{[\text{ppm HF}]_{N_2}}{20} \times \frac{\text{Nitrogen flow rate}}{\text{Buffer flow rate}} \times \frac{\text{Density of } N_2}{\text{Density of HMTA}} \times 10^{-6}$$

where the density of the nitrogen carrier gas at the temperature of the tower (14°C) can be taken as 1.22 g/ℓ and that of the buffer solution as 1.00 g/ml. Thus, the electrode response should vary in a logarithmic fashion with the nitrogen or the buffer flow rates as well as with the HF concentrations.

The variations of electrode response with the flow rates are summarized in Fig. 3. Curve (*a*) refers to the results obtained by maintaining a constant flow rate and constant pressure in the HF generator, directing part of the gas to waste and allowing a variable amount to pass through the analyser with a flow rate d_{HF/N_2}. A linear relationship is obtained with a slope −57.8 mV/log (flow rate) up to flow rates of 0.5 ℓ min^{-1}. At higher flow rates a non-Nernstian response can be ascribed to a decreased scrubbing efficiency as noted above.

Curve (*b*) refers to the results obtained by maintaining a fixed HF/N_2 flow rate of 280 ml min^{-1}, a fixed concentration of 120 ppm HF, and varying the flow rate of the HMTA buffer from 0.2 to 2 ml min^{-1}. A linear response was obtained with a slope 64 mV/log (flow rate) somewhat greater than the theoretical value of 58.5 mV. This difference is

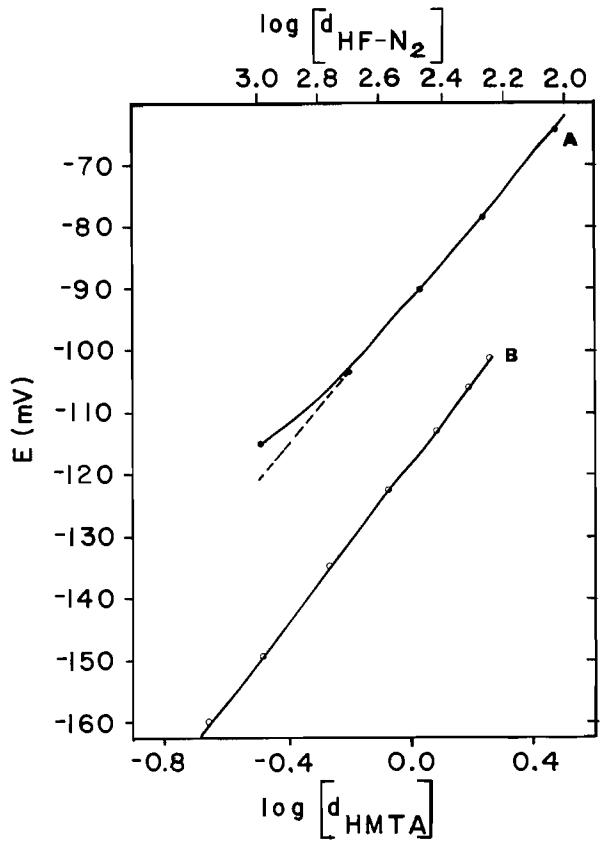

FIG. 3. Electrode response as a function of nitrogen gas and buffer flow rates in the absorption tower. (*A*), Gas flow rate in analyser, d_{HF}/N_2 in ml min^{-1}. Flow rate in generator 1.6 ℓ min^{-1} at 125 ppm HF buffer flow rate 1.53 ml min^{-1}. (*B*), Buffer flow rate in ml min^{-1}. Gas flow rate in analyser and generator 280 ml min^{-1} at 125 ppm HF.

thought to be due to the streaming potential developed by pumping the low ionic strength HMTA buffer through Teflon tubing. A similar effect was observed when standard NaF solutions were employed. Adding an inert electrolyte such as NaCl or KCl to the buffer has been suggested (6) in order to reduce the streaming potential but may promote crystallization when the analyser is left unattended.

HF Generator

For reasons outlined below, the pressure at the outlet of the bifluoride reactor should be maintained at a constant value if possible, and all flow restrictions with the exception of a 7 micron filter (Nupron B-4FT7-7 $C_V = 0.15$) should be placed upstream. When packed with $NaHF_2$ crystals the columns constitute a major restriction to the gas flow rate and will only allow a flow of about 7 ℓ/min for a 10 psi pressure drop. This gas stream (stream *1*, Fig. 1) can be diluted with pure carrier gas (stream *2*, Fig. 1) yielding a fixed quantity of HF in a variable amount of carrier gas, or a concentration varying according to:

$$[7] \quad [HF]_{1+2} = \frac{[HF]_1 \times \text{Flow rate 1}}{(\text{Flow rate 1} + \text{flow rate 2})}$$

The initial tests on the bifluoride reactor have been confined to studies at low flow rates 1, zero flow rate 2, and such low exit pressures that the value of P_T (eq. [6] can be assumed to equal 1 atm). The steady state values for a gas flow about 350 ml min^{-1} in the reactor are given in Fig. 4 and compared with the predictions of Miller (3) and Fisher (1). A least-squares fit to our data yields the expression

$$[8] \quad \log P_{HF}\,(\text{atm}) = 7.205 - \frac{4013}{T}\,(340 \text{ to } 400\,\text{K})$$

When expressed in terms of a weight fraction in a nitrogen atmosphere eq. [8] becomes:

$$[9] \qquad \log\,(\text{ppm HF}) = 13.072 - \frac{4013}{T}$$

and concentrations between 25 to 1000 ppm HF are available by choosing temperatures between 70 to 125°C.

Our numerical values are almost exactly twice those obtained by Miller (3) and some ten times smaller than those reported by Fisher (1), the latter being the most widely quoted in the literature. Using for reaction [1] the free energy function calculated by Miller (3), we obtain an enthalpy of decomposition of $NaHF_2$ $\Delta H^0_{298} = 18.06 \pm 0.1$ kcal/mol at 25°C. This is in excellent agreement with the theoretical value predicted by Higgins and Westrum (7) as 17.88 ± 0.2 kcal/mol.

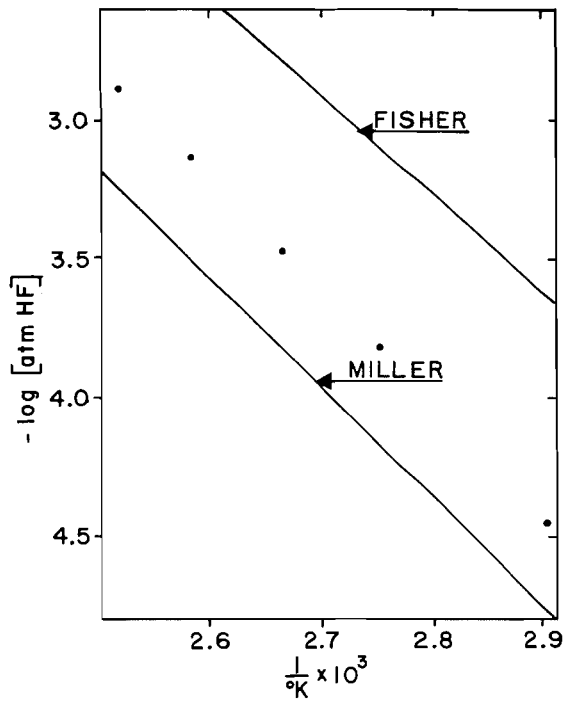

FIG. 4. Partial pressure of HF in the $NaHF_2$ reactor at various temperatures. Included are predictions based on eqs. [3] and [5] and our experimental results.

An appreciable pressure drop in the $NaHF_2$ reactor itself would affect the kinetic response, i.e. the speed with which equilibrium HF concentration is attained at the exit port. Furthermore, according to eq. [6] the pressure at the exit port determines the HF concentration although it does not affect the HF partial pressure. Any flow restriction after the HF reactor, such as the filter or an external reaction cell, will increase P_T at high flow rates and thereby reduce the HF concentration. By deliberately throttling the gas flow using a fine metering valve in place of an external reaction cell we have verified that eq. [6] is obeyed at least up to 40 psi.

The HF concentration in the carrier gas could thus be calculated from eq. [6], the temperature of the bifluoride reactor and a manometer reading at the exit port. A less cumbersome and more direct method is also available. Using the control panel and the metering valve R_0 it is possible to place an equivalent flow restriction in the by-pass of the external reaction cell. Switching the four way valve (S-Analyser) will send either stream (1 + 2) or stream 3 to the analyser without provoking any pressure changes. At all times it is thus possible to measure the HF concentrations directly in the carrier gas before or after the external cell.

The time necessary to attain steady state HF con-

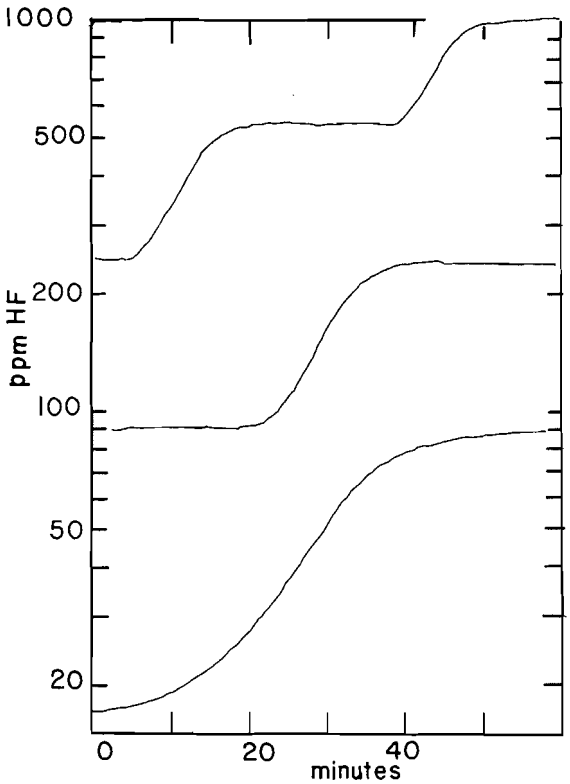

FIG. 5. Time response of the HF generator. Temperature jumps from 72°C to 91°C to 103°C to 116°C to 126°C. Nitrogen flow rate 4.7 ℓ min^{-1}, absorbant flow rate 8.4 ml min^{-1} 2% HMTA solution.

centrations is relatively short. Typical results are illustrated in Fig. 5 for the variation of the HF analyser signal as the temperature of the $NaHF_2$ generator is increased in a stepwise fashion from 72 to 126°C. Since the electrode potential is proportional to log [F^-], the logarithmic chart paper is calibrated to read directly [HF] in ppm. Even at the high nitrogen flow rates employed here (5 ℓ/min) and hence the non-negligible pressure inside the $NaHF_2$ generator, HF concentrations stable to within 1% are rapidly attained. The equilibration time is roughly proportional to the relative HF concentration changes or the temperature increment (about 1 min/°C). It is thus possible to change the HF concentration in the carrier gas from 20 to 1000 ppm within 1 h without changing the gas flow rates or diluting the gas in any manner.

The long term stability of the reactor was evaluated over a 48 h period. The electrode response drifted about 1 mV/day due to temperature changes in the laboratory. When the electrodes were occasionally recalibrated with standard NaF solutions, the potentials remained constant to within ± 0.2 mV.

Conclusions

The HF generator yields very stable concentrations of hydrogen fluoride gas, relatively independent of the nature, or the flow rate of the carrier gas. Unlike the effusion techniques presently employed for calibration of analytical instruments, the generator can furnish high HF concentrations at high flow rates over extended periods of time with approximately the same requirements for temperature control. Also, unlike cylinders of anhydrous HF and associated metering valves, or dilute gaseous mixtures presently used for adsorption studies, the HF generator constitutes a safe, relatively cheap source of dilute gaseous mixtures whose composition is governed by thermodynamic principles.

Synthesis and vibrational spectra of tin(II) isothiocyanate adducts with some O- and N-donor ligands[1]

TEWFIK B. ABSI, RAMESH C. MAKHIJA, AND MARIO ONYSZCHUK[2]
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received June 28, 1977

TEWFIK B. ABSI, RAMESH C. MAKHIJA, and MARIO ONYSZCHUK. Can. J. Chem. **56**, 2039 (1978).

Five new adducts of $Sn(NCS)_2$ have been prepared and characterized: $Sn(NCS)_2 \cdot 2L$ (L = 2,6-dimethyl-γ-pyrone and *N*,*N*-dimethylacetamide), $Sn(NCS)_2 \cdot LL$ (LL = 1,10-phenanthroline and 2,2′-bipyridine), and Sn(NCS)(ox) (ox = 8-hydroxyquinolinate). By comparing their infrared and Raman spectra with those of $SnX_2 \cdot L$ (X = Cl, NCS; L = triphenylphosphine oxide), $SnX_2 \cdot 2L$ (X = Cl, NCS; L = dimethylsulphoxide and pyridine-*N*-oxide), $SnCl_2 \cdot LL$ (LL = 1,10-phenanthroline and 2,2′-bipyridine), and SnCl(ox), assignments have been made for ν(CN), ν(CS), and δ(NCS) vibrations; these suggest the presence of N-bonded and —NCS— bridge-bonded thiocyanate groups. Molecular weight, conductivity, and X-ray powder diffraction data support the conclusion that the adducts with the oxygen donor ligands are molecular with only N-bonded thiocyanate groups. Adducts with the bidentate nitrogen donor ligands are polymeric and have —NCS— bridging and N-bonded thiocyanate.

TEWFIK B. ABSI, RAMESH C. MAKHIJA et MARIO ONYSZCHUK. Can. J. Chem. **56**, 2039 (1978).

On a préparé et caractérisé cinq nouveaux adduits du $Sn(NCS)_2$: $Sn(NCS)_2 \cdot 2L$ (L = diméthyl-2,6 γ-pyrone et *N*,*N*-diméthylacétamide), $Sn(NCS)_2 \cdot LL$ (LL = phénanthroline-1,10 et bipyridine-2,2′) et Sn(NCS)(ox) (ox = hydroxy-8 quinolinate). En comparant leurs spectres infrarouge et Raman avec ceux de $SnX_2 \cdot L$ (X = Cl, NCS; L = oxyde de triphénylphosphine), $SnX_2 \cdot 2L$ (X = Cl, NCS; L = diméthylsulphoxyde et pyridine *N*-oxyde), $SnCl_2 \cdot LL$ (LL = phénanthroline-1,10 et bipyridine-2,2′) et SnCl(ox), on a pu faire des attributions pour les vibrations du ν(CN), ν(CS) et δ(NCS); celles-ci suggèrent la présence de groupes thiocyanates liés par l'azote et pontés par le —NCS—. Les données de poids moléculaires, de conductivité et de diffraction de rayon-X des poudres sont en accord avec la conclusion que les adduits avec les ligands donneurs d'oxygène sont moléculaires et n'impliquent que des groupes thiocyanates liés par l'azote. Les adduits avec les ligands d'azote donneurs bidentates sont des polymères et possèdent des groupes NCS assurant les ponts et des thiocyanates liés par l'azote.

Introduction

Although several complex ions (1–3) and neutral adducts (4) of tin(II) thiocyanate have been reported, little is known about their vibrational frequencies and mode of thiocyanate bonding, which may be —NCS, —SCN, —NCS—, or variations of the latter. We have re-examined the previously reported neutral complexes (4) and have made five new ones with the objective of obtaining physical data and vibrational spectra which might reveal the type of thiocyanate bonding.

Experimental

Anhydrous tin(II) thiocyanate (3) and tin(II) chloride (5) were prepared by literature methods. *N*,*N*-Dimethylacetamide (dma) and dimethylsulphoxide (dmso) were dried over a molecular sieve and distilled before use. The crystalline ligands 2,6-dimethyl-γ-pyrone (dmp), 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen), triphenylphosphine oxide (tppo), and 8-hydroxyquinoline (Hox) had the required melting points after commercial samples were dried in a vacuum. All manipulations were done under dry nitrogen in a glove-bag.

Infrared spectra (4000–400 cm^{-1}) of samples as Nujol mulls and ethanol solutions were recorded on a Perkin-Elmer 521 spectrophotometer. Raman spectra (3000–30 cm^{-1}) of powdered samples in sealed capillary tubes at −40°C were recorded on a Jarrell-Ash 25-300 instrument using either 647.1 or 514.5 nm laser excitation. Electrical conductivities[3] at 25°C of freshly prepared ethanol solutions of $Sn(NCS)_2$ and acetone solutions of $Sn(NCS)_2$ adducts with the oxygen donor ligands were made with a Radiometer-Copenhagen Model CDM3 conductivity meter. Molecular weights[3] in acetone solution were determined by vapour pressure osmometry by Galbraith Laboratories Inc., Knoxville, Tennessee. X-ray powder diffraction *d*-spacings[3] were obtained with a Debye-Scherrer camera using Ni-filtered CuK_α radiation (λ = 1.5418 Å). Microanalyses for C, H, and N were done by Chemalytics Inc., Tempe, Arizona. Tin was determined as the oxide after samples were treated with nitric acid and ignited at 800°C. Chlorine was determined gravimetrically as silver chloride.

The adducts $Sn(NCS)_2 \cdot 2dmso$, $Sn(NCS)_2 \cdot tppo$, $SnCl_2 \cdot 2dmso$, $SnCl_2 \cdot 2pno$, $SnCl_2 \cdot bipy$, $SnCl_2 \cdot phen$, and SnCl(ox)

were prepared as previously reported (4–6). Satisfactory melting points and tin and/or chlorine analyses were obtained in all cases.

$Sn(NCS)_2$·2dma was obtained when water was added dropwise to a solution of $Sn(NCS)_2$ (0.01 mmol, 2.4 g) in dma (20 ml) until white needles precipitated; these were filtered and washed with ether. *Anal.* calcd. for $C_{10}H_{18}N_4O_2S_2Sn$: C 29.36, H 4.43, N 13.70, Sn 29.01; found: C 28.5, H 4.5, N 13.4, Sn 29.9; mp 92°C; yield 63%. After adding a solution of $Sn(NCS)_2$ (0.01 mmol, 2.4 g) in ethanol (20 ml) to a solution of bipy (0.01 mmol, 1.6 g) in ethanol (15 ml), a yellow precipitate formed. This mixture was stirred overnight and the yellow product, *$Sn(NCS)_2$·bipy*, was filtered and washed with ether. *Anal.* calcd. for $C_{12}H_8N_2S_2Sn$: C 36.86, H 2.06, N 14.32, Sn 30.35; found: C 36.6, H 2.4, N 14.5, Sn 30.3; mp 235°C (dec.); yield 81%. The following adducts were prepared similarly: *$Sn(NCS)_2$·phen. Anal.* calcd. for $C_{14}H_8N_4S_2Sn$: C 40.51, H 1.94, N 13.50, Sn 28.60; found: C 41.1, H 2.1, N 13.7, Sn 27.9; mp 252°C (dec.); yield 90%. *Sn(NCS)(ox). Anal.* calcd. for $C_{10}H_6N_2OSSn$: C 37.43, H 1.88, N 8.73, Sn 36.98; found: C 36.9, H 1.7, N 9.0, Sn 36.3; mp 290°C (dec.); yield 83%. *$Sn(NCS)_2$·2dmp. Anal.* calcd. for $C_{16}H_{16}N_2O_4S_2Sn$: C 39.78, H 3.34, N 5.80, Sn 24.57; found: C 39.5, H 3.3, N 5.4, Sn 24.6; mp 154°C; yield 65%; was obtained when $Sn(NCS)_2$ (0.01 mmol) and dmp (0.02 mmol) were combined in ethanol (35 ml).

Results and Discussion

The splitting of the ν(CN) and ν(CS) bands in the infrared spectrum of crystalline $Sn(NCS)_2$ (Table 1) is consistent with the presence of two crystallographically distinct thiocyanate groups as shown recently by an X-ray diffraction crystal structure determination (7). Although each thiocyanate group fulfils a bridging function, the shortest distances (2.20 and 2.27 Å) are Sn—N, mainly covalent, interactions. Therefore, it is not surprising that $Sn(NCS)_2$ is monomeric in acetone solution (M, found: 226; calcd.: 235) and a nonelectrolyte in ethanol solution (molar conductance, $\Lambda(0.0313\ M) = 2.64 \times 10^{-3}$ ohm^{-1} cm^2 mol^{-1}). Retention of N-bonded thiocyanate groups by $Sn(NCS)_2$ in ethanol solution is confirmed by the intensity of ν(CN), measured by Ramsay's direct integration method (8), being $26.5 \times 10^4\ M^{-1}$ cm^{-2} (per thiocyanate group) which is in the range $17–32 \times 10^4\ M^{-1}$ cm^{-2} characteristic of N-bonded transition metal thiocyanates in methanol solution (9). Moreover, the change of the ν(CN) absorption from two peaks at 2113 and 2080 cm^{-1} in the solid state to a single band at 2050 cm^{-1} in ethanol solution is also consistent with the disappearance of thiocyanate bridges and the presence of only N-bonded thiocyanate (9, 10).

The oxygen donor ligands: pno, dmso, dma, and dmp form 1:2 complexes which (*i*) melt sharply at moderate temperatures (90 to 160°C), (*ii*) dissolve readily in such polar solvents as ethanol and acetone, and (*iii*) are highly dissociated in acetone solution (dissociation 40 to 76%, calculated from the molecular weight data) in which they are also nonelectrolytes ($\Lambda = 6.5 \times 10^{-3}$ to 15.8×10^{-3} ohm^{-1} cm^2 mol^{-1}). These physical properties, together with the lowering of the ν(CN) and raising of the ν(CS) frequencies relative to those of $Sn(NCS)_2$, support

the conclusion that these complexes are molecular in the solid state with thiocyanate groups N-bonded. X-ray powder diffraction patterns of the dmso and dma adducts consisted of 21 and 17 sharp lines respectively, indicating low crystal symmetry. The coordination sphere around Sn(II) in 1:2 adducts should be tetrahedral if the lone electron pair is not stereochemically important, or bisphenoid if the lone electron pair occupies an equatorial site in a trigonal bipyramidal arrangement of electron pairs around Sn(II) (11).

The bidentate nitrogen-donor ligands bipy and phen form 1:1 complexes which melt with decomposition at 235 and 250°C, respectively, and are insoluble in common polar and non-polar organic solvents; properties which strongly suggest that they are polymeric. Their ν(CN), ν(CS), and δ(NCS) frequencies are consistent with the presence of both N-bonded and bridging thiocyanate groups, suggesting that units are linked together by thiocyanate bridges. The oxinate Sn(NCS)(ox) also has physical properties and thiocyanate frequencies consistent with a polymeric structure in which thiocyanate groups are bridging.

Study of the electrolytic reduction of Cr(VI) in aqueous solutions of chromic acid by the rotating disc electrode method

HÉLIO C. CHAGAS

Instituto de Química, Universidade de São Paulo, C. P. 20780, São Paulo, Brasil

Received December 15, 1977

HÉLIO C. CHAGAS. Can. J. Chem. **56**, 2042 (1978).

The Cr^{6+}/Cr^{3+} reduction in aqueous solution is studied in the presence of sulfate and chloride ions by the rotating disc electrode method. In the low chromic acid concentration region, the results exhibit some differences in relation to those obtained using more concentrated solutions. However, it is demonstrated that in the presence of sulfate and chloride ions there is a chemical reaction preceding the electrochemical process, confirming a previous suggestion. Results for Cr^{6+}/Cr^{3+} reduction process in perchloric acid medium at various temperatures are presented and a reduction mechanism is suggested.

HÉLIO C. CHAGAS. Can. J. Chem. **56**, 2042 (1978).

On a étudié la réduction Cr^{6+}/Cr^{3+} en solution aqueuse, en présence d'ions sulfates et d'ions chlorures, en faisant appel à la méthode d'électrode de disque tournant. A de basses concentrations d'acide chromique, les résultats présentent quelques différences par rapport à ceux obtenus dans des solutions plus concentrées. Toutefois, on a démontré lorsque l'on travaille en présence d'ions sulfates et d'ions chlorures, qu'il se produit une réaction chimique précédant le processus électrochimique; cette démonstration confirme une suggestion antérieure. On présente des résultats relatifs au processus de réduction Cr^{6+}/Cr^{3+} en milieu acide perchlorique à diverses températures et on suggère un mécanisme pour la réduction.

[Traduit par le journal]

Introduction

Although the kinetics of the electrolytic reduction of chromium have been extensively studied, a theoretical model which explains all of the available experimental results remains to be formulated. Ryan (1) has reviewed the state of this problem up to 1964.

It is known that the deposition of chromium from aqueous solutions of hexavalent electrolytes occurs only in the presence of certain added ions such as SO_4^{2-}.

Polarization curves for the reduction of chromic acid in the presence of SO_4^{2-} ions exhibit two regions (2–4). In the first region, which has two maxima, a process corresponding to the reduction Cr^{6+}/Cr^{3+} and the formation of a cathode film occur. In the second region, i.e., at more cathodic potentials, three simultaneous processes are observed: the reduction Cr^{6+}/Cr^{3+}, evolution of gaseous hydrogen ($2H^+/H_2$), and deposition of metallic chromium (Cr^{6+}/Cr^0). The SO_4^{2-} ions play a role in the formation of the cathodic film, via which the reduction to metallic chromium takes place.

Various investigators (1, 5, 6) have emphasized the importance of the formation of complex ions in the reduction of chromium. Thus, the intermediate formation of complex chromium–chromate ions at the electrode surface was suggested by Ryan (1) as a possible mechanism through which hexavalent chromium could be deposited electrolytically as metallic chromium.

On the other hand, participation of atomic hydrogen in the reduction Cr^{6+}/Cr^{3+} was pointed out by Usachev (7) and confirmed by Marchenko and coworkers (8). Additional evidence for the role of atomic hydrogen in the reduction Cr^{6+}/Cr^{3+} was obtained by Jones and Saiddington (9) from microscopic studies.

Using the rotating disc electrode method and working at the potential of the first maximum of the polarization curve for the reduction of chromic acid in the presence of SO_4^{2-} ions (region in which only the reduction Cr^{6+}/Cr^{3+} occurs), Budevskii and Toshev (10) demonstrated that a chemical process must occur prior to the electrode process. These authors also noted that phenomena such as dissolution of the cathodic film, formation of electroactive complexes, etc. might also be responsible for the observed behavior.

As has been observed by Biryukov (11), it is difficult to make valid comparisons between the mechanisms of reduction of chromium in stirred and stationary systems. Thus, for example, the cathodic films formed at stationary electrodes in the presence of sulfuric acid at low chromic acid concentrations attain considerable thickness and are visually observable (4); in contrast, film formation could not be visually detected at the rotating disc electrode at velocities above 25 rd/s.

Nevertheless, in addition to other advantages, the well defined hydrodynamic conditions for material transport which are obtained in the rotating disc electrode method justify its application to the eluci-

dation of the mechanism of the chromium reduction process.

In the present work, we report the results of a rotating disc electrode study of the effects of SO_4^{2-} and Cl^- ions on the Cr^{6+}/Cr^{3+} reduction process in aqueous solutions of chromic acid. In addition, we utilize the rotating disc electrode method to examine the Cr^{6+}/Cr^{3+} reduction kinetics at various temperatures in perchloric acid medium.

Experimental

The rotating disc electrode apparatus utilized in this work has been previously described (12, 13). Curves of the current as a function of the working electrode potential were automatically recorded for each frequency of electrode rotation. This frequency was varied in integral steps of the square root of the frequency $f^{1/2}$ from 2 to 10 $Hz^{1/2}$.

The electrode potential scan rate was fixed at 10 mV/s in all experiments, curves always being registered from less cathodic to more cathodic potentials.

A gold disc electrode having a diameter of 4.61 mm was employed throughout. This electrode was polished and checked for the existence of leakage in the manner previously described (12). A platinum foil electrode with an approximate area of 12 cm^2 was used as the auxiliary electrode and a saturated calomel electrode (SCE) utilized as the reference electrode.

The electrolytic cell employed was similar to that described by Johnson (14), having a capacity of about 200 ml and an external thermostatable water jacket.

Chromic acid solutions were prepared by dissolution of chromic oxide (Carlo Erba, AR grade) in triply distilled water. Stock solutions of sulfuric, hydrochloric, and perchloric acids were similarly prepared in triply distilled water from analytical grade reagents.

The study of the reduction of hexavalent chromium ions in the presence of sulfate ions was carried out at 25°C employing chromic acid concentrations of 0.1, 0.2, 0.3, and 0.4 *M*. The reduction in the presence of chloride ions was studied at a chromic acid concentration of 0.1 *M*, varying the chloride ion concentration in the range 0.3–2.6 m*M*.

In these experiments, the SO_4^{2-} and Cl^- ion concentrations were varied in increments by addition of aliquots from the appropriate stock solution to the electrolyte present in the electrolytic cell.

In order to obtain reproducible voltammograms, the gold electrode was periodically polished with Buehler 0.05 μm gamma micropolish, and the potential scan limited to the region up to the first maximum of the polarization curve.

In the study of the reduction Cr^{6+}/Cr^{3+} in 0.5 *M* perchloric acid, the hexavalent chromium concentration was varied from 0.10 to 0.29 m*M*, experiments being carried out at 25.0, 30.0, 35.0, and 40.0°C.

Oxygen was eliminated from the solutions by bubbling with purified nitrogen for 30 min and all subsequent manipulations and measurements carried out under a nitrogen atmosphere.

Kinematic viscosities of 0.5 *M* perchloric acid were calculated from density and viscosity measurements at various temperatures.

Results and Discussion

Effect of SO_4^{2-} Ions on the Reduction Cr^{6+}/Cr^{3+}

Curves of the current as a function of the electrode potential for the Cr^{6+}/Cr^{3+} reduction process in the presence of SO_4^{2-} ions exhibit a relatively broad maximum. Denoting the maximum measured current density by i_{lim}, graphs of $i_{lim}/f^{1/2}$ vs. i_{lim} were constructed from the polarization curves. These graphs, which refer to a chromic acid concentration of 0.2 *M*, are shown in Fig. 1. Analogous results were obtained at chromic acid concentration of 0.1, 0.3, and 0.4 *M*.

Within the framework of the theory developed by Vielstich and Jahn (15) the linear behavior of these graphs permits us to infer that the electrochemical process is preceded by a chemical reaction under these conditions.

For a system of the type

$$A_1 \underset{k_2}{\overset{k_1}{\rightleftarrows}} A_2$$

$$A_1 + ne^- \rightarrow P$$

in which a chemical reaction takes place in the solution and a charge transfer reaction occurs at the surface of the rotating disc electrode, Vielstich and Jahn have developed the following expression:

$$[1] \qquad (i_{lim}/\omega^{1/2}) = b + ci_{lim}$$

where $b = 0.62\, nF\nu^{-1/6}D^{2/3}C^0 = i_{lim}{}^d/\omega^{1/2}$, $i_{lim}{}^d$ = limiting diffusion current density, $c = -(1/1.62 D^{1/3}\nu^{1/6})\,(k_1/k_2)\,\delta_k$, and $\delta_k = 1/\sqrt{(k_1 + k_2)/D}$ = thickness of the kinetic layer, and n, F, ν, D, C^0, and ω have the usual significance.

In the limit of $\omega^{1/2} \rightarrow \infty$, eq. [1] permits us to

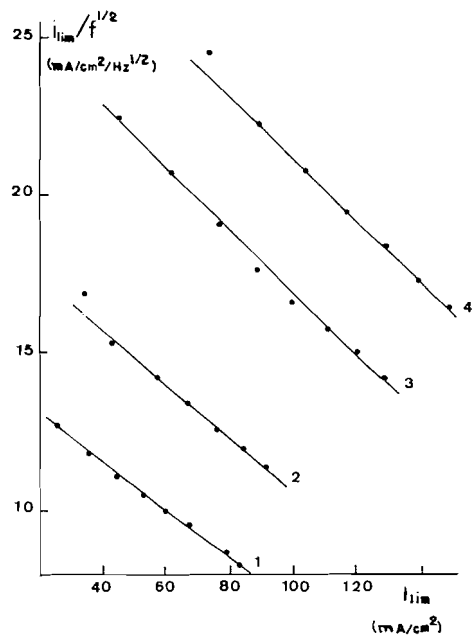

FIG. 1. Plot of $i_{lim}/f^{1/2}$ vs. i_{lim}, $[CrO_3] = 0.2$ *M*. $[SO_4^{2-}]$: (*1*) 1.76 m*M*; (*2*) 2.34 m*M*; (*3*) 3.46 m*M*; (*4*) 4.68 m*M*. $t = 25$°C.

For personal use only.

determine the current density i_k corresponding to the kinetic process

$$[2] \qquad i_k = -(b/c)$$

which should be independent of ω.

Equation [1] can thus be put in the following form:

$$[3] \qquad (1/i_{lim}) = (1/i_{lim}^{d}) + (1/i_k)$$

Equation [3] has been derived by Budevskii (16) for the same mechanistic model and utilized by Budevskii and Toshev (10) in their study of the Cr^{6+}/Cr^{3+} reduction process in 2 *M* chromic acid in the presence of SO_4^{2-} ions.

As shown in Figs. 2 and 3, the values of $i_{lim}^{d}/f^{1/2}$ and i_k, calculated from the plots of $i_{lim}/f^{1/2}$ vs. i_{lim}, depend on the concentration of SO_4^{2-} ions and of chromic acid.

As can be seen in Fig. 2 for 0.1, 0.2, and 0.4 *M* chromic acid solutions, the variation of the ratio $(i_{lim}^{d}/f^{1/2})$ with SO_4^{2-} concentration gives evidence for two linear regions of different slope. Thus, at low sulfate ion concentrations, this ratio is directly proportional to the sulfate ion concentration. The value of the slope in this region varies little with the chromic acid concentration and is larger than that observed at higher SO_4^{2-} concentrations.

Figure 3 demonstrates that at SO_4^{2-} concentrations above 2 m*M*, a linear increase in the kinetic current is observed.

Effect of the Presence of Cl^- Ions on the Cr^{6+}/Cr^{3+} Reduction Process

The study of the effect of Cl^- ions on the Cr^{6+}/Cr^{3+} reduction process was performed in a manner similar to that described for SO_4^{2-} ions.

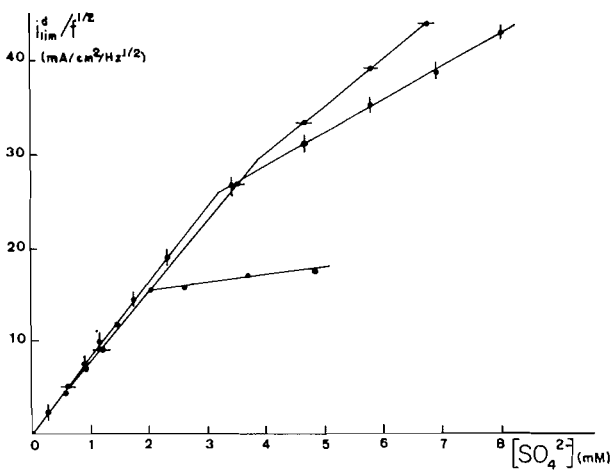

FIG. 2. Plot of $i_{lim}^{d}/f^{1/2}$ vs. $[SO_4^{2-}]$. $[CrO_3]$: ●, 0.1 *M*; ◐, 0.2 *M*; ◒, 0.4 *M*. t = 25°C.

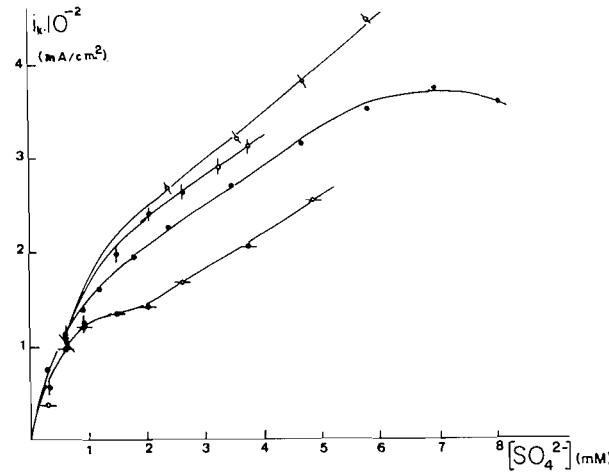

FIG. 3. Plot of i_k vs. $[SO_4^{2-}]$. $[CrO_3]$: ○, 0.1 *M*; ●, 0.2 *M*; ◐, 0.3 *M*; ◒, 0.4 *M*. t = 25°C.

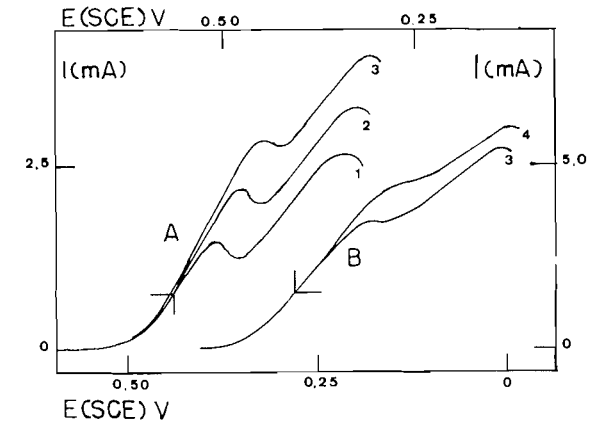

FIG. 4. Voltamograms. *A*, f = 16 Hz; *B*, *f* = 64 Hz. $[Cl^-]$: (*1*) 1.64 m*M*; (*2*) 1.96 m*M*; (*3*) 2.28 m*M*; (*4*) 2.60 m*M*. t = 25°C.

The polarization curves obtained for 0.1 *M* chromic acid solution in the presence of Cl^- ions are shown in Fig. 4. These curves exhibit two waves at potentials more positive than that at which electrode passivation occurs. In contrast to the behavior observed in the presence of SO_4^{2-} ions, the peaks (limiting currents) of the polarization curves are sharp in the presence of Cl^-. At the higher Cl^- concentrations, the first wave again tends to disappear as the velocity of rotation of the electrode is increased.

Graphs of $i_{lim}/f^{1/2}$ as a function of i_{lim} at various Cl^- concentrations for the first and second waves are shown in Figs. 5 and 6, respectively.

The linear behavior of the plots of Fig. 5 indicates that the Cr^{6+}/Cr^{3+} reduction process in the presence of Cl^- ions must also be preceded by a chemical reaction. Plots of values of the ratio $i_{lim}^{d}/f^{1/2}$ and of

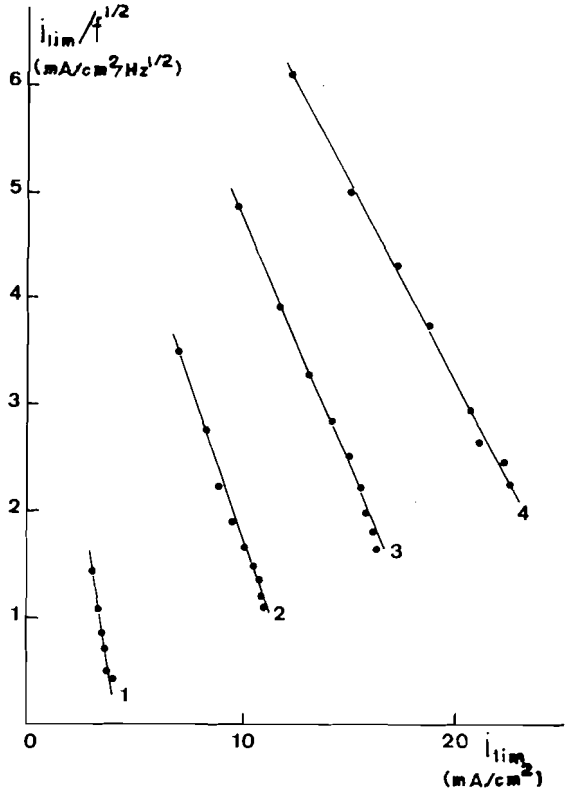

FIG. 5. Plot of $i_{lim}/f^{1/2}$ vs. i_{lim}, t = 25°C for the less cathodic wave. [CrO_3] = 0.1 M and [Cl^-]: (*1*) 1.32 mM; (*2*) 1.64 mM; (*3*) 1.96 mM; (*4*) 2.28 mM. t = 25°C.

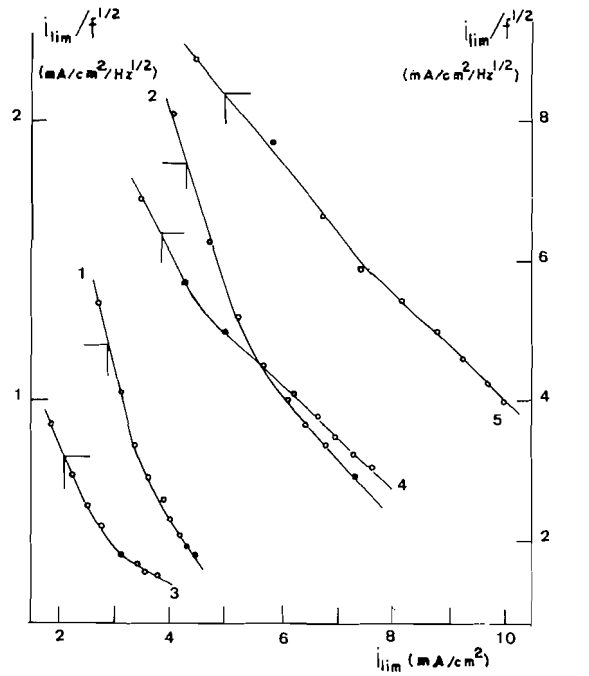

FIG. 6. Plot of $i_{lim}/f^{1/2}$ vs. i_{lim} for the more cathodic wave. [CrO_3] = 0.1 M and [Cl^-]: (*1*) 0.66 mM; (*2*) 0.99 mM; (*3*) 1.32 mM; (*4*) 1.96 mM; (*5*) 2.60 mM. t = 25°C.

the kinetic current density i_k vs. the Cl^- ion concentration are shown in Fig. 7.

Over the small interval of Cl^- concentration in which the first wave could be studied, the kinetic current density i_k is linearly related to the Cl^- concentrations above 1 mM (Fig. 7).

Study of the Reduction Cr^{6+}/Cr^{3+} in 0.5 M Perchloric Acid

At the $Cr_2O_7^{2-}$ concentrations and electrode rotation rates employed, the polarization curves for the reduction Cr^{6+}/Cr^{3+} in 0.5 M perchloric acid exhibit a well-defined plateau corresponding to a limiting diffusion current density i_{lim}^d. These limiting currents obey the Levich equation, being directly proportional to $f^{1/2}$, at the various $Cr_2O_7^{2-}$ concentrations (Fig. 8). Additionally, the ratio $i_{lim}^d/f^{1/2}$ is a linear function of the $Cr_2O_7^{2-}$ concentration throughout the temperature range investigated (Fig. 9).

Table 1 presents data for the kinematic viscosity of 0.5 M perchloric acid at various temperatures, diffusion coefficients obtained by application of the Levich equation to the disc electrode data, and solvodynamic radii calculated from the Stokes-Einstein equation: $(D\eta/T) = k/6\pi r$.

In the experimental temperature range, the diffusion coefficient data exhibit typical Arrhenius behavior ($D \times 10^5$ cm^2/s) = 1153 exp ($-2060/T$) with an activation energy for diffusion of E_D = 4.1 kcal/mol.

The experimental polarization curve data were analyzed in terms of the treatment developed by Opekar and Beran (17), using the following equation

$$[4] \quad \log (I/I_{lim}^d - I) = A - 2.30\,(\alpha_i n_i F/RT)\,(E - E_i^0)$$

In this equation, A is a constant (dependent on $f^{1/2}$), E_i^0 the standard potential, α_i the charge transfer coefficient, and n_i the number of electrons involved in the process.

Curves of log $(I/I_{lim}^d - I)$ as function of the elec-

trode potential E at a rotation frequency of $f = 49$ Hz and a $Cr_2O_7{}^{2-}$ concentration of 0.13 mM are shown in Fig. 10.

These curves exhibit two linear portions of different slope at all temperatures investigated, indicating that the reduction Cr^{6+}/Cr^{3+} occurs in two steps. Values of the products $\alpha_i n_i$ calculated from the slopes of Fig. 10 corresponding to the linear regions at less cathodic ($\alpha_1 n_1$) and more cathodic ($\alpha_2 n_2$) potentials are presented in Table 2. In addition, this table contains values of the charge transfer coefficients α_1 and α_2 calculated assuming that n_1 and n_2 refer to one- and two-electron steps, respectively.[1]

[1]In principle the data are not sufficient to eliminate the possibility that the two rate determining steps occur in parallel with $\alpha_2 n_2$ corresponding to a 3-electron process which becomes the faster step at more cathodic electrode potentials.

Conclusions

The present work demonstrates that, in the presence of sulfate ions, the reduction Cr^{6+}/Cr^{3+} must be preceded by a chemical reaction, confirming the previous suggestion of Budevskii and Toshev (10). Our results at low chromic acid concentrations exhibit,

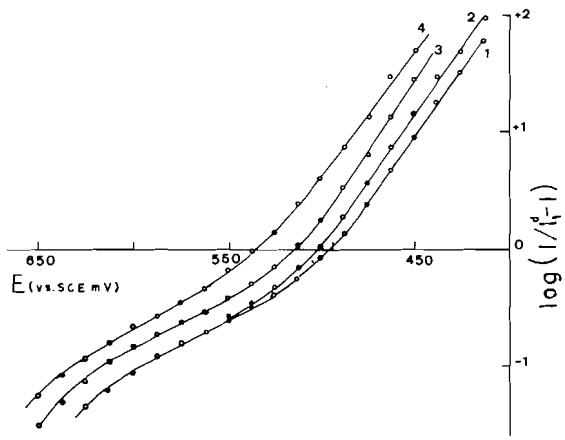

FIG. 10. Dependence of log $I/I_{lim}^{d} - I$ upon electrode potential, $f = 49$ Hz, $[Cr_2O_7^{2-}] = 0.13$ mM. $[ClO_4^-] = 0.5$ M. t: (*1*) 25.0°C; (*2*) 30.0°C; (*3*) 35.0°C; (*4*) 40.0°C.

TABLE 2. Charge transfer coefficients for Cr^{6+}/Cr^{3+} reduction

T (°C)	$\alpha_1 n_1$	n_1	α_1	$\alpha_2 n_2$	n_2	α_2
25.0	0.56	1	0.56	1.28	2	0.64
30.0	0.52		0.52	1.47		0.74
35.0	0.51		0.51	1.36		0.68
40.0	0.56		0.56	1.41		0.71
			$\bar{\alpha}_1 = 0.54$			$\bar{\alpha}_2 = 0.69$

however, several differences in relation to those obtained by these authors. Although the kinetic current i_k does depend on the sulfate ion concentration (see Fig. 3), we do not observe the direct proportionality reported by Budevskii and Toshev using more concentrated solutions.

If we assume that the chemical reaction preceding the electrochemical process is attributable to reduction of hexavalent chromium by atomic hydrogen (8):

$$Cr_2O_7^{2-} + 8H^+ + 6H_{at} \rightarrow 2Cr^{3+} + 7H_2O$$

we can conclude that the generation of atomic hydrogen, catalyzed by the presence of sulfate ions (7) in the cathode film, may be 'inhibited' by excess SO_4^{2-} ions. Such 'inhibition' would lead to a decrease in the kinetic current, of the type observed in Fig. 3 at chromic acid concentration of 0.2 M and for sulfate concentrations above 6 mM. Potential sources of an inhibitory effect of this type would be modifications of the composition and/or structure of the cathode film.

The sulfate concentrations which correspond to the sharp breaks in the curves of $i_{lim}^{d}/f^{1/2}$ vs. SO_4^{2-} concentration (Fig. 2) are approximately those above which a linear relationship is observed between the kinetic current i_k and SO_4^{2-} concentration (Fig. 3). This change in behavior probably bears a relationship as well, to modifications of the cathode film.

Using a value of 1×10^{-5} to 3×10^{-5} cm^2/s for the diffusion coefficient in the Levich equation, and an analysis similar to that employed by Budevskii and Toshev, we calculate that, in the region where $i_{lim}^{d}/f^{1/2}$ is directly proportional to the sulfate concentration, the number of electrons exchanged is of the order of 50–25 per sulfate ion. Since three electrons are consumed in the reduction per molecule of CrO_3, we obtain the result that approximately 17–8 molecules of CrO_3 are reduced per sulfate ion in the cathode film. This latter value is roughly twice that calculated by Budevskii and Toshev.

As can be seen in Figs. 4 and 6 the effect of Cl^- ion on the reduction Cr^{6+}/Cr^{3+} is more complex than that of SO_4^{2-} ions. The two peaks of the curve in Fig. 4 are associated with the formation of cathodic films on the electrode surface at two different potentials. The breaks in the curves of Fig. 6 may be related to the interaction of the effects of these two films on the reduction process.

In the non-complexing perchloric acid medium, the reduction Cr^{6+}/Cr^{3+} occurs in an entirely different manner. Thus, in the range of temperatures studied, the reduction process exhibits a region which is limited by convective diffusion, the calculated activation energy ($E_D = 4.1$ kcal/mol) being within the normal range for a diffusional process. It was additionally verified (Tables 1 and 2) that the solvodynamic radius of the dichromate ion and the charge transfer coefficients α_1 and α_2 are temperature independent.

Taken as a whole, the results indicate that in perchloric acid the Cr^{6+}/Cr^{3+} reduction process occurs in two steps in accord with the following scheme:

$$Cr^{6+} \xrightarrow{1e^-,\ \bar{\alpha}_1 = 0.54} Cr^{5+} \xrightarrow{2e^-,\ \bar{\alpha}_2 = 0.69} Cr^{3+}$$

At less cathodic potentials, the first step is rate limiting and at more cathodic potentials the second step is rate limiting.

Reçu le 30 janvier 1978

JEAN-CLAUDE RICHER, MARC-ANDRÉ POIRIER, YVETTE MARONI et GEORGES MANUEL. Can. J. Chem. **56**, 2049 (1978).

On présente la réaction d'époxydation des *tert*-butyl-1 (**1***a*), triméthylsilyl-1 (**1***b*) et triméthylgermyl-1 (**1***c*) diméthyl-4,4 cyclohexènes et on examine la stéréochimie de l'ouverture des époxydes correspondants (**3***a*, **3***b*, **3***c*) par l'hydrure double de lithium et d'aluminium, par le méthanol et enfin par l'eau en milieu acidulé; on note que par opposition à la régiochimie de l'ouverture de **3***a*, celle de **3***b* et **3***c* est complètement inversée par les effets électroniques des groupes triméthylsilyle et triméthylgermyle.

JEAN-CLAUDE RICHER, MARC-ANDRÉ POIRIER, YVETTE MARONI, and GEORGES MANUEL. Can. J. Chem. **56**, 2049 (1978).

Epoxidation of 1-*tert*-butyl (**1***a*), 1-trimethylsilyl (**1***b*), and 1-trimethylgermyl (**1***c*) 4,4-dimethylcyclohexenes is described and the stereochemistry of the ring opening of the resulting epoxides (**3***a*, **3***b*, **3***c*) by lithium aluminium hydride as well as methanol and water in acidic medium is examined. The regiochemistry of the ring opening of **3***a* is completely reversed, in the case of **3***b* and **3***c*, by the electronic effects of the trimethylsilyl and trimethylgermyl groups.

Introduction

Dans une publication antérieure (1), on a décrit la synthèse des alcènes vinyliques et allyliques des types **1** et **2**, tout en examinant la stéréochimie de leur réaction d'hydroboration (2).

L'étude d'α,β-époxyvinylsilanes suscite beaucoup d'intérêt (3–7). Dans cette communication, on rapporte les résultats obtenus lors de l'époxydation des alcènes du type **1** par l'acide *m*-chloroperbenzoïque (AMCP) et lors de l'ouverture des époxydes du type **3** par l'hydrure double de lithium et d'aluminium ($LiAlH_4$), par le méthanol et l'eau acidulés. Ces résultats permettent de mettre en évidence les influences relatives des groupes *tert*-butyle et triméthylsilyle (ou germyle).

a M = C; R = CH_3
b M = Si; R = CH_3
c M = Ge; R = CH_3

Résultats et discussion

La réaction d'époxydation de l'alcène carboné **1***a* par l'acide *m*-chloroperbenzoïque (AMCP), conduit à l'époxyde **3***a*. L'époxydation de l'alcène silylé **1***b* (8) et germylé (**1***c*) par AMCP conduit d'une façon analogue aux époxydes **3***b* et **3***c*.

TABLEAU 1. Pourcentages relatifs des isomères obtenus par réduction des époxydes du type **3**

	% alcool	
		Epoxyde	**4**	**5**
3*a*	0	100
3*b*	99	1
3*c*	96	4

Les résultats obtenus lors de la réduction des époxydes du type **3** par l'hydrure double de lithium et d'aluminium sont rapportés dans le tableau 1. Comme l'indique le tableau 1, l'ouverture de l'époxyde carboné **3***a* par $LiAlH_4$ procède par une ouverture *trans* et diaxiale avec attaque sur le carbone le plus dégagé. En série silylée (**3***b*) et germylée (**3***c*), la régiochimie de la réaction est inversée.

La réduction des époxydes silylé (**3***b*) et germylé (**3***c*), en accord avec les résultats de Robbins et

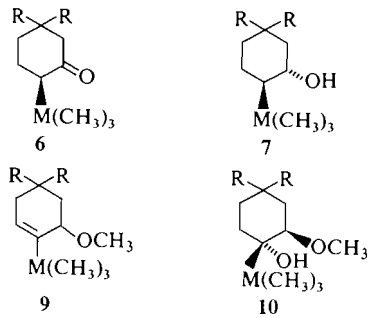
8*a* 8*b*

SCHÉMA 1

Whitham (9), procède par une attaque nucléophile au carbone-1 avec inversion de configuration, conduisant respectivement aux alcools **4***b* et **4***c*. La régiospécificité observée peut être expliquée par un état de transition (schéma 1, **8***a* M = Si, Ge) similaire à celui proposé par Eisch et Trainor (10) dans le cas des α,β-époxyvinylsilanes.

L'effet électronique développé dans cet état de transition par le groupe triméthylsilyle (8) l'emporte sur les fortes interactions pouvant intervenir entre l'un des méthyles du groupe $(CH_3)_3M$ et le réactif. L'hypothèse d'un réarrangement, en présence d'un acide de Lewis (8, 9, 11), des époxydes silylés et germylés en cétone **6** puis réduction de celle-ci ne



peut être retenue, puisque la réduction de **6***b* par $LiAlH_4$ conduit à 15% de **7***b* et 85% de **4***b* (12) et d'ailleurs la préférence de l'ouverture en α,β-époxysilanes a déjà été observée dans plusieurs travaux (8, 9, 13).

La régiochimie de l'ouverture des époxydes carbonés, silylés et germylés par le méthanol en milieu acide est la même que celle observée lors de leur réduction par $LiAlH_4$. L'ouverture de l'époxyde carboné **3***a* par le méthanol en milieu légèrement acide, conduit à 67% de *tert*-butyl-2 diméthyl-5,5 cyclohexanone **6***a* et à 33% d'éther allylique **9***a*. L'éther allylique **9***a* provient essentiellement de l'hydroxy-éther **10***a* qui se forme d'une façon transitoire et qui se déshydrate facilement en milieu acide (14). On a montré que la cétone **6***a* peut se former par réarrangement de l'éther allylique **9***a* en milieu acide en remettant le mélange **6***a*–**9***a* dans les conditions décrites précédemment et en notant que celui-ci évoluait vers un nouveau mélange constitué presqu'uniquement de cétone **6***a*. On pourrait aussi suggérer que la cétone **6***a* provient d'un réarrangement pur et simple de **3***a* en milieu acide; le fait que l'on n'isole pas de cétone **6***a* par traitement de **3***a* en milieu acide aqueux indique que cette dernière suggestion ne doit pas être retenue.

Plusieurs études concernant l'ouverture d'α,β-époxyvinylsilanes en milieu acide ont été rapportées jusqu'à maintenant (9, 6, 15). Stork et Colvin (14) ont montré que l'ouverture des α,β-époxyvinylsilanes en milieu acide conduit à des composés carbonylés et ils ont suggéré que cette réaction procède suivant le schéma 2. Par ailleurs Hudrlik *et al.* (15) ont

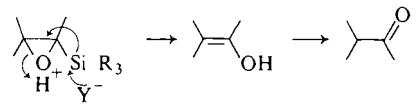


SCHÉMA 2

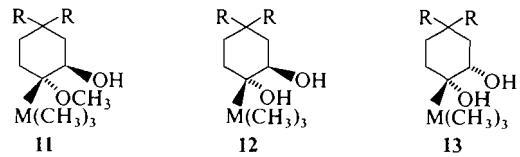
récemment observé des résultats semblables en série acyclique pour l'hydrolyse catalysée en milieu acide tandis qu'ils notaient la formation de diols en série cyclique.

Dans notre cas, l'ouverture des époxydes **3***b* et **3***c* par le méthanol en milieu acide dilué conduit uniquement aux composés de type **11**, en accord avec les résultats de Robbins et ses collaborateurs (9) et l'obtention de l'hydroxy éther **11** peut être expliquée



en se basant uniquement sur le fait que les groupes OH et $(CH_3)_3M$ où M = Si, Ge ne peuvent pas adopter la configuration *anti* nécessaire à une β-élimination (15).

La stéréo- et régiospécificité de cette réaction peut être rationalisée d'une façon similaire à celle proposée pour la réduction des époxydes **3***b* et **3***c* par $LiAlH_4$ (voir schéma 1, **8***b*).

On remarque que l'atome de germanium introduit des facteurs stéréoélectroniques comparables à ceux introduits par l'atome de silicium au cours de l'ouverture des époxydes du type **3**.

La stéréochimie de l'ouverture des époxydes **3** par l'eau en milieu acide ressemble beaucoup à celle de l'ouverture par le méthanol en milieu acide (9). Cette dernière nous a permis en premier lieu d'établir le sens de l'ouverture des époxydes du type **3**.

L'ouverture de l'époxyde **3***a* par l'eau en milieu acide conduit uniquement au composé **12***a*. Les résultats peuvent être interprétés par un mécanisme

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

similaire à celui proposé pour l'ouverture par le méthanol acidulé (schéma 1, **8***b*). Le diol **12***a* ne conduit pas à des produits de déshydratation ou de réarrangement et pourrait s'expliquer par des raisons de solubilité dans le milieu réactionnel.

L'ouverture des époxydes **3***b* et **3***c* par l'eau en milieu acide conduit aux diols *trans* **12***b* et **12***c* (9). Dans chacun des cas, seulement un stéréoisomère est isolé. Les configurations ont été déterminées par des méthodes spectrométriques telles que la rmn et par comparaison avec leurs isomères *cis* (**13**) obtenus par action du tétroxyde d'osmium (16, 17) sur les alcènes du type **1**.

Partie expérimentale

Les points de fusion ont été déterminés sur un appareil Cole-Parmer de la compagnie Instrument & Equipment.

Les spectres ir ont été pris sur un spectrophotomètre Beckman modèle IR-8 à double faisceau et sauf indication contraire, tous les spectres ont été pris entre deux plaques de NaCl.

Les spectres de résonance magnétique nucléaire ont été déterminés sur un spectromètre modèle C-60-H de la compagnie JEOL. Le solvant choisi est le $CDCl_3$ pour les séries carbonées et le tétrachlorure de carbone pour les séries silylées et germylées. Les déplacements chimiques sont exprimés en ppm et se réfèrent au tétraméthylsilane utilisé comme référence interne pour les séries carbonées; le chloroforme est utilisé comme référence interne pour les séries silylées et germylées. Les indices de réfraction ont été déterminés à l'aide d'un réfractomètre du type Abbé. La pureté de tous les nouveaux produits décrits dans ce travail a été déterminée par chromatographie en phase gazeuse et leur identité confirmée par spectrométrie de masse à l'aide d'un spectromètre Hitachi-Perkin-Elmer modèle RMU6-D opérant avec une énergie de faisceau d'électrons ionisant de 70eV.

Epoxydation des alcènes

De l'alcène carboné **1**a

Dans un ballon de 50 ml surmonté d'un refrigérant, on introduit (1.0 g) 6 mmol d'alcène **1***a* (18) dilué dans 6 ml de $CHCl_3$ et 12 ml de CH_2Cl_2. A cette solution, on ajoute rapidement 2.0 g (12 mmol) d'acide *m*-chloroperbenzoïque et on chauffe à 40–45°C le ballon sous agitation, pendant 24 h.

Le mélange réactionnel est filtré et le précipité lavé avec du chloroforme. Le filtrat est lavé avec une solution de soude 5% puis à l'eau et la phase organique séchée sur du K_2CO_3, filtrée et concentrée sous vide, conduit à 1.0 g d'époxyde **3***a* (90% du rendement théorique) dont les caractéristiques sont les suivantes: pé 78°C/11 Torr; n_D^{23} 1.4500; ir: 860, 750 (C—O); rmn (CCl_4): 2.92 (C<u>H</u>(O)—C—, m), 0.92 (9 protons du groupe *tert*-butyle, s) 0.87 et 0.82 ppm (6 protons correspondants au *gem*-diméthyle).

Des alcènes silylé **1**b *et germylé* **1**c

On procède comme pour l'époxydation de l'alcène carboné **1***a*, à ceci près que la réaction a lieu à −5°C pendant 45 min. Le mélange réactionnel est extrait comme précédemment et conduit respectivement aux époxydes **3***b* et **3***c* (92% du rendement théorique).

Epoxyde **1**b—pé 28°C/0.25 Torr; n_D^{23} 1.4519; ir 1245 ($SiCH_3$), 980, 960, 830, 740 cm^{-1} (correspondant à la vibration C—O); rmn (CCl_4): 2.83 (C<u>H</u>(O)—C—, m) 0.90, 0.80 (6 protons correspondants au *gem*-diméthyle), 0.03 ppm (singulet 9 protons du $SiMe_3$).

Epoxyde **1**c—pé 88°C/10 Torr; n_D^{18} 1.4721; ir: 1230, 750 (C—O), 820 ($GeMe_3$) cm^{-1}; rmn (CCl_4): 2.80 (correspondant au proton époxyde), 0.90 et 0.83 (6 protons du groupe *gem*-diméthyle), 0.43 ppm (singulet 9 protons du $GeMe_3$).

Réduction par $LiAlH_4$

La réduction des époxydes de type **3** a été réalisée comme suit; dans un ballon de 100 ml refroidi à 0°C, on introduit 0.5 g de $LiAlH_4$ en suspension dans 10 ml d'éther anhydre. Par une ampoule à brome, on ajoute une solution contenant 5.5 mmol d'époxyde dans 10 ml d'éther anhydre. On porte le mélange réactionnel au reflux du solvant pendant 20 h, puis refroidit à 0°C. Après hydrolyse avec une solution de soude 5%, on extrait les produits organiques à l'éther. La phase éthérée est alors séchée sur du Na_2SO_4, filtrée et concentrée sous vide. Les rendements moyens en alcool sont de 85%.

Analyse des produits

Les mélanges d'alcools provenant des réactions de réduction des époxydes par $LiAlH_4$ ont été analysés par chromatographie en phase gazeuse à l'aide d'un chromatographe à ionisation de flamme Research Chromatograph 700 de la compagnie F et M muni d'une colonne de 6 pied × ⅛ po remplie de Diatoport 5750 (80–100) supportant 6% de son poids de LAC 728. Les temps de rétention (en minute) des alcools dans ces conditions sont résumés dans le tableau 2. L'identification des pics a été réalisée par superposition avec des échantillons authentiques préparés par une autre voie (1).

TABLEAU 2. Temps de retention (en min) des alcools

Alcool	Série *a*	Série *b*	Série *c*
5	3.7	3.2	5.3
4	5.5	4.3	6.4
7	7.3	5.1	7.2

Ouverture par le méthanol acidulé

L'ouverture des époxydes du type **3** a été réalisée sur des échantillons de 1.2 mmol d'époxydes en solution dans 14 ml de méthanol anhydre et 0.3 ml d'acide sulfurique. Le mélange réactionnel est agité à 45°C pendant 24 h, refroidi et extrait de la façon habituelle. Les rendements moyens de cette réaction sont de 75%.

L'analyse du mélange de la série a a été effectuée par cpg en utilisant une colonne de 10 pied × ¼ po remplie avec 15% de Carbowax 20 M déposé sur chromosorb W 60–80 mesh, chauffé à 120°C et un débit de 66 ml/mn.

Composé **6**a—Voir réf. 19.

Composé **9**a—ir: 3065 (C=C), 1080 (C—O) cm^{-1}; rmn (CCl_4): 5.30 (C<u>H</u>=C), 3.57 (C<u>H</u>—O), 3.10 (OMe), 0.93 et 0.83 (correspondant à 6 protons du groupe *gem*-diméthyle), 1.03 ppm (9 protons du *tert*-butyle).

Composé **11**b—pé 66–68°C/0.8 Torr; n_D^{20} 1.4735; ir 3480, 2840, 1245, 975 cm^{-1}; rmn (CCl_4): 3.93 (proton carbinolique), 3.23 (OMe), 0.96 (*gem*-diméthyle, s) et 0.13 ppm (Me_3Si); rmn (DMSO-d_6): doublet à 4.43 ppm, J_{H-OH} = 3.60 Hz.

Composé **11**c—pé 80–82°C/0.8 Torr; n_D^{20} 1.4873; ir: 3450, 2840, 1045, 815 cm^{-1}; rmn (CCl_4): 3.83 (proton carbinolique), 3.23 (OMe), 0.93 (*gem*-diméthyle, s) 0.28 (Me_3Ge); rmn (DMSO-d_6): doublet à 4.63 ppm, J_{H-OH} = 3.60 Hz.

Ouverture par l'eau acidulée

D'une façon générale, l'ouverture des époxydes du type **3** a

été réalisée en maintenant un mélange formé de 14 ml d'eau, 0.3 ml H_2SO_4 concentrée et 0.6 g (11 mmol) d'époxyde à 45°C pendant 24 h. Après refroidissement et extraction de la façon habituelle, les diols ont pu être isolés avec des rendements moyens de 50%.

Composé ***12***a—pf 144–145°C; ir (Nujol): 3300 cm^{-1} (O—H); rmn (CCl_4): 3.73 (proton carbinolique), 1.07 (9 protons du *tert*-butyle), 0.77, 0.87 ppm (6 protons du *gem*-diméthyle); rmn (DMSO-d_6): doublet mal résolu à 4.30 ppm et singulet à 3.73 ppm.

Composé ***12***b—pf 78–80°C; ir (Nujol): 3420, 1240 cm^{-1}; rmn (CCl_4): 3.83 (proton carbinolique), 1.19 (*gem*-diméthyle, s), 0.36 ppm (Me_3Si); rmn (DMSO-d_6): doublet à 4.76 ppm, J_{H-OH} = 4.00 Hz et singulet à 3.83 ppm.

Composé ***12***c—pf 92–94°C; ir (Nujol): 3410, 1380, 1370, 840 cm^{-1}; rmn (CCl_4): 3.66 (proton carbinolique), 0.96 (*gem*-diméthyle, s) 0.23 ppm (Me_3Ge); rmn (DMSO-d_6): doublet à 4.56 ppm, J_{H-OH} = 3.90 Hz, singulet à 3.90 ppm.

Obtention des diols cis (***13***)

L'obtention des diols *cis* (**13**) a été réalisée comme suit: dans un ballon de 100 ml à 25°C et à l'obscurité, 30 ml d'éther anhydre et 0.8 g (5 mmol) d'alcène sont introduits. On ajoute 1 g de tétroxyde d'osmium préalablement dissous dans 5–10 ml d'éther, et le mélange réactionnel est maintenu 40 h à 25°C. L'éther est évaporé et le mélange traité par 25 ml d'eau, 5 g de mannitol, 2 g de KOH et 30 ml de CH_2Cl_2. On porte au reflux le mélange réactionnel pendant 5 h puis on extrait à l'éther les produits organiques. Après sublimation, 0.7 g de diol est obtenu. Les rendements moyens de cette réaction sont de 70%.

Composé ***13***a—pf 126–127°C; ir (Nujol): 3340, 1370, 1360, 1060 cm^{-1}; rmn (CCl_4): 3.90 (proton carbinolique), 0.93 et 0.87 (*gem*-diméthyle), 1.03 ppm (9 protons du *tert*-butyle); rmn (DMSO-d_6): doublet mal résolu à 3.83 ppm et singulet à 3.20 ppm.

Composé ***13***b—pf 122–123°C; ir (Nujol): 3350, 1375, 1350, 1040, 960 cm^{-1}; rmn (CCl_4): 3.60 (C*H*—O), 0.93 et 0.86 (*gem*-diméthyle), 0.03 ppm (Me_3Si); rmn (DMSO-d_6): doublet à 4.00 ppm, J_{H-OH} = 6.80 Hz, singulet à 2.97 ppm.

Composé ***13***c—pf 122–123°C; ir (Nujol): 3320, 1380, 1365, 1070, 1050 cm^{-1}; rmn (CCl_4): 3.86 (C*H*—O), 1.23 et 1.16 (*gem*-diméthyle), 0.46 ppm (Me_3Ge); rmn (DMSO-d_6): doublet à 4.03 ppm, J_{H-OH} = 6.80 Hz, singulet à 3.26 ppm.

Remerciements

Les auteurs remercient vivement le Conseil national de recherches Canada, le CNRS français et les autorités chargées d'administrer les accords Franco-Québécois pour l'aide financière apportée sous forme d'octroi de recherches, de bourses d'études et de frais de mission. Les auteurs tiennent à remercier le Dr Pierre Maroni pour l'accueil chaleureux réservé à M. Marc-André Poirier durant son stage à Toulouse. Les auteurs tiennent aussi à exprimer leur reconnaissance aux Dr Mazerolles et Lesbre pour leur compréhension et leurs discussions utiles.

Solvolysis rates in aqueous – organic mixed solvents. V. Kinetics of the alkaline decarboxylation of trichloroacetate ion in water – ethanol solutions

EL-HUSSIENY M. DIEFALLAH[1] AND A. M. EL-NADI
Department of Chemistry, Assiut University, Assiut, Egypt

Received March 15, 1978

EL-HUSSIENY M. DIEFALLAH and A. M. EL-NADI. Can. J. Chem. **56**, 2053 (1978).

The kinetics of the alkaline decarboxylation of trichloroacetate ion in ethanol–water solutions have been studied over the temperature range 35.0 to 70.0°C. The rate of reaction is first order with respect to the trichloroacetate ion and is independent of the concentration of the hydroxide ion. The reactivity is enhanced by increasing the concentration of ethanol in the water–ethanol solutions and the rate of reaction varies with ethanol addition in a nonlinear manner. The rate of reaction increases with the reciprocal of the dielectric constant of the medium and the plot of log k vs. $1/D$ is approximately linear for solvent mixtures with less than about 0.7 water mole fraction but is strongly curved towards the pure water end. The activation parameters for the reaction show a regular increase in the solvent composition range 0.3 to 1.0 water mole fraction. The results are discussed in terms of the influence of solvent internal pressure and polarity on reactivity and of the increased amount of hydrogen-bonded structure in the water-rich solutions.

EL-HUSSIENY M. DIEFALLAH et A. M. EL-NADI. Can. J. Chem. **56**, 2053 (1978).

On a étudié à des températures allant de 35 à 70°C, la cinétique de la décarboxylation alcaline de l'ion trichloroacétate dans des solutions d'éthanol–eau. La vitesse de réaction est du premier ordre par rapport à l'ion trichloroacétate et elle est indépendante de la concentration de l'ion hydroxyde. Il y a une augmentation de la réactivité lorsque l'on augmente la concentration de l'éthanol dans des solutions d'eau–éthanol et la vitesse de la réaction varie avec l'addition d'éthanol d'une façon qui n'est pas linéaire. La vitesse de réaction augmente d'une façon parallèle à la constante diélectrique du milieu et une courbe de log k en fonction de $1/D$ est approximativement linéaire pour des mélanges de solvants contenant une fraction molaire d'eau plus petite que 0.7; toutefois il se produit une incurvation importante lorsque l'on approache de l'eau pure. Les paramètres d'activation de la réaction augmentent d'une façon régulière lorsque la fraction molaire d'eau dans le solvant varie de 0.3 à 1.0. On discute des résultats en terme d'une part de l'influence de la pression interne du solvant et de la polarité sur la réactivité et d'autre part de l'augmentation de la quantité de structure contenant des ponts hydrogène dans des solutions riches en eau.

[Traduit par le journal]

Introduction

Studies have been undertaken by several investigators to test for different theories accounting for the effect of solvent on the rates of chemical reactions in aquo-organic solvent binaries (1–10). Several factors influence solvent effects on chemical reaction rates; their relative importance seems to be a function of substrate, detailed mechanism of reaction, and experimental conditions. The influence of solvent variation on reaction rates may be examined conveniently in terms of the changes in the activation parameters, $\Delta H^{\neq}$ and $\Delta S^{\neq}$. For some solvolysis reactions in binary alcohol–water systems, changes in the activation parameters upon solvent variation were related to the accompanying solvent reorganization attending the activation process. The effect of solvent structure has been shown to be important in some cases but the sensitivity to solvent structural effects cannot always be demonstrated clearly and is dependent upon the nature of the organic co-solvent and on the temperature and the detailed mechanism of reaction. Dack (11) pointed out that solvent effects can generally be understood in terms of changes in volumes of activation and the cohesive energy density of the molecules of solvent, reactants and activated complex.

We have been undertaking a detailed study of the rates and mechanisms of the alkaline solvolysis of chloroacetate ions (1–4) in water–alcohol solutions, in order to test various theories of solvent effects on chemical reactions in solution. In the present study, we report the results of investigating solvent effects on the rate and mechanism of the alkaline solvolysis of sodium trichloroacetate in water–ethanol solutions.

Experimental

The details of the experimental procedure including methods for the characterization of the products of the reaction are similar to those previously outlined (1). The rate of reaction

TABLE 1. Effect of temperature and solvent composition on the rate constants of the alkaline solvolysis of trichloroacetate ion in water–ethanol solutions

Solvent water–ethyl alcohol (v/v)	Water mol fraction	Rate constant, $k \times 10^6$ (s^{-1})				
		35.0°C	45.0°C	50.0°C	56.0°C	70.0°C
Water	1.0	0.0384±0.0003	0.184±0.003	0.399±0.003	0.879±0.003	7.68±0.02
90.5:9.5	0.96	0.102 ±0.002	0.43 ±0.01	0.85 ±0.015	1.49 ±0.03	9.59±0.03
81.0:19.0	0.93	0.144 ±0.002	0.51 ±0.02	1.17 ±0.01	2.13 ±0.035	12.05±0.01
71.5:28.5	0.89	0.206 ±0.001	0.55 ±0.03	1.49 ±0.02	2.98 ±0.01	14.39±0.015
62.0:38.0	0.84	0.278 ±0.002	0.86 ±0.01	1.81 ±0.035	3.41 ±0.015	15.99±0.02
43.0:57.0	0.71	0.352 ±0.002	1.41 ±0.02	2.55 ±0.04	5.12 ±0.02	18.39±0.025
24.0:76.0	0.505	0.576 ±0.003	1.79 ±0.01	3.19 ±0.03	5.76 ±0.02	20.79±0.01
14.5:85.5	0.35	0.704 ±0.003	2.05 ±0.01	3.68 ±0.02	6.39 ±0.05	25.58±0.02

was followed in the temperature range 35.0 to 70.0°C, using a titrimetric method by following the release of chloride ions according to Volhard's technique. The initial concentrations of the trichloroacetic acid were in the range 0.10 to 0.05 mol/ℓ, while the initial concentrations of the base were in the range 0.80 to 0.40 mol/ℓ. In each reaction mixture, the concentration of the base was more than about five times that of the trichloroacetic acid.

Results and Discussion

The kinetics of the alkaline decarboxylation reaction of trichloroacetate ion in ethanol–water solutions showed certain similarities to that in the methanol–water solutions (1). In both cases the rate of reaction was found to be independent of the concentration of hydroxide ion and first order with respect to the trichloroacetate ion. Figure 1 shows typical first-order plots obtained in water–ethanol solutions at 50.0°C. The rate constants were evaluated from the slopes of such linear plots; data obtained with different solvent compositions and at the several temperatures are listed in Table 1. At least four kinetic runs were performed at each combination of reaction temperature and solvent composition.

Figure 2 shows the effect of solvent composition on the rate constants. It can be seen that the reactivity is enhanced by increasing the concentration of ethanol in the solution, and the rate of reaction varies with ethanol addition in a nonlinear manner. The change from methanol to ethanol should not produce a change in mechanism.

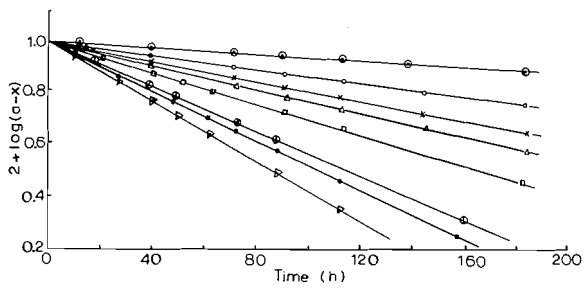

FIG. 1. First-order plots at 50.0°C in water–ethanol solutions. Water mol fraction: ⊙, 1.0; ○, 0.96; ×, 0.93; △, 0.89; □, 0.84; ⊗, 0.71; ●, 0.50; △, 0.35.

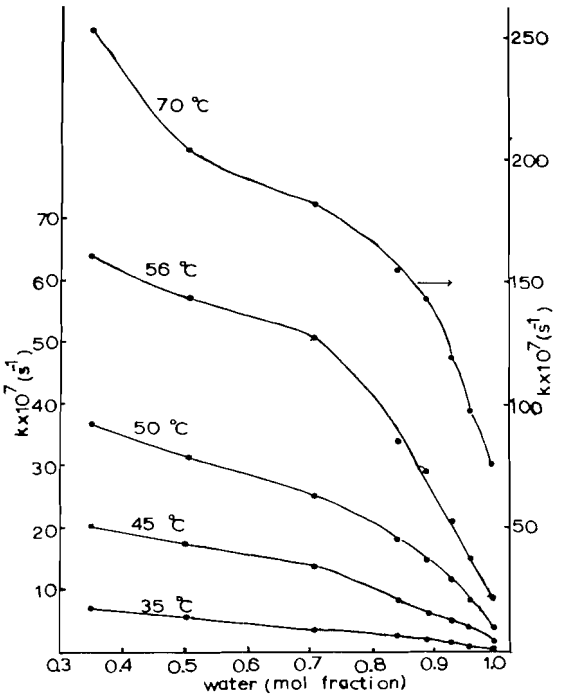

FIG. 2. Dependence of the first-order rate constants on solvent composition.

The kinetics of the reaction suggest a mechanism (12, 13) in which the rate-determining step is the breaking of the carbon–carbon bond with concomitant release of CO_2 and the formation of trichloromethyl carbanion intermediate:

[1] $$Cl_3C—COO^- \rightarrow Cl_3C^- + CO_2$$

The cumulative electron-withdrawing effect of the three chlorine atoms causes the C—C bond to break easily. The carbanion then expels chloride ion to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

form dichlorocarbene:

[2] $$Cl_3C^- \rightarrow Cl_2C: + Cl^-$$

Bigeleisen and Allen (14) determined the relative rates of decomposition of 1-^{12}C and 1-^{13}C trichloroacetate ions in water and showed that the 1-^{12}C ion decomposes 1.0338 times as fast as the 1-^{13}C ion. This has been taken to support rate determining formation of Cl_3C^- but is also in accord with a rate limiting, one step formation of dichlorocarbene:

[3] $$Cl_3C—COO^- \rightarrow Cl^- + CO_2 + CCl_2$$

A choice between [1] and [3] could be made if it were known whether or not the reaction exhibits a chlorine isotope effect but such studies are not available at the present time. It is noted that [3] is a fragmentation process and this would result in an increased $\Delta S^{\ddagger}$ owing to the gain of translational, rotational, and vibrational degrees of freedom (15). In the alkaline decomposition of chloroform it is commonly assumed that the rate-determining step in the reaction is the unimolecular elimination of chloride ion from trichloromethyl anion to form dichlorocarbene (16–19). Measurements of the pressure coefficient of the rate constant (16) strongly suggested that H_2O electrostatically bound to the Cl_3C^- ion is released during the reaction and that the transition state goes on to free CCl_2.

The electrophile dichlorocarbene reacts with base to yield carbon monoxide and formate (17–20). Robinson (20) has proposed on kinetic evidence that carbon monoxide and formate are not formed simultaneously but that carbon monoxide is the primary product from which formate is produced by a subsequent slow reaction with hydroxide ions. Measurement of the concentrations of CO and $H{\cdot}COO^-$ during the course of the alkaline hydrolysis showed that the concentration–time curves are typically those of consecutive reactions. The decomposition of dichlorocarbene therefore includes the following consecutive reactions:

[4] $$CCl_2 \xrightarrow{2OH^-,\ H_2O} CO$$

[5] $$CO \xrightarrow{OH^-\ (slow)} H{\cdot}COO^-$$

Kinetic studies (20) of the reaction in which formate is produced from carbon monoxide and aqueous alkalis suggested that the mechanism involves a direct slow attack by hydroxide ions on the carbon atom in carbon monoxide followed by a prototropic rearrangement to formate. The ultimate end products of the reaction of trichloroacetate ion with base therefore has been identified as salts of hydrochloric, formic and carbonic acids (1).

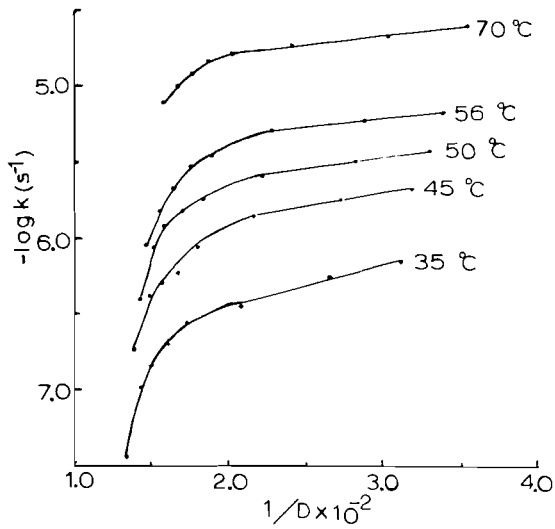

FIG. 3. Dependence of the first-order rate constants on the dielectric constant of the medium.

The rate of the reaction studied here decreases with increasing dielectric constant of the medium and the plot of log k vs. $1/D$ (Fig. 3) is approximately linear for solvent mixtures with less than about 0.7 water mole fraction but is strongly curved toward the pure water end. The use of $(D - 1)(2D + 1)^{-1}$ instead of D^{-1} did not improve the plot.

The enthalpy and entropy of activation for the reaction were calculated making use of the transition state theory (21) and the results together with E_a, the energy of activation and $\Delta G^{\ddagger}$, the free energy of activation are listed in Table 2. Figure 4 shows that $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ increase regularly with increase of water concentration in the solution without extrema or inflection points in the rich-water solvent mixtures (1, 2). The change in $\Delta S^{\ddagger}$ amounts to about 26.8 cal K^{-1} mol^{-1} between 1.0 and 0.35 water mole fraction, and that for $\Delta H^{\ddagger}$ is about 10.1 kcal mol^{-1} in the same composition range. The plot of $\Delta H^{\ddagger}$ vs. $\Delta S^{\ddagger}$ (Fig. 5) gave rise to a linear relationship as might be expected from solvents playing similar roles in the reaction (22).

The volumes of the reactant species and that of the activated complex in a given solvent depend on the structure of the species and on the ability of the solvent to compress this volume by electrostriction (11). In the above mechanism there is a net loosening of bonds in the transition state, so we may expect the volume of activation to be a positive quantity and the internal pressure of the reactant ion to be higher than that of the activated complex. The effect of solvent change on the rate is determined by the influence of solvent internal pressure and polarity on the volume of activation. The increase in solvent

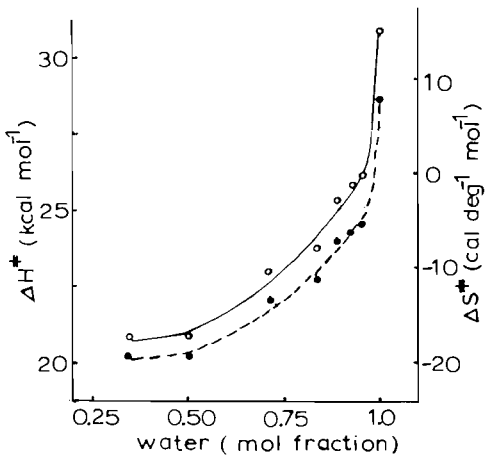

FIG. 4. Dependence of the activation parameters, ΔH^* and ΔS^* on solvent composition: ○, ΔH^*, ●, ΔS^*.

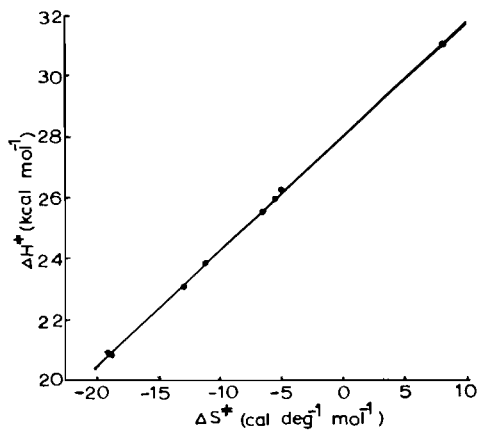

FIG. 5. A plot of ΔH^* vs. ΔS^* for the alkaline solvolysis of trichloroacetate ion in water–ethanol solutions.

polarity increases solvent electrostriction around the reactants relative to the activated complex, thereby causing the activation volume to be more positive and the rate of reaction to decrease. Alternatively, it may be pointed out that, since the transition state is bigger than the ground state and is involving the release of the neutral CO_2 molecule and the delocalization of charge, it is expected to be relatively less solvated by water than the reactant ion as the dielectric constant of the medium increases (16). If the reactants are relatively more solvated than the activated complex, there is an increase in entropy of activation, a decrease in potential energy of the reactants, the activation energy is increased and the reaction rate is consequently diminished.

If a simple electrostatic theory of medium effects (23) is considered, the rate constant of the reaction may be written as:

$$(6)\quad \ln k = \ln k_0 + (Z^2e^2/2D(R/N)T)((1/r) - (1/r^*))$$

where, k_0 can be regarded as the rate constant in a medium of infinite dielectric constant, r and r^* are the radii of the reactant ion and the activated complex; (R/N) is the Boltzmann constant, Z is the valency of the reactant ion, e is the electronic charge, D is the macroscopic dielectric constant, and T is the absolute temperature. Figure 3 shows that a linear relationship between log k and D^{-1} is not strictly obeyed. The main reason for this is that the success of the electrostatic theory has been limited due to its neglect of solvent structural effects, also the macroscopic dielectric constant is not adequate for describing the molecular interactions. However, if we use data obtained at 50.0°C and assume that the trichloroacetate ion has a radius of 3.4 Å (this is about the same value calculated from the average volume occupied per molecule of trichloroacetic acid in the liquid state), then for media with water mole fractions less than about 0.7, eq. [6] gives for the radius of the transition state complex a value of about 5.5 Å, i.e., the volume of the activated complex is about four times that of the reactant ion. In the water-rich region of the composition scale a similar calculation (over the short linear portion of the log $k - D^{-1}$ plot, i.e., 1.0 to about 0.9 water mole fraction) gives $(1/r) - (1/r^*) = 3.26$ Å^{-1}. This value means that both the reactant ion and the activated complex are much compressed by electrostriction in the highly aqueous solutions to the extent that the radius of the reactant ion must be less than

1 Å for eq. [6] to hold. On the basis of the above discussion, one would conclude that the dielectric theory of medium effects does not particularly apply for the water-rich solutions where the structural nature of the solvent and the increased amount of hydrogen-bonded structures play a more important role in the determination of solvent behaviour.

Cyclopropanation of steroidal A-ring 2-enol derivatives

JOHN FREELAND TEMPLETON, VOLKER GUSTAV PASLAT, AND CHWI WAN WIE
Faculty of Pharmacy, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 28, 1977

JOHN FREELAND TEMPLETON, VOLKER GUSTAV PASLAT, and CHWI WAN WIE. Can. J. Chem. **56**, 2058 (1978).

Cyclopropanation of 2-enol derivatives of 17β-acetoxy-5α-androstan-3-one has been studied. The preparation of A-ring cyclopropanol derivatives from the Simmons–Smith reagent or dibromocarbene is described. Long range shielding effects of the cyclopropane ring in the ^{1}Hmr spectrum are discussed.

JOHN FREELAND TEMPLETON, VOLKER GUSTAV PASLAT et CHWI WAN WIE. Can. J. Chem. **56**, 2058 (1978).

On a étudié la cyclopropanation de dérivés énoliques en position 2 de l'acétoxy-17β androstan-5α one-3. On décrit la préparation de dérivés cyclopropanols attachés au cycle A faisant appel à la réaction de Simmons–Smith ou avec du dibromocarbène. On discute des effets de blindage à longue distance du cycle cyclopropane sur les spectres rmn du ^{1}H.
[Traduit par le journal]

Introduction

The synthesis of steroidal cyclopropanol derivatives has been carried out since the development of methylene yielding reagents (1, 2). The iodomethylzinc iodide reagent, prepared from a zinc–copper couple and diiodomethane (3), has been shown to react with enol ethers more rapidly than with the analogous double bond (4) but to be less reactive towards enol acetates (5, 6). Recently, the electron-rich silyl enol ethers have been shown to readily add methylene from this reagent (7). Addition of methylene to an oxygen substituted double bond is a direct way of forming oxygenated cyclopropane derivatives containing an oxygen atom derived from a parent molecule and a method of preparation of methyl substituted carbonyl compounds (8–10). Because cyclopropanols are sensitive to basic and acidic media and to heat, it is necessary that the enolic derivative be easily cleaved. An alternative approach to the direct methylenation of the enolic double bond is the initial addition of a dihalocarbene followed by dehalogenation (11, 12). A number of methods are available for the dehalogenation of unsubstituted dihalocyclopropane derivatives (13).

The addition of methylene, derived from either the Simmons–Smith reagent or via dibromocarbene, to enolic derivatives of 17β-acetoxy-5α-androstan-3-one (**1**) leading to tertiary 3β-oxygen substituted cyclopropanol derivatives has been investigated. A preliminary report has appeared (14).

Results and Discussion

17β-Acetoxy-5α-androstan-3-one (**1**) on treatment with methanol in the presence of acid gave the 3,3-dimethoxy ketal (**2***a*) which, on pyrolysis at reduced pressure, yielded the known methyl enol ether (**3***a*). Addition of methylene to the enolic double bond on treatment with the Simmons–Smith reagent was shown by the presence of high field resonance characteristic of cyclopropyl protons in the ^{1}Hmr spectrum, the absence of the enolic double bond in the ir spectrum, and an increase of 14 amu in the highest mass ion in the mass spectrum of the product. The iodomethylzinc iodide reagent has been shown to be sensitive to steric effects (15); therefore, the presence of the 19-methyl substituent would be expected to cause addition from the α face to give 17β-acetoxy-3β-methoxy-2α,3-cyclopropano-5α-androstane (**4***a*) as in the analogous addition of methylene to steroidal 2-olefins (16). Acidic hydrolysis of the cyclopropyl ether (**4***a*) at room temperature led to the 17β-alcohol (**4***b*) without opening of the cyclopropyl ether. Treatment with dilute acid in methanol at reflux gave 17β-hydroxy-2α-methyl-5α-androstan-3-one (**5**), identified by comparison with an authentic sample.

Treatment of the cyclopropyl ether (**4***a*) with boron trifluoride etherate in acetic anhydride gave the acetoxymethyl derivative (**6***a*). The ^{1}Hmr spectrum showed an olefinic proton and a two-proton singlet assigned to the methylene unit of the acetoxymethyl group. Reaction of the cyclopropyl ether (**4***a*) with boron tribromide gave a monobromo compound (**6***b*) in high yield with no indication of cyclopropanol formation.

