Received July 15, 1977

J. B. CUMMING and P. KEBARLE. Can. J. Chem. **56**, 1 (1978).

The complete ladder of ΔG_1^0 determinations obtained from measurements of some 110 gas phase proton transfer equilibria $A_1^- + A_2H = A_1H + A_2^-$ involving some 60 acids AH and connecting to the standard acid HCl is given. Evaluation of the entropy changes leads to values for the deprotonation energies ΔH_D^0 and ΔG_D^0 (at room temperature) corresponding to the gas phase process $AH = A^- + H^+$; $\Delta H_D^0 = D(A—H) - EA(A) + 313.6$ kcal/mol. Comparison of the present data with literature determinations of the bond dissociation energies and electron affinities shows agreement within 2 kcal/mol. Some experimentally determined entropy changes ΔS_1^0 are compared with the theoretically calculated values.

J. B. CUMMING et P. KEBARLE. Can. J. Chem. **56**, 1 (1978).

On rapporte une échelle complète des déterminations de ΔG_1^0 qui a été obtenue à partir des mesures de 110 équilibres de transfert de proton en phase gazeuse $A_1^- + A_2H = A_1H + A_2^-$ impliquant environ 60 acides AH et donnant une relation avec l'acide standard HCl. L'évaluation des changements d'entropie conduit à des valeurs pour les énergies de déprotonation, ΔH_D^0 et ΔG_D^0 (à température ambiante), correspondant au processus en phase gazeuse $AH = A^- + H^+$; $\Delta H_D^0 = D(A—H) - EA(A) + 313.6$ kcal/mol. Une comparaison des données obtenues dans ce travail avec les résultats rapportés dans la littérature pour les énergies de dissociation de liaisons et pour les affinités électroniques présentent une bonne corrélation à l'intérieur de 2 kcal/mol. On a aussi comparé quelques changements d'entropie ΔS_1^0 déterminés expérimentalement avec des valeurs calculées théoriquement.

[Traduit par le journal]

Introduction

Gas phase acidities for a variety of compounds AH determined by measuring the equilibrium constants for the gas phase proton transfer reaction 1 were published in several reports from this laboratory.

[1] $$A_1^- + A_2H = A_1H + A_2^-$$

The classes of compounds were: aliphatic carboxylic acids (1–3), substituted benzoic acids (4, 5), phenols (5), and a variety of carbon and nitrogen acids (6–9). The gas phase equilibria [1] were measured with a pulsed electron beam high ion source pressure mass spectrometer. Measurement of $\Delta G_1^0 = -RT \ln K_1$ permits the establishment of quantitative gas phase acidity orders and continuous acidity ladders. The free energy changes can be related to a standard acid A_0H measuring some equilibria [2] involving the standard acid.

[2] $$A_0^- + AH = A_0H + A^-$$
$$Cl^- + AH = ClH + A^-$$

In the acid determinations from this laboratory the standard acid A_0H selected was HCl. All published acidities were obtained by relating the given compound AH through a continuous ladder of multiple proton transfer equilibria to HCl. In some of the publications (5, 6) partial ladders were published, in others (7–9), only the ladders to a secondary reference compound like pyrolle were given. The secondary reference compound had been previously connected with equilibria to HCl.

We feel that the present publication of the com-

plete ladder connecting all compounds whose acidity was measured in our laboratory will be useful to other workers in the field and users of the data.

The free energy and enthalpy changes for deprotonation ΔH_D^0 and ΔG_D^0 are defined by eq. 3.

$$[3] \qquad AH_{(g)} = A^-_{(g)} + H^+_{(g)} \qquad \begin{matrix} \Delta G_3^0 = \Delta G_D^0 \\ \Delta H_3^0 = \Delta H_D^0 \end{matrix}$$

ΔH_D is identical to the often used expressions: proton affinity of A^-, $PA(A^-)$ and heterolytic bond dissociation energy $D(A^-—H^+)$.

The relationship [4] permits the determination of $D(A—H) - EA(A)$ from ΔH_2 and the known

$$[4] \quad \Delta H_2^0 = \Delta H_D(AH) - \Delta H_D(A_0H) = D(A—H) - EA(A) - D(A_0—H) + EA(A_0)$$

$D(A_0—H)$ and $EA(A_0)$ of the standard acid. For HCl at 300 K: $D(H—Cl) - EA(Cl) = 20$ kcal/mol (10) and $\Delta H_D = 20 + I_p(H^+) = 333.6$ kcal/mol, where $I_p(H^+) = 313.6$ kcal/mol. In order to obtain ΔH_2^0 from ΔG_2^0 either the temperature dependence of the proton transfer equilibria must be measured and ΔH_2^0 obtained from a van't Hoff plot or ΔS_2^0 must be calculated from theory. Most of the acidity measurements (1–9) were done at a single temperature (600 or 500 K) and values for $D(A—H) - EA(A)$ were obtained via [4] and the assumption that $\Delta G_2^0 = \Delta H_2^0$, i.e. that $\Delta S_2^0 = 0$. The relatively high temperatures of 500–600 K were used for the equilibria determinations since at lower temperatures proton bound dimers AHA^- are formed by reaction 5.

$$[5] \qquad A^- + AH = AHA^-$$

The AHA^- are in equilibrium with A^- and AH and at 500–600 K the equilibria [1] can be measured; however, at low temperatures the concentration of A^- becomes too small to measure accurately, particularly when strongly hydrogen bonding AH (halogen, oxygen, or nitrogen acids) are involved. The temperature dependence of several proton transfer equilibria [1] was examined in earlier work and in general $|\Delta S_1^0|$ was found to be small, i.e. less than 2 cal/deg. At 500 K this leads to a difference between ΔG_1^0 and ΔH_1^0 of 1 kcal/mol and to a similar error in the $D(A—H) - EA(A)$ determinations. Considering the almost complete lack of thermochemical data for the AH systems a 1 kcal/mol error seemed quite acceptable.

The assumption that the entropy change in proton transfer reactions is small has been also made for reaction 6 involving positive ions. The assumption was confirmed by measurement of the temperature dependence of K_6 for several such reactions. Mea-

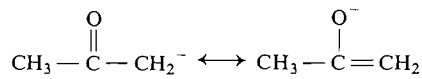
$$[6] \qquad B_1H^+ + B_2 = B_1 + B_2H^+$$

surements of proton transfer equilibria by the ion cyclotron resonance method (icr) can be made at room temperature because the reactions forming the proton held dimers are third order at low pressures and therefore very slow at icr conditions ($\sim 10^{-6}$ Torr). A comparison of ΔG_6^0(600 K) determined by high pressure mass spectrometry and ΔG_6^0(300 K) determined by icr involving a large number of compounds has shown (11) that the assumption $\Delta S_6^0 \approx 0$ is adequate for many reactions and that for nearly all cases ΔS_6^0 can be quite accurately estimated by considering only the rotational symmetry numbers of reactants and products. Measurement of the temperature dependence of K_6 for substituted benzenes was possible over a wide temperature range and these results (12) provided small ΔS_6^0 changes which could be accurately predicted by consideration of symmetry numbers only.

Recently, through the electron photodetachment measurements of Brauman and co-workers (13–16) a number of electron affinities EA(A) have become available. The availability of such new data makes it clearly desirable to improve the quantitative accuracy of the $D(A—H) - EA(A)$ values obtained from the gas phase acidity measurements.

A reexamination of the assumption that the entropy change ΔS_1^0 for the negative ion proton transfer equilibria is small led to the discovery of an oversight. The equilibrium [2] with the standard acid HCl is exactly a reaction where a significant entropy change can be expected. This comes about from the loss of two rotational degrees of freedom in the change $HCl \rightarrow Cl^-$. This loss is generally not fully compensated by the process $A^- \rightarrow AH$. For example if AH is a carboxylic acid or a phenol only one (internal) rotation will be created for the two rotations disappearing in $HCl \rightarrow Cl^-$. For carbon acids like fluorene there will not even be the appearance of one rotation. Unfortunately no experimental determinations of the temperature dependence of K_2 had been made in the previous work.

Another special problem that arises with acids AH is the appearance of barriers to internal rotation. For example for AH = acetone, the change $CH_3COCH_3 \rightarrow CH_3COCH_2^-$ involves conversion of the near free internal rotation of a methyl group to the very hindered rotation of the CH_2 group, because of partial double bond formation in the enolate anion as shown in structure **1**. The problem created by rotational barriers had been recognized earlier (6) and attempts were made to determine the associated



1

For personal use only.

entropy changes by measuring the temperature dependence of selected equilibria [1]. However, the results proved inconclusive (6).

The present work, as already mentioned, combines the previous determinations in one continuous ladder of equilibria. Some new determinations of equilibria [1] were made at key places of the ladder where it appeared necessary to obtain additional multiple cycles. Entropy changes ΔS_2^0 were also evaluated using standard statistical mechanics equations and structural data for AH and A^-. With these ΔS_2^0, ΔH_2^0 and ΔG_D^0 and ΔH_D^0 for AH at 300 K were calculated. Some experimental determinations of entropy changes were also made measuring the temperature dependence of equilibrium constants.

Experimental

The acidity measurements were made by determining the equilibrium constants for the gas phase proton transfer equilibria

[1] $$A_1H + A_2^- = A_1^- + A_2H$$

The method was the same as that used earlier (1–9). A_1H and A_2H at known pressures in the mTorr range were carried in slow flow by ~4 Torr methane carrier gas. The gas also contained some 20 mTorr of NF_3. Short electron pulses through the ion source produced F^- ions by the electron capture reaction $NF_3 + e = F^- + NF_2$. The ions A_1^- and A_2^- resulted from proton transfer from AH to F^-. The reaction mixture was sampled by bleeding a fraction of the gas into a mass spectrometer where the ions were mass analyzed and detected.

Results and Discussion

a. Summary of Equilibrium Measurements and Gas Phase Deprotonation Energies

The free energy changes ΔG_1^0 determined experimentally from $-RT \ln K_1 = \Delta G_1^0$ of reaction 1 are shown in Fig. 1. Almost all of the ΔG_1^0 data shown were published previously (1–9) but only as partial sections of the ladder. Examining the cases where mutiple cycles are available one finds that the ΔG_1^0 values are consistent to ~0.2 kcal/mol. The ΔG_2^0 relating AH to the standard HCl are also shown in Fig. 1. These were obtained by combining the various ΔG_1^0 determinations between AH and HCl. The ΔS_2^0 changes at the experimental temperature were calculated by methods described in the next section. These ΔS_2^0 were used to evaluate the corresponding ΔH_2^0 from $\Delta G_2^0 = \Delta H_2^0 - T\Delta S_2^0$. The ΔH_2^0 at the experimental temperature were corrected to ΔH_2^0 at 300 K by using calculated heat capacity changes $\Delta(C_p)_2$ which require the same data as the ΔS_2^0 evaluations. From $\Delta H_2^0(300)$ and $\Delta S_2^0(300)$, $\Delta G_2^0(300)$ was evaluated. The deprotonation energies $\Delta H_D^0(300)$ and $\Delta G_D^0(300)$ were evaluated from the corresponding $\Delta H_2^0(300)$ and $\Delta G_2^0(300)$ and eqs. 5 and 6 which follow from eq. 4 and the known thermochemical data (10) for HCl.

$$\Delta H_2^0(300) = \Delta H_D^0(AH) - \Delta H_D^0(HCl)$$
$$= \Delta H_D^0(AH) - 333.6 \text{ kcal/mol}$$
$$\Delta G_2^0(300) = \Delta G_D^0(AH) - \Delta G_D^0(HCl)$$
$$= \Delta G_D^0(AH) - 327 \text{ kcal/mol}$$

The ΔH_2^0 at the experimental temperature, and the ΔH_D^0 and ΔG_D^0 at 300 K are given in Fig. 1. Since in the previous publications (1–6), $\Delta S_2^0 = 0$ had been assumed, the D(A—H) − EA(A) data given in these publications actually correspond to the present ΔG_2^0(600 or 500) + D(H—Cl) − EA(Cl), i.e. ΔG_2^0(600 or 500) + 20 kcal/mol.

As shown in the next section, in the average, $\Delta S_2^0 \approx 6$ cal/mol. This leads to a $T\Delta S_2$ term at 600 K of 3.6 kcal/mol. Therefore, the D − EA given in Fig. 1 are, in the average, higher by 3–4 kcal/mol from the D − EA quoted in the earlier work where the assumption $\Delta S_2^0 = 0$ had been made.

Lack of information on energy barriers for internal rotation in the anions A^- introduces some error in the ΔS calculations given in the next section. Therefore it is of interest at this point to compare the present data with data available in the literature. This is done in Table 1. The values compared are D(A—H) − EA(A) from separate determinations of D(A—H) and EA(A) in the literature with D(A—H) − EA(A) = ΔH_D(A—H) − 313.6 kcal/mol from Fig. 1, where 313.6 kcal/mol corresponds to the ionization potential of hydrogen. The EA for compounds other than Cl and HS involve polyatomic species. The literature data for these species are based on electron photodetachment thresholds (Brauman and co-workers (13–16)). Considerable difficulties exist in interpreting the photodetachment threshold curves and extracting electron affinities from them, particularly because of uncertainty whether the photodetaching A^- have vibrational excitation or not. However, the authors (13–16) have made considerable efforts to interpret the threshold curves. Therefore, the electron affinities are probably within a few kcal/mol of the true adiabatic values. The bond dissociation energies D(A—H) for the polyatomic AH are mostly obtained by kinetic methods and are also probably uncertain to within ~2 kcal/mol. Comparing the D − EA literature data with the equilibrium data in Table 1 we find that the agreement is within 1–2 kcal/mol, i.e. certainly within the uncertainty of the literature data and the equilibrium data. The equilibrium data appear to be consistently higher by about 1 kcal/mol. Of special interest is the comparison for H_2S, since the electron

TABLE 1. Comparison between D(A—H) − EA(A) from ion equilibria measurements and thermochemical data[a]

AH	D(A—H)[c]	Ref.	EA(A)[d]	Ref.	D(A—H) − EA(A) Literature	D(A—H) − EA(A) Equilibria
HCl	103	10	83	10	20	20[b]

CH_3CN	92.9	20	34.8	16	58.1	59.3

[a]All values in kcal/mol; D(A—H) − EA(A) (equilibria) is obtained by subtracting I_p(H) = 313.6 kcal/mol from H_D^0 given in Fig. 1.
[b]Primary standard used in equilibria measurements.
[c]Error in literature bond dissociation energy determinations generally ±2 kcal/mol except for HCl which is accurately known.
[d]Error in literature electron affinity generally ±2 kcal/mol except for Cl and HS.

affinity (21) for the diatomic HS is probably accurate to less than 1 kcal/mol. Unfortunately the bond energy appears to be less well known. Thus, Kerr (22) gives limits 90 ± 2 kcal/mol. Taking the upper limit of 92, rather than the 91.1 kcal/mol (10) used in the table, one predicts D − EA of 38.5 which is in complete agreement with the equilibrium result.

Hydrogen sulfide lies roughly halfway up on the energy scale between HCl and the compound with highest ΔH_D^0 (Me_2SO) in Fig. 1. Clearly it would have been desirable to fix the upper part of the scale through measuring equilibria with an AH whose D − EA is accurately known. The suitable compound exists; it is HF for which D(H—F) − EA(F) = 57.4 kcal/mol (23, 24). Experiments were undertaken to measure proton transfer equilibria involving HF. However, the major ion observed was not F^- but SiF_5^-. This ion was evidently formed from F^- and SiF_4, the latter being produced by reaction of the HF with glass present in the apparatus. We hope to report HF equilibria with modified apparatus containing no glass. McIver and co-workers reported recently (25) measurements of proton transfer equilibria performed with an ion cyclotron resonance spectrometer which gave ΔG_D^0(HF) − ΔG_D^0(Me_2SO) = 0.3 kcal/mol at 25°C. Using ΔG_D^0(HF) = ΔH_D(HF) − $T\Delta S_D$ = 57.4 + 313.6 − 5.7 = 365.3 kcal/mol one obtains ΔG_D^0(Me_2SO) = 365 kcal/mol. The ΔG_D^0(Me_2SO) = 367.2 kcal/mol is obtained in the present results (see Fig. 1). The present result is higher by ~2 kcal/mol from the value of McIver and co-workers (25). Considering that the present Me_2SO result is calibrated to HCl which is some 41 kcal/mol and many equilibrium steps away, and that ΔG_D^0 at 300 K involved evaluation of entropy changes, a cumulative error of 2 kcal/mol is not surprising. It seems that the best probable data would be obtained if the ΔH_D^0 and ΔG_D^0 in Fig. 1 for compounds between H_2S and Me_2SO were reduced by ~1 kcal/mol.

b. Evaluation of Entropy Changes and Comparison with Experiment

The evaluation of the entropy changes for reaction 2 can be split up into evaluation of the entropy

[2] $$Cl^- + AH = ClH + A^-$$

change for the two half reactions:

[2*a*] $$Cl^- = ClH$$

[2*b*] $$AH = A^-$$

In both cases, one requires the third law entropies for each species. These are given by the well known expression

[7] $$S^0 = S^0_{trans} + S^0_{rot} + S^0_{vib} + S^0_{el}$$

$\Delta S^0_{trans}(2) \approx 0$ is obtained from the Sackur–Tetrode equation. $S^0_{el} = 0$, since singlet states are involved. Using for S^0_{rot}(HCl) the well known equation for rotational entropy of diatomic molecules and $\Delta S^0_{vib}(2a) = 0$, one obtains ΔS^0(2*a*, 298 K) = 8 cal/deg and ΔS^0(2*a*, 600 K) = 9.4 cal/deg. At 298 K

FIG. 1. Experimental free energy changes in kcal/mol for gas phase proton transfer reactions 1: A_2^- + A_2H = AH + A_2^- shown beside vertical double arrows. Experimental determinations were made at 600 and 500 K. A_1H is the compound shown at the bottom of the double arrow. Acidity increases from top to bottom. ΔG_2^0 and ΔH_2^0 refer to proton transfer reactions involving standard compound HCl (eq. 2) Cl^- + AH = ClH + A^-. ΔH_D^0 and ΔG_D^0 refer to deprotonation of AH: AH = A^- + H^+. These values were obtained from the experimental ΔG_2^0 (500 or 600) and evaluation of the entropy changes. Estimated accuracy of ΔG_1^0 values ±0.2 kcal/mol, ΔH_D^0 and ΔG_D^0 ±2 kcal/mol. Data obtained for substituted phenols and benzoic acids (5) are not included in Fig. 1.

[e]Author's estimate based on barriers given in ref. 33.
[f]Barrier assumed to be equal to that in acetaldehyde.

and 600 K these lead to $T\Delta S$ terms of 2.4 kcal/mol and 5.6 kcal/mol respectively. The $\Delta S_{2a}{}^0$ change makes the major contribution to $\Delta S_2{}^0$. The smaller $\Delta S_{2b}{}^0$ changes are generally negative and amount for the 'average' compound to −3 cal/deg.

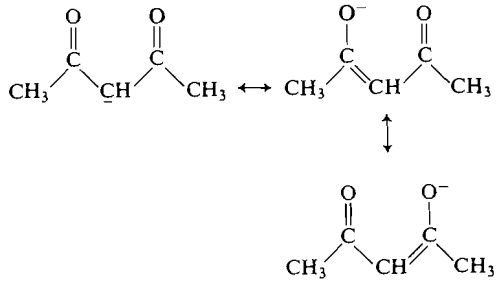
The rotational entropy contributions to $\Delta S_{2b}{}^0$ were evaluated by splitting the rotational motion into external rotation and internal rotation. When considering external rotation the changes of the moment of inertia in AH and A^- were taken into account. Significant changes occur only for HCl and H_2S but smaller changes as for example in $CH_3CN \rightarrow CH_2CN^-$ were also considered. Significant rotational entropy changes occur also because of changes in external rotation symmetry numbers. These were evaluated with the standard formula $\Delta S^0{}_{\text{rot sym}} = R \ln (\sigma_{AH}/\sigma_{A^-})$. These corrections are not always unambiguous. Thus for the CH_2CN^- the symmetry number may be 2 or 1 depending on whether the CH_2 group is assumed planar (sp^2) or trigonal (sp^3). In the above case and the enolate systems we have assumed planar carbanions. The symmetry numbers used for the external rotations are shown in Table 2.

Only the internal rotations which would change in the dissociation AH → A^- were considered. The prime examples in this class are the disappearing rotation around the C—O bond on dissociation of hydroxy acids and the already mentioned stiffening of internal rotation in the resonance stabilized ions A^- like the acetonyl ion shown in structure **1**. The calculations of the restricted internal rotation entropies were made by using the table of Pitzer and Gwinn (26, 27). In this table the entropy for internal rotation around a given bond is tabulated as a function of the partition function for free rotation Q_f and the expression V/RT where V is the energy barrier for the internal rotation. Q_f is evaluated (26) by [8],

$$[8] \qquad Q_f = (8\pi^3 I_r kT)^{1/2}/nh$$

where I_r is the reduced moment of inertia for the internal rotation and n is the number of equivalent positions per turn, i.e. the symmetry number for the internal rotation.

The energy barriers V for the internal rotation in the neutrals AH can be estimated to within ~1 kcal/mol. In many cases these barriers are available directly from the literature (28–39). Where no literature data were available estimates by analogy were made. The barriers used in the calculations are summarized in Table 2. No literature data for the internal rotations in A^- are available. Therefore, these had to be estimated. For ions in which charge delocalization occurs equal weighting was given to each possible valence bond structure. Thus the rotation of the CH_2 group in acetonyl$^-$ (see structure **1**) was taken to have a barrier equivalent to that of $\frac{1}{2}\pi$ bond. In the diketones where three resonance structures are possible the barrier for rotation of the CH_3CO group was taken to be that of $\frac{1}{3}\pi$ bond barrier (see structure **2**).



2

The potential barrier V = 26 kcal/mol in ethylene (40) was taken as the π bond barrier. Thus, the assumed barrier in structure **1** was 13 and in **2**, 8.7 kcal/mol. Small adjustments to these barriers were made for cases where the rotating groups were large and could be expected to interfere sterically. The barriers in A^- obtained by such procedures and used in the calculations are shown in Table 2. Evidently errors in V as large as 5 kcal/mol may well be present. These lead to an error of about 1 cal/deg in the entropy.

The tables of Pitzer and Gwinn (26) used for obtaining the values for the hindered rotation $\Delta S^0{}_{\text{rot}}$ are valid for rotation of a symmetric top about a rigid framework. Most of the cases involved in the

[a] ΔS_1^0 values for reaction $A_1^- + A_2H = A_1H + A_2^-$. Entropies given in (cal/deg), ΔH_1^0 values in kcal/mol. The calculated entropies were taken from Table 2. The experimental data are from Fig. 2.

present systems involve rotating groups that are not symmetric tops and the rest of the molecule is also non-rigid. However, the tables have approximate validity also for such systems when applied as shown in Pitzer (27). In any case the error, because of use of the tables for molecules without symmetric tops, should be smaller than the errors due to the estimates of the potential energy barriers.

Estimates of the small vibrational changes for the reaction $AH \rightarrow A^-$ were obtained by considering only the disappearance of bending vibrations. The frequencies of such vibrations were taken from a table of group frequencies (41). The entropy of the vibration in AH was evaluated from the harmonic oscillator vibrational partition function. The vibrational ΔS changes amounted in the average to a loss of 2 cal/deg at 600 K.

The ΔS_{2b} for the reaction $AH \rightarrow A^-$ obtained by summing all the contributions described above are shown in Table 2.

The experimentally measured entropy changes for proton transfer reactions 1 obtained from van't Hoff plots of the equilibrium constant K_1 are given in Table 3. The corresponding van't Hoff plots are shown in Fig. 2.

Some difficulties in measuring the temperature dependence of K_1 should be mentioned. Because of formation of AHA^- at low temperature by reaction 5 and pyrolysis of AH or A^- at high temperature, the available temperature range is quite restricted. Furthermore in the lower temperature range where appreciable AHA^- is present at equilibrium, dissociation of AHA^- outside the ion source (42) can produce non-equilibrium A^-. This A^- can falsify the temperature dependence of the observed equilibrium constant. As shown by Farneth and Brauman (43), the proton transfer reactions 1 involving delocalized anions A^- are slow even in the exothermic direction. Therefore the establishment of the equilibrium [1] particularly where both A_1^- and A_2^- are delocalized may take milliseconds. Such a long reaction time reduces the accuracy of the measurements since the concentrations of A_1^- and A_2^- are affected by diffusion to the wall and this diffusion has strong temperature dependence (44). Unfortunately all these factors reduce the confidence in the temperature dependence measurements.

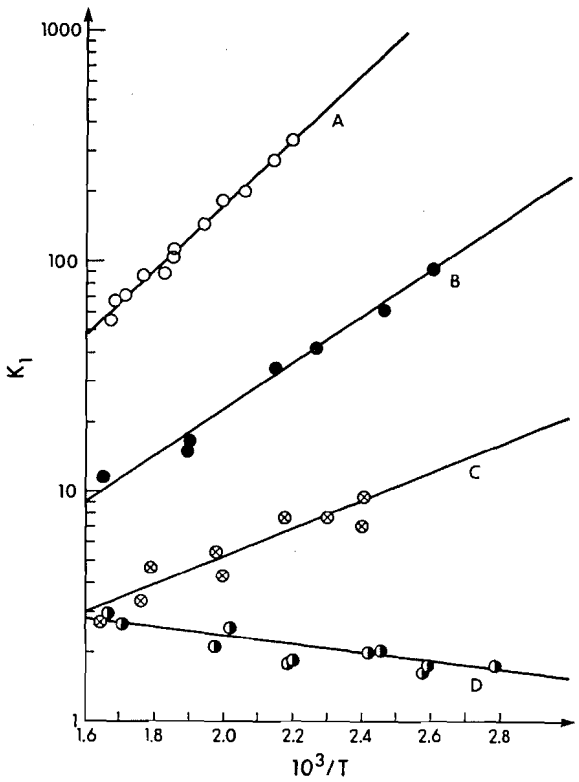

FIG. 2. Van't Hoff plots of experimentally measured temperature dependence of equilibrium constants K_1 for proton transfer reactions $A_1^- + A_2H = A_1H + A_2^-$: (*A*) A_1H pyrrole, A_2H *p*-nitrotoluene, (*B*) A_1H acetonitrile, A_2H acetone, (*C*) A_1H acetone, A_2H diethylketone, (*D*) A_1H $PhCH_2COCH_3$, A_2H fluorene.

Comparing the $\Delta S^0{}_{1(exp)}$ obtained from the van't Hoff plots with the $\Delta S^0{}_{1(calc)}$ obtained from the entropy changes in Table 2 we notice that the agreement is fair. The reaction

$$CH_2CN^- + CH_3COCH_3 = CH_3CN + CH_3COCH_2^-$$

shows the largest deviation between $\Delta S^0{}_{(calc)} = -0.5$ cal/deg and $\Delta S_{(exp)} = -3$ cal/deg. It should be realized that a difference of 2.5 cal/deg is not really large considering some of the difficulties encountered

in the measurements and the calculations. As mentioned previously, the C atom in CH_2CN^- is assumed to be sp^2, i.e. planar with a symmetry number $\sigma = 2$ for external rotation. However, if the pyramidal structure (sp^3) is the correct one, this change would lead to $\Delta S^0_{(calc)} \approx -2$ cal/deg, which is much closer to $\Delta S^0_{(exp)} = -3 \pm 0.5$ cal/deg. We believe that neither the calculated nor the experimental ΔS^0 are better than ± 2 cal/deg. For data obtained at 500 and 600 K this leads to an error in the $\Delta H_D{}^0$ of ± 1 kcal/mol. Considering also a sliding error in the acidity ladder, $\Delta H_D{}^0$ given in Fig. 1 should have a confidence of ± 2 kcal/mol. The same conclusion was reached in the preceding section by comparison of the present results with literature data. The relative values $\Delta G_1{}^0$ at the experimental temperature have much smaller errors (± 0.2 kcal/mol) and are better suited for acidity comparisons.

The heterogeneous catalytic reaction between carbon monoxide and nitrous oxide over manganous oxide and cobalto-cobaltic oxide

BORDAN WALTER KRUPAY AND ROBERT ANDERSON ROSS

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received June 27, 1977

BORDAN WALTER KRUPAY and ROBERT ANDERSON ROSS. Can. J. Chem. **56**, 10 (1978).

The catalytic reaction between carbon monoxide and nitrous oxide has been studied on MnO from 493 to 573 K and on Co_3O_4 from 383 to 493 K. The apparent activation energy on MnO was 130 ± 4 kJ mol^{-1}, while for Co_3O_4, a change from 31 ± 4 to 105 ± 4 kJ mol^{-1} was observed at 450 K. The rate-controlling step for the catalytic reaction on MnO was associated with the surface reaction between carbon monoxide and nitrous oxide in a manner similar to that previously reported for NiO, while for Co_3O_4, the rate-determining step was related to the formation of an intermediate surface carbonate. The changes in E_A may be a consequence of the surface reaction proceeding via a concerted redox reaction in the low temperature region and then to a stepwise mechanism at higher temperatures resulting from the presence of structurally and energetically different forms of the intermediate surface carbonate.

BORDAN WALTER KRUPAY et ROBERT ANDERSON ROSS. Can. J. Chem. **56**, 10 (1978).

On a étudié la réaction du monoxyde de carbone et de l'oxyde nitreux catalysée par du MnO entre 493 et 573 K et du Co_3O_4 entre 383 à 493 K. L'énergie d'activation apparente sur MnO est de 130 ± 4 kJ mol^{-1} alors que pour Co_3O_4 on observe un changement de 31 ± 4 à 105 ± 4 kJ mol^{-1} à 450 K. L'étape déterminante de la réaction catalysée par le MnO est associée avec la réaction de surface entre le monoxyde de carbone et l'oxyde nitreux d'une façon semblable à celle rapportée antérieurement pour NiO alors que pour le Co_3O_4, l'étape déterminante est reliée avec la formation d'une carbonate intermédiaire à la surface. Les changements dans les E_A peuvent être une conséquence de la réaction de surface qui procéderait par l'intermédiaire d'une réaction concertée rédox dans la région de basse température; à des températures élevées, la réaction de surface procéderait par étapes grâce à la présence à la surface de formes des carbonates qui diffèrent tant par leur structure que par leur énergie.

[Traduit par le journal]

Introduction

Relationships between the surface chemical properties of manganese oxides and their activities in heterogeneous catalytic reactions have recently been explored in studies of the decomposition of isopropanol (1) and formic acid (2), and also the water–gas shift reaction (3). The rate-controlling step in the mechanism of the latter was related to the reducing action of adsorbed carbon monoxide on a surface oxygen species. These studies have now been extended to include an investigation of the reaction between carbon monoxide and nitrous oxide on manganous oxide catalysts and expanded to include cobalto-cobaltic oxide, Co_3O_4.

The oxidation of carbon monoxide and the decomposition of nitrous oxide have separately received considerable attention as model catalytic reactions (4) and yet few studies have been reported for the interaction of the two gases on solid surfaces. In recent years, however, through technological interest in the development of catalysts suitable for the control of nitrogen oxide emissions, considerable impetus has been given to investigations of reactions between carbon monoxide and nitrogen oxides (5). While most attention has been focussed on the role of the higher oxides of nitrogen, work on the catalytic reaction between carbon monoxide and nitrous oxide has been reported recently for oxides of tin (6), nickel (7), and vanadium (8).

Experimental

Apparatus and Procedure

The all-glass flow system and quartz reactor have been described previously (1–3). High purity helium was used as the carrier gas at atmospheric pressure in the flow system and Beckman GC-5 gas chromatograph. Carbon monoxide, nitrogen, carbon dioxide, and nitrous oxide were analyzed by a thermal conductivity bridge using stainless steel columns, 183 × 0.32 cm od, packed with 61 cm 'Carbosieve B' and the remainder with 'Poropak Q' at a column temperature of 353 K which was sufficient to resolve all components.

The reacting gas mixture consisted of carbon monoxide and nitrous oxide each at a partial pressure of 5.33 kN m^{-2} (40 Torr), except, if stated otherwise, at a total gas flow rate of 350 ml min^{-1} (NTP). All reaction rate measurements were recorded after steady catalyst activity was attained; for example, 3 h at 493 K for Co_3O_4 with a maximum conversion level of ~7% using 1 g samples of the oxide catalysts.

Manganese(II) oxide was prepared by exposing manganese(III) oxide to the same reaction mixture at 573 K for 5 h. At steady catalytic activity the conversion level was 61.3% which was well above the levels usually acceptable for determining kinetic data (9, 10) by this method. The composition of the reaction mixture was then altered to achieve ~17% as a

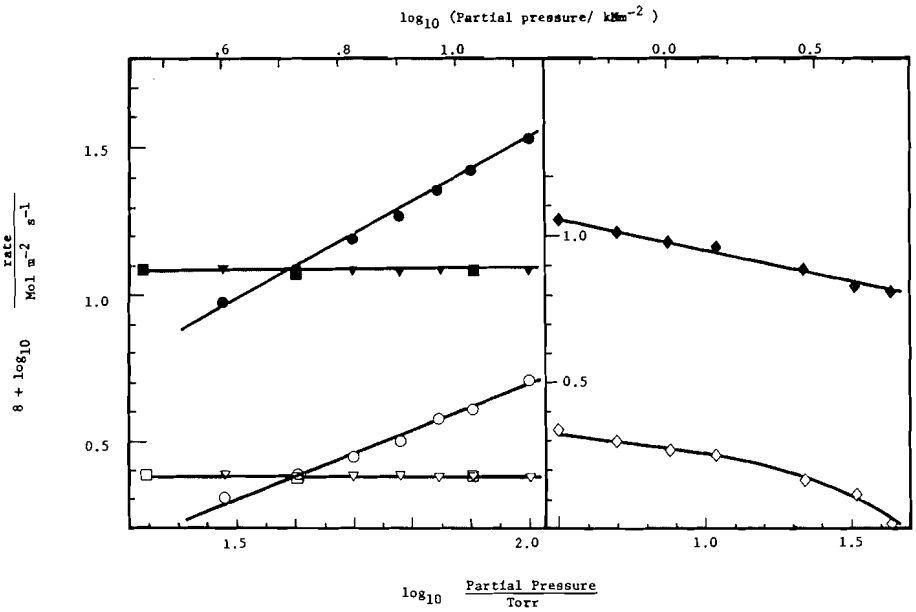

FIG. 1. Reaction rate dependency on variations in the partial pressures of nitrous oxide (●, ○), carbon monoxide (▽), ▼, nitrogen (■, □), and carbon dioxide (◆, ◇) on MnO at 573 and 523 K, respectively.

maximum steady conversion level at 573 K after 5 h by reducing the carbon monoxide partial pressure to 2.67 kN m^{-2} (20 Torr). X-ray powder diffraction photographs taken before and after catalysis were identical for Co_3O_4. For the manganese oxide the structure after catalysis was confirmed to be manganese(II) oxide by X-ray powder diffraction photographs and chemical analysis (3). The brown colour of the samples did indicate, however, that some excess oxygen had been retained (3, 11, 12). In contrast, no perceptible colour change was evident with Co_3O_4 samples after catalysis.

Preliminary experiments with both oxides established that diffusion phenomena did not influence the measurements at the stated conditions (9, 10). 'Blank' runs confirmed that reaction on the quartz wool and reactor walls reached 1% conversion at 853 K. Surface areas were determined by low temperature krypton adsorption (BET; 77K; $\sigma = 21.5$ Å) and values of 9.5 and 4.5 $m^2\ g^{-1}$ were obtained for MnO and Co_3O_4, respectively. The bulk catalyst volumes for the corresponding oxides were 0.82 and 0.94 $cm^3\ g^{-1}$, respectively.

Materials

Cobalto-cobaltic oxide was prepared by heating cobalt carbonate (B.D.H. Ltd.) at 873 K in air for 10 h. Complete decomposition of the carbonate was confirmed by thermogravimetric analysis in air using a Stanton–Redcroft Thermobalance Model HT5A. The preparation of the manganese(III) oxide starting material has been described (1).

Carbon monoxide (C.P.; 99.5% minimum), carbon dioxide (Coleman; 99.99%), nitrogen (super-pure; 99.99%), nitrous oxide (99.9% minimum), and helium (high purity; 99.995%) were used as supplied.

Results

Reaction Rate Order Measurements

Carbon Monoxide

MnO—The dependence of the reaction rate on variations in the carbon monoxide partial pressure from 1.33 to 16.0 kN m^{-2} was examined at 523 and 573 K with nitrous oxide maintained constant at 5.33 kN m^{-2}. At 523 K, the rate order with respect to carbon monoxide partial pressure was zero throughout the range investigated, while at 573 K a sharp change from zero to first order occurred at 8.00 kN m^{-2} (Fig. 1).

Co_3O_4—With nitrous oxide partial pressure fixed at 5.33 kN m^{-2} the reaction rate order with respect to carbon monoxide partial pressure was determined from 1.33 to 18.7 kN m^{-2} at 413 and 453 K. At both temperatures, the reaction rate was independent of the carbon monoxide partial pressure throughout the range (Fig. 2).

Nitrous Oxide

MnO—The effect of variations in nitrous oxide partial pressure on the reaction rate was examined with partial pressures from 2.67 to 10.7 kN m^{-2} at 523 K with the carbon monoxide partial pressure maintained at 2.67 kN m^{-2} (at 573 K the percent conversion rose to 58.8% at 8.00 kN m^{-2} nitrous oxide which limited the range of partial pressure variation). Within these partial pressure ranges, the reaction rate order with respect to nitrous oxide was 1.0 at 523 and 573 K (Fig. 1).

Co_3O_4—With the carbon monoxide partial pressure maintained at 5.33 kN m^{-2}, the nitrous oxide partial pressure was varied from 1.33 to 18.7 kN m^{-2} at 413 and 453 K. Throughout this range and at both temperatures, the reaction rate order with

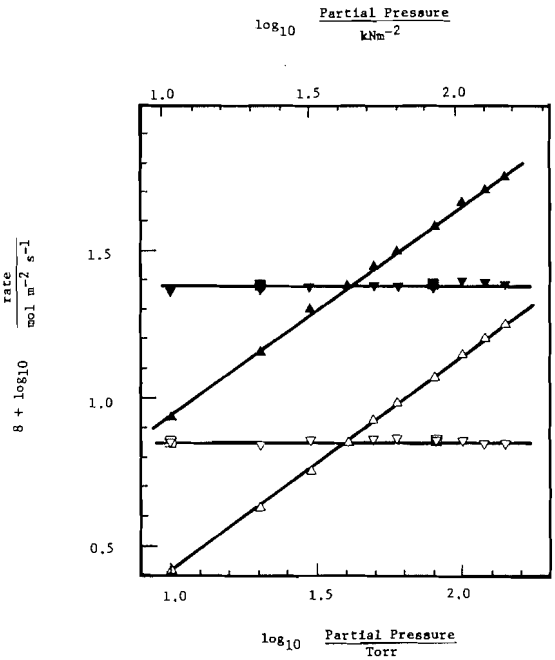

FIG. 2. Reaction rate order for Co_3O_4 at 453 and 413 K for nitrous oxide (▲, △), carbon monoxide (▼, ▽), and nitrogen (■, □).

respect to nitrous oxide partial pressure was 0.7 (Fig. 2).

Nitrogen

MnO—The partial pressures of carbon monoxide and nitrous oxide were fixed at 2.67 and 5.33 kN m^{-2}, respectively, and the partial pressure of nitrogen was varied from 2.67 to 10.7 kN m^{-2}. A zero rate order with respect to nitrogen partial pressure was observed at 523 and 573 K (Fig. 1).

Co_3O_4—The reaction rate order with respect to nitrogen partial pressure in the stated range at 413 and 453 K was zero with the carbon monoxide and nitrous oxide partial pressures each at 5.33 kN m^{-2} (Fig. 2).

Carbon Dioxide

MnO—The composition of the gas mixture with respect to carbon monoxide and nitrous oxide was the same as that in the nitrogen experiments. The effect of variations in carbon dioxide partial pressure on the reaction rate was examined from 0.67 to 5.79 kN m^{-2} at 573 and 523 K (Fig. 1). At both temperatures, a nonlinear relationship was observed in which the inhibitory effect increased with carbon dioxide partial pressure. The reaction rate order with respect to this component at the lowest partial pressures was -0.3 at both temperatures. This value was used in the calculation of rate constants since the levels of carbon dioxide production in the catalytic reaction in the absence of the added component were approached in this partial pressure region.

On the basis of these experiments, the rate of reaction, r (mol m^{-2} s^{-1}), at 523 and 573 K for MnO can be expressed as

$$[1] \qquad r = kP_{N_2O}/P_{CO_2}{}^{0.3}$$

where P_{N_2O} and P_{CO_2} represent the partial pressures of nitrous oxide and carbon dioxide, respectively, and the rate expression applies to the temperature and pressure regions specified.

Co_3O_4—The partial pressures of carbon monoxide and nitrous oxide were maintained at 5.33 kN m^{-2} throughout these experiments. At 453 K, 1.45 kN m^{-2} carbon dioxide was added continuously to the gas stream. The catalytic reaction rate increased from 2.45×10^{-8} mol m^{-2} s^{-1}, in the absence of carbon dioxide, to 83.2×10^{-8} mol m^{-2} s^{-1} measured 3 min after carbon dioxide introduction. After a total of 19 min, the rate decreased to a steady 7.59×10^{-8} mol m^{-2} s^{-1} which was 3.1 times greater than the initial reaction rate observed without the addition of carbon dioxide. Under these circumstances, a rate order dependence upon carbon dioxide partial pressure could not be defined in the usual manner and a rate order of zero was assumed.

Thus, the experimental reaction rate for catalysis on Co_3O_4 becomes

$$[2] \qquad r = kP_{N_2O}{}^{0.7}$$

In separate experiments, Co_3O_4 was exposed to the standard gas mixture at 453 K until activity levels were constant and reproducible with those prior to carbon dioxide admission. Carbon monoxide and nitrous oxide were then turned off and a continuous 5.79 kN m^{-2} of carbon dioxide only was introduced into the helium gas stream. After 2 min no carbon monoxide, nitrous oxide, or carbon dioxide could be detected in the exhaust stream but continuous sampling over a 30 min interval showed a progressive increase in the amount of carbon dioxide present in the gas stream after each sampling. It may be significant that carbon monoxide was not produced during the course of these experiments. The behaviour was markedly different to that observed with MnO (3) where conversion to carbon monoxide was almost completed initially on the introduction of carbon dioxide.

Next, a continuous stream of 5.33 kN m^{-2} nitrous oxide alone was added to the helium carrier and an initial 1.18×10^{-8} mol m^{-2} s^{-1} of nitrogen production was observed which gradually decreased with time. In order to compare the nature of the catalyst surface with that originally obtained at the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

steady level, the standard gas mixture was introduced and the results are shown in Table 1. The catalytic reaction rate prior to these experiments was 2.45×10^{-8} mol m^{-2} s^{-1} and it is apparent from Table 1 that the ratios of the rates of nitrogen and carbon dioxide production were not constant. Thus, the reactions involving carbon monoxide and nitrous oxide would appear to be proceding independently during this stage of catalysis.

The Effect Of Temperature On the Reaction Rate

MnO

After equilibration in the mixture consisting of 5.33 kN m^{-2} nitrous oxide and 2.67 kN m^{-2} carbon monoxide at 573 K for 5 h, the catalytic reaction was examined by cycling from 493 to 573 K at 10 K intervals. Using rate constants calculated by integration of [1], the Arrhenius plot yielded an apparent activation energy of 130 ± 4 kJ mol^{-1} (Fig. 3).

Co_3O_4

When steady catalytic activity was attained at 493 K after 3 h, the reaction rate was determined from 493 to 383 K at 10 K intervals using the standard gas mixture. Rate constants were calculated using [2] and the Arrhenius plot is presented

TABLE 1. Reaction rate results for Co_3O_4 after consecutive exposure to carbon dioxide and nitrous oxide (see text for details)

Time (min)	Reaction rate × 10^8 (mol m^{-2} s^{-1}) Nitrogen (r_1)	Carbon dioxide (r_2)	(r_1/r_2)
3	206	4.42	46.6
13	15.3	1.96	7.8
25	6.57	1.64	4.0

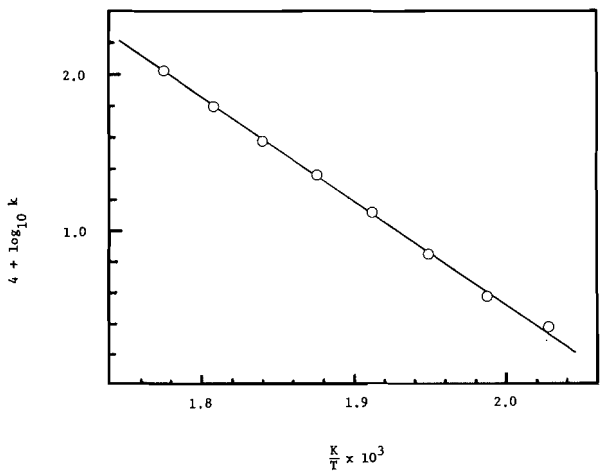

FIG. 3. Arrhenius plot for the reaction of carbon monoxide (2.67 kN m^{-2}) and nitrous oxide (5.33 kN m^{-2}) on MnO.

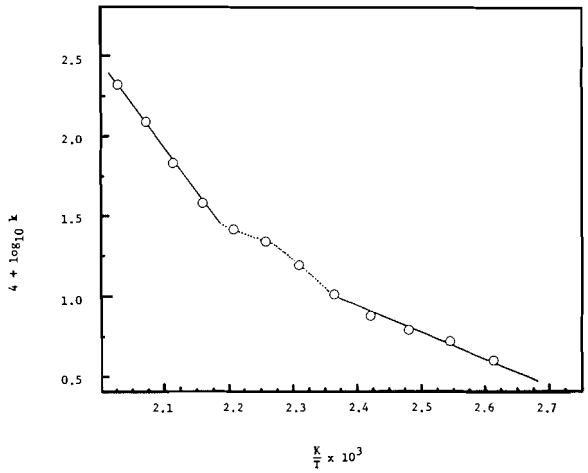

FIG. 4. Arrhenius plot for the reaction of carbon monoxide and nitrous oxide both at 5.33 kN m^{-2} on Co_3O_4.

in Fig. 4. The apparent activation energies were 31 ± 4 kJ mol^{-1} (383 to 433 K) and 105 ± 4 kJ mol^{-1} (453 to 493 K). In the range 433 to 453 K, the rate constants did not lie on the straight lines obtained at the upper and lower temperature regions.

Preliminary experiments had established that diffusion processes did not influence the kinetic data, but considering the low value of apparent activation energy at the lower temperatures, the results of these tests are presented.

Conversion levels were determined at total gas flow rates of 300, 350, and 400 ml min^{-1} (NTP) at both 413 and 383 K. At the former temperature, the corresponding percent conversions were 0.29, 0.30, and 0.32 while at 383 K, the respective values were 0.18 at all total gas flow rates. The slope of the plot, $\log_{10}$ rate versus reciprocal temperature, for the three total gas flow rates gave 20 ± 4, 24 ± 4, and 25 ± 4 kJ mol^{-1}, respectively. The absence of a systematic variation in conversion with total gas flow rate at either temperature, together with the values of the slope, which were within the experimental error, seem to indicate that the measurements represent the intrinsic activity of the oxide catalyst within the accuracy of this method (13).

Discussion

Several plausible reaction schemes for MnO were evaluated using the results of the nitrous oxide and carbon dioxide rate order experiments and the best correlations for both sets of data (Figs. 5 and 6) were obtained with the following kinetic equation:

[3] $$r = k\frac{a\sqrt{P_{N_2O}}}{(1 + a\sqrt{P_{N_2O}} + P_{CO_2})^2}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

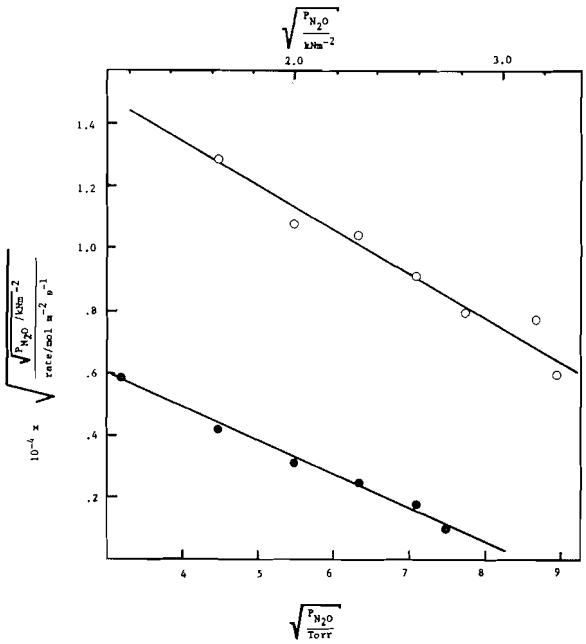

FIG. 5. Reduced plot of the Langmuir–Hinshelwood type expression 3 on MnO. Symbols correspond to Fig. 1.

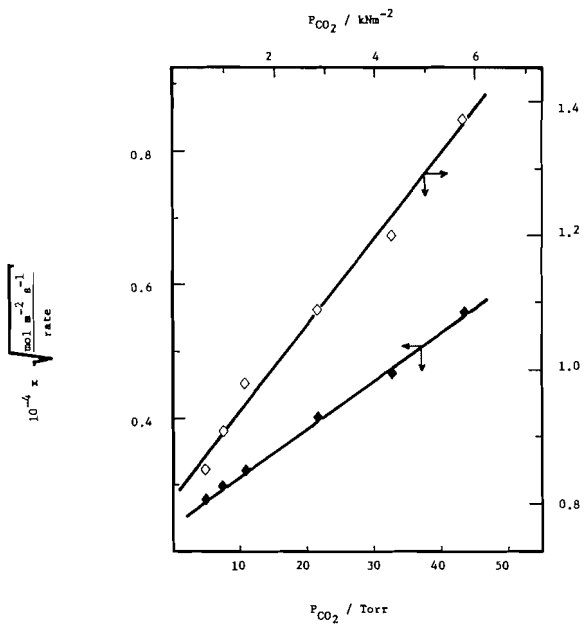

FIG. 6. Reduced plot of the Langmuir–Hinshelwood type expression 3 for carbon monoxide on MnO. Symbols correspond to Fig. 1.

This relationship may be regarded as a Langmuir–Hinshelwood expression. The limitations inherent in adducing correlations between such statistical relationships and the classical Langmuir–Hinshelwood surface reaction model have been documented (14, 15) and thus [3] was regarded as an initial guide to the interpretation of the kinetic results. The following proposal for the surface reaction was consistent with [3] and analogous to the reaction mechanism suggested for NiO (7):

[4] $$CO + S \rightleftharpoons CO(ads.)$$

[5] $$N_2O + S + CO(ads.) \rightarrow N_2 + CO_2(ads.) + S$$

[6] $$CO_2(ads.) \rightarrow CO_2 + S$$

with step 5 rate-controlling; N_2O and CO are absorbed on adjacent adsorption sites, S. Increasing the surface coverage with absorbed CO_2 would inhibit the reaction and catalysis may be regarded as involving a redox cycle similar to that proposed for the water–gas shift reaction on MnO (3). A short-lived, intermediate carbonate may form on the surface (19, 20) but the generation and decomposition of such a species would not be rate-limiting in the present context.

A comparison of the apparent activation energies for reaction on MnO and NiO with those reported (21) for oxygen desorption from the metal oxides (Table 2) shows a close correspondence and suggests that metal–oxygen bond rupture may be involved in the rate-controlling step.

Analysis of the nitrous oxide results for catalysis on Co_3O_4 yielded the expression

[7] $$r = k\frac{aP_{N_2O}\sqrt{P_{N_2O}}}{(1 + a\sqrt{P_{N_2O}} + \ldots)^2}$$

which best accommodated the data (Fig. 7).

A surface mechanism consistent with [7] was formulated:

[8] $$CO + S \rightleftharpoons CO(ads.)$$

[9] $$N_2O + S + CO(ads.) \rightarrow CO_2(ads.) + N_2$$

[10] $$N_2O + CO_2(ads.) \rightarrow CO_3(ads.) + N_2$$

[11] $$CO + CO_3(ads.) \rightarrow 2CO_2 + 2S$$

N_2O adsorption and decomposition would occur on two sites, one of which retains an adsorbed carbon monoxide molecule. Since P_{N_2O} appears in the numerator of [7], step 10 would be rate-controlling while step 11 preserves the stoichiometry of the reaction. No quantitative information concerning

TABLE 2. Activation energies of oxygen desorption (kJ mol^{-1}) (21) and the catalytic reaction between carbon monoxide and nitrous oxide

	State No.	MnO_2	Co_3O_4	NiO	
	0	67	84	105

	2	—	213	259	
Observed	—	130±4	105±4	103±4	kJ mol^{-1}

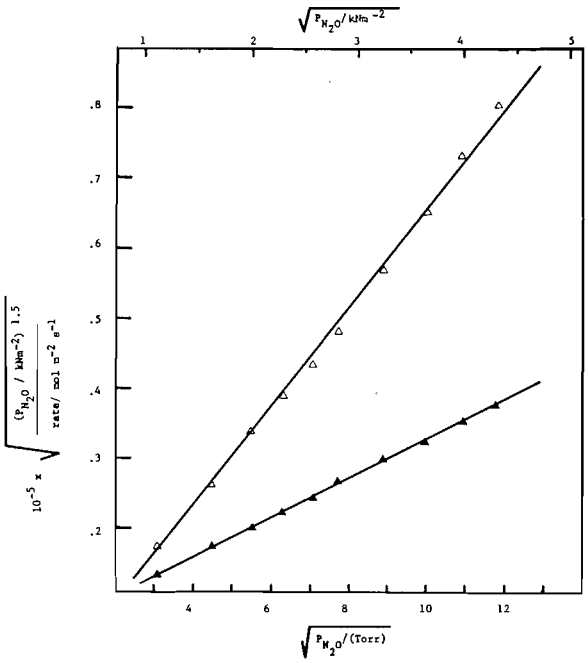

FIG. 7. Reduced plot of the Langmuir–Hinshelwood type expression 7 on Co_3O_4. Symbols correspond to Fig. 2.

the rate dependence on carbon dioxide partial pressure was obtained and hence step 7 must be regarded as an overview.

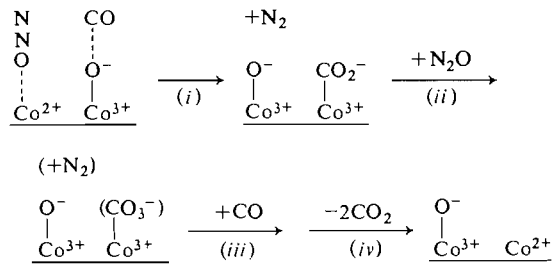
Certain experimental features can be explained through this mechanism. Thus, absence of carbon monoxide production when the catalyst was exposed only to carbon dioxide can be rationalized since the mechanism is not a simple redox process. Rather, the absorbed carbon dioxide species would appear to occupy a specific catalyst site.

The observed decomposition of nitrous oxide following catalyst exposure to carbon dioxide can be accommodated by step 10 in which a surface carbonate is produced. Similarly, the addition of carbon dioxide to the reacting gas mixture and subsequent increase in the catalytic conversion level may be attributed to the increased presence of reactive carbon dioxide on the surface resulting in a greater proportion of the surface contributing to catalysis.

It has been shown previously (16) that a transition from a concerted redox process (associative), usually observed at lower temperatures, to a sequential process (regenerative) at higher temperatures is accompanied by an increase in the value of the apparent activation energy, E_A. Thus, the low value of E_A observed in the low temperature region can be explained if the surface reaction proceeds on a large number of surface sites via a surface complex involving the catalyst and reactants. The change in surface mechanism to the sequential process would then be accompanied by blockage of the low energy sites. Four distinct adsorbed carbon dioxide species have been observed on a similar preparation of this oxide by temperature programmed desorption (17). The desorption maximum of the third species (γ-form) was noted at 451–456 K, which corresponds to the region in which the E_A changes in this study. The two high-temperature sorption forms of carbon dioxide, γ and δ, have been attributed (17) to the presence of surface and bulk cations of different oxidation states Co^{2+} and Co^{3+} which, respectively, provide energetically different adsorption sites. Thus, the loss of the intermediate γ-carbonate present in the low-temperature region and the formation of the more stable δ form may account for the observed change in E_A. Further, Co^{3+} has been reported (18) to be much less active than Co^{2+} in the decomposition of nitrous oxide and this was related to the different strengths of the metal-to-oxygen bonds. The consequence of the transformation of Co^{2+} to Co^{3+} was a more stable surface oxygen bond and an electronic interaction between these two ions was proposed.

With these considerations, the surface process may be represented by [12].

[12]



The scheme preserves stationary catalyst composition and suggests that the cobalt oxidation state alternates with each reaction cycle. Stage (*ii*) would be rate-controlling in the formation of the intermediate carbonate, the structure of which has not been specified since it may alter in the two kinetic regions. The subsequent stages (*iii*) and (*iv*) are not clear although reaction with a second carbon monoxide molecule is required while the subsequent desorption of carbon dioxide may proceed in one or two separate stages.

The apparent lack of agreement in Table 2 regarding the closest state for Co_3O_4 may be taken as further evidence supporting the hypothesis of intermediate carbonate formation on this oxide. These E_A values all lie in the region reported for the catalytic oxidation of carbon monoxide (4) while the low value observed for Co_3O_4 corresponds to those found with the oxides of nickel, copper, and manganese near room temperature (4).

An explanation of reported participation of hydrated electrons as intermediates in electrochemical reduction reactions

JOHN R. DUNCAN[1] AND GRAHAM A. WRIGHT

Chemistry Department, University of Auckland, Auckland, New Zealand

Received October 21, 1976[2]

JOHN R. DUNCAN and GRAHAM A. WRIGHT. Can. J. Chem. **56**, 17 (1978).

Suggestions that $e^-_{(aq)}$ is involved as a reactant in reduction reactions at metal electrodes are examined. It is shown that an experimental test of the participation of $e^-_{(aq)}$ can be devised. The results of this test show that the conventional theory, involving electron transfer directly from the electrode to the species being reduced, provides a better explanation of the reduction process in aqueous solution.

JOHN R. DUNCAN et GRAHAM A. WRIGHT. Can. J. Chem. **56**, 17 (1978).

On examine diverses suggestions à l'effet que $e^-_{(aq)}$ est impliqué comme réactif dans des réactions de réduction à des électrodes métalliques. On montre que l'on peut développer une technique expérimentale pour vérifier la participation des $e^-_{(aq)}$. Les résultats de cette vérification montrent que la théorie conventionnelle impliquant un transfert d'électrons directement de l'électrode vers les espèces qui sont réduites fournit la meilleure explication du processus de réduction en solution aqueuse.

[Traduit par le journal]

There have been many studies carried out on the behaviour of the hydrated electron in electrolytes over the last 15 years, so that its reactions are now well-documented (1–3) and there are quite advanced theories on its structure (4, 5). Formation of solvated electrons under the stimulus of radiation is well-known (5), and it has been known for many years that electrons solvated by ammonia or amines (6, 7) are very stable. However, the suggestion that the hydrated electron may be an important intermediate in electrochemical reduction reactions (8–11) is totally at variance with previously accepted theories of electrode kinetics and electrochemical reduction (12).

The conventional theory of electrochemical reduction, which will be designated as the electrode model in the rest of this paper, requires that the ion or molecule which is to be reduced at the electrode must diffuse from the bulk solution to the electrode surface. During this diffusion, it passes through the diffusion layer and is finally adsorbed into the double layer, i.e. the layer of electrolyte lying immediately adjacent to the electrode surface. The thickness of the diffusion layer, δ, depends on the solution composition and the stirring conditions in the bulk solution, usually being of the order of 10 μm. The double layer is normally only of the order of 1 nm thick, again depending on the solution composition, and has definite structure because of orientation effects exerted by the charge on the electrode. Within the double layer, the substrate species may be adsorbed onto the electrode surface, or there may simply be deformation of its solvation shell. Either of these processes aids the transfer of the electron from the cathode to the substrate. The particular cathode material has been shown to exert a considerable effect on the mechanism and rate of the electrode process, and this is explained for this electrode model in terms of the adsorption effects at the electrode surface (13).

A model of the electrochemical reduction process which involved hydrated electrons as intermediates was first invoked to explain results found in sodium amalgam discharge experiments (8), and has been suggested to apply in hydrogen evolution at an inert metal cathode (9, 10), though this has been disputed since it was first suggested (14). No exact definition of the process involving hydrated electrons has yet been proposed, but analogy with a model proposed for photo-emission from a mercury cathode (15) would require that the electron be ejected from the electrode surface and become thermalised and hydrated, to provide a homogeneous distribution of $e^-_{(aq)}$ throughout a reaction layer which will have a thickness of the same order as that of the double layer invoked in the electrode model. Evidence has been presented to suggest that hydrated electrons may move 2 nm or more from an electrode after photo-emission, before becoming solvated (16). Bulk solution ions which have diffused inwards to this layer must then presumably be reduced by reaction, in a normal ion–ion interaction, with the hydrated electrons in this reaction layer.

The essential difference between the electrode model and the hydrated electron model is thus the

[1]Present address: Building Research Association of New Zealand, Wellington, New Zealand.

involvement of the mobility and reactivity of the hydrated electron in the latter model. The discussion and experiments presented in the rest of this paper were designed to examine the validity of the claims made for $e^-_{(aq)}$ involvement here.

Hughes and Roach (8) measured the total volume, standardized to 273 K and 760 Torr pressure, of gaseous hydrogen evolved per gram of sodium when a known amount of sodium amalgam was reacted to completion with an aqueous solution containing excess hydrogen ions, and compared this volume with that evolved when inorganic metal ions were present as competitors for the hydrated electrons which they believed to be involved as intermediates in the reaction. The results were found to fit a relationship

$$[1] \qquad V_0/V = 1 + A(c_2/c_1)$$

where V_0 = volume of hydrogen evolved in absence of competing ions, V = volume of hydrogen evolved in presence of a concentration c_2 (mol ℓ^{-1}) of competing ions, and c_1 (mol ℓ^{-1}) = hydrogen ion concentration.

These workers proposed reactions 2 to 5 as the mechanism whereby this effect occurred:

$$[2] \qquad Na(Hg) \rightarrow Na^+ + e^-_{(aq)}$$

$$[3] \qquad e^-_{(aq)} + H^+ \rightarrow H$$

$$[4] \qquad H + H \rightarrow H_2$$

$$[5] \qquad S^{z+} + e^-_{(aq)} \rightarrow S^{(z-1)+}$$

The homogeneous rate constants for reactions 3 and 5 are respectively $k_3 = 2.1 \times 10^{10}$ ℓ mol^{-1} s^{-1} (2) and $k_5 = 3 \times 10^{10}$ ℓ mol^{-1} s^{-1} (1), where the competing ion S^{z+} is Cu^{2+}. Hughes and Roach (8) expressed the volumes evolved in terms of the concentrations of the ions present and the homogeneous rate constants of their reactions with the hydrated electron, and assumed that the generation of hydrated electrons would be the rate-determining step. The value of A (in [1]) was then given by the ratio $k_5:k_3$.

There are several reasons for believing that Hughes and Roach have made some incorrect assumptions in deriving this expression. The most important of these is the energetic favorability of sodium oxidation when sodium amalgam is in contact with an aqueous solution; the potential of sodium discharge to form an amalgam is known to be in the region of -1850 mV (nhe) (17), while hydrogen ion discharge occurs at potentials around -1260 mV (nhe) at a dropping mercury electrode (18). It might therefore be expected that supply of electrons at the interface would not be the rate-determining process, and in view of the magnitude of the homogeneous rate constants, the solution reaction might not be expected to be rate determining, either.

Bartlett *et al.* (19) recognized that the model proposed by Hughes and Roach was incompatible with existing theories of electrochemical reduction, and also that the conventional theories would require diffusion of the reacting species to the electrode surface. They therefore proposed that [1] should be rewritten as

$$[6] \qquad \frac{V_0}{V} = 1 + \frac{n_2 D_2}{D_1}\frac{c_2}{c_1}$$

where n_2 = number of electrons transferred to S^{z+} during the reduction, and D_1 and D_2 are respectively the diffusion coefficients of the hydrogen ion and the competing ion in the solution. It was claimed that this equation should represent the relationship between the volume yields and ion concentrations if the electrode model is valid, but this is not true, in that no attention has been paid to electrode kinetic aspects of the reactions in deriving this equation. More accurate relationships will be derived later in this paper.

Bartlett *et al.* (19) found that the values of A in [1] which they found experimentally (in repeating the experiments of Hughes and Roach, and in experiments of their own) did not fit [6] as well as they fitted a different modification of [1], in which $A = k_5'/k_3'$, where $k_n' = 10^{-0.2z}k_n$ (z being the charge on the ion). Barker *et al.* (15) had previously reported that this correction had been found empirically to be required to allow comparison of rate constants determined in pulse radiolysis experiments (at concentrations of the order of 10^{-6} mol ℓ^{-1}) with those found at higher solute concentrations (0.2 to 1 mol ℓ^{-1}). Table 1 contains the results obtained by Hughes and Roach and Bartlett *et al.*, and the theoretical values of n_2D_2/D_1 and $k_5':k_3'$, which have been recalculated where necessary, using the data sources of ref. 19, to remove some errors which appear to have been included in the values computed in ref. 19. The results presented in this table do not lend unequivocal support to any of the relationships discussed so far. The differences in the values observed by the two sets of workers could be attributable to the different amalgam and solution concentrations which were used in the two sets of experiments (Table 2). The experimental method was the same in both cases; a small volume of amalgam was shaken with an excess of solution, so that the concentrations of hydrogen ion and competing ion were maintained essentially constant throughout the experiment.

Though they correctly assumed that diffusion to the reaction site should be an important process,

	Hughes and Roach	Bartlett *et al.*
Sodium amalgam concentration	1–2	~5
Hydrogen ion concentration	0–0.25	~0.5
Competing ion concentration	~0.3	0.1–2.5

Bartlett *et al.* appear to have overlooked a basic difference between the hydrated electron model and the electrode model: while the hydrated electron model predicts a strictly competitive reaction, the electrode model predicts that electrode reactions will proceed at different rates depending on the electrode potential. Thus the formation of a sodium amalgam proceeds at significant rates only at potentials more cathodic than −1850 mV (nhe). The expression which they have derived is therefore not sufficient to describe the electrode model.

When a redox reaction occurs at an electrode, it may be interpreted as the sum of two partial currents of opposite polarity. Electrode kinetic considerations require that these currents are functions of the electrode potential, and the rate of the reaction is limited by the limiting current which the reactants can carry. The limiting cathodic current will flow when the electrode is so negatively charged that the rate-limiting step is diffusion of the reducible species to the cathode, and conversely the limiting anodic current will flow when the electrode potential is so positive that diffusion becomes the rate-limiting step in the charge-transfer process. The limiting current, I_d, may be calculated by [7] for the case of steady-state diffusion through a stationary boundary layer in a stirred solution (31), which is an approximation of the conditions used in the amalgam discharge experiments under discussion.

$$[7] \qquad I_d = nFcDA/\delta$$

n = number of electrons transferred per ion, F = Faraday constant, c = concentration of electro-active species, D = diffusion coefficient, A = area of electrode, and δ = diffuse layer thickness.

Since the relative values of total anodic and total cathodic currents affect the course of the reaction, different reaction paths might be expected for Figs. 1*a* and 1*b*. The potential at which the anodic and cathodic currents are of equal magnitude but opposite sign, so that the total current flowing is zero, is called the mixture potential, E_m, and is the potential at which the system will lie if no external potential is applied. The partial currents flowing at the mixture potential are equivalent to the limiting current for the reaction.

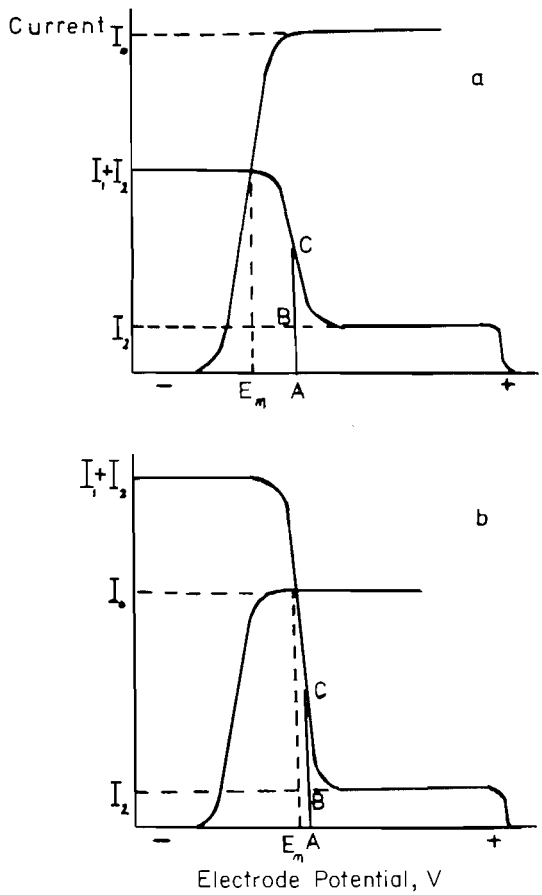

FIG. 1. Schematic mixture potential diagrams for the system Na(Hg)/H^+, scavenger. E_m = mixture potential. (*a*) Total available anodic current exceeds total available cathodic current. (*b*) Total available cathodic current exceeds total available anodic current.

The concepts outlined above may be applied to predicting the outcome of the amalgam dissolution experiments performed by Hughes and Roach and Bartlett *et al.* Because the aqueous phase reactants were arranged to be in considerable excess over the sodium in the amalgam, there will be virtually no change in scavenging ion or hydrogen ion concentrations during the hydrogen evolution reaction, and thus negligible change in the limiting currents carried by these species.

Consider Fig. 1*a*. The electrode model requires that the limiting current which will flow here will be the total cathodic current, $I_1 + I_2$, where I_1 and I_2 are the limiting currents (derived from [7]) due to hydrogen ion discharge and copper amalgam formation. (The copper amalgam formation reaction may occur as two 1-electron-transfer steps; these will occur at such relatively anodic potentials compared to the hydrogen evolution reaction, however, that the amalgam formation will be assumed to be a single 2-electron transfer for this paper.) I_0 is the current for the anode reaction $Na(Hg) \rightarrow Na^+_{(aq)} + e^-$. Assuming no change in I_1 or I_2, the total currents at the end of the reaction will be anodic current = 0 and cathodic current = $I_1 + I_2$, and V_0/V can be expressed in terms of these partial currents. In absence of a competing ion, the volume of hydrogen evolved is

$$[8] \qquad V_0 = KI_0$$

where K is a proportionality constant. In the presence of a competing ion, the volume V evolved will be the sum of the volumes evolved in the different stages of the reactions; i.e. $V = \sum_i V_i$, where

$$[9] \quad V_1 = \text{volume evolved while } I_0 \text{ decreases to } I_1 + I_2 = K(I_0 - (I_1 + I_2))\frac{I_1}{I_1 + I_2}$$

The last factor in [9] expresses the fraction of the current which is consumed in discharge of hydrogen ions.

$$V_2 = \text{volume evolved while } I_0 \text{ decreases from } I_1 + I_2 \text{ to } I_2 = KI_1 \frac{\text{BC}}{\text{AC}} \text{ on Fig. 1}a$$

where BC/AC is the average fraction of current spent on hydrogen ion discharge, and is approximated by $\frac{1}{2}I_1/(\frac{1}{2}I_1 + I_2)$. Thus

$$V_2 = KI_1^2/(I_1 + 2I_2)$$

$$[10] \quad V_3 = \text{volume evolved while } I_0 \text{ decreases from } I_2 \text{ to } 0 = 0$$

since none of the current which flows is spent on hydrogen ion discharge. During this stage of the process, the mixture potential will have quite positive values. Thus

$$[11] \quad V = V_1 + V_2 + V_3 = \frac{KI_1[I_0(I_1 + 2I_2) - 2I_2(I_1 + I_2)]}{(I_1 + I_2)(I_1 + 2I_2)}$$

and

$$[12] \quad \frac{V_0}{V} = \frac{I_0(I_1 + I_2)(I_1 + 2I_2)}{I_1(I_0(I_1 + 2I_2) - 2I_2(I_1 + I_2))}$$

for the case of Fig. 1*a*.

A similar derivation for the case of Fig. 1*b* gives

$$[13] \qquad \frac{V_0}{V} = \frac{I_0(I_0 + I_2)}{(I_0 - I_2)^2}$$

Plots of V_0/V against c_2/c_1, as predicted by the electrode model, may be drawn by selecting values of amalgam, hydrogen ion, and competing ion concentrations, computing the values of I_0, I_1, and I_2 which correspond to them by using [7], and computing V_0/V by whichever of [12] and [13] is appropriate. Both of these expressions lead to curved plots, so that it should be possible to differentiate between the electrode model (curved plot) and the hydrated electron model (straight-line plot).

Another means of differentiating between the two models is a plot of the ratio of instantaneous rates of gas evolution, v_0/v, against the concentration ratio, c_2/c_1, which is also curved for the electrode model but straight for the hydrated electron model. For Fig. 1*a*, addition of competing ions will not affect the rate of hydrogen evolution until $I_0 = I_1 + I_2$, since until this time the cathodic current is the limiting parameter and hydrogen is being evolved at the maximum rate. When $I_0 = I_1 + I_2$, the case of Fig. 1*b* holds and

$$[14] \qquad v_0 = kI_0$$

$$[15] \qquad v = k(I_0 - I_2)$$

so that

$$[16] \qquad v_0/v = I_0/(I_0 - I_2)$$

Choice of suitable values allows computation of plots such as those shown in Fig. 2.

Using [12] and [13], it is possible to estimate values of concentrations within the ranges used by earlier workers which will allow computation of data which approximates their reported results. An example of this is given in Table 3. While it is not claimed that the values used to compute these data are those used in the actual experiments by Hughes and Roach,

TABLE 3. Comparison of results found by Hughes and Roach (8) with results obtained by calculation from [13]

Concentration ratio $[Cu^{2+}]/[H^+]$ (8)	0.75	1.4	2.4	2.8	3.5
Evolved gas volume ratio V_0/V (8)	1.8	2.7	3.2	4.2	4.8
Amalgam concentration, M	1.4	1.4	1.3	1.1	1.0
H^+ ion concentration, M	0.20	0.20	0.125	0.11	0.09
Cu^{2+} ion concentration, M	0.15	0.28	0.30	0.32	0.31
V_0/V (eq. 13)	1.7	2.7	3.2	4.2	4.7

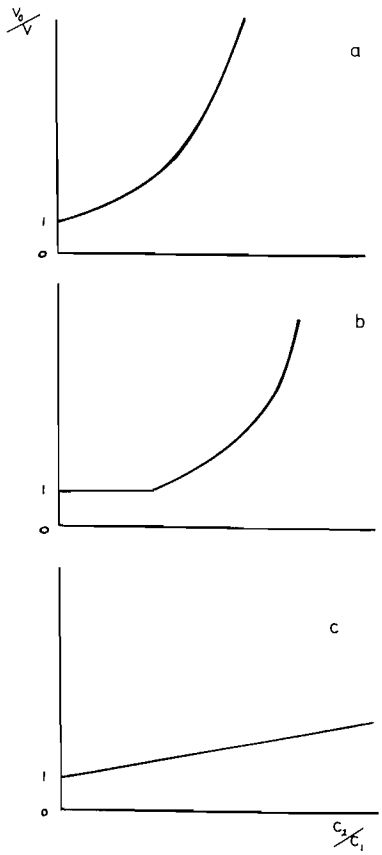

FIG. 2. Schematic representations of plots of v_0/v against c_2/c_1 (see text for definitions). (*a*) Electrode model, $I_0 < I_1$. (*b*) Electrode model, $I_0 > I_1$. (*c*) Hydrated electron model.

Table 3 clearly shows how small changes in reactant concentrations could have significant effects on the V_0/V ratio.

One method of determining more precisely the true mechanism would be to hold all concentrations constant except one, and examine the effect on the reaction rate of changes in this concentration. A cell was designed in which this could be done, and experiments were performed on this theme.

The two-chamber cell (Fig. 3) was built in such a way that sodium amalgam which was manufactured in one chamber by electrolysis of a concentrated sodium hydroxide solution could be transported to the other chamber by the action of a large glass

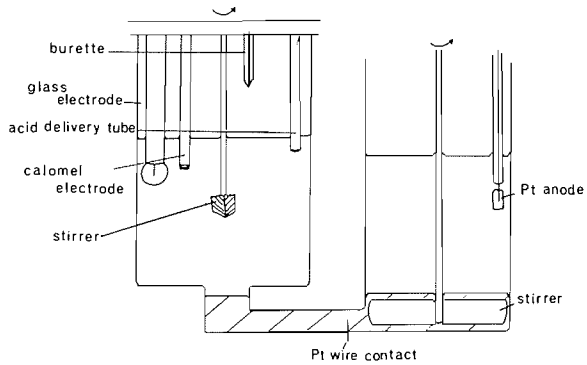

FIG. 3. Cell used to investigate amalgam–solution reaction rates.

paddle, and there reacted with an aqueous solution. The solution in the second chamber was held at a steady pH by a pH-stat (TTTl titrimeter, SBR2 recorder and motor-driven burette (Radiometer, Copenhagen)). This device continuously monitors the solution pH, and adds (in this case) acid automatically from a reservoir to maintain a preset pH value. It was possible to deduce the rate of sodium amalgam reaction at the interface (which had an area of approximately 300 mm^2) from the rate of acid addition needed in absence of competing ions. This enabled balancing of the rates of amalgam formation and reaction, by altering the electrolysis current. This current was supplied by a Duffers Associates Model 600 potentiostat which was operating in a galvanostatic mode, producing currents in the range 0 to 2.5 A.

Experimental

It was decided to investigate thoroughly the effect of added cupric ions on the rate of acid addition needed to maintain constant pH in a solution containing 0.03 M HCl, which was in contact with a 0.1 M sodium amalgam. The amalgam was prepared by passing the appropriate amount of charge through the electrolysis cell, into which had been placed a weighed amount of mercury, before the aqueous solution was introduced to the reaction chamber. During this period, the pH-stat was calibrated using the solution which had been prepared for addition to the reaction chamber. Immediate addition of acid from the reservoir normally occurred when the solution was introduced to the reaction chamber, suggesting that some of the amalgam could have reacted with the atmosphere during its preparation, but a period then followed during which little or no acid addition was necessary. Extrapolation of the slope

which was found after this plateau back to zero acid addition usually led to $t \sim 0$.

An adequate steady state was apparently set up for the case $I_0 < I_1$. On three occasions, there was an invariant acid addition rate for more than 45 min, and in these cases calculations of the fluxes from the current in the electrolysis cell and the rate of acid addition gave values which agreed within 8%. For the case $I_0 > I_1$, conditions were never obtained in which the acid addition rate was steady enough for a valid claim to have established a steady state. To reach $I_0 > I_1$, the acid concentration was reduced to 3×10^{-3} M; part of the inaccuracy may have been due to improper deoxygenation of the solution. (An oxygen-saturated solution would have contained approximately 2×10^{-3} M O_2.)

When the rate of acid addition was steady, an aliquot of concentrated $CuCl_2$ solution was added from a burette and the rate allowed to reach a new equilibrium value; this normally took 1 to 2 min to achieve. This process was then repeated until the addition of an aliquot of $CuCl_2$ solution completely inhibited hydrogen evolution, so that no acid addition was required to maintain the pH. On the electrode model, this corresponds to $I_0 < I_2$.

Stirring conditions were kept constant for all experiments, so that values of k in [17] (where $k = AF/\delta$) should remain

$$[17] \qquad I = nkcD$$

constant for all measurements, though k might have different values in the amalgam and solution phases. The value of k in the amalgam, k_0, was determined by assuming a steady state to have been established, in which the current flowing in the electrolysis cell is the limiting current, I_0, flowing at the reaction interface. n, c, and D are known, so that if $I_0 = 0.2$ A (as was used in most experiments), it may be calculated that $k_0 = 2.5 \times 10^8$ C cm mol^{-1}.

The value, k_2, for the solution phase was assumed to be the same for both Cu^{2+} and H^+, though it is known that δ values for these are likely to be different. k_2 was evaluated graphically as 5.1×10^8 C cm mol^{-1}, from the results of spectrophotometric analysis (using a Shimadzu QV50 instrument) for Cu^{2+} of aliquots withdrawn from the reaction chamber at regular time intervals after addition of a known amount of $CuCl_2$.

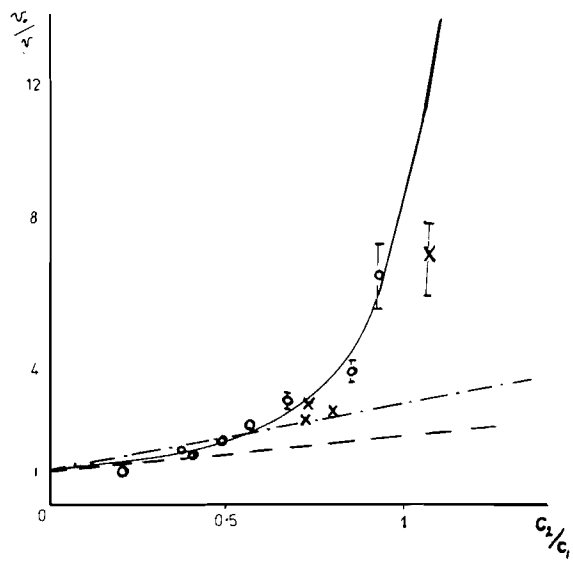

FIG. 4. Comparison of experimental rates of amalgam–solution reaction with theoretical predictions ($I_0 < I_1$). (×, ○) Individual runs. (- ·) After Bartlett *et al.* (19). (--) After Hughes and Roach (8). (—) Electrode model.

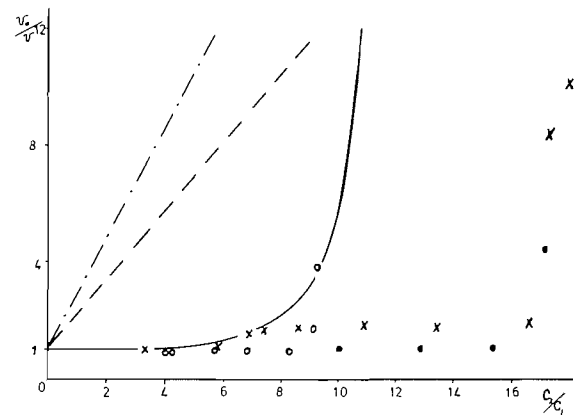

FIG. 5. Comparison of experimental rates of amalgam–solution reaction with theoretical predictions ($I_0 > I_1$). (×, ○) Individual runs. (- ·) After Bartlett *et al.* (19). (--) After Hughes and Roach (8). (—) Electrode model.

It was assumed that c_0 and c_1 were being held constant by the external circuits. The Cu^{2+} ion concentration, c_2, at each point at which the rate v of hydrogen evolution was measured (by calculation from the rate of addition of acid) was calculated using [18]. The ratio v_0/v was plotted against c_2/c_1, and compared with the plots predicted by the hydrated electron and electrode models. The results are shown in Figs. 4 and 5.

$$[18] \qquad C_2(t) = C_2(0) \exp\left[-\frac{D_2 k_2}{FV} t\right]$$

Discussion of Experiments

The results of these experiments suggest that the conventional electrode model provides a better prediction of the behaviour of the Na(Hg)–Cu^{2+}–H^+ system than does the hydrated electron model. There are four possible errors in determining values of v_0/v.

(*1*) Inaccurate measurement from the recorder chart of the rate of addition of acid. Such errors will become more significant as cupric ion concentration rises.

(*2*) Hydrogen evolution by direct reduction of water. It seems unlikely, though, that this will be a major source of hydrogen gas in a solution with pH ~2 to 3.

(*3*) There will be non-uniform transport conditions in the aqueous solution because of the stirring at the interface produced by gas bubble evolution.

(*4*) The surface of the amalgam will become adulterated by the presence of dissolved copper, which may cause variations in the hydrogen evolution.

In spite of these possible errors, the data for the case $I_0 < I_1$ (Fig. 4) fit the prediction of the electrode model fairly well; the best-fit line (correlation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

coefficient = 0.942) corresponds to

$$\frac{v_0}{v} = \frac{0.934 I_0}{I_0 - I_2}$$

compared with the theoretical line given by [16], but does not fit the hydrated electron models proposed by earlier workers (8, 19). A point is reached where $I_2 > I_1$ at $c_2/c_1 = 1.25$, at which the ratio v_0/v is found to be infinite, in accord with the electrode model, while the hydrated electron model predicts $v_0/v = 2.5$ at this concentration ratio. This is compelling evidence for the validity of the electrode model.

The data for the case $I_0 > I_1$ (Fig. 5) are rather scattered, and do not fit any of the models very closely. This scatter is probably due in large part to the absence of a steady state from the system. There is qualitative fit to the electrode model, insofar as the data display a clear plateau region, with a relatively constant value of v_0/v, up to $c_2/c_1 = 15$, with v_0/v then climbing steeply. This qualitative behaviour cannot be reconciled with a hydrated electron model.

Published tables (16) of polarographic constants measured at a dropping mercury electrode suggest that all the depolarizing ions considered by Bartlett *et al.* (19) should reach their limiting currents at potentials more positive than the potential at which sodium amalgam dissolution reaches a limiting current.

This study would therefore appear to refute the claims of Hughes and Roach (8) and Bartlett *et al.* (19) of the occurrence of the hydrated electron as an intermediate in reactions during amalgam dissolution. Conway and Mackinnon (14) have discussed the claim by Pyle and Roberts (10) that $e^-_{(aq)}$ is involved in reactions at platinum electrodes, and deemed this unlikely. There is apparently, therefore, no unequivocal evidence for the existence of hydrated electrons as intermediates in electrochemical reduction mechanisms in the absence of photochemical excitation.

Measurements at 25°C with flow calorimeters and densimeters have led to heat capacities and densities of aqueous solutions of 11 1:1 electrolytes: $NaClO_3$, $NaBrO_3$, $NaIO_3$, $NaNO_3$, $NaClO_4$, NH_4NO_3, $KClO_3$, $KBrO_3$, KIO_3, NH_4Cl, and NH_4ClO_4. The first 6 salts were studied up to near saturation. We have used results of these measurements to obtain apparent molal heat capacities and apparent molal volumes of the various solutes. Extrapolation to infinite dilution on the basis of the Debye–Hückel theory has led to $\phi_C^\ominus$ and $\phi_V^\ominus$ values for each solute. We have compared these standard values with results of earlier investigations.

Des mesures de capacités calorifiques et de densités ont été effectuées à 25°C au moyen de microcalorimètres et de densimètres dynamiques sur des solutions aqueuses de 11 électrolytes 1:1: $NaClO_3$, $NaBrO_3$, $NaIO_3$, $NaNO_3$, $NaClO_4$, NH_4NO_3, $KClO_3$, $KBrO_3$, KIO_3, NH_4Cl et NH_4ClO_4. Les 6 premiers sels ont été étudiés presque jusqu'à la saturation. Les capacités calorifiques et volumes molaires apparents ont été calculés et extrapolés à dilution infinie en se basant sur la théorie de Debye–Hückel. Ces valeurs standards $\phi_C^\ominus$ et $\phi_V^\ominus$ ont été comparées aux valeurs antérieurement publiées.

Introduction

As part of our program of determination of thermal and volumetric properties of aqueous solutions, we have made calorimetric measurements leading to apparent molal heat capacities and density measurements leading to apparent molal volumes of 11 1:1 electrolytes at 25°C. Results of these measurements and our thermodynamic calculations are reported in this paper.

Experimental

Heat capacity measurements were made with flow calorimeters that have been described previously (1). A small systematic error in some of the measurements has been identified and corrected as recently described (2, 3).

Densities have been measured with flow densimeters that have been described previously (4).

All results refer to 25.00 ± 0.05°C.

Chemicals used in Sherbrooke were as follows. Fisher Certified samples of $NaClO_3$, $NaBrO_3$, and $NaNO_3$ were dried in a vacuum oven at 100°C. $NaIO_3$ from Mallinckrodt and $NaClO_4$ from Alfa Inorganic Ventron were dried in a vacuum oven at 70°C. NH_4NO_3 (Fisher Certified) was recrystallized from methanol and then dried in vacuum at 80°C.

Chemicals used in Lethbridge were as follows. Reaction of concentrated solution of NH_4NO_3 (Fisher Certified) with concentrated $HClO_4$ (Baker Analytical Reagent) yielded a precipitate of NH_4ClO_4, which was recrystallized several times from 80% ethanol and then twice from water ($pH = 4.5$) before being dried at 105°C. Fisher Certified samples of $KBrO_3$, KIO_3, and NH_4NO_3 were dried at 110°C. $KClO_3$ (BDH Analar) was dried at 96°C and NH_4Cl (BDH Analar) was dried at 110°C.

All solutions used in Sherbrooke were made from known masses of solute and water; most solutions used in Lethbridge were prepared similarly. Some solutions of NH_4ClO_4 were prepared by dilution of stock solutions that had been made by mass, while concentrations of a few solutions of $KBrO_3$ and KIO_3 were determined by titration with $S_2O_3^{2-}$ after reaction with excess I^-.

Results and Discussion

Apparent molal properties of solutions (ϕ_Y) are defined by the expression

$$[1] \qquad \phi_Y = [Y(\text{soln}) - n_1 Y_1^0]/n_2$$

in which the symbols have the following meanings: Y

is the property (heat capacity or volume for our purposes) of a specified quantity of solution, n_1 is the number of moles of solvent in this specified quantity of solution, Y_1^0 is the property (heat capacity or volume) of 1 mol of pure solvent, and n_2 is the number of moles of solute in the specified quantity of solution. Our experimental results (compositions of solutions, heat capacities, densities) have been used to obtain apparent molal heat capacities (ϕ_C) and apparent molal volumes (ϕ_V).[5]

Apparent molal properties of dilute solutions of electrolytes are accurately described by equations of the form of

$$[2] \quad \phi_Y = \phi_Y^\ominus + A_Y(d_1^0 m)^{1/2} + B_Y m + C_Y m^{3/2} + \ldots$$

in which $\phi_Y^\ominus$ is the value of ϕ_Y at infinite dilution, A_Y is the limiting slope derived from the Debye–Hückel theory, d_1^0 is the density of the pure solvent, m is the molality, and B_Y, C_Y, etc. are adjustable parameters. Our principal interest in this work has been in determining $\phi_Y^\ominus$ values which are identical with the corresponding partial molal properties at infinite dilution ($\bar{Y}_2^\ominus$). For our calculations we have used $A_C(d_1^0)^{1/2} = 28.95$ J K^{-1} mol$^{-3/2}$ kg$^{1/2}$ and $A_V(d_1^0)^{1/2} = 1.865$ cm^3 mol$^{-3/2}$ kg$^{1/2}$ as previously reported (2).

One way to treat our experimental results has been to construct graphs of ($\phi_Y - A_Y(d_1^0 m)^{1/2}$) versus m and then obtain values of $\phi_Y^\ominus$ and B_Y from the intercepts, respectively, of the best (judged by eye) straight lines through the points that represent dilute solutions. Another similar approach can be based on a least-squares or other statistical fit of experimental results of [2]. Treatment of all results obtained in Lethbridge has been based on least-squares fits of all results (no points omitted) using [2] up to terms in m from about $m = 0.03$ mol kg^{-1} to about $m = 0.3$ mol kg^{-1}. The derived $\phi_C^\ominus$, B_C, $\phi_V^\ominus$, and B_V are summarized in Table 1.

Results obtained in Sherbrooke are more complicated to analyze since they were made over a much larger concentration range, and the values of $\phi_C^\ominus$ and $\phi_V^\ominus$ depend to some extent on the number of parameters used in [2]. Two approaches have been used for this purpose. First, graphs were made of ($\phi_Y - A_Y(d_1^0 m)^{1/2}$) vs. m. On the basis of these graphs we have made subjective decisions to ignore a few experimental points which appeared definitely out of line and set upper limits on the concentrations where the functions can be considered linear. The data were then treated by linear least squares ([2] with terms to m only) without weight factors. The derived parameters are summarized in Table 2. In the second approach the data up to saturation were treated with [2] using weighted least squares, with as many parameters as needed to reproduce the experimental data. Parameters obtained in this way are given in Table 3 with the standard deviations and the limits of validity. While [2] can reproduce the experimental ϕ_Y inside the expected uncertainties some caution must be used in evaluating partial molal quantities by way of [2] ($\bar{Y} = \phi_Y + m\, d\phi_Y/dm$) at high concentrations since some anomalous curvature is then observed.

The agreement between $\phi_V^\ominus$ in Tables 2 and 3 is, in general, excellent. On the other hand, for $\phi_C^\ominus$ the values in Tables 2 and 3 generally differ by about 1 J K^{-1} mol^{-1} (more for $NaBrO_3$). The linear least-squares treatment emphasizes the low concentration data and should in principle give the most reliable $\phi_C^\ominus$ values. However, because the B_C parameters are quite large, compared with alkali halides (3) for example, it is possible that neglect of higher terms in [2] leads to some error in $\phi_C^\ominus$. These considerations added to previous experience with the calorimeters and densimeters used in this investigation suggest that uncertainties in $\phi_C^\ominus$ values are no more than ± 3 J K^{-1} mol^{-1} and that uncertainties in $\phi_V^\ominus$ values are no more than ± 0.5 cm^3 mol^{-1} for 1:1 electrolytes. Our following comparisons and calculations support these limits on uncertainties.

The $\phi_C^\ominus$ values obtained in Sherbrooke and in Lethbridge for aqueous NH_4NO_3 agree well with each other; we consider our average $\phi_C^\ominus = -2$ J K^{-1} mol^{-1} for NH_4NO_3(aq) to be better than the $\phi_C^\ominus = -6.7$ J K^{-1} mol^{-1} cited in Parker's (5) thorough review of earlier measurements. Our $\phi_V^\ominus = 47.2$ cm^3 mol^{-1} from Sherbrooke and $\phi_V^\ominus = 47.5$ cm^3 mol^{-1} from Lethbridge are in good agreement with $\phi_V^\ominus = 47.24$, 47.4, and 47.56 cm^3 mol^{-1} cited by Millero (6). We recommend $\phi_V^\ominus = 47.4$ cm^3 mol^{-1} as the best value for NH_4NO_3(aq).

The $\phi_C^\ominus = 16.6$ J K^{-1} mol^{-1} obtained in Sherbrooke for $NaClO_4$(aq) agrees well with $\phi_C^\ominus = 15.2$ J K^{-1} mol^{-1} reported earlier (7) from Lethbridge and with $\phi_C^\ominus = 17.6$ J K^{-1} mol^{-1} (based on an estimated C_p^0 for $NaClO_4$(c)) from Mastroianni and Criss (8). We select $\phi_C^\ominus = 17$ J K^{-1} mol^{-1} as the best value for $NaClO_4$(aq). The $\phi_V^\ominus = 43.0$ cm^3 mol^{-1} from Sherbrooke agrees well with $\phi_V^\ominus = 42.8$ cm^3 mol^{-1} from unpublished results obtained in Lethbridge and with several values cited by Millero (6). On the basis of our results and Millero's (6) preferred $\phi_V^\ominus = 42.93$ cm^3 mol^{-1}, we confidently select $\phi_V^\ominus = 42.9$ cm^3 mol^{-1} as the best available value for $NaClO_4$(aq).

'Reasonable' interpretations of the ϕ_C results from

Sherbroke for aqueous $NaNO_3$ lead to $\phi_C^\ominus$ values ranging from $-28._3$ to $-30._5$ $J\,K^{-1}\,mol^{-1}$, depending on rejection or acceptance of results for several very dilute solutions and on choice of upper concentration to be included in the analysis. As indicated in Table 2, we have selected $\phi_C^\ominus = -29$ $J\,K^{-1}\,mol^{-1}$ for $NaNO_3$(aq), based on measurements made in Sherbrooke. An earlier investigation (9) in Lethbridge led to $\phi_C^\ominus = -28.9\,J\,K^{-1}\,mol^{-1}$ for $NaNO_3$(aq). Still earlier investigations cited by Parker (5) led to a less certain $\phi_C^\ominus = -40\,J\,K^{-1}\,mol^{-1}$. We therefore adopt $-29\,J\,K^{-1}\,mol^{-1}$ as the best value. The $\phi_V^\ominus = 28.3\,cm^3\,mol^{-1}$ from Sherbrooke and $\phi_V^\ominus = 28.2\,cm^3\,mol^{-1}$ from earlier measurements in Lethbridge (9) are in excellent agreement with each other and in fair agreement with values (27.8, 27.48, and 28.0 $cm^3\,mol^{-1}$) cited by Millero (6). We suggest that $\phi_V^\ominus = 28.2\,cm^3\,mol^{-1}$ is best for $NaNO_3$(aq).

Our measurements in Lethbridge have led to $\phi_C^\ominus = -55.6\,J\,K^{-1}\,mol^{-1}$ for aqueous NH_4Cl. Earlier measurements in Sherbrooke (3) led to $\phi_C^\ominus = -56.6\,J\,K^{-1}\,mol^{-1}$, while Parker (5) has cited a less certain $\phi_C^\ominus = -56.5\,J\,K^{-1}\,mol^{-1}$. We adopt the average of our values ($\phi_C^\ominus = -56\,J\,K^{-1}\,mol^{-1}$) as best for NH_4Cl(aq). Our measurements in Lethbridge have also led to $\phi_V^\ominus = 36.2\,cm^3\,mol^{-1}$ for aqueous NH_4Cl, while earlier measurements in Sherbrooke led (10) to $\phi_V^\ominus = 35.79\,cm^3\,mol^{-1}$. Millero (6) has cited still earlier investigations that led to $\phi_V^\ominus = 35.98$, 36.0, 36.26, and 36.0 $cm^3\,mol^{-1}$. We select $\phi_V^\ominus = 36.0\,cm^3\,mol^{-1}$ as best for NH_4Cl(aq).

We do not know of any prior calorimetric mea-

surements leading to a ϕ_C^{Θ} for $NH_4ClO_4(aq)$ to compare with our $\phi_C^{\Theta} = 47.2$ J K^{-1} mol^{-1} based on measurements made in Lethbridge. There are, however, some simple calculations that will serve to test the relationship of this ϕ_C^{Θ} value to ϕ_C^{Θ} values for some other electrolytes. First, using results reported in this paper, we obtain $[\phi_C^{\Theta}(NH_4ClO_4) - \phi_C^{\Theta}(NaClO_4)] = 47.2 - 17 = 30.2$ J K^{-1} mol^{-1}. We similarly calculate $[\phi_C^{\Theta}(NH_4Cl) - \phi_C^{\Theta}(NaCl)] = -56.1 - (-84.5) = 28.4$ J K^{-1} mol^{-1}, in which $\phi_C^{\Theta}(NH_4Cl)$ is from this paper and $\phi_C^{\Theta}(NaCl)$ is the average of −84.4 and −84.6 J K^{-1} mol^{-1} reported previously from Sherbrooke (3) and Lethbridge (11). The 1.9 J K^{-1} mol^{-1} difference between 30.3 and 28.4 J K^{-1} mol^{-1} is within the limits set by our proposed maximum uncertainty in ϕ_C^{Θ} values. We suggest that our $\phi_V^{\Theta} = 62.2$ cm^3 mol^{-1} may be more accurate than the $\phi_V^{\Theta} = 61.5$ cm^3 mol^{-1} listed in Millero's (6) compilation.

Our ϕ_V^{Θ} values for $NaClO_3$, $NaBrO_3$, $NaIO_3$, $KClO_3$, $KBrO_3$, and KIO_3 are all in satisfactory agreement with results of earlier investigations cited by Millero (6); we suggest that our results are better than those from earlier investigations of these electrolytes. Parker (5) has reviewed earlier investigations of heat capacities and has derived the following: $\phi_C^{\Theta}(NaClO_3) = -36.0$ J K^{-1} mol^{-1}, $\phi_C^{\Theta}(NaBrO_3) = -15.4$ J K^{-1} mol^{-1}, and $\phi_C^{\Theta}(KIO_3) = -102.1$ J K^{-1} mol^{-1}. On the basis of previous assessments of results from our laboratories and those of authors cited by Parker (5) as sources of these values, we suggest that our ϕ_C^{Θ} values listed in Tables 1 and 2 for these solutes are the best ones available.

Using ϕ_C^{Θ} values from Tables 1 and 2, we calculate the following:

$$\phi_C^{\Theta}(KClO_3) - \phi_C^{\Theta}(NaClO_3) = -25.7 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$\phi_C^{\Theta}(KBrO_3) - \phi_C^{\Theta}(NaBrO_3) = -26.8 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$\phi_C^{\Theta}(KIO_3) - \phi_C^{\Theta}(NaIO_3) = -24.7 \text{ J K}^{-1} \text{ mol}^{-1}$$

The almost constancy of these $\Delta\phi_C^{\Theta}$ values is within the limits imposed by our proposed uncertainties in ϕ_C^{Θ} values.

Desnoyers *et al.* (3) have followed the customary procedure of assigning $\phi_C^{\Theta}(H^+) \equiv 0$ and then have developed a table of ionic ϕ_C^{Θ} values based on results of many investigations of heat capacities in Sherbrooke. From their table we calculate $\phi_C^{\Theta}(K^+) - \phi_C^{\Theta}(Na^+) = 13 - 43 = -30$ J K^{-1} mol^{-1}, as compared to the average $\Delta\phi_C^{\Theta} = -26$ J K^{-1} mol^{-1} calculated in the preceding paragraph.

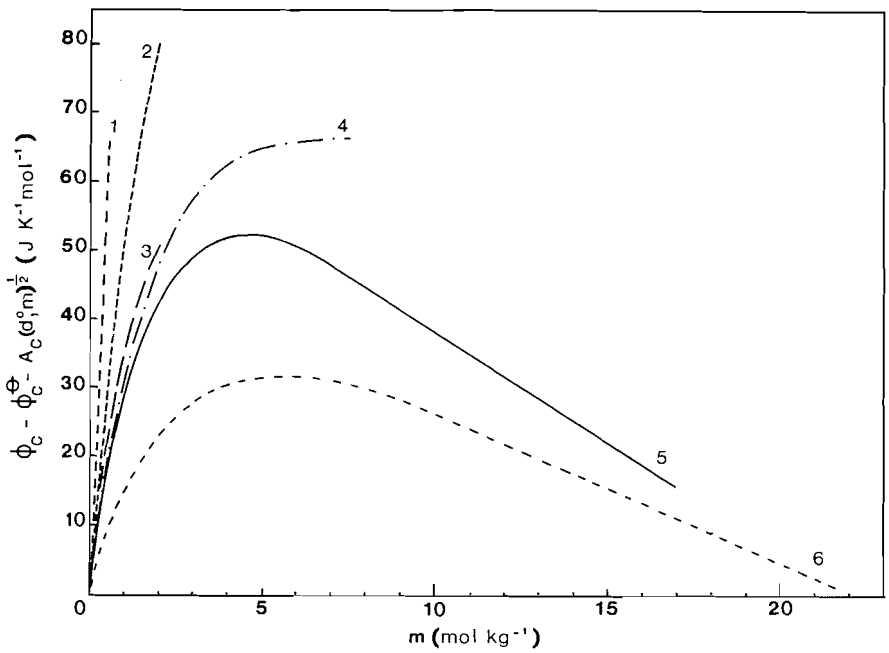

FIG. 2. Apparent molal heat capacities at 25°C of some 1:1 electrolytes at high concentration: *1*, $NaIO_3$; *2*, $NaBrO_3$; *3*, $NaNO_3$; *4*, $NaClO_3$; *5*, $NaClO_4$; *6*, NH_4NO_3.

As previously demonstrated in many investigations, it is useful to assign values for the thermodynamic properties of individual ions in aqueous solution at infinite dilution. To make use of our best ϕ_C^{Θ} and ϕ_V^{Θ} values in this way, we follow the customary procedure of assigning $\phi_C^{\Theta} \equiv 0$ and $\phi_V^{\Theta} \equiv 0$; we also use the ϕ_C^{Θ} values of Desnoyers *et al.* (3) and the ϕ_V^{Θ} values from Millero (6) for $Na^+(aq)$, $K^+(aq)$, and $NH_4^+(aq)$. Results of all of these calculations are summarized in Table 4.

The concentration dependences of ϕ_C and ϕ_V at high concentrations are illustrated in Figs. 1 and 2. For this purpose, $\phi_Y - \phi_Y^{\Theta} - A_Y(d_1^0 m)^{1/2}$ values, based on results obtained in Sherbrooke, are plotted against m.

Comment: On the application of RRKM theory to the unimolecular isomerization of monofluorocyclopropane: a reaction with multiple fall-off characteristics?

MICHAEL C. FLOWERS

Department of Chemistry, The University, Southampton, SO9 5NH, England

Received July 5, 1977

MICHAEL C. FLOWERS. Can. J. Chem. **56**, 29 (1978).

Monofluorocyclopropane isomerizes at 475°C to form *cis*- and *trans*-1-fluoropropene, 2-fluoropropene, and 3-fluoropropene. The relative amounts of these products formed are pressure dependent. It is shown that, using the previously determined Arrhenius parameters for the formation of each product, RRKM theory does account satisfactorily for the pressure dependence of the product yields for *all* the reaction products.

MICHAEL C. FLOWERS. Can. J. Chem. **56**, 29 (1978).

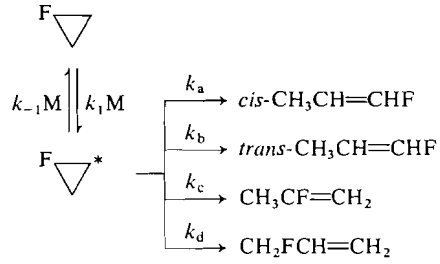
Le monofluorocyclopropane s'isomérise à 475°C pour former des fluoro-1 propène *cis*- et *trans*-, du fluoro-2 propène et du fluoro-3 propène. Les quantités relatives des produits formés dépendent de la pression. On a montré, par l'utilisation des paramètres d'Arrhénius déterminés antérieurement pour la formation de chacun des produits, que la théorie RRKM explique d'une façon satisfaisante la relation qui existe entre la pression et les rendements de *tous* les produits de la réaction.

[Traduit par le journal]

Baghal-Vayjooee, Yau, and Pritchard (BYP) (1) in a recent paper come to the conclusion that conventional RRKM theory cannot account for the fall-off behaviour observed for some of the isomerization products from monofluorocyclopropane. We feel that their interpretation of what constitutes *conventional* RRKM theory is unnecessarily restrictive and that their test of the theory is unreasonable.

Casas *et al.* (2) determined the fall-off characteristics for the formation of the various fluoropropenes (see Fig. 1), measured the Arrhenius parameters of the overall reaction, and observed that 2-fluoropropene and 3-fluoropropene had activation energies ca. 4 kcal mol^{-1} and 1 kcal mol^{-1} respectively higher than for the formation of 1-fluoropropene. The test of the RRKM theory by BYP consisted of applying the theory separately to each product with the additional assumption that the activation energies for all products were the same. It is important to note that even if the experimental activation energies had been the same the fall-off curves would be incorrectly predicted by treating the reactions independently. Presented here are the results of calculations that consider the four reactions as occurring competitively; similar calculations for other reactions have appeared before (3).

Scheme 1 represents the reaction scheme for the isomerization of monofluorocyclopropane. The rate constants, except for k_{-1} which is assumed energy independent, are the specific rate constants for a monofluorocyclopropane molecule of energy ε. The measured unimolecular rate constant for formation



SCHEME 1

of product p is then

$$k_p = \int_{\varepsilon_{0,p}}^{\infty} \frac{k_p \, d(k_1/k_{-1})}{\left(1 + \sum_{p=a,b,c,d} k_p/k_{-1}M\right)}$$

The values of k_a, k_b, k_c, k_d, and $d(k_1/k_{-1})$ are given by the usual RRKM expressions (see refs. 3 or 4 for the actual RRKM equations).

In order to calculate the k_p's transition state (ts) frequencies were assigned so that the experimental and theoretical high pressure rate constants at 475.1°C agreed. The experimental rate constants were calculated from the quoted Arrhenius parameters for the total rate constant (2) and the product distribution also quoted in the paper (unfortunately this is at 453°C). The activation energies used were those estimated by the experimental workers and have not been adjusted in any way. The Appendix to this paper contains details of the various parameters used in the calculation. The vibrational frequencies of fluorocyclopropane are those quoted by BYP.

Details of the computational procedure can be found in ref. 3. A step size of 20 cm^{-1} was used in the integration. All collisions were assumed to be strong.

The solid curves in Fig. 1 are the calculated RRKM curves; no shift along the pressure axis has been made. It can be seen that very good agreement between theory and experiment is found for *trans*-1-fluoropropene and 2-fluoropropene. Agreement for *cis*-1-fluoropropene is not quite as good. However, Scheme 1 omits the possible interconversion of *cis*- and *trans*-1-fluoropropene. On the basis of the Arrhenius parameters for the *cis–trans* isomerization of other olefins (4), and group additivity estimates for the heats of formation of fluorocyclopropane and 1-fluoropropene (5, pp. 40–48), the interconversion of the initially formed chemically activated *cis*- and *trans*-1-fluoropropene would be expected to become increasingly important as the pressure is reduced. The results of calculations on a reaction scheme modified to include the above chemical activation effects are included in Fig. 1; the scheme and data used are included in the Appendix. It can be seen that the experimental curve shapes for both *cis*- and *trans*-1-fluoropropene can now be matched but that the position of fall-off is in slight error. Better agreement could no doubt be obtained by changing either the estimated high pressure rate constants or the Arrhenius parameters for these reactions, all of which have significant uncertainties. Experimental data for 3-fluoropropene is badly scattered but agreement between theory and experiment is reasonable, though a higher value for the activation energy of the reaction would perhaps be indicated (the dashed curve in Fig. 1 is calculated for an activation energy of 63.5 kcal mol^{-1}).

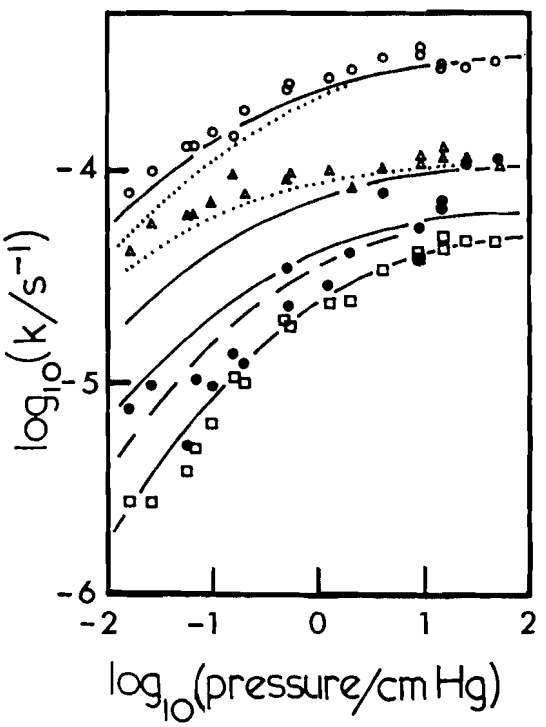

FIG. 1. Experimental rates taken from the work of Casas *et al.* (2) for the formation of *trans*-1-fluoropropene (○), *cis*-1-fluoropropene (△), 2-fluoropropene (□), and 3-fluoropropene (●) from monofluorocyclopropane as a function of pressure at 475.1°C. Solid curves are the calculated RRKM rates based on the experimental data of Casas *et al.* and using the parameters listed in the Appendix of the current paper. The dashed curve is the calculated curve for 3-fluoropropene with an assumed activation energy of 63.5 kcal mol^{-1}. The dotted curves relate to the modified reaction scheme in which interconversion of the initially formed chemically activated *cis*- and *trans*-1-fluoropropene occurs.

It can thus be seen that RRKM theory does fit the data for the isomerization of monofluorocyclopropane and there is no need to invoke alternative theoretical approaches as adopted by BYP, though there may be other valid reasons for so doing. We do, however, support the contention of BYP that the observed fall-off behaviour of the isomerization products from monofluorocyclopropane is consistent with the occurrence of competing reaction pathways having different activation energies; some caution should perhaps be exercised here as doubts as to the reliability of the experimental data have been raised (5, p. 247).

CHEBROLU RAMA MOHAN RAO and PRATAP NARAIN MEHROTRA. Can. J. Chem. **56**, 32 (1978).

The transformation of aragonite to calcite (A–C) is an irreversible reconstructive transformation involving a change from 6 to 9 in the primary coordination. Cationic impurities like Na^+, Mg^{2+}, Zn^{2+}, Y^{3+}, La^{3+}, Nd^{3+}, Gd^{3+}, Dy^{3+} have been doped in pure aragonite and their effect on the kinetics and energetics of its transformation to calcite is studied. By employing a DTA technique, the enthalpy and energy of activation for the transformation have been calculated. The ir spectra of aragonite and calcite in pure form and with various impurities have been studied and the effect of impurities on absorption bands discussed.

CHEBROLU RAMA MOHAN RAO et PRATAP NARAIN MEHROTRA. Can. J. Chem. **56**, 32 (1978).

La transformation de l'aragonite en calcite (A–C) est une transformation reconstructive irréversible impliquant un changement de 6 à 9 dans la coordination primaire. On a dopé de l'aragonite pure avec des impuretés cationiques comme Na^+, Mg^{2+}, Zn^{2+}, Y^{3+}, La^{3+}, Nd^{3+}, Gd^{3+}, Dy^{3+} et on a étudié leur effet sur la cinétique et les profils énergétiques de sa transformation en calcite. Faisant appel à la technique de la DTA, on a pu calculer l'enthalpie et l'énergie d'activation de la transformation. On a étudié les spectres infrarouges de l'aragonite et de la calcite sous forme pure et avec diverses impuretés et on discute de l'effet des impuretés sur les bandes d'absorption.

Introduction

The aragonite to calcite transformation (A–C) is an irreversible reconstructive transformation involving a change from 6 to 9 in the primary coordination; the transformation is therefore expected to be sluggish and associated with high activation energy (1). Although the thermal transformation of A–C has been examined by several workers, there is limited information in the literature on the effect of impurities on the enthalpy, kinetics, and energetics of the transformation. Such a study is of value because most of the reported preparations of aragonite were in the presence of unknown amounts of different impurities and it has been shown (1) that impurities markedly effect a phase transformation of solids. Furthermore, there is a practical significance for such a study as calcium carbonate finds extensive use in chromatography and its efficiency in such work depends not only on the size of the particles but also on the aragonite–calcite ratio. Again, aragonite and calcite are found in nature and their origin is of particular importance in the interpretation of geological phenomena.

In the present investigation the kinetics and energetics of the A–C transformation with known amounts of different impurity cations have been studied. The values of enthalpy of transformation (ΔH) and energy of activation (E_a), for different impurity doped samples of calcium carbonate, have been evaluated from DTA data. The ir spectra have been used to identify the aragonite and calcite forms of calcium carbonate and also to study the effect of impurities on the absorption bands of each of these two forms.

Experimental

All the samples of aragonite were prepared by hydrolysis of the trichloroacetate salts (2). The procedure yields pure samples and avoids unintentional incorporation of impurities. For the preparation of doped samples known amounts of impurity cations (Na^+, Mg^{2+}, Zn^{2+}, Y^{3+}, La^{3+}, Nd^{3+} Sm^{3+}, Gd^{3+}, Dy^{3+}) were taken in the form of carbonates or oxides along with the sample of pure calcium carbonate before reacting with trichloroacetic acid. The impurity cations were chosen on the basis of their ionic size and their effect on the polymorphic compositions of precipitated calcium carbonate (3). All the chemicals used were of analytical grade.

The DTA curves were obtained by employing a 'Fisher Differential Thermalyzer' Model 260, fitted with an automatic voltage stabilizer, recorder, and an amplifier. The curves were recorded with a constant heating rate of 10°C/min under controlled conditions (packing, particle size, etc.). Calcined α-alumina was used as the reference material. The activation energy was calculated following the method of Borchardt and Daniels (4). ΔH values were computed by comparing the area of the transformation peak for the doped sample with the (orthorhombic–hexagonal) transformation peak of pure potassium sulphate (5, 7) and also with the (orthorhombic(II)–rhombohedral(I)) transformation peak of pure potassium nitrate (6, 7).

The ir spectra of the solid samples were obtained by employing a Beckman IR20 spectrophotometer using Nujol mull as a medium.

†ΔH for the transformation peak of pure potassium sulphate is taken as standard.
‡ΔH for the transformation peak of pure potassium nitrate is taken as standard.

Results and Discussion

The ΔH values estimated from the peak areas may have an uncertainty of $\pm 10\%$. The activation energy values obtained by employing the procedure of Borchardt and Daniels may have large uncertainties, but comparison of values in related systems is valid (7).

The temperature at the starting point of the peak (T_i), transformation temperature (T_t), i.e. peak temperature, ΔH, and E_a values for the pure and the various doped samples are listed in Table 1.

It is evident from Table 1 that the incorporation of impurities affects the T_i, T_t, ΔH, and E_a values. The E_a value of 86 kcal/mol for the transformation of pure aragonite to calcite agrees well with a result reported earlier (8). The E_a values for the various doped samples range from 38.2 to 168 kcal/mol in comparison to 60 to 110 kcal/mol for the pure aragonite reported in the literature (8–11). The variation in the value of ΔH is also fairly large ranging from 234 to 1166 cal/mol compared to 837 cal/mol for the pure aragonite when potassium sulphate is taken as standard. A similar variation in the ΔH values was obtained using potassium nitrate as standard. The ΔH values obtained by us are higher than those reported by other workers (8, 12). We have checked these values by taking two standards and obtained almost identical values with both standards. The ΔH for the A–C transformation for a pure sample has also been calculated from heat capacity data (13) which gives the value 500 cal/mol compared to 40–160 cal/mol given by some earlier workers (12). A higher temperature of transformation and a larger particle size are probably responsible for high values of ΔH in our studies.

The increase of sodium ion impurity in aragonite decreases E_a values and increases ΔH values regularly up to 0.5 at.%, but neither E_a nor ΔH values show a regular pattern on further increase in impurity content. The transformation temperature follows the trend of ΔH values. With an increase in Mg^{2+} and Zn^{2+} impurity content from 0.01–1.5 at.%, the E_a values increase regularly, but the ΔH values first decrease up to 0.5 at.% impurity and thereafter they start to increase. The T_i and T_t values follow the trend of the E_a and ΔH values respectively. The same trend is observed in both Mg^{2+} and Zn^{2+} doped

†Values obtained by the authors.

samples. With the increase in Y^{3+} content the ΔH values decrease up to 1% while the E_a values do not show any regular pattern. The T_i values follow the trend of the ΔH values. In the case of lanthanide impurity doped samples, E_a and ΔH values decrease regularly from lanthanum to dysprosium as the ionic radii decrease (for the same at.% impurity, i.e. 0.5%).

A perusal of the data given in Table 1 for the doped samples in general shows that as the E_a values increase the starting point of the peak also shifts to a higher temperature and with an increase in ΔH values the transformation temperatures increase.

The variation of the T_i, T_i, and E_a of the A–C transformation with impurities is understandable (1, 20) but no reasoning can be put forward for the variation in the ΔH values with impurities. It seems likely that in the case of lanthanide ion impurity doped samples the lower ΔH values may be due to the fact that the A–C transformation occurs over wider temperature ranges causing broad and shallow DTA peaks. Accordingly, the ΔH values are low when the T_t values are low. This statement may become true for other doped samples, provided that the valency, electronic configuration, and the percentage of the impurity cation are similar. The wide variation in the T_t and ΔH values for pure aragonite reported in the literature is mainly due to the fact that most of the samples contained unknown amounts of different impurities. Difference in particle size may be another factor responsible for the wide variation in the ΔH values (6). This has also been observed by us by carrying out the DTA analysis of aragonite samples of different particle size. As the particle size decreases the ΔH of the transformation also decreases considerably. This may be attributed to the variation of surface area and surface energy with particle size.

The present findings reveal that if the valency state of the impurity cations is the same but the ionic radii are different (e.g. Mg^{2+} and Zn^{2+}) the trend in the variation of E_a and ΔH values is more or less similar, although there is a contrast in their behaviour when the absolute values of E_a and ΔH are considered. It is also observed that Na^+ and Y^{3+} impurities in aragonite affect the transformation characteristics in a different manner in spite of their similar ionic sizes. The difference in the behaviour may probably be attributed to their different oxidation states and electronic configuration. There may be some effect from the cation and anion vacancies produced by +1 and +3 ions but these effects are difficult to assess from the present investigation. In the case of lanthanide impurity doped samples, the T_t, T_i, ΔH, E_a values increase with the size of the impurity cation (for the same percentage of the impurity).

We have studied the ir spectra of doped samples of

aragonite as well as calcite and the data obtained are given in Table 2 along with the data for the pure sample. From site group analysis it can be shown that calcite and aragonite will give ν_2, ν_3, ν_4 and ν_1, ν_2, ν_3, ν_4 bands respectively and that each of the ν_3 and ν_4 bands in aragonite is split into two (14–16). We have made similar observations in our present study. ν_3 is not reported in Table 2 as it is overlapped by Nujol bands. In the case of doped samples, the replacement of calcium ions by different cationic impurities results in an alteration of the site symmetry. It is evident from Table 2 that with the change in site symmetry the vibrational frequencies of the various ir absorption bands of both aragonite and calcite are changed markedly. The extent of change in vibrational frequencies varies with different impurity cations and with their different atomic percentages. Although site group analysis does not predict splitting of the ν_2 band in aragonite, in the case of trivalent impurity doped samples (Y^{3+}, La^{3+}, Nd^{3+}, Sm^{3+}, Gd^{3+}, Dy^{3+}) the ν_2 absorption band of the aragonite splits into two bands. The splitting is attributed to the coupling between neighbouring ions (17) and change in site symmetry (18, 19) which occurs when the valency state of impurity cation is changed from +2 to +3. In the case of pure aragonite and other univalent or bivalent cation doped samples the splitting of the ν_2 band is not observed because the coupling is small due to smaller cationic radii compared to those for trivalent lanthanide impurity cations. That the splitting of the ν_2 band in aragonite is due to coupling between neighbouring ions and change in site symmetry is further supported by the observation that the splitting increases as the size of trivalent cation impurity is increased, and the splitting occurs only when Ca^{2+} ions are replaced by trivalent lanthanide ions which change the site symmetry.

Limits to barriers to internal rotation in benzal fluoride, chloride, and bromide in solution by the *J* method

TED SCHAEFER, WERNER DANCHURA, AND WALTER NIEMCZURA
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 27, 1977

TED SCHAEFER, WERNER DANCHURA, and WALTER NIEMCZURA. Can. J. Chem. **56**, 36 (1978).

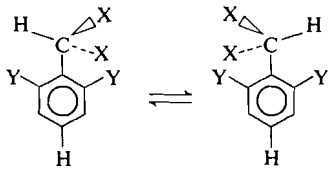
On the basis of the long-range couplings over six bonds between the protons on the side chain and the ring protons in benzal fluoride, chloride, and bromide and some of their derivatives, a hindered rotor model (*J* method) yields limits to the barriers to internal rotation. These are 0.0 to 1.8, 0.7 to 2.4, and 1.7 to 3.8 kcal/mol for the fluoride, chloride, and bromide, respectively. Refinement of the model suggests barriers of 1.1 ± 0.2, 2.2 ± 0.3, and 3.5 ± 0.6 kcal/mol, respectively. The barrier values in the chloride and bromide are considerably less sensitive to the model parameters than is the barrier in the fluoride. It would be of interest to have gas phase values for these barriers. It is also shown that a σ–π mechanism holds for the six-bond proton–proton coupling constant in benzal fluoride but that the analogous coupling between ^{19}F on the side chain and the *para* ring proton carries a non σ–π contribution of +0.3 Hz.

TED SCHAEFER, WERNER DANCHURA et WALTER NIEMCZURA. Can. J. Chem. **56**, 36 (1978).

Sur la base des couplages à longue distance à travers six liaisons entre les protons de la chaîne latérale et les protons du cycle du fluorure, du chlorure et du bromure de benzal et de quelques-uns de leurs dérivés, un modèle rotor empêché (méthode *J*) fournit les limites pour les barrières à la rotation interne. Celles-ci sont respectivement de 0.0 à 1.8, 0.7 à 2.4 et 1.7 à 3.8 kcal/mol pour le fluorure, le chlorure et le bromure. Un affinement de la méthode suggère des barrières respectives de 1.1 ± 0.2, 2.2 ± 0.3 et 3.5 ± 0.6 kcal/mol. Les valeurs des barrières pour le chlorure et pour le bromure sont beaucoup moins sensibles aux paramètres du modèle que la barrière pour le fluorure. Il serait intéressant d'obtenir des valeurs en phase gazeuse pour ces barrières. On a aussi montré qu'un mécanisme σ–π tient pour la constante de couplage proton–proton à travers six liens dans le fluorure de benzal mais que le couplage analogue entre le ^{19}F de la chaîne latérale et le proton en para du cycle comporte une contribution non σ–π de +0.3 Hz.
[Traduit par le journal]

Introduction

In **1**, the barrier to the internal rotation which interconverts **1***a* and **1***b* rises from about 15 kcal/mol



1*a* **1***b*

when X = Y = Cl to 21 kcal/mol when Y = Cl, X = I (1–4). Classical mechanics calculations (3–5) agree with these measurements and strongly indicate a two-fold potential, the high energy form having the C—H bond of the side chain in a plane perpendicular to the benzene plane.

The measurements depend on the well-established broadening of nmr peaks (T_2 effects), caused by dephasing of the magnetization as the nuclear spins hop between sites of different Larmor frequencies. Under even the most favourable experimental conditions, this technique becomes insensitive to rotational barriers below about 5 kcal/mol.

An alternative method (*J* method) for the determination of internal barriers depends on a knowledge of the rotational angle dependence of nuclear spin–spin coupling constants. Coupled with a hindered rotor treatment the method is useful for twofold barriers lying somewhere between about 0.2 and perhaps 3 kcal/mol (6, 7). It has been applied to a variety of benzene derivatives, in particular to phenylethane (8), isopropyl benzene (9), and to phenylcyclopropane (10).

When Y = H in **1**, the line-shape method cannot be applied because the barriers are too small. However, the *J* method may well be useful here and this paper reports on estimates, obtained in this way, of the rotational barriers to internal rotation in benzal fluoride, chloride, and bromide.

Experimental

The preparation of benzal fluoride and of its 3,5-dichloro derivative has been described (11). Benzal chloride and bromide had a commercial origin, while the 3,5-dichlorobenzal chloride was prepared from the toluene by free radical chlorination of the methyl group in a manner described previously (1). 4-Methylbenzal fluoride was prepared from the benzaldehyde derivative in the previous way (11).

Degassed solutions, containing some tetramethylsilane, were carefully calibrated in the frequency sweep mode on an HA100 spectrometer at a probe temperature of 305 K. Manual and sweep oscillator frequencies were read at approximately 5 Hz intervals and the procedure was repeated five times.

Deviations from the average peak position were 0.02 Hz or less, comparing well with the rms deviations between observed and calculated peak positions in the analyses described below.

The 10-spin system represented by the spectrum of 4-methylbenzal fluoride was first simplified by decoupling of the methyl protons. The decoupled spectrum was calibrated and analyzed. The fully coupled ^{1}H nmr spectrum was also calibrated. Partial decoupling experiments showed that $^7J_p^{F,CH_3}$ was of the same sign as $^2J^{H,F}$, i.e., positive (11).

Results and Discussion

Spectral Analyses

The computer program LAME (12, 13) led to calculated spectra in satisfactory agreement with the observed spectra. Table 1 gives the spectral data obtained for benzal bromide. In Fig. 1, the observed and calculated spectra of the side-chain proton are displayed to illustrate the resolution and fit. The calculated spectrum assumes a line width at half height of 0.09 Hz.

The analysis of the ^{1}H nmr spectrum of 4-methylbenzal fluoride, methyl protons decoupled, gave the spectral data in Table 2. Use of the program NUMARIT (14) in the noniterative mode allowed the extraction of the couplings to the methyl protons, also given in Table 2. The standard deviations quoted in the table suggest an accuracy of 0.02 Hz or better in the spectral parameters.

Rather than tabulate all spectral parameters for the other compounds, the data of immediate interest, the long-range couplings, are collected in Table 3. All these couplings are thought to be accurate to 0.02 Hz.

The Angular and Substituent Dependence of $^6J_p^{H,CH}$

In toluene, theoretical and experimental data (15–17) agree that $^6J_p^{H,CH} \propto \sin^2\theta$, where θ is the angle by which the C—H bond of the methyl group twists out of the plane of the ring. In other words, ^6J is transmitted by a σ–π mechanism (18, 19). In toluene, ^6J is -1.24 Hz when $\theta = 90°$ (17, 20) and the average or expectation value of $\sin^2\theta$, indicated by angular brackets, is $\langle\sin^2\theta\rangle = 0.5$ because the barrier to internal rotation is only 0.014 kcal/mol (21).

§In Hz.

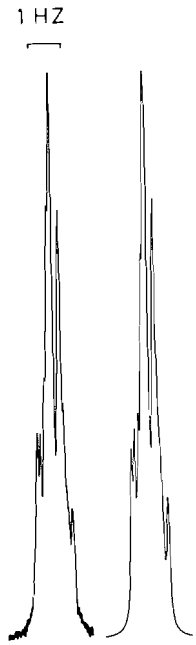

FIG. 1. The observed and calculated proton magnetic resonance spectrum at 100 MHz of the side-chain proton of benzal bromide as a 10 v/v % solution in CS_2. The peak width at half height of the calculated spectrum is set at 0.09 Hz. The peak separation of the small doublet on the left of the observed spectrum is just under 0.1 Hz. The asymmetric structure is a consequence of the relative signs of the couplings to the ring protons.

There exists no evidence that ^6J changes its maximum magnitude when one or two hydrogen atoms are replaced by groups of closely similar electronegativity to that of hydrogen, e.g. CH_3 or SH groups (8, 10, 22). In such molecules, a hindered rotor treatment yields the quantum mechanical expectation value of $\sin^2\theta$ in terms of a twofold hindering potential, the reduced moment of inertia, and the temperature (6, 23). The measured value of $^6J_p^{H,CH}$, divided by -1.24, yields a value of $\langle\sin^2\theta\rangle$, which can be matched to the theoretical values and so yield a barrier.

When X in the CHX_2 fragment is substantially more electronegative than hydrogen, it is conceivable that $^6J(\theta = 90°)$ decreases in magnitude because the X group will polarize the C—H bond, causing smaller σ–π overlap between this σ bond and the adjacent π system of the benzene ring. Theoretical evidence for a reduction in $^6J(\theta = 90°)$ can be adduced. INDO MO FPT calculations of $^6J_p^{H,CH}$ in toluene (18) reproduce the $\sin^2\theta$ dependence and agree exactly with experiment (20). For the CHF_2 group, $^6J(\theta = 90°)$ is calculated as -0.87 Hz (11), the fractional reduction

in magnitude agreeing very closely with the reduction in magnitude calculated for the β proton hyperfine coupling in the $CF_2H\dot{C}H_2$ radical (24), also transmitted via a σ–π mechanism. The latter calculations are consistent with experimental data (24).

That $^6J(\theta = 0°)$ vanishes is suggested by the nmr spectrum of 2,6-dichlorobenzal bromide, in which $^6J_p^{H,CH}$ is not observable, i.e. < 0.03 Hz, and the C_α—H bond prefers the benzene plane to the extent of 18 kcal/mol (3). Furthermore, this coupling is also unobservable for 2,6-dichlorobenzalfluoride (11) in which the barrier to rotation is known to be not larger than 8 kcal/mol (11).

$^6J_p^{H,CH}$ *and the Barrier to Internal Rotation*

Plots of $\langle\sin^2\theta\rangle$ versus the twofold barrier to rotation at 305 K were prepared in the prescribed way (6) for various reduced moments of inertia, not being very sensitive to the latter. The experimental values of −0.26, -0.19_5, and −0.12 Hz, respectively, for CHF_2, $CHCl_2$, and $CHBr_2$ yield various values of $\langle\sin^2\theta\rangle$, depending on the appropriate value of $^6J(\theta = 90°)$. For example, if $^6J(\theta = 90°)$ were −0.52 Hz for CHF_2, then $\langle\sin^2\theta\rangle$ would be 0.5, corresponding to a zero barrier.

In Fig. 2, the values of the $^6J(\theta = 90°)$ are plotted against the barrier to internal rotation for ^6J ranging from −0.54 to −1.14 Hz and employ reduced moments of inertia of −0.4, 1.02, and 1.27×10^{-38} g cm^2 for CHF_2, $CHCl_2$, and $CHBr_2$, respectively.

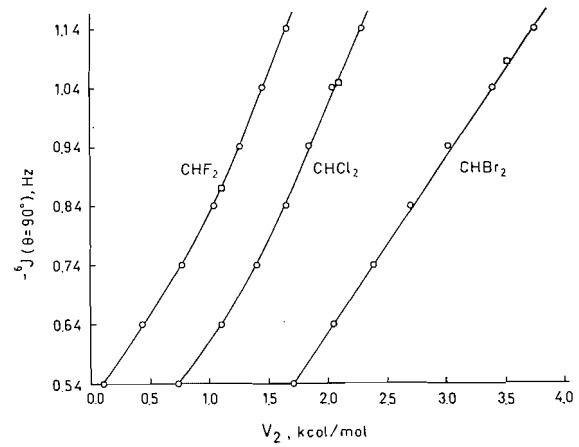

FIG. 2. The value of $^6J_p^{H,CH}$ is plotted versus the twofold barrier to internal rotation as deduced from the hindered rotor model described in the text. The squares indicate preferred values of V_2.

These plots are obtained for a ground state conformation in which the C—H bond of the side-chain lies in the plane of the benzene ring. If conformations corresponding to **2** and **3** were of lowest energy, a finite barrier would imply that $\langle \sin^2\theta \rangle$ were greater than 0.5, corresponding to a $^6J(\theta = 90°)$ of less than

2 **3**

0.52 Hz in magnitude for each compound, a possibility which we consider absurd.

The assignment of barriers is more problematical. It can be said with confidence (Fig. 2) that the barrier limits are 0.0 to 1.8, 0.7 to 2.4, and 1.7 to 3.8 kcal/mol for CHF_2, $CHCl_2$, and $CHBr_2$, respectively. These limits can be somewhat reduced as follows.

In view of the theoretical value of $^6J(\theta = 90°)$ for CHF_2 of -0.87 Hz, obtained from the same parameterization as that which gives agreement with hyperfine couplings in esr spectra, it can be said with lesser confidence that, for CHF_2, the barrier to internal rotation is 1.1 ± 0.2 kcal/mol, the quoted error arising from the uncertainty in the experimental data only; $\langle \sin^2\theta \rangle = 0.30 \pm 0.02$. If $^6J(\theta = 90°)$ depends linearly on the electronegativity of X, then reasonable estimates are -1.05 Hz for X = Cl and -1.09 Hz for Br (from a plot of $^6J(\theta = 90°)$ versus E_X with endpoints given by X = H and F). It follows that the internal barriers are then 2.2 ± 0.3 and $3.5_5 \pm 0.6$ kcal/mol for Cl and Br; $\langle \sin^2\theta \rangle = 0.19 \pm 0.02$ and 0.11 ± 0.02, respectively.

At 305 K, the shape of the $\langle \sin^2\theta \rangle$ versus barrier curve is such that a change of 0.02 in $\langle \sin^2\theta \rangle$ corresponds to a change of about 0.1 kcal/mol in a barrier of 0.2 kcal/mol, whereas at a barrier of 3.5 kcal/mol such a change in $\langle \sin^2\theta \rangle$ corresponds to a change of 0.7 kcal/mol. In other words, above about 3 kcal/mol the J method becomes rather insensitive for molecules of the present kind, i.e. where $\langle \sin^2\theta \rangle$ varies between 0.0 and 0.5.

The barrier to internal rotation about the sp^2–sp^3 carbon–carbon bond in 3,5-dibromoisopropyl benzene, as derived by present methods, is 2.0 ± 0.2 kcal/mol (9). The van der Waals radius of the methyl group is larger than that of chlorine (25) but for such different substituents the barriers need not be directly proportional to these radii. Hyperconjugation effects should also be considered (26). In fact, even the internal rotational barriers in XH_3—CH_2Y (X = C, Si, Ge; Y = H, CH_3) cannot be interpreted solely in terms of steric repulsions (27).

Ab initio molecular orbital calculations at the STO-3G level (26) yield an internal barrier of 0.18 kcal/mol for benzal fluoride, with **1** as the low-energy conformation. Such a barrier implies that $^6J_p^{H,CH}$ $(\theta = 90°)$ is -0.59 Hz in benzal fluoride. Assuming a linear dependence of $^6J(\theta = 90°)$ on substituent electronegativity ($E_F = 4.0$, $E_{Cl} = 3.0$, $E_{Br} = 2.8$, $E_H = 2.1$), $^6J(\theta = 90°)$ then becomes -0.99 Hz for benzal bromide and -0.93 Hz for benzal chloride. It then follows from Fig. 2 that the internal barrier is 1.8 and 3.2 kcal/mol for the chloride and bromide, respectively.

In other words, the internal barriers in benzal chloride and benzal bromide are considerably less sensitive to the model parameters than is the barrier in benzal fluoride.

The Long-range Coupling to ^{19}F in Benzal Fluoride

The long-range couplings to protons on the side chain in toluene and its derivatives are insensitive to intrinsic substituent effects (28, 29), as are those in the compounds listed in Table 2. For example, in benzal bromide and its *para*-COOEt derivative, $^4J_o^{H,CH}$ and $^5J_m^{H,CH}$ are invariant. $^6J_p^{H,CH}$ in the 3,5-dichloro derivatives is apparently about 0.03 Hz larger in magnitude than in the benzal chloride or fluoride parent. The former have higher reduced moments of inertia and, in principle, should possess somewhat larger magnitudes for ^6J_p, although not to the extent indicated by the data in Table 2. Accordingly, the differences may well arise from experimental error, from unrecognized solvent effects, or from slightly different barriers in the 3,5-disubstituted compounds. In any event, such perturbations are apparently of minor importance in comparison to the uncertainty in $^6J(\theta = 90°)$. That $^6J_p^{H,CH}$ is transmitted by a π electron mechanism in a substituted methyl group has been confirmed for benzyl bromide derivatives (7).

Turning to benzal fluoride, the question arises of the intrinsic substituent dependence of the long-range couplings to ^{19}F and of a pure σ–π mechanism. In benzal fluoride, $^4J_o^{H,CF}$ and $^6J_p^{H,CF}$ are -1.16 and -1.14 Hz, respectively (11). In the 3,5-dichloro derivative, $^4J_o^{H,CF}$ becomes -1.02 Hz and $^6J_o^{H,CF}$ changes to -0.95 Hz, suggesting a substantial intrinsic substituent perturbation by *meta* substituents.

The σ–π dependence was investigated via the spectrum of 4-methylbenzal fluoride. In this compound, $^4J_o^{H,CF}$ is -1.17 Hz and $^5J_m^{H,CF}$ is 0.89 Hz, within experimental error of the data for benzal fluoride (the corresponding values of $^4J_o^{H,CH}$ and $^5J_m^{H,CH}$ also agree to within 0.01 Hz), suggesting a negligible perturbation of these couplings by the methyl substituent. Furthermore, $^7J_p^{H,H}$ is 0.23 ± 0.02 Hz in the methyl derivative, again within ex-

perimental error equal to the magnitude of $^6J_p^{H,CH}$ in benzal fluoride, and confirming the σ–π mechanism, i.e. a $\sin^2\theta$ dependence of $^6J_p^{H,CH}$. Therefore the discussion in the previous sections is unaltered.[1]

On the very reasonable assumption that $^7J_p^{F,CH_3}$ is transmitted solely by a σ–π mechanism, one may argue as follows. $^7J_p^{F,CH_3}$ is 1.46 ± 0.02 Hz in 4-methylbenzal fluoride. Comparison with the value of -1.14 Hz for $^6J_p^{H,CF}$ in benzal fluoride implies $+0.3$ Hz as the component of $^6J_p^{H,CF}$ which is not transmitted by a σ–π mechanism. The θ dependence of this component is unknown. It appears that $^6J_p^{H,CF}$ suffers from two disadvantages from the viewpoint of its use in deriving internal rotational barriers. In contrast to $^6J_p^{H,CH}$, it contains an appreciable non σ–π electron contribution and is sensitive to intrinsic (electronic) perturbations from substituents on the benzene ring. Consequently, although $^6J_p^{H,CF}$ is rather larger in magnitude then $^6J_p^{H,CH}$ and its determination demands less experimental skills, it must be concluded that its use in barrier determinations will be problematical.

For example, the value of $^6J_p^{H,CF}$ ($\theta = 90°$) needed to reproduce the above barrier of 1.1 kcal/mol is -2.43 Hz, i.e. $\langle\sin^2\theta\rangle_F = 0.60 = -1.46/^6J_{90}^{H,CF}$ because for a ground state conformation **1**, $\langle\sin^2\theta\rangle_F$ is decreasing from 0.75 for a very large barrier to 0.50 for a zero barrier. On the dubious assumption that the non σ–π component of $^6J_p^{H,CF}$ is independent of θ and is $+0.3$ Hz, it follows that, at $\theta = 60°$, the observed $^6J_p^{H,CF}$ must be -1.60 Hz, i.e., 0.75 $(-2.43 + 0.3)$ Hz. The observed value in 2,6-dichlorobenzal fluoride is -1.25 Hz, so that the intrinsic substituent effect on $^6J_p^{H,CF}$ would be $+ 0.35$ Hz. This is a reasonable value in view of the substituent perturbation caused by chlorine atoms at the 3,5-positions (see above). Nevertheless, this line of argument illustrates how tenuous would be a barrier derived from $^6J_p^{H,CF}$.

Acknowledgment

We are grateful to the National Research Council of Canada for financial assistance.

[1]Note that, for a σ–π mechanism, $^6J_p^{H,CH_3} = -^7J_p^{CH_3,CH_3}$, as observed in toluene and *p*-xylene and their derivatives (15, 17).

Sur la réduction par $NaBH_4$ de quelques nitriles α,β-insaturés

YVON PÉPIN,[1] HASSAN NAZÉMI[2] ET DANIEL PAYETTE

Département de Chimie, Université du Québec à Montréal, C.P. 8888, Montréal (Qué.), Canada H3C 3P8

Reçu le 18 août 1977

YVON PÉPIN, HASSAN NAZÉMI et DANIEL PAYETTE. Can. J. Chem. **56**, 41 (1978).

L'étude de différentes réactions de réductions par $NaBH_4$ de nitriles α,β-insaturés démontre que celles-ci s'effectuent via une addition 1:4 conduisant aux nitriles saturés. Lorsque le temps de réaction est prolongé, des produits d'hydrolyse ou de substitution du nitrile saturé sont observés. Les vitesses de réduction relatives sont dans l'ordre: phényl-2 butèno-2 nitrile **1** > diphényl-2, 3 propèno-2 nitrile **2** > phényl-3 propèno-2 nitrile **3** > butèno-2 nitrile **4**.

YVON PÉPIN, HASSAN NAZÉMI, and DANIEL PAYETTE. Can. J. Chem. **56**, 41 (1978).

A study of several different reductions of α,β-unsaturated nitriles by $NaBH_4$ shows that these proceed by way of a 1:4 addition to form saturated nitriles. At long reaction times, hydrolysis products or those of substitution of the saturated nitrile are observed. The relative rates of reduction follow the order: 2-phenyl-2-butenenitrile **1** > 2,3-diphenyl-2-propenenitrile **2** > 3-phenyl-2-propenenitrile **3** > 2-butenenitrile **4**.

[Journal translation]

Introduction

L'utilisation du borohydrure de sodium pour la réduction de doubles liaisons conjuguées avec des groupes fonctionnels tels que —COR, —CO_2R, —CN et quelques autres a été largement employée depuis les quelques trente dernières années (1–16). L'étude du mécanisme de ces réactions a aussi fait l'objet de nombreux travaux (17–21). Cependant, aucun mécanisme n'a été proposé pour la réduction de nitriles insaturés quoique plusieurs études sur ce sujet aient été publiées (22–25).

Dans ce travail, nous nous sommes d'abord intéressés à vérifier si le mécanisme de réduction de la double liaison pouvait-être similaire à celui proposé par la réduction des groupes carbonyles α,β-insaturés. Par la suite, nos études ont porté sur la nécessité et l'influence de la position d'un groupe aromatique (phényle) sur la vitesse de réduction. Les molécules modèles utilisées sont le phényl-2 butèno-2 nitrile **1**, le diphényl-2,3 propèno-2 nitrile **2**, le phényl-3 propèno-2 nitrile **3** et le butèno-2 nitrile **4**.

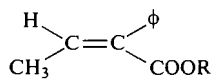
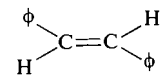
Résultats

Sur la configuration des produits de départ

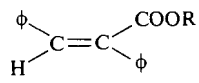
Le butèno-2 nitrile **4**, disponible commercialement (Eastman), est un mélange d'isomères *E* et *Z*. Le phényl-3 propèno-2 nitrile **3**, aussi disponible commercialement (Eastman), possède la configuration *E*. Le spectre de rmn ne montre que deux doublets à τ 4.20 et 2.72 ppm, J = 17.3 Hz, qui ne sont compatible qu'avec une configuration *E* (26). Le phényl-2 butèno-2 nitrile **1** possède une configuration *Z* prépondérante (94%). L'attribution de celles-ci est faite par comparaison des protons vinyliques en spectroscopie de rmn avec ceux des phényl-2 crotonates d'alcoyles **5** (15). Le diphényl-2,3 propèno-2 nitrile **2** possède probablement une configuration *Z*. L'attribution de celles-ci est faite par comparaison du spectre uv avec ceux des stilbènes **6** (26) et des diphényl-2,3 acrylates d'alcoyles **7** (27).



5 (*Z*)



6 (*E*)



7 (*Z*)

Sur les réductions

La réduction par le borohydrure de sodium des nitriles insaturés **1**, **2** et **3** conduit aux nitriles saturés **8**, **12** et **13** correspondant. Cependant, lorsque la réaction de réduction de **1** est laissée à reflux plusieurs jours, des produits secondaires apparaissent: le phényl-2 butamide **9**, l'acide phényl-2 butanoïque **10** et le phényl-2 propanol **11**.

L'apparition du dérivé alcoolique s'est aussi manifestée lors de la réduction prolongée du nitrile **2** pour conduire au diphényl-1,2 éthanol **13**. Le butèno-2 nitrile **4** ne réagit pas dans les conditions présentes de réduction.

La réduction par $NaBD_4$ du dérivé **1** conduit exclusivement au produit monodeutérié en position 3, **8***b*. L'addition de D_2O après une réduction normale avec $NaBH_4$ ne conduit qu'à 25% d'incorporation. Il est nécessaire de faire la réduction directement dans un mélange de tétrahydrofuranne et d'eau deutériée afin d'obtenir au plus 86% d'incorporation conduisant au produit deutérié en position 2, **8***c*.

Les vitesses relatives furent déterminées en réduisant des mélanges équimoléculaires de **1** et **2**, de **1** et **3** et de **2** et **3** par un excès de $NaBH_4$.

ϕ—CR_1CN—CHR_2—CH_3

8*a* $R_1 = R_2 = H$
8*b* $R_1 = H, R_2 = D$
8*c* $R_1 = D, R_2 = H$

ϕ—$CHCONH_2$—CH_2CH_3 **9**

ϕ—$CHOH$—CH_2—CH_3 **11**

ϕ—$CHCOOH$—CH_2—CH_3 **10**

ϕ—$CHOH$—$CH_2\phi$ **13**

ϕ—$CHCN$—$CH_2\phi$ **12**

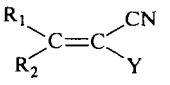
Les analyses des produits de réduction furent principalement faites par la spectrométrie de rmn. Les différents pourcentages relatifs des produits obtenus furent déterminé par intégration du proton méthyne sur les mélanges réactionnels bruts.

Discussion

Sur le mécanisme

La plupart des études rapportées dans la littérature (9, 10, 13–16, 22–25) concernent des systèmes insaturés du type suivant:



$Y = CN, COOR, CONH_2$
$R_1, R_2 = H, Alkyl, Aryl$

Seuls, à notre connaissance, Knabe *et al.* (11) et Husson *et al.* (12) ont réduit un système insaturé similaire au diphényl-2,3 propèno-2 nitrile **2**.

Considérant l'hypothèse de Kadin (24) sur la création de centre électrophyle et notre propre étude, nous sommes amenés à proposer que le mécanisme de la réduction d'une double liaison conjuguée avec un groupe nitrile est similaire à celui proposé pour la réduction de carbonyles α,β-insaturés (18, 20, 21). Dans la première étape de la réaction, il y aurait une addition 1:4 de l'anion borohydrure pour conduire à un complexe intermédiaire qui s'hydrolyserait par l'action de l'isopropanol ou de l'eau (20, 40) pour conduire au nitrile saturé. Ce mécanisme s'appuie sur les réactions de réductions par $NaBD_4$ où le deutérure s'additionne sur la carbone β de la double liaison, tandis que l'hydrolyse du complexe intermédiaire par l'eau deutérié introduit un atome de deutérium en position α.

La réaction de réduction de **1** étant particulièrement rapide, la formation des produits secondaires **9**, **10** et **11** ne peut que provenir du phényl-2 butanenitrile **8**. Le nitrile **8** fut soumis à l'action de NaOH 5% dans l'isopropanol pour conduire aux trois produits **9**–**11**. La même réaction fut observée lorsque du borohydrure de sodium partiellement hydrolysé (28, 41) remplace l'hydroxyde de sodium. L'amide **9** et l'acide **10** sont donc des produits d'hydrolyse basique du nitrile correspondant.

La substitution du groupe nitrile par un hydroxyle aurait pu se rapprocher de celles rapportées lors de la réduction de cyano stéroides (29–31). Ces auteurs invoquent une oxydation par l'oxygène de l'air en se basant sur les travaux de Stevens et Gasser (32), mais aucun mécanisme n'est proposé.

Lors de notre étude nous avons tenté d'augmenter la quantité d'alcool formé (**8**, **13**) par l'addition durant la réaction de réduction de peroxyde d'hydrogène ou en barbottant de l'air sec, mais sans aucun succès. En se basant sur les réactions du phényl-2 butanenitrile **8** en présence de bases, nous formulons l'hypothèse d'une substitution directe du nitrile par un ion hydroxyle. Il faut noter que la présence d'un phényle en α favorise une telle réaction.

Sur les vitesses de réductions

Les vitesses relatives de réduction sont dans l'ordre: **1** > **2** > **3** > **4**. Ceci implique qu'en plus de l'influence électrophilique (24) du groupe nitrile, la présence et la position d'un groupe phényle a aussi un effet très important sur la vitesse de réduction de la double liaison.

Dans le cas du phényl-1 butèno-2 nitrile **1**, la délocalisation des électrons de la double liaison par le phényle s'additionne à l'effet du nitrile pour créer en β un centre électrophile particulièrement important et la vitesse de réduction est très rapide. Dans le cas du phényl-3 propèno-2 nitrile **3**, les deux effets s'opposent et la vitesse de réduction est relativement lente. Le diphényl-2,3 propèno-2 nitrile **2** cumule les effets positif et négatif des nitriles **1** et **3**, et nous observons une vitesse de réaction intermédiaire entre **1** et **3**. Dans ce dernier cas, il y a peut-être aussi un empêchement stérique à l'approche de l'hydrure qui n'est pas négligeable et qui réduirait la vitesse de la réduction (15, 23). L'absence de réduction de butèno-2 nitrile **4** peut-être comparée à celles rapportées pour d'autres composées aliphatiques similaires (25, 33).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Il semble contradictoire, cependant, que le dérivé nitrile **3** ayant un phényle en β qui ralentit la réaction, ait une vitesse de réduction quand même beaucoup plus grande que celle de **4** qui ne subit pas cet effet négatif. Autrement dit, le dérivé **4** devrait pouvoir se comparer à **2**, ce qui est loin d'être le cas. La grande réactivité des dérivés **2** et **3** implique donc que la délocalisation des électrons de la double liaison par conjugaison avec des groupes aromatiques semble être une condition nécessaire pour que le centre électrophile puisse se créer (sous l'influence prépondérante du groupe nitrile) et favoriser ainsi l'addition d'un hydrure.

Partie expérimentale

Les points de fusion sont déterminés sur un "Melting Point Apparatus" du type Fisher-Johns de la compagnie Fisher à l'aide d'un thermomètre calibré. Les indices de réfraction sont mesurés sur un réfractomètre Bausch et Lomb du type Abbe de la compagnie Fisher. Les spectres infrarouge sont pris sur un appareil Perkin-Elmer, modèle 457, à double faisceaux, entre deux plaques de NaCl. Les spectres de résonnance magnétique nucléaire sont pris sur un appareil de Perkin-Elmer, modèle R-12. Les déplacement chimiques sont exprimés en valeur τ. Le CCl_4 est utilisé comme solvant et le TMS comme référence interne (s = singlet, d = doublet, t = triplet, q = quartet). Les spectres ultraviolet sont pris dans l'éthanol 95% sur un appareil Perkin-Elmer, modèle 402. Les spectres de masse sont déterminés sur un appareil Hitachi, modèle RMU-6L, à 70 eV.

Les produits suivants sont disponibles commercialement: phényl-3 propèno-2 nitrile **3** (Eastman), butèno-2 nitrile **4** (Eastman), phényl-3 propionitrile **14** (Eastman), diphényl-1,2 éthanol **13** (Eastman), acide phényl-2 butanoïque **10** (Aldrich), phényl-1 propanol-1 **11** (Aldrich).

*Phényl-2 butèno-2 nitrile **1***

Une solution de 2.3 g (0.1 mol) de sodium dans 50 ml d'éthanol absolu est ajoutée goutte à goutte avec forte agitation, dans une solution de 7.5 g (0.17 mol) d'acétaldéhyde et 20 g (0.17 mol) de phényl acétonitrile dans 100 ml d'éthanol. Après une agitation de 10 min la solution est versée dans l'eau et extraite à l'éther de la manière habituelle. L'évaporation des solvants conduit à une huile qui est fractionnée sous vide partiel. On recueille 5 g de **1**, 30% du rendement théorique; péb 150°C/36 Torr (litt. (34) 100–103°C/1 Torr); $\eta^{20°}$ 1.5558 (litt. (34) 1.5555); rmn τ: 2.6 (s, phényl), 3.4 (q, J = 7.4 Hz), méthyne), 7.88 (d, J = 7.4 Hz, méthyle); ir 2210 cm^{-1} (C≡N); uv λ_{max} (ε) 217 (13 000), 222 (11 800), 266 nm (20 200); spectre de masse *m/e* :143 (ion moléculaire, pic majeur).

*Diphényl-2,3 propèno-2 nitrile **2** (35)*

Une solution de 7 g (0.3 mol) de sodium dans 500 ml d'éthanol absolu est ajoutée lentement avec forte agitation, dans une solution de 106 g (1 mol) de benzaldéhyde fraîchement distillé et de 117 g (1 mol) de phényl acétonitrile dans 650 ml d'éthanol. Le mélange réactionnel se solidifie. Celui-ci est refroidit sur la glace et le précipité est filtré, lavé avec 20 ml d'eau et 50 ml d'éthanol 95%. La recristallisation dans 700 ml d'éthanol 95% conduit à 180 g de **2** (88% de rendement), pf 84°C (litt. (35) 88°C); rmn τ: 2–3 (multiplet); ir 2210 cm^{-1} (C≡N); uv λ_{max} (ε) 229 (12 000) et 313.5 nm (22 700); spectre de masse *m/e* 205 (ion moléculaire, pic majeur).

*Diphényl-2,3 propionitrile **12***

A une solution de 0.7 g (0.03 mol) de sodium dans 200 ml d'éthanol absolu sont ajoutés 3.7 g (0.03 mol) de phényl acétonitrile. Le mélange est porté à reflux pendant 3 h et 4 g (0.03 mol) d'α-chlorotoluène sont ajoutés. Le reflux est poursuivi pendant 18 h. Le NaCl formé est filtré et la majeure partie de l'alcool est évaporée. L'huile résiduelle est reprise à l'éther et lavée à l'eau. L'éther est évaporé et le produit est distillé sous vide. Celui-ci se solidifie à la température de la pièce, pf 58°C (litt. (36) 55°C); rmn τ: 2.8 (s, phényles), 6.13 (t, J = 7.4 Hz, méthyne), 7.03 (d, J = 7.4 Hz, méthylène); ir: 2240 cm^{-1} (C≡N); spectre de masse *m/e*: 207 (ion moléculaire).

*Réduction du phényl-2 butèno-2 nitrile **1***

(i) Temps de réaction de 24 h

Un mélange de 3.0 g (0.021 mol) de **1** et 3.0 g (0.079 mol) de $NaBH_4$ dans 200 ml d'isopropanol anhydre est mis à reflux pour 24 h. Le mélange est hydrolysé avec 100 cc d'eau et extrait à l'éther de la manière habituelle. L'évaporation de celui-ci conduit au phényl-2 butanenitrile **8**, rendement quantitatif, péb 128–129°C/22 Torr (litt. (37) 110–112°C/9 Torr); $\eta^{23°}$: 1.5065 (litt. (37) 1.5075); rmn τ: 2.8 (s, phényle), 6.34 (t, J = 7.4 Hz, méthyne), 8.2 (quintet, J = 7.4 Hz, méthylène), 9.04 (q, J = 7.4 Hz, méthyle); ir: 2240 cm^{-1} (C≡N); spectre de masse *m/e*: 145 (ion moléculaire).

(ii) Temps de réaction de 13 jours

Un mélange de 1 g de **1** et 1 g de $NaBH_4$ dans 70 ml d'isopropanol est mis à reflux pendant 13 jours. Après addition d'eau, la solution est extraite à l'éther. La phase organique est séparée, séchée et évaporée pour conduire à une huile, 0.82 g, composés de trois produits: le phényl-2 butanenitrile **8** (44%), le phényle-2 butanamide **9** (14%) et phényl-1 propanol-1 **11** (24%); rmn (mélange brut) τ: 2.8 (s, phényles), 3.86 (s, amide), 6.05 (s, hydroxyle), 6.34 (t, J = 7.4 Hz, méthyne de **8**), 6.70 (t, J = 7.4 Hz, méthyne de **11**), 6.82 (t, J = 7.4 Hz, méthyne de **9**), ≃8.2 (multiplet, méthylène de **8**, **9** et **11**), 9.04 (t, J = 7.4 Hz, méthyle de **8**, **9** et **11**); ir: 3420 (OH), 3340 et 3180 (NH_2), 2240 (C≡N) et 1665 cm^{-1} (C=O).

L'amide **9** peut-être séparé du mélange par extractions répétées au HCl 0.5 *M*. Celui-ci est isolé en neutralisant la phase aqueuse et en extrayant celle-ci par l'éther, pf 84°C (litt. (37) 81–85°C); rmn τ: 2.8 (s, phényle), 4.05 (s, amide), 6.82 (t, J = 7.4 Hz, méthyne), 8.15 (multiplet, méthylène), 9.2 (t, J = 7.4 Hz); ir: 3350 et 3160 (—NH_2) et 1665 cm^{-1} (C=O); spectre de masse *m/e*: 163 (ion moléculaire).

La phase aqueuse de la première extraction est acidifiée avec du HCl 0.5 *M* et extraite à l'éther. L'évaporation de celui-ci conduit à l'acide phényl-2 butanoïque **10**, 0.18 g (18%), pf 46°C (litt. (38) 47.5°C); rmn τ: 2.75 (s, phényle), 6.5 (t, J = 7.4 Hz, méthyne), 8.2 (multiplet, méthylène), 9.06 (t, J = 7.4 Hz, méthyle); ir: 3500–2700 (OH) et 1690 cm^{-1} (C=O); spectre de masse *m/e* 164 (ion moléculaire).

*Réduction de **1** par $NaBD_4$*

Le mode d'opération est identique à celui de la réduction par $NaBH_4$ pendant 24 h. Rendement quantitatif en **8***b*; rmn τ: 2.62 (s, phényle), 6.34 (d, J = 7.4 Hz, méthyne), 8.2 (q, J = 7.4 Hz, méthylène monodeutérié), 9.04 (d, J = 7.4 Hz, méthyle); spectre de masse *m/e*: 146 (ion moléculaire).

Hydrolyse avec D_2O

(i) Dans l'isopropanol

Un mélange de 300 mg de **1** et 300 mg de $NaBH_4$ dans 20 ml d'isopropanol est mis à reflux pendant 3 h. L'hydrolyse est effectuée avec 2 ml de D_2O et l'agitation est continue pendant ½ h. Le mélange réactionnel est extrait de façon habituelle à

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

l'éther pour conduire à un mélange de **8** (75%) et de **8***b* (25%); rmn τ: 2.62 (s, phényle), 6.34 (t, J = 7.4 Hz, méthyne (75%)), 8.2 (multiplet, méthylène), 9.02 (t, J = 7.4 Hz, méthyle).

(ii) Dans le THF

Un mélange de 500 mg de **1** et de 450 mg de $NaBH_4$ dans 40 ml de THF anhydre et 6 ml de D_2O est mis à reflux pour 3 h. L'extraction habituelle à l'éther conduit à un mélange de **8** (14%) et de **8***b* (86%); rmn τ: 2.62 (s, phényle), 6.34 (t, J = 7.4 Hz, méthyne (14%)), 8.2 (q, J = 7.4 Hz, méthylène), 9.2 (t, J = 7.4 Hz, méthyle); spectre de masse *m/e*: 146 (ion moléculaire).

*Réaction du phényl-2 butanenitrile **8** avec les bases*

(i) Avec NaOH

Un mélange de 300 mg de **8** dans une solution de 150 mg de NaOH et 60 ml d'isopropanol est gardé à reflux pendant 4 jours. L'extraction à l'éther, selon la méthode décrite pour la réduction de **1** pendant 13 jours, conduit aux produits suivants: phényl-2 butanenitrile **8** (8%), phényl-2 butanamide **9** (54%), acide phényl-2 butanoïque **10** (24%) et phényl-1 propanol-1 **11** (14%). Les proportions de **8**, **9** et **11** sont déterminées par intégration du proton méthyne en rmn: la proportion d'acide **10**, par le rapport des poids des produits d'extraction.

(ii) Avec les produits d'hydrolyse de $NaBH_4$

Les produits d'hydrolyse de $NaBH_4$ sont obtenus par le traitement avec de l'eau, pendant 18 h, de $NaBH_4$ à la température de la pièce. L'eau est évaporée et le résidu solide séché sous vide poussé. Celui-ci devrait contenir un peu de NaOH, de $B(OH)_3$ et du $NaBH_4$ résiduel (41).

Un mélange de 300 mg de **8** et de 300 mg des "produits d'hydrolyse de $NaBH_4$" dans 40 ml d'isopropanol est gardé à reflux pendant 7 jours. L'extraction à l'éther selon la méthode précédente conduit aux produits suivants: phényl-2 butanenitrile **8** (14%), phényl-2 butanamide **9** (23%), acide phényl-2 butanoique **10** (25%) et phényl-1 propanol-1 **11** (38%). Les proportions du mélange sont déterminées comme précédemment.

*Réduction du diphényl-2,3 propèno-2 nitrile **2***

(i) Temps de réaction de 3 h

Un mélange de 500 mg (2.4 mmol) de **2** et de 500 mg (13 mmol) de $NaBH_4$ dans 70 ml d'isopropanol est mis à reflux pendant 3 h. L'hydrolyse avec l'eau et l'extraction habituelle à l'éther conduit au diphényl-2,3 propionitrile **12**, rendement quantitatif, pf 60°C (litt. (36) 57°C). Les spectres sont identiques au produit préparé plus haut.

(ii) Temps de réaction de 18 h

La même réaction qu'en (*i*) est gardée pendant 18 h à reflux. L'extraction habituelle à l'éther conduit au diphényl-2,3 propionitrile **12** (77%) et au diphényl-1,2 éthanol **13** (23%). Spectres des produits bruts: rmn τ: 2.8 (s, phényles), 5.35 (t, J = 6.7 Hz, méthyne de **13** (23%)), 6.13 (t, J = 7.4 Hz, méthyne de **12** (77%)), 7.03 (d, J = 7.4 Hz, méthylène de **12**), 7.1 (d, J = 6.7 Hz, méthylène de **13**); ir: 3480 (OH) et 2240 cm^{-1} (C≡N). L'alcool **13** peut-être isoler par cristallisation de l'éther, pf 68°C (litt. (39) 66–67°C); spectre de masse *m/e*: 198 (ion moléculaire).

*Réduction du phényl-3 propèno-2 nitrile **3***

Un mélange de 500 mg de **3** et de 500 mg de $NaBH_4$ dans 70 ml d'isopropanol est gardé à reflux pendant 48 h. L'extraction habituelle à l'éther conduit à 90% de phényl-3 propionitrile **14** et 10% de produit de départ **3**. Spectres du mélange brut: rmn τ: 2.8 (d, J = 17.4 Hz, proton vinylique de **3** (10%)), 2.86 (s, phényles), 4.3 (d, J = 17.4, proton vinylique de **3** 10%)), 7.20–7.85 (multiplet, méthylènes de **14** (90%)); ir: 2240 cm^{-1} (C≡N); spectre de masse *m/e*: 131 (ion moléculaire). Les spectres sont identiques au produit commercial.

*Réduction du butèno-2 nitrile **4***

La réduction de **4** selon la méthode habituelle pendant 48 h ne conduit qu'au produit de départ **4**.

Vitesses relatives de réduction

Méthode générale

Un mélange de 1 mmol de A et 1 mmol de B et de 8 mmol de $NaBH_4$ dans 40 ml d'isopropanol est mis à reflux pour x min. L'hydrolyse avec l'eau et l'extraction habituelle à l'éther conduit à un mélange brut qui est analysé par rmn.

*(i) Vitesse relative de **1** et **2***—Après un temps de réaction de 15 min, l'on obtient: 100% de phényl-1 butanenitrile **8**, 33–35% de diphényl-2,3 propionitrile **12** et 65–67% de diphényl-3,3 propèno-2 nitrile **2**.

*(ii) Vitesse relative de **1** et **3***—Après un temps de réaction de 30 min, l'on obtient: 100% de phényl-1 butane nitrile **8**, 9% de phényl-3 propionitrile **14** et 91% de phényl-3 propèno-2 nitrile **3**.

*(iii) Vitesse relative de **2** et **3***—Après un temps de réaction de 35 min, l'on obtient: 100% de diphényl-2,3 propionitrile **12**, 9–10% de phényl-3 propionitrile **14** et 90–91% de phényl-3 propèno-2 nitrile **3**.

Remerciements

Un des auteurs (Y.P.) remercie vivement le CNRC pour l'octroi d'une subvention de recherche (A-6180). Des remerciements s'adressent aussi à MM. Pierre Hudon et Réal Lafortune qui ont initié le travail de recherche comme étudiants d'été.

Etudes d'hétérocycles pentagonaux polyhétéroatomiques par résonance magnétique nucléaire du ^{13}C. Thiazoles et thiazolo[2,3-*e*]tétrazoles

ROBERT FAURE,[1] JEAN-PIERRE GALY, EMILE-JEAN VINCENT ET JOSÉ ELGUERO

Laboratoires de Chimie Organique Physique et de Chimie Moléculaire, Rue Henri Poincaré, 13397 Marseille Cedex 4, France

Reçu le 12 juillet

ROBERT FAURE, JEAN-PIERRE GALY, EMILE-JEAN VINCENT et JOSÉ ELGUERO. Can. J. Chem. **56**, 46 (1978).

Les spectres de rmn du carbone-13 de 18 thiazoles diversement substitués (R = CH_3, C_6H_5, Cl, Br, NH_2 et N_3) ont été enregistrés. Les déplacements chimiques $\delta^{13}C$ et les constantes de couplage ^nJ(C,H) sont discutés en fonction de la nature du substituant et de la structure électronique du noyau thiazolique. Les composés substitués en position 2 par un groupement azide présentent la tautomérie azido–tétrazole, ce qui a permis de réaliser une étude comparative des effets de substituant dans les cycles thiazolique et thiazolotétrazolique. Ces études ont été étendues à d'autres hétérocycles: benzothiazole, isothiazole et isoxazole.

ROBERT FAURE, JEAN-PIERRE GALY, EMILE-JEAN VINCENT, and JOSÉ ELGUERO. Can. J. Chem. **56**, 46 (1978).

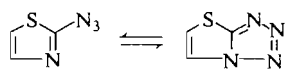
Carbon-13 nmr spectra of 18 thiazoles with different substituents (R = CH_3, C_6H_5, Cl, Br, NH_2 et N_3) have been recorded. The ^{13}C chemical shifts and the ^nJ(C,H) coupling constants are discussed as a function of the nature of the substituent and the electronic structure of the thiazole ring. The 2-azido substituted thiazoles show azido–tetrazole isomerism, making possible a comparative study of substituent effects in thiazole and thiazolotetrazole rings. These studies have been extended to other heterocycles: benzothiazole, isothiazole, and isoxazole.

Introduction

Différents auteurs (1–4) ont récemment étudié l'influence des substituants sur les déplacements chimiques du ^{13}C et sur les constantes de couplage ^nJ(C,H) du noyau isothiazolique. Par contre, dans le cas de la structure isomère, le thiazole, seulement trois travaux relativement succints ont été réalisés, concernant des alkylthiazoles (5), le benzothiazole (6) et enfin certains thiazoles (en particulier l'amino-2 et le bromo-2) marqués au ^{13}C (42). Dans cette dernière étude les auteurs présentent les valeurs de quelques constantes de couplage ^nJ(C,H).

Dans le but de remédier à ce manque de données structurales et dans le cadre d'une étude sur des systèmes hétérocycliques pentagonaux comportant plus d'un hétéroatome (4–12), nous avons entrepris une analyse des effets de substituant en série thiazolique qui constituera la première partie de ce mémoire.

Certains composés thiazoliques de cette étude possèdent un groupement azide en position 2, et par conséquent présentent la tautomérie azido $\rightleftharpoons$ tétrazole (A $\rightleftharpoons$ T).



A T

[1]Auteur à qui la correspondance doit être adressée.

Nous avons déjà longuement étudié ce problème en série pentagonale (13–15), et nous connaissons avec certitude la position de l'équilibre pour chacune des structures qui présentent un tel phénomène. Notre intention, et ce sera la deuxième partie de ce travail, est de comparer les effets de substituant observés pour ces structures tétrazoliques avec les résultats obtenus pour le cycle thiazolique.

Dans une troisième partie nous étendrons la comparaison entre cycle simple et bicycle à d'autres systèmes hétéroatomiques: benzothiazole, isothiazole et isoxazole.

Partie expérimentale

Les spectres de ^{13}C ont été enregistrés sur un spectromètre Varian CFT-20. Les composés ont été étudiés à la température de 28 ± 2°C, en solution dans le diméthylsulfoxyde hexadeuterié. Les déplacements chimiques mesurés sur les spectres découplés par bruit par rapport à la raie centrale du solvant, sont ensuite rapportés au signal du TMS par la relation [1] (16), et sont donnés avec une précision supérieure à 0.1 ppm (largeur spectrale de 4000 Hz correspondant à une accumulation sur 8192 points).

$$[1] \quad \delta_{TMS} = \delta_{DMSO\text{-}d_6} + 39.6 \text{ ppm } (\delta \text{ en ppm})$$

Les constantes de couplage sont mesurées sur les spectres non découplés avec une erreur absolue de 0.5 Hz. Pour bénéficier du gain de sensibilité provenant de l'effet nucléaire Overhauser, le système de spins a été irradié durant l'intervalle de temps compris entre deux impulsions successives selon la technique du "gated decoupling." L'analyse des spectres non découplés en haute résolution a été effectuée au premier ordre,

les spectres du proton ayant été eux-mêmes interprétés au premier ordre (13, 17).

Les différents produits étudiés ont été synthétisés selon des méthodes dont les références sont cités dans les tableaux correspondants (tableaux 1, 3, 5, 8 et 9).

Discussion

Cas du thiazole

Effets de substituant sur les déplacements chimiques du thiazole

Dans le tableau 1 sont rassemblées les valeurs des déplacements chimiques du thiazole et de quelques uns de ses dérivés monosubstitués. Les produits **1**, **2** et **3** on déjà fait l'objet d'une étude en rmn du ^{13}C mais n'ont pas été examinés en solution (5); dans l'intention de ne pas apporter d'autres perturbations que celles créées par les substituants, nous avons enregistré de nouveau les spectres de ces composés. Dans le tableau 2 sont présentées les variations de déplacements chimiques engendrées par les différentes substitutions.

Avant d'aborder la discussion en série thiazolique, il est nécessaire de rappeler quelques résultats importants obtenus pour des hétérocycles voisins, le thiophène (18, 19) et l'isothiazole (1–4).

Dans le cas de la molécule de thiophène, les effets α des substituants sont plus prononcés pour les thiophènes substitués en position 2; la seule exception concerne l'atome de brome pour lequel on observe un comportement inverse, l'effet α étant plus important pour le bromo-3 thiophène. En série isothiazolique, et bien que les résultats soient plus fragmentaires, la perturbation directe qui dépend encore de la position du substituant est plus importante en α du soufre (position 5).

D'autre part, en ce qui concerne les thiophènes substitués en 2, et bien qu'on observe quelques différences dans la comparaison des effets de substituant, les positions 3, 4 et 5 peuvent être comparées respectivement aux positions *ortho*, *méta* et *para* des dérivés benzéniques correspondants (20).

TABLEAU 2. Effets de substitution sur les déplacements chimiques des carbones du thiazole

Substituants	Δδ* C-2	C-4	C-5
Méthyl-2	11.6	−1.0	−0.3
Méthyl-4	−0.7	9.8	−5.9
Méthyl-5	−1.8	−2.1	13.7
Bromo-2	−16.8	0.7	5.6
Bromo-5	2.7	1.3	−10.5
Chloro-2	−3.0	−1.9	3.2
Chloro-4	1.3	−4.5	−4.8
Amino-2	16.7	−4.3	−11.9
Azido-2	8.2	−2.9	−2.0
Phényl-4	0.6	12.0	−5.6

*En ppm; les valeurs positives indiquent un déplacement vers les hautes fréquences.

Revenons maintenant à l'étude en série thiazolique. Le groupement méthyle en position 4 provoque sur le carbone en α un déblindage d'environ 10 ppm; cette perturbation est beaucoup plus importante (13.7 ppm) lorsque le substituant alkyle est en position 5, en α de l'atome de soufre. Toutefois pour le méthyl-2 thiazole la perturbation se produit aussi en α du soufre, et cet effet n'est que de 11.6 ppm. Les résultats de la littérature sont comparables, à savoir que, dans le cas du thiophène ou de l'isothiazole, l'effet α d'un groupement méthyle est plus important ($\geq$ 14 ppm) lorsque la perturbation a lieu sur le carbone adjacent à l'atome de soufre.

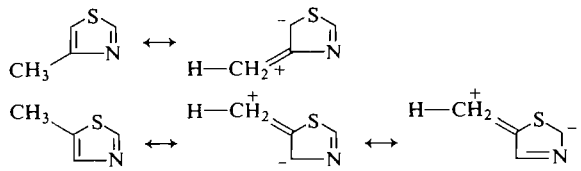
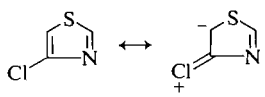
Les carbones en β et γ de la substitution sont relativement sensibles aux effets des méthyles. La perturbation la plus notable est observée pour le carbone-5 du méthyl-4 thiazole (−5.9 ppm), en accord avec les résultats du méthyl-3 thiophène (18, 19) ou du méthyl-4 isothiazole (1–4). Ces effets à longue distance sont plus faibles pour les méthyl-2 et -5 thiazoles, et, dans le cas de **4**, la perturbation est identique en position 4 (β) et en position 2 (γ). Ce comportement est compatible avec la "prédominance" des structures dipolaires suivantes:



Nous pouvons noter que de telles structures ont déjà été proposées pour expliquer certains effets de substituant en série thiophénique (18, 19) et isothiazolique (1).

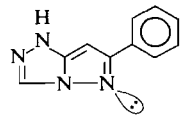
Dans le bromo-2 thiazole l'effet de l'halogène sur le déplacement du carbone substitué est plus important (−16.8 ppm) que celui pour le dérivé bromé en 5 (−10.5 ppm). Pour les dérivés chlorés cette perturbation directe est beaucoup plus faible et, si les effets sont pratiquement similaires en position 2 et 4, ils diffèrent nettement des résultats de la littérature concernant le thiophène (4.1 ppm en 2, −1.6 ppm en 3). Comme précédemment, les effets à longue distance des halogènes peuvent être expliqués par l'importance de certaines des structures mesomères; par exemple le blindage en C_5 du chloro-4 thiazole:



La substitution par un groupement amino perturbe fortement le cycle thiazolique. Si l'effet α de 16.7 ppm est identique à la valeur observée pour le benzothiazole (21), l'effet γ de −11.9 ppm en C_5 est tout à fait comparable à l'effet *para* du groupement amino dans l'aniline (−9.5 ppm) (22). En position 4 l'effet γ est également un effet de blindage, mais sa valeur est moins importante (−4.3 ppm).

En ce qui concerne le groupement azido, l'influence de ce substituant sur les déplacements chimiques du ^{13}C a été très peu étudiée. Les résultats enregistrés pour le cycle thiazolique (tableau 2) sont proches des valeurs observées pour les molécules de phénylazide (23) ou d'azido-3 indazole (24).

Dans le phényl-4 thiazole, le groupement phényle fait un angle de 45° avec le plan contenant le cycle thiazolique (25); cette perte de coplaneité entre les deux cycles peut être mise en évidence par le faible écart enregistré entre les déplacements chimiques des carbones *méta* et *ortho* du noyau benzénique, $\Delta = \delta C_{méta} - \delta C_{ortho}$ (26). La perturbation directe du groupement phényle est très différente de ce que l'on observe en série isothiazolique: 16.5 ppm en 4 et 19.5 ppm en 5 (3). Cette différence dans les effets pourrait traduire l'existence d'une importante interaction entre le groupement phényle et le doublet libre de l'azote. Cette hypothèse est confirmée par les résultats obtenus dans la série du pyrazolo[3,2-*c*]-*s*-triazole (12) pour lequel on observe une perturbation tout à fait comparable en position 5 (l'effet du phényle étant identique à l'effet d'un groupement méthyle).



Dans le cas du cycle isothiazolique, ce type de perturbation n'intervient pas pour le phényl-4 isothiazole tandis que, pour la position 5, les interactions du phényle avec les doublets libres du soufre doivent être plus faibles.

Ces résultats permettent de remarquer que les effets de substituant en série thiazolique dépendent de la position de la substitution et que les perturbations en position 2 et 4 sont comparables entre elles.

Additivité des effets de substituant

A partir des effets de substituant du tableau 2, il est possible d'évaluer d'une manière théorique les déplacements chimiques de certains thiazoles disubstitués, par la simple additivité de ces incréments. Dans le tableau 3, nous avons rassemblé les valeurs expérimentales et théoriques (calculées selon le schéma précédent) des déplacements du ^{13}C pour quelques dérivés disubstitués du thiazole. Nous avons récemment montré (27) que les écarts entre théorie et expérience représentaient une perturbation du second ordre qui décrit la disposition relative des différents substituants dans la molécule.

Des résultats du tableau 3 on peut remarquer que les déplacements des dérivés disubstitués en position 2 et 4 étaient dans l'ensemble bien reproduits; par contre, dans le cas des composés 2,5-disubstitués, on observe d'importants écarts entre la théorie et l'expérience. Ces différences pouvant s'expliquer par l'existence d'interactions supplémentaires, certainement de type stérique, qui n'apparaissent pas dans les dérivés monosubstitués.

On peut également noter que, pour l'ensemble des substrats, le déplacement théorique du carbone non substitué est dans l'ensemble en très bon accord avec

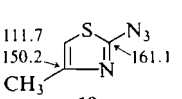
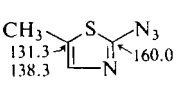
la valeur expérimentale, et ce, quelle que soit la position de la substitution.

De plus à partir des effets de substituant du tableau 2, nous pouvons calculer les valeurs des déplacements chimiques des thiazoles **19** et **20**. En effet ces composés présentent un phénomène de tautomérie azido ⇌ tétrazole fortement déplacé vers le tautomère tétrazole, la proportion des formes azides étant inférieure à 3% (15).



19



20

En tenant compte des remarques précédentes concernant l'additivité des effets de substituant, on peut s'attendre à ce que les valeurs théoriques des déplacements de **19** et **20** soient surestimées, et que dans le cas de **20** le désaccord entre théorie et expérience soit plus important.

Effets de substituant sur les constantes de couplage du cycle thiazolique

^1J(C,H)—Dans le thiazole la valeur de $^1J(C_5,H)$ est plus élevée que celle de $^1J(C_3,H)$; comme pour l'isothiazole (2,4), le couplage direct est donc plus important pour le carbone en α du soufre que pour celui adjacent à l'atome d'azote.

Ces couplages dépendent de la nature des différentes substitutions comme le montre le tableau 4. En ce qui concerne les dérivés disubstitués, ces effets de substituant présentent un certain caractère d'additivité: par exemple, pour le bromo-5 amino-2 thiazole, la valeur calculée pour $^1J(C_4,H)$ est de 189.3 Hz, soit un écart de 0.7 Hz par rapport à la valeur expérimentale.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

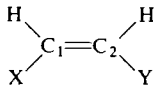
Les variations de ^1J(C,H) en fonction de la nature du substituant sont comparables à celles que l'on observe en série hétérocyclique (2, 4, 19) ou en série benzénique (28–30).

^2J(C,H)—Considérons le système éthylénique suivant:

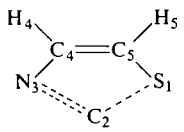


Il est bien connu que les valeurs $^2J(C_2,H_1)$ et $^2J(C_1,H_2)$ dépendent de l'électronégativité des substituants X et Y (31). Si X est plus électronégatif que Y nous aurons alors la relation suivante:

$$^2J(C_2,H_1) > {}^2J(C_1,H_2)$$

Si nous appliquons ce genre d'argument au cas de la liaison C_4—C_5 de la molécule de thiazole, et puisque l'atome d'azote sp^2 N_3 est plus électronégatif que le soufre, l'inégalité suivante devrait être vérifiée:

$$^2J(C_5,H_4) > {}^2J(C_4,H_5)$$



Effectivement on observe (cf. tableau 4) que $^2J(C_5,H_4)$ est le double de $^2J(C_4,H_5)$.

De plus ces couplages géminés ^2J(C,H) sont fonction non seulement des différents substituants en 4 ou 5 (les valeurs diminuent lorsque l'électronégativité du substituant augmente, comme dans le chloro ou nitrobenzène (28, 30, 32)), mais encore de la substitution en 2.

Il convient encore de noter que les valeurs des couplages ^2J(C,H) entre les protons du méthyle et le carbone substitué (~7.0 Hz) sont "habituelles" en série hétérocyclique (4, 5).

^3J(C,H)—A l'inverse des hétérocycles hexagonaux, où ^3J(C,H) est généralement plus grand que ^2J(C,H), dans le thiazole, comme dans l'isothiazole (2, 4), la relation entre ces deux types de couplage est plus complexe et dépend du carbone considéré.

Dans aucun des thiazoles étudiés dans ce mémoire nous n'avons observé de couplages $^3J(C_5,H_2)$. De plus l'inégalité suivante est toujours vérifiée, quel que soit le substrat:

$$^3J(C_2,H_5) < {}^3J(C_4,H_2) \sim {}^3J(C_2,H_4)$$

De ces observations on peut déduire que ces couplages ^3J(C,H) doivent être interprétés en termes de localisation électronique et de conjugaison plutôt qu'en termes d'électronégativité (il est nécessaire de rappeler que la molécule de thiazole est considérée comme peu aromatique et que le doublet libre de l'atome de soufre est peu délocalisé (17)).

Dans les dérivés substitués par un groupement méthyle on observe les couplages suivants:

$$^3J(CH_3,H) \sim 2 \text{ Hz}$$
$$^3J(C,CH_3) \sim 5 \text{ Hz}$$

Pour expliquer la valeur de ces couplages, on peut invoquer la localisation de la liaison C_4—C_5, mais également d'autres facteurs structuraux, tels l'orientation du groupement méthyle ou l'électronégativité des substituants (33, 43).

Vögeli et von Philipsborn (43) ont proposé une relation empirique entre les constantes de couplage vicinales ^3J(C,H) et ^3J(H,H).

$$[2] \qquad {}^3J(CH_3,H) \simeq 0.6\,{}^3J(H,H)$$

En série thiazolique ^3J(H,H) vaut environ 3.5–3.6 Hz (13, 15, 17), tandis qu'en série thiazolotétrazolique ce couplage est légérement plus important: 4.3 Hz (13, 15). En appliquant l'éq. 2, on obtient des couplages vicinaux entre le carbone du méthyle et l'hydrogène qui sont de 2.1 Hz (monocycle) et de 2.5 Hz (bicycle). Expérimentalement (tableaux 4 et 7), on observe des couplages $^3J(CH_3,H)$ plus petits en série thiazolique qu'en série thiazolotétrazolique, c'est à dire un ordre identique à celui que donne [2]; cependant la différence entre les valeurs dans les deux types de structures est de l'ordre de l'erreur expérimentale, ce qui empêche tout autre conclusion.

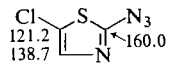
Par ailleurs, signalons qu'il ne nous a pas été possible d'obtenir les couplages ^nJ(C,H) relatifs au composé **10**, en raison, d'une part de la faible solubilité de ce substrat, et d'autre part du déplacement de l'équilibre azido–tétrazole vers la forme tétrazole (K_e = [A]/[T] = 0.2).

Enfin, notons que les valeurs pour le bromo-2 et l'amino-2 thiazole sont en trés bon accord avec les résultats de la réf. 42.

Série du thiazolo[2,3-e]tétrazole

Les déplacements chimiques du ^{13}C déterminés dans cette série sont rassemblés dans le tableau 5. Nous indiquons dans le tableau 6 les valeurs des perturbations apportées par les différentes substitutions. Le choix des substituants a été conduit de manière à pouvoir réaliser une comparaison de ces effets de substituants avec ceux obtenus en série thiazolique, excepté le composé **26**, puisque le chloro-5 thiazole n'a pas fait l'objet d'une étude de ^{13}C.

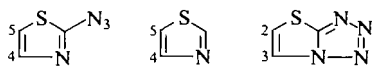
Par ailleurs cette structure tétrazolique **26** est en équilibre avec la forme azide **27** dont les paramètres magnétiques sont les suivants:



27

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Un calcul CNDO/S[2] (34) des indices de liaison π conduit aux résultats suivants:



$l_{45} = 0.9055$ $l_{45} = 0.9029$ $l_{23} = 0.9412$

Comme on pouvait d'ailleurs s'y attendre, le calcul indique que la liaison C_{23} du thiazolo[2,3-*e*]tétrazole est plus localisée que la liaison C_{45} du cycle thiazolique. Cependant, la comparaison des effets de substituants (tableau 2 et tableau 6) indique que les perturbations sont tout à fait comparables entre elles.

En réalité, le caractère dienique du thiazole est assez prononcé (17), et notre calcul CNDO/S doit un peu exagérer la différence entre les indices de liaison π, ce qui expliquerait la similitude des effets de substituant.

Dans le tableau 7 sont réunis les constantes de couplage ^nJ(C,H) relatives à quelques unes de ces formes tétrazoliques. Du fait de leur faible solubilité, même dans un solvant polaire comme le diméthylsulfoxyde, nous avons dû nous limiter à l'étude du thiazolo[2,3-*e*]tétrazole et de ses deux dérivés méthylés. De plus, certains couplages n'ont pu être observés, en particulier ceux relatifs au carbone C_{6a} qui se relaxe très lentement.

Les deux résultats les plus frappants que l'on peut tirer de l'analyse de ces couplages sont les suivants. (*i*) D'une part, et contrairement à ce que l'on observe en série thiazolique, le couplage direct du carbone en α du soufre est moins important que celui du carbone adjacent à l'atome d'azote. (*ii*) D'autre part les constantes ^2J(C,H), très différentes dans le thiazole, ont pour cette structure tétrazolique des valeurs très proches: $^2J(C_2,H_3) = 10.6$ Hz tandis que $^2J(C_3,H_2) = 8.3$ Hz.

Une explication simple de ce comportement peut être la suivante: dans les deux structures l'hybridation de l'azote est différente ce qui entraine une variation de l'électronégativité de cet atome, et, par voie de conséquence, une modification des constantes de couplage (35).

Autres systèmes hétérocycliques

Série du benzothiazole

Nous ne discuterons pas dans ce mémoire du problème de l'attribution des déplacements chimiques du benzothiazole **28** et de l'azido-2 benzothiazole **29**, puisque cette étude fait l'objet d'un travail séparé (6, 21). L'analyse du spectre de ^{13}C du tétrazolo[5,1-*b*]benzothiazole **30**, forme tautomère de

[2]Les géométries utilisées dans ce calcul ont déjà été décrites dans un précédent travail (14).

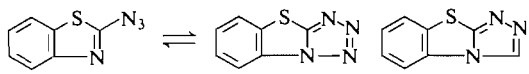
Méthyl-3	−6.4	8.9_5	-0.7_5
Phényl-3	−5.3	8.2	0.1_5
Bromo-2	−12.5	1.6_5	-1.4_5
Chloro-2	3.9	-0.0_5	-3.4_5

*En ppm; les valeurs positives indiquent un déplacement vers les hautes fréquences.

29, a été réalisée par comparaison avec les résultats du triazolo[3,4-*b*]benzothiazole **31** (36).

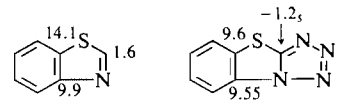
Nos résultats de rmn protonique (15) indiquent une très forte proportion de forme tétrazole pour l'équilibre **29** ⇌ **30** (K_e = [A]/[T] = 0.08 dans le dimethylsulfoxyde). Par conséquent, pour pouvoir observer les signaux de la forme azide il est nécessaire de déplacer la position de l'équilibre vers ce dernier tautomère, sans pour cela modifier notablement les valeurs des déplacements chimiques. Ces conditions sont réalisées par une élévation de température (14) et les paramètres magnétiques du tableau 8 ont été déterminés à la température de 80°C.



29 **30** **31**

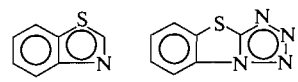
Les perturbations apportées par le groupement azido sur les valeurs des déplacements chimiques du benzothiazole sont les suivantes: δC_2 = 8.0 ppm; δC_{3a} = −3.0 ppm et δC_{7a} = −2.4 ppm. On peut noter que les effets à longue distance (en position γ) sont tout à fait comparables aux résultats obtenus en série thiazolique, tandis que la perturbation directe (effet α) est identique dans cette série benzohétérocyclique.

Par ailleurs, il est possible de réaliser une comparaison des effets engendrés par l'annélation, en série mono et bicyclique; les résultats sont les suivants:



28 **30**

Contrairement aux valeurs obtenues pour une simple substitution (voir précédemment), ce type d'effet dépend du noyau considéré. Cette variation des effets, ainsi qu'une réactivité chimique différente (36) peut s'expliquer par une délocalisation plus importante du système π du noyau benzénique dans les systèmes du type **30** (36), ce qui autorise l'écriture limite suivante pour ces structures:



28 **30**

Série de l'isothiazole et de l'isoxazole

L'étude des effets de substituants sur les déplacements du ^{13}C et sur les constantes de couplage ^nJ(C,H) a déjà fait l'objet de plusieurs travaux en série isothiazolique et isoxazolique (1–4); aussi, dans ce chapitre, nous contenterons-nous de déterminer les perturbations apportées par les groupements amino et azido sur ces systèmes aromatiques. L'ensemble des résultats est rassemblé dans les tableaux 9 et 10.

Il convient tout d'abord de noter que, en ce qui concerne l'azido-3 méthyl-5 isoxazole **37**, l'équilibre est totalement déplacé vers la forme azide (15), alors que le méthyl-3 azido-5 isothiazole **34** ne peut présenter une phénomène de tautomérie.

Le fait le plus marquant que l'on peut relever est l'importance des effets de substitution en position 5 en série isothiazolique. En série isoxazolique, la perturbation a lieu en α de l'azote et les valeurs de ces effets sont très proches des résultats observées en série thiazolique (position 2).

Ce résultat est en bon accord avec les conclusions des chapitres précédents, à savoir qu'en α du soufre

Nuphar thiaspirane sulfoxides. ^{13}C nuclear magnetic resonance determined configuration and utilization in the interconversion of thiaspirane stereochemical types

R. T. LaLonde and C. F. Wong

Department of Chemistry, State University of New York, College of Environmental Science and Forestry, Syracuse, NY 13210, U.S.A.

Received July 15, 1977

R. T. LaLonde and C. F. Wong. Can. J. Chem. **56**, 56 (1978).

The configuration of the sulfoxide oxygen in *syn*- and *anti*-thiobinupharidine sulfoxide was determined by employing the ^{13}C nmr sulfoxidation increments of C-6. Establishment of the ^{13}C nmr line assignments for C-6 included the study of the C-6 and C-6′ deuterated thiobinupharidine and the corresponding sulfoxides. Thermolysis of *syn*-thiobinupharidine sulfoxide in DMSO and subsequent reduction with sodium borodeuteride in methanol yielded thiobinupharidine, labelled with deuterium only at C-6, and thionuphlutine B, labelled with deuterium at both C-6 and C-6′. Treatment of the *anti* sulfoxide in xylene or DMSO resulted in no thiobinupharidine or thionuphlutine B. Similarly, *syn*-neothiobinupharidine sulfoxide gave neothiobinupharidine and a new thiaspirane, thionuphlutine C. These two compounds were not produced from *anti*-neothiobinupharidine sulfoxide heated in xylene.

R. T. LaLonde et C. F. Wong. Can. J. Chem. **56**, 56 (1978).

On a déterminé la configuration de l'oxygène du sulfoxyde dans les sulfoxydes *syn*- et *anti*- de la thiobinupharidine en faisant appel aux incréments de sulfoxydation en C-6 en rmn du ^{13}C. L'attribution des raies en rmn du ^{13}C pour la position C-6 implique l'étude de thiobinupharidines deutérées en C-6 et C-6′ et des sulfoxydes correspondants. La thermolyse du sulfoxyde de la thiobinupharidine *syn* dans le DMSO et la réduction subséquente par le borodeutérure de sodium dans le méthanol fournissent respectivement de la thiobinupharidine marquée par du deutérium uniquement en position C-6 et de la thionuphlutine B marquée avec du deutérium en positions C-6 et C-6′. La réaction du sulfoxyde *anti* dans le xylène ou le DMSO ne conduit à aucune thiobinupharidine ou thionuphlutine B. De la même manière, le sulfoxyde de la néothiobinupharidine *syn* conduit à la néothiobinupharidine et à un nouveau thiaspirane, la thionuphlutine C. Ces deux composés ne se produisent pas lorsque l'on chauffe le sulfoxyde de la néothiobinupharidine *anti* dans le xylène.

[Traduit par le journal]

Three of the four possible stereochemical types of thiaspirane alkaloids isomeric at C-7 and C-7′ have been extracted from *Nuphar*, a genus of fresh-water macrophytes. These are thiobinupharidine (**1**), neothiobinupharidine (**2**), and thionuphlutine B (**3**). The fourth, which we designate thionuphlutine C (**4**), has not been uncovered in nature. The purpose of the work described herein was to demonstrate that **1** could be converted to **3** and **2** to **4** and gain some information regarding the nature of the transformations. These conversions have been achieved by the thermolysis of a mixture of *syn*- (**5**) and *anti*-neothiobinupharidine sulfoxide (**6**)[1] (1) and by the thermolysis of a mixture of *syn*- (**7**) and *anti*-thiobinupharidine sulfoxide (**8**), which has been obtained from the oxidation of thiobinupharidine with hydrogen peroxide in acetic acid.

A knowledge of the sulfoxide configuration was required to establish the dependency of the transformation on configuration. This gave us the opportunity to extend to the thiobinupharidine sulfoxides the ^{13}C nmr method which we had previously employed (1) to ascertain the configuration of sulfoxides **5** and **6**.

The Configuration of syn- *(7) and* anti-*Thiobinupharidine Sulfoxide (8)*

Carbon-6 was used as an indicator carbon for determining the magnitude of the γ-sulfoxidation effect and for probing the configuration of the sulfoxide oxygen in the previously reported case of the neothiobinupharidine sulfoxides (1). The sulfoxidation increment ($\Delta_{C\text{-}6'} = \delta_{C\text{-}6}{}^{S\text{-}O} - \delta_{C\text{-}6}{}^{S}$), the change in chemical shift of C-6 upon sulfoxidation, was a greater negative value when the oxygen atom and the indicator carbon were *syn* than when they were *anti*.

The use of the ^{13}C nmr sulfoxidation increment requires the unequivocal assignment of chemical shifts (δ) for the indicator carbon in thiobinupharidine and its two sulfoxides. The $\delta_{C\text{-}6}{}^{S}$ of thiobinupharidine had been determined previously by model and deuterium labelled compound comparisons (2).

[1]The designations *syn* and *anti* refer to the configuration of the sulfoxide oxygen in relation to the nitrogen atom of the AB quinolizidine ring: X = O, *syn*; Y = O, *anti*.

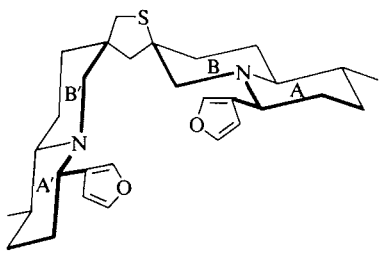
7, X = O; Y = Electron pair
8, X = Electron pair; Y = O



3
Thionuphlutine B

Similarly, the $\delta_{C\text{-}6}{}^{S-O}$ have been determined with the help of the sulfoxides labelled at C-6 and C-6′. Thus the partially ^1H decoupled triplets centered at 63.9 and 59.1 ppm in the spectrum of the unlabelled *anti*-thiobinupharidine sulfoxide (**8**) appeared as slightly shifted triplets in the totally ^1H decoupled spectrum of sulfoxide **8**-6,6′-d_2. The 63.9 ppm signal also appeared as a slightly shifted triplet in the totally ^1H decoupled spectrum of a mixture of *syn*-thiobinupharidine-6′-d_1 sulfoxide (**7**-6′-d_1) and **8**-6′-d_1 while the 59.1 ppm signal appeared as a fully collapsed singlet. Therefore the 59.1 ppm signal was assigned to C-6 and the 63.9 ppm signal was assigned to C-6′.

As for the *syn* sulfoxide (**7**), the partially ^1H decoupled triplets occurring at 64.4 and 56.5 ppm in the spectrum of the unlabelled sample appeared as slightly shifted triplets in the totally ^1H decoupled spectrum of the sulfoxide **7**-6,6′-d_2. The 64.4 ppm signal appeared slightly shifted, overlapping the 63.9 ppm triplet in the totally ^1H decoupled spectrum of the mixture of sulfoxides **7**-6′-d_1 and **8**-6′-d_1. Therefore the 64.4 ppm signal was assigned to C-6′ and the 56.5 ppm signal was assigned to C-6. The ^{13}C shift resulting from the ^2H effect was in all cases -0.5 ppm.

Once the C-6 indicator assignments had been secured, the sulfoxidation increments were determined. The pertinent chemical shift data and sulfoxidation increments for C-6 are summarized in Table 1. Also included in this table are values for C-8, another potential indicator carbon. The values for C-6′ and C-8′ have been added to complete the data for carbons attached to the thiolane ring. However the chemical shift assignments for C-8 and C-8′ rest on an analogy with sulfoxides **5** and **6** (1). The thiobinupharidine sulfoxide having the larger negative $\Delta_{C\text{-}6}$ value was assigned the *syn* configuration. The incremental difference, 2.6 ppm, agrees with the 3–4 ppm difference observed in the study of the neothiobinupharidine sulfoxides and the 2,2,4,4- and 2,2,5,5-tetramethylthiolanes (1).

The Interconversion of Thiaspirane Stereochemical Types

A mixture of *syn*- and *anti*-thiobinupharidine sulfoxides, estimated to consist of 56% *syn* (**7**) and 44% *anti* (**8**) by ^{13}C nmr, was warmed at 135–140°C in DMSO. Thin-layer chromatography indicated the presence of mostly highly polar compounds but a small amount of the less polar bisamines thiobinupharidine (**1**) and thionuphlutine B (**3**) was detected. Reduction of the reaction mixture with sodium borodeuteride in methanol and separation of polar and non-polar components by chromatography yielded a mixture of unconsumed **7** and **8** and **1**-*d* and **3**-*d*. The mixture of unconsumed sulfoxides was estimated by ^{13}C nmr to consist of 43% of the *syn* epimer and 57% of the *anti* epimer. The deuterium labelled bisamines were isolated and identified through tlc, ms, and ^1H nmr comparisons with authentic samples. The region of the ^1H nmr, where C-6-eq, C-6′-eq, or C-4 and C-4′ protons occur, integrated for less than four protons in the case of

anti-Thiobinupharidine sulfoxide, **8**	59.1	−6.9	63.9	+0.5	28.6	−11.0	42.1, 38.7	+1.2 to +4.6

*C-8 was identified as the only new resonance appearing within the 27.0–33.0 ppm region when the sulfoxide spectra are compared with that of thiobinupharidine.
†When more than one value is given, one or the other value is the most likely assignment for C-8′ based on comparison with the neothiobinupharidine sulfoxides.

the **1**-*d* and showed slightly less than four protons and a modified splitting pattern in the case of the **3**-*d*.[2]

Mass spectral analysis of the **1**-*d* showed that the latter contained 39.3% d_0 and 59.1% d_1, but virtually all the deuterium was located at C-6. In contrast, the same type of analysis of **3**-*d* demonstrated the presence of 32.0% d_0 and 65.6% d_1 species but the deuterium was distributed between C-6 and C-6′. The ms analysis for location of deuterium was based on earlier work which demonstrated that *m/e* 178 is shifted to *m/e* 179 when deuterium is located at C-6 but *m/e* 178 is retained when the deuterium is located at C-6′ (4). The location of deuterium at only the C-6 and C-6′ positions was supported by observing that each of the peaks in the series *m/e* 136, 107, 94, and 81, a series characteristic of *Nuphar* quinolizidines (5), was retained and indicated no deuterium had found its way into rings A or A′. The retention of *m/e* 447 indicated that no deuterium had been introduced into the thiomethylene center.

On a much smaller scale sulfoxide **7** was heated and subsequently reduced with sodium borohydride as the mixture of epimers had before. No **8** could be detected by tlc before reduction and after reduction **1** and **3**, in addition to unconsumed **7**, were detected by tlc. When the sulfoxide **8** was treated in the same manner, no **7** was detected before reduction and neither **1** nor **3** after.

The epimeric *syn*- (**5**) and *anti*-neothiobinupharidine sulfoxide (**6**) were heated separately in xylene solution. The thermolysis mixtures were then reduced with sodium borohydride. Neothiobinupharidine (**2**) and another non-polar substance, having similar but not the same tlc properties as **1** and **3**, resulted from sulfoxide **5**. The *anti* epimer **6** produced no non-polar substances; none of the thiaspirane bisamines could be detected by the customary tlc analysis.

The two-step thermolysis–reduction sequence was then carried out on a larger quantity of a mixture of **5** and **6**. A solution in DMSO heated to 154–160°C yielded, after sodium borohydride reduction, **2** and thionuphlutine C (**4**), in addition to unconsumed **5** and **6**. The gross structure of **4** was indicated by the molecular formula, determined by high resolution mass spectrometry, and the similarity of the ms fragmentation with those of the other three stereoisomeric thiaspiranes. The infrared spectrum showed Bohlmann bands in the same position and as strong as those of the known thiaspiranes. The ^1H nmr also reflected the presence of the thiaspirane structure in **4**. The resonances attributable to the α- and β-furyl protons, the C-6 and C-6′ equatorial protons, the C-4 and C-4′ protons, and the C-1 and C-1′ methyl groups were observed at their normal positions and with the usual splitting characteristics. The thiomethylene AB quartet, appearing at 2.75 ppm in chloroform, was shifted downfield to 2.90 ppm in benzene. Both the position of the resonance and the direction and magnitude of the benzene induced shift (+9.0 Hz at 60 MHz) were consistent with the same properties for the axial thiomethylene in **2** and similar quinolizidines possessing axial thiomethylene groups but are different from the chemical shift and benzene induced shift of the thiomethylene in **1**, **3**, and similar quinolizidines possessing equatorial thiomethylene groups (6, 7). The spectral indications coupled with tlc properties demonstrate that **4** is isomeric with the other thiaspiranes. The nature of the isomerism was evident from the ^{13}C nmr. Figure 1 gives the correlation of resonances found in the high field half of the spectra. Carbon-12 of **4** and **3** is axial to one quinolizidine ring system and equa-

[2]The modified splitting for the C-6′-eq proton of **3**-*d* is attributed to the presence of some axial deuterium at C-6′. The axial incorporation of deuterium at C-6′ in the reduction of 6,6′-dihydroxythionuphlutine B has been reported (3).

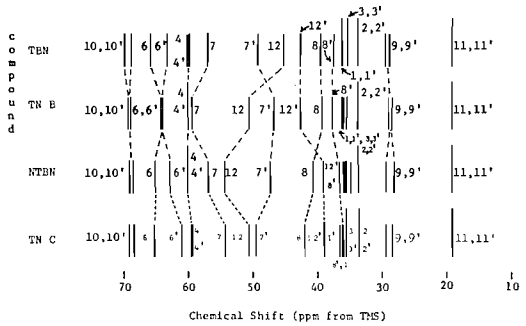

FIG. 1. Chemical shift correlation of thiaspirane bisamines: thiobinupharidine (**1**, TBN); thionuphlutine B (**3**, TN B); neothiobinupharidine (**2**, NTBN); and thionuphlutine C (**4**, TN C).

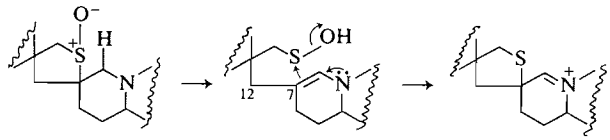
torial with respect to the other whereas in **1** and **2**, C-12 is respectively axial and equatorial to both quinolizidine systems. Since the chemical shift of C-12 reflects the number of axial and equatorial attachments (2), the appearance of the C-12 resonance of **4** at 50.7 ppm, virtually the same value as the C-12 resonance of **3** (50.6 ppm) and intermediate between the C-12 resonance values of **1** (45.3 ppm) and **2** (54.4 ppm), indicated that C-12 in **4** was axial with respect to one quinolizidine system but equatorial with respect to the other. Since both ^1H and ^{13}C thiomethylene resonances of **2** and **4** were the same and indicated the axial thiomethylene attached to the A′B′ system in both, C-12 in **4** must be axial to the AB quinolizidine system but equatorial to the A′B′ quinolizidine system.

Discussion

Only the *syn* sulfoxides of thiobinupharidine and neothiobinupharidine are thermolyzed to compounds which are reduced by sodium borohydride in methanol to thiaspirane bisamines. Presumably the compounds undergoing reduction are immonium salts or hemiaminals. The dependence of the thermolytic process on sulfoxide stereochemistry is reminiscent of the [2,3] sigmatropic shifts of penicillin sulfoxides wherein hydrogen of the C-2 methyl group *syn* to the sulfoxide migrates to sulfoxide oxygen with simultaneous carbon–sulfur bond rupture and sulfenic acid and carbon–carbon double bond formation (8, 9). Such transformations occur under a wide variety of conditions including those employing acids and anhydrides (10), halogenated solvents (11), and tertiary amines (11, 12). A similar process is envisaged for the thiaspirane sulfoxides as shown in Scheme 1. The thiaspirane structure is reestablished by electrophilic attack of the sulfenic acid sulfur atom on the enamine β carbon. If carbon–sulfur bond formation occurs before rotation or after an even number of 180° rotations of the AB quinolizidine ring about the C-7,C-12 bond, then the original thiaspirane (**1** and **2**) stereochemical type is regenerated. But if carbon–sulfur bond formation occurs after an odd number of 180° rotations then the C-7 stereoisomeric thiaspirane results (**3** and **4**). However, the deuterium location studies carried out in connection with the *syn* sulfoxide **7** investigation indicates a complication. When the immonium ion center in the AB quinolizidine system is *syn* to the nitrogen of the A′B′ quinolizidine system, proton migration from C-6′ to C-6 occurs with resulting transfer of immonium ion location to the A′B′ quinolizidine system.



SCHEME 1

The stereoisomerism which we have achieved, albeit in low conversion, indicates a potential for further study: optimization of the isomerization process, identification of other products, and the stereochemical preferences for hydrogen migration from C-6.

Experimental[3]

Spectra were determined as follows: mass spectra (ms) on a Hitachi-Perkin-Elmer RMU6E using a direct inlet, with chamber temperature 200°C and voltage 70 eV, infrared spectra (ir) as indicated on a Perkin-Elmer 137 spectrometer; ^1H nmr at 100 MHz in $CDCl_3$ in 5-mm tubes on an XL-100-15 spectrometer operating in the FT absorption mode (m, s, d, t, and q referring to multiplet, singlet, doublet, triplet, and quartet, respectively); ^{13}C nmr in $CDCl_3$, used also to furnish a secondary reference (77.2 ppm from TMS at δ 0.00 ppm) and the deuterium resonance for field-frequency lock, on an XL-100-15 operating at 25.19 MHz in the FT absorption mode employing 8192 data points. The multiplicity (s, d, t, q) of spectral lines as indicated was determined from the ^1H off-resonance decoupled spectra while the multiplicity of peaks following the designation ^{13}C (^1H) nmr indicates the splitting in the ^1H wide-band noise fully decoupled spectra resulting from the presence of deuterium. In all cases ^{13}C nmr spectral widths were 5000 Hz and acquisition times were 0.8 s. Pulse widths for all spectral determinations ranged from 65–75 μs. Fully ^1H noise decoupled and off-resonance decoupled ^{13}C nmr were determined on 11–102 mg of compound in 0.25–0.30 ml of solvent using 5–97 K transients. High resolution mass spectra (hrms) were performed by the Cornell University Mass Spectrometry Center. Thin-layer chromatography (tlc) was carried out on microscopic size plates uniformly coated with 0.25 mm of SiO_2 or Al_2O_3.

Preparation of syn- *(7) and* anti-*(8) Thiobinupharidine Sulfoxide*

A 199 mg sample of thiobinupharidine (**1**) was treated with

[3]A version of the Experimental Section containing complete ir, ^1H nmr, ^{13}C nmr, and mass spectral data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

H_2O_2–HOAc (1) and thereby was obtained 212 mg of a mixture of sulfoxides: tlc (Al_2O_3, five times with C_6H_6) R_f 0.3; (Et_2O–$CHCl_3$, 1:9) R_f 0.8; (Et_2O–hexane, 2:3) R_f 0.6; (Et_2O–C_6H_6) R_f 0.8; (SiO_2, three times with Et_2O–C_6H_6) R_f 0.5. Chromatography of 212 mg on a neutral alumina (4% H_2O) column (13 cm × 1 cm) was effected with 50 ml of C_6H_6 and nine 7-ml portions of CH_2Cl_2 (fractions 2–10). Fractions 2 and 3 combined amounted to 36 mg of pure oily *syn*-thiobinupharidine sulfoxide (7): $[\alpha]_D^{25}$ −7.7° (19.8 mg/ml, 95% EtOH).

A 15 mg sample of the *syn* sulfoxide in 1 ml of MeOH was treated with 2 equiv. of 0.2 *M* aqueous $HClO_4$. The solid residue obtained after evaporating to dryness was recrystallized from MeOH to obtain **7** diperchlorate: mp 228–230°C. *Anal.* calcd. for $C_{30}H_{44}O_{11}N_2SCl_2$: C 50.63, H 6.23, N 3.94, S 4.51; found: C 50.48, H 6.34, N 3.91, S 4.37.

Fractions 4–10 consisted of an oily mixture of *syn* and *anti* epimers which combined amounted to 185 mg. To a 36 mg amount of the mixture was added 6 drops of glacial HOAc and 0.3 ml of $CHCl_3$. The resulting solution was applied to a SiO_2 column which was eluted with portions of $CHCl_3$ and then $CHCl_3$–MeOH. From 5:95 MeOH–$CHCl_3$ was obtained fraction 2, which was dissolved in water. The p*H* was adjusted to 12 with NaOH and the basic solution was extracted with $CHCl_3$. The extract was dried and the solvent was removed by vacuum evaporation to obtain 11 mg of pure *anti*-thionupharidine sulfoxide, **8**: crystalline at 0°C; $[\alpha]_D^{20}$ −70.5 (24 mg/ml, 95% EtOH). *Anal.* calcd. for $C_{30}H_{42}O_3N_2S$: C 70.55, H 8.29, N 5.48, S 6.28; found: C 70.46, H 8.20, N 5.20, S 6.39.

Treatment of later fractions in a manner similar to fraction 2 yielded an additional 13 mg of pure *syn* sulfoxide (**7**).

Thermolysis of a Mixture of syn- *and* anti-*Thiobinupharidine Sulfoxides*

An 88 mg mixture of the sulfoxides was estimated to contain 56% *syn* and 44% *anti* epimers from the relative intensities of the ^{13}C resonance at δ 40.3 ppm (*syn*) and δ 38.7 ppm (*anti*). This mixture in 50 ml of DMSO was degassed repeatedly, put under an atmosphere of N_2, and heated in an oil bath at 135–140°C for 25 h. The DMSO was removed by evacuation at 45°C. The residue in 1 ml of MeOH was treated with three 10-mg portions of $NaBD_4$ periodically over a period of 1 h. Work-up yielded 100 mg of a brown oily residue which was chromatographed on Al_2O_3 (4% H_2O) eluted with C_6H_6 and $CHCl_3$. In this manner were obtained 56 mg of *syn*- and *anti*-thiobinupharidine sulfoxide consisting of 57% *anti* epimer and 43% *syn* epimer estimated from the relative intensities of ^{13}C resonances at δ 40.3 ppm (*syn*) and 38.7 (*anti*), the spectra being determined under precisely the same conditions as the original mixture of isomers.

Also obtained from the benzene fractions were 20 mg which were chromatographed on Al_2O_3 (4% H_2O) using Et_2O–hexane (5:95) in 20 ml, 34 ml, 10 ml, and 50 ml fractions. The second fraction, 3.6 mg, consisted of pure thiobinupharidine-*d*: ^1H nmr (100 MHz, $CDCl_3$) was identical to that of unlabelled thiobinupharidine except that the C-6, C-6′ and C-4, C-4′ proton region (δ 2.70–3.10 ppm) contained 3.4 protons; ms *m/e*: 495 (39.3% d_0, 59.1% d_1, 1.6% d_2), and 179 (100%) (43.6% d_0, 55.9% d_1, and 0.5% d_2). Therefore the deuterium distribution is 39.3% d_0, 59.1% C-6-d_1, and 1.6% C-6′-d_1. Fraction 4, 4.7 mg, consisted of thionuphlutine B-*d*: ^1H nmr (100 MHz, $CDCl_3$) was identical to that of authentic thionuphlutine B (3), except in the C-6_{eq} and C-$6'_{eq}$ region (δ 2.45–2.85 ppm) where differences were observed because of the incorporation of deuterium at both C-6 and C-6′; ms *m/e*: 495 (32.0% d_0, 65.6% d_1, and 2.4% d_2), and 179 (100%) (59.0% d_0, 35.9% d_1, and 5.1% d_2). Therefore the deuterium distribution is 32% d_0, 35.9% C-6 eq-d_1, and 29.7% C-6′ eq-d_1.

Thermolysis of a Mixture of syn- *(5) and* anti- *(6) Neothionupharidine Sulfoxides*

A 70 mg mixture of the title sulfoxides, prepared from neothiobinupharidine (**2**) with H_2O_2–HOAc, was dissolved in 50 ml of DMSO, degassed repeatedly, put under an atmosphere of N_2, and heated in an oil bath at 154–160°C for 20 h. The DMSO was removed by evacuation at 45°C. The dark brown oily residue in 3 ml of MeOH at 25°C was treated with 200 mg of $NaBH_4$ portionwise for 1 h. MeOH was vacuum evaporated and the residue was chromatographed repeatedly on Al_2O_3 (activity 2) with C_6H_6 and then $CHCl_3$. In this manner was obtained pure neothiobinupharidine (10.8 mg) as determined by the identity of its ^1H nmr (100 MHz, $CDCl_3$) with that of an authentic sample. Also obtained was 2 mg of pure thionuphlutine C: $[\alpha]_D^{25}$ −88.4° (6.3 mg/ml, 95% EtOH); tlc (Al_2O_3, three times with Et_2O–hexane, 1:9) R_f 0.73 (neothiobinupharidine, R_f 0.33; thionuphlutine B, R_f 0.61; thiobinupharidine, R_f 0.78); hrms calcd. for $C_{30}H_{42}O_2N_2S$: 494.2967; found: 494.2944.

Preparation of syn- *and* anti-*Thiobinupharidine-6′-*d_1 *Sulfoxides*

Oxidation of 22 mg of thiobinupharidine-6′-d_1 (3), with H_2O_2–HOAc produced 22 mg of a mixture of the labelled sulfoxides: ^{13}C (^1H) nmr δ: 64 ppm (t, C-6′ overlapping in *syn*- and *anti*-thiobinupharidine-6′-d_1, sulfoxides).

Preparation of syn- *and* anti-*Thiobinupharidine-6,6′-*d_2 *Sulfoxides*

Oxidation of 105 mg of thiobinupharidine-6,6′-d_2 (3) with H_2O_2–HOAc produced a 103 mg mixture of the doubly labelled sulfoxides: ^{13}C (^1H) nmr δ: 64 ppm, (t, C-6′ overlapping in *syn*- and *anti*-thiobinupharidine-6,6′-d_2 sulfoxides), 59.1 ppm (t, C-6 in *anti*-thiobinupharidine-6,6′-d_2 sulfoxide), 56.5 ppm (t, C-6 in *syn*-thiobinupharidine-6,6′-d_2 sulfoxide).

Separation of syn- *and* anti-*Thiobinupharidine-6,6′-*d_2 *Sulfoxides*

To a 100 mg mixture of *syn*- and *anti*-thiobinupharidine-6,6′-d_2 sulfoxide was added 5 drops of glacial HOAc and 0.5 ml of $CHCl_3$. The resulting solution was applied to an SiO_2 (10% H_2O) column which was eluted with $CHCl_3$ and then with 2.5% MeOH in $CHCl_3$. An early MeOH–$CHCl_3$ fraction was dissolved in H_2O, the p*H* of the resulting solution was adjusted to 12 with NaOH, and the basic solution was extracted with $CHCl_3$. The extract was dried (Na_2SO_4) and the solvent was removed by vacuum evaporation to obtain 37 mg of pure *anti*-thiobinupharidine-6,6′-d_2 sulfoxide: ^{13}C (^1H) nmr δ: 63.9 ppm (t, C-6′), 59.1 (t, C-6).

A later MeOH–$CHCl_3$ fraction was treated in a similar manner to obtain 50 mg of pure *syn*-thionupharidine-6,6′-d_2 sulfoxide.

Thermolysis of syn-*Neothiobinupharidine Sulfoxide*

A solution of 23 mg of the title compound in 10 ml of xylene was heated at 145–150°C for 72 h. Evaporation of the solvent under vacuum, reduction of the residue with 50 mg of $NaBH_4$ in MeOH for 1 h, evaporation under vacuum to dryness, addition of 10 ml of water, extraction with $CHCl_3$, drying, and evaporation under vacuum resulted in 27 mg of residue: tlc (Al_2O_3, 1:9 Et_2O–hexane) R_f 0.00 (major), 0.42 (neothiobinupharidine), 0.55 (unknown), 0.67 (unknown), 0.73 (thionuphlutine C).

Thermolysis of anti-*Neothiobinupharidine Sulfoxide*

A solution of 11 mg of the title compound in 10 ml of xylene was heated at 145–150°C for 24 h. Reduction and pro-

cessing in the manner applied to the *syn* isomer gave a 9 mg residue: tlc (Al_2O_3, 1:9 Et_2O–hexane) R_f 0.21, 0.35, 0.70 (uv and Dragendorff active), 0.82; tlc of neothiobinupharidine (R_f 0.42), thionuphlutine B (R_f 0.70, Dragendorff active, uv inactive), thionuphlutine C (R_f 0.73), and thiobinupharidine (R_f 0.79) was carried out for comparison.

Thermolysis of syn-*Thiobinupharidine Sulfoxide*

A solution of 10 mg of the *syn* sulfoxide in 1 ml of DMSO was degassed then heated under N_2 at 140°C for 1 h at the end of which time 2 drops were withdrawn and the remainder was heated for an additional 23 h. The solvent was removed from the 1-h sample by vacuum evaporation, the residue was dissolved in 5 drops of $CHCl_3$, and 1 drop of glacial HOAc was added. The 24-h sample was treated in a similar fashion and both samples were examined by tlc (SiO_2, 0.7 ml CH_3OH, 10 ml $CHCl_3$, and 2 drops of HOAc), the 1-h sample showing R_f 0.27 (*syn* sulfoxide), 0.44 but no R_f 0.36 (*anti* sulfoxide) or R_f 0.18, and the 24-h sample showing R_f 0.18, 0.27 (*syn* sulfoxide), 0.44, and 0.50, but no R_f 0.36 (*anti* sulfoxide). The 24-h sample also showed by tlc (Al_2O_3, 10% Et_2O–hexane) R_f 0.0 (*syn* sulfoxide), 0.33, 0.7 (thionuphlutine B), and 0.8 (thiobinupharidine). The 24-h $CHCl_3$–HOAc solution was chromatographed on a 1 cm × 7 cm column of SiO_2 (activity 2) with 2.5% MeOH-$CHCl_3$ in 30 ml (fraction 1, 1.0 mg), 40 ml (fraction 2, 7 mg), and 20 ml (fraction 3, 5 mg) amounts. Fraction 2 (tlc (SiO_2 0.7 ml CH_3OH and 10 ml $CHCl_3$) R_f 0.27, 0.44, and 0.50) in 0.5 ml of MeOH was treated with 20 mg of $NaBH_4$ at 25°C for 1 h. The solvent was removed by vacuum evaporation, the residue was dissolved in 0.5 ml of $CHCl_3$ and the resulting solution was filtered through a 0.5-ml layer of Al_2O_3 which was subsequently washed with 20 ml of $CHCl_3$. The combined filtrate and washing was vacuum-evaporated to afford 2 mg of oil: tlc ($Al_2O_3HF_{254}$, 1:9 Et_2O–hexane) R_f 0.0 (*syn* sulfoxide), 0.7 (thionuphlutine B), and 0.8 (thionuphlutine A).

Total synthesis of indole and dihydroindole alkaloids. XII.[1,2] Selective functionalization of various bisindoles. Efficient syntheses of leurosine and related bisindole alkaloid derivatives

JAMES P. KUTNEY, JOHN BALSEVICH, GORDON H. BOKELMAN, TOSHIHIKO HIBINO, TOSHIO HONDA, ISAMU ITOH, ARNOLD H. RATCLIFFE, AND BRIAN R. WORTH

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, B.C., Canada V6T 1W5

Received June 30, 1977

JAMES P. KUTNEY, JOHN BALSEVICH, GORDON H. BOKELMAN, TOSHIHIKO HIBINO, TOSHIO HONDA, ISAMU ITOH, ARNOLD H. RATCLIFFE, and BRIAN R. WORTH. Can. J. Chem. **56**, 62 (1978).

Studies involving selective functionalization of the indole unit in a number of bisindole alkaloids and related synthetic derivatives are described. These investigations include such reagents as *tert*-butyl hydroperoxide, which provides an efficient procedure for epoxidation of olefinic linkages, mercuric acetate, osmium tetroxide, and iodine under basic conditions and oxygenation under acidic conditions. Efficient syntheses of leurosine (**8**) and various novel vinblastine derivatives are developed.

JAMES P. KUTNEY, JOHN BALSEVICH, GORDON H. BOKELMAN, TOSHIHIKO HIBINO, TOSHIO HONDA, ISAMU ITOH, ARNOLD H. RATCLIFFE et BRIAN R. WORTH. Can. J. Chem. **56**, 62 (1978).

On décrit des études impliquant la fonctionnalisation sélective d'unités indoliques dans un certain nombre d'alcaloïdes dérivés du bisindole et de dérivés de synthèse qui leur sont reliés. Ces études comprennent des réactifs tels que: l'hydroperoxyde de *tert*-butyle qui permet d'effectuer d'une façon efficace l'époxydation de doubles liaisons, l'acétate mercurique, le tétroxyde d'osmium et l'iode en milieu basique ainsi que l'oxygénation en milieu acide. On a développé des synthèses efficaces de la leurosine (**8**) et de divers dérivés nouveaux de la vinblastine.

[Traduit par le journal]

In a continuing research program directed at the laboratory synthesis of bisindole alkaloids of the vinblastine–vincristine series, we have considered various approaches in the hope of developing efficient procedures for the preparation of these clinically important agents. Our previous investigations (1–3, 5) involved studies in which appropriate indole and dihydroindole units were coupled to provide the desired bisindole systems. In another study we have considered the development of selective reactions which would allow specific functionalization of appropriate bisindole systems already available from previous experiments. The results presented herein illustrate the success of such an approach.

It has already been noted (Part XI, ref. 4) that electrophilic addition to the olefinic linkage of the catharanthine system is complicated by competitive side reactions at the indole or the basic nitrogen site in the molecule. A similar difficulty was observed with the cleavamine system, the indole unit normally present in the bisindole alkaloids. After much frustration with the more common electrophilic reagents generally employed in olefin functionalization, we turned our attention to oxygen and hydroperoxide oxidation of alkenes, a reaction which is not generally utilized by synthetic chemists (6–9).

The intermediate chosen for this study was N_a-carbomethoxy-18β-carbomethoxycleavamine (**1**) since this compound was expected to exhibit properties similar to those of the indole unit present in the bisindole alkaloids. The preparation of this intermediate was accomplished by reacting the readily available 18β-carbomethoxycleavamine (1, 10) with strong base to remove the indolic hydrogen and treating the resultant anion with methyl chloroformate.

Oxidation of **1** with oxygen in a tetrahydrofuran solution containing trifluoroacetic acid provided two main products, which on the basis of their spectral data, were assigned the structures **2** and **3**. The major component (51% yield) was the lactam epoxide **3** while the desired N_a-carbomethoxy-18β-carbomethoxy - 3β,4β - epoxydihydrocleavamine (**2**) was isolated in only 10–15% yield. Of particular importance in allowing the structural assignment for **2** was the characteristic fragmentation pattern in the mass spectrum. The most significant fragmentation occurs in the manner indicated with cleavage at 'a' and 'b' providing the ion **5** (*m/e* 152, 17%; $C_9H_{14}NO$

[1]For part XI see ref. 5.

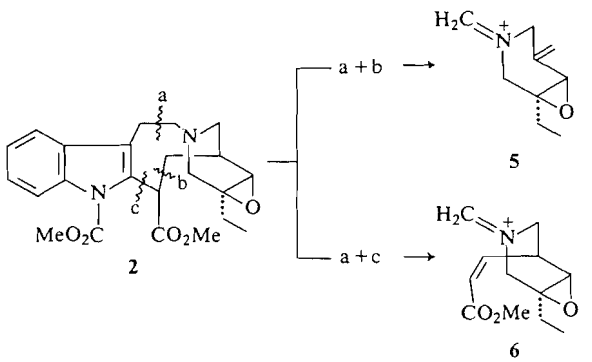
requires 152.107; found: 152.106) and at 'a' and 'c' to provide ion **6** (*m/e* 224, base peak; $C_{12}H_{18}NO_3$ requires 224.129; found: 224.128).



2 5 6

Clearly the data provided thus far did not allow any stereochemical assignment to the epoxide ring as shown in **2** and **3** but further chemical evidence settled this question. Lithium aluminum hydride reduction of **2** in refluxing *N*-methylmorpholine provided the diol **4** (R = H) in 80% yield. The structure of the latter follows directly from the fact that the known triol **4** (R = OH) available from a previous study (11) could be similarly reduced to **4** (R = H). Since the interrelationship of the triol (**4**, R = OH) with isovelbanamine (11) firmly establishes the absolute configuration of the tertiary hydroxy group as shown, it is clear that the epoxide ring in the oxidation products **2** and **3** must be in a β orientation.

Further studies to improve the yield of the desired epoxide intermediate **2** in the oxygenation reaction met with failure but reaction of **1** with the hydroperoxide in aqueous trifluoroacetic acid provided **2** in 67% yield and thereby suggested an attractive application of this reaction to the bisindole series.

The most attractive intermediate from the bisindole series which appeared suitable for studies with the hydroperoxide procedure was 3′,4′-dehydrovinblastine (**7**), a synthetic vinblastine analogue available from our earlier studies (2, 3) and independent investigations conducted elsewhere (12, 13). This compound was treated with *tert*-butyl hydroperoxide and trifluoroacetic acid in tetrahydrofuran as solvent. The product, obtained in 51% yield, was identified as the bisindole alkaloid leurosine **8** by appropriate comparisons with an authentic sample. As already indicated in the previous publication (Part XI, ref. 5) the stereochemistry of the epoxide ring in this alkaloid is as shown in **8**, thereby establishing attack of the hydroperoxide from the α face of the indole unit in **7**. The epoxidation process was selective in that products resulting from reaction at the olefinic linkage in the vindoline unit of **7** were not observed.

An even more efficient route to leurosine (62%) was realized by treatment of the hydrochloride salt of **7** with mercuric acetate and subsequent quenching with sodium borohydride.

In recent isolation studies it has been demonstrated that vicinal diols are present in some bisindole alkaloids as exemplified by vincadioline (14). Thus it appeared appropriate to evaluate selective diol formation with 3′,4′-dehydrovinblastine in the hope that such studies would allow entry into this series of compounds. For this purpose a detailed investigation with osmium tetroxide was initiated and a summary of the results is presented in Fig. 1.

It was found that the nature and relative yields of the products obtained from osmylation of **7** depended markedly on the reaction conditions employed. Initial investigations with **7** and osmium tetroxide revealed a complex reaction product mixture but results with the *N*-oxide derivative **9** were much more encouraging and further studies were performed.

7 R = CO_2CH_3 8

Reaction of **9** with 1 or less than 1 equiv. of osmium tetroxide provided two main products which from spectral and chemical data could be assigned the structures **10** (R_1 = OH) and **11** (R_2 = O).

The major component (53% yield) was 3′,4′-dehydro-19′-oxovinblastine (**11**, R_2 = O) and represented a product in which normal hydroxylation of the olefinic linkage in the indole unit had not occurred but rather oxidation at the basic nitrogen site to provide the lactam. The expected product resulting from hydroxylation of the 3′,4′-double bond in **9** and tentatively assigned the name 3′-hydroxyvinblastine (see later) was isolated only as a minor component (10% yield). In addition, leurosine (3–5% yield) was isolated as a very minor component.

Reaction of **9** with 2 equiv. of osmium tetroxide provided another product (64% yield) which, again on the basis of spectroscopic evidence, was tentatively assigned the name, 3′-hydroxy-19′-oxovinblastine.

More recent studies with several salt derivatives of 3′,4′-dehydrovinblastine provided optimum conditions for obtaining the diol and lactam diol derivatives isolated in the above investigations. Experiments were performed with the hydrochloride and hydrosulfate derivatives, with the latter providing the best results. Thus reaction of the hydrosulfate derivative with 1.2 equiv. of osmium tetroxide afforded a 42% yield of the amine diol, whereas with 2.2 equiv. of this reagent a 63% yield of the lactam diol was obtained. Again leurosine was isolated as a minor component in these reactions.

It is important to emphasize at this point in the discussion that the initial experiments involving *tert*-butyl hydroperoxide, and osmium tetroxide, with 3′,4′-dehydrovinblastine, as reported in preliminary communications (19), were completed prior to our studies (5, 15) which established with certainty the epoxide stereochemistry in leurosine. In those early studies it was assumed that attack of reagents to the 3′,4′-double bond in **7** would occur from the β face of the indole unit. The synthesis of leurosine via the hydroperoxide procedure discussed earlier clearly establishes α attack at the 3′,4′ position in **7**. The isolation of leurosine in the osmylation studies also provides evidence for a similar reaction with osmium tetroxide thereby suggesting stereochemical assignment of the vicinal diol system in **10** and **12** as indicated. On this basis these two compounds are derivatives of leurosidine (**17**, R = CO_2CH_3, R_1 = OH), the C-4′ isomer of vinblastine (16). Conclusive chemical evidence for this stereochemical assignment was obtained in the following manner.

