The structure is composed of $[p\text{-}Et_2NC_6H_4\text{-}NNPPh_3]^+$ cations and tetrafluoroborate anions occupying general positions in the space group $P2_1/c$. Before discussing the geometry of the complex cation (Fig. 1), we note some features which indicate the level of reliability of the dimensions in this determination. The average C—C distance in the triphenylphosphine moiety is 1.372 Å with the greatest and the least observed values deviating by 3–4 σ, at 1.400(8) Å and 1.342(10) Å; the average internal angle is 120.0° with the greatest and the least observed values again differing by 3–4 σ at 121.4(9)° and 117.1(7)°. The three angles subtended at the phosphorus atom by C(1), C(7), and C(13) agree closely and show a maximum deviation of only 1.1(3)° from the mean value of 109.3°. By contrast, the angle enclosed by N(1) and C(1) is only 105.1(3)° whilst the angles N(1)—P—C(7) and N(1)—P—C(13) are 111.4(3)° and 112.6(3)° respectively, and this inequality can be seen to be due to the orientation of the bent diazenyl function away from C(1) and toward C(7) and C(13).

The bond lengths and interbond angles within the C(19)···C(24) cycle follow the pattern which would be expected on the basis of a contribution from **1***b* to the electronic structure. Thus, bonds C(20)—C(21) and C(23)—C(24) are clearly short, at 1.342(8) and 1.351(8) Å compared with the remaining four bonds which range 1.413(8) to 1.429(8); and the angles at C(19) and C(22) are both smaller (117.9(6) and 118.9(6)) than the remainder. Note that whilst this pattern is chemically sensible, individual values are barely outside the extreme variation observed in individual values for the aromatic PPh_3 rings; however, the PPh_3 rings do not display any such systematic bond length or angle variation. It therefore seems that the pattern observed for the C(19)···C(24) ring is probably chemically significant. This view obtains good support from other observations,

from planar (Table 4*f*). The bond N(2)—C(19) is similarly short (1.356(7)), whilst the N(1)—N(2) bond at 1.308(6) Å is longer than a typical double bond value for N=N (1.24 Å in PhN:NPh and HN:NH (6)). Values of N—N bond lengths in some aryldiazenido–metal complexes, ArNNM, having a *trans*-doubly-bent geometry similar to that observed here, are generally even smaller at 1.17–1.19 Å (7). This alternation of long and short bonds throughout the skeleton includes also the P—N(1) bond. The calculated Pauling covalent radii for P—N single and double bonds are respectively 1.78 Å and 1.64 Å (8). The value of 1.648(5) observed here is similar to the P=N distance of 1.641(2) in $Ph_2FP:NMe$ (9), but is longer than the value in $Ph_3P:NC_6H_4Br$ (1.567(7) Å) (10) or in cyclic phosphonitrilic compounds (11).

All features can be reconciled with a significant contribution from structure **1***b* to the electronic structure of the cation, so that the crystallographic results are in qualitative agreement with the earlier spectroscopic data (1).

Lignin and related compounds. V. The hydrogenolysis of aspen wood lignin using rhodium-on-charcoal as catalyst

JAMES M. PEPPER AND REGINALD W. FLEMING

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received September 6, 1977

JAMES M. PEPPER and REGINALD W. FLEMING. Can. J. Chem. **56**, 896 (1978).

The hydrogenolysis of aspen lignin using rhodium-on-charcoal as catalyst has been studied. The maximum yield of chloroform-soluble lignin degradation products was obtained at a reaction temperature of 195°C. Analysis of this chloroform-soluble fraction revealed that the monomeric fraction was composed essentially of the four compounds, **1–4**, only, and in a total yield representing at least 40% of the original lignin.

Solvent extraction was shown to be preferred over thermal distillation as a preparative procedure for the separation of these phenolic derivatives. The significance of the isolation of these lignin degradation products is discussed.

JAMES M. PEPPER et REGINALD W. FLEMING. Can. J. Chem. **56**, 896 (1978).