Bis(2-chloroethoxy)-5α-androstan-17β-yl acetate (**2***b*) was prepared by azeotropic removal of water from a solution of 17β-acetoxy-5α-androstan-3-one (**1**) in benzene containing *p*-toluenesulfonic acid and 2-chloroethanol. Pyrolysis of the chloroethoxy ketal (**2***b*) gave the 2,3-unsaturated enol ether (**3***b*) of sufficient purity to be used directly in the next reaction with an excess of Simmons–Smith reagent to give the

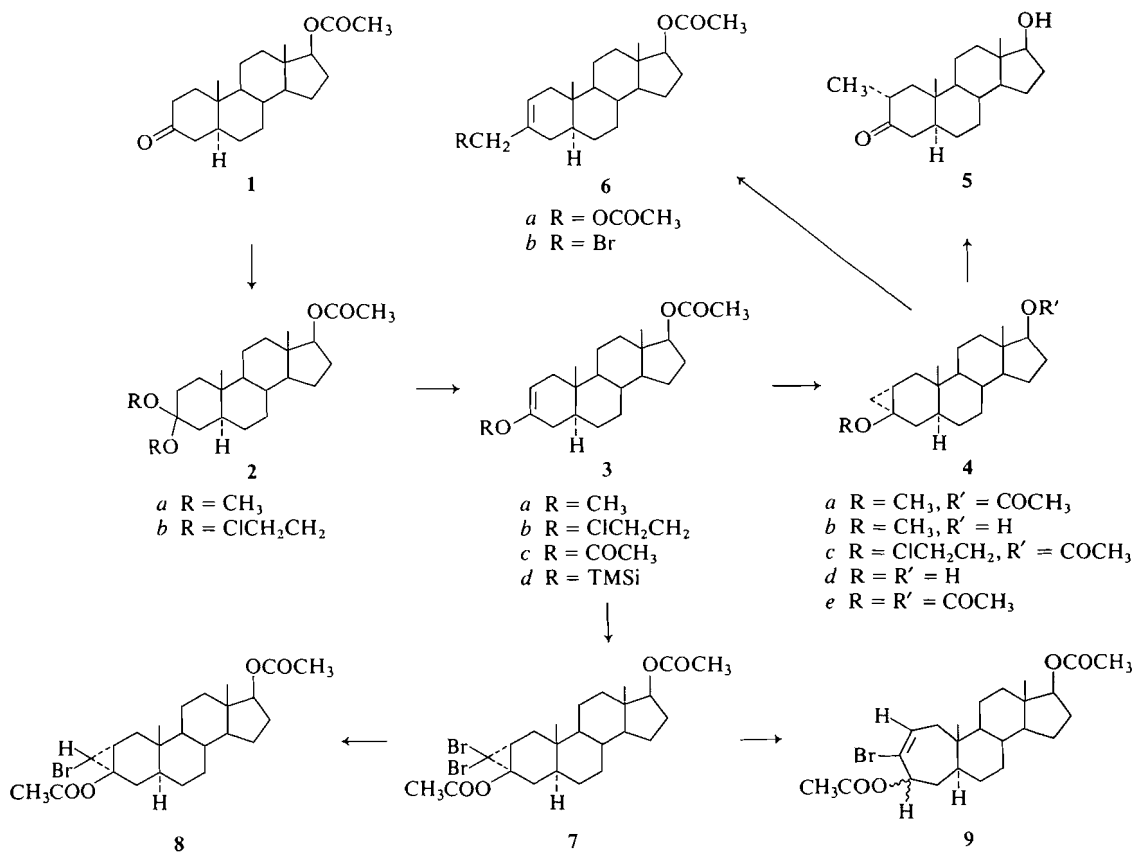
For personal use only.



cyclopropyl 2-chloroethyl enol ether (**4***c*). Treatment of this enol ether (**4***c*) with *n*-butyl lithium using the method of Schollköpf *et al.* (17) yield the tertiary cyclopropanol (**4***d*). This heat labile compound gave a melt showing two components on tlc corresponding to the starting material and 17β-hydroxy-2α-methyl-5α-androstan-3-one (**5**). On recrystallization from chloroform, retention of $\frac{1}{2}$ mol of solvent per mole of steroid was shown by ms and elemental analysis. Recrystallization from acetone gave, on the basis of elemental analysis, a hemihydrate. These solvates did not decompose when dried at room temperature under reduced pressure. In the ir the above product showed strong hydroxylic absorption and cyclopropyl C—H stretching and no carbonyl absorption. The ^{1}Hmr spectrum showed high-field resonance consistent with cyclopropyl protons (18). Treatment of the hemihydrate of the cyclopropanol (**4***d*) under either dilute acidic or basic conditions gave 17β-hydroxy-2α-methyl-5α-androstan-3-one (**5**), as shown by comparison of the spectra (ir, ^{1}Hmr, ms) and melting point when mixed with an authentic sample. Acetylation of the cyclopropanol (**4***d*) with acetic anhydride in pyridine gave the diacetate (**4***e*).

The enol acetate (**3***c*) of 17β-acetoxy-5α-androstan-3-one (**1**) was prepared by treatment of the ketone with acetic anhydride in the presence of phosphorous oxychloride. Addition of methylene from an excess of the Simmons–Smith reagent to the 2-enol acetate (**3***c*) gave the diacetate (**4***e*) in low yield. Simmons–Smith addition to the 16-enol acetate has been reported to take place more readily (11, 19), consistent with the greater reactivity of five-membered over six-membered ring olefins (15).

Dibromocarbene addition to the 2-enol acetate (**3***c*) was carried out using the phase-transfer technique (20) to give the expected dibromocyclopropano derivative (**7**). Treatment of the dibromocyclopropano derivative (**7**) with a zinc–copper couple removed the sterically less hindered *exo* bromine to give the *endo*-bromocyclopropane (**8**). The *endo* structure was assigned on the basis of the coupling constant (J = 9 Hz) in agreement with a *cis* cyclopropyl coupling in the monobromocyclopropano derivative (**8**) (21). Hydrogenation of the dibromocyclopropano derivative (**7**) over Raney nickel catalyst also effected removal of the *exo* bromine atom to yield **8**. Further treatment of the monobromocyclopropano derivative (**8**) with either the zinc–copper couple or Raney nickel was unsuccessful

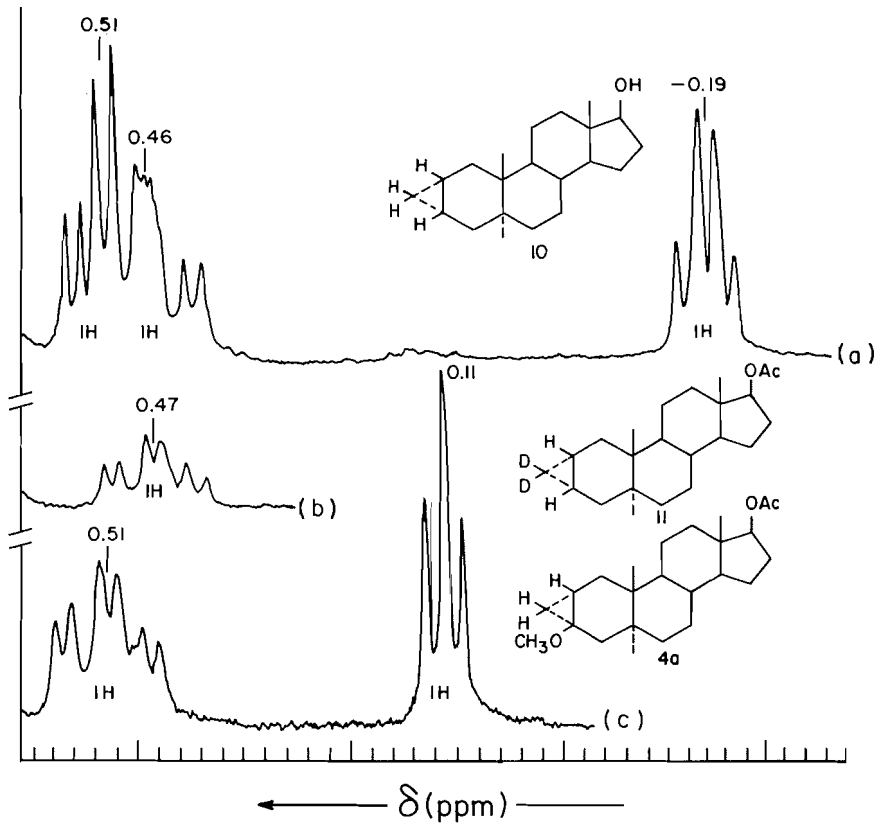

FIG. 1. High-field bands in the 220 mHz ^{1}Hmr spectra of 2α,3α-cyclopropanosteroid derivatives.

in removing the *endo* bromine atom. Lithium aluminium hydride reduction of the dibromocyclopropano derivative (**7**) resulted in the removal of one bromine atom and opening of the cyclopropane ring to yield the A-homoandrostene (**9**) after acetylation. Similar steroid ring enlargements have been observed (12).

The ^{1}Hmr spectrum of the crude reaction product obtained from treatment of the trimethylsilyl derivative (**3***d*) with the Simmons–Smith reagent showed high-field protons corresponding to cyclopropane formation but no crystalline products were obtained from the complex reaction mixture. Olefinic products have been isolated in similar reactions (22).

The ^{1}Hmr spectra of these cyclopropanoandrostanes show the presence of a six-line band at high field which cannot be assigned to a cyclopropyl proton. The spectrum of 17β-hydroxy-2α,3α-cyclopropano-5α-androstane (**10**) has three high-field protons (Fig. 1*a*). Comparison of this spectrum with the dideuterated derivative (**11**) shows the loss of two protons (Fig. 1*b*). These two protons are assigned to the *exo* and *endo* protons which are expected to appear as six- and four-line bands, respectively, as observed, because the *exo* proton undergoes two equivalent *cis* couplings ($J_{exo,2\beta} = J_{exo,3\beta} = 12$ Hz) and one smaller *gem* coupling ($J_{gem} = 5$ Hz) whereas the *endo* proton undergoes three equivalent couplings ($J_{endo,2\beta} = J_{endo,3\beta} = J_{gem} = 5$ Hz) (23). The remaining proton also appears as a six-line band. Examination of the 2β- and 3β-H shows that both are coupled to five protons from which a more complex coupling should result. Deuterium substitution of the 2β- and 4,4-protons does not alter the number of high-field protons observed, thereby eliminating them as the source of this six-line absorption. Substitution of the 3β-proton by an oxygen function causes the loss of one up-field proton leaving a six-line band and a triplet (Fig. 1*c*). The triplet is assigned to the *endo* proton which loses one *trans* coupling and has undergone a shift to lower field. The remaining six-line band is inconsistent with the *exo* proton because that proton should now show one less *cis* coupling and should undergo a shift to lower field. Similar overlapping high-field multiplets are observed in the ^{1}Hmr spectrum of the 4β- and 6α-hydroxyl derivatives of 17β-hydroxy-2α,3α-cyclopropano-5α-androstane (**10**) (24). Further evidence that the six-line proton is not due to a cyclopropyl proton follows from the spectra of the brominated derivatives both

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of which show this signal centered at 0.66 ppm. The 2β-H, like the 1α- and 1β-H to which it is coupled, is expected to appear as a doublet of doublets. Similarly the unaltered coupling observed for the monobrominated derivative is inconsistent with assignment of the six lines to the 2β-proton. Of the remaining protons in the molecule the observed six-line band may arise, on the basis of the coupling constant, from the 9α-,12α-, or 14α-H.

Generally signals which occur at higher field than other alicyclic protons can be assigned to cyclopropyl protons. Bhacca *et al.* (25) has reported the presence of a high-field proton in the ^{1}Hmr spectrum of 3,3′-spirocyclopropano-5α-androstane not present in the spectrum of 5α-androstane which could not be assigned to a cyclopropyl proton. On the basis of the coupling constants, this signal was assigned to a proton at the 6α-,7β-,11α-position resulting from a very long range shielding effect of the cyclopropane ring by an unknown mechanism. The spectra of 2α,3α-cyclopropano-5α-androstane derivatives also show the presence of a high-field signal which cannot be assigned to a cyclopropyl proton and is, therefore, another example of this phenomenon.

These compounds were prepared in connection with studies on the metabolism of 17β-hydroxy-2α,3α-cyclopropano-5α-androstane (**10**) (24).

The above procedures yield 2α,3α-cyclopropano androstane derivatives having either a hydroxyl function at C-3 and C-17, or afforded disubstituted derivatives. A derivative at C-3, which would yield the 3-alcohol and selectively retain the 17-ester function, would give compounds of interest for biological testing, since they avoid the extremes of high and low lipid solubility of the disubstituted and diol compounds (26).

Experimental

For general experimental details of work-up procedures and the acetylation method see ref. 27. Unless otherwise stated, ir (Perkin-Elmer Model 267) and ^{1}Hmr (Varian A56/60A) spectra are recorded in carbon tetrachloride and specific rotations in chloroform. Proton magnetic resonance spectra of compounds **4***a*, **4***c–e*, **6***a–b*, 7, **8**, and **9** were recorded in deuteriochloroform on a Varian HR 220 instrument by the Canadian 220 MHz NMR Centre, Ontario Research Foundation, Toronto, Ontario. Proton magnetic resonance spectra of compounds containing a cyclopropane ring were recorded both with and without the internal TMS standard. Assignment of the six peaks at δ 0.46–0.52 ppm in the ^{1}Hmr spectra of compounds **4***a*, **4***c–e*, and δ 0.66 ppm in compounds 7 and **8** is discussed above. Brockmann Activity II alumina (35–40 × the weight of substance) was used for column chromatography. Neutral alumina was prepared by the ethyl acetate treatment described by Fieser and Fieser (28). Elemental analyses were performed by either Mr. George Crouch, School of Pharmacy, University of London, England, or Pascher and Pascher, Bonn, West Germany.

*3-Methoxy-5α-androst-2-en-17β-yl Acetate (**3**a)*

A flask containing 3,3-dimethoxy-5α-androstan-17β-yl acetate (**2***a*) (29) (7 g) under reduced pressure (water pump) was immersed in an oil-bath (200–210°C). Vigorous reaction ceased after 10 min and the residue was cooled; a drop of pyridine was added, followed by recrystallization from ether–methanol to give the methoxyenol ether (**3***a*) (5 g) mp 122–127°C. Recrystallization gave a sample mp 126.5–129.5°C (lit. (29) mp 127–129°C); ^{1}Hmr δ: 4.28–4.70 (2H, m, vinylic and 17α-protons), 3.44 (s, methoxy), 1.98 (s, 17-acetoxy), 0.78 (s, 18- and 19-methyl) ppm.

*3β-Methoxy-2α,3-cyclopropano-5α-androstan-17β-yl acetate (**4**a)*

The methoxyenol ether (**3***a*) (2.15 g) was treated with the Simmons–Smith reagent as described for the enol ether (**3***b*). Chromatography over alumina gave fractions from petroleum ether which on recrystallization from ether–methanol gave the cyclopropyl ether (**4***a*) (720 mg), mp 138–140°C; $[\alpha]_D^{24}$ +36° (*c* 0.23); ir ν_{max}: 3096 (cyclopropyl C—H), 1730 (ester C=O) cm^{-1}; ^{1}Hmr δ: 4.57 (t, J = 8 Hz, 17α-proton), 3.27 (s, methoxy), 2.04 (s, 17-acetoxy), 0.84 (s, 19-methyl), 0.77 (s, 18-methyl), 0.51 (1H, J = 4.5, 11.5, 12 Hz), 0.11 (1H, dd, $J_{gem} = J_{trans}$ = 5.5 Hz, *endo*-cyclopropyl proton) ppm; ms *m/e*: 360 (M$^+$). *Anal.* calcd. for $C_{23}H_{36}O_3$: C 76.61, H 10.07; found: C 76.39, H 10.28.

*3β-Methoxy-2α,3-cyclopropano-5α-androstan-17β-ol (**4**b)*

The cyclopropyl ether (**4***a*) (463 mg) was dissolved in methanol (22.5 ml) and diethyl ether (27.5 ml) containing concentrated hydrochloric acid (5.4 ml). After 22 h all starting material had disappeared (according to tlc) and a slower fraction had developed. The reaction was worked up to give a crude product which crystallized from petroleum ether 320 mg, mp 105–108°C. Several recrystallizations from petroleum ether gave 3β-methoxy-2α,3-cyclopropano-5α-androstan-17β-ol (**4***b*), mp 109–110°C; $[\alpha]_D^{23}$ +27° (*c* 0.16); ir ν_{max}: 3623 (free O—H), 3480 (bonded O—H), 3067 (cyclopropyl C—H) cm^{-1}; ^{1}Hmr δ: 3.47 (t, J = 8 Hz, 17α-proton), 3.16 (s, methoxy), 0.84 (s, 19-methyl), 0.67 (s, 18-methyl), −0.02 (1H, t, J = 4 Hz, cyclopropyl proton) ppm; ms *m/e*: 318 (M$^+$). *Anal.* calcd. for $C_{21}H_{34}O_2$: C 79.19, H 10.76; found: C 79.05, H 10.87.

*17β-Hydroxy-2α-methyl-5α-androstan-3-one (**5**) from Acid Treatment of the Cyclopropyl Ether (**4**a)*

The cyclopropyl ether (**4***a*) (121 mg) was dissolved in dioxane (4 ml) and methanol (12 ml) containing concentrated hydrochloric acid (1.44 ml). As the starting material decreased (by tlc) two slower fractions developed, the faster corresponding to the 17β-alcohol (**4***b*). After 4½ h only the slower fraction remained. The reaction product was worked up to yield after several recrystallizations from ether – petroleum ether, 17β-hydroxy-2α-methyl-5α-androstan-3-one (**5**) (62 mg), mp 151.5–153°C (lit. (30) 153–154°C); ir ν_{max} (KBr): 3509 (bonded O—H), 1706 (six-membered ring C=O) cm^{-1}; ^{1}Hmr δ: ($CDCl_3$) 3.62 (t, J = 8 Hz, 17α-H), 1.05 (s, 19-methyl), 0.99 (d, J = 6 Hz, 2α-methyl), 0.76 (s, 18-methyl) ppm.

*3-Acetoxymethyl-5α-androst-2-en-17β-yl acetate (**6**a)*

3β-Methoxy-2α,3-cyclopropano-5α-androstan-17β-yl acetate (**4***a*) (120 mg) was dissolved in acetic anhydride (4 ml) and cooled in an ice–salt bath. Boron trifluoride etherate (0.7 ml) was added and the solution allowed to stand at 0°C for 20 h. The reaction mixture was poured into ice-water and extracted with ether; removal of the ether yielded a brown crystalline residue (127 mg). Filtration through neutral alumina in petroleum ether gave fractions (80 mg) from which was obtained on recrystallization from ether–methanol, 3-acetoxymethyl-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

5α-androst-2-en-17β-yl acetate (*6a*) (18 mg), mp 117–119°C C; ir ν_{max}: 1745, 1738 (ester C=O) cm^{-1}; ^{1}Hmr δ: 5.65 (m, olefinic proton), 4.59 (t, J = 8.5 Hz, 17α-H), 4.45 (s, acetoxymethyl protons), 2.07 (s) and 2.05 (s, acetoxy-methylene), 0.78 (s, 19-methyl), 0.73 (s, 18-methyl) ppm; ms *m/e*: 388 (M^+). *Anal.* calcd. for $C_{24}H_{36}O_4$: C 74.19, H 9.34; found: C 74.27, H 9.42.

3-Bromomethyl-5α-androst-2-en-17β-yl acetate (6b)

Boron tribromide (bromine free) (0.6 ml) was added to a solution of the cyclopropyl ether (*4a*) (256 mg) in dichloromethane (10 ml) cooled in a Dry Ice – acetone bath. After 2 h the reaction mixture was poured into ice-water and extracted with dichloromethane to give on recrystallization from dichloromethane–methanol, 3-bromomethyl-5α-androst-2-en-17β-yl acetate (*6b*) (243 mg), mp 158–161°C, recrystallization gave mp 163–164°C; ir ν_{max}: 1736 (ester C=O), 1662 w (C=C) cm^{-1}; ^{1}Hmr δ: 5.78 (br m, olefinic proton), 4.59 (t, J = 8.5 Hz, 17α-H), 3.94 (s, bromomethylene protons), 2.05 (s, 17-acetoxy), 0.79 (s, 19-methyl), 0.73 (s, 18-methyl) ppm; ms *m/e*: 408, 410 (M^+), 329 (M^+ − Br). *Anal.* calcd. for $C_{22}H_{33}O_2Br{\cdot}CH_3OH$: C 62.57, H 8.45; found: C 62.46, H 7.88.

3,3-Bis(2-chloroethoxy)-5α-androstan-17-yl Acetate (2b)

17β-Acetoxy-5α-androstan-3-one (**1**) (1.1 g) was added to a solution of benzene (90 ml) and 2-chloroethanol (10 ml) containing *p*-toluenesulfonic acid monohydrate (100 mg). The solution was fitted with a Dean–Stark apparatus for 3 h of reflux, cooled, and poured into excess cold aqueous sodium bicarbonate, washed with water, dried, and evaporated at reduced pressure with minimal heating. The crude product was recrystallized from ether–methanol containing a trace of pyridine to give the ketal (*2b*) (615 mg), recrystallization gave an analytical sample, mp 94–95°C; $[\alpha]_D^{24}$ +11° (*c* 1.01); ir ν_{max}: 1735 (ester C=O), 671 (C—Cl) cm^{-1}; ^{1}Hmr δ: 4.46 (t, J = 8 Hz, 17α-proton), 3.54 (m, chlorcethoxy protons), 1.93 (s, 17-acetoxymethyl), 0.78 (s, 19-methyl), 0.72 (s, 18-methyl) ppm; ms *m/e*: 474, 476, 478 (M^+). *Anal.* calcd. for $C_{25}H_{40}O_4Cl_2$: C 63.15, H 8.48, Cl 14.91; found: C 62.90, H 8.67, Cl 14.74.

3(2-Chloroethoxy)-5α-androst-2-en-17β-yl Acetate (3b)

A flask containing the ketal (*2b*) (600 mg) was immersed in an oil-bath (200–210°C) under reduced pressure (water pump). After 10 min reaction ceased and the crude product was recrystallized from methanol containing a trace of pyridine to give enol ether (*3b*) (200 mg), mp 123–126°C; $[\alpha]_D^{24}$ +44° (*c* 1.00); ir ν_{max}: 1735 (ester C=O), 1675 (C=C), 671 (C—Cl) cm^{-1}; ^{1}Hmr δ: 4.44 (m, olefinic and 17α-proton), 3.68 (m, chloroethoxy protons), 1.94 (s, 17-acetoxy methyl), 0.75 (s, 18- and 19-methyl) ppm; ms *m/e*: 394 (M^+). *Anal.* calcd. for $C_{23}H_{35}O_3Cl$: C 69.94, H 8.93, Cl 8.96; found: C 70.36, H 9.08, Cl 8.56.

3β(2-Chloroethoxy)-2α,3-cyclopropano-5α-androstan-17β-yl Acetate (4c)

The enol ether (*3b*) (1.6 g) in dry ether (30 ml) was added to a 10 molar excess of the Simmons–Smith reagent prepared from zinc–copper couple (4 g) and methylene iodide (3.32 ml). After 24 h reflux the ir spectrum showed enolic double bond absorption; a second 10 molar excess was added after 48 h and the reaction heated to reflux for a total of 3 days. The reaction product was poured into aqueous sodium bicarbonate and extracted with ether. The residue from the ether extraction was taken up in petroleum ether and chromatographed over neutral alumina. Elution with petroleum ether afforded a major fraction (733 mg) which on crystallization from methanol yielded an analytical sample (433 mg) of the cyclopropyl ether (*4c*), mp 129–130°C; $[\alpha]_D^{24}$ +23° (*c* 1.03); ir ν_{max}: 3075 (cyclopropyl C—H), 1735 (ester C=O), 1235, 1031 (C—O), 669 (C—Cl) cm^{-1}; ^{1}Hmr δ: 4.58 (t, J = 8 Hz, 17α-proton), 3.52–3.82 (m, chloroethoxy protons), 2.04 (s, 17-acetoxy methyl), 0.84 (s, 19-methyl), 0.77 (s, 18-methyl), 0.51 (1H, J = 4, 11.5, 12.5 Hz), 0.15 (1, dd, $J_{gem} = J_{trans}$ = 6 Hz, *endo*-cyclopropyl proton) ppm; ms *m/e*: 408 (M^+). *Anal.* calcd. for $C_{24}H_{37}O_3Cl$: C 70.47, H 9.12, Cl 8.67; found: C 70.38, H 9.28, Cl 8.31.

2α,3-Cyclopropano-5α-androstane-3β,17β-diol (4d)

The 2-chloroethoxycyclopropane ether (*4c*) (1 g) in dry ether (20 ml) was cooled in an ice-bath under a nitrogen atmosphere. *n*-Butyl lithium in petroleum ether (2.3 *M*) (6 ml) was added to the stirred solution and after 15 min the reaction mixture was poured into one equivalent of cold dilute acetic acid (200 ml). The reaction was extracted with ether, the ether was washed with aqueous sodium bicarbonate, water, dried, and evaporated under reduced pressure at room temperature. The crude product was dissolved in acetone at room temperature and concentrated in a stream of nitrogen to yield the cyclopropanol (*4d*) (390 mg), mp 135–144°C. Recrystallization of the heat labile substance from acetone gave a mp 145–155°C. This material showed only one substance on tlc in the following four solvent systems 25% ethyl acetate – petroleum ether, 50% ether–benzene, 5% acetone–chloroform, and 5% methanol – carbon tetrachloride. Analysis by glc as the trimethylsilyl derivative (24) showed one fraction; $[\alpha]_D^{24}$ +18° (*c* 0.963, dioxane); ir ν_{max}: (KBr) 3400 (broad, O—H), 3090 (cyclopropyl C—H), 1058 (C—O) cm^{-1}, heating this disc at 180°C gave a diminished 3400 peak and a new absorption at 1725 (ketone C=O) cm^{-1}; ^{1}Hmr δ: (pyridine-d_5) 3.91 (t, J = 8.5 Hz, 17α-proton), 0.97 (s, 19-methyl), 0.93 (s, 18-methyl), 0.46 (1H, J = 12, 11.5, 4 Hz), 0.35 (1H, t, $J_{gem} = J_{trans}$ = 5 Hz, *endo*-cyclopropyl proton), ppm; ms *m/e*: 304 (M^+). *Anal.* calcd. for $C_{20}H_{32}O_2{\cdot}\frac{1}{2}H_2O$: C 76.62, H 10.61; found: C 76.71, H 10.48. Recrystallization from chloroform, mp 123–128°C. *Anal.* calcd. for $C_{20}H_{32}O_2{\cdot}\frac{1}{2}CHCl_3$: C 67.61, H 9.00, Cl 14.60; found: C 68.60, H 9.11, Cl 12.01.

2α,3-Cyclopropano-5α-androstane-3β,17β-diol Diacetate (4e)

The diol (*4d*) (25 mg) was acetylated (27) and the product (one component on tlc) recrystallized from acetone to give the diacetate (*4e*) (19 mg), mp 162–163°C; $[\alpha]_D^{22}$ +15° (*c* 1.58); ir ν_{max}: 3090 (cyclopropyl C—H), 1735 (ester C=O), 1235, 1176, 1087 (ester C—O) cm^{-1}; ^{1}Hmr δ: 4.55 (t, J = 8 Hz, 17α-proton), 2.03 (s) and 1.96 (s, 3- and 17-acetoxy methyl), 0.91 (s, 19-methyl), 0.77 (s, 18-methyl), 0.52 (1H, J = 12, 11.5, 4.5 Hz), 0.47 (1H, dd, $J_{gem} = J_{trans}$ = 5.5 Hz *endo*-cyclopropyl proton) ppm; ms *m/e*: 388 (M^+) 346 (M^+ − ketene). *Anal.* calcd. for $C_{24}H_{36}O_4$: C 74.19, H 9.34; found: C 74.35, H 9.24.

Acid Treatment of 2α,3-Cyclopropano-5α-androstane-3β,17β-diol (4d)

The diol (*4d*) (170 mg) was dissolved in a solution (17 ml) of concentrated hydrochloric acid in methanol (15% v/v) and heated to reflux for 1 h. The solution was then poured into excess aqueous saturated sodium bicarbonate and extracted with ether to yield a crude product (108 mg) which showed one fraction equivalent to 17β-hydroxy-2α-methyl-5α-androstan-3-one (**5**) on tlc. Recrystallization from acetone gave mp 152.5–153.5°C (lit. (30) mp 152–154°C); mp on admixture with an authentic sample of **5** was not depressed. Spectra (ir, ^{1}Hmr) were identical to those of authentic **5**.

Base Treatment of 2α,3-Cyclopropano-5α-androstane-3β,17β-diol (4d)

The diol (*4d*) (60 mg) was heated under reflux for 2 h with a solution (100 ml) of methanolic potassium hydroxide (2%

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

w/v). The reaction, which showed one fraction moving faster than the starting material on tlc, was concentrated and dilute hydrochloric acid was added. Extraction with ether gave a residue which was recrystallized from acetone, mp 146–148°C; ir and ^{1}Hmr spectra were identical to authentic 17β-hydroxy-2α-methyl-5α-androstan-3-one (**5**).

5α-Androst-2-ene-3,17β-diol Diacetate (3c)

Acetic anhydride (10 ml), followed by phosphorous oxychloride (2 ml), were added to a solution of 17β-hydroxy-5α-androstan-3-one (5 g) in dichloromethane (50 ml). The solution was allowed to stand at room temperature overnight and then poured into cold water. The organic layer was separated, washed with water and excess sodium bicarbonate solution, dried over anhydrous sodium sulfate, and evaporated at reduced pressure to yield the diol diacetate (**3c**). Recrystallization from dichloromethane–methanol gave crystals (3.3 g), mp 168–171°C (lit. (31) mp 168–170°C); ir ν_{max}: 1750 (enol acetate C=O), 1735 (17β-acetate C=O), 1695 (C=C) cm^{-1}; ^{1}Hmr δ: 5.25 (m, vinyl proton), 4.62 (t, J = 7 Hz, 17α-proton), 2.08 (s, 3-acetoxy methyl), 2.02 (s, 17β-acetoxy methyl), 0.85 (s, 19-methyl), 0.85 (s, 18-methyl) ppm.

Simmons–Smith Treatment of 5α-Androst-2-ene-3,17β-diol Diacetate (3c)

The enol acetate (**3c**) (1.05 g) was treated with a 10 molar excess of the Simmons–Smith reagent, prepared by the method of Rawson and Harrison (32). After 25 h a second 10 molar excess was added and reflux continued for a further 20 h. Chromatography of the crude product over alumina in petroleum ether gave on elution with 5–25% benzene – petroleum ether fractions (207 mg) from which was obtained on recrystallization from ether the cyclopropyl diacetate (**4e**), mp 163–164°C, identical with the previously prepared cyclopropyl diacetate (**4e**) by comparison of the ir, ^{1}Hmr, and mixture mp.

2α,3α-Dibromocyclopropano-5α-androstane-3β,17β-diol Diacetate (7)

A stirred solution of cetyltrimethylammonium bromide (2 g) in 50% aqueous sodium hydroxide (100 ml) was heated to reflux and a solution of 5α-androst-2-ene-3,17β-diol diacetate (**3c**) (4.6 g) in tribromomethane (25 ml) was added dropwise. After 1 h the exothermic reaction was cooled, diluted with brine, neutralized with 6 *N* sulfuric acid and extracted with chloroform. Evaporation of the chloroform left a dark gummy residue which on filtration through alumina in benzene gave a crystalline product (4 g). Successive recrystallizations from acetone gave the dibromocyclopropanoandrostane (**7**) (1.3 g), mp 199–200°C; $[\alpha]_D^{23}$ +20° (*c* 0.995); ir ν_{max}: 1765 (cyclopropyl ester), 1735 (17β-acetoxy C=O) cm^{-1}; ^{1}Hmr δ: 4.62 (t, J = 8 Hz, 17α-proton), 2.10 (s, 3β-acetoxy), 2.02 (s, 17β-acetoxy), 0.83 (s, 19-methyl), 0.78 (s, 18-methyl), 0.66 (1H, J = 12, 11.5, 4 Hz) ppm; ms *m/e*: 544, 546, 548 (M^+), 502, 504, 506 (M^+ − ketene), 465, 467 (M^+ − Br), 423, 425 [M^+ − (ketene + Br)]. *Anal.* calcd. for $C_{24}H_{34}Br_2O_4$: C 52.76, H 6.27, Br 29.25; found: C 53.04, H 6.36, Br 29.33.

2α,3-(endo)-Bromocyclopropano-5α-androstane-3β,17β-diol Diacetate (8)

(*a*) A stirred mixture of Zn dust (3.3 g) and cuprous chloride (4.9 g) in dry ether (10 ml) were heated to reflux for 30 min to give a zinc–copper couple (32). The dibromocyclopropanoandrostane (**7**) (546 mg) was added and reflux continued for a further 4.5 h. The reaction mixture as poured into aqueous sodium bicarbonate and extracted with ether to give a crude residue (344 mg). Recrystallization from ether–methanol gave the monobromo derivative (**8**), mp 163–164°C; ir ν_{max}: 1752 (cyclopropyl ester), 1735 (17β-acetoxy C=O) cm^{-1}; ^{1}Hmr δ: 4.58 (t, J = 8 Hz, 17α-proton), 3.37 (d, J = 10 Hz, *exo*-cyclopropyl proton), 1.98, 2.03 (2 × s, 3β- and 17β-acetoxy methyl) 0.88 (s, C-19 methyl), 0.77 (s, C-18 methyl), 0.66 (1H, J = 12, 12, 4 Hz) ppm; ms *m/e*: 387 (M^+ − Br), 345 [M^+ − (Br + ketene)], 285 [M^+ − (Br + ketene + HOAc)]. *Anal.* calcd. for $C_{24}H_{35}O_4Br$: C 61.66, H 7.55; found: C 61.87, H 7.59.

(*b*) To a solution of the dibromocyclopropanoandrostane (**7**) (292 mg) in dry dioxane (30 ml) and triethylamine (0.2 ml) was added 2 teaspoonsful of Raney nickel which had been stored under ethanol. This mixture was vigorously stirred under a hydrogen atmosphere for 32 h after which time the catalyst was filtered off and washed with diethyl ether. The ether filtrate was washed with dilute hydrochloric acid, distilled water, and brine. After drying over magnesium sulfate, the ether phase was evaporated at reduced pressure to give a crystalline material (106 mg), mp 160–161°C; recrystallization from hot methanol gave 2α,3-(*endo*)-bromocyclopropano-5α-androstane-3β,17β-diol diacetate (**8**), mp 162–162.5°C; ir ν_{max}: (KBr) 3070 (cyclopropyl, C—H), 1740 (3β-ester, C=O), 1734 (17β-ester, C=O) cm^{-1}; ms *m/e*: 387 (M^+ − Br), 345 [M^+ − (Br + ketene)], 285 [M^+ − (Br + ketene + HOAc)].

3-Bromo-5α-A-homoandrost-2-ene-3aξ,17β-diol Diacetate (9)

A stirred solution of the dibromocyclopropanoandrostane (**7**) (548 mg) and lithium aluminium hydride (500 mg) was heated to reflux in dry ether (15 ml). After 40 h the reaction mixture was poured onto crushed ice and extracted with ether. The crude product was treated overnight at room temperature with acetic anhydride and pyridine. Chromatography of the acetylation product over neutral alumina gave fractions on elution with 5% ether – petroleum ether (77 mg) which on recrystallization from ether – petroleum ether gave the A-homoandrostene (**9**), mp 158–159.5°C; ir ν_{max}: 1740 (3ξ-ester, C=O), 1733 (17β-ester, C=O) cm^{-1}; ^{1}Hmr δ: 6.13 (heptet, J = 10, 6, 2.5 Hz, vinyl proton), 5.50 (d, J = 11 Hz, 3aξ-proton) 4.89 (dd, J = 7, 8.5 Hz, 17α-proton), 2.41 (dd, J = 15, 10 Hz, 1α- or 1β-proton), 2.03, 2.13 (2 × s, 3β- and 17β-acetoxy methyl), 0.75, 0.77 (2 × s, C-18 and C-19 methyl) ppm; ms *m/e*: 466, 468 (M^+), 406, 408 (M^+ − HOAc), 387 (M^+ − Br), 327 [M^+ − (HOAc + Br)].

3-Trimethylsiloxy-5α-androst-2-en-17β-yl Acetate (3d)

The silyl enol ether (**3d**) was prepared by the procedure of House *et al.* (Method A, ref. 33), mp 90–103°C; ir ν_{max}: 1736 (ester C=O), 1669 (enolic C=C cm^{-1}; ^{1}Hmr δ: 4.1–4.6 (m, vinyl and 17α-protons), 1.81 (s, acetoxy), 0.64 (s, C-18 and C-19 methyl), 0 (s, trimethylsiloxy) ppm. *Anal.* calcd. for $C_{24}H_{40}O_3Si$: C 71.24, H 9.96; found: C 71.23, H 10.01.

Simmons–Smith Treatment of 3-Trimethylsiloxy-5α-androst-2-en-17β-yl Acetate (3d)

The silyl enol ether (**3d**) was treated with an excess of the Simmons–Smith reagent as described above for **3c**. The crude product showed the presence of a complex multiplet centered at δ 0.56 ppm (cyclopropyl protons) in the ^{1}Hmr spectrum. Chromatography over alumina gave no clearly defined products or crystalline fractions.

17β-Hydroxy-2α,3α-cyclopropano-5α-androstane (10)

This product was prepared by the Simmons–Smith procedure in ref. 24, mp 129–130°C (lit. (16) mp 130–132°C).

17β-Acetoxy-2α,3α-deuteriocyclopropano-5α-androstane-d_2 *(11)*

Prepared by the procedure in ref. 24, using CD_2I_2, mp 99–101.5°C; ms 98% d_2 (lit. (16) mp 105–106°C).

17β-Hydroxy-2α,3α-cyclopropano-5α-androstane-2β,4,4-d_3

17β-Acetoxy-5α-androstan-3-one-2,2,4,4-d_4 was prepared by

the procedure in ref. 34. Treatment of the crude product with 1 equiv. of bromine in CH_2Cl_2 gave the 2α-bromo derivative which was reduced to the 3ξ-alcohols with sodium borohydride. The epimeric mixture was treated with a zinc–copper couple in acetic acid as in ref. 24 to give 17β-acetoxy-5-androstene-2,4,4-d_3, mp 95–99°C (lit. (35) mp 96°C); ms: d_3 35%, d_2 40%, d_1 21%; ^{1}Hmr the ratio of 17α-H to vinyl proton shows 75% 2β-D. Treatment of the olefin with CH_2I_2 as in ref. 24 gave a product which on hydrolysis yielded 17β-hydroxy-2α,3α-cyclopropano-5α-androstane-2β,4,4-d_3, mp 128–129°C (lit. (16) mp 130–132°C); ms: d_3 24%, d_2 46%, d_1 25%; ^{1}Hmr δ −0.18 (1H, m), 0.50 (2H, m) ppm.

Molécules modèles des motifs des poly-1,4-glucosides. I. Synthèse et correspondance configurationelle de diastéréoisomères avec les motifs de la cellulose et de l'amylose

FRANÇOISE LAFUMA ET CLAUDE QUIVORON

Laboratoire de Physico-Chimie Macromoléculaire de l'Université Pierre et Marie Curie (Paris VI), Ecole Supérieure de Physique et de Chimie, 10 rue Vauquelin - 75231, Paris Cedex 05 - France

Reçu le 20 janvier 1977[1]

FRANÇOISE LAFUMA et CLAUDE QUIVORON. Can. J. Chem. **56**, 2065 (1978).

Afin de confirmer ou de préciser les types de chelations les plus probables existant dans les chaînes de cellulose et d'amylose, ainsi que dans les mono- et les disaccharides correspondants, nous avons entrepris des recherches sur des molécules modèles représentant, en partie, les motifs cellobiose et maltose. Ces molécules modèles sont des acétals intra-extracycliques de type cyclohexyloxy-2 tétrahydropyranne, porteurs de groupements hydroxyle primaire ou secondaire, de telle sorte que leurs dispositions covalentes, par rapport à la fonction acétal, soient analogues à celles des groupements (OH)2, (OH)3′, (OH)6 et (OH)6′ de l'amylose et de la cellulose. Vingt et un modèles ont été préparés à partir du dihydro-2,3 pyranne, de l'hydroxyméthyl-2 dihydro-2,3 pyranne ou de leurs époxydes. La plupart des diastéréoisomères correspondant aux modèles possèdant au moins deux atomes de carbone asymétrique, ont été séparés par chromatographie par perméation de gel, en mettant à profit la technique de recyclage. La correspondance configurationnelle de ces diastéréoisomères avec les motifs α-D- et β-D-glucose de l'amylose et de la cellulose, a été étudiée par résonance magnétique nucléaire du proton et du carbone 13. Ce travail d'attribution nous a permis de reconnaître, parmi les 30 diastéréoisomères séparés, 6 représentant les dispositions configurationnelles de l'amylose et 5, celles de la cellulose.

FRANÇOISE LAFUMA and CLAUDE QUIVORON. Can. J. Chem. **56**, 2065 (1978).

To confirm or to elucidate the most probable types of chelation existing in the chains of cellulose or amylose as well as in the corresponding mono- and disaccharides, we have undertaken studies on model molecules which represent, in part, the cellobiose and maltose entities. These model molecules are some intra- extra cyclic acetals of the type 2-cyclohexyloxytetrahydropyran. These molecules contain primary or secondary hydroxyl groups whose covalent dispositions relative to the acetal function are analogous to those of the groups (OH)2, (OH)3′, (OH)6, and (OH)6′, of amylose and cellulose. Twenty-one model compounds have been prepared from 2,3-dihydropyran, 2-hydroxymethyl-2,3-dihydropyran, or their expoxides. Most of the diastereoisomers corresponding to the model compounds containing at least two asymmetric carbon atoms have been separated by gel permeation chromatography using a recycling system to some advantage. The configurational correspondence of the diastereoisomers to the entities α-D- and β-D-glucose of amylose and of cellulose have been studied by proton and carbon-13 nuclear magnetic resonance. These assignments have permitted the recognition, among the 30 diastereoisomers of 6 which have the configuration of amylose and of 5 which have that of cellulose.

[Journal translation]

Introduction

Les interactions hydrogène et, en particulier, les liaisons hydrogène intramoléculaires, qui participent à l'établissement des structures, à l'état solide, de l'amylose, de la cellulose et de leurs mono- et disaccharides, ont fait l'objet d'un grand nombre de travaux expérimentaux et théoriques. En raison de leur insolubilité dans les milieux non aqueux, ces 1,4-glucosides ont été surtout étudiés par diffraction des rayons X. Cependant, les interprétations des clichés obtenus conduisent, notamment dans le cas de la cellulose et de l'amylose, à des systèmes de chélation qui diffèrent, le plus souvent d'un auteur à l'autre. C'est le cas également des divers calculs conformationnels publiés sur ces composés glucosidiques.

En ce qui concerne les monosaccharides comme l'α-D-glucose ou le β-D-glucose, à l'état solide, les auteurs (1, 2) s'accordent à penser qu'il n'existe aucune chélation dans ces composés. Dans le cas des disaccharides et des polysaccharides, les divers travaux théoriques et expérimentaux amènent à considérer des liaisons hydrogène intramoléculaires faisent intervenir des sites situés sur chacun des cycles pyranosidiques. Ainsi, la chélation (OH)3′···O5′ est unanimement admise dans les mailles cristallines du cellobiose (3–5), du méthyl β-cellobioside (6) et de la cellulose (7–12).[2] Divers auteurs proposent, en outre, pour la cellulose deux autres types de chélation qui concernent directement ou indirectement la participation de chaque groupement hydroxyméthylé: ces derniers pourraient être engagés dans une liaison hydrogène intramoléculaire (OH)2···(OH)6′ (12–14)

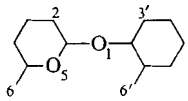
ou ne donner lieu qu'à des liaisons interchaînes (10, 15, 16). Par ailleurs, une troisième chélation: (OH)2···O1 a été proposée par Quivoron *et al.* (17–20), à la suite d'études de chélation, par spectroscopie infrarouge, de molécules modèles représentant partiellement le motif cellobiose.

Pour le maltose (21, 22), le méthyl β-maltoside (23), les cyclodextrines (24, 25) et les différentes variétés cristallines d'amylose (1, 26, 27), la liaison hydrogène intramoléculaire la plus fréquemment citée est la chélation (OH)2···(OH)3′. Quivoron et Néel (19) ainsi que Fialeyre *et al.* (28) sont les seuls à proposer une chélation de type (OH)2····O1, à partir d'études effectuées sur des molécules modèles (17, 18) ou sur le maltose (28) en solution. La liaison hydrogène intramoléculaire (OH)6′····O5 a été, en particulier, suggérée par Quivoron et Néel (19).

Afin de confirmer ou de préciser les types de liaison hydrogène intramoléculaires les plus probables, rencontrés dans la cellulose, l'amylose et dans leurs disaccharides, nous avons entrepris des recherches sur des molécules modèles représentant, en partie, les motifs cellobiose ou maltose, selon la méthode préconisée par Quivoron et Néel (17–19). Ces molécules modèles sont des acétals intra-extracycliques, de type cyclohexyloxy-2 tétrahydropyranne: por-

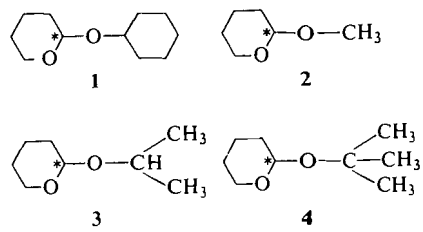


teurs d'un, de deux, voire de trois groupements hydroxyle primaire ou secondaire, de telle sorte que leurs dispositions covalentes, par rapport à la fonction acétal, soient analogues à celles des groupements (OH)2, (OH)3′, (OH)6 et (OH)6′ de l'amylose ou de la cellulose.

Nous exposons dans cette Partie I, la synthèse des molécules modèles retenues, dont la plupart présentent deux atomes de carbone asymétrique. Nous décrivons également la correspondance configurationnelle avec les motifs de la cellulose et de l'amylose, établie pour chacun des racémiques séparés par chromatographie (29). La Partie II (57), est consacrée à l'étude, par spectroscopie infrarouge, des conformations chélatées des diastéréoisomères et à une discussion des résultats, dans le cadre des chélations dans les mono-, di- et poly-1,4-glucosides.

Synthèse des molécules modèles

Les molécules modèles ont été préparées par action du dihydro-2,3 pyranne, de l'hydroxyméthyl-2 dihydro-2,3 pyranne ou de leur époxyde respectif, sur le monoalcool ou sur le diol cyclohexanique approprié. Les modes opératoires sont rapportés dans la partie expérimentale.



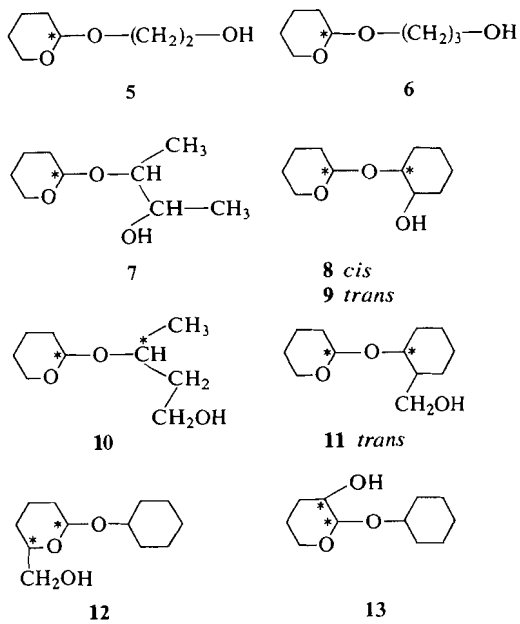
1 2 3 4

Acétals simples

Afin d'obtenir des informations d'ordre conformationnel sur les dérivés monosubstitués du tétrahydropyranne, nous avons synthétisé ces quatre alcoxy-2 tétrahydropyrannes par réaction, en milieu acide, du monoalcool correspondant sur le dihydro-2,3 pyranne (30–33).

Acétal-monoalcools

Les modèles (**5–9**) ont été obtenus par le même type de réaction, en remplaçant le monoalcool par le diol correspondant (17, 34), en grand excès. Pour **8** et **9**, les alcools sont respectivement les cyclohexanediols *cis* et *trans*, préalablement séparés (17).



5 6 7 **8** *cis* **9** *trans* 10 **11** *trans* 12 13

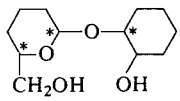
Dans le cas des composés **10** et **11**, les diols de départ ont été respectivement le butane-diol-1,3 et le *trans*-hydroxyméthyl-2 cyclohexanol. Afin d'éviter la condensation du dihydro-2,3 pyranne sur la fonction alcool primaire de chacun de ces diols, il s'est avéré nécessaire de bloquer, au préalable, sélectivement celle-ci sous forme de tosylate, puis de régénérer cette fonction après addition du groupement hydroxyle secondaire (voir Partie expérimentale).

De la même façon, le modèle **12** a été obtenu par réaction du cyclohexanol sur l'hydroxyméthyl-2

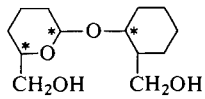
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

dihydro-2,3 pyranne, préparé par réduction du dimère de l'acroléine (35, 36), préalablement acétylé. L'hydrolyse finale de la fonction acétate, à froid en milieu basique, évite toute rupture possible de la liaison acétal formée.

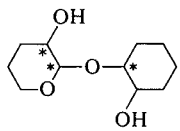
L'acétal-alcool **13** résulte de l'addition du cyclohexanol sur l'époxyde du dihydro-2,3 pyranne. Cet époxyde est préalablement préparé par action de l'acide para-nitroperbenzoïque (37).



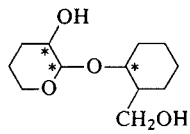
14 *cis*
15 *trans*



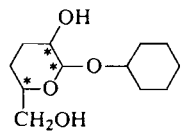
16 *trans*



17 *cis*
18 *trans*



19 *trans*



20

Acétal-diols

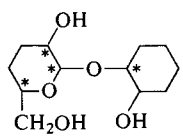
Les composés **14** et **15** ont été préparés par action respective des cyclohexane-diols-1,2 *cis* et *trans* sur l'hydroxy-méthyl-2 dihydro-2,3 pyranne acétylé (voir modèle **12**). La réaction est analogue dans le cas du modèle **16**, à partir du *trans*-hydroxyméthyl-2 cyclohexanol préalablement tosylé sur la fonction alcool primaire.

Les molécules modèles **17** et **18** sont issues de l'addition des cyclohexane diols-1,2 *cis* et *trans* sur l'époxyde du dihydro-2,3 pyranne (38); le diol de départ est le *trans*-hydroxyméthyl-2 cyclohexanol pour le composé **19**.

L'acétal-diol **20** a été obtenu par addition du cyclohexanol sur l'époxyde de l'acétate de l'hydroxyméthyl-2 dihydro-2,3 pyranne (voir Partie expérimentale).

Acétal-triol

Par analogie avec le modèle précédent (**20**), cet acétal-triol a été préparé par réaction de l'acétate de l'hydroxyméthyl-2 dihydro-2,3 pyranne sur le cyclohexane-diol-1,2 *trans*.



21 *trans*

Séparation chromatographique des diastéréoisomères

Ces séparations ont été réalisées pour la plupart d'entre eux par chromatographie par perméation sur gel en utilisant la technique de recyclage et sont décrites par ailleurs (29, 39).

Le tableau 1 rassemble les différentes fractions obtenues pour les molécules modèles **7**–**20**, c'est à dire comportant deux ou trois atomes de carbone asymétrique. Ces fractions correspondent à des racémiques purs et leur pureté a été caractérisée par spectroscopie, notamment par résonance magnétique nucléaire du proton et du carbone 13. Il ne nous a pas été possible de séparer les diastéréoisomères relatifs au composé **21**, en raison de son insolubilité dans les solvants chromatographiques utilisés (tétrahydrofuranne, éther diisopropylique).

Correspondance configurationnelle de certains diastéréoisomères avec les motifs de la cellulose et de l'amylose

Lorsque l'on considère les diastéréoisomères racémiques correspondant à une même structure covalente, ils diffèrent entre eux par les positions axiales et équatoriales des substituants hydroxyle et des liaisons C—O pontales. Comme dans les chaînes de cellulose et d'amylose, ces groupements O—H et ces liaisons C—O pontales ont des configurations axiales et équatoriales bien déterminées, il convenait, avant l'étude des conformations chélatées (voir Partie II), de déterminer, parmi les diastéréoisomères séparés par chromatographie, ceux qui correspondent aux dispositions configurationnelles des motifs de la cellulose et de l'amylose.

Dans le cas des acétals monohydroxylés de type cyclohexyloxy-2 tétrahydropyranne (deux atomes de carbone asymétrique), certains d'entre eux présentent un racémique possèdant une correspondance configurationnelle avec la cellulose, le second avec l'amylose. A titre d'exemple, les deux racémiques du modèle **9**, que nous avons pu séparer, diffèrent entre eux par les configurations relatives des carbones C1 et C4′. Dans ces conditions, l'un correspond à la disposition (OH)3′/O5 de la cellulose (liaison C1—O1 équatoriale); l'autre a la même disposition dans la chaîne d'amylose (liaison C1—O1 axiale). Dans le cas des acétal-diols qui se présentent, en toute rigueur, sous forme de quatre racémiques diastéréoisomères (trois atomes de carbone asymétrique), l'examen des modèles moléculaires montre qu'excepté les molécules modèles **14** et **17** qui comportent un groupement hydroxyle cyclohexanique *cis*, tous les autres modèles ont chacun un diastéréoisomère décrivant les configurations des hydroxyles cellulosiques et un second spécifique des hydroxyles de l'amylose.

TABLEAU 1. Différentes fractions obtenues par chromatographie pour les molécules modèles **7–20**

Composé	Nombre de C*	Fractions pures	Remarques
7 à **13**	2	Deux fractions notées A et B	
14	3	**14**A, **14**B, **14**C	Absence de **14**D
15	3	**15**A, **15**B, **15**C	Absence de **15**D
16	3	**16**A	**16**B, **16**C, **16**D non résolus
17	3	**17**A, **17**B, **17**C, **17**D	
18	3	**18**A, **18**B, **18**C	**18**D enrichi
19	3	**19**A, **19**B	**19**C, **19**D non résolus
20	3	**20**A, **20**B	**20**C enrichi **20**D non résolu

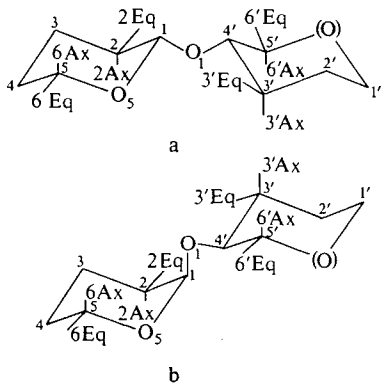


FIG. 1. Correspondance configurationnelle des diastéréoisomères des molécules de type cyclohexyloxy-2 tétrahydropyranne, avec les séquences de la cellulose (*a*) et de l'amylose (*b*).

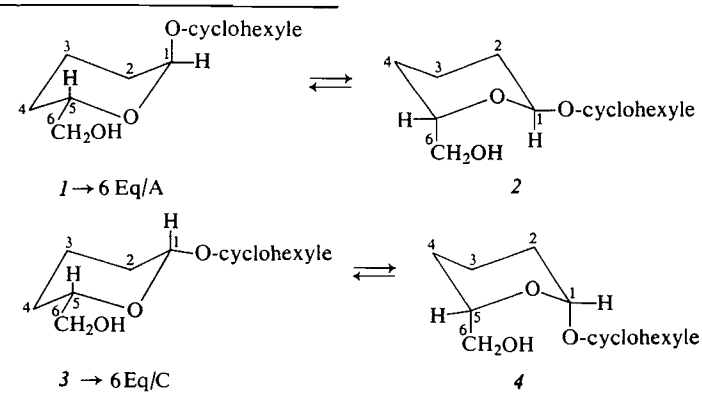
La fig. 1 indique les structures conformationnelles générales des molécules modèles de type cyclohexyloxy-2 tétrahydropyranne, représentées dans le cadre, soit des séquences de la cellulose, soit des séquences de l'amylose. Ces schémas conformationnels permettent, indépendamment des équilibres de conformations inter-chaises, d'affecter un symbole configurationnel à chaque diastéréoisomère. Ainsi, le diastéréoisomère de type **9** associé à la cellulose (C) sera dénoté: 3′Eq/C; celui de même type associé à l'amylose (A): 3′Eq/A. Avec cette convention de correspondance, l'acétal-diol **18**, par exemple, comportera deux diastéréoisomères intéressants, de symbole: 2 Eq/3′ Eq/C et 2 Eq/3′ Eq/A.

Nous avons proposé, dans le présent travail, une correspondance configurationnelle entre certains des diastéréoisomères séparés et les motifs séquentiels de la cellulose et de l'amylose. Cette correspondance a été étudiée essentiellement à partir des spectres de résonance magnétique nucléaire (rmn) du proton et du carbone 13. Toutefois, pour quelques diastéréoisomères, le profil des bandes infrarouges ν(O—H) de chélation nous a permis d'attribuer leurs configurations.

Equilibres conformationnels des tétrahydropyrannes substitués

Les équilibres de conversion entre formes chaises, qui n'existent pas au niveau des résidus α-D- et β-D-glucose des chaînes d'amylose et de cellulose, sont toujours présents dans les tétrahydropyrannes alcoxylés et compliquent l'interprétation des spectres de rmn. L'analyse des équilibres conformationnels n'est pas simple également dans le cas des cycles au moins disubstitués, tels que les acétal-monoalcools et les acétal-diols, en raison de l'intervention des facteurs classiques de stabilité (40–43).

Si nous considérons, à titre d'exemple, le cas des deux diastéréoisomères du modèle **12**, les équilibres conformationnels sont les suivants:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

TABLEAU 2. Différents facteurs jouant un rôle dans la stabilité de chacune des conformations **12**

Conformation	Facteurs de stabilisation	Facteurs de destabilisation
1 → 6 Eq/A	(*1*) Effet anomère (*2*) CH_2OH équatorial	—
2	—	(*1*) Absence d'effet anomère (*2*) CH_2OH axial
3 → 6 Eq/C	CH_2OH équatorial	Absence d'effet anomère
4	Effet anomère	Substituants en 1 et 5 axiaux

Ainsi que le désignent les symboles configurationnels définis précédemment, *1* est le modèle du groupement CH_2OH de l'amylose et *3*, celui correspondant à la cellulose. Le tableau 2 rassemble les différents facteurs jouant un rôle dans la stabilité de chacune de ces conformations. Dans le cas du premier diastéréoisomère *1*/*2*, la conformation la plus probable est donc la conformation *1*, puisqu'il n'apparait aucun facteur d'instabilité alors que la conformation *2* est, au contraire, très défavorisée. Le diastéréoisomère modèle de l'hydroxyle (OH)6 de l'amylose aurait, par conséquent, la même conformation que les résidus d'α-D-glucose (H1 équatorial). Pour le second diastéréoisomère *3*/*4*, le choix est moins évident entre les deux conformations. Nous pensons cependant que la conformation *3*, analogue à celle des résidus celloglucane (H1 axial), est la plus favorisée, en raison du facteur important "1–3 diaxial" qui doit déstabiliser fortement la conformation *4*.

Ce type d'analyses conformationnelles que nous avons effectuées pour les autres diastéréoisomères modèles, nous a permis de faciliter l'interprétation et l'attribution des spectres rmn, dans le but de déterminer les correspondances configurationnelles des diastéréoisomères obtenus par chromatographie, avec les motifs d'amylose et de cellulose.

Détermination des correspondances configurationnelles par résonance magnétique nucléaire du proton

Spectres de résonance magnétique nucléaire du proton des molécules modèles

Les spectres rmn des alcoxy-2 tétrahydropyrannes se présentent, à 60 et à 100 MHz, sous forme de trois massifs distincts et non résolus: le proton "anomère" situé entre 4.5 et 5.0 ppm (en échelle δ par rapport au TMS); les protons portés par des atomes de carbone liés directement à des atomes d'oxygène (3–4 ppm) et les autres protons qui résonent à des champs plus forts (1–2 ppm). La fig. 2*a* représente, à titre d'exemple, le spectre rmn 60 MHz du cyclohexyloxy-2 tétrahydropyranne, molécule modèle **1**. Dans le cas des acétals hydroxylés, les protons des fonctions alcool résonent dans la zone 3–4 ppm.

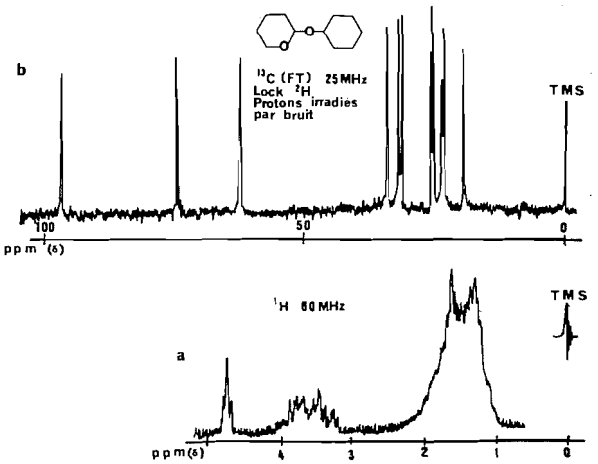


FIG. 2. Spectres de résonance magnétique nucléaire de la molécule modèle **1**: (*a*): spectre de protons enregistré à 60 MHz; (*b*): spectre des carbones 13 enregistré à 25 MHz; solvant: benzène deutérié; référence: tétraméthylsilane.

La seule indication qu'il est possible d'obtenir directement des spectres de ce type, concerne le proton anomère, bien que le déplacement chimique et que le couplage de ce proton soient des moyennes pondérées des deux conformations chaises tétrahydropyranniques. Dans ce type de composé, le proton anomère est préférentiellement en position équatoriale (44).

Outre ces observations liées aux protons anomères, nous nous sommes efforcés de résoudre les massifs des autres protons. Nous avons ainsi étudié, dans un travail annexe, les déplacements chimiques induits, dans les spectres rmn 60 MHz de certains alcoxy-2 tétrahydropyrannes (45) et acétals monohydroxylés (46), par addition de tri(dipivalométhanato) europium $(DPM)_3Eu$, ce qui nous a permis d'attribuer certains protons ou groupes de protons.

*Correspondance configurationnelle des diastéréoisomères de type **12** et **13***

D'une manière générale, les diastéréoisomères correspondant à une même molécule modèle et séparés par chromatographie par perméation de gel, présentent des spectres rmn différents. Cependant, la faible résolution des spectres ne permet pas, en

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

pratique, d'interpréter les différences observées et, de ce fait, d'attribuer les configurations des diastéréoisomères. Dans le cas des acétals monohydroxylés sur le cycle tétrahydropyrannique (molécules modèles **12** et **13**), il nous a toutefois été possible de déterminer la correspondance configurationnelle des quatre diastéréoisomères correspondants.

Nous avons indiqué précédemment que les conformations les plus probables des deux diastéréoisomères de type **12**, étaient vraisemblablement les conformations *1*: 6 Eq/A (proton anomère équatorial) et *3*: 6 Eq/C (proton anomère axial). La fig. 3*a* représente le spectre rmn 60 MHz du mélange des deux diastéréoisomères de type **12**, dans la zone (4–5 ppm) des protons anomères. On observe un signal relativement étroit vers 5 ppm et une résonance large à champ plus fort. La première résonance est due à un proton équatorial (A), la seconde à un proton axial (B) (33, 40, 44). Nous avons ainsi été conduits à attribuer le premier signal à la conformation *1* et le second à la conformation *2*. L'enregistrement séparé des spectres rmn de chacun des deux diastéréoisomères nous a permis, par comparaison avec le spectre du mélange, d'établir la correspondance configurationnelle suivante: **12**A: 6 Eq/A et **12**B: 6 Eq/C.

Nous avons pu obtenir la correspondance configurationnelle des diastéréoisomères **13**A et **13**B, en suivant un raisonnement sensiblement analogue. Le spectre rmn 60 MHz du mélange de diastéréoisomères est reproduit sur la fig. 3*b*. Cette zone 4–5 ppm montre les résonances des deux protons anomères, dont les profils résultent d'un couplage avec le proton vicinal H2 respectif. Par analogie avec les diastéréoisomères de type **12**, la résonance à 4.8 ppm (J = 3 Hz) correspond au proton équatorial; celle à 4.3 ppm (J = 6 Hz), au proton axial. La correspondance configurationnelle des diastéréoisomères séparés par chromatographie est donc: **13**A: 2 Eq/A et **13**B: 2 Eq/C.

Détermination des correspondances configurationnelles par résonance magnétique nucléaire du carbone 13

Il ne nous a pas été possible d'établir, par rmn du proton, les correspondances configurationnelles des diastéréoisomères autres que ceux des type **12** et **13**, en raison de la faible résolution des spectres. Nous avons ainsi été amenés à poursuivre ces analyses configurationnelles par rmn du carbone 13, en utilisant la technique de résonance pulsée par transformée de Fourier. Outre le domaine beaucoup plus important des déplacement chimiques, l'intérêt majeur de cette technique, que nous avons mis à profit dans la détermination des correspondances

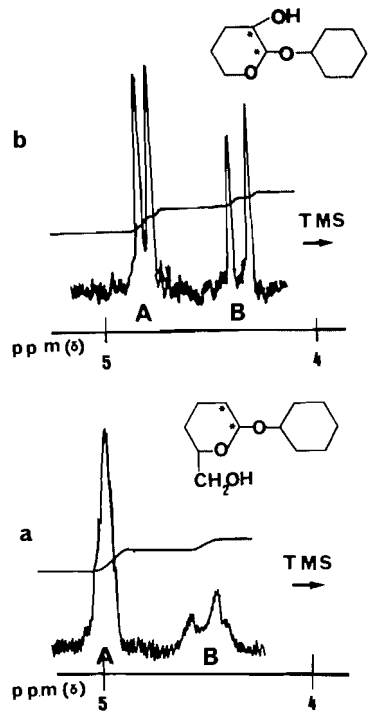

FIG. 3. Spectres de résonance magnétique nucléaire 60 MHz des mélanges de diastéréoisomères de type **12** (spectre *a*) et de type **13** (spectre *b*); solvant: chloroforme deutérié; référence: tétraméthylsilane.

configurationnelles, réside dans la grande sensibilité des déplacements chimiques des ^{13}C, aux effets stériques. La rmn du ^{13}C est, à ce titre, un outil de choix dans l'étude des conformations en série cyclohexanique par exemple (47), où la présence d'un seul substituant suffit souvent à procurer un spectre du premièr ordre (48). Toute contrainte stérique apportée par l'introduction d'un substituant, provoque, en effet, un déplacement vers les champs forts (blindage) de la résonance du carbone qui porte ce substituant (47–50). Ces phénomènes spectraux, propres à la rmn du ^{13}C, ont permis de nombreuses attributions dans la série des inositols (51) et dans celle des monosaccharides (52).

Méthodes d'études utilisées

Les valeurs des déplacements chimiques dans les spectres totalement découplés, permettent de classer les différents carbones dans les trois catégories suivantes:

Carbone anomère C1	:	90 ppm < δ < 110 ppm
Carbone portant un substituant oxygéné (OH ou OR)	:	60 ppm < δ < 85 ppm
Carbone non substitué:		15 ppm < δ < 45 ppm

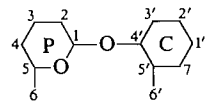
La fig. 2*b* représente, à titre d'exemple, le spectre

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

rmn ^{13}C du cyclohexyloxy-2 tétrahydropyranne (**1**), où l'on remarque que les 11 catégories différentes de ^{13}C donnent 11 raies fines distinctes. Les spectres "off resonance" nous ont, par ailleurs, fourni des données supplémentaires concernant le type de substitution des différents carbones. Enfin, les spectres en présence de $(DPM)_3Eu$ nous ont permis d'obtenir des renseignements complémentaires sur l'attribution des correspondances configurationnelles, compte tenu de ce que nous avions observé en résonance du proton. Cependant, ils n'ont été enregistrés que dans le cas des acétal-monoalcools pour lesquels le site de complexation de l'ion europium est connu (45, 46).

Exemples d'attributions et de correspondances configurationnelles

Il nous a semblé fastidieux de présenter tous les résultats numériques issus des spectres rmn ^{13}C que nous avons enregistrés à partir des 4 acétals simples, des 14 acétal-monoalcools diastéréoisomères et des 17 diastéréoisomères acétals-diols séparés. Nous présentons ici un exemple d'attribution spectrale dans chacun de ces trois cas. D'une manière générale, les attributions des différents ^{13}C des cycles tétrahydropyranniques (P) et cyclohexaniques (C) ont été désignées avec les symboles suivants.



Acétals simples—Nous avons choisi de présenter les attributions spectrales faites à partir du cyclohexyloxy-2 tétrahydropyranne (molécule modèle **1**), étant donné que ce composé constitue le squelette de base des acétal-alcools. De plus, les valeurs numériques des déplacements chimiques de différents ^{13}C dont nous proposons l'attribution, nous ont servi lors de l'interprétation des spectres rmn ^{13}C des acétals mono- et dihydroxylés. Le tableau 3 rassemble les résultats obtenus pour ce composé. La première colonne représente les différents déplacements chimiques mesurés à partir du spectre totalement découplé. ΔEu désigne les différences observées entre les déplacements chimiques mesurés en présence et en absence de $(DPM)_3Eu$ dans le benzène deutérié, extrapolées pour des rapports molaires $(DPM)_3Eu$:soluté égaux à 1 (45, 46). Les natures des différentes contraintes stériques permettant d'attribuer les ^{13}C tétrahydropyranniques et cyclohexaniques, ont été déterminées en fonction des valeurs des déplacements de signaux (47–52).

Acétal-monoalcools—Les spectres rmn ^{13}C des diastéréoisomères correspondants ont été interprétés sur la base des attributions des ^{13}C du cyclohexyloxy-2 tétrahydropyranne (tableau 3). Nous prendrons comme exemple le cas des deux diastéréoisomères de la molécule modèle **13** pour lesquels une correspondance configurationnelle a été proposée par rmn du proton. Le tableau 4 rassemble les résultats obtenus pour les diastéréoisomères **13**A et **13**B, où les déplacements Δδ, exprimés en ppm, sont relatifs aux variations des déplacements chimiques, par rapport aux ^{13}C correspondants du cyclohexyloxy-2 tétrahydropyranne (**1**). Ces valeurs sont affectées d'un signe + lorsqu'ils s'effectuent vers les champs forts et d'un signe −, vers les champs faibles. La comparaison des valeurs Δδ et des contraintes stériques permet de vérifier que le groupement cyclohexyloxy est préférentiellement axial dans **13**A et préférentiellement équatorial dans **13**B. Compte tenu des conformations tétrahydropyranniques les plus favorisées, nous retrouvons ici les correspondances configurationnelles déterminées par rmn du proton: 2 Eq/A pour **13**A et 2 Eq/C pour **13**B. Il a été, de la même façon, possible de confirmer les correspondances configurationnelles des diastéréoisomères **12**A et **12**B, décrites précédemment et de proposer des correspondances pour les autres acétal-monoalcools (voir tableau 6). Dans le cas du couple **9**A, **9**B, les différences de déplacements chimiques des ^{13}C de ces deux diastéréoisomères ne sont pas toujours assez significatives pour préciser avec certitude leurs correspondances configurationnelles. Ces dernières, indiquées dans le tableau 6, ont été, dans ce cas, confirmées à partir des spectres infrarouge de chélation (voir Partie II).

Acétal-diols—Les spectres rmn ^{13}C des diastéréoisomères des différents acétal-diols étudiés, sont

TABLEAU 3. Observations et attributions effectuées à partir du spectre rmn ^{13}C du composé **1**. La nature des différentes contraintes stériques a été déterminée sur la base des résultats bibliographiques (50–53) et les références spectrales sont le déplacement chimique du cyclohexane (δ 27.6 ppm) pour les ^{13}C de type cyclohexanique et ceux du tétrahydropyranne (68.8, 27.4 et 24.3 ppm) pour les ^{13}C tétrahydropyranniques

δ (en ppm)	ΔEu	Nature de la contrainte stérique	Attributions proposées

d'une interprétation plus délicate en ce qui concerne leurs attributions, en raison de la présence simultanée de deux fonctions alcool sur le squelette cyclohexyloxy-2 tétrahydropyrannique. De plus, il n'est pas significatif, dans ce cas, d'enregistrer les spectres en présence de sels d'europium, ainsi que nous l'avons signalé précédemment.

Les attributions spectrales ont été faites en comparant systématiquement les données avec celles du cyclohexyloxy-2 tétrahydropyranne, d'une part, et avec celles des diastéréoisomères relatifs aux deux acétal-monoalcools correspondants. Ainsi, dans le cas de la molécule modèle **16**, les acétals monohydroxylés parents sont les modèles **11** et **12**. La correspondance configurationnelle d'un diastéréoisomère de type acétal-diol est, par conséquent, une résultante directe des configurations possibles des deux acétal-monoalcools dont il dérive.

Lors des analyses de spectres que nous avons faites, nous avons admis que les effets dûs aux contraintes stériques, au niveau de chaque déplacement chimique de ^{13}C, sont une combinaison linéaire de ceux observés pour les acétals monohydroxylés parents. Cette hypothèse paraît vraisemblable s'il n'y a pas une variation trop importante des équilibres conformationnels, par rapport aux acétals monohydroxylés. Les effets dûs aux contraintes stériques que nous avons été amenés à évaluer, ne tiennent pas compte des nouvelles perturbations apportées par la présence simultanée des deux groupements alcool. Nous ne les avons donc pas considérés comme des valeurs absolues mais ils nous ont permis, dans certains cas, de trancher entre deux structures configurationnelles. De plus, nous avons tenu compte du type de conformation chélatée, déduit par spectroscopie infrarouge (voir Partie II) et de l'examen parallèle des modèles moléculaires qui nous a permis, pour certains diastéréoisomères, d'écarter la ou les structures configurationnelles incompatibles avec le type de chélation observé expérimentalement. Le tableau 5 représente, à titre d'exemple, les déplacements chimiques δ observés pour le diastéréoisomère **15**A ainsi que les déplacements chimiques calculés dans le cas d'une filiation **9**A + **12**A (déplacement

motifs de la cellulose et 6 avec ceux de l'amylose. Nous décrivons, dans la Partie suivante, les conformations chélateés préférentiellement adoptées par ces diastéréoisomères modèles, dans le but de préciser certaines chélations pouvant survenir dans les polyglucosides.

Partie expérimentale

Molécules modèles

Composés 1–4

Ces composés ont été obtenus suivant le mode opératoire de Parham et Anderson (34) avec un rendement de 80 à 90%: **1**, pé 39–40°C/0.05 Torr (17, 31); **2**, pé 35°C/20 Torr (30); pé 50°C/15 Torr (32); pé 58°C/15 Torr (32).

Composés 5–9

La synthèse de ces molécules modèles a déjà été décrite antérieurement (18). Nous avons légèrement modifié le mode opératoire en effectuant la réaction dans le chlorure de méthylène (250 cm^3 pour 1 mol de dihydropyranne). Les rendements réactionnels sont alors compris entre 48 et 53%: **5**, pé 82°C/1 Torr; **6**, pé 62°C/0.1 Torr; **7**, pé 49°C/0.1 Torr; **8**, pé 120°C/2 Torr; **9**, pé 78°C/0.1 Torr.

Composés 10 et 11

Le transhydroxyméthylcyclohexanol a été préparé suivant le procédé de Smissman et Mode (53). Les monotosylates de ce diol et du butanediol-1,3 ont été obtenus par la méthode de Siegel (54). Ces monotosylates sont des huiles visqueuses légèrement jaunes. Toute purification de ces huiles par distillation est exclue car elles se décomposent vers 90°C même sous atmosphère d'azote. Dans le cas de l'hydroxyméthyl-2 cyclohexanol, l'huile peut cristalliser lentement. Les cristaux obtenus, recristallisés dans l'éther absolu fondent à 75°C.

L'addition sur le dihydropyranne (voir ci-dessus) est effectuée sur l'huile brute. Le produit de la réaction est une huile visqueuse qu'il n'est possible ni de cristalliser, ni de distiller. L'hydrolyse non réductrice du tosylate ayant conduit à des résultats infructueux, nous avons transformé celle-ci en fonction acétate plus facile à hydrolyser en milieu basique. Nous avons suivi un mode opératoire décrit (55) mais dans notre cas particulier, le meilleur rendement en fonctions acétate/tosylate est obtenu au bout de 5 h de reflux (55% pour le dérivé du butanediol-1,3, pé 126°C/10 Torr et 49% pour celui de l'alcool cyclique pé 81°C/0.05 Torr.

L'hydrolyse de la fonction acétate est effectuée à froid par un mélange méthanol anhydre/méthanolate de sodium (56). Après évaporation du méthanol, le résidu est repris à l'eau puis extrait à l'éther. La solution éthérée est séchée sur du sulfate de sodium; l'éther puis l'extrait sont distillés (rendement 97%): **10**, pé 68°/1 Torr (25% par rapport au diol de départ); **11** pé 102°C/0.05 Torr (20% par rapport au diol de départ).

Composés 12, 14–16

L'hydroxyméthyl-2 dihydropyranne, préparé par réduction du dimère de l'acroléine (35, 36), a été acétylé selon la méthode de Zelinski *et al.* (36). Après addition du monoalcool ou du diol correspondant, la fonction acétate est hydrolysée (56) et l'acétal-alcool, purifié: **12**, pé 98°C/0.05 Torr (82% par rapport à l'alcool de départ); **14**, pé 120°C/0.05 Torr (43%); **15**, pé 118°C/0.05 Torr (49%); **16**, ce modèle a été purifié par chromatographie sur gel au cours de la séparation des isomères.

Composés 13, 17–21

A une suspension de 70 g d'acide paranitroperbenzoïque (préparé suivant le procédé de Vilkas (37)) dans 200 ml de chloroforme (sec et débarassé de toute trace d'éthanol par distillation sur de l'anhydride phosphorique), on ajoute progressivement une solution de 0.35 mol de dihydropyranne sec (ou de son dérivé) dans 100 ml de chloroforme sec. La température est maintenue inférieure à 15°C pendant toute l'addition. Lorsque tout le dihydropyranne a été ajouté et que la température n'a plus tendance à s'élever spontanément, on filtre rapidement et l'on rince trois fois au chloroforme pur. La solution chloroformique est alors lavée à la soude pour éliminer toute trace d'acide et séchée sur sulfate de sodium.

La solution précédente est ramenée à 100 ml et on ajoute ensuite 0.3 mol de l'alcool (ou du diol) approprié ainsi que 300 mg d'acide paratoluène-sulfonique. On agite 3 h au reflux, puis on reprend par 200 ml de chloroforme et on lave à la soude normale. La phase organique est ensuite séchée sur sulfate de sodium. On évapore le solvant puis on distille éventuellement le produit obtenu s'il n'est pas trop lourd et surtout s'il ne se dégrade pas trop à la chaleur. Dans le cas des dérivés de l'hydroxyméthyl-2 dihydropyranne, on effectue en dernier lieu une hydrolyse basique de la fonction acétate: **13**, pé 78°C/0.05 Torr; (72% par rapport au dihydropyranne); **17** pé 89°C/0.05 Torr (29%); **18** (38), pé 90°C/0.05 Torr (35%); **19**, pé 120°C/0.05 Torr (16%); **20**, pé 120°C/0.05 Torr (59%); **21**, ce composé n'a pu être purifié ni par distillation, ni par chromatographie en phase liquide, en raison de son insolubilité dans les solvants chromatographiques organiques.

Purification des produits finaux

En raison de la sensibilité à la chaleur de la fonction acétal, il n'a pas toujours été possible de purifier les composés par distillation directe, notamment dans le cas des acétal-diols. La purification a été alors réalisée au cours de la séparation chromatographique des isomères en prélevant les impuretés au fur et à mesure des recyclages (29). Les fractions finales ont toutes été contrôlées par spectroscopie infrarouge et résonance magnétique nucléaire. Ce sont des huiles très visqueuses ou des solides à point de fusion voisin de la température ambiante.

Spectres de résonance magnétique nucléaire

Les spectres des protons ont été enregistrés sur les appareils Varian A60 à 60 MHz, Varian HA 100 ou XL 100 à 100 MHz avec pour référence le tétraméthylsilane (TMS) et pour solvant le chloroforme deutérié, le benzène deutérié ou le tétrachlorure de carbone.

Les spectres en présence de $(DPM)_3Eu$ ont, en particulier, été enregistrés à partir de solutions 0.5 *M* des composés dans le tétrachlorure de carbone en augmentant progressivement la quantité du réactif.

Les spectres des carbones ont été enregistrés à 25 MHz sur les appareils JEOL PS 100 ou Varian XL 100 munis de la transformée de Fourier avec pour référence le TMS et pour solvant le benzène deutérié dont le signal n'interfère en aucun cas avec ceux des composés étudiés. Le signal du deutérium de ce solvant est d'autre part utilisé pour le lock.

Molécules modèles des motifs des poly-1,4-glucosides. II. Etude, par spectroscopie infrarouge, des conformations chélatées des diastéréoisomères modèles et discussion dans le cadre des chélations glucosidiques

FRANÇOISE LAFUMA ET CLAUDE QUIVORON

Laboratoire de Physico-Chimie Macromoléculaire de l'Université Pierre et Marie Curie (Paris VI), Ecole Supérieure de Physique et de Chimie, 10 rue Vauquelin - 75231, Paris Cedex 05 - France

Reçu le 20 janvier 1977[1]

FRANÇOISE LAFUMA et CLAUDE QUIVORON. Can. J. Chem. **56**, 2076 (1978).

Nous avons étudié, d'une façon systématique, les spectres infrarouges de chélation, dans la région 3700–3300 cm^{-1}, de chacun des 30 diastéréoisomères séparés, en solution diluée dans le tétrachlorure de carbone. Les diastéréoisomères présentant une correspondance configurationnelle avec les chaînes de la cellulose et de l'amylose ont été plus particulièrement examinés. Suivant la structure covalente de la molécule modèle et la configuration du diastéréoisomère, nous avons observé des bandes d'absorption ν(O—H) spécifiques de chélations à 5, 6, 7 et 8 chaînons. Le plus souvent, la géométrie des conformations chélatées varie, pour une même molécule modèle, d'un diastéréoisomère à un autre. Les diastéréoisomères des acétals hydroxylés nous ont permis de connaître ce qui résulte d'une compétition de deux groupements hydroxyle, vis à vis d'un même site accepteur de proton. La discussion de nos résultats expérimentaux dans le cadre des chélations glucosidiques, nous a conduit à proposer les chélations (OH)2···O1; (OH)3′···O5 et (OH)6···O3, pour le cellobiose, le méthyl β-cellobioside et la cellulose. Dans le cas du maltose, du méthyl β-maltoside et de l'amylose, nous avons confirmé la chélation de type (OH)2···(OH)3′, et il nous paraît vraisemblable que la chélation (OH)2···O1 puisse exister dans ces α-1,4-glucosides.

FRANÇOISE LAFUMA and CLAUDE QUIVORON. Can. J. Chem. **56**, 2076 (1978).

We have made a systematic study of the infrared spectra, in the chelation region 3700–3300 cm^{-1}, of each of 30 separate diastereoisomers in dilute solution in carbon tetrachloride. Those diastereoisomers which have configurations corresponding to those of cellulose or amylose were examined more carefully. Depending on the structure of the model molecule and its diastereoisomeric configuration, it was possible to observe absorption bands corresponding to chelation in rings of 5, 6, 7 or 8 members. Most frequently the geometry of the chelated conformations varies from one diastereoisomer to another of a single molecule. The diastereoisomers of hydroxylated acetals have permitted the recognition of the result of a competition between two hydroxyl groups for the same proton accepting site. Discussion of these experimental results in terms of glucosidic chelations have led to the hypothesis that the chelations are (OH)2···O1, (OH)3′···O5 and (OH)6···O3 in cellobiose, in methyl β-cellobioside and in cellulose, respectively. We have confirmed the chelation (OH)2···(OH)3′ in the case of maltose, methyl β-maltoside and amylose and it seems reasonable to suggest that a chelation (OH)2···O1, can exist in these α-1,4-glucosides.

[Journal translation]

Introduction

Nous avons exposé, dans la Partie I précédente (1), la synthèse de diastéréoisomères, modèles des séquences disaccharidiques de la cellulose et de l'amylose ainsi que leurs correspondances configurationnelles avec les motifs α-D- et β-D-glucose (voir tableau 6, Partie I). Dans le présent mémoire, nous avons étudié, d'une façon systématique, les spectres infrarouges, dans la région des vibrations de valence ν(O—H), de chacun de ces diastéréoisomères en solution très diluée dans le tétrachlorure de carbone, afin de connaître la ou les conformations chélatées préférentiellement adoptées par ces diastéréoisomères en solution.

La spectroscopie infrarouge est la méthode de choix pour étudier la formation de liaisons hydrogène intramoléculaires. L'observation la plus caractéristique, dans le spectre d'un soluté se prêtant à une chélation de type O—H···O, est la différence de fréquences Δν (exprimée en cm^{-1}) entre les maximums des bandes de vibration de valence ν(O—H) des groupements hydroxyle "libre" et "chélaté". Les valeurs des différences Δν publiées dans le domaine des diols (2–5), des éther-alcools (6) et des acétal-alcools (7, 8), montrent qu'elles dépendent, d'une manière générale, de la position relative des deux sites donneur et accepteur de proton dans la molécule étudiée. Les différentes catégories de cycles de chélation sont les suivantes, si l'on compte tous les atomes constituant de tels cycles:

[d]Valeur calculée en se référant à la valeur 3633 cm^{-1} pour la fréquence d'absorption (OH) libre.

Cycles à 5 chaînons : $25 < \Delta\nu < 40\ cm^{-1}$

Cycles à 6 chaînons : $75 < \Delta\nu < 110\ cm^{-1}$

Cycles à 7 chaînons : $150 < \Delta\nu < 200\ cm^{-1}$

Cycles à 8 chaînons : $120 < \Delta\nu < 150\ cm^{-1}$

En ce qui concerne la stabilité de ces différents cycles de chélation, il semble qu'elle varie, pour une série homologue de produits, dans l'ordre décroissant (6, 7): 5 > 6 > 7 > 8.

Nous avons étudié les spectres infrarouges de chélation, dans la gamme 3700–3300 cm^{-1}, ainsi que les conformations chélatées, des diastéréoisomères modèles qui ont été séparés par chromatographie (9). Bien que chaque diastéréoisomère ait fait l'objet d'une étude systématique, nous décrivons ci-dessous les résultats obtenus avec ceux présentant une correspondance configurationnelle avec les motifs de la cellulose et de l'amylose.

Dans ce travail, nous avons été amenés à comparer, dans le cas des diastéréoisomères d'une même structure covalente, les densités optiques des bandes ν(O—H) libre et chélaté, dans le but d'estimer qualitativement l'importance des conformations chélatées. Cette comparaison directe suppose que les coefficients d'extinction moléculaire des bandes correspondantes, ne varient sensiblement pas d'un diastéréoisomère à l'autre. Aucune donnée bibliographique n'étant publiée sur ce sujet, nous avons supposé que cette hypothèse pouvait être admise sans trop de réserves.

Conformations chélatées des diastéréoisomères de type acetal-monoalcool

Les molécules modèles **5** et **6**, qui ne sont pas des mélanges de diastéréoisomères (un seul atome de carbone asymétrique), ont déjà fait l'objet d'un travail antérieur (7). Nous n'avons pas rapporté les spectres de chélation des diastéréoisomères **8**A et **8**B qui ne présentent aucune correspondance configurationnelle avec les séquences d'amylose ou de cellulose. Les spectres de chélation des diastéréoisomères des modèles **7**, **10** et **13** sont décrits par ailleurs (10) et montrent une dépendance très notable de la configuration sur la conformation chélatée adoptée, phénomène général que nous avons retrouvé pour la plupart des autres couples de diastéréoisomères étudiés.

Le tableau 1 rassemble les résultats obtenus pour les autres acétal-monoalcools; nous y avons adjoint ceux des diastéréoisomères **13**A et **13**B (10) qui présentent des correspondances configurationnelles avec les séquences d'amylose (**13**A) et de cellulose (**13**B) (1).

Diastéréoisomères 9

Ces deux diastéréoisomères sont d'un grand intérêt, puisque **9**A: 3′Eq/A est un modèle configurationnel de l'amylose et que **9**B: 3′Eq/C est un modèle de la cellulose. Les deux spectres de chélation correspondants sont consignés sur la fig. 1. On observe une différence extrêmement importante entre les deux spectres. Ainsi, le diastéréoisomère **9**A est majoritairement chélaté d'une façon pentagonale sur l'atome d'oxygène pontal, puisqu'il n'est pas possible de mettre en évidence une absorption vers 3400–3450 cm^{-1} qui serait due à une chélation heptagonale sur l'atome d'oxygène cyclique. Au contraire, dans le cas du diastéréoisomère **9**B, les deux types de chélations pentagonale et heptagonale sont présents avec une prépondérance de la conformation chélatée à sept atomes. On constate donc ici une influence notable de la configuration sur les conformations préférentiellement chélatées, tout à fait analogue à celle observée pour le composé 7 (10) qui préfigurait ce modèle.

Nous avons, par ailleurs, décelé des empêchements stériques de formation de chélation, en con-

For personal use only.

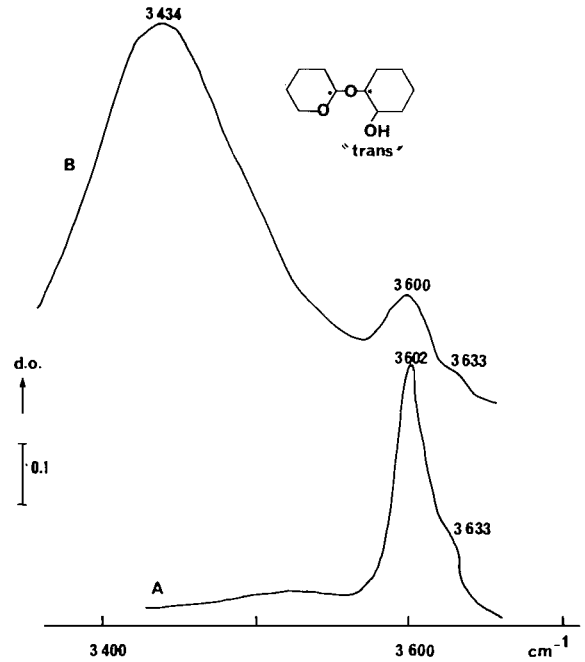

FIG. 1. Spectre infrarouge de chélation des isomères du composé **9**.

struisant les modèles moléculaires des diastéréoisomères **9**A et **9**B. L'examen de ces modèles montre que si la chélation heptagonale est aisée dans le cas de **9**B, elle est exclue, d'un point de vue stérique pour **9**A; ce qui confirme les correspondances configurationnelles proposées (1) et les observations spectroscopiques.

Diastéréoisomères 11

Ces deux diastéréoisomères, dont les correspondances configurationnelles n'ont pas été attribuées d'une façon certaine, ont des spectres infrarouges de chélation qui s'apparentent aux diastéréoisomères de type **10** (10) (voir tableau 1), avec une population en conformation chélatée probablement beaucoup plus grande pour **11**B que pour **11**A.

Diastéréoisomères 12

Le diastéréoisomère **12**A: 6 Eq/A correspond, d'un point de vue configurationnel, aux séquences de l'amylose; **12**B: 6 Eq/C, aux séquences de la cellulose. Ces modèles schématisent donc l'interaction de l'hydroxyle (OH)6 avec la fonction acétal. Les spectres de chélation de ces deux diastéréoisomères sont analogues à celui de l'hydroxyméthyl-2 tétrahydropyranne (tableau 1) et présentent de faibles différences entre eux, en fréquences comme en intensités. Les cycles pentagonaux observés correspondent donc à une chélation sur l'atome d'oxygène tétrahydropyrannique.