Tosylation of the lactam diol (**12**, R_1 = R_3 = OH, R_2 = O) provided the secondary monotosylate (**12**, R_1 = OH, R_3 = OTos, R_2 = O) and the latter upon reaction with sodium cyanoborohydride afforded leurosine (**8**). This conversion established the α orientation for the tertiary hydroxyl group (R_1) in **12** and, in turn, the same orientation for the secondary function (R_3) since osmylation is well known to be a *cis* hydroxylation process. On this basis the amine diol **10** (R_1 = OH) is given the name, 3′α-hydroxyleurosidine while **12** (R_1 = R_3 = OH, R_2 = O) is 3′α-hydroxy-19′-oxoleurosidine.

The above studies suggested an efficient synthetic entry into a series of novel lactam derivatives in the natural bisindole alkaloid family. The osmylation studies, for example, revealed selective oxidation of the basic nitrogen in the indole unit in the highly functionalized bisindole system and since such intermediates would be important in subsequent investi-

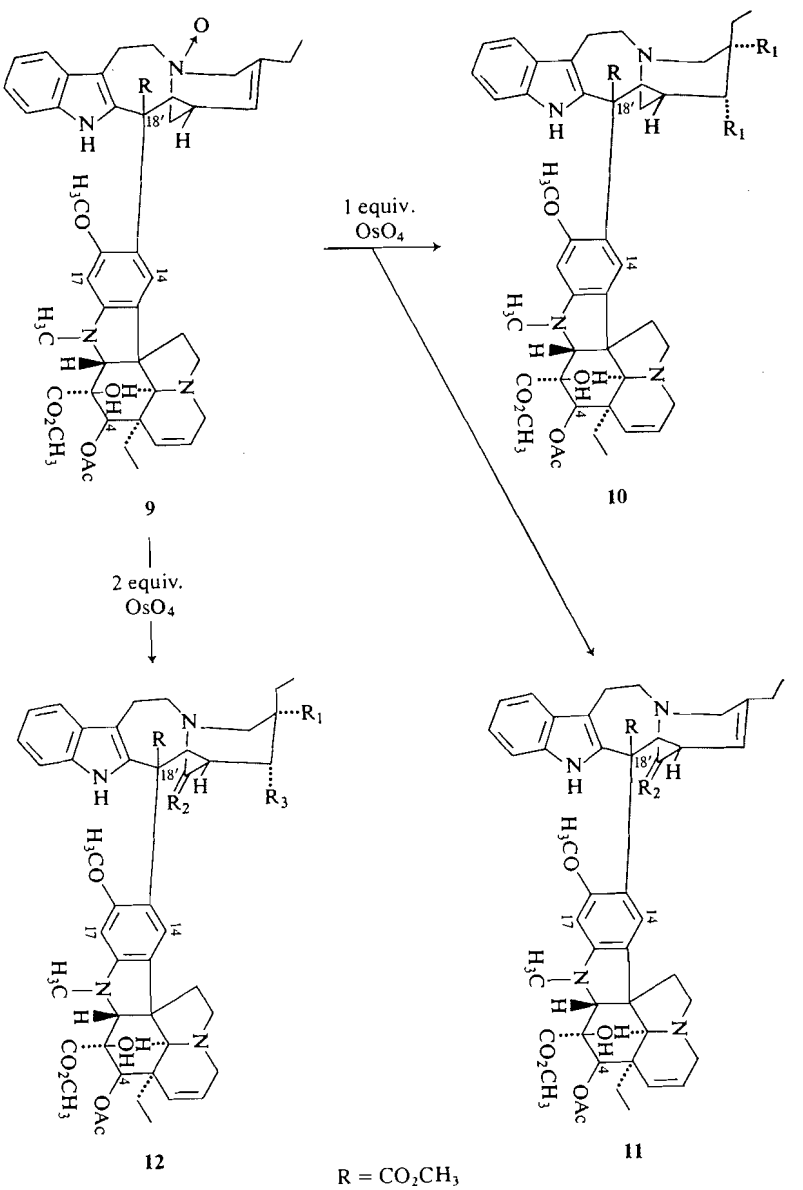

FIG. 1. The reaction of the *N*-oxide intermediate **9** with osmium tetroxide under various conditions.

gations concerned with structure–activity relationships, it was decided to pursue a more thorough investigation in this direction.

We had demonstrated in earlier experiments (4, 17) that conversion of the catharanthine system to the corresponding lactam series could be accomplished by reaction with iodine under basic conditions. The utilization of this reagent with the natural alkaloids vinblastine (**15**, R = CO_2CH_3, R_1 = OH), leurosidine (**17**, R = CO_2CH_3, R_1 = OH), and leurosine (**8**) came under investigation. Figures 2 and 3 provide a summary of the results obtained.

Reaction of vinblastine with iodine and sodium bicarbonate in a tetrahydrofuran solution at room temperature provided 19′-oxovinblastine (**16**, R = CO_2CH_3, R_1 = OH, R_2 = O; 32% yield), whereas a similar oxidation with leurosidine afforded 19′-oxoleurosidine (**18**, R = CO_2CH_3, R_1 = OH, R_2 = O; 62% yield).

The rather unstable alkaloid leurosine can be converted to its lactam derivative **13** (R_1 = O) in 56% yield by means of the iodine oxidation procedure.

The trifluoroacetic acid catalyzed oxygenation

15 16 17 18

FIG. 2. The conversion of vinblastine (**15**, R = CO_2CH_3, R_1 = OH) and leurosidine (**17**, R = CO_2CH_3, R_1 = OH) to lactam derivatives by means of iodine under basic conditions.

procedure discussed earlier was also evaluated for the purpose of providing lactam derivatives in the bisindole area. It was interesting to observe that with this procedure another series of lactams became available. Thus leurosine was converted to 5′-oxoleurosine (**14**, R_1 = O; 15% yield). A more efficient synthesis of this intermediate (34% yield) involved the direct oxygenation of the synthetic derivative, 3′,4′-dehydrovinblastine (**7**).

In summary, the above investigations with various reagents which allow specific functionalization of the indole unit provided reasonably efficient synthetic entries into a whole series of novel bisindole derivatives. The above synthesis of leurosine, by mercuric acetate oxidation, is the most efficient and most easily adaptable for commercial purposes of those reported (5, 15, 18). Further studies in this direction are currently underway.

Experimental

Melting points were determined on a Kofler block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in ethanol solution. The wavelengths of absorption maxima are reported in nanometres (nm) with log ε values in parentheses. Infrared (ir) spectra were measured on a Perkin Elmer model 710 or 457 spectrophotometer in chloroform solution. The absorption maxima are reported in wavenumbers (cm^{-1}), calibrated with respect to the absorption band of polystyrene at 1601 cm^{-1}. Proton magnetic resonance (^{1}Hmr) spectra were measured in deuterochloroform ($CDCl_3$) solution at ambient temperature on either a Varian HA-100 or XL-100 spectrometer. Chemical shift values are given in the δ (ppm) scale relative to tetramethylsilane (TMS) used as internal standard. The integrated peak areas, signal multi-

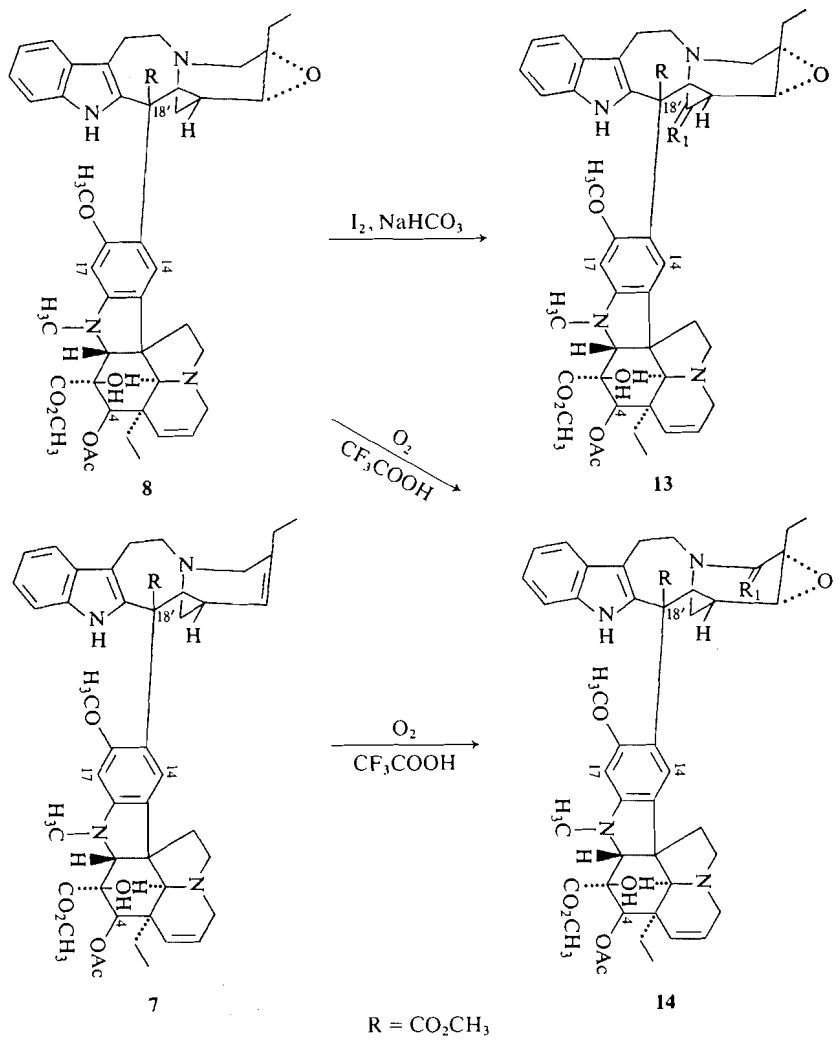

FIG. 3. The conversion of leurosine (**8**) and 3′,4′-dehydrovinblastine (**7**) to lactam derivatives.

plicities and proton assignments are given in parentheses. Low resolution mass spectra (ms) were determined on either an AEI-MS-902 or an Atlas CH-4B spectrometer. High resolution mass spectra were measured on an AEI-MS-902 instrument. Microanalyses were carried out by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia.

Thin-layer chromatography (tlc) utilized Merck silica gel G (according to Stahl) containing 2% fluorescent indicator. For preparative-layer chromatography (plc), plates (20 × 20 or 20 × 60 cm) of 1 mm thickness were used. Visualization was effected by viewing under ultraviolet light and/or by colour reaction with ceric sulphate spray reagent. Column chromatography utilized Merck silica gel 60 (70–230 mesh) or Merck aluminum oxide 90 (neutral).

As a matter of routine, all reagents and solvents were recrystallized or distilled before use.

N_a-Carbomethoxy-18β-carbomethoxycleavamine (1)

A solution of 18β carbomethoxycleavamine (502 mg, 1.5 mmol) in dry tetrahydrofuran (50 ml) under an atmosphere of nitrogen was treated with a suspension of potassium hydride in mineral oil (300 mg, 22.5% KH, 1.7 mmol). After stirring for 10 min at ambient temperature the resultant mixture was treated with methyl chloroformate (290 mg, 3.1 mmol) and stirred for a further 1 h. Acetic acid (0.5 ml) was added to the mixture and stirring continued for 5 min. The solvent was removed *in vacuo* and the residue chromatographed on alumina (activity III, petroleum ether – benzene) to give N_a-carbomethoxy-18β-carbomethoxycleavamine (**1**) (461 mg, 78%), mp 124–125°C (acetone–ether); uv λ_{max}: 294 (3.66), 283 (3.80), 268 (4.09), 262 (4.11), 228 (4.37); ir ν_{max}: 1725; ^{1}Hmr δ: 8.08 (1H, m, C_{14}-*H*) 7.23 (3H, m, C_{11}-*H*, C_{12}-*H*, C_{13}-*H*), 5.77 (1H, d, J = 6 Hz, C_{18}-*H*), 5.37 (1H, m, C_3-*H*), 3.88 (3H, s, N—CO_2CH_3), 3.53 (3H, s, —CO_2CH_3), 0.98 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e* 396 (M^+), 273 (base peak), 136, 124; ^{13}Cmr δ: 12.66 (C-21), 122.25 (C-3), 141.11 (C-4). High resolution molecular weight determination calcd. for $C_{23}H_{28}N_2O_4$: 396.2048; found: 396.2070. *Anal.* calcd. for $C_{23}H_{28}N_2O_4$: C 69.67, H 7.12, N 7.07; found: C 69.86, H 7.10, N 6.87.

Autoxidation of N_a*-Carbomethoxy-18β-carbomethoxycleavamine (1)*

A solution of N_a-carbomethoxy-18β-carbomethoxycleavamine (**1**) (400 mg, 1 mmol) in peroxide-free tetrahydrofuran (10 ml) containing aqueous 1% trifluoroacetic acid (1 ml) was stirred at ambient temperature in the presence of air for a period of 8 days. After drying (K_2CO_3) the solvent was removed *in vacuo* to give an amber gum. Chromatography on alumina (activity III) afforded the *epoxide* **2** (40 mg, 10%) and the *epoxy lactam* **3** (230 mg, 54%).

N_a-Carbomethoxy-18β-carbomethoxy-3β,4β-epoxydihydrocleavamine (**2**), mp 131–132°C (ether); uv λ_{max}: 294 (3.66), 283 sh (3.76), 268 (4.08), 262 (4.09), 227 (4.32); ir ν_{max}: 1728; ^{1}Hmr δ: 8.1 (1H, m, C_{14}-*H*), 7.3 (3H, m, C_{11}-*H*, C_{12}-*H*, C_{13}-*H*), 5.84 (1H, d, *J*=6 Hz, C_{18}-*H*), 3.91 (3H, s, N—CO_2CH_3), 3.57 (3H, s, —CO_2CH_3), 1.00 (3H, t, *J* = 7.5 Hz, —CH_2CH_3); ms *m/e* 412 (M^+), 224 (base peak), 152, 138; ^{13}Cmr δ: 8.93 (C-21), 60.6 (C-3), 62.7 (C-4). Oxidation of N_a*-Carbomethoxy-18β-carbomethoxycleavamine (1) using* tert*-Butyl Hydroperoxide*

A solution of **1** (1.76 g, 4.4 mmol) in freshly distilled tetrahydrofuran (50 ml) containing aqueous 1% trifluoroacetic acid (10 ml) and *tert*-butyl hydroperoxide (9 ml) was stirred at ambient temperature for 21 h. The mixture was taken up in $NaHCO_3$ solution (40 ml) and extracted with ethyl acetate (2 × 30 ml). The combined organic portion was washed with 5% NaOH solution (1 × 20 ml), water (1 × 20 ml), and brine (1 × 20 ml). After drying (Na_2SO_4) the solvent was removed *in vacuo* to give a viscous oil. Chromatography on alumina (activity III, φH) afforded the epoxide **2** (1.22 g, 67%) identical with that obtained above.

Reduction of N_a*-Carbomethoxy-18β-carbomethoxy-3β,4β-epoxydihydrocleavamine*

A solution of **2** (25 mg, 0.06 mmol) in dry *N*-methylmorpholine (2.5 ml) under an atmosphere of nitrogen was treated with lithium aluminum hydride (75 mg, 2 mmol) in tetrahydrofuran (0.5 ml). The tetrahydrofuran was distilled out of the reaction mixture and the remaining solution was refluxed for 2 h. Excess lithium aluminum hydride was destroyed by careful addition of water (10 ml). The mixture was extracted with ethyl acetate (4 × 5 ml), the combined organic portion was dried (Na_2SO_4), and the solvents were removed *in vacuo*. Chromatography on silica gel (ethyl acetate) afforded the *diol* **4** (R = H) (16 mg, 80%), mp 145–150°C (methanol); uv λ_{max}: 291 (3.81), 283 (3.84), 275 sh (3.79), 228 (4.51); ir ν_{max}: 3600, 1510, 1025; ^{1}Hmr δ: 8.55 (1H, bs, N—*H*), 7.51 (1H, m, C_{14}-*H*), 7.24 (3H, m, C_{11}-*H*, C_{12}-*H*, C_{13}-*H*), 4.24 (1H, quintet, *J* = 5 Hz, C_{18}-*H*), 3.86 (2H, d, *J* = 5 Hz, —CH_2OH), 0.96 (3H, t, *J* = 7 Hz, —CH_2CH_3); ms *m/e* 328 (M^+) 311, 310, 299, 297, 187, 154 (base peak). High resolution molecular weight determination calcd. for $C_{20}H_{28}N_2O_2$: 328.2150; found: 328.2146. *Anal.* calcd. for $C_{20}H_{28}N_2O_2 \cdot \frac{1}{2}CH_3OH$:[3] C 71.48, H 8.78, N 8.13; found: C 71.36, H 8.71, N 8.10.

Reduction of 4β,18-Dihydroxy-18-hydroxymethyldihydrocleavamine (4, R = OH) to 4β-Hydroxy-18β-hydroxymethyldihydrocleavamine

A solution of the triol **4** (R = OH) (37 mg, 0.11 mmol) in *N*-methylmorpholine (3 ml) was treated with lithium aluminum hydride (110 mg, 3 mmol) in tetrahydrofuran (0.75 ml) as described above. Isolation of the product by preparative tlc (silica, ethyl acetate) afforded the diol **4** (R = H) (33 mg, 93%). The physical (tlc, mixture mp) and spectral properties (ir, ^{1}Hmr, ms) showed the product to be identical with the one obtained above.

Synthesis of Leurosine (8) from 3′,4′-Dehydrovinblastine (7) using tert*-Butyl Hydroperoxide*

A solution of 7 (81 mg, 0.1 mmol) in peroxide-free tetrahydrofuran (4 ml) containing aqueous 1% trifluoroacetic acid (0.4 ml) and *tert*-butyl hydroperoxide (0.4 ml) was stirred at ambient temperature for 9 h. The mixture was poured into ice-water (15 ml), made basic with concentrated NH_4OH, and extracted with dichloromethane (3 × 10 ml). The combined organic portion was washed with 3% NaOH solution (1 × 8 ml), dried ($MgSO_4$), and the solvent was removed *in vacuo*. Chromatography on silica gel (ethyl acetate – 10% methanol) afforded leurosine (**8**) (43 mg, 52%) which was identified by comparison with an authentic sample (tlc, ^{1}Hmr, ir, ms, and mixture mp).

Synthesis of Leurosine (8) from 7 using Mercuric Acetate

A solution of the hydrochloride salt of 7 (20 mg) in tetrahydrofuran (1 ml) and water (1 ml) was added at ambient temperature to a suspension of mercuric acetate (16 mg) in tetrahydrofuran (1 ml) and water (1 ml) with stirring. The mixture was stirred for a further 30 min then quenched with 3 *N* NaOH (0.5 ml) and sodium borohydride (excess). After 2 h at ambient temperature the mixture was saturated with sodium chloride and extracted with chloroform. The extract was dried (Na_2SO_4), evaporated, and chromatographed on silica gel to give leurosine (12 mg, 62%) identical with an authentic sample.

The N*-Oxide Derivative (9) of 3′,4′-Dehydrovinblastine*

A solution of 3′,4′-dehydrovinblastine (7) (100 mg, 0.126 mmol) in dichloromethane (5 ml) was cooled to −4°C. *m*-Chloroperbenzoic acid (21.8 mg, 0.126 mmol) was added and the mixture stirred at ca. −4°C for 10 min. Then the solvent was evaporated *in vacuo*. The residue was chromatographed on alumina (grade III, ca. 10 g). Elution with 3:1 ethyl acetate – methanol afforded the *N*-oxide derivative (**9**) (100.7 mg, 99%); mp 194–197°C (methanol); uv λ_{max}: 306 (3.99), 292 (4.24), 283 (4.33), 265 (4.46), 213 (4.98), ir ν_{max}: 3460, 2950, 1735, 1610; ^{1}Hmr δ: 9.76 (1H, bs, O*H*), 8.15 (1H, bs, N*H*), 7.67 (1H, m, $C_{14'}$-*H*), 7.11 (3H, m, $C_{11'}$–$C_{13'}$-*H*'s), 6.43 (1H, s, C_{14}-*H*), 6.10 (1H, s, C_{17}-*H*), 5.83 (1H, m, $C_{7'}$-*H*), 5.39 (1H, m, $C_{3'}$-*H*), 5.39 (1H, s, C_4-*H*), 5.24 (1H, d, *J* = 10 Hz, C_6-*H*), 4.81–3.57 (6H, m, $C_{5'}$, $C_{7'}$, $C_{19'}$-*H*'s), 3.81 (3H, s, OCH_3), 3.77 (3H, s, OCH_3), 3.67 (3H, s, OCH_3), 2.69 (3H, s, NCH_3), 2.07 (3H, s, OCOCH_3), 1.01 (3H, t, *J* = 7 Hz, —CH_2CH_3), 0.61 (3H, t, *J* = 7 Hz, —CH_2CH_3); ms *m/e* 808 (M^+), 792, 610, 136, 135, 122, 121, 120, 107, 106 (base peak). High resolution molecular weight determination calcd. for $C_{46}H_{56}N_4O_9$: 808.4046; found: 808.3995.

[3]For analytical purposes, complete removal of solvent of crystallization was impossible without decomposition of the compounds.

Osmylation of the N*-Oxide Derivative (**9**) of 3′,4′-Dehydrovinblastine*

(a) With One or Less than One Equivalent of Osmium Tetroxide

A suspension of the *N*-oxide **9** (100 mg, 0.124 mmol) in dry tetrahydrofuran (4 ml) and pyridine (1 ml) was cooled to ca. −5°C under an atmosphere of argon. Osmium tetroxide (31.4 mg, 0.124 mmol) in dry tetrahydrofuran (0.4 ml) was added and the mixture stirred at −5°C for 45 min. Then hydrogen sulfide was bubbled through the mixture for 5 min. The resultant mixture was filtered and the filtrate evaporated *in vacuo*. The oily product was purified by preparative-layer chromatography (silica gel, 19:1 dichloromethane–methanol).

The major product (least polar on tlc) (53 mg, 53%) was identified as 3′,4′-dehydro-19′-oxovinblastine (**11**, R_2 = O), mp 210–212°C (methanol); uv λ_{max}: 293 (4.47), 283 (4.53), 262 (4.63), 213 (5.17); ir ν_{max}: 3460, 2950, 1735, 1655, 1610; ^{1}Hmr δ: 8.10 (1H, bs, N*H*), 7.60 (1H, m, $C_{14'}$-*H*), 7.21 (3H, m, $C_{11'}$–$C_{13'}$-*H*'s), 6.69 (1H, s, C_{14}-*H*), 6.19 (1H, s, C_{17}-*H*), 6.15 (1H, m, $C_{3'}$-*H*), 5.90 (1H, m, $C_{7'}$-*H*), 5.52 (1H, s, C_4-*H*), 5.34 (1H, d, J = 10 Hz, C_6-*H*), 4.92 (1H, m, $C_{2'}$-*H*), 3.84 (6H, bs, 2 × OC*H*$_3$), 3.79 (1H, s, C_2-*H*), 3.62 (3H, s, OC*H*$_3$), 2.75 (3H, s, NC*H*$_3$), 2.13 (3H, s, OCOC*H*$_3$), 1.01 (3H, t, J = 7 Hz, —CH_2CH_3), 0.85 (3H, t, J = 8 Hz, —CH_2CH_3); ms *m/e* 806 (M^+), 748, 670, 136, 135 (base peak), 122, 121, 107, 106. High resolution molecular weight determination calcd. for $C_{46}H_{54}N_4O_9$: 806.3890; found: 806.3873. *Anal.* calcd. for $C_{46}H_{54}N_4O_9 \cdot CH_3OH$: C 67.28, H 6.97, N 6.68; found: C 66.98, H 6.80, N, 6.43.

The second product (more polar on tlc) was leurosine (**8**, R = CO_2CH_3) (3.6 mg, 4%). The identity of this compound was established by tlc mobility, spectral comparison (^{1}Hmr, ms), and mixture melting point determination with an authentic sample.

The third product (most polar on tlc) was 3′α-hydroxyleurosidine (**10**, R_1 = OH; formerly designated '3′-hydroxyvinblastine') (9.4 mg, 9%); uv λ_{max}: 294 (4.37), 285 (4.40), 258 (4.49), 212 (5.00); ir ν_{max}: 3550, 3460, 2960, 1735, 1610; ^{1}Hmr δ: 8.00 (1H, bs, N*H*), 7.50 (1H, m, $C_{14'}$-*H*), 7.15 (3H, m, $C_{11'}$–$C_{13'}$-*H*'s), 6.60 (1H, s, C_{14}-*H*), 6.13 (1H, s, C_{17}-*H*), 5.86 (1H, m, $C_{7'}$-*H*), 5.48 (1H, s, C_4-*H*), 5.30 (1H, d, J = 10 Hz, C_6-*H*), 3.82 (3H, s, OC*H*$_3$), 3.80 (3H, s, OC*H*$_3$), 3.75 (1H, s, C_2-*H*), 3.63 (3H, s, OC*H*$_3$), 2.72 (3H, s, NC*H*$_3$), 2.10 (3H, s, OCOC*H*$_3$), 0.96 (3H, t, J = 7 Hz, —CH_2CH_3), 0.90 (3H, t, J = 8 Hz, —CH_2CH_3); ms *m/e* 826 (M^+), 809, 285 (base peak), 136, 135, 122, 121, 107, 106. High resolution molecular weight determination calcd. for $C_{46}H_{58}N_4O_{10}$: 826.4153; found: 826.4178. The hydrochloride salt had mp > 200°C (dec.). *Anal.* calcd. for $C_{49}H_{59}N_4O_{10}Cl$: C 63.98, H 6.89, N 6.50; found: C 64.18, H 6.85, N 6.17.

(b) With Two Equivalents of Osmium Tetroxide

A suspension of the *N*-oxide **9** (50 mg, 0.062 mmol) in dry tetrahydrofuran (2 ml) and pyridine (0.5 ml) was cooled to 0°C under an atmosphere of argon. Osmium tetroxide (32 mg, 0.126 mmol) in dry tetrahydrofuran (0.4 ml) was added and the mixture stirred at ca. 0°C for 1.5 h. Hydrogen sulfide was then bubbled through the mixture for 5 min. The resultant mixture was filtered and the filtrate evaporated *in vacuo*. The crude product was purified by preparative-layer chromatography (silica gel, 23:2 dichloromethane–methanol).

The major product (33.7 mg, 65%) was 3′α-hydroxy-19′-oxoleurosidine (**12**, R_1 = R_3 = OH, R_2 = O; formerly designated '3′-hydroxy-19′-oxovinblastine'), mp 227–229°C; uv λ_{max}: 293 (4.33), 283 (4.39), 261 (4.45), 213 (5.01); ir ν_{max}: 3600–3500, 3460, 2960, 1735, 1645, 1615; ^{1}Hmr δ: 8.04 (1H, bs, N*H*), 7.54 (1H, m, $C_{14'}$-*H*), 7.18 (3H, m, $C_{11'}$–$C_{13'}$-*H*'s), 6.66 (1H, s, C_{14}-*H*), 6.17 (1H, s, C_{17}-*H*), 5.89 (1H, m, $C_{7'}$-*H*), 5.53 (1H, s, C_4-*H*), 5.33 (1H, d, J = 10 Hz, C_6-*H*), 4.65 (1H, m, $C_{2'}$-*H*), 3.83 (6H, bs, 2 × OC*H*$_3$), 3.81 (1H, s, C_2-*H*), 3.60 (3H, s, OC*H*$_3$), 2.76 (3H, s, NC*H*$_3$), 2.12 (3H, s, OCOC*H*$_3$), 1.04 (3H, t, J = 7 Hz, —CH_2CH_3), 0.85 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e* 840 (M^+), 423, 282, 149, 135 (base peak), 122, 121, 107. High resolution molecular weight determination calcd. for $C_{46}H_{56}N_4O_{11}$: 840.3945; found: 840.3904. *Anal.* calcd. for $C_{46}H_{56}N_4O_{11}$: C 65.70, H 6.71, N 6.66; found: C 65.45, H 6.61, N 6.51.

*3′α-Hydroxyleurosidine (**10**, R_1 = OH)*

Osmium tetroxide (36 mg, 0.14 mmol) in dry tetrahydrofuran (0.5 ml) was added to the hydrochloride salt of 3′,4′-dehydrovinblastine 7, (111 mg, 0.135 mmol) in dry tetrahydrofuran (2 ml) at 0°C under an atmosphere of dry nitrogen. After 15 min dry pyridine (0.03 ml, 0.0294 g, 0.372 mmol) was added and stirring continued at 0°C for 2 h. Hydrogen sulphide was bubbled through the solution for 5 min, the mixture diluted with ethyl acetate, washed with dilute ammonia solution, dried (Na_2SO_4) and concentrated *in vacuo*. Chromatography on silica gel gave **10** (R_1 = OH), 25 mg (23%), identical with that obtained earlier.

*3′α-Hydroxy-19′-oxoleurosidine (**12**, R_1 = R_3 = OH, R_2 = O) and 3′α-Hydroxyleurosidine (**10**, R_1 = OH)*

(*a*) Osmylation of the hydrosulfate salt of 7 with osmium tetroxide (2.2 equiv.) in dry tetrahydrofuran at 0°C as described directly above afforded the lactam diol (**12**, R_1 = R_3 = OH, R_2 = O) (63%) and the diol (**10**, R_1 = OH) (12%). These products were identical with the respective authentic samples.

(*b*) Osmylation as in (*a*), using 1.2 equiv. of osmium tetroxide gave the diol (**10**, R_1 = OH) (42%).

*The Tosylate (**12**, R_1 = OH, R_3 = OTos, R_2 = O)*

Toluenesulfonyl chloride (10 mg) was added to a solution of the lactam diol (**12**, R_1 = R_3 = OH, R_2 = O) (18 mg) in dry pyridine (2 ml). The mixture was heated at 40°C for 4 h, allowed to stand at ambient temperature for 16 h, poured into water, and extracted with chloroform. The extracts were combined, dried (Na_2SO_4) and concentrated *in vacuo*. Chromatography on silica gel afforded the monotosylate (6 mg, 63%); mp 218–220°C; uv λ_{max}: 312 (sh, 3.88), 295 (4.18), 286 (4.23), 272 (4.27), and 265 (4.27); ir ν_{max}: 3475, 1730, 1660, 1360; ^{1}Hmr δ: 8.68 (1H, bs, —N*H*), 7.73 (2H, d, J = 8 Hz, Tos protons), 7.60 (1H, m, $C_{14'}$-*H*), 7.41 (2H, d, J = 8 Hz, Tos protons), 7.24 (3H, m, indole aromatic protons), 6.71 (1H, s, C_{14}-*H*), 6.27 (1H, s, C_{17}-*H*), 5.96 (1H, dd, J = 10, 4 Hz, $C_{7'}$-*H*), 5.57 (1H, s, C_4-*H*), 5.36 (1H, d, J = 10 Hz, C_6-*H*), 4.72 (1H, bd, J = 13 Hz, $C_{2'}$-*H*), 4.22 (1H, bs, C*H*—OTos), 3.97 (3H, s, —OC*H*$_3$), 3.86 (3H, s, —OC*H*$_3$), 3.70 (3H, s, —OC*H*$_3$), 2.81 (3H, s, —NC*H*$_3$), 2.53 (3H, s, Ph—C*H*$_3$), 2.17 (3H, s, —OCOC*H*$_3$). *Anal.* calcd. for $C_{53}H_{62}N_4O_{13}S$: C 63.86, H 6.28, N 5.63; found: C 63.81, H 6.40, N 5.25.

Starting material (10 mg) was recovered.

*Leurosine Lactam (**13**, R_1 = O) from the Monotosylate*

Excess sodium cyanoborohydride was added to a solution of **12** (R_1 = OH, R_2 = O, R_3 = OTos) (10 mg) in dry HMPA (2 ml). The mixture was heated at 90°C for 20 h, poured into water and extracted with ethyl acetate. The organic layer was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on silica gel afforded **13** (R_1 = O) (2.5 mg, 30%), identical with an authentic sample.

*19′-Oxovinblastine (**16**, R = CO_2CH_3, R_1 = OH, R_2 = O)*

Iodine (20 mg) was added to a mixture of vinblastine (**15**, R = CO_2CH_3, R_1 = OH) (18 mg) and sodium bicarbonate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(20 mg) in aqueous 70% tetrahydrofuran (4 ml). The mixture was stirred at ambient temperature for 10 min, diluted with saturated sodium bicarbonate solution (4 ml), and extracted with dichloromethane. The organic phase was washed with 10% sodium bisulphite solution, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on silica gel gave **16** (R = CO_2CH_3, R_1 = OH, R_2 = O) (6 mg, 33%) as a foam from methanol; uv λ_{max}: 311 (sh, 3.74), 294 (3.99), 285 (4.02), 259 (4.14), 213 (4.69); ir ν_{max}: 3475, 1740, 1640; ^{1}Hmr δ: 8.06 (1H, bs, —N—*H*), 7.54 (1H, m, $C_{14'}$-*H*), 7.20 (3H, m, $C_{11',12',13'}$-*H*), 6.68 (1H, s, C_{14}-*H*), 6.18 (1H, s, C_{17}-*H*), 5.91 (1H, dd, *J* = 3.5, 10.5 Hz, C_7-*H*), 5.54 (1H, s, C_4-*H*), 5.34 (1H, d, *J* = 10.5 Hz, C_6-*H*), 4.70 (1H, m, $C_{2'}$-*H*), 3.82 (3H, s, —CO_2CH_3), 3.80 (3H, s, —CO_2CH_3), 3.60 (3H, s, —OCH_3), 2.75 (3H, s, —NCH_3), 2.12 (3H, s, —$OCOCH_3$), 0.87 (6H, bt, *J* = 7.5 Hz, 2 × —CH_2CH_3); ms *m/e* 824 (M^+), 765, 665, 135 (base peak). High resolution molecular weight determination calcd. for $C_{46}H_{56}N_4O_{10}$: 824.3996; found: 824.3971. *Anal.* calcd. for $C_{46}H_{56}N_4O_{10}\cdot CH_3OH$:[3] C 65.89, H 7.01, N 6.54; found: C 65.14, H 7.20, N 6.60.

*19'-Oxoleurosidine (**18**, R = CO_2CH_3, R_1 = OH, R_2 = O)*

Oxidation of leurosidine (**17**, R = CO_2CH_3, R_1 = OH), as described above for the oxidation of vinblastine, gave the lactam (**18**, R = CO_2CH_3, R_1 = OH, R_2 = O) (62%) as a clear glass mp 196–210°C; uv λ_{max}: 309 (sh, 3.74), 294 (4.00), 285 (4.04), 262 (4.11), 214 (4.66); ir ν_{max}: 3477, 1738, 1644; ^{1}Hmr δ: 8.07 (1H, bs, —N*H*), 7.51 (1H, m, $C_{14'}$-*H*), 7.16 (3H, m, $C_{11',12',13'}$-*H*), 6.63 (1H, s, C_{14}-*H*), 6.16 (1H, s, C_{17}-*H*), 5.88 (1H, dd, *J* = 10, 4 Hz, C_7-*H*), 5.50 (1H, s, C_4-*H*), 5.32 (1H, bd, *J* = 10 Hz, C_6-*H*), 4.73 (1H, m, $C_{2'}$-*H*), 3.82 (6H, s, 2 × —CO_2CH_3), 3.60 (3H, s, —OCH_3), 2.74 (3H, s, —NCH_3), 2.11 (3H, s, —$OCOCH_3$), 1.17 (3H, t, *J* = 7.5 Hz, —CH_2CH_3), 0.96 (3H, t, *J* = 7.5 Hz, —CH_2CH_3); ms *m/e* 824 (M^+), 765, 282, 135 (base peak). High resolution molecular weight determination calcd. for $C_{46}H_{56}N_4O_{10}$: 824.3996; found: 824.3953.

*19'-Oxoleurosine (**13**, R = CO_2CH_3, R_1 = O)*

Oxidation of leurosine (**8**, R = CO_2CH_3) as described above gave the lactam (**13**, R = CO_2CH_3, R_1 = O) (56%) as a foam from methanol; uv λ_{max}: 309 (sh, 3.74), 294 (4.00), 284 (4.05), 262 (4.13), 214 (4.66); ir ν_{max}: 3470, 1738, 1644; ^{1}Hmr δ: 8.06 (1H, bs, —N*H*), 7.57 (1H, m, $C_{14'}$-*H*), 7.18 (3H, m, $C_{11',12',13'}$-*H*), 6.65 (1H, s, C_{14}-*H*), 6.19 (1H, s, C_{17}-*H*), 5.90 (1H, dd, *J* = 10.5, 3.5 Hz, C_7-*H*), 5.51 (1H, s, C_4-*H*), 5.33 (1H, bd, *J* = 10.5 Hz, C_6-*H*), 4.76 (1H, m, $C_{2'}$-*H*), 3.85 (3H, s, —CO_2CH_3), 3.83 (3H, s, —CO_2CH_3), 3.63 (3H, s, —OCH_3), 3.04 (1H, d, *J* = 3.5 Hz, $C_{3'}$-*H*), 2.76 (3H, s, —NCH_3), 2.12 (3H, s, —$OCOCH_3$), 1.01 (3H, t, *J* = 7.5 Hz, —CH_2CH_3), 0.84 (3H, t, *J* = 7.5 Hz, —CH_2CH_3); ms *m/e* 822 (M^+), 763, 282, 135 (base peak). High resolution molecular weight determination calcd. for $C_{46}H_{54}N_4O_{10}$: 822.3839; found: 822.3806. *Anal.* calcd. for $C_{46}H_{54}N_4O_{10}\cdot CH_3OH$:[3] C 66.04, H 6.80, N 6.56; found: C 65.26, H 6.91, N 6.76.

*5'-Oxoleurosine (**14**, R_1 = O)*

(*a*) A solution of leurosine (**8**) (30 mg) in tetrahydrofuran (2 ml) containing aqueous 1% trifluoroacetic acid (0.2 ml) was stirred in the presence of air for 11 days. The mixture was diluted with saturated sodium bicarbonate solution (5 ml) and extracted with dichloromethane. The organic layer was dried (Na_2SO_4) and concentrated *in vacuo*. Chromatography on silica gel gave leurosine (4 mg) and the lactam (**14**, R_1 = O) (4 mg, 15%) as a clear glass, mp 185–191°C; uv λ_{max}: 307 (3.91), 290 (4.04), 283 (4.06), 263 (4.15), 215 (4.70); ir ν_{max}: 3425, 1738, 1681, 1652; ^{1}Hmr δ: 8.16 (1H, bs, —N*H*), 6.88 (1H, s, C_{14}-*H*), 5.99 (1H, s, C_{17}-*H*), 5.32 (1H, bd. *J* = 10.5 Hz, C_6-*H*), 3.80 (6H, s, 2 × —OCH_3), 3.70 (3H, s, —OCH_3), 2.68 (3H, s, —NCH_3), 2.10 (3H, s, —$OCOCH_3$), 0.70 (3H, t, *J* = 7.5 Hz, —CH_2CH_3), 0.40 (3H, t, *J* = 7.5 Hz, —CH_2CH_3); ms *m/e* 822 (M^+), 662, 149, 135 (base peak). High resolution molecular weight determination calcd. for $C_{46}H_{54}N_4O_{10}$: 822.3839; found: 822.3915. *Anal.* calcd. for $C_{46}H_{54}N_4O_{10}$: C 67.15, H 6.57, N 6.81; found: C 66.51, H 6.55, N 6.87.

(*b*) Oxidation of (**7**) as described above in (*a*) gave the lactam (**14**, R_1 = O), (34%), identical with that obtained earlier.

Acknowledgments

Financial aid from the National Research Council of Canada and from Contract NO1-CM-23223, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, is gratefully acknowledged. We are grateful to the Lilly Research Laboratories for supplies of catharanthine and vindoline and a sample of leurosine.

Synthesis of substituted thietanes and thiolanes from α- and β-chloroepoxides and their oxidation to 1,1-dioxides

FRANK S. ABBOTT AND KATSUJI HAYA

Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received June 16, 1977

FRANK S. ABBOTT and KATSUJI HAYA. Can. J. Chem. **56**, 71 (1978).

Treatment of 3-chloro-1-phenylpropylene oxide-1,2 (**7**) or 1-chloro-4-phenylbutylene oxide-3,4 (**8**) with H_2S saturated ethanolic NaOEt gave 3-hydroxy-2-phenylthietane (**9**) and 3-hydroxy-2-phenylthiolane (**10**) respectively. A similar treatment of 3-chloro-2-phenylpropylene oxide-1,2 (**12**) at low temperatures gave 3-chloro-2-hydroxy-2-phenylpropanethiol (**13**); at reflux temperatures or by refluxing **13** in ethanolic NaOEt, 3-hydroxy-3-phenylthietane (**14**) was formed.

Oxidation of **9**, **10**, and **14** with *m*-chloroperbenzoic acid or H_2O_2–HOAc gave the respective 1,1-dioxides **19**, **20**, and **25**. The alcohols **19** and **20** were dehydrated to their corresponding cyclic olefins through the benzylsulfonate esters. Under the conditions of the Ritter reaction **25** dehydrated to the cyclic olefin. Treatment of **19** with mineral acid gave benzyl methyl ketone, while refluxing **19** in base gave benzyl methyl sulfone. Ethoxylation of 2-phenylthiete 1,1-dioxide (**23**) to the 3-ethoxy derivative **34** was achieved under basic conditions. Attempted chlorination of **9** resulted in desulfurization to 3-chloropropenylbenzene (**5**).

FRANK S. ABBOTT et KATSUJI HAYA. Can. J. Chem. **56**, 71 (1978).

Les réactions du chloro-3 phényl-1 propylèneoxyde-1,2 (**7**) ou du chloro-1 phényl-4 butylène-oxyde-3,4 (**8**) avec du NaOEt éthanolique saturé par H_2S conduisent respectivement à l'hydroxy-3 phényl-2 thiétane (**9**) et à l'hydroxy-3 phényl-2 thiolane (**10**). Un traitement similaire du chloro-3 phényl-2 propylèneoxyde-1,2 (**12**) à basse température conduit au chloro-3 hydroxy-2 phényl-2 propanethiol (**13**); si l'on effectue les réactions au reflux ou si l'on porte **13** au reflux dans du NaOEt éthanolique, il se forme de l'hydroxy-3 phényl-3 thiétane (**14**).

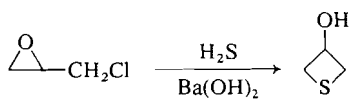
Les oxydations de **9**, **10** et **14** par de l'acide *m*-chloroperbenzoique ou par H_2O_2–HOAc conduisent respectivement aux dioxydes **19**, **20** et **25**. On a déshydraté les alcools **19** et **20** pour obtenir les oléfines cycliques correspondantes par l'intermédiaire de leurs esters benzylsulfonates. Dans des conditions de la réaction de Ritter, **25** se déshydrate pour conduire à une oléfine cyclique. Le traitement de **19** par des acides minéraux conduit à la méthylbenzylcétone alors que le traitement de **19** par de la base au reflux fournit de la méthylbenzylsulfone. On a pu effectuer l'éthoxylation de la phényl-2 thiètedioxyde-1,1 (**23**) conduisant au dérivé éthoxy-3 **34** en travaillant dans des conditions basiques. Des essais de chloruration de **9** ont conduit à sa désulfurisation en chloro-3 propénylbenzène (**5**).

[Traduit par le journal]

Introduction

Several 2-phenyl substituted thietanes were required as intermediary compounds for the synthesis of small ring sulfur compounds of pharmacological interest. Although 2-phenylthietane 1,1-dioxides can be readily prepared, their reduction to 2-phenylthietanes has not been accomplished (1). The exposure of 3-chloropropylene oxide-1,2 (**1**) to a saturated solution of H_2S in $Ba(OH_2)$ gave 3-thietanol (**2**) (2) (Scheme 1), and the application of this procedure to aromatic epoxides seemed to be the most likely route to 2-phenyl substituted thietanes.

Included in this study are a number of experiments which were performed to investigate the chemical properties of substituted thietanes and thiolanes.



1 **2**

SCHEME 1. Preparation of 3-thietanol

Results and Discussion

The nmr spectrum of commercially available 3-chloropropenylbenzene (**5**) was attributable to that of pure *trans*-**5** (J_{ab} = 16 Hz) (3). As expected the epoxidation of **5** with monoperphthalic acid gave only *trans*-3-chloro-1-phenylpropylene oxide-1,2 (**7**) (Scheme 2); the nmr spectrum showed a coupling constant (J_{ab} = 2 Hz) in agreement with spectra of *trans* substituted epoxides (3). Exposure of **7** to a saturated solution of H_2S in NaOEt gave a highly unstable crystalline material, which decomposed in a few days if left exposed to the atmosphere at room temperature. However, it could be stored at −15°C under nitrogen for at least 1 year without any detectable decomposition. This product proved to be 3-hydroxy-2-phenylthietane (**9**).

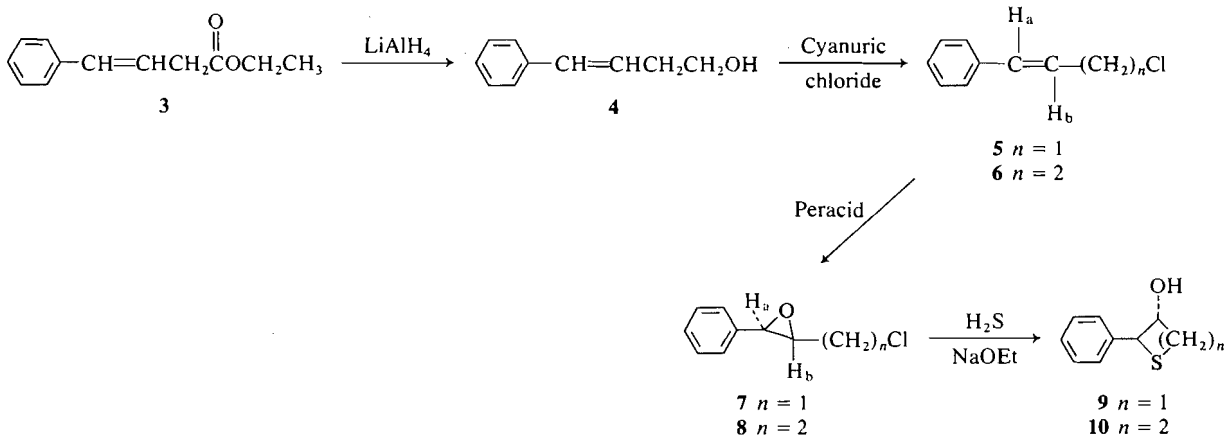

SCHEME 2. Synthetic scheme to 3-hydroxy-2-phenylthietane (**9**) and 3-hydroxy-2-phenylthiolane (**10**)

Reduction of ethyl-*trans*-4-phenyl-3-butenoate (**3**) with $LiAlH_4$ in anhydrous ether gave pure *trans*-4-phenyl-3-buten-1-ol (**4**) (4, 5). Chlorination of **4** with cyanuric chloride (6) at 100°C gave 1-chloro-4-phenyl-3-butene (**6**). The ir spectrum of **6** showed a strong absorption at 975 cm^{-1} and the nmr spectrum showed a vicinal coupling constant, J_{ab} of 16 Hz, both indicative of a *trans* configuration for **6**. Epoxidation of **6** with monoperphthalic acid gave a mixture of *cis*- and *trans*-1-chloro-4-phenylbutylene oxide-3,4 (**8**). A glc analysis of the mixture indicated it to be 70% *trans*-**8** and 30% *cis*-**8**. A pure sample of the *cis*-isomer was obtained by preparative glc and the pure *trans*-isomer was obtained by fractional distillation. The nmr spectrum of *trans*-**8** showed the expected coupling constant (2.5 Hz) for H_aH_b (3). In the nmr spectrum of the *cis*-isomer the peaks due to the ring protons were not sufficiently separated to allow determination of the coupling constants for H_aH_b. From the exposure of *trans*-**8** to a saturated solution of H_2S in ethanolic NaOEt, only 3-hydroxy-2-phenylthiolane (**10**) was isolated.

Treatment of 1,3-dichloro-2-phenylpropan-2-ol (**11**) with base gave 3-chloro-2-phenylpropylene oxide-1,2 (**12**) (Scheme 3). Reaction of **12** with a saturated solution of H_2S in NaOEt gave 3-hydroxy-3-phenylthietane (**14**), a light yellow foul smelling liquid, which has previously been prepared from the reaction of phenylmagnesium bromide with 3-thietanone (7). On the other hand, treatment of the epoxide **12** with a $Ba(OH_2)$ or NaOH solution saturated with H_2S required heating at 80°C to give the thietane **14**. At temperatures of 50°C or less the main product was 3-chloro-2-phenylpropanethiol (**13**). Refluxing the thiol **13** in ethanolic NaOH gave the thietane **14**.

The mechanism for the formation of these heterocyclic sulfur compounds from epoxy halides is described in Scheme 4. Epoxide **7** is used as the example. Nucleophilic attack by sulfhydride ion initially opens the epoxide ring to an intermediate **15** which can then cyclize by nucleophilic displacement of chloride ion. An alternative mechanism whereby sulfhydride ion initially replaces the chloride ion by an S_N2 reaction followed by a ring closure step involving attack on the epoxide seems far less likely. In an analogous system where this latter mechanism has been invoked (8) no compelling evidence was given to substantiate this route. Isolation of the acyclic thiol **13** at the lower reaction temperatures is certainly supportive of the mechanism given in Scheme 4, as were similar results reported for epichlorohydrin reactions with H_2S (9).

Products **9**, **10**, and **14** obtained from the epoxide reactions in the present work appear generally consistent with ring opening reactions of epoxides (9, 10). Under alkaline conditions nucleophilic attack of unsymmetrical epoxides occurs selectively at the less-substituted carbon atom. In the case of **12** the

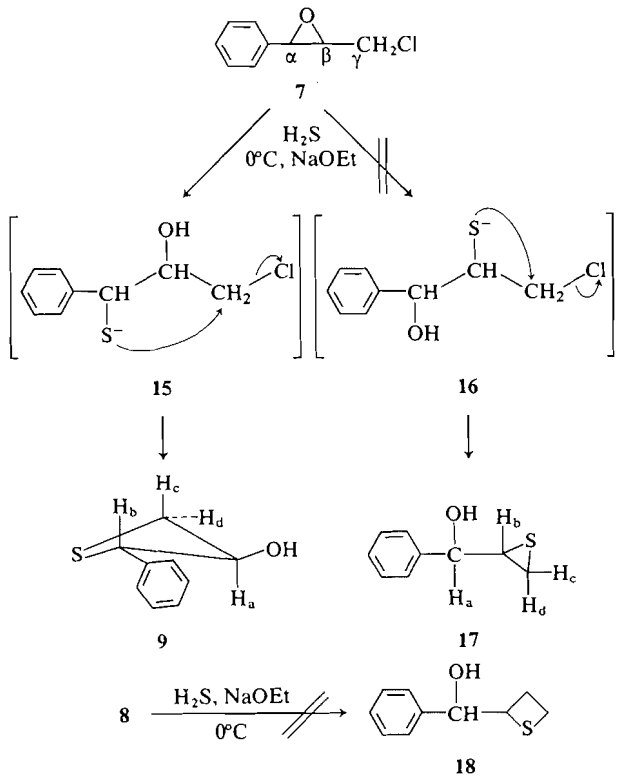

SCHEME 4. Proposed mechanism for the reaction of epoxide with sulfhydride ion

compounds **13** and **14** derived from the ring opening reaction (Scheme 3) are therefore readily predictable. For the epoxides **7** and **8**, however, ring opening at either the α- or β-carbon atom seemed initially to be quite feasible. Hence attack by the sulfur nucleophile at the β-carbon atom of **7** (Scheme 4) to give the intermediate **16**, should also give the thiirane **17**. A similar mechanism for **8** would give the thietane **18**. No evidence was obtained for the presence of either **17** or **18** in the respective reaction mixtures. While the instability of a thiirane could have precluded its isolation, such would not be the case with a thietane such as **18**. This observed predominant, if not exclusive, attack of the sulfur nucleophile at the α-carbon of epoxides **7** and **8** can also be explained in part on the basis of steric effects. But an additional factor is operative with these epoxides, which complements the direction of ring opening favored by the steric considerations. Conjugative effects of the aromatic ring, by stabilizing carbonium ion characteristics at the benzylic carbon atom, would also favor α-attack by an S_N1-type fission (11). For example the isomer ratio of primary and secondary alcohols obtained from the ring opening reaction of styrene oxide by sodium benzene – thiolate in methanol was found to be quite sensitive to *para* substituent effects in the styrene oxide (11).

It follows from the proposed mechanism of the reaction that *trans* substituted epoxides would lead to *trans* substituted thietanes and thiolanes. Because of complexities in the nmr spectra, configurations were not assigned for **9** and **10**. Other evidence supports the *trans* configuration for **9** and **10** (see later).

Infrared, nmr and elemental analysis data of the compound isolated from the reaction of epoxide **7** with sulfhydride ion did not conclusively differentiate between the thietane **9** and the thiirane **17**. The mass spectrum of the product provided evidence in support of **9**. The major fragments at *m/e* 122 ($C_6H_5CHS^{\ddagger}$) the base peak and *m/e* 121 ($C_6H_5CS^+$) are indicative of a thietane (13). If the material isolated had been the thiirane **17**, then strong peaks at *m/e* 105 and 106 due to $(C_6H_5CO)^+$ and $(C_6H_5CHO)^{\ddagger}$ would be expected as these are relatively stable ions and should be readily formed from **17**. Final and conclusive proof of structure **9** was obtained through the conversion of **9** to 2-phenylthiete 1,1-dioxide (**23**) (Scheme 5), which was identical to a sample of **23** prepared by an alternate route (1).

The oxidation of **9** to 3-hydroxy-2-phenylthietane 1,1-dioxide (**19**) with *m*-chloroperbenzoic acid in the present study gave better yields (72% vs. 30–50%) than employing previously published (14, 15) procedures using H_2O_2–HOAc. On the other hand, the oxidation of the thiolane **10** with *m*-chloroperbenzoic acid gave the corresponding 1,1-dioxide **20** in only 27% yield. The oxidation of cyclic sulfides with *m*-chloroperbenzoic acid to the corresponding sulfones, however, appears to be a superior method, particularly from the point of view of safety (16, 17).

The nmr data for **19** and **20** indicated a *trans* configuration between the phenyl and the hydroxyl substituents. In the preferred conformations both groups are equatorial. Assuming Karplus correlations are reliable here (as they are with certain thietane 1,1-dioxides (18, 19)), the coupling constant (6.5 Hz) for H_aH_b in **19** (Scheme 5) indicates a *trans* diaxial interaction. If the protons were in a *cis* relationship, the coupling constants would be expected to be smaller, the dihedral angle being near 90° in the puckered ring. This is supported by the coupling constants observed for the H_a proton with the methylene protons at C-4. The coupling constants were 7.0 and 2.5 Hz which are due to *trans* (diaxial) and *cis* (axial–equatorial) interaction of the protons respectively. The coupling constants of the methylene protons are similar to those found in 3-acetoxy-

9 $n = 1$ **10** $n = 2$ **19** $n = 1$ **20** $n = 2$ **21** $n = 1$ **22** $n = 2$ **23** $n = 1$ **24** $n = 2$

14 **25** **26**

SCHEME 5. Oxidation of thietane and thiolane; elimination reactions of the 1,1-dioxides

thietane 1,1-dioxide, which was shown to have dihedral angles between the C-3 proton and the methylene protons of 109° and 28° and J values of 3.5 and 8 Hz respectively (20). With **20** the observed coupling constant for H_aH_b (9 Hz) was indicative of an interaction of the protons in a five-membered ring (3). The *trans* relationship of the phenyl and hydroxyl groups in **19** and **20** provides evidence that these substituents were *trans* in **9** and **10**, since the oxidation reaction should not affect the configuration of the compounds. This is the expected relationship from the proposed mechanism for the synthesis of **9** and **10**.

The cyclic sulfones **19** and **20** were dehydrated using triethylamine treatment of the benzylsulfonate esters **21** and **22** (Scheme 5), a method reported for the dehydration of 3-hydroxythietane 1,1-dioxide (21). Under the acidic conditions of the Ritter reaction (see ref. 22 for original references) (Scheme 5) the tertiary alcohol **25** readily dehydrates. Two main components were isolated, 3-phenylthiete 1,1-dioxide (**26**) (23) and a small hexane soluble portion which showed a carbonyl absorption in the ir (1755 cm^{-1} strong), but was not further characterized.

The attempted dehydration of **19** with 85% H_3PO_4 or concentrated H_2SO_4 in glacial acetic acid resulted in the formation of benzyl methyl ketone (**30**) a rather novel reaction in terms of thietane chemistry. This acid catalyzed desulfurization and ring cleavage is postulated to proceed by the mechanism[1] outlined in Scheme 6. Protonation of the sulfone **19** results in the formation of the protonated epoxide **27**, which under the acid conditions rapidly undergoes solvolysis to the glycol **28**. 1-Phenyl-1,2-propanediol under the present conditions has been shown to be converted to benzyl methyl ketone (**30**) (24, 25). Similarly the glycol **28** could give the unstable β-ketosulfinic acid **29** which desulfonates to the ketone **30** (cf. decarboxylation of β-ketocarboxylic acids).

When **19** was heated at reflux in 20% NaOH and then cooled, a 70% yield of benzyl methyl sulfone (**33**) precipitated from the reaction mixture. This type of ring cleavage is well known for thiete 1,1-dioxides (1, 26) and for 3-alkoxythietane 1,1-dioxides (27). The mechanism proposed for the thiete 1,1-dioxides involves a reverse aldol condensation proceeding through an intermediate analogous to **31**, and the ring opened aldehyde **32** (Scheme 7). The isolation of **33** from the base treatment of **19** may be interpreted as supporting this previously proposed mechanism.

Exposure of 2-phenylthiete 1,1-dioxide (**23**) to alcoholic KOH at room temperature results in the addition product, 3-ethoxy-2-phenylthietane 1,1-dioxide (**34**). This is typical of other thiete 1,1-dioxides which have been shown to undergo Michael addition of nucleophiles (26, 28, 29).

When **9** was treated with thionyl chloride in dry $CHCl_3$ (30) the expected 3-chloro-2-phenylthietane (**35**) was not isolated. Distillation of the crude product gave a 48% yield of 3-chloropropenylbenzene (**5**). Thionyl chloride with pyridine or 2,4,6-collidine has been used to chlorinate 3-thietanol 1,1-dioxide (2, 17), but this method resulted in isolation of polymeric material when attempted with **9**. Dehydrohalogenation of 3-chlorothietane 1,1-dioxide to thiete 1,1-dioxide was found to readily occur in base (2). In the attempted chlorination of **9**, it is possible that **35** was formed, but the pyridine or 2,4,6-collidine was sufficiently basic to cause dehydrohalogenation to 2-phenylthiete. Since thietes are known to be unstable compounds and spontaneously polymerize (31, 32) this may explain the

[1]This mechanism developed from the suggestion of a referee and while the initial protonation of the sulfone is less favoured than protonation of the hydroxyl, if the steps are rapid and irreversible, this could be the pathway.

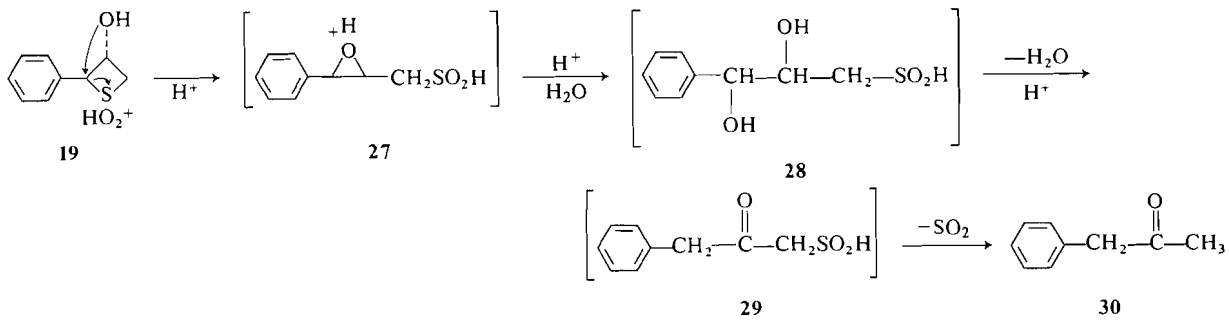
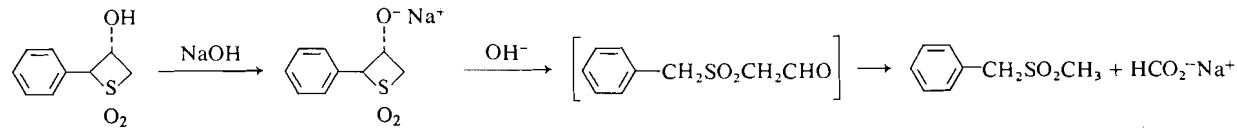
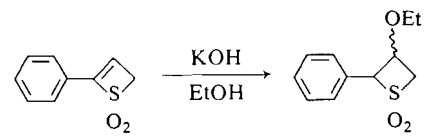


SCHEME 6. Proposed mechanism for the acid catalyzed desulfonation of 3-hydroxy-2-phenylthietane 1,1-dioxide (**19**)

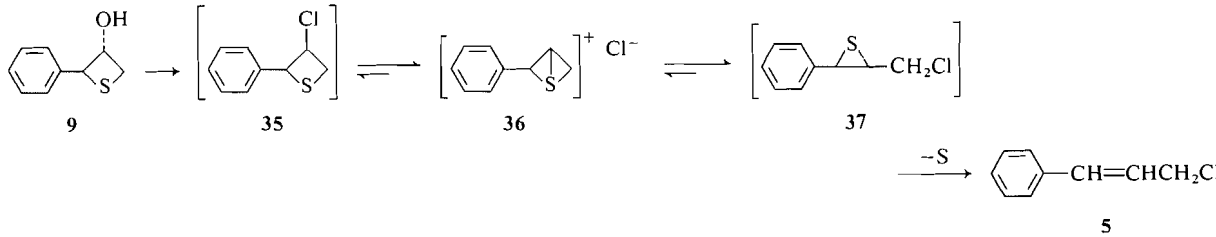


(*A*) 3-Hydroxy-2-phenylthietane 1,1-dioxide (**19**)



(*B*) 2-Phenylthiete 1,1-dioxide (**23**)

SCHEME 7. Effect of base on thietane 1,1-dioxides



SCHEME 8. Proposed route of desulfurization of 3-hydroxy-2-phenylthietane (**9**)

isolation of polymeric material. Cyanuric chloride has been reported as a convenient chlorinating reagent for alcohols, possessing the advantage that it requires no added base (6). When **9** was treated with cyanuric chloride, again **5** and polymer were obtained. Since the treatment of 3-chlorothietane with triphenylphosphine results in desulfurization and is thought to occur via a sulfonium ion to allyl chloride (33), the desulfurization of **9** may proceed through a similar pathway (Scheme 8). Thus chlorination of **9** results in the rearrangement of **35** through the sulfonium ion **36** to 3-chloromethyl-2-phenylthiirane (**37**). Aromatically substituted thiiranes readily lose elemental sulfur to give the corresponding olefin (12), and thus would explain the isolation of **5**. Several other attempts have been made to displace the —OH in **9** including the use of a crude benzylsulfonate ester and all have proved unsuccessful.

Experimental

Melting points were determined using a Thomas-Hoover capillary melting point apparatus. All melting and boiling points are reported uncorrected. Infrared spectra were recorded on a Beckman IR-10 spectrophotometer, the nmr spectra on a Varian A-60 spectrophotometer, and ms spectra on a Varian MAT-111 GC/MS. The concentrations of the nmr solutions were approximately 10% and trimethylsilane served as the internal standard. Gas–liquid chromatography was carried out using a MicroTek gas chromatograph model MT-200 equipped with a flame ionization detector and a Disc Integrator model 222. Preparative glc was carried out with a Beckman model GC-2 gas chromatograph equipped with a

thermoconductivity detector. Microanalyses were performed by Alfred Bernhardt, Microanalytisches Laboratorium, West Germany.

trans-*3-Chloro-1-phenylpropylene Oxide-1,2 (7)*

Freshly distilled 3-chloropropenylbenzene (**5**) (60.84 g, 0.4 mol) (Aldrich) was added to a 500 ml ether solution of monoperphthalic acid (105 g, 0.58 mol) (34).[2] The solution was filtered and washed with 150 ml portions of saturated Na_2CO_3 solution until the washings remained basic. The ether portion was washed with 100 ml of H_2O, dried, and concentrated under vacuum. The resulting yellow oil was vacuum distilled with the aid of Vigreaux stillhead to give 47 g (70% yield) of a colourless liquid: bp 69°C (0.5 Torr) (lit. (35) bp 67°C, 0.3 Torr); ir (neat): 890, 940, 1275 cm^{-1} (epoxide); nmr ($CDCl_3$) δ: 3.22 (dt, 1, J = 2, 5 Hz, CH), 3.64 (d, 2, J = 5 Hz, CH_2Cl), 3.77 (d, 1, J = 2 Hz, ArCH), and 7.30 (m, 5, *Ar*).

3-Hydroxy-2-phenylthietane (9)

Sodium metal (6.13 g, 0.266 g-at.) was added in small fragments to 250 ml of absolute EtOH. When the sodium had completely reacted, the solution was cooled to 0–5°C and saturated with H_2S (Matheson) by bubbling the H_2S through the cooled solution for 1 h. After the 3-chloro-1-phenylpropylene oxide-1,2 (7) (22.27 g, 0.132 mol) was added dropwise over a period of 1 h the H_2S was shut off. A white precipitate began to form almost immediately. The reaction was stirred at 0–5°C for 12 h, filtered, and concentrated under vacuum at room temperature to approximately $\frac{1}{4}$ the original volume, diluted with 200 ml of H_2O, and extracted with 3 × 150 ml of $CHCl_3$. The $CHCl_3$ extracts were pooled, washed with 150 ml of H_2O, dried, and concentrated under vacuum. The yellow oil which remained was solidified by scratching with a glass rod. This solid residue was extracted with successive portions of hot hexane leaving a yellow hexane insoluble gum in the flask. Upon cooling the combined fractions, 13.77 g (62.5% yield) of white needle-like crystals precipitated, mp 52–54°C (56.5–57.5°C upon further recrystallization from hexane); ir (KBr): 1065, 3220, 3310 cm^{-1} (alcohol); nmr ($CDCl_3$) δ: 2.68 (s, 1, OH), 3.17 (dd, 2, J = 1.5, 6 Hz, SCH_2), 4.62 (m, 2, ArCHCH-OH), 7.34 (m, 5, *Ar*); ms *m/e*: 166 (molecular ion), 122 ($(C_6H_5CHS)^+$ base peak), 121 ($(C_6H_5CS)^+$), 91 ($(C_7H_7)^+$), 77 ($(C_6H_5)^+$). *Anal.* calcd. for $C_9H_{10}OS$ (166.3): C 65.02, H 6.06, S 19.29; found: C 64.86, H 5.92, S 19.19.

If the crystals were left at room temperature in contact with the atmosphere, the crystals completely decomposed into a yellow gum within a few days. Storage in a tightly capped container at −15°C under N_2 showed no detectable decomposition after 1 year.

3-Chloro-2-hydroxy-2-phenylpropanethiol (13)

A solution of NaOH (4.8 g, 0.12 mol) in 150 ml of H_2O at 0–5°C was saturated with H_2S. After the dropwise addition of 3-chloro-2-phenylpropylene oxide-1,2 (**12**) (10 g, 0.06 mol) (36), the H_2S was shut off and the reaction mixture was stirred at room temperature for 2 h, then extracted with 3 × 50 ml of ether. The pooled ether extracts were washed with 50 ml of H_2O, dried, and concentrated under vacuum. The residual oil was vacuum distilled and the fraction boiling at 80–85°C (0.05 Torr) was collected. Redistillation through a Vigreaux stillhead gave 8.0 g (65% yield) of a colourless liquid, bp 85°C (0.05 Torr); n_D^{20} 1.5851; ir (neat): 2560 (thiol), 3500 cm^{-1} (alcohol). *Anal.* calcd. for $C_9H_{11}ClOS$ (202.7): C 53.32, H 5.47; found: C 53.57, H 5.53.

3-Hydroxy-3-phenylthietane (14)

(*a*) Using the same procedure as described for (**9**), a solution of sodium (2.76 g, 0.12 g-at.) and H_2S in 200 ml of absolute EtOH was reacted with 3-chloro-2-phenylpropylene oxide-1,2 (**12**) (10 g, 0.06 mol). In this case, the reaction was refluxed for 3 h, cooled, and worked up as previously described for **9**. The residual oil was vacuum distilled to give 7.2 g (36% yield) of a liquid; bp 90–95°C (0.1 Torr). Redistillation gave a yellow liquid, bp 91–93°C (0.1 Torr); n_D^{20} 1.6048 (lit. (7) bp 110–112°C, (0.7 Torr); n_D^{23} 1.6039); ir: 3380 cm^{-1} (alcohol); nmr (CCl_4) δ: 3.52 (s, 4, CH_2SCH_2), 3.75 (s, 1, OH), 7.5 (m, 5, *Ar*). *Anal.* calcd. for $C_9H_{10}OS$ (166.2): C 65.02, H 6.06, S 19.29; found: C 64.86, H 5.96, S 18.96.

(*b*) The reaction was also carried out using aqueous NaOH or $Ba(OH_2)$ as described in the preparation of **13**, except heating at 80°C for 1 h is required. Yields of **14** are 30% or less. (At 50°C or less **13** is the main product.)

(*c*) A solution of sodium (1.5 g, 0.065 g-at.) in 75 ml of absolute EtOH was added dropwise to **13** (8.8 g, 0.043 mol) in 100 ml of absolute EtOH at reflux temperatures. The reaction mixture was refluxed for 4 h, cooled, and worked up as previously described for **9**. The yield of crude thietane **14** was 35%.

4-Phenyl-3-buten-1-ol (4)

Finely powdered $LiAlH_4$ (5.7 g, 0.15 mol) was stirred in 300 ml of Na dried ether for 24 h at room temperature and filtered in an N_2 atmosphere to give a translucent solution. The $LiAlH_4$ was added to a stirred solution of ethyl-4-phenyl-3-butenoate (**3**) (37)[3] (48.3 g, 0.254 mol) in 300 ml of Na dried ether at such a rate to maintain a gentle reflux. The mixture was refluxed for a further 2 h, cooled, and excess $LiAlH_4$ destroyed using 5.7 ml of H_2O, 5.7 ml of 20% NaOH, and 18.1 ml of H_2O. After filtration of the mixture, the ether fraction was separated, dried, and concentrated under vacuum. The residual yellow oil was vacuum distilled with a Vigreaux stillhead to give 28.46 g (77% yield) of a colourless liquid, bp 105–108°C (0.8 Torr) (lit. (4) 137–138°C (12 Torr); ir (neat): 970 (olefin), 1050, 3340 cm^{-1} (alcohol); nmr ($CDCl_3$) δ: 2.05 (s, 1, OH), 2.39 (q, 2, J = 6 Hz, $CHCH_2$), 3.67 (t, 2, J = 6 Hz, CH_2OH), 6.16 (dt, 1, J = 16, 6 Hz, $CHCH_2$), 6.48 (d, 1, J = 16 Hz, ArCH), 7.26 (m, 5, *Ar*).

1-Chloro-4-phenyl-3-butene (6)

Finely powdered cyanuric chloride (20 g, 0.108 mol) (Aldrich) was added in small portions to **4** (28.46 g, 0.192 mol) at 100°C (oil bath temperature). The suspension was heated for another 2 h, cooled, and filtered. The yellow filtrate was vacuum distilled to give 23 g (72% yield) of a clear colourless fraction, bp 98–104°C (0.65 Torr); ir (neat): 975, 3035 cm^{-1} (olefin); nmr ($CDCl_3$) δ: 2.67 (q, 2, J = 7 Hz, $CHCH_2$), 3.62 (t, 2, J = 7 Hz, CH_2Cl), 6.24 (dt, 1, J = 7, 16 Hz, $CHCH_2$), 6.54 (d, 1, J = 16 Hz, ArCH), 7.32 (m, 5, *Ar*).

1-Chloro-4-phenylbutylene Oxide-3,4 (8)

Using the same conditions as in the preparation of **7**, **6** (23 g, 0.138 mol) was reacted with monoperphthalic acid (34.6 g, 0.19 mol). Fractional distillation of the crude oil gave 2 fractions: (*a*) bp 96–105°C (0.8 Torr), (*b*) bp 105–108°C (0.8 Torr). Gas–liquid chromatographic analysis on a Chrom-

[2]The solution was prepared and standardized as described and concentrated to approximately 500 ml prior to use.

[3]Under the conditions of the Wittig reaction the double bond shifts from the 2 to the 3 position.

port-SE 30 (5%) column, with the oven temperature at 125°C and N_2 flow rate of 45 ml/min showed that (*a*) contained two components of R_t = 4 min (30%) and 6 min (60%), and (*b*) contained 2 components of R_t = 6 min (20%) and 11 min (80%). Preparative glc of (*a*) on a Carbowax column gave the material with the 6 min R_t in 90% purity. Fractional distillation of (*b*) gave pure samples of the materials with R_t = 6 min and 11 min. The R_t = 6 min was taken to be *cis*-**8**, bp 85–87°C (0.45 min); ir (neat): 1040, 1315 cm^{-1} (epoxide); nmr ($CDCl_3$) δ: 1.76 (dt, 2, J = 2, 7 Hz, $CHCH_2$), 2.60 (m, 2, $CHCH$), 3.54 (disturbed t, 2, J = 7 Hz, CH_2Cl), 7.2 (m, 5, *Ar*). The R_t = 11 min was taken to be *trans*-**8**: ir (neat) 895, 950, 1040, 1300 cm^{-1} (epoxide); nmr ($CDCl_3$) δ: 2.12 (m, 2, $CHCH_2$), 3.09 (dt, 1, J = 2.5, 5 Hz, $CHCH_2$), 3.66 (t, 2, J = 5.5 Hz, CH_2Cl), 3.68 (obscured d, 1, J = 2.5 Hz, ArC*H*), 7.26 (m, 5, *Ar*). Fractions (*a*) and (*b*) represented 21.67 g (86% yield) of **8**. In subsequent reactions the crude product upon glc analysis was indicated to be 70% *trans*-**8**.

*3-Hydroxy-2-phenylthiolane (**10**)*

The procedure was the same as outlined for **9**, using 5 g (27.4 mmol) of *trans*-**8**. The residual dark oil was vacuum distilled to give 2.6 g of a colourless liquid, bp 100–114°C (0.1 Torr); ir (neat): 1065, 3400 cm^{-1} (alcohol); nmr ($CDCl_3$) δ: 2.10 (m, 2, $CHCH_2$), 2.36 (s, 1, O*H*), 3.02 (m, 2, SCH_2), 4.32 (m, 2, ArC*H*CH), 7.35 (m, 5, *Ar*).

*3-Hydroxy-2-phenylthietane 1,1-Dioxide (**19**)*

A solution of 3-hydroxy-2-phenylthietane (**9**) (5 g, 0.03 mol) in 50 ml of $CHCl_3$ was added dropwise to a stirred solution of *m*-chloroperbenzoic acid (16.25 g of 80% purity, 0.08 mol) in 150 ml of $CHCl_3$. The resulting pale yellow solution was stirred at room temperature for a further 10 h. The precipitated *m*-chlorobenzoic acid was removed by suction filtration and the filtrate was concentrated under vacuum. The resulting residue was triturated with 3 × 150 ml of H_2O. The H_2O insoluble material was removed by suction filtration. The filtrates were pooled and the H_2O was removed under vacuum to give 5.1 g (85% yield) of a white solid: mp 75–77°C. Recrystallization from ether–petroleum ether (30–60°C) gave 4.39 g (71.5% yield) of white plate-like crystals, mp 76.2–78°C; ir (KBr): 1070, 3500 (alcohol), 1140, 1185, 1285 cm^{-1} (sulfone); nmr ($CDCl_3$), δ: 3.35 (br s, 1, OH), 4.05 (dd, 2, J = 2.5, 7 Hz, SCH_2), 4.70 (m, 1, C*H*OH), 5.30 (d, 1, J = 6.5 Hz, ArC*H*), 7.35 (m, 5, *Ar*); ms *m/e*: 198 (weak molecular ion), 134 ($(C_6H_5CHCHOHCH_2)^+$), 116 ($(C_6H_5CHCHCH)^+$), 105 ($(C_6H_5CO)^+$), 91 ($(C_7H_7)^+$ base peak), 77 ($(C_6H_5)^+$). *Anal.* calcd. for $C_9H_{10}O_3S$ (198.3): C 54.53, H 5.08, S 16.17; found: C 54.62, H 4.96, S 16.29.

*3-Hydroxy-3-phenylthietane 1,1-Dioxide (**25**)*

To a solution of 3-hydroxy-3-phenylthietane (**14**) (12.2 g, 0.07 mol) in 75 ml of 50:50 glacial AcOH–Ac_2O cooled to 0°C was added 30% H_2O_2 (20.67 g) dropwise. The reaction was then stirred at room temperature for 12 h. A small amount of Pd black was added to destroy excess peroxide. The mixture was filtered and the filtrate concentrated. Addition of H_2O to the residual oil caused the precipitation of a buff-coloured solid. The solid was collected by filtration and dried to give 12.5 g (86% yield) of crude product. Recrystallization from EtOH–hexane gave white crystals; mp 105°C; ir (KBr): 1150, 1305 (sulfone) (with splitting at 1160, 1265), 3450 cm^{-1} (alcohol). *Anal.* calcd. for $C_9H_{10}O_3S$ (198.3): C 54.53, H 5.08; found: C 54.38, H 4.99.

*3-Hydroxy-2-phenylthiolane 1,1-Dioxide (**20**)*

The procedure was the same as outlined for **19**. A solution of 3-hydroxy-2-phenylthiolane (**10**) (5 g, 27.8 mmol) in 50 ml of $CHCl_3$ was reacted with *m*-chloroperbenzoic acid (16.25 g of 85% pure, 80 mmol). After filtration of the reaction mixture, it was extracted with saturated Na_2CO_3 solution until the aqueous washings were basic. The organic layer was washed with 25 ml of H_2O, dried, and concentrated under vacuum. The resulting gummy residue was recrystallized from hexane–ether to give 1.61 g (27.3% yield) of white crystals, mp 95–96.5°C; ir (KBr): 1075, 3410 (alcohol), 1130, 1305 cm^{-1} (sulfone); nmr ($CDCl_3$) δ: 1.8–2.9 (m, 2, CH_2CH), 2.38 (s, 1, O*H*) 3.25 (m, 2, SCH_2), 4.00 (d, 1, J = 9 Hz, ArC*H*), 4.58 (dt, 1, J = 6, 9 Hz, C*H*OH), 7.39 (m, 5, *Ar*). *Anal.* calcd. for $C_{10}H_{12}O_3S$ (212.3): C 56.58, H 5.70, S 15.11; found: C 56.65, H 5.70, S 14.95.

*2-Phenylthiete 1,1-Dioxide (**23**)*

Et_3N (240 mg, 2.42 mmol) was added dropwise to a solution of **19** (390 mg, 1.97 mmol) and benzylsulfonyl chloride (410 mg, 2.16 mmol) in 30 ml of freshly distilled THF. The reaction was stirred at room temperature for 45 min, filtered, and concentrated under vacuum. The residue was dissolved in 50 ml of CH_2Cl_2 and washed with 3 × 25 ml of H_2O to remove any residual amount of $Et_3N{\cdot}HCl$. The organic fraction was dried and concentrated under vacuum to give 380 mg (60%) of a light brown scaly residue of **21**, mp 115–122°C dec.; ir (KBr): 1145, 1175, 1320 (sulfone), 1200, 1360 cm^{-1} (sulfonate); ms (no molecular ion) *m/e*: 116 ($(C_6H_5CCHCH_2)^+$), 115 ($(C_6H_5CCCH_2)^+$), 105 ($(C_6H_5CO)^+$), 91 ($(C_7H_7)^+$ base peak).

A solution of Et_3N (1.01 g, 10 mmol) in 3 ml of benzene was added to a solution of **21** (380 mg, 1.18 mmol) in 15 ml of benzene. The reaction was stirred at room temperature for 45 min, filtered, and concentrated under vacuum. The residue was dissolved in 50 ml of ether and washed with 3 × 25 ml of H_2O. The ether layer was dried, and concentrated under vacuum to give a white solid. The solid was recrystallized from EtOH–hexane to give 95 mg (45% yield) of white plate-like crystals, mp 94–95°C (this was identical to a sample of **23** prepared by an alternate method (1)); ir (KBr): 1140, 1180, 1300, 1310 cm^{-1} (sulfone); nmr ($CDCl_3$) δ: 4.52 (d, 2, J = 2 Hz, SCH_2), 7.02 (t, 1, J = 2 Hz, CC*H*), 7.46 (m, 5, *Ar*), ms *m/e*: 180 (weak molecular ion), 116 ($(C_6H_5CCHCH_2)^+$), 115 ($(C_6H_5CCCH_2)^+$ base peak), 105 ($(C_6H_5CO^+$), 89 ($(SO_2CCH)^+$), 77 ($(C_6H_5)^+$).

*2-Phenylthiolene 1,1-Dioxide (**24**)*

The same procedure as outlined for **23** was used starting with 1 g (4.72 mmol) of **20**. This gave 1.25 g (75% yield) of 1,1-dioxy-2-phenyl-3-thiolanyl benzylsulfonate (**22**) as a waxy residue, mp 120–130°C (dec.); ir (KBr): 1130, 1290, 1320 (sulfone), 1183, 1365 cm^{-1} (sulfonate). Treatment of **22** with Et_3N gave a solid residue which was recrystallized from benzene – petroleum ether (30–60°C) to give 0.2 g (46% yield) of **24** as white crystals, mp 113.5–116°C; ir (KBr): 1130, 1200, 1280 cm^{-1} (sulfone); nmr ($CDCl_3$) δ: 2.88 (m, 2, $CHCH_2$), 3.37 (m, 2, SCH_2), 6.70 (t, 1, J = 2.5 Hz, CC*H*), 7.47 (m, 5, *Ar*). *Anal.* calcd. for $C_{10}H_{10}O_2S$ (194.3): C 61.83, H 5.19, S 16.51; found: C 62.00, H 5.08, S 16.48.

Attempted Synthesis of 3-Formamido-3-phenylthietane 1,1-Dioxide (Ritter Reaction)

This reaction was carried out in a fume hood and the apparatus was connected to a 10% NaOH solution trap. NaCN (1.47 g, 0.03 mol) was added in small portions to 15 ml of glacial AcOH at 0°C. A cooled solution of concentrated H_2SO_4 (5.88 g, 0.06 equiv.) in 5 ml of glacial AcOH was then added dropwise, while maintaining the temperature at 20°C. After **25** (5 g, 0.025 mol) was added the reaction was heated at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

50°C for 1 h, then stirred at room temperature overnight. The reaction mixture was poured into 50 ml of ice-cold H_2O and the resulting precipitate was collected and dried. Neutralization of the filtrate with K_2CO_3 resulted in the further precipitation of solid (1 g), which was collected, dried, and recrystallized from xylene and identified as the starting material, **25**. Boiling the initial precipitate in hexane and removal of the insoluble portion by filtration and concentration of the filtrate gave a few milligrams of white solid, mp over 25°C range: ir (KBr): 1755 (carbonyl), 1125, 1315 cm^{-1} (sulfone). Attempts to purify this compound for identification were unsuccessful.

The hexane insoluble portion was decolourized with charcoal in hot EtOH and cooled to give 1 g (22% yield) of 3-phenylthiete 1,1-dioxide **26** as colourless needles, mp 147°C (lit. (23) 145–147°C).

*Treatment of 3-Hydroxy-2-phenylthietane 1,1-Dioxide (**19**) with Acid*

A solution of **19** (1.5 g, 7.6 mmol) in 10 ml of 85% H_3PO_4 (or $AcOH–H_2SO_4$) was refluxed for 25 min and cooled. The dark solution was extracted with $CHCl_3$, and the pooled $CHCl_3$ extracts were dried and concentrated under vacuum. The residual oil was vacuum distilled. No accurate bp was recorded since the product was forced over with a flame (approximately 101°C, 13 Torr). The material isolated (0.5 g, 49.5%) was identified as benzyl methyl ketone (**30**), by virtue of identical ir and nmr spectra given for **30** in Sadtler (38). A crude 2,4-DNPH derivative had a mp of 142–140°C (lit. (39) 153°C, (40) 142–144°C). A methylene chloride extract of the reaction mixture when run on the gc/ms (70°C for 1 min, program at 10°C/min) gave one major peak, the mass spectrum of which showed *m/e* 43 (100), 91 (99), 92 (69), 134 (44), 65 (43), 39 (28). The mass spectrum and retention times were identical to an authentic sample. A very minor gc peak showing *m/e* 105 in the mass spectrum as the base peak indicated some phenylvinyl ketone present. Refluxing a sample of **19** in xylene for 24 h did not result in any detectable reaction.

*Treatment of 3-Hydroxy-2-phenylthietane 1,1-Dioxide (**19**) with Base*

A solution of **19** (0.5 g, 2.53 mmol) in 2% aqueous NaOH was refluxed for 12 h. Upon cooling a white precipitate was collected and recrystallized from EtOH–hexane to give 0.266 g (62% yield) of benzyl methyl sulfone, 124.5–126.5°C (lit. (39) 124–125.5°C); ir identical with that given in Sadtler (38); nmr ($CDCl_3$) δ: 2.76 (s, 3, CH_3), 4.25 (s, 2, CH_2), 7.48 (m, 5, *Ar*).

*3-Ethoxy-2-phenylthietane 1,1-Dioxide (**34**)*

To a solution of **23** (1 g, 5.5 mmol) in 15 ml of EtOH was added a 1 ml portion of a KOH solution (1 g KOH – 5 ml H_2O – 5 ml EtOH) to give a pale yellow solution. The solution was stirred for 1 h then let stand for 1 h, during which time a white precipitate formed. Recrystallization of the precipitate from EtOH–hexane gave fluffy white crystals, mp 107–108°C; ir (KBr): 1105, 1210, 1330 (sulfone), 1080, 1160 cm^{-1} (ethoxy ether); nmr ($CDCl_3$) δ: 1.15 (t, 3, $J = 7$ Hz, CH_3), 3.43 (q, 2, $J = 7$ Hz, OCH_2), 3.95–4.68 (m, 3, $OCHCH_2S$), 5.38 (d, 1, $J = 6$ Hz, $ArCH$), 7.41 (m, 5, *Ar*); ms (no molecular ion) *m/e*: 133 ($(C_6H_5CHCHOCH_2)^+$), 115 ($(C_6H_5CHCCH)^+$), 105 ($(C_6H_5CO)^+$ base peak), 91 ($(C_7H_7)^+$), 90 ($(C_7H_6)^+$). *Anal.* calcd. for $C_{11}H_{14}O_3S$ (226.3): C 58.38, H 6.24, S 14.17; found: C 58.61, H 6.03, S 14.22.

*Attempted Chlorination of 3 Hydroxy-2-phenylthietane (**9**); Isolation of 3-Chloropropenylbenzene (**5**)*

Freshly distilled $SOCl_2$ (3.72 g, 0.0316 mol) in 10 ml of $CHCl_3$ was added dropwise to a solution of **9** (5 g, 0.0316 mol) in 15 ml of $CHCl_3$. After stirring vigorously for 20 h, concentration of the mixture left a thick orange oil. Vacuum distillation of this oil gave 2.2 g of a pale yellow liquid, bp 55–60°C (0.7 Torr). The ir and nmr spectra were superimposable with that of an authentic sample (Aldrich). This represented 48% conversion of **9** to **5**. Similar results were obtained using cyanuric chloride (for procedure see ref. 6).

The cyclopentadienide anion and tropylium cation analogs of triptycene

DOUGLAS N. BUTLER AND INDRANIL GUPTA
Chemistry Department, York University, Downsview, Ont., Canada M3J 1P3

Received July 18, 1977

DOUGLAS N. BUTLER and INDRANIL GUPTA. Can. J. Chem. **56**, 80 (1978).

The cyclopentadienide analog of triptycene **1** and the tropylium cation analog of triptycene **2** have been synthesized. Some comparative spectroscopic data of these ions relative to triptycene are discussed.

DOUGLAS N. BUTLER et INDRANIL GUPTA. Can. J. Chem. **56**, 80 (1978).

On a synthétisé l'ion cyclopentadiénure, analogue du triptycène **1**, et le cation tropylium, analogue du triptycène **2**. On discute de quelques données spectroscopiques comparées de ces ions par rapport à celles observées pour du triptycène.

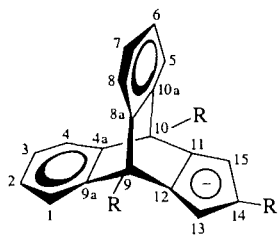
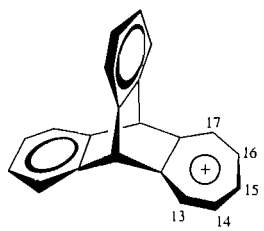
For personal use only.

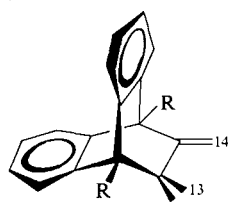
The question of intramolecular orbital interaction of the rigid and spatially proximal aromatic rings of triptycene has prompted us to synthesize the triptycene-cyclopentadienide anion analog ('triptycepide') **1***a* and the related tropylium cation analog ('triptopylium') **2**. Shortly after we had succeeded in this goal, the synthesis of **2** was published by Murata and Nakazawa (1), however the simplicity and good yields of our route recommended its description.



1*a* (R = H)
1*b* (R = D)



2



3*a* (R = H)
3*b* (R = D)

The Anion 1

Addition of dichlorocarbene (from phenylbromodichloromethylmercury) to 2,3-dimethylenedibenzobicyclo[2,2,2]octa-5,7-diene **3***a* (2) afforded the adduct **4***a*[1] as the major product together with the bis-adduct **5**. The four sharp singlets in the δ 4–6 ppm region of the proton magnetic resonance spectrum of **4***a* were assigned by a combination of specific deuterium labelling and nuclear Overhauser enhancement (nOe) techniques. Preparation of **4***b* from 9,10-anthracene-d_2 (3) removed the resonances at δ 4.90 and 4.27. The nOe enhancements of the integrated intensities of the four proton singlets are given in Table 1.

Obviously, the proton resonance at δ 4.27 is H_D and is too remote from the other three to exhibit any nOe. The assignment of the δ 5.29 resonance to H_B follows from its large positive enhancement to both H_A (δ 4.90) and H_C (δ 4.58). The other nOe values are typical of a linear three-spin system of this geometry (4).

Following the sequence described by Skattebøl (5), treatment of the adduct **4***a* with excess methyllithium in ether led (after aqueous work-up) directly to 'triptycepene' **6***a* (^{1}Hmr spectrum Fig. 1*a*). Deprotonation of **6***a* using potassium *tert*-butoxide in dimethylsulfoxide (DMSO) instantaneously formed a dark solution of the anion **1***a* (^{1}Hmr spectrum Fig. 1*b*). Addition of water to this basic solution precipitated **6***a* whereas the use of D_2O led to **6***b*. This type of site specificity of anion protonation has also been observed in the anion **7** leading exclusively to **8** (6).

In the present case, repetition of the deprotonation experiment in DMSO-d_6 rapidly removed the vicinal coupling to the vinylic proton at δ 5.32 ppm

TABLE 1. Nuclear Overhauser enhancements (%) of **4***a*

Resonance irradiated (δ)	Resonance observed (δ)			
	5.29	4.90	4.58	4.27
5.29	—	+16	+35	0
4.90	+14	—	−2	0
4.58	+32	−7	—	0
4.27	0	0	0	—

[1]All new compounds have been correctly analyzed and their spectroscopic data are in accordance with the structures shown.

6*c* ($R_{1,2}$ = D)

via D–H solvent exchange at the central site C_{14} in the presence of the strong base (see insert Fig. 1*b*). Quenching at this time with D_2O afforded **6***c*. The remaining vinylic proton ($C_{13,15}$) of **1***b* very slowly exchanged with time being about 80% exchanged after 4 weeks at room temperature under the particular conditions of this experiment.

A simple experiment to test possible [1,5] sigmatropic shifts in **6** was conducted by heating a solution ($CDCl_3$) of **6***c* at 100°C for 8 h. No evidence for diminution of the intensity of the remaining vinylic

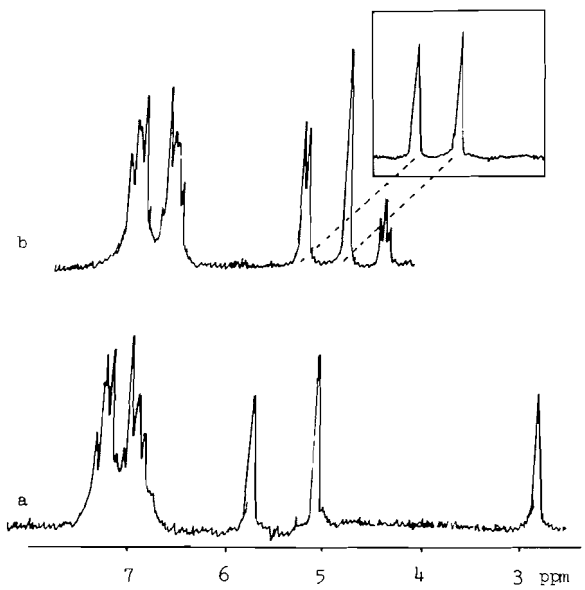

FIG. 1. (*a*) ^{1}Hmr spectrum of **3***a* in DMSO-d_6. (*b*) ^{1}Hmr spectrum of **1***a* in DMSO (inset in DMSO-d_6).

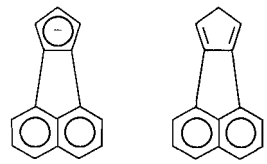
C—H resonance was found. From these results in both the anion **1** and its conjugate acid **6**, incyclic double bond character in the cyclopentadieno two-carbon arm of the dibenzobicyclo[2,2,2]octadiene skeleton appears to be thermodynamically unfavourable. It is worth noting also that the diene **6** shows no tendency to dimerize although Diels–Alder adducts with dimethyl acetylenedicarboxylate and maleic anhydride were readily prepared (compare **8** (6)).

The Cation 2

Our route to the 'triptopylium' cation **2** likewise began with the diene **3** (2). The Diels–Alder adduct **9** with cyclopropene (7) was directly dehydrogenated to the cation **2** using 2,3-dichloro-5,6-dicyanobenzoquinone and converted into the tetrafluoroborate salt (1) with tetrafluoroboric acid. Treatment of the cation **2** (as its perchlorate salt) with sodium hydride suspension in dioxane led to a complex



7 **8**

hydrocarbon mixture from which a low yield of the cycloheptatriene **10** could be isolated and shown to be identical to the intermediate described by Nakazawa and Murata (1).

Of relevance to proposed synthetic exercises directed to the 'bi-polar triptycene' **11** ⇄ **12**, the following competitive Diels–Alder reactions also bear upon the relative reactivity of buta-1,3-diene vs. cyclopentadiene toward electron-rich and electron-deficient dienophiles. With the latter, cyclopentadiene is reported to be 1.35×10^3 times more reactive than buta-1,3-diene (8). The two dienes **3** and **6** represent equally substituted examples of the above parent systems; however, the locked *cisoid* form of **3** removes the rotameric uncertainty component of the reported rate difference. In competitive kinetic experiments using dimethyl acetylenedicarboxylate as the dienophile, the cyclopentadiene **6** reacted exclusively (at least as revealed by ^{1}Hmr spectroscopic estimation). Conversely, in competition for the electron-rich dienophile cyclopropene, only **3** could be discerned to have reacted. As mentioned, this impressive differential reactivity provides good augury for a potential synthesis of **11** ⇄ **12** via routes parallel to those described herein.

Comparative Spectroscopic Data

The bridged cyclopentadiene **6** and its conjugate

9 10

11 12

anion **1***a* (Li^+ salt) showed no discernable difference in their uv spectra in dry tetrahydrofuran. The uv maximum absorptions of **1** (Table 2) show a small hypsochromic shift relative to those of triptycene **13** (9). These spectra should be compared with that of the cation **2** where a broad charge-transfer band in the 300–450 nm region has been observed (1).

The ^1H and ^{13}C chemical shifts (referenced to TMS) and assignments pertinent to these systems are shown in Fig. 2 together with the $^1J_{^{13}C-H}$ (Hz) coupling constants. Chemical shift corrections between the solvents employed (DMSO for **1***a*, CS_2 for **13** (10), CD_3CN for **2**) have not been applied but they would not be expected to alter the general trends revealed by the data. For the ^1H shifts, a respective shielding for **1***a* and deshielding for **2** relative to triptycene **13** is observed for all the resonances, with the magnitude of these being relatively greater in the cation than in the anion. In both cases, the clear effect of the electric charge is manifest in the chemical shifts of the protons attached to the carbon atoms in the charge bearing rings and these should be compared with the values for the parent six-π aromatic systems (11) (see Fig. 2). The strong shielding of C_{14} in **1***a* is consistent with the protonation results discussed above. For the cation, hydride attack is observed at $C_{14,16}$ for the most deshielded of the perimeter carbon atoms, though this may be simply fortuitous. The published assignments for triptycene (10) suggested those for **1***a* and **2**. These were confirmed by specific ^1H frequency off-resonance decoupling experiments.[2]

For clarity, the ^{13}C shifts and assignments relevant to this discussion are reproduced graphically in Fig. 3 with connections between C atoms having a common structural relationship. The ^{13}C resonances, whilst again generally reflecting the expected direct field effects throughout the systems involved, do show two interesting features. Firstly, the bridgehead resonances ($C_{9,10}$) do not show a monotonic response to the adjacent charged ring relative to **13**. This may be a consequence of the geometric changes associated with the accommodation of the respective five, six, and seven-membered rings in these three systems. Secondly, the four fully substituted carbon atoms ($C_{4a,8a,9a,10a}$) of the uncharged aromatic rings reveal shifts *opposite* to the general trends. We interpret this result as a field-induced π-polarization effect of the type discussed by Reynolds and Hamar (13).

In conclusion it may be noted that the routes to bridged cyclopentadienide anions and tropylium cations described above should be applicable to many of the exocyclic dienes we have previously synthesized (2).

Experimental

All melting points are uncorrected. The ir spectra were taken on a Unicam SP1000 spectrophotometer as Nujol mulls or KBr discs. The ^1Hmr spectra were taken on either Varian EM360 or HA100 instruments in the solvents indicated. The cmr spectra were obtained on a Varian CFT20 instrument in the solvents indicated. The uv spectra were run on a Unicam SP800A spectrophotometer. Mass spectra were taken at 70 eV using a Hitachi-Perkin Elmer RMU-6E instrument. Microanalyses were obtained from A. B. Gygli, Toronto.

Dichlorocarbene Adduct ***4***

Phenylbromodichloromethylmercury (14) 4.40 g (0.01 mol) was added to a solution of 11,12-dimethylene-9,10-dihydro-9,10-ethanoanthracene **3***a* (2) 2.30 g (0.01 mol) in dry benzene (10 ml). This mixture was subject to reflux and magnetic stirring for 6 h then cooled; the precipitated phenylmercuric bromide was filtered off with the aid of a pad of Celite and the filtrate passed through a column of alumina (1 × 10 cm Woelm, grade 1) using an additional 150 ml of benzene to wash the column. After solvent evaporation under vacuum the residue was recrystallized from CCl_4 thus providing the adduct **4***a*, 2.57 g (82%), mp 174°C; ^1Hmr ($CDCl_3$) δ_{Me_4Si}: 7.07–7.53 (m, 8H), 5.29 (s, 1H), 4.90 (s, 1H), 4.58 (s, 1H), 4.27 (s, 1H), 1.76 (d, J = 8 Hz, 1H) and 1.36 (d, J = 8 Hz, 1H) ppm; *m/e* M^+ 312, $(M^+ + 2)$ 314, $(M^+ + 4)$ 316 (relative intensities 100:65:11), base peak 178 (anthracene). *Anal.* calcd. for $C_{19}H_{14}Cl_2$: C 72.86, H 4.50; found: C 72.71, H 4.36.

From the mother liquors of the recrystallization of the

[2]For a full discussion on the assignments of α and β carbon atoms in Diels–Alder adducts of anthracene see ref. 12.

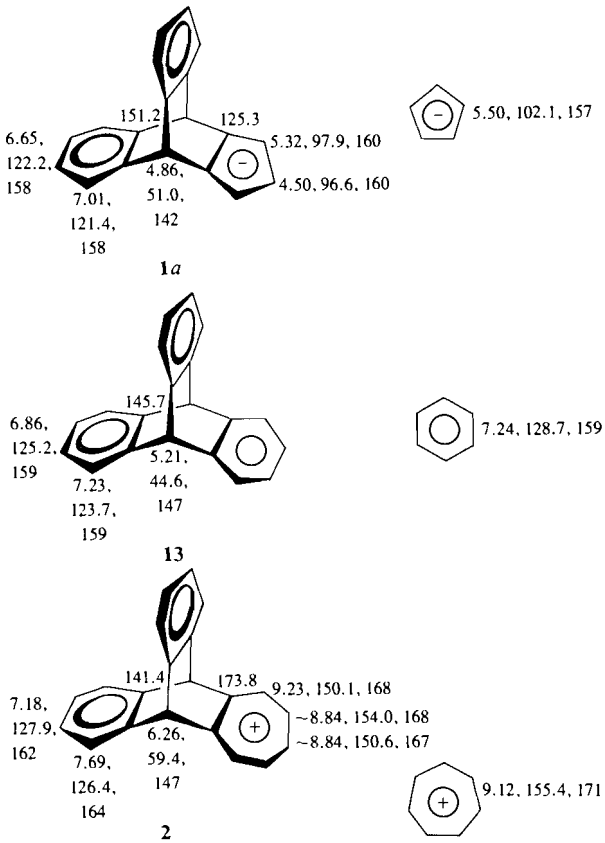

FIG. 2. Chemical shifts in ppm from TMS for ^1H and ^{13}C and coupling constants $^1J_{^{13}C-H}$ (Hz) for **1***a*, **13**, and **2**.

monoadduct **4***a* a small yield of the bis-adduct **5** was obtained, mp 201.5–202°C (ethanol); ^{1}Hmr ($CDCl_3$) δ_{Me_4Si}: 7.10–7.55 (m, 8H), 4.09 (s, 2H), 2.89 (d, J = 8 Hz, 2H) and 1.37 (d, J = 8 Hz, 2H) ppm; *m/e* M^+ 394, $(M^+ + 2)$ 396, $(M^+ + 4)$ 398, $(M^+ + 6)$ 400, and $(M^+ + 8)$ 402 (relative intensities 77:100:47:9:1), base peak 178 (anthracene). *Anal.* calcd. for $C_{20}H_{14}Cl_4$: C 60.64, H 3.56; found: C 60.53, H 3.71.

The synthesis of **3***b* from 9,10-dideuterioanthracene (3) provided the adduct **4***b* via the above method. This material did not show ^{1}Hmr signals at δ 4.90 and 4.27 ppm.

'Triptacepene' 6

To a solution of the adduct **4***a* (1.7 g) in dry ether (75 ml) was added 30 ml of 1.5 *M* methyllithium in ether and the mixture allowed to stand overnight at room temperature before it was cautiously poured over a mixture of ice and water. The organic phase was separated and the aqueous phase extracted with ether (2 × 30 ml). The combined ether phases were then dried ($MgSO_4$) and evaporated under vacuum to afford the crude product which was purified by passage in 3:1 hexane–benzene through a short column of alumina (Woelm, grade 1) and recrystallization from a large volume of ether to give **6***a*, 0.48 g (62%), mp 220°C; ^{1}Hmr ($CDCl_3$) δ_{Me_4Si}: 7.43–7.20 (m, 4H), 7.15–6.97 (m, 4H), 5.87 (t, $J \approx 1$ Hz, 2H), 5.10 (s, 2H), 2.37 (t, $J \approx 1$ Hz, 2H) ppm; ^{13}Cmr (DMSO-d_6) δ_{Me_4Si}: 148.9 (s, $C_{11,12}$), 143.8 (s, $C_{4a,8a,9a,10a}$), 125.9 (d, $C_{2,3,6,7}$), 124.1 (d, $C_{1,4,5,8}$), 118.0 (d, $C_{13,15}$), 47.8 (d, $C_{9,10}$), 43.2 (t, C_{14}) ppm; uv (THF) λ_{max} (log ε_{max}): 226 (4.58), 254 (3.72), 267 (3.59), and 275 (3.48) nm; ir (KBr): 712, 722, 763, 891, 905, 928, 971, 1024, 1150, 1190, 1249, 1354, 1371, 1457, 2951, 3001, 3070 cm^{-1}; *m/e*: M^+ 242 (base peak), 226, 215, 178, 165, 122, 120. *Anal.* calcd. for $C_{19}H_{14}$: C 94.18, H 5.82; found: C 94.30, H 5.58.

Lithium 'Triptacepide' 1a·Li$^+$

The bridged cyclopentadiene **6***a* (42 mg) was dissolved in DMSO (0.4 ml) and excess potassium *tert*-butoxide (≈60 mg) added. This produced a dark brown solution which was directly used to record the ^{1}H and ^{13}C nmr spectra (see text). Addition of water to this solution precipitated **6***a*, whilst D_2O afforded **6***b*. When DMSO-d_6 was used in a similar experiment, the resonance triplet at δ 4.50 disappeared over about 12 min with concurrent collapse of the δ 5.32 doublet to a sharp singlet (see Fig. 1).

At this point, addition of water produced **6***b* whilst D_2O gave **6***c*. After 4 weeks at ambient temperature, the basic DMSO-d_6 solution exhibited a decrease in the δ 5.32 signal to a value about 20% of its original integrated intensity. The uv spectrum was obtained by adding 1 drop of *n*-BuLi (1.2 *M* in hexane) to a solution of **6***a* in dry THF.

Cyclopropene Adduct 9

During 4 h, cyclopropene gas generated by the dropwise

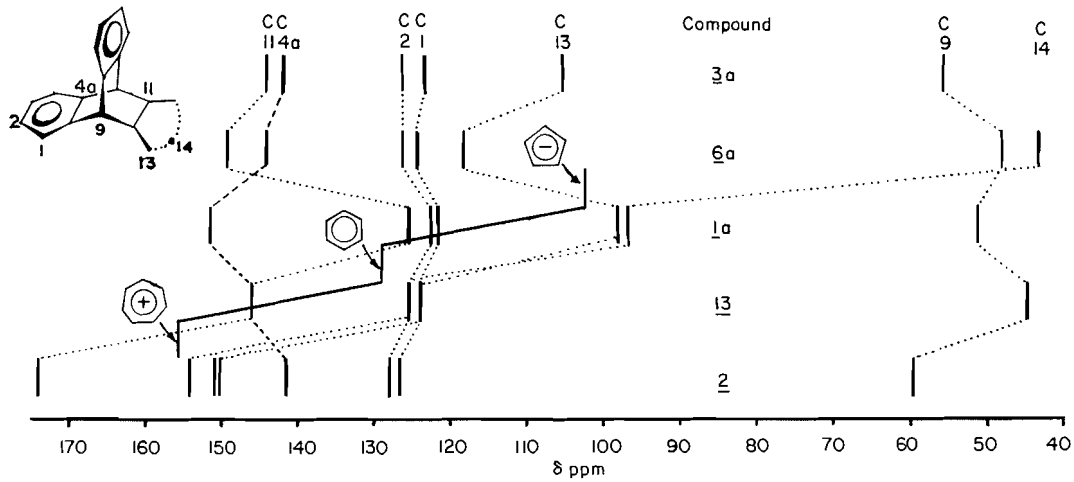

FIG. 3. ^{13}C chemical shifts and assignments for compounds **3***a*, **6***a*, **1***a*, **13**, and **2**.

addition of a solution of allyl chloride (30 g) in mineral oil (150 ml) to a stirred suspension of sodamide (12 g) in mineral oil (50 ml) held at 80°C (7), was passed through a solution of the diene **3***a* (1 g) in CCl_4 (30 ml) until ^{1}Hmr spectroscopy showed the disappearance of the characteristic diene signals. The reaction residue obtained by removal of the solvent was passed in benzene through a short column (1 × 8 cm) of alumina (Woelm, grade 1). Trituration of the evaporated eluate with methanol produced a solid which was recrystallized from ether to afford the adduct **9**, 504 mg (43%), mp 145°C. The mother liquors of this recrystallization were subject to preparative tlc on silica plates developed in hexane–acetone (10:4). A further 287 mg of **9** were obtained (total yield 68%). ^{1}Hmr ($CDCl_3$) δ_{Me_4Si}: 7.37–7.03 (m, 4H), 7.01–6.67 (m, 4H), 4.60 (s, 2H), 2.57 (br. s, 4H), 1.3–0.5 (m, 4H) ppm; ir (KBr): 639, 715, 745, 766, 807, 1018, 1157, 1435, 1457, 2803, 2844, 2865, 2942, 3005 cm^{-1}; *m/e*: M^+ 270. *Anal.* calcd. for $C_{21}H_{18}$: C 93.29, H 6.71; found: C 93.43, H 6.59.

'Triptopylium' Tetrafluoroborate **2**·BF_4^-

To a magnetically stirred solution of the adduct **9** (150 mg) in CH_2Cl_2 (10 ml), DDQ (350 mg) was added and the dark mixture stirred at room temperature for 0.5 h. The CH_2Cl_2 was removed on a rotary evaporator under vacuum and the resulting red complex stirred for 0.5 h with HBF_4 (6 ml, 48%) and CH_3CN (10 ml). The white solid was filtered off and the filtrate concentrated under vacuum and cooled in ice. The yellow green salt was filtered off and recrystallized from CH_3CN and dried over KOH pellets for 14 h under vacuum to afford **2**·BF_4^-, 114 mg (58%) which slowly decomposed at 193–200°C. (See text and ref. 1 for spectroscopic data.)

Bridged Cycloheptatriene **10**

Perchloric acid (1 ml, 60%) was added to a solution of the adduct 9 (200 mg) in glacial acetic acid (8 ml). Then DDQ (400 mg) was added and the mixture stirred overnight. The precipitated solid was filtered off and water (80 ml) added to the filtrate. The crude perchlorate salt of **2** which precipitated was filtered off, dried over KOH pellets in vacuum, then added to a stirred suspension of sodium hydride (200 mg) in dry dioxan (25 ml) and the stirring continued for 3 h under N_2. After this time, the reaction mixture was carefully decomposed with ice-water, extracted with CH_2Cl_2, and the extract washed with water and dried (Na_2SO_4). On evaporation, the residue was passed through a column of alumina (Woelm, grade 1, 1 × 12 cm) in benzene. On evaporation of the eluate and recrystallization of the residue there was obtained the cycloheptatriene **10** (1) 24 mg (12%), mp 202°C. The ^{1}Hmr spectrum was the same as that reported (1); *m/e*: M^+ 268.

Competitive Diels–Alder Reactions of 3a and 6a

The diene **3***a* (23 mg, 0.10 mmol) and the cyclopentadiene **6***a* (24.2 mg, 0.10 mmol) were mixed in an nmr tube with dimethyl acetylenedicarboxylate (DMAD) (11.36 mg, 0.08 mmol) in $CDCl_3$ (0.35 ml) and held at 30°C in a thermostat for 22 h. Inspection of the ^{1}Hmr spectrum revealed no discernable signals for the diene **3***a*–DMAD adduct (15).

The above mixture of **3***a* and **6***a* in $CDCl_3$ was treated with cyclopropene gas (10) until the ^{1}Hmr signals of **3***a* disappeared. Conversely to the DMAD experiment, no signal for the **6***a*-cyclopropene adduct could be detected. In a separate experiment **6***a* in $CDCl_3$ was subjected to a large excess of cyclopropene gas but no evidence for reaction could be found.

Acknowledgments

The authors wish to thank Dr. C. E. Holloway for assistance in obtaining and assigning the ^{13}Cmr spectra and to Dr. W. F. Reynolds for helpful discussions.

Résonance magnétique nucléaire du carbone-13 de composes oxa- et azabicyclo[3.3.1]- et -[4.2.1]nonaniques

M. Barrelle, M. Apparu et C. Gey

Laboratoire de Chimie Organique, Université Scientifique et Médicale de Grenoble, B.P. 53 Centre de Tri 38041, Grenoble-Cédex, France

Reçu le 6 décembre 1976[1]

M. Barrelle, M. Apparu et C. Gey. Can. J. Chem. **56**, 85 (1978).

Les spectres de rmn du ^{13}C de 25 composés oxa- et azabicyclo[3.3.1]- et -[4.2.1]nonaniques ont été enregistrés. Les résultats obtenus pour les oxa-9 bicyclo[3.3.1]nonanes substitués en position 2 par des groupements hydroxyles ou alkyl- et phénylamino, ainsi que ceux obtenus pour des *N*-alkyl- ou *N*-phényl-aza-9 bicyclo[3.3.1]nonanols-2 apportent des informations supplémentaires, relatives aux structures de ce type déjà étudiées. Suivant le substituant des blindages et des déblindages dûs à des interactions γ et δ stériques sont notés. L'étude relative aux composés oxabicyclo[4.2.1]nonaniques substitués ou non en positions 2 ou 7 (par des groupes hydroxyles) et azabicyclo[4.2.1]nonaniques substitués en position 2 (par les mêmes groupes) apportent d'intéressants renseignements sur l'équilibre conformationnel de ces composés, dû à la flexibilité du cycle à sept chaînons. L'équilibre conformationnel pourrait être déplacé vers la forme bateau du cycle à sept chaînons pour les composés non substitués. Pour les autres composés, des conformations *gauches* sont proposées pour rendre compte des observations expérimentales, les formes chaise et bateau pures étant exclues. Deux cétones sont en outre étudiées.

M. Barrelle, M. Apparu, and C. Gey. Can. J. Chem. **56**, 85 (1978).

Carbon-13 nmr spectra have been recorded for 25 oxa- and azabicyclo[3.3.1]- and -[4.2.1]-nonanes. Results obtained for the 9-oxabicyclo[3.3.1]nonanes, 2-substituted by hydroxyl or alkyl- and phenylamino groups, as well as those obtained for the *N*-alkyl- or *N*-phenyl-9-azabicyclo[3.3.1]nonan-2-ols, provide supplementary information regarding the previously studied structures of these types. Shielding and deshielding due to γ and δ steric interactions were observed depending on the substituent. The study of the oxabicyclo[4.2.1]nonanes, substituted or not substituted in positions 2 and 7 by hydroxyl groups, and of the azabicyclo[4.2.1]-nonanes substituted in position 2 by the same group, yields interesting results on the conformational equilibria in these compounds which is caused by the flexibility of the seven-membered ring. The conformational equilibrium is displaced toward the boat form of the seven-membered ring for the unsubstituted compounds. *Gauche* conformations are proposed for the other compounds in order to account for the experimental observations; the pure chair and boat forms are excluded. Two ketones also have been studied.

[Journal translation]

Introduction

Les effets de substituants sur les déplacements chimiques en rmn du ^{13}C ont été trés étudiés et peuvent apporter d'importants renseignements d'ordre stéréochimique (1–3). En particulier les déplacements chimiques à champ fort de carbones situés en γ de groupes méthyles et éclipsés par ceux-ci sont dus à des interactions stériques (4). L'influence du groupe hydroxyle a été étudiée dans les systèmes bicycliques conformationnellement fixes (série bicyclo[2.2.1]-heptanique ou -[2.2.2]octanique, série de l'adamantane) ou peu flexibles (série bicyclo[3.2.1]octanique) (5–16). Dans des séries de décalols (17) et de stéroïdes (17, 18), l'influence du groupe OH sur les carbones en γ et en δ de ce substituant a aussi été étudiée; des effets γ de -3.3 à -7.3 ppm ont pu ainsi être mis en évidence. Ainsi dans les structures de types cités ci-dessus d'importants résultats conformationnels ont pu être obtenus.

Le passage à l'étude de systèmes conformationnellement flexibles du type bicyclo[3.3.1]nonane est plus récent, les structures ainsi étudiées possédaient en position 9 soit un carbone soit un hétéroatome (N, S, P) et étaient diversement substituées (19–23).

Pour ces composés une conformation prédominante chaise-chaise a été trouvée conformément aux études antérieures ne faisant pas intervenir la rmn du ^{13}C (24), sauf dans le cas ou un substituant en position *endo*-3 subit une interaction répulsive avec une hydrogène du carbone-7 (20, 21): on a alors une conformation chaise-bateau pour la molécule.

Les problèmes conformationnels des systèmes bicyclo[4.2.1]nonaniques n'ont pas à notre connaissance retenu beaucoup l'attention, la flexibilité du cycle à sept chaînons rendant l'étude stéréochimique plus difficile. Signalons toutefois les ré-

sultats (obtenus par calculs EFF) de Schleyer et coll. (25), sur le bicyclo[4.2.1]nonane, qui plaident en faveur d'une conformation chaise majoritaire pour le cycle à sept chaînons.

Disposant des produits oxa- et azabicyclo[3.3.1]- et -[4.2.1]nonaniques répertoriés ci-dessus, nous en avons enregistré les spectres de rmn de ^{13}C, analysé les déplacements chimiques et étudié les diverses interactions pouvant conduire à une représentation convenable des conformations, en particulier en série hétérobicyclo[4.2.1]nonanique.

Résultats et discussion

Les déplacements chimiques enregistrés pour ces composés, ainsi que les différences de déplacements chimiques entre les composés substitués et les composés parents (**1**, **8**, **10**, **13**, **18**, **21**) sont consignés dans les tableaux 2 et 4.

Composés bicyclo[3.3.1]nonaniques

*Composés non fonctionnels (**1**, **8**, **10**)*

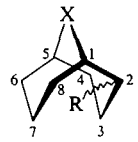
Dans une récente publication, Lambert et coll. (26) montrent que les déplacements chimiques des carbones d'hétérocycles à six chaînons sont reliés à l'électronégativité de l'hétéroatome: les carbones en α de l'hétéroatome sont déblindés fortement, ceux en β et γ sont blindés par rapport aux carbones du cyclohexane de référence (le blindage du carbone en β étant de plus fonction du substituant porté par l'hétéroatome).

Sur le tableau 1, on s'aperçoit que l'évolution des blindages des carbones α, β, γ des hétérobicyclononanes par rapport au bicyclononane se fait dans le même sens que celle des blindages des hétérocyclohexanes par rapport au cyclohexane.

Le problème du déplacement des carbones 3 et 7 à champ fort n'est pas totalement élucidé.[2] Dans les composés **1**, **8**, **10** auxquels on peut ajouter l'analogue soufré, les déplacements chimiques des carbones 3 et 7 semblent reliés plus directement aux électronégativités des hétéroatomes, la structure rigide du cycle à six chaînons dans ces composés éliminant les perturbations dues à la plus grande flexibilité d'un cycle à six chaînons isolé. Des exemples plus nombreux seraient nécessaires toutefois pour confirmer cette hypothèse.

Composés fonctionnels

Les composés substitués que nous avons étudiés pouvaient à priori présenter des effets similaires à ceux étudiés par Heumann et Kolshorn (19) pour des composés où X = C=O. Répulsion C_3—C_7 conduisant à un plus ou moins grand aplatissement de



cycle, à laquelle s'ajoute une gêne stérique au niveau de C_4 ou C_8 suivant que R est *exo* ou *endo*, la taille et la nature de R constituant des facteurs supplémentaires à considérer. De même les études de Wiseman et Krabbenhoft (20) ont permis de détailler certains paramètres d'interaction de type γ et δ pour des structures où X = N—R_1.

Indépendamment des comparaisons faites avec les produits de même structure déjà cités ainsi que l'étude des spectres couplés, l'attribution des signaux a pu être menée à bien par les constatations suivantes.

*Composés **2**, **4**, **5**, **6**, **7**, **9**, **11** et **12***

Les déplacements chimiques des carbones C_1, C_2, C_5 sont déterminés sans ambiguïté, les effets de substituants sur le carbone 2 étant cohérents avec ceux déjà décrits dans la littérature à plusieurs reprises (29, 30).

On peut de même attribuer au carbone C_6, quand il n'est pas affecté par des effets de substituants, la

[2]Wiseman et coll. (22*a*) proposent pour différents hétérobicyclo[3.3.1]nonanes un calcul du déplacement chimique des C_3 et C_7 à partir des valeurs du déplacement de C_4 dans les hétérocyclohexanes correspondants. Certaines de ces valeurs sont anciennes et ont été revues récemment dans la réf. 27. A partir de ces nouvelles valeurs, en considérant un effet δ de 4.7 ppm proposé par Wiseman et coll. on trouve un déplacement chimique de 18.9 et 17.4 ppm pour les carbones C_3 et C_7 de **1** et **8** respectivement, ce qui pour **8** est loin de la valeur mesurée (20.4 ppm). Il faut alors considérer que l'effet est différent selon la nature de l'hétéroatome (plus ou moins grand aplatissement des cycles) ou que l'adjonction de 2 méthyles axiaux en α de l'hétéroatome du cycle à six chaînons provoque un blindage du carbone en position γ différent suivant la nature de l'hétéroatome.

valeur la plus proche de celle d'un carbone identique dans le composé parent, les valeurs attribuées à ce carbone dans **9** et **12** étant justifiées plus loin. Le même raisonnement peut être tenu pour C_7. A ces composés substitués sur le carbone 2 par OH ou N—R en *endo* nous attribuons les déplacements chimiques des carbones restants C_3, C_4 et C_8 en remarquant que C_3 doit être déblindé puisqu'il est en β d'un substituant OH ou N—R, que C_8 doit être blindé à cause de l'effet stérique du substituant (position éclipsée de C_8—H et OH ou N—R). La valeur de déplacement chimique restant est attribuée à C_4 bien que, comme il est noté dans le tableau 2 elle puisse être interchangée parfois avec des valeurs proches attribuées à C_6 ou C_3. Les déplacements des carbones de **12** sont attribués par comparaison avec ceux de **9**. Pour ce dernier composé l'attribution de C_6 a été faite avec certitude par deutériation de ce site en position 6 (cf. partie expérimentale).

Ce blindage du carbone C_6 dans **9**, alors que le

For personal use only.

reste de la série présente des valeurs cohérentes, est attribué à une effet γ stérique de 2.9 ppm entre le méthyle porté par l'azote et les hydrogènes des carbones C_6 et C_8. On note par ailleurs que l'effet d'un groupement hydroxyle *endo* sur C_8 est de -6.9 et -7.7 ppm environ pour **2** et **11** alors que la valeur pour **9** serait de -9.5 ppm; cette valeur s'explique très bien par l'effet additionnel de l'hydroxyle (-6.6 ppm environ) et du méthyle (-2.9 ppm). Les déblindages observés pour C_4 et C_2 dans **9**, par rapport aux autres composés, montrent inversement que l'effet γ du méthyle vis à vis de ces deux carbones n'a pas lieu et amènent à conclure que l'introduction d'un substituant OH en *endo* produit un aplatissement de cycle qui éloigne les sites susceptibles d'interagir stériquement, ou qu'il y a contribution d'une forme chaise-bateau.

Ce explications données, il ressort que pour les carbones C_1, C_2, C_4, C_5, C_6 et C_7 des composés *endo* on obtient une bonne corrélation des valeurs de déplacement chimique, entre elles, quelques écarts s'expliquent par des effets de substituants sur lesquels nous reviendrons plus loin. Pour les carbones C_3 les valeurs attribuées pour les composés hydroxylés montrent des effets de substituants de 9.4, 9.7 et 9.8 ppm qui correspondent bien aux valeurs de la littérature (17, 19) relatives aux effets d'un hydroxyle en β du carbone considéré. Pour **4** où le substituant est amino un effet similaire de 9.5 ppm, et pour **7** de 8.7 ppm, est trouvé, alors que si l'azote est substitué par un méthyle (**5**) ou un tertiobutyle (**6**) les effets sont différents. La comparaison avec **4** peut permettre d'expliquer ces différences. Dans le cas de **5** le groupement méthyle introduit sur C_3 un effet de blindage γ qui se superpose à l'effet β déblindant, on peut ainsi évaluer l'effet γ à environ -5.2 ppm. Inversement pour **6** le groupement tertiobutyle introduirait sur C_3 un effet δ déblindant d'environ 2.2 ppm (31). A propos de l'étude du composé **9** ci-dessus, nous avons noté l'effet d'un groupement hydroxyle *endo* sur C_8 dans les composés **2** et **11**. Sur ce même carbone C_8 dans les composés aminés **4**, **5**, **6** et **7**, l'effet de blindage γ dû au groupement substituant C_2 est trouvé égal à 6.4 ppm donc du même ordre de grandeur que celui d'un hydroxyle, avec une exception pour **5** (-2.1 ppm) qui s'explique parfaitement si on considère qu'à un effet γ blindant d'environ 6.4 ppm, se superpose un effet δ déblindant dû au méthyle substituant l'azote, cet effet δ serait de 4.3 ppm environ. Pour assurer les bases de cette discussion nous avons étudié un composé supplémentaire obtenu en remplaçant dans **2** le groupement OH par OCH_3; les valeurs de déplacement chimique relatives à ce nouveau composé devenant directement comparables à celles de **2** et **5**. En particulier le groupement méthyle doit jouer le même rôle que dans **5**; nous avons trouvé pour C_3 et C_8 deux valeurs de déplacement de 22.9 et de 26.2 ppm respectivement. Si on considère sur C_3 un effet β d'environ 9.8 ppm, le méthyle introduirait un effet γ blindant de -5.8 ppm environ. Sur C_8 un effet γ blindant de l'hétéroatome d'environ -6.9 ppm se superposerait un effet δ déblindant du méthyle d'environ 3.7 ppm. Ces valeurs sont clairement comparables à celles attribuées au composé **5**. Notons que les autres carbones du composé méthoxylé ont des déplacements comparables à ceux de **2**.

Composé 3

L'attribution des carbones C_3, C_4 et C_8 pour ce composé tient compte des effets de substituant de la manière suivante: on observe en effet qu'une valeur correspond à un déblindage et deux valeurs à des blindages. Comme dans les exemples précédents, C_3 en β du substituant doit être déblindé, raison pour laquelle nous lui attribuons 25.8 ppm soit un blindage de -2.9 ppm par rapport au carbone similaire de **2**, car l'effet d'un groupement OH sur le carbone β est d'environ 6 ppm si l'OH est axial alors qu'il est de 9 ppm environ si l'OH est équatorial. On note encore que la position axiale du groupement OH dans ce cas peut entrainer une déformation de cycle ou la contribution d'un autre conformère puisque le carbone C_7 est blindé de -1.4 ppm contrairement à ce que l'on observe dans tous les autres exemples. Il est logique d'attribuer la valeur de 29.5 ppm à C_6, comme dans les cas précédents. Pour les deux carbones restants C_4 et C_8, l'attribution est faite en considérant que l'un d'eux C_4 subit un blindage par effet γ stérique, alors que l'autre serait blindé par effet *anti*-γ dû à un arrangement *anti* périplanaire du carbone considéré et de l'hétéroatome (32). La valeur la plus faible est attribuée à C_4 comme dans d'autres exemples de la littérature (19) mais aucune preuve ne peut être apportée pour l'instant à cette attribution.

Autres effets observés

Les effets β sur le carbone C_1 en tête de pont sont dans tous les cas les plus faibles que sur C_3 ce qui a déjà été observé par d'autres auteurs (17) ces effets sont plus faibles pour les composés substitués par N—R que pour ceux substitués par OH, sauf dans le cas de **6**, ce qui peut s'expliquer si on envisage un effet stérique δ (environ 2.4 ppm) dû à une interaction entre les hydrogènes des méthyles du groupe tertiobutyle et l'hydrogène en tête de pont (20, 31).

L'effet de la taille du substituant de l'azote sur le déplacement chimique de C_2 est aussi remarquable dans les composés **4**, **5**, **6** et **7**. Le remplacement de NH_2 par $N—CH_3$ déblinde le carbone C_2 de 5.3

TABLEAU 3. Deplacements chimiques

Composé	R	X	δ (ppm) Cα	Cβ	Référence
	H	CH_2	25.6		2
	H	O	68.6	26.7	27
	H	NMe	56.9	24.6	27
	H	NPh	48.5	28.3	27
	CH_3	O	75.4	33.2	Ce travail

NOTE: Pour les composés **13**, **18** et **21** voir le tableau 4; la réf. 14 donne

ppm. Le remplacement par N—*t*Bu ou N—Ph blinde ce carbone. Il est vraisemblable que dans le cas de **6** et **7** une interaction de type γ-*gauche* a lieu entre l'hydrogène porté par C_2 et les méthyles du groupe tertiobutyle dans le cas de **6**, et un hydrogène *ortho* du groupe phényle dans le cas de **7**. La nécessité pour ces gros groupements de se dégager du système bicyclique impose malgré tout certaines interactions, et l'interaction γ-*gauche* est moindre (en rmn de ^1H le déplacement chimique à champ faible du proton porté par C_2 (3.8 ppm) indique qu'il se situe dans le plan du cycle phényle (33)).

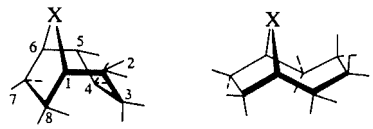
Enfin l'étude du composé **12** a été faite pour voir si le remplacement d'un méthyle par un éthyle avait une grosse influence, ce type de substitution a été reconnu comme déplaçant la résonance des carbones en α de l'éthyle à champ faible et ceux en β à champ fort (dans ce dernier cas, 1.4–4.4 ppm) (14). Les carbones concernés ici sont ceux en tête de pont et sont effectivement blindés de 2.6 ppm pour C_1 et 2.2 ppm pour C_5. On constate par ailleurs que les déplacements chimiques des autres carbones de **9** et **12** sont très proches. Ces blindages, de même que ceux des carbones C_1 et C_5 de **10** par rapport à **8**, et de **11** par rapport à **9**, peuvent encore s'interpréter par un effet de type γ stérique (interactions de CH_3 de l'éthyle et de C—H *ortho* du cycle phényle avec C_1—H).

Composés bicyclo[4.2.1]nonaniques

Composés non fonctionnels

Dans le tableau 3 nous montrons que les déblindages des systèmes bicyclo[3.2.1]octaniques et bicyclo[4.2.1]nonaniques par rapport au composé à cinq chaînons de références présentent des analogies. Par ailleurs les carbones des cycles à six ou sept chaînons situés en tête de pont ou en α des carbones tête de pont sont beaucoup plus déblindés que leurs analogues de la série bicyclo[3.3.1]nonanique. Cette première constatation est insuffisante pour l'attribution des déplacements chimiques mais cette attribution peut se faire sans ambiguïté en comparant les déplacements chimiques de **13**, **18** et **21** avec ceux de l'alcool **24** si on note que dans cet alcool le groupe OH *exo* ne peut donner lieu à aucune interaction stérique. Les quatre couples de déplacement chimique sont ainsi déterminés.

Nous avons publié (34) que l'analyse des déplacements chimiques de **13**, **23** et **24** impliquait la conformation B (bateau pour le cycle à sept chaînons), pour ces composés, ceci sur la base d'analyse des interactions du groupe OH de **23** vis à vis de différents carbones du cycle. Cette conclusion insuffisante doit être modifiée par la possibilité d'un équilibre entre A et B et en particulier si la forme A est présente, un effet γ stérique important doit avoir lieu entre les couples C_3/C_4 et C_7/C_8.



A B

Bien que le diméthyl-2,5 tétrahydrofuranne *cis* ait vraisemblablement une conformation un peu différente de celle de **13** il nous a été suggéré que l'étude de ce composé (réf. 35 et tableau 3) pouvait apporter quelques renseignements par comparaison des déplacements chimiques des carbones C_3/C_4 de ce composé et C_8/C_7 de **13**. Le déplacement chimique trouvé pour ce dernier couple est de 31.6 ppm soit une valeur inférieure de 1.6 ppm par rapport au couple C_3/C_4 du tétrahydrofuranne substitué. Au cas ou ce dernier modèle serait correct pour faire une comparaison valable, on concluerait à un équilibre entre les formes A et B pour **13** sans pouvoir donner les populations respectives des deux conformères. Comme par ailleurs une interconversion rapide entre les conformères C et D impliquerait l'observation de quatre valeurs de déplacements chimiques par rmn, l'étude de ces derniers s'avère insuffisante pour une conclusion en faveur d'une conformation préférentielle.

Pour les composés **18** et **21** on remarque que les couples C_3/C_4 ont à peu prés le même déplacement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

chimique que dans **13**, ceci impose en particulier pour **18** que le méthyl n'ait pas d'interaction avec C_3/C_4 car ces carbones devraient subir un déblindage par effet δ stérique, dans le cas de la forme bateau; les carbones C_2/C_5 devraient eux subir un blindage par effet γ stérique dans le cas de la forme chaise (comparer le déplacement de C_2 dans **1** et **8** d'une part, **13** et **18** d'autre part). Ceci tend à prouver que le méthyle dans **18** est préférentiellement au-dessus du cycle pyrrolidinique. Donc les déplacements chimiques des couples C_3/C_4 imposent le même équilibre conformationnel pour **13**, **18** et **21**, et subissent ou non la même influence de la part du doublet libre de l'hétéroatome.

Composés fonctionnels

Les composés **23** et **24** ont été analysés dans la réf. 34 et dans ces deux cas la valeur des déplacements chimiques des couples C_3/C_4 proche de celles des composés étudiés ci-dessus semble indiquer que leur comportement conformationnel est similaire à celui des produits précités. Dans le cas de **23** en particulier la présence d'un groupe hydroxyle en *endo* provoque une gêne stérique considérable entre C_3/C_4 et OH, ce qui impose pour le moins un aplatissement important du cycle à sept chaînons, à partir de la position chaise.

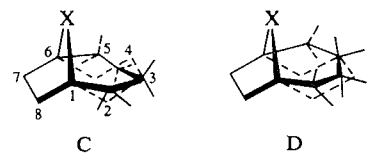
*Composés **14**, **15**, **19**, et **22***

Pour ces composés ayant un substituant *endo* en position 2 l'attribution des carbones C_1, C_2 et C_6 est faite sans ambiguïté. On attribue aux carbones C_5 et C_7 les valeurs les plus proches de celles des carbones similaires dans les composés parents, car d'une part, ils sont éloignés du substituant (quatre liaisons) et ne subissent pas d'effet inductif de celui-ci; d'autre part les interactions stériques qu'ils pourraient subir dans certaines conformations envisageables pour la molécule ne conduiraient pas à des valeurs cohérentes pour les déplacements chimiques des autres carbones (nous y reviendrons plus loin à propos de l'étude conformationnelle).

Le carbone C_3 étant situé en β du groupement substituant doit être déblindé, comme nous l'avons vu avec la première série de composés et les écarts de déplacements chimiques observés ont un ordre de grandeur qui justifie l'attribution ainsi faite. Pour les deux carbones restants, C_4 et C_8, l'attribution proposée est basée sur le fait que ces carbones situés en γ du substituant peuvent être blindés. En particulier la valeur attribuée à C_8 correspondrait à un blindage de ce carbone de -8.3 à -9.1 ppm (compatible avec celui du carbone C_5 dans le composé **23** quand l'hydroxyle *endo* est porté par C_7). Sauf si la molécule est en conformation chaise pure (ce qui est improbable, cf. plus loin) le carbone C_8 peut en effet donner lieu à un blindage de la part du substituant en position γ par rapport à lui (éclipse des liaisons C_8—H ... O—H). La valeur restante correspondant à un blindage de -4.9 à -5.1 ppm (pour les substituants OH) est attribuée à C_4.

L'interconversion des valeurs ainsi attribuées à C_8 et à C_4 conduirait à des effets de blindage pour ces deux carbones dans **14**, **19** et **22** beaucoup plus grand pour C_8 et plus petit pour C_4 (**14** par exemple: -12.3 et -1.2 ppm respectivement). De plus ces effets seraient assez différents d'un composé à l'autre alors qu'ils sont dus au même substituant. Il ne semble pas possible de lever cette indétermination pour l'instant.

En ce qui concerne l'étude conformationnelle de ces molécules les formes A et B peuvent être exclues. Dans le cas de A par exemple la valeur de C_7 (plus déblindé que dans le composé parent) exclut une forte interaction entre C_3/C_4 et C_7/C_8. On devrait de même dans ce cas observer un effet δ sur C_5 par exemple dû à l'interaction C_2—H - - - H—C_5. Enfin les blindages de C_4 et C_8 par le substituant *endo*-2 ne sont pas explicables par des effets stériques, ou des dispositions antipériplanaires des atomes concernés (32). On peut exclure la conformation B pure pour des raisons du même type. L'analyse conformationnelle de tous les dérivés bicyclo[4.2.1]nonaniques substitués, à partir des déplacements chimiques est ardue car on ne connait pas les conformations privilégiées des composés non substitués et le déplacement chimique induit par le substituant et celui dû aux changements conformationnels influencent ceux des composés substitués.



C D

Des conformations *gauches* C et D peuvent être envisagées et se justifient par les valeurs des déplacements chimiques des différents carbones. On peut remarquer que le déplacement du méthyle à bas champ de 1.7 ppm dans **19** pourrait être dû à une interaction de ce dernier et des hydrogènes de C_3 et C_4 suivant que l'équilibre C ⇌ D est en faveur de l'une ou l'autre forme. Le cycle à sept chainons étant flexible il y a peu de chance dans les conditions de température où l'on opère d'avoir une seule conformation, et les valeurs de déplacement ainsi observées sont certainement des valeurs moyennes d'où les difficultés d'attribution et d'interprétation. Il n'en reste pas moins que les formes C et D représentent des modèles où les interactions entre atomes sont moindres et sont certainement celles qui sont statistiquement observées, ce qui n'exclut pas qu'elles

soient les intermédiaires de l'équilibre plus général $A \rightleftharpoons B$

Composés 16 et 20

Les attributions sont faites selon le même principe que dans les molécules précédentes, les atomes C_4 et C_8 étant blindés par effet stérique du substituant pour le premier et par effet *anti*-γ dû à la disposition *anti* périplanaire possible de OH et C_4 pour le second. Dans le composé **20** on note le fort déblindage du méthyle porté par l'azote, 3.7 ppm par rapport à **18** et 2 ppm par rapport à **19**, qui traduit certainement des interactions différentes de celles qui avaient lieu dans les composés précédents. Il n'est pas impossible de penser dans ce dernier cas à un effet sur le méthyle dû à une interaction OH ... H_3C, par exemple.

Composés 17 et 25

Les attributions de déplacements chimiques ont été faites en comparant les effets du groupement C=O de ces deux cétones avec ceux de cétones de structures rigides connues (14–16). La deutériation des carbones 6 et 8 dans **25** permet la mesure des déplacements des seuls carbones du cycle à sept chaînons.

L'examen du tableau 4 permet de voir que le groupement C=O perturbe le déplacement chimique de C_5 (blindage de 4.4 ppm). Des blindages de cette nature ont déjà été relevés pour des cétones cyclohexaniques (31). Le carbone C_4 en position δ par rapport à l'oxygène du groupement carbonyle est blindé de 2.1 ppm, ce qui est cohérent avec ce que l'on observe en série bicyclooctanique où des blindages sont notés pour des carbones situés en position δ par rapport à l'oxygène d'un groupement C=O (13, 15).

Le carbone C_3 ne change pas de déplacement chimique par rapport au composé non substitué, ceci conduit à penser que **25** donne lieu à un équilibre conformationnel identique à celui de **13** par exemple.

Les effets de substituants sur la cétone **17** pré-

sentent deux caractéristiques essentielles. (*i*) Le déblindage du carbone C_1 en β du groupement carbonyle est faible, et du même ordre de grandeur que celui obtenu pour un groupement OH (dans la bicyclo[3.2.1]octanone-2, cet effet est de 15.1 ppm pour C_1); (*ii*) Deux carbones C_4 et C_8 sont blindés respectivement de 5.6 et 4.9 ppm, et ceci peut être dû soit à une double interaction du type =O ... HC, soit à une interaction du type précédent sur C_8 et une interaction γ stérique sur C_4 du doublet de l'oxygène du pont. Il est toutefois difficile de proposer une conformation au vu de ces résultats qui permettent d'éliminer les formes chaise et bateau pour **17**.

Partie expérimentale

Produits

Les produits **1** et **13** ont été préparés selon la réf. 36, **2**, **3**, **14**, **17**, **23** et **24** selon la réf. 37, **25** selon la réf. 38 et **4**, **5**, **6**, **7**, **8**, 9, **10**, **11**, **12**, **15**, **18**, **19**, **21** et **22** selon la réf. 33. Ces derniers produits étant préparés par aminomercuration intramoléculaire d'aziridines ou d'aminoalcools, suivie d'une réduction du mercurique par $NaBH_4$, nous avons ainsi pu deutérer le carbone C_6 du produit 9 en réduisant son mercurique précurseur par $NaBD_4$.

Le produit **20** a été préparé selon la réf. 39.

Appareillage

Les spectres rmn ^{13}C ont été tracés sur un spectromètre à impulsions Brucker-W.P. 60 fonctionnant à 15.08 MHz dans un champ de 14 090 G, avec transformée de Fourier, donnant les déplacements chimiques au $\frac{1}{10}$ de ppm.

Les échantillons utilisés avaient une concentration de l'ordre de 0.5 *M* dans $CDCl_3$ en tubes de 10 mm.

Ils ont été examinés avec irradiation totale par bruit des protons, afin de faire apparaître chaque carbone sous forme de singulet.

Des expériences de découplage "off-resonance" ont été effectuées afin de permettre l'attribution de différents carbones par la multiplicité des raies qu'ils présentaient.

Stereochemically controlled syntheses of some bicyclo[*n*.3.0]alkane-1-carboxylic acids

E. W. WARNHOFF, W. T. TAI, AND Y. C. TOONG

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received August 8, 1977

E. W. WARNHOFF, W. T. TAI, and Y. C. TOONG. Can. J. Chem. **56**, 93 (1978).

Stereospecific methods of synthesis of some *cis*- and *trans*-bicyclo[*n*.3.0]alkane-1-carboxylic acids are described, specifically **5***a*, **5***b*, and **11**. The *cis* ring fusion is insured by use of the Diels–Alder reaction, and the *trans* ring fusion is fixed by the necessity of a *cis* attachment of an intermediate five-membered cyclic lactamol to the existing cyclopentane ring in **9**.

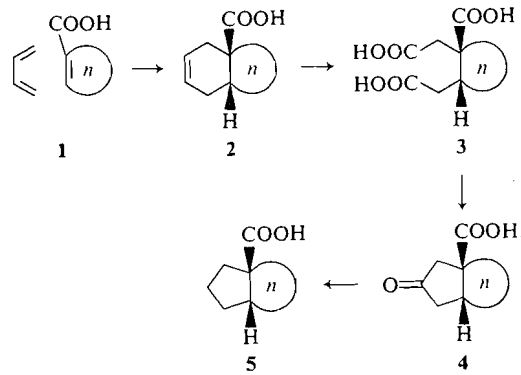
E. W. WARNHOFF, W. T. TAI et Y. C. TOONG. Can. J. Chem. **56**, 93 (1978).

On décrit des méthodes stéréospécifiques de synthèses de quelques acides bicyclo[*n*.3.0]alcanecarboxyliques-1 *cis* et *trans* et en particulier de **5***a*, **5***b* et de **11**. On s'assure de la fusion *cis* du cycle par l'utilisation d'une réaction de Diels–Alder; la fusion *trans* du cycle est déterminée par la nécessité d'avoir un point d'attache *cis* pour un intermédiaire lactamol cyclique à cinq chaînons au noyau cyclopentanique existant dans **9**.

[Traduit par le journal]

As part of a study of certain Favorskii rearrangements (1), authentic samples of several bicyclo-[*n*.3.0]alkane-1-carboxylic acids of unambiguously established geometry were required for comparison with reaction products. An acid corresponding in structure to one of the needed *cis*-acids, bicyclo-[3.3.0]octane-1-carboxylic acid, has already been prepared in three ways (2–4). While the *cis* isomer **5***a* is clearly more stable than the corresponding *trans* epimer, and while each of the three routes probably gave the *cis* isomer, one is left feeling queasy since none of them *guaranteed* a *cis* fusion. One of the routes was the Favorskii rearrangement (2) whose mechanism and stereochemistry were under study (1).[1] The second preparation (3) by the Koch–Haaf carboxylation of the bicyclo[3.3.0]octyl-1-cation unfortunately has associated with it in principle the *cis*/*trans* ambiguities found for the same reaction applied to the bicyclo[4.4.0]decyl-1-cation (5). The third synthesis, the Dieckmann cyclization of the triester of a 1-carboxycyclopentane-1,2-diacetic acid of unknown stereochemistry (4), relies for its assignment of *cis* geometry on the assumption that the *trans*-diacetic ester would not cyclize, which in turn was based on analogy with the closely related, but different, case of cyclopentane-1,2-diacetic ester (6). Further doubt is raised by discrepancies in melting points of the amide derivative (131°C) reported in this last work and of that (107.5 and 108°C) found in the first two syntheses. In view of our need to be certain, this *cis*-acid **5***a* and its higher homolog **5***b* were synthesized by the general procedure outlined in Scheme I which employs the Diels–Alder reaction of a 1-cycloalkenecarboxylic acid with butadiene to insure the *cis* ring fusion. Contraction of the newly formed cyclohexene ring in **2** by oxidative cleavage and subsequent cyclization of the resulting diacid **3**, followed by decarboxylation and Wolff–Kishner reduction yielded the desired *cis*-acids **5**. Since the same bicyclo[3.3.0]octane-1-carboxylic acid was obtained as from the three previously described syntheses (2–4), this acid is now established with certainty to have the *cis* geometry. The melting point of the amide of **5***a* prepared via the Diels–Alder route was 108°C in agreement with refs. 2 and 3.

On the other hand, the synthesis of pure *trans*-bicyclo[5.3.0]decane-1-carboxylic acid was less straightforward. The initial intent was to add cyanide to the conjugated ketone **6**, reduce the carbonyl



SCHEME I

[1]The correlation of the amide of the bicyclo[3.3.0]octane-1-carboxylic acid with the product of nitration of *cis*-bicyclo-[3.3.0]octane carried out in ref. 2 rests on the assumption that the *cis*-nitro compound is formed.

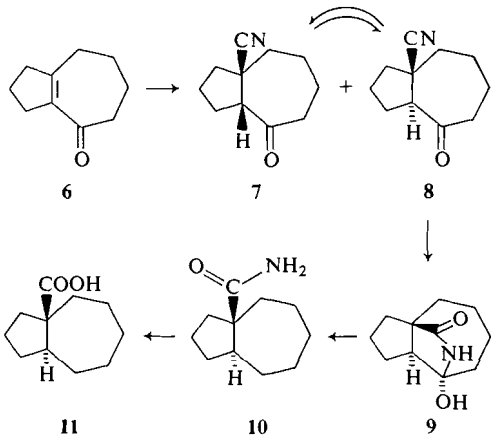
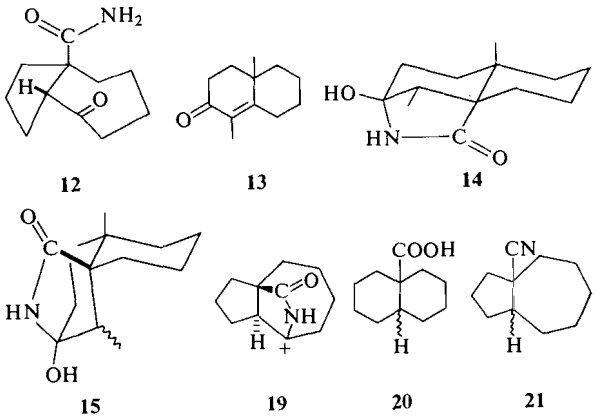
group, and hydrolyze the nitrile. This simple approach seemed worthwhile in view of the ready availability of enone **6**, although it was realized that, even if *anti*-conjugate addition occurred to yield *trans*-keto nitrile **8**, the ring junction was under control of the equilibration permitted by the adjacent carbonyl group (7). In a number of such fused 5/7 ring systems the *cis* and *trans* isomers are of comparable stability (8), but perhaps the *trans* isomer might undergo reduction more rapidly. In the event, conjugate addition of cyanide yielded a mixture of about equal amounts of both *cis*- and *trans*-keto nitriles **7** and **8** (Scheme 2), and unfortunately Wolff–



SCHEME 2

Kishner reduction of this mixture produced the *cis*-acid **5***b* plus another acid which was presumed to be the *trans*-acid **11**. Although the acids were separable by glpc of their methyl esters, it was preferable to have a synthesis which would yield unequivocally only the *trans* stereoisomer. Attainment of this goal was aided by a third crystalline product formed in varying amounts in the conjugate addition of cyanide to **6**.

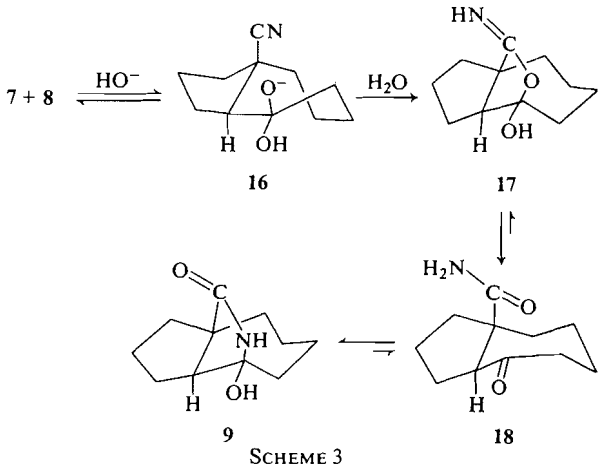
Thus from one conjugate addition reaction, the major product was this crystalline solid containing neither nitrile nor ketone functions. The presence of amide C=O, NH, and OH infrared absorption, in conjunction with Wolff–Kishner reduction of the compound to the *cis*-acid **5***b*, allowed the solid to be identified as a lactamol, R—(C=O)—NH—C—OH. Examination of Dreiding models revealed that only the *trans* ring fusion of keto amide **18** (Scheme 3) would allow a strainless intramolecular addition of the amide NH to the ketone as in **9**; for the *cis*-epimer **12**, lactamol formation would not occur because it would force a strained *trans* fusion of two five-membered rings. This situation is in contrast to that obtaining for similar lactamols **14** and **15** from the octalone **13** (and from its non-methyl derivative)



for which both the *cis* and *trans* ring fusions allow strain-free lactamol formation (9).[2] Therefore, since it was known with confidence that the crystalline lactamol **9** possessed the *trans* carbocyclic ring fusion, further efforts to prepare pure *trans* **11** centered around finding conditions to reduce the potential ketone group without allowing epimerization via enolization. The Wolff–Kishner reduction of **9** to **5***b* had occurred with epimerization, and hence the Clemmensen reduction was tried, but it gave a low yield of a mixture of *cis*- and *trans*-acids **5***b* and **11** with *cis* predominating. Finally, resort was had to the just published electrolytic procedure of Throop and Tökés (11) which had been shown to reduce ketones to methylene groups with little or no prior enolization in spite of the strong acid electrolyte. Although the lactamol gave no evidence of any keto tautomer **18** in its infrared spectrum, it was hoped that there would be sufficient **18** for reduction or else that a cationic species such as **19** would be reduced. Gratifyingly, **9** did undergo electroreduction to a single crystalline amide, **10**, mp 156°C, which was converted into the crystalline *trans*-acid **11**, mp 101.5°C, by diazotization. The conceivable possibility that the lactamol **9** or its open keto amide tautomer **18** might have rearranged (12) during reduction in the strong acid medium to a bicyclo-[4,4,0]decane-1-carboxylic acid **20** is excluded by the fact that these known compounds have quite different melting points: *cis*, mp 124°C; *trans*, mp 137°C (5, 10); likewise the melting points of their amides (*cis*, mp 132°C, *trans*, mp 128°C) are different from that of **10**. This synthetic method could presumably be used for other homologous *trans*-bicyclo[*n*.3.0]-1-carboxylic acids.

A remaining point of interest is the differing reactivity exhibited by the cyano group in this series of

[2]The *trans* keto acid corresponding to **18** behaves in the same way as **18** (10).



SCHEME 3

compounds. Although hydrolysis occurred under the vigorous high temperature Wolff–Kishner conditions applied to the keto nitrile mixture **7** + **8** and lactamol **9**, in other reactions the inertness of a cyano group at the tertiary junction of a bicyclic system toward the usual hydrolytic reagents was evident. Thus the nitrile **21** from electrolytic reduction of **7** + **8** was not touched by the usually effective hydroxide – hydrogen peroxide reagent, nor was any hydrolysis product formed in hot phosphoric acid. The cyano group of the keto nitrile mixture **7** + **8** was not hydrolyzed by hot phosphoric acid. In view of this demonstrated reluctance to react, the conversion of the keto nitrile mixture **7** + **8** to the lactamol **9** under the relatively mild conditions of refluxing methanolic hydroxide is best interpreted as the result of an intramolecular addition to the nitrile made possible by the nearby ketone function (Scheme 3). The activation energy for the addition **16** → **17** will be less than for an intermolecular reaction of **8** or **21** with hydroxide mainly because in **16** the translational entropy of hydroxide has already been lost in the preceding step. Similar intramolecular effects were noted for the nitriles from **13** (9).

Experimental

General

Melting points were taken on a Reichert Kofler microscope hot stage and are corrected. Infrared spectra were recorded on a Beckman IR-5A or IR-10 spectrophotometer. ^{1}Hmr spectra were determined on a Varian A-60 or T-60 spectrometer. Camag DF-5 silica gel was used for tlc plates developed in various proportions of EtOAc–PE or $CHCl_3$–HOAc (94:6). Mass spectra were obtained by Mr. Doug Hairsine on a MAT 311A instrument. A Glowall Model 400 instrument fitted with a 1.8 × 3.4 mm spiral glass column packed with 5% DEGS on non-acid-washed 60–80 mesh Chromosorb P was used for glpc with argon or helium carrier gas and a hydrogen flame detector. The dc generator for electrolytic reduction was a Harrison Laboratory Model 855B. Organic solutions were washed to neutrality and dried by shaking with saturated NaCl and standing over anhydrous $MgSO_4$. Microanalyses were carried out in the laboratories of A. B. Gygli, Toronto, Ontario, and A. Bernhardt, Mülheim, West Germany. The following abbreviations are used: PE = petroleum ether of bp 60–80°C, pe = petroleum ether of bp 30–60°C, EtOH = ethanol, EtOAc = ethyl acetate, MeOH = methanol, HOAc = acetic acid, s = singlet, t = triplet, and b = broad.

cis-*Bicyclo[4.3.0]non-3-ene-1-carboxylic Acid* **2a**

This acid was prepared by the Diels–Alder reaction between 5 ml of liquefied butadiene and 1.90 g (16.9 mmol) of cyclopentene-1-carboxylic acid **1a** (13), mp 120–121°C, according to the procedure of Kronenthal and Becker (14). A sealed Pyrex tube containing the reactants was heated at 170°C for 26 h. Work-up gave 1.91 g (68%) of crude acid **2a**, mp 65–81°C. Three recrystallizations from HOAc–H_2O raised the mp to 80–81°C (lit. (14) mp 80.5°C).

1-Carboxycyclopentane-cis-*1,2-diacetic Acid* **3a**

To a solution of 3.92 g (23.6 mmol) of unsaturated acid **2a** in 45 ml of water containing 2.0 g of KOH was added with stirring a solution of 9.20 g (58.2 mmol) of $KMnO_4$ in 220 ml of water. The reaction temperature was maintained at 30°C by an ice-water bath. After the $KMnO_4$ had been consumed (30 min), the reaction mixture was acidified (50% H_2SO_4), heated, and filtered while hot. The undissolved MnO_2 was washed with more hot water. The combined aqueous filtrates were concentrated to ~70 ml and chilled. Filtration of the crystallized solid and recrystallization from water yielded 2.76 g (51%) of colorless plates of the *triacid* **3a**, mp 155–160°C. Further recrystallization and drying at 100°C (0.05 Torr) gave an analytical sample, mp 157–160°C (reported (4) for an acid of the same structure but unproven stereochemistry: (150°C). *Anal.* calcd. for $C_{10}H_{14}O_6$ (230.2): C 52.17, H 6.13; found: C 52.74, H 6.20; neutralization equivalent calcd.: 76.7; found: 77.8.

cis-*3-Oxobicyclo[3.3.0]octane-1-carboxylic Acid* **4a**

An intimate mixture of 234 mg (1.01 mmol) of triacid **3a** and 17 mg of BaO under vacuum (150 Torr) in a horizontal tube was slowly heated to 260°C over a period of 2 h and then kept at this temperature until no more product distilled.[3] Redistillation of the product at a lower pressure (0.1 Torr) afforded 55 mg (32%) of oily keto acid **4a**; ir (CCl_4): 3300–2400 (carboxyl OH), 1750 (five-ring C=O), and 1695 cm^{-1} (carboxyl C=O).

The *2,4-dinitrophenylhydrazone* was prepared and partitioned between $CHCl_3$ and aqueous $NaHCO_3$. The ether-washed $NaHCO_3$ solution was acidified (10% H_2SO_4) and extracted with ether. Two recrystallizations from $CHCl_3$–PE gave small golden rosettes, mp 109–111°C. *Mol. Wt.* calcd. for $C_{15}H_{16}N_4O_6$: 348.1070; found (high resolution ms): 348.1066.

cis-*Bicyclo[3.3.0]octane-1-carboxylic Acid* **5a**

(a) Preparation of Semicarbazone

A mixture of 475 mg (2.82 mmol) of crude keto acid **4a**, 500 mg of semicarbazide·HCl, 750 mg of NaOAc, and 4 ml of H_2O were heated with stirring until dissolution. On cooling 530 mg (83%) of semicarbazone crystallized. Three recrystallizations from EtOH–H_2O (decolorizing carbon removed some yellow contaminant) yielded 330 mg of pure derivative, mp 188–190°C dec. *Mol. Wt.* calcd. for $C_{10}H_{15}N_3O_3$: 225.1113; found (high resolution ms): 225.1116.

[3]If the distillation was not conducted slowly, the reaction was incomplete, and the product was mostly the five-ring anhydride carboxylic acid (ir($CHCl_3$): 1850 and 1780 (five-ring anhydride) and 1715 cm^{-1} (carboxyl C=O)).

(b) Wolff–Kishner Reduction

A mixture of 165 mg (0.73 mmol) of the semicarbazone of **4***a*, 12 KOH pellets, 1 ml of 85% $H_2NNH_2 \cdot H_2O$, and 3 ml of *tert*-amyl alcohol in a sealed thick-walled glass tube was heated at 165–170°C for 7 h. The reaction was partitioned between water and ether. The aqueous layer was washed once more with ether, acidified (concentrated HCl), and extracted with ether. Evaporation of the water-washed and dried ether solution left 105 mg (95%) of colorless oily **5***a* which crystallized and gave a single tlc spot. A small sample was recrystallized from pe to yield crystals of *cis*-acid **5***a*, mp 43–46°C (reported (2, 4) for an acid of the same structure but unproven stereochemistry: 46–47 and 43–44°C). The rest of the **5***a* was evaporatively distilled at 110°C (40 Torr) to give white crystals; ir (CS_2): 3400–2400 (carboxyl OH) and 1695 cm^{-1} (carboxyl C=O). *Mol. Wt.* calcd. for $C_9H_{14}O_2$: 154.0993; found (high resolution ms): 150.0995. This acid was identical (mp, mixture mp, ir, tlc) with the acid prepared according to ref. 2*b*.

The *amide* of **5***a* was prepared by treatment of 40 mg of **5***a* with $SOCl_2$ at reflux, evaporation of excess $SOCl_2$, addition of benzene, and introduction of NH_3 gas. Recrystallization of the neutral portion of the reaction product from ether–PE gave 10 mg of colorless micaceous flakes, mp 106–108°C (lit. (2*a*) mp 107.5°C); ir (CS_2): 3520, 3440, 3200 (amide NH_2), and 1680 cm^{-1} (amide C=O). *Mol. Wt.* calcd. for $C_9H_{15}NO$: 153.1153; found (high resolution ms): 153.1149.

1-Cycloheptenecarboxylic Acid ***1b***

This acid was prepared in 71% overall yield from cycloheptanone by dehydration and hydrolysis of the cyanohydrin according to Wheeler and Lerner (15). After recrystallization from pe the colorless plates melted at 50.5–51.5°C (lit. (16) mp 49°C); ir (CCl_4): 3200–2500 (carboxyl OH), 1675 (carboxyl C=O), and 1640 cm^{-1} (C=C); ^{1}Hmr ($CDCl_3$) δ: 7.35 (1H, t J = 7 Hz, =CH—(CH_2)) and 11.61 ppm (1H, s, COOH).

cis-*Bicyclo[5.4.0]undec-9-ene-1-carboxylic Acid* ***2b***

The acid **1***b* (3.23 g, 23 mmol) and butadiene (8 ml of liquid) were heated at 170°C for 24 h in two sealed glass tubes. Extraction with aqueous NaOH, washing of the basic solution with benzene and ether, acidification (concentrated HCl), and filtration yielded 2.0 g (44%) of crude acid, mp 73–76°C. Recrystallization from HOAc–H_2O gave colorless plates of the *bicyclic acid* **2***b*, mp 76–77.5°C; ir (CCl_4): 3500–2400 (carboxyl OH) and 1690 cm^{-1} (carboxyl C=O); ^{1}Hmr ($CDCl_3$) δ: 5.60 (2H, bs, CH=CH) and 10.12 ppm (1H, s, COOH). *Anal.* calcd. for $C_{12}H_{18}O_2$ (194.3): C 74.19, H 9.34; found: C 74.39, H 9.43.

1-Carboxycycloheptane-cis-*1,2-diacetic Acid* ***3b***

To a solution of 1.0 g (5.1 mmol) of unsaturated acid **2***b* in 10 ml of 5% aqueous KOH was added in portions with stirring (magnetic bar) 2.40 g of $KMnO_4$. After 0.5 h the reaction mixture was acidified (dilute H_2SO_4), filtered through sintered glass, concentrated to ~30 ml, and chilled to yield 0.40 g (31%) of the *triacid* **3***b*. Three recrystallizations from water gave colorless plates, mp 172–173°C; ir (Nujol): 3500–2250 (carboxyl OH), and 1725–1665 cm^{-1} (broad superimposed carboxyl C=O's). *Anal.* calcd. for $C_{12}H_{18}O_6$ (258.3): C 55.81, H 7.02; found: C 55.65, H 7.04.

cis-*9-Oxobicyclo[5.3.0]decane-1-carboxylic Acid* ***4b***

A thorough mixture of 342 mg (1.32 mmol) of triacid **3***b* and 10 mg of BaO was heated in a horizontal glass tube at 150°C (150 Torr) for 3 h and then at 240°C (60 Torr) until no more product distilled. The 135 mg (52%) of yellow oily *keto acid* **4***b* showed only a trace of impurity on tlc. Evaporative distillation at 133°C (1 Torr) gave a colorless analytical sample: ir (CCl_4): 3500–2400 (carboxyl OH), 1750 (five-ring C=O), and 1700 cm^{-1} (carboxyl C=O). *Anal.* calcd. for $C_{11}H_{16}O_3$ (196.2): C 67.32, H 8.22; found: C 67.29, H 8.18.

The *2,4-dinitrophenylhydrazone* was prepared and isolated by extraction from ether into aqueous $NaHCO_3$. Acidification, extraction into ether, and two recrystallizations from $CHCl_3$ – petroleum ether gave clumps of small golden blades; mp 106–108°C. *Mol. Wt.* calcd. for $C_{17}H_{20}N_4O_6$: 376.1382; found (high resolution ms): 376.1383.

cis-*Bicyclo[5.3.0]decane-1-carboxylic Acid* ***5b***

A mixture of 191 mg (0.98 mmol) of keto acid **4***b*, 1.5 ml of $H_2NNH_2 \cdot H_2O$ (85%), 0.5 g of KOH, and 6 ml of triethylene glycol was refluxed for 1.5 h after which time the excess $H_2NNH_2 \cdot H_2O$ was distilled. The remaining reactants were heated at 200°C for 22 h. The reaction mixture was diluted with water, washed with $CHCl_3$, acidified (concentrated HCl), and extracted with $CHCl_3$ to yield 179 mg (98%) of crude product containing about 5% of **4***b*. Purification by thick-layer chromatography (silica gel developed in PE–EtOAc, 65:35) followed by two recrystallizations from pe gave colorless plates of the *cis-acid* **5***b*, mp 58–60°C; ir (CS_2): 3400–2300 (carboxyl OH) and 1690 cm^{-1} (carboxyl C=O). *Anal.* calcd. for $C_{11}H_{18}O_2$ (182.3): C 72.49, H 9.95; found: C 72.40, H 9.75. *Mol. Wt.* calcd. for $C_{11}H_{18}O_2$: 182.1306; found (high resolution ms): 182.1304.

$\Delta^{1,7}$-*Bicyclo[5.3.0]decen-2-one* ***6***

This conjugated ketone (ir (CCl_4): 1640 cm^{-1} (conjugated C=O)) was prepared in 86% yield by $NaHCO_3$-catalyzed intramolecular condensation of 1,6-cyclodecanedione (17), mp 101–102°C, in turn prepared in 30% yield by ozonolysis of $\Delta^{9,10}$-*octalin* in aqueous HOAc at 0°C (18). Crude $\Delta^{9,10}$-*octalin* (~80% pure) from P_2O_5-catalyzed dehydration of 2-decalol (19) was used.

cis- *and* trans-*1-Cyanobicyclo[5.3.0]decan-6-one* ***7*** + ***8***

A solution of 1.5 g (10 mmol) of conjugated ketone **6**, 1.0 g (20 mmol) of NaCN, and 4 ml of H_2O in 25 ml of MeOH was refluxed for 5 h. The solvent was evaporated and the residue partitioned between $CHCl_3$ and water. Evaporation of the water-washed and dried $CHCl_3$ solution left 1.0 g (57%) of crude product which was mostly a mixture of the *cis*- and *trans*-cyano ketones **7** + **8** (two tlc spots). Purification of a sample by preparative tlc and evaporative distillation at 100°C (0.1 Torr) gave a colorless oil **7** + **8** which still showed two tlc spots; ir (CCl_4): 2225 (C≡N) and 1725 cm^{-1} (seven-ring C=O). *Anal.* calcd. for $C_{11}H_{15}NO$ (177.2): C 74.54, H 8.53, N 7.90; found: C 74.35, H 8.45, N 7.73.

Lactamol ***9*** *of* trans-*Bicyclo[5.3.0]decan-6-one-1-carboxamide*

A solution of 6.0 g (40 mmol) of conjugated ketone **6**, 5.2 g (106 mmol) of KCN, and 16 ml of H_2O in 200 ml of MeOH was refluxed for 5.5 h. The cooled solution was neutralized with HOAc and the solvent was evaporated. The residue was partitioned between $CHCl_3$ and water. Evaporation of the dried $CHCl_3$ solution left 6.0 g (77%) of crude solid **9**. Three recrystallizations from $CHCl_3$–PE gave fine colorless needles of *trans*-lactamol **9**, mp 141–142°C; ir (CCl_4): 3500–3000 (OH, NH) and 1675 cm^{-1} (amide C=O); ^{1}Hmr ($CDCl_3$) δ: 4.47 (1H, s, OH) and 7.10 ppm (1H, bs, NH). *Anal.* calcd. for $C_{11}H_{17}NO_2$ (195.3): C 67.66, H 8.78, N 7.17; found: C 67.12, H 8.90, N 7.46. *Mol. Wt.* calcd. for $C_{11}H_{17}NO_2$: 195.1259; found (high resolution ms): 195.1257.

trans-*Bicyclo[5.3.0]decane-1-carboxamide* ***10***

The reduction (11) was carried out in an H-shaped electrolysis cell with a sintered glass partition between the two 40 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

compartments. Each electrode was a 12 cm^2 piece of freshly cleaned lead, the cathode being coated with PbO_2 before use. A stirred (magnetic bar) solution of 746 mg (3.82 mmol) of *trans*-lactamol **9** in 20 ml of 10% aqueous H_2SO_4 and 20 ml of peroxide-free dioxane was electrolyzed at room temperature in the cathode compartment at 18 V and 1.5 A. The anode compartment contained the same electrolyte. After 135 h the cathode solution was extracted with ether to yield 633 mg of crude product. Chromatography on 25 g of silica gel yielded 297 mg of recovered *trans*-lactamol **9** (eluted last) and 190 mg (46% based on recovered **9**) of colorless needles of *trans*-carboxamide **10** which melted at 155–156°C after recrystallization from ether–PE; ir ($CHCl_3$): 3500, 3400, 3100 (NH_2), 1670 (amide C=O), and 1575 cm^{-1} (amide II band); ^{1}Hmr ($CDCl_3$) δ: 5.72 ppm (2H, b lump, $CONH_2$). *Mol. Wt.* calcd. for $C_{11}H_{19}NO$: 181.1466; found (high resolution ms): 181.1462.

trans-*Bicyclo[5.3.0]decane-1-carboxylic Acid* ***11***

The amide **10** (132 mg, 0.73 mmol) was diazotized at room temperature with a solution of 0.7 ml of concentrated H_2SO_4 in 2 ml of 20% aqueous $NaNO_2$; a precipitate appeared immediately. After 3 h the reaction mixture was basified with aqueous KOH, washed with ether, acidified with aqueous HCl, and extracted with ether. Evaporation of the ether left 50 mg (37%) of *trans*-acid **11**, which after slow sublimation at 50–60°C (0.1 Torr) gave colorless crystals, mp 100.5–101.5°C; ir (CCl_4): 3300–2225 (carboxyl OH) and 1690 cm^{-1} (carboxyl C=O); ^{1}Hmr ($CDCl_3$) δ: 1.0–2.8 (17H, CH, CH_2) and 12.10 ppm (1H, s, COOH). *Anal.* calcd. for $C_{11}H_{18}O_2$ (182.3): C 72.49, H 9.95; found: C 72.88, H 9.89. *Mol. Wt.* calcd. for $C_{11}H_{18}O_2$: 182.1306; found (high resolution ms): 182.1302.

Gas–liquid partition chromatography (120°C) of the methyl ester of the reduction product gave a single peak (retention time 4.4 min) with no trace of the methyl ester of the *cis*-acid **5***b* which on co-injection had a retention time of 5.2 min.

The *cis*- and *trans*-acids **5***b* and **11** are also readily distinguished by the pattern of their ir peaks in the 1500–1150 cm^{-1} region (CS_2 or CCl_4 solution); *cis*: 1405 m, 1305 m, 1265 m, and 1210 s cm^{-1}; *trans*: 1450 m, 1410 w, 1265 s, and 1210 m cm^{-1}.

Wolff–Kishner Reduction of Keto Nitriles ***7 + 8***

A solution of 803 mg (4.53 mmol) of **7 + 8**, 3 g of KOH, and 4.5 ml of $H_2NNH_2{\cdot}H_2O$ (85%) in 20 ml of triethylene glycol was heated at 140°C for 1 h and then at 210°C for 5 h while excess $H_2NNH_2{\cdot}H_2O$ was distilled. The cooled reaction mixture was diluted with water, washed with $CHCl_3$, acidified with aqueous HCl, and extracted with $CHCl_3$ to yield 295 mg (35%) of a mixture of the *cis*- and *trans*-acids **5***b* and **11** in a ratio of 88:12 *cis*:*trans* from glpc (120°C) of its methyl ester.

Wolff–Kishner Reduction of trans-*Lactamol* ***9***

A solution of 2.12 g (10.8 mmol) of **9**, 6.0 g of KOH, and 20 ml of $H_2NNH_2{\cdot}H_2O$ (85%) in 30 ml of triethylene glycol were heated at 140°C for 1 h and then at 210°C for 5 h while excess $H_2NNH_2{\cdot}H_2O$ was distilled. The reaction mixture was worked up as described in the preceding experiment to yield 1.07 g of acid which after thick-layer chromatography afforded 940 mg (48%) of *cis*-acid **5***b* (tlc, ir, ^{1}Hmr). Three recrystallizations from PE gave colorless plates of pure **5***b*, mp 58–59°C undepressed on admixture with the authentic specimen from the Diels–Alder route.

Clemmensen Reduction of trans-*Lactamol* ***9***

A mixture of 2.0 g (10 mmol) of **9**, 10 g of amalgamated ($HgCl_2$) mossy zinc, 7.5 ml of water, 10 ml of concentrated HCl, and 10 ml of benzene was refluxed briskly for 48 h during which time a 3 ml portion of concentrated HCl was added every 4 h. The cooled reaction mixture was diluted with ice and extracted with ether to yield only 197 mg of product. Dissolution in aqueous KOH, washing with ether, acidification with aqueous HCl, and extraction with ether gave 97 mg (5%) of acid fraction which glpc (120°C) of the methyl esters revealed to be 75% *cis*-acid **5***b* and 25% *trans*-acid **11**.

1-Cyanobicyclo[5.3.0]decane ***21***

A stirred (magnetic bar) solution of 400 mg (2.26 mmol) of the mixture of keto nitriles **7 + 8** in 20 ml of 10% aqueous H_2SO_4 and 20 ml of peroxide-free dioxane was reduced (11) at room temperature in the cathode compartment of the apparatus described above for electrolytic reduction of **9**. A current of 1.5 A at 18 V was passed for 20 h. Extraction with ether afforded 370 mg (100%) of liquid **21**; ir (CCl_4): 2225 cm^{-1} (C≡N), absence of C=O absorption.

Attempted Hydrolyses of ***21***

(*a*) A solution of 350 mg of **21**, 6 ml of 10% aqueous KOH, 6 ml of 30% H_2O_2, and 6 ml of EtOH was heated at 80°C for 5 h and then refluxed for a further 12 h after addition of 2 ml more of 30% H_2O_2. Acidification of the cooled solution (concentrated HCl) and extraction with $CHCl_3$ yielded 370 mg of an oil whose ir spectrum contained an intense C≡N peak and only weak C=O absorption corresponding to ~10% of amide.

(*b*) The material recovered from (*a*) was dissolved in 10 ml of 85% H_3PO_4 and heated at 180°C for 40 h. The black solution was diluted with ice and extracted with ether to yield 165 mg of dark brown residue which had no C≡N or C=O ir absorption. A retro-Ritter reaction may have occurred.

Attempted Hydrolysis of ***7 + 8***

A solution of 150 mg of the mixture of **7 + 8** in 5 ml of 85% H_3PO_4 was heated at 180°C for 4 h. Dilution with water and extraction with $CHCl_3$ gave 50 mg (33%) of recovered impure **7 + 8**.

Acid-catalyzed reactions of cyclobutanones. III.[1] Formation of substituted 2-tetralones from α-phenylcyclobutanones

VICTOR P. ABEGG,[2] ALAN C. HOPKINSON, AND EDWARD LEE-RUFF
Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3

Received August 2, 1977

VICTOR P. ABEGG, ALAN C. HOPKINSON, and EDWARD LEE-RUFF. Can. J. Chem. **56**, 99 (1978).

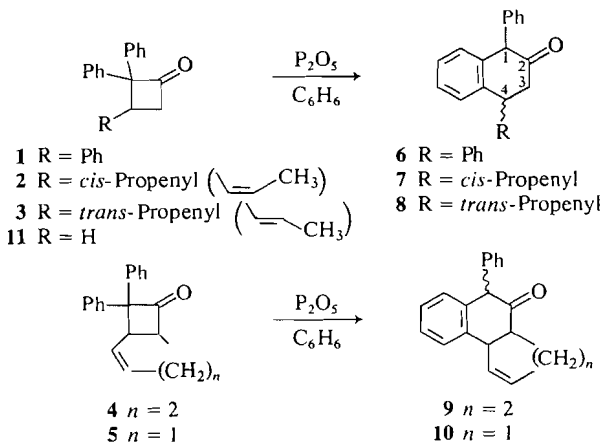
A series of cyclobutanones **1–5** were found to rearrange to β-tetralones **6–10**, respectively, in the presence of phosphorous pentoxide in benzene at room temperature. The structures of the β-tetralones were inferred by conversion of a number of these known naphthalene derivatives. Possible mechanistic pathways are discussed.

VICTOR P. ABEGG, ALAN C. HOPKINSON et EDWARD LEE-RUFF. Can. J. Chem. **56**, 99 (1978).

On a trouvé qu'une série de cyclobutanones **1–5** se réarrangent respectivement en β tétralones **6–10** en présence de pentoxyde de phosphore dans le benzène à la température ambiante. On a déduit les structures des β tétralones du fait que l'on peut en transformer un certain nombre en dérivés naphtaléniques connus. On discute de différents mécanismes possibles.

[Traduit par le journal]

The reactive nature of cyclobutanones with the extensive variation of ring-opening reactions (1–3) has placed these compounds in a class of synthetically important intermediates. With the recent additions of new routes to such systems, cyclobutanone derivatives become accessible synthons to a host of key functional groups required in alkylation reactions (4). During the course of our investigations on the acid-catalyzed rearrangements of cyclobutanones we found that 2-phenylcyclobutanones bearing an activating group in the 3 position are extremely acid labile and undergo facile rearrangements to substituted 2-tetralones.[3] We report here the details of these rearrangements and the supporting evidence for the structural assignments of the rearrangement products.



SCHEME 1

Results and Discussion

Cyclobutanones **1–5** and **11** were prepared according to the method of Huisgen and co-workers (5, 6). Treatment of cyclobutanones **1–5** with P_2O_5 in benzene (Scheme 1) gave β-tetralones **6–10**, respectively, with yields exceeding 85%. Reactions were conducted at room temperature and completion times varied from 15 min for **2** and **3** to 24 h for **4**. Carbon 3 of the ring must be bound to an unsaturated carbon or a heteroatom (*vide infra*) for this rearrangement to take place. When 2,2-diphenylcyclobutanone (**11**) is subjected to the same reaction conditions, no apparent reaction takes place after several days.

The existence of inseparable isomeric tetralones (vis-à-vis the 1,4 positions), as indicated by the nmr spectra, made it difficult to obtain physical parameters. Compounds **8**, **9**, and **10** were oils and **6** and **7** had broad melting points. The assignments for the 2-tetralone structure were based on the following evidence. The infrared spectra of all derivatives (**6–10**) exhibited a strong absorption in the region 1713 to 1729 cm^{-1} consistent with a non-conjugated ketone. The nmr spectra of these derivatives were also consistent with the 2-tetralone structure. Worthy of note is the signal at ca. δ 4.80 (singlet) assigned to the diphenylmethyl acyl hydrogen which undergoes rapid exchange with D_2O. Unambiguous proof for the naphthalene backbone was established by their conversion to the substituted naphthalenes via the di-

[1]For part II of this series see ref. 1.

[2]Department of Chemistry, California State Polytechnical University, Pomona, CA.

[3]Earlier examples of such rearrangements involving a 3-substituted heteroatom have been reported by Huisgen and co-workers (9, 10).

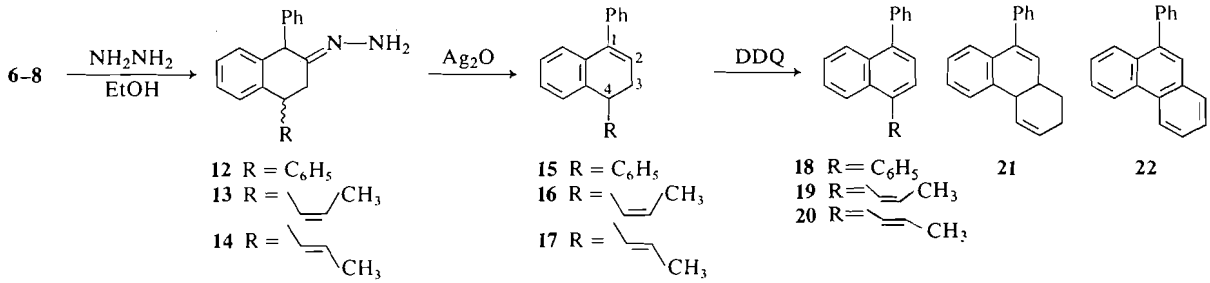


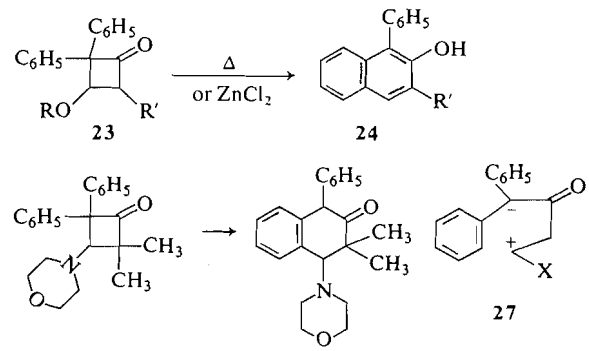
SCHEME 2

hydronaphthalenes. The route to these naphthalenes entailed formation of hydrazones **12–14** (Scheme 2), their oxidation to unstable diazo compounds, and elimination to dihydronaphthalenes. The dihydronaphthalenes were oxidized to the naphthalenes with 2,3-dichloro-5,6-dicyanoquinone (DDQ). In this way the known hydrocarbons **18** and **22** were prepared from **6** and **9**, respectively, and compared with authentic samples (8, 9). Spectral data for all of the dihydronaphthalenes **15–17** and **21** were consistent with the structural assignment and hence pointed to the 4 position for the substituent group R. Evidence for the retention of stereochemistry of the propenyl group in **7** and **8** is based on the following data. Rearrangement products **7** and **8** were shown to have different retention volumes by high pressure liquid chromatography (hplc) (retention volumes of 26.2 and 27.8 ml, respectively). The *trans*-propenyl derivatives **3**, **8**, and **17** all showed strong absorptions at 965–970 cm^{-1} in the ir spectra, attributed to the *trans*-olefinic wagging frequency and which were absent in the *cis*-derivatives.

The mechanism by which the rearrangement of these cyclobutanones to 2-tetralones occurs deserves some comment. Huisgen and co-workers (9, 10) observed that β-naphthols **24** and tetralone **26** were formed (Scheme 3) by thermal and Lewis acid catalyzed rearrangement of cyclobutanones **23** and **25**, respectively.[4] They proposed a zwitterionic intermediate **27** to account for *o*-alkylation of the phenyl group resulting in the observed ring-expanded cyclized products. Alternatively, Lewis acid assisted ring opening of cyclobutanones may involve the intermediacy of diphenylmethyl cation **28** (Scheme 4) which could also undergo *o*-alkylation to one of the phenyl groups. Such a mechanism was postulated to account for the deuterium scrambling between positions 2 and 3 in cyclobutanone **29** (11). Furthermore cyclopropyl carbinyl cations (e.g. **28**) are known resonance contributors to cyclobutyl cations (12).

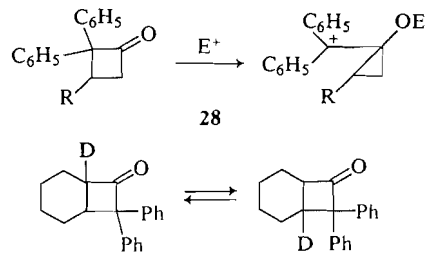
[4]One of the referees indicated a further example of such rearrangements involving a diphenylketene α-methylstyrene adduct (15).

Our results, however, do not support a mechanism involving a cyclopropyl carbinyl cation **28**. These rearrangements only proceed if the substituent at carbon-3 of cyclobutanone can stabilize a positive



SCHEME 3

charge. No such requirement is necessary for the cyclopropylcarbinyl cation mechanism. Furthermore if intermediate **28** were involved then a mixture of 3- and 4-R-substituted tetralones would be expected. Our data conclusively indicate the substituent R to be located exclusively at carbon-4 of the 2-tetralone



SCHEME 4

system. The retention of stereochemistry of the propenyl group going from **2** and **3** to **7** and **8** respectively can be accounted for by the relatively high energy barrier for rotation for allyl cations. The reported stereomutation of the *cis*, *trans*-allyl cation **30** to the *trans,trans* isomer **31** requires 24 kcal/mol (Scheme 5), the lifetime of **30** being 10 min at 35°C

TABLE 1. Physical properties of rearrangement products

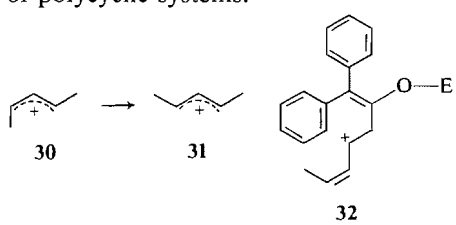
Starting material	Tetralone	Reaction time	Yield (%)	Melting point (°C) (solvent)[a]	Infrared (cm^{-1}) C=O	Infrared (cm^{-1}) C=C[b]	*m/e* (parent)
1	**6**	1 h	Above 85	105–116 (ethanol)	1727		298[c]
2	**7**	Under 15 min	ca. 85	103–107 (softens above 95)	1717[d] 1729	1663	262[c]
3	**8**	Under 15 min	Above 85	Oil	1723	1661 970	262[c]
4	**9**	24 h	Above 90	104–106 (benzene–hexane at −20°C)	1713		274
5	**10**	Under 12 h	Above 85	Oil	1716		
11			No reaction				

[a]The samples sublime as oils or glasses. On standing these oils and glasses begin to yellow.
[b]It is unclear whether the absorptions at 1663 and 1661 cm^{-1} are due to the isolated unsaturation in the molecules or are shoulders to the carbonyl absorption. These absorptions are not present in the immediate dihydronaphthalene derivatives of the proposed 2-tetralones. The peak at 970 cm^{-1} is clearly due to the *trans*-double bond.
[c]The spectrum is not clean but shows small peaks for higher molecular weight material (oxidation). Such diphenylacylmethyl derivatives are known to undergo air oxidation (7).
[d]Doublet.

(13). It is, therefore, not likely that within the reaction time (15 min) and conditions (25°C) the corresponding allyl cation **32** will equilibrate with its more stable *trans,trans* rotamer.

In summary, we have shown the 2-phenylcyclobutanones with an activating group undergo facile acid-catalyzed rearrangements at room temperature to 2-tetralones.

With the availability of cyclobutanone derivatives, extension of these reactions to other bicyclic derivatives could constitute a novel method in the synthesis of polycyclic systems.



30 **31** **32**

SCHEME 5

Experimental

Melting points were determined on a Fisher-Johns hot-stage melting point apparatus. All melting points and boiling points are uncorrected. Infrared (ir) spectra were determined on a Unicam SP 1000 Spectrophotometer and nuclear magnetic resonance (nmr) spectra were recorded at 60 MHz (Varian EM-360). Chemical shifts are reported in parts per million (δ) relative to Me_4Si (δ 0.0 ppm) as an internal standard. High pressure liquid chromatography was performed on a Waters Model R-400 instrument using a μ Bondapak C_{18} column. Abbreviations used are: s = singlet, d = doublet, t = triplet, m = multiplet, dd = doublet of doublets, td = triplet of doublets, q = quartet, b = broad, w = weak, med = medium, sh = sharp, st = strong.

Diphenylketene was prepared according to the method of Huisgen and Feiler (5).

2,2-Diphenylcyclobutanone (**11**) was prepared according to the method of Huisgen and Feiler (5). The yellow product mixture was treated with diethyl ether to yield a white solid (also insoluble in acetone and benzene) and a yellow solution. The ether insoluble solid became blood red when treated with H_2SO_4. The ethereal solution was extracted with Na_2CO_3. The material contained in the ethereal layer was chromatographed on silicic acid with varying amounts of benzene–hexane to yield 1.70 g of **11** from 5.88 g of diphenylketene (15%).

The Na_2CO_3 extract was acidified and the product shown to be a carboxylic acid mixture by ir and extraction into $NaHCO_3$. Upon treatment with H_2SO_4 and quenching the blood red solution with water, the acids were transformed into ketone products (sh C=O at 1715 cm^{-1}) which could only be extracted into Na_2CO_3 solution and not $NaHCO_3$.

7,7-Diphenylbicyclo[3.2.0]-2-hepten-6-one (**5**), 3-(cis-propenyl)-2,2-diphenylcyclobutanone (**2**), 3-(*trans*-propenyl)-2,2-diphenylcyclobutanone (**3**), and 8,8-diphenylbicyclo[4.2.0]-2-octen-7-one (**4**) were made by the method of Huisgen and Otto (6).

General Method for the P_2O_5-catalyzed Rearrangement of the Cyclobutanones

About 1 g of the cyclobutanone was dissolved in 25–50 ml of benzene and treated with 1–2 g of P_2O_5. Vigorous stirring was continued until tlc indicated completion of rearrangement. The dark red mixture was gravity filtered through paper and the red P_2O_5 cake was washed well with benzene. After concentrating the combined, water-white filtrates by rotary evaporation and chromatographing over silicic acid with benzene as eluent, the product was obtained in high yield. For the sake of a clean and easy chromatography, it is important that the rearrangement be complete, but to avoid decomposition of the product by P_2O_5, the reaction should be allowed to proceed no longer than necessary.

Typical yields after chromatography, reaction times, and physical properties are given in Table 1.

The nmr spectra ($CDCl_3$) of the rearrangement products are as follows:

Compound **6** δ : 2.53–3.30 (m, 2H), 4.23–4.62 (m appears as an unresolved q, 1H), 4.78 (s with a shoulder on the downfield side, 1H), and 6.7–7.6 (m, aromatic, 9H).

Compound **7** δ : 1.71 (td, J_d = 1.5 and J_t = 13.5 Hz, 3H), 2.18–3.03 (m, 2H), 3.98–4.45 (m, 1H), 4.81 (s) and 4.96 (s)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(both together represent 1H), 5.21–6.09 (m, vinyl, 2H), and 6.5–7.6 (m, aromatic, 9H).

Compound **8** δ : 1.71 (unresolved d, J = ca. 4 Hz, 3H), 2.25–3.13 (m, 2H), 3.63–4.05 (m, 1H), 4.73 (s with a shoulder on the downfield side, 1H), 5.38–5.67 (m, vinyl, 2H), and 6.8–7.65 (m, aromatic, 9H).

Compound **9** δ : 1.58–2.32 (m, 4H), 2.77–3.07 (m, 1H), 3.68–4.1 (m, 1H), 4.75 (s with spiked shoulder at 4.81, 1H), 5.81 (s, vinyl, 2H), and 6.71–7.45 (m, aromatic, 9H).

Compound **10** δ : 2.41–2.9 (m, 2H), 3.21 (td, J_t = 9 and J_d = 4 Hz, 1H), 4.25–4.63 (s with a spiked shoulder at 4.90, 1H), 5.88 (m, vinyl, 2H, very complex pattern on expansion with very small J values), and 6.8–7.5 (m, aromatic, 9H).

Examination of **7** and **8** by hplc clearly indicated that there had been no isomerization of the double bond during rearrangement; **7** has retention volume of 26.2 ml and **8** of 27.8 ml. A mixture of the two clearly shows two peaks. The individual products show only one peak somewhat broad. This broadening is thought to be due to the isomerism of the 2-tetralones.

General Method for Converting the 2-Tetralones to Dihydronaphthalene Derivatives

About 350 mg of the rearranged product (freshly prepared) was dissolved in 30 ml of ethanol and treated with 1 ml of 97% hydrazine. After stirring for 18 h, the solution was added to diethyl ether and extracted with distilled water until neutral. The dried ethereal layer was reduced to 25 ml and silver oxide (1 g) added. A silver mirror appeared and the mixture was filtered after 24 h. Chromatography on silicic acid using a benzene-hexane mixture (1:3 v/v) afforded the dihydronaphthalene in 23–35% yield. A bright yellow product is also formed, but has not been identified (only two kinds of aliphatic absorptions are noted in the nmr).

On one occasion the heat- and light-sensitive hydrazone **12** was isolated and had ir bands at 3400, 3300, and 3210 (N—H) and 1600 cm^{-1} (broad, involving C=N, C=C conjugated, and C=C aromatic). Its nmr ($CDCl_3$) had absorptions at δ 2.2–3.2 (m, 3.95–4.38 (m), 4.87 (s with a spiked shoulder at 4.93), 4.8 (b, N—H, bordering the 3.95–4.38 m and having the 4.87 s superimposed on it, 4H total), and 6.65–7.4 (m, aromatic, 14H or 15H).

The dihydronaphthalenes formed were all liquids or oils and could not be crystallized. Their ir spectra were similar showing peaks at 3050–2800 (C—H stretch), 1600 (aromatic C=C stretch), 1495–1480 (d), 1440 (methylene band), and 780–690 cm^{-1} (aromatic substitution patterns). In addition **17** displayed a strong absorption at 965 cm^{-1} indicative of the *trans*-unsaturation. Compound **21** shows a strong *m/e* peak at 258 with some minor peaks at higher molecular weight.

The nmr spectra are as follows.

Compound **15** δ : 2.73 (dd, J = 8 and 5 Hz, 2H), 4.17 (t, J = 8 Hz, 1H), 5.99 (t, J = 5 Hz, 1H), and 6.77–7.52 (m, aromatic, 14H).

Compound **16** δ : 1.71 (d, J = 5 Hz, 3H), 2.20–2.60 (m, 2H), 3.60–4.15 (m, 1H), 5.43–5.70 (m, 2H), 5.98 (t, J = 5 Hz, 1H), and 6.95–7.47 (m, aromatic, 9H).

Compound **17** δ : 1.72 (d, J = 5 Hz, 3H), 2.30–2.61 (m, 2H), 3.28–3.72 (m, 1H, appears as an unresolved q), 5.40–5.70 (m, 2H), 5.98 (t, J = 5 Hz, 1H), and 6.90–7.50 (m, aromatic, 9H).

Compound **21** δ : 1.71–2.40 (m, 4H, contains t with J = 5 Hz), 2.70–3.11 (m, 1H), 3.43–3.72 (m, 1H), 5.80 (m, superimposed on d with J = ca. 5 Hz, 3H), and 6.90–7.48 (m, aromatic, 9H).

Other Methods of Preparing the Dihydronaphthalenes

(*i*) Subjecting the hydrazone **12** prepared as indicated above to potassium *tert*-butoxide in DMSO (anhydrous) yielded 18% of **15** after work-up and chromatography.

(*ii*) The freshly prepared, crude hydrazone **13** was treated with activated MnO_2 rather than Ag_2O. After the mixture in anhydrous THF was stirred for 18 h, chromatographic work-up afforded **16** in 27% yield.

(*iii*) The procedure with Ag_2O was repeated using PbO_2 on hydrazone **14**. Dihydronaphthalene **17** was obtained after chromatography in 10% yield.

(*iv*) Treating **6** with hydrazinium sulfate in ethanol, stirring for 18 h, and then refluxing for 3 h yielded 14% of **17** after chromatography.

(*v*) The tosylhydrazone of **6** was prepared, treated with CH_3Li, and heated, affording no hydrocarbon product.

*Oxidation of 1,2-Dihydro-1,4-diphenylnaphthalene (**15**) to 1,4-Diphenylnaphthalene (**18**)*

A 74 mg sample of **14** was refluxed in benzene (50 ml) with an excess (200 mg) of 2,3-dichloro-5,6-dicyanoquinone (DDQ) for 1 h. Chromatographic work-up on silicic acid using benzene–hexane as eluent (1:3 v/v) afforded 70 mg (96%) of **18**. Recrystallization from ethanol afforded material identical to a known sample by ir, nmr, tlc, mixture mp, and mp 136–137°C (lit. (8) mp 134.5–136°C).

*9-Phenylphenanthrene (**22**)*

Oxidation of **21** by DDQ in a manner as above afforded, after chromatography, a near quantitative yield of **22**; ir (KBr): 3060 (b), 2940 (b), 1595 (w), 1490 and 1450 (d, med), 888 (sh, med), 779 (sh), 764 (sh), 753 (sh), 740 (sh, st), 721 (sh, st), and 699 cm^{-1} (sh, st). The nmr was identical to that given in the literature (9). Recrystallization of a sample from ethanol afforded crystals with mp 103–104°C (lit. (14) mp 105–106°C).

*Attempted Oxidation of **16** and **17***

The same procedure was followed as above using an excess of DDQ. No hydrocarbon starting material or product could be found.

*Attempted Addition of Reagents to the Carbonyl of **6***

(*i*) An ethereal solution of **6** (380 mg) was treated with an excess of ethereal CH_3Li (1.56 M, ca. 2 ml). An initial solid dissipated with further addition of CH_3Li and gas evolution accompanied the process. Acidification with dilute HCl, work-up, and chromatography over silicic acid employing 5% diethyl ether in benzene (v/v) afforded 235 mg (ca. 628) of a hydroxyketone (ir: 3615 (w), 3430 (st), and 1713 cm^{-1} (st)). Treatment with P_2O_5 gave an unsaturated ketone (1710 cm^{-1}).

Treatment with methylmagnesium bromide gave the same result.

(*ii*) Reduction of the carbonyl to an alcohol was attempted by adding $NaBH_4$ (30 mg) to 300 mg of **6** in 10 ml of ethanol. Slow evolution of gas resulted. The crude product after acidification with dilute HCl and work-up had an ir similar to the hydroxyketone cited above.

(*iii*) Similar results were obtained on using LAH in THF, but the product was less pure.

Crown ether catalysis of decarboxylation: a general survey of reactivity and a detailed analysis of the triphenylacetate anion

D. H. HUNTER, M. HAMITY, V. PATEL, AND R. A. PERRY

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 29, 1977

D. H. HUNTER, M. HAMITY, V. PATEL, and R. A. PERRY. Can. J. Chem. **56**, 104 (1978).

The effect of 18-crown-6 ether **3** on the decarboxylation rate in THF of sodium salts of carboxylic acids formally derived from hydrocarbons has been investigated and these acids include 9-phenylfluorene-9-carboxylic acid, fluorene-9-carboxylic acid, phenylacetylene carboxylic acid, triphenylacetic acid, and diphenylacetic acid. Addition of equimolar **3** resulted in an increase in decarboxylation rate of 13- to 500-fold and there was a correlation between the decarboxylation rate and the pK_a value of the product hydrocarbon.

The decarboxylation of triphenylacetate was investigated in detail. The effect on reaction rate of cation (Li^+, Na^+, K^+), crown ether concentration, water concentration, and solvent polarity has provided information as to optimum reaction conditions and has helped to clarify the reaction mechanism.

D. H. HUNTER, M. HAMITY, V. PATEL et R. A. PERRY. Can. J. Chem. **56**, 104 (1978).

On a étudié l'effet des couronnes-18 éther-6 (**3**) sur la vitesse de décarboxylation, dans le THF, de sels de sodium d'acides carboxylique dérivés d'une façon formelle d'hydrocarbures; parmi ces acides on retrouve les acides phényl-9 fluorènecarboxylique-9 fluorénecarboxylique-9, phénylacétylènecarboxylique, triphénylacétique et diphénylacétique. Lors de l'addition de quantités équimolaires de **3** les vitesses de décarboxylation sont multipliées par des facteurs allant de 12 à 500 et il existe une corrélation entre la vitesse de décarboxylation et le pK_a de l'hydrocarbure formé.

On a étudié en détail la décarboxylation de l'anion triphénylacétate. Un examen de l'effet, sur la vitesse de réaction, de cations (Li^+, Na^+, K^+), de la concentration de couronne éther, de la concentration d'eau et de la polarité du solvant, a fourni des informations sur les conditions réactionnelles optimum et permet de clarifier le mécanisme de la réaction.

Introduction

The decarboxylation of carboxylic acids and their derivatives has received significant attention (1) from biological, synthetic, and mechanistic points of view. From the variety of mechanistic approaches that have been used, reaction pathways involving both the ionized and unionized form of the carboxyl group have been identified. While a range of substrates have been observed to decarboxylate through the ionized or carboxylate form, most detailed studies have payed particular attention to the effect of solvent on the reaction. The effect of micelles (2) and inclusion complexes (3) on decarboxylation rates also have been investigated.

In an important study (4) involving benzisoxazole-3-carboxylates **1**, Kemp and co-workers observed a rate dependence on solvent covering a range of $\sim 10^8$ and demonstrated that hydrogen-bonding of solvent to the carboxylate group is one of the major factors responsible for the observed deactivation by protic solvents. In a less ambitious study (5) of the sodium salt of 3-(fluoren-9-ylidene)-2-phenyl-acrylate **2**, we also observed a strong dependence of decarboxylation rate on solvent which implicated hydrogen bonding. However the role of ion-pairing on the rate of decarboxylation in tetrahydrofuran was also in-

vestigated by observing the rate enhancing effect of dibenzo-18-crown-6 ether. An apparent rate enhancement of about 10^3 to 10^5 was sufficient to encourage us to look in more detail at both the source and the generality of this acceleration.

Our study of the effect of crown ethers on decarboxylation in aprotic solvents has involved both a survey of several carboxylate anions and a more thorough study of a selected example, the triphenylacetate anion. The range of carboxylate anions included those formally derived from hydrocarbons as well as several examples of β,γ-unsaturated carboxylic acids. This article will be limited to the results pertaining to the carboxylic anions formally derived from hydrocarbons.

Results and Discussion

For purposes of discussion our study of the effects of crown ethers on decarboxylation of carboxylate anions can be conveniently subdivided. First a general survey of reactivity as a function of structure of the carboxylate will be presented followed by a detailed study of the triphenylacetate anion. In the case of the triphenylacetate anion several variables were systematically changed and these include the nature of the cation, the water concentration, the crown ether concentration, and the solvent polarity. Throughout this study 18-crown-6 ether **3** was used because of its complexing ability with the alkali metal cations, its solubility in a range of solvents and its ready availability.

The Structure of the Carboxylate Anion

A study of a series of carboxylate anions was undertaken to determine: (*i*) the generality of crown ether assistance to decarboxylation; (*ii*) possible correlations between structure and reactivity; and (*iii*) the practical range of usefulness of the crown ether assisted decarboxylations. Initially it seemed likely that the rate of decarboxylation of a carboxylate anion ($R—CO_2^- \rightarrow R^- + CO_2$) might well respond to the stability of the carbanion being produced with changes in the R group having a greater effect on the stability of the carbanion (R^-) than on the carboxylate anion ($R—CO_2^-$).

With this in mind a series of carboxylic acids was selected in which the pK_a values of the derived hydrocarbons (RH) spanned the range 18–32[1] and these are 9-phenylfluorene-9-carboxylic acid **4**, fluorene-9-carboxylic acid **5**, phenylacetylenecarboxylic acid **6**, triphenylacetic acid **7**, and diphenylacetic acid **8**. The pK_a values (DMSO) of the derived hydrocarbons are 17.9 for 9-phenylfluorene, 22.6 for fluorene, 28.8 for phenylacetylene, 30.7 for triphenylmethane, and 32.1 for diphenylmethane. Acids **5** and **8** were available commercially while **4**, **6**, and **7** were prepared via carbonation of the appropriate organolithium. The sodium salts were obtained as solids after lyophilization of a titrated aqueous solution.

To provide a comparison with the previously reported system **2**, the decarboxylation reactions were run in ether solvents (primarily THF) at a temperature at which the decarboxylation both in the presence and absence of 18-crown-6 ether **3** could be followed conveniently. The results of this study are presented in Table 1. In runs 4, 5, 7, and 9 the reactions showed reasonable first-order behaviour over at least two half-lives while often the reactions run in the absence of **3** (runs 3, 6, and 8) were sufficiently slow that the reactions were followed to only about 50% at which point first-order plots were still reasonably linear. For this reason half-lives have been used to facilitate comparisons. Runs 1 and 2 were too fast to follow with ease and runs 10 and 11 were too slow. For purposes of comparison, half-lives were calculated for these runs from a first-order rate expression although we have no firm evidence as to the actual order in substrate. The reactions run in the absence of **3** were two-phase reactions and in dioxane the sodium salt of **6** was only partially soluble even in the presence of equimolar amounts of **3**. In spite of the semiquantitative nature of some of these results and the uncertainty in some cases as to the actual kinetic order, the observed changes are sufficiently large to be of practical significance and to indicate trends.

With the exception of **6** which has limited solubility in dioxane, it is clear that there is a correlation between the rate of decarboxylation and the pK_a of the product, with the most acidic product being formed most rapidly both in the presence and absence of **3**. From the conditions required to decarboxylate **8** it would appear that even compounds with pK_a values near or above 32 can be decarboxylated although in sealed tubes. For all these substrates, the acid forms were quite resistant to decarboxylation and decarboxylation through the salt is the more facile and preferred process. In the presence of equimolar water, the inorganic product is bicarbonate which frequently precipitates so that the entire reaction is run under only mildly basic conditions.

$$R—CO_2M + H_2O \xrightarrow[THF]{3} R—H + MHCO_3\downarrow$$

For all substrates equimolar amounts of the crown ether **3** had an accelerating effect on the rate of decarboxylation which ran from 13 times for **6** (runs

[c]Corresponds to 20.1% reaction at 135 min.
[d]Corresponds to 48% reaction at 4 min.
[e]Corresponds to 20% reaction at 189 h.
[f]Corresponds to 8.4% reaction at 30 min and 38% reaction at 150 min.

6 and 7) to 500 times for **5** (runs 3 and 5). For the substrates that were soluble in the presence of equimolar **3**, the acceleration was in the range of 100–500. Runs 4 and 5 show that changing the crown ether to substrate ratio from 0.1 to 1.0 changes the relative ratio of the half-lives by a factor of 6. Thus while the rate is sensitive to the amount of **3** present, the dependence seems to be less than first order. From a practical point of view, a ratio of 0.1 still produces an acceleration of 83 (runs 3 and 4) which means **3** can be used in reduced amounts. However, a simple extraction procedure has been developed for recovery of **3** (6) which minimizes the disadvantages of using equimolar amounts of **3**.

Interpretation of the accelerating effects of **3** on the various substrates is complicated by the fact that **3** presumably increases the reactivity of *dissolved substrate* but also acts as a phase transfer agent by increasing the solubility of substrate. While the overall reactivity in both the presence and absence of **3** parallels the pK_a value of the product, it is not clear what factors determine the solubilities of substrate in the absence of **3** and thus the net rate of reaction. The fact that the substrates alone have quite limited solubility in THF suggests that the major effect of **3** is as a phase transfer agent.

Decarboxylation of Triphenylacetates

The observation of enhanced decarboxylation rates in a range of substrates upon the addition of a crown ether, **3**, as well as the opportunity to investigate the role of crown ethers in a simple reaction led us to a more detailed study of one of the substrates. Triphenylacetate was chosen because it had appropriate reactivity at readily accessible temperatures. Tetrahydrofuran was used as the solvent for most of the studies because of its ease of handling and because it dissolved the complexed form of most of the salts. A later study of the effect of solvent on reaction rate (*vide infra*) confirmed the accidental sensibility of this initial decision.

Nature of the Cation

Table 2 contains the half-lives for decarboxylation of the lithium, sodium, and potassium salts of triphenylacetate. The reactions were run at reflux in THF both in the absence of **3** and in the presence of equimolar **3**. Again the reactions run in the absence of **3** (runs 12, 8, and 14) and the reaction involving lithium and **3** (run 13) were two-phase reactions. Since the actual kinetic order is in doubt, the times for 50% reaction ($t_{\frac{1}{2}}$) under the stated conditions have been reported for purposes of rough comparison.

Two trends are apparent from the results. First, the presence of **3** produces a rate enhancement of about 100-fold with each of lithium (runs 12 and 13),

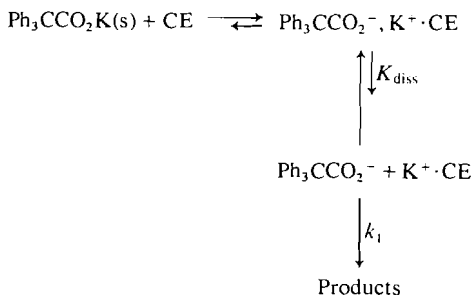
sodium (runs 8 and 9), or potassium (runs 14 and 15) and the magnitude is about the same for all three cations. Second, the reactivity order is K > Na > Li either in the absence of **3** (runs 12, 8, and 14) or in its presence (runs 13, 9, and 15). The magnitude of the change is about the same in either case with the potassium salts (runs 14 and 15) being about 10 times[2] more reactive than sodium (runs 8 and 9) which in turn are about 10 times more reactive than lithium (runs 12 and 13).

From a practical point of view it is clear that the most reactive system involves the complexed potassium salt. From an interpretive point of view the situation is much fuzzier even though the changes are reasonably large. Comparisons involving the two-phase reactions (runs 12, 13, 8, and 14) are clouded by our lack of knowledge of the solubilities of the salts and our ignorance of the actual reactive intermediates. A comparison of the homogeneous reactions involving complexed potassium, sodium, and perhaps lithium (runs 15, 9, and 13) is more justifiable since only the complexed form is appreciably soluble and the solubility behaviour is consistent with a one to one complex between **3** and the cations. As will be discussed later, kinetic results with potassium triphenylacetate **9** suggest that the reactive intermediate is a small equilibrium amount of dissociated triphenylacetate (Scheme 1).



SCHEME 1

The trend with cation above implies that complexed potassium triphenylacetate is more dissociated than sodium than lithium. Analogous observations have been made by esr on alkali metal ketyls with dibenzo-18-crown-6 ether in THF (7). Studies (8) of the effect of dibenzo-18-crown-6 on the relative proportion of solvent separated and contact ion pairs in THF have shown, in contrast, that the preference for solvent separated ion pairs is in the order $Na^+ > Li^+ > K^+$ and in the absence of crown ethers the order is $Li^+ > Na^+ > K^+$ (9). While the reasons for this difference are complex, it has been noted that the equilibria between ion pairs is temperature sensitive. Thus the relative reactivities and perhaps even the order of decarboxylation rates might change with temperature.

Effect of Crown-ether Concentration

Since complexed potassium triphenylacetate was the most reactive of the triphenylacetates and thus is of practical interest, we decided to look in detail at its behaviour. Because of the high rate of reaction at reflux in THF, the temperature was lowered to 30°C for most of the subsequent studies. It was felt that the reaction rate may be sensitive to water in THF, so the concentration of water was monitored by Karl-Fischer titration.

The first parameter to be discussed here is the effect of the concentration of **3**. The results (Table 3) can be conveniently subdivided into those runs involving greater than equimolar **3** (runs 16–23) and those involving less than equimolar **3** (runs 24–30), since equimolar **3** was necessary to effect complete solution of potassium triphenylacetate **9**; a result consistent with formation of a one-to-one complex. In the absence of **3**, potassium triphenylacetate **9** did not have detectable solubility (<0.0001 *M*) in THF at 30°C.

For runs 16–23 which began as homogeneous solutions, the rates of decarboxylation were consistent with a first-order dependence in added triphenylacetate over about 90% reaction and it is these first-order rate constants (k_1^{obs}) that are reported in Table 3. In spite of reasonable kinetic behaviour the solutions did not remain homogeneous throughout the course of the reaction. Filtration (run 17) yielded a white solid (*ca.* 30% yield) whose equivalent weight by titration was consistent with potassium bicarbonate not complexed with **3**.

The results of runs 17, 19, 20, 21, and 22 show the effect of increasing the concentration of **3** with a constant concentration of **9** (0.020 *M*) and of water (0.047–0.053 *M*). While the changes were not large there was a consistent decrease in rate with increase in crown ether concentration beyond equimolar **3**. Because even modest concentrations of **3** can represent fairly substantial weight percentages, it seemed feasible that the rate reducing effect of **3** may be due to changes in solvent polarity. In an attempt to mimic this effect of excess **3** on the solvent polarity, a comparison was made (run 23) using sufficient dioxane to produce a solution of the same weight percentage. There was a rate decrease (3.6×10^{-4} s^{-1}) compared to run 24 (4.6×10^{-4} s^{-1}) but the change was

[2]An extrapolation from rate data at 20, 30, and 40°C yielded a half-life of 1 min at 60°C as well as activation parameters: $\Delta H^{\ddagger} = 21.2$ kcal/mol; $\Delta S^{\ddagger} = -6.5$ eu. The pseudo first-order rate constants ($\times 10^4$, s^{-1}) were 1.18, 3.49, and 11.7, respectively, and were obtained for reaction mixtures 0.020 *M* in substrate, 0.053 *M* in H_2O, and 0.040 *M* in **3**.

not as large as that brought about by **3** (2.3×10^{-4} s^{-1} for run 29). Thus the observed effect of excess **3** may well be through the macroscopic properties of the medium since at a microscopic level the expectations seem to be in the opposite direction, e.g. formation of a 2:1 complex should be activating.

A series of experiments was directed at determining the effect of dissolved salt concentration on the reaction rate. One simple comparison is shown in runs 16 and 17 where the ratio of **9** to **3** to water was kept constant but the total dissolved salt concentration was doubled. As can be seen, an increase in salt concentration produced a decrease in rate constant. This is also evidenced in run 18 where added complexed potassium tetrafluoroborate produced a marked decrease in reaction rate. These concentration effects pointed to a reaction passing through a small equilibrium amount of dissociated ions (Scheme 1).

In an attempt to quantify the suggestion that the reaction involves dissociated ions, a series of reactions were run using less than equimolar **3** (runs 24–30). These reactions were characterized by an initial heterogeneous stage which showed zero-order kinetics followed by first-order kinetic behaviour for the remainder of the reaction. The break in the kinetic behaviour coincided with complete dissolution of substrate and appeared to occur when the amount of unreacted **9** equaled the amount of **3** added initially. Qualitatively the zero-order rate constant increases with increasing concentration of dissolved **9**, or added **3** concentration. In runs 25, 26, 27, and 30 the water concentration was held constant and sufficient **9** was added to provide a 0.010 M solution if totally dissolved. The actual dissolved substrate concentration was determined by the amount of **3** added and thus as the complexed substrate concentration was increased from 0.0011 M (run 25) to 0.070 M (run 30) the observed zero-order rate constant (k_0^{obs}) changed from 5.8×10^{-7} to 19.5×10^{-7}. As shown in Fig. 1, the k_0^{obs} showed a half-power dependence on dissolved complexed substrate concentration over the range 0.001–0.01 M.

The mechanism shown in Scheme 1 is consistent with this result provided (*a*) the solution remains saturated with complexed substrate ($Ph_3CCO_2K \cdot CE$) during the heterogeneous stage, (*b*) the dissolved substrate exists primarily as ion pairs, and (*c*) the decarboxylation proceeds through dissociated ions.

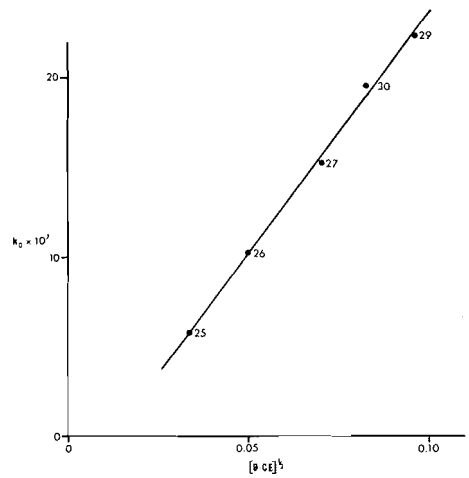

FIG. 1. Plot of zero-order rate constants (runs 25–30 of Table 3) vs. the square root of the dissolved salt concentration $[9 \cdot CE]^{\frac{1}{2}}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Thus the zero-order behaviour during any particular run is a consequence of a constant concentration of both ion-paired and dissociated substrate during the heterogeneous stage. The half-order dependence of the k_0^{obs} on the concentration of dissolved complexed substrate could arise if

$$[K^+\cdot CE] = [Ph_3CCO_2^-] \ll [Ph_3CCO_2K\cdot CE]$$

Since

$$\text{rate} = k_1[Ph_3CCO_2^-]$$

and from the definition of K_{diss} with $[K^+\cdot CE] = [Ph_3CCO_2^-]$

$$[Ph_3CCO_2^-] = (K_{diss}[Ph_3CCO_2K\cdot CE])^{\frac{1}{2}}$$

then

$$\text{rate} = k_1K_{diss}^{\frac{1}{2}}[Ph_3CCO_2K\cdot CE]^{\frac{1}{2}}$$

The apparent first-order behaviour of the homogeneous runs also is consistent with the mechanism in Scheme 1 provided the concentration of $K^+\cdot CE$ remains nearly constant over the course of the reaction. Thus from the definition of K_{diss}

$$\text{rate} = k_1[Ph_3CCO_2^-] = \frac{k_1K_{diss}}{[K^+\cdot CE]}[Ph_3CCO_2K\cdot CE]$$

The assumption that $[K^+\cdot CE]$ may not change a lot during the course of a particular run is supported by the observation that in the presence of equimolar **3** only about 30% of the expected $KHCO_3$ seems to precipitate even at long reaction times. This expression also shows that the rate of the reaction should be decreased by increasing $[K^+\cdot CE]$ either by increasing the substrate concentration (runs 16 and 17) or by adding a different complexed potassium salt (runs 17 and 18).

These results certainly seem consistent with the mechanism of Scheme 1. However, Scheme 1 has not been demonstrated to be the only mechanism consistent with the results. In fact, as will be seen later the mechanism may well be significantly more complex. An indication of this is given in runs 27 and 28 in which just the water concentration was changed producing a rate change. Our concern over the role water might be playing in this reaction, led us to a more thorough study of the effect of water concentration.

Effect of Water Concentration

As is presented in Table 4 and illustrated in Fig. 2, the effect of water on the reaction rates was not simple. The conditions chosen for this study involved homogeneous solutions in THF of **9** (0.020 *M*) and **3** (0.020 *M*) and the ratio of water to complexed substrate was changed from 0.03 to 36. With less than

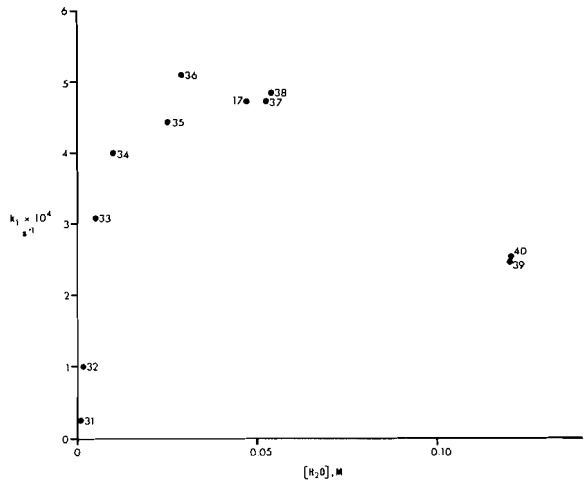

FIG. 2. Plot of first-order rate constants (runs 31–40 of Table 4) vs. the water concentration.

equimolar water [0.020 *M*] the rate increased with increasing water concentration. The rate leveled off when the ratio water/**9** was in the range of 1–3 and then decreased again at higher water concentrations. A second feature of the reactions containing less than 0.010 *M* water was the cessation of reaction when both available water protons had been consumed. Thus run 33 proceeded smoothly until about 40% reaction and run 32 to about 25% reaction. A number of the runs in Table 4 demonstrate the reproducibility of the rate data and confirm the changes with water concentration.

From a practical point of view these results indicate that water is necessary for a successful reaction but with slightly more than equimolar water the rate

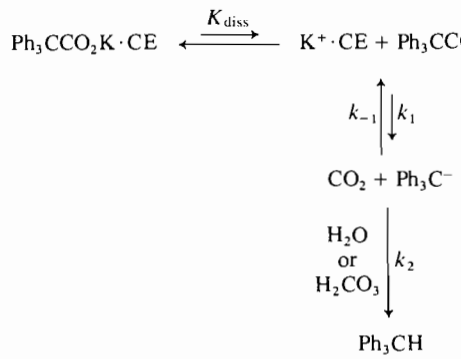
is not highly sensitive to water concentration. From the observation that water can both accelerate and decelerate the rate of decarboxylation it is clear that water must be capable of playing a dual role in the reaction scheme. Although there are probably several ways in which excess water could serve to slow the decarboxylation, hydrogen-bonding stabilization of the carboxylate ion is the most obvious and has precedent (4).

More intriguing is the question of how water can act to accelerate the decarboxylation at low water concentrations. One possible role for the water is to assist in the dissociation of the carboxylate ion pair. In this way the water could act to replace the triphenylacetate ion in the coordination shell of the complexed potassium ion. Crystal structures of

$$Ph_3CCO_2K{\cdot}CE + H_2O \rightleftharpoons Ph_3CCO_2^- + H_2O{\cdot}\overset{+}{K}{\cdot}CE$$

crown complexed cations frequently reveal an open face coordinated to the counter anion (10). This suggestion implies that water should be significantly better as a ligand than the solvent, THF, which is present in large excess. Such selectivity has been demonstrated for sodium ions in THF by sodium nmr chemical shift studies (11) and therefore is likely for potassium also. If water is acting to assist in ion pair dissociation, it should be capable of being a fairly general catalyst for crown ether assisted reactions in other solvents.

Another seemingly reasonable way in which water could accelerate decarboxylation is by competitively trapping the intermediate carbanion. This requires extending Scheme 1 to include the protonation step, with loss of CO_2 no longer the rate determining step (Scheme 2). This possibility was tested (run 42) by determining the effect of added CO_2 on the rate of decarboxylation since in Scheme 2 the rate should decrease as the CO_2 concentration increases. Indeed this was the case (run 34 cf. run 42) indicating also that the rate of carbonation of the triphenylmethyl anion must be comparable in magnitude to the rate of its protonation.



SCHEME 2

While this experiment provides support for Scheme 2 the actual situation is undoubtably more complex. A Karl-Fischer titration of the reaction solution which was originally 0.010 *M* in water showed no free water present (<0.001 *M*) when saturated with CO_2 (~0.2 *M*).[3] Presumably all the water had been converted to carbonic acid in THF. A similar situation appears to occur with ether as solvent (13). Thus in run 42, the reactants competing for the triphenylmethide anion are CO_2 and H_2CO_3 with CO_2 present in about a 10-fold excess. However, during a typical decarboxylation reaction, the water is present in excess and while both H_2O and H_2CO_3 are available for protonation[4] there may be very little CO_2 available for competitive carbonation until after the H_2O has been consumed. While CO_2, when present in excess, can compete with protonation, we think there is still insufficient evidence to confirm this as the way in which water accelerates the rate of decarboxylation.

Effect of Solvent

Since our study has been carried out using THF as solvent, we felt it was important to determine if indeed it was the solvent of choice. Thus the rate of decarboxylation of **9** (0.020 *M*) in the presence of **3** (0.020 or 0.040 *M*) and a 1.5- to 2.5-fold excess of water was measured for seven aprotic solvents of varying polarity (Table 5). While the total range of reactivity was large (~10^4) most of the activating solvents were bunched together within a factor of 10 to each other and THF was among these. From the standpoint of reaction rate, there is little to choose between several of the solvents and a choice of solvent can be made then on other factors such as solubility considerations or ease of removal of solvent.

Since acetonitrile has been chosen for many crown ether catalyzed reactions (14), a comparison was made of the decarboxylation rate in acetonitrile in the presence and absence of **3**. As runs 46 and 47 show, while acetonitrile is among the activating solvents it is at the bottom end of these and at least a factor of 2 slower than THF. Also a comparison of run 47 with run 48 shows a rate enhancement due to the addition of **3** of 60-fold which is somewhat less than that observed in THF (Table 2), although again the reaction in the absence of **3** was a two-phase reac-

[3]Concentration extrapolated from the lower temperature data of Bodor *et al.* (12).

[4]NOTE ADDED IN PROOF: A control study has shown that KOH·**3** in THF will deprotonate triphenylmethane. Thus H_2CO_3 rather than H_2O may be the species that protonates the triphenylmethide anion.

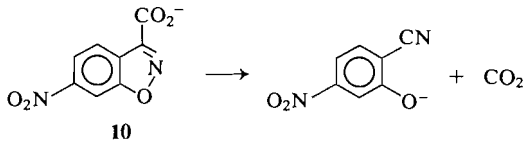
tion for which a first-order rate constant is not really valid.

Although the solvents chosen covered a fairly even distribution of polarities, the reaction rates were bunched into two groups with the reaction being about 10^3 slower in either benzene or dioxane than in 1,2-dimethoxyethane, THF, acetonitrile, pyridine, or dimethylsulfoxide. Correlations were sought with many different parameters of solvent polarity or density, but we had no significant success as might be expected. This is illustrated in Fig. 3 where our data have been plotted against values of E_T (15) showing the scatter that typically results.

The lack of correlation between the results of Table 5 and any simple solvent parameter may be attributed to the fact that the decarboxylation does not appear to be a simple one-step reaction. In fact, if Scheme 2 is correct there are at least five rate constants each of which would be altered upon changing solvent and thus any correlation would seem fortuitous. As a result we were rather surprised to discover a reasonable relationship between our data and those of Kemp and Paul (4). They had studied the decarboxylation of 3-carboxy-6-nitrobenzisoxazole **10** in the presence of a large excess of tetramethyl-



10

guanidine in a wide range of solvents. Five solvents were common between the two studies and Fig. 4 illustrates the common response of both reactions to a change of solvent. While neither reaction correlates with the usual solvent parameters, Kemp and Paul found a correlation of their rate data with the energy of an electronic transition of the reaction

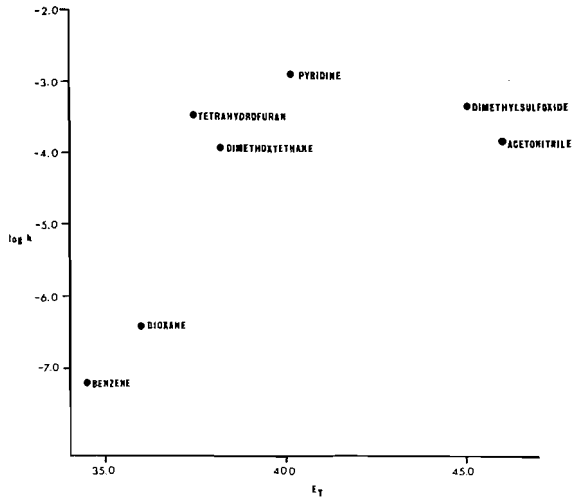


FIG. 3. Plot of log (first-order rate constants) in various solvents vs. the value of E_T (15) for that solvent.

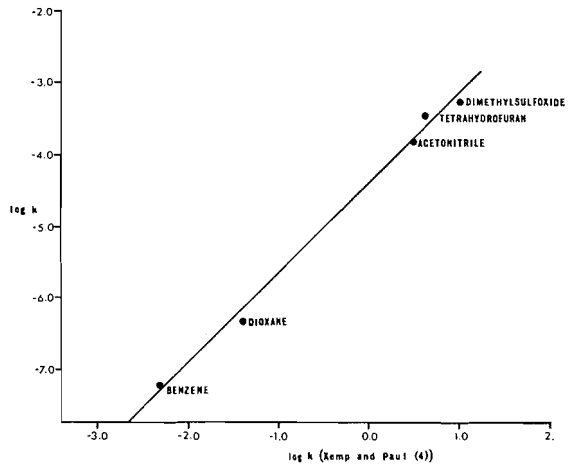

FIG. 4. Plot of the log of the first-order rate constant for decarboxylation of **9** vs. the log of the rate constant for decarboxylation of **10** in various solvents.

product. We made no such study of the triphenylmethyl anion.

While a mechanistic similarity between the two has not been established, from a practical point of view the observed correlation may be of general value. If other decarboxylation reactions proceeding through the salt form can be assumed to behave similarly, then our data and the extensive solvent studies of Kemp and Paul may assist in the choice of reaction conditions.

These studies have demonstrated that catalysis of decarboxylation of sodium carboxylates is a fairly general phenomenon and for those salts which are soluble in THF in the presence of **3**, rate enhancements in the order of 100–500 are observed. Also

there is a correlation between crown ether assisted decarboxylation rates and the stability of the carbanion produced as a transient intermediate.

An analysis of the behaviour of the triphenylacetate anion has provided results which should be of value to the practitioner and which also give an insight into the mechanism of the catalysis. From a practical point of view, optimum decarboxylation rates should be obtained using the potassium salt in the presence of equimolar **3**.[5] Water is essential to the reaction but should not be in large excess with optimum rates being obtained with a two- to threefold excess of water. While a number of solvents give similar rates, the two best were THF and pyridine.

From a mechanistic point of view, the reaction of **9** in the presence of **3** in THF seems to proceed through dissociated ions which are present in a small equilibrium amount. Water has both an accelerating and decelerating effect on the reaction. The decelerating effect points to hydrogen-bonding of water to the carboxylate while the source of accelerating effect remains ambiguous. The rate depressing effect of added CO_2 indicates that trapping of the intermediate carbanion by CO_2 can be competitive with trapping by protonation.

Experimental

Solvents

The benzene, tetrahydrofuran, and dioxane were freshly distilled from lithium aluminum hydride before use. Spectroscopy quality (Anachemia) acetonitrile, dimethyl sulfoxide, dimethoxyethane, and pyridine were further treated (17) before use. The water content of the solvents and solutions was determined by Karl-Fischer Titration-Photovolt Aquatest.

Substrates

The 18-crown-6 ether was prepared by the usual procedure (18). Fluorene-9-carboxylic acid and diphenylacetic acid were purchased and purified before use. The 9-phenylfluorene-9-carboxylic acid, triphenylacetic acid, and phenylacetylene carboxylic acid were prepared by carbonation of the corresponding organolithium. The preparation of triphenylacetic acid typifies this procedure.

Triphenylmethyllithium was prepared by reacting 12 g (50 mmol) of triphenylmethane in 100 ml of THF at −78°C under an argon atmosphere with 21 ml (50 mmol) of 2.5 *M* *n*-butyllithium in hexane (Ventron). The solution was warmed to room temperature for 15 min and then transferred over about a ½ h period to 75 ml of THF at room temperature that was constantly resaturated with dry carbon dioxide. After most of the THF was removed by rotary evaporator the reaction mixture was extracted using water–ether. After two ether washes, the water layer was acidified and then reextracted with ether. After drying, solvent removal, and recrystallization from toluene, triphenylacetic acid (mp 269°C, lit. (19) mp 270°C) was obtained in 45% yield. Similarly phenylacetylene carboxylic acid (mp 136–137°C, lit. (20) mp 137°C) was obtained in 70% yield and 9-phenylfluorene-9-carboxylic acid (mp 194°C, lit. (21) mp 194°C) was obtained in 78% yield.

The lithium, sodium, and potassium salts of the carboxylic acids were prepared by reaction of the acid with an aqueous solution of the corresponding hydroxide. The titration was stopped short of the equivalence point and the excess acid was removed by filtration. The salts were isolated by lyophilization. The water content was determined by Karl-Fischer titration of THF solutions.

Analytical Procedures

The decarboxylation reactions were run on doubly degassed solutions under an argon atmosphere. Typically 25 ml of solvent were used and sufficient substrate, glc standard, and 18-crown-6 ether to provide concentrations in the range 0.01–0.05 *M*. Aliquots of these solutions were removed for Karl-Fischer water analysis and to determine the progress of the decarboxylation reaction. For the heterogeneous reactions that were run an attempt was made to remove representative samples. Rate constants were obtained by plotting ln (100 − % decarboxylation) vs. time.

The progress of the decarboxylation reactions was measured by glc with added internal standards calibrated for response to the thermal conductivity detector. Typically an aliquot of the reaction mixture was removed and treated by extraction with water–ether to remove the unreacted salt. The ether layer containing the product hydrocarbon, the internal standard and some 18-crown-6 ether was concentrated and an aliquot was injected for glc analysis. Phenanthrene was used as an internal standard for diphenylmethane, triphenylmethane, 9-phenylfluorene, and fluorene while mesitylene was used with phenylacetylene. The glc analysis was performed using a 5 ft × ¼ in. column of 5% SE-30 on Chromsorb W.

[5]For similar accelerating effects of crown ethers in the decarboxylation of alkali metal trichloroacetates see Idemori *et al.* (16). While they observed a decrease in carbene adduct to cyclohexene when using crown ethers, our work on the 18-crown-6 ether catalyzed decomposition of sodium trichloroacetate shows increased yields in chloroform solvent.

Mercury photosensitized decomposition of thietane

DAVID R. DICE AND RONALD P. STEER[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received August 2, 1977

DAVID R. DICE and RONALD P. STEER. Can. J. Chem. **56**, 114 (1978).

The mercury photosensitized decomposition of thietane vapour at room temperature has been studied. Quantum yields of the products, ethylene, propylene, cyclopropane, 1,2-dithiocane, and 1,5-hexadiene, have been measured as a function of substrate pressure, percent decomposition, and intensity and the influence of added NO and propylene has been examined. At low pressures quantum yields of thietane decomposition exceed unity. A mechanism involving thiatrimethylene and 4,5-dithiahexamethylene biradicals is proposed.

DAVID R. DICE et RONALD P. STEER. Can. J. Chem. **56**, 114 (1978).