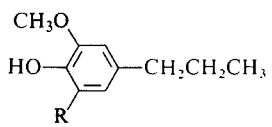
On a étudié l'hydrogénolyse de la lignine du tremble utilisant le rhodium sur charbon comme catalyseur. On obtient un rendement maximal de produits de dégradation solubles dans le chloroforme en opérant à une température de réaction de 195°C. L'analyse de cette portion soluble dans le chloroforme révèle que la fraction monomère est formée presqu'entièrement de quatre composés soit **1–4** le rendement global représente au moins 40% de la lignine originale.

On a montré que l'extraction par solvant est préférable à la distillation thermique comme méthode applicable pour la séparation de ces dérivés phénoliques. On a discute de la signification de l'isolement de ces produits de dégradation de la lignine.

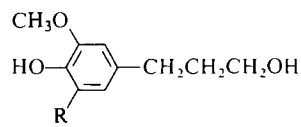
[Traduit par le journal]

Introduction

In an earlier publication (1), rhodium-on-charcoal was shown to be an effective catalyst for the low pressure hydrogenolysis of spruce wood lignin. Under the conditions reported (dioxane–water (1:1) medium, initial pressure of hydrogen of 500 psi, 5 h at 195°C) all the lignin was degraded and converted into a chloroform-soluble material. By gas chromatographic analysis of the diethyl ether soluble fraction of this product, a significant amount of the original lignin was found as monomeric (phenylpropanoid) compounds. Of these, two compounds, **1** and **2**, were predominant: together equalling at least 20% of the original lignin.



1 R = H
3 R = OCH_3



2 R = H
4 R = OCH_3

This paper reports the results of a similar catalytic hydrogenolysis of aspen wood lignin. Initially, experiments were made to determine the optimum temperature for the reaction, with the criteria to be considered being the weights of the chloroform-soluble fraction obtained from the extraction of the filtered hydrogenolysis mixture and the degree of diethyl ether solubility of this fraction. These data are given in Table 1. Since the Klason lignin content of the 10 g aspen wood meal sample was 1.88 g a reaction temperature of 195°C was chosen for subsequent studies. This same temperature had been shown earlier (2) to be preferable for the similar hydrogenolysis of aspen wood meal using Raney nickel as the catalyst.

Using a procedure of hydrogenolysis and extraction similar to that reported for spruce wood (1), a chloroform-soluble fraction was obtained. This was analyzed by gas chromatography. As expected from a hardwood the four monomeric compounds (**1–4**), were detected. The relative abundances of these lignin degradation products for two separate hydrogenolyses are given in Table 2.

TABLE 1. Effect of temperature on yields of hydrogenolysis products*

Temperature (°C)	Yield (g)	
	Chloroform-soluble	Ether-soluble
170	1.48	0.79
180	1.92	1.23
195	2.20	1.89
210	2.17	1.90
230	2.08	1.66

*Preextracted aspen wood meal (10 g), Rh–charcoal (1 g), dioxane–water (1:1, 150 ml) initial hydrogen pressure (500 psig), 5 h.

TABLE 2. Gas–liquid chromatographic analyses of aspen lignin hydrogenolysis products

Compound	Relative retention time	Abundance* Run A	Run B	Average
1	1	7.1	5.4	6.3
2	1.7	3.6	3.6	3.6
3	1.9	12.8	9.1	11.0
4	2.6	19.6	24.2	21.9
Total		43.1	42.3	42.8

*Reported as percentage of total chloroform-soluble fraction.

It was of interest to examine procedures for the separation of the combined monomeric compounds, **1** → **4**, from the remainder of the lignin material in the chloroform solution. Such a separation would be important as a preparative procedure for these phenolic lignin derivatives as well as a means of recovering the unknown lignin material for further chemical study. Solvent extraction and thermal distillation were studied.

Sequential extraction of the original organo-aqueous filtrate from a typical hydrogenolysis run was effected with two different combinations of solvents. For one set, A, the order was cyclohexane, benzene, diethyl ether (each by continuous liquid–liquid extraction), and chloroform (separatory funnel), whereas for the second set, B, the order was *n*-hexane, benzene, chloroform, and diethyl ether. The relative abundances of the extracted material are given in Table 3.