Diastéréoisomères 13

Le diastéréoisomère **13**A correspond au groupement (OH)2 des résidus α-D-glucose de l'amylose (2 Eq/A); le diastéréoisomère **13**B à celui des résidus β-D-glucose de la cellulose (2 Eq/C). Ces deux diastéréoisomères sont presque entièrement chélatés en solution. Le diastéréoisomère **13**A, dont le spectre ne fait apparaître aucune absorption ν(O—H) "libre", serait plus chélaté que **13**B.

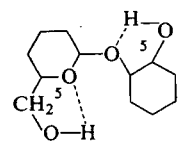
La comparaison entre les valeurs de Δν observées pour **13**A et **13**B, et les valeurs trouvées par Kuhn (2) pour les cyclohexanediols-1,2, *cis* et *trans* suggère d'apparenter, d'un point de vue configurationnel, le diastéréoisomère **13**A au diol-1,2 *cis* et **13**B au diol-1,2 *trans* (10), ce qui correspond bien aux attributions proposées antérieurement (1).

Conformations chélatées des diastéréoisomères de type acetal-diol

Parmi les 20 diastéréoisomères de type acétal-diol qui ont pu faire l'objet d'une séparation par chromatographie, 5 correspondent à des dispositions configurationnelles de la cellulose ou de l'amylose: **15**A, **15**C, **18**A, **18**C et **20**B. Les diastéréosiomères **19**A et **19**B, effectivement séparés, n'ont pas reçu de correspondance configurationnelle certaine (1). Nous exposons uniquement ci-dessous les résultats obtenus dans le cas de ces diastéréoisomères. La plupart de ces modèles nous ont permis de connaître ce qui résulte d'une compétition entre les chélations de deux hydroxyles sur un même site accepteur de proton d'une fonction acétal, ainsi que cela a lieu au sein des polyglucosides eux-mêmes. Le tableau 2 rassemble les principaux résultats spectroscopiques obtenus pour ces composés.

Diastéréoisomères 15A et 15C

La fig. 2 représente les spectres de chélation de ces deux diastéréoisomères, ainsi, à titre indicatif, que celui du diastéréoisomère **15**B. Le diastéréoisomère **15**A, possèdant une correspondance configurationnelle avec l'amylose (6 Eq/3′ Eq/A), présente, dans son spectre, une bande unique à 3608 cm^{-1}, spécifique de chélations pentagonales. Il est donc vraisemblable d'admettre que sa conformation chélatée prépondérante soit la conformation *1*.



Conformation *1*

Dans le cas du diastéréoisomère **15**C, les deux bandes principales observées sont situées à 3606 cm^{-1}

[a]Faible épaulement.
[b]Avec ce modèle, il n'est pas possible de construire de cycle 5 chaînons avec le groupement (O—H) primaire ou de cycle à 6 chaînons avec le groupement (O—H) secondaire.
[c]Valeur obtenue en se référant à une valeur de 3630 cm^{-1} pour ν(O—H libre).

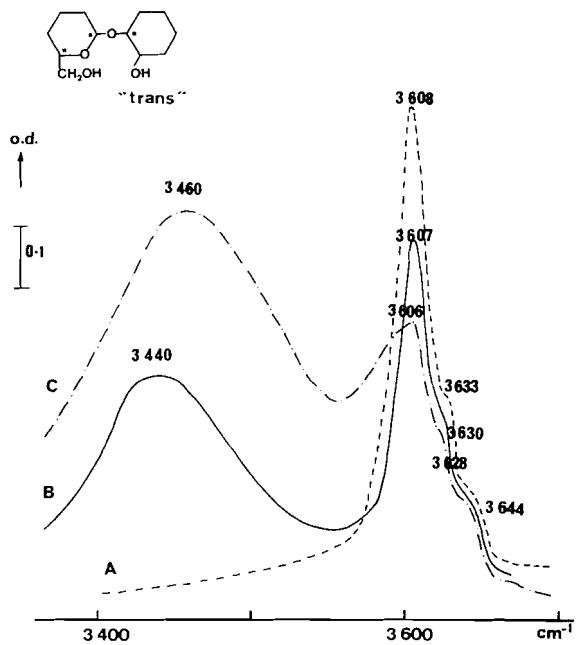

FIG. 2. Spectre infrarouge de chélation des isomères du composé **15**.

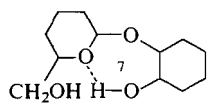
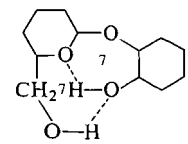
(cycle de chélation pentagonale) et à 3460 cm^{-1} (cycle de chélation heptagonale). Il y a donc certainement ici équilibre entre des conformations chélatées de type *1* (voir ci-dessus) et de type *2*.



Conformation *2*

Cependant, étant donné la forte absorption à 3460 cm^{-1}, il est possible que les deux conformations chélatées précèdentes soient en équilibre avec la conformation *3*.



Conformation *3*

qui fait apparaître un second cycle de chélation heptagonale. Cette possibilité est d'autant plus envisageable que le groupement OH secondaire voit son caractère accepteur de proton renforcé par la formation de sa propre chélation.

Diastéréoisomères 18A et 18C

Ces modèles schématisent, par rapport à la fonction acétal intraextracyclique, les hydroxyles (OH)2 et (OH)3′ de l'amylose et de la cellulose: **18**A: 2 Eq/3′ Eq/A et **18**C: 2 Eq/3′ Eq/C. En ce qui concerne le diastéréoisomère **18**A, la présence simultanée de bandes de chélations pentagonale et octogonale, ainsi qu'une absorption non négligeable des vibrateurs O—H "libre", est incompatible avec l'existence d'une seule conformation chélatée. Il est, par conséquent, certain que ce diastéréoisomère soit le siège d'un équilibre entre les conformations chélatées suivantes (schéma 1).

Au contraire, le diastéréoisomère **18**C existerait sous forme de trois conformations chélatées en équilibre entre elles (schéma 2).

Diastéréoisomères 19A et 19B

Deux des quatre diastéréoisomères de la molécule modèle **19**, préparée à partir de l'hydroxyméthyl-2 cyclohexanol *trans*, ont été séparés par chromatographie. Deux diastéréoisomères correspondent, en

SCHÉMA 1

toute rigueur, à la cellulose et à l'amylose mais n'ont pas été attribués d'une façon certaine.

Nous avons représenté sur la fig. 3 les spectres de chélation du diastéréoisomère pur **19**A, de la fraction enrichie **19**B et celui du mélange **19**C + **19**D. Dans le cas des diastéréoisomère **19**A et **19**B, on observe deux massifs principaux, l'un situé vers 3588–3604 cm^{-1}, l'autre vers 3538–3540 cm^{-1}. Ces deux zones d'absorption sont respectivement spécifiques de chélations pentagonale et hexagonale. Par analogie avec les chélations observées pour les acétals mono-alcools correspondants **11** et **13**, les deux diastéréoisomères **19**A et **19**B seraient le siège d'un équilibre entre formes chélatées (schéma 3).

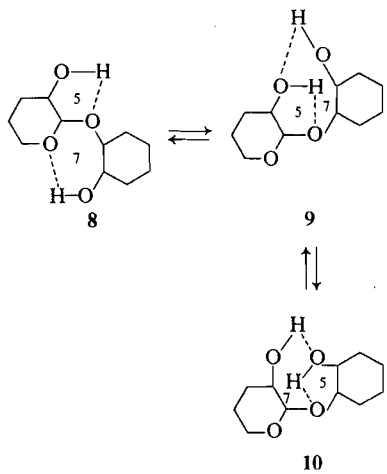

SCHÉMA 2

Le spectre de l'isomère **19**A montre, de plus, une absorption vers 3440 cm^{-1} qui persiste même à haute dilution. Une telle bande, caractérisée par des valeurs $\Delta\nu = 200$ et 190 cm^{-1}, suivant que l'on se réfère aux vibrateurs O—H "libre" primaire ou secondaire, est relative vraisemblablement à une chélation de type heptagonal. Il est possible que cette faible absorption soit due à la chélation, dans la conformation *12*, de l'hydroxyle secondaire sur l'atome d'oxygène de la fonction alcool primaire.

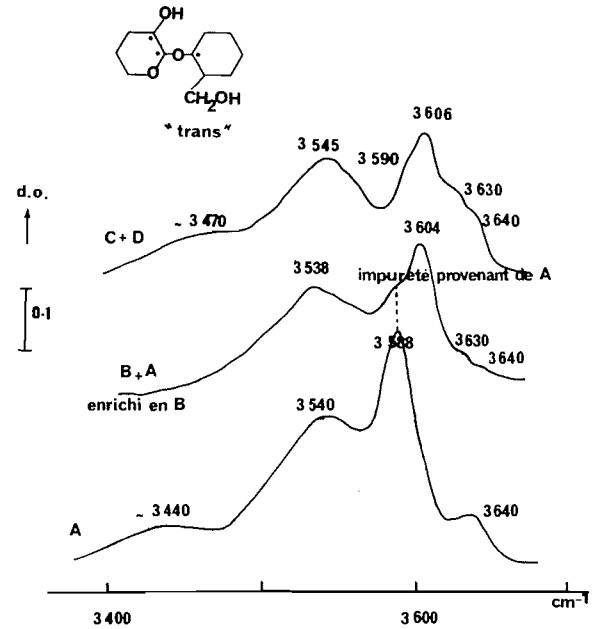

FIG. 3. Spectre infrarouge de chélation des isomères du composé **19**.

Diastéréoisomère 20B

Les fréquences d'absorption (3606 et 3587 cm^{-1}) relevées sur le tableau 2 sont caractéristiques de deux chélations pentagonales différentes. La conformation préférentiellement adoptée par ce diastéréoisomère serait ainsi la suivante.

Discussion des résultats dans le cadre des chélations glucosidiques

La mise en évidence directe de liaisons hydrogène intramoléculaires au sein des chaînes de polysaccharides comme la cellulose et l'amylose est, ainsi que nous l'avons indiqué dans la Partie I (1), difficilement réalisable. Le cas des mono- et des disaccharides n'est guère plus accessible directement: seul Fialeyre *et al.* (11) a pu montrer récemment, par spectroscopie infrarouge, l'existence de cycles pentagonaux de chélation dans certains mono- et disaccharides en solution. L'étude des conformations chélatées des

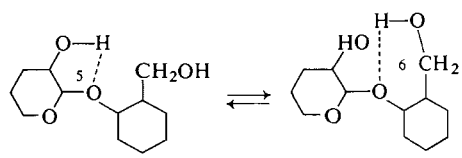

SCHÉMA 3

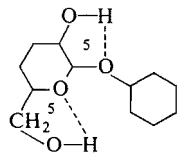

diastéréoisomères modèles correspondant, d'un point de vue configurationnel, aux séquences d'amylose et de cellulose, que nous avons réalisée au cours de ce travail, devrait se révéler très efficace quant aux liaisons hydrogène intramoléculaires, capables de prendre naissance au sein des poly-1,4 glucosides eux-mêmes.

Avant de discuter les résultats expérimentaux obtenus, il convient de faire trois remarques préalables, concernant leur extrapolation au cas de la cellulose, de l'amylose et de leurs mono- et disaccharides. En premier lieu, les diastéréoisomères modèles ne représentent, par principe, que très partiellement les séquences α-D- et β-D-glucosidiques. Cependant, les renseignements issus de la chélation des acétaldiols nous ont permis de connaître ce qui résulte de la compétition de deux fonctions hydroxyle vis à vis d'un même atome d'oxygène acétal. En second lieu, l'étude des conformations chélatées des diastéréoisomères a été effectuée en solution diluée dans un solvant inerte. L'extrapolation des résultats au cas des composés glucosidiques solides ou aux mono- et disaccharides en solution dans l'eau, paraît, dans ces conditions, assez hasardeuse. Nos propres résultats doivent néanmoins permettre de savoir si telle ou telle chélation, proposée dans le cas des composés glucosidiques, par diffraction des rayons X par exemple, est ou non vraisemblable. De plus, nous décrirons ici quelques spectres infrarouges de diastéréoisomères, enregistrés, dans la région ν(O—H), à l'état liquide pur. Ces observations nous ont permis de déceler une persistance de certaines chélations, sous cet état condensé. La troisième remarque concerne les équilibres conformationnels des diastéréoisomères étudiés. Il est, en effet, certain que ces équilibres sont beaucoup plus perturbés en solution qu'à l'état solide (cas des composés glucosidiques). Il en résulte, ainsi que nous l'avons observé, une possibilité d'existence de plusieurs conformations chélatées, pour certains diastéréoisomères. Il nous sera, cependant possible d'écarter certaines des conformations chélatées observées, lorsque ces dernières sont envisagées au sein des chaînes de cellulose et d'amylose, pour des raisons de restriction de liberté de rotation autour des liaisons glucosidiques 1—4′.

Chélations dans les mono- et disaccharides

Les travaux publiés sur les monosaccharides à l'état solide, n'envisagent pas l'existence de liaisons hydrogène intramoléculaires (12, 13). Les réseaux de liaison hydrogène proposés ne font, en effet, intervenir que des interactions intermoléculaires. Dans le cas des disaccharides, la plupart des publications décrivent, en plus des liaisons hydrogène intermoléculaires, des chélations relatives à des sites accepteur et donneur appartenant aux deux cycles pyranosidiques. Ces chélations sont respectivement la liaison (OH)3′···O5 pour le cellobiose (14) et la liaison (OH)2···(OH)3′ pour le maltose (15).

Nous discuterons de la possibilité d'existence de chélations dans les mono- et les disaccharides, dans le cadre de nos propres résultats.

Persistance de chélations dans certains diastéréoisomères à l'état liquide

Afin de tenter de relier les résultats obtenus sur la chélation des diastéréoisomères en solution, avec ceux publiés dans le cas des mono- et des disaccharides en solution ou à l'état solide, nous avons enregistré les spectres infrarouges de certains diastéréoisomères, à l'état liquide pur, dans la gamme 3400–3700 cm^{-1}.

La fig. 4 représente, à titre d'exemple, les spectres obtenus pour les diastéréoisomères **12**A, **12**B, **13**A et **13**B. Chaque spectre présente un large massif vers

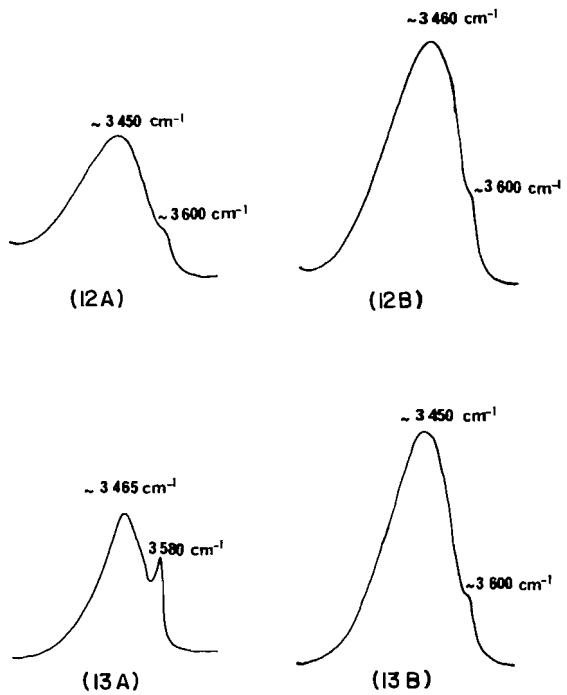

FIG. 4. Spectres infrarouges à l'état liquide pur des isomères des composés **12** et **13** dans la région ν(O—H) 3000–4000 cm^{-1}; appareil Perkin-Elmer 225; faces NaCl.

TABLEAU 3. Valeurs (en Å) des distances O···O calculées en considérant, dans les mono- et les disaccharides, des couples d'atomes d'oxygène appartenant à un même cycle pyranosidique, d'après les références 15, 18–21

	Distance (Å)											
Sucre	O1···O2	O2···O3	O3···O4	O4···O6	O6···O5	O6···O1	O1′···O2′	O2′···O3′	O3′···O1	O6′···O1	O6′···O5′	O6′···O1′
α-D-Glucose	2.81	2.86	2.91	3.61	2.89	5.16						
β-D-Glucose	2.85	2.90	2.90	3.51	2.81	4.90						
Cellobiose	2.75	2.92	2.86	4.36	2.69	4.71	2.89	2.76	3.00	4.18	2.89	4.89
Maltose	2.85	2.88	2.89	4.25	2.84	4.46	2.82	2.93	2.82	3.54	2.89	5.03
Méthyl β-cellobioside	2.89	2.93	2.94	4.31	2.73	4.70	2.85	2.92	3.08	3.64	2.78	4.90
Méthyl β-maltoside	2.78	2.88	2.84	4.24	2.81	4.48	2.87	2.92	2.79	3.46	2.89	5.01

3450–3465 cm^{-1}, qui est dû aux liaisons hydrogène intermoléculaires. On remarque, vers les hautes fréquences, des faibles épaulements vers 3600 cm^{-1} et une bande de moyenne intensité à 3580 cm^{-1}, dans le cas du diastéréoisomère **13**A. La position en fréquence de ces épaulements et de cette absorption à 3580 cm^{-1}, qui accompagnent le massif des liaisons intermoléculaires, nous a conduit à les attribuer à des liaisons hydrogène intramoléculaires de type pentagonal. En effet, pour le diastéréoisomère **13**A, la bande à 3580 cm^{-1} correspond tout à fait avec celle située à 3582 cm^{-1} pour la solution diluée dans le tétrachlorure de carbone (10) et qui est spécifique d'une chélation de type pentagonal. De la même façon, les épaulements situés vers 3600 cm^{-1} pour les diastéréoisomères **12**A, **12**B et **13**B correspondent à la zone des chélations pentagonales observées en solution.

Nous avons également observé une légère persistance de chélations pentagonales à l'état liquide, dans le cas des diastéréoisomères **15**A et **20**B. Il ne nous a pas été possible de savoir si les autres types de chélation persistent à cet état condensé, car les bandes correspondantes sont situées à des fréquences bien inférieures à 3600 cm^{-1} et sont, si elles existent, masquées par le large massif des interactions intermoléculaires.

Il paraît donc très vraisemblable qu'il existe des liaisons hydrogène intramoléculaires, au moins de type pentagonal, dans les mono- et les disaccharides en solution dans les solvants généralement choisis lors des études antérieures, c'est à dire dans l'eau et dans le diméthylsulfoxyde.

Distances O···O dans les cristaux de mono- et de disaccharides

Bien que la plupart des travaux antérieurs s'accordent à ne pas envisager de chélation dans les monosaccharides à l'état solide, ce problème nous semble toujours posé, en raison de la persistance de certaines chélations, pour les diastéréoisomères en solution ou à l'état liquide. Lorsque l'on détaille les différentes publications, relatives essentiellement à des études radiocristallographiques, on remarque, le plus souvent, qu'elles ne font pas toujours appel à toutes les possibilités d'interactions entre sites oxygénés. En particulier, les atomes d'oxygène acétal, reconnus par Quivoron et Neel (16) comme les sites les plus accepteurs de proton, ne sont pas souvent considérés, sauf pour le cellobiose: chélation (OH)3′···O5.

Dans le but de relier nos propres résultats sur les conformations chélatées des diastéréoisomères, avec des distances O···O privilégiées dans les mono- et les disaccharides à l'état solide, nous avons repris, d'une façon systématique, les données radiocristallographiques antérieures et calculé toutes les distances O···O dans le cas de l'α-D-glucose (17, 18), du β-D-glucose (19), du cellobiose (19), du maltose (15), du méthyl β-cellobioside (20) et du méthyl β-maltoside (21). Le tableau 3 rassemble les valeurs des distances O···O calculées en considérant des couples d'atomes d'oxygène appartenant à un même cycle pyranosidique. Le tableau 4 contient, au contraire, les valeurs des distances O···O, lorsque l'on envisage deux sites "oxygène" situés chacun sur un cycle différent. Ce dernier tableau n'est donc relatif qu'aux quatre disaccharides examinés.

Discussion des résultats

D'une manière générale, les radiocristallographes estiment qu'une liaison hydrogène a une existence "présumée", à l'état solide, lorsque la distance O···O calculée est inférieure ou égale à 2.9–3.0 Å. Le tableau 3 relatif aux chélations au sein d'un même cycle pyranosidique, contient un grand nombre de valeurs inférieures à cette limite, correspondant à des liaisons hydrogène intramoléculaires de type cyclohexanediol-1,2 *cis* ou *trans* ou hydroxyméthyl-2 tétrahydropyranne.

En solution, de telles chélations de type pentagonal sont observées pour les dérivés du cyclohexane (2) et du tétrahydropyranne (3) ainsi que pour nos modèles où elles persistent parfois même à l'état pur. Tous ces éléments nous permettent d'envisager

TABLEAU 5. Chélations mises en évidence, par spectroscopie infrarouge, dans les diastéréoisomères ayant une correspondance configurationnelle avec les séquences de la cellulose

Diastéréoisomère	Modèle de chélation(s)	Observations
 **9B**	(OH)3′···O5 (OH)3′···O1	Chélation heptagonale prépondérante
 **12B**	(OH)6···O5	Chélation pentagonale prépondérante
 **13B**	OH)2···O1	Chélation pentagonale prépondérante
 **15C**	(OH)3′···O5 (OH)3′···O1 (OH)6···O5 (OH)6···O3′	Equilibre entre les trois conformations chélatées *1*, *2* et *3*
 **18C**	(OH)2···O1 (OH)3′···O1 (OH)3′···O5 (OH)3′···(OH)2	Equilibre entre les trois conformations chélatées *8*, *9* et *10*

comme assez vraisemblable, l'existence de liaisons hydrogène intramoléculaires entre sites appartenant à un même cycle pyranosidique, dans les mono- et dans les disaccharides à l'état solide.

En ce qui concerne les chélations faisant intervenir deux sites situés chacun sur un cycle différent (disaccharides du tableau 4), les distances O···O optimales, c'est à dire inférieures ou égales à 2.9–3.0 Å, sont en nombre plus limité. Dans le cas du cellobiose et du méthyl β-cellobioside, les seules distances à retenir sont celles relatives aux chélations (OH)3′···O5 (d = 2.77 Å) et (OH)6···O3′ (d = 2.96–3.14 Å). La première de ces chélations a été proposée, d'une façon unanime, dans les mailles cristallines du cellobiose (14, 19, 22) et du méthyl β-cellobioside (20). Elle se retrouve dans tous les diastéréoisomères en correspondance configurationnelle avec le cellobiose, où elle est susceptible d'exister (**9**B, **15**C, **18**C). L'étude de **18**C montre que sa présence est conjointe à celle d'une chélation (OH)2···O1; lorsqu'il n'y a plus possibilité de rotation autour des liaisons pontales, la conformation *8* serait donc la plus favorisée comme l'ont suggéré Quivoron et Neel (23). La seconde liaison hydrogène intramoléculaire, déduite des valeurs du tableau 4 est l'interaction (OH)6···O3′. Elle a été proposée, en 1970, par Ham et Williams (20) dans la maille cristalline du méthyl β-cellobioside, conjointement avec la chélation (OH)3′···O5 précédente. Le diastéréoisomère **15**C se prête bien à cette double éventualité, comme nous l'avons indiqué précédemment (voir conformation *3*). Il nous semble, en définitive, possible de proposer, dans le cadre de

 **12A**	(OH)6···O5	Chélation pentagonale prépondérante
 **13A**	(OH)2···O1	Chélation pentagonale prépondérante
 **15A**	(OH)3′···O5 (OH)3′···O1 (OH)6···O5 (OH)6···O3′	Double chélation pentagonale prépondérante
 **18A**	(OH)2···O1 (OH)3′···O1 (OH)3′···O5 (OH)3′···(OH)2	Equilibre entre les quatre conformations chélatées *4*, *5*, *6* et *7*
 **20B**	(OH)2···O1 (OH)6···O5	Double chélation pentagonale prépondérante

nos résultats expérimentaux, un système de chélations (OH)2···O1, (OH)3′···O5 et (OH)6···O3′, à la fois pour le cellobiose et pour le méthyl β-cellobioside.

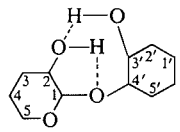
En ce qui concerne le maltose et le méthyl β-maltoside, les données du tableau 4 montrent qu'une seule possibilité de chélation peut, a priori, avoir lieu. Il s'agit de la liaison hydrogène (OH)2···(OH)3′: distances O···O de 2.79 et 2.82 Å. Cette liaison hydrogène a, en effet, été proposée pour ces deux disaccharides à l'état solide (15, 21) et en solution (24). L'étude du diastéréoisomère **18**A montre qu'une telle interaction est bien présente dans les conformations chélatées *6* et *7* sans qu'il ne nous soit pour autant possible d'écarter définitivement les conformations *4* et *5*.

Chélations dans les chaînes de cellulose et d'amylose

Parmi l'ensemble des diastéréoisomères étudiés, nous avons attribué, d'un point de vue configurationnel, cinq diastéréoisomères à la cellulose: **9**B, **12**B, **13**B, **15**C et **18**C. Le tableau 5 rassemble les résultats obtenus, par spectroscopie infrarouge, pour ces 5 diastéréoisomères. Une discussion détaillée de ces résultats, dans le cadre des chélations cellulosiques, a été récemment publiée (25). Nous avons proposé, comme dans le cas du cellobiose et du méthyl β-cellobioside, les chélations (OH)2···O1, (OH)3′···O5 et (OH)6···O3′. Ces trois interactions hydrogène pourraient coexister dans les zones désorganisées de la cellulose. Dans les zones cristallines, les groupements (OH)6 pourraient assurer la forte cohésion des chaînes cellulosiques entre elles, par rupture des chélations (OH)6···O3′ et par rotation, perpendiculairement à l'axe des chaînes, des liaisons covalentes O6—H6.

Dans le cas de l'amylose, les diastéréoisomères modèles **9**A, **12**A, **13**A, **15**A, **18**A et **20**B ont permis l'étude, par spectroscopie infrarouge, des chélations pouvant survenir dans les chaînes de ce polysaccharide (voir tableau 6). La discussion de nos résultats expérimentaux, ne dégage pas ici, contrairement au cas de la cellulose (25), de conclusions définitives sur les chélations mises en jeu. Les liaisons hydrogène intramoléculaires que nous pouvons retenir sont les chélations (OH)2···O1, (OH)6···O5 et (OH)2···(OH)3′. Dans le cas de la chélation (OH)6···O5, des travaux effectués par Fialeyre *et al.* (11), à partir de solutions de certains des diastéréoisomères dans des mélanges tétrachlorure de carbone – diméthyl sul-

foxyde, ont montré que cette interaction est moins favorisée que la chélation (OH)2...O1. Il nous semble ainsi vraisemblable qu'il puisse exister, dans les chaînes d'amylose, une double chélation du type:



Partie expérimentale

Tous les spectres de chélation ont été enregistrés avec un appareil Perkin-Elmer, modèle 225, à partir de solutions dans le tétrachlorure de carbone de concentrations inférieures dans tous les cas à 5×10^{-3} mol/ℓ, afin d'éviter les associations intermoléculaires.

Dans ces conditions de concentration, il est nécessaire d'opérer avec des cellules suffisamment épaisses pour obtenir des densités optiques mesurables; nos mesures ont été réalisées avec des cuves Infrasil de 2 cm d'épaisseur.

Le tétrachlorure de carbone (produit Prolabo pour spectrophotométrie) a été séché sur des tamis moléculaires 4 Å.

Les spectres sont reproductibles à ± 1 cm^{-1} et les densités optiques ont été mesurées avec une précision de 5%.

Aminoglycoside antibiotics. The total synthesis of 5-deoxykanamycin A

GERRY KAVADIAS,[1] PIERRE DEXTRAZE, ROBERT MASSÉ, AND BERNARD BELLEAU

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received December 16, 1972

GERRY KAVADIAS, PIERRE DEXTRAZE, ROBERT MASSÉ, and BERNARD BELLEAU. Can. J. Chem. **56**, 2086 (1978).

Condensation of 1,6-*N*,*O*-carbonyl-3-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**7**) with 6-azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl chloride by the Koenigs–Knorr reaction produced the α-glycoside **10**. The cyclic carbamate of **10** was opened with ethanol in the presence of sodium ethoxide and the resulting 4-*O*-(6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**12**) was glycosidated with 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl chloride (**21**) to give the α,α-diglycoside **22**. Hydrogenation of the azido group and removal of the protective groups gave 5-deoxykanamycin A (**25**), an antibiotic with a potency about half that of kanamycin A.

GERRY KAVADIAS, PIERRE DEXTRAZE, ROBERT MASSÉ et BERNARD BELLEAU. Can. J. Chem. **56**, 2086 (1978).

La condensation de la *N*,*O*-carbonyl-1,6 *N*-éthoxycarbonyl-3 didéoxy-2,5 streptamine (**7**) avec le chlorure de l'azido-6 tri-*O*-benzyl-2,3,4 déoxy-6 α-D-glucopyrannosyle, en faisant appel à la réaction de Koenigs–Knorr, conduit à l'α glycoside **10**. On a ouvert le carbamate cyclique de **10** avec de l'éthanol en présence d'éthylate de sodium et la *O*-(azido-6 tri-*O*-benzyl-2,3,4 déoxy-6 α-D-glucopyrannosyl)-4 *N*,*N*′-diéthoxycarbonyl didéoxy-2,5 streptamine (**12**) qui en résulte a été soumise à une réaction de glycosidation avec le chlorure de l'acétamido-3 tri-*O*-benzyl-2,4,6 déoxy-3 α-D-glucopyrannosyle (**21**) pour conduire à l'α,α-diglycoside **22**. L'hydrogénation du groupe azido et l'enlèvement des groupes protecteurs conduit à la déoxy-5 kanamycine A (**25**), un antibiotique dont la puissance est à peu près égale à la moitié de celle de la kanamycine A.

[Traduit par le journal]

In recent years, extensive studies have been carried out on the modification of aminoglycoside antibiotics with the purpose of studying the structure–activity relationship and of producing new antibiotics that are effective against resistant bacteria (1).

Most of the modifications have been directed at the aminosugar part of the molecule and only a few studies have been reported on the relationship between the structural features of the aminocyclitol moiety and the activity of the antibiotics (2).

The present paper describes the synthesis of 5-deoxykanamycin A (**25**) by glucosidation of the readily available and suitably protected 2,5-dideoxystreptamines (3) **7** and **14** by the Koenigs–Knorr reaction and demonstrates the usefulness of **7** and **14** as key intermediates for the synthesis of other 5-deoxyaminocyclitol antibiotics. With the exception of the mutamicins 2 and 2a, no other 5-deoxyaminocyclitol antibiotics have been reported (4). The interesting antibacterial properties of mutamicin 2 was an added incentive in the pursuit of our goals.

In the synthesis of aminoglycosides of 2-deoxystreptamine by the Koenigs–Knorr reaction, mercuric cyanide and dioxane–benzene or dioxane–chloroform are commonly used as catalyst and solvent, respectively (5–13). The role of dioxane in assisting the formation of α-glycosides has been discussed (7). The low solubility of the protected 2-deoxy- and 2,5-dideoxystreptamines in dioxane–benzene solutions led us to examine the use of dimethylformamide as the solvent in this coupling reaction. To establish workable experimental conditions for the synthesis of 5-deoxykanamycin A using dimethylformamide as the solvent, the condensation of **7** and **14** with the readily available 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl chloride (**6**) (14) was examined first.

Reaction of **7** with **6** in DMF in the presence of mercuric cyanide at 65°C for 24 h gave, after purification on a silica column, 4-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-1,6-*N*,*O*-carbonyl-3-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**8**) in 80% yield. The nmr signal for the anomeric proton in **8** was not clearly defined so that structure **8** could only be inferred. Removal of the protective benzyl groups by catalytic reduction of **8** in the presence of 10% palladium-on-carbon followed by opening of the carbamate ring of **9** with a catalytic amount of sodium in absolute ethanol gave 4-*O*-(α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**11**). The nmr spectrum of **11** in deuterium oxide showed a doublet at δ 5.08 with a coupling of 2.8 Hz, values which are characteristic of the

expected signal for the anomeric hydrogen of α-D-glucopyranosides.

Condensation of 3,4-*N*,*O*-carbonyl-1-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**14**) with **6** as described above for the synthesis of **8** afforded 6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-3,4-*N*,*O*-carbonyl-1-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**15**) as crystals, mp 188–190°C (75.5% yield). To establish the anomeric configuration of this compound, the benzyl protective groups were removed by hydrogenation and the cyclic carbamate opened with sodium in ethanol to give 6-*O*-(α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**18**) as a crystalline solid, mp 218–220°C, in 84% yield based on **15**. The nmr spectrum of **18** clearly supported the α-glucosidic structure since it exhibited a doublet at δ 5.02 with a coupling of 3.5 Hz for the anomeric hydrogen.

The synthesis of 6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl chloride (**5**) has been reported (15) and the advantages afforded by this intermediate in glycosidation reactions by comparison with the acylamino or aryloxycarbonylamino derivatives of the glycosyl halides have been discussed (8). In this synthesis, 6-azido-2,3,4,-tri-*O*-benzyl-6-deoxy-D-glucose (**4**) (the precursor of **5**) was obtained from the methylglucoside **3** by acid hydrolysis with hydrochloric acid in acetic acid. In our hands, the hydrolysis of **3** by the above method gave poor yields (10–15%) of **4**, the major product being a polar compound with R_f 0 (tlc). The hydrolysis of **3** to **4** was best accomplished by heating **3** in aqueous dioxane in the presence of *p*-toluenesulfonic acid (38% yield). The reaction was slow (5 days) but the only other major component of the reaction mixture was the starting material **3**.

Condensation of 1,6-*N*,*O*-carbonyl-3-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**7**) with **5** in DMF in the presence of mercuric cyanide at 80–85°C for 24 h produced, after purification on a silica column, 4-*O*-(6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-1,6-*N*,*O*-carbonyl-3-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**10**) in 53.5% yield. The cyclic carbamate of **10** was opened by heating in boiling ethanol in the presence of a catalytic amount of sodium to give 4-*O*-(6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**12**), mp 167–168°C, in 70% yield. Compound **12** was hydrogenated over palladium hydroxide whereupon the azido group was reduced and the benzyl protecting groups removed. The product was then heated in boiling aqueous barium hydroxide to give 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2,5-dideoxystreptamine (**13**), mp 235–237°C with decomposition beginning at 220°C; $[\alpha]_D^{25}$ +83.6°, $[\alpha]_{436}^{25}$ +168°; $\Delta[M]_{TACu}^{16}$ +767.

The observed positive $\Delta[M]_{TACu}^{16}$ for compound **13** shows that it is the 4-isomer and therefore establishes the absolute configuration of **7** as was previously reported (3).

Condensation of **14** with the 6-azido sugar **5** afforded in 55% yield, 6-*O*-(6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-3,4-*N*,*O*-carbonyl-1-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**17**), mp 150–151°C. Reaction of **17** with a catalytic amount of sodium in ethanol gave compound **19**, mp 201–203°C, in 80% yield. The protective groups of **19** were removed as described above for the synthesis of **13**, to give 6-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2,5-dideoxystreptamine (**20**), mp 240–244°C (dec.); $[\alpha]_D^{25}$ +58.3, $\Delta[M]_{TACu}$ −444. The negative $\Delta[M]_{TACu}$ for **20** indicates that it is the 6-isomer and this confirms the assigned absolute configuration of **14** (3).

Condensation of 4-*O*-(6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**12**) with **21** (17) gave crystalline 4-*O*-(6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-6-*O*-(3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**22**), in 70% yield. The azido group of **22** was reduced catalytically and the resulting amino group acetylated to give 4-*O*-(6-acetamido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-6-*O*-(3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**23**), mp 210–213°C, in 67% yield. Debenzylation of **23** in the usual manner produced crystalline **24**. The nmr spectrum of the latter showed the signals for the anomeric hydrogens, H-1″ and H-1′, at δ 4.98 and 5.06 with a coupling of 3.5 Hz indicating that both amino sugar units are in the α configuration. Removal of the protective groups of **24** by hydrolysis with aqueous barium hydroxide afforded the desired 5-deoxykanamycin A (**25**). 5-Deoxykanamycin A showed the same spectrum of antibiotic activity as kanamycin A but about half the potency of the latter. Its antibiotic properties are summarized in Table 1.

Experimental

The melting points were determined on a Mel-Temp melting point apparatus and are not corrected. Optical rotations were measured with a Perkin–Elmer Model 141 polarimeter. Nuclear magnetic resonance spectra were taken with a Varian A-60A spectrometer. Tetramethylsilane (for solution other than deuterium oxide) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (for the solutions of deuterium oxide) were used as internal standards. Thin-layer chromatography (tlc) was carried out on microscope slides coated with silica gel and the spots were visualized with perchloric acid.

[a]45% antibiotic assay broth, 50% Mueller–Hinton broth, and 5% serum. All others are Mueller–Hinton broth.
[b]10^{-3} organism dilution. All others are 10^{-4} organism dilution.

*Methyl 6-Azido-6-deoxy-2,3,4-tri-*O*-acetyl-α-*D*-glucopyranoside (1)*

This compound was prepared by the method described by Castro *et al.* (18), mp 102–103°C (lit. (19) mp 103°C).

*Methyl 6-Azido-6-deoxy-α-*D*-glucopyranoside (2)*

A solution of 68.2 g methyl 6-azido-6-deoxy-2,3,4-tri-*O*-acetyl-α-D-glucopyranoside in 600 ml dry methanol to which 150 mg sodium hydride had been added (300 mg of 50% NaH–oil suspension washed with benzene), was stirred at room temperature for 45 min and then neutralized with carbon dioxide and the mixture filtered. Evaporation of the filtrate gave 43.3 g of **2** as a syrup; $[\alpha]_D^{22}$ +122° (*c* 1, H_2O) (lit. (15) $[\alpha]_D^{22}$ +122° (*c* 1, H_2O)).

*Methyl 6-Azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-*D*-glucopyranoside (3)*

This compound was prepared from methyl 6-azido-6-deoxy-α-D-glucopyranoside by reaction with benzyl chloride in DMF in the presence of potassium hydroxide according to the published method (15).

*6-Azido-2,3,4-tri-*O*-benzyl-6-deoxy-*D*-glucose (4)*

A solution of 53.5 g (107.3 mmol) of **3** and 81.5 g (430 mmol) *p*-toluenesulfonic acid monohydrate in 430 ml of 70% dioxane–water was heated under reflux for 5 days. After cooling to room temperature, the reaction mixture was poured onto water (500 ml) and the mixture extracted with chloroform (3 × 200 ml). The combined extracts were washed successively with water, aqueous sodium bicarbonate, and water and after drying over sodium sulfate, it was evaporated to dryness. The dark-brown residue showed on tlc (silica, 10% ether–benzene) three spots with R_f values of 0.58 (compound **3**), 0.25 (compound **4**), and 0. The crude product was chromatographed on silica gel (activity II), (300 g, 20 cm × 6.1 cm id) and eluted with 2% ether–benzene. The effluent was collected in 50 ml fractions. Fractions 1–12 were combined and evaporated to dryness to give 23.5 g (44% recovery) of unreacted starting material. Fractions 13–18 gave, after evaporation, 5.0 g of a mixture of starting material **3** and product **4**. The column was then washed with 25% ether–benzene to give 19.3 g (38%) of **4** as a syrup (a mixture of the two anomers) which solidified upon standing at room temperature. This material was used as such in the next reaction.

*6-Azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-*D*-glucopyranosyl Chloride (5)*

This compound was prepared as described by Tagaki *et al.* (15) by reacting **4** with thionyl chloride.

*4-*O*-(2,3,4,6-Tetra-*O*-benzyl-α-*D*-glucopyranosyl)-1,6-*N,*O*-carbonyl-3-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (8)*

To a flame-dried and nitrogen-purged 50-ml three-neck flask fitted with condenser, mechanical stirrer, and nitrogen inlet and outlet tubes was added 2.16 g (8.8 mmol) of **7** (3), 7.3 g of anhydrous calcium sulfate, and 12 ml of dry DMF and the mixture heated to 65°C while stirring under a nitrogen stream. After 1 h, 5.7 g of mercuric cyanide was added together with a solution of 5.5 g (9.8 mmol) of 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl chloride (**6**) (14) in 15 ml of DMF. The mixture was stirred at 65°C for 27 h and after cooling to room temperature, it was diluted with chloroform (50 ml), filtered, and the solids washed with chloroform (3 × 20 ml). The combined filtrate and washings were washed with water, dried, and evaporated to dryness. The residue was chromatographed on a silica column (240 g, 55 cm × 3.3 cm id) and eluted with MEK–benzene (1:4) to give 5.4 g (80%) of **8** as a homogeneous syrup (tlc on silica, 2% MeOH in $CHCl_3$ as solvent). This material was used as such in the next reaction. A sample was crystallized from isopropyl alcohol – diisopropyl ether and then recrystallized from isopropyl alcohol to give the analytical sample, mp 172–173°C; $[\alpha]_D^{25}$ +38.2 (*c* 1.2, $CHCl_3$); ir (KBr): 1760 (cyclic carbamate) 1700 and 1530 cm^{-1} ($NHCO_2Et$). *Anal.* calcd. for $C_{44}H_{50}N_2O_{10}$: C 68.91, H 6.57, N 3.65; found: C 69.02, H 6.63, N 3.72.

*4-*O*-(α-*D*-Glucopyranosyl)-*N,N'*-diethoxycarbonyl-2,5-dideoxystreptamine (11)*

A solution of 4.46 g (5.8 mmol) of **8** in ethanol (220 ml) was hydrogenated over 10% Pd-on-carbon (0.9 g) under a hydrogen pressure of 3 cm of mercury at room temperature for 48 h. The catalyst was removed, washed with ethanol (2 × 30 ml), and the combined filtrate and washings evaporated to give 2.22 g (94%) of **9** as a syrup. Thin-layer chromatography on silica (chloroform–methanol (3:1)) showed a single spot with R_f 0.39.

Compound **9** (2.22 g) was dissolved in absolute ethanol (115 ml) in which 50 mg of sodium hydride had been dissolved (55% suspension in oil) and the solution heated under reflux for 3 h. After cooling to room temperature, it was neutralized with a cation exchange resin and evaporated to dryness to give crystalline **11**, mp 273–275°C (EtOH), $[\alpha]_D^{25}$ +81.0° (*c*, 0.2, H_2O); nmr spectrum at 80 MHz showed δ: 1.24 and 4.08, (triplet and quartet for N—CO_2Et, J = 7.1 Hz), 5.08 (d, 1, H-1, J = 2.8 Hz). *Anal.* calcd. for $C_{18}H_{32}N_2O_{11}$: C 47.78, H 7.13, N 6.19; found: C 47.65, H 7.11, N 6.35.

6-O-(2,3,4,6,Tetra-O-benzyl-α-D-glucopyranosyl)-3,4-N,O-carbonyl-1-N-ethoxycarbonyl-2,5-dideoxystreptamine (15)

A quantity of 1.8 g (7.3 mmol) of 3,4-*N,O*-carbonyl-1-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**14**) (3) was reacted with 5.2 g (9.3 mmol) of **6** in DMF (25 ml) in the presence of mercuric cyanide and anhydrous calcium sulfate as described above for the synthesis of **8**. After work-up, the crude syrupy product crystallized upon exposure to ether. The crystalline product was filtered off to give 3.91 g (70%) of **15**, mp 188–190°C. Thin-layer chromatography on silica (2% methanol in chloroform) showed a single spot with R_f 0.24. The mother liquor was evaporated to dryness and chromatographed on a column of silica (60 g, 12 cm × 3.1 cm id) using MEK–benzene 1:2 as the eluent. The fractions containing **15** were combined and evaporated to dryness to give 470 mg which on trituration with ether gave 300 mg of crystalline **15**, mp 190–192°C. This fraction was combined with the first crop above to give a total of 4.21 g (75.5%). Recrystallization from ethanol gave the analytical sample, mp 190–192°C; $[\alpha]_D^{25}$ +19.9 (*c*, 1.4, $CHCl_3$); ir (KBr): 1770 (cyclic carbamate), 1700 cm^{-1} ($NHCO_2Et$). *Anal.* calcd. for $C_{44}H_{50}N_2O_{10}$: C 68.91, H 6.57, N 3.65; found: C 68.84, H 6.60, N 3.72.

6-O-(α-D-Glucopyranosyl)-3,4-N,O-carbonyl-1-N-ethoxycarbonyl-2,5-dideoxystreptamine (16)

A mixture of 4.0 g (5.2 mmol) of **15** in ethanol (400 ml) was hydrogenated over 0.8 g of 10% Pd/C as described for the synthesis of **11** above. Removal of the ethanol solvent by evaporation gave crystalline **16**. Recrystallization from ethanol gave 2.08 g (88.5%) of crystalline **16** containing **1** mol of EtOH of crystallization, mp 242–243°C; $[\alpha]_D^{25}$ +45.4 (*c*, 2.0, H_2O); ir (KBr): 3320, 1745, 1705, 1690, and 1543 cm^{-1}; nmr (D_2O) δ: 5.02 (d, one proton, H-1, $J_{1,2}$ = 3.5 Hz). *Anal.* calcd. for $C_{18}H_{20}N_2O_{10}\cdot C_2H_5OH$: C 47.78, H 7.13, N 6.19; found: C 47.87, H 7.17, N 6.34.

6-O-(α-D-Glucopyranosyl)-N,N′-diethoxycarbonyl-2,5-dideoxystreptamine (18)

Compound **16** (1.0 g, 2.46 mmol) in absolute ethanol (30 ml) in which a catalytic amount of sodium hydride had been dissolved was heated under reflux for 3 h and the product isolated as described above for the synthesis of **11** to give compound **18** in 95% yield, mp 218–220°C (EtOH); $[\alpha]_D^{25}$ +67.0 (*c*, 0.75, H_2O); ir (KBr): 1695 and 1540 cm^{-1} ($NHCO_2Et$): nmr (D_2O) δ: 5.02 (d, one proton, H-1, $J_{1,2}$ = 3.5 Hz). *Anal.* calcd. for $C_{18}H_{32}N_2O_{11}$: C 47.78, H 7.13, N 6.19; found: C 47.55, H 7.14, N 6.11.

4-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-1,6-N,O-carbonyl-3-N-ethoxycarbonyl-2,5-dideoxystreptamine (10)

A flame-dried, nitrogen purged, three-neck flask (100 ml) equipped with a condenser, mechanical stirrer, and nitrogen inlet and outlet tubes was charged with 2.44 g (10 mmol) of (**7**) (3) and 15 ml dry DMF. Under a slow stream of nitrogen, 5.5 g anhydrous calcium sulfate was added and the mixture stirred at room temperature for 30 min followed by heating to 80°C for 15 min. A solution of 5.1 g (10.3 mmol) of 6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl chloride (**5**) in 5 ml dry DMF was then added, followed by the addition of 6.3 g of mercuric cyanide. The mixture was heated at 80–85°C under nitrogen with stirring for 17 h. Fresh mercuric cyanide, 3.0 g was added and heating continued for 3 h. After cooling to room temperature, the reaction mixture was diluted with chloroform (150 ml) and filtered. The solids were washed with chloroform (2 × 10 ml) and the combined filtrate and washings were washed with water (5 × 100 ml), dried, and evaporated to dryness to give a dark brown sticky residue. On tlc (silica, 5% MeOH–$CHCl_3$) it showed five spots with R_f 0, 0.28 (major, compound **10**), 0.38, 0.5, and 0.92, respectively. The crude product was dissolved in 20 ml chloroform and the solution added dropwise with stirring to 175 ml of petroleum ether (bp 40–60°C). The petroleum ether phase was decanted and the residue dissolved in $CHCl_3$ (20 ml) and the latter solution again added to petroleum ether (175 ml). The petroleum ether phase was again decanted and combined with the preceding petroleum ether phase. The residue, 4.1 g, showed on tlc one major spot with R_f 0.28 (compound **10**) and two minor ones with R_f 0 and 0.38, respectively. The petroleum ether phase showed on tlc a small spot for **10** (R_f 0.28) and the spots with R_f 0.38, 0.5, and 0.92 and upon standing at room temperature overnight it deposited 200 mg of compound **10**. The combined yield of **10** was 4.3 g. This material was further purified by passing through a column of silica (activity II) (45 g, 6.5 cm × 4.3 cm id) using 10% methanol in chloroform as the eluent (250 ml). This treatment removed the impurity with R_f 0. The eluent was evaporated to dryness to give 3.75 g (53.5%) of a brown syrup which on tlc showed one major spot with R_f 0.28 (compound **10**) and a trace of a compound with R_f 0.38. This material was used as such in the next reaction.

An analytical sample was obtained by crystallization from ether, mp 75–85°C; $[\alpha]_D^{25}$ +87.4 (*c*, 1.0, $CHCl_3$); ir ($CHCl_3$): 2110 (N_3), 1760 (cyclic carbamate), 1710 and 1520 cm^{-1} (N—CO_2Et). *Anal.* calcd. for $C_{37}H_{43}N_5O_9$: C 63.32, H 6.18, N 9.98; found: C 63.35, H 6.14, N 9.83.

4-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2,5-dideoxystreptamine (12)

A solution of 3.75 g of the preceding crude **10** in 30 ml absolute ethanol in which 20 mg NaH (55% in oil) had been dissolved was heated under reflux for 3 h with exclusion of moisture. After cooling to room temperature, acetone (35 ml) was added to dissolve the solids and the solution neutralized by passing through a column containing 4.0 g Amberlite IR-120 (H^+ form, washed with water and EtOH). The neutral effluent was evaporated to dryness to give a residue which on tlc (silica; benzene–MEK, 2:1) showed one major spot with R_f 0.39 (compound **12**) and four minor ones with R_f 0, 0.72, 0.89, and 1.0. It was chromatographed through a column packed with 100 g of silica (activity II) (14.5 cm × 4.0 cm id) and the product eluted with benzene–MEK (2:1). Fractions of 20 ml were collected and the material eluted in tubes 6–20. The combined elutes were evaporated, the residue dissolved in 20 ml of boiling ethanol and the mixture filtered. The filtrate was evaporated to dryness to give 2.8 g (70%) of crystalline compound **12**. Recrystallization from ethyl acetate (10 ml) – petroleum ether (20 ml) gave 2.4 g, mp 167–168°C; $[\alpha]_D^{25}$ +77.4° (*c*, 1.0, $CHCl_3$); ir ($CHCl_3$): 2110 (N_3), 1705 and 1520 cm^{-1} (N—CO_2Et). *Anal.* calcd. for $C_{39}H_{49}N_5O_{10}$: C 62.63, H 6.60, N 9.36; found: C 62.28, H 6.54, N 9.04.

4-O-(6-Amino-6-deoxy-α-D-glucopyranosyl)-2,5-dideoxystreptamine (13)

A mixture of 251 mg of **12** in methanol was hydrogenated in a Paar apparatus over 20% $Pd(OH)_2$-on-carbon (200 mg) at room temperature and at an initial hydrogen pressure of 45 psi. After 16 h, the mixture was filtered through a Celite bed and the cake washed with methanol (25 ml). The combined filtrate and washings were evaporated to dryness to give 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-*N,N′*-diethoxycarbonyl-2,5-dideoxystreptamine as a foam. Thin-layer chromatography on silica with MeOH–$CHCl_3$–NH_4OH (4:1:1) as the solvent showed a single spot (ninhydrin spray). The material was dissolved in water (10 ml), barium hydroxide (1.2 g) was added, and the solution heated at reflux under nitrogen for 22 h. The mixture was diluted with water (20 ml) and the excess barium hydroxide neutralized by passing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

carbon dioxide through the solution. The resulting mixture was heated to boiling and filtered through a bed of Celite and the solids washed with boiling water (2 × 20 ml). The filtrate and the washings were combined and acidified with 1 *N* sulfuric acid to precipitate barium. The mixture was filtered through Celite, the filtrate neutralized with an anion exchange resin (Rexyn 201, OH^- form), and the solution evaporated to dryness to give a syrupy residue which solidified on treatment with methanol. Thin-layer chromatography on silica using $CHCl_3$—MeOH—NH_4OH—H_2O (1:4:2:1) as solvent showed one major spot with R_f 0.40 (ninhydrin spray) and some impurities with lower R_f values. This material was absorbed on a cation exchange resin (Rexyn 102, NH_4^+ form, 3 ml) and the column was first washed with water (50 ml) and then with 0.2 *N* aqueous ammonium hydroxide which after evaporation gave **13** (51 mg, 50%) as a solid, mp 235–237°C (it foamed and decomposed); $[\alpha]_D^{25}$ +83.6 (*c* 0.30, H_2O), $[\alpha]_{436}^{25}$ +168° (*c*, 0.30, H_2O), $[\alpha]_{436}^{25}$ +418 (*c*, 0.35, TACu), $\Delta[M]_{TACu}$ +767.

*6-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-3,4-N,O-carbonyl-1-N-ethoxycarbonyl-2,5-dideoxystreptamine (**17**)*

Compound **14** (2.70 g, 11.14 mmol) was reacted with 5.96 g (12.1 mmol) of 6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl chloride (**5**) in dry DMF (23 ml) at 83–85°C, in the presence of mercuric cyanide and calcium sulfate as described above for the synthesis of **10**. After the reaction was completed (20 h) the reaction mixture was cooled to room temperature, diluted with chloroform (150 ml), and filtered. The solids were washed with chloroform (3 × 20 ml) and after combining the washings with the filtrate, the solution was washed with water, dried and evaporated to dryness to give 6.54 g of a brown syrup. Thin-layer chromatography on silica using 5% methanol in chloroform as solvent showed two spots with R_f 0.33 (major, compound **17**) and 0.61 (minor). The crude product was chromatographed on a column of silica (activity III) (150 g, 20 cm × 3.8 cm id) using MEK–benzene (1:4) mixture as the eluent. Fractions of 10 ml were collected and fractions 4–15 contained the compound with R_f 0.61 (silica, 5% MeOH–$CHCl_3$). They were combined and evaporated to dryness to give 1.4 g of a syrup which consisted of 6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-D-glucose (**4**). The fractions 20–98 were combined and evaporated to dryness to give 4.29 g (54.8%) of compound **17** as a syrup. It was crystallized from ethanol–ether to give crystalline **17**, mp 150–151°C; $[\alpha]_D^{25}$ +33.0 (*c*, 1.0, $CHCl_3$); ir (Nujol): 3340 (NH), 2110 (N_3), 1750 (cyclic carbamate) 1710 cm^{-1} (*N*-carbethoxy). *Anal.* calcd. for $C_{37}H_{43}N_5O_9$: C 63.32, H 6.18, N 9.98; found: C 63.35, H 6.15, N 10.16.

*6-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2,5-dideoxystreptamine (**19**)*

A solution of 2.22 g (3.2 mmol) of **17** in dry ethanol (50 ml) in which 20 mg of sodium hydride (55% oil suspension) had been dissolved was heated under reflux for 3 h. After cooling to room temperature, it was neutralized by treatment with Amberlite IR 120 (H^+ form), the resin filtered off, and the filtrate evaporated to dryness to give 2.4 g (100%) of solid material which on tlc (silica, 5% MeOH–$CHCl_3$) showed one major spot with R_f 0.30 (compound **19**) and traces of a compound with R_f 0.12. Recrystallization from ethanol–ethylacetate (5:1) gave 1.92 g (80.6%) of **19**, mp 201-203°C; $[\alpha]_D^{25}$ +40.2 (*c*, 1.45, $CHCl_3$); ir (Nujol): 3310 (NH, OH), 2110 (N_3), 1690 and 1540 cm^{-1} (*N*-carbethoxy). *Anal.* calcd. for $C_{39}N_{49}N_5O_{10}$: C 62.63, H 6.60, N 9.36; found: C 62.50, H 6.51, N 9.48.

*6-O-(6-Amino-6-deoxy-α-D-glucopyranosyl)-2,5-dideoxystreptamine (**20**)*

A solution of 1.10 g of **19** in methanol (30 ml) was hydrogenated over 1 g of 20% $Pd(OH)_2$-on-carbon as described for the preparation of **13** above. The product was hydrolyzed with aqueous barium hydroxide and purified as described above (compound **13**) to give 252 mg of **20** as an amorphous solid, mp 240–244°C (dec.); $[\alpha]_D^{25}$ +58.3 (*c*, 0.75, H_2O), $[\alpha]_{436}^{25}$ +114 (*c*, 0.75, H_2O), $[\alpha]_{436}^{25}$ −30.8 (*c*, 0.51, in TACu), $\Delta[M]_{TACu}$ −444.5.

*4-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-6-O-(3-acetamido-2,4,6-tri-O-benzyl-3-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2,5-dideoxystreptamine (**22**)*

A flame-dried nitrogen purged 50 ml two-neck flask fitted with mechanical stirrer, condenser, and nitrogen inlet and outlet tubes was charged with 2.99 g (4 mmol) of compound **12** and 10 ml dry DMF and the mixture stirred at room temperature under nitrogen until dissolution was complete. Anhydrous calcium sulfate (3.0 g) was then added and the mixture stirred at room temperature for 30 min. To this was added 1.3 g (4.0 mmol) of 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl chloride (**21**) followed by 3.0 g of powdered mercuric cyanide. The mixture was heated at 80°C while stirring under nitrogen. After 9 h, 1.31 g of **21** and 1.5 g $Hg(CN)_2$ were added, the mixture stirred again at 80°C for 12 h after which time 1.0 g of **21** and 1.0 g $Hg(CN)_2$ were again added. After stirring for 22 h at 80°C, the mixture was cooled to room temperature, diluted with $CHCl_3$ (150 ml), filtered, and the solids washed with $CHCl_3$ (2 × 10 ml). The combined filtrate and washings were washed with water (5 × 150 ml), dried, and evaporated to dryness. Thin-layer chromatography (alumina, 2% MeOH–$CHCl_3$) showed one major spot R_f 0.51 (compound **22**) and three minor ones with R_f values of 0.17, 0.27, and 0.76. The sticky residue on treatment with ethyl acetate – ether crystallized. It was chromatographed through a column packed with alumina (activity II) (150 g) (21.5 cm × 2.8 cm id) and the product eluted in 20 ml fractions with 1% MeOH–$CHCl_3$. Tubes 6–17 were combined and after evaporation gave 4.7 g of a colorless sticky residue which on tlc showed one major spot for **22** and a minor one with R_f 0.76. It was treated with boiling ethyl acetate (40 ml) and the mixture filtered to remove some insoluble solids (220 mg). The filtrate was evaporated to dryness, dissolved into 15 ml of boiling ethyl acetate, and the solution diluted with 30 ml ether. After standing at room temperature overnight, the crystalline product **22** was collected to give 3.40 g (70%), mp 178–188°C. *Anal.* calcd. for $C_{68}H_{80}N_6O_{15}$: C 66.87, H 6.60, N 6.88; found: C 67.28, H 6.67, N 6.57.

*4-O-(6-Acetamido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-6-O-(3-acetamido-2,4,6-tri-O-benzyl-3-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2,5-dideoxystreptamine (**23**)*

A solution of 3.0 g (2.46 mmol) of **22** in 100 ml of 90% EtOH–water was hydrogenated in a Paar apparatus over Raney nickel at room temperature and at an initial hydrogen pressure of 55 psi. After 3 h, the reaction mixture was filtered and the catalyst washed with EtOH. The combined filtrate and washings were evaporated to dryness to give 2.77 g (94.5%) of a syrup which solidified. Infrared spectroscopy confirmed that hydrogenation was complete (absence of azido band). Thin-layer chromatography on silica (10% MeOH–$CHCl_3$) showed one major spot with R_f 0.43 and four minor ones. The material was dissolved in dry pyridine (10 ml) and acetic anhydride (1.5 ml) was added. After standing at room temperature for 1 h, water (0.5 ml) was added, the solution diluted

For personal use only.

with $CHCl_3$ (150 ml), and washed first with water (3 × 100 ml), then with 5% aqueous HCl (100 ml), and finally with water (100 ml). After drying and removal of the solvent by evaporation, the sticky residue was treated with boiling ethylacetate (25 ml) and the crystalline product **23** collected to give 1.95 g (67%), mp 210–213°C. Recrystallization from EtOH produced an analytical sample; mp 217–218°C. *Anal.* calcd. for $C_{70}H_{84}N_4O_{16}$: C 67.96, H 6.84, N 4.53; found: C 68.09, H 6.90, N 4.57.

4-O-(6-Acetamido-6-deoxy-α-D-glucopyranosyl)-6-O-(3-acetamido-3-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2,5-dideoxystreptamine (24)

A solution of 700 mg of compound **23** in 80 ml 95% ethanol–water was hydrogenated over 100 mg of Pd/C (10%) at room temperature and at atmospheric pressure for 24 h. The reaction mixture was filtered and the catalyst washed with boiling 70% EtOH–water (4 × 15 ml). The combined filtrate and washings were evaporated to dryness to give 360 mg of crystalline **24**; mp 260–262°C (dec.). The nmr spectrum at 100 MHz in D_2O showed δ: 1.22 and 1.24 (two triplets for CH_3 of $NHCO_2Et$), 4.10 and 4.12 (two quartets for CH_2 of $NHCO_2Et$), 2.03 (s, 6H, NHAc), 4.98 (d, 1, H-1″, $J_{1'',2''}$ = 3.5 Hz) 5.06 (d, 1, H-1′, $J_{1',2'}$ = 3.5 Hz). *Anal.* calcd. for $C_{28}H_{48}N_4O_{16}$: C 48.27, H 6.94, N 8.04; found: C 47.53, H 6.84, N 7.64.

5-Deoxykanamycin A (25)

A solution of 360 mg (0.515 mmol) of **24** in 20 ml of 1 *N* aqueous barium hydroxide was heated at reflux for 24 h while excluding CO_2. It was then diluted with 30 ml water, neutralized with CO_2, heated to boiling, filtered, and the solids washed with boiling water (3 × 30 ml). The filtrate and washings were combined, 5 ml of 1 *N* H_2SO_4 added to precipitate barium, and the solids removed by filtration. The filtrate was passed through a column containing 10 g Rexyn 201 (strongly basic resin in the OH^- form) to remove the acids (H_2SO_4 and AcOH) and the effluent evaporated to dryness to give 200 mg of sticky residue. Thin-layer chromatography on silica (H_2O–MeOH–NH_4OH–$CHCl_3$, 1:4:2:1, ninhydrin spray) showed two spots with R_f 0.19 (major, compound **25**) and R_f 0.49 (probably the cyclic urea). The material was chromatographed using a column packed with Rexyn 102 (NH_4^+ form) (0.9 cm id × 10.2 cm). The column was washed first with water (100 ml), then with 1 *N* ammonium hydroxide (300 ml). The effluent containing compound **25** was evaporated to dryness, the residue dissolved in water and the solution treated with an anion exchange resin (Rexyn 201, OH^- form) to remove some ammonium carbonate. After evaporation of the resin filtrate to dryness, the residue was treated with ethanol and the crystalline material filtered to give 140 mg of **25**, mp 250–255°C (dec.) (decomposition started at 160°C); $[\alpha]_D^{25}$ +101.8 (*c*, 0.33, water). The nmr spectrum at 100 MHz in D_2O showed δ: 5.17 (d, 1, H-1″, $J_{1'',2''}$ = 3.75 Hz), 5.22 (d, 1, H-1′, $J_{1',2'}$ = 3.75 Hz). *Anal.* calcd. for $C_{18}H_{36}N_4O_{10}$: C 46.15, H 7.74; found: C 45.95, H 7.67.

Reaction of 1,1-diphenylpropene with stannic chloride and hydrogen chloride[1]

STANLEY BYWATER AND DENIS J. WORSFOLD

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received February 15, 1978

STANLEY BYWATER and DENIS J. WORSFOLD. Can. J. Chem. **56**, 2093 (1978).

$SnCl_4$ and HCl have been found to react with 1,1-diphenylpropene to form a small equilibrium amount of the diphenylethylcarbenium ion. No further reaction is detectable, and the equilibrium between the three reactants may be determined from the uv absorption of the ion. The electrical conductances of the solutions have also been measured. The results are consistent with the formation of the salt of this carbenium ion with the $SnCl_5^-$ anion. The salt in the concentrations formed in these experiments (ca. 10^{-5}–10^{-4} M) was nearly all dissociated into free ions in methylene chloride solution. The equilibrium constant for formation of the salt was 2.0 M^{-2} at −30°C, and the dissociation constant into ions 4.4×10^{-4} M. The overall heat of reaction to the carbenium ion salt was 8.8 kcal, most of which is attributed to the initial formation of the undissociated salt.

STANLEY BYWATER et DENIS J. WORSFOLD. Can. J. Chem. **56**, 2093 (1978).

On a trouvé que le $SnCl_4$ et HCl réagissent avec le diphényl-1:1 propène pour conduire, à l'équilibre, à une faible quantité d'ions diphényléthylcarbénium. Il a été impossible de détecter aucune réaction subséquente et l'équilibre entre les trois réactifs peuvent être déterminés à partir de spectre d'absorption uv de l'ion. On a aussi mesuré la conductivité électrique des solutions. Les résultats sont en accord avec la formation du sel de l'ion carbénium avec l'anion $SnCl_5^-$. Aux concentrations de sel formées au cours de ces expériences (environ 10^{-5} à 10^{-4} M), celui-ci est à toutes fins pratiques complètement dissocié en ions libres pour des solutions dans le chlorure de méthylène. La constante d'équilibre pour la formation du sel est de 2.0 M^{-2} à 30°C et la constante de dissociation en ions est de 4.4×10^{-4} M. La chaleur globale de la réaction conduisant au sel des ions carbénium est de 8.8 kcal; on attribue la plus grande partie de cette valeur à la formation initiale du sel non-associé.

[Traduit par le journal]

Several authors have described the reaction of 1,1-diphenylethylene with Friedel–Crafts reagents as a model system for cationic polymerization (1–4), but this reaction has been shown to have several complicating factors. If only the initiation step of cationic polymerization is to be studied, a better model monomer is 1,1-diphenylpropene (DPP). Only the initial cationic centre the diphenylethylcarbenium ion, is formed, and its equilibrium with initiator and monomer may be studied. No dimers or higher molecular weight products are detectable, and the secondary reactions found with 1,1-diphenylethylene are absent. Such a study has already been made on the boron trifluoride – water system, which shows rather complex behavior (5). A system that proved to be uncomplicated and which demonstrates the usefulness of this method of studying the equilibria involved in the initiation reaction is the reaction of the DPP with $SnCl_4$ and HCl, in methylene chloride solution.

Experimental

$SnCl_4$ was fractionally distilled from P_2O_5 and stored on a vacuum rack. It was measured as a vapour in a known volume. HCl gas was dried over P_2O_5 and purified by trap-to-trap distillation. It also was measured as a gas. The reactions were carried out under vacuum in all glass apparatus fitted with breakseals; experimental details are given elsewhere (5). Most reactions were performed at −30°C. The diphenylethylcarbenium ion was measured by uv spectrophotometry (λ_{max}, 438 mμ; ε, 35 000).

Results

In the absence of HCl, methylene chloride solutions of DPP and $SnCl_4$ gave only small uv absorptions due to diphenylethylcarbenium ions (ca. 2×10^{-6} M) at −30°C, presumably caused by residual water. Additions of HCl gave an immediate increase in absorption, the increase being above half power but less than first power in the HCl concentration in the range 1.3–20 $\times 10^{-3}$ M, at three different $SnCl_4$ concentrations.

Solutions of HCl and DPP gave very small concentrations of diphenylethylcarbenium ions. Additions of $SnCl_4$ caused a large increase in ion concentration, again with a dependence slightly greater than half power on the stannic chloride over the range 1.8–28 $\times 10^{-3}$ M. The dependence on the DPP concentration was similar over the range 1.4–6 $\times 10^{-2}$ M.

The concentration of carbenium ions was in the range 10^{-5}–10^{-4} M, dependent on temperature. The concentration decreased reversibly as the tempera-

ture was raised. From a plot of ln [Ion] vs. $1/T$ over the temperature range $-10°C$ to $-50°C$ the temperature dependence corresponded to an overall heat of reaction of $-8\,800$ cal.

The solutions showed considerable electrical conductance. Solutions of HCl and $SnCl_4$ showed appreciable conductance themselves, although much lower than in the presence of DPP, so that no exact conductiometric analysis of the system was possible. If it is assumed, however, that Λ_0 at 20°C is the same, 89, as that found in the system with BF_3 measured previously, and allowing for the change in viscosity with temperature by Walden's rule, Λ_0 at $-30°C$ can be estimated to be near 60. With this value of Λ_0, solutions having total concentration of diphenylethylcarbenium ions in the region of 10^{-4} M, gave conductances consistent with an ion-pair dissociation constant about 5×10^{-4} M.[2]

Discussion

From these results it is possible to propose the following equilibrium:

$$SnCl_4 + HCl + CH_3CH{=}CPh_2 \underset{}{\overset{K_1}{\rightleftharpoons}} CH_3CH_2\overset{+}{C}Ph_2 \cdot SnCl_5^- \qquad \overset{K_2}{\updownarrow}$$

$$CH_3CH_2{-}\overset{+}{C}Ph_2 + SnCl_5^-$$

If this scheme is valid it is possible to show that if the total ion concentration is small compared with the reactants, as was found (<2%), then the equation

$$\frac{[DPP^+]_{total}}{[HCl]_0[SnCl_4]_0[DPP]_0} = K_1 + \frac{(K_1K_2)^{1/2}}{[HCl]_0^{1/2}[SnCl_4]_0^{1/2}[DPP]_0^{1/2}}$$

should hold. The high degree of dissociation of the initial ion pair leads to the approach to half power dependence of the total ion concentration. $[DPP^+]_{total}$ is the spectroscopically measured diphenylethylcarbenium ion concentration (the sum of the free ion and ion-pair concentrations).

Hence a plot of $[DPP^+]_{total}/[HCl]_0[SnCl_4]_0[DPP]_0$ against $[HCl]_0^{-1/2}[SnCl_4]_0^{-1/2}[DPP]_0^{-1/2}$ should be linear, with an intercept K_1. Then from the slope, $(K_1K_2)^{1/2}$ may be found and hence K_2. This plot is shown in Fig. 1, and from it K_1 is found to be 2.0 M^{-2}, and K_2 is 4.4×10^{-4} M. The value of $K_2 = 4.4 \times 10^{-4}$ M compares well with the approximate value of 5×10^{-4} M found from the conductance data.

[2]Tables of the variation of ion concentration with reagent concentrations may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

An alternative scheme whereby the compound $(R^+)_2SnCl_6^{2-}$ is formed which dissociates to $R^+SnCl_6^{2-} + R^+$, when given a similar analysis is not consistent with the experimental data. Neither is the formation of this ion pair followed by a double ionization consistent with the results.

The heat of reaction to form the ionic species, -8.8 kcal, is a composite quantity containing contributions from both K_1 and K_2, the heat of reaction to form the ion pair from the starting reagents and their heat of dissociation into free ions. The proximity of the ionic dissociation constant found here at $-30°C$ to that found in a similar system at $+20°C$ (5) suggests that temperature has only a small effect on the ionic dissociation constant. In fact from the spectroscopic data at $-10°C$, which do however involve rather a long extrapolation, K_2 at this temperature is virtually unchanged. Such a compensation of the effect of the temperature on K_D caused by the change in ε with temperature and the heat of ionic dissociation, is common. Hence the value of -8.8 kcal is probably close to the enthalpy change to form the initial ion pair.

A few experiments were carried out on other initiating systems. When water was used as a co-catalyst, difficulties were encountered from the formation of a white precipitate at appreciable water concentrations. This was aggravated by the low temperature ($-70°C$) needed to obtain reasonable ion concentrations. A temperature dependent equilibrium was

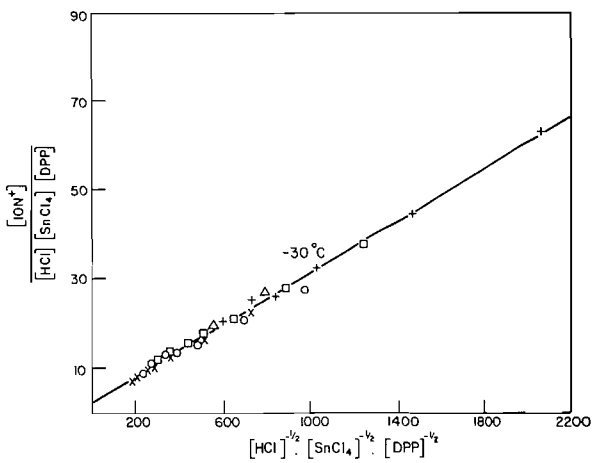

FIG. 1. The concentration of the diphenylethylcarbenium ion as a function of the concentration of HCl, $SnCl_4$, and DPP at $-30°C$. +, $[SnCl_4] = 3.5 \times 10^{-3}$ M, $[DPP] = 5.2 \times 10^{-2}$ M; □, $[SnCl_4] = 1.0 \times 10^{-2}$ M, $[DPP] = 5.1 \times 10^{-2}$ M; ×, $[SnCl_4] = 3.0 \times 10^{-2}$ M, $[DPP] = 5.1 \times 10^{-2}$ M; ○, $[DPP] = 5.8 \times 10^{-2}$ M, $[HCl] = 1.0 \times 10^{-2}$ M; △, $[SnCl_4] = 1.1 \times 10^{-2}$ M, $[HCl] = 1.0 \times 10^{-2}$ M; the other reactant was varied.

found to be established. The presence of excess water over $SnCl_4$ resulted in a decrease in ion formation.

$TiCl_4$ was also used, and it was found that the largest carbenium ion concentrations were produced in the absence of added water. Under these conditions the ion formation was slow, many hours being required to attain equilibrium At low $TiCl_4$ concentrations ($<2 \times 10^{-3}$ M) one diphenylethylcarbenium ion was formed per 2 molecules of $TiCl_4$, when DPP was in large excess. At higher concentrations of $TiCl_4$, ion formation levelled off. Destruction of the ions with methanol regenerated DPP, and no other product could be detected by thin layer chromatography even if 20% of the DPP had been converted to ions. Auto-ionization of the $TiCl_4$ could be suggested to explain these results, but in view of the difficulties Sigwalt (6) has described with the titanium tetrachloride/methylene chloride system, reaction with solvent or impurities could not be discounted.

The photochemistry of acrylonitrile vapour at 213.9 nm[1]

A. GANDINI AND P. A. HACKETT

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received March 20, 1978

A. GANDINI and P. A. HACKETT. Can. J. Chem. **56**, 2096 (1978).

The photolysis of acrylonitrile vapour in the $\pi^* \leftarrow$ n transition was carried out at 213.9 nm. Evidence is presented for two molecular elimination channels, one to yield acetylene and hydrogen cyanide ($\Phi = 0.50$), the other to yield cyanoacetylene and hydrogen ($\Phi = 0.31$). Experiments on acrylonitrile-1-*d* gave evidence that molecular elimination proceeds by α–β elimination following rapid intramolecular scrambling of deuterium by H/D migration in the excited state.

A. GANDINI et P. A. HACKETT. Can. J. Chem. **56**, 2096 (1978).

On a étudié la photolyse de l'acrylonitrile en phase vapeur à 213.9 nm (transition $\pi^* \leftarrow$ n). Les résultats indiquent que la décomposition s'effectue par deux réactions d'élimination moléculaire, une donnant l'acétylène et l'acide cyanidrique ($\Phi = 0.50$), et l'autre donnant le cyanoacetylène et l'hydrogéne ($\Phi = 0.31$). Des expériences avec l'acrylonitrile-1-*d* suggèrent que ces réactions procèdent par l'élimination α–β après une rédistribution intramoléculaire rapide du deuterium par migration H/D dans l'état excité.

Introduction

The photolysis of simple organic nitriles has received little attention. The only thorough investigation in this field is the photolysis of methyl cyanide (1) where both hydrogen atoms and CN radicals were produced in competitive primary steps. However, there have been many studies of the production of $\tilde{A}(^2\Pi_i)$ CN from the photolytic cleavage of a large number of nitriles (2, 3) in which the CN $\tilde{A}(^2\Pi_i) \rightarrow$ CN $\tilde{X}(^2\Sigma^+)$ luminescence was examined.

In a study of the ir laser induced decomposition of acrylonitrile (4) it was found that molecular rather than radical fragments were formed. In order to correlate these results with other studies of the uv and multiphoton ir decomposition of substituted ethylenes we have investigated the photolysis of acrylonitrile vapour in its first excited electronic transition $\pi^* \leftarrow$ n (5).

Experimental

Acrylonitrile (Aldrich) was distilled in a vacuum line from P_2O_5 rejecting generous head and tail portions. Although the purified product polymerised slowly, its purity as shown by glc analysis was not affected. Acrylonitrile-1-*d* (90% D) was prepared by double exchange with D_2O in a basic medium (6).

Photolyses were carried out in a 10 cm long quartz cell provided with 1 in. diameter Suprasil windows. Light from a Philips Spectral zinc resonance lamp, filtered by two 7 mm thick sodium chloride discs and a chlorine filter, was collimated through the cell with a quartz lens and detected by a Hamamatsu R788 solar blind photodiode. Frequent spectral analysis showed that the only line detected by the photodiode and absorbed by the substrate was that at 213.9 nm.

Pressures of products not condensable at -196°C were measured using a MKS Baratron capacitance manometer (1.2 Torr head). Hydrogen content was determined by diffusion through a palladium thimble. Products not condensable at -98°C (acetylene) were analysed by glc. Other products were characterised by mass spectrometry. In the photolysis of acrylonitrile-1-*d* $H_2/HD/D_2$ compositions were determined by glc, using an alumina column, treated with $MnCl_2$, at -196°C (7). Ratios of ethylene-to-acetylene-*d* were also determined by mass spectrometry at low ionisation voltage.

Quantum yields were determined by measuring the hydrogen produced in the photolysis of ammonia-d_3 in the presence of 300 Torr of propane (8).

Results

Four major products were identified, viz. acetylene, hydrogen cyanide, hydrogen, and cyanoacetylene. Experiments at high pressures also produced a white non-volatile polymeric material. No other low molecular-weight products (up to C_4) were detected. An infrared spectrum of polymer formed on the cell walls in a high-pressure photolysis of acrylonitrile-1-*d* was consistent with that of poly(acrylonitrile-1-*d*) (9).

A search was made for luminescence; none was detected.

The quantum yields of hydrogen and of acetylene were both independent of pressure over the range (0–50) Torr, and of D isotope substitution. Their values were measured as $\phi(H_2 + HD) = 0.50 \pm 0.05$ and $\phi(C_2H_2 + C_2HD) = 0.31 \pm 0.03$, while the ratios HD/H_2 and C_2HD/C_2H_2 were both 1.5 ± 0.2. No D_2 was detected.

Discussion

According to Mullen and Orloff (5) the uv absorption spectrum of acrylonitrile contains three transitions $\pi^* \leftarrow$ n (210.7 nm, $\varepsilon \simeq 150$), $\pi^* \leftarrow \pi$ (203.0 nm, $\varepsilon \simeq 2000$), and $\sigma^* \leftarrow \sigma$ (172.5 nm, $\varepsilon \simeq$

[1]NRCC No. 16753.

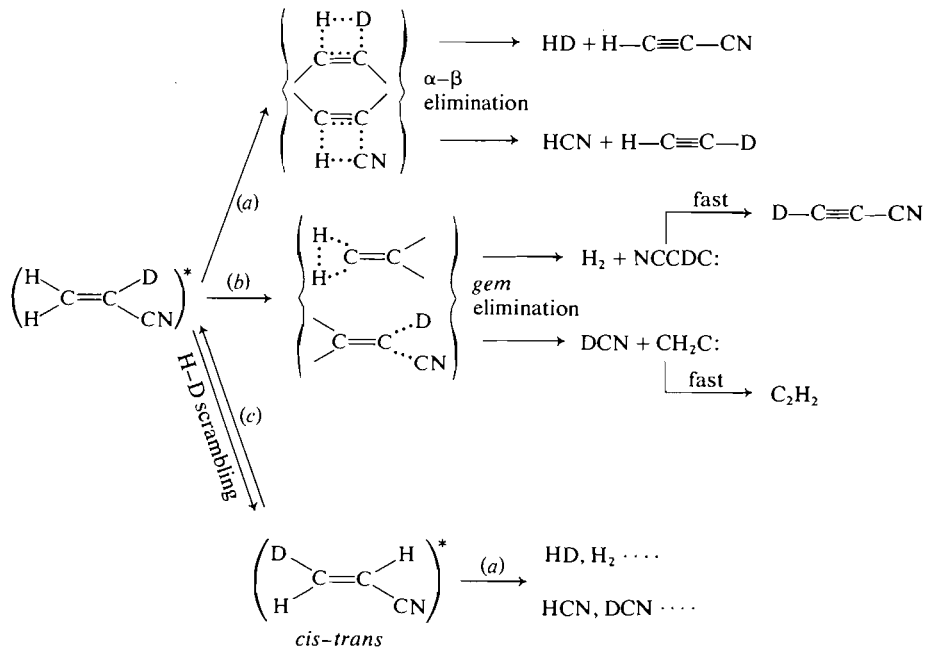
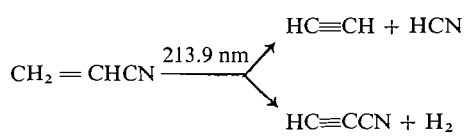
For personal use only.



2000). In this context it is interesting to note that we obtained an apparent quantum yield of H_2 at 206.5 nm, using an unfiltered Zn lamp, that was much lower and pressure dependent, in contrast with the results obtained with the 213.9 nm line alone. Whilst this observation seems to confirm the existence of two different electronic states, or the onset of a radical channel at higher energy, we concentrated our efforts on the simpler situation following 213.9 nm excitation only.

The independence of the yield of hydrogen on acrylonitrile pressure and presence of propane (300 Torr) suggests that only molecular elimination is responsible for its formation. This is further confirmed by the presence of equivalent amounts of cyanoacetylene as a product and the absence of products derived from hydrogen atom addition or abstraction reactions. Similarly, the constancy of the acetylene yield and its indifference to the presence of oxygen (10 Torr) suggest a second molecular elimination channel, confirmed by the presence of equivalent amounts of hydrogen cyanide and the absence of products derived from the vinyl radical (e.g. ethylene, butadiene). Therefore the primary steps can be represented as



$$\phi_1/\phi_2 = 1.6$$

$$\phi_1{}^{+}\phi_2 = 0.81$$

The quantum yield deficit could be accounted for by polymer formation (from excited acrylonitrile or acetylene) and/or internal conversion, as no luminescence was observed.

The isotopic ratios in the photolysis products of acrylonitrile-1-*d* are interesting. They can be rationalised by either of the following mechanistic reductions, (*a*) a *gem* elimination of H_2 or deuterium cyanide followed by rapid isomerisation of the vinylidene fragment to cyanoacetylene or acetylene, concurrent with α–β elimination of HD or hydrogen cyanide (route *c* not required); in this case αβ eliminations would occur 1.5 times more frequently than αα elimination; (*b*) intramolecular H–D atom scrambling in excited acrylonitrile followed by α–β elimination only (route *b* not required).

Four pieces of evidence favour the second alternative, namely: (*i*) the equality of the ratios HD/H_2 and C_2HD/C_2H_2; (*ii*) the value of these ratios is exactly that expected statistically in the case of α–β elimination from a 90% acrylonitrile-1-*d* mixture in which scrambling of deuterium in the excited molecule is complete; (*iii*) the same value of these ratios is obtained in the multiphoton ir decomposition of acrylonitrile-1-*d* (4); (*iv*) intramolecular atom scrambling has been observed in the gas phase photosensitized reactions of deuterated ethylenes (10–12) and in the matrix isolated uv photolysis (13, 14) and multiphoton ir photolysis (15) of substituted ethylenes.

The absence of free radical formation parallels the results obtained in the multiphoton ir decomposition

in which the same two channels were observed (4). Whilst it is reasonable to expect that the C—CN bond would not easily be cleaved (2) at this wavelength ($E = 133.7$ kcal) it is surprising that no evidence is found for fission of the C—H bond.

Synthesis and coordinating properties of the anionic tridentate ligand, methyl tris(1-pyrazolyl)gallate, $[MeGa(N_2C_3H_3)_3]^-$. X-ray crystal structure of $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$

KENNETH R. BREAKELL, STEVEN J. RETTIG, DOUGLAS L. SINGBEIL, ALAN STORR, AND JAMES TROTTER

The anionic tridentate ligand, $[MeGa(N_2C_3H_3)_3]^-$, has been characterized and its coordinating properties studied. It acts as a six-electron chelating ligand to divalent transition metal ions giving complexes of the type, $[MeGa(N_2C_3H_3)_3]_2M$ (M = Mn, Fe, Co, Ni, Cu, Zn), believed to possess an octahedral MN_6 core. The ligand also forms numerous carbonyl complexes and its coordinating ability in Mo, W, and Mn carbonyl derivatives is compared with that of similar boron ligands and the $\eta^5\text{-}C_5H_5$ ligand. From ir measurements and bond length data it appears that the $[MeGa(N_2C_3H_3)_3]^-$ ligand is superior in creating an electron-rich transition metal centre, and it also affords greater steric protection for the central metal. The expected tridentate chelating nature of the new ligand has been demonstrated through a crystal structure determination of the complex $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$. Crystals of this complex are tetragonal, $a = 26.217(3)$, $c = 10.723(2)$ Å, $Z = 16$, space group $I4_1/a$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to a final R of 0.030 and R_w of 0.031 for 2582 reflections with $I \geq 3\sigma(I)$.

KENNETH R. BREAKELL, STEVEN J. RETTIG, DOUGLAS L. SINGBEIL, ALAN STORR et JAMES TROTTER. Can. J. Chem. **56**, 2099 (1978).

On a caractérisé le ligand tridentate anionique $[MeGa(N_2C_3H_3)_3]^-$ et on a étudié ses propriétés coordonnantes. Il agit comme ligand chélatant à six électrons vis-à-vis des ions divalantes des métaux de transition qui donnent des complexes du type $[MeGa(N_2C_3H_3)_3]_2M$ (M = Mn, Fe, Co, Ni, Cu, Zn), pour lesquels on croit que le noyau possède une symétrie octaédrique MN_6. Le ligand forme aussi de nombreux complexes carbonyles et on a comparé sa facilité de coordonner dans des dérivés carbonylés du Mo, W et Mn avec celle de ligands semblables de bore et du ligand $\eta^5\text{-}C_5H_5$. En se basant sur des mesures i.r. et des données de longueurs de liaison, il semble que le ligand $[MeGa(N_2C_3H_3)_3]^-$ possède les qualités supérieures pour créer un centre de métal de transition qui est riche en électrons et qu'il fournit aussi une meilleure protection stérique pour le métal central. On a démontré la nature chélatante tridentate attendue du nouveau ligand par une détermination de la structure cristalline du complexe $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$. Les cristaux de ce complexe sont tétragonaux: $a = 26.217(3)$, $c = 10.723(2)$ Å, $Z = 16$, groupe d'espace $I4_1/a$. On a résolu la structure par des synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.030 et R_w de 0.031 pour 2582 réflexions avec $I \geq 3\sigma(I)$.

[Traduit par le journal]

Introduction

Numerous reports (1–4) have described the synthesis and coordination chemistry of the bidentate anionic ligands of the type $Me_2Ga(N_2C_3H_3)_2^-$. The present account details the synthesis of the anionic tridentate chelating ligand, methyl tris(1-pyrazolyl)-gallate, $[MeGa(N_2C_3H_3)_3]^-$, and describes its coordination compounds with transition metal M^{2+} ions (M = Mn, Fe, Co, Ni, Cu, and Zn) and also describes derivatives formed by interaction of the

ligand with Mo, W, and Mn carbonyl compounds. The tridentate chelating character of the ligand is demonstrated conclusively in the X-ray crystal structure determination of the compound $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$.

Experimental

Starting Materials

Air-sensitive materials were handled in a glove-box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over lithium aluminum hydride and was used immediately following distillation. Pyrazole (K and K laboratories) and sodium hydride (Alfa) were used as supplied. Methyl gallium dichloride was prepared by a standard procedure (5) from gallium trichloride (6) and tetramethylsilane. Molybdenum and tungsten hexacarbonyls were used as supplied (Strem). Manganese pentacarbonyl bromide was prepared from dimanganese decacarbonyl (Strem) by a standard route (7). Allyl bromide and 2-methylallyl chloride were distilled under nitrogen prior to use. $FeCl_2 \cdot 1.5THF$ was prepared as previously described (8). Isoamyl nitrite was used as purchased (MCB).

Preparative Details

Sodium Methyl Tris(1-pyrazolyl)gallate Na^+-$[MeGa(N_2C_3H_3)_3]^-$

$$MeGaCl_2 + 3Na^+(N_2C_3H_3)^- \xrightarrow[\text{r.t.}]{\text{THF}} Na^+[MeGa(N_2C_3H_3)_3]^- + 2NaCl$$

Methyl gallium dichloride (4.761 g, 30.6 mmol) in THF solution was treated with a 3-molar equivalent of sodium pyrazolide (8.262 g, 91.8 mmol) in the same solvent. The mixture was stirred for 2 days and the white precipitate (NaCl) was then filtered off and washed with THF. The filtrate and the washings were made up to a standard volume and aliquots of the resulting solution were employed in subsequent reactions.

Preparation of $[MeGa(N_2C_3H_3)_3]_2M$ Complexes (M = Mn, Fe, Co, Ni, Cu, Zn)

The procedure was similar for each experiment and may be illustrated by describing the preparation of the nickel complex. The transition metal starting materials for all of the preparations are listed in Table 1 along with analytical data for the resulting complexes.

$$NiBr_2 + 2Na^+[MeGa(N_2C_3H_3)_3]^- \xrightarrow{\text{THF}} 2NaBr + [MeGa(N_2C_3H_3)_3]_2Ni$$

An aliquot of the ligand solution, prepared as described above and containing $Na^+[MeGa(N_2C_3H_3)_3]^-$ (1.890 g, 6.12 mmol), was added to a slurry of $NiBr_2$ (0.669 g, 3.06 mmol) in THF. The resulting mixture was stirred overnight and gave a lilac solution and a white precipitate. The precipitate was allowed to settle and the clear lilac solution isolated. The THF solvent was removed under vacuum and the resulting lilac powder was recrystallized from methylene chloride. The product was obtained as air-stable lilac crystals.

Preparation of $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$

Step 1

$$Na^+[MeGa(N_2C_3H_3)_3]^- + Mo(CO)_6 \xrightarrow[\text{reflux}]{\text{THF}} Na^+[MeGa(N_2C_3H_3)_3]Mo(CO)_3^- + 3CO$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Step 2

$$Na^+[MeGa(N_2C_3H_3)_3]Mo(CO)_3^- + C_3H_5Br \xrightarrow{THF}$$

$$[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5) + NaBr + CO$$

$Mo(CO)_6$ (1.40 g, 5.30 mmol) in THF and an aliquot of ligand solution containing $Na^+[MeGa(N_2C_3H_3)_3]^-$ (1.890 g, 6.12 mmol) were introduced into two separate parts of a break-seal apparatus. Both solutions were frozen at −196°C and the whole apparatus was evaculated and then sealed off. The apparatus was next warmed to room temperature and the solutions mixed. An immediate yellow coloration developed. The mixture was refluxed for several days after which time the CO evolution was measured (354 ml, 15.8 mmol). The clear yellow–orange solution was then treated with an excess of allyl bromide and the resulting solution refluxed for a few hours. Further gas evolution was noticed. The precipitated NaBr was separated from the solution and the solvent was removed from the latter. The resulting air-stable yellow powder was recrystallized from benzene to yield large golden crystals. Analytical data for this compound and the carbonyl compounds reported below are given in Table 1.

Preparation of $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_4H_7)$

This complex was prepared in a manner similar to the one described above, substituting 2-methylallyl chloride for allyl bromide in step 2 of the synthesis. The product was an air-sensitive bright yellow solid which was purified by vacuum sublimation at 120°C.