On a étudié la décomposition, photosensibilisée par le mercure, de vapeurs de thiétane à la température ambiante. On a mesuré les rendements quantiques des produits, l'éthylène, le propylène, le cyclopropane, le dithio-1,2 cane et l'hexadiène-1,5, en fonction de la pression du substrat, du pourcentage de décomposition, de l'intensité et de l'influence provoquée par l'addition de NO et de propylène. Aux basses pressions, les rendements quantiques de la décomposition du thiétane sont plus grands que l'unité. On propose un mécanisme impliquant les biradicaux thiatriméthylène et dithia-4,5 hexaméthylène.

[Traduit par le journal]

Introduction

Whereas reports of the direct photodecomposition of cyclic organic sulfides are now relatively numerous (1–8), there have been but two brief previous reports of triplet sensitized photodecomposition of these molecules. Weibe and Heicklen (4) reported that the $Hg6(^3P_1)$ sensitized decomposition of thietane, $\underline{CH_2CH_2CH_2S}$, yielded ethylene, propylene, and cyclopropane with high pressure limiting quantum yields of 0.71, 0.02, and 0.005, respectively, unaffected by the addition of up to 10 Torr of O_2. These authors postulated that ethylene resulted from the molecular fragmentation of a thietane triplet but provided no conclusive evidence against the alternative, two-step decomposition involving a biradical intermediate. In a more recent study (9) of the mercury photosensitized decomposition of *cis*- and *trans*-3-ethyl-2-propylthietane vapour, however, we showed the major product must arise exclusively from the fragmentation of a free biradical intermediate, the lifetime of which is long in comparison with the period of C—C bond rotation.

Several sources suggest that there are a number of interesting aspects of the chemistry of the triplet states of the cyclic sulfides and the biradicals derivable from them which may be amenable to study by sensitization techniques. The lowest triplet state of thiirane, $\underline{CH_2CH_2S}$, has been implicated in the addition of $S(^3P)$ atoms to olefins, and in the thermolysis and photolysis of this compound. This state has been the subject of extensive theoretical and experimental investigation by Strausz and coworkers (1–3, 10–14) and is thought to have a substantial degree of biradical character, to be highly resistant to collisional deactivation, and to be capable of inducing the isomerization of olefins with very large quantum yield via a unique reversible addition reaction in which the sulfide retains its geometric configuration. In the thietane system we have shown (9) that triplet 1,4-biradicals derived from the sensitized photolysis of 2,3-dialkylthietanes are much longer lived than their singlet counterparts despite the fact that the degree of interaction between the two unpaired electrons must be relatively small in these species.

The present study has therefore been undertaken to elucidate the mechanistic details of the mercury photosensitized decomposition of thietane in order to explore further the triplet chemistry of the cyclic sulfides.

Experimental

Most of the apparatus and analytical procedures employed in the present work has been described in detail previously (6, 8). In the mercury photosensitization experiments a Hanovia, Model LO735A-7 low pressure mercury lamp was employed as a light source and either a 254 nm interference filter or short wavelength cut-off filters were used to isolate the 253.7 nm line. The transmitted light intensity was monitored with an RCA 935 phototube coated with sodium salicylate which produced a linear response over the range of intensities employed.

A fresh drop of mercury was placed in a side arm of the cell prior to each run. The temperature of the side arm was maintained at 25.0 ± 0.1°C whereas the cell itself was kept at 28 ± 1°C. After the reactants had been measured into the cell and thoroughly degassed, the contents of the cell were allowed to equilibrate for 1 h prior to photolysis. The cell was cleaned frequently to remove solid deposits.

Lorentz pressure broadening correction factors were measured using the method of Strausz *et al.* (15). For these measurements a Bausch and Lomb high intensity grating monochromator and lens system was used to isolate and collimate the 253.7 nm line; 100% transmittance was set using a freshly cleaned cell containing no mercury vapour. Mercury was then added to the cell side arm and the transmittance of the mercury resonance line measured as a function of addend pressure.

Actinometry was carried out using both the propane ($\phi(H_2) = 0.58$ after pre-irradiation) and N_2O ($\phi(N_2) = 1.00$) systems (16, 17) which yielded identical results. Quantum yields were determined with a precision of $\pm 2\%$ for ethylene; $\pm 5\%$ for propylene, 1,2-dithiocane, and 1,5-hexadiene; and $\pm 25\%$ for cyclopropane which was present in trace amounts only.

Propane (Phillips, Research Grade) was used without further purification. N_2O was purified by passing it through a 5 ft silica gel column at $-95°C$, followed by low temperature vacuum distillation from $-160°C$ to $-196°C$. All other materials were purified as previously described.

Results

The Hg6($^3P_1$) quenching cross section for thietane was measured using the method of Cvetanovic (17) by determining the quantum yield of N_2 from the mercury sensitized photolysis of N_2O-thietane mixtures. The results are shown in Fig. 1. The slope of the $\phi(N_2)^{-1}$ vs. $P(C_3H_6S)/P(N_2O)$ plot is 2.00 ± 0.05, in good agreement with previous results (4), from which a quenching rate constant of $2.86 \times 10^{11}\ M^{-1}\ s^{-1}$ and a cross section of 44.1 Å^2 for thietane may be obtained, assuming that the quenching rate constant for N_2O is $1.43 \times 10^{11}\ M^{-1}\ s^{-1}$ (17).

In addition to the three products, ethylene, propylene, and cyclopropane, previously reported (4), analysis of the $-130°C$ condensable fraction of the reaction mixture revealed the presence of two additional products; 1,2-dithiocane (DTO), previously identified in the direct photolysis of thietane (8), and a product of molecular weight 82, tentatively identified as 1,5-hexadiene (HXD) on the basis of its mass spectrum and gc retention time. CS_2, H_2S, and H_2 were present in trace amounts, and a white solid consisting of a mixture of organosulfide polymer and sulfur was also formed but was not analyzed routinely.

Quantum yields (based on the number of photons absorbed by mercury vapour and corrected for pressure broadening of the mercury absorption line) of all products as a function of thietane pressure are shown in Fig. 2. Previous determinations of the quantum yields of ethylene, propylene, and cyclopropane (4) are in excellent agreement with the present work and are shown for comparison.

Experiments in which product yields from the photolysis of 10 Torr of thietane were measured as a function of exposure time revealed that quantum yields were constant up to about 3% decomposition and declined thereafter. Quantum yield ratios remained constant to much larger percentage decompositions, however, indicating that the decline in quantum yields at long exposure times is likely the result of the deposition of light attenuating solid on the cell windows. Unlike the direct photolysis system (6), no evidence of secondary photolytic reactions was obtained. Nevertheless, in all other experiments reported herein, decomposition was restricted to 3% or less.

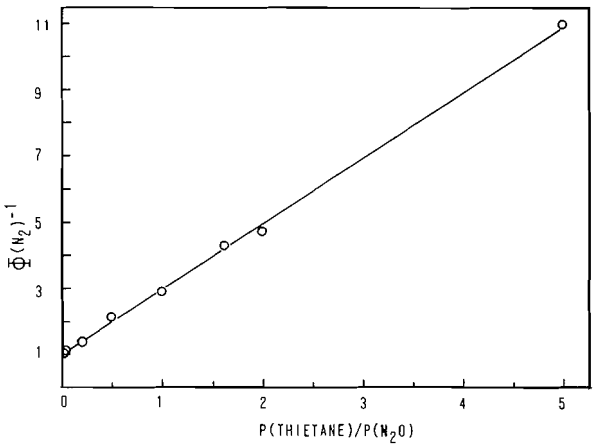

FIG. 1. $\phi(N_2)^{-1}$ vs. $[\square_S]/[N_2O]$ from the Hg6($^3P_1$) sensitization of thietane – nitrous oxide mixtures at a total pressure of 30 Torr.

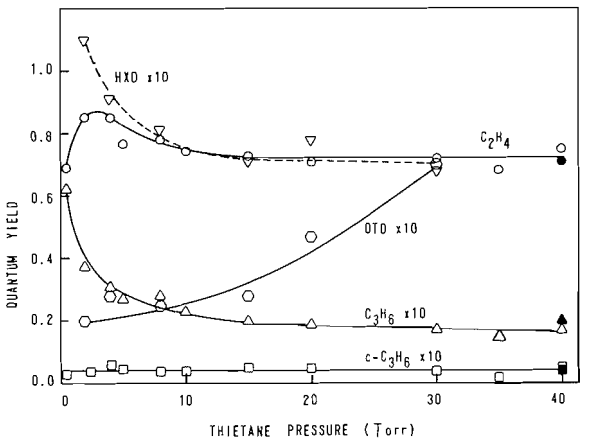

FIG. 2. Quantum yields of products as a function of thietane pressure. $I_a = 3.94 \times 10^{-7}$ einsteins per minute. Solid symbols are data of Weibe and Heicklen (4).

Product quantum yields from the Hg6($^3P_1$) sensitized decomposition of 20 Torr of thietane were found to be independent of absorbed intensity between 1.44×10^{16} and 2.59×10^{17} quanta per second.

In order to determine if free sulfur atoms were produced, 7 Torr of propylene was added to 50

TABLE 1. Effect of NO on the Hg6($^3P_1$) sensitized decomposition of thietane vapour[a]

P(NO) (Torr)	$1/f$[b]	ϕ (C_2H_4)	ϕ (C_3H_6)	ϕ (cyclo-C_3H_6)	ϕ (DTO)	ϕ (HXD)

0.5	1.02	0.73	0.019	0.005	0.014	0.066
1.0	1.04	0.72	0.018	0.003	0.009	0.025
2.0	1.07	0.70	0.019	0.006	0.003	0.023

[a] $P(\square_S)$ = 20 Torr. $I_a = 4.30 \times 10^{-7}$ einsteins per minute.

[b] $$f = \frac{P(\square_S)\sigma^2(\square_S)}{P(\square_S)\sigma^2(\square_S) + P(NO)\sigma^2(NO)}.$$

Torr of thietane and subjected to 3% thietane photodecomposition. Under these conditions 90% of the Hg6($^3P_1$) atoms will be quenched by thietane. No propylene episulfide, which results from the addition of S(^3P) to propylene, was detected.

Nitric oxide was added to determine the sensitivity of the product quantum yields to the presence of a free radical scavenger. The results of adding up to 2 Torr of NO to 20 Torr of thietane are given in Table 1. Quantum yields have been corrected for the fraction of Hg6($^3P_1$) quenched by NO. Both DTO and HXD showed significant decreases in quantum yield with increasing NO pressure whereas the C_2 and C_3 hydrocarbon products were unaffected. The latter observation is in agreement with the previous work of Weibe and Heicklen (4) who showed that these products have quantum yields which are unchanged by the addition of up to 10 Torr of O_2.

Discussion

The interaction of Hg6($^3P_1$) with 0.5 Torr of either pure *cis*- or pure *trans*-3-ethyl-2-propylthietane at room temperature has previously been shown (9) to result in the production of both *cis*- and *trans*-3-heptene and isomerized substrate. The ratio of the rates of production of the isomeric 3-heptenes was sensitive to the pressure of argon, added as an inert thermalizing gas, at pressures less than *ca.* 100 Torr, but converged to a common value at high pressures regardless of which thietane isomer was employed. These results indicate that a 1,4-biradical in which free C—C bond rotation takes place must be the precursor of all of the olefin which results from C—C cleavage. There is no evidence that thietane and its 2,3-dialkylderivatives exhibit different pathways leading to C—C cleavage products. Therefore, contrary to the mechanism of Weibe and Heicklen (4), it will be assumed that ethylene is produced exclusively via one or more biradical precursors in the present system.

The following mechanism is in qualitative accord with experiment.

[1] $$Hg6(^1S_0) + h\nu \rightarrow Hg6(^3P_1)$$

[2] $$Hg6(^3P_1) \rightarrow Hg6(^1S_0) + h\nu$$

[3] $$Hg6(^3P_1) + \square_S \rightarrow Hg6(^1S_0) + {}^3\square_S$$

[4] $${}^3\square_S \rightarrow \cdot\!\!\sim\!\!S\cdot$$

[5] $$\cdot\!\!\sim\!\!S\cdot \rightarrow C_2H_4 + CH_2S$$

[6] $$\cdot\!\!\sim\!\!S\cdot \rightarrow \diagup\!\!\diagdown + S(^3P)$$

[7] $$\cdot\!\!\sim\!\!S\cdot \rightarrow \triangle + S(^3P)$$

[8] $$\cdot\!\!\sim\!\!S\cdot \rightarrow HS\cdot + C_3H_5\cdot$$

[9] $$\cdot\!\!\sim\!\!S\cdot \xrightarrow{M} \square_S$$

[10] $$\cdot\!\!\sim\!\!S\cdot \rightarrow \cdot\!\!\sim\!\!S{-}S\!\!\sim\!\!\cdot \xrightarrow{M} DTO$$

[11] $$S(^3P) + \square_S \rightarrow S_2 + \diagup\!\!\diagdown$$

[12] $$S(^3P) + \square_S \rightarrow S_2 + \triangle$$

[13] $$2S(^3P) \xrightarrow[Wall]{M} S_2$$

[14] $$2C_3H_5\cdot \rightarrow C_6H_{10}$$

[15] $$nCH_2S \rightarrow (CH_2S)_n$$

Neither of the minor hydrocarbon products, propylene and cyclopropane, is affected by the free radical scavengers O_2 + NO. However, the propylene yield is clearly pressure sensitive and the total C_3 yield increases substantially with decreasing pressure. We take this as good evidence that propylene is not produced from the isomerization of hot cyclopropane and that neither propylene nor cyclopropane are produced from the trimethylene biradical (18, 19). Both C_3 fragments must result from the loss of sulfur from the substrate either by direct extrusion of a S(^3P) atom or subsequent to attack of the substrate by triplet thietane or a thiatrimethylene biradical.

Attempts to trap S(^3P) atoms yielded inconclusive results. Under the conditions which had to be

[a]Lorentz pressure broadening correction factor.
[b]Incomplete quenching correction factor.
[c]See text. Values at 0.50 Torr by extrapolation assuming ϕ'(DTO) = 0.02 and ϕ'(HXD) = 0.15.

employed in the trapping experiments, only a small fraction (likely of the order of 10%) of any S atoms produced would have been scavenged by propylene. Small yields of S(^3P) atoms, such as might accompany the formation of cyclopropane in reaction 7, would have yielded amounts of propylene episulfide too small to detect. Indeed a propylene episulfide yield equal to 10% of the total C_3 yield at high pressure was barely detectable in the presence of large amounts of residual substrate. Since these scavenging experiments could only be carried out at pressures at which the hydrocarbon products had attained their high pressure limiting values, the production of small yields of S(^3P) atoms, particularly at low pressures, cannot be eliminated by the absence of episulfide in these experiments. On the contrary, since sulfur atoms are known to be produced in high yield from triplet thiirane (1–3) the production of S(^3P) in the thietane system might be expected.

The fact that both DTO and HXD have quantum yields which decline with increasing NO pressure indicates that both of these products have scavengeable radical precursors. Because the yield of DTO, unlike all other products, increases with increasing thietane pressure, it must result from the bimolecular reaction of the thiatrimethylene biradical (or alternatively triplet thietane) with substrate. Since there is good evidence (6) that the thiatrimethylene biradical cannot be scavenged by NO, the scavengeable species in the sequence of reactions leading to DTO must be one produced as a result of, or subsequent to, this bimolecular reaction. HXD most likely results from a reaction sequence which, on the basis of its pressure dependence, starts with a unimolecular fragmentation of $\cdot C_3H_6S\cdot$ into HS$\cdot$ and $C_3H_5\cdot$ followed by combination of two $C_3H_5\cdot$ radicals. The $C_3H_5\cdot$ radical is known to be a relatively stable species (20) and is expected to be long lived enough in this system to be scavenged by NO. The fate of HS$\cdot$ is unknown but trace amounts of H_2 and H_2S may result from self-disproportionation and abstraction reactions of this species.

Quantum yields based on the number of photons absorbed by mercury (Fig. 2) must be corrected to account for incomplete quenching at low thietane pressures. Using the value of $k_3 = 2.86 \times 10^{11}\ M^{-1}\ s^{-1}$ and a value of $k_2 = 2.61 \times 10^6\ s^{-1}$ from Holstein's imprisonment formula (21), one may calculate the yields of each product per mercury atom quenched by thietane. These corrected quantum yields are given in Table 2. As presented the mechanism requires that $\phi'(C_2H_4) + \frac{1}{2}\{\phi'(C_3H_6) + \phi'(\text{cyclo-}C_3H_6)\} + 2\phi'(\text{HXD}) + \phi'(\text{DTO}) = \sum\text{I} \leq 1.0$ if $k_{13} \ll k_{11} + k_{12}$ or $\phi'(C_2H_4) + \phi'(C_3H_6) + \phi'(\text{cyclo-}C_3H_6) + 2\phi'(\text{HXD}) + \phi(\text{DTO}) = \sum\text{II} \leq 1.0$ if $k_{13} \gg k_{11} + k_{12}$. The quantum yield of substrate reformation cannot, of course, be measured directly for thietane itself. Nevertheless, the presence of major amounts of isomerized substrate in the mercury photosensitized decomposition of *cis*- and *trans*-2,3-dialkylthietanes (9) requires that such a step be included in the reaction mechanism. Thus either $\sum$I or $\sum$II should equal unity as an upper limit only, based on the mechanism represented by reactions 1 to 15.

The fact that both $\sum$I and $\sum$II substantially exceed unity at low pressures (cf. Table 2) indicates that at least one important additional substrate decomposing reaction must be included in the mechanism. Strausz and co-workers have proposed (13, 14) that the thiirane triplet can undergo a bimolecular reaction with ground state thiirane which results in the decomposition of both reacting molecules.

[16] 
A similar set of reactions in the thietane system would account for the required additional yields of products. However, reaction between thiatrimethylene biradicals and the substrate seems equally plausible and would, additionally, satisfy the requirement that all of the olefin produced by C—C cleavage must have a precursor in which free C—C bond rotation can take place. The following, more detailed reaction sequence is therefore tentatively proposed to replace reaction [10].

[17]

[18] 
[19] 
[20] 
At low pressures where both the thiatrimethylene and 4,5-dithiahexamethylene biradicals are vibrationally hot, the entire reaction sequence would then lead to the required hydrocarbon yield but little DTO. At higher pressures both the rate of ring opening in the thietane triplet and the rate of unimolecular decomposition of the resulting biradicals would be diminished whereas an increased rate of collisionally assisted ring closure of the 4,5-dithiahexamethylene biradical, reaction 20, would lead to increased yields of DTO as required.

The chromous chloride promoted addition of *N*-haloamides to olefins. V.[1] The addition of *N*-chloroamides to enol ethers: synthesis of acyloxy and acyl derivatives of α-amino acetals and ketals (aldehydes and ketones) and of 2-amino sugars[2]

HUGUES DRIGUEZ,[3] JEAN-PAUL VERMES, AND JEAN LESSARD

Département de Chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received June 3, 1977

HUGUES DRIGUEZ, JEAN-PAUL VERMES, and JEAN LESSARD. Can. J. Chem. **56**, 119 (1978).

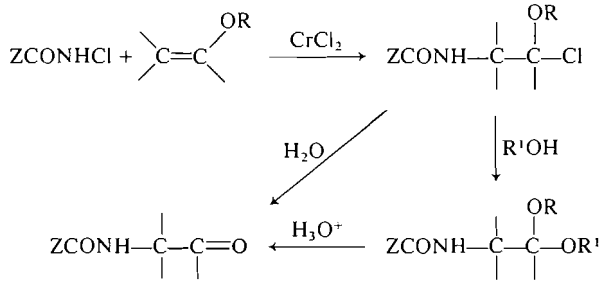
The chromous chloride promoted addition of *N*-chlorocarbamates and *N*-chlorocarboxamides to 1-methoxycyclohexene, ethoxyethylene, dihydropyran, and (1-methoxyethylidene)-cyclohexane gave, in 60 to 85% yields, either α-acyloxy- or α-acylamino ketals and acetals, or the corresponding ketones and aldehydes depending on the work-up conditions. The regiospecificity of the addition was higher with the first two enol ethers (≥97%) than with the latter two (≥85%). *N*-Chlorourethane was added to 17-methoxymethylenandrost-4-en-3-one (**19**) and the sole addition product isolated was the 17α-chloro-20-ethoxycarbonylamino derivative **20** in 75% yield. Additions to triacetyl-D-glucal and 3-*O*-acetyl-4,6-*O*-benzylidene-D-glucal followed by solvolysis under Koenigs–Knorr conditions led predominantly to 2-amino-glucopyranosides in 30 to 65% yields, whereas additions to 3-*O*-acetyl-4,6-*O*-benzylidene-D-allal gave 2-amino altropyranosides in 40 to 56% yields.

HUGUES DRIGUEZ, JEAN-PAUL VERMES et JEAN LESSARD. Can. J. Chem. **56**, 119 (1978).

L'addition, catalysée par le chlorure chromeux, de *N*-chloroamides au methoxy-1 cyclohexène, à l'éthoxyéthylène, au dihydropyranne et au (méthoxy-1 éthylidène)cyclohexane donne, suivant le mode opératoire utilisé, soit des α-acyloxy- ou α-acylamino acétals, soit les cétones et aldéhydes correspondants avec des rendements de 60 à 85%. L'addition aux deux premiers éthers d'énol est plus regiospécifique (≥97%) que l'addition aux deux autres (≥85%). Le *N*-chlorouréthane s'additionne au méthoxyméthylène-17 androstène-4 one-3 (**19**) et on isole, comme seul produit d'addition, le dérivé chloro-17α éthoxycarbonylamino-20 (**20**) avec un rendement de 75%. Les additions au triacetyl D-glucal et à l'acétyl-3 benzylidène-4,6 D-glucal, suivies d'une réaction Koenigs–Knorr, donnent comme produits principaux (rendements de 30 à 65%) des glucopyranosides aminés en position 2. Les additions à l'acétyl-3 benzyliden-4,6 D-allal donnent par contre des amino-2 altropyranosides avec des rendements de 40 à 60%.

Introduction

Recently we reported a study of the chromous chloride promoted addition of various *N*-chloro- and *N*-bromoamides to a variety of olefins (1*a*). We also presented a discussion of a working hypothesis concerning the mechanism (1*b*). This paper describes a study of the addition of *N*-chloroamides to enol ethers aimed at evaluating the potential of the method for the synthesis of α-amido acetals and ketals (aldehydes and ketones) and 2-amido sugars (Scheme 1).[4] *N*-Bromoamides cannot be used for that purpose since electrophilic bromination is important under the reaction conditions (see the Experimental for the reaction of *N*-bromocetamide with 1-methoxycyclohexene).



Z = *O*-alkyl, alkyl

SCHEME 1

Results and Discussion

The conditions and results for the additions to various types of enol ethers are reported in Table 1, and those for the additions to glycals are recorded in Table 2. All the compounds had ir and ^{1}Hmr spectra, elemental analyses, and/or mass spectra consistent with their structures. The analysis and interpretation of the spectra are straightforward (see Experimental) and will not be given unless helpful to the discussion.

[a]The additions were carried out with an excess of *N*-chloroamide **1** (2 mol per mol of glycal) under the usual conditions ($CHCl_3$–CH_3OH, −78°C). The reaction mixture was then poured into an ice-cold saturated sodium bicarbonate solution then rapidly extracted in the cold. The crude products, containing 2-amidopyranosyl chlorides according to the ^{1}Hmr spectra, were solvolyzed under Koenigs–Knorr conditions.
[b]The following 2-amidopyranosides have been reported in the literature: **28***a*(R = CH_3CO), ref. 7; **28***d*(R = CH_3), ref. 8; **28***d*(R = CH_3CO), ref. 7; **28***d*(R = $C_6H_5CH_2$), ref. 8; **28***e*(R = CH_3), ref. 9; **28***f*(R = CH_3), ref. 10.
[c]The yields refer to compounds obtained by recrystallization of chromatographic fractions and are based on the glycal.
[d]The yield between brackets include the additional amount obtained by deacetylation of the mother liquors, recrystallization, then reacetylation of the crystals.

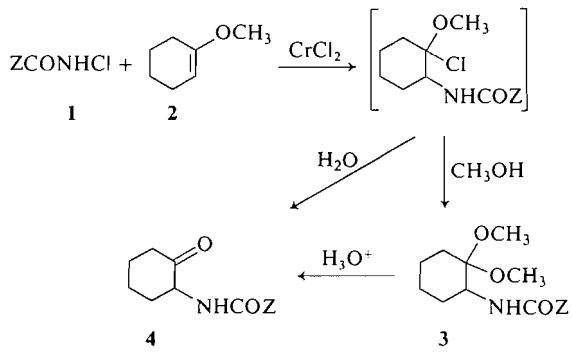
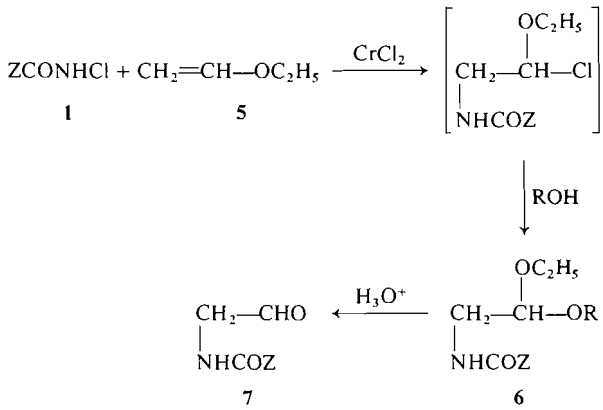
Additions to the Enol Ethers of Table 1

In the additions to *1-methoxycyclohexene* (**2**) (Scheme 2), it was possible to obtain either the ketal **3** or the ketone **4** depending on the work-up procedure. The sodium methoxide work-up allowed the isolation of ketal **3**[5] in good yields (entries 3, 5, and 6) but small amounts of ketone **4** were also formed by hydrolysis of the intermediate α-chloro ether due to the water (6.3 mol per mol of Cr(II)) present in the chromous chloride solution (1*a*). When using the dilute sulfuric acid work-up, hydrolysis of ketal **3** was complete after 4 h to give the ketone **4** in very good yields (entries 1, 4, and 7). If water only was added, the hydrolysis was not complete after 4 h (entry 2). These additions appear to be highly regiospecific, the material balance (ketal **3** and/or ketone **4** plus amide) accounting for more than 96% of starting *N*-chloroamide. α-Chlorocyclohexanone, which could be derived from addition of the amido radical at C-1 and/or electrophilic chlorination followed by hydrolysis, was present in very small amounts (< 1%) in the crude products according to vpc analysis.



SCHEME 2

In the additions to *ethoxyethylene* (**5**) (Scheme 3), we used the alkoxide work-up and the acetal **6** was isolated in good yields. The addition of *N*-chlorochloroacetamide (**1***f*) was carried out in chloroform–ethanol in order to avoid the formation of a mixed acetal. We did not isolate any aldehyde **7** from the chromatographic fractions although it was probably formed to a small extent by reaction of the intermediate α-chloro ether with the water present in the reaction medium. The acetal **6** and the parent amide accounted for 90% or more of the starting *N*-chloroamide. No 1-amido-2-chloro-1-ethoxyethane or 1-amido-1-ethoxyethane resulting from addition of the amido radical at C-1 was isolated or detected. Such adducts have been isolated from radical additions to disubstituted enol ethers derived from aldehydes (18) (see the addition of *N*-chlorourethane (NCU) to **19** below). Thus the additions to **5** appear to be highly regiospecific also.



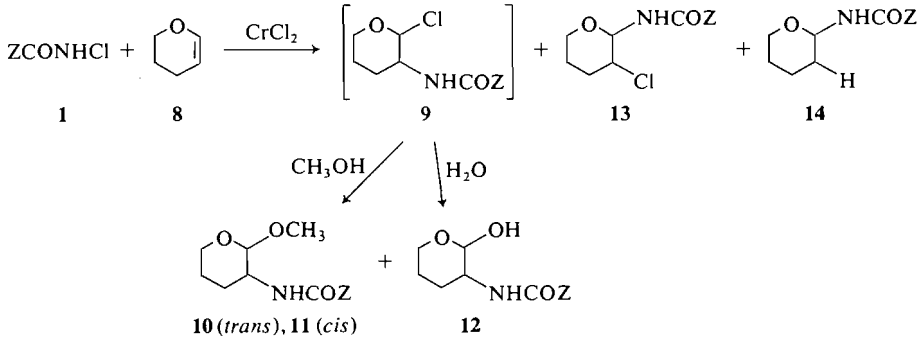
SCHEME 3

The acetals **6***b* and **6***d* were hydrolyzed to the corresponding aldehydes **7***b* and **7***d* (Scheme 3) with 70% aqueous acetic acid at 70°C in 65 and 80% yield, respectively (based on the conversion to their 2,4-DNP derivatives).

The additions to *dihydropyran* (**8**) (Scheme 4) led to the *trans* α-amido acetal **10** as the major product probably as a result of participation of the carbamate group in the methanolysis of the intermediate α-chloro ether **9**[6] (Scheme 5). The *cis* acetal **11** could result from direct attack of methanol on the cation B and/or from partial isomerization of the *trans* acetal **10** since the reaction medium is acidic. Equilibration of either the *trans* isomer **10***a* or the *cis* isomer **11***a* with hydrogen chloride in methanol led to a 1:1.8 mixture of **10***a* and **11***a*. The more stable isomer was assigned the *cis* configuration **11** with the carbamate group equatorial and the methoxy group axial, a consequence of the anomeric effect (3): $J_{2,3}$ = 3.0 Hz for **11***a*, 3.5 Hz for **11***d*, in $CDCl_3$. The *trans* isomer **10** exists predominantly in the *trans* diaxial conformation ($J_{2,3}$ = 2.6 Hz for **10***a* and **10***g*, 2.0 Hz for **10***d*, in $CDCl_3$) again as a result of the anomeric effect (3); the proportion of diaxial conformer decreases as the polarity of the solvent increases in agreement with the greater polarity of the diequatorial conformer and with the fact that the anomeric effect varies inversely with the dielectric constant of the solvent (4): $J_{2,3}$ for **10***a* = 2.0 Hz in CS_2, 2.6 Hz in $CDCl_3$, 3.9 Hz in CD_3OD. The ^{1}Hmr spectrum of the *trans* adducts **10***a* and **10***g* was studied at low temperature. At 173 K, only the

[5]The pure ketals **3***b*, **3***c*, and **3***d* were hydrolysed to the corresponding ketones **4***b*, **4***c*, and **4***d* in 98, 92, and 89% yield, respectively.

[6]The *cis* isomer is probably predominant as in the additions to cyclohexene and norbornene (1*a*) and to triacetylglucal (**24**) (see below).

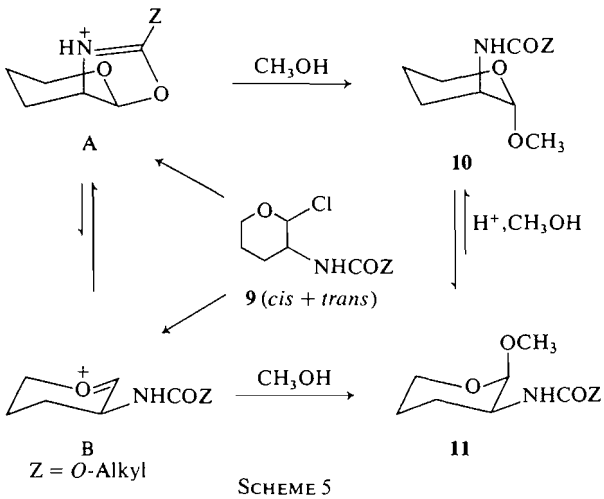


1 8 9 13 14

10 (*trans*), 11 (*cis*) 12

SCHEME 4

diaxial conformer could be observed even in CD_3OD: the proton at C-3 appeared as a singlet, the width at half height being less than 2 Hz ($J_{2,3}$ < 2 Hz).[7]



SCHEME 5

The hemiacetal **12** results most probably from reaction of the α-chloro ether **9** with the water present in the reaction medium. Isolation of the adducts **13***a* and **14***a* resulting from addition of the amido radical at C-2 indicates that the additions to dihydropyran (**8**) are less regiospecific than the additions to 1-methoxycyclohexene (**2**) and ethoxyethylene (**5**).[8]

[7]We thank Professor R. R. Fraser, Ottawa University, for recording these spectra.

[8]One of the referees suggested that the adducts **13***a* and **14***a* might be formed by electrophilic addition. However, we believe it is not very probable for the following reasons. On one hand, treatment of ethyl vinyl ether and methoxymethylenecyclohexane with *N*-chlorourethane (**1***a*) in methanol or in methanol containing chromic chloride for 5 h at room temperature led exclusively to the corresponding α-chloro acetal (>95%); there was no detectable reaction after 5 h at −78°C (18). On the other hand the formation of **14***a* by electrophilic addition would imply the reduction of **13***a* and we have shown that 1,2-adducts of *N*-chloroamides (and even *N*-bromoamides) to olefins are not reduced by chromous chloride under such mild conditions as those used for the additions (**1***a*).

The addition of NCU (**1***a*) to *(1-methoxyethylidene)cyclohexane* (**15**) (Scheme 6), a fully substituted enol ether, is noteworthy since no addition was observed upon photochemical initiation (19). Besides **16** and **17**, the other compounds present in the crude product were acetylcyclohexane and urethane according to vpc analysis. The α-chloro ketone **17** could result either from addition of the ethoxycarbonylamino radical to the carbon bearing the methoxy group or from electrophilic chlorination.

In the addition of NCU (**1***a*) to *17-methoxymethylene-androst-4-en-3-one* (**19**) (Scheme 7), the sole addition product isolated in a 75% yield was the 17α-chloro-20-ethoxycarbonylamino-20-methoxy derivative **20** (mixture of diastereoisomers) resulting from the addition of the ethoxycarbonylamino radical on the less hindered carbon of the double bond. No addition occurred on the unreactive Δ^4-3-keto system as expected (1*a*). Hydrolysis of the adduct **20** (70% aqueous acetic acid at 70°C) gave the α-chloro aldehyde **21** in an 82% yield (Scheme 7). The α configuration was tentatively assigned to the chlorine on the basis that the chlorine-atom transfer on the intermediate adduct radical should be easier from the α side. The preparation of enol ether **19** (mixture of geometrical isomers) from 3β-acetoxyan-

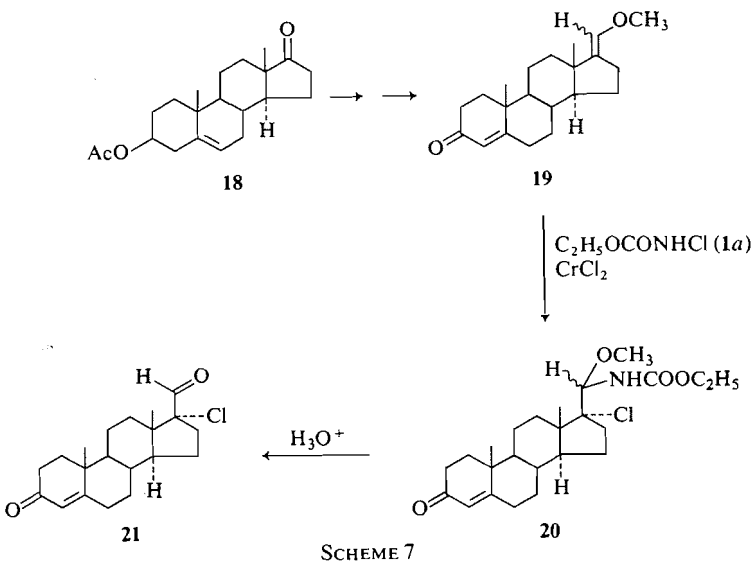


SCHEME 7

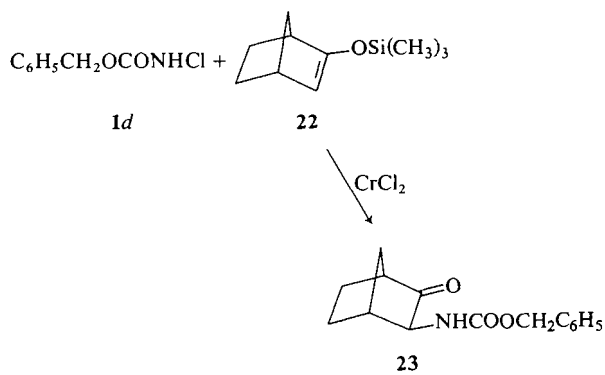
drost-5-en-3-one (**18**) is described in the Experimental.

The addition of *N*-chlorobenzylcarbamate (**1***d*) to *2-trimethylsiloxy-2-norbornene* (**22**) (Scheme 8) gave a low yield (19%) of the expected α-benzyloxycarbonylaminonorbornanone (**23**),[9] the other product isolated besides benzylcarbamate being norbornanone (80%). It would be surprising if the silyl enol ether **22** would be much less reactive than norbornene which gave high yields of addition with *N*-chlorocarbamates (1*a*), and we attribute the low yield of **23** to the fact that hydrolysis of **22** under the reaction conditions was faster than the addition reaction. Edwards *et al.* (5) added calcium carbonate to the chromous chloride solution in order to remove the acid but did not observe any improvement of the yield of addition. However, water was always present and they used a longer reaction time.

The orientation of radical additions to olefins depends on the interplay of steric effects, polar effects (e.g. preferential attack of an electrophilic radical on the carbon having the highest electron density), and bond-strength terms according to Tedder and Walton (6).[10] The orientation of the addition to the steroid enol ether **19** must be governed mainly by steric effects; the polar effect would be expected to favor the addition of an amido radical at C-17 whether the radical is free or complexed with a metal ion (1*b*). In the additions to 1-methoxycyclohexene (**2**), ethoxyethylene (**5**), and the silyl enol ether **22**, both steric and electronic effects (e.g. the polar effect) should favor the addition of the amido radical on the less substituted carbon atom, hence the high regioselectivity observed. The lower regioselectivity of the addition to dihydropyran (**8**) probably reflects the fact that, both ends of the double bond being monosubstituted, the steric effects at C-2 and C-3, although not identical (C—O bonds are shorter than C—C bonds), should not be appreciably different; the orientation of the addition is probably controlled by electronic effects to a large extent. In the case of (1-methoxyethylidene)cyclohexane (**15**), the preferential addition at the ring carbon is most probably determined by electronic effects.

Additions to Glycals

The yields given in Table 2 represent minimum yields of addition since the ^{1}Hmr spectra of the mother liquors from recrystallization of the chromatographic fractions (footnote *a*) showed that they still contained appreciable amounts of 2-amino derivatives, and since the Koenigs–Knorr reactions were not quantitative. In all the isolated products, the amido group at position 2 and the oxygenated



SCHEME 8

[9]We thank Dr. O. E. Edwards, National Research Council of Canada, for providing us with samples of **22** and **23**.

[10]It seems difficult to dissociate the bond-strength terms from other effects since both steric and electronic effects should have a bearing on the strength of the new bond formed in the initial addition step.

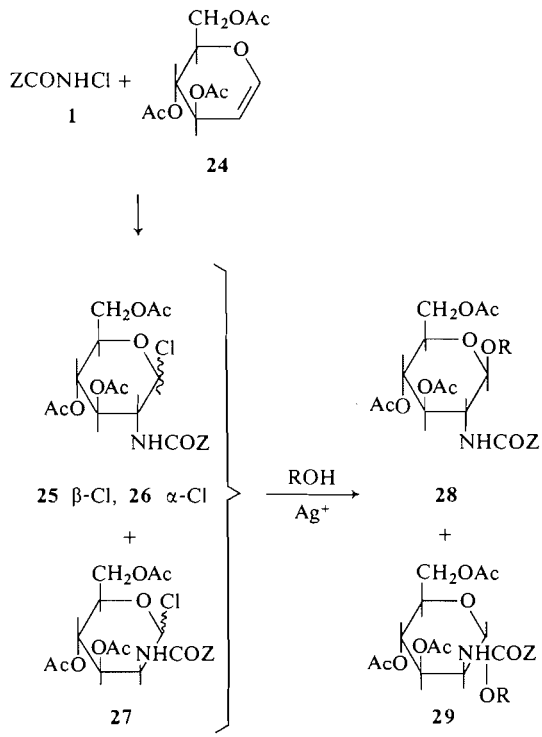
function at position 1 are *trans* most probably as a result of the participation of the amido group during solvolysis of the pyranosyl chlorides (e.g. Scheme 5).

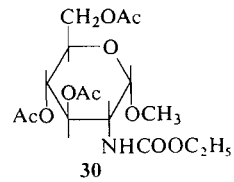
The main products from the additions to *triacetyl-*D*-glucal* (**24**) (Scheme 9) are the β-D-gluco derivatives **28**. Some α-D-manno derivatives **29** were also formed, but in smaller amount, as suggested by the ^{1}Hmr spectrum of chromatographic fractions and/or mother liquors from recrystallizations. Methyl 2-chloroethoxycarbonylamino-α-D-mannopyranoside **29***b* (R = CH_3) was the sole manno derivative isolated in a pure state and characterized; the doublet of H-1 at 4.80 ppm, J = 1.6 Hz, in the ^{1}Hmr spectrum shows clearly the equatorial orientation of H-1 and H-2.



SCHEME 9

The two anomeric chlorides **25***a* and **26***a* were prepared from the β-acetate **28***a* (R = $COCH_3$) in 62 and 87% yield, respectively, as shown in Scheme 10. Anomerization of the β-chloride **25***a* with titanium tetrachloride in chloroform at room temperature took 3 days and was quantitative (Scheme 10).

Methanolysis of the β-chloride **26***a* under Koenigs–Knorr conditions afforded the pure methyl β-D-glucopyranoside **28***a* (R = CH_3)[11] in 87% yield; from the α-chloride **25***a*, the yield of **28***a* (R = CH_3) was 98%. However, when the methanolysis under the same conditions was carried out on a 2:2:1 mixture of β-chloride **25***a*, α-chloride **26***a*, and triacetyl-D-glucal (**24**), the yield of pure methyl β-D-glucopyranoside **28***a* (R = CH_3) was 65% only after chromatographic separation. Anomerization of **28***a* (R = CH_3) with titanium tetrachloride in chloroform at room temperature was complete after 3 days according to the ^{1}Hmr spectrum. Chromatographic separation yielded 70% of pure methyl α-D-glucopyranoside **30**.



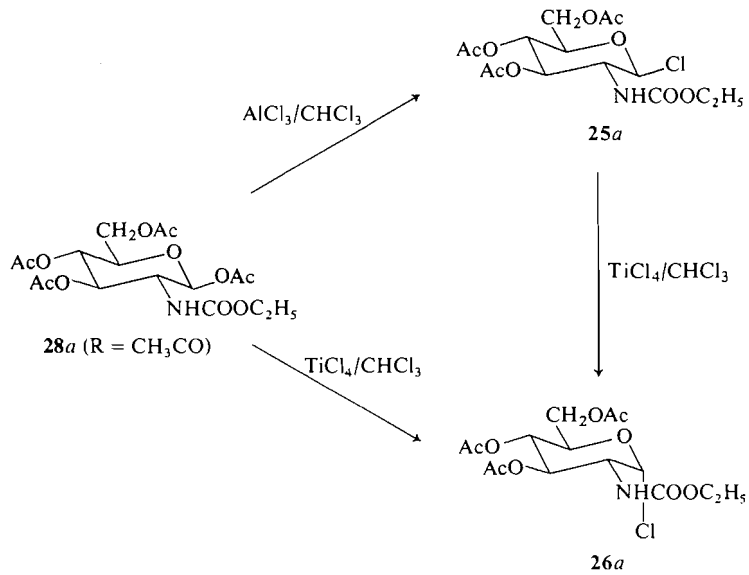
30

We compared the ^{1}Hmr spectrum of the crude reaction product from the addition of NCU (**1***a*) (before the Koenigs–Knorr reaction) with that of a 2:2:1 mixture by weight of β-chloride **25***a*, α-chloride **26***a*, and triacetyl-D-glucal (**24**). In both spectra, the doublet of H-1 of the α-chloride **26***a* at 6.28 ppm (J = 3.7 Hz) and the signal of H-1 of **24** at 6.56 ppm (d of d, J = 6 and 1 Hz) were easily seen whereas the signal of H-1 of the β-chloride **25***a* was masked by other peaks. By integrating the signals at 6.28 and 6.56 ppm and taking the quantity of triacetylglucal (**24**) recovered after the Koenigs–Knorr reaction as the amount present in the crude reaction mixture, the yield of α-chloride **26***a* was estimated to be approximately 59%. Since 18% of **24** was recovered, the maximum yield of β-chloride **25***a* would be 23%. Thus the 1,2-addition of NCU to triacetylglucal (**24**) appears to be predominantly *cis* as with other cyclic olefins (e.g. cyclohexene, norbornene) (1*a*).

The addition of NCU (**1***a*) to *3-O-acetyl-4,6-O-benzylidene-*D*-glucal* (**31**) followed by methanolysis is described in Scheme 11. Chromatographic separation gave a mixture of urethane and pyranosides from which 12% of methyl benzylidene-β-glucopyranoside **32** could be isolated after sublimation of urethane and recrystallization. Hydrolysis of the mother liquors and of chromatographic fractions followed by acetylation and chromatographic separation led to the isolation of methyl β-glucopyranoside **28***a* (R = CH_3) in 30% yield (total yield of gluco derivative, 42%) and methyl α-mannopyranoside **29***a* (R = CH_3) in 9% yield. The gluco-to-manno ratio appears to be slightly lower (~4.4) than in the additions to triacetylglucal (**24**), e.g. **28***b*:**29***b* ≃ 7.8.

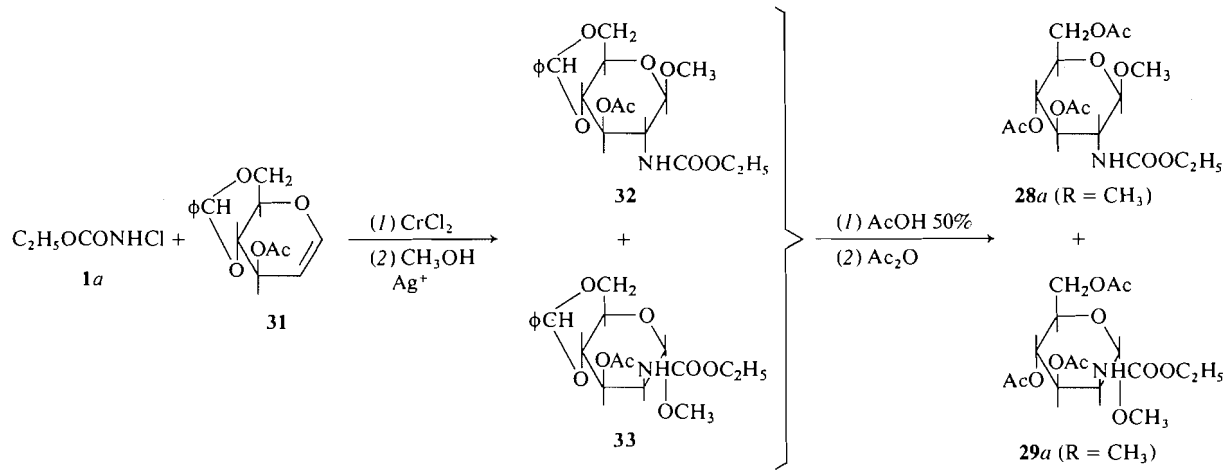
In the additions to *3-O-acetyl-4,6-O-benzylidene-*D*-allal* (**34**) (Scheme 12), the sole products isolated were methyl 2-amido altrosides (**35** and/or **36**) re-

[11]We thank professor S. Hanessian, Université de Montréal, for providing us with a sample of methyl 2-methoxycarbonylamino-β-D-glucopyranoside **28** (Z = OCH_3, R = CH_3) for comparison purposes.



SCHEME 10

sulting from addition of the amido radical on the β face of **34**. Partial deacetylation and partial acetal cleavage occurred upon chromatographic separation. In the case of the addition of NCU (**1***a*), some 40% of methyl benzylidenaltropyranoside **35***a* was nevertheless isolated from the chromatographic fractions; 16% of methyl triacetylaltroside **36***a* (total yield of 2-amido altrosides, 56%) could be obtained by hydrolysis then acetylation of the more polar fractions. In the case of *N*-chlorotrichloroethylcarbamate (**1***c*), part of the chromatographic fractions were hydrolyzed then acetylated to yield 65% of methyl triacetylaltroside **36**. Another part was treated with zinc in glacial acetic acid then acetylated to yield 63% of methyl benzylidenaltropyranoside **35***e* (11) which proved identical to an authentic sample.[12] Finally, from the addition of *N*-chloroacetamide (**1***e*), the sole addition product that could be obtained pure was the oxazoline **37** (18% yield). Its mass spectrum showed the characteristic fragments of oxazolines (12) (see the Experimental). It was converted to the known **36***e* (11) by treatment with *p*-toluenesulfonic acid in methanol and acetylation.



SCHEME 11

Thus the addition of *N*-chloroamides, in particular of *N*-chlorocarbamates, to the glucals **24** and **31** and to the allal **36**, followed by solvolysis under Koenigs–Knorr conditions, led to 2-amido derivatives in yields that can be of preparative value. Higher yields

[12]We thank professor R. U. Lemieux, University of Alberta, for providing us with a generous sample of **35***e*.

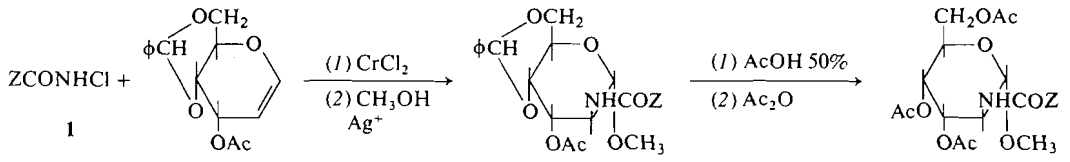
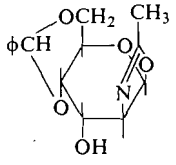


SCHEME 12

could probably be obtained by using a larger excess of *N*-chloroamide (the excess *N*-chloroamide is simply reduced to the amide which can be recovered) and by using improved Koenigs–Knorr conditions.[13] The influence of the configuration of the acetoxy group at C-3 on the direction of attack of the double bond by an amido radical is noteworthy. When the acetoxy group is α as in allal **34** the attack occurs preferentially from the β face leading to 2-amido altrosides; no 2-amido allosides were isolated. When the acetoxy group is β as in the glucals **24** and **31**, the attack occurs preferentially from the α face leading to 2-amido gluco derivatives; 2-amido manno derivatives were formed and isolated but in much smaller amounts. The steric hindrance to the attack of the π electrons at C-2, in a direction perpendicular to the plane of the double bond and on the same side as the 3-acetate, could be greater in the allal **34** than in the glucals **24** and **31**, assuming a quasi-axial orientation of the 3-acetate in **34** and a quasi-equatorial orientation of the 3-acetate in **24** and **31**. The preferential addition of an amido radical on the α face of **24** and **31** is in contrast with the preferentrial addition of the thioacetyl radical (13*a*)



37

and the chlorine atom (13*b*) on the β face of triacetylglucal **24**: β attack:α attack = 2.2–3.3 (13). One possible explanation could be the larger size of an amido radical with respect to that of a thioacetyl radical or a chlorine atom.[14] One could argue. that the amido radical is complexed with a metal ion (1*b*) and thus effectively much larger. However, in the photochemical addition of *N*-chlorochloroacetamide (**1***f*) to triacetyl-D-glucal (**24**) in methylene chloride, the addition of the free amido radical occurs preferentially from the α face also. Indeed the sole product isolated after methanolysis was the 2-amidoglucopyranoside **28***f* (R = CH_3) (19).

Conclusion

The results presented in this paper show that α-alkoxycarbonylamino and α-acylamino acetals, ketals, aldehydes, and ketones can be obtained in high yields by the chromous chloride promoted addition of *N*-chloroamides to enol ethers. The method was even successful with a fully substituted enol ether. However, it cannot be applied to a β,β-disubstituted enol ether since the addition of the amido radical occurs preferentially on the less hindered α position ($CHOCH_3$ end).[15] It was not successful either with a trimethylsilyl enol ether because, under the reaction conditions, hydrolysis of the enol ether was faster than the addition reaction. With glycals, 2-alkoxycarbonylamino and 2-acylamino sugars were obtained in good yields. The use of *N*-chloro-2,2,2-trichloroethylcarbamate (**1***c*) and of *N*-chlorobenzylcarbamate (**1***d*) illustrates the potential of these additions for the synthesis of *N*-protected α-amino acetals and ketals or of the corresponding *N*-protected α-amino carbonyl derivatives. For instance 2-trichloroethoxycarbonylaminocyclohexanone (**4***c*) was converted into 2-acetylaminocyclohexanone (**4***e*) (15) in a 90% yield by zinc reduction followed by acetylation; also the α-benzyloxycarbonylamino ketal **3***d* was converted into the acetylamino ketal **3***c* in an 87% yield by hydrogenolysis and acetylation. It is noteworthy that in all the additions to the various enol ethers, we did not isolate any β-amido ether (e.g. ZCONH—C—CH—OCH_3) resulting from chromium(II) reduction of the intermediate adduct radical (e.g. ZCONH—C—Ċ—OCH_3) followed by protonolysis (1,H-addition) even with *N*-chloroacetamide (**1***e*) which was shown to lead predominantly to 1,H-addition with 1-octene, cyclohexene, and norbornene (1*a*).

[13]R. U. Lemieux, private communication.

[14]From the conformational energies of monosubstituted cyclohexanes (14), an NH_2 group appears to be larger than a SH group which, however, would be larger than a chlorine.

[15]A detailed study of the orientation of radical additions to β,β-disubstituted enol ethers will be presented in a forthcoming paper (see ref. 18).

Experimental[16]

The pertinent general information and a description of the apparatus used for the chromous chloride promoted additions have been given in part III (*1a*). The solvents from extractions were evaporated on a rotating evaporator. Unless specified otherwise, the chromatographic separations were carried out on silica gel. The *N*-chloroamides were prepared by the sodium hypochlorite method (16).

Typical Procedure for the Chromous Chloride Promoted Addition of N-*Chloroamides to Enol Ethers*

Addition of N-*Chloro-2,2,2-trichloroethylcarbamate (1c) to 1-Methoxycyclohexene (2)*

The *N*-chlorocarbamate **1***c* (1.33 g, 98% active chlorine, 5.74 mmol) was dissolved in chloroform (4 ml) and absolute methanol (1.2 ml) and the solution was cooled to ca −78°C. A solution of 1-methoxycyclohexene (**2**) (1.5 ml, ~12 mmol) in chloroform (2 ml), pre-cooled to −78°C, was added. The 1 *M* chromous chloride solution was then added dropwise until the starch–iodide paper test was negative: 5 ml (5 mmol) added over 60 min.

Acid work-up—The cooling bath was removed and air was allowed in the reaction vessel. Dilute sulfuric acid was added (1 ml of a 1 *N* solution) and the mixture was stirred at room temperature for 4 h. It was poured into water (50 ml) then extracted with methylene chloride (3 × 100 ml). The organic phases were washed with water (2 × 25 ml) then combined and dried. The solvent was evaporated and the crude product (1.51 g) separated by preparative-layer chromatography (plc) (ether–hexane 1:4) to afford two fractions. The less polar fraction consisted of *2-(N-trichloroethoxycarbonyl)aminocyclohexanone* (**4***c*), mp 75–78°C (1.302 g, 86%). One recrystallization from hexane afforded the analytical sample, mp 80–80.5°C; ν_{max} (CCl_4): 3405 (NH), 1745 (C=O), 1720 (C=O), 1500 (NH), 1310 1205, 1110, and 1050 cm^{-1}; ν_{max} (CS_2): 785 and 765 cm^{-1} (C—Cl); (CCl_4) δ: 4.22 (t of d with J = 12 and 6 Hz; d of d with J = 11.5 and 6 Hz after exchange with D_2O; H-2), 4.63 (s, OCH_2CCl_3), 5.92 ppm (m, NH). *Anal.* calcd. for $C_9H_{12}Cl_3NO_3$: C 37.44, H 4.19, Cl 36.89, N 4.85; found: C 37.43, H 4.17, Cl 37.10, N 5.02. The other fraction consisted 2,2,2-trichloroethylcarbamate, mp 60–62°C (0.185 g), identical (ir, ^{1}Hmr) to an authentic sample.

Sodium methoxide work-up—The reaction was carried out as above on similar quantities. A sodium methoxide solution (0.59 g of Na in 15 ml of absolute methanol) was added to the reaction mixture at −78°C which was then allowed to warm up to room temperature. It was poured into water (50 ml) then extracted with methylene chloride (3 × 100 ml). The organic phases were washed with water (2 × 25 ml) then dried and the solvent evaporated. The crude product was separated by plc (ether–hexane 1:4) to afford three fractions. The less polar fraction consisted of *2-(N-trichloroethoxycarbonyl)aminocyclohexanone dimethyl acetal* (**3***c*) (1.44 g, 75%), an oil which was purified by microdistillation at 80–82°C/0.01 Torr; ν_{max} (CCl_4): 3440 (NH), 1742 (C=O), 1512 (NH), 1215, 1120, 1105, 1070, and 1055 cm^{-1}; ($CDCl_3$) δ: 3.18 (s, OCH_3), 3.23 (s, OCH_3), 3.87 (m, $\Delta\nu_{1/2}$ = 20 Hz, H-2), 4.73 (OCH_2CCl_3), and 5.47 ppm (br d, J = 8 Hz, NH). *Anal.* calcd. for $C_{11}H_{18}Cl_3NO_4$: Cl 31.78; found: Cl 31.61. The second fraction consisted of *2-(N-trichloroethoxycarbonyl)aminocyclohexanone* (**4***c*), mp 76–78°C (0.116 g, 7%), identical (ir, ^{1}Hmr) to the sample obtained above. The third fraction consisted of 2,2,2-trichloroethylcarbamate, mp 59–61°C (0.192 g).

The addition of *N*-bromoacetamide to **2** carried out as above using the acid work-up gave *α-bromocyclohexanone* (20% by vpc) and *2-acetylaminocyclohexanone* (**4***e*), mp 88–91°C (14% by plc), identical (ir, ^{1}Hmr) to the sample obtained from the addition of *N*-chloroacetamide (**1***e*).

The other additions to 1-methoxycyclohexene (**2**), the additions to ethoxyethylene (**5**) and dihydropyran (**8**), the addition of NCU (**1***a*) to (1-methoxyethylidene)cyclohexane (**15**) and 2-trimethylsiloxy-2-norbornene (**22**), the hydrolysis of ketals **3***b*, **3***c*, **3***d*, and **3***e*, and the hydrolysis of acetals **6***b* and **6***d* are described in the supplementary material.[16]

Removal of the Trichloroethoxycarbonyl Group of Ketone 4c

The ketone **4***c* (577 mg, 2 mmol) was treated with freshly activated zinc dust (600 mg added in 200 mg portions) in glacial acetic acid (6 ml) at room temperature for 1 h. The reaction mixture was made alkaline (pH = 13) with ice-cold 4 *N* NaOH then extracted with ether (5 × 100 ml) in the presence of ice. The ether layer was dried and the solvent evaporated. The resulting liquid was acetylated in the usual way (Ac_2O, 1 ml; pyridine, 2 ml) to give *2-acetylaminocyclohexanone* (**4***e*) (15), mp 90–92°C (363 mg, 90%), identical (ir and ^{1}Hmr) to the sample obtained from *N*-chloroacetamide (**1***e*) and 1-methoxycyclohexene (**2**).

Hydrogenolysis of 2-Benzyloxycarbonylaminocyclohexanone Dimethyl Acetal (3d)

The acetal **3***d* (205 mg, 0.7 mmol) in methanol (60 ml) was hydrogenated over 10% palladium-on-charcoal at atmospheric pressure for 24 h. The catalyst was filtered and the solvent evaporated to yield *2-aminocyclohexanone dimethyl acetal* as a liquid (107 mg, 96%); ν_{max} (CCl_4): 3400 and 3330 (NH_2), 1110 and 1060 cm^{-1} (C—O—C); (CCl_4) δ: 1.53 ppm (m, 10H) and 3.13 ppm (s, OCH_3). It was acetylated to give *2-acetylaminocyclohexanone dimethyl acetal* (**3***e*), mp 110–112°C (123 mg, 87%). Recrystallization from methylene chloride – ether afforded the analytical sample, mp 117–118°C; ν_{max} ($CHCl_3$): 3410 (NH), 1670 (C=O), 1510 (NH), 1110 and 1065 cm^{-1} (C—O—C); ($CDCl_3$) δ: 1.98 (s, $COCH_3$), 3.22 and 3.28 (two s, OCH_3), 4.15 (m, $\Delta\nu_{1/2}$ = 18 Hz, H-2) and 5.82 ppm (m, NH); *m/e*: 201 (M^+). *Anal.* calcd. for $C_{10}H_{19}NO_3$: C 59.68, H 9.52, N 6.96; found: C 59.26, H 9.48, N 6.68.

Equilibration of 10a and 11a

The *trans* adduct **10***a* (748 mg, 3.7 mmol) was dissolved in methanolic HCl (40 ml of a 0.6 *N* solution, 24 mmol) and kept at room temperature for 6 days. Sodium bicarbonate (2.5 g, 25 mmol) was added. The solution was filtered, evaporated to dryness, and an aliquot (516 mg) of the crude product (736 mg) was separated by plc (ether–hexane 1:1) to yield the *cis* adduct **11***a*, mp 62–63°C (298 mg) and the *trans* isomer **10***a* (164 mg), identical (ir, ^{1}Hmr, tlc) to authentic samples (**11***a*:**10***a* = 1.8). The *cis* adduct **11***a* (140 mg, 0.7 mmol) was treated as above with methanolic HCl (5.5 ml) for 20 h. Work-up and separation gave the *cis* isomer **11***a*, mp 62–63°C (83 mg) and the *trans* isomer **10***a* (46 mg) (**11***a*:**10***a* = 1.8).

Preparation of 17-Methoxymethylenandrost-4-en-3-one (19)

A Wittig reaction on 3β-acetoxyandrost-5-en-17-one (**18**) (8.25 g, 125 mmol) was carried out according to Corey's modification (17) with methoxymethylenetriphenylphosphonium chloride (42.8 g, 125 mmol), sodium hydride (5.23 g, 125

[16]Reactions and products not included in the Experimental are fully described in the Supplementary Material placed in the Depository of Unpublished Data. Photocopies of this material are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

For personal use only.

mmol), and DMSO (150 ml). The mixture was kept at 40°C for 18 h then poured into cold water and extracted with ether. The crystals (ϕ_3PO) obtained after evaporation of the solvent were filtered, washed with ether, and the solvent evaporated. The residue was separated on basic alumina activity III (ether–pentane 1:2) to yield *17-methoxymethylenandrost-4-en-3β-ol*, mp 135–140°C (5.30 g, 67%); ν_{max} ($CHCl_3$): 3550 (OH) and 1670 cm^{-1} (C=C); ($CDCl_3$) δ: 0.88 (s, 18-CH_3), 1.03 (s, 19-CH_3), 3.45 and 3.55 (two s, OCH_3 of geometric isomers), 5.34 (m, H-4), and 5.72 ppm (t, J = 2 Hz, H-20). An Oppenauer oxidation was carried out on the above alcohol (1.67 g, 5 mmol) with potassium tertiobutylate (0.58 g, 5 mmol) and benzophenone (1.82 g, 10 mmol) in refluxing benzene (80 ml) for 18 h. The mixture was poured into cold water and extracted with ether. Separation of the crude product (3.27 g) on basic alumina activity III (ether–pentane 1:2) gave *17-methoxymethylenandrost-4-en-3-one* (**19**), mp 156–159°C (1.16 g, 72%); ν_{max} ($CHCl_3$): 1665 cm^{-1} (C=O and C=C); ($CDCl_3$) δ: 0.87 (s, 18-CH_3), 1.19 (s, 19-CH_3), 3.43 and 3.50 (two s, OCH_3 of geometric isomers), and 5.58 ppm (H-4 and H-20); *m/e* 316 (M^+).

Addition of NCU (1a) to 17-Methoxymethylenandrost-4-en-3-one (19)

The reaction was carried out with 2 mmol of NCU, 1 mmol of **19**, $CHCl_3$ (5 ml), CH_3OH (1 ml), and $CrCl_2$ (14 mmol) for 2 h. The crude product (470 mg) was separated by plc on Florisil (ether–methanol 99:1) to yield the *adduct* **20** as a mixture of diastereoisomers, mp 108–138°C (330 mg, 75%); λ_{max} (EtOH): 240 nm (ε 16 000); ν_{max} ($CHCl_3$): 3440 and 3340 (NH), 1730 (carbamate), 1680 and 1620 (C=C—C=O), 1490 (NH), 1225, 1100, 1070 cm^{-1}; ($CDCl_3$) δ: 0.95 (br s, 18-CH_3), 1.20 (two very closed s, 19-CH_3), 1.26 (t, J = 7 Hz, OCH_2CH_3), 3.32 (s, OCH_3) 4.15 (q, J = 7 Hz, OCH_2CH_3), 5.04 and 5.10 (two d, J = 10 Hz, H-20), 5.45 (br d, J = 10 Hz, NH), 5.65 ppm (s, H-4); *m/e*: 437, 439 (3:1, M^+). *Anal.* calcd. for $C_{24}H_{36}ClNO_4$: Cl 8.11; found: Cl 8.28.

Hydrolysis of the Steroid Adduct 20

The adduct **20** (175 mg, 0.4 mmol) was heated at 70°C for 2 h in 70% aqueous acetic acid (5 ml). Evaporation to dryness after adding benzene and plc (ether–pentane 5:1) yielded the *aldehyde* **21**, mp 158–160°C (109 mg, 81%). It was recrystallized from ether–pentane, mp 162–163°C; λ_{max} (EtOH): 240 nm (ε 18 100); ν_{max} (CCl_4): 2720 and 2830 (C—H of aldehyde), 1730 (C=O of aldehyde), 1670 and 1620 cm^{-1} (C=C—C=O); ($CDCl_3$) δ: 0.80 (s, 18-CH_3) 1.18 (s, 19-CH_3) 5.67 (s, H-4), and 9.44 ppm (s, H-20); *m/e*: 334, 336 (3:1, M^+) *Anal.* calcd. for $C_{20}H_{27}ClO_2$: C 71.73, H 8.13, Cl 10.59; found: C 71.17, H 8.29, Cl 10.34.

Typical Procedure for the Chromous Chloride Promoted Addition of N-*Chloroamides to Glycals*

Addition of NCU (1a) to Triacetyl-D-glucal (24) Followed by Solvolysis

A solution of **24** (5.445 g, 20 mmol) in chloroform (20 ml) and absolute methanol (4 ml) was cooled to ca. −78°C. A solution of NCU (4.74 g, 96% active chlorine, 40 mmol) in chloroform (20 ml) and absolute methanol (4 ml), pre-cooled to −78°C, was then added. The 1 *M* methanolic chromous chloride solution (80 ml, 80 mmol) was added dropwise over 8 h. The reaction mixture was poured into an ice-cold saturated $NaHCO_3$ solution (100 ml) then extracted rapidly with ether (4 × 200 ml) in the presence of ice. The organic layers were washed with ice-cold water (2 × 50 ml) then dried. The solvent was evaporated, the temperature of the water bath being maintained at 30–35°C, to yield 9.76 g of crude product; ($CDCl_3$) δ: 1.25 (t, J = 7 Hz, OCH_2CH_3), 205 and 2.09 (two s, $OCOCH_3$), 3.9–4.6 (m), 4.89 (d of d, J = 6 and 3 Hz, H-2 of **24**), 5.1–5.5 (m), 5.62 (d, J = 9 Hz, NH), 6.28 (d, J = 3.7 Hz, H-1 of α-chloride **26***a*), and 6.56 ppm (d of d, J = 6 and 1 Hz, H-1 of **24**); the relative integration of the absorptions at 2.05–2.09, 6.28, and 6.56 ppm gave 42:2.6:1. The relative integration of the same peaks in a standard 2:2:1 mixture by weight of triacetylglucal **24**, α-chloride **26***a*, and β-chloride **25***a* gave 31:1.1:1 (the absorption of H-1 of the β-chloride **25***a* was masked by other signals). Thus the molar ratio of α-chloride **26***a* to **24** in the crude product was about 3.3. Since 3.6 mmol (18%) of **24** was recovered, the minimum amount of α-chloride **26***a* would be 11.9 mmol (59%).

Methanolysis—An aliquot (570 mg) of the above crude product was dissolved in absolute methanol (20 ml) and cooled in an ice bath. A solution of silver nitrate (285 mg) and pyridine (0.15 ml) in methanol (20 ml) was then added. A precipitate was formed immediately. The mixture was stirred at room temperature overnight then filtered and the solvent evaporated. The residue was taken in chloroform and filtered again. The filtrate was evaporated to dryness after adding benzene. Separation by plc (ether–hexane 2:1) gave two main fractions. The less polar fraction consisted of unreacted **24**, mp 44–50°C (56 mg, 18%) identical (ir, ^{1}Hmr) to an authentic sample. The other fraction (360 mg) was crystalline, mp 90–95°C. It was recrystallized from ether–chloroform to give *methyl-2-deoxy-2-ethoxycarbonylamino-3,4,6-tri-O-acetyl-β-D-glucopyranoside* (**28***a*, R = CH_3), mp 133–135°C (193 mg, 42%). Two additional recrystallizations afforded the analytical sample, mp 136.5–137°C; $[\alpha]_D^{25}$ +6.0° (*c* 2.0, $CHCl_3$); ν_{max} ($CHCl_3$): 3440 and 3420 (NH), 1740 (C=O), 1515 (NH), 1240 and 1040 cm^{-1} (C—O—C); ($CDCl_3$) δ: 1.25 (t, J = 7 Hz, OCH_2CH_3), 2.02 and 2.10 (two s, $OCOCH_3$) 3.52 (s, OCH_3), 4.15 (q, J = 7 Hz, OCH_2CH_3), 4.62 (d, J = 8 Hz, H-1), 5.22 ppm (d, J = 9 Hz, NH). *Anal.* calcd. for $C_{16}H_{25}NO_{10}$: C 49.10, H 6.43, N 3.57; found: C 49.22, H 6.24, N 3.54. The mother liquors from the first recrystallization (168 mg) were deacetylated by sodium methoxide (~1 mg) in methanol (10 ml) at room temperature for 20 h. The solvent was evaporated and the residue (99 mg) recrystallized in methanol–ether. Acetylation of the crystals in the usual way, Ac_2O (2 ml) and pyridine (4 ml), gave 84 mg of β-pyranoside **28***a* (R = CH_3), mp 137°C (total yield 277 mg, 61%).

Acetolysis—A mixture of silver acetate (2 g) and glacial acetic acid (40 ml) was heated to reflux then cooled to room temperature. This solution was added to a solution of a second aliquot (5.76 g) of the crude product in glacial acetic acid (20 ml) and acetic anhydride (20 ml). After stirring for 3 h, the reaction mixture was filtered then evaporated to dryness. The residue was washed with water (2 × 10 ml), dried, and the solvent evaporated. Separation by column chromatography (ether–hexane 3:1) gave some unreacted **24**, mp 40–50°C (0.560 g, 18%), and a crystalline fraction, mp 120–129°C (3.41 g). Recrystallization from chloroform and ether gave *2-deoxy-2-ethoxycarbonylamino-1,3,4,6-tetra-O-acetyl-β-D-glucopyranose* (**28***a*, R = $COCH_3$), mp 139–142°C (1.99 g, 41%). Another recrystallization gave a sample melting at 144.5°C; $[\alpha]_D^{25}$ +18° (*c* 2.0, $CHCl_3$) (lit. (7) mp 144–145°C, $[\alpha]_D^{25}$ +16.1° (*c* 0.6, $CHCl_3$)); ν_{max} $CCHCl_3$): 3420 (NH), 1750 (br, C=O), 1515 (NH), 1235 (br), 1085, and 1050 cm^{-1} (C—O—C); ($CDCl_3$) δ: 1.25 (t, J = 7 Hz, OCH_2CH_3), 2.02, 2.08, and 2.12 (three s, $OCOCH_3$), 5.50 (d, J = 9 Hz, NH), and 5.78 ppm (d, J = 8.5 Hz, H-1). The ^{1}Hmr of the mother liquors from the first crystallization showed a doublet at 6.10 ppm (J = 1 Hz), which could be attributed to the mannopyranose **29***a* (R = $COCH_3$), in addition to the doublet at 5.78 ppm (J = 8.5 Hz) due to the glucopyranose **28***a* (R = $COCH_3$).

Solvolysis in benzyl alcohol—A third aliquot (527 mg) of the crude product was stirred at room temperature for 24 h in benzyl alcohol (5 ml) in the presence of silver carbonate (100 mg) and Drierite (100 mg). After filtration of the solids and evaporation to dryness, the residue was separated by plc (ether–hexane 1:1) to give some unreacted **24**, mp 142–155°C (53 mg, 17%), and a crystalline fraction, mp 142–155°C (318 mg). Recrystallization from chloroform–ether gave *benzyl 2-deoxy-2-ethoxycarbonylamino-3,4,6-tri-O-acetyl*-β-D-*glucopyranoside* (**28***a*, R = $CH_2C_6H_5$), mp 153–155°C (270 mg, 53%). One additional recrystallization gave the analytical sample, mp 157–158°C; $[\alpha]_D^{25}$ −28° (*c* 1.6, $CHCl_3$); ν_{max} ($CHCl_3$): 3430–3410 (NH), 1750 (br, C=O), 1240, 1220, and 1050 cm^{-1} (C—O—C); ($CDCl_3$) δ: 1.20 (t, *J* = 7 Hz, OCH_2CH_3), 2.00 and 2.08 (two s, $OCOCH_3$), 3.5–5.3 (complex, 12H), and 7.32 ppm (s, aromatic H). *Anal.* calcd. for $C_{22}H_{29}NO_{10}$: C 56.53, H 6.25, N 3.00; found: C 56.57, H 6.45, N 3.42.

The other additions to triacetyl-D-glucal (**24**), the addition of NCU (**1***a*) to 3-*O*-acetyl-4,6-*O*-benzylidene-D-glucal (**31**), and the additions to 3-*O*-acetyl-4,6-*O*-benzylidene-D-allal (**34**) are described in the supplementary material.[16]

Synthesis of β-*Chloride* **25***a*

The β-glucopyranose **28***a* (R = $COCH_3$) (1.0 g, 2.4 mmol) was dissolved in chloroform (25 ml) freshly distilled over P_2O_5. Aluminum chloride (0.180 g, 1.35 mmol) was added and the mixture stirred at room temperature for 45 min. After the addition of dry benzene (25 ml) and silicic acid (0.25 g), the mixture was filtered and the filtrate poured into ice-cold water (7 ml). The organic phase was separated, dried, and the solvent evaporated, all these operations being carried out quickly and in a cold bath. Crystallization in ether gave *2-deoxy-2-ethoxycarbonylamino-3,4,6-tri-O-acetyl*-β-D-*glucopyranosyl chloride* **25***a*, mp 115–116°C (0.576 g, 61%). One recrystallization in ether afforded the analytical sample, mp 115–116°C; $[\alpha]_D^{25}$ +17.5° (*c* 2.0, $CHCl_3$); ν_{max} ($CHCl_3$): 3410 (NH), 1745 (C=O), 1515 (NH), 1235 and 1040 cm^{-1} (C—O—C); ($CDCl_3$) δ: 1.25 (t, *J* = 7 Hz, OCH_2CH_3), 2.10 and 2.15 (two s, $OCOCH_3$), 4.18 (q, *J* = 7 Hz, OCH_2CH_3) 5.55 ppm (d, *J* = 8 Hz, H-1), the NH is masked by other signals. *Anal.* calcd. for $C_{15}H_{22}ClNO_9$: C 45.52, H 5.60, Cl 8.96, N 3.54; found: C 45.47, H 5.54, Cl 8.25, N 3.56. The mother liquors from the first crystallization contained essentially the α-*chloride* **26***a* (174 mg, 18%) according to the ^{1}Hmr spectrum (see below).

Synthesis of α-*Chloride* **26***a*

From β-*Glucopyranose* **28***a* (*R* = $COCH_3$)

The glucopyranose **28***a* (R = $COCH_3$) (119 mg, 0.29 mmol) and titanium tetrachloride (0.5 ml) in chloroform (2 ml) were heated to reflux for 3 h. The mixture was poured into cold water (10 ml) then extracted with chloroform (3 × 50 ml). The organic phases were washed with cold water, dried, and the solvent evaporated (cold bath) to yield pure *2-deoxy-2-ethoxycarbonylamino-3,4,6-tri-O-acetyl*-α-D-*glucopyranosyl chloride* (**26***a*) (97 mg, 85%) as an amorphous solid which crystallized after many months in the refrigerator, mp 47–52°C; $[\alpha]_D^2$ +11° (*c* 1.62, $CHCl_3$); ν_{max} ($CHCl_3$): 3410 (NH), 1740 (C=O), 1510 (NH), 1240 and 1040 cm^{-1} (C—O—C); ($CDCl_3$) δ: 1.22 (t, *J* = 7 Hz, OCH_2CH_3), 2.05 and 2.10 (two s, $OCOCH_3$), 4.15 (q, *J* = 7 Hz, OCH_2CH_3), and 6.22 ppm (d, *J* = 3.5 Hz, H-1). *Anal.* calcd. for $C_{15}H_{22}ClNO_9$: C 45.52, H 5.60, Cl 8.96; found: C 45.41, H 5.43, Cl 8.89.

By Anomerization of the β-*Chloride* **25***a*

The anomerization of **25***a* (110 mg, 0.28 mmol) by titanium tetrachloride (0.6 ml) in chloroform (30 ml) was complete after 3 days at room temperature according to the ^{1}Hmr spectrum. The reaction mixture was poured into ice-cold saturated $NaHCO_3$ solution and the product was extracted with chloroform (3 × 50 ml). The organic phases were washed with cold water (2 × 10 ml), dried, and the solvent evaporated (cold bath) to yield quantitatively (109 mg) the pure α-chloride **26***a*, identical (ir, ^{1}Hmr) to the sample obtained above.

Methanolysis of Chlorides **25***a and* **26***a*

β-*Chloride* **25***a*

The chloride **25***a* (40 mg, 0.1 mmol) was treated by silver nitrate (70 mg) in methanol (10 ml) containing pyridine (4 drops) as described above to give *methyl* β-*glucopyranoside* **28***a* (R = CH_3), mp 132–134°C (39 mg, 98%), identical (ir, ^{1}Hmr) to an authentic sample.

α-*Chloride* **26***a*

The chloride **26***a* (93 mg, 0.23 mmol) was solvolyzed in methanol (12 ml) in the presence of Ag_2CO_3 (200 mg) and Drierite (200 mg) under the usual conditions to give *methyl* β-*glucopyranoside* **28***a* (R = CH_3), mp 131–134°C (78 mg, 86%).

Mixture of Triacetylglucal (**24**), **25***a, and* **26***a*

A mixture of **24** (17.5 mg), β-chloride **25***a* (35 mg), and α-chloride **26***a* (35 mg) was solvolyzed in the conditions used for the methanolysis of **25***a* (see above). The crude product was separated by plc (ether–hexane 2:1) to give triacetylglucal (**24**) (17 mg) and a crystalline fraction, mp 121–129°C (66 mg). It was recrystallized from ether–chloroform to yield pure *methyl* β-*glucopyranoside* **28***a* (R = CH_3), mp 136–136.5°C (45 mg, 64%).

Anomerization of Methyl β-*Glucopyranoside* **28***a* (*R* = CH_3)

Titanium tetrachloride (1 ml) in dry chloroform (10 ml) was added to a solution of **28***a* (R = CH_3) (136 mg, 0.34 mmol) in chloroform (20 ml). The reaction was followed by ^{1}Hmr spectroscopy and was complete after 3 days at room temperature. The reaction mixture was poured into an ice-cold saturated $NaHCO_3$ solution (20 ml) and extracted with chloroform (4 × 30 ml). The organic phases were washed with water (2 × 20 ml), dried, and the solvent evaporated. The crude product (151 mg) was filtered over silica gel to afford pure *methyl 2-deoxy-2-ethoxycarbonylamino-3,4,6-tri-O-acetyl*-α-D-*glucopyranoside* (**30**), amorphous (97 mg, 70%); $[\alpha]_D^{25}$ +99° (*c* 1.5, $CHCl_3$); ν_{max} ($CHCl_3$): 3420 (NH), 1740 and 1720 (sh) (C=O), 1510 (NH), 1235 and 1040 cm^{-1} (C—O—C); ($CDCl_3$) δ: 1.22 (t, *J* = 7 Hz, OCH_2CH_3), 2.06 and 2.13 (two s, $OCOCH_3$), 3.50 (s, OCH_3), 4.19 (q, *J* = 7 Hz, OCH_2CH_3), 4.85 ppm (d, *J* = 3.8 Hz, H-1). *Anal.* calcd, for $C_{16}H_{25}NO_{10}$: C 49.10, H 6.43, N 3.57; found: C 49.26, H 6.53, N 3.64.

Experimental and theoretical studies of proton removal from propene

GERVASE I. MACKAY, MIN H. LIEN, ALAN C. HOPKINSON, AND DIETHARD K. BOHME[1]

Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3

Received June 21, 1977

GERVASE I. MACKAY, MIN H. LIEN, ALAN C. HOPKINSON, and DIETHARD K. BOHME. Can. J. Chem. **56**, 131 (1978).

The kinetics and energetics of proton removal from propene, which contains several sites of different acidities, were investigated both theoretically and experimentally. Rate and equilibrium constants were measured for the proton-transfer reaction $OH^- + C_3H_6 \rightleftharpoons C_3H_5^- + H_2O$ at 296 ± 2 K using the flowing afterglow technique. The rate constants were determined to be $k_{forward} = (1.1 \pm 0.3) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} and $k_{reverse} = (5.4 \pm 1.9) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. The ratio of rate constants, $k_f/k_r = 2.1 \pm 0.7$, was found to be in agreement with the equilibrium constant, $K = 2.2 \pm 0.8$, determined from equilibrium concentrations. *Ab initio* molecular orbital calculations predicted the removal of a methyl proton from propene to yield the allyl anion to be energetically favoured. This prediction was supported by measurements of deuteron removal from CD_3CHCH_2. The measured value of K corresponds to a standard free energy change, ΔG^0_{298}, of -0.44 ± 0.14 kcal mol^{-1} which provided values for the standard enthalpy change $\Delta H^0_{298} = +0.5 \pm 0.4$ kcal mol^{-1}, the proton affinity, $PA_{298}(C_3H_5^-) = 391 \pm 1$ kcal mol^{-1}, the heat of formation, $\Delta H^0_{f,298}(C_3H_5^-) = 29.0 \pm 0.8$ kcal mol^{-1}, and the electron affinity $EA(CH_2CHCH_2) = 12.4 \pm 1.9$ kcal mol^{-1}. The experimentally established value for the proton affinity of the allyl anion was in reasonable accord with the value of 422.3 kcal mol^{-1} determined by calculation. The electron affinity of the allyl radical derived in this study is supported by previous calculations and several limiting values obtained experimentally.

GERVASE I. MACKAY, MIN H. LIEN, ALAN C. HOPKINSON et DIETHARD K. BOHME. Can. J. Chem. **56**, 131 (1978).

On a examiné, tant du point de vue théorique qu'expérimental, la cinétique et les énergies impliquées lors de l'enlèvement d'un proton du propène qui contient plusieurs sites différents par leur acidité. On a mesuré les vitesses et les constantes d'équilibre de la réaction de transfert de proton: $OH^- + C_3H_6 \rightleftharpoons C_3H_5^- + H_2O$ à 296 ± 2 K en faisant appel à la technique d'écoulement post-luminescent. On a déterminé les constantes de vitesse k_f (réaction) = $(1.1 \pm 0.3) \times 10^{-9}$ cm^3 molécule^{-1} s^{-1} et k_r (réaction inverse) = $(5.4 \pm 1.9) \times 10^{-10}$ cm^3 molécule^{-1} s^{-1}. Le rapport des constantes de vitesse $k_f/k_r = 2.1 \pm 0.7$ est en bon accord avec la constante d'équilibre de $K = 2.2 \pm 0.8$ déterminée à partir de concentrations à l'équilibre. Des calculs d'orbitales moléculaires *ab initio* ont prédit que l'enlèvement d'un proton du méthyle du propène conduisant à l'anion allyle serait favorisé d'un point de vue énergétique. Cette prédiction est appuyée par des mesures d'enlèvements de deutérons à partir du CD_3CHCH_2. La valeur mesurée de K correspond à un changement d'énergie libre standard ΔG^0_{298} de -0.44 ± 0.14 kcal mol^{-1} qui fournit des valeurs de changement d'enthalpie standard $\Delta H^0_{298} = +0.5 \pm 0.4$ kcal mol^{-1}, d'affinité de proton $PA_{298}(C_3H_5^-) = 391 \pm 1$ kcal mol^{-1}, de chaleur de formation $\Delta H^0_{f,298}(C_3H_5^-) = 29.0 \pm 0.8$ kcal mol^{-1}, et d'affinité électronique $EA(CH_2CHCH_2) = 12.4 \pm 1.9$ kcal mol^{-1}. L'accord entre la valeur établie expérimentalement pour l'affinité du proton de l'anion allylique avec la valeur de 422.3 kcal mol^{-1} déterminée à partir de calculs est raisonnable. L'affinité pour un électron du radical allyle obtenue dans cette étude est en accord avec des calculs antérieurs et plusieurs valeurs limitantes obtenues expérimentalement.

Introduction

Gas-phase measurements of rate and equilibrium constants for proton-transfer reactions of the type

[1] $$X^- + YH \rightleftarrows Y^- + XH$$

constitute an important means of determining intrinsic thermochemical properties for Brønsted acids and their conjugate bases (1–5). In particular, such measurements have provided proton affinities and heats of formation of anions and electron affinities of their corresponding radicals of sufficient accuracy to be of both academic and practical value. When the proton donor, YH, has only one acidic site the structure of the anion, Y^-, is likely to be unique so that the corresponding measurements and thermodynamic assignments should be unambiguous. For proton donors with more than one acidic site, YH_n ($n > 1$), several tautomeric forms of the conjugate base, YH^-_{n-1}, having different energies, may become both thermodynamically and kinetically acces-

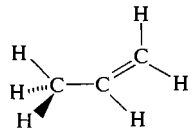
sible although the higher energy forms will be discriminated against as the reaction exothermicity decreases.

This study is directed towards the determination of the proton affinity, PA, and heat of formation, ΔH^0_f, of the allyl anion, and the electron affinity, EA, of the allyl radical. The allyl anion was derived from propene by proton removal according to the reaction:

[2] $$OH^- + CH_3CHCH_2 \rightarrow \ddot{C}H_2\ddot{C}H\ddot{C}H_2 + H_2O$$

In its optimum conformation propene has been shown (6, 7) to have one hydrogen of the methyl group in the plane of the carbon nuclei as shown in structure **1**. The rationale for this eclipsed structure



1

being preferred is that this configuration maximizes the distance between the out-of-plane hydrogen atoms and the double bond, thereby decreasing the destabilizing 4π-electron interaction. In this conformation the propene molecule has five chemically different protons and deprotonation could therefore conceivably produce five different anions. Reaction 2, which was chosen deliberately for its low exothermicity (2), should be selective in establishing the allyl anion which is expected to be the lowest energy tautomer. This was confirmed by *ab initio* molecular orbital calculations. An attempt was also made to establish experimentally additional confidence in the assignment of the allylic structure to the carbanion by measurements of the reaction of OH^- with propene-3,3,3-d_3 designed to identify the most acidic site on propene.

Experimental

The experiments were carried out in a flowing plasma-mass spectrometer (flowing afterglow) system for which the details of construction and the method of operation and data analysis have been described elsewhere (8). Hydrogen and helium were both used as the carrier gas. The OH^- ions were produced either via proton transfer from H_2O to NH_2^- or to H^- according to the rapid reactions (9)

[3] $$NH_2^- + H_2O \rightarrow OH^- + NH_3$$

[4] $$H^- + H_2O \rightarrow OH^- + H_2$$

or by electron impact on water vapour added upstream from the ionizer (10). NH_2^- and H^- were generated by dissociative ionization of NH_3 introduced upstream of the electron gun. When helium was used as the carrier gas small amounts of H_2 were added to remove the O^- (also produced by electron impact of H_2O) according to the associative detachment reaction (11):

[5] $$O^- + H_2 \rightarrow H_2O + e$$

In these experiments the filament of the electron gun was biased negatively in the range from 35 to 70 V with respect to the grid envelope held at ground potential. The emission current was typically 1 mA. The water vapour, which also served as the neutral back reactant, was introduced through a capillary tube in the usual manner either in its pure form at pressures below its vapour pressure, or diluted with helium (1 part H_2O to 9 parts He). The mixtures were prepared by allowing the H_2O vapour to equilibrate in the gas inlet system to the ambient temperature (at a pressure <0.8 of the vapour pressure) and subsequently adding helium. Measurement of the H_2O flow required a separate determination of the viscosity of both the pure and diluted vapour (4). The propene was added sufficiently downstream of the ion production region to ensure that all the reactions producing OH^- had gone to completion and that the OH^- ions experienced enough collisions with the carrier gas to become thermalized at the ambient temperature (296 ± 2 K). The ions present in the flowing plasma were sampled through a small orifice in the tip of a nose cone situated at the end of the reaction region and mass analyzed with a quadrupole mass filter. The variation in the reactant and product ion signals as a function of neutral reagent addition provided the raw data from which the rate and equilibrium constants were determined (8).

A number of tests were carried out to establish confidence in the attainment of true equilibrium. The forward and reverse rate constants and the ratio of the ion concentrations were determined at different relaxation and reaction times, various flows of neutral back reactant, in both helium and hydrogen at several pressures, at various electron and ion densities, and under different sampling conditions.

The gases used were helium (Linde, Prepurified Grade, 99.995% He), hydrogen (Linde, Very Dry Grade, 99.95% H_2), ammonia (Matheson, anhydrous, >99.99% NH_3 (liquid phase)), propene (Matheson, C.P. Grade 99.0% C_3H_6 (liquid phase)), and propene-3,3,3-d_3 (Merck, Sharp & Dohme, >98% D). The water vapour was derived from either boiled tap water or boiled distilled water.

Results

Experimental

Figure 1 shows the data obtained upon the addition of C_3H_6 into a He–H_2O plasma in which OH^- is initially a dominant negative ion. The negative ions with m/e = 17, 35, 37, 41, and 46, the major ions present in the range m/e = 1–60 for the range of C_3H_6 flows used, were monitored as a function of C_3H_6 addition. These ions were identified as OH^-, Cl^- (m/e = 35 and 37), $C_3H_5^-$, and NO_2^- respectively. Cl^- and NO_2^-, which are unreactive impurity ions generally present in the negative ion spectrum, were monitored to confirm constant sampling throughout an experiment. The behaviour shown is representative of the observations made in 12 separate experiments performed under the following conditions: effective reaction length, L = 61 cm (in 7 experiments) and 85 cm (in 5 experiments), average flow velocity, $\bar{v} = 7.7$ to 8.1×10^3 cm s^{-1}, total pressure, $P = 0.390$ to 0.76 Torr, and flow of $H_2O = 7.9 \times 10^{16}$ to 3.47×10^{18} molecules s^{-1}.

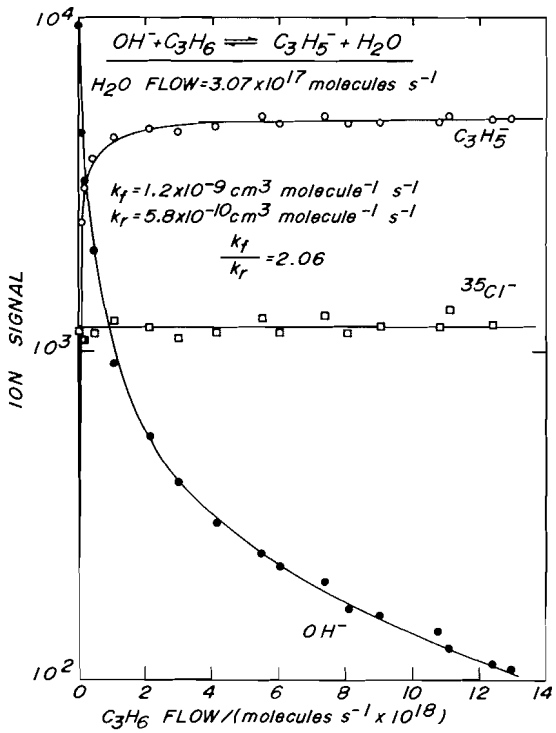

FIG. 1. The variation of the major negative ion signals recorded upon the addition of C_3H_6 into a flowing H_2O–He plasma in which OH^- is initially a dominant negative ion. The solid line through the OH^- decay is a computer fit. T = 296 K, P = 0.54 Torr, $\bar{v}$ = 8.1 × 10^3 cm s^{-1}, and L = 61 cm.

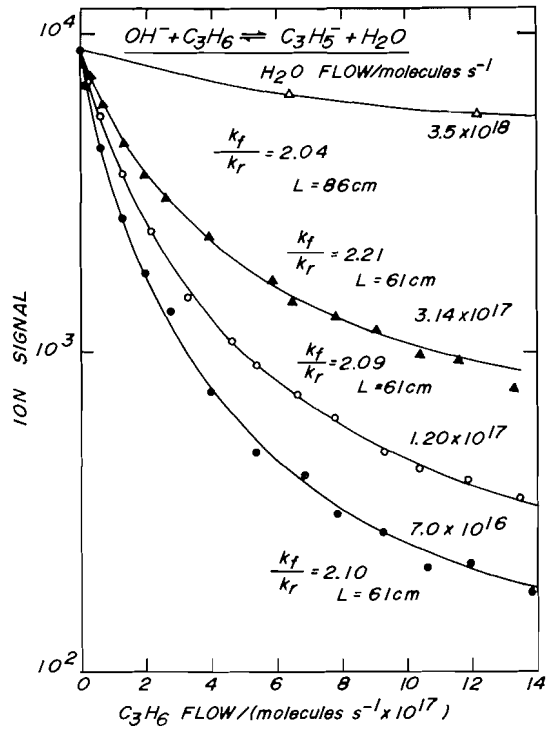

FIG. 2. The variation of the OH^- signals as a function of C_3H_6 addition at various additions of H_2O. P = 0.54 Torr, T = 296 K, and $\bar{v}$ = 7.7–8.1 × 10^3 cm s^{-1}. The points are experimental and the solid lines are computer fits.

Addition of C_3H_6 gave rise to the rapid decline of the OH^- signal and the concomitant increase in the $C_3H_5^-$ signal. There was no evidence for the occurrence of competing reactions so that the entire variation in the OH^- and $C_3H_5^-$ signals with C_3H_6 addition could be ascribed to the transfer of a proton. The curvature in the logarithmic decay of the OH^- signal can be attributed to the occurrence of the reverse proton transfer from H_2O to $C_3H_5^-$. The solid curve drawn through the data points for the OH^- decay represents the best computer fit obtained using analysis B of ref. 8.

In eight investigations the amount of back-reaction was sufficient to introduce curvature in the OH^- decay without attaining equilibrium at low C_3H_6 flows. This allowed the determination of unique values for k_f = (1.1 ± 0.1) × 10^{-9} cm^3 molecule^{-1} s^{-1}, for k_r = (5.4 ± 1.0) × 10^{-10} cm^3 molecule^{-1} s^{-1} and for $(k_f/k_r)_{ne}$ = 2.1 ± 0.3. In three other investigations the reaction was already so close to equilibrium at low C_3H_6 flows that the application of the fitting procedure could only yield a unique value for the ratio of rate constants, $(k_f/k_r)_e$ = 2.1 ± 0.1. Figure 2 shows a family of OH^- decays which encompass the range of back-reactant H_2O flows as well as the two values of the reaction length employed in this study.

In all 12 experiments equilibrium was established at high flows of C_3H_6 and fits to the linear portions of the ratio plots (analysis C in ref. 8) allowed the determination of the equilibrium constant, K, from the equilibrium concentrations. The ratio of the ion signals, $I(C_3H_5^-)/I(OH^-)$, when corrected for mass discrimination, is a measure of the ratio of the ion concentrations $[C_3H_5^-]/[OH^-]$. The method employed for the determination of the mass discrimination factor, m, has been reported previously (8). Figure 3 indicates the approach to and attainment of equilibrium at several flows of back-reactant H_2O. At the highest flow of H_2O equilibrium is established at the lowest measurable addition of C_3H_6. The 12 measurements led to a mean value for K of 2.2 ± 0.1.

The sampling conditions were altered in several of the 12 experiments either by varying the potential of the nose cone with respect to the flow tube (NP) at a fixed potential difference between the nose cone and the axis of the quadrupole mass filter (AP) or by adjusting AP at a fixed value for NP. Both k_f/k_r and K were observed to be independent of these variations within the experimental uncertainty.

Our analysis of the approach to and attainment

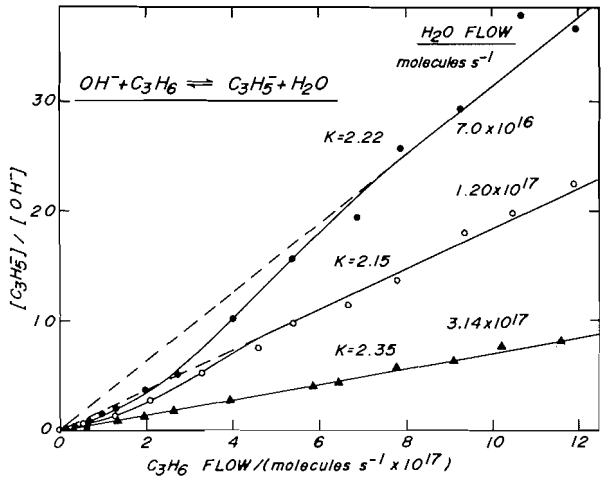

FIG. 3. The variation of $[C_3H_5^-]/[OH^-]$ as a function of C_3H_6 flow at various additions of H_2O. The slopes of the straight lines through the experimental points are proportional to the equilibrium constant K. $L = 61$ cm, $P = 0.54$ Torr, $T = 296$ K, and $\bar{v} = 8.1 \times 10^3$ cm s^{-1}. $m = 2.11$, 2.98, and 2.35 respectively from high to low H_2O flow.

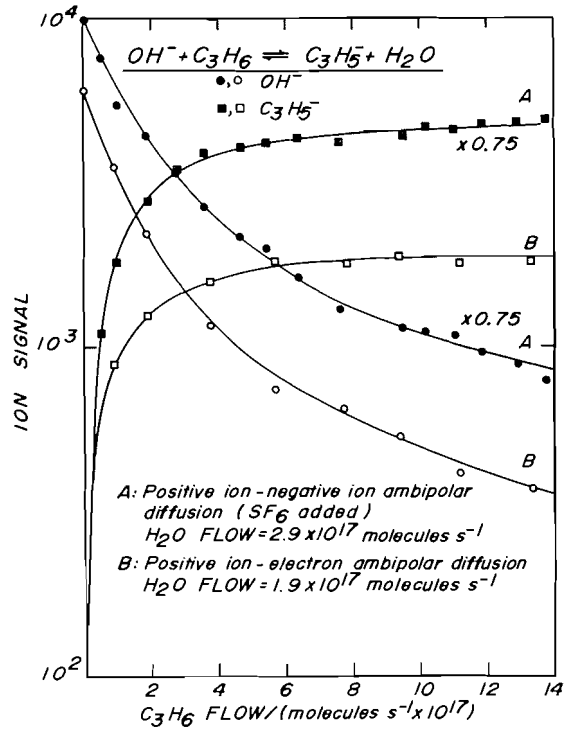

FIG. 4. The effect of SF_6 addition on the variation of the OH^- and $C_3H_5^-$ signals with C_3H_6 addition. The experimental operating conditions were otherwise quite similar. The curves drawn through the OH^- decays represent best computer fits to the experimental points: curve A, $k_f/k_r = 2.3$; curve B, $k_f/k_r = 2.1$. $P = 0.53$ Torr, $\bar{v} = 8.1 \times 10^3$ cm s^{-1}, $T = 296$ K, and $L = 61$ cm.

of equilibrium in the flowing afterglow assumes equal diffusive losses for the reactant and product ions (8). Under normal operating conditions the loss of negative ions due to diffusion in the flowing plasma is controlled by positive ion–electron ambipolar diffusion. In these experiments H_3O^+ ($m/e = 19$) was the dominant positive ion present in the H_2O–He(H_2) plasma. As C_3H_6 was added to the reaction region the H_3O^+ was observed to react rapidly via proton transfer to give $C_3H_7^+$ ($m/e = 43$) as the dominant positive ion with $k = (1.5 \pm 0.3) \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}. For positive ions with $m/e > 20$ the ion–electron ambipolar diffusion coefficients in hydrogen and helium are very similar (12). Therefore, the assumption of equal losses for OH^- and $C_3H_5^-$ by diffusion should not represent a serious error. It is possible to test the validity of this assumption experimentally by adding trace amounts of SF_6 into the reaction region (13). The addition of SF_6 changes the diffusion mode from positive ion – electron to positive ion – negative ion which is less rapid and less discriminating.

Figures 4 and 5 explore the effect of diffusion on the equilibrium constant measurements. Figure 4 shows the expected enhancement of the ion signals as SF_6 is added. However, the shape of the OH^- decay and hence the value of k_f/k_r derived from a fit to this decay remains essentially unchanged as would be expected if OH^- and $C_3H_5^-$ have similar diffusion coefficients. The equilibrium constants derived from the ion–signal ratio at equilibrium in the absence and presence of SF_6 again agree within experimental error when a correction is made for mass discrimination (Fig. 5).

Table 1 summarizes the experimental results and includes an assessment of the accuracy in each case. The sources of error have been described previously (8, 13). In these experiments the largest uncertainty in the determination of k_f/k_r and K was introduced by the uncertainty in the measurement of the flow of water vapour.

Figure 6 shows the observed variation in the major negative ion signals detected upon the addition of propene-3,3,3-d_3 into a He–H_2O plasma in which OH^- was initially a dominant negative ion. The introduction of CD_3CHCH_2 into the reaction region gave rise to a decrease in the OH^- signal and a concomitant increase in the ion signals at $m/e = 18$ (OD^-), $m/e = 41$ ($C_3H_5^-$), $m/e = 42$ ($C_3DH_4^-$), $m/e = 43$ ($C_3D_2H_3^-$), and $m/e = 44$ ($C_3D_3H_2^-$). There was no evidence for subsequent rapid reaction of any of the carbanions with CD_3CHCH_2.

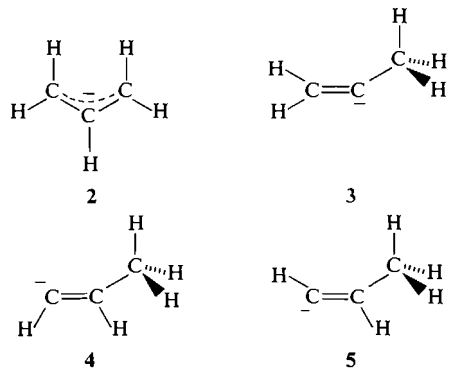
of the five chemically different protons of propene were examined using *ab initio* molecular orbital calculations. The removal of any proton from the methyl group was found to produce the same *planar* allyl anion. This reduces the number of possible anions to four (structures **2** to **5**). The cyclopropyl anion, another possible tautomer, was not examined in this study. It cannot be established directly by proton removal from propene and, furthermore, earlier calculations have established it to be very unstable (14).



2 **3** **4** **5**

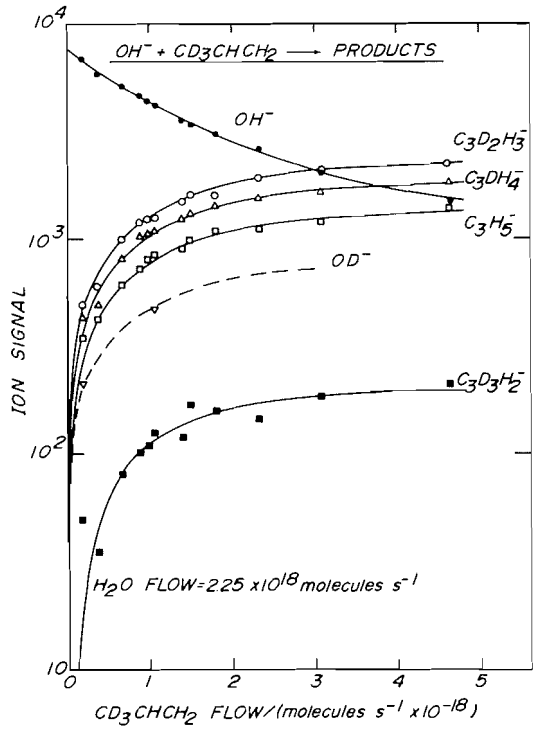


FIG. 6. Observed variation of major negative ion signals recorded upon the addition of propene-3,3,3-d_3 into a flow H_2O–He plasma in which OH^- is initially a dominant negative ion. The product ion signals have not been corrected for mass discrimination. $T = 296$ K, $P = 0.357$ Torr, $v = 7.8 \times 10^3$ cm s^{-1}, and $L = 59$ cm.

The geometry of propene has been optimized with the minimal STO-3G basis set (15) and there is good agreement between the experimental (16) and computed (6) geometries. This same basis set was employed to optimize the geometries of the four anions. Larger basis set (6-31G) calculations (17) using these optimum geometries were then performed to obtain more reliable energies for these anions.

Removal of a proton from the methyl group produces the planar allyl anion (**2**) in which both terminal methylene groups are equivalent. In this structure (Fig. 7) the carbon–carbon bond lengths (1.370 Å) are intermediate between single and double bond lengths and are close to previously calculated values of 1.38 Å (14) and 1.388 Å (18). The internal angle between the carbon atoms (132.9°) is almost 8° larger than in propene, a fact which is attributable to the negative charge formally located on the terminal carbon atoms. Again there is good agreement with the literature values of 133.1° (18) and 134° (19).

Preliminary studies on the other three anions showed the methyl group to prefer the same conformation as in propene. In the subsequent geometry

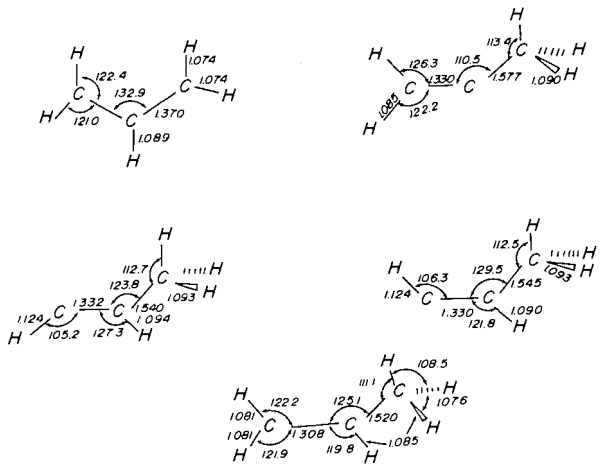

FIG. 7. Optimum geometries of propene and the tautomeric forms of $C_3H_5^-$ as computed with the STO-3G basis set. Bond lengths are given in angstroms and angles in degrees.

optimizations it was assumed that the bond lengths and angles for all three hydrogens in a methyl group were the same. This approximation reduced the number of geometric parameters and thereby reduced the computational cost of the optimizations. An estimate of the magnitude of the error introduced by this approximation is available from the same type of optimization on propene. The overall geometry computed for propene using this approximation is almost identical to that produced in the *complete* optimization and the total energy is inferior by only 0.5 kcal/mol (at STO-3G level) and by less than 0.13 kcal/mol with the more extensive 6-31G basis set.

Geometry optimizations on anions **3**, **4**, and **5** produced bond lengths similar to, but slightly longer than, the corresponding bonds in propene, showing the valence bond structures to be satisfactory descriptions of the molecular structure. The angle between the three carbon atoms appears to be particularly sensitive to the site of deprotonation. Removal of the proton from the central carbon atom produces a decrease in this angle by almost 15°, possibly caused by the newly generated σ-lone pair repelling the two bonds. Deprotonation of the methylene group produces less dramatic changes and these can also be attributed to lone pair – bond pair repulsions. Comparison of the relative energies of the carbanions as computed by both the STO-3G and 6-31G basis sets shows the allyl anion (**2**) to be the most stable by a substantial margin (Table 2 and Fig. 8).

Table 2 also includes proton removal energies taken as the difference in the computed energies of C_3H_6 and $C_3H_5^-$ for the reaction

$$[6] \qquad C_3H_6 \rightarrow C_3H_5^- + H^+$$

Since these proton removal energies may also be regarded as acidities, the order of acidities as computed by both the STO-3G and 6-31G basis sets is $CH_3 \gg CH > CH_2$. This order, deduced from the equilibrium energies, differs from that predicted by the computed net-atomic charges from a Mulliken overlap population on propene (using the 6-31G basis set), showing use of a ground state property is unsatisfactory to predict equilibrium stabilities.

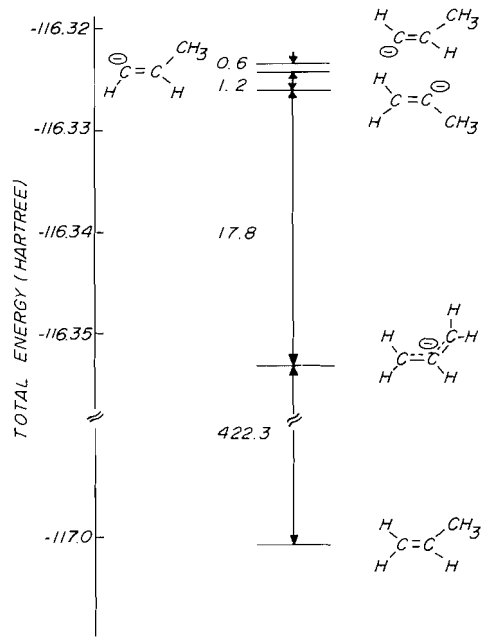

FIG. 8. Relative energies of propene and the tautomeric forms of $C_3H_5^-$ as computed with the 6-31G basis set. Energy differences are in kcal mol^{-1}.

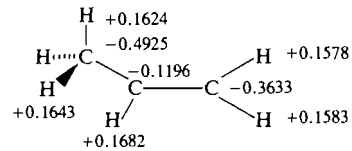

Discussion

Flowing afterglow studies of the reaction of OH^- with propene have been performed previously by Bohme *et al.* (2) who reported a value for $k_f = 2.7 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1} and by Bierbaum *et al.* (20) who determined a value for $k_f = 2.5 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}. The observations reported here, which provided a value for $k_f = 1.1 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}, suggest that these earlier numbers should be regarded as lower limits to the true value of k_f. Our experience indicates that only small amounts of H_2O are needed to achieve equilibrium for this reaction under typical flowing afterglow operating conditions even at low propene additions. Indeed we have observed that impurity amounts of

H_2O can result in sufficient back-reaction to modify the OH^- decay to such an extent that the application of the standard rate constant analysis can only provide a lower limit to the true value of the forward rate constant (8).

The results given in Table 1 indicate that satisfactory agreement is found in this study between the following quantities: (*1*) the ratio of rate constants, $(k_f/k_r)_{ne}$, determined from the fit to the OH^- ion decays obtained under nonequilibrium conditions; (*2*) the ratio of rate constants, $(k_f/k_r)_e$, determined from the fit to the OH^- ion decays under equilibrium conditions; and (*3*) the equilibrium constant, K, determined from equilibrium concentrations. It should be emphasized here that $(k_f/k_r)_{ne}$ and $(k_f/k_r)_e$ do not require the correction for mass discrimination necessary in the determination of K from the equilibrium concentrations. These results, together with the observed independence of the measured ratio of rate constants and the equilibrium constant on the range of reaction times, neutral concentrations, electron and ion densities (diffusion mode), and the potentials in the sampling region, provide confidence that these measured values represent a true equilibrium constant.

The values of k_f/k_r and K provide a best estimate (21) of the true value (a weighted mean) of the equilibrium constant at 296 ± 2 K of 2.1 with a standard error of ±0.5. The thermodynamic information which can be derived from a knowledge of this equilibrium constant is summarized in Table 3. The value of $K = 2.1 \pm 0.5$ corresponds to a standard free energy change, ΔG^0_{298}, of -0.44 ± 0.14 kcal mol^{-1}. A standard entropy change, ΔS^0_{298}, of 3 ± 1 eu may be calculated from the reported values of the standard entropies of H_2O, C_3H_6, and OH^- (22, 23) and an estimated value for S^0_{298} ($C_3H_5^-$) of 63 ± 1 cal deg^{-1} mol^{-1}. This leads to a standard enthalpy change, ΔH^0_{298}, of $+0.5 \pm 0.4$ kcal mol^{-1}.

The standard enthalpy change determined in this study corresponds to a difference in proton affinity $PA(C_3H_5^-) - PA(OH^-) = +0.5 \pm 0.4$ kcal mol^{-1}. Adoption of the values for $\Delta H^0_{f,298}$ (H_2O, OH, H^+) given in the JANAF tables (22) and $EA_0(OH) = 42.09 \pm 0.043$ kcal mol^{-1} (24) leads to a value for $PA_{298}(OH^-) = 390.9 \pm 0.09$ kcal mol^{-1} and thus a value for $PA_{298}(C_3H_5^-) = 391.4 \pm 0.5$ kcal

TABLE 3. Thermodynamic parameters for the reaction $OH^- + C_3H_6 \rightleftharpoons C_3H_5^- + H_2O$ at 296 ± 2 K. The standard error is given along with the best estimate of the true value

$K = 2.1 \pm 0.5$
$\Delta G^0 = -0.44 \pm 0.14$ kcal mol^{-1}

mol^{-1}. However, the equilibrium measurements per se do not unequivocably establish the tautomeric form of $C_3H_5^-$. Although it is reasonable to expect that the equilibrium involves the allyl anion which our calculations have shown to be the most stable form, the possibility remains that the reaction of OH^- with propene produces a higher energy tautomer which does not isomerize in the helium or hydrogen bath to the allylic form prior to reverse reaction with H_2O. In this case the proton affinity determined from these measurements would refer to the higher energy form and not to the allyl anion. However, this possibility can be readily discounted by a comparison of the ~18 kcal mol^{-1} difference between the allyl anion and the next lowest energy tautomer established by our calculations and the difference allowed by experimental observations. A proton affinity of 391 kcal mol^{-1} for the high energy tautomer would require a proton affinity for the allyl anion of only 373 kcal mol^{-1}. Such a low value would make the allyl anion thermodynamically accessible to the reaction

[7] $$CH_3O^- + C_3H_6 \rightleftharpoons C_3H_5^- + CH_3OH$$

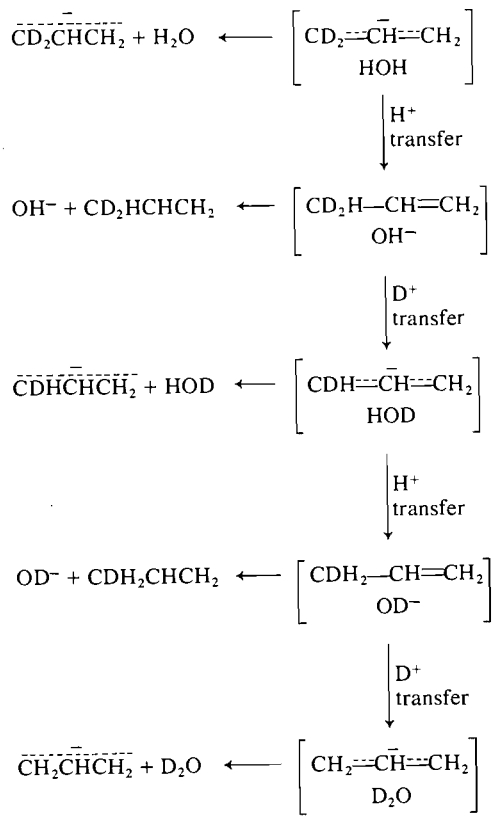
since $PA_{298}(CH_3O^-) = 381 \pm 2$ kcal mol^{-1} (25). However, equilibrium measurements made in this laboratory indicate a value for $K_7 < 10^{-5}$ which requires the proton affinity for the allyl anion to be >388 kcal mol^{-1} and, when combined with the value for $PA_{298}(C_3H_5^-) = 391$ kcal mol^{-1}, would allow a proton affinity difference of at most 3 kcal mol^{-1} between the allyl ion and the next lowest energy tautomer. This result is clearly not supported by the theoretical expectations. On this basis we conclude that the carbanion produced by the reaction of OH^- with propene is indeed the allyl anion.

Our assignment of the allylic structure to the observed $C_3H_5^-$ is also supported, albeit indirectly, by the deuterated propene experiments whose results were considerably more complex than we had naively anticipated. Although the expected $C_3D_2H_3^-$ was the dominant product ion, significant concentrations of other carbanions with various extents of deuteration, viz. $C_3DH_4^-$, $C_3H_5^-$, and $C_3D_3H_2^-$, as well as some OD^- were observed. The $C_3H_5^-$, which cannot arise from the reaction of OH^- with CD_3CHCH_2, is presumed to result from secondary hydrogen–deuterium exchange reactions of the various deuterated carbanions with water vapour (the parent gas of OH^-) present in the reaction region according to

[8] $$C_3D_2H_3^- + H_2O \rightarrow C_2DH_4^- + HOD$$
$$\rightarrow C_3H_5^- + D_2O$$

[9] $$C_3DH_4^- + H_2O \rightarrow C_3H_5^- + HOD$$

The exchange is believed to proceed in the reaction



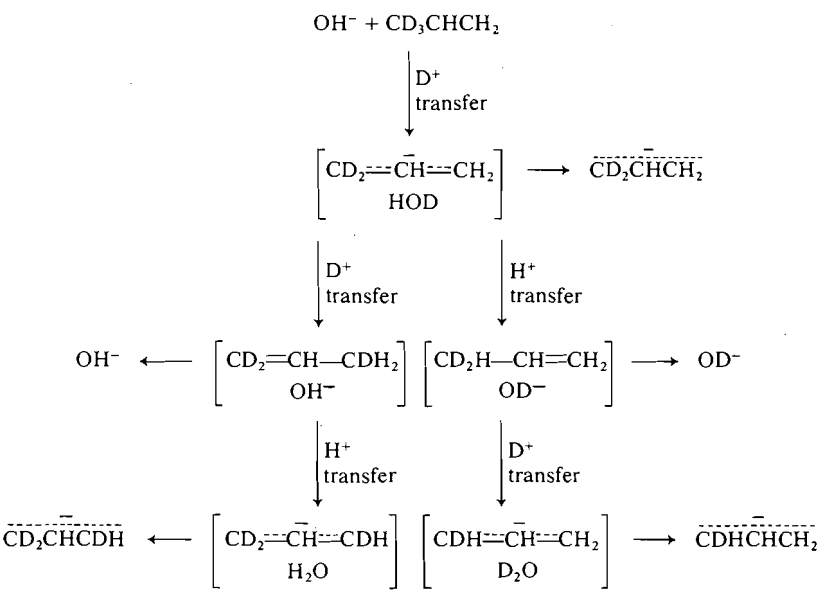
SCHEME 1

intermediate via sequential proton–deuteron transfer made possible by the symmetry of the allylic structure (Scheme 1). This sequence, which is meant only to be illustrative of the general nature of the mechanism, does not include all modes of proton–deuteron transfer. An analogous mechanism should also be involved for the forward reaction (Scheme 2). This reaction sequence (again abridged) allows the formation of $C_3D_3H_2^-$ in addition to the other anions observed.[2]

The thermochemical values for the allyl anion and radical derived from the equilibrium constant measurement for reaction 2 are summarized in Table 4. A value for $\Delta H^0_{f,298}$ (allyl anion) of 29.0 ± 0.8 kcal mol^{-1} is obtained when the values for $\Delta H^0_{f,298}(OH^-) = -34.3 \pm 0.4$ (22, 24), $\Delta H^0_{f,298}(H_2O) = 57.7979$ kcal mol^{-1} (22), $\Delta H^0_{f,298}(C_3H_6) = 4.88 \pm 0.1$ kcal mol^{-1} (23), and the present value of ΔH^0_{298} for reaction 2 are combined according to

[10] $$\Delta H^0_f(\bar{C}H_2\bar{C}H\bar{C}H_2) = \Delta H^0_f(C_3H_6) - \Delta H^0_f(H_2O) + \Delta H^0_f(OH^-) + \Delta H^0$$

[2]J. H. Stewart, R. H. Shapiro, C. H. DePuy, and V. M. Bierbaum have independently proposed a similar mechanism of sequential proton–deuteron transfer in connection with their flowing afterglow studies of reactions of carbanions with D_2O (C. H. DePuy, private communication).



SCHEME 2

TABLE 4. Thermochemical values determined in this study

$PA_{298}(\bar{C}H_2\bar{C}H\bar{C}H_2)$	$= 391.4 \pm 0.5$ kcal mol^{-1}
$\Delta H^0_{f,298}(\bar{C}H_2\bar{C}H\bar{C}H_2)$	$= 29.0 \pm 0.8$ kcal mol^{-1}
$EA_{298}(CH_2CHCH_2)$	$= 12.4 \pm 1.9$ kcal mol^{-1}

Combination of this result for the heat of formation of the allyl anion with a value of 41.4 ± 1 kcal mol^{-1} for the heat of formation of the allyl radical (26) according to

$$EA(CH_2CHCH_2) = \Delta H^0_f(CH_2CHCH_2) - \Delta H^0_f(\bar{C}H_2\bar{C}H\bar{C}H_2)$$

leads to a value for $EA_{298}(CH_2CHCH_2) = 12.4 \pm 1.9$ kcal mol^{-1}.

Our experimental value for PA_{298}(allyl anion) $= 391.4 \pm 0.5$ kcal mol^{-1} is somewhat ($\sim 8\%$) lower than the absolute value (not corrected for zero-point energy or thermal energy) of 422.3 kcal mol^{-1} derived from our molecular orbital calculations with the 6-31G basis set. Such a difference between theory and experiment is not unexpected (4) and could be reduced with the use of a more extensive basis set. Other theoretical studies have provided a variety of values for the electron affinity of the allyl radical. An early molecular orbital calculation by Hush and Pople (27) provided a value for $EA(CH_2CHCH_2) = 5.5$ kcal mol^{-1}. Subsequent calculations by Ehrenson (28) and Hoyland and Goodman (29) led to values of -3.2 and 12 kcal mol^{-1}, respectively. Reliable experimental values were not available for comparison at that time. More recently, flowing afterglow measurements have provided an upper limit for $EA_{298}(CH_2CHCH_2) \leq 12.6 \pm 0.8$ kcal mol^{-1} (corrected for entropy changes), based on the observation of the electron transfer reaction

[11] $\bar{C}H_2\bar{C}H\bar{C}H_2 + O_2 \rightarrow O_2^- + CH_2CHCH_2$

with $k_{11} = 2.8 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} (28). The electron affinity of O_2 at 298 K is 11.6 kcal mol^{-1} (30) and we have allowed for a possible endoergicity of 0.5 kcal mol^{-1} given by $-RT \ln k_{11}/k_L$, where k_L is the Langevin collision rate constant (31). A lower limit for $EA_{298}(CH_2CHCH_2)$ of 12.1 ± 1.8 kcal mol^{-1} (corrected for entropy changes) can be derived (2) from the observation of reaction 2. These limiting values and the value calculated most recently by Hoyland and Goodman (29) are in accord with the value of 12.4 ± 1.9 kcal mol^{-1} determined in the present study. Very recently Zimmerman and Brauman (32) have reported electron photodetachment measurements for $\bar{C}H_2\bar{C}H\bar{C}H_2$ produced by reaction 2. A theoretical fit to the relative cross-sections near threshold provided a value for the electron affinity at 0 K of 12.7 ± 1.2 kcal mol^{-1} where the error limits reflect the lack of data at threshold.

Hydrogen bonding in organic synthesis. Part 9. The sulphenylation of fluoride-activated β-dicarbonyls

JAMES H. CLARK AND JACK M. MILLER

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received August 4, 1977

JAMES H. CLARK and JACK M. MILLER. Can. J. Chem. **56**, 141 (1978).

Various α-arylthio-β-dicarbonyls have been prepared by the room temperature reaction of β-dicarbonyltetraethylammonium fluoride monosolvates with aryl disulphides. The disulphides are formed by the *in situ* fluoride-assisted air oxidation of aryl thiols.

JAMES H. CLARK et JACK M. MILLER. Can. J. Chem. **56**, 141 (1978).

On a préparé divers composés α-arylthio β-dicarbonylés en faisant réagir, à température ambiante, le complex monosolvaté du fluorure de tétraéthylammonium et de la forme énolique d'un dérivé β-dicarbonylé avec des disulfures d'aryles. On forme les disulfures par l'oxydation *in situ* d'aryles thiols effectuée par l'air assisté par des fluorures.

[Traduit par le journal]

A variety of synthetic methods for the preparation of α-thio-β-dicarbonyls have been developed since these compounds are considered as valuable synthetic intermediates. For example, α-arylthiodialkyl malonates have been used as intermediates in the synthesis of a number of heterocycles (1) including coumarins and α-pyrones (2). Furthermore, α-thio-β-diketones have been shown to represent interesting examples of strong intramolecular hydrogen bonding (3). Previous methods of preparation have usually involved the use of sulphenyl halides (4–6) or of α-halodicarbonyls (3) although an alternative method involving sulphenamides has been proposed (7).

We now wish to report a new simple procedure for the preparation of α-thio-β-dicarbonyls which involves the reaction of β-dicarbonyltetraethylammonium fluoride monosolvates with aryl disulphides, the latter being formed *in situ* by the fluoride-assisted air oxidation of arylthiols. To the best of our knowledge, this is the first reported one-pot synthesis of α-arylthio-β-dicarbonyls starting from the β-dicarbonyl and arylthiol.

Experimental

^{1}H nmr spectra were recorded in $CDCl_3$ with a Varian A60 (60 MHz) spectrometer ($SiMe_4$ standard). Mass spectra were obtained on an AE1 MS-30 double-beam mass spectrometer.

Tetraethylammonium fluoride was prepared by neutralisation of 20% aqueous tetraethylammonium hydroxide with 51% aqueous hydrofluoric acid. Pentane-2,4-dione was distilled before use. Other reagents were generally commercial grade samples used without further purification.

Reactions

Two techniques are available for the preparation of β-dicarbonyltetraethylammonium fluoride monosolvates. For β-diketones, an aqueous solution of the fluoride was evaporated in the presence of the β-dicarbonyl, whereas for dialkyl malonates and ethyl acetoacetate, the aqueous fluoride was first reduced to a solid hydrate by evaporation, followed by treatment, at room temperature, with a dimethylformamide solution of the β-dicarbonyl. Details of these methods are given elsewhere (8, 9). An equimolar amount of the arylthiol was added to the dimethylformamide solution of the monosolvate and the whole stirred at room temperature over 5 Å molecular sieves in an open vessel. Reactions were monitored by ^{1}H nmr spectroscopy and/or by tlc and were usually stopped when complete unless stated otherwise in Table 1. Most reactions were complete within 16–20 h. The technique of separation used in each case was virtually the same, with only minor modifications. Diethyl ether was added and any precipitated fluoride was removed by filtration. The ethereal extracts were then shaken with equal volumes of water (3×) to remove the DMF and any remaining fluoride. The ethereal solution was dried ($MgSO_4$) and evaporated. Most products were solids and once crystallised by cooling were recrystallised usually from EtOH. Liquid products were purified by column chromatography (silica gel).

All products are known compounds and gave melting points or boiling points consistent with those reported in the literature (see Table 1) and ^{1}H nmr and mass spectra consistent with their structure and, where reported data is available, consistent with those reported in the literature (3).

Details of a representative preparation are given below.

Preparation of 2-Benzenethio-1,3-diphenylpropane-1,3-dione

An aqueous solution of tetraethylammonium fluoride containing 0.02 mol of the fluoride was briefly concentrated (ca. 5 min) by evaporation at ca. 80°C (water bath) under a mild vacuum (aspirator). 1,3-Diphenylpropane-1,3-dione (0.02 mol) in dimethylformamide (ca. 25 ml) was added and the whole evaporated (same conditions) with shaking for 10–15 min or until no further ebullition occurred. Benzene thiol (0.02 mol) in dimethylformamide (ca. 25 ml) was added dropwise to the cooled solution of the solvate giving a red coloration. The resulting solution was then stirred at room temperature (25°C) over 5 Å molecular sieves for 16 h at which point sampling and ^{1}H nmr analysis showed no starting material remaining. The reaction mixture was extracted in diethyl ether, washed with water (3×), dried ($MgSO_4$), and evaporated. The partially solid residue was extracted in hot EtOH–ligroin (60–100°C) and cooled giving a solid which on recrystallization from hexane gave crystals of 2-benzenethio-1,3-diphenylpropane-1,3-dione (0.0168 mol, 84%); mp 86°C

Results and Discussion

β-Dicarbonyl compounds are capable of behaving as H-bond electron acceptors in the presence of fluoride ions (8, 9). Although the situation is less clear with malonates, β-diketones are totally enolised in the presence of tetraethyl- or tetrabutylammonium fluorides and stable, crystalline monosolvates containing very strong enol hydroxy–fluoride H-bonds have been isolated (8, 9). The synthetic utility of these H-bond activated β-dicarbonyls as sources of highly reactive β-dicarbonyl nucleophiles has already been demonstrated in their reaction with alkyl iodides (8, 9).

Despite the very strong H-bonding that exists in dimethylformamide solutions of tetraethylammonium fluoride and β-dicarbonyls, the equilibrium [1]

[1]

at room temperature will be such that significant amounts of free fluoride ions are present in solution. A comparable system is the very strongly H-bonded tetrabutylammonium fluoride – acetic acid monosolvate in chloroform which has been shown to contain about 7% free fluoride at room temperature and a solvate molarity of 1.0 (10). The free fluoride in the β-dicarbonyl system provides the opportunity for secondary H-bonding between fluoride and the much weaker H-bond electron acceptor thiol molecule (11), which will provide the driving force for air oxidation of the thiol to disulphide [2].

[2] $2R^2—SH\cdots\bar{F} \xrightarrow{[O]} R^2—SS—R^2 + HOH\cdots\bar{F}$

Although water is consequently introduced into the reaction system at this stage, its presence does not affect the outcome of the reaction.

Thus, on stirring a solution of the β-dicarbonyl-fluoride monosolvate (8, 9) in dimethylformamide (tetrahydrofuran may also be used with some loss in reactivity) with an equimolar amount of an arylthiol at room temperature, the α-arylthio-β-dicarbonyl is formed via the aryl disulphide giving the overall reaction 3.

[3] $RCOCH_2COR' + R^2SH + [O] \xrightarrow{\bar{F}} RCOCH(SR^2)COR' + H_2O$

Recently, a general method for the sulphenylation of ketones using disulphides in the presence of a strong base, such as lithium diisopropylamide, was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

reported (12). Presumably, this method could be used for the sulphenylation of β-dicarbonyls although no examples were given in the article. The essential advantage of our method for the preparation of α-arylthio-β-dicarbonyls over such an alternative lies in the choice of 'base.' Strong bases such as lithium amides are destroyed by air and hence sulphenylations using such bases cannot involve the *in situ* air oxidation of a thiol to a disulphide. Thus, reactions must start with a disulphide so that one half of the disulphide is 'wasted' and a quantitative amount of thiol or disulphide would be generated on quenching the reaction mixture, perhaps leading to potential separation problems.

With regard to the previously reported methods for preparing the title compounds, that is, those involving sulphenyl halides or α-halodicarbonyls, it is clear that direct reaction of the more readily available thiol and β-dicarbonyl is the more desirable. Furthermore, tetraalkylammonium fluorides are considerably easier to prepare and use than many more conventional strong organic bases and in the reactions described here and indeed in many other reactions (13–15) they operate essentially as a catalyst and may be removed and recovered in water and subsequently re-used.

The reactions that have been attempted are summarised in Table 1. It is interesting to note that on increasing the acidity of the thiol, the time required for sulphenylation increases. The reason for this is not readily apparent as one might expect that the more acidic the thiol, the weaker the S—S bond in the corresponding disulphide. It may be that the products of the reactions involving the more acidic thiols are better H-bond electron acceptors than the original β-dicarbonyls assuming that the sulphenyl group behaves as an electron withdrawing substituent through $p\pi$–$d\pi$ conjugation at the sulphur atom directly attached to the α-position of the β-dicarbonyl. The products would act to partly block the fluoride to a degree dependent on the overall electron withdrawing powers of the sulphenyl group.

Attempts to introduce a second sulphenyl group into these molecules were unsuccessful. This is not unexpected when one considers that most β-dicarbonyls are totally enolised in the presence of fluoride (8, 9) and β-dicarbonyls containing one α-substituent (particularly where that substituent is electron withdrawing) will have their one remaining acidic hydrogen firmly locked in a very strong H-bond to fluoride.

Syntheses related to the octodiose in apramycin. Part II

HAROLD C. JARRELL AND WALTER A. SZAREK
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received November 10, 1977

HAROLD C. JARRELL and WALTER A. SZAREK. Can. J. Chem. **56**, 144 (1978).

Derivatives of two octodioses have been synthesized from methyl α-D-glucopyranoside and have been shown to possess a *trans*-decalin structure. The new octodiose derivatives may be useful in the synthesis of aminooctodioses which occur in apramycin and oxyapramycin.

HAROLD C. JARRELL et WALTER A. SZAREK. Can. J. Chem. **56**, 144 (1978).

On a effectué la synthèse de dérivés de deux octodioses à partir de l'α-D-glucopyrannoside de méthyle et on a démontré qu'ils possèdent une structure *trans*-décalinique. Les nouveaux dérivés de l'octodiose peuvent être utiles dans la synthèse d'aminooctodioses qui se retrouvent dans l'apramycine et l'oxyapramycine.

[Traduit par le journal]

Recently, apramycin (**1**) (1) and oxyapramycin (**2**) (2) have been shown to be components of an aminocyclitol antibiotic complex, namely, nebramycin (3). Structural studies (2, 4) have shown that the unusual aminooctodioses **3** and **4** are components of compounds **1** and **2**, respectively. It may be seen from structures **1** and **2** that the interesting features are the presence of a nonreducing disaccharide linkage, an octodiose having a *trans*-decalin structure, and 2-deoxystreptamine. In addition to its unique structural features, apramycin is of interest because it has been found to be a potent antibiotic relative to neamine (for a summary of biological data see ref. 5) and has not been reported to be inactivated by any of the known aminoglycoside-inactivating enzymes (5, 6). Interestingly, replacement of the terminal 4-amino-4-deoxy-D-glucose moiety in apramycin with a methyl group yields a cyclitol derivative which has a similar antimicrobial spectrum (5). In view of the latter result, pseudodisaccharides containing the unique aminooctodioses **3** and **4** or their analogs may prove to be of value. Part of the initial work done in this laboratory has been to investigate the preparation of octodioses which are related to structures **3**

and **4**, and which might be of use in their synthesis. In an earlier report (7) the synthesis of two octodioses and an unsuccessful attempt to convert one of them into a *trans*-decalin structure were presented. In this Communication we report what we believe to be the first synthetic examples of octodioses which have a *trans*-decalin structure.

The synthetic approach which was used is outlined in Scheme 1.[1] Readily available compound **5** (8) was selectively benzoylated to give crystalline **6** in 77% yield. Compound **6** was converted, by a known procedure (9), into **7** which was debenzoylated to give crystalline **8** in 66% yield (from **6**). A Grignard reaction with aldehyde **9**[2] (prepared by the oxidation (10) of **8**) afforded a mixture of epimeric products **10** (67.4%) and **11** (12.2%) which were readily separable with **10** being the preponderant isomer. Acetylation of **10** gave **12** in 91% yield; removal of the methylthiomethyl group (9) from **12** gave **13** in 84% yield. Conversion of **13** into **15** was effected in three steps; the product had mp 163–165°C and $[\alpha]_D$ +137.8° (H_2O). The enantiomer of **15** has been reported (11) to have mp 167.5–169°C and $[\alpha]_D$ −142° (H_2O). These data establish that the configuration at C-6 in **15**, **10**, and **11** is that which is shown.

Deacetylation of **13** afforded crystalline **14** (80%) which on treatment with *m*-chloroperbenzoic acid gave compound **16** in 76% yield. Opening the anhydro ring in **16** with azide (12) afforded a mixture of epimeric azides **17** (79%) which could not be resolved. Photolysis of **17** by a standard procedure (13) gave a mixture of **18** and **19** in a yield of 33%. Methanolysis of **18** afforded a mixture of glycosides **20** and **21** (48.5%), whereas **19** afforded **22** (68%) as the only isolated product. The structures assigned to compounds **20**, **21**, and **22** were established by ^1H and ^{13}C nmr spectroscopy. Compound **22** was debenzylated to give crystalline **23** in 84% yield.

The present approach has been demonstrated to provide a viable access to structures which are analogs of those found in **3** and **4**. It is evident that the present scheme is flexible in that, by a suitable choice of starting monosaccharide, other octodioses may be prepared and, by a judicious choice of protecting groups, linkages at C-1 and C-8 may be introduced in which the aglycons may be different as is the case in **1** and **2**.

[1]All compounds gave correct elemental analyses and had pmr and ^{13}C nmr spectra which were in accord with their structures. Optical rotations were measured at 25°C in chloroform, unless otherwise stated. Melting points are uncorrected.

[2]Aldehyde **9** was characterized by treatment with *N,N'*-diphenyl-1,2-diaminoethane to give the corresponding imidazolidine derivative.

A. W. BOYD, O. A. MILLER, and C. WILLIS. Can. J. Chem. **56**, 147 (1978).

Measurements of the yield of NO_2 in N_2–NO mixtures give a neutral dissociative excitation yield of $G(N_2 \rightsquigarrow 2N) = 2.8 \pm 0.2$ in good agreement with those derived from excitation cross-section measurements and from product yield measurement in the radiolysis of N_2–O_2 mixtures.

The dependence of exchange yields in the radiolysis of $^{28}N_2$–$^{30}N_2$ mixtures on pressure, O_2 concentration, and dose-rate has been measured. The results are consistent with a significant contribution to these yields from the isotopic exchange reaction of N^+ with N_2. They also indicate that dose-rates of the order of $> 10^{22}$ eV g^{-1} s^{-1} are required for the N_2^+ ions to contribute to the exchange yield.

A. W. BOYD, O. A. MILLER et C. WILLIS. Can. J. Chem. **56**, 147 (1978).

En mesurant les rendements en NO_2 dans des mélanges de N_2–NO, on peut évaluer que le rendement d'excitation dissociative neutre $G(N_2 \rightsquigarrow 2N)$ est de 2.8 ± 0.2; cette valeur est en bon accord avec des valeurs obtenues à partir de mesures de sections efficaces d'excitation et de mesures de rendements de produits lors de la radiolyse de mélanges de N_2–O_2.

On a pu évaluer la relation qui existe entre les rendement d'échange lors de la radiolyse de mélanges de $^{28}N_2$–$^{30}N_2$ et la pression, la concentration en O_2 et l'intensité de radiation. Les résultats sont en accord avec une interprétation impliquant une contribution importante à ces rendements provenant de la réaction d'échange isotopique de N^+ avec N_2. Ils indiquent aussi qu'il est nécessaire d'utiliser des intensités de l'ordre de $> 10^{22}$ eV g^{-1} s^{-1} pour que les ions N_2^+ contribuent au rendement d'échange.

[Traduit par le journal]

Introduction

Two major uncertainties remain in the radiation chemistry of nitrogen (1). Firstly, the yield of neutral dissociative excitation is based on two rather indirect measurements: a value of $G(N_2 \rightarrow 2N) = 2.5 \pm 0.5$ has been derived (1) from the total dissociative excitation cross section measured by heterogeneous absorption of N-atoms (2); a value of $G(N_2 \rightarrow 2N) = 2.9 \pm 0.2$ has been deduced from product yields in the radiolysis of N_2–O_2 mixtures (3). Secondly, the observed exchange yields in the radiolysis of $^{28}N_2$–$^{30}N_2$ mixtures (4–7) are apparently mechanistically inconsistent with the yields of ions and excited states (1). In the absence of isotope effects, in the irradiation of an equimolal mixture of $^{28}N_2$ and $^{30}N_2$ half of the molecules formed by N-atoms will be $^{29}N_2$ and thus the exchange yield is defined as $G(\text{exch.}) = 2G(^{29}N_2)$. Experimental measurements give $G(\text{exch.})$ in the range 7.3 to 9.5 (4–7) for pressures in the range 13 to 53 kPa, doses in the range 6×10^{20} to 1.5×10^{22} eV g^{-1} and for dose-rates from 10^{15} to 10^{17} eV g^{-1} s^{-1}. The most reliable value appears to be $G(\text{exch.}) = 7.5 \pm 0.5$ (5, 7). The primary ionization yields in the radiolysis of nitrogen can be derived by combining cross-section measurements with the W-value to give $G(N_2 \rightarrow N_2^+ + e) = 2.2$;

$G(N_2 \rightarrow N^+ + N + e) = 0.7$ (1). The primary neutral dissociation yield as discussed above can be taken to be $G(N_2 \rightsquigarrow 2N) = 2.7 \pm 0.3$. At the dose-rates used in these studies (4–7) it is very unlikely that N_2^+ will contribute to the total N-atom yield. Once it has undergone the rapid clustering reaction to form N_4^+ (8), its lifetime with respect to charge neutralization is so long that it will undergo charge exchange with impurities in the system. The N^+ primary ion will cluster to give N_3^+ (8) and either on charge transfer or charge neutralization, this should give just one N-atom. On the basis of these arguments the total N-atom yield should be:

$$G(N)_{total} = 2G(N_2 \rightsquigarrow N^+ + N + e) + 2G(N_2 \rightsquigarrow 2N)$$
$$= 2 \times 0.7 + 2 \times 2.7 \pm 0.3 = 6.8 \pm 0.6$$

Thus G(exch.) should be in the range 3.1 to 3.7. Clearly this prediction is at variance with the experimental yields.

Since the experimental exchange yields were reported and our review written the rate constant for isotopic exchange of N^+ with N_2 has been published (9).

[1] $$^{15}N^+ + {}^{28}N_2 \rightarrow {}^{14}N^+ + {}^{29}N_2$$
or
$$^{14}N^+ + {}^{30}N_2 \rightarrow {}^{15}N^+ + {}^{29}N_2$$
$$k_1 = 3.3 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

Including reaction 1 in the exchange mechanism leads to a chain reaction. This possibility had previously been ruled out because of the observed lack of dose-rate dependence on the exchange yields. However, the chain length will be determined not only by reaction 1, the propagation step, but also by reaction 2 which will presumably be the termination step.

[2] $$N^+ + 2N_2 \rightarrow N_3^+ + N_2$$
$$k_2 = 5 \times 10^{-29} \text{ cm}^6 \text{ molecule}^{-2} \text{ s}^{-1} \text{ (8)}$$

Simple kinetic considerations lead to expression [3]

[3] $$G(\text{exch.})_{N^+ \text{ chain}} = 2G(N_2 \rightsquigarrow N^+ + N + e) \cdot k_1/k_2[N_2]$$

for the contribution of this process to the exchange yield. Since this expression is derived from terms which are all first order in the concentration of primary species the contribution to the exchange yield should be independent of dose-rate. There are some qualitative uncertainties in the above treatment, for example the three body limit of reaction 2 is not known, but, as will be discussed, it does provide at least a partial explanation for the observed high exchange yield.

We have measured the yield of the neutral dissociation process by a more direct method and we have investigated the contribution of reaction 1 to the radiolytic exchange by varying the pressure and by the use of additives.

Experimental

Dosimetry

A single dosimeter system, N_2O containing 1 mol% SF_6, was used for the Gammacell, Van de Graaff, and linear accelerator irradiations so that all the data would be as self-consistent as possible. The initial yield from this mixture, $G(N_2) = 8.0$ (10–12), is independent of dose-rate over the range 10^{16}–10^{28} eV g^{-1} s^{-1}. The absorbed dose in the $^{28}N_2$–$^{30}N_2$ sample irradiations with the linear accelerator and the Van de Graaff was obtained by monitoring with a secondary electron counter which was then normalized against the N_2O–SF_6 dosimeter system. To reduce any error due to this monitoring the N_2O–SF_6 dosimeters were given doses in the range 5×10^{20} to 2×10^{21} eV g^{-1}. As the yields of N_2 from N_2O–SF_6 at these high doses have not been previously reported they were determined by irradiations of this dosimeter in the Gammacell. The results are given in Table 1.

Irradiations

Gammacell-220 (CRNL)

Samples were irradiated in Pyrex cells either 1 cm or 4 cm in diameter (volumes ~10 and ~100 cm^3 respectively). The absorbed dose-rate was 2.5×10^{16} eV g^{-1} s^{-1}.

Van de Graaff (CRNL)

In the present experiments we used pulses 1 μs long of 2.25 MeV electrons at a frequency of 20 Hz. Samples were contained in Pyrex cells 0.8 cm diameter, 10 cm long fitted with 0.05 cm thick windows. The absorbed dose per pulse was 2×10^{17} eV g^{-1} giving a dose-rate of 2×10^{23} eV g^{-1} s^{-1}.

Linear Accelerator (NRCC)

With this source we used pulses 40 ns long of 35 MeV electrons at a frequency of 720 Hz. Sample cells were similar to those used with the Van de Graaff. The absorbed dose per pulse was 2.5×10^{17} eV g^{-1} giving a dose-rate of 6×10^{24} eV

g^{-1} s^{-1}. Because of the high rate of energy deposition the temperature of the samples rose some 200–300°C during irradiation. Previous work (13) has shown that exchange yields in nitrogen are independent of temperature in the range 300–1300 K so that this temperature excursion should not be significant.

Febetrons (CRNL)

Both a Febetron 705 and a Febetron 706 were used. The samples were irradiated in quartz cells 4 cm diameter × 7 cm long for the 705 and 2.5 cm diameter × 2 cm long for the 706 with both cells having 0.05 cm windows. The absorbed doses per pulse in these cells from N_2O dosimetry $G(N_2) = 12.4$ (10, 14, 15) were 1×10^{20} eV g^{-1} ($\sim 2 \times 10^{27}$ eV g^{-1} s^{-1}) and 7.2×10^{19} eV g^{-1} ($\sim 2 \times 10^{28}$ eV g^{-1} s^{-1}) for the 705 and 706 respectively.

Materials and Analyses

The $^{28}N_2$–$^{30}N_2$ mixture was prepared using nitrogen supplied by Monsanto with a specified ^{15}N content of > 99% and a purity > 99.99%. This was mixed with Matheson research grade nitrogen. Analysis of this mixture gave $^{28}N_2$ 48.5%, $^{29}N_2$ 1.2%, $^{30}N_2$ 50.3%. Because there was some uncertainty regarding the oxygen content of samples in some experiments the substrate was exposed to a sodium mirror before irradiation. These experiments gave results which were indistinguishable from those where no exposure to a sodium mirror was made.

The O_2, SF_6, NO, and N_2O were all obtained from Matheson. The SF_6 and N_2O were freed of permanent gases. The NO was freed from NO_2 and N_2O_3 by distillation at 195 K and from N_2O by passing through 3A molecular sieve.

Isotopic analysis was done with a CEC-2-610 mass spectrometer.

The NO_2 formed in the N_2–NO mixtures was determined measuring its optical density after all NO had been removed by low temperature distillation to prevent formation of N_2O_3. A Cary 17 spectrophotometer was used and the extinction coefficients were taken from ref. 16. Corrections were made for the equilibrium $2NO_2 \rightleftharpoons N_2O_4$.

Results

Yield of N-atoms in Radiolysis of Nitrogen

The primary yield of N-atoms was determined by irradiating mixtures of nitrogen with added NO in the Gammacell. All samples contained 0.5 mol% SF_6 which was added to eliminate the possibility of charge neutralization yielding any N-atoms. The measured yields of NO_2 given in Table 2 are independent of dose and of the concentration of NO in the range 2–4%.

Exchange Yields

The calculation of the exchange yields was done as described previously (4–6).

Gammacell Irradiations

Preliminary experiments with 1-cm diameter cells gave results with a good deal of scatter at pressures below 13 kPa both with and without the addition of O_2. This was attributed to the importance of wall effects and impurities at these low pressures and we attempted to lessen the effects by using larger diameter cells in subsequent experiments. The exchange yields for both sets of irradiations are given in Table 3. In agreement with previous work (4, 5) the yields are decreased by the addition of O_2. Only one previous measurement at pressures below 13 kPa has been reported: at 4.4 kPa G(exch.) = 11 (5) which is 15% higher than the value found by the same authors at 13 to 50 kPa.

Van de Graaff and Linear Accelerator

The results of these irradiations are given in Table 4. The scatter in the results at low pressures is again attributed to wall effects and impurities.

Febetrons

The yields in the Febetron irradiations which were expected to be the same as those with the Van de Graaff and linear accelerator are given in Table 5. Possible explanations for the anomalously high values observed are given at the end of the discussion.

Discussion

To provide a basis for the discussion of the results the rate constants for reactions that can take place in the mixtures we have irradiated are listed in Table 6. The lifetimes of ions and atoms under various conditions derived from these rate constants are given in Table 7.

Yields of NO_2 in the N_2–NO–SF_6 Mixtures

At low doses all N-atoms produced in these mixtures should undergo reaction with NO,

[28] $$N + NO \rightarrow N_2 + O$$

and, the O-atoms produced should react to give NO_2 by reaction 29.

[29] $$O + NO + N_2 \rightarrow NO_2 + N_2$$

At larger doses, the concentration of NO_2 may be high enough to give back reactions and make the interpretation of the yields difficult; however, the lack of dependence of our values on dose (Table 2) shows that sufficiently low doses were maintained. The data given in the table also show that amounts of O_2 in the samples did not contribute significantly to the NO_2 levels measured at low doses.

The situation as regards reaction of ionic species is not quite so clear. There should be no contribution to the NO_2 yield from N_2^+ ions. In these mixtures, N_2^+ will cluster to form N_4^+ (8) and by analogy with other reactions of N_4^+, this can be expected to undergo charge transfer with NO, reaction 18′.

[18′] $$N_4^+ + NO \rightarrow NO^+ + 2N_2$$

Dissociative neutralization of NO^+ is suppressed by the addition of SF_6.[2]

The N^+ ions will first form N_3^+, reaction 2, which can then react with NO,

[16] $$N_3^+ + NO \rightarrow N_2O^+ + N_2$$

[17] $$N_3^+ + NO \rightarrow NO^+ + N_2 + N$$

$$k_{16} + k_{17} = 1.4 \times 10^{-10}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$$

As pointed out in ref. 23, $k_{16} + k_{17}$ is much smaller than the limiting Langevin simple charge transfer rates which suggests that a reaction intermediate is formed thereby favouring the more exothermic channel, reaction 16. Thus, to a fair degree of approximation, the dominant contribution to the NO_2 yield from the primary process ($N_2 \rightsquigarrow N^+ + N + e$) will be from the N-atoms formed directly. On the basis of the above arguments, the yield of NO_2 should be

$$G(NO_2) = 2G(N_2 \rightsquigarrow 2N) + G(N_2 \rightsquigarrow N^+ + N + e)$$

Taking the present value of $G(NO_2) = 6.3 \pm 0.4$ gives

$$G(N_2 \rightsquigarrow 2N) = (6.3 \pm 0.4 - 0.7)/2 = 2.8 \pm 0.2$$

This falls between the value derived from excitation cross-sections of 2.5 (1) and that deduced from product yields in N_2–O_2 radiolysis of 2.9 (3).

Exchange Yields

Gammacell Experiments

The yields obtained using 1-cm diameter cells at pressures of 13 kPa or greater give $G(\text{exch.}) = 7.5 \pm 0.5$ which is in good agreement with those of Dawes and Back (5) and Wood and Mascall (6). The results at lower pressures show an increase but with considerable scatter. The yields with the 4-cm diameter cells show a fairly consistent increase with decreasing pressure and this supports our suggestion that the variation in the small cell yields is due to wall effects and impurities.

We suggest in the Introduction that there are three main contributions to the exchange yield: that from the primary dissociative excitation giving N-atoms, that from the neutralization (or charge transfer) from

[c]The data in (8) are also consistent with this 2-body rate constant over the pressure range used.
[d]Assumed value above 25 kPa.

the primary N^+ ion, and that arising from the N^+-chain sequence.

From our N_2–NO measurements and the previous measurements of $G(N_2 \rightsquigarrow 2N)$ the contribution of the first of these to the exchange yield is

$$G(\text{exch.})_{\text{N atoms}} = (6.3 \pm 0.4)/2$$

The value of $G(N^+) = 0.7$ gives

$$G(\text{exch.})_{N^+} = 0.7/2$$

The contribution of the N^+ chain is then the difference between the observed G(exch.) and the above two values

TABLE 7. Ion and atom lifetimes in irradiated nitrogen at 100 kPa

Species	Reaction	Conditions	Lifetime (s)
N_2^+	$N_2^+ + 2N_2 \rightarrow N_4^+ + N_2$		8×10^{-11}
N_2^+	$N_2^+ + e \rightarrow N + N$	2×10^{27} to 2×10^{28} eV g^{-1} s^{-1}	5 to 15×10^{-9}
N_4^+	$N_4^+ + O_2 \rightarrow 2N_2 + O_2^+$	10 ppm O_2	10^{-5}
N_4^+	$N_4^+ + e \rightarrow 2N + N_2$	2.5×10^{16} eV g^{-1} s^{-1}	10^{-3}[a]
		2×10^{23} eV g^{-1} s^{-1}	5×10^{-7}[a]
		6×10^{24} eV g^{-1} s^{-1}	10^{-7}[a]
N	$N + N + N_2 \rightarrow 2N_2$	2.5×10^{16} eV g^{-1} s^{-1} for $G(N) = 7$	2
N	$N + O_2 \rightarrow NO + O$	10 ppm O_2	40

[a]Assuming $k_{(N_4^+ + e)} = 1 \times 10^{-6}$ cm^3 molecule^{-1} s^{-1}.

$$G(\text{exch.})_{N^+ \text{ chain}} = G(\text{exch.})_{obs} - [G(\text{exch.})_{N^+} + G(\text{exch.})_{N \text{ atoms}}]$$

Therefore,

$$G(\text{exch.})_{N^+ \text{ chain}} = G(\text{exch.})_{obs} - 3.5 \pm 0.4$$

To test the applicability of expression 3 the contribution from N^+ chain processes for both the 1-cm and 4-cm diameter cell experiments are plotted in Fig. 1 as a function of the reciprocal pressure. As we have previously stated we attribute the difference between the two sets of data as being due to impurities and we further attribute the obvious curvature in the 4-cm cell data at low pressures to increasing effects of impurities and walls.

The non-zero intercept of the plot is presumably due to the clustering reaction 2 becoming effectively 2-body. The limiting contribution of $G(\text{exch.})_{N^+ \text{ chain}} = 4.0$ gives a total $G(\text{exch.}) = 7.5$ which is in very good agreement with that of other workers already discussed. The value of the intercept suggests a high pressure limiting rate for reaction 2 of

$$k_2 \text{ (high pressure limit)} = \frac{2G(N^+)}{G(\text{exch.})_{N^+ \text{ chain}}} \times k_1$$

$$= \frac{2 \times 0.7}{4.0} \times 3.3 \times 10^{-10}$$

$$= 1.2 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

The pressures used for the measurement of the rate constant for the addition of N^+ to N_2 at 300 K (ref. 8) were 0.08 to 0.16 kPa. These gave values of k_2 in the range 4 to 6×10^{-29} cm^6 molecule^{-2} s^{-1}. The value of k_2 calculated from extrapolation of the straight line drawn in Fig. 1 to this pressure range and substituting in expression 3 is $k_2 = 4.4 \times 10^{-29}$ cm^6 molecule^{-1} s^{-1}.

We conclude that the high and low pressure extrapolations provide reasonable support for assuming that the high exchange yields arise from reaction 1.

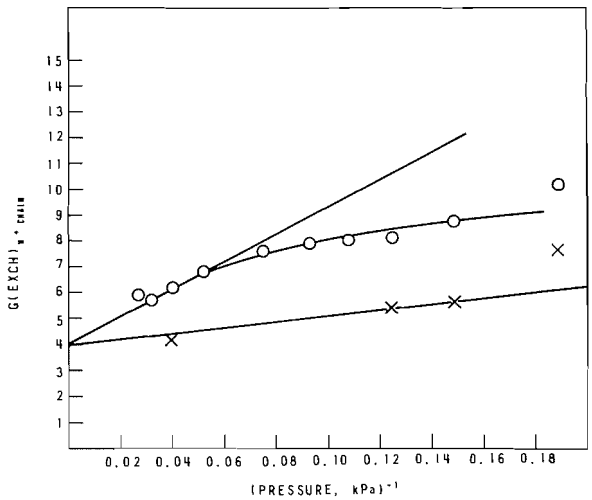

FIG. 1. Pressure dependence of the exchange yield attributed to the N^+ chain reaction. ○, 4-cm cells; ×, 1-cm cells.

O_2 Dependence

It might be hoped that the exchange yields as a function of O_2 concentration would give the contribution of reaction 1 to these yields as the rate constants for $N^+ + O_2$, reactions 7 and 8 are very much larger than that for $N + O_2$, reaction 2. However as a result of the high doses used the concentrations of NO and NO_2 became significant. The reactions of these with N^+, N_3^+, N_4^+, and N make the interpretation of the results very difficult.

It appears that all that can be said is that the effect of O_2 is not inconsistent with the proposed mechanism.

Van de Graaff and Linear Accelerator Exchange Yields

The limiting exchange yield at Gammacell dose-rates where no contribution from N_2^+ ions is expected is $G(\text{exch.})_{\text{Gammacell}} = 7.5 \pm 0.5$. The limiting value obtained in Van de Graaff irradiations is $G(\text{exch.})_{\text{VdG}} = 10.3 \pm 0.6$. The difference between these values, $\Delta G(\text{exch.}) = 2.8 \pm 0.8$ agrees within

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the wide experimental error with the primary yield of N_2^+ ions of $G(N_2 \rightarrow N_2^+ + e) = 2.2$ (1). The results from the linear accelerator experiments show more scatter but are consistent with this.

The reduction in the exchange yields at lower pressures shown in Table 4 is presumably due to the sensitivity of the N_4^+ contribution to G(exch.) to very small impurity levels.

Febetron Results

From the above discussion of the yields from the irradiations with the other accelerators and the Gammacell the expected exchange yield from the Febetron irradiations of pure $^{28}N_2$–$^{30}N_2$ mixtures is G(exch.) = 10.5 ± 0.5. The addition of SF_6 should reduce this considerably as it will lead to the suppression of dissociative neutralization and will react with N^+ (reaction 18). Although the yield in pure $^{28}N_2$–$^{30}N_2$ with the Febetron 706, G(exch.) = 11 ± 0.6 is consistent with this reasoning, none of the other yields are. The yield in the pure isotopic mixture with the Febetron 705 is twice as large as expected and with 4% added SF_6 it should be less than 8 instead of the observed value of G(exch.) = 10 ± 1. Even more inconsistent is the exchange yield in the Febetron 706 irradiations which increases by about 50% on the addition of 1 to 10% SF_6.

The increase in the values in the Febetron 705 irradiations could possibly have an explanation similar to that proposed to account for the anomalously high yields in N_2O, NH_3, and the hydrogen halides with the 705 (38). In these irradiations the yields increased with decreasing pressure below ~80 kPa. We suggested that the electrons in the very intense beam were accelerated across the beam and at low pressures could attain sufficient energy to cause dissociation. It is not clear that such a mechanism occurred in the $^{28}N_2$–$^{30}N_2$ irradiations but it seems reasonable to suggest that the relative rates of reactions 1 and 2 could be changed under such extreme conditions. This does not account for the results with Febetron 706. However we have observed that in Febetron 705 irradiations of N_2O at pressures below 6 kPa the addition of SF_6 increases the amount of nitrogen produced.[3] The mechanism of this is not understood but it may involve an ionic chain reaction. A similar effect might be operating on the addition of SF_6 at the higher dose-rate of the Febetron 706.

It is obviously not possible to establish precise mechanisms for the Febetron yields. We believe though, that the anomalies are due to the sensitivity of the N^+–N_2 exchange reaction to the high intensities of the Febetron pulses. Unfortunately these results do not provide any reliable yields in irradiated nitrogen.

[3]A. W. Boyd and C. Willis. Unpublished data.

Conclusions

The yields of neutral dissociative excitation in the radiolysis of N_2 derived from cross-section measurements (1), O_3 yields in N_2–O_2 mixtures (3), and NO_2 yields in N_2–NO mixtures (this work) are in good agreement and give $G(N_2 \rightsquigarrow 2N) = 2.7 \pm 0.2$.

The high exchange yield in the radiolysis of $^{28}N_2$–$^{30}N_2$ mixtures which was previously thought to be contrary to primary yield data can be explained by the exchange reaction between N^+ ions and N_2 molecules. The pressure dependence of this yield suggests that the three body limit of the addition of N^+ to N_2 is above 30 kPa.

The increase in the exchange yield between dose-rates of 10^{16} eV g^{-1} s^{-1} and 10^{23} eV g^{-1} s^{-1} is consistent with the yield of N_2^+ ions and the lifetimes of the ions with respect to possible O_2 impurities and neutralization.

An aid to the interpretation of electrochemical data measured with spherical and cylindrical electrodes: corrections to the Cottrell equation

NAROTTAM P. BANSAL[1] AND JAMES A. PLAMBECK

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 17, 1977

NAROTTAM P. BANSAL and JAMES A. PLAMBECK. Can. J. Chem. **56**, 155 (1978).

An analysis of the theoretical correction factors for diffusion toward spherical and cylindrical electrodes has been made. The Cottrell equation is a limiting case for spherical and cylindrical diffusion and is accurate only when both $D^{1/2}/r_0$ and t are small.

NAROTTAM P. BANSAL et JAMES A. PLAMBECK. Can. J. Chem. **56**, 155 (1978).

On a effectué une analyse des facteurs théoriques de corrections pour la diffusion vers des électrodes sphériques et cylindriques. L'équation de Cottrell est un cas limite pour les diffusions sphériques et cylindriques et n'est exacte que lorsque $D^{1/2}/r_0$ et t sont petits en même temps.
[Traduit par le journal]

Introduction

The effect of electrode sphericity and cylindricity upon chronopotentiometric results has been reported (1, 2) as modifications of the Sand equation. For a chronopotentiometric process controlled by semi-infinite linear diffusion at a planar electrode, the time dependence of the current is described by the Cottrell (3) equation. The Cottrell equation predicts that, under conditions of semi-infinite linear diffusion, the current decays as $t^{-1/2}$ and the quantity $It^{1/2}$ should be constant at all times after application of the potential step. For linear diffusion, the area from which the electroactive substance can diffuse is independent of the thickness of the diffusion layer, while for spherical and cylindrical diffusion the area from which material can diffuse constantly increases with time as the diffusion layer extends further into the solution; thus $It^{1/2}$ continues increasing with time.

For diffusion towards a spherical electrode such as the hanging mercury drop electrode (hmde) a ratio of the spherical diffusion current I_{sph} (4) to the linear Cottrell diffusion current I_{lin} yields

$$[1] \qquad I_{sph}/I_{lin} = 1 + \pi^{1/2}t^{1/2}D^{1/2}/r_0$$

The second term on the right-hand side, henceforth called R, is the relative difference between spherical and linear diffusion and is a function of time t, diffusion coefficient D, and electrode radius r_0.

For cylindrical diffusion, as to a wire electrode, the ratio of the cylindrical diffusion current I_{cyn} (4) to the Cottrell diffusion current yields

$$[2] \qquad I_{cyn}/I_{lin} = 1 + \pi^{1/2}t^{1/2}\frac{D^{1/2}}{r_0'} \times [\tfrac{1}{2} - \tfrac{1}{4}(\phi/\pi)^{1/2} + \tfrac{1}{8}\phi + \ldots]$$

where r_0' and A are the radius and area of the cylindrical electrode, ϕ represents the dimensionless quantity $Dt/r_0'^2$, and the other terms have the same significance as in [1]. Excluding unity, the right-hand side, henceforth called R', is the relative difference between linear and cylindrical diffusion and is a function of t, D, and r_0'.

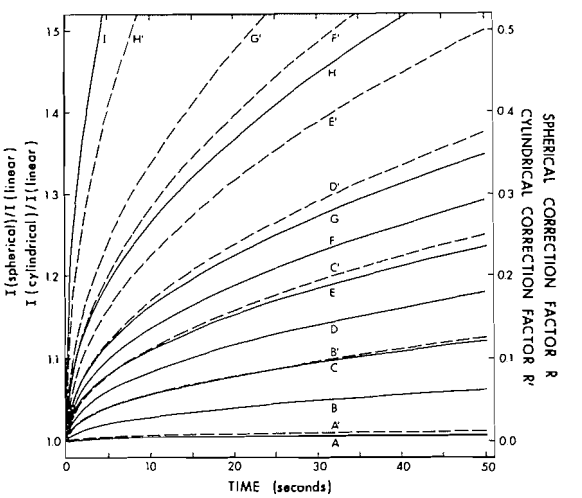

FIG. 1. Ratios of spherical and cylindrical to linear currents and the correction factors R and R' for spherical and cylindrical electrodes as a function of electrolysis time for various selected values of $D^{1/2}/r_0$ ($s^{-1/2}$): A,A', 0.001; B,B', 0.01; C,C', 0.020; D,D', 0.030; E,E', 0.040; F,F', 0.050; G,G', 0.060; H,H', 0.10; I, 0.30; solid line, cylindrical; dashed line, spherical diffusion.

Results and Discussion

The values of the correction factors R and R' were calculated using the AMDAHL 470/V6 computer system and have been deposited in the Depository of Unpublished Data.[2] Plots of the ratio I_{sph}/I_{lin} and I_{cyn}/I_{lin} as a function of the electrolysis time t for a few selected values of $D^{1/2}/r_0$ are depicted in Fig. 1. The value of R is approximately, but not exactly, twice that of R' for the same values of the experimental parameters; this is because the first term in the square brackets of [2] is the most significant.

By a judicious choice of the experimental conditions, the effect of sphericity or cylindricity can be made negligible. For example, to make the correction R or R' less than 0.01 (1%), r_0 and r_0' must be greater than 0.53 and 0.26 cm for $D = 10^{-5}$ cm^2/s and electrolysis times of 1 s. Since $D \leq 10^{-5}$ cm^2/s for most species in media of analytical interest, chronoamperometric measurements made with spherical or cylindrical electrodes of practical and usual size will differ significantly from those calculated using the simple Cottrell equation.

Metal complexes as antioxidants. V. Inhibition of hydrocarbon autoxidation by cupric complexes of dialkyldithiophosphoric and dialkyldithiocarbamic acids[1]

J. H. B. CHENIER, J. A. HOWARD,[2] AND J. C. TAIT[3]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received May 2, 1977

J. H. B. CHENIER, J. A. HOWARD, and J. C. TAIT. Can. J. Chem. **56**, 157 (1978).

Liquid-phase reactions of alkylperoxy radicals with cupric complexes of dialkyldithiophosphoric and dialkyldithiocarbamic acids have been examined. These complexes have been shown to be extremely efficient peroxy radical scavenging antioxidants for hydrocarbon autoxidation. Initial rates of oxygen absorption by typical hydrocarbons were extremely slow implying inhibition rate constants $>10^6\ M^{-1}\ s^{-1}$. The initial rate of disappearance of the dithiocarbamate was equal to the rate of chain initiation (R_i) whereas the rate of disappearance of the dithiophosphate was twice as fast as R_i. In both cases the rate of complex disappearance slowed down as the complex was consumed. Autoxidation of styrene commenced as soon as the complex disappeared while cumene did not absorb oxygen for a considerable length of time after complex destruction. Cumylperoxy radicals were converted to α-cumyl alcohol, α-methylstyrene, and acetophenone by reaction with these complexes and the copper ions were eventually precipitated as copper sulphate. In the case of the dithiocarbamate three intermediate cupric complexes were detected by epr spectroscopy.

J. H. B. CHENIER, J. A. HOWARD et J. C. TAIT. Can. J. Chem. **56**, 157 (1978).

On a étudié les réactions en phase liquide des radicaux alkylpéroxy avec des complexes cuivriques d'acides dialkyldithiophosphorique et dialkyldithiocarbamique. On a montré que ces complexes sont des antioxydants extrêmement efficaces pour piéger les radicaux péroxy responsables de l'autoxydation des hydrocarbures. Les vitesses initiales d'absorption d'oxygène par des hydrocarbures typiques sont entrêmement lentes; ce qui implique des constantes de vitesse d'inhibition supérieures à $10^6\ M^{-1}\ s^{-1}$. Le taux initial de disparition du dithiocarbamate est égal à la vitesse d'initiation de la chaîne (R_i) alors que le taux de disparition du dithiophosphate est deux fois plus grand que R_i. Dans chacun des cas, la vitesse de disparition du complexe est ralentie à mesure que le complexe est consumé. L'autoxydation du styrène commence aussitôt que le complexe est disparu alors que l'absorption d'oxygène par le cumène ne commence que longtemps après la destruction du complexe. Les radicaux cumylpéroxy sont transformés en alcool α-cumylique, en α-méthylstyrène et en acétophénone par réaction avec ces complexes et les ions cuivriques précipitent éventuellement sous forme de sulfate de cuivre. Dans le cas du dithiocarbamate, on a pu détecter trois complexes intermédiaires par spectroscopie rpe.

[Traduit par le journal]

Introduction

Zinc and nickel complexes of dialkyldithiophosphoric acids, $[(RO)_2PS_2]_2M$, and dialkyldithiocarbamic acids, $[R_2NCS_2]_2M$, where M is Zn or Ni and R is CH_3, C_2H_5, i-C_3H_7, etc., are reasonably efficient alkylperoxy radical (R'OO·) scavenging antioxidants (1–3). Inhibition rate constants (k_{inh}) fall in the range 10^3–$10^4\ M^{-1}\ s^{-1}$ with the nature of the transition metal and ligand having no obvious influence on antioxidant activity. The principal peroxy radical derived product is the alcohol, R'OH, while the transition metal ion is eventually precipitated as the sulphate.

The related cupric complexes also inhibit autoxidation (4–7) and in this paper we report the results of an investigation of the inhibition kinetics for these complexes and a product study of their reaction with alkylperoxy radicals.

Experimental

The preparation of the cupric complexes, purification of the oxidizable substrates and solvents, procedures used to measure rates of autoxidation, induction periods, cupric complex concentrations, and volatile reaction product analyses have been described in previous papers in this series (1, 2, 8). Bis(dimethyldithiocarbamoyl) disulphide was prepared by oxidation of sodium dimethyldithiocarbamate (Aldrich) with ammonium persulphate. The crude product was recrystallized from methanol–benzene, mp 157–161°C. *tert*-Butylperoxy and α-cumylperoxy radicals were prepared by photolysis of 2,2,4,4-tetramethyl-3-pentanone (Chemical Samples Co.) and thermolysis of azocumene (50°C), respectively, in air saturated solvent.

Liquid chromatography was conducted on a Spectra-Physics (3500) chromatograph employing a 2.1 × 20 cm column packed with 5 μ Spherisorb and a uv detector (SP 8200). The eluting solvent was hexane–chloroform (5:1) at a flow rate of 1 $cm^3\ min^{-1}$.

Results and Discussion

(i) Inhibition of Hydrocarbon Autoxidation Kinetics

We have previously suggested (1, 2) that *initial* rates of oxygen absorption by hydrocarbons (tetralin, styrene, cumene, etc.) containing a free-radical initiator (α,α′-azobisisobutyronitrile) and zinc and nickel complexes of dialkyldithiocarbamic and dialkyldithiophosphoric acids (A) at 30–50°C are approximately described by the rate expression

$$[1] \qquad \left(\frac{-\mathrm{d}[O_2]}{\mathrm{d}t}\right) = \frac{k_p[RH]R_i}{nk_{inh}[A]_0} + R_i$$

where R_i is the rate of chain initiation, k_p is the propagation rate constant, k_{inh} is the termination rate constant, n is the number of peroxy radicals scavenged by each molecule of A, and the subscript zero refers to initial rates and concentrations.

This expression is consistent with a mechanism in which there is a competition for the chain propagating peroxy radicals between the hydrocarbon [2] and the complex [3]

$$[2] \qquad ROO^{\cdot} + RH \xrightarrow{k_p} ROOH + R^{\cdot}$$

$$[3] \qquad ROO^{\cdot} + A \xrightarrow{k_{inh}} X$$

$$[4] \qquad ROO^{\cdot} + X \xrightarrow{\text{fast}} \text{Non-radical products}$$

Cupric dialkyldithiophosphates and dialkyldithiocarbamates inhibit hydrocarbon autoxidation (4–7) and if the reaction mechanism is the same as that for the zinc and nickel complexes, inhibited rates of oxygen absorption should obey [1].

Recently we have suggested (8) that the reaction of peroxy radicals with these cupric complexes is best described by reactions 5–9, where A_1, A_2, A_3, and

$$[5] \qquad ROO^{\cdot} + A \xrightarrow{k_{inh}} RO^{\cdot} + A_1$$

$$[6] \qquad ROO^{\cdot} + A_1 \longrightarrow RO^{\cdot} + A_2$$

$$[7] \qquad ROO^{\cdot} + A_2 \longrightarrow RO^{\cdot} + A_3$$

$$[8] \qquad ROO^{\cdot} + A_3 \longrightarrow RO^{\cdot} + A_4$$

$$[9] \qquad ROO^{\cdot} + A_4 \longrightarrow \text{Non-radical products}$$

A_4 are oxidized forms of A. Under steady state conditions consideration of reactions 5 to 9 rather than 3 and 4 gives the rate expression [1] with $n = 1$.

Preliminary experiments on the 2,2,3,3-tetraphenylbutane (TPB) initiated autoxidation of tetralin and cumene at 30°C indicated that $Cu[(RO)_2PS_2]_2$ and $Cu[R_2NCS_2]_2$ were extremely efficient peroxy radical scavenging antioxidants. Thus rates of oxidation were very close to the rate of chain initiation at complex concentrations as low as 10^{-4} M.

Detectable differences between $(-\mathrm{d}[O_2]/\mathrm{d}t)$ and R_i were observed in styrene at 30°C. The kinetic data obtained in this substrate are given in Table 1 and presented as a plot of $(-\mathrm{d}[O_2]/\mathrm{d}t)/2[TPB]$ against [RH]/[A] in Fig. 1. The intercept of this plot on the ordinate axis should be equal to k_d, the first-order rate constant for the formation of radicals from TPB, while the slope is equal to $k_d k_p/k_{inh}$ (9). The value of the intercept for $Cu[Et_2NCS_2]_2$ and $Cu[(i\text{-}PrO)_2PS_2]_2$ is $\sim 3 \times 10^{-6}$ M^{-1} s^{-1} while $k_d = 2 \times 10^{-6}$ M^{-1} s^{-1} (10). This difference between the intercept and k_d is probably associated with the difficulties in accurately measuring initial rates rather than a mechanistic complexity. The value of $k_d k_p/k_{inh}$ from Fig. 1 is $< 10^{-11}$ s^{-1} for both complexes and since $k_p = 41$ M^{-1} s^{-1} (11) $k_{inh} > 8 \times 10^6$ M^{-1} s^{-1}.

Kinetic data for the cupric complex inhibited autoxidation of the α,α′-azobisisobutyronitrile initiated autoxidation of 9,10-dihydroanthracene at 50°C are summarized in Table 2. Equation 1 would appear to be obeyed by this system with $k_{inh} \sim 10^6$ M^{-1} s^{-1} for the dithiophosphate and $\sim 2 \times 10^6$ M^{-1} s^{-1} for the dithiocarbamate.

It is clear from these results that cupric dialkyldithiophosphates and dithiocarbamates are very efficient peroxy radical scavenging antioxidants and are significantly more efficient than the analogous zinc and nickel complexes. The rate constants for reaction with $ROO^{\cdot}$ must be greater than 10^6 M^{-1} s^{-1}. Unfortunately it is not possible to accurately determine rate constants of this magnitude by conventional kinetic studies of inhibited hydrocarbon autoxidation.

Induction Periods

The decrease in complex concentration and concentration of oxygen absorbed, as a function of time, for TPB (0.0085 M) initiated autoxidation of styrene containing $Cu[Et_2NCS_2]_2$ (1.24×10^{-4} M) are shown in Fig. 2. The rate of complex disappearance was almost linearly dependent on its concentration unlike most radical scavenging antioxidants which disappear by a zero order process at a constant rate of chain initiation. This result suggests that termination reactions other than reaction of the chain propagating peroxy radical with the complex become rate determining as the complex is consumed. The initial rate of disappearance of $Cu[Et_2NCS_2]_2$ was nearly equal to R_i indicating an *initial* stoichiometric factor of one.

The disappearance of $Cu[Et_2NCS_2]_2$ was accompanied by the appearance of the cupric transient I which we have previously observed in the reaction

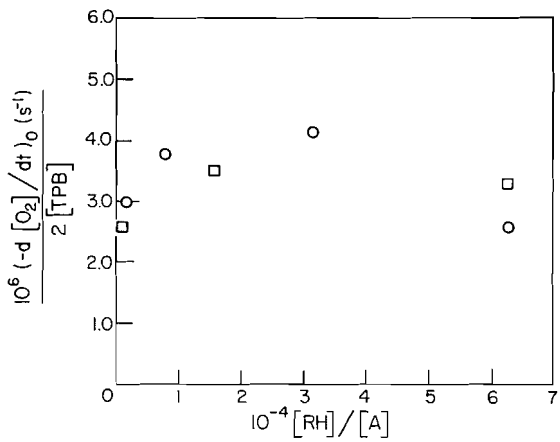

FIG. 1. Rates of oxygen absorption by styrene and TPB at 30°C inhibited by $Cu[(RO)_2PS_2]_2$ (○) and $Cu[R_2NCS_2]_2$ (□).

of this complex with *tert*-butyl hydroperoxide (8) and was also observed by Zverev *et al.* (5) during the $Cu[Et_2NCS_2]_2$ inhibited autoxidation of ethylbenzene. This transient reached a maximum concentration equal to 32% of the initial concentration of $Cu[Et_2NCS_2]_2$ when 90% of the complex had disappeared. The concentration of I then declined and two other cupric transients (II and III) were evident. I, II, and III disappeared when rapid absorption of oxygen commenced at a rate equal to the uninhibited rate.

$(-d[Cu[Et_2NCS_2]_2]/dt)_0$ was also equal to R_i in cumene but did not slow down as rapidly as in styrene. The complex was, therefore, consumed in a shorter period of time (Fig. 3). The cupric transient I was formed in this substrate, again reaching a maximum concentration when the $Cu[Et_2NCS_2]_2$ had almost disappeared. Unlike the inhibited autoxidation of styrene, oxygen absorption by cumene did not commence for a considerable length of time after both the $Cu[Et_2NCS_2]_2$ and I had disappeared. A further difference between cumene and styrene was that oxygen absorption by the former substrate, after the induction period, decreased very rapidly after the absorption of a small amount of O_2 (typically 10^{-2} M). $-d[O_2]/dt$ was then equal to R_i for a considerable length of time.

In chlorobenzene containing TPB, $-d[Cu(Et_2NCS_2)_2]/dt$ was zero order with respect to the complex concentration and I accumulated and was

[b]Data for the BMeOP ($1.1 \times 10^{-4}\ M$) inhibited autoxidation.

destroyed in the same way as was observed in the oxidizable substrates.

The $Cu[Et_2NCS_2]_2$ inhibited autoxidation of 9,10-dihydroanthracene at 50°C behaved just like the inhibited autoxidation of cumene at 30°C (Fig. 4). There was a very slow rate of oxygen uptake while the complex was destroyed. The rate then increased slightly and was autoretarding until the uninhibited rate was reached. During the period from complete complex destruction and rapid oxygen uptake, the concentration of cupric species was below the concentration detectable by the esr spectrometer. While the $Cu[Et_2NCS_2]_2$ was being destroyed, the transient species I was formed but its maximum concentration was much lower than the concentration detected at 30°C.

Values of the stoichiometric factor, n, for peroxy radical scavenging antioxidants, such as hindered phenols (AH), can be calculated from

$$\tau_{O_2} = n[AH]/R_i \qquad [10]$$

where τ_{O_2} is the induction period. The values of τ_{O_2} and n for $Cu[Et_2NCS_2]_2$ in styrene, tetralin, and cumene are given in Table 3 and, for comparison, the value for 2,6-di-*tert*-butyl-4-methoxyphenol.

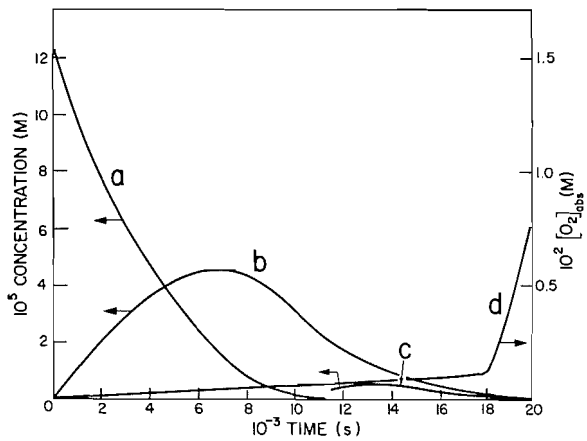

FIG. 2. Concentration–time profiles for $Cu[Et_2NCS_2]_2$ ($1.25 \times 10^{-4}\ M$) inhibited autoxidation of styrene ($7.83\ M$) at 30°C. (*a*) $Cu[Et_2NCS_2]_2$, (*b*) I, (*c*) II and III, (*d*) O_2.

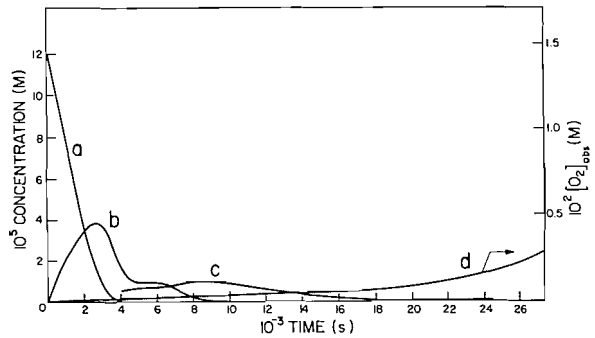

FIG. 3. Concentration–time profiles for $Cu[Et_2NCS_2]_2$ ($1.25 \times 10^{-4}\ M$) inhibited autoxidation of cumene ($7.17\ M$) at 30°C. (*a*) $Cu[Et_2NCS_2]_2$, (*b*) I, (*c*) II and III, (*d*) O_2.

Alternatively, n can be calculated from the initial rate of scavenger disappearance since

$$n = R_i/(-d[A]/dt)_0 \qquad [11]$$

The initial rates of disappearance of $Cu[Et_2NCS_2]_2$ are given in Table 3 along with the n values calculated from [11].

It is clear from the data in Table 3 that each molecule of complex reacts with *one* peroxy radical whereas the *overall* stoichiometry of ~5 must be the result of peroxy radical scavenging by complex derived products.

The induction periods obtained in the aralkanes were slightly longer than in styrene. This may be because of heterolytic decomposition of the small amount of aralkyl hydroperoxide to a phenol during the induction period.

Induction periods and initial rates of complex disappearance for cupric dialkyldithiophosphate inhibited hydrocarbon autoxidation are given in Table 4. Initial rates of complex disappearance were approximately twice as fast as R_i implying a stoichiometric factor of 0.5. This rate was nearly proportional to the complex concentration in styrene while in the other substrates an almost zero-order dependence was observed. A careful examination of the concentration–time profile for the complex revealed that after an initial first- or zero-order decay the

rate of complex disappearance slowed down until 5% of the complex remained, whereupon the rate increased to complete complex destruction. This overall behavior is very similar to the concentration–time profiles obtained for the destruction of $Cu[(RO)_2PS_2]_2$ by alkyl hydroperoxides (8).

Oxygen absorption by styrene at the uninhibited rate commenced immediately the complex had disappeared while much longer induction periods were observed with the other substrates. Oxygen absorption by cumene was extremely autoretarding after the induction period and the rate fell to R_i after the absorption of as little as $7.5 \times 10^{-3}\ M\ O_2$.

Although the overall behavior of hydrocarbon autoxidation inhibited by dithiophosphates and dithiocarbamates during and after the induction period were similar transient cupric complexes analogous to I, II, and III were not detected with the thiophosphate.

(ii) Pro-oxidant Effect

Addition of $Cu[(i\text{-}PrO)_2PS_2]_2$ (0.016 M) to styrene (1.74 M) in chlorobenzene at 30°C containing $(CH_3)_3COOH$ (0.01 M) gave an initial rate of oxygen absorption of $1.2 \times 10^{-6}\ M\ s^{-1}$. We have previously shown (8) that the rate of radical production from a mixture of $Cu[(i\text{-}PrO)_2PS_2]_2$ and $(CH_3)_3COOH$ is given by the rate expression $d[R^\cdot]/dt = 2.4\ [A][ROOH]$. Substitution of this rate into the inhibition rate expression [1] gives

$$(-d[O_2]/dt)_0 = 2.4k_p[RH][ROOH]/k_{inh}$$

and since $k_p = 41\ M^{-1}\ s^{-1}$, $k_{inh} = 1.4 \times 10^6\ M^{-1}\ s^{-1}$ which is in good agreement with rate constants obtained using conventional initiators. This agreement must be somewhat fortuitous because chain lengths were very much less than 1.0 and alkoxy as well as peroxy radicals could be propagating the chain.

Mixtures of $Cu[Et_2NCS_2]_2$ and $(CH_3)_3COOH$ also gave measurable inhibited rates of oxidation of styrene. The kinetics for the generation of radicals by this binary system are, however, not simple (8) and we have not attempted to calculate k_{inh} from the pro-oxidant effect produced by this complex.

(iii) Low Temperature Electron Spin Resonance Studies

Rates of disappearance of *tert*-butylperoxy radicals in the presence of excess complex could not be followed by the esr method (1, 2) because the copper complex $M_I = -\frac{1}{2}$ transition occurs at the same field position as the signal from $(CH_3)_3COO^\cdot$. Direct evidence for a rapid reaction between $(CH_3)_3COO^\cdot$ and $Cu[R_2NCS_2]_2$ and $Cu[(RO)_2PS_2]_2$ was, however, obtained by this method. Thus $(CH_3)_3COO^\cdot$ ($2.5 \times 10^{-5}\ M$) was rapidly destroyed upon addition of the complex ($5 \times 10^{-5}\ M$) in the dark at −90°C. At this temperature approximately two peroxy radicals were destroyed by each molecule of complex. There was no evidence for the production of transient cupric complexes probably because they were destroyed by reaction with peroxy radicals.

(iv) Products

Peroxy Radical Derived Products

α-Methylstyrene and α-cumyl alcohol were the principal volatile products from reaction of cumylperoxy radicals with $Cu[i\text{-}Pr_2NCS_2]_2$ in chloro-

0.026	—	—	0.04	0.5	—	0.27
0.025	$Cu[(i\text{-}PrO)_2PS_2]_2$	0.025	0.056	0.11	0.65	0.04
0.025	$Cu[i\text{-}Pr_2NCS_2]_2$	0.025	0.067	0.01	0.62	0.27

[a]Yields relative to the total concentration of cumylperoxy radicals produced.

benzene at 50°C. Acetophenone was also formed in low yield (Table 5). α-Methylstyrene was almost certainly produced by dehydration of α-cumyl alcohol by a Lewis acid formed in the system while acetophenone was formed by β-scission of cumyloxy radicals. The overall ratio of α-cumyl alcohol to acetophenone was, therefore, 89:1 which can be compared with a ratio of 0.54 produced in the absence of the complex.

The same three products were formed from reaction of cumylperoxy radicals with $Cu[(i\text{-}PrO)_2PS_2]_2$. The relative yields were, however, quite different. In this case the α-cumyl alcohol was more efficiently dehydrated while the ratio of α-methylstyrene + α-cumyl alcohol to acetophenone was 6.3:1.

Complex Derived Products

$Cu[Et_2NCS_2]_2$ (10^{-4} M) was rapidly destroyed when it was photolysed in air-saturated toluene–chlorobenzene (5:1) containing di-*tert*-butyl ketone. Photolysis of this ketone in the presence of oxygen is an efficient method of generating *tert*-butylperoxy radicals and it was by reaction with these radicals that the complex was destroyed.

$$[12]\quad (CH_3)_3CC(=O)(CH_3)_3 \xrightarrow{h\nu,\ O_2} 2(CH_3)_3COO^{\cdot} + CO$$

$$[13]\quad (CH_3)_3COO^{\cdot} + Cu[Et_2NCS_2]_2 \longrightarrow \text{Reaction products}$$

At least three transient cupric complexes, I, II, and III were formed by this reaction before the copper ions were finally quantitatively precipitated as copper sulphate. These transients were readily distinguished from each other and $Cu[Et_2NCS_2]_2$ by their g-factors which increased in the order $Cu[Et_2NCS_2]_2 < I < II < III$ (Table 6). The concentration–time profiles for the disappearance of $Cu[Et_2NCS_2]_2$ and the appearance and disappearance of I, II, and III at −40°C are shown in Fig. 5. This temperature was chosen for these experiments because line broadening was at a minimum.

The rate of disappearance of $Cu[Et_2NCS_2]_2$ was approximately 5–6 times slower than $+d[(CH_3)_3COO^{\cdot}]/dt$ while $+d[I]/dt$ was approximately equal to $-d[Cu[Et_2NCS_2]_2]/dt$. The complex I reached a maximum concentration of 4.6×10^{-5} M when

Complex	g-factor	a_{Cu} (G)
$Cu[Et_2NCS_2]_2$	2.0458	78.3
I	2.0643	76.8
II	2.0857	77.4
III	2.0891	71.0

[a]Measured in toluene–chloroform (1.5:1) at −30°C.

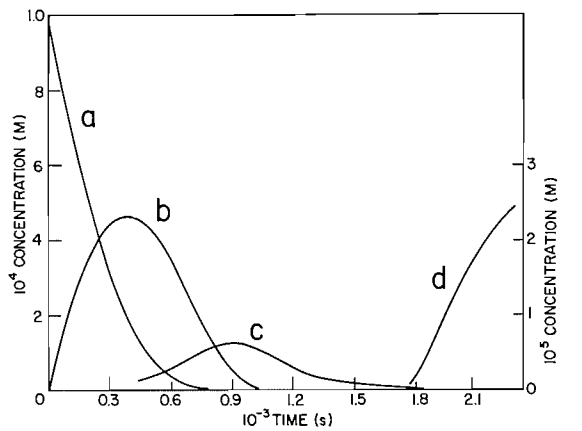

FIG. 5. Concentration–time profiles for the products of photolysis of di-*tert*-butyl ketone (0.5 M) in air-saturated toluene–chlorobenzene (5:1) containing $Cu[Et_2NCS_2]_2$ ($10^{-4}M$) at −40°C. (*a*) $Cu[Et_2NCS_2]_2$, (*b*) I, (*c*) II and III, (*d*) $(CH_3)_3COO^{\cdot}$.

8×10^{-5} M of $Cu[Et_2NCS_2]_2$ had disappeared. The concentration of I then began to fall and it was completely destroyed just after the disappearance of $Cu[Et_2NCS_2]_2$. The maximum concentrations of II and III seemed to occur soon after I had disappeared and *tert*-butylperoxy radicals did not reach a detectable concentration until these complexes had disappeared.

If the light was shuttered when I had reached its maximum concentration the concentration of this complex increased slowly by a further 20% while the concentration of $Cu[Et_2NCS_2]_2$ decreased slowly to a lower stationary concentration. Since the generation of $(CH_3)_3COO^{\cdot}$ would have stopped immediately photolysis was ceased this observation is best explained by a reaction between $(CH_3)_3COO^{\cdot}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and $Cu[Et_2NCS_2]_2$ which gives an intermediate that decomposes to I and a species that leads to the production of peroxy radicals and the further destruction of $Cu[Et_2NCS_2]_2$.

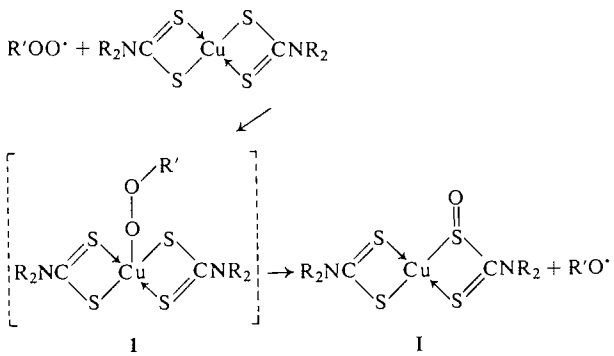
We could find no direct evidence for the production of bis(dimethyldithiocarbamoyl) disulphide during the reaction of $Cu[Me_2NCS_2]_2$ with *tert*-butylperoxy radicals. This does not prove that the disulphide was not formed as it is not stable in the presence of photochemically generated *tert*-butylperoxy radicals.

Conclusions

This work confirms the findings of other workers (4–7) that cupric dialkyldithiocarbamates and dialkyldithiophosphates are extremely efficient peroxy radical scavenging antioxidants. Our kinetic results indicate that they are at least several orders of magnitude more efficient than the related zinc and nickel complexes. Further advantages of these complexes are the long *overall* induction periods that they produce before substrate oxidation commences which must result from the production of efficient radical scavengers during inhibited autoxidation.

The principal advantage of cupric complexes as models for this class of antioxidant is their paramagnetism. Their concentration can, therefore, be easily followed by the epr method, a technique that is considerably more informative than the uv spectroscopic method that we used for the nickel complexes (2). This is certainly true for the dithiocarbamates for which we detected three transient cupric complexes in the conversion to copper sulphate.

From a mechanistic viewpoint we believe that our results for the dithiocarbamate are best explained on the basis of the production of an intermediate **1** by reaction of a peroxy radical at the metal centre. This intermediate could rearrange to give the cupric complex I and an alkoxy radical



1 I

The cupric complexes I, II, and III detected by epr are almost certainly the products A_1, A_2, and A_3 of reactions [5], [6], and [7]. We have spectroscopic evidence that the structure of A_1 or I takes the form shown above.[4] This structure is analogous to the one suggested by Chien and Boss (13) for the initial complex-derived product from reaction of alkyl hydroperoxide with nickel dialkyldithiocarbamates. These workers, however, speculated that this intermediate was produced by non-radical reduction of the hydroperoxide to alcohol. We previously concluded (8) that the cupric transients I, II, and III observed during the destruction of $Cu[R_2NCS_2]_2$ by alkyl hydroperoxides were produced by reaction of alkylperoxy radicals with the complex. The results of the present work confirm this conclusion and show that the reaction is extremely facile.

Metal complexes as antioxidants. VI. An electron spin resonance study of the transient cupric complexes formed in the reaction of cupric dialkyldithiocarbamates with alkylperoxy radicals and alkyl hydroperoxides[1]

JAMES ANTHONY HOWARD[2] AND JOHN CHARLES TAIT[3]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received June 14, 1977

JAMES ANTHONY HOWARD and JOHN CHARLES TAIT. Can. J. Chem. **56**, 164 (1978).

The epr spectra of three intermediate copper(II) complexes formed by oxidation of bis[*N*,*N*-dialkyl(dithiocarbamato-*S*,*S*′)] copper(II) by alkyl hydroperoxides and alkylperoxy radicals are reported. Isotropic and anisotropic spectra of the complexes formed from alkylperoxy radicals enriched with ^{17}O are consistent with the following structures: $[Cu(S_2CNR_2)(OS_2CNR_2)]$ (I), $[Cu(OS_2CNR_2)_2]$ (II), and $[Cu(OS_2CNR_2)(O_2S_2CNR_2)]$ (III). The isotropic ^{17}O hyperfine interaction of I is 19.2 G while the anisotropic spectrum of II indicates that the two oxygen nuclei are equivalent. The anisotropic ^{17}O hyperfine splitting constants are consistent with a structure for these complexes in which the S—O bond(s) is directed out of the plane of the complex and not coordinated to the copper.

JAMES ANTHONY HOWARD et JOHN CHARLES TAIT. Can. J. Chem. **56**, 164 (1978).

On rapporte les spectres rpe de trois complexes de cuivre formés comme intermédiaires lors de l'oxydation du bis[*N*,*N*-dialkyl(dithiocarbamato-*S*,*S*′)] cuivre(II) par les hydroperoxydes d'alkyle et des radicaux alkylperoxy. Les spectres isotropes et anisotropes des complexes formés à partir de radicaux alkylperoxy enrichis avec du ^{17}O sont en accord avec les structures suivantes: $[Cu(S_2CNR_2)(OS_2CNR_2)]$ (I), $[Cu(OS_2CNR_2)_2]$ (II) et $[Cu(OS_2CNR_2)(O_2S_2CNR_2)]$ (III). L'interaction hyperfine isotrope de ^{17}O de I est 19.2 G alors que le spectre anisotrope de II indique que les deux noyaux d'oxygène sont équivalents. Les constantes de couplage hyperfines anisotropes de ^{17}O sont en accord avec une structure pour ces complexes dans lesquels le(s) lien(s) S—O est dirigé hors du plan du complexe et n'est pas coordonné avec le cuivre.

[Traduit par le journal]

In 1972 Vinogradova and Maizus (1) detected a transient paramagnetic copper species during the bis-hexamethylenimine-dithiocarbamato copper(II) inhibited, α,α′-azobisisobutyronitrile initiated, autoxidation of ethylbenzene at 75°C. They concluded that this species was produced by reaction of the dithiocarbamate with 1-phenylethylperoxy radicals ($RO_2^{\cdot}$) according to [1], where R = $C_6H_5CH(CH_3)$, L =

[1] $$RO_2^{\cdot} + CuL_2 \rightarrow Cu(L_{ox})_2$$

$R_2'NCS_2$ and L_{ox} is an oxidized form of the ligand. These workers also discovered that this transient was formed by reaction of the dithiocarbamate with 1-phenylethyl hydroperoxide.

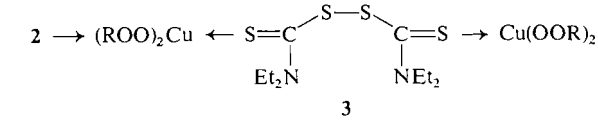
More recently, Zverev *et al.* (2) demonstrated that a transient cupric complex was formed during the bisdiethyldithiocarbamato copper inhibited autoxidation of ethylbenzene and attributed it to 1-phenylethylperoxo diethyldithiocarbamato copper, **1**, formed by substitution of a diethyldithiocarbamato radical from copper by a 1-phenylethylperoxy radical [2].

[2] $$Cu[Et_2NCS_2]_2 + RO_2^{\cdot} \rightarrow \{Cu[Et_2NCS_2]_2 \ldots RO_2\} \rightarrow \{Cu[Et_2NCS_2]_2^{+} \ldots RO_2^{-}\} \rightarrow ROOCuS_2CNEt_2 + Et_2NCS_2^{\cdot}$$

1

Furthermore these workers suggested that **1** was destroyed by reaction with a second peroxy radical to give bis(1-phenylethylperoxo) copper coordinated to a diethyldithiocarbamato radical, **2**, which subsequently dimerized to give an insoluble species **3**.

[3] 
2



3

The electron spin resonance spectrum attributed to **1** was characterized by an isotropic *g*-factor (2.066) that was larger than the *g*-factor for the dithiocarbamate (2.047) while the isotropic copper hyperfine splitting constants for the two complexes were very similar.

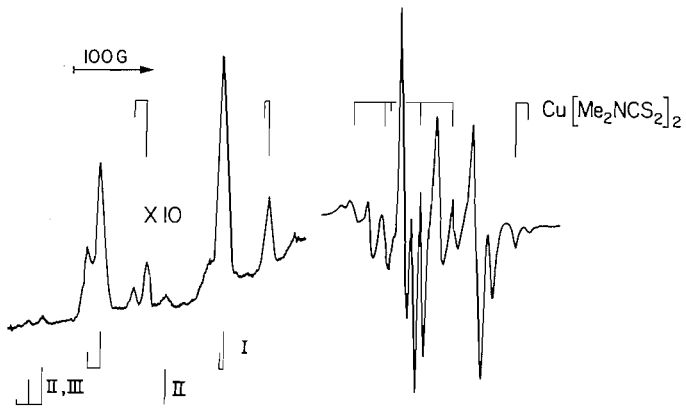

FIG. 1. The epr spectrum at 135 K of products from reaction of $Cu[Me_2NCS_2]_2$ (0.02 *M*) and *t*-BuOOH 0.2 *M* in toluene at 263 K.

In the course of our kinetic and product studies of the reaction of cupric dialkyldithiocarbamates with alkyl hydroperoxides (3) we also found that a cupric complex I was formed as the original $Cu[R_2NCS_2]_2$ was destroyed. This copper species was not stable in the presence of excess hydroperoxide and as it was destroyed at least two other transient cupric species, II and III, were detected before the copper ions were quantitatively precipitated as copper sulphate. Thus at least three cupric complexes are involved as intermediates in the overall conversion of cupric dialkyldithiocarbamates to copper sulphate rather than one as originally reported (1, 2). We have also detected these three complexes during cupric dialkyldithiocarbamate inhibited hydrocarbon autoxidation and during the continuous generation of *tert*-butylperoxy radicals in the presence of the dithiocarbamate (4).

Our previous experimental observations would appear to confirm Vinogradova and Maizus' conclusion that the transient cupric species I formed in oxidizing systems is produced by reaction of the dithiocarbamate with alkylperoxy radicals. The observation of at least two other cupric transients does, however, cast considerable doubt on the conclusion that I is an alkylperoxo dialkyldithiocarbamato copper complex. Our observations are, perhaps, more consistent with a mechanism that involves successive oxidation of the ligand sulphur atoms.

In experiments designed to eliminate the other transient radicals involved in autoxidation as possible sources of I, II, and III, we found that anaerobic, thermal generation of *tert*-butoxy and *tert*-butyl radicals from di-*tert*-butyl hyponitrite and azoisobutane in $Cu[R_2NCS_2]_2$ solutions resulted only in the destruction of the complex. Only when oxygen was admitted to these systems were the transient Cu(II) species observed, confirming that they are due to ligand oxidation by peroxy radicals.

We have previously reported (4) that during photolysis of an oxygenated toluene solution of di-*tert*-butyl ketone (DTBK) (0.4 *M*) and $Cu[Et_2NCS_2]_2$ (0.0001 *M*) a transient cupric species I was produced from the beginning of the reaction at a rate equal to the rate of disappearance of the dithiocarbamate. This species reached a maximum concentration equal to about 50% of the $Cu[Et_2NCS_2]_2$ when about 90% of the latter had been destroyed. The concentration of I then slowly decreased and it finally disappeared just after the complete disappearance of $Cu[Et_2NCS_2]_2$. The two other transient cupric species II and III were observed to build up and decay in a similar manner to I when all of the $Cu[Et_2NCS_2]_2$ and most of I had decayed.

Experiments on the dithiocarbamate initiated decomposition of *tert*-butyl hydroperoxide and cumene hydroperoxide at 253 K revealed a behaviour identical to the photolysis results.

In order to characterize the new species formed, a $Cu[Me_2NCS_2]_2$-hydroperoxide solution in toluene at 263 K was rapidly cooled to 135 K at successive stages of the reaction to observe the changes in the frozen solution spectrum. From Fig. 1 it is evident that $g_{\parallel}$ and $g_{\perp}$ for the newly formed species are significantly larger than the original complex. The analysis of the $g_{\perp}$ region is hindered by the strong overlap of lines from the various species; however, main features can be distinguished when different stages of the reaction are compared. As can be seen from Fig. 1, at least three new copper(II) species have been formed, each exhibiting successively higher $g_{\parallel}$ values (and consequently higher g_{iso}). The changes in $A_{\parallel}$ and $A_{\perp}$ are much less significant.

The epr spectrum of the Cu(II) transients was the same for both hydroperoxides and it was assumed that the species formed were identical. In reaction with the hydroperoxides, the final stages of reaction were difficult to observe due to the formation of solid $CuSO_4$ which obscured the spectral region of interest. To circumvent this, aerated solutions of DTBK and $Cu[Me_2NCS_2]_2$ in toluene were photolysed for short intervals at 3650 Å (where photolytic decomposition of the complex was shown to be insignificant), and the samples were centrifuged and then degassed by flushing the solution with a stream of argon. The species formed in this reaction were found to have identical epr parameters with those formed in the hydroperoxide reaction and there was no reason to suspect that they were due to different species.

In order to establish the nature of the new species, the DTBK experiments were repeated, except that pure oxygen enriched to 50% with ^{17}O was used to saturate the solution. When an appreciable concentration of the species I was achieved, the solution was degassed to eliminate line broadening by oxygen. In Fig. 2 superhyperfine structure due to the interaction of one ^{17}O nucleus ($I = \frac{5}{2}$) was observed on the high field side of the isotropic ($-\frac{3}{2}$) line of the $Cu[Et_2NCS_2]_2$ (^{17}O hyperfine on the lower field lines was obscured by their inherently broad linewidth). The spectrum was consistent with species I containing *one* ^{17}O nucleus (a_{iso} (^{17}O) = 19.2 G). Spectra run under high gain revealed no evidence for a second equivalent oxygen or an oxygen with a hyperfine ≥ 1.5 G which would be the smallest observable splitting.

Hyperfine structure was also observed in the spectrum of the frozen solution in both the $g_{\parallel}$ and $g_{\perp}$ regions (Fig. 3) and was again consistent with only one observable ^{17}O nucleus. Upon continued photolysis in the presence of ^{17}O enriched oxygen, species II could be observed before the complete decay of $Cu[Et_2NCS_2]_2$. Again it was apparent that this species contained one ^{17}O nucleus with $a_{iso} = 19.2$ G. There was also evidence for a second, equivalent ^{17}O at half the intensity of species II with one ^{17}O consistent with an ^{17}O enrichment of 50%. This would suggest that a second sulfur in the dithiocarbamate complex was oxidized before subsequent oxidation occurred. The epr parameters for the cupric dialkyldithiocarbamates and the transient species formed are collected in Tables 1 and 2. The anisotropic hyperfine and g-tensor parameters were calculated from a second-order solution to the Hamiltonian (5) by varying the g and A tensor components until agreement was reached with the observed line positions. The spectra were then simulated using a polycrystalline lineshape simulation program (6).

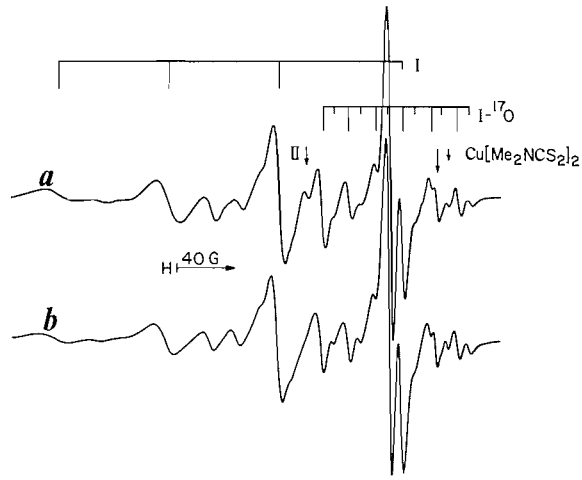

FIG. 2. (*a*) The epr spectrum at 243 K of reaction products from the photolysis of a 60% toluene – 40% $CHCl_3$ solution of $Cu[Me_2NCS_2]_2$ and DTBK which had been saturated with O_2 containing 50% $^{17}O_2$. (*b*) Computer simulation using epr parameters in Tables 1 and 2 and allowing for the M_I dependence of linewidth of Cu. The species included $Cu[Me_2NCS_2]_2$, I and I + ^{17}O and both isotopes of Cu.

In all cases contributions from nuclear Zeeman and quadrupole terms were neglected as have slight deviations from axiality because the overlap of species in the $\perp$ region precluded accurate parameter determination. A typical simulation is shown in Fig. 4.

In an attempt to synthesize the transient cupric species, H_2O_2 (0.01 mol) was reacted with an aqueous solution of $Na[Me_2NCS_2]$ (0.02 mol) at $-5°C$ and the resulting salt reacted with an aqueous solution of $CuSO_4$ (7). This would supposedly have given the mixed salt $Cu[Me_2NCS_2][Me_2NCS_2O]$. This product, however, could not be isolated in a pure form, despite repeated recrystallizations. The epr spectrum of the product in toluene showed that several salts of oxidized forms of $Cu[Me_2NCS_2]_2$ as well as ~10% of the unoxidized complex were present. The epr spectrum of a solution of these salts in 60% toluene – 40% chloroform at 135 K was identical to that obtained from species I, II, and III in the photolysis of DTBK and $Cu[Me_2NCS_2]_2$.

The recrystallized reaction products were extracted with toluene to give a toluene soluble fraction (A) whose composition by epr intensities was ~10% $Cu[Me_2NCS_2]_2$, 80% I, and 10% II + III. The toluene insoluble fraction was extracted with chloroform to give after removal of the solvent a fraction (B) which contained <2% of the dithio-

carbamate. Fraction B was then passed down an alumina column and a fraction whose composition by epr was >95% II was collected.

The results of elemental analyses on these fractions are presented in Table 3. Fraction A is consistent with a mixture whose composition is 10% $Cu[Me_2NCS_2]_2$ and 80% $Cu[Me_2NCS_2][Me_2NCS_2O]$ + 10% $Cu[Me_2NCS_2O]_2$. The analysis of fraction B is consistent with the molecular formula $Cu[Me_2NCS_2O]_2$. Mass spectra were run on these samples; however, the only parent peaks observable were at m/e = 303, 305, 307 corresponding to the isotopes of $Cu[Me_2NCS_2]_2^+$ and at m/e = 120, 88 corresponding to the $Me_2NCS_2^+$ and $Me_2N{=}C{=}S^+$ fragments (8). It is evident that thermal deoxygenation of the compounds must occur during vaporization in the mass spectrometer since the epr spectrum and elemental analysis on fraction B showed <1% $Cu[Me_2NCS_2]_2$.

The ^{17}O hyperfine coupling constants for a number of oxygen chelated Cu(II) complexes have been reported (9–12) and are presented in Table 2 along

with those evaluated in this work. All of these previously studied chelates exhibit similar ^{17}O hyperfine tensors in which the dipolar tensor is close to being axial with the largest component directed along the Cu—O bond and associated with the $g_\perp$ features. This is not unexpected, as the unpaired electron occupies the Cu $d_{x^2-y^2}$ orbital in these square planar complexes which allows direct interaction with the ligand *s* and p_σ orbitals. That the transient species observed is also due to the unpaired electron occupying the $d_{x^2-y^2}$ or d_{xy} orbital on Cu, is confirmed by the *g*-tensor which is very similar to other Cu(II) species with square planar coordination. If the highest occupied orbital were d_{z^2}, $g_\perp$ values in the range 2.15–2.25 and $g_\parallel \simeq 2.03$ would be expected (13).

For the transient species, the ^{17}O hyperfine tensor is nearly isotropic and the largest component of the dipolar tensor is associated with $g_\parallel$, suggesting that the bonding orbital is directed parallel to the *z* axis of the Cu complex, and not basally coordinated as in the cases in Table 2. If the oxygen were apically coordinated to Cu, a considerably weaker hyperfine coupling from that observed for the basally coordinated oxygen would be expected since the p_z ligand orbital would be orthogonal to the $d_{x^2-y^2}$ orbital (12). From the ^{17}O hyperfine tensor then, it is suggested that the oxygen is bonded to the sulfur ligand and takes a position in which the S—O bond is directed out of the plane of the complex.

It is supposed that the major source of the ^{17}O hyperfine splitting is due to electron delocalization via sulfur to the oxygen atom by a mechanism similar to that in dialkyldithiophosphato copper complexes, where a large isotropic ^{31}P hyperfine coupling is observed (14). The oxygen is expected to be weakly π bonded to sulfur by donation from the filled *p*-orbitals to the unfilled *d*-orbitals on sulfur, and will not be very effective in delocalizing the unpaired electron. Thus the main mechanism for delocalization must be through direct *s–s* and *s–p* overlap between oxygen and sulfur. Spin polarization of the *s* electrons on O by the unpaired electron in the in-plane $d_{x^2-y^2}$ orbital on Cu could also be a contributing factor.

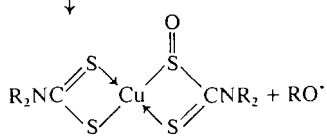
The more highly oxidized species II and III are almost certainly due to successive oxidation of the sulfur ligands. Due to the larger uncertainties in the epr parameters, it is difficult to propose a structure for these species. It is evident, however, that the *g*-values continue increasing while a_{iso} decreases substantially for species III. The increase in *g*-value is indicative of a lowering in covalency of the Cu—S bond and the decrease in a_{iso} is also consistent with an increase in delocalization of the electron onto the ligands. It is possible that the oxygen eventually becomes the coordinating ligand, which would form a more ionic bond, further increasing the *g*-value. Unfortunately this cannot be confirmed from these experiments due to the loss of spectral resolution as the species are successively oxidized.

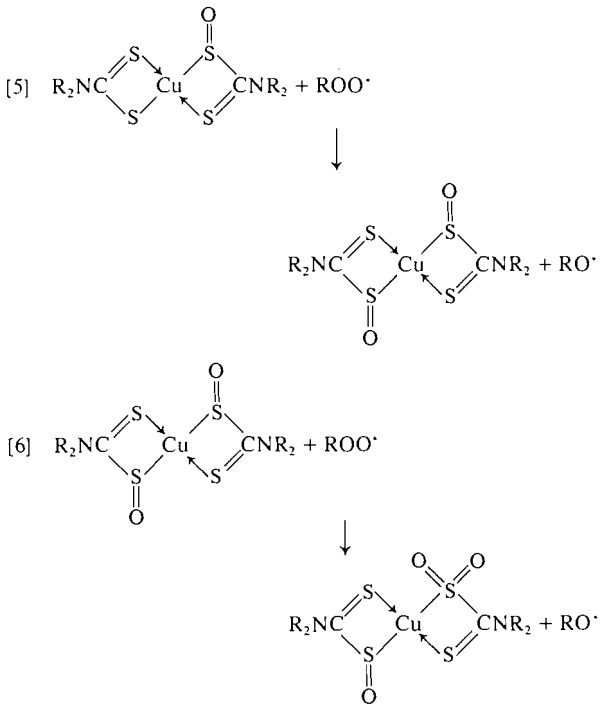
Reaction Mechanism

The results presented here are not consistent with the mechanism suggested by Zverev *et al.* (2) for the reaction of alkylperoxy radicals with cupric dialkyldithiocarbamates and summarized by [2] and [3]. It is evident that the initial paramagnetic product cannot be alkylperoxo dialkyldithiocarbamato copper ($ROO{\cdot}Cu{\cdot}S_2CNR_2$) as predicted by an S_H2 or electron transfer mechanism.

We believe that our results are more consistent with the reaction mechanism given by [4]–[6] with

[4] 





further oxidation of the cupric complexes until the copper is eventually precipitated as copper sulphate. This mechanism is similar to the one proposed by Chien and Boss (15) for the reaction of nickel dialkyldithiocarbamates with alkyl hydroperoxides. These workers did, however, propose that the hydroperoxide was the oxidizing species whereas we believe alkylperoxy radicals are the oxidizing species.

Experimental

Cupric dialkyldithiocarbamates were prepared by the procedure described previously (3). ^{17}O enriched oxygen was obtained from Yeda Inc., Israel. The spectra were recorded on a Varian E-4 spectrometer equipped with a variable temperature accessory. The microwave frequency was measured with a Syntron-Donner Model 6016 frequency counter, which also monitored the frequency of a proton magnetometer used to measure the magnetic field.

Absolute rate constants for hydrocarbon autoxidation. 24. Rate constants and Arrhenius parameters for reaction of *tert*-butylperoxy radicals with 3-methylpentane[1]

J. A. HOWARD, J. H. B. CHENIER, AND D. A. HOLDEN[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received February 18, 1977[3]

J. A. HOWARD, J. H. B. CHENIER, and D. A. HOLDEN. Can. J. Chem. **56**, 170 (1978).

Autoxidation of 3-methylpentane in the presence of *tert*-butyl hydroperoxide gives, after reduction with triphenylphosphine, 3-methyl-3-pentanol and 3-methyl-2-pentanol as the major reaction products. The overall rate constant for reaction of $(CH_3)_3COO^\cdot$ with this substrate at 30°C is 0.008 ± 0.001 M^{-1} s^{-1} which consists of k/tertiary C—H = 0.007 ± 0.001 M^{-1} s^{-1} and k/secondary C—H = 0.0002 ± 0.0001 M^{-1} s^{-1}. The products from cooxidation of cumene and 3-methylpentane in the presence of *tert*-butyl hydroperoxide are formed in yields which are consistent with these rate constants relative to a value of 0.16 M^{-1} s^{-1} for cumene. The Arrhenius equations for reaction of $(CH_3)_3COO^\cdot$ with the *t*-C—H and *s*-C—H of 3-methylpentane relative to the Arrhenius equation for reaction of $(CH_3)_3COO^\cdot$ with cumene (log $(k_{10}/M^{-1}\ s^{-1}) = (8.7 \pm 0.3) - (13.2 \pm 0.4)/\theta$) are

$$\log (k_4(t)/M^{-1}\ s^{-1}) = (9.5 \pm 0.5) - (16.3 \pm 0.7)/\theta$$

$$\log (k_4(s) \text{ per H}/M^{-1}\ s^{-1}) = (8.9 \pm 0.7) - (17.5 \pm 0.8)/\theta$$

respectively, where $\theta = 2.303RT$ kcal mol^{-1}.

J. A. HOWARD, J. H. B. CHENIER et D. A. HOLDEN. Can. J. Chem. **56**, 170 (1978).

L'autoxydation du méthyl-3 pentane en présence d'hydroperoxyde de *tert*-butyle conduit, après réduction avec la triphénylphosphine, aux méthyl-3 pentanol-3 et méthyl-3 pentanol-2 comme produits principaux de la réaction. La constante de vitesse globale pour la réaction de $(CH_3)_3COO^\cdot$ avec ce substrat à 30°C est de 0.008 ± 0.001 M^{-1} s^{-1}; cette valeur est formée de k/C—H tertiaire = 0.007 ± 0.001 M^{-1} s^{-1} et k/C—H secondaire = 0.0002 ± 0.0001 M^{-1} s^{-1}. Les rendements des produits de la cooxydation du cumène et du méthyl-3 pentane en présence d'hydroperoxyde de *tert*-butyle sont en accord avec ces constantes de vitesse elles-même relatives à une valeur de 0.16 M^{-1} s^{-1} pour le cumène. Les équations d'Arrhénius pour la réaction de $(CH_3)_3COO^\cdot$ avec le C—H tertiaire et le C—H secondaire du méthyl-3 pentane par rapport à l'équation d'Arrhénius pour la réaction de $(CH_3)_3COO^\cdot$ avec le cumène (log $(k_{10}/M^{-1}\ s^{-1}) = (8.7 \pm 0.3) - (13.2 \pm 0.4)/\theta$) sont respectivement

$$\log (k_4(t)/(M^{-1}\ s^{-1}) = (9.5 \pm 0.5) - (16.3 \pm 0.7)/\theta$$

$$\log (k_4(s) \text{ par H}/M^{-1}\ s^{-1}) = (8.9 \pm 0.7) - (17.5 \pm 0.8)/\theta$$

où $\theta = 2.303RT$ kcal mol^{-1}.

[Traduit par le journal]

Introduction

Absolute rate constants for reaction of alkylperoxy radicals with a wide variety of aralkanes, aralkenes, and C—H bonds adjacent to a functional group have been determined by the rotating sector technique and the hydroperoxide method (1–8). In contrast there have been few measurements of absolute rate constants for alkanes although rate constants for reaction of *tert*-butylperoxy with the secondary aliphatic C—H bonds in cyclohexane, hexadecane, and tridecane have been reported (4, 8). These rate constants are, however, of low accuracy because of the very short kinetic chain lengths involved in the autoxidations (4). Alkanes with tertiary C—H bonds are much more susceptible to autoxidation than alkanes such as cyclohexane. We have, therefore, employed the hydroperoxide method to measure the reactivity of 3-methylpentane to the *tert*-butylperoxy radical at 30°C. This substrate undergoes reaction at the tertiary and secondary C—H's and relative product yields enable the overall rate constant to be separated into contributions from reaction at each position. These rate constants have been confirmed by product yields from co-oxidation of cumene and 3-methylpentane in the presence of *tert*-butyl hydroperoxide. In addition these co-oxidations have been performed over a temperature range and we are able to report Arrhenius parameters for reaction of *t*-$BuO_2^\cdot$ with the *t*-C—H and *s*-C—H bonds in 3-

methylpentane relative to the Arrhenius parameters for cumene.

Experimental

Materials

3-Methylpentane and cumene (Phillips Research Grade) were used after distillation from triphenylphosphine and percolation through basic alumina. *tert*-Butyl hydroperoxide (Lucidol) was purified by fractional distillation and α,α′-azo-bis-isobutyronitrile, AIBN, (Aldrich) by recrystallization from ethyl alcohol below 40°C, mp = 102°C. 3-Methyl-3-pentanol, 3-methyl-2-pentanol, and α-cumyl alcohol were commercial samples which were used without further purification.

Kinetic Procedure

Rates of oxygen absorption were determined by means of the automatic recording gas apparatus previously described (9). Rates of chain initiation were measured for *all* kinetic experiments by the induction period method (10) using 2,6-di-*tert*-butyl-4-methylphenol as the radical scavenger. Because of the substantial vapour pressure of 3-methylpentane induction periods of >20 h were needed to ensure that both sides of the pressure transducer were at the same pressure before oxygen absorption commenced.

Co-oxidation

3-Methylpentane and cumene were co-oxidized in the presence of AIBN and *tert*-butyl hydroperoxide from 30 to 80°C. These runs were performed in glass-lined stainless steel high pressure vessels at ca. 5 atm of O_2.

Reaction Products

The major products from autoxidation of 3-methylpentane and co-oxidation of 3-methylpentane and cumene in the presence of *tert*-butyl hydroperoxide were identified (after reduction with a slight excess of triphenylphosphine) and relative yields were estimated by standard gas chromatography procedures.

Steady-state alkylperoxy radical concentrations were measured relative to a standard solution of 2,2,6,6-tetramethylpiperid-4-one 1-oxyl (10^{-4} *M*) by electron spin resonance spectroscopy (6).

Results

Oxidation of 3-Methylpentane

Oxygen was absorbed very slowly by 3-methylpentane (RH) at 30°C containing α,α′-azo-bis-isobutyronitrile (0.05 *M*) and the kinetic chain length was about 1. Upon addition of *tert*-butyl hydroperoxide (1.0 *M*) there was a significant increase in the overall rate and kinetic chain lengths of 7–30 were obtained. We have previously demonstrated (4, 6) that autoxidation of most hydrocarbons in the presence of this concentration of *tert*-butyl hydroperoxide can be described by the elementary reactions [1]–[6], where X· represents

Initiation

$$[1] \qquad R'N_2R' \xrightarrow{O_2} R'O_2\cdot + N_2$$

Chain transfer

$$[2] \qquad X\cdot + (CH_3)_3COOH \rightarrow XH + (CH_3)_3COO\cdot$$

$$[3] \qquad 2(CH_3)_3COO\cdot \xrightarrow{2k_3} 2(CH_3)_3CO\cdot + O_2$$

Propagation

$$[4] \qquad (CH_3)_3COO\cdot + RH \xrightarrow{k_4} (CH_3)_3COOH + R\cdot$$

$$[5] \qquad R\cdot + O_2 \xrightarrow{k_5} ROO\cdot$$

Termination

$$[6] \qquad 2(CH_3)_3COO\cdot \xrightarrow{2k_6} (CH_3)_3COOC(CH_3)_3 + O_2$$

radical species other than $(CH_3)_3COO\cdot$ and $R'N_2R'$ represents AIBN. Thus *tert*-butylperoxy radicals are the only radicals involved in rate controlling propagation and termination reactions.

The observed rate of oxygen absorption is given by

$$[7] \quad \left\{\frac{-d[O_2]}{dt}\right\}_{obs} = k_5[R\cdot][O_2] + 2ek_1[R'N_2R'] - k_1[R'N_2R'] - k_3[(CH_3)_3COO\cdot]^2 - k_6[(CH_3)_3COO\cdot]^2$$

where $k_1[R'N_2R']$ is the rate of nitrogen evolution from AIBN. Under steady state conditions [7] becomes

$$[8] \quad \left\{\frac{-d[O_2]}{dt}\right\}_{obs} = \frac{k_4[RH]R_i^{1/2}}{(2k_6)^{1/2}} + 2ek_1[R'N_2R'] - k_1[R'N_2R'] - \left\{\frac{k_3 + k_6}{k_6}\right\}\frac{R_i}{2}$$

where R_i is the rate of chain initiation which may be greater than $2ek_1[R'N_2R']$ because of initiation by homolysis of *t*-BuOOH.

We have previously shown that $(k_3 + k_6)/2k_6 = 2.6$ and $e = 0.5$ at 30°C (4). The rate of absorption of oxygen by RH is, therefore, given by

$$[9] \quad \left\{\frac{-d[O_2]}{dt}\right\}_{corr} = \left\{\frac{-d[O_2]}{dt}\right\}_{obs} + 2.6R_i = \frac{k_4[RH]R_i^{1/2}}{(2k_6)^{1/2}}$$

where k_4 is the rate controlling propagation rate constant and is the overall rate constant for reaction of $(CH_3)_3COO\cdot$ with RH and $2k_6$ is the rate controlling termination rate constant.

The kinetic data presented in Table 1 indicate that the overall rate was independent of the hydroperoxide concentration after allowance was made for its effect on the rate of chain initiation, in accordance with eq. 9.

The steady state alkylperoxy radical concentration in the AIBN initiated autoxidations was too weak to be measured with any degree of accuracy. More intense signals were obtained using 2,2′,3,3′-

TABLE 1. Kinetic data for autoxidation of 3-methylpentane in the presence of *tert*-butyl hydroperoxide at 30°C[a]

[RH] (M)	[ROOH] (M)	$10^7 R_i$ ($M\ s^{-1}$)	$10^7(-d[O_2]/dt)_{obs}$ ($M\ s^{-1}$)	$10^7(-d[O_2]/dt)_{corr}$[b] ($M\ s^{-1}$)	$\frac{10^4(-d[O_2]/dt)_{corr}}{[RH]\ R_i^{1/2}}$ ($M^{-1/2}\ s^{-1/2}$)
7.75	—	0.068	~0.06	~0.06	—

[a]All runs were performed in the presence of α,α'-azobisisobutyronitrile (0.05 M) and 2,6-di-*tert*-butyl-4-methylphenol (0.8–4 × 10^{-4} M).
[b]Obtained from eq. 9.

tetraphenylbutane and rate constants calculated from

$$R_i = 2k_6[ROO^\cdot]_{ss}^2$$

were close to the 'best' value of $(1.2 \pm 0.3) \times 10^3$ $M^{-1}\ s^{-1}$ calculated from $\log (2k_6/M^{-1}\ s^{-1}) = (9.2 \pm 0.2) - (8.5 \pm 0.2)$ kcal $mol^{-1}/2.303RT$ (4).

The average value of $k_4/(2k_6)^{1/2} = (2.4 \pm 0.1) \times 10^{-4}$ $M^{-1/2}\ s^{-1/2}$ in conjunction with the 'best' value of $2k_6$ gives $k_4 = 0.008 \pm 0.001$ $M^{-1}\ s^{-1}$ for the *overall* reactivity of 3-methylpentane.

Autoxidation of 3-methylpentane at 30°C gave, after reduction with triphenylphosphine, two major products, 3-methyl-3-pentanol and 3-methyl-2-pentanol, indicating that both the secondary and tertiary C—H bonds had been attacked by *tert*-butylperoxy radicals.

$$(CH_3)_3COO^\cdot + CH_3CH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2CH_3 \xrightarrow{k_4(t)} CH_3CH_2\underset{\displaystyle CH_3}{\underset{|}{\overset{\displaystyle \cdot}{C}}}CH_2CH_3 + (CH_3)_3COOH$$

$$(CH_3)_3COO^\cdot + CH_3CH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2CH_3 \xrightarrow{k_4(s)} CH_3CH_2\underset{\displaystyle CH_3}{\underset{|}{C}}\overset{\displaystyle \cdot}{C}HCH_3 + (CH_3)_3COOH$$

The average relative yield of 3-methyl-3-pentanol to 3-methyl-2-pentanol from 8 runs was 8.2 ± 0.8 which indicates that the tertiary C—H bond is ca. eight times more reactive than the secondary C—H bonds. The absolute value of $k_4(t)$ is, therefore, 0.007 ± 0.001 $M^{-1}\ s^{-1}$ and $k_4(s)$ per active hydrogen is 0.0002 ± 0.0001 $M^{-1}\ s^{-1}$.

Co-oxidation of Cumene and 3-Methylpentane

The rate controlling propagation reactions for the co-oxidation of 3-methylpentane and cumene in the presence of >0.5 M *tert*-butyl hydroperoxide are [4] and [10].

$$[10]\quad (CH_3)_3COO^\cdot + C_6H_5C(CH_3)_2H \xrightarrow{k_{10}} (CH_3)_3COOH + C_6H_5\dot{C}(CH_3)_2$$

The ratio of α-cumyl alcohol to 3-methyl-3-pentanol is therefore given by

$$\frac{[C_6H_5C(CH_3)_2OH]}{[t\text{-ROH}]} = \frac{k_{10}[C_6H_5C(CH_3)_2H]}{k_4(t)[RH]}$$

and the ratio of α-cumyl alcohol to 3-methyl-2-pentanol by

$$\frac{[C_6H_5C(CH_3)_2OH]}{[s\text{-ROH}]} = \frac{k_{10}[C_6H_5C(CH_3)_2H]}{k_4(s)[RH]}$$

Typical yields of these three alcohols produced after co-oxidations of cumene and 3-methylpentane and reduction with $(C_6H_5)_3P$ from 30 to 80°C were measured and are summarized in Table 2.

At 30°C $k_{10}/k_4(t) = 24 \pm 2$ and $k_{10}/k_4(s) = 190 \pm 22$. Since $k_{10} = 0.16 \pm 0.01$ $M^{-1}\ s^{-1}$, $k_4(t) = 0.007 \pm 0.001$ $M^{-1}\ s^{-1}$, and $k_4(s)$ per active H = 0.0002 ± 0.0001 $M^{-1}\ s^{-1}$, rate constants that are in excellent agreement with the values obtained from rate measurements on the oxidation of 3-methylpentane in the presence of *t*-BuOOH.

Accurate values of k_4 cannot be obtained above 30°C by the hydroperoxide method because of the high vapour pressure of 3-methylpentane. Accurate values of k_{10} can, however, be obtained from 30–60°C by this technique (Table 3). The Arrhenius plot of these data was linear (Fig. 1) and a least squares analysis yielded the Arrhenius expression

40	0.34
45	0.47
50	0.67
55	0.98
60	1.10

[a]Averages of at least two runs at each temperature at different cumene and *tert*-butyl hydroperoxide concentrations. Above 40°C *tert*-butyl benzene was used as diluent.

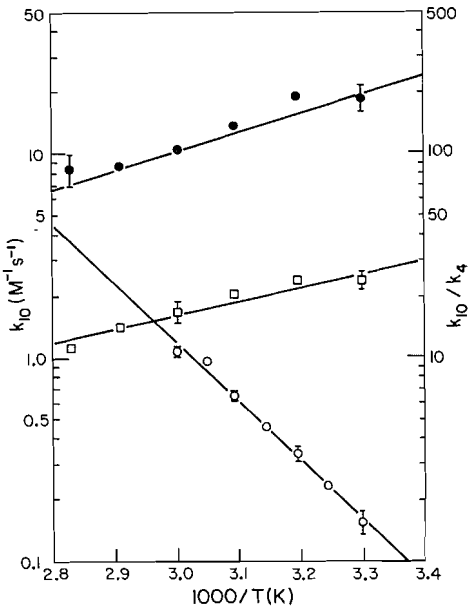

FIG. 1. Arrhenius plots of log $(k_{10}/M^{-1}$ s$^{-1})$ ⊙, log $(k_{10}/k_4(t))$ □, and log $(k_{10}/k_4(s))$ ● against $1000/T$ (K).

$$\log (k_{10}/M^{-1}\ s^{-1}) = (8.7 \pm 0.3) - (13.2 \pm 0.4)/\theta$$

where $\theta = 2.303RT$ kcal mol^{-1}.

These Arrhenius parameters are very similar to those reported by Howard *et al.* (11) for reaction of cumylperoxy with cumene (2×10^8 M^{-1} s^{-1} and 12.4 kcal mol^{-1}) and are quite different to those recently reported (12) for the rate controlling propagation reaction for the liquid-phase autoxidation of cumene with lead oxide (2×10^5 M^{-1} s^{-1} and 7.2 kcal mol^{-1}). The difference between these two sets of data is well beyond the limits of error and raises doubt about the validity of kinetic data obtained from the heterogeneous autoxidation.