Gas chromatographic analysis of the cyclohexane (or *n*-hexane), benzene and diethylether extracts leads to three important observations: (*i*) all the monomeric compounds were removed by either combination of the initial two solvents; (*ii*) the aryl propanes (compounds **1** and **3**) were *selectively* removed by the cyclohexane or *n*-hexane whereas the propanols (compounds **3** and **4**) were extracted subsequently by benzene; and (*iii*) some other higher molecular weight lignin material was associated with the monomers.

TABLE 3. Solvent extraction of filtrate from hydrogenolysis of aspen wood*

Solvent system A	Extract (g)	Solvent system B	Extract (g)
Cyclohexane	0.93	*n*-Hexane	0.75
Benzene	0.80	Benzene	0.74
Diethyl ether	0.37	Chloroform	0.10
Chloroform	0.03	Diethyl ether	0.36
Total	2.13	Total	1.95

*Preextracted aspen wood meal (10 g) Klason lignin (1.88 g), 5% Rh-charcoal (1 g), dioxane–water (1:1, 150 ml), 5 h at 195°C.

Thermal distillation was also examined as a preparative method of separation of the monomeric degradation products. Distillation of the chloroform-soluble fraction up to a vapour temperature of 240°C/1.5 Torr, left none of compounds **1**–**4** in the residue but led to some unwanted degradation as evidenced by the production of low boiling products that were collected in the cold traps. Evidence that these more volatile compounds did not arise from the compounds **1**–**4**, was provided by an initial removal by low temperature distillation of these volatile materials, cleaning of the cold traps and continued distillation of the monomeric substances. No further low boiling products were obtained.

Rehydrogenolysis of the unidentified higher molecular weight lignin residues was examined. Both a residue resulting from a thermal distillation (vapour temperature > 160°C/1.5 Torr) and one remaining after removal of the diethyl-ether-soluble component of an initial chloroform-soluble hydrogenolysis product were studied. The conditions of the rehydrogenolysis were the same as those used initially for the wood meal, keeping the residue–catalyst ratio at 10:1.

The product from the distillation residue, which by gas chromatographic analysis was free of any of compounds **1**–**4** showed a trace of **1** only. Elemental analysis of the rehydrogenolysis product gave: C 66.6, H 6.9, a result which suggests retention of oxygen in the polymer other than that attached to the aromatic rings. A product from the ether-insoluble residue, also initially free of any of the monomeric compounds, **1**–**4**, and analyzing for C 63.9, H 7.2, was obtained which analyzed for C 63.8, H 7.8 and which on chromatographic analysis was shown to contain small amounts of the four monomeric compounds in essentially the same relative abundance as obtained in the original hydrogenolysis. It is apparent that solvent extraction is preferred over distillation as an initial method to separate the monomeric products. In the latter case, the evidence is that internal structural changes have occurred, probably including loss of water (supported by the elemental analysis) and leading to more complex structures which are resistant to further hydrogenolytic breakdown.

This research emphasizes the usefulness of the hydrogenolysis method of lignin degradation in studies involving both the classification and chemical structure of lignins. It is particularly adaptable to a relatively small-scale procedure. The data reported here, if compared with those previously published for the similar hydrogenolysis of spruce wood (1) clearly support the greater ease of liberation of lignin degradation products from hardwoods over softwoods. In

the present case, the combined total yield of the compounds **1–4** represents a significant recovery of over 40% of the original lignin in the aspen wood. Since a large percentage (ca. 60%) of these identified compounds are of the phenylpropanol type (**2** and **4**), it is evident that the γ-oxygen linkages are prevalent in the lignin and readily cleaved under the hydrogenolytic conditions. The ratio of approximately 3.3:1 for the combined syringyl-type compounds (**3** and **4**) to the combined guaiacyl-type compounds (**1** and **2**) is typical of the ratio of these nuclei obtained by other modes of lignin degradation (3).

An indication has been given of a potentially large source of phenolic chemicals of the type illustrated by compounds **1–4**. Their initial separation from the other lignin degradation products, as well as their subsequent separation into the substituted propanes (**1** and **3**) and the substituted propanols (**2** and **4**) has been shown to be possible by simple solvent extraction.