Preparation of $[MeGa(N_2C_3H_3)_3]Mo(CO)_2NO$

To a THF solution of $Na^+[MeGa(N_2C_3H_3)_3]Mo(CO)_3^-$ (see above) was added an excess of isoamyl nitrite and the resulting mixture was refluxed briefly. Gas evolution was observed and from the product solution an orange material was obtained. On recrystallization from benzene this gave well-formed bright orange crystals of the desired product.

Preparation of $[MeGa(N_2C_3H_3)_3]W(CO)_2(\eta^3\text{-}C_3H_5)$

Attempts to prepare this complex using the route employed for the analogous Mo compound described above were not successful and the complex was obtained using $(MeCN)_3W(CO)_3$ (9) as starting material.

Step 1

$$(MeCN)_3W(CO)_3 + \text{xs } C_3H_5Br \xrightarrow[\text{r.t.}]{THF}$$

$$(MeCN)_2W(CO)_2(\eta^3\text{-}C_3H_5)(Br) + MeCN + CO$$

Step 2

$$(MeCN)_2W(CO)_2(\eta^3\text{-}C_3H_5)(Br) + Na^+[MeGa(N_2C_3H_3)_3]^- \xrightarrow{THF}$$

$$[MeGa(N_2C_3H_3)_3]W(CO)_2(\eta^3\text{-}C_3H_5) + 2MeCN + NaBr$$

An excess of allyl bromide was added to a slurry of $(MeCN)_3W(CO)_3$ (1.381 g, 3.534 mmol) in THF at room temperature. The color of the mixture changed from yellow to red and the product was a clear solution. $Na^+[MeGa(N_2C_3H_3)_3]^-$ (1.092 g, 3.534 mmol) in THF was added with a concomitant change of color to orange and the formation of a white precipitate. The isolated solution yielded a waxy orange solid which yielded yellow–orange crystals upon recrystallization from benzene.

The $[MeGa(N_2C_3H_3)_3]W(CO)_2(\eta^3\text{-}C_4H_7)$ compound was prepared via a similar route but employing an excess of 2-methylallyl chloride in step 1 of the synthesis in place of allyl bromide.

Preparation of $[MeGa(N_2C_3H_3)_3]W(CO)_2NO$

This compound was prepared using a route similar to that used for the corresponding Mo compound. A THF solution of $Na^+[MeGa(N_2C_3H_3)_3]W(CO)_3^-$ (obtained from $W(CO)_6$ and $Na^+[MeGa(N_2C_3H_3)_3]^-$) was treated with an excess of isoamyl nitrite and the reaction, on work-up, yielded bright orange crystals of the nitrosyl complex.

Preparation of $[MeGa(N_2C_3H_3)_3]Mn(CO)_3$

$$Mn(CO)_5Br + Na^+[MeGa(N_2C_3H_3)_3]^- \rightarrow$$

$$[MeGa(N_2C_3H_3)_3]Mn(CO)_3 + 2CO + NaBr$$

$Mn(CO)_5Br$ (0.774 g, 2.82 mmol) in THF solution and $Na^+[MeGa(N_2C_3H_3)_3]^-$ (0.874 g, 2.83 mmol) in the same solvent were mixed and the resultant combination was refluxed for a few hours. Gas evolution was brisk and at the end of the reaction a pale yellow solution and a white precipitate were obtained. The isolated clear solution gave an off-white solid on removal of the THF solvent. Recrystallization from benzene gave pale yellow crystals of the product.

Spectra

Mass spectra were recorded on a Varian MAT CH4 mass spectrometer at 70 eV with an ion source temperature of 100–180°C. Infrared spectra were recorded on a Perkin Elmer 457 spectrophotometer either as Nujol mulls or as solution spectra in cyclohexane or in benzene solvents. Proton nmr spectra in C_6D_6 were recorded on Varian T60 and XL-100 spectrometers. For complexes of low solubility FT techniques were employed in the recording of their ^1H nmr spectra.

X-ray Crystallographic Analysis of $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$

The crystal (a parallelepiped with (010), (100), (10$\bar{2}$) developed) was mounted with c parallel to the goniostat axis and had dimensions of ca. 0.5 × 0.5 × 0.5 mm. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 22 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71069 Å). Crystal data (at 22°C) are:

$C_{15}H_{17}GaMoN_6O_2$ fw = 479.0

Tetragonal, a = 26.217(3), c = 10.723(2) Å, V = 7370(1) Å^3, Z = 16, ρ_c = 1.727 g cm^{-3}, $F(000)$ = 3808, μ(Mo K_α) = 22.3 cm^{-1}. Absent reflections: hkl, $h + k + l \neq 2n$, $hk0$, $h(k) \neq 2n$, and $00l$, $l \neq 4n$ in addition to Laue symmetry $4/m$ determine uniquely the space group $I4_1/a$ (C_{4h}^6, No. 88).

Intensities were measured with zirconium-filtered Mo K_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. Background counts (10 s) were measured at each end of the scan. Data were measured to 2θ = 55°. The intensities of the check reflections, measured every 50 reflections throughout the data collection, remained constant to within ±1.5% throughout the data collection. After data reduction, an absorption correction was applied using the Gaussian integration method (10, 11). Transmission factors ranged from 0.346 to 0.427. Of the 4233 independent reflections measured, 2582 (61%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + B + (0.02S)^2$ with S = scan count and B = time-averaged background count.

The positions of the molybdenum and gallium atoms were determined from the Patterson function and those of the O, N, and C atoms from a subsequent difference map. After full-matrix refinement of all non-hydrogen atoms with anisotropic thermal parameters to R = 0.037, a difference map gave the positions of all 17 hydrogen atoms, which were subsequently included in the refinement with isotropic thermal parameters. The scattering factors of ref. 12 were used for non-hydrogen atoms and those of ref. 13 for hydrogen atoms. Anomalous scattering factors from ref. 14 were used for the

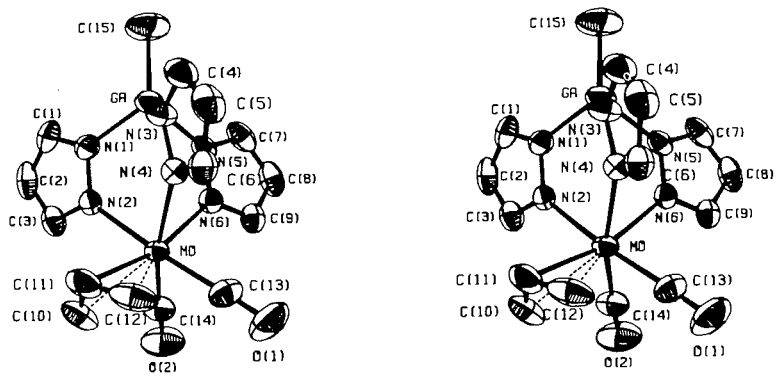

FIG. 1. Stereo view of the dicarbonyl[methyltris(1-pyrazolyl)gallato($N(2)$, $N(2')$, $N(2'')$)](η^3-allyl)molybdenum molecule, 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been omitted for the sake of clarity.

Mo and Ga atoms. The weighting scheme, $w = [1 + \{(|F_o| - 117.5)/47.5\}^2]^{-1}$ and $w = 0.0625$ for the unobserved reflections, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. A correction for secondary extinction was approximated by basing the least-squares refinement on the minimization of $\Sigma w[|F_o| - |F_c|/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was $5.8(2) \times 10^{-7}$. Convergence was reached at $R = 0.030$ and R_w of 0.031 for 2582 reflections with $I \geq 3\sigma(I)$. For all 4233 reflections $R = 0.069$ and $R_w = 0.040$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.02 and 0.21σ respectively. The mean error in an observation of unit weight was 2.527. A final difference map showed maximum fluctuations of −1.5 to +0.6 e Å^{-3} near Mo and ±0.3 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 2 and 3 respectively.[1] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (15) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0025 Å^2. Analysis of the entire molecule (rms $\Delta U_{ij} = 0.0074$ Å^2) showed that the atoms O(1), O(2), C(10), C(12), and C(15) exhibit significant independent motion. These atoms were excluded from the rigid-body, resulting in a physically reasonable set of rigid-body thermal parameters (rms $\Delta U_{ij} = 0.0044$ Å^2). The appropriate bond distances have been corrected for libration (16), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values. Corrected bond angles differ by less than 1σ from the uncorrected values given in Table 5.

Results and Discussion

Infrared Spectra

Carbonyl Complexes

The metal carbonyl complexes show important trends in their ir spectra. The wave numbers of ν_{CO} vibrations for the complexes are listed in Table 6

[1]The structure factor table and Table 3 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

together with pertinent ν_{CO} bands for comparable compounds (17, 18). It is noteworthy that the ν_{CO} vibrations for the gallium complexes are consistently ~ 10 cm^{-1} lower than those of the corresponding boron complexes, suggesting a more electron-rich transition metal centre with the introduction of the gallium ligand with consequent increased back-bonding to the carbonyl groups. The results are entirely in agreement with the bond lengths in $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$ and $[HB(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ (see Crystal Structure section). As with the boron complexes (18), the ν_{CO} values for the gallium complexes decrease by ~ 10 cm^{-1} in going from Mo to W. In the analogous $LMo(CO)_2(\eta^3\text{-}C_3H_5)$ series (where L = $\eta^5\text{-}C_5H_5$, $HB(N_2C_3H_3)_3$, or $MeGa(N_2C_3H_3)_3$), the highest ν_{CO} values occur when L = $\eta^5\text{-}C_5H_5$, the lowest when L = $MeGa(N_2C_3H_3)_3$. Another noteworthy feature is that only in the complex $[MeGa(N_2C_3H_3)_3]W(CO)_2(\eta^3\text{-}C_3H_5)$ do four ν_{CO} bands become apparent, a feature previously reported for the complex $(\eta^5\text{-}C_5H_5)Mo(CO)_2(\eta^3\text{-}C_3H_5)$ (17). This suggests the occurrence of two isomers in the cyclohexane solution of this tungsten complex with the allyl group in one of the isomers rotated in the opposite direction to that depicted in the crystal structure of the Mo derivative (see Fig. 1). The intensities of the two sets of doublets are in approximately a 2:1 ratio suggesting one isomer being preferred over the other. From the crystal structure data in this report, and in the report on the similar boron structure (19), it is apparent that it is preferable for the central atom of the allyl group (whether it bears a hydrogen atom or a methyl group) to orient into the space between the two pyrazolyl groups. Indeed the complex, $[MeGa(N_2C_3H_3)_3]W(CO)_2(\eta^3\text{-}C_4H_7)$, shows only two ν_{CO} bands, suggesting that the C—Me group projecting towards the two CO groups is not energetically favored. The gallium complexes which display just two bands are all thought to be similar, with respect to orientation of their allyl groups, to that illustrated for the $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$ complex (Fig. 1). The larger size of the W atom over the Mo atom may be responsible for the occurrence of a small amount of the less favored isomer in the cyclohexane solution of the $[MeGa(N_2C_3H_3)_3]W(CO)_2(\eta^3\text{-}C_3H_5)$ complex.

The manganese tricarbonyl complex, $[MeGa(N_2C_3H_3)_3]Mn(CO)_3$, showed the expected two ν_{CO} bands in cyclohexane and these occurred at 10 cm^{-1} lower than the ν_{CO} values reported for similar boron complexes (see Table 6) as expected. The Nujol mull spectrum of this complex, however, displayed a split asymmetric ν_{CO} vibration and gave three bands in the ν_{CO} region at 2020, 1922, and 1890 cm^{-1}. Unfortunately the two nitrosyl complexes, $[MeGa(N_2C_3$-

$H_3)_3]M(CO)_2NO$ (M = Mo, W), were not sufficiently soluble to give spectra in cyclohexane or in CH_2Cl_2. The spectra recorded in Table 6 are taken in Nujol. Four bands (two of strong and two of medium intensity) were found in the ν_{CO} region in each complex and a complex band envelope was observed in the ν_{NO} region of the spectra at $\sim$1650 cm^{-1}. These splittings could well arise from the necessity to use Nujol mull samples, but it is clear that the tungsten complex again displays the lower ν_{CO} frequencies, $\sim$20 cm^{-1} below those for the corresponding molybdenum compound.

[MeGa(N$_2$C$_3$H$_3$)$_3$]$_2$M Complexes (M = Mn, Fe, Co, Ni, Cu, Zn)

The Nujol mull spectra of all six complexes listed in Table 1 were essentially identical, indicating a probable isomorphism in the octahedral complexes. An X-ray structural study of the nickel complex is in progress and should confirm the pseudo-octahedral arrangement of the six ligating nitrogen atoms about the central nickel atom. Such an arrangement has been demonstrated in the crystal structure determination of the boron complex $[HB(N_2C_3H_3)_3]_2Co$ (20).

Two sharp strong bands occurred in the region usually associated with Ga—C stretching vibrations, 628 and 595 cm^{-1}, in each of the spectra. The band at lower frequency is probably the Ga—C stretching vibration for the compounds and the one at 628 cm^{-1}, a little high for a ν_{Ga-C} stretch (21), may be due to a pyrazolyl ring mode.

complexes of Mo and W are listed in Table 7. All six spectra give signals for the pyrazolyl protons which indicate that two pyrazolyl groups are in like positions whilst the third pyrazolyl group is unique. The assignment of the individual signals to specific pyrazolyl protons follows by analogy with the assignments of Meakin *et al.* for similar boron compounds (22). It is noteworthy that the pyrazolyl protons in $[HB(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$ (22) do not approach the resolution of those in the room temperature spectrum of $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$ until −45°C. In fact, at room temperature, due to a rapid rotation of the $HB(N_2C_3H_3)_3$ moiety about the B...Mo axis, the three pyrazolyl groups appear equivalent. Less severe steric interactions about the molybdenum atom in the boron complex, due to shorter B—N distances relative to Ga—N distances, probably account for the observed difference in the proton nmr spectra. Higher temperature spectra on the gallium complex may demonstrate a similar ability of the $[MeGa(N_2C_3H_3)_3]$ moiety to rotate about the Ga...Mo axis. Comparison of the spectra of the nitrosyl compounds with those of the allyl compounds reveals a significant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

upfield shift of the signal due to the 3-H proton of the unique pyrazolyl group in the nitrosyl compounds. The signals due to the 3-H protons of the two similarly positioned pyrazolyl groups do not change significantly on changing allyl for nitrosyl in the compounds. Both the η^3-allyl groups and the nitrosyl groups are *trans* to the 3-H proton of the unique pyrazolyl group in the pseudooctahedral complexes (see Fig. 1) and it seems possible that some type of *trans* effect is responsible for the observed shift. Another feature of note is that the signals due to the pyrazolyl protons of the η^3-2-methylallyl complexes are not as well resolved as those in the corresponding η^3-allyl complexes. A variable temperature ^{1}H nmr study is being undertaken on these complexes in an attempt to explain these observations.

The allyl protons gave clearly resolved signals except for the unique proton of the η^3-C_3H_5 group. The signals are assigned in Table 7 following assignments for the comparable allyl complexes $(\eta^5$-$C_5H_5)$-$Mo(CO)_2(\eta^3$-$C_3H_5)$ (23, 24) and $(\eta^5$-$C_5H_5)Mo$-$(CO)_2(\eta^3$-$C_4H_7)$ (24) and also using assignments given in ref. 25. Again a variable temperature ^{1}H nmr study would be useful on these complexes in the 'allyl' region of the spectra to determine if rotation of the allyl groups is possible or whether steric interactions restrict the molecular arrangement of these groups to one or the other of the two possible isomers discussed above. A stereochemically rigid system might well be confirmed for the gallium complexes on the nmr time scale within the experimentally accessible temperature range. It is interesting to note that the room temperature ^{1}H nmr spectrum of the complex $[MeGa(N_2C_3H_3)_3]W(CO)_2(\eta^3$-$C_3H_5)$ in C_6D_6 did not indicate the presence of two isomers as suggested by the ir spectrum in cyclohexane solvent. However it is well documented that changing the solvent can radically alter the distribution of isomers in this type of system (26). The ir spectrum of the complex in benzene solvent displayed but two peaks in the ν_{CO} region of the spectrum.

Mass Spectra

$[MeGa(N_2C_3H_3)_3]_2M$ Compounds (M = Mn, Fe, Co, Ni, Cu, Zn)

The mass spectra of all six complexes listed in Table 1 displayed strong signals due to the parent ions and also strong signals corresponding to the $[MeGa(N_2C_3H_3)_3]M^+$ ions. In addition to other weak signals arising from 'mixed metal' ions two strong signals occurred in all six spectra which were assigned to ions containing two gallium atoms, viz. $MeGa_2(N_2C_3H_3)_4^+$ and $Me_2Ga_2(N_2C_3H_3)_3^+$. These ions must arise, after ejection of the transition metal and pyrazolyl groups from the parent species, by a recombination of '$MeGa(N_2C_3H_3)_x$' fragments. It is noteworthy in this regard that a strong signal due to the $MeGa(N_2C_3H_3)^+$ ion occurs in all of the spectra.

Carbonyl Derivatives

Signals due to parent ions were observed in the mass spectra of all seven carbonyl complexes listed in Table 1.

In the spectrum of the manganese compound, $[MeGa(N_2C_3H_3)_3]Mn(CO)_3$, all signals were weak compared to the very strong signal attributable to the $[MeGa(N_2C_3H_3)_3]Mn^+$ ion.

The mass spectra of the three molybdenum derivatives gave well-defined 9-line patterns, of close to the theoretical intensity ratio, for all ions containing both a Ga and a Mo atom. The spectra all displayed as their most intense signal the one arising from the parent ion minus two CO groups. The parent ions themselves gave signals about one-fifth as intense as the above signals.

The mass spectra of the tungsten derivatives gave well-defined 6-line patterns of expected intensity ratio for all ions containing both a Ga and a W atom. The spectrum of the nitrosyl derivative, $[MeGa$-$(N_2C_3H_3)_3]W(CO)_2NO$, displayed as its most intense signal that corresponding to parent ion stripped of two CO groups and a methyl group. The spectra of the tungsten allyl compounds displayed as their most intense signals those arising from parent ions minus two CO groups. In all three tungsten compounds the parent ion signals themselves were about two-fifths as intense as the strongest signals in the spectra. In all six spectra strong signals arising from the $[MeGa(N_2C_3H_3)_3]M^+$ ion (M = Mo or W) were again observed.

In summary, all thirteen complexes listed in Table 1 are sufficiently volatile and stable to give readily observable parent ion signals in their mass spectra. The appearance of signals due to other ions indicates fragmentation patterns which are predictable for these complexes. The intensity ratios of the individual peaks in multi-peak signals agree closely with theoretical predictions based on the percentage isotope compositions of the contributing metal atoms.

Crystal Structure of $[MeGa(N_2C_3H_3)_3]Mo(CO)_2$-$(\eta^3$-$C_3H_5)$

The present structure confirms unequivocally the tridentate chelating character of the new ligand, $[MeGa(N_2C_3H_3)_3]^-$, and warrants close comparison with the structure reported for the similar boron complex, $[HB(N_2C_3H_3)_3]Mo(CO)_2(\eta^3$-$C_4H_7)$ (19). Differences in properties of the compounds are to be expected, due primarily to the much longer mean Ga—N bond distance (1.926(8) Å) compared with the mean B—N distance of 1.545 Å. This difference leads to a greater steric crowding about the Mo atom

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in the gallium complex since the 3-H atoms of the pyrazolyl groups are forced into closer proximity to the Mo atom than in the boron compound. In both structures the M—(N—N)$_2$—Mo (M = B or Ga) boat having the allyl group projecting towards it is flattened compared to the other two such boats having CO groups in close proximity (mean magnitudes of the N—[Mo—N]—N dihedral angles in the present structure are 22.5° for the unique ring and 52.4° for the other rings). The difference is more pronounced in the case of gallium as a result of the greater steric crowding mentioned above. Another noticeable effect of the bulky allyl substituent is that in both structures the shortest Mo—N bond distances are *trans* to the allyl group (2.232(3) vs. 2.309(3) and 2.328(3) Å for the gallium complex and 2.207 vs. 2.312 Å for the boron complex).

Comparison of the Mo—CO and C—O bond distances reveals that the C—O bonds are longer and the Mo—CO bonds significantly shorter in the gallium compound than in the boron compound. This reflects a more electron-rich Mo centre in the gallium complex which may result from an increase in donor strength (or a decrease in acceptor ability) of the gallium ligand over the boron ligand. The bond lengths do reflect an increase in $d\pi$–π^* back-bonding to the CO groups in the gallium complex with concomitant decreases in Mo—CO distances and increases in C—O bond lengths (Mo—CO = 1.959(6) and 1.958(4) Å for B, 1.936(5) and 1.948(5) Å for Ga; C—O = 1.151(7) and 1.150(5) Å for B, 1.162(6) and 1.166(6) Å for Ga). The effect is also reflected in the ν_{CO} vibrations in the ir spectra for the two complexes where the gallium complex exhibits ν_{CO} bands 10 cm^{-1} lower than the boron compound (see above).

The Mo—C—O groupings show a slight deviation from linearity (177.2(5) and 176.5(5)°) which most probably results from local packing forces. The geometry about the Mo atom is distorted octahedral with the η^3-allyl group occupying one of the octahedral positions as a π-donating ligand (Mo—C = 2.228(5), 2.338(5), and 2.360(5) Å). The gallium atom is in a distorted tetrahedral environment with normal Ga—N and Ga—C bond distances (2, 27–35). Other bond lengths and angles in the molecule are as expected. It is interesting that in both the boron structure (19) and the gallium structure the three allyl carbons interacting with the Mo atom occupy the same relative positions, even though in the boron compound the central allyl carbon atom bears a methyl group instead of a hydrogen atom as in the gallium complex.

Steric crowding about the Mo atom results in torsional twists about the pyrazolyl N—N bonds, particularly those *cis* to the allyl group. The Mo—[N—N]—Ga torsion angles (ideally = 0°) are 18.2(2), —18.2(2), and 5.5(2)° respectively for the N(1), N(3), and N(5) pyrazolyl rings. One of the pyrazolyl groups (that containing N(1)) is significantly non-planar (χ^2 = 9.5) while the other two are planar within experimental error. The Ga and Mo atoms are significantly displaced from all three pyrazolyl ring mean planes. The crystal structure consists of well-separated molecules of [MeGa(N$_2$-C$_3$H$_3$)$_3$]Mo(CO)$_2$(η^3-C$_3$H$_5$), the shortest intermolecular distances corresponding to normal van der Waals interactions.

Reçu le 20 janvier 1978

D. TAVERNIER, J. C. JAMOULLE et C. L. LAPIÈRE. Can. J. Chem. **56**, 2109 (1978).

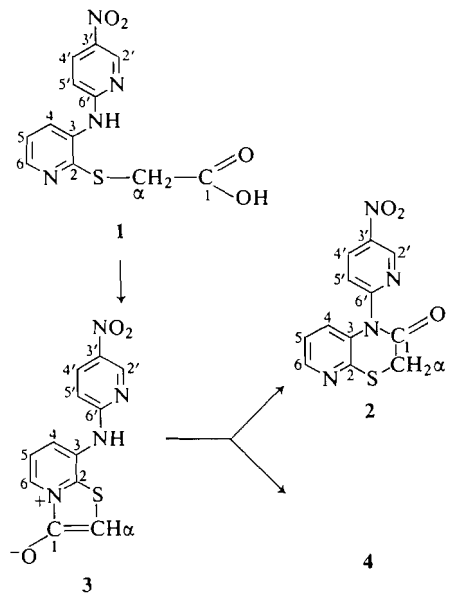
Lors de la cyclisation de l'acide [(nitro-5 pyridyl-2) amino-3 pyridyl-2]mercaptoacétique, le produit principal de la réaction est constitué par l'hydroxylate-3 de {[(nitro-5 pyridyl-2) amino-3 pyridyl-2]mercaptoacétyl}-2[(nitro-5 pyridyl-2)amino]-8 pyridyl[2,1-*b*]thiazolium (**4**). Sa structure a été déterminée essentiellement par rmn du ^1H et du ^{13}C.

D. TAVERNIER, J. C. JAMOULLE, and C. L. LAPIÈRE. Can. J. Chem. **56**, 2109 (1978).

The principal product from the cyclization of {[3-(5-nitropyridine-2-yl)-amino]pyridine-2-yl}thioacetic acid is 2-{[3-nitropyridine-2-yl)amino]pyridine-2-yl}thioacetyl-8-[(5-nitropyridine-2-yl)amino]-3-oxidopyrido[2,1-*b*]thiazolium (**4**). Its structure was determined primarily by ^1H and ^{13}C nmr.

[Journal translation]

La cyclisation des acides (arylamino-3 pyridyl-2) mercaptoacétiques **1** a été étudiée dans une publication antérieure (1). En choisissant judicieusement les conditions opératoires, cette cyclisation peut être orientée vers la formation et l'isolement de composés pyridothiaziniques **2** ou de dérivés du pyridothiazolium **3**.[2]



En effectuant l'opération par chauffage à reflux dans le xylène, nous isolons, d'une façon générale, le composé pyridothiazinique par extraction du résidu d'évaporation du xylène, au moyen de méthanol. Dans le cas de l'acide non substitué en α sur la chaîne mercaptoacétique, le rendement en composé pyridothiazinique est faible et le résidu insoluble dans le méthanol est important. Ce résidu peut être recristallisé du nitrobenzène, fournissant ainsi une substance à pf 265–267°C (**4**). L'analyse élémentaire donne des résultats identiques à ceux fournis précédemment par la pyridothiazine et le pyridothiazolium correspondants.

Ce produit présente cependant des caractéristiques physiques et physicochimiques qui le différencient aussi bien du produit de départ que des deux produits de cyclisation isolés antérieurement: il présente une coloration verte; il est pratiquement insoluble dans les solvants usuels; il est chromatographiquement pur et son R_f est différent de ses congénères. La ccm a été réalisée sur plaques de silica gel (Merck 60F, 254), utilisant comme phases mobiles, soit un mélange diméthylformamide–nitrobenzène (1:7), soit un mélange acide acétique – acétate d'éthyle (1:4). Le produit est déposé en solution à 70°C dans la diméthylformamide, et, avant développement, la plaque est séchée à 70°C dans une étuve ventilée; le spectre ir, en pastille de KBr, présente une bande large à 3280 et 3095 cm^{-1} et une bande à 1675 cm^{-1}. On n'observe pas de bande thiocarbonyle vers 1140 cm^{-1}, ni le trio de bandes A, B et C, caractéristique de la fonction acide de départ (3200, 2450 et 1900 cm^{-1}) (2, 3).

La substance a été soumise à la spectrométrie de

TABLEAU 1. Paramètres spectraux de ^1H de **1**, **3** et **4**

(*a*) Déplacements chimiques

Composé	Hydrogène 4	5	6	2′	4′	5′	NH	α
1	7.76	7.22	8.35	8.91	8.31	6.82	9.79	3.97
4 Fragment A	7.76	7.20	8.34	8.91	8.29	6.82	9.79	4.81
Fragment T	8.69	7.79	8.87	9.03	8.45	7.24	10.70	—
3	8.29	7.67	8.73	9.02	8.43	7.18	10.31	5.41

(*b*) Constantes de couplages des protons en Hz

Composé	*J* 4,5	4,6	5,6	2′,4′	4′,5′
1	7.9	≃1.5	4.7	2.7	9.25
4 Fragment A	7.7	≃1.5	4.7	[a]	[a]
Fragment T	7.5	≃1	6.25	[a]	[a]
3	7.5	≃1	6.5	[a]	[a]

NOTE: Déplacements chimiques en δ par rapport au TMS. Solvant DMSO-d_6. Les spectres ont été enregistrés sur un appareil Varian HR-300 MHz, à la température ambiante, sauf pour 3 (≃60°C). Chacun des quatre cycles pyridiniques porte trois hydrogènes, et l'appartenance de trois hydrogènes à un même cycle a été déduite d'expériences INDOR.

[a]Les constantes de couplage des protons du cycle nitropyridinique sont les mêmes pour **1**, **3** et **4**.

masse afin d'obtenir le poids moléculaire de ce composé. Les informations fournies par cette technique ne sont pas utilisables, car, comme le révèle l'étude thermogravimétrique, le produit se pyrolyse à partir de 150°C avec formation de mercapto-2 nitro-5′ dipyridylamine-3,2′.

Nous nous sommes adressés ensuite à la rmn. En rmn du ^1H il est possible d'attribuer tous les pics enregistrés et de déterminer les constantes de couplage. L'examen spectrométrique indique que **4** contient 12 protons aromatiques différents permettant de conclure à la présence de quatre cycles pyridiniques disubstitués.

On peut reconnaître d'une part deux pyridines-2,3 disubstituées et deux pyridines-2,5 disubstituées. On observe également deux pics différents échangeables par l'eau lourde et attribuables aux hydrogènes mobiles des fonctions diarylamines ainsi que deux protons appartenant à un CH_2 aliphatique déblindé.

Les paramètres spectraux de **1**, **3** et **4** rassemblés dans le tableau 1 mettant bien en évidence que pour les pyridines-2,3 disubstituées, les déplacements chimiques de trois protons pyridiniques présentent des valeurs analogues à celles enregistrées pour le pyridothiazolium **3** tandis que les déplacements chimiques des trois autres protons pyridiniques présentent des valeurs voisines de celles enregistrées pour l'acide de départ. Les valeurs relevées pour cet acide ne présentent rien d'exceptionnel. Notons toutefois, dans le noyau pyridine porteur d'un groupement nitro, l'accroissement du couplage $J_{H_4',H_5'} = 9.25$ Hz par rapport à la pyridine elle-même (7.62 Hz) (4, 5). Cet accroissement est dû au groupement nitro (6, 7). La différence assez marquée des couplages $^3J_{H_5,H_4}$ et $^3J_{H_5,H_6}$ est typique des dérivés pyridiniques.

Les données rmn du noyau pyridinique-2,5 disubstitué pour les composés **4** et **3** sont quasi identiques.

Quand on examine les données spectroscopiques de la pyridine-2,3 disubstituée du pyridothiazolium **3**, on constate un déplacement chimique important des protons (surtout H_4) vers les champs faibles. Quant aux constantes de couplage, $^3J_{H_6,H_5}$ augmente sensiblement tandis que $^4J_{H_6,H_4}$ (8, 9) décroit. Ces variations par rapport au produit de départ peuvent être expliquées par une charge positive sur l'azote pyridinique provoquée par une protonation ou une quaternisation de cet azote. Un phénomène analogue se présente dans **4** pour une des deux pyridines-2,3 disubstitutuées que l'on trouve dans ce composé.

En fonction de ces observations, il est vraisemblable qu'il s'agit de ce qu'on pourrait appeler abusivement un "dimère" asymétrique. La molécule contiendrait une structure pyridothiazolium à côté d'un enchaînement pyridylmercaptoacétyle. Il reste à trouver le mode d'enchaînement des deux "monomères" et leur point d'attache.

En spectrométrie ir, comme nous l'avons déjà fait remarquer, on note une bande νC=O à 1675 cm^{-1} moins intense cependant que celle observée dans la pyridothiazinone **2**. Le trio de bandes A, B et C caractéristique de la fonction acide du dérivé pyridyl-

TABLEAU 2. Paramètres spectraux de ^{13}C de **1** et **4**[a]

Composé		Carbone											
		2	3	4	5	6	2′	3′	4′	5′	6′	α	1
1		154.7	137.0	134.7	120.3	147.1	146.4	132.3	133.3	109.1	160.7	31.96	171.04

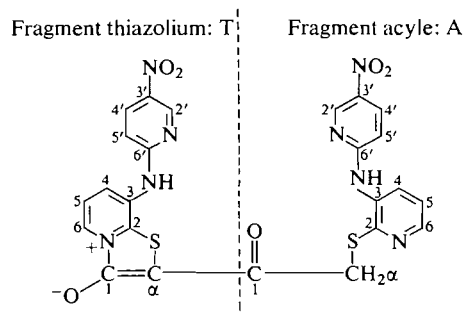
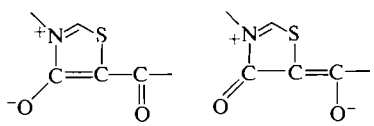
NOTE: Solvant DMSO-d_6. Température 35°C pour **1**, 80°C pour **4**. Les spectres ont été enregistrés sur un appareil Varian XL 100. Déplacements chimiques en δ par rapport au TMS. Le spectre de **1**, totalement couplé avec les hydrogènes, a demandé 103.881 transients, le temps d'acquisition fut 0.533 s, la largeur du spectre était 7500 Hz. Le spectre de **4**, avec couplage partiel des hydrogènes, demandait 52.861 transients dans les mêmes conditions.
[a]Les attributions des carbones marqués* (non fixés à un hydrogène) ou † (carbones fixés à un hydrogène) peuvent être inversés.
[b]Ce carbone ne fut observé qu'après l'addition d'acétylacétonate de chrome(III) et l'emploi d'un champs faible d'irradiation des hydrogènes.

mercaptoacétique est absent. Cette fonction acide est donc engagée dans une liaison où le carbonyle subsiste et d'autre part l'enchaînement entre les deux fragments du "dimère" se fait en toute logique sur le carbone α du thiazolium étant donné que seuls les produits **1** possédant cette position libre donnent lieu à la formation d'un tel produit secondaire. Nous pouvons donc dès à présent proposer la structure **4** pour le JJC 164.



4

La divergence entre le déplacement chimique des protons de **3** et de **4** pour ce qui est de la partie pyridinique *ortho* disubstituée T, serait expliquable par une mésomérie du type **5**, **6** où la délocalisation



5 **6**

de la charge négative sur l'oxygène du groupe alkyle accentue la charge positive sur l'azote. Ceci peut être responsable d'un déplacement vers les champs faibles, plus prononcé pour les protons de la pyridine-2,3 disubstituée T de **4** que pour les protons de la pyridine-2,3 disubstituée de **3** (10–12).

D'un point de vue chimique, la formation de ce composé peut être considéré comme une condensation apparentée à celle de Friedel et Crafts. Cette condensation se fait entre deux molécules de pyridothiazolium **3**. Il est en effet possible de préparer **4** en mettant en oeuvre le pyridothiazolium **3** seul.

Comme l'instabilité thermique du produit rendait impossible la détermination du poids moléculaire par spectrométrie de masse, il nous a paru prudent de corroborer la structure proposée par spectrométrie de rmn du ^{13}C (tableau 2). Nous trouvons comme prévu 24 carbones dont 11 ne portent pas d'hydrogène. Si ce n'est le pic à 185.7 ppm attribuable à un groupement carbonyle, on constate une coïncidence totale d'une part entre les déplacements chimiques des carbones de **1** et de 11 des carbones de **4** et d'autre part, entre les couplages résiduels de ces 11 carbones en irradiant "off-resonance" les hydrogènes de **1** et **4**. Il est de ce fait intéressant d'attribuer les résonances de l'acide **1** et de transférer ensuite ces attributions à **4**. Les déplacements chimiques et tous les couplages $J_{^{13}C,H}$ de la pyridine sont connus (13, 14). Une première classification ou attribution partielle est possible en admettant une additivité des effets de substituant sur les déplacements chimiques, semblables en série benzénique et en série pyridinique (15*b*), $-NO_2$ (15*a*), —NHR (15*a*), $-SCH_3$ (16).

L'attribution non équivoque est possible grâce à un spectre ^{13}C pris sans découplage des hydrogènes. On sait que les substituants influencent les couplages $J_{^{13}C,H}$ (17–20). Une étude très poussée a été publiée récemment (21). Nous retiendrons de ces travaux qu'un substituant électronégatif diminue le couplage $^3J_{^{13}C,H}$ dans l'unité C=C(X)—C—H et que le couplage $^3J_{^{13}C,H}$ dans l'unité X—C=C—C—H est plus grande pour X = NO_2 que pour X = NH_2. L'application de ces critères permet de discriminer C(2′) de C(6), C(4) de C(4′) et C(3) de C(3′). C(2) est identifié grâce à un couplage triplet avec les deux hydrogènes du groupe —S—CH_2—CO—. Nous n'avons pas observé de couplage avec le proton fixé sur l'azote, ni avec l'azote.

Il n'a pas été possible d'enregistrer un spectre satisfaisant de **4** totalement couplé avec les hydrogènes, la perte d'effet nOe et la solubilité réduite de **4** dépassaient les possibilités du spectromètre. Néanmoins, les couplages résiduels observés en irradiant "off-resonance" les hydrogènes, laissent déjà percer les plus importants des $^nJ_{^{13}C,H}$. Il est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ainsi possible d'attribuer avec confiance les carbones 5′, 5, 2′, 6′ du fragment de **4T**. Il reste encore à identifier trois carbones directement liés à un atome d'hydrogène, dont seulement un appartient à un cycle nitropyridinique. Il faut constater que les déplacements chimiques de ces carbones protonés se trouvent en moyenne vers les champs forts en comparaison avec **1**. Il est connu que la protonation de la pyridine a pour résultat des changements importants dans les déplacements chimiques, un effet paramagnétique étant observé pour C(3) en C(4), un effet diamagnétique pour C(2) (22, 23). La quaternisation de la pyridine entraîne des changements semblables (24, 25).

Parmi les cinq carbones non identifiés non porteurs d'hydrogène, il y en a deux qui se trouvent en dehors de la région normale des carbones aromatiques l'un à $\delta = 95$, l'autre à $\delta = 170$. L'analogie avec la forme énolique de l'acétylacétone et ses sels métalliques est frappante (15*c* et *d*). L'observation de ces deux fréquences nous fournit donc la preuve la plus directe du cycle pyridothiazolium.

Metabolites of bird's nest fungi. Part 9.[1] Diterpenoid metabolites of *Cyathus africanus* Brodie

WILLIAM A. AYER, TAKASHI YOSHIDA, AND DIRK M. J. VAN SCHIE
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 13, 1978

WILLIAM A. AYER, TAKASHI YOSHIDA, and DIRK M. J. VAN SCHIE. Can. J. Chem. **56**, 2113 (1978).

The diterpenoid metabolites produced when the fungus *Cyathus africanus* Brodie (Nidulariaceae) is grown in liquid culture have been examined. The known compounds cyathin A_3 (**1**) and allocyathin B_3 (**2**) were isolated along with four new diterpenoids which have been named cyafrin A_4, cyafrin B_4, allocyafrin B_4, and cyafrin A_5. The structures of these substances have been determined by chemical and physical methods to be **3***a*, **10***a*, **12***a*, and **15***a*, respectively. Cyafrin A_4 (**3***a*), allocyafrin B_4 (**12***a*), and cyafrin A_5 (**15***a*) have been correlated with cyathin A_3 by chemical transformations. The absolute stereochemistry of cyathin A_3 has been confirmed by the exciton chirality method.

WILLIAM A. AYER, TAKASHI YOSHIDA et DIRK M. J. VAN SCHIE. Can. J. Chem. **56**, 2113 (1978).

On a étudié les métabolites diterpénoïdes qui sont produits lorsque des champignons *Cyathus africanus* Brodie (nidulariaceae) croissent dans des cultures liquides. On a pu isoler les composés connus cyathine A_3 (**1**) et allocyathine B_3 (**2**) de même que quatre nouveaux diterpénoïdes auxquels on a attribué les noms cyafrine A_4, cyafrine B_4, allocyafrine B_4 et cyafrine A_5. On a déterminé, par des méthodes chimiques et physiques, que les structures de ces composés correspondent respectivement à **3***a*, **10***a*, **12***a* et **15***a*. Faisant appel à des transformations chimiques, on a établi une corrélation entre la cyafrine A_4 (**3***a*), l'allocyafrine B_4 (**12***a*) et la cyafrine A_5 (**15***a*) avec la cyathine A_3. On a confirmé la stéréochimie absolue de la cyathine A_3 par la méthode exciton de la chiralité.

[Traduit par le journal]

In 1966, D. Hocking of this university brought from Tanzania two specimens of a bird's nest fungus which he had discovered growing on dead twigs on Mount Kilimanjaro at an altitude of about 8000 ft (2). H. J. Brodie determined this to be a previously unrecognized species of the genus *Cyathus* and named it *Cyathus africanus* (2, 3). We now wish to report on some of the metabolites formed when this species is grown in liquid culture. The crude metabolites were isolated by ethyl acetate extraction of the culture broth obtained after the fungus had grown in still culture on Brodie medium (ref. 3, p. 36) for 30 days. The crude material was separated into its components by column chromatography over silicic acid followed by preparative thin-layer chromatography (ptlc) over silica gel. In this way six different components, A (least polar), B, C, D, E, and F (most polar) were isolated.

Components A and B were shown to be the diterpenoids cyathin A_3 (**1**) (4) and allocyathin B_3 (**2**) (4), respectively, by comparison with authentic samples. These compounds have previously been isolated from *Cyathus helenae* (4, 5). The two other *Cyathus* species which have been investigated, *C. bulleri* (6) and *C. intermedius* (7), have not provided diterpenoids of this or any other type. Cyathin A_3 (**1**) is the most abundant of the metabolites of *C. africanus*, occurring to the extent of about 30 mg/ℓ of culture broth. The next most abundant metabolite is component E, occurring to the extent of about 6 mg/ℓ of culture broth.

Component E was obtained as colorless needles, mp 200–201°C, of molecular formula[2] $C_{20}H_{30}O_4$. This compound has not been isolated previously and has been given the trivial name[3] cyafrin A_4.

Structure **3***a*, which is in tautomeric equilibrium with its internal hemiacetal form **4***a*, is assigned to cyafrin A_4. The solid phase infrared spectrum of cyafrin A_4 does not show carbonyl absorption, indi-

[1]For Part 8, see ref. 1.

[2]Because of the small quantities of pure material available, most molecular formulas have been established by high resolution mass spectrometry (hrms). Eventual correlation with compounds of established molecular formula validates the deductions made in this manner.

[3]The following system of trivial nomenclature, similar to that used for the cyathins (5), has been adopted for those diterpenoid metabolites of *C. africanus* which are not found in *C. helenae*: a cyafrin is a C_{20} compound; cyafrins with 30 hydrogens belong to the A series, those with 28 hydrogens to the B series; the subscript after the letter denotes the number of oxygens present. Isomers of the first isolated cyafrins are placed in the allo series, e.g., both cyafrin B_4 and allocyafrin B_4 are $C_{20}H_{28}O_4$.

cating that the compound crystallizes in the hemiacetal form **4***a*. The solution ($CHCl_3$) spectrum, however, shows a broad carbonyl absorption band of medium intensity centered at 1680 cm^{-1} indicating the presence of some of the hydroxyketone tautomer **3***a*. Acetylation of cyafrin A_4 yields a tri-*O*-acetyl derivative **3***b*, which shows absorption for the α,β-unsaturated ketone at 1660 cm^{-1}. The ^{1}Hmr spectrum of **3***b* is strikingly similar to that of *O*,*O*-diacetylcyathin A_3 (**1***b*) with the exception that the spectrum of **3***b* shows an extra acetyl methyl signal and an extra one proton signal at δ 4.89 (apparent triplet, splitting 8 Hz) which may be assigned to a proton geminal to the extra acetoxyl function. This indicated that the extra hydroxyl group in cyafrin A_4 is located at C-1, C-2, C-7, or C-8. C-10 was excluded since the multiplicity of the signal for the proton on C-11 (δ 5.33, apparent triplet, splitting 6.5 Hz) is the same as in cyathin A_3.

To protect the hydroxyl groups on C-11 and C-15 while we explored the environment of the extra hydroxyl function, cyafrin A_4 was treated with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid to give the crystalline acetonide **5***a*. The ^{1}Hmr spectrum of **5***a* is very similar to that of cyathin A_3 acetonide, with the exception that there is a one proton signal at δ 3.88 (apparent triplet, splitting 7 Hz) for the hydrogen geminal to the hydroxyl group. Double irradiation experiments show that this hydrogen is coupled to two hydrogens of chemical shift δ 2.3–2.5. The chemical shift of the latter two hydrogens suggested that they are allylic and thus located at C-2 (the allylic hydrogens of cyclopentene resonate at δ 2.28 (8)) and that the 'extra' hydroxyl group is therefore located at C-1. Oxidation of the acetonide **5***a* with Jones' reagent provided the ketone **6** which shows carbonyl absorption at 1746 cm^{-1}, confirming that the hydroxyl group is in the five-membered ring. The ^{1}Hmr spectrum of **6** shows a new two proton AB quartet at δ 2.99 (J = 19 Hz) attributed to the protons on C-2 which are now both allylic and α to a carbonyl.

To firmly establish the proposed structure we set out to directly correlate cyafrin A_4 with allocyathin B_3 (**2**) or one of its derivatives. Mesylation of the acetonide **5***a* provided the mesylate **5***b*. Attempts to eliminate methanesulfonic acid from **5***b* under a variety of conditions (refluxing lutidine, 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) in refluxing tetrahydrofuran, DBU in refluxing benzene, potassium *tert*-butoxide in dimethyl sulfoxide) lead to recovery of the mesylate **5***b*. However, treatment of **5***b* with DBU in refluxing dioxane lead to the formation of an isomeric mesylate which is assigned structure **7**, in which the ring C double bond has migrated to the

β,γ-position. Compound **7** shows carbonyl absorption at 1708 cm^{-1}, no uv absorption for an α,β-unsaturated ketone (**5***a* shows λ_{max} 236 nm (6300)) and a ^{1}Hmr spectrum (see Experimental) consistent with structure **7**. Since it is often possible to replace the mesyloxy group with a hydrogen by reduction with lithium aluminum hydride (LAH), the mesylate **5***b* was treated with methanolic hydrogen chloride which removes the acetonide group and then forms the internal methyl acetal **8**. Reduction of **8** with LAH in tetrahydrofuran led to sulfur–oxygen cleavage to give cyafrin A_4 methyl acetal (**4***b*), identical with a sample prepared by treating cyafrin A_4 (**3***a* ⇄ **4***a*) with methanolic HCl.

Correlation was finally achieved by treatment of *O*-mesylcyafrin A_4 methyl acetal (**8**) for 45 h with DBU in refluxing toluene to give allocyathin B_3 methyl acetal (**9**), identical with an authentic sample (**4**). This correlation confirms the structure and stereochemistry (relative and absolute) of cyafrin A_4 (**3***a* ⇄ **4***a*) except for the stereochemistry of the hydroxyl group at C-1.

The stereochemistry at C-1 was first assigned by ^{1}Hmr spectroscopy using Wenkert's pyridine shift method for determining the dihedral angle between a hydroxyl group and a vicinal methyl group (9). For this purpose the ^{1}Hmr spectra of cyafrin A_4 acetonide (**5***a*) and cyathin A_3 acetonide were recorded in pyridine and in $CDCl_3$. In $CDCl_3$ the methyl at C-9 in cyathin A_3 acetonide appears at δ 1.06 and C-6 methyl at δ 1.10. In pyridine the C-9 methyl is at δ 1.06 and the C-6 methyl at δ 1.18 (C-6 methyl displaced to lower field by contact shift of pyridine with C-14 carbonyl, the spectrum in benzene shows the same shift of the C-6 methyl). Cyafrin A_4 acetonide in $CDCl_3$ shows the C-9 methyl at δ 1.09 and the C-6 methyl at δ 1.00, in pyridine the C-6 methyl appears at δ 1.21 and the C-9 methyl at δ 1.30, thus Δ_{py} for the C-9 methyl is −0.21 ppm, indicative (9) of a *cis* relationship between the C-1 hydroxyl group and the C-9 methyl. Application of Brewster's benzoate rule (10) indicates ($[M]_D$**5***d* − $[M]_D$**5***a* = −62.7) that C-1 has the *R* configuration and thus the hydroxyl group is β (i.e., *cis* to the C-9 methyl). The stereochemistry at C-1 may also be assigned by application of ^{13}Cmr spectroscopy.[4]

Component C, present to the extent of about 4 mg/ℓ of culture broth, has the molecular formula $C_{20}H_{28}O_4$ and thus is named cyafrin B_4. Structure **10***a* ⇄ **11***a* is tentatively assigned to cyafrin B_4 on the following grounds. Acetylation affords an *O*,*O*-diacetyl derivative (**10***b*) the ^{1}Hmr spectrum of which shows appropriate signals for the hydrogens on C-11, C-13, and C-15, as well as signals for the four methyl groups. In addition, a two proton singlet at δ 2.21 is assigned to the C-1 methylene protons. The ir spectrum shows carbonyl absorption at 1695 cm^{-1} and uv absorption at 241 nm which was at first attributed to the ring C unsaturated ketone. However, treatment with methanolic HCl gave a methyl acetal (**11***b*) which also showed carbonyl absorption at 1690 cm^{-1} and uv absorption at 242 nm (ε 13 900) indicating the presence of an α,β-unsaturated keto group in the acetal **11***b*. Both the acetal **11***b* and its *O*-acetyl derivative **11***c* showed a two-proton singlet near δ 2.15 attributable to the C-1 methylene group and the other features of the spectra are consistent with the proposed structure. Attempts to correlate cyafrin B_4 with either cyathin A_3 (**1***a*) or allocyathin B_3 (**2**) via the tosylhydrazone of the methyl acetal **11***b* or by reduction–dehydration of the acetyl derivative **11***c* were unsuccessful, and were abandoned when our supply of cyafrin B_4 was exhausted.

Component D, separated from cyafrin B_4 by preparative tlc was present to the extent of only ca. 0.2 mg/ℓ of broth. High resolution mass spectrometry indicates that this component is isomeric with cyafrin B_4 ($C_{20}H_{28}O_4$) and it is thus named allocyafrin B_4. Structure **12***a* ⇄ **13***a* is assigned to this metabolite. Acetylation provides *O*,*O*-diacetylallocyafrin B_4 (**12***b*), the ^{1}Hmr spectrum of which shows, in addition to the expected methyl signals and signals for the ring C functionality, a singlet at δ 6.00 assigned to the proton on C-2. The uv spectrum of the methyl acetal **13***b* shows a maximum at 235 nm indicative of the ring A unsaturated ketone. This functionality also gives rise to ir absorption at 1700 and 1600 cm^{-1} in **13***b*. Treatment of the acetonide of dehydrocyafrin A_4 (**6**) with methanolic HCl brought about migration of the double bond and cleavage of the acetonide to give allocyafrin B_4 methyl acetal (**13***b*), providing strong support for the structural assignment. The stereochemistry at C-4 has not been established, although we note that 5α-androst-15-en-17-one (**14**) is stable to dilute acid (11), and thus tend to favor a *trans*-AB ring juncture in allocyafrin B_4.

The mother liquors from crystallization of cyafrin A_4 deposited crystals which proved to be co-crystals of cyafrin A_4 and a compound $C_{20}H_{30}O_5$ (component F) which we have called cyafrin A_5. Separation of the two was achieved by ptlc using a solvent system of chloroform–acetonitrile (all solvent systems

[4]Chemical shift assignments for the various cyathins and cyafrin A_4 have been made and are the subject of a forthcoming paper; Can. J. Chem. In press.

containing protic solvents failed to separate the two). Cyafrin A_5 is assigned structure **15***a* on the basis of the following observations. The infrared spectrum, both in the solid state and in solution, does not show carbonyl absorption, indicating that cyafrin A_5 exists mainly in the hemiacetal form **15***a*, with little contribution from the hydroxy ketone form **16***a*. The ^{13}Cmr spectrum does not show carbonyl carbon absorption and reveals the presence of only two olefinic carbons, at δ 138.0 and 136.5, shifts similar to those for C-3 and C-4 (δ 136.7 and 136.3) in cyafrin A_4 methyl ketal (**4***b*). Acetylation of **15***a* under mild conditions (acetic anhydride – pyridine, room temperature) gives the diacetyl derivative **15***b*, which again shows no ketonic carbonyl absorption, but does show hydroxyl absorption. The ^{1}Hmr spectrum of **15***b* shows the expected methyl signals and, in the lower field region, an AB doublet of doublets for the C-15 hydrogens at δ 4.48, a triplet for the C-1 hydrogen at δ 4.90, a multiplet at δ 4.29 for the C-11 hydrogen, and a singlet at δ 3.68 assigned to the C-13 hydrogen. The presence of the epoxide at C-12 and C-13 was first suggested by the observation that in the ^{13}Cmr spectrum of **15***a* the olefinic signals usually associated with these two carbons are replaced by two new signals in the region δ 55–65. When cyafrin A_5 was acetylated in the presence of 4-dimethylaminopyridine (12) a mixture of two triacetyl derivatives, **15***c* and **16***b*, was obtained. The triacetyl derivative **15***c* shows only ester carbonyl absorption (1750 cm^{-1}), whereas the triacetate of the hydroxy ketone form shows, besides ester absorption (1745 cm^{-1}), ketonic carbonyl absorption at 1690 cm^{-1}.

To confirm the structural assignment, cyafrin A_4 (**3***a*) was treated with an alkaline solution of hydrogen peroxide in methanol. The product was a mixture of two crystalline epoxides, the major product being identical with cyafrin A_5. The minor product is the diastereoisomeric epoxide **17***a*, which exists mainly in the hydroxy ketone form (ir absorption at 1710 cm^{-1}). Acetylation of **17***a* provides **17***b*, the triacetyl derivative of the hydroxy ketone form (ir absorption at 1738 and 1710 cm^{-1}).

The assignment of the stereochemistry of the epoxide ring in cyafrin A_5 rests on two pieces of evidence. In cyafrin A_5, the internal hemiacetal form **15***a* is favored over the hydroxy ketone tautomer **16***a*, whereas in the isomeric β-epoxide **17***a* the hydroxy ketone form is favored. Inspection of molecular models reveals that in the hemiacetal form of the β-epoxide there is a serious nonbonded interaction between the oxirane oxygen and the β-hydrogen at C-5 (see **18**), whereas the hydroxy ketone may adopt the strain-free cycloheptanone chair form **19**. In the α-epoxide there appear to be no serious nonbonded interactions in the hemiacetal form **20**, whereas in the hydroxy ketone cycloheptanone chair

form **21** the oxirane oxygen is close to the methyl at C-6 and to one of the hydrogens on C-10. The second piece of evidence is that epoxidation of both double bonds in cyafrin A_4 (**3***a* ⇄ **4***a*) with *m*-chloroperbenzoic acid gives a diepoxide **22**, identical with the diepoxide obtained when cyafrin A_5 is treated with *m*-chloroperbenzoic acid. It has previously been established (1) that peracid epoxidation of the C-3, C-4 double bond in the cyathins results in the formation of the β-3,4-epoxide. It has been shown that peracid oxidation of allylic alcohols results in an epoxide in which the epoxide oxygen is *cis* to the allylic hydroxyl (13). If the assumption is made that the hydroxyl group at C-11 directs epoxidation of the C-12,C-13 double bond, then the α-12,13-epoxide will be formed from cyafrin A_4. We conclude that the stereochemistry of the epoxide oxygen in cyafrin A_5 is most likely that depicted in **15** and **16**.

The absolute configuration of the cyathins was assigned on the basis of X-ray diffraction studies on the internal hemiacetal form of cyathin A_3 (**1***a*) using the anomalous dispersion resulting from the oxygen atoms.[5] Since the *C. africanus* extracts provided us with a substantial quantity of cyathin A_3 (**1***a*) we have applied the exciton chirality rule (14) to verify this assignment. Since we wished to investigate the dipole–dipole interaction between the ring C enone and a benzoyloxy group at C-11, it was necessary to protect the C-15 hydroxyl group before benzoylation of the C-11 hydroxyl. Treatment of cyathin A_3 (**1***a*) for a short time with a limited amount of acetic anhydride – pyridine in methylene chloride gave the C-15 monoacetyl derivative **1***c*. Benzoylation (benzoyl chloride – pyridine) afforded the C-11 benzoate **1***d* and treatment of **1***c* with *p*-bromobenzoyl chloride in the presence of 4-dimethylaminopyridine (12) furnished the *p*-bromobenzoate **1***e*. In both the benzoate **1***d* and the *p*-bromobenzoate **1***e* the C-11 proton appears as an apparent triplet, splitting 7 Hz. If we make the reasonable assumption that C-11, C-12, C-13, C-14, and C-6 are in the same plane, the coupling constants indicate that ring C adopts the conformation illustrated in **23**, in which the dihedral angle between the C-11 hydrogen and C-10 hydrogen *a* approaches ~20–30°, and the C-11 H, C-10 H_b dihedral angle is 150–160°. The positive Cotton effect (**1***d*, 236 nm; **1***e*, 247 nm) indicates a positive chirality between the axis of the two electric dipole transition moments (14), in agreement with the absolute configuration illustrated in **23**, and thus in **1***d* and **1***e*.

Experimental

High resolution mass spectra were recorded on an A.E.I. MS-50 mass spectrometer coupled to a DS 50 computer. Infrared spectra were recorded on a Unicam SP 1000 or a Nicolet 7199 FT spectrometer. Specific rotations at the D line were determined using a Perkin-Elmer 141 automatic polarimeter and circular dichroism (cd) spectra on a Jasco model SS-20-2 spectropolarimeter. Nuclear magnetic resonance spectra were determined on a Varian HA-100 spectrometer (^{1}Hmr) interfaced to a Digilab FTS/NMR-3 data system and on a Bruker HFX-90 spectrometer (^{13}Cmr), with TMS as internal standard.

Preparative tlc (ptlc) was carried out on 0.75 mm layers of silica gel G (W. Merck, Darmstadt) containing 1% electronic phosphor (General Electric, Cleveland). The solvent systems used were: *A*, Skellysolve B – acetone (3:1); *B*, benzene – acetone – acetic acid (75:25:1); *C*, chloroform–acetonitrile (3:2); *D*, benzene – methanol – acetic acid (18:2:1). Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C. Melting points were recorded on a hot-stage Fisher-Johns apparatus and are uncorrected.

Growth of Cyathus africanus *Brodie*

Slant tubes of *Cyathus africanus* Brodie (strain 66120) were obtained from Prof. H. J. Brodie. The fungus was grown in liquid culture on Brodie medium (3) and the metabolites were isolated as described previously for *C. bulleri* (6). The yield of metabolites was about 0.2 g per litre of culture broth.

Isolation of Metabolites

The crude metabolites (2.7 g) were chromatographed over silicic acid (MN-Kieselgel, 150 g) using chloroform–methanol (19:1) as eluant. Fractions (7 ml) were collected and monitored by tlc (solvent system *B*). Fractions 101–110 contained a mixture of cyathin A_3 and allocyathin B_3 (418 mg) which was separated into its components by ptlc over 10% $AgNO_3$ – silica gel (solvent system *A*) (4). The *cyathin* A_3 (**1**, ~250 mg) and *allocyathin* B_3 (**2**, ~30 mg) isolated were identical (tlc, ir, ^{1}Hmr) with authentic samples. Fractions 123–130 contained cyafrin B_4 and allocyafrin B_4. Separation by ptlc (solvent system *D*) gave *cyafrin* B_4 (R_f 0.6, 49 mg) and *allocyafrin* B_4 (R_f 0.5, 3 mg).[6] Fractions 228–254 yielded crude *cyafrin* A_4 (114 mg) which was purified by recrystallization from acetone.[6] Fractions 255–276 gave a mixture of cyafrin A_4 and cyafrin A_5 which was separated by ptlc (solvent system *C* triple elution). *Cyafrin* A_5 (6 mg) was purified by recrystallization from acetone–benzene.[6]

Cyafrin A_4 (**3**a ⇆ **4**a)

Cyafrin A_4 crystallized from methanol–benzene as colorless needles, mp 200–201°C; $[\alpha]_D^{25}$ −125° (*c* 0.4, CH_3OH); ir (KBr): 3300 (br), no carbonyl; uv: 230 (sh) nm (ε 1500); ^{1}Hmr (pyridine) indicated a mixture of hydroxy ketone and hemiacetal forms. *Exact mass* calcd. for $C_{20}H_{30}O_4$: 334.2144; found (ms): 334.2152.

Cyafrin B_4 (**10**a ⇆ **11**a)

Cyafrin B_4 was obtained as a colorless syrup, $[\alpha]_D^{25}$ −156.5° (*c* 0.34, $CHCl_3$); ir ($CHCl_3$): 3630, 3420, 1695, 1623 cm^{-1}; uv: 241 nm (ε 11 000); ^{1}Hmr, poorly resolved (tautomeric equilibrium). *Exact mass* calcd. for $C_{20}H_{28}O_4$: 332.1988; found (ms): 332.1983.

Allocyafrin B_4 (**12**a ⇆ **13**a)

Allocyafrin B_4 was obtained as a colorless syrup, $[\alpha]_D^{25}$ −157.8° (*c* 0.27, $CHCl_3$); ir ($CHCl_3$): 3600, 3440, 1700, 1680 (sh), 1600 cm^{-1}; uv: 239 nm (ε 16 400); ^{1}Hmr ($CDCl_3$) δ: 1.08 (s, 3H), 1.12 (s, 3H), 1.22 and 1.26 (each 3H, d, J = 7 Hz), 4.42 (m, 3H), 5.98 (bs, 1H), 6.04 (bs, 1H). *Exact mass* calcd. for $C_{20}H_{28}O_4$: 332.1988; found (ms): 332.1985.

Cyafrin A_5 (**15**a)

Cyafrin A_5 was obtained as colorless needles from acetone–benzene, mp 208–209°C; $[\alpha]_D^{25}$ −77.9° (*c* 0.154, CH_3OH); ir

O,O,O-*Triacetylcyafrin* A_4 (*3*b)

Cyafrin A_4 (60 mg) was dissolved in pyridine (2 ml) and acetic anhydride was added. The solution was allowed to stand overnight at room temperature and then toluene (15 ml) was added and the solvents were removed under reduced pressure. The residue was purified by ptlc (solvent system *A*) to give *O,O,O*-triacetylcyafrin A_4 (*3b*) as a viscous liquid (45 mg); ir: ($CHCl_3$) 1740, 1660 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.97 and 1.01 (each 3H, d, J = 7 Hz, isopropyl methyls), 1.02 (s, 3H), 1.14 (s, 3H), 2.02 (s, 3H), 2.07 (s, 3H), 2.12 (s, 3H), 4.70 (2H, t, J = 1.5 Hz, C-15 H's), 4.89 (1H, t, J = 8 Hz, C-1 H), 5.33 (1H, t, J = 6.5 Hz, C-11 H), 6.12 (1H, t, J = 1.5 Hz). *Exact mass* calcd. for $C_{24}H_{32}O_5$ (M^+ − HOAc): 400.2250; found (ms): 400.2245.

Cyafrin A_4 *Methyl Acetal* (*4*b)

Cyafrin A_4 (18 mg) was dissolved in a saturated solution of HCl in CH_3OH (0.5 ml) and kept at room temperature for 4 h. The solution was concentrated and the residue dissolved in $CHCl_3$ (10 ml). The $CHCl_3$ solution was washed with saturated $NaHCO_3$, then brine, and evaporated. Purification by ptlc (solvent *B*) gave cyafrin A_4 methyl acetal (*4b*, 7.5 mg), mp 93–94°C (from benzene); $[\alpha]_D^{25}$ −98° (*c* 0.39, $CHCl_3$); ir (film): 3390 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.87 and 0.96 (each 3H, d, J = 7 Hz), 0.90 (3H, s), 0.96 (3H, s), 3.33 (3H, s, OCH_3), 3.86 (1H, dd, J = 9 and 7 Hz, C-1 H), 4.32 (2H, d, J = 1 Hz, C-15 H's), 4.74 (1H, m, C-11 H), 6.02 (1H, t, J = 1 Hz, C-13 H). *Exact mass* calcd. for $C_{21}H_{32}O_4$: 348.2300; found (ms): 348.2295.

Cyafrin A_4 *Acetonide* (*5*a)

Cyafrin A_4 (20 mg) was dissolved in 2,2-dimethoxypropane (1 ml) and acetone (0.5 ml) containing *p*-toluenesulfonic acid (2 mg). After 1 h at room temperature the reaction mixture was concentrated to half volume and applied to a ptlc plate, which was developed with solvent *B*. The band at R_f 0.42 gave, after elution, cyafrin A_4 acetonide (*5a*), mp 170–171°C (from ether – Skellysolve B) as colorless needles; $[\alpha]_D^{25}$ −58° (*c* 0.4, $CHCl_3$); ir ($CHCl_3$): 3610 (vw), 1658 cm^{-1}; uv (CH_3OH): 236 nm (ε 6300); ^{1}Hmr ($CDCl_3$) δ: 1.00 (3H, s, C-6 methyl) 1.00 (6H, d, J = 7 Hz), 1.09 (3H, s, C-9 methyl) 1.40 and 1.48 (each 3H, s, acetonide methyls), 3.88 (1H, t, J = 7 Hz, C-1 H), 4.30 (3H, m, C-15 and C-11 H's), 5.69 (1H, q, J = 2 Hz, C-13 H); ^{1}Hmr (C_5D_5N) δ: 1.21 (3H, s, C-6 methyl), 1.30 (3H, s, C-9 methyl), 0.91 and 1.01 (each 3H, d, J = 7 Hz, isopropyl methyls). *Exact mass* calcd. for $C_{23}H_{34}O_4$: 374.2457; found (ms): 374.2455.

Dehydrocyafrin A_4 *Acetonide* (*6*)

Cyafrin A_4 acetonide (*5a*, 12 mg) in dry pyridine (0.1 ml) was added to CrO_3 (40 mg) – pyridine (0.4 ml) and the mixture was stirred for ½ h at room temperature, then diluted with water and extracted with $CHCl_3$. The $CHCl_3$ layer was washed with dilute acid, bicarbonate solution, and brine. The residue after removal of $CHCl_3$ was purified by ptlc (R_f 0.5, benzene – ethyl acetate (4:1)) and crystallized from methanol to give dehydrocyafrin A_4 acetonide (**6**) (4.6 mg), mp 144–146°C; $[\alpha]_D^{25}$ −84.25° (*c* 0.4, $CHCl_3$); ir (film) 1746, 1650 cm^{-1}; uv (CH_3OH), 236 nm (ε 8500); ^{1}Hmr ($CDCl_3$) δ: 1.04 and 1.08 (each 3H, d, J = 7 Hz, isopropyl methyls), 1.12 (3H, s), 1.14 (3H, s), 1.41 and 1.48 (each 3H, acetonide methyls), 2.99 (2H, dd, J = 19 Hz, C-2 H's), 4.34 (3H, m, C-11 and C-15 H's), 5.75 (1H, q, J = 1.5 Hz, C-13 H). *Exact mass* calcd. for $C_{23}H_{32}O_4$: 372.2300; found (ms): 372.2299.

Mesylate of Cyafrin A_4 *Acetonide* (*5*b)

Cyafrin A_4 acetonide (*5a*, 13 mg) was dissolved in CH_2Cl_2 (1 ml) and methanesulfonyl chloride (0.01 ml) and triethylamine (0.01 ml) added at 0°C. After 20 min at 0°C, the solution was concentrated to small volume and applied to a ptlc plate which was then developed with solvent system *B*. Elution gave the mesylate *5b* (14 mg) which was crystallized from benzene, mp 159–160°C, $[\alpha]_D^{25}$ −38° (*c* 0.3, $CHCl_3$); ir ($CHCl_3$): 1660 br, 1365, 1340 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.03 (6H, d, J = 7 Hz, isopropyl methyls), 1.06 (3H, s), 1.10 (3H, s), 1.42 and 1.46 (each 3H, s, acetonide methyls), 3.02 (3H, s, —SO_2—CH_3), 4.30 (3H, m, C-11 and C-15 H's), 4.75 (1H, t, J = 8 Hz, C-1 H), 5.70 (1H, bs, C-13 H).

Rearrangement of 5b *to* **7**

O-Mesylcyafrin A_4 acetonide (*5b*, 7.5 mg) in dioxane (2 ml) containing 1,5-diazabicyclo[5.4.0]undec-5-ene (0.2 ml) was heated to 90°C for 5 h. The reaction mixture was then concentrated, taken up in chloroform, washed with dilute acid and water, dried, and evaporated. The residue was purified by ptlc (solvent *B*, R_f 0.65) to give 7 as a colorless syrup (3 mg); ir ($CHCl_3$): 1708, 1365, 1340 cm^{-1}; uv, no maximum above 210 nm; ^{1}Hmr ($CDCl_3$) δ: 0.99 and 0.97 (each 3H, d, J = 7 Hz, isopropyl methyls), 1.03 (3H, s), 1.15 (3H, s), 1.36 and 1.43 (each 3H, s, acetonide methyls), 3.02 (3H, s, —SO_2—CH_3), 4.03 (2H, bs, C-15 H's), 4.74 (1H, t, J = 8 Hz, C-1 H).

Mesylate of Cyafrin A_4 *Methyl Acetal* (*8*)

O-Mesylcyafrin A_4 acetonide (*5b*, 9 mg) was dissolved in 2.43 *N* hydrogen chloride in methanol (0.5 ml) and left at room temperature for 17 h. The solution was then diluted with $CHCl_3$ and the resulting solution washed with saturated $NaHCO_3$ and then brine. Removal of the chloroform and purification of the residue by ptlc (solvent *B*, R_f 0.55) gave **8** as a colorless oil (5 mg), $[\alpha]_D^{25}$ −82.7° (*c* 0.34, $CHCl_3$); ir ($CHCl_3$): 3610, 1606 (w), 1363 (s) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.88 and 0.97 (each 3H, d, J = 7 Hz isopropyl methyls), 0.95 (3H, s), 0.98 (3H, s), 2.98 (3H, s, —SO_2—CH_3), 3.28 (3H, s, OCH_3), 4.21 (2H, s, C-15 H's), 4.74 (1H, m, C-11 H), 4.68 (1H, t, J = 9 Hz, C-1 H), 6.01 (1H, bs, C-13 H). *Exact mass* calcd. for $C_{22}H_{34}O_6{}^{32}S$: 426.2076; found (ms): 426.2091.

Allocyathin B_3 *Methyl Acetal* (*9*) *From* **8**

Mesylate **8** (12 mg) was dissolved in toluene (0.8 ml) containing 1,5-diazabicyclo[5.4.0]undec-5-ene (0.2 ml) and the solution was heated under reflux in a nitrogen atmosphere for 45 h. The solution was then diluted with benzene and washed successively with dilute H_2SO_4 and brine. Evaporation and purification by ptlc (solvent *B*, double elution) gave allocyathin B_3 methyl acetal (**9**, 4.5 mg), identical (ir, ^{1}Hmr, tlc, and rotation) with an authentic sample (4).

Benzoate of Cyafrin A_4 *Acetonide* (*5*d)

Cyafrin A_4 acetonide (*5a*, 8 mg) in CH_2Cl_2 (0.4 ml) was treated with benzoyl chloride (0.03 ml) and pyridine (0.03 ml) at room temperature for 30 min. Work-up and purification by ptlc (solvent *A*, double elution) gave the benzoate *5d* as a colorless gum (7 mg), $[\alpha]_D^{25}$ −58.5° (*c* 0.518, $CHCl_3$); ir (CCl_4): 1705, 1650 (br), 1640, 1590 (w) cm^{-1}; uv (CH_3OH): 231 nm (ε 18 400), 280 (sh) (ε 900); ^{1}Hmr ($CDCl_3$) δ: 1.02 and 1.06 (each 3H, d, J = 7 Hz), 1.13 (6H, s), 1.42 and 1.47 (each 3H), 4.33 (3H, m, C-15 and C-11 H's), 5.72 (1H, bs, C-13 H),

For personal use only.

7.48 and 8.06 (5H, m, benzoyl H's). *Exact mass* calcd. for $C_{30}H_{38}O_5$: 478.2719; found (ms): 478.2712.

O,O-*Diacetylcyafrin* B_4 (*10*b)

Cyafrin B_4 (10 mg) was acetylated as described above for cyafrin A_4 to give a colorless oil (8 mg) after purification by ptlc (solvent B); ir ($CHCl_3$): 1740, 1685 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.17 (3H, s), 1.28 (3H, s), 1.19 and 1.23 (each 3H, d, J = 7 Hz), 2.06 (3H, s), 2.12 (3H, s), 2.21 (2H, s, C-1 H's), 4.70 (2H, m, C-15 H's), 5.41 (1H, t, J = 6 Hz, C-11 H), 6.18 (1H, t, J = 1 Hz, C-13 H). *Exact mass* calcd. for $C_{24}H_{32}O_6$: 416.2199; found (ms): 416.2202.

Cyafrin B_4 *Methyl Acetal* (*11*b)

Cyafrin B_4 (27 mg) was dissolved in a saturated solution of HCl in CH_3OH (0.5 ml) and left overnight at room temperature, then the solution was concentrated and applied to a ptlc plate. Development with solvent B (R_f = 0.46) and elution afforded cyathin B_4 methyl acetal (**11***b*) (16 mg) as a colorless oil, $[\alpha]_D^{25}$ −153.95° (*c* 0.91, $CHCl_3$); ir (film): 3400, 1690, 1615 cm^{-1}; uv (CH_3OH): 242 nm (ε 13 900); ^{1}Hmr ($CDCl_3$) δ: 0.98 (3H, s), 1.16 (3H, s), 1.16 and 1.20 (each 3H, d, J = 7 Hz, isopropyl methyls), 2.14 (2H, s, C-1 H's), 3.31 (3H, s, OCH_3), 4.36 (2H, s, C-15 H's), 4.80 (1H, m, C-11 H), 6.12 (1H, bs, C-13 H). *Exact mass* calcd. for $C_{21}H_{30}O_4$: 346.2144; found (ms): 346.2144.

O,O-*Diacetylallocyafrin* B_4 (*12*b)

Allocyafrin B_4 (3 mg) in CH_2Cl_2 (2 ml) was treated with acetic anhydride (0.05 ml) and pyridine (0.05 ml) for 5 h at room temperature. Addition of toluene and concentration at reduced pressure afforded a crude product which was purified by ptlc (solvent B, R_f 0.47) to give a colorless oil (2 mg); ir (film): 1745, 1698, 1598 cm^{-1}; uv (CH_3OH): 235 nm (ε 12 000); ^{1}Hmr ($CDCl_3$) δ: 1.08 (3H, s), 1.11 (3H, s), 1.16 and 1.23 (each 3H, d, J = 7 Hz, isopropyl methyls), 2.04 (3H, s), 2.08 (3H, s), 4.66 (2H, dd, J = 14 Hz, C-15 H's), 5.48 (1H, m, C-11 H), 6.00 (1H, bs, C-2 H), 6.04 (1H, d, J = 2 Hz). *Exact mass* calcd. for $C_{24}H_{32}O_6$: 416.2198; found (ms): 416.2204.

Allocyafrin B_4 *Methyl Acetal* (*13*b)

Allocyafrin B_4 (3 mg) was treated with methanolic HCl as described above for cyafrin B_4 to give a colorless oil (2.5 mg) after purification by ptlc (solvent *A*); ir (film): 3410, 1700, 1600 cm^{-1}; uv (CH_3OH): 235 nm (ε 9500); ^{1}Hmr ($CDCl_3$): 1.00 (3H, s), 1.16 (3H, s), 1.12 and 1.25 (each 3H, d, J = 7 Hz, isopropyl methyls), 3.30 (3H, s, OCH_3), 4.38 (2H, bs, C-15 H), 4.84 (1H, m, C-11 H), 5.88 (1H, bs, C-2 H), 6.04 (1H, t, J = 2 Hz). *Exact mass* calcd. for $C_{21}H_{30}O_4$: 346.2144; found (ms): 346.2140.

O,O-*Diacetylcyafrin* A_5 (*15*b)

Cyafrin A_5 (2 mg) was acetylated with acetic anhydride (0.3 ml) and pyridine (0.3 ml) at room temperature and worked up in the usual manner. Purification by ptlc (solvent, benzene – ethyl acetate (4:1)) gave a colorless oil (1.3 mg), $[\alpha]_D^{25}$ −40° (*c* 0.1, $CHCl_3$); ir (film): 3420, 1734 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.94 and 1.00 (each 3H, d, J = 7 Hz), 1.01 (3H, s), 1.03 (3H, s), 2.08 (3H, s), 2.10 (3H, s), 3.68 (1H, s, C-13 H), 4.48 (2H, dd, J = 13 Hz, C-15 H's), 4.90 (1H, t, J = 8 Hz, C-1 H), 4.29 (1H, m, C-11 H). *Exact mass* calcd. for $C_{22}H_{30}O_5$ (M^+ − HOAc): 374.2093; found (ms): 374.2093.

Cyafrin A_5 *Triacetyl Derivatives* ***15***c *and* ***16***b

Cyafrin A_5 (4.7 mg) was dissolved in CH_2Cl_2 (0.3 ml) containing 4-dimethylaminopyridine (10 mg) and acetic anhydride (0.015 ml) added. After 2 h at room temperature CH_2Cl_2 and water were added and the CH_2Cl_2 layer was separated and washed with dilute HCl and brine. After removal of the solvent, the residue was purified by ptlc (solvent *A*, double elution) to yield **15***c* (1.8 mg, R_f 0.28) and **16***b* (2.8 mg, R_f 0.34), both as colorless oils.

Triacetate ***15***c—$[\alpha]_D^{23}$ −21° (*c* 0.12, $CHCl_3$); ir (film): 1750 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.93 and 1.00 (each 3H, d, J = 7 Hz), 1.01 (3H, s), 1.03 (3H, s), 2.07 (3H, s), 2.11 (3H, s), 2.13 (3H, s), 4.33 and 4.63 (2H, dd, J = 13 Hz, C-15 H's), 4.56 (1H, s, C-13 H), 4.86 (1H, t, J = 9 Hz, C-1 H), 4.33 (1H, m, C-11 H). *Exact mass* calcd. for $C_{24}H_{32}O_6$ (M^+ − HOAc): 416.2199; found (ms): 416.2205.

Triacetate ***16***b—ir (film): 1745, 1690 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.95 and 1.02 (each 3H, d, J = 7 Hz), 0.97 (3H, s), 1.24 (3H, s), 2.05 (3H, s), 2.06 (3H, s), 2.10 (3H, s), 3.70 (1H, s, C-13 H), 4.07 and 4.43 (2H, dd, J = 12 Hz, C-15 H's), 4.88 (1H, t, J = 8 Hz), 5.19 (1H, dd, J = 10 and 3 Hz, C-11 H). *Exact mass* calcd. for $C_{24}H_{32}O_6$ (M^+ − HOAc): 416.2199; found (ms): 416.2022.

Epoxidation of Cyafrin A_4 *with* H_2O_2

Cyafrin A_4 (**3***a*, 8 mg) was dissolved in CH_3OH (0.3 ml) and 30% H_2O_2 (0.02 ml) and 6 *N* NaOH (0.03 ml) added. The reaction mixture was left at 20°C for 12 h, then it was applied directly to a ptlc plate (solvent C, triple elution). The material (4.7 mg) eluted from the band at R_f 0.33 was crystallized from acetone to give *cyafrin* A_5, mp 210–212°C, identical (ir, tlc, mmp) with an authentic sample. Elution of a band at R_f 0.52 provided the β-epoxide **17***a* (1 mg), mp 201–203°C (from acetone); ir (film): 3380, 1710 cm^{-1}; ^{1}Hmr (C_5D_5N + D_2O) δ: 0.83 and 0.95 (each 3H, d, J = 7 Hz), 1.26 (3H, s), 1.45 (3H, s), 3.91 (1H, m, C-11 H), 4.18 (1H, t, J = 8 Hz, C-1 H), 4.65 and 4.88 (2H, dd, J = 13 Hz, C-15 H's), 4.65 (1H, s, C-13 H). *Exact mass* calcd. for $C_{20}H_{30}O_5$: 350.2093; found (ms): 350.2088.

Triacetate of β-*Epoxide* (*17*b)

β-Epoxide **17***a* (1.3 mg) in CH_2Cl_2 (0.1 ml) was acetylated by treatment with acetic anhydride (0.005 ml) and 4-dimethylaminopyridine (3 mg) at room temperature. The reaction mixture was submitted directly to ptlc (solvent *A*) and the band at R_f 0.26 eluted to give triacetate **17***b* (1.1 mg) as colorless needles, mp 193–195°C (from Skellysolve B – acetone); $[\alpha]_D^{23}$ −54.5° (*c* 0.11, $CHCl_3$); ir (film): 1738, 1710 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.95 and 1.04 (each 3H, d, J = 7 Hz), 1.01 (3H, s), 1.20 (3H, s), 2.06 (3H, s), 2.10 (3H, s), 2.11 (3H, s), 3.83 (1H, s, C-13 H), 4.34 (1H, m, C-11 H), 4.38 and 4.64 (2H, dd, J = 13 Hz, C-15 H's), 4.88 (1H, t, J = 8 Hz, C-1 H). *Exact mass* calcd. for $C_{24}H_{32}O_6$ (M^+ − HOAc): 416.2199; found (ms): 416.2204.

Epoxidation of Cyafrin A_4

Cyafrin A_4 (5 mg) was added to a solution of *m*-chloroperbenzoic acid (10 mg) in $CHCl_3$ (2 ml) and the reaction mixture was stirred for 2.5 h at room temperature, then washed with saturated $NaHCO_3$ and brine. After evaporation of solvent the residue was subjected to ptlc (solvent *C*, triple elution), and the band at R_f 0.44 eluted to give the diepoxide **22** (1.5 mg) as colorless needles, mp 235–236°C; $[\alpha]_D^{25}$ −47° (*c* 0.14, CH_3OH); ir (film) 3420, 3370 cm^{-1}. *Exact mass* calcd. for $C_{20}H_{30}O_6$: 366.2024; found (ms): 366.2033.

Epoxidation of Cyafrin A_5

A mixture of cyafrin A_5 (0.5 mg) and *m*-chloroperbenzoic acid (1 mg) in $CHCl_3$ (0.1 ml) was left at room temperature for ½ h, then applied to a ptlc plate (solvent *C*, triple elution) to give the diepoxide **22** (0.2 mg), R_f 0.44, identical (tlc, ir) with that obtained from cyafrin A_4.

*15-O-Acetylcyathin A_3 (**1c**)*

Acetic anhydride (0.08 ml) and pyridine (0.3 ml) was added to a solution of cyathin A_3 (40 mg) in CH_2Cl_2 (2 ml). After 40 min the reaction mixture was poured onto ice water and extracted with CH_2Cl_2. The extract was washed with 5% hydrochloric acid, saturated $NaHCO_3$, and brine and then concentrated. The residue was purified by ptlc (solvent *A*) to yield 15-*O*-acetylcyathin A_3 (**1c**, R_f 0.3, 31 mg) and *O*,*O*-diacetylcyathin A_3 (**1b**, R_f 0.4, 8.5 mg). 15-*O*-Acetylcyathin A_3 (**1c**) was obtained as a colorless syrup, $[\alpha]_D^{23}$ −117.3° (*c* 0.358, $CHCl_3$); ir ($CHCl_3$): 3580, 3440 (br), 1740, 1660 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.02 (6H, d, J = 7 Hz), 0.99 (3H, s), 1.06 (3H, s), 2.11 (3H, s), 4.77 (3H, m, C-11 and C-15 H's), 6.10 (1H, bs, C-13 H). *Exact mass* calcd. for $C_{22}H_{32}O_4$: 360.2301; found (ms): 360.2298.

*15-O-Acetyl-11-O-benzoylcyathin A_3 (**1d**)*

15-*O*-Acetylcyathin A_3 (15 mg) in pyridine (0.5 ml) was treated with benzoyl chloride (0.05 ml) at room temperature for 2 h. The reaction mixture was poured into ice water and extracted with $CHCl_3$ in the usual manner. The product in $CHCl_3$ was filtered through alumina and then further purified by ptlc (solvent *A*) to yield the benzoate **1d** as a colorless gum (7 mg), $[\alpha]_D^{25}$ −40.9° (*c* 0.425, $CHCl_3$); ir ($CHCl_3$): 1745, 1724, 1680, 1665, 1605 cm^{-1}; uv (CH_3OH): 230 (ε 16 800), 274 (sh, ε 1200), 282 nm (sh, ε 980); ^{1}Hmr ($CDCl_3$) δ: 0.98 (6H, d, J = 7 Hz), 1.09 (3H, s), 1.18 (3H, s), 2.06 (3H, s), 4.73 (2H, d, J = 1.5 Hz, C-15 H's), 5.70 (1H, t, J = 7 Hz, C-11 H), 6.20 (1H, t, J = 1.5 Hz, C-13 H), 7.45 (3H, m), 7.99 (2H, dd, J = 8 and 2 Hz); cd (*c* 0.0011 *M*): 236 nm (Δε +13.1). *Exact mass* calcd. for $C_{29}H_{36}O_5$: 464.2563; found (ms): 464.2564.

*15-O-Acetyl-11-O-p-bromobenzoylcyathin A_3 (**1e**)*

p-Bromobenzoyl chloride (200 mg) was added to a solution of 15-*O*-acetylcyathin A_3 (63 mg) and 4-dimethylaminopyridine (111 mg) in CH_2Cl_2 (5 ml). After 15 min at room temperature the solution was diluted with CH_2Cl_2, washed with 5% HCl, saturated $NaHCO_3$, and brine. Evaporation left a colorless syrup which was purified by ptlc (solvent *A*) to give, after crystallization from methanol, 15-*O*-acetyl-11-*O*-*p*-bromobenzoylcyathin A_3 (60 mg), mp 102–103°C, $[\alpha]_D^{23}$ −15.8° (*c* 0.4, $CHCl_3$); ir ($CHCl_3$): 1745, 1720, 1685, 1660 (sh), 1593 cm^{-1}; uv (CH_3OH): 208 (ε 15 900), 246 (ε 18 200), 282 nm (sh, ε 770); ^{1}Hmr ($CDCl_3$) δ: 0.99 (6H, d, J = 7 Hz), 1.10 (3H, s), 1.18 (3H, s), 2.07 (3H, s), 4.72 (2H, s, C-15 H's), 5.67 (1H, t, J = 7 Hz, C-11 H), 6.20 (1H, t, J = 1.5 Hz, C-13 H), 7.71 (4H, dd, J = 9 Hz); cd (*c* 0.0018 *M*, ethanol–dioxane (4:1)): 247 nm (Δε +8.2). *Exact mass* calcd. for $C_{29}H_{35}O_5{}^{81}Br$: 544.1647, for $C_{29}H_{35}O_5{}^{79}Br$: 542.1668; found (ms): 544.1657, 542.1677. *Anal.* calcd. for $C_{29}H_{35}O_5Br$: C 64.08, H 6.49, Br 14.70; found: C 64.02, H 6.53, Br 14.92.

Raman and infrared spectra of multilayer dispersions of 1,2-perdeuterodipalmitoyl-*sn*-glycero-3-phosphocholine in water are studied as a function of temperature for the CD stretching region. It is found that the bands associated with these vibrations can be used as a sensitive probe to monitor the gel – liquid crystal phase transition which occurs at a lower temperature in the perdeuterated phospholipid than in the corresponding natural (light) lipid.

S. SUNDER, D. CAMERON, H. H. MANTSCH et H. J. BERNSTEIN. Can. J. Chem. **56**, 2121 (1978).

Faisant appel à la spectroscopie Raman et infrarouge, on a étudié, en fonction de la température, les vibrations de valence CD de dispersions de multicouches de perdeutérodipalmitoyl-1,2 *sn* glycérophosphocholine-3 dans l'eau. On a trouvé que les bandes associées avec ces vibrations peuvent être utilisées comme sonde sensible pour évaluer la transition de phase gel – cristal liquide qui se produit à une température inférieure dans le phospholipide perdeutéré par rapport au lipide naturel correspondant (léger).

[Traduit par le journal]

Introduction

Isotopically labelled model compounds are being increasingly used to gain detailed information about the structure and function of biomembranes (refs. 1–20 and references therein). This can supply information about the specific section of the membrane with minimal perturbation. Such systems have been investigated by multinuclear magnetic resonance spectroscopy (1–12) but relatively few studies are available in vibrational spectroscopy (14–20). Isotopic labelling, particularly the replacement of ^1H by ^2H, offers a powerful tool in the study of membranes by vibrational (Raman and infrared) spectroscopy as the mass change causes drastic shifts in the vibrational frequencies with very little change in the chemical nature of the system. In this communication we present a temperature dependence study of the infrared and Raman spectra of 1,2-perdeuterodipalmitoyl-*sn*-glycero-3-phosphocholine as multilayer dispersions in excess water for the temperatures between 20 and 50°C.

Experimental

Material

High purity samples of 1,2-perdeuterodipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC-d_{62}) were obtained from Lipid Specialties Inc., Boston. Thin-layer chromatography showed the absence of any impurity. Polarimetry measurements indicated that the *sn*-3 stereochemistry of the natural glycerophospholipid was retained in the DPPC-d_{62} sample.

[1]NRCC No. 16620.

Method

Infrared Spectroscopy

Multibilayers for infrared measurements were obtained by dissolving about 2 mg of DPPC-d_{62} in chloroform and spreading it on the central area of a freshly cleaned CaF_2 plate (~ 1 cm^2). The chloroform was evaporated under vacuum and the plate soaked in double distilled water for 10 min. The CaF_2 plate bearing the phospholipid film was mounted in a thermostated cell holder and the fully hydrated multibilayers kept at 100% humidity during the measurement. This method of producing planar multibilayers is extensively used in the epr studies of model membranes (21). Temperatures were measured by a Newport digital pyrometer with a thermocouple placed on the CaF_2 plate bearing the film. The temperature reproducibility was estimated to ± 0.05°C. Infrared spectra were obtained with a Perkin-Elmer model 180 grating spectrophotometer at a resolution of ~ 2 cm^{-1}.

Raman Spectroscopy

Samples for Raman studies were prepared by coating the inside of a test tube with the deuterated phospholipid by evaporating a chloroform solution under a gentle stream of nitrogen gas. Last traces of chloroform were removed by placing the tube containing the sample in a vacuum dessicator and pumping over it for more than two hours. Water was added to the sample, followed by shaking on a vortex mixer. The sample was transferred into a glass capillary tube and centrifuged for a few minutes in a table top centrifuge to concentrate the multilayer aggregates. The sample capillary was sealed and placed in a variable-temperature cell described earlier (22). The temperature accuracy for Raman measurements is believed to be ± 1°C.

Raman scattering was obtained by excitation with ~ 300 mW of 514.5 nm radiation from an argon ion gas laser (Coherent radiation model 52). The spectra were recorded at a resolution of ~ 3 cm^{-1} using a Spex 14018 double monochromator, a cooled RCA C31034 photomultiplier, photon counting detection and operating under a Nicolet NIC-1180

data system. The spectra were recorded both in analog form with a strip-chart recorder and in digital form in the Nicolet system. Four or more scans were averaged for each spectrum to enhance the signal-to-noise ratio.

Results and Discussion

The infrared and Raman spectra of DPPC-d_{62} multilayer dispersions in the presence of excess water are shown in Figs. 1 and 2, respectively, for the CD stretching region. The frequencies of the observed features are listed in Table 1. The frequency accuracy is believed to be ± 1 cm^{-1} for the infrared spectra and ± 2 cm^{-1} for the Raman spectra. However, the relative displacements of the frequencies of the spectral features could be measured to much better accuracy, up to ± 0.2 cm^{-1} for the infrared and ± 0.5 cm^{-1} for the Raman spectra. The poorer resolution and frequency accuracy for Raman spectra in the present system are due to the presence of fluorescence.

The suggested assignments for the observed features in the infrared and Raman spectra of DPPC-d_{62} are also given in Table 1. These are in agreement with the literature for similar compounds (14–20). The Raman spectrum of polycrystalline DPPC-d_{62} has been recently reported by Bunow and Levin (19). It is interesting to note that the Raman spectrum for the CD stretching region of polycrystalline DPPC-d_{62} and its spectrum as multilayer dispersions at room temperature, in the gel phase, Fig. 2, are very similar. This suggests that the hydrocarbon chains of the phospholipid in the gel phase of the multibilayers have a structure very similar to that in polycrystalline samples.

It has been shown that several spectral parameters derived from the vibrational spectra of phospholipids, such as band intensities, frequency shifts and bandwidths, can be used to follow the structural changes occurring in model membrane systems (14–16, 19, 23–36). Most of this work has been done with 'normal' phospholipids (15, 16, 19). Here we have applied this approach to a deuterated phospholipid and shown that various spectral parameters contained in the infrared and Raman spectra of deuterated lipids can be used to study their phase changes.