The yields of 3-methyl-3-pentanol and 3-methyl-2-pentanol relative to α-cumyl alcohol from co-oxidations over a temperature range were measured and plots of log $(k_{10}/k_4(t))$ and log $(k_{10}/k_4(s))$ against the reciprocal of the absolute temperature (Fig. 1) gave

$$\log (A_{10}/A_4(t)) = -0.82 \pm 0.18$$
$$E_4(t) - E_{10} = 3.1 \pm 0.3 \text{ kcal mol}^{-1}$$
$$\log (A_{10}/A_4(s)) = -0.80 \pm 0.4$$
$$E_4(s) - E_{10} = 4.3 \pm 0.4 \text{ kcal mol}^{-1}$$

The Arrhenius equations for 3-methylpentane relative to cumene are, therefore,

$$\log (k_4(t)/M^{-1}\ s^{-1}) = (9.5 \pm 0.5) - (16.3 \pm 0.7)/\theta$$

$$\log (k_4(s) \text{ per C—H}/M^{-1}\ s^{-1}) = (8.9 \pm 0.7) - (17.5 \pm 0.8)/\theta$$

Discussion

Neat 3-methylpentane does not absorb oxygen at a significant rate at 30°C whereas chain lengths of 7–30 are obtained in the presence of *tert*-butyl hydroperoxide. Product studies on the latter system

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

suggest that significant concentrations of the secondary hydroperoxide, 3-methyl-2-pentyl hydroperoxide are formed, indicating a significant contribution from secondary alkylperoxy radicals to the overall concentration of *substrate* derived peroxy radicals. Thus chain termination for neat 3-methylpentane must involve 3-methyl-2-pentylperoxy (*s*-ROO•) as well as 3-methyl-3-pentylperoxy (*t*-ROO•) radicals.

[11] $t\text{-ROO}^\bullet + t\text{-ROO}^\bullet \rightleftharpoons t\text{-ROOOOR-}t \begin{cases} \rightarrow 2t\text{-RO}^\bullet + O_2 \\ \rightarrow t\text{-ROOR-}t + O_2 \end{cases}$

[12] $t\text{-ROO}^\bullet + s\text{-ROO}^\bullet \xrightarrow{2k_{12}}$

[13] $s\text{-ROO}^\bullet + s\text{-ROO}^\bullet \xrightarrow{2k_{13}}$ Non-radical products

The *overall* termination rate constant for the neat liquid will consist of contributions from $2k_{11}$, $2k_{12}$, and $2k_{13}$ and also contributions from the rate constants associated with the alkylperoxy radicals produced by β-scission of the 3-methyl-3-pentoxy radicals formed in reaction [11]. This overall rate constant will be significantly larger than the value expected for 3-methyl-3-pentylperoxy radicals and must be the principal reason for the resistance to autoxidation exhibited by 3-methylpentane. This substrate, therefore, behaves like other hydrocarbons with more than one type of reactive C—H bond, such as *p*-cymene which is more resistant to autoxidation than cumene because *p*-isopropylbenzylperoxy radicals are involved in termination (13, 14).

The average value of $k_4(t) = 0.007 \pm 0.001$ M^{-1} s^{-1} at 30°C for 3-methylpentane, determined by the hydroperoxide method and co-oxidation, is slightly larger than the estimated value of $k_4(t) = 0.003$–0.005 M^{-1} s^{-1} for isobutane (3, 4, 15). There is, however, no reason to believe that there will be any difference in reactivity between these two hydrocarbons. The experimental values of log $(A_4(t)/M^{-1}$ $s^{-1})$ and $E_4(t)$ are 9.5 and 16.3 kcal mol^{-1} relative to values of 8.7 and 13.2 kcal mol^{-1} for cumene. This preexponential factor is in good agreement with the estimated value of 9.4 for reaction of $t\text{-RO}_2^\bullet$ with a tertiary aliphatic C—H bond (3) while the activation energy is slightly larger than the value calculated from the overall activation energy for autoxidation of isobutane $(E_4 - \frac{1}{2}E_6) = 11.3$ kcal mol^{-1} quoted by Allara and co-workers (16) and our value of $E_6 = 8.5$ kcal mol^{-1} (4).

Extrapolation of our Arrhenius equation to 753 K gives $k_4(t) = 5.8 \times 10^4$ M^{-1} s^{-1} which compares favorably with the rate constant of 8.5×10^4 M^{-1} s^{-1} estimated by Baldwin for $HO_2^\bullet + i\text{-}C_4H_{10}$ in the gas phase (17), considering that $HO_2^\bullet$ may be slightly more reactive than $(CH_3)_3COO^\bullet$ at this temperature (18).

The value of $k_4(s)$ per active hydrogen $= 0.0002 \pm 0.0001$ M^{-1} s^{-1} at 30°C for 3-methylpentane is of similar magnitude to the values of $k_4(s) = 0.00026$ M^{-1} s^{-1} for cyclohexane, 0.00031 M^{-1} s^{-1} for tridecane, and 0.00034 M^{-1} s^{-1} for hexadecane, rate constants that were obtained by the hydroperoxide method on the individual hydrocarbons (4).

The activation energy for reaction of $s\text{-BuO}_2^\bullet$ with *n*-butane can be calculated to be 16.6 ± 3 kcal mol^{-1} from $E_p - E_t/2 = 15.3 \pm 3$ kcal mol^{-1} (19) and $E_t = 2.7$ kcal mol^{-1} (20). We have previously shown (4) that $s\text{-RO}_2^\bullet$ is about 5 times more reactive than $t\text{-RO}_2^\bullet$ in hydrogen abstraction from the same hydrocarbon at 30°C, which corresponds to a difference in activation energy of ~1 kcal mol^{-1}. We can, therefore, estimate that the activation energy for abstraction of a secondary hydrogen from *n*-butane by $t\text{-BuO}_2^\bullet$ is 17.6 ± 3 kcal mol^{-1}, very similar to our value for 3-methylpentane.

Bennett *et al.* (21) have recently determined the overall propagation rate constant for autoxidation of 2,6,10,14-tetramethylpentane at 413 K as 38 M^{-1} s^{-1}. Using the Arrhenius equations reported in this work for reaction of $t\text{-BuO}_2^\bullet$ with tertiary and secondary aliphatic C—H bonds we can calculate an overall reactivity of 2,6,10,14-tetramethylpentane to $t\text{-BuO}_2^\bullet = 4 \times 7.5 + 18 \times 0.44 = 38$ M^{-1} s^{-1} at 413 K, a value in excellent agreement with the directly measured value (21).

In conclusion the kinetic parameters reported in this work can be compared with kinetic parameters for Br•, a free radical that has the same endothermicities as ROO• in its reaction with aliphatic C—H bonds. Thus the selectivity of $t\text{-BuO}_2^\bullet$ to aliphatic *s*-C—H and *t*-C—H is ~1:35 at 30°C while the selectivity of Br• to these two bonds at 40°C is ~1:40 (15). Furthermore, $E^s - E^t$ for Br• is 2.5 kcal mol^{-1} (22) while this difference is 1.2 ± 1.5 kcal mol^{-1} for $t\text{-BuO}_2^\bullet$.

Electron paramagnetic resonance spectra of the *tert*-butylperoxy and *tert*-butoxy adducts to phenyl *tert*-butyl nitrone and 2-methyl-2-nitrosopropane. Oxygen-17 hyperfine coupling constants[1]

JAMES ANTHONY HOWARD AND JOHN CHARLES TAIT[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received July 13, 1977

JAMES ANTHONY HOWARD and JOHN CHARLES TAIT. Can. J. Chem. **56**, 176 (1978).

tert-Butylperoxy radicals enriched with oxygen-17 react with phenyl *tert*-butyl nitrone to give α-*tert*-butylperoxybenzyl *tert*-butyl nitroxide with a_N = 13.42 G, a_H = 0.95 G, a_O^β = 2.9 G, g = 2.0064. The O-hfsc decreases with an increase in temperature while the H-hfsc increases with an increase in temperature. This radical is not stable above about 273 K and is replaced by α-*tert*-butoxybenzyl *tert*-butyl nitroxide, a_N = 13.62 G, a_H = 1.72 G, a_O^β = 5.05 G, g = 2.0064.

Alkylperoxy radicals are also trapped by 2-methyl-2-nitrosopropane to give alkylperoxy *tert*-butyl nitroxide a_N = 28.7 G, a_O^{ROO} = 4.6 G, g = 2.0056 while the epr parameters for alkoxy *tert*-butyl nitroxide are a_N = 27.25 G, a_O^{RO} = 1.03 G, g = 2.0057.

JAMES ANTHONY HOWARD et JOHN CHARLES TAIT. Can. J. Chem. **56**, 176 (1978).

Les radicaux *tert*-butylperoxy enrichis en oxygène-17 réagissent avec la phényle *tert*-butyle nitrone pour conduire au nitroxyde de l'α-*tert*-butylperoxybenzyle et de *tert*-butyle avec a_N = 13.42 G, a_H = 0.95 G, a_O^β = 2.9 G, g = 2.0064. Le O-hfsc diminue avec une augmentation de la température alors que le H-hfsc augmente avec une augmentation de température. Ce radical n'est pas stable au dessus d'environ 273 K et est remplacé par le nitroxyde de l'α-*tert*-butoxybenzyle et de *tert*-butyle, a_N = 13.62 G, a_H = 1.72 G, a_O^β = 5.05 G, g = 2.0064.

On peut aussi piégé les radicaux alkylperoxy par le méthyl-2 nitroso-2 propane pour conduire aux nitroxydes d'alkylperoxy et de *tert*-butyle a_N = 28.7 G, a_O^{ROO} = 4.6 G, g = 2.0056 alors que les paramètres rpe pour le nitroxyde d'alkoxy et de *tert*-butyle sont a_N = 27.25 G, a_O^{RO} = 1.03 G, g = 2.0057.

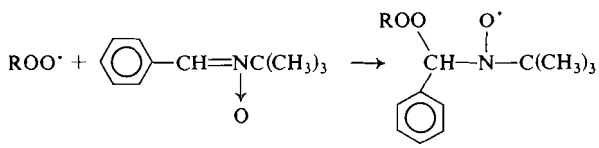
Introduction

Merritt and Johnson (1) have recently reported the preparation and epr spectra of alkylperoxy radical (ROO·) adducts to phenyl *tert*-butyl nitrone (PBN).



These radicals were prepared by reaction of $Pb(OAc)_4$ at −80°C with the alkyl hydroperoxide (ROOH) in the presence of PBN. The reported epr parameters for the nitroxide with R = *t*-Bu were a_N = 13.39 G, a_H = 1.19 G, and g = 2.0062. The only other authentic peroxy radical adduct to PBN is the hydroperoxy adduct with R = H (a_N = 14.8 G, a_H^β = 2.75 G, and g = 2.0057) which was prepared by photolysis of 30% H_2O_2 containing the nitrone (2).

We have studied the *direct* reaction of the *tert*-butylperoxy radical with phenyl *tert*-butyl nitrone, 2-methyl-2-nitrosopropane, and some other spin traps by the epr method. Two oxy radical adducts were observed with each trap using peroxy radicals enriched with ^{17}O. One of these was the alkoxy adduct while the second has been identified as the alkylperoxy adduct. Unambiguous identification of alkylperoxy radical adducts to phenyl *tert*-butyl nitrone and 2-methyl-2-nitrosopropane means that these traps can be used as probes for the intermediacy of alkylperoxy radicals in free-radical reactions.

Experimental

tert-Butylperoxy radicals were prepared directly in the cavity of the spectrometer by photolysis of di-*tert*-butyl ketone in oxygen-saturated solvent (toluene, fluorotrichloromethane, and carbon tetrachloride). ^{17}O enriched oxygen was purchased from Yeda Inc., Israel. The spin traps were gifts from Dr. E. Janzen (Guelph) and Dr. K. U. Ingold (NRCC, Ottawa).

The epr spectra were observed using a Varian E-4 spectrometer equipped with a variable temperature accessory. The microwave frequency was measured with a Syntron-Donner Model 6016 frequency counter, which also monitored the frequency of a proton magnetometer used to measure the magnetic field.

Results

tert-BuO_2· + *PBN*

The *tert*-butylperoxy radical is extremely persistent at −80°C and photolysis of di-*tert*-butyl ketone in oxygen-saturated toluene gave ca. 10^{-5} *M* of radical

which to all intents and purposes was completely stable. The radical did, however, disappear slowly upon the addition of PBN (10^{-2} *M*) to give two nitroxides **1** (a_N = 12.85 G, g = 2.0063) and **2** (a_N = 7.79 G; g = 2.0071). Neither of these radicals exhibited proton hyperfine splitting at this temperature.

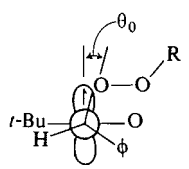
The spectrum did not change as the temperature of the solution was slowly increased until −20°C when **1** resolved into a triplet of doublets (a_N = 13.42 G; a_H = 0.95 G; g = 2.0064). This nitroxide was not stable above 0°C and was replaced by the *tert*-butoxy adduct to PBN, **3** (a_N = 13.62 G; a_H = 1.72 G, g = 2.0064) (3).

The epr parameters for **1** are very similar to the parameters assigned to the *tert*-butylperoxy adduct to PBN by Merritt and Johnson (1). Confirmation that **1** was indeed α-*tert*-butylperoxybenzyl *tert*-butyl nitroxide was obtained by preparing ^{17}O enriched *tert*-butylperoxy and allowing it to react with PBN. The nitroxide **1** exhibited hyperfine splitting from one oxygen nucleus ($I = \frac{5}{2}$), a_O^{β} = 2.9 G at −60°C. There was no observable hyperfine splitting from the second oxygen.

The *tert*-butoxy adduct to PBN also exhibited hyperfine splitting from one oxygen nucleus, a_O^{β} = 5.05 G at 25°C.

It should be noted that the hydrogen and oxygen hyperfine splitting constants (hfsc) of the *tert*-butylperoxy and *tert*-butoxy adducts to PBN were dependent on the temperature. The oxygen-17 hfsc decreased with an increase in temperature while the proton hfsc increased with an increase in temperature. These temperature dependent hfsc's suggest that the nitroxides prefer a conformation with the oxyl group partially eclipsed by the *p* orbital containing the unpaired electron at low temperatures. Rotation about the N—C bond would increase as the temperature was increased with an associated decrease in a_O and increase in a_H.

The H-hfsc for **1** is comparatively small and the value at −20°C reflects an average C—H dihedral angle, θ_H = 74°. The value of θ_O is, therefore, most probably 14°.



The H-hfsc for **3** is larger than it is for **1** and θ_H = 70°. The dihedral angle between the orbital containing the unpaired electron and the alkoxy group is, therefore, 10°. It would, therefore, appear that the most stable conformation for **3** has the alkoxy group eclipsed to a greater extent than the peroxy group in **1**.

tert-BuO$_2^{\cdot}$ + *tert-BuNO*

tert-Butylperoxy radicals reacted slowly with 2-methyl-2-nitrosopropane in toluene at −90°C to give di-*tert*-butyl nitroxide (a_N = 15.7 G, g = 2.0063) and *tert*-butoxy *tert*-butyl nitroxide (a_N = 27.25 G, g = 2.0057). At −20°C the concentration of these radicals increased substantially and the spectrum from benzyl *tert*-butyl nitroxide (4) developed (a_N = 14.75 G, a_H = 7.35 G; g = 2.0063). This latter radical almost certainly arose by addition of benzyl, formed by H-atom abstraction from the solvent, to the trap. There was no evidence for a spectrum that could be attributed to *tert*-butylperoxy *tert*-butyl nitroxide. If the *tert*-butylperoxy radical was prepared from ^{17}O enriched oxygen the spectrum from *tert*-butoxy *tert*-butyl nitroxide contained a hyperfine splitting from one oxygen-17 nucleus, a_O^{RO} = 1.03 G, at −40°C.

In a somewhat different experiment di-*tert*-butyl peroxide was photolyzed at −170°C in propane containing ^{17}O enriched oxygen. At this temperature some of the 2-propylperoxy radicals must combine with *tert*-butoxy radicals to give 2-propyl-*tert*-butyl trioxide (5) according to reactions 1, 2, and 3.

[1] $$(CH_3)_3COOC(CH_3)_3 \rightarrow 2(CH_3)_3CO^{\cdot}$$

[2] $$(CH_3)_3CO^{\cdot} + CH_3CH_2CH_3 \xrightarrow{O_2} (CH_3)_3COH + (CH_3)_2CHOO^{\cdot}$$

[3] $$(CH_3)_2CHOO^{\cdot} + (CH_3)_3CO^{\cdot} \rightarrow (CH_3)_2CHOOOC(CH_3)_3$$

The temperature of the solution was then increased and solid 2-methyl-2-nitrosopropane was added at −90°C. At this temperature epr spectra from di-*tert*-butyl nitroxide and the *tert*-butylperoxy radical were evident. Toluene was then added and the solution was saturated with argon. At −40°C the propane evaporated and no radicals could be detected. Upon warming to −10°C, di-*tert*-butyl nitroxide, an alkoxy *tert*-butyl nitroxide, benzyl-*tert*-butyl nitroxide, and a fourth radical, **4**, with a_N = 28.7 G, a_O = 4.6 G, g = 2.0056 were detected. This latter radical was either *tert*-butylperoxy *tert*-butyl nitroxide or isopropylperoxy *tert*-butyl nitroxide or a mixture of these radicals. It would, therefore, appear that the O-hfsc for alkylperoxy *tert*-butyl nitroxide is larger than a_O^{RO} for alkoxy *tert*-butyl nitroxide. This difference in O-hfsc's must reflect a difference in the extent of transfer of spin from the nitrogen nucleus to the oxygen orbitals arising from spin polarization. This difference is not unexpected as the ROO adduct has an electron

withdrawing group attached to the α-oxygen while the RO adduct has an electron donating group attached to this oxygen.

Other Spin Traps

tert-Butylperoxy radicals react rapidly at −90°C with a variety of other spin traps (nitrosobenzene, 2,4,6-tri-*tert*-butyl nitrosobenzene, and 5,5-dimethyl-1-pyrrolene-1-oxide). The epr spectra of the *tert*-$BuO_2^{\bullet}$ adducts were, however, either too complex or too unstable for these traps to be of much use as diagnostic probes for the intermediacy of alkylperoxy radicals in free-radical reactions.

Studies of the rhenium–oxygen bond. II.[1] The crystal and molecular structure of μ-oxobis(*cis*-dichloro-*cis*-di(pyridine)-*trans*-oxorhenium(V)), $ORe(C_5H_5N)_2Cl_2ORe(C_5H_5N)_2Cl_2O$

COLIN JAMES LYNE LOCK[2] AND GRAHAM TURNER

Institute for Materials Research, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 28, 1977

COLIN JAMES LYNE LOCK and GRAHAM TURNER. Can. J. Chem. **56**, 179 (1978).

The crystal structure of μ-oxobis(*cis*-dichloro-*cis*-di(pyridine)-*trans*-oxorhenium(V)), $ORe(C_5H_5N)_2Cl_2{\cdot}O{\cdot}Re(C_5H_5N)_2Cl_2O$ has been studied by single crystal X-ray methods. The crystals were orthorhombic with lattice parameters $a = 15.367(2)$, $b = 10.283(2)$, $c = 16.685(2)$ Å. The space group was $Pna2_1$ and there were four formula weights per unit cell. A total of 3339 reflections, of which 2990 were observed, were examined, and the structure refined by full matrix least squares (treating the pyridine rings as groups) to an R_2 value of 0.0449. The dimer had a roughly rectilinear O—Re—O—Re—O backbone with pairs of chlorine atoms and pyridine molecules arranged *cis* in each half of the dimer. The two halves of the dimer were arranged such that the pairs of *cis* atoms in one half were rotated about the Re(1)–Re(2) axis almost 113° when compared to the corresponding pair in the other half. Important bond lengths (Re—O(terminal), 1.715(16), 1.764(16); Re—O(bridging), 1.943(16), 1.903(16); Re—Cl, 2.356(5)–2.390(5); Re—N, 2.116(16)–2.180(16)) were close to previously observed values. The molecule was markedly disturbed from the idealized structure and this was caused by intramolecular non-bonded interactions.

COLIN JAMES LYNE LOCK et GRAHAM TURNER. Can. J. Chem. **56**, 179 (1978).

On a étudié la structure cristalline du μ-oxobis(*cis*-dichloro-*cis*-di(pyridine)-*trans* oxorhénium(V)), $ORe(C_5H_5N)_2Cl_2{\cdot}O{\cdot}Re(C_5H_5N)_2Cl_2O$, par la diffraction de rayons-X de monocristaux. Les cristaux sont orthorhombiques avec des paramètres de mailles $a = 15.367(2)$, $b = 10.283(2)$, $c = 16.685(2)$ Å. Le groupe d'espace est $Pna2_1$ et il y a quatre unités par maille. On a examiné un total de 3339 réflexions desquelles on a observé 2990; la structure a été affinée par la méthode des moindres carrés (matrice complète) (en traitant les cycles pyridiniques comme groupe) jusqu'à une valeur de R_2 de 0.0449. Le dimère possède un squelette O—Re—O—Re—O qui est approximativement rectiligne avec des paires d'atomes de chlore et de molécules de pyridine arrangées *cis* dans chaque moitié du dimère. L'arrangement des deux portions du dimère est tel que, par rapport à l'axe Re(1)–Re(2), les paires d'atomes *cis* dans une moitié sont tournés d'environ 113° lorsqu'on les compare avec la paire correspondante dans l'autre moitié. Les longueurs des liaisons importantes (Re—O(terminal), 1.715(16), 1.764(16); Re—O (le pont), 1.943(16), 1.903(16); Re—Cl, 2.356(5)–2.390(5); Re—N, 2.116(16)–2.180(16)) se rapprochent des valeurs observées antérieurement. La molécule existe sous une forme qui diffère considérablement de la structure idéalisée et ce phénomène provient d'interactions intramoléculaires non-liées.

[Traduit par le journal]

Introduction

We have been attempting to derive a relationship between Re—O bond lengths and the Re—O stretching frequencies and derived force constants. Although over 40 structures have been determined that contain Re—O bonds, relatively few compounds have both been examined in detail by vibrational spectroscopy, and have had the structures determined to an accuracy that allows a detailed mathematical relationship to be derived. We have been attempting to determine structures of compounds that might be suitable for spectroscopic examination and to redetermine other structures accurately where good spectroscopic data are available. One series of compounds that appeared to be worth investigating contained pyridine as a counter ligand. One of the compounds in this series is $Re_2O_3(C_5H_5N)_4Cl_4$. We have determined the structure of this compound by single crystal X-ray diffraction. Despite very careful work, the structure determination is not of sufficient accuracy to fulfil the original purpose of the work. Nevertheless, the structure is of interest since it is different from the structure assumed previously (2, 3). We report the structure of $Re_2O_3(C_5H_5N)_4Cl_4$ here.

[1]We regard the first paper in this series as the paper shown as ref. 1.

Experimental

Preparation of μ-Oxo-bis(cis-dichloro-cis-di(pyridine)-trans-oxorhenium(V))

$Re_2O_3Cl_4(C_5H_5N)_4$

The compound was prepared by reacting $ReOCl_3((C_6H_5)_3P)_2$ (yellow–green isomer) with pyridine in benzene according to Method B of Johnson *et al.* (2). *Anal.* calcd. for $C_{20}H_{20}Cl_4N_4O_3Re_2$: C 27.3, H 2.3, N 6.4, Cl 16.1; found: C 27.4, H 2.4, N 6.4, Cl 15.3. Crystals suitable for X-ray studies were obtained by crystallization from acetone at 5°C.

Crystallography

The title compound crystallizes as green orthorhombic prisms. An irregularly shaped small crystal, roughly 0.10 × 0.07 × 0.16 mm, showing sharp extinctions every 90° when viewed by polarized light, was mounted along the longest dimension. Preliminary precession photographs indicated orthorhombic symmetry; photographs of the hkn (n = 0–2) and mkl (m = 0–2) layers showed systematic absences of the type $0kl$, $k + l = 2n + 1$ and $h0l$, $h = 2n + 1$, which indicated the possible space groups as $Pna2_1$ (#33) or $Pnam$ (an unconventional setting of $Pnma$) (#62).

The space group $Pna2_1$ was chosen; choice of this space group will be justified later.

The density of a few single crystals was obtained by flotation in a carefully degassed aqueous solution of zinc bromide. The crystal was transferred to a Syntex $P\bar{1}$ automatic diffractometer and accurate unit cell parameters were obtained by least squares refinement of 15 accurately centered reflections in the range $20° < 2\theta < 25°$. Crystal data were:

$C_{20}H_{20}Cl_4N_4O_3Re_2$ fw = 879
Orthorhombic, a = 15.367(2), b = 10.283(2), c = 16.685(2) Å, V = 2636.5(5) Å^3, $Pna2_1$, (#33), ρ_o = 2.20(1) g cm^{-3}, Z = 4, ρ_c = 2.21(1) cm^{-3} (22°, MoKα, λ = 0.71069 Å, μ = 101.2 cm^{-1}).

Intensity data were collected using MoKα radiation made monochromatic by reflection from the 002 face of an oriented mosaic single crystal of graphite. Data were collected using a coupled θ(crystal)–2θ(counter) scan up to $2\theta = 35°$. The scan rate was chosen by the program supplied with the instrument and varied from 8 to 24 deg min^{-1}. Above 35° most reflections were not significantly above background. The intensity of a standard reflection was monitored after every 49 reflections; the intensity of this standard showed only random fluctuation with a standard deviation of 2.4%. A total of 2705 reflections were collected in one quadrant (h, k, $\pm l$). After the removal of 328 reflections that were not above background, the remaining reflections were averaged, yielding 1347 symmetry independent reflections, of which 1025 were considered observed and 322 were considered unobserved (see ref. 4 for a detailed discussion of data processing). Data were corrected for Lorentz and polarization effects, but not for absorption. The coarse features of the structure were obtained from this data set.

A second data set was obtained from a larger crystal, which was hand cut from a very large plate. The crystal used was a parallelpiped with one corner removed and was bounded by the faces {100}, {010}, {001}, and {1$\bar{1}$0}. The sets of faces were 0.182, 0.090, 0.060, and 0.104 mm, respectively, from the centre of the crystal. The only difference in instrumental conditions was that the scan rate was varied from 4 to 24 deg min^{-1}. A total of 4349 reflections were collected in the hemisphere $\pm h$, $\pm k$, l to $2\theta = 55°$, the standard reflection, 2, 0, 4, being measured after every 49 reflections. The standard reflection showed only statistically random variation: the standard deviation was 1.43%. The 495 reflections that were not significantly above background were rejected. The remaining reflections were corrected for absorption on the basis of the dimensions given above,[3] and corrected for Lorentz and polarization effects as described previously. Symmetry equivalent reflections were averaged, leaving 2328 unique reflections of which 2015 were considered observed.

The final refinement obtained from this second data set was still unsatisfactory. The space group chosen was acentric, and because of the large anomalous dispersion correction of the rhenium atoms, Friedel's law should not apply. The independent data for the space group $Pna2_1$ are ($hkl = h\bar{k}l = \bar{h}kl = \bar{h}\bar{k}l$) ≠ ($hkl = \bar{h}kl = h\bar{k}l = \bar{h}\bar{k}l$). No data had been obtained for the hemisphere with negative l, where the Friedel's law inequivalencies would show up. A third data set was therefore collected.

This data set consisted of a complete sphere ($\pm h$, $\pm k$, $\pm l$) of low angle ($2\theta \leq 30°$) reflections. These data were collected on a Syntex $P2_1$ diffractometer with scan rates varying from 1.8 to 24 deg min^{-1}, depending on the intensity of the reflection. Three standard reflections from different areas of reciprocal space (5 −1 2, 7 −1 −2, and −2 0 −4) were measured after every 97 reflections. These standard reflections showed only statistically random variations with an overall standard deviation of 1.8%. A total of 3339 reflections were collected, of which 349 were rejected as being not significantly above background. The remaining 2990 reflections were corrected for absorption, Lorentz, and polarization effects. The crystal used for collecting these data was a regular parallelpiped, bounded by {100}, {010}, and {001}, these faces being 0.081, 0.013, and 0.032 mm, respectively, from the centre of the crystal. The crystal was mounted about b^*, and deliberately misset by 3° from this axis. The symmetry equivalent reflections were then averaged, leaving 1067 unique reflections, all of which were considered observed. These data were used in the final stages of refinement as outlined below. Of the 478 pairs of reflections of type hkl and $hk\bar{l}$ that were collected, 412 pairs did not differ by more than 3σ, 50 pairs differed by between 3σ and 5σ, and 16 pairs differed by more than 5σ.

Solution of the Structure

The Patterson diagram was solved, with some difficulty, to give two independent rhenium atoms at 0.29, 0.52, 0.5 and 0.20, 0.48, 0.29. This solution ruled out the centrosymmetric space group $Pnam$, with an eight-fold general position. In the chosen space group, $Pna2_1$, the coordinate z was defined by fixing the z coordinate of one rhenium atom. The two rhenium atom positions could not be transformed into one other by any of the symmetry operations of the space group $Pnam$. The space group choice was confirmed by the successful solution of structure.[4] There was, however, pseudosymmetry

[3]All calculations were carried out on a CDC6400 computer. The programs DATCO3, ABSORB, DATRDN, ORTEP were taken from the X-RAY 71 package. The full matrix least squares program CUDLS and group least squares program GROUPLS were written locally by J. S. Stephens. The Fourier program SYMFOU was written by J. S. Rutherford and the least squares plans program PALS by P. G. Ashmore.

[4]To eliminate completely the possibility of the space group $Pnam$, refinement was tried in this space group using each of the rhenium positions. R factors were 0.50. Attempts to add chlorine atoms led to no improvement in the R factor and caused the temperature factors to rise to completely unacceptable values.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

between the two rhenium atom positions ($x_1 + x_2 \approx \frac{1}{2}$, $y_1 + y_2 \approx 1$). These values of y, close to, but not exactly, $\frac{1}{2}$, lead to broad peaks in the Patterson diagram. An initial structure factor calculation, phased on the two rhenium atoms, with fixed isotropic temperature factors and varying only the scale factor, gave $R_1 = 0.22$.[5] Variation of rhenium positional parameters and isotropic temperature factors (eight parameters, one rhenium atom z coordinate being fixed) gave $R_1 = 0.18$. An electron density difference synthesis revealed the positions of four chlorine, three oxygen, four nitrogen, and seven carbon atoms. Refinement of positional and isotropic temperature factors for all atoms gave $R_1 = 0.105$ (80 parameters). Subsequent refinement cycles and difference syntheses did not reveal the positions of four of the remaining carbon atoms of one pyridine ring. The final R factor was $R_1 = 0.079$, with the rhenium and chlorine atoms having anisotropic temperature factors, for a total of 125 variable parameters. The esd's in bond lengths were quite large (e.g. Re—O(terminal), 1.74(6) Å), in view of the relatively low R factor. A decision was made at this point to recollect data using a well shaped larger crystal, and then to apply an absorption correction.

The data from the second crystal and the final atom parameters from the first crystal were used as the basis for the least squares refinement. One cycle of refinement, varying only the scale factor, gave $R_1 = 0.0722$. A difference synthesis revealed the remaining four carbon atoms (C12, C13, C14, and C15). In all further cycles of refinement the chlorine and rhenium atoms were given anisotropic temperature factors. Refinement converged to $R_1 = 0.0563$ for 163 variable parameters. The pyridine rings did not show the expected geometry. Carbon–carbon bond lengths varied from 1.25 to 1.6 Å, and individual pyridine ring atoms showed large random shifts in each cycle without improving the refinement. The pyridine rings were treated as rigid groups, using the known geometry (5) by a method similar to that of Scheringer (6) and LaPlaca and Ibers (7). The program GROUPLS was used, which allows the variation of six group positional parameters and individual isotropic temperature factors for each atom in the group. Atom positions from the CUDLS refinement were used to generate the exact atomic positions of a rigid pyridine ring of standard geometry. The refinement converged to $R_1 = 0.0541$ (114 variable parameters). At this stage, the errors in the various Re—O bond lengths had dropped to 0.025 Å, which was still considered large. All refinements using this second set of data gave atomic positions that resulted in certain 'chemically' equivalent bond lengths in the different halves of the dimer being significantly different. Although there are no symmetry requirements relating equivalent parts of the two halves of the dimer, it seems reasonable to suppose that atoms that have superficially similar environments should have similar bond lengths. It was felt that many of the difficulties in refinement and in the structural parameters would be resolved if the Friedel independent data (in this case hkl and $hk\bar{l}$) were used in refinement. Accordingly, the third set of data was collected and used in refinement. These data were included in a third refinement of the structure. This third refinement used the following reflection data: 1067 reflections with $2\theta \leq 30°$, collected from the third crystal, which were averaged with the equivalent reflections from the second crystal; 1754 reflections with $30° < 2\theta < 55°$ from the second crystal; a total of 2821 reflections were used in this final refinement.

After correction for secondary extinction by the method of Larsen (8) a weighting scheme was applied such that $\omega/||F_o| - |F_c||^2$ was locally independent of F_o and sin θ/λ.[6] Refinement converged to $R_1 = 0.0453$ and $R_2 = 0.0449$. In the final cycle of refinement, no parameter shifted by more than 1/12 of its error; the average shift was 0.01σ. A final difference synthesis revealed no peak greater than 0.93 e/Å^3 (at 0.29, 0.51, 0.50, close to Re(1)) and no valley less than -0.52 e/Å^3 (at 0.28, 0.49, 0.49, also close to Re(1)). In all calculations the atomic scattering factors for the neutral atoms were taken from the *International Tables for X-ray Crystallography* (9) and anomalous dispersion corrections (10) were used for rhenium and chlorine. The final atom parameters are given in Table 1 and the moduli for F_o and F_c are given in Table 2.[7]

Discussion

The molecule is pictured in Fig. 1 and selected interatomic distances and angles are given in Table 3. The molecule has a pseudo-two-fold axis through O(2). The pairs of pyridine rings in each half of the dimer are *cis*, in contrast to the suggested structure (3), in which, on the basis of vibrational spectra, the pyridine groups were considered to be *trans*. There are no symmetry requirements relating equivalent parts of the two halves of the dimer, but chemically equivalent bond lengths do not, in general, differ significantly. There are, however, marked differences in certain pairs of angles which might be expected to be equivalent. We suggest these effects may be caused by the exigencies of intramolecular packing.

The Re—N bond lengths (2.116(16)–2.180(16) Å) do not differ significantly and are similar to distances observed previously for similar compounds (range 2.11(2)–2.17(5) Å) (11, 12). The Re—Cl distances are not equivalent: the minimum and maximum values (2.356(5), 2.390(5) Å) differ by $4.80(\sigma_1^2 + \sigma_2^2)^{1/2}$. Nevertheless, neither of these values differs significantly from the intermediate values and all distances lie well within the range observed for Re—Cl bond lengths (2.182(7)–2.563(4) Å) (13, 14) and are close to the range, 2.37–2.38 Å, considered by Ibers and co-workers to be 'normal' (14, 15).

The Re—O(terminal) bonds (1.715(16), 1.764(16) Å) do not differ significantly, nor do the Re—O (bridge) bonds (1.903(16), 1.943(16) Å). Again, both sets of bonds agree reasonably well with values found with similar compounds containing the O—Re—O—Re—O framework (Re—O(terminal), range, 1.67(5)–1.723(7) Å; Re—O(bridge), range 1.903(5)–1.917(5)) (16–18).

[5] $R_1 = \dfrac{\Sigma||F_o| - |F_c||}{\Sigma|F_o|}$; $R_2 = \left\{\dfrac{\Sigma\,\omega(|F_o| - |F_c|)^2}{\Sigma\,\omega F_o^2}\right\}^{1/2}$

[6] ω was chosen such that

$$\omega = 1/(47.1 - 0.594|F_o| + 0.00255|F_o|^2).$$

*Estimated standard deviations from the least squares program are given in parentheses in terms of the least significant figure.

†The temperature factor parameters U_{ij} were obtained from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where β_{ij}'s appear as a temperature effect through $\exp[-(\beta_{11}h^2 + \ldots + \beta_{12}hk + \ldots)]$ in the structure factor expression and b_i are the reciprocal lattice vectors.

Examination of the least squares planes data (Table 4) and angular parameters (Table 3) shows some fairly marked distortions in the structure. In both planes 6 and 7 the ligand atoms lie in a plane, but for plane 7 the rhenium atom is displaced 0.10 Å from this plane. Figure 1*A* shows this displacement clearly; Re(2) is displaced away from O(2) and towards O(3). Of the other two ligand atom planes containing Re(2) and roughly at right angles to plane 7, plane 9 shows only a small distortion but the distortion in plane 8 is more marked. Any distortion is towards tetrahedral geometry. Thus, in plane 9, O(3) and O(2) are out of the plane in the opposite direction to Cl(4) and N(4). The two corresponding planes on Re(1) (10 and 11) showed a greater distortion, again towards a tetrahedral geometry. It should be noted that in planes 8, 10, and 11, if one considers the rhenium atom not to be displaced, then most of the distortion appears to arise from the position of the oxygen atoms.

In considering further details of the structure it is of interest to consider the other O—Re—O—Re—O

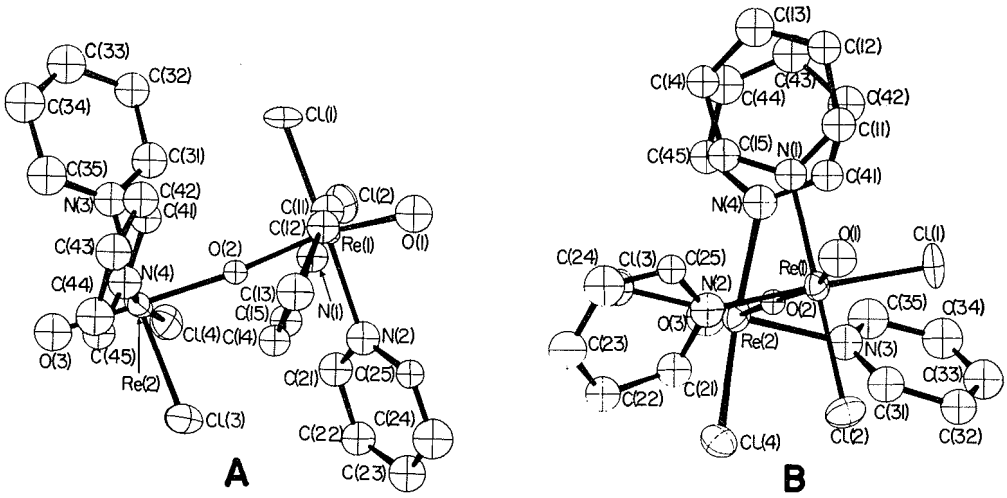

FIG. 1. The molecular structure of $ORe(C_5H_5)_2Cl_2 \cdot O \cdot Re(C_5H_5N)_2Cl_2O$ viewed from different directions. The numbering of the atoms is the same as in Table 1.

structures, namely those of $Re_2O_3(S_2CN(C_5H_5)_2)_4$ (17), $Re_2O_3Cl_4(NH_2 \cdot CH_2 \cdot CH_2 \cdot NH_2)_2$ (16), and $K_4Re_2O_3(CN)_8$ (18). Both $Re_2O_3Cl_4(NH_2 \cdot CH_2 \cdot CH_2 \cdot NH_2)_2$ and $K_4Re_2O_3(CN)_8$ have a centre of symmetry at the bridging oxygen atom and thus Re—O—Re is constrained to be rectilinear and the 'equatorial' ligands in one half of the dimer are eclipsed with respect to the other half. Fletcher and Skapski (17) have noted that for $Re_2O_3(S_2CN(C_2H_5)_2)_4$, where there is no centre of symmetry, the two halves of the dimer are rotated about the Re—O—Re bond by about 40° from the eclipsed position, but they have suggested no reason for this. In our compound no centre of symmetry is present and a similar twist is observed, although it is larger (113°). We suggest that in our molecule this twist is caused by the intramolecular packing requirements of the pyridine rings.

In considering the asymmetry of our molecule we were faced with questions such as "Why is there so much asymmetry in a formally very symmetric molecule?", "Why is this particular shape adopted; why not a system similar to $Re_2O_3Cl_4(en)_2$, where although the nitrogen atom positions in each half of this dimer are *cis*, the two halves are related by an inversion centre?", or "Since the monomer precursor has been postulated to have the pyridine rings *trans*, and the monomer ethanolysis product has been shown to have the pyridine rings *trans* (19), why is the structure not that postulated by Johnson *et al.* (2) and Cotton *et al.* (3)?"

Pyridine rings are very restrictive in their packing requirements (11), the α-protons interacting with other groups attached to the metal, and it appeared that interactions of the pyridine rings might provide the answer to all the above questions. We therefore made a series of very simple calculations, based on idealized structures and normal values for bond lengths and van der Waals radii.[8] Arguments on stability were based on differences between calculated non-bonded distances and sums of van der Waals radii. The calculations were applied first to the idea form of the structure observed, and in light of their success, to the other structures shown in Fig. 2.

To move the α-hydrogen atom away from a *cis* chlorine atom to the van der Waals contact distance it was necessary to rotate the pyridine ring about the Re—N bond by 61° from the position where all atoms are coplanar. Similarly, when the chlorine atom was replaced by an oxygen atom, the rotation of the pyridine ring was 66° (terminal) or 63° (bridging). Clearly, rotation of 60° could not be achieved, since in rotating away from a chlorine atom the ring rotated towards an oxygen atom. We could not calculate the final rotational angle, but since the ideal angle is close to 60° in each case, it seemed reasonable that the angle would be close to

[8]The following assumptions were made in all calculations: Re—Cl, 2.377 Å, Re—O (terminal), 1.73 Å; Re—O (bridging), 1.92 Å; Re—N, 2.15 Å; N—C, 1.34 Å; C—H, 1.08 Å; Re—N—C, 121.6°; N—C—H, 115.9°, the pyridine ring and the Re—N bond were coplanar, all *cis* angles at rhenium were 90°, van der Waals radii, Cl, 1.81 Å; O, 1.40 Å; H, 1.29 Å, pyridine ring half thickness, 1.7 Å. In the isomer calculations it was assumed the pyridine rings were rotated 45°, about the Re—N bond, from the position where the pyridine ring was coplanar with the rhenium–chlorine bond, unless another angle is specifically mentioned. In describing the direction of rotation, in every case it was assumed that the pyridine ring was viewed from the rhenium atom to which it was bonded.

45° from either chlorine or oxygen atoms. Angles of rotation of roughly 45° are well established (20–23) and where no rotation is observed unusually long M—N distances are observed (24). In Table 4 it can be seen that the pyridine rings are rotated 37–51° from the position where they are coplanar with the rhenium and chlorine atoms.

Considering now the whole molecule, (*f*) in Fig. 2, when the first and fourth pyridine rings are rotated in the same sense by 45° their interplanar

contact distance is 2.7 Å, much less than the van der Waals contact distance of 3.4 Å. The rings can be moved away from each other if one half of the dimer is twisted about the Re(1)—Re(2) vector. Calculations for an ideal model suggest this angle should be 26° compared with the observed angle of 23°. The twist can be seen in Fig. 1*B* and is illustrated more clearly in Fig. 3. Figure 1 *A* and *B* also shows that the effect of this twist is that, while it increases the interpyridine ring distance, it also brings the rings to a position where each lies more nearly over the other, which will increase the attractive London interaction between the polarizable π-clouds.

Further consideration of the twists of the second and third pyridine rings shows that the second ring comes in contact with Cl(3) (Cl(3)—C(21), 3.38(2) Å) and the third ring with Cl(1) (Cl(1)—C(31), 3.44(2) Å). The result is a very tightly packed molecule, and in particular, O(2), which should be the attack point for any reaction, such as hydrolysis or ethanolysis, which gives a monomer, is particularly well protected. Indeed, the only contact distance between the two halves of the dimer that is greater than the van der Waals contact distance is Cl(3)—Cl(4) at 4.02(1) Å. This may explain why ethanolysis of this molecule is such a slow reaction (19).

The twist of the second and third pyridine rings causes two further short interactions, namely between the hydrogen atom on C(31) and Cl(2) and the hydrogen atom on C(21) and Cl(4). These interactions can be relieved in two ways, either by angular distortions or by increasing the lengths of the Re—N or Re—Cl bonds.

The twist about the Re(1)—Re(2) axis required to move py1 and py4 apart shortens both the C(31)—Cl(2) and C(21)—Cl(4) distances. Other relevant angles show significant differences, however. Ignoring errors at this point, Re(2)—N(3)—C(31), 122(2)°, is the second largest Re—N—C angle, whereas Re(1)—N(2)—C(21), 116(2)°, is the smallest. O(2)—Re(2)—N(3), 88.1(6), is the largest O(2)—Re—N angle, while O(2)—Re(1)—N(2), 83.3(6) is the

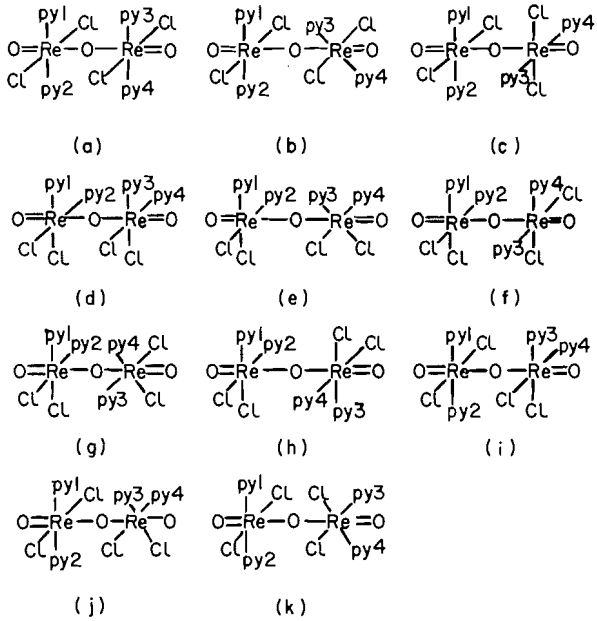

FIG. 2. Possible structures for conformations of $ORe(C_5H_5N)_2Cl_2{\cdot}O{\cdot}Re(C_5H_5N)_2Cl_2O$.

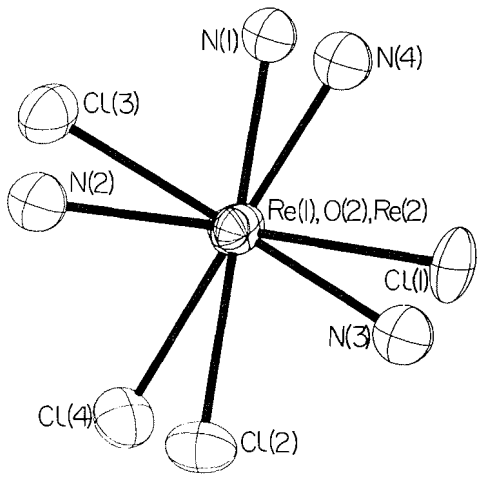

FIG. 3. The nearest neighbour 'equatorial' atoms of the rhenium atoms viewed as a projection down Re(1)—Re(2), and showing the rotation between the two halves of the dimer in $ORe(C_5H_5N)_2Cl_2{\cdot}O{\cdot}Re(C_5H_5N)_2Cl_2O$.

smallest of the four angles. Further, while O(2)—Re(1)—Cl(2), 92.4(5), is the second largest O(2)—Re—Cl angle and O(2)—Re(2)—Cl(4), 88.1(5) is the third largest angle they are significantly different as are all the pairs given above. Thus, angular relief may minimize the C(31)—Cl(2) interaction, but it is unlikely to do so for C(21)—Cl(4). Further calculation of the H—Cl distance, using H positions calculated from the ideal pyridine geometry (5), show that both H(C(21))—Cl(4) and H(C(31))—Cl(2) distances are ~2.7 Å. Thus, we suggest that for C(31)—Cl(2), the steric interaction is minimized by angular distortion but although Re(1)—N(2) has the longest mean Re distance, errors preclude the conclusion that the C(21)—Cl(4) interaction is relieved by bond lengthening.

Because the calculations we had undertaken on our molecule gave answers that were close to the observed parameters, (i.e., answering the first question) we have applied the calculations to other possible structures. The structures considered are shown in Fig. 2.

In (*c*), if the pyridine rings on one end of the dimer are rotated in the clockwise sense, then those on the other end must be rotated anticlockwise to minimize ring interaction. In this position there is interaction between an α-hydrogen on a ring and its eclipsed chlorine atom on the other end of the dimer. The distance is 2.80 Å. No reduction of this distance can be achieved by simple twists without increasing other repulsive interactions. The distance is very close to that observed for the two α-hydrogen–chlorine interactions in our molecule, although there are four such interactions in (*c*). The structure may be possible. A similar argument applies to (*h*).

For case (*a*), py1 and py3 must rotate in the same sense, as must py2 and py4. Further, a twist of about 25° must be introduced about the Re—O—Re bond between the two halves of the dimer to keep py1 and py3 (or py2 and py4) far enough apart. This twist is only possible if both py1 and py2 (and py3 and py4) are rotated in the same sense. In this position, however, the shortest distance between the α-hydrogen on a pyridine ring on one half of the dimer and a chlorine atom on the other half of the dimer is 2.53 Å, about 0.57 Å shorter than the van der Waals radii sum. Since there are four such contacts, and any angular distortion to increase one separation will only shorten another, it seems unlikely such an isomer can exist.

Similar calculations for (*b*) indicate an α-hydrogen chlorine interaction, with a distance of 2.56 Å. There are four such interactions, and again they cannot be relieved through angular distortion without increasing other interactions. Similar arguments apply to (*g*) and (*k*). Thus, we think these isomers are unlikely.

Any system with all rings eclipsed or with a ring on one end of the dimer lying between two rings on the other end (*d*, *e*, *j*) can be ruled out because of ring–ring interactions.

The final structure to consider is (*i*). As the structure is drawn, if py1 is rotated clockwise, so must py3 and py4 and this causes py2 to rotate anticlockwise. The molecule must rotate about Re—Re by

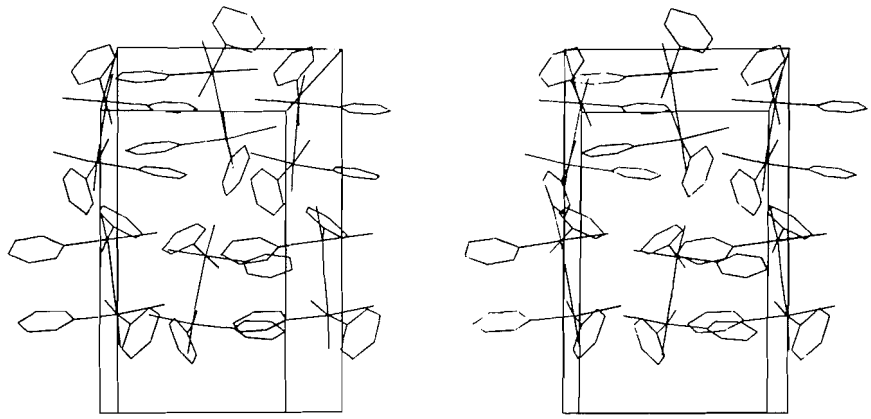

FIG. 4. Stereogram (stereoscopic pair of perspective projections) showing the packing of $ORe(C_5H_5N)_2Cl_2 \cdot O \cdot Re(C_5H_5N)_2Cl_2O$ within the unit cell. Six molecules are shown. The cell is viewed down the ***a*** axis and the ***b*** axis is parallel to the top of the page and the ***c*** axis is parallel to the side of the page.

23° to relieve the py1, py3 interaction and this twist causes py4 to interact with py2. Indeed, if py1, py2, and py3 are rotated to position and then the 23° twist is applied, py4 cannot rotate at all before coming into contact with py2. Thus, (*i*) is not possible.

In doing the calculations we ignored minor distortion that might stabilize a structure, but on the basis of calculations we can divide the structures into groups. They are: not possible, *d*, *e*, *i*, *j*; possible, unlikely, *a*, *b*, *g*, *k*; possible (four repulsions), *c*, *h*; possible (two repulsions), *f*; which is the conformation whose structure is reported in this paper. Thus, all the anomalies in the chemistry, and the answers to the questions posed earlier can be explained in terms of the intramolecular packing requirements of the pyridine rings.

The packing of the molecules in the unit cell is shown in Fig. 4. In the ***b*** direction the atoms Cl(2) and Cl(4) on one molecule are in contact with the hydrogen atoms on the first and fourth pyridine rings in the next translationally equivalent molecule. The small angle between the Re(1)—Re(2) axis and the *ac* plane means that Cl(4) actually fits in between the hydrogen atoms attached to C(13) and C(43).

In both the ***a*** and ***c*** directions the packing pattern is more complicated but the most important feature appears to be contact between chlorine or oxygen atoms and the pyridine rings. There is no parallel contact between pyridine rings, such as we have already noted in each individual molecule, or as we have observed before between molecules containing phenyl rings (25). In the ***c*** direction the chlorine and oxygen atoms on one molecule contact pyridine rings on a neighbour related by the 2_1 operation. In the ***a*** direction the packing can be described in two ways. The molecules are arranged such that the pair of parallel pyridine rings (1 and 4) point roughly along the ***b*** direction. The packing can then be considered about the glide planes at $y = 1/4$ and 3/4. In one case the pairs of molecules related by the *n* glide lie with the pairs of pyridine rings pointing towards the glide planes; in the other case it is Cl(2) and Cl(4) on each molecule which points at the planes. Nevertheless, in both cases the prime contact in the ***a*** direction is between chlorine atoms and pyridine rings, although there are pyridine–pyridine contacts close to the $y = 1/2$ plane. Thus there are no anomalous packing features in the structure and since all distances mentioned above are greater than or equal to the van der Waals contact distances, we conclude that intermolecular packing factors are not of major importance in determining the intramolecular structure.

General method for the synthesis of [*n*.3.3]propellanes, $n \geq 3$

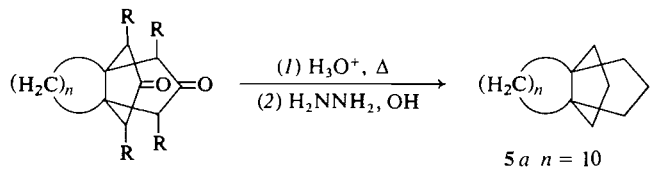
ROBERT W. WEBER AND JAMES M. COOK

Department of Chemistry, University of Wisconsin-Milwaukee, Milwaukee, WI 53201, U.S.A.

Received July 4, 1977

ROBERT W. WEBER and JAMES M. COOK. Can. J. Chem. **56**, 189 (1978).

Reaction of alicyclic-1,2-diones (**2***a–d*) with dimethyl 3-ketoglutarate **1** at room temperature in aqueous buffer (p*H* = 5.6) provided good yields of the tetramethylpropellanedione tetracarboxylates (**3***a–d*), respectively. Hydrolysis and decarboxylation of the β-ketoester functions, followed by Wolff–Kishner reduction of the corresponding propellanediones (**4***a–d*) has resulted in synthesis of [10.3.3]-, [6.3.3]-, [4.3.3]-, and [3.3.3]propellanes (**5***a–d*). The ^{13}C nmr of propellanes **5***a–c* are also reported.



3 *a* $n = 10$ R = CO_2CH_3

[Traduit par le journal]

In 1965 the first reports of the preparation of compounds termed propellanes (1) appeared, and since that time these Y-shaped molecules have received much attention. Investigation of members of the series comprised of small rings has been stimulated by interest in the hybridization (2) and reactivity (3) of the bridgehead–bridgehead, central bond. Ultimately, this has resulted in the construction of a derivative of [2.2.2]propellane (4). In addition, interactions between blades of the individual propellane derivatives have been observed both chemically (5) and spectroscopically (5–7).

The reaction of α-dicarbonyl compounds with dimethyl 3-ketoglutarate **1**, studied recently in some detail, has resulted in preparation of several interesting cyclopentanoid compounds (8*a–d*). Most important for the present work is the reaction of 1,2-cyclododecanedione **2***a* with **1** to yield tetramethyl-[10.3.3]propellane-14,17-dione 13,15,16,18-tetracarboxylate **3***a* which was eventually converted into [10.3.3]propellane **5***a* (8*b*) (Scheme 1). This result, coupled with earlier work in the area (8*a*), has provided a facile, general method for the synthesis of [*n*.3.3]propellanes, $n \geq 3$.

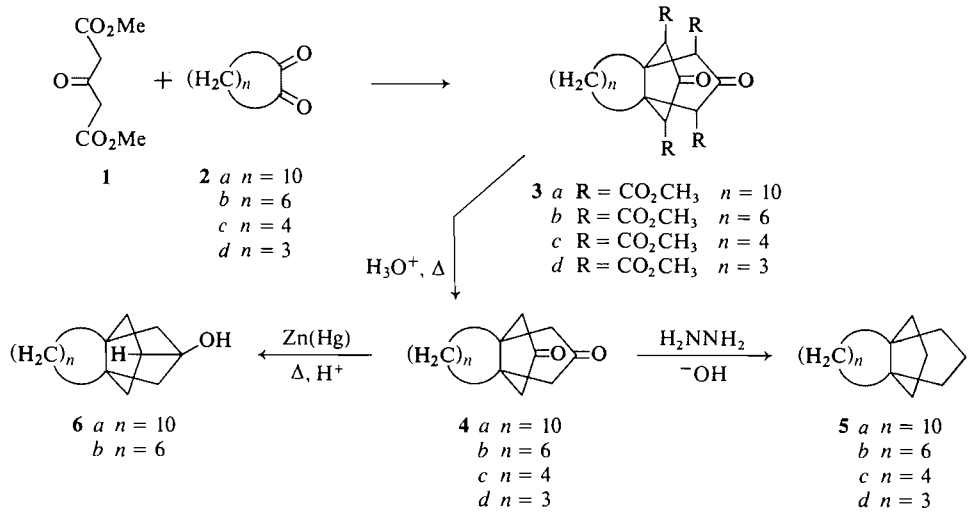

SCHEME 1

The appropriate cycloalkane-1,2-diones were dissolved in aqueous acidic buffer[1] and **1** was added to the mixture. After the mixture was stirred for several days, the tetramethylpropellanedione tetraesters precipitated from the solution. Using this method, the cyclic 1,2-diones **2***a–d* were converted into the corresponding β-ketoesters **3***a–d*, respectively, in yields ranging from 70–95%. Acid hydrolysis of the ester functions and decarboxylation, followed by Wolff–Kishner reduction of the appropriate propellanediones **4***a–d*, provided [10.3.3]-, [6.3.3]-, [4.3.3]-, and [3.3.3]propellanes **5***a–d*, respectively. Because of the various equilibria involved in formation of the tetraesters (8*c*) the proposed preparation of the [3.3.2]propellane system, via dimethylsquarate was unsuccessful. Presumably the strain involved in forming the [3.3.2] system was too great, hence the above procedure is limited to alicyclic-1,2-diones composed of five carbon atoms or more. Conversion of the β-ketoesters **3***a–d* into the propellanediones **4***a–d* was carried out in yields greater than 80%. The poorest reaction in the three-step sequence was the Wolff–Kishner reduction but this transformation was effected consistently at a level of 50% for propellanediones **4***a–d* (60% yield based on recovered starting material).

Clemmensen reduction of the propellanediones **4***a* and **4***b*, under reflux, provided the tetracyclic alcohols **6***a* and **6***b* but not the parent hydrocarbons (8*c*) **5***a* and **5***b*. However, if the Clemmensen reduction of **4***a–d* was carried out at room temperature for 3 weeks a 2–5% yield of the corresponding propellanes **5***a–d* could be obtained.

Although the prospect of rearrangement of the propellanediones under the conditions of reduction is somewhat limited, the ^{13}C nmr of the [10.3.3]-, [6.3.3]-, and [4.3.3]propellanes were recorded to determine if this had occurred. The propellanes described here belong to the C_{2v} point group; consequently, the number of lines in the ^{13}C nmr spectrum should correspond to half the number of equivalent carbon atoms present in the parent hydrocarbon. On examination of the carbon spectra this was found to be the case. In addition, the quaternary carbons could be easily identified at 51.21 ppm, 53.32 ppm, and 54.79 ppm in the [4.3.3]-, [6.3.3]-, and [10.3.3]propellanes, respectively, while the other signals appeared at chemical shifts quite consistent with the structures of the hydrocarbons (see Table 1). The signals in the proton nmr spectra of the propellanes **5***a–d* likewise correlate well with the chemical shifts of adsorptions from methylene groups contained in cyclopentane, cyclohexane, cyclooctane, and cyclododecane rings (9).

This route provides facile entry into a variety of [*n*.3.3]propellanes and could be extended to substituted [*n*.3.3]propellane derivatives. The limitations on extension of the method require that the starting dione **2** contain functionality stable both to acid hydrolysis and to base catalyzed reduction. Entry into these systems should provide templates for study of the steric interactions between blades of a homologous series of propellane derivatives.

Experimental

Microanalyses were performed on an F & M Scientific Corp. carbon, hydrogen, nitrogen analyzer model 185; some

[1]The actual citrate–phosphate buffer employed in this work had a p*H* of 5.6; however, addition of methanol to the reaction to solubilize the α-dicarbonyl compounds resulted in a p*H* of 6.0 to 6.8 depending on the amount of methanol necessary for dissolution of the diones.

analyses were carried out at the National Institutes of Health, Bethesda, MD. Melting points were taken on a Thomas-Hoover apparatus and are uncorrected. Nuclear magnetic resonance spectra were recorded on Varian T-60 and CFT-20 spectrometers. Infrared spectra were recorded on a Beckman Acculab-1 instrument while mass spectra were taken on an Hitachi RMU-6 mass spectrometer.

The citrate–phosphate buffer was prepared by dissolving $Na_2HPO_4 \cdot 7H_2O$ (11.67 g) and citric acid (3.68 g) in water (900.00 ml). Cyclohexane-1,2-dione was purchased from Aldrich Chemical Co.

Cyclododecane-1,2-dione **2***a* (10), cyclooctane-1,2-dione **2***b* (11), and cyclopentane-1,2-dione **2***d* were prepared by published methods. In a previous paper in this series we described the preparation of [10.3.3]propellane **5***a*, tetramethyl[6.3.3]propellane-10,13-dione 9,11,12,14-tetracarboxylate **3***b*, and [6.3.3]-propellane-10,13-dione **4***b* (8*b*).

[6.3.3]Propellane 5b

The propellanedione **4***b* (2 g, 9.1 mmol), hydrazine (11 ml of 95%), and KOH (9 g) were added to diethyleneglycol (40 ml). The resulting mixture was refluxed at 135°C for 2.5 h, at which time the water was distilled from the solution until the pot temperature reached 220°C. The water which distilled from the reaction was extracted with ether (4 × 25 ml) and the combined extracts were dried (Na_2SO_4). The pot residue, which remained, was acidified (aqueous HCl) and then extracted with benzene (5 × 25 ml). The benzene extracts were combined and dried over Na_2SO_4. Evaporation of solvent from either the benzene extract or the ether extract provided a clear oil which contained **5***b*. The oils were combined and chromatographed on alumina (Skelly-B) to yield **5***b* (0.85 g, 50% yield), bp 275–277°C at 760 Torr; ir (neat): 2940 and 2860 cm^{-1}; nmr ($CDCl_3$) δ: 1.50–1.60 (two overlapping singlets); ms *m/e*: 192 (M^+, 81.3), 164 (100), 149 (97.3), 135 (100), 122 (98), and 108 (60). *Anal.* calcd. for $C_{14}H_{24}$: C 87.42, H 12.58; found: C 87.30, H 12.30.

Tetramethyl[4.3.3]propellane-8,11-dione 7,9,10,12-Tetracarboxylate 3c

Cyclohexane-1,2-dione **2***c* (10 g, 0.09 mol) was dissolved in citrate–phosphate buffer (500 ml, p*H* = 5.6) and **1** (31 g, 0.18 mol) was added. After the solution was stirred at room temperature for 2 h, a white precipitate began to form. The mixture was stirred for an additional 2 weeks and then the solid was filtered from the reaction to provide **3***c* (25 g, 70% yield), mp 171–175°C (from methanol); ir (KBr): 2940 (C—H), 1730 (C=O), and 1650 cm^{-1} (enol form of β-ketoester); nmr ($CDCl_3$) δ: 1.45 (4H, m), 1.91 (4H, m), 3.66 (15H, several overlapping singlets of unequal intensity), and 9.90 (1H, s); ms *m/e*: 424 (M^+). *Anal.* calcd. for $C_{20}H_{24}O_{10}$: C 56.60, H 5.70; found: C 56.33, H 5.74.

When **2***c* and **1** were stirred for 2 weeks at p*H* = 8.4 and the solution was then acidified, an 81% yield of crystalline **3***c* was obtained.

[4.3.3]Propellane-8,11-dione 4c

The tetraester **3***c* (5 g, 0.012 mol) was added to hydrochloric acid (100 ml, 6 *N*) and the resulting mixture refluxed for 10 h. A portion of the acid was removed under reduced pressure. The residue was basified with aqueous sodium bicarbonate and then extracted with chloroform (5 × 25 ml). The combined organic extracts were dried over Na_2SO_4. Removal of solvent under reduced pressure furnished an oil which crystallized from methanol to provide **4***c* (1.6 g) in 71% yield, mp 173–174°C; nmr and ir spectra were identical to the spectra obtained on an authentic sample of **4***c* (8*a*).

[4.3.3]Propellane 5c

The propellanedione **4***c* (2 g, 0.01 mol) was added to a mixture of hydrazine (11 ml of 95%), potassium hydroxide (9 g), and diethyleneglycol (40 ml). The slurry was refluxed at 136°C for 2.5 h after which the water was distilled from the reaction until the pot temperature reached 220°C. During the distillation **5***c* crystallized on the condenser. The product was re-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

moved from the condenser and the distillate by washing with ether. The combined extracts were dried (Na_2SO_4) and the ether removed under reduced pressure to provide a white solid **5***c* (0.7 g, 41% yield), mp 100–101°C (from methanol). When the residue from the distillation was acidified and extracted with ether, additional amounts of **5***c* (0.2 g) were obtained: total yield 50%. The combined solids were chromatographed on alumina (Skelly-B) and further purified by vacuum sublimination; nmr ($CDCl_3$) δ: 1.40 (8H, s) and 1.58 (12H, s); ir (KBr): 2920 and 2860 (C—H); ms *m/e* 164 (40, M^+), 136 (60), 121 (100), 107 (13). *Anal.* calcd. for $C_{12}H_{20}$: C 87.73, H 12.27; found: C 87.48, H 12.00.

[3.3.3]Propellane **5***d*

The [3.3.3]propellanedione **4***d* was prepared from **1** and **2***d* by a sequence of reactions exactly analogous to those reported for preparation of the [4.3.3]propellanedione **4***c* (see above), mp 185–187°C (lit. (8*a*) 183°C). The dione **4***d* was then reduced to [3.3.3]propellane **5***d* by the same method employed to prepare the [4.3.3]propellane. The yield of **5***d* was 49%, mp 130°C (lit. 133°C); ir (KBr): 2940 and 2860 cm^{-1}; nmr ($CDCl_3$) δ: 1.50 (this compound **5***d* was prepared independently by Professor Roger Alder, private communication, who kindly provided us with the experimental details of his procedure).

*Conversion of the [*n*.3.3]Propellanediones to [*n*.3.3]Propellanes by Clemmensen Reduction*

Mercuric chloride (0.2 g) was dissolved in a mixture of water (2 ml) and concentrated hydrochloric acid (0.4 ml). To the resulting solution zinc dust (2 g) was added slowly, with stirring. After 5 min the stirring was discontinued and the aqueous solution was decanted from the small lumps of zinc amalgam which had formed. The propellanedione was then added to the amalgam, followed by addition of a solution of concentrated HCl (4 ml), glacial acetic acid (2 ml), and water (1 ml). Many of the propellanediones were not soluble under the above reaction conditions; therefore, acetic acid was added to the reaction 3 days later. Because acetic acid would decompose the amalgam, small portions of amalgam (1 g) had to be added to the mixture five times over the course of a 3 week period. The reaction mixture was stirred at room temperature for 3 weeks.

The amalgam was filtered from the mixture and the mother liquor then made basic with sodium hydroxide (50 ml, 6 *N*). Extraction of the basic solution with ether followed by removal of the ether under reduced pressure provided an oil which was chromatographed on Al_2O_3 to provide small amounts (2–5%) of the propellanes **5***a–d*.

Received July 15, 1977

KENICHIRO TANAKA, GERVASE I. MACKAY, and DIETHARD K. BOHME. Can. J. Chem. **56**, 193 (1978).

The flowing afterglow technique has been employed in the measurement of rate and equilibrium constants at 296 ± 2 K for unsolvated proton transfer reactions of the type $XH^+ + Y \leftrightarrows YH^+ + X$ and several solvated proton transfer reactions of the type $XH^+\cdot X + Y \leftrightarrows YH^+\cdot X + Y$ where X and Y may be H_2O, H_2S, HCN, or H_2CO. Where possible, direct comparisons are made with similar measurements performed with other techniques. The equilibrium constant measurements provide a measure of the relative proton affinities of H_2O, H_2S, HCN, and H_2CO and absolute values for $PA(H_2O) = 166.4 \pm 2.4$ kcal mol^{-1}, $PA(H_2S) = 170.2 \pm 1.8$ kcal mol^{-1}, and $PA(HCN) = 171.0 \pm 1.7$ kcal mol^{-1} when reference is made to $PA(H_2CO) = 170.9 \pm 1.2$ kcal mol^{-1} which can be derived from available thermochemical information. The rate constant measurements reinforce the generalization that unsolvated proton transfer involving simple molecules proceeds with high efficiency and provide information about the influence of solvation on this efficiency.

KENICHIRO TANAKA, GERVASE I. MACKAY et DIETHARD K. BOHME. Can. J. Chem. **56**, 193 (1978).

On a utilisé la technique d'écoulement post-luminescent dans le but de mesurer les constantes de vitesse et d'équilibre à 296 ± 2 K des réactions de transfert de protons non-solvatés du type $XH^+ + Y \leftrightarrows YH^+ + X$ et pour plusieurs réactions de transfert de protons solvatés du type $XH^+\cdot X + Y \leftrightarrows YH^+\cdot X + Y$ où X et Y peuvent être H_2O, H_2S, HCN ou H_2CO. Lorsque la possibilité existait, on a fait des comparaisons directes avec des mesures semblables effectuées par d'autres techniques. Les mesures de constante d'équilibre nous ont fourni une mesure des affinités relatives des protons pour H_2O, H_2S, HCN et H_2CO et des valeurs absolues pour $PA(H_2O) = 166.4 \pm 2.4$ kcal mol^{-1}, $PA(H_2S) = 170.2 \pm 1.8$ kcal mol^{-1} et $PA(HCN) = 171.0 \pm 1.7$ kcal mol^{-1} lorsque l'on se réfère à une valeur de $PA(H_2CO) = 170.9 \pm 1.2$ kcal mol^{-1} qui peut être obtenue à partir de données thermochimiques. Les mesures de constantes de vitesse renforcent la généralisation à l'effet que le transfert d'un proton non-solvaté impliquant des molécules simples se produit avec une grande efficacité et fournissent une information concernant l'influence de la solvatation sur cette efficacité.

[Traduit par le journal]

Introduction

Over the past few years a variety of gas-phase experimental techniques have been applied to the determination of the relative proton affinities of molecules through measurements which attempt to establish values for equilibrium constants of proton-transfer reactions of the type

$$[1] \qquad XH^+ + Y \rightleftarrows YH^+ + X$$

proceeding in partially ionized gas mixtures at both low and high total pressures (1). Such measurements have led to reports of relative proton affinity 'ladders' incorporating a large number and variety of inorganic and organic molecules. Absolute scales are assigned to such ladders usually with the aid of thermodynamic information gained from (nonequilibrium) photon or electron impact studies.

The purpose of this study is twofold. It is directed in part towards a determination of the absolute proton affinities of HCN, H_2S, and H_2O. Equilibrium constant measurements are attempted for reactions of type [1] which allow the construction of a relative proton affinity ladder which links these molecules to H_2CO. Absolute values for proton affinities are derived to within ±2 kcal mol^{-1} by referring to the proton affinity of H_2CO which can be established from the photoionization appearance potential measurements of H_2COH^+ from CH_3OH reported by Refaey and Chupka (2). Such an accuracy is acceptable for most chemical applications. The proton affinity of H_2O is, of course, of special importance and interest. Unfortunately, its value has experienced a considerable variation with time. Only very recently, equilibrium constant measurements made

with a high-pressure pulsed electron-beam ion source mass spectrometer (3) and with low-pressure pulsed ion cyclotron resonance (4) have suggested values for $PA_{298}(H_2O) = 169 \pm 2$ and 170 ± 2 kcal mol^{-1}, respectively, which are somewhat higher than the value of 165 ± 3 kcal mol^{-1} previously preferred by Long and Munson (5).

Secondly, the equilibrium constant measurements chosen in this study allow direct comparisons to be made with similar measurements performed with other techniques which employ a variety of modes of ion production, containment, and detection and encompass a wide range of operating conditions such as total pressure, ion and neutral concentrations, temperature, reaction time, and ambient electric fields. Such comparisons, which have not been as frequent as one might have expected, are instructive in establishing the applicability and reliability of the various techniques which have been employed for such measurements (6–8).

Experimental

The experiments were performed with a flowing afterglow system in the manner described previously (9). The reactant ions $XH^+ = H_3O^+$, H_3S^+, H_2CN^+, and H_2COH^+ were established in a flowing hydrogen plasma by fast proton-transfer reactions of the type

$$[2] \qquad H_3^+ + X \rightarrow XH^+ + H_2$$

which proceed upon the addition of the appropriate gas X downstream of the ionizer. H_3^+ was established by the fast reaction

$$[3] \qquad H_2^+ + H_2 \rightarrow H_3^+ + H$$

Sufficient X was added to ensure that reaction 2 reached completion prior to the reaction region. H_3O^+ was also generated in a helium–water vapour plasma by the reaction

$$[4] \qquad H_2O^+ + H_2O \rightarrow H_3O^+ + OH$$

The neutral reactants were added sufficiently downstream of the ion production region to ensure thermalization of the XH^+ ions by collisions with the carrier gas molecules to the ambient temperature of 296 ± 2 K prior to reaction. The total pressure in the reaction region was in the range $P = 0.27$ to 0.65 Torr, the effective reaction length had values in the range $L = 59$–85 cm, and the average flow velocity had values in the range $\bar{v} = 7.3$–8.2×10^3 cm s^{-1}. At the end of the reaction region the plasma was sampled with a quadrupole mass spectrometer through a small orifice mounted at the tip of a sampling nose cone. The observed variations in the reactant and product ion signals as a function of reactant gas addition at a fixed addition of the back-reactant gas provided the raw data from which the rate and equilibrium constants were derived.

The gases used were helium (Linde, Prepurified Grade, 99.995% He), hydrogen (Linde, Very Dry Grade, 99.95% H_2), and H_2S (Matheson, C.P. Grade, 99.5% H_2S). The water vapour was derived from either boiled tap water or boiled distilled water. The HCN was prepared by the action of sulfuric acid on an aqueous solution of KCN (10), dried by passing over anhydrous $CaCl_2$, and further purified by distillation *in vacuo*. Monomeric formaldehyde was prepared from paraformaldehyde (Fisher Scientific, Purified Grade) by an adaptation of the method developed by Spence and Wild (11). Paraformaldehyde was distilled at low pressures at ~370 K. The formaldehyde was then dried by passing it through a cold trap at 195 K and frozen out at liquid nitrogen temperatures. A gaseous mixture of ~5% formaldehyde in helium was used in these studies. The partial pressure of the formaldehyde was maintained at between 5 and 7 Torr to avoid polymerization. The monomer could be stored at these pressures for several days with negligible polymerization.

All experiments were carried out at a room temperature of 296 ± 2 K.

Results

The results of the measurements of rate and equilibrium constants for the proton-transfer reactions investigated in this study are summarized in Tables 1 and 2. An account of the data analysis and sources of error has been given previously (9, 14). Complications which may arise as a result of diffusion, competing reaction channels, and clustering reactions of the reactant and product ions have also been dealt with in detail elsewhere (14, 15).

Reaction 5

$$[5] \qquad H_3O^+ + H_2S \rightleftharpoons H_3S^+ + H_2O$$

The reaction of H_3O^+ with H_2S was observed to proceed rapidly by proton transfer to produce H_3S^+. Equilibrium was achieved in both H_2 (eight experiments) and He (five experiments) carrier gases over a range of $P = 0.290$–0.65 Torr and flow of H_2O from 2.13 to 4.96×10^{18} molecules s^{-1}. There was no evidence for the occurrence of competing reaction channels and no serious complications were introduced into the data analysis under these conditions by the clustering reactions of H_3O^+ with H_2O and H_3S^+ with H_2S. Figure 1 illustrates the determination of k_5, k_{-5} and k_5/k_{-5} from a fit to the H_3O^+ decay, whereas Fig. 2 indicates the determination of K_5 from the variation of the product to reactant ion signal ratio (corrected for mass discrimination) with H_2S addition. The cluster ions $H_3O^+ \cdot H_2O$ and $H_3O^+ \cdot 2H_2O$ did not react rapidly with H_2S, $k \lesssim 10^{-12}$ cm^3 $molecule^{-1}$ s^{-1}. Their initial decay shown in Fig. 1 is due to the depletion in the reaction region of the precursor ions, H_3O^+ and $H_3O^+ \cdot H_2O$, respectively.

Trace amounts of SF_6 were added in one H_2 and one He experiment to test the validity of the assumption of equal diffusion losses for H_3O^+ and H_3S^+. The values derived for k_5/k_{-5} (from the fit to the H_3O^+ decay) and K_5 (from the ratio plot) were observed to be insensitive to the change in the mode of diffusion from ion–electron to ion–ion brought about by the added SF_6.

Reaction 6

[6] $H_3O^+ + HCN \rightleftharpoons H_2CN^+ + H_2O$

H_3O^+ was observed to react rapidly with HCN to produce H_2CN^+ in four experiments in which H_2 was used as the carrier gas. Equilibrium was achieved in all four experiments over a range of $P = 0.342$–0.405 Torr and a range of H_2O flow from 3.61 to 4.59×10^{18} molecules s^{-1}. Again there was no evidence for the occurrence of competing reaction channels and no serious complications were introduced into the data analysis by the occurrence of clustering reactions. $H_3O^+ \cdot H_2O$ appeared to react with HCN, $k = 1 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}. A concomitant increase in the $m/e = 46$ signal suggested the occurrence of what might, in this context, be more appropriately regarded as a solvated proton-transfer reaction:

[7] $H_3O^+ \cdot H_2O + HCN \rightarrow H_2CN^+ \cdot H_2O + H_2O$

rather than a solvent 'switching' reaction:

[8] $H_3O^+ \cdot H_2O + HCN \rightarrow H_3O^+ \cdot HCN + H_2O$

The analysis of the behaviour of the $H_3O^+ \cdot 2H_2O$ signal was complicated by its overlap at $m/e = 55$ with $H_2CN^+ \cdot HCN$.

Reaction 9

[9] $H_3S^+ + HCN \rightleftharpoons H_2CN^+ + H_2S$

The equilibrium for this reaction was approached from both directions in H_2 carrier gas. Seven experiments were carried out in the forward direction over a range of $P = 0.362$–0.51 Torr and flow of H_2S from 0.247 to 3.24×10^{18} molecules s^{-1}. Proton transfer was the only observed reaction channel. Equilibrium was achieved in six experiments. The product H_2CN^+ was observed to react further at large additions of HCN to produce the cluster ion $H_2CN^+ \cdot HCN$. Our standard analysis (9) allowed a good fit to the H_3S^+ decay and the H_2CN^+/H_3S^+ ion signal ratio plot at additions of HCN below $\sim 1 \times 10^{18}$ molecule s^{-1}. At higher additions the rate of the reaction of H_2CN^+ with HCN appeared to approach that for the back reaction of H_2CN^+ with H_2S to an extent sufficient to drive the reaction slightly out of equilibrium (case 5 in ref. 14).

The perturbation introduced by the further reaction of the product ion with the added reactant gas apparent in the attainment of equilibrium in the forward direction was observed to be less severe in the reverse direction presumably as a result of the lower rate of association of H_3S^+ with H_2S. Five experiments were carried out in the reverse direction in H_2 carrier gas at pressures $P = 0.363$–0.61 Torr

$H_3O^+\cdot H_2O + HCN \rightarrow H_2CN^+\cdot H_2O + H_2O$	0.10	2		
$H_2CN^+\cdot HCN + H_2S \rightarrow H_3S^+\cdot HCN + HCN$	≲0.001			

[a]Values for $k_{forward}$ were determined using either analysis A or B (9). The limits given along with the mean value represent the precision. The accuracy is estimated to be ±20% for the reactions of H_3O^+, ±25% for the reactions of H_3S^+, and ±30% for the reactions of $H_2CN^+\cdot HCN$ and $H_3O^+\cdot H_2O$.

[b]N represents the number of measurements.

[c]The value of K represents the weighted mean together with the standard error of measurements of k_f/k_r and K in one or both directions of the reaction (12).

[d]Includes seven previous determinations (13).

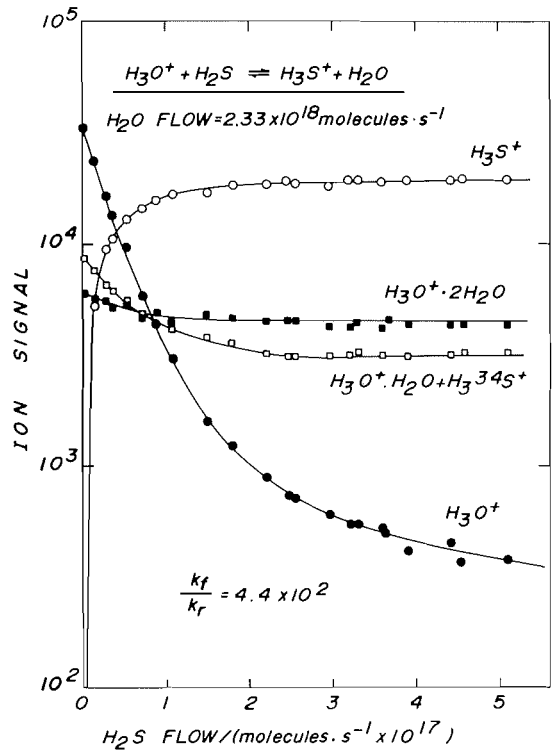

FIG. 1. The observed variation of H_3O^+, $H_3O^+\cdot H_2O$, and $H_3O^+\cdot 2H_2O$ upon the addition of H_2S into a H_2O–H_2 plasma in which H_3O^+ is initially a dominant ion. The solid line drawn through the H_3O^+ decay is a fit which provides the values $k_f = 1.9 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}, $k_r = 4.4 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}, and $k_f/k_r = 4.4 \times 10^2$ for the proton transfer to H_2S; $T = 296$ K, $P = 0.432$ Torr, $\bar{v} = 7.7 \times 10^3$ cm s^{-1}, and $L = 85$ cm.

and HCN flows in the range from 0.92 to 3.05 × 10^{17} molecules s^{-1}. The equilibrium constant derived from fits to the observed H_2CN^+ decays and the H_3S^+/H_2CN^+ ion signal ratio plots corrected

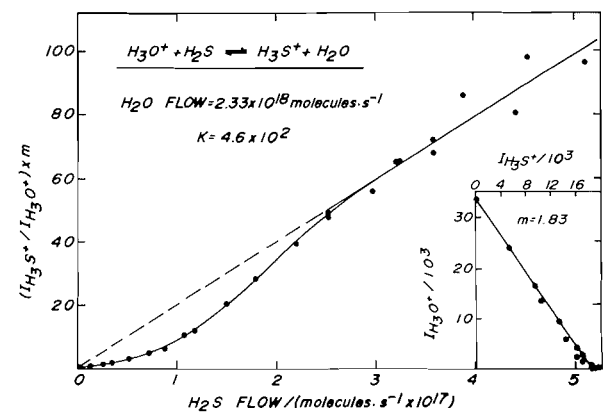

FIG. 2. The observed variation of the product to reactant ion signal ratio (corrected for mass discrimination) with the flow of neutral reactant, H_2S, at constant flow of neutral back reactant, H_2O. The initial curvature reflects the approach to equilibrium. The insert illustrates the determination of the mass discrimination factor, m; $T = 296$ K, $P = 0.432$ Torr, $\bar{v} = 7.7 \times 10^3$ cm s^{-1}, and $L = 85$ cm.

for mass discrimination was in good agreement with that determined from the study of the forward direction. The $H_2CN^+\cdot HCN$ present in the reaction region was observed not to react rapidly with the added H_2S, $k \gtrsim 10^{-12}$ cm^3 molecule^{-1} s^{-1}.

Reaction 10

[10] $H_3S^+ + H_2CO \rightleftharpoons H_2COH^+ + H_2S$

This reaction was also investigated in both directions in H_2 carrier gas. Four experiments were carried out in the forward direction over a range of P = 0.268–0.336 Torr and flow of H_2S from 2.04 to 9.6 × 10^{17} molecules s^{-1}. The results for one of these experiments is shown in Fig. 3 which indicates the production of H_2COH^+ from H_3S^+ as H_2CO is added into the flowing plasma. H_2COH^+ appears to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

react further with H_2CO to form the cluster ion $H_2COH^+ \cdot H_2CO$ presumably via a three-body association reaction. The production of CH_3S^+, which was observed to be enhanced at the higher flows of H_2S, can be attributed to reaction 11 which is exothermic by several kcal mol^{-1}. Both reaction 11 and the association reaction of H_2COH^+ with H_2CO act as sinks for H_2COH^+ which compete with the reverse proton transfer [−10] and can prevent the establishment of true equilibrium. The incorporation of reasonable rates for these reactions into an extended analysis (case 2 and case 5 in ref. 14) indicated that the decay of H_3S^+ shows decreased curvature under these conditions so that the apparent value of k_{10}/k_{-10} determined from a fit to the H_3S^+ decay should be regarded as an upper limit to the true value. However the apparent value of the equilibrium constant determined from the ratio plot should still be nearly equal to the true value under these same conditions.

[11] $$H_2COH^+ + H_2S \rightarrow CH_3S^+ + H_2O$$

Four experiments were carried out in which H_2S was added into a flowing H_2 plasma in which H_2COH^+ was initially the dominant ion. Values of P were in the range 0.296–0.339 Torr and the flow of H_2CO had values in the range 0.71–1.95 × 10^{17} molecules s^{-1}. The proton-transfer reaction −10 was again observed to proceed in competion with reaction 11. Neither H_3S^+ nor CH_3S^+ appeared to react further with H_2S, $k \gtrsim 10^{-12}$ cm^3 $molecule^{-1}$ s^{-1}. The H_3S^+/CH_3S^+ ion signal ratio at saturation which was observed to be independent of H_2CO addition led to a value for $k_{-10}/k_{11} \cong 5$. In this case the extended analysis (case 4 in ref. 14) indicated that the apparent value of k_{-10}/k_{10} determined from a fit to the H_2COH^+ decay should be regarded as an upper limit to the true value and hence a lower limit to the true value of k_{10}/k_{-10}. However, the ratio plot should again provide a good measure of the true equilibrium constant.

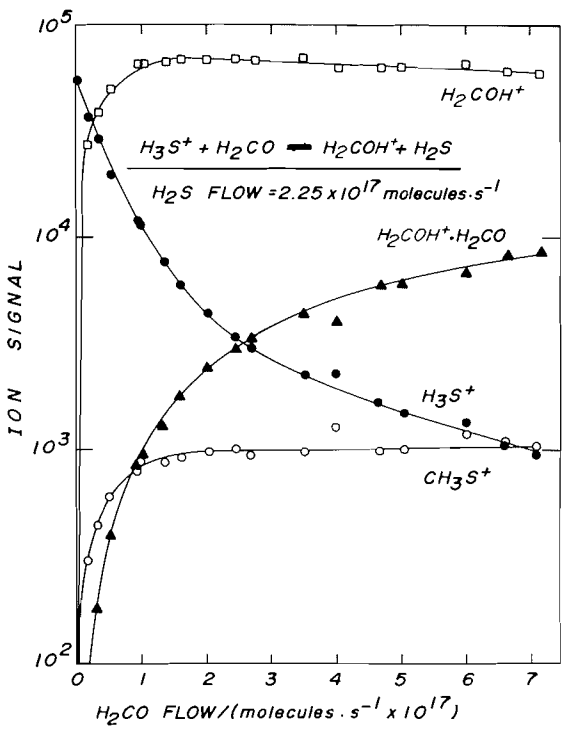

FIG. 3. The observed variation of ion signals with the flow of H_2CO at constant flow of H_2S. The solid line drawn through the H_3S^+ decay is a fit which provides values for $k_f = 2.1 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1} and $k_f/k_r \leq 15$; $T = 297$ K, $P = 0.308$ Torr, $\bar{v} = 7.5 \times 10^3$ cm s^{-1}, and $L = 59$ cm.

Reaction 12

[12] $$H_2CN^+ + H_2CO \rightleftharpoons H_2COH^+ + HCN$$

The interconversion of ions observed upon the addition of H_2CO into a flowing HCN–H_2 plasma in which H_2CN^+ is initially a dominant ion is illustrated in Fig. 4. H_2CN^+ appeared to react with H_2CO by proton transfer only to produce H_2COH^+ which reacted further with H_2CO to form the

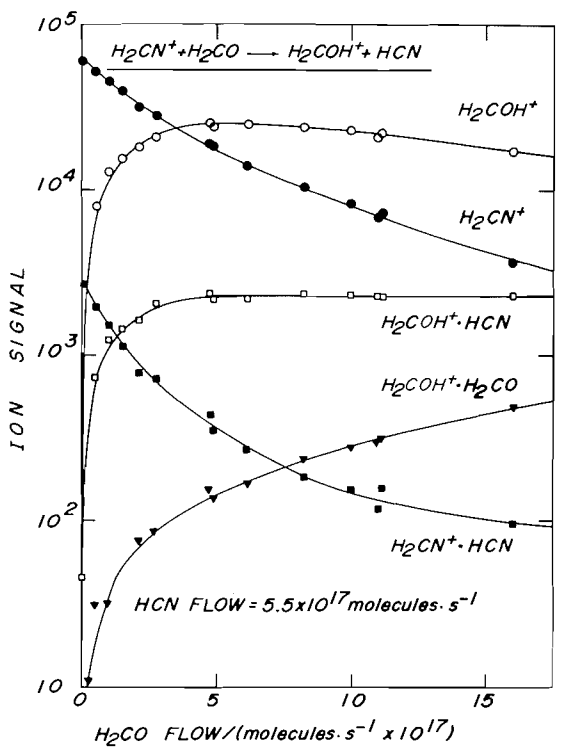

FIG. 4. The observed variation of ion signals with the flow of H_2CO at constant flow of HCN. The solid line drawn through the H_2CN^+ decay is a fit which provides values for $k_f \geq 1.6 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1} and $k_f/k_r < 4$; $T = 297$ K, $P = 0.371$ Torr, $\bar{v} = 8.1 \times 10^3$ cm s^{-1}, and $L = 85$ cm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$H_2COH^+ \cdot H_2CO$ cluster ion. The rate of this latter reaction was sufficient to allow the determination of only a reliable upper limit to k_{12}/k_{-12} (case 5 in ref. 14) from a fit to the H_2CN^+ decay while the corresponding ratio plot still allowed a reasonable measure of K_{12}.

It is also apparent from Fig. 4 that $H_2CN^+ \cdot HCN$ reacts with H_2CO in a manner which may be represented by the solvated proton-transfer reaction

[13] $H_2CN^+ \cdot HCN + H_2CO \rightarrow H_2COH^+ \cdot HCN + HCN$

The decay of the $H_2CN^+ \cdot HCN$ signal and the $H_2COH^+ \cdot HCN/H_2CN^+ \cdot HCN$ ratio plot provided values for $k_{13} = (6 \pm 2) \times 10^{-10}$ cm^3 molecules^{-1} s^{-1} and $K_{13} = 8.9 \pm 2.2$.

The study of reaction 12 in its reverse direction allowed a more reliable determination of its equilibrium constant largely as a result of the somewhat slower rate of clustering of H_2CN^+ with HCN in the H_2 carrier gas. The values of k_{-12}/k_{12}, determined from a fit to the H_2COH^+ decay, and K_{-12}, determined from the H_2CN^+/H_2COH^+ ratio plot, were found to be in agreement within experimental error in three experiments in which P had values from 0.363 to 0.370 Torr and the flow of H_2CO had values in the range 4.72–8.1 $\times 10^{16}$ molecules s^{-1}. The $H_2COH^+ \cdot H_2CO$ cluster ion present in the flowing H_2CO–H_2 plasma was observed to react with HCN ($k \gtrsim 1 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) in a manner which can be represented by the solvated proton-transfer reaction

[14] $H_2COH^+ \cdot H_2CO + HCN \rightarrow H_2CN^+ \cdot H_2CO + H_2CO$

The $H_2CN^+ \cdot H_2CO/H_2COH^+ \cdot H_2CO$ ratio plots indicated that equilibrium was established for this reaction at all flows of HCN and provided a value for $K_{14} = 1.6 \pm 0.6$. A ratio plot analysis of the further reaction of $H_2CN^+ \cdot H_2CO$ with HCN provided three additional determinations of $K_{13} = 8.6 \pm 3.0$ with the equilibrium state now being approached from the reverse direction.

Discussion

Equilibrium Constant Measurements

Confidence in the assertion that the equilibrium constants measured in this study represent true equilibrium is provided by the following observations, each of which is required for equilibria of elementary reactions such as those investigated in this study (7, 9, 15):

(*i*) The agreement between the ratios of rate constants determined from fits to the primary ion decays (which are independent of mass discrimination in the sampling system) and the equilibrium constants determined from the measured equilibrium ion concentrations (corrected for mass discrimination).

(*ii*) The constancy of the measured ratios of rate constants and equilibrium constants over the range in reaction time, neutral concentrations and total pressure adopted in these experiments. In the case of reaction 5, constancy was also observed over the range of electron and ion densities achieved by the addition of SF_6.

(*iii*) The independence of the measured ratios of rate constants and equilibrium constants on the direction of approach to equilibrium (in the case of reactions 9, 10, and 12).

(*iv*) The internal consistency between single-step and multi-step measurements. The equilibrium constant of $(5.8 \pm 1.3) \times 10^2$ determined from a direct study of the H_3O^+/H_3S^+ system agrees within experimental error with the value of $(7.8 \pm 2.7) \times 10^2$ determined indirectly from a study of the H_3O^+/H_2CN^+ and H_3S^+/H_2CN^+ systems. Also the value of 5.1 ± 0.6 for the equilibrium constant of the H_3S^+/H_2CN^+ system compares favourably with the value of 6.3 ± 3.0 which can be derived from the equilibrium constants determined for the H_3S^+/H_2COH^+ and H_2CN^+/H_2COH^+ systems.

A number of reported equilibrium constant measurements performed with a variety of experimental techniques are available for comparison, particularly in the case of reaction 5. These are summarized in Table 3. The deuterium analogue of reaction 5:

[15] $D_3O^+ + D_2S \rightleftarrows D_3S^+ + D_2O$

was investigated by Chong *et al.* (16) in electron impact ion source mass spectrometer experiments involving intensity measurements of D_3O^+ and D_3S^+ in mixtures of D_2O and D_2S in various known proportions at total pressures in the range 0.339–0.680 Torr. Chong *et al.* (16) reported a value for the equilibrium constant of 14.4 ± 1.9 at an ion source temperature of 340 ± 5 K. Hopkins and Bone (17) approached the equilibrium state for [5] in the reverse direction in a photoionization source in mixtures of pure H_2O and H_2S at total pressures ≤ 1.22 Torr and temperatures of 296, 355, and 426 K at which somewhat lower values of 6.7, 2.8, and 1.6, respectively, were obtained for the apparent equilibrium constant. Yamdagni and Kebarle (3) have recently investigated this equilibrium at higher temperatures in the range 570 to 660 K at total pressures in the range 0.5–4 Torr in a pulsed electron-beam ion source. High purity methane was used as the carrier gas in these latter experiments. Moet-Ner and Field (18) have also examined this equilibrium in a pulsed electron-beam ion source in a four-component mixture of 3% H_2O + 1% H_2S + 1% CS_2 in CH_4. In

these experiments the temperature was varied between 480 and 580 K at total pressures in the range 0.7–2.5 Torr. Recent pulsed ion cyclotron resonance measurements (4) of the equilibrium state at 303 K for the reactions

[16] $H_3O^+ + CF_3CH_2OH \rightleftarrows CF_3CH_2OH_2^+ + H_2O$

[17] $CF_3CH_2OH_2^+ + H_2S \rightleftarrows H_3S^+ + CF_3CH_2OH$

also provide a value for $K_5 = K_{16}K_{17} = (4.4 \pm 0.5) \times 10^2$ which was borne out by one direct measurement of K_5. These measurements were taken at a total pressure of $\sim 10^{-6}$ Torr in the absence of a carrier gas. The flowing afterglow measurements reported here were carried out at 296 ± 2 K in the presence of a large excess of either H_2 or He at total pressures in the range 0.290–0.65 Torr. The results of all six groups of investigators are compared in the Van't Hoff plot shown in Fig. 5. Reasonable agreement is apparent only between the extrapolated high-pressure ion source results of Yamdagni and Kebarle (3), the ion cyclotron resonance measurement at 303 K and the flowing afterglow result reported here. The higher values and temperature dependence of the equilibrium constant implied by the measurements of Moet-Ner and Field (18) lead to a difference of almost an order of magnitude at room temperature. The values of the equilibrium constants reported by Chong *et al.* (16) and Hopkins and Bone (17) are both lower by more than one order of magnitude from the corresponding extrapolated values. In the case of reactions 9, 10, and 12 further comparisons can be made between the results obtained with the ion cyclotron resonance and flowing afterglow techniques. It is apparent from the values given in Table 3 that the equilibrium constants determined with these two techniques for these three reactions disagree within the quoted experimental uncertainties, albeit never by more than a factor of 2.

There are several possible origins for the discrepancies between the various types of measurements. Differences may arise from uncertainties associated with the detection and measurement of ion signals and the measurement of neutral concentrations and temperature. The extent to which such uncertainties contribute to the observed differences could not be ascertained since an adequate assessment of the overall accuracy of the measurements was not always reported. Discrepancies may also arise from differences in conditions prevailing in the actual reaction regions of the various techniques, especially as regards the presence of ambient electric fields, the magnitudes of the temperatures as well as the partial and total pressures and the presence of a carrier gas. The influence of an ambient electric field on equilibrium constant measurements has recently been carefully investigated by Meisels *et al.* (8) particularly in conjunction with such measurements as they are carried out by high-pressure ion source mass spectrometry of the type employed by Chong *et al.* (16). In their systematic study of the equilibrium

[18] $CO_2H^+ + CH_4 \rightleftarrows CH_5^+ + CO_2$

these authors have observed a strong variation of the value of the equilibrium constant with field strength: for this exothermic reaction the equilibrium constant was observed to decrease substantially as the strength of the ambient field increased, viz. as the average ion energies were shifted upward and the ion velocity distributions lost Maxwell–Boltzmann character. On

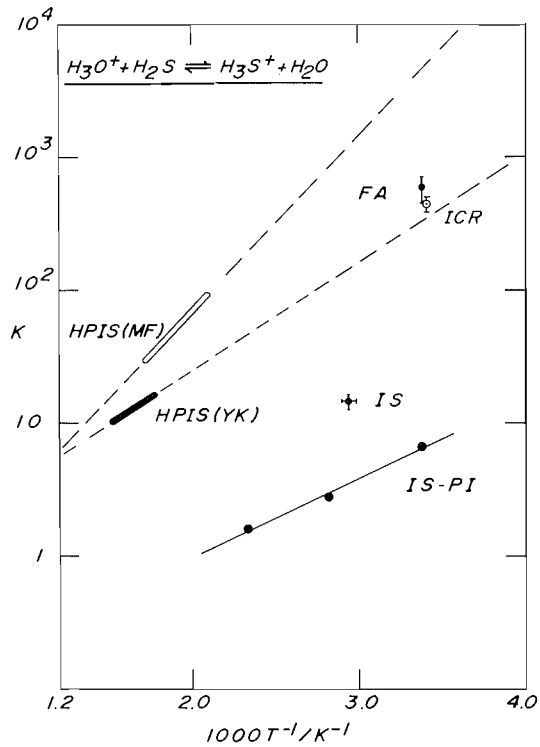

FIG. 5. Van't Hoff plot showing a comparison of the apparent equilibrium constants measured for the reaction $H_3O^+ + H_2S \rightleftarrows H_3S^+ + H_2O$ with a variety of experimental techniques: IS, electron beam ion source mass spectrometer (16); IS–PI, photo-ionization source mass spectrometer (17); HPIS, pulsed electron beam high-pressure ion source mass spectrometer (3, 18); ICR, pulsed ion cyclotron resonance (4); and FA, flowing afterglow, this work.

the basis of these observations, Meisels *et al.* (8) drew attention to the systematic error that can generally be introduced into equilibrium constant measurements with techniques which employ external fields unless the field strength approaches zero. A second complication is readily apparent from the observations reported by Hopkins and Bone (17) in their study of reaction 5 in its reverse direction. At the temperatures, partial pressures of H_2O and total pressures employed in their experiments, complications were introduced by the clustering of H_3O^+ to higher hydrates, an extraneous sink for H_3O^+ which must be properly taken into account in a complete data analysis. Apparently the rate of clustering of H_3O^+ in these experiments was sufficiently high to prevent the establishment of equilibrium between H_3O^+ and H_3S^+ at all convenient operating conditions. Not being able to determine equilibrium constants directly from a measured H_3O^+ ion signal ratio, these authors were led instead to analyze their data kinetically in terms of a steady state assumption. While the partial pressures of H_2O employed by Chong *et al.* (16) were similar to those used in the photoionization source experiments of Hopkins and Bone (17), those used in the flowing afterglow experiments, the ion cyclotron resonance experiments and the ion source experiments of Yamdagni and Kebarle (3) were many orders of magnitude lower. In the latter two sets of experiments the tendency of H_3O^+ to cluster was reduced still further by the lower total pressures and higher prevailing temperatures, respectively. We have recently considered in detail the constraints introduced into equilibrium constant determinations under flowing afterglow conditions by the occurrence of clustering reactions, indeed of competing reactions generally (14, 15). It was evident from these considerations that a judicious choice of partial pressures of the neutral reagents and the direction of approach to equilibrium is often required to ensure a successful determination of an equilibrium constant. A similar analysis has since been reported by ion cyclotron resonance practitioners (19) who have come to similar conclusions. Finally, only in the high-pressure ion source measurements and the flowing afterglow measurements reported here was it common practice to add a carrier gas in large excess. A carrier gas is normally required to allow both the reactants and products to establish thermal equilibrium with their common surroundings prior to reaction. The uncertainties introduced by the failure to use a carrier gas will be determined in part by the extent to which the product ions are initially formed in disequilibrium and can therefore be expected to be reaction specific. The extent to which the low values of equilibrium constant for [5] obtained in the experiments by Chong *et al.* (16) and Hopkins and Bone (17) which were carried out in pure H_2O/H_2S (D_2O/D_2S) mixtures and the differences between the ion cyclotron resonance and flowing afterglow results for reactions 5, 9, 10, and 12 can be accounted for in this way is uncertain.

Thermochemistry

The changes in standard free energy derived from the equilibrium constant measurements for the five unsolvated proton-transfer reactions and the two solvated proton-transfer reactions investigated in this study are summarized in Table 4. Changes in standard entropy were estimated from changes in molecular rotational symmetry numbers; viz, it was assumed that $\Delta S^0 \approx \Delta S^0_{rot}$ (3, 4). Such a treatment has recently been found to be valid to within ± 1.5 cal mol^{-1} deg^{-1} for a large number and variety of proton-transfer reactions (4). In the determination of the rotational symmetry numbers of the ions, account has been taken of what is known from calculations about their geometry (20, 21). The use of

[c]Determined with the relationship $\Delta H^0 = \Delta G^0 + T\Delta S^0$.

entropies of isoelectronic species (given in parentheses) for the ions H_3O^+ (NH_3), H_3S^+ (PH_3), and H_2CN^+ (C_2H_2) provides values for ΔS^0_{298} of 0 ± 0.5, −1.1 ± 1.0, and −1.2 ± 1.0 cal mol^{-1} deg^{-1} for reactions 5, 6, and 9, respectively, when the entropies are taken from the JANAF tables (22). The agreement with the results obtained from the calculations using symmetry numbers is good in the case of reaction 5 but poor for the latter two reactions since the isoelectronic arguments fail to take into account the difference in the rotational symmetry numbers of H_2CN^+ ($H—C\equiv\overset{+}{N}—H$) and C_2H_2. Previous direct experimental determinations of standard entropy changes are available only for reaction 5 and the reaction

[19] $$H_3O^+ + H_2CO \rightleftarrows H_2COH^+ + H_2O$$

Yamdagni and Kebarle (3) obtained a value of −1.0 ± 0.4 cal mol^{-1} deg^{-1} for ΔS^0 of reaction 5 but these authors were quick to point out that this value is not supported by what is known about the geometrics of H_3O^+ and H_3S^+. Allowing for possible inaccuracies in their experimental determination of ΔS^0, they preferred the value of 0 cal mol^{-1} deg^{-1} arrived at from the isoelectronic and symmetry considerations just mentioned. The value of −5.5 ± 0.2 cal mol^{-1} deg^{-1} derived by Hopkins and Bone (17) from their Van't Hoff plot is clearly unreasonable, while the value of −2.2 ± 1.0 cal mol^{-1} deg^{-1} reported by Moet-Ner and Field (18) appears to be too high. Reaction 19 has been investigated in a variable-temperature flowing afterglow by Fehsenfeld and co-workers (23) who obtained a standard entropy change at a mean temperature of 470 K of 2.2 ± 3.0 cal mol^{-1} deg^{-1} for this reaction which agrees remarkedly well with the sum of the standard entropy changes derived for reactions 5 and 10 from the rotational symmetry arguments.

The value of −3.8 ± 0.6 kcal mol^{-1} for ΔH^0_{298} determined here for reaction 5 may be compared with those which have derived from the Van't Hoff plots shown in Fig. 5: −3.7 ± 0.3 kcal mol^{-1} (3), −2.9 ± kcal mol^{-1} (17), and −5.0 ± 0.4 kcal mol^{-1} (18). Good agreement is apparent only with the results of Yamdagni and Kebarle (3). A comparison may also be made with the value for ΔH^0_{298} which can be derived indirectly from the standard enthalpy changes determined previously by pulsed high-pressure ion source mass spectrometer measurements of the temperature dependence of the equilibrium constants for the reactions [20]–[22]:

[20] $$H_3O^+ + H_2O \rightleftarrows H_3O^+ \cdot H_2O$$

[21] $$H_3O^+ \cdot H_2O + H_2S \rightleftarrows H_3S^+ \cdot H_2O + H_2O$$

[22] $$H_3S^+ \cdot H_2O \rightleftarrows H_3S^+ + H_2O$$

[5] $$H_3O^+ + H_2S \rightleftarrows H_3S^+ + H_2O$$

Cunningham *et al.* (24) report a value of −31.6 ± 1 kcal mol^{-1} for ΔH^0 of reaction 20. The very recent measurements of Moet-Ner and Field (25) yielded $\Delta H^0 = -33.0 \pm 1.5$ kcal mol^{-1} for this reaction. These two values combine to yield a weighted mean of −32.1 kcal mol^{-1} with a standard error of ±0.8 kcal mol^{-1} (12). Hiraoka and Kebarle (26) report a value of +6.7 ± 1 kcal mol^{-1} for ΔH^0 of reaction 21 while Moet-Ner and Field (25) obtained a value of +17 ± 1.5 kcal mol^{-1} for ΔH^0 of reaction 22. When these values are adopted, the analysis of the thermodynamic cycle represented by the above four reactions provides a value of −8.4 ± 3.3 kcal mol^{-1} for ΔH^0_{298} of reaction 5 which is considerably higher than the values obtained from the direct measurements of the equilibrium constant for [5]. We are unable to assign the exact origin of this large discrepancy. It appears likely, however, that it reflects a serious shortcoming, presumably of the type discussed in the previous section, in one or more of the equilibrium constant measurements for reactions 20–22. The variable-temperature flowing afterglow measurements for [19] provided a value for $\Delta H^0_{470} = -5.2 \pm 0.8$ kcal mol^{-1} (23) which agrees, within experimental error, with the value for

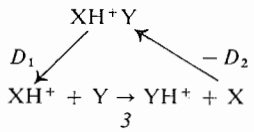
[a]$\Delta H_f^0(XH^+) = \Delta H_f^0(X) + \Delta H_f^0(H^+) - PA(X)$. Values for $\Delta H_f^0(X)$ and $\Delta H_f^0(H^+)$ were taken from the JANAF tables (22).
[b]Reference value, see text.

$\Delta H^0_{298} = -4.5 \pm 1.1$ kcal mol^{-1} derived from the standard enthalpy changes determined in this study for reactions 5 and 10.

When combined with those of the corresponding unsolvated proton-transfer reactions, the standard free energy changes derived from the equilibrium constant measurements for the solvated proton transfer reactions provide information about the standard free energies of dissociation of the solvated ions. In the case of 'heterogeneous' solvated ions, XH^+Y in which the proton is shared between two different molecules, we can distinguish between two paths of dissociation and therefore two free energies of dissociation which are related according to the following thermochemical cycle:

[23]



The standard free energies of dissociation D_1 and D_2 differ by an amount given by the standard free energy change associated with the proton-transfer step *3*. This notion is expressed explicitly by the manner in which we have chosen to write the molecular formula of the solvated ions, viz. we have artificially distinguished between $XH^+\cdot Y$ and $YH^+\cdot X$. This convention facilitates the comparison of unsolvated and solvated proton transfer and is not meant to imply a difference in structure or energy. It is readily apparent from a comparison of reaction 1 and the generalized solvated proton-transfer reaction

[24] $$XH^+\cdot X + Y \rightleftarrows YH^+\cdot X + X$$

that the standard free energy change associated with a solvated proton-transfer reaction will differ from that associated with its unsolvated counterpart by the difference in the standard free energies of dissociation of the two solvated ions, viz. $D(XH^+ - X) - D(YH^+ - X)$. Thus a comparison of the values for ΔG^0 determined for reactions 12 and 13 provides a value for the difference in standard free energies of dissociation, $D(H_2COH^+ - HCN) - D(H_2CN^+ - HCN)$, of $+1.0 \pm 0.3$ kcal mol^{-1} whereas such a comparison for reactions 12 and 14 provides a value for $D(H_2CN^+ - H_2CO) - D(H_2COH^+ - H_2CO)$ of $+0.6 \pm 0.4$ kcal mol^{-1}. A value of $+0.3 \pm 0.1$ kcal mol^{-1} is obtained for $D(H_2CN^+ - H_2CO) - D(H_2COH^+ - HCN)$ when ΔG^0 determined for reaction 12 is incorporated into the thermochemical cycle [23]. This result simply reflects the slightly higher basicity (expressed as a free energy) of H_2CO. Finally a thermochemical analysis of the cycle comprising reactions 12–14 provides a value for $D(H_2COH^+ - H_2CO) - D(H_2CN^+ - HCN) = +0.7 \pm 0.5$ kcal mol^{-1}.

Proton Affinities

The standard enthalpy changes determined in this investigation for the reactions of type [1] are presented in Table 5 in the form of a proton affinity 'ladder' together with the corresponding proton affinities and heats of formation of the protonated species. The proton affinity ladder is referenced to the proton affinity of H_2CO which was derived from the photoionization appearance potential of 11.67 ± 0.03 eV for H_2COH^+ from CH_3OH as measured by Refaey and Chupka (2). Adoption of the values for $\Delta H^0_{f,0}(H)$ and $\Delta H^0_{f,0}(CH_3OH)$ tabulated in the recent compilation by Rosenstock *et al.* (27) leads to a value for $\Delta H^0_{f,0}(H_2COH^+) = 172.1 \pm 0.7$ kcal mol^{-1} and for $\Delta H^0_{f,298}(H_2COH^+) = 170.3 \pm 1.1$ kcal mol^{-1} when a correction is made for temperature by comparison with similar molecules (2); (we have assigned an uncertainty of ±20% to this correction). A value for $PA_{298}(CH_2O) = 170.9 \pm 1.2$ kcal mol^{-1} can then be derived using $\Delta H^0_{f,298}(CH_2O) = -25.95 \pm 0.11$ kcal mol^{-1} as determined by Fletcher and Pilcher (28) and the $\Delta H^0_{f,298}(H^+)$ in the JANAF tables (22).

Our values for $PA_{298}(HCN)$ and $PA_{298}(H_2S)$ agree within experimental error with the value 170 ± 3 kcal mol^{-1} derived for the proton affinity of these two molecules by Haney and Franklin (29). The value of $PA(H_2S)$ was determined by these latter authors

C = 0.144, 0.252, and 0.234 for the reactions with H_2S, HCN, and H_2CO respectively; $\alpha(HCN)$ = 2.59 Å^3 (33), $\alpha(H_2S)$ = 3.64 Å^3 (34), $\alpha(H_2CO)$ = 2.81 Å^3 (35); $\mu_D(HCN)$ = 2.98 D, $\mu_D(H_2S)$ = 0.97 D, $\mu_D(H_2CO)$ = 2.33 D (36).

from appearance potential measurements for electron impact fragmentation of ethanethiol and dimethylsulfide while PA(HCN) was tied to PA(H_2S) through the observation of proton transfer between these two molecules. Our value for $PA_{298}(H_2O)$ agrees within experimental error with the 'best' value of 165 ± 3 kcal mol^{-1} adopted by Long and Munson (5) in their consideration of the proton affinities of oxygenated compounds but is somewhat lower than the values of 168.9 ± 2 kcal mol^{-1} derived recently by Yamdagni and Kebarle (3) and 170.3 ± 2 kcal mol^{-1} preferred by Wolf *et al.* (4).

One problem generally encountered in equilibrium studies directed towards the determination of an accurate absolute value of the proton affinity of a specific molecule has been to incorporate that molecule into a proton affinity ladder in close proximity to a reference molecule whose absolute proton affinity has been accurately established with other methods. The uncertainty in the proton affinity of the desired molecule is then determined both by the uncertainty in the absolute standard and the uncertainty which accumulates according to the number of equilibrium steps between that molecule and the reference molecule. In the case of single temperature measurements this uncertainty will include that associated with the estimation of ΔS^0. As regards the determination of $PA_{298}(H_2O)$, we are fortunate in this study to have available as a reference a relatively accurate value for $PA_{298}(CH_2O)$ with CH_2O being only two equilibrium steps removed from H_2O. In the equilibrium studies of Yamdagni and Kebarle (3) isobutene was chosen as the reference molecule. It was only three equilibrium steps removed from NH_3, the molecule whose proton affinity was desired, but at least ten equilibrium steps removed from H_2O. For each step between isobutene and H_2O, including the H_2S/H_2O equilibrium for which a value for ΔH^0 had actually been derived from a Van't Hoff plot, ΔG^0_{600} was assumed to be equal to ΔH^0_{298}. These considerations, including the uncertainty in PA_{298} (isobutene) which we estimate to be ≲4 kcal mol^{-1} (largely due to the uncertainty in ΔH_f(*tert*-butyl radical) (30)), are probably sufficient to account for the apparent discrepancy between the values for $PA(H_2O)$ determined by these authors and in the present study. The origin of the value for $PA(H_2O)$ of 170.3 ± 2 kcal mol^{-1} was not discussed in the paper by Wolf *et al.* (4). It is due to appear in a separate publication by these authors.

Rate Constant Measurements

The unsolvated proton-transfer reactions investigated in this study were all observed to proceed rapidly ($k \gtrsim 1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}) in the forward (exoergic) direction, in accord with expectations based on our growing experience for such reactions (31). The measured rate constants for the individual reactions are summarized in Table 6. They appear not to have been determined previously by other workers although Chong *et al.* (16) have reported a rate constant in the range 0.8–1.9 × 10^{-9} cm^3 molecule^{-1} s^{-1} for reaction 15, the deuterium analogue of reaction 5. Table 6 also includes a comparison of the measured reaction rate constants with collision rate constants calculated using the Average-Dipole-Orientation theory (32). The consonance between these two sets of values is again not surprising (31).

The much larger range in values observed for the rate constants of the solvated proton-transfer reactions (see Table 2) is most readily understood in terms of overall reaction energetics. For several of these reactions the difference in the standard free energies of dissociation of the two solvated ions appears to be sufficient to cause a change in the sign of the standard free energy change associated with the unsolvated counterpart. This is not surprising in view of the low exoergicity, $\Delta G^0_{298} \lesssim 5$ kcal mol^{-1}, generally exhibited by the corresponding unsolvated reactions. In the case of reactions 12–14 our equilibrium constant measurements indicate that the solvation of H_2CN^+ by one HCN molecule actually increases the exoergicity for proton transfer by 1.0 kcal mol^{-1} while solvation by one H_2CO molecule decreases the exoergicity from −0.3 to +0.3 kcal mol^{-1}. These observations are borne out by the corresponding rate constant measurements which

indicate that $H_2CN^+ \cdot HCN$ still undergoes proton transfer with H_2CO with a relatively large rate constant, albeit slightly lower than that for its unsolvated counterpart, and that $H_2COH^+ \cdot H_2CO$ reacts rapidly with HCN to produce $H_2CN^+ \cdot H_2CO$. The rate constant for proton transfer between H_3O^+ and HCN is decreased significantly upon the solvation of H_3O^+ with one H_2O molecule. The low value for k_7 of 1×10^{-10} cm^3 molecule^{-1} s^{-1} suggests that this solvated reaction may in fact be slightly endoergic with $D(H_3O^+ - H_2O) - D(H_2CN^+ - H_2O) \approx 6$ kcal mol^{-1}. There is much less doubt about the overall energetics of the reaction of unsolvated and solvated H_3O^+ with H_2S. The recent measurements of Hiraoka and Kebarle (26) indicate standard free energy changes at 300 K for the reactions

[25] $$H_3O^+ \cdot H_2O + H_2S \rightleftarrows H_3S^+ \cdot H_2O + H_2O$$

[26] $$H_3O^+ \cdot 2H_2O + H_2S \rightleftarrows H_3S^+ \cdot 2H_2O + H_2O$$

of $+7.1 \pm 0.5$ and $+6.3 \pm 0.6$ kcal mol^{-1}, respectively, which correspond to a decrease of ~ 10 kcal mol^{-1} in ΔG^0 upon hydration of H_3O^+. Our observations indicate a concomitant decrease in the value of k by more than 10^3 from 1.9×10^{-9} to $\lesssim 1 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}. Finally the drop in the value of k from 3×10^{-10} to $\lesssim 1 \times 10^{-12}$ cm^3 molecule s^{-1} observed for the endoergic proton transfer from H_2CN^+ to H_2S suggests an even larger endoergicity for the $H_2CN^+ \cdot HCN$ reaction with $D(H_2CN^+ - HCN) > D(H_3S^+ - HCN)$.

TIMOTHY R. CERKSUS, VALERIA M. CSIZMADIA, GEORGE H. SCHMID, and THOMAS T. TIDWELL. Can. J. Chem. **56**, 205 (1978).

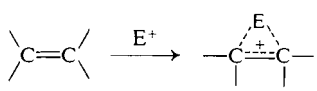
The reactivity of a series of cyclopropylalkenes, as well as norbornene and cyclohexene, with *p*-chlorobenzenesulfenyl chloride in CH_2Cl_2 at 25°C have been measured. Rates of reaction of several of the substrates were also measured in acetic acid and 1,1,2,2,-tetrachloroethane so that factors for converting rates from one solvent to another could be obtained. The rates of the sulfenyl halide additions varied over a total range of 193 from the least reactive alkene, ethylene, to the most reactive, 1,1-dicyclopropylethylene. This relatively small variation is in accord with all of these reactions involving bridged rate-determining transition states. The corresponding range in reactivity for acid-catalyzed hydration, a reaction involving protonation on carbon to give an open carbonium ion, is 10^{16}. These two reactions are proposed as bases for structure–reactivity comparisons to determine whether other reactions involve bridged or open transition states.

TIMOTHY R. CERKSUS, VALERIA M. CSIZMADIA, GEORGE H. SCHMID et THOMAS T. TIDWELL. Can. J. Chem. **56**, 205 (1978).

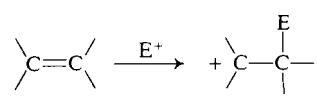
On a mesuré la réactivité d'une série de cyclopropylalcènes de même que celle du norbornène et du cyclohexène vis-à-vis le chlorure de *p*-chlorosulfényle dans le CH_2Cl_2 à 25°C. On a aussi mesuré les vitesses de réaction de plusieurs substrats dans de l'acide acétique et du tétrachloro-1,1,2,2 éthane de façon à obtenir les facteurs permettant d'évaluer les vitesses dans un solvant à l'aide des vitesses dans un autre solvant. Les vitesses d'addition de l'halogénure de sulfényle varient de 1 à 193 lorsque l'on passe de l'alcène le moins réactif, l'éthylène, vers le plus réactif le dicyclopropyl-1,1 éthylène. Cette variation relativement faible est en accord avec un mécanisme suggérant que toutes ces réactions impliquent des ions pontés comme états de transition déterminant la vitesse. L'écart correspondant de réactivité pour l'hydration acido-catalysée, une réaction impliquant la protonation d'un carbone conduisant à un carbocation ouvert, est de 10^{16}. On suggère que ces deux réactions peuvent servir de base pour des comparaisons de structure et de réactivité afin de déterminer si d'autres réactions impliquent des états de transition pontés ou ouverts.

[Traduit par le journal]

The intermediates in electrophilic additions to olefins, and the transition states leading to them, may be divided into two distinctive types. On the one hand there are those reactions that proceed through bridged transition states and intermediates [1] and on the other hand there are those that involve rate determining attack at carbon to form open carbonium ions (the $A_{SE}2$ mechanism) as shown in eq. 2 (1, 2). The best example of the first class of reaction



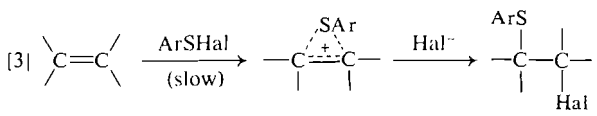
[1]



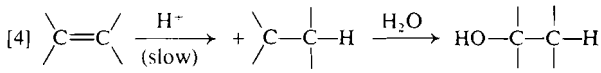
[2]

is addition of sulfenyl halides (3) to olefins [3]. Protonation of alkenes in acid-catalyzed hydrations is a reaction which clearly fits in the second category (4).

[1]Reactions of sulfenyl chlorides and their derivatives, Part 18. For Part 17, see ref. 12*b*.



[3]



[4]

The mechanism of sulfenyl halide additions are securely based on rate–structure correlations, product stereochemistry, and direct observation of the bridged intermediates (3). In turn the mechanism of the hydration reaction is supported by the correlation of rates with structure, solvent isotope effects, acidity dependence, and other kinetic criteria (4). Interestingly, these reactions had been the object of only sporadic quantitative investigations and their mechanisms have been clearly defined only rather recently, as reviewed in refs. 1–4.

It is somewhat anomalous that two much more ambiguous electrophilic reactions of alkenes, namely bromination and oxymercuration, have been the object of earlier and generally more intensive mech-

anistic study. Bromonium ion formation as in eq. 1 was proposed in 1937 (5) and mercurinium ions were suggested as intermediates in 1939 (6). Both bromination (7) and oxymercuration (8) of olefins have been the subject of intensive examination since that time.

Despite the immense amount of careful work which has been devoted to these reactions there is still some ambiguity as to the respective contribution of bridged and open ions in such additions. We believe that a useful approach to solving this problem is to compare the effect of systematic variations of alkene structure on the different types of reaction. By comparing the structure–reactivity profiles of the reactions in question with sulfenyl halide additions, which are known to involve bridging, and hydrations, which are known to involve open ions, it should be possible to gain an insight into the details of the borderline cases.

A substituent which has proved particularly informative is cyclopropyl (4, 9). This substituent is capable of strong electron donation by resonance to an adjacent empty *p* orbital, assuming that the proper bisected (Fig. 1) geometry can be attained. For example cyclopropyl is 1000 times more effective than phenyl at accelerating the solvolysis of *p*-nitrobenzoate esters RMe_2COPNB (10). On the other hand this group is inductively electron withdrawing if resonance donation is precluded by geometrical constraints (11). Bridging should also prevent the cation stabilizing effect of this substituent from being effective by preempting the adjacent *p* orbitals, so the substituent effect of cyclopropyl should provide a critical test of transition state structure.

We have completed and published (4) a survey of the effects of representative substituents on alkene hydrations. This paper deals with the assessment of the effect of the cyclopropyl substituent on arylsulfenyl halide additions. Also a limited study of the effect of solvent variation on rates of sulfenyl halide addition has been carried out. Rate measurements on some cycloalkenes were also included for comparison. The use of the rates of sulfenyl halide addition in the elucidation of the mechanism of oxymercuration (12*a*) and bromination (12*b*) has been reported elsewhere. It was also of interest to briefly compare the effect of cyclopropyl on the product determining steps in sulfenyl halide additions relative to other electron-donating substituents (13, 14).

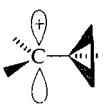

FIG. 1. Favourable bisected geometry.

Results

Kinetics of the sulfenyl halide additions were measured by stopped-flow ultraviolet spectroscopy as described previously (14). The observed rate constants are given in Table 1.

The rates of addition agree well with published results where comparisons can be made. Thus our average value for the ratio k(cyclohexene)/k(1-hexene) of 6.6 agrees with a reported value of 9.5 (15) and our average value of 11.0 for k(norbornene)/k(cyclohexene) agrees with that reported of 12.9 (16).

The products were examined by ^1H nmr spectroscopy by mixing the reactants in an nmr tube at $-20°C$ and immediately observing the spectra, which were then rescanned at intervals until the product composition ceased to change. In this way an estimate could be made of both the kinetic products formed initially and the thermodynamic product which was favored on extended reaction time. The assignments of the signals are given in Table 2 and the basis of these assignments is given in the Appendix.

Discussion

The products of the reactions were not a major concern but were given some attention to insure there was no untoward behavior which might complicate the analysis of the kinetic results. These observations of the products are consistent with the reactions proceeding by usual addition of the sulfenyl halide to the double bond, with isomerization and ring cleavage (17) occurring subsequently in some cases. Details are given in the Appendix.

The rates of addition of *p*-chlorobenzenesulfenyl chloride show a vivid contrast to the rates of acid-catalyzed hydration. The total range in relative rates for the former reaction is 193, whereas for the latter it is 1.3×10^{16}. This vast difference in the sensitivity of the rates to changes in substitution confirms the fundamental difference in the reaction mechanisms, namely that sulfenyl halide addition proceeds through a bridged rate-determining transition state, whereas acid-catalyzed hydration involves an open ion. This effect is especially noticeable when comparing the isomeric dicyclopropylethylenes. The 1,1,-isomer is 10^6 more reactive than the 1,2-isomers in hydration but only five-fold faster in sulfenyl halide addition. This result emphasizes the value of the cyclopropyl group as a transition state probe.

The observed solvent effects show that the greater reactivity in hydration does not arise from a more polar solvent. Indeed the *p*-chlorobenzenesulfenyl halide additions are slower in more polar solvents. Average relative rate factors for the solvents acetic

[f]J = 7 and 5 Hz.

acid, CH_2Cl_2, and $CHCl_2CHCl_2$ are 1.0, 2.3, and 7.8, respectively. This fact suggests a decrease in polarity of the reactants in attaining the transition state for addition. By contrast the addition of 2,4-dinitrobenzenesulfenyl chloride to cyclohexene is 10^3 times faster in acetic acid than in carbon tetrachloride (18). Evidently this sulfenyl halide has much less polar character in the S—Cl bond in the reactant so there is an increase in polarity in the transition state which is aided by a more ionic medium.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

This assessment depends upon the assignment of relative solvent polarity as HOAc > CH_2Cl_2 > $C_2H_2Cl_4$ > CCl_4. The dielectric constants of the first three of these solvents are almost identical (6.2, 8.9, and 8.2, respectively) but the E_T and Z solvent parameters indicate acetic acid is much more polar than methylene chloride (19). Apparently these solvent parameters have not been reported for $C_2H_2Cl_4$.

The determination of the rates of *p*-chlorobenzenesulfenyl chloride addition in acetic acid make comparisons possible with published rates for 2,4-dinitrobenzenesulfenyl chloride addition. The former halide is more reactive toward 1-hexene (3*b*, 15), cyclohexene (15, 16), norbornene (16), and styrene (20) by factors of 15×10^3, 8.1×10^3, 6.9×10^3, and 22×10^3, respectively (the rates for the dinitro compound were measured at 30°C for cyclohexene and norbornene and the rate of the *p*-Cl compound with cyclohexene was calculated using the rates in the other solvents). The low reactivity of the dinitrobenzenesulfenyl chloride may be interpreted in terms of the electron deficiency on sulfur in the transition state being destabilized by the nitro groups.

In summary this study provides a structure–reactivity correlation for a reaction known to involve bridged transition states. This provides a standard by which to judge the transition state geometries of other reactions, which we have done for oxymercuration (12*a*) and bromination (12*b*). Our preliminary study of solvent effects on sulfenyl halide additions has been suggestive of the relative charge distributions in the reactants and products in this reaction, but a thorough study of this topic is clearly warranted.

Experimental

Cyclopropylalkenes were obtained as reported previously (4) and the other alkenes were commercial material. Acetic acid was purified by refluxing with acetic anhydride for 10 days followed by slow distillation. Methylene chloride was shaken three times with concentrated sulfuric acid, twice with water, and twice with sodium bicarbonate solution and was then dried successively over $CaCl_2$ and K_2CO_3. Freshly distilled material was used in kinetic runs. Commercial tetrachloroethane (*Caution*, toxic vapour) was purified by the same procedure as methylene chloride.

Kinetic measurements were carried out using a Durrum D110 Stopped Flow Spectrophotometer as previously described (3*a*). Product studies were carried out by adding 1.5 mmol *p*-chlorobenzenesulfenyl chloride to 1.4 mmol alkene in 0.5 mL $CDCl_3$ in an nmr tube cooled to −20°C with Dry Ice. The reactions were exothermic, particularly for the more reactive alkenes. After mixing the solutions were frozen, and then melted, placed in the probe of the Varian T-60 operating at normal room temperature and recorded immediately. Spectra were remeasured after standing at room temperature at various intervals until the spectra no longer appeared to change.

In the kinetic runs alkene concentrations typically in the range 0.005–0.015 *M* were used and the arylsulfenyl chloride concentrations were less by a factor of 10. The calculated second-order rate constants were independent of the initial concentrations of reagents within this range.

Appendix

The structures of the products from **4**–**7** were assigned according to Scheme 1 on the basis of their proton nmr spectra, which agreed well with the large body of these reported in the literature (3*a*). In particular the resonances of the protons on chlorine-bearing carbon and sulfur-bearing carbon were in the region of δ 2.5–4.0. In accordance with the normally observed behaviour (3*a*), the higher field resonance was assigned to the latter protons when these were well separated (in **10**, **12**, **13**, and **14**). Products **10** and **12** from *Z*- and *E*-1-cyclopropyl-

[5] *c*-PrCH=CHMe → *c*-PrCHClCHMeSAr → *c*-PrCHSArCHMeCl
7 (*Z*) **9** (*threo*) **10** (*threo*)

[6] *c*-PrCH=CHMe → *c*-PrCHClCHMeSAr → *c*-PrCHSArCHMeCl
6 (*E*) **11** (*erythro*) **12** (*erythro*)

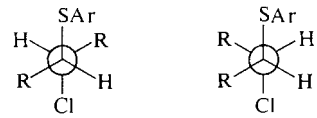
[7] *c*-PrCH=CH-*c*-Pr → *c*-PrCHClCHSAr-*c*-Pr
5(*Z*) **13** (*threo*)

[8] *c*-PrCH=CH-*c*-Pr → *c*-PrCHClCHSAr-*c*-Pr
4 (*E*) **14** (*erythro*)

SCHEME 1

propene, respectively, were not the initially formed products but were derived from rearrangement of the original adducts **9** and **11**. Accordingly, **9** and **11** were assigned as having the positions of the Cl and S reversed from **10** and **12**.

The additions to **4**–**7** were assigned as being *anti* on the basis that the initial additions were stereospecific, and the fact that this is the normal mode of addition. Normally the *threo* and *erythro* isomers which result from addition of sulfenyl halides to 1,2-disubstituted ethylenes may be differentiated on the basis of the larger vicinal coupling constant between



erythro *threo*

the protons shown in the *erythro* isomer than in the *threo* (*cf*, J = 6.0 and 3.0 (R = Me (13*a*)), J = 6.8 and 3.2 (R = Et (13*b*)), J = 10.5 and 5.6 (R = *i*-Pr (13*c*)), and J = 3.2 and 0.5 Hz (R = *t*-Bu (13*d*), respectively). However, in the case of adducts **9**–**14** the differences in these coupling constants were too small to serve as reliable bases for determination. The only examples of sulfenyl halide additions that do not give *anti* addition are cases in which one of the substituents is a powerful electron donor, such as *p*-anisyl. In such cases both *syn* and *anti* addition is observed, and these results have been interpreted in terms of a bridged rate-determining transition state but with an open ion intervening before the product-determining transition state (13*e*). We have found cyclopropyl to be a stronger electron donor than *p*-anisyl (ref. 4*b*, as measured by the σ^+ parameter for the entire group) but the stereospecific formation of a single initial product from these reactions indicates that only bridged ions are formed from **4**–**7**. The assigned stereochemistries of the kinetically controlled products are thus as shown in eqs. 5–8.

The nmr spectrum of the product from cyclopropylethylene (**1**) was unusual in that the protons on the carbons bearing Cl and S appeared as two closely spaced singlets without the normal vicinal coupling or the coupling to the methine proton of the cyclopropyl group. The structure may confidently be assigned the structure *c*-PrCHClCH$_2$SAr (**8**) as the protons on the carbon bearing sulfur are consistently shifted to higher field by an adjacent cyclopropyl in **10**, **12**, **13**, and **14**. This regiochemistry is also consistent with the result observed with styrene, which gives 83% Markovnikoff adduct in the kinetic product and 100% at equilibrium (14).

The reaction of 2-cyclopropylpropene (**3**) showed the initial formation of two adducts in the approximate ratio of 5:1. The observed chemical shifts were consistent with the formation of *c*-PrMeCClCH$_2$SAr and *c*-PrMeCSArCH$_2$Cl but because of the similarity of the spectra the isomers could not be positively identified. For comparison 2-phenylpropene gives an 87% preference for Markovnikoff addition in the kinetic product (14). The initial adducts from **3** underwent further reaction, presumably rearrange-

ment by cyclopropane homoallylic ring opening (4*a*, 17), which has been documented in the addition of arylsulfenyl halide to α-cyclopropylstyrene (eq. 9) (17*b*).

$$[9]\quad c\text{-PrCPh}{=}CH_2 \xrightarrow{\text{ArSCl}} c\text{-PrCPh}{=}CHSAr + ClCH_2CH_2CH{=}CPhCH_2SAr$$

1,1-Dicyclopropylethylene (**2**) underwent rapid initial conversion to an adduct with a singlet resonance at δ 3.52 which rapidly disappeared with the emergence of a complex spectrum. The chemical shift of the signal noted of the initial adduct is consistent with the formation of either $c\text{-Pr}_2CClCH_2SAr$ or $c\text{-Pr}_2CSArCH_2Cl$, and the further changes in the spectrum suggest a mixture of products are then formed with ring opening of one of the cyclopropane rings with formation of a double bond.

The synthesis of D,L-*cis*-*N*-oxalamido-3-*N*-phenylacetamido-4-methoxymethyl-2-azetidinone

GEORGE JUST AND TENG-JIAM LIAK

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received August 15, 1977

GEORGE JUST and TENG-JIAM LIAK. Can. J. Chem. **56**, 211 (1978).

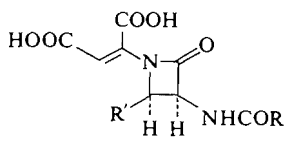
The title compound γ_{max} 1810 cm^{-1}, has been synthesized in 18% yield, starting from L-serine.

GEORGE JUST et TENG-JIAM LIAK. Can. J. Chem. **56**, 211 (1978).

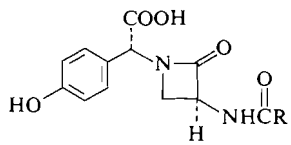
En commencant avec la L-serine, le composé **17**, γ_{max} 1810 cm^{-1}, a été synthétisé avec un rendement de 18%.

A high β-lactam absorption frequency is a necessary prerequisite for high antimicrobial activity of β-lactam antibiotics (penicillin: γ_{max} 1790 cm^{-1}; cephalosporin: γ_{max} 1785 cm^{-1}) but does not necessarily lead to antibiotic activity. The only exception to that rule is provided by the monocyclic nocardicin, where other factors such as an in vivo oxidation may play an important role.

We therefore set out to synthesize β-lactams, in which the ring strain of penicillin and cephalosporin, which seem to be responsible for the high frequency of the β-lactam absorption, are replaced by electronic activation. Lowe and Yeung (1) had synthesized β-lactam analogs A, based on the same principle. The diester of A absorbs at 1790 cm^{-1}.



A R′ = H, CH_3



Nocardicin

No absorption frequency was reported for the free acid. Compound A showed no significant antibacterial activity but it could not be ruled out that this lack of activity may be due to reduced electron-withdrawing capacity of the acrylate moiety in A due to anion formation.

Our synthetic goal was **17**, in which the electronic activation is provided by a carbonyl group attached to the β-lactam nitrogen. The side chain at C-4 should not influence unduly the biological activity since it has been shown that the sulphur atom of cephalosporin may be replaced by oxygen or carbon (2–4). The nature of the side-chain derives from its mode of synthesis, in which the essential *cis*-substitution at C-3 and C-4 had to be maintained. The substituent at C-3 is a conventional group known to confer antibiotic activity to β-lactam antibiotics (5).

We chose as our starting material readily available L-serine methyl ester hydrochloride (**6**). It was converted in nearly quantitative yield to its *tert*-butyldimethylsilyl derivative **7**. Using the procedure recently described by Doyle *et al.* (6), **7** was transformed to its stable Schiff base **1**, which upon reaction with azidoacetyl chloride and triethylamine in methylene chloride at −10°C gave β-lactam **2**, mp 74.5–75.5°C in 50% yield based on **7** (Scheme 1).

The nmr spectrum and tlc behaviour of the crude reaction product and of the mother liquors of crystallization indicated that there was one isomer only, in addition to some impurities which made recrystallization of the mother liquors difficult.

β-Lactam **2** appeared to be one compound, since it and all substances derived from it travelled as one spot on tlc, using different systems, and since its ^{1}Hmr spectrum and that of all compounds derived from it never indicated the presence of more than one isomer. The coupling constant of the two hydrogens attached to the β-lactam ring indicated in all cases in which they did not seriously overlap with other signals that the fusion was *cis* (J = 5.5 Hz (7, 8)). The geometry at C-1 will be discussed later, as well as the fact that all β-lactams formed were racemic. However, it should be pointed out that this 'diastereomeric purity' is quite remarkable, since it has been found in our and other laboratories (6, 9–11) that similar additions give rise to both possible diastereomers in approximate equal yields. We have no explanation for this phenomenon. β-Lactam **2** was reduced with triethylamine – hydrogen sulphide in methylene chloride (6) to give amine **8**, mp 94–95°C, which could be transformed without purification to the corresponding phenylacetamide **9**, mp

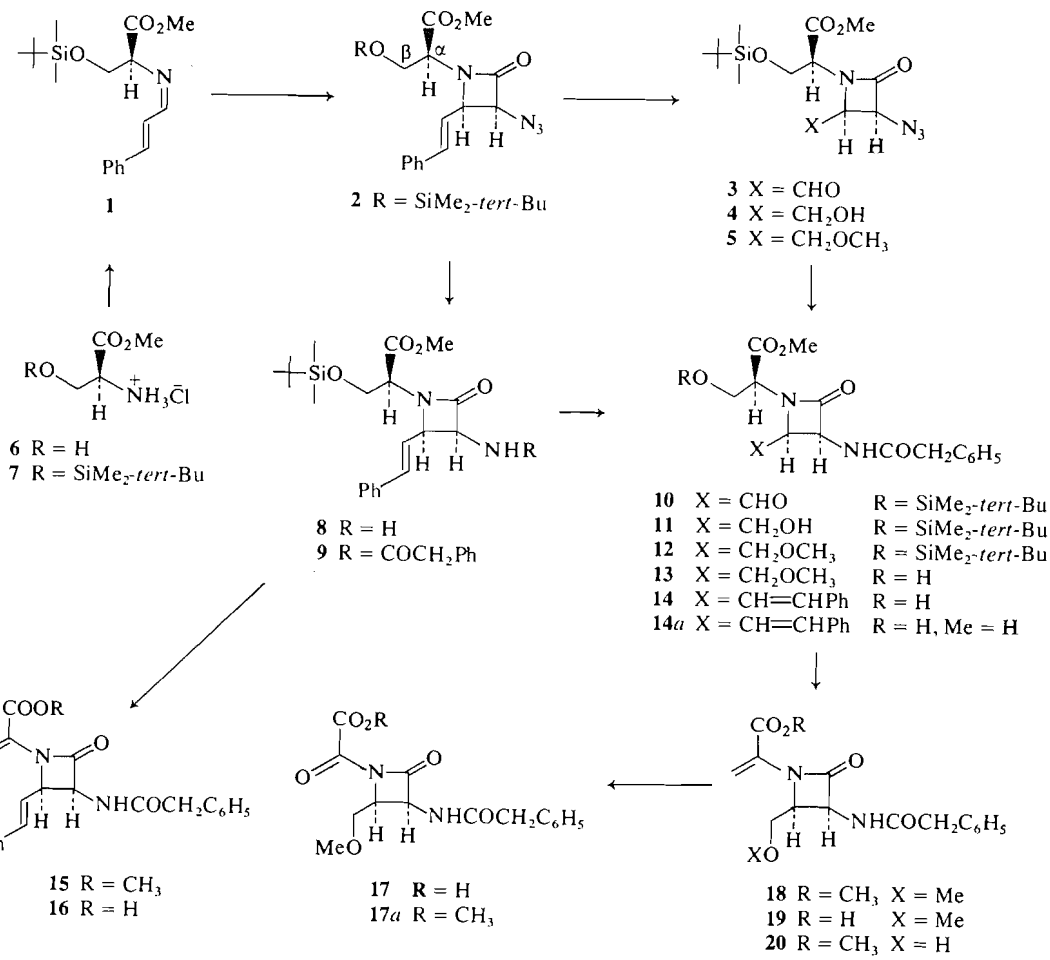

SCHEME 1

72–73°C, in high yield. An attempt to remove the silyl protecting group in **9** by means of tetraethylammonium fluoride in dry tetrahydrofuran (THF) gave an easily separable 1:4 mixture of alcohol **14**, mp 154–155°C, and acrylic ester **15**, mp 161–162°C. Alcohol **14** could be obtained as the sole product when the reaction was repeated, adding 2 equiv. of acetic acid. It was converted quantitatively to acrylate **15**, mp 161–162°C, γ_{max} 1780 cm^{-1}, by treatment with mesyl chloride and triethylamine at −78°C.

In order to ascertain whether the acrylic ester could be hydrolysed in the presence of the strained β-lactam function, **15** was treated with 3 equiv. of sodium hydroxide in H_2O–MeOH or H_2O–THF. In either case, a mixture of acrylic acid **16** and the corresponding β-hydroxy acid **14***a*, was obtained, implying that the rate of hydrolysis of the ester and the rate of Michael addition of hydroxide ion to the ester are approximately equal. Since it is known (12) that rates of hydrolysis of esters in 85% aqueous dimethyl sulfoxide are two orders of magnitude larger, the hydrolysis was repeated using the latter solvent system, and 1 or 3 equiv. of sodium hydroxide. Pure acrylic acid **16**, mp 147–148°C, was obtained in quantitative yield in each case. Having elaborated methods to introduce the acrylic acid function, we next turned our attention to the removal of the side chain. Ozonolysis of **9** in methanol at −78°C, followed by reaction with sodium borohydride at −40°C, gave exclusively the unstable hydroxyacrylate **20** (ir and nmr, only) which seemed to cyclize over a period of a few hours to give **23**, the structure of which was not rigorously established (Scheme 2). When the ozonolysis was carried out in methylene chloride and the ozonide reduced with dimethyl sulphide (13), the resulting aldehyde **10**, mp 176–177°C, could be cleanly converted to the desired alcohol **11** by means of lithium aluminum tri-*tert*-butoxy hydride in dry THF at 0°C. Attempts to convert **11** to its methyl ether **12** by means of methyl iodide – silver oxide (14) failed and dia-

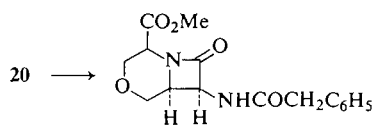
zomethane–borontrifluoride etherate (15) led either to recovered starting material (0.1 mol equiv. of $BF_3{\cdot}Et_2O$) or to complete degradation (1 mol equiv. of $BF_3{\cdot}Et_2O$). This is not surprising in view of the results of Doyle *et al.* on an attempted BF_3-catalysed cyclization of a similar alcohol with an acetal.

Since it was essential to block the alcohol function in order to avoid at a later stage cyclizations of type **20** → **23**, and since it had been shown that methylation of a similar alcohol function could be carried out in the presence of an azide function,[1] the styrene **2** was ozonized in methylene chloride at −78°C. Treatment with dimethyl sulphide gave aldehyde **3** and the epoxide or the ozonide[2] of **2** in a ratio of 1:3. Ozonolysis of **2** in methanol followed by treatment with dimethyl sulphide, gave aldehyde **3** as its methanol adduct. Slow distillation of its benzene solution gave pure aldehyde **3**, mp 72–73°C in quantitative yield. Reduction with lithium aluminum tri-*tert*-butoxy hydride gave **4**, mp 67–69°C, which was converted to its methyl ether **5**, mp 71–72°C, by means of diazomethane – boron trifluoride etherate.

Reduction of the azide function, followed by acylation, gave **12**, mp 76–77°C. Treatment of **12** with $\overset{+}{N}Et_4F^-$ in THF containing 2 equiv. of acetic acid gave **13**, mp 93–94°C, which was converted quantitatively to acylate **18**, mp 133–134°C, by means of MsCl–NEt_3 at −78°C. Hydrolysis with a slight excess of sodium hydroxide in DMSO–H_2O (85:15) gave acrylic acid **19**, mp 195–196°C (dec.). Ozonolysis of acrylic acid **19** in methanol, followed by dimethyl sulphide reduction, gave a product which did not contain a β-lactam absorption in its infrared spectrum. When the reaction was repeated in methylene chloride containing a few drops of DMSO in order to solubilize the acid, the oxalic acid derivative **17**, mp 102–103°C, was obtained. The overall yield for the sequence **6** → **7** → **1** → **2** → **3** → **4** → **5** → **13** → **19** → **17** was approximately 18%.



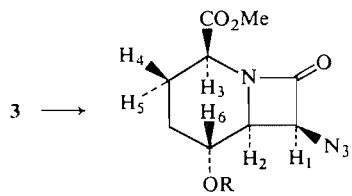
23

SCHEME 2

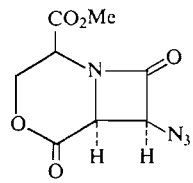
Ozonolysis of **18** gave **17***a*, which was identical to **17***a*, obtained by methylation of **17** with diazomethane. β-Lactam **17** possessed the remarkable ir absorption at 1810 cm^{-1} for its β-lactam carbonyl, which was in accordance with what we expected. Its ^{1}Hmr in DMSO-d_6 and D_2O, showed a three-proton singlet for methoxy ether at 3.07 ppm, a two-proton multiplet at 3.20–3.40 ppm (CH_2OCH), a two-proton singlet at 3.50 ($CH_2C_6H_5$), a one-proton multiplet for β-lactam C_4 proton, a doublet (J = 7 Hz) for β-lactam C_3 proton, and a sharp singlet for aromatic proton at 7.26 ppm.

Although ozonolysis of acrylic acid **19** in methanol had destroyed the β-lactam function, presumably by opening of the ring by methanol, acid **17** and its ester **17***a* were reasonably stable in DMSO-D_2O (5:1), as ascertained by ^{1}Hmr, which indicated that the half-life of **17** at room temperature was 2 days, whereas $T/2$ for **17***a* was 4 days.

To establish the relative stereochemistry of the carbomethoxy group with respect to the β-lactam hydrogens, the silyl group of aldehyde **3** was hydrolysed (Scheme 3). The resulting aldehyde alcohol



21 R = H
21*a* R = Ac



22

SCHEME 3

was isolated as the corresponding lactol **21**. Attempts to convert **21** to lactone **22** using Jones, Fetizon or Moffatt reagents failed. In the latter case, a good yield of crystalline acetate **21***a* was obtained.

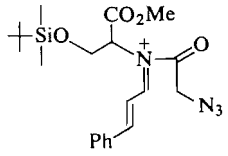
Proton magnetic resonance analysis of **21***a*, assuming a chair conformation of the six-membered ring, indicated that the acetate and carbomethoxy group had an equatorial conformation, and was fully consistent with the structure proposed. Thus $J_{1,2}$ was 5.0 Hz, and $J_{2,6}$ 8.0 Hz; H_4 and H_5 appeared as an AB quartet (J = 12.2 Hz), in which the low-field equatorial proton H_5 was further split ($J_{3,5}$ = 2.2 Hz), whereas the high-field hydrogen showed an appropriate axial–equatorial coupling constant $J_{3,4}$ = 5.5 Hz. A boat conformation for the six-

[1]R. Zamboni, personal communication.

[2]We wish to thank the referee for this suggestion. The ^{1}Hmr data (δ 5.51, 5.91 ppm) are more consistent with the latter possibility.

membered ring with opposite relative stereochemistry for the carbomethoxy group would be equally consistent with the ^{1}Hmr data but is quite unlikely since it would result in two severe flagpole interactions, namely H_3–H_6 and H_2–H_5.

It has been suggested by Doyle *et al.* that the mechanism of azidoacetyl chloride addition to cinnamyl Schiff base of type **1** involves the formation of an acylimmonium ion **24**. Our present work supports this view since it could be demonstrated that Schiff base **1** does not racemize during its formation, or upon addition of triethylamine at −10°C, but that the further addition of azidoacetyl chloride results in complete racemization as evidence by complete lack of optical rotation of several intermediates. It seems that acyl immonium ions labilize α-hydrogens more than the corresponding Schiff bases.



24

Biological tests indicated that **17** was inactive against gram-negative and gram-positive organisms at a level of 128 μg/ml.

Experimental

L-*Serine Methyl Ester* tert-*Butyldimethylsilyl Ether (7)*

To L-serine methyl ester hydrochloride **6** (1.00 g, 6.34 mmol) in dry *N,N*-dimethylformamide (5 ml) was added imidazole (1.53 g, 22.47 mmol) and *tert*-butyldimethylchlorosilane (1.05 g, 6.97 mmol). The solution was stirred at room temperature overnight, then partitioned between ether (100 ml) and water (30 ml). The organic layer was further washed with water (3 × 25 ml), dried (Na_2SO_4), and evaporated. The crude silyl ether was chromatographed on silica gel. Elution with ethyl ether afforded a quantitative yield of amine **7**; ^{1}Hmr (CCl_4) δ: 0.05 (s, 6H, Si(CH_3)$_2$), 0.85 (s, 9H, Si—*tert*-Bu), 1.44 (s, 2H, exchangeable with D_2O, NH_2), 3.27 (t, 1H, J = 4.0 Hz), 3.53 (s, 3H, COOCH_3), 3.63, 3.66, ppm (each d, 2H, J = 4.0 Hz); ir (film) γ_{max}: 3400–3200 (NH_2), 1745 (C=O), 1250 cm^{-1}; ms (60°C) *m/e*: 218 ($M^+ - CH_3$), 204, 176 (M^+ − *tert*-Bu), 175 ($M^+ - COOCH_3$), 144, 116.

*Methyl α-Amino-(*N*-cinnamylidine)-β-tert-butyldimethylsilyloxypropionate (1)*

To amino ester **7** (1.20 g, 0.515 mmol) in 60 ml dry methylene chloride was added cinnamaldehyde (0.68 g, 0.515 mmol). The solution was heated, and methylene chloride distilled off slowly with the constant addition of more dry methylene chloride. After 1 h the solution was cooled and magnesium sulfate added. The suspension was stirred for 1 h, filtered, and evaporated to give a quantitative yield of Schiff base **1**; ^{1}Hmr ($CDCl_3$) δ: 0.05 (s, 6H, Si(CH_3)$_2$), 0.85 (s, 9H, Si—*tert*-Bu), 3.60 (s, 3H, COOCH_3), 3.78–4.10 (m, 3H), 6.78 (d, 2H, J = 4.0 Hz, C_6H_5CH=CH), 7.18 (m, 5H, C_6H_5), 7.78 ppm (t, 1H, J = 4.0 Hz, CH=N); ir (film) γ_{max}: 1735 (C=O), 1670 (C=N), 1630 cm^{-1} (C=C).

cis-N-*(α-Carbomethoxy-β-tert-butyldimethylsilyloxyethyl)-3-azido-4-styryl-2-azetidinone (2)*

To a solution of Schiff base **1** (1.73 g, 5 mmol) and triethylamine (505 mg, 5 mmol) in 100 ml dry methylene chloride at −10°C (ice–methanol bath) was added azidoacetyl chloride (595 mg, 5 mmol) in 10 ml methylene chloride dropwise over a period of 1 h. After the addition was complete, the solution was stirred an additional 15 min and washed with water (50 ml × 3). The organic layer was dried over sodium sulfate, filtered, and evaporated. The crude product (brown oil) was treated with active charcoal (neutral) in 100 ml of anhydrous ether, filtered through Celite, and evaporated to give a yellow solid. Recrystallization from ether–hexane afforded 1.08 g (50%) of β-lactam **2** as colourless crystals, mp 74.5–75.5°C; ^{1}Hmr ($CDCl_3$) δ: 0.05 (s, 6H, Si(CH_3)$_2$), 0.85 (s, 9H, Si—*tert*-Bu), 3.64 (s, 3H, COOCH_3), 3.90 (d, 2H, J = 5 Hz, SiOCH_2), 4.38 (t, 1H, J = 5 Hz, CHCOOCH$_3$), 4.46–4.88 (m, 2H, CH—CH—N$_3$), 6.18 (ddt, 1H, J_1 = 16 Hz, J_2 = 6 Hz, J_3 = 1.5 Hz, C_6H_5—CH=CH), 6.60 (d, 1H, J = 16 Hz, C_6H_5—CH=CH), 7.20 ppm (s, 5H, C_6H_5); ir (KBr) γ_{max}: 2100 (N$_3$), 1780 (β-lactam C=O), 1755 and 1740 cm^{-1} (COOCH$_3$); ms (180°C) *m/e*: 415 ($M^+ - CH_3$), 402 ($M^+ - N_2$), 345 ($M^+ - N_2$—*tert*-butyl), 290 (M^+ − COCHN$_3$—*tert*-butyl). *Anal.* calcd. for $C_{21}H_{30}N_4O_4Si_1$: C 58.60, H 6.97, N 13.02; found: C 58.81, H 7.09, N 13.16.

cis-N-*(α-Carbomethoxy-β-tert-butyldimethylsilyloxyethyl)-3-amino-4-styryl-2-azetidinone (8)*

To a solution of azido-β-lactam **2** (860 mg, 2 mmol) and triethylamine (212 mg, 2.1 mmol) in methylene chloride (30 ml) at 0°C was bubbled in hydrogen sulfide gas for 5 min and the solution allowed to stand for 1 h (evolution of nitrogen was observed). Nitrogen gas was passed in for 15 min and the solvent evaporated under reduced pressure. An additional 50 ml of methylene chloride was added and the solution again evaporated. This procedure was repeated twice more. The crude oil was then redissolved in 40 ml of methylene chloride, washed with water (20 ml × 3), dried (Na_2SO_4), and evaporated. Trituration with hexane gave a pale yellow solid. Recrystallization from ether–hexane afforded 647 mg (80%) of amine **5** as colourless crystals, mp 94–95°C; ^{1}Hmr ($CDCl_3$) δ: 0.05 (s, 6H, Si(CH_3)$_2$), 0.85 (s, 9H, Si—*tert*-Bu), 1.68 (bs, 2H exchangeable with D_2O, NH_2), 3.67 (s, 3H, COOCH_3), 3.9 (d, 2H, SiOCH_2), 4.26–4.76 (m, 3H), 6.10 (dd, 1H, J_1 = 16 Hz, J_2 = 7 Hz, C_6H_5CH=CH), 6.60 (d, 1H, J = 16 Hz, C_6H_6 CH=CH), 7.20 ppm (m, 5H, C_6H_5); ir (film) γ_{max}: 3360 and 3280 (NH_2), 2900, 2820, 1745 (β-lactam C=O and COOCH$_3$), 1240 cm^{-1}.

cis-N-*(α-Carbomethoxy-β-tert-butyldimethylsilyloxyethyl)-3-*N*-phenylacetamido-4-styryl-2-azetidinone (9)*

To a solution of amine **8** (808 mg, 2 mmol) and pyridine (158 mg, 2 mmol) in 30 ml dry methylene chloride was added dropwise phenylacetyl chloride (308 mg, 2 mmol) in 5 ml methylene chloride. After the addition was completed, the solution was stirred an additional 5 min and washed with water (20 ml × 2). The organic layer was dried (Na_2SO_4), filtered, and evaporated. The crude oil was chromatographed on silica gel. Elution with ether afforded amide **9** in quantitative yield, mp 72–73°C; ^{1}Hmr ($CDCl_3$) δ: 0.01, 0.05 (each s, Si(CH_3)$_2$), 0.85 (s, 9H, Si—*tert*-Bu), 3.51 (s, 2H, $C_6H_5CH_2$), 3.76 (s, 3H, COOCH$_3$), 4.0 (dd, 2H, SiOCH_2, J_1 = 4.5 Hz, J_2 = 2 Hz), 4.50 (t, 1H, J = 4.5 Hz), 4.80 (dd, 1H, C_6H_5CH=$CHCH$, J_1 = 8 Hz, J_2 = 5 Hz), 5.46 (dd, 1H, $C_6H_5CH_2CONHCH$, J_1 = 8.5 Hz, J_2 = 5 Hz), 6.0 (dd, 1H, C_6H_5CH=CH, J_1 = 8 Hz, J_2 = 16 Hz), 6.50 (d, 1H, NH, J = 8.5 Hz), 6.61 (d, 1H, C_6H_5CH=CH, J = 16 Hz), 7.02 (s,

5H, C_6H_5), 7.24 ppm (s, 5H, C_6H_5); ir ($CHCl_3$) γ_{max}: 3380 (NH), 1750 (β-lactam C=O), 1735 ($COOCH_3$), 1670 cm^{-1} (amide C=O); ms (150°C) *m/e*: 522 (M^+), 465 (M^+ – *tert*-Bu). *Anal.* calcd. for $C_{29}H_{38}N_2O_5Si_1$: C 66.66, H 7.27, N 5.36; found: C 66.87, H 7.09, N 5.03.

cis-N-*(α-Carbomethoxy-β-hydroxyethyl)-3*-N-*phenylacetamido-4-styryl-2-azetidinone (**14**)*

To the silyl protected β-lactam **9** (400 mg, 0.76 mmol) and glacial acetic acid (182 mg, 3.04 mmol) in dry tetrahydrofuran (10 ml) was added tetraethylammonium fluoride (223 mg, 1.50 mmol). After stirring at room temperature for 3 h the solvent was removed under reduced pressure. The residue was dissolved in ethyl acetate (30 ml), washed with saturated sodium bicarbonate solution and water, dried, and evaporated. Recrystallization from methylene chloride – ether afforded 264 mg (85%) of alcohol **14**, mp 154–155°C; ^{1}Hmr ($CDCl_3$) δ: 3.36 (s, 2H, $C_6H_5CH_2$), 3.63 (s, 3H, $COOCH_3$), 3.63–4.06 (bm, 3H, one exchangeable with D_2O, CH_2OH), 4.18–4.46 (m, 1H, $CHCOOCH_3$), 4.61 (dd, 1H, J_1 = 5 Hz, J_2 = 8 Hz, C_6H_5CH=$CHCH$), 5.28 (dd, 1H, J_1 = 5 Hz, J_2 = 8.5 Hz, $C_6H_5CH_2CONHCH$), 5.97 (dd, 1H, J_1 = 16 Hz, J_2 = 8 Hz, C_6H_5CH=CH), 6.52 (d, J_1 = 16 Hz, C_6H_5CH=CH), 6.92 (s, 5H, C_6H_5), 7.06 (d, 1H, J=8.5 Hz, NH), 7.18 ppm (s, 5H, C_6H_5); ir (KBr) γ_{max}: 3490 and 3425 (OH), 3270 (NH), 1770 (β-lactam C=O), 1740 and 1720 ($COOCH_3$), 3050, 2920, 1650 cm^{-1} (amide C=O); ms (150°C) *m/e*: 407 (M^+ – 1), 390 (M^+ – H_2O), 273 ((M^+ – 1) – $C_6H_5CH_2CONH$), 233 (M^+ – $C_6H_5CH_2CONHCHCO$). *Anal.* calcd. for $C_{23}H_{24}N_2O_5$: C 67.65, H 5.88, N 6.86; found: C 67.95, H 5.76, N 6.76.

cis-N-*(α-Methylacrylyl)-3*-N-*phenylacetamido-4-styryl-2-azetidinone (**15**)*

To a solution of alcohol **14** (204 mg, 0.5 mmol) and triethylamine (101 mg, 1 mmol) in 25 ml dry methylene chloride at −78°C was added dropwise methanesulfonyl chloride (112 mg, 0.5 mmol) in 3 ml methylene chloride. After the addition was completed the mixture was washed with p*H* 4.4 buffer (0.2 *M*, KH_2PO_4 solution) and water, dried (Na_2SO_4), and evaporated. Recrystallization from methylene chloride – hexane afforded a quantitative yield of olefin **15**, mp 161–162°C; ^{1}Hmr ($CDCl_3$) δ: 3.40 (s, 2H, $C_6H_5CH_2$), 3.63 (s, 3H, $COOCH_3$), 5.0 (dd, 1H, J_1 = 5 Hz, J_2 = 8 Hz, C_6H_5CH=CH—CH), 5.40 (dd, 1H, J_1 = 5 Hz, J_2 = 8.5 Hz, $C_6H_5CH_2CONHCH$), 5.83 (dd, 1H, J_1 = 16 Hz, J_2 = 8 Hz, C_6H_5CH=CH), 5.77, 5.90 (each s, 2H, C=CH_2), 6.40 (d, 1H, J = 16 Hz, C_6H_5CH=CH), 6.41 (d, 1H, J = 8.5 Hz, NH), 6.90 (s, 5H, C_6H_5), 7.10 ppm (s, 5H, C_6H_5); ir (KBr) γ_{max}: 3260 (NH), 3020, 2930, 1760 (β-lactam C=O), 1725 ($COOCH_3$), 1650 cm^{-1} (amide C=O). *Anal.* calcd. for $C_{23}H_{22}N_2O_4$: C 70.77, H 5.64, N 7.18; found: C 70.75, H 5.71, N 7.41.

cis-N-*(α-Acrylyl)-3*-N-*phenylacetamido-4-styryl-2-azetidinone (**16**)*

To β-lactam ester **15** (55 mg, 0.14 mmol) at room temperature was added 1.6 ml sodium hydroxide (0.1 *N*) in aqueous dimethyl sulfoxide (H_2O–DMSO 15:85). The suspension was stirred until all the ester dissolved, giving a clear solution to which p*H* 4.4 phosphate buffer (15 ml) was added. The mixture was extracted with ethyl acetate (10 ml × 4), washed with a small amount of water, dried (Na_2SO_4), and evaporated. Recrystallization from chloroform afforded 41 mg (80%) acid **16**, mp 147–148°C (dec.); ^{1}Hmr (acetone-d_6) δ: 3.50 (s, 2H, $C_6H_5CH_2$), 3.89–4.55 (m, 2H, two β-lactam protons), 5.77, 5.94 (each s, 2H, CH_2=C), 6.20 (dd, 1H, J_1 = 16 Hz, J_2 = 8 Hz, C_6H_5CH=CH), 6.62 (d, 1H, J = 16 Hz, C_6H_5-CH=CH), 7.04 (m, 5H, C_6H_5), 7.23 (s, 5H, C_6H_5), 7.60–8.05 ppm (b, 1H, NH); ir (KBr) γ_{max}: 3350 (NH), 3040, 3070, 2800–2500 (COOH), 1745 (β-lactam C=O), 1725 (C=O), 1655 cm^{-1} (amide C=O).

cis-N-*(α-Methylacrylyl)-3*-N-*phenylacetamido-4-hydroxymethyl-2-azetidinone (**20**)*

A solution of β-lactam **9** (300 mg, 0.57 mmol) in dry methanol (30 ml) was ozonized at −78°C (Dry Ice – acetone bath) until the solution turned blue. The excess ozone was removed by passing in dry nitrogen for 10 min. Sodium borohydride (23 mg, 0.6 mmol) was added and the solution was allowed to warm up slowly to room temperature. The solvent was removed under reduced pressure. The residue after addition of p*H* 4.4 phosphate buffer was extracted with chloroform (10 ml × 4), washed with water, and dried over sodium sulfate. Evaporation of the solvent afforded a mixture of unstable olefinic alcohol **20** and benzyl alcohol; ^{1}Hmr ($CDCl_3$) δ: 3.60 (s, 2H, $C_6H_5CH_2$), 3.79 (s, 3H, $COOCH_3$), 3.92–4.26 (b, 3H, CH_2—OH), 4.42 (m, 1H, $CHCH_2OH$), 5.41 (dd, 1H, J_1 = 5 Hz, J_2 = 8.5 Hz, $C_6H_5CH_2CONHCH$), 5.89, 6.09 (each s, 2H, CH_2=CH), 7.16 ppm (bs, 6H, C_6H_5 and NH); ir (CH_2Cl_2) γ_{max}: 3600–3200 (OH), 3420 (NH), 2920, 2840, 1780 (β-lactam C=O), 1770 ($COOCH_3$), 1695 (amide C=O), 1620 cm^{-1} (C=C).

cis-N-*(α-Carbomethoxy-β-tert-butyldimethylsilyloxyethyl)-3*-N-*phenylacetamido-4-formyl-2-azetidinone (**10**)*

A solution of β-lactam **9** (400 mg, 0.76 mmol) in dry methylene chloride (50 ml) was ozonized at −78°C (Dry Ice – acetone bath) until the solution turned blue. The excess ozone was removed by passing in dry nitrogen. Dimethyl sulfide (0.5 ml) was added and the solution was allowed to warm up slowly to room temperature. The solution was washed with water (20 ml × 3), dried (Na_2SO_4), and evaporated. The semisolid residue was heated under high vacuum for 20 h at 50°C to remove benzaldehyde. Recrystallization from methylene chloride – ether afforded 294 mg (86%) aldehyde **10**, mp 176–177°C; ^{1}Hmr ($CDCl_3$) δ: 0.01 (s, 6H, $Si(CH_3)_2$), 0.80 (s, 9H, Si—*tert*-Bu), 3.44 (s, 2H, $C_6H_5CH_2$), 3.63 (s, 3H, $COOCH_3$), 4.12 (dd, 2H, J_1 = 3 Hz, J_2 = 7 Hz, $SiOCH_2$), 4.50–5.0 (m, 3H, 2 β-lactam protons and $CHCOOCH_3$), 6.36 (bd, 1H, J = 6 Hz, NH), 7.10 (s, 5H, C_6H_5), 9.66 ppm (d, 1H, J = 1.5 Hz, CHO); ir (KBr) γ_{max}: 3250 (NH), 3080, 2960, 2860, 1775 (β-lactam C=O), 1740 ($COOCH_3$), 1720 (CHO), 1645 cm^{-1} (amide C=O).

cis-N-*(α-Carbomethoxy-β-tert-butyldimethylsilyloxyethyl)-3*-N-*phenylacetamido-4-hydroxymethyl-2-azetidinone (**11**)*

To aldehyde **10** (448 mg, 1 mmol) in dry tetrahydrofuran (30 ml) at 0°C under nitrogen was added lithium aluminum tri-(*tert*-butoxy) hydride (431 mg, 1.5 mmol). The mixture was stirred at 0°C for 3 h. Dilute hydrochloric acid (2%) was added slowly (in ice bath) to the mixture until p*H* 5, followed by 1 g of Celite. The suspension was stirred for 20 min, filtered through Celite, and the Celite washed twice with tetrahydrofuran (10 ml × 2). The combined solution was evaporated under reduced pressure. To the residue was added 30 ml of water. The solution was extracted with ethylacetate (20 ml × 3), washed with water, dried (Na_2SO_4), and evaporated. The crude product was chromatographed on silica gel (activity II–III). Elution with chloroform afforded a colorless solid. Recrystallization from ether–hexane afforded 365 mg (81%) alcohol **11**, mp 81–82°C; ^{1}Hmr ($CDCl_3$) δ: 0.1 (s, 6H, $Si(CH_3)_2$), 0.86 (s, 9H, Si—*tert*-Bu), 3.40–3.60 (b, 1H, D_2O exchangeable, OH), 3.53 (s, 2H, $C_6H_5CH_2$), 3.66 (s, 3H, $COOCH_3$), 3.73–4.26 (m, 5H), 4.46 (m, 1H, CH—CH_2OH),

5.50 (dd, 1H, J_1 = 10 Hz, J_2 = 5 Hz, $C_6H_5CH_2CONHCH$), 6.73 (bd, 1H, J = 10, NH), 7.16 ppm (s, 5H, C_6H_5); ir (KBr) γ_{max}: 3200 (OH), 3060, 3040, 2960, 2925, 2860, 1780 (β-lactam C=O), 1745 ($COOCH_3$), 1660 cm^{-1} (amide C=O). *Anal. calcd.* for $C_{22}H_{34}N_2O_6Si_1$: C 58.67, H 7.56, N 6.22; found: C 58.61, H 7.82, N 6.51.

cis-N-*(α-Carbomethoxy*-β-tert-*butyldimethylsilyloxyethyl)-3-azido-4-formyl-2-azetidinone (**3**)*

A solution of azido-β-lactam **2** (1.505 g, 3.50 mmol) in dry methanol (150 ml) was ozonized at −30°C for 90 min. The excess ozone was removed by passing in dry nitrogen. Dimethyl sulfide (1.5 ml) was added and the solution was allowed to warm up slowly to room temperature. Methanol was removed under reduced pressure and the residue was dissolved in 60 ml of benzene, washed with water (20 ml × 3), and dried over sodium sulfate. The benzene solution was azeotroped for 1 h followed by evaporation. The oily residue was heated under high vacuum for 20 h at 50°C to remove benzaldehyde. The aldehyde **3** was obtained in quantitative yield, mp 72–73°C; ^{1}Hmr ($CDCl_3$) δ: 0.01 (s, 6H, $Si(CH_3)_2$), 0.81 (s, 9H, Si—*tert*-Bu), 3.63 (s, 3H, $COOCH_3$), 3.82–4.35 (m, 2H, CH_2—OSi), 4.52 (m, 2H), 4.95 (d, 1H, J = 5.7 Hz, CHN_3), 9.32 ppm (d, 1H, J = 3 Hz, CHO); ir (KBr) γ_{max}: 2960, 2940, 2895, 2860, 2140, and 2110 (N_3), 1790 (β-lactam C=O), 1750 ($COOCH_3$), 1745 cm^{-1} (CHO).

cis-N-*(α-Carbomethoxy*-β-tert-*butyldimethylsilyloxyethyl)-3-azido-4-hydroxymethyl-2-azetidinone (**4**)*

To aldehyde **3** (1.246 g, 3.5 mmol) in tetrahydrofuran (80 ml) at 0°C was added lithium aluminium tri(*tert*-butoxy) hydride (1.78 g, 7 mmol). After stirring under nitrogen for 3 h (0°C), the mixture was acidified with dilute hydrochloric acid (2%) to pH 5, and 1 g of Celite was added. The suspension was stirred for 10 min, filtered, and evaporated. To the residue was added 60 ml ethyl acetate, washed with brine (20 ml × 3), dried (Na_2SO_4), and evaporated. The crude alcohol was chromatographed on silica gel. Elution with chloroform afforded 1.00 g (80%) of alcohol **4**, mp 67–69°C; ^{1}Hmr ($CDCl_3$) δ: 0.1 (s, 6H, $Si(CH_3)_2$), 0.89 (s, 9H, Si—*tert*-Bu), 2.84 (t, 1H, D_2O exchangeable, J = 7 Hz, OH), 3.66 (s, 3H, $COOCH_3$), 3.69–4.03 (m, 4H), 4.03–4.29 (m, 1H, CH—CH—N_3), 4.52 (t, 1H, J = 5 Hz, $CHCOOCH_3$), 4.65 ppm (d, 1H, J = 5 Hz, CHN_3); ^{1}Hmr ($CDCl_3$ + D_2O) δ: 0.1 (s, 6H, $Si(CH_3)_2$), 0.89 (s, 9H, Si—*tert*-Bu), 3.66 (s, 3H, $COOCH_3$), 3.79 (d, 2H, J = 4 Hz, CH_2—OD), 3.93, 3.94 (each d, J = 5 Hz, CH_2—OSi), 4.03–4.29 (m, 1H, CH—CH—N_3), 4.52 (t, 1H, J = 5 Hz, $CHCOOCH_3$), 4.65 ppm (d, 1H, J = 5 Hz, CHN_3); ir (KBr) γ_{max}: 3460 (OH), 2960, 2940, 2900, 2860, 2140 (N_3), 1770 (β-lactam C=O), 1750 cm^{-1} ($COOCH_3$). *Anal.* calcd. for $C_{14}H_{26}N_4O_5Si_1$: C 46.93, H 7.26, N 15.64; found: C 46.81, H 7.50, N 15.68.

cis-N-*(α-Carbomethoxy*-β-tert-*butylmethylsilyloxyethyl)-3-azido-4-methoxymethyl-2-azetidinone (**5**)*

To azido alcohol **4** (358 mg, 1 mmol) and boron trifluoride etherate (0.1 mmol) in dry methylene chloride (40 ml) at 0°C was added diazomethane (10 mmol) in absolute ether in portions over a period of 30 min. After stirring for another hour the solution was washed with saturated sodium bicarbonate solution (15 ml × 2) and water (15 ml × 2), dried (Na_2SO_4), and evaporated. The crude product was chromatographed on silica gel. Elution with chloroform – methylene chloride afforded 316 mg (85%) methyl ether **5**, mp 71–72°C; ^{1}Hmr (CCl_4) δ: 0.06 (s, 6H, $Si(CH_3)_2$), 0.92 (s, 9H, Si—*tert*-Bu), 3.27 (s, 3H, OCH_3), 3.50 (d, 2H, J = 5.5 Hz, CH_2OCH_3), 3.63 (s, 3H, $COOCH_3$), 3.76–4.39 (m, 4H), 4.57 ppm (d, 1H, J = 5 Hz); ir (KBr) γ_{max}: 2940, 2900, 2860, 2120 (N_3), 1780 (β-lactam C=O), 1755 and 1745 cm^{-1} ($COOCH_3$).

cis-N-*(α-Carbomethoxy*-β-tert-*butylmethylsilyloxyethyl)-3-amino-4-methoxymethyl-2-azetidinone (**8a**)*

To a solution of azido-β-lactam **5** (372 mg, 1 mmol) and triethylamine (106 mg, 1.05 mmol) in methylene chloride (20 ml) at 0°C was bubbled in hydrogen sulfide gas for 3 min and the solution allowed to stand for 1 h (evolution of nitrogen was observed). Nitrogen gas was passed in for 15 min and the solvent evaporated under reduced pressure. An additional 30 ml methylene chloride was added and the solution again evaporated. This procedure was repeated twice more. The residue was redissolved in 30 ml of methylene chloride, washed with water (15 ml × 3), dried (Na_2SO_4), and evaporated. The crude product was chromatographed on silica gel. Elution with chloroform – ethyl acetate afforded 284 mg (82%) amine **8*a***; ^{1}Hmr ($CDCl_3$) δ: 0.06 (s, 6H, $Si(CH_3)_2$), 0.86 (s, 9H, Si—*tert*-Bu), 1.91 (bs, 2H, NH_2), 3.27 (s, 3H, OCH_3), 3.36–3.70 (m, 2H, CH_2OCH_3), 3.66 (s, 3H, $COOCH_3$), 3.76–4.06 (m, 3H), 4.15 (d, 1H, J = 5 Hz, $CHNH_2$), 4.42 ppm (t, 1H, J = 4 Hz, $CHCOOCH_3$); ir (film) γ_{max}: 3380 and 3320 (NH_2), 2940, 2895, 2860, 1760 (β-lactam C=O), 1745 cm^{-1} ($COOCH_3$).

cis-N-*(α-Carbomethoxy*-β-tert-*butyldimethylsilyloxyethyl)-3-N-phenylacetamido-4-methoxymethyl-2-azetidinone (**12**)*

To a solution of amine **8*a*** (360 mg, 1 mmol) and pyridine (79 mg, 1 mmol) in dry methylene chloride (20 ml) was added dropwise phenylacetyl chloride (154 mg, 1 mmol) in 3 ml methylene chloride. After the addition was complete, the solution was stirred an additional 5 min and washed with water (15 ml × 2). The organic layer was dried (Na_2SO_4), filtered, and evaporated. The crude oil was chromatographed on silica gel. Elution with ether–chloroform afforded the amide **12** in quantitative yield, mp 76–77°C; ^{1}Hmr ($CDCl_3$) δ: 0.01 (s, 6H, $Si(CH_3)_2$), 0.82 (s, 9H, Si—*tert*-Bu), 2.84 (s, 3H, OCH_3), 2.85–3.23 (m, 2H, CH_2OCH_3), 3.50 (s, 2H, $CH_2C_6H_5$), 3.60 (s, 3H, $COOCH_3$), 3.62–4.15 (m, 3H), 4.40 (t, 1H, J = 4 Hz, $CHCOOCH_3$), 5.41 (dd, 1H, J_1 = 5.5 Hz, J_2 = 10 Hz, CHNH), 6.37 (bd, 1H, J = 10 Hz, NH), 7.08 ppm (s, 5H, C_6H_5); ir (KBr) γ_{max}: 3250 (NH), 2940, 2920, 2880, 2840, 1768 (β-lactam C=O), 1740 ($COOCH_3$) 1645 cm^{-1} (amide C=O).

cis-N-*(α-Carbomethoxy*-β-*hydroxyethyl)-3*-N-*phenylacetamido-4-methoxymethyl-2-azetidinone (**13**)*

To the silyl protected β-lactam **12** (464 mg, 1 mmol) and glacial acetic acid (240 mg, 4 mmol) in dry tetrahydrofuran (10 ml) was added tetracthylammonium fluoride (294 mg, 2 mmol). After stirring at room temperature for 3 h the solvent was removed under reduced pressure. The residue was dissolved in ethyl acetate (30 ml), washed with saturated sodium bicarbonate solution and water, dried, and evaporated. Recrystallization from ether–hexane afforded 294 mg (84%) of alcohol **13**, mp 93–94°C; ^{1}Hmr ($CDCl_3$) δ: 2.97 (s, 3H, CH_2OCH_3), 3.03–3.43 (m, 2H, CH_2OCH_3), 3.50 (s, 2H, $CH_2C_6H_5$), 3.66 (s, 3H, $COOCH_3$), 3.67–3.99 (m, 3H, (CH_2OH), 4.13 (m, 1H, $CHCH_2OCH_3$), 4.42 (m, 1H, $CHCOOCH_3$), 5.51 (dd, 1H, J_1 = 5 Hz, J_2 = 9 Hz, CHNH), 6.50 (bd, 1H, J = 9 Hz, NH), 7.10 ppm (s, 5H, C_6H_5); ^{1}Hmr ($CDCl_3$ + D_2O) δ: 2.97 (s, 3H, CH_2OCH_3), 3.03–3.43 (m, 2H, CH_2OCH_3), 3.50 (s, 2H, $CH_2C_6H_5$), 3.66 (s, 3H, $COOCH_3$), 3.73 (d, 2H, J = 5 Hz, CH_2OD), 4.13 (m, 1H, $CHCH_2OCH_3$), 4.42 (t, 1H, J = 5 Hz, CH—$COOCH_3$), 5.51 (dd, 1H, J_1 = 5 Hz, J_2 = 9 Hz, CHNH), 6.93 (bd, 1H, J = 9 Hz, NH), 7.10 ppm (s, 5H, C_6H_5); ir (KBr) γ_{max}: 3400 (OH), 3300 (NH), 3040, 3010, 2940, 2910, 2885, 1750 (β-lactam C=O), 1730 ($COOCH_3$), 1660 cm^{-1} (amide C=O).

cis-N-*(α-Methylacrylyl)-3*-N-*phenylacetamido-4-methoxymethyl-2-azetidinone (**18**)*

To a solution of alcohol **13** (350 mg, 1 mmol) and triethyl-

For personal use only.

amine (202 mg, 2 mmol) in 30 ml dry methylene chloride at −78°C was added dropwise methane sulfonyl chloride (224 mg, 1 mmol) in 5 ml methylene chloride. After the addition was completed the mixture was washed with p*H* 4.4 buffer (0.2 *M* KH_2PO_4 solution) and water, dried (Na_2SO_4), and evaporated. Recrystallization from methylene chloride–ether afforded a quantitative yield of olefin **18**, mp 133–134°C; ^{1}Hmr ($CDCl_3$) δ: 2.90 (s, 3H, CH_2OCH_3), 2.97–3.46 (m, 2H, CH_2OCH_3), 3.53 (s, 2H, $CH_2C_6H_5$), 3.70 (s, 3H, $COOCH_3$), 4.42 (m, 1H, $CHCH_2OCH_3$), 5.48 (dd, 1H, J_1 = 6 Hz, J_2 = 10 Hz, CHNH), 5.81, 6.07 (each s, 2H, CH_2=C), 6.37 (bd, 1H, J = 10 Hz, NH), 7.13 ppm (s, 5H, C_6H_5); ir (KBr) γ_{max}: 3295 (NH), 3010, 2930, 2910, 1755 (β-lactam C=O), 1725 ($COOCH_3$), 1658 (amide C=O), 1612 cm^{-1} (C=C). *Anal.* calcd. for $C_{17}H_{20}N_2O_5$: C 61.45, H 6.02, N 8.43; found: C 61.49, H 6.29, N 8.69.

cis-N-*(α-Acrylyl)-3*-N-*phenylacetamido-4-methoxymethyl-2-azetidinone (19)*

To β-lactam ester **18** (166 mg, 0.5 mmol) at room temperature was added 5.72 ml sodium hydroxide (0.1 *N*) in aqueous dimethyl sulfoxide (H_2O–DMSO 15:85). The suspension was stirred until all the ester dissolved, giving a clear solution to which p*H* 4.4 phosphate buffer (15 ml) was added. The mixture was extracted with ethyl acetate (15 ml × 4), washed with a small amount of water, dried (Na_2SO_4), and evaporated. The solid residue was washed with ether and filtered to afford 129 mg (81%) acid **19**, mp 195–196°C (dec.); ^{1}Hmr ($CDCl_3$ + DMSO-d_6) δ: 3.04 (s, 3H, OCH_3), 3.35 (d, 2H, J = 4.2 Hz, CH_2OCH_3), 3.43 (s, 2H, $CH_2COCH_2C_6H_5$), 4.36 (bm, COOH, H_2O, and $CHCH_2OCH_3$), 5.12 (dd, 1H, J_1 = 5 Hz, J_2 = 9 Hz, CHNH), 5.59, 5.74 (each s, 2H, CH_2=C), 7.03 (s, 5H, C_6H_5), 8.12 ppm (d, 1H, J = 9 Hz, NH); ir (KBr) γ_{max}: 3250 (NH), 2800–2600 (b, COOH), 1758 (β-lactam C=O), 1695 (acid, C=O), 1658 (amide, C=O), 1596 cm^{-1} (C=C).

cis-N-*Methyloxalamido-3*-N-*phenylacetamido-4-methoxymethyl-2-azetidinone (17a)*

A solution of β-lactam **18** (50 mg, 0.15 mmol) in dry methylene chloride (25 ml) was ozonized at −78°C until the solution turned blue. The excess ozone was removed by passing in dry nitrogen. Dimethyl sulfide (0.2 ml) was added and the solution was allowed to warm up slowly to room temperature. The solution was washed with water (10 ml × 3), dried (Na_2SO_4), and evaporated to afford a quantitative yield of oxalate derivative **17***a*, mp 112–113°C; ^{1}Hmr ($CDCl_3$) δ: 2.97 (s, 3H, CH_2OCH_3), 3.10–3.36 (m, 2H, CH_2OCH_3), 3.56 (s, 2H, $CH_2C_6H_5$), 3.83 (s, 3H, $COOCH_3$), 4.26 (m, 1H, $CHCH_2OCH_3$), 5.64 (dd, 1H, J_1 = 7 Hz, J_2 = 10 Hz, CHNH), 6.44 (bd, 1H, J = 10 Hz, NH), 7.16 ppm (s, 5H, C_6H_5); ir (CH_2Cl_2) γ_{max}: 3370 (NH), 1810 (β-lactam C=O), 1775 ($COOCH_3$), 1700 (C=O), 1680 (amide C=O), 1508, 1372 cm^{-1}.

cis-N-*Oxalamido-3*-N-*phenylacetamido-4-methoxymethyl-2-azetidinone (17)*

The acid **19** (80 mg, 0.25 mmol) was ozonized at −78°C in a mixture of methylene chloride (20 ml) and dimethyl sulfoxide (0.25 ml) until the solution became blue. The excess ozone was removed by passing in dry nitrogen. Dimethyl sulfide (0.25 ml) was added and the solution was allowed to warm up slowly to room temperature. After removal of solvent under high vacuum, the β-lactam **17**, mp 102–103°C, was obtained in quantitative yield; ^{1}Hmr (D_2O + DMSO-d_6) δ: 3.07 (s, 3H, OCH_3), 3.20–3.40 (m, 2H, CH_2OCH_3), 3.50 (s, 2H, $CH_2C_6H_5$), 4.32 (m, 1H, $CHCH_2OCH_3$), 5.38 (d, 1H, J = 7 Hz, CHND), 7.26 ppm (s, 5H, C_6H_5); ir (CH_2Cl_2) γ_{max}: 3230 (NH), 2900, 2720–2440 (COOH), 1810 (β-lactam C=O), 1750–1660 (b, C=O, COOH, NHCO), 1530 cm^{-1}.

1-α-Hydroxy-4-β-carbomethoxy-7-β-azido-O-2-isocepham (21) (3)

To aldehyde **3** (150 mg, 0.42 mmol) and glacial acetic acid (101 mg, 1.68 mmol) in dry tetrahydrofuran (10 ml) was added tetraethylammonium fluoride (124 mg, 0.84 mmol). After stirring at room temperature for 2.5 h the solvent was removed under reduced pressure. The residue was dissolved in ethyl acetate (25 ml), washed with brine (10 ml × 3), dried (K_2CO_3), and evaporated to afford 73 mg (~70%) lactol **21**; pmr ($CDCl_3$ + D_2O) δ: 3.76 (s, 3H, $COOCH_3$), 3.77–4.45 (m, 5H), 4.83 (d, 1H, J = 8 Hz, O—CH—OH), 4.93 ppm (d, 1H, J = 5 Hz, CHN_3); ir (CH_2Cl_2) γ_{max}: 3600 and 3400 (OH), 2140 (N_3), 1786 (β-lactam C=O), 1760 cm^{-1} ($COOCH_3$).

1-α-Acetoxy-4-β-carbomethoxy-7-β-azido-O-2-isocepham (21a)

A solution of lactol **21** (50 mg, 0.21 mmol) in dimethyl sulfoxide (1.5 ml) and acetic anhydride (1 ml) was stirred at room temperature overnight. To the mixture chloroform (30 ml) was added and washed with water (10 ml × 2), dried (Na_2SO_4), and evaporated. The crude product was chromatographed on silica gel. Elution with chloroform afforded 45 mg (75%) of acetate **21***a*; ^{1}Hmr ($CDCl_3$) δ: 2.09 (s, 3H, $COCH_3$), 3.75 (s, 3H, $COOCH_3$), 3.81 (dd, 1H, J_1 = 5 Hz, J_2 = 8 Hz, $CHCH—N_3$), 3.95 (dd, 1H, J_1 = 5.5 Hz, J_2 = 12.2 Hz, OCH_4), 4.21 (dd, 1H, J_1 = 2.2 Hz, J_2 = 12.2 Hz, OCH_5), 4.39 (dd, 1H, J_1 = 2.2 Hz, J_2 = 5.5 Hz, $CHCOOCH_3$), 4.91 (d, 1H, J = 5.0 Hz, CHN_3), 5.75 (d, 1H, J = 8 Hz, $CHOCOCH_3$); ir (film) γ_{max}: 2995, 2160 (N_3), 1790–1740 cm^{-1} (β-lactam C=O, $COOCH_3$, $OCOCH_3$).

Received June 1, 1977

M. JAWDOSIUK, I. KMIOTEK-SKARŻYŃSKA, and W. WILCZYŃSKI. Can. J. Chem. **56**, 218 (1978).

Substituted *o*-nitrohalobenzenes react in aprotic solvents in the presence of powdered potassium hydroxide with deoxybenzoin to form corresponding nitroarylated deoxybenzoins. The latter on reduction form substituted 2,3-diphenylindoles which under certain conditions undergo oxidation with atmospheric oxygen to form 2,3-diphenylindolenyl-3-hydroperoxides.

M. JAWDOSIUK, I. KMIOTEK-SKARŻYŃSKA et W. WILCZYŃSKI. Can. J. Chem. **56**, 218 (1978).

Dans des solvants aprotiques et en présence d'hydroxyde de potassium en poudre, les *o*-nitrohalobenzènes substitués réagissent avec la déoxybenzoine pour conduire aux déoxybenzoines nitroarylés correspondantes. Ces dernières, par réduction, donnent naissance aux diphényl-2,3 indoles substitués. Ces indoles subissent dans certaines conditions des oxydations par l'oxygène atmosphérique pour conduire à des diphényl-2,3 indolénylehydroperoxydes-3.

For nearly a century, the Fischer synthesis of indoles involving intramolecular cyclization of suitable phenylhydrazones has been employed as one of the most useful methods for the synthesis of these compounds (1). The original method has undergone substantial modification and improvement. For example, Dave (2) has recently described a one-step procedure for the synthesis of 2,3-dialkylindoles from appropriate ketones and phenylhydrazine hydrochlorides. The versatility of indoles in organic synthesis, as well as their biological activity gives the stimulus for the further search for new, convenient methods for the preparation of indole derivatives (3, 4).

It has been known from the literature, that one of the possible routes leading to indole formation is the reductive ring closure of suitable aromatic nitro compounds (1, 4). Unfortunately there are not many potential precursors for such cyclizations. Our past work on nitroarylation of carbanions (5) and subsequent cyclization of the products to heterocyclic compounds (6) suggested a new route to indoles via nitroarylation of ketone enolates.

The goal of the present paper is to show a new, simple route leading to substituted 2,3-diphenylindoles which have been the subject of some recent studies on their synthetic (7) and practical (8) applications. In the course of this work we also succeeded in the preparation of 2,3-diphenylindolenyl-3-hydroperoxides. Earlier attempts to obtain these hydroperoxides have failed (9).

Our method consists of aromatic nucleophilic substitution of a halogen atom in substituted *o*-halonitrobenzenes by deoxybenzoin enolate anion (10) and subsequent reduction of the products resulting in the closure of the five-membered ring as shown in Scheme 1. Deoxybenzoin anion produced in dipolar aprotic solvents by the action of powdered potassium hydroxide displaces chlorine in substituted *o*-halonitrobenzenes to afford the corresponding aromatic nucleophilic substitution products. The latter when reduced with iron in acetic acid or hydrogenated on a Pd–C catalyst give indoles in yields exceeding 80%. The results and analytical data are presented in Table 1. *o*-Nitrobenzylphenylketone (2-nitrodeoxybenzoin) also undergoes cyclization under the same conditions to produce 2-phenylindole in 91% yield. This method can be recommended as an alternative source of the title indoles which have been prepared previously from phenylhydrazones of deoxybenzoin (11) or by condensation of primary aromatic amines with benzoin (12).

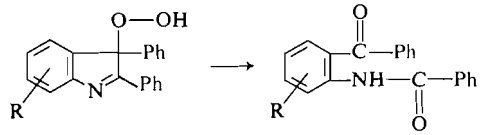
TABLE 1. Summary of analytical data for substituted 2,3-diphenylindoles **4**

Compound R	Formula (mol. wt.)	Yield[a] (%)	Melting point (°C) This work	Melting point (°C) Literature (ref.)
H	$C_{20}H_{15}N$ 269.35	92	123–126	122–123 (14) 124–125 (15)
5-Cl	$C_{20}H_{14}ClN$ 303.80	85	134–136	135 (16)
6-Cl	$C_{20}H_{14}ClN$ 303.80	81	116–118[b]	
6-CH_3	$C_{21}H_{17}N$ 283.38	83	110–112	114–116 (7)

[a]Yields obtained when compounds **3** were reduced with iron in acetic acid. Yields obtained by hydrogenation were of comparable range if some precautions against auto-oxidation were taken.
[b]*Anal.* calcd. for $C_{20}H_{14}ClN$: C 79.07, H 4.65, N 4.61; found: C 79.03, H 4.55, N 4.52.

In the course of this work we observed that reduction of nitro compounds **3** with iron in acetic acid always gave good and reproducible yields of **4**, and the resulting compounds were resistant to auto-oxidation. Although catalytic hydrogenation of **3** seemed to be the simplest way of reduction, and indeed reactions proceeded easily and rapidly, we encountered some unexpected difficulties. When a reduced sample was processed immediately the yields of **4** exceeded 90%; however when it was exposed to air for several hours the characteristic blue fluorescence of the solution disappeared, and after partial evaporation of solvent a corresponding hydroperoxide **5** crystallized in high yield. Undoubtedly auto-oxidation of **4** was catalyzed by traces of the catalyst present in the solution even after filtration of the mixture through a paper filter. The catalytic oxidation of 2,3-disubstituted indoles was reported in the literature a long time ago; however, the resulting hydroperoxyindolenines were unstable and formed 2,3-disubstituted-3-hydroxy-indolenines (13). Interestingly samples of indoles, obtained by reduction with iron, which were dissolved in benzene and agitated with a stream of air for 24 h did not form any detectable amount of hydroperoxide even at elevated temperatures. Addition of a small quantity of the catalyst used for hydrogenation did not change the result. So far we have not been able to convert such indoles into their hydroperoxides. On the other hand the reaction mixtures maintained overnight in open flasks, after hydrogenation was completed, produced **5** exclusively. To our knowledge these hydroperoxides are new compounds. The analytical data are presented in Table 2. Hydroperoxides **5** undergo typical transformations for hydroperoxides of this structure. For instance, methanolic solutions of **5** (R = H, 6-CH_3) when refluxed with some quantity of 2 *N* aqueous sodium hydroxide formed corresponding 2-benzamidobenzophenones (Scheme 2).



SCHEME 2

Experimental

Reaction of Deoxybenzoin with Substituted o-*Nitrobenzenes*

General Procedure (10)

In a three-necked flask equipped with an efficient mechanical stirrer, thermometer, and dropping funnel 19.6 g (0.1 mol) of deoxybenzoin, 12 g of powdered KOH, and 60 ml of DMSO were stirred for 5–10 min. Then 0.1 mol of nitrocompound dissolved in 30 ml of DMSO was added dropwise to the stirred mixture. The reaction was carried out for 1–1.5 h at 45–50°C and then the mixture was poured into water. The product was filtered off or extracted with benzene and then recrystallized from methanol. Recrystallized products were obtained in a 50–60% yield.

Substituted 2,3-Diphenylindoles 4

Reduction with Iron-dust

A portion (3 g) of nitrocompound **3** was dissolved in 30 ml of warm acetic acid. To this solution 6 g of powdered iron was added and the mixture was refluxed for 3 h. The solution was poured into 100 ml of water and the precipitated product was filtered off, dried, and finally powdered in a mortar. The resulting material was refluxed with benzene and the filtered

[c]Mass spectrum 70 eV, *m/e* (relative intensity, %): 315 (M^+, 25), 299 (52), 283 (37), 270 (37), 210 (31), 196 (10), 195 (16), 181 (17), 165 (25), 133 (100), 105 (47), 77 (63).

solution was concentrated and precipitated with petroleum ether. Yields and analytical data for **4** are given in Table 1.

Catalytic Hydrogenation

Compound **3** (2 mmol) was hydrogenated in 30 ml of methanol or dioxane in the presence of 0.1 g of a 5% Pd–C (Degussa Typ E1ON) or $Pd–Al_2O_3$ catalyst (Degussa Typ E207R). After the reaction mixture had consumed 6 mmol of hydrogen, the catalyst was immediately filtered off, the solvent was evaporated to dryness, and the residual oil was recrystallized from methanol or ligroin as quickly as possible to avoid excessive exposure to air. Following this procedure indoles **4** were obtained in 50–80% yields depending on the duration of the processing of the reaction mixture. The residual filtrates after subsequent evaporation yielded hydroperoxides **5** in a 15–45% yield.

Substituted 2,3-Diphenylindolenyl-3-hydroperoxides 5

A portion (2 mmol) of **3** was hydrogenated as described above. The reaction mixture was left for 2 days and then the catalyst was filtered off and the filtrate was partially evaporated to give a 50–85% yield of **5**. To accelerate the formation of **5** a slow stream of oxygen was passed through the solution at 50°C. After a period of 4–5 h glc did not show the presence of **4** and the only isolable product was **5**. Analytical data are presented in Table 2.

Decomposition of 5 to 6

Hydroperoxide **5** (1 g) was dissolved in 40 ml of boiling methanol. To this solution 5 ml of 2 *N* aqueous NaOH was added and the mixture was refluxed for 2 h. The mixture was diluted with water and the product was extracted with benzene; the extract was dried over $MgSO_4$, evaporated, and recrystallized from ethanol. Compound **5**, R = H, gave a 85% yield of 2-benzamidobenzophenone, mp 84–86°C (7); compound **5**, R = 6-CH_3, gave a 70% yield of 2-benzamido-4-methyl-benzophenone.

Pyrrole chemistry. XVIII. The thio-Claisen rearrangement

KANG-ER TEO, GRAHAM H. BARNETT, HUGH J. ANDERSON, AND CHARLES E. LOADER
Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X7

Received August 30, 1977

KANG-ER TEO, GRAHAM H. BARNETT, HUGH J. ANDERSON, and CHARLES E. LOADER. Can. J. Chem. **56**, 221 (1978).

The thio-Claisen rearrangement has been carried out on 2-allylthiopyrrole, 1-methyl-2-allylthiopyrrole, and 2,5-diallylthiopyrrole. The products were trapped by acetylation of the β-allyl-α-thiols. Raney nickel desulfurization of these products gave the corresponding β-propylpyrroles but attempts to functionalize the β-allyl group failed. 1-Methyl-3-propylpyrrole and 3,4-dipropylpyrrole were also synthesized by other routes for comparison.

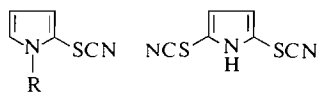
KANG-ER TEO, GRAHAM H. BARNETT, HUGH J. ANDERSON et CHARLES E. LOADER. Can. J. Chem. **56**, 221 (1978).

On a effectué un réarrangement de thio-Claisen sur l'allylthio-2 pyrrole, le méthyl-1 allylthio-2 pyrrole et le diallylthio-2,5 pyrrole. On a piégé les produits par acétylation des β-allyl α-thiols. La désulfurisation, par le nickel de Raney, de ces produits conduit aux β-propylpyrroles correspondants mais des essais pour fonctionnaliser le groupe β-allyle n'ont donné aucun résultat. Pour fins de comparaison on a aussi synthétisé les méthyl-1 propyl-3 pyrrole et dipropyl-3,4 pyrrole par d'autres méthodes.

[Traduit par le journal]

The thio-Claisen rearrangement apparently has not been investigated in the pyrrole series, possibly because of the expected instability of the allyl pyrrolethiol reaction products (1). In view of the recent success of the thio-Claisen rearrangement of indoles (2, 3), it seemed worthwhile to examine the potential of this rearrangement with 2-allylthio pyrroles as it offered an approach to 2,3-disubstituted pyrroles. If the reaction was fruitful, Raney nickel desulfurization of the product would lead to a β-substituted pyrrole. It was also of interest to see whether or not a double thio-Claisen rearrangement would take place.

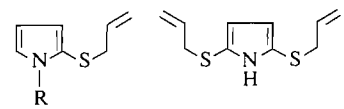
Thiocyanation (4, 5) of pyrrole and 1-methylpyrrole in methanol with copper(II) thiocyanate furnished 2-thiocyanopyrrole (**1***a*) and 1-methyl-2-thiocyanopyrrole (**1***b*), respectively, in fair yield



1 **2**

(*a*) R = H
(*b*) R = CH_3

(48–68%), whereas pyrrole with thiocyanogen in methanol gave a low yield of 2,5-dithiocyanopyrrole (**2**) as the only isolated product. Treatment of a methanolic solution of the thiocyanopyrroles, **1***a*, **1***b*, or **2**, and allyl bromide at 0°C with an excess of aqueous methanolic potassium hydroxide furnished, essentially quantitatively according to nmr spectra, the corresponding allylthiopyrroles **3***a*, **3***b*, and **4**. However purification by column chromatography followed by repeated short path, reduced pressure distillations resulted in considerable loss of material. The allylthiopyrroles were light yellow liquids which

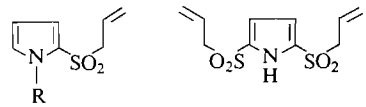


3 **4**

had the expected spectroscopic properties including the correct molecular ion peaks in their mass spectra.

The mass spectra of all these allylthiopyrroles have a fragmentation peak corresponding to the loss of a vinyl group ($M - 27$) and an allyl group ($M - 41$). The loss of a thiol unit ($M - 33$) from **3***a* and **3***b* may arise from a thermal thio-Claisen rearrangement to the thiol followed by a loss of the SH group. The corresponding peak for **4** is at $M - 67$, presumably from the loss of two SH groups and a hydrogen atom.

The microanalyses of all of the allylthiopyrroles, **3***a*, **3***b*, and **4** were unsatisfactory; each being low in carbon. The corresponding sulfones, **5***a*, **5***b*, and **6**, proved more stable and gave the expected ir, uv, nmr, and mass spectra. Correct microanalyses were obtained for **5***a* and **6** but **5***b* was repeatedly low in carbon.



5 **6**

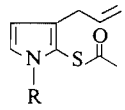
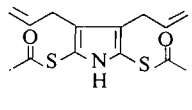
Several attempts to rearrange 2-allylthiopyrrole (**3***a*) in triethylene glycol or in quinoline under nitrogen at 100 or 170°C for several hours led to deep red gums which showed no pyrrolic proton absorption in the nmr spectrum. At shorter reaction times, most of the starting material **3***a* was recovered unchanged with a small amount of the red gum. As *N*-alkylpyrroles are often more stable, attention was turned to 1-methyl-2-allylthiopyrrole (**3***b*) and it was decided to attempt to trap the expected thiol by acetylation. The rearrangement of 1-methyl-2-allylthiopyrrole with quinoline and acetic anhydride was successful, and the acetylated product **7***b* was isolated. These conditions were then found to be satisfactory for 2-allylthiopyrrole (**3***a*).



7



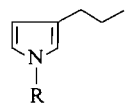
8

Both **3***a* and **3***b* were shown to rearrange efficiently and the *S*-acylated products **7***a* and **7***b* were isolated in good yield under two sets of conditions: (*i*) in quinoline at 170°C under nitrogen for 15 min; (*ii*) in *N*,*N*-dimethylaniline at 90–100°C under nitrogen for 15 h.

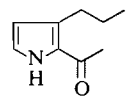
The nmr spectrum of the rearrangement product **7***a* showed two triplets in the aromatic region which collapsed to two doublets upon the treatment with deuterium oxide. The coupling constant, ($J_{4,5} \approx 2.8$ Hz) supported a 2,3-disubstituted pyrrole (6). The rearrangement product **7***b* also showed the expected nmr spectrum. The ir spectra of **7***a* and **7***b* showed carbonyl absorption consistent with an acetylated thiol (7) and not with an acetyl group directly attached to the pyrrole ring (8). When 2,5-diallylthiopyrrole (**4**) was heated in the presence of acetic anhydride and quinoline at 170°C for 15 min a double thio-Claisen rearrangement occurred to afford **8** in excellent yield. Products **7***a* and **8** were fairly stable whereas **7***b* darkened considerably on standing but all three gave good microanalytical results. Mass, ir, and nmr spectra of these compounds were consistent with the structures assigned.

Several attempts were made to modify the double bond of the rearrangement products **7***a* and **7***b* so that, after the removal of the sulfur side chain, a β-functionalized pyrrole might be obtained. Attempted hydration of **7***a* with mercury(II) acetate in water–tetrahydrofuran followed by sodium borohydride – sodium hydroxide reduction (9) gave only recovered starting material. Attempted oxidative rearrangement of **7***a* with thallium(III) nitrate in methanol (10) gave a brown liquid showing no pyrrolic proton in its nmr spectrum. Lemieux – von Rudloff oxidation (11) on **7***a* resulted in loss of the starting material. With *m*-chloroperoxybenzoic acid in methylene chloride at 25°C for 25 h (12), **7***a* did not react, while after refluxing for several hours about 30% of the starting material was recovered and no desired epoxide was obtained. An attempt to ozonize **7***b* also resulted in the loss of starting material. Thus the double bond resisted mild conditions but the pyrrole ring did not survive stronger conditions.

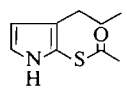
Attempts to remove the sulfur side chain from **7***b* using zinc dust – aqueous acetic acid reflux gave only starting material. Stirring and refluxing **7***a* with Raney nickel in acetone gave a moderate yield of 3-propylpyrrole (**9***a*), together with a very small amount of 2-acetyl-3-propylpyrrole (**10**). A comparable yield of 1-methyl-3-propylpyrrole (**9***b*) was obtained under similar conditions from **7***b* accompanied by a trace of a compound whose spectral properties corresponded to 1-methyl-3-propyl-2-acetylthiopyrrole (**11**). Compound **8** gave the expected Raney nickel product, 3,4-dipropylpyrrole (**12**), and some 2-acetyl-3,4-dipropylpyrrole (**13**).



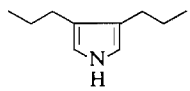
9



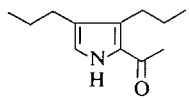
10



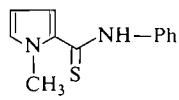
11



12



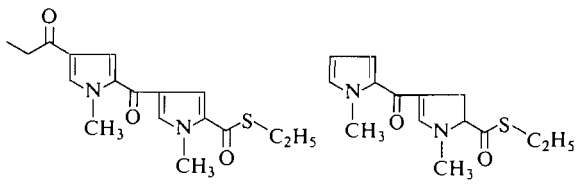
13



14

The new β-propyl pyrroles **9***b* and **12** were then synthesized by other methods to confirm structures and to compare ease of preparation. Friedel–Crafts propanoylation of 1-methyl-2-pyrrolethiolcarboxylate prepared via the thiocarbanilide (**14**) gave the desired 4-propanoyl derivative as well as a small amount of the dipyrrolyl ketone (**15**). When milder conditions were used for propanoylation another dipyrrolyl ketone by-product (**16**) was obtained together with significant amounts of unreacted starting material.

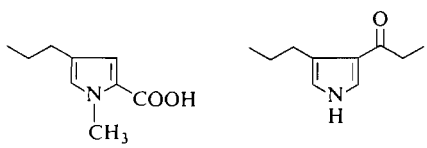
The Wolff–Kishner reduction of compound **14** also caused hydrolysis of the thiol ester but not decarboxylation (13), giving 1-methyl-3-propyl-2-pyrrolecarboxylic acid (**17**). It was found that the addition of copper chromite and more potassium hydroxide to the Wolff–Kishner reaction mixture then



15 16

led to decarboxylation and formation of the desired product (**9***b*) in good yield.

The reaction of ethylmagnesium bromide with 2-hexenal gave 4-octen-3-ol which could be oxidized with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) to 4-octen-3-one (**18**). Condensation of **18** with *p*-toluenesulfonylmethyl isocyanide (14) then gave 3-propanoyl-4-propylpyrrole (**19**) which was reduced with lithium aluminum hydride to 3,4-



17 19

dipropylpyrrole (**12**). Thus, thio-Claisen rearrangement of readily prepared allylthiopyrroles followed by Raney nickel desulfurization is a way to synthesize β-propylpyrroles but functionalization of the β-allyl group has not been accomplished. Other synthetic approaches to these β-propylated pyrroles proved quite competitive, much less offensive from an odor standpoint, and produced more stable intermediates.

Experimental

Melting points were determined on a Thomas–Hoover apparatus and are not corrected. The proton magnetic resonance spectra were obtained with a Varian EM360 spectrometer at 60 MHz in $CDCl_3$, unless otherwise stated, and are recorded on the δ scale. Analyses were determined by Atlantic Microlab, Inc., Atlanta, GA, U.S.A., Memorial University Water Analysis Facility, and Alfred Bernhardt, West Germany. Other instruments were as described in ref. 13. Ultraviolet spectra were recorded in 95% ethanol and infrared spectra in carbon tetrachloride unless otherwise specified.

2-Thiocyanopyrrole and 2,5-Dithiocyanopyrrole

The copper(II) thiocyanate method of Matteson and Snyder (4) gave 48% of 2-thiocyanopyrrole. Spectral data corresponded to those of ref. 5.

From the thiocyanogen method (4) for 2-thiocyanopyrrole about 17% of 2,5-dithiocyanopyrrole was obtained. Spectral data corresponded to those of ref. 15.

1-Methyl-2-thiocyanopyrrole

The method of Matteson and Snyder afforded 68% of 1-methyl-2-thiocyanopyrrole, bp 40–45°C/0.2 Torr (lit. (16) bp 108–110°C/13 Torr); ir ν: 2155 cm^{-1}(C≡N); nmr δ: 7.10 (1H, m), 6.57 (1H, m), 6.10 (1H, m), 3.68 (3H, s).

2-Allylthiopyrrole

The method of Matteson and Snyder (4) for 2-methylthiopyrrole was adapted using allyl bromide to give 82% of 2-allylthiopyrrole (**3***a*), bp 40–44°C/0.2 Torr, as a yellow oil which darkened rapidly; ir showed a free N—H at ν 3450 cm^{-1}; nmr δ: 8.23 (1H, br, D_2O exchanged); 6.70 (1H, m), 6.30 (1H, m), 6.12 (1H, m), 5.75 (1H, m), 4.87 (2H, d), 3.20 (2H, d); ms showed M^+ 139. *Anal.* calcd. for C_7H_9NS: C 60.39, H 6.52, N 10.06; found: C 59.46, H 6.45, N 9.76.

1-Methyl-2-allylthiopyrrole

1-Methyl-2-thiocyanopyrrole was converted by the above procedure to 90% of 1-methyl-2-allylthiopyrrole (**3***b*), a colorless liquid, bp 60°C/0.3 Torr, pure by tlc and nmr; uv λ_{max}: 222 (ε 6100), 248 nm (ε 6700); nmr δ: 6.68 (1H, m), 6.28 (1H, m), 6.03 (1H, m), 5.70 (1H, m), 4.87 (2H, m), 3.63 (3H, s), 3.19 (2H, d). Analyses repeatedly low in carbon.

2,5-Diallylthiopyrrole

2,5-Dithiocyanopyrrole was converted by the above procedure to 85% of 2,5-diallylthiopyrrole (**4**), pale yellow liquid, bp 80°C/0.3 Torr, pure by tlc and nmr; uv λ_{max}: 220 (ε 8500) 264 nm (ε 11 100); ir ν: 3445 cm^{-1}; nmr δ: 8.3 (1H, broad s), 6.25 (2H, d), 5.75 (2H, m), 4.85 (4H, m), 3.22 (4H, d). Analyses repeatedly low in carbon.

2-Allylsulfonylpyrrole

2-Allylthiopyrrole (1.39 g, 10.0 mmol) was dissolved in acetic acid (8 ml) and cooled in an ice bath with stirring. Hydrogen peroxide (30% aq, 9 ml, 100 mmol) was added in portions. The solution became black and heat was evolved. After stirring at room temperature for 50 h the colour of the solution had changed to orange. The mixture was diluted with water and then extracted three times with methylene chloride. The combined organic extracts were washed (5% aqueous $NaHCO_3$, H_2O, saturated brine), dried ($MgSO_4$), and then the solvent was removed. The thick yellow-brown oil residue was chromatographed on silica gel. The eluate containing the product gave an oil which was distilled bulb-to-bulb (0.35 Torr, oven temperature 100°C) to give (350 mg, 20%) of 2-allylsulfonylpyrrole (**5***a*), a colorless oil; ir ν: 3430, 3350 (NH, free and H-bonded), 1318, 1131 cm^{-1} (sulfone); uv λ_{max}: 237 nm (ε 10 100); nmr δ: 9.7 (1H, broad s), 6.92 (1H, m), 6.74 (1H, m), 6.16 (1H, m), 5.30 (3H, m), 3.80 (2H, d), $J_{3,4} = 3.8$, $J_{4,5} = 2.8$, $J_{3,5} = 1.4$ Hz. *Anal.* calcd. for $C_7H_9NO_2S$: C 49.11, H 5.30, N 8.18; found: C 49.16, H 5.34, N 8.03.

1-Methyl-2-allylsulfonylpyrrole

The procedure above was applied to 1-methyl-2-allylthiopyrrole. After failure to obtain an analytically pure specimen it was rechromatographed on thick-layer plates of silica gel giving 15% of 1-methyl-2-allylsulfonylpyrrole (**5***b*) a colorless semi-solid; ir ν: 1320, 1140 cm^{-1} (sulfone); nmr δ: 7.10 (1H, q), 6.60 (1H, q), 6.39 (1H, q), 5.3 (3H, m), 3.78 (2H, d), 3.69 (3H, s). *Anal.* calcd. for $C_8H_{11}NO_2S$: C 51.87, H 5.99; found: C 50.66, H 5.97. This analysis could not be improved.

2,5-Bis(allylsulfonyl)pyrrole

The oxidation procedure above was applied to 2,5-diallylthiopyrrole. After repeated crystallization from methylene chloride – hexane, a 35% yield of 2,5-bis(allylsulfonyl)pyrrole (**6**) was obtained as a white solid mp 115–117°C; uv λ_{max}: 237 nm (ε 17 400); ir (Nujol) ν: 1314, 1142 cm^{-1} (sulfone); nmr δ: 10.5 (1H, broad s), 6.84 (2H, d), 5.4 (6H, m), 3.95 (4H, d). *Anal.* calcd. for $C_{10}H_{13}NO_4S_2$: C 43.62, H 4.76, N 5.09, S 23.29; found: C 43.60, H 4.78, N 5.06, S 23.21.

Rearrangement of 2-Allylthiopyrrole

(*a*) A mixture of 2-allylthiopyrrole (1.39 g, 10.0 mmol) and

acetic anhydride (6 ml) was added all at once with stirring to quinoline (6 ml) which had been heated to 170°C under nitrogen. These conditions were maintained for 15 min then the reaction mixture was cooled and diluted with ethyl ether. This solution was successively washed three times with 2 *M* HCl, water, 5% aqueous $NaHCO_3$, saturated brine, and dried ($MgSO_4$). Removal of the solvent gave a brown oil which was chromatographed on silica gel. The fractions containing solid were combined and recrystallized from hexane to give (1.28 g, 71%) colorless 3-allyl-2-acetylthiopyrrole (*7a*), mp 42.5–43.5°C; uv λ_{max}: 226 (ε 10 500), 241 nm (ε 10 900); ir ν: 3468, 1735, 1702 cm^{-1}; nmr δ: 8.3 (1H, broad s, D_2O exchanged), 6.83 (1H, t) 6.15 (1H, t), 5.11 (1H, m), 4.87 (1H, m), 3.21 (2H, d), 2.26 (3H, s), $J_{4,5}$ = 2.8 Hz. *Anal.* calcd. for $C_9H_{11}NOS$: C 59.64, H 6.12, N 7.73; found: C 59.46, H 6.15, N 7.81.

(*b*) A solution of 2-allylthiopyrrole (280 mg, 2 mmol) in *N*,*N*-dimethylaniline (1.5 ml) and acetic anhydride (1.5 ml) was stirred at 90–100°C under nitrogen for 15 h. It was worked up as above to give 335 mg (92%) of crude crystalline product after solvent removal.

Rearrangement of 1-Methyl-2-allylthiopyrrole

Following procedure (*a*) above, 1-methyl-2-allylthiopyrrole (1.47 g, 9.6 mmol) was rearranged and worked up to give (1.77 g, 95%) 1-methyl-3-allyl-2-acetylthiopyrrole (*7b*), a pale yellow oil which was almost pure by tlc and nmr. The analytical sample was prepared by two bulb-to-bulb distillations: uv λ_{max}: 227 (ε 10 600), 245 nm (ε 11 700); ir ν: 1720 cm^{-1}; nmr δ 6.75 (1H, d), 6.03 (1H, d), 5.02 (1H, m), 4.80 (1H, m), 3.47 (3H, s), 3.18 (2H, d), 2.23 (3H, s), $J_{4,5}$ = 2.8 Hz. *Anal.* calcd. for $C_{10}H_{13}NOS$: C 61.51, H 6.71, N 7.17; found: C 61.61, H 6.75, N 7.04.

Rearrangement of 2-5-Diallylthiopyrrole

Following procedure (*a*) above, 2,5-diallylthiopyrrole (1.75 g, 8 mmol) was rearranged and worked-up to give (2.01g, 85%) 3,4-diallyl-2,5-diacetylthiopyrrole (**8**) as a pale brown oil. Rechromatographed to give single tlc spot: uv λ_{max}: 256 nm (ε 15 300); ir ν: 1702 cm^{-1}; nmr δ: 8.7 (1H, broad s) 5.7 (2H, m), 5.00 (2H, m), 4.73 (2H, m), 3.18 (4H, d), 2.28 (6H, s). *Anal.* calcd. for $C_{14}H_{17}NO_2S_2$: C 56.92, H 5.80, N 4.74; found: C 56.88, H 5.73, N 4.87.

Desulfurization of 3-Allyl-2-acetylthiopyrrole

3-Allyl-2-acetylthiopyrrole (980 mg, 5.42 mmol) was dissolved in a small amount of acetone and W-5 Raney nickel (10 g), which had been washed three times with acetone, was added. The volume was made up to 100 ml with acetone and the mixture stirred and refluxed for 1 h. The Raney Ni was removed by filtration through a pad of Celite and the solvent removed to give a yellow oil. Thick-layer chromatography on silica gel gave (350 mg, 58%) of liquid with spectral properties corresponding to those reported for 3-propylpyrrole (**9***a*) (17) and a colorless solid, (12 mg after sublimation) 2-acetyl-3-propylpyrrole (**10**) mp 63–64°C; uv λ_{max}: 291 nm (ε 12 700); ir ν: 3433, 3275, 1641 cm^{-1}; nmr δ: 9.7 (1H, broad s), 6.83 (1H, m), 6.04 (1H, m), 2.72 (2H, m), 2.41 (3H, s), 1.7 (2H, m), 0.95 (3H, t). Mass calcd. for $C_9H_{13}NO$: M^+ 151.0997; found: 151.0999.

Desulfurization of 1-Methyl-3-allyl-2-acetylthiopyrrole

Repetition of the above procedure with 1-methyl-3-allyl-2-acetylthiopyrrole (400 mg, 2.05 mmol) gave (130 mg, 53%) of 1-methyl-3-propylpyrrole (**9***b*) as a pale yellow oil from thick-layer chromatography; nmr δ: 6.36 (1H, m), 6.24 (1H, m), 5.85 (1H, m), 3.52 (3H, s), 2.38 (2H, t), 1.5 (2H, m), 0.91 (3H, t). *Anal.* calcd. for $C_8H_{13}N$: C 77.99, H 10.64; found: C 77.73, H 10.77.

After repeated thick-layer chromatography about 10 mg of a pale yellow oil was obtained whose spectra suggested 1-methyl-3-propyl-2-acetylthiopyrrole (**11**): ir ν: 1708 cm^{-1}; ms M^+ 197; nmr δ: 6.76 (1H, d), 6.07 (1H, d), 3.49 (3H, s), 2.7 (2H, m), 2.28 (3H, s), 1.7 (2H, m), 0.9 (3H, m), $J_{4,5}$ = 2.9 Hz.

Desulfurization of 3,4-Diallyl-2,5-diacetylthiopyrrole

Repetition of the above procedure using 3,4-diallyl-2,5-diacetylthiopyrrole (540 mg, 1.8 mmol) gave (180 mg, 66%) of pale yellow liquid obtained from thick-layer chromatography on silica gel, 3,4-dipropylpyrrole (**12**), bp 69.5–70.5°C/1 Torr; nmr δ: 7.6 (1H, broad s), 6.37 (2H, d), 2.37 (4H, m), 1.5 (4H, m), 0.93 (6H, t), $J_{2,5}$ = 2.5 Hz. *Anal.* calcd. for $C_{10}H_{17}N$: C 79.41, H 11.33; found: C 79.30, H 11.35.

In addition, 60 mg of colorless solid was isolated, 2-acetyl-3,4-dipropylpyrrole (**13**), mp 71–73°C; uv λ_{max}: 297 nm (ε 19 600); ir ν: 3430, 3240, 1635 cm^{-1}; nmr δ: 9.3 (1H, broad s), 6.69 (1H, d), 2.40 (3H, s), 2.8–0.7 (14H, complex m). *Anal.* calcd. for $C_{12}H_{19}NO$: C 74.57, H 9.91; found: C 74.37, H 9.95.

Alternate Synthesis of 1-Methyl-3-propylpyrrole

(a) 1-Methyl-2-pyrrolethiocarbanilide

To a stirred suspension of aluminum chloride (67 g, 0.50 mol) in dichloromethane (200 ml) maintained at 0°C under N_2 was added 1-methylpyrrole (40.5 g, 0.50 mol) in dichloromethane (150 ml). A solution of phenyl isothiocyanate (67.5 g, 0.50 mol) in dichloromethane (200 ml) was added dropwise over about 45 min and allowed to stir at room temperature a further 2 h under N_2. The mixture was poured onto ice and the two-phase system stirred vigorously 15 min. The organic layer was separated, washed (H_2O), and dried ($MgSO_4$). After removal of solvent, a yellow crystalline mass was obtained which was triturated with ether and filtered, giving yellow needles. More product was recovered from the filtrate after evaporation. The product (64.7 g, 60%) 1-methyl-2-pyrrolethiocarbanilide (**14**) was recrystallized from chloroform–petroleum and sublimed, mp 100–100.5°C; nmr δ: 8.8 (1H, broad s), 7.3 (5H, m), 6.71 (1H, t), 6.46 (1H, q), 6.01 (1H, q), 3.89 (3H, s). *Anal.* calcd. for $C_{12}H_{12}N_2S$: C 66.65, H 5.59, N 12.96; found: C 66.78, H 5.60, N 13.02.

(b) Ethyl 1-Methyl-2-pyrrolethiolcarboxylate

A mixture of 1-methyl-2-pyrrolethiocarbanilide (59 g, 0.27 mol), 6 *M* aqueous NaOH (175 ml), and bromoethane (43.6 g, 0.40 mol) was heated on a steam bath with vigorous stirring for 2.5 h. The solution was cooled and extracted with ether. The ether layer was washed thoroughly with water, then 3 *M* aqueous H_2SO_4 (180 ml) was added and the two-phase system heated under N_2 on a steam bath, allowing the ether to escape. After 1 h, the mixture was cooled and the dark supernatant oil was extracted into ether. The aqueous phase was carefully neutralized (solid Na_2CO_3) and extracted thoroughly with ether. The combined ether extracts were washed (aqueous $NaHCO_3$, water) and dried ($MgSO_4$). Removal of solvent and distillation gave the crude product (31.0 g, 66%) as a yellow oil. Redistillation gave pure ethyl 1-methyl-2-pyrrolethiolcarboxylate, bp 96–96.5°C/25 Torr; ir ν: 1635 cm^{-1}; nmr δ: 6.93 (1H, q), 6.65 (1H, t), 5.97 (1H, q), 3.82 (3H, s), 2.93 (2H, q), 1.26 (3H, t). *Anal.* calcd. for $C_8H_{11}NOS$: C 56.77, H 6.55; found: C 56.77, H 6.49.

(c) Ethyl 1-Methyl-4-propanoyl-2-pyrrolethiolcarboxylate

Following the acetylation procedure of ref. 18, ethyl 1-methyl-2-pyrrolethiolcarboxylate (4.65 g, 27 mmol) was acylated with propanoyl chloride (2.78 g, 30 mmol) to give a yellow oil after evaporation of the dried solution. The product was chromatographed on neutral alumina (40 g) eluting with dichloromethane–petroleum to give a pale yellow oil which crystallized. Recrystallization from ether–petroleum gave (4.50 g, 73%) ethyl 1-methyl-4-propanoyl-2-pyrrolethiolcarboxylate, mp 60–61.5°C; ir (Nujol) ν: 1645 cm^{-1}; nmr δ: 7.3 (2H, m), 3.88 (3H, s), 2.99 (2H, q), 2.75 (2H, q), 1.31 (3H, t),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

1.16 (3H, t). *Anal.* calcd. for $C_{11}H_{15}NO_2S$: C 58.64, H 6.71; found: C 58.62, H 6.74.

Continued elution of the column gave (0.27 g) ethyl 4-(1′-methyl-4′-propanoyl-2′-pyrrolecarbonyl)-1-methyl-2-pyrrolethiolcarboxylate (**15**), mp 151–152.5°C (dichloromethane–petroleum); ir (Nujol) ν: 1610, 1635, 1670 cm^{-1}; nmr δ: 7.41 (3H, m), 7.22 (1H, m), 3.94 (6H, s), 2.99 (2H, q), 2.76 (2H, q), 1.30 (3H, t), 1.17 (3H, t). *Anal.* calcd. for $C_{17}H_{20}N_2O_3S$: C 61.42, H 6.06, N 8.43; found: C 61.41, H 6.05, N 8.44.

Under conditions where the propanoylation was incomplete and starting material was recovered, ethyl 4-(1′-methyl-2′-pyrrolecarbonyl)-1-methyl-2-pyrrolethiolcarboxylate (**16**) was also obtained, mp 79.5–81.5°C (dichloromethane–petroleum); ir (Nujol) ν: 1600, 1645 cm^{-1}; nmr δ: 7.36 (1H, d), 7.25 (1H, d), 6.74 (2H, m), 6.02 (1H, m), 3.88 (6H, s), 2.95 (2H, q), 1.28 (3H, t), $J_{3,5} = 2.0$ Hz). *Anal.* calcd. for $C_{14}H_{16}N_2O_2S$: C 60.85, H 5.84, N 10.14; found: C 60.89, H 5.84, N 10.14.

(d) 1-Methyl-3-propylpyrrole

A solution of ethyl 1-methyl-4-propanoyl-2-pyrrolethiolcarboxylate (1.125 g, 5.0 mmol), potassium hydroxide pellets (1.00 g, 18.0 mmol), and hydrazine hydrate 85% aqueous (1.00 g, 17.0 mmol) in triethylene glycol (10 ml) was heated at ca. 125°C under N_2 for 1.5 h. Water was allowed to distil off through a short-path condenser. Then copper chromite powder (0.30 g) and potassium hydroxide pellets (3.0 g) were added and the mixture heated at 210–220°C for 2 h. The mixture was cooled and the p*H* reduced to 6–7 with 6 *M* aqueous HCl, then reheated to distil water and the product as a supernatant oil which could be removed by pipetting. Yield of crude 1-methyl-3-propylpyrrole (**9b**) was 0.442 g (72%). This material was identical to that obtained from the desulfurization synthesis above.

When the combined Wolff–Kishner, hydrolysis and decarboxylation procedure described in ref. 13 was followed, no product distilled. Acidification of that reaction mixture gave (0.51 g, 71%) 1-methyl-4-propyl-2-pyrrolecarboxylic acid (**17**), mp 69.5–70.5°C (sublimation); ir (Nujol) ν: 1665 cm^{-1}; nmr δ: 6.86 (1H, d), 6.56 (1H, d), 3.82 (3H, s), 2.37 (2H, t), 1.5 (2H, m), 0.91 (3H, t), $J_{3,5} = 1.6$ Hz. *Anal.* calcd. for $C_9H_{13}NO_2$: C 64.65, H 7.84, N 8.38; found: C 64.69, H 7.85, N 8.39.

Alternate Synthesis of 3,4-Dipropylpyrrole

(a) 4-Octen-3-ol

Ethylmagnesium bromide (0.30 mol in ether) was prepared and treated with *trans*-2-hexenal (9.8 g, 0.10 mol) in ether and worked up to give (11.2 g, 88%) 4-octen-3-ol, bp 89–92°C/27 Torr; ir ν: 3300 cm^{-1} (broad); nmr δ: 5.4 (2H, m), 3.89 (1H, q), 2.13 (1H, s, exchanges), 1.97 (2H, q), 1.4 (4H, m), 0.87 (6H, t). *Anal.* calcd. for $C_8H_{16}O$: C 74.94, H 12.58; found: C 75.07, H 12.66.

(b) 4-Octen-3-one

A solution of 4-octen-3-ol (4.10 g, 32 mmol) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (8.0 g, 35 mmol) in anhydrous benzene (80 ml) was stirred in a stoppered flask for 8 h at room temperature (19). After removal of most of the solvent and filtration, the solution was chromatographed on neutral alumina (dichloromethane) and distilled to give (3.07 g, 76%) 4-octen-3-one (**18**), bp 95.5–96.5°C/40 Torr; ir ν: 1660, 1620 cm^{-1}; nmr (CCl_4) δ: 6.63 (1H, m), 5.90 (1H, d), 2.43 (2H, q), 2.09 (2H, t), 1.5 (2H, m), 0.9 (6H, m). *Anal.* calcd. for $C_8H_{14}O$: C 76.14, H 11.18; found: C 76.14, H 11.21.

(c) 4-Propyl-3-propanoylpyrrole

Following the method of van Leusen *et al.* (14) but working under nitrogen, using degassed solvents and extending the addition over 2.5 h, 4-octen-3-one (4.43 g, 35 mmol), *p*-toluenesulfonylmethyl isocyanide (7.8 g, 40 mmol), and sodium hydride (2.0 g of 58% mineral oil dispersion, 50 mmol) gave a pale yellow oil and solid mixture. Ether was added and the solid collected by filtration and washed with more cold ether. More solid product was obtained by chromatography of the filtrate on neutral alumina. Yield of 4-propyl-3-propanoylpyrrole (**19**) was 2.34 g (40%), mp 113.5–114.5°C (sublimation); ir ($CHCl_3$) ν: 3220, 1635 cm^{-1}; nmr δ: 9.3 (1H, broad s), 7.32 (1H, q), 6.53 (1H, m), 2.7 (4H, m), 1.7 (2H, m), 1.15 (3H, t), 0.93 (3H, t). *Anal.* calcd. for $C_{10}H_{15}NO$: C 72.68, H 9.14; found: C 72.71, H 9.18.

(d) 3,4-Dipropylpyrrole

Following the procedure of Hinman and Theodoropulos (20), 4-propyl-3-propanoylpyrrole (1.65 g, 10 mmol) was reduced with $LiAlH_4$, (0.070 g, 20 mmol) in tetrahydrofuran (100 ml) and worked-up to give (0.776 g, 51%) a colorless oil, 3,4-dipropylpyrrole (**12**), identical to the product from the desulfurization synthesis.

Synthesis of 3-carboxylated 2,5-dihydrothiophenes[1]

JOHN M. MCINTOSH AND ROBERT A. SIELER

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received July 21, 1977

JOHN M. MCINTOSH and ROBERT A. SIELER. Can. J. Chem. **56**, 226 (1978).