Experimental

Aspen sapwood (*Populus tremuloides*, Michx) was ground to ca. 20 mesh in a Wiley mill, extracted 48 h with ethanol–benzene (1:1), and air dried. Found: Klason lignin 18.8%, moisture 4.57%.

The catalyst, 5% rhodium-charcoal, was obtained from K & K Laboratories, Inc. The dioxane was purified according to Vogel (4). Copies of the gas chromatograms are available from the Depository of Unpublished Data.[1]

General Reaction Procedure

Aspen wood meal (10 g), 5% Rh–C (1 g) and dioxane–water (1:1) (150 ml) were mixed in a 1410 ml capacity bomb of an Aminco hydrogenator. The reactor was flushed twice with hydrogen and then filled to an initial pressure of 500 psig. The temperature was raised (about 120°C/h) and controlled automatically at 195 ± 5°C for 5 h. During the heating period the reactor was rocked continuously.

After cooling, the reactor contents were suction filtered. The residual pulp and catalyst were washed with dioxane–water (1:1). The washings and original filtrate were combined, transferred to a separatory funnel and extracted with chloroform (5 × 100 ml). The extract was dried over anhydrous sodium sulfate, filtered and the solvent removed under reduced pressure keeping the temperature below 40°C. The resulting yellow-brown oil was weighed as the chloroform-soluble fraction. The ether-soluble component of such a chloroform-soluble fraction was obtained by extraction under reflux with anhydrous ether (2 × 200 ml), removal of the ether and drying to constant weight in a vacuum desiccator.

Gas–Liquid Chromatographic Analyses

All analyses were conducted using an F & M Chromatograph, model 5750 with dual flame ionization detectors and temperature programming. The columns (6 ft × ⅛ in.) (purchased from Chromatographic Specialties, Brockville, Ont.) were packed with 10% SE-30 on Chromosorb W (100–120 mesh, AW-DMCS treated). All chromatograms were obtained under similar conditions of helium flow rate of 40 ml/min; temperature programmed from 100–270°C at 4°/min; injection temperature 260°C; detector temperature 280°C; and recorder chart speed 0.5 in./min. Identification of the compounds represented by the peaks was made by comparison of the retention times and mass spectra with those similarly obtained from authentic reference compounds (2).

The quantitative analytical data were obtained using the procedure reported earlier (1) but with 1,2,3-trimethoxybenzene as the internal standard.

Lignin and related compounds. VI. A study of variables affecting the hydrogenolysis of spruce wood lignin using a rhodium-on-charcoal catalyst

JAMES M. PEPPER AND PUNSRI SUPATHNA

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received September 6, 1977

JAMES M. PEPPER and PUNSRI SUPATHNA. Can. J. Chem. **56**, 899 (1978).

The effect of reaction conditions on the hydrogenolysis of spruce wood lignin over a rhodium-on-charcoal catalyst has been studied and monitored by the yields of the three major degradation products, **1**, **2**, and **5**. Variables included: initial pressure of hydrogen, amount of catalyst, and acidity–basicity of the media. Little variation occurred under moderate acidic or basic conditions with yields of 18–20% of lignin recovered as monomers. Under strongly acidic or basic conditions both yields and relative abundances changed appreciably. Initial hydrogen pressures less than 500 psig resulted in slightly decreased yields in some cases. In strongly alkaline media similar results were obtained with or without added hydrogen provided the catalyst were present.

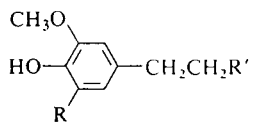
JAMES M. PEPPER et PUNSRI SUPATHNA. Can. J. Chem. **56**, 899 (1978).