Figures 3 and 4 contain the results of a temperature study of the strong bands at ~2089 and ~2194 cm^{-1}, respectively, in the CD stretching region of the infrared spectra of DPPC-d_{62}. These figures contain the absorbance, halfwidth (fullwidth at half height) as well as the frequency maxima for the two infrared bands, plotted as a function of temperature. All three spectral parameters show a phase transition at 37.5 ± 0.5°C in the multilayer dispersions of

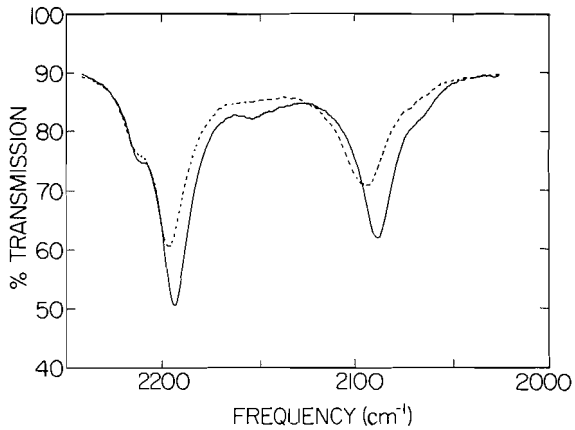

FIG. 1. Infrared spectra of 1,2-perdeuterodipalmitoyl-*sn*-glycero-3-phosphocholine multilayer dispersions in water above (---) and below (—) the gel – liquid crystal phase transition temperature. Spectral slit width ~2 cm^{-1}.

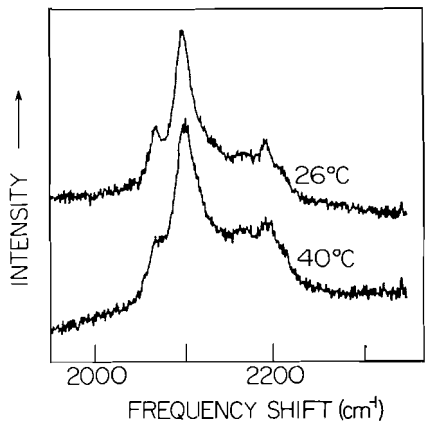

FIG. 2. Raman spectra of 1,2-perdeuterodipalmitoyl-*sn*-glycero-3-phosphocholine multilayer dispersions in water at room temperature (top curve) and at 40°C (bottom curve). Spectral slit width ~3 cm^{-1}. Excitation source ~300 mW of 514.5 nm radiation.

DPPC-d_{62}. This transition is most clearly shown by the absorbance vs. temperature plots (Figs. 3*A* and 4*A*) which indicates a phase transition temperature of 37.5 ± 0.2°C. The uncertainty in the transition temperature reported takes into account the errors in measuring the absolute temperature values; temperature changes in the infrared cell could be measured within an accuracy of ± 0.05°C. It is clear from Figs. 3 and 4 that, in addition to the absorbance, the halfwidths of these bands are also sensitive indicators of the order–disorder transition. Changes in the frequency values of these infrared bands offer additional parameters for following the phase transition with less sensitivity for the 2194 cm^{-1} band than for the 2089 cm^{-1} band.

Raman spectra were also used to follow the phase changes in the multilayer dispersions of DPPC-d_{62}. Figure 5*A* contains a plot of the bandwidth of the strong Raman band with a maximum around 2100 cm^{-1}. The bandwidths were measured at three-quarter height of the maximum instead of the usual half height to avoid interference from the shoulder around 2130 cm^{-1}. Also shown are plots of the ratio of the intensity of the 2195 cm^{-1} band to the 2100 cm^{-1} band (Fig. 5*B*), and the ratio of the intensity of the 2177 cm^{-1} band to the 2100 cm^{-1} band (Fig. 5*C*) as a function of temperature. Intensities were approximated by peak heights. Both the intensity ratio plots, Figs. 5*B* and 5*C*, and the bandwidth plot, Fig. 5*A*, derived from the Raman spectra, indicate a phase transition at 37 $\pm$ 2°C, in agreement with the value of 37.5$\pm$0.5°C obtained from the infrared studies. The higher uncertainty in the transition temperature obtained by Raman spectra is due to the lower signal-to-noise ratio of the Raman spectra compared with that of the infrared spectra.

The phase transition occurring at 37.5°C as seen in the infrared and Raman spectra is accompanied by the increase in the bandwidths of Raman and infrared bands. This is typical of an order to disorder phase transition (16, 35–37). Bandwidths in vibrational spectra increase with an increase in disorder and/or molecular mobility. The higher bandwidths in the high temperature phase reflect the increased disorder and mobility of the high temperature phase, the liquid crystal phase, compared with the low temperature phase, the gel phase. At present it is difficult to understand the changes in the intensity ratio of these Raman bands. In the light (protonated) lipids in going from gel to liquid crystal phase the intensity of the band assigned to the asymmetric CH_2 vibrations decreases relative to that of the symmetric CH_2 vibrations (16, 29). However, we observe an increase in the corresponding ratio with increasing temperature for the deuterated lipid. Also, it is the band assigned to the CH_2 *asymmetric* mode which is the strongest band in the Raman spectra of the 'light' phospholipids, while it is the band assigned to the *symmetric* vibration which is the strongest in the spectra of deuterated phospholipids. This reversal of the intensity ratio is typical of compounds containing long hydrocarbon chains (15). In spite of the uncertainty about the origin of the changes in the relative intensities of Raman bands, it is clear from Figs. 5*B* and 5*C* that their intensity ratios are a convenient indicator of the phase changes. In the infrared spectra we have used the absorbance of the individual bands (as measured at the peak position) directly. The decrease in the peak absorbance is related to the increase in the halfwidth. Increased disorder in the liquid crystal phase will result in a spread in the density of state vs. frequency curve with the concomitant decrease in the value of peak absorbance (38).

Phase transitions in DPPC-d_{62} multilayer dispersions were also studied by Peterson *et al.* (13) by differential thermal analysis and optical density measurements. They reported a pretransition at 33°C in addition to the main transition at 37.5°C. Our data does not show convincingly the presence of a pretransition but the main transition is clearly seen and is in excellent agreement with their results.

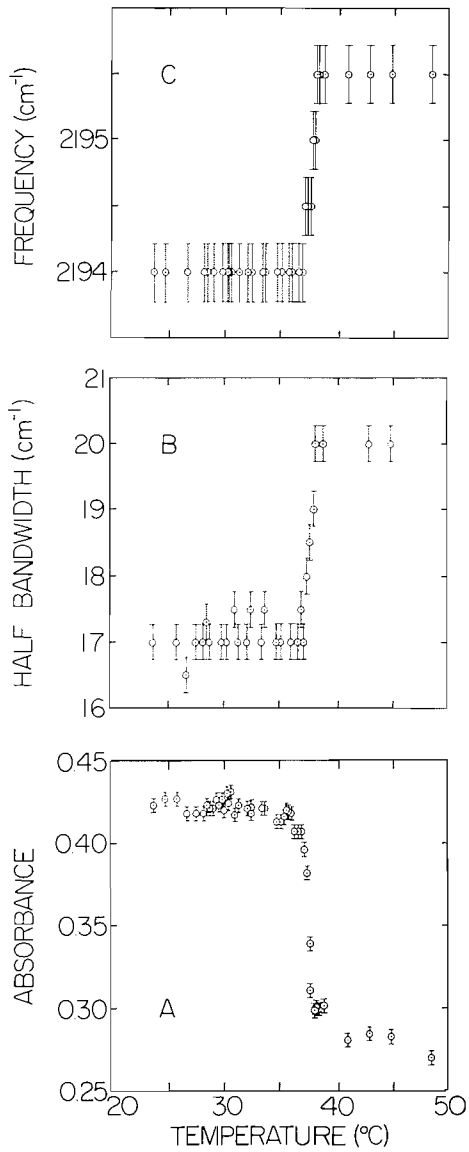

FIG. 4. Temperature dependence of the band with the frequency maximum at ~2194 cm^{-1} in the infrared spectrum of multilayer dispersions of DPPC-d_{62}: (*A*) absorbance; (*B*) halfwidth; (*C*) frequency of the maximum.

We also observe that the main transition is extremely sharp, being essentially complete within seven-tenths of a degree.

The multilayer dispersions of the corresponding light compounds, i.e., DPPC-d_0 also indicated a sharp transition at 41.5 ± 0.2°C in the infrared study. Again the 'pretransition' was not seen very convincingly in the temperature plots. This suggests that at the pretransition the changes in the spectral parameters used here are not much larger than the experimental uncertainty in the present measurements.

The lowering in the phase transition temperature on deuteration is probably related to the slightly lower value of the CD bond length compared with that of the CH bond length. This slightly lowered carbon–hydrogen bond length probably decreases the interlocking of the hydrocarbon chains which facilitates the onset of disorder at lower temperatures.

Here it may be mentioned that a recent study of the

order–disorder phase transition in the molecular crystal charge transfer complex of naphthalene and tetracyanobenzene indicated that when the naphthalene-d_0 is replaced by naphthalene-d_8, the transition temperature is lowered by about 7°C.[2] Although the two systems, glycerophospholipid bilayers and molecular crystal complexes are quite different, the effect of deuteration on the order–disorder transition temperature is in the same direction in both cases. It appears necessary to understand first the effect of deuteration itself on the bilayer structure and the phase transitions before one can confidently use the deuterated derivatives as probe molecules.

Excess volumes of binary mixtures of chloroform and bromoform with the following *n*-alcohols: methanol, ethanol, and *n*-propanol have been measured as a function of composition at 303.15 K by a dilatometric method.

PREM P. SINGH, BUTA R. SHARMA et KULJIT S. SIDHU. Can. J. Chem. **56**, 2127 (1978).

On a mesuré les volumes d'excès de mélanges binaires de chloroforme et de bromoforme avec les alcools suivants: méthanol, éthanol et propanol; ces mesures ont été effectuées en fonction de la composition à 303.15 K par une méthode dilatométrique.

[Traduit par le journal]

Introduction

Alcohols are strongly self-associated (1) but there is considerable disagreement as to the identification of the predominant associated species (2–5). Furthermore, for binary solution rich in alcohol a three-dimensional network of hydrogen bonded alcohol molecules is believed to be present (6, 7). The purpose of the present investigation is to study the effect of chloroform or bromoform on the excess volumes of their mixtures with some normal alcohols.

Experimental

Materials

Analytical grade chloroform, bromoform, methanol, ethanol, and *n*-propanol were purified by standard procedures (8). Their densities at 298.15 ± 0.01 K (except for chloroform and bromoform for which they were measured at 303.15 ± 0.01 K) agreed within 0.00008 g cm^{-3} with those in the literature (9–11). Excess volumes as a function of composition[1] were determined dilatometrically (12) and are shown in Fig. 1.

Results

The results at 303.15 ± 0.01 K are given in Table 1.[1] The results were fitted to the expression

$$[1]\quad V^E/x_A x_B \text{ cm}^3 \text{ mol}^{-1} = [V_0 + V_1(x_A - x_B) + V_2(x_A - x_B)^2]$$

where V_0, V_1, and V_2 are adjustable parameters and x_A and x_B are the mole fractions of components A and B in the mixture. The parameters were evaluated by fitting experimental values of $V^E/x_A x_B$ to [1] by the method of least-squares. The values obtained are given in Table 2. The standard deviation $\sigma(V^E)$ is also given.

[1]A complete set of the V^E data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Discussion

The excess volumes V^E for chloroform (A) + methanol (B) and bromoform (A) + methanol (B) are all negative and the curves against x_A are not symmetrical about $x_A = 0.50$. For chloroform + ethanol and bromoform + ethanol, V^E is positive at high mole fractions of chloroform or bromoform in these mixtures but is negative over the rest of the concentration range. Furthermore, V^E is consistently more negative throughout the entire chloroform or bromoform concentration range and the minima shift to still lower x_A when chloroform is replaced by bromoform in its mixture with these alcohols. The V^E data for chloroform + *n*-propanol and bromoform + *n*-propanol are negative to about 50 mol% of chloroform or bromoform and subsequently become positive for solutions rich in chloroform or bromoform. However, V^E is consistently more positive for the latter mixture as compared to the former mixture. Moreover, while for equimolar mixtures or those rich in chloroform or bromoform, V^E increases in the order *n*-propanol > ethanol > methanol, it increases in the order *n*-propanol > methanol > ethanol for solutions for which $x_A = 0.35$.

Numerous studies (12–14) indicate that alcohols are associated through hydrogen-bonded linear chains (with restricted rotation about hydrogen bonds) into variable degrees of polymerisation. The observed V^E data for these mixtures may be explained if it is assumed that (*i*) alcohols have a three-dimensional hydrogen-bonded network and the addition of

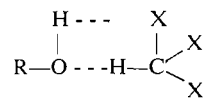
the second component A causes rupture of some of the hydrogen bonds, (*ii*) the alcohol chain fragments then interact with the component (A) due to specific



(X = Cl or Br) interactions, and that there is (*iii*) steric repulsion between the alkyl chain of the alcohol and the X (X = Cl or Br) of the CHX_3. The observed V^E would then be the cumulative sum of the contributions due to these factors; the factors (*i*) and (*iii*) require an increase of volume whereas factor (*ii*) requires a decrease. The V^E data for methanol + chloroform and methanol + bromoform suggest that the contribution due to the factor (*ii*) always outweighs those due to the factors (*i*) and (*iii*); consequently V^E is negative throughout the entire concentration range. For other mixtures, depending upon x_A, these factors make appreciable contributions to the volume, so that V^E is either positive or negative. Furthermore, for the same CHX_3, since steric repulsion due to factor (*iii*) mentioned above would increase in the order *n*-propanol > ethanol > methanol, V^E for *n*-propanol + CHX_3 should be positive at a lower x_A as compared to that for ethanol + CHX_3. The V^E data support this conjecture. This scheme of analysis would then expect that V^E should be more positive for *n*-propanol + bromoform as compared to that for *n*-propanol + chloroform as indeed has been observed.

Carbon-13 nuclear magnetic resonance studies of (*Z*)-5-fluoro-2-methyl-1-{[*p*-(methylsulfinyl)phenyl] methylene}-1*H*-indene-3-acetic acid (sulindac) and some related compounds

ALAN WILMOT DOUGLAS

Merck Sharp and Dohme Research Laboratories, P.O. Box 2000, Rahway, NJ 07065, U.S.A.

Received February 20, 1978

ALAN WILMOT DOUGLAS. Can. J. Chem. **56**, 2129 (1978).

Carbon-13 nuclear magnetic resonance spectra have been obtained and fully assigned for a number of 2-methyl-1-{[*p*-(methylthio) or -(methylsulfinyl)phenyl]methylene}-1*H*-indene-3-acetic acid derivatives, including the potent anti-inflammatory compound sulindac, **1***Z*. Paired *E* and *Z* isomers were studied along with the sulindac sodium salt and ethyl ester in the *Z* series. Variations in steric crowding in *E* vs. *Z* isomers produce chemical shift effects which alternate with the number of intervening bonds. Fluorine substituent effects and ^{19}F nuclear spin coupling to ^{13}C nuclei, second-order features in off-resonance proton-decoupled spectra, and values of long-range ^{13}CH nuclear spin coupling constants have been employed in making a complete set of assignments.

ALAN WILMOT DOUGLAS. Can. J. Chem. **56**, 2129 (1978).

On a obtenu les spectres de résonance magnétique nucléaire du carbone 13 et l'on fait des attributions complètes pour un certain nombre de dérivés d'acide méthyl-2 {[*p*-(méthylthio) ou -(méthylsulfinyl)phényl] méthylène}-1*H* indène-acétique-3, dont le composé anti-inflammatoire très efficace sulindac, **1***Z*. On a étudié les paires d'isomères *E* et *Z* de même que les isomères *Z* du sel de sodium du sulindac ainsi que de son ester éthylique. Les variations de l'encombrement stérique dans les isomères *E* en comparaison avec les *Z* conduisent à des effets de déplacements chimiques qui alternent avec le nombre de liens. On a utilisé les effets des substituants fluor, les couplages de spin du ^{19}F avec le noyau ^{13}C, les caractéristiques du second ordre dans le spectre de proton partiellement découplé ainsi que les valeurs à longues distances des constantes de couplage de spin nucléaire ^{13}CH pour faire les attributions complètes.

[Traduit par le journal]

Introduction

In support of the development of a synthetic route (1) to sulindac, (*Z*)-5-fluoro-2-methyl-1-{[*p*-(methylsulfinyl)phenyl]methylene} - 1*H* - indene - 3 - acetic acid, **1***Z*, a potent, nonsteroidal anti-inflammatory agent (1*a*), carbon-13 nmr studies of this and several related compounds were undertaken. As is often the case with large molecules, a number of techniques was required in order to arrive at a complete set of assignments of ^{13}C nmr signals to the structures. In addition to recognition of characteristic chemical shifts (ref. 2, Chapts. 2–5; ref. 3, Chapts. 3, 5, and 8) for saturated, unsaturated, and functional carbons, substituent effects (4, 5; compare ref. 5 with ref. 2, Chapt. 4 and ref. 3, Chapt. 5) in aromatic systems can be useful; effects of fluorine (6), methylthio (7), and methylsulfinyl (7) groups have been employed here. Off-resonance proton-decoupled ^{13}C spectra reveal proton population on carbon atoms as 0, 1, 2, or 3 by the appearance of singlets, doublets, triplets, or quartets, respectively (ref. 2, Chapt. 1; ref. 3, Chapt. 2). Depending upon proton–proton coupling constants, however, certain second-order effects appear in off-resonance decoupled spectra (8–11) and these may be used in distinguishing among possible assignments. In particular, distinction of 'isolated' aromatic ^{13}C—H groups, i.e., those not flanked by other hydrogen atoms, is straightforward in the compounds studied here. Comparison of ^{13}C–F spin coupling constants in the fluorinated indene moiety with those of fluorobenzene (12) was also made. Long range ^{13}C–H coupling constants were used particularly to identify three-bond relationships of carbon nuclei and protons (13, 14) as well as to confirm the *Z* and *E* geometries of benzylidene groups originally assigned from proton nmr considerations (1*b*, 15). Interesting γ-shielding (ref. 3, Chapt. 3) and δ-deshielding (16, 17) effects due to the proximate benzylidene ring occur in the indenyl moiety, and correlation of behavior on *Z* vs. *E* isomers served to complete the assignment process.

Results and Discussion

Carbon-13 chemical shifts have been obtained and assigned for all carbon atoms of *Z* and *E* isomers of the sulfinyl and sulfide compounds **1***Z*, **1***E*, **2***Z*, and **2***E*, as well as for *Z* isomers of the desfluoro and desfluorodesoxy compounds **3** and **4**, respectively, and the sodium salt and ethyl ester of **1***Z*, **5**, and **6**,

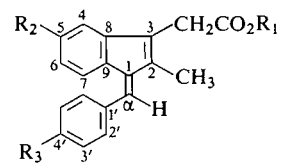
[a]D, DMSO-d_6; C–M, ~9:1 $CDCl_3$–CD_3OD.
[b]Saturated solution. Compounds **1***E* and **6** were studied only in the chloroform–methanol medium for convenience in sample recovery; 1*Z* was studied in the same medium for comparison.
[c]Partially obscured by the stronger signal due to C 3′,5′.

respectively. Data are presented in Table 1, where values for **1***Z* are reported for DMSO-d_6 and approximately 9:1 v/v $CDCl_3$–CD_3OD solvents. Compound **1***E* and ester **6** were run only in the mixed solvent; all other compounds were run in DMSO-d_6. Concentrations and solvents are indicated in Table 1. Carbon-13–fluorine nuclear spin coupling constants for **1***Z*, **1***E*, **2***Z*, **2***E*, **5** and **6** are presented in Table 2, where the corresponding values in fluorobenzene (12) also appear. Assignments of C5, C7, C8, and the pair C4 and C6 are firmly established by association of their ^{13}C–F coupling with ^{13}C–F spin coupling in fluorobenzene. Distinction between C4 and C6 was based on off-resonance proton decoupling results (below).

Consideration of ^{13}C–^{19}F coupling alone does not



1*Z* $R_1 = H, R_2 = F, R_3 = S(O)CH_3$
2*Z* $R_1 = H, R_2 = F, R_3 = SCH_3$
3 $R_1 = R_2 = H, R_3 = S(O)CH_3$
4 $R_1 = R_2 = H, R_3 = SCH_3$
5 $R_1 = Na^+, R_2 = F, R_3 = S(O)CH_3$
6 $R_1 = C_2H_5, R_2 = F, R_3 = S(O)CH_3$

allow distinction between carbons assigned as C3 and C9 but this choice may be made based upon long-range ^{13}C–H coupling. The fluorine splitting of C3 is in accord with similar ones found in fluorotoluenes (12) or fluorobenzocycloalkanes (18) for a 'zig-zag' path. In benzene (19) or substituted benzenes only the one- and three-bond ^{13}C–H couplings are larger than about 1–2 Hz. In addition to the small fluorine splitting, the pattern observed for the signal assigned to C9 in **1***Z* was a gross quartet due to three non-identical, long-range splittings ascribed to H4, H6, and the benzylidene hydrogen. The sum of the three couplings, all through planar three-bond pathways, was some 24.5 Hz. The appearance of the pattern indicated that one of these couplings was nearly 10 Hz with the other two approximately equivalent at about 7–8 Hz. Carbon 9 is expected to be split by 7–8 Hz by H4 and H6 based on observations in benzene (19) or fluorobenzene (20). For **1***E* a similar quartet of long-range couplings to the carbon signal assigned to C9 is observed, indicating three splittings essentially equivalent at approximately 7 Hz. On the other hand, the proton-coupled pattern of C3 in **1***Z*, although partially obscured, shows no clearly resolved splittings. In **1***E* the proton-coupled signal for C3 is clearly visible and is only a broad multiplet revealing no details of long-range proton coupling.

Values of ~7 and ~10 Hz for the three-bond coupling of C9 to the benzylidene hydrogen in the *E* and *Z* isomers, respectively, are in agreement with the familiar geometrical rules governing ^{13}C–H (and H–H) couplings through olefinic bonds (ref. 21 and references therein) and therefore fully support isomeric structure assignments made earlier on the basis of shielding anisotropy in ^1H nmr spectra (1*b*, 15).

It may be noted in Table 1 that differential shift effects for corresponding *Z* and *E* isomers for C7 and the 2-CH_3 'anticorrelate' with one another, i.e., the isomeric variation which shifts one of these carbons upfield shifts the other down, with the size of the differential shift approximately 3.5 ppm. These are quite reasonable proximity effects (not, it may be noted, anisotropic shielding effects as observed for corresponding protons in earlier ^1H nmr studies (15)) consistent with the established *Z*–*E* isomerism of the compounds. Although it must be emphasized that the complementary behavior of C7 and the 2-CH_3 is the key point, it is of interest to note at least similar deshielding effects upon δ substitution have been observed in 1,8-dimethylnaphthalene (16) as well as in several aliphatic systems (16, 22).

A similar complementarity must be called upon to distinguish between C1 and C2 of the indene ring system in these molecules, i.e., complementary behavior of C2 and C9 will be anticipated, while the observation of a small, long-range splitting by fluorine is taken as identifying C3. It is observed that C9 exhibits a significant differential shift to lower field upon going from *Z* to *E* isomers in either methylsulfinyl or methylthio derivatives, the differential shifts being 3.3 and 3.6 ppm, respectively. If C2 is assigned at 138.2 ppm in **1***Z*, 135.2 ppm in its *E* isomer, and at 138.1 and 134.5 ppm, respectively, in the *Z*- and *E*-methylthio analogs, the differential shifts of −3.0 and −3.6 may be taken as reflecting the geometrical complementarity of carbons 2 and 9. Proximity shielding by a γ substituent is common in acyclic and simple cyclic systems (3), although it would have been risky to assume direct transferability of such effects into the present, more complicated structural system.

Distinction of C4 and C6, both *ortho* to fluorine and proton bearing, is straightforward when single-frequency off-resonance decoupling (SFORD) is performed at the hydrogen radio frequency (ref. 2, Chapt. 1, ref. 3, Chapt. 2). For C6, which bears a proton strongly coupled to that at C7, a pattern more complex than a simple doublet appears, further split, of course, by ^{19}F. On the other hand, C4 exhibits a simple doublet of doublets, due to the residual ^{13}C–H coupling and the two-bond ^{13}C–F coupling. The complexity or simplicity of SFORD patterns arises from a Bloch–Siegert collapse of the proton chemical shift (23) with the H–H coupling still exerting its full effect (24, 25).

The preceding arguments suffice to allow confident assignment of the nine carbon atoms of the indene ring system itself. Chemical shifts and SFORD multiplicities make assignments of 2-CH_3, 3-CH_2, CO_2H, and —S(O)CH_3 carbons a routine matter, as well as identifying Cα, the benzal carbon, as the only remaining single sp^2-carbon-bearing hydrogen. Assignment of carbons in the sulfur-bearing ring is also straightforward following the work of Buchanan *et al.* (7). The shifts reported for 4-methanesulfinyltoluene in chloroform agree closely with those in Table 1 for carbons 1′ through 6′ of **1***Z* and **1***E* which were obtained in chloroform–methanol solution, the average deviation being only some 0.7 ppm. In fact, if differences of nearly 1.5 ppm are neglected for C1′, attached here to an olefinic rather than an aliphatic carbon, the average disparity falls

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to slightly less than 0.5 ppm. Agreement is less impressive for sulfides **2***Z* and **2***E*, although the DMSO solvent employed in the present work obviates a strict comparison with the published chloroform solution results (7). In any event, the assignments for the sulfur-bearing ring, although of no critical importance, may be confidently made as in Table 1. Long-range ^{13}C–H coupling constants support the assignments given, in that C3′ and C5′ exhibit only a single long-range splitting larger than 1–2 Hz, while C2′ and C6′ experience approximately 5 Hz long-range couplings to two protons, one located *meta* on the ring and one situated three bonds away at Cα, i.e., the benzylidene hydrogen.

Attention may now be directed to the 'desfluoro' analogs of sulindac, structures **3** and **4**. The very helpful fluorine splittings are now absent but differential shifts based on a fluorobenzene–benzene comparison (6) may be used, along with SFORD results, to lead to a set of assignments. Table 3 presents fluorine differential shift effects for **1***Z* and its desoxy analog, **2***Z*, which result from the choice of assignments made for the corresponding desfluoro compounds. The effect of fluorine substitution on all carbon atoms of the benzylidene group should be insignificant; in fact no observed incremental shift there exceeds 0.3 ppm in either direction with assignments made as given. Small shifts at C1, C2, and C3 are noted, with the effect at C2 being a downfield incremental shift of 2.3 ppm upon fluorine substitution and the effects at C1 and C3 somewhat smaller in magnitude, 0.8 and 1.4 ppm, and in the opposite direction. No significant effect is observed for the 2-methyl, 3-methylene, or carboxyl carbons.

SFORD experiments confirm the assignments of Cα and of C4 and C7 vs. C5 and C6. The use of 'second-order' effects in off-resonance proton decoupled ^{13}C spectra for assigning the α and β carbons of symmetrically *ortho*-disubstituted benzenes has been noted (9). The desfluoro compounds under discussion here do not possess symmetry as far as 'α' and 'β' carbons of the indene portion of the molecules is concerned but the same distinction in terms of general pattern appearance may be expected in view of the large Bloch–Siegert shift compression (23). That is, effective shifts of only a few Hertz should allow comparable domination of the proton–proton spin couplings in the determination of the second-order patterns as if zero shift conditions actually applied. Results for some coumarins indicate this is the case (11) and it is taken to be true here. Proton spectra of the desfluoro compounds indicate that the protons at C4 through C7 are rather closely spaced in chemical shift and the general appearance of off-resonance proton-decoupled ^{13}C patterns is consistent with the assignments made.

TABLE 3. Differential shift effects (fluoro–desfluoro)

	$\Delta\delta^{13}C$		
Carbon	**3** → **1***Z*	**4** → **2***Z*	C_6H_6 → PhF
C4	−12.4	−12.5	−14.1 (*Co*)
C5	+34.5	+34.6	+35.1 (*Ci*)
C6	−14.1	−14.2	−14.1 (*Co*)
C7	+1.2	+2.1	+1.6 (*Cm*)
C8	+2.7	+2.6	+1.6 (*Cm*)
C9	~−3.9	−2.9	−4.4 (*Cp*)

The situation for Cα is straightforward. It is the only single carbon bearing a single, isolated proton in the molecule, and as such, exhibits a simple doublet under SFORD conditions. The only carbon which actually behaved in this way has been assigned to Cα.

Conclusions

In addition to the better known techniques involving ^{13}C chemical shift arguments, ^{13}C spin coupling to ^{1}H and ^{19}F, and the use of first-order SFORD multiplet patterns, extensions of some of these have been used in obtaining complete ^{13}C spectral assignments for sulindac and related compounds. It is of particular interest that the availability of *Z* and *E* isomer pairs allowed the set of molecules serve as its own model system for assignments involving some of the substituted carbon atoms in the indene moiety. It is often worthwhile to attempt to carry out limited chemical transformations in ^{13}C assignment problems, in addition to focusing on physical parameters such as shielding, spin coupling, relaxation, and the like. If a known variation exists in a localized area of a large structure, whether created by the chemist or as a result of biochemical variations in naturally occurring materials, effects at nearby carbons, even if not directly interpretable in terms of γ or δ effects, etc., may frequently distinguish them from otherwise similar carbons. The same principle holds true for ^{13}C observation of evolving chemistry where mechanistic predictions may be tested against observed ^{13}C spectral modifications which arise when reaction intermediates are observed (26, 27). An interplay of chemical insight and physical data is usually more informative than either used alone.

Second-order effects in SFORD spectra should be useful in a wide variety of situations. In addition to giving aromatic substitution information, distinction of axial vs. equatorial C—H groups in pyranoses and related structures and of methyl groups of *C*-ethyl vs. *N*- or *O*-ethyl groups should follow from inspection of SFORD patterns. In certain large molecules where methyl groups attached to olefinic carbons are interspersed in ^{13}C chemical shift with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

others attached to nonfunctionalized methine or methylene groups, distinction of the former by means of the 'pure' quartets they exhibit in SFORD observations may be made.[1] The governing factors here are the existence of large proton–proton spin couplings and the strong Bloch–Siegert compression of an initially not very large proton chemical shift (23–25). Opportunities for exploitation of this phenomenon should be sought. Only a general knowledge or even a good estimate of proton shift separations is needed to make effective use of complexity vs. simplicity in SFORD patterns.

Experimental

Carbon-13 nmr spectra were obtained with a Varian Associates CFT-20 spectrometer. Typical operation involved 4 kHz spectral widths, 0.5 s acquisition times, 30–45° nutation angles, noise-modulated proton decoupling, and weighting of free induction decays by $\exp(-t/0.4)$. Chemical shifts were referenced to tetramethyl silane (TMS), internal, with most runs in DMSO-d_6 using the solvent as secondary reference at 39.5_3 ppm. SFORD and gated decoupling experiments employed 4 kHz spectral widths, 1.0 s acquisition times, and 1.0 s negative exponential weighting constants. Frequency offsets for SFORD experiments were chosen between approximately 400 and 1000 Hz, as necessary to clearly develop second-order features, with irradiation power levels ($\gamma H_2/2\pi$) of approximately 4.8 kHz for 10 mm or 5.6 kHz for 8 mm sample tubes, respectively.

Desfluoro compounds **3** and **4** have not been previously reported. Synthetic and analytical data are available.

Phase-transfer catalyzed synthesis of activated cyclopropanes[1]

JOHN M. MCINTOSH AND HAMDY KHALIL

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received March 3, 1978

JOHN M. MCINTOSH and HAMDY KHALIL. Can. J. Chem. **56**, 2134 (1978).

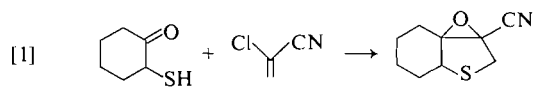
The phase-transfer catalyzed condensation of diethyl bromomalonate (*7d*) with Michael acceptors **8**–**12** leads to cyclopropanes in high yields. More hindered acceptors and other haloesters do not react, while condensation of *7d* with crotonaldehyde leads to a 2:1 adduct via a subsequent Darzens condensation. The synthetic potential of the products is also outlined.

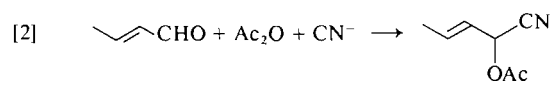
JOHN M. MCINTOSH et HAMDY KHALIL. Can. J. Chem. **56**, 2134 (1978).

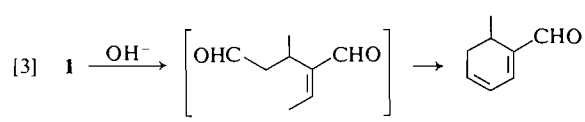
La condensation, catalysée par transfert de phase, du bromomalonate de diéthyle (*7d*) avec les accepteurs de Michael **8**–**12** conduit à des cyclopropanes avec de bons rendements. Il n'y a pas de réaction avec des accepteurs empêchés ou d'autres esters halogénés; la condensation de *7d* avec le crotonaldéhyde conduit à un adduit 2:1 par l'intermédiaire d'une condensation subséquente de Darzens. On définit le potentiel de synthèse des produits.

[Traduit par le journal]

Recently our interest has been centered on the use of phase-transfer catalysis of reactions between nucleophiles and conjugated carbonyl compounds. This interest was triggered by the observation that, with apparently very little change in reaction conditions, a complete reversal from conjugate to 1,2-addition occurs. For example, reaction of enones with α- or β-mercaptocarbonyl compounds leads exclusively to products derived by 1,4-addition (1), eq. [1], but addition of cyanide ion leads only to 1,2-addition (2), eq. [2]. Furthermore, the cyclodimerization of crotonaldehyde (**1**) leads,[2] by way of **2**, to **3**, eq. [3]. This also involves conjugate addition as the initial step.

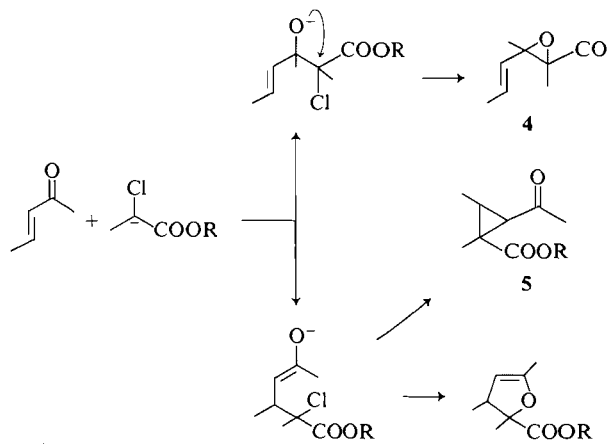






2 **3**

The generally accepted theory of phase-transfer catalysis involves a poorly solvated, tight ion pair (3) as the reactive species. Thus it would appear reasonable that association of the cation Q^+ with the position of highest electron density (the carbonyl oxygen) should lead to preferential 1,2-addition. However, it may be that the nature of the nucleophilic species may play the major role in determining the dominant mode of addition. Thus, soft nucleophiles (e.g., RS^-) would prefer conjugate addition whereas harder ones (e.g., CN^-) would undergo kinetic attack at the carbonyl group (4). To further elucidate the role of the nucleophile, we have investigated some other carbon-based species.



4 **5** **6**

SCHEME 1

The base-catalyzed reaction between α-haloesters and carbonyl groups leads to epoxides (5). This reaction proceeds well under phase-transfer catalysis (1, 6). When conjugated enones are used, three product types (**4**, **5**, or **6**) are possible, depending on the initial mode of addition (Scheme 1). A previous study of this reaction under homogeneous reaction conditions (7) showed that simple α-haloesters afforded products of type **5** under aprotic conditions but not in alcoholic solution. However, using diethyl bromomalonate (DBM, *7d*), the yields of **5** ranged from 45–60% in both protic and aprotic

solvents. In neither case were products of type **4** or **6** reported. In view of the assumed close analogy between phase-transfer and aprotic conditions, we investigated this type of reaction under phase-transfer conditions.

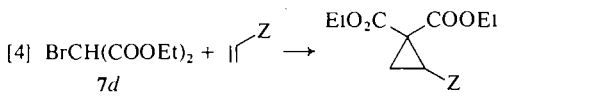
Results and Discussion

The results of the reactions run are summarized in Table 1. Simple α-haloesters ($ClCH_2COOEt$ (*7a*), $BrCH_2COOEt$ (*7b*), and $ClCH_2COOtBu$ (*7c*) did not react at room temperature and could be recovered in high yield. Neither ester hydrolysis nor halogen substitution occurred. In view of the reported (8) successful Darzens condensations using *7c* with unconjugated compounds, it is likely that the anion is being formed but that the reduced electrophilicity of the enone is preventing condensation. Very recent reports (9, 10) of successful cyclopropanations using *7c* show that this reaction will proceed with Michael acceptors which are more stable to the basic reaction conditions (esters, nitriles, sulfones) but these do not address the question of conjugate vs. 1,2-addition.

Reactions of DBM (*7d*) proved more rewarding,

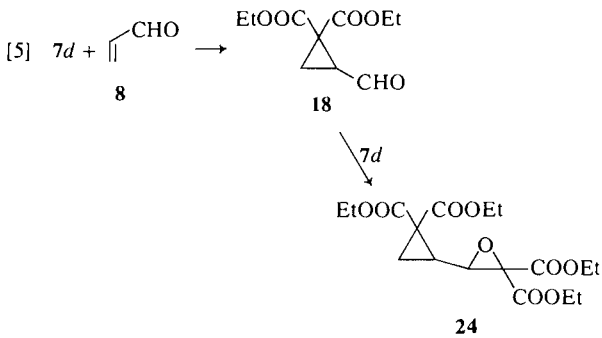
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

affording high yields of products of type **5** with acceptors **8–12**, eq. [4]. The only contaminant in

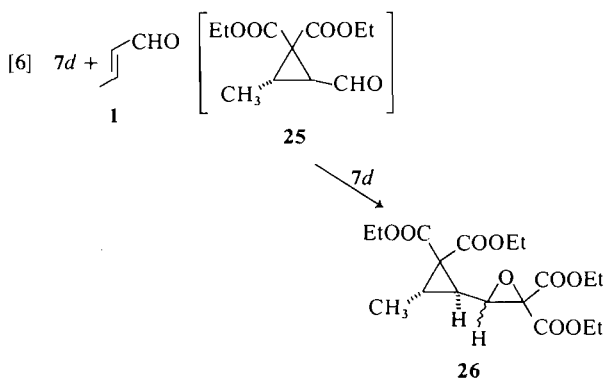


these reactions, aside from some residual starting material, was tetraester **23**. The products were characterized by the lack of a vinyl hydrogen absorption in their nmr spectra. On the other hand, acceptors **13–16** gave **23** as the only isolated product. As in the previous study (7), the presence of two β-substituents completely blocks the conjugate addition but even in these cases no 1,2-addition product was observed.

Condensation of *7d* with acrolein (**8**) occurred normally and afforded **18** in quantitative yield. This could be condensed with a second molecule of *7d* to afford **24**, eq. [5]. However, when crotonaldehyde



(**1**) was reacted with *7d*, none of the expected **25** could be detected at any time during the reaction, although this is the reported product (7) under homogeneous conditions. The only product formed, in addition to minor amounts of **23**, was **26**, which is analogous to **24**, eq. [6]. To verify the details of

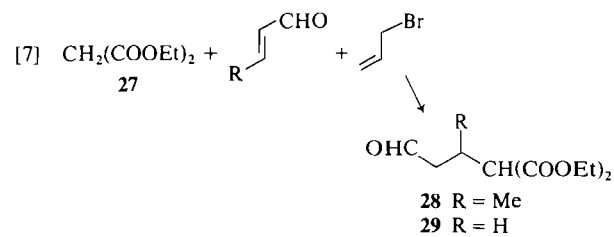


formation of **26**, **25** was prepared (7) and subjected to the usual phase-transfer conditions. An exceptionally rapid reaction occurred, leading exclusively to **26**. It is worthy of mention that a significant by-product in the synthesis of **25** is **26**, which remains as a residue after distillation of **25**. Thus it appears that only the relative rates of the two condensations are different under the two types of reaction conditions.

Both **24** and **26** show a one-proton absorption between δ 3.2–3.6 as a doublet of doublets which we assign to the proton on the oxirane ring. Careful glc analysis indicated the presence of two diastereomers (not separable) in each case. The nmr spectrum of **25** indicates the presence of only one diastereomer (*trans*) and this is supported by its reported transformations (7). Thus further condensation leads to only two diastereomers of **26**. Integration of the doublets at δ 3.47 and 3.27 indicates a 1:2 ratio of diastereomers but the assignment of these is ambiguous. In the case of **24**, the lower field (δ 3.59) doublet is quite sharp but the higher field signal (δ 3.20) is definitely coupled further. In this case the integrated ratios of these two doublets is 2:1.

Although **24** is formed from **18**, we were unable to effect condensation of **19** or simple aldehydes (butanal, cyclohexanecarboxaldehyde) with DBM under comparable conditions! Thus the exclusive formation of **24** remains unexplained.

Another curious result was obtained when we attempted to trap the 1,2-addition product from **1** or **8** and diethyl malonate (**27**) using allyl bromide (2). Reaction of 1 equiv. of each of **27**, **1** (or **8**) and allyl bromide and 10 *N* aqueous sodium hydroxide under the standard conditions led to a rapid disappearance of *all* organic material from the methylene chloride phase. Acidification of the aqueous layer led to moderate yields of the simple Michael addition products **28** and **29**, respectively, eq. [7].



No diethyl allylmalonate was formed. Although it appears that allyl bromide does not enter into this reaction, it is also true that when it is omitted, the yields of **28** and **29** are very substantially reduced and several minor products are also formed. We are unable to offer a reasonable explanation for this result.

TABLE 2. Physical and spectral characteristics of products

Compound	Infrared (cm^{-1})[a]	Nuclear magnetic resonance[b]	Mass spectrum (m/e)[c]

[c]Molecular ion followed by four strongest peaks.
[d]Weak or absent.
[e]Confirmed by field ionization experiments.
[f]Run under field desorption conditions (18).

Conclusions

Cyclopropanations of the type reported here appear limited in scope. It appears that synthetically useful yields are obtained only with DBM and unhindered enones. However, only products of 1,4-addition are formed and several of these appear to possess synthetic potential. The recent report (11) of the use of **19** is illustrative. In particular, compounds of type **21** offer the potential of introducing cyclopropylidene residues via the Wittig reaction (12) whereas both **20** and **22** appear to be ideally suited to nucleophilic ring opening (13, 14) with the generation of elaborated olefinic materials. We hope to investigate these in the near future.

On the basis of the available, admittedly incomplete evidence, it appears that the competition between 1,2- and 1,4-addition may be controlled by the hardness of the nucleophilic species (4). The similarity between our results and those of Evans *et al.* (15) using trimethylsilyl cyanide and thiolate in aprotic media is striking and again illustrates the similarity of phase-transfer and aprotic conditions.

Experimental

Nuclear magnetic resonance spectra were run in deuteriochloroform on a JEOL C60HL spectrometer and are reported in ppm downfield from TMS as internal standard; infrared spectra were determined in chloroform solution on a Beckman IR 12 spectrometer. Gas chromatographic analyses were run on an F and M model 720 instrument using a 10 ft column packed with 20% SE 30 on Chromosorb W. Microanalyses were by A. B. Gygli, Microanalyses Laboratory, Toronto, Ont.

Materials

Compounds **9**, **10**, **11**, **13**, **14**, and benzyltriethylammonium chloride were used as purchased. Compounds **1**, **8**, and **15** were distilled before use. Compounds **12** (16) and **16** (17) were prepared as outlined in previous publications.

General Method for Cyclopropanation Reactions

To a mixture of 40 ml of methylene chloride and 4.1 ml of 9.5 *N* aqueous sodium hydroxide (0.04 mol) was added ca. 100 mg of benzyltriethylammonium chloride (TEBAC). The system was purged with nitrogen and cooled to 0°C in an ice–salt bath. To this solution was added a mixture of 0.4 mol of each of the donor and acceptor molecule at 0°C with good stirring. The addition required ca. 10 min. Stirring was continued for 1 h at 0°C and a further 2 h at ambient temperature. The solution was diluted with 35 ml of water, the layers separated, and the organic phase dried over Na_2SO_4. After removal of solvent, anhydrous ether was added and the catalyst removed by filtration. Evaporation afforded an oil which was analyzed by glc. In each case, the product was as shown in Table 1, in some cases contaminated by small amounts (<10%) of tetraester **23**. Products were purified where necessary by chromatography over alumina, using 5% ether – petroleum ether as eluent. Analytical samples were collected from glc. All new compounds gave acceptable elemental analyses; spectral characteristics of the products are presented in Table 2.

Approaches to the synthesis of triterpenoids. IV. The ABC + E ring approach to the pentacyclic triterpene skeleton. Synthesis of a pentacyclic compound suitable for triterpene synthesis[1,2]

JOHN W. APSIMON,[3] SATYANAND BADRIPERSAUD, JOHN W. HOOPER, AND RICHARD PIKE
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

AND

GEORGE I. BIRNBAUM, CAROL HUBER, AND MICHAEL L. POST
Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received January 30, 1978

JOHN W. APSIMON, SATYANAND BADRIPERSAUD, JOHN W. HOOPER, RICHARD PIKE, GEORGE I. BIRNBAUM, CAROL HUBER, and MICHAEL L. POST. Can. J. Chem. **56**, 2139 (1978).

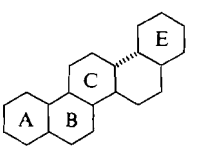
Studies on the ABC + E ring construction of the pentacyclic triterpene skeleton are described. Acid-catalysed cyclisation of the mixture of diastereoisomers **11** led to preferential cyclisation of one isomer to 10-methoxy-2,2,4aβ,6aβ, 12bβ-pentamethyl-1,2,3,4,4a,5,6,6a, 6bα,7,8,12b,13,14-tetradecahydro-1-picenone (**12**). An X-ray analysis was performed on this compound which crystallizes in the monoclinic space group $P2/c$. There are four molecules in the unit cell which has dimensions $a = 6.456(2)$, $b = 42.518(6)$, $c = 8.519(2)$ Å, $\beta = 100.92(3)°$. The structure was solved by direct methods and refined by block-diagonal least-squares to a final R value of 0.042 for all 3234 observed reflections. The molecular structure found by X-ray diffraction confirms the stereochemical reasoning used in the synthetic steps.

JOHN W. APSIMON, SATYANAND BADRIPERSAUD, JOHN W. HOOPER, RICHARD PIKE, GEORGE I. BIRNBAUM, CAROL HUBER et MICHAEL L. POST. Can. J. Chem. **56**, 2139 (1978).

On décrit des études concernant la synthèse des cycles ABC + E du squelette pentacyclique des triterpènes. Une cyclisation acido-catalysée d'un mélange de diastéréoisomères de **11** conduit à la cyclisation préférentielle d'un isomère en méthoxy-10 pentaméthyl-2,2,4aβ,6aβ,12bβ tétradécahydro-1,2,3,4,4a,5,6,6a,6bα,7,8,12b,13,14 picénone-1 (**12**). On a effectué une analyse par rayon X de ce composé qui cristallise dans le groupe d'espace $P2/c$. Il existe quatre molécules par maille de dimension $a = 6.456(2)$, $b = 42.518(6)$, $c = 8.519(2)$ Å, $\beta = 100.92(3)°$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (blocs diagonaux) jusqu'à une valeur finale de R de 0.042 pour les 3234 réflexions observées. La structure moléculaire, qui a été déterminée par diffraction de rayon X, confirme le raisonnement stéréochimique utilisé dans les étapes de la synthèse.

[Traduit par le journal]

We wish to report recent studies aimed at a convergent synthesis[4] of the pentacyclic triterpene system (2) based on an ABC + E ring construction **1**, followed by formation of one bond (dotted in **1**) to



1

yield the polycyclic array. The advantage of this approach lies in the rapid provision of a polycyclic species with preformed stereochemistry, whereas the disadvantage lies in the control of stereochemistry during the vital cyclisation step.

Our basic strategy is outlined in Scheme I. There exists a basic flaw in this plan in that the condensation of two racemates[5] **2** and **3** is unlikely to lead to any chiral induction in view of the distance between the reacting sites and any asymmetry and in fact it is reasonable to expect the production of a 50:50 mixture of the diastereoisomers ***4a***. However, at the outset we felt this route worth pursuing since we were of the opinion from inspection of molecular models and from the belief that the internal aldol-like process (***4b*** → **5**) necessitates a strict stereoelectronic arrangement for cyclisation (3, 4) that one of the diastereoisomers represented as ***4b*** would cyclise preferentially *with respect to* the other, and it ap-

[1]Portions of this work are described in the Ph.D. thesis of S.B. (Carleton University, Ottawa, Ont. 1976). For Part III see ref. 1.

[2]NRCC No. 16712.

[3]To whom inquiries should be directed.

[4]For other successful triterpene syntheses see refs. 4–11 in Part III of this series (1).

[5]With the exception of structure **6**, which represents a natural product, all structures used in this paper represent racemates. Only that enantiomer bearing a direct relationship to the natural series is shown for convenience.

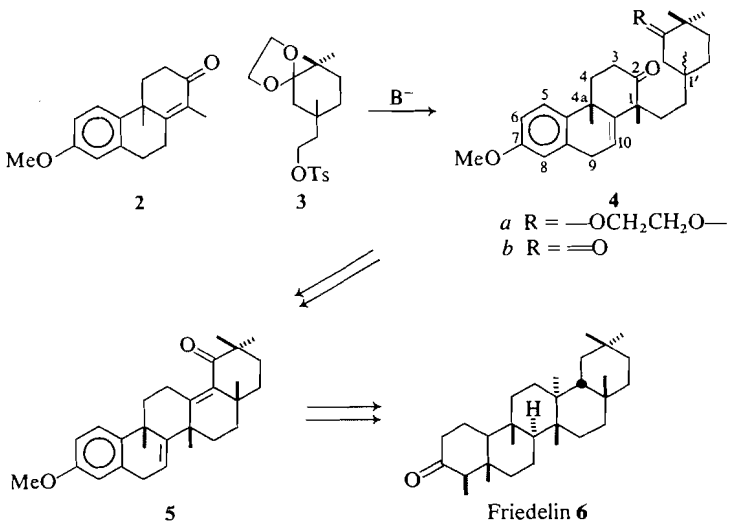
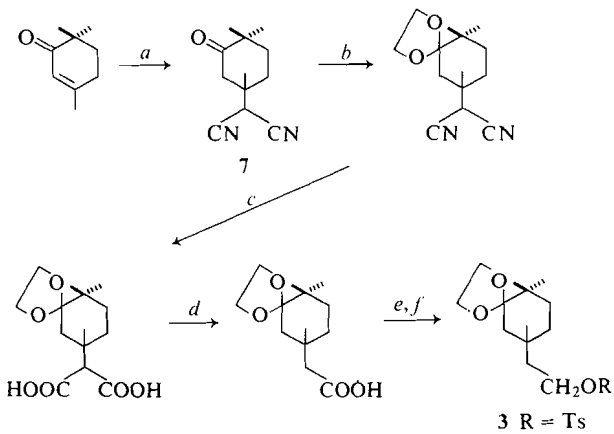


SCHEME 1

peared to us that the isomer cyclising should lead to **5** possessing the correct stereochemistry for further elaboration to friedelin **6**. Thus, although the basic strategy legislated for the loss of 50% of material, the other 50% should consist of a pentacyclic material close in structure to the target molecule. This surmise turned out to be at least partly correct as revealed in the sequel.

As starting material for our work we used tricyclic ketone **2** (5) and the tosylate **3**. The latter compound was available to us from the substituted malononitrile **7** obtained from the potassium fluoride catalysed Michael reaction between 3,3,6-trimethyl-2-cyclohexenone and malononitrile (6). A series of unexceptional steps as outlined in Scheme 2 led to the tosylate **3** in an overall yield of 26% from **7**.

Tricyclic enone **2** was alkylated via its dienolate ion



SCHEME 2. Reagents: (*a*) $CH_2(CN)_2$, KF; (*b*) $HOCH_2$-CH_2OH, *p*-TSA–H_2O; (*c*) KOH; (*d*) heat 140–145°C, 2 h; (*e*) $LiAlH_4$; *p*-toluenesulphonyl chloride, pyridine.

generated using potassium *tert*-amyloxide in dry benzene (7), with tosylate **3** to provide **4***a* in 54% yield, which crystallized although nuclear magnetic resonance spectroscopy and thin-layer chromatography indicated a mixture of diastereoisomers to be present. Acid hydrolysis of the ethylene ketal group provided the crystalline mixture of ketones **4***b*. The stereochemistry of the alkylation step at C(1) is based on the observations of previous workers (5,7,8) and on the use of benzene induced shifts of the methyl signals observed in the nmr spectra of our alkylated compounds (5). This assignment is confirmed by the X-ray structure determination quoted later.

Ketone mixture **4***b* was stable in crystalline form but solutions rapidly turned yellow with the formation of another species that was separated by column chromatography on alumina. This material is assigned structure **8** on the basis of its spectroscopic properties[6] including the appearance of the peak at *m/e* 270 in its mass spectrum, arising by cleavage as shown. Compound **8** could also be prepared from **4***b* on oxidation with Jones' reagent indicating the ease of oxidation of the C (9) benzylic-allylic position. Deoxygenated solutions of **4***b* were stable.

We next turned our attention to the cyclisation of the diketone mixture **4***b*. Attempts to effect the intramolecular aldol-like condensation using a variety of bases were singularly unsuccessful under a wide range of conditions. The use of *tert*-butylmagnesium chloride (9) as a cyclisation base at first seemed promising in that one component of the diastereoisomeric mixture reacted (tlc observation) while the other was inert under the conditions used. However, after isola-

[6]For brevity we chose to describe unexceptional spectroscopic values in the experimental section only.

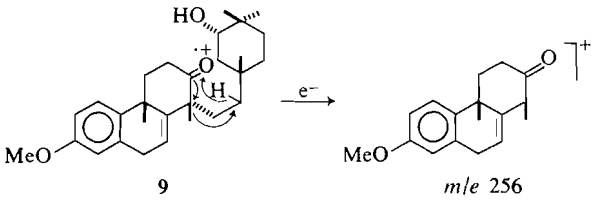
8 *m/e* 270

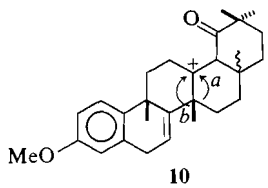
tion and characterisation it became apparent that simple carbonyl reduction had occurred by hydride transfer from the Grignard reagent (ref. 10 and refs. cited therein) to yield **9** in 39% yield from **4***b* (i.e.,



9 *m/e* 256

78% yield based on the reduction of one diastereoisomer). That the ring E carbonyl group had been reduced in this case was supported by the observation that the base peak in the mass spectrum of **9** appears at *m/e* 256 assigned as shown. Further comments on the stereochemistry depicted for **9** are presented later in this report.

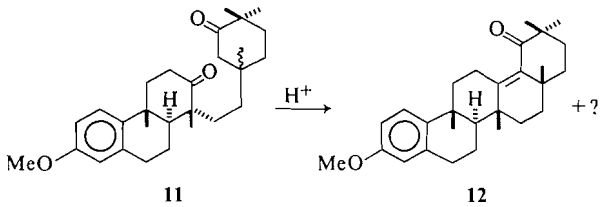
With the singular failure of base catalysis to induce cyclisation of **4***b* we next examined acid-induced reactions. In boiling xylene in the presence of *p*-toluenesulphonic acid, **4***b* yields a crystalline product mp 117–121°C whose physical properties indicated a structure far removed from the desired **5**. At first we suspected a simple rearrangement product arising from cation **10** via pathways *a* or *b*. However this



10

proved not to be the case. The structure of this product is discussed in the following paper (11).

It appeared to us that the failure of this cyclisation to provide pentacyclic species could lie in the lability of cation **10** leading to more stable allylic or benzylic species in competing processes. We therefore turned our attention to the cyclisation in the absence of the C(1a)—C(10) double bond in **4***b*. We have previously shown (5, 12) that hydrogenation of compounds related to **4** proceeds stereoselectively depending on the conditions used. In the event, reduction of mixture **4***b* by hydrogen in boiling xylene using palladium-on-charcoal as the catalyst was readily accomplished to yield the mixture of diketones **11**. Once again the stereochemistry assigned (5) to the new chiral centre at C-1a is based on the use of benzene-induced solvent shifts in the nmr spectrum of **11** (See Table 1).



11 12

Reaction of **11** with *p*-toluene sulphonic acid in boiling xylene contradicted our prediction concerning the reactivity of one diastereoisomer compared to the other, since both components of the mixture **11** appeared to cyclise under these conditions. One reaction product crystallised after chromatography on silica gel. This material, mp 182–183°C was obtained in 90% yield based on the cyclisation of one diastereoisomer (i.e., overall 45% yield for this step). The other product from the cyclisation proved more difficult to purify and as yet has not been fully characterised. The crystalline product was assigned structure **12** based on its spectroscopic properties (see Experimental) and was simultaneously analyzed by X-ray diffraction.

Final parameters[7] from this analysis are listed in Tables 2 and 3, and a stereoscopic view of the molecular structure is shown in Fig. 1. This clearly confirms the above assignment, and underlines the sound basis for our other stereochemical predictions in this sequence. Figure 2 shows the final bond lengths, for which the estimated standard deviations are 0.002–0.003 Å. The bond lengths are very much as expected and require no special comments.

Endocyclic torsional angles are shown in Fig. 3. Ring A is approximately (within ±0.007 Å) planar, with distortions giving it a slight boat shape. Rings B and D have half-chair conformations, whereas rings C and E are chair shaped. The B/C ring junction is *trans*. There is some ring flattening in ring C near C(14) and in ring E near C(20). The three methyl groups at ring junctions are mutually *cis* and the ring system is convex toward them (cf. Fig. 1). The 1,3 diaxial methyl groups, C(24) and C(25), are separated by only 3.27 Å and this is despite an angle of 22.9° between the C(9)—C(24) and C(14)—C(25) vectors (which should in an ideal chair be parallel). The re-

[7]Tables of observed and calculated structure amplitudes and of bond angles are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

pulsion between C(24) and C(25) is reflected also in lengthening of the C(9)—C(8) and C(8)—C(14) bonds (to 1.553 and 1.567 Å), and in opening of the C(9)—C(8)—C(14) angle (to 117.7°). C(25) and C(26), however, are 4.69 Å apart, and there is thus probably no repulsion between them. Despite the presence of the C(13)—C(18) double bond in the present compound, which partially flattens the ring C/D/E region, the general shape of this molecule is quite similar to that of epifriedelinol (13) and campanulin (14), another friedelin-type triterpene.

There is no apparent conjugation between the C(13)—C(18) double bond and the C(19)—O(2) carbonyl group; the C(13)—C(18)—C(19)—O(2) torsional angle is −66.7° and the C(18)—C(19) bond, 1.501 Å, is about 0.06 Å longer than expected for a conjugated system. The twist of C(19)—O(2) out of the C(12),C(13),C(18) plane is necessary to avoid too close a nonbonded contact with one of the hydrogen atoms on C(12).

Packing of the molecules in the crystal structure is governed by van der Waals forces; there are no hydrogen bonds or other short intermolecular contacts.

Thus, pentacyclic material **12** is easily obtainable in 16% yield from **2** and **3** and possesses four chiral centres corresponding to friedelin **6**. Work on its conversion to a triterpene as well as other applications of the described intramolecular cyclisation are in progress in our laboratory.

Earlier, structure **9** was assigned to the reduction product of mixture **4***b*, one of the diastereomeric constituents undergoing reduction whilst the other remained unchanged. This latter constituent was separated, hydrogenated and subjected to the acid-catalysed cyclisation process described above. No trace of pentacycle **12** could be detected from this reaction leading us to the conclusion that the C-1′ methyl group in this isomer is α oriented thus the reduction product is assigned a β-methyl group at the same position. The nmr spectrum of **9** exhibits a doublet of doublets at δ 3.40 that is partially hidden by the benzylic proton resonance, which being coupled to the olefinic proton, appears as a doublet. Decoupling of the olefinic proton causes the benzylic protons signal to collapse to a singlet and the doublet of doublets assigned to the carbinol hydrogen becomes clear. The coupling constants observed for this signal are 12 and 6 Hz, corresponding to an axial hydrogen in a cyclohexane flanked by one methylene group. This leads to the conclusion that the hydroxyl group is equatorial and that the complete stereochemical description of **9** is as shown. Attempts to oxidise **9** to the corresponding diketone for conversion to **12** were thwarted by the reactivity of the C-10 benzylic allylic position. Lack of material and other

priorities have so far precluded further work on the finer details of this problem.

As already stressed we have often relied on benzene induced solvent shifts of the methyl group resonances in the nmr spectra of synthetic materials for the assignment of stereochemistry (cf. Table 1). In this particular study the spectra of compounds **4**, **8**, **9**, and **11** were complicated in the methyl region because of the presence of the *gem*-dimethyl system in the pendant potential E ring. In order to enable an unambiguous assignment of the methyl signals in the nmr spectra of our intermediate we undertook synthesis of tosylate **13** as outlined in Scheme 3; this, in turn was used to alkylate **2** to yield mixture **14***a* which was deketalised to **14***b* and hydrogenated to **15**. This route is reminiscent of that already described and served to confirm the assignment of nmr signals made previously. We did perform some cyclisation

attempts on **14***b* and **15** but preliminary indications were not promising. We do not plan any further studies in this particular direction.

The original impetus for the work described herein came from the assumption that the optimum energy pathway for an internal aldol-like cyclisation is that by which the orbital overlap between the enolate π system of one ketone and that of the carbonyl group of the other occurs in a perpendicular manner (see **16**) modified by the suggestions of Burgi *et al.* (ref. 3, see also ref. 4) that nucleophilic attack on the carbon atom of a carbonyl group is directed down 'a funnel of reactivity' whose axis is slightly behind the perpendicular axis of the carbonyl group as in **17**. Inspection of molecular models can often distinguish between two possible modes of attack if severe steric interactions are to be avoided in any transition state assumed to take account of the restrictions summarised in **16** and **17**. In the cases we have reported this is obviously not the complete story but we have detected differences in reactivity toward cyclisation in work that is at present incomplete[8] that can apparently be explained using these concepts. The present

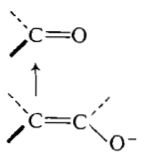
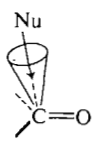
work falls nicely into the framework presented recently by Baldwin and co-workers (19) where orbital overlap considerations have been elegantly summarised in a series of rules for ring closure.



16



17

Experimental

For general information concerning experimental procedures and spectroscopic analysis see Part III of this series (1).

*2-Keto-1β,4aβ-dimethyl-1α-[2-(1′,4′,4′-trimethyl-3′-ethylenedioxycyclohexyl)ethyl]-7-methoxy-1,2,3,4,4a,9-hexahydrophenanthrene (**4**a)*

The method of Stork and Schulenberg (7) was followed. A mixture of potassium (810 mg, 20.78 mmol), *tert*-amyl alcohol (4 ml), and dry benzene (80 ml) was refluxed under a nitrogen atmosphere to give a solution of potassium *tert*-pentoxide. The tricyclic ketone **2** (5 g, 19.53 mmol) was added to the cooled solution and, while fresh benzene was being added, the reaction mixture was heated for 5 h to distill off a mixture of benzene – *tert*-pentyl alcohol. The resulting green-brown suspension of the potassium salt of **2** was cooled to room temperature and tosylate (solid) **3** (7.2 g, 18.8 mmol) was added. The mixture was refluxed for 2 h and then stirred at room temperature overnight. The greenish black syrupy mixture was poured into an ice–water mixture (250 ml) and acidified with 2 *N* H_2SO_4. The organic material was extracted with ether (×3) washed with ether (×3), washed with saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. Evaporation of the solvent gave a yellow oil which crystallized on standing. Recrystallization of this solid from methanol yielded light yellow crystals (4.58 g, 53.5%), mp 107–115°C. Two more recrystallizations furnished an analytical sample: mp 114–115°C; ir (Nujol): 1705 (C=O) and 1600 cm^{-1} (aromatic); nmr ($CDCl_3$) δ: 0.85 (s, 3, C-1 CH_3), 0.88 (s, 6, *gem*-dimethyl), 1.15 (s, 3, C-4a CH_3), 3.42 (d, 2, J = 4 Hz, C-9 CH_2), 3.78 (s, 3, —OCH_3), 3.83 (s, 4, —OCH_2—CH_2—O), 5.80 (t, 1, J = 4 Hz, C-10 H), and 6.67–7.33 (m, 3, ArH); ms *m/e* (relative intensity): 466 (14), 451 (7), 395 (21), 183 (100). *Anal.* calcd. for $C_{30}H_{42}O$: C 77.21, H 9.07; found: C 77.28, H 9.04.

*2-Keto-1β,4aβ-dimethyl-1α-[2-(3-keto-1,4,4-trimethylcyclohexyl)ethyl]-7-methoxy-1,2,3,4,4a,9-hexahydrophenanthrene (**4**b)*

A solution of ketals **4***a* (4.58 g, 9.82 mmol) in methanol (100 ml) and 5% oxalic acid (enough to make the solution slightly turbid) was refluxed for 2 h. Water was added and the mixture extracted with ether (×3). The ether layer was washed with saturated solution of sodium bicarbonate, then water, and was dried over anhydrous sodium sulphate. Evaporation of the ether under reduced pressure gave a red oil. The oil was dissolved in 20 ml methanol and placed in the refrigerator overnight. The yellow crystals formed were isolated by filtration to give 2.7 g (65%) of the diketones **4***b*: mp 106–112°C; ir (Nujol): 1700 (C=O) and 1610 cm^{-1} (aromatic); nmr ($CDCl_3$) δ: 0.80 (s, 3, C-1′ CH_3), 0.98 (s, 3, C-4′ CH_3), 1.04 (s, 3, C-4′

*Thermal factor exp $[-2\pi^2(U_{11}a^{*2}h^2 + \text{-------} + 2U_{23}b^*c^*kl + \text{-----} + \text{---})]$.

CH_3), 1.18 (s, 3, C-1 CH_3), 1.32 (s, 3, C-4a CH_3), 3.45 (d, 2, J = 4 Hz, C-9 CH_2), 3.84 (s, 3, OCH_3), 5.86 (t, 1, J = 4 Hz, C-10 H), and 6.60–7.40 (m, 3, ArH); nmr (C_6D_6) δ: 0.62 (s, 3, C-1′ CH_3), 0.88 (s, 3, C-4′ CH_3), 0.94 (s, 3, C-4′ CH_3), 1.06 (s, 3, C-1 CH_3), 1.41 (s, 3, C-4a CH_3), 3.24 (d, 2, J = 4 Hz, C-9 CH_2), 3.41 (s, 3, OCH_3), 5.68 (t, 1, J = 4 Hz, C-10 H), and 6.60–7.20 (m, 3, ArH); ms *m/e* (relative intensity): 422 (10), 389 (45), 256 (100). *Anal.* calcd. for $C_{28}H_{38}O_3$: C 79.57, H 9.06; found: C 79.37, H 9.07.

Jones' Oxidation of the Diones 4b

The pair of diastereoisomers, 4*b*, (50 mg) was dissolved in acetone (5 ml) and cooled in an ice-bath. Jones' reagent was added dropwise until an orange colour persisted. There was a green precipitate of chromous salt formed. After stirring for 1 h, water was added and the organic material extracted with ether (× 3). The ether layer was washed with water, saturated brine and dried ($MgSO_4$). Evaporation of the solvent gave 45 mg (90%) of the triones **8**. Two recrystallizations from methanol gave an analytical sample: mp 160–170°C; uv max (95% C_2H_5OH): 362 (10 900), 332 (2300), 224 (18 500), 212 nm (8200); ir (CH_2Cl_2): 1700 (C=O), and 1650 (C=O), 1605 cm^{-1} (aromatic, olefinic); nmr ($CDCl_3$) δ: 0.83 (s, 3, C-1′ CH_3), 1.03 (s, 6, *gem*-dimethyl), 1.37 (s, 3, C-1 CH_3), 1.43 (s, 3, C-4a CH_3), 3.90 (s, 3, O—CH_3), 6.50 (s, 1, C-10 H), 7.00–7.70 (m, 3, ArH); nmr (C_6D_6) δ: 0.62 (s, 3, C-1′ CH_3), 0.88, 0.97 (2 s, 3 each, C-4′ *gem*-dimethyl), 1.00 (s, 6, C-1 and C-4′ CH_3), 1.40 (s, 3, C-4a CH_3), 3.42 (s, 3, OCH_3), 6.55 (s, 1, C-10 H), and 6.71–8.00 (m, 3, ArH); ms *m/e* (relative intensity): 436 (100), 380 (80), 270 (65), 255 (70). *Anal.* calcd. for $C_{28}H_{36}O_3$: C 77.03, H 8.31; found: C 77.04, H 8.28.

The isomer *4b (C-1′ methyl α)* was similarly treated with Jones' reagent as above to give the trione ***8** (C-1′ methyl α)* in 93% yield: mp 183–185°C; ir (CH_2Cl_2): 1700 (C=O), 1650 (C=O), and 1605 cm^{-1} (aromatic, olefin); nmr (C_6D_6) δ: 0.58 (s, 3, C-1′ CH_3), 0.97, 0.98 (2 s, 3 each, C-4′ *gem*-dimethyl), 0.97 (s, 3, C-1 CH_3), 1.33 (s, 3, C-4a CH_3), 3.47 (s, 3, O—CH_3), 6.63 (s, 1, C-10 H), and 6.66–8.00 (m, 3, ArH); nmr ($CDCl_3$) δ: 0.86 (s, 3, C-1′ CH_3), 1.06 (s, 6, *gem*-dimethyl), 1.36 (s, 3, C-1 CH_3), 1.43 (s, 3, C-4a CH_3), 3.90 (s, 3, O—CH_3), 6.47 (s, 1, C-10 H), and 7.00–7.67 (m, 3, ArH); ms *m/e* (relative intensity) 436 (100), 380 (80), 270 (65), 255 (70). *Anal.* calcd. for $C_{28}H_{36}O_3$: C 77.03, H 8.31; found: C 77.15, H 8.29.

Attempted Cyclizations of Diones 4b

A solution of 1.06 g (2.51 mmol) diones **4***b* in 60 ml dimethoxyethane (DME) under an argon sweep, was cooled in a Dry Ice – acetone bath and 14.5 ml of 1.1 *M* (15.95 mmol) *tert*-butylmagnesium chloride in THF was added through a septum by the aid of a syringe. The mixture was stirred for 1 h during which time a white precipitate was formed. This was then refluxed for 1 h and the solution became clear. The mixture was cooled and poured into a beaker containing ice and ammonium chloride (solid). This was extracted with ether (× 3) and the ether layer was washed with water, saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. Evaporation of the solvent gave an oil which, as shown by analytical thin-layer chromatography, contained two products. The mixture was separated by column chromatography using grade III aluminum oxide. Elution with petroleum ether gave compound *4*b *(C-1′ methyl α)* which corresponded to one of the starting diastereoisomers (75% recovery after recrystallization) and elution with 50% petroleum ether in benzene gave the new compound which was found to be the reduced product **9**, mp 133–135°C, 78.8% yield (based on one diastereoisomer). Two further recrystallizations afforded an analytical sample: ir (Nujol): 3450 (OH), 1700 (C=O), and 1605 cm^{-1} (aromatic, olefin); nmr ($CDCl_3$) δ: 0.78, 0.81 (2 s, 3 each, *gem*-dimethyl), 0.97 (s, 3, C-1′ CH_3), 1.23 (s, 3, C-1 CH_3), 1.33 (s, 3, C-4a CH_3), 3.43 (d, 2, J = 4 Hz, C-10 H), 3.40 (d of d, 1, J = 12 and 6 Hz, C-3′ H), 3.80 (s, 3, O—CH_3), 5.90 (t, 1, J = 4 Hz, C-9 H), and 6.67–7.43 (m, 3, ArH); nmr (C_6D_6) δ: 0.70, 0.75 (2 s, 3 each, *gem*-dimethyl), 0.97 (s, 3, C-1′ CH_3), 1.08 (s, 3, C-1 CH_3), 1.43 (s, 3, C-4a CH_3), 3.20 (d, 2, J = 4 Hz, C-9 H), 3.40 (s, 3, O—CH_3), 5.70 (t, 1, J = 4 Hz, C-10 H), and 6.53–7.33 (m, 3 ArH); ms *m/e* (relative intensity): 424 (10), 411 (14), 391 (50), 255 (100). *Anal.* calcd. for $C_{28}H_{40}O_3$: C 79.20, H 9.50; found: C 79.40, H 9.29.

Compound *4*b *(C-1′ methyl α)*: mp 118–122°C; ir: 1700 (C=O) and 1605 cm^{-1} (aromatic, olefin); nmr in $CDCl_3$ and C_6D_6 are identical to that of the mixture of diastereoisomers 4*b*; ms *m/e* (relative intensity): 422 (10), 389 (45), 256 (100). *Anal.* calcd. for $C_{28}H_{38}O_3$: C 79.57, H 9.06; found: C 79.35, H 9.11.

*Hydrogenation of 2-Keto-1,4a-dimethyl-1-[3-keto-1,4,4-trimethylcyclohexylethyl]-7-methoxy-1,2,3,4,4a,9-hexahydrophenanthrene (*4b)

A suspension of 500 mg of 10% palladium-on-charcoal in 15 ml *p*-xylene was hydrogenated at room temperature and atmospheric pressure for 4 h. Olefinic diketones 4*b* (1 g) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

10 ml *p*-xylene were added and hydrogenated at atmospheric pressure at 140°C for 18 h. The solution was filtered and the *p*-xylene evaporated under reduced pressure. The resulting clear oil was dissolved in methanol and allowed to stand overnight during which time it crystallized to give 600 mg (60%) of the hydrogenated product **12**, mp 108–112°C. Two recrystallizations of a portion gave an analytical sample: mp 117–120°C; ir (Nujol): 1700 (C=O) and 1605 cm^{-1} (aromatic, olefin); nmr ($CDCl_3$) δ: 0.87 (s, 3, C-1′ CH_3), 1.08 (s, 3, C-4′ CH_3), 1.12 (s, 6, C-1, C-4′ CH_3), 1.26 (s, 8, C-4a CH_3), 3.78 (s, 3, —O—CH_3), 6.58 (d, 1, J = 3 Hz (*m*), ArC-8 H), 6.72 (d of d, 1, J = 9 (*o*) and 3 Hz (*m*), ArC-6 H), and 7.26 (d, 1, J = 9 Hz (*o*) ArC-5 H); nmr (C_6D_6) δ: 0.75 (s, 3, C-1′ CH_3), 0.86 (s, 3, C-4′ CH_3), 1.04 (s, 6, C-1, C-4′ CH_3), 1.09 (s, 3, C-4a CH_3), 3.42 (s, 3, O-CH_3), 6.56 (d, 1, J = 3 Hz (*m*) ArC-8 H), 6.74 (d of d, 1, J = 9 (*o*) and 3 Hz (*m*), ArC-6 H), and 6.96 (d, 1, J = 9 Hz (*o*) ArC-5 H); ms *m/e* (relative intensity): 424 (100), 409 (70), 391 (10), 367 (5), 258 (26), 243 (24). *Anal.* calcd. for $C_{28}H_{40}O_3$: C 79.20, H 9.50; found: C 79.24, H 9.59.

2-(3-Ethylenedioxy-1,4,4-trimethylcyclohexyl)malononitrile

Dicyanide **7** (6) (10 g, 0.049 mol) was dissolved in 400 ml benzene containing 15 ml ethylene glycol and 200 mg *p*-toluenesulfonic acid. This solution was refluxed for 24 h. The benzene layer was separated, washed with water, then with saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. After rotary evaporation of the solvent the product crystallized. Recrystallization from hexane yielded 11 g (90%) of the ketal: mp 91–93°C; ir (Nujol): 2250 cm^{-1} (C≡N), no carbonyl absorption; nmr ($CDCl_3$) δ: 0.90, 1.03 (2 s, 3 each, *gem*-dimethyl), 1.60 (s, 3, C-1 CH_3), 3.97 (s, 4, —O—CH_2—CH_2—O—), and 4.73 (s, 1, —$CH(CN)_2$). M^+ calcd. for $C_{14}H_{20}O_2N_2$: 248.1825; found: 248.1832.

2-(3-Ethylenedioxy-1,4,4-trimethylcyclohexyl)ethanoic Acid

A mixture of the above ketal dicyanide (14 g, 0.056 mol), ethylene glycol (32 ml) and potassium hydroxide (50 g, 0.893 mol) in 25 ml water was refluxed for 48 h. The reaction mixture was cooled to room temperature, acidified with cold 3 *N* H_2SO_4 (p*H* 4) and extracted twice with ether. The ether layer was washed with water, saturated sodium chloride, and dried over anhydrous magnesium sulphate. After evaporation of the solvent the crude diacid was decarboxylated by heating at 140–145°C (oil bath) during 2½ h. The nuclear magnetic resonance spectrum of this oil showed that the product had been deketalized. The oil was taken up in benzene; *p*-toluenesulfonic acid (200 mg) and ethylene glycol (15 ml) were added and the mixture refluxed overnight through a Dean–Stark trap. Separation of the benzene layer followed by washing with water, drying ($MgSO_4$), and rotary evaporation of the solvent gave 13.79 g (98%) of the monoacid as an oil. M^+ calcd. for $C_{13}H_{22}O_4$: 242.1518; found (mass spectrum): 242.1457.

2-(3-Ethylenedioxy-1,4,4-trimethylcyclohexyl)ethanol

To a suspension of 6.4 g (0.168 mol) of lithium aluminum hydride in dry diethyl ether (250 ml) was added dropwise 17.2 g (0.071 mol) of the above ketal acid. After completion of addition the mixture was refluxed overnight. The mixture was cooled to ice bath temperature and the excess lithium aluminum hydride was decomposed by careful addition of a saturated solution of Rochelle salt. The ether layer was separated and the aqueous layer extracted twice with ether. The combined ether layer was washed with water, saturated sodium chloride, and dried ($MgSO_4$). Evaporation of the solvent gave 11.8 g of the alcohol which was used in the next reaction without further purification: ir (neat): 3350 cm^{-1} (OH) and no carbonyl absorption; nmr ($CDCl_3$) δ: 0.93 (s, 6, *gem*-dimethyl), 0.98 (s, 3, C-1 CH_3), 3.70 (t, 2, J = 7 Hz, CH_2OH), and 3.92 (s, 4, —O—CH_2—CH_2—O—). M^+ calcd. for $C_{13}H_{24}O_3$: 228.1725; found (mass spectrum): 228.1784.

2-(3-Ethylenedioxy-1,4,4-trimethylcyclohexyl)ethanol Tosylate (3)

The above ketal alcohol (20 g, 0.088 mol) was dissolved in 200 ml dry pyridine and this was cooled in an ice bath. *p*-Toluenesulfonylchloride (purified by recrystallization) (25.5 g, 0.134 mol) was added to the mixture and stirred until dissolved. The reaction mixture was left in the refrigerator overnight. Water was added and the crystals formed (34 g) were collected by filtration. Recrystallization from ether gave 23 g (69%) of pure tosylate **3**: mp 100–104°C; ir (Nujol): 1590 cm^{-1} (aromatic), no carbonyl or hydroxyl absorption; nmr ($CDCl_3$) δ: 0.88 (s, 3, C-1 CH_3), 0.92 (s, 6, *gem*-dimethyl), 2.43 (s, 3, Ar CH_3), 3.83 (s, 4, —O—CH_2—CH_2—O—), 4.08 (t, 2, J = 7 Hz, CH_2—OTs), 7.30 (d, 2, J = 8 Hz, ArH), and 7.75 (d, 2, J = 8 Hz, ArH). *Anal.* calcd. for $C_{20}H_{30}O_5S$ (M^+ 382): C 62.87, H 7.85, O 58.39; found (M^+ 382): C 62.88, H 7.75, O 58.27.

Oxidation of 2-Keto-1β,4aβ-dimethyl-1-(3α-hydroxy-1,4,4-trimethylcyclohexylethyl)-7-methoxy-1,2,3,4,4a,9-hexahydrophenanthrene (9)

Alcohol **9** (50 mg, 0.12 mmol) was dissolved in acetone (5 ml) and cooled in an ice bath. Jones' reagent was added dropwise until a yellow colour persisted. A green precipitate of the chromous salt was formed. After stirring for 1 h at room temperature, water was added and the organic layer extracted with ether (×3). The ether extract was washed with water, saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. Evaporation of the solvent under reduced pressure gave an oil which was crystallized from ether to give 45 mg (90%) of trione **8** (C-1′ methyl β), mp 152–154°C. Two recrystallizations furnished an analytical sample: mp 182–183°C; uv max: 362 (10 900), 332 (2300), 224 (18 500), and 212 nm (8200); ir (CH_2Cl_2): 1700 (C=O), 1650 (C=O), and 1605 cm^{-1} (aromatic, olefin); nmr ($CDCl_3$) δ: 0.80 (s, 3, C-1′ CH_3), 1.03 (s, 6, *gem*-dimethyl), 1.37 (s, 3, C-1 CH_3), 1.43 (s, 3, C-4a CH_3), 1.43 (s, 3, C-4a CH_3), 3.90 (s, 3, OCH_3), 6.47 (s, 1, C-10 H), and 7.33–7.67 (m, 3, ArH); nmr (C_6D_6) δ: 0.57 (s, 3, C-1′ CH_3), 0.86, 0.93 (2 s, 3 each, *gem*-dimethyl), 0.96 (s, 3, C-1 CH_3), 1.30 (s, 3, C-4a CH_3), 3.33 (s, 3, O—CH_3), and 6.66–8.00 (m, 3, ArH). *Anal.* calcd. for $C_{28}H_{36}O_3$ (M^+ 436): C 77.03, H 8.31; found (M^+ 436): C 77.08, H 8.25.

10-Methoxy-2,2,4aβ,6aβ,12bβ-pentamethyl-1,2,3,4,4a,5,6,6a,6bα,7,8,12b,13,14-tetradecahydro-1-picenone (12)

A solution of 200 mg of diketones **11** and 200 mg of *p*-toluenesulfonic acid in 20 ml *p*-xylene under an atmosphere of nitrogen was refluxed for 16 h. Water was added and the benzene layer separated. The aqueous layer was extracted (×2) with ether. The combined extracts were washed with water, saturated sodium chloride solution, and dried over magnesium sulphate (anhydrous). Evaporation of the solvent gave an oil which was chromatographed on silica gel using increasing concentrations of ether in benzene as eluent. The major fraction (100 mg) was crystallized from methanol to give the pentacyclic ketone **12**, mp 145–150°C (45 mg, 47%). Two recrystallizations of a portion gave an analytical sample: mp 156–158°C; ir (neat): 1684 (C=O) and 1625, 1605 cm^{-1} (aromatic, olefinic); nmr ($CDCl_3$) δ: 0.98 (s, 3, C-4a CH_3), 1.04 (s, 3, C-2 CH_3), 1.08 (s, 3, C-2 CH_3), 1.12 (s, 3, C-6a CH_3), 1.31 (s, 3, C-12b CH_3), 3.78 (s, 3, O—CH_3), 7.56 (d, 1, J = 3 Hz (*m*), ArC-9 H), 7.68 (d of d, 1, J = 9 (*o*) and 3 Hz (*m*), ArC-11 H), and 7.70 (d, 1, J = 9 Hz (*o*), ArC-12 H); nmr (C_6D_6) δ: 0.92 (s, 6, C-4a and C-12 CH_3), 1.00 (s, 3, C-6a CH_3), 1.21 (s, 5, C-12 and C-12b CH_3), 3.42 (s, 3, —OCH_3), 6.60 (d, 1, J = 3 Hz (*m*), ArC-9 H), 6.70 (d of d, 1, J = 9 (*o*) and 3 Hz (*m*), ArC-11 H), and 7.03 (d, 1, J = 9 Hz (*o*), ArC-12 H); ms *m/e* (relative intensity): 406 (42), 187 (100). *Anal.* calcd. for $C_{28}H_{38}O_2$: C 82.71, H 9.42; found: C 82.66, H 9.48.

*1,2,3,4,4a,9-Hexahydro-7-methoxy-1α-[2-(3-ethylenedioxy-1-methylcyclohexyl)ethyl]-1β-dimethyl-2(1H)-phenanthrone (**14**a)*

A mixture of potassium metal (810 mg, 20.78 mmol), *tert*-pentyl alcohol (4 ml), and dry benzene (80 ml) was refluxed (4 h) under a nitrogen atmosphere to give a solution of potassium *tert*-pentoxide. The tricyclic ketone **2** (5 g, 19.53 mmol) was added to the cooled solution and while fresh benzene was being added, the reaction mixture was heated for 5 h to distill off a mixture of benzene – *tert*-pentyl alcohol. The resulting green-brown suspension of the potassium salt of **2** was cooled to room temperature and the tosylate **13** (solid) (6.67 g, 18.84 mmol) was added. The mixture was refluxed for 2 h and then stirred at room temperature overnight. The greenish black syrupy mixture was poured into an ice–water mixture (250 ml) and acidified with 2 *N* H_2SO_4. The organic material was extracted with ether (×3), washed with saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. Evaporation of the solvent gave a yellow oil which solidified on standing. Recrystallization of this solid from methanol yielded light yellow crystals (4.5 g, 53%), mp 88–97°C. Two more recrystallizations provided an analytical sample of the diastereoisomers **14***a*: ir (Nujol): 1700 cm^{-1} (C=O); nmr ($CDCl_3$) δ: 0.86 (s, 3, C-1′ CH_3), 1.16 (s, 3, C-1 CH_3), 1.33 (s, 3, C-1 CH_3), 1.33 (s, 3, C-4a CH_3), 3.47 (d, 2, J = 4 Hz, C-9 H), 3.80 (s, 3, O—CH_3), 5.86 (d, 1, J = 4 Hz, C-10 H), and 6.78–7.43 (m, 3, ArH); nmr (C_6D_6) δ: 0.90 (s, 3, C-1′ CH_3), 1.08 (s, 3, C-1 CH_3), 1.47 (s, 3, C-4a CH_3), 3.23 (d, 2, J = 4 Hz, C-9 H), 3.43 (s, 3, O—CH_3), 3.50, 3.53 (2 s, 4, —OCH_2—CH_2—O—), 5.70 (t, I, J = 4 Hz, C-10 H), and 6.57–7.23 (m, 3, ArH); ms *m/e* (relative intensity): 438 (31), 423 (57), 361 (25), 255 (100). *Anal.* calcd. for $C_{28}H_{38}O_4$: C 76.68, H 8.73; found (M^+ 438): C 76.54, H 8.70.

*3,4,4a,9-Tetrahydro-7-methoxy-1α-[2-(3-keto-1-methylcyclohexyl)ethyl]-1β,4aβ-dimethyl-2(1H)-phenanthrone (**14**b)*

The keto ketals **14***a* (1 g) were dissolved in 25 ml methanol and were heated to near boiling point. A solution of oxalic acid (5%) was added until the mixture was slightly cloudy. This mixture was refluxed for 2.5 h and water was added and the methanol was evaporated under reduced pressure. The aqueous layer was extracted with ether (×3). The ether extract was washed with saturated sodium bicarbonate solution, water and saturated sodium chloride solution and dried over anhydrous magnesium sulphate. Evaporation of the solvent gave an oil (749 mg, 83%) which appeared homogeneous by thin-layer chromatography. Crystallization from methanol gave light yellow crystals, mp 105–109°C. Two recrystallizations from methanol afforded an analytical sample: mp 117–120°C; ir (Nujol): 1700 (C=O) and 1605 cm^{-1} (aromatic, olefinic); nmr ($CDCl_3$) δ: 0.83 (s, 3, C-1′ CH_3), 1.18 (s, 3, C-1 CH_3), 1.13 (s, 3, C-4a CH_3), 3.43 (d, 2, J = 4 Hz, C-9 H), 3.82 (s, 3, OCH_3), 5.88 (t, 1, J = 4 Hz, C-10 H), and 6.73–7.38 (m, 3, ArH); nmr (C_6D_6) δ: 0.63 (s, 3, C-1′ CH_3), 1.07 (s, 3, C-1 CH_3), 1.37 (s, 3, C-4a CH_3), 3.27 (d, 2, J = 4 Hz, C-9 H), 3.47 (s, 3, —O—CH_3), 5.72 (t, 1, J = 4 Hz, C-10 H), and 6.67–7.10 (m, 3, ArH); ms *m/e* (relative intensity): 394 (10), 379 (10), 361 (22), 255 (100). *Anal.* calcd. for $C_{26}H_{34}O_4$: C 79.15, H 8.69; found: C 79.17, H 8.55.

*3,4,4a,9,10aα-Hexahydro-7-methoxy-1α-[2-(3-keto-1-methylcyclohexyl)ethyl]-1β,4aβ-dimethyl-2(1H)-phenanthrone (**15**)*

A suspension of 200 mg of 10% palladium-on-charcoal in 10 ml *p*-xylene was hydrogenated for 2 h at room temperature and atmospheric pressure. The olefinic diketones **14***b* (300 mg) in 10 ml *p*-xylene were added to the suspension of catalyst and the mixture hydrogenated at 140°C and atmospheric pressure for 18 h. The reaction mixture was filtered and the *p*-xylene evaporated under reduced pressure to give an oil (180 mg) homogeneous by thin-layer chromatography. Attempts to induce crystallization failed: ir (neat): 1700 cm^{-1} (C=O); nmr ($CDCl_3$) δ: 0.83 (s, 3, C-1′ CH_3), 1.03 (s, 3, C-1 CH_3), 1.18 (s, 3, C-4a CH_3), 3.70 (s, 3, OCH_3), and 6.50–7.27 (m, 3, ArH); ms *m/e*: 396 (M^+).

3-Methyl-3-vinylcyclohexanone

Copper(I) iodide (3.81 g, 0.02 mol) was suspended in 75 ml of dry ether in a 250 ml three-necked, round-bottomed flask under argon. This suspension was stirred and cooled to −90°C in a Dry Ice – ether bath. Vinyl lithium (18 ml of 2.2 *M* solution, 0.04 mol) was added. The mixture became viscous and yellow. After stirring for 15 min at −90°C, 3-methyl-2-cyclohexenone (3.3 g, 0.03 mol) was added during 5 min. The mixture was stirred for another 5 min and was then quenched with excess methanol. The organic material was extracted three times, each with 50 ml ether, and the combined ether extract was washed successively with water, 5% ammonium hydroxide solution, water, saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. After filtering off the magnesium sulphate, the ether was evaporated under reduced pressure to give an oil. This crude oil was distilled to yield 3.5 g (88%) of the product: bp 40–46°C/0.8 Torr; ir (neat): 1710 (C=O) and 1640, 990 cm^{-1} (—CH=CH_2). M^+ calcd. for $C_9H_{14}O$: 138; found (mass spectrum): 138.

1-Ethylenedioxy-3-methyl-3-vinylcyclohexane

3-Methyl-3-vinylcyclohexanone (13.2 g) was dissolved in 150 ml benzene. Ethylene glycol (10 ml) (excess) and *p*-toluenesulfonic acid (300 mg) were added and the mixture refluxed for 18 h while stirring vigorously. A Dean–Stark trap was used to separate the water formed. After the mixture was cooled, water was added, and the benzene layer was separated. The water layer was extracted with ether (×2) and the benzene and ether extracts were pooled together and washed with water, saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. After removal of the magnesium sulphate by filtration the solvents were distilled at the rotary pump to give an oil. Distillation gave the product in 79% yield: bp 35°C/0.1 Torr; ir (neat): 1635 (C=C), 1065, 1090, 1150, 1180 cm^{-1} (ketal group); nmr ($CDCl_3$) δ: 1.10 (s, 3, CH_3), 3.90 (s, 4, —O—CH_2—CH_2—O—), 5.97 (d of d, 1, J = 18 and 10 Hz, —CH=CH_2), and 4.90 (m, 2, —CH=CH_2); ms *m/e*: 182 (M^+). *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95, M^+ 182; found: C 72.56, H 10.06.