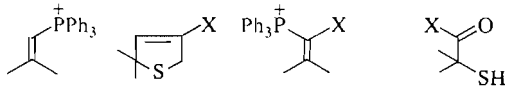
Vinylphosphonates **11**, readily prepared from diethyl carbomethoxymethyl phosphonate (**10**) react with α-mercaptocarbonyl compounds to afford substituted 3-carbomethoxy-2,5-dihydrothiophenes in excellent yields. The scope of this synthesis is indicated and the use of the products in the synthesis of substituted 2-carboxy-1,3-butadienes is illustrated.

JOHN M. MCINTOSH et ROBERT A. SIELER. Can. J. Chem. **56**, 226 (1978).

Les vinylphosphonates **11** qui peuvent être préparés facilement à partir du phosphonate de carbométhoxyméthyle et de diéthyle (**10**), réagissent avec des composés α-mercaptocarbonyle pour conduire aux carbométhoxy-3 dihydro-2,5 thiophènes substitués et ceci avec d'excellents rendements. On indique la généralité de cette synthèse et on illustre aussi l'utilisation des produits dans la synthèse de carboxy-2 butadiènes-1,3 substitués.

[Traduit par le journal]

In recent years, we have been engaged in delineating the reactions of mercaptocarbonyl compounds with various types of Michael acceptors. Much of that work has centered on the use of vinylphosphonium salts (**1**) and we have shown that substituted 2,5-dihydrothiophenes (1) and dihydrothiopyrans (2) are readily prepared using these reagents. These products are useful synthons for a variety of organic structures, in particular, as sources of specifically alkylated conjugated dienes (3). While the synthesis is highly successful for alkylated materials, compounds having functional groups directly attached to the ring offer more obstacles. For instance, methoxy- or carboalkoxy-substituted dienes would require the preparation of dihydrothiophenes of general structure **2**. These in turn would necessitate the use of either **3** as the vinyl salt or **4** as the mercaptocarbonyl compound. Esters (**4***a*) do not gen-

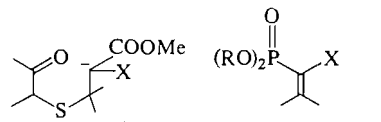


1 **2***a* X = OR **2***b* X = COOR **3***a* X = OR **3***b* X = COOR **4***a* X = OR **4***b* X = COOR

erally give olefins on treatment with a phosphorane (4) although some exceptions are known (5), and α-keto-β-mercaptoesters (**4***b*) are both difficult to prepare and offer ambiguity in the site of attack by a phosphorane. A single example of **3***a* is known (6) and it does not behave satisfactorily in the annulation reaction (1*c*). Finally, compounds of type **3***b* are not readily available and the phosphorane formed by attack of thiolate ion would be of a type (**5***a*) well known to react with aldehydes but very poorly with ketones (7).

[1]Dihydrothiophenes, Part VII. For Part VI, see ref. 1*c*.

It is known that phosphonate anions (**5***b*) are more nucleophilic than **5***a* (4) and thus the use of vinylphosphonates (**6**) was suggested. Furthermore, a considerable number of compounds of type **6** bearing a variety of functionality are known (see for example ref. 8) and they have been shown to undergo addition reactions with nucleophiles (9). However, there is



5*a* X = $Ph_3\overset{+}{P}$ **5***b* X = P(O)(OR)$_2$ **6***a* X = OR **6***b* X = COOR

ample evidence in the literature (10) to indicate that a Wittig-type reaction of phosphonate anions only proceeds well when electron-withdrawing substituents are adjacent to phosphorus. Thus, we centered our attention on the preparation and use of compounds of type **6***b*.

The importance of these functionalized dihydrothiophenes lies in their ready conversion to functionalized dienes. While terminally carboxylated conjugated dienes can be prepared using Knoevenagel-type conditions (11) compounds of type **7** cannot and their obvious utility in the Diels–Alder reaction makes them of considerable synthetic interest. The parent compound **7***a*(12) rapidly polymerizes and the possibility of storing **7** in the form of sulfone **8**, which can be easily converted to **7** as required, was a distinctly attractive possibility. In addition, **2***b* has excellent dienophilic character as was shown by Stork and Stotter (13) and desulfurization of the Diels–Alder adducts can lead to easy assembly of complex organic structures.

Results and Discussion

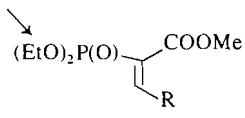
Synthesis of Phosphonates

Although the literature on the preparation of vinylphosphonates is enormous, reports of the preparation of **6***b* are not common. We chose not to pursue the isomerization of the allylic isomer **9**, the approach which proved so successful in the preparation of **1** (1), since **9** is a significant synthetic challenge in itself.

Several reports suggest that, under proper conditions, interaction of phosphonate **10** with aldehydes leads, not to a Wittig olefination reaction, but rather to an aldol type condensation. This would allow the formation of a series of vinylphosphonates (10) from a common precursor [1]. Using a method based on

[1] $(EtO)_2P(O)CH_2COOMe$ + RCHO

10



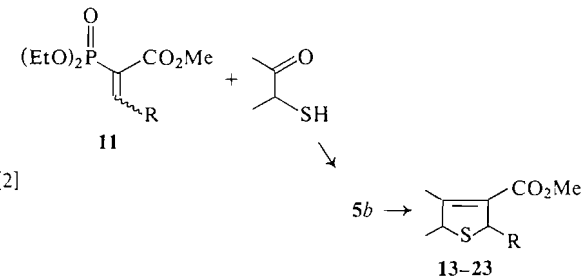
11

the work of Patai and Schwartz (14) we have prepared three vinylphosphonates (**11***b* → **11***d*). In addition, the unsubstituted phosphonate **11***a* was prepared by condensation of formaldehyde with **10** in methanolic solution (15). The yield and simplicity of these reactions obviate the need for the more exotic and costly sequence recently published (16).[2] It should be noted that we have been unsuccessful in condensing ketones with **10**. In these cases the selenium-mediated (16) route may be advantageous. The phosphonates prepared and their spectral data are summarized in Table 1. In all cases, the methyl ester was used to simplify the nmr spectra.

The stereochemistry of the phosphonates has not been investigated in detail, but is undoubtedly a mixture of *E* and *Z* isomers (17).[3]

Synthesis of 2,5-Dihydrothiophenes

The reaction used to prepare the dihydrothiophenes **13–23** is shown in [2]. The proposed mech-



11

[2]

13–23

anism is entirely analogous to that proposed for the vinylphosphonium salt reactions (1). Since the acidity of phosphonates is substantially lower than the corresponding phosphonium salts, we initially employed sodium hydride as the basic reagent. Subsequently, it was found that triethyl amine was sufficiently basic to catalyze the condensations of α-mercaptoaldehydes.

[2]We thank Prof. Heathcock for informing us of his experimental procedure before publication.

[3]^{31}P spectra indicate such a mixture.

[a]All products gave acceptable elemental analyses.
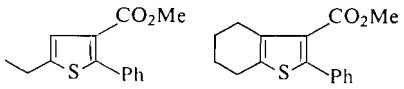
[b]No stereochemistry implied.
[c]Four most intense peaks.
[d]See Experimental for coding and solvent.

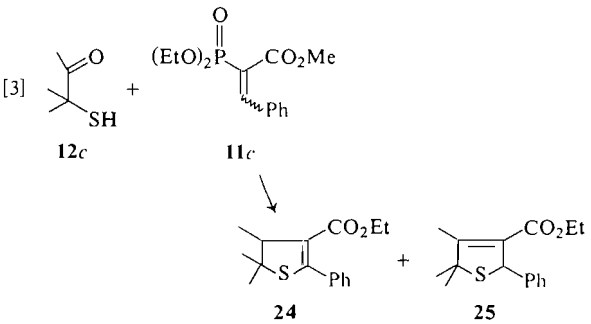
The reactions run and products obtained are shown in Table 2, and the physical and spectral characteristics are summarized in Table 3. As can be seen, excellent yields of the cyclized products are obtained in almost every instance.

In two cases (**19** and **21**), the corresponding thiophenes (**19***a* and **21***a*) were also formed as byproducts. These structures were confirmed by comparison with authentic samples. Thiophene formation was minimized by rigorous exclusion of air from the reaction mixture.



19*a* **21***a*

In only one case did the reaction take an unexpected course. The condensation of **11***c* with **12***c* led to a low yield of a mixture of two products, tentatively identified as **24** and **25** on the basis of their spectral characteristics [3]. The transesterification of the carboxylic ester was not observed in any other case. Finally, when the reaction of ketone **12***d* with



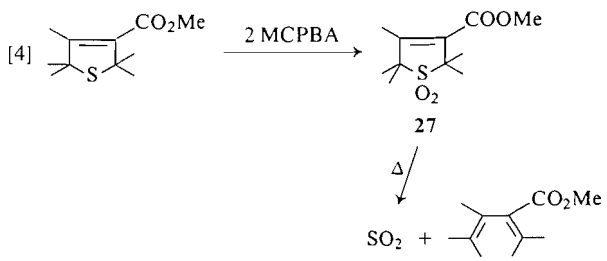
12*c* **11***c* **24** **25**

phosphonate **11***c* was attempted, no dihydrothiophene of any type was isolated. The only product which was isolated in very low yield, appeared to be the simple addition product $EtCOCH(CH_3)SCH(Ph)CH(COOMe)PO_3Et_2$ (**26**).

At this time, the stereochemical composition of the products is unknown. However, the product **19** derived from **11***c* and **12***a* shows a clear doublet of doublets for the benzylic proton (δ 5.46). If, as seems likely, these signals are due to stereoisomers, the isomeric ratio appears to be approximately 60:40, but the identity of the major isomer is not clear. Further work on the stereochemistry of compounds **13–23** is in progress.

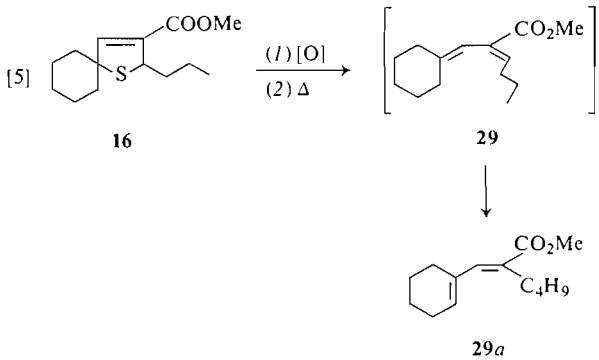
Diene Formation

The peracid oxidation of dihydrothiophenes leads to sulfolenes (1). However, in some cases thiophenes have been formed when the ring bears strongly electronegative substituents (18). In order to test our diene synthesis, it was necessary to verify the proposed oxidation–pyrolysis sequence of reactions [4]. This has been done in three cases (Table 4). In



every instance, peracid oxidation gave the sulfone **27** with no trace (nmr) of thiophene. Injection of **26** into a gas chromatograph effected elimination of sulfur dioxide and the dienes were isolated by collection. Since these reactions have been performed on a small scale, it is difficult to obtain accurate yields. However, nmr analysis of crude **27** indicated no significant impurities and no other volatile products were eluted from the gas chromatograph. Thus it appears that the yields of dienes are excellent. In the case of **16**, rearrangement of the initially formed **29** to **29***a* occurred [5]. This isomerization may be avoided by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



16 29 29*a*

conducting the pyrolysis at a lower temperature in the presence of a dienophile (cf. ref. 1*a*).

In conclusion, it appears that the synthesis of dihydrothiophenes from vinyl phosphonates is a viable synthetic route to compounds of type **2***b* and that these can be converted to dienes. We are currently engaged in applying the method to the synthesis of more complex organic materials.

Experimental

Infrared spectra were recorded on a Beckman IR-12 in chloroform solution; nmr spectra were obtained on either a JEOL C60HL or Varian EM 360 spectrometer in deuteriochloroform solution and are reported in parts per million downfield from Me_4Si as internal standard. The tabulation of nmr data follows the order: chemical shift (δ); multiplicity; number of protons; and coupling constant. Mass spectra were obtained on a Varian MAT CH-5DF instrument. Gas–liquid chromatographic analyses were carried out on an F and M Model 720 instrument using either a 20% SE 30 on Chromosorb W or a 10% Dexsil on Chromosorb W column. Compositions of mixtures were determined using a disc integrator. Unless otherwise noted the drying agent used was anhydrous sodium sulfate, solvents were removed at reduced pressure and preparative tlc was performed on 2 mm thick plates coated with silica gel GF-270. Microanalyses were performed by A. B. Gygli, Microanalysis Laboratory, Toronto.

Preparation of Phosphonates ***11***

Method A

Phosphonate **11***a* was prepared by a variation of the literature procedure (15). Paraformaldehyde (6 g, 0.06 mol) was dissolved in methanol (300 ml) containing 10 drops of piperidine, by refluxing the solution for 0.5 h. Phosphonate **10** (19) (20 g, 0.095 mol) was added all at once and the solution was heated at reflux for 19 h. Evaporation of the methanol afforded an oil which showed no vinyl proton absorption in the nmr spectrum. This oil was dissolved in toluene, a catalytic amount of toluenesulfonic acid was added, and the mixture was refluxed under a Dean–Stark water separator for 8 h. The solvent was removed and the residue distilled to give **11***a*, 16 g (76%), bp 93–99 (1 Torr) (lit (15) 100–101 (1 Torr)).

Method B

Phosphonates **11***b–d* were prepared as follows (14). The aldehyde (0.1 mol) and phosphonate **10** (0.1 mol) were dissolved in benzene (150 ml) containing a mixture of acetic acid (1.5 ml) and piperidine (0.3 g). The mixture was heated at reflux under a Dean–Stark water separator for 22 h. In the case of volatile aldehydes, the use of a five-fold excess was beneficial. The solvent was removed and the residue distilled to give the products shown in Table 1.

General Procedures for Dihydrothiophene Preparation

(A) For Mercaptoaldehydes ***12a*** *(20),* ***12b*** *(16)*

A solution of 0.01 mol of phosphonate **11** and 0.01 mol of triethyl amine in 75 ml dry pyridine was put under a nitrogen atmosphere. To this was added a solution of the appropriate mercaptoaldehyde in 25 ml of pyridine, dropwise with stirring at room temperature. The mixture was stirred at ambient temperature for 1.5 h after the final addition and then at reflux for 18–20 h. The cooled solution was diluted with 200 ml of water and extracted with 4 × 50 ml of ether and 4 × 50 ml of pentane. The combined extracts were washed with 10% hydrochloric acid and water, dried and evaporated under nitrogen to afford a brown oil which was purified by tlc using 1:1 pentane–ether as eluant. Analytical samples were collected from glc. The yields shown in Table 2 were derived by multiplying the crude weight of product by the purity as determined by glc analysis.

(B) For Mercaptoketones ***12c*** *(21),* ***12d*** *(3), and* ***12e*** *(22)*

To a slurry of 0.012 mol of sodium hydride in 50 ml of dry pyridine was added a solution of 0.01 mol of ketone in 50 ml of the same solvent, dropwise with stirring under a nitrogen atmosphere. After hydrogen evolution had ceased, phosphonate **11** was added slowly at room temperature and stirring was continued for 1.5 h. After refluxing for 18–20 h, the solution was worked up as in the previous method.

Formation of isomers ***24*** *and* ***25***

When the reaction between **11***c* and **12***c* was carried out using the sodium hydride procedure, an oil was obtained which contained two components. These were separated by glc and shown to be ethyl 2-phenyl-4,5,5-trimethyl-2,5-dihydrothiophene-3-carboxylate (**25**); nmr: 7.32 (s, 5), 5.55 (q, 1, J = 1.8 Hz), 4.05(d, q, 2, J = 7, 2 Hz), 2.20(d, 3, J = 1.8 Hz), 1.62(s, 3), 1.58(s, 3), 0.97(t, 3, J = 7 Hz); and ethyl 2-phenyl-4,5,5-trimethyl-4,5-dihydrothiophene-3-carboxylate (**24**); mp 49–51°C; nmr: 7.27(s, 5), 3.98(q, 2, J = 7 Hz), 3.09(q, 1, J = 6.7 Hz) 1.57(s, 3), 1.40(s, 3), 1.25(d, 3, J = 6.7 Hz), 1.00(t, 3, J = 7 Hz); *m/e* 276 (M^+, 100%); ir: 2990, 1690, 1330, 1265 cm^{-1}.

Peracid Oxidation of Dihydrothiophenes ***15–17***

The oxidation was carried out according to a published procedure (3). Injection of the crude sulfones into the glc effected elimination of sulfur dioxide and the dienes were collected directly. The spectral data for the products are given in Table 4.

Thiophene ***21a***

This was prepared according to the procedure of Bohlmann and Bresinsky (23). To a solution of 2.6 g (0.02 mol) of **12***e* in 50 ml DMSO was added 30 mg of potassium *tert*-butoxide and 3.2 g (0.02 mol) of methyl phenylpropiolate. The flask was purged with nitrogen and heated at 85–90°C for 90 min with stirring. The cooled solution was poured into 200 ml of 10% sulfuric acid and extracted with 4 × 100 ml of ether. The extracts were washed with water, dried and evaporated to give an oil which solidified on standing and which was recrystallized from ether – petroleum ether to give **21***a*; mp 62–64°C; nmr: 7.47(s, 5), 3.65(s, 3), 2.78(m, 4), 1.82(m, 4); ir: 1710, 1280, 1150 cm^{-1}; *m/e* 272 (M^+, 100%). *Anal.* calcd. for $C_{16}H_{16}O_2S$: C 70.56, H 5.92; found: C 70.41, H 5.81.

Thiophene ***19a***

Using the same procedure and molar amounts, the condensation of **12***a* and methyl phenylpropiolate gave an orange

Resonance Raman labels: spectroscopic studies on *cis*- and *trans*-4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one and an isotopically substituted analog[1]

K. KUMAR, D. J. PHELPS, AND P. R. CAREY

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received June 22, 1977

K. KUMAR, D. J. PHELPS, and P. R. CAREY. Can. J. Chem. **56**, 232 (1978).

The absorption and preresonance Raman spectra of *cis*- and *trans*-4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one are reported. Although steric considerations suggest that the π electron pathway in the *cis* isomer is considerably distorted compared to the *trans* isomer, the Raman and absorption spectra of the two isomers are strikingly similar. Preresonance Raman excitation profiles for the *cis* and *trans* isomers indicate that the main features in the Raman spectra owe their intensity to coupling to the 360 nm absorption band present in both isomers. It is proposed that both the electronic dipole transition responsible for this absorption and the vibrational modes giving rise to the intense Raman bands are localized in the —C=C—N=C—Ph part of the molecule. Thus the main Raman and absorption bands are insensitive to isomerization in the benzylidene portion. Support for a localized electronic transition, polarized along the —C=C—N=C—Ph long axis, comes from Raman depolarization ratio (ρ) measurements which show that all intense Raman features in both *cis* and *trans* isomers have $\rho \sim 0.33$. Further support comes from ir and resonance Raman spectra of *trans*-4-(4-dimethylamino-3-nitrobenzylidene)-2-phenyloxazolin-5-one substituted either with ^{13}C in the 4 position, or with ^{15}N, in the oxazolinone ring. These spectra indicate that the main Raman feature seen in all 4-benzylidene-2-phenyloxazolinones at 1561 cm^{-1} is a symmetric stretching mode associated with the —C=C—N=C— chain and that this feature has some C=N stretching character. The substitution experiments also show that the weak 1654cm^{-1} Raman band has a high degree of C=C stretching character and may represent an essentially antisymmetric mode from the C=C—N=C moiety. The preresonance Raman excitation profiles show that the intensity enhancement follows an F_B^2 type dependence. The utility of the Raman spectrum as a probe for the chromophore responsible for the electronic transition in a highly conjugated system is discussed.

K. KUMAR, D. J. PHELPS et P. R. CAREY. Can. J. Chem. **56**, 232 (1978).

On rapporte les spectres d'absorption et de pré-résonance Raman des benzylidène-4 phényl-2 Δ^2-oxazolinones-5 *cis* et *trans*. Quoique des considérations stériques suggèrent que les voies des électrons π dans l'isomère *cis* devraient être considérablement déformées par rapport à l'isomère *trans*, les spectres Raman et d'absorption des deux isomères sont très semblables. Les profils d'excitation Raman en pré-résonance pour les isomères *cis* et *trans* indiquent que les principales caractéristiques du spectre Raman doivent leur intensité à un couplage avec la bande d'absorption à 360 nm présente dans chacun des isomères. On suggère que la transition dipolaire électronique responsable pour cette absorption ainsi que les modes de vibrations donnant lieu aux bandes Raman intenses sont localisés dans la portion —C=C—N=C—Ph de la molécule. Ainsi les bandes principales des spectres Raman et d'absorption seraient insensibles à l'isomérie dans la portion benzylidène. On trouve des données permettant d'appuyer le concept d'une transition électronique localisée, polarisée le long de l'axe —C=C—N=C—Ph, à partir de mesures de rapports de dépolarisation Raman (ρ) qui montrent que toutes les caractéristiques Raman intenses dans les isomères *cis* et *trans* ont un ρ d'environ 0.33. On obtient un soutien supplémentaire en se basant sur les spectres ir et de résonance Raman de la (diméthylamino-4 nitro-3 benzylidène)-4 phényl-2 oxazolinone-5 *trans* substituée soit par du ^{13}C en position 4 ou du ^{15}N dans le cycle oxazolinone. Ces spectres indiquent que la principale caractéristique Raman qui peut être observée dans tous les benzylidène-4 phényl-2 oxazolinones à 1561 cm^{-1} est une vibration de valence symétrique associée avec la chaîne —C=C—N=C— et que cette caractéristique possède un peu du caractère de vibration de valence du C=N. Des expériences de substitution montrent aussi que la bande Raman faible à 1654 cm^{-1} possède un haut degré de caractère de vibration de valence C=C et peut représenter un mode essentiellement antisymétrique de la portion C=C—N=C. Les profils d'excitation Raman en pré-résonance indiquent que l'augmentation d'intensité varie suivant une relation du type F_B^2. On discute de l'utilisation des spectres Raman comme sonde pour déterminer le chromophore responsable d'une transition électronique dans un système hautement conjugué.

Introduction

Resonance Raman labels enable detailed vibrational spectra to be obtained from a ligand at a key site in a complex biological system (1). For example, by using chromophoric substrates resonance Raman spectroscopy has provided unique information on enzyme–substrate interactions during enzymolysis (2–4). Laser excitation within an absorption band of the substrate gives an intense resonance Raman spectrum of the substrate and in mixture of enzyme, substrate, and solvent it is possible to obtain and monitor the vibrational spectrum of the substrate throughout the course of the reaction. Interpretation of these spectra in terms of enzyme mechanism requires an understanding of the interrelation between structure, absorption, and resonance Raman spectra for chromophoric substrates and the present work represents a step towards this goal.

Oxazolinones[2] were chosen since some molecules in this class are chromophoric substrates for proteolytic enzymes (5, 6) and thus offer an additional source of systems to study by the resonance Raman technique. Furthermore it has been suggested that oxazoline type intermediates may occur in some enzyme catalyzed reactions (3, 7). In the most general and important sense, however, the ideas and principles enunciated for oxazolinones are directly transferable to other chromophoric substrate systems. For oxazolinones it has been possible to explore the relationships between group conjugation in a π electron system and the appearance of features in the Raman spectrum and between the electronic dipole transition and Raman depolarization ratios. In this paper these relationships are investigated for the *cis* and *trans* isomers of 4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one (Fig. 1). Isotopic substitution using ^{15}N and ^{13}C in a *trans* analog of this compound provides important supportive evidence. Raman intensity excitation profiles are used to test theoretical predictions and to identify the chromophore responsible for Raman intensity enhancement.

Experimental

Raman and absorption spectral measurements were performed as detailed in previous publications (3, 4). Infrared spectra were recorded on a Perkin Elmer 521 spectrometer. Neither photodecomposition nor photoisomerization was observed in the laser beam. Raman spectra recorded using stationary cells were identical to those taken using the rotating cell technique (8). In the latter the sample molecules are only exposed to the laser beam for tens of microseconds.

Syntheses

Syntheses of *trans*-4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one and isotopically labelled *trans*-4-(4-dimethylamino-3-nitrobenzylidene)-2-phenyloxazolin-5-one were carried out by literature methods (9, 10). They were characterized by mp, nmr, ir, and Raman spectroscopy.

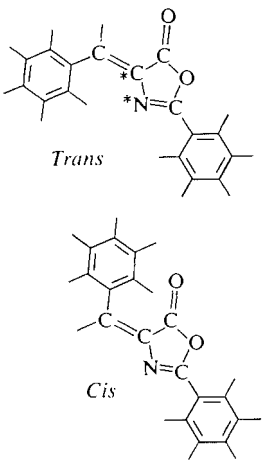

FIG. 1. *trans*- and *cis*-4-Benzylidene-2-phenyl-Δ^2-oxazoline-5-one (adapted from ref. 17).

cis-*4-Benzylidene-2-phenyloxazoline-5-one (11)*

The *trans* isomer (1.0 g, mp 165–167°C) was suspended in 48% aqueous hydrobromic acid (20 ml) and cooled in an ice bath. The stirring suspension was treated with hydrogen bromide gas for ½ h, maintaining the temperature between 0 and 5°C, and the reaction flask was stoppered and stored in the cold overnight. The reaction mixture was then poured on ice (100 g) and, after the ice had melted, collected by suction and dried to yield 0.97 g (97%) of a pale yellow solid, mp 144–147°C (lit. (11) mp 148.5); mixture mp with authentic *trans* isomer 124–126°C. *Anal.* calcd. for $C_{16}H_{11}NO_2$: C 77.09, H 4.53, N 5.62; found for *cis* isomer: C 76.40, H 4.29, N 5.53; found for *trans* isomer (starting material): C 76.10, H 4.21, N 5.53.

Results and Discussion

Absorption Spectra and the Use of Depolarization Ratios as a Test for a Localized Electronic Transition

The absorption spectra of many oxazolinones have been studied by a number of workers (12–15). The spectra of the *cis* and *trans* isomers of 4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one (Fig. 1) were first reported by Buckles *et al.* (16) and more recently by Brocklehurst and Williamson (5). The absorption spectra reported herein (Fig. 2) are in excellent agreement with those of Brocklehurst and Williamson. The spectra of the *cis* and *trans* isomers are strikingly similar, with the isomers possessing identical λ_{max}'s in the near uv and very similar extinction coefficients. However the fine structure is less well resolved in the long wavelength band of the *cis* isomer and the intensity distribution differs in the components of the high energy band centered at 240 nm (Fig. 2).

The salient features of the stereochemistry of *cis*- and *trans*-oxazolinones can be derived from the recently published crystallographic study on 4-(2,4-

[2]Throughout this paper oxazolinones refers to analogs of 4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one.

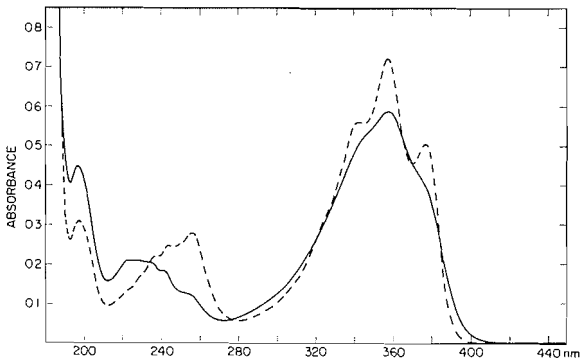

FIG. 2. Absorption spectra of *trans* (---) and *cis* (—) isomers of 4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one. Both compounds 2.0×10^{-5} *M* in CH_3CN; 1-cm path length.

dinitrobenzylidene)-2-phenyloxazolin-5-one (17). The nitro substituted molecule crystallized in the *trans* form and is approximately planar. From the X-ray data it is immediately apparent that the *trans* form experiences little steric hindrance. However, in the *cis* isomer considerable repulsion would occur between the carbonyl oxygen and the ortho hydrogen on the benzylidene ring. For the *cis* isomer in solution this will result in twisting about the Ph—C bond in Ph—C(H)=C with a concomitant loss in conjugation through that bond. As it appears, on the basis of the present study, that substitution on the benzylidene ring only causes minor perturbations to the benzylidene-2-phenyloxazolinone structure it will be assumed that these conclusions may be transferred to the unsubstituted molecule (Fig. 1) viz. the *trans* isomer is essentially planar while the *cis* is non-planar with twisting probably occurring about the Ph—C bond in Ph—C(H)=C.

Two compounds, stilbene and 1,4-diphenyl-1,3-butadiene, are classic examples on the behaviour of long wavelength absorption bands upon *cis–trans* isomerization. *trans*-Stilbene is sterically unhindered while the *cis* isomer undergoes considerable distortion. Compared to the *trans* isomer, *cis*-stilbene shows a blue shift in λ_{max} and a reduction in molar extinction coefficient for this band (18). Similar behaviour is observed in the absorption spectra of *trans-trans*, *trans-cis*-, and *cis-cis*-1,4-diphenyl-1,3-butadiene (19, 20) and the important generalization established by these and other examples is that a decrease in conjugation causes a blue shift in λ_{max} with a concomitant decrease in the extinction coefficient of that band. Thus the problem in interpreting the absorption spectra of *cis*- and *trans*-oxazolinone is that although the X-ray data establish that for the *cis* isomer distortion from planarity of the benzylidene ring almost certainly takes place, no change in λ_{max} is observed, and very little, if any, change is observed in the integrated absorption intensity centered at 360 nm.

The apparent contradiction between the X-ray data suggesting strong steric hindrance in the *cis* isomer and the lack of evidence for this in the absorption spectra is resolved by assuming that the benzylidene ring makes only a minimal contribution to the electronic transition centered at 360 nm. Furthermore it will be seen that although the benzylidene ring may be necessary as a reservoir of π electrons it makes only a minor contribution to the Raman and preresonance Raman spectra. It is thus relegated to the role of an end group such as a keto moiety at the end of a polyene chain which has only very weak intensity in preresonance and resonance Raman spectra. This analogy is strengthened by the fact that subtle changes at the end of polyene chains have no effect in the position of λ_{max} or in the resonance Raman spectrum but can have a marked effect on the appearance of vibronic structure in the absorption spectra (21). In the *cis*-oxazolinone the benzylidene may cause a loss of resolution of vibronic structure by perturbing solvent interactions around the C=O or possibly by existing in more than one conformation about the Ph—C(H)=C single bond.

The position of λ_{max} for the oxazolinones is red shifted compared to e.g. 1,4-diphenyl-1,3-butadiene and this may be due to the presence of the N atom and a mechanism such as π–π^* n–π^* mixing. It is likely that the C=O acts as only an ineffectual end group in terms of its properties in absorption and Raman spectra and thus does not appreciably affect the position of λ_{max}.

The 'end group concept' of the benzylidene ring, in which this ring does not participate in the electronic transition, received support from isotopic substitution (below), from the substituted compounds discussed in the following paper and from measurements of the depolarization ratios of unsubstituted *cis* and *trans* isomers. As has been discussed by Behringer (22) measurements of depolarization ratios, ρ, can provide some evidence about the linearity of an electronic transition.

Starting with a delocalized π electron system in which the electronic transition is essentially linear the depolarization ratios equal $\frac{1}{3}$. Any isomerization in the system which perturbs this linearity makes $\rho \neq \frac{1}{3}$. Thus by monitoring ρ values for two isomers, e.g. *cis*- and *trans*-oxazolinones, participation of the group undergoing isomerization, in this case the benzylidene group, in the transition can be probed.

Although the qualitative origin of resonance Raman intensity will be discussed under Excitation Profiles, the relationship between Raman depolarization ratios and the polarization of an electronic

transition can be derived from the following considerations (22). Raman scattering intensity is proportional to the square of the polarizability tensor α_{ik}' ($i, k, = x, y, z$). Using the approximations of Behringer (22) the elements of α_{ik}' are related to the transition moments of the electronic dipole moment operator μ by

$$\alpha_{ik}' = \mu_{eg,i}(0)\mu_{ge,k}(0)\left(\frac{\partial f}{\partial Q}\right)_0$$

where e and g are quantum numbers for pure electronic excited and ground states, respectively, $\mu(0)$ is the value of the electronic moment at zero point amplitude and $\partial f/\partial Q$ is the frequency factor depending on ν_0, ν_{eg} and ν, the frequencies of the exciting radiation, the first coupled electronic transition, and the Raman mode, respectively.

When the electronic transition moment $\mu_{eg}(0)$ has a definite direction, e.g. x, all α_{ik}' except α_{xx} vanish. Then in the case of plane polarized light and a symmetric scattering tensor $\rho = \frac{1}{3}$ (23). This should hold true for all nondegenerate fundamental vibrations in molecules with a single Raman active absorption band which is electronically allowed and which results from a transition lying in a definite molecular direction. Although this derivation supposes Raman intensity enhancement occurs by coupling with a single excited electronic state, and some evidence is found from excitation profiles (*vide infra*) that two excited states are involved, we shall continue to use it as a working hypothesis.

cis- and *trans*-Stilbene (Fig. 3) illustrate how a change in polarization of the electronic dipole affects the Raman depolarization ratios. For *trans*-stilbene the intense bands have $\rho \sim 0.33$ (Table 1) suggesting a well-defined linear electronic transition; however for *cis*-stilbene $\rho \neq 0.33$ strongly suggesting that the electronic transition does not lie in a definite molecular axis.

For the *cis*- and *trans*-oxazolinones the measured depolarization ratios for the three intense bands in 1500–1600 cm^{-1} region are given in Table 2. Taking into account the intrinsic experimental errors in measuring intensities these values are considered to be indistinguishable from 0.33. This strongly suggests that the electronic transition responsible for Raman intensity enhancement has a fixed linear direction for both *cis* and *trans* isomers and that it is not perturbed by isomerization. This is consistent with the benzylidene ring not participating in the 360 nm electronic transition.

Excitation Profiles

The variation of Raman intensities with excitation wavelength, the excitation profile, is capable of

providing information on vibronic structure which lies unresolved in an absorption spectrum (21, 24, 25). However in the present case, in which excitation frequencies do not closely approach absorption bands, the major utility of excitation profiles is to indicate the identity of an absorption band responsible for the intensity enhancement of Raman bands and to provide a comparison of experimental Raman intensity enhancements with those predicted by theory.

Qualitatively, the origin of the resonance Raman effect has been understood for some time (for recent reviews see ref. 26). There are essentially two scattering mechanisms, called by Albrecht A and B terms, which depend on coupling to one and more than one excited electronic state, respectively. The A term is based on a shift of equilibrium nuclear position along the normal mode upon exciting into its first excited state (in the present case in the near uv). The B term deals with the vibronic coupling of the first excited electronic state with a whole family of states in the deep ultraviolet having similar polarizations. The frequency dependence of the A and B terms are given by the factors F_A and F_B, respectively (27):

$$F_A = \frac{\nu^2(\nu_e^2 + \nu_0^2)}{(\nu_e^2 - \nu_0^2)^2}$$

$$F_B = \frac{\nu^2(\nu_e\nu_s + \nu_0^2)}{(\nu_e^2 - \nu_0^2)(\nu_s^2 - \nu_0^2)}$$

The functions F_A and F_B carry the full ν_0 dependence and in the case of a single mechanism Raman intensity is proportional to F_A^2 or F_B^2. ν_0 is the frequency of the exciting radiation and ν the frequency of the scattered photons. ν_e is the frequency of the major active electronic state and it is assumed that active virtual states, s, lie at sufficiently high energies to permit the use of an average ν_s. The frequency for ν_s is normally taken as the frequency of an electronic transition in the far uv having the same polarization as the major active electronic state. The F_A and F_B terms have been derived using the assumption that only one of the components α_{xx}, α_{yy}, or α_{zz} is active. For *cis*- and *trans*-oxazolinones this condition is satisfied since the depolarization ratios have a value ~0.33 under all conditions (see above and Table 2). The frequency factors F_A and F_B can be easily calculated from the absorption spectrum and the theoretical relative intensity of Raman lines subsequently determined, provided that the Raman intensity is uniquely derived from either F_A or F_B terms.

The experimental Raman intensities were obtained by measuring the intensities at different exciting frequencies relative to a CH_3CN line at 924 cm^{-1} as internal standard. Use of dilute solutions obviated the need for a correction for self absorption. However a ν^4 correction was made where the experimental intensity is defined as

$$S = \frac{I}{I_a}\left(\frac{\nu_a}{\nu}\right)^4$$

where ν and I denote the frequency and intensity of the sample's line, ν_a and I_a denote the frequency and intensity of the acetonitrile peak at 924 cm^{-1}. The measured intensities were also corrected for spectral sensitivity and Table 3 shows the calculated and

measured Raman intensities of the *cis*- and *trans*-oxazolinones in the preresonance region. F_A^2 and F_B^2 were calculated using $\nu_c = 27.77$ kK and $\nu_s = 41.66$ kK. Due to availability of laser lines measurements could not be made below 457.9 nm. Upon going from normal to preresonance conditions there were no drastic changes in the intensities of the Raman bands around 1600 cm^{-1} and the overall pattern of the spectra remained the same. This and the agreement between experiment and theory in the preresonance region suggests that all the intense modes are coupled to the strong electronic transition ~360 nm. Both *cis* and *trans* isomers show good agreement between experimental and the theoretical F_B^2 terms for intensity enhancement. Although some studies on dependence of Raman intensity upon frequency have reported better agreement with F_A type terms it now appears (23, 25, 27) that in compounds based on a substituted benzenoid nucleus that F_B^2 mechanism is predominant. This could be due, in part, to the fact that these compounds *viz.* nitroanilines, substituted azobenzenes, cinnamic acid derivatives, and oxazolinones have a nitrogen atom in the π electron pathway. Thus the opportunity for π–π^* n–π^* mixing exists and this could result in both an F_B^2 two state type dependence in the Raman intensity enhancement and red shifted intense absorption bands. Similar effects have been characterized in nitrogen heterocycles by Ito and coworkers (28).

Preresonance Raman Spectra and Isotopic Substitution

The preresonance Raman spectra of *cis*- and *trans*-oxazolinone are shown in Fig. 4 and are dominated by three bands at 1561, 1588, and 1601 cm^{-1}. These bands also dominate the normal Raman spectrum (647.1 nm excitation). They are at the same frequency for both *cis* and *trans* isomers and show a similar intensity distribution in both (Fig. 4). This, at first a surprising finding, is related to the localized nature of the electronic transition and the relationship between the electronic transition and Raman intensity which were both discussed above. It was shown that the three intense bands in the 1550 cm^{-1} region gain intensity by coupling to the electronic transition at 360 nm. Since this transition and the 1550 cm^{-1} modes are localized in the —C=C—N=C—Ph portion this part of the Raman spectrum is insensitive to *cis-trans* isomerization of the benzylidene ring.

The most intense Raman band at 1561 cm^{-1} has a major contribution from the —C=C—N=C— chain (*vide infra*). However its occurrence at 1561 cm^{-1} is difficult to explain on the basis of (*a*) delocalized π electrons in a diphenylpolyene-like system, or (*b*) the effect of the oxazolinone ring, or (*c*) the effect of the C=O group.

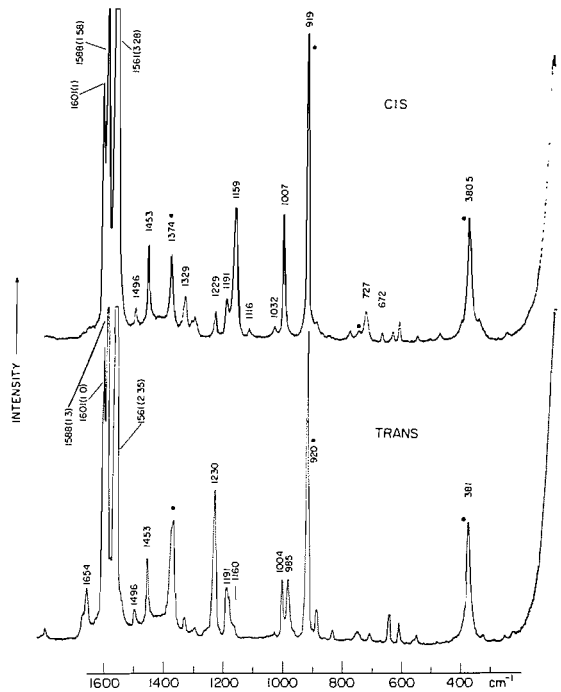

FIG. 4. Preresonance Raman spectra of *trans*- and *cis*-4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one: approx. 10^{-2} M in CH_3CN (indicated by *); 514.5 nm; ~100 mW, 5 cm^{-1} spectral slit.

The major features in the Raman spectra of linear polyenes are bands in the region 1500–1650 cm^{-1} and 1100–1250 cm^{-1} (29). The strong peak near 1600 cm^{-1} is due to a coupled —C=C motion of the chain. In the case of diphenylpolyenes there are two very strong bands in the 1580–1600 cm^{-1} and they have been assigned to polyene —C=C— stretch and benzene ring normal modes (30). However the low frequency of the 1561 cm^{-1} band in *cis*- and *trans*-oxazolinones cannot be ascribed to the effects of conjugation in the Ph—C=C—N=C—Ph system since it is not until four double bonds are interposed between the rings that the chain mode approaches 1570 cm^{-1} (30).

The effect of ring size on —C=C— frequencies has been discussed by Bellamy (31). On the basis of simple theory and given the bond angles shown in Fig. 1, $\nu_{C=N}$ of the oxazolinone ring is expected to be greater than 1610 cm^{-1}. This is borne out experimentally by measurements on 2-phenyl-Δ^2-oxazolin-5-one, where $\nu_{C=N}$ occurs at ~1660 cm^{-1}.[3]

The possibility of the 1561 cm^{-1} band being mainly $\nu_{C=C}$ which is lowered by conjugation with C=O can be ruled out by isotopic substitution (below) and by analogy with the vibrational spectra

[3]K. Kumar, D. J. Phelps, and P. R. Carey. Unpublished work.

of cinnamic acid derivatives in which $\nu_{C=C}$ normally occurs between 1620 and 1640 cm^{-1} (4).

Crucial evidence on the nature of the 1561 cm^{-1} band comes from the combined Raman and ir data on isotopically labelled 4-(4-dimethylamino-3-nitrobenzylidene)-2-phenyl-Δ^2-oxazolin-5-ones. The ^{15}N and ^{13}C substituted compounds were separately labelled at the positions denoted * in Fig. 1. The Raman spectra are shown in Fig. 5, and are very similar, in the 1500–1600 cm^{-1} region, to those of the *trans* and *cis* isomers of unsubstituted oxazolinone (Fig. 4). Figures 6 and 7 compare the ir spectra of the labelled and unlabelled compounds and the shifts in features which can be identified in both the ir and Raman spectra between 1550 and 1650 cm^{-1} are given in Table 4. Care was taken to reduce error to less than ± 1 cm for intense bands in this region. These results are consistent with the following interpretation which applies for all the substituted oxazolinones having as a basic skeleton the structure shown in Fig. 1. The —C=C—N=C— grouping

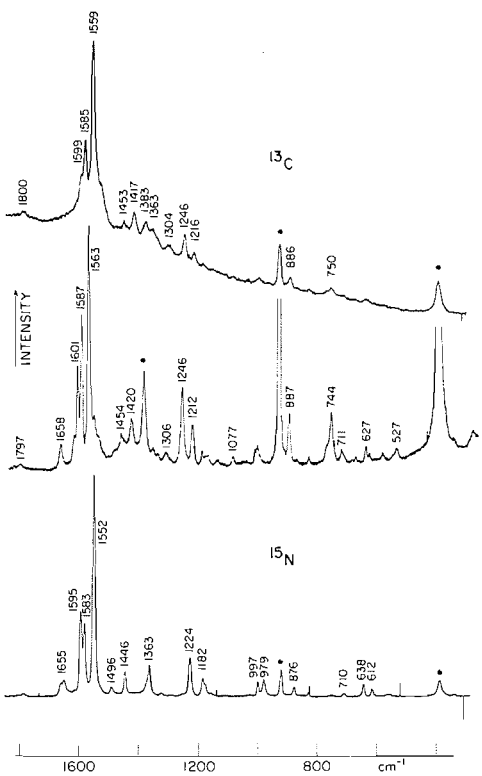

FIG. 5. Resonance Raman spectra of isotopically substituted *trans*-4-(4-dimethylamino-3-nitrobenzylidene)-2-phenyl-Δ^2-oxazolin-5-one: Top ^{13}C in 4 position of oxazolinone ring (see Fig. 1); bottom, ^{15}N in oxazolinone ring; middle, unsubstituted; 441.6 nm; 50 mW; spectral slit ~9 cm^{-1}; approx 10^{-4} *M* in CH_3CN (indicated by *).

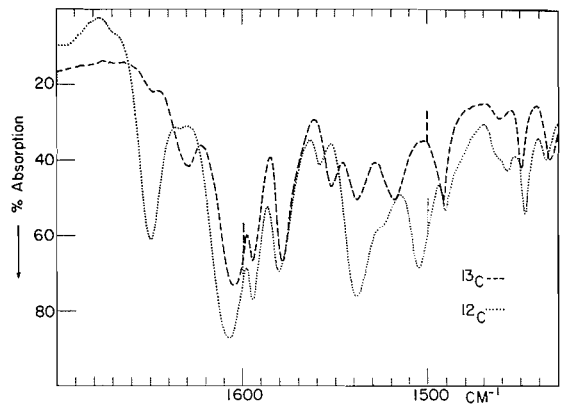

FIG. 6. Infrared spectra ^{12}C and ^{13}C substituted *trans*-4-(4-dimethylamino-3-nitrobenzylidene)-2-phenyl-Δ^2-oxazolin-5-one. Substitution is in the 4 position of oxazolinone ring. KBr pellet.

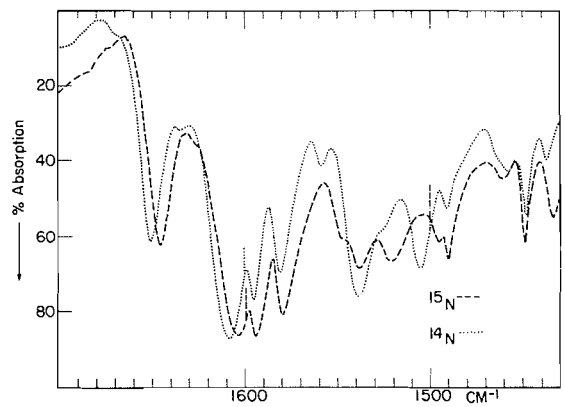

FIG. 7. Infrared spectra of ^{14}N and ^{15}N substituted *trans*-4-(4-dimethylamino-3-nitrobenzylidene)-2-phenyl-Δ^2-oxazoline-5-one. Substitution is in the oxazolinone ring. KBr pellet.

gives rise to two vibrations, one an essentially symmetric mode (intense Raman, weak ir) near 1560 cm^{-1} and the other an essentially asymmetric mode (very weak Raman and medium ir) near 1650 cm^{-1}. The 1560 cm^{-1} band has a degree of C=N character and the 1650 cm^{-1} feature a high degree of C=C character. The latter designation receives support from the Raman of the unsubstituted *cis*- and *trans*-oxazolinones (Fig. 4) in which, for the sterically crowded *cis* isomer, the weak 1650 cm^{-1} band is not observed. This could possibly be due to the reduced polarizability of the C=C following reduction of conjugation with the benzylidene ring.

Figure 5 and Table 4 show that the Raman spectrum is far more sensitive to ^{15}N compared to ^{13}C substitution. The shift from 1246 → 1224 cm^{-1} upon ^{15}N substitution indicates that this band may have C—N single bond stretching character. The bands

at 1587 and 1601 cm^{-1} are probably benzene ring modes, from the N=C—Ph, which on the basis of the ^{15}N shifts are coupled to the 1561 cm^{-1} mode. Indeed the many shifts in the weaker features seen upon ^{15}N substitution indicate that the majority of weaker bands in the Raman spectra emanate from the —N=C—Ph portion of the molecule.

The important conclusion from the present work is that extensive π electron conjugation is a necessary but not sufficient condition for the appearance of relatively intense preresonance or even normal Raman features. Raman bands of high or medium intensity appear only from that part of the molecule associated with the electronic transition. Isotopic substitution and in some cases depolarization ratio may be used to locate the position of the electronic dipole transition in the conjugated system. The use of the Raman spectrum to locate the electronic transition appears to be a novel application of the Raman technique.

Resonance and preresonance Raman spectra of nine substituted *trans*-4-benzylidene-Δ^2-oxazolin-5-ones are reported. The seven analogs with phenyl in the 2 position of the oxazolinone ring have either an electron donating or attracting group on one of the phenyl rings. Although shifts in λ_{max} of up to 100 nm are observed the Raman spectra are very similar to that of the unsubstituted *trans* isomer. However, in the substituted compounds modes from the benzylidene portion may become weakly intensity enhanced. Replacing the 2-phenyl group by 2-methyl in the oxazolinone ring results in quite gross changes in the Raman spectrum. Substitution by ^{15}N in the ring of a 2-methyloxazolinone reveals that a change in the vibrational coupling scheme occurs. Excitation profiles for the 2-phenyl and the 2-methyl analogs of 4-(*p*-nitrobenzylidene)-oxazolinone indicate that in each compound all intensity enhanced modes are coupled to the intense low energy absorption band near 350 nm and the intensity enhancement fits the F_B^2 terms of Albrecht and Hutley. However, differences in the relative intensity of the benzylidene nitro feature in the 2-methyl and 2-phenyl analogs, taken with the excitation profiles, suggest that in the 2-methyl compound the electronic transition responsible for Raman intensity enhancement is no longer primarily located in the C=C—N=C—Ph moiety.

D. J. PHELPS, R. G. CARRIERE, K. KUMAR et P. R. CAREY. Can. J. Chem. **56**, 240 (1978).

On rapporte les spectres Raman de résonance et de pré-résonance de neuf benzylidène-4 Δ^2-oxazolinones-5 *trans* substituées. Les sept analogues avec un phényle en position 2 du cycle oxazolinone possèdent soit un groupe électrodonneur ou électroaffinitaire sur l'un des cycles phényle. Quoique l'on peut observer des déplacements allant jusqu'à 100 nm dans le λ_{max}, les spectres Raman sont très semblables à ceux de l'isomère *trans* non-substitué. Toutefois, dans les composés substitués, les modes de la portion benzylidène peuvent avoir des intensités qui ont subi une faible augmentation. En remplaçant le groupe phényle en position 2 du cycle oxazolinone par un méthyle, il se produit des changements très importants dans le spectre Raman. L'introduction d'un ^{15}N dans le cycle d'une méthyl-2 oxazolinone révèle qu'il se produit un changement dans le schéma de couplage vibrationnel. Les profils d'excitation pour les analogues phényl-2 et méthyl-2 de la (*p*-nitrobenzylidène)-4 oxazolinone indiquent que, dans chacun de ces composés, tous les modes où l'intensité est augmentée sont couplés avec la bande d'absorption intense de basse énergie près de 350 nm et que l'augmentation d'intensité est une fonction des termes F_B^2 d'Albrecht et Hulley. Toutefois, les différences dans l'intensité relative des caractéristiques du benzylidènenitro des analogues méthyl-2 et phényl-2 de concert avec les profils d'excitation suggèrent que, dans le composé méthyl-2, la transition électronique responsable pour l'augmentation de l'intensité du spectre Raman n'est plus liée principalement avec la portion C=C—N=C—Ph.

[Traduit par le journal]

Introduction

In the preceding and accompanying paper (1) the unsubstituted *cis* and *trans* isomers of 4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one were discussed. To explain the unexpected similarity between the absorption and preresonance Raman spectra of the two isomers it was proposed that the electronic dipole transition responsible for the intense low energy absorption band and the vibrational modes responsible for the intense Raman lines are localized in the —C=C—N=C—Ph part of the molecule. Support for this concept came from depolarization ratio measurements and isotopic substitution. The present paper explores the consequences of adding an electron donating or accepting group to the benzylidene phenyl ring (Fig. 1) and in separate experiments replacing the 2-phenyl on the oxazolinone ring by a methyl group. Although large shifts in λ_{max} are

sometimes observed, substituents in the benzylidene ring have little effect on the Raman spectra indicating only minor perturbations in the factors responsible for Raman intensity. However, replacement of the 2-phenyl by a methyl group results in far more radical changes in both the vibrational and vibronic coupling schemes.

Experimental

Raman, ir, and absorption spectroscopic measurements were made using procedures outlined in previous publications (2, 3). As in the preceding and accompanying paper (1) no evidence was found for photodecomposition or photoisomerization. Synthesis of the oxazolinones was carried out by literature methods (4). All oxazolinones were determined pure by tlc and were characterized by nmr, ir, and Raman spectroscopy. Their melting points are as follows: 4-(4-nitro)benzylidene-2-phenyl- mp 235–239°C (lit. (5) mp 240–242°C); 4-(2-nitro)benzylidene-2-phenyl- mp 163–164°C (lit. (6) mp 160–164°C); 4-(3-nitro)benzylidene-2-phenyl- mp 174–176°C (lit. (7) mp 175–176°C); 4-(4-dimethylamino)benzylidene-2-phenyl- mp 210–212°C (lit. (8) mp 220); 4-(4-dimethylamino-3-nitro)benzylidene-2-phenyl- mp 180–181°C (lit. (9) 181°C); 4-benzylidene-2-(4-nitro)phenyl- mp 236–237°C (lit. (10) 206°C); 4-benzylidene-2-methyl- mp 149–151°C (lit. (11) mp 152–154°C; 4-(4-nitro)benzylidene-2-methyl mp 172°C (dec) (lit. (12) mp 186–187°C). 4-(2,4-Dinitro)benzylidene-2-phenyloxazolin-5-one was generously donated by Dr. H. Schneider.

It has been concluded that stable oxazolinones have the *trans* configuration from nmr (13–15), X-ray (16, 17), and other considerations (18, 19).

Results and Discussion

o-, m-, *and* p-*Nitro Substitutions in the Benzylidene Ring*

The absorption and preresonance Raman spectra of these analogs are shown in Figs. 2 and 3, respectively. The absorption spectra of *m*- and *p*-NO_2 show clear structure in the main bands while *o*-NO_2 does not. The loss of structure may reflect steric interactions between the *o*-nitro and ethylenic hydrogen atoms (1, 17). The preresonance Raman spectra (Fig. 3) are very similar, and, for the *cis* and *trans* unsubstituted compounds, are dominated by the three bands in the 1560–1610 cm^{-1} region. This similarity is strong evidence that the vibronic interactions responsible for the Raman intensity enhancement are essentially unperturbed. However, the presence of the —NO_2 chromophore in the benzylidene ring does result in a Raman feature of weak-to-medium intensity from this part of the molecule, e.g. the 1349 cm^{-1} band in the *p*-NO_2 compound (Fig. 3, bottom).

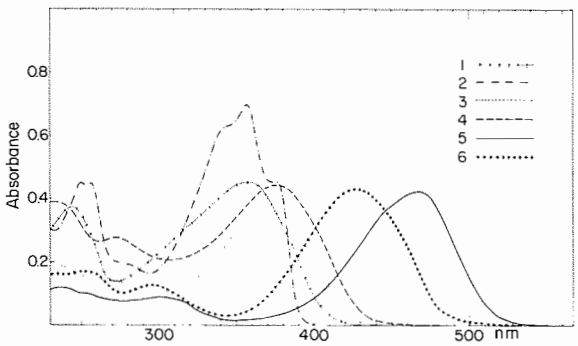

FIG. 2. Absorption spectra of 4-benzylidene-2-phenyl-Δ^2-oxazolin-5-one substituted in the benzylidene ring: (*1*) *o*-nitro 2×10^{-5} *M*, (*2*) *m*-nitro- 1.99×10^{-5} *M*, (*3*) *p*-nitro- $\sim 2 \times 10^{-5}$ *M*, (*4*) 2,4-dinitro- 2×10^{-5} *M*, (*5*) *p*-dimethylamino- 0.82×10^{-5} *M*, (*6*) 4-dimethylamino-3-nitro- 1.05×10^{-5} *M*; solvent CH_3CN, 1-cm path length.

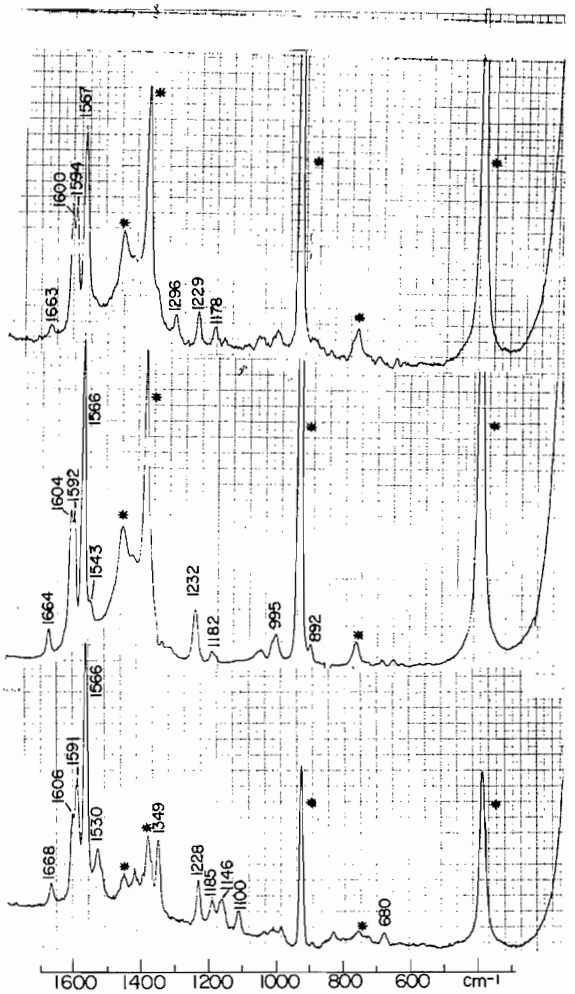

FIG. 3. Preresonance Raman spectra of 4-(*o*-nitrobenzylidene)- (top), 4-(*m*-nitrobenzylidene)- (center), and 4-(*p*-nitrobenzylidene)-2-phenyl-Δ^2-oxazolin-5-one (bottom): $\sim 2 \times 10^{-3}$ *M* in CH_3CN (indicated by *); 457.9 nm; 100 mW; 9-cm^{-1} spectral slit.

Other Nitro Substitutions

Nitro groups in the 2,4 positions of the benzylidene ring give rise to an absorption spectrum (Fig. 2)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with a λ_{max} similar to that of the compound substituted in the 4 position alone. However, structure is not resolved in the absorption spectrum and this may be again due to steric interactions of the *o*-nitro group. The preresonance Raman spectrum is shown in Fig. 4 and its strong resemblance to the *o*-, *m*-, and *p*-monosubstituted and unsubstituted compounds again testifies to the minor role played by the benzylidene ring in the mechanism of Raman intensity enhancement. The absorption spectrum of the analog substituted *para* in the 2-phenyl ring is shown in Fig. 6. Its preresonance Raman spectrum (Fig. 5) still bears strong resemblance to that of the unsubstituted molecules. However, slight differences, e.g. in the position of the 1580 cm^{-1} band, are detectable and these differences are greater than those found within the series characterized by NO_2 substitutions in the benzylidene ring.

p-*Dimethylamino Substitution in the Benzylidene Ring*

In keeping with the strong electron donating power of the dimethylamino group, this substitution results in a large red shift in λ_{max} (Fig. 2). The resonance Raman spectrum (Fig. 4) is still dominated by features in the 1540–1610 cm^{-1} region but there is evidence of a shoulder at 1545 cm^{-1} not appearing in the compounds discussed above. However, it is apparent that the electron rearrangement caused by the dimethylamino group has had only a minor effect

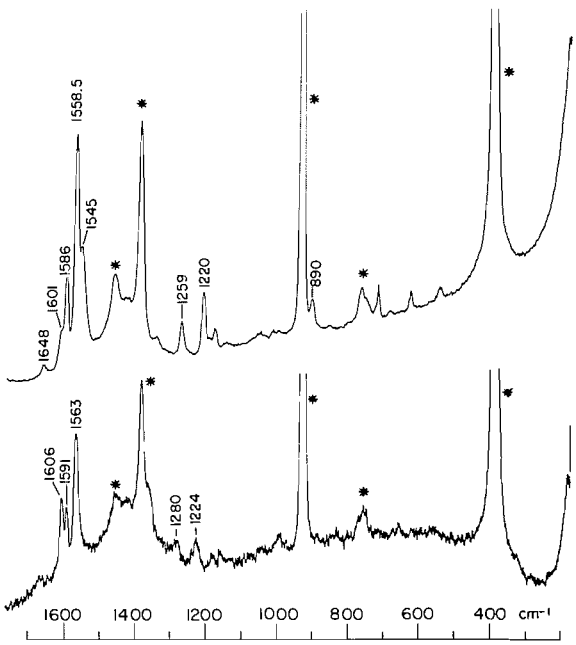

FIG. 4. Raman spectra of 4-(4-dimethylaminobenzylidene)- (top) and 4-(2,4-dinitrobenzylidene)-2-phenyl-Δ^4-oxazolin-5-one (bottom); $\sim 2 \times 10^{-3}$ *M* in CH_3CN (indicated by *); 647.1 nm; 300 mW, 8-cm^{-1} spectral slit.

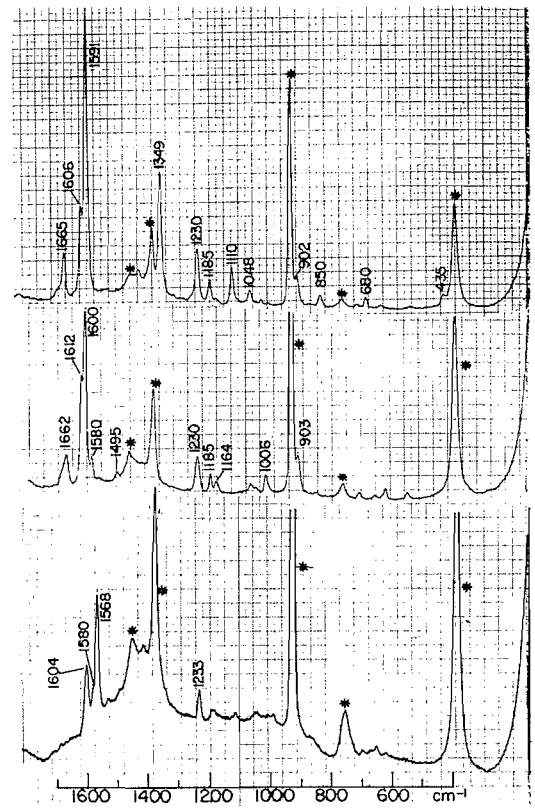

FIG. 5. Preresonance Raman spectra of 4-(*p*-nitrobenzylidene)-2-methyloxazolin-5-one (top), 4-benzylidene-2-methyloxazolin-5-one (center), and 4-benzylidene-2-(*p*-nitrophenyl)-oxazolin-5-one (bottom); 1–2 $\times 10^{-3}$ *M* in CH_3CN (indicated by *); 457.9 nm; 100 mW, 8 cm^{-1} spectral slit.

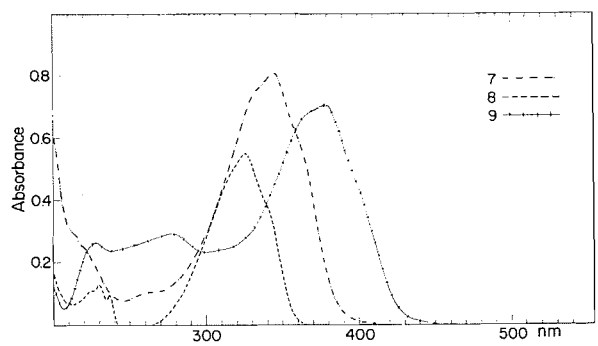

FIG. 6. Absorption spectra of (*7*) 4-(*p*-nitrobenzylidene)-2-methyloxazolin-5-one 2.85×10^{-5} *M*, (*8*) 4-benzylidene-2-methyloxazolin-5-one 2×10^{-5} *M*, (*9*) 4-benzylidene-2-(*p*-nitrophenyl)oxazolin-5-one 2.4×10^{-5} *M*; solvent CH_3CN; 1-cm path length.

on the vibrational coupling scheme in the oxazolinone skeleton and on the position of the electronic dipole responsible for Raman intensity enhancement. It is interesting to compare this case with the changes observed during some enzyme–substrate reactions. In certain of the latter (9), large red shifts in substrate

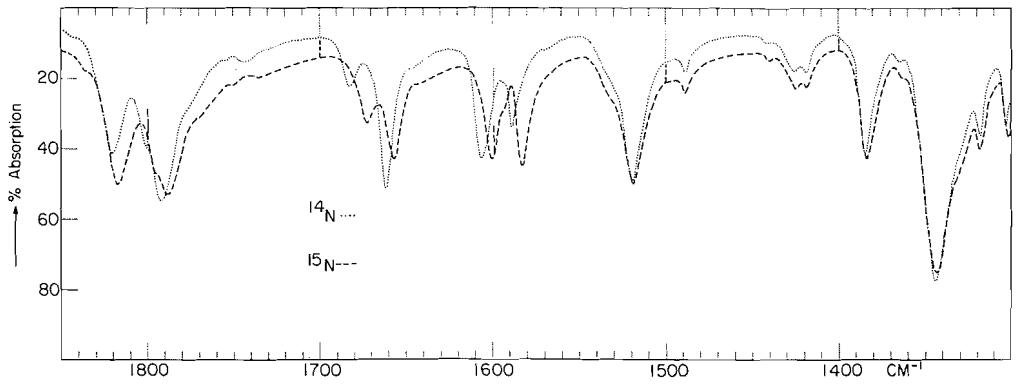

FIG. 7. Infra red spectra of ^{14}N and ^{15}N (substituted in the oxazolinone ring) 4-(*p*-nitrobenzylidene)-2-methyloxazolin-5-one; KBr pellet.

absorbance upon forming an enzyme–substrate complex are accompanied by a total change in the appearance of the resonance Raman spectrum. Good model systems, which mimic these absorption and Raman properties, have been found for the effects of the enzyme.[2] These enzyme–substrate and model systems thus contrast strongly with the present case in which a large red shift is accompanied by a minimal perturbation of the resonance Raman spectrum.

4-(4-Dimethylamino-3-nitrobenzylidene)-2-phenyl-Δ^2-oxazolin-5-one

Again this compound illustrates that substitution in the benzylidene ring does little to affect the overall appearance of the Raman spectra. Resonance Raman and ir data are reported for ^{13}C and ^{15}N substituted analogs of this compound in the preceding paper and the absorption spectrum is shown in Fig. 2. The isotopically substituted analogs established that the intense Raman band at 1563 cm^{-1} had a degree of C=N stretching character but only a small degree of C=C stretching character while for the weak Raman band at 1658 cm^{-1} this situation is reversed. The 1563 cm^{-1} band was assigned to an essentially symmetric mode from the —C=C—N=C portion of the molecule while the band at 1658 cm^{-1} represents an essentially antisymmetric vibration of this moiety.

Replacing the 2-Phenyl on the Oxazolinone Ring by Methyl

In contrast to the above examples replacement of the 2-phenyl ring by methyl causes a substantial change in the appearance of the Raman spectra. This change is not predictable on the basis of the absorption spectra (Fig. 6). The characteristic three Raman bands in the 2-phenyl compounds of medium and high intensity between 1560 and 1610 cm^{-1} are replaced, in the 2-methyl analogs, by two bands whose center of gravity shifts 25–30 cm^{-1} to higher wave numbers. Furthermore the NO_2 feature near 1350 cm^{-1} has a much higher relative intensity in the 2-methyl substituted 4-(*p*-nitrobenzylidene)oxazolinone compared to the 2-phenyl analog. There appear to be two sources for these changes, firstly a change in vibrational coupling and secondly a partial relocation of the electronic transition responsible for Raman intensity enhancement. The change in vibrational coupling in the 2-methyl compared to the 2-phenyl analog is revealed by ^{15}N substitution in the oxazolinone ring of 4-(*p*-nitrobenzylidene)-2-methyloxazolin-5-one. The intense Raman peak at 1591 cm^{-1} shows a ^{15}N shift of about 5 cm^{-1} as do less intense peaks at 1607 and 1662 cm^{-1} (Table 1). Figure 7 compares the ir spectra of the ^{14}N and ^{15}N compounds. All four intense ir features between 1580 and 1700 cm^{-1} move significantly upon ^{15}N substitution; the 1682 cm^{-1} (Fig. 7) band is a very weak shoulder in the Raman (Fig. 5). Thus the present situation contrasts strongly with the 2-phenyl substituted compounds where the most intense Raman band at 1563 cm^{-1} showed the greatest ^{15}N shift (14 cm^{-1}, see preceding

paper, ref. 1). It is apparent that in the 2-methyl substituted compounds the modes in the double bond region are mixed and no single band can be assigned a high degree of C=N stretching character.

The relationship between Raman intensity and the electronic dipole transition is discussed under Excitation Profiles in the preceding paper. Evidence that in the 2-methyl compounds the electronic transition is no longer primarily in the C=C—N=C—Ph moiety comes from considering both the relative intensities of the Raman bands and their excitation profiles. The experimental excitation profiles of 4-(4-nitro-benzylidene)oxazolin-5-one substituted with 2-methyl or 2-phenyl (Fig. 8) demonstrate that in both compounds the NO_2 feature at 1349 cm^{-1} and the intense bands in the double bond region have the same degree of enhancement upon going from 514.5 nm to 457.9 nm. The depolarization ratios for the intense features in both 4-(*p*-nitrobenzylidene)-2-methyl-Δ^2-oxazolin-5-one (Table 2) and the 2-phenyl analog are all ~0.33 showing that only one element of the scattering tensor is dominant and permitting the calculation of theoretical excitation profiles. Good agreement is observed between experimental intensity enhancement and theoretical F_B^2 terms (1, 20) using the transition at ~350 nm for the theoretical calculation (Fig. 8). Moreover the relative intensities in each spectrum remain essentially the same using 647.1 nm excitation. Thus for both the 2-phenyl and 2-methyl analogs in the preresonance region the nitro and double bond features are coupled to the intense electronic transition at ~350 nm. However, comparing the 2-methyl and 2-phenyl spectra, the relative intensities of the nitro band and the double bond features are very different. The integrated intensity of the 1349 cm^{-1} band compared to the total integrated intensity of the bands between 1550 and 1650 cm^{-1} is 1:2.7 for the 2-methyl molecule and 1:6.2 for the 2-phenyl molecule. The intensity ratio for the 2-methyl is quite close to that for *p*-nitro cinnamic acid, which is 1:2.1 (Fig. 9). Recent theoretical studies (21) have emphasized the importance of relative Raman intensities as a source of molecular information and these, together with the data presented here, lead us to propose that in the 2-methyl substituted compounds the electronic dipole transition responsible for intensity enhancement is no longer primarily located in the C=C—N=C—Ph moiety. In the 2-methyl compounds the benzylidene ring becomes important in the Raman intensity enhancement mechanism. In this sense the chromophore can be said to have switched in part from C=C—N=C—Ph to the benzylidene portion.

For 2-phenyl calculations ν_e = 375 nm, ν_s = 280 nm, F_B^2 shown for 1570 cm^{-1} Raman line; for 2-methyl ν_e = 345 nm, ν_s = 260 nm, F_B^2 shown for 1590 cm^{-1} Raman line.

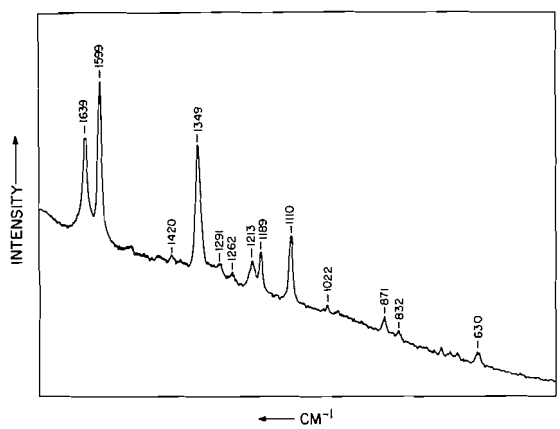

FIG. 9. Preresonance Raman spectrum of *p*-nitrocinnamic acid: KBr pellet; rotating cell; 457.9 nm; 100 mW; 9-cm^{-1} spectral slit.

Two conclusions stem from the present work. Firstly, although strongly electron attracting or donating groups attached to the benzylidene ring may cause large shifts in λ_{max}, the position and relative intensities of the Raman peaks are only minimally perturbed. Secondly it is shown that replacement of the 2-phenyl group by methyl on the oxazolinone ring results in rearrangement of the vibrational coupling scheme and in a partial relocation of the electronic transition responsible for Raman intensity enhancement with the benzylidene moiety assuming increasing importance.

Terpenoids. Part 44. Oxidative rearrangement of 17-nor-13β-kauran-16-one with thallium(III) nitrate

EIICHI FUJITA AND MASAHITO OCHIAI

Institute for Chemical Research, Kyoto University, Uji, Kyoto-Fu 611, Japan

Received July 6, 1977

EIICHI FUJITA and MASAHITO OCHIAI. Can. J. Chem. **56**, 246 (1978).

17-Nor-13β-kauran-16-one (**1**) on treatment with thallium(III) nitrate in acetic acid gives an oxidatively rearranged product, 9,10-*friedo*-17-norkaur-5(10)-en-12-one (**2**). On heating in the presence of acid, compound **2** undergoes rearrangement to give an αβ-unsaturated ketone, 17-norkaur-9(11)-en-12-one (**8**). The structure and stereochemistry of the compound **8** were established by the total synthesis of its racemate.

EIICHI FUJITA et MASAHITO OCHIAI. Can. J. Chem. **56**, 246 (1978).

Traitée par le nitrate de thallium(III) dans l'acide acétique, la nor-17 kauran-13β one-16 (**1**) donne un produit transformé oxydiquement, la *friedo*-9,10 nor-17 kaurèn-5(10) one-12 (**2**). Par chauffage en présence d'acide, le composé **2** subit la transformation, en donnant une cétone non-saturée, la nor-17 kaurèn-9(11) one-12 (**8**). La structure et la stéréochimie ont été établies par la synthèse totale de son composé racémique.

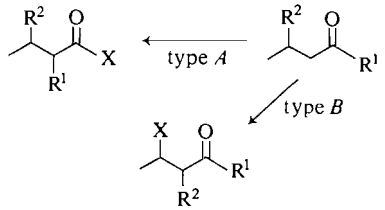
For personal use only.

It is well known that oxidation (1) and/or oxidative rearrangements (2) occur in the reaction of carbonyl compounds with thallium(III) salts. The oxidative rearrangements are of two types, *A* and *B*, as shown in Scheme 1.

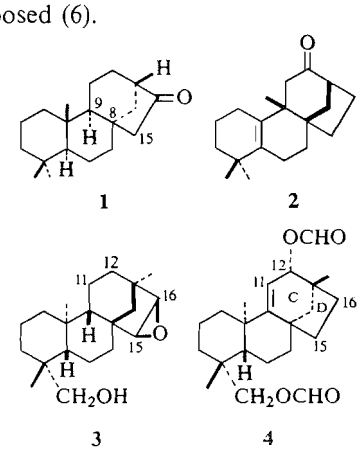


SCHEME 1

Recently we reported (3) the type *B* rearrangement in the reaction of *ent*-17-norkauran-16-one with thallium(III) nitrate (TTN), for which the type *A* reaction seemed unfavorable because it would have to form a highly strained product. It appeared interesting to check the same reaction with other carbonyl compounds, for which both types of rearrangements seem disadvantageous for some reason. Thus we chose 17-nor-13β-kauran-16-one (**1**) (4): its type *A* rearrangement should be difficult for the same reason as in the case of *ent*-norkauranone; its type *B* rearrangement should also be difficult because of the severe strain in two of the rings of the expected product resulting from the migration of the 8,9-bond to the 15-carbon atom.

Compound **1** on treatment with TTN in acetic acid at room temperature for 4 days, gave a product in 81% yield. Its molecular formula was shown to be $C_{19}H_{28}O$ and the presence of a cyclohexanone system was suggested by its infrared spectrum. A tetrasubstituted double bond (or a fifth ring) was suggested by the number of sites of unsaturation and its nmr spectrum. Its cd spectrum showed a large positive maximum (5). These data as well as consideration of the following facts led to the tentative assignment of structure **2** to this product.

In 1974, Murray *et al.* (6) published the transformation of **3** into **4** in which carbons 11 and 12 of **3** become carbons 15 and 16 in the product **4** and carbons 15 and 16 of **3** become carbons 11 and 12 of the product. A mechanism for the transformation was proposed (6).



Consideration of the same type of mechanism for our rearrangement is reasonable. Thus, as shown in Scheme 2, the initial electrophilic attack of TTN from the less-hindered α side of the enol form of compound **1** yields a π complex, which immediately forms the 15α-Tl substituted compound **5**. The

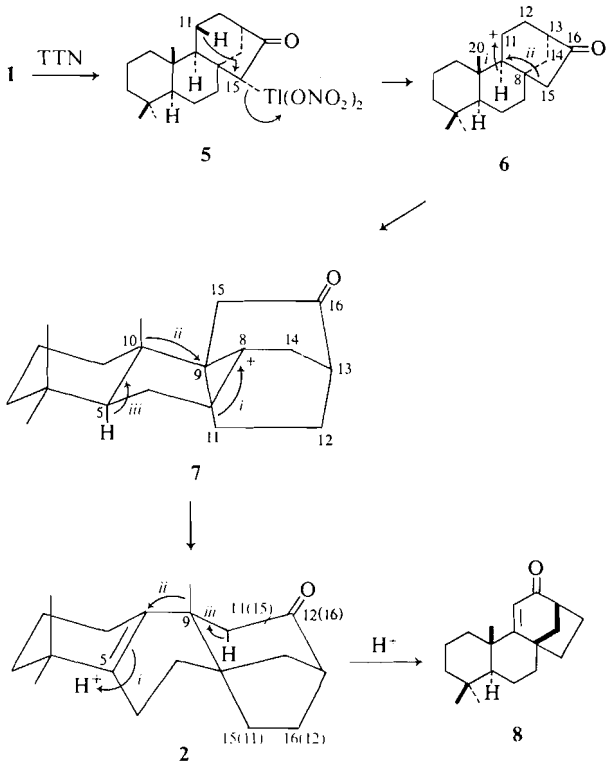


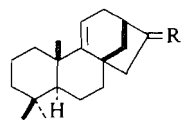
SCHEME 2

successive heterolysis of the C-15—Tl bond cannot be followed by rearrangement of the 8,9 bond into the 15-carbon atom (*vide supra*) but instead is followed by a 1,4-hydride shift of the 11β-H, which is suitably located, to give a cation **6**. Subsequent 1,2-hydride shift from 9α to 11α followed by a 1,2-alkyl shift from 8 (15) to 9 forms a cation **7**. An alternative 1,2-hydride shift of 12α-H to 11α and subsequent 1,2-alkyl shift of the 13,16-bond to 12 forming a bicyclo[2.2.2.]octane system must be unfavorable because of large nonbonded interaction between the 15-methylene and the 20-methyl group. The final deprotonation of the 5α-H after the two successive 1,2-shifts from cation **7** as shown yields the product **2**.

Compound **2** on treatment with a little nitric acid in acetic acid at 100°C gave a rearranged product in 92% yield. It was shown to have the same molecular formula ($C_{19}H_{28}O$) as the starting material. The presence of an αβ-unsaturated ketone in the molecule was suggested by the spectroscopic data (uv (EtOH) λ_{max}: 244 nm; ir ($CHCl_3$) ν_{max}: 1655 and 1593 cm^{-1}; nmr δ: 5.72 (1H, d, J = 1.5 Hz)). The initial protonation at C-5 from the α side, the 1,2-shift of the methyl group on C-9, and subsequent deprotonation of 11α-H would convert the compound **2** into a product having structure **8**. The assignment of this structure to the rearranged product was confirmed by a total synthesis of its racemate.

rac-17-Norkaur-9(11)-en-16β-ol (**9**) which had been synthesized[1] from 5-methoxy-2-tetralone was subjected to successive Jones' oxidation, Wolff–Kishner reduction, and oxidation with chromium trioxide in acetic acid to give *rac*-17-norkaur-9(11)-en-12-one (**8**) via the ketone **10** and the unsaturated hydrocarbon **11**. Compound **8** formed in this manner was identical with the optical active form described above. Compound **11** was auto-oxidized to ketone **8** on standing for a few months.

Thus the product from the reaction of 17-nor-13β-kauran-16-one (**1**) with TTN in acetic acid is now established to be 9,10-*friedo*-17-norkaur-5(10)-en-12-one (**2**).



9 R = α-H, β-OH
10 R = O
11 R = H_2

Experimental

Melting points were determined on a micro hot-stage apparatus. The ir spectra were recorded on a Hitachi EPI-S2 spectrometer and the nmr spectra on a Varian T-60 spectrometer for solutions in deuteriochloroform (tetramethylsilane as internal standard). Mass spectra were determined with a JEOL JMS-OISG double-focusing spectrometer. The uv spectrum was recorded on a Hitachi model EPS-3 spectrophotometer. The circular dichroism was measured with a JASCO J-20 spectropolarimeter. Optical rotations were measured with a JASCO DIP-180 automatic polarimeter. Extracts were dried over anhydrous Na_2SO_4. Mallinckrodt silicic acid and Kieselgel 0.05–0.2 mm (Merck) were used for column chromatography.

*9,10-*friedo*-17-Norkaur-5(10)-en-12-one (2)*

TTN (139 mg) was added to a solution of the ketone **1** (56 mg) in acetic acid (3 ml). The mixture was stirred vigorously for 4 days at room temperature, precipitating white thallium(I) nitrate gradually. The inorganic salt was filtered off and a small amount of water was added to the filtrate. Extraction with *n*-hexane, washing with sodium carbonate and water, and then evaporation left a crystalline residue, which was purified by chromatography to give the rearranged ketone, *9,10-*friedo*-17-norkaur-5(10)-en-12-one* (**2**), (45 mg, 81% yield) as needles, mp 110–113°C (recrystallized from acetonitrile); $[\alpha]_D^{25}$ −60° (*c* 0.22, MeOH); cd (*c* 0.017, MeOH) : $[\theta]_{320}$ 0, $[\theta]_{284}$ −29 000, $[\theta]_{233}$ 0, $[\theta]_{212}$ +14 000, $[\theta]_{199}$ 0; ir ($CHCl_3$) ν_{max} : 1705, 910 cm^{-1}; nmr δ : 0.75, 0.86, 1.01 (each 3H, s); ms *m/e* : 272 (M^+), 257 ($M^+ - CH_3$). *Anal.* calcd. for $C_{19}H_{28}O$: C 83.77, H 10.36; found: C 83.60, H 10.35.

17-Norkaur-9(11)-en-12-one (8)

To a solution of the ketone **2** (13 mg) in acetic acid (2 ml) was added nitric acid (*d*, 1.42) (0.3 ml) and the mixture was heated at 100°C for 2 h. Water was added and the mixture was extracted with ether. After washing with sodium carbonate and water and drying, evaporation left a crystalline mass,

[1]The detailed manuscript has been accepted by Chem. Pharm. Bull. (Jpn).

which was chromatographed to give *17-norkaur-9(11)-en-12-one* (**8**) (11 mg, 92% yield). The analytical sample was prepared by crystallization from acetonitrile as colorless prisms, mp 111°C; $[\alpha]_D^{25}$ −96° (*c* 0.28, MeOH); cd (*c* 0.014, MeOH): $[\theta]_{372}$ 0, $[\theta]_{319}$ −21 000, $[\theta]_{276}$ 0, $[\theta]_{245}$ +47 000, $[\theta]_{226}$ 0, $[\theta]_{217}$ −15 000; ir ($CHCl_3$) ν_{max}: 1655, 1593, 885 cm^{-1}: nmr δ: 0.88, 0.97, 1.17 (each 3H, s), 5.72 (1H, d, J = 1.5 Hz, 11-H); uv (EtOH) λ_{max}: 244 (ε 15 800), 319 (ε 120) nm; ms *m/e*: 272 (M^+), 257 ($M^+ - CH_3$). *Anal.* calcd. for $C_{19}H_{28}O$: C 83.77, H 10.36; found: C 83.69, H 10.54.

rac-*17-Norkaur-9(11)-en-16-one* (***10***)

To an ice-cooled solution of *rac*-17-norkaur-9(11)-en-16β-ol (**9**) (50 mg) in acetone (7 ml), Jones' reagent was added dropwise until yellow color persisted. Excess of the reagent was decomposed with isopropyl alcohol, and the solution was concentrated *in vacuo*. Extraction with ethyl acetate after addition of a little water and the usual work-up gave a crude crystalline product, which was chromatographed to yield *rac-17-norkaur-9(11)-en-16-one* (**10**) (40 mg, 81% yield). The analytical sample was prepared by crystallization from aqueous methanol as needles, mp 89-89.5°C; ir ($CHCl_3$) ν_{max}: 1735 cm^{-1}; nmr δ: 0.82, 0.92, 1.08 (each 3H, s), 5.20 (1H, m, 11-H); ms *m/e*: 272 (M^+). *Anal.* calcd. for $C_{19}H_{28}O$: C 83.77, H 10.36; found: C 83.87, H 10.13.

rac-*17-Norkaur-9(11)-ene* (***11***)

To a solution of the ketone **10** (108 mg) in triethylene glycol (4 ml) hydrazine was added (heated at reflux over sodium hydroxide and distilled) (1 g) and the mixture was heated at 160°C for 4 h under a nitrogen atmosphere. After the addition of hydrazine (0.5 g), a solution of sodium (200 mg) in triethyl ene glycol (4 ml) was added, then the temperature was raised to 220°C by distilling off the low boiling material and the solution was heated at this temperature for 1 h. After cooling, water was added and the solution extracted with *n*-hexane. Usual work-up of the extract gave an oily substance, which was purified by chromatography to yield rac-*17-norkaur-9(11)-ene* (**11**) (102 mg, 100% yield) as an oil; nmr δ: 0.83, 0.90, 1.05, (each 3H, s), 5.12 (1H, m, 11-H).

rac-*17-Norkaur-9(11)-en-12-one* (***8***)

To a solution of *rac*-17-norkaur-9(11)-ene (**11**) (52 mg) in acetic acid (2 ml) was added chromium trioxide (50 mg) at room temperature and the solution was stirred for 2 h. Excess reagent was decomposed with isopropyl alcohol and the solution was concentrated *in vacuo*. After addition of a little water, extraction with *n*-hexane and the usual work-up gave a crystalline mass, which was chromatographed to yield rac-*17-norkaur-9(11)-en-12-one* (**8**) (35 mg, 64% yield). Recrystallization from acetonitrile gave colorless plates, mp 78–79°C; its ir (in $CHCl_3$), nmr, and mass spectra were identical with those of (−)-17-norkaur-9(11)-en-12-one (**8**).

Acknowledgements

We are indebted very much to Prof. R. C. Cambie, University of Auckland, for the gift of 13β-kaur-16-ene. We thank Dr. S. Takahashi, Mrs. J. Tanaka, and Miss T. Hirasawa for the cd and mass spectra and elemental analyses.

Studies related to antitumor antibiotics. Part XIII. Reactivity of 2- and 3-indolylcarbinyl compounds as models for mitosane action

J. WILLIAM LOWN AND GORDON L. WEIR[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 16, 1977

J. WILLIAM LOWN and GORDON L. WEIR. Can. J. Chem. **56**, 249 (1978).

The base-catalyzed methanolyses of 1-methylgramine methiodide **2**, 1-methylisogramine methiodide **3**, and 1-methylindol-2-ylmethyl *N-tert*-butylcarbamate **4** were studied in the temperature range 50–90°C in order to gain information about the relative reactivity of 2- and 3-indolylcarbinyl systems, analogous to the proposed reactive sites of the mitosane antitumor antibiotics when enzymatically reduced. The leaving groups were also analogous to those found in the mitosanes. The methanolysis of **2** proceeds with strict first-order kinetics in accord with indole nitrogen lone pair assistance of the displacement. The comparable reactions of **3** and **4** proceed with second-order kinetics in accord with a direct S_N2 process and the carbamate moiety is the better leaving group by a factor of 10. Gramine methiodide **5** undergoes a very rapid elimination of the elements of $(CH_3)_3\overset{+}{N}HI^-$ followed by addition of a nucleophile such as methanol at a rate which is too rapid to follow kinetically even at −78°C. In accord with the model for the mode of action of the mitosanes, 2.2 m*M* **5** alkylates and cross-links DNA to the extent of 71% at p*H* 7 and 37°C. The extent of cross-linking is proportional to the (G + C) content of DNA's as was found for the mitosanes and occurs at a position other than N-7 on guanine. The results suggest that in the reaction of the mitosane antibiotics with DNA the inherent greater reactivity of the 10-carbamate moiety towards nucleophilic displacement is more than offset by the rate enhancement of the 1 position due to relief of aziridine ring strain.

J. WILLIAM LOWN et GORDON L. WEIR. Can. J. Chem. **56**, 249 (1978).

On a étudié la méthanolyse, catalysée par les bases, de l'iodométhylate de méthyl-1 gramine (**2**), de l'iodométhylate de méthyl-1 isogramine (**3**) et du *N-tert*-butylcarbamate de méthyl-1 indolylméthyle-2 (**4**) à des températures allant de 50–90°C; on a réalisé ces études afin d'obtenir des informations concernant les réactivités relatives des systèmes indolylcarbinyles-2 et -3 qui, lorsqu'ils sont réduits d'une façon enzymatique, sont des sites réactifs proposés pour les antibiotiques antitumoraux mitosanes. Les nucléofuges sont aussi analogues à ceux trouvés dans les mitosanes. La méthanolyse de **2** se produit d'après une cinétique de premier ordre strict tel que prévu si l'on fait l'hypothèse que la paire d'électrons libres de l'azote de l'indole fournit une aide lors du déplacement. Les réactions comparables de **3** et **4** se produisent suivant des cinétiques du deuxième ordre tel que l'on peut le supposer pour une réaction S_N2; par opposition au groupe iodométhylate le groupe carbamate est un meilleur nucléofuge par un facteur de 10. L'iodométhylate de gramine **5** subit une élimination très rapide de $(CH_3)_3\overset{+}{N}HI^-$ qui est suivie par une addition de nucléophiles, comme le méthanol, à une vitesse qui est trop rapide pour être mesurée même à −78°C. Tel qu'on peut le supposer en se basant sur le modèle pour le mode d'action des mitosanes, le composé **5**, à des concentrations de 2.2 m*M*, provoque une alkylation et une réticulation avec l'DNA jusqu'à un taux de 71% à un p*H* 7 et une température de 37°C. Comme on l'a montré avec les mitosanes, le taux de réticulation est proportionnel au contenu (G + C) des DNA et cette réticulation ne se produit par à la position N-7 de la guanine. Les résultats suggèrent que, dans la réaction des antibiotiques misotanes avec la DNA, le groupe carbamate en 10 est beaucoup plus réactif vis-à-vis une substitution nucléophile mais cette réactivité inhérente est plus que contrebalancée par une augmentation de vitesse en position 1 qui provient de l'élimination de la contrainte stérique dans le cycle aziridine.

[Traduit par le journal]

Introduction

The mitosane antitumor antibiotics **1**, isolated from *Streptomyces caespitosus* (1) have a unique four-ring structure (2, 3) and contain three carcinostatic groups: quinone, urethane, and aziridine (4). Although quite toxic, the mitosanes exhibit broad spectrum activity against a variety of neoplasms and mitomycin C and porfiromycin are currently used clinically in Japan for the treatment of breast, stomach, lung, and colon cancer (5).

Considerable evidence indicates the nucleic acids of the cell are the principal targets for mitosane action (6). The action is twofold: (*i*) after NADPH mediated reduction the 'activated' mitosanes become bifunctional alkylating agents which can covalently link the complementary strands of DNA and (*ii*) the extensive degradation of DNA which we have shown proceeds by the autoxidation of acti-

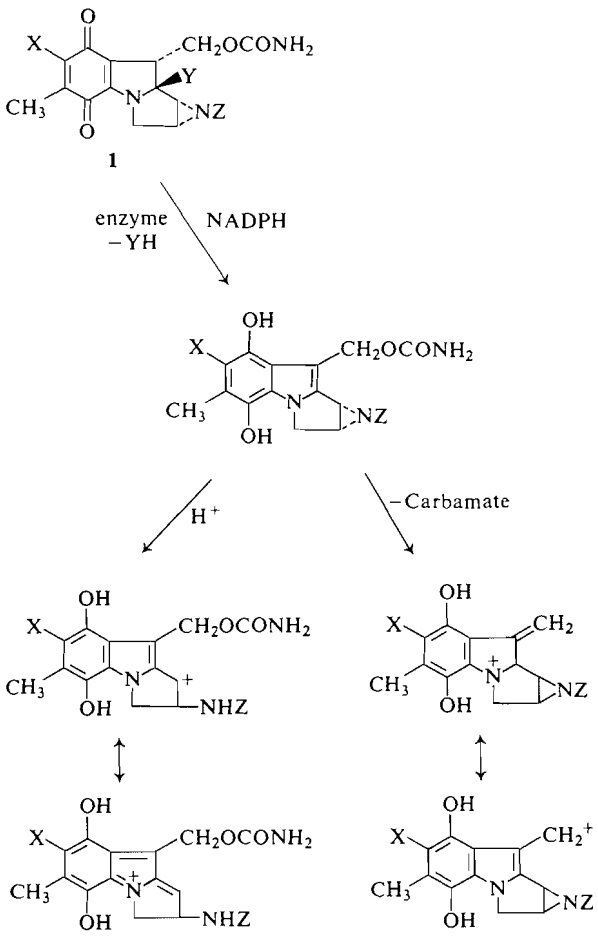
7-Hydroxyporfiromycin	OH	OCH_3	CH_3

vated mitosanes to produce superoxide and hydroxyl radicals (7).

A plausible mechanism for the cross-linking process put forward by Iyer and Szybalski (6), suggests aromatization of ring A in the enzymatic reduction generates two potential alkylating sites at the 2 and 3 position of the *indole* moiety which are presumed to react with DNA bases, principally guanine (Scheme 1). Szybalski and Iyer showed that the rate



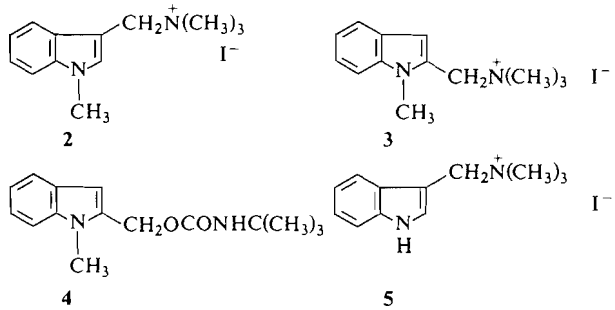
SCHEME 1

of cell death correlated well with the degree of DNA cross-linking (7). While synthetic analogues of the mitosanes bearing the carcinostatic moieties of the parent antibiotics cross-link DNA efficiently in vitro (8) there have been virtually no chemical studies on the relative reactivities of substituted 2- and 3-indolylcarbinyl systems which are structurally analogous to the activated mitosanes.

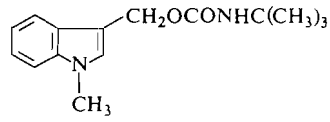
To this end a number of 2- and 3-indolyl compounds have been synthesized and their relative reactivities in nucleophilic displacements examined as well as the comparative reactivity of the trialkylammonium and carbamate leaving groups.

Synthesis of 2- and 3-Indolylcarbinyl Compounds

To gain an insight into the step-wise nature of the cross-linking process the 2- and 3-indolylcarbinyl reaction sites were studied separately on model compounds **2** and **3** with the same leaving group (comparable with that at position 1 of the activated mitosanes). In addition, one of the reacting sites was studied with different leaving groups (**3** and **4**) analogous to those at positions 1 and 10 of the reduced mitosanes, respectively. It was not possible



to synthesize compound **6** isomeric with **4** although this failure in itself is consistent with the other findings for this series of compounds. Gramine

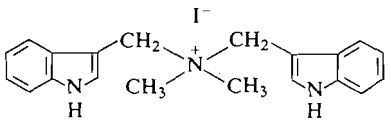


6

methiodide **5** was also investigated in conjunction with the study of its *N*-methyl derivative **2** and proved to have quite different properties with DNA.

Compounds **2** and **3** were prepared by known procedures involving the Fischer indole synthesis, followed by a Mannich reaction and quaternization (9–13). The literature preparation of gramine methiodide **5** was found to give substantial amounts of **7** as evidenced by the nmr spectrum (singlets at 2.85 and 7.30 δ in $CDCl_3$) (14). An improved method was devised involving the addition of a nearly

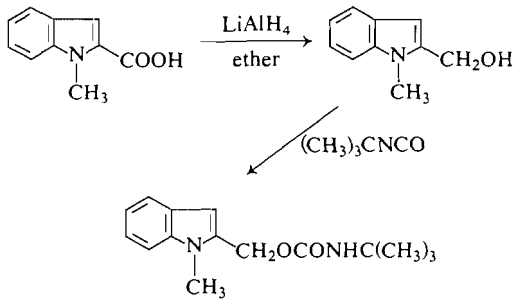
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



7

saturated ethereal solution of gramine to neat methyl iodide which provided **5** free from contamination by **7**.

Compound **4** was synthesized as outlined in Scheme 2.

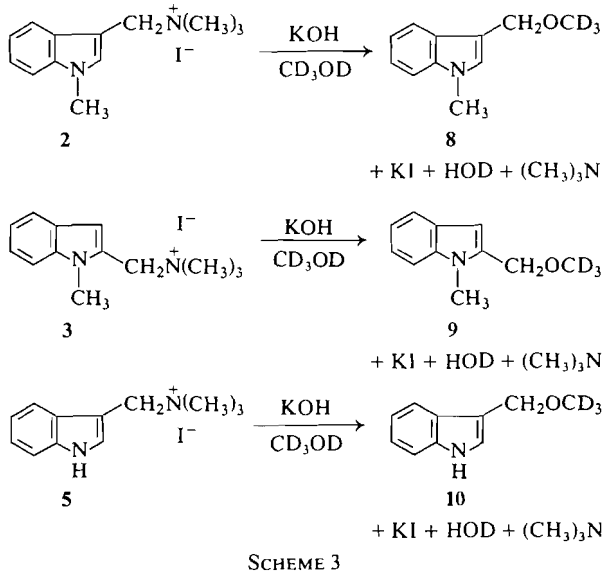


SCHEME 2

Kinetic Study of Nucleophilic Displacements of 2- and 3-Indolylcarbinyl Derivatives

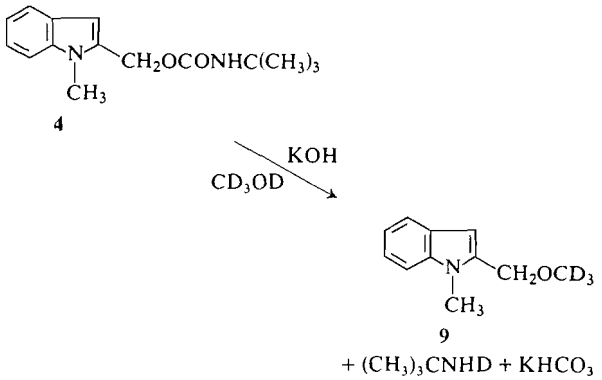
Since the reduced mitosanes cross-link DNA by attack on the two exposed electrophilic centers (corresponding to the 2- and 3-indolylcarbinyl positions) by nucleophiles principally on guanine, we examined the base-catalyzed solvolysis of model compounds, **2–5** (Scheme 3).

By performing the reaction with the gramine derivatives in a sealed nmr tube, using deuterated methanol, it was possible to follow kinetically the disappearance of the singlet in the nmr spectrum due to $-\overset{+}{N}(CH_3)_3$ (3.09 δ from hexamethyldisilane, HMDS for **2** and 3.13 δ for **3**) together with the appearance of the singlet at 2.18 δ from HMDS due to $N(CH_3)_3$.



SCHEME 3

The corresponding reaction of the carbamate **4** gave the same indole product **9** (Scheme 4). However the nmr absorption of the *tert*-butyl group in the product had virtually the same chemical shift as that of the *tert*-butyl group in **4** and so this signal could not be followed in a kinetic study. However, the methylene protons absorbed at 5.12 δ from HMDS in the carbamate **4** and at 4.68 δ from HMDS in the ether **9**, thus facilitating the kinetic study.



SCHEME 4

Results

The product of the solvolysis reaction of **2** was established by carrying the reaction to completion in methanol with potassium hydroxide. Recovery of the protium analogue of **8** was quantitative. A reaction performed with sodium hydroxide as base and water as solvent gave an orange oil the mass spectrum and nmr spectrum of which are consistent with structure **11**. The formation of **11** is in accord with the known chemistry of hydroxymethylindoles (such as the presumed intermediate) in the presence of base (15). Reaction of **2** with sodium methoxide in *tert*-butyl alcohol gave a low yield of the *tert*-butyl ether **12**. The rate of the reaction of **2** to **8** was studied at five temperatures 50, 60, 70, 80, and 90°C. In all cases a plot of the integrated first-order rate expression against time gave a straight line. Two additional kinetic runs were carried out at 80°C in which the base concentration was in turn approximately doubled and halved. The reaction rates were virtually unchanged (see Table 1) in accord with a unimolecular process.

In the product run of **3**, compound **9** was recovered in 94% yield (based on the unreacted **3**). The rate of

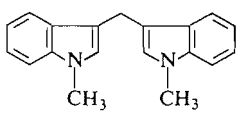
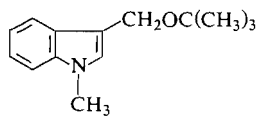
[a]Individual runs showed strict linear adherence to least-square analysis of second-order kinetics. The results of adding rather high concentrations of KOH appear to be due to medium effects on the rate of reaction.

this reaction was determined at 70, 80, and 90°C and was found to follow second-order kinetics over 80% of the reaction as demonstrated by straight line computer least-squares analysis with 12 points for an individual run. An additional run at 90°C with 0.428 of the original amount of base proceeded at a rate consistent with this reaction order (Table 2).



11



12

The product run of **4** afforded the ether **9** also obtained from **3**. This confirms that nucleophilic attack occurs at the 2-indolylcarbinyl position and not at the carbamate carbonyl which would be expected to yield the 2-indolylcarbinol. A kinetic study of this reaction at the temperatures 50, 70, and 80°C revealed as in the solvolysis of **3** strict second-order kinetics (Table 2). Using the rate constants to plot ln (k_1) vs. ($1/T$) and ln (k_1/T) vs. ($1/T$) the activation parameters E_a, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ were calculated (16).

Preparative scale base catalyzed methanolysis of **5** gave the deuterium analog of the known methyl ether **10** quantitatively. Since the reaction of gramine methiodide **5** with even very low concentrations of base and in methanol was found to be extremely rapid even at −78°C, it was not possible to follow this reaction kinetically.

Reaction of 3-Indolylcarbinyl Derivatives with Natural DNA's

If the interpretation of the mode of antitumor action of the mitosanes proposed by Iyer and Szybalski (6) is correct one would anticipate that a suitably substituted indolylcarbinyl derivative would alkylate and/or produce interstrand links in DNA. Treatment of PM2-ccc-DNA[2] (85% ccc) with **5** at a concentration of 7.0 mM resulted in a progressive fall in the ethidium fluorescence before heat denaturation characteristic of removal of potential ethidium intercalation sites as a result of alkylation of the bases (7). The corresponding fluorescence readings taken after heat denaturation and cooling showed an initial rapid fall interpreted as thermally induced removal of alkylated bases followed by rapid alkaline hydrolysis of the exposed ribosephosphate backbone in the pH 11.8 assay medium (17). Subsequently the fluorescence readings rose suggestive of interstrand cross-links which provide nucleation sites for renaturation of the PM2-oc-DNA (7, 8).

The cross-linking of DNA by **5** was confirmed by reaction with linear λ-DNA at 37°C. At pH 7 and 37°C, 2.2 mM **5** produced 71% cross-linking of

[2]Abbreviations: clc, covalently linked complementary; ccc, covalently closed circular; oc, open circular.

For personal use only.

λ-DNA after 300 min, and at p*H* 8.7 and 37°C 2.9 m*M* **5** produced 79% cross-linking after 170 min.

The dependence of the extent of cross-linking by **5** on the (G + C) content was determined by using the following DNA's: *Clostridium perfringens* (30% G + C), calf thymus (40%), and *Escherichia coli* (50%). Allowance was made for differences in their average molecular weights which were determined by sedimentation velocity. Assuming a Poisson's distribution of the links and further, that one link is sufficient to permit spontaneous renaturation of the molecule (18) the average number of cross links per nucleotide m ($m = \ln(1/P_0)$ where P_0 is the proportion of unlinked molecules) was estimated to be ($\times 10^5$) 1.77, 3.46, and 20.6 for the three DNA's at a concentration of **5** of 3.4×10^{-3} *M* (see fig. 1). When the clc assay was performed at p*H* 7.0 as well as at the normal assay conditions of p*H* 11.8 it was found that the fluorescence readings taken before heat denaturation values were constant for 1 h at both p*H* values. None of the compounds **2**, **3**, or **4** cross-links DNA.

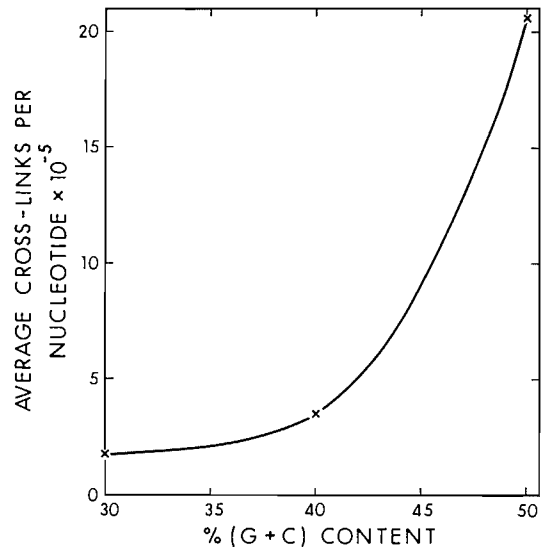

FIG. 1. Dependence of efficiency of covalent cross-linking of DNA's by gramine methiodide **5** on the (G + C) content of the DNA. Reactions were performed at 37°C and contained DNA at 1.25 A_{260}, 0.05 *M* phosphate buffer p*H* 8.7, and gramine methiodide **5** at 3.4×10^{-3} *M*.

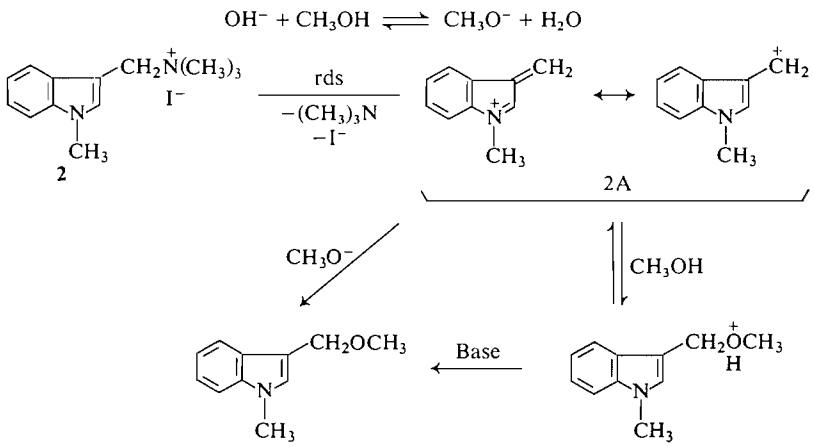
Discussion

The kinetics of the solvolysis of 1-methylgramine methiodide **2** are consistent with a rate-determining unimolecular elimination of trimethylamine followed by a faster attack by the nucleophile (Scheme 5). This elimination can be assisted and the resulting intermediate stabilized by the lone pair of the indole nitrogen.

The role of the base in this reaction appears to be more than just that of a proton sponge. One possible explanation is that the active nucleophile is the methoxide ion formed in a prior equilibrium with the low available concentration of hydroxide ion. The pK_a values of water and methanol in aqueous solution at 25°C are, respectively, 15.74 and 15.5 (19), which would give a substantial proportion of available methoxide ion by equilibration.

The negative entropy value is unusual for unimolecular reactions which involve a molecular fragmentation with a concomitant increase in disorder. However this may be due in the present case to the restricted rotation at the indole 3 position as the hybridization of the reaction center changes from sp^3 (in **2**) to sp^2 (in **2**A).

The nucleophilic displacement of the same leaving group for 1-methylisogramine **3** is not only slower but also exhibits second-order behavior. This result suggests that the type of electron pair assistance analogous to that for the 1-methylgramine **2** does not



SCHEME 5

make a significant contribution to the reaction process despite suggestions to the contrary by Iyer and Szybalski (6) and by Sartorelli and co-workers (20).

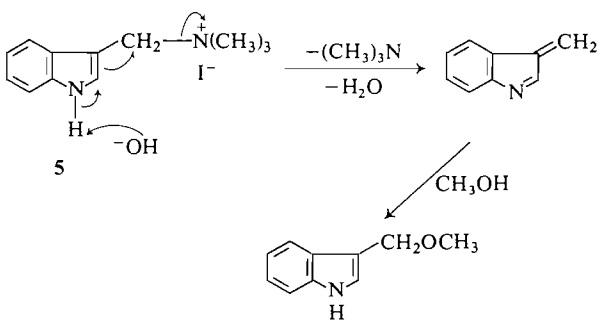
Since the carbenium ion process is not favored in this way, compound **3** behaves as a normal primary system and undergoes an S_N2 type of displacement. The positive value observed for $\Delta S^{\ddagger}$ may be rationalized in terms of the partial neutralization of unlike charges taking place in the transition state. This in turn would bring about less ordering of the solvent shell surrounding the substrate ions.

The studies with the corresponding carbamate **4** show that this compound reacts more rapidly than the trimethylammonium salt **3** (about 10-fold at 80°C) and suggest that the carbamate moiety is a better leaving group for this series of reactions.

This greater reactivity of the carbamate compounds would also explain why it is not possible to synthesize the isomeric carbamate **6**, in which the more reactive leaving group is located on the more reactive 3 position of the indole.

All attempts to prepare such a carbamate, even under the mildest conditions, resulted in mixtures which showed extensive decomposition.

Gramine methiodide **5** undergoes a very rapid elimination of the elements of $(CH_3)_3\overset{+}{N}H\ I^-$ followed by an addition of a nucleophile such as solvent methanol (Scheme 6). The process is too fast to



SCHEME 6

follow kinetically even at very low base concentrations due to the acceleration of the S_N1 displacement provided by the indole anion. Nevertheless such a mechanism could account for the method by which this compound alkylates DNA and why the alkylation and cross-linking of the latter by **5** is promoted by higher p*H* values. The rates of nucleophilic displacement of **2–4** are evidently too slow to allow alkylation of DNA.

Despite the fact that **5** contains only one obvious alkylating center it cross-links DNA quite efficiently and the cross-linking shows a similar dependence on (G + C) content as for the comparable reaction with mitomycin C (16, 17). The dependence of the extent of cross-linking on $(G + C)^2$ content suggests the necessity of locating two adjacent G residues on the complementary DNA strands to complete the cross-link. The constancy of the fluorescence readings at p*H* 11.8 suggests alkylation of DNA by **5** takes place at a position other than N-7 on guanine (21). Interstrand cross-linking of DNA by monofunctional alkylating agents (e.g. methyl methanesulfonate) has been observed but only after heating at 50°C at p*H* 8 for 4 h (22). In that case since the extent of cross-linking is proportional to depurination, the mechanism appears to involve exposure of an aldehyde function at C-1 of the deoxyribose at the depurination site which subsequently reacts with a chemical group in the opposite DNA strand creating a cross-link.

However, since neither mitomycin C nor synthetic analogues which cross-link DNA cause any depurination (7, 8) it follows that a second reactive site in **5** is responsible for completion of the cross-link. The N-1 position of the indole is implicated because of the lack of reactivity towards DNA of the 1-methyl derivative. Murakami has postulated involvement of the N-4 position (tertiary in this case) of the activated mitomycins acting as polyfunctional agents in bonding to DNA bases (23).

The ability of **5** to cross-link DNA provides evidence for the participation in the cross-linking process of the site corresponding to the methylurethane group in the mitosanes. The present studies support the conclusion that the C-10 carbenium ion in the activated mitosanes, once formed, is more stable than the C-1 cationic center. Yet evidence has accumulated to show that the 1 position is in fact the first to react (6, 7). This suggests that a rate enhancement for the 1 position due to relief of the aziridine ring strain is more than sufficient to offset the inherent comparative stabilities of these two cationic centres.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer grating infrared spectrophotometer Model 421 and generally only the principal peaks are reported. Absorption spectra were measured in either distilled water or spectrograde solvents and were run on either a Beckman DB spectrophotometer, a Gilford 250 spectrophotometer, or a Unicam SP1700 uv spectrophotometer. Proton magnetic resonance spectra were recorded on Varian A-60 and HA-100 analytical instruments and were generally measured on 10–15% (w/v) solutions of the compound in the appropriate deuterated solvent. The reference compound was tetramethylsilane (TMS), except for the nmr kinetic runs, where hexamethyldisilane (HMDS) was used as the reference because of its lower volatility. Line positions are reported in ppm from the reference. Mass spectra were determined with Associated

Electrical Industries MS2, MS9, MS12, or MS50 (DS50) mass spectrometers. In general the ionization energy was 70 eV.

Materials

Ethidium bromide, and calf thymus DNA were purchased from Sigma Chemical Co. The λ and PM2-ccc-DNA's were prepared as before (25). *Escherichia coli* and *C. perfringens* DNA's were obtained from Dr. A. R. Morgan.

Anhydrous methanol for the product runs was prepared from commercially available methanol by treatment with magnesium methoxide and distilled as described by Fieser (ref. 25, p. 289).

2,6-Lutidine was prepared as follows: Eastman practical grade 2,6-lutidine was dried over potassium hydroxide for 24 h then refluxed and distilled from barium oxide as described by Fieser for the preparation of anhydrous pyridine (ref. 25, p. 291). The center cut (138–140°C) was treated with boron trifluoride etherate as described by Brown *et al.* (26).

1-Methylgramine

This compound was prepared from 1-methylindole (9) as an amber oil in 63% yield by a method similar to that reported by Snyder and Eliel (10); nmr ($CDCl_3$) δ_{TMS}: 2.27 (s, 6H, $N(CH_3)_2$, 3.61 (s, 2H, CH_2), 3.69 (s, 3H, indole NCH_3), 6.97 (s, 1H, indole 2-H), 7.05–7.91 (m, 4H, aryl protons).

1-Methylgramine Methiodide **2**

This compound was prepared according to Snyder and Eliel (10) by the alkylation of 1-methylgramine with methyl iodide. The crude material was formed in 98% yield as a pink solid which was recrystallized from methanol–ether to give small white leaflets, mp 177–178°C (dec.) (lit. (10) inst. decomposition point 195°C); (DMSO-*d*) δ_{TMS}: 3.12 (s, 9H, $^+N(CH_3)_3$), 3.88 (s, 3H, indole NCH_3), 4.79 (s, 2H, CH_2), 7.74 (s, 1H, indole 2-H), 7.09–8.09 (m, 4H, aryl protons). *Anal.* calcd. for $C_{13}H_{19}N_2I$: C 47.29, H 5.80, N 8.48, I 38.43; found: C 47.31, H 5.88, N 8.37, I 38.29.

*Indole-1-methyl-2-(*N,N-*dimethyl)carboxamide*

Patterned after the method of Schindler (11) 9.2 g of 1-methylindole-2-carboxylic acid was suspended in 135 ml of benzene (freshly distilled from sodium) under a nitrogen atmosphere. Thionyl chloride (13.5 ml) distilled from quinoline was added dropwise with magnetic stirring over a period of 45 min. The mixture was then heated to 45–50°C for 1 h, during which time the acid dissolved and the solution became dark green. The solvent and excess thionyl chloride were then removed on a high-vacuum distillation apparatus, 70 ml of dry benzene was added to the residue, and this solution was added dropwise to 150 ml of benzene which had been saturated with dimethylamine gas. After the addition was completed, more dimethylamine gas was bubbled into the brown solution to ensure an excess of the amine.

After standing overnight in a refrigerator, the mixture was treated with water to dissolve the dimethylamine hydrochloride. The organic layer was removed and dried (Na_2SO_4). Removal of the solvent gave a quantitative yield of a brown oil which solidified on standing to a material with mp 83–84°C (lit. (12) mp 95°C); ir ν_{max}(film): 1620 (C=O), 1455 (C—N) cm^{-1}.

1-Methylisogramine

Following the general method of Schindler (11) 6 g of lithium aluminum hydride was mixed with 110 ml of tetrahydrofuran and cooled to below 10°C. Over a period of 2 h at ambient temperature a solution of 11.0 g of indole-1-methyl-2-(*N,N*-dimethyl)carboxamide in 90 ml of tetrahydrofuran was added dropwise with stirring. The mixture was then stirred overnight, cooled in ice water, and carefully treated with water to decompose the unreacted lithium aluminum hydride. The mixture was filtered and the solvent removed from the filtrate to give a residue which was treated with 25 ml of 2 *M* sodium hydroxide solution and extracted with ether. The ether extract was dried (Na_2SO_4) and evaporated to give 9.1 g (89% yield) of product as a brown liquid; nmr ($CDCl_3$) δ_{TMS}: 2.21 (s, 6H, $N(CH_3)_2$), 3.48 (s, 2H, CH_2), 3.72 (s, 3H, indole NCH_3), 6.36 (s, 1H, indole 3-H), 6.93–7.70 (m, 4H, aryl protons).

1-Methylisogramine Methiodide **3**

Following the procedure of Schindler (11) 9.0 g of 1-methylisogramine was alkylated with methyl iodide to give 14.0 g (89% yield) of a brownish solid. A portion of this was recrystallized from methanol–ether to give a cream-colored solid, mp 207°C (lit. (11) mp 217–219°C); nmr (DMSO-d_6) δ_{TMS}: 3.16 (s, 9H, $^+N(CH_3)_3$), 3.88 (s, 3H, indole NCH_3), 4.92 (s, 2H, CH_2), 6.90 (s, 1H, indole 3-H), 7.00–7.87 (m, 4H, aryl protons). *Anal.* calcd. for $C_{13}H_{19}N_2I$: C 47.29, H 5.80, N 8.48, I 38.43; found: C 47.04, H 5.82, N 8.51, I 38.80.

2-Hydroxymethyl-1-methylindole

A solution of 5 g of 1-methylindole-2-carboxylic acid in 100 ml of tetrahydrofuran was treated cautiously with 3.5 g of lithium aluminum hydride, then refluxed for 1 h. The mixture was then cooled and treated with ethyl acetate and then water to decompose the excess of lithium aluminum hydride. The resulting mixture was filtered and the filtrate dried (Na_2SO_4). Upon evaporation of the solvent this solution yielded 4.0 g (87% yield) of a light yellow solid, mp 92–93°C (lit. (13) mp 108–110°C). The nmr spectrum indicated a purity sufficient for subsequent steps; nmr ($CDCl_3$) δ_{TMS}: 1.95 (br, 1H, OH), 3.67 (s, 3H, CH_3), 4.67 (s, 2H, CH_2), 6.37 (s, 1H, indole 3-H), 6.96–7.68 (m, 4H, aryl protons).

1-Methylindol-2-ylmethyl N-tert-*Butylcarbamate* **4**

A mixture of 1.50 g of 2-hydroxymethyl-1-methylindole and 2.3 ml of *tert*-butyl isocyanate was warmed on a steam bath until all the solid material had dissolved. The solution was then cooled overnight in a refrigerator, the resulting precipitate collected, washed with petroleum ether (bp 60–100°C), and evaporated to give 1.51 g of a dark brown material. Extraction of this substance with ether left a brown earthy residue and gave a solution from which 0.78 g (32% yield) of a cream-colored material precipitated upon concentration. This substance was recrystallized from either acetone–water or ether–*n*-pentane to give crystals, mp 103°C; ir ($CHCl_3$) ν_{max}: 3440, 2970, 1720 (carbamate C=O), 1495, 1460, 1390, 1360, 1335, 1315, 1255, 1135, 1065 cm^{-1}; nmr ($CDCl_3$) δ_{TMS}: 1.33 (s, 9H, $C(CH_3)_3$), 3.74 (s, 3H, NCH_3), 4.47–4.95 (br, 1H, NH), 5.23 (s, 2H, CH_2), 6.57 (s, 1H, indole 3-H), 6.93–7.70 (m, 4H, aryl protons). *Anal.* calcd. for $C_{15}H_{20}N_2O_2$: C 69.20, H 7.74, N 10.76; found: C 59.32, H 7.89, N 10.88. *Mol. Wt.* calcd. for $C_{15}H_{20}N_2O_2$: 260.1524; found (mass spectrum): 260.1519.

Gramine Methiodide **5**

The method of Geissman and Armen (14) was found to give a sticky material containing impurities of dimethyldi-(3-indolylmethyl)ammonium iodide **7**, as evidenced by the nmr spectrum (singlets at 2.85 and 7.30 δ_{TMS} in $CDCl_3$).

An improved method involved first dissolving 2.75 g of gramine in 300 ml of ether and adding this nearly saturated solution dropwise with stirring to 100 g of methyl iodide. As the addition proceeded a white-to-pale-yellow solid precipitated from the reaction mixture in quantitative yield. The product was recrystallized from methanol–ether as white crystals, mp 168–170°C (lit. (14) mp 168–169°C); nmr (DMSO-d_6) δ_{TMS}: 3.12 (s, 9H, $^+N(CH_3)_3$), 4.80 (s, 2H, CH_2), 7.76 (d, J =

For personal use only.

2.5 Hz, 1H, indole 2-H), 7.05–8.03 (m, 4H, aryl protons), 11.57 (br, 1H, NH). *Anal.* calcd. for $C_{12}H_{17}N_2I$: C 45.58, H 5.42, N 8.86, I 40.14; found: C 45.63, H 5.67, N 8.65, I 40.14.

Treatment of 1-Methylgramine Methiodide **2** *with Sodium Hydroxide in Methanol*

A solution of 1.495 g (4.53 mmol) of 1-methylgramine methiodide **2** and 0.181 g (4.53 mmol) of sodium hydroxide in 100 ml of anhydrous methanol was placed in a stoppered volumetric flask and suspended for 209 h in an oil bath thermostated at 70.0°C. The solvent was then removed *in vacuo* and the organic portion of the residue extracted with ether. Recovery was 0.790 g (4.51 mmol, 99.6%) of 3-methoxymethyl-1-methylindole (protium analogue of **8**) as a brown oil which became hard and vitreous on prolonged standing; ir ($CHCl_3$) ν_{max}: 2900, 1635, 1590, 1450, 1350, 1305, 1130, 990 cm^{-1}; nmr ($CDCl_3$) δ_{TMS}: 3.36 (s, 3H, OCH_3), 3.67 (s, 3H, NCH_3), 4.63 (s, 2H, CH_2), 6.99 (s, 1H, indole 2-H), 7.07–7.82 (m, 4H, aryl protons). *Mol. Wt.* calcd. for $C_{11}H_{13}NO$: 175.0997; found (mass spectrum): 175.0993.

Treatment of 1-Methylgramine Methiodide **2** *with Sodium Hydroxide in Water*

A solution of 0.159 g (0.483 mmol) of 1-methylgramine methiodide **2** and 0.021 g (0.531 mmol) of sodium hydroxide in 10 ml of distilled water was stoppered in a 25-ml pear-shaped flask and suspended for 48 h in an oil bath at 70.0°C. The ether extract of the residue after evaporation gave 60 mg of an orange oil. The mass spectrum (m = 274) and the aryl:CH_2 and aryl:CH_3 ratios of the nmr integrations indicated that this product was di-(1-methylindoyl)methane **11**.

Treatment of 1-Methylgramine Methiodide **2** *with 2,6-Lutidine in Methanol*

A solution of 0.115 g (0.347 mmol) of 1-methylgramine methiodide **2** and 0.044 g (0.409 mmol) of 2,6-lutidine in 5 ml of anhydrous methanol was sealed in a test tube and placed into a 70.0°C oil bath for 259 h. The work-up as described above gave only 1 mg of the ether (protium analogue of **8**) (mass spectrum, m = 175) plus 50 mg of solid materials which could not be identified.

Treatment of 1-Methylgramine Methiodide **2** *with Sodium Methoxide in* tert-*Butyl Alcohol*

1-Methylgramine methiodide **2** (0.136 g (0.412 mmol)) and 0.024 g (0.437 mmol) of sodium methoxide were suspended in 10 ml of *tert*-butyl alcohol and placed in a 70.0°C oil bath for 187 h. From the work-up was isolated 20 mg of a yellowish oil which from the nmr spectrum and mass spectrum (m = 217) was identified as 3-*tert*-butoxymethyl-1-methylindole **12**; nmr ($CDCl_3$) δ_{TMS}: 1.35 (s, 9H, $C(CH_3)_3$), (s, 3H, NCH_3), 3.72 (s, 3H, NCH_3), 4.65 (s, 2H, CH_2), 6.97–7.36 (br m, 5H, aryl plus indole 2-H protons).

Treatment of 1-Methylisogramine Methiodide **3** *with Sodium Hydroxide in Methanol*

A solution of 1.257 g (3.81 mmol) of 1-methylisogramine methiodide **3** and 0.152 g (3.81 mmol) of sodium hydroxide in 100 ml of anhydrous methanol was placed in a 70.0°C oil bath for 425 h. The solution was then evaporated to dryness and extracted with ether to give 0.19 g (31% yield) of 2-methoxymethyl-1-methylindole as a yellow solid, mp 44–47°C; 69% of unreacted **3** was also obtained from the ether-insoluble residue; ir ($CHCl_3$) ν_{max}: 2930, 1660, 1605, 1460, 1395, 1335, 1310, 1135, 1075, 905 cm^{-1}; ($CDCl_3$) δ_{TMS}: 3.31 (s, 3H, OCH_3), 3.73 (s, 3H, NCH_3), 4.57 (s, 2H, CH_2), 6.46 (s, 1H, indole 3-H), 6.87–7.73 (m, 4H, aryl protons). *Mol. Wt.* calcd. for $C_{11}H_{13}NO$: 175.0997; found (mass spectrum): 175.0994.

Treatment of 1-Methylindol-2-ylmethyl N-tert-*Butylcarbamate* **4** *with Potassium Hydroxide in Methanol-*d_4

1-Methylindol-2-ylmethyl *N-tert*-butylcarbamate **4** (20.00 mg, 0.0768 mmol) and 8.18 mg of 86.5% potassium hydroxide (0.126 mmol) were sealed in an nmr tube with 1.0 ml of methanol-d_4 containing 1 drop of HMDS. The nmr spectrum was recorded and the tube was then placed in a 90.0°C oil bath for 164 h. After this the nmr spectrum was again recorded and found to be that of *tert*-butylamine plus 2-(trideuteromethoxy)-methyl-1-methylindole **9**; nmr (CD_3OD) δ_{HMDS} before heating: 1.25 (s, 9H, $C(CH_3)_3$), 3.66 (s, 3H, NCH_3), 4.90 (s, exchangeable protons), 5.12 (s, 2H, CH_2), 6.41 (s, 1H, indole 3-H), 6.82–7.52 (m, 4H, aryl protons); after heating: 1.24 (s, 9H, $C(CH_3)_3$, 3.72 (s, 3H, NCH_3), 4.90 (s, exchangeable protons), 4.68 (s, 2H, CH_2), 6.32 (s, 1H, indole 3-H), 6.82–7.50 (m, 4H, aryl protons).

Treatment of Gramine Methiodide **5** *with Sodium Hydroxide in Methanol*

A solution of 1.405 g (4.44 mmol) of gramine methiodide **5** and 0.178 g (4.45 mmol) of sodium hydroxide in 100 ml of anhydrous methanol was placed in a pressure bottle in an oil bath at 70.0°C for 99 h. The solvent was then removed and the residue extracted with ether to give 0.700 g (4.34 mmol, 98% yield) of 3-methoxymethylindole (protium analogue of **10**) as a solid, mp 94–95°C after recrystallization from benzene–*n*-pentane (lit. (27) mp 99–100°C). Thin-layer chromatography on silica gel with either benzene of benzene–*n*-pentane 10:90 as the developing solvent showed a single component. The mass spectrum showed a parent ion at m/e = 161; ir ($CHCl_3$) ν_{max}: 3475, 3000, 2930, 1455, 1415, 1335, 1085 cm^{-1}; nmr ($CDCl_3$) δ_{TMS}: 3.40 (s, 3H, OCH_3), 4.67 (s, 2H, CH_2), 6.99 (d, J = 2.5 Hz, 1H, indole 2-H), 7.08–7.89 (m, 4H, aryl protons), 8.21 (br, 1H, NH).

Kinetic Studies

For each kinetic run, the salt or carbamate ester was weighed into a clean nmr tube. The calculated amount of 86.5% potassium hydroxide was dissolved in about 0.5 ml of CD_3OD in a 1-ml volumetric flask. The flask was then filled to the mark with CD_3OD and 2 drops of HMDS as an internal standard. The contents of the volumetric flask were transferred to the nmr tube which was then sealed.

The slower reactions were conducted in a constant temperature bath with the tube being quenched in ice water prior to the spectrum recordings; for the faster reactions, the reaction was conducted directly in the heated probe of the nmr instrument. The technique consisted of monitoring the integrals of the *N*-trimethyl signals for the salts, and the methylene signal for the carbamate ester. The percentage reaction at timed intervals was established by calculating the ratio of the *N*-trimethyl (or methylene) integral due to the reaction product, to the total *N*-trimethyl (or methylene) integral.

Except for the faster runs, integrations of the spectra were usually run in duplicate or triplicate, and the results averaged to reduce random fluctuations.

Interstrand Cross-linking of λ-DNA by Gramine Methiodide **5** *Fluorescence Assay for Detecting Covalently Linked Complementary Sequences in DNA and Synthetic Polynucleotides and the p*H *Dependence*

All measurements were performed on a G. K. Turner and Associates model 430 spectrofluorometer equipped with a cooling fan to minimize fluctuations in the xenon lamp source. Wavelength calibration was performed as described in the manual for the instrument. One-centimetre square cuvettes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

were used. The excitation wavelength was 525 nm and the emission wavelength 600 nm. The 100×-scale of medium sensitivity was generally used and water was circulated between the cell compartment and a thermally regulated bath at 22°C. The alkylation experiments with gramine methiodide **5** were conducted on a 200 μl scale at 37°C. The reaction mixture contained PM2-ccc-DNA (86% ccc) at 1.0 A_{260}, 0.05 *M* potassium phosphate buffer p*H* 7.0, and **5** at 7.0 m*M*. A control was run containing no compound **5**. Samples of 20 μl were withdrawn at intervals over a period of 130 min.

The cross-linking of DNA by **5** was performed with λ-DNA at 1.2 A_{260}, 0.05 *M* potassium phosphate p*H* 7.0 or 8.7, and **5** at 2.2×10^{-4} *M*. For both p*H* values a control experiment was run with no **5**. In each case samples (15 μl) were withdrawn at intervals and analyzed for the extent of cross-linking by addition to 2 ml of the standard p*H* 11.8 assay solution. This contained 20 m*M* potassium phosphate p*H* 11.8, 0.4 m*M* EDTA, and 0.5 μg/ml ethidium bromide. The fluorescence was measured using a blank without added sample. For the heat denaturation, the solutions were heated for 3 min at 96°C on a tempblok and cooled to 23°C. Under these conditions only clc DNA shows return of fluorescence since the covalent links provide a nucleation site for renaturation (7, 28). The ratio of the fluorescence intensity after the heat denaturation to the fluorescence before the heat denaturation gave the extent of covalent cross-linking of the DNA.

Procedure for Determining Covalent Cross-linking of DNA's of Different (G + C) Content by Gramine Methiodide **5**

The DNA's used in this study were *C. perfringens* (mol. wt. 11.4×10^6, (G + C) content 30%), calf thymus (mol. wt. 9.1×10^6, (G + C) content 40%), and *E. coli* (mol. wt. 7.7×10^5, (G + C) content 50%). The molecular weights were determined by sedimentation velocity studies. Reactions were performed at 37°C and contained DNA at 1.25 A_{260}, 0.05 *M* potassium phosphate buffer p*H* 8.7, and **5** at 3.4 m*M*. Aliquots were removed at intervals and analyzed for the extent of covalent cross-linking by the ethidium assay as described above.

Nitration of 4-*tert*-butyl-*o*-xylene in acetic anhydride. Formation and rearomatization of adducts

ALFRED FISCHER AND KHAY CHUAN TEO

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received August 18, 1977

ALFRED FISCHER and KHAY CHUAN TEO. Can. J. Chem. **56**, 258 (1978).

Nitration of 4-*tert*-butyl-1,2-dimethylbenzene in acetic anhydride gives *trans*-1-*tert*-butyl-3,4-dimethyl-4-nitro-1,4-dihydrophenyl acetate (**6**), *trans*-1-*tert*-butyl-3,4-dimethyl-4-nitro-1,4-dihydrophenol, 2-*tert*-butyl-4,5-dimethylphenyl acetate, 5-*tert*-butyl-2-methylbenzaldehyde, 4-*tert*-butyl-1,2-dimethyl-5-nitrobenzene, and 4-*tert*-butyl-1,2-dimethyl-6-nitrobenzene. 2-*tert*-Butyl-4,5-dimethylphenyl acetate and 3,4-dimethylphenyl acetate are the major products of solvolysis of **6** in moist acetic acid. Both of these compounds are likely formed via the cation generated by ionization of the nitro group. Under more acidic conditions 5-*tert*-butyl-2-methylbenzaldehyde and 4-*tert*-butyl-1,2-dimethyl-6-nitrobenzene, formed via the cation generated by acid-catalysed loss of acetate, become dominant, the balance between these products being controlled by the basicity of the solvent. More basic solvents deprotonate the cation to a triene, a key step in the formation of the aldehyde, at a competitive rate with the nitro group migration.

ALFRED FISCHER et KHAY CHUAN TEO. Can. J. Chem. **56**, 258 (1978).

La nitration du *tert*-butyl-4 diméthyl-1,2 benzène dans l'anhydride acétique conduit à l'acétate du *tert*-butyl-1 diméthyl-3,4 nitro-4 dihydro-1,4 phényle *trans* (**6**), au *tert*-butyl-1 diméthyl-3,4 nitro-4 dihydro-1,4 phénol *trans*, à l'acétate du *tert*-butyl-2 diméthyl-4,5 phényle, au *tert*-butyl-5 méthyl-2 benzaldéhyde, au *tert*-butyl-4 diméthyl-1,2 nitro-5 benzène et au *tert*-butyl-4 diméthyl-1,2 nitro-6 benzène. Les acétates du *tert*-butyl-2 diméthyl-4,5 phényle et diméthyl-3,4 phényle sont les produits principaux de la solvolyse de **6** dans l'acide acétique humide. Chacun de ces composés se forme vraisemblablement par l'intermédiaire du cation produit par l'ionisation du groupe nitro. Utilisant des conditions plus acides, la perte acido-catalysée du groupement acétate conduit à la formation d'un cation qui fournit du *tert*-butyl-5 méthyl-2 benzaldéhyde et du *tert*-butyl-4 diméthyl-1,2 nitro-6 benzène comme produits prédominants; les quantités relatives de ces produits sont contrôlées par la basicité du solvant. Dans les solvants les plus basiques la vitesse de déprotonation du cation conduisant à un triène, une étape clé dans la formation de l'aldéhyde, devient compétitive avec la migration du groupe nitro.

Nitration of appropriately substituted arenes in acetic anhydride is accompanied by the formation of nitronium acetate (acetyl nitrate) adducts initiated by the attack of nitronium ion at a substituted (*ipso* (1)) position (2–4). Only in the case of *p*-*tert*-butyltoluene has a 1,2 adduct, **1***a*, been obtained, in addition to the normal 1,4 adduct (2).[1] Formation of the 1,2 adduct has attributed to the steric effect of the *tert*-butyl substituent. The present study of 4-*tert*-butyl-1,2-dimethylbenzene (4-*tert*-butyl-*o*-xylene) was undertaken in order to determine if a general preference for 1,2 adduct formation existed in *tert*-butylbenzene derivatives. Related studies are those on 1,2,4-trimethylbenzene (pseudocumene (5)) and, less directly, other substituted *o*-xylenes such as 3,4-dimethylacetophenone (6). In all of these compounds, as in the parent *o*-xylene itself, the position *ipso* to one methyl group is activated by the second, *ortho* methyl and as a result *ipso* nitration and adduct formation is a dominant reaction (7, 8).

[1]These descriptions retain the enumeration of the parent hydrocarbon for the adducts. Thus the 1(nitronium), 4(acetate) adduct is 4-acetoxy-1-nitro-1,4-dihydro-*p*-*tert*-butyltoluene (more appropriately named 1-*tert*-butyl-4-methyl-4-nitro-1,4-dihydrophenyl acetate), whereas the 1,2 adduct is 2-acetoxy-1-nitro-1,2-dihydro-*p*-*tert*-butyltoluene (5-*tert*-butyl-2-methyl-2-nitro-1,2-dihydrophenyl acetate).

Results and Discussion

Nitration and Formation of Adducts

Nitration of 4-*tert*-butyl-*o*-xylene (**2**) in acetic anhydride gave a product mixture containing ca. 68% of diene adducts. Since 13% of **2** was recovered it is evident that *ipso* attack and addition in this system occurs to the extent of at least 78% of all attack by the nitrating electrophile. Low-temperature chromatography of the product gave the unreacted **2**, the 5- and 6-nitro derivatives **3***a* and **4***a*, respectively, 5-*tert*-butyl-2-methylbenzaldehyde (**5**), 2-*tert*-butyl-4,5-dimethylphenyl acetate (**3***b*), one diastereoisomer of 1-*tert*-butyl-3,4-dimethyl-4-nitro-1,4-dihydrophenyl

acetate (**6**),[2] and the corresponding diastereoisomer of 1-*tert*-butyl-3,4-dimethyl-4-nitro-1,4-dihydrophenol (**7**).[3] The correspondence of the stereochemistry was established by reduction of the acetate **6** to the alcohol **7** with aluminum hydride. The sample of **7** so obtained had identical ir and nmr to that isolated from the nitration mixture. That the adducts isolated are 1,4 rather than 1,2 is clearly indicated by their uv absorption: only end-absorption to 225 nm was observed with ε being 150 for the acetate and 120 m^2mol^{-1} for the alcohol. These values are consistent with the 2,5 diene pattern of structures **6** and **7** but inconsistent with the 2,4 (conjugated) diene structures **1***b* or **1***c*. The 1,2 adduct **1***a* has an appropriate absorption peak for a conjugated cyclohexadiene: 255 nm, ε 580 m^2mol^{-1} (2). At the same wavelength the acetate **6** and alcohol **7** both have ε 20 m^2mol^{-1}. Additional evidence is provided by the nmr spectra. The *tert*-butyl absorption of **1***a* is at 1.07 whereas that of its 1,4 isomers is at 0.93 and 0.96 ppm (2), the 0.1 ppm difference being a consequence of the attachment of the *tert*-butyl to a vinylic carbon in **1***a* and to a saturated carbon in the 1,4 isomers. For acetate **6** and alcohol **7** the absorption is at 0.99 and 0.97 ppm, respectively.[4] The shift reagent *tris*(1,1,1,2,2,3,3-heptafluoro-7,7-[$^2H_6$]dimethyl-4,6-[$^2H_3$]octanedionato)europium(III) {Eu([$^2H_9$]fod)$_3$} moves the *tert*-butyl peak relatively rapidly downfield (relative gradient 0.40), as is appropriate if the *tert*-butyl and acetate or hydroxyl are attached to the same carbon (Table 1). In **1***a* with the acetate and *tert*-butyl isolated and thus with the europium comparatively distant from the *tert*-butyl, the peak moves very slowly (relative gradient 0.04 (2)), whereas in the 1,4 isomer of **1***a* it again moves rapidly (relative gradient 0.40). Additional arguments can be adduced to rule out structures **1***b* and **1***c* and also to reject other isomeric 1,2 and 1,4 adduct structures (cf. 9).

TABLE 1. Relative gradients of proton chemical shifts for diene adducts resulting from the addition of Eu([$^2H_9$]fod)$_3$

6		7	
Assignment	Relative gradient[a]	Assignment	Relative gradient[b]
1-C(CH$_3$)$_3$	0.40	1-C(CH$_3$)$_3$	0.137
2-H	0.87	2-H	0.221
3-CH$_3$	0.31	3-CH$_3$	0.043

Calculations based on the known susceptibility of the 1(*ipso*), 3, and 4 positions of *o*-xylene to attack by nitronium ion (8), and on partial rate factors for nitration of *tert*-butylbenzene in acetic anhydride (10) predict that in 4-*tert*-butyl-*o*-xylene attack at the 1 position should occur to the extent of more than 90%. Attack at the other ring positions is predicted to occur to at most a few percent in each case. It is, therefore, not surprising that no 2,5 adduct, or 4,1 adduct,[5] or 3-nitroarene was detected. The 3 position is activated by two *ortho* alkyl groups but is very hindered. The 4 position, being *ipso* to the bulky *tert*-

[2]4-Acetoxy-1-nitro-1,4-dihydro-4-*tert*-butyl-*o*-xylene.
[3]4-Hydroxy-1-nitro-1,4-dihydro-4-*tert*-butyl-*o*-xylene.

[4]In the mother liquors from recrystallization of **6** there was an absorption 0.1 ppm further downfield, indicative of the presence of the expected 1,2 adduct. Chromatography of the residues from the mother liquors gave fractions in which the 1,2 adduct was a major component. This adduct decomposed in the course of determining the ^{13}C nmr spectrum of combined fractions.

[5]The nitro-de-*tert*-butylation product, 4-nitro-*o*-xylene (**8***a*), is the expected product from nitration at the 4 position, rather than the 4,1 adduct (cf. (11)). However, no **8***a* was obtained. The absence of attack *ipso* to the *tert*-butyl group parallels the behaviour of *p*-*tert*-butyltoluene (2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

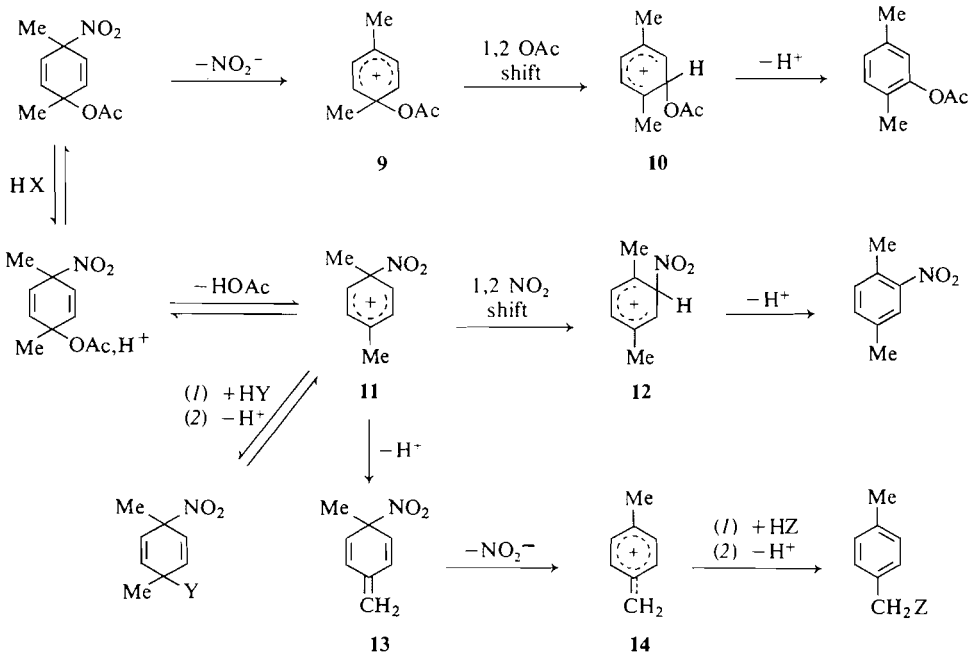
butyl group, is also very hindered. 5-*tert*-Butyl-2-methylbenzaldehyde (**5**), a side-chain substitution product, and the aryl acetate **3***b* are rearomatization products of adduct **6**. Their formation is discussed further below but here it might be noted that if account is taken of the fact that these are formed from **6** then the extent of *ipso* attack is more complete than it first appears. The hydroxynitrodiene **7** is probably not formed directly but is, rather, a solvolysis product from the acetoxynitrodiene **6** or, perhaps, a nitritonitrodiene (12). Support for this suggestion is provided by the observation that when aqueous acetic acid was added to a nitration mixture after the nitration had been carried out at −40°C, and the resulting solution stirred at 0°C before work-up, the acetoxynitrodiene **6** was not obtained but good yields of aryl acetate **3***b* and hydroxynitrodiene **7** were formed. The formation of hydroxynitrodienes has been noted in the nitration of durene (12) *p*-cymene (13) and *p*-xylene (14). When the *p*-xylene nitration mixture is worked up under completely anhydrous conditions, no hydroxynitrodiene is obtained.[6]

Although in each case only one of the pair of diastereoisomers of **6** and **7** was isolated it is likely that the other diastereomer of each pair was also formed. From the nmr spectra of some of the column fractions it was evident that small amounts of other dienes, with absorptions in positions appropriate for the diastereoisomers, were present. Both diastereoisomers of the 1,4 nitronium acetate adduct of *p*-*tert*-butyltoluene were formed but one was obtained in much smaller amount than the other (2). It is likely that the acetate and alcohol diastereomers isolated have the nitro and acetoxy or hydroxy groups *trans*. For **6** the gradient of the chemical shift of the 4-Me group on the addition of Eu([$^2H_9$]fod)$_3$ is larger than that for the 3-Me group and is similar to that for the 5-H. This implies that the protons in each of these groups are of comparable distances from the europium, complexed at the acetate. This would seem possible in the *trans* isomer (with 4-Me *cis* to acetate and europium) but unlikely in the *cis* isomer with 4-Me on the other side of the ring to the europium.

Rearomatization Reactions

Adduct **6** is a tertiary acetate. Under conditions of low acidity tertiary acetate adducts undergo loss of nitrous acid accompanied by 1,2 shift of the acetate group to a neighbouring position, to form an aryl acetate (7*b*, 14). Myhre and co-workers (15*a*) have presented convincing evidence that the elimination of nitrous acid from the secondary acetate, 3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate (the adduct of 1,2,3-trimethylbenzene), to form the unrearranged aryl acetate, is a two-step (E1 type) process, involving initial loss of the nitro group as nitrite anion to form a cyclohexadienyl cation, which loses the proton in a subsequent step to form the aryl acetate. A similar mechanism involving initial formation of the acetoxycyclohexadienyl cation **9** (a *tert*-acetate) by ionization of the nitro group, followed by shift of the acetate group to form the secondary acetate, cation **10**, which is rapidly deprotonated, is likely to apply to tertiary acetate adducts (15*b*) and is depicted in the upper part of Scheme 1 (a one-step, concerted, process was proposed earlier for the elimination to aryl acetate (14)). At higher acidities the *ipso*-nitrocyclohexadienyl cation **11** is formed by protonation of the acetate group and loss of acetic acid. If the solvent is of low nucleophilicity the lifetime of the cation is sufficiently long for shift of the nitro group to occur to form the (secondary) nitrocyclohexadienyl cation **12** which is rapidly deprotonated to the nitroarene (Scheme 1, middle). If the solvent is more nucleophilic, capture of cation **11** occurs, before rearrangement, to form a new adduct and/or the cation is deprotonated at that methyl group originally *ipso* to the acetate group in the adduct, to form a triene **13**, which is the precursor to benzylic derivatives (12, 14) (Scheme 1, lower). In the earlier paper it was proposed that the conversion of the triene to benzylic derivative(s) is an S_N1' or S_N2' process, the group Z being introduced as a nucleophile. Now that the nitro group has been shown to ionize readily from an adduct (15) the unimolecular pathway, involving formation of the benzyl cation **14**, seems the more probable. Thus the products obtained on rearomatization of tertiary acetate adducts (as typified by the *p*-xylene adduct) depend, in the first instance, upon competition between the ionization of nitro to form the cyclohexadienyl cation **9**, leading to 2,5-dialkylphenyl acetate, and the loss of acetate to form cation **11**, leading to 1,4-dialkyl-2-nitrobenzene and 4-alkylbenzyl compounds. Apparently nitro is a better anionic leaving group than acetate (the 2,5-dimethylphenyl acetate obtained from the *p*-xylene adduct had only exchanged with [$^2H_4$] acetic acid solvent to a small extent (14)). Thus neutral, strongly ionizing, conditions favour ionization of the nitro group and the formation of the aryl acetate product, whereas strongly acidic conditions enhance the *catalysed* loss of acetate as acetic acid, allowing this pathway to supersede the noncatalysed loss of the nitro group, and thus these conditions favour the formation of nitroarene and benzyl products. The balance between nitroarene and benzyl compound(s) is determined by the basicity of the solvent, which controls the outcome of the secondary competition between **11** → **12** and **11** → **13**. The

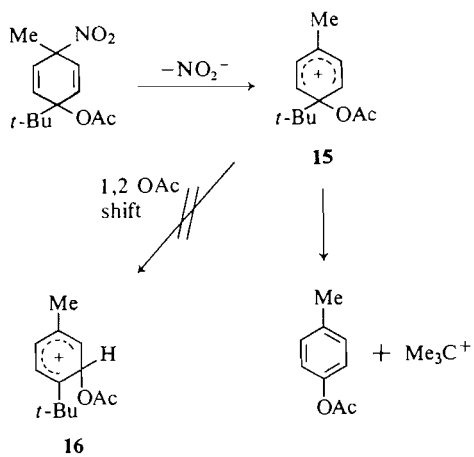
[6]Unpublished work with R. J. Thompson.



SCHEME 1

exchange of acetate for another nucleophile and thus the interconversion of dienes, which also involves cation **11** as an intermediate, should be most favoured by a nucleophilic solvent made sufficiently acid such that the formation of **11** just supersedes formation of **9**. At higher levels of acidity, or on prolonged reaction times, reversion of the exchanged diene to **11** gives further opportunity for the competing irreversible rearomatization to nitroarene and benzyl compounds to occur.

In the case of the 1,4-nitroacetoxy adduct of *p-tert*-butyltoluene the above scenario is modified (2). Under weakly acidic ionizing conditions the predominant rearomatization product is *p*-tolyl acetate, formed by elimination of the nitro and *tert*-butyl groups. The likely mechanism of this reaction is shown in Scheme 2, a parallel of that proposed by Myhre for the formation of aryl acetate from secondary acetate adducts. Only the *tert*-butyl cation is sufficiently stable to be eliminated in this way, in contrast to other alkyl groups. The cleavage of the *tert*-butyl cation in **15** is faster than the 1,2 acetate shift, which would convert **15** into **16** and ultimately 2-*tert*-butyl-5-methylphenyl acetate, since none of this expected product was formed under any of the conditions investigated. 5-*tert*-Butyl-2-methylphenyl acetate was obtained under all (acidic) conditions investigated and was the major product when acetic acid made more acidic by the addition of 1% trifluoroacetic acid was used. The 1,2 adduct **1***a* has been suggested to be an intermediate in this reaction (2). Support for this suggestion is provided by the observation that, when the reaction is carried out at a higher concentration of trifluoroacetic acid but at lower temperature, the 1,2 adduct is obtained with little rearomatization.[7] Thus the sequence involving acid-catalysed loss of acetate from the 4 position, (formation of **17**) its recombination at the 2 position (formation of **1***a*), followed by ionization of the



SCHEME 2

nitro group in **1***a* to form cation **18** (Y = OAc), which is deprotonated, is predicated (Scheme 3). Formation of 4-*tert*-butyl-2-nitrotoluene also occur-

[7]Unpublished work with L. M. Iyer.

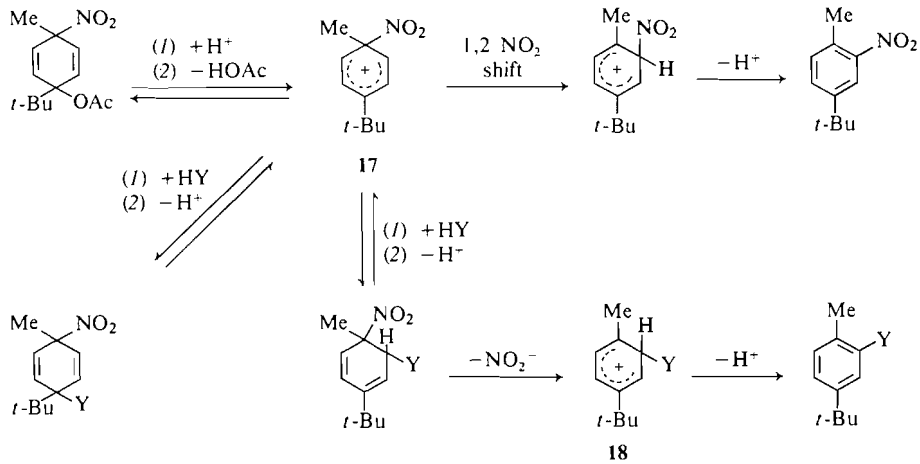
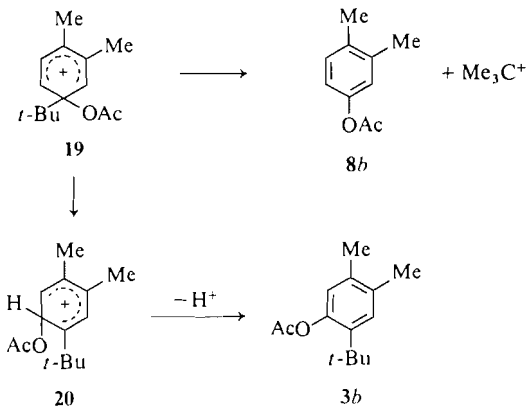


SCHEME 3

red and it was the dominant product under strongly acidic conditions, as expected. Thus, as in the case of the *p*-xylene adduct, the rearomatization products are determined by a primary competition between ionization of nitro and acid-catalysed loss of acetate, but these products are *p*-tolyl acetate, on the one hand, and the nitroarene plus 5-*tert*-butyl-2-methylphenyl acetate on the other. The secondary competition which determines the ratio of the last two products is controlled by the acidity and nucleophilicity of the solvent; strongly acidic conditions and weakly nucleophilic solvents favouring the formation of the nitroarene. No benzyl derivatives are formed since the quaternary centre prevents the formation of the triene analog of **13** from cation **17**.

The reactions of adduct **6** can be interpreted in terms of the pathways shown in Schemes 1–3. Under the most favourable conditions investigated for ionization of the nitro group and formation of cation **19**, reaction in aqueous acetic acid, 87% of the product (70% **3***b*, 17% **8***b*) can be accounted for as being derived via this intermediate (Scheme 4) and a further 3% were the corresponding phenols presumably formed via the analog of **19** containing OH in place of OAc. This cation is the product of ionization of nitro from **7**, itself obtained from **6** by prior exchange with solvent water via **21**. Unlike the case of *p*-*tert*-butyltoluene the 1,2 shift of the acetate is not superseded by the cleavage of the *tert*-butyl group, indeed the acetate shift is predominant. This is understandable in terms of the greater stability of **20** than **16** and of corresponding relationship between the transition states leading to these ions. Compared with **16** cation **20** has an electron-donating methyl substituent located at one of the three centres of positive charge.[8] It is interesting that although the rearomatization reactions of cation **19** dominate those of **21** the latter ion is formed more rapidly. Both the **3***b* and the **8***b* formed contained [$^2H_3$]acetate and it follows that formation of **21** and its recombination with [$^2H_4$]acetic acid must have preceded the formation of **19** and from it the labelled **3***b* and **8***b*. The other reactions of **21** (Scheme 5) must be slower than these reactions of **19**. In these weakly acidic ionizing conditions not more than a few percent of the products were derived by rearomatization of **21**.

When the reaction was repeated in less ionizing conditions, acetic acid made anhydrous by addition



SCHEME 4

[8]Acetate **3***b* obtained in the nitration of **2** is clearly formed from adduct **6**, since, as noted above, when aqueous acetic acid was added to the reaction mixture before work-up (conditions known to favour formation of aryl acetate (14)) the yield of **3***b* was enhanced at the expense of **6**. (As discussed earlier **7** was also formed during work-up).

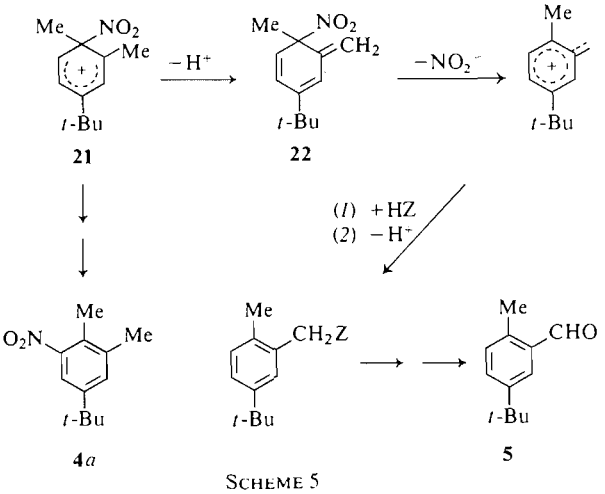

SCHEME 5

of acetic anhydride, the products formed via **19** were reduced (46% **3***b*, 5% **8***c*) and the products formed via **21** were enhanced (10% **4***a*, 6% **5**). The nitroarene **4***a* would be expected to be formed by the normal 1,2 nitro shift and deprotonation. The sequence shown in Scheme 5 (Z = ONO_2 (16) or ONO (17)) is the likely pathway to the aldehyde **5**. Normally the methyl group substituted in forming benzyl derivatives is that *para* to the position of *ipso* attach by the nitronium ion. In the absence of this possibility in **21** the unusual deprotonation at the 2-methyl group occurs to form **22** and eventually **5**. The benzaldehyde **5** was also obtained from the nitration of **2** (see above), presumably through the same sequence of intermediates. As in aqueous acetic acid, exchange of acetate in **6** for acetate from the solvent was noted.

When rearomatization was carried out in acetic acid containing acetic anhydride and made successively more acidic by the addition of sulfuric acid the yield of products from **19** steadily decreased and those from **21** increased, reaching 78% in 50% sulfuric acid. Furthermore, in the competition between benzaldehyde, **5** and nitroarene **4***a* the aldehyde was favoured when the sulfuric acid constituted only a small portion of the solvent and thus the acetic acid was effective in deprotonating **21** to **22**. In the very acidic solutions in which the solvent would be much less available for deprotonation the nitroarene **4***a* became the dominant product. All of this is in accord with the foregoing discussion. The absence of other than a trivial amount of acetate **4***b* in the rearomatization of **6** (contrast the *p-tert*-butyltoluene adduct) correlates with the greater difficulty of forming the 1,2 adduct **1***b* or **1***c* as compared with **1***a* of the *p-tert*-butyltoluene case. Furthermore, the 1,2 adduct, once formed, may be relatively less reactive than in the *p-tert*-butyltoluene case. The additional methyl group in **21** is suitably located for maximum stabilization of the cation, in contrast to the situation in the cations generated by ionization of nitro from **1***b* or **1***c*. This difference should be reflected in the relative stabilities and ease of formation of the transition states leading to these ions. In the more dilute sulfuric acid solutions the initial formation of adducts isomeric with **6** could be followed. These reactions provide further evidence of the rapid formation of cation **21**.

When rearomatization reactions were carried out using trifluoroacetic acid or boron trifluoride etherate as reagents, nitroarene **4***a* was formed effectively instantly and in over 90% yield at −70°C. Under these strongly acidic conditions **21** is formed very rapidly. The solvent species are too weakly basic to be effective in the deprotonation of **21** to triene **22** thus formation of benzylic derivatives cannot compete with the 1,2 nitro shift leading to **4***a*.

Reaction of diene **6** in ether with hydrogen chloride gave a mixture which appeared to contain a chloronitro diene, i.e. exchange of chloride for acetate had occurred. However, after work-up and chromatography only a mixture of the chloroarenes **3***d* and **4***d* was obtained. Formation of **4***d* could conceivably involve an intermediate 1,2 nitrochloro adduct which subsequently eliminates nitrous acid. Formation of **3***d* could involve formation of a 1,4 nitrochloro adduct which undergoes 1,2 shift of the chloride and elimination of nitrous acid.

Reaction of the diene acetate **6** with sodium methoxide in methanol gave the phenol **3***c* as the major product and lesser amounts of 3,4-dimethylphenol (**8***c*) the phenol **4***c*, the aryl acetate **3***b*, a nitroarene and small amounts of unidentified products. The main reaction is rearomatization of the adduct to aryl acetate **3***b* accompanied by cleavage of the acetate group. The formation of **8***c* parallels the formation of *p*-cresol from the 1,4 nitroacetoxy adduct of *p-tert*-butyltoluene on reaction with sodium methoxide (2).

Thermolysis of the acetate adduct **6** gave the parent hydrocarbon **2** as the major product. Thermolysis of the nitrohydroxy adduct **7** gave similar amounts of parent hydrocarbon **2** and 3,4-dimethylphenol (**8***c*) as well as other products.

Experimental

Infrared spectra were obtained on a Perkin-Elmer 337 spectrophotometer. ^1H nuclear magnetic resonance spectra at 90 MHz were determined using a Perkin-Elmer R32 spectrometer. ^{13}C nuclear magnetic resonance spectra were measured on solutions in deuteriochloroform with tetramethylsilane reference, using a Nicolet TT-14 spectrometer, operating in the

Fourier transform (FT) mode at 15.1 MHz, under optimized conditions of complete noise decoupling. Mass spectra were obtained on an Hitachi Perkin-Elmer RMU-7 spectrometer and, for glc mass studies, on a Finnigan 3300 system. Microanalyses were by Dr. D. McGillivray. Gas–liquid chromatography analyses were performed on a Varian Aerograph 2400 gas chromatograph using stationary phases SE 30 (3%) and DEGS (10%) on acid-washed Chromosorb W. Nitric acid, ether and pentane were purified as previously described (6). Alumina was deactivated with 3% of 10% acetic acid. *o*-Xylene (Eastman), *tert*-butyl alcohol (Mallinckrodt), and [$^2H_4$]acetic acid (99.5%, Aldrich) were commercial products.

4-tert-*Butyl-1,2-dimethylbenzene (2)*

A mixture of *tert*-butylalcohol (2.0 mol) and *o*-xylene (0.50 mol) was added dropwise with stirring, over 0.5 h, to a mixture of *o*-xylene (2.0 mol) and pulverized anhydrous aluminium chloride (1.0 mol) at −8°C (18). The reaction mixture was heated to ca. 65°C and maintained at that temperature for 1.5 h. The dark red solution was cooled to 0°C and decomposed with 6 *M* HCl (400 cm^3) and extracted with pentane (4 × 100 cm^3). The pentane extracts were combined and washed with brine (300 cm^3), saturated sodium bicarbonate (200 cm^3), and brine (3 × 150 cm^2) and dried over anhydrous magnesium sulfate. Rotatory evaporation under reduced pressure afforded 357 g of crude product which contained 78% of 4-*tert*-butyl-1,2-dimethylbenzene (**2**) by glc, an 86% yield. Pure (> 99.9%) **2** was obtained by distillation at 45°C/65 Pa using a spinning band column and had ir (CCl_4): 1500, 1450, 1275, 1145, 1020, 994, 815 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.26 (s, 9H, $C(CH_3)_3$), 2.18 (s, 3H, 1-CH_3), 2.21 (s, 3H, 2-CH_3), 6.93–7.14 ppm (m, 3H, ArH_3); ^{13}C nmr listed in Table 2; mass spectrum (70 eV) *m/e* (relative intensity): 162.150 (42, M_r ($^{12}C_{12}{}^1H_{18}$) 162.141), 148 (21), 147 (100, $M-CH_3$), 119 (25), 107 (17).

Nitration of 4-tert-*Butyl-1,2-dimethylbenzene (2) in Acetic Anhydride*

A solution of freshly distilled nitric acid (12.6 g, 0.20 mol) in acetic anhydride (35 cm^3) was added to **2** (16.2 g, 0.10 mol) in acetic anhydride (40 cm^3) at −65°C over a period of 5 min. The reaction mixture was stirred for 20 min at −60°C and then allowed to warm to ca. −40°C and maintained at that temperature for 30 min. The mixture was cooled to −78°C and cold dry ether (200 cm^3) was stirred in slowly. Ammonia was condensed into the solution (ca. 1 drop/5 s) with constant stirring. The temperature during neutralization was held below −50°C. Aqueous ammonia (150 cm^3) was added to the mixture to dissolve the ammonium salts and acetamide, and the aqueous phase was extracted with ether (2 × 100 cm^3). The combined ethereal solution was washed with 10% brine (4 × 100 cm^3) and dried over anhydrous magnesium sulfate. Removal of the ether solvent under reduced pressure (below 20°C) yielded an oily yellow crystalline solid. The ^1H nmr spectrum indicated that the crude product contained ca. 68% of diene(s).

Chromatography of the crude product on 3% deactivated alumina at −45°C and elution first with pentane and then with ether–pentane gave unreacted **2** (2.1 g, 13 mmol) in the first 5% ether fraction. The second 5% ether fraction (2.1 g) was rechromatographed and the various constituents were isolated or enriched in different sub-fractions as follows. Mixtures of 4-*tert*-butyl-1,2-dimethyl-5-nitro- and -6-nitrobenzene (**3***a* and **4***a*) in the ratio of ca. 75:25 (1.76 g, 8.5 mmol) and 50:50 (0.65 g, 3.1 mmol) were obtained from the pentane and 0.4% ether fractions, respectively. 4-*tert*-Butyl-1,2-dimethyl-5-nitrobenzene (**3***a*) from the pentane fraction had ir (liquid film): 1520, 1360 (NO_2), 1282, 875, 809 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.35 (s, 9H, $C(CH_3)_3$), 2.18 (s, 3H, 1-CH_3), 2.24 (s, 3H, 2-CH_3), 7.04 (s, 1H, 3-*H*), 7.25 ppm (s, 1H, 6-*H*); mass spectrum (70 eV) *m/e* (relative intensity): 207.136 (7, M_r ($^{12}C_{12}{}^1H_{17}{}^{14}N^{16}O_2$) 207.126), 192 (14, $M-CH_3$), 162 (20), 161 (100). The 0.8% ether fraction, after rechromatography for a second time yielded 5-*tert*-butyl-2-methylbenzaldehyde (5, 0.11 g, 0.6 mmol) as a yellow oil, ir (liquid film): 1680 (CHO), 1215, 1195, 1140, 825 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.34 (s, 9H, $C(CH_3)_3$), 2.62 (s, 3H, 2-CH_3), 7.17 (d, 1H, J = 7.8 Hz, 3-*H*), 7.49 (d-d, 1H, J = 2.3 and 7.8 Hz, 4-*H*), 7.81 ppm (d, 1H, J = 2.3 Hz, 6-*H*); mass spectrum (70 eV) *m/e* (relative intensity): 176.124 (51, M_r ($^{12}C_{12}{}^1H_{16}{}^{16}O$) 176.120), 162 (19), 161 (100, $M-CH_3$), 133 (22), 105 (24).

In the first 10% ether fraction a mixture of 2-*tert*-butyl-4,5-dimethylphenyl acetate **3***b* and one diastereoisomer of 1-*tert*-butyl-3,4-dimethyl-4-nitro-1,4-dihydrophenyl acetate (**6**) with a little nitroarene was obtained (1.85 g). The second 10% and the 15% ether fractions gave essentially pure diene acetate **6** 11.0 g, 41.2 mmol). Recrystallization (×3) from a mixture of pentane – methylene chloride gave pure **6** (6.2 g) as white prismatic crystals, mp 73.0–73.5°C; uv (CH_3OH): 225 nm (ε 150 m^2 mol^{-1});[9] ir (CCl_4): 1740 and 1250 ($OCOCH_3$), 1540 and 1365 cm^{-1} (NO_2); ^1H nmr ($CDCl_3$) δ: 0.99 (s, 9H, $C(CH_3)_3$), 1.78 (s, 3H, 4-CH_3), 1.85 (d, 3H, 3-CH_3), 1.95 (s, 3H, $OCOCH_3$), 5.79 (m, 1H, 2-*H*), 5.99 (d, 1H, 6-*H*), 6.00 ppm (s, 1H, 5-*H*), $J_{2,3\text{-}CH_3}$ = 1.5, $J_{2,6}$ = 1.3 Hz; addition of Eu([$^2H_9$]fod)$_3$ moved the 6-H to lower field than the 5-H and revealed the 10 Hz coupling between the 5-H (d) and 6-H (d of d); ^{13}C nmr ($CDCl_3$) δ_C: (TMS) 18.4 (3-CH_3), 21.7 ($OCOCH_3$), 22.3 (4-CH_3), 25.2 ($C(CH_3)_3$), 39.1 ($C(CH_3)_3$), 80.5 (*C*-1), 88.7 (*C*-4), 127.7 (*C*-6), 129.7 (*C*-2 or *C*-5), 130.1 (*C*-5 or *C*-2), 133.9 (*C*-3), 169.4 ppm ($OCOCH_3$). *Anal.* calcd. for $C_{14}H_{21}NO_4$: C 62.90, H 7.92, N 5.24; found: C 63.29, H 7.81, N, 5.15.

[9]The limit of measurement under the conditions used was 225 nm, where only end absorption was observed.

Rotatory evaporation of the combined mother liquors from recrystallization of **6**, under reduced pressure, at 15°C, yielded a dark brown oil (2.1 g). ^{1}H and ^{13}C nmr spectra of the oil established[10] that a significant component was the 1,2-diene acetate **1***b*, which was relatively unstable since it decomposed with evolution of nitrogen dioxide when the decoupled and off-resonance ^{13}C nmr spectra were taken over a period of 1 and 1.5 h, respectively, at a probe temperature of +37°C.

The 50–80% ether fractions gave one diastereoisomer of 3,4-dimethyl-1-*tert*-butyl-4-nitro-1,4-dihydrophenol (**7**, 2.97 g, 13.2 mmol). After recrystallization (×3) from pentane-methylene chloride pure **7** (1.0 g) was obtained as white prismatic crystals, mp 81–82°C; uv (CH_3OH): 225 nm (ε 120 m^2 mol^{-1}); ir: (CCl_4) 3620 (OH), 1530, 1320 (NO_2), 1217, 1127, 1053, 990, 970, 963, 650 cm^{-1}; nmr ($CDCl_3$) δ : 0.97 (s, 9H, C-(CH_3)$_3$), 1.72 (s, 1H, 1-O*H*), 1.76 (s, 3H, 4-CH_3), 1.87 (d, 3H, 3-CH_3), 5.92 (d, 1H, 5-*H*), 5.98 (m, 1H, 2-*H*), 6.17 (d-d, 1H, 6-*H*), $J_{2,3\text{-}CH_3}$ = 1.2, $J_{2,6}$ = 2.1, $J_{5,6}$ = 10.2 Hz; addition of Eu([$^2H_9$]fod)$_3$ moved the 2-H downfield from its overlapping position with 5-H and clearly revealed the 10 Hz coupling in the 5-H; ^{13}C nmr ($CDCl_3$) δ_C (TMS): 18.8 (3-CH_3), 24.9 (4-CH_3), 25.4 (C(CH_3)$_3$), 38.4 (*C*(CH_3)$_3$), 72.7 (*C*-1), 87.1 (*C*-4), 128.4 (*C*-5), 132.2 (*C*-3), 132.5 (*C*-6), 134.6 ppm (*C*-2). *Anal.* calcd. for $C_{12}H_{19}NO_2$: C 63.98, H 8.50, N 6.22; found: C 63.89, H 8.57, N 6.08.

Nitration of **2** *in Trifluoroacetic Acid: 4-*tert*-Butyl-1,2-dimethyl-6-nitrobenzene (**4***a*)*

A solution of nitric acid (5.0 g, 80 mmol) in a mixture of trifluoroacetic anhydride (4 cm^3) and trifluoroacetic acid (36 cm^3) was added to a solution of **2** (8.1 g, 50 mmol) at −78°C. The mixture was allowed to warm to 5°C and maintained at that temperature for 10 min. The solution was then cooled and worked up to give a product consisting of 50% nitroarene and 50% **2** (by nmr). Chromatography on alumina and elution with pentane gave 4-*tert*-butyl-1,2-dimethyl-6-nitrobenzene (**4***a*), ir (film): 1525, 1360 (NO_2), 880; ^{1}H nmr ($CDCl_3$) δ: 1.31 (s, 9H, C(CH_3)$_3$), 2.31 (s, 3H, 2-CH_3), 2.35 (s, 3H, 1-CH_3), 7.38 (d, 1H, J = 1.9 Hz, 3-*H*), 7.59 ppm (d, 1H, J = 1.9 Hz, 5-*H*); mass spectrum (70 eV) *m/e* (relative intensity): 207.137 (67, M_r ($^{12}C_{12}{}^1H_{17}{}^{14}N^{16}O_2$) 207.126), 193 (35), 192 (100, $M-CH_3$), 190 (70, $M-OH$), 14 (37, $M-CH_3NO_2$), 131 (30, $M-C_2H_6NO_2$), 91 (29).

Nitration of **2** *in Acetic Anhydride with Hydrolytic Work-up: 2-*tert*-Butyl-4,5-dimethylphenol (**3***c*) and 5-*tert*-Butyl-2,3-dimethylphenol (**4***c*)*

The hydrocarbon **2** (8.1 g, 50 mmol) was nitrated by preparing a solution of it with nitric acid (4.7 g, 75 mmol) in acetic anhydride (15 cm^3) at −60°C and then allowing the temperature of the mixture to rise to −40°C. Aqueous (10%) acetic acid (20 cm^3) was added, the temperature allowed to rise to 0°C and stirring continued at that temperature for 10 min. After work-up ^{1}H nmr indicated that the composition of the product was hydrocarbon **2** (20%), acetate **3***b* (30%), diene **7** (20%), nitroarene **4***a* (5%), and unidentified compounds (25%). Chromatography on alumina and elution with pentane and ether–pentane mixtures gave in the 20% ether fraction 2-*tert*-butyl-4,5-dimethylphenyl acetate (**3***b*), ir (CCl_4): 1750 and 1215 (C=O), 1440, 1370, 1355, 875, 860 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.31 (s, 9H, C(CH_3)$_3$), 2.16 (s, 3H, CH_3), 2.18 (s, 3H, CH_3), 2.24 (s, 3H, OCOCH_3), 6.72 (s, 1H, 6-*H*), 7.08 ppm (s, 1H, 3-*H*); mass spectrum (70 eV) *m/e* (relative intensity): 220.146 (28, M_r ($^{12}C_{14}{}^1H_{20}{}^{16}O_2$) 220.146), 178 (77), 164 (29), 163 (100, $M-C_4H_9$), 135 (18). The 50–70% ether fractions gave 2-*tert*-butyl-4,5-dimethylphenol (**3***c*), ir (CCl_4): 3620 (s), 3530 (m), ~3250–3450 (broad) (OH); 1185 (s, C—O), 880 (m), 840 (m) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.37 (s, 9H, C(CH_3)$_3$), 2.12 (s, 3H, CH_3), 2.14 (s, 3H, CH_3), 4.65 (broad, 1H, O*H*), 6.41 (s, 1H, 6-*H*), 6.98 ppm (s, 1H, 3-*H*); mass spectrum (70 eV) *m/e* (relative intensity): 178 (32, M), 163 (100, $M-CH_3$), 135 (28, $M-C_3H_7$). The 85–100% ether fractions gave 5-*tert*-butyl-2,3-dimethylphenol (**4***c*), ir (CCl_4): 3625, 3600–3200 (broad) (OH), 1610, 1570, 1440, 1390, 1340, 1280, 1180 (C—O), 1075, 1045, 939, 880, 840 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.25 (s, 9H, C(CH_3)$_3$), 2.10 (s, 3H, 2-CH_3), 2.22 (s, 3H, 3-CH_3), ~4.6 (s, 1H, O*H*), 6.63 (b, 1H, J ~ 1.5 Hz, 6-*H*), 6.77 ppm (b, 1H, J ~ 1.5 Hz, 4-*H*); mass spectrum (70 eV) *m/e* (relative intensity): 178 (36, M), 164 (16), 163 (100, $M-CH_3$), 135 (23, $M-C_3H_7$), 123 (12).

Aluminium Hydride Reduction of Diene **6**

Diene **6** (140 mg, 0.53 mmol) in dry tetrahydrofuran (THF) was added to a solution of excess AlH_3 (2.75 mmol in 15 cm^3 THF) and stirred at 0°C for 10 min. The nmr and ir spectra of the oily solid obtained on work-up showed that the product was the hydroxy diene **7** (ir (CCl_4): 3620 (OH), 1530, 1320 (NO_2); nmr ($CDCl_3$) δ: 0.97, 1.76, 1.87, 5.92, 5.98, 6.17 ppm).

Reaction of Diene **6** *with Moist* [$^2H_4$]*Acetic Acid*

A solution of the diene **6** (50 mg, 0.19 mmol) in a mixture of H_2O (10 mm)[3] and CD_3COOD (500 mm^3) was prepared at 0°C and the reaction was observed by nmr at 35°C. No obvious reaction took place over a period of 40 min. A vigorous reaction took place with the evolution of brown fumes of nitrogen dioxide, when the temperature was raised to 100°C. After work-up, nmr and glc – mass spectrometry established the major product to be the deuterated acetate **3***b* (70%, M^+ 223), with lesser amounts of the deuterated acetate **8***b* (17%, M^+ 167), the phenol **8***c* (2%, M^+ 122), an isomer of **3***b* (2%, M^+ 223), a nitroarene (2%, M^+ 207), an isomer of **8***b* (6%, M^+ 167) and a phenol, probably **3***c* (1%, M^+ 178).

Reaction of Diene **6** *with Sulfuric Acid in Acetic Anhydride – [$^2H_4$]Acetic Acid*

A solution of diene **6** (107 mg, 0.4 mmol) in $CDCl_3$ (150 mm^3) was treated in successive experiments with a solution of 0, 0.05, 0.5, 5, and 50% H_2SO_4 (by weight) in 10% Ac_2O–CD_3CO_2D (250 mm^3). The reactions were followed by nmr as the temperature was raised from 0°C to ambient (23°C). After work-up, the product distributions, shown in Table 3, were determined by nmr and glc – mass spectrometry.

Rearomatization was slow ($t_{\frac{1}{2}}$ ~ 56 h) in the case of the reaction carried out in the absence of sulfuric acid. The diene acetate group was exchanged with the deuterated solvent and this was essentially complete (90%) after 47 h. Under sulfuric acid catalysis the diene acetate also exchanged the acetate group with the solvent prior to rearomatization and the rapid formation of isomeric adducts could be observed when the sulfuric acid concentration was 0.05% and 0.5%.

[10]The ^{1}H nmr spectra exhibited a *tert*-butyl peak at 1.12 ppm and vinylic-allylic absorptions at 5.9 ppm as well as the peaks characteristic of **6**. The *tert*-butyl peak in **6** is at 0.99 ppm and the lower-field *tert*-butyl peak is characteristic of a *tert*-butyl group attached to a double bond (2). The ^{13}C spectra exhibited peaks, in addition to those of **6**, at 29.8 (CH_3 of *tert*-butyl), 35.0 (4°-*C* of *tert*-butyl), 65.2 and 65.1 (3°-*C* of ring), and 87.8 and 89.6 ppm (4°-*C* of ring). The peaks for the tertiary and quaternary carbons were assigned with the aid of undecoupled spectra. The *tert*-butyl absorptions are closely similar to those of the 1,2 adduct of 4-*tert*-butyltoluene (2) and significantly shifted from the absorptions of the 1,4 adduct. The 3°-*C* absorption can only be attributed to a 1,2 adduct. The doubling of the ring carbon peaks indicates that a *pair* of diastereoisomeric 1,2 adducts was formed.

TABLE 3. Yields[a] of products of rearomatization of diene **6** with sulfuric acid and 10% acetic anhydride in [$^2H_4$]acetic acid

% H_2SO_4	**3***b*	**4***a*	**5**	**8***c*	Others
0	46	10	6	5	12,[b] 8,[c] 13[c]
0.05	43	17	21	3	17[b]
0.5	37	29	22	3	6,[b] 3[c]
5.0	26	57	15	3	
50		66	12	5	17[d]

[a]From glc – mass spectral data, peaks appeared in the order with observed M^+: **8***c* (122), **5** (176), **3***b* (223, [$^2H_3$]acetate), nitroarene (207), **4***a* (207).
[b]Nitroarene, probably benzylic derivative or **3***a*.
[c]Unidentified compound.
[d]A nitroarene (M^+ 207), probably **3***a* or benzylic derivative.

*Reaction of Diene **6** with Trifluoroacetic Acid*

Diene **6** (107 mg, 0.40 mmol) in $CDCl_3$ (200 mm^3) was cooled to −60°C and mixed with CF_3COOH (200 mm^3). The nmr spectrum showed that the reaction was complete on mixing. After work-up,[11] nmr and glc – mass spectral analyses established the major product as **4***a* (92%). Two minor products (4% each) appeared to be isomeric nitroarenes (M^+ 207), one of them the benzylic derivative (^{1}H nmr ($CDCl_3$) δ: 5.25 ppm).

*Reaction of Diene **6** with Boron Trifluoride*

Diene **6** (107 mg, 0.40 mmol) was dissolved in $CDCl_3$ (200 mm^3), cooled to −70°C and $BF_3 \cdot Et_2O$ (200 mm^3) was added. Observation by nmr indicated that the reaction was complete at −70°C. After work-up and examination by ^{1}H nmr and glc – mass spectrometry, the products were identified as **4***a*, (97%) and an isomeric nitroarene (3%, M^+ 207).

*Reaction of Diene **6** with Hydrogen Chloride*

A solution of diene **6** (500 mg, 1.87 mmol) in dry ether (25 cm^3) was cooled to −5°C and hydrogen chloride was bubbled through the solution for ca. 20 min. The ^{1}H nmr spectrum after work-up indicated that chloronitrodiene adducts had been formed. Chromatography on alumina yielded a pale greenish liquid. Nuclear magnetic resonance and glc – mass spectrometry showed the products after chromatography to be 4-*tert*-butyl-5-chloro-1,2-dimethylbenzene (**3***d*), (76%) and 4-*tert*-butyl-6-chloro-1,2-dimethylbenzene (**4***d*), (24%). The chloronitrodiene adducts had decomposed.

*Reaction of Diene **6** with Sodium Methoxide in Methanol*

A solution of diene **6** (100 mg, 0.38 mmol) in $CDCl_3$ (200 mm^3) was treated with a solution of CH_3ONa (0.75 mmol) in CH_3OH (250 mm^3) at 0°C. After 10 min the solution turned bright orange and sodium acetate precipitated. The product was acidified and worked up, and the composition was established by nmr and glc – mass spectrometry: **8***c* (15%, M^+ 122), two unidentified compounds (2% each), **4***c* (13%, M^+ 178), **3***c* (56%, M^+ 178), **3***b* (8%, M^+ 220), nitroarene (4%, M^+ 207).

[11]Small-scale reactions were worked up by adding the solution to methylene chloride (5 cm^3) followed by neutralization with gaseous ammonia, aspiration of the excess ammonia, drying over magnesium sulfate, filtration, and removal of the solvent under reduced pressure.

*Thermolysis of Diene **6***

A solution of **6** in pentane was injected into the inlet of a gas chromatograph at 260°C. Thermolysis proceeded smoothly giving rise to five well-resolved peaks. These peaks were identified by comparison of their retention times with those of authentic samples, and by glc – mass spectrometry. The products were in the order of retention time: parent hydrocarbon **2** (68%, M^+ 162), **8***b* (8%, M^+ 164), a nitroarene (1%, M^+ 207), **3***b* (16%, M^+ 220), **4***a* (7%, M^+ 207).

*Thermolysis of Diene **7***

An ethereal solution of **7** was injected into the inlet of a gas chromatograph at 260°C. Thermolysis proceeded smoothly giving rise to seven well-resolved peaks. Five peaks were identified by comparison of their retention times with those of authentic samples and by glc – mass spectrometry. The compounds were in order of retention time: parent hydrocarbon **2** (32%, M^+ 162), **8***c* (30%, M^+ 122), two unidentified compounds (3%, 5%), **4***c* (19%, M^+ 178), **3***c* (5%, M^+ 178), a nitroarene (6%, M^+ 207).

Crystal and molecular structure of bis(perchlorato)(γ-*C*-*meso*-5,5,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane)copper (II)

EI-ICHIRO OCHIAI, STEVEN J. RETTIG, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received August 22, 1977

EI-ICHIRO OCHIAI, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **56**, 267 (1978).

Crystals of bis(perchlorato) (γ-*C*-*meso*-5,5,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane)copper(II) are monoclinic, $a = 14.061(1)$, $b = 8.908(1)$, $c = 19.710(1)$ Å, $\beta = 90.912(5)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to a final R of 0.054 and R_w of 0.069 for 2945 reflections with $I \geq 3\sigma(I)$. The copper(II) ion has tetragonally distorted octahedral coordination geometry. The four nitrogen atoms of the macrocyclic ligand occupy the equatorial sites and two perchlorate oxygen atoms are in the axial positions. Bond lengths (corrected for libration) are: Cu—N, 2.024(4)–2.051(4), Cu—O, 2.657(5) and 2.697(5), Cl—O, 1.420(4)–1.473(6), N—C, 1.463(6)–1.508(6), and C—C, 1.498(8)–1.542(8) Å.

EI-ICHIRO OCHIAI, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **56**, 267 (1978).

Les cristaux du bis(perchlorato) (γ-*C*-*méso*-hexaméthyl-5,5,7,12,14,14 tétraaza-1,4,8,11 tétradécane)cuivre(II) sont monocliniques: $a = 14.061(1)$, $b = 8.908(1)$, $c = 19.710(1)$ Å, $\beta = 90.912(5)°$, $Z = 4$, groupe d'espace $P2_1/c$. On a résolu la structure par des synthèses de Patterson et Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.054 et R_w de 0.069 pour 2945 réflexions avec $I \geq 3\sigma(I)$. L'ion cuivrique-(II) possède un géométrie de coordination octaédrique déformée d'une façon tétraédrique. Les quatre atomes d'azote du ligand macrocyclique occupent des sites équatoriaux et les deux atomes d'oxygène du perchlorate sont en positions axiales. Les longueurs de liaison (corrigées pour les librations) sont: Cu—N, 2.024(4)–2.051(4), Cu—O, 2.657(5) et 2.697(5), Cl—O, 1.420(4)–1.473(6), N—C, 1.463(6)–1.508(6) et C—C, 1.498(8)–1.542(8) Å.

[Traduit par le journal]

Introduction

The metal complexes of synthetic macrocyclic ligands have attracted considerable attention in recent years (1–4). Nickel(II) and cobalt(II) derivatives dominated earlier studies, partly because of their interesting stereochemistries (1, 5).

Cobalt(II or III) (6) and iron(II or III) (7) derivatives of synthetic macrocycles obviously serve as model compounds for such important biologically active molecules as cobalamin (vitamin B_{12}), and iron porphyrins in hemoglobin and peroxidase.

The macrocyclic ligand in the present study, *meso*-5,5,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane(1,4-CTH), is derived from 5,7,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-1(14),4-diene (1,4-CT) (2, 8). The ligand was allowed to react with copper(II) perchlorate, forming the present complex, $[Cu(1,4\text{-}CTH)](ClO_4)_2$.

Earlier studies of related macrocycle copper(II) complexes include work on $[Cu(1,4\text{-}CT)]^{2+}$ and $[Cu(1,7\text{-}CT)]^{2+}$ (9) where 1,7-CT refers to 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-1(14),7-diene. The crystal structures of $[Ni(1,7\text{-}CT)](ClO_4)_2$ (10) and $[Ni(1,4\text{-}CT)](ClO_4)_2$ (11) were determined as early as 1966. The skeletal structure of both 1,4-CTH and 1,7-CTH is represented by cyclam (1,4,8,11-tetraazacyclotetradecane). A number of transition metal complexes incorporating saturated macrocyclic tetraaza ligands have been characterized by X-ray crystallography: $[Ni(cyclam)]Cl_2$ (12),

Experimental

Preparation of Bis(perchlorato) (γ-C-meso-5,5,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane)copper(II)

The complex was prepared by a method similar to the one described by Curtis (22). (5,7,7,12,12,14-Hexamethyl-1,4,8,11-tetraazacyclotetradeca-1(14),4-diene)nickel(II) perchlorate was prepared from acetone and tris(ethylenediamine)nickel(II) perchlorate (2), and was then hydrogenated with platinum oxide catalyst (22). The ligand was isolated by adding sodium cyanide to the nickel complex. The stoichiometric amounts of copper(II) perchlorate and the perchlorate salt of the ligand were mixed, and the solution was slowly evaporated to give needle crystals. *Anal.* calcd. for $Cu(C_{16}H_{36}N_4)(ClO_4)_2$: C 35.14, H 6.63, N 10.24; found: C 35.00, H 6.67, N 10.15.

X-Ray Crystallographic Analysis of Bis(perchlorato) (γ-C-meso-5,5,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane)copper(II)

The crystal chosen for study was mounted with *b* parallel to the goniostat axis and had dimensions of ca. 0.3 × 0.4 × 0.25 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by least squares on 2 sin θ/λ values for 30 reflections measured on a diffractometer with Cu K_α radiation (λ = 1.5418 Å). Crystal data (at 22°C) are:

$C_{16}H_{36}Cl_2CuN_4O_8$ fw = 546.9

Monoclinic, a = 14.061(1), b = 8.908(1), c = 19.710(1) Å, β = 90.912(5)°, V = 2468.5(5) Å^3, Z = 4, ρ_c = 1.472 g cm^{-3}, $F(000)$ = 1148, μ(Cu K_α) = 37.2 cm^{-1}. Absent reflections: $0k0$, $k \neq 2n$ and $h0l$, $1 \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with nickel-filtered Cu K_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed; 10 s background counts were measured at each end of the scan. Data were measured to 2θ = 145°. The intensities of the check reflections, measured every 40 reflections throughout the data collection, decreased slowly and uniformly to values which were 0.84 times the initial values. Lorentz and polarization corrections and batch check reflection scaling were applied, and the structure amplitudes were derived. No absorption correction was made due to irregularity of the crystal surface. Of the 4890 independent reflections measured, 2957 (60%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + B +$

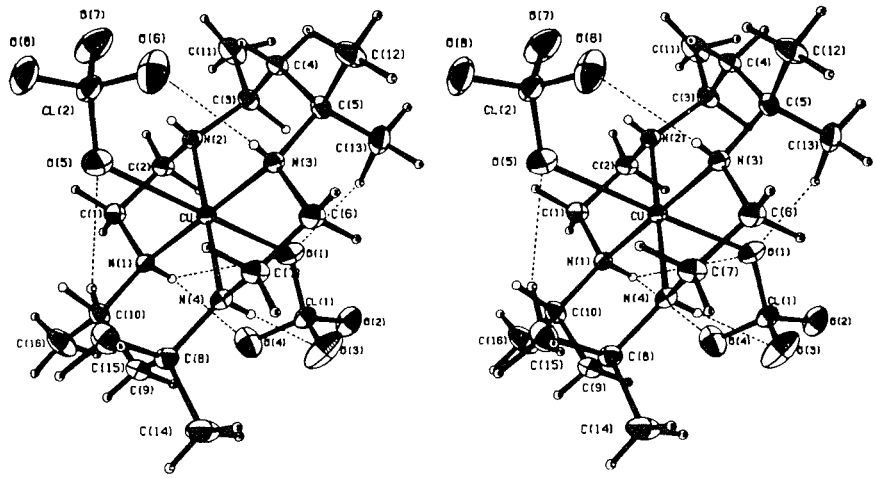

FIG. 1. A stereo view of the bis(perchlorato)(γ-*C*-*meso*-5,5,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane)-copper(II) molecule, 50% ellipsoids are shown for the nonhydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

$(0.06S)^2$ with S = scan count and B = time averaged background count.

The initial stages of the structure determination and refinement were carried out using the 1299 observed reflections with $2\theta \leq 90°$. The positions of the copper and chlorine atoms were determined from the three-dimensional Patterson function. Two cycles of full-matrix least-squares refinement of the Cu and Cl atoms with isotropic thermal parameters gave R = 0.451. An electron density difference map gave positions for the oxygen, nitrogen, and 10 of the 16 carbon atoms. These atoms were refined for two cycles giving R = 0.216 and a difference map revealed the positions of the remaining carbon atoms. The 31 nonhydrogen atoms were refined for one cycle with isotropic thermal parameters, and then for two cycles with anisotropic thermal parameters, resulting in an R value of 0.076. The hydrogen atom positions were taken from a difference map calculated at this point. The entire structure (hydrogen atoms having isotropic thermal parameters and using the complete data set) was refined for three cycles giving a final R of 0.054 and R_w of 0.069 for 2945 reflections with $I \geq 3\sigma(I)$ (12 observed and 2 unobserved reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were treated as unobserved in the final stages of refinement; instrumental error was suspected for these reflections but it seemed unwise to bias the data by remeasuring them; none of the disagreements were exceptionally bad). For all 4890 reflections R = 0.094 and R_w = 0.088.

A correction for secondary extinction was approximated by basing the least-squares refinement on the minimization of $\Sigma w[|F_o| - |F_c|/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was 3.7 $\times 10^{-8}$. The scattering factors of ref. 23 were used for the nonhydrogen atoms and those of ref. 24 for the hydrogen atoms. Anomalous scattering factors from ref. 25 were used for the nonhydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$

where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement the mean parameter shift was 0.38σ and the largest shift (3.2σ) was associated with a hydrogen atom. The mean error in an observation of unit weight was 1.503. The final positional and thermal parameters appear in Tables 1 and 2, respectively; measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the nonhydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (T), libration (**L**), and screw (**S**) motion (26) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0035 Å^2. Analyses of the two perchlorate and [Cu, N(1)–N(4), C(1)–C(10)] groups (rms ΔU_{ij} = 0.0026, 0.0016, and 0.0039 Å^2, respectively) gave physically reasonable rigid-body thermal parameters.

The appropriate bond distances have been corrected for

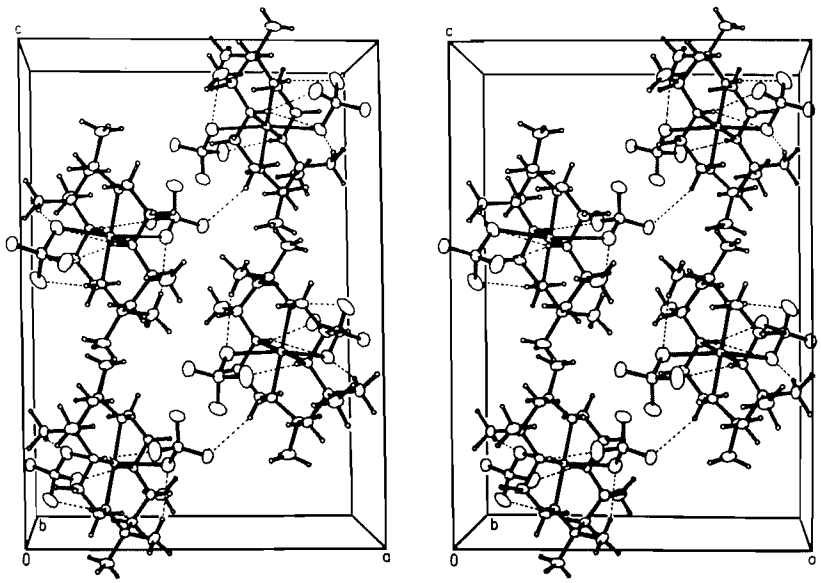

FIG. 2. The crystal structure of bis(perchlorato)(γ-*C*-*meso*-5,5,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane)-copper(II) viewed along *b*.

libration (27, 28), using shape parameters q^2 of 0.08 for all atoms involved. Bonds involving the methyl groups were corrected for independent motion based on the ΔU_{ij} (29, 30). Corrected bond lengths appear in Table 3[1] along with the uncorrected values. Corrected bond angles are not significantly different from the uncorrected value listed in Table 4.[1]

Results and Discussion

A general view of the complex, with the crystallographic numbering scheme, is shown in Fig. 1 and the packing arrangement is shown in Fig. 2. Intraannular torsion angles are given in Table 5 and the geometry of the O···H contacts in Table 6*b*. Deviations of atoms from the CuN_4 mean plane (Table 7) and selected nonbonded distances (Table 6*a*) have been deposited.[1]

The crystal structure consists of discrete molecules of Cu(1,4-CTH)$(ClO_4)_2$ linked by a network of weak C—H···O interactions (there are five intermolecular O···H distances between 2.5 and 2.6 Å, see Table 6*b*).

The copper(II) ion has a typical tetragonally distorted octahedral coordination geometry. The four nitrogen atoms of the macrocyclic ligand occupy the equatorial sites at distances ranging from 2.024(4) to 2.051(4) Å. The axial positions are occupied by perchlorate oxygen atoms at distances of 2.657(5) and 2.697(5) Å. The equatorial CuN_4 group is planar within experimental error ($\chi^2 = 0.76$). Bond angles at the copper atom within the equatorial group differ significantly, those in the five-membered chelate rings being 85.9(2) and 85.5(2)° and those in the six-membered rings being 94.6(2) and 94.0(2)°. The angle between the axial oxygen atoms is 168.2(2)° and angles between equatorial and axial substituents range from 82.0(2) to 98.1(2)°. These values are in good agreement with those found in other complexes which have saturated tetraaza ligands occupying equatorial coordination sites (12–17).

The Cu—O bonds are longer than the value of 2.57(4) Å in the centrosymmetric complex Cu(cyclam)$(ClO_4)_2$ (13), probably as a result of steric interactions with the six methyl groups. The geometry of the weakly coordinated perchlorate groups is similar to that found for a number of octahedral copper(II) complexes (summarized in ref. 13) and the related complex bis(perchlorato)(1,4,8,11-tetrathiacyclotetradecane)copper(II) (31). In addition to weak Cu—O bonds, the perchlorate groups are also linked to the rest of the molecule by a number of weak intramolecular N (and C) —H···O interactions (summarized in Table 6*b*). The Cu—N distances are as expected for this type of complex (13, and summaries in ref. 32).

The complex has approximate C_2 symmetry with the twofold axis passing through the midpoints of the C(1)—C(2) and C(6)—C(7) bonds and the copper atom. The ligand has the energetically favorable γ conformation (18) with both amine hydrogen atoms of one six-membered chelate ring on one side of the molecular plane and both amine hydrogen atoms of the second six-membered ring on the opposite side of the plane. The saturated macrocyclic tetraaza ligands sometimes adopt folded conformations and occupy *cis* coordination sites about an octahedral metal (18, 19, 21, 22) or occupy two equatorial and two axial positions about a trigonal bipyramidal metal (20). The α conformation of the ligand (with adjacent

*Superscripts refer to atoms at positions: [1] $-x, 1-y, 1-z$; [2] $1-x, 1/2+y, 3/2-z$; [3] $1-x, 1-y, 1-z$; [4] $x, 3/2-y, 1/2+z$; [5] $x, y-1, z$; [6] $1-x, y-1/2, 3/2-z$; [7] $-x, 1/2+y, 3/2-z$; [8] $x, 1+y, z$.

amine hydrogen atoms alternately above and below the molecular plane) is particularly prone to folding. Structural examples of all three possible ligand conformations exhibiting planar coordination are given for $[Ni(1,7\text{-CTH})]^{2+}$ (16).

The torsion angles around the 14-membered ring (Table 5) (which are ideally ± 60 or 180° for planar coordination) indicate relatively low ring strain, intermediate between that observed for cyclam and 1,7-CTH complexes (see Table III in ref. 31 for example). The five-membered chelate rings have slightly distorted *gauche* conformations and the six-membered chelate rings have distorted chair conformations (torsion angles are given in Table 5).

Bond lengths and angles in the macrocyclic ligand itself are in good agreement with those in related metal complexes (12–22) and those in $(H_2cyclam)(ClO_4)_2$ (33).

Acknowledgments

We thank the National Research Council of Canada for financial support and the University of British Columbia Computing Centre for assistance. The synthetic work on the title compound was initiated while one of the authors (E.I.O.) was at Ohio State University. He wishes to thank Dr. D. H. Busch for providing him with the opportunity.

Comparison of orbital symmetry allowed and forbidden ring opening of aziridines

A. C. OEHLSCHLAGER, A. S. YIM, AND M. H. AKHTAR
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received May 17, 1977

A. C. OEHLSCHLAGER, A. S. YIM, and M. H. AKHTAR. Can. J. Chem. **56**, 273 (1978).

The rates of reactions of *N*-aryl-*cis*-2,3-diphenyl aziridines (**4***a–d*) with dimethyl acetylenedicarboxylate (DMAD) are dependent only on aziridine concentration suggesting slow conversion of aziridines to azomethine ylides which subsequently react in 1,3-dipolar cycloadditions to yield Δ^3-pyrrolines. The Hammett reaction constant (-0.80) determined for the *N*-substituents in the slow ring opening further suggests direct generation of azomethine ylides from these aziridines. The stereochemistry of the cycloaddition products derived from *cis*-1,2,3-triphenylaziridine with DMAD, maleic anhydride, dimethyl maleate, and dimethyl fumarate is consistent with the conrotatory generation of the ylides followed by their stereospecific *cis-cis* cycloaddition to the dipolarophiles.

Similarly, cycloaddition of 7-aryl-6a,7a-dihydroacenaphtha-[1,2]-aziridines (**5***a–f*) with DMAD yields bicyclic Δ^3-pyrrolines and the rate is dependent only on aziridine concentration. This suggests the reaction proceeds via a slow disrotatory cleavage of the aziridine rings producing azomethine ylides which undergo subsequent addition to DMAD. The Hammett reaction constant for the ring opening step is $+0.74$ suggesting that the transition state for the ring cleavage is electron deficient in the aziridinyl ring but the cycloaddition reactions of **5***a* with isomeric dipolarophiles as well as several dienes and cycloheptatriene reveal only stereospecific 1,2-cycloadditions expected of an azomethine ylide intermediate.

A. C. OEHLSCHLAGER, A. S. YIM et M. H. AKHTAR. Can. J. Chem. **56**, 273 (1978).

Les vitesses de réaction des *N*-aryl diphényl-2,3 aziridines *cis* (**4***a–d*) avec l'acétylènedicarboxylate de diméthyle (DMAD) dépendent uniquement de la concentration des aziridines; ces résultats suggèrent qu'il s'effectue une conversion lente des aziridines en ylures d'azométhine qui réagissent subséquemment par des cycloadditions dipolaires 1,3 pour fournir des Δ^3-pyrrolines. La constante de Hammett de la réaction (-0.80), déterminée pour des substituants sur l'azote dans l'ouverture lente du cycle, suggère de plus, qu'il peut se produire une formation directe d'ylures d'azométhine à partir de ces aziridines. La stéréochimie des produits de cycloaddition, obtenus par réactions de la triphényl-1,2,3 aziridine *cis* avec la DMAD, l'anhydride maléique, le maléate de méthyle et le fumarate de méthyle, est en accord avec une formation conrotatoire des ylures suivie par une cycloaddition *cis-cis* stéréospécifique avec le dipolarophile.

De la même manière, les cycloadditions d'aryl-7 dihydro-6a,7a acénaphta [1,2]aziridines (**5***a–f*) avec de la DMAD conduisent à des Δ^3-pyrrolines bicycliques et les vitesses de réaction dépendent uniquement de la concentration des aziridines. Ces résultats suggèrent que la réaction se produit par l'intermédiaire d'une coupure lente disrotatoire des cycles aziridines pour conduire à des ylures d'azométhine qui réagissent d'une façon subséquente avec la DMAD. La constante de Hammett pour la réaction de l'étape d'ouverture du cycle est de $+0.74$. Cette valeur suggère que l'état de transition pour l'ouverture du cycle est déficient en électron au niveau du cycle aziridinyle; toutefois les réactions de cycloaddition de **5***a* avec des dipolarophiles isomères, de même qu'avec plusieurs diènes et le cycloheptatriène, conduisent uniquement aux cycloadditions-1,2 stéréospécifiques attendues pour des ylures d'azométhine intermédiaires.

[Traduit par le journal]

Introduction

The value and validity of the orbital symmetry rules of Woodward and Hoffmann (1) and others for predicting the stereoselectivity of concerted pericyclic reactions are well established. Most interpretations of pericyclic reactions are in terms of correlations of bonding states or orbitals between reactants and products and do not provide predictions of how electron density changes at the reacting atoms during the course of reaction will influence the progress of reaction.[1]

As the organic chemist endeavors to achieve forbidden reactions of high stereospecificity he will undoubtedly turn not only to alteration of the steric environment but to the electronic environment of the reacting atoms to achieve his desired goals.

Since it is becoming increasingly apparent (3, 4) that the magnitude of the differences in activation energies between analogous allowed and forbidden reactions is not so large as to prevent forbidden concerted processes it is now indeed possible to consider methods for achieving forbidden reactions with low activation energies.

It occurred to us that for the conversion of three-membered heterocycles to their open-chain analogs,

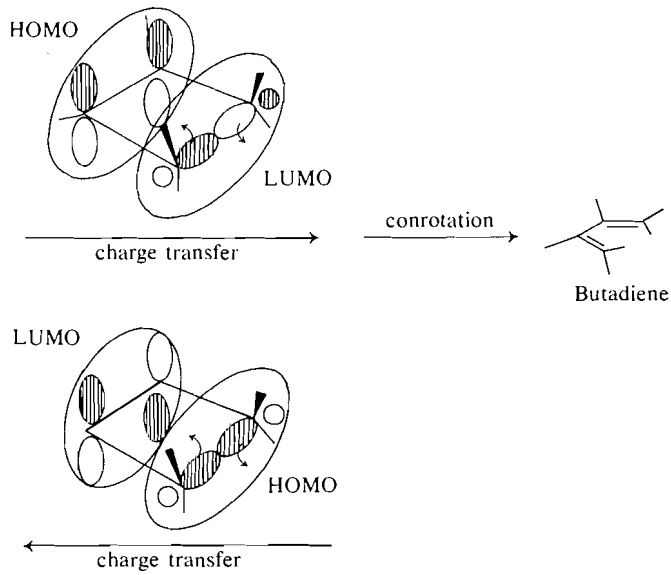

FIG. 1. Modes of the HOMO–LUMO interaction in the ring opening of cyclobutene.

the analysis of Fukui (5*a*) contained intriguing implications with regard to how to approach the design of three-membered heterocycles capable of undergoing forbidden processes. In Fukui's (5*a*) analysis of pericyclic transformations, reaction is considered to be initiated by mutual charge transfer from the highest occupied molecular orbital (HOMO) of one bond undergoing reaction and the lowest unoccupied molecular orbital (LUMO) of another bond participating in the reaction (5). According to Fukui the stereochemical course of such reactions is strongly biased in a direction which achieves maximum overlapping of the HOMO and LUMO of the participating bonds. For most electrocyclic reactions the several possible choices of HOMO–LUMO interaction lead to the prediction of the same stereochemical outcome. Thus, thermal conrotatory cyclobutene to butadiene conversion is predicted regardless of the dominant HOMO–LUMO interaction (Fig. 1).

In the case of electrocyclic opening of three-membered rings the implications of this analysis are that the stereochemical sense of ring opening will be influenced by the dominant HOMO–LUMO interaction and perhaps vice versa (Fig. 2).

Thus, if interaction *a* is predominant the ring

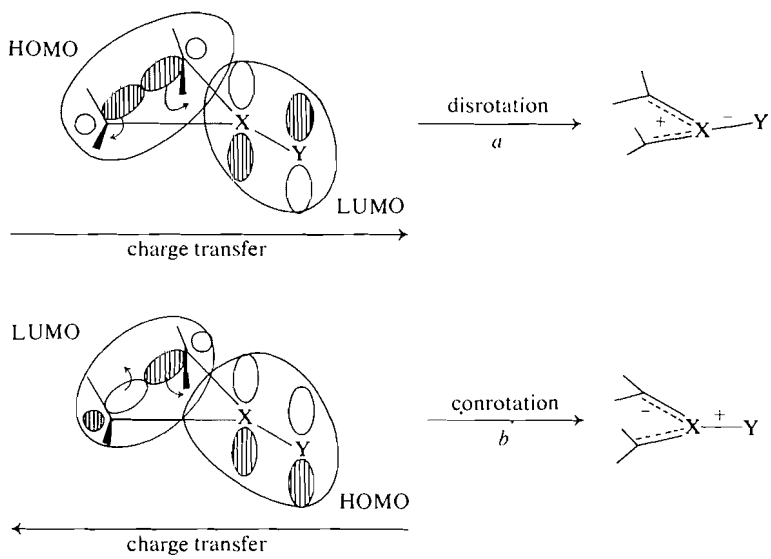

FIG. 2. Modes of HOMO–LUMO interaction in ring opening of a three-membered ring.

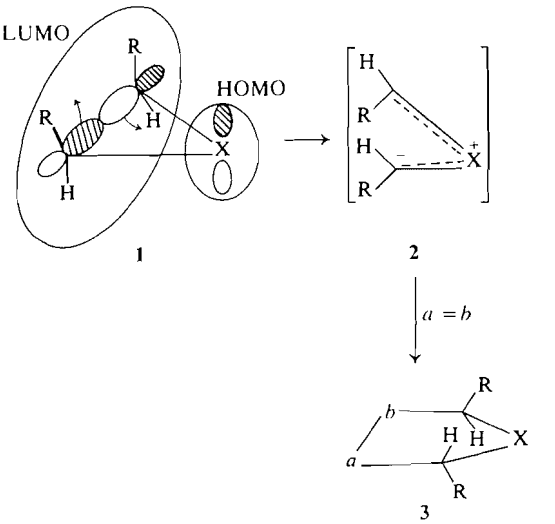
opening would be expected to occur in a disrotatory sense. If *b* is predominant conrotation is to be expected. The favored interaction is expected to be determined by the electronegativities of X and Y since the relative electronegativities of these ring substituents will determine the amplitude of the participating HOMO or LUMO at X. In general, the greater the amplitude of a given MO at X the greater the predominance of the interaction involving the participation of that MO. In cyclopropanones (X = C, Y = O) interaction *a* will be favorable because the relative electronegativities of carbon and oxygen give the carbonyl LUMO a large amplitude at the carbonyl carbon (5). A disrotatory ring opening of cyclopropanone is thus expected (6). Although the stereochemical sense of cyclopropanone opening remains to be determined, the ring-opened forms of substituted cyclopropanones have been trapped in 1,4-cycloaddition to 1,3-dienes and thus appear to possess the dipolar character indicated in Fig. 2*a* (6). The solvolysis of cyclopropyl halides (7) (X = C, Y = halogen) and *N*-chloroaziridines (8) (X = N, Y = Cl) proceed via ionization of the halogen with simultaneous disrotatory C_2—C_3 bond cleavage in which interaction *a* must predominate.

The cycloaddition reactions of substituted aziridines (9) and epoxides (10) (**1**; X = N—R, O) have been interpreted as involving preferred conrotatory ring opening via C_2—C_3 bond scission generating ylides (**2**; X = N—R, O) which in the presence of dipolarophiles undergo *cis-cis*-cycloaddition giving high yields of heterocycles **3** (Scheme 1). Indeed the direct conversion of these heterocycles to ylides must involve charge flow as indicated in Fig. 2*b* (10).

From Scheme 1 one can easily develop the point of view that thermal disrotatory cleavage of aziridines would involve predominantly interaction *a*. If this is a valid opinion then to aid a disrotatory aziridine ring opening one might further reason that electron withdrawing groups attached to nitrogen would be beneficial. To investigate these expectations we have ascertained the effect of *N*-aryl substitution on the rates of conrotatory opening of triaryl aziridines **4***a–d* and on the rates of disrotatory opening of the tetracyclic arylaziridines **5***a–f*. Since we obtained evidence for the predominance of interaction *b* in the reactions involving conrotation and interaction *a* in the reactions involving disrotation we have trapped the ring-opened species from both processes to determine their cycloadditive properties.

Although it was certain that thermal conrotatory cleavage of the arylaziridines **4***a–d* studied would lead to an azomethine ylide that would react stereospecifically with added dipolarophiles we were uncertain as to the expected behavior of the species



SCHEME 1

generated from thermal disrotatory cleavage of the tetracyclic aziridines (**5***a–f*) studied.

Since disrotatory aziridine cleavage occurred with predominance of interaction *a* (Fig. 2) attendant cycloaddition reactions might be expected to occur involving 4π dipolarophiles via a $\sigma 2s + \pi 4s$ process (1). Hence, we considered it of prime importance in these trapping experiments to determine the stereochemistry of the cycloadditions and examine any tendency of the ring-opened species from the tetracyclic aziridines studied to undergo addition to 4π systems.

Results

The reactions of **4***a–d* with dimethyl acetylenedicarboxylate (DMAD) in benzene gave 1:1 cycloadducts (**6**) in nearly quantitative yield. Kinetic investigation of the reaction was carried out by nmr

integration of the carbomethoxy resonances due to DMAD and adducts vs. toluene as an internal standard. It was found that when both reactants were present in comparable concentrations, the reaction rate was dependent only on the concentra-

For personal use only.

tion of the aziridine. This observation parallels that made (9) for the reaction of closely related carboalkoxy substituted aziridines with dipolarophiles and implies a slow conversion of aziridine to an azomethine ylide that subsequently reacts rapidly with DMAD. Such a sequence may be treated kinetically by application of the steady-state approximation to the azomethine ylide.

This formulation leads to the rate expression

$$\text{Aziridine} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{[Azomethine ylide]}$$

$$\text{[Azomethine ylide]} + \text{DMAD} \xrightarrow{k_2} \text{Cycloadduct}$$

$$[1] \qquad \frac{d[P]}{dt} = \frac{k_1 k_2 [Az][DMAD]}{k_{-1} + k_2[DMAD]}$$

where [P] = [Cycloadduct] and [Az] = [Aziridine].

From eq. 1 it is apparent that if product k_2 [DMAD] is sufficiently large, compared to k_{-1}, the latter may be neglected in the denominator and eq. 1 reduces to eq. 2.

$$[2] \qquad \text{rate} = k_1[Az]$$

This will obtain if k_2 is large compared to k_1 or if high concentrations of DMAD are present. Inspection of Table 1 reveals that the overall rate of aziridine reaction is relatively insensitive to changes in concentration of DMAD at moderate concentration levels, indicating the steady state approximation is valid, i.e. k_2[DMAD] $\gg k_{-1}$. By this analysis k_1 is rate limiting and represents the conversion of aziridine to azomethine ylide. The increase in the observed changes in the rate of reaction with *N*-aryl substitution (treated in a Hammett plot in Fig. 3) are thus ascribed to their effect on the ring-opening reaction.

That this ring opening proceeds in a conrotatory fashion producing ylide **7**, which subsequently adds in a *cis-cis* fashion to the reacting dipolarophile is supported by several observations. Huisgen and co-workers (9*g*) have put forward convincing arguments to indicate the C_2 and C_5 phenyl groups in **6***a* are *trans*. This stereochemistry is expected from *cis* addition of a ylide having the geometry of **7** to DMAD. The geometry of **7** is that expected from conrotatory opening of an *N*-aryl-*cis*-2,3-diphenylaziridine, **4**. That the *N*-aryl aziridines made by the method of Taylor (11, used in this study) indeed possess *cis*-2,3 substitution was indicated by independent synthesis of *cis*-1,2,3-triphenylaziridine (**4***a*) from *cis*-2,3-diphenylaziridine (12) and benzyne (13).

One could consider the possibility that the *cis*-2,3-diphenylaziridines **4***a–d* were converted to their *trans* isomers in rapid equilibrium reactions. Such a pre-equilibrium followed by rate determining addition of the *trans* aziridines to the olefins used would alter somewhat the structural similarity of the systems under study. Two considerations indicate such a *cis-trans* pre-equilibrium does not occur in the present cases. First, a search by nmr (detection limit ~5%) and by tlc of the reaction mixture of **4***b* and DMAD failed to reveal resonances or chromatographic bands attributable to *trans* **4***b*. Secondly, addition of *trans* isomers of **4***a–d* to olefins would be expected to yield adducts in which the phenyl substituents are *cis*.

To confirm that the cycloadditions of the ylides produced from *N*-aryl-2,3-diphenyl aziridines were *cis* with respect to the dipolarophile we repeated the previously reported (14) cycloaddition of **4***a* to maleic anhydride, dimethyl maleate, and dimethyl fumarate (Scheme 2). Reaction of **4***a* with maleic anhydride gave the previously reported (14) adduct **8** in which the two phenyl groups are *trans*. Reaction

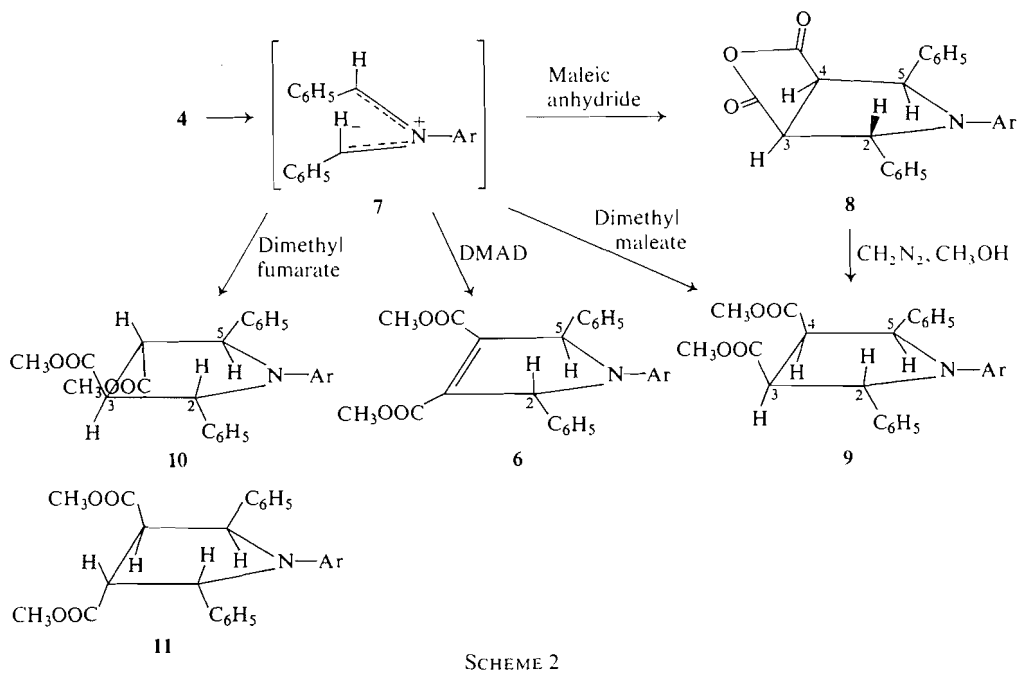
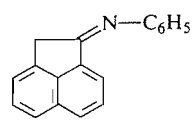


SCHEME 2

of **4***a* with dimethyl maleate gave **9** which was also formed upon reaction of **8** with ethereal methanolic diazomethane. Our mild conversion of **8** to **9** by ethereal diazomethane was chosen to avoid C_3,C_4 isomerization. The maintenance of *cis*-3,4-stereochemistry, although not obvious from the vicinal couplings (9*h*) observed in the nmr spectrum of **9** ($J_{2,3} = 7.5$ Hz, $J_{3,4} = 7.5$ Hz, and $J_{4,5} = 7.0$ Hz), is apparent from the appearance of H_3 and H_4 at different positions (δ 3.39, 3.89). This would be expected only if there had been no isomerization to the thermodynamically more stable **10** or **11** since both have a twofold symmetry axis. Heine has previously assigned the stereochemistry of **11** to the adduct produced upon reaction of **4***a* with diethyl maleate (although see Huisgen and co-workers (9*f*, *g*) for assignment of structure **9**). Structure **10** is easily assigned to the major adduct obtained from **4***a* and dimethyl fumarate since the twofold symmetry axis produces equivalent chemical shifts for the C_2 and C_5 as well as the C_3 and C_4 hydrogens. The *trans* stereochemistry of all groups in **10** is indicated by small vicinal couplings (9*h*) (2.5 Hz). Huisgen and coworkers (9*h*, *g*) have reported that **11** is also formed in minor amounts in the **4***a* dimethyl fumarate reaction. In all of these cycloadditions the stereochemistry of the dipolarophile is maintained and there is a *trans* relationship between the two phenyl groups at C_2 and C_5 indicating *cis* reaction of an azomethine ylide produced upon conrotatory opening of *cis*-1,2,3-triphenyl aziridine.

Aziridines **5***a–f* were obtained by reaction of a 1.5–2.0 molar excess of the appropriately substituted aryl azide with acenaphthylene for 4–15 days at 60–70°C. After this time the aziridines precipitated in 60–80% yield. Thus, the reaction of phenyl azide with acenaphthylene gave an addition product, $C_{18}H_{13}N$, the nmr spectrum of which possessed a 2 hydrogen singlet at δ 4.33 and an 11 hydrogen multiplet in the δ 6.67–7.63 region. Only the imine (**12**) and aziridine (**5***a*) structure are compatible with this spectral pattern (15). The absence of a strong infrared absorption in the 1600–1700 cm^{-1} region (C=N stretching (16)) as well as the failure of the azide–acenaphthylene adducts to undergo hydrolytic cleavage to aniline and a ketone indicated the adduct was not an imine and thus was aziridine **5***a*.



12

Aziridines **5***a–f* condense readily with DMAD to form 1:1 cycloadducts in high yield. These reactions displayed first-order kinetics with respect to aziridine and were zero order with respect to DMAD. The changes in the rates of reaction (Table 2) of these tetracyclic aziridines with alteration of the *N*-aryl (Fig. 4) indicate the effect of this substitution on the necessarily disrotatory ring-opening reaction.

To compare the activation parameters for the ring

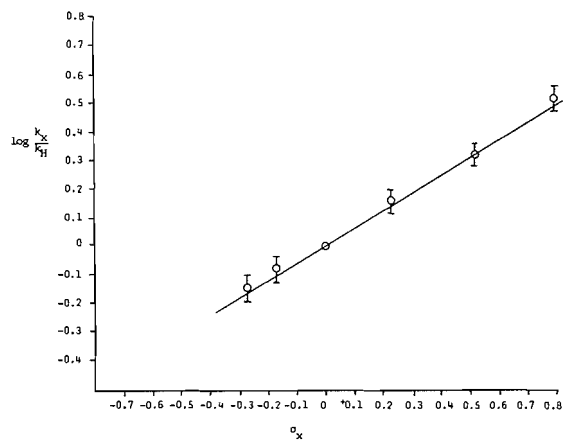

FIG. 4. Correlation of $\log k_x/k_H$ and σ_x for the decomposition of tetracyclic aziridines (**5***a–f*).

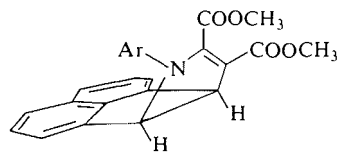
opening of monocyclic aziridines with their tetracyclic analogs we investigated the rate of reaction of monocyclic aziridine **4***a* and its tetracyclic analog (**5***a*) with DMAD each at six temperatures over the range of 90–130°C. Analysis of the rates as a function of temperature by standard methods (15) yielded activation parameters of $\Delta H^{\ddagger} = 21.6 \pm 0.4$ kcal and $\Delta S^{\ddagger} = -0.4 \pm 1$ eu for the ring opening of **4***a*. The calculated activation parameters for the ring opening of **5***a* were $\Delta H^{\ddagger} = 25.1 \pm 0.4$ kcal and $\Delta S^{\ddagger} = -0.1 \pm 1$ eu.

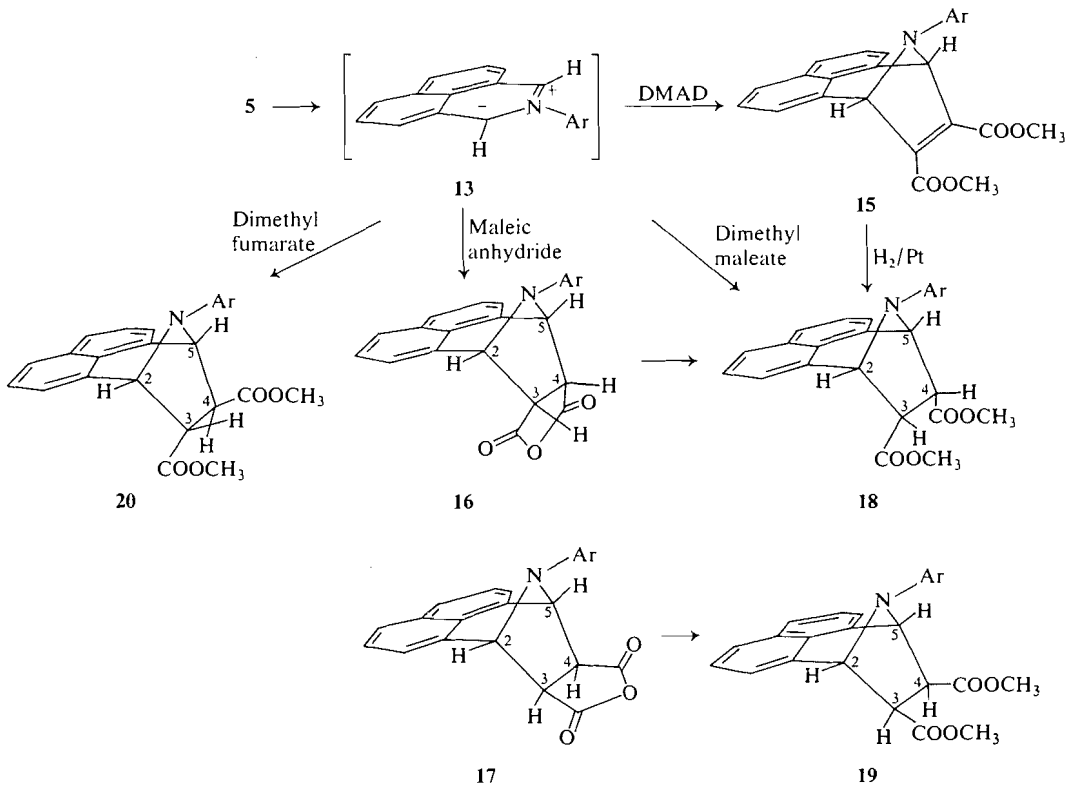
The structures of the cycloadducts produced from reaction of **5***a–f* with DMAD were deduced from inspection of their infrared and nmr spectra. Thus, the infrared spectrum of the adduct obtained (93%) upon reaction of **5***a* with DMAD showed an absorption at 1720 cm^{-1} attributable to a conjugated ester. An absorption at 1645 cm^{-1} is attributed to a tetrasubstituted double bond conjugated with a carbonyl. Two structures **14** and **15** are consistent with the elemental analysis and infrared spectrum. The former was eliminated by inspection of the nmr spectrum of the adduct which exhibited a 6 hydrogen resonance at δ 3.73, a 2 hydrogen singlet at δ 5.78, and an 11 hydrogen multiplet in the δ 6.45–7.71 region. Reaction of aziridine, **5***a*, with maleic anhydride gave **16** and **17** which upon treatment with methanolic ethereal diazomethane gave **18** and **19**, respectively (Scheme 3). The latter two compounds were the only adducts produced upon reaction of **5***a* with dimethyl maleate. The *endo-cis*-3,4-stereochemistry of **18** was indicated by its production upon catalytic reduction of **15**. Inspection of molecular models of **16–20** revealed that in the *endo* adducts (**16** and **18**) the *exo*-C_3,C_4 hydrogens lie near the periphery of the naphthyl system (deshielding area) and the dihedral angle of these hydrogens with their bridgehead neighbors (H_2 and H_5) is approximately 30° for which couplings of 6–7 Hz are expected. The *exo*-C_3,C_4 hydrogens in *cis-endo* adducts should thus be at lower field and coupled strongly with the bridgehead hydrogens compared to those at C_3 and C_4 in *cis-exo* adducts since the hydrogens at C_3 and C_4 in *exo* adducts are below the plane of the naphthyl ring (shielding area) and have dihedral angles of nearly 90° with the neighboring bridgehead hydrogens.



14

In accord with these expectations the nmr spectrum of **18** revealed both ester methyls were identical and resonated at higher field (δ 3.29) than those of **19** (δ 3.73). The nmr spectrum of **18** also revealed the signals due to the C_3 and C_4 pyrrolidine hydrogens in an A_2X_2 pattern ($J_{2,3} = J_{4,5} = 6.7$ Hz) at lower field (δ 3.86) than their counterparts in **19** (δ 3.47) which appeared as a singlet. Similar differences were observed in the nmr spectra of **16** and **17** and have been used by Cava and co-workers (18) to deduce the structures of similar adducts of 2-thiaphenalene.

The reaction of dimethyl fumarate with **5***a* gave a single adduct (**20**) which possessed two different ester functions. The infrared spectrum of **20** possessed absorption at 1730 and 1748 cm^{-1} while its nmr spectrum contained signals due to two different ester groups at δ 3.46 (*endo*) and 3.75 (*exo*). A one



SCHEME 3

TABLE 3. *Exo*:*endo* ratio for thermal and photolytic cycloaddition of **5***a–e* to dimethyl maleate

	Thermal		Photolytic		
Aziridine	*Exo*:*endo*	Total *cis* yield (%)	*Exo*:*endo*	Total *cis* yield (%)	*Trans* yield (%)
5*a*	31:69	89	34:66	84	5
5*b*	30:70	79	36:64	91	4
5*c*	34:66	78	40:60	89	4
5*d*	24:76	85	29:71	81	~5
5*e*	14:86	93	13:87	75	~5

hydrogen doublet at δ 3.66 ($J_{3,4}$ = 5.7 Hz) was assigned to an *endo* hydrogen at C_4. A one hydrogen doublet of doublets at δ 4.28 ($J_{3,4}$ = 5.7 Hz; $J_{4,5}$ = 7.0 Hz) was assigned to an *exo*-C_3 hydrogen. The hydrogen at C_5 was observed as a singlet (δ 5.55) while the C_2 hydrogen was a doublet (δ 5.49, J = 7.0 Hz).

Since the structures of aziridines **5***a–e* made them suitable for studying the effect of nitrogen substitution on *exo*:*endo* addition ratio in the absence of steric effects this aspect of the cycloaddition of these aziridines to dimethyl maleate under both thermal and photochemical conditions was undertaken. Reaction of **5***a–e* with dimethyl maleate under both thermal and photochemical conditions gave mixtures of adducts. The relative amounts of *exo* and *endo* addition (Table 3) of these were assigned by comparison of the chemical shifts of the methoxyl groups in each set of adducts according to the arguments presented above.

To investigate the possible σ2*s* behavior of the ring-opened species generated from the tetracyclic aziridines under study (to give adducts of the general structure **21**) we attempted the cycloaddition of these aziridines to numerous dienes and trienes. In the majority of cases only aziridine dimers were detected but with three polyenes we obtained cycloaddition products.

Reaction of **5***a* with dimethyl *trans-trans*-1,3-butadiene-1,4-dicarboxylate gave a low melting 1:1

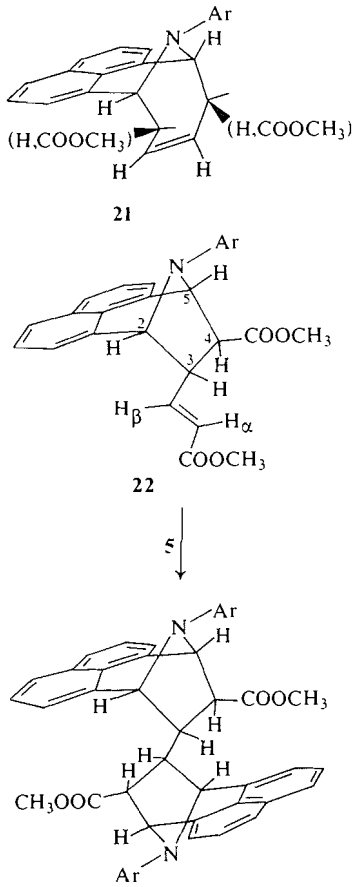
adduct **22**, (63%) and a high melting *bis* adduct, **23** (31%) derivable from the monoadduct by further reaction with **5***a* (Scheme 4). That 1,2- and not 1,4-



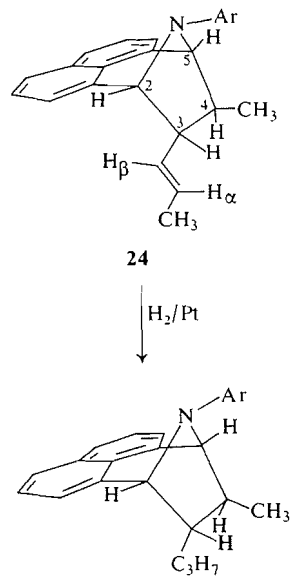
SCHEME 4

addition had occurred to give the 1:1 adduct was deduced from the presence of both an unconjugated (1733 cm^{-1}) and an α,β-unsaturated ester (1710 cm^{-1}) as well as a *trans*-disubstituted alkene (970 cm^{-1}) function. The stereochemistry of adduct **22** was deduced from its nmr spectrum which possessed a singlet (δ 5.52) attributable to the C_5 hydrogen indicating an *endo*-C_4 hydrogen, a doublet ($J_{3,4}$ = 6.2 Hz) at δ 2.93 assignable to the latter, and a doublet at δ 5.20 ($J_{2,3}$ = 6.0 Hz) assignable to the C_2 hydrogen suggesting an *exo*-C_3 hydrogen. The latter appeared at δ 3.98 as a multiplet which collapsed to a triplet upon irradiation of the β-vinyl hydrogen. Further evidence for the *exo* stereochemistry of the ester function in **22** may be obtained from the observation that the chemical shifts of the C_5 hydrogens in **21** and **20** are nearly identical whereas the positions of C_2—H,C_3—H, and C_4—H resonance in the 1:1 adduct show a positive shift in comparison to their counterparts in **20**. This is attributable to the shielding effect of the *endo*-α,β-unsaturated ester. If this group had been in an *exo* position an appreciable positive shift of the C_5 hydrogen in **22** as compared to **20** would have been anticipated.