2-(3-Ethylenedioxy-1-methylcyclohexyl)ethanol

Disiamylborane was prepared by the method of Brown and co-workers (20). A mixture of sodium borohydride (2.13 g, 0.056 mol) and 2-methyl-2-butene (15.3 ml, 10.2 g, 0.145 mol) in freshly distilled tetrahydrofuran (75 ml) was cooled in an ice bath under a nitrogen atmosphere. Boron trifluoride etherate (9 ml, 10.1 g, 0.07 mol) was added dropwise over a period of 30 min and left stirring for 90 min at 0°C. To this mixture was added the 1-ethylenedioxy-3-methyl-3-vinylcyclohexane (1.47 g, 0.008 mol) very quickly and left to warm to room temperature. After 3 h the flask was cooled in an ice bath and 30.1 ml of 3 *N* NaOH was added followed by 20.0 ml 30% H_2O_2 (cautiously). The tetrahydrofuran was evaporated and the resulting mixture extracted with ether. The ether layer was washed with water, then with saturated sodium chloride solution, and dried over anhydrous magnesium sulphate. After removal of the magnesium sulphate by filtration, the solvent was evaporated under reduced pressure to give an oil which was distilled to yield 0.95 g (58%) of the alcohol: bp 80–85°C/0.01 Torr; ir (neat): 3420 cm^{-1} (OH); nmr ($CDCl_3$) δ: 0.95 (s, 3, CH_3), 3.90 (s, 4, —O—CH_2—CH_2—O—), and 3.67 (t, 2, J = 7 Hz, CH_2—OH); ms *m/e*: 200 (M^+). *Anal.* calcd. for $C_{11}H_{20}O_3$: C 65.97, H 10.07; found: C 65.99, H 10.17.

2-(3-Ethylenedioxy-1-methylcyclohexyl)ethanol Tosylate (13)

2-(3-Ethylenedioxy-1-methylcyclohexyl)ethanol (10 g, 0.05 mol) was dissolved in 100 ml dry, distilled pyridine and cooled in an ice bath. Solid *p*-toluenesulfonyl chloride (11.2 g, 0.059 mol) was added and the mixture left in the refrigerator overnight. Water was added to this mixture and the crystals formed were collected by filtration (79%). The crude crystals were recrystallized twice from ether to give an analytical sample: mp 66–68°C; ir (Nujol): no hydroxyl or carbonyl absorption, 1590, 1450 cm^{-1} (aromatic); nmr ($CDCl_3$) δ: 1.00 (s, 3, CH_3), 2.53 (s, 3, Ar CH_3), 3.92 (s, 4, —O—CH_2—CH_2—O—), 4.17 (t, 2, J = 7 Hz, CH_2—OTs), 7.43 (d, 2, J = 8 Hz, ArH), and 7.90 (d, 2, J = 8 Hz, ArH); ms *m/e*: 354 (M^+). *Anal.* calcd. for $C_{18}H_{26}O_5S$: C 60.99, H 7.39, S 9.05; M^+ 354; found: C 61.08, H 7.28, S 9.17.

X-ray Data Collection

Compound **12** crystallized from methanol as colourless laths elongated along a^*. The specimen used for data collection was cut to approximate dimensions 0.5 × 0.3 × 0.5 mm, and was mounted with b^* as rotation axis. Crystal data are as follows.

$C_{28}H_{38}O_2$ fw = 406.6
Monoclinic, a = 6.456(2), b = 42.518(6), c = 8.519(2) Å, β = 100.92(3)° (based on λ(CuKα$_1$) = 1.54051 and λ(CuKα$_2$) = 1.54433 Å), V = 2296.1 Å^3. Z = 4, ρ_c = 1.176 g cm^{-3}, space group $P2_1/c$, μ(CuKα) = 5.59 cm^{-1}.

Intensity data were measured with a Picker four-circle diffractometer in the θ/2θ scan mode using scan ranges of 2–3° and a (2θ) scan speed of 2°/min. All measurements were made at room temperature with Ni-filtered Cu radiation. The intensity of a check reflection, monitored at intervals of about 30 reflections, showed only small random fluctuations, and these measurements were used to place all the intensities on a single (arbitrary) scale. All 3908 accessible (2θ ≤ 130°) independent reflections in the *hkl* and $\bar{h}kl$ octants were measured, and of these, 3234 were considered as observed. The remainder, with net counts less than 12 or less than $\frac{1}{10}$ of the total background, were excluded from the least-squares refinement. Structure-factor amplitudes were obtained after applying Lorentz and polarization corrections, and an extinction correction was applied at a later stage. Absorption corrections were considered unnecessary (μ = 5.6 cm^{-1}).

Structure Determination and Refinement

The structure was determined by the symbolic addition procedure, and refinement was by block-diagonal least-squares minimizing $\Sigma w(|F_o| - |F_c|)^2$. The weighting scheme used in the final stages of refinement was of the form:

$$w = w_1 \times w_2$$

where

$$w_1 = 1 \Big/ \left[1 + \left(\frac{F_o - 11.0}{8.0}\right)^2\right]$$

$$1.7 < F_o < 194$$

and $w_2 = 4 \sin^2\theta$ if $\sin^2\theta < 0.25$, otherwise $w_2 = 1$. Hydrogen atoms were all located on a difference map and were subsequently refined isotropically while nonhydrogen atoms were refined anisotropically. Scattering factor values for oxygen and carbon atoms were taken from Hanson *et al.* (15) and for hydrogen from Stewart *et al.* (16). In the final least-squares cycle the mean (shift/estimated standard deviation) was 0.08 and the largest shift was 0.38 σ. The final R value for all 3234 observed reflections was 0.042. A final difference – Fourier map showed no significant features. Computer programs used in the analysis were those of Ahmed *et al.* (17) and Johnson (18).

Received January 30, 1978

JOHN W. APSIMON, SATYANAND BADRIPERSAUD, MICHAEL L. POST, and ERIC J. GABE. Can. J. Chem. **56**, 2150 (1978).

The reaction of 2-keto-1β,4aβ-dimethyl-1α-[2-(3-keto-1,4,4-trimethylcyclohexyl)ethyl]-7-methoxy-1,2,3,4,4a,9-hexahydrophenanthrene **1***a* and *b* with *p*-toluenesulphonic acid in boiling xylene yields the rearranged product, 1,10-dimethyl-2-[2-(3-keto-1,4,4-trimethylcyclohexyl)-ethyl]-7-methoxy-3,4-dihydroanthracene (**3**). Crystals of **3** are monoclinic, space group $P2_1/c$, $Z = 4$, with $a = 7.2684(3)$, $b = 30.942(2)$, $c = 10.5544(7)$ Å, $\beta = 98.24(1)°$. The structure was determined by direct methods from diffractometer data and refined by block-diagonal least-squares to an R of 0.043 for 1810 observed reflections. The molecule exhibits no unusual geometric features, although positional disorder is apparent in the cyclohexanone moiety.

A possible route for the formation of **3** from **1***a* and *b* is presented.

JOHN W. APSIMON, SATYANAND BADRIPERSAUD, MICHAEL L. POST et ERIC J. GABE. Can. J. Chem. **56**, 2150 (1978).

La réaction de l'oxo-2 diméthyl-1β,4aβ [(oxo-3 triméthyl-1,4,4 cyclohexyl)-2 éthyl]-1α méthoxy-7 hexahydro-1,2,3,4,4a,9 phénanthrène (**1***a* et *b*) avec l'acide *p*-toluènesulfonique dans le xylène à l'ébullition conduit au diméthyl-1,10 [(oxo-3 triméthyl-1,4,4 cyclohexyl)-2 éthyl]-2 méthoxy-7 dihydro-3,4 anthracène (**3**), un produit de réarrangement. Les cristaux de **3** sont monocliniques, groupe d'espace $P2_1/c$, $Z = 4$ avec $a = 7.2684(3)$, $b = 30.942(2)$, $c = 10.5544(7)$ Å, $\beta = 98.24(1)°$. On a déterminé la structure par des méthodes directes à partir de données de diffraction de rayon X et on l'a affinée par la méthode des moindres carrés (blocs diagonaux) jusqu'à une valeur de R de 0.043 pour 1810 réflexions observées. La molécule ne présente aucune caractéristique géométrique inhabituelle quoique le désordre de position est apparent dans la portion de la cyclohexanone.

On présente une route possible permettant d'expliquer la formation de **3** à partir de **1***a* et *b*.
[Traduit par le journal]

In the previous paper (1) we described the synthesis of the mixture of substituted reduced phenanthrenes **1***a* and *b* and its conversion into the pentacyclic picenone **2** suitable as an intermediate in triterpene synthesis.

During our studies we noted that the reaction of a mixture of **1***a* and *b* with *p*-toluenesulphonic acid in boiling xylene or benzene gave, after chromatography, a product whose physical properties did not correspond to those expected for a normal cyclisation product of **1***a* and *b* although its molecular weight

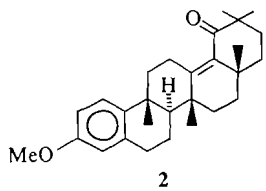
a Me group α
b Me group β



2

(M^+ 404) corresponded to the loss of one molecule of water from **1***a* or **1***b* (M^+ 422). Thus the mass spectrum of the cyclisation product showed a parent ion at *m/e* 404.2717 corresponding to a molecular formula of $C_{28}H_{36}O_2$ and a base peak at *m/e* 237.1264 corresponding to a fragment of structure $C_{17}H_{17}O$. This loss of a fragment $C_{11}H_{19}O$ (mol. wt. 167) suggested that the pendant trimethyl cyclo-

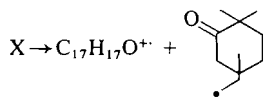
22,23,24	24.8, 25.4 (2)	—C—CH_3	3	9	
		Total	C = 28	H = 36	O = 2

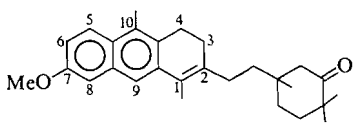
*Carbon locations assigned as shown in Fig. 1.

hexanone ring had been lost together with its side chain:



This behaviour is reminiscent of that observed for species such as **1***a* and *b* but not identical since in this latter case a McLafferty-type hydrogen rearrangement (1) is noted.

The 100 MHz proton magnetic resonance spectrum of the product 'X' indicated retention of the phenolic methyl ether system and the presence of two low field methyl groups, present as olefinic or aromatic substituents. The triplet for the olefinic proton appearing at δ 5.86 in the nmr spectrum of **11** was noted to be shifted downfield to δ 7.50 probably attributable to an isolated aromatic proton. The 25.15 MHz carbon-13 nmr spectrum indicated the presence of one carbonyl group (215.7 ppm) as well as eight sp^2 fully substituted carbon atoms. Table 1 summarises the carbon ^{13}C nmr spectrum. A single crystal X-ray structure determination was carried out on this material and revealed its structure to be the dihydroanthracene **3**. All of the spectroscopic properties (see Experimental) accord with this structure.



3

A view of the molecule as determined by X-ray diffraction is shown in Fig. 1 and final atomic coordinates and bond lengths and angles for the non-hydrogen atoms are presented in Tables 2 and 3. Full details concerning the H atoms and their bonding geometry have been placed in the Depository of Unpublished Data.[4] The average of all C—H bond lengths is 0.97 Å while that for associated angles is 109° (sp^3) and 119° (sp^2). The geometric features of the molecule show no remarkable deviation from those expected. Thus, the aromatic portion of the anthracene moiety is close to planar (±0.036 Å) and the fused cyclohexene ring, with torsion angles C(1a)—C(1)—C(2)—C(3) and C(1)—C(1a)—C(4a)—C(4) $< \pm 1°$, has a conformation best described as midway between a 'sofa' and a 'boat'. The extended dimethylene bridge, with torsion angles C(1)—C(2)—C(14)—C(15) and C(2)—C(14)—C(15)—C(16) of 95 and 176°, links to the trimethylcyclohexanone ring which is in 'chair' form. The intra-ring bond angle at the carbonyl group(s) approaches sp^2 values. The crystal packing forces in the structure are of the van der Waals type with a majority of the closest intermolecular contacts occurring between the carbonyl O atom(s) and symmetry related H atoms of —CH_2— and —CH_3 groups.

The formation of this species in acid can be explained by the stepwise transformation shown in Scheme 1; for a review of other acid-catalysed ketone rearrangements see ref. 2. It is interesting to note that in the initial rearrangement step it is the equatorial group that migrates rather than the methyl group, although it could be argued that other non-isolated reaction products could arise by an alternate route. We have been unable to detect other species of a similar nature to **3** although, as can be seen from the Experimental, **3** has been isolated in pure form in only about 25% yield. It is also interesting to note

[4]Tables of observed and calculated structure factors, anisotropic thermal parameters, hydrogen atom coordinates, and isotropic thermal parameters together with bond lengths and angles involving the hydrogen atoms are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

that **3** now contains only one asymmetric centre and is racemic whereas **1***a* and *b* was a mixture of diastereoisomers containing three such centres.

Experimental

For general procedures and details of spectroscopic analyses see Part III of this series (4).

*Acid-catalysed Rearrangement of 2-Keto-1β,4aβ-dimethyl-1α[2-(3-keto-1,4-trimethylcyclohexyl)ethyl]-7-methoxy-1,2,3,4,4a,9-hexahydrophenanthrene (***1***a + b)*

The olefinic diketones **1***a* and *b* (100 mg) were dissolved in 20 ml dry benzene under nitrogen. Solid *p*-toluenesulfonic acid (200 mg) was added and the mixture was refluxed for 7 h. Thin-layer chromatography indicated no loss of the starting material. An additional 200 mg of *p*-toluenesulfonic acid was added and reflux continued overnight. Thin-layer chromatography analysis showed, in addition to starting material, a new product of lesser polarity. After cooling the reaction mixture, water was added and the benzene layer separated. The aqueous layer was further extracted with ether (×3). The combined organic layer was washed with saturated sodium bicarbonate solution, water, saturated sodium chloride solution and dried over magnesium sulphate (anhydrous). Evaporation of the solvent gave an oil which was column chromatographed on silica gel. Elution with benzene gave 25 mg of the rearranged material (**3**) as an oil and further elution with 10% ether in benzene gave the starting diketones (60 mg).

The reaction was repeated under the above conditions except that the benzene was replaced by the higher boiling *p*-xylene. After column chromatography the product was obtained in higher yield (47%) as an oil. Although this material was homogeneous on thin layer chromatography, it was shown by nmr to be a mixture. Crystallization from methanol gave 24 mg of colorless crystals from 45 mg of the oil. The mother liquor appeared to be a mixture of compounds (nmr) which could not be resolved by column or thin-layer chromatography. Recrystallization of the crystalline material gave analytical sample of **3**: mp 117–120°C; uv max (95% C_2H_5OH): 308 (12 900), 295 (14 700), 257 (47 900); ir (Nujol): 1700 (C=O) and 1600 cm^{-1} (aromatic, olefin); nmr ($CDCl_3$) δ: 1.00 (s, 3, CH_3), 1.14 (s, 3, CH_3), 1.16 (s, 3, CH_3), 2.14 (s, 3, C—CH_3), 2.58 (s, 3, =C—CH_3), 3.93 (s, 3, O—CH_3), and 7.00–8.00 (m, 4, ArH); nmr (C_6D_6) δ: 0.82 (s, 3, CH_3), 1.04 (s, 3, CH_3), 1.08 (s, 3, CH_3), 2.18 (s, 3, CH_3), 2.42 (s, 3, CH_3), 2.54 (s, 3, O—CH_3), and 7.00–8.00 (m, 4, ArH); ms *m/e* (relative intensity): 404 (60), 202 (37), 237 (100); high resolution mass spectrum ion 404: mass calcd. for $C_{28}H_{36}O_2^+$: 404.2715; measured 404.2717; ion *m/e* 237; mass calcd. for

X-ray Analysis of **3**

Crystallographic data for crystals of (**3**) are shown below. Preliminary work was carried out with Weissenberg and precession cameras and all intensity and cell data were measured on a Picker diffractometer using a locally written Fortran IV routine (5) on a PDP 8E computer. Accurate orientation and cell parameters were derived with a least-squares treatment of 34 reflections (17 Friedel pairs) with $2\theta > 80°$. The crystal data are as follows

$C_{28}H_{36}O_2$ fw = 404.57

Monoclinic, space group $P2_1/c$ from systematic absences $h0l$ $l = 2n + 1, 0k0$ $k = 2n + 1$; $a = 7.2684(3), b = 30.942(2)$, $c = 10.5544(7)$ Å, $\beta = 98.24(1)°$, $V = 2349.2$Å^3; $\rho_c = 1.14$, $\rho_m = 1.15$ g cm^{-3} (flotation in KCl solution); $Z = 4$. ($F_{000} =$

SCHEME 1

880; CuKα, λ = 1.54056 Å, graphite monochromator; μ = 5.46 cm^{-1}; crystal dimensions 0.27 × 0.29 × 0.07 mm. Data collection details: $2\theta_{max} = 100°$, temperature 23°C, θ/2θ scan at 2° min^{-1} scan speed and background measurements of 21 s at each end of the scan; 2414 unique measured reflections of which 1810 were considered observed at the 2σ level.)

The data collection scheme used was that described by Grant (6) for obtaining a set of controlled precision measurements. A maximum measuring time of 600 s per reflection was allowed and after a preliminary scan the routine decides:

(*i*) Whether the reflection is observed with $I_{net} > 2\sigma(I_{net})$. If not, no further measurement is made and the reflection is considered unobserved.

(*ii*) If it is above this level, can the reflection be measured to 3% statistical accuracy within the allotted time? If it can be so measured, the scan is repeated the required number of times.

(*iii*) If it cannot be measured to 3%, can the reflection be measured to *at least* 15% using the whole of the allotted time? If this precision can be achieved the routine spends the remaining time to do so. If not, no further time is spent on the reflection and it is again considered unobserved. The values 3% and 15% are input parameters to the routine. All unobserved reflections have I_{net} set to $\frac{2}{3}\sigma(I_{net})$.

Three reference measurements were taken after every 50 reflections and no drift was observed. The normal data reduction techniques were used to correct the intensity data to F_o and E values. No absorption corrections were made.

The structure was solved with MULTAN (7) after some initial difficulty. An E-map was computed with $246|E| \geq 1.6$ which showed the 30 nonhydrogen atoms in the top 36 peaks. Refinement was carried out by block-diagonal least-squares methods, and following initial cycles a high thermal parameter on the carbonyl O atom together with evidence from a difference map, indicated positional disorder in the carbonyl group; the major and minor sites being related by a pseudo-mirror plane, defined approximately by the three methyl groups on the cyclohexanone ring. Refinement was continued with both sites included in the structural model. At an R[5] of 15%, 32 of the hydrogen atoms were located in a difference map, the remainder being found at later stages, and following their inclusion with isotropic thermal parameters and anisotropic refinement of the nonhydrogen atoms, convergence was attained at an R of 0.043 for the observed data (R for all data = 0.063)[4] with R_w[5] = 0.043. The goodness of fit[5] values was 1.88. A final difference map showed no peaks > ±0.17 e. The occupancies on the carbonyl sites were 0.85 and 0.21 (i.e., approximately 4:1) and no attempt was made to locate the partially occupied H atoms sites on C(18), any electron density owing to these atoms being compensated by high anisotropy on the adjacent O atom (nb, this also accounts for the sum of occupancies >1.0). Throughout refinement the function minimised was $\Sigma w(|F_o| - |F_c|)^2$ with weights, w, based upon counting statistics. Scattering factor constants were taken from *International Tables for X-ray Crystallography* (8) and were

[5] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2\}^{1/2}$. Goodness of fit = $\{\Sigma w(|F_o| - |F_c|)^2/(N_o - N_v)\}^{1/2}$ where N_o and N_v are the numbers of observations and variables.

employed in the analytical form: $f_s = c + \sum_{i=1}^{4} a_i \exp(-b_i s^2)$. All calculations were carried out on a PDP-8E computer using mostly locally written programs (9).

Diterpene chemistry. VI. Some chemistry of 8,14-epoxypimaric acid.[1] Comments on the biosynthesis of tetracyclic diterpenes

JOHN W. APSIMON AND STEVEN F. HALL

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received October 14, 1977

JOHN W. APSIMON and STEVEN F. HALL. Can. J. Chem. **56**, 2156 (1978).

The cleavage of methyl pimarate 8,(14) α-epoxide (**4**) was studied with a variety of acidic reagents. The major products observed were the corresponding $\Delta^{7,8}$-14α-alcohol and dienes. Participation of the vinyl group was not detected.

Consideration of the stereoelectronic requirements for cyclisation of olefins with carbonium ions at C-8 of the pimarane skeleton suggest that the pimaranes are not the biogenetic precursors of the tetracyclic diterpenes. A modification of the traditional route is presented as a working hypothesis.

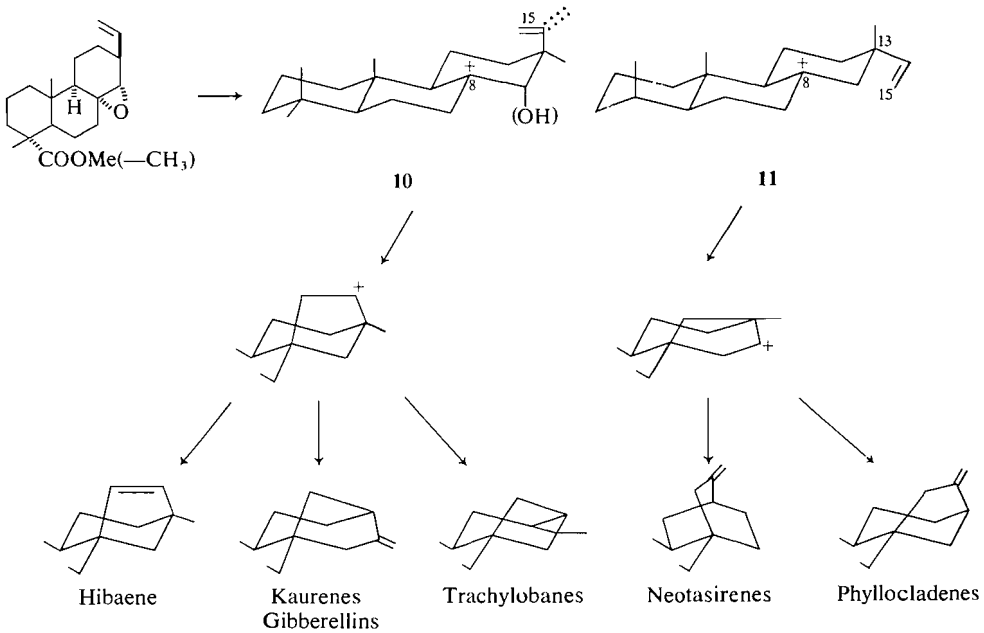
JOHN W. APSIMON et STEVEN F. HALL. Can. J. Chem. **56**, 2156 (1978).

On a étudié la réaction de clivage de l'époxyde-8(14)α pimarate de méthyle (**4**) sous l'influence d'une variété de réactifs acides. Les produits majeurs observés sont le $\Delta^{7,8}$ alcool-14α et des dièns correspondants. On n'a pu détecter la participation du groupe vinyle.

Si l'on considère les facteurs stéréoélectroniques requis pour une cyclisation des oléfines avec les carbocations en C-8 du squelette pimarane, on peut suggérer que les pimaranes ne sont pas les précurseurs biogénétiques des diterpènes tétracycliques. On propose une hypothèse de travail impliquant une modification de la route traditionnelle.

[Traduit par le journal]

As part of our studies of the reactions of certain diterpene epoxides (2, 3) we were intrigued by the possibility that the vinyl group of pimaric acid (**1**) might participate in the opening of an 8,14α-epoxide and thus provide a biomimetic route to the tetracyclic diterpenes (4) as outlined in Scheme 1. This possibility was reinforced by the observations we have already made in the case of ester **2** which is readily converted to hydroxy lactone **3** (2). This route, if successful, could then provide a direct chemical test of the Wenkert proposal (4) for the biosynthesis of the tetracyclic diterpenes from the pimaranes. There have been many unsuccessful attempts at such conversions (5–26, 57).



SCHEME 1

[1]For Part V see ref. 1.

Accordingly, the 8,14α-epoxide of methyl pimarate (**4**) was prepared by treatment of methyl pimarate (**1***a*) with 1.1 equiv. of *m*-chloroperbenzoic acid. Our observations in this and similar experiments correspond to those reported recently (27) for methyl sandarocopimarate (**1***d*). The monoepoxide **4** was reacted with a variety of acidic reagents but we were unable to detect involvement of the vinyl group in the production of cleavage products except in the case of extended treatment with boron trifluoride etherate where a product was observed in which the characteristic proton nuclear magnetic resonance (nmr) signal for the vinyl group had disappeared. However, closer examination of this material indicated the formation of dimeric materials that appeared to be derived from compounds **5** or **6**. All of the cleavage reactions studied led to varying amounts of compounds **5**, **6**, **7**, and **8** depending on the conditions used; the results are summarised in Table 1. The structural elucidation of these compounds is unexceptional and the information is confined to the experimental section of this report.

TABLE 1. Cleavage of methyl pimarate 8(14)α-epoxide (**4**)

Reaction conditions	Product*				
	5	**6**	**7**	**8**	Dimer

$SnCl_4$	80%				Trace

*Isolated yield based on starting epoxide.
†Plus unreacted starting material.

In separate experiments we noted that the allylic alcohol **7** is converted into **5** by acidic reagents and the latter is in turn converted into **6**. It therefore appears that the major pathway for epoxide opening in the case of **4** is by the route *4* → *7* → *5* → *6* (cf. ref. 28). There appears to be no involvement of the vinyl group in an intramolecular sense during this cleavage. The formation of the allylic alcohol **7** rather than the $\Delta^{8,9}$ species suggests a concerted epoxide opening reaction since it is well known that carbonium ions centered at C-8 deprotonate preferentially to provide the tetra-substituted 8,9 double bonds. This observation is then in agreement with our earlier proposition concerning the reactive (and preferred) conformation of α-epoxides in this diterpene series (2, 3). In fact, it was this supposition that led us to believe that some vinyl group participation might be possible in the reactions studied.

That no cyclisation was observed could simply be a matter of the preferred conformation of the vinyl group being that indicated by the dotted lines in structure **10** of Scheme 1, or of the choice of reaction conditions. However, there does rest the possibility that up to this time the reason the lack of in vitro cyclisation in the sense proposed by Wenkert (4) has not been observed is because it is chemically unlikely (ref. 56, p. 164; ref. 57).[2] Thus, in order for bonding to occur between a developing cationic centre (in a chemical or biological sense) and a

[2]It must be stressed that there is an inherent danger in assuming a direct parallel between an in vitro and an in vivo process and using this to make statements concerning actual biosynthetic steps. We do however consider this technique a useful one in suggesting such parallels could exist and in delineating new areas of study.

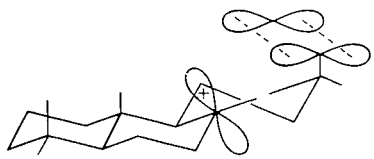
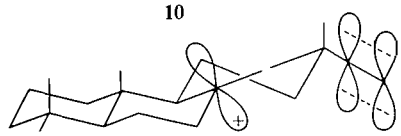
double bond it is necessary for the π bond to overlap with the electron deficient centre. Examination of the pimarene case indicates that such overlap would be very inefficient because of the rigidity of the skeletal system and the stereochemistry of the vinyl group as indicated in **10**. The orthogonal arrangement of the vinyl group π system and the C-8 carbonium ion (or equivalent) suggests that cyclisation of this system is unlikely. The same stereoelectronic argument pertains for the case of the sandoracopimaric acid (**1***c*) derived cation **11**. This being the case, then



10



11

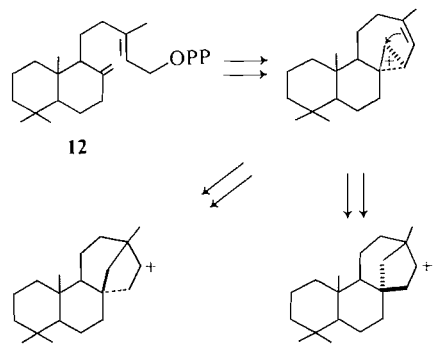
it is not surprising that previous in vitro (5–26, see also refs. 40–44) and in vivo (29–39) attempts to imitate the proposed biosynthetic scheme or close models (45, 46) have been unsuccessful. Other cases of cyclisation involving a 1,4 relationship between a carbonium ion centre and a π system have been reported but in all cases the molecules studied either possessed flexible skeletal arrangements allowing efficient overlap or involved hetero atoms in which lone pairs could be involved in the cyclisation process (2, 47–51).

Comments concerning the intermediacy of pimarene derived cations[3] have recently appeared (56, 57) where it is stated that the biosynthetic enzymes could aid in the attainment of the necessary orbital overlap for cyclization, or that some alternative scheme for tetracyclic diterpene biosynthesis via copalyl pyrophosphate (**12**) exists. Other reports have also questioned the traditionally accepted route (32, 52).

At first sight the formal route outlined in Scheme 2 would appear attractive as an alternative mode for tetracyclic diterpene formation. However, as the referees have pointed out[4] this modification does raise other problems that must be answered. Firstly a *trans* → *cis* isomerisation of the side-chain double

[3]In fact the enantiomeric ions to **10** and **11** would be those involved, considering the absolute configuration of the tetracyclic diterpenes observed to date.

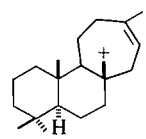
[4]We heartily thank both referees for their constructive comments concerning the biosynthetic proposals.



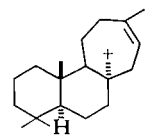
12

SCHEME 2

bond of copalyl pyrophosphate is required before cyclization necessitating an extra step in the biosynthetic pathway and it should be noted that the enzyme kaurene synthetase uses the *trans* isomer as its normal substrate. More serious, however, are the stereochemical implications of this proposal; in particular, if the bridged nonclassical ion indicated in Scheme 2 is the species involved then its trapping should proceed by inversion, a stereoelectronically unlikely step, and trapping by retention has no precedent.[2] These chemical objections can be circumvented by invoking enzyme-stabilised intermediates such as the classical ions **13** and **14**. The immed-

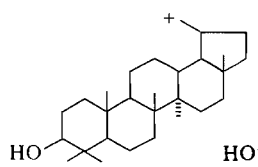


13

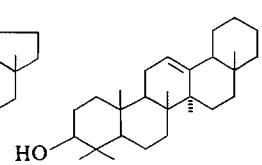


14

iate reaction to this proposal must be that **13** and **14** are primary carbonium ions, albeit neopentyl in nature: species which are traditionally discounted as biosynthetic intermediates. However, it is worth pointing out that at least in one case the primary carbonium ion **15** derived from 29,30-bisnor-2,3-oxidosqualene (synthetic substrate) has been enzymatically converted to 29,30-bisnoramyrin **16** (58),



15



16

indicating that at least in this case that biosynthetic systems can cope with primary carbonium ions, although we stress that the substrate **15** is not natural.

The conjecture raised by Scheme **2** may confuse

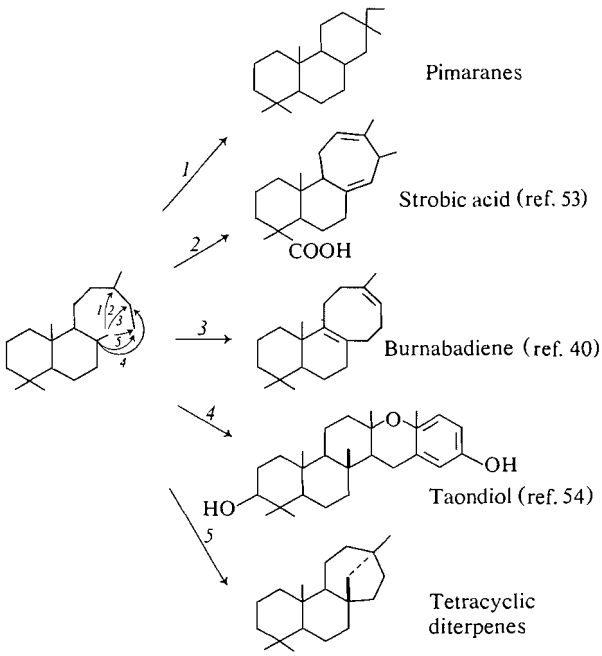
For personal use only.

the issue of tetracyclic diterpene biosynthesis[5] yet in view of the apparent need for further work we put forward this proposition especially as it emphasises the importance of considering stereoelectronic aspects of cyclisation processes in both chemical and biochemical cases (cf. ref. 55).

The net effect of the proposed route represents the 'missing-link' in the variety of cyclisation processes leading from labdane precursors to polycyclic diterpenes as outlined in Scheme 3. It must be noted that route *3* in this scheme has been only observed in vitro to date.



SCHEME 3

Experimental

All melting points were taken on a Kofler hot stage and are uncorrected. Thin-layer chromatography was carried out on precoated silica gel plates obtained from E.M. Reagents (silica gel F-254, 0.25 or 2.0 mm) unless otherwise stated; the plates were developed either by exposure to iodine vapour or by spraying with a solution of ceric sulphate and heating. The nuclear magnetic spectra were obtained on a Varian Model T-60 or Varian H-A 100 spectrometer with tetramethylsilane as internal standard. Chemical shifts are expressed in the δ scale and the usual abbreviations apply. Infrared spectra were determined on a Perkin-Elmer Model 237B grating infrared spectrometer and Beckman AccuLab 2 infrared spectrometer. The ultraviolet spectra were run on a Cary recording spectrometer Model 14 or Perkin-Elmer 202 ultraviolet–visible spectrophotometer. Low resolution mass spectra were obtained on an AEI MS12 instrument at Trent University, Peterborough. Combustion analyses were performed by Spang Microanalytical Laboratory, Ann Arbor, Michigan. Vapour phase chromatographic analyses were performed on a Perkin-Elmer 990 gas chromatograph using a flame ionisation detector and a 5 ft × ¼ in. column packed with 20% DEGS on HMDS treated Chrom W. Methyl pimarate was prepared by the diazomethane treatment of an ethereal solution of pimaric acid.

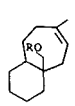
Methyl Pimarate 8(14)α-Epoxide (4)

To a solution of methyl pimarate (1.46 g, 5 mmol) in dry ether (50 ml) was added *m*-chloroperbenzoic acid (1.2 g, 6.6 mmol) and the reaction mixture was allowed to stir at room temperature for 2 days (protected from light). The reaction mixture was washed with 1% $NaHSO_3$, 5% $NaHCO_3$, and water, dried over anhydrous $MgSO_4$, and evaporated to give a colourless oil (1.595 g) whose nmr showed that the absorption at δ 5.17 (1H, broad singlet) corresponding to the C-14 olefinic proton in the starting material had disappeared and that a new peak at δ 2.73 (1H, sharp singlet) corresponding to the C-14 proton of the 8(14)-epoxide had appeared. The combined products of several epoxidation reactions gave a total of 3.68 g of material which was purified by column chromatography on activity III neutral alumina (250 g, dead volume 250 ml). Methyl pimarate (61 mg) was eluted by 5% benzene in petroleum ether. Benzene in petroleum ether (20:80) eluted a mixture of methyl pimarate 8(14)α-epoxide and a minor amount of two impurities which ran slightly ahead of the epoxide on silica gel tlc plates, eluting with benzene or with 10% ether–benzene (367 mg); 30 through 40% benzene in petroleum ether eluted pure methyl pimarate 8(14)α-epoxide (**4**) (2.117 g); mp 65–67°C; ν_{max}: 1725s, 1245s, 912m cm^{-1}; nmr δ: 2.75 (singlet, 1H), 1.23, 1.10, 0.97 (singlets, $3CH_3$ groups); *m/e* 332 (m^+); $[\alpha]_D^{25}$ −17.4°. *Anal.* calcd. for $C_{21}H_{32}O_3$ (mol. wt. 332.49); C 75.86, H 9.70; found: C 75.82, H 9.61. Benzene eluted methyl pimarate 8(14)α,15-diepoxide (306 mg) (diastereoisomeric mixture); mp 85–86°C; ν_{max}: 1720s, 1250s cm^{-1}; nmr δ: 2.3–3.2 (multiplet, 4H, protons attached to epoxide ring), 1.23, 1.03, 9.98, 9.87 (singlets, $3CH_3$ groups); *m/e* 348 (m^+). *Anal.* calcd. for $C_{21}H_{32}O_4$ (mol. wt. 348.49): C 72.38, H 9.26; found: C 72.35, H 9.18.

Rearrangement of Methyl Pimarate 8(14)α-Epoxide on Alumina

A column was packed from 5 g neutral activity alumina in benzene (dead volume 6.5 ml). Methyl pimarate-8(14)α-epoxide (84 mg) was placed on the column as a solution in the minimum amount of benzene, 1 dead volume of benzene was eluted, and the column allowed to stand overnight. The column was eluted with 4 dead volumes of ether to give a colourless oil (63 mg) which appeared as one major spot on silica gel tlc (20% ether–benzene). This product was purified by preparative tlc on four 20 cm × 20 cm × 2 mm silica gel plates eluting with 20% ether–benzene to give methyl pimara-7,15-diene-14α-olate (**7**) (60 mg); ν_{max}: 3520s, 1725s, 1250s, 920m cm^{-1}; nmr δ: 6.1–4.7 (multiplet, 4H, vinyl group plus one extra vinyl

[5]Obviously this proposition must be considered as a working hypothesis yet in view of our observations and those of others (32, 52, 56, 57) we believe it worthy of examination. In our own laboratory we have commenced a study of the solvolysis of substrates such as **17**.



17

proton), 3.80 (sharp singlet, 1H, H-6—OH), 2.27, 1.08, 0.83 (sharp singlets, $3CH_3$ groups); *m/e*: 332 (m^+). *Anal.* calcd. for $C_{21}H_{32}O_3$ (mol. wt. 332.45): C 75.86, H 9.70; found: C 75.77, H 9.62.

Methyl Pimara-7,15-diene-14-oneate (9)

A solution of methyl pimara-7,15-diene-14α-olate (**7**) (34 mg) in dry petroleum ether (3 ml) was stirred with active MnO_2 (300 mg) at room temperature for 3 days. Thin-layer chromatography on silica gel eluting with 20% ether in benzene showed a single spot at higher R_f than the starting material, of which there was no trace. The reaction mixture was centrifuged, the residue washed with ether, the supernatants combined and evaporated to give a clear oil (19 mg) whose ir spectrum showed no O—H peak. This product was purified by preparative tlc on two 20 cm × 20 cm × 2 mm silica gel plates eluting with 20% ether–benzene to give methyl pimara-7,15-diene-14-oneate (**9**) (10 mg); ν_{max}: 1733s, 1690s cm^{-1}; nmr δ: 6.82 (broad singlet, 1H, H—C=C—C=O), 1.25, 1.08, 0.80 (sharp singlets, $3CH_3$ groups); λ_{max}: 243 nm (calculated value: 242 nm) ε 6020; *m/e* 330 (m^+). *Anal.* calcd. for $C_{21}H_{30}O_3$: C 76.33, H 9.15; found: C 76.22, H 9.07.

Rearrangement of Methyl Pimarate 8(14)α-Epoxide (4) on Silica Gel

A silica gel column was packed from 5 g silica gel in benzene (dead volume 10 ml). Methyl pimarate 8(14)α-epoxide (**4**) (104 mg) was placed on the column as a solution in the minimum amount of benzene and 1 dead volume of benzene was eluted and the column allowed to stand overnight. The column was eluted with 4 dead volumes of ether to give a yellow oil (86 mg). Thin-layer chromatography on silica gel eluting with benzene showed two major spots at lower R_f than the starting material of which there was no trace. The nmr spectrum of this material had no peak at δ 2.75  and was similar in all respects to that of methyl pimara-7,15-diene-14α-olate (**7**).

Rearrangement of Methyl Pimarate 8(14)α-Epoxide (4) with $BF_3 \cdot Et_2O$ for 20 h

To a solution of methyl pimarate 8(14)α-epoxide (**4**) (1.982 g) in dry benzene (165 ml) was added freshly distilled $BF_3 \cdot Et_2O$ (1.7 ml) whereupon the reaction mixture turned black. The reaction was stirred at room temperature for 20 h after which time tlc on silica gel plates eluting with benzene or with 10% ether–benzene showed two major spots at higher R_f than the starting material of which there was no trace. Ether (150 ml) was added to the reaction mixture and the solution washed with saturated $NaHCO_3$ solution and with water, then dried over anhydrous $MgSO_4$ and evaporated to give a red gum (2.138 g) of which 1.801 g were separated by column chromotography on silica gel (100 g; dead volume 220 ml) packed in petroleum ether, collecting 25 ml fractions. Petroleum ether eluted fraction *A* (827 mg); 60% benzene – petroleum ether eluted methyl pimara-7,9(11),15-trienoate (**6**) (313 mg) as a colorless oil; uv λ_{max}: 236 (212, 500), 242 (215, 500), 251 (ε 14 000), ir ν_{max}: 1724s, 1245s, 912m cm^{-1}; nmr δ: 6.2–4.6 (multiplet, 5H, vinyl protons) 2.27, 0.98, 0.95 (sharp singlets, $3CH_3$ groups), 2.20–1.85 (multiplet, 6H, H—C—C=C). *Anal.* calcd. for $C_{21}H_{30}O_2$ (M^+ 314): C 80.21, H 9.62; found: C 80.02, H 9.43. Benzene eluted a mixture (110 mg) of methyl pimara-7,9(11),15-trienoate and fraction *A*; 10% ether–benzene eluted fraction *A* (32 mg) and fraction *B* (317 mg).

Fraction A

Thin-layer chromatography on silica gel showed two spots running very close together at R_f 0.36 and 0.40 eluting with benzene and at R_f 0.65 and 0.71 eluting with 10% ether–benzene; ir ν_{max}: 1719 cm^{-1} (no absorption at 900 cm^{-1}); nmr δ: 7.05 (broad singlet, 0.5 H), 3.70 (sharp singlet, 3H, CH_3O_2C—), 1.67 (broad singlet), 1.28 (sharp singlet), 1.23 (sharp singlet), (total integration: δ 2.3–0.1 ≡ 30H: δ 6.5–4.0 ≡ < 0.5H); *m/e* 628 (m^+). This fraction eluded all attempts at further purification and attempts to hydrolyse the carboxymethyl group.

Fraction B

Thin-layer chromatography on silica gel eluting with 10% ether–benzene showed two major spots at R_f 0.50 and 0.39. This fraction was separated by preparative tlc on 11 20 cm × 20 cm × 0.25 mm silica gel plates eluting with 10% ether–benzene. The band at R_f 0.50 gave fraction *A* (24 mg). The band at R_f 0.39 gave methyl pimar-15-ene-14-oneate (**8**) (105 mg); ir ν_{max}: 1725s, 1705s, 1249s, 935m cm^{-1}; nmr δ: 6.3–4.7 (ABX pattern, 3H, vinyl group), 2.85–2.25 (broad multiplet, 1H, H—C—C=O), 1.18, 1.10, 0.97 (sharp singlets, $3CH_3$ groups). M^+ calcd. for $C_{21}H_{32}O_3$: 332.5; found: 332.

Base Treatment of Methyl Pimara-15-ene-14-oneate (8)

A solution of methyl pimara-15-ene-14-oneate (**8**) (25 mg) and sodium methoxide (37 mg) in anhydrous methanol (3 ml) was stirred at room temperature during 22 h. Water (10 ml) was added, the reaction extracted with ether, the extracts combined, washed with water, dried over anhydrous $MgSO_4$, and evaporated to give back methyl pimara-15-ene-14-oneate (**8**) (23 mg). This experiment substantiates the *trans*-BC ring junction.

BF_3–Et_2O Catalysed Rearrangement of Methyl Pimarate (1b)

To a solution of methyl pimarate **1***b* (100 mg) in dry benzene (8 ml) was added freshly distilled $BF_3 \cdot Et_2O$ (100 μl) whereupon the solution darkened. The reaction mixture was stirred at room temperature during 20½ h. Ether (10 ml) was added and the solution washed with saturated $NaHCO_3$ solution then with water, dried over anhydrous magnesium sulphate and evaporated to give pimara-8(9),15-dienoate (93 mg); ν_{max}: 1725s, 1250s, 910m cm^{-1}; nmr δ: 6.2–4.7 (multiplet, 3H, vinyl group), 1.2, 0.98, 0.93 (sharp singlets, $3CH_3$ groups).

Rearrangement of Methyl Pimarate 8(14)α-Epoxide (±) with $BF_3 \cdot Et_2O$ for 1 min in Dilute Solution

To a solution of methyl pimarate 8(14)α-epoxide (**4**) (256 mg) in dry benzene (2500 ml) was added freshly distilled $BF_3 \cdot Et_2O$ (175 μl) and the solution stirred at room temperature during 1 min. The reaction mixture was washed with saturated $NaHCO_3$ solution and water, dried over anhydrous calcium chloride, and evaporated to give a yellow oil (220 mg) whose tlc on silica gel eluting with benzene showed two major spots at R_f 0.062 and 0.375. This crude product was separated by preparative tlc on 17 20 cm × 20 cm × 25 mm silica gel plates eluting with benzene and the band at R_f 0.375 collected to give methyl pimara-6,8(14),15-trienoate (**5**) (80 mg) as a colourless oil; ir ν_{max}: 1730s, 1250s, 920m cm^{-1}; nmr δ: 6.3–4.6 (multiplet, 6H, vinyl group + 3 additional vinyl hydrogens), 1.22, 1.07, 0.75 (sharp singlets, $3CH_3$ groups); λ_{max} 233.8 (ε 9810), 240.5 (ε 10 600), 249.0 nm (ε 7500); ms M^+ calcd.: 314.2246; found: 314.2241. *Anal.* calcd. for $C_{21}H_{30}O_2$ (M^+ 314.5): C 80.21, H 9.62; found: C 79.90, H 9.31.

Rearrangement of Methyl Pimara-7,15-diene-14α-olate (7) with $BF_3 \cdot Et_2O$ for 1 min in Dilute Solution

To a solution of methyl pimara-7,15-diene-14α-olate (**7**) (7.5 mg) in dry benzene (100 ml) was added freshly distilled $BF_3 \cdot Et_2O$ (0.01 ml) and the solution stirred at room temperature for 1 min. The reaction mixture was washed with saturated $NaHCO_3$ solution and water, dried over anhydrous calcium chloride, and evaporated to give a colourless oil (6.5 mg)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

whose tlc on silica gel and on silica gel impregnated with silver nitrate, eluting with benzene, showed one major spot at the same R_f as methyl pimara-6,7(14),15-trienoate (**5**). Peak enhancement by vpc and nmr spectroscopy also indicated that this compound was the major product.

$BF_3 \cdot Et_2O$ Treatment of Methyl Pimara-6,8(14),15-trienoate (5) in Dilute Solution

To a solution of methyl pimara-6,8(14),15-trienoate (**5**) (56 mg) in dry benzene (750 ml) was added freshly distilled $BF_3 \cdot Et_2O$ (7.5 ml) and the solution stirred at room temperature during 30 min. The reaction mixture was washed with saturated $NaHCO_3$ solution and water, dried over anhydrous calcium chloride, and evaporated to give a colourless oil. The above procedure was repeated for further periods of 3, 1, and $15\frac{1}{2}$ h. Nuclear magnetic resonance spectroscopy and peak enhancement by vpc showed a steady decrease in the amount of methyl pimara-6,8(14),15-trienoate (**5**) and a steady increase in the amount of methyl pimara-7,9(11),15-trienoate (**6**) until, after a total of 20 h of reaction, the two compounds were present in approximately equal concentrations.

$BF_3 \cdot Et_2O$-catalysed Rearrangement of Methyl Pimarate 8(14)α-epoxide (4) in Dilute Solution for 20 h

To a solution of methyl pimarate 8(14)α-epoxide (**4**) (99 mg) in dry benzene (1500 ml) was added freshly distilled $BF_3 \cdot Et_2O$ (15 ml) and the solution stirred at room temperature protected from light during 20 h. The reaction mixture was washed with saturated $NaHCO_3$ solution until the washings remained basic, then washed with water and dried over anhydrous $MgSO_4$ to give, after evaporation, a yellow oil (90 mg), whose nmr and ir spectra resembled very closely those of the crude reaction mixture obtained from the more concentrated 20 h reaction. A portion (77 mg) of the reaction product was separated by preparative tlc on five 20 cm × 20 cm × 0.25 mm silica gel plates eluting with benzene and the band at R_f 0.41 was collected to give a clear oil (10 mg) which nmr spectroscopy showed to be an approximately equimolar mixture of methyl pimara-6,8(14),15-trienoate (**5**) and methyl pimara-7,9(11),15-trienoate (**6**). The material on the remaining areas of the plates was recovered to give a yellow oil (50 mg) which was separated by preparative tlc on five 20 cm × 20 cm × 0.25 mm silica gel plates eluting with 10% ether–benzene and the band at R_f 0.63 collected to give a yellow oil (11 mg) which was shown by nmr spectroscopy and by tlc on silica gel plates eluting with 10% ether–benzene to be identical with fraction *A*.

Blank Run of $BF_3 \cdot Et_2O$ Reaction Work-up Procedure on Methyl Pimarate-8(14)α-epoxide (4)

A solution of methyl pimarate-8(14)α-epoxide (62 mg) in benzene (1500 ml) was washed with saturated $NaHCO_3$ solution four times, then with water four times, dried over anhydrous $MgSO_4$, and evaporated to give a clear oil (50 mg) which was shown by ir and nmr spectroscopy and by tlc on silica gel eluting with benzene or with 10% Et_2O–benzene to be methyl pimarate 8,(14)α-epoxide (**4**) indicating that the products detected in the $BF_3 \cdot Et_2O$ catalysed rearrangements are not artifacts of the rearrangement of unreacted starting material during the work-up procedure.

Rearrangement of Methyl Pimarate 8(14)α-epoxide with BF_3 Gas

To a solution of methyl pimarate 8(14)α-epoxide (**4**) (32 mg) in dry benzene (50 ml) was bubbled BF_3 gas for 2 min. The reaction immediately turned cloudy yellow. The solution was stirred at room temperature. After a few minutes this solution went deep red and after about 2 h the solution had gone clear and there was a deep red oil sitting on top of the solution. Stirring was continued for a total of 21 h after which time the solution was clear and a dark red gum adhered to the sides of the flask. The reaction mixture was washed with saturated $NaHCO_3$ solution, the aqueous basic layer washed with benzene, the benzene fractions combined, washed with water, dried over anhydrous $MgSO_4$, and evaporated to give a pale yellow oil (4 mg). The above-mentioned red gum, was dissolved in ether to give a yellow solution which was washed with water, dried over anhydrous $MgSO_4$ and evaporated to give a yellow oil (20 mg) shown by ir and nmr spectroscopy and by tlc on silica gel eluting with benzene or with 10% ether–benzene to consist almost entirely of fraction *A*.

Acetic Acid Catalysed Rearrangement of Methyl Pimarate 8(14)α-Epoxide (4)

A solution of methyl pimarate 8(14)α-epoxide (**4**) (50 mg) in glacial acetic acid (50 ml) was stirred at room temperatures for 1 h, added to water (300 ml), neutralised with Na_2CO_3, and extracted with ether. The ether extracts were combined, washed with water, dried over anhydrous $MgSO_4$, and evaporated to give a colourless oil (45 mg) which was shown by ir and nmr spectroscopy and by tlc on silica gel, eluting with benzene or with 10% ether–benzene, to consist predominantly of methyl pimara-7,15-diene-14α-olate (**7**). No trace of the two isomeric trienes was detected. An identical result was obtained when the reaction was repeated but allowed to run for 21 h.

$SnCl_4$ Catalysed Rearrangement of Methyl Pimarate 8(14)α-Epoxide (4) (1 h)

To a solution of methyl pimarate 8(14)α-epoxide (**4**) (20 mg) in dry benzene (50 ml) was added purified $SnCl_4$ (0.5 ml). The solution was stirred at room temperature and 1 ml samples withdrawn after a total reaction time of 0, 1, 10, and 30 min. During this time the reaction remained a homogeneous clear royal blue solution. The withdrawn samples were evaporated under vacuum and the residue run on silica gel tlc eluting with 10% ether–benzene and the chromatograms were identical showing a single spot at R_f 0.66. The reaction mixture was allowed to stir for a further $\frac{1}{2}$ h and then washed with saturated $NaHCO_3$ solution until the washings remained basic. The aqueous layers were extracted with benzene, the benzene extracts combined, washed with water, dried over anhydrous $MgSO_4$, and evaporated to give a yellow oil (16 mg) which was shown by ir and nmr spectroscopy and by tlc on silica gel eluting with benzene to consist mainly of methyl pimara-6,8(14),15-trienoate (**5**) with a trace of fraction *A* and other unidentified impurities.

Organometallic peroxy radicals. 4. Electron spin resonance spectra of the radicals produced by reaction of organophosphorus(IV) and organoarsenic(IV) radicals with ^{17}O-enriched oxygen[1]

J. A. HOWARD AND J. C. TAIT[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received February 13, 1978

J. A. HOWARD and J. C. TAIT. Can. J. Chem. **56**, 2163 (1978).

It has been shown that some tetra-coordinate phosphorus and arsenic radicals combine with oxygen to give peroxy radicals. The magnitude of the oxygen isotropic and anisotropic hyperfine coupling constants indicates that nearly all the unpaired spin is associated with the two oxygen nuclei with ca. 60% on the terminal oxygen. The large isotropic *g*-factors associated with Group VB peroxy radicals relative to alkylperoxy radicals is attributed to a small change in geometry of the peroxy function.

The radicals with $a_P \sim 9$ G obtained during the reaction of photochemically generated *tert*-butoxy radicals with trialkylphosphites in the presence of oxygen are secondary species which appear to contain only one oxygen atom.

J. A. HOWARD et J. C. TAIT. Can. J. Chem. **56**, 2163 (1978).

On montre que quelques radicaux tétra-coordonnés de phosphore et de l'arsenic se combinent avec l'oxygène pour conduire à des radicaux peroxy. L'amplitude des constantes des couplages isotropes et anisotropes hyperfins de l'oxygène indiquent que pratiquement tout le spin non-pairé est associé avec les deux oxygènes alors qu'environ 60% se retrouve sur l'oxygène terminal. On attribue le fait que les valeurs des facteurs *g* isotropes associés avec les radicaux peroxy du groupe VB sont plus élevées que celles associées aux radicaux alkylperoxy à un petit changement dans la géométrie du groupe peroxy.

Les radicaux avec $a_P \sim 9$ G obtenus par réaction, en présence d'oxygène, de trialkylphosphites avec des radicaux *tert*-butoxy produits photochimiquement, sont des espèces secondaires qui semblent contenir un seul atome d'oxygène.

[Traduit par le journal]

In 1972 two groups of workers (1, 2) reported the detection of tetra-alkoxyphosphoranylperoxy radicals by epr spectroscopy during photolysis of oxygenated solutions of dialkyl peroxide, ROOR, and trialkyl phosphite, $(R'O)_3P$, at low temperatures according to reactions [1]–[3].

$$\text{[1]} \qquad \text{ROOR} \xrightarrow{h\nu} 2\text{RO}^{\cdot}$$

$$\text{[2]} \qquad \text{RO}^{\cdot} + (\text{R}'\text{O})_3\text{P} \rightarrow \text{RO}(\text{R}'\text{O})_3\text{P}^{\cdot}$$

$$\text{[3]} \qquad \text{RO}(\text{R}'\text{O})_3\text{P}^{\cdot} + \text{O}_2 \rightarrow \text{RO}(\text{R}'\text{O})_3\text{PO}_2^{\cdot}$$

where R = *t*-Bu or Et and R′ = Me, Et, *i*-Pr, or *t*-Bu.

The esr spectra of these radicals were characterized by a small phosphorus hyperfine coupling constant (a_P = 8.9–9.45 G) and a high *g*-factor (~2.022). About the same time Furimsky, Howard, and Morton reported that the four-coordinate arsenic radical t-$BuO(Ph)_3As^{\cdot}$ reacts with oxygen to give the peroxy radical t-$BuO(Ph)_3AsO_2^{\cdot}$ (3). In this case hyperfine splitting from the arsenic nucleus (I = 3/2) was not observed while the *g*-factor was similar to the values reported for phosphoranylperoxy radicals.

In an attempt to confirm the structure of these radicals and estimate the influence of the phosphorus and arsenic nuclei on the spin density on the two oxygen atoms we have investigated the esr spectra of the radicals produced by reaction of phosphoranyl and arsanyl radicals with ^{17}O-enriched oxygen. In several cases phosphoranylperoxy and arsanylperoxy radicals have been unambiguously identified. On the other hand this work does cast considerable doubt on the authenticity of previously assigned tetra-alkoxyphosphoranylperoxy radicals.

Experimental

Electron spin resonance spectra were obtained with a Varian E-4 spectrometer equipped with a variable temperature accessory. The microwave frequency was measured with a Syntron-Donner Model 6016 frequency counter which also monitored the frequency of a proton magnetometer used to measure the magnetic field.

Di-*tert*-butyl peroxide (DTBP) was purified by preparative gas liquid chromatography. Triphenylarsine and triphenylphosphine were purified by recrystallization while trimethyl phosphite, triethyl phosphite, and trimethyl arsine were purified by vacuum distillation. The isotopically enriched

oxygen was obtained from Yeda Research and Development Company and its composition was 59.6% ^{17}O and 36.1% ^{18}O.

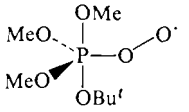
Results

Trimethylphosphite

The esr spectrum observed during photolysis of solutions of di-*tert*-butyl peroxide and trimethylphosphite in oxygenated cyclopropane at 173 K consisted of two components. A broad singlet, $\Delta H_{ms} \sim 13$ G at $g = 2.033$ (**1**) and a much sharper doublet, $a_P = 9.2$ G, at $g = 2.0213$ (**2**). When the light was shuttered **2** was observed to decay much more rapidly than **1**. If a solution was rapidly cooled immediately after cessation of photolysis the anisotropic spectrum of **1** was obtained; $g_{xx} = 2.0022$, $g_{yy} = 2.0086$, $g_{zz} = 2.0991$, and $g_{ave} = 2.037$.

When these experiments were conducted in the presence of ^{17}O-enriched oxygen the spectrum of **2** consisted of a strong doublet from the species with no magnetic oxygen flanked by a sextet of doublets (**3**), $a_O = 16.4$ G, $a_P = 9.1$ G, $g = 2.0215$. In addition there were weaker transitions from a species **4** with $a_O = 24.2$ G, $a_P = 9.2$ G, and $g = 2.0225$. There was no evidence for a radical with two equivalent or inequivalent oxygen nuclei. The esr spectrum of these species is shown in Fig. 1.

We were not able to produce an isotropic spectrum of **1** labelled with ^{17}O because of the very broad lines associated with this radical. The anisotropic spectrum, obtained upon freezing the solution, contained two sets of equally spaced lines centred about g_{xx} arising from two singly labelled radicals with $A_{xx}(^{17}O) = 76.2$ G and 69.3 G and transitions from the doubly labelled radical. This species is almost certainly a phosphoranylperoxy radical and we are fairly confident that its structure can be represented by



1

a structure that has previously been assigned to **2**, the radical with the 9 G coupling constant (1, 2).

It is possible that **2** is an organophosphorus peroxy radical with magnetically inequivalent oxygens and that **3** and **4** are the radicals with one or other of the oxygen nuclei substituted with ^{17}O. The doubly labelled species would then have to be unresolvable because of very broad lines. There are, however, a number of experimental observations which are not consistent with this assignment. These are: (*i*) the linewidth ($\Delta H_{ms} = 1.8$ G) is uncharacteristically narrow for a peroxy radical; (*ii*) the *g*-factor for **4** is significantly larger than the *g*-factor for **2** and **3**, which is impossible if they are all the same radical; (*iii*) the absence of the spectrum from the doubly labelled species; (*iv*) the relative concentration of **3** and **4** depends on the temperature. Thus at 173 K [**4**]/[**3**] is significantly larger than the ratio at 148 K; and (*v*) there is an induction period before **2** appears upon photolysis of a freshly prepared reaction mixture. The rate of formation of **2** then increases slowly with time and it is present after prolonged photolysis. A concentration time profile of this nature is indicative of a *secondary* species. The rate of production of **2** is much faster for a sample in which **2** has been generated and allowed to decay. If the solution is then warmed to room temperature for a short period of time, cooled, and re-photolyzed the accumulation of **2** again follows a S-shaped concentration–time profile. It would, therefore, appear that **2** is formed from an unstable product of the photochemically initiated autoxidation of $(MeO)_3P$ and contains only *one* oxygen nucleus.

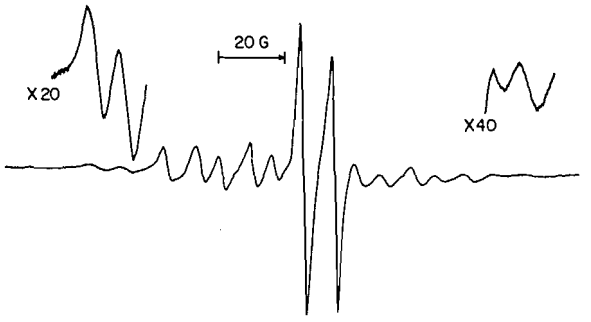


FIG. 1. The esr spectrum of *t*-BuO$(MeO)_3PO^{\cdot}$ enriched with oxygen-17 in cyclopropane at 153 K.

Triethylphosphite

Triethylphosphite behaved just like trimethylphosphite in the presence of photochemically generated *tert*-butoxy radicals and oxygen giving a peroxy radical ($g_{iso} = 2.033$) and species which appeared to contain only one oxygen nucleus ($a_P = 9.4$ G, $g_{iso} = 2.0214$).

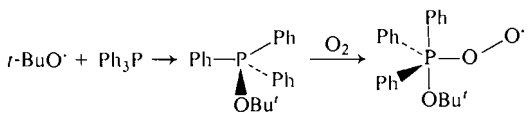
Triphenylphosphine

Photolysis of solutions of DTBP and Ph_3P in cyclopropane containing ^{17}O-enriched oxygen at 153 K gave a spectrum consisting of a doublet (~ 3.6 G) at $g = 2.0247$ from a radical with no magnetic oxygen and two sets of sextets with the same *g*-factor (~ 15.5 G and ~ 24.5 G) from radicals containing one ^{17}O nucleus. When the solution containing these radicals was frozen an anisotropic spectrum was observed with $g_{xx} = 2.0022$, $g_{yy} = 2.0079$, and $g_{zz} = 2.0647$ ($g_{ave} = 2.0249$) in which two sets of six equally spaced lines centred about

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

g_{xx} were resolved arising from two labelled species ($A_{xx}(^{17}O)$ = 85 G and 70 G).

It has been reported (4) that *tert*-butoxy radicals add to triphenylphosphine to give *tert*-butoxytriphenylphosphoranyl with an approximately tetrahedral disposition of ligands about the phosphorus nucleus. Oxygen must add to the phosphorus nucleus of this radical to give a radical with a pseudo trigonal bipyramidal structure



Triphenylarsine

The anisotropic esr spectrum obtained when a solution of DTBP and triphenylarsine in cyclopentane containing ^{17}O-enriched oxygen was photolysed at 193 K and rapidly cooled to 93 K is shown in Fig. 2. Four radicals can easily be identified from this spectrum. A radical with no magnetic oxygen, two radicals containing one ^{17}O nucleus with different hyperfine coupling constants (A_{xx} = 91 G and 61 G), and one radical containing two inequivalent ^{17}O nuclei (A_{xx} = 91 G and 61 G). The average *g*-factors for these four radicals are identical (2.0281) and equal, within experimental error, to the isotropic *g*-factor (2.0274). It is, therefore, quite clear that $Bu^tO(Ph_3)_3As^·$ reacts with oxygen in solution to give $Bu^tO(Ph_3)_3AsO_2^·$.

Trimethylarsine

tert-Butoxytrimethylarsanyl, prepared by reaction of photochemically generated *tert*-butoxy radicals with trimethylarsine (5), reacts with ^{17}O-enriched oxygen in solution to give a broad singlet spectrum (ΔH_{ms} = 7.5 G), centred at g = 2.0278, flanked by two sextets with the same *g*-factor. This spectrum can be analyzed in terms of a peroxy radical containing two inequivalent oxygen nuclei (18.6 and 24.4 G). Neither arsenic hyperfine coupling nor the radical containing two inequivalent oxygen nuclei could be resolved in solution. On the other hand the anisotropic spectrum clearly showed the presence of a radical containing two inequivalent oxygen nuclei in addition to the radicals containing one magnetic oxygen with different coupling constants (A_{xx} = 86.5 and 64.4 G).

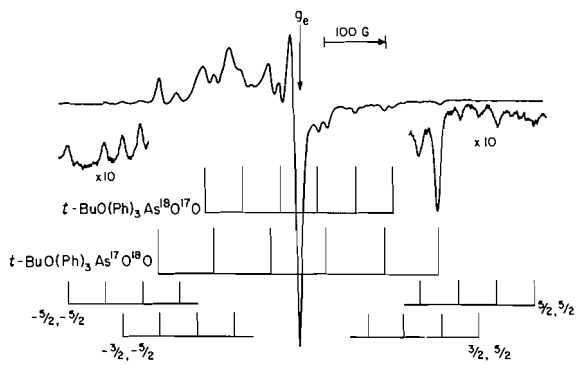


FIG. 2. The esr spectrum of $(CH_3)_3CO(C_6H_5)_3AsO_2^·$ enriched with oxygen-17 in cyclopentane at 93 K.

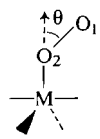
Discussion

We can conclude unambiguously from this work that four coordinate phosphorus and arsenic radicals react with molecular oxygen to give peroxy radicals that are persistent enough to be studied by esr spectroscopy. In general hyperfine coupling with P and As is not resolved because of the broad lines associated with these radicals although $Bu^tO(Ph)_3PO_2^·$ does exhibit a small isotropic phosphorus coupling constant (~3.6 G). The spin density on phosphorus in this radical, calculated from a_P and A_0 = 13 306 MHz (6), is, however, <0.1%.

All the Group VB peroxy radicals that we have been able to prepare contain magnetically inequivalent oxygen nuclei and strongly anisotropic **g**-tensors implying that the peroxy function is bent. The magnitude of the isotropic oxygen hyperfine coupling constants are very similar to the values for the *tert*-butylperoxy radical (a_{O_1} = 23.87 G, a_{O_2} = 17.63 G). The sums of these coupling constants are close to 41 G and it would appear that all of the unpaired spin is associated with the two oxygen nuclei with 60% on the terminal oxygen (7).

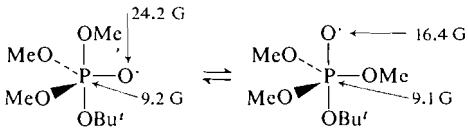
The only significant difference between esr parameters for Group VB organometallic peroxy radicals and alkylperoxy radicals occurs in the magnitude of the isotropic *g*-factor. The *g*-factors for the former radicals are larger solely due to an increase in the *g*-factor associated with the oxygen–oxygen internuclear axis. If, as we have concluded above, the unpaired electron is confined mainly to the oxygen nuclei most of the increase in $g_{||}$ can be attributed to a decrease in the magnitude of θ, the angle between the M—O_2 and O_1—O_2 axes (8). The smaller the angle θ, the less the degeneracy of the oxygen π orbitals will be lifted and the greater will be $g_{||}$.



The radicals with phosphorus hyperfine coupling constants of ca. 9 G observed during reaction of photochemically generated *tert*-butoxy radicals with trimethyl phosphite and related compounds in the

presence of oxygen appear to contain only one oxygen nucleus. It is possible that these radicals are tetra-alkoxyphosphoranyloxy radicals analogous to the recently discovered $F_4PO^{\cdot}$ (9). This radical has, however, a smaller *g*-factor (2.01038) and larger phosphorus (41.1 G) and oxygen (22.8 G) hyperfine coupling constants than our species.

The observation of a second, less intense species (**4**) with larger spectral parameters (g and a_0) is somewhat disconcerting. We did consider the possibility that **3** and **4** are different conformations of t-$BuO(MeO)_3PO^{\cdot}$ with **3** having the oxy function in an apical position and **4** having the oxy function in an equitorial position.



4 **3**

However, as was pointed out by a referee, **3** would almost certainly have C_{3v} symmetry. This would mean that the π-orbitals on oxygen would be degenerate or nearly degenerate and the radical would not be detected in solution because of a line broadening mechanism (10). On the other hand, **3** would have lower symmetry if the *tert*-butoxy ligand occupies an equitorial position.

It could perhaps be argued that **2** really is an organophosphorus peroxy radical (although not t-$BuO(MeO)_3PO_2^{\cdot}$) and because of environmental effects, e.g., association with the parent phosphorus III compound, the lines from the species with the terminal oxygen enriched with ^{17}O are very much broader than the analogous lines from a 'free' peroxy radical. The *g*-factor difference between **3** and **4** is, however, not consistent with this explanation.

In conclusion it would appear that tetra-alkoxyphosphoranyloxy and tetra-alkoxyphosphoranylperoxy can be detected by esr spectroscopy during the reaction of tetra-alkoxyphosphoranyl radicals with oxygen although the identification of the phosphoranyloxy radical is by no means unambiguous.

An internal coordinate model for molecular vibrations: the energy levels of H_2O and H_2S and related isotopic molecules

JAN BRON

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

AND

R. WALLACE

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 15, 1978

JAN BRON and R. WALLACE. Can. J. Chem. **56**, 2167 (1978).

Refinement of a previously described model for describing the anharmonic vibrations of polyatomic molecules is presented. The nonlinear molecules XY_2 (H_2O, D_2O, H_2S, D_2S) are used as examples and it is shown that quite good agreement with the observed spectrum can be obtained for the first twenty vibrational excitations with a six parameter potential function. Apart from its relative simplicity, the main improvement over previously reported work is the inclusion of the bending vibration within the formalism and refinement of the form of potential. It is pointed out that the model is readily extendable to the vibrational analysis of larger molecules.

JAN BRON et R. WALLACE. Can. J. Chem. **56**, 2167 (1978).

On présente un affinement du modèle décrit antérieurement pour décrire les vibrations inharmoniques de molécules polyatomiques. On utilise les molécules non-linéaires XY_2 (H_2O, D_2O, H_2S, D_2S) comme exemples et on montre qu'un très bon accord avec les spectres observés peut être obtenu pour les 20 premières excitations vibrationnelles avec une fonction potentielle contenant six paramètres. En plus de sa simplicité relative, l'amélioration principale par rapport aux travaux rapportés antérieurement est l'inclusion de vibrations de déformation angulaire à l'intérieur du formalisme et un affinement de la forme du potentiel. On peut remarquer que le modèle peut facilement être étendu à l'analyse vibrationnelle de molécules plus grandes.

[Traduit par le journal]

Introduction

A few years ago a paper appeared (1), which presented an alternative to the semi-empirical "local mode" theory of Siebrand and Williams (2) and Henry and Siebrand (3) and the complex normal mode theory, as reviewed by Nielsen (4, 5).

The normal mode theory leads to the following expression for the vibrational energy levels of simple molecules without vibrational degeneracy:

$$[1]\quad E(n_1, n_2, \ldots) = G_0 + \sum_i (v_i + \tfrac{1}{2})\omega_i + \sum_i \sum_j x_{ij}(v_i + \tfrac{1}{2})(v_j + \tfrac{1}{2}) + \text{higher order terms}$$

The unit of energy in [1] is cm^{-1}. The constant term G_0 is of no significance to the vibrational spectroscopist, but is to be considered in statistical mechanical applications (6) of spectroscopy; it cannot be determined experimentally. The quantities x_{ij} are anharmonicity constants, ω_i is the harmonic or normal frequency of vibration, and v_i is a quantum number. The higher order terms in [1] are usually ignored. The expressions, corresponding to [1], for highly symmetric molecules are more complex (7–9). Numerical values for ω_i and x_{ij} may be obtained from an analysis of the vibrational spectrum.

Formulae for G_0 and x_{ij}, in terms of potential constants, rotational and Coriolis constants, have been obtained by means of second order perturbation theory (10). The algebraic complexity of such a perturbation treatment is not trivial. When certain relationships between harmonic frequencies hold, second order perturbation theory may break down, "resonances" occur (4), and further complications may be introduced. Expressions for G_0 and x_{ij} usually involve force constants in dimensionless normal coordinates (5, 11), which are isotope dependent and of limited value. It may be advantageous to obtain, in certain cases, force constants which are independent of isotopic substitution. This can be accomplished by a tedious non-linear transformation of force constants in dimensionless normal coordinates to force constants in internal coordinates (12). Due to limitations of computer time, molecules with more than four or possibly five atoms have not yet been considered. Furthermore, the normal mode theory is so complex that only specialists understand all the details.

In recent publications (1, 13, 14), it has been shown that, in practice, simplification of the vibrational theory of polyatomic molecules is possible. These simplifications come about from the use of an internal coordinate model and the representation of

For personal use only.

the potential for each internal coordinate by a simple function capable of describing anharmonicity (usually the Morse potential). While previous applications have been restricted to bond stretching coordinates only, the present paper includes the bending coordinate within the same framework. For relatively low excitation of the bending mode this procedure should be satisfactory on account of the empirical nature of the potential. The theory presented below has the following advantages. (*1*) It is readily understood in physical terms. (*2*) The small number of parameters leads to good agreement with observed spectra and can themselves be interpreted physically. (*3*) The need for the tedious transformations, mentioned above, disappears. (*4*) Calculations are fast, computer programs can be short, and the restriction 'for small molecules only' is, in principle, removed. (*5*) The Morse potential can represent the vibrations of other internal coordinates. (*6*) Since no separation of 'modes' is involved, the concept of resonance and associated complications disappear.

Theoretical Considerations

The Hamiltonian operator in terms of internal coordinates, R_i, may be written as (1)

$$[2]\quad \hat{H} = \sum_i \hat{H}_i^{(0)} - \hbar^2 \sum_{i<j}\sum [G_{ij}(\partial^2/\partial R_i \partial R_j) - \hbar^{-2} F_{ij} R_i R_j]$$

in which

$$[3]\quad \hat{H}_i^{(0)} = -\tfrac{1}{2}\hbar^2 G_{ii}(\partial^2/\partial R_i^2) + V_i$$

The quantities G_{ij} are Wilson's **G** matrix elements (15) and F_{ij} is an interaction force constant. The potential energy term in [3] is defined by means of the Morse function (1)

$$[4]\quad V_i = D_i[1 - \exp(-a_i R_i)]^2$$

where D_i and a_i are the Morse parameters for the ith internal coordinate. Compared to the expression used previously (1), [2] contains the additional interaction terms $F_{ij}R_iR_j$, which are necessary to obtain the correct fundamentals and isotope shifts (14). It may be observed that D_i, a_i, and F_{ij} are isotope independent and are, therefore, the same for molecules differing only in isotopic substitution.

The vibrational energy levels of a molecule can be determined by means of [2] and the variation method. A suitable linear variation function has the form

$$[5]\quad \psi = \sum_r c_r \phi_r$$

In [5], the coefficients c_r are parameters to be determined by minimizing the variational integral (16). The functions ϕ_r have been defined as (1)

$$[6]\quad \phi_r = \prod_i |n_i\rangle = |n_1, n_2, \ldots, n_p\rangle$$

There are p or $3N - 6$ (5) internal coordinates that define the vibration of a molecule containing N atoms. The slightly different meaning of the quantum numbers n_i in [6] and v_i in [1] should be noted. As before, $|n_i\rangle$ is the eigenfunction (Morse oscillator function) in the equation

$$[7]\quad \hat{H}^{(0)}|n_i\rangle = [D_i - A_i^{-2}(K_i - n_i - \tfrac{1}{2})^2]|n_i\rangle$$

The constants A_i and K_i are equal to

$$[8]\quad A_i = (2/G_{ii})^{1/2}(a_i\hbar)^{-1};\quad K_i = A_i D_i^{1/2}$$

To find the eigenvalues of the secular determinant requires the evaluation of the integrals (16)

$$[9]\quad H_{ij} = \langle\phi_i|\hat{H}|\phi_j\rangle = H_{ji}$$

and

$$[10]\quad S_{ij} = \langle\phi_i|\phi_j\rangle = S_{ji} = \delta_{ij}$$

In [10], δ_{ij} is the Kronecker δ. The utility of the above method will be illustrated by means of examples.

Examples

The calculations of the vibrational energy levels of the non-linear molecules YX_2 will serve as examples. More specifically, the vibrational energy levels of H_2O, D_2O, H_2S, and D_2S will be evaluated. For YX_2 the matrix elements H_{ij} can now be written as

$$[11]\quad H_{ij} = \langle n_1^{(i)}, n_2^{(i)}, n_3^{(i)}|\hat{H}|n_1^{(j)}, n_2^{(j)}, n_3^{(j)}\rangle$$

where

$$[12]\quad \hat{H} = (\hat{H}_1^{(0)} + \hat{H}_2^{(0)} + \hat{H}_3^{(0)}) - \hbar^2[G_{12}(\partial^2/\partial R_1\partial R_2) + G_{13}(\partial^2/\partial R_1\partial R_3) + G_{23}(\partial^2/\partial R_2\partial R_3)] + F_{12}R_1R_2 + F_{13}R_1R_3 + F_{23}R_2R_3$$

The internal coordinates R_i for YX_2 have been defined in Table 1. It may be readily seen that

$$[13]\quad \langle\phi_i|\hat{H}_i^{(0)}|\phi_i\rangle = \langle n_1^{(i)}, n_2^{(i)}, n_3^{(i)}|\hat{H}_i^{(0)}|n_1^{(i)}, n_2^{(i)}, n_3^{(i)}\rangle$$

are the only non-zero matrix elements of this type and that [13] *and* H_{ii} are equal to

$$[14]\quad H_{ii} = \sum_{j=1}^{3} [D_j - A_j^{-2}(K_j - \tfrac{1}{2} - n_j^{(i)})^2]$$

Division by (hc) converts the units of H_{ii} to wavenumbers (cm^{-1}).

Let us calculate for YX_2 the energies of the states

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

generated by $n_1, n_2, n_3 = 0, 1, 2, 3$. The corresponding functions ϕ_i are then defined as follows

[15]

Excitations	States	Permutations
0	$\|000\rangle$	1
1	$\|100\rangle$	3
2	$\|200\rangle$	3
2	$\|110\rangle$	3
3	$\|300\rangle$	3
3	$\|111\rangle$	1
3	$\|012\rangle$	6

Hence, there are a total of 20 states and **H** is a (20 × 20) matrix, leading to a secular determinant of order 20. In the evaluation H_{ij} $(i \neq j)$, it will be assumed that matrix elements that vanish according to *harmonic oscillator* selection rules will be taken as zero. This is justified by the parametric character of our approach and the fact that, if matrix elements are zero when evaluated by means of harmonic oscillator functions, they are small when determined by means of the (proper) Morse oscillator functions, *if* the quantum numbers n_i are not too large. Additional reasons are that the algebra and the number of matrix elements to be evaluated are greatly reduced. Expressions for **G** matrix elements can be found in ref. 15.

The required harmonic oscillator matrix elements can be obtained by means of the recursion relationships

$$[16] \quad [(n_i + 1)h\nu_i]^{1/2}|n_i + 1\rangle - (n_i h\nu_i)^{1/2}|n_i - 1\rangle + \hbar(2G_{ii})^{1/2}\left(\frac{d}{dR_i}\right)|n_i\rangle = 0$$

and

$$[17] \quad [(n_i + 1)h\nu_i]^{1/2}|n_i + 1\rangle + (n_i h\nu_i)^{1/2}|n_i - 1\rangle - (8/G_{ii})^{1/2}\,\pi\nu_i R_i|n_i\rangle = 0$$

In [16] and [17] the frequency ν_i can be expressed in terms of the Morse parameters a_i and D_i. The frequency, ν_i, is equal to

$$[18] \quad \nu_i = (2\pi)^{-1}(f_i G_{ii})^{1/2}$$

The force constant, f_i, can be written as a function of the Morse parameters by differentiating [4] twice and evaluating (17) this second derivative at $R_i = 0$. The result is

$$[19] \quad f_i = 2a_i^2 D_i; \quad a_i = +(f_i/2D_i)^{1/2}$$

and

$$[20] \quad \nu_i = (a_i/2\pi)(2D_i G_{ii})^{1/2}$$

All off-diagonal matrix elements are of the type

$$[21] \quad H_{ij} = \langle n_i^{(i)}, n_2^{(i)}, n_3^{(i)}\,|\hat{P}|n_1^{(j)}, n_2^{(j)}, n_3^{(j)}\rangle$$

where $\hat{P}$ is defined by [2]

$$[22] \quad \hat{P} = \hat{H} - \textstyle\sum_i \hat{H}_i^{(0)} = -\hbar^2 \sum_{i<j}\sum[G_{ij}(\partial^2/\partial R_i \partial R_j) - \hbar^{-2}F_{ij}R_i R_j]$$

Since off-diagonal **H** matrix elements will be evaluated by means of *harmonic* oscillator functions, harmonic oscillator matrix elements are needed. These can be obtained by multiplication of [16] and [17] by $\langle n_i + 1|$, to give the results

$$[23] \quad \langle n_i + 1\left|\frac{d}{dR_i}\right|n_i\rangle = -[(n_i + 1)(f_i/G_{ii})^{1/2}(2\hbar)^{-1}]^{1/2} = -\langle n_i\left|\frac{d}{dR_i}\right|n_i + 1\rangle$$

and

$$[24] \quad \langle n_i + 1|R_i|n_i\rangle = [\tfrac{1}{2}\hbar(n_i + 1)(f_i/G_{ii})^{-1/2}]^{1/2} = +\langle n_i|R_i|n_i + 1\rangle$$

For YX_2, [15] shows that there are 190 off-diagonal matrix elements to be determined. It is not too difficult to write a computer program that evaluates these matrix elements in seconds. After **H** has been determined it should be diagonalized in order to find the 20 energy levels, after diagonalization, the zero point energy (lowest energy level) is subtracted from the other energy levels found after diagonalization, in order to determine the fundamental and other bands.

How to determine H_{ij} $(i \neq j)$ will be shown by means of a few examples:

(A) $H_{ij} \equiv \langle 000|\hat{P}|101\rangle$

$$= -\hbar^2 G_{13}(hc)^{-1}\langle 000|\partial^2/\partial R_1 \partial R_3|101\rangle + F_{13}(hc)^{-1}\langle 000|R_1 R_3|101\rangle$$

$$= -\hbar^2 G_{13}(hc)^{-1}\langle 00|\partial^2/\partial R_1 \partial R_3|11\rangle + F_{13}(hc)^{-1}\langle 00|R_1 R_3|11\rangle$$

$$= -\hbar^2 G_{13}(hc)^{-1}\langle 0\left|\frac{d}{dR_1}\right|1\rangle\langle 0\left|\frac{d}{dR_3}\right|1\rangle + F_{13}(hc)^{-1}\langle 0|R_1|1\rangle\langle 0|R_3|1\rangle$$

$$= -\hbar^2 G_{13}(hc)^{-1}(2\hbar)^{-1}(f_1/G_{11})^{1/4}(f_3/G_{33})^{1/4} + F_{13}(hc)^{-1}(\tfrac{1}{2}\hbar)(f_1/G_{11})^{-1/4}(f_3/G_{33})^{-1/4}$$

This final expression can be evaluated by means of the constants given in Table 1 and the following expressions for the required **G** matrix elements (15) for YX_2:

TABLE 1. Values for various parameters used in calculations

Parameters	H_2O	H_2S
Bond angle: $\alpha \equiv 1—3—2$	104.5°	92.2°
Bond length (Å): $r = r_{13} = r_{23}$	0.95721	1.336
$f_1 = f_2$ (10^5 dyn cm^{-1})	8.45400	4.14832
f_3 (10^{-11} dyn cm)	0.69250	0.73278
F_{12} (10^5 dyn cm^{-1})	−0.092	−0.012
$F_{13} = F_{23}$ (10^{-3} dyn)	0.0	0.0
$D_1 = D_2$ (10^{-11} erg)	0.81804	1.12812
D_3 (10^{-11} erg)	0.48490	1.18199
R_1 (stretching)	Δr_{13}	Δr_{13}
R_2 (stretching)	Δr_{23}	Δr_{23}
R_3 (bending)	$\Delta\alpha$	$\Delta\alpha$

$$G_{11} = m_1^{-1} + m_3^{-1} = G_{22} = m_2^{-1} + m_3^{-1}$$

$$G_{33} = (m_1 r_{13}^2)^{-1} + (m_2 r_{23}^2)^{-1} + [r_{13}^{-2} + r_{23}^{-2} - 2(r_{13}r_{23})^{-1}\cos\alpha]/m_3$$

$$G_{12} = m_3^{-1}\cos\alpha$$

$$G_{13} = G_{23} = -(r_{23}m_3)^{-1}\sin\alpha$$

The factor $(hc)^{-1}$ has been introduced to change the units of H_{ij} from ergs to cm^{-1}. The mass of the ith atom is m_i.

(B) $$H_{ij} \equiv \langle 101|\hat{P}|103\rangle = 0$$

This matrix element vanishes because the harmonic oscillator selection rule, $\Delta n_i = \pm 1$, is not obeyed.

(C) $$H_{ij} \equiv \langle 000|\hat{P}|111\rangle = 0$$

This matrix element vanishes because the coordinates R_i and R_j in $\hat{P}$ occur only in pairs (R_iR_j or $\partial^2/\partial R_i\partial R_j$) and the eigenfunctions $|n_k\rangle$ are orthonormal.

The force constant f_i is related to the Morse parameter a_i by [19]. Therefore, the matrix elements [23] and [24] can also be expressed in terms of a_i. However, f_i is preferred to a_i, because f_i has a greater physical meaning. Also, [8] and [14] can be expressed in terms of f_i.

As has been discussed before (13), the parameters $f_1 = f_2$, $D_1 = D_2$ and F_{12} can be determined from the (observed) fundamentals. Similarly, the parameters f_3 and D_3 can be evaluated from the bands ν_2, $2\nu_2$ (XY_2), or by ν_2 (H_2Y) and ν_2 (D_2Y) and the (mass) relationships for isotopic molecules implied in the above equations. We found that satisfactory values for f_3 and D_3 can be obtained from observed frequencies, the equation (see [14])

[25] $$E_n - E_0 = (A_3^2 hc)^{-1}(2n_3K_3 - n_3 - n_3^2)$$

and $F_{13} = F_{23} = 0$. It has been assumed that A_3 and K_3 have been expressed, via [8] and [19], in terms of f_3 and D_3.

Results and Discussion

The computational results, based on the data given in Table 1, are presented in Tables 2 and 3. Agreement with observed values is good and on the average to within 0.5%. The observed values for H_2O, D_2O, and H_2S generated by means of [1] and the harmonic frequencies and anharmonicity constants given by Kuchitsu and Morino (18). Similarly the observed bands for D_2S have been based on the

2	0	1	7673	7617	0.73	5589	5581	0.14

data given by Miller *et al.* (19). As is usual for the Morse oscillator, the agreement with observed values gets worse when v_1, v_2, and v_3 increase, if the force constants and D_i have been obtained by fitting to the bands of lower excitation, such as the fundamentals. Although the results have not been given, the vibrational energy levels for HDO, HDS, and all other possible isotopic variants of H_2O and H_2S, have also been calculated and, again, agreement between observed and calculated band positions was excellent.

Table 4 lists the harmonic frequencies and anharmonicity constants for H_2O and H_2S. The calculated values for ω_i were obtained by Wilson's (15) **F**, **G** matrix theory and the data in Table 1. The force constants f_i were taken as the diagonal **F** matrix elements. These values for ω_i were then used, together with the frequencies corresponding to the first six states given in Tables 1 and 2, in [1] to solve for the six anharmonicity constants. It may be seen that agreement with 'experimental' values is reasonable, especially for ω_i and x_{ii}. A redetermination of the frequencies by means of the calculated values of ω_i and x_{ij} *may* lead to improvement in agreement with the observed values. For example, the observed, calculated, and recalculated values for the frequency defined by the state $|002\rangle$ are 7414, 7457, and 7418 cm^{-1}, respectively. This improvement cannot always be expected to occur, but it is not unreasonable to expect it to happen when agreement of the calculated first six frequencies with the experimental values is good.

The results given in Table 2 can be compared with the values obtained by Smith and Overend (20), who used the standard normal mode theory (4, 5). The agreement these workers obtained with experimental values is impressive. But it should be realized, however, that Smith and Overend used for H_2O a 19 parameter potential function and that their method cannot be used, in practice, for larger molecules. Our six parameter potential function and simpler theory can readily be applied to larger molecules. It is for larger molecules, containing five or more atoms, that the model presented in this paper becomes more useful. Furthermore, as has been shown for UF_6 (14), our approach to the vibrational problem yields the splitting of overtone and combination levels by numerical analysis, without the explicit use of group theory.

Some empirical observations concerning the liquid scintillation counting of coloured solutions[1]

DONALD C. WIGFIELD AND CATHERINE M. E. COUSINEAU
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received July 29, 1977

DONALD C. WIGFIELD and CATHERINE M. E. COUSINEAU. Can. J. Chem. **56**, 2173 (1978).

The colour quenching capabilities of nine dyes have been examined, and compared with the visible absorption spectra of the dyes in toluene solution. From these data an empirical relationship is derived, from which the liquid scintillation counting efficiency is estimated simply from the λ_{max} (wavelength of maximum absorption) of the dye and its absorption, A, at that wavelength. For the particular instrument, window settings, and scintillator solutions used in this work the relationship was

$$\% \text{ efficiency} = A[0.75(\lambda_{max} - 380) - 143] + 84.5$$

Colour quenching agents are classified as severe (λ_{max} 380–480 nm), moderate (λ_{max} 480–520 nm), light (λ_{max} 520–560 nm), or zero (λ_{max} > 560 nm).

The normal external standard channels ratio method for obtaining counting efficiency of chemically quenched samples has been applied to samples that contain colour quenchers and various combinations of colour and chemical quench. The results are in excellent agreement with the actual counting efficiencies; this result is in direct contrast to current views on the matter. It appears, therefore, that the counting of samples quenched both chemically and by colour may not always be impossible and the user is well advised to investigate his own system to evaluate whether results within acceptable error may be obtained.

DONALD C. WIGFIELD et CATHERINE M. E. COUSINEAU. Can. J. Chem. **56**, 2173 (1978).

On a examiné les aptitudes de neuf colorants à agir comme inhibiteurs et on les a comparés avec les spectres d'absorption visibles des colorants en solution dans le toluène. A l'aide de ces données, on a pu tirer une relation empirique à partir de laquelle on peut évaluer l'efficacité de comptages par scintillation liquide en se basant uniquement sur le λ_{max} (longueur d'onde d'absorption maximum) du colorant et son absorption, A, à cette longueur d'onde. Pour notre instrument avec son arrangement des fenêtres et les solutions de scintillateurs utilisés dans ce travail, la relation est

$$\% \text{ efficacité} = A[0.75(\lambda_{max} - 380) - 143] + 84.5$$

On a classifié les colorants comme inhibiteurs sévère (λ_{max} 380–480 nm), modéré (λ_{max} 480–520 nm), léger (λ_{max} 520–560 nm) ou zéro (λ_{max} > 560 nm).

On a appliqué la méthode habituelle des rapports des canaux standards externes pour obtenir l'efficacité du comptage d'échantillons soumis à une inhibition chimique, qui contenaient des colorants inhibiteurs ou diverses combinaisons d'inhibiteurs chimiques et de colorants. Les résultats sont en accord avec les efficacités réelles des comptages; ces résultats sont en opposition directe avec les vues actuelles sur ce sujet. Il semble donc qu'il soit quelquefois possible de faire le comptage d'échantillons soumis à des inhibitions soit chimique soit par colorants et qu'il serait avantageux pour les usagers de bien étudier leur propre système pour évaluer si des résultats à l'intérieur d'erreurs acceptables peuvent être obtenus.