The reaction of *trans-trans*-2,4-hexadiene with **5***d* gave a single 1:1 adduct (**24**) in 58% yield. In addition aziridine dimer **25***d* was obtained in 22% yield. That **24** was derived via 1,2-addition was deduced from the presence of resonance due to two *trans*-vinyl hydrogens (δ_α 4.96 and δ_β 5.50, $J_{\alpha\beta}$ = 15.0 Hz) and a vinyl methyl (δ 1.47, J_α = 6.5 Hz, J_β = 1.0 Hz) in its nmr spectrum. Upon catalytic reduction of **24** to **26** the vinyl methyl resonance is replaced by a triplet at δ 0.78 (J = 6.5 Hz), whereas the doublet (δ 1.31) assigned to the methyl at C_4 remained unaffected.

The stereochemistry of the adduct was deduced by examination of the signals assigned to the bridgehead hydrogens. Thus, a singlet (δ 4.57) due to the C_5-H indicated an *endo*-hydrogen at C_4 whereas a doublet ($J_{2,3}$ = 6.0 Hz) at δ 4.96 assigned to the C_2-H indicated an *exo*-C_3-H. The *trans* relationship of the C_3 and C_4 hydrogens is also indicated by the quintet structure of the signal (δ 2.89) attributable to the C_4-H requiring $J_{3,4}$ to be 6.5 Hz.

The reaction of 1,3-cyclohexadiene with **5***f* gave a 1:1 adduct in 72% yield along with small amounts of aziridine dimers (**25** and **27**). The nmr spectrum of the 1:1 adduct revealed two multiplets due to four methylene hydrogens (δ 1.21–1.81) and to two methine hydrogens (δ 2.90–3.45). The two bridge-



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

head hydrogens (C_2,C_5) were exhibited as a doublet (J = 6.2 Hz) at δ 5.07 whereas the two vinyl hydrogens were exhibited as a multiplet centered at δ 5.48. Although it could not be discerned from the above whether 1,2- or 1,4-addition had occurred, the former was confirmed by reduction of the 1:1 adduct **28** to the adduct (**29**) obtained (7%) when cyclohexene was reacted with **5***f*. The *endo* configuration of the cyclohexene ring in the latter was evident from the coupling (J = 6.2 Hz) between the bridgehead hydrogens (C_2,C_5); one doublet at δ 5.03, and their vicinal neighbors (C_3,C_4).

The less reactive aziridine, **5***a*, gave only a 34% yield of 1:1 adduct with 1,3-cyclohexadiene along with appreciable amounts of aziridine dimers.

Reaction of tetracyclic aziridines with tropone and cycloheptatriene were also investigated. Only the latter reaction led to identifiable products. The reaction of **5***d* with cycloheptatriene gave a 37% yield of a 1:1 adduct and major amounts of aziridine dimers. The structure of the 1:1 adduct was deduced to be as in **30** by reduction to the 1:1 adduct **31** obtained from **5***d* and cycloheptene. That the alternate product of π4*s* + π2*s* cycloaddition, **32**, was not the correct formulation for the cycloheptatriene–**5***d* adduct was also deduced by observation of coupling ($J_{4,6}$ = 2.5 Hz, $J_{4,7}$ = 12 Hz) between a methine hydrogen (H-4) and the methylene hydrogens (H-6 and H-7) of the cycloheptyl ring. That the adduct was asymmetric with respect to a plane bisecting the fused aromatic rings was also evident from the distinctly different chemical shifts observed for the two bridgehead hydrogens (δ$_2$ 4.98 and δ$_5$ 5.08). The *endo* stereochemistry of the cycloheptyl rings in both **30** and **31** was deduced from the coupling of the bridgehead hydrogens with their methine neighbors (J = 6 Hz) in both compounds.

Several of the reactions of tetracyclic aziridines, **5**, with alkenes not possessing conjugated carbonyls resulted in low yields of cycloaddition products and competing formation of aziridine dimers. Heating aziridine **5***a* in benzene at 140°C for 14 h resulted in complete consumption of the aziridine and the formation of two separable dimers **25***a* and **27***a*. The mass spectrum of each showed a parent ion peak at *m*/*e* 486 and a base peak at *m*/*e* 243. Assignment of structures to **25***a* and **27***a* was made by comparison

28

of the relative chemical shifts of the bridgehead hydrogens (δ 5.09 and 5.79, respectively) and the naphthyl hydrogens (δ 7.33–7.83 and 6.63–7.03, respectively) with those of the analogous hydrogens in the acenaphthylene photodimers (19–21). Thus, the nmr spectrum of α-heptacyclene, **33**, revealed the benzylic hydrogens at δ 4.07 vs. 4.78 for these hydrogens in β-heptacyclene, **34**. Furthermore the naphthyl hydrogens of **33** appear in the region δ 7.76–7.83 whereas in **34** these hydrogens occur in the δ 6.58–7.28 region. The differences between the chemical shifts of the aromatic hydrogens in **25***a* and **27***a* as well as between **33** and **34** are readily attributable to the shielding effects of the naphthyl rings in the *cis* isomers. In the *trans* isomers (**25***a* and **33**) the methine hydrogens are shielded by these rings.

Discussion

We examined cycloaddition reactions of monocyclic (**4***a–d*) and tetracyclic aziridines (**5***a–f*) with numerous 2π, 4π, and 6π systems. In all cases only

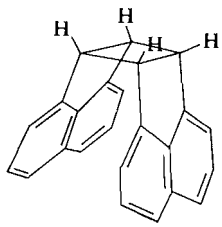
33



34

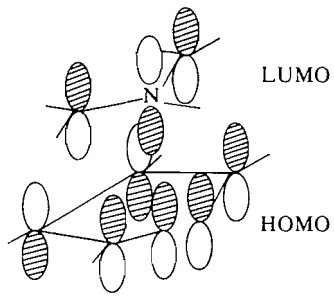
stereospecific *cis*-1,2-addition to the reacting dipolarophiles was observed. These results indicate the respective azomethine ylides **7** and **13** are the reactive intermediates in these reactions and support the suggestion (17) that the lack of stereospecificity previously noted in similar aziridine cycloadditions resulted from alkene isomerization prior to reaction.

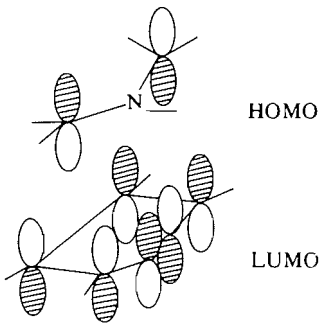
Evidence that azomethine ylides are the product forming intermediates in the thermal cycloaddition of tetracyclic aziridines (**5**) to dipolarophiles such as dimethyl maleate also comes from a comparison of the ratios of *exo* to *endo* adducts that are formed during the thermal and photochemical cycloaddition of these reactants. It is established (9) that photochemical C—C bond cleavage of substituted aziridines such as **5** proceeds by disrotatory ring opening to produce azomethine ylides that are the product forming intermediates in subsequent cycloaddition reactions. If azomethine ylides are the product forming intermediates in the thermal cycloaddition of the tetracyclic aziridines (**5**) used in the present study then the ratio of *exo* to *endo* adduct formation with olefins such as dimethyl maleate should be similar for both photochemical and thermal cycloaddition of a given aziridine.

Examination of the *exo*:*endo* ratios of adducts from **5***a–e* and dimethyl maleate (Table 3) reveals no significant difference in this reaction parameter when a given aziridine is consumed under photochemical or thermal conditions.

An additional argument that can be brought to bear on the question of the involvement of azomethine ylides in the cycloaddition of the tetracyclic aziridines (**5**) to dipolarophiles makes use of the variation of *exo*:*endo* ratio observed in Table 3 with the nature of the *N*-aziridinyl substituent. It can be predicted on the basis of secondary orbital interactions (1, 22) that attraction between LUMO of a 4π electron system such as an azomethine ylide and the HOMO of a reacting olefinic dipolarophile leads to a bonding interaction favoring *cis-endo* addition. As the electronegativity of the *N*-substituent in such ylides increases so does the coefficient of the N–*p* orbital in the LUMO of the ylide making this bonding interaction stronger. The relative amount of *endo* adduct for such a ylide would therefore be expected to increase if steric factors remained unchanged. The data reported in Table 3 indeed reveals that as the *N*-substituent of the reacting aziridines becomes more electronegative the relative amount of *endo* addition increases.

The above argument, based on secondary orbital interactions between the N–*p* orbital in the ylide LUMO and π_{CO} orbitals in the dipolarophile HOMO, predicts the trend of *exo*:*endo* ratios observed but





does not predict the *endo* adduct as the major product. It can be argued that since azomethine ylides are HOMO controlled 1,3-dipoles which react best with electron deficient alkenes the addition of ylides **5***a–f* to dimethylmaleate should involve a predominant ylide HOMO-dipolarophile LUMO interaction. If this is the case there should be no interaction between the N–*p* orbital of the ylide and the π_{CO} of the dipolarophile since there is a node at the N atom in the HOMO of the former.

Secondary orbital interaction leading to *endo*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

adduct is possible between the π_{CO} in the LUMO of dimethylmaleate and the π-naphthalene HOMO. This interaction could be stronger than π_{CO} dipolarophile LUMO–π_{Ar}–dipole HOMO interaction which would lead to *exo* adduct formation. The changes in *exo*:*endo* ratios may, in this argument, be attributed to differences in magnitudes of the secondary orbital interactions between π_{CO} and π_{Ar}. As electron-withdrawing substituents decrease interactions between the π_{Ar} HOMO and the π_{CO} dipolarophile LUMO a decrease in the *exo*:*endo* adduct ratio should be observed.[2]

The present observations complement the reports that the carbonyl ylides produced upon both thermal conrotatory (10) and thermal disrotatory (21) cleavages of tetracyclic epoxides undergo stereospecific cycloaddition to 2π-dipolarophiles.

Thus, available evidence indicates that regardless of the rotatory motion involved in the thermal conversion of aziridines and epoxides to their respective ylides the latter are generated in a form for which stereospecific 1,2-cycloaddition is the usual mode of reaction.

It is noteworthy that we saw no evidence for nonstereospecific addition of either the monocyclic or tetracyclic aziridines to dimethyl maleate or dimethyl fumarate expected (23) if a diradical species were involved in these cycloadditive processes. This is an especially important observation in the case of addition of the tetracyclic aziridines to these dipolarophiles since, according to the arguments of Dewar and Kirschner (**4***c*), diradical behavior of species generated during thermally forbidden disrotatory opening of aziridines would be most likely in those cases (such as **5**) where symmetry is enforced by severe geometrical constraint on the transition state leading to the ring-opened species.

In agreement with recent calculations by Dewar and co-workers (4), indicating there is often a fairly small difference in the activation energies for analogous allowed and forbidden reactions, we found the enthalpy of activation for the disrotatory ring opening of the tetracyclic aziridine, **5***a*, to be only 3.5 kcal greater than that for the conrotatory opening of its monocyclic analog, **4***a*.

The observation (Fig. 3) that increasing electron donating power of *N*-aryl substituents of the monocyclic aziridines (**4***a–d*) increased their rate of conrotatory opening was expected. This indicates that the interaction in Fig. 2*b* predominates during this ring opening and that the azomethine ylide (**7**) is the product of the process.

The observation that electron withdrawal from nitrogen (Fig. 4) increases the rate of disrotatory opening of the tetracyclic aziridines (**5***a–f*) indicates the interaction described in Fig. 2*a* predominates during this ring-opening process. This means that during the approach to the transition state for this process electron density decreases in the aziridinyl portion of the molecule. Since all evidence points to azomethine ylide **13** as the reactive intermediate involved in the cycloaddition reactions of the tetracyclic aziridines, the electron density in the aziridinyl region of these compounds must increase to full 4π electron status after the transition state for disrotatory opening is achieved.

The kinetic behavior of the *N*-substituted tetracyclic aziridines studied can be viewed in two ways. First, one could conclude that Fukui's analysis (Fig. 2) has validity in terms of net charge flow during electrocyclic reactions of three-membered rings and that we have observed a manifestation of predominant HOMO–LUMO interactions in both possible directions. Secondly, in a broader context one might view the flow of electron density from the aziridine nitrogen to its aryl appendage during disrotatory opening as an attempt to achieve minimum electron density in the reacting portion of the molecule during this forbidden process. On further thought one might expect this behavior to be generally observed since, by this decrease, electronic interactions attending thermally forbidden reactions are minimized in those orbitals where the greatest destabilizing interactions occur.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Elemental analyses were performed either by Alfred Berhardt Microanalysisches Laboratorium, Mulheim, Germany, or in this laboratory. The infrared spectra were determined with a Unicam SP200 or a Beckman IR-12 instrument. Ultraviolet spectra were recorded on either a Unicam SP800 or Cary 14 spectrometer. The nmr spectra were recorded at 60 MHz on a Varian A56/60 instrument using tetramethylsilane as an internal standard. Mass spectra were obtained on a Hitachi Perkin-Elmer RMU-6E spectrometer using an ionization voltage of 70 eV and an inlet temperature of 175–200°C.

Preparation of N-*Aryl*-cis-*2,3-diphenyl Aziridines (4a–d)*

These aziridines (Table 4) were prepared in good yields

using the procedures described (11) for the preparation of **4***a* except that the yields in the reduction of the hydroxy imine intermediates were appreciably improved by slowly leaching the hydroxy imines into ethereal solutions of LAH (Soxhlet).

Stereospecific Synthesis of **4***a*

To a solution of 3.5 g of *cis*-2,3-diphenylaziridine (12) in 80 ml of THF was added 2.55 g of benzenediazonium-2-carboxylate (13). The suspension was stirred at 50°C until the solid dissolved, then concentrated, and approximately $\frac{1}{3}$ of the concentrate chromatographed on 40 g of silica gel. Elution with 4:1 benzene – petroleum ether gave initial fractions (2 × 50 ml) containing *cis*- and *trans*-stilbenes (50 mg). Subsequent fractions gave a mixture of stilbenes and *N*-phenyl-*cis*-2,3-diphenylaziridine, **4***a* (60 mg), mp 98–100°C. Mixture mp with **4***a* prepared above 98–100°C.

*Preparation of 7-Aryl-6a,7a-dihydroacenaphtha-[1,2-*b*]-aziridines 5a–f*

Solutions of acenaphthylene (~3 g) and a 1.5–2.0 molar equivalent of the appropriately substituted aryl azide in 15 ml of benzene were heated at 60–70°C for 4 (Ar = *p*-NO_2—C_6H_4) to 15 (Ar = *p*-$CH_3OC_6H_4$) days during which time a granular product deposited. Removal of the solvent and recrystallization from ether – petroleum ether gave aziridines **5***a–f* in yields recorded in Table 5.

In the absence of excess azide the dimerization and polymerization of acenaphthylene become undesirable side reactions. Reaction temperatures above 100°C caused dimerization of aziridines.

Kinetic and Product Analysis of Reaction of **4***a–d and* **5***a–f with DMAD*

Materials

The aziridines **4***a–d* and **5***a–f* were purified by at least three recrystallizations from appropriate solvents followed by drying at 70–75°C (0.1 Torr). The dimethyl acetylene dicarboxylate was prepared by a published procedure (24), was distilled twice, bp 130–131°C (10 Torr), and stored at 0°C until used. Spectroscopic grade benzene was distilled over LAH prior to use.

The requisite amounts of aziridine, toluene (internal standard), and dimethyl acetylenedicarboxylate were weighed into 10 ml volumetric flasks and made up to volume with solvent. The nmr tubes were filled with samples of the reaction mixture using a hypodermic syringe and sealed under N_2 atmosphere. The tubes were withdrawn at appropriate intervals, and the reaction was quenched by cooling to −70°C. The tubes were allowed to warm to room temperature, and the nmr spectra were recorded.

The concentration of aziridines, products, and esters were calculated by comparison of the spectra of the respective peak area with that of the peak area of known concentrations of toluene (internal standard). The rates of adduct formation were determined by comparison of the adduct methoxyl resonance intensities with that of the toluene methyl internal standard. In the case of **4***b*, the area of methyl signals was used in calculating the concentration of the product. The nmr spectra were recorded using sweep width of 250 Hz and sweep time of 250 s.

The yields of products from the kinetic runs were obtained by placing the tubes in an oil bath at 140°C after recording the spectra, for varying lengths of time to ensure complete reaction. The reaction mixtures were then transferred to a flask. The solvent was removed at 50–55°C and the residue was diluted with methanol (10 ml) to precipitate the product which was filtered, washed, dried, and weighed.

The yields of adducts and their physical properties are collected in Tables 6 and 7.

Reaction of **4***a with Maleic Anhydride*

Refluxing a toluene (25 ml) solution of **4***a* (275 mg) and maleic anhydride (100 mg) for 6 h gave, after evaporation of the solvent, **8** as a pale yellow solid which after washing with methanol yielded 342 mg (93%), mp 212–214°C. Recrystallization from benzene – petroleum ether (1:10) gave mp 215–216°C (lit. (14) mp 214–215.5°C). Reaction of **8** with an excess of ethereal diazomethane containing methanol gave **9** in 90% yield, mp 180–181.5°C. Mixture mp with **9** prepared from **4***a* and dimethyl maleate was 180–181°C.

Reaction of **4***a with Dimethyl Maleate*

A solution of **4***a* (273 mg) and dimethyl maleate (145 mg) was refluxed in toluene (25 ml) for 14 h. Removal of the solvent *in vacuo* gave a light yellow oil which solidified on standing to give **9** which further precipitated by treating the reaction mixture with methanol, 385 mg (92%), mp 178–181°C. An analytical sample was obtained by recrystallization from methanol, mp 180–181.5°C. *Anal.* calcd. for $C_{26}H_{25}NO_4$: C 75.16, H 6.06; found: C 75.04, H 6.24. *Mol. wt.* calcd. for $C_{26}H_{25}NO_4$: 415; found: 415.

Reaction of **4***a with Dimethyl Fumarate*

A toluene solution (25 ml) of **4***a* (276 mg) and dimethyl fumarate (147 mg) was refluxed for 15 h. After removal of solvent, a pale yellow oil was obtained. Trituration of the oil with methanol gave **10**, 392 mg (94%), mp 218–221°C. Recrystallization from hot methanol gave an analytical sample, mp 221–222°C. *Anal.* calcd. for $C_{26}H_{25}NO_4$: C 75.16, H 6.06; found: C 75.25, H 6.20. *Mol. wt.* calcd. for $C_{26}H_{25}NO_4$: 415; found: 415.

Reaction of 5a with Maleic Anhydride

A solution of **5***a* (500 mg) and maleic anhydride (200 mg) in benzene (15 ml) was heated in a sealed tube at 140°C for 8 h. Removal of the solvent gave a semisolid which was washed with ether to yield **17** as a solid. The solid was filtered, washed with ether, and dried to give 400 mg (60%); mp 255–257°C. Recrystallization from hot toluene afforded a pure sample of **17**, mp 256–257.5°C. *Mol. wt.* calcd. for $C_{22}H_{15}NO_3$: 341 (M^+); found: 341 (M^+).

Evaporation of the filtrate gave a beige oil, **16**, which resisted crystallization. Its ir spectrum (thin film) showed absorption due to an anhydride moiety at 1853 and 1776 cm^{-1}, and the nmr ($CDCl_3$) had two sets of doublets centered at δ 4.19 (2H), and another two sets of doublets centered at δ 5.42 (2H).

Conversion of 16 to 18

The oil from above in 10 ml of methanol was treated with an excess of ethereal diazomethane. Evaporation of the solvent at 50°C left a semicrystalline material which was treated with methanol to give **18**, 210 mg (28%); mp 202–204°C. The nmr and ir spectra of **18** prepared in this manner were identical to those of **18** prepared upon reaction of dimethyl maleate with **5***a*. The mixture melting point of **18** from the two sources was undepressed.

Conversion of 17 to 19

A suspension of anhydride adduct **17** (200 mg) in ether–methanol solution (20 ml) was treated with an excess of ethereal diazomethane solution at −70°C and was allowed to warm to room temperature. The usual work-up procedure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

afforded needles, 200 mg (90%), mp 188–190°C. The nmr and ir spectra of this dimethyl ester were identical to those of the diester **19** obtained from reaction of dimethyl maleate with **5***a*.

Reaction of 5a with Dimethyl Maleate

A benzene solution (10 ml) of **5***a* (750 mg) and dimethyl maleate (450 mg) was heated in a sealed tube at 140°C for 14 h. Removal of the solvent left a red oil which was taken up in 75–80 ml of boiling ethanol. Standing at room temperature for 6–8 h gave a thick layer of **18**, 340 mg, mp 201–203°C. The filtrate was concentrated to half its volume. On standing this concentrate gave another 150 mg of **18** (41%). An analytical sample was obtained by recrystallization from hot methanol: mp 202–203°C. *Anal.* calcd. for $C_{24}H_{21}NO_4$: C 74.40, H 5.46; found: C 74.31, H 5.42. *Mol. wt.* calcd. for $C_{24}H_{21}NO_4$: 387; found: 387.

Further concentration of the mother liquor gave 137 mg of a mixture of **18** and **19**, mp 180–195°C. The filtrate was concentrated and treated with petroleum ether which on standing overnight yielded **19**, 390 mg (32%), mp 188–190.5°C. Evaporation of the solvent to dryness gave a mixture of **18** and **19**, 70 mg, mp 187–190°C. An analytical sample of **19** was prepared by recrystallization from benzene – petroleum ether (1:10), mp 189–190.5°C. *Anal.* calcd. for $C_{24}H_{21}NO_4$: C 74.40, H 5.46; found: C 74.68, H 5.28. *Mol. wt.* calcd. for $C_{24}H_{21}NO_4$: 387; found: 387.

Hydrogenation of 15

A solution of **15** (245 mg) in toluene (10 ml) and methanol (50 ml) containing 50 mg of 5% Pt-on-charcoal was stirred under H_2 at 50 psi for 24 h. The removal of the solvent gave **18**, 232 mg (94%), mp 201–203°C. The nmr and the ir spectra of **18** prepared in this manner were identical to those of **18** prepared by reaction of dimethyl maleate with **5***a*. The mixture melting point of **18** from these two sources was undepressed.

Reaction of 5a with Dimethyl Fumarate

A benzene solution (10 ml) of **5***a* (500 mg) and dimethyl fumarate (291 mg) was heated at 140°C for 14 h in a sealed tube. Removal of the solvent under reduced pressure gave a red liquid which crystallized from methanol – petroleum ether (1:10) to afford **20**, 683 mg (89%), mp 144–146.5°C. An analytically pure sample was obtained by further crystallization from methanol – petroleum ether, mp 145–146.5°C. *Anal.* calcd. for $C_{24}H_{21}NO_4$: C 74.40, H 5.46; found: C 74.24, H 5.55. *Mol. wt.* calcd. for $C_{24}H_{21}NO_4$: 387; found: 387.

Thermal Reaction of 5a–e with Dimethyl Maleate

Benzene-d_6 solutions 0.2 *M* each in **5** and dimethyl maleate were degassed, sealed in nmr tubes, and heated at 110°C for 1–3 days. After consumption of the aziridine the reaction mixture was analyzed directly by nmr. The relative amounts of adducts (**18** and **19** respectively) reported in Table 3 are based on integration of the ester resonances of the adducts.

After evaporation of the solvent the *exo* adducts crystallized easily from boiling ethanol while the *endo* adducts crystallized from cold ethanol in total overall yields of 80–90%.

Prolonged (10 days) heating of benzene-d_6 solutions of pure **18** or **19** or the reaction mixture at 110°C indicated (nmr) no interconversion of **18** and **19** occurred under the reaction conditions.

Photolytic Reaction of 5a–e with Dimethyl Maleate

Benzene-d_6 solutions 0.2 *M* in each aziridine **5** and dimethyl maleate were degassed and sealed in nmr tubes. The tubes were suspended approximately 1 in. from a Pyrex jacketed 200 W Hanovia mercury lamp for 1–3 days. After completion of reaction the ratios of **18** to **19** were determined by integration of the nmr spectra of the ester groups of the adducts. Under the photochemical conditions using benzene-d_6 solutions of **18** and **19** were stable as was the fumarate adduct. The fumarate adduct was detected (by nmr) in the photolysate of all photolyses. Dimethyl maleate was observed to photoequilibrate with dimethyl fumarate under the conditions used for the addition of **5** to the former.

Reaction of 5a with Dimethyl trans,-trans-*1,3-Butadiene-1,4-dicarboxylate*

A benzene solution (15 ml) of **5***a* (500 mg) and dimethyl muconate (340 mg) was heated in a sealed tube at 140°C for 14 h. The reaction mixture on cooling at room temperature gave white needles of unreacted diester, 70 mg (19%), mp 155–157°C (lit. (25) mp 156–157°C).

Evaporation of the filtrate afforded an oil which was crystallized from hot methanol. The crystalline product was filtered, washed with cold methanol, and dried to yield **23**, 210 mg (31%), mp 296–299°C, Further crystallization from benzene – petroleum ether (1:10) gave **23**, mp 298–300°C. *Anal.* calcd. for $C_{44}H_{36}N_2O_4$: C 80.48, H 5.48; found: C 80.57, H 5.65. *Mol. wt.* calcd. for $C_{44}H_{36}N_2O_4$: 656; found: 656.

The mother liquor was evaporated and treated with hot petroleum ether to give **22**, 520 mg (63%), mp 146–149°C. An analytical sample was obtained by recrystallization from benzene – petroleum ether (1:10): mp 148–149.5°C. *Anal.* calcd. for $C_{26}H_{23}NO_4$: C 75.53, H 5.61; found: C 75.48, H 5.52. *Mol. wt.* calcd. for $C_{26}H_{23}NO_4$: 413; found: 413.

Conversion of 22 to 23

Heating a benzene (10 ml) solution of **22** (100 mg) and **5***a* (68 mg) in a sealed tube at 140°C for 14 h gave a red oil. Dilution of the oil with ether deposited a small amount of dimer **25** which was removed by filtration. The filtrate was concentrated to dryness and treated with hot methanol to yield **23**, 120 mg (75%), mp 297–300°C.

*Reaction of 2,4-*trans-trans-*Hexadiene with 5d*

A benzene solution of **5***d* (650 mg) and 2,4-*trans-trans*-hexadiene (400 mg) was allowed to react at 140°C for 16 h in a sealed tube. Removal of the solvent afforded a red liquid which on dilution with ether gave dimer **25** which was filtered, washed with ether, and dried to yield 142 mg (22%), mp > 300°C. Mass calcd. for $C_{36}H_{24}Br_2N_2$: 642 (M^+); found: 642 (M^+).

The ethereal mother liquor was evaporated and treated with hot methanol – petroleum ether (1:10) to give on cooling **24**, 469 mg (58%), mp 197–199.5°C. Recrystallization from benzene – petroleum ether (1:10) gave mp 198–199.5°C. *Anal.* calcd. for $C_{24}H_{22}BrN$: C 71.29, H 5.48; found: C 71.13, H 5.59. *Mol. wt.* calcd. for $C_{24}H_{22}BrN$: 403; found: 403.

Catalytic Hydrogenation of 24

To a suspension of 50 mg of 5% Pt-on-charcoal in methanol (50 ml) was added **24** (110 mg). Reaction under hydrogen at 50 psig for 8 h followed by filtration and evaporation of the solvent yielded **26** as an oil which solidified on standing, 107 mg (97%), mp 134–137°C. A pure sample was obtained by crystallization from methanol – petroleum ether (1:10) mixture mp 136–137.5°C. *Mol. wt.* calcd. for $C_{24}H_{24}BrN$: 405 (M^+); found: 405 (M^+).

Reaction of 5f with 1,3-Cyclohexadiene

A benzene solution (10 ml) of **5***f* (315 mg) and 1,3-cyclohexadiene (400 mg) was heated in a sealed tube at 140°C for 16 h. On cooling a small amount of solid deposited which was removed by filtration. Evaporation of the solvent and treatment with ether deposited the dimer, **25**, which was washed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with ether, and dried to yield 40 mg (13%), mp > 300°C. Removal of the solvent to dryness gave a semisolid compound which on dilution with benzene – petroleum ether (1:10) deposited 280 mg (72%) of **28**, mp 193–196°C. A pure sample was obtained by crystallization from hot benzene – petroleum (1:10) ether, mp 197–198.5°C. *Anal.* calcd. for $C_{24}H_{19}Cl_2N$: C 73.45, H 4.88; found: C 73.33, H 4.78. *Mol. wt.* calcd. for $C_{24}H_{19}Cl_2N$: 391; found: 391.

Reaction of 5f with Cyclohexene

A benzene solution (10 ml) of **5***f* (700 mg) and cyclohexene (1.5 g) was heated in a sealed tube at 140°C for 14 h. On cooling dimer **25** deposited (20 mg). Evaporation of the solvent and treatment with ether gave additional dimer which was washed with ether and dried to yield 460 mg, 38%, mp > 300°C. Removal of the solvent to dryness gave a semisolid which upon dilution with petroleum ether deposited **29**, which was filtered and dried to yield 12 mg, 7%, mp 180–182°C.

Hydrogenation of 28

A solution of **28** (70 mg) in distilled methanol (25–30 ml) containing 20 mg of 5% Pt-on-charcoal was placed under 45 psig of hydrogen. Hydrogen uptake was completed in 3 h. After reaction for an additional 2 h the catalyst was removed and the solvent evaporated to yield **29**, 68 mg (96%), mp 180–182°C. A pure sample was prepared by recrystallization from warm petroleum ether, mp 181–182.5°C. A mixture of this hydrogenated product, mp 181–182.5°C, with **29** from reaction of **5***f* with cyclohexene, mp 180–182°C, gave mp 180–182°C.

Reaction of 1,3-Cyclohexadiene with 5a

A benzene solution (10 ml) of **5***a* (500 mg) and 1,3-cyclohexadiene (200 mg) was heated at 140°C for 14 h in a sealed tube. On cooling the reaction mixture dimer **25** deposited and was removed by filtration, washed twice with benzene, and dried to yield 120 mg (24%), mp 318–322°C (dec.).

The filtrate was evaporated to dryness and on treatment with methanol gave dimer **27**, which was washed with methanol, and dried to yield 97 mg (20%), mp 278–282°C (dec.).

The methanolic solution was evaporated to dryness to give an oil which was then dissolved in warm benzene – petroleum ether (1:10). On cooling the **28** (Ar = C_6H_5) which deposited was filtered, washed with benzene – petroleum ether (1:20), and dried to yield 207 mg (32%), mp 172–176°C. An analytical sample was obtained by recrystallization from hot benzene – petroleum ether (1:10); mp 175–176.5°C. *Anal.* calcd. for $C_{24}H_{21}N$: C 89.13, H 6.54; found: C 88.97, H 6.63. *Mol. wt.* calcd. for $C_{24}H_{21}N$: 323; found: 323.

Reaction of 5d with Cycloheptatriene

A benzene solution (10 ml) of **5***d* (0.5 g) and cycloheptatriene (1.5 g) was heated in a sealed tube at 110°C for 3 days. Upon cooling dimer **25** precipitated and was removed. The solvent was evaporated and methanol added to precipitate dimer **27**. The filtrate from this filtration was evaporated to dryness and the residue crystallized from benzene – petroleum ether (1:10) to give **30**, 234 mg (37.6%), mp 182–184°C. *Mol. wt.* calcd. for $C_{25}H_{20}BrN$: 413, 415 (M^+); found: 413, 415 (M^+).

Hydrogenation of 30

A solution of **30** (200 mg) in methanol (50 ml) was reduced using PtO_2 (100 mg) and 60 psig H_2 pressure for 21 h. Removal of the catalyst and evaporation of the solvent *in vacuo* afforded a yellow oil which crystallized from ether – petroleum ether (1:3) to give **31**, mp 280–282°C. The **31** produced in this manner gave no melting point depression upon mixture with **31** derived from cycloheptene and **5***d* as described below.

Reaction of 5d with Cycloheptene

A solution of **5***d* (250 mg) and cycloheptene (250 mg) in 10 ml benzene were heated at 110°C in a sealed tube for 4 days. After cooling dimer **25** precipitated and was removed. Addition of methanol precipitated dimer **27**. The filtrate from this filtration was evaporated to dryness to give **31** which precipitated from benzene – petroleum ether (1:10 64 mg 20%), mp 281–282°C. *Mol. wt.* calcd. for $C_{25}H_{22}BrN$: 415, 417 (M^+); found: 415, 417 (M^+).

Thermal Dimerization of 5a

A benzene solution (10 ml) of **5***a* (250 mg) was heated at 140°C in a sealed tube for 14 h. On cooling the reaction mixture **25** precipitated, was filtered, washed with benzene, and dried to yield 117 mg (47%), mp 318–321°C (dec.). A pure sample was obtained by crystallization from boiling toluene: mp 322–324°C (dec.). *Anal.* calcd. for $C_{36}H_{26}N_2$: C 88.85, H 5.38; found: C 88.61, H 5.47. *Mol. wt.* calcd. for $C_{36}H_{26}N_2$: 486; found: 486.

Evaporation of the solvent gave **27**, 102 mg (41%), mp 278–281°C (dec.). Recrystallization from benzene – petroleum ether (1:10) gave mp 280–282°C (dec.). *Anal.* calcd. for $C_{36}H_{26}N_2$: C 88.85, H 5.38; found: C 88.57, H 5.52. *Mol. wt.* calcd. for $C_{36}H_{26}N_2$: 486; found: 486.

Photoreactions of iminophosphoranes

A. S. YIM, M. H. AKHTAR, A. M. UNRAU, AND A. C. OEHLSCHLAGER
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received August 23, 1977

A. S. YIM, M. H. AKHTAR, A. M. UNRAU, and A. C. OEHLSCHLAGER. Can. J. Chem. **56,** 289 (1978).

The irradiation of *N*-aryltriphenyliminophosphoranes in inert solvents leads to efficient production of triphenylphosphine and the diaryl azo compounds derived from the *N*-aryl ylide substituent. The irradiation of *N*-alkyltriphenyliminophosphoranes leads to rearrangements of the *N*-alkyl substituent analogous to those observed during the irradiation of the corresponding azides. Triphenyliminophosphoranes which possess *N*-substituents capable of strong delocalization of the nitrogen lone pair (e.g. benzene sulfonyl, benzoyl) are photostable. Since all attempts to trap nitrene intermediates suspected to be formed during the photoreactions of the photolabile iminophosphoranes were unsuccessful, the reactions are considered to proceed via excited ylide intermediates.

A. S. YIM, M. H. AKHTAR, A. M. UNRAU et A. C. OEHLSCHLAGER. Can. J. Chem. **56,** 289 (1978).

L'irradiation de *N*-aryltriphényliminophosphoranes dans des solvants inertes conduit à une formation efficace de triphénylphosphine et de composés diarylazo provenant du substituant *N*-aryl de l'ylure. L'irradiation de *N*-alkyltriphényliminophosphoranes conduit à des réarrangements de substituants *N*-alkyles semblables à ceux observés durant l'irradiation des azotures correspondants. Les triphényliminophosphoranes portant, au niveau de l'azote, des substituants pouvant favorisés une délocalisation importante de la paire d'electrons libres sur l'azote (e.g. benzènesulfonyle ou benzoyle) sont photostables. On avait cru que des intermédiaires nitrènes pouvaient se former au cours des photoréductions des iminophosphoranes photolabiles; toutes les tentatives effectuées en vue de piéger ces intermédiaires se sont avérées vaines. On considère donc que les réactions se produisent par l'intermédiaire d'ylures excités.

Introduction

Many ylides are susceptible to photolytic fragmentation of the ylide bond. In theory, homolytic dis-

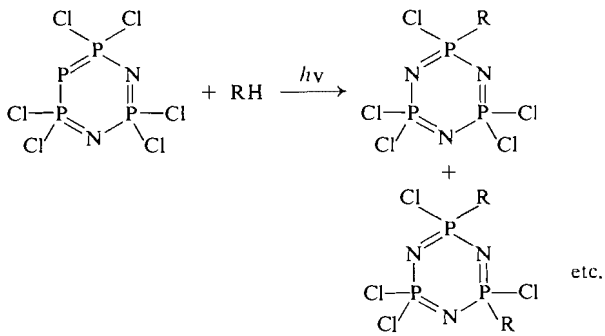
$$R_nX{=}YR_m \xrightarrow{h\nu} R_nX{:}\quad {:}YR_m$$

sociation of the heteromultiple bonds of phosphorus–carbon, phosphorus–nitrogen, and analogous sulfur ylides can lead to stable phosphorus and sulfur derivatives and carbene or nitrene species. Most of the evidence for the intervention of carbene and nitrene intermediates in the photoreactions of P=C (1), S=C (2), and S=N (3) ylides comes from comparisons of the products formed in such reactions with those formed when these reactive intermediates are generated by alternate routes.

The relatively few investigations of photoreactions of phosphorus–nitrogen ylides have revealed that a variety of reactions are possible.

Zimmer and Jayawant (4) studied the irradiation of *N*-tert-butyltriphenyliminophosphorane in cyclohexene. They observed the formation of triphenylphosphine, its oxide, *tert*-butylamine, di-*tert*-butylamine, *tert*-butylcyclohexenylamine, 3,3′-bicyclohexenyl, benzene, nitrogen, and hydrogen, which were considered to be derived from competing P—N and C—N bond cleavage as shown in Scheme 1.

Irradiation of cycloiminophosphoranes in hydrocarbon solvents results in low yields of the organo substituted derivatives as the only characterizable products (5).



Our main objective in the present study was to investigate the course of the photoreactions of triphenyliminophosphoranes. Since the uv irradiation of these ylides yields triphenylphosphine and characterizable products derived from the nitrogen containing fragment, we sought to ascertain if the latter were derived from nitrenes formed via photodis-

Experimental

General Description of Equipment and Services

Infrared spectra were recorded with Unicam SP200 or Beckman IR-12 spectrophotometer. The nmr spectra were taken on a Varian A 56-60 spectrometer with tetramethylsilane as an internal standard. Ultraviolet spectra were recorded on either Unicam SP/800 or Cary 14 spectrophotometers.

Mass spectra were obtained on a Perkin-Elmer Hitachi RMU-6E spectrometer using an ionization voltage of 70 eV and an inlet temperature of 175–200°C.

Preparation of Azides

Azides were prepared according to established (16) procedures and purified by passing through a Woelm Alumina (Activity I) column (wt. ratio 10:1) in petroleum ether. Further purification was carried out by recrystallization as ylide.

Preparation of Ylides

Triphenylphosphine (0.1 mol) in benzene (100 ml) was added dropwise at room temperature to 0.11 mol of azides in 100 ml benzene under anhydrous conditions. Evolution of nitrogen occurred instantaneously. The mixtures were stirred overnight, the solvent removed, and the ylides crystallized from benzene – petroleum ether in 60–90% yields (see Table 1).

General Conditions of Irradiation

All solvents were distilled over lithium aluminum hydride or dried over molecular sieve 5A. The reaction mixtures (8–10 m*M*) were made up under dry nitrogen atmosphere. After transfer to the photocell, the photolysates were purged for an hour with helium dried through three trains of anhydrous calcium chloride. A condenser was fitted on the purge gas outlet with an anhydrous calcium chloride drying tube. The source of irradiation was a 200 W Hanovia mercury lamp with the appropriate filter cooling jacket.

Analyses were carried out by gas–liquid partition chromatography on Varian Aerograph Autoprep and Series 1200 gas chromatography units. The column used was 6 ft × $\frac{1}{8}$ in. (6 ft × $\frac{1}{4}$ in. for preparative gas chromatography), 20% SE-30 silicone oil stationary phase on 100–200 mesh HMDS washed Chromosorb W support. Each analysis was temperature programmed from 60–300°C at a rate of 4°C per minute.

Yields were determined by inclusion of an octadecane internal standard (IS) in the reaction solution and applying the usual equations:

$$\text{Specific response} = \frac{\text{Wt. X}}{\text{Response X}} \div \frac{\text{Wt. IS}}{\text{Response IS}}$$

$$\text{Wt. X} = \text{Specific response} \times \frac{\text{Response X}}{\text{Response IS}} \times \text{Wt. IS}$$

Irradiation of Ylides 1–4

A 30 m*M* solution of the ylide in 110 ml of benzene (with octadecane as internal standard) was irradiated for 8 h through a Pyrex filter cooling jacket. The reaction mixture was concentrated to ~10 ml and subjected to glpc analysis. The ratio of ylide to octadecane remained unchanged from the initial concentrations and no triphenylphosphine was detected. Evaporation of the solvent and recrystallization from benzene/petroleum ether gave 90% recovery of the ylide.

Irradiation of Ylides 5, 8–11, 18

A 25–30 m*M* solution (clear to pale yellow) of each ylide in benzene (110 ml) with octadecane internal standard was irradiated for 1 h through a Pyrex filter cooling jacket. The

photolysate (brick red to brown) was concentrated to ~10 ml and subjected to glpc analysis. The identity of azoaryl, aryl amine, triphenylphosphine, and triphenylphosphine oxide was determined by mixed injection with authentic samples. The yields given in Table 2 were determined as described above. The photoreactions listed in Table 3 were carried out in a similar manner except that the initial ylide concentrations were 10 m*M*.

Quantum Yield Determination for **5**

The method of Hatchard and Parker (20) was followed. The light source was found to emit 1.05×10^{15} photons per second. Ylide consumption as well as triphenylphosphine and azobenzene formation for the first 10 min, when absorption interference from azobenzene was negligible, were determined by glpc with authentic samples using octadecane as internal standard.

Irradiation of Ylide **13**

A 25 m*M* solution (110 ml) of ylide **13** in benzene was irradiated through a Pyrex filter for 3 h. The photolysate was concentrated to 10 ml and analyzed by glpc. Comparison of the retention characteristics of the photolysate components with 2-ethyl-2,3-dihydroindole and 2-methyltetrahydroquinoline generated by photocyclisation of *o*-butylphenyl azide (9) revealed these components were not formed (<0.1%) during irradiation of ylide **13**. Two components were detected (85%) in addition to triphenylphosphine (90%) and 2-butylaniline (5%) and were isolated from the photolysate by preparative glpc. Mass calcd. for $C_{20}H_{26}N_2$: 295 (M^+); found: 294 (M^+).

They were found to interconvert upon separate irradiation and possessed uv_{max} at 320 and 285 nm. By analogy with *trans* (λ_{max} 319 nm) and *cis* (λ_{max} 280 nm) azobenzene (21) these two compounds are considered to be the *trans*- and *cis*-*o*,*o*′-dibutylazobenzenes.

Irradiation of Ylide **14**

Solutions (110 ml) of ylide **14** (27 m*M*) in the solvents given in Table 4 containing octadecane standard were each irradiated for 9 h through a Pyrex filter. The photolysate was concentrated to 10 ml and analyzed by glpc. Biphenyl, *o*-aminobiphenyl, carbazole, triphenylphosphine, and azobiphenyl were identified by mixed injection with authentic samples. Yields given in Table 4 were calculated in the usual manner.

Irradiation of 2-Aminobiphenyl with Triphenylphosphine

A 110 ml benzene solution of 2-aminobiphenyl (0.856 g) and triphenylphosphine (1.336 g) with octadecane as internal standard was irradiated for 6 h with air as purge gas. *o*-Aminobiphenyl remained unreacted but triphenylphosphine was partially converted to triphenylphosphine oxide (46.8%).

Irradiation of **3** *in Presence of Phenyl Azide*

A 110 ml benzene solution of ylide **3** (1.0 g) and phenyl azide (0.8 g) containing octadecane standard was irradiated for 6 h through Pyrex filter. Analysis of the concentrated photolysate by glpc indicated no asymmetric azobenzene or triphenylphosphine was formed. Azobenzene (40%) and aniline (<1%) were formed. Ylide **3** remained unreacted.

Irradiation of p-*Tolyl Azide and Ylide* **5** *Mixture*

A 110 ml benzene solution of *p*-tolyl azide (0.37 g) and ylide **5** (1.0 g) containing octadecane standard was irradiated for 3 h through a Pyrex filter. The photolysate was concentrated to 10 ml and analyzed by glpc (see Discussion).

Irradiation of **18** *and Phenyl Azide Mixture*

A benzene solution (110 ml) of phenyl azide (0.40 g) and ylide **18** (1.05 g) was irradiated for 3 h through a Pyrex filter. The photolysate was concentrated to 10 ml and analyzed by glpc (see Discussion).

Irradiation of **5** *and* **18**

A 110 ml benzene solution of ylide **5** (0.7 g) and ylide **18** (0.6 g) was irradiated for 3 h through a Pyrex filter. The photolysate was concentrated to 10 ml and analyzed by glpc (see Discussion).

Irradiation of Methyl Azidoformate and **5**

A 110 ml benzene solution of methyl azidoformate (0.3 g) and ylide **5** (1.0 g) was irradiated for 3 h through a Pyrex filter. The photolysate was concentrated to 10 ml and analyzed by glpc. Ylide **3** and azobenzene were the only products formed.

Irradiation of Ylide **19**

An ether solution (110 ml) of ylide **19** (1 g) containing octadecane standard was irradiated for 12 h through a Pyrex filter. The photolysate was concentrated to 10 ml and analyzed by glpc. Products listed in Table 6 were identified by mixed injection with the authentic samples. The major products, **20** and

triphenylphosphine were isolated by preparative glpc. Mass calcd. for $C_{12}H_{21}N$: 179 (M^+); found: 179 (M^+).

Irradiation of Ylide **23**

A 110 ml ether solution of ylide **23** (1 g) containing octadecane standard was irradiated for 12 h through a Pyrex filter. The photolysate was concentrated to 10 ml and analyzed by glpc. Triphenylphosphine and imine, **24**, were isolated by preparative glpc. For **24** mass calcd. for $C_{14}H_{13}N$: 195 (M^+); found: 195 (M^+). Acid hydrolysis of **24** afforded benzaldehyde and benzylamine.

Irradiation of Ylide **26**

A benzene solution (110 ml) of ylide **26** (0.5 g) containing octadecane standard was irradiated for 6 h through a Pyrex filter. The photolysate was concentrated to 10 ml and analyzed by glpc. Triphenylphosphine and *N*-phenylbenzophenone imine, **27**, were the only products formed. For **27** mass calcd. for $C_{19}H_{15}N$: 257 (M^+); found: 257 (M^+). The imine (**27**) was identical to the condensation product of aniline and benzophenone.

Results and Discussion

The triphenyliminophosphoranes used in this study were prepared by reacting triphenylphosphine with the corresponding azide (6). The iminophosphorane products were characterized (Table 1, Experimental) and stored under dry nitrogen until use. Irradiations were generally carried out using a medium pressure Hg lamp in a Pyrex vessel (>300 nm). Because of the hydrolytic instability of most iminophosphoranes, irradiations were conducted in freshly distilled, dry solvents under dry nitrogen or helium. Under these irradiation conditions, *N*-benzenesulfonyl- (**1**), *N*-benzoyl- (**2**), *N*-carbomethoxy- (**3**), and *N-cis*-1,2-diphenylvinyl-triphenyliminophosphoranes (**4**) are stable. These ylides were recovered in nearly quantitative yield after 8 h of irradiation.

$Ph_3P{=}N{-}R$
1 R = $SO_2C_6H_5$
2 R = COC_6H_5
3 R = CO_2CH_3
4 R = (*cis*)CPh=CHPh

The photochemical stability of **1–4** parallels the stability of such ylides toward hydrolysis and reaction with polar bonds (6). Ylides **1–4** possess the common feature of nitrogen substituents that allow extensive resonance delocalization of the nitrogen lone pair. This delocalization leads to an alteration of the uv absorption spectra of these ylides compared to photolabile triphenyliminophosphoranes. The uv spectra of all triphenyliminophosphoranes studied possess an intense ($\varepsilon \approx 1.35 \times 10^4$) broad absorption in the 220–280 nm region due to the aromatic phosphorous substituents. In addition there is a weak ($\varepsilon \approx 10^2$) absorption shoulder centered at 315 nm in photolabile triaryliminophosphoranes. This latter absorption is in the borosilicate transparent region of the uv and undoubtedly is receiving irradiation in the present experiments. We attribute this absorption to the $n \rightarrow \pi^*$ transition of the ylide nitrogen lone pair. In the photostable ylides (**1–4**) the 315 nm absorption is not noticeable.

Irradiation of *N*-phenyltriphenyliminophosphorane (**5**) in benzene led to nearly quantitative yields of triphenylphosphine (**6**) and azobenzene (**7**). These products were identified by chromatographic isolation and comparison with authentic samples. The quantum yield for this irradiation based on azobenzene formation was 0.7. In several runs of this and other ylide photoreactions the formation of both triphenylphosphine oxide and amine (aniline in this case) was noted. The yield of these products was reduced when moisture was rigorously excluded from the photolysis solution. We therefore attribute their formation to ylide hydrolysis.

Substitution of the *N*-aryl ring with electron withdrawing (*p*-Br (**8**), *p*-NO_2 (**10**)) or electron donating (*p*-OCH_3 (**9**), *o*-tolyl (**11**), and *p*-tolyl (**18**)) groups did not noticeably alter the course of the photoreaction (Table 2).

Comparison of the course of photolysis of phenyl azide with the photolysis of ylide, **5**, in benzene revealed that only a small amount of azobenzene was formed from the azide photolysis (7). Most of the azide was converted to aniline.

Several attractive mechanisms come to the fore in considering the photoconversion of iminophosphoranes to azo compounds. These can be envisioned as involving reaction via an excited ylide (reaction sequence *a,c* or *a,d*) or a nitrene (*b,e*; *b,c*; or *a,d*). Since reaction between highly reactive species, i.e. excited ylide and nitrene generated in low concentration, is less probable than reaction of these same species with available solvent or ylide, pathways such as *a,d* and *b,e* can be eliminated from consideration. One is therefore led to consider the reaction as proceeding via excited ylide combination with ylide (*a,c*) or nitrene combination with ylide (*b,c*). To

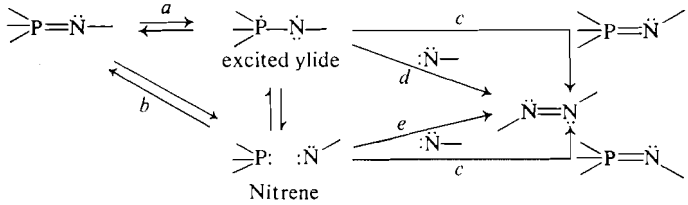
*Ph_3PO: photolysis of *p*-NO_2-phenyl ylide yields many additional, very complicated products probably due to deoxygenation by Ph_3P formed during photolysis.

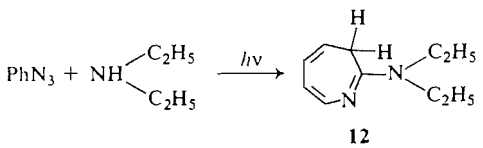


differentiate between these two routes, a search for independent evidence for the intervention of aryl nitrenes in these reactions was conducted.

It was considered likely that the failure of aryl azides to produce the high yields of azo compounds which are ordinarily obtained from ylide photoreactions could be due to the lesser nucleophilicity of azides compared to that of ylides. This difference would lead to a lower rate of reaction of any nitrene intermediates with their parent azides allowing alternate reactions such as hydrogen abstraction to proceed.

To increase the likelihood that any nitrene generated during ylide photolysis would be trapped by reaction with substrates other than ylide, we investigated the photolysis of **5** in the presence of various solvents (Table 3). We varied the reactivity of the solvent to include nucleophilic olefins (cyclohexene, styrene, dihydropyran), solvents capable of undergoing facile hydrogen abstraction reactions (cumene), and nucleophilic solvents capable of reaction with any nitrene generated (acetonitrile, diethylamine). In only one case were products detected which were attributable to reaction other than azo compound formation or ylide hydrolysis. This was the formation of aniline (but no triphenylphosphine oxide) from irradiation of **5** in cyclohexene. Although this was presumably due to allylic hydrogen abstraction of the photogenerated intermediate with cyclohexene, no products such as 3,3′-dicyclohexenyl were detected.

The irradiation of **5** in diethylamine was designed to trap any nitrene formed as an azepine. This and related nucleophiles have been reported to trap phenylnitrene generated from a variety of sources (8) with the concomitant formation of azepines (**12**).



12

We repeated (7, 8) the irradiation of phenyl azide in diethylamine and indeed isolated azepine **12**. When irradiation of the corresponding ylide **5** was conducted under the same reaction conditions, no azepine was detected by glpc or tlc.

Failing to obtain any evidence for intermolecular reaction of suspected nitrene intermediates in the foregoing ylide irradiations, attention was directed to the detection of intramolecular reactions. We irradiated the triphenyliminophosphoranes **13** and **14**, respectively, from *o*-butylphenyl azide and its *o*-phenyl analog. Irradiation of ylide **13** in benzene gave only triphenylphosphine, 2-butylaniline, and azoaryls. No insertion into the *ortho* aliphatic side chain of the ylide was observed. This contrasts with the reported production of moderate yields of C—H insertion products when *o*-butylnitrobenzene is reduced with triethylphosphite (9) or when the corresponding azide is irradiated in inert solvent (10).

Irradiation of the azide from which ylide **14** was derived has been studied in some detail. The important azide reaction characteristics for the present study were considered to be the reported efficient formation of carbazole (**15**) when the reaction was carried out under singlet sensitization (11) and the variation of product distribution with solvent (11). Both facets of the reaction were used in arguments that were later confirmed by flash irradiation (12) to invoke a nitrene intermediate. Irradiation of ylide **14** in a variety of solvents gave nearly quantitative yields of azobiphenyl, small amounts of *o*-aminobiphenyl, triphenylphosphine, and its oxide but no carbazole. Singlet sensitization of the reaction did not yield any detectable amount of carbazole and the nature of the solvent had no appreciable effect on product distribution (Table 4).

When dry air was used as a purge gas during the irradiation of ylide **14** in benzene, carbazole was formed in good yield (Table 5). Since it is known (13) that 2-aminobiphenyl undergoes oxidative cyclization to carbazole under similar conditions 2-aminobiphenyl was irradiated in the presence of triphenylphosphine with oxygen as the purge gas. The amine was recovered unreacted and no carbazole was detected.

The most attractive remaining route for the formation of carbazole from ylide in the presence of oxygen is via triphenylphosphine deoxygenation of *o*-nitrosobiphenyl (**16**) formed by oxygenation of ylide **14** (Scheme 2). Indeed *o*-nitrosobiphenyl was detected in the photolysate when the irradiation of **14** was conducted using oxygen as a purge gas, condi-

tions which might be expected to result in the consumption of triphenylphosphine prior to its reaction with *o*-nitrosobiphenyl.

It should be pointed out that azobiphenyl can be formed from ylide **14** by thermal or photoreaction with *o*-nitrosobiphenyl.

To determine whether aryl nitrenes could be trapped by ylides under our conditions, phenylnitrene was generated photochemically and thermally from phenyl azide in the presence of a photochemically stable ylide (**3**). The ylide remained unreacted under both sets of conditions and no triphenylphosphine, its oxide or carbomethoxyazoaryl (**17**) was formed.

When *p*-tolylnitrene from *p*-tolyl azide was generated thermally in the presence of ylide **5**, the ylide remained unreacted. However, when *p*-tolyl azide and **5** were irradiated in benzene, the expected azoaryls were formed. The same three azoaryls were formed when *N*-*p*-tolyltriphenyliminophosphorane (**18**) and phenyl azide were irradiated and when ylides **5** and **18** were irradiated together. When methyl azidoformate and ylide **5** were irradiated together, azobenzene and photostable ylide (**3**) were formed.

We conducted several irradiations to determine the course of reaction of *N*-alkyltriphenyliminophosphoranes (Table 6). As seen from these data, the irradiation of these ylides induces both P—N and C—N cleavage depending on the substitution. The most prominent reaction observed was migration

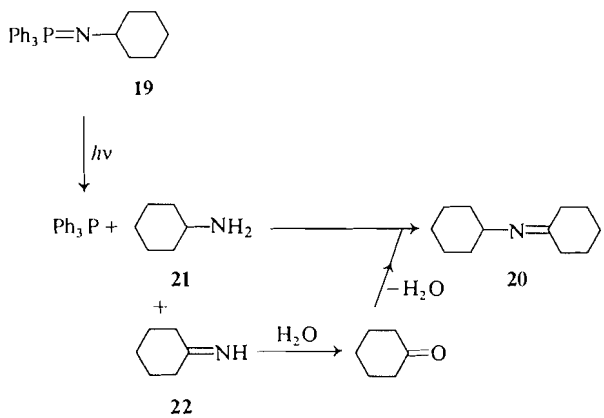
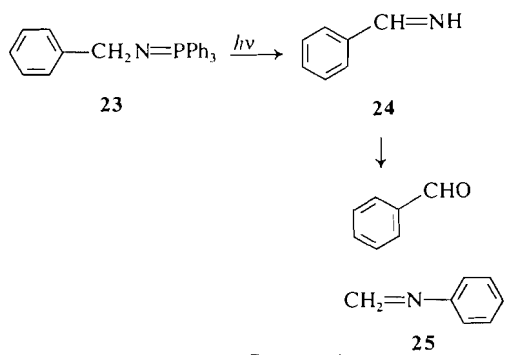
or loss of a substituent bound to the carbon bearing nitrogen.

Irradiation of *N*-cyclohexyltriphenyliminophosphorane (**19**) gave triphenylphosphine, its oxide, *N*-cyclohexylcyclohexanone imine (**20**), and cyclohexylamine (**21**) (Scheme 3). Subtracting the amount of cyclohexylamine formed from presumed hydrolysis of the ylide (equimolar to triphenylphosphine oxide formed) revealed that the ratio of cyclohexanone imine (**22**) to amine (**21**) formed from the photoreaction is in good agreement with that formed during photolysis of cyclohexyl azide (14). The interpretation that this photoreaction involves a nitrene can't be made with certainty since imine **20** could also be derived from reaction of cyclohexanone with ylide **19**.



SCHEME 3



SCHEME 4

Irradiation of *N*-benzyltriphenyliminophosphorane (**23**) gave essentially the same type of product distribution as ylide **19** (Scheme 4). Although both phenyl and hydrogen migration occur to the same extent during the photolysis of benzyl azide (14), only products (**24**) of hydrogen migration are isolated from the irradiation of ylide **23**. The trimer of imine **25** which should have been derived from phenyl migration was synthesized independently from

aniline and formaldehyde but not detected in the photolysate of ylide **23**. Irradiation of *N*-tritylimino-phosphorane, **26**, gave imine **27**, the product of trityl azide photodecomposition (15).

$$\underset{\mathbf{26}}{Ph_3CN{=}PPh_3} \xrightarrow{h\nu} \underset{\mathbf{27}}{Ph_2C{=}N{-}Ph} + Ph_3P$$

The reactions observed upon irradiation of the triaryliminophosphoranes studied are easily attributable to excited ylide intermediates. In all instances where ylide structure would allow detection of characteristic nitrene reactions, such were not observed. From a synthetic point of view the photoreactions of triaryliminophosphoranes represent an extremely efficient route to diaryl azo compounds.

Some stereochemical aspects of two-bond $^{13}C-^{1}H$ spin–spin coupling. Sign determination in natural abundance ^{13}C nuclear magnetic resonance spectra[1]

NATSUKO CYR, GORDON K. HAMER, AND ARTHUR S. PERLIN

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7

Received July 19, 1977

NATSUKO CYR, GORDON K. HAMER, and ARTHUR S. PERLIN. Can. J. Chem. **56**, 297 (1978).

The magnitudes and signs of two-bond $^{13}C-^{1}H$ coupling constants (^{2}J) in the array $O-^{13}C_A-C_B-^{1}H$, appear to be determined by the relative orientations of the $O-^{13}C_A$ and $C_B-^{1}H$ bonds, as shown with a variety of carbohydrate derivatives. The data have been observed from natural abundance ^{1}H-coupled ^{13}C nmr spectra, and signs of ^{2}J have been determined by the 'selective population transfer' technique. When C_B bears one oxygen atom, the observed ^{2}J values range from -6 to 0 Hz, whereas a range of 0 to $+8$ Hz is found when C_B bears two oxygen atoms. By contrast, for arrays in which C_B bears one oxygen atom and C_A two, the ^{2}J values vary from -6 to $+6$ Hz. In general, the results confirm earlier indications that the larger the torsional angle between the $O-^{13}C_A$ and $C_B-^{1}H$ bonds, the more positive is the value of ^{2}J. These findings are supported by calculations for model compounds, i.e., propane-1,1,2-triol and butane-2,3-diol.

NATSUKO CYR, GORDON K. HAMER et ARTHUR S. PERLIN. Can. J. Chem. **56**, 297 (1978).

Les amplitudes et les signes des constantes de couplage $^{13}C-^{1}H$ à travers deux liaisons (^{2}J) dans des arrangements $O-^{13}C_A-C_B-^{1}H$ semblent être déterminées par les orientations relatives des liaisons $O-^{13}C_A$ et $C_B-^{1}H$; ces conclusions dérivent d'observations faites à l'aide d'un certain nombre de dérivés de carbohydrate. On a obtenu des données à partir de spectres rmn ^{13}C en abondance naturelle et couplés avec le proton; on a déterminé les signes de ^{2}J par la technique de transfert sélectif de population. Lorsque C_B porte un atome d'oxygène, les valeurs ^{2}J observées varient de -6 à 0 Hz alors que l'on trouve des valeurs allant de 0 à $+8$ Hz lorsque C_B porte deux atomes d'oxygène. Par opposition, les arrangements dans lesquels C_B et C_A portent respectivement un et deux atomes d'oxygène, les valeurs de ^{2}J varient de -6 à $+6$ Hz. En général les résultats confirment des indications antérieures à l'effet que des angles de torsion plus grands entre les liens $O-^{13}C_A$ et $C_B-^{1}H$, provoquent des valeurs plus positives de ^{2}J. On trouve des données expérimentales appuyant des conclusions obtenues à l'aide de calcul sur des composés modèles comme le propanetriol-1,1,2 et de butanediol-2,3.

[Traduit par le journal]

Introduction

Coupling between a carbon-13 nucleus and a proton across two bonds ($^{2}J_{C-H}$) varies with the orientation of substituents appended to the carbon atom (1–5). For experimental reasons, studies of ^{2}J values in the sugar series have dealt mainly with ^{1}H spectra of ^{13}C-enriched compounds (2–5), and have been restricted largely to terminally-labelled positions (i.e. coupling between C-1 and H-2, or C-6 and H-5). Due to recent developments in FT nmr spectroscopy, natural abundance ^{13}C spectra offer a far more convenient and versatile source of $^{13}C-^{1}H$ coupling information (6–8). The current data have been obtained in this manner, making possible a much fuller description than heretofore available of the stereochemical dependence of ^{2}J in carbohydrate molecules.

Results and Discussion

Influence of Substituent Orientation

A wide variety of structural and geometrical arrangements of ^{13}C and ^{1}H nuclei separated by two bonds is found among carbohydrate molecules. In the vicinity of the anomeric centre, stereochemical differences give rise to a large range of values for coupling between C-1 and H-2: as shown recently by ^{1}H spectroscopy of ^{13}C-1 labelled β-D-glucopyranose, α-D-glucopyranose, and 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose, respectively, $^{2}J_{C\text{-}1,H\text{-}2}$ is -5.7 Hz, 0 Hz, and $+5.5$ Hz (5). During the current study, these results were confirmed with non-enriched samples of the same compounds by ^{13}C nmr spectroscopy, in combination with the 'selective population transfer' (spt) technique for sign determination (9–12) (see below). That is, the respective $^{2}J_{C\text{-}1,H\text{-}2}$ values were found to be -5.7, 0, and $+5.5$ Hz.[2]

In accounting empirically for such differences, it has been suggested (4, 5) that the magnitude of ^{2}J is

[1]Presented in part at the 59th Canadian Chemical Conference, Chemical Institute of Canada, London, Ont., June 6–9, 1976.

[2]It should be noted that these values and others presented below (Table 1) are *observed spacings*. Undoubtedly, some are not true ^{2}J values, owing to second order effects, as discussed earlier (8). The estimated error in the measurement of these spacings is ± 0.2 Hz, due to the limits of the computer digital resolution.

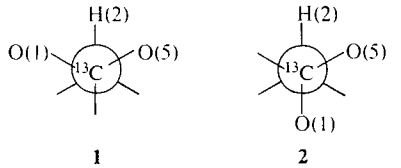
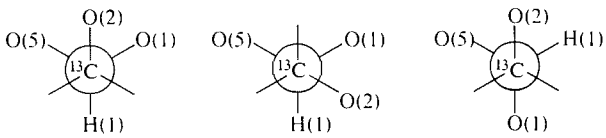
affected by the orientation of the O—^{13}C—O bonds with respect to the C-2—^{1}H-2 bond. For example, in β-glucose the ^{13}C-1—O-1 and C-2—^{1}H-2 bonds are *gauche* (**1**) whereas the corresponding bonds are *antiperiplanar* (**2**) in the α-anomer. It appears, therefore, that when the dihedral angle between these bonds is large, a *positive* contribution is made to ^{2}J.



1 **2**

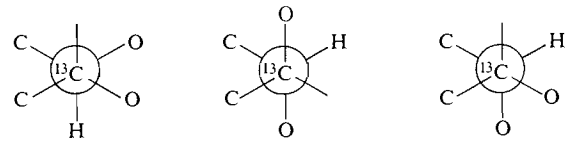


3 **4*a*** **4*b***

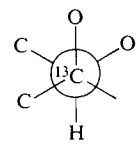
Other arrays of ^{13}C and ^{1}H nuclei described below were previously not amenable to the ^{13}C-enrichment and ^{1}Hmr approach because of experimental limitations, as already noted. One such system involves coupling between ^{13}C-2 and the anomeric proton (^{1}H-1), which is the converse of the pathway in **1** and **2**, in that the carbon bears only a single oxygen whereas the proton is flanked by two oxygens. Two basically different spatial arrays of this kind have been examined in (*a*) β-D-mannopyranose, methyl β-D-mannopyranoside, and 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose, which exhibit spacings ($^{2}J_{\text{C-2,H-1}}$) of 8, 7, and 5.6 Hz, respectively, and (*b*) in α- and β-D-glucopyranose, α- and β-D-galactopyranose, and α-D-mannopyranose, for each of which $^{2}J < 1$ Hz. That is, a large spacing is observed when the ^{13}C-2—O-2 bond is *anti* (or approaches such an orientation) with respect to the C-1—^{1}H-1 bond (**3**, $\phi \sim 120$–$180°$), whereas there is no appreciable two-bond coupling when they are *gauche* (e.g., **4*a*** or **4*b***).[3] As illustrated below for the di-*O*-isopropylidene derivative, representative of **3**, a sign determination by the spt technique showed that $^{2}J_{\text{C-2,H-1}}$ is +5.6 Hz; analogously, the ^{2}J values for the β-*manno* compounds are taken to be +8 and +7 Hz. Therefore, these findings are consistent with the earlier comments (4, 5) to the effect that a ^{13}C—O bond makes a *positive* contribution to ^{2}J when angle ϕ is large, as in **3**.

A type of array that is most common in carbohydrate molecules is one in which each of the vicinal carbons bears only a single oxygen and hydrogen: i.e., two-bond coupling involving secondary carbons of aldo- and ketopyranoses. Data for some 90 examples in this general category have been accumulated during the course of studies in this laboratory, and representative values are given in Table 1. In a number of instances, regioselectively deuterated analogs have been used to check the origin of ^{1}H coupling with the ^{13}C nucleus of interest. As shown in Table 1, the data fall into two categories: invariably, the observed spacing is close to 5 Hz when a *gauche* arrangement of the ^{13}C—O—C—^{1}H bonds (**5*a*–5*c***) pertains, whereas when these bonds are *anti* (**6**) there is no detectable interaction between the nuclei ($^{2}J < 1$ Hz).

As a representative of **5**, methyl β-D-glucopyranoside was selected in order to determine the sign of coupling between ^{13}C-2 and ^{1}H-3 by the spt technique. It was found in this instance that ^{2}J is *negative*, and therefore it appears reasonable to



5*a* (O_e,O_e) **5*b*** (O_a,O_a) **5*c*** (O_a,O_e)



6

assume that the other examples of **5** studied, each of which exhibits a two-bond coupling of ~5 Hz, also represent negative values of ^{2}J. Hence, in comparing the geometries illustrated in **5** and **6**, an *anti* orientation of the ^{13}C—O bond relative to the C—^{1}H bond is again found to be associated with a *positive* contribution to the absolute value of ^{2}J.

For purposes of comparison with these findings, MO calculations have been carried out for model systems. The theoretical angular dependence of $^{2}J_{\text{C–H}}$ in structures such as **1** and **2**, or **3** and **4**, was assessed through calculations with propane-1,1,2-triol, and with butane-2,3-diol for structures of type **5** and **6**. Each of the plots obtained for these calculated values of $^{2}J_{\text{C–H}}$ vs. dihedral angle takes the general shape illustrated in Fig. 1, which is similar to results calculated earlier for simpler alcohols. Most of the coupling constants obtained either by the CNDO/2 (13) or INDO finite perturbation (14) method, were of negative sign and were smaller than

[3]Differences in the relative orientations of the *vic*-O atoms, as in **4*a*** as compared with **4*b***, appear to have no appreciable influence on the magnitude of ^{2}J.

*Data for the anhydrosugars were obtained in collaboration with R. G. S. Ritchie.

observed values. Nevertheless, the trend represented by Fig. 1, in which an increase of ϕ from 60 → 180° is accompanied by an increasingly positive value of ^2J, is in accord with the experimental results of this study.

These calculated results show consistency also with another feature of the observed data. That is, the ^{13}C–^1H coupling pathway represented by structures **3**, **4***a*, and **4***b*, in which the proton is bonded to a carbon bearing two oxygens is characterized by ^2J values more positive than those of the other arrays of nuclei. Experimentally, the effect is similar to that found (15) in comparing $^2J_{C\text{-}2,H\text{-}1}$ in the series: ethane (−4.8 Hz), chloroethane (2.6 Hz), and 1,1-dichloroethane (~1 Hz) (although the signs of the latter two values are not known), which implies that an electronegative element makes a positive contribution to ^2J. Hence, this effect is reproduced qualitatively in Fig. 1 by the more positive values of coupling between C-2 and H-1 than between C-1 and H-2 in 1,1,2-propanetriol.

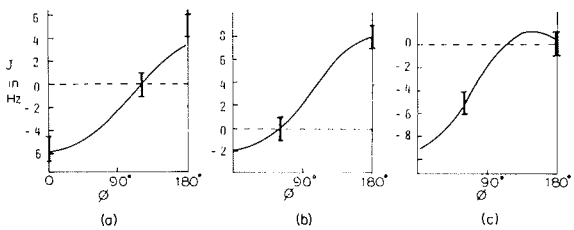

FIG. 1. Dependence of $^2J_{C-H}$ on the magnitude of the torsional angle (ϕ). The curves represent values of ^2J calculated by the CNDO/2 method for the following model compounds. (*a*) $(OH)_2{}^{13}CH—C^1H(OH)CH_3$, for types **1** and **2**; (*b*) $(OH)_2C^1H—{}^{13}CH(OH)CH_3$, for types **3** and **4**; (*c*) $CH_3—(OH)^{13}CH—C^1H(OH)CH_3$, for types **5** and **6**. The vertical bars are examples of ^2J values observed for carbohydrate molecules containing arrays of nuclei analogous to those in the model compounds. The calculated values are proportional to these ^2J values, although on an arbitrary scale.

Determination of the Sign of $^2J_{C-H}$

The sign of $^2J_{C-H}$ was determined by the pulsed double resonance selective population transfer (spt) technique (10–12). In the spt experiment, a selective pulse applied to a given ^1H transition alters the equilibrium distribution of spins in the upper and lower energy levels. The effect on the ^{13}C spectrum

is monitored by a conventional $\pi/2$ pulse applied immediately after the ^1H irradiation. There are three practical requirements for the experiment (12): (*a*) the power of the ^1H pulse ($\gamma H_2/2\pi$) must be low enough that adjacent transitions are not perturbed (i.e. $\gamma H_2/2\pi < {}^3J_{HH}$); (*b*) the pulse time (t) must be adjusted to give a significant population redistribution (e.g., complete population inversion requires that $t = \pi/\gamma H_2$); (*c*) the pulse must not be so long that secondary population changes occur (i.e. $t \ll T_1$ where T_1 is the shortest spin-lattice relaxation time for all connected transitions). For monosaccharides, where $T_1(^{13}C) \sim 0.5$–1 s (16–18) and ${}^3J_{HH} \sim 3$–8 Hz, these requirements dictate that $t \sim 0.2$ s and $\gamma H_2/2\pi \sim 1$–4 Hz.

In analyzing the spt experiments the ^{13}CH–CH spin system was treated as an AMX case; i.e., $^{13}C(X)H(A)$—CH(M) (Fig. 2); J_{AM} was obtained from the ^1H nmr spectrum (${}^3J_{HH}$), whereas J_{AX} and J_{MX} were obtained from the ^1H-coupled ^{13}C spectrum (${}^1J_{CH}$ and ${}^2J_{CH}$, respectively). The exact resonance frequency of H_A (ν_A) was determined graphically (19) from a series of single-frequency off-resonance decoupled ^{13}C spectra (decoupler power, $\gamma H_2/2\pi = 350$ Hz). Selective population transfer experiments were then carried out at each of the four A transition frequencies ($\nu_A \pm \frac{1}{2}(J_{AX} \pm J_{AM})$), using a ^1H power level $\gamma H_2/2\pi \sim 2$–3 Hz and a pulse time of 0.2 s (these parameters being adjusted to give the maximum response). Generally 1000–1500 transients were accumulated (sample concentration ~ 2 *M*). Selective population transfer difference spectra (20, 21) were recorded by subtracting the normal ^1H-coupled ^{13}C spectrum (obtained under otherwise identical conditions) from the spt response. Typical experimental results are shown in Figs. 3 and 4.

The Sign of ${}^2J_{C\text{-}1,H\text{-}2}$ *in* β-D-*Glucose (Solvent, D_2O)*

Here ${}^1J_{C\text{-}1,H\text{-}1} = 161$ Hz, ${}^3J_{H\text{-}1,H\text{-}2} = 8.1$ Hz and $|{}^2J_{C\text{-}1,H\text{-}2}| = 5.7$ Hz. Selective irradiation of A1 ($\nu_A - \frac{1}{2}J_{AX} - \frac{1}{2}J_{AM}$) at a power level $\gamma H_2/2\pi = 3$ Hz caused partial inversion of transition X2 and

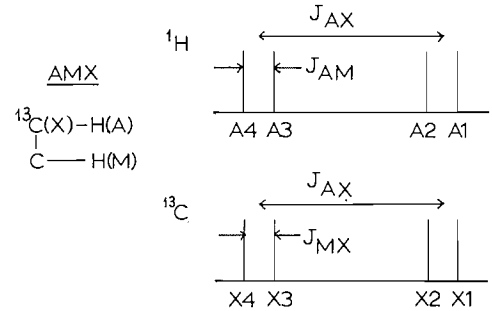

FIG. 2. Stick diagram of the $^1H(A)$ and $^{13}C(X)$ nmr spectra of the $^{13}C(X)H(A)$—CH(M) spin system.

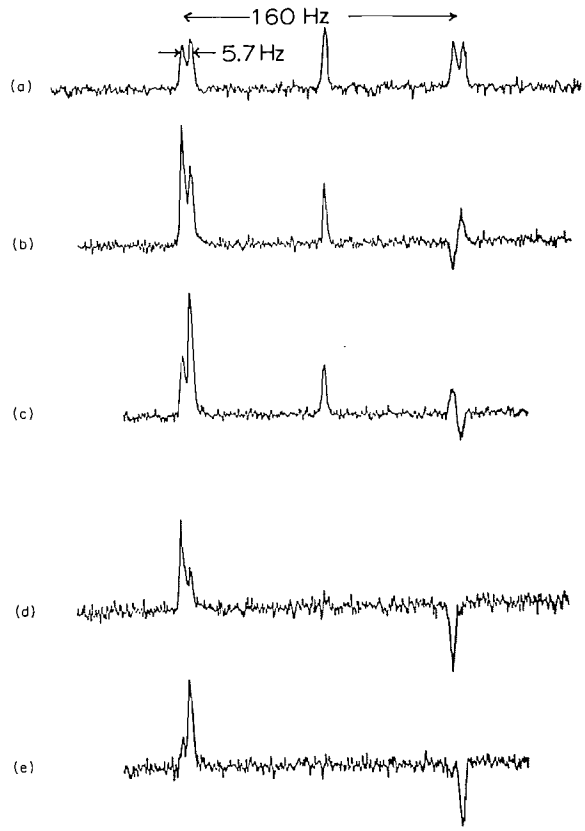

FIG. 3. ^{13}C nmr spectra of the C-1 carbon of β-D-glucopyranose: (*a*) normal ^1H-coupled spectrum; (*b*) spt spectrum obtained by pulsed irradiation at the frequency of transition A1, and (*c*) of transition A2; (*d*) and (*e*) spt-difference spectrum of (*b*) *minus* (*a*), and (*c*) *minus* (*a*), respectively.

enhancement of X4 (Fig. 3*b*). Irradiation of A2 ($\nu_A - \frac{1}{2}J_{AX} + \frac{1}{2}J_{AM}$) caused inversion of X1 and enhancement of X3 (Fig. 3*c*). These results indicate that ${}^2J_{C\text{-}1,H\text{-}2}$ and ${}^3J_{H\text{-}1,H\text{-}2}$ are of opposite sign; i.e. ${}^2J_{C\text{-}1,H\text{-}2} < 0$. Consistent results were obtained for irradiation of lines A3 and A4. The spt-difference spectra (Figs. 3*d* and 3*e*) show that the ^1H irradiation was not completely selective; in Fig. 3*d* for example, X3 is also perturbed. However, since all four A transitions have been examined, there is no ambiguity in this experiment as to the correct sign of ${}^2J$.

The Sign of ${}^2J_{C2,H1}$ *in 1,2:5,6-di-*O*-Isopropylidene-*α*-*D*-Glucofuranose-3-*d*(Solvent, $CDCl_3$)*

The 3-*d* analog of the diketal was used to simplify the ^{13}C–^1H and ^1H–^1H coupling patterns. Here ${}^1J_{C\text{-}2,H\text{-}2} = 160$ Hz, ${}^3J_{H\text{-}1,H\text{-}2} = 3.6$ Hz and $|{}^2J_{C\text{-}2,H\text{-}1}| = 5.6$ Hz. Selective irradiation of A1 ($\gamma H_2/2\pi = 2$ Hz, $t = 0.2$ s) nulled transition X1 and enhanced X3 (Fig. 4*b*). Irradiation of A2 nulled X2 and enhanced X4 (Fig. 4*c*). Thus ${}^2J_{C\text{-}2,H\text{-}1} > 0$. Again, consistent results were obtained for irradiation of A3 and A4.

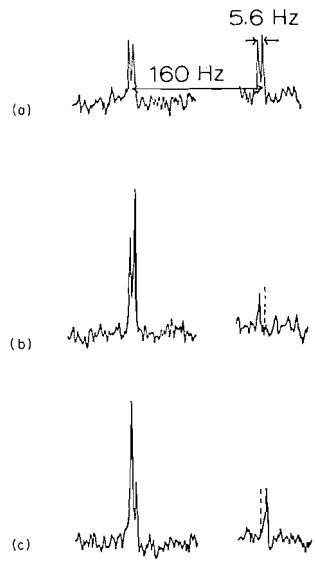

FIG. 4. ^{13}C nmr spectra of the C-2 carbon of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose-3-*d*: (*a*) normal ^{1}H-coupled spectrum; (*b*) spt spectrum obtained by pulsed irradiation at the frequency of transition A1, and (*c*) of transition A2.

In this set of experiments inversion of lines was not clearly evident. This is a consequence of the reduced power level of the ^{1}H irradiation (required for selectivity) and, possibly, secondary population changes during the pulse.

Experimental

Natural abundance ^{13}C nmr spectra were recorded on a Bruker WH-90 FT spectrometer equipped with a B-SV WH model decoupler. However, the 500 ohm 1-turn decoupler output power control was replaced with a 10-turn potentiometer so that the low ^{1}H power levels required in the spt experiments could be set more precisely. A Heathkit model 1B-1103 rf frequency counter was used to monitor the decoupler frequency. Pulse timing was controlled by the Bruker gated multipulser.

Photolysis of 1,2-dipropyl-3,5-diethyl-1,2-dihydropyridine. A model for some elastin cross-links

MIREILLE GUAY AND FRANÇOIS LAMY

Département de Biochimie, Faculté de Médecine, Université de Sherbrooke, Sherbrooke, Qué., Canada J1H 5N4

Received December 21, 1976[1]

MIREILLE GUAY and FRANÇOIS LAMY. Can. J. Chem. **56**, 302 (1978).

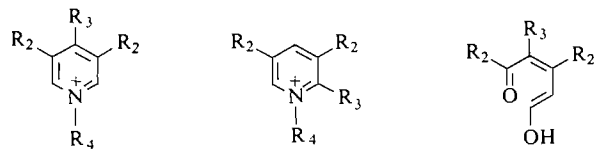
Photolysis of 1,2-dipropyl-3,5-diethyl-1,2-dihydropyridine **4**, at $\lambda > 300$ nm, results in the opening of the ring to give an iminodiene **5**, which upon reduction leads to an aminodiene **6**. The imine **5** releases propylamine at acid p*H*. The dihydropyridine **4** is a model for analogous dihydro compounds which cross-link polypeptide chains in elastin. Thus photolysis would seem to be a specific method for breaking this type of cross-link in the insoluble fibrous protein.

MIREILLE GUAY et FRANÇOIS LAMY. Can. J. Chem. **56**, 302 (1978).

Le noyau du dipropyl-1,2-diéthyl-3,5-dihydro-1,2 pyridine **4**, s'ouvre par photolyse à $\lambda > 300$ nm pour donner un iminodiène **5** qui après réduction conduit à l'aminodiène **6**. L'imine **5** s'hydrolyse à p*H* acide pour produire de la propylamine. La dihydropyridine **4** sert de modèle pour des composés dihydro analogues des liaisons croisées entre les chaînes polypeptidiques de l'élastine. Ainsi la photolyse semblerait être une méthode spécifique pour briser ces liaisons croisées dans la protéine fibreuse insoluble.

Introduction

Elastin, a fibrous protein from connective tissue, is an elastomer composed of polypeptide chains cross-linked by special amino acids: desmosine and isodesmosine **1**, **2**. These consist of tetrasubstituted pyridinium rings.[2] We have studied the photolysis of these compounds at 254 nm (1) and found that in analogy to the work of Kaplan *et al.* (9) the pyridinium salt most probably rearranged to an azabicyclo-[3.1.0]hexenyl carbonium ion which was trapped by water. The resulting product could then open at low p*H* to yield an imine which hydrolysed to give free lysine and an analogue of glutaconaldehyde **3**. Other



1 **2** **3**

$R_n = (CH_2)_n-CH(CO_2H)(NH_2)$

compounds in addition to these aromatic compounds, can cross-link the polypeptide chains in elastin. For example, Paz *et al.* (2) have shown by mass spectrometry that tetrasubstituted dihydro- and tetrahydropyridines were present. Since the general aim of our work is to develop techniques for the selective attack of the elastin cross-links in order to obtain soluble subunits, we thought it appropriate to study the action of uv light upon dihydropyridine compounds. In this paper, we present a study of the photolysis of 1,2-dipropyl-3,5-diethyl-1,2-dihydropyridine, **4**, a model of dihydroisodesmosine.

Compound **4** was synthesized from *N*-butylidenepropylamine (3) by the method of Patrick (4). It was a liquid which was readily oxidized to the corresponding aromatic compound. The final product was obtained by distillation under nitrogen. The structure was confirmed by observing an uv absorption band at 330 nm and nmr signals at 5.43 ppm for the olefinic protons and 3.51 ppm for the methine proton. A specific rotation of +1.68 indicated that the product was a racemic mixture.

Irradiation of **4** was carried out at $\lambda > 300$ nm. To determine the kinetics of the reaction a solution (4.1×10^{-4} M/ℓ) in anhydrous ethanol was irradiated under nitrogen at 15°C, for various lengths of time. The logarithm of the absorbance at 330 nm decreased linearly with time, giving a first-order rate constant $k = 1.46 \times 10^{-3}$ s^{-1}. The quantum yield of the reaction ($\Phi = 0.213$) was determined by a method described by Parker and Hatchard (5), in which a solution of ferrous oxalate was photolysed under exactly the same conditions as those used for **4**. The photochemical susceptibility was calculated to be 571.

For preparative purposes 80 mg of **4** in anhydrous ethanol was photolysed under nitrogen at 15°C for 4 h (Scheme 1). The nmr spectrum exhibited two singlets at 7.76 and 6.04 ppm, and a triplet at 5.26 ppm ($J = 7$ Hz). This suggested that the product of photolysis was **5**, an iminodiene. Attempts to purify

[1]Revision received August 31, 1977.

[2]Trivial names: desmosine, 4-(4-amino-4-carboxybutyl)-1-(5-amino-5-carboxypentyl)-3,5-bis(3-amino-3-carboxypropyl)-pyridinium; isodesmosine, 2-(4-amino-4-carboxybutyl)-1-(5-amino-5-carboxypentyl)-3,5-bis(3-amino-3-carboxypropyl)-pyridinium).

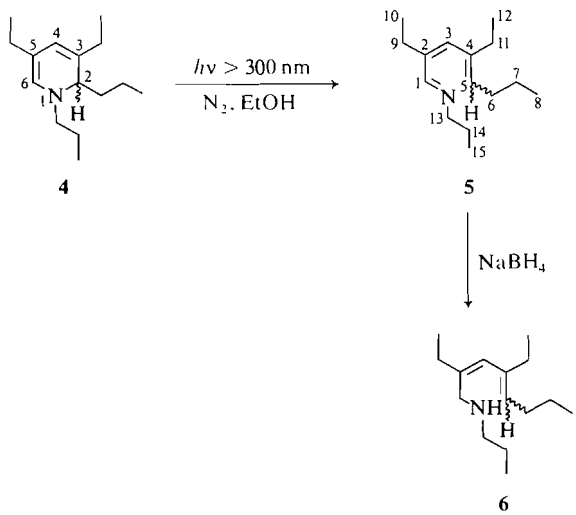

SCHEME 1

5 by chromatography on silica gel, even at 4°C, led to the decomposition of the product. Consequently we were unable to determine if the two isomers **5***a* and **5***b* were present or if only one was favored. In any case **5** was reduced with sodium borohydride to give **6** which was purified by silica gel chromatography. In the nmr spectrum the signal at 7.76 ppm disappeared indicating that the imino group was reduced. It showed signals at 5.65 and 5.20 ppm characteristic of olefinic protons. The structure **6** was confirmed by other spectral data such as the infrared band at 3500–3200 cm^{-1} characteristic of N—H and the observation of a molecular ion with an $m/e = 223$ by mass spectroscopy. A ^{13}C nmr spectrum was recorded and indicated the presence of only one isomer. The elucidation of the structure of this isomer is not simple, even with the help of ^{13}C nmr spectroscopy since in acyclic compounds, several conformations may exist. Four planar conformations are possible for the diene moiety in compound **6**: *cisoid* and *transoid* **6***a* and *cisoid* and *transoid* **6***b*. For the *transoid* conformation of **6***b* an Overhauser effect should be observed between the protons in positions 3 and 5 since these protons have an internuclear distance of 2.4 Å (6). For the *cisoid* conformation of **6***b* this effect would occur between the protons in positions 1 and 5 as these protons are in close proximity. For the two rotamers of **6***a* no effect should be observed at either olefinic proton by irradiation of the protons 1 and 3. The nOe experiments (i.e. irradiation of protons at C(3) and then C(1) were carried out and no area increases were observed, showing that the **6***a* isomer was present.[3] The only uncertainty which remains concerns the *transoid* or *cisoid* nature of the conformation. However this is of little consequence for the mechanism of the photolytic opening itself.

Baldwin and Krueger (7) and Courtot (8) studied the mechanism of the photolytic opening of cyclohexadienes. They have shown that the mechanism is conrotatory, and that the substituents on the saturated carbons rotate in a direction which depends upon the helicity of the diene; therefore two antipodes will give the same open product and two conformers will give two different isomers.

For the original dihydropyridine compound, we can draw the two conformations **4***a*′ and **4***b*′ for one isomer and the two conformations, **4***a* and **4***b*, for the other (Scheme 2). In each case we assume that the unpaired electrons on the nitrogen atom are in a pseudo-axial position. From the examination of models, one can assume that the conformations **4***a* and **4***a*′ of the enantiomeric pair are more stable than **4***b* and **4***b*′ since the propyl group in position 2 is pseudo-axial. Taking into account the general mechanism of cyclohexadiene ring opening (7, 8) we conclude that isomers **4***a* and **4***a*′ will give exclusively **5***a* while **4***b* and **4***b*′ will give **5***b*. Since reduction of the iminodiene gave only **6***a* it is clear that the most stable form of the dihydropyridine is also its most reactive form.

The yield of **6** was only 52%, although **5** was obtained practically quantitatively from **4**. This was because **6** is very volatile and unstable, and was partially lost during experimental manipulations.

The open-chain compound **5** can be easily hydrolysed at acid p*H*, releasing propylamine as detected by chromatography in an amino acid analyzer.

In conclusion, we have shown that dihydropyridine compounds can be photolysed, like the corresponding aromatic compounds, albeit at a different wavelength and according to a different mechanism. In both cases at acid p*H*, an amine is released by the hydrolysis of the imino group which results from the photolytic reactions. The differences observed between the photolysis of the two classes of compound should be useful in the study of the cross-link distribution in elastin itself.

Experimental

The uv spectra were taken on a model 118-C Cary spectrophotometer. The ir spectra were recorded on a Perkin-Elmer spectrophotometer, model 457. Proton nmr spectra (δ value) were taken on a Varian T-60 spectrometer in CCl_4 with TMS as internal standard. The ^{13}C nmr spectra were recorded on a Bruker HX-90 spectrometer with a Nicolet 1083 computer operating in the Fourier transform mode. The solvent was CCl_4 containing 15% deuterated benzene. Chemical shifts were recorded relative to TMS. Mass spectra were recorded in an AEI MS 30 double beam spectrometer. The nOe experi-

[3]To illustrate the sensitivity of the method we detected an average increase of 26% in the intensity of the signals due to olefinic protons, when protons in position 6 were irradiated.

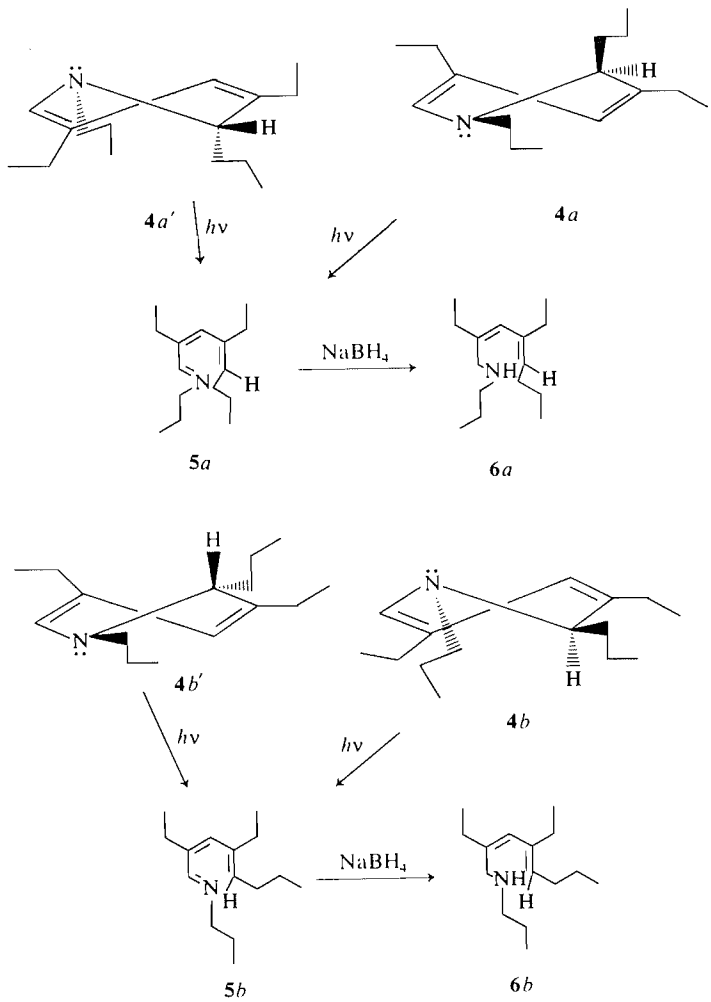

SCHEME 2

ments were recorded on a Bruker WP-60 operating in the Fourier transform mode. Silica gel (100 mesh) for column chromatography was obtained from Malinckrodt chemical works.

System of Photolysis

One Pyrex test tube (diameter = 17 mm) was placed inside a larger one (diameter = 35 mm). The volume between the two contained the solution to be irradiated. A low pressure mercury lamp (model PCQ, Ultraviolet Product Inc., San Gabriel, CA) was placed inside the smaller test tube. The system was closed with a three-holed rubber stopper which permitted the bubbling of nitrogen and the removal of samples. The inside test tube (between the lamp and the solution) served to filter the light at $\lambda > 300$ nm. The effectiveness of this filter was confirmed by irradiating a solution of 3,5-diethyl-1,2-dipropylpyridinium. At a concentration of 1.86×10^{-4} *M* (*A* = 0.980 at 278 nm) the absorbance remained constant for 35 min while a similar solution irradiated with the same lamp for the same length of time, but without the Pyrex filter, decreased in absorbance by 40%.

1,2-Dipropyl-3,5-diethyl-1,2-dihydropyridine 4

Compound **4** was synthesized according to the method of Patrick (4). The nmr spectrum of the crude product showed that it was a mixture of 2-ethyl-2-hexenal, *N*-(2-ethyl-2-hexenylidene)propylamine, 1,2-dipropyl-3,5-diethyl-1,2-dihydropyridine, and an unknown product. Distillation to isolate compound **4** was carried out under nitrogen. The sample, a yellow oil, was at once transferred under nitrogen into bottles with serum stoppers and kept in a freezer. Yield 62%; uv (EtOH) λ_{max}: 330 nm (ε 2510); nmr (CCl_4) δ: 2.88 (2H, t, J = 6.5 Hz, —CH_2—N), 3.51 (1H, bs, C(2)-H), 5.43 (2H, bs, C(4)-H and C(6)-H); ms *m/e* 221 (M^+), 220 ($M^+ - H$), 206 ($M^+ - CH_3$), 192 ($M^+ - C_2H_5$), 178 ($M^+ - C_3H_7$); $[\alpha]_{578}^{25}$ +1.68 (*c* 1.01, EtOH).

N-(2,4-diethyl-2,4-octadienylidene)propylamine 5

The dihydropyridine (84 mg, 0.38 mmol in 140 ml anhydrous ethanol) was irradiated for 4 h at 15°C, under constant nitrogen bubbling. The alcohol was vacuum evaporated at room temperature. The unstable product obtained proved to be *N*-(2,4-diethyl-2,4-octadienylidene)propylamine **5**, ir (liquid film) ν_{max}: 1665 (C=N), 1635 and 1615 cm^{-1} (C=C); nmr (CCl_4) δ: 3.33 (2H, bt, J = 7 Hz, —C(13)H_2—N=), 5.26 (1H, bt, J = 7 Hz, =C(5)H—CH_2), 6.04 (1H, bs, =C(3)H—C), 7.76 (1H, s, —C(1)H=N—); uv (EtOH) λ_{max}: 226 nm (ε 7150).

1-Propylamino-2,4-diethyl-2,4-octadiene **6**

The photolytic product **5** (254 mg, 1.15 mmol) was dissolved in 10 ml of cold methanol. Sodium borohydride (50 mg, 1.3 mmol) was added. The reaction proceeded at 0°C, for 2 h under agitation. The methanol was then evaporated under vacuum at room temperature and the residue was dissolved in 25 ml H_2O. The solution was extracted four times with 15 ml of ether. The combined extracts were dried on sodium sulfate, filtered, and vacuum evaporated at room temperature. The residue (266 mg) was chromatographed on silica gel at 4°C. The reduced compound **6**, 1-propylamino-2,4-diethyl-2,4-octadiene was recognized by thin-layer chromatography. It was a volatile, pale yellow liquid; 113 mg was recovered which represented a yield of 52% taking in account the presence of 15% of impurities in the starting material **4**; ir (liquid film) ν_{max}: 3500–3200 (N—H) and 1650 cm^{-1} (C=C); nmr (CCl_4) δ: 3.14 (2H, s, C(1)H_2N), 5.20 (1H, split t, $J = 7$ Hz, $J = 1.3$ Hz —C(5)H—CH_2), 5.65 (1H, bs, =C(3)H); uv (EtOH) λ_{max}: 220 nm (ε 6150); ms *m/e*: 223 (M^+), 208 ($M^+ - CH_3$), 194 ($M^+ - C_2H_5$), 180 ($M^+ - C_3H_7$); ^{13}C nmr (CCl_4) δ: 10.5, 11.8, 11.8, 12.6 (C(8)H, C(10)H, C(12)H, C(15)H), 21.5, 21.9, 26.4, 30.1, 30.2, (C(6)H, C(7)H, C(9)H, C(11)H, C(14)H), 48.3, 50.5 (C(1)H, C(13)H) 125.2, 126.7 (C(3)H, C(5)H), 139.5, 163.2 (C(2)H, C(4)H). No picrate derivative could be obtained and the compound itself was not stable enough to give good elemental analysis.

Propylamine

The compound was identified on the short column of an amino acid analyzer (Beckman 120-C, at 55.5°C). Resin UR-35 (Beckman) was used and the eluting buffer consisted of 0.4 *N* sodium citrate p*H* 5.35. Under these conditions propylamine was eluted approximately 37 min after ammonia.

Acknowledgements

We wish to express our sincere appreciation to Dr. J. K. Saunders, Department of Chemistry, University of Sherbrooke, without whom the nOe experiment would not have been performed and much less conceived. We thank also Mr. R. Langlois, who recorded the mass spectra with competence, and J. R. Martin and D. Viens for their technical assistance in the nOe experiments. This work was supported by the Medical Research Council, Grant MT-4003.

A simple synthesis of aucantene

HSING-JANG LIU AND ERIC N. C. BROWNE
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 15, 1977

HSING-JANG LIU and ERIC N. C. BROWNE. Can. J. Chem. **56**, 306 (1978).

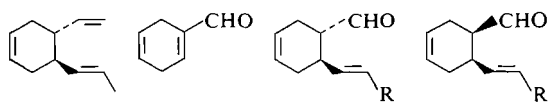
Aucantene (**1**) has been synthesized from propynal in three stages involving the conjugate addition of lithium di-(*E*)-propenylcuprate to α,β-unsaturated aldehyde **2** as a key step.

HSING-JANG LIU et ERIC N. C. BROWNE. Can. J. Chem. **56**, 306 (1978).

On a synthétisé l'aucatène (**1**) à partir du propynal; cette transformation implique trois étapes dont une addition conjuguée du di-(*E*)-propénylcuprate de lithium à l'aldéhyde α,β non-saturé **2** comme étape clé.

[Traduit par le journal]

Since several methods were developed in the early 1970's for the conjugate addition of lithium divinylcuprates to α,β-unsaturated ketones (1–3), this approach has been widely used for the preparation of γ,δ-enones (4). A logical extension to the synthesis of γ,δ-unsaturated aldehydes, however, is little known. We wish to describe a three-step synthesis, in racemic form, of aucantene (**1**) (5), a constituent of the anisogamous brown alga *Cutleria multifida*. In addition to providing an efficient alternative route to the naturally occurring hydrocarbon (6), the synthesis also demonstrates the feasibility of constructing γ,δ-unsaturated aldehydes by 1,4-addition using lithium divinylcuprates.



1 **2** **3** R = CH_3, **5** R = H **4** R = CH_3, **6** R = H

Aldehyde **2**[1] was prepared in 58% yield from propynal (8) by Diels–Alder reaction with 1,3-butadiene at room temperature using boron trifluoride etherate as a catalyst. This compound was subsequently treated with lithium di-(*E*)-propenylcuprate (9) in ether at −78°C for 1 h. Under these conditions,[2,3] the addition reaction proceeded smoothly with retention of the stereochemical integrity of the reagent, to give, in 77% yield, a mixture of two epimers **3**[4] and **4** in a ratio of ca. 3:2 as determined by gas chromatographic analysis. Preparative liquid chromatography of the mixture resulted in the separation of pure **3** and another mixture containing mainly **4** (~80%) in a total recovery of 74%. When the latter mixture was subjected to base treatment (10% aqueous potassium carbonate in methanol), an equilibrium was established after 4 h. Gas chromatographic analysis showed that the resulting mixture was composed of two parts of **3** and one part of **4**. In addition to confirming the epimeric nature of these two compounds, this finding strongly supported the stereochemical assignments since the *trans* isomer **3** is expected to be more stable and thus should be formed preferentially under thermodynamically controlled conditions. Moreover, the epimerization of **4** → **3** proved that the former compound is equally useful for the present synthesis.

Wittig reaction of **3** with methylenetriphenylphosphorane prepared from methyltriphenylphosphonium bromide and *n*-butyllithium in ether gave rise to a 74% yield of aucantene (**1**) whose ir and nmr spectra were found to be in agreement with those reported (5, 6).

Experimental

General

Mass spectra were recorded on AEI MS-50 and MS-12 spectrometers. Infrared spectra were obtained by using Perkin Elmer model 457 and 257 spectrophotometers. Nuclear magnetic resonance spectra were recorded on an HR-100 spectrometer using tetramethylsilane as internal standard. Elemental analyses were performed by the microanalytical laboratory of this department. Gas chromatographic (gc) analyses were performed using an Hewlett-Packard model 5750 instrument with an 8 ft × 1/8 in. stainless steel column of Carbowax 20 M on 80–100 mesh Chromosorb W.

1-Formyl-1,4-cyclohexadiene (2)

Propynal was prepared from propargyl alcohol according to the described procedure (8).

[1]A previous preparation involves the thermal Diels–Alder reaction of propynal and 1,3-butadiene (7).

[2]It is interesting to note that, whereas 1,4-additions of lithium divinylcuprates to conjugated enones are facilitated by a complexing agent, e.g., tetrakis(iodo(tri-*n*-butylphosphinecopper(I)) (1) or diisopropylsulfide (3), such an additional reagent is unnecessary in the present case.

[3]The addition of lithium divinylcuprate to **2** carried out in a similar manner resulted in the formation of a mixture of **5** and **6** in 72% yield and in a ratio of 1:2. The two aldehydes have been previously prepared by Marner and Jaenicke (6) using a different route and applied to their synthesis of **1** and its epimer.

[4]A mixture of **3** and a skeletal isomer has previously been synthesized in poor yield by a different approach (6).

To a solution of propynal (20 g, 0.37 mol) in ether (500 ml) under a nitrogen atmosphere, was added dropwise over a period of 20 min a solution of boron trifluoride etherate (26.26 g, 0.185 mol) in ether (100 ml). The resulting solution was stirred at room temperature for 15 min and a solution of benzene (500 ml) saturated with 1,3-butadiene was introduced dropwise over 40 min. After stirring for 20 h, the reaction mixture was cooled to 0°C and saturated aqueous sodium bicarbonate (200 ml) was slowly added. The organic layer was separated and the aqueous solution extracted three times with ether. The organic solutions were washed with water, combined, dried ($MgSO_4$), filtered, and concentrated to give 31.742 g of reddish oil. A portion (1.015 g) of the crude product was purified by column chromatography on silica gel. Elution with a solution of 5% ether in *n*-pentane gave 0.739 g (58% yield) of **2** as a colorless liquid. The remaining crude product was distilled at 78–79°C/16 Torr to give 20.361 g of **2**. The following properties were observed for **2**: ir (KBr, film): 3030 (C=CH and HC=CH), 2805, 2705 (CHO), 1685 (C=O), 1633 (C=C), and 760 (HC=CH); nmr (CCl_4) δ: 2.75, 3.01 (both m, 2H each, $-CH_2-$), 5.70 (m, 2H, $-CH=CH-$), 6.71 (m, 1H, $-C=CH-$), and 9.41 (s, 1H, —CHO); ms M^+ 108.0572 (calcd. for C_7H_8O: 108.0576). *Anal.* calcd. for C_7H_8O: C 77.75, H 7.46; found: C 77.75, H 7.57.

trans- *(3) and* cis-*4-((E)-1-Propenyl)-5-formylcyclohexene (4) and Epimerization*

To a suspension of cuprous iodide (4.73 g, 24.8 mmol) in ether (30 ml) under nitrogen at −78°C, was added a 1.075 *N* solution of (*E*)-1-propenyllithium (9) in ether (46.2 ml, 49.6 mmol) in a dropwise manner over a period of 40 min. The temperature was allowed to rise to −35°C over 1 h, and tetrahydrofuran (40 ml) was added over a 20 min period. After stirring at −35°C for 15 min, the mixture was cooled to −78°C. A solution of **2** (1.7 g, 18.3 mmol) in ether (30 ml) was then added dropwise over 30 min. The resulting mixture, after stirring for 30 min, was poured into 200 ml of ice-cold saturated aqueous ammonium chloride and filtered. The residue was washed thoroughly with ether. The organic layer of the filtrate was separated and the aqueous solution extracted four times with ether. The organic solutions were washed with 10% aqueous ammonium chloride (adjusted to ~p*H* 7 with concentrated ammonium hydroxide), water, and saturated aqueous sodium chloride, dried ($MgSO_4$), filtered, and concentrated. Column chromatography of the crude product thus obtained on silica gel using a solution of 4% ether in Skelly B gave 1.818 g (77% yield) of a mixture of **3** and **4** in a ratio of ca. 3:2 by gc analysis. A portion (1.186 g) of this material was subjected to preparative liquid chromatography (Waters Associates Prep LC/System 500; silica gel cartridge). Elution with a solution of 100% ether in petroleum ether gave 0.417 g of pure **3**: ir (KBr, film): 3010 (HC=CH), 2820, 2700 (CHO), 1722 (C=O), 1655 (C=C), 970 (*trans* HC=CH), and 720 (*cis* HC=CH); nmr (CCl_4) δ: 1.66 (dd, 3H, $J = 5$, $J' = 2.5$ Hz, $-CH_3$), 1.80–3.00 (complex, 6H, $-CH_2CHCHCH_2-$), 5.15–5.55 (complex, 2H, $-CH=CHCH_3$), 5.62 (br s, 2H, —CH=CH—), and 9.54 (d, 1H, $J = 2$ Hz, —CHO); ms M^+ 150.1041 (calcd. for $C_{10}H_{14}O$: 150.1044). *Anal.* calcd. for $C_{10}H_{14}O$: C 79.96, H 9.39; found: C 79.58, H 9.40.

Further elution with the same solvent system gave a mixture of **3** and **4** in a ratio of ca. 1:4 (gc and nmr). The nmr spectrum (CCl_4) showed a set of signals corresponding to **3** and another, set for **4** consisting of signals at δ 1.64 (d, 3H, $J = 4$ Hz, $-CH_3$), 1.80–3.20 (complex, 6H, $-CH_2CHCHCH_2-$), 5.20–5.60 (complex, 2H, $-CH=CHCH_3$), 5.62 (m, 2H, —CH=CH—), and 9.59 (s, 1H, —CHO). The ir spectrum was found to be similar to that of **3**.

The above mixture (85 mg) was dissolved in methanol (2 ml) and a 100% aqueous potassium carbonate solution (2 ml) was added. The mixture was stirred at room temperature under a nitrogen atmosphere and the reaction was monitored by gc. Within 4 h, an equilibrium (**3**:**4** ≃ 2:1) was established. The mixture was poured into water and extracted with methylene chloride. Work-up of the extracts in the usual manner followed by column chromatography of the crude product on silica gel using a solution of 5% ether in *n*-pentane as eluent gave 74 mg (87% recovery) of a mixture of **3** and **4** in a ratio of ~2:1 (gc).

Aucantene (1)

To a suspension of methyltriphenylphosphonium bromide (625 mg, 1.75 mmol) in ether (10 ml), was added a 1.72 *N* solution of *n*-butyllithium in hexane (1.02 ml, 1.75 mmol). The mixture was stirred at room temperature under a nitrogen atmosphere for 1 h and a solution of **3** (210 mg, 1.40 mmol) in ether (10 ml) was added dropwise over a 15 min period. Afterstirring for 3.5 h, the reaction mixture was poured into ice-cold water. The organic layer was separated and the aqueous layer extracted three times with ether (total 50 ml). The organic solutions were washed with saturated aqueous sodium chloride, dried ($MgSO_4$) and filtered. The volume of the filtrate was reduced under aspirator pressure without heating to ~2 ml. This solution was filtered to remove a small amount of triphenylphosphine oxide which was washed with *n*-pentane (~1 ml). The filtrate was concentrated using the same procedure described above. Column chromatography of the crude product on neutral alumina (activity I, ~1 g) using *n*-pentane as an eluent gave 153 mg (74% yield) of **1**. The ir and nmr spectra were shown to be in agreement with those reported (5, 6) and the mass spectrum displayed M^+ at 148.

Thermolysis of Δ^3-1,3,4-oxadiazolin-2-ones and 2-phenylimino-Δ^3-1,3,4-oxadiazolines derived from α,β-epoxyketones. An alternative method for the conversion of α,β-epoxyketones to alkynones and alkynals[1]

GERALD A. MACALPINE AND JOHN WARKENTIN

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 23, 1977

GERALD A. MACALPINE and JOHN WARKENTIN. Can. J. Chem. **56**, 308 (1978).

Thermolyses in polar solvents, of Δ^3-1,3,4-oxadiazolin-2-ones or 2-phenylimino-Δ^3-1,3,4-oxadiazolines derived from α,β-epoxyketones, yields acetylenic carbonyl compounds. Good yields of acetylenic aldehydes and ketones are obtained for those cases in which the epoxide is ring fused. Extension to acyclic cases failed primarily due to predominance of a parallel decomposition pathway. The method complements the procedures developed by Eschenmoser and co-workers for the conversion of α,β-epoxyketones into acetylenic carbonyl compounds.

GERALD A. MACALPINE et JOHN WARKENTIN. Can. J. Chem. **56**, 308 (1978).

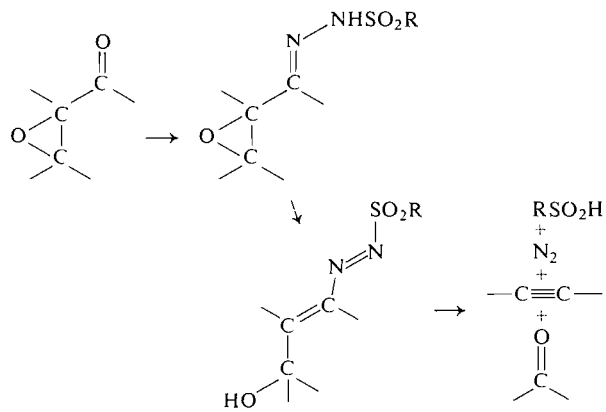
La thermolyse, dans des solvants polaires, de Δ^3-oxadiazoline-1,3,4 ones-2 ou de phénylimino-2 Δ^3-oxadiazolines-1,3,4 obtenues à partir d'α,β-époxycétones, conduit à des composés carbonylés acétyléniques. On obtient de bons rendements d'aldéhydes et de cétones acétyléniques dans tous les cas ou l'époxyde est juxtaposé à un cycle. Il n'a pas été possible d'étendre ces conclusions à des cas acycliques; dans ces cas une voie parallèle de décomposition devient prédominante. La méthode sert de complément aux propositions de Eschenmoser et de ses collaborateurs pour la conversion d'α,β-époxycétones en composés carbonylés acétyléniques.

[Traduit par le journal]

Introduction

The transformation of α,β-epoxyketones into acetylenic carbonyl compounds is a useful synthetic procedure. New syntheses of exaltone and muscone (1, 2), which are macrocyclic ketones of importance in the fragrance industry, a stereoselective synthesis of *exo*-brevicomin (3), which is the principal sex attractant of the western pine beetle *Dendrocotnus brevicomis*, an 8-methylprostanoid synthon (4), as well as the synthesis of several acetylenic seco-steroids (5, 6) have all involved this fragmentation process. Several methods are known which bring about this transformation. *p*-Toluenesulfonylhydrazine was first used by Eschenmoser and Ohloff (1, 2, 7) and independently by Tanabe and co-workers (5, 6). Later Corey and Sachdev (4) introduced 2,4-dinitrobenzenesulfonylhydrazine as a milder reagent. The transformation may be viewed as outlined in Scheme 1.

Although the *p*-toluenesulfonylhydrazine method works well for β-substituted cyclic α,β-epoxyketones, β-unsubstituted and acyclic α,β-epoxyketones do not give good yields of the fragmentation products. To overcome some of these shortcomings, Eschenmoser and co-workers (8–10) developed an alternative method based on the thermolysis of hydrazones of α,β-epoxyketones derived from *N*-aminoaziridines (8, 9, 10). This process probably proceeds through the intermediacy of a diazoalkane as outlined in Scheme 2. This method has been successfully employed for a wide range of α,β-epoxyketones and works well for cyclic as well as acyclic cases.



SCHEME 1

A number of related fragmentations have also been reported. Treatments of oximes of α,β-epoxyketones with hydroxylamine-*O*-sulfonic acid yields the corresponding acetylenic carbonyl compounds in a number of steroidal cases (11). As well, certain suitably functionalized diazirines undergo fragmentation to acetylenic carbonyl compounds under acidic conditions (12). It is probable that these two reactions also proceed through a diazoalkane intermediate.

Lead tetraacetate (LTA) oxidation of ketone

[1]Presented in part at the Canadian Chemical Conference of the Chemical Institute of Canada, London, Ontario, June 1976.

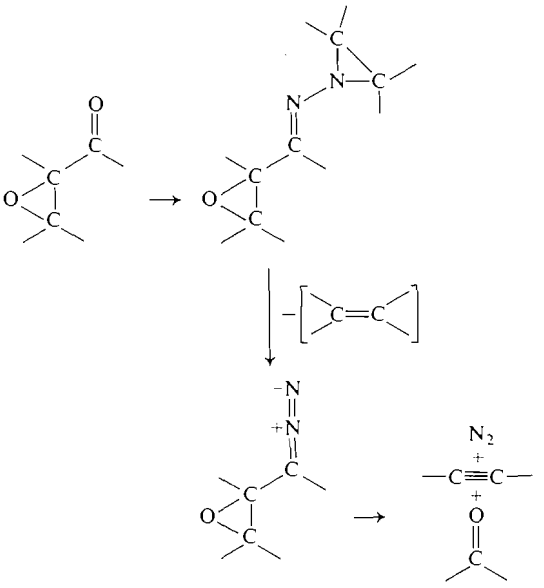
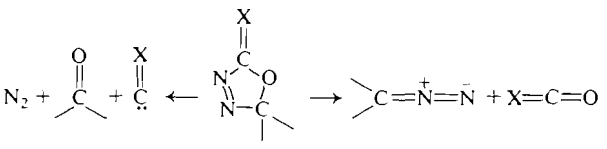


SCHEME 2

semicarbazones gives 5,5-disubstituted-2-imino-Δ^3-1,3,4-oxadiazolines (13–15). These interesting compounds can be hydrolyzed to the corresponding oxadiazolinones which are easily purified by crystallization or sublimation. Compounds of this type undergo thermolysis (16), by two competing paths, to give diazoalkane and heterocumulene or ketone and the appropriate cofragments (Scheme 3). Which pathway predominates may be controlled by choice of the solvent. In polar solvents, the formation of diazoalkane is favoured, whereas in nonpolar solvents ketone formation is the main process.

Since ketone semicarbazones are easily prepared and LTA oxidation to oxadiazolines proceeds in good yield, it seemed of value to investigate the thermolysis of oxadiazolines derived from the semicarbazones of α,β-epoxyketones as an alternative method to bring about the transformation of α,β-epoxyketones to acetylenic carbonyl compounds. The advantages of such an alternative were expected to be: (*i*) a simpler product isolation because of gaseous by-products (i.e., CO_2 and N_2 for oxadiazolinones); (*ii*) mild reaction conditions; and, (*iii*) generality for all types of α,β-epoxyketones. It should be noted that the use of α,β-epoxyaldehydes is not feasible because aldehyde semicarbazones are



X = O, NR

SCHEME 3

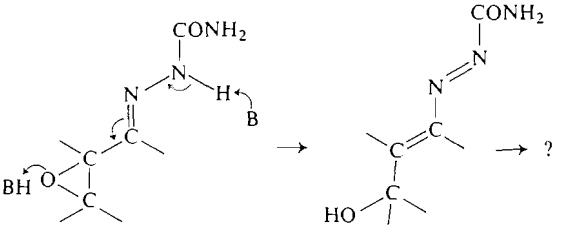
cyclized to 2-amino-1,3,4-oxadiazoles on LTA oxidation (17–20).

Results and Discussion

We initially chose to investigate the decomposition of oxadiazolinones derived from α,β-epoxyketones instead of the corresponding imino oxadiazolines. The reasons for this were twofold: the thermolyses could be carried out at lower temperatures and the co-products for the desired process would be gases, nitrogen and carbon dioxide, whereas for the imino oxadiazolines the co-products would be nitrogen and an isocyanate. We felt that the presence of an isocyanate could complicate product isolation.

It was necessary to demonstrate that α,β-epoxyketones are suitable substrates for oxadiazolinone formation (see Table 1). This required that the semicarbazones be formed in good yield and that subsequent LTA oxidation and hydrolysis should not affect the epoxide ring. To this end we first looked at isophorone oxide (**1**) (20). The semicarbazone was easily prepared and underwent LTA oxidation followed by aqueous acid hydrolysis to give crystalline, solid oxadiazolinone (**13**) in 75% yield, mp 97–100°C. Compound **13**[2] was obtained as a mixture of diastereoisomers as evidenced by its ^{1}Hmr and ^{13}Cmr spectra. Thermolysis of **13** in refluxing acetonitrile gave a mixture of 4,4-dimethyl-6-heptyn-2-one (**20**) and isophorone oxide (**1**) in the approximate ratio 3:1 (glc and ^{1}Hmr). The two products formed are the result of competitive decomposition via the two pathways. The product composition from reaction in ethylene glycol at 150°C was essentially the same. The two products were separated by chromatography on neutral alumina; 4,4-dimethyl-6-heptyn-2-one (**20**) was obtained in 44% yield.

The semicarbazones of some epoxyketones could not be prepared by reaction with semicarbazide under a number of conditions. It seems probable that in these cases the initially formed semicarbazone is unstable and undergoes further reaction with opening of the epoxide ring (Scheme 4). This is ana-



SCHEME 4

[2]The name of this compound is 4,4,6-trimethylspiro[7-oxabicyclo[4.1.0]-heptane-2,2′-[Δ^3-1,3,4]oxadiazolin]-5′-one. We are indebted to Dr. Kurt Loening, Nomenclature Director, Chemical Abstracts Service, Columbus, Ohio for his assistance in this matter.

logous to the known dehydrohalogenation of α-haloketones by 2,4-dinitrophenylhydrazine (22).

Even when semicarbazone formation proceeds readily an additional problem arises when an attempt is made to hydrolyze the intermediate imino oxadiazoline. Compound **16**, obtained by LTA oxidation of β-4,5-epoxycholestan-3-one semicarbazone (**9**) (23), hydrolyzed in a mixture of dilute aqueous hydrochloric acid and dichloromethane to yield substantial quantities of cholest-4-en-3-one. The enone is most likely formed by the process outlined in Scheme 5.[3] To overcome this problem, the crude oxidation product (**16**) was thermolyzed in nitrobenzene at 110°C to give a 38% yield of oily, acetylenic ketone (**22**) after purification by chromatography on neutral alumina. Thus the use of oxadiazolinones is limited not only at the semicarbazone-forming step but also at the hydrolysis stage.

We next turned our attention to preparing and studying the thermolysis of substituted imino oxadiazolines derived from α,β-epoxyketones. Since 4-phenylsemicarbazide is stable and easily prepared (24) we chose to use it as the substituted semicarbazide. It reacted with equivalent quantities of α,β-epoxyketones in dichloromethane at ambient temperature to give nearly quantitative yields of 4-phenylsemicarbazones of all the α,β-epoxyketones studied (Table 1). LTA oxidation of the 4-phenylsemicarbazones proceeded readily to give phenyl-

[3]Oxadiazolin-2-ones derived from α,β-epoxyketones are very susceptible to attack by nucleophiles. For example, compound **13** gave a near quantitative yield of 3-hydroxy-3,5,5-trimethylcyclohexanone on reaction with an aqueous methanolic solution of sodium cyanide.

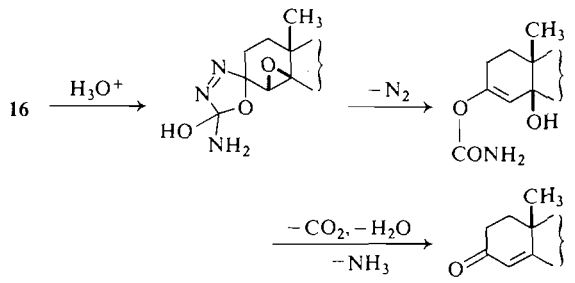
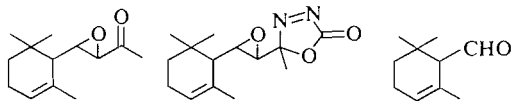


SCHEME 5

imino oxadiazolines as crystalline, yellow solids in good yield. These compounds are more stable than the corresponding oxadiazolinones and thus, if necessary, can be chromatographically purified. Usually the oxidation produced a mixture of diastereoisomers. In the steroidal case, the diastereoisomers (**17**) could be chromatographically separated but no difference in their thermolytic behaviour was observed.

Thermolyses were generally carried out in ethylene glycol. Ethylene glycol served not only as a suitable polar solvent, but also to scavenge the phenyl isocyanate produced as a co-product. Temperatures of the order of 140°C were necessary to initiate decomposition; refluxing methanol or acetonitrile did not result in appreciable decomposition. In general, acetylenic carbonyl compounds were formed in good yield in a clean reaction. Only small amounts of α,β-epoxyketones, derived from the alternative decomposition pathway, were detected. In contrast to decomposition of oxadiazolinone **13**, where a 3:1 ratio of acetylenic ketone to α,β-epoxyketone was observed, only a trace amount of **1** was formed on thermolysis of **14**. It should be noted that acetylenic aldehydes were formed in good yield. The carbonyl compounds were usually isolated as their 2,4-dinitrophenylhydrazones. In one case compound **19** was thermolyzed in the presence of a catalytic amount of *p*-toluenesulfonic acid and the aldehyde was isolated as the acetal (**25**). This may be an important feature for cases in which the newly formed carbonyl is highly reactive.

Attempts to extend the method to acyclic cases failed. Thermolysis of compound **27** in ethylene glycol or in a number of other polar solvents gave complex product mixtures. No synthetically useful yield of the desired aldehyde was obtained. The main product in the thermolysis was the α,β-epoxyketone **26**. Thermolysis of neat **27** resulted in formation of a low yield of aldehyde **28** plus a substantial quantity of α,β-epoxyketone **26**.



26 **27** **28**

In summary, oxidation and thermolysis of phenylsemicarbazones derived from cyclic α,β-epoxyketones is a useful alternative to bring about their conversion to acetylenic carbonyl compounds. Use of oxadiazolinones is less general as problems arise in making the required semicarbazones and in the isolation of unstable oxidation products. Furthermore, it appears that phenylimino oxadiazolines are more selective, in the desired sense, in the choice of decomposition pathway.

Experimental

General

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. Microanalyses were performed by Schwarzkopf Microanalytical Laboratory. Infrared (ir) spectra ($CHCl_3$ solutions unless otherwise indicated) were taken on either a Beckman-IR5 or a Perkin-Elmer model 283 spectrophotometer. ^{1}Hmr spectra were measured on either a Varian T-60 or EM-390 spectrometer in deuteriochloroform with tetramethylsilane as internal reference unless otherwise noted. Mass spectra (ms) were recorded on a CEC-21-110B spectrometer. Gas chromatographic (glc) analyses were performed using an Aerograph A90-P3 with a column of 15% Carbowax 20M on 60-80 Mesh Chromosorb P. Thin-layer chromatography (tlc) was carried out on Merck plates (0.25 mm thick) pre-coated with silica gel 60F-254 or aluminum oxide F-254 (type E). Preparative-layer chromatography (plc) was done on plates (20 × 20 cm; 2 mm thick) prepared from silica gel GF-254 or aluminum oxide GF-254 (type 60/E). Chlorocarbon extracts were dried over anhydrous sodium sulfate and diethyl ether extracts over anhydrous magnesium sulfate. Light petroleum refers to the fraction boiling between 30–60°C; hexane refers to 'Baker analyzed' reagent, boiling point range 68.5–69.3°C.

Materials

4-Phenylsemicarbazide was prepared by the method of Wheeler, mp 120–122°C (lit. (24) mp 120–123°C). 2,4-Dinitrophenylhydrazine reagent refers to a solution of 2,4-dinitrophenylhydrazine (1 g) in methanol (30 ml) and concentrated H_2SO_4 (2 ml).

General Procedure for Epoxidation of α,β-Unsaturated Ketones

The temperature of a solution of α,β-unsaturated ketone (~1 *M*) in anhydrous methanol containing 30% aqueous H_2O_2 (1.2 equiv.) was adjusted to between 0–15°C by means of an ice-water bath. Sodium hydroxide (6 *N*) was added dropwise to the rapidly stirred solution and the reaction was monitored by tlc. In some cases the temperature was allowed to rise to 20°C. When all the starting material had been consumed the reaction mixture was diluted with H_2O and extracted with ether. The organic extracts were combined and washed several times with a cold, saturated solution of $FeSO_4$, then H_2O, and finally brine. Drying and removal of the solvent at reduced pressure gave crude α,β-epoxyketone. Usually the α,β-epoxyketone was used without further purification.

4,4,6-Trimethyl-7-oxabicyclo[4.1.0]heptan-2-one (Isophorone Oxide) 1

This compound was prepared from isophorone by the method of House and Wasson (21) in 70% yield, bp 80–84°C/10 Torr (lit. (21) bp 70–73°C/5 Torr).

1,6-Epoxy-p-*menth-8-en-2-one* **2**

This compound was prepared by the general procedure from (−)-carvone (1 h at 0–4°C) in 50% yield, bp 73–76°C/1 Torr (lit. (25) bp 160°/7 Torr) as a mixture of diastereoisomers; ^{1}Hmr δ: 1.40 (s, 3H, CH_3), 1.72 (s(b), 3H, C=C—CH_3), 1.80–2.93 (m, 5H, CH and CH_2), 3.43  , 4.77 (m, 2H, C=CH_2); ir: 1706 (s, C=O), 1644 (w, C=CH_2).

β-*4,5-Epoxycholestan-3-one* **3**

This compound was prepared from 4-cholesten-3-one by the method of Plattner, mp 117–117.5°C (lit. (23) mp 116°C).

1-Acetyl-7-oxabicyclo[4.1.0]heptane **4**

This compound was prepared by the general method (20 h at 20°C) in 70% crude yield; ^{1}Hmr δ: 1.20–2.43 (m, 8H, CH_2), 2.05 (s, 3H, $COCH_3$), 3.33  .

8-Oxabicyclo[5.1.0]octan-2-one **5**

This compound was prepared by the general method (3 h at 0°C) in 94% crude yield; ^{1}Hmr δ: 1.50–2.50 (m, 8H, CH_2), 2.53–2.87  , 3.33–3.50  .

3,4-Epoxy-4-(2′,6′,6′-trimethyl-2′-cyclohexenyl)-butan-2-one **26**

This compound was prepared from α-ionone in 60% yield by the method of Eschenmoser and co-workers (10), mp 34.5–35.5°C (lit. (10) mp 36–38°C).

General Procedure for the Preparation of Semicarbazones and 4-Phenylsemicarbazones

For semicarbazone formation the α,β-epoxyketone was added to an aqueous solution of semicarbazide hydrochloride (1.2 *M*) containing 1 equiv. of sodium acetate trihydrate at 20°C. Sufficient 95% ethanol was added to bring about a homogeneous solution. The semicarbazone usually began to precipitate immediately, it was then filtered and dried under vacuum over P_2O_5. For 4-phenylsemicarbazone formation, a CH_2Cl_2 solution (~1 *M*) of the α,β-epoxyketone containing 1.1 equiv. of 4-phenylsemicarbazide was stirred over anhydrous Na_2SO_4 at 20°C for 4–20 h. The reaction was followed by tlc and was usually complete after 4 h. The Na_2SO_4 was removed by filtration and the solvent removed at reduced pressure. One crystallization furnished pure 4-phenylsemicarbazone.

Preparation of Semicarbazone 6 from 4,4,6-Trimethyl-7-oxabicyclo[4.1.0]heptan-2-one **(1)**

This compound was prepared by the general procedure in 84% yield, mp 213°C (lit. (26) mp 216°C (dec.)) from 95% ethanol.

Preparation of 4-Phenylsemicarbazone 7 from 4,4,6-Trimethyl-7-oxabicyclo[4.1.0]heptan-2-one **(1)**

This compound was prepared by the general procedure in 84% yield, mp 204–205°C (dec.) from ethyl acetate; ^{1}Hmr δ: 0.93 (s, 3H, CH_3), 1.03 (s, 3H, CH_3), 1.43 (s, 3H, CH_3), 1.51–2.53 (m, 4H, CH_2), 3.42  , 6.97–7.67 (m, 5H, C_6H_5), 8.37 (s, 1H, $CONHC_6H_5$), 9.97 (s, 1H, C=NNHCO); ir: 3390 (m, NH), 1690 (s, C=N and C=O); ms: M^+ 287.

Preparation of 4-Phenylsemicarbazone 8 from 1,6-Epoxy-p-*menth-8-en-2-one* **(2)**

This compound was prepared by the general procedure, in nearly quantitative yield, as a mixture of diastereoisomers. As this mixture was difficult to crystallize, it was used without purification, ^{1}Hmr δ: 1.58 and 1.68 (s, 6H, 2 CH_3), 1.81–2.91 (m, 5H, CH_2 and CH), 3.41  , 4.80 (s(b), 2H, C=CH_2), 6.91–7.61 (m, 5H, C_6H_5), 8.37 (s, 1H, $CONHC_6H_5$), 9.78 (s, 1H, C=NNHCO); ir (KBr): 3370 (m, NH), 1685 (s, C=N and C=O).

Preparation of Semicarbazone 9 from β-*4,5-Epoxycholestan-3-one* **(3)**

This compound was prepared in 60% yield, mp 189–192°C (dec.) from ether–hexane by the general procedure, ^{1}Hmr δ: 3.33  , 6.87–7.63 (m, 5H, C_6H_5), 8.3 (s(b), 1H, $CONHC_6H_5$), 9.4 (s(b), 1H, C=NNHCO); ir: 3390 (m, NH), 1700 (s, C=N and C=O).

Preparation of 4-Phenylsemicarbazone **11** *from 1-Acetyl-7-oxabicyclo[4.1.0]heptane* **(4)**

This compound was prepared in 57% yield by the general procedure, mp 153–155°C from ethyl acetate – hexane, ^{1}Hmr δ: 1.47 (m, 4H, CH_2), 1.78 (s, 3H, $COCH_3$), 1.83–2.62 (m, 4H, CH_2), 3.23 , 7.00–7.67 (m, 4H, C_6H_5), 8.20 (s(b), 1H, $CONHC_6H_5$), 8.8 (s(b), 1H, C=NNHCO); ir: 3390 (m, NH), 1695 (s, C=N and C=O).

Preparation of 4-Phenylsemicarbazone **12** *from 8-Oxabicyclo-[5.1.0]octan-2-one* **(5)**

The 4-phenylsemicarbazone was prepared by the general method in 84% yield, mp 180–181°C (dec.) from ethyl acetate, ^{1}Hmr δ: 1.14–3.00 (m, 8H, CH_2), 3.24–3.58 , 3.70 and 3.99 (both d, $J \sim 5$ Hz, total of 1H, *syn*- and *anti*-4-phenylsemicarbazones), 6.93–7.63 (m, 5H, C_6H_5), 8.30 (s(b), 1H, $CONHC_6H_5$), 9.77 and 10.13 (both s(b), 1H, C=NNHCO, *syn*- and *anti*-4-phenylsemicarbazones); ir: 3390 (m, NH), 1695 (s, C=N and C=O).

The Preparation of 4-Phenylsemicarbazone of 3,4-Epoxy-4-(2′,6′,6′-trimethyl-2′-cyclohexenyl)butan-2-one **(26)**

The 4-phenylsemicarbazone was prepared by the general method in 78% yield, mp 180–181°C from chloroform-hexane, ^{1}Hmr δ: 0.97 (s, 3H, CH_3), 1.24 (s, 3H, CH_3), 1.31–1.70 (m, 3H, CH_2 and CH), 1.59 (s, 3H, CH_3), 2.04 (m, 2H, allylic CH), 2.83 , 3.49 , 5.53 (m, 1H, C=CH), 6.99–7.63 (m, 5H, C_6H_5), 8.25 (s(b), 1H, $CONHC_6H_5$), 9.12 (s(b), 1H, C=NNHCO); ir: 3390 (m, NH), 1695 (s, C=N and C=O).

Lead Tetraacetate Oxidation of Semicarbazones and 4-Phenylsemicarbazones

A specific procedure is given below for the oxidation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

semicarbazone **6** and 4-phenylsemicarbazone 7 derived from isophorone oxide (**1**). For all other cases, a similar procedure was followed.

LTA Oxidation of Semicarbazone 6

Lead tetraacetate (5.40 g, 0.012 mol) was added to a stirred suspension of the semicarbazone (2.11 g, 0.01 mol) in dry CH_2Cl_2 (100 ml) at −10°C. There was an immediate formation of a yellow, homogeneous solution which formed a precipitate over the next 0.5 h. After 4 h at −10°C ice-cold H_2O (50 ml) was added to the now colourless reaction mixture, followed by 2.4 *N* HCl (30 ml). The reaction mixture was stirred at 0°C for 0.5 h to ensure complete hydrolysis of the intermediate imino oxadiazoline. The reaction mixture was then filtered through Celite, the organic phase separated, and the aqueous phase extracted with CH_2Cl_2 (3 × 20 ml). The organic extracts were combined, washed with H_2O (20 ml), dried, and the solvent removed at reduced pressure to give crude oxadiazolinone **13** (1.87 g) in 87% yield. Crystallization from ether–hexane gave 1.52 g (75%) of pure **13**, mp 97–100°C as a mixture of diastereoisomers; ^{1}Hmr (DMSO-d_6) δ: 0.98, 1.18, 1.35 and 1.37 (all s, total 9H, $3CH_3$), 1.63 (s(b), 2H, CH_2), 1.83 (s(b), 2H, CH_2), 3.05  ; ir (KBr): 1825 (s, C=O); *Anal.* calcd. for $C_{10}H_{14}N_2O_3$: C 57.13, N 6.71, N 13.33; found: C 57.31, H 6.77, N 13.05.

LTA Oxidation of 4-Phenylsemicarbazone 7

A solution of LTA (3.55 g, 0.008 mol) in dry CH_2Cl_2 (25 ml) was added dropwise over 0.3 h to a stirred solution of 4-phenylsemicarbazone **7** (2.16 g, 0.0075 mol) in dry CH_2Cl_2 (50 ml) at 0°C. After all the LTA solution had been added, the reaction mixture was stirred at 0°C for 3 h, diluted with cold H_2O (15 ml), and stirred an additional 0.25 h. The reaction mixture was filtered through Celite and the organic phase separated. The aqueous phase was extracted with CH_2Cl_2 (3 × 20 ml). The extracts were combined, washed with H_2O, and dried. Removal of the solvent at reduced pressure gave crude **14** (2.17 g). Crystallization from CH_2Cl_2 – light petroleum gave **14** as a mixture of diastereoisomers (1.19 g) mp 112–126°C (dec.) in 50% yield; tlc (SiO_2, 3:7 ether–hexane) R_F 0.64 and 0.55; ^{1}Hmr δ: 1.08, 1.10, 1.31, 1.42 and 1.48 (all s, total of 9H, 3 CH_3), 1.64–2.01 (m, 4H, CH_2), 2.63 (minor diastereoisomer) and 2.67 (major diastereoisomer)  , 7.11–7.63 (m, 5H, C_6H_5); ir: 1700 (s, C=N); *Anal.* calcd. for $C_{16}H_{19}N_3O_2$: C 67.35, H 6.71, N 14.73; found: C 67.37, H 6.80, N 14.71.

LTA Oxidation of 4-Phenylsemicarbazone 8

Compound **8** (1.50 g, 0.005 ml) was oxidized at −15°C and the crude product purified by chromatography on neutral alumina (grade III) using 10% ether – light petroleum as eluant to give a 53% yield (0.79 g) of **15** as a mixture of diastereoisomers. An analytical sample was prepared by three crystallizations from ether–hexane, mp 114–115.5°C; tlc (SiO_2, 1:1 ether–hexane R_F 0.8; ^{1}Hmr δ: 1.07 (s(b), 3H, CH_3), 1.33–2.83 (m, total of 8H, CH, CH_2 and CH_3, latter s(b) at 1.73), 3.38  , 4.80 (m, 2H, C=CH_2), 7.13–7.77 (m, 5H, C_6H_5); ir: 1695 (s, C=N); *Anal.* calcd. for $C_{17}H_{19}N_3O_2$: C 68.66, H 6.44, N 14.13; found: C 68.47, H 6.44, N 13.99.

LTA Oxidation of Semicarbazone 9

Semicarbazone **9** (0.192 g, 0.004 mol) was oxidized at 0°C and the crude imino oxadiazoline **16** (0.19 g) isolated as an oil. Since this compound was unstable it was used directly for fragmentation without further purification.

LTA Oxidation of 4-Phenylsemicarbazone 10

4-Phenylsemicarbazone **10** (0.33 g, 6.8 mmol) was oxidized at 0°C for 4 h and then at 20°C for 16 h to give crude **17** as a mixture of diastereoisomers (0.28 g) in 83% yield. The two diastereoisomers were separated by chromatography on neutral alumina (grade III) using 10% ether – light petroleum as eluant. An analytical sample of the major diastereoisomer was obtained by crystallization from ether–hexane, mp 177–179°C; tlc (SiO_2, 3:7 ether–hexane) R_F 0.93; ^{1}Hmr δ: 2.67 , 7.13–7.70 (m, 5H, C_6H_5); ir: 1700 (s, C=N); *Anal.* calcd. for $C_{34}H_{49}N_3O_2$: C 76.79, H 9.29, N 7.90; found: C 76.88, H 9.13, N 7.98. A pure sample of the minor diastereoisomer was obtained by crystallization from ether–hexane, mp 128–129°C; tlc (SiO_2, 3:7 ether–hexane) R_F 0.83; ^{1}Hmr δ: 2.65 , 7.23–7.62 (m, 5H, C_6H_5); ir: 1700 (s, C=N).

LTA Oxidation of 4-Phenylsemicarbazone 11

Compound **11** was oxidized at 0°C for 3 h and then at 20°C for 1 h. The crude product was purified by chromatography on neutral alumina (grade III) using 10% ether – light petroleum as eluant. Compound **18** was obtained in 77% yield (0.455 g) as a mixture of diastereoisomers, mp 75–80°C. An analytical sample was prepared by two crystallizations from ether–hexane, mp 82–83°C; tlc (SiO_2, 1:1 ether–hexane) R_F 0.77; ^{1}Hmr δ: 1.12–1.59 (m, 4H, CH_2), 1.72 (s, 3H, CH_3), 1.79–2.23 (m, 4H, CH_2), 3.30 and 3.40 diastereoisomers), 7.16–7.60 (m, 5H, C_6H_5); ir: 1700 (s, C=N); *Anal.* calcd. for $C_{15}H_{17}N_3O_2$: C 66.40, H 6.32, N 15.49; found: C 66.73, H 6.37, N 15.32.

LTA Oxidation of 4-Phenylsemicarbazone 12

Compound **12** (0.52 g, 0.002 mol) was oxidized at 0°C for 3 h. Crystallization from ether–hexane gave **19** as a mixture of diastereoisomers in 60% yield, mp 96–97°C (dec.). An analytical sample was prepared by two crystallizations from ether–hexane, mp 132.5–135°C (dec.); tlc (SiO_2, 3:7 ether–hexane) R_F 0.68; ^{1}Hmr δ: 1.10–2.57 (m, 8H, CH_2), 2.71 , 3.31 , 7.13–7.70 (m, 5H, C_6H_5); ir: 1700 (s, C=N); *Anal.* calcd. for $C_{14}H_{15}N_3O_2$: C 65.35, H 5.88, N 16.33; found: C 65.50, H 5.97, N 16.30.

4,4-Dimethyl-6-heptyn-2-one 20

(*A*) A solution of oxadiazolinone **13** (1.05 g, 0.005 mol) was refluxed in dry acetonitrile (50 ml) under a nitrogen atmosphere for 7 h. The solvent was removed by careful distillation; glc and ^{1}Hmr analysis indicated that the ratio of alkynone **20** to α,β-epoxyketone **1** was approximately 3:1. Chromatography of the residue on neutral alumina (50 g, grade III) using 20% ether – light petroleum gave 0.30 g (44%) of 4,4-dimethyl-6-heptyn-2-one (**20**): tlc (Al_2O_3, 3:7 ether–hexane) R_F 0.9; ^{1}Hmr δ: 1.05 (s, 6H, *gem*-dimethyl), 2.04 (t, J = 2.5 Hz, 1H, C=CH), 2.12 (s, 3H, $COCH_3$), 2.24 (d, J = 2.5 Hz, 2H, CH_2), 2.47

For personal use only.

(s, 2H, CH_2); ir: 3330 (m, C≡CH), 2120 (w, C≡C), 1721 (s, C=O). There was also obtained 0.14 g of a mixture of compounds **20** and **1**, as well as 0.07 g of pure α,β-epoxyketone **1**.

(*B*) Phenylimino oxadiazoline **14** (0.143 g, 0.50 mmol) was added to ethylene glycol (5 ml) at 150–160°C (oil bath temperature). Gas evolution began at once and after 0.5 h the reaction mixture had turned from yellow to colourless. The reaction mixture was cooled to 20°C, poured into H_2O, and extracted with ether. The extracts were combined, washed with brine, water, and dried. The solvent was removed by careful distillation to give crude alkynone **20**. The residue was dissolved in CH_3OH (2 ml) and treated with 2,4-DNP reagent (3 ml). After standing at ambient temperature for 16 h 0.103 g (71%) of the 2,4-DNP of compound **20** was obtained, mp 102–103°C from 95% ethanol: ^{1}Hmr δ: 1.23 (s, 6H, *gem*-dimethyl), 2.09 (t, J = 2.5 Hz, 1H, C≡CH), 2.16 (s, 3, CH_3), 2.23 (d, J = 2.5 Hz, 2H, CH_2), 2.50 (s, 2H, CH_2), 7.98 (d, J = 10 Hz, 1H, ArH), 8.34 (dd, J = 10 and 2 Hz, 1H, ArH), 9.17 (d, J = 2 Hz, 1H, ArH), 11.09 (s(b), 1H, NH); *Anal.* calcd. for $C_{15}H_{18}N_4O_4$: C 56.59, H 5.70, N 17.60; found: C 56.38, H 5.69, N 17.31.

3-Isopropenyl-5-heptynal ***21***

Phenylimino oxadiazoline **15** (0.297 g, 1.0 mmol) was added to ethylene glycol (10 ml) at 150°C under a nitrogen atmosphere. After 0.75 h the reaction mixture was cooled to 20°C and diluted with H_2O (10 ml). The product was extracted with ether and the combined ethereal extracts washed with brine, H_2O, and dried. Careful removal of the solvent by distillation gave crude alkynal **21**. This material was treated with 2,4-DNP reagent (15 ml) and after 16 h the 2,4-DNP (0.273 g, 83%) was isolated by chloroform extraction and chromatography on neutral alumina (grade III) using 20% ether – light petroleum as eluant, mp 91–93°C from methanol. An analytical sample was prepared by crystallization from 95% ethanol, mp 93–94°C: ^{1}Hmr δ: 1.70–1.87 (complex, 6H, $2CH_3$), 1.98–2.97 (m, 5H, CH and CH_2), 4.86 (m, 2H, C=CH_2), 7.53 (t, J = 5 Hz, 1H, CH=N), 7.94 (d, J = 10 Hz, 1H, ArH), 8.31 (dd, J = 10 and 2 Hz, 1H, ArH), 9.1 (d, J = 2 Hz, 1H, ArH), 11.05 (s(b), 1H, NH); *ir* (KBr): *1625* (s, C=N); *Anal.* calcd. for $C_{16}H_{18}N_4O_4$: C 58.17, H 5.49, N 16.96; found: C 58.37, H 5.67, N 16.96. The alkynal **21** could be isolated by plc on SiO_2 using 1:1 ether – light petroleum as eluant: ^{1}Hmr δ: 1.70–1.83 (complex, 6, $2CH_3$), 2.19–2.82 (m, 5H, CH and CH_2), 4.83 (m, 2H, C=CH_2), 9.79 (t, J = 1.5 Hz, 1H, CHO); ir: 2730 (w, aldehydic CH), 1725 (s, C=O).

4,5-Seco-3-cholestyn-5-one ***22***

(*A*) Crude imino oxadiazoline **16** (1.12 g) prepared by LTA oxidation of semicarbazone **9** (1.16 g) was heated in nitrobenzene (50 ml) at 110°C for 5 h. The solvent was removed at reduced pressure and the residue chromatographed on neutral alumina (grade III) using 20% ether – light petroleum as eluant to give compound **22** (4) (0.30 g) as a colourless oil in 38% overall yield: tlc (Al_2O_3, 1:7 ether–hexane) R_F 0.50; ^{1}Hmr δ: 0.75, 0.85, 0.91 and 1.1 (complex, CH_3's); ir: 3310 (m, C≡CH), 2110 (w, C≡C), 1700 (s, C=O); *Mol. Wt.* calcd. for $C_{27}H_{44}O$: 384.3392; found (high resolution ms): 384.3402. There was also obtained from the column 0.19 g of a mixture of compounds **3** and **22**.

(*B*) Phenylimino oxadiazoline **17**, mp 177–179°C (major diastereoisomer), (0.037 g, 0.07 mmol) was dissolved in dry HMPA (5 ml) and heated at 150°C under a nitrogen atmosphere for 1 h. The reaction mixture was cooled to 20°C, diluted with H_2O (30 ml) and extracted with ether. After drying the solvent was removed at reduced pressure and the residue chromatographed (plc) on neutral alumina (5:1 ether–hexane as eluant; developed three times). 4,5-seco-3-cholestyn-5-one (**22**) was obtained in 63% yield (0.017 g) and β-4,5-epoxycholestan-3-one (**3**) in 12.5% yield (0.0035 g). Similar results were obtained using the minor diastereoisomer.

6-Octynal ***23***

Phenylimino oxadiazoline **18** (0.136 g, 0.50 mmol) was added to ethylene glycol (5 ml) at 140°C under a nitrogen atmosphere. The reaction mixture was stirred at this temperature for 0.5 h, cooled to ambient temperature, poured into H_2O (20 ml), and extracted with ether (4 × 20 ml). After washing the combined ether extracts with brine (20 ml) and H_2O (20 ml), and drying, the solvent was removed by careful distillation and the residue treated with 2,4-DNP reagent (5 ml). After 5 h at 20°C the 2,4-DNP was isolated by extraction with CH_2Cl_2 and plc on neutral alumina using 1:4 ether – light petroleum. The 2,4-DNP of 6-octynal (**23**) was obtained in 36% yield (0.054 g), mp 118–121°C from methanol; ^{1}Hmr δ: 1.41–1.98 (complex, 7, CH_2 and CH_3, latter at 1.79, t, J = 2 Hz), 2.00–2.62 (m, 4, CH_2), 7.6 (t, J = 5 Hz, 1H, CH=N), 7.97 (d, J = 10 Hz, 1H, ArH), 8.33 (dd, J = 10 and 2 Hz, 1H, ArH), 9.14 (d, J = 2 Hz, 1H, ArH), 11.1 (s(b), 1H, NH); ir: 1620 (s, C=N); *Anal.* calcd. for $C_{14}H_{16}N_4O_4$: C 55.25, H 5.30, N 18.41; found: C 55.45, H 5.58, N 18.28.

7-Heptynal ***24***

Phenylimino oxadiazoline **19** (0.0129 g, 0.5 mmol) was added to ethylene glycol (5 ml) at 140°C. The reaction mixture was heated for 5 h under a nitrogen atmosphere, cooled to 20°C, diluted with H_2O, and extracted with ether (4 × 20 ml). The combined ethereal extracts were washed with brine, H_2O, and dried. The residue was treated with 2,4-DNP reagent (9 ml) at ambient temperature for 24 h. The 2,4-DNP was isolated by extraction with CH_2Cl_2 and plc on silica gel using 1:1 ether–hexane as eluant. The 2,4-DNP of 7-heptynal (**24**) was obtained in 74% yield (0.107 g), mp 103–103.5°C from methanol; ^{1}Hmr δ: 1.40–1.93 (m, 4H, CH_2), 1.99 (t, J = 2 Hz, 1H, C≡CH), 2.1–2.67 (m, 4H, CH_2), 7.6 (t, J = 5 Hz, 1H, CH=N), 7.97 (d, J = 10 Hz, 1H, ArH), 8.34 (dd, J = 10 and 2 Hz, 1H, ArH), 9.16 (d, J = 2 Hz, 1H, ArH), 11.5 (s(b), 1H, NH); ir: 3310 (m, C≡CH), 2115 (w, C≡C), 1620 (s, C=N); *Anal.* calcd. for $C_{13}H_{14}N_4O_4$: C 53.79, H 4.86, N 19.30; found: C 53.58, H 4.92, N 19.03.

8,8-Ethylenedioxy-1-heptyne ***25***

Phenylimino oxadiazoline **19** (0.025 g, 0.10 mmol) was heated in ethylene glycol (5 ml) containing *p*-toluenesulfonic acid monohydrate (12 mg) at 150°C for 0.25 h. The reaction mixture was cooled to 20°C, poured into saturated aqueous sodium bicarbonate solution, and extracted with ether. After drying the solvent was removed by careful distillation and the residue subjected to plc on silica gel using 1:1 ether–hexane as eluant, to give **25** (7.3 mg, 47%); ^{1}Hmr δ: 1.42–1.83 (m, 6H, CH_2), 1.89 (t, J = 2 Hz, 1H, C≡CH), 2.07–2.33 (m, 2H, CH_2), 3.81–4.06 (m, 4H, CH_2), 4.89 (m, 1H, O—CH—O); ir: 33.0 (m, C≡CH), 2115 (w, C≡C).

Thermolysis of Phenylimino Oxadiazoline ***27***

Phenylimino oxadiazoline **27** (0.33 g, 0.97 mmol) was heated under vacuum at 170°C for 0.75 h. The residue was chromatographed by plc on silica gel using 1:2 ether–hexane as eluant to give α,β-epoxyketone **26** (34 mg) and aldehyde **25** (10) (15 mg); ^{1}Hmr δ: 0.90 and 1.00 (s, 6H, *gem*-dimethyl), 1.20–2.43 (m, 8H, CH_2 and CH_3, latter at 1.61d, J = 1.5 Hz), 5.72 (m, 1H, C=CH), 9.52 (d, J = 6 Hz, 1H, CHO); ir: 2720 (w aldehydic CH), 1715 (s, C=O).

Evidence for five-coordination in titanium(IV) complexes. A nuclear magnetic resonance investigation

ARPAD SOMOGYVARI AND NICK SERPONE

Department of Chemistry, Sir George Williams Campus, Concordia University, Montreal, P.Q., Canada H3G 1M8

Received August 11, 1977

ARPAD SOMOGYVARI and NICK SERPONE. Can. J. Chem. **56**, 316 (1978).

Diketonato complexes of titanium(IV), $(X_3Ti(dik))_2$ (X = Cl, Br; dik = anions of dipivaloylmethane and benzoylacetone), of apparent five-coordinate stoichiometry have been prepared and investigated in nitrobenzene solutions using the variable temperature nuclear magnetic resonance technique. The nmr spectra reveal the existence of two equilibrium species; a five-coordinate $X_3Ti(dik)$ and a six-coordinate $X_2Ti(dik)_2$ complex. The data are interpreted in terms of a symmetric dissociation of the six-coordinate titanium(IV) dimer, $(X_3Ti(dik))_2$, into two five-coordinate monomers which then undergo a disproportionation reaction to the four-coordinate titanium tetrahalide and the six-coordinate $X_2Ti(dik)_2$ species.

ARPAD SOMOGYVARI et NICK SERPONE. Can. J. Chem. **56**, 316 (1978).

On a préparé des complexes dicétonato du titane (IV), $(X_3Ti(dik))_2$ (X = Cl, Br; dik = les anions du dipivaloylméthane et de la benzoylacétone), qui possèdent apparemment une stoechiométrie pentacoordonnée; on les a aussi étudié en solution dans le nitrobenzène en faisant appel à la technique de la résonance magnétique nucléaire à température variable. Les spectres rmn indiquent la présence de deux espèces en équilibre; un complexe pentacoordonné $X_3Ti(dik)$ et un complexe hexacoordonnée $X_2Ti(dik)_2$. On interprète les données en termes d'une dissociation symétrique du dimère hexacoordonné du titane (IV), $(X_3Ti(dik))_2$, en deux monomères pentacoordonnés qui subissent alors une réaction de disproportionation conduisant à un tétrahalogénure de titane tétracoordonné et à des espèces hexacoordonnées $X_2Ti(dik)_2$.

[Traduit par le journal]

Introduction

The characterization of titanium(IV) complexes possessing six-coordinate (1, 2) geometry has been the object of much activity. In contrast, the corresponding five-coordination in these species has received less attention in the light of current interest in less common coordination geometries (3–7).

Apparent five-coordination for titanium(IV) has been postulated by Yamamoto and Kambara (8) and by Mehrotra and co-workers (9–11) for various alkoxy $(OR)_3Ti(dik)$ and $Cl_3Ti(acac)$ complexes (dik = a 1,3-diketonate anion; acac = anion of acetylacetone) on the basis of elemental analyses, infrared spectra, and chemical reactions. Later, after a systematic characterization (molecular weights and molar conductivities in nitrobenzene and benzene) of several diketonate $X_3Ti(dik)$ complexes, Thompson,[1] and Thompson, Somers, and Workman (12) concluded that these species of stoichiometry $X_3Ti(dik)$ are monomeric and nonelectrolytes. Holloway and Sentek (13), on the other hand, have suggested that this apparent five-coordination in titanium(IV) may actually be an equilibrium mixture of the more familiar four- and six-coordinate complexes, weakly associated in solution according to

[1] $$(dik)_2TiX_2 + TiX_4 \rightleftharpoons (dik)_2TiX_2TiX_4$$

reaction 1 in which the two titanium atoms are bridged by the two X ligands.

To establish the stereochemistry of these apparent five-coordinate species, we (14, 15) recently undertook a study of the crystal and molecular structure of one such $X_3Ti(dik)$ species. In particular, when X is Cl and dik is acac, the solid state structure of di-μ-chlorotetrachlorobis(acetylacetonato)dititanium(IV) consists of a cyclic dimer with the two titanium(IV) atoms linked by two chlorine bridges, and the observed space group ($P2_1/n$) requires this dimer to be centrosymmetric and not as suggested in reaction 1. It appears therefore that a structural disproportionation must take place upon dissolution of the dimer to be consistent with the monomeric and non-ionic nature of these species in solution. In agreement with this expectation, nmr and infrared spectral evidence suggests that $Cl_3Ti(bzac)$ is five-coordinate in nitrobenzene solutions and is involved in the equilibrium (16)

[2] $$2\ Cl_3Ti(bzac) \rightleftharpoons TiCl_4 + Cl_2Ti(bzac)_2$$

In a more recent study on the stereochemical nature of $(OR)_3TiL$, where L is a uninegative bidentate ligand with an ethane backbone (e.g., Me_2NCH_2-CH_2NMe), Alyea and Merrell (17) report that some

of these species truly represent pentacoordinate titanium(IV) complexes in solutions and, further, have questioned the validity of equilibria 1 and 2 above.

In an attempt to verify this five-coordination in titanium(IV) complexes, we have investigated the nature of the species $X_3Ti(dik)$, where X is Cl or Br and dik is bzac or dpm, in nitrobenzene solutions using the variable temperature nuclear magnetic resonance technique.

Experimental

Titanium tetrachloride (Fisher Certified Reagent), titanium tetrabromide (Alfa), and Aldrich benzoylacetone were used without further purification. Dipivaloylmethane was prepared[2] by reacting pinacolone (Aldrich) with phenyl pivalate in the presence of $NaNH_2$ in ether. The dimeric species $(X_3Ti(dik))_2$ (X = Cl, Br; dik = bzac, dpm) were synthesized from procedures reported earlier (15). Their purity was checked by nmr and infrared spectra, and by melting point determinations.[1] The corresponding six-coordinate $X_2Ti(dik)_2$ complexes were prepared by standard methods (18). Nitrobenzene (Fisher Reagent) was purified by a modified procedure of that of Taylor and Krauss (19), and stored over molecular sieves (Linde, 4A). A nmr spectrum of this solvent revealed no impurities even under very high amplification.

Syntheses, handling of compounds, and subsequent physical measurements were carried out under anhydrous conditions in an inert nitrogen atmosphere.

Infrared spectra were taken on a Perkin-Elmer 457 grating spectrophotometer as Nujol mulls between KBr windows.

Variable temperature nuclear magnetic resonance spectra were recorded in the temperature range 28–100°C with a high resolution Varian A60-A nmr spectrometer operating at 60 MHz, and equipped with a V-6040 variable temperature controller. All spectra were taken from samples in vacuum-sealed tubes. The sweep width of the spectrometer was calibrated against a standard sample of $CHCl_3$–TMS in carbon tetrachloride. Temperatures were estimated with the Van Geet (20) equations. Reported chemical shifts are believed accurate to ±0.01 ppm.

[2]We thank Prof. R. C. Fay for providing us with the recipe.

Results and Discussion

Nuclear magnetic resonance spectra for the four titanium(IV) species, $X_3Ti(dik)$, in nitrobenzene solution are depicted in Fig. 1. While conductivity and molecular weight data[1] (16) are consistent with non-ionic and monomeric five-coordinate $X_3Ti(dik)$ (X = Cl, Br; dik = bzac, dpm) complexes, the proton resonance spectra indicate two methyl proton resonances of unequal intensity. Consideration of the parentage of these resonances suggests that the species in solution are neither the dimer $(X_3Ti(dik))_2$, nor the monomer alone possessing a trigonal bipyramidal or a square pyramidal stereochemistry. The observation of two such proton signals of different intensity implies the presence of two distinct ketoenolate species. To identify these two species, an experiment was carried out in which solutions were made up containing (*i*) only the 'dimer,' (*ii*) only the corresponding six-coordinate $X_2Ti(dik)_2$, (*iii*) a mixture of the 'dimer' and $X_2Ti(dik)_2$, and (*iv*) the 'dimer' and the parent titanium tetrahalide. The results have been summarized in Table 1.

When X is Cl and dik is dpm, the methyl proton spectrum of solution *i* reveals a signal at 1.38 and one at 1.28 ppm. The latter resonance corresponds closely to the chemical shift of the time-averaged methyl signal of $Cl_2Ti(dpm)_2$. Also, the sample with the mixture 'dimer' and $Cl_2Ti(dpm)_2$ shows only two methyl group resonances with chemical shifts 1.38 and 1.29 ppm, albeit with a different intensity ratio from that of solution *i*. Moreover, the sample containing the 'dimer' and an excess of $TiCl_4$ reveals only *one* methyl proton signal at 1.38 ppm.

For personal use only.

Analogously, in the case of $Br_3Ti(dpm)$ resonances are observed at 1.40 and 1.29 ppm; the time-averaged methyl signal for $Br_2Ti(dpm)_2$ occurs at 1.29 ppm. Addition of the six-coordinate complex to solution *i* shows signals also at 1.40 and 1.28 ppm, whereas addition of an excess of $TiBr_4$ to solution *i* quenches the upfield resonance. When X is Cl and dik is bzac, our data (Table 1) are in agreement with those reported by Thompson *et al.* (16). Interestingly, the nmr spectrum (16) of $Cl_2Ti(bzac)_2$ in nitrobenzene containing an excess of $TiCl_4$ shows only a single resonance whose chemical shift (2.56 ppm) corresponds closely to that of the downfield signal (2.53 ppm) observed for the sample containing the 'dimer' alone. Lastly, in the case of $Br_3Ti(bzac)$, the methyl nmr spectrum reveals signals at 2.48 and 2.38 ppm.

On the basis of the above data (see Table 1), the upfield resonance line in the spectrum of solution *i* is attributed to the methyl groups of the six-coordinate $X_2Ti(dik)_2$ complex, while the downfield signal is assigned to the methyl groups of the five-coordinate $X_3Ti(dik)$ species. We interpret[3] the experimental evidence in terms of the following scheme in

$$[3]\quad (X_3Ti(dik))_2 \xrightarrow{PhNO_2} 2\,X_3Ti(dik) \rightleftharpoons X_2Ti(dik)_2 + TiX_4$$

which dissolution of the dimer leads to a symmetric cleavage of the TiX_2Ti bridge bonds in the dimeric structure (15) to yield the five-coordinate complex. The latter subsequently disproportionates, probably via a rapid intermolecular ligand exchange process, to give the six-coordinate $X_2Ti(dik)_2$ and four-coordinate TiX_4 species in equilibrium with $X_3Ti(dik)$. The small resonance line (noted x) in Fig. 1 is observed for the dpm complexes only, and can be attributed neither to a solvent impurity nor to the free ligand as the methyl resonance of dipivaloylmethane occurs upfield (1.20 ppm) from the highest field signal. If this resonance were attributable to the dimer, it would indicate that the dimer is not involved in the equilibrium reaction.

Chemical evidence also lends credence to the above scheme [3]. First, the five-coordinate species can be prepared either by reacting TiX_4 with Hdik in a 1:1 molar ratio or by reacting the six-coordinate $X_2Ti(dik)_2$ complexes with TiX_4 also in a 1:1 molar ratio (12, 15). Second, a solution of $X_3Ti(dik)$ reacts with a variety of other ligands[4] (e.g., 1,3-diketones, pyridines, phosphines, etc.) to give six-coordinate species. Third, Frazer and Rimmer (21) have also reported evidence for equilibrium 4

$$[4]\quad Cl_2Sn(C_6H_9NO)_2 + SnCl_4 \rightleftharpoons 2\,Cl_3Sn(C_6H_9NO)$$

where C_6H_9NO is the quinolate anion.

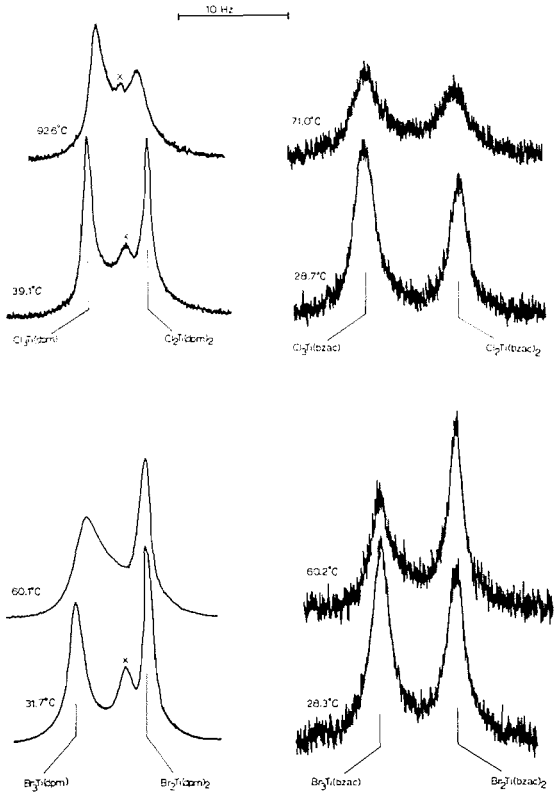

FIG. 1. The 50 Hz methyl proton resonance spectra for the $X_3Ti(dik)$ species investigated. For the significance of the small resonance denoted x in the dpm spectra, see text.

[3]A referee has suggested that the equilibrium in reaction 3 could equally be represented as a fluxional dimer breaking symmetrically to give the six- and four-coordinate species, and that the dimer merely represents an unstable intermediate state. We wish to point out, however, that to get the $X_2Ti(dik)_2$ and TiX_4 species, the dimer would have to undergo intramolecular ligand exchange *prior* to the asymmetric breakup to produce as some intermediate state a dimeric species of the type shown in equilibrium 1 (see text). Unfortunately, the solubility of the $(X_3Ti(dik))_2$ dimer precludes studies designed to distinguish between the two types of cleavage.

Synthesis of cyclohexapyrrolizidines: *C*-methylation of vinylogous amides

RONALD B. KELLY AND SANDRA J. ALWARD

Department of Chemistry, University of New Brunswick, P.O. Box 5050, Saint John, N.B., Canada E2L 4L5

Received September 8, 1977

RONALD B. KELLY and SANDRA J. ALWARD. Can. J. Chem. **56**, 320 (1978).

A synthesis of the cyclohexapyrrolizidines **32** and **33** is described; the structure of the latter was determined by X-ray crystallography. It is anticipated that this synthesis will serve as a model for the construction of a similar pyrrolizidine system during a projected synthesis of thelepogine **2**.

A convenient method for the *C*-methylation of cyclic vinylogous amides is also described. This procedure, which is similar to published procedures, affords high yields of methylated product and is regiospecific.

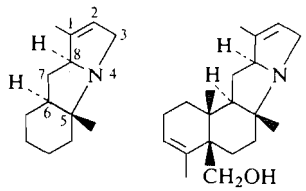
RONALD B. KELLY et SANDRA J. ALWARD. Can. J. Chem. **56**, 320 (1978).

On décrit une synthèse des cyclohexapyrrolizidines **32** et **33**; on a déterminé la structure du dernier composé par crystallographie de rayon-X. On croit que cette synthèse pourra servir de modèle dans la préparation d'un système pyrrolizidine semblable au cours d'une synthèse en voie d'élaboration de la thélépogine **2**.

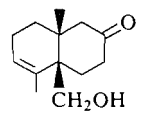
On décrit aussi une méthode convenable de *C*-méthylation d'amides vinylogues cycliques. Cette méthode, qui est semblable à celles qui ont déjà été publiées, fournit de bons rendements de produit méthylé et elle est régiospécifique.

[Traduit par le journal]

The cyclohexapyrrolizidine derivative **1** represents a moiety of the novel structure assigned to the diterpenoidal alkaloid thelepogine **2** (1). For this reason we are interested in devising methods for the synthesis of such cyclohexapyrrolizidine systems. Another structural moiety of thelepogine, the



1 **2**

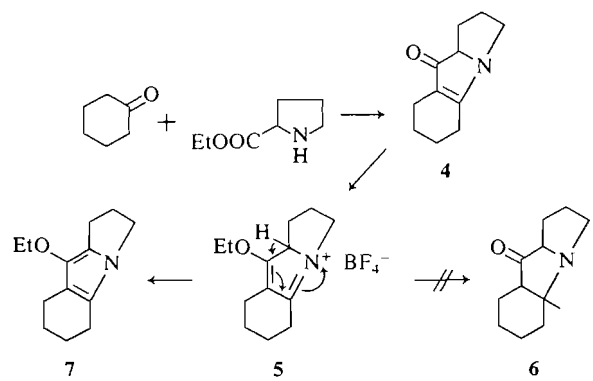


3

stereospecific synthesis of which has recently been described by us (2), is the octalone **3**. Obviously, the successful fusion of the appropriate pyrollizidine moiety onto **3** would constitute a total synthesis of thelepogine. With this in mind we undertook some model studies, substituting cyclohexanone for **3**, which were aimed at the delineation of methods for the conversion of **3** into thelepogine. We now wish to describe some aspects of this work.

Our initial approach involved the utilization of our experience with the condensation of cyclic ketones with cyclic β-amino esters (3). Such condensations afford vinylogous amides as the result of internal enamine acylations (3). Applied to the present work, this approach is illustrated in Scheme 1.

The vinylogous amide **4**, possessing the required tricyclic system, was prepared from cyclohexanone and ethyl prolinate by a procedure similar to those already described (4). We then attempted to introduce the angular methyl group by the sequence shown in Scheme 1 and thereby obtain **6**. This involved converting **4** to the iminium salt **5** by treatment with triethyloxonium fluoroborate (Meerwein's reagent (5)). The appearance of bands at 1620 and 1525 cm^{-1} attests to the successful formation of the iminium salt. The salt **5**, however, failed to undergo alkylation with either methyl lithium or methyl magnesium iodide, as demonstrated by the absence in the nmr spectrum of any signal for a methyl group. The properties of the crude intractable product are in accord with structure **7** which



7 **5** **6**

SCHEME 1

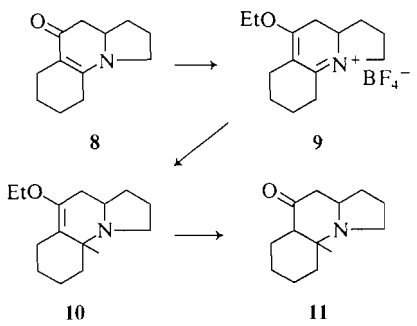
possesses a substituted pyrrole nucleus and would likely be impervious to methylation by the procedure employed. The ir spectrum of the crude product showed bands at 1655 and 1590 cm^{-1} attributable to pyrrole double bonds. The formation of **7** from **5** can be explained in terms of abstraction of the methine proton next to the nitrogen atom by the reagents (methyl lithium or methyl magnesium iodide) followed by bond rearrangement as indicated in **5**. Thus, the inherent basicity of the methylating agents precluded the methylation of **4** to give **6**.

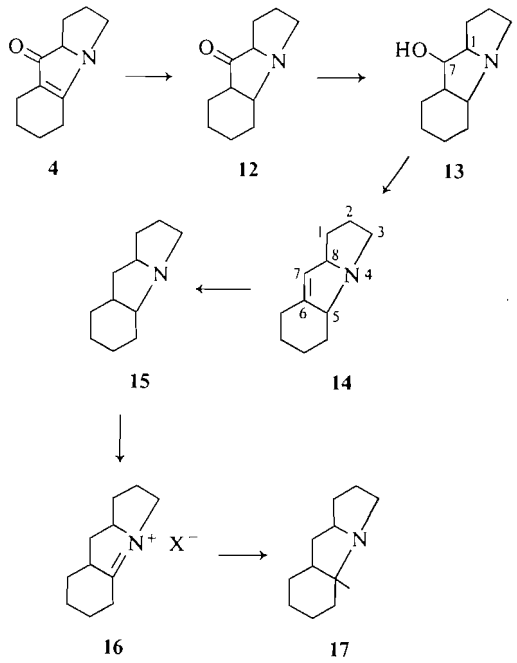
The failure of **4** to undergo methylation by the sequence just described (Scheme 1) is in direct contrast to the behavior of its analog **8** (*3b*, see Experimental) when subjected to the same sequence (Scheme 2). Treatment of **8** with the Meerwein reagent and subsequent treatment of the resulting iminium salt **9** with methyl lithium afforded the enol ether **10** in 81% yield. A three-proton singlet in the nmr spectrum of **10** revealed the presence of the angular methyl group. Treatment of **10** with ethanolic hydrochloric acid and purification of the product through the picrate afforded **11** (ν_{max} 1700 cm^{-1}; nmr δ 0.75 (s, 3H, angular CH_3) in 74% yield. The methylation of **8** in good yield, as described above, and reports (6) of similar alkylations demonstrates the usefulness of this approach for the *C*-alkylation of vinylogous amides.

Despite the failure to methylate **4**, it was hoped that this enamino ketone would yet prove to be a useful intermediate and that it might be transformed, by a different approach, into **1** or stereoisomers thereof. To this end, it was envisaged that **4** could be reduced to the amine **15** which might then be oxidized to the iminium salt **16**. Methylation of the latter would afford **17** which might be oxidized to provide functionality for the introduction of the vinylic methyl group (Scheme 3).

The amine **15** was obtained without difficulty by the following sequence (Scheme 3). The enamino ketone **4** was reduced with sodium in liquid ammonia to the amino ketone **12** (ν_{max} 1740 cm^{-1})



SCHEME 2



SCHEME 3

which was reduced quantitatively to the crystalline amino alcohol **13** (ν_{max} 3050 cm^{-1} (hydrogen bonded OH); nmr δ 3.58 (m, 1H, proton at C-7)). Dehydration of **13** gave the olefin **14** (ν_{max} 1660 cm^{-1}; nmr δ 5.18 (s, 1H, vinylic proton)). The assignment of the double bond in **14** to the 6–7 position rather than the 7–8 position is based on the absence of bands attributable to a conjugated enamine in the ir spectrum.

Hydrogenation of **14** over a platinum catalyst in ethanol containing hydrochloric acid afforded, quantitatively, the hydrochloride of **15** from which the free amine was obtained. The ir and nmr spectra of **15** provided evidence for the absence of an olefinic bond. Unfortunately, we were unable to satisfactorily oxidize **15** to the iminium salt **16** and were therefore obliged to abandon this approach.

Eventually, application of the sequence outlined in Scheme 4 resulted in a synthesis of **32** and **33**, stereoisomers of **1**. The fact that these two isomers, rather than **1** and its C_8 epimer, were the end products of the model studies is the consequence of the arbitrary choice of the intermediate *cis*-isomer **22** rather than the *trans*-isomer **21**. This choice was made under circumstances whereby we were unable to distinguish between the two intermediates. It was only after completion of the model synthesis that X-ray crystallographic studies[1] on the picrolonate of one of the end products revealed that it had

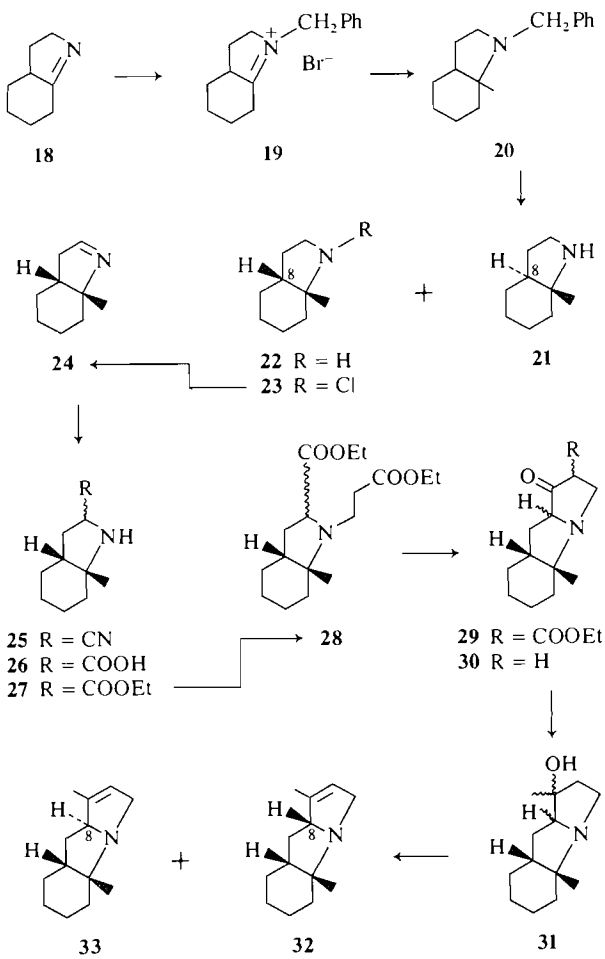
[1]P. White and E. Stanley. To be published.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

stereostructure **33** and that we had therefore chosen the *cis*-isomer **22**. The structures assigned to **21**, **22** and all succeeding compounds in Scheme 4 are based on structure **33**.

It was felt that, with the completion of the synthesis of **32** and **33**, the model studies had served their purpose in that the sequence outlined in Scheme 4 could as well be applied to the intermediate **21**. In the latter case the expected end products would be **1** and its C_8 epimer.

The sequence outlined in Scheme 4 was carried out as follows. The hexahydroindole **18**, prepared from cyclohexanone by a published procedure (7), was converted into the iminium salt **19** by treatment with benzyl bromide. Treatment of **19** with methyl magnesium iodide afforded the angularly methylated perhydroindole **20**, subsequently found to be a mixture of *cis*- and *trans*-isomers. A three-proton singlet in the nmr spectrum at δ 1.07 attested to the presence of the angular methyl group in **20**.



SCHEME 4

Removal of the benzyl group from **20** by hydrogenolysis afforded a mixture of two isomeric amines, **21** and **22**. The presence of two three-proton singlets at δ 1.00 and 1.12 in the nmr spectrum of the hydrogenolysis product revealed the presence of the two amines and showed that **20** was also a mixture of two isomers. Fractional crystallization of the hydrochlorides derived from the hydrogenolysis product left an essentially pure hydrochloride (40%) in the mother liquors which was later shown to be the hydrochloride of **22** (*vide supra*).

The *cis*-amine **22** was transformed, via the chloroamine **23** into the imine **24**. Cyanation of **24** afforded the epimeric amino nitriles **25**. The presence of epimers in the cyanation product was revealed by the appearance of two cyano bands at 2250 and 2200 cm^{-1} in the ir spectrum and two methyl singlets at δ 1.13 and 1.20 in the nmr spectrum.

Hydrolysis of **25** to the corresponding acid **26** followed by esterification afforded the amino ester **27**, also as a mixture of epimers (two methyl singlets at δ 1.12 and 1.18). Condensation of the epimeric mixture **27** with ethyl acrylate afforded a mixture of epimeric diesters, **28**. Cyclization of **28** afforded the keto ester **29**, which after saponification and decarboxylation of the acid gave the epimeric amino ketones **30**. Treatment of **30** with methyl lithium gave a mixture of isomeric alcohols **31** the nmr spectrum of which displayed three methyl singlets at δ 1.17, 1.27 and 1.30.

Finally, dehydration of the mixture of alcohols **31** followed by chromatography of the product on alumina afforded two amines one of which was shown, by X-ray crystallography (*vide supra*), to possess stereostructure **33**. The other amine could therefore be assigned stereostructure **32**.

Experimental

Instrumentation, Methods, and Materials

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. The ir spectra were recorded on a Perkin-Elmer model 237B spectrophotometer and uv spectra were determined with a Perkin-Elmer Coleman model 124 instrument. The nmr spectra were recorded with a Varian T-60 instrument; chemical shifts were expressed in ppm (δ values) downfield from the signal for tetramethylsilane which is used as an internal standard.

Petroleum ether refers to the fraction with boiling point range 30–60°C.

Brine refers to a saturated solution of sodium chloride.

Enamino Ketone **4** *(cf. ref. 4)*

A solution of 2.0 g of ethyl prolinate, 1.6 g of cyclohexanone and a few crystals of *p*-toluenesulfonic acid in 18 ml of dry benzene was refluxed, under nitrogen, for 68 h. Water produced was absorbed by molecular sieve (Linde, type 4A) in a small Soxhlet apparatus. The appearance and gradual increase in intensity of a peak at 334 nm in the uv spectrum was observed. Evaporation of the solvent and distillation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

residue *in vacuo* afforded 1.73 g (70%) of **4** as an oil, bp 136–138°C (0.9 Torr), (lit. (*4a*) bp 150°C (2.5 Torr)); λ_{max} (EtOH): 334 nm (ε 9000); ν_{max} (film): 1670 and 1595 cm^{-1} (vinylogous amide); nmr (CCl_4) δ: 3.07 (m, 2H, N—CH_2), 3.60 (m, 1H, N—CH); *m/e* calcd. for $C_{11}H_{15}NO$: 177; found: 177.

Attempted Formation of Amino Ketone 6

A solution of 177 mg of **4** (4) in 2 ml of methylene chloride was added, under nitrogen, to a solution of 190 mg of Meerwein's reagent (5) in 7 ml of methylene chloride at room temperature. The mixture was stirred for 1 h and left to stand overnight. The solvent was evaporated *in vacuo* to give the iminium salt **5**, ν_{max} (film) 1620 and 1525 cm^{-1} (conjugated iminium salt).

A solution of the iminium salt in 5 ml of ether was cooled in an ice bath and treated with 2 ml of an ether solution of 2.2 *M* methyl lithium. The mixture was stirred at room temperature for 5 h and then the excess methyl lithium was destroyed with 15 ml of saturated aqueous ammonium chloride. Work-up in the usual manner with ether, 1 *M* ammonium hydroxide and brine gave 183 mg of intractable oil with spectral properties indicative of **7**, ν_{max} (film): 1655 and 1590 cm^{-1} (pyrrole double bonds); nmr (CCl_4) δ: 1.22 (t, J = 6.5 Hz, 3H, OCH_2—CH_3) and 3.63 (q, J = 6.5 Hz, OCH_2—CH_3).

The same results were obtained when the preceding reaction was repeated employing methylmagnesium iodide as the alkylating agent.

Enamino Ketone 8

A solution of 2.35 g of ethyl 2-pyrrolidineacetate, 0.63 ml of trifluoroacetic acid, 2.2 g of cyclohexanone, and 47 ml of dry toluene was refluxed under a nitrogen atmosphere for 28 h. Water formed during the reaction was absorbed by Linde, type 4A, molecular sieve in a Soxhlet apparatus. The solution was worked up in the usual manner with benzene, saturated sodium bicarbonate solution, and water. The benzene extracts were dried over anhydrous potassium carbonate and evaporated *in vacuo* to give 3.06 g of oil. Crystallization from ether – petroleum ether yielded 1.83 g (64%) of **8**, mp 48–49°C; λ_{max} EtOH: 343 nm (ε 14 800); ν_{max} ($CHCl_3$): 1603 and 1540 cm^{-1} (vinylogous amide); nmr ($CDCl_3$) δ: 3.45 (m, 3H, N—CH_2 and N—CH). *Anal.* calcd. for $C_{12}H_{17}NO$: C 75.30, H 8.95, N 7.32; found: C 75.48, H 8.56, N 7.15.

Enol Ether 10 and Amino Ketone 11

The enamino ketone **8** (573 mg) was converted, via the iminium salt **9**, to the enol ether **10** by the same procedure as was attempted in the case of the enamino ketone **4** (*vide supra*). Utilization of methyl lithium as the alkylating agent gave 570 mg of **10** (81%) as an oil, ν_{max} (film): 1670 cm^{-1} (olefin); nmr (CCl_4) δ: 0.93 (s, 3H, angular methyl), 1.13 (t, J = 6.0 Hz, 3H, OCH_2—CH_3) and 3.55 (q, J = 6.0 Hz, 2H, OCH_2—CH_3).

A solution of 1.1 g of **10**, 66 ml of ethanol and 45 ml of 1 *M* aqueous hydrochloric acid was refluxed for 4 h. The ethanol was evaporated *in vacuo* and the aqueous solution worked up in the usual manner with methylene chloride, 1 *M* ammonium hydroxide and brine to give 650 mg (74%) of **11** as an oil, ν_{max} film): 1700 cm^{-1} (ketone); nmr (CCl_4) δ: 0.75 (s, 3H, angular methyl).

The amino ketone **11** was analysed as its picrate, mp 225°C. *Anal.* calcd. for $C_{19}H_{24}N_4O_8$: C 52.29, H 5.54, N 12.84; found: C 52.16, H 5.42, N 12.74.

Amino Ketone 12

A solution of 2.01 g of **4** (4) in 50 ml of dry tetrahydrofuran was added dropwise to 0.8 g of lithium in 280 ml of liquid ammonia. After stirring on a Dry Ice – acetone bath for 2 h, excess reagent was destroyed by the addition of solid ammonium chloride and the ammonia was allowed to evaporate at room temperature. To the residue was added 500 ml of ice water and the resulting aqueous solution was acidified with 1 *N* hydrochloric acid, washed with ether, rendered alkaline with 1 *M* sodium carbonate and extracted with methylene chloride. The methylene chloride extracts were evaporated and the resulting residue was converted in the usual manner to a crystalline picrate derivative. The amino ketone **12** (1.07 g) was obtained from the picrate as an oil, ν_{max} (film): 1740 cm^{-1}, and was analysed as the picrate, mp 202°C. *Anal.* calcd. for $C_{17}H_{20}N_4O_8$: C 50.00, H 4.94, N 13.72; found: C 50.32, H 4.95, N 13.72.

Amino Alcohol 13

A mixture of 610 mg of **12**, 750 mg of lithium aluminum hydride, and 120 ml of ether was refluxed under a nitrogen atmosphere overnight. The excess lithium aluminum hydride was destroyed with aqueous sodium sulfate solution and the resulting mixture was stirred for 1 h. Then anhydrous sodium sulfate was added and the mixture was stirred for another 30 min. The residue was removed by filtration and washed with methylene chloride. The filtrate was evaporated *in vacuo* to give 616 mg (100%) of the amino alcohol **13**, mp 114–117°C; ν_{max} (Nujol): 3050 cm^{-1} (OH); nmr (DMSO) δ: 3.58 (m, 1H, *CH*—OH) and 4.30 (broad singlet, 1H, hydroxyl). *Anal.* calcd. for $C_{11}H_{19}NO$: C 72.88, H 10.56, N 7.73; found: C 72.42, H 10.49, N 7.78.

Enamine 14

The alcohol (**13**, 2.21 g) was dissolved in 65 ml pyridine and cooled in an ice bath. Then 5.2 ml of phosphorous oxychloride was added and the mixture was kept in the dark at room temperature for 20 h. The solution was then added to 200 ml of ice water and stirred for 15 min. After basifying with 1 *M* sodium carbonate, the resulting aqueous solution was worked up in the usual manner with methylene chloride and 1 *M* sodium carbonate to give 1.356 g (68%) of **14** as an oil, ν_{max} (film): 1660 cm^{-1} (olefin); nmr ($CDCl_3$) δ: 5.18 (m, 1H, vinylic proton).

The enamine **14** was analysed as its picrate, mp 165–167°C. *Anal.* calcd. for $C_{17}H_{20}N_4O_7$: C 52.03, H 5.15, N 14.28; found: C 52.20, H 5.36, N 14.52.

Amine 15

A mixture of 106 mg of **14** and 80 mg of platinum oxide, in 10 ml of ethanol with a few drops of hydrochloric acid, was hydrogenated at 4 atm pressure for 3 h. The mixture was filtered to remove the catalyst and the catalyst was washed with methanol. Evaporation of the filtrate *in vacuo* gave 140 mg (100%) of the hydrochloride of **15**, mp 195–200°C. *Anal.* calcd. for $C_{11}H_{20}NCl$: C 65.47, H 10.01, N 6.96, Cl 17.57; found: C 65.31, H 9.93, N 6.88, Cl 17.66.

Extraction of an alkaline sodium carbonate solution of the hydrochloride with methylene chloride gave 98 mg of the amine **15** as a liquid.

Benzyl Amine 20

A solution of 1.23 g of imine **18** (7), 6.13 g of benzyl bromide, and 20 ml of ethanol was refluxed under a nitrogen atmosphere for 90 min. The solvent was evaporated *in vacuo* and the residue washed with dry ether. The residue (**19**) was then treated dropwise with 100 ml of a 1 *M* ether solution of methyl magnesium iodide and the resulting mixture was refluxed for 40 h.

The reaction mixture was then cooled and a saturated solution of ammonium chloride was added. The aqueous phase was diluted with 300 ml of brine, basified with ammonium hydroxide and then worked up in the usual manner

For personal use only.

with ether and brine to give 2.114 g of oil. The oil was purified by column chromatography using grade II neutral alumina with hexane as solvent. This gave 1.513 g (66%) of **20** as an oil, ν_{max} (film): 3000 to 3100, 1600 to 2000, and 700 to 800 cm^{-1} (multiple aromatic bands); nmr ($CDCl_3$) δ: 1.07 (s, 3H, angular methyl), 3.37 and 3.58 (doublets, J = 12 Hz, 1H each N—CH_2—Ph) and 7.20 (m, 5H, aromatic protons).

The benzyl amine **20** was analysed as its hydrobromide, mp 179–180°C. *Anal.* calcd. for $C_{16}H_{24}NBr$: C 61.94, H 7.80, N 4.52; found: C 61.88, H 7.98, N 4.33.

Amine 21

A mixture of 2.17 g of **20**, 800 mg of 10% palladium-on-charcoal and 40 ml of acetic acid was hydrogenated at 4 atm pressure for 3 days. The mixture was filtered to remove the catalyst and the catalyst was washed with methanol. The combined filtrates were treated with 1.5 ml of concentrated hydrochloric acid and the solvent was evaporated *in vacuo*. Acid–base work-up of the residue with ether gave 1.185 g (90%) of the free amine as a mixture of *cis*- and *trans*-isomers **21** and **22**. The nmr indicated an approximate ratio of 3:2 of *cis*:*trans* on the basis of the angular methyl signal which occurs at δ 1.12 in the case of the *cis*-isomer **22** and at δ 1.00 in the case of the *trans*-isomer **21**.

Fractional crystallization of the mixture of hydrochlorides from methylene chloride and ether and subsequent freeing of the amine resulted in the isolation from the mother liquors of the *cis*-amine **22** (40%) as an oil; ν_{max} (film): 3250 cm^{-1} (NH); nmr ($CDCl_3$) δ: 1.12 (s, 3H, angular methyl), 2.40 (s, 1H, NH) and 3.00 (t, J = 6.0 Hz, 2H, N—CH_2).

The amine **22** was analysed as its picrate, mp 216–219°C. *Anal.* calcd. for $C_{15}H_{20}N_4O_7$: C 48.91, H 5.47, N 15.21; found: C 48.89, H 5.53, N 15.17.

Amino Nitrile 25

An ice-cold solution of 112 ml of 0.67 *N* aqueous sodium hypochlorite was treated dropwise with 5.2 g of the *cis*-amine **22** in 7.5 ml of 5 *M* acetic acid. The resulting mixture was immediately extracted with ether and the ether was dried and evaporated *in vacuo* to give the chloroamine **23**.

The chloroamine **23** was added to a hot solution of 2.5 g of potassium hydroxide in 25 ml of 95% ethanol. The mixture was refluxed for 20 min and then stirred at room temperature for 1 h. Water (12 ml) and 4 g of potassium cyanide were added and the reaction mixture was treated dropwise with 82 ml of 1 *N* hydrochloric acid, while cooling in an ice bath. The solution was stirred overnight at room temperature, made alkaline with 2 *N* sodium hydroxide and extracted with methylene chloride. Evaporation of the methylene chloride extracts gave 6 g of oil which was purified by column chromatography on grade III basic alumina with petroleum ether – ether as solvent. This yielded 1.938 g (32%) of the amino nitrile **25** as a mixture of epimers, ν_{max} (film): 3360 (NH), 2250 and 2200 cm^{-1} (CN); nmr ($CDCl_3$) δ: 1.13 and 1.20 (two singlets, 3H, angular methyls of two isomers), 4.03 (t, J = 6.5 Hz, 1H, methine next to nitrogen).

Amino Ester 27

The amino nitrile **25** (1.85 g) was refluxed in 30 ml of 6 *N* hydrochloric acid for 6 h. The solvent was evaporated *in vacuo* to give 3 g of the hydrochloride of the amino acid **26** which was dissolved in 150 ml of ethanol. The alcoholic solution was saturated with hydrogen chloride gas with cooling on an ice bath. The reaction solution was left for 3 h at room temperature and the solvent was evaporated *in vacuo* to give 2.92 g of the hydrochloride of **27**. The amine was freed from its hydrochloride to give 2.4 g (100%) of the amino ester **27**, ν_{max} (film): 3350 (NH) and 1730 cm^{-1} (ester); nmr ($CDCl_3$) δ: 1.12 and 1.18 (two singlets, 3H, angular methyls of two isomers), 1.27 (t, J = 7.0 Hz, 3H, OCH_2—CH_3), 3.83 and 4.16 (q, J = 7.0 Hz, 2H, OCH_2—CH_3).

The amino ester **27** was analysed as its picrate, mp 139–145°C. *Anal.* calcd. for $C_{18}H_{24}N_4O_9$: C 49.09, H 5.49, N 12.72; found: C 49.17, H 5.73, N 12.80.

Amino Ketone 30

A solution of 2.0 g of **27** and 4 ml of ethyl acrylate was heated in a sealed tube at 135°C for 20 h. Acid–base work-up of the product with ether gave 2.22 g (75%) of the amino diester **28** as an oil, ν_{max} (film): 1730 cm^{-1} (ester); nmr ($CDCl_3$) ca. δ: 1.27 (two triplets, J = 7.0 Hz, 3H each, OCH_2—CH_3) and 4.07 and 4.13 (two quartets, J = 7.0 Hz, 2H each, OCH_2—CH_3).

A solution of 700 mg of 57% sodium hydride (oil dispersion) in 35 ml of toluene, under a nitrogen atmosphere, was treated dropwise with 2.1 g of **28** in 35 ml of toluene. The solution was heated at 60°C for 5 h. Then the reaction mixture was extracted with 70 ml of 1 *N* hydrochloric acid and two 35-ml portions of water. The combined aqueous phases were then refluxed for 3 h with 98 ml of a concentrated aqueous solution of hydrochloric acid. Evaporation of the solvent *in vacuo* and trituration of the residue with chloroform gave 1.185 g (76%) of the hydrochloride of the amino ketone **30**.

Extraction of an aqueous alkaline solution of the hydrochloride with ether and evaporation of the extract gave the amino ketone **30**, ν_{max} (film): 1740 cm^{-1} (ketone); nmr ($CDCl_3$) δ: 1.12 (s, 3H, angular methyl), 3.15 (m, 2H, N—CH_2), and 3.63 (m, 1H, N—CH).

The amino ketone **30** was analysed as its picrolonate, mp 156–157°C. *Anal.* calcd. for $C_{22}H_{27}N_5O_6$: C 57.76, H 5.95, N 15.31; found: C 57.37, H 6.03, N 15.36.

Amines 32 and 33

An ice-cold solution of 10 ml of 1.5 *M* methyl lithium (ether solution) in 10 ml of tetrahydrofuran, under a nitrogen atmosphere, was treated dropwise with 400 mg of the hydrochloride of **30** in 20 ml of tetrahydrofuran. The reaction mixture was stirred at room temperature for 22 h. The excess methyl lithium was destroyed with 16 ml of 1 *N* hydrochloric acid and the solvent was evaporated *in vacuo*. The residue was basified with 10 *N* sodium hydroxide and the solution was extracted continuously with methylene chloride for 3 h. The extract was evaporated *in vacuo* to give 358 mg (98%) of amino alcohol **31** as an oil, ν_{max} (film): 3400 cm^{-1} (OH); nmr ($CDCl_3$) δ: 1.17, 1.27 and 1.30 (three singlets, 3H, angular methyls of isomers), 1.73 (s, 1H, hydroxyl proton), 2.80 (m, 2H, N—CH_2) and 3.40 (m, 1H, N—CH).

An ice-cold solution of 500 mg of alcohol **31** in chloroform (5 ml) was treated with phosphorous pentachloride (1.5 g). The reaction mixture was refluxed for 1 h. Acid–base work-up with 1 *N* hydrochloric acid, 10 *N* sodium hydroxide, and methylene chloride gave 381 mg of an oil. Purification of the product by column chromatography on grade II basic alumina (employing petroleum ether, benzene, and ether as solvents) yielded the amino olefins **32** and **33**.

The faster moving isomer **32** (48 mg) was isolated as an oil, ν_{max}: 1650 cm^{-1} (olefin); nmr ($CDCl_3$) δ: 1.18 (s, 3H, angular methyl), 1.70 (d, J = 2 Hz, 3H, vinylic methyl) and 4.88 (m, 1H, vinylic proton); *m/e* calcd. for $C_{13}H_{21}N$: 191; found: 191.

The slower moving isomer **33** (73 mg) was also isolated as an oil; ν_{max} (film): 1640 cm^{-1} (olefin); nmr ($CDCl_3$) δ: 1.12 (s, 3H, angular methyl), 1.68 (d, J = 2.0 Hz, 3H vinylic methyl), 3.57 (m, 2H, N—CH_2), 4.13 (m, 1H, N—CH) and 5.22 (m, 1H, vinylic proton).

The amine **33** was analysed as its picrolonate, mp 222–

225°C. *Anal.* calcd. for $C_{23}H_{29}N_5O_5$: C 60.64, H 6.42, N 15.38; found: C 60.47, H 6.56, N 15.40.

Nucleoside analogs, namely 6-benzamido-9-(3-benzoyl-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidin-5(*S*)-yl)-9*H*-purine (**7**) and 6-chloro-9-[(3-benzoyl-2,2-dimethylthiazolidin-4(*R*)-yl)-methyl]-9*H*-purine (**8**), were obtained from 3-benzoyl-5(*S*)-benzoyloxy-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidine (**23**) and 3-benzoyl-4(*R*)-hydroxymethyl-2,2-dimethylthiazolidine (**24**), respectively, the former, by treatment with 6-benzamidochloromercuripurine and titanium tetrachloride in 1,2-dichloroethane and the latter, by treatment with 6-chloropurine, triphenylphosphine, and diethyl azodicarboxylate in tetrahydrofuran. Compound **23** was obtained from 3-benzoyl-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidine (**13**) by treatment with benzoyl peroxide in refluxing benzene whereas compound **24** was obtained from **13** by borohydride reduction. The stereochemistry of the isomeric sulfoxides **18***a* and **18***b*, obtained from **13** by treatment with *m*-chloroperbenzoic acid, was assigned by means of ^{1}Hmr spectroscopy. Reaction of the sulfoxides **18***a* and **18***b* under the Pummerer-reaction conditions afforded the rearranged product, 4-benzoyl-3(*R*)-methoxycarbonyl-5-methyl-3,4-dihydro-2*H*-1,4-thiazine (**20**). The chiral shift reagent, tris-[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]europium(III), was used to confirm the enantiomeric purity of the key intermediates and the product nucleosides. The carbon-13 nmr spectra of the key compounds are reported.

MASAHARU IWAKAWA, B. MARIO PINTO et WALTER A. SZAREK. Can. J. Chem. **56**, 326 (1978).

On a pu obtenir des analogues de nucléosides, soit la benzamido-6[benzoyl-3 méthoxycarbonyl-4(*R*) diméthyl-2,2 thiazolidinyl-5(*S*)]-9 9*H* purine (**7**) et la chloro-6[(benzoyl-3 diméthyl-2,2 thiazolidinyl-4(*R*))méthyl]-9 9*H* purine (**8**), en faisant réagir d'une part la benzoyl-3 benzoyloxy-5(*S*) méthoxycarbonyl-4(*R*) diméthyl-2,2 thiazolidine (**23**) avec la benzamido-6 dichloro mercuripurine et le tétrachlorure de titane dans le dichloro-1,2 éthane et d'autre part la benzoyl-3 hydroxyméthyl-4(*R*) diméthyl-2,2 thiazolidine (**24**) avec la chloro-6 purine, la triphénylphosphine et l'azodicarboxylate de diéthyle dans le tétrahydrofuranne. On a obtenu le composé **23** à partir de la benzoyl-3 méthoxycarbonyl-4(*R*) diméthyl-2,2 thiazolidine (**13**) par réaction du peroxyde de benzoyle dans le benzène au reflux alors que l'on a obtenu le composé **24** à partir de **13** par réduction avec du borohydrure. On a attribué la stéréochimie des sulfoxydes isomères **18***a* et **18***b*, obtenus à partir de **13** par réaction avec l'acide *m*-chloroperbenzoique, en se basant sur des données de spectroscopie rmn ^{1}H. La réaction des sulfoxydes **18***a* et **18***b* dans des conditions de la réaction de Pummerer fournit un produit de réarrangement, le benzoyl-4 méthoxycarbonyl-3(*R*) méthyl-5 dihydro-3,4 2*H* thiazine-1,4 (**20**). On a utilisé le tris[(trifluorométhylhydroxyméthylène-3) *d*-camphorato] europium(III) pour confirmer la pureté d'énantiomère des intermédiaires clés et des nucléosides obtenus comme produits. On rapporte les spectres rmn ^{13}C des composés clés.

[Traduit par le journal]

Introduction

An active area of research in this laboratory has been the synthesis of novel nucleoside analogs in which the carbohydrate moiety has been replaced with a variety of heterocyclic systems. Thus far, we have reported the synthesis (1, 2) and conformational analysis (3) of nucleoside-base derivatives of six-membered heterocycles, namely 1,4-oxathiane (**1** and **2**), 1,4-dithiane (**3**), 1,4-dioxane (**4**), 1-oxa-4-azacyclohexane (**5**), and 1-thia-4-azacyclohexane (**6**); some of these compounds have exhibited anticancer activity.[2] We now wish to report the synthesis of nucleoside analogs containing a five-membered heterocyclic ring, namely 6-benzamido-9-(3-benzoyl-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidin-5-(*S*)-yl)-9*H*-purine (**7**) and 6-chloro-9-[(3-benzoyl-2,2-dimethylthiazolidin-4(*R*)-yl)-methyl]-9*H*-purine (**8**) from the amino-acid precursor, L-cysteine. It is noteworthy that thiazolidine derivatives having diazo ketone and chloro ketone functions have been investigated as potential antitumor agents (5). Carbon-13 magnetic resonance (Cmr) and proton magnetic resonance (^{1}Hmr) spectroscopic data of all intermediates and product nucleosides are also reported in this paper; these data have been employed for proof of structure and assignment of stereochemistry. We also report the use of the chiral shift reagent, tris-[3-(trifluoromethylhydroxymethylene)-

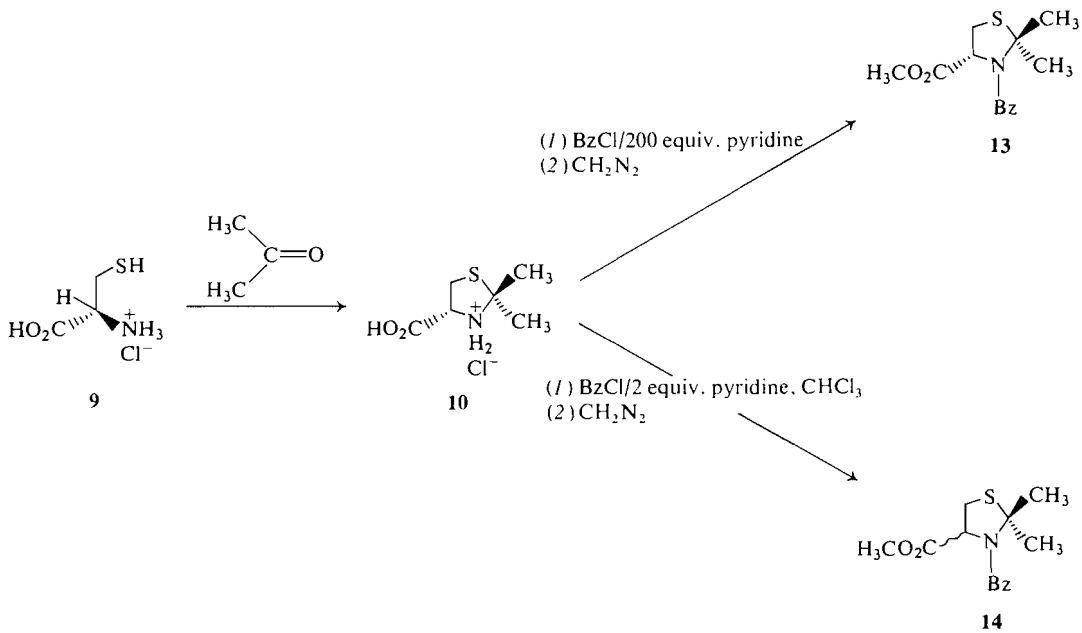
d-camphorato]europium(III), in the confirmation of enantiomeric purity of the key intermediates and the product nucleoside analogs.

Results and Discussion

Commercially available L-cysteine hydrochloride monohydrate (**9**) was readily converted into 2,2-dimethyl-4(*R*)-carboxythiazolidine hydrochloride (**10**) (see Scheme 1) by condensation with acetone (6). Interestingly, the benzoylation of compound **10** yielded results that were dependent on the amount of pyridine used in the reaction. Thus, treatment of **10** with benzoyl chloride in 200 equiv. of pyridine and subsequent methylation of the product **11** with diazomethane (7) afforded 3-benzoyl-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidine (**13**), whereas treatment of **10** with benzoyl chloride in chloroform containing 2 equiv. of pyridine and subsequent methylation of the product **12** with diazomethane afforded a racemic mixture (**14**) of the 4(*R*) and 4(*S*) isomers. It would appear that racemization at C-4 of **10** is a consequence of an equilibrium reaction involving deprotonation and protonation at C-4, possibly by means of an elimination–addition mechanism. The results also seem to suggest that the reaction involving abstraction of H-4 in the zwitterion formed from **10** and the benzoylation reaction are competitive, parallel reactions, although the former process, namely, the abstraction of the hydrogen α to the carboxylate anion, seems unlikely. Nevertheless, the observation that the benzoylation of **10** in an excess of pyridine proceeds with predominant retention of configuration at C-4 suggests that, in this case, the rate of the benzoylation reaction is greatly enhanced relative to the rate of the reaction involving loss of H-4. To gain some understanding of the dependence of the stereochemical outcome of this reaction on the type of system involved, 4(*R*)-carboxythiazolidine hydrochloride (**15**), prepared from L-cysteine hydrochloride monohydrate (**9**) by treatment with formaldehyde (8), was subjected to each of the benzoylation conditions (see Scheme 2). Thus, treatment of **15** with benzoyl chloride in pyridine and subsequent methylation of the product afforded optically active 3-benzoyl-4(*R*)-(methoxycarbonyl)thiazolidine (**16**). Similarly, the optically active compound **16** was obtained upon treatment of **15** with benzoyl chloride in aqueous sodium bicarbonate solution. However,



9 **10** **13** **14**

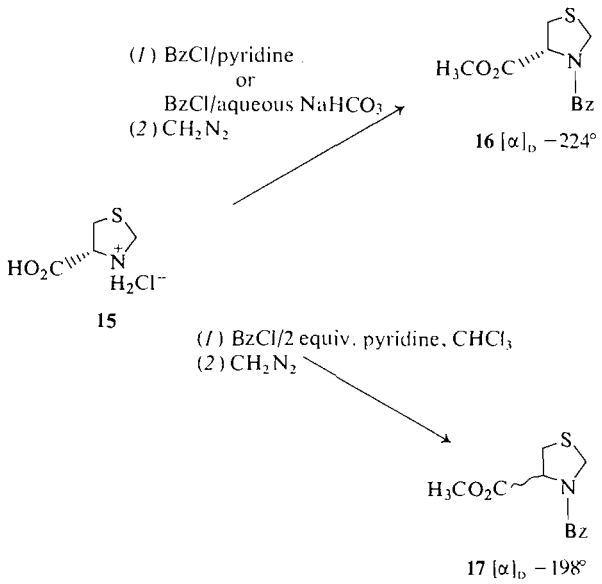

SCHEME 2

when the benzoylation reaction was carried out in chloroform containing 2 equiv. of pyridine, the product **17** obtained after methylation showed a slight loss of optical activity. The lack of total racemization of **15** in this reaction is in contrast to the earlier observation that compound **10** racemizes under the same conditions, a result which is probably indicative of the relative stabilities of the thiazolidine and 2,2-dimethylthiazolidine ring systems. The fact that the thiazolidine system is more stable to ring opening than the 2,2-dimethylthiazolidine system is also evidenced by the decomposition of 2,2-dimethyl-4(*R*)-carboxythiazolidine hydrochloride (**10**) in water to give the constituent amino acid in contrast to the stability of 4(*R*)-carboxythiazolidine hydrochloride (**15**) in water. The enantiomeric purity of 3-benzoyl-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidine (**13**) was confirmed by use (9) of the chiral shift reagent, tris-[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]europium(III). Thus, the nmr spectrum of **13** in chloroform containing 0.2 equiv. of the chiral shift reagent exhibited two singlets for the C-2 methyl resonances, whereas the nmr spectrum of the racemate **14** in chloroform with 0.2 equiv. of the chiral shift reagent exhibited a differential shift of 0.07 ppm between the C-2 methyl resonances in the two enantiomers; interestingly, a separation of only one of the diastereotopic methyl group signals was observed in the spectrum of **14** upon addition of the shift reagent.

Parallel syntheses of the product nucleosides utilizing the optically active compound **13** and the racemic compound **14** as starting materials were performed. The enantiomeric purity of the key intermediates and the product nucleosides was confirmed by their nmr spectra in deuterochloroform containing the chiral shift reagent; in each case, the optimum amount of shift reagent used and the signals that provided differentiation of the enantiomers in the racemic compounds are indicated in the Experimental.

Oxidation of 3-benzoyl-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidine (**13**) with *m*-chloroperbenzoic acid afforded a mixture of the isomeric sulfoxides **18***a* and **18***b* in a ratio of 1.5:1, as indicated by its nmr spectrum. Crystallization from methanol–hexane afforded the pure isomer **18***a* as a white crystalline solid; this permitted the unambiguous assignment of signals to the two isomers **18***a* and **18***b* in the ^{1}Hmr and Cmr spectra of the isomeric mixture of sulfoxides. The chemical shifts and coupling constants obtained from the LAOCN-4A analysis (10) of the two ABX systems, corresponding to the methine and methylene proton signals in **18***a* and **18***b*, in the 220-MHz spectrum recorded at 293 K are given in Table 1. The assignment of sulfoxide stereochemistry in **18***a* and **18***b* was made on the basis of the signs and magnitudes of the sulfoxidation chemical-shift increments ($\Delta\delta H\text{-}i = \delta H\text{-}i^{S\to O} - \delta H\text{-}i^{S}$) of the methine and methylene proton signals in the ^{1}H nmr spectra of the two isomers. Examination of the spectra of **13** and **18***a* shows that the H-4 signal in the spectrum of isomer **18***a* is shifted downfield by 0.6 ppm relative to the corresponding signal in the spectrum of the sulfide **13**. This deshielding has been ascribed to electric field effects and/or the acetylene-like anisotropy of the S=O bond, and is consistent with a *syn*-axial relationship of H-4 to the sulfinyl group (11, 12). In contrast, the spectrum of sulfoxide **18***b* shows that the H-4 signal is shifted downfield by only 0.2 ppm relative to the corresponding signal in the sulfide **13**. The isomer **18***a* is therefore, assigned the *R* stereochemistry and the isomer **18***b* is assigned the *S* stereochemistry at sulfur. An analogous assignment has been made by Jonsson and Holmquist (13) in the case of the isomeric sulfoxides of thiolane-3,4-dicarboxylic acid.

The nmr spectral data recorded in Table 1 also

allow one to comment on the conformational preferences of the thiazolidine ring in the isomeric sulfoxides. Previous studies (14) of the conformations of five-membered rings containing hetero atoms have indicated that the ring may exist in a variety of interconverting pseudorotational forms, although the presence of potential energy barriers in certain systems owing to the nature, number, positions, and steric requirements of the substituents sometimes restricts such pseudorotation and gives rise to preferred conformations of the five-membered ring having definite energy minima (15–17). The diastereotopic methylene proton signals appear in the spectrum of **18***b* at 3.22 and 3.51 ppm; the higher field signal appears as a doublet of doublets with a vicinal coupling constant ($J_{4,5}$) of 7.7 Hz, whereas the lower field signal appears as a broadened doublet with a vicinal coupling constant ($J_{4,5'}$) of about 0 Hz. Examination of Dreiding models suggests a preponderance of conformation B having dihedral angles of 20° and 90°, and the sulfinyl group in a pseudoaxial orientation, as illustrated in Fig. 1. Baldwin *et al.* (18) have suggested the preponderance of the same conformation for a series of similar thiazolidine derivatives. The signal at 3.22 ppm is therefore assigned to the hydrogen at C-5 having a *cis* relationship to H-4, namely, the *pro-R* methylene hydrogen, and that at 3.51 ppm to the *pro-S* methylene hydrogen in isomer **18***b*. In the spectrum of **18***a*, the H-5′ and H-5 signals appear as distinct AB quartets at 3.09 and 3.38 ppm with vicinal coupling constants of 10.3 and 6.9 Hz, respectively. Examination of Dreiding models suggests a preponderance of conformation A (see Fig. 1) having dihedral angles of about 170° and 30°, and the sulfinyl group in a pseudoaxial orientation. Parthasarathy *et al.* (17) have assigned similar twist conformations to the thiazolidine ring, having the S and C(5) atoms displaced in opposite directions with respect to the plane of C(2), N(3), and C(4), in the stable conformers of *N*-acetyl-2-(*p*-tolyl)-thiazolidine 4-carboxylic acid by X-ray and nmr studies; the H(4)—C(4)—C(5)—*pro-R*H(5) torsion angles in the preferred conformers were found to be −31° and −35°, respectively. The signal having the larger vicinal coupling constant may be assigned to the methylene proton having an *anti* relationship to the hydrogen at C-4. Wilson and Bazzone (16) have assigned the larger vicinal coupling constant in the spectrum of 2-*tert*-butyl-1,3-thiazolidine to coupling between protons in a *trans*-diaxial orientation.

18*b* X = Electron pair, Y = O

FIG. 1. Conformational equilibrium in 3-benzoyl-4(*R*)-(methoxycarbonyl)-2,2-dimethylthiazolidine 1(*R*)-oxide (**18***a*) and 3-benzoyl-4(*R*)-(methoxycarbonyl)-2,2-dimethylthiazolidine 1(*S*)-oxide (**18***b*).

The resonance at 3.09 ppm is therefore assigned to the *pro-S* methylene hydrogen and that at 3.38 ppm to the *pro-R* hydrogen in isomer **18***a*. It is interesting to note that the signal of the *pro-R* methylene hydrogen in the spectrum of **18***a* is shifted downfield by 0.29 ppm relative to the signal of the *pro-S* methylene hydrogen, whereas the *pro-S* methylene hydrogen signal in the spectrum of **18***b* is shifted downfield by 0.29 ppm relative to the signal of the *pro-R* methylene hydrogen. Since the magnitude of the chemical shift difference between the methylene hydrogen signals is the same in both isomers (**18***a* and **18***b*), it is indicative of a similar orientation of the lone pair of electrons of the sulfinyl group relative to the α-methylene hydrogens (19) in both isomeric sulfoxides and is consistent with the assignment of the sulfinyl group to the pseudoaxial orientation in both isomers. Further evidence for the similarity in orientation of the lone pair with respect to the methylene hydrogens in **18***a* and **18***b* may be obtained by consideration of the geminal coupling constants in the two isomers. Previous studies (19, 20) have indicated a significant difference in geminal coupling constants for the α-methylene protons when the lone pair was axial or equatorial. In our case, however, the geminal coupling constants in the two isomers differ by only 1.0 Hz. The result is also in accord with the proposed acetylene-like anisotropy of the S=O bond since, in both isomers, the α proton *syn* to the sulfinyl group is deshielded with respect to its diastereotopic counterpart *anti* to the sulfinyl group. This observation is not in agreement with results obtained in some sulfoxides in which the α-proton *syn* to the sulfinyl group was found to be shielded with respect to the α proton *anti* to the sulfinyl group (11, 20), thereby suggesting a carbonyl-like anisotropy of the S=O bond.

Treatment of a mixture of the isomeric sulfoxides **18** with 5 equiv. of acetic anhydride in refluxing benzene containing a trace of *p*-toluenesulfonic acid monohydrate afforded 4-benzoyl-3(*R*)-methoxycarbonyl-5-methyl-3,4-dihydro-2*H*-1,4-thiazine (**20**) and not the Pummerer-reaction product (**19**) (see Scheme 3). A possible mechanism for the conversion of **18** to **20** involves the rearrangement of the sulfoxide **18**

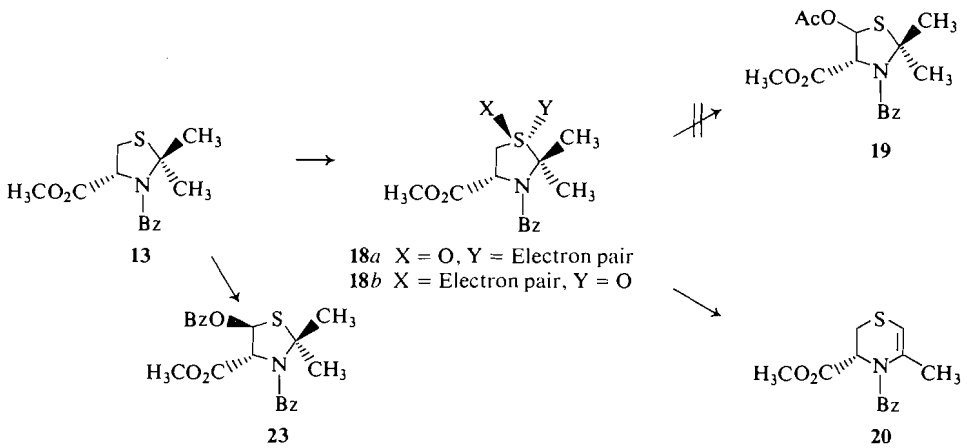
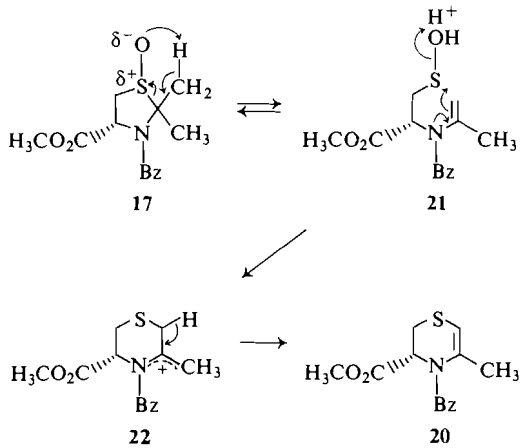


SCHEME 3

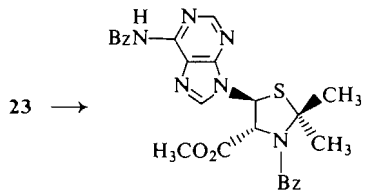
to the sulfenic acid intermediate **21** which, after ring closure, gives the nitrogen-stabilized carbonium ion **22** which, in turn, gives **20** upon deprotonation, as illustrated in Scheme 4. Some evidence for such a mechanism has been obtained by Chen (21) for the ring expansion reaction of 1,3-dithiolane 1-oxides to the dihydro-1,4-dithiins. Analogous rearrangements of the halosulfonium salts of some 1,3-oxathiolane derivatives to give the corresponding 1,4-oxathienes have also been reported (22).

Functionalization at C-5 of 3-benzoyl-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidine (**13**) was achieved by treatment with dibenzoyl peroxide in refluxing benzene, as described by Baldwin *et al.* (18). This resulted in the stereospecific conversion of **13** into 3-benzoyl-5(*S*)-benzoyloxy-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidine (**23**), as illustrated in Scheme 3; the stereospecificity of the reaction is presumably due to shielding of one face of the molecule by the methoxycarbonyl group. Compound **23** was converted stereospecifically into the nucleoside analog, namely, 6-benzamido-9-(3-benzoyl-4(*R*)-



SCHEME 4

methoxycarbonyl-2,2-dimethylthiazolidin-5(*S*)-yl)-9*H*-purine (**7**), in 40% yield by treatment with 6-benzamidochloromercuripurine and titanium tetrachloride in 1,2-dichloroethane (23) (Scheme 5); the



SCHEME 5

observed stereospecificity results from double inversion at C-5 of **23** via the intermediate chloride. The enantiomeric purity of compound **7** was confirmed by use of the chiral shift reagent. Thus, for example, the ^{1}H nmr spectrum at 220 MHz of optically active **7** in chloroform-*d* containing 0.2 equiv. of the shift reagent exhibited slightly broadened singlets for the C-2 methyl proton signals, whereas the corresponding signals in the spectrum of the optically inactive nucleoside analog in chloroform-*d* with 0.2 equiv. of shift reagent exhibited differential shifts of 0.11 and 0.15 ppm between the C-2 methyl group signals in the two enantiomers, as illustrated in Fig. 2. The maximal uv absorptions for **7** at 232 and 281 nm in neutral solution and at 285 nm in acidic solution are in agreement (24) with a 9-substituted 6-benzamidopurine.

In addition, the synthesis of an analog of a 1′-homonucleoside, namely, 6-chloro-9-[(3-benzoyl-2,2-dimethylthiazolidin-4(*R*)-yl)methyl]-9*H*-purine (**8**), was readily achieved in 62% yield by treatment (2) of 3-benzoyl-4(*R*)-hydroxymethyl-2,2-dimethylthiazolidine (**24**), obtained from **13** (see Scheme 6) by borohydride reduction, with 6-chloropurine, triphenylphosphine, and diethyl azodicarboxylate in tetra-

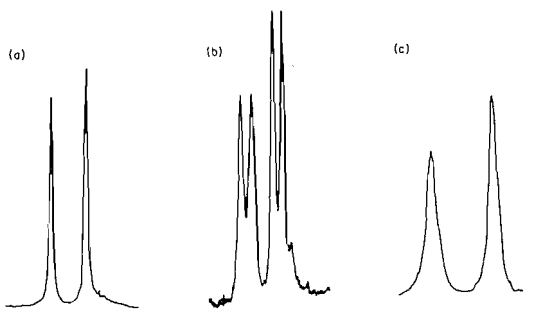

FIG. 2. C-2 methyl signals in the ^{1}H nmr spectrum ($CDCl_3$) at 220 MHz of the nucleoside analog **7**: (*a*) mixture of enantiomers; (*b*) mixture of enantiomers with 0.8 equiv. chiral shift reagent; (*c*) (4*R*,5*S*)-isomer with 0.8 equiv. chiral shift reagent.

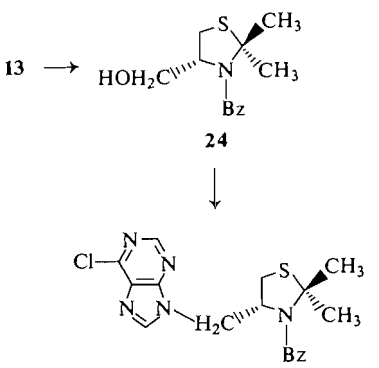
hydrofuran at room temperature. The maximal uv absorption for **8** at 265 nm in neutral, acid, or basic solution is in agreement (25) with a 9-substituted 6-chloropurine. The enantiomeric purity of compound **8** was confirmed by use of the chiral shift reagent. Thus, for example, the C-2 methyl group signals in the spectrum of **8** in chloroform-*d* with 0.2 equiv. of the shift reagent appeared as singlets, whereas differential shifts of 0.10 and 0.14 ppm between the C-2 methyl signals in the two enantiomers were observed in the spectrum of the corresponding racemic compound in chloroform-*d* with 0.2 equiv. of the shift reagent.

The carbon-13 nmr data of the 1,3-thiazolidine derivatives that were prepared in this study are presented in Tables 2 and 3. The chemical shift assignments in all the compounds were facilitated by consideration of the substituent effects on the ^{13}C chemical shifts in the spectra of related heterocyclic compounds containing sulfur and nitrogen (2), and were confirmed by means of gated decoupling experiments.

The assignment of signals to the diastereotopic methyl groups in the spectra of the isomeric sulfoxides **18***a* and **18***b* was made on the basis of knowledge of the chemical shift dependence of the C-2 methyl group signals on the orientation of the sulfinyl group in related sulfoxides. For example, it has been demonstrated (26) in the case of the sulfoxides of tetramethylthiolanes, that the C-2 methyl group *cis* to the sulfoxide oxygen is shielded to a greater extent than is the C-2 methyl group *trans* to the sulfoxide oxygen relative to the corresponding methyl groups in the parent sulfide. This has also been found to be the case in certain penicillin sulfoxides (27, 4). Thus, the methyl signal appearing at 20.6 ppm in the spectrum of **18***a* may be assigned to the methyl group *cis* to the sulfoxide oxygen, namely, the *pro-S* methyl group and that at 23.0 ppm to the *pro-R* methyl group. Similarly, the signal appearing at 19.3 ppm in the spectrum of **18***b* may be assigned to the *pro-R* methyl group and that at 22.7 ppm to the *pro-S* methyl group.



SCHEME 6

Experimental

Melting points were determined with a Fisher-Johns melting point apparatus and are uncorrected. The ir spectra were recorded on a Perkin-Elmer 180 spectrophotometer. Ultraviolet (uv) spectra were recorded on a Beckman ACTA MIV spectrophotometer. Proton magnetic resonance (^{1}Hmr) spectra at 60 MHz were recorded on a Varian EM-360 or Bruker HX-60 spectrometer in chloroform-*d* with tetramethylsilane as the internal standard. The ^{1}Hmr spectra at 220 MHz were measured on a Varian HR-220 spectrometer at the Canadian 220 MHz NMR Centre. The Cmr spectra were recorded in chloroform-*d* solution on a Bruker HX-60 spectrometer equipped with an FT60M Fourier transform accessory at 15.09 MHz; chemical shifts are given in ppm downfield from TMS. A chiral shift reagent, (tris-[3-trifluoromethylhydroxymethylene)-*d*-camphorato]europium(III), was purchased from Aldrich Chemical Co. Optical rotations were determined on a Perkin-Elmer 141 polarimeter. Thin-layer chromatography was performed with silica gel G (E. Merck) as adsorbent in the following solvent systems (v/v): (*A*) benzene – ethyl acetate, 9:1; (*B*) 4:1; (*C*) 1:1; (*D*) 1:4; (*E*) ethyl acetate. The developed plates were air-dried, and exposed to uv light and/or sprayed with a solution of cerium sulfate (1%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at ~150°C. Column chromatography was performed on Brinkmann silica gel 60 (E. Merck). Solvents were evaporated under reduced pressure and below 40°C.

*3-Benzoyl-2,2-dimethyl-4(*R*)-carboxythiazolidine (**11**)*

To a solution of 2,2-dimethyl-4(*R*)-carboxythiazolidine hydrochloride (**10**) (4.0 g, 20 mmol), prepared from L-cysteine hydrochloride monohydrate (**9**) by the method of Sheehan *et al.* (6), in pyridine (400 ml, 4.95 mol) at 0°C was added benzoyl chloride (2.87 g, 20 mmol) dropwise. The mixture was stirred at room temperature for 8 h and then pyridine was evaporated. The residue was dissolved in dichloromethane (150 ml) and the solution was washed with water. The organic layer was dried over anhydrous sodium sulfate and the solvent evaporated to afford a half crystalline mass. Compound **11** was obtained from chloroform–hexane as needles (4.0 g, 74%), mp 180–182°C (dec.), $[\alpha]_D^{24}$ −154° (*c* 0.83, chloroform), −266° (*c* 1.2, pyridine); ^{1}Hmr 60 MHz δ: 1.98 (6-H, bs, Me), 3.08 (1-H, d of d's, $|J_{5,5'}| = 10$ Hz, $J_{4,5} = 4$ Hz, H-5), 3.38 (1-H,

sulfate. The solvent was evaporated to afford crystals, which were recrystallized from chloroform–hexane to give **12** as fine prisms (404 mg, 71%), mp 180–180.5°C, $[\alpha]_D^{30}$ −0.8° (*c* 2.4, chloroform).

*3-Benzoyl-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidine (**13**)*

To a solution of 3-benzoyl-2,2-dimethyl-4(*R*)-carboxythiazolidine (**11**) (1.06 g, 4 mmol) in methanol (20 ml) at 0°C was added a slight excess of diazomethane in ether. The mixture was stirred for 12 h and then the solvent evaporated to afford a white crystalline product. Compound **13** was obtained from ether–hexane as white prisms (0.93 g, 83%), mp 105–106.5°C, $[\alpha]_D^{23}$ −180° (*c* 0.92, chloroform), R_F 0.40 (solvent *A*). A racemic mixture of 3-benzoyl-4-methoxycarbonyl-2,2-dimethylthiazolidine (**14**) was obtained in the same manner from the corresponding carboxylic acid **12**; ir (KBr): 1745 (O=C), 1640 (N–C=O) cm^{-1}; ^{1}Hmr δ: 1.95 (3-H, s, Me), 2.01 (3-H, s, Me), 3.22 (2-H, m, 2 H-5's), 3.64 (3-H, s, OMe), 4.79 (1-H, m, H-4), 7.34 (5-H, s, Ph); optically active **13** (with 0.2 equiv. chiral shift reagent); δ: 2.74 (3-H, s's, Me), 3.07 (3-H, s, Me); optically inactive **14** (with 0.2 equiv. chiral shift reagent); δ: 2.59 (3-H, bs, Me), 2.79, 2.86 (3-H, s, Me). *Anal.* calcd. for $C_{14}H_{17}NO_3S$: C 60.19, H 6.13, N 5.01, S 11.48; found: C 60.17, H 6.13, N 4.93, S 11.54.

*4(*R*)-Carboxythiazolidine Hydrochloride (**15**)*

4(*R*)-Carboxythiazolidine (1.34 g, 10 mmol), obtained from L-cysteine hydrochloride monohydrate (**9**) by the method of Ratner and Clarke (8) was dissolved into 2*N* hydrochloric acid (5 ml) and then water was immediately evaporated to give the hydrochloride **15** as white crystals (1.72 g, 100%).

*3-Benzoyl-4(*R*)-(methoxycarbonyl)thiazolidine (**16**)*

To a solution of 4(*R*)-carboxythiazolidine hydrochloride (**15**) (500 mg, 3 mmol) in pyridine (50 ml, 620 mmol) at 0°C was added benzoyl chloride (424 mg, 3 mmol) and the mixture was stirred for 8 h at room temperature. Pyridine was evaporated and the residue was dissolved in dichloromethane (100 ml). The organic layer was washed with aqueous sodium chloride (3 × 50 ml) and dried (anhydrous sodium sulfate); evaporation of the solvent gave a syrup which was treated with an ethereal solution of diazomethane to give a thick oil whose tlc indicated the presence of three components having R_F values of 0.41, 0.2, and 0.06 (solvent *B*). The component having an R_F value of 0.41 was isolated by column chromatography on silica gel and then distilled under vacuum to give compound **16** (7) as a clear oil; bp 130–140°C/0.07 Torr $[\alpha]_D^{23}$ −224° (*c* 1.6, chloroform); ir: 1750 (O=C), 1650 (N–C=O) cm^{-1}; ^{1}Hmr (60 MHz) δ: 3.3 (2-H, d, J = 6 Hz, 2 H-5's), 3.78 (3-H, s, OMe), 4.62 (2-H, bs, 2 H-2's), 5.22 (1-H, b, H-4), 7.45 (5-H, s, Ph).

*3-Benzoyl-4-(methoxycarbonyl)thiazolidine (**17**)*

To a vigorously stirred suspension of 4(*R*)-carboxythiazolidine hydrochloride (**15**) (500 mg, 3 mmol) in chloroform (15 ml) at 0°C was added pyridine (512 mg, 6.6 mmol) in chloroform (8 ml) and then benzoyl chloride (422 mg, 3 mmol) in chloroform (7 ml). The mixture was stirred for 16 h at room temperature and then diluted with chloroform (100 ml). The chloroform solution was washed successively with 2 *N* hydrochloric acid (2 × 50 ml) and aqueous sodium chloride solution (2 × 50 ml), and dried over anhydrous sodium sulfate. Evaporation of the solvent afforded a syrup which was treated with ethereal diazomethane solution to give a thick oil. Thin-layer chromatography of the oil indicated the presence of three components having R_F values of 0.42, 0.19, and 0.06 (solvent *B*). The component having an R_F value of 0.42 was isolated by column chromatography on silica gel; subsequent distillation afforded **17** as a clear oil; bp 120–140°C/0.06 Torr $[\alpha]_D^{23}$ −198° (*c* 1.1, chloroform).