[Traduit par le journal]

The view that the counting efficiency of samples containing both colour and chemical quench cannot be obtained accurately by the conventional external standard ratio method was put forward by Neary and Budd a number of years ago (1). This view is widely held, and was strongly reiterated recently by Stanley (2). Nevertheless, the need for counting coloured solutions (presumably also with their share of chemical quench) frequently arises, especially in the biological and medical sciences, and, despite the fact that in these applications a modest error or uncertainty is often tolerable, there seems to be little tangible advice in the literature on how to handle these solutions or on the extent of inaccuracy incurred if conventional quench correction methods are applied to them. Clearly some colours will be more severe quenchers than others. In this paper we report (*a*) a reinvestigation of the relationship between the optical properties (absorbance, wavelength) of the liquid scintillation counting solutions and their counting efficiency, partly as an independent means of measuring the decrease in counting efficiency as a result of colour quenching, but most importantly to be able to generate some empirical

rules concerning the severity of quenching for various types of coloured solutions, and (*b*) an investigation of the actual errors incurred by using the conventional external standard ratio method for quench correction on samples of various degrees of chemical and colour quench.

Results and Discussion

Relationship between Counting Efficiency and the Absorbance Characteristics of Solutions

1. Selection of Dyes

In order to draw conclusions relevant to a variety of coloured solutions, nine dyes were selected giving a range of λ_{max} (wavelength of maximum absorption) from 410 to 660 nm. These dyes, together with their absorption characteristics of methanolic solutions (100 μl) in toluene (15 ml), are listed in Table 1. Toluene solution was employed to ensure that the optical data obtained would be relevant to the subsequent liquid scintillation counting data. Most, but not all, of the absorbance bands gave linear Beer's law plots. The extinction coefficients obtained are all large and within an order of magnitude of each other (10^4–10^5); thus the quantity of dye present in counting solutions is small and relatively constant. Since also the structures of the dyes are chemically rather similar, it is unlikely that the counting differences are to any extent due to chemical quenching. The chemical quenching of 100 μl of methanol is almost unnoticeable.

2. Relationship between Absorbance and Counting Efficiency

A series of counting samples were prepared, using 1-^{14}C-hexadecane as the radio-active source, containing various quantities of each dye. For each sample both the absorbance and the counting efficiency were recorded. These results are presented graphically in Fig. 1 and Table 2. Clearly there is, in most cases, a good linear relationship between counting efficiency and the quantity of dye present, as noted previously by Ross and Yerick (3), using three coal-tar dyes. Also, the slopes (dQ/dA, counting efficiency vs. absorbance) of the lines depend markedly on the wavelength of the dye, and all intersect at the efficiency in the absence of added quench;[2] in this case 84.5% ± 0.5%.

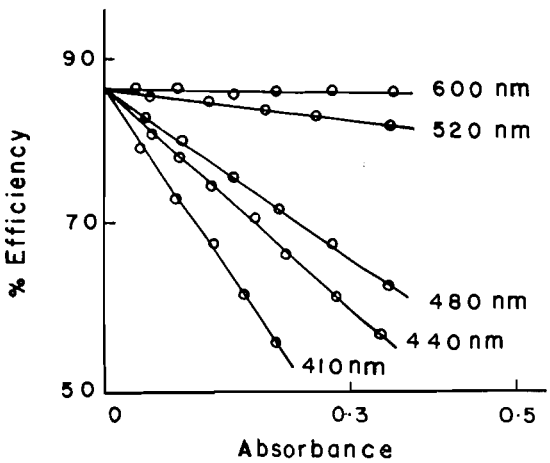

FIG. 1. Examples of relationships between counting efficiency and absorbance at various λ_{max} wavelengths.

3. Effect of Wavelength

The lines of Fig. 1 may be represented mathematically by

$$[1] \qquad \% \text{ efficiency} = (dQ/dA)A + 84.5$$

[2]Refers to normally prepared (as opposed to argon-flushed) samples. The counting efficiency of 84.5% as opposed to the more usual value of ≃90% is a reflection of the lower discriminator set higher than usual, a practice used in these laboratories to avoid phosphorescence complications (see Experimental).

TABLE 2. Dependence of quenching on wavelength difference between λ_{max} of the dye and maximum emission wavelength of the fluor ($\Delta\lambda$)

Dye	Form	$\Delta\lambda_{max}$ (nm)	Slope (dQ/dA)	r (plots of Fig. 1)	Intercept
Methyl violet	Basic	220	−2.02	0.667	83.8

					Ave. 84.5

where the value of (dQ/dA), the slope of the plot of counting efficiency vs. absorbance, is clearly some function of the wavelength of absorption. It seemed worth testing whether the value of (dQ/dA) could be usefully treated as a simple linear function of λ_{max}, within certain limits. The fluors used in this study were a mixture of 2,5-diphenyloxazole (PPO) and 1,4-bis[2-(5-phenyloxazolyl)]-benzene (POPOP) (as noted in the Experimental section) with wavelengths of maximum emission of 380 and 440 nm respectively. Since increase in quench continues as the wavelength of dye absorption decreases between 440 nm and 380 nm, the wavelength parameter used, $\Delta\lambda$, the difference in wavelength between colour quencher and fluor, is ($\lambda_{max} - 380$). A plot of (dQ/dA) as a function of this $\Delta\lambda$ is shown in Fig. 2. Although there is considerable scatter, there is clearly a relationship from $\Delta\lambda = 0$ to $\Delta\lambda = 180$ nm, beyond which there is evidently insufficient spectral overlap between dye and fluor for quenching to occur. Considering that no effect of band width or band shape of the absorption spectra of the dye have been taken into consideration, the scatter in Fig. 2 is remarkably small.

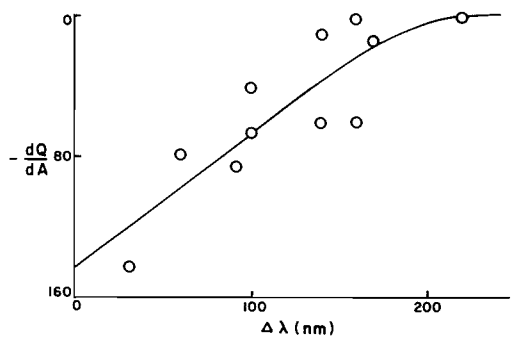

FIG. 2. Relationship of dQ/dA on wavelength difference between fluor and dye.

4. Calculation of Counting Efficiency from the Absorption Spectrum

The linear portion of Fig. 2 is represented by

[2] $$(dQ/dA) = 0.75(\Delta\lambda) - 143$$

for $0 < \Delta\lambda < 180$ nm. Combining eqs. [1] and [2], one obtains

[3] $$\% \text{ efficiency} = A[0.75(\lambda - 380) - 143] + 84.5$$

Clearly eq. [3] allows simple calculation of the counting efficiency change caused by colour quenching purely from the absorption spectrum of the solution.[3] For example, if a solution has $\lambda_{max} = 440$ nm, with $A = 0.22$, the counting efficiency is given by

$$\% \text{ efficiency} = 0.22[0.75(60) - 143] + 84.5$$
$$= 63\%$$

In order to exemplify how the scatter of Fig. 2 is translated into counting efficiency error, comparisons of calculated and observed counting efficiencies for various solutions are shown in Table 3.

These results indicate that the agreement between calculated and observed counting efficiencies is within 3%.[4] This method represents a simple alternative to the Ross and Yerick calculation (3), using essentially the same approach. As Ross and Yerick (3) have pointed out, in order to obtain more accurate estimations of the colour quenching a more detailed computer approach taking into account the entire absorption spectrum, and not just the absorbance at λ_{max}, would be required. Since this present approach was merely to provide some rules for

[3]Clearly this particular equation is applicable only to solutions of this particular fluor.

[4]A 3% error in absolute efficiency can cause a considerably larger error in computing the activity, especially at very low counting efficiencies.

	0.09	72.1	73.7	+1.6

guidance concerning levels of quench to be expected, such a detailed approach would not seem justified.

5. Empirical Rules concerning the Counting of Coloured Solutions

The above data quantitate the decreasing severity of colour quenching as the wavelength of absorbance of the coloured solution moves away from the wavelength of the fluor. It may be useful to classify coloured solutions in the following manner as quenchers of the PPO system: (*a*) *severe quenchers*: λ_{max} 380–480 nm, e.g., in a solution with λ_{max} 430 nm, $A = 0.5$, the counting efficiency will be reduced to 35%; (*b*) *moderate quenchers*: λ_{max} 480–520 nm, e.g., in a solution with λ_{max} 500 nm and $A = 0.5$, the efficiency will be 61%; (*c*) *light quenchers*: λ_{max} 520–560 nm, e.g., in a solution with λ_{max} 540 nm and $A = 0.5$, the efficiency will be 75%; (*d*) solutions with $\lambda_{max} > 560$ nm do not colour quench the PPO–POPOP system.

External Standard Ratio Calibration Curves for Chemical and Colour Quench

Because of the doubts concerning the counting of solutions with both colour and chemical quench, we planned to make some comparative measurements of counting efficiency of coloured solutions using both the optical method described above, and the external standard channels ratio method, using a calibration curve based on standard samples with chemical quench. To our surprise, it was immediately apparent that there was excellent agreement between the actual counting efficiency and that obtained by the external standard channels ratio method. Thus, on our Beckman LS system[5] with the discriminator settings used and for the dyes examined, reliable counting efficiencies for solutions of pure colour quench are ap-

[5]Examination of the equations governing liquid scintillation counting suggests that the origin of the obvious difference between our results and those of others may lie in the difference between the logarithmic amplification of the Beckman instruments and the linear amplification of other instruments. Details of this are given in the M.Sc. thesis of Catherine M. E. Ashley, Carleton University (1977). A referee has suggested that the raising of the lower level discriminator may also be a contributing factor (cf. footnote 2).

parently obtained using the usual calibration curve for chemical quench, in direct contrast with the report of Stanley (2). To examine whether the same agreement would be obtained with solutions containing both chemical and colour quench, a series of such solutions were prepared and examined. As indicated in Table 4, the agreement between actual efficiency and that obtained by the External Standard Channels Ratio method is excellent, with the mean deviation being only 1.7%, and all determinations being within 4% even when very low counting efficiencies were being examined.[4] Few determinations require accuracy higher than this, and, on the Beckman LS system it is clear that, unless higher accuracy is being looked for, the determination of counting efficiency of samples having both chemical and colour quench is simply not a practical problem. Clearly it may be a worthwhile study for the user to investigate whether results on his particular instrument are satisfactory in this regard.

Conclusions

Several previous workers have found that colour and chemical quench correction curves differ significantly and that therefore quench correction of samples quenched both by colour and chemically can be subject to dangerous error. Among these workers, Stanley (2), Bush (5), and Noujaim and co-workers (6) have used Searle, Nuclear Chicago, and Picker Nuclear instruments respectively. Rapkin, on the other hand, has claimed that a single calibration curve is valid for all quenching agents (6, 7). The instrumental difference has generally been ignored in considering this problem, but appears to be an important factor. The present results, obtained on a Beckman LS150 instrument, clearly demonstrate that the accurate counting of solutions quenched both chemically and by colour is not always impractical, and the user is well advised to investigate his particular instrument with mixed chemical, and colour, quenched samples to evaluate whether on his system results of sufficient accuracy are obtained. The dogma that it is impossible to get satisfactory results should be abandoned and replaced by one of individual assessment.

Experimental

Liquid Scintillation counting measurements were obtained on a Beckman LS 150 Liquid Scintillation Counter, with samples prepared in low background glass spectravials (Amersham-Searle) with Spectrafluor solution (Amersham-Searle) diluted as recommended (PPO 4 g/ℓ; POPOP 50 mg/ℓ) with freshly distilled spectral grade toluene. The volume of the counting solution was kept constant at 15 ml by means of an automatic tilting dispenser. Carbon-14 activities were measured using the modified[6] ^{14}C channel, discriminator values 150–500.

Absorption spectra were recorded using a Beckman-25 spectrophotometer calibrated using a holmium oxide standard.

Purification of Dyes

All dyes were recrystallized three times from the appropriate solvent, rinsed with ether and benzene, and dried. Dyes were dissolved in absolute methanol (100 µl) and diluted to 15 ml with toluene for absorption measurements.

Quenched Samples

These were prepared by the addition of varying amounts of chloroform (chemical quench) or dye solution (colour quench) to the counting solution. The ^{14}C standard used was 1-^{14}C-hexadecane (New England Nuclear) delivered to the solutions by means of a Hamilton syringe. Activities per sample were generally kept in the neighbourhood of 50 000 dpm. Total counts accumulated were approximately 160 000 per sample (0.5% (2 σ) error).

Liquid crystal/glass interface effects on the orientation of lyotropic liquid crystals in magnetic fields

FRED Y. FUJIWARA[1] AND LEONARD W. REEVES[2]

Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received March 13, 1978

FRED Y. FUJIWARA and LEONARD W. REEVES. Can. J. Chem. **56**, 2178 (1978).

Lyotropic mesophases of both positive (type I) and negative (type II) diamagnetic anisotropy have been prepared. The deuterium magnetic resonance signal from D_2O in the sample has been studied during the process of orientation in a magnetic field. A type II mesophase oriented by a magnetic field in a cylindrical tube perpendicular to the lines of force does not achieve a uniform distribution of directors in a plane perpendicular to the field. The re-orientation of a type I mesophase after an initial displacement of the director at an angle to the field has been studied. Previous equations derived for thermotropic liquid crystals are applicable but the velocity of re-orientation was found to be an inverse function of the radius, for nmr tubes of less than 4 mm in diameter, indicating that liquid crystal/glass interface effects are important.

FRED Y. FUJIWARA et LEONARD W. REEVES. Can. J. Chem. **56**, 2178 (1978).

On a préparé des mésophases lyotropes d'anisotropie diamagnétique positive (type I) ainsi que négative (type II). On a étudié le signal de résonance magnétique du deutérium provenant du D_2O dans l'échantillon au cours du processus d'orientation dans le champ magnétique. Une mésophase du type II orientée par un champ magnétique dans un tube cylindrique perpendiculaire aux lignes de force ne produit pas une distribution uniforme des directeurs dans un plan perpendiculaire au champ. On étudié la réorientation d'une mésophase du type I après un déplacement initial du directeur à un angle par rapport au champ. On peut appliquer les équations dérivées antérieurement pour des cristaux liquides thermotropes; toutefois on a trouvé que la vitesse de réorientation est une fonction inverse du rayon des tubes de rmn de moins de 4 mm de diamètre ce qui indique que les effets d'interfaces cristal liquide/verre sont importants.

[Traduit par le journal]

Introduction

The lyotropic liquid crystals, based on water and amphiphiles, in certain systems have a significant property that they spontaneously orient in magnetic fields (1). Both positive (type I) and negative (type II) diamagnetic anisotropies occur for these lyotropic uniaxial fluids (2, 3) and a considerable amount of chemical work has been done to extend the number of known systems which have this useful property (2–7). The chemical flexibility includes variations of the counter ion, added electrolytes, detergents, and amphiphiles as well as solubilizates of various kinds.

The dynamics of the orientation process in these lyotropic mesophases in magnetic fields has not been previously reported in any detail. This contrasts with the extensive number of studies reported for thermotropic nematic mesophases. The dynamical properties of nematics has been formalized in a chapter in the recent book of de Gennes (8). Since the pioneering studies of Tsvetkov (9, 10) there have been several recent studies of the behaviour of nematic mesophases in rotating magnetic fields (11–19). These mesophases which have a positive diamagnetic anisotropy ($\Delta\chi = \chi_{\parallel} - \chi_{\perp}$, where $\chi_{\parallel}$ and $\chi_{\perp}$ are the diamagnetic susceptibilities measured, respectively, parallel and perpendicular to the optic axis) orient with the optic axis direction parallel to the magnetic field. In a rotating magnetic field (or in the equivalent case where the sample is rotated in a magnetic field) the director (optic axis) assumes an angle ϕ from the magnetic field direction such that the frictional torque and the magnetic torque, $(1/2)\Delta X B^2 \sin 2\phi$, balance. The following equation, derived from the continuum theory model (13), expresses the relationship between the phase lag, ϕ, and the angular frequency, ω:

$$[1] \qquad -\lambda_1\omega = (1/2)\Delta\chi B^2 \sin 2\phi$$

where B is the magnetic field strength and λ_1 is a twist viscosity coefficient taken to be negative (13). The theoretical analysis, which neglects surface effects, predicts that at angular velocities greater than the critical value $\omega_c = -\Delta X B^2/2\lambda_1$ the director will rotate with respect to the magnetic field direction.

Measurements of the angle ϕ as a function of ω,

by electron spin resonance (esr) and nuclear magnetic resonance (nmr) spectroscopy (12–14, 16–19), were accurately described by eq. [1] except in the region near the critical velocity. The angle observed was smaller than predicted and an inhomogeneity in the director alignment developed which increased smoothly until at high speeds ($\omega > \omega_c$) the directors adopt an isotropic distribution in the plane containing the magnetic field (16). The rotation of the director was observed but the homogeneity of the alignment decayed quickly (13). This dispersion of the director alignment at angular velocities greater than ω_c has been recently studied in very low magnetic fields (18). In the magnetic fields employed (a few hundred gauss) the rate of the director dephasing process at high angular velocities was very much slower and could be followed in the esr spectra of a paramagnetic probe dissolved in the mesophase. From the dependence of this rate on the angular velocity and the field strength, the authors concluded that the motion of the sample cell surface relative to the mesophase creates twist walls at the interface (8) which propagate towards the nematic bulk.

The lyotropic mesophases provide an opportunity to study the behaviour in magnetic fields of another uniaxial fluid with a completely different composition and internal structure. At present the shapes and long range organization of the surfactant micelles in these systems is not well understood. However, the evidence available indicates that neither the type I nor the type II mesophases belong to the classical lamellar or hexagonal systems.

Qualitatively it has been apparent (1, 2) that the velocity with which initially random directors become oriented to a macroscopically oriented liquid crystal in a magnetic field is considerably slower than for the thermotropic nematic mesophases so far encountered. The rotating magnetic field experiments can be repeated for lyotropic media but in a static rather than dynamic form. The purpose of the present paper is to present a survey of the deuterium magnetic resonance lineshapes encountered during the orientation process of lyotropic mesophases as well as to investigate the influence of glass/liquid crystal interface effects on the kinetics and consequent director angle distributions of type I and type II mesophases.

Experimental

The preparation of the surfactants used have been previously reported (2, 3). The surfactants were recrystallized two to three times and dried under vacuum at 60°C. The Pyrex nmr sample tubes were cleaned with Teepol detergent, thoroughly rinsed with distilled water, and dried at 120°C. The internal diameters of the tubes were determined from volume–weight measurements using water or mercury. For the standard 5 and 10 mm tubes, the manufacturer's specifications were taken.

The samples were prepared by weighing the components into test tubes containing a narrow constriction. After the tubes were sealed the samples were centrifuged back-and-forth until the samples were homogeneous. The type I mesophases studied were ternary systems composed of detergent/heavy water/electrolyte. The detergents used were sodium decylsulfate (SDS), cesium decylsulfate (CDS), and potassium laurate (KL). In the absence of the electrolyte, the binary systems in the concentration region used are known to be hexagonal mesophases (20), which will not orient in the magnetic field presumably because of their very high viscosities. The addition of electrolyte induces a first order phase change to produce the type I mesophases used here. A report of the phase diagrams of these systems is being prepared. The composition of the samples prepared are as follows (compositions given in weight %): sample A, 47.77% D_2O, 50.21% CDS, 2.01% Na_2SO_4; sample B, 64.56% D_2O, 33.22% KL, 2.21% KCl; sample C, 55.69% D_2O, 39.77% SDS, 4.54% Na_2SO_4; and sample D, 63.76% D_2O, 33.98% KL, 2.27% KCl. The type II mesophase used had the composition: 51.71% D_2O, 6.25% decanol, 37.48% SDS, 4.28% Na_2SO_4.

The spectrometer used was a Bruker SXP-60 externally locked to a proton signal in water at 60 MHz. The deuterium frequency occurs at 9.21 MHz. Each of the spectra taken over the course of a kinetic study was obtained in a period of less than 5 s using 1 to 10 pulses.

Results and Discussion

The orientation of the mesophase director can be conveniently monitored by the deuterium nmr spectrum of the D_2O. The deuterium quadrupole splitting $\Delta\nu$ is given by

$$[2] \qquad \Delta\nu = \tfrac{3}{2}QS_{zz}\tfrac{1}{2}(3\cos^2\Omega - 1)$$

where Q is the quadrupole coupling constant, S_{zz} is the degree of order with respect to the director of the principal axis of the electric field gradient, and Ω is the angle between the director and the magnetic field direction. If the directors of the mesophase are randomly oriented in three dimensions (powder pattern) the line shape can be approximated by (21):

$$[3] \qquad g(\nu) = N\left(1 \pm \frac{2\nu}{c}\right)^{-1/2}$$

where $c = \frac{3}{2}QS_{zz}$ and $-c \leq \nu \leq c/2$ for the negative sign and $-c/2 \leq \nu \leq c$ for the positive sign combination. N is a normalization constant.

A relevant equation is that describing the line shape for a mesophase in which the directors are randomly oriented in a plane which includes the magnetic field direction (two dimensional powder pattern) and is given by:

$$[4] \qquad g(\nu) = N'(\sin 2\Omega)^{-1}$$

N' is similarly a normalization constant. In this case $0 \leq \Omega \leq \pi$ represents the angle between the directors and the magnetic field, and $\nu = \frac{3}{8}QS_{zz}$

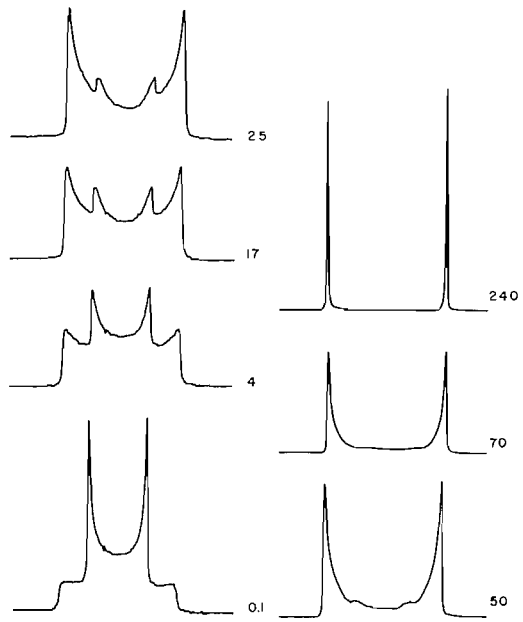

FIG. 1. Deuterium nmr spectra of D_2O in a type I mesophase after various times, given in minutes, in the magnetic field. The doublet separation of the oriented sample was 593 Hz at 30.6°. The composition is listed in the Experimental section as sample A.

$(3\cos^2\Omega - 1)$. In eqs. [3] and [4] the effect of the linewidth is neglected.

In Fig. 1 the line shapes observed for the orientation process of a type I mesophase prepared from the cesium decylsulfate detergent are shown. The sample illustrated had not achieved complete orientation after 240 min. At equilibrium the quadrupole splitting was 592.8 Hz and the linewidth at half-height was 3.9 Hz, approximately 1 Hz greater than the peak for pure D_2O. After only 4 min the intensity of the signals from the directors at $\Omega = 0°$ (the extremes of the spectra) become accentuated and continuously grow at the expense of all other angles as the experiment proceeds. The magnetic torque on a diamagnetic anisotropy ΔX has a sin 2Ω dependence and is a maximum for directors at 45° to the field (8). It becomes zero at 0° and 90°. The persistence of observable intensity for directors at 90° to the magnetic field is clearly seen for the deuterium magnetic resonance spectrum recorded at 70 min after immersion in the field. The theoretical description of the line shape evolution with lack of definite solutions of the dynamic equations for $\Omega > 45°$ (13) is complicated and not necessary since the velocity constant of orientation can be obtained from the following type of experiment.

The dynamic spinning experiments used to study thermotropic nematic mesophases (12, 13, 16, 17) are impractical for the study of these lyotropic mesophases because of the very slow spinning speeds required. However, the same information can be obtained from a static experiment. A type I mesophase was first allowed to orient fully in a magnetic field and subsequently rotated by a fixed angle about an axis perpendicular to the field. The orientation of the director to the static field and the angular distribution in the directors can be monitored as a function of time from the deuterium nmr spectrum. Equation [1] can be integrated to express the instantaneous angle Ω between the director and the magnetic field as a function of time t and the initial sample rotation angle Ω_0. This equation is,

$$[5] \qquad \ln \tan \Omega = -kt + \ln \tan \Omega_0$$

where the rate constant $k = -\Delta\chi B^2/\lambda_1$, the symbols having the same meanings as in eq. [1].

This equation was found to describe the experimental results with an extremely high correlation when the sample was rotated by less than ca. 25°. A typical plot of the experimental data is shown in Fig. 2. During the course of the reorientation the distribution of the directors was observed to be homogeneous; the linewidth of the D_2O doublet increased slowly by only 3 to 4 Hz and then sharpened as the directors approached the equilibrium alignment parallel to the field. For larger rotation angles (but less than 45°) the directors initially rotate with the same rate constant but then began to deviate from the behaviour predicted by eq. [5]. As the process progressed the rate constant gradually increased and this was accompanied by an increase in the director distribution. This behaviour appears to be completely analogous to that observed for the

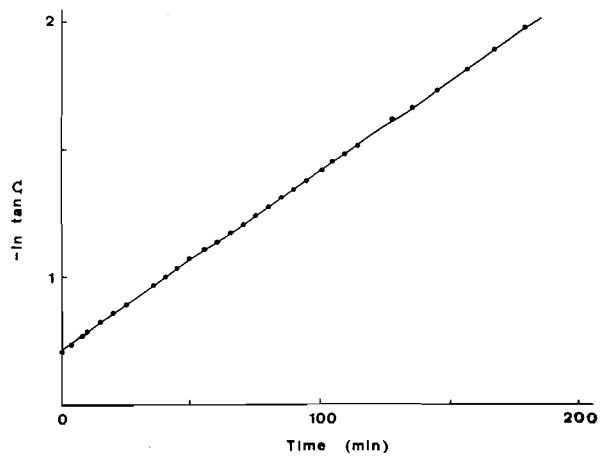

FIG. 2. The dependence of the angle Ω between the magnetic field direction and the director as a function of the time after an initial rotation of 26.3°. The angle was determined from the quadrupole splitting of the D_2O in the mesophase (sample C in Experimental section).

dynamic sample spinning experiments based on eq. [1] for the thermotropic mesophases. The phase lag ϕ was observed to be smaller than expected and a broad distribution of director directions developed at higher angular velocities.

In order to investigate the possible effects of the glass/liquid crystal interface, the angular velocity constant, k, was determined in cylindrical Pyrex sample tubes of different diameter in the same magnetic field strength, with the same sample at the same temperature. The internal diameters of the tubes varied between 1.3 and 9.07 mm. In all cases the form of eq. [5] accurately described the kinetics for initial rotation angles of less than ca. 25°. However, as indicated in Fig. 3 the observed rate constant k is a strong linear function of the inverse radius of the tube up to ca. 4 mm in diameter. For larger tubes the velocity of orientation is slower and independent of the tube radius. The surprising result is that the smaller the tube diameter the higher the velocity of orientation in the magnetic field and that these effects are evidently provoked by liquid crystal/surface interface forces. While the theory responsible for eqs. [1] and [5] does not admit surface effects the results nevertheless obey the form of the equation accurately for all tube sizes. The behaviour observed here for lyotropic mesophases is in contrast to that for thermotropic mesophases where no dependence on the sample size was observed for tubes of 1 to 5 mm diameters (16).

The effect of the composition of the sample tube was investigated using a cylindrical Teflon tube. The rate constant measured for a sample in this tube was identical to that for the same sample in a Pyrex tube.

The effect on a type I mesophase of rapid spinning about a perpendicular axis to the field was investigated. The sample was first allowed to orient in the magnetic field and then was subject to spinning about the nmr tube axis in the normal way at about 5 Hz for several hours. Immediately on cessation of spinning a deuterium spectrum, shown at the top of Fig. 4, was observed which clearly results from a random orientation of directors in a plane containing the magnetic field (eq. [4]). The act of spinning at an angular velocity greater than the re-orientation rate of the mesophase directors (which is ca. 3×10^{-4} s^{-1} for this sample) leads to randomization in the plane perpendicular to the axis of spinning and parallel to the field. While spinning, the modulations of frequency because of variations of the angles Ω result in extensive side band frequencies which mask the true angular distribution of director angles.

The behaviour of the lyotropic mesophases in these experiments parallels that of the thermotropic mesophase in almost every aspect in spite of the differences in chemical composition. The major exception is the

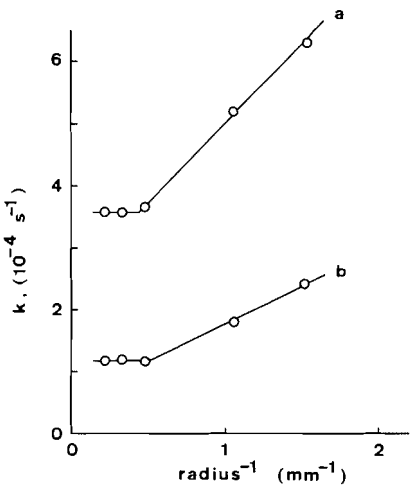

FIG. 3. The dependence of the rate constant on the sample tube size for the reorientation of the director of type I mesophases: curve *a*: a potassium laurate mesophase (sample B in Experimental section) measured at 30.0°, curve *b*: a sodium decylsulfate mesophase (sample C in Experimental section) studied at 29.1°C. The quadrupole splittings were 601 and 723 Hz, respectively.

increased reorientation rate observed in small tubes for the lyotropic media. Equation [5] appears to accurately describe the behaviour of the lyotropic mesophases in large samples when the initial angular displacement is not too large. Consequently these experiments provide a convenient method for the determination of the ratio $\Delta\chi/\lambda_1$. The rate constants in the limiting regions for the two samples shown in Fig. 3 are $1.17 \times 10^{-4}\ s^{-1}$ and $3.57 \times 10^{-4}\ s^{-1}$ in a field of 14.1 kG. The ratios of $\Delta\chi/\lambda_1$ of 5.89×10^{-13} and 1.80×10^{-12} (in cgs units) for these two lyotropic mesophases are 4 to 5 orders of magnitude smaller than for the thermotropic mesophases. Typical values of this ratio for the nematic mesophases MBBA (11), PAA (11), and Merck Phase IV (13) are 1.12×10^{-7}, 1.4×10^{-8}, and 2.24×10^{-8} respectively. This large difference must be due to the combined effects of a much smaller diamagnetic anisotropy as well as perhaps a larger viscosity coefficient.

The enhanced reorientation rate constant observed in small tubes probably reflects the effects of twist walls created at the interface between the homogeneously oriented bulk medium and the layer strongly anchored at the surface (8, 22). The coherent length (23) of this surface layer is small compared to the dimensions of the samples studied here. However de Gennes (ref. 8, p. 177) has postulated that the dissipation measured in these rotating field measurements may be influenced by nucleation, migration, and annihilation of the defects produced by the rotation of the directors in the bulk relative to the surface layer. This effect has not been observed for nematic mesophase in samples down to 1 mm in diameter at low angular velocities (16). Presumably in lyotropic mesophases with their much larger viscosity coefficient this relaxation mechanism becomes apparent in much larger samples.

The distribution of director angles in an oriented type II lyotropic mesophase was also investigated. The sample, in a 10 mm nmr tube, was allowed to orient and then was rotated by 90°. The results of this experiment are illustrated in Fig. 5. The initial powder pattern spectrum is replaced by a sharp doublet equal to the separation of the powder pattern maxima. After rotation of the sample tube by 90° the distribution of the directors in the perpendicular plane can be monitored and this is shown in the spectrum recorded at the head of Fig. 5. The result is not a truly random distribution in the plane of the magnetic field as described by eq. [4]. The non-random distribution of directors must originate from the effects of the liquid crystal/glass interface. In the stationary type II mesophase the directors assume a 90° orientation to the field with a high degree of homogeneity. However, in this plane perpendicular

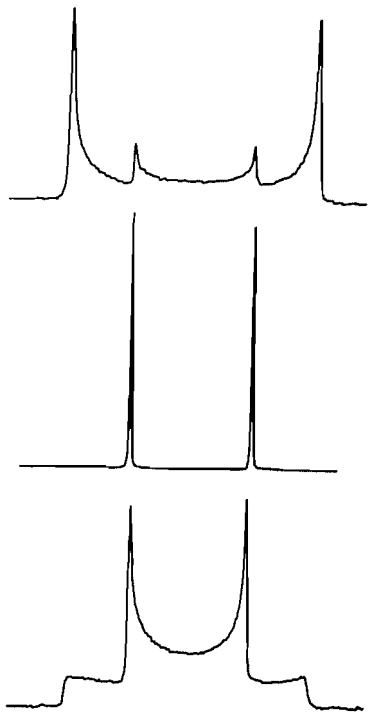

FIG. 5. Deuterium nmr spectra of a sodium decylsulfate type II mesophase (composition given in Experimental section) containing D_2O; bottom, immediately after being placed in the magnet; middle, after the sample was allowed to orient without sample spinning; top, immediately after the oriented sample was rotated 90°. The doublet separation of the oriented sample was 522 Hz at 31°C.

to the field the directors tend to adopt a perpendicular alignment to the cylinder walls in preference to the direction parallel to the tube axis. From the experiment performed here it is evident that the interface effects are propagated into the body of the liquid crystal over distances of several millimetres. These long range interface effects are of course weaker than the magnetic torque exerted on the director in these samples since continuous spinning results in an alignment of the directors parallel to the tube axis with a high degree of homogeneity.

The orientation of the director perpendicular to the surface in the type II mesophases is consistent with our limited knowledge of the micellar structure in these mesophases. The orientation of amphiphilic solutes in these systems indicates that the director is perpendicular to the aqueous/hydrophobic interface. In both lamellar and hexagonal mesophases, this interface is known to align parallel to glass surfaces (24).

The nonstereospecific addition of benzeneselenenyl chloride to 3,4-dihydro-2*H*-pyran

DENNIS G. GARRATT

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received January 19, 1978

DENNIS G. GARRATT. Can. J. Chem. **56**, 2184 (1978).

The addition of benzeneselenenyl chloride to 3,4-dihydro-2*H*-pyran in methylene chloride at 25°C gives 65% of the *trans* and 35% of the *cis* Markownikoff adduct: 2-chloro-3-phenylselenotetrahydropyran under conditions of kinetic control. The above reaction was observed to be reversible, the adducts subsequently reacting with the benzeneselenenyl chloride under conditions similar to those used for the reaction with 3,4-dihydro-2*H*-pyran to give diphenyl diselenide and 2,3-dichlorotetrahydropyran in good yield. There was no evidence for the formation of 3-chloro-2-phenylselenotetrahydropyran under conditions of either kinetic or thermodynamic control. Kinetic studies support a mechanism involving a seleniranium ion that opens to an oxacarbonium ion before the product determining step.

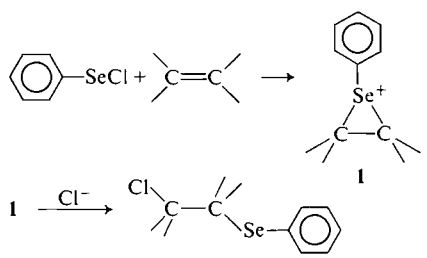
DENNIS G. GARRATT. Can. J. Chem. **56**, 2184 (1978).

L'addition du chlorure de benzènesélénenyle au dihydro-3,4 2*H*-pyranne, dans le chlorure de méthylène à 25°C, conduit, dans des conditions favorisant le contrôle cinétique, à l'adduit prévu par la règle de Markownikoff soit le chloro-2 phényl-3 sélénotétrahydropyranne contenant 65% de produit *trans* et 35% de produit *cis*. On a observé que cette réaction est réversible; les adduits réagissent ultérieurement avec le chlorure de benzènesélénenyle, dans des conditions semblables à celles utilisées pour la réaction du dihydro-3,4 2*H*-pyranne, pour conduire au disélénure de diphényle et au dichloro-2,3 tétrahydropyranne avec de bons rendements. Il n'y a aucune indication à l'effet que du chloro-3 phényl-2 sélénotétrahydropyranne pourrait se former dans des conditions de contrôle soit cinétique soit thermodynamique. Les résultats des études cinétiques sont en accord avec un mécanisme impliquant un ion séléniranium qui s'ouvre pour conduire à un ion oxacarbonium avant l'étape déterminant la nature du produit.

[Traduit par le journal]

Introduction

The reaction of areneselenenyl chlorides with alkenes has been found to be a stereospecific *anti* addition by numerous workers (1). This observation in addition to supplementary kinetic evidence has been used as the basis for postulating a mechanism involving a seleniranium ion **1** intermediate before



the product forming step (2). Since general mechanistic conclusions are too often drawn from the data of a reaction of an electrophile with alkenes of only one structural type or from a limited number of compounds (3), it seemed advisable to study the reaction of a selenenyl chloride with an olefinic species where a suitable open carbonium ion might be generated during the course of the reaction. We have previously reported the reaction of 2,4-dinitrobenzeneselenenyl chloride with *cis*- and *trans*-1-phenylpropene to be *anti*-stereospecific (4). The major significance of this work rests on the premise that the two nitro groups destabilize the development of positive charge on selenium, thus promoting the formation of an open benzylic carbonium ion. The absence of *non*stereospecific addition therefore is taken as indicative of the greater stability of seleniranium ions relative to benzylic carbonium ions under these conditions. It was clear from this work that an olefinic precursor to a more stable carbonium ion would be necessary if nonstereospecific addition were to be observed.

We wish to report the first case of a nonstereospecific addition of an areneselenenyl chloride to an olefin and discuss its mechanistic implications.

Results

Product Studies

The addition of benzeneselenenyl chloride to 3,4-dihydro-2*H*-pyran in methylene chloride solution gives two products, **2** and **3**, in 35 and 65% yields, respectively. No difference in products was observed in the presence of added oxygen, isoamyl nitrite, or in the presence or absence of light. The reaction was investigated over a wide temperature range −60 to 30°C. The product distribution was observed to be essentially invariant over this range indicating that the *cis* and *trans* adducts are configurationally stable under these reaction conditions. Furthermore it was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

found that the reaction products are unstable in methylene chloride eliminating HCl or reacting further with benzeneselenenyl chloride in a slow reaction to yield diphenyl diselenide and a 1:2 mixture of *cis*- and *trans*-2,3-dichlorotetrahydropyran. Despite numerous attempts **2** and **3** could not be obtained in their pure state. Control experiments indicated that although the initial reaction proceeded essentially to completion there was in fact an equilibrium between adduct and starting material. Benzeneselenenyl chloride, formed as a result of this reversibility, reacts quantitatively with the adducts **2** and **3**. A similar result has been previously observed with respect to the adduct of benzeneselenenyl chloride with 2,3-dimethyl-2-butene (2).

Structural assignments were based on the 80 and 100 MHz ^{1}H nmr spectra of the crude product mixtures. The chlorine atom at the newly developed anomeric center (C-2) is axial as is predicted by the anomeric effect and confirmed by ^{1}H nmr analysis since the vicinal coupling constants are small (J_{ea} = 3.1 Hz, *cis* isomer and J_{ee} = 4.3 Hz, *trans* isomer (5)). The *cis* and *trans* adducts were assigned using ^{1}H nmr spectroscopy via the criteria that the equatorial anomeric proton at C-2 for the *cis* diastereomer is, in general, shifted further downfield than that of the corresponding *trans* isomer (5). A comparison of ^{1}H nmr parameters of **2** and **3** with the previously published data for the analogous Markownikoff and anti-Markownikoff phenylthio and ethylthio chlorotetrahydropyrans clearly shows them to have the Markownikoff regiochemistry (ref. 5*a*, p. 2152; ref. 6). Thus compounds **2** and **3** may be assigned as *cis*- and *trans*-2-chloro-3-phenylselenotetrahydropyran, respectively.

Kinetic Studies

The rate of the addition of benzeneselenenyl chloride to 3,4-dihydro-2*H*-pyran in methylene chloride at 25°C was followed by the stopped-flow technique using a Durrum–Gibson stopped-flow spectrophotometer. The rate of disappearance of benzeneselenenyl chloride was followed by measuring the decrease in its absorption at 433 nm. The addition was found to exhibit second-order kinetics, first order in olefin and first order in selenenyl chloride to at least 80% completion of the reaction. No correlation was found between the raw kinetic data and integrated first- or third-order rate expressions. The results are given in Table 1.

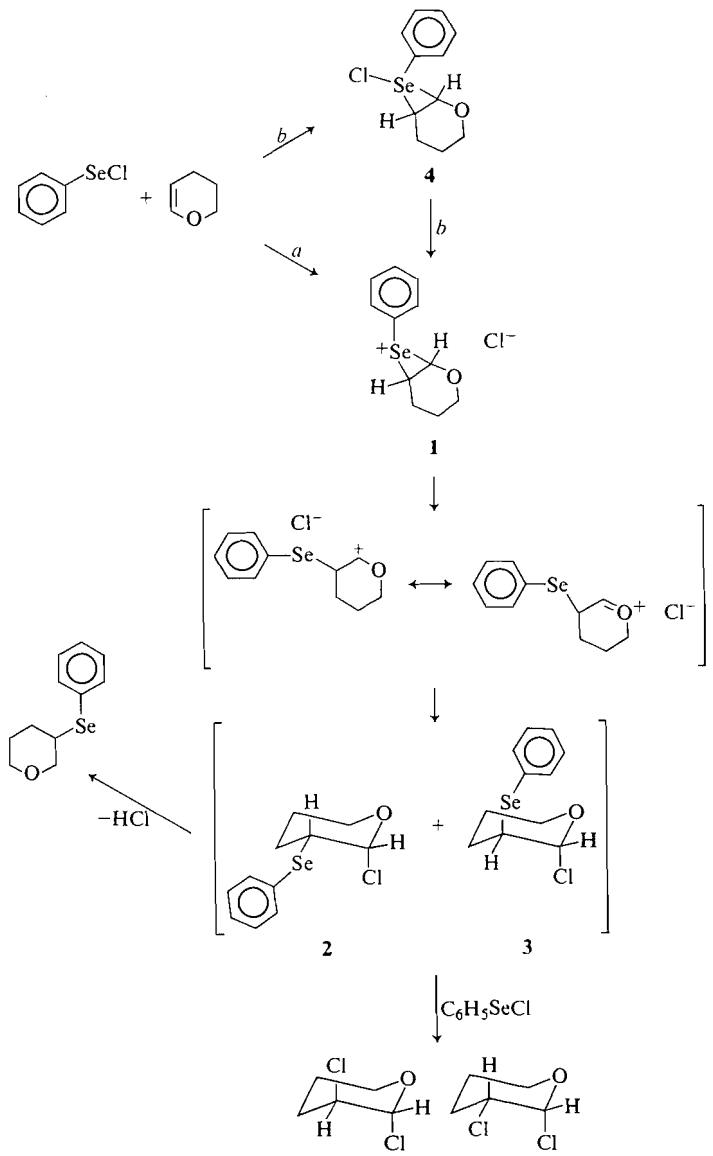
Discussion

From the data presented it is clear that the addition of benzeneselenenyl chloride to 3,4-dihydro-2*H*-pyran is nonstereospecific. These results are in contrast to the stereospecific *anti* additions observed for the reaction of ArSeX species to simple alkenes. Despite this change in the degree of stereospecificity, simple second-order kinetics are observed in analogy with previously studied systems.

Considering the nature of the rate determining transition state, it is clear from the data given in Tables 1 and 2 and that available elsewhere (2) that electron donating groups enhance the rate of reaction compared to ethylene. The reaction may thus be considered to be Ad_E2 in nature (7). It is thus somewhat surprising initially that cyclohexene reacts at only half the rate of ethylene and that 3,4-dihydro-2*H*-pyran reacts at a rate equivalent to that of ethylene. A priori one might have expected cyclohexene and *Z*-2-butene to have similar reactivity and to observe a dramatic increase in reactivity for 3,4-dihydro-2*H*-pyran based on its potential for delocalizing charge development on carbon and the increased nucleophilicity of its double bond. Such a postulate would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



SCHEME 1

be readily supported by the observed *non*stereospecific addition which clearly involves an open carbonium ion rather than a bridged ion intermediate prior to the product determining step. In fact such a variation in reaction rates had been observed for the analogous reactions of 4-chlorobenzenesulphenyl chloride to these alkenes under similar reaction conditions (see Table 2). Furthermore the stereochemistry of the addition of sulphenyl chlorides to 3,4-dihydro-2*H*-pyran is stereospecific *anti*! Consequently it appears increasingly unlikely that an open carbonium ion can be the first formed intermediate.

The equivalency of the rates of reaction of benzeneselenenyl chloride with ethylene and 3,4-dihydro-2*H*-pyran plus the two-fold decrease in reactivity for cyclohexene and 1-methylcyclohexene suggest the presence of a large steric retardation effect which counteracts the expected rate enhancements through electron donation. Alternatively these results might be explained by charge delocalization almost entirely on selenium plus a steric interaction mechanism of somewhat lesser importance.

The mechanism most consistent with these facts involves a bridged transition state in the rate determining step leading to a seleniranium ion **1** intermediate which then opens to an oxacarbonium ion intermediate. In this mechanism only the product determining transition state resembles the open carbonium ion intermediate. A variant of the first mechanism (Scheme 1, route *a*) involving an episelenurane 'like'

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

transition state or intermediate **4** is also consistent with our data (Scheme 1, route *b*) and may explain the observed steric effects in the rate determining transition state somewhat better (8).

Although steric crowding and ring strain in the seleniranium ion or the episelenurane can be relieved by opening to the carbonium ion, this does not appear to be the major driving force for the reaction with 3,4-dihydro-2*H*-pyran. Such a scenario would require that the ether oxygen is sterically more bulky than a methylene group, comparing the reactions of cyclohexene and 3,4-dihydro-2*H*-pyran which seems unlikely. A more suitable explanation appears to be that under our reaction conditions an oxacarbonium ion is more stable than a seleniranium ion which is correspondingly more stable than either a secondary or tertiary carbonium ion. It is noted here that the addition of benzeneselenenyl chloride to both cyclohexene and 1-methylcyclohexene is stereospecific *anti*.

In summary we conclude on the basis of the available data that our experimental results for the addition of areneselenenyl chloride to alkenes are consistent with the formation of a bridged rate determining transition state followed by either a seleniranium ion or open carbonium ion intermediate prior to the product determining transition state depending upon the structure of the alkene.

Experimental

General

All melting and boiling points are uncorrected. Nuclear magnetic resonance spectra were recorded on Varian Associates CFT80 and HA-100 spectrometers using TMS as internal reference. Microanalysis was carried out by Scandinavian Microanalysis Laboratories, Herlev, Denmark. 3,4-Dihydro-2*H*-pyran was obtained commercially from Aldrich and purified before use by distillation, bp 85.6–86.2°C (lit. (9) bp 86–87°C). *Benzeneselenenyl chloride* was similarly obtained from Aldrich and recrystallized before use from methylene chloride, mp 63.7–64.5°C (lit. (10) mp 64°C); uv (n → π* Se—Cl); λ max: 433 nm (ε 264 ℓ mol^{-1} cm^{-1}).

Product Studies

Reactions were carried out in both the presence and absence of light, oxygen and/or isoamyl nitrite. No difference in product composition was observed with respect to these variables. Because of the propensity for the adducts **2** and **3** to react with benzeneselenenyl chloride it was necessary to add solutions of the selenenyl chloride to the alkene.

General Procedure

To a quantity (2.185 g, 0.0260 mol) of 3,4-dihydro-2*H*-pyran in 25 ml of methylene chloride was added dropwise a solution of 4.971 g (0.0260 mol) of benzeneselenenyl chloride in 25 ml of methylene chloride. The reaction was carried out in a 125 ml three-neck flask equipped with a gas inlet for nitrogen and a magnetic stirrer. All nitrogen was predried and deoxygenated before use. The reaction was thermostated in a water bath at 25 ± 0.03°C. Removal of the solvent by rotary evaporation at room temperature gave the mixture of **2** and **3** as a light yellow oil. At elevated temperatures substantial decomposition was observed giving mixtures of *cis*- and *trans*-2,3-dichlorotetrahydropyran and an elimination product *5-phenylseleno-3,4-dihydro-2H-pyran*. *cis*-2-Chloro-3-phenylselenotetrahydropyran (**2**): ^{1}H nmr (CD_2Cl_2) δ: 6.31 (d, J = 3.1 Hz (*CH*Cl), anomeric proton), 3.1–4.1 (broad multiplet), 1.5–2.4 (broad multiplet), 7.2 (m (3H)), 7.4 (m (2H)). *trans*-2-Chloro-3-phenylselenotetrahydropyran (**3**): ^{1}H nmr (CD_2Cl_2) δ: 6.24 (d, J = 4.3 Hz (*CH*Cl) anomeric proton), 7.2 (m (3H)), 7.4 (m (2H)). Attempts to isolate **2** and **3** via preparative tlc on silica gel were unsuccessful. 5-Phenylseleno-3,4-dihydro-2*H*-pyran: ^{1}H nmr ($CDCl_3$) δ: 6.88 (s, (1H) olefinic proton), 3.5–4.2 (broad multiplet), 1.5–2.2 (broad multiplet), 7.2 (m (3H)), 7.4 (m (4H)). The *cis* and *trans* isomers of 2,3-dichlorotetrahydropyran were prepared by the published procedures (5*a* and *d*): ^{1}H nmr ($CDCl_3$) anomeric protons *cis* δ 6.01; *trans* δ 5.95.

Kinetic Procedure

All kinetic runs were carried out on a Durrum-Gibson stopped-flow spectrophotometer as previously described (11).

Further studies of the specificity of carboxypeptidase A towards hippuric acid esters

JOHN W. BUNTING AND SAMUEL S.-T. CHU

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received February 13, 1978

JOHN W. BUNTING and SAMUEL S.-T. CHU. Can. J. Chem. **56**, 2188 (1978).

The kinetics of hydrolysis of a series of 10 new hippurate esters ($C_6H_5CONHCH_2CO_2CRR_1CO_2H$ (I)) by bovine pancreatic carboxypeptidase A have been investigated at pH 7.5, 25°C, and ionic strength 0.5. Pronounced substrate inhibition was displayed by I: R = H, $R_1 = C_6H_5(CH_2)_2$, 3-indolylmethyl, 4-$HOC_6H_4CH_2$, and 4-FC_6H_4 whereas pronounced substrate activation was observed for I: R = H, R_1 = 4-$CH_3C_6H_4$, 4-$C_2H_5C_6H_4$, 4-C_6H_5-C_6H_4, 1-naphthyl, 2-naphthyl, and R = $R_1 = C_2H_5$. In all cases substrate activation and substrate inhibition were shown to be consistent with ES_2 complex formation similar to that previously observed for other hippurate esters. Kinetic parameters were evaluated for each ester and it is noted that all 13 hippurate esters now known to display substrate inhibition have $k_{cat}/K_m > 10^6\ M^{-1}\ min^{-1}$, whereas $k_{cat}/K_m < 10^6\ M^{-1}\ min^{-1}$ for all 9 hippurate esters known to display substrate activation. The enzymic specificity for the R_1 unit of I suggests binding of R_1 in a 'bent' hydrophobic pocket having a restricted entrance.

JOHN W. BUNTING et SAMUEL S.-T. CHU. Can. J. Chem. **56**, 2188 (1978).

On a étudié, à un pH de 7.5, à 25°C et à une force ionique de 0.5, la cinétique de l'hydrolyse d'une série de 10 nouveaux esters hippuriques ($C_6H_5CONHCH_2CO_2CRR_1CO_2H$) (I) par la carboxypeptidase A du pancréas des bovins. Il y a une inhibition marquée du substrat par I: R = H, $R_1 = C_6H_5(CH_2)_2$, indolylméthyl-3, $OHC_6H_4CH_2$-4 et FC_6H_4-4 alors qu'il existe une activation importante du substrat pour I: R = H, $R_1 = CH_3C_6H_4$-4, $C_2H_5C_6H_4$-4, $C_6H_5C_6H_4$-4, naphtyl-1, naphtyl-2 et R = $R_1 = C_2H_5$. Dans tous les cas d'inhibition et d'activation du substrat, on a montré qu'il y a concordance avec la formation d'un complexe ES_2 semblable à celui observé antérieurement pour d'autres esters hippuriques. On a évalué les paramètres cinétiques pour chaque ester et on a noté que les 13 esters hippuriques qui sont maintenant connus et qui montrent une inhibition du substrat ont $k_{cat}/K_m > 10^6\ M^{-1}\ min^{-1}$ alors que les neuf esters connus présentant une activation du substrat possèdent un $k_{cat}/K_m < 10^6\ M^{-1}\ min^{-1}$. La spécificité enzymatique pour le groupe R_1 de I suggère que l'attachement de R_1 se fait dans une couche hydrophobe incurvée ayant une entrée restreinte.

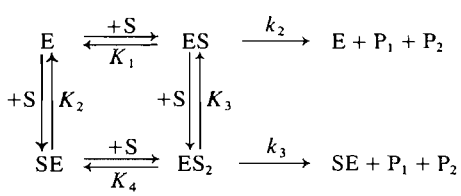
[Traduit par le journal]

Introduction

The kinetics of the hydrolysis of hippurate esters (**I**) by bovine pancreatic carboxypeptidase A are

$$C_6H_5CONHCH_2CO_2CRR_1CO_2H$$
I

complicated by substrate activation and/or substrate inhibition (1–9). Considerable progress has been made in quantitatively describing these phenomena and it has been shown that both substrate activation and substrate inhibition can be ascribed to the formation of 1:2 enzyme–substrate complexes (ES_2) via Scheme 1 (7–10). Some progress has been made in elucidating the relationship between the structure of the alcohol moiety of the ester (i.e., the nature of R and R_1 in **I**) and the occurrence of substrate activation or substrate inhibition; however, more detailed studies are necessary to confirm these ideas. A further complication arises from the observation that there are apparently two different types of ES_2 complex which can lead to substrate activation (7, 9). Furthermore, there are several esters which are known to display both substrate activation and substrate inhibition (7).



SCHEME 1

In the present work, we have studied the hydrolysis of a further 10 hippurate esters by carboxypeptidase A. Detailed analyses of the kinetics of the enzymic hydrolysis of these esters confirm the interpretations previously made on the basis of more limited data. The current data also considerably extend the knowledge of the specificity of carboxypeptidase A for the alcohol moiety of ester substrates and, in combination with literature data for peptide substrates, allow a comparison of the specificity of this enzyme for specific ester and peptide substrates.

Experimental

α-Hydroxy Acids

DL-3-Indolelactic acid and 2-ethyl-2-hydroxybutanoic acid were obtained commercially.

TABLE 1. Characterization of hippurate esters (I)

Ester	R	R_1	Solvent[a]	Melting point (°C)	^{1}H nmr spectrum (CF_3CO_2H), δ (ppm)
1	H	$C_6H_5(CH_2)_2$	CH_3CN–CCl_4(1:1)	150–151	2.4 (2H, t, J = 6 Hz), 2.8 (2H, m), 4.5 (2H, broad), 5.35 (1H, t, J = 6 Hz), 7.2 (5H, s), 7.4–7.8 (6H, m)
2	H	3-Indolylmethyl	$CH_3CO_2C_2H_5$–C_6H_{14}(1:1)	150–151	3.4 (2H, broad), 4.4 (2H, broad), 5.6 (1H,t, J = 6 Hz), 7.1–7.8 (12H, m)
3	H	4-$HOC_6H_4CH_2$	$CH_3CO_2C_2H_5$–C_6H_{14}(1:1)	108–110	3.4 (2H, m), 4.55 (2H, d, J = 4 Hz), 5.55 (1H, t, J = 6 Hz), 6.8 (2H, d, J = 9 Hz), 7.2 (2H, d, J = 9 Hz), 7.5–7.9 (6H, m)
4	H	4-FC_6H_4	CH_3CN–CH_2Cl_2(1:1)	172–173	4.6 (2H, d, J = 4 Hz), 6.25 (1H, s), 7.0–8.0 (10H, m)
5	H	4-$CH_3C_6H_4$	CH_3CN–CH_2Cl_2(1:1)	173–174	2.35 (3H, s), 4.6 (2H, broad), 6.25 (1H, s), 7.3–8.0 (10H, m)
6	H	4-$C_2H_5C_6H_4$	$CH_3CO_2C_2H_5$	179–180	1.25 (3H, t, J = 7 Hz), 2.7 (2H, q, J = 7 Hz), 4.6 (2H, broad), 6.2 (1H, s), 7.3–7.8 (10H, m)
7	H	4-$C_6H_5C_6H_4$	CH_3COCH_3	191–192	4.65 (2H, broad), 6.35 (1H, s), 7.3–7.9 (15H, m)
8	H	1-Naphthyl	$CH_3CO_2C_2H_5$–C_6H_{14}(1:1)	171–172	4.55 (2H, broad), 6.95 (1H, s), 7.3–8.2 (13H, m)
9	H	2-Naphthyl	CH_3OH	194–195	4.65 (2H, broad), 6.4 (1H, s), 7.4–8.0 (13H, m)
10	C_2H_5	C_2H_5	C_2H_5OH	149–150	1.0 (6H, t, J = 8 Hz), 2.2 (4H, q, J = 8 Hz), 4.5 (2H, broad), 7.5–7.9 (6H, m)

[a]Recrystallization solvent.

DL-3-(*p*-Hydroxyphenyl)lactic acid was prepared from 5-(*p*-hydroxybenzylidene)hydantoin (11, 12) as follows. A solution of 5 *M* sodium hydroxide was deoxygenated by purging with nitrogen. This alkaline solution (180 ml) was added to 5-(*p*-hydroxybenzylidene)hydantoin (6.5 g, 0.032 mol) and the solution heated at reflux for 3 h under an atmosphere of nitrogen. The solution was cooled to room temperature. A deoxygenated solution of sodium borohydride (1.22 g, 0.032 mol) in 2% sodium hydroxide (50 ml) was added dropwise over 15 min and the mixture stirred under nitrogen at room temperature for 2 h. Concentrated hydrochloric acid (80 ml) was added slowly and the solution filtered free of white solid and allowed to stand overnight. The solution was acidified with concentrated hydrochloric acid (10 ml), extracted with ether (800 ml), and the ether solution dried over anhydrous magnesium sulfate. Removal of the ether under reduced pressure yielded DL-3-(*p*-hydroxyphenyl)lactic acid (4.6 g, 79%) as a pale yellow, almost colourless solid, mp 106–110°C (dec.).

The remaining α-hydroxy acids were synthesized from the appropriate aldehydes by the general method of Vogel (13).

Synthesis of Esters

All esters were synthesized via the pyridine-catalyzed esterification of hippuryl chloride and the appropriate α-hydroxy acid as previously described (7). The crude products were recrystallized several times to give analytically pure esters. Table 1 contains melting point and ^{1}Hmr spectral data for each ester.

Kinetic Studies

Preparation of enzyme and substrate stock solutions and all kinetic details are as previously described (8, 14). All kinetic data are for pH 7.5, 25°C, and ionic strength 0.5. All calculations are in terms of the concentrations of the L-ester of racemic mixtures. It is well established that the D-esters are neither substrates nor competitive inhibitors for the hydrolysis of the L-esters by carboxypeptidase A (1, 2, 4, 8, 15).

Results

For each of the esters in Table 1, the initial velocity of enzymic hydrolysis was measured at pH 7.5, 25°C, and ionic strength 0.5 over a range of substrate concentration (S) of approximately 0.1–100 mM.

The esters **1–3** displayed substrate inhibition (8, 9). The experimental data for each of these esters were fitted to eq. [1] by the iteration technique

$$[1] \qquad \frac{v}{E} = \frac{k_2^{app}S + k_3S^2/K_{SS}^{app}}{K_S^{app} + S + S^2/K_{SS}^{app}}$$

previously described (16) and the values obtained for the parameters in this way are given in Table 2.

Ester **4** (**I**: R = H, R_1 = 4-FC_6H_4) also displayed substrate inhibition; however, attempts to fit the experimental data for this ester to eq. [1] gave multiple sets of solutions, all of which require K_S^{app} > 2 mM and have k_2^{app}/K_S^{app} = 1.3 × 10^6 M^{-1} min^{-1}. This result is consistent with the observation that the velocity is proportional to the substrate concentration up to S = 2 mM, with $k_{cat}/K_m = k_2^{app}/K_S^{app}$ = 1.3 × 10^6 M^{-1} min^{-1}. In the region where substrate inhibition occurs, v/E is linear in $1/S$ over the range S = 8–50 mM and this allows evaluation of k_3 = 860 min^{-1} and $k_2^{app}K_{SS}^{app}$ = 14 M min^{-1} from the ordinate intercept and slope, respectively, of eq. [2].

$$[2] \qquad v/E = (k_2^{app}K_{SS}^{app}/S) + k_3$$

The esters **5–10** displayed substrate activation (7).

[e]Not experimentally determinable.

For esters **5–8** and **10**, Lineweaver–Burk plots are linear at the lowest substrate concentrations investigated and values of $k_2^{app}/K_S^{app}(=k_{cat}/K_m)$ may thus be evaluated (Table 2). Ester **9** is an extremely poor substrate and substrate activation is apparent at even the lowest substrate concentrations that are experimentally accessible. Thus only a maximum value of k_2^{app}/K_S^{app} may be estimated in this case. For each of esters **5–10**, values of k_3 and $K_S^{app}K_{SS}^{app}$ were evaluated from plots of S^2E/v against S^2 according to eq. [3] (7). Such plots are linear over at least a five-fold range in substrate concentration in the vicinity of

$$[3] \qquad S^2E/v = k_3S^2 + K_S^{app}K_{SS}^{app}/k_3$$

the maximum rates observed in this work. Parameters obtained for esters **5–10** are summarized in Table 2.

For ester **8**, substrate inhibition was observed in the range $S = 20$–50 mM, however solubility limitations prevented a detailed investigation of this phenomenon.

Discussion

The results summarized in Table 2 for the esters **1–10** extend our earlier studies (7, 8) of the specificity of carboxypeptidase A for the R and R_1 substituents of the alcohol moiety of hippurate esters (**I**). It has recently been shown (17) that the specificity of carboxypeptidase A for hippurate esters, as measured by k_{cat}/K_m $(=k_2^{app}/K_S^{app})$, is typical of the specificity of this enzyme for the alcohol moiety of other specific ester substrates. Thus the values for k_2^{app}/K_S^{app} in Table 2, in conjunction with our earlier data (7, 8, 10, 17), may be used as a guide for the prediction of the relative reactivities of a wide range of ester substrates towards hydrolysis by carboxypeptidase A.

Esters **1–4**, which display substrate inhibition, are the most rapidly hydrolyzed of the new substrates reported in this work, and have specificity constants (k_2^{app}/K_S^{app} in Table 2) in the same range (3×10^6–2×10^8 M^{-1} min^{-1} (8)) as those hippurate esters which have previously been shown to display substrate inhibition.

Esters **5–10** which display substrate activation are quite poor substrates, having $k_2^{app}/K_S^{app} < 10^5$ M^{-1} min^{-1}. The most reactive hippurate ester known to display substrate activation is *O*-hippuryl-2-methyllactic acid (ester **15** in Table 2) having $k_2^{app}/K_S^{app} = 3\times10^5$ M^{-1} min^{-1} (7). On the basis of the data now available, there is a clear relationship between the reactivity of hippurate esters towards enzymic hydrolysis and the occurrence of substrate activation or substrate inhibition. Thus all 13 hippurate esters which display pronounced substrate inhibition have $k_2^{app}/K_S^{app} > 10^6$ M^{-1} min^{-1}, whereas all 9 hippurate esters which display pro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

nounced substrate activation have $k_2^{app}/K_S^{app} < 10^6$ M^{-1} min^{-1}. Interestingly, slight activation followed by pronounced inhibition has been suggested (8) for *O*-hippuryl-L-lactic acid, which has $k_2^{app}/K_S^{app} = 3 \times 10^6$ M^{-1} min^{-1} and thus seems to be a borderline case in terms of the above ranges. However, in the present study we could not detect any evidence of substrate activation for ester **4** which has $k_2^{app}/K_S^{app} = 1.9 \times 10^6$ M^{-1} min^{-1} and so is also a borderline case.

In terms of Scheme 1, the parameters in eq. [1] are given by eqs. [4]–[6].

$$[4] \qquad k_2^{app} = k_2/(1 + K_1/K_2)$$

$$[5] \qquad K_S^{app} = K_1/(1 + K_1/K_2)$$

$$[6] \qquad K_{SS}^{app} = K_3(1 + K_1/K_2)$$

Equation [1] predicts (7) that substrate activation will be observed when

$$[7] \qquad K_S^{app} > (k_2^{app}/k_3 - 1)S$$

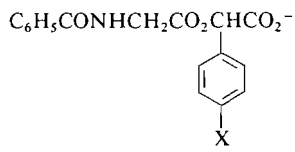
whereas substrate inhibition will be observed if

$$[8] \qquad K_S^{app} < (k_2^{app}/k_3 - 1)S$$

All substrates that are known to display substrate inhibition have $k_2^{app} > k_3$ (e.g., esters **1–4**, **11**, **12** in Table 2) so that, consistent with inequality [8], substrate inhibition is observed for substrate concentrations $S > K_S^{app}/(k_2^{app}/k_3 - 1)$. Inequality [7] may also be satisfied for $k_2^{app} > k_3$ provided that K_S^{app} is quite large (case *i*). However, if $k_2^{app} < k_3$, then inequality [7] is satisfied for all values of S irrespective of the size of K_S^{app} (case *ii*). Case *i* arises if productive binding of the first substrate molecule to the enzyme is weak, whereas case *ii* suggests a situation in which the rate of hydrolysis within an ES complex is much smaller than within an ES_2 species. Clearly, both case *i* (large K_S^{app}) and case *ii* (small k_2^{app}) predict much smaller values for k_2^{app}/K_S^{app} for esters which display substrate activation than for those which display substrate inhibition. This prediction is consistent with the relationship mentioned above between the size of k_2^{app}/K_S^{app} and the occurrence of substrate activation or substrate inhibition.

For *O*-hippuryl-L-*p*-chloromandelic acid (ester **13** in Table 2), it was originally suggested (7) that case *i* was probably applicable. However, more recent comparative studies of the enzymic hydrolysis of other *O*-acyl-L-*p*-chloromandelic acids, which are not as prone to substrate activation as the hippurate ester, and the corresponding *O*-acyl-L-mandelic acids are now available (17). These studies indicate that the introduction of the *p*-chloro substituent results in a dramatic 200-fold decrease in k_2^{app} but only a modest two- to fivefold increase in K_S^{app}. Such data imply that substrate activation in the enzymic hydrolysis of *O*-hippuryl-L-*p*-chloromandelic acid actually arises via case *ii* rather than via case *i*. Consistent with this suggestion, prediction of k_2^{app} for this ester as 1/200 of k_2^{app} for *O*-hippuryl-L-mandelic acid gives $k_2^{app} = 1.1 \times 10^4/200 = 55$ min^{-1} which is considerably less than the observed value of 900 min^{-1} for k_3 for this ester (7) and so is consistent with case *ii*.[1]

Whereas **II**: X = H and **II**: X = F both display substrate inhibition, all other esters **II** in Table 2 are



II

much poorer substrates and display substrate activation (X = Cl, CH_3, C_2H_5, C_6H_5). A similar dramatic influence of a substituent X on a phenyl ring has also been observed for *para*-substituted benzoate ions (**III**) acting as reversible inhibitors of the hydrolysis of hippurate esters by carboxypeptidase A (18). Small X groups lead to competitive inhibition by **III** of

III

hippurate ester hydrolysis, whereas large X groups lead to noncompetitive inhibition. The simplest explanation for these results is in terms of competitive inhibition by **III** requiring the phenyl ring to bind in a hydrophobic pocket which has a geometry that will not accommodate large X groups. The similar dramatic effects of the size of X on the enzymic hydrolysis of **II** (cf. F vs. Cl and H vs. CH_3 in Table 2) strongly suggest that the same steric constraint influences the binding of **II** and **III**. This is consistent with the considerable experimental evidence (8, 19, 20) that points towards the hydrophobic groups of simple competitive inhibitor carboxylate ions binding to the same hydrophobic region of the enzyme as the hydrophobic side chains of the alcohol moieties of ester substrates.

There is not, however, a 1:1 correspondence between the observation of substrate activation or substrate inhibition for X in **II** and the induction of noncompetitive or competitive inhibition by X in **III**. In particular, the hydrolysis of **II** appears to be even

[1]The earlier estimates (7) of $k_2^{app} > 200$ min^{-1} and $K_S^{app} > 50$ mM for *O*-hippuryl-L-*p*-chloromandelic acid are probably in error as a result of an incorrect assumption as to the acceptable range of values for K_{SS}^{app} for this ester.

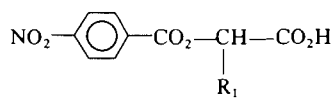
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

more sensitive to the size of X than does the binding of the competitive inhibitors **III**. Thus, whereas **III**: X = CH_3 is a competitive inhibitor (K_i = 8.8 mM) that binds only slightly more weakly than **III**: X = H(K_i = 6 mM), the ester **II**: X = CH_3 is almost a 4000-fold poorer substrate (based on k_2^{app}/K_S^{app}) than **II**: X = H. If it is assumed that the binding of **II** and **III** to the enzyme requires interaction of the carboxylate anion with the same enzymic site, then the greater sensitivity to the size of X in the hydrolysis of **II** than in the binding of **III** can be readily ascribed to the greater distance of X from the terminal carboxylate group in **II** than in **III**.

It seems reasonable to assume that the conclusion reached above for case *ii* being applicable for the hydrolysis of **II**: X = Cl should also be applicable to the other *para*-substituted mandelic acid derivatives (**II**) in Table 2. Case *ii* indicated that the reduced reactivity for large X groups in **II** is predominantly a rate phenomenon (k_2^{app}) rather than a binding phenomenon (K_S^{app}). This suggests that the steric interactions of large X groups with the enzyme can be overcome by reorientation of the substituted phenyl ring by making use of the conformational flexibility provided by the presence of the saturated α-carbon atom of the alcohol moiety. However, this orientation relative to the unsubstituted derivative (**II**: X = H) comes at the expense of the orientation of the hydrolyzable ester bond relative to the catalytically active functional group(s) of the enzyme, and so results in a diminished value for k_2^{app}. This hypothesis suggests that less reorientation should be required for **II**: X = F than for **II**: X = Cl, and thus k_2^{app} is predicted to be larger for X = F than for X = Cl. This prediction is consistent with the experimental observation (Table 2).

The observed enzymic specificity for R_1 in Table 2 may be used to approximately map the enzymic hydrophobic region in which R_1 is bound. The strong binding of esters **2**, **3**, and **11** clearly indicates that the hydrophobic region must be large enough to readily accommodate the 3-indolylmethyl and *p*-hydroxybenzyl groups. The ability of the enzyme to readily accommodate this latter *para*-substituted benzyl group, whereas the *para*-substituted phenyl groups of **II** seem to experience serious steric interactions which result in displaced binding (see above), can be best explained in terms of a 'bent' hydrophobic pocket having a restricted entrance. The conformational flexibility that the β-methylene groups give the *p*-hydroxybenzyl and 3-indolylmethyl groups allows these R_1 groups to position themselves in the pocket without serious interactions with the enzyme 'wall.' However, the rigid R_1 = 4-XC_6H_4, 1-naphthyl, and 2-naphthyl groups encounter serious interactions with the 'wall' near the pocket entrance in attempts to bind so that the hydrolyzable bond is optimally oriented for maximum catalytic effectiveness. As discussed above, these serious interactions can apparently be overcome by a reorientation of the molecule relative to the catalytically active functional groups of the enzyme, which allows a deeper penetration of the R_1 group into the hydrophobic pocket. The shape of the hydrophobic region is also reflected by the much greater reactivity of the α-naphthalene derivative, ester **8**, than the isomeric β-naphthalene derivative, ester **9**. The very low k_2^{app}/K_S^{app} for ester **9** stresses the steric constraints that exist in the vicinity of the hydrophobic pocket entrance, and the requirement for a 'bent' pocket in order to allow for the ready accommodation of the 3-indolylmethyl unit of ester **2**.

The ester **1**, $R_1 = C_6H_5(CH_2)_2$, is an interesting case, since it has the largest k_2^{app} value of any hippurate ester yet studied, and yet K_S^{app} is 100-fold larger than for the most strongly bound hippurate ester known (for $R_1 = (CH_3)_2CHCH_2$, K_S^{app} = 0.021 mM, k_2^{app} = 4400 min^{-1} (8)). The lower homolog, ester **11**, appears to bind about 10-fold more strongly than ester **1** and this suggests that the phenethyl group cannot be accommodated in the hydrophobic pocket in its energetically most favourable conformation. The relationship between esters **1** and **11** should be compared with the corresponding *p*-nitrobenzoate esters (**IV**). For these



IV

latter esters, K_S^{app} for $R_1 = C_6H_5(CH_2)_2$ is also much larger than for $R_1 = C_6H_5CH_2$ but unlike esters **1** and **11**, this homologation is also accompanied by a 30-fold decrease in k_2^{app} (21).

The similarity of the k_3 values for the fluoro- and chloromandelic acid derivatives further reinforces the conclusion that equivalent ES_2 complexes are responsible for substrate activation and substrate inhibition in these hippuric acid derivatives, and that the observation of one or the other of these phenomena is simply a matter of the relative values of the parameters leading to consistency with inequality [7] or inequality [8]. It is interesting that for **II**, the values of k_3 are in the order Cl ≈ F > H > CH_3 ≈ C_2H_5, which is the order expected based on the electronic effects of these X substituents. Thus the large variations in the rate (k_2^{app}) of hydrolysis of

the ES complexes of these esters appear to have been eliminated in the hydrolysis of the ES_2 species.

The ester **10** has not been considered in any of the above discussion. For the related ester **14**, it has been argued (7, 9) on the basis of the large k_3 value, an enhanced k_3/k_{OH} ratio and the pH dependence of k_3, that substrate activation in the enzymic hydrolysis of this ester arises via an ES_2 complex that is not equivalent to the ES_2 complex involved in substrate activation for *O*-hippuryl-L-*p*-chloromandelic acid. The value of $k_3 = 3000$ min^{-1} for ester **10** is also much larger, relative to the other k_3 values in Table 2, than can be accounted for on the basis of simple substituent effects. In particular, for **I**: R = H, $R_1 = C_2H_5$, k_3 is only 200 min^{-1} (8) and so nonequivalent ES_2 complexes are indicated for this ester and ester **10**. It thus appears that for those hippurate esters that do not have a hydrogen atom on the α-carbon atom of the alcohol moiety, an alternative mode of substrate activation is available other than that discussed in connection with case *ii* above.

It is interesting that the specific ester substrates having R = $C_6H_5CH_2$, 4-$HOC_6H_4CH_2$, and 3-indolylmethyl are among the best ester substrates for carboxypeptidase A. It is noteworthy, that these side chains are those present in phenylalanine, tyrosine, and tryptophan, respectively, and that the best peptide substrates for this enzyme have one of these three amino acids present at the C-terminus. Although it is tempting to suggest that this indicates that the C-terminal side chains of productively bound ester and peptide substrates interact with the same hydrophobic region of the enzyme, such a conclusion is inconsistent with a growing body of experimental evidence that is most simply reconciled in terms of distinct productive binding sites for ester and peptide substrates (15, 22–24). In particular, the observation that the 3-phenylpropanoate and 3-indolylacetate ions are competitive inhibitors of esterase activity (19, 23) but noncompetitive inhibitors of peptidase activity (23, 25) is not readily rationalized in terms of common binding sites for the C-terminal sidechains of ester and peptide substrates.

Oxidative cyclization of carbonyl derivatives. 5-Imino-Δ^1-1,2,4-triazolines from alkylideneimino guanidines

LUBOMIRA M. CABELKOVA-TAGUCHI AND JOHN WARKENTIN

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 10, 1978

LUBOMIRA M. CABELKOVA-TAGUCHI and JOHN WARKENTIN. Can. J. Chem. **56**, 2194 (1978).

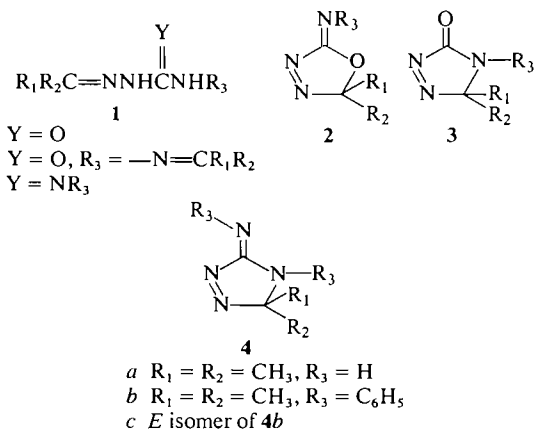
Treatment of 2-propylideneimino guanidinium acetate with lead tetraacetate, in methylene chloride containing solid sodium carbonate, afforded the previously unknown 3,3-dimethyl-5-imino-Δ^1-1,2,4-triazoline. Similarly, *N,N'*-diphenyl-*N''*-(2-propylideneimino)guanidinium acetate afforded *Z*-4-phenyl-5-phenylimino-Δ^1-1,2,4-triazoline as the major oxidation product and the corresponding *E* isomer as a minor product. Stereochemistry was established spectrophotometrically and also by isomerizing the minor (*E*) isomer to the major (*Z*) isomer.

LUBOMIRA M. CABELKOVA-TAGUCHI et JOHN WARKENTIN. Can. J. Chem. **56**, 2194 (1978).

La réaction de l'acétate de propylidèneimino-2-guanidinium avec le tétraacétate de plomb dans le chlorure de méthylène contenant du carbonate de sodium solide conduit à la diméthyl-3,3 imino-5 Δ^1 triazoline-1,2,4 qui était inconnue. De la même manière, l'acétate du *N,N'*-diphényl *N''*-(propylidèneimino-2) guanidinium conduit à la phényl-4 phénylimino-5 Δ^1 triazoline-1,2,4(*Z*) comme produit d'oxydation majeur alors que l'isomère *E* correspondant est le produit mineur. On a établi la stéréochimie d'une façon spectrophotométrique et aussi par isomérisation de l'isomère (*E*) en isomère majeur (*Z*).

[Traduit par le journal]

Oxidation of ketone semicarbazones (**1***a*), either with lead tetraacetate (LTA) (1) or by air in the presence of neutral alumina (2), leads to cyclization products **2** and **3**, respectively. Analogous oxidation



a Y = O
b Y = O, R_3 = —N=CR_1R_2
c Y = NR_3

1 **2** **3**

4

a $R_1 = R_2 = CH_3$, R_3 = H
b $R_1 = R_2 = CH_3$, $R_3 = C_6H_5$
c *E* isomer of **4***b*

of carbohydrazones (**1***b*) yields **2** (R_3 = —N=CR_1R_2) (3) which are of some interest as precursors of diazetidinium hydroxide inner salts (4, 5). As part of a continuing study of the chemistry of cyclic azo systems (5–9), we investigated the oxidation of alkylideneimino guanidines (guanyl hydrazones) (**1***c*) to iminotriazolines **4**, which were unknown. Other Δ^1-1,2,4-triazoline systems were scarce too[1] although there were many examples of 1,2,4-triazoles in the literature. Moreover, we were interested in the stereochemistry of cyclization of **1***c* to **4** because of our earlier finding that **1***a* is oxidized selectively to the *Z* isomer of **2** (10).

Results and Discussion

Oxidation of 2-propylideneimino guanidine[2] (**1***c*, $R_1 = R_2 = CH_3$, R_3 = H) with LTA in CH_2Cl_2 gave 5-imino-3,3-dimethyl-Δ^1-1,2,4-triazoline (**4***a*) in 28% yield. Oxidation with bromine in acetic acid gave the same product in 17% yield. In either case there were numerous by-products which were not identified. The gross structure of **4***a* was established from analytical and spectral data; the strong ir band at 1680 cm^{-1}, characteristic of the exocyclic C=N function (11), was taken as evidence for the imine structure rather than the tautomeric amine structure. Attempts to detect and to separate both *E* and *Z* isomers of **4***a* were unsuccessful. Iminotriazoline **4***a* is readily decomposed by dilute acid or by water to yield acetone. We were unable to find **3**[3] ($R_1 = R_2 = CH_3$, R_3 = H) or the amino tautomer of **4***a*[4] among the products.

Oxidation of *N,N'*-diphenyl-*N''*-(2-propylidene-

[1]The only examples that we were able to find were 1,2,4-triazolinones (**3**) (2).

[2]We assume that it is the free guanidine, not the guanidinium ion, which is oxidized.

[3]Our experience with **3** ($R_1 = R_2 = CH_3$, $R_3 = C_6H_5$), suggests that **3** ($R_1 = R_2 = CH_3$, R_3 = H) would have survived the procedure.

[4]The formation of this tautomer as an intermediate is not precluded, of course, for it may undergo rapid subsequent reactions.

imino)guanidine (**1***c*, $R_1 = R_2 = CH_3$, $R_3 = C_6H_5$) with LTA in CH_2Cl_2 afforded **4***b* (40%) and its *E* isomer (1%). These isomers have indistinguishable ^{1}Hmr and ^{13}Cmr spectra and both have ir bands at 1680 (C=N) and 1590 (N=N) cm^{-1}. Assignment of stereochemistry was based on their uv spectra and on the result of an isomerization experiment.

The uv spectra, λ_{max} (95% ethanol) 410 and 395 nm, for the major and minor isomers, respectively, indicate that the latter is less conjugated than the former. Nonbonded interactions between proximate phenyl groups of the *E* isomer, forcing them out of the plane of the triazoline ring, is the only obvious conjugation-inhibiting feature. The minor isomer was therefore assigned the *E* geometry and the major isomer the *Z* geometry (**4***b*, as drawn).

Partial inhibition of resonance because of steric hindrance between phenyl groups of the *E* isomer should mean that its ground state energy is higher than that of the *Z* isomer. Treatment of the minor isomer with aniline–anilinium buffer converted it (50% yield) to the major isomer, under conditions which left a trace of the minor isomer. Thus, the minor isomer is less stable, thermodynamically, than the major isomer and the assignment based on uv data is supported.

Experimental

3,3-Dimethyl-5-imino-Δ^1-1,2,4-triazoline

LTA Method

2-Propylideneimino guanidinium acetate, mp 221–222°C (lit. (12) mp 222°C) was prepared in 78% yield from aminoguanidine bicarbonate (12). To the acetate (1.7 g, 0.01 mol) in 75 ml of ice-cold dichloromethane was added anhydrous sodium carbonate (2.1 g, 0.025 mol) and the mixture was stirred under nitrogen for 3 h. Lead tetraacetate (2.2 g, 5 mmol, washed with petroleum ether) was added and the resulting yellow slurry was stirred for 10 min before a cold solution of sodium bicarbonate (5.0 g in 20 ml of water) was added. The brown slush which formed was stirred for 15 min and then filtered through Celite. The organic layer was separated and washed three times with ice water before it was dried over magnesium sulfate. Evaporation of dichloromethane at ca. 10°C in a rotary evaporator left a crude solid from which **4***a* (0.25 g, 28%) was obtained by sublimation at room temperature and 10^{-2} Torr: mp 70°C (d); ir 3550, 3490 (NH), 1680 (C=N) cm^{-1}; ^{1}Hmr δ: 1.5, s; uv, λ_{max} (95% ethanol): 285 (2.375). *Anal.* calcd. for $C_4H_8N_4$: C 42.86, H 7.16, N 50.00; found: C 42.80, H 7.09, N 50.11.

Br_2 Method

2-Propylideneimino guanidinium acetate (1.7 g, 0.01 mol) in 50 ml of anhydrous methanol was stirred with anhydrous sodium carbonate (2.1 g, 0.025 mol) for 1 h at ice bath temperature. Bromine (0.60 g, 7.5 mmol) was added dropwise and the yellow solution was stirred for 15 min after addition of Br_2 was complete. Filtration and evaporation of the solvent left a solid which was dissolved in water (25 ml). Extraction with ether (25 ml), washing with water, drying, removal of the ether, and sublimation of the solid residue as described above gave **4***a* (0.15 g) in 17% yield.

3,3-Dimethyl-4-phenyl-5-phenylimino-Δ^1-1,2,4-triazolines (4b and the E *Isomer)*

Acetone-4-phenylthiosemicarbazone (**5**) (13) was methylated by a procedure modelled after Kirsten and Smith's methylation of thioureas (14). To an ice-cold solution of **5** (21 g, 0.1 mol) in 200 ml of absolute ethanol was added methyl iodide (15 g, 0.1 mol) and the resulting solution was stirred for 3 h at ice temperature and subsequently for 12 h at room temperature. During this time, a white suspended solid dissolved leaving a clear yellow solution. Most of the ethanol was evaporated with a rotary evaporator and the resulting viscous, yellow oil was chromatographed on silica gel (80–200 mesh) with 1:1 petroleum ether in CCl_4. From the second fraction was obtained, after recrystallization from alcohol, *N*-phenyl-*N'*-(2-propylideneimino)-*S*-methylisothiouronium iodide (**6**) (16.5 g, 79%) as white crystals: mp 43–44°C; ^{1}Hmr δ: 2.05 (s, 3H), 2.10 (s, 3H), 2.40 (s, 3H), 7.25 (s, broad, 5H), 8.20 (s, broad, 1H).

The salt **6** (18 g, 0.05 mol) was heated on a steam bath under an air condenser with aniline (4.65 g, 0.05 mol, freshly distilled) in 50 ml of dry benzene. When the evolution of methanethiol was no longer detectable by odour (about 24 h), the benzene was removed with a rotary evaporator to leave *N,N'*-diphenyl-*N''*-(2-propylideneamino)guanidinium iodide (**7**) as a syrup (87% yield). This product was used directly in the next step.

The procedure for oxidation of **7** with LTA was analogous to that described above. Evaporation of dichloromethane in the work-up procedure left a dark brown oil which was stirred for 12 h with 50 ml of 1:1 petroleum ether in ether. The orange solvent layer was decanted and the extraction was repeated twice more. Evaporation of the combined extracts left a gummy orange residue which was chromatographed on silica gel (80–200 mesh) using petroleum ether (30–60°C) in ether (4:1) as eluent. Crystallization of the main orange fraction afforded 1.2 g (40%) of **4***a* as orange crystals: mp 89.5–90°C (dec.); ^{1}Hmr δ: 1.66 (s, 6H), 7.16 (s, broad, 5H), 7.3 (s, broad, 5H); ^{13}Cmr δ: 156.11, 147.53, 135.79, 129.55, 128.44, 127.40, 126.78, 123.73, 123.37, 102.60, 24.06; ir: 1680 (s, C=N), 1590 (m, N=N) cm^{-1}; uv λ_{max} (95% ethanol): 410 (3.38), 345 (3.67), 235 (4.11) nm; ms: 264 (molecular ion). *Anal.* calcd. for $C_{16}H_{16}N_4$: C 72.73, H 6.10, N 21.19; found: C 72.97, H 6.45, N 20.97.

A yellow to orange lead fraction from the column gave yellow crystals of **4***c* (0.03 g, 1%): mp 93–94°C; ir ^{1}Hmr, and ^{13}Cmr data identical to those listed above; uv λ_{max} (95% ethanol): 395 (3.88), 338 (3.93), 230 (4.69) nm; ms: 264 (molecular ion). *Anal.* calcd. for $C_{16}H_{16}N_4$: N 72.73, H 6.10, N 21.19; found: C 72.75, H 6.38, N 20.86. Mixture mp (**4***a* and **4***b*): 85–87°C.

Isomerization of 4c *to* 4b

To freshly distilled aniline (10 ml) were added 3 drops of concentrated HCl and **4***c* (0.08 g). The solution was kept at ca. 45°C for 4 h, together with a control sample containing only aniline and HCl. The uv spectrum of a portion of the first solution showed a new absorption band at 410 nm which was not present in the uv spectrum of the control sample. Vacuum distillation of the aniline from the test solution and thin layer chromatography of the residue showed that compounds with the R_f values of **4***b* and **4***c* were present. Column chromatography on silica gel afforded **4***b* (0.041 g, 50%): mp 89–90°C; spectra identical to those of **4***a* obtained by oxidation of **7**.

Metabolites of bird's nest fungi. Part 10.[1] Carbon-13 nuclear magnetic resonance studies on the cyathins

WILLIAM A. AYER, THOMAS T. NAKASHIMA, AND DALE E. WARD
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received April 5, 1978

WILLIAM A. AYER, THOMAS T. NAKASHIMA, and DALE E. WARD. Can. J. Chem. **56**, 2197 (1978).

The carbon-13 magnetic resonance spectra of cyathin A_3 and several related compounds have been measured and the chemical shifts have been assigned. The chemical shift data have been used to determine the stereochemistry at C-1 in cyafrin A_4 and to determine the position of the bromine in 1-bromoallocyathin A_3 methyl acetal.

WILLIAM A. AYER, THOMAS T. NAKASHIMA et DALE E. WARD. Can. J. Chem. **56**, 2197 (1978).

On a mesuré les déplacements chimiques et on a fait les attributions pour des spectres de résonance magnétique du ^{13}C de la cyathine A_3 et de plusieurs composés qui lui sont reliés. On a utilisé les données concernant les déplacements chimiques afin de déterminer la stéréochimie en C-1 de la cyafrine A_4 ainsi que la position du brome dans le méthylacétale de la bromo-1 allocyathine A_3.

Introduction

The cyathins are a group of diterpenoids first discovered several years ago in these laboratories (2). In 1972 we showed that cyathin A_3, a metabolite of the bird's nest fungus *Cyathus helenae*, possessed structure **1***a* (in tautomeric equilibrium with **1***b*) and thus represented a new structural type among the diterpenoids (3). Since that time the structures of several other metabolites of *C. helenae* possessing the same cyathane carbon skeleton **2** have been elucidated (4–6) and related compounds have been obtained from *C. africanus* (1) and *C. earlei*.[2] As a prelude to the investigation of the biosynthesis of the cyathins and cyafrins, which all contain the cyathane skeleton **2**, and as an aid in assigning structures to newly discovered members of this class of diterpenoids, we have studied the carbon-13 nuclear magnetic resonance (^{13}Cmr) spectra of representative compounds and wish to report here the results of this study. These results are then used to assign the relative stereochemistry at C-1 and C-9 in cyafrin A_4 (1), and to assign the position of a bromo substituent in one of the transformation products of cyathin A_3 (6).

Experimental

The ^{13}Cmr spectra were obtained on natural abundance samples at a concentration of approximately 0.2–0.5 *M* in $CDCl_3$ – 5% TMS at a frequency of 22.63 MHz (Bruker HFX-90) and at 15.08 MHz (Bruker WP-60) in 10 mm sample tubes. For those samples (**8**, **9**, and **10**) of limited quantity, a 1.7 mm microinsert was used. Cyclohexane (~2 μl) was used as the

internal reference in these cases and the data converted to the TMS scale ($\delta_{C_6H_{12}} = 27.7$). All the chemical shifts obtained in this manner appeared to be too high by an average of 0.9 ppm; consequently the reported values in Table 1 have been corrected. For the shift reagent study, $Eu(fod)_3$-d_{10} (Norell Chemical Company, Inc.) was added stepwise, up to 0.0168 g of reagent to 0.020 g of **4**, 0.192 g of reagent to 0.130 g of **5**, and 0.075 g of reagent to 0.050 g of **8**. ^{1}Hmr spectra were obtained in $CDCl_3$ on a Varian HA-100. Cyathin A_3 (**1***a* ⇄ **1***b*) was isolated as previously described (4). The preparation of **3**, **4** and **5** has been described (4) as has the preparation of **6**, **8**, **9**, and **10** (6). Compound **7** was prepared by Dr. T. Yoshida from cyafrin A_4 as previously described (1).

Results and Discussion

The ^{13}C chemical shifts of **1** and **3**–**10** are summarized in Table 1. The ^{13}C spectrum of **1** resulted in 40 distinct carbon resonances due to the slow interchange (on the nmr time scale) between hemiacetal and hydroxy ketone forms, which are represented by structures **1***a* and **1***b*, respectively. The complete analysis of this spectrum proved to be difficult so a number of derivatives of **1**, in which the molecular framework is 'locked' in either the open (hydroxy ketone) or closed (acetal) form, were prepared and their ^{13}Cmr spectra obtained. A comparison of the ^{13}C shieldings of **1** with those obtained for **4** and **5** reveals a one to one correspondence of the ^{13}C resonances (except for carbons α and β to a substituent change, e.g., an —OH replaced by an —OAc group) of both closed forms (**1***a* and **5**) and both open forms (**1***b* and **4**). That is, the ^{13}C spectrum obtained from the tautomeric mixture (**1***a* and **1***b*) can be 'synthesized' by combining the spectra obtained for **4** and **5**. Thus, assignments of the ^{13}C resonances of **4** and **5**, along with the other derivatives, leads to the separate assignments of **1***a* and **1***b*.

Assignments of the ^{13}C resonances were made in the following manner. The carbon shieldings may be grouped into approximately four regions (7): (*i*) those corresponding to carbonyl carbons at ~190 ppm; (*ii*) those to olefinic carbons at ~130 ppm; (*iii*) those to carbons bound to oxygen at ~60 ppm; and (*iv*) those to saturated carbons at ~30 ppm. The carbonyl carbon resonances were readily assigned. In the second group, proton selective (for **3**, **4**, and **5**) and off-resonance decoupling (for **3**–**6**) unambiguously distinguished the resonances of C-13 from those due to C-3, C-4, and C-12. The shielding of C-13 is decreased by ~20 ppm upon introduction of —CHO (**6** and **9**) in place of —CH_2OH (**5**, **7**, and **8**) or —CH_2OAc (**3**, **4**, and **10**) as expected (7). The resonances due to C-12 may be separated from those due to C-3 and C-4 by additivity (β acetoxy in **3** vs. β hydroxy in **5**; **3** → **5** for C-12, ~ +5 ppm). For **8**, **9**, and **10** two additional signals due to C-1 and C-2 appear in this region and the more shielded carbon is assigned to C-2 (8).

The third group, C-11, C-14, C-15, and the $-OCH_3$ were assigned unambiguously based on their characteristic shieldings and multiplicity in the off-resonance spectrum.

In the fourth group, the resonances due to C-6 and C-9 were separated on the basis of their multiplicities obtained in the off-resonance spectrum. Little change in shielding is expected for C-9 upon ring closure (**4** → **3**) and on this basis the resonances of C-6 and C-9 were assigned. Selective proton decoupling (for **3**, **4**, and **5**) unambiguously assigned the resonance due to C-18; the remaining methine carbon in this region is due to C-5. The shieldings of these carbons should remain relatively constant for this series of compounds. Selective proton irradiation on **3**, **4**, and **5** allowed the assignment of C-2; again no change in shielding is expected for this carbon in **1** and **3–6**.

Turning to the methyl carbons, C-16 is expected to be the most shielded due to its crowded environment. It also shows the largest shift on ring closure (i.e., **4** → **3**). C-17 is assigned to the least shielded of the methyl resonances because of the higher degree of α and β branching. The acetyl methyls in **3** and **4** were assigned by selective proton decoupling.

The remaining methylene carbons in **1** and **3–6** (C-1, C-7, C-8, and C-10) were assigned in the following manner. Examination of Table 1 shows good agreement of the resonances for **4** and **5** when compared to those obtained for the tautomeric mixture, **1***a* and **1***b*. The only discrepancy in this region occurs at δ 31.7 for **4** when compared to δ 35.6 for **1***b*. The only expected change in shielding should occur at C-10 for which a β-hydroxyl group in **1***b* is replaced by a β-acetyl group in **4** (for C-10; **1***b* → **4**, −5 ppm (7)). Changing from the open form (e.g., **1***b* or **4**) to the closed form (e.g., **1***a* or **5**) causes two of the methylene carbons to become slightly less shielded (~1 ppm) and the other two to become more shielded (~−5 ppm). In **5**, one of the protons of C-10 is in a *syn*-axial orientation with respect to C-16; thus, C-10 is assigned to the most shielded of the methylene carbons. The other methylene carbons which might be affected by internal acetal formation would be C-7 *or* C-8; the close approach of the C-10 proton to those of C-16 could result in a large perturbation on C-8. Alternatively the shielding of C-7 could be influenced, either electronically or sterically, depending upon the functionality at C-14.

To explore this point further a $Eu(fod)_3$ shift study was undertaken to distinguish between C-1, C-7, and C-8 (as well as to confirm some of the other assignments) in **4**, **5**, and **8** and the results are summarized in Table 1. It is well established that lanthanide induced shifts are quantitatively reproduced by the pseudo contact or dipolar shielding term given by (9):

$$\Delta_i = C(1 - 3\cos^2\theta_i)/R_i^3$$

where Δ_i is the induced shift at nucleus i, C is a constant at a given temperature, $(1 - 3\cos^2\theta_i)$ is an orientational factor and R_i is the distance of the shift reagent to nucleus i. The equation is known to break down for carbons α and β to the complexing site (generally a Lewis base) because of the presence of a contact interaction contribution to the shielding (9). Thus, for **4**, **5**, and **8** the shielding of C-7 is expected to be more sensitive to the addition of $Eu(fod)_3$ than C-8 which in turn should be more sensitive than C-1 and the signals were assigned accordingly. The $Eu(fod)_3$ induced shifts for the other carbons in **4**, **5**, and **8** are consistent with the previous assignments.

The stereochemistry of the hydroxyl group at C-1 in cyafrin A_4 (**11**) was originally assigned by application of the pyridine shift (^{1}Hmr) method and by application of Brewster's benzoate rule (1). Examination of the ^{13}Cmr shift data for cyafrin A_4 methyl acetal (**7**) in Table 1 dramatically confirms this assignment. Thus, the C-9 methyl signal is shifted upfield by ca. 8 ppm in **7** relative to **5**, demonstrating the γ-*gauche* relationship between the C-1 hydroxyl and C-17.

In an earlier paper we described the conversion of cyathin A_3 (**1**) into allocyathin B_3 (hydroxy ketone form of acetal **8**) via the monobromo compound **10**. The method of preparation of **10** did not allow us to determine whether the bromine is located at C-1 or C-2. Examination of the ^{13}Cmr spectrum of **10** (Table 1) shows that C-1 is strongly shielded in **10** (relative to **8** and **9**) which is consistent with the location of the bromine at C-1 (10).

Stereochemical analysis of aromatic oximes. ^{13}C–^{15}N nuclear spin coupling and ^{13}C shieldings as conformational probes

GERALD W. BUCHANAN AND BRIAN A. DAWSON

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received January 2, 1978

GERALD W. BUCHANAN and BRIAN A. DAWSON. Can. J. Chem. **56**, 2200 (1978).

^{13}C nmr chemical shifts and ^{13}C–^{15}N spin couplings over one, two, and three bonds are reported for six aromatic oximes including two benz annelated compounds. Preferred geometries have been calculated via the GEMO program. Fermi contact contributions to carbon–nitrogen coupling have been evaluated and, in general, agreement between experimental and theoretical values is poor. Vicinal ^{13}C–^{15}N couplings are shown to depend on both dihedral angle and oxime valence angle. Oxime carbon chemical shifts do not provide a measure of deviation from planarity between the oxime group and the aromatic ring.

The sign of $^1J_{CN}$ in *E*-benzaldoxime has been determined to be negative.

GERALD W. BUCHANAN et BRIAN A. DAWSON. Can. J. Chem. **56**, 2200 (1978).

On rapporte les déplacements chimiques en rmn du ^{13}C et les couplages de spin ^{13}C–^{15}N à travers une, deux et trois liaisons dans six oximes aromatiques incluant deux composés benz-orthocondensés. On a calculé les géométries préférentielles à l'aide du programme GEMO. On a évalué les contributions des contacts de Fermi aux couplages carbone–azote; d'une façon générale, l'accord entre les valeurs expérimentales et théoriques est mauvais. On montre que les couplages ^{13}C–^{15}N vicinaux dépendent à la fois de l'angle dièdre et de l'angle de valence de l'oxime. Les déplacements chimiques du carbone de l'oxime ne fournissent pas une mesure de la déviation de la planarité entre le groupe oxime et le cycle aromatique.

On a déterminé que le signe $^1J_{CN}$ dans le (*E*)-benzaldoxime est négatif.

[Traduit par le journal]

Introduction

A number of recent studies have focussed on the theory and calculations of ^{13}C–^{15}N nuclear spin couplings in simple organic molecules (1, 2). Over the past three years work in this laboratory (3, 4) has dealt with the application of ^{13}C–^{15}N coupling as a tool for spectral assignment in aromatic oximes (3) and with the use of geminal ^{13}C–^{15}N *J* values as a configurational probe (4). We now wish to report data for a series of six aromatic oximes in which detailed experimental and theoretical work has been carried out, with a view to establishing the potential of vicinal ^{13}C–^{15}N coupling as a conformational probe and the possibility of using oxime carbon shifts as indicators of steric inhibition of resonance.

To date, no ^{13}C–^{15}N coupling calculations have been published for oximes other than those derived from formaldehyde (5) and acetaldehyde (1). In the present work, the conformational energy minimization of the six aromatic oximes has been accomplished using the GEMO (6) program. Subsequently the optimized geometries have been used to calculate the Fermi contact contribution to ^{13}C–^{15}N couplings over one, two, and three bonds. Results are compared with experimental data. Where possible, the relative signs of $J_{^{13}C^{15}N}$ have been determined by the off resonance ^1H decoupling procedure (4).

Results and Discussion

Coupling Constants

Direct Couplings

Observed and calculated values are presented in Table 1.

Until now, no sign determination of $^1J_{CN}$ has been carried out for oximes, although the sign has been suggested to be negative based on results for related materials (2, 7). For formaldoxime, $^2J_{NH}$ is +2.68 for H_A whereas $^2J_{NH}$ for H_B is −13.88 Hz (8). In the case of *E*-benzaldoxime, $^2J_{NH}$ is nearly identical to $^2J_{NH_A}$ above, namely 2.80 Hz.

Formaldoxime *E*-Benzaldoxime

Assuming that the sign of this coupling is also positive, one can determine the relative sign of $^1J_{CN}$ using off-resonance decoupling (4). The technique is applicable for determining the relative sign of $^nJ_{CX}$ and the corresponding $^{n+1}J_{HX}$ coupling, where X is a spin $\frac{1}{2}$ nucleus, i.e., ^{15}N. Use is made of the *difference* observed for residual splittings, $J_{residual(CH)} = 2\pi\Delta\nu J_{CH}/\gamma H_2$ in the ^{13}C spectrum of the $J_{^{13}C-X}$ doublet. For *E*-benzaldoxime, off-resonance ^1H decoupling on the high-field side ($\Delta\nu$ = 65 Hz, γH_2 = 1600), caused a reduction in the residual splitting

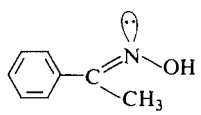
‡Nonresolvable (i.e. <0.6 Hz).

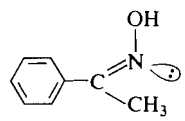
for the low-field lines, indicating $^1J_{CN}$ and $^2J_{H-C-N}$ have opposite signs.

As a check, off-resonance decoupling on the low-field side caused a reduction in the residual J_{CH} on the high-field side. Therefore $^1J_{CN}$ and $^2J_{HCN}$ do indeed have opposite signs and $^1J_{CN}$ is negative.

There is poor agreement between calculated and observed magnitudes of $^1J_{CN}$, although the predicted and observed signs are consistent. It has been calculated (1) that the N lone pair makes a *positive* contribution to $^1J_{CN}$. Assuming that $^1J_{CN}$ is negative for acetophenone oximes as well as the benzaldoxime (9), it is interesting to compare results for **1** and **2**.



1
$^1J_{CN} = -3.8$ Hz



2
$^1J_{CN} = -3.1$ Hz

The phenyl group has a larger effective size than the CH_3. This is reflected in the observation that **1** is considerably more stable than **2**. Accordingly in **1**, the bulky phenyl moiety, being *cis* to the lone pair, will sterically perturb the lone pair relative to **2**. Therefore, there will be less lone pair (positive) contribution to $^1J_{CN}$ in **1** and the enhanced negative value is found.

Geminal Couplings

Earlier experimental results from this laboratory (4) demonstrated that $^2J_{^{13}C-C-^{15}N}$ is large and negative in sign when the N lone pair is *cis* to the CH_3 group (i.e., in **2**) whereas the geminal coupling is small and positive in sign when the N lone pair is *trans* to the CH_3 group (i.e., in **1**). It is interesting to note that calculations for **1** and **2**, based on the Fermi contact mechanism, are consistent with the experimental findings with respect to sign, although the magnitudes are not predicted by the theory. For compounds **3** and **4**, the observed geminal couplings between ^{15}N and the oxime CH_3 are not resolvable (i.e., <0.6 Hz). In **5** and **6**, where larger values are found, we have now determined the signs to be positive using the off-resonance ^1H decoupling procedure (4). Thus for all cases to date, geminal ^{15}N-C–CH_3 J values are positive in situations where the N lone pair is *trans* to the CH_3.

As our procedure for relative sign determination depends on the coupling carbon having a directly

bonded proton, no sign determinations have been done for the geminal interactions to the C-2 (aromatic carbon) of **1**–**6**. Experimentally these values are rather large (range 8.0 → 9.2 Hz) for **1**, **3**, **4**, **5**, and **6**, again indicating that the presence of the *cis* lone pair on N enhances the absolute value of ^2J (11).

Vicinal Couplings

Three bond ^{13}C–^{15}N J values were observed in all materials except **2** where peak overlap precluded the measurements. Data for the remaining compounds are presented in Table 2 along with the dihedral angles (θ) and the  valence angles (ϕ)

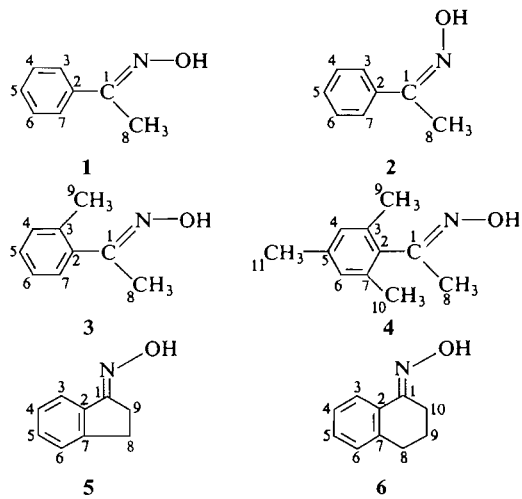

FIG. 1. Structures and numbering scheme for aromatic oximes **1**–**6**.

obtained from GEMO. For **1**, which is calculated to be nearly planar, ^3J is 2.9 Hz. This represents an average value over the two planar conformations, since rotation about the aryl–oxime bond is fast even at −100°C. We have not yet been able to freeze out this process.

In the case of the *ortho*-methyl derivative **3**, the dihedral angles are very similar to **1** but the vicinal couplings are reduced to ca. 1 Hz. A rationale for this reduction comes from examination of the valence angles ϕ. In **3**, the molecule distorts, to reduce steric interactions between the oxime and the *o*-CH_3, by expansion of ϕ to 121.9°, compared to 119.5° in **1**. This expansion renders the N lone pair of electrons more distant from the vicinal carbon in **3** and thus may lead to reduced coupling. Certainly for *geminal* interactions, the coupling has maximum absolute value when the N lone pair is spatially proximate to the coupled carbon (3, 4).

For **4** the coupling of 1.2 Hz is identical to that found for the corresponding 2,4,6-trimethylbenzaldoxime (10). The GEMO calculations suggest that the steric congestion between the oxime function and the two *o*-CH_3 groups is reduced by a deviation from planarity of ca. 36° between the plane of the aromatic ring and the oxime group. It is interesting to note that the ϕ value of **4** is identical to **1**, since **4** escapes steric compression by altering θ. Therefore, for a common ϕ, it appears that there *is* a dihedral angle dependence of ^3J, with maximal coupling found in planar or near planar situations.

The dihedral dependence of $^3J_{CN}$ in **5** and **6** is interesting, albeit unexplained, at present. In **5**, coupling to the *trans*-coplanar carbon (C-7) is considerably larger than that to the *cis*-coplanar carbon (C-3). By

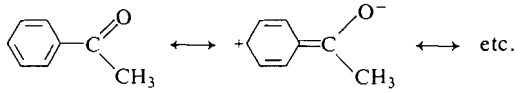
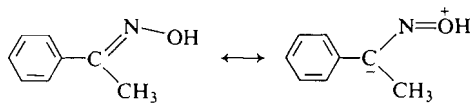
contrast in **6**, the coupling to the *cis*-coplanar carbon (C-3) is 3.8 Hz, whereas that to the *trans*-coplanar carbon (C-7) is only 2.9 Hz.

Chemical Shifts

Results for **1** and **2** have been discussed in detail earlier (4). In the case of the *ortho*-alkylated systems **3** and **4**, we wished to explore the possible existence of steric inhibition to resonance, which has been amply demonstrated for the related ketones (12–14). Deviations in planarity between the carbonyl group and the aromatic ring in *ortho*-alkylated acetophenones are known to induce substantial deshielding of the carbonyl group due to less efficient resonance overlap between the phenyl and carbonyl moieties.

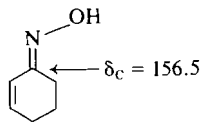


In the present molecules the oxime carbon shift could, in principle, be used to monitor such effects. For the planar system **1**, the C=N resonates at $\delta = 155.9$ ppm, whereas in **3** and **4** there is a minor deshielding (ca. 2 ppm) at this site (Table 3). The effects are much less pronounced than in the corresponding ketones, where the C=O of mesityl methyl ketone is ca. 10 ppm deshielded relative to that of acetophenone (12, 13). Furthermore, examination of the GEMO results indicates that the dihedral angles θ are essentially identical in **3** to those of **1**, only the oxime valence angle ϕ expands in **3** as was noted earlier. In **4** the deviation from planarity is ca. 36° between the oxime function and the aromatic ring but the oxime shift is nearly identical to that of **3**. Clearly the oxime shifts do not provide a mechanism for estimation of torsional angles between the aromatic ring and the substituent group. A factor which may complicate the present situation is a second type of resonance interaction, shown below, which is available to oximes but not to ketones.



In view of these results, it is useful to compare the oxime shifts of the benz-fused compounds **5** and **6** with those for cyclopentanone and cyclohexanone oxime, respectively (15). For **5**, there is a 2.7 ppm shielding of the oxime resonance compared to the alicyclic case, whereas in **6** the upfield shift due to benz annelation is 5.0 ppm. Therefore there is apparently some conjugative electron release by the aromatic ring into the oxime functions of **5** and **6**. The calculated torsional angles between the oxime group and the aromatic ring of **5** and **6** are nearly identical. This suggests that more subtle bond angle influences may be present to account for the differential shielding in **5** and **6** as a function of ring size.

For *E*-cyclohexenone oxime (below) the oxime carbon is deshielded by only 1 ppm relative to **6**.[1] Thus the electron release from a single conjugated double bond into the oxime moiety appears to be similar to that from an aromatic ring.



Experimental

Spectra

^{13}C spectra were recorded at 25.16 MHz using a Varian XL-100-12 nmr spectrometer equipped with a Nicolet TT-100 Fourier transform data system. Samples were examined as 0.1 *M* solutions in $CDCl_3$ solution in 5 mm sample tubes. For coupling constant determinations spectral widths were commonly 1000 Hz and a minimum of 8K data points were employed. For chemical shift measurements, spectra widths of 5000 Hz were used. Relative signs of $J_{^{13}C^{15}N}$ were determined as described earlier (4).

Calculations

The initially specified molecular geometries for the oximes, used as input for the GEMO program (6) were derived from standard parameters (16). Subsequently GEMO carries out a systematic variation of bond lengths, bond angles and torsional angles to minimize the conformational energy of the molecule. Parameters were iterated until a convergence criterion of 0.01 kcal/mol was met. The barrier to rotation about the aryl–oxime bond was taken as 9.0 kcal/mol by analogy with results from similar molecules (17). Constants for the van der Waals interactions were taken from COMOL, a program written for conformational energy calculations, by Michel H. J. Koch, Laboratoire de Chimie Physique et de Cristallographie, Universite de Louvain-Belgium. In the present treatment, methyl hydrogens on a given carbon atom are considered equivalent.

The ^{13}C–^{15}N couplings were calculated using the finite perturbation calculation procedure outlined by Pople *et al.* (18), with a program obtained from Quantum Chemistry Program Exchange #224, Bloomington, Indiana.

Materials

The synthesis and properties of **1** and **2** were reported earlier (3, 4). Below are described synthetic procedures for the other materials.

E-o-*Methylacetophenone Oxime* (*3*)

o-Methylacetophenone (0.150 g), $^{15}NH_2OH{\cdot}HCl$ (0.100 g), and KOH (0.20 g) were added to 3 ml EtOH (95%) and the solution was refluxed for 4 h. The solution was then poured into 15 ml cold water, neutralized with 1 *N* HCl, and placed in a freezer for 1 h. The solid was collected and recrystallized from EtOH–H_2O; mp 61–62°C (lit. (19) mp 64.5–65.5°C).

E-*Mesityl Methyl Ketoxime* (*4*)

This compound was prepared according to the procedure of Hauser and Hoffenberg (20) using 95% ^{15}N-enriched hydroxylamine hydrochloride obtained from Merck, Sharpe, and

Studies with model membranes. Part XXIV. Evaluation of thermodynamic activation parameters, effective fixed charge density, and test of the theory of bi-ionic potential based on the thermodynamics of irreversible processes

FASIH A. SIDDIQI, M. NASIM BEG, M. IBADUR RAHMAN KHAN, ABDUL HAQ, S. K. SAKSENA, AND BADRUL ISLAM

Membrane Research Laboratory, Department of Chemistry, Aligarh Muslim University, Aligarh, 202001 India

Received November 3, 1976[1]

FASIH A. SIDDIQI, M. NASIM BEG, M. IBADUR RAHMAN KHAN, ABDUL HAQ, S. K. SAKSENA, and BADRUL ISLAM. Can. J. Chem. **56**, 2205 (1978).

The various ionic processes in the membrane system, notably (*a*) ionic transport, (*b*) membrane potential, (*c*) electrical conductivity, (*d*) ionic distribution equilibria, and (*e*) spatial distribution of ions and the potential within the membrane have been thoroughly studied with parchment-supported membranes. By applying the theory of absolute reaction rate, various thermodynamic parameters, namely, enthalpy of activation ΔH^*, energy of activation ΔF^*, and entropy of activation ΔS^* were evaluated. The ΔS^* values were found to be negative, indicating that diffusion takes place with partial immobilization in the membrane phase. A formal relation between $\Delta H_{\text{hydration}}$, $\Delta F_{\text{hydration}}$, and $\Delta S_{\text{hydration}}$ of cations with corresponding values of ΔH^*, ΔF^*, and ΔS^* for diffusion was also worked out. Thermodynamically fixed charge density was evaluated using methods based on thermodynamics of irreversible processes. Potentiometric selectivity and recent theory of bi-ionic potential based on nonequilibrium thermodynamics was tested and found applicable to parchment membranes.

FASIH A. SIDDIQI, M. NASIM BEG, M. IBADUR RAHMAN KHAN, ABDUL HAQ, S. K. SAKSENA et BADRUL ISLAM. Can. J. Chem. **56**, 2205 (1978).

On a étudié d'une façon extensive, à l'aide de membranes supportées par des parchemins, les divers processus ioniques des systèmes de membranes, à savoir: (*a*) le transport ionique, (*b*) le potentiel de la membrane, (*c*) la conductivité électrique, (*d*) les équilibres de distributions ioniques, (*e*) la distribution spatiale. Une application de la théorie des vitesses absolues a permis d'évaluer divers paramètres thermodynamiques, à savoir l'enthalpie d'activation ΔH^*, l'énergie libre d'activation ΔF^* et l'entropie d'activation ΔS^*. On a trouvé que les valeurs de ΔS^* sont négatives; ceci indique que la diffusion a lieu par une immobilisation partielle dans la phase de la membrane. On a aussi pu établir une relation formelle entre les $\Delta H_{\text{hydratation}}$, $\Delta F_{\text{hydratation}}$ et $\Delta S_{\text{hydratation}}$ des cations avec les valeurs correspondantes de ΔH^*, ΔF^* et ΔS^* pour la diffusion. On a évalué la densité de charge fixe thermodynamique en faisant appel à des méthodes basées sur la thermodynamique de processus irréversibles. On a évalué la sélectivité potentiométrique et la théorie récente du potentiel bi-ionique, basée sur la thermodynamique des phénomènes irreversibles, et on a trouvé qu'on peut l'appliquer aux membranes de parchemin.

[Traduit par le journal]

Introduction

We have been engaged in the studies of (*a*) parchment-supported, (*b*) polymeric-composite, and (*c*) polystyrene-based ion exchange membranes (1–8) which can serve as models for biological systems. Membrane theories of Kedem and Katchalsky (9), Spiegler (10), Scathchard (11), Scattergood and Lightfoot (12), etc., have been used to evaluate various membrane parameters.

This article deals with the following aspects of parchment-supported membranes: (*A*) application of Nernst–Planck flux equations and Fick's diffusion law (13) and evaluation of various thermodynamic activation parameters, (*B*) evaluation of thermodynamically effective fixed charge density by the most recent methods of Nagasawa and co-workers (14, 15) and others (16–21) based on thermodynamics of irreversible processes, and (*C*) evaluation of potentiometric selectivity coefficient and test of the most recent theories of membrane potential and bi-ionic potential developed by Toyoshima and Nozaki (22) based on non-equilibrium thermodynamics.

Experimental

Preparation of Parchment-supported Membranes

The membranes of silver tungstate and chromic ferricyanide were prepared by the method of interaction suggested by Weiser (23) and Siddiqi *et al.* (2). First parchment was soaked in distilled water for about 2 h and then tied carefully to the flat mouth of a beaker in which 0.2 *M* solution of $AgNO_3$ was taken. This was suspended for about 72 h in a 0.2 *M* sodium tungstate solution. The temperature was kept at 25°C. The two solutions were interchanged and kept for another 72 h.

[1]Revision received April 20, 1978.

In this way fine deposition of silver tungstate was obtained on the surface of parchment paper. Similar procedure was adopted for chromic ferricyanide membrane by taking 0.2 *M* solutions of chromic chloride and potassium ferricyanide. The temperature maintained in this case was kept at 72°C and the time for deposition was 3 h. Both the membranes thus prepared were well washed with deionized water for the removal of free electrolytes. The vegetable parchment paper was supplied by M/S Baird and Tatlock (London) Ltd.

Part A. Studies of Diffusion of Electrolytes Through Parchment-supported Silver Tungstate Membrane

The apparatus and procedures used to measure membrane potential $\Delta\phi_m$, membrane resistance R_m, and electrolyte concentrations are those described by Siddiqi *et al.* (2–4). The half cells contained 125 ml of the electrolyte solutions while the capacity of each of the cells holding the membrane was about 130 ml. Initially the concentrations C_1 and C_2 across parchment-supported silver tungstate membrane were 0.001 *M* and 0.1 *M* of the same electrolyte, respectively. Each of the half cell was fitted with two platinized platinum electrodes firmly fixed to follow concentration changes and two anion reversible Ag–AgCl electrodes: one a disc type to pass a small d.c. current and the other a J-shaped wire electrode placed very near the membrane surface to measure membrane potential (by Pye Precision Potentiometer No. 7568) and changes in membrane potential following current flow. The solutions in both the half cells were kept well stirred by magnetic stirrers. The whole cell assembly was immersed in a water thermostat maintained at 10, 15, 20, 25, and 30°C (±0.1°C).

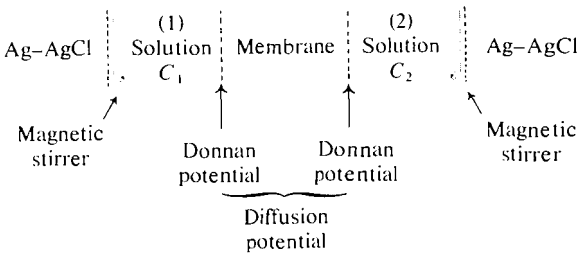
The changes in conductance on the dilute solution side was followed by means of the conductivity bridge (Cambridge Instrument Co., England, No. L-350140). The exact concentration of the solution at any given time was estimated from a calibration curve. The membrane resistance was determined by applying an external emf to the disc-type Ag–AgCl electrodes and measuring the change in potential across the membrane using J-type wire electrodes. The current passed through the membrane system was determined by measuring *IR* drop across a precision Kilo-Ohm resistor. The current was kept very low in order to minimize the ion transfer during the period (2–3 min) required for each resistance measurement. The direction of current flow was reversed in each successive measurement. The surface of the membrane was controlled during membrane resistance measurements but on account of the changes in salt concentration due to diffusion on the dilute solution side, the control was not 100% perfect. However, reproducible results were obtained during resistance measurements. The d.c. current densities at the electrode and membrane surfaces were also determined in mA cm^{-2}. The resistance measurements gave a value of the entire system, namely,

Electrolyte film – Membrane – Electrolyte film

In order to measure R_m directly the wire electrodes should be placed strictly on the membrane surfaces. When this was done, membrane resistance values were not 100% reproducible. The value of membrane resistance determined in this way includes additional film (very thin) resistance which is outside of the membrane itself. Although the membrane potential could be measured to a better accuracy than ±1%, the estimation of membrane resistance was accurate to ±4%.

Part B. Membrane Potential Measurements

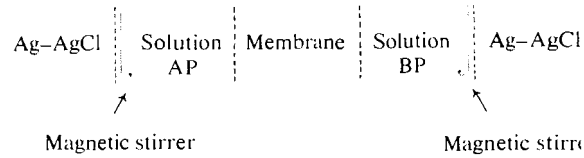
Separate measurements of membrane potentials were carried out by setting another electrochemical cell of the following type



with fixed concentration ratio $C_1/C_2 = \sigma = 10$ throughou the experiment (concentration varied from 1.0 *M* to 1.0 × 10^{-3} *M*). The temperature was kept constant at 25 ± 0.1° and the solutions were vigorously stirred. The membran potentials were measured for parchment-supported silve tungstate and chromic ferricyanide membranes.

Part C. Bi-ionic Potential Measurements

The measurements were recorded by constructing anothe new electrochemical cell of the following type



In this cell concentrations of both AP and BP types of elec trolyte solutions (KCl–NaCl, KCl–LiCl, and KCl–NH_4C were kept the same on both sides of the membrane (parch ment-supported silver tungstate membrane only). The bi-ioni potentials were measured at 25°C (±0.1°C) across the parch ment-supported silver tungstate membrane using KCl–NaC KCl–LiCl, and KCl–NH_4Cl electrolyte sets in each successiv measurement. The solutions were vigorously stirred by mear of the magnetic stirrers on both sides of the membrane. Th measurements were recorded when three changes in the te solutions did not lead to potential variation ±0.2 mV. A least two membranes were utilized in each experiment. Th membrane potential measurements with silver tungstate men brane were further carried out to obtain two membrane paran eters V_N and θ/K_N (N = A, B) which are required for th evaluation of theoretical values of bi-ionic potentials. Th membrane potentials were measured by constructing a cell the type described in Part B. The concentration ratio σ w kept constant at 10 for each electrolyte solution (e.g. KC NaCl, LiCl, NH_4Cl etc.) used in the present investigation.

Results and Discussion

Part A. Evaluation of Activation Parameters, Namely, ΔH^*, ΔF^*, and ΔS^* for Diffusion of Various Electrolytes through Parchment-supported Silver Tungstate Membrane

When an ionic gradient is maintained using tw solutions of different concentrations of the sam electrolyte on either side of the membrane, diffusio of electrolytes from the region of higher concentr tion takes place. These transport phenomena a often described by some extended form of Nerns Planck flux equation (24). Evaluation of flows r quire integration of these flux equations under sui able boundary conditions governing the behavi

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of the membrane–electrolyte system. Kittelberger (25) from the simple laws of electrolysis developed the following equation [1] for the evaluation of diffusion rates through membranes. This equation is found to be applicable as is evident from Fig. 1 to the system of parchment-supported silver tungstate membrane.

$$[1] \quad \frac{dQ_+}{dt} = \frac{1}{Z_+ F R_m}\left[\frac{RT}{Z_+ F}\ln\frac{a_2}{a_1} - \Delta\phi_m\right] \times \left[\frac{Z_+ Z_-}{Z_+ + Z_-}\frac{\Delta\phi_m}{(RT/F)\ln a_2/a_1} + \frac{Z_+}{Z_+ + Z_-}\right]$$

where Q_+ is the milliequivalents of cation diffusing in time t s, Z_+ and Z_- are the valencies of the cation and anion, respectively. R_m is the resistance in ohms of the membrane, $\Delta\phi_m$ is the membrane potential in mV, a_1 and a_2 are the activities of the two electrolyte solutions on either side of the membrane, R, T, and F have their usual meanings.

The rates at which various electrolytes diffuse through the membrane were calculated at different temperatures from eq. [1]. The calculated values of diffusion rate (dQ/dt) or D_r in mol/s at 25 ± 0.1°C are given in Table 1. The changes in R_m and $\Delta\phi_m$ and electrolyte flux (dQ/dt) or D_r through silver tungstate membrane are shown in Fig. 2. The diffusion rate derived electrometrically or conductometrically determined changes in the salt concentration of the test solution C_1 is called 'observed' diffusion rate while the values computed from the measured concentration potential and electrolytic resistance of the membrane is designated the 'computed' diffusion rate. The observed and computed diffusion rates are plotted against time (Fig. 1) for various electrolytes diffusing through silver tungstate membrane at 25 ± 0.1°C. It is found that the two methods show somewhat systematic deviations. The reason for these deviations probably has its origin in additional film resistances to mass transfer which are outside of the membrane itself. It was also noted that very small error in the measured salt concentration can produce a large error in the 'observed' diffusion rate. The physical imperfections in the membranes can also contribute towards the deviation.

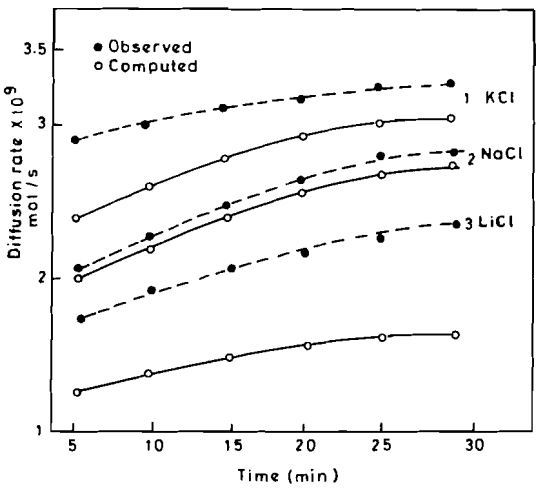


FIG. 1. Plots of observed and computed diffusion rates against time for diffusion of electrolytes through silver tungstate membrane.

The emf measured across the membrane using J-type Ag–AgCl electrodes is made up of two components. The first is the electrode potential difference $\Delta\phi_c$ due to the Ag–AgCl electrodes existing in two chloride solutions of different activities a_1 and a_2 of the same electrolyte and second is due to the membrane potentials $\Delta\phi_m$ arising across the membrane due to flow of electrolyte through it.

$\Delta\phi_c$ is given by the following equation:

$$[2] \quad \Delta\phi_c = (RT/Z_- F)\ln(C_2\gamma_2)/C_1\gamma_1)$$

where γ_1 and γ_2 are the activity coefficients of the electrolyte solutions on either side of the membrane (taken from the literature). Since Z_- is always unity and $C_1\gamma_1(a_1)$ and $C_2\gamma_2(a_2)$ are known, $\Delta\phi_c$ can be computed. As $(\Delta\phi_c + \Delta\phi_m)$ is measured directly, the value of $\Delta\phi_m$ can be evaluated by subtraction.

$\Delta\phi_m$ values for various electrolytes display a very interesting phenomena. In the case of 1:1 electrolytes, the values are all positive indicating that the membrane is cation selective. On the other hand, for 2:1 and 3:1 systems of electrolytes $\Delta\phi_m$ changes sign. It means that the membrane is now anion selective. This change in the selectivity character of the membrane is evidently due to adsorption of multivalent ions leading to a state where a net positive charge is

TABLE 1. Experimental activation energies and the activation parameters derived from transition state theory of rate process for diffusion of various electrolytes by the end of 2 h periods at 25 ± 0.1°C through parchment-supported silver tungstate membrane

	Parameters

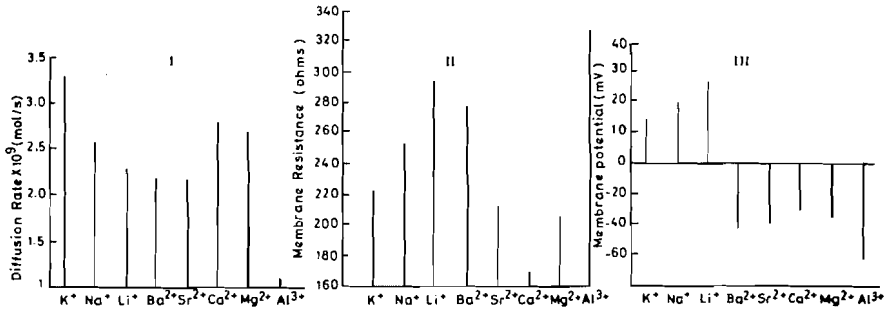

FIG. 2. Plots of diffusion rates, membrane resistance, and membrane potential through silver tungstate membrane against various cations.

left on the membrane surface making it anion selective. Adsorption of Al^{3+} makes the membrane more anion selective than it is with the adsorption of divalent cations. At any given time the membrane resistance R_m increases in the following order

$$LiCl > NaCl > KCl$$

and

$$BaCl_2 > SrCl_2 > MgCl_2 > CaCl_2$$

for 1:1 and 2:1 electrolytes and 3:1 system of electrolyte produces the highest value for membrane resistance.

The rate of flow measured for different electrolytes through silver tungstate membrane follows the sequence

$$KCl > NaCl > LiCl$$

and

$$CaCl_2 > MgCl_2 > SrCl_2 > BaCl_2$$

for 1:1 and 2:1 systems of electrolytes. The diffusion rates are calculated at different temperatures through the investigated membrane and are plotted against $1/T$ (K) (Fig. 3).

The theory of absolute reaction rates has been applied to diffusion by several investigators (26–28). According to Laidler and co-workers (27, 28) the integral diffusion coefficient D is given by

$$[3] \qquad D = Ae^{-E_a/RT}$$

where E_a is the observed activation energy for diffusion and A is the frequency factor. Thus if $\log D_r$ is plotted against $1/T$ (K), the slope gives the value of E_a. The values derived in this way for E_a are given in Table 1 at 25 ± 0.1°C. The derived values of D from eq. [3] are also given in Table 1. Various thermodynamic activation parameters, namely, enthalpy of activation, ΔH^*, entropy of activation, ΔS^*, and free energy of activation, ΔF^*, are also calculated with the help of Gibbs Helmholtz equations. The derived values of ΔH^*, ΔS^*, and ΔF^* are given in Table 2. The values of ΔS^* are found to be negative.

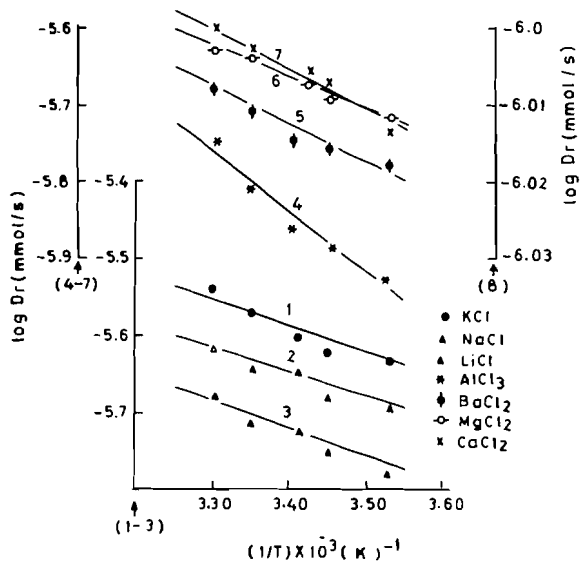

FIG. 3. Plots of diffusion rates of various electrolytes against different temperatures through silver tungstate membrane.

TABLE 2. The thermodynamic activation parameters calculated from the transition state theory of rate processes for electrolyte diffusion at 25 ± 0.1°C through silver tungstate membrane

Electrolytes	ΔH^* (kcal/mol)	ΔS^* (eu)	ΔF^* (kcal/mol)
KCl	5.62	−0.12	5.66
NaCl	5.39	−1.79	5.93
LiCl	5.16	−2.98	6.06
$BaCl_2$	4.24	−7.13	6.37
$CaCl_2$	4.97	−3.83	6.09
$MgCl_2$	4.59	−5.46	6.22
$AlCl_3$	5.85	−3.82	6.99

The negative ΔS^* indicates that the electrolyte dif fusion is taking place with the partial immobilizatio in the membrane phase (28). This partial immobilit increases in a relative manner with increase in th

valence of ions constituting the electrolyte with parchment-supported silver tungstate membrane.

Part B. Evaluation of Thermodynamically Effective Fixed Charge Density by the Use of Membrane Potential Values

Both the most recent method by Nagasawa and co-workers (14, 15) as well as the method developed by Kobatake and co-workers (16–21) are based on thermodynamics of irreversible processes applied here for the evaluation of fixed charge density of membranes.

The Method by Kobatake and Co-workers

The following expression used for charge density evaluation is given by Kobatake and co-workers (16–21):

$$[4] \quad \Delta\phi = -\frac{RT}{F}\left[\frac{1}{\beta}\ln\frac{C_2}{C_1} - \left(1 + \frac{1}{\beta} - 2\alpha\right) \times \ln\frac{C_2 + \alpha\beta\theta}{C_1 + \alpha\beta\theta}\right]$$

where

$$[5] \quad \alpha = [u_+/(u_+ + u_-)]$$

and

$$[6] \quad \beta = [1 + (KF\theta/u_+)]$$

The symbols u_+ and u_- represent the molar mobilities of positive and negative ions; K is a constant which is considered to depend upon the viscosity of the solution and the structural details of the polymer network of which the membrane is composed; θ is the fixed charge density (in equivalent/ℓ) of the membrane; C_1 and C_2 are the concentrations of electrolyte solutions across the membrane; R, T, and F have their usual meanings.

Kobatake and co-workers (16–21) have derived two limiting forms of eq. [4] useful for the analysis of experimental data on membrane potential. These are

(*a*) When C_2 becomes sufficiently small with σ fixed, eq. [4] may be expanded to give

$$[7] \quad |\Delta\phi_r| = \frac{1}{\beta}\ln\sigma - \left(\frac{\sigma - 1}{\alpha\beta\sigma}\right)\left(1 + \frac{1}{\beta} - 2\alpha\right)\frac{C_2}{\theta}$$

where $|\Delta\phi_r|$ is the absolute value of reduced membrane potential defined by

$$[8] \quad |\Delta\phi_r| = F\Delta\phi/RT$$

Equation [7] indicates that the value of β and a relation between α and θ may be obtained by determining the intercept and the initial slope of a plot for $|\Delta\phi_r|$ against C_2. The value of intercept is given by $(1/\beta) \times \ln\sigma$ from which β may be evaluated.

(*b*) In the region of high concentration the apparent transference number $t_{-\text{app}}$ is defined by

$$[9] \quad |\Delta\phi_r| = (1 - 2t_{-\text{app}})\ln\sigma$$

Substituting for $|\Delta\phi_r|$ in eq. [4] and expanding the resulting expression for $1/t_{-\text{app}}$ in powers of $1/C_2$ gives

$$[10] \quad \frac{1}{t_{-\text{app}}} = \frac{1}{1 - \alpha} + \frac{(1 + \beta + 2\alpha\beta)(\sigma - 1)\alpha\theta}{2(1 - \alpha)^2(\ln\sigma)C_2}$$

Equation [10] indicates that the intercept for a plot of $1/t_{-\text{app}}$ against $1/C_2$ at fixed σ allows the value of α to be determined. For the evaluation of α from eq. [10], plots of $1/t_{-\text{app}}$ against $1/C_2$ for various electrolytes through parchment-supported silver tungstate and chromic ferricyanide membranes are drawn (Fig. 4). The value of intercept is given by $1/(1 - \alpha)$ from which α is evaluated. Therefore from the predetermined β and α values, θ is evaluated and its values are given in Table 3 for various electrolytes with investigated membranes.

Test of the Kobatake Theory

Kobatake and co-workers (16–21) also suggested the following procedure for comparison of the theory

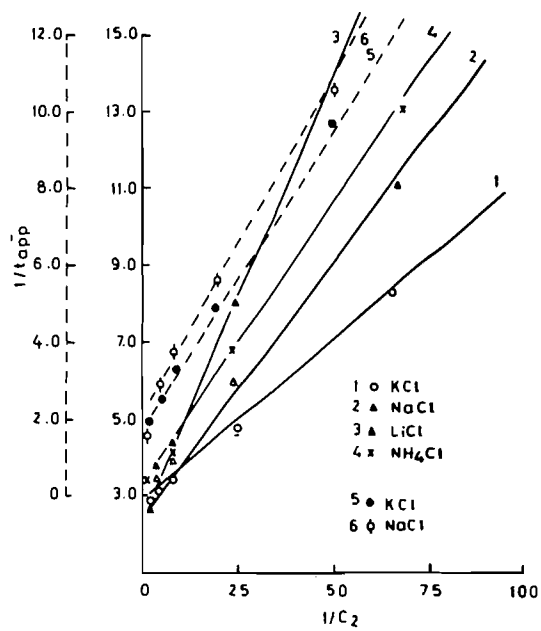

FIG. 4. Plots of $1/t_{-\text{app}}$ against $1/C_2$ for various electrolytes through (*i*) — silver tungstate and (*ii*) --- chromic ferricyanide membranes. (*i*) KCl (○), NaCl (△), LiCl (▲), and NH_4Cl (×); (*ii*) KCl (●), NaCl (ϕ).

TABLE 3. Values derived for thermodynamically effective fixed charge density θ (in equiv./ℓ) of parchment-supported membranes at σ = 10

	Membranes			
	Silver tungstate		Chromic ferricyanide	
Electrolytes	Kobatake method	Nagasawa method	Kobatake method	Nagasawa method
KCl	0.0557	0.032	0.045	0.020
NaCl	0.0813	0.032	0.031	0.080
LiCl	0.0610	0.024	—	—
NH_4Cl	0.0730	0.048	—	—

and experiment by taking the following expressions

$$[11] \qquad (\sigma - e^q)/(e^q - 1) = Z$$

where

$$[12] \qquad q = \frac{|\Delta\phi_r| + (1 - 2\alpha)\ln\sigma}{1/\beta + 1 - 2\alpha}$$

and

$$[13] \qquad Z = C_2/\alpha\beta\theta$$

Thus if eq. [4] is valid, the values of $(\sigma - e^q)/(e^q - 1)$ calculated from measured $\Delta\phi$ and predetermined α, β, and θ values at a known value of σ (= 10) must fall on a straight line which has a unit slope and passes through the origin when plotted against log Z. Figure 5 demonstrates that the theoretical prediction from membrane potential equation is borne out quite satisfactorily by our experimental results with these investigated membranes.

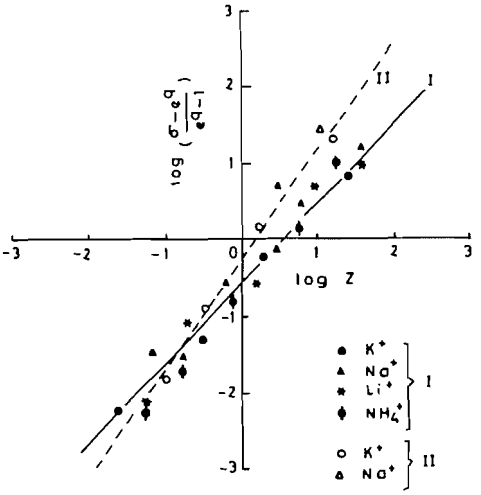

FIG. 5. Plots of log $(\sigma - e^q)/(e^q - 1)$ against log Z for various electrolytes through (*i*) — silver tungstate and (*ii*) --- chromic ferricyanide membranes. (*i*) KCl (●), NaCl (▲), LiCl (*), and NH_4Cl (◆); (*ii*) KCl (○), NaCl (△).

The Method of Nagasawa and Co-workers

Nagasawa and co-workers (14, 15) used the following equations by making various assumptions for activity and mobility of small ions, which are applied here. The membrane potential equation is given by

$$[14] \qquad -\Delta\phi = \frac{RT}{F}\frac{\theta}{2}\frac{\sigma - 1}{\sigma}\frac{1}{C_2} + \frac{RT}{F}\frac{u_+ - u_-}{u_+ + u_-}\frac{\left[1 - \dfrac{\theta J_0}{RT\bar{C}_0(u_+ - u_-)K}\right]}{\left[1 - \dfrac{\theta J_0}{2RT\bar{C}_0 u_- K}\right]}\ln\sigma + \frac{RT\theta}{2Fu_+u_-}\left(\frac{J_0}{RT\bar{C}_0K}\right)^2\frac{\left[1 - \dfrac{\theta J_0(u_+ + u_-)}{4RT\bar{C}_0u_+u_-K}\right]}{\left[1 - \dfrac{\theta J_0}{2RT\bar{C}_0u_-K}\right]}(\sigma - 1)C_2$$

where J_0 is the flux of water, θ is the thermodynamically effective fixed charge density, $\bar{C}_0$ is the concentration of water in the membrane phase, u_+ and u_- are the cation and anion mobilities in the membrane phase, σ is the concentration ratio equal to C_1/C_2, K is a constant defined by

$$[15] \qquad K = \frac{1}{\delta}\left\{\bar{C}_{-(2)} - \bar{C}_{-(1)} - \frac{\bar{C}_{-(2)} + \bar{C}_{-(1)}}{2RT\bar{C}_0u_-} + \frac{\theta^2J_0}{4RT\bar{C}_0(\bar{C}_{-(2)} - \bar{C}_{-(1)})}\ln\frac{\bar{C}_{-(2)} + \frac{\theta}{2}}{\bar{C}_{-(1)} + \frac{\theta}{2}}\right\}$$

where $\bar{C}_{-(1)}$ and $\bar{C}_{-(2)}$ are the anionic concentrations in the membrane phase for ions 1 and 2 on two sides 1 and 2 of the membrane; δ is the thickness of the membrane (in cm). At significant electrolyte concentration eq. [14] reduces to

$$[16] \qquad -\Delta\phi = \frac{RT}{F}\frac{\theta}{2}\frac{\sigma - 1}{\sigma}\frac{1}{C_2}$$

except at extremely high concentrations where the potential is significantly affected by J_0. The plots of $[\Delta\phi/\{(\sigma - 1)/\sigma\}]$ against $1/C_2$ are drawn (Fig. 6) for the evaluation of θ, the thermodynamically effective fixed charge density of membrane. The slope of eq. [16] is given by

$$[17] \qquad \frac{RT}{F}\cdot\frac{\theta}{2}$$

This was equated to the graphical value of the slope obtained from Fig. 6. The values of θ thus determined are given in Table 3 for various electrolytes through the investigated membranes.

Part C. Determination of Potentiometric Selectivity Coefficient K_A^{Pot} and Test of Nozaki's Theory of Bi-ionic Potential (BIP)

The mechanism of bi-ionic potential has been considered in detail by a number of workers (29–35). Sollner (35) found that not only the mobility of counter ions is important but the selectivity of the membrane material plays a significant role in the development of BIP. The relations of selectivity of membranes to the various physicochemical parameters have also been given by a number of investigators. The selectivity of membrane is governed by both the mobility of ions in the membrane phase and the equilibrium that exists at the membrane–solution interfaces (e.g., partition coefficients, ion-exchange equilibrium constants). The various factors responsible for the selectivity of the parchment membrane arising from differences in the mobilities of the ions in the membrane are described here. The factors controlling or responsible for the membrane selectivity due to physicochemical equilibrium conditions have been analysed by Reichenberg (36) and intensively pursued by Eisenman and co-workers (37–43). The important facts emerging from the studies of investigators are that (*i*) the pattern of selectivity is predominantly governed by field strength, (*ii*) the number of water molecules in the neighbourhood of the cationic and anionic sites influences only the magnitude and not the sequence of selectivity, and (*iii*) the spatial distribution of anionic site influences the selectivity through the overlap of electrostatic forces.

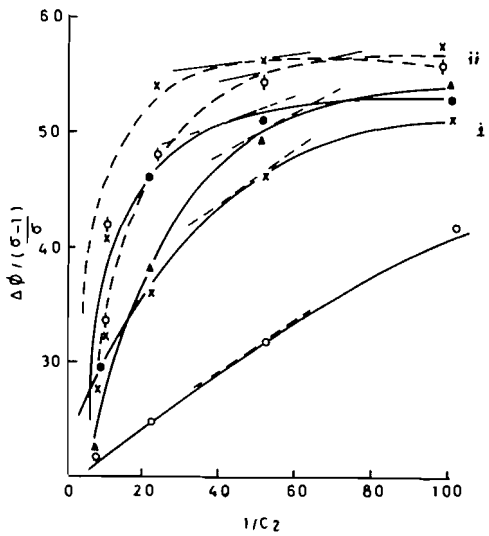

FIG. 6. Plots of $\Delta\phi\sigma/(\sigma - 1)$ against $1/C_2$ for various electrolytes through (*i*) silver tungstate (—) and (*ii*) chromic ferricyanide (---) membranes. (*i*) KCl (●), NaCl (×), LiCl (○), and NH_4Cl (▲); (*ii*) KCl (ϕ), NaCl (×).

Marshall and Krinbill (44) developed the following equation [18] for the bi-ionic potential

$$[18] \qquad \Delta\phi_{BIP} = (RT/F)\ln(a_A\bar{u}_A/a_B\bar{u}_B)$$

where $(\bar{u}_A/\bar{u}_B)$ is the mobility ratio in the membrane phase of the two ions. The values derived for mobility ratios across silver tungstate membrane for 1:1 set of electrolytes are given in Table 4. The BIP values are related to the potentiometric selectivity coefficient K_{BA}^{Pot} by the following relation:

$$[19] \qquad \Delta\phi_{BIP} = \text{constant} + (nRT/F) \times \ln[a_A^{1/n} + (K_{BA}^{Pot}a_B)^{1/n}]$$

which is the extended form of Nicolsky's equation (45–51), with n, R, T, and F having their usual meanings. Super Pot signifies potentiometric selectivity coefficient. According to an IUPAC report # 43, January 1975 on nomenclature for ion selective electrodes, the potentiometric selectivity coefficient is designated K_{BA}. However, the present existing litera-

KCl–NaCl	KCl–LiCl	KCl–NH_4Cl
1.131	1.096	1.131

ture uses the nomenclature above almost exclusively (52). Conti and Eisenman (53–55) and others (56, 57) have given most complete derivation and analysis of various equations involving the term potentiometric selectivity for permeable ions of the same sign through membranes containing a distribution of fixed sites, including the usual uniform distribution. The various values of BIP obtained with silver tungstate membrane are plotted against mean ion activities and straight lines as shown in Fig. 7 are obtained. From the slopes of the lines the values of K_{BA}^{Pot} are thus obtained and are given in Table 5 for various 1:1 sets of electrolytes (KCl–NaCl, KCl–LiCl, and KCl–NH_4Cl) through silver tungstate membrane.

More recently Toyoshima and Nozaki (22) derived various theoretical equations for membrane potential and bi-ionic potential based on thermodynamics of irreversible processes which are applied and tested here with parchment-supported silver tungstate membrane. The various assumptions for the concentration dependence of u_i and a_i of ion i ($i = +, -$) in the membrane phase are as follows:

$$[20] \qquad u_+C_+ = u_+^0C_+(C_- + \theta)$$

$$[21] \qquad u_-C_- = u_-^0C_-$$

$$[22] \qquad a_+ = \gamma_i^0(C_- + \theta)$$

$$[23] \qquad a_- = \gamma_-^0C_-$$

Here u_i^0 and γ_i^0 are the mobility and activity coefficients of ion i in the free solution. The quantity θ is the thermodynamically effective fixed charge density of the membrane.

According to Toyoshima and Nozaki (22) the system studied consists of two kinds of 1:1 electrolytes (KCl and NaCl) separating a negatively charged membrane. No electric field is applied externally across the membrane, and no electric charge is transported from one side of the membrane to the other. The theoretical equation eq. [24] for bi-ionic potential using variables which contains four parameters (V_{K^+}, V_{Na^+}), (θ/K_{K^+}, θ/K_{Na^+}), (g_{K^+}/g_{Na^+}) and (K_{K^+}/K_{Na^+}) is given by

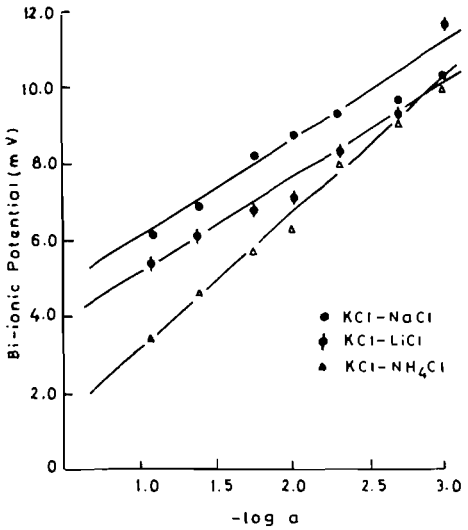

FIG. 7. Plots of observed bi-ionic potential (mV) against $-\log a$ through silver tungstate membrane for various sets of electrolytes at 25 ± 0.1°C.

$$[24] \qquad \Delta\phi_{BIP} = \left(2 \ln \frac{K_{K^+}}{K_{Na^+}} + \ln \frac{JV_{K^+} + 1}{JV_{Na^+} + 1}\right) \frac{F}{RT}$$

where (K_{K^+}/K_{Na^+}) is the selectivity constant of a membrane for positive ion species K^+ to Na^+.

$$[25] \qquad V_{K^+} = 1 + (u_{K^+}^0/u_{Cl^-}^0)$$

and

$$[26] \qquad V_{Na^+} = 1 + (U_{Na^+}^0/U_{Cl^-}^0)$$

For the evaluation of flux J of ion species, Toyoshima and Nozaki (22) gave the following equation [27] which is also used in the present investigation

$$[27] \qquad (2J + 1) \ln \frac{g_{K^+} + 2J}{g_{Na^+} + 2J} - \ln \frac{JV_{K^+} + 1}{JV_{Na^+} + 1} - \ln \frac{g_{K^+}}{g_{Na^+}} = 0$$

where

$$[28] \qquad g_{K^+} = 1 + [1 + (2K_{K^+}C/\theta)^2]^{1/2}$$

and

$$[29] \qquad g_{Na^+} = 1 + [1 + (2K_{Na^+}C/\theta)^2]^{1/2}$$

In order to evaluate (V_{K^+}, V_{Na^+}), (θ/K_{K^+}, θ/K_{Na^+}) for KCl–NaCl set of uni-univalent electrolytes, the following equation [30] given by Toyoshima and Nozaki (22) for membrane potential, $\Delta\phi$, is utilized here.

For KCl electrolyte

$$[30]\quad \Delta\phi_{KCl} = -\ln\sigma - \frac{1.2}{V_{K^+}}\ln\frac{[1+(2C_2K_{K^+}/\theta)^2]^{1/2}+(1-2/V_{K^+})}{[1+(2C_1K_{K^+}/\theta)^2]^{1/2}+(1-2/V_{K^+})} + \ln\frac{[1+(2C_2K_{K^+}/\theta)^2]^{1/2}+1}{[1+(2C_1K_{K^+}/\theta)^2]^{1/2}+1}\frac{RT}{F}$$

For NaCl electrolyte

$$[31]\quad \Delta\phi_{NaCl} = -\ln\sigma - \left(1-\frac{2}{V_{Na^+}}\right)\ln\frac{[1+(2C_2K_{Na^+}/\theta)^2]^{1/2}+(1-2/V_{Na^+})}{[1+(2C_1K_{Na^+}/\theta)^2]^{1/2}} + \left(1-\frac{2}{V_{Na^+}}\right)\ln\frac{[1+(2C_2K_{Na^+}/\theta)^2]^{1/2}+1}{[1+(2C_1K_{Na^+}/\theta)^2]^{1/2}+1}\left(\frac{RT}{F}\right)$$

where C_1 and C_2 are the concentrations of electrolyte solution on two sides of the membrane in each case

$$[32]\quad \sigma = C_1/C_2$$

Expanding eqs. [30] and [31] in powers of $1/C_2$ with fixed σ yields:

For KCl electrolyte

$$[33]\quad \Delta\phi_{KCl} = -\left(1-\frac{2}{V_{K^+}}\right)\ln\sigma - 2\left(1-\frac{1}{V_{K^+}}\right)\left(\frac{1}{V_{K^+}}\right)\left(1-\frac{1}{\sigma}\right)\left(\frac{\theta}{K_{K^+}}\right)\left(\frac{1}{C_2}\right)$$

For NaCl electrolyte

$$[34]\quad \Delta\phi_{NaCl} = -\left(1-\frac{2}{V_{Na^+}}\right)\ln\sigma - 2\left(1-\frac{1}{V_{Na^+}}\right)\left(\frac{1}{V_{Na^+}}\right)\left(1-\frac{1}{\sigma}\right)\left(\frac{\theta}{K_{Na^+}}\right)\left(\frac{1}{C_2}\right)$$

The transference number t_{-app} for anion is defined by eq. [9]. Introducing eq. [33] into eq. [9] and eq. [34] into eq. [9] and expanding separately $1/t_{-app}$ as a power series in $1/C_2$, the following expressions are obtained.

For KCl electrolyte

$$[35]\quad \frac{1}{t_{-app}} = V_{K^+} + (V_{K^+}-1)\left(\frac{\sigma-1}{\sigma\ln\sigma}\right) \times \left(\frac{\theta}{K_{K^+}}\right)\left(\frac{1}{C_2}\right)$$

For NaCl electrolyte

$$[36]\quad \frac{1}{t_{-app}} = V_{Na^+} + (V_{Na^+}-1)\left(\frac{\sigma-1}{\sigma\ln\sigma}\right) \times \left(\frac{\theta}{K_{Na^+}}\right)\left(\frac{1}{C_2}\right)$$

The above equations, [35] and [36], were used for the evaluation of V_{K^+}, V_{Na^+}, θ/K_{K^+}, and θ/K_{Na^+} in the following way:

The different values of $1/t_{-app}$ were plotted against $1/C_2$ (Fig. 4) for KCl and NaCl electrolytes through silver tungstate membrane at fixed $\sigma = 10$. Equations [35] and [36] indicate that the intercept of a plot of $1/t_{-app}$ against $1/C_2$ at fixed σ allows the values of V_{K^+} and V_{Na^+} to be determined. For the evaluation of θ/K_{K^+} and θ/K_{Na^+}, the slopes of eq. [35] and eq. [36] are given by the following factors.

For KCl electrolyte

$$[37]\quad \left[\frac{(V_{K^+}-1)(\sigma-1)}{\sigma\ln\sigma}\right]\left(\frac{\theta}{K_{K^+}}\right) = \text{Slope}_{K^+}$$

For NaCl electrolyte

$$[38]\quad \left[\frac{(V_{Na^+}-1)(\sigma-1)}{\sigma\ln\sigma}\right]\left(\frac{\theta}{K_{Na^+}}\right) = \text{Slope}_{Na^+}$$

are first determined. The graphical values of slopes evaluated from Fig. 4 are equated with the above factors, [37] and [38], and then by substituting V_{K^+} and V_{Na^+}, the values of θ/K_{K^+} and θ/K_{Na^+} are evaluated. The same procedures were employed for the other sets of electrolytes (KCl–LiCl and KCl–NH_4Cl); V and θ/K thus determined for various electrolytes, namely KCl, NaCl, LiCl, and NH_4Cl and the values are given in Table 6. The values of g (for K^+, Na^+, Li^+, and NH_4^+) were calculated by substituting θ/K in eq. [28] and eq. [29] for KCl and NaCl electrolytes and the values of g are given in Table 7. The same method was adopted for NH_4Cl and LiCl and the values of g are given in Table 7. The theoretically determined values of BIP from eq. [24] are plotted against log C (Fig. 8) (for KCl–NaCl set). For comparison the observed values of BIP are plotted in the same figure with silver tungstate membrane. For other sets (KCl–LiCl, and KCl–NH_4Cl) the calculated and observed BIP were also plotted in Fig. 8. It is quite evident from Fig. 8 that

the agreement between the observed and theoretical values of BIP are quite fair and it may be concluded that the theory of BIP developed by Toyoshima and Nozaki (22) based on thermodynamics of irreversible processes is applicable to the system of parchment-supported membrane.

Effects of potassium ion on the electron-transfer reaction between $Fe(CN)_6^{4-}$ and TCNQ or chloranil

SADAYUKI MATSUDA AND AKIHIKO YAMAGISHI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060, Japan

Received September 29, 1977

SADAYUKI MATSUDA and AKIHIKO YAMAGISHI. Can. J. Chem. **56**, 2216 (1978).

The effects of potassium ion on the electron-transfer reactions between $Fe(CN)_6^{4-}$ and 7,7,8,8-tetracyanoquinodimethane (TCNQ) or chloranil (QCl_4) were studied with temperature-jump equipment; $Fe(CN)_6^{4-}$ + TCNQ (or QCl_4) $\rightleftharpoons$ $Fe(CN)_6^{3-}$ + $TCNQ^-$ (or QCl_4^-). The solvent was a 1:1 (v/v) mixture of acetonitrile–water. In both systems, the forward rate constants (k_f) were unaffected by the addition of KCl; $k_f(Fe(CN)_6^{4-}/TCNQ) = (2.9 \pm 0.2) \times 10^6\ M^{-1}\ s^{-1}$, and $k_f(Fe(CN)_6^{4-}/QCl_4) = (5.2 \pm 0.4) \times 10^4\ M^{-1}\ s^{-1}$. On the other hand, the backward rate constants (k_b) increased with the increase of the KCl concentration. The results are interpreted in terms of ion-pairing equilibria of $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$.

SADAYUKI MATSUDA et AKIHIKO YAMAGISHI. Can. J. Chem. **56**, 2216 (1978).

Faisant appel à un appareil de saut de température, on a étudié l'effet des ions potassium sur les réactions de transferts d'électrons entre le $Fe(CN)_6^{4-}$ et le tétracyano-7,7,8,8 quinodiméthane (TCQD) ou le chloranil (QCl_4); $Fe(CN)_6^{4-}$ + TCNQ (ou QCl_4) $\rightleftharpoons$ $Fe(CN)_6^{3-}$ + $TCNQ^-$ (ou QCl_4^-). On a utilisé un mélange 1:1 (v/v) d'acétonitrile–eau comme solvant. Dans chacun des systèmes, les constantes de vitesse vers la droite ne sont pas affectées par l'addition de KCl; $k_f(Fe(CN)_6^{4-}/TCNQ) = (2.9 \pm 0.2) \times 10^6\ M^{-1}\ s^{-1}$ et $k_f(Fe(CN_6^{4-}/QCl_4) = (5.2 \pm 0.4) \times 10^4\ M^{-1}\ s^{-1}$. Par ailleurs, il y a augmentation des constantes de vitesses inverses avec une augmentation de la concentration de KCl. On interprète les résultats en termes d'équilibres d'ions $Fe(CN)_6^{4-}$ et $Fe(CN)_6^{3-}$ en paires.

[Traduit par le journal]

Introduction

It has been reported by several authors that the rates of electron-transfer reactions between negatively charged metal complexes are remarkably accelerated by the presence of alkali metal cations (1, 2). For example, alkali metal ions and tetraalkylammonium ions enhance the electron-exchange rates between $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ in the order of $Cs^+ > K^+ > NH_4^+ > Li^+$ (1). It is not reasonable to ascribe the effects to the ion-pair formation of $M^+Fe(CN)_6^{4-}$ or $M^+Fe(CN)_6^{3-}$, since the rate enhancement was observed in such a low concentration of cations there was no appreciable amount of ion-paired species present. Based on the fact that the above order agrees with the lability of desolvation of cation, it is proposed that in a transition state a naked cation, M^+, is shared by two electron-exchanging anions (3)

$$[1] \qquad Fe(CN)_6^{4-} \text{ --- } M^+ \text{ --- } Fe(CN)_6^{3-}$$

This structure is considered to decrease the activation free energy of reaction, because the positive charge of M^+ shields the electrostatic repulsion between reacting anions.

Recently the extension of the above effects to the heterogeneous electron-transfer from organic crystal to $Fe(CN)_6^{3-}$ was reported (4). In this system, the electron-transfer rate was accelerated by alkali metal cations in the order of $Cs^+ > K^+ > Li^+$. These facts suggest that alkali cations play a similar role in the electron–transfer involving organic compounds.

At this stage, it is worthwhile to elucidate the role of cations in homogeneous electron-transfer between an organic molecule and $Fe(CN)_6^{4-}$;

$$[2] \qquad Fe(CN)_6^{4-} + R \rightleftharpoons Fe(CN)_6^{3-} + R^-$$

where R denotes an organic compound with appropriate electron-affinity.[1] The main objective to examine this system is to see if a cation decreases the activation free energy of reaction by forming the transition state,

$$[1'] \qquad Fe(CN)_6^{4-} \text{ --- } M^+ \text{ --- } R$$

which is the analogy of [1].

The present work describes the temperature-jump study of the electron-transfer between $Fe(CN)_6^{4-}$ and 7,7,8,8-tetracyanoquinodimethane (TCNQ) or chloranil. The rate was measured in the presence of potassium chloride in a 1:1 (v/v) mixture of acetonitrile–water. The role of K^+ in electron-transfer was established by obtaining the K^+ effect on both the forward and backward rates.

[1]Although there are a few works concerning the reactions of type (2), no special attentions have been paid to the role of cations (6).

Experimental

7,7,8,8-Tetracyanoquinodimethane (TCNQ) and chloranil (QCl_4) were sublimed *in vacuo*. Potassium salt of TCNQ (K^+TCNQ^-) was prepared by reducing TCNQ with potassium iodide in acetonitrile. Potassium salt of QCl_4 ($K^+QCl_4^-$) was prepared similarly in acetone. $K_3Fe(CN)_6$ of G.R. grade was used without further purification. KCl was recrystallized once from an aqueous HCl solution. Acetonitrile of G.R. grade was used without further purification. Water was deionized and distilled. Solvent used was a 1:1 (v/v) mixture of water and acetonitrile.

The electronic spectra were taken at 15°C with a Hitachi EPS-3T spectrophotometer. The rate was measured with a Union Giken temperature-jump apparatus. The application of the present apparatus to the reactions in organic solvents was described elsewhere (5). The reaction was monitored by the transmittance change at 739 nm (λ_{max} of $TCNQ^-$). The sample solution was thermostated at 10°C before the temperature-rise. The temperature-rise was about 5°C, thus both the equilibrium and kinetic results were obtained at 15°C.

Results

(a) $Fe(CN)_6^{4-}$/TCNQ System

When $K_3Fe(CN)_6$ (ca. 10^{-2} *M*) was added to a solution of TCNQ (ca. 10^{-4} *M*), K^+TCNQ^- (ca. 10^{-5} *M*), and KCl (ca. 10^{-2} *M*), the absorbance at 840 nm (λ_{max} of $TCNQ^-$) decreased, depending on the added amount of $K_3Fe(CN)_6$. This indicated the establishment of the following equilibrium.

$$[3] \quad Fe(CN)_6^{4-} + TCNQ \rightleftharpoons Fe(CN)_6^{3-} + TCNQ^-$$

The apparent equilibrium constant of the above reaction defined by

$$K_{ap} = \frac{[TCNQ^-][Fe(CN)_6^{3-}]_t}{[TCNQ][Fe(CN)_6^{4-}]_t}$$

was determined spectrophotometrically in the following way. Here subscript t denotes the total concentration of a bracketed species, considering the fact that $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ are at least partially associated with K^+ (7). $[TCNQ^-]$ was determined from the absorbance at 840 nm ($\varepsilon = 4.33 \times 10^4$). [TCNQ] was obtained from the mass balance of

$$[TCNQ]_0 + [TCNQ^-]_0 = [TCNQ] + [TCNQ^-]$$

where subscript zero denotes the initial concentration of a bracketed species before $K_3Fe(CN)_6$ was added. $[Fe(CN)_6^{4-}]_t$ was equated to the decrease of $[TCNQ^-]$. $[Fe(CN)_6^{3-}]$ was equated to the initial value, since it was present in large excess over other species. The calculated K_{ap} was constant at 56 ± 5 for 0.012 *M* of $K_3Fe(CN)_6$ and 0.019 *M* of KCl, where the ratio of [TCNQ] to $[K^+TCNQ^-]$ was varied more than five times in the ranges of $1.0–2.0 \times 10^{-4}$ *M* of TCNQ and $0.3–1.6 \times 10^{-5}$ *M* of K^+TCNQ^-, respectively.

When the concentrations of $K_3Fe(CN)_6$ and KCl were varied, K_{ap} was found to be no longer a constant value. The dependence of K_{ap} on the total concentration of K^+, $[K^+]_t$, is shown in Fig. 1, where $[K^+]_t$ was equated to $3[K_3Fe(CN)_6]_t + [KCl]$. The interpretation of this result is given in the following discussions.

The rates of electron-transfer were measured with a temperature-jump apparatus. The reaction was studied under the conditions of large excess of $K_3Fe(CN)_6$, TCNQ, and KCl over K^+TCNQ^- and $K_4Fe(CN)_6$. Under this condition, it was expected that the forward and backward rates of reaction [3] were mainly determined by the concentration of TCNQ and $K_3Fe(CN)_6$, respectively. At temperature-rise, the exponential decrease of transmittance was observed at 739 nm (λ_{max} of $TCNQ^-$). In order to establish the mechanistic aspects of the reaction [3], the following three series of experiments were performed: (*i*) The relaxation time, τ, was obtained by changing the concentration of TCNQ at the constant concentration of $K_3Fe(CN)_6$ and KCl. The results are displayed in Fig. 2; (*ii*) τ was obtained by changing the concentration of $K_3Fe(CN)_6$ ($0.5–1.2 \times 10^{-2}$ *M*), keeping the concentration of KCl and TCNQ at 0.17 *M* and 7.1×10^{-5} *M*, respectively. τ^{-1} was found to follow the equation,

$$[4] \quad \tau^{-1} = (7.5 \pm 5) \times 10^4 [K_3Fe(CN)_6]_t \ s^{-1}$$

(*iii*) τ was obtained by varying the concentration of KCl at the constant amounts of TCNQ (7.1×10^{-5} *M*) and $[K_3Fe(CN)_6]_t$ (0.012 *M*). The results are shown in Fig. 3, where $[K_3Fe(CN)_6]_t\tau$ is plotted against the reciprocal of $[K]_t$.

Summarizing the above results, the following kinetic expression was obtained.

$$[5] \quad \tau^{-1} = k_1[TCNQ] + k_2[K_3Fe(CN)_6]_t \times [K^+]_t/(1 + A[K^+]_t)$$

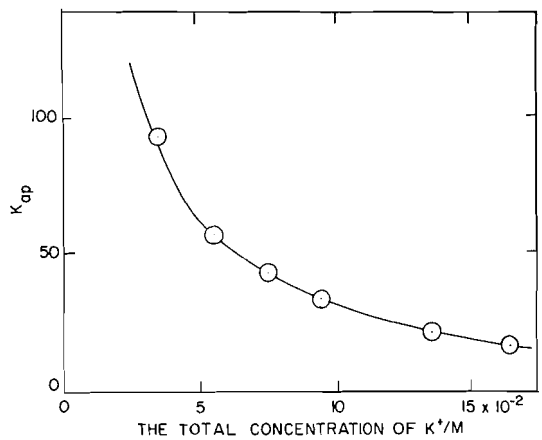

FIG. 1. Dependence of K_{ap} on the total concentration of K^+ for the system of TCNQ/$Fe(CN)_6^{4-}$.

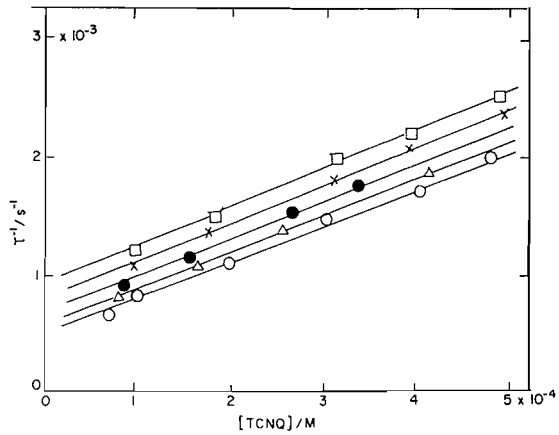

FIG. 2. Dependence of $1/\tau$ on [TCNQ] at various concentrations of $[K^+]_t$; $[K^+]_t$ = (□) 17 × 10^{-2} M, (×) 14 × 10^{-2} M, (●) 9.6 × 10^{-2} M, (△) 5.6 × 10^{-2} M, and (○) 3.6 × 10^{-2} M.

where $k_1 = (2.9 \pm 0.2) \times 10^6\ M^{-1}\ s^{-1}$, $k_2 = (9.9 \pm 1.0) \times 10^5\ M^{-1}\ s^{-1}$, and $A = (9 \pm 2)\ M^{-1}$. The interpretation of this expression is given in the Discussion section.

(b) $Fe(CN)_6^{4-}/QCl_4$ System

The apparent equilibrium constant of the following reaction was determined spectrophotometrically in

$$Fe(CN)_6^{4-} + QCl_4 \rightleftharpoons Fe(CN)_6^{3-} + QCl_4^-$$

a similar way to system (*a*). In this case, the decrease of the absorption peak at 450 nm due to QCl_4^- was measured as the function of the added amount of $K_3Fe(CN)_6$ (ca. 10^{-4} M), QCl_4 (ca. 10^{-4} M), and KCl (ca. 10^{-2} M). The dependence of K_{ap} on the total concentration of K^+ is shown in Fig. 4, in

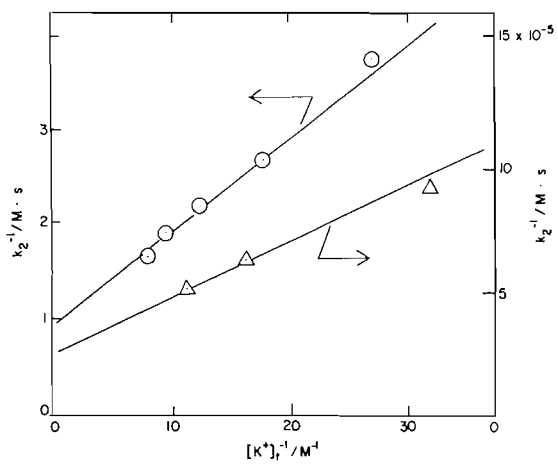

FIG. 3. Dependence of the reciprocal of backward rate, i.e. $[K_3Fe(CN)_6]_t\tau$ on the reciprocal of $[K^+]_t$; (○) TCNQ/$Fe(CN)_6^{4-}$ and (△) $QCl_4/Fe(CN)_6^{4-}$.

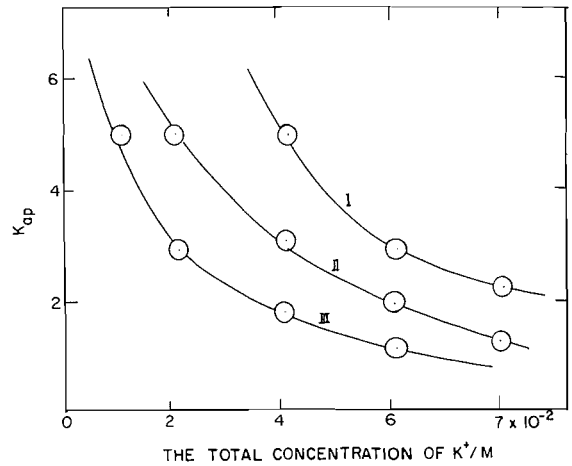

FIG. 4. Dependence of K_{ap} on the total concentration of K^+ for the system of $QCl_4/Fe(CN)_6^{4-}$; solvents are (I) 1:1, (II) 2:1, and (III) 3:1 (v/v) acetonitrile–water.

which K_{ap} was determined for three kinds of mixed solvents.

The temperature-jump measurements were performed for a solution containing the excess amount of $K_3Fe(CN)_6$ and QCl_4 over $K_4Fe(CN)_6$ and $K^+QCl_4^-$, respectively. This simplifies the interpretation of kinetic results as in system (*a*). The experiments similar to system (*a*) lead to the following kinetic expression (Figs. 3 and 5).

$$[6] \quad 1/\tau = k_1[QCl_4] + k_2[K_3Fe(CN)_6]_t \times [K^+]_t/(1 + A[K^+]_t)$$

where $k_1 = (5.2 \pm 0.1) \times 10^4\ M^{-1}\ s^{-1}$, $k_2 = (4 \pm 1) \times 10^{-5}\ M^{-1}\ s^{-1}$, and $A = (10 \pm 4)\ M^{-1}$. The interpretation of this result is given in the following section.

Discussion

To interpret the present equilibrium and kinetic results, we assume the following scheme:

$$[7] \quad \begin{array}{ccc} & \overset{K_0}{} & \\ Fe(CN)_6^{4-} + TCNQ & \rightleftharpoons & Fe(CN)_6^{3-} + TCNQ^- \\ K^+ \Big\downarrow\Big\uparrow K_{II} & & K^+ \Big\downarrow\Big\uparrow K_{III} \\ K^+Fe(CN)_6^{4-} + TCNQ & \rightleftharpoons & K^+Fe(CN)_6^{3-} + TCNQ^- \end{array}$$

where K_{II} and K_{III} are the equilibrium constants of association of $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ with K^+, respectively, and K_0 the equilibrium constant of eq. [2]. Under the above reaction scheme, the experimentally obtained K_{ap} is related to K_0, K_{II} and K_{III} as below.

$$[8] \quad K_{ap} = K_0(1 + [K^+]_f K_{III})/(1 + [K^+]_f K_{II})$$

where $[K^+]_f$ denotes the concentration of free K^+

TABLE 1. The summary of the equilibrium and kinetic results

System	$k_f'/(M^{-1}\,s^{-1})$	$k_b'/(M^{-1}\,s^{-1})$*	k_f'/k_b'	K_{III}†	K_{II}‡
(*a*) $Fe(CN)_6^{4-}$/TCNQ	$(2.9\pm0.2)\times10^6$	$(1.1\pm0.1)\times10^5$	26 ± 3	9 ± 2	130 ± 60
(*b*) $Fe(CN)_6^{4-}$/QCl_4	$(5.2\pm0.4)\times10^4$	$(4.0\pm1)\times10^4$	1.3 ± 0.3	10 ± 4	140 ± 70

*Obtained from the intercept of a straight line in Fig. 3.
†Obtained by dividing the intercept by the slope of a straight line in Fig. 3 (see eqs. [5] and [10]). The observed agreement of this quantity between systems (*a*) and (*b*) supports the validity of eqs. [9] and [10].
‡Obtained by multiplying K_{III} by the quantity, K_{II}/K_{III}, which was determined from Figs. 1 and 4 (see text).

ion.[2] When we compared this relation with the results in Figs. 1 and 4, the following results are obtained: $K_0 = K_{ap}$ (at $[K^+]_f = 0) = (2 \pm 0.5) \times 10^2$ and 15 ± 5 for $Fe(CN)_6^{4-}$/TCNQ and $Fe(CN)_6^{4-}$/QCl_4, respectively. $K_{III}/K_{II} = K_{ap}$ (at $[K^+]_f \to \infty)/K_0 = (7 \pm 3) \times 10^{-2}$ for both $Fe(CN)_6^{4-}$/TCNQ and $Fe(CN)_6^{4-}$/QCl_4. The larger value of K_0 for $Fe(CN)_6^{4-}$/TCNQ as compared to $Fe(CN)_6^{4-}$/QCl_4 reflects the higher electron affinity of TCNQ. The fact that both systems (*a*) and (*b*) give the similar value of K_{III}/K_{II} supports the validity of the above reaction scheme.[3]

Under the above scheme, the relaxation time is related to the forward (k_f) and backward (k_p) rate constants of electron transfer as shown below.

$$[9]\quad \tau^{-1} = \left(k_f \frac{1}{1 + [K^+]_f K_{II}} + k_f' \frac{[K^+]_f K_{II}}{1 + [K^+]_f K_{II}}\right)[R] + \left(k_b \frac{1}{1 + [K^+]_f K_{III}} + k_b' \frac{[K^+]_f K_{III}}{1 + [K^+]_f K_{III}}\right)[Fe(CN)_6^{3-}]_t$$

where k_f, k_b and k_f', k_b' denote the rate constants of electron-transfer reactions involving free and ion-paired ions, respectively. In deriving the above equation, we use the experimental conditions of $[R] \gg [Fe(CN)_6^{4-}]_t$ and $[Fe(CN)_6^{3-}]_t \gg [R^-]$. It is assumed also that the ion-pairing equilibria of $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ proceed much faster than the electron-transfer equilibria. When we compare

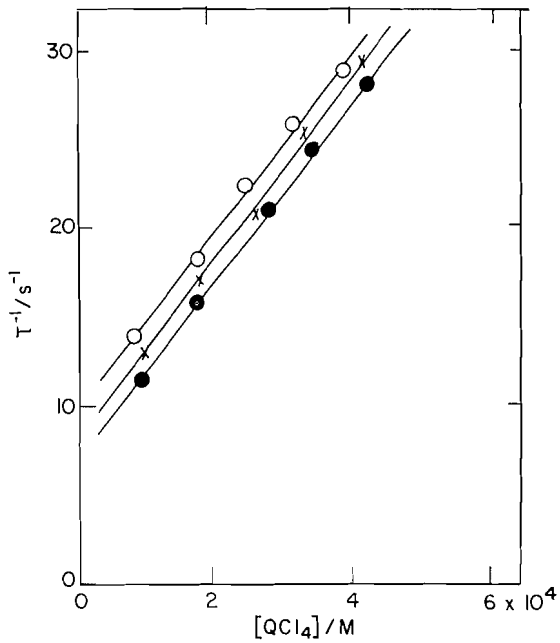

FIG. 5. Dependence of $1/\tau$ on $[QCl_4]$ at various concentrations of $[K^+]_t$; $[K^+]_t$ = (○) 9.0×10^{-2} *M*, (×) 6.0×10^{-2} *M*, and (●) 3.0×10^{-2} *M*.

the theoretical expression [9] with the experimental results [5] and [6], we arrived at the conclusion that [9] becomes identical with [5] and [6] under the conditions of $1 \ll [K^+]_f K_{II}$ and $k_f \ll k_f'[K^+]_f K_{II}$. If this is the case, the following simple relations are obtained:

$$[10]\quad k_1 = k_f' \qquad k_2 = k_b' K_{III} \qquad A = K_{III}$$

In other words, $Fe(CN)_6^{4-}$ is mostly present in the form of $K^+Fe(CN)_6^{4-}$ and the electron-transfer occurs by way of this ion-paired species. In Table 1, the numerical values of equilibrium and rate constants are summarized. It should be noted that the condition, $[K^+]_f K_{II} \gg 1$, assumed for deriving the above relations is satisfied under the present condition. The following points are noted for the present results: (*i*) k_f' for $Fe(CN)_6^{4-}$/TCNQ is much faster than that for $Fe(CN)_6^{4-}$/QCl_4. This corresponds to

[2]The deviation of $[K^+]_t$ from $[K^+]_f$ arises mainly from the association of K^+ with Cl^-. The association constant of K^+ and Cl^- in the present solvent (dielectric constant 54) is concluded to be less than 1, since the association constants in 44% ethanol/water (dielectric constant 42) and 38% ethanol/water (dielectric constant 56) are 1.2 and 0.3, respectively (7). Therefore $[K^+]_t$ is almost equal to $[K^+]_f$ provided that $[K^+]_t$ is less than 0.1 *M*.

[3]The association constants of K^+ with $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ in water are reported to be 31 and 7.0 at $\mu = 0.1$ and 35°C, respectively (8). The association of K^+ with $TCNQ^-$ was neglected.

the larger electron affinity of TCNQ than QCl_4. In other words, the electron-transfer rate is influenced by the free energy change of reaction, as is well established in the electron-transfer reaction between metal ions (9). This result is in marked contrast with what was previously observed for the electron-transfer reaction between organic compounds, e.g., $TCNQ^-$/substituted quinone systems (5). In the latter systems, the rate is always nearly a diffusion-controlled one provided that the free energy change of the reaction is negative. Therefore the present results suggest the interaction for the electron-transfer between $Fe(CN)_6^{4-}$ and TCNQ is more similar to the metal ion – metal ion interaction than for organic molecule – organic molecule interactions. (*ii*) The ion-paired species are more reactive in electron-transfer than free ions: i.e. $k_f \ll k_f' \times [K^+]_f K_{II}$. At first glance, this fact seems to support the view that K^+ plays the role of a bridging ion between $Fe(CN)_6^{4-}$ and R (eq. [1′]). If this were correct, however, $[K^+]_t$ would enhance both the forward (k_f') and backward (k_b') reaction rates. It has already been established that k_f' is unaffected by $[K^+]_t$ (eq. [10]). Therefore K^+ does not play a catalytic role as in the reaction of $Fe(CN)_6^{4-}$/$Fe(CN)_6^{3-}$. Consequently the transition state suspected in the Introduction (eq. [I′]) is not realized in the present systems.

An approach to the synthesis of the hex-4-enopyranosid-3-ulose **5** has been investigated. The readily available 3-keto derivative **8** is easily debenzylidinated but the resulting diol is benzoylated preferentially at carbon 4 rather than at the primary position. However, tritylation occurs at the primary position and the product is sulfonylated to give the 4-*O*-methylsulfonyl derivative (**11***b*). Iodinolysis of this α-ketosulfonate did not follow an S_N2 course giving the desired axial iodide **14***b*. Instead a course of reductive elimination was observed involving the presumed intermediacy of an enolic hypoiodite. β elimination of methanesulfonic acid from **11***b* was in fact possible by using diazabicyclononene in benzene–tetrahydrofuran solution. The process undoubtedly involves epimerisation, and the product consists of a mixture of the desired **5** (R = CPh_3) and its 2-epimer **22**. These enones are prone to base-catalysed decomposition so that although the three steps from the starting ketone **8** to the sulfonate **11***b* can each be carried out in excellent yield, the final elimination proceeds in 39% yield after isolation.

MARK BERNARD YUNKER et BERT FRASER-REID. Can. J. Chem. **56**, 2221 (1978).

On a étudié une approche à la synthèse des hexèno-4 pyrannosiduloses-3 (**5**). On peut facilement enlever le groupe benzylidène du dérivé céto-3 (**8**) facilement accessible mais le diol qui en résulte est benzoylé préférentiellement au niveau du carbone-4 plutôt que dans la position primaire. Toutefois la tritylation se produit en position primaire et le produit peut être sulfonylé pour obtenir le dérivé *O*-méthylsulfonyl-4 (**11***b*). L'iodolyse de cet α-cétosulfonate ne se produit pas suivant un mécanisme S_N2 pour conduire à l'iodure axial désiré (**14***b*). Il se produit plutôt une élimination réductrice impliquant vraisemblablement un hypoiodure énolique comme intermédiaire. L'élimination β de l'acide méthanesulfonique à partir de (**11***b*) est possible si l'on fait appel au diazabicyclononène dans une solution de benzène–tétrahydrofuranne. Le processus implique sans aucun doute une épimérisation et le produit comporte un mélange du produit (**5**) désiré (R = CPh_3) et de son épimère-2 (**22**). Ces énones peuvent subir facilement des décompositions catalysées par les bases; ceci implique que même si trois étapes peuvent être effectuées, avec de bons rendements, à partir de la cétone (**8**) pour conduire au sulfonate (**11***b*), l'élimination finale ne se produit qu'avec un rendement de 39% en produit isolé.