*3-Benzoyl-4(*R*)-(methoxycarbonyl)-2,2-dimethylthiazolidine 1-Oxide (**18**)*

To a solution of the methyl ester **13** (614 mg, 2.2 mmol) in dichloromethane (20 ml) at 0°C was added *m*-chloroperbenzoic acid (444 mg, 2.2 mmol) in dichloromethane (25 ml). The mixture was stirred at room temperature for 3 h and then diluted with dichloromethane (30 ml). The solution was washed successively with aqueous sodium bicarbonate solution (2 × 25 ml), aqueous sodium chloride solution (25 ml), and dried over magnesium sulfate. Evaporation of the solvent afforded an isomeric mixture of **18***a* and **18***b* as a solid (648 mg, 99%) in a ratio of 1.5:1, as determined by ^{1}Hmr spectroscopy. The isomer **18***a* was obtained from methanol–hexane as white crystals (112 mg); mp 169–170°C, $[\alpha]_D^{22}$ −283° (*c* 0.2, 5% ethanol in chloroform); R_F 0.14 (solvent *C*); ir (KBr): 1770 (O–C=O), 1640 (N–C=O), 1050 (S=O) cm^{-1}; ^{1}Hmr (220 MHz) of **18***a*; δ: 1.72 (3-H, s, Me), 1.84 (3-H, bs, Me), 3.09 (1-H, d of d's, $|J_{5,5'}|$ = 13.6 Hz, $J_{5',4}$ = 10.5 Hz, *pro-S* H-5'), 3.38 (1-H, d of d's, $J_{5,4}$ = 7.2 Hz, *pro-R* H-5), 3.49 (3-H, s, OMe), 5.41 (1-H, m, H-4), 7.46 (5-H, d, Ph); ^{1}Hmr (220 MHz) of **18***b*; δ: 1.50 (3-H, s, Me), 1.97 (3-H, s, Me), 3.22 (1-H, d of d's, $|J_{5,5'}|$ = 14.6 Hz, $J_{5,4}$ = 8.0 Hz, *pro-R* H-5), 3.51 (1-H, bd, *pro-S* H-5'), 3.48 (3-H, s, OMe), 4.99 (1-H, bd, H-4), 7.37 (5-H, d, Ph); **18***a* (60 MHz); δ: 3.47 (3-H, s, OMe); optically active **18***a* (with 0.3 equiv. chiral shift reagent); δ: 3.67 (3-H, s, OMe); optically inactive **18***a* (with 0.3 equiv. chiral shift reagent); δ: 3.63, 3.71 (3-H, s's, OMe). *Anal.* calcd. for $C_{14}H_{17}NO_4S$: C 56.93, H 5.80, N 4.74, S 10.86; found: C 56.89, H 5.86, N 4.79, S 10.79.

*4-Benzoyl-3(*R*)-methoxycarbonyl-5-methyl-3,4-dihydro-2H-1,4-thiazine (**20**)*

A solution of sulfoxides **18***a* and **18***b* (294 mg, 1 mmol) in benzene (25 ml) containing acetic anhydride (0.5 ml, 5.3 mmol) and *p*-toluenesulfonic acid (~10 mg) was stirred at room temperature for 3.5 h and a further 2.5 h at reflux temperature. Aqueous sodium bicarbonate solution (20 ml) was added to the reaction mixture and then the mixture was stirred for 10 h at room temperature. The benzene layer was separated and washed with water (15 ml), and dried (magnesium sulfate). Evaporation of the solvent afforded a syrup. Chromatography on silica gel (10% ethyl acetate in benzene) gave compound **20** as a pale yellow solid (157 mg, 60%), mp 93–94°C, $[\alpha]_D^{23}$ −391° (*c* 0.8, chloroform), R_F 0.38 (solvent *A*); ir (KBr): 1750 (O–C=O), 1650 (N–C=O) cm^{-1}; ^{1}Hmr (60 MHz) δ: 1.65 (3-H, s, Me), 3.40 (2-H, m, H-2, H-2'), 3.78 (3-H, s, OMe), 5.47 (1-H, bs, H-6), 5.89 (1-H, m, H-3), 7.44 (5-H, m, Ph); optically active **20** (with 0.2 equiv. chiral shift reagent) δ: 2.41 (3-H, s, Me); optically inactive **20** (with 0.2 equiv. chiral shift reagent) δ: 2.16, 2.24 (3-H, s's, Me). *Anal.* calcd. for $C_{14}H_{15}NO_3S$: C 60.63, H 5.45, N 5.05, S 11.56; found: C 60.79, H 5.44, N 5.22, S 11.56.

*3-Benzoyl-5(*S*)-benzoyloxy-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidine (**23**)*

A solution of 3-benzoyl-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidine (**13**) (2.62 g, 9.4 mmol) and dibenzoyl peroxide (4.54 g, 18.8 mmol) in benzene (250 ml) was refluxed for 20 h under nitrogen. The solution was washed with aqueous sodium bicarbonate solution and dried over magnesium sulfate. Evaporation of the solvent afforded a syrup. Thin-layer chromatography indicated the presence of a major component having R_F value of 0.45 (solvent system *A*). Chromatography on silica gel (3% ethyl acetate in benzene) and recrystallization gave compound **23** (0.76 g, 20%), mp 142°C, $[\alpha]_D^{25}$ +195° (*c* 0.4, chloroform); ir (KBr): 1740, 1720 (O—C(=O)—), 1640 (—N—C(=O)—) cm^{-1}; ^{1}Hmr (60 MHz) δ: 2.05, 2.15 (two 3-H s's, 2 Me's), 3.74 (3-H, s, OMe), 5.16 (1-H, s, H-4), 6.63 (1-H, s, H-5), 7.38 (5-H, s, NCOPh), 7.50, 8.05 (5-H, m's, OCOPh); optically active **23** (with 0.3 equiv. chiral shift reagent) δ: 2.60, 2.88 (two 3-H, s's, 2 Me's); optically inactive **23** (with 0.3 equiv. chiral shift reagent) δ: 2.88 (3-H, s, Me), 2.98, 3.08 (3-H, s's, Me). *Anal.* calcd. for $C_{21}H_{21}NO_5S$: C 63.14, H 5.30, N 3.51, S 8.03; found: C 63.25, H 5.39, N 3.67, S 7.89.

*6-Benzamido-9-(3-benzoyl-4(*R*)-methoxycarbonyl-2,2-dimethylthiazolidin-5(*S*)-yl)-9*H*-purine (**7**)*

A mixture of the benzoate **23** (212 mg, 0.53 mmol), 6-benzamidochloromercuripurine (306 mg, 0.65 mmol), and Celite (200 mg) in dry 1,2-dichloroethane (30 ml) was heated to reflux, and about 7 ml of the solvent was distilled to remove moisture, and then titanium tetrachloride (0.075 ml, 0.68 mmol) in 1,2-dichloroethane (2 ml) was added dropwise. The mixture was refluxed for 7 h and then cooled to room temperature. Saturated aqueous sodium bicarbonate solution (10 ml) was added with vigorous stirring and the mixture was filtered through a layer of Celite, which was thoroughly washed with chloroform. The organic layer was separated and washed successively with water (30 ml), 30% aqueous potassium iodide (2 × 25 ml) and dried over anhydrous sodium sulfate. The solvent was evaporated to leave a brown syrup which contained a major component having an R_F value of 0.64 (solvent *E*) on tlc. Preparative tlc (ethyl acetate) on silica gel afforded compound **7** as a white foam (105 mg, 38%), $[\alpha]_D^{24}$ +53.8° (*c* 1.2, chloroform); ir (KBr): 3250 (NH), 1740 (—O—C(=O)—), 1690, 1590, and 1570 (aromatic, purine ring), 1650 (—N—C(=O)—) cm^{-1}; uv λ_{max} (ethanol): 281 (ε 21 300) (purine ring), 262 (ε 13 000) sh (purine ring), 232 nm (ε 16 230); λ_{max} (ethanol containing a trace amount of hydrochloric acid): 285 nm (ε 21 300); ^{1}Hmr (60 MHz) δ: 2.02, 2.11 (two 3-H s's, Me), 3.83 (3-H, s, OMe), 5.86 (1-H, s, H-4′), 6.41 (1-H, s, H-5′), 6.66–7.66, 7.8–8.15 (10-H, m's, Ph), 8.62, 8.66 (two 1-H, s's, H-4, H-8), 9.3 (1-H, bs, NH); (220 MHz) δ: 2.04, 2.15 (two 3-H, s's, Me); optically active **7** (220 MHz with 0.8 equiv. chiral shift reagent): 2.14, 2.29 (two 3-H, s's, Me); optically inactive **7** (220 MHz with 0.8 equiv. chiral shift reagent) δ: 2.12, 2.15 (3-H, s's, Me), 2.27, 2.31 (3-H, s's, Me). *Anal.* calcd. for $C_{26}H_{24}N_6O_4S$: C 60.45, H 4.68, N 16.27, S 6.21; found: C 60.30, H 4.88, N 16.09, S 6.14.

*3-Benzoyl-4(*R*)-hydroxymethyl-2,2-dimethylthiazolidine (**24**)*

To a suspension of sodium borohydride (5.0 g, 132 mmol) in methanol at ~25°C was added the methyl ester **13** (1.83 g, 6.6 mmol) in methanol (15 ml) over the period of 30 min with stirring and then the mixture was further stirred for 3 h. Thin-layer chromatography (solvent *B*) indicated the presence of a new component having an R_F value of 0.23 together with the unreacted starting material **13** (R_F 0.60). The mixture was cooled and water (30 ml) was added. Methanol was evaporated under reduced pressure and then the residue was extracted with dichloromethane (2 × 50 ml). The organic layer was washed with water, dried over anhydrous sodium sulfate, and the solvent evaporated to afford a syrup which was chromatographed on silica gel with solvent *B* as eluant to give the component having an R_F value of 0.23. Compound **24** was obtained from ether–hexane as prisms (1.31 g, 80%), mp 114.5–116.5°C, $[\alpha]_D^{24}$ −104° (*c* 2.3, ethanol); ir: 3320 (OH), 1600 (—N—C(=O)—) cm^{-1}; ^{1}Hmr (60 MHz) δ: 1.86 (6-H, s, Me), 2.68–3.9 (5-H, m's, 2 H-5's, CH_2OH, OH), 4.0–4.5 (1-H, m, H-4), 7.32 (5-H, s, Ph); optically active **24** (with 0.4 equiv. chiral shift reagent) δ: 3.05, 3.13 (3-H, s's, Me); optically inactive **24** (with 0.4 equiv. chiral shift reagent) δ: 3.31, 3.41 (3-H, s's, Me), 3.68 (3-H, s, Me). *Anal.* calcd. for $C_{13}H_{17}NO_2S$: C 62.12, H 6.82, N 5.57, S 12.76; found: C 62.25, H 6.98, N 5.62, S 12.59.

*6-Chloro-9-[(3-benzoyl-2,2-dimethylthiazolidin-4(*R*)-yl)-methyl]-9*H*-purine (**8**)*

To a mixture of 6-chloropurine (74 mg, 0.48 mmol), triphenylphosphine (125 mg, 0.48 mmol), and diethyl azodicarboxylate (103 mg, 0.59 mmol) in dry tetrahydrofuran (3 ml) was added 3-benzoyl-4(*R*)-hydroxymethyl-2,2-dimethylthiazolidine (**24**) (120 mg, 0.48 mmol) in dry tetrahydrofuran (2 ml) with stirring. The stirring was continued for 16 h. The reaction mixture was concentrated, and the residue was chromatographed on silica gel, with solvent *D* as eluant, to give a component having an R_F value of 0.45 in solvent *D*. Compound **8** was obtained by preparative tlc of the component (solvent *D*), and recrystallized (ethanol–hexane) to give prisms (115 mg, 62%), mp 156.5–159°C, $[\alpha]_D^{25}$ +4.9° (*c* 1.2, chloroform); ir (KBr): 1585, 1552 and 1492 (purine ring), 1615 (C=O) cm^{-1}; uv λ_{max} (ethanol): 265 nm (ε 6191) (purine ring); λ_{max} (ethanol containing a trace of hydrochloric acid): 264.8 nm (ε 6137) (purine ring); λ_{max} (ethanol containing a trace of sodium hydroxide): 265 nm (ε 6280) (purine ring); ^{1}Hmr (60 MHz) δ: 1.93, 2.05 (two 3-H, s's, Me), 2.64–4.6 (4-H, m, 2 H-5's, CH_2—N), 4.65–5.15 (1-H, m, H-4′), 6.85–7.35 (5-H, m's, Ph), 7.52, 8.46 (two 1-H, s's, purine); optically active **8** (with 0.2 equiv. chiral shift reagent) δ: 1.95, 2.1 (two 3-H, s's, Me); optically inactive **8** (with 0.2 equiv. chiral shift reagent) δ: 2.38, 2.52 (3-H, s's, Me), 2.52, 2.62 (3-H, s's, Me). *Anal.* calcd. for $C_{18}H_{18}N_5OSCl$: C 55.74, H 4.68, N 18.06, S 8.27; found: C 55.52, H 4.85, N 17.87, S 8.37.

The electrochemical formation of mercuric oxide in alkaline solution

REMIGIO GERMANO BARRADAS, STEPHEN FLETCHER, AND JOHN DOUGLAS PORTER

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received May 9, 1977

REMIGIO GERMANO BARRADAS, STEPHEN FLETCHER, and JOHN DOUGLAS PORTER. Can. J. Chem. **56**, 336 (1978).

The electrochemical formation of mercuric oxide on mercury in alkaline solutions is described. The reaction was investigated because of its importance as a reference electrode system, and also because it provides a model test of recent theoretical developments. Various derived data are compared to computer simulations of the growth mechanism.

REMIGIO GERMANO BARRADAS, STEPHEN FLETCHER et JOHN DOUGLAS PORTER. Can. J. Chem. **56**, 336 (1978).

On décrit la formation électrochimique d'oxyde mercurique sur du mercure en solutions alcalines. On a étudié la réaction à cause de son importance comme système d'électrode de référence et aussi parce qu'elle fournit un bon modèle pour vérifier de récents développements théoriques. On peut comparer diverses données déduites avec des simulations par ordinateur du mécanisme de croissance.

Introduction

The anodic behaviour of mercury in hydroxide ion solutions was studied by Armstrong *et al.* (1), who demonstrated that a layer of mercuric oxide in the (010) orientation was formed. The first stage in the growth of the layer was shown to be the formation of a monolayer by the nucleation and subsequent growth of two-dimensional centres at the electrode surface. This was followed by the generation of a three-dimensional layer, the growth of which caused the electrode to passivate. In particular, models of the growth processes were described at constant overpotential. Verification of the models was then achieved by the potential step technique. The slow step in both two- and three-dimensional growth was concluded to be at the edge of the expanding crystal lattices, whilst it was assumed that sufficient nuclei were present in both cases for the Avrami (2) theorem to be applicable.

Recently we extended these models by computer simulation to include the linear potential sweep technique (lps) and the staircase voltammogram technique (sv). The simulations were based on the assumption that the surface coverage functions $S(t)$ responded instantaneously to small changes of potential, ΔE, so that a steady-state rate of nucleation was observed at any given potential. Under these circumstances (3–5) the current corresponding to a given mechanism was evaluated as a function of both potential and time. Furthermore, it was possible to investigate the influence of uncompensated ohmic overpotential on the experimental data. This is clearly desirable, because the large current densities observed in passivation studies are invariably distorted by ohmic effects.

The purpose of the present paper, therefore, is to report the results of a comparison between certain results of the computer simulations and experimental data obtained using the model Hg/HgO system.

Experimental

All computer programs were written in either FORTRAN IV or BASIC, and the computations were performed on a Xerox SIGMA-9 computer. The electrodes, considered to be sections of a sphere, were generated *in situ* by the extrusion of mercury via a micrometer-controlled syringe through the tip of a wide-bore glass capillary (0.05 cm). The all-Pyrex cell (illustrated in Fig. 1) was undivided, a cylindrical platinum gauze concentric with the working electrode serving as the counter electrode. An adjustable luggin reference probe was also incorporated in the cell design, in order to minimize the ohmic contribution to the applied potential. Deoxygenation was performed by bubbling purified nitrogen through the apparatus between measurements. Potentials were measured ± 0.05 mV, and are quoted vs. the mercury/mercuric oxide reference electrode in the same solution (5 *M* KOH). The strong KOH solution was chosen in order to minimize the solution component of the total ohmic potential drop. Experimental data were recorded photographically from Tektronix type 549 and 503 oscilloscopes and subsequently analyzed by enlargement.

Results

(a) The Potential Step Technique

In this section the results obtained from the potential step technique will be reported. Only data relating to three-dimensional growth will be described because of the poor definition of two-dimensional growth in this instance (see, for example, Fig. 11). As shown previously (3) the computer simulation predicts that the current maximum in the experimental transients (i_m (in mA)) obeys an equation of the form

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[1] $$\log (i_m) = a_1(E - i_mR) + b_1$$

where a_1 and b_1 are experimentally determined constants, E is the applied potential (mV), R is the resistance (Ω, Ω cm^{-2}), and the product i_mR is the ohmic overpotential at the current maximum. Simple differentiation gives

[2] $$\frac{\partial E}{\partial \log (i_m)} = \frac{1}{a_1} + 2.303 i_m R$$

so that the experimentally determined plot of $\partial E/\partial \log(i_m)$ as a function of i_m should be linear, the intercept giving $1/a_1$ whilst the gradient gives R. Unfortunately, the potential step technique necessitates the acquisition of data one point at a time, so that the gradient $\partial E/\partial \log(i_m)$ may not be easily obtained as a continuous function in i_m. In order to resolve this problem a combination of spline function approximations with least squares best-fit procedures (6) was utilized in order to fit an accurate continuous function to the $\log(i_m)$ vs. E data. The gradient of this function at each i_m value could then be obtained exactly. A typical result is shown in Fig. 2. It is clear that [2] is closely obeyed for low i_m. Insertion of resistors of variable value (1 Ω, 2 Ω, etc.) into the electrical circuit between the potentiostat and the working electrode also confirmed the validity of [2], since identical intercepts at $i_m = 0$ were obtained in each case.

Once R values have been obtained in this way, it is possible to substitute back into [1] and hence compensate for ohmic distortions in log (i_m) vs. E plots by shifting the potential scales by an amount i_mR. This results in an extraordinary improvement in the resolution of log (i_m) vs. E data as demonstrated in Fig. 3. For the first time the presence of a discontinuity becomes apparent, bounded by two approximately linear sections. In the past such a discontinuity has not been observed because of the dominance of ohmic effects; the effect of only 1 Ω, say, would be to shift the discontinuity by $\sim$100 mV. Further evidence of discontinuous behaviour may be observed by applying a similar compensation procedure to log (t_m) vs. E data where t_m is the time

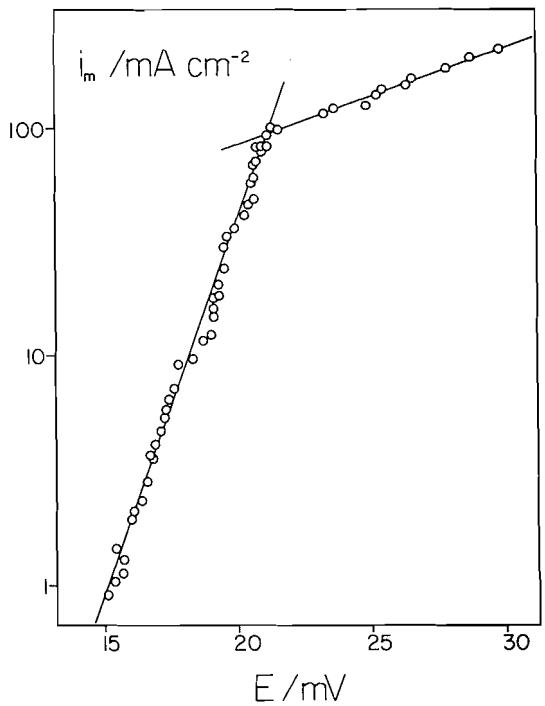

FIG. 3. Log (i_m) vs. E, after correction for ohmic overpotential. 5 M KOH, A = 0.073 cm^2.

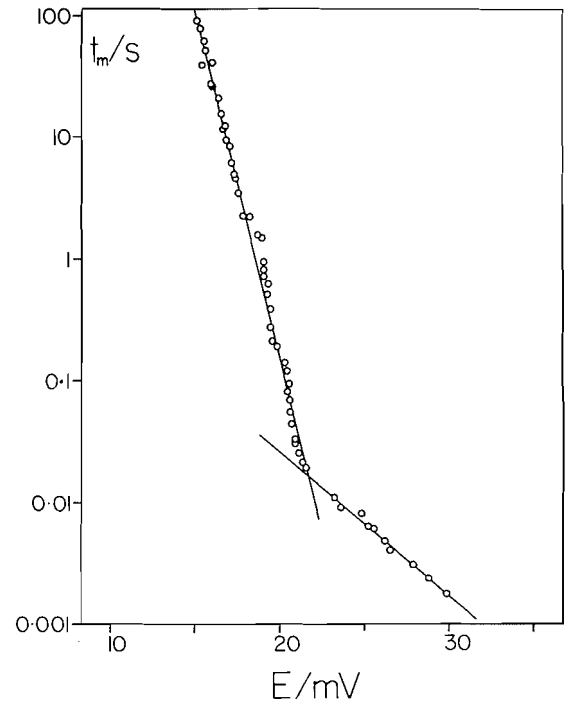

FIG. 4. Log (t_m) vs. E, after correction for ohmic overpotential. 5 M KOH, A = 0.073 cm^2.

taken to achieve i_m (s), although in this case the procedure has been shown to become increasingly inaccurate as E increases (3). Even so, the improvement in the data is substantial and allows the observation of a similar discontinuity to the log (i_m) case (Fig. 4).

Figure 5 shows the variation of log ($i_m t_m$) as a function of E, without including ohmic compensation. Because $i_m t_m \propto Q$ (the charge required to form the 3-D layer (in mC cm^{-2})) this is essentially a plot of log (Q) vs. E. A linear dependence is observed at low overpotentials. Such a variation is a diagnostic criterion of 3-D growth; obviously 2-D (monolayer) growth involves smaller, constant, charge consumption during formation of a layer.

(b) The Linear Potential Sweep Technique

The response of the Hg/KOH (aq) interface to lps is illustrated in a sequence of photographs in Fig. 6. The smaller peak corresponds to monolayer formation whilst the larger peak results from the formation of the three-dimensional multilayer. Concurrent with the observed monolayer formation is the dissolution of Hg(II) species into the bulk of solution. This dissolution reaction is observed in the potential region in which a faradaic pseudo-capacitance was reported by Armstrong *et al.* (1), which was attri-

buted to

$$[3] \qquad 2OH^- + Hg \overset{-2e}{\rightleftharpoons} Hg(OH)_2$$

However the contribution to the overall current from this reaction is small. An interesting observation here, clear from Fig. 6, is that the presence of the monolayer does not appear to inhibit the dissolution reaction at all, in agreement with the observations of Armstrong *et al.* (1). A further interesting feature of the voltammograms of Fig. 6 is that the current maximum in voltammograms (i_p (mA)) corresponding to the two-dimensional nucleation and growth process 'catches up' with the current maximum due to the three-dimensional nucleation and growth process as the potential scan rate is increased. At the low scan rates this is in accordance with predictions made on the basis of the computer-simulated data, which may be summarized:

$$[4] \qquad \frac{\partial \log (i_p)}{\partial \log (\nu)} = \text{constant} \; (= 1)$$

where ν is the scan rate (mV s^{-1}), for monolayer formation (4), and

$$[5] \qquad \frac{\partial \log (i_p)}{\partial \log (\nu)} = \text{constant} \; (< 1)$$

for thick layer formation. These predictions are tested experimentally in Figs. 7 and 8 for low values of ν. The expected linearity is observed, although the monolayer case is found to have a gradient slightly less than unity, possibly because of the presence of background currents due to the dissolution process. At high scan rates (and hence high current densities) the influence of ohmic overpotential becomes important, as is also clear in Fig. 6. Although the overall effect is complex (3), the effect of R on i_p and E_p (the peak current and the peak potential at current maximum (mV) respectively) may be determined both in the case of the experiment and the computer simulation. The results are shown in Figs. 9 and 10 for thick layer formation. Identical trends are observed in theory and practice. The diminution of i_p with increasing R is close to exponential, whilst E_p varies almost linearly with R at high R values.

Discussion

(a) Monolayer Growth

A typical current–time transient corresponding to the progressive nucleation and subsequent growth of a monolayer of the (010) plane of mercuric oxide is shown in Fig. 11. The experimental curve is highly distorted because of the presence of uncompensated

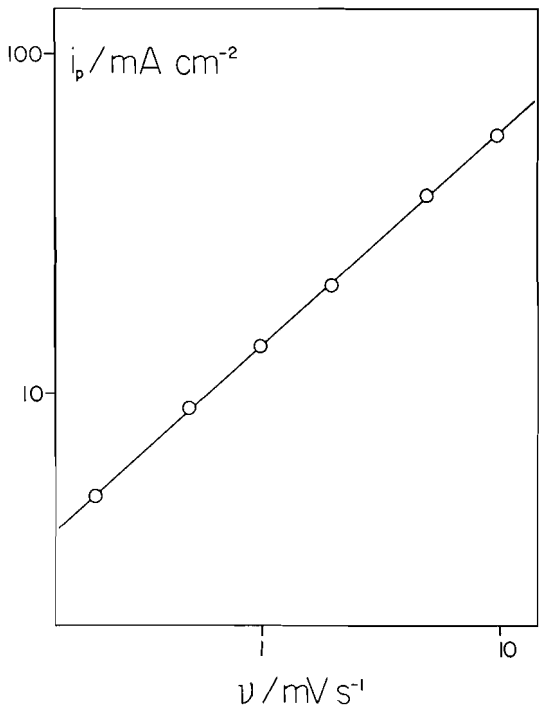

FIG. 8. Linear potential scan, multilayer region. Log (i_p) vs. log (v). 5 *M* KOH, $A = 0.073$ cm^2. Gradient = 0.62.

ohmic overpotential. However, in the absence of any ohmic contribution the current response (i) is given by

$$[6] \quad i = \frac{nFl\pi k^2 A t^2 M}{\rho} \exp\left[\frac{-\pi M^2 k^2 A t^3}{3\rho^2}\right]$$

where l is the height of a monolayer (cm), k is the rate constant for lattice growth (mol cm^{-2} s^{-1}), A is the steady-state nucleation rate constant (nuclei cm^{-2} s^{-1}), M is the gram-molecular weight, and ρ is the density of the layer (g cm^{-3}). Comparison of Fig. 11 with Fig. 6 indicates that when it is desired to minimize ohmic effects on observable parameters, monolayer growth may be more clearly investigated by linear sweep methods than by potential pulse techniques. The theoretical voltammogram has recently been described, and the interested reader is referred to the original paper for details (3). A further advantage of lps techniques is that complications, such as those which frequently arise from dissolution reactions in the potential step method, may be minimized by appropriate adjustment of the scan rate. Furthermore, at very high scan rates the qualitative features of a given system may also be easily identified. This is illustrated in Fig. 6 for the present case of HgO formation.

(b) Multilayer Growth

A model for the growth of the thick layer of HgO on mercury has been described by Armstrong *et al.* (1). Individual nuclei are approximated as right circular cones expanding on the electrode surface. In the absence of ohmic effects the current response of the system at constant step potential is

$$[7] \quad i = nFk_2[1 - \exp(-\pi M^2 k_1^2 A t^3/3\rho^2)] \times \exp(-\pi M^2 k_1^2 A t^3/3\rho^2)$$

where k_1 is the rate constant describing crystal growth parallel to the electrode surface (mol cm^{-2} s^{-1}), k_2 is the rate constant describing crystal growth orthogonal to the electrode surface, and A is the nucleation rate constant. Expressions for i_m and t_m, the current and time at the transient maximum, can be obtained from this equation. Thus

$$[8] \quad i_m = nFk_2/4$$

$$[9] \quad t_m = [3\rho^2 \ln(2)/\pi M^2 k_1^2 A]^{1/3} = \left[\frac{\ln(2)}{\beta}\right]^{1/3}$$

where β is a constant. Combination of [8] and [9] yields

$$[10] \quad i_m t_m = 0.221 nFk_2(3\rho^2/\pi M^2 k_1^2 A)^{1/3}$$

The expression for the charge consumed in the

$$[11] \qquad Q = \int_0^\infty i\,dt$$

Substitution of [7] in [11] gives the result that

$$[12] \qquad Q = \tfrac{1}{3}nFk_2\Gamma(\tfrac{1}{3})[\beta^{-1/3} - (2\beta)^{-1/3}] = 0.184nFk_2(3\rho^2/\pi M^2 k_1{}^2 A)^{1/3}$$

where Γ is the gamma function. Combination of [10] and [12] shows that

$$[13] \qquad i_m t_m = 1.20Q$$

Equations 10 and 12 contain typographical errors in the original paper (1). The potential dependences of $k_1{}^2A$, k_2, and Q may now be evaluated from the ohmically corrected data shown in Figs. 3 and 4. The results at low overpotentials are

$$[14] \quad \partial \log (k_2)/\partial E = (3.1 \pm 0.2 \text{ mV decade}^{-1})^{-1}$$

$$[15] \quad \partial \log (k_1{}^2A)/\partial E = (0.7 \pm 0.1 \text{ mV decade}^{-1})^{-1}$$

$$[16] \quad \partial \log Q/\partial E = (-5.7 \pm 0.4 \text{ mV decade}^{-1})^{-1}$$

As described earlier, it is apparent that discontinuities appear in the corrected experimental data at high overpotentials. Comparison with the computer-simulated data indicates that only $\partial \log (k_2)/\partial E$ may be evaluated with complete accuracy in such overpotential regions, via eq. 8. The result is that, at high overpotentials,

$$[17] \quad \partial \log (k_2)/\partial E = ((30 \pm 5) \text{ mV decade}^{-1})^{-1}$$

Unfortunately, no model in the literature is able to explain the observed discontinuities, although k_2 is expected to behave according to

$$[18] \quad k_2 = k'\left[\exp\frac{\alpha nF}{RT}\eta - \exp\frac{(1-\alpha)nF}{RT}\eta\right]$$

where k' is a constant and η is the overpotential (mV), in regions of high overpotential (7). For a reversible two-electron transfer reaction this equation predicts a 30 mV decade^{-1} Tafel slope in close agreement with that obtained. Further discussion of this point may be found elsewhere (3, 5).

Using the assumption that the rate constants for lattice growth (k_1,k_2) exhibit an exponential dependence on overpotential (1), the computer simulation is able to predict the response of both the monolayer (4) and the thick layer (8) to linear scans of potential. Typical experimental data are shown in Fig. 6, and the theory is tested in Figs. 7 and 8. The expected dependences are observed in accordance with [4] and [5], but some residual doubt remains concerning the accuracy of the derived gradients. This is more true of the monolayer than the thick layer, because of its proximity to the dissolution reaction. The observed value of $\partial \log(i_p)/\partial \log(v)$ for the thick layer is 0.62. This should be compared with the value 0.50 which would be observed for a diffusion-controlled reaction.

Finally, the computer-simulated dependence of i_p and E_p on R for the thick layer is compared to experiment in Figs. 9 and 10. The experimental trends are in very close agreement with prediction, although exact numerical correlation is naturally precluded because of the arbitrary values of the growth parameters employed in the simulation.

Conclusion

The formation of mercuric oxide on mercury has been examined in aqueous alkaline solution. The system was investigated because of its importance as a reference electrode system, and also because it provides a model with which to test recent theoretical predictions. An improvement in the accuracy of experimentally determined parameters is reported, principally due to the application of developments in ohmic compensation procedures (3). The results are compared to computer simulations of the growth mechanisms, and good agreement has been found.

Complex fluoroanions in solution. VII. Replacement of fluoride by trifluoroacetate[1]

S. BROWNSTEIN

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received August 2, 1977

S. BROWNSTEIN. Can. J. Chem. **56**, 343 (1978).

Binary fluorides of groups III, IV, V, VI, and VII of the periodic table form complex fluoroanions with the trifluoroacetate ion. There is frequently disproportionation to yield species containing more than one trifluoroacetate group. Fluorine and trifluoroacetate exchange reactions are usually slow on the nmr time scale at −70°C.

S. BROWNSTEIN. Can. J. Chem. **56**, 343 (1978).

Les fluorures binaires des groupes III, IV, V, VI et VII de la table périodique forment des fluoroanions complexes par réaction avec l'ion trifluoroacétate. Il se produit fréquemment une dismutation conduisant à des espèces contenant plus qu'un groupe trifluoroacétate. Les réactions d'échange du fluor et du trifluoroacétate sont généralement lentes par comparaison avec l'échelle de temps de la rmn à −70°C.

[Traduit par le journal]

Introduction

Trifluoroacetates have been extensively studied and in some ways are similar to fluorides (1). Only three fully substituted anionic species, $B(TFA)_4^-$, $Ge(TFA)_6^{2-}$, and $Te(TFA)_6^{2-}$, where TFA is trifluoroacetate, have been reported (1). The only mixed species containing both fluoride and TFA radicals found thus far are $HSbF_5TFA$ and perhaps $(SbF_5)_2TFA^-$ (2). Fluoroanions frequently form fluorine bridged complex fluoroanions with binary fluorides (3). It is of interest to see if mixed fluoride, TFA species can be prepared and if they are capable of complex anion formation.

Experimental

Fluorine resonance spectra were obtained at 94.1 MHz on either a 'Varian Associates' HA-100D or XL-100A spectrometer. In the latter case Fourier transform spectra were obtained with a 'Nicolet Instruments' TT100A accessory. Chemical shifts are reported in ppm with respect to $CFCl_3$ as zero and with shifts to high field considered negative. Samples were prepared with great care to exclude moisture using standard vacuum line and dry box techniques. Vapor pressure studies were done in a manner previously described except for pressure measurement by a 'Baratron' diaphragm manometer rather than a constant volume mercury manometer (4).

Tetramethylammonium trifluoroacetate (TMATFA) and tetrabutylammonium trifluoroacetate (TBATFA) were prepared by reaction of sodium trifluoroacetate with the corresponding ammonium chloride in methanol as solvent. After filtration of the sodium chloride the solvent was evaporated and the product recrystallized from a suitable solvent (acetone in the case of TMATFA and methylene chloride – ether for TBATFA).

Aluminum trifluoride, purchased from Ozark-Mahoning, was used as received. Tin tetrafluoride, titanium tetrafluoride, and zirconium tetrafluoride were purified by vacuum sublimination shortly before use. These four solids were manipulated at all times in a vacuum dry box.

Silicon tetrafluoride, purchased from Matheson, germanium tetrafluoride, sulfur tetrafluoride, and tellurium hexafluoride, purchased from Ozark-Mahoning, and phosphorus trifluoride, purchased from PCR Research Chemicals, were used directly from the cylinder. Iodine pentafluoride, purchased from Allied Chemical, was purified by trap to trap distillation. Boron trifluoride, phosphorus, arsenic, vanadium, niobium, and tantalum pentafluorides and molybdenum and tungsten hexafluorides were handled as described in earlier articles in this series (3).

Results and Discussion

It is found that complexing of binary fluorides with the trifluoroacetate ion is very widespread. The complexes will be described according to the position of the binary fluoride in the periodic table.

Group III

Boron Trifluoride

Reaction proceeds according to eqs. 1 and 2 from the results of fluorine resonance spectroscopy. The nuclear resonance parameters are listed in Table 1.

$$[1] \qquad BF_3 + CF_3COO^- \rightarrow BF_3CF_3COO^-$$

$$[2] \qquad 2BF_3CF_3COO^- \rightleftharpoons BF_4^- + BF_2(CF_3COO)_2^-$$

Further disproportionation to $BF(CF_3COO)_3^-$ or $B(CF_3COO)_2^-$ cannot be excluded, although a large percentage of $BF(CF_3COO)_4^-$ would have been observed in the fluorine resonance spectrum. Assignment of the line for BF_4^- was made by comparison with an authentic sample, and the remainder from relative intensities. The spectrum is shown in Fig. 1. With an excess of BF_3 there is an averaging of all the signals from fluorine bonded to boron, even at −100°C. From vapor pressure measurements of BF_3 over a methylene chloride solution of TBATFA it is found that 1.59 equivalents of BF_3 is complexed at −40°C and 1.64 equivalents at −53°C. Com-

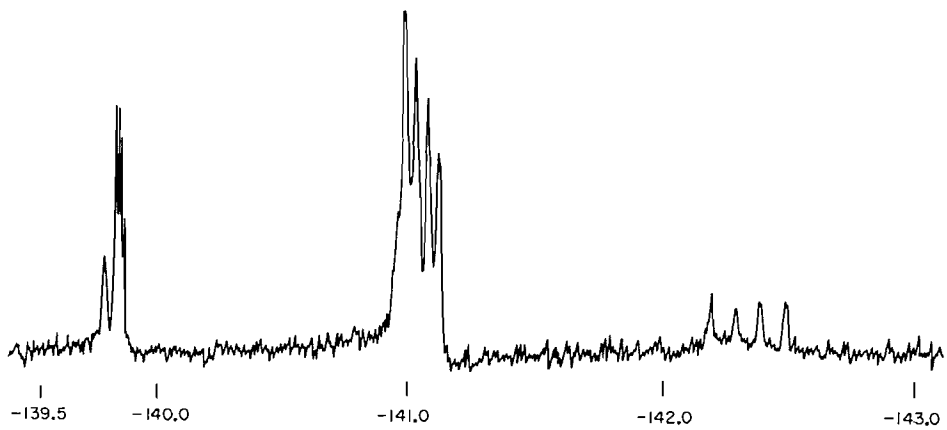

FIG. 1. The fluorine bonded to boron region of the reaction products of BF_3 and $(CH_3)_4NTFA$.

plexes containing more than one BF_3 per anion are required to explain this result.

Aluminum Trifluoride

No complex formation is observed.

Group IV

Silicon Tetrafluoride

A complex is formed in sulfur dioxide solution at −70°C with a fluorine chemical shift of −130.6 (sharp line).

Germanium Tetrafluoride

Complexes are formed which give many well resolved fluorine resonance lines from −87 to −100 ppm.

Tin Tetrafluoride

The situation is the same as for germanium tetrafluoride except for the chemical shifts from −110 to −130 ppm and a different pattern of lines.

Titanium Tetrafluoride

More than 80 well resolved resonance lines are observed for fluorine bonded to titanium, probably from a variety of complexes. Bridging fluorine signals are found from −10 to −20 ppm and directly bonded fluorine signals appear from 150 to 240 ppm. These are in the regions previously reported for binary complex fluoroanions of titanium, but do not correspond with any of the previously reported species (5).

Zirconium Tetrafluoride

No complex formation is observed.

Group V

Phosphorus Trifluoride

No complex formation is observed.

Phosphorus Pentafluoride

With an excess of TFA^- a complex of structure **1**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

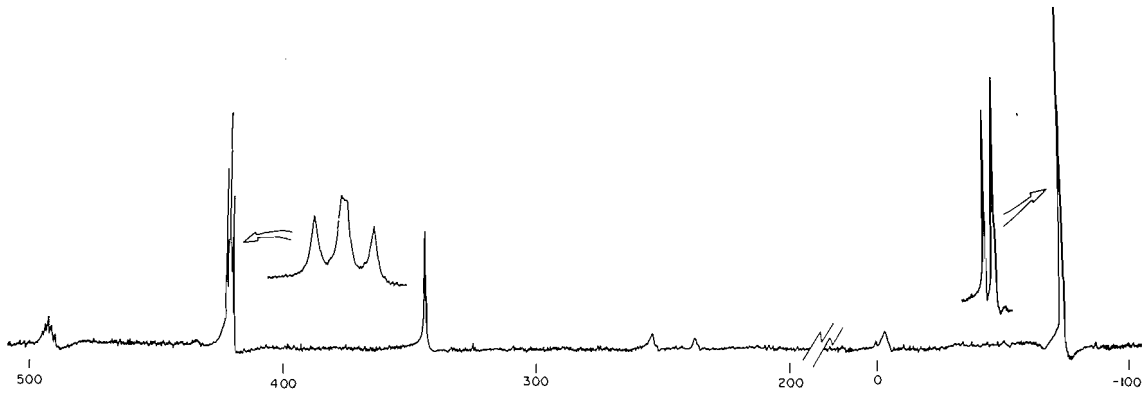

FIG. 2. The fluorine resonance spectrum of an equimolar solution of TBATFA and VF_5 in SO_2ClF at $-100°C$.

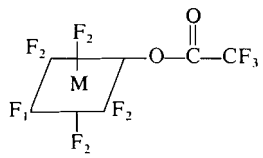
is formed. Its fluorine resonance parameters are listed in Table 1. With an excess of PF_5 only a single broad line is observed for fluorine bonded to phosphorus because of rapid averaging. There is no evidence, from vapor pressure measurements, for complexing of PF_5 beyond a 1:1 ratio.



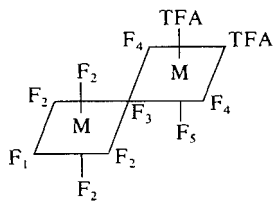
1

Arsenic Pentafluoride

With an excess of TFA^- and at $-120°C$ fluorine exchange is sufficiently slowed that a complex of structure I may be identified by its fluorine resonance spectrum. The parameters are listed in Table 1.

Vanadium Pentafluoride

The spectrum from equivalent amounts of VF_5 and TBATFA, shown in Fig. 2, may be explained as



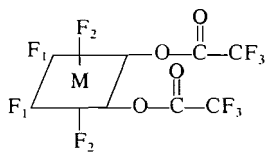
2

arising from structure **2**. The quintet is attributed to F_1. In similar complex fluoroanions the terminal fluorine is found at about 500 ppm (3). The doublet of doublets is assigned to F_2, spin coupled to F_1 and F_3. Fluorines in this environment have been observed near 430 ppm. The bridging fluorine, F_3, is allocated to the broad line at -14 ppm, in agreement with the value 13 in polymeric vanadium pentafluoride. The lines at 254 and 236 ppm are assigned to F_4 and F_5 respectively. These are halfway between 345 and 130 ppm, the chemical shifts of VF_6^- and $VF_4(OH)_2^-$. A possible mode of formation is given by eqs. 3 and 4.

[3] $$2VF_5TFA^- \rightarrow cis\ VF_4(TFA)_2^- + VF_6^-$$

[4] $$cis\ VF_4(TFA)_2^- + VF_5 \rightarrow V_2F_9(TFA)_2^-$$

These reactions are consistent with the formation of a *cis* 1:2 complex by TaF_5 and further complexing with the binary fluoride as found with BF_3. It would be difficult to fit the observed spectrum to a species with a bridging trifluoroacetate group. The fluorine resonance parameters are listed in Table 1.



3

Niobium Pentafluoride

Solutions of NbF_5 and TBATFA give a single rather broad line for fluorine bonded to niobium at 128 ppm. It was not possible to lower the temperature sufficiently to slow the fluorine exchange. The chemical shift value indicates that complex formation has occurred.

Tantalum Pentafluoride

A 1:1 complex of structure **1** and a 1:2 complex of structure **3** are both formed. The fluorine resonance parameters are listed in Table 1.

Group VI

Sulfur Tetrafluoride

A 1:2 complex of structure **3** is formed. An additional line in the fluorine resonance spectrum at 16.8 may be from the *trans* 1:2 complex. The com-

TABLE 2. Relative intensities of fluorine resonance signals in TFA–WF_6 samples[a]

	Species 1		Species 2		Species 3		Species 4		Species 5	
Time	Shift	Intensity	Shift	Intensity	Shift	Intensity	Shift	Intensity	Shift	Intensity
					1:1 Sample					
Initial	166.70	547	148.50	1068	65.50	373				
1 h	166.70	323	148.51	820	65.53	377				
4 h	166.72	245	145.64	684	65.65	556				
					2:1 Sample					
Initial	166.67	44	148.51	532			172	—	—	
1 h	—	—	148.62	217			140	57.92	134	
4 h	—	—	148.78	171			138	58.11	202	

[a]Relative to $CFCl_3$ as 100.

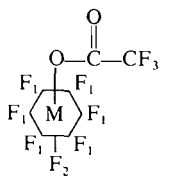
plexes are completely dissociated at room temperature.

Tellurium Hexafluoride

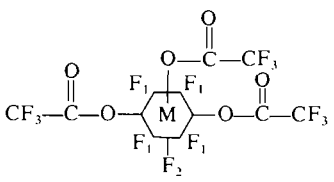
In SO_2 solution at $-70°C$ there is a broad weak peak at -53.8 in the fluorine resonance spectrum which may be due to partial complex formation. In CH_2Cl_2 as solvent there is no complex formation even at $-100°C$.

Molybdenum Hexafluoride

Two complexes have been identified with structures **4** and **5**. The fluorine resonance parameters are listed in Table 1. Justification for these assignments will be given for the corresponding complexes with tungsten hexafluoride.



4



5

Tungsten Hexafluoride

Several complexes are formed with the trifluoroacetate ion. The fluorine resonance spectrum of an equilibrated sulfur dioxide solution of equimolar quantities of TMATFA and WF_6 at $-70°C$ is shown in Fig. 3. It is difficult to find a reasonable structure, other than **4** which has six and one magnetically equivalent fluorines. The proposed hexagonal bipyramid structure is also consistent with that proposed for $WF_6[(CH_3)_2S]_2$ (6). There is rapid exchange on the nmr time scale at room temperature for the fluorines in the different chemical environments. It is found that after some time at room temperature and subsequent cooling to $-70°C$ the fluorine resonance spectra of TMATFA + WF_6 samples are changed. This behaviour is presented in Table 2. Species 1 (WF_6) and Species 2 decrease in concentration with time while Species 3 (WF_7TFA^{2-}) increases. These results may be explained by the reactions shown in eqs. 5 and 6.

$$[5] \qquad WF_6 + TFA^- \rightarrow WF_6TFA^-$$

$$[6] \qquad 2WF_6TFA^- \rightarrow WF_7TFA^{2-} + WF_5TFA$$

The line at 148.5 (Species 2) must then be attributed to a rapidly averaging mixture of WF_6TFA^- and WF_5TFA since these are the only species not accounted for. The chemical shift and absence of satellites from fluorine–tungsten spin coupling for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

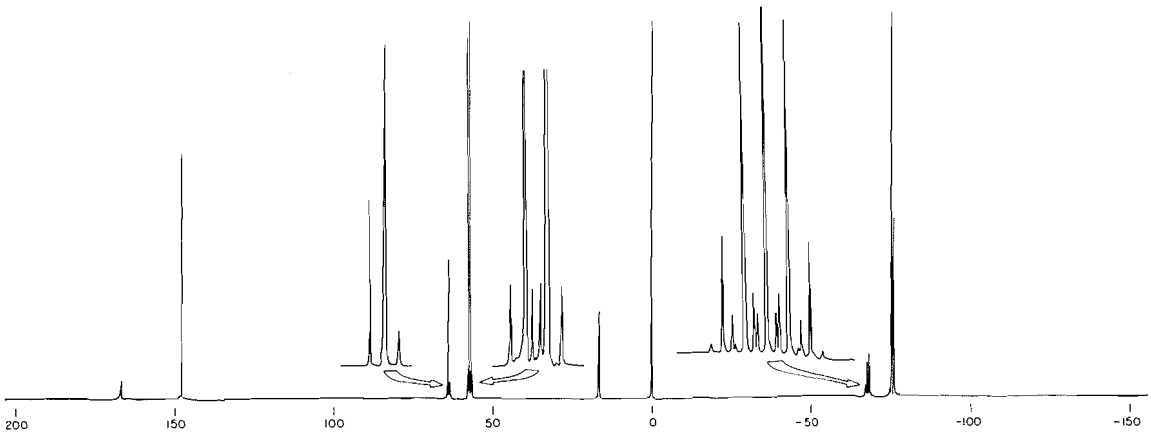


FIG. 4. The fluorine resonance spectrum at −70°C of an SO_2 solution of WF_6 and two equivalents of TMATFA.

this signal are consistent with the results obtained with other Lewis bases (6), and with rapid averaging. A solution of the same composition but with $CHFCl_2$ as solvent has the same fluorine resonance spectrum with the addition of a weak doublet at 56.4 (J = 51 Hz).

With two equivalents of TFA for each WF_6 in $CHFCl_2$ as solvent an additional line is found at 60.8 with satellites from W–F spin coupling. A solution of the same composition in sulfur dioxide, when well equilibrated, has the fluorine resonance spectrum shown in Fig. 4. The doublet and quintuplet are assigned to $WF_5(TFA)_3^{2-}$ with the geometry of Structure **5**, and may be formed according to eq. 7 or 8.

[7] $3WF_6TFA^- + 3TFA^- \rightarrow WF_8^{2-} + 2WF_5(TFA)_3^{2-}$

[8] $3WF_7TFA^{2-} \rightarrow 2WF_8^{2-} + WF_5(TFA)_3^{2-}$

Support for this scheme comes from the time dependence of the fluorine resonance spectrum of a 2:1 sample as listed in Table 2. Free WF_6 rapidly disappears and the 1:1 complex slowly disappears as reactions 6 and 7 occur. Further study is needed to fully elucidate the details of this system. The fluorine resonance parameters are listed in Table 1.

Group VII

Iodine Pentafluoride

A 1:1 complex of structure **1** is formed at low temperature and has the fluorine resonance parameters given in Table 1.

Conclusions

The trifluoroacetate ion complexes readily with binary fluorides to yield mixed fluoroanions. In some cases these undergo disproportionation to yield anions containing more than the original number of trifluoroacetate groups. With boron, vanadium, titanium, and tin there is strong evidence for complex fluoroanion formation via fluorine bridging.

Received June 22, 1977

JAMES MALCOLM SANGSTER, MARIE-CHRISTINE ABRAHAM, and MAURICE ABRAHAM. Can. J. Chem. **56**, 348 (1978).

Vapour pressures of aqueous solutions of the mixed melt $AgNO_3$ + $TlNO_3$ + $Cd(NO_3)_2$ have been measured at 98.5°C by the static technique. The Ag/Tl mole ratio was fixed at 1.06, and the mole fractions Cd/(Ag + Tl + Cd) of Cd in the melt were 0, 0.05, 0.075, 0.10, and 0.125. Adapted BET isotherms and their constants were obtained for each of the five melt mixtures. It has been shown, in the present study, from the BET equation itself, and verified experimentally, that certain systems can give rise to a 'crossover point', that is, a reversal of sign of the deviation from Raoult's law. The BET constants of the systems conform to simple additivity rules. The water concentration range over which the BET equation is valid is unexpectedly wide.

JAMES MALCOLM SANGSTER, MARIE-CHRISTINE ABRAHAM et MAURICE ABRAHAM. Can. J. Chem. **56**, 348 (1978).

Par mesure des pressions de vapeur, à l'aide de la méthode statique, on a déterminé les constantes BET de dissolution de l'eau dans cinq mélanges fondus $AgNO_3$ + $TlNO_3$ + $Cd(NO_3)_2$ à 98.5°C, pour un rapport molaire Ag/Tl = 1.06 et des rapports molaires Cd/Ag + Tl + Cd = 0, 0.05, 0.075, 0.1 et 0.125. On a montré, dans cette étude, par application de la théorie BET adaptée, et vérifié expérimentalement, que certains systèmes peuvent présenter un point dit "de compensation", situé hors du domaine d'idéalité de Raoult, où l'activité de l'eau est égale à sa fraction molaire. Les constantes de la théorie BET adaptée suivent des règles d'additivité que l'on a discutées. Ces systèmes sont remarquables pour le grand intervalle de concentration en eau où la théorie BET adaptée s'applique d'une manière satisfaisante.

Introduction

In an earlier article (1), we reported the results of vapour pressure measurements of the system (Ag, Tl)NO_3 + H_2O at 98.5°C, at the mole ratio Ag/Tl = 1.14. When this ratio is near 1, the system is liquid at temperatures near 100°C at all water concentrations (2). This system showed positive deviations from Raoult's law throughout the water concentration range studied. This behaviour is quite rare among aqueous electrolyte solutions, and it was postulated that this observation is connected with the fact that Ag^+ and Tl^+ are both relatively weakly hydrated ions.

To test this idea, it was decided to add another cation which was more strongly hydrated than Ag^+ or Tl^+, and which would form melts with the same water solubility as previous ones. Cadmium answered these requirements, and we report here vapour pressure measurements of the system (Ag, Tl, Cd)NO_3 + H_2O at 98.5°C, varying separately the Cd content of the melt, and the water concentration as before. This first article presents the vapour pressure data and discusses the Raoult's law behaviour and BET isotherms of five Cd concentrations in the melt. The second article will discuss the results in terms of Henry's law and the excess free energy.

[1]Author to whom correspondence should be addressed.

Experimental

Vapour pressures were measured by the static technique, the details of which were given previously (1). The same sample manipulation was used, except that $Cd(NO_3)_2 \cdot 4H_2O$ (Fisher, 99.9%) was added to the melt to give the desired cadmium content, and the water was driven off by heating *in vacuo* at about 200°C. The Ag/Tl ratio was fixed at 1.06, corresponding to the composition of an $AgNO_3/TlNO_3$ eutectic (3); this ratio is very close to the one used previously (1). All measurements were done at 98.50 ± 0.05°C.

The data were treated in the same manner as before, the fugacity f being calculated from the pressure p by means of the second virial coefficient of water vapour at 98.5°C, and the water activity a_w from the ratio f/f_0, f_0 being the fugacity of pure water at the same temperature. The mole fraction activity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

coefficient of water, γ_w, was the ratio a_w/x_w, where x_w is the mole fraction of water in the solution.

Results and Discussion

To facilitate the presentation and discussion of the results, we have adopted the designation S_X to indicate the cadmium content of the melt[2] in a solution. The subscript X indicates the mole percentage of $Cd(NO_3)_2$ in the melt, and Table 1 gives this information explicitly for the five Cd contents used in this work. For example, S_5 indicates a solution $AgNO_3 + TlNO_3 + Cd(NO_3)_2 + H_2O$, obtained by adding water to the melt whose composition is, in mole fractions: $AgNO_3$, 0.489; $TlNO_3$, 0.461: $Cd(NO_3)_2$, 0.050.

Experimental values of p, f, a_w, and γ_w for the systems S_0, S_5, $S_{7.5}$, S_{10}, and $S_{12.5}$ are given elsewhere.[3]

Raoult's Law

Plots of a_w vs. x_w are given in Fig. 1 for the systems S_0, $S_{7.5}$, and $S_{12.5}$. (To avoid undue clutter in the figure, the curves for S_5 and S_{10} are not included; they lie, however, in the appropriate positions intermediate among the three shown.) As was found previously (1), the cadmium-free system shows positive deviations throughout. As Cd is added successively, the curves are pushed downward in a regular manner, i.e., for any x_w, a_w decreases step by step as the Cd content of the melt is increased. This tends to confirm our expectation that positive and negative deviations from Raoult's law are connected with the presence of weakly and strongly hydrated cations respectively.

The curve is at the same time distorted into an S shape upon addition of Cd. As a consequence, each of the curves for intermediate Cd concentrations (S_5, $S_{7.5}$, and S_{10}) crosses the ideal Raoult's law line at one point (and one point only). The crossover point is displaced toward the pure water end as the Cd concentration increases and the curve, originally concave to the abscissa (system S_0), gradually becomes more convex. The change from concave to convex does not proceed via a general flattening (as one might naively have expected), but via the S shape.

BET Isotherms

This rather complicated behaviour can perhaps be better understood in the light of the conformity of these systems to the BET isotherm equation. This

TABLE 1. Explanation of the nomenclature used for designating the composition of the melt

	Composition (mole fraction)		
Designation	$AgNO_3$	$TlNO_3$	$Cd(NO_3)_2$
S_0	0.515	0.485	0
S_5	0.489	0.461	0.050
$S_{7.5}$	0.476	0.449	0.075
S_{10}	0.464	0.436	0.100
$S_{12.5}$	0.451	0.424	0.125

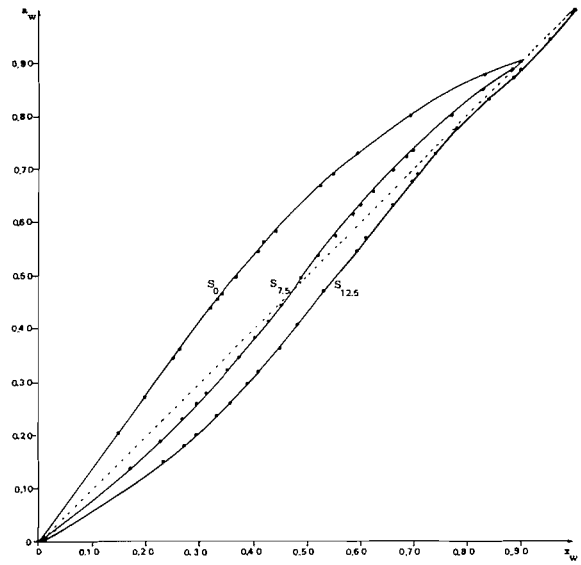

FIG. 1. Raoult's law curves for the system (Ag, Tl, Cd)NO_3 + H_2O at 98.5°C, for three Cd concentrations in the melt. Dashed line represents ideal behaviour.

equation was adapted by Stokes and Robinson (4) to very concentrated electrolyte solutions, and can be written as

$$[1] \quad a_w(1 - x_w)/x_w(1 - a_w) = 1/cr + (c - 1)a_w/cr$$

in which r and c are the BET constants. The number of water molecules adsorbed per complete monolayer on a solute molecule is r, and c is given approximately by $c = \exp[-(E - E_L)/RT]$, $(E - E_L)$ being the difference between the energy of adsorption of water in the monolayer and the energy of liquefaction of bulk water.

Figure 2 shows that all five systems studied here conform to the BET equation over the same wide range of water concentration, as previously observed (1). It follows from this result that the Raoult's law curve may have *only one* crossover point, as suggested by Fig. 1. At the crossover point, $a_w = x_w$; making this substitution in eq. 1, we solve for x_w and

[2]The word 'melt' in this article signifies the anhydrous electrolyte mixture.

[3]A complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

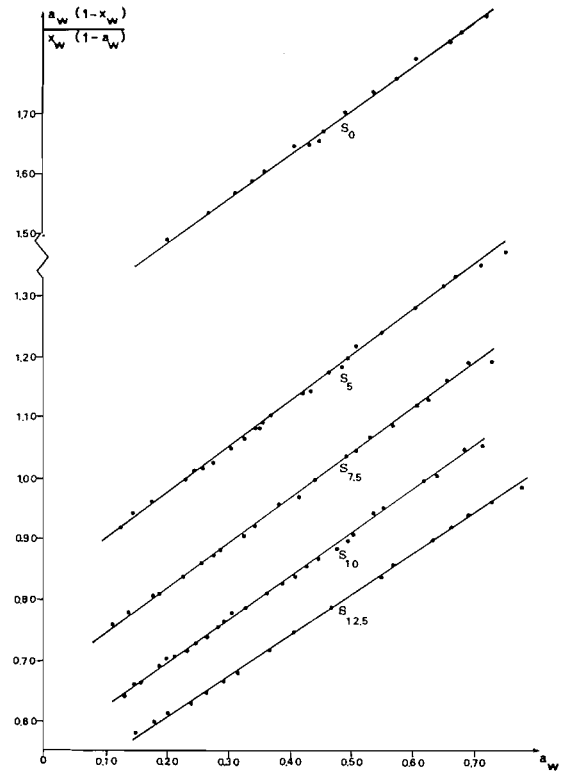

FIG. 2. The BET isotherms for the system (Ag, Tl, Cd)NO_3 + H_2O at 98.5°C, for five Cd concentrations in the melt.

obtain

$$[2] \qquad x_w = (cr - 1)/(c - 1)$$

Equation 2 shows that the crossover point is uniquely determined by the BET constants. Since $0 \leq x_w \leq 1$, eq. 2 also implies that

$$[3] \qquad 0 \leq (cr - 1)/(c - 1) \leq 1$$

for any system exhibiting a crossover point. This ratio is given in Table 2 for the five systems studied. It is seen that eq. 3 is a necessary, *though not sufficient*, condition for the appearance of a crossover point in these systems.

Additivity Rules

Table 2 shows that r and $-(E - E_L)$ increase regularly with Cd concentration. This suggests the possibility of finding linear dependences upon Cd mole fraction (say). For r, we take r_0 as the number of moles of water in the complete monolayer of 1 mol of solute in system S_0 (we shall suppose that cations only are hydrated). The corresponding number of moles of water for 1 mol of Cd^{2+} in S_5, $S_{7.5}$, S_{10}, and $S_{12.5}$ is r_1. We would expect r to be a weighted sum of r_0 and r_1, such as

TABLE 2. The constants of the BET equation (eq. 1) for the system (Ag, Tl, Cd)NO_3 + H_2O at 98.5°C, and the upper a_w limit of validity of this equation

	r	c	$-(E - E_L)$ (kcal/mol)	$\frac{cr - 1}{c - 1}$	a_w limit
S_0	0.486	1.54	0.317	−0.47	0.75
S_5	0.639	1.90	0.474	0.24	0.70
$S_{7.5}$	0.715	2.10	0.548	0.55	0.70
S_{10}	0.801	2.27	0.605	0.64	0.70
$S_{12.5}$	0.883	2.39	0.642	0.80	0.80

$$[4] \qquad r = X_{(Ag+Tl)}r_0 + X_{Cd}r_1$$

where the X's are cationic mole fractions in the melt (for example, if n represents number of moles, $X_{Cd} = n_{Cd}/(n_{Ag} + n_{Tl} + n_{Cd})$). If the substitution $X_{(Ag+Tl)} = 1 - X_{Cd}$ is made in eq. 4, then upon rearrangement we have

$$[5] \qquad r = r_0 + (r_1 - r_0)X_{Cd}$$

It has been assumed here that r_1 and r_0 are independent of X_{Cd}.

A plot of r vs. X_{Cd} is given in Fig. 3*a*. The slope and intercept of the straight line, found from least squares analysis, are 3.19 and 0.48 respectively, from which are found the values $r_0 = 0.48$ and $r_1 = 3.67$. The value for r_0 is close to that found in the previous work ($r_0 = 0.5$) and the value for r_1 is the same as that determined from isopiestic measurements for $Ca(NO_3)_2$ at this temperature (5). It is probably not fortuitous that r_1 is also close to the number of waters of hydration in the hydrate $Cd(NO_3)_2 \cdot 4H_2O$.

The validity of an additivity rule for r (eq. 4 or 5) suggests the possibility of a similar rule for the quantity rE, where E is the energy of adsorption per mole of water, defined after eq. 1. The equation for rE, precisely analogous to eq. 5, is

$$[6] \qquad rE = r_0E_0 + (r_1E_1 - r_0E_0)X_{Cd}$$

where E_0 and E_1 are individual energies of adsorption defined in the same manner as r_0 and r_1 above. In order to test eq. 6, we have to transform it into one containing energy *differences* $(E - E_L)$, etc. This is accomplished by multiplying eq. 5 by E_L,

$$[7] \qquad rE_L = r_0E_L + (r_1E_L - r_0E_L)X_{Cd}$$

and subtracting eq. 6 from eq. 7 to give

$$[8] \qquad -r(E - E_L) = -r_0(E_0 - E_L) - [r_1(E_1 - E_L) - r_0(E_0 - E_L)]X_{Cd}$$

In Fig. 3*b* the quantity $-r(E - E_L)$ is plotted against X_{Cd}, and the straight line obtained has slope 3.34 and intercept 0.15. Using these values and the previously determined value $r_1 = 3.67$, we arrive at the energy

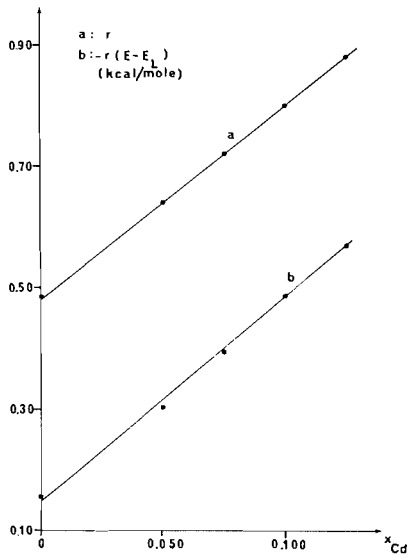

FIG. 3. (*a*) The BET constant r as a function of the cadmium content of the melt. (*b*) The product, $-r(E - E_L)$, of two BET parameters as a function of cadmium content of the melt.

of adsorption term for $Cd(NO_3)_2$, $-(E_1 - E_L) = 0.95$ kcal/mol. This value can be compared with those for other nitrates at 100°C (5), as shown in the series: $Ca(NO_3)_2$, 1.5; $LiNO_3$, 1.2; (Ca, Cs)NO_3, 1.0; $Cd(NO_3)_2$, 0.95 (this work); (Li, K)NO_3, 0.7.

Range of BET Linearity

The upper a_w limit to which the BET equation remains valid is given in Table 2; this limit is ≥ 0.7 in these systems. This is as high, or higher, than the upper limits previously observed (6) for systems containing at least 50 mol% of strongly hydrated cation in the melt (e.g. Li, Ca). This is surprising, since considering the assumptions of the BET theory, one would expect the equation to become invalid when the monolayers become complete. In the case of the weakly hydrated Ag^+ and Tl^+, one might have expected this limit to be noticeably less than $a_w = 0.7$.

The dielectric relaxation of some diols in *p*-dioxane solution

J. CROSSLEY

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received August 2, 1977

J. CROSSLEY. Can. J. Chem. **56**, 352 (1978).

Dielectric constant and loss data at up to nine microwave frequencies have been obtained for 1-butanol, 1,4-butanediol, 1,7-heptanediol, 1,8-octanediol, 1,10-decanediol, and 1,12-dodecanediol at 25°C, and for 1,6-hexanediol at 15, 25, 40, and 55°C, in *p*-dioxane. In each case the dielectric dispersion is adequately described by a Cole–Cole distribution. The relaxation times for the diols are almost independent of the length of the alkyl group. An intramolecular relaxation process appears to be primarily responsible for the dielectric absorption.

J. CROSSLEY. Can. J. Chem. **56**, 352 (1978).

On a obtenu des données relatives aux constantes diélectriques, à diverses (jusqu'à neuf) fréquences de microonde, pour le butanol-1, le butanediol-1,4, l'heptanediol-1,7, l'octanediol-1,8, le décanediol-1,10 et le dodécanediol-1,12 à 25°C et pour l'hexanediol-1,6 à 15, 25, 40 et 55°C dans le *p*-dioxanne. Dans chaque cas, la dispersion diélectrique est décrite d'une façon adéquate par une distribution Cole–Cole. Les temps de relaxation pour les diols sont pratiquement indépendants de la longueur de la chaîne carbonée. Il semble que l'absorption diélectrique est principalement due à un processus de relaxation intramoléculaire.

Introduction

Dielectric measurements have provided valuable information on the nature of association in liquid alcohols. Monohydric *n*-alcohols show a single Debye-type principal dielectric dispersion (1). In contrast, the principal dispersion region for many polyhydroxyl alcohols is better described by the Cole–Davidson (2) empirical relation (3, 4). It is generally considered that relaxation in all alcohols occurs via cooperative motions of molecules and involves the formation and rupture of hydrogen bonds. Intramolecular hydrogen bonding in polyhydroxyl alcohols leads to a less regular liquid structure, and evidently hinders the cooperative relaxation. The effect is determined by the proximity of the OH groups in the same molecule (3, 5).

Dielectric constant, dipole moment, and dielectric relaxation measurements on monohydric alcohols diluted with non-polar hydrocarbon solvents have been particularly useful in examining the nature of the hydrogen bonding (6). Because of their sparse solubility in most non-polar solvents, no such work has been reported for polyhydroxyl alcohols. Diols, however, are sufficiently soluble in *p*-dioxane to allow accurate dielectric constant and loss measurements, and it seemed that an examination of such solutions would be of interest. This paper reports the work on *p*-dioxane solutions of a series of diols with hydroxyl groups at the chain ends. The results are compared with earlier data for monohydric alcohols in non-polar solvents.

Experimental

The apparatus and procedure used to determine the dielectric constant (ε') and loss (ε'') at up to nine microwave frequencies between 1 and 35 GHz have been described previously (7, 8). Low frequency dielectric constants (ε_0) were measured at 2 MHz using a WTW Dipdmeter. Dioxane itself has a small dielectric dispersion. The solvent was measured at each frequency and the solution ε' and ε'' values were corrected accordingly. All the chemicals were dried and distilled or recrystallized prior to use.

Results

The Cole–Cole (9) plots for all the solutions gave smooth depressed centre arcs (Fig. 1). The experi-

1,10-Decanediol	<0.02	25	9.4	0.16	2.402	2.234	—
1,12-Dodecanediol	<0.02	25	10.1	0.16	2.305	2.227	—

mental ε_0, ε', and ε'' data were fitted to the Cole–Cole equation as described previously (10) to obtain the high frequency dielectric constant (ε_∞), mean relaxation time (τ_0), and distribution parameter (α) values listed in Table 1. The apparent dipole moments (μ) given in Table 1 were calculated from:

$$\mu = \left[\frac{9kT(\varepsilon_0 - \varepsilon_\infty)(2\varepsilon_0 + \varepsilon_\infty)}{4\pi N\varepsilon_0(\varepsilon_\infty + 2)^2}\right]^{1/2}$$

where N is the number of alcohol molecules per ml of solution and k is the Boltzmann constant.

Discussion

The ε' and ε'' values reported here for diols in *p*-dioxane solution are well represented by a Cole–Cole distribution. A similar result is observed for 1-butanol (Table 1), methanol, and decanol in *p*-dioxane (11). This is in contrast to the Cole–Davidson skewed arc behaviour (2) shown by many pure liquid diols (3, 4). Johari and Smyth (11) reported τ_0 values of 3, 5, and 9 ps for methanol, 1-butanol, and 1-decanol, respectively, at about 0.05 mol fraction in *p*-dioxane solution at 25°C. Their result for 1-butanol, which showed a Cole–Cole α of 0.17, is in good agreement with that reported here (Table 1). The remarkable feature of the results presented in Table 1 is that the τ_0 values for the C_4 to C_{12} diols at 25°C are very similar. The relaxation times for corresponding 1-alkenes and 1-bromoalkanes, which are by no means rigid molecules, are considerably longer than those found here for diols (12).

A 1,6-hexanediol solution was measured at four temperatures (Table 1). The Cole–Cole α values show the usual small decrease with increased temperature. The plot of $\ln \tau T$ against $1/T$ is linear and yields an activation energy of 3.1 kcal/mol. This value is almost identical with those calculated from Johari and Smyth's (11) data for 1-butanol in *p*-dioxane/*n*-heptane mixtures.

The close similarity in the τ_0 values for diols of quite different size strongly suggests that an intramolecular relaxation process is the dominant factor in the dielectric absorption. Hydroxyl group rotation for alcohols and phenols gives rise to relaxation times of about 3 ps (11, 13, 14). The longer values obtained here may be partially explained in terms of OH rotation which is restricted by solute–solvent interactions. In fact, such interactions have a significant effect upon the OH group relaxation time in phenols (15). If hydroxyl group rotation were solely responsible for the dielectric absorption of the dioxane solutions, then one would expect τ_0 for 1-butanol and 1,4-butanediol to be similar, which is not the case. It is quite possible that this observation and the increase in τ_0 from methanol to 1-butanol to 1-decanol is due to a small contribution from some molecular species. The results for 1,6-hexanediol reveal that τ_0 has detectable concentration dependence. The limited solubility of the higher molecular weight diols meant that they were studied at lower concentrations than some of the other diols. A comparison of the τ_0 values in Table 1 for (*i*) 1,4-butanediol and 1,6-hexanediol ($f_2 = 0.0555$), (*ii*) 1,6-hexanediol ($f_2 = 0.0408$), 1,7-heptanediol, and 1,8-octanediol, and (*iii*) 1,6-hexanediol ($f_2 = 0.022$), 1,10-decanediol, and 1,12-dodecanediol does reveal a quite small, but consistent, lengthening of τ_0 with increased molecular size. These observations support a dielectric absorption dominated by an intramolecular process with a small contribution from 'molecular' reorientation. Attempts have been made to analyze the ε' and ε'' data for these solutions in terms of two discrete relaxation times. Meaningful analyses were not obtained. This is perhaps not altogether surprising since 'molecular' reorientation referred to above could involve diol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

monomers and diol–dioxane complexes. In view of this, the distribution of relaxation times is only to be expected.

Electrolytes in mixed solvents: indium trichloride in water–dimethylsulfoxide mixtures

ALAN N. CAMPBELL

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received July 8, 1977

ALAN N. CAMPBELL. Can. J. Chem. **56**, 355 (1978).

This paper is concerned with the investigation of the conductances (some 160 determinations) of potassium chloride and of indium trichloride in water–dimethylsulfoxide mixtures. The behaviour of potassium chloride in these mixtures is practically identical with its behaviour in water, up to 50 wt% DMSO. Thus Walden's rule is followed very closely, implying that the only effect on the speeds of the ions is that of viscosity. The behaviour of indium trichloride is very different. The conductance increases rapidly with dilution, in the dilute region, and it is time dependent. It is practically certain that the ionization of indium trichloride takes place in steps and that, in dilute solution, progressive hydrolysis occurs. By extrapolating the measurements as a straight line, below concentrations of 0.01 *N*, an approximation to the limiting value of Λ is obtained.

ALAN N. CAMPBELL. Can. J. Chem. **56**, 355 (1978).

Dans cet article, on rapporte les résultats d'une étude sur la conductivité (environ 160 déterminations) du chlorure de potassium et du trichlorure d'indium dans des mélanges d'eau et de diméthylsulfoxyde. Le comportement du chlorure de potassium dans des mélanges contenant jusqu'à 50% en poids de DMSO est pratiquement identique avec son comportement dans l'eau. La règle de Walden est donc suivie très fidèlement et ceci implique que les seuls effets agissant sur les vitesses des ions sont ceux de la viscosité. Le comportement du trichlorure d'indium est très différent. Dans la région diluée, la conductivité augmente rapidement avec la dilution et dépend du temps. Il est pratiquement certain que l'ionisation du trichlorure d'indium se produit par étapes et qu'en solution diluée, une hydrolyse progressive se produit. En extrapolant les mesures sous forme de ligne droite à des concentrations plus basses que 0.01 *N*, on peut obtenir une approximation de la valeur limite de Λ.

Introduction

Because of the hydrolysis of indium trichloride in dilute aqueous solutions, it is impossible to determine the limiting conductance of indium trichloride and, therefore, that of the indium ion, $\frac{1}{3}In^{3+}$, by the usual method of conductance. The matter is further complicated by the probability, indeed almost the certainty, that the ionization of the indium trichloride molecule occurs in stages. It has recently been shown by Jarv *et al.* (1) that the ionization of the $InCl_3$ molecule gives rise to the species: $(InCl(H_2O)_5)^{2+}$, $(InCl_2(H_2O)_4)^{+}$, $(InCl_3(H_2O)_3)$, and $(InCl_4(H_2O)_2)^{-}$, as well as, no doubt, $(In(H_2O)_6)^{3+}$. The method used by Jarv *et al.* (1) was that of Raman spectroscopy. Conductance measurements give no evidence of the existence of the negatively charged complex ion. The conductance decreases with increasing concentration of indium trichloride to a very low value for the saturated solution. If an appreciable amount of the negative ion were present, the conductance would pass through a minimum but it decreases continuously. This is not to say that the negative ion does not exist in solution but that the amount of it cannot be large in comparison with those of the other ions.

Alternatively, the limiting conductance of the $\frac{1}{3}In^{3+}$ ion can be obtained from transport number determinations but a very high degree of accuracy in the determination of transport number is necessary to obtain even moderate accuracy in the ionic conductance. The author has attempted this on two occasions (2, 3) and hopes that his last figure, if not definitive, is at least an improvement on his previous one.

On the face of it, it would seem that if measurements of conductance were made in a solvent other than water, in which hydrolysis could not occur, at least part of the problem would be solved. If Λ^0 were obtained in a given solvent, the value of $\Lambda^0\eta$ for the non-aqueous solvent should yield Λ^0 for water. Admittedly, Walden's rule ($\Lambda^0\eta$ = constant) has little theoretical justification but it does apply in many instances. At least, this seemed a justification for further experimental work.

As solvent, dimethylsulfoxide was chosen, since it has a reasonably high dielectric constant (ε = 46.7, as against 78.3 for water) and it can be obtained cheaply in a pure condition. A great practical advantage is the ease of purification, as compared with, for example, formamide. Passage through a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

molecular sieve is sufficient to remove any trace of water. In the present work, passage through a molecular sieve did not lower the already very low specific conductance, and the product was used as it came from the supplier.

An obvious objection to dimethylsulfoxide is the (relatively) low dielectric constant, which would imply that complex ions would occur even more abundantly than in water. By lowering the concentration to the practical limit of 0.0005 N, however, it was hoped that a straight line plot of Λ vs. $\sqrt{C}$ would yield Λ^0. At least, this is what was done by Gordon and his school (4) working in methanol; their limiting concentration was 0.0001 N. Since the dielectric constant of methanol is so low (32.63) one is inclined to wonder if the extrapolation is justified.

In addition to a series of measurements in pure dimethylsulfoxide, complete series of measurements were made in solvents containing 10, 20, etc., up to 90 wt% water. The densities, viscosities, and dielectric constants of each of these solvents were determined. It was hoped that the plots of $\Lambda\eta$ vs. $\sqrt{C}$ would yield a value for $\Lambda^0\eta$ in pure dimethylsulfoxide and hence, by application of Walden's rule, the value of Λ^0 for pure water. To some extent, this expectation has been justified.

Because of the complicated form of the ionization of indium trichloride, an identical set of measurements was made with potassium chloride as solute, potassium chloride being the ideal normal electrolyte. These extensive measurements have yielded a family of curves which is very instructive as to the nature of the ionization of the two solutes.

Starting with an electrolyte concentration of 0.1 N, the solutions were diluted by weighing down to 0.001 N and lower. The values of $\Lambda\eta$ were then plotted against $\sqrt{C}$.

The heats of mixing of water and dimethylsulfoxide were determined over the complete concentration range, as well as the heats of solution of indium trichloride in water–dimethylsulfoxide mixtures, but the latter measurements could not be pushed to high concentrations of DMSO, because of the decreasing solubility of indium trichloride.

Experimental

Materials

The potassium chloride was reagent grade, analysed. It was dried in a platinum dish over a Meker burner, avoiding fusion. Fisher certified dimethylsulfoxide was used as supplied. Specific conductance = 7.2×10^{-7} mho. All the methods of determination have been described previously (2, 3, 6). The anhydrous indium trichloride was a Ventron Alfa Product.

Results

The data for density, dielectric constant, and viscosity of dimethylsulfoxide–water mixtures are to be found in 'Physical Chemistry of Organic Solvent Systems' (5).

The conductance measurements, amounting to some 160 in all, were made both for potassium chloride and for indium trichloride. In each case, the strongest or starting solution (about 0.1 N) was analysed gravimetrically as chloride and subsequent dilutions were made by weighing. The densities were taken as those of the pure solvent as were the viscosities, a procedure which may have introduced a slight error into the measurements on the strongest (0.1 N) solution. These numerous numerical results are to be found in the Depository of Unpublished Data in Tables 1 and 2.[1] The results are expressed graphically (for certain strengths only, to avoid confusion in the diagram) as the product $\Lambda\eta$ vs. $\sqrt{N}$ in Figs. 1 and 2.

The heats of mixing of dimethylsulfoxide and water are given in Table 3.[1] The results are expressed graphically in Fig. 3. There is a pronounced maximum at about 45 mol% dimethylsulfoxide. The heats of solution of indium trichloride in water and water–dimethylsulfoxide mixtures are given in Table 4.

Discussion

The extensive measurements of conductance are to be found in the Depository material but an inspection of Figs. 1 and 2 reveals the main features. The straight line plot of $\Lambda\eta$ vs. $\sqrt{N}$ of potassium chloride is hardly influenced by the presence of dimethylsulfoxide and Walden's rule is very closely followed, as shown by Table 5.

Walden's rule applies exactly at a weight concentration of 10.5% giving a Λ_0 value of 121.1 for KCl in 10.5 wt% DMSO. The rule continues to apply approximately up to 51.83 wt% DMSO (ratio $(\Lambda\eta)_0(\text{water})/(\Lambda\eta)_0(\text{solvent}) = 1.054$). Within the limits of this approximation Λ_0 for KCl has been reduced from 149.8 mho cm^{-1} to 44.79, principally as a result of increased viscosity of the medium. Further increase of DMSO content results in rather serious deviation from the Walden rule.

The state of affairs is very different for $InCl_3$, as Fig. 2 shows. At concentrations less than 0.01 N, the conductance rises rapidly with dilution and at concentrations less than 0.001 N becomes time dependent. The explanation of this is twofold. The time dependence is due to increasing hydrolysis with time, as the products of hydrolysis separate from solution. In addition, however, the step-wise ionization of $InCl_3$ must be taken into account. The ionization in

79.29	106.9	28.89	1.402

TABLE 6. Straight line extrapolation of Λη for indium trichloride

Concentration in wt% DMSO	$(\Lambda\eta)^0$ KCl	$(\Lambda\eta)^0$ $InCl_3$	Ratio $(\Lambda\eta)^0(KCl)/(\Lambda\eta)^0(InCl_3)$
100	80.9	11.8	6.856
80	104.0	31.8	3.270
70	114.8	39.1	2.936
60	127.8	50.7	2.520
50	142.2	66.4	2.142
40	146.6	77.4	1.894
30	147.4	92.6	1.592
20	149.86	137.0	1.094
0.0	149.86	125.9	1.190

time dependent with increasing water content, $(\Lambda\eta)$'s have been calculated by extending the experimental results down to a concentration of 0.01 N only and extrapolating as a straight line from that point. The results are given in Table 6.

The data in Table 6 would suggest that $(\Lambda\eta)_0$ and

therefore Λ_0 ($\eta = 1.000$) for $InCl_3$ lie between 137 and 125.9. The figure of the author's last determination of Λ_0 (3) is 132.9.

Table 4 gives the heats of solution of indium trichloride in water and a water–dioxane mixture. It would seem that the enthalpy of solution decreases with increasing DMSO content. This is to be expected. The molar volume, viscosity, and heat of mixing all indicate that the DMSO molecule is strongly hydrated. If the solution of indium trichloride can only take place in 'free' water, some dissociation of the DMSO–water complex, with absorption of energy, will have to occur before solution of $InCl_3$ is possible.

Raman and nuclear quadrupole resonance studies of the phase transition in pentachlorophenol

H. F. SHURVELL, J. KORPPI-TOMMOLA, AND R. J. C. BROWN
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received April 20, 1977

H. F. SHURVELL, J. KORPPI-TOMMOLA, and R. J. C. BROWN. Can. J. Chem. **56**, 359 (1978).

Raman and nqr spectra of pentachlorophenol (PCP) have been recorded at temperatures above and below the transition at 62 ± 2°C. The complete loss of structure in the Raman external mode region and the disappearance of the ^{35}Cl nuclear quadrupole resonances above the transition temperature indicate a disordered structure for the high temperature phase. Supercooling is observed in nqr and Raman spectra when the sample is cooled through the transition temperature. No evidence for any new crystal phase is observed on cooling the sample to liquid nitrogen temperature. Eleven of the 12 external modes predicted from the reported crystal structure of PCP have been observed in the Raman spectrum at 77 K.

H. F. SHURVELL, J. KORPPI-TOMMOLA et R. J. C. BROWN. Can. J. Chem. **56**, 359 (1978).

On a enregistré les spectres Raman et rqn du pentachlorophénol (PCP) à des températures supérieures et inférieures à celle de la transition (62 ± 2°C). La perte complète de structure dans la région de mode externe du spectre Raman et la disparition des résonances quadrupolaires nucléaires du ^{35}Cl au-dessus de la température de transition indiquent la présence d'une structure désordonnée dans la phase existant à température élevée. On observe de la surfusion dans les spectres rqn et Raman lorsque l'on refroidit l'échantillon à une température inférieure à celle de la transition. On n'observe aucune indication relative à la présence d'une nouvelle phase cristalline lorsque l'on refroidit l'échantillon jusqu'à la température de l'azote liquide. Dans le spectre Raman du PCP mesuré à 77 K, on a observé 11 des 12 modes externes qui avaient été prédits à partir de la structure cristalline déterminée antérieurement.

Introduction

Pentachlorophenol (PCP) is an important industrial chemical widely used as a plant pesticide. It is of interest from the point of view of hydrogen bonding, since it does not appear to self-associate in solution and forms H-bonded complexes with various other molecules.

In the crystalline state, PCP is known to undergo a phase transition near 62°C (1). The transition has been studied by Rohleder and co-workers using near-infrared spectroscopy (2) and microcalorimetry (3). A nuclear quadrupole resonance and X-ray study of the crystal structure was carried out at room temperature (4) following an earlier nqr study at 77 K (5).

An infrared spectrum of PCP is found in the Aldrich Library of Infrared Spectra (6) and in ref. 2. However, we are not aware of any published Raman spectrum of this compound in the chemical literature. We are therefore including a Raman survey spectrum in this paper.

As the title suggests, our main interest lies in the nature of the phase transition in solid PCP. To study this, we have recorded Raman spectra of the external (lattice) mode region and the ^{35}Cl nuclear quadrupole resonance of PCP at various temperatures above and below the reported (2, 3) transition temperature.

Experimental

Reagent grade pentachlorophenol was obtained from J. T. Baker Chemical Co. Samples for Raman spectroscopy were recrystallized from CCl_4 solution and sublimed under vacuum. Pellets were prepared by means of the apparatus usually used to make KBr pellets for ir studies. The sample pellet was mounted on a copper block in our low temperature Raman cell (7). The spectra were excited by the 514.5 nm line of an Ar^+ laser operating at a power of 200 mW. Even at this relatively low power it was noticed that some sublimation and recrystallization of the sample occurred during several hours of illumination. This resulted in a considerable improvement in signal to noise ratio in the spectrum.

Raman spectra were recorded using a Jarrell-Ash 25-100 monochromator, a cooled RCA C31034-02 photomultiplier, and photon counting electronics. The spectra were calibrated using emission lines from a neon lamp (8). Spectra were recorded at liquid nitrogen temperature and at various temperatures between room temperature and 100°C. The latter temperatures were obtained by means of a controlled 'Firerod' heater (Watlow Electric Co.), immersed in ethylene glycol in the refrigerant container of the low temperature cell. Temperatures were monitored with a Fe/constantan thermocouple and are believed to be accurate to within ±2°C.

For the nqr spectra, the pentachlorophenol was used without further purification. Samples were sealed in glass tubes under vacuum and placed in a gas-flow cryostat, which maintained

the temperature constant to ±0.2°C. The temperature was measured with a Cu/constantan thermocouple taped to the outside of the sample tube. The nuclear quadrupole resonances were recorded using a conventional super-regenerative spectrometer.

Results

A Raman survey spectrum of PCP is shown in Fig. 1 and the observed wave numbers and relative intensities are listed in Table 1. Figure 2 shows the external mode region at liquid nitrogen and room temperatures and Table 2 lists the observed Raman wave numbers. Figure 3 shows the results of typical temperature cycling through the transition temperature.

TABLE 3. Observed nuclear quadrupole resonance frequencies

Resonance (following Sakurai (4))	Frequency (25°C) (kHz)	$(\partial\nu/\partial T)_P$ (kHz K^{-1})
ν_3	38 029	−3.36
ν_4	37 762	−2.76
ν_2	37 716	−2.46
ν_1	36 985	−2.38
ν_5	36 668	−2.62

Five nqr frequencies were observed at 25°C. These are listed in Table 3, together with their temperature coefficients. The resonance frequencies are linear functions of temperature above room temperature up to 64.2°C. No resonance was detected at temperatures above 64.2°C in the frequency range 36.02–39.20 MHz. The intensities of the resonances appeared to be independent of temperature below 64.2°C.

Discussion

Crystal Structure and External Modes

The crystal structure of PCP at room temperature is reported to be monoclinic with eight molecules per unit cell (4). The space group is $C2/c$ (C_{2h}^6) and the eight molecules are located on general sites (Wykoff position *f*). Using the method of Adams (9, 10), we find that the 24 external vibrations of the unit cell comprise

$$6A_g + 6B_g + 6A_u + 6B_u \text{ modes}$$

of which $1A_u + 2B_u$ are acoustic modes. Thus, the low frequency Raman spectrum should contain 12 lines and the far ir spectrum 9 absorption bands due to external modes. The observed ir and Raman wave numbers may not be coincident due to the centrosymmetric unit cell.

The low temperature Raman spectrum of the lattice mode region (Fig. 2) shows 10 clearly resolved lines and a very weak band is observed at 103 cm^{-1} (Fig. 1). Thus, we appear to have observed 11 of the 12 predicted Raman active external modes.

Although there is a marked improvement in the Raman spectrum on cooling to 77 K from room temperature, there is no indication of any new crystalline phase at low temperatures. The sharpening of lines, with resulting improvement in resolution, together with some frequency shifts as the temperature is lowered are observations normally expected in the external mode spectrum of a crystal.

Temperature Cycling Studies

As the sample is warmed from room temperature to about 59°C, there is no noticeable change in the Raman spectrum (Fig. 3*a*). However, if the temperature is maintained at 60°C for several minutes, the external modes decrease in intensity and broaden, until no structure remains, apart from a broad feature centred near 40 cm^{-1}. The Rayleigh line also broadens considerably. No significant changes were observed in the internal mode spectrum during the transition.

On cooling the sample from 80°C to below 60°C, the lattice modes reappear in the spectrum. However, there is a considerable relaxation time involved. Under our experimental conditions, it was not possible to obtain reproducible times for the reappearance of the spectrum but this aspect of the phase transition has been studied previously by microcalorimetry (3). A typical supercooling effect is shown in Fig. 3*b* (upper trace) where it is seen that the high temperature spectrum is still present at 45°C. After cooling to room temperature over a period of 20–30 min, the spectrum of the low temperature phase is obtained.

The nqr spectrum shows a similar result. The resonance frequencies (Table 3) decrease as the temperature is increased from room temperature up to a temperature of 64.2°C. At this point, the signal disappears and no resonance at all is detected above this temperature. On recooling to below 64.2°C, the signals reappear, but again, a supercooling effect is observed.

Conclusions

The disappearance of both the external modes and the ^{35}Cl nuclear quadrupole resonances above the transition temperature suggests rapid reorientation of the molecules in the high temperature phase. It has been suggested previously (2, 3) that the low temperature phase can be considered to be an intermolecular (OH...O) hydrogen bonded solid polymer, whereas the high temperature form consists of

monomeric PCP units, with intramolecular (OH...Cl) hydrogen bonds. This change from hydrogen bonded polymer to monomeric molecules can be seen in the infrared spectrum (2). The ir spectrum of the high temperature phase is very similar to that of a dilute solution of PCP in carbon tetrachloride. The interpretation of the infrared studies is consistent with the present spectroscopic observations, since an intramolecular hydrogen bonded structure would be able to reorient rapidly in the plane of the benzene ring.

There is no reason to suppose that a disordered structure is obtained on rapid cooling through the transition temperature. The structure of the high temperature phase is temporarily retained below the equilibrium temperature. This is ordinary supercooling, which is common and characteristic of first order phase changes.

Hydrothermal reaction kinetics. The decomposition of nickel(II) hydroxide

THOMAS W. SWADDLE[1] AND TONY C. T. WONG

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 2, 1977

THOMAS W. SWADDLE and Tony C. T. WONG. Can. J. Chem. **56**, 363 (1978).

The fractional extent α of decomposition of ripened $Ni(OH)_2$ into green NiO in alkaline hydrothermal conditions under nitrogen is given by the rate law $\alpha^{1/3} = k_c[OH^-]t$, where $k_c = 2.4 \times 10^{-5}$ kg mol^{-1} s^{-1} at 561 K. The Arrhenius activation energy is 220 $\pm$ 25 kJ mol^{-1}. The reaction is accelerated moderately by O_2 (giving black $NiO_{1+\delta}$) and strongly by added NiO. A reaction mechanism involving dissolution of $Ni(OH)_2$ as $Ni(OH)_3^-$(aq) and rate-determining, surface-controlled reprecipitation of this as NiO is proposed.

THOMAS W. SWADDLE et TONY C. T. WONG. Can. J. Chem. **56**, 363 (1978).

A 561 K, on peut exprimer la fraction, α, de la décomposition de $Ni(OH)_2$ vieilli en NiO *vert dans des conditions hydrothermiques alcalines sous atmosphère d'azote par la loi de* vitesse $\alpha^{1/3} = k_c[OH^-]t$ ou $k_c = 2.4 \times 10^{-5}$ kg mol^{-1} s^{-1}. L'énergie d'activation d'Arrhénius est de 220 $\pm$ 25 kJ mol^{-1}. Il y a une légère accélération de la réaction par la présence de O_2 (conduisant à du $NiO_{1+\delta}$ noir) et une forte accélération par l'addition de NiO. On propose un mécanisme de réaction impliquant la dissolution de $Ni(OH)_2$ sous forme de $Ni(OH)_3^-$(aq) et une reprécipitation sous forme NiO, contrôlée par la surface, déterminant la vitesse.

[Traduit par le journal]

Introduction

The study of the kinetics and thermodynamics of the conversion of nickel(II) hydroxide into nickel(II) oxide under hydrothermal conditions is of tech-

$$[1] \qquad Ni(OH)_2(c) \rightarrow NiO(c) + H_2O(l)$$

nological interest in connection with the corrosion of nickel alloy components (such as heat exchangers in water-cooled nuclear power plants) by neutral or alkaline water at elevated temperatures (1–3). It may also be expected to provide an experimentally convenient model for the mechanisms of hydrothermal reactions of transition metal hydroxides and oxides in general.

There is, however, no general agreement regarding the thermodynamics of reaction 1. Data published by the U.S. National Bureau of Standards (NBS) (4), and calculations based on these (5), indicate that reaction 1 should proceed spontaneously at or near the saturated vapor pressure throughout the entire liquid range of water, whereas experimentally it has, with one exception (6), been found not to occur below about 545 K (7–15), although decomposition of $Ni(OH)_2$ can be observed at 470 K or less in the 'dry' state (14, 16–23).

This apparent discrepancy arises partly because nickel(II) hydroxide can exist in more than one form. When freshly precipitated at or near room temperature, it takes the form of poorly crystalline particles (21) of size on the order of 3–8 nm (24, 25) and composition best represented by $Ni(OH)_2 \cdot xH_2O$ where $x = 0.5$–0.7 (12) which grow on standing in water ('aging' or 'Ostwald ripening') into hexagonal plates with the brucite structure following loss of intercalary water, ultimately reaching some 40 nm in diameter and 7 nm in thickness (25–27). The poorly crystalline (turbostratic) initial material, often designated α-$Ni(OH)_2$, is characterized by a reflection in the powder X-ray diffraction pattern corresponding to a spacing of 0.81–0.85 nm (11, 14, 25, 28), and an idealized crystal structure based on an expanded brucite-type lattice corresponding to the formula $3Ni(OH)_2 \cdot 2H_2O$ has been proposed (11), but detailed consideration of this poorly reproducible material has provoked controversy (13, 20, 29). The fully 'aged' or β-$Ni(OH)_2$ form, however, is relatively well-crystallized and reproducible; a similar material of composition $Ni(OH)_2 \cdot xH_2O$ (where $x = 0.17 \pm 0.10$, decreasing to 0.07 on warming) can be obtained by precipitating $Ni(OH)_2$ in *boiling* water (16), while hydrothermal ripening (7, 10–14, 30) gives essentially stoichiometric β-$Ni(OH)_2$ in platelets with crystallite dimensions around 30 nm thick and 50 nm across (30). Hydrothermal ripening is generally favored by high temperatures (up to 543 K in plain water) (11) and high hydroxide ion concentrations (up to 40% KOH at 513 K) (12), although other standard hydrothermal 'mineralizers' such as KCl or NH_4I seem to be ineffective (10).

It is clearly β-$Ni(OH)_2$ which is relevant to the present hydrothermal study. The solubility product of 6.5×10^{-18} reported by Gayer and Garrett (31) evidently refers to the β form, since these authors prepared $Ni(OH)_2$ by precipitation from hot solutions.

Combining this result with thermodynamic data for NiO and H_2O (4), we obtain $\Delta G_f^0 = -458.1$ kJ mol^{-1} for β-Ni(OH)$_2$(c), which is 10.9 kJ mol^{-1} more negative than the NBS value (4) (which evidently refers to the ill-defined α-Ni(OH)$_2$(c)) but which agrees well with the value adopted by Naumov *et al.* (32). This leads to $\Delta G^0 = +9.25$ kJ mol^{-1} for reaction 1 at 298 K, i.e., NiO(c) is actually *unstable* with respect to β-Ni(OH)$_2$(c) in liquid water at 298 K, as pointed out by Baes and Mesmer (33), although it is stable relative to α-Ni(OH)$_2$(c). Knowledge of the temperature dependence of ΔG_f^0 of β-Ni(OH)$_2$(c) is needed to determine the minimum temperature at which reaction 1 becomes thermodynamically favored in water at its saturated vapor pressure; such data seem to be lacking, although Mukaibo *et al.* (3) have estimated this temperature to be about 440 K, whereas others (7, 9, 10) have published purported phase relationships which suggest transition temperatures of about 560 K.

A major factor contributing to the confusion over the occurrence of reaction 1 is its slowness, even at temperatures on the order of 500 K. A primary objective of this study was to demonstrate that failure to observe reaction 1 at elevated temperatures (7–15) may result from a combination of the form of the rate law and a high activation energy, rather than from unfavorable thermodynamic factors.

Experimental Section

Nickel(II) hydroxide was prepared using only polyethylene or polytetrafluoroethylene laboratory ware. Contact between the solutions and glassware led to the appearance of one well-defined and one diffuse extraneous reflection, corresponding to spacings at 0.725 and 0.95 nm respectively, in the powder X-ray diffraction pattern of the final product, indicating the hydrothermal formation of nickel antigorite ($Ni_3Si_2O_5(OH)_4$) and a trace of nickel montmorillonite ($Ni_3Si_4O_{10}(OH)_2$) (34). Typically, 1 mol nickel(II) nitrate or chloride in 400 cm^3 water was added dropwise with stirring to 4 mol NaOH in 600 cm^3 water at room temperature. The mixture was stirred overnight and filtered under suction, and the solid was washed with 1000 cm^3 NaOH (1.0 *m*; *m* = mol kg^{-1}) followed by several dm^3 water until the filtrate was neutral. Then, the wet solid was either dried under reduced pressure at 110°C for 1–3 h and the resulting cake ground to a fine powder for future use, or else dispersed in 1.0 *m* NaOH (about 0.1 mol Ni(OH)$_2$ to 25 cm^3), sealed under nitrogen in PTFE-lined autoclaves of 35 cm^3 capacity (35), and heated at 200°C for 24 h. The resulting 'ripened' solid β-Ni(OH)$_2$ was filtered, washed with water until the filtrate was neutral, and dried under reduced pressure at 110°C.

The ripened solid was seen under the transmission electron microscope to consist of hexagonal lamellae, 70–160 nm in diameter. Powder X-ray diffraction patterns detected no crystalline compounds other than β-Ni(OH)$_2$, and indicated the lamellae to be about 20–40 nm thick according to the Scherrer formula (36) (which, however, was at the limit of its applicability). The BET(N_2) surface area of the ripened material was determined using a Micromeritics Model 2200 High-Speed Surface Area Analyzer to be ~16 m^2 g^{-1}, as compared with over 200 m^2 g^{-1} for the dry, unripened Ni(OH)$_2$.

Kinetics of the Hydrothermal Reaction

Weighed amounts of β-Ni(OH)$_2$ were placed in capped 35 cm^3 PTFE liners with (usually) 20 cm^3 NaOH solution, and sealed into titanium/0.2% palladium alloy autoclaves (35) leaving ~25 cm^3 gas space. These operations were carried out in a nitrogen-filled glovebox, when oxygen was to be excluded; measurements using a Rexnord oxygen meter showed the O_2 content of solutions handled in this way to be less than 0.1 μg/g (cf. 8 μg/g for water in equilibrium with air at 294 K and 90 kPa). The sealed vessels were thermostatted (±0.2 K) in a preheated forced-convection oven as described previously (37), and quenched in cold water after chosen intervals t_f. The solid reaction products were filtered, washed with water, and dried under reduced pressure at 110°C for 1 h. Thermogravimetric analysis of 5–10 mg portions over the range 300–800 K with a Perkin-Elmer TGS-1 thermobalance gave the relative amounts of Ni(OH)$_2$ and NiO. These analyses were confirmed semi-quantitatively by powder X-ray diffraction measurements, which also showed that NiO and β-Ni(OH)$_2$ were the only detectable solid phases present.

Kinetics of Decomposition of Ni(OH)$_2$ in Dry Environments

Isothermal thermogravimetric analyses were carried out with the Ni(OH)$_2$ in a shallow layer in an open dish in atmospheres of helium or, as desired, oxygen. Sample temperature measurements were calibrated against the magnetic transition temperatures of alumel, nickel, perkalloy, and iron.

Results

Despite the availability of much data in the literature (14, 16–23), the isothermal decomposition kinetics of dry Ni(OH)$_2$ in helium were investigated again in the present study for purposes of direct comparison with the hydrothermal measurements on similarly prepared material, since the mode of preparation of Ni(OH)$_2$ is known to affect the decomposition rate (10, 14, 18, 19). The rate in helium decreased progressively, and could be represented by the equation

$$[2] \qquad 1 - (1 - \alpha)^{1/n} = k_n t/nN_0^{1/n}$$

where α is the mole fraction of NiO formed by time t, N_0 is the molar amount of Ni(OH)$_2$ originally present, k_n is a rate coefficient, and the index n is 2 for a 'contracting area' and 3 for a 'contracting volume' process (18). Hazell and Irving (19) interpreted their rate data for the decomposition of dry Ni(OH)$_2$ on the basis of the contracting area formula, arguing that the brucite-type layer structure would favor inward progress of decomposition along the planes of the lamellae from the edges. Marcellini and Teichner (18), however, found empirically that n was close to 3 for samples in an open dish, and this is supported by the correlation coefficients r listed in Table 1. The distinction is, however, a fine one, especially since the effective zero of the reaction time scale had to be treated as a parameter to be calculated (in practice, the calculated zero time followed

[a]Hydrothermally ripened (specific surface ~16 $m^2\ g^{-1}$) except as indicated; initial quantity N_0 = 0.08–0.10 mmol.
[b]Pressure 90 kPa.
[c]Standard error ±2%.
[d]Unripened $Ni(OH)_2$ (specific surface ≥ 200 $m^2\ g^{-1}$).

the beginning of the formal reaction time scale t_f by as little as 35–70 s). The reaction was not followed beyond $\alpha \sim 0.8$ because of the retention of some water by the NiO product (18, 19, 22); indeed Erkelens and Egginck-DuBurck (22) took $\alpha = 0.8$ to represent complete reaction, which gave $n \sim 1$.

The rate coefficients k_3 listed in Table 1 are obviously influenced not only by the particle size but also by the nature and flow rate of the gas, as suggested by the results of Marcellini and Teichner (18), and furthermore the omission of the factor $N_0^{1/n}$ by other authors makes direct comparison of our k_n values with their data difficult. Our isothermal measurements give an Arrhenius activation energy E_a of 132 ± 8 kJ mol^{-1} in helium (flowing or still) for the decomposition of dry, hydrothermally ripened $Ni(OH)_2$, and this value was confirmed by thermal volatilization measurements *in vacuo*; unripened $Ni(OH)_2$ gave E_a = 114 kJ mol^{-1} in isothermal thermogravimetry. These values are similar to, or slightly higher than, those reported by other authors (14, 18, 19, 22).

For the hydrothermal decomposition reaction, Table 2 shows that the fractional extent of decomposition of β-$Ni(OH)_2$ per given time is independent of the quantities both of the aqueous phase and of $Ni(OH)_2$, so that the mole fraction α of NiO product is again a useful quantity for expressing reaction rate. It is seen that α is reproducible to ±0.02.

Table 3 presents values of α, determined in four independent series of hydrothermal experiments, which are to be correlated with the effective reaction time t, where t is the time t_f spent by the vessels in the furnace less the warm-up time (shown previously (37) to be about 0.8 h for reaction temperatures near 570 K). In contrast with the dry decomposition reaction, the hydrothermal reaction is seen to be very slow initially but to accelerate progressively, and one is faced with the problem of choosing an appropriate mathematical function to represent the data. Such a

$k_E = (2.9 \pm 0.3) \times 10^{-5}$ s^{-1}, and correlation coefficient $r = 0.9894$, using all 16 data points.

Equations such as [3] were originally developed for solid state reactions on the basis of assumed rate control by propagation of reaction product growth from nuclei within crystals of the starting material, and, even though more detailed theoretical considerations (40) indicate that the empirical usefulness of eq. 3 beyond the stage where α is small is somewhat fortuitous, the choice of eq. 3 implies the assignment of a solid-state, internal nucleation mechanism to reaction 1. There are, however, several reasons for rejecting this assignment in favor of a dissolution mechanism.

Firstly, the rate law for the decomposition of $Ni(OH)_2$ in the dry state (eq. 2) bears no resemblance to eq. 3, and suggests surface rather than internal nucleation. It could, however, be argued that the surface nucleation process involves reversible dehydration and that this is suppressed in liquid water; indeed, the hydrothermal reaction is much slower than dry decomposition, the rate of which is sensitive to the gaseous environment.

Secondly, the rate of hydrothermal decomposition of $Ni(OH)_2$ is essentially proportional to $[OH^-]$ at high pH (see below). This suggests a dissolution mechanism, but could still be accommodated by an intracrystalline nucleation mechanism of the type proposed by Ball and Taylor (41) for the decomposition of dry brucite ($Mg(OH)_2$, isomorphous with β-$Ni(OH)_2$), which depends on chain transfers of protons from internal nuclei to surfaces and which could be facilitated by surface adsorption of OH^-.

Thirdly, transmission electron microscopy showed that, even after only 4% reaction in 0.474 m NaOH under N_2 at 573 K, the newly formed cubes of NiO were typically of 1 μm edge, whereas the diameters of the hexagonal $Ni(OH)_2$ crystals had increased only slightly and were on the order of 100–200 nm (BET measurements confirmed that the $Ni(OH)_2$ had undergone some further hydrothermal ripening at this high temperature, reducing the surface area by a factor of about 3, but it was established that neither NiO nor $Ni(OH)_2$ could have reached dimensions on the order of 1 μm by hydrothermal ripening under these conditions). Towards the end of the reaction, the well-crystallized NiO cubes had reached sizes of 3–6 μm side, i.e., their masses had increased in proportion to the extent of reaction α. These observations rule out all topotactic mechanisms, and indicate growth of NiO by crystallization from solution on to a fixed number of nuclei in the sample.

[4a] $Ni(OH)_2(c) + xOH^-(aq) \rightleftharpoons Ni(OH)_{2+x}{}^{x-}(aq)$

[4b] $Ni(OH)_{2+x}{}^{x-}(aq) \rightarrow NiO(c) + xOH^-(aq) + H_2O$

The importance and relatively rapid establishment of the equilibrium 4a at 540–575 K is demonstrated by the effectiveness of alkali in promoting hydrothermal growth of β-$Ni(OH)_2$ even at 470 K, although the absence of massive dissolution of $Ni(OH)_2$ indicates that the equilibrium 4a still lies far to the left. Thus, step 4b must be rate controlling, involving deposition of fresh NiO on pre-existing NiO crystals or nuclei, and the rate of the overall reaction 4 will be proportional to the xth power of the hydroxide ion activity a_{OH} and to the available surface area of NiO.

If this mechanism is correct, added NiO should accelerate the reaction greatly; this was found to be true (see below), and so we can write, for a single NiO crystal and hydroxide activity a_{OH},

$$[5] \qquad dm/dt = k(\text{area of NiO})a_{OH}{}^x = ka_{OH}{}^x\sigma m^{2/3}V^{2/3}$$

where k is the rate coefficient, m is the mass (in mol) of NiO in the given NiO crystal, V is the molar volume of NiO, and σ is a shape factor (6, for a perfect cube). The total mass M of NiO in a $Ni(OH)_2$ sample containing N growth centers (i.e., NiO crystals) is Nm, and, if p is the number of such centers per mol of original $Ni(OH)_2$, then

$$[6] \qquad N = pM_0$$

where M_0 is *either* the molar amount of $Ni(OH)_2$ originally present in the decomposing sample *or* the molar amount of NiO seeds deliberately added at the start of the reaction (in the latter case, all NiO growth would occur on the seeds, to the exclusion of latent nuclei in the $Ni(OH)_2$). Then,

$$[7] \qquad m = M/pM_0$$

$$[8] \qquad \frac{1}{pM_0}\left(\frac{dM}{dt}\right) = ka_{OH}{}^x\sigma(V/pM_0)^{2/3}M^{2/3}$$

Integration then gives

$$[9] \qquad (M_2{}^{1/3} - M_1{}^{1/3})/M_0{}^{1/3} = (\tfrac{1}{3}k\sigma p^{1/3}V^{2/3})a_{OH}{}^x t$$

$$[10] \qquad = k'a_{OH}{}^x t$$

$$[11] \qquad = k_{obsd}t \quad \text{at a given } [OH^-]$$

where M_2 = NiO in mol present at time t, and M_1 = NiO present at $t = 0$. When $M_1 = 0$, M_2 ranges from 0 at $t = 0$ to M_0 at the end of the reaction, so

$$[12] \qquad (M_2/M_0)^{1/3} = \alpha^{1/3} = k_{obsd}t$$

The validity of eq. 12 was tested by carrying out a linear regression analysis of ln t on ln α, using the data of Table 3 (which are unedited experimental

results); the correlation coefficient r was 0.9915 for all 16 data points, giving a slope (index of α) of 0.32 ± 0.01 and $k_{obsd} = (2.49 \pm 0.05) \times 10^{-5}$ s^{-1}. Similarly, the constancy of the calculated values of k_{obsd} in Table 3 (mean $k_{obsd} = (2.45 \pm 0.12) \times 10^{-5}$ s^{-1}) is remarkably good (fortuitously so, for $\alpha <$ 0.10), and vindicates the use of eq. 12. Table 3 refers only to hydrothermally ripened $Ni(OH)_2$ as the starting material; experiments using unripened $Ni(OH)_2$ gave somewhat faster but poorly reproducible rates.

Activity coefficients for aqueous hydroxide ion are not available for the conditions of this study, but, by analogy with values for 298 K, it may be assumed that they remain tolerably constant from 0.1 to 1.0 mol kg^{-1} NaOH. Thus, the data of Table 4 show that x in eqs. 4, 5, and 8–10 may be taken to be unity, and we can write

$$[13] \qquad \alpha^{1/3} = k_c[OH]t$$

This confirms that the main nickel(II) species present in strongly alkaline water is indeed $Ni(OH)_3^-(aq)$ (or, more generally, $[HNiO_2 \cdot yH_2O]^-$), as has been assumed by Gayer and Garrett (31). Attempts to follow reaction 1 at pH values near neutral led to poorly reproducible, very slow reaction rates.

The activation energy E_a from Table 4 is 220 ± 25 kJ mol^{-1}, i.e., roughly twice that of the dry decomposition reaction. Table 4 also shows that the presence of O_2 causes a marked acceleration of the hydrothermal decomposition, the product being black $NiO_{1+\delta}$ rather than the leaf green, stoichiometric (42–44) NiO that was obtained in the reactions under nitrogen. Green NiO prepared hydrothermally was not visibly affected by subsequent exposure to air, whereas green NiO prepared by decomposition of dry $Ni(OH)_2$ *in vacuo* turned black immediately on contact with air; this difference may be attributed to the much larger specific surface of the small, porous (30) NiO particles formed by the vacuum decomposition relative to the small ($\leq$0.2 m^2 g^{-1}, BET) specific surface of the hydrothermal NiO.

In principle, eq. 11 permits the calculation of the time-dependence of reaction 1 catalyzed by added NiO (hydrothermally prepared, to ensure the appropriate value of σ). In practice, the separate hydrothermal preparations of NiO tend to yield agglomerates of crystals which must be completely broken up and dispersed in the fresh reaction medium without crushing the individual crystals, and this is difficult to achieve. Nevertheless, the experimental fractional extents of reaction ($M_2 - M_1$) listed in Table 5 approach the calculated values sufficiently closely to indicate that eqs. 9–11 and the underlying theory describe the hydrothermal decomposition of $Ni(OH)_2$ accurately.

The large catalytic effect of NiO illustrated by Table 5 was considerably reduced when undispersed NiO agglomerates were used, as expected for a surface-controlled reaction.

Discussion

In practical terms, k_{obsd} represents the reciprocal of the time required for reaction 1 to reach 100% completion. More significantly, eq. 13 and the k_c values of Table 4 permit extrapolations to be made

to calculate the times needed for an experimentally significant extent of reaction to occur in the absence of pre-existing NiO; thus, the first 1% reaction requires about 80 days at 523 K, or over 2 years at 473 K, in 1.0 *m* NaOH, and proportionately longer times at lower $[OH^-]$.

This initial slowness of reaction 1 raises doubts concerning the thermodynamic validity of the experimental pressure–temperature phase relations reported for the $Ni(OH)_2$–NiO–H_2O system (7, 9, 10). The calculations of Mukaibo *et al.* (3), on the other hand, seem realistic; a thermodynamic threshold of about 440 K is predicted for reaction 1 at the saturated vapor pressure of water, which accommodates the considerable thermodynamic stability of β-$Ni(OH)_2$ at 298 K noted in the Introduction and also its apparent catalytic conversion to NiO in some ferrite syntheses at 473 K (6). This explains why all attempts to demonstrate the hydration of NiO to $Ni(OH)_2$ have failed (1, 7, 9, 10); the reaction is probably thermodynamically possible only below about 440 K, and even at this temperature 1% conversion would require over 200 years in 1.0 *m* NaOH (since $k_c \sim 3 \times 10^{-11}$ kg mol^{-1} s^{-1}, and the forward and back reactions would have the same rates).

The slightly faster and rather poorly reproducible rates observed for reaction 1 when unripened $Ni(OH)_2$ was used in place of the hydrothermally prepared hydroxide are unlikely to originate in the relatively rapid pre-equilibrium

$$[14] \quad Ni(OH)_2(c) + OH^-(aq) \rightleftharpoons Ni(OH)_3^-(aq)$$

but may reflect a greater (and variable) number of growth centers p per mol of unripened $Ni(OH)_2$, which would facilitate the rate determining step

$$[15] \quad Ni(OH)_3^-(aq) \rightarrow NiO(c) + OH^-(aq) + H_2O(l)$$

Similarly, the accelerating effect of O_2 may originate in the creation of Ni^{3+} defects in NiO, so assisting the formation of growth spirals; certainly, $NiO_{1+\delta}$ is the product when O_2 is present. Alternatively, the normal mechanism of reactions 14 and 15 may be supplemented by a sequence of the type

$$[16] \quad \beta\text{-}Ni(OH)_2 \overset{O_2}{\rightleftharpoons} \beta\text{-}NiO_{2\delta}(OH)_{2-2\delta} \quad (0 < 2\delta < 1)$$

$$[17] \quad \beta\text{-}NiO_{2\delta}(OH)_{2-2\delta} \rightarrow \gamma\text{-}NiO_{2\delta}(OH)_{2-2\delta}$$

$$[18] \quad \gamma\text{-}NiO_{2\delta}(OH)_{2-2\delta} \rightarrow NiO_{1+\delta} + (1-\delta)H_2O$$

Under hydrothermal conditions, reaction 17 evidently proceeds at about 513 K, and reaction 18 near 563 K (10, 12, 45). Reaction 16 may be expected to occur to a small extent on the surface of a β-$Ni(OH)_2$ crystal, as the electrochemical analogue of this reaction proceeds smoothly with 2δ ranging from 0 to 1 without changing the main structural features of the crystal (reaction 18 similarly involves minimal structural changes) (12, 46).

To conclude, the alkaline hydrothermal decomposition of $Ni(OH)_2$ in the absence of oxygen consists of a rate-determining, autocatalytic precipitation reaction following relatively rapid dissolution of the metastable β-$Ni(OH)_2$ as $Ni(OH)_3^-$(aq). This is in accordance with the general observation (47) that dissolution and ripening reactions (reaction 14) occur by relatively rapid diffusion-controlled processes, whereas precipitation of new phases (reaction 15) occurs by slower, interfacial processes. For this reason, the dissolved nickel(II) species of eqs. 4, 14, and 15 is more appropriately written as $Ni(OH)_3^-$ than as $NiO(OH)^-$, etc., implying readier reprecipitation as $Ni(OH)_2$ than as NiO. The practical significance of this reaction mechanism and the large E_a ($\sim$220 kJ mol^{-1}) associated with it is that $Ni(OH)_2$ can exist metastably in water at temperatures on the order of 570 K for remarkably long periods, especially if the pH is not high and there is little O_2 or solid NiO in the system. It follows that β-$Ni(OH)_2$ will often be an important product of the hydrothermal corrosion of nickel alloys, and that its thermodynamic properties should be used in place of those of NiO in calculations relating to the courses of chemical reactions in high-temperature aqueous systems. The same is probably true of cobalt(II) hydroxide, the pink β-form of which is isostructural with β-$Ni(OH)_2$ and forms hydrothermally from the blue α-$Co(OH)_2$ (6).

Finally, this study serves to emphasize the importance of reaction mechanism, as well as thermodynamics, in determining the outcome of hydrothermal reactions.

Expansion coefficients and thermal pressure coefficients γ have been measured at 25°C for members of the following series of compounds: (*1*) SnR_4 (R = CH_3, C_2H_5, C_3H_7, C_4H_9, $C_{12}H_{25}$). (*2*) $Si(OR)_4$ (R = being the same except for C_6H_{13} and C_8H_{17} instead of $C_{12}H_{25}$). (*3*) NR_3, R from C_2H_5 to $C_{12}H_{25}$ except C_9H_{19} and $C_{11}H_{23}$; two NR_3' where R′ is a branched (br) alkyl radical isopentyl and isooctyl and $N(CH_3)_2(C_{12}H_{25})$. (*4*) *n*-C_7H_{16}, 3-3-diethylpentane (3,3-DEP), dimethylsulfoxide (DMSO), 2,2,4,4,6,8,8-heptamethylnonane (br-C_{16}). The variation of γ between 25 and 80°C is obtained for the following compounds: br-C_{16}, $N(isopent)_3$ and $N(Dec)_3$. The comparison of the cohesive energies for the different members of a series or from one series to another is made with P^* rather than with γ. $P^* = \gamma\tilde{v}^2T$. For the three series the limiting values, when *n* increases, of the pressure reduction parameter P^* and of the expansion coefficients are very similar. The P^* do not have regular values for the NR_3, SnR_4, and $Si(OR)_4$ series for low values of the molecular weights. One explanation of these irregularities is the different shape of the molecules. The surface to volume ratios of the different molecules are calculated with a spherical model or a cylindrical model. Values of cohesive energies per unit surface P^*/s are compared. P^*/s for the linear and branched alkanes are on the same curve while the P^* were not. However, no similar smoothing is accomplished for the lower members of the other series. The high values of P^*/s for the sterically hindered $SnEt_4$, $SnPr_4$, and 3,3-DEP seem to indicate that measurements of γ and P^* can be a method to evaluate steric hindrance in the different members of a series. Report is made of calorimetric results on the same sterically hindered compounds in solution. Higher P^*'s may also come from increased polarity in the lower members of a series.

ROBERT PHILIPPE, GENEVIÈVE DELMAS et MICHÈLE COUCHON. Can. J. Chem. **56**, 370 (1978).

Les coefficients d'expansion et les coefficients thermiques de pression γ ont été mesurés à 25°C pour les séries des composés suivants: (*1*) SnR_4 (R = CH_3, C_2H_5, C_3H_7, C_4H_9, $C_{12}H_{25}$). (*2*) $Si(OR)_4$ (R est le même sauf pour C_6H_{13} et C_8H_{17} au lieu de $C_{12}H_{25}$). (*3*) NR_3, R varie de C_2H_5 à $C_{12}H_{25}$ excepté C_9H_{19} et $C_{11}H_{23}$, deux NR_3' où R′ est un radical alkyle ramifié, isopentyl et isooctyl ainsi que $N(CH_3)_2(C_{12}H_{25})$. (*4*) *n*-C_7H_{16}, diethyl-3,3 pentane (3,3-DEP), diméthylsulfoxyde (DMSO), heptaméthyl-2,2,4,4,6,8,8 nonane (br-C_{16}). La variation de γ entre 25 et 80°C est obtenue pour les composés suivants br-C_{16}, $N(isopent)_3$ et $N(Dec)_3$. La comparaison des énergies de cohésion d'une série à l'autre ou pour les différents composés d'une même série se fait sur P^* plutôt que sur γ, $P^* = \gamma\tilde{v}^2T$. Pour les trois séries, les valeurs limites, quand *n* augmente, du paramètre de pression réduite P^* et des coefficients d'expansion sont très similaires. Les paramètres P^* pour les *n*-alcanes donnent une courbe régulière quand *n* augmente tandis que les valeurs obtenues pour les composés à bas poids moléculaire des séries NR_3, SnR_4 et $Si(OR)_4$ ne donnent rien de semblable. Ces irrégularités peuvent s'expliquer par la différence de forme de ces molécules. Les rapports surface–volume des différentes molécules sont calculés à partir d'un modèle sphérique ou d'un modèle cylindrique. On compare alors les énergies de cohésion par unité de surface P^*/s. P^*/s pour les alcanes linéaires et les alcanes ramifiés apparaissent sur une même courbe alors que les P^* sont dispersés. Cependant aucun lissage similaire n'est obtenu pour les premiers composés des autres séries. Les valeurs élevées des P^*/s pour les composés stériquement encombrés tels $SnEt_4$, $SnPr_4$ et 3,3-DEP semblent indiquer que les mesures de γ et P^* peuvent être une méthode d'évaluation de l'encombrement stérique pour les différents composés d'une série. On rapproche alors ces résultats de ceux de calorimétrie obtenus sur les mêmes composés stériquement encombrés, en solution. Un P^* plus élevé peut aussi provenir de l'augmentation de polarité des premiers composés d'une série.

Introduction

Modern theories of solutions of non-polar molecules (Prigogine (1), Patterson and Delmas (2), Flory *et al.* (3)) have shown the importance of two main contributions to the excess thermodynamic properties. The first one depends on the difference

in chemical nature of the two components. This chemical term gives a positive contribution to the heats of mixing and to the excess volume and a negative one to the excess entropy. The second contribution, which has been recognized more recently, depends on the difference of state of expansion (or free volume) of the two components mixed. It gives a negative contribution to H^E, TS^E, and V^E. Solution properties of mixtures (4–6) consisting of molecules of different shape, such as a globular molecule and a linear one, have shown that a third contribution depending on the shape of the molecule should be added. In the case of the heats, this third contribution can be a positive term related to the destruction of orientational order (4–6) and a negative one due to the 'condensation' or steric hindrance effect (7, 8).

The prediction of these different contributions depends on the knowledge of the expansion coefficient $\alpha = 1/V(\partial V/\partial T)_P$ and the thermal pressure coefficient $\gamma = (\partial P/\partial T)_V$.

The thermal pressure coefficient of a liquid is sensitive to the shape of its molecules. For instance, γ (5) is higher (0.888 J cm^{-3} K^{-1}) for the linear *n*-octane than for the branched isomer 2,2,4-trimethylpentane (0.798 J cm^{-3} K^{-1}). It has seemed interesting to us to measure the variation of γ for molecules in a series such as the SnR_4 and $Si(OR)_4$, where R is an alkyl radical. The characteristic of these series is that the shape of the molecule changes gradually from globular to linear when the chain length increases. Heat of mixing (9, 10) measurements on members of these series do not vary regularly with the chain length. This has been explained by the existence of different degrees of steric hindrance among members of the same series. For this reason, we would like to call these series the 'differently sterically hindered' series (dsh) to distinguish them from a normal series such as the *n*-alkanes.

On the other hand, the knowledge of the thermal pressure coefficient of the pure components is needed to calculate the pressure reduction parameter P^*. The comparison of V^E(calc.) and V^E(exp.) is possible only if the P^* are known, since an important contribution to V^E(calc.) comes from the difference in P^* of the components (2, 7). It should be noted that for the calculation of H^E the difference in expansion coefficients or of free volume is more important than that of P^*.

Moreover, it is hoped that the measurement of this macroscopic property on the pure compounds in the series would possibly give information on the 'condensation effect' (7–10) which has been seen in solutions: heats of mixing of the SnR_4 series with $Sn(Laur)_4$ (10) show an unexpected negative contribution with $SnEt_4$. Other heats[1] give similar results. The origin of this effect, which cannot be explained by free volume contributions, may be related to steric hindrance but it is not clearly understood.

Measurements of the thermal pressure coefficients have been made on some *n*-alkanes (12, 13) and branched (br) alkanes (14), cycloalkanes (15), aromatic and polar compounds (16), and polymers (17). Apparently, no measurements have been done on the SnR_4, $Si(OR)_4$, and NR_3 series. α and γ measurements at 25°C of the following 29 compounds are presented here: (*a*) SnR_4, R = CH_3, C_2H_5, C_3H_7, C_4H_9, $C_{12}H_{25}$. (*b*) $Si(OR)_4$ for the same alkyl radicals except that R = $C_{12}H_{25}$, which was not available, has been replaced by R = C_6H_{13} and R = C_8H_{17}. (*c*) NR_3, R from C_2H_5 to $C_{12}H_{25}$ except C_9H_{19} and $C_{11}H_{23}$, two NR_3' where R′ is a branched alkyl radical (isopentyl and isooctyl) and $N(CH_3)_2C_{12}H_{25}$. (*d*) *n*-C_7H_{16}, 3,3-diethylpentane (3,3-DEP), dimethylsulfoxide (DMSO), 2,2,4,4,6,8,8-heptamethylnonane (br-C_{16}). The variation of between 25 and 80°C is obtained for the following compounds: br-C_{16}, $N(isopent)_3$ and $N(Dec)_3$. In the text, the dodecyl derivatives will be called Lauryl, $N(Laur)_3$ for instance.

Experimental

Solvents

The sources of solvents are indicated in Table 1 and have been used without further purification. Their density and refractive index have been measured as a test of their purity and are given in the same table.

Thermal Expansion Coefficients

Values of thermal expansion coefficients have been measured with an Anton Paar digital precision density meter (distributed by the Fisher Co.). The temperature was read on the same quartz thermometer used for the thermal pressure coefficients and the densities were measured over a 10 deg interval (20–30°C).

Thermal Pressure Coefficients

The basic experimental procedure is that of Westwater *et al.* (18) and the method has been used by several other workers (13–17). The equipment used was built by Bardin (14) and consists of a constant volume pressure vessel, Pyrex glass cell, thermometer, pressure gauge, and a constant temperature bath. The schematic diagram of this is presented in Fig. 1.

The constant volume pressure vessel built by the American Instrument Co. was made of stainless steel with a 1.5 ℓ capacity and could withstand a pressure greater than 200 bars at 350°C.

Procedure

The liquid sample, about 8 cm^3, is placed in the Pyrex glass cell and degassed by repeated freezing with liquid nitrogen and

[1]R. Philippe, G. Delmas, and Phuong Nguyen Hong, unpublished results on the following systems: SnR_4 + *n*-C_{16}, NR_3 + $N(R')_3$, and NR_3 + alkanes.

melting under vacuum. The capillary is then filled with a known weight of degassed mercury and the mercury level adjusted at the extremity of the tungsten wire for the desired temperature. As the mercury rises up the capillary of the cell, it makes contact with the sharpened tungsten wire (ec) and shuts off an electric circuit.

The temperature of the bomb is measured by a Hewlett-Packard quartz thermometer (model 2801 A) with a temperature-sensing probe (S/N 980-2 type 2880 C model). The probe,

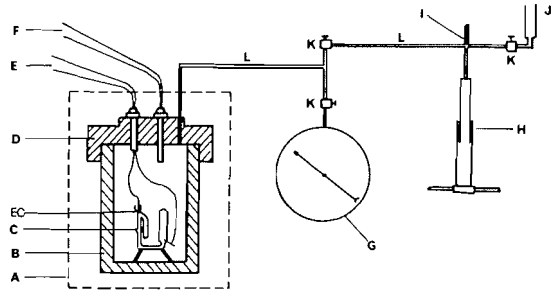

FIG. 1. Schematic diagram of the equipment used in the determination of thermal pressure coefficients: A thermoregulated water bath, B pressure vessel, C glass cell, D pressure vessel cap, E leads for the constant volume checking circuit, F temperature probe leads, G high pressure gauge, H pressure generator, I safety head assembly, J reservoir for the pressure fluid, K valves, L high pressure tubing, ec contact between the mercury and the tungsten wire.

screwed into the top of the bomb, gives the pressure-transmitting fluid (200 Dow Corning) temperature with a resolution of 10^{-4}°C and a precision of ± 0.02°C. The large mass of the bomb minimizes temperature fluctuations of the thermoregulated bath.

The pressure is applied with a manual pump (High Pressure Equipment Co., capacity 20 cm^3) and is measured with a precalibrated Bourdon-type gauge (Seegers Instrument Co. SS 2792 A 600). This gauge operates between 0 and 40 bars and gives a visual display of the pressure measured with a resolution of 0.02 bar.

Calculation

As pointed out previously (17), the application of small temperature increments increases the reproducibility of the results. The total temperature interval for one γ measurement is not larger than 2°C and the data can be fitted adequately by a straight line.

A least squares fitting procedure is employed on four to six (p, T) points to obtain the slope of the line, γ_{obs}, and the temperature at zero pressure. The γ_{obs} data are then corrected using eq. 1 (13):

$$[1] \qquad \gamma = \gamma_{obs} \frac{\alpha_l V_l}{\alpha_l V_l + (\alpha_{Hg} - \gamma_{obs}\beta_{Hg})V_{Hg} - (\alpha_g - \gamma_{obs}\beta_g)V_g}$$

where α is the thermal expansion coefficient, β the isothermal compressibility, and V the volume. The indices g, Hg, and l refer to the glass, mercury, and liquid samples respectively. Data needed in eq. 1 have been found in the literature or measured.

Comparison with Literature Data

Data are given in the text table below. As these data have been obtained on two different compounds (non-polar and polar) the agreement is quite satisfactory.

Theory

Equation of State Parameters

The simple Van der Waals relation between energy and volume, $\tilde{U} = -1/\tilde{v}$, gives equally good predictions as the more complex expressions (2). It has been used with the Flory model to obtain the volume, pressure, and temperature reduction parameters V^*, P^*, and T^*. The experimental densities,

expansion coefficients, thermal pressure coefficients given in Tables 1 and 2 are used with eq. 2 (3, 19). The reduced volume and the reduction parameters are respectively:

$$\tilde{v}^{1/3} = ((4/3)\alpha T + 1)/(\alpha T + 1)$$
$$V^* = V/\tilde{v} \text{ with } V = M/d$$
$$T^* = T/\tilde{T} = T\tilde{v}/(1 - \tilde{v}^{-1/3}) \quad [2]$$
$$P^* = \gamma\tilde{v}^2 T$$

The number of external degrees of freedom for the whole molecule is given by c in eq. 3

$$c = P^*V^*/RT^* \quad [3]$$

Results and Discussion

Table 2 gives the experimental values of γ for the different compounds. The first three columns show the temperature of the measurement, the γ value, and the standard deviation. Columns 4 to 6 indicate the expansion coefficient α, the γ value computed at 25°C exactly, and the reduced volume $\tilde{v}$. Columns 7 to 10 give pressure, volume, and temperature reduction parameters P^*, V^*, T^*, and c. The last two columns are calculated surface to volume ratios for the different molecules using the spherical and cylindrical models. The temperature variation of γ, $(d\gamma/dT)_{P=0} = (2\alpha T + 1)\gamma/T$ has been used to obtain $\gamma_{25°C}$. Although this relation does not predict well the temperature variation of γ, its use on a small temperature interval does not change the results significantly.

Comparison of P* *for Members of a Series and for the Different Series*

Comparison of the cohesive energy of the compounds will be made on P^* rather than on γ, since γ also reflects the state of expansion which varies considerably along the series. P^* is calculated from eq. 2 and the experimental values of α and γ. As can be seen from Fig. 2 the characteristic features of these results are the following: (*a*) The P^*'s tend towards a limiting value when the molecular weight increases.

The limiting values do not vary by more than about 5% and the order appears to be $Si(OR)_4 < SnR_4 < NR_3 < n\text{-}C_n$. The branched alkanes and the branched amines have distinctively lower P^*'s but the limiting value cannot be extrapolated. (*b*) The P^* values for the lower members of the DSH series do not vary smoothly with molecular weight as is the case for the normal or the three branched alkanes shown on Fig. 2. The high values found for NEt_3, $Si(OMe)_4$, and $Si(OEt)_4$ can be explained by the more polar character of these molecules compared to the longer members of the series. The higher values of P^* for $SnEt_4$, $SnPr_4$, and possibly $NBut_3$,

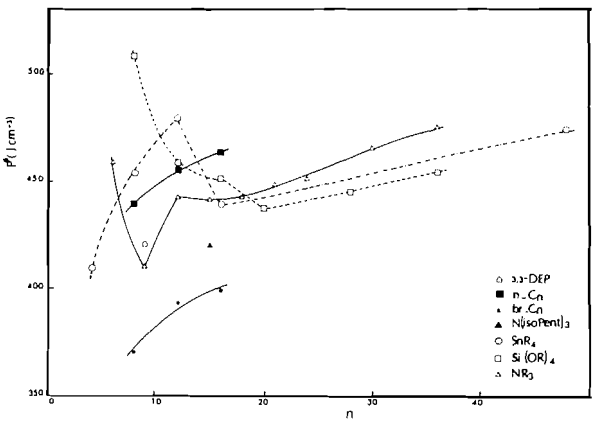

FIG. 2. Pressure reduction parameter P^* plotted against n the total number of carbon atoms for SnR_4 (○), $Si(OR)_4$ (□), n-C_n (■), br-C_n (●), $N(isopent)_3$ (▲), 3,3-DEP (△). The points for $N(isooct)_3$ and $(CH_3)_2N(laur)$ which are very close to $N(oct)_3$ and n-C_{14} have not been put on the graph. The abcissa n for the $Si(OR)_4$ has been calculated as if the oxygen atoms were carbon atoms. br-C_n stands for three highly branched alkanes 2,2,4-trimethylpentane (br-C_8), 2,2,4,6,6,-pentamethylheptane (br-C_{12}), and br-C_{16} used in previous work for comparison with n-alkanes.

$Si(OEt)_4$, and $Si(OPr)_4$ must be related to the steric hindrance of these molecules. A similar feature exists for 3,3-diethylpentane (3,3-DEP) whose P^* (420 J/mol) is higher than that of a hydrocarbon in C_9 of the same shape, 2,2-dimethylpentane (390 J/mol). $SnEt_4$ and 3,3-DEP with four ethyl groups attached to a tetravalent central atom have similar shapes.

The irregularities of P^* in the series are assumed not to be due to the inadequacy of the theory to obtain P^* from the experimental quantity γ. This assumption is reasonable for two reasons: the same theory gives a smooth P^* variation for the n-alkanes and the experimental γ values in the series do not vary smoothly.

External Degrees of Freedom

The number of external degrees of freedom c can be calculated from d, α, and γ and from eqs. 2 and 3. It would be interesting to see if the steric hindrance of $SnEt_4$ and $SnPr_4$ changes the number of external degrees of freedom in a series The column before the last in Table 2 gives c for the different series. A plot of c versus n, the total number of carbon atoms for the three series, not shown here, gives a single curve for the series with some scatter of the points for the low molecular weight compounds. In this plot, as in Fig. 2, the oxygen atoms of the $Si(OR)_4$ compounds have been counted as a carbon atom. The points corresponding to $SnEt_4$ and $SnPr_4$ have higher values of the external degrees of freedom due to their high P^*. The external degrees of freedom can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

expressed by segment for chain-like molecules. The Prigogine definition of a segment has been used to calculate c/r as shown in Fig. 3: the number of segments, r, of a linear molecule with n carbon atoms is $(n + 1)/2$. In the present case, the central atom has not been counted and the oxygen atom of the $Si(OR)_4$ compounds has been considered equivalent to a carbon atom. Figure 3 shows that the external degrees of freedom have comparable values in the four series for $n \geq 14$. The higher values for the shorter members of the series can be due to higher cohesive energies which increases c, having no relation with external degrees of freedom. On the other hand, one would expect that the globular shape of the shorter compounds would cause the c/r values to increase towards 1. It does not seem possible to separate the different contributions (shape and polarity) to this increase. In any case, the sterically hindered compounds show c/r higher on the plot: this means that steric hindrance changes P^* more than it does V^* and T^*. Available data on isomers of different steric hindrance indicate that the sterically hindered compounds have lower V and higher T^* since the molecule has a higher density and lower expansion coefficient and also a lower core volume V^*.

Surface to Volume Ratio s *for a Molecule and Values of* P*/s

As interactions of molecules take place between molecular surfaces, the comparison of energies by unit surface P^*/s is more meaningful than that of energies by unit volume P^*. s depends on the shape of the molecule and can be calculated from S and V the molecular surface and molecular volume. s can be obtained from a spherical or cylindrical model.

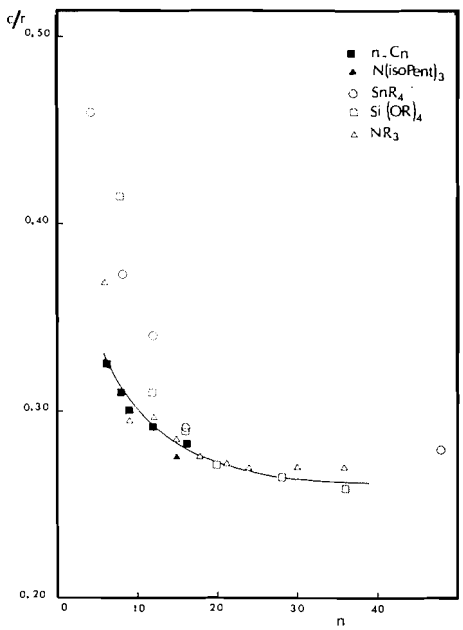

FIG. 3. External degrees of freedom by segment c/r plotted against the total number of carbons for SnR_4 (○), $Si(OR)_4$ (□), NR_3 (△), n-C_n (■), $N(isopent)_3$ (▲). $c = P^*V^*/RT^*$ and $r = (n + 1)/2$ even for the lower members of the series.

Sphere

A globular molecule can be approximated to a sphere which gives a value of $s = 4.083(V^*)^{-1/3}$ (V^* expressed in cm^3).

Cylinders

Linear alkanes can be represented by a right cylinder having a diameter of 4.98 Å (23*b*) and very branched alkanes by a 6.98 Å diameter cylinder (23*a*).

Group of Cylinders

The SnR_4, $Si(OR)_4$, NR_2 molecules are represented as an assembly of three or four cylinders attached to the central atom, the cylinder having the same diameter as a free alkane chain. The surface of the central atom which could be available for contact with other molecules has been neglected, its core volume obtained by extrapolating to zero carbon atom the V^* of the other members of the series. For the N, Si, Sn atoms, the core volumes are found to be 26, 40, 49 cm^3 respectively. The surface of the base of the cylinder attached to the central atom has been neglected in the counting of the surface available for contacts with other molecules. Accordingly s is given by

$$s = (n/V^*)(0.473D^2 - V^*_{ca}(4/nD))$$

n is the number of branches, D the cylinder diameter in Å, and V^* and V^*_{ca} the core volume of the molecule and of the central atom respectively in cm^3. The P^*/s values are plotted on Fig. 4 versus the carbon atom number. The P^*/s values of the linear and branched alkanes are now quite comparable. This is also true for $N(isopent)_3$ and $N(isooct)_3$. For $N(isopent)_3$, a 6 Å diameter cylinder has been used, a value between that of a linear and a branched alkane. The spherical model would give a small s and an unreasonable value of P^*/s. This must mean that even with a branched alkyl chain, there is a surface available for extramolecular contacts in between the three chains of the NR_3 molecule when R contains more than three carbon atoms.

SnR_4 Series

Contrary to the case of the branched and linear alkanes, the relative values per unit surface, P^*/s, with s(cylinder) are not significantly different from those of P^*. The values for $SnEt_4$ and $SnPr_4$ are still higher than expected from a regular curve and would

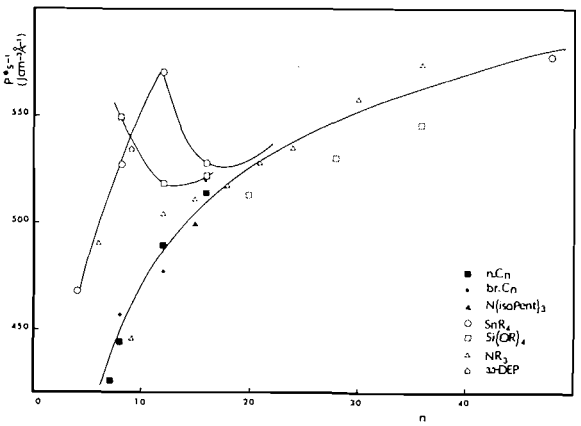

FIG. 4. P^*s^{-1} plotted against the total number of carbon atoms for SnR_4 (○), $Si(OR)_4$ (□), NR_3 (△), n-C_n (■), br-C_n (●), N(isopent)$_3$ (▲), 3,3-DEP (□). The surface to volume ratio s Å^{-1}, characteristic of the molecular shape, is obtained from molecular models of the molecules.

be much larger if the spherical model were used for the shorter members of the series.

NR_3 Series

The P^*/s values with s(cylinder) give a smooth curve for the derivatives longer than that of propyl. The low value for NPr_3 appears relatively normal if compared to the alkane with the same carbon atom number. It is possible that the higher value for NEt_3 comes from increased polarity. However, the spherical model would bring the P^*/s values to 534 J/mol for both NEt_3 and NPr_3 while the s intermediate between the two models would give $P^*/s = 495$ for NEt_3.

Heats of mixing of the NR_3 series with the branched and normal alkanes[1] indicate that the heats with NPr_3 and $NBut_3$ are nearer to each other than NPr_3 from NEt_3. This could be in agreement with the rather similar P^*/s for the NPr_3 and $NBut_3$ and with a somewhat higher value for NEt_3. Detailed analysis of the heats of mixing of the $NR_3 + NR_3'$ systems[1] currently being done could give more information on the relative cohesive energies of the different members of the NR_3 series.

$Si(OR)_4$ Series

The P^*/s are somewhat lower than those of the NR_3 or SnR_4 compounds but are likely to reach the same limiting value for large n. $Si(OPr)_4$ has a higher P^*/s and this may be due to steric hindrance. It is not possible to decide the proportion of increased polarity and that of steric hindrance in the higher $Si(OEt)_4$ value.

Temperature Dependence of the Thermal Pressure Coefficient

Measurements of γ versus T were made in order to investigate the effect of the shape of the molecule on the change of the cohesive energy of the molecule with temperature, a change which could not be due only to molecular expansion. The relation $P^* = \gamma\tilde{v}^2T$ takes account of the volume variation with temperature but at the same time introduces a non-experimental quantity $\tilde{v}$ obtained from the expansion coefficient and the model. In the variation of P^* with temperature, we would like to ascertain whether it is possible to separate the part due to an imperfection of the theory and the part which depends on the change of orientational order with temperature. Measurements were made on N(isopentyl)$_3$, N(Dec)$_3$, and br-C_{16} and compared to literature data (13) on linear alkanes like n-C_{16}. N(Dec)$_3$ and n-C_{16} have in the pure state correlation of molecular orientations which disappear rapidly when the temperature increases while the more globular molecules like N(isopent)$_3$ and br-C_{16} have much less order or 'structure'. It could be expected that P^* would diminish faster for ordered compounds. The P^* values (J cm^{-3}) at different temperatures are given in Table 2 but they can be represented between 25 and 80°C by the following equations with T in K: N(isopent)$_3$ $P^* = 972 - 1.8T$, N(Dec)$_3$ $P^* = 583 - 0.40T$, br-C_{16} $P^* = 380$ between 40 and 80°C (399 at 25°C).

Patterson (11) has shown that the reducing parameter of the compressibilities P^* does not vary over a wide range of temperature and chain length from butane to polymethylene when it is obtained from the corresponding state principle rather than from an equation of state. However, if values of P^* for different T and n are plotted against αT (or $\alpha\tilde{T}$) a single curve is obtained. This could be a way of separating the different contributions in the temperature variations of P^*. On Fig. 5, P^*/s is plotted against αT for the different members of the series and for some alkanes from published data: the P^*/s values situated on the main curve should be due to the imperfect equation of state; the P^*/s values outside the curve may have a physical significance. One can see it is possible to make the P^*/s points corresponding to the NR_3 compounds and the octane at different temperatures fit on the same curve. It seems, however, that there is not a unique dependence of P^*/s on αT. More globular molecules like N(isopent)$_3$ and octane show a more rapid decrease than the linear compounds such as N(Dec)$_3$ and n-C_{16}. The sterically hindered br-C_{16} shows no decrease of P^*/s between 40 and 80°C. These results seem to indicate that for relatively low molecular weight compounds there is a rapid decrease of P^*/s with αT. For larger molecules P^*/s decreases more slowly but there seems to be a difference between ordered liquids such as n-C_{16} and N(Dec)$_3$ and

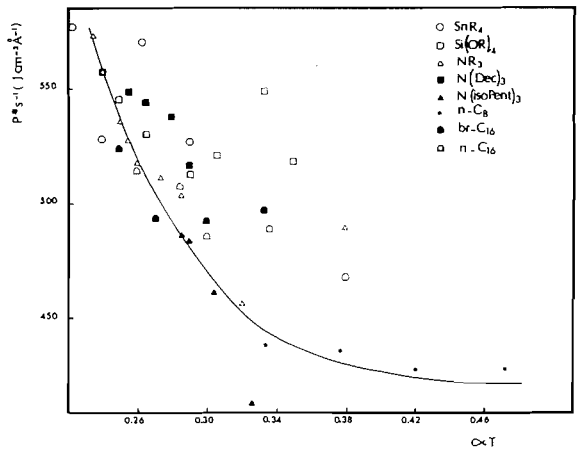

FIG. 5. P^*s^{-1} plotted against the equation of state parameter αT. Most of the points correspond to α and γ measurements at 25°C. For n-C_8 (ref. 13 (●)), n-C_{16} (ref. 13 (⏢)), N(isopent)$_3$ (this work (▲)), br-C_{16} (this work (⬟)), N(Dec)$_3$ (this work (■)), the different points correspond to α and γ measurements at different temperatures. SnR_4 (○), $Si(OR)_4$ (□), NR_3 (△).

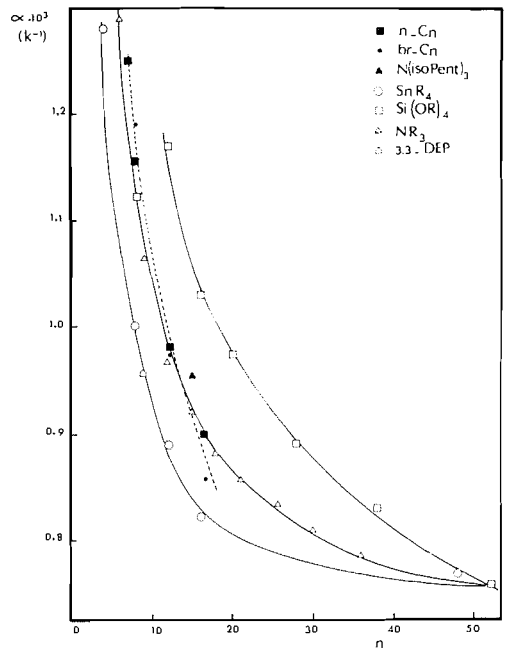

FIG. 6. Expansion coefficients α measured at 25°C plotted against n the total number of carbon atoms for the different series: SnR_4 (○), $Si(OR)_4$ (□), NR_3 (△), n-C_n (■), br-C_n (●), N(isopent)$_3$ (▲), 3,3-DEP (⏢).

not ordered liquids as br-C_{16}. P^*/s for ordered liquids apparently diminishes faster than for globular ones. However, measurements on more systems would be necessary to ascertain that it is a general feature. The four points well outside the curve belong to more polar molecules or to sterically hindered molecules. Table 2 gives results of γ and P^*/s obtained on other compounds for comparison purposes; P^*/s for N(isooct)$_3$ is very similar to that of N(Oct)$_3$ since a methyl at the end of a relatively long chain does not alter too much its molecular shape.

Figure 6 shows the experimental values of α for the different series against the atom carbon number. At short or intermediate chain lengths the order of increasing α is $SnR_4 < NR_3 < n\text{-}C_n < Si(OR)_4$ but the expansion coefficients tend to the same limit when the chain length increases. The branched alkanes usually have higher values of α than the linear alkanes except for the sterically hindered br-C_{16}. It is impossible to see any irregularity in the expansion coefficient curve for the sterically hindered $SnEt_3$ and $SnPr_3$ because of the very rapid decrease of α with n from one member to the next one. Comparison of the temperature dependence of α for the different members could give some complementary information. However, these measurements have not been done since it is known that the theory predicts a too large temperature dependence for the n-alkanes (13).

Thermal Pressure Coefficients and Steric Hindrance

Steric hindrance within the molecule has a marked effect on the macroscopic properties of the liquid especially on the equation of state quantities such as the molar volume, thermal expansion coefficient, and thermal pressure coefficient. This can be seen for isomers of the same alkane which have different degrees of steric hindrance (9, 24).

These different degrees of steric hindrance are more difficult to deduce from density comparison between members of a series since the effect of molecular weight on density overcomes that of steric hindrance. It is therefore particularly valuable to find, by this work, that the thermal pressure coefficient indicates the presence of steric hindrance in cases where densities and expansion coefficients cannot give the information.

Steric Hindrance and Solution Properties

Heats of mixing of non-polar, alkane-like compounds have been measured for a few years (4, 9). It has been possible to separate them in an almost quantitative way, into different contributions such as the h^E_{dis} (disorder) present when long-chains are disordered by the second component and the negative free volume contribution h^E_{fv} due to the difference in expansion coefficients of the components. However, unexpected results have been found in the heats of mixing of linear alkanes, for instance with some globular alkanes (9, 10, 24). An exothermic contribution has to be added to explain the small endothermic heats or exothermic heats. The importance

of this term seems to be related to the steric hindrance of the branched alkane. A strong effect called 'the condensation effect' or the steric hindrance contribution is found with 3,3-diethylpentane and $SnEt_4$ (9, 10, 24). For instance the heat of mixing of the 2,2,4,4-tetramethylpentane with n-C_{16} is 235 J/mol at $x = 0.5$ while it is 18.3 for the sterically hindered isomer 3,3-diethylpentane. It is worthwhile noting that the steric hindrance of a compound can be seen on the thermal pressure coefficient, thus confirming the heats of mixing results.

Acknowledgements

A simpler method to evaluate the isotopic shifts in fundamental stretching frequencies of polyatomic molecules

JAN BRON AND R. WALLACE

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 12, 1977

JAN BRON and R. WALLACE. Can. J. Chem. **56**, 379 (1978).

As an alternative to the more exact, but much more complex theory, a simpler method to estimate the isotope shifts in fundamental (stretching) frequencies of molecules is proposed. By means of examples, it is shown that good agreement between calculated and observed frequencies can be obtained.

JAN BRON et R. WALLACE. Can. J. Chem. **56**, 379 (1978).

On propose une nouvelle méthode plus simple pour remplacer la théorie beaucoup plus complexe et plus exacte qui existe déjà pour trouver un estimé des déplacements isotopiques dans les fréquences fondamentales (vibration) des molécules. Aux moyens d'exemples, on montre qu'il existe un bon accord entre les valeurs calculées et les fréquences observées.

Introduction

In view of current interest in vibrational pumping as a means to achieve isotopic separation and the very substantial complexity of calculating isotopic shifts in the spectra of polyatomic molecules by conventional normal mode theory (1), a simpler model capable of predicting isotopic shifts would seem appropriate. In this connection it has been shown recently (2) that many of the features of polyatomic vibrational spectra (fundamental, anharmonic overtones, etc.) can be predicted on the basis of a simple internal coordinate anharmonic model. The present work is essentially an adaptation of that model, designed to obtain isotopic shifts in the vibrational spectra of polyatomic molecules.

All of the molecules currently considered (H_2O/D_2O; CH_4/CD_4; $^{235}UF_6/^{238}UF_6$) are of the type AX_n, in which the mass of X is much less than that of A. To a good degree of approximation, this permits the separation of bending from stretching vibrations. For convenience we shall restrict consideration to the isotopic shifts in the stretching vibrations only. Relatively simple expressions will be obtained for the various fundamental frequencies. Since the effect of particle masses is explicitly contained in these expressions, it is a simple matter to obtain isotopic shift information. The results for the molecules mentioned above compare favourably with experimental data and have been obtained with relatively little labour.

The Schrödinger Equation

The vibrational Hamiltonian operator to be used has the form

$$[1]\quad \hat{H} = \sum_i \hat{H}_i^{(0)} - \hbar^2 \sum_{i<j}\sum G_{ij}(\partial^2/\partial S_i \partial S_j) + \sum_{i<j}\sum R_{ij}S_iS_j$$

in which

$$[2]\quad \hat{H}_i^{(0)} = -\tfrac{1}{2}\hbar^2 G_{ii}(\partial^2/\partial S_i^2) + V_i$$

The quantities G_{ij} are Wilson's **G** matrix elements (3), R_{ij} is a force constant, and S_i is an *internal stretching coordinate*. The potential energy term in [2] is defined by means of the Morse function (1)

$$[3]\quad V_i = D_i[\exp(-2a_iS_i) - 2\exp(-a_iS_i)]$$

where D_i and a_i are the Morse parameters. Compared to the expression used previously (1), [1] contains the additional interaction terms $R_{ij}S_iS_j$, which are necessary to obtain the correct isotopic shift for the fundamental frequencies. It may be observed that D_i, a_i, and R_{ij} are isotope independent and are, therefore, the same for molecules differing only in isotopic substitution.

The vibrational energy levels of a molecule can be determined by means of [1] and the variation method. A suitable linear variation function has the form

$$[4]\quad \phi = \sum_i \gamma_i \psi_i$$

In [4], the coefficients γ_i are parameters to be determined by minimizing the variational integral (4). The functions ψ_i are in turn defined as

$$[5]\quad \psi_i = N_i \sum_j c_{ij} f_j$$

in which f_i has been defined as (1)

$$[6]\quad f_i = \prod_{i=1}^{n} |\alpha_i(S_i)\rangle$$

There are n bonds in the molecule. As before, $|\alpha_i(S_i)\rangle$ are the eigenfunctions in the equation

$$[7]\quad \hat{H}_i^{(0)}|\alpha_i(S_i)\rangle = -A_i^{-2}(K_i - v_i - \tfrac{1}{2})^2|\alpha_i(S_i)\rangle$$

The constants A_i and K_i are equal to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$[8] \qquad A_i = (2\mu_i)^{1/2}(a_i\hbar)^{-1}$$
$$K_i = A_i D_i^{1/2}$$

while v_i is a quantum number, refering to the ith Morse oscillator, and μ_i is the reduced mass of the two atoms defining the ith bond. Finding the eigenvalues of the secular determinant requires the evaluation of the integrals (4)

$$[9] \qquad H_{ij} = \langle\psi_i|\hat{H}|\psi_j\rangle = H_{ji}$$

and

$$[10] \qquad S_{ij} = \langle\psi_i|\psi_j\rangle = S_{ji}(= \delta_{ij})$$

The integral S_{ij} is for our purposes equal to the Kronecker δ_{ij}. The matrix element H_{ij} can also be written as

$$[11] \quad H_{ij} = \langle\psi_i|\hat{H}|\psi_j\rangle$$
$$= N_iN_j\langle\textstyle\sum_i c_{ik}f_k|\sum_r H_r^{(0)} - \hbar^2\sum_{r<s}\sum G_{rs}(\partial^2/\partial S_r\partial S_s) + \sum_{r<s}\sum R_{rs}S_rS_s|\sum_j c_{jl}f_l\rangle$$
$$= N_iN_j\Big[\textstyle\sum_k\sum_l c_{ik}c_{jl}\sum_r\langle f_k|H_r^{(0)}|f_l\rangle - \hbar^2\sum_k\sum_l c_{ik}c_{jl}\sum_{r<s}\sum G_{rs}\langle f_k|\partial^2/\partial S_r\partial S_s|f_l\rangle + \sum_k\sum_l c_{ik}c_{jl}\sum_{r<s}\sum R_{rs}\langle f_k|S_rS_s|f_l\rangle\Big]$$

Although [11] suggests that many matrix elements are to be evaluated in order to obtain H_{ij}, in actual fact many matrix elements are zero or, using *harmonic* oscillator selection rules, so small that they can be ignored. At this point it is best to use examples to illustrate how numerical values for H_{ij} can be obtained. It should be noted that no tedious transformation of internal to dimensionless normal coordinates is required (5).

H_2O and D_2O

To determine the fundamental frequencies of X_2O (X = H, D), the ground and first excited states should be evaluated (Bohr frequency rule: $\Delta E = h\nu$). For H_2O and D_2O the variation functions may be defined as

$$[12] \qquad \phi = \gamma_1\psi_1 + \gamma_2\psi_2$$

To diagonalize the secular determinant, ψ_1 and ψ_2 will be symmetrized states (3)

$$[13] \qquad \psi_1 = 2^{-1/2}(f_1 + f_2)$$
$$\psi_2 = 2^{-1/2}(f_1 - f_2)$$

The functions f_1 and f_2 are

$$[14] \quad f_1 = |\alpha_1(S_1, v_1)\rangle|\alpha_2(S_2, v_2)\rangle = |v_1, v_2\rangle$$
$$f_2 = |\alpha_1(S_1, v_2)\rangle|\alpha_2(S_2, v_1)\rangle = |v_2, v_1\rangle$$

The quantum numbers v_1 and v_2 are, in this case, restricted to zero or unity. Let us start by determining the energy of the first (two) excited states.

For X_2O the functions ψ_1 and ψ_2 are

$$[15] \qquad \psi_1 = 2^{-1/2}(|10\rangle + |01\rangle)$$
$$\psi_2 = 2^{-1/2}(|10\rangle - |01\rangle)$$

These functions will diagonalize the secular determinant and, hence, values for H_{11} and H_{22} only need to be found. Because $a_1 = a_2$ and $D_1 = D_2$, the subscripts of a, D, K, and A will be dropped. Therefore:

$$[16] \quad H_{11} = \langle\psi_1|\hat{H}|\psi_1\rangle$$
$$= \tfrac{1}{2}\langle f_1 + f_2|\hat{H}|f_1 + f_2\rangle$$
$$= \langle f_1|\hat{H}|f_1\rangle + \langle f_1|\hat{H}|f_2\rangle$$
$$= \langle 10|\hat{H}|10\rangle + \langle 10|\hat{H}|01\rangle$$
$$= \langle 10|\hat{H}_1{}^{(0)} + \hat{H}_2{}^{(0)}|10\rangle - \hbar^2G_{12}\langle 10|\partial^2/\partial S_1\partial S_2|10\rangle + R_{12}\langle 10|S_1S_2|10\rangle + \langle 10|\hat{H}_1{}^{(0)} + \hat{H}_2{}^{(0)}|01\rangle - \hbar^2G_{12}\langle 10|\partial^2/\partial S_1\partial S_2|01\rangle + R_{12}\langle 10|S_1S_2|01\rangle$$

Equation 16 can now be reduced to[1]

$$[17] \quad H_{11} = \langle 1|\hat{H}^{(0)}|1\rangle + \langle 0|\hat{H}^{(0)}|0\rangle + \hbar^2G_{12}\left\langle 1\left|\frac{d}{dS}\right|0\right\rangle^2 + R_{12}\langle 1|S|0\rangle^2$$

The relationship [17] follows from [16], if redundant subscripts are dropped, small matrix elements ignored, and use is made of the fact that d/dS is an anti-Hermitian operator. The matrix element $\langle 1|S|0\rangle$ is difficult to evaluate when Morse oscillator eigenfunctions are used. Therefore, $\langle 1|S|0\rangle$ will be determined by harmonic oscillator functions. This is reasonable, since anharmonicity at the bottom of the well, defined by the Morse potential, is not so important yet. After evaluating matrix elements, [17] becomes

[1]In this case G_{ij} is equal to the product of the cosine of the bond angle and inverse of the mass of oxygen atom (3). Note also that R_{12} refers to the interaction force constant of the *internal* coordinates S_1 and S_2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$[18]\quad H_{11}(\mathrm{cm}^{-1}) = -[(K-\tfrac{3}{2})^2 + (K-\tfrac{1}{2})^2](hcA^2)^{-1} + hG_{12}a^2(2K-1)(16\pi^2c)^{-1} + R_{12}(16\pi^2c^2\mu F)^{-1/2}$$

In [18] the force constant F is equal to $(2a^2D)$; an equality obtained from [3]. Similarly, the expression for H_{22} is

$$[19]\quad H_{22}(\mathrm{cm}^{-1}) = -[(K-\tfrac{3}{2})^2 + (K-\tfrac{1}{2})^2](hcA^2)^{-1} - hG_{12}a^2(2K-1) \times (16\pi^2c)^{-1} - R_{12}(16\pi^2c^2\mu F)^{-1/2}$$

The ground state energy is simply

$$[20]\quad E_0(\mathrm{cm}^{-1}) = \langle 00|\hat{H}|00\rangle \simeq -2(K-\tfrac{1}{2})^2(hcA^2)^{-1}$$

The fundamental (stretching) frequencies, ν_1 and ν_3, are then

$$[21]\quad \nu_1(\mathrm{cm}^{-1}) = H_{11} - E_0 = C_1 + G_{12}C_2 + R_{12}C_3$$
$$\nu_3(\mathrm{cm}^{-1}) = H_{22} - E_0 = C_1 - G_{12}C_2 + R_{12}C_3$$

where

$$[22]\quad C_1 = 2(K-1)(hcA^2)^{-1}\ \mathrm{cm}^{-1}$$
$$C_2 = hF(2K-1)(32\pi^2cD)^{-1}\ \mathrm{g\ cm}^{-1}$$
$$C_3 = (16\pi^2c^2\mu F)^{-1/2}\ \mathrm{dyn}^{-1}$$

In [22], a^2 has been replaced by $(F/2D)$. A close examination of [21] and [22] reveals that ν_1 and ν_3 are determined by three parameters (F, D, and R_{12}), which are independent of isotopic substitution in the molecule X_2O. Two other examples will be discussed below.

CH_4, CD_4 and $^{235}UF_6$, $^{238}UF_6$

The symmetrized functions, ψ_i, for CX_4 are (3)

$$[23]\quad \psi_1(A_1) = \tfrac{1}{2}(f_1 + f_2 + f_3 + f_4)$$
$$\psi_2(F_2) = \tfrac{1}{2}(f_1 + f_2 - f_3 - f_4)$$

and two other functions, where f_1 is equal to $|1000\rangle$ etc. By means of [1], [4], [23], and the above example X_2O, the two stretching frequencies $\nu_1(A_1)$ and $\nu_3(F_2)$ become

$$[24]\quad \nu_1(A_1) = C_1 + 3C_2G_{12} + 3R_{12}C_3$$
$$\nu_3(F_2) = C_1 - C_2G_{12} - R_{12}C_3$$

The constants C_i have been defined by [22]. It follows from the symmetry of CX_4 that all quantities G_{ij} and R_{ij} $(i \neq j)$ are the same and, therefore, have been equated to G_{12} and R_{12}. Although CX_4 has two more bonds than X_2O, the fundamentals in [24] are also functions of three parameters only.

The molecules $^xUF_6$ have octahedral structures (six U—F bonds). The symmetrized functions are (6)

$$\psi_1(A_{1g}) = 6^{-1/2}(f_1 + f_2 + f_3 + f_4 + f_5 + f_6)$$
$$[25]\quad \psi_2(E_g) = \tfrac{1}{2}(f_1 + f_4 - f_3 - f_6) \quad [\text{one other}]$$
$$\psi_3(F_{1u}) = 2^{-1/2}(f_1 - f_4) \quad [\text{two others}]$$

The bonds 1 and 4, 2 and 5, and 3 and 6 form angles of 180°, while all other bond angles are 90°. The only non-zero matrix elements are G_{14}, G_{26}, and G_{36}; all three **G** matrix elements are equal to the negative value of the reciprocal mass of the central uranium atom in $^xUF_6$ (3). Symmetry reduces the number of force constants to two types only: R_{14} and R_{12}. The constant R_{14} accounts for interaction between bonds forming an angle of 180°, while R_{12} is the interaction force constant of bonds making a 90° angle. It is known from experiment (7) that R_{14} is much smaller than R_{12}.

By means of [25] and other equations given above, it follows that for $^xUF_6$ the three frequencies are:

$$[26]\quad \nu_1(A_{1g}) = C_1 + C_2G_{14} + (4R_{12} + R_{14})C_3$$
$$\nu_2(E_g) = C_1 + C_2G_{14} + (R_{14} - 2R_{12})C_3$$
$$\nu_3(F_{1u}) = C_1 - C_2G_{14} - R_{14}C_3$$

In this case there are four parameters that determine ν_1, ν_2, and ν_3: F, D, R_{12}, and R_{14}.

Numerical Results and Discussion

As pointed out above, the fundamentals of H_2O and D_2O depend upon three unknown parameters: F, D, and R_{12}. In general, a value for these parameters may be obtained by analogy to other, closely related molecules (8). Another method is to assume a reasonable value for F and find D and R_{12} by means of [21] from the two observed fundamentals of H_2O: two equations with two unknowns are obtained when F is fixed. Stated differently: it is possible to choose such values for F, D, and R_{12} that will give exact agreement with the observed frequencies (9) of H_2O and then, by means of [21] and [22], ν_1 and ν_3 for D_2O can be calculated. The numerical results for D_2O obtained by the method of fitting are displayed in Table 1. It can be seen that the agreement with the observed values of ν_i is quite satisfactory, even though no interaction of any kind with the bending mode has been assumed. The calculated values for ν_1 and ν_3 given in Table 1 are based on $F = 8.454$ mdyn Å^{-1} (10), determined from harmonic frequencies, $D = 8.18 \times 10^{-12}$ erg and $R_{12} = -0.092$ mdyn Å^{-1}.

TABLE 1. A comparison of observed and calculated frequencies (cm^{-1})

	ν_1		ν_2		ν_3	
Compound	Obs.	Calc.	Obs.	Calc.	Obs.	Calc.
D_2O	2672 (9)	2680	—	—	2788	2789
CD_4	2085 (10)	2082	—	—	2258	2259
$^{235}UF_6$	667[a]	667.05	534[a]	533.98	626.65 (7)	626.56

[a]See text.

The calculated fundamentals for CD_4 are also shown in Table 1. The listed values of ν_1 and ν_3 for CD_4 are based on $F = 5.2$ mdyn Å^{-1}, $D = 10.81 \times 10^{-12}$ erg, and $R_{12} = 0.043$ mdyn Å^{-1}. Again, the magnitudes of the parameters F, D, and R_{12} have been chosen in such a way as to obtain complete agreement between the observed (11) and calculated frequencies for CH_4. As can be seen in Table 1, the agreement between the observed and calculated frequencies for CD_4 is improved with respect to D_2O. This better fit is a result of optimization of F. The dependence of the calculated results on F is shown in Fig. 1. It can be seen that the relationship is (almost) linear. The calculated values of the fundamentals in Fig. 1 have been obtained as follows. For a given F, D and R_{12} can be formed by means of [24] and the observed fundamentals for CH_4. The parameters evaluated in such a way were then used to calculate ν_1 and ν_3 for CD_4. Figure 1 also shows that unreasonably large values of F, which is approximately the stretching force constant of the C—X bond, result in large deviations from the observed frequencies.

Finally, Table 1 shows results for UF_6. The calculated isotopic shift in ν_1 and ν_2 cannot be compared with experiment, since spectroscopic techniques do not allow such small shifts to be measured. The observed shift in ν_3 is 0.65 ± 0.09 cm^{-1}, hence the calculated shift of 0.56 cm^{-1} agrees within experimental error. The calculated values are based on $F = 3.85$ mdyn Å^{-1}, $D = 5.085 \times 10^{-12}$ erg, $R_{14} = -0.02$ mdyn Å^{-1}, and $R_{12} = 0.3$ mdyn Å^{-1}. As above, the quantities D, R_{12}, and R_{14} have been calculated by means of [26], the observed values (7) for ν_1, ν_2, and ν_3 and $F = 3.85$ mdyn Å^{-1}.

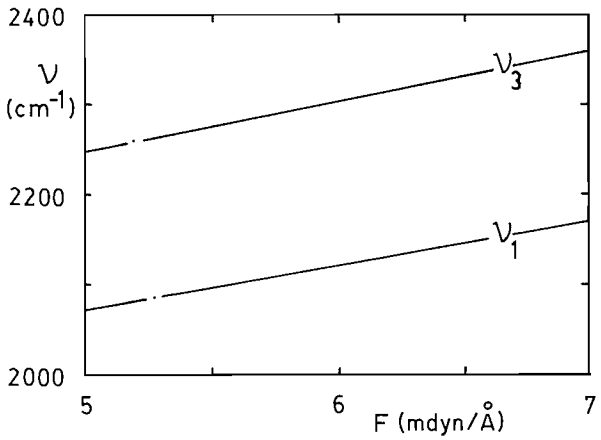

FIG. 1. A plot of the fundamental frequencies, ν_1 and ν_3, of CD_4 versus the force constant F. The dots represent the observed frequencies.

The main features of the method presented in this paper to evaluate the isotopic shifts may be summarized as follows:

(*1*) The method is a simpler alternative to the more exact but much more complicated normal mode theory (1).

(*2*) The tedious and computer time consuming transformation of isotope dependent force constants in dimensionless normal coordinates to isotope independent force constants internal coordinates (5) has been eliminated; this transformation is the main reason why 'large' molecules such as UF_6 cannot be considered in normal mode theory.

(*3*) The algebraic complexity of the (quantum mechanical) problem is greatly reduced.

(*4*) The number of parameters is much smaller: in order to deal with anharmonicity the normal mode theory requires a knowledge of numerous cubic and quartic force constants (5, 9).

(*5*) Equation 1 and a slight modification of the above techniques may be used to determine the isotopic shifts in overtone and combination bonds.

Re-investigation of the alkaloids of *Corydalis solida* yielded two further bases, ochotensine and solidaline. Spectral analysis has shown the latter to be representative of a new class of protoberberine-related isoquinoline alkaloids.

RICHARD H. F. MANSKE, RUSSELL RODRIGO, HERBERT L. HOLLAND, DONALD W. HUGHES, DAVID B. MACLEAN et JOHN K. SAUNDERS. Can. J. Chem. **56**, 383 (1978).

Une nouvelle étude des alcaloïdes du *Corydalis solida* a permis d'isoler deux nouvelles bases, l'ochotensine et la solidaline. Sur la base d'une analyse spectrale, on a pu montrer que ce dernier composé correspond à une nouvelle classe d'alcaloïdes de l'isoquinoléine qui se rapproche de la protoberbérine.

[Traduit par le journal]

Reinvestigation of the alkaloids of *Corydalis solida* (L.) Swartz (1) has yielded two further bases. One is identical with ochotensine from *C. ochotensis* (2), and the second is a hitherto unreported alkaloid, to which we have assigned the name solidaline.

Spectral analysis of solidaline, $C_{23}H_{27}NO_6$ (see Experimental) did not permit unequivocal assignment to any known group of isoquinoline alkaloids. The mass spectrum, however, indicated a protoberberine alkaloid: fragment ions at *m/e* 206 ($C_{12}H_{14}O_3$) and 207 ($C_{11}H_{13}NO_3$) which together comprise the entire molecule, may readily arise from the molecular ion at *m/e* 413 by a fragmentation characteristic of this class of alkaloid (3). Spectral data showed the presence of non-phenolic hydroxyl, one tertiary *C*-methyl, four methoxy groups, and two tetrasubstituted aromatic rings. The ^{1}Hmr data, although suggestive of a protoberberine skeleton (4), were not uniquely interpretable, but a combination of ^{1}Hmr and ^{13}Cmr spectral data enabled us to assign tentatively structure **2** to solidaline (Fig. 1).

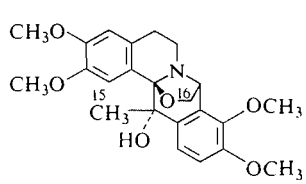

FIG. 1. Proposed structure of solidaline **2**.

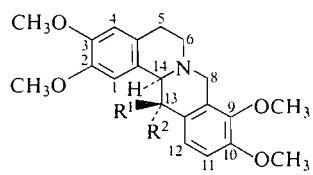
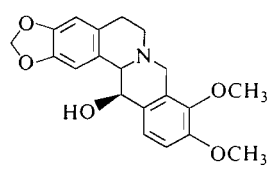
[1]Present address: Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1.

Comparison of the ^{13}Cmr spectrum of **2** with that of corydaline (**1***a*) (also in *C. solida*) (5), mesocorydaline (**1***b*) (5), ophiocarpine (**1***c*), and hydrastinine

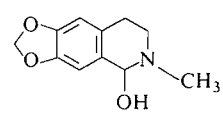


Corydaline **1***a*: $R^1 = CH_3$, $R^2 = H$
Mesocorydaline **1***b*: $R^1 = H$, $R^2 = CH_3$

(**3**) strengthened the proposal of structure **2** for solidaline. The Cmr assignments for **2** are given in Table 1, those with an asterisk being tentative. The



1*c* Ophiocarpine



3 Hydrastinine

chemical shift of C-15 of **2** is similar to that in **1***b*: the deshielding effect of the OH at the α carbon is compensated for by the shielding effect of the oxygen at C-14. The resonance for C-8 of **2** should be deshielded from that of **1***b*, as observed, and the resonance at 78.3 ppm, assigned to C-14, is shielded from the corresponding carbon, C-1, of **3**. Quaternary carbons are often shielded relative to methine carbons (of steroids) in similar environments due to

*Tentative assignments.

different gauche interactions (6). This may also account for the slight shielding of C-13 of **2** relative to **1***c*.

The Cmr spectrum also showed resonances corresponding to CH_2 carbons at 30.7 and 46.3 ppm which were assigned to C-5 and C-6 of a *cis*-quinolizidine structure by comparison with the spectrum of the *cis*-quinolizidine **1***b* (5). The observation of the C-15 resonance of **2** at 22.2, corresponding with the value for C-15 of **1***b* rather than that of **1***a* (see Table 1), strengthens the assignment of the *cis*-quinolizidine stereochemistry to **2**. The aliphatic carbon resonances, other than those corresponding to C-5, C-6, and OCH_3 groups, appeared at 22.2 (CH_3), 68.7 (CH_2), 60.9 (CH), and 78.3 ppm (C). The ABX system observed in the ^{1}Hmr spectrum (*vide infra*) must therefore correspond to a CH_2—CH moiety.

The location of the C-methyl of **2** pseudoequatorial at C-13 was confirmed by the observation of a 21% nuclear Overhauser enhancement (^{1}H spectrum, 100 MHz, CD_2Cl_2 solution) of one half of the AB quartet (δ 7.25), upon irradiation at δ 1.73 (C-methyl). This irradiation also caused a 24% enhancement of signal intensity at δ 7.15. These data suggest a substitution pattern identical with that of corydaline, namely methoxyl groups at C-2, -3, -9, and -10, and a methyl at C-13. The observed nOe is between the methyl group and hydrogens at C-1 and

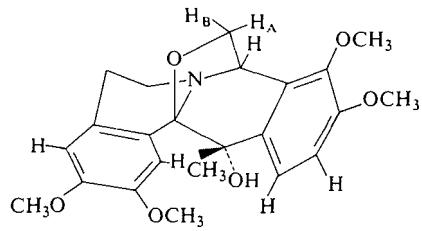

FIG. 2. Relative stereochemistry of solidaline.

C-12. The data also suggest the relative stereochemistry at C-13 and C-14 shown in Fig. 2, in which the β methyl at C-13 is located close to the hydrogens at both C-1 and C-12. Inspection of models reveals that significant nOe's such as those described above would not be anticipated if the methyl were located α at C-13.

The ^{1}Hmr spectrum also showed signals at δ 3.61 (1H, d, J = 7 Hz), 4.03 (1H, q, J = 4, 7 Hz) and 4.70 (1H, d, J = 4 Hz). Irradiation at δ 3.61 caused collapse of the signal at δ 4.03 to a doublet (J = 4 Hz), while irradiation at δ 4.70 also caused collapse at δ 4.03 to a doublet (J = 7 Hz). These data may be interpreted in the light of the structure shown in Fig. 2. The C-8 hydrogen, assigned resonance at δ 4.70, is coupled only to the C-16 hydrogen at δ 4.03 (J_{vic} = 4 Hz). The downfield shift of C-8 H relative to the analogous hydrogen of other *cis*-quinolizidine protoberberine alkaloids (eg. *meso*-corydaline, **1***b*, C-8 H at δ 3.97 (4)) is attributed to additional deshielding by the nitrogen lone pair and the aromatic ring D. A similar effect is observed in the synthetic homoprotoberberine alkaloids (7). Inspection of models reveals that the dihedral angle between C-8 H and C-16 H_A is close to 90°; coupling will therefore be close to zero, indicating resonance of the latter at δ 3.61 and its coupling only to C-16 H_B at δ 4.03 (J_{gem} = 7 Hz). The assignment of C-16 H_A at δ 3.61 and C-16 H_B at δ 4.03 is also consistent with shielding of the former hydrogen by the aromatic ring D, above which it is rigidly held. The observed value of J_{gem} is similar to that noted in analogous tetrahydrooxazole systems (8), militating against a structure for solidaline in which the ether bridge to C-14 and the hydroxyl at C-13 are transposed. This alternate structure would also be inconsistent with the magnitude of the vicinal coupling between the C-8 and C-16 hydrogens.

Structure **2** accounts for all the major fragment ions of the mass spectrum (Scheme 1). The fragmentation parallels the pattern observed for the protoberberine alkaloids (3). The failure of the ion at *m/e* 207 to lose hydrogen, giving a fully aromatic system (as is observed with the protoberberine alkaloids) may be attributed to the presence of oxygen at

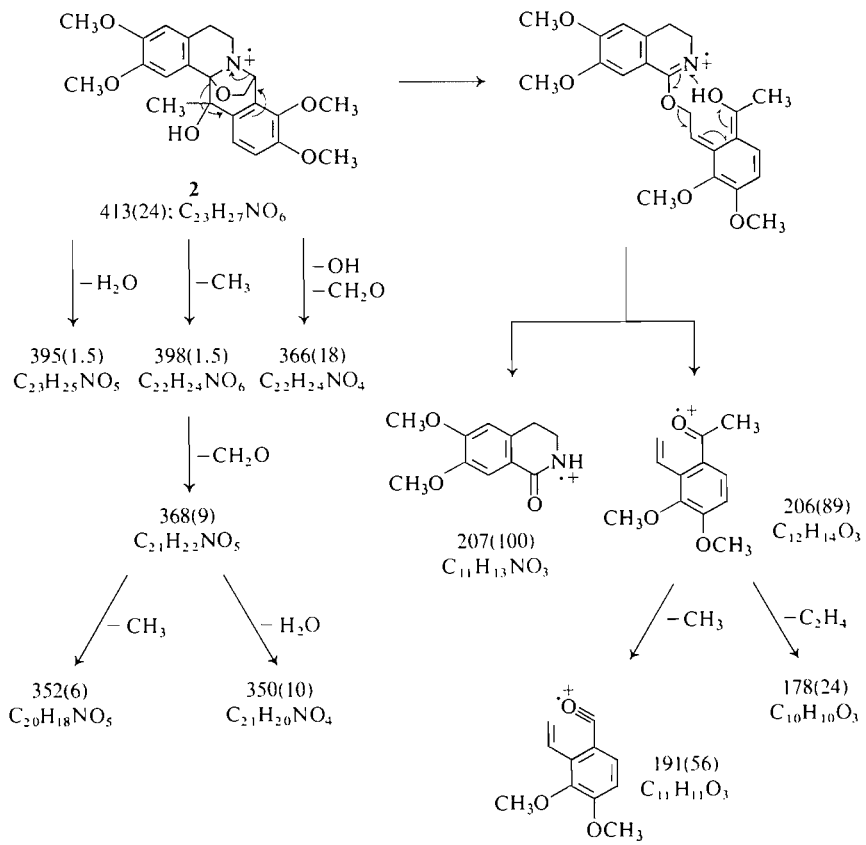

SCHEME 1. Mass spectrum of solidaline

C-14; *m/e* 207 is essentially an amidic ion, as indicated in Scheme 1.

This structure is also compatible with the irreversible change observed in the uv spectrum of solidaline on heating with acid. Addition of acid at room temperature caused a reversible change in the spectrum (see Experimental) but on heating a further irreversible change occurred. This phenomenon is interpreted as resulting from a reversible immonium ion – carbinolamine ether equilibrium (Scheme 2), followed by a dehydration under more vigorous acidic conditions to give the berberine like structure **4**: the uv and ir spectra of **4** (see Experimental) indicate a structure similar to that of tetradehydrocorydaline **5** (λ_{max} (log ε): 268 (4.43), 336 (4.35), 420 (3.81); ν_{max} (cm^{-1}): 1600, 1500, 1460, 1370, 1340, 1280, 1170, 1150, 1110, 1025).

We have considered the possibility that solidaline

5

may be an artefact of isolation, produced by the addition of formaldehyde to ring C of tetradehydrocorydaline **5**. However, we feel that this hypothesis may be discounted on two grounds; firstly, we have been unable to effect reaction of formaldehyde with **5** under a variety of conditions, and secondly, such reaction, if it were to occur, would be expected to produce a bridged species in which the nucleophilic C-8 is bonded to oxygen, and not carbon as observed in solidaline. Further evidence for the natural origin of solidaline is provided by the existence of analogous benzophenanthridine alkaloids containing a C-8 hydroxymethyl group (9).

The biosynthetic origin of the C-8 substituted protoberberines such as solidaline and the related benzophenanthridines (9) is not clear. The presence of solidaline in a plant whose major alkaloid is corydaline (**1***a*) suggests that it may be derived *in vivo* from the latter by the addition of a one carbon unit (e.g. from methionine) (10), but the possibility that solidaline is formed from an *N*-ethyl or *N*-acetyl precursor, prior to closure of the berberine bridge, cannot be exluded.

Experimental

Materials and Methods

Melting points are uncorrected. Infrared spectra were obtained with a Perkin-Elmer 337 spectrophotometer, and ultra violet spectra in methanol solution with a Bausch and Lomb Spectronic 600 spectrophotometer. ^1H nuclear magnetic resonance spectra were obtained at 100 MHz on a Varian HA 100, and at 220 MHz on the Varian HR 220 instrument of the Ontario Research Foundation, Sheridan Park, Ontario. ^{13}C magnetic resonance spectra (broad band and off-resonance) were obtained in both $CDCl_3$ and CD_2Cl_2–CCl_4 solution at 22.628 MHz on a Bruker HX 90 instrument at the University of Sherbrooke, Sherbrooke, Quebec. Mass spectra were recorded on a CEC 21-110B spectrometer. High resolution mass measurements were performed by the reported method (11).

Isolation of the Alkaloids

In a typical extraction, *Corydalis solida* (L) Swartz (2.5 kg) was extracted by the reported procedure (1). Ochotensine (8 mg), isolated from fractions BCE and EEC, was identified by mp and spectral comparisons with an authentic sample (2). The mother liquors from fraction BC from which corydaline and stylopine had been removed were treated with oxalic acid and extracted exhaustively with ether. The bases were regenerated with potassium hydroxide and extracted with a large volume of ether. Solidaline crystallized from the dried (Na_2SO_4) ether solution, mp 197°C. Recrystallization from chloroform–methanol yielded 9 mg, mp 198°C; ir (KBr): 3400, 1285 cm^{-1}; ($CHCl_3$): 3550, 1270 cm^{-1}; uv λ_{max} (log ε): 364(3.33), 316(3.42), 281(3.51), 233(4.03); after addition of HCl λ_{max} (log ε): 367(3.90), 318(3.92), 248(4.02). This change was reversed by the addition of aqueous ammonia. The ms *m/e* (%), composition:[2] 413(24), $C_{23}H_{27}NO_6$; 398 (1.5), $C_{22}H_{24}NO_6$; 395(1.5), $C_{23}H_{25}NO_5$; 368(9), $C_{21}H_{22}NO_5$; 367(14), $C_{22}H_{25}NO_4$; 366(18), $C_{22}H_{24}NO_4$; 365(12.5), $C_{22}H_{23}NO_4$; 352(6), $C_{20}H_{18}NO_5$; 350(10), $C_{21}H_{20}NO_4$; 207(100), $C_{11}H_{13}NO_3$; 206(89), $C_{12}H_{14}O_3$; 205(25), $C_{12}H_{13}O_3$; 192(14), $C_{11}H_{12}O_3$; 191(56), $C_{11}H_{11}O_3$; 179(8), $C_{10}H_{11}O_3$, 178(24), $C_{10}H_{10}O_3$. ^1Hmr (220 MHz, CD_2Cl_2) δ: 1.73 (3H, s C—CH_3), 2.50–3.23 (4H, m, C-5 and C-6 H's), 3.61 (1H, d, J = 7 Hz, C-16 H), 3.83 (6H, s, 2 × OCH_3), 3.84 (6H, s, 2 × OCH_3), 4.03 (1H, q, J = 4, 7 Hz, C-16 H), 4.70 (1H, d, J = 4 Hz, C-8 H), 6.64 (1H, s, C-4 H), 6.86, 7.25 (2H, ABq, J = 8.5 Hz, C-11 and C-12 H's), 7.15 (1H, s, C-1 H). At 100 MHz ($CDCl_3$) a signal at δ 2.55 (1H, br s, disappears on adding D_2O) has been assigned to OH. *Anal.* calcd. for $C_{23}H_{27}NO_6$: C 66.81, H 6.58, N 3.38, 4(OCH_3) 30.02; found: C 66.55, H 6.25, N 3.77, OCH_3 30.14.

Treatment of Solidaline with Acid

A solution of solidaline (28 mg) in methanol (10 ml) and concentrated HCl (2 ml) was refluxed for 3 h. The solution was then cooled and evaporated to give a residue which was dissolved in aqueous ammonia and extracted several times with chloroform. The extract was washed with water, dried, and evaporated; ir ($CHCl_3$) ν_{max}: 1600, 1495, 1460, 1370, 1340, 1280, 1160, 1100, 1020 cm^{-1}; uv λ_{max} (log ε): 266(4.63), 344(4.41), 405(4.22). Addition of aqueous ammonia caused no appreciable change in the uv spectrum.

Deactivation of HF($v = 1, 2$) by fluoroethylenes

S. J. ARNOLD AND G. H. KIMBELL

Defence Research Establishment Valcartier, P.O. Box 880, Courcelette, P.Q., Canada G0A 1R0

Received August 4, 1977

S. J. ARNOLD and G. H. KIMBELL. Can. J. Chem. **56**, 387 (1978).

A discharge flow tube technique has been used to measure the deactivation of HF($v = 1, 2$). Effective vibrational deactivation rate constants for HF($v = 1, 2$) relaxed by C_2H_4, C_2H_3F, 1,1-$C_2H_2F_2$, *cis*-1,2-$C_2H_2F_2$, *trans*-1,2-C_2H_2F, C_2HF_3, and C_2F_4 have been determined. For HF($v = 1$) the values of the rate constants range from 4.9×10^4 s^{-1} $Torr^{-1}$ for C_2H_4 to 3.5×10^3 s^{-1} $Torr^{-1}$ for C_2F_4 and for HF($v = 2$) from 1.3×10^5 s^{-1} $Torr^{-1}$ to 8.8×10^3 s^{-1} $Torr^{-1}$. The cross sections for the deactivation of HF($v = 1$) and HF($v = 2$) by C_2H_4 and the fluoroethylenes are observed to scale linearly with the number of hydrogen atoms.

S. J. ARNOLD et G. H. KIMBELL. Can. J. Chem. **56**, 387 (1978).

On a utilisé la "technique du tube d'écoulement de décharge" pour mesurer la désactivation de HF($v = 1, 2$). On a pu évaluer les constantes de vitesse pour la désactivation vibrationnelle effective de HF($v = 1, 2$) relaxé par C_2H_4, C_2H_3F, $C_2H_2F_2$-1,1, $C_2H_2F_2$-1,2 *cis*, C_2H_2F-1,2 *trans*, C_2HF_3 et C_2F_4. Pour HF($v = 1$), les valeurs des constantes de vitesse varient de 4.9×10^4 s^{-1} $Torr^{-1}$ pour le C_2H_4 à 3.5×10^3 s^{-1} $Torr^{-1}$ pour C_2F_4 alors que pour HF($v = 2$) les valeurs s'étalent entre 1.3×10^5 s^{-1} $Torr^{-1}$ à 8.8×10^3 s^{-1} $Torr^{-1}$. On a observé que les sections efficaces pour la désactivation de HF($v = 1$) et HF($v = 2$) par du C_2H_4 et des fluoroéthylènes varient d'une façon linéaire avec le nombre d'atomes d'hydrogène.

[Traduit par le journal]

Introduction

With the increasing interest in and development of HF and DF lasers, numerous studies have been undertaken to supply the requisite information on both vibrational–vibrational and vibrational–translational deactivation of vibrationally excited HF and DF. The three principal experimental methods used were: laser-excited fluorescence (1, 2), discharge flow tube technique (3, 4), and the 'steady state' chemiluminescence technique (5). For the deactivation of HF by CO_2, one of the few reactions studied by all three techniques, the agreement among the results obtained by all three techniques appears to be very good.

Very little attention has been given to the deactivation of HF by either fluorinated or unsaturated hydrocarbons. Anlauf *et al.* (3) measured the rate of deactivation of HF($v = 1, 2$) by C_2H_4 to be 5×10^4 $Torr^{-1}$ s^{-1} and 2.2×10^5 $Torr^{-1}$ s^{-1} respectively. Bott and Cohen (1) obtained values of $(4.2 \pm 0.6) \times 10^2$, $(1.6 \pm 0.5) \times 10^2$, and $(6.3 \pm 1.0) \times 10^2$ $Torr^{-1}$ s^{-1} respectively for the deactivation of HF($v = 1$) by CF_4, C_2H_6, and C_4H_8. Recent studies by Jones and Matinopoulous (6) of the infrared chemiluminescence produced by the reaction of H atoms with fluoroethylenes has prompted an interest in the rates of deactivation of HF($v = 1, 2$) by fluoroethylenes. Consequently, the present study using the discharge flow tube technique was undertaken to determine the rates of deactivation of HF($v = 1, 2$) by C_2H_4 and all the fluoroethylenes.

Experimental

The experimental apparatus consisted of a medium pressure (~ 1.7 Torr) flow tube having a diameter of 3.4 cm (Fig. 1). The F atoms were generated by passing SF_6 diluted with argon through a 2450 MHz microwave discharge in a 13 mm side arm. The discharge and the flow tube were both coated with phosphoric acid to inhibit atom recombination. The fuel, CH_4, and the deactivant along with additional argon were injected into the F atom argon stream by means of a moveable probe. This probe consisted of a glass tube with a Teflon tip having four spokes with 16 holes of 0.25 mm diameter per spoke. The holes were oriented perpendicular to the flow axis. The probe position could be varied from the observation position to a point 15 cm upstream. Characterization of the flow was accomplished by measuring pressure with a quartz spiral gauge (Texas Instruments) and the flow rates of the reactant gases with Fisher Porter flowmeters.

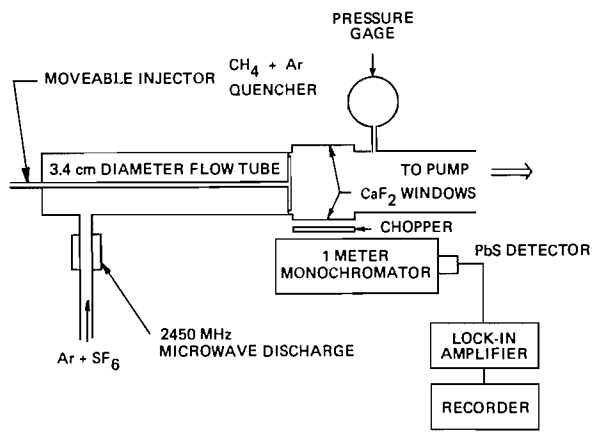

FIG. 1. Experimental apparatus.

The detection system consisted of CaF_2 windows mounted flush with the walls of the flow tube, a McPherson 1 m monochromator equipped with a Dry ice – acetone cooled PbS detector chopped at 200 Hz by a Bulova L8HH optical chopper and a Hewlett-Packard lock-in amplifier. The 2 mm slit of the chopper acted as an iris limiting the field of view. This gave a spatial resolution of 4.4 mm along the flow axis.

Typical experimental conditions were: molar flow rates (μmol s^{-1}) Ar 884, SF_6 0.45, CH_4 5.24; pressure 1.65 Torr; average linear velocity 1.85×10^3 cm s^{-1}; temperature (298 ± 2) K.

Results and Discussion

Vibrationally excited HF is produced by the fast reaction

$$[1] \qquad CH_4 + F \rightarrow HF(v \leq 3) + CH_3$$

which has a rate constant $k = 5.48 \times 10^{-10} \exp(-575/T)$ cm^3 $molecules^{-1}$ s^{-1} (7). The emission spectrum of the HF fundamental vibrational rotational band is well resolved permitting the use of the $R_1(2)$ and $R_2(4)$ lines as a monitor of the HF($v = 1$) and HF($v = 2$) concentration.

HF($v = n$) is deactivated by the quenching reaction

$$[2] \qquad HF(v = n) + Q \rightarrow HF(v = n - 1) + Q$$

where Q is the added quencher, as well as undergoing collisional deactivation with reactants and products, radiative decay, and wall deactivation. The method of analysis employed is similar to that used by Kwok and Wilkins (8). The flow is treated as fully developed, viscous, laminar, axially symmetric pipe flow having a parabolic radial dependence. Axial diffusion and coupling between HF(v) levels is assumed to be negligible. Mixing of the reactants at the injector is assumed to be instantaneous. The value of the number density averaged along the tube diameter, $\bar{N}_v$, as a function of the radial coordinate z is approximately

$$[3] \qquad \bar{N}_v(z) = \bar{N}_v(z = 0) \exp(-z/\tau_v U')$$

where $\tau_v^{-1}(z)$ is the overall decay rate. The velocity U' compensates for the distortion of the density $\bar{N}_v$ caused by the paraboloidal velocity profile. $U' = \phi\bar{U}$ where $\bar{U}$ is the average velocity calculated from the continuity equation. The correction factor ϕ can be calculated for specified diffusion coefficients and given wall loss conditions using the method outlined by Poirier and Carr (9). Figure 2 shows a typical plot of observed number density, $\bar{N}_v$, against distance along the z axis. The decay slopes obtained from these plots

$$[4] \qquad \text{Slope} = S_v = \frac{d(\ln \bar{N}_v)}{dz} = (\tau_v U')^{-1}$$

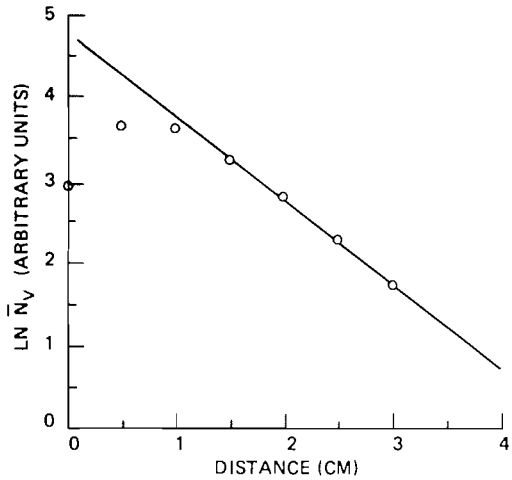

FIG. 2. Plot of observed number density, $\bar{N}_v$, against distance along the z axis.

are then plotted against quencher concentration Q to give the quenching rate constant

$$[5] \qquad dS_v/dQ = k_q/U'$$

Figure 3 shows a representative plot of S_v vs. Q for the deactivation of HF($v = 2$) by C_2HF_3.

The flow system was very steady during the measurements with changes in gas pressure and discharge parameters being less than 5%. The flows were steady to within 5% with the uncertainty in their absolute values calculated to be less than 20% of value. Detector sensitivity was sufficient to permit the decay of HF($v = 1$) to be monitored over a distance of 10 cm and HF($v = 2$) over a distance of 5 cm. The signal for $\bar{N}_1$ at the 1 cm position varied by less than 2% over 10 min and at the 10 cm posi-

TABLE 1. Comparison of rate constants for the deactivation of HF($v = 1$) by CH_4, C_2H_6, and CO_2

Quencher	k_q (Torr^{-1} s^{-1})	Temperature (K)	Method	Reference
CH_4	3.5×10^4	298	Discharge flow tube	Present work
	2.1×10^4	298	Discharge flow tube	Kwok and Cohen (4)
	6.4×10^4	298	Discharge flow tube	Anlauf *et al.* (3)
	$(5.3 \pm 0.8) \times 10^4$	295	Laser fluorescence	Hancock and Green (2)
C_2H_6	9.3×10^4	298	Discharge flow tube	Present work
	$(1.1 \pm 0.16) \times 10^5$	295	Laser fluorescence	Hancock and Green (2)
	5.6×10^4	298	Discharge flow tube	Anlauf *et al.* (3)
CO_2	4.0×10^4	298	Discharge flow tube	Present work
	4.1×10^4	298	Discharge flow tube	Kwok and Cohen (4)
	$(3.6 \pm 0.2) \times 10^4$	295	Laser fluorescence	Bott and Cohen (10)
	4.0×10^4	298	Steady-state chemiluminescence	Airey and Smith (5)
	$(5.9 \pm 0.2) \times 10^4$	294	Laser fluorescence	Hancock and Green (11)
	$(4.25 \pm 0.6) \times 10^4$	299	Laser fluorescence	Lucht and Cool (12)
	$(3.9 \pm 0.4) \times 10^4$	295	Laser fluorescence	Bott (13)

tion by less than 5%. As can be seen from Fig. 2 the scatter about the least-squares line drawn through the straight portion of the curve is small permitting an accurate determination of the slope. Similarly plots of S_v vs. Q exhibit only small fluctuations from the expected linearity (Fig. 3).

In order to test the experimental method and the assumptions made in the analysis, the rate of deactivation of HF($v = 1$) by CH_4, C_2H_6, and CO_2 was determined. The values of the rate constants obtained in the present study together with literature values are given in Table 1. Good agreement with the literature values is obtained in the case of CO_2 and good agreement with the preferred value in the case of C_2H_6. For CH_4 the present value lies intermediate between the two preferred values.

The rate of deactivation of HF($v = 2$) by CH_4 and CO_2 was also determined. For CH_4 a value of 7.5×10^4 Torr^{-1} s^{-1} was obtained, which is in reasonable agreement with the Kwok and Cohen (4) value of 6.9×10^4 Torr^{-1} s^{-1}. For CO_2, the value of 1.3×10^5 Torr^{-1} s^{-1} is somewhat lower than the values of 1.6×10^5 Torr^{-1} s^{-1} (4), 1.6×10^5 Torr^{-1} s^{-1} (5), and $(2.0 \pm 0.2) \times 10^5$ Torr^{-1} s^{-1} (13) obtained by other workers.

The rate constants for the deactivation of HF($v = 1$) and HF($v = 2$) by C_2H_4 and all the fluoroethylenes are given in Table 2. Several determinations of each rate constant were made, six being the normal number with three being the minimum. The maximum deviation between values was 15% with the average deviation being considerably less. The values of the rate constants are considered to have uncertainties of less than a factor of 2 although the agreement between the values obtained for the deactivation of HF($v = 1$) by CH_4, C_2H_6, and CO_2 and the literature values indicates that the uncertainty is probably considerably less. The values of 4.9×10^4 and 2.2×10^5 obtained for the deactivation of HF($v = 1$) and HF($v = 2$) by C_2H_4 are thus in good accord with the approximate values of 5×10^4 and 2.2×10^5 given by Anlauf *et al.* (3).

TABLE 2. Rate constants for the deactivation of HF($v = 1$, 2) by fluoroethylenes

Quencher	k_q (Torr^{-1} s^{-1}) HF($v = 1$)	HF($v = 2$)
C_2H_4	4.9×10^4	1.3×10^5
C_2H_3F	3.4×10^4	8.7×10^4
1,1-$C_2H_2F_2$	2.7×10^4	6.5×10^4
cis-1,2-$C_2H_2F_2$	3.1×10^4	5.9×10^4
trans-1,2-$C_2H_2F_2$	2.9×10^4	6.6×10^4
C_2HF_3	1.9×10^4	4.2×10^4
C_2F_4	3.5×10^3	8.8×10^3

The cross section for the deactivation of HF($v = 1$) and HF($v = 2$) by fluoroethylenes ($C_2H_{2x-m}F_m$) appears to scale linearly with the number of hydrogen atoms ($2x - m$) which is equal to the number of CH stretching frequencies (Figs. 4 and 5). Since the CH stretching frequencies for the fluoroethylenes fall within the range 3060 ± 75 cm^{-1}, the energy defect, ΔE, for each member of the series of reactions

$$[6] \quad HF(v = n) + C_2H_{2x-m}F_m \rightarrow HF(v = n - 1) + C_2H_{2x-m}F_m + \Delta E$$

is essentially the same and the increased efficiency can be attributed to an increase in the number of CH stretching modes available. Hancock and Green (2) observed a similar dependence of collision cross section on the number of hydrogen atoms for the deactivation of HF($v = 1$) by alkanes.

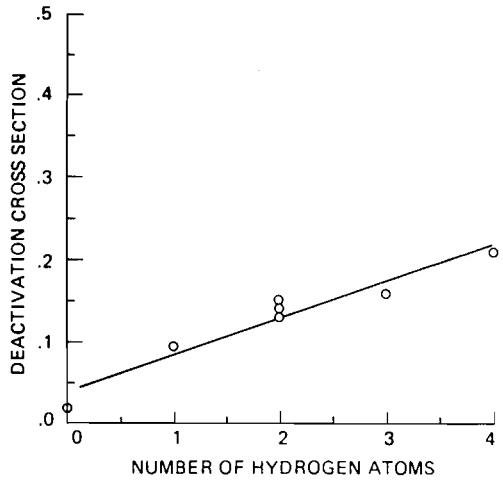

FIG. 4. Plot of deactivation cross section (σ (Å^2)) for HF(v = 1) against number of hydrogen atoms in fluoroethylene.

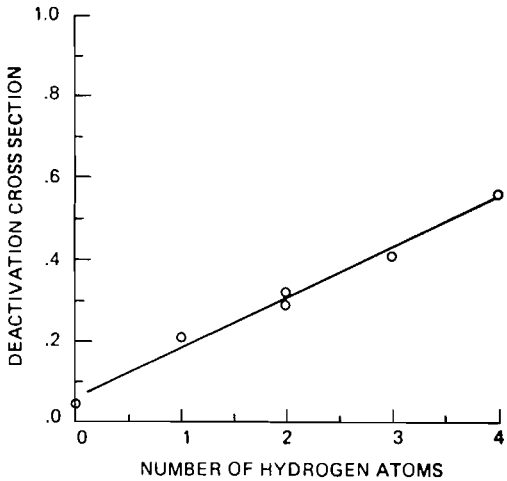

FIG. 5. Plot of deactivation cross section (σ (Å^2)) for HF(v = 2) against number of hydrogen atoms in fluoroethylene.

Conclusions

A discharge flow tube method has been used to determine the rate of deactivation of HF(v = 1) and HF(v = 2) by CO_2, CH_4, C_2H_6, C_2H_4, and all the fluoroethylenes. The values of the rate constants obtained for the deactivation of HF(v = 1) by CO_2, CH_4, and C_2H_6 are in good agreement with the literature values indicating that the discharge flow tube method with the assumptions made in the analysis is capable of yielding satisfactory results. For the deactivation of HF(v = 1) the value of the rate constants ranged from 4.9×10^4 Torr^{-1} s^{-1} for C_2H_4 to 3.5×10^3 Torr^{-1} s^{-1} for C_2F_4 and for HF(v = 2) from 1.3×10^5 Torr^{-1} s^{-1} for C_2H_4 to 8.8×10^3 Torr^{-1} s^{-1} for C_2F_4. The cross sections for the deactivation of HF(v = 1) and HF(v = 2) by C_2H_4 and the fluoroethylenes is observed to scale linearly with the number of hydrogen atoms.

Appendix

The data were analysed in the manner described by Kwok and Wilkins (8) and Poirier and Carr (9). Consequently, only a brief resume of the method will be given here. The flow reactor is axially symmetrical with flow in the axial direction only. The reactions are assumed to occur isothermally in laminar flow. Thus, the differential equation describing the system is

$$[A.1] \quad -v_z\left(\frac{\partial C_i}{\partial_z}\right) + D_i\left(\frac{\partial^2 C_i}{\partial r^2} + \frac{1}{r}\frac{\partial C_i}{\partial r} + \frac{\partial^2 C_i}{\partial_z{}^2}\right) - R_i = 0$$

$$i = 1, 2, \ldots, n$$

where v_z = axial velocity, z = axial coordinate measured from the reactor inlet, r = radial coordinate measured from the tube axis, C_i = concentration, D_i = molecular diffusivity, R_i = reaction rate of the ith component. When the velocity profile is described by Poiseuille's equation, axial diffusion is negligible in comparison to radial diffusion and when there is no volume change on reaction, [A.1] for an irreversible first order reaction is

[A.2] $$-v_0\left(1-\left(\frac{r}{R}\right)^2\right)\frac{\partial C}{\partial_z} + D\left(\frac{\partial^2 C}{\partial r^2}+\frac{1}{r}\frac{\partial C}{\partial r}\right) - kC = 0$$

where v_0 = center line velocity and R = tube radius. In dimensionless form [A.2] is

[A.3] $$-(1-u^2)\frac{\partial C}{\partial \lambda}+\alpha\left(\frac{\partial^2 C}{\partial U^2}+\frac{1}{U}\frac{\partial C}{\partial U}\right) - C = 0$$

with $C = 1$ at $\lambda = 0$, $\partial C/\partial\lambda = 0$ at $U = 0$, and $-\alpha\partial C/\partial U = \beta C$ at $U = 1$; where $U = r/R$, $C = C/C_0$, $\lambda = k_z/v_0$, $\alpha = D/kR^2$, and $\beta = k_w/kR$. For a homogeneous first order reaction with a concurrent first order wall reaction, the parameter β in the boundary condition $-\alpha\partial C/\partial U = \beta C$ has positive values. The continuity equation (eq. A.3) was solved using a finite difference technique. Concentrations were averaged along a principal diameter of the reactor

[A.4] $$\bar{C}_1 = \int_0^1 C\,du$$

and plots of $-\log \bar{C}_1/C_0$ vs. λ were obtained as a function of α and β as is done in ref. 9. The slope, $(-\log \bar{C}_1/C_0)/\lambda$ for the experimentally determined values of α and β, is ϕ, the correction to the average flow velocity required to compensate for the distortion of the number density, $\bar{N}_v$, caused by the parabolic velocity profile.

Mesure de la constante de vitesse de réaction des atomes d'hydrogène sur l'éthane et le propane en réacteurs tubulaire et parfaitement agité ouverts

JACQUES LEDE ET JACQUES VILLERMAUX

Laboratoire des Sciences du Génie Chimique, C.N.R.S. – E.N.S.I.C, 1, rue Grandville, 54042 Nancy Cedex, France

Reçu le 16 novembre 1976[1]

JACQUES LEDE et JACQUES VILLERMAUX. Can. J. Chem. **56**, 392 (1978).

On étudie la constante de vitesse de la réaction des atomes d'hydrogène produits par décharge électrique, sur l'éthane et le propane dans deux types de réacteurs ouverts: tubulaire et parfaitement autoagité par jets gazeux. Les mesures sont faites grâce à l'utilisation d'une nouvelle méthode très sensible de dosage des atomes. Les résultats obtenus au voisinage de la température ambiante sont parfaitement compatibles avec ceux d'autres auteurs résultant d'études effectuées sous des températures nettement plus élevées. Il est possible de proposer les estimations suivantes:

$$H + C_2H_6 \xrightarrow{k_5} H_2 + C_2H_5: \quad k_5 = 10^{13.7\pm0.6} \exp -((9100 \pm 600)/RT)\ (cm^3\ mol^{-1}\ s^{-1})$$

$$H + C_3H_8 \xrightarrow{k_{13}} H_2 + C_3H_7: \quad k_{13} = 10^{13.8\pm0.3} \exp -((7800 \pm 100)/RT)\ (cm^3\ mol^{-1}\ s^{-1})$$

JACQUES LEDE and JACQUES VILLERMAUX. Can. J. Chem. **56**, 392 (1978).

The rate constant for the reaction of hydrogen atoms, generated by electrical discharge, with ethane and propane has been studied in tubular and perfectly stirred open reactors. Measurements are made with a new and very sensitive method of analysis of the hydrogen atom concentration. The results obtained near room temperature are in good agreement with those of other authors operating at much higher temperatures. The following estimates may be made:

$$H + C_2H_6 \xrightarrow{k_5} H_2 + C_2H_5: \quad k_5 = 10^{13.7\pm0.6} \exp -((9100 \pm 600)/RT)\ (cm^3\ mol^{-1}\ s^{-1})$$

$$H + C_3H_8 \xrightarrow{k_{13}} H_2 + C_3H_7: \quad k_{13} = 10^{13.8\pm0.3} \exp -((7800 \pm 100)/RT)\ (cm^3\ mol^{-1}\ s^{-1})$$

Introduction

Un certain nombre d'articles de revues rassemblant les principales réactions des atomes d'hydrogène apparaissent régulièrement dans la littérature (1–3). Parmi elles, les réactions sur les alcanes ont suscité d'assez nombreux travaux.

Il est généralement admis que le processus initial correspond à l'arrachement d'un atome H avec formation d'une molécule H_2 et d'un radical alkyle R (processus métathétique):

$$H + RH \rightarrow H_2 + R$$

Les expériences sont menées dans des systèmes très variés (limite d'explosion du mélange H_2–O_2; flammes; radiolyse; photolyse; décharge; etc). Très souvent, les méthodes sont assez indirectes, la constante de ce processus étant déduite d'autres constantes supposées parfaitement connues. Dans la majorité des cas, la température de travail est nettement supérieure à 400 K et, dans les systèmes en écoulement, la pression totale inférieure à 10 Torr.

Les effets de paroi (recombinaison d'une fraction des atomes H sur les parois de l'enceinte) peuvent avoir une grande importance sur la cinétique apparente. Pour s'y soustraire, les auteurs effectuent soit des traitements de parois destinés à en minimiser les effets (4, 5) (mais ces processus étant activés peuvent prendre une importance insoupçonnée à haute température); soit des corrections (6); soit des mesures quantitatives préalables (7, 8).

Dans une étude récente, Lede et coll. (9, 10) ont préconisé l'utilisation de deux types de réacteurs ouverts en vue de l'étude de réactions homogènes: le réacteur tubulaire en régime d'écoulement laminaire et le réacteur parfaitement autoagité par jets gazeux turbulents. Ils ont notamment proposé plusieurs méthodes de dépouillement d'expériences permettant de calculer des constantes de vitesse homogènes après avoir déterminé sur le plan expérimental la constante de vitesse de la réaction parasite aux parois, le coefficient de diffusion moléculaire du réactif et l'importance de l'hydrodynamique de l'écoulement gazeux.

Ces méthodes sont applicables à des réactions modérément rapides et se justifient donc parfaitement pour l'étude de réactions de métathèse dans des conditions où celles-ci sont peu étudiées: au voisinage de la température ambiante et sous une pression totale pouvant atteindre l'atmosphère. Un autre

intérêt d'une telle étude est de faire appel à une technique nouvelle de mesure de la concentration en atome H (11) applicable à des concentrations très faibles.

Dispositif expérimental

Il est le même quel que soit le réacteur utilisé. Ayant déjà décrit ce dispositif à plusieurs reprises (12, 13), nous n'en rappellerons que les points essentiels.

Généralités

Un courant d'hydrogène de qualité "U" de l'"Air Liquide" ($[H_2] > 99.995\%$) traverse une vanne à aiguille puis une zone dans laquelle il est partiellement dissocié par décharge électrique Corona. A cette zone, délimitée en sortie par une pastille en PTFE percée d'un trou de 0.01 cm^2, succède le réacteur où la réaction est étudiée en obervant la concentration résiduelle des atomes d'hydrogène. Les gaz traversent ensuite une seconde vanne à aiguille et une pompe pour vide primaire. Le domaine de pressions étudié va de quelques Torr à la pression atmosphérique et les débits volumiques de 50 à 1000 $cm^3\ s^{-1}$ (mesurés sous la pression de travail).

Une canalisation secondaire munie d'une troisième vanne à aiguille permet d'introduire dans le réacteur un débit secondaire connu (rotamètres) d'alcane de qualité "N 35" (pureté $>99.95\%$). Celui-ci est auparavant débarrassé de toute trace d'oxygène et d'éthylène par passage sur un lit d'amiante palladiée et platinée en présence d'une très faible concentration d'hydrogène.

Réacteurs tubulaires

Il s'agit de tubes cylindriques en Pyrex dont les parois peuvent être modifiées facilement grâce à différents chemisages internes. Trois types de réacteurs tubulaires à parois différentes ont été utilisés: un réacteur à parois en PTFE (diamètre 1.2 cm); un réacteur à parois en Pyrex (diamètre 1.45 cm); un réacteur à parois en platine (diamètre 1.16 cm).

Des mesures ont été faites à différentes températures. Le réacteur est à cet effet entouré d'un tube coaxial dans lequel circule de l'eau thermostatée, l'ensemble étant calorifugé par un manchon de laine de verre. Avant la zone de mesure, la surface interne du réacteur est tapissée sur une longueur de 80 cm par un tube en PTFE ce qui permet (compte tenu du faible pouvoir catalytique de ce matériau) de transporter les atomes avec un minimum de recombinaison tout en permettant la mise en régime thermique du gaz.

Le courant d'alcane (éthane ou propane) est introduit par un simple tube débouchant à l'entrée du réacteur. Le parfait mélangeage avec le courant principal est assuré par de nombreuses chicanes en PTFE. Les mesures ne sont effectuées qu'après une abscisse l telle que le régime d'écoulement laminaire stable soit réétabli. Des expériences de visualisation de l'écoulement ont permis de proposer la relation (13):

$$l = 2R(0.035Re + 1)$$

dans laquelle R est le rayon du réacteur et Re le critère de Reynolds correspondant à l'expérience.

Réacteur agité

Sa conception technique est entièrement décrite dans la réf. 10. Rappelons simplement que le flux d'hydrogène pénètre dans le réacteur (sphère en "Pyrex" ayant un volume utile de 26 cm^3) par l'intermédiaire d'un injecteur ayant la forme d'un croissillon portant quatre tuyères situées à mi-rayon. Celles-ci ont un diamètre tel que les jets d'hydrogène soient turbulents et assurent grâce à de nombreux recyclages internes un vigoureux brassage du milieu gazeux. Les conditions de parfaite autoagitation ont été énoncées par David et coll. (14, 15). L'injecteur est en PTFE afin de minimiser la quantité d'atomes susceptibles de se recombiner entre la sortie de la décharge électrique et le débouché des tuyères.

L'arrivée d'alcane se fait par un simple tube débouchant dans le réacteur, le mélangeage étant, dans ce cas, parfaitement assuré par la turbulence que règne dans le milieu. Les expériences sont faites dans une gamme de temps de passage où les déterminations préalables de distributions de temps de séjour (13) ont prouvé la parfaite agitation du réacteur.

Les mesures ont été faites à la température ambiante.

Mesure de la concentration en atomes d'hydrogène

Il s'agit d'une méthode nouvelle décrite en détail dans la réf. 11. Son principe de fonctionnement repose sur le fait que l'oxyde de mercure HgO est sélectivement réduit par les atomes d'hydrogène pour former du mercure, libéré en phase gazeuse lorsque l'on opère avec de faibles concentrations atomiques. En réacteur ouvert, la vapeur de mercure est entraînée en continu et son dosage est effectué en sortie par la mesure spectrophotométrique de l'absorption d'un faisceau de rayonnement 253.7 nm.

La comparaison de cette méthode avec d'autres utilisant des sondes de natures très différentes (16) a permis d'en souligner la fiabilité et la linéarité. Les risques encourus par un éventuel dépôt de mercure sur les parois peuvent être exclus, aucune variation du coefficient de recombinaison hétérogène des atomes sur celles-ci n'ayant été observée en utilisant d'autres types de sondes (17). Si cette technique est essentiellement relative, des évaluations absolues de concentrations peuvent être faites grâce notamment à des expériences d'étalonnage réalisées en introduisant des concentrations connues de vapeur de mercure (11). La limite inférieure de concentration atomique détectable peut être ainsi estimée proche de 5×10^{-13} at-g cm^{-3}.

D'un point de vue pratique, la sonde proprement dite est constituée par une fine grille en verre "Pyrex" interceptant le courant gazeux et sur laquelle est déposé l'oxyde. La position de la surface sensible peut être réglée à volonté depuis l'extérieur du montage grâce à un système d'aimant.

Les études cinétiques en réacteur tubulaire sont menées en positionnant la sonde à différentes abscisses. L'information expérimentale est donc le profil axial de concentration. Les études cinétiques en réacteur agité sont menées grâce au jeu de deux sondes parfaitement identiques positionnées à l'entrée et à la sortie du réacteur. L'information expérimentale est donc cette fois le rapport des concentrations d'entrée et de sortie.

Méthodes de dépouillement des expériences

Ces méthodes ont déjà fait l'objet de descriptions détaillées, rappelons cependant ici les points nécessaires à la compréhension de cet article. Que ce soit avec le réacteur tubulaire ou le réacteur agité, les deux méthodes ont en commun le fait que les expériences sont menées en deux étapes correspondant aux cas où la réaction homogène existe ou non (arrivée d'alcane mise en service ou bien coupée).

Expériences en réacteur tubulaire

Les conditions sont telles que réactions homogène et hétérogène et processus diffusionnels soient com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

pétitifs. La pression de travail est suffisamment forte pour que l'hypothèse d'un écoulement piston ne puisse être formulée. Les dépouillements tiennent donc compte du profil radial parabolique des vitesses dans le réacteur.

(*1*) On se propose dans la première étape, de mesurer les deux constantes caractérisant les phénomènes chimiques (rendement de recombinaison hétérogène γ) et diffusionnel (coefficient de diffusion D) dans les conditions de l'expérience. En accord avec ce qui est généralement rapporté dans la littérature (12) l'expérience montre que la réaction de recombinaison des atomes aux parois est un phénomène d'ordre un (mécanisme de Rideal): allure parfaitement exponentielle des profils axiaux de concentration et indépendance de ceux-ci avec la concentration atomique initiale (13, 18).

Les atomes parviennent à la paroi par un processus de diffusion en phase gazeuse. Villermaux (19) a montré dans ces conditions que le phénomène global reste d'ordre un avec une constante de temps caractéristique τ qui peut s'écrire sous la forme:

$$[1] \qquad \tau = \frac{2R}{\gamma \bar{C}} + \frac{R^2}{3.66D}$$

R est le rayon du réacteur; $\bar{C}$ est la vitesse moyenne d'agitation thermique des atomes; γ est le rendement de recombinaison sur les parois; D est le coefficient de diffusion moléculaire; 3.66 est un coefficient numérique traduisant la nature de l'écoulement gazeux (laminaire avec profil parabolique).

L'expression 1 montre que les variations de τ en fonction de la pression sont linéaires, ce qui offre une méthode expérimentale originale d'accès à γ et D.

Cette étude a été menée systématiquement entre 50 et 760 Torr et de 277 à 333 K dans trois réacteurs ayant des parois de nature catalytique différentes (12). Elle a permis de calculer l'énergie d'activation de la recombinaison sur Pyrex ainsi que les paramètres d'interaction moléculaire du couple H,H_2. Les résultats se sont avérés être en très bon accord avec ceux d'autres auteurs ayant opéré dans des conditions très différentes.

(*2*) Dans la seconde étape, un débit connu et constant d'alcane est introduit, toutes autres conditions étant restées inchangées. Si l'on désigne par k la constante de vitesse d'ordre ou de pseudo ordre un de cette réaction homogène, on peut montrer (9) que si $k \ll 30D/R^2$, le profil axial de concentration reste en première approximation exponentiel malgré les forts couplages entre phénomènes chimiques, diffusionnels et hydrodynamiques:

$$[2] \qquad C_m \sim \exp(-\lambda z/R)$$

C_m est la concentration moyenne en atomes dans une section droite du réacteur; λ est une fonction de γ, D et k.

Les paramètres γ et D ont été obtenus dans l'étape précédente; λ est calculé par la méthode des moindres carrés sur les droites expérimentales $\log C_m$ en fonction de z; une procédure d'optimisation menée sur ordinateur (9) permet de calculer la meilleure valeur de k.

Expériences en réacteur agité

Ici encore les conditions sont telles que réactions homogène et hétérogène sont compétitives. La pression de travail est suffisamment forte pour que l'agitation soit assurée par la turbulence du milieu et non pas par diffusion moléculaire.

(*1*) Dans la première étape, on mesure le rapport des concentrations d'entrée et de sortie $(C_0/C_S)'$ qui peut s'écrire (10):

$$[3] \qquad \left(\frac{C_0}{C_S}\right)' = 1 + \frac{(\gamma\bar{C}/4)k_g}{(\gamma\bar{C}/4) + k_g}\frac{S}{Q}$$

S est la surface active intérieure; Q est le débit volumique total du gaz; k_g est la conductance de transfert du réactif à travers la couche limite qui isole la paroi du milieu gazeux turbulent.

Notons que l'expression 3 permet la mesure expérimentale du rendement de recombinaison sur le matériau constituant la surface intérieure du réacteur agité, compte tenu d'une hypothèse sur les valeurs de k_g. Les résultats obtenus sur le verre Pyrex recoupent très favorablement ceux d'autres déterminations (10).

(*2*) Dans la second étape, un débit constant et connu d'alcane est introduit, toutes autres conditions étant restées inchangées. On mesure cette fois un rapport des concentrations d'entrée et de sortie C_0/C_S tel que:

$$[4] \qquad \frac{C_0}{C_S} = 1 + \frac{(\gamma\bar{C}/4)k_g}{(\gamma\bar{C}/4) + k_g}\frac{S}{Q} + k\frac{V}{Q}$$

V désignant le volume du réacteur, l'association de [3] et [4] permet de calculer simplement k:

$$\frac{C_0}{C_S} - \left(\frac{C_0}{C_S}\right)' = k\frac{V}{Q}$$

Une telle procédure ne nécessite pas de faire le moindre calcul ou hypothèse sur la part quantitative de la réaction aux parois et des phénomènes de transfert, les paramètres γ et k_g disparaissant dans la différence.

Résultats et discussion

Les mesures ont été faites avec l'éthane et le propane dans les conditions suivantes:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$[H] \ll [C_2H_6, C_3H_8]$: condition de réaction de pseudo premier ordre.

$[C_2H_6, C_3H_8] \ll [H_2]$: condition nécessaire pour que la présence de l'alcane ne modifie pas sensiblement les propriétés de transport du milieu par rapport aux expériences faites sans alcane.

Les concentrations initiales en atomes d'hydrogène ont été ajustées en agissant sur la tension appliquée entre les deux électrodes de la décharge électrique de telle manière que les concentrations atomiques régnant dans la zone de mesure soient compatibles avec les limites de sensibilité de la sonde à oxyde mercurique (5×10^{-11} à 5×10^{-13} at-g cm^{-3}). Le fait que tous les phénomènes observés soient du premier ordre a rendu inutile la mesure précise des concentrations initiales absolues correspondant à chaque expérience.

Réaction avec l'éthane

On se propose de mesurer la constante de vitesse k_5 de la réaction:

$$[5] \qquad H + C_2H_6 \xrightarrow{k_5} H_2 + C_2H_5$$

La cinétique est suivie en observant la baisse de concentration des atomes H et il convient de tenir compte de réactions secondaires et en premier lieu de leur réaction de combinaison avec les radicaux C_2H_5 formés par [5]:

$$[6] \qquad H + C_2H_5 \xrightarrow{k_6} C_2H_6^*$$

Ce processus donne naissance à une molécule d'éthane dont l'excès d'énergie est suffisant pour rompre la liaison C—C:

$$[7] \qquad C_2H_6^* \xrightarrow{k_7} 2CH_3$$

Les radicaux méthyle ainsi formés réagissent à leur tour sur les atomes H pour former du méthane, seul produit effectivement détecté (7, 21):

$$[8] \qquad 2(CH_3 + H \xrightarrow{(M)\,k_8} CH_4)$$

On peut noter que les processus de cette séquence constituent les étapes essentielles consécutives à l'addition d'atomes H sur l'éthylène (22–26).

L'intégration numérique complète des équations de vitesse représentant les processus [5] à [8] a été menée sur ordinateur en prenant $k_5 = 1.29 \times 10^7$ cm^3 mol^{-1} s^{-1}; $k_6 = 3 \times 10^{13}$ cm^3 mol^{-1} s^{-1}; $k_7 = 3 \times 10^8$ s^{-1}; $k_8 = 3 \times 10^{13}$ cm^3 mol^{-1} s^{-1} et avec les conditions moyennes suivantes: concentration en atomes d'hydrogène à l'instant initial: 10^{-11} at-g cm^{-3}; pression totale: 300 Torr; titre en éthane: 4%; température: 300 K.

Sauf pour les tout premiers temps de réaction, la loi d'atteinte de l'état stationnaire pour les espèces intermédiaires peut être représentée avec une bonne approximation par une relation du type:

$$R_t = R_\infty(1 - e^{-300t})$$

R_t: concentration en espèce intermédiaire à un instant t; R_∞: concentration stationnaire.

En se fixant une borne $(R_\infty - R_t)/R_\infty < 0.1$, on trouve que ces conditions sont atteintes après 8×10^{-3} s, limite au delà de laquelle les expériences devront être effectuées. Dans ces conditions, le schéma cinétique proposé conduit à l'équation stoechiométrique:

$$[9] \qquad 4H + C_2H_6 = H_2 + 2CH_4$$

La constante apparente de pseudo premier ordre k_{app} mesurée dans nos conditions vaut alors

$$[10] \qquad k_{app} = 4k_5[C_2H_6]$$

Il ne faut pas exclure, à priori, la possibilité d'intervention de la réaction 11 inverse de [5]:

$$[11] \qquad H_2 + C_2H_5 \xrightarrow{k_{11}} H + C_2H_6$$

étant donné la valeur élevée du rapport $[H_2]/[H]$ prévalant dans nos expériences. En prenant les valeurs suivantes à 300 K: $[H_2] = 1.6 \times 10^{-5}$ mol cm^{-3} (300 Torr); $[C_2H_5] = 3 \times 10^{-13}$ mol cm^{-3} (valeur stationnaire donnée par l'intégration numérique); $[H] = 10^{-11}$ mol cm^{-3}; $[C_2H_6] = 6.4 \times 10^{-7}$ mol cm^{-3} (4% d'éthane); $k_5 = 1.29 \times 10^7$ cm^3 mol^{-1} s^{-1}; $k_{11} = 3.7 \times 10^2$ cm^3 mol^{-1} s^{-1} (20); le rapport des vitesses des processus [5] et [11] vaut:

$$\frac{k_5[H][C_2H_6]}{k_{11}[H_2][C_2H_5]} = 4.6 \times 10^4$$

Le processus [11] peut donc être parfaitement négligé.

Le tableau 1[2] donne pour quelques expériences typiques: la température, la nature de la paroi du réacteur, les valeurs de D et de $2R/\gamma\bar{C}$ obtenues dans la première étape sans éthane, les conditions de pression et de titre en éthane, la valeur de λ (argument de l'exponentielle de décroissance de concentration en atomes H mesuré expérimentalement le long de l'axe du réacteur en présence d'éthane) et la valeur de k_5 obtenue par optimisation. Figurent également dans le tableau, les moyennes des valeurs

[2]On peut obtenir la série complète des tableaux 1 et 2 à un prix nominal, en s'adressant au Depôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa (Ont.), Canada K1A 0S2.

For personal use only.

de k_5 obtenues à même température mais dans d'autres conditions de pression, de débit et de titre en éthane. La non dépendance des valeurs de k_5 avec le type de paroi est une preuve de la validité de la méthode de dépouillement utilisée (9), compte tenu des valeurs du rendement de recombinaison des atomes très différents dans chaque cas.

Dans un diagramme d'Arrhénius, la fig. 1 reproduit les valeurs de k_5 comparées aux résultats d'autres auteurs. Très peu de mesures ont été réalisées au voisinage de la température ambiante. Celles effectuées par Yang (27) nécessitaient une hypothèse sur la constante de vitesse de la réaction entre H et C_3H_6. Seuls les travaux de Berlie et Le Roy (7) (mesure des concentrations par sonde calorimétrique) et de Azatyan et coll. (4, 5) (technique rpe) ont été effectués en mesurant la variation de la concentration des atomes H. Ces auteurs ont opéré également en réacteur tubulaire mais sous des pressions telles (<4 Torr) que le régime piston pouvait être très valablement supposé (coefficient de diffusion élevé).

Si l'énergie d'activation proposée par Berlie et coll. (6.8 kcal mol^{-1}) apparaît trop faible compte tenu des valeurs généralement admises pour ce genre de réaction, l'accord entre les valeurs de Azatyan et coll. et celles du présent travail obtenues dans des conditions d'écoulement laminaire avec profil parabolique des vitesses est très satisfaisant compte tenu également des méthodes de dosage très différentes.

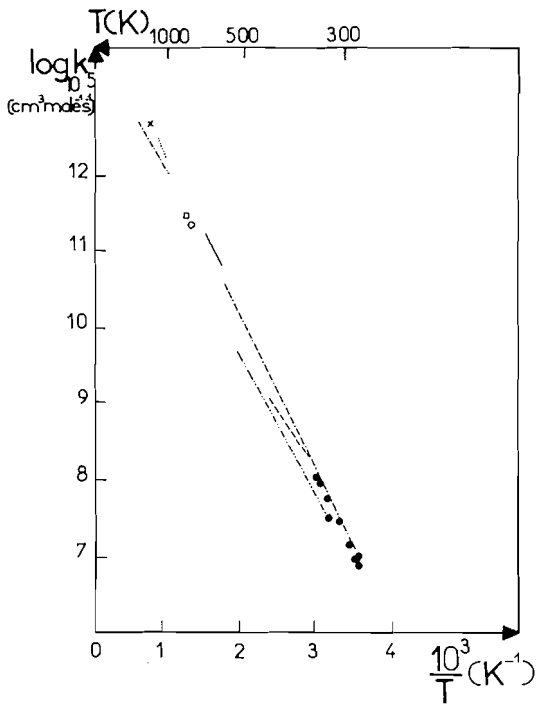

FIG. 1. Comparaison de la moyenne des valeurs de la constante de vitesse k_5 de la réaction $H + C_2H_6 \rightarrow H_2 + C_2H_5$ obtenues dans le présent travail ((●) réacteur tubulaire) avec celles publiées par d'autres auteurs: (---) réf. 5; (--) réf. 7; (-·-) réf. 22; (-·-·-) réf. 26; (□) réf. 27; (···) réf. 28; (—) réf. 29; (○) réf. 30; (×) réf. 31.

Cet accord indique en outre que le processus:

[12] $$C_2H_6^* + M \rightarrow C_2H_6 + M$$

concurrent de [7] et susceptible d'interrompre la séquence réactionnelle de consommation des H reste négligeable même sous les pressions assez fortes régnant dans nos conditions.

L'étude de la compétition entre les réactions 7 et 12 a été souvent abordée par les auteurs étudiant les réactions consécutives à l'acte d'addition des atomes H sur l'éthylène. Après stabilisation du radical éthyle formé par le processus $H + C_2H_4 \rightarrow C_2H_5^*$ les atomes restant peuvent en effet donner lieu aux réactions 6, 7, 8 et 12. Barker et coll. (24) citant les travaux de Rabinovitch et Setser (29) indiquent que le processus [12] est négligeable sous des pressions inférieures à 10 Torr de C_2H_4 pur, la production de radicaux CH_3 étant largement majoritaire. Michael et coll. (26) précisent que ce processus devient compétitif sous une pression voisine de une atmosphère en supposant une efficacité de collision égale à 1. Des conclusions comparables ont été également apportées par Kurylo et coll. (30). D'autres auteurs (2, 23) enfin envisagent directement le processus

$$H + C_2H_5 \rightarrow 2CH_3$$

Tous ces travaux indiquent que, dans nos conditions, le processus [12] peut être négligé devant [7] même en supposant que seuls les chocs sur d'autres molécules C_2H_6 sont à prendre en compte (pression partielle en alcane toujours inférieure à 10 Torr).

Il y a tout lieu de penser cependant que sous des pressions partielles d'éthane modérément plus élevées, [12] pourrait devenir compétitif, ce qui aurait pour conséquence d'arrêter la séquence réactionnelle après cette étape. Dans ce cas, la stoechiométrie de la réaction vis-à-vis des atomes H passerait de la valeur 4 à la valeur 2. Notre système expérimental capable de fonctionner sous des pressions élevées ne peut cependant se prêter directement à cette vérification. Les importantes concentrations d'éthane nécessaires auraient pour effet d'augmenter fortement la valeur de la constante apparente de pseudo premier ordre et le profil axial de concentration atomique deviendrait trop abrupt pour pouvoir être mesuré avec précision. Les mesures devraient également être faites à proximité de la zone de mélange où le régime d'écoulement laminaire stable n'est pas encore établi.

Il apparaît enfin tout à fait raisonnable de ne pas tenir compte d'un éventuel processus de désactivation des molécules $C_2H_6^*$ à la paroi. En effet, en

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

supposant les limitations diffusionnelles négligeables, la constante de temps $2R/\gamma\bar{C}$ de ce phénomène hétérogène vaut 3.3×10^{-5} s dans le cas extrême où $\gamma = 1$. Cette valeur est 10^3 fois supérieure à celle de la constante de temps du processus [7] proposée par Growcock et coll. (28).

La fig. 1 indique également que nos valeurs recoupent très bien celles obtenues dans le domaine des hautes températures (31–36) et en particulier celles publiées par Baldwin et coll. (32, 35).

Clark et Dove (37) ont proposé la relation:

$$k_5 = 10^{-3.27} T^{3.5} \exp\left(-\frac{5200}{RT}\right) (\text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1})$$

susceptible de rendre compte d'un éventuel écart au comportement "Arrhénius" de k_5 entre 300 et 1800 K. Cette relation rend bien compte des résultats des réfs 7, 31, 32, 35. Par contre, ceux de Azatyan et coll. (4, 5) ainsi que ceux du présent travail tendent à montrer que cette relation est trop sévère au voisinage de la température ambiante. La précision de l'ensemble de tous les résultats reproduits sur la fig. 1 semble interdire de pouvoir déceler expérimentalement un tel écart.

En prenant l'ensemble de toutes ces valeurs on obtient entre 281 et 1485 K l'estimation suivante:

$$k_5 = 10^{13.7 \pm 0.6} \exp -\left(\frac{9100 \pm 600}{RT}\right) \quad (\text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1})$$

Les marges d'erreur figurant dans cette relation sont relativement faibles compte tenu du large domaine de températures représenté et des méthodes expérimentales fort différentes utilisées par les divers auteurs.

Réaction avec le propane

On se propose de mesurer la constante de vitesse k_{13} de la réaction:

$$[13] \qquad H + C_3H_8 \xrightarrow{k_{13}} H_2 + C_3H_7$$

Ici encore la cinétique est étudiée en observant la vitesse de consommation des atomes d'hydrogène.

Ceux-ci donnent lieu à une séquence de processus radicalaires débutant par une combinaison d'un H et d'un radical C_3H_7 pour former une molécule de propane porteuse d'un excès d'énergie vibrationnelle:

$$[14] \qquad H + C_3H_7 \rightarrow C_3H_8^*$$

Cet excès d'énergie est suffisant pour rompre une liaison C—C avec formation de deux radicaux CH_3 et C_2H_5:

$$[15] \qquad C_3H_8^* \rightarrow CH_3 + C_2H_5$$

dont la combinaison avec d'autres atomes H conduit à une suite de réactions identiques à celles prévalant dans le cas de l'éthane: processus [6], [7] et [8].

Ce mécanisme consiste donc en un craquage de proche en proche de la chaine tricarbonée avec formation de méthane, seul produit important de la réaction qui ait été observé (8, 16).

L'intégration numérique complète des équations de vitesse représentant cette séquence réactionnelle n'a pas été menée compte tenu des temps de calculs nécessaires. Nous supposerons que l'ordre de grandeur des résultats obtenus avec l'éthane sont transposables au cas du propane.

Les conditions de l'état quasi stationnaire étant atteintes au bout d'un certain temps t en réacteur tubulaire, on peut se demander s'il en est de même dans un réacteur parfaitement agité fonctionnant sur un temps de passage $t_S = t$. La concentration en espèces intermédiaires R_a en réacteur agité est donnée par l'expression:

$$R_a = \int_0^\infty R_t \frac{1}{t_S} e^{-t/t_S}\, dt = R_\infty \frac{300 t_S}{1 + 300 t_S}$$

En se fixant une borne $(R_\infty - R_a)/R_\infty < 0.1$, on constate qu'il convient d'opérer avec des valeurs $t_S > 3 \times 10^{-2}$ s. On est donc en droit de baser nos calculs sur la relation stoechiométrique suivante:

$$[16] \qquad 6H + C_3H_8 = H_2 + 3CH_4$$

à condition d'opérer avec le réacteur tubulaire sur des temps de réaction supérieurs à 8×10^{-3} s et avec le réacteur agité sur des temps de passage supérieurs à 3×10^{-2} s.

La constante apparente de pseudo premier ordre k'_{app} mesurée dans nos conditions vaut alors:

$$k'_{app} = 6k_{13}[C_3H_8]$$

Le tableau 2^2 donne les résultats de quelques expériences typiques réalisées dans divers types de réacteurs et accompagnées des conditions expérimentales correspondantes. On retrouve à nouveau la non dépendance des valeurs de k_{13} avec le type de paroi de même qu'un accord très satisfaisant entre les mesures effectuées en réacteur tubulaire et agité. La fig. 2 permet de comparer ces résultats avec ceux publiés par d'autres auteurs.

La littérature est moins riche en valeurs de k_{13} que dans le cas de l'éthane, aucune mesure n'ayant semble-t-il été faite auparavant à température ambiante. Les valeurs proposées dans le présent travail sont compatibles avec celles issues des mesures assez indirectes de Yang (38) et en accord excellent avec celles, extrapolées, de Kazmi et coll. (8) obtenues dans des conditions semblables à celles de la réf. 7.

Cet accord indique en outre que les processus:

	Pyrex	271	184.33	0.60	8.53	4.08	1.75
	Pyrex	630	219.78	0.41	25.41	11.16	1.79
			Moyenne de 11 mesures différentes				1.46
			Valeurs extrêmes				0.92–1.95

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[17] $C_3H_8^* + M \rightarrow C_3H_8 + M$

[18] $C_3H_8^* + \text{paroi} \rightarrow C_3H_8 + \text{paroi}$

susceptibles ici encore d'interrompre la séquence réactionnelle de consommation des atomes d'hydrogène restent négligeables dans nos conditions.

Il convient de signaler que s'il en était ainsi, le coefficient stoechiométrique passerait de la valeur 6 à la valeur 2 et le facteur 3 ainsi introduit rendrait nos valeurs de k_{13} nettement incompatibles avec celles des autres auteurs (fig. 2) et en particulier Kazmi et coll. (8). D'un point de vue plus quantitatif on peut montrer que dans le cas du réacteur tubulaire, dans l'hypothèse où tous les chocs hétérogènes sont efficaces ($\gamma = 1$) et sans limitation diffusionnelle, la constante de temps du processus [18] vaut 2.7×10^{-5} s. Celle-ci est supérieure d'au moins une puissance de 10 à celle caractérisant le processus de décomposition [15] voisine, elle, de 2×10^{-6} s (43). Nos résultats indiquent par contre que l'efficacité de désactivation homogène par choc d'une molécule $C_3H_8^*$ serait inférieure à 2×10^{-2} (fréquence de collision sous 10 Torr voisine de 10^{-8} s) ce qui peut paraître assez faible.

Comme dans le cas de l'éthane, le domaine des basses températures se raccorde assez bien à celui des hautes températures où les travaux ont été plus nombreux (39–42), sans qu'il soit possible de pouvoir observer une éventuelle courbure dans la représentation d'Arrhénius de la constante k_{13}.

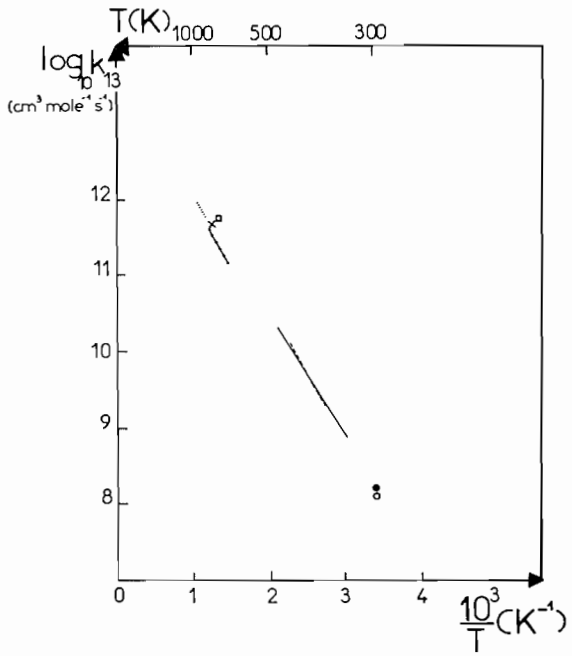

FIG. 2. Comparaison de la moyenne des valeurs de la constante de vitesse k_{13} de la réaction $H + C_3H_8 \rightarrow H_2 + C_3H_7$ obtenues dans le présent travail ((●) réacteur tubulaire; (○) réacteur agité) avec celles publiées par d'autres auteurs: (--) réf. 8; (—) ref. 38; (·–·–·) réf. 39; (×) réf. 40; (···) réf. 41; (□) réf. 42.

L'ensemble de ces valeurs permet de proposer entre 295 et 953 K l'estimation suivante:

$$k_{13} = 10^{13.8 \pm 0.3} \exp\left(-\frac{7800 \pm 100}{RT}\right) \times (\text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1})$$

Ici encore les marges d'erreur sont faibles compte tenu de la diversité des conditions opératoires prévalant dans les mesures effectuées par les divers auteurs.

Conclusion

Les travaux exposés dans cet article ont permis de montrer les points suivants:

Le réacteur tubulaire et le réacteur parfaitement agité peuvent être très valablement utilisés pour des études de cinétiques d'espèces très réactives même sous des pressions avoisinant l'atmosphère.

Les méthodes de dépouillement proposées permettent de mesurer des constantes de vitesse de réactions en phase gazeuse dans des conditions où ces processus homogènes sont concurrencés par des phénomènes hétérogènes, diffusionnels et hydrodynamiques.

L'utilisation de techniques de conception très simples et peu onéreuses a permis de déterminer les constantes de vitesse de réaction des atomes d'hydrogène sur l'éthane et le propane indépendamment du type de paroi utilisé. Les valeurs obtenues par d'autres auteurs sous des températures nettement plus élevées peuvent être extrapolées jusqu'au voisinage de la température ambiante par l'utilisation d'une simple loi d'Arrhénius.

Hydrothermal preparation of magnetite from iron chelates

MEINDERT BOOY AND THOMAS WILSON SWADDLE

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 24, 1977

MEINDERT BOOY and THOMAS WILSON SWADDLE. Can. J. Chem. **56**, 402 (1978).

The hydrothermal decomposition of iron(II) or iron(III) aminopolycarboxylate complexes can produce well-crystallized, stoichiometric Fe_3O_4. Best results were obtained when 0.1 *m* nitrilotriacetatoiron(III) was decomposed under N_2 in 0.2–0.4 *m* NaOH at 497 K for 70 h or more.

MEINDERT BOOY et THOMAS WILSON SWADDLE. Can. J. Chem. **56**, 402 (1978).

La décomposition hydrothermique de complexes aminopolycarboxylates de fer(II) ou de fer(III) peut conduire à du Fe_3O_4 bien cristallisé et stoechiométrique. On obtient les meilleurs résultats quand on décompose une solution de 0.1 *m* de nitrilotriacétatofer(III) sous une atmosphère d'azote en présence de NaOH 0.2–0.4 *m* à 497 K pour 70 h ou plus.

[Traduit par le journal]

The preparation of stoichiometric magnetite (Fe_3O_4) as reproducible, roughly monodisperse samples consisting of well-formed discrete crystals of size on the order of 1 μm to 1 mm is often desired, e.g., for dissolution studies in connection with corrosion phenomena but presents several difficulties. Preparative methods involving solid reactants, e.g., the oxidation of elemental iron by steam containing hydrogen (1), tend to give a sintered product, are usually slow, and leave room for doubt concerning the homogeneity and purity of the product. The latter problems persist in heterogeneous hydrothermal syntheses of Fe_3O_4 from metallic iron and hematite (α-Fe_2O_3) (2, 3) or from solid iron(II) hydroxide by the Schikorr reaction (4, 5).

$$[1] \qquad 3Fe(OH)_2 = Fe_3O_4 + 2H_2O + H_2$$

although hydrothermal methods can produce well-crystallized magnetite (2, 6, 7).

The hydrothermal syntheses of magnetite reported to date (2–7) require rather severe conditions and depend upon the maintenance of the correct redox potential, which can be difficult when done through the hydrogen pressure (6). We now report a hydrothermal synthesis in which magnetite is directly deposited at relatively low temperature and pressure from homogeneous alkaline solutions of decomposing iron chelates which maintain an appropriate reducing environment automatically (8).

Experimental

Analytical grade reagents were used throughout. Nitrilotriacetatoiron(III) monohydrate ($FeNTA \cdot H_2O$) was prepared as a yellow solid by boiling 20 g ammonium iron(III) sulfate 12-hydrate and 8 g nitrilotriacetic acid in 400 cm^3 water for 1 h; the precipitate was washed with water and dried in air overnight.

The hydrothermal reactions were carried out in capped PTFE liners in small autoclaves of type 316 stainless steel (free volume ~17 cm^3). For $FeNTA \cdot H_2O$, the solid was weighed into the liner and 10 cm^3 of the desired aqueous solution was added; in the other cases, the required amounts of iron(II) or iron(III) chloride or sulfate were mixed in solution with the chelating agent and sodium hydroxide. These operations and the closure of the autoclaves were in general carried out under nitrogen in a glove box. The autoclaves were heated in a forced convection oven (± 1 K) for the desired time then quenched in cold water and the precipitated solid was filtered, washed with water, and dried in a vacuum oven at ~380 K for 1 h.

Results

The hydrothermal decomposition of iron(II) or iron(III) chelates in the absence of oxygen under appropriate conditions of alkalinity, concentration, and temperature yielded well-formed octahedra of magnetite of size up to 0.1 mm. The effectiveness of various aminopolycarboxylate ligands in this respect, as gauged by the size and regularity of the magnetite crystals, was nitrilotriacetate > methyliminodiacetate > iminodiacetate ≫ ethylenedinitrilotetraacetate. Better results were obtained when the iron was present initially as *either* iron(II) *or* iron(III) than when as a mixture of these. When the iron was initially present as iron(III) reduction of part of this to iron(II) occurred as the organic ligand decomposed. The optimal initial molar ratio of iron(II) or iron(III) to chelating agent was 1:1, at a concentration of up to 0.2 *m*. A reaction temperature of at least 490 K for $Fe^{III}NTA^0$ (or 530 K for $Fe^{II}NTA^-$) was required and the longer the reaction time the larger were the crystals (reaction times of over 70 h were not tried), although the addition of unmounted seed crystals seemed not to facilitate the growth of large crystals significantly.

For $Fe^{III}NTA^0$, the size of the Fe_3O_4 crystals produced by hydrothermal decomposition was not significantly affected by the presence of NaCl (up to 4.0 *m*) or NH_4Cl (up to 0.5 *m*), or by the degree of filling of the vessel, but the presence of a platinum

For personal use only.

surface or of very high [NaOH] ($\gtrsim 1.3$ *m*) resulted in the formation of maghemite (γ-Fe_2O_3), presumably by facilitating direct decomposition of $Fe^{III}NTA^0$ without reduction of the iron ion. Insufficient NaOH (≤ 0.1 *m*, with [Fe^{III}NTA] = 0.1 *m*), however, led to the precipitation of the iron(II) compound $Fe_3(NTA)_2 \cdot H_2O$, at 497 K. The presence of O_2 produced hematite in various amounts together with Fe_3O_4.

The optimal conditions for magnetite preparation were found to be [Fe^{III}NTA] = 0.10 *m*, $0.20 \leq$ [NaOH] ≤ 0.40 *m*, under nitrogen at 497 K for 70 h or more; these give shining, well-formed, jet-black octahedra, 10–100 μm in diameter. These crystals can easily be freed from the surface of the liner, in 70% yield. The unit cell parameters, derived using a Debye-Scherrer X-ray diffraction camera and an internal silicon standard (9), were 839.71 ± 0.06 and 839.65 ± 0.04 pm for two independently-prepared samples of magnetite. These are not significantly different from the value of 839.67 pm derived from the 10 highest-angle reflections in the accepted X-ray diffraction data for stoichiometric magnetite (JCPDS file number 19-629), and correspond to a bulk composition of $Fe_{3.00\pm0.01}O_4$ at the 99.5% confidence level, or $Fe_{3.000\pm0.007}O_4$ at 95%, based on an assumed linear relationship between unit cell dimensions and composition for magnetite–maghemite solid solutions. Determination of the oxygen content of the same samples by thermogravimetry in a stream of hydrogen, though relatively imprecise, confirmed the validity of these analyses ($Fe_{3.01\pm0.05}O_4$) and the absence of significant amounts of substances other than magnetite. Analysis of samples with different degrees of crystallinity by flame emission spectrophotometry showed that the sodium ion content was less than 0.02%.

Discussion

The observation (5) that solid iron(II) hydroxide and 'green rusts' decompose to magnetite under hydrothermal conditions *at the solid–water interface* strongly suggests that the Schikorr reaction [1] proceeds by decomposition of *dissolved* $Fe(OH)_2$. It is therefore likely that the hydrothermal syntheses of magnetite described in this article proceed by a modified Schikorr reaction in which the supply of iron(II) hydroxide is strictly limited by the slow decomposition of the iron chelate in homogeneous solution, thereby leading to controlled and regular growth of magnetite crystals without the intermediate formation of solid iron(II) hydroxide or green rusts.

The decomposition of the organic ligand creates and helps maintain a mildly reducing environment (8), so that oxidation of the product to maghemite or a magnetite–maghemite solid solution is prevented. The relatively low specific surfaces of the magnetite crystals also help suppress oxidation; our attempts to produce stoichiometric Fe_3O_4 powders by hydrothermal ripening of aqueous suspensions of $Fe(OH)_2 + 2Fe(OH)_3$ at about 470 K (cf. hydrothermal ferrite syntheses (10, 11)) invariably produced black or chocolate-brown ferromagnetic powders intermediate in composition between Fe_3O_4 and γ-Fe_2O_3 when reasonable precautions were taken to exclude air, and pure γ-Fe_2O_3 when air was freely admitted. The BET surface areas of these latter powders were typically 100 $m^2\ g^{-1}$, as against 0.1 $m^2\ g^{-1}$ or less for magnetite made by alkaline hydrothermal decomposition of Fe^{III}NTA.

Aminocyclitols. 2,5-Dideoxystreptamine and derivatives

GERRY KAVADIAS,[1] STEPHAN VELKOF, and BERNARD BELLEAU

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received July 12, 1977

GERRY KAVADIAS, STEPHAN VELKOF, and BERNARD BELLEAU. Can. J. Chem. **56**, 404 (1978).

2,5-Dideoxystreptamine (**11**) was synthesized via the cyclic hydrazine intermediate **10**, itself obtained by reaction of the *cis*-1,4-diepoxycyclohexane (**7**) with hydrazine. Compound **11** was converted into *d,l*-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**12**) and the latter resolved into its optical isomers (1*N*-ethoxycarbonyl- and 3*N*-ethoxycarbonyl-2,5-dideoxystreptamines **16** and **14**). 1,6-*N,O*-carbonyl-3*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**1**) and 3,4-*N,O*-carbonyl-1*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**2**) were synthesized from **14** and **16** respectively. A practical process for the preparation of *cis*-1,4-diepoxycyclohexane is described.

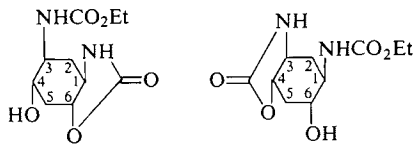
GERRY KAVADIAS, STEPHAN VELKOF et BERNARD BELLEAU. Can. J. Chem. **56**, 404 (1978).

On a synthétisé la didéoxy-2,5 streptamine (**11**) par l'intermédiaire de l'hydrazine cyclique **10** qui a elle même été obtenue par réaction du diépoxy-1,4 cyclohexane *cis* (**7**) avec de l'hydrazine. On a pu transformer le composé **11** en *d,l*-*N*-éthoxycarbonyle didéoxy-2,5 streptamine (**12**) et on a résolu ce dernier en isomères optiques (éthoxycarbonyl-1*N* et éthoxycarbonyl-3*N* didéoxy-2,5 streptamine **16** et **14**). Utilisant respectivement les composés **14** et **16** comme produits de départ, on a synthétisé le *N,O*-carbonyl-1,6 éthoxycarbonyl-3*N* didéoxy-2,5 streptamine (**1**) et le *N,O*-carbonyl-3,4 éthoxycarbonyl-1*N* didéoxy-2,5 streptamine (**2**). On décrit un procédé pratique pour la préparation du diépoxy-1,4 cyclohexane *cis*.

[Traduit par le journal]

In a research project directed at the synthesis of 5-deoxyaminoglycoside antibiotics (e.g. the 5-deoxykanamycins, gentamycins, and nebramycins) a properly protected, 2,5-dideoxystreptamine was required as the aglycon component. It became apparent that the protected 2,5-dideoxystreptamine should meet the following structural requirements: (*a*) all the functional groups except for one hydroxyl group should be protected. If both hydroxyls were free, the glycosidation reaction would yield a mixture of pseudodisaccharides (two diastereoisomers) and a symmetrical pseudotrisaccharide; and (*b*) the protected, 2,5-dideoxystreptamine should be resolved into its optical antipodes. If the *d,l* mixture were to be used, two diastereoisomeric pseudodisaccharides would be formed.

The carbamates **1** and **2** meet the above requirements since their functional groups are all protected except for their respective 4- and 6-OH, groups.[2] It is therefore possible to introduce one aminosugar either at the 4- or 6-position of the 2,5-dideoxystreptamine molecule. The position of attachment of the aminosugar is expected to be of importance for antibiotic activity, since in the aminoglycosides possessing a 2-deoxystreptamine entity, the positional isomers greatly differ in antibiotic activity. For example, 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine is biologically active whereas the 6-*O*-isomer is not (1). After glycosidation of the free OH in **1** or **2** the remaining OH can be deprotected and functionalized by another aminosugar.



1 **2**

The present paper describes the synthesis of **1** and **2** and provides evidence for their assigned structures.

The key intermediate in the present synthesis was *cis*-1,4-diepoxycyclohexane (**7**) and an easy access to this valuable intermediate will be described first. Craig *et al.* (2) have described the synthesis of **7** via the bromohydrin **4** by epoxidation followed by alkaline hydrolysis (Scheme 1). These authors have reported that bisepoxidation of 1,4-cyclohexadiene (**3**) with perbenzoic acid or monoperphthalic acid produced exclusively the *trans*-bisepoxide **8** whereas bisepoxidation with *m*-chloroperbenzoic or peracetic acids produced 2:1 mixtures of *trans*- and *cis*-bisepoxides, respectively. They further reported that the *cis*-bisepoxide **7** could not be separated from the mixture owing to its tendency to form a 1:1 crystalline complex with the *trans*-isomer. Initially, we adopted the above process for the synthesis of **7** and several modifications and improvements were introduced. Reaction of 1,4-cyclohexadiene with *N*-

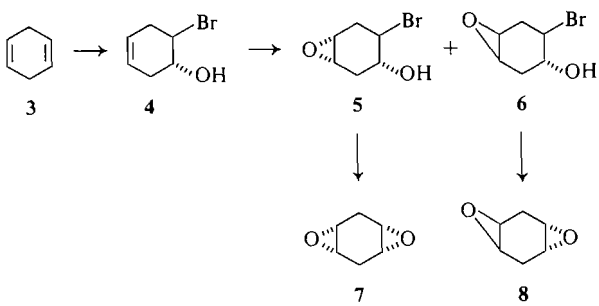

SCHEME 1

bromosuccinimide (NBS) in water produced the bromohydrin **4** in yields ranging from 65 to 88% depending on the source of NBS. However, reproducible yields of 85–88% were obtained when recrystallized NBS was used (3). Epoxidation of compound **4** with *m*-chloroperbenzoic acid produced a mixture of the epoxybromohydrins **5** and **6** in high yield (90%) and the isomer ratio was the same when monoperphthalic acid (2) was used. The ratio of **5** to **6** was slightly dependent on the reaction temperature. Thus, at 0 and 25°C the ratios of **5** to **6** were 85:15 and 75:25, respectively. The *cis*-bromohydrin **5** was separated from the mixture as previously described and several recrystallizations were necessary for the pure product to be obtained. Treatment of **5** with base produced the bisepoxide **7**.

Bisepoxidation of 1,4-cyclohexadiene with *m*-chloroperbenzoic acid turned out to be the most convenient method for the synthesis of the *cis*-bisepoxide **7**. It led to a mixture of the bisepoxides **7** and **8** (90%) where, contrary to the previous report (2), the *cis*-bisepoxide **7** was the predominant isomer (70%). The ratio of **7** to **8** varied slightly with the reaction temperature. At 0 and 25°C the ratio was 70:30 and 63:37 respectively. Separation of the *cis*-bisepoxide **7** from the mixture was easily effected by liquid–liquid extraction. Isomers **7** and **8** exhibited markedly different solubilities in water and in organic solvents. As would be expected on the basis of their dipole moments (2) (compound **7**, 3.3 D; **8**, 0.0 D), the *trans*-isomer **8** had a substantially higher partition coefficient than the *cis*-isomer **7** in ether–water and petroleum ether – water systems. Extraction of an aqueous solution of **7** and **8** with ether or continuous extraction with petroleum ether selectively removed the *trans*-bisepoxide **8** leaving the *cis*-isomer in the aqueous phase. The latter was then extracted with an organic solvent.

A most promising potential route for the synthesis of 2,5-dideoxystreptamine (**11**) involves the reaction of *cis*-bisepoxide **7** with hydrazine to form **10** followed by hydrogenolysis. (Scheme 2). It was anticipated that one epoxide ring in **7** would initially open diaxially to give **9** through attack by a hydrazine molecule and that subsequently the second epoxide ring of the latter would suffer intramolecular attack by the hydrazino group at position 3 rather than 4 as would be required by the rule of diaxial opening. Indeed, reaction of **7** with hydrazine in ethanol produced the 1,3-hydrazino compound **10** in 84.5% yield. Hydrogenation of **10** in aqueous acetic acid in the presence of a palladium catalyst (11) afforded the acetate salt of **11** in 78% yield. The free base **11** was obtained simply by treatment with an anion exchange resin. The structure of **11** was confirmed by nmr spectroscopy. The nmr spectrum of the hydrochloride salt of **11** showed a two-proton double triplet at δ 3.78 with spacings of 4.5 and 11.0 Hz which were assigned to the magnetically equivalent H-4 and H-6. It also showed a two-proton double triplet at δ 3.25 with spacings of 4.5 and 11.0 Hz which were assigned to H-1 and H-3. Thus, all the substituents in **11** are equatorially oriented as expected. After completion of our work, two reports appeared in the literature describing the synthesis

of **11** by similar methods (4, 5). However, the preparation of key dissymmetric intermediates was not reported. This gap was filled as follows: reaction of 2,5-dideoxystreptamine (**11**) with 1 mol of ethylchloroformate in aqueous methanol, in the absence of base, produced a mixture of the monocarbethoxy compound **12** (53%) and the biscarbethoxy derivative **13** (23%) from which **12** was easily separated. Obviously, the liberated hydrogen chloride in the mono acylation reaction effectively protects the second amino group against acylation. In the presence of a base the reaction yielded mainly the biscarbethoxy compound **13** as expected.

The monocarbethoxy compound **12** was resolved into the optical isomers **14** and **16** via the 2-nitrotartranilate salts. Treatment of a solution of **12** with $\frac{1}{2}$ mol of (−)-2-nitrotartranilic acid (6) gave a tartranilate salt ($[\alpha]_D$ −43.4) from which the free base **14** ($[\alpha]_D$ +37.3) was generated by treatment with an anion exchange resin. Treatment of the mother liquors with (+)-2-nitrotartranilic acid (6) yielded a salt ($[\alpha]_D$ +43.3) from which the free base **16** ($[\alpha]_D$ −37.6) was generated as above.

The configurations of 3-*N*-ethoxycarbonyl- and 1-*N*-ethoxycarbonyl-2,5-dideoxystreptamines (**14** and **16**) were established by determination of their respective $\Delta[M]$ values in tetramine copper(II) sulfate solutions (TACu) (7). The dextrorotary isomer had a $\Delta[M]$TACu of +600, thus indicating a positive projected angle between the adjacent amino and hydroxyl groups (7, 8). On that basis absolute configuration **14** is assigned to this isomer. The other isomer had a $\Delta[M]$TACu of −550 and is thus assigned configuration **16**. The magnitudes of the $\Delta[M]$TACu values for **14** and **16** are lower than would be expected (7) (~900) and this might be due to partial conversion of **14** and **16** to the corresponding optically inactive 1,3-cyclic ureas in the tetramine copper sulfate solutions.

The conversion of **14** and **16** to the corresponding cyclic carbamates **1** and **2** respectively, was carried out by the general procedure of Umezawa *et al.* (9) as applied to the conversion of 1,2-*trans*-di-equatorial amino alcohols to cyclic carbamates. Thus, reaction of **14** with phenylchloroformate in aqueous acetone in the presence of sodium bicarbonate afforded crystalline **15** in 91% yield. Treatment of the latter with triethylamine in aqueous acetone gave carbamate **1** in high yield (92%). When, however, a solution of **15** in aqueous acetone was treated with a strong anion-exchange resin (9) the yield of **1** was appreciably lower (~60%) because of partial hydrolysis of **1** to **14** under these conditions.

Application of the same sequence of reactions to **16** led to carbamate **2** in high yield.

The structures of **1** and **2** were verified by elemental analysis and spectroscopic determinations. Furthermore, when **1** and **2** were treated with a catalytic amount of sodium ethoxide in ethanol the cyclic carbamate functions suffered opening (9) to give the optically inactive 1,3-*N*,*N*′-diethoxycarbonyl-2,5-dideoxystreptamine (**13**).

Experimental

The melting points were determined on a Mel-Temp melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin-Elmer Model 141 polarimeter. Nuclear magnetic resonance spectra were taken with a Varian A-60A spectrometer. Tetramethylsilane (for solution other than deuterium oxide) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (for the solutions of deuterium oxide) were used as internal standards. Thin-layer chromatography (tlc) was carried out on microscope slides coated with silica gel, and the spots were visualized with perchloric acid.

Preparation of Starting Materials

trans-*4-Hydroxy-5-bromocyclohexene (4)*

This compound was prepared by reaction of 1,4-cyclohexadiene with an equimolar amount of *N*-bromosuccinimide (NBS) by the procedure described by Craig *et al* (2). Compound **4** was obtained in reproducibly high yields of 85–88% when recrystallized (3) NBS was used. The yields varied from 65–88% when unpurified NBS from various suppliers was used; bp 109–110°C/15 Torr. (lit. (2) bp 109–110°C/15 Torr).

cis-*4,5-Epoxy*-trans-*2-bromocyclohexanol (5)*

To a stirred suspension of 49.0 g (240 mmol) *m*-chloroperbenzoic acid (Aldrich, technical grade, 85% pure) in methylene chloride (200 ml) previously cooled to 0°C, was added dropwise with stirring a solution of 41.0 g of **4** in methylene chloride (100 ml) at a rate to maintain the solution temperature at 0–2°C. After the addition (15 min), stirring in the cold was continued for 4 h and the mixture stored at 0°C overnight. The reaction mixture was filtered and the solids were washed with methylene chloride (2 × 60 ml). The combined filtrates and washings were washed with 20% aqueous sodium sulfite (100 ml) and then with 8% aqueous sodium bicarbonate (2 × 100 ml). The washings were combined and back-extracted with methylene chloride (2 × 100 ml); these extracts were combined with the first methylene chloride extract and after drying (Na_2SO_4) the solvent was removed under reduced pressure to give 41.0 g (92.5%) of a mixture of the epoxybromohydrins **5** and **6** as an oil. The proportions of the two isomers in the mixture were determined as follows. A sample was treated with aqueous sodium hydroxide and converted to a mixture of the bisepoxides **7** and **8**. The latter mixture was analyzed by nmr and found to contain 85% of the *cis*-bisepoxide **7** and 15% of the *trans*-isomer **8**, thus establishing that the bromohydrin mixture contained 85% of the *cis*-isomer **5** and 15% of the *trans*-isomer **6**.

The crude product was dissolved in ether (60 ml), diluted with hexane (40 ml) and allowed to crystallize first at room temperature and then at 0°C to give 26 g of **5**, mp 51–54°C. Recrystallization from the same solvent system gave 19.0 g, mp 53–58°C. Two additional recrystallizations raised the mp to 58–60°C (lit. (2) mp 55–56°C).

In another experiment where the epoxidation was carried out at 25°C, the ratio of **5** to **6**, determined as above, was 75:25.

cis-*4,8-Dioxatricyclo*[*5.1.0.0*^{3,5}]*octane (7)* (cis-*1,4-diepoxycyclohexane, by Epoxidation of 1,4-Cyclohexadiene with* m-*Chloroperbenzoic Acid*

To a stirred suspension of 335 g of *m*-chloroperbenzoic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(Aldrich, 85% pure) in methylene chloride (1.6 ℓ), previously cooled to 0°C, was added dropwise a solution of 64.2 g (800 mmol) of 1,4-cyclohexadiene (Aldrich, 97% purity) in methylene chloride (170 ml) at a rate to maintain the solution temperature at 0–2°C. After completion of the addition (1 h), stirring at 0°C was continued for 8 h and the mixture kept at room temperature overnight (16 h). The mixture was filtered and the cake was washed with methylene chloride (2 × 150 ml). The combined filtrates and washings were rigorously stirred with 20% aqueous sodium sulfite solution (100 ml), at room temperature for 1 h, to decompose the excess peracid. The organic phase was separated and the aqueous phase was extracted with methylene chloride until tlc (silica, ether) indicated complete recovery (8 × 50 ml). All the methylene chloride extracts were combined and stirred with powdered calcium hydroxide (10) (100 g) to remove *m*-chlorobenzoic acid. The mixture was filtered and the solids washed with methylene chloride. After combining the filtrates and washings, the solvent was removed *in vacuo* at 40°C to give 85.0 g (95%) of a liquid that slowly crystallized. Thin-layer chromatography (silica, ether) showed two components with respective R_F values of 0.10 (*cis*-isomer **7**) and 0.50 (*trans*-isomer **8**). The nmr spectrum indicated that the ratio of **7** to **8** was 70:30. When the epoxidation was carried out at 25°C, the ratio was 63:37.

Separation of the Two Epoxides

Method A—The crude product (85.0 g) was dissolved in warm water (100 ml) and the solution filtered to remove some insoluble matter (2.5 g). This material seemed to be calcium *m*-chloroperbenzoate (only aromatic protons in the nmr spectrum; it gave a slow iodine test, it exploded when heated, it left a residue after burning and was insoluble in ethanol). The aqueous solution was placed in a separatory funnel and extracted with an equal volume of ether (100 ml). The ether phase was transferred to a second funnel containing water (100 ml) and after shaking, the ether-phase was removed. This process was repeated 10 times (10 × 100 ml). The combined ether extracts were dried and evaporated to dryness (at 40°C) to give 22.5 g of solids which contained about 80% *trans*-bisepoxide **8** and 20% *cis*-bisepoxide **7** as ascertained by nmr. Two recrystallizations from ethanol (20 ml) gave 14.5 g (17% based on 1,4-cyclohexadiene) of **8**, mp 108–109°C (lit. (2) mp 106.5–107.5°C); nmr ($CDCl_3$), δ 2.26 (b s, 4H, $2CH_2$) 2.96 (b s, 4H, 4 epoxide hydrogens). The mother liquors yielded 8.0 g of a syrup after evaporation of the solvent. This syrup was recycled. The aqueous phases from the two funnels were combined (200 ml), sodium chloride was added, followed by extraction with 70 ml portions of methylene chloride until tlc of the aqueous phase showed complete removal of **7** (10 extractions). The methylene chloride extracts were combined, dried and evaporated to dryness at 40°C to give 52.5 g solid material shown by nmr to contain 92% *cis*-bisepoxide **7** and 8% of the *trans*-isomer **8**. This mixture could be used without further purification in the next step. When pure **7** was required, the crude product was dissolved in boiling petroleum ether (bp 90–120°C) (750 ml), ether (50 ml) was added and the product allowed to crystallize first at room temperature and then at 0°C to give 38.5 g of **7**, mp 59–60°C (lit. (2) mp 60–61°C); nmr ($CDCl_3$) δ 2.50 (b q, 4H, J= 17 Hz, 2—CH_2—) and 3.09 (b s, 4H, 4 epoxide hydrogens). The mother liquors were evaporated to dryness (40°C) and the residue dissolved in 250 ml of boiling petroleum ether, the solution diluted with 50 ml ether and the product allowed to crystallize as above to give an additional 6.5 g of **7**, mp 59–60°C. The two crops were combined to give a total of 45.0 g (52% based on **3**). The mother liquors were kept for recycling. This method was quite effective for the separation of as much as 350 g of a mixture of **7** and **8**.

Method B—The crude mixture of solid epoxidation product (43.0 g) was dissolved in water (200 ml) and the solution filtered to remove insoluble matter (see above). The p*H* of the aqueous solution was adjusted to 7.0 with sodium bicarbonate and extracted continuously with petroleum ether (bp 39–47°C). The progress of the extraction was followed by tlc (silica, ether) of the aqueous and the organic phases and was continued until all or most of the *trans*-isomer **8** was removed. After 16 h the petroleum ether solution was evaporated to dryness to give 15.5 g solid material shown by nmr to be a mixture of *trans*- and *cis*-epoxides in a ratio of 60:40. Fresh petroleum ether was added and extraction continued for an additional 4 h. The extract was dried and evaporated to leave 1.3 g of a residue shown by nmr to consist of a mixture of *trans*- and *cis*-epoxide in a ratio of 22:78. The solid material from the first extract (15.5 g) was recrystallized twice from ethanol (2 ml/g) to give 8.0 g of **8**, mp 108–109°C. The mother liquor was kept for recycling. The aqueous phase was extracted continuously with ether for 48 h (or repeatedly with methylene chloride as in method A above). The extracts, after drying and evaporation yielded 22.0 g of solid material shown by nmr to consist of 95–98% *cis*-bisepoxide **7** and 2–5% *trans*-isomer. This material was used as such in the next reaction with hydrazine. When pure **7** was required, it was recrystallized as described above in method A. In another run, 350 g of a mixture of **7** and **8** was effectively fractionated by the above process.

*6,7-Diazabicyclo[3.2.1]octane-(2S,4R)-2,4-diol (**10**)*

A solution of 17.2 g (153.5 mmol) of the *cis*-epoxide **7** and 6.6 g (206 mmol) anhydrous hydrazine in dry EtOH (100 ml) was refluxed under nitrogen. After 1 h, a crystalline precipitate appeared. The progress of the reaction was followed by tlc (silica, 5% EtOH in ether). After 12 h, the spot corresponding to **7** (R_F 0.40) had disappeared and a new spot with R_F 0 (**10**) had appeared. After boiling for 17 h, the reaction mixture was cooled in ice. The crystalline product was collected, washed with ether (25 ml), and dried to give 17.5 g of **10** (79.5%) mp 180–190°C (dec.). The mother liquors were evaporated to dryness. Ethanol (35 ml) was added to the residue and the solution left in the refrigerator overnight. The crystalline precipitate, collected by filtration, consisted of 1.0 g of **10**; mp 180–190°C (dec.). The combined yield amounted to 18.5 g (84.5%). The analytical sample was obtained by recrystallization from ethanol, mp 185–190°C (dec.). *Anal.* calcd. for $C_{16}H_{12}N_2O_2$: C 49.97, H 8.38, N 19.42; found: C 50.16, H 8.54, N 19.17.

The yield of **10** was not affected when hydrazine hydrate was used. Crystalline **10** was also obtained when crude **7** (containing 5–8% of *trans*-isomer **8**) was used.

*2,5-Dideoxystreptamine (**11**)*

A solution of 17.7 g (122.5 mmol) of compound **10** in a mixture of glacial acetic acid – water (1:1, 100 ml) and 2.0 g of 10% Pd/C was shaken under hydrogen in a Parr apparatus at 60°C and an initial pressure of 50 psi. When uptake had ceased (7 h), the mixture was cooled to room temperature and filtered. The catalyst was washed with acetic acid and the washings and filtrate combined. The solution was colorless in the beginning but it turned brown on evaporation and exposure to the atmosphere. The acetic acid was removed by evaporation and the solid residue was stirred with 100 ml of boiling ethanol. After cooling to room temperature, the mixture was filtered and the solid washed with ice-cold ethanol and dried to give 20.0 g of the acetate salt of **11**, mp 205–207°C (dec.), (darkens at 185°C). Evaporation of the mother liquor, left a residue which was treated with 30 ml ethanol as above to give an additional 3.0 g of the acetate salt of **11**. The combined crops weighed 27.0 g (78%). The mother liquor, after evaporation gave 5.5 g of a dark brown sticky residue. *Anal.*

calcd. for $C_{10}H_{22}N_2O_6 \cdot H_2O$: C 42.24, H 8.51, N 9.85; found: C 43.14, H 8.64, N 10.00.

The acetate salt (27.0 g) was dissolved in water (75 ml) and the solution passed through a column containing 220 g of Rexyn 201 (Fisher Scientific Co., strongly basic resin, OH form) and the column washed with water (600 ml). The effluent was evaporated to dryness to give in quantitative yield the amine **11**, mp 173–180°C (darkens at 165°C). A sample of 2.7 g was recrystallized from water (2.0 ml) – ethanol (25 ml) to give 1.95 g, mp 182-183°C (monohydrate) and resolidifies to melt at 198–199°C. *Anal.* calcd. for $C_6H_{14}N_2O_2 \cdot H_2O$: C 43.88, H 9.82, N 17.06; found: C 43.91, H 9.95, N 17.13.

The hydrochloride salt of **11** had mp >350°C; nmr (D_2O), δ: 3.78 (d of t, 2, H-4 and H-6, J = 11 and 4.5 Hz) 3.25 (d of t, 2, H-1 and H-3, J = 11 and 4.5 Hz).

d,l-N-*Ethoxycarbonyl-2,5-dideoxystreptamine* (*12*)

A solution of 54.0 g (329 mmol) of 2,5-dideoxystreptamine (**11**) in 270 ml water was diluted with 180 ml of methanol and cooled in an ice-bath while stirring. Ethylchloroformate (37.4 g or 345 mmol) was added dropwise and at a rate to maintain the solution temperature at 4–6°C. After completion of the addition (45 min), stirring was continued for 1 h at 4–6°C and then at room temperature for an additional h. The solvent was removed by evaporation at 55–60°C and the traces of water removed by coevaporation with ethanol (3 × 100 ml). The partly solid residue consisted of a mixture of the hydrochloride of **12**, the *bis*-hydrochloride of **11** and the *bis*-carbamate **13**. A sample was basified and examined by tlc (silica, 10% MeOH – ethyl acetate): two spots with R_F 0.34 (**13**) and 0 (**11** and **12**) were observed.

The crude product was treated while stirring with boiling dry ethanol for 5–10 min, the mixture cooled to room temperature, the insoluble *bis*-hydrochloride of **11** removed by filtration and the solid washed with hot ethanol (2 × 50 ml) to give a mass weighing 14.0 g. The combined filtrate and washings were evaporated to dryness, the sticky residue dissolved in water and the solution extracted continuously with ethyl acetate until all the biscarbethoxy compound **13** was removed (48 h). The ethyl acetate extract was evaporated to dryness to give 21.7 g (22.8%) of crystalline **13**, mp 204–205°C. *Anal.* calcd. for $C_{12}H_{22}N_2O_6$: C 49.64, H 7.64, N 9.65; found: C 49.58, H 7.70, N 9.61.

The aqueous phase containing mainly the hydrochloride of **12** and some salt of **11** was decolorized with charcoal, evaporated to dryness and the traces of water removed by coevaporation with ethanol (3 × 100 ml). The sticky residue was dissolved in boiling ethanol (200 ml) and after cooling to room temperature the solution was diluted with ether (100 ml) while cooling in ice. The precipitated bishydrochloride of **11** was removed by filtration (2.5 g) and the filtrate evaporated to dryness to give 43.1 g (52%) of the hydrochloride of **12** as a brittle foam.

Regeneration of ***12*** *from the Hydrochloride Salt*

Some Rexyn 201 resin (220 g) was packed into a column and washed with 6% NaOH (1.5 ℓ) to generate the hydroxide form. It was then washed with distilled water until the effluent was neutral. The size of the column bed was 37.5 cm × 3.5 cm id. A solution of 35.0 g (137.5 mmol) of the hydrochloride of **12** in 50 ml water was poured onto the column and the column subsequently washed with distilled water at a rate of 1.5 ℓ/h. A fast elution was important since prolonged contact with the resin resulted in conversion of **12** to 1,3-cyclic urea. The first 175 ml of the effluent was neutral and discarded. The following 400 ml had a pH > 7.0 and was evaporated to dryness (at 40–45°C) to give 28.8 g (96%) of crystalline **12**. Thin-layer chromatography (silica, 10% water in ethanol, iodine as developer) showed one spot with R_F 0.29 and a faint spot with R_F 0. This material was thus pure enough for purposes of resolution into its optical isomers, A sample of 1.0 g was recrystallized from ethanol (2 ml) – ether (4 ml) and gave 0.7 g of an analytical sample, mp 132–134°C. *Anal.* calcd. for $C_9H_{18}N_2O_4$: C 49.51, H 8.31, N 12.83; found: C 49.34, H 8.35, N 12.80.

*l-*N*-Ethoxycarbonyl-2,5-dideoxystreptamine* (***16***) *and 3-*N*-Ethoxycarbonyl-2,5-dideoxystreptamine* (***14***) *by Resolution of* d,l-N-*Ethoxycarbonyl-2,5-dideoxystreptamine* (***12***)

A warm solution of 20.0 g (91.5 mmol) of **12** in 95% ethanol–water (100 ml) was added to a warm solution of 12.38 g (45.8 mmol) (−)-2-nitrotartranilic acid (6) in the same solvent (100 ml) and crystallization allowed to take place at room temperature. In some experiments the crystalline precipitate was mixed with a jelly-like solid. In such cases, the mixture was heated to selectively dissolve the jelly and the solution allowed to stand at room temperature overnight. The crystalline salt was collected, washed with absolute ethanol (40 ml) and dried to give 19.2 g (86%) of the nitrotartranilate salt of **14** mp 195–199°C (dec.) $[\alpha]_D^{25}$ −45.4 (*c* 1.0, H_2O). The rotation indicated an optical purity of 94%. A sample was dissolved in a boiling water – ethanol mixture (1 : 1), (3 ml/g), the solution diluted with absolute ethanol (13.4 ml/g) and the product allowed to crystallize at room temperature. Two more recrystallizations from the same solvent system afforded the analytical sample mp 207–209°C, $[\alpha]_D^{25}$ −43.4 (*c* 1.0, H_2O). *Anal.* calcd. for $C_{19}H_{28}N_4O_{11}$: C 46.71, H 5.77, N 11.50; found: C 46.50, H 5.84, N 11.52.

The mother liquors containing the other optical isomer mainly as the free base were evaporated to dryness at 40°C and the residue dissolved in 35 ml of water. Rexyn 201 resin (OH form, 15 ml) was added, the mixture shaken for 2–3 min and filtered. The resin was washed with water (2 × 10 ml) and the combined filtrate and washings evaporated to dryness at 40°C to give 10.2 g of a solid residue. This was dissolved in 95% EtOH–H_2O (90 ml) and the solution added to a warm solution of 10.8 g (40 mmol) (+)-2-nitrotartranilic acid (6) in the same solvent (90 ml). The product was allowed to crystallize at room temperature overnight and was then collected, washed with dry EtOH (40 ml) and dried to give 17.4 g of the nitrotartranilate salt of **16**, mp 207–208°C (dec.) $[\alpha]_D^{25}$ + 43.36(*c* 1.0, H_2O). Two recrystallizations from 90% EtOH–water did not alter the mp or the rotation. *Anal.* calcd. for $C_{19}H_{28}N_4O_{11}$: C 46.71, H 5.77, N 11.50; found: C 47.06, H 5.84, N 11.51.

Free Bases ***14*** *and* ***16*** *from their 2-Nitrotartranilate salts Compound* ***16***

A column of 3.4 cm id was packed with Rexyn 201 resin (200 g) and the resin washed with 6% sodium hydroxide (1.5 ℓ) followed by distilled water until the effluent was neutral. A solution of 44.0 g (90 mmol) of the dextrorotary salt of **16** ($[\alpha]_D^{25}$ +43.3) in 70 ml of water (initially warmed to facilitate dissolution) was poured onto the column followed by washing with water at a rate of 3 ℓ/h. A fast elution of the product is very important at this stage because at slow elution rates, the effluent was colored yellow owing to decomposition of the 2-nitrotartranilic acid by the resin. Also, prolonged contact with the resin resulted in formation of the 1,3-cyclic urea. The first 200 ml of effluent was neutral and was discarded. The next 600 ml (pH > 7.0) of effluent containing the desired material was quickly evaporated to dryness at 40–45°C (receiver cooled in an ice-ethanol mixture). Evaporation at higher temperatures and prolonged heating favored urea formation. To the syrupy residue was added ethanol which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

after evaporation, gave 18.2 g (93%) of crystalline **16**. A sample was recrystallized from ethanol–ether (1:10); mp 154–156°C, $[\alpha]_D^{25}$ −37.6 (*c* 1.0, H_2O). $\Delta[M]$TACu −550.

*Compound **14***

A solution of 33.0 g (67.5 mmol) of the levorotary salt ($[\alpha]_D^{25}$ −43.7) in 70 ml of water was processed as described above to yield 14.6 (99%) of compound **14**; mp 154–156°C (ethanol–ether), $[\alpha]_D^{25}$ +37.3 (*c* 1.0, H_2O); $\Delta[M]$TACu +600.

1-N-*Ethoxycarbonyl-3*-N-*phenoxycarbonyl-2,5-dideoxystreptamine (**17**)*

To a solution of 8.44 g (38.6 mmol) of **16** and 3.70 g (44 mmol) of sodium bicarbonate in water (40 ml) was added 40 ml acetone and the mixture cooled in an ice-bath while stirring. Phenylchloroformate (6.73 g or 43 mmol) was added dropwise (over 10 min), the mixture stirred in the cold for 1 h and then diluted with water (80 ml). The precipitate was collected, washed with water (2 × 30 ml) and dried in a vacuum desiccator to give 10.6 g of **17**. From the filtrate, after concentration *in vacuo* to ¼ of the volume and addition of water (50 ml), an additional 0.9 g of **17** was obtained to give a total of 11.5 g (88.5%); mp 136–141°C; $[\alpha]_D^{25}$ +6.0 (*c* 1.0, EtOH).

*3*N-*Ethoxycarbonyl-1*N-*phenoxycarbonyl-2,5-dideoxystreptamine (**15**)*

Reaction of **14** (13.55 g, 62 mmol) with phenylchloroformate by the procedure described above gave 19.18 g (91.5%) of **15**; mp 135–140°C; $[\alpha]_D^{25}$ −6.7 (*c* 1.0, ethanol).

3,4-N,O-*Carbonyl-1*-N-*ethoxycarbonyl-2,5-dideoxystreptamine (**2**)*

A suspension of 11.2 g (33.2 mmol) of **17** in 90% acetone–water (90 ml) containing 2.4 ml triethylamine was stirred at room temperature until dissolution (45 min). After stirring for 5 h, 20 ml of Dowex 50W-X4 resin (H^+ form) previously washed with water and acetone was added and the mixture stirred for 3 min (to remove the triethylamine). The resin was removed by filtration and the filtrate evaporated to dryness (40–45°C). The crystalline residue was stirred for 10 min with acetone (15 ml), the mixture diluted with ether (50 ml), the solid collected, washed with ether and dried under vacuum at 65°C overnight to give 7.5 g (92.5%) of **2**; mp 203–205°C, $[\alpha]_D^{25}$ −58.5 (*c* 1.0, H_2O). *Anal.* calcd. for $C_{10}H_{16}N_2O_5$: C 49.17, H 6.60, N 11.47; found: C 48.84, H 6.48, N 11.64.

1,6-N,O-*Carbonyl-3*-N-*ethoxycarbonyl-2,5-dideoxystreptamine (**1**)*

Compound **15**, (18.85 g or 55.7 mmol) was treated with triethylamine (4.0 ml) as described above to give 12.6 g (92.5%) of **1**; mp 203–205°C; $[\alpha]_D^{25}$ +57.5 (*c* 1.0, H_2O). *Anal.* calcd. for $C_{12}H_{16}N_2O_5$: C 49.17, H 6.60, N 11.47; found: C 49.13, H 6.71, N 11.47.

The α-alkoxycarbonylation of saturated carbonyl compounds. The synthesis of 17α-hydroxymethyl 20-keto steroids[1,2]

D. MUKHERJEE[3] AND CH. R. ENGEL

Department of Chemistry, Laval University, Quebec, P.Q., Canada G1K 7P4

Received July 26, 1977

D. MUKHERJEE and CH. R. ENGEL. Can. J. Chem. **56**, 410 (1978).

It is shown that enolate ions, in particular lithium enolates obtained from enol acetates of saturated ketones by reaction with methyllithium, may not only be alkylated and carboxylated, but also alkoxycarbonylated (in position α to the original saturated keto group). By this method, saturated 20-keto steroids were transformed into 17α-methoxycarbonyl 20-ketones. Thus, from pregnenolone, 17-methoxycarbonylpregnenolone was prepared and was then converted to 17-hydroxymethylprogesterone and to some of its esters. This method for preparing 17-hydroxymethylated hormone analogues of the progesterone-corticoid group is simpler and more efficient than the pathway implying a free-radical functionalization of a 17α-methyl group.

D. MUKHERJEE et CH. R. ENGEL. Can. J. Chem. **56**, 410 (1978).

Des ions énolate, en particulier des énolates de lithium, obtenus par réaction d'acétates d'énols de cétones saturées avec du méthyllithium, peuvent non seulement être alkylés et carboxylés mais aussi alkoxycarbonylés, en position α par rapport à la fonction carbonyle saturée originale. Par cette méthode des 20-céto stéroïdes ont été transformés en 20-cétones 17α-méthoxycarbonylées. Nous avons préparé, à l'aide de cette réaction, à partir de la pregnénolone, la 17-méthoxycarbonylpregnénolone qui fut convertie en 17-hydroxyméthylprogestérone et en certains de ses esters. Cette méthode de préparation d'analogues d'hormones 17-hydroxyméthylés du groupe progestéro-corticoïde est plus simple et plus efficace que celle impliquant une fonctionnalisation radicalaire d'un groupe 17α-méthyle.

Recently (1) we reported the first synthesis of 17-hydroxymethyl- and 17-acetoxymethylprogesterone (**9** and **9***a*). The novel 17α-substituent had been arrived at (1, 5) by functionalization of the 17α-methyl group of a 17α-methyl 12α-hydroxy etio ester (**4**), by a photolytic Barton transfer reaction (cf. refs. 6, 7) on its 12-nitrite (**4***a*), the 17-methyl etio ester having been prepared from a 17-bromo 20-ketone (**1***c*) with the help of a Favorsky rearrangement (5*b*, 8) (sequence **1***b* → **1***c* → **4** → **4***a* → **7** → **8** → **9** in Scheme 1). While the yields in the various steps of this synthesis had been, with the exception of the moderate result of the Barton reaction, very satisfactory, the overall pathway was lengthy and not entirely rewarding since a 21-methyl 20-ketone had to be transformed into a 17-methyl etianate, the 20-ester function of which had to be reconverted at a later stage to a 21-methyl 20-keto side chain. Furthermore, the 12-hydroxy group, necessary for the transfer reaction, had to be removed after having served its purpose and, finally, the starting material, 3α,12α-diacetoxy-5β-pregnan-20-one (**1***b*), is not readily available anymore.

Under the circumstances an alternate pathway to 17-hydroxymethyl derivatives of steroid hormones of the progesterone-corticoid group seemed desirable. An attractive approach towards the direct introduction of a 17α-substituent into 20-keto steroids appeared to consist of their α-alkoxycarbonylation, since this should open the way not only to 17-alkoxycarbonyl and 17-carboxy derivatives but also to 17-hydroxymethylated products.

For the realization of this objective, the use of enolate ions seemed promising. Deghenghi and colleagues (9) and, independently, Weiss and coworkers (10) have shown that enolate ions generated by metal hydride reduction from 16-unsaturated 20-ketones, according to a general method described by Stork *et al.* (11), or from 17-hydroxy, 17-acetoxy, or 17-bromo 20-ketones (10), could be alkylated in position 17α. Stork *et al.* (11) also showed that lithium enolates generated from α,β-unsaturated ketones could be carboxylated with solid carbon dioxide. On the other hand, it is known (12) that enolate ions may be formed readily from saturated ketones by treatment of the corresponding enol acetates with alkyllithium or Grignard reagents, in aprotic, polar solvents. Since 16,17-saturated 20-keto steroids are in general readily available, sometimes

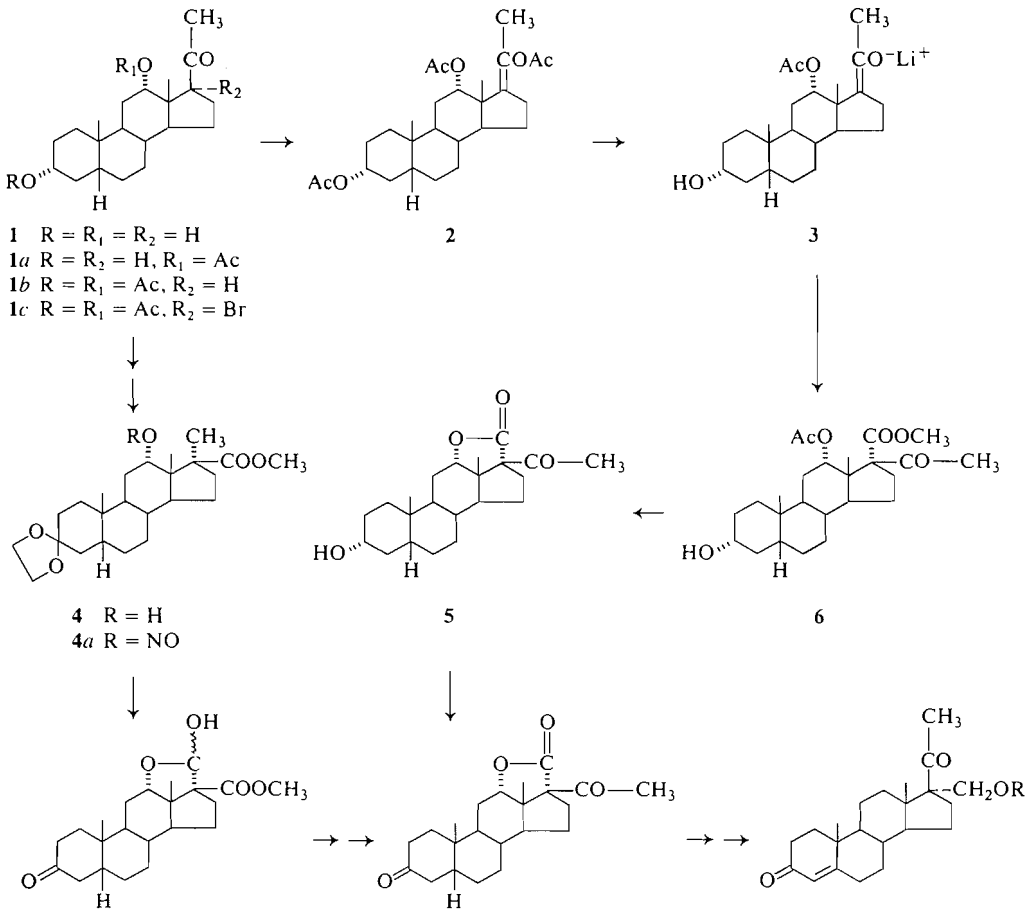

SCHEME 1

more readily than the corresponding 16-unsaturated derivatives, and since they are easily converted to 17-en-20-ol acetates (13, 14), we decided to attempt the transformation of unconjugated 20-keto steroids into lithium 17,20-enolates and to explore the alkoxycarbonylation of such enolate ions; finally, in the case of success, to investigate the conversion of the resulting 17-alkoxycarbonyl 20-ketones to 17α-hydroxymethylated 20-keto steroids (cf. Schemes 1 and 2).

In a preliminary experiment (Scheme 1), we wished not only to establish the feasibility of a 17α-alkoxycarbonylation of an unconjugated 20-keto steroid but also its stereochemical course, by choosing a substrate which would lead to a product already obtained, sterically unequivocally, with the help of the Barton transfer reaction (see above). We therefore transformed 3α,12α-diacetoxy-5β-pregnan-20-one (**1***b*) with acetic anhydride and *p*-toluenesulfonic acid into the *cis*/*trans* mixture of its 17,20-enol acetates (**2**) (15), which we subjected to the action of methyllithium in dimethoxyethane at 5°C. The resulting mixture of lithium enolates (**3**) was treated in its original solution with dimethyl carbonate. The product contained, apart from partly hydrolyzed starting material (**1***a*), the crude 3-hydroxy 17α-methoxycarbonyl 20-ketone **6**. Without purification, the material was saponified with methanolic potassium hydroxide at reflux temperature; ether extraction of the alkaline solution afforded the hydrolyzed starting material **1**. Acidification of the remaining aqueous product led to the hydroxy lactone **5** which was immediately oxidized with Jones' reagent (16) to the 3-oxo 12α-hydroxy 17α-acetyl 17β-etianic acid lactone (20 → 12) (**8**) which we had previously prepared (1) by functionalization of a 17α-methyl group. Thus, the feasibility of α-alkoxycarbonylations of lithium enolates, formed from 16,17-saturated 20-ketones, was demonstrated and the stereochemistry of this reaction, which proceeded, as expected, from the less hindered side, was established. In this preliminary experiment we

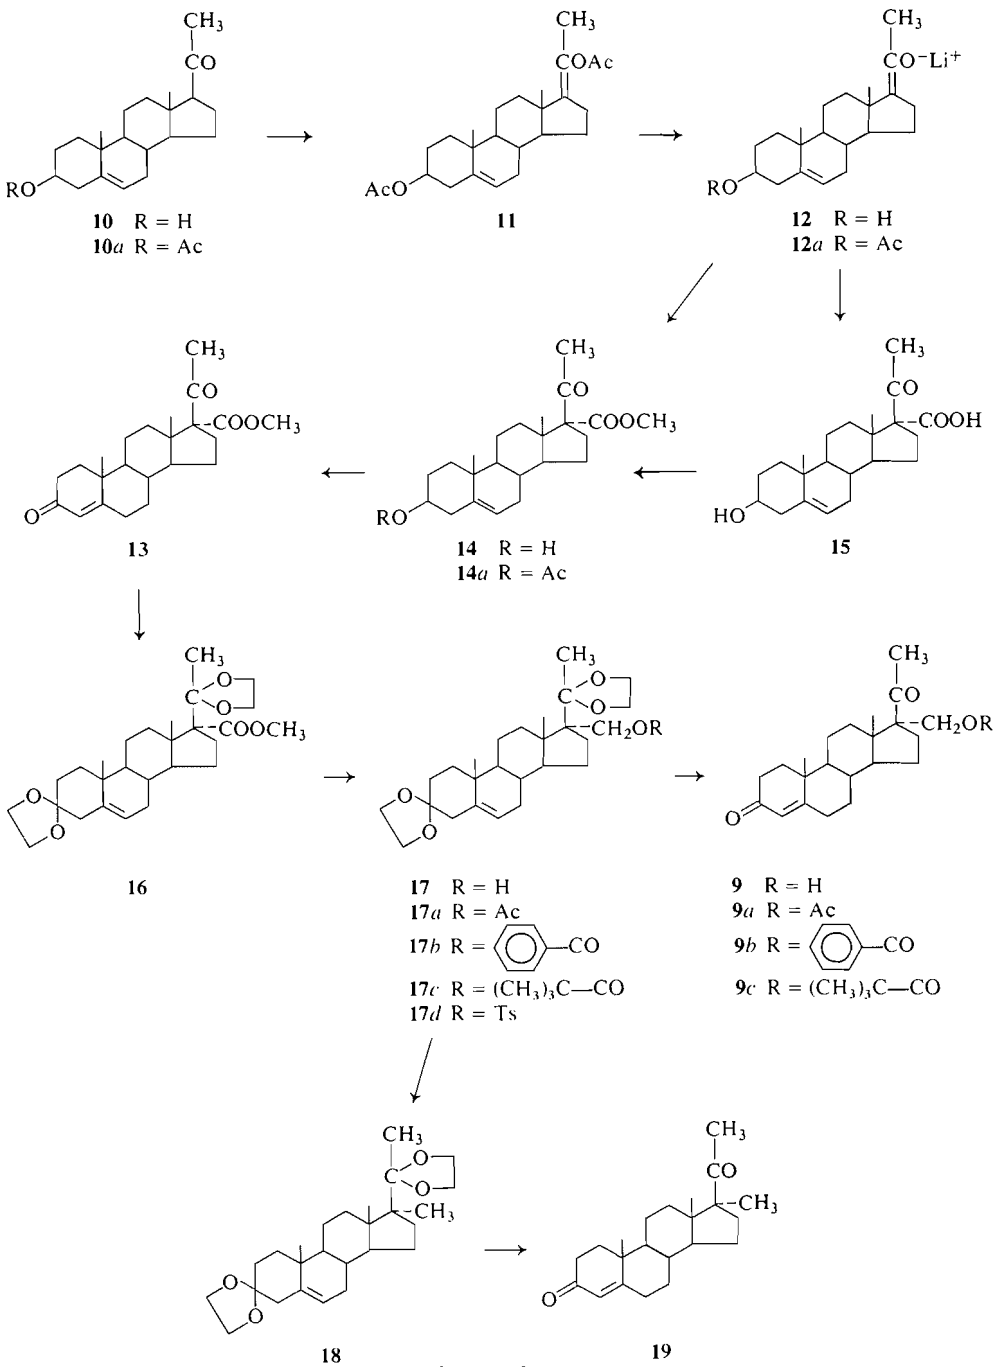

SCHEME 2

did not attempt to isolate the intermediates and to optimize the yields.

We now applied this method of α-alkoxycarbonylation of a saturated ketone to the synthesis of 17-hydroxymethylprogesterone (**9**) and some of its esters (Scheme 2). The very readily available pregnenolone **10** was transformed with acetic anhydride and *p*-toluenesulfonic acid into the *cis*/*trans* mixture of its enol acetates (**11**) (13, 14, 17) which was treated, as described above, in dimethoxyethane with methyllithium. The resulting mixture of lithium enolates (**12** and **12***a*) was subjected, as described above, to the action of dimethyl carbonate. By crystallization, 17-methoxycarbonyl pregnenolone acetate (**14***a*) was isolated. From the mother liquors, the 3-hydrolyzed product (**14**) was obtained. Ace-

tylation of the mother liquors gave the acetylated starting material, pregnenolone acetate (**10***a*). Considering this recovery of starting material, the yield of the acetoxy methyl ester **14***a* amounted to 53%, that of the hydroxy methyl ester **14** to 4.5%. The acetate of ester **14***a* could be selectively hydrolyzed with potassium bicarbonate in aqueous methanol in approximately 95% yield to the hydroxy methyl ester **14**. When the crude mixture obtained upon methoxycarbonylation of the lithium enolates was directly treated with potassium bicarbonate in aqueous methanol, the yield of the 3-hydroxy 17-methoxycarbonyl pregnenolone **14**, from pregnenolone (**1**), was raised to 60% (taking into account the recovery of starting material).

Alternatively, the 3-hydroxy 17-methoxycarbonyl 20-ketone **14** was obtained by carboxylation of the mixture of the lithium enolates **12** and **12***a*, by treatment with solid carbon dioxide, under the conditions described by Stork *et al.* (11*b*). From the ether extract of the resulting product the starting material **10** was isolated. Acidification of the remaining aqueous solution led to the 17-carboxy derivative **15** which was methylated with diazomethane. The resulting 3-hydroxy ester **14** was thus obtained in a yield of 63% from pregnenolone (**10**), considering the recovery of starting material.

The transformation of 17-methoxycarbonylpregnenolone (**14**) into 17-hydroxymethylprogesterone (**9**) was now performed by well-established methods. Jones' oxidation (16), followed by treatment with hydrochloric acid (see also ref. 18), gave in 85% yield the pure 4-unsaturated 3,20-diketo ester **13**, also obtained in 80% yield by Oppenauer oxidation with cyclohexanone and aluminum *tert*-butoxide. The keto functions were protected (in 88% yield) by ketalization with ethylene glycol and *p*-toluenesulfonic acid and the 17-methoxycarbonyl diketal **16** was reduced in 90% yield with lithium aluminum hydride to the 17-hydroxymethyl diketal **17**, which was transformed, again in 90% yield, with acetone and *p*-toluenesulfonic acid, into 17-hydroxymethylprogesterone (**9**). Alternatively, the 17-hydroxymethyl diketal **17** was acetylated to its acetate **17***a* whose ketal groups were removed, as just described, in 99% yield. The hydrolysis with potassium carbonate of the resulting 17-acetoxymethylprogesterone (**9***a*) to 17-hydroxymethylprogesterone (**9**) has already been described (1). This product (**9**), as well as its acetate **9***a*, proved in every respect identical with the products previously synthesized from 3α,12α-diacetoxy-5β-pregnane 20-one (**1***b*) (1).

We have already reported (1) that 17-hydroxymethylprogesterone (**9**) and its acetate **9***a* showed, unexpectedly, no appreciable progestational activity in the Clauberg–McPhail test (19). It seemed possible that the primary acetate group of 17-acetoxymethylprogesterone (**9***a*) would be hydrolyzed in vivo and that the free 17-hydroxymethylprogesterone (**9**) lacked noteworthy progestational activity because of the conformation of the 17β-methyl ketone side chain which, as a result of hydrogen bonding between the 20-carbonyl group and the 17^1-hydroxyl group, should differ from that of the biologically active progesterones (cf. ref. 20). We therefore prepared less readily hydrolyzable esters of 17-hydroxymethylprogesterone (**9**), namely the benzoate (**9***b*) and the pivalate (**9***c*). For that purpose the 17-hydroxymethyl diketal **17** was transformed, on one hand with benzoyl chloride and pyridine into the benzoate **17***b* and, on the other hand, with trimethylacetyl chloride in pyridine to the pivalate **17***c*. The benzoate **9***b* and pivalate **9***c* of 17-hydroxymethylprogesterone (**9**) were obtained in high yields by exchange reactions with acetone and *p*-toluenesulfonic acid. Both the benzoate **9***b* and the pivalate **9***c* now proved, even at high dose levels, progestationally practically inactive in the Clauberg–McPhail test. Since the hydrolysis of these ester groups, especially of the trimethylacetate group, under physiological conditions, seems unlikely, one has to rule out that the progestational inactivity of 17-hydroxymethylprogesterone and its esters is due to hydrogen bonding in the unesterified product (**9**), and thus to the particular side chain conformation of this hormone analogue. Under the circumstances, we wished to prove once more and by a direct method the 17β-configuration of the methyl ketone side chain of 17-hydroxymethylprogesterone (**9**) and its esters. We therefore prepared (in 85% yield) the tosylate **17***d*, and reduced it with lithium aluminum hydride to the 17α-methyl diketal **18** which we transformed with acetone and *p*-toluenesulfonic acid into the well-known and progestationally very active 17α-methylprogesterone (**19**) (17). This sequence of reactions confirmed the configuration in position 17 of 17-hydroxymethylprogesterone (**9**) and its esters. These products thus represent the first progesterone analogues with bulky 17α-substituents which exhibit no appreciable progestational activity.

From a chemical point of view, the experiments reported demonstrate that saturated ketones may not only be carboxylated, but also, and readily, alkoxycarbonylated by reaction, with dialkyl carbonates, of their lithium enolates, prepared from their enol acetates. One thus disposes of another, simple, route to a variety of α-substituted ketones.

Experimental

The melting points were taken in evacuated capillaries and the temperatures were corrected. For elution chromatography, neutral aluminum oxide Woelm, activity III, and Davison's

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

silica gel no. 923 were employed, unless otherwise stated. Dry-column chromatography was performed with Woelm dry-column chromatography silica gel, activity III; thin-layer chromatography with Merck-Darmstadt silica gel. The ir spectra were recorded on Beckman IR-4 and IR-12 spectrophotometers, and the uv spectra on a Beckman DK-1A instrument. The nmr spectra were taken at 60 and 90 MHz on Varian A-60 and Brucker HFX-90 spectrometers, tetramethylsilane serving as internal standard and deuteriochloroform as solvent. The microanalyses were performed by the late Dr. F. Pascher, Bonn, Germany, and by Ayerst Laboratories, Montreal (under the direction of Dr. G. Schilling).[4]

(Z)- and (E)-3α,12α,20-Triacetoxy-5β-pregn-17-enes (2)

To a solution of 30 g of 3α,12α-diacetoxy-5β-pregnan-20-one (**1***b*), mp 139–141°C, in 1.5 ℓ of absolute acetic anhydride, 8.43 g of *p*-toluenesulfonic acid was added. The solution was heated and the solvent was then slowly distilled during 8 h. The volume was further reduced to approximately 100 ml by distillation *in vacuo*. The reaction mixture was cooled and extracted with ether. The ethereal solution was washed with water, a saturated sodium bicarbonate solution, again with water, and was dried over sodium sulfate. Removal of the solvent gave 36.5 g of a dark-brown semicrystalline product which was chromatographed on 1 kg of aluminum oxide. Petroleum ether – benzene (9:1 and 4:1) eluted 26.9 g (82%) of a crystalline mixture of the enol acetates **2**, mp 160–166°C. Recrystallization from ether–hexane raised the mp to 172–174°C. A sample was recrystallized twice from ether–hexane for analysis; mp 172–174°C; $[\alpha]_D^{26}$ +160.7° (*c* 1.000, $CHCl_3$); ν_{max} (KBr):1735 and 1250 cm^{-1} (acetates); δ (90 MHz): 0.95 (s, 3H, 19-CH_3), 0.98 (s, 3H, 18-CH_3), 1.8 (s, 3H, 21-CH_3), 2.06 (s, 6H, 3,12-$OCOCH_3$), 2.10 (s, 3H, 20-$OCOCH_3$). *Anal.* calcd. for $C_{27}H_{40}O_6$: C 70.40, H 8.75; found: C 70.59, H 8.61.

3-Oxo-12α-hydroxy-17β-acetyl-5β,17α-etianic Acid Lactone (20 → 12) (8)

The solvent was removed from 20 ml of a 1.5 *M* ethereal methyllithium solution and the residue was taken up in 30 ml of absolute dimethoxyethane. A few crystals of triphenylmethane were added and the mixture was cooled to 5°C. To this solution was added, dropwise and with stirring, a solution of 2 g of the above-described mixture of the enol acetates **2**, mp 160–166°C, in 50 ml of absolute dimethoxyethane, until the red colour was almost completely discharged, 40 ml of the enol acetate solution having been consumed. To this product, 5 ml of dimethyl carbonate in 20 ml of absolute dimethoxyethane was added and, after 5 min, the reaction mixture was carefully acidified, in the cold, with 2 *N* hydrochloric acid, to the Congo-blue reaction. Subsequently, the mixture was poured into ice water, the precipitate was extracted with ether, and the ethereal solution was washed with water and was dried over sodium sulfate. Evaporation of the solvent provided 1.65 g of a yellow foam, representing a mixture containing partially hydrolyzed starting material, *3α-hydroxy-12α-acetoxy-5β-pregnan-20-one* (**1***a*), and crude *methyl 3α-hydroxy-12α-acetoxy-17β-acetyl-5β,17α-etianate* (**6**); ν_{max} (KBr): 3440–3420 (OH), 1750–1740 (esters), 1705 (ketone), 1270 and 1250 cm^{-1} (methyl ester and acetate). The product was treated without purification with 75 ml of a 6.8% methanolic potassium hydroxide solution, for 4 h at reflux temperature. After cooling, the solution was poured onto ice, the precipitate was extracted with ether, the ethereal solution was washed with water, and was dried over sodium sulfate. Evaporation of the solvent provided 923 mg of the 'neutral fraction'. The aqueous alkaline solution remaining after the extraction, together with the first washings of the 'neutral fraction', were acidified with 2 *N* sulfuric acid to the Congo-blue reaction. The mixture was extracted with ether and the ethereal layer was washed with water and was dried over sodium sulfate. Evaporation of the solvent gave 230 mg of the 'acid fraction',[5] a yellow foam, representing crude *3α,12α-dihydroxy-17β-acetyl-5β,17α-etianic acid lactone (20 → 12)* (**5**); ν_{max} (KBr): 3400 (OH), 1775 (lactone), 1705 cm^{-1} (ketone).

The 'neutral fraction' was acetylated with 2 ml of acetic anhydride in 4 ml of pyridine at reflux temperature, for 1.5 h. The usual work-up gave 1.2 g of an amorphous product which was chromatographed on 36 g of aluminum oxide. Petroleum ether – benzene (4:1 and 1:1) eluted 723 mg of *3α,12α-diacetoxy-5β-pregnan-20-one* (**1***b*), mp 126–128°C. The identity of the product was established by the determination of a mixture melting point and by the comparison of its infrared spectrum with that of an authentic sample.

The 'acid fraction' was dissolved in 10 ml of absolute acetone and was treated at 0°C with 0.4 ml of Jones' reagent (16). The product was stirred for 5 min. The usual work-up gave 228 mg of a partly crystalline product which was chromatographed on 8 g of aluminum oxide. Elutions with petroleum ether – benzene (4:1) gave 130 mg of *3-oxo-12α-hydroxy-17β-acetyl-5β,17α-etianic acid lactone (20 → 12)* (**8**), mp 176–180°C. The identity of the product was established by the determination of a mixture melting point and by the comparison of its infrared and nmr spectra with those of an authentic sample (1).

3β-Acetoxy-17-methoxycarbonyl-5-pregnen-20-one (14a) and 3β-Hydroxy-17-methoxycarbonyl-5-pregnen-20-one (14)

According to the procedure of Fieser and Huang-Minlon (14), 50 g of pregnenolone (**10**), mp 182–187°C, was transformed with 2.5 ℓ of acetic anhydride and 13.9 g of *p*-toluenesulfonic acid into 62.3 g of a crude mixture of the (*Z*)- and (*E*)-*3β,20-diacetoxy-5,17-pregnadienes* (**11**), presenting itself as a dark-brown semi-crystalline product. Filtration through 1.5 kg of aluminum oxide (eluent: petroleum ether – benzene (1:1)) gave 49.8 g of a purified, crystalline, product, mp 137–143°C; ν_{max} (KBr):1750 (enol acetates), 1730 (3-acetate), 1250 and 1230 cm^{-1} (acetates); δ (90 MHz): 0.82 and 1.00 (s's, 18- and 19-CH_3), 1.85 (s, 3H, 21-CH_3), 2.00 (s, 3H, 3-acetate), 2.15 (s, 3H, 20-acetates), 5.40 (m, 1H, 6-H).

From 27 ml of a 1.5 *M* ethereal methyllithium solution, the solvent was removed *in vacuo* under slight nitrogen pressure. The residue was dissolved in 40 ml of absolute dimethoxyethane at 5°C, the solution was treated with 10 mg of triphenylmethane and there was added, dropwise and with stirring, a solution of 4 g of the above-described mixture of the enol acetates **11**, mp 137–143°C, in 100 ml of absolute dimethoxyethane. When 90 ml of the enol acetate solution had been used, the red colour almost disappeared. The addition was interrupted and the reaction mixture was treated with a solution of 0.9 ml of dimethyl carbonate in 3 ml of dimethoxyethane. After 5 min the product was poured into cold 2 *N* hydrochloric acid, the precipitate was extracted with ether, and the ethereal solution was washed with water and was dried over sodium sulfate. Removal of the solvent gave 3.53 g of a foam which crystallized upon addition of a few drops of ether. Recrystallization from dichloromethane–methanol

[4]We pay tribute to Dr. Pascher and express our sincere appreciation to the management and staff of the analytical laboratories.

[5]The name 'acid fraction' merely indicates its origin, not its acidity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

afforded 1.05 g (30% yield) of *3β-acetoxy-17-methoxycarbonyl-5-pregnen-20-one* (**14***a*), mp 178–181°C. A sample was recrystallized twice from dichloromethane–methanol for analysis; colourless, fine plates, mp 182–184°C; $[\alpha]_D^{23}$ +45° (*c* 1.000, $CHCl_3$); ν_{max} (KBr): 1745 (acetate), 1735 (methyl ester), 1705 (ketone), 1250 cm^{-1} (acetate); δ (90 MHz): 0.70 and 0.98 (s's, 6H, 18- and 19-CH_3), 2.12 (s, 3-acetate), 2.18 (s, $COCH_3$), 3.70 (s, $OCOCH_3$), 4.42 (m, 3α-H), 5.40 (t, 6-H). *Anal.* calcd. for $C_{25}H_{36}O_5$: C 72.08, H 8.71; found: C 71.98, H 8.87.

The mother liquors of the crystallization were taken to dryness and chromatographed on 60 g of aluminum oxide. Elutions with benzene gave 93 mg (2.5%) of *3α-hydroxy-17-methoxycarbonyl-5-pregnen-20-one* (**14**), mp 221–223°C. A sample was recrystallized twice from methanol for analysis; colourless needles, mp 221–223°C; $[\alpha]_D^{23}$ +63° (*c* 1.000, $CHCl_3$); ν_{max} (KBr):3500 (OH), 1735 (methyl ester), 1700 cm^{-1} (ketone); δ (90 MHz):0.71 and 0.98 (s's, 6H, 18- and 19-CH_3), 2.18 (s, 3H, $COCH_3$), 3.70 (s, 3H, $OCOCH_3$), 5.40 (t, 6-H). *Anal.* calcd. for $C_{23}H_{34}O_4$: C 73.76, H 9.15; found: C 73.75, H 9.23.

The other eluates were acetylated in 6 ml of pyridine with 3 ml of acetic anhydride at reflux temperature for 45 min. The usual work-up gave 2.78 g of a product which, upon crystallization from ether–hexane, afforded 1.43 g (44%) of acetylated starting material, *pregnenolone acetate* (**10***a*), mp 149–151°C, identified by the determination of a mixture melting point and by comparison of its infrared spectrum with that of an authentic sample. Considering the recovery of starting material, the yield of 3β-acetoxy-17-methoxycarbonyl-5-pregnen-20-one (**14***a*) amounted to 53%, that of 3β-hydroxy-17-methoxycarbonyl-5-pregnen-20-one (**14**) to 4.5%.

Partial Hydrolysis of 3β-Acetoxy-17-methoxycarbonyl-5-pregnen-20-one (14a)

To a solution of 800 mg of the acetoxy keto ester **14***a*, mp 178–181°C, in 200 ml of methanol, a solution of 230 mg of potassium bicarbonate in 10 ml of water and 25 ml of methanol was added. The mixture was stirred at room temperature and the course of the reaction was followed by tlc analysis. After 5 days, no starting material was left and the solution was poured into ice water. The precipitate was extracted with ether, the ethereal solution was washed with water, and was dried over sodium sulfate. Evaporation of the solvent provided 697 mg (94% yield) of *3β-hydroxy-17-methoxycarbonyl-5-pregnen-20-one* (**14**), mp 218–221°C. Recrystallization from methanol afforded 610 mg of the same product, melting at 221–223°C. The material was found identical, by the determination of a mixture melting point and by the comparison of the infrared and nmr spectra, with that described in the previous section.

3β-Hydroxy-17-methoxycarbonyl-5-pregnen-20-one (14) from the Enol Acetates 11 without Isolation of 3β-Acetoxy-17-methoxycarbonyl-5-pregnen-20-one (14a)

Ether was removed *in vacuo* from 140 ml of a 0.7 *M* methyllithium solution. The residue was dissolved in 200 ml of absolute dimethoxyethane and a solution of 10 g of the mixture of enol acetates **11**, mp 137–143°C, in 250 ml of absolute dimethoxyethane was added dropwise, with vigorous stirring, at 0°C, 2,2′-bipyridyl serving as indicator. The red colour was almost discharged when 200 ml of the solution (corresponding to 8 g of the enol acetates) had been consumed. The addition was stopped, and the mixture was treated with 1.5 ml of dimethyl carbonate in 10 ml of dimethoxyethane. After 5 min of stirring at 0°C, 200 ml of a 20% ammonium chloride solution was added. The product was extracted with ether, the ethereal solution was washed with water and was dried over sodium sulfate. Removal of the solvents gave 6.49 g of a brown foam (ν_{max} (KBr): 3540 (sharp) and 3400 (br) (OH), 1735 (esters), 1708 (ketone), 1250 (esters); δ (60 MHz): 0.7 and 0.82 (18-CH_3), 1.05 (s, 19-CH_3), 2.18 and 2.20 (s's, $COCH_3$), 3.73 (s, $COOCH_3$), 5.40 (m, 5-H)). This product was dissolved without purification in 250 ml of methanol and a solution of 1 g of potassium bicarbonate in 40 ml of water and 100 ml of methanol was added. The mixture was left at room temperature for 22 h and then poured into cold water. The product was extracted with ether, the ethereal layer was washed with water, and was dried over sodium sulfate. Removal of the solvents gave 6.28 g of a semisolid product which was chromatographed on 150 g of aluminum oxide, activity IV. Petroleum ether – benzene mixtures (1:1 and 1:4) eluted 2.25 g (30%) of *17-methoxycarbonylpregnenolone* (**14**), mp 216–220°C; benzene–ether (1:1) and pure ether eluted 3.2 g of *pregnenolone* (**10**) (50.5% yield). The identities of the products were established in the usual fashion. Considering the recovery of pregnenolone (**10**), the yield of 17-methoxycarbonylpregnenolone (**14**) amounted to 60%.

3β-Hydroxy-17α-methoxycarbonyl-5-pregnen-20-one (14) from the Lithium Enolates 12 and 12a by Carboxylation and Subsequent Methylation

A mixture of the lithium enolates **12** and **12***a*, prepared as described above from 1 g of the isomeric mixture of the enol acetates **11**, mp 137–143°C, in 50 ml of ether, and from 6 ml of an ethereal 1.5 *M* methyllithium solution, was treated in the original solution in the presence of 2,2′-bipyridyl which served as indicator, with an excess of solid carbon dioxide (solid carbon dioxide remaining in the mixture). The product was poured into ice water and the organic material was extracted with ether. The ethereal solution was washed with water and dried. Evaporation of the solvent gave 227 mg of a product which was dissolved in 1 ml of pyridine and treated at reflux temperature for 90 min with 0.5 ml of acetic anhydride. The usual work-up provided 300 mg of a solid which was recrystallized from ether–hexane to give 230 mg of *pregnenolone acetate* (**10***a*), mp 149–151°C. The identity of the product was established by the determination of a mixture melting point and by the comparison of its infrared spectrum with that of an authentic sample.

The aqueous solution remaining after the ether extraction was acidified with 2 *N* sulfuric acid to the Congo-blue reaction and the thus precipitated *3β-hydroxy-17-carboxy-5-pregnen-20-one* (**15**) was extracted with ether. The ethereal solution was dried and was then treated with 50 ml of a 2% ethereal diazomethane solution. The excess diazomethane was destroyed with a few drops of acetic acid and the solvents were removed to give 515 mg (51.5% yield) of *3β-hydroxy-17-methoxycarbonyl-5-pregnen-20-one* (**14**), mp 212–217°C. Considering the recovery of acetylated starting material (**10***a*), the yield of the unpurified hydroxy keto ester **14** amounted to 63%. One recrystallization from dichloromethane–methanol gave 437 mg of pure product, mp 221–223°C, identified by the determination of a mixture melting point and by the comparison of its ir and nmr spectra with those of an authentic sample (see above).

17-Methoxycarbonyl-4-pregnene-3,20-dione (13)

(a) By Jones' Oxidation

To a solution of 1 g of the hydroxy keto ester **14**, mp 221–223°C, in 50 ml of absolute acetone, there was added, at 0°C, dropwise and with stirring, 1 ml of Jones' reagent (16), in the course of 15 min. The mixture was left at 0°C for another 10 min and then poured into ice water. The organic product was extracted with ether, the ethereal solution was washed with water, and was dried over sodium sulfate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Removal of the solvent gave 985 mg of a crystalline product which was dissolved in 30 ml of methanol and 0.5 ml of water containing a drop of concentrated hydrochloric acid. The solution was warmed to 50°C for 5 min, cooled, and diluted with 300 ml of cold water. The mixture was extracted with ether, the ethereal solution was washed with water, and was dried over sodium sulfate. Evaporation of the solvent gave 975 mg (98% yield) of crystalline 17-methoxycarbonyl-4-pregnene-3,20-dione (**13**), mp 178–184°C. Recrystallization from ether–hexane gave 845 mg (85% yield) of pure product, mp 190–192°C. A sample was recrystallized twice from ether–hexane for analysis; colourless prisms, mp 190–192°C; $[\alpha]_D^{23}$ +192° (*c* 1.000, $CHCl_3$); λ_{max} (EtOH): 240 nm (log ε 4.2); ν_{max} (KBr): 1735 (ester), 1705 (20-ketone), 1673 and 1618 cm^{-1} (Δ^4-3-keto doublet); δ (60MHz): 0.71 (s, 3H, 18-CH_3), 0.98 (s, 3H, 19-CH_3), 2.10 (s, methyl ketone), 3.70 (s, $COOCH_3$), 5.70 (4-H). *Anal.* calcd. for $C_{23}H_{32}O_4$: C 74.16, H 8.66; found: C 74.04, H 8.50.

(b) By Oppenauer Oxidation

A solution of 300 mg of 3β-hydroxy-17-methoxycarbonyl-5-pregnen-20-one (**14**), mp 221–223°C, in 30 ml of absolute benzene was refluxed for 18 h with 267 mg of aluminum *tert*-butoxide and 1 ml of freshly redistilled cyclohexanone. The mixture was cooled and poured into ice water. The precipitate was extracted with ether, the organic solution was washed with water, and was dried over sodium sulfate. Evaporation of the solvent left 287 mg (96% yield) of crystalline diketo ester **13**. Recrystallization from ether–hexane provided 238 mg (80% yield) of pure product, mp 188–190°C. The identity of the material with the product described under (*a*) was established by the usual methods.

3,20-Bis(ethylenedioxy)-17-methoxycarbonyl-5-pregnene (16)

From a solution of 1.86 g of the diketo ester **13**, mp 188–190°C, and of 75 mg of *p*-toluenesulfonic acid in 200 ml of freshly distilled ethylene glycol, the solvent was slowly distilled at 78–80°C at 0.5 Torr, during 6 h. The residue was cooled and poured into an ice-cold saturated sodium bicarbonate solution. The product was extracted with dichloromethane, the organic layer was washed with water and was dried over sodium sulfate. Removal of the solvent gave 2.35 g of a solid which, upon crystallization from ether, gave 2.02 g (88% yield) of diketal **16**, mp 185–187°C. A sample was recrystallized twice from ether–dichloromethane for analysis; colourless needles, mp 187–189°C; $[\alpha]_D^{23}$ +23° (*c* 1.000, $CHCl_3$); ν_{max} (KBr): 1730 and 1255 (ester), 1090 and 1080 cm^{-1} (ketals); δ (90 MHz): 0.98 and 1.1 (s's, 18- and 19-CH_3), 1.60 (s, 3H, 21-CH_3), 3.7 (s, 3H, $COOCH_3$), 3.9 (s, 8H, ketals); mass calcd. for $C_{27}H_{40}O_6$: 460; found: 460. *Anal.* calcd. for $C_{27}H_{40}O_6$: C 70.40, H 8.75; found: C 70.06, H 8.65.

3,20-Bis(ethylenedioxy)-17-hydroxymethyl-5-pregnene (17)

A solution of 1 g of the diketal ester **16**, mp 185–187°C, in 200 ml of absolute tetrahydrofuran was added dropwise and with vigorous stirring to a suspension of 1.75 g of lithium aluminum hydride in 100 ml of absolute tetrahydrofuran. The mixture was refluxed for 15 h with continuous stirring. The excess reagent was destroyed with ice, the organic solution was filtered and was dried over sodium sulfate. Removal of the solvent gave 930 mg of a solid which, upon recrystallization from ether, gave 880 mg (93% yield) of the 17-hydroxymethyl diketal **17**, mp 172–175°C. A sample was recrystallized twice from ether for analysis; colourless needles, mp 175–177°C; $[\alpha]_D^{23}$ +15° (*c* 1.000, $CHCl_3$); ν_{max} (KBr): 3360 (br) and 3520 (hydroxyl), 1105 and 1080 cm^{-1} (ketals); δ (90 MHz): 0.92 and 1.02 (s's, 18- and 19-CH_3), 1.40 (s, 3H, 21-CH_3), 3.85 (2H, dd, ν = 21 Hz, *J* = 8 Hz, 17-CH_2OH), 3.90 (s, 8H, ketals), 5.33 (m, 1H, 6-H); mass calcd. for $C_{26}H_{40}O_5$: 432; found: 432. *Anal.* calcd. for $C_{26}H_{40}O_5$: C 72.19, H 9.32; found: C 72.51, H 9.25.

17¹-Acetate 17a

A solution of 500 mg of the hydroxy diketal **17**, mp 172–175°C, in 2.5 ml of pyridine was treated at room temperature for 18 h with 0.3 ml of acetic anhydride. After addition of a few drops of methanol, the solvents were removed under reduced pressure and the product was dried by repeated evaporation of its benzene solutions. Thus, 543 mg (99.8% yield) of crystalline acetate **17***a*, mp 146–150°C, was obtained. Recrystallization from ether–hexane gave 491 mg (86% yield) of pure 3,20-bis(ethylenedioxy)-17-acetoxymethyl-5-pregnene (**17***a*), mp 150–152°C. A sample was recrystallized twice from ether–hexane for analysis; colourless needles, mp 152–154°C; $[\alpha]_D^{23}$ +31° (*c* 1.000, $CHCl_3$); ν_{max} (KBr): 1735 and 1250 (acetate), 1100 and 1080 cm^{-1} (ketals); δ (90 MHz): 0.96 and 1.05 (s's, 18- and 19-CH_3), 1.42 (s, 3H, 21-CH_3), 3.90 (s, 8H, ketals), 4.26 (dd, ν = 18 Hz, *J* = 12 Hz, 2H, 17-CH_2OAc), 5.33 (m, 1H, 6-H). *Anal.* calcd. for $C_{28}H_{42}O_6$: C 70.85, H 8.92; found: C 70.74, H 8.85.

17¹-Benzoate (17b)

A solution of 100 mg of the hydroxymethyl diketal **17**, mp 172–175°C, in 0.25 ml of absolute pyridine was left with 0.1 ml of benzoyl chloride at room temperature for 18 h. Subsequently, the mixture was diluted with ether, the ethereal solution was washed with a cold 2 *N* sodium carbonate solution and with water, and was dried over sodium sulfate. The solvents were evaporated and the product was dried for 24 h in high vacuum. Thus, 120 mg of crude, solid, 3,20-bis-(ethylenedioxy)-17-benzoyloxymethyl-5-pregnene (**17***b*) was obtained; ν_{max} (KBr): 1720 and 1270 (benzoate), 1100 cm^{-1} (ketals). The product was converted without purification to 17-benzoyloxymethylprogesterone (**9***b*) (see below).

17¹-Pivalate (17c)

A solution of 100 mg of the hydroxymethyl diketal **17**, mp 172–175°C, in 0.25 ml of absolute pyridine was left for 18 h at room temperature with 0.1 ml of trimethylacetyl chloride. The mixture was taken to dryness *in vacuo* and the solid residue was dried in high vacuum for 24 h. This gave 118 mg of crude, solid, 3,20-bis(ethylenedioxy)-17-trimethylacetoxymethyl-5-pregnene (**17***c*); ν_{max} (KBr): 1725 and 1270 (ester), 1100 (ketals). This product was transformed without purification into 17-hydroxymethylprogesterone pivalate (**9***c*) (see below).

17¹-Tosylate (17d)

A solution of 200 mg of the hydroxy diketal **17**, mp 173–176°C, and of 300 mg of *p*-toluenesulfonyl chloride, mp 67–69°C, in 5 ml of absolute pyridine was flushed with nitrogen and the flask was sealed. The mixture was heated for 3 days at 50°C. The product was then poured into 100 ml of an ice-cold saturated sodium bicarbonate solution, the precipitate was extracted with ether, the ethereal layer was washed with a cold saturated sodium bicarbonate solution and with water, and was dried over sodium sulfate. Removal of the solvent *in vacuo* gave 230 mg (85%) of crystalline 3,20-bis(ethylenedioxy)-17-tosyloxymethyl-5-pregnene (**17***d*), mp 130–138°C. One recrystallization from ether gave 189 mg (70% yield) of purified product, mp 149–151°C; λ_{max} (EtOH): 227 nm (log ε 4.1). This product was not further purified but used directly in the formation of 17-methylprogesterone (**19**) (see below).

17-Hydroxymethylprogesterone (9)

A solution of 100 mg of 3,20-bis(ethylenedioxy)-17-hydroxymethyl-5-pregnene (**17**), mp 173–176°C, and of 50 mg of *p*-toluenesulfonic acid in 50 ml of absolute acetone was allowed to stand for 10 h at room temperature. Ice and a potassium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

bicarbonate solution were added and the precipitate was extracted with ether. The ethereal solution was washed with water and was dried over sodium sulfate. Removal of the solvent gave 82 mg (86% yield) of crystalline 17-hydroxymethylprogesterone (**9**), mp 216–220°C. Recrystallization from dichloromethane–ether gave 74 mg (80% yield) of pure product, mp 220–222°C, identified by the determination of a mixture melting point and by the comparison of the infrared, ultraviolet, and nmr spectra with those of an authentic sample (1).

*17-Acetoxymethylprogesterone (**9a**)*

*(a) From the Acetoxy Diketal **17a***

A solution of 300 mg of 3,20-bis(ethylenedioxy)-17-acetoxymethyl-5-pregnene (**17a**), mp 150–152°C, and of 35 mg of *p*-toluenesulfonic acid in 140 ml of absolute acetone was left at room temperature for 7 h. The mixture was worked up as described above for 17-hydroxymethylprogesterone (**9**). Thus, 244 mg (99% yield) of crude acetate **9a** was obtained. Recrystallization from ether gave 195 mg (80% yield) of pure 17-acetoxymethylprogesterone (**9a**), mp 169–171°C, identified by the determination of a mixture melting point and by the comparison of the infrared, ultraviolet, and nmr spectra with those of an authentic sample (1).

*(b) From 17-Hydroxymethylprogesterone (**9**)*

A solution of 200 mg of 17-hydroxymethylprogesterone (**9**), mp 216–220°C, in 1 ml of pyridine was treated at room temperature for 12 h with 0.5 ml of acetic anhydride. The excess acetic anhydride was destroyed with methanol and the mixture was taken to dryness *in vacuo*, and was further dried in high vacuum for 24 h. The crystalline residue (220 mg, 98% yield) melted at 160–167°C. Recrystallization from ether–hexane gave 178 mg (85% yield) of pure 17-acetoxymethylprogesterone (**9a**), mp 169–171°C, the identity of which was established in the usual fashion by comparison with an authentic sample (1).

*17-Benzoyloxymethylprogesterone (**9b**)*

A solution of the crude 3,20-bis(ethylenedioxy)-17-benzoyloxymethyl-5-pregnene (**17b**) (120 mg) described above and of 20 mg of *p*-toluenesulfonic acid in 25 ml of absolute acetone was left at room temperature for 12 h and was then poured into cold water. The mixture was extracted with ether, the ethereal solution was washed with a cold sodium bicarbonate solution and with water, and was dried with sodium sulfate. Removal of the solvent left 82 mg (81% yield) of crystalline benzoate **9b**, mp 172–180°C. Recrystallization from ether–hexane gave 57 mg (56%) of purified product, mp 183–185°C. For analysis a sample was recrystallized twice from ether–hexane; white needles, mp 184–186°C; $[\alpha]_D^{30}$ +42° (*c* 1.000, $CHCl_3$); λ_{max} (EtOH): 238 nm (log ε 4.15); ν_{max} (KBr): 1720 (benzoate), 1700 (20-ketone), 1675 and 1620 (Δ^4-3-keto doublet), 1610 and 1530 (aromatic), 1270 cm^{-1} (benzoate); δ (60 MHz): 0.8 (s, 3H, 18-CH_3), 1.16 (s, 3H, 19-CH_3), 2.18 (s, 3H, CO-CH_3), 4.26 (dd, ν = 21 Hz, *J* = 12 Hz, 17-CH_2—O—CO—), 5.80 (s, 1H, 4-H), 7.3 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{29}H_{36}O_4$: C 77.64, H 8.09; found: C 77.68, H 8.21.

*17-Trimethylacetoxymethylprogesterone (**9c**)*

A solution of the crude 3,20-bis(ethylenedioxy)-17-trimethylacetoxymethyl-5-pregnene (**17c**) (118 mg) described above and of 20 mg of *p*-toluenesulfonic acid in 25 ml of absolute acetone was left at room temperature for 12 h and was then poured into cold water. The mixture was extracted with ether, the ethereal solution was washed with a cold saturated sodium bicarbonate solution and with water, and was dried over sodium sulfate. Removal of the solvent gave 89 mg (90% yield) of crystalline pivalate **9c**, mp 160–168°C. Three recrystallizations from ether–hexane gave 59 mg (61% yield) of pure pivalate **9c**, mp 169–171°C. For analysis a sample was recrystallized twice from ether–hexane; colourless prisms, mp 175–177°C; $[\alpha]_D^{30}$ +85° (*c* 1.000, $CHCl_3$); λ_{max} (EtOH): 237 nm (log ε 4.1); ν_{max} (KBr): 1725 (ester), 1708 (20-ketone), 1675 and 1620 (Δ^4-3-keto doublet), 1270 cm^{-1} (ester); δ (90 MHz): 0.72 (s, 3H, 18-CH_3), 1.10 (s, 9H, $(CH_3)_3C$—COO), 1.18 (s, 3H, 19-CH_3), 2.16 (s, 3H, CO—CH_3), 4.26 (dd, ν = 18 Hz, *J* = 12 Hz, 2H, CH_2—O—CO—), 5.80 (s, 1H, 4-H); mass calcd. for $C_{27}H_{40}O_4$: 428; found: 428. *Anal.* calcd. for $C_{27}H_{40}O_4$: C 75.66, H 9.41; found: C 75.80, H 9.43.

*17-Methylprogesterone (**19**)*

A solution of 180 mg of the tosyloxymethyl diketal **17d**, mp 149–151°C, (see above) in 20 ml of absolute tetrahydrofuran was added dropwise and with vigorous stirring to a suspension of 200 mg of lithium aluminum hydride in 25 ml of absolute tetrahydrofuran. Subsequently, the mixture was refluxed for 18 h with continuous stirring and was then cooled. The excess reagent was destroyed by addition of ice. The organic solution was filtered and dried over sodium sulfate. Removal of the solvent gave 129 mg of crude *3,20-bis(ethylenedioxy)-17-methyl-5-pregnene* (**18**), transparent to ultraviolet light in the region of 227 nm; ν_{max} (KBr): 1100 and 1080 cm^{-1} (ketals); δ (90 MHz): 0.85 and 1.12 (s's, 18- and 19-CH_3), 1.23 (s, 17-CH_3), 1.43 (s, 21-CH_3), 3.9 (s, ketals), 5.35 (m, 6-H).

Without purification, 120 mg of this crude diketal (**18**) and 60 mg of *p*-toluenesulfonic acid were dissolved in 60 ml of absolute acetone and the mixture was allowed to stand for 12 h at room temperature. Subsequently, the product was diluted with ether, the ethereal solution was washed with a sodium carbonate solution and with water, and was dried over sodium sulfate. Removal of the solvent gave 90 mg (91% from tosylate **17d**) of crude, crystalline, *17α-methylprogesterone* (**19**), mp 116–122°C. Recrystallization from ether–hexane gave 64 mg (65% from tosylate **17d**) of 17α-methylprogesterone (**19**), mp 122–125°C. A second recrystallization from methanol raised the melting point to 129–130°C. The identity of the product was established by the comparison of its infrared spectrum with that of an authentic sample and by the determination of a mixture melting point.

Acknowledgements

Sincere thanks are extended to Dr. T. Iwadare for fruitful discussions, and to Mrs. J. Capitaine and Mr. J. Zee for excellent collaboration. We gratefully acknowledge the devoted technical assistance of Mrs. G. Pelletier and Miss D. Thibault. Part of this study was performed pursuant to contract NIH-NICHD No. 72-2714 with the National Institutes of Health, U.S. Department of Health, Education, and Welfare, to whom we are also indebted for the majority of the biological assays, summarily mentioned in this paper. We express our gratitude for this support and cooperation, especially to Dr. M. Karten of the NICHD, Bethesda, MD. We also assure Dr. E. G. Shipley and her coworkers of our appreciation for some tests carried out at Endocrine Laboratories, Madison WI. We acknowledge with sincerest thanks the financial assistance of the National Research Council of Canada, of the Ministère de l'Education du Québec, and of Ayerst Laboratories, Montreal.

Cyanoethylations and Michael additions. VIII.[1] The use of preformed enolate ions in Michael additions. Part I[2,3]

GERVAIS DIONNE[4] AND CH. R. ENGEL

Department of Chemistry, Laval University, Quebec, P.Q., Canada G1K 7P4

Received August 4, 1977

GERVAIS DIONNE and CH. R. ENGEL. Can. J. Chem. **56**, 419 (1978).

Some Michael additions involving preformed enolate ions as nucleophiles were studied. High regioselectivity was observed in the additions of the lithium enolate of 2-methylcyclohexanone to ethyl acrylate and to methyl β-chloroacrylates, the latter reactions being by far superior to those involving classical Michael additions. The addition to *cis*- and *trans*-β-chloroacrylates proceeded with appreciable stereoselectivity. Michael addition of a preformed enolate ion, derived from a ketone, to a *cis*-β-chloroacrylate constitutes an efficient pathway to 6-substituted α-pyrones, as exemplified by the synthesis of 5,6,7,8-tetrahydrocoumarin from cyclohexanone.

GERVAIS DIONNE et CH. R. ENGEL. Can. J. Chem. **56**, 419 (1978).

On rapporte des additions de Michael impliquant comme nucléophiles des ions énolate préformés. Une régiosélectivité marquée s'observe lors d'additions de l'énolate de lithium de la méthyl-2 cyclohexanone à l'acrylate d'éthyle et aux β-chloroacrylates de méthyle, les dernières réactions s'avérant bien supérieures à des réactions de Michael classiques. Les additions aux *cis*- et *trans*-β-chloroacrylates procèdent en plus avec une stéréosélectivité appréciable. L'addition de Michael d'un *cis*-β-chloroacrylate et d'un ion énolate préformé, dérivé d'une cétone, représente un procédé efficace pour le formation d'α-pyrones 6-substituées, comme le montre la synthèse de la tétrahydro-5,6,7,8 coumarine à partir de la cyclohexanone.

Our success in employing preformed enolate ions for α-alkoxycarbonylations of ketones, useful for the synthesis of 17-substituted 20-keto steroids (4), as well as our interest in α-pyrone syntheses, prompted us to investigate the potential of lithium enolates for Michael additions of relevance to the preparation of α-pyrones. We were particularly interested in syntheses involving acrylates and β-chloroacrylates as electrophiles.

In a preliminary exploration, we studied the replacement of the not highly regioselective Michael addition of 2-methylcyclohexanone (**1**) to an alkyl acrylate under classical conditions (catalysis with *tert*-butoxide) (5) by a reaction involving a preformed enolate ion as Michael donor (Scheme 1). The reaction of ethyl acrylate with the lithium enolate **3**, prepared via the enol acetate **2**, gave a mixture from which we isolated only products arising from addition in position 2, the 'normal' Michael addition product **4** (isolated in approximately 28% yield) and products arising from a double Michael addition, followed by cyclizations: the hydroxy dicarbethoxy derivative **5** (obtained in the pure state in 25% yield), formed by an aldol cyclization of the di-addition product, and the diketo bicyclo[3.3.1]nonane **6** (isolated in 17% yield), formed by a Dieckmann condensation of the di-addition adduct.

The structures of the products are apparent from their analytical and spectroscopic data. In the mass spectrum of the mono-addition product **4** appear, apart from the molecular peak (*m/e* 212), a peak at *m/e* 167 (*M* − OEt), and one at *m/e* 112 (resulting from a McLafferty rearrangement). The product was further characterized by its 2,4-dinitrophenylhydrazone **4***a*. The relatively low infrared frequency of one of the ester groups of the aldol condensation product **5** (1715 cm^{-1} in CCl_4) seems to indicate that its carbonyl group is chelated (6). We also note the particularly high frequency of the carbonyl absorptions of the keto groups of the Dieckmann cyclization product **6** (1750 and 1730 cm^{-1} in KBr) which is not surprising since β-diketones which are not enolizable in a classical fashion are known to show high infrared absorption frequencies (7). For analytical and spectral details we refer to the Experimental.

The main result of the experiment is the confirmation that the use of preformed enolate ions as nucleophiles has, over classical Michael donors, the advantage of a significantly higher regioselectivity.[5]

[1]For paper VII, see ref. 1.

[2]This communication represents paper IV in our series on α-pyrones. For paper III, see ref. 2.

[3]The results of this paper were part of communications to the 9th International (IUPAC) Symposium on the Chemistry of Natural Products, Ottawa, Ont., June 24–28, 1974 (see ref. 3).

[4]Abbreviated from part of the doctoral thesis of G. Dionne, presented to the School of Graduate Studies, Laval University, Quebec, P.Q., 1975.

[5]Indeed, although in the case of the performance of the reaction under classical Michael conditions (5) the mono-addition product contained 7–12% of the adduct arising from addition in position 6, no 6-addition product could be detected in our reaction mixture.

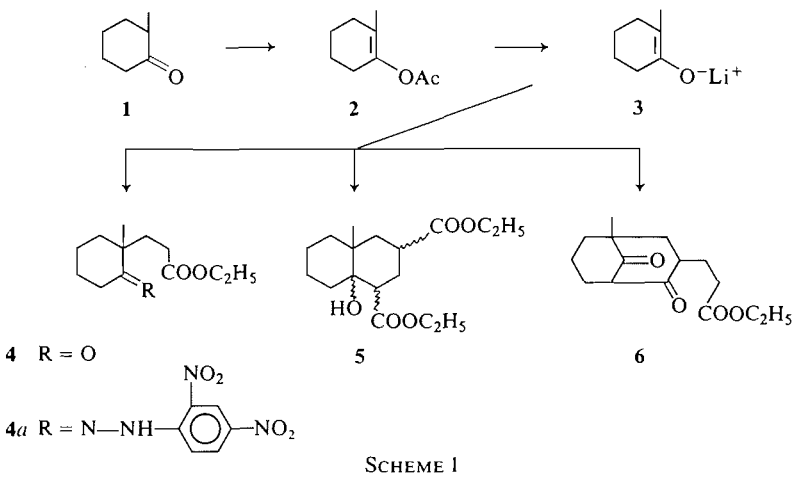
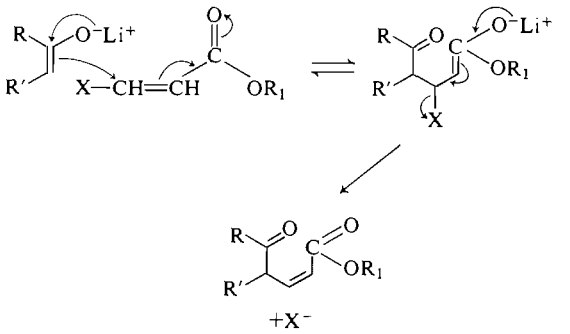


SCHEME 1

The fact that a greater proportion of di-addition products was formed in the reaction under investigation, in comparison with the classical Michael addition (5), was only of secondary interest and not surprising. In 1972, Kretchmer *et al.* (8) reported that in the reaction of methyl vinyl ketone with the iodomagnesium enolate of 3-methylcyclohexanone a di-addition product was formed, and Stork and coworkers (9) have shown that polyadditions of Michael electrophiles to preformed lithium enolates may be avoided when the electrophile carries a trialkylsilyl substituent in position α to the carbonyl function, and that such a substituent may readily be removed after the Michael addition (see also ref. 10).[6]

In view of our interest in the synthesis of α-pyrones, we now turned our attention to the attachment of a 2-butenoic acid or ester moiety in position α to a carbonyl group. For that purpose the addition of a preformed enolate ion, derived from a carbonyl compound, to a propiolic ester could have been taken into consideration; however, in this case again, the addition of a second molecule of the Michael electrophile to the anion formed by the first addition had to be contended with. It seemed logical that the second addition would be suppressed if the propiolic ester were to be replaced by a β-halo acrylic ester since, by elimination of the halogen anion from the anionic mono-addition product, the negative charge responsible for the second addition would be removed (Scheme 2).

In a first experiment (Scheme 3), we thus allowed the lithium enolate **3** of 2-methylcyclohexanone (**1**) to react with methyl *trans*-β-chloroacrylate. We obtained in over 40% crude yield (the completely pure product was isolated in 25% yield) the *trans*-cyclohexylacrylate **7**, arising from addition in position 2.



SCHEME 2

No product formed by addition in position 6 could be detected.

Addition of methyl *cis*-β-chloroacrylate to the lithium enolate **3** gave a mixture of three products arising from a Michael addition in position 2. Indeed, we isolated by dry-column chromatography in 18% yield the *trans* acrylic ester **7**, in 29% yield the *cis* isomer **8**, and in 20% yield diketone **9**, which represents the Dieckmann condensation product of the *cis* keto ester **8**. The structure of these products follow from their analytical and spectral characteristics (see Experimental). The *trans* configuration of adduct **7** and the *cis* configuration of its isomer **8** are evident from the coupling constants of the olefinic protons (16 Hz for compound **7**, 12 Hz for compound **8**). The ultraviolet spectrum of the bicyclic diketone **9**, which shows a maximum (in ethanol) at 225 nm, agrees well with that of an α,β-unsaturated β-monosubstituted ketone, and one notes in the infrared (film) a doublet at 1680 and 1615

[6]Under the circumstances, we made no attempt to minimize the formation of products arising from polyadditions by changing the experimental conditions. However, in applying Michael additions involving preformed enolate ions to the synthesis of α-pyrones, we chose Michael electrophiles, the constitution of which excludes the formation of polyaddition products (see the following paragraph and also the subsequent paper of this series (11)).

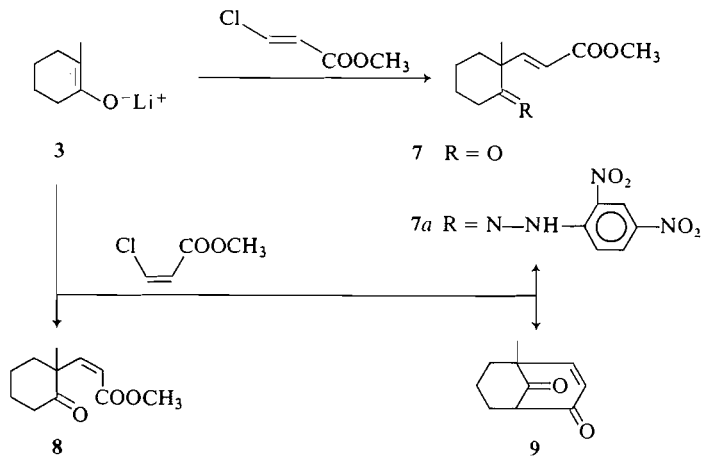


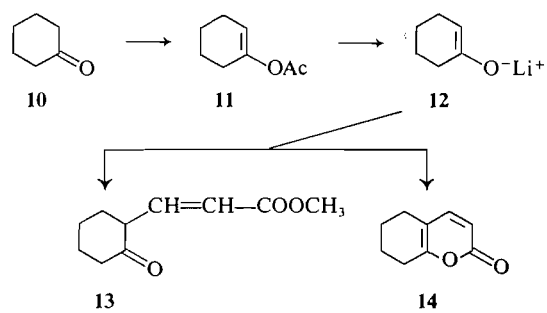
SCHEME 3

cm^{-1}, typical of an α,β-unsaturated ketone, and the absorption of the non-enolizable saturated ketone at 1735 cm^{-1}. The coupling constant of the olefinic protons (10 Hz) is again indicative of a *cis* configuration.

These results must be compared with those reported by House *et al.* (5) for corresponding Michael additions under classical conditions. In the case of the reaction of 2-methylcyclohexanone (**1**) with methyl *trans*-β-chloroacrylate they obtained in only 5–15% yield a mixture of 2- and 6-addition products (the latter predominating) and thus observed no regioselectivity. In the case of the reaction with methyl *cis*-β-chloroacrylate, they obtained no Michael addition product at all but, rather, observed the formation of an adduct arising from an aldol addition to ketone **1** of methyl propiolate, generated by dehydrochlorination of the chloroacrylate. Our experiments thus demonstrate that the use of preformed enolate ions in this kind of reaction may have considerable advantages.[7]

We may remark also on the stereochemistry of the reaction. The addition of *trans*-β-chloroacrylate had given exclusively the *trans*-acrylate **7**, whereas the addition of the *cis*-β-chloroacrylate had led in a proportion of 73% to the *cis*-acrylate **8** and its cyclization product **9**. A similar stereoselectivity has already been observed, and explained, by Jones *et al.* (13) in the reaction of ethyl β-chlorocrotonates with thiophenoxide and ethyl mercaptide (cf. also ref. 14).

We now applied the above-described reaction to an α-pyrone synthesis, by subjecting (Scheme 4) the lithium enolate **12** of unsubstituted cyclohexanone (**10**), prepared via the enol acetate **11**, to the action of methyl *cis*-β-chloroacrylate. Spectral analysis of the crude reaction product revealed that it contained some 32% of the desired α-pyrone, 5,6,7,8-tetrahydrocoumarin (**14**), accompanied by the non-cyclized product **13**. When the crude reaction mixture was treated at reflux temperature with hydrochloric acid in methanol, the pure tetrahydrocoumarin **14** could be obtained by distillation, 30% yield from enol acetate **11**. We have not attempted to optimize the yields but even so this simple sequence of reactions represents one of the most efficient syntheses of 5,6,7,8-tetrahydrocoumarin (**14**) and should be considered a truly useful approach to the preparation of 6-substituted α-pyrones.



SCHEME 4

Experimental

Melting points were taken in evacuated capillaries and temperatures were corrected. For dry-column chromatography, silica gel Woelm, activity III, was used. The ir spectra were recorded on Beckman IR-12 and Perkin-Elmer 457 instruments, the ultraviolet spectra on Beckman DK-1A and Zeiss DMR-21 spectrometers, the nmr spectra at 60 MHz on a Varian A-60 instrument, tetramethylsilane being used as internal reference, and, if not otherwise stated, deuteriochloroform as solvent. The mass spectra were recorded on a

[7]However, it must be pointed out that the use of preformed enolate ions in Michael additions does not *always* represent a synthetic advantage over 'classical' Michael reactions. In this respect we may refer to the recent article by House and Lusch (12). In the perspective of practical synthetic utility, the situation is thus not without analogy to the one with which one is confronted when deciding whether to use classical Michael electrophiles or Mannich salts.

Varian M-66 spectrometer. The microanalyses were performed by the late Dr. and Mrs. F. Pascher, Bonn, Germany, by Dr. C. Daesslé, Montreal, and by Ayerst Laboratories (under the direction of Dr. G. Schilling), Montreal.[8]

Lithium 2-Methylcyclohexenolate (3)

With exclusion of moisture and under nitrogen, 47 ml of an ethereal 1.82 *M* methyllithium solution was introduced through a diaphragm with the help of a syringe into a three-neck flask containing 10 mg of 2,2-bipyridyl, and the ether was removed *in vacuo*. The residue was dissolved in 150 ml of anhydrous 1,2-dimethoxyethane, the solution was cooled to 0°C, and there was added, dropwise and with vigorous stirring, a solution in 10 ml of dimethoxyethane, of 6.1 g of enol acetate **2**, bp 81–82°C 18 Torr, prepared according to the method of Gall and House (15) from 2-methylcyclohexanone (**1**). The persistence of an orange coloration indicated the presence of an excess of methyllithium. This product, containing lithium 2-methyl cyclohexenolate (**3**), was used directly in the following reaction.

Reaction of Lithium Enolate 3 with Ethyl Acrylate

To the above-described solution of the lithium enolate **3** in dimethoxyethane, there was added, rapidly, at 0°C, 4.7 ml of ethyl acrylate. The solution was stirred for 3 min at 0°C and was then poured into 500 ml of cold 2 *N* sulfuric acid. The product was extracted with ether, the ethereal layer was washed with water and was dried over sodium sulfate. Evaporation of the solvent gave 8.32 g of a yellowish oil. A portion of 3.11 g of that product was subjected to dry-column chromatography on 450 g of silica gel, petroleum ether – ether (4:1) serving as eluent. Thus, 892 mg (28%) of crude *ethyl 3-(1′-methyl-2′-oxocyclohexyl)propanoate* (**4**) was obtained; bp 92–95°C 1 Torr (lit. (16) bp 150°C 15 Torr); ν_{max} (film): 1735 (ester), 1710 (ketone), 1190 cm^{-1} (ester); δ: 1.01 (s, 1′-CH_3), 1.2 (t, J = 7 Hz, $COOCH_2CH_3$), 4.01 (q, J = 7 Hz, $COOCH_2CH_3$); ms *m/e* 212 (M^+), 167 (M − OEt), 112.

2,4-Dinitrophenylhydrazone 4a

The 2,4-dinitrophenylhydrazone **4***a* was prepared in the usual fashion (17): mp 88–90°C; λ_{max} (EtOH): 365 nm (log ε 4.3); ν_{max} (KBr): 3220 (NH), 3120 (aromatic C—H), 1730 (ester), 1630 and 1600 (aromatic), 1520 and 1340 (nitro functions), 1280 (ester), 830 cm^{-1} (aromatic); δ: 1.22 (t, J = 7 Hz, $COOCH_2CH_3$), 1.25 (s, 1′-CH_3), 4.13 (q, J = 7 Hz, $COOCH_2CH_3$), 7.95 (d, J = 9 Hz), 8.25 (m) and 9.16 (d, J = 2.5 Hz), (aromatic protons), 10.8 (s, N*H*). *Anal.* calcd. for $C_{18}H_{24}N_4O_6$: C 55.09, H 6.17, N 14.28; found: C 54.90, H 5.88, N 14.44.

From the above-mentioned dry-column chromatogram, there was further obtained 1.146 g (25% yield) of *2ξ,5ξ-bis(ethoxycarbonyl)-8aξ-methyldecal-4a-ol* (**5**). A sample was purified for analysis by vacuum distillation; bp 102°C 0.02 Torr; n^{25} 1.4842; ν_{max} ($CHCl_3$): 3520 (OH), 1735, 1715, and 1185 cm^{-1} (esters); δ: 1.01 (s, 3H, 8a-CH_3), 1.21 and 1.25 (t, 6H, J = 7 Hz, $COOCH_2CH_3$), 3.1 (1H, exchanged with D_2O, OH), 4.03 and 4.15 (q, 4H, J = 7 Hz, $COOCH_2CH_3$); ms *m/e* 312 (M^+), 294 (M − H_2O), 112 (base peak). *Anal.* calcd. for $C_{17}H_{28}O_5$: C 65.36, H 9.03; found: C 65.81, H 8.97.

Finally, from the above-described chromatogram, 680 mg (17.3%) of *ethyl 3-(1′-methyl-4′,9′-dioxo-3′-bicyclo[3.3.1]-nonanyl)propanoate* (**6**), mp 85–88°C, was obtained. For analysis, a sample was recrystallized three times from ether–hexane; prisms, mp 91–91.5°C; ν_{max} (KBr): 1750 and 1730 (ketones), 1220 cm^{-1} (ester); δ: 1.22 (s, 3H, 1′-CH_3), 1.27 (t, 3H, J = 7 Hz, $COOCH_2CH_3$), 2.03 (m, 1H, 3′-H), 2.94 (dd, 1H, J = 9.5 Hz and 3.5 Hz, 5′-H), 4.6 (q, 2H, J = 7 Hz, $COOCH_2CH_3$); ms *m/e* 266 (M^+), 221 (M − OEt), 220. *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.64, H 8.33; found: C 67.50, H 8.47.

Reaction of Methyl trans-β-*Chloroacrylate with Lithium 2-Methylcyclohexenolate (3)*

As described above, 2.3 g of methyl *trans*-β-chloroacrylate, obtained by diazomethane methylation of *trans*-β-chloroacrylic acid, synthesized according to the method of Kurtz *et al.* (18) from propiolic acid via *cis*-β-chloroacrylic acid, was treated at 0°C for 3 min in 80 ml of dimethoxyethane with a solution of the lithium enolate **3**, prepared from 2.7 g of the enol acetate **2** and 20.8 ml of a 1.82 *M* ethereal methyllithium solution in 70 ml of dimethoxyethane. The usual work-up gave 3.29 g of a crude product, a 2.8 g portion of which was subjected to dry-column chromatography on 200 g of silica gel, petroleum ether – ether (1:3.5) serving as eluent. Thus, 613 mg (25% yield) of pure *methyl trans-3-(1′-methyl-2′-oxocyclohexyl)acrylate* (**7**) was obtained; bp 75–76°C 0.02 Torr; λ_{max} (EtOH): 212 nm (log ε 3.9); ν_{max} (film): 1720 (carbonyls), 1645 (double bond), 1180 cm^{-1} (ester); δ (CCl_4): 1.16 (s, 3H, 1′-CH_3), 3.64 (s, 3H, $COOCH_3$), 5.65 (d, 1H, J = 16 Hz, H_α), 7.0 (d, 1H, J = 16 Hz, H_β); ms *m/e* 196 (M^+), 165 (M − OCH_3), 137 (M − $COOCH_3$), 93.

2,4-Dinitrophenylhydrazone 7a

The dinitrophenylhydrazone **7***a* of the keto ester **7** was prepared in the usual fashion (17): mp 121–123°C; λ_{max} (EtOH): 355 nm (log ε 4.3); ν_{max} (KBr): 3300 (NH), 3120 and 3090 (aromatic and olefinic C—H), 1720 (ester), 1625 and 1600 (aromatic), 1520 and 1340 (nitro groups), 1290 (ester), 835 cm^{-1} (aromatic); δ: 1.45 (s, 1′-CH_3), 3.75 (s, $COOCH_3$), 5.76 (d, J = 16 Hz, H_α), 7.15 (d, J = 16 Hz, H_β), 7.88 (d, J = 10 Hz), 8.3 (dd, J = 10 and 2.5 Hz) and 9.15 (d, J = 2.5 Hz) (aromatic protons), 11.28 (s, large, NH). *Anal.* calcd. for $C_{17}H_{20}N_4O_6$: C 54.25, H 5.36, N 14.89; found: C 54.35, H 5.11, N 14.92.

Reaction of Methyl cis-β-*Chloroacrylate with Lithium 2-Methylcyclohexenolate (3)*

As described above, 4.6 g of methyl *cis*-β-chloroacrylate, prepared by methylation of *cis*-β-chloroacrylic acid, synthesized according to the method of Kurtz *et al.* (18), was treated at 0°C for 3 min in 160 ml of dimethoxyethane with a solution of the lithium enolate **3** of 2-methylcyclohexanone (**1**), prepared from 5.5 g of enol acetate **2** and 50 ml of an ethereal 1.5 *M* methyllithium solution in 150 ml of dimethoxyethane. The usual work-up gave 6.74 g of a yellowish oil, 3.45 g of which was purified by dry-column chromatography on 300 g of silica gel, petroleum ether – ether (1:1) serving as eluent. Thus, 636 mg (18% yield) of *methyl* trans-*3-(1′-methyl-2′-oxocyclohexyl)acrylate* (**7**), bp 76–78.5°C 0.03 Torr, was obtained. The identity of the product with the one described above was established by the comparison of the ir, uv, nmr, and mass spectra.

From the chromatogram, there was also obtained 1.044 g (29%) of *methyl* cis-*3-(1′-methyl-2′-oxocyclohexyl)acrylate* (**8**), bp 80–82°C 0.03 Torr; n^{25} 1.5035; λ_{max} (EtOH): 210 nm (log ε 3.8); ν_{max} (film): 1720 (carbonyls), 1645 (double bond), 1205 cm^{-1} (ester); δ (CCl_4): 1.22 (s, 3H, 1′-CH_3), 3.56 (s, 3H, $COOCH_3$), 5.72 (d, 1H, J = 12 Hz, H_α), 6.18 (d, 1H, J = 12 Hz, H_β); ms *m/e* 196 (M^+) (base peak), 168 (M − CO), 165 (M − OCH_3), 137 (M − $COOCH_3$). *Anal.* calcd. for $C_{11}H_{16}O_3$: C 67.32, H 8.22; found: C 67.50, H 8.29.

Treatment, under usual conditions, of the *cis* keto ester **8** with 2,4-dinitrophenylhydrazine in methanol at room temperature did not lead to the formation of a dinitrophenylhydrazone derivative. However, when the reaction was carried out for 3 h at 100°C, there was obtained, upon cooling, a crystalline precipitate, representing the 2,4-dinitrophenyl-

[8]We pay tribute to the late Dr. and Mrs. Pascher and express our appreciation to the management and the staff of the analytical laboratories mentioned.

For personal use only.

hydrazone **7***a* of the *trans* keto ester **7**. The identity of the material with the above-described product was established by the determination of a mixture melting point and by the comparison of the infrared, ultraviolet, and nmr spectra.

Finally, from the above-described chromatogram, there was obtained 605 mg (20% yield) of *1-methylbicyclo[3.3.1]non-2-ene-4,9-dione* (**9**), bp 125°C 0.02 Torr; n^{25} 1.5135; λ_{max} (EtOH): 225 nm (log ε 3.8); ν_{max} (film): 1735 (saturated ketone), 1680 and 1615 cm^{-1} (α,β-unsaturated keto doublet); δ (CCl_4): 1.22 (s, 3H, 1-CH_3), 3.15 (m, 1H, 5-H), 6.30 (d, 1H, J = 10 Hz, 2-H), 6.77 (d, 1H, J = 10 Hz, 3-H); ms *m/e* 164 (M^+) (base peak), 121, 108. *Anal.* calcd. for $C_{10}H_{12}O_2$: C 73.14, H 7.34; found: C 72.81, H 7.21.

*1-Acetoxycyclohexene (**11**)*

For 14 h, 105 ml of cyclohexanone (**10**) and of 200 ml of isopropenyl acetate were refluxed with 1 g of *p*-toluenesulfonic acid. After cooling, approximately 100 ml of isopropenyl acetate was removed *in vacuo* and 1 g of sodium carbonate was added. The product was subjected to fractional distillation. Thus, 123.5 g (86%) of enol acetate **11** was obtained. For analysis, a sample was redistilled under vacuum; bp 83°C 25 Torr (lit. (19) bp 84–85°C 25 Torr); n^{25} 1.4595 (lit. (19) n_D^{25} 1.4555); ν_{max} (film): 1755 (enol acetate), 1690 cm^{-1} (double bond); δ:1.96 (s, acetate), 5.22 (m, olefinic proton). *Anal.* calcd. for $C_8H_{12}O_2$: C 68.54, H 8.63; found: C 68.49, H 8.64.

*5,6,7,8-Tetrahydrocoumarin (**14**)*

As described above, 2.8 g of methyl *cis*-β-chloroacrylate was treated for 10 min at −15°C in dimethoxyethane with a solution of the lithium enolate **12** of cyclohexanone (**10**), prepared from 3 g of enol acetate **11** and 25 ml of an ethereal 1.9 *M* methyllithium solution in 80 ml of dimethoxyethane. The usual work-up gave 3.64 g of a yellowish oil containing some methyl *cis*-β-chloroacrylate which was removed by heating the product for 15 h under vacuum to 50°C. The resulting oil (2.762 g) represented a mixture of tetrahydrocoumarin (**14**) and of non-cyclized addition products (cf. **13**); λ_{max} (EtOH): 308 nm (log ε 3.4); ν_{max} (film): 1740 (large, carbonyls), 1635 and 1570 cm^{-1} (diene); δ (CCl_4): 3.6 (s, $COOCH_3$), 5.6–7.1 (m, olefinic protons). To a solution of this mixture in 500 ml of methanol, 50 ml of concentrated hydrochloric acid was added and the product was refluxed for 41 h. After cooling, most of the methanol was evaporated *in vacuo*. The product was poured into 500 ml of water and the mixture was extracted with ether. The organic solution was washed with a saturated sodium bicarbonate solution and with water, and was dried over sodium sulfate. Evaporation of the solvent gave 2.22 g of an oil, λ_{max} (EtOH) 308 nm (log ε 3.5), which was purified by fractional vacuum distillation, followed by crystallization from ether – petroleum ether. Thus 958 mg (30% yield from enol acetate **11**) of *5,6,7,8-tetrahydrocoumarin* (**14**) was obtained; mp 55–60°C. Recrystallization from ether – petroleum ether raised the melting point to 57–61°C (lit. (20) mp 64.5–65°C); λ_{max} (EtOH): 222 nm (log ε 3.5), 308 nm (log ε 3.8) (lit. (20) 222 nm (log ε 3.46), 309 nm (log ε 3.85)); ν_{max} (film) 3100 (double bonds), 1720 (lactone), 1650 and 1570 (diene); δ (CCl_4): 1.5–1.98 (m, 4H, 6- and 7-CH_2), 2.2–2.6 (m, 4H, 5- and 8-CH_2), 6.14 (d, 1H, J = 9 Hz, 3-H), 7.1 (d, 1H, J = 9 Hz, 4-H); ms *m/e* 150 (M^+), 122, 94, 66.

*Maleic Anhydride Derivative of Tetrahydrocoumarin **14***

This derivative was prepared according to Dreiding and Tomasewski (20). From 250 mg of the above-described tetrahydrocoumarin **14**, 177 mg of the addition product, mp 301.5–302°C, was obtained. Recrystallization from xylene gave prisms, mp 305–305.5°C (lit. (20) mp 310–311°C); ν_{max} (KBr): 3080 (double bond), 1860 and 1780 (anhydride), 1630 cm^{-1} (double bond). *Anal.* calcd. for $C_{16}H_{14}O_6$: C 63.57, H 4.67; found: C 63.65, H 4.63.

Acknowledgements

Sincere thanks are extended to Mrs. J. Capitaine for much appreciated assistance in some of the experiments. We acknowledge gratefully the technical cooperation of Mrs. G. Pelletier and Miss D. Thibault. High appreciation is expressed to the National Research Council of Canada, the Ministère de l'Education du Gouvernement du Québec, and to Ayerst Laboratories, Montreal, Quebec, for financial assistance. One of us (G.D.) extends sincere thanks to the National Research Council of Canada for the award of a scholarship.

α-Pyrones. V.[1,2] The synthesis of bufadienolides. Part IV[3,4]

CH. R. ENGEL AND GERVAIS DIONNE[5]

Department of Chemistry, Laval University, Quebec, P.Q., Canada G1K 7P4

Received September 1, 1977

(Dedicated to Professor EDGAR LEDERER on the occasion of his seventieth birthday)

CH. R. ENGEL and GERVAIS DIONNE. Can. J. Chem. **56**, 424 (1978).

Additions of preformed enolate ions, derived from esters, to α-methylene carbonyl compounds, the methylene group of which carries in the terminal position a leaving group, were studied. The reaction of steroidal 20-chloromethylene 21-aldehydes with preformed diethyl sodiomalonate results in a Michael addition which allowed an efficient synthesis of a 23-alkoxycarbonyl bufadienolide. In contrast, the reactions of the same chloromethylene aldehydes and of an analogous 20-methoxymethylene 21-aldehyde with ethyl lithioacetate give rise to 1,2-additions. The reaction of lithioacetate with the methoxymethylene aldehyde was used for the most efficient bufadienolide synthesis yet realized. Treatment with lithioacetate of 20-acetoxymethylene and 20-hydroxymethylene 21-aldehydes gave no addition products. The reactions of preformed sodiomalonate and lithioacetate with α-chloromethylene and α-methoxymethylene cyclohexanones proceeded analogously to those of the steroidal aldehydes.

CH. R. ENGEL et GERVAIS DIONNE. Can. J. Chem. **56**, 424 (1978).

L'étude concerne des additions d'ions énolate, préformés à partir d'esters, à des composés carbonylés α-méthyléniques dont le groupe méthylène porte en position terminale un substituant nucléofuge. La réaction de 21-aldéhydes stéroïdiques 20-chlorométhyléniques avec le sodiomalonate de diéthyle préformé résulte en une addition de Michael qui fut utilisée pour une synthèse efficace d'un bufadiénolide 23-alkoxycarbonylé. Par contre, les réactions des mêmes aldéhydes chlorométhyléniques, ainsi que d'un 21-aldéhyde 20-méthoxyméthylénique analogue, avec le lithioacétate d'éthyle donnèrent lieu à des additions aldoliques. La réaction du lithioacétate avec l'aldéhyde méthoxyméthylénique permit la réalisation d'une synthèse d'un bufadiénolide qui dépasse en efficacité toutes les synthèses connues de ce type de cardiotoniques. Le traitement avec un lithioacétate des 21-aldéhydes 20-hydroxyméthylénique et 20-acétoxyméthylénique ne conduit pas à des produits d'addition. Les réactions du sodiomalonate de diéthyle et du lithioacétate d'éthyle préformés avec les α-chlorométhylène et α-méthoxyméthylène cyclohexanones procèdent de la même façon que les réactions avec les aldéhydes stéroïdiques correspondants.

Some years ago we published (6) a bufadienolide synthesis which consisted of the Michael addition of diethyl malonate to a 20-methylene 21-aldehyde and the transformation of the resulting aldehydo diester into an enol lactone which was then dehydrogenated to the α-pyrone (Scheme 1). Since the yields of the last step were not very satisfactory, we attempted to 'prefigure' the non-enolic double bond in the Michael nucleophile by using bromomalonate as Michael

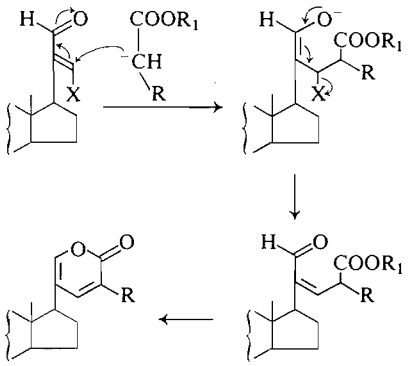

SCHEME 2

donor (7). This indeed led to the expected cyclopropane derivative but the conversion of that product to an α-pyrone proved unsuccessful (Scheme 1).

It now seemed conceivable to retain the basic strategy of our approach, by incorporating an appropriate leaving group, not in the Michael nucleophile, but in the Michael electrophile, as depicted in Scheme 2 (for related reactions, see ref. 8). We therefore prepared derivatives of the 20-methylene 21-aldehyde which had served for our first bufadienolide synthesis, in which the methylene group carries a leaving group (structures **2**-**2***d*, **3**, and **5** of Scheme 3).

The dimethyl acetal **1***a* of aldehyde **1**, previously prepared in our laboratory (6), was subjected, according to the method employed by the Roussel group in the first bufadienolide synthesis (9), to a Vilsmeier-Haack reaction (10, see also ref. 11). This led to a mixture of the geometrically isomeric methoxymethylene aldehydes **2***d* and **3**, the *Z*-isomer **2***d* being obtained in 64% yield, the *E*-isomer **3** in 15% yield. The ultraviolet maxima (in ethanol), 253 nm for the *Z*-isomer and 275 nm for the *E*-isomer, agree well with those reported by Sondheimer *et al.* (12) for similar products. The configurational assignment is substantiated by the consideration that it is known that α-hydroxymethylene ketones and aldehydes exist as '*cis*'-isomers (13, 14) and that the methylation and acetylation of the 3-hydroxy (*Z*)-hydroxymethylene aldehyde **2**, whose configuration was confirmed by its infrared spectrum (see below), led indeed to the 3-acetoxy 20-methoxymethylene aldehyde **2***d*.[6]

The 3-hydroxy-(*Z*)-20-hydroxymethylene 21-aldehyde **2** was obtained in 85% yield by vinylogous saponification (cf. refs. 9, 12) of the (*Z*)-methoxymethylene aldehyde **2***d*. Again, the ultraviolet spectrum of this derivative corresponds to that of an analogous product reported by Sondheimer *et al.* (12). In the infrared spectrum we note an intramolecular hydrogen bond, confirming the *Z*-configuration (cf. refs. 13, 14). Treatment of the 3-hydroxy-(*Z*)-hydroxymethylene aldehyde **2** with acetic anhydride in pyridine gave in almost quantitative yield the diacetate **2***b* which is, however, unstable in solution.

According to the procedure employed by Skoldinov and co-workers (15) for the preparation of β-chloroacroleins from β-methoxyacroleins, both the (*Z*)-methoxymethylene aldehyde **2***d* and its *E*-isomer **3** were transformed, in 85% and 68% yield, respectively, by reaction with thionyl chloride in dichloromethane and by subsequent treatment of the resulting dichloro derivative with ice, into a mixture of geometrically isomeric 20-chloromethylene 21-aldehydes (**5**) which could not be separated. The presence of both isomers was revealed by the nmr spectrum which shows two signals for each, the olefinic (7.0 and 7.16 δ) and the aldehydic protons (9.60 and 10.04 δ).

In a first series of experiments, we explored the applicability of the general pathway outlined in Scheme 2 to the synthesis of bufadienolides, by investigating the addition of diethyl malonate to the (*Z*)-hydroxymethylene aldehyde **2** and to the (*Z*)-methoxymethylene aldehyde **2***d*. In contradistinction to the situation in the case of a number of hydroxymethylene and methoxymethylene ketones (8*a*,*b*, 16), no 1,4-additions could be observed under a variety of conditions; using, as basic catalysts, sodium ethoxide, potassium hydroxide, or Triton B, and as solvents ethanol, *tert*-butanol, or dioxane, no reaction took place. A negative result was also encountered when a reaction was attempted with preformed diethyl sodiomalonate in hexamethylphosphoric triamide.[7] On the other hand, when piperidine in boiling ethanol was used as a base, aldehyde **2***d* gave in 80% yield the 21-nor 23-ethoxycarbonyl cholenic ester **4***a*. Under similar conditions, the hydroxymethylene aldehyde **2** gave in 45% yield the corresponding 3-hydroxy derivative **4**, readily acetylated to acetate **4***a*. The structure of ester **4***a* follows from the results of its elemental analysis and from its spectra (see Experimental). The nmr spectrum reveals a single olefinic proton, appearing as a triplet, which confirms the presence of an adjacent methylene group, and the ultraviolet spectrum (λ_{max} (EtOH) 217 nm (log ε 4)) corresponds well to that of an α,β-unsaturated α,β-disubstituted ester (17). In the mass spectrum, apart from the molecular ion, appear peaks arising from the

[6]The comparison of the spectral data of the non-acetylated methoxymethylene aldehyde **2***c* and of the acetylated product **2***d* confirms that no isomerization occurred during acetylation.

[7]These negative experiments are not recorded in the Experimental.

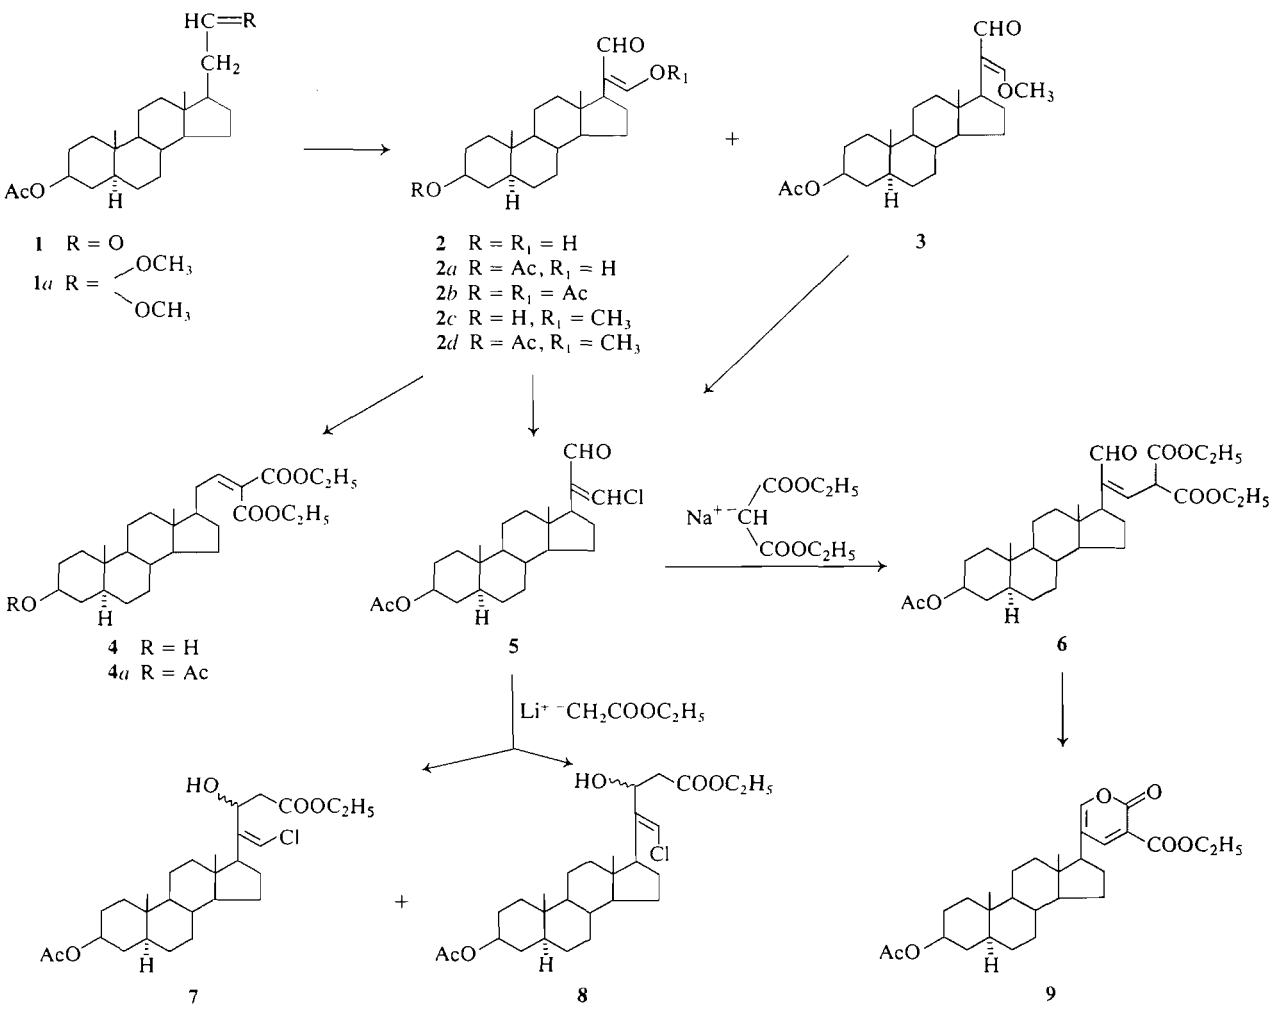

SCHEME 3

rupture of the side chain in position 17. The analytical and spectral results of the 3-hydroxy derivative **4** again agree with the suggested structure. The formation of the esters **4** and **4***a* may be explained by an aldol condensation of the Knoevenagel type, followed by deformylation which, in the case of the reaction of the methoxymethylene derivative, is preceded by the hydrolysis of the enol ether.

The desired Michael addition (Schemes 2 and 3) could be realized when the 20-chloromethylene 21-aldehydes **5** were used as electrophiles. Under classical Michael conditions, no reaction occurred with diethyl malonate but the addition succeeded well with preformed sodiomalonate in hexamethylphosphoric triamide (HMPT). The infrared spectrum of the resulting product (**6**) revealed the presence of the α,β-unsaturated aldehyde and that of the ester groups. The structure was confirmed by the nmr spectrum and by the ultraviolet characteristics, typical of an α,β-disubstituted α,β-unsaturated aldehyde. The aldehydo diester **6** could not be isolated in the pure state since it cyclizes spontaneously to the α-pyrone **9**, a 23-alkyloxycarbonyl bufadienolide. The cyclization is accelerated when the crude reaction mixture containing the aldehydo ester **6** is heated, when it is treated with acid, or when it is passed through a silica gel column. The bufadienolide **9** was obtained directly, in 38% yield from the chloromethylene aldehydes **5**, by simply subjecting the reaction product to dry-column chromatography on silica gel. The 3-alkoxycarbonyl α-pyrone structure is shown by the ultraviolet absorption (in ethanol) at 322 nm and the constitution of the product is confirmed by elemental analysis and by its infrared and nmr spectra. We note, for instance, that the absorptions of the 21- and 22-protons correspond to those of the corresponding protons of the 5-unsubstituted 3-ethoxycarbonyl-α-pyrone (ref. 7, see also ref. 18).

While the above described synthesis represents an efficient pathway to 23-alkoxycarbonyl bufadieno-

lides and their derivatives, it would not be useful for the synthesis of 23-unsubstituted products since it is known (8*d*, 19) that decarboxylations of 3-carboxy α-pyrones are difficult to realize. The addition of a preformed enolate ion, derived from an alkyl acetate, to a 20-methylene 21-aldehyde with a suitable leaving group in position 22 would constitute an elegant and direct route to 23-unsubstituted bufadienolides, if the course of the reaction were analogous to that of the addition of preformed sodiomalonate to the 20-chloromethylene 21-aldehydes **5**. However, the sodium enolate of an alkyl acetate should not lend itself well to such a reaction because of its instability and of its facile self-condensation (20). On the other hand, alkyl lithioacetates can be readily prepared (21), but it is known (22) that in reactions of organolithium compounds with α,β-unsaturated carbonyl products, 1,2-additions are favoured over 1,4-additions;[8] thus, the reaction of lithioacetates with chloromethylene aldehydes of type **5** did not appear very promising for bufadienolide syntheses. However, it seemed reasonable to assume that in the case of the addition of a lithioacetate to α-methylene 21-aldehydes, possessing as β-substituent a group such as an alkoxy function, the reaction product should lend itself to a ready transformation, by hydrolysis and dehydration, into an unsaturated δ-oxo ester, easily convertible to an α-pyrone (see below).

Considering that Dreiding and Nickel (16*b*) had observed an appreciable proportion of a 1,4-addition upon reaction of an organolithium compound with an α-alkoxymethylene cyclohexanone, we still investigated the addition of ethyl lithioacetate to the 20-chloromethylene 21-aldehydes **5**. Indeed, it could be assumed that the improbability of hydrolysis, in the medium, of the chlorine substituent should allow us to differentiate readily a 1,2-addition product from a 1,4-addition product. No 1,4-addition product could be isolated. Instead, the reaction gave rise, in very high yield, to the geometrically isomeric 1,2-addition products **7** and **8**, the *Z*-isomer **7** being isolated in 50% yield, the *E*-isomer **8** in 41% yield. The infrared spectra of the products are indicative of hydrogen bonding between the hydroxy group and the ester carbonyl function, as evidenced by a weak carbonyl absorption and by the position of the hydroxyl maximum (at 3520 cm^{-1} in CCl_4 and 3480 cm^{-1} in KBr). The configurations could be deduced from the chemical shifts of the olefinic protons which appear at 5.94 and 6.48 δ. The values calculated according to the rules of Pascual *et al.* (23) would correspond to 5.88 δ for the *Z*-isomer and to 5.96 δ for the *E*-isomer. On the basis of the important difference of the chemical shift of the relevant proton of one of the isomers with respect to either calculated value, we assign to this product the *E*-configuration, since this difference may be attributed to deshielding, due to the diamagnetic anisotropy of the carbonyl group of the ester, and since this effect should only be felt significantly by the olefinic proton of the *E*-isomer.

It is known (24) that certain salts, particularly copper salts, favour a 1,4-addition over a 1,2-addition in reactions of organometallic compounds with α,β-unsaturated carbonyl derivatives. However, even in the presence of cuprous chloride, the addition of ethyl lithioacetate to the aldehydes **5** proceeded as described above.

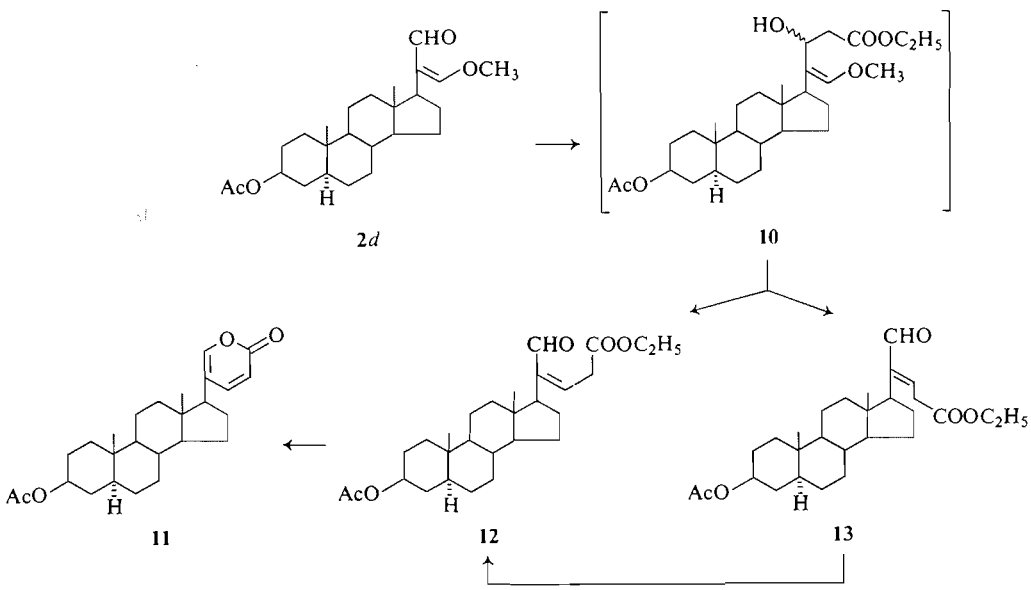
As expected, addition of ethyl lithioacetate to the 20-methoxymethylene 21-aldehyde **2***d* took an analogous course and allowed us to realize a most fruitful bufadienolide synthesis (Scheme 4). Treatment of the reaction product with hydrochloric acid led in 78% yield to a mixture of the (*Z*)- and (*E*)-aldehydo cholenic esters **12** and **13**. Nuclear magnetic resonance spectroscopy revealed that the major constituent was the *Z*-isomer **12**. The mixture could not be separated into its components; when it was recrystallized from dichloromethane–hexane, the *E*-isomer **13** was converted quantitatively to the *Z*-isomer **12**.[9] The structures of the products follow from analytical and spectral data. Treatment of the aldehydo cholenic ester **12** with hydrochloric acid in boiling ethanol, followed by reacetylation, gave in 60% yield the bufadienolide **11**, previously prepared in our laboratory (6). The over-all yield of the bufadienolide **11** from the methoxymethylene aldehyde **2***d* amounted to 47% and this pathway to bufadienolides thus seems to represent the most efficient method for the synthesis of that class of compounds, its yield exceeding even that realized (3) by the use of Bélanger and Brassard's α-pyrone synthesis (25).[10]

The fact that the aldehydo esters **12** and **13** were not formed by a 1,4-addition of the Michael type, could be proved by omitting treatment with acid in the work-up. This allowed the isolation, in good yield, of the aldol-type addition product **10** which was converted in quantitative yield, by reaction with hydrochloric acid at room temperature, to the

[8]This does, however, not mean that 1,4-additions are excluded (see below).

[9]The geometry around the double bond of the two isomers **12** and **13** was deduced by comparing the chemical shifts of the C(22)-protons with the values calculated according to the rules of Pascual *et al.* (23).

[10]For other direct pathways to bufadienolides, see refs. 6, 9, and 26. Pettit and co-workers also developed an interesting method for the transformation of cardenolides into bufadienolides (27).



SCHEME 4

mixture of the aldehydo cholenic esters **12** and **13**.[11] Our new bufadienolide synthesis is thus, mechanistically, analogous to the α-pyrone synthesis of Plattner *et al.* (28), involving a Reformatzky reaction on an α-benzoyloxymethylene ketone and not to the α-pyrone synthesis realized by Dreiding and Tomasewski (16*c*), by treatment of the corresponding hydroxymethylene ketone with the Reformatzky reagent.

It seemed of interest to establish whether or not ethyl lithioacetate could be added also to the hydroxymethylene aldehyde **2**. This would correspond to substituting a lithioacetate for the Reformatzky reagent employed in the first successful but, in the perspective of yields, not too attractive pathway to bufadienolides (9, see also ref. 12). However, when the hydroxymethylene aldehyde **2** was treated with ethyl lithioacetate, the starting material was recovered quantitatively. Apparently, the reaction resulted only in the formation of the lithium enolate of the 'dialdehyde' **2**. When the 3-acetoxy 20-acetoxymethylene 21-aldehyde **2***b* was treated with ethyl lithioacetate, it was merely transformed into the 3-acetoxy 20-hydroxymethylene 21-aldehyde **2***a*. These results contrast with those observed in the case of analogous reactions involving Reformatzky reagents (9, 16*c*, 28).

The courses of the reactions of preformed sodiomalonates and lithioacetates with α-chloromethylene and α-methoxymethylene carbonyl compounds, established for steroidal 21-aldehydes, were confirmed with analogously constituted cyclic ketones. We used 2-chloromethylenecyclohexanone (**15**) and 2-methoxymethylenecyclohexanone (**20**) as substrates (Scheme 5). Upon addition (in HMPT) of preformed diethyl sodiomalonate to the chloromethylene ketone **15**, we obtained directly the ethoxycarbonyl tetrahydrocoumarin **18**. As in the case of the reaction with the analogous steroidal α-chloromethylene aldehydes **5**, a Michael-type 1,4-addition must have occurred (cf. intermediate **16**, which could not be isolated), since a 1,2-aldol-type addition would have afforded the chloromethylene diester **14**, the transformation of which into an α-pyrone (under the reaction conditions, in any case, highly improbable)[12] would have led to the ethoxycarbonyl α-pyrone **17**. The nmr spectrum of the tetrahydrocoumarin obtained (**18**), clearly differentiates it from its isomer **17**; the only proton (in position 4) of its α-pyrone system appears at 7.97 δ, which corresponds well to the chemical shift of the corresponding proton of 3-ethoxycarbonyl-2-pyrone (7), whereas the only proton of the α-pyrone system of a product of structure **17** should appear around 8.35 δ (7).

On the other hand, treatment of the methoxy-

[11]The difference in the course of the additions of sodiomalonates and lithioacetates to α,β-unsaturated aldehydes was corroborated by a preliminary experiment (not reported in the Experimental) which establishes that the reaction of ethyl lithioacetate with the unsubstituted 20-methylene 21-aldehyde leads to an aldol-type addition product, whereas, as shown previously (ref. 6, see also the introduction to this paper), the reaction of this aldehyde with sodiomalonate results in a Michael-type addition.

[12]Not only on theoretical grounds; indeed, treatment with hydrochloric acid of the steroidal β-hydroxy-γ-chloromethylene esters **7** and **8** (see above) did not lead to an α-pyrone.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

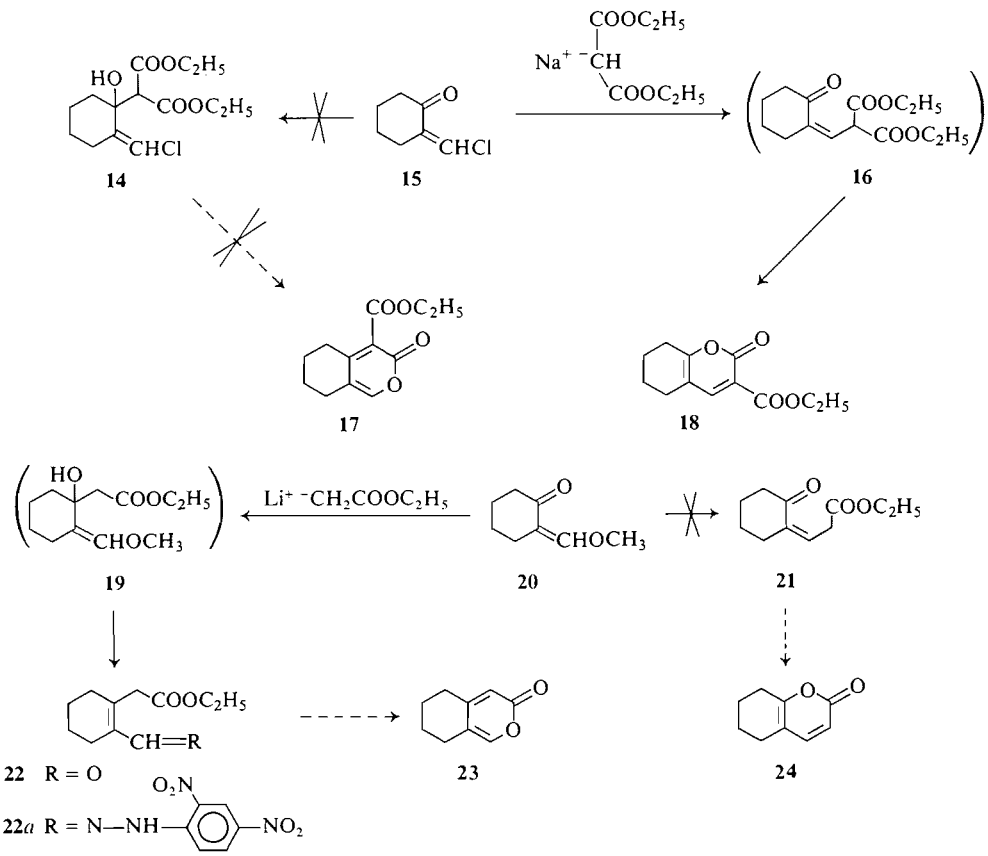

SCHEME 5

methylene cyclohexanone **20** with ethyl lithioacetate resulted exclusively, as in the case of the corresponding steroidal 20-methoxymethylene 21-aldehyde **2***d*, in a 1,2-addition; the intermediate β-hydroxy-γ-methoxymethylene ester **19** was not isolated, but the unsaturated aldehydo ester **22** was obtained in approximately 65% yield.[13] A conjugate (Michael-type) addition would have afforded the keto ester **21**.[14] The structure of the aldehydo ester **22** was substantiated by its spectral data and by the characteristics of its dinitrophenylhydrazone derivative **22***a*.

In summary, whereas the reactions of the α-methoxymethylene and α-chloromethylene carbonyl compounds with ethyl lithioacetate resulted in 1,2-additions, leading in the case of the methoxymethylene derivatives to β,γ-unsaturated γ-formyl esters which can be transformed into 5-substituted (in the case of ketonic starting materials, into 4,5-disubstituted) α-pyrones, the reactions of the α-chloromethylene carbonyl compounds with preformed diethyl sodiomalonate gave rise to 1,4-additions which lead, through cyclization, to 5-substituted (in the case of ketonic starting materials, to 5,6-disubstituted) 3-ethoxycarbonyl α-pyrones.

Experimental

Melting points were taken in evacuated capillaries and the temperatures were corrected. For elution chromatography, neutral aluminum oxide Woelm and Davison's silica gel 923 were employed. Dry-column chromatography was performed with Woelm dry-column chromatography silica gel, activity III; for thin-layer chromatography, Merck silica gel GF-254 and Baker silica gel 7G were used. The ir spectra were recorded on Beckman IR-12 and Perkin-Elmer 457 instruments, uv spectra on Beckman DK-1A and Zeiss DMR-21 spectrometers. The nmr spectra were obtained at 60 and 90 MHz on Varian A-60 and Bruker HX-90 instruments, tetramethylsilane serving as internal standard and, if not otherwise stated, deuteriochloroform as solvent. Mass spectra were recorded, if not otherwise indicated, on a Varian A-66 instrument. For the drying of organic extracts, sodium sulfate was used. The microanalyses were performed by the late Dr. and Mrs. F. Pascher, Bonn, Germany, and by the microanalytical section of Ayerst Laboratories, Montreal (under the direction of Dr. G. Schilling), as well as by Dr. C. Daesslé, Montreal.[15]

[13]Cyclization of the aldehydo ester **22** would lead to the α-pyrone **23**.

[14]The cyclization of that ester would lead to the α-pyrone **24**.

[15]We pay tribute to the late Dr. and Mrs. Pascher and express our appreciation to the staff and management of the analytical laboratories.

3β-Acetoxy-21,21-dimethoxy-5α-pregnane (1a)

A solution of 12.36 g of 3β-acetoxy-5α-pregnan-21-al (**1**) (6) and of 360 mg of *p*-toluenesulfonic acid in 380 ml of anhydrous methanol was refluxed for 1 h. The solution was concentrated to 200 ml at atmospheric pressure and then to 75 ml under vacuum. The product was precipitated in 1 ℓ of ice water and the mixture was extracted with ether. The ethereal layer was washed with an iced sodium bicarbonate solution and with water, and was dried. Evaporation of the solvents left 14.01 g of a viscous oil, the infrared spectrum of which revealed partial hydrolysis of the 3-acetate group (ν_{max} (film) 3420 cm^{-1}). The product was treated in 80 ml of pyridine with 40 ml of acetic anhydride for 18 h at room temperature. The majority of the pyridine and of the acetic anhydride was removed by vacuum distillation and the product was precipitated in 500 ml of ice water. The mixture was extracted with ether, the ethereal layer was washed with iced dilute hydrochloric acid, cold sodium bicarbonate solution, and water, and was dried. Evaporation of the solvent left 14.31 g (98% yield) of crystalline acetal **1a**, mp 76–79°C. For analysis a sample was recrystallized three times from methanol – water; mp 81.5–82°C; $[\alpha]_D^{25}$ + 7.9° (*c* 1.042, $CHCl_3$); ν_{max} (KBr): 1720 (acetate), 1258 and 1248 (C—O), 1120 cm^{-1} (acetal); δ (60 MHz): 0.56 (s, 3H, 18-CH_3), 0.83 (s, 3H, 19-CH_3), 2.01 (s, 3H, acetate), 3.30 and 3.33 (s, 6H, acetal), 4.46 (m, 1H, 3α-H). *Anal.* calcd. for $C_{25}H_{42}O_4$: C 73.85, H 10.41; found: C 74.04, H 10.34.

(Z)-3β-Acetoxy-20-methoxymethylene-5α-pregnan-21-al (2d) and (E)-3β-Acetoxy-20-methoxymethylene-5α-pregnan-21-al (3)

To 13 ml of anhydrous dimethylformamide, 6 ml of freshly redistilled phosphorous oxychloride was added dropwise at 0°C. Subsequently, the mixture was heated for 0.5 h to 50°C and then cooled to 0°C. To this product a solution of 7.52 g of acetal **1a**, mp 76–79°C, in 60 ml of DMF was added. The mixture was heated for 3 h to 50°C then cooled and poured into an iced sodium carbonate solution. The precipitate was extracted with ether and the organic layer was washed with water and dried. The solvent was removed and the residue, still containing some dimethylformamide, was dissolved in ether, the ethereal solution was washed repeatedly with water and was dried. Evaporation left 7.22 g of a yellowish foam which was subjected to dry-column chromatography on 400 g of silica gel, petroleum ether – ether (1:2) serving as eluent. Thus, 4.7 g (64% yield) of (Z)-*3β-acetoxy-20-methoxymethylene-5α-pregnan-21-al* (**2d**), mp 148–150°C, was isolated. For analysis, a sample was recrystallized 3 times from methanol–water; colorless powder, mp 152–153.5°C; $[\alpha]_D^{22}$ −15.7° (*c* 0.900, $CHCl_3$); λ_{max} (EtOH): 253 nm (log ε 4.2); ν_{max} (KBr): 2780 (aldehyde), 1735 (acetate), 1675 and 1640 (doublet of α,β-unsaturated aldehyde), 1250 cm^{-1} (acetate); δ (90 MHz): 0.63 (s, 3H, 18-CH_3), 0.81 (s, 3H, 19-CH_3), 2.0 (s, 3H, acetate), 3.88 (s, 3H, OCH_3), 4.17 (m, 1H, 3α-H), 6.85 (s, 1H, olefinic proton), 9.18 (s, 1H, aldehyde); ms *m/e* 402.5 (M^+), 371, 213, 111. *Anal.* calcd. for $C_{25}H_{38}O_4$: C 74.59, H 9.52; found: C 74.72, H 9.57.

From the above described chromatogram, there was also obtained 1.08 g (15% yield) of (E)-*3β-acetoxy-20-methoxymethylene-5α-pregnan-21-al* (**3**), mp 178–181°C. For analysis a sample was recrystallized 3 times from chloroform–methanol; colorless prisms, mp 182–184.5°C; $[\alpha]_D^{22}$ −23.1° (*c* 1.110, $CHCl_3$); λ_{max} (EtOH): 275 nm (log ε 3.95); ν_{max} (KBr): 3100 (double bond), 1735 (acetate), 1665 and 1635 (doublet of α,β-unsaturated aldehyde), 1260 cm^{-1} (acetate); δ (90 MHz): 0.60 (s, 3H, 18-CH_3), 0.79 (s, 3H, 19-CH_3), 1.97 (s, 3H, acetate), 3.79 (s, 3H, OCH_3), 4.66 (m, 1H, 3α-H), 6.85 (s, 1H, olefinic proton), 10.13 (s, 1H, aldehyde); ms *m/e* 402.5 (M^+), 370.5, 316, 217. *Anal.* calcd. for $C_{25}H_{38}O_4$: C 74.59, H 9.52; found: C 74.53, H 9.63.

(Z)-3β-Hydroxy-20-hydroxymethylene-5α-pregnan-21-al (2)

A portion of 1 ml of an aqueous ethanolic NaOH solution, prepared from 1.5 g of NaOH, 1.5 ml of water, and 7 ml of ethanol, was added to a solution of 500 mg of the *3β*-acetoxy aldehyde **2d** in 8 ml of ethanol. The mixture was heated for 18 h under nitrogen to 30°C, was subsequently diluted with 25 ml of water and was acidified to the Congo-blue reaction with 2 *N* hydrochloric acid. The product was poured into 100 ml of ice water and the precipitate was extracted with a (3:1) ether–dichloromethane mixture. The organic phase was washed with water and was dried. Evaporation of the solvent gave 362 mg (85% yield) of (*Z*)-3β-hydroxy-20-hydroxymethylene-5α-pregnan-21-al (**2**), mp 192–196°C. A sample was recrystallized 3 times from ethanol–water for analysis; colorless powder, mp 198–198.5°C; $[\alpha]_D^{22}$ −22.5° (*c* 0.930, CH_3OH); λ_{max} (EtOH): 253 nm (log ε 4.1); ν_{max} (KBr): 3500–2300 (hydroxyls), 2720 (aldehyde), 1635 (chelated β-dicarbonyl structure (29)), 1600 (double bond), 1260 and 1250 (C—O), 1040 and 1030 cm^{-1} (hydroxyls); δ (90 MHz, CD_3OD): 0.62 (s, 3H, 18-CH_3), 0.82 (s, 3H, 19-CH_3), 2.64 (m, 1H, 17α-H), 8.33 (s, 2H, protons of the mesomeric aldehydes); ms *m/e* 346.5 (M^+), 328.5, 217. *Anal.* calcd. for $C_{22}H_{34}O_3$: C 76.26, H 9.89; found: C 76.09, H 9.90.

Methylation and Acetylation

A solution of 233 mg of (*Z*)-3β-hydroxy-20-hydroxymethylene-5α-pregnan-21-al (**2**) in 10 ml of tetrahydrofuran was treated for 18 h with 10 ml of a 1.2% ethereal diazomethane solution. The usual work-up gave 240 mg (quantitative yield) of (Z)-*3β-hydroxy-20-methoxymethylene-5α-pregnan-21-al* (**2c**), as a foam; λ_{max} (EtOH): 253 nm (log ε 4.2); ν_{max} (KBr): 3440 (hydroxyl), 2750 (aldehyde), 1675 and 1630 cm^{-1} (doublet of α,β-unsaturated aldehyde); δ (90 MHz): 0.57 (s, 3H, 18-CH_3), 0.79 (s, 3H, 19-CH_3), 3.88 (s, 3H, OCH_3), 6.88 (s, 1H, olefinic proton), 9.31 (s, 1H, aldehyde). This product was dissolved in 10 ml of pyridine and treated with 5 ml of acetic anhydride for 15 h at room temperature. The mixture was poured into 150 ml of ice water and the product was extracted with ether. The usual work-up afforded 259 mg (96% yield) of (Z)-*3β-acetoxy-20-methoxymethylene-5α-pregnan-21-al* (**2d**), mp 140–146°C. Recrystallization from methanol–water gave 202 mg of pure product, mp 147.5–150°C; its identity with the product obtained by the Vilsmeier–Haack reaction (see above) was established in the usual fashion.

Diacetylation

A solution of 1.0 g of the dihydroxy aldehyde **2** in 14 ml of pyridine was treated for 20 h at room temperature with 7 ml of acetic anhydride. The mixture was precipitated into 300 ml of ice water. The usual work-up gave 1.216 g (98% yield) of a foamy product, representing (Z)-*3β-acetoxy-20-acetoxymethylene-5α-pregnan-21-al* (**2b**), mp 54–58°C; λ_{max} (EtOH): 245 nm (log ε 4); ν_{max} (KBr): 2710 (aldehyde), 1780 (enol acetate), 1730 (acetate), 1690 and 1650 cm^{-1} (doublet of α,β-unsaturated aldehyde); δ (60 MHz): 0.61 (s, 3H, 18-CH_3), 0.85 (s, 3H, 19-CH_3), 1.95 (s, 3H, 3-acetate), 2.26 (s, 3H, enol acetate), 4.6 (m, 1H, 3α-H), 7.98 (s, 1H, olefinic proton), 9.42 (s, 1H, aldehyde); ms[16] *m/e* 430 (M^+), 388, 370, 310, 215. Since the product is unstable, particularly in solution, it was impossible to purify it sufficiently to obtain satisfactory results of an elemental analysis.

[16]We express sincere thanks to Dr. G. Schilling of Ayerst Laboratories, Montreal, for kindly having performed this mass spectral analysis for us.

(Z)- *and* (E)-*3β-Acetoxy-20-chloromethylene-5α-pregnan-21-als* (*5*)

(*a*) To a solution of 3.28 g of (*Z*)-3β-acetoxy-20-methoxymethylene-5α-pregnan-21-al (**2***d*) in 80 ml of dichloromethane, 1.08 ml of thionyl chloride was added dropwise and with stirring at 0°C. The mixture was heated for 3 h to 56°C, and then was cooled and taken to dryness *in vacuo*. There were added 50 ml of dichloromethane and 100 ml of ice water and the mixture was shaken vigorously for 45 min; its ether extract was washed with water and was dried. Evaporation gave 3.37 g of a yellow solid which was filtered through 60 g of aluminum oxide, activity III. Elutions with benzene gave 2.67 g (81%) of a mixture of the *Z* and *E* aldehydes **5**, mp 195–199°C. For analysis a sample was recrystallized 3 times from ether – petroleum ether; colorless prisms, mp 203–204°C; $[\alpha]_D^{25}$ −73.6° (*c* 1.010, $CHCl_3$); λ_{max} (EtOH): 247 nm (log ε 4.1); ν_{max} (KBr): 3080 and 3060 (double bond), 2740 (aldehyde), 1725 (acetate), 1690 and 1590 (α,β-unsaturated aldehyde), 1250 cm^{-1} (acetate); δ (60 MHz): 0.63 (s, 3H, 18-CH_3), 0.80 (s, 3H, 19-CH_3), 1.98 (s, 3H, acetate), 7.0 and 7.16 (s, 1H, olefinic proton), 9.60 and 10.04 (s, 1H, aldehyde); ms *m/e* 409 (M^+ + 2), 407 (M^+), 346, 331, 226. *Anal.* calcd. for $C_{24}H_{35}O_3Cl$: C 70.82, H 8.67, Cl 8.71; found: C 71.05, H 8.61, Cl 8.75.

(*b*) An analogous reaction was carried out with 200 mg of (*E*)-3β-acetoxy-20-methoxymethylene-5α-pregnan-21-al (**3**) and 0.6 ml of thionyl chloride. This led to 198 mg of the crude mixture of the chloromethylene aldehydes **5**. Filtration through 10 g of aluminum oxide, activity III, gave 140 mg of the pure mixture, mp 196–198°C. The identity of the product with that described under (*a*) was established by the determination of a mixture melting point and by the comparison of the uv, ir, and nmr spectra.

Ethyl 3β-Hydroxy-23-ethoxycarbonyl-21-nor-5α-chol-22-en-24-oate (*4*) *and Ethyl 3β-Acetoxy-23-ethoxycarbonyl-21-nor-5β-chol-22-en-24-oate* (*4a*)

(*a*) A solution of 1.0 g of aldehyde **2***d*, mp 148–150°C, of 0.46 ml of diethyl malonate and of 0.29 ml of piperidine in 24 ml of absolute ethanol was refluxed under nitrogen for 3 h. The product was cooled and precipitated into 250 ml of ice water. The mixture was extracted with ether, the ethereal layer was washed with an iced dilute hydrochloric acid solution, a cold sodium bicarbonate solution and water, and was dried. Evaporation of the solvent gave 1.12 g of an oil which was subjected to dry-column chromatography on 250 g of silica gel, petroleum ether – ether (1:2) being used as eluent. Thus, 885 mg of *ethyl 3β-acetoxy-23-ethoxycarbonyl-21-nor-5α-chol-22-en-24-oate* (**4***a*) was obtained; the product crystallized from petroleum ether, mp 98–100°C. A quantity of 118 mg of starting material (**2***d*) was recovered; considering this recovery, the yield of ester **4***a* corresponded to 80%. For analysis, a sample of ester **4***a* was recrystallized 3 times from petroleum ether; colorless needles, mp 102–103°C; $[\alpha]_D^{23}$ +20.9° (*c* 1.080, $CHCl_3$); λ_{max} ($CHCl_3$): 217 nm (log ε 3.5); ν_{max} (KBr): 1720 (esters), 1650 (double bond), 1250 cm^{-1} (esters); δ (90 MHz): 0.61 (s, 3H, 18-CH_3), 0.94 (s, 3H, 19-CH_3), 1.28 (t, *J* = 7 Hz, 3H) and 1.33 (t, *J* = 7 Hz, 3H), $COOCH_2CH_3$), 2.0 (s, 3H, acetate), 4.23 (q, *J* = 7 Hz, 2H), and 4.30 (q, *J* = 7 Hz, 2H) ($COOCH_2CH_3$), 7.0 (t, *J* = 8 Hz, 1H, 22-H); ms *m/e* 502.5 (M^+), 457, 317, 185.5. *Anal.* calcd. for $C_{30}H_{46}O_6$: C 71.68, H 9.22; found: C 71.52, H 9.00.

(*b*) A quantity of 266 mg of the dihydroxy aldehyde **2**, mp 192–196°C, was treated with 0.18 ml of diethyl malonate and 0.11 ml of piperidine in 18 ml of absolute ethanol, as described under (*a*) for the acetate **2***d*. The usual work-up gave 264 mg of a yellowish oil which was subjected to dry-column chromatography on 50 g of silica gel, ether being used as eluent. Thus, 80 mg of starting material (**2**) was recovered and 111 mg of *ethyl 3β-hydroxy-23-ethoxycarbonyl-21-nor-5α-chol-22-en-24-oate* (**4**), mp 125–130°C, was obtained (yield, considering the recovery of starting material, 45%); λ_{max} (EtOH): 215 nm (log ε 3.8); ν_{max} (KBr): 3380 (hydroxyl), 1730 (esters), 1650 (double bond), 1250 cm^{-1} (esters): δ (90 MHz): 0.58 (s, 18-CH_3), 0.80 (s, 19-CH_3), 1.25 (m, 6H, $COOCH_2CH_3$), 2.38 (s, 1H, exchanged with D_2O, OH), 3.57 (m, 1H, 3α-H), 4.22 (m, 4H, $COOCH_2CH_3$), 7.0 (t, *J* = 8 Hz, 1H, 22-H).

A quantity of 95 mg of this product (**4**) was acetylated in the usual fashion at room temperature with 1 ml of acetic anhydride in 2 ml of pyridine. Thus, 103 mg (quantitative yield) of *ethyl 3β-acetoxy-23-ethoxycarbonyl-21-nor-5α-chol-22-en-24-oate* (**4***a*), mp 97–100°C, was obtained. The identity of the product with the one described under (*a*) was established by the determination of a mixture melting point and by the comparison of the uv, ir, and nmr spectra.

3β-Acetoxy-23-ethoxycarbonyl-5α,14α-bufa-20,22-dienolide (*9*)

A solution of sodium ethoxide, prepared from 30 mg of sodium and 5 ml of absolute ethanol, was taken to dryness. The residue was dissolved in 10 ml of anhydrous hexamethylphosphoric triamide (HMPT) and 0.25 ml of freshly redistilled diethyl malonate was added. After 0.5 h, a solution of 500 mg of the *cis–trans* mixture of the chloromethylene aldehydes **5** in 20 ml of HMPT was added with stirring. The mixture was further stirred for 2.5 h at room temperature and was subsequently kept for 18 h at 0°C. After acidification with a few drops of glacial acetic acid, the product was poured into 400 ml of ice water. The mixture was extracted with ether, the ethereal layer was washed with a saturated sodium bicarbonate solution and water, and was dried. Evaporation of the solvent gave 658 mg of an oil, containing *ethyl 3β-acetoxy-23-ethoxycarbonyl-21-oxo-5α-chol-20-en-24-oate* (**6**); λ_{max} (EtOH): 238 nm (log ε 3.75); ν_{max} (film): 2710 (aldehyde), 1730 (esters), 1700 (aldehyde), 1640 (double bond), 1250 cm^{-1} (esters); δ (90 MHz): 0.60 (s, 3H, 18-CH_3), 0.85 (s, 3H, 19-CH_3), 1.3 (t, *J* = 7 Hz, 6H, $COOCH_2CH_3$), 1.93 (s, 3H, acetate), 4.21 (q, *J* = 7 Hz, 4H, $COOCH_2CH_3$), 6.4 (d, *J* = 10 Hz, 1H, 22-H), 10.06 (s, 1H, aldehyde). This product could not be purified since it cyclized as a consequence of the corresponding operations. It was subjected to dry-column chromatography, first on 150 g of silica gel, activity III, using petroleum ether – ether (1:2) as eluent, and again on 150 g of the same absorbent, using petroleum ether – ether (2:1) as eluent. There was recovered 90 mg of the starting material, the mixture of the isomeric aldehydes **5**, and there was further obtained 185 mg (38% yield, considering the recovery of starting material) of *3β-acetoxy-23-ethoxycarbonyl-5α,14α-bufa-20,22-dienolide* (**9**). This product did not crystallize but was found homogeneous by thin-layer analysis; $[\alpha]_D^{23}$ +42.2° (*c* 0.920, $CHCl_3$); λ_{max} (EtOH): 322 nm (log ε 3.7); ν_{max} (KBr): 1760 (lactone), 1730 (ester), 1640 and 1550 (conjugated diene), 1240 cm^{-1} (ester); δ (90 MHz): 0.53 (s, 3H, 18-CH_3), 0.82 (s, 3H, 19-CH_3), 1.28 (t, *J* = 7 Hz, 3H, $COOCH_2CH_3$), 2.0 (s, 3H, acetate), 4.37 (q, *J* = 7 Hz, 2H, $COOCH_2CH_3$), 4.68 (m, 1H, 3α-H), 7.45 (d, *J* = 2.5 Hz, 1H, 22-H), 8.12 (d, *J* = 2.5 Hz, 1H, 21-H); ms[16] *m/e* 484.5 (M^+), 345, 302, 287, 248, 216. *Anal.* calcd. for $C_{29}H_{40}O_6$: C 71.87, H 8.32; found: C 71.47, H 8.48.

Ethyl (Z)-*21-Chloro-3β-acetoxy-22ξ-hydroxy-5α-chol-20(21)-enoate* (*7*) *and Ethyl* (E)-*21-Chloro-3β-acetoxy-22ξ-hydroxy-5α-chol-20(21)-enoate* (*8*)

To a solution of 0.27 ml of hexamethyldisilazane in 1 ml of absolute ether and 3 ml of anhydrous *n*-pentane, there was added, with exclusion of moisture and in a nitrogen atmosphere, with a syringe, through a septum, 0.825 ml of a 1.52 *M* *n*-butyllithium solution in *n*-pentane. The mixture was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

refluxed for 0.5 h and was subsequently cooled. The solvent was evaporated *in vacuo* and the residue was dissolved in 3 ml of absolute tetrahydrofuran. This solution was cooled to −78°C and, with vigorous stirring, 0.1 ml of anhydrous ethyl acetate was added slowly. The mixture was stirred at −78°C for 15 min and, through a septum, a solution of 407 mg of the *cis–trans* mixture of the chloromethylene aldehydes **5** in 5 ml of THF was added. The product was stirred for 10 min at −78°C, treated with 8 ml of 2 *N* hydrochloric acid, and then allowed to reach room temperature. The mixture was precipitated into water and the product was extracted with ether. The ethereal layer was washed with a saturated sodium bicarbonate solution and water, and was dried. Evaporation of the solvent gave 526 mg of a mixture of the isomeric cholenates 7 and **8**. Recrystallization from ether–hexane gave 200 mg (41% yield) of *ethyl* (E)-*21-chloro-3β-acetoxy-22ξ-hydroxy-5α-chol-20(21)-enoate* (**8**), mp 141–144°C. For analysis, a sample was recrystallized 3 times from ether–hexane; colorless powder, mp 161–162°C; $[\alpha]_D^{25}$ −21.6° (*c* 1.250, $CHCl_3$); ν_{max} (KBr): 3410 (hydroxyl), 3100 (double bond), 1730 (acetate), 1710 (ethyl ester), 1625 (double bond), 1280 cm^{-1} (esters); δ (90 MHz): 0.72 (s, 3H, 18-CH_3), 0.93 (s, 3H, 19-CH_3), 1.26 (t, J = 7 Hz, 3H, $COOCH_2CH_3$), 2.4 (d, J = 9 Hz, 2H, $CH_2COOC_2H_5$), 4.16 (q, J = 7 Hz, 2H, $COOCH_2CH_3$), 4.66 (m, 2H, 3α-H and 21-H), 6.48 (s, 1H, olefinic proton). *Anal.* calcd. for $C_{28}H_{43}O_5Cl$: C 67.92, H 8.75, Cl 7.16; found: C 67.54, H 8.70, Cl 7.05.

Recrystallization of the mother liquors from ether–hexane gave 249 mg (50% yield) of *ethyl* (Z)-*21-chloro-3β-acetoxy-22ξ-hydroxy-5α-chol-20(21)-enoate* (7), mp 101–108°C. For analysis a sample was recrystallized 3 times from ether–hexane; colorless powder, mp 107–110°C; $[\alpha]_D^{25}$ +14.5° (*c* 1.035, $CHCl_3$); ν_{max} (KBr): 3480 (hydroxyl), 3100 (double bond), 1730 (acetate), 1710 (ethyl ester), 1625 (double bond), 1270 cm^{-1} (esters); ν_{max} (CCl_4): 3520 cm^{-1}; δ (90 MHz): 0.67 (s, 3H, 18-CH_3), 0.81 (s, 3H, 19-CH_3), 1.28 (t, J = 7 Hz, 3H, $COOCH_2CH_3$), 2.6 (d, J = 9 Hz, 2H, $CH_2COOC_2H_5$), 4.16 (q, J = 7 Hz, 2H, $COOCH_2CH_3$), 4.66 (m, 1H, 3α-H), 5.16 (m, 1H, 21-H), 5.94 (s, 1H, olefinic proton). *Anal.* calcd. for $C_{28}H_{43}O_5Cl$: C 67.92, H 8.75, Cl 7.16; found: C 67.80, H 8.68, Cl 6.90.

The reaction was repeated, employing the same procedure, in the presence of 5 mg of cuprous chloride, which led to an identical result.

Ethyl (Z)-*3β-Acetoxy-21-oxo-5α-chol-20(22)-enoate* (**12**) *from* (Z)-*3β-Acetoxy-20-methoxymethylene-5α-pregnan-21-al* (**2***d*) *without Isolation of the Hydroxy Cholenoate* **10**

Using the procedure described in the previous experiment leading to the chloro cholenoates **7** and **8**, 1.206 g of the methoxymethylene aldehyde **2***d*, mp 148–150°C, was treated in THF at −78°C for 10 min with a solution of ethyl lithioacetate obtained from 0.3 ml of ethyl acetate and a solution of lithium hexamethyldisilazine, the latter having been prepared from 2.58 ml of 1.52 *M* *n*-butyllithium and 0.81 ml of hexamethyldisilazane. The usual work-up gave 1.463 g of a product which was subjected to dry-column chromatography on 80 g of silica gel, petroleum ether – ether (1:1) serving as eluent. Thus, 1.047 g (78% yield) of a *cis–trans* mixture of the *ethyl 3β-acetoxy-21-oxo-5α-chol-20(22)-enoates* **12** and **13**, mp 149–154°C, was obtained; λ_{max} (EtOH): 233 (log ε 3.95), 300 nm (log ε 3.25); ν_{max} (KBr): 2740 (aldehyde), 1745 (shoulder) and 1730 (esters), 1683 and 1630 (α,β-unsaturated aldehyde), 1250 cm^{-1} (esters); ν_{max} (film) 2720 (broad, aldehyde), 1742, 1730 (esters), 1697 and 1636 (α,β-unsaturated aldehyde), 1250 cm^{-1} (esters); δ (90 MHz): 0.6 (s, 3H, 18-CH_3), 0.8 (s, 3H, 19-CH_3), 1.25 and 1.27 (t, J = 7 Hz, 3H, $COOCH_2CH_3$), 2.0 (s, 3H, acetate), 3.42 (d, J = 7 Hz, 2H, 23-H_2), 4.16 and 4.18 (q, J = 7 Hz, 2H, $COOCH_2CH_3$), 6.52 and 6.77 (t, J = 7 Hz, 1H, olefinic proton), 9.46 and 9.96 (s, 1H, aldehyde). Recrystallization from dichloromethane–hexane raised the melting point to 157–160°C. The nmr spectra of the recrystallized product and of its mother liquors indicated the presence of only the *Z-isomer* **12**. For analysis, a sample was recrystallized 3 times from dichloromethane–hexane; colorless prisms, mp 163.5–165°C; $[\alpha]_D^{25}$ −56.7° (*c* 1.180, $CHCl_3$); λ_{max} (EtOH): 233 nm (log ε 4.05), 300 nm (log ε 3.4); ν_{max} (KBr): 2740 (aldehyde), 1745 and 1730 (esters), 1685 and 1630 (α,β-unsaturated aldehyde), 1250 cm^{-1} (esters); δ (90 MHz): 0.61 (s, 3H, 18-CH_3), 0.81 (s, 3H, 19-CH_3), 1.27 (t, J = 7 Hz, 3H, $COOCH_2CH_3$), 2.0 (s, 3H, acetate), 3.43 (d, J = 7 Hz, 2H, $CH_2COOC_2H_5$), 4.18 (q, J = 7 Hz, 2H, $COOCH_2CH_3$), 6.77 (t, J = 7 Hz, 1H, olefinic proton), 9.48 (s, 1H, aldehyde). *Anal.* calcd. for $C_{28}H_{42}O_5$: C 73.32, H 9.23; found: C 73.58, H 9.21.

Ethyl (Z)-*3β-Acetoxy-21-methoxy-22ξ-hydroxy-5α-chol-20(21)-enoate* (**10**)

As described above, 602 mg of aldehyde **2***d* was treated in THF at −78°C for 10 min with a solution of ethyl lithioacetate, obtained from 0.15 ml of ethyl acetate and a solution of lithium hexamethyldisilazine, prepared from 1.3 ml of a 1.52 *M* *n*-butyllithium solution and 0.40 ml of hexamethyldisilazane. However, in contradistinction to the experiment described in the previous section, in the work-up the product was not hydrolyzed with hydrochloric acid but with water. Thus, 646 mg of a material was obtained which was subjected to dry-column chromatography on 42 g of silica gel, petroleum ether – ether (1:1) being used as eluent. This gave 306 mg (42% yield) of the hydroxy cholenoate **10**, mp 139–143°C. For analysis, a sample was recrystallized 3 times from ether–hexane; colorless powder, mp 143.5–145°C; $[\alpha]_D^{25}$ −18.8° (*c* 1.120, $CHCl_3$); ν_{max} (KBr): 3450 (hydroxyl), 1730 (acetate), 1715 (ethyl ester), 1655 (double bond), 1250 cm^{-1} (esters); δ (90 MHz): 0.64 (s, 3H, 18-CH_3), 0.81 (s, 3H, 19-CH_3), 1.25 (t, J = 7 Hz, 3H, $COOCH_2CH_3$), 2.53 (d, J = 6 Hz, 2H, $CH_2COOC_2H_5$), 3.51 (s, 3H, CH_3O), 4.15 (q, J = 7 Hz, 2H, $COOCH_2CH_3$), 4.3–4.9 (m, 2H, 3α-H and 21-H), 6.24 (s, 1H, olefinic proton). *Anal.* calcd. for $C_{29}H_{46}O_6$: C 70.98, H 9.45; found: C 71.03, H 9.39.

Ethyl (Z)-*3β-Acetoxy-21-oxo-5α-chol-20(22)-enoate* (**12**) *from the Hydroxy Cholenoate* **10**

For 10 min, at room temperature, 102 mg of ethyl (*Z*)-3β-acetoxy-21-methoxy-22ξ-hydroxy-5α-chol-20(21)-enoate (**10**), mp 139–143°C, was treated in 10 ml of tetrahydrofuran with 6 ml of 2 *N* hydrochloric acid. The usual work-up gave 96 mg (quantitative yield) of the *cis–trans* mixture of the aldehydo cholenoates **12** and **13**. One recrystallization from dichloromethane–hexane gave the *Z*-isomer **12**, mp 155–159°C, identified by the determination of a mixture melting point and by the comparison of its ir, uv, and nmr spectra with those of the product described above.

3β-Acetoxy-5α,14α-bufa-20,22-dienolide (**11**)

A solution of 347 mg of ethyl (*Z*)-3β-acetoxy-21-oxo-5α-chol-20(22)-enoate (**12**), mp 157–160°C, in 65 ml of ethanol was refluxed with 6.5 ml of concentrated hydrochloric acid, under nitrogen, for 18 h. The mixture was cooled and was then precipitated into 650 ml of ice water. After 1 h, the product was filtered, the solid material was washed with water and was dissolved in dichloromethane. The solution was dried, the solvent was evaporated, and the residue (292 mg) was dissolved in 25 ml of pyridine and treated for 16 h at room temperature with 12.5 ml of acetic anhydride. The product was precipitated into 300 ml of ice water and the mixture was extracted with ether. The ethereal solution was washed with iced dilute

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

hydrochloric acid, a cold sodium bicarbonate solution, and water, and was dried. Evaporation of the solvent gave 317 mg of a solid which was subjected to dry-column chromatography on 20 g of silica gel, petroleum ether – ether (2:3) serving as eluent. Thus, 138 mg of the bufadienolide **11**, mp 175–180°C, and 92 mg of the starting material, the aldehydo ester **12**, were obtained (yield, considering the recovery of starting material, 60%). Recrystallization of the bufadienolide **11** from ether–hexane raised the melting point to 180–183°C; λ_{max} (EtOH): 298–300 nm (log ε 3.7); ν_{max} (KBr): 3100 (double bond), 1755 (lactone), 1735 (acetate), 1645 and 1545 (conjugated diene), 1240 cm^{-1} (acetate); δ (90 MHz): 0.51 (s, 3H, 18-CH_3), 0.81 (s, 3H, 19-CH_3), 2.0 (s, 3H, acetate), 4.72 (m, 1H, 3α-H), 6.25 (d, J = 10 Hz, 1H, 22-H), 7.22–7.33 (m, 2H, 21-H and 23-H). The identity of the product was confirmed by the determination of a mixture melting point and by the comparison of its spectra with those of an authentic sample (6).

Treatment of (Z)-*3β-Acetoxy-20-acetoxymethylene-5α-pregnan-21-al (2b) with Ethyl Lithioacetate*

Using the above described method, 430 mg of (*Z*)-3β-acetoxy-20-acetoxymethylene-5α-pregnan-21-al (**2***b*) was treated in THF at −78°C for 10 min with a solution of ethyl lithioacetate, prepared from 0.1 ml of ethyl acetate and a solution of lithium hexamethyldisilazine, obtained from 0.825 ml of a 1.52 *M n*-butyllithium solution and 0.27 ml of hexamethyldisilazane. The usual work-up gave 444 mg of a crude product, mp 240–245°C, consisting essentially of *3β-acetoxy-20-hydroxymethylene-5α-pregnan-21-al* (**2***a*). One recrystallization from dichloromethane–hexane gave 175 mg of the pure product, mp 243–247°C; λ_{max} (EtOH): 253 nm (log ε 4.1); ν_{max} (KBr): 3500–2400 (hydroxyl), 2700 (aldehyde), 1730 (acetate), 1640 and 1585 (strong, α,β-unsaturated aldehyde), 1240 (ester), 1025 cm^{-1} (hydroxyl); δ (60 MHz): 0.53 (s, 3H, 18-CH_3), 0.83 (s, 3H, 19-CH_3), 2.03 (s, 3H, acetate), 8.4 (s, 2H, mesomeric aldehyde groups)

Reacetylation

A quantity of 25 mg of the acetoxy hydroxymethylene aldehyde **2***a* was acetylated with 3 ml of acetic anhydride in 6 ml of pyridine in the usual fashion. This led to 26 mg (quantitative yield) of *3β-acetoxy-20-acetoxymethylene-5α-pregnan-21-al* (**2***b*), obtained as a foam. The identity of the product was established by the comparison of its uv, ir, and nmr spectra with those of authentic diacetate **2***b* (see above).

Treatment of (Z)-*3β-Hydroxy-20-hydroxymethylene-5α-pregnan-21-al (2) with Ethyl Lithioacetate*

Using the above described method, 345 mg of the hydroxymethylene aldehyde **2** was treated in THF at −78°C for 1 h with an excess of ethyl lithioacetate (5.5 equiv.), obtained from 0.55 ml of ethyl acetate and a solution of lithium hexamethyldisilazine, prepared from 4.53 ml of a 1.52 *M n*-butyllithium solution and 1.48 ml of hexamethyldisilazane. The usual work-up gave 337 mg (quantitative yield) of a yellowish solid which was identified, by thin-layer, ultraviolet, infrared, and nmr analyses, as starting material **2**.

3-Ethoxycarbonyl-5,6,7,8-tetrahydrocoumarin (18)

A solution of sodium ethoxide, prepared from 10 ml of absolute EtOH and 90 mg of Na, was taken to dryness. The product was dissolved in 30 ml of anhydrous HMPT and 0.67 ml of freshly redistilled diethyl malonate was added. After 0.5 h, a solution of 557 mg of 2-chloromethylenecyclohexanone (**15**) (30) in 3 ml of HMPT was added with stirring. The mixture was further stirred for 1.5 h at room temperature and was then left for 18 h at 0°C. After acidification with a few drops of glacial acetic acid, the product was poured into 300 ml of ice water. The product's ether extract was washed with a saturated sodium bicarbonate solution and with water, and was dried. Evaporation of the solvent gave 1.012 g of a dark-brown oil, the ir and nmr spectra of which indicated the presence, to a considerable extent, of the starting materials, the uv spectrum of which, however, showed a maximum at 243 nm. The product was left for 2 days at room temperature. The black material was dissolved in ether, the ethereal solution was washed with water and was dried. Evaporation gave 780 mg of a brown oil, showing an α-pyronic structure (λ_{max} (EtOH) 332 nm (log ε 3.95); ν_{max} (film): 1645 and 1570 cm^{-1} (conjugated diene); δ (90 MHz): 7.88 (s, α-pyronic proton)). This product was subjected to dry-column chromatography on 50 g of silica gel, petroleum ether – ether (1:1) serving as eluent. Thus, 192 mg of the tetrahydrocoumarin **18**, mp 86–89°C, and 117 mg of the starting material **15** were obtained. For analysis, a sample of the tetrahydrocoumarin **18** was recrystallized twice from ether – petroleum ether; colorless prisms, mp 90.5–90°C; λ_{max} (EtOH): 335 nm (log ε 4); ν_{max} (KBr): 3040 (double bond), 1755 (large, lactone and ester), 1640 and 1570 (conjugated diene), 1235 cm^{-1} (ester); δ (90 MHz): 1.34 (t, J = 7 Hz, 3H, $COOCH_2CH_3$), 1.7–1.9 (m, 4H, 6-H_2 and 7-H_2), 2.4–2.6 (m, 4H, 5-H_2 and 8-H_2), 4.33 (q, J = 7 Hz, 2H, $COOCH_2CH_3$), 7.97 (s, 1H, 4-H). *Anal.* calcd. for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 64.96, H 6.33.

1-Formyl-2-carbethoxymethyl-1-cyclohexene (Ethyl (2′-Formylcyclohexenyl) Acetate) (22)

Using the above described procedure, 3.0 g of 2-methoxymethylenecyclohexanone (**20**) (31) prepared from 2-hydroxymethylenecyclohexanone according to the method employed by Gusakova *et al.* (32) for the synthesis of 2-ethoxymethylenecyclohexanone, was treated at −78°C in THF for 10 min with a solution of ethyl lithioacetate, prepared from 2.0 ml of ethyl acetate and a solution of lithium hexamethyldisilazine, obtained from 16.5 ml of 1.52 *M n*-butyllithium and 5.4 ml of hexamethyldisilazane. The usual work-up gave 3.65 g of a product which was subjected to dry-column chromatography on 300 g of silica gel, petroleum ether – ether (3:1) being used as eluent. Thus, 2.74 g (64% yield) of the aldehydo ester **22**, bp 94–97°C/1.0 Torr, was obtained; λ_{max} (EtOH): 247 nm (log ε 4.1); ν_{max} (film): 2740 (aldehyde), 1730 (ester), 1670 and 1640 (α,β-unsaturated aldehyde), 1230 cm^{-1} (ester); δ (90 MHz): 1.25 (t, J = 7 Hz, 3H, $COOCH_2CH_3$), 1.55–1.8 (m, 4H, 4-H_2 and 5-H_2), 2.2–2.5 (m, 4H, 3-H_2 and 6-H_2), 3.58 (s, 2H, $CH_2COOC_2H_5$), 4.2 (q, J = 7 Hz, 2H, $COOCH_2CH_3$), 10.2 (s, 1H, aldehyde).

2,4-Dinitrophenylhydrazone 22a

The 2,4-dinitrophenylhydrazone **22***a* was prepared in the usual fashion (33): mp 199.5–200°C (lit. (16*c*) 196–197°C); λ_{max} (EtOH): 261 (log ε 4.2), 292 (log ε 3.95), 380 nm (log ε 4.45) (lit. (16*c*) 257.5 (log ε 4.22), 291 (log ε 3.99), 381 nm (log ε 4.48)); ν_{max} (KBr): 3260 (NH), 3100 (aromatic C—H), 1705 (ester), 1615 and 1595 (aromatic), 1515 and 1330 (nitro groups), 1280 (ester), 835 cm^{-1} (aromatic); δ (90 MHz): 1.27 (t, J = 7 Hz, 3H, $COOCH_2CH_3$), 1.60–1.85 (m, 4H, 4-H_2 and 5-H_2), 2.22–2.60 (m, 4H, 3-H_2 and 6-H_2), 3.3 (s, 2H, $CH_2COOC_2H_5$), 4.17 (q, J = 7 Hz, 2H, $COOCH_2CH_3$), 8.22 (s, 1H, CH=N), 7.92 (d, J = 9 Hz, 1H), 8.20–8.35 (m, 1H), 9.1 (d, J = 2.5 Hz, 1H) (aromatic protons), 11.7 (s, large, 1H, NH). *Anal.* calcd. for $C_{17}H_{20}N_4O_6$: C 54.25, H 5.36, N 14.89; found: C 54.48, H 5.20, N 14.82.

Acknowledgements

Sincere thanks are extended to Mrs. J. Capitaine for her excellent cooperation in this study. We express our appreciation to Mrs. G. Pelletier and

Miss D. Thibault for devoted technical assistance. We are very grateful to the National Research Council of Canada, to the Ministère de l'Education du Gouvernement du Québec, and to Ayerst Laboratories, Montreal, for financial support, to Ayerst Laboratories also for very kind cooperation. One of us (G.D.) wishes to acknowledge scholarships from the National Research Council of Canada and the Ministère de l'Education du Québec.

Hydrolysis of Co(II) at elevated temperatures[1]

GAÉTAN GIASSON[2] AND PARAM H. TEWARI[3]

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received May 25, 1977

GAÉTAN GIASSON and PARAM H. TEWARI. Can. J. Chem. **56**, 435 (1978).

Hydrolysis of Co(II) has been studied up to 200°C using a concentration cell with liquid junction of the type $Pt(H_2)|H^+(a_1)||H^+(a_2)|(H_2)Pt$. The effect of varying the initial solution p*H* and cobalt concentration has been studied at different ionic strengths. The hydrothermal hydrolysis for cobalt solutions between p*H* 3.9 and 9.6 is consistent with the equilibrium $Co^{2+} + H_2O \rightarrow CoOH^+ + H^+$. Higher hydrolytic species are not important. Hydrolysis increases with temperature and produces a buffering action at 200°C. Thermodynamic quantities for the hydrolysed species are reported.

GAÉTAN GIASSON et PARAM H. TEWARI. Can. J. Chem. **56**, 435 (1978).

On a étudié l'hydrolyse de Co(II) à des températures allant jusqu'à 200°C; pour y parvenir, on a fait appel à une cellule de concentration avec une jonction liquide du type $Pt(H_2)|H^+(a_1)||H^+(a_2)|(H_2)Pt$. On a étudié l'effet produit par la variation du p*H* et de la concentration du cobalt à diverses forces ioniques. L'hydrolyse hydrothermique de solutions de cobalt à des p*H* allant de 3.9 à 9.6 est en accord avec l'équilibre $Co^{2+} + H_2O \rightarrow CoOH^+ + H^+$. Les espèces hydratées plus élevées ne sont pas importantes. L'hydrolyse augmente avec la température et provoque une action de tampon à 200°C. On rapporte les paramètres thermodynamiques des espèces hydrolysées.

[Traduit par le journal]

Introduction

The hydrolysis of Co(II) ion has been studied by several workers (1–5) but these studies are limited to temperatures up to 50°C. The reported hydrolysis constants, even at 25°C, vary by a factor of more than 10^4. Therefore there is a need for more reliable values for the constants.

We have shown that hydrolysis enhances the adsorption of Co(II) on oxide surfaces (6, 7) in aqueous suspensions. Since oxides containing Co(II) become a contributing factor in the transport of ^{60}Co radioactivity in the coolant circuits of nuclear reactors, hydrolysis of Co(II) has been studied to understand its adsorption on oxides. To obtain better values for the hydrolysis constants, especially at higher temperatures, we have also studied the hydrolysis of Co(II) up to 200°C, using electrometric acidity measurements. In this work, hydrolysis studies between 25 and 200°C are reported as a function of p*H* of the initial solution, Co(II) concentration, and the ionic strength of the medium.

Experimental

The concentration cell with liquid junction of the type $Pt(H_2)|H^+(a_1)||H^+(a_2)|(H_2)Pt$ used to measure the acidity up to 200°C is shown in Fig. 1. The cell consists of two Teflon compartments housed in a high pressure autoclave. The two compartments contain solutions connected through a liquid junction (plug) of porous Teflon which was soaked in a saturated potassium chloride solution. The leakage rate through the plug was 2 μl/h but this was insufficient to introduce any significant error in the acidity of the solutions. The two compartments achieved a balanced H_2 pressure through a 1 mm hole located at the top of the inner Teflon wall.

Two platinum-encased thermocouples served as temperature sensors as well as reversible hydrogen electrodes for the cell. The electrodes were electrically isolated from the cell body by

[1]AECL No. 6027.

[2]Present address: Aluminum Company of Canada Limited, Arvida, Quebec, Canada.

[3]To whom correspondence should be addressed.

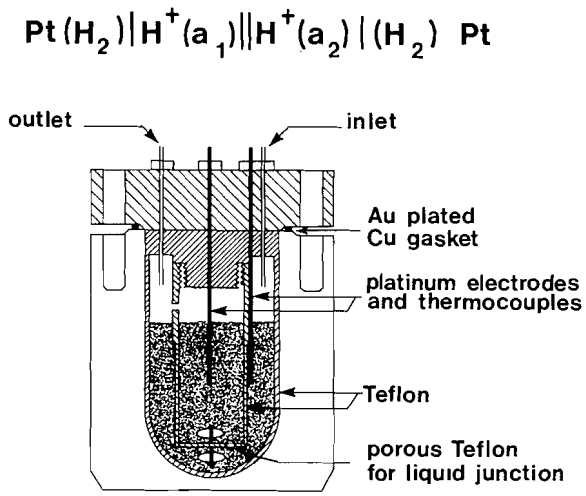

FIG. 1. High temperature concentration cell with liquid junction.

Teflon washers. The lower parts of the electrodes were platinized before each new set of measurements.

The entire autoclave assembly was put in a flush-fitting heating jacket and its heating was regulated by a thermocouple. The temperature of the two compartments was monitored continuously on a chart recorder and readings of cell emf were taken only after the temperature readings on the recorder were constant for an hour. The temperature was controlled between 25°C and 200°C to ±0.2°C. The potential difference of the cell was measured on a high-impedance digital millivoltmeter. Equilibrium emf values, as shown by their constancy on the recording chart paper, were used for calculations. The instrument could detect 0.1 mV changes in voltage between the two hydrogen electrodes. The solutions in the two compartments were stirred by Teflon-coated magnetic stirrers. All solutions were bubbled with H_2 before putting them into the cell and then were pressurized and purged repeatedly with H_2 to remove all traces of air or oxygen. Finally the cell was pressurized with 0.7 kPa of H_2 and sealed. At 25°C the equilibrium potential was attained in about 3 to 4 h after sealing the cell. The cell was then heated to the desired temperatures and at each equilibrium temperature the potential difference was noted.

Materials

Analytical grade $CoCl_2$, KCl, and HCl were used. KCl was further recrystallized. Deionized double-distilled water of conductivity $< 5.0 \times 10^{-6}$ Ω^{-1} m^{-1} was used. The reference (outer) compartment contained an HCl/KCl mixture with $H^+ = 1.0 \times 10^{-2}$ mol/kg and the inner compartment contained Co(II)/KCl solution mixtures at different initial acidities. Cobalt concentration was varied between 10^{-3} and 10^{-1} mol/kg and KCl concentration was varied between 0 and 1.0 mol/kg. Solutions of cobalt were prepared by weighing $CoCl_2 \cdot 6H_2O$ and their concentrations were checked by atomic absorption spectroscopy. The concentration of Cl^- and the ionic strength of the medium were maintained at the same value in both compartments by addition of KCl. The pH of the reference solution was periodically checked against a standard solution at 25°C and was found to remain constant to within 0.005 pH.

Acidity Measurements at Higher Temperatures

The potential difference E between the two hydrogen electrodes of the concentration cell $Pt(H_2)|H^+(a_1)||H^+(a_2)|(H_2)Pt$ is given by eq. 1,

$$[1] \qquad E = \frac{2.303RT}{F} \log \frac{a_2}{a_1} + E_J$$

$$= \frac{2.303RT}{F} \log \frac{\gamma_2 m_2}{\gamma_1 m_1} + E_J$$

$$= \frac{2.303RT}{F} (pH_1 - pH_2) + E_J$$

where a_1 and a_2 refer to the activities, γ_1 and γ_2 the activity coefficients, and m_1 and m_2 the molalities of H^+ in the inner and outer compartments respectively. E_J is the liquid junction potential. E_J was estimated by the method described by Macdonald and others (8) using diffusion coefficient, molality, and equivalent conductance data for ionic species in the solution. The liquid junction potential thus calculated for solutions of different ionic strengths seldom exceeded 0.1 mV, an insignificant fraction of the total measured potential difference (100–200 mV). Also, since the ionic strength of the two compartments was kept the same, the term $\log \gamma_2/\gamma_1$ can be eliminated without introducing significant error (8). Therefore, from the values of the potential difference E, and the pH_1 and m_1 of the reference compartment, pH_2 and m_2 for the cobalt containing solutions were calculated at different temperatures using [1].

Some hysteresis was observed with cobalt concentrations $> 10^{-1}$ mol/kg. This was probably due to hydrolytic precipitation on the electrodes; however, no detectable precipitation was observed. The electrodes were scraped to analyse for any precipitated material on them by X-ray diffraction but apart from platinum lines the patterns were very weak and no cobalt was detected. Also no metallic cobalt was detected under the reducing H_2 atmosphere at 200°C.

To test the reliability of the high temperature cell, K_w, the ionisation constant of water as a function of temperature was studied with acidic and alkaline (H^+ and OH^-) solutions in the outer and inner compartments respectively. The results were in close agreement (within 6%) with those reported in the literature (8, 9) which indicated that the cell was working satisfactorily.

Results and Discussion

Values for pH decreased with increasing temperature (Fig. 2). For solutions with higher initial pH, the drop in p$H(T)$ with temperature was steep; however, for solutions with lower pH, the decrease was small. Steeper p$H(T)$ changes showed a larger degree of hydrolysis for solutions of higher initial pH in contrast to solutions of lower pH. However, for all cobalt solutions with initial pH ranging from 3.9 to 9.6, the p$H(T)$ converged at higher temperatures and the final p$H(T)$ at 200°C for all the solutions was 3.78 ± 0.05. Thus the acidity at 200°C was insensitive to the pH at 25°C. This buffering action of the hydrolysis equilibria for cobalt is apparent from Fig. 3, where a p$H(T)$ vs. p$H(25)$ graph shows that p$H(T)$ was dependent on p$H(25)$ at lower temperatures but became almost independent at 200°C. Only at the highest pH (>5.5) does p$H(T)$ increase significantly from 3.75 at 200°C.

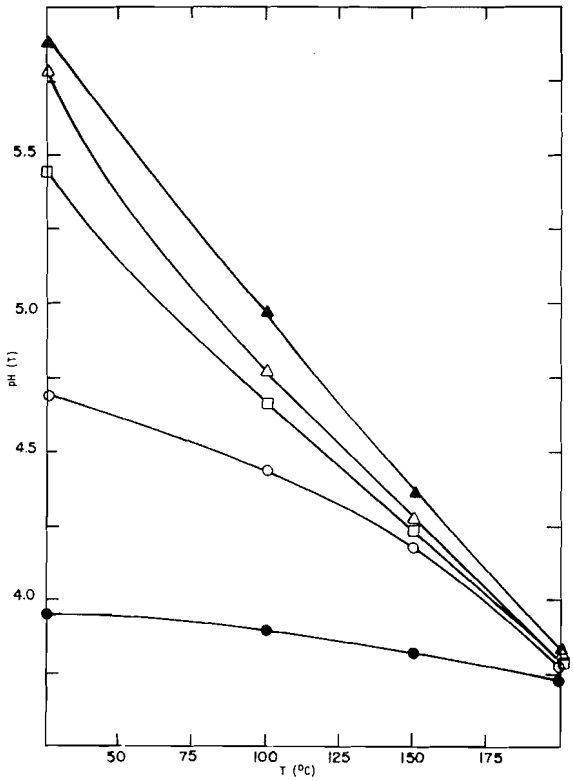

FIG. 2. p$H(T)$ versus temperature for different initial solution p$H(25)$, Co(II) 0.010 mol/kg and KCl 1.02 mol/kg: ●, pH 3.94; ○, pH 4.70; □, pH 7.92; △, pH 9.10; ▲, pH 9.62.

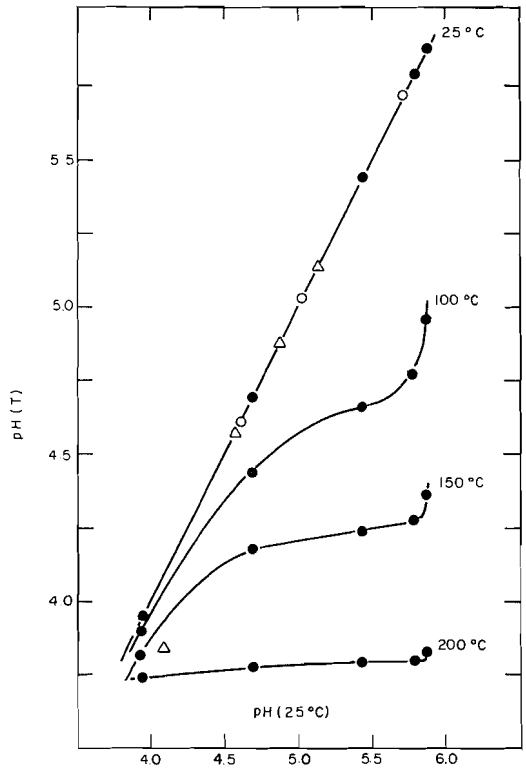

FIG. 3. p$H(T)$ versus p$H(25)$ at different temperatures: Co(II) = ●, 0.010, ○, 0.05, △, 0.102 mol/kg; Cl^- = 1.02 mol/kg.

High Temperature Hydrolysis

The temperature dependence of hydrolysis may be understood by defining a term $Z(T)$ as equal to the average number of OH^- ions bound per metal ion in the system. $Z(T)$ can be evaluated from experimental data of the hydrogen ion concentration in the solution before and after hydrolysis at each temperature (8–10) by [2], where h is the acidity after hydrolysis, H is the acidity before hydrolysis, $Q_{w(T)}$ is the equilibrium quotient for self-dissociation of water at temperature T, $Q_{w(25)}$ is the equilibrium quotient for self-dissociation of water at 25°C, and M_{Co} is total cobalt concentration.

$$[2] \quad Z(T) = \left[\left(h - \frac{Q_{w(T)}}{h}\right) - \left(H - \frac{Q_{w(25)}}{H}\right)\right] \Big/ M_{Co}$$

$Z(T)$ increases rapidly with temperature above 100°C (Fig. 4). The increase in $Z(T)$ is greater for solutions of higher pH at the same temperatures, indicating higher hydrolysis which is also evident from Fig. 2 where the largest drops in p$H(T)$ values, with temperature, are seen for solutions of higher pH.

In a plot of $Z(T)$ versus p$H(T)$ (T = 25°C) for different initial concentrations of Co(II) (Fig. 5), all the points fall on the same curve, i.e., $Z(T)$ is independent of cobalt concentration. This shows that the complexes present in appreciable amounts are homonuclear (1, 11, 13) and are probably represented by the hydrolysis equilibrium

$$[3] \quad Co^{2+} + H_2O \rightleftarrows CoOH^+ + H^+$$

Similarly at 200°C (Fig. 6), the points for the three concentrations of cobalt, with two exceptions, fall on one curve, showing that even at 200°C only homonuclear species are present. The two points which do not fit well on the curve are for solutions at the initial pH of 3.94 where hydrolysis is least and, therefore, the error in $Z(T)$ is high for these least hydrolysed samples.

Values of $Z(T)$ versus p$H(T)$ (Figs. 4, 7) at three Cl^- concentrations (from 0.02–1.02 mol/kg) at different temperatures fall on the same curve. Also a plot of $Z(T)$ against $Z(25)$ for different chloride ion concentrations is insensitive to chloride concentration. These results indicate that there is no formation of CoOHCl or mixed hydroxochloro complexes, and that OH^- is a stronger ligand than Cl^- for Co.

Hydrolysis Equilibria

The formation of different cobalt complexes in the

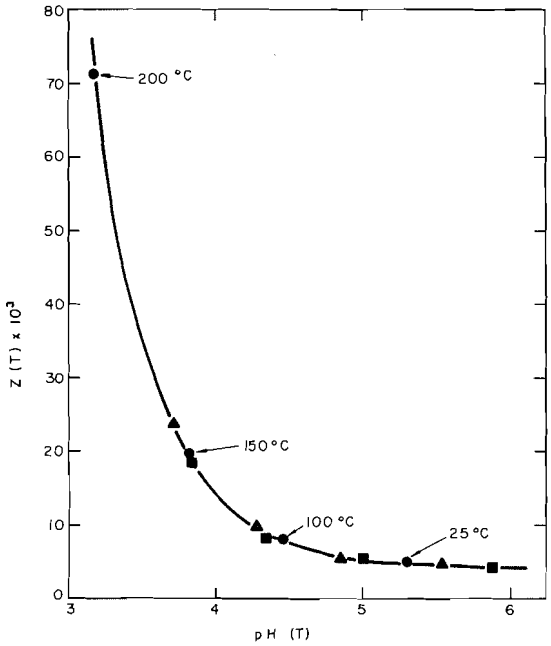

FIG. 4. Variation of $Z(T)$ with $pH(T)$ for different chloride concentrations; starting $pH(25)$ in the range 9.62–9.65: Co(II) = 0.01 mol/kg; Cl^- = ●, 0.02, ▲, 0.10, ■, 1.02 mol/kg.

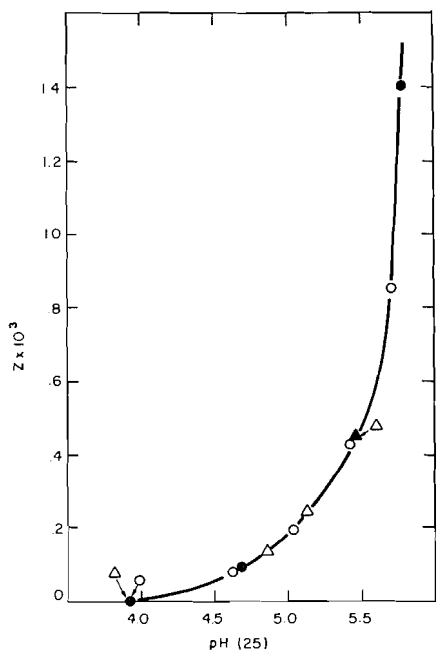

FIG. 5. Variation of $Z(T)$ with $pH(T)$ at T = 25°C: Co(II) = ●, 0.010, ○, 0.051, △, 0.102 mol/kg; Cl^- = 1.02 mol/kg.

KCl solution can be represented by

$$[4]\quad x\mathrm{Co}^{2+} + y\mathrm{H_2O} + z\mathrm{Cl}^- \overset{K_n}{\rightleftharpoons} \mathrm{Co}_x(\mathrm{OH})_y\mathrm{Cl}_z^{(2x-y-z)+} + y\mathrm{H}^+$$

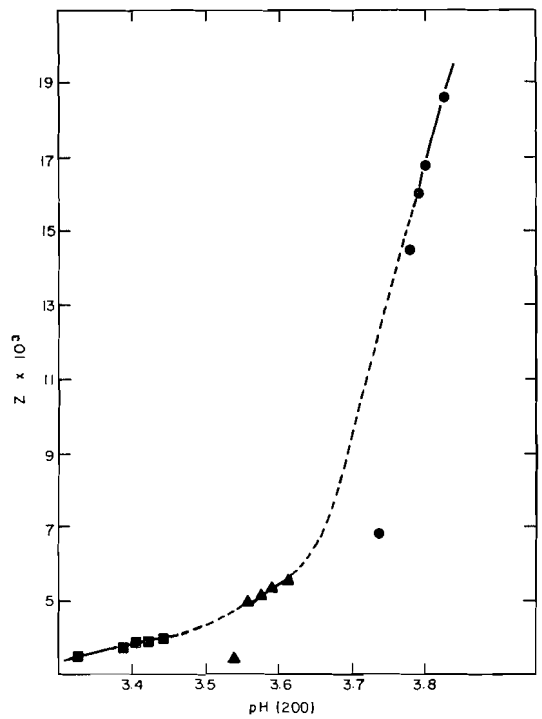

FIG. 6. Variation of $Z(T)$ with $pH(T)$ at T = 200°C: Co(II) = ●, 0.010, ▲, 0.051, ■, 0.102 mol/kg; Cl^- = 1.02 mol/kg.

where $x = 1, \ldots, n$, $y = 0, \ldots, n$, and $z = 0, \ldots, n$. K_n is the nth hydrolysis constant of [3].

$Z(T)$ is related to M_{Co} (total cobalt), x, y, z, and K_n at the temperature of interest through [5] and [6].

$$[5]\quad M_{Co} = [\mathrm{Co}^{2+}]_{free} + \sum_z \sum_y \sum_x xK_n \frac{[\mathrm{Co}^{2+}]^x[\mathrm{Cl}^-]^z}{[\mathrm{H}^+]^y}$$

$$[6]\quad [\mathrm{OH}^-]_{bound} = \sum_z \sum_y \sum_x yK_n \frac{[\mathrm{Co}^{2+}]^x[\mathrm{Cl}^-]^z}{[\mathrm{H}^+]^y}$$

Values of K_n were derived using a modified version of the computer program SCOGS, adopted for potentiometric measurements (12), which calculates K_n by minimizing the difference between $Z(T)$ calculated ([5] and [6]), and $Z(T)$ measured ([2]).

Since the fit of the experimental data (Table 1) is better when only $CoOH^+$ is considered, the results seem to be consistent with the presence of only $CoOH^+$, with little contribution from $Co(OH)_2$, under the conditions of the experiment (between pH 3 and 9.6 and for Co(II) solutions between 10^{-3} and 10^{-1} mol/kg).

At 25°C, our calculated value of pK_1 is similar to that reported by Bolzan and Arvia (1) but lower than that of Shanker and DeSouza (4) and Collados *et al.* (5). However, in these cases 1–5 mol/kg $Ba(ClO_4)_2$ and $NaClO_4$ were used to control the ionic strength,

TABLE 1. Calculated pK's

Species considered	Temperature (°C) 25	100	150	200
Only $CoOH^+$	$pK_1 = 9.82 \pm 0.02$	7.62 ± 0.03	6.59 ± 0.02	6.02 ± 0.04
$\mu = 1.0$	$\sigma = 1 \times 10^{-4}$	$\sigma = 3 \times 10^{-4}$	$\sigma = 7 \times 10^{-4}$	$\sigma = 3 \times 10^{-3}$
$CoOH^+$ and $Co(OH)_2$	$pK_1 = 9.84 \pm 0.09$	7.60 ± 0.10	6.63 ± 0.08	6.08 ± 0.12
	$pK_2 = 16.12 \pm 0.15$	12.89 ± 0.19	11.53 ± 0.18	9.64 ± 0.16
	$\sigma = 2 \times 10^{-4}$	$\sigma = 4 \times 10^{-4}$	$\sigma = 6 \times 10^{-4}$	$\sigma = 4.8 \times 10^{-3}$
pK_1 at zero ionic strength	10.02 ± 0.02	7.79 ± 0.02	6.86 ± 0.03	6.10 ± 0.06
pK_1 from literature	9.8 (1)			
	10.82 (4)			
	10.20 (5)			

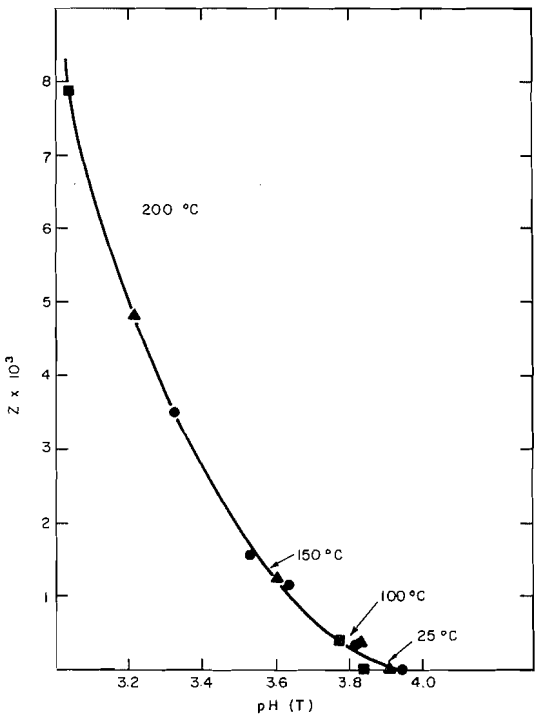

FIG. 7. Variation of $Z(T)$ with p$H(T)$ for different chloride concentrations; starting p$H(25)$ = 3.84 to 3.94: Cl^- = ●, 0.205, ▲, 0.512, ■, 1.02 mol/kg; Co(II) = 0.102 mol/kg.

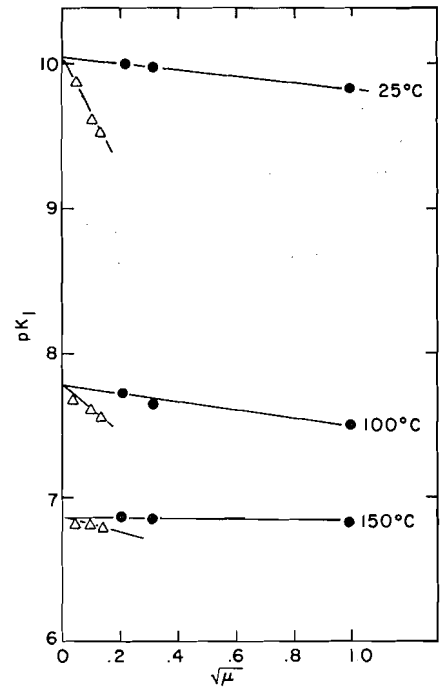

FIG. 8. Variation of pK_1 with $\sqrt{\mu}$ (ionic strength = μ) at different temperatures for Co(II) = ●, 1.0×10^{-2}, △, 1.0×10^{-3} mol/kg.

as compared to 1.0 mol/kg KCl used in this study. The difference may be due either to the anions or to some oxidation of Co(II) to Co(III) in the previous studies. There are no reported data for pK_1 at higher temperatures to which our data may be compared.

Higher hydrolytic polymers like $Co_2(OH)^{3+}$ and $Co_4(OH)_4{}^{4+}$ at relatively higher concentrations of Co(II) ($\approx$1.0 mol kg^{-1}) have been reported but their formulae are not uniquely established (13). In the concentration range of Co(II) used in our experiments, higher hydrolytic polymeric species do not appear to be present in significant quantities. When the results are analysed assuming the presence of both $CoOH^+$ and $Co(OH)_2$, pK_1 values do not differ significantly from those where only $Co(OH)^+$ is considered, and the pK_2 value, at 25°C, is lower than that reported in the literature (13) ($pK_2 \approx 18$). There are no data to compare at higher temperatures.

Calculation of Thermodynamic Functions

The hydrolysis constants have also been evaluated at different ionic strengths of the medium, and pK_1 versus $\sqrt{\mu}$, the square root of ionic strength, is plotted for different temperatures in Fig. 8. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

curves are extrapolated to zero ionic strength. At all temperatures and for two concentrations of cobalt, the extrapolated values at zero ionic strength are within the experimental errors, which reinforces the validity of the data obtained for pK_1.

Between 25 and 200°C, the free energy change ΔG^0 for the hydrolysis reaction $Co^{2+} + H_2O \rightarrow CoOH^+ + H^+$ does not change significantly. At 25°C the ΔG value is 57 ± 3 kJ/mol and at 200°C, 55 ± 3 kJ/mol. The enthalpy change ΔH, calculated from a linear plot of pK_1 versus $1/T$, at zero ionic strength is 60 ± 3 kJ/mol and ΔS^0 is 20 ± 8 J/(mol K) at 25°C. This value for ΔS^0 compares with values of 4 J/(mol K) and 13 ± 13 J/(mol K) for hydrolysis of Fe(II) (14) and Ni(II) (15) respectively. Our value is more reasonable than that of Bolzan and Arvia (1) (73 J/mol) which was calculated from results for temperatures up to only 40°C and without extrapolating to zero ionic strength.

In summary, hydrolysis of Co(II) increases with temperature and produces a buffering action at 200°C. For Co(II) solutions between 10^{-3} and 10^{-1} mol/kg with initial pH between 3.9 and 9.6, $CoOH^+$ is the dominant species with no detectable contributions from higher hydrolytic species.