On a étudié l'effet des conditions de la réaction sur l'hydrogénolyse de la lignine de bois d'épinette effectuée en présence d'un catalyseur de rhodium sur charbon et on a évalué ces effets par les rendements des trois produits principaux de dégradation soit **1**, **2** et **5**. Les variables comprennent: la pression initiale d'hydrogène, la quantité de catalyseur et l'acidité–basicité du milieu. Il se produit peu de variations dans des conditions acides ou basiques modérées et l'on récupère 18–20% de la lignine sous forme de monomères. Lorsque des conditions fortement acides ou basiques sont utilisées, les rendements ainsi que les quantités relatives de produits changent d'une façon appréciable. A des pressions initiales d'hydrogène de moins que 500 psig, il se produit, dans quelques cas, une légère diminution des rendements. Lorsque le catalyseur est présent dans un milieu fortement alcalin, on obtient des résultats semblables avec ou sans addition d'hydrogène.

[Traduit par le journal]

Introduction

Previous work in these laboratories has shown that rhodium-on-charcoal is an effective catalyst for the hydrogenolysis of both softwoods (spruce; ref. 1) and hardwoods (aspen; ref. 2) since by such a technique essentially all the lignin may be extracted from the wood as a chloroform-soluble fraction. Furthermore the lignin has been largely degraded into smaller fragments of which a significant percentage has been identified as being of the phenylpropanoid type as illustrated by compounds **1**–**4**.



1	R = H, R' = CH_3	**2**	R = H, R' = CH_2OH
3	R = OCH_3, R' = CH_3	**4**	R = OCH_3, R' = CH_2OH
5	R = R' = H	**6**	R = H, R' = OH
7	R = OCH_3, R' = H	**8**	R = OCH_3, R' = OH

From spruce wood, compounds **1** and **2** have been shown to represent together at least 20% and from aspen wood, compounds **1**–**4** represent at least 40% of the original lignin material. The significance of these observations with respect to the protolignin structure and with respect to the potential source of such phenolic chemicals has been discussed (1, 2). The reaction conditions used in these studies were those that had been adopted for similar earlier studies on the hydrogenolysis of aspen but using Raney nickel as the catalyst (3). Although apparently effective if applied to the use of rhodium-on-charcoal, it could not be assumed that such conditions were optimal for production of either the lignin monomeric derivatives (**1**–**4**) or of degradation products of different structure. Of particular interest were the effects of the amount of catalyst and of the initial hydrogen pressure should the process be studied at some later date for possible commercialization; and the effect of the initial 'pH'[1] of the solvent medium.

Several workers had earlier reported (4–7) that the initial 'pH' had a marked effect on the nature of the lignin hydrogenolysis products. In studies involving both spruce and aspen wood (4), using both Raney nickel and palladium-on-charcoal, it was found that the major products using initially neutral conditions were the phenylpropanol derivatives (**2** and **4**). If initially the medium were to be made acidic, the yield of the phenylpropane derivatives increased at

[1]'pH' is used to refer to the reading indicated by a pH meter used to monitor the acidity of the initial dioxane–water (1:1) medium.

the expense of the phenylpropanol compounds, and if initially the medium were to be made alkaline, the corresponding phenylethane or phenylethanol type products were predominant. Several other workers (5–7) had noted that under initially alkaline conditions, the catalytic hydrogenolysis of lignin gave rise to essentially phenylethanoid rather than phenylpropanoid fragments.

This paper reports the results of a study of the effect of changing the various conditions of the hydrogenolysis of spruce wood using rhodium-on-charcoal as the catalyst. The hydrogenolyses and subsequent isolation and identification of products were carried out by the procedure reported earlier (1) using 10 g of preextracted woodmeal, the variations being in the deliberate change of one of the reaction conditions at a time. The effect of these changes was monitored by a quantitative gas chromatographic determination of the major monomeric products (**1**, **2**, **5**, **6**) that were produced.

Discussion of Results

The choice of an initial hydrogen pressure of 500 psig had been based on earlier studies (8) but in which Raney nickel was used as a catalyst and the effectiveness of the procedure determined solely by the extent of chloroform solubility of the released lignin products. With the different catalyst (Rh–C) and improved monitoring procedures it was of interest to determine again the effect of initial hydrogen pressure. For runs using an initial hydrogen pressure of 500, 100, 50, and 0 psig, the corresponding yields of 4-*n*-propylguaiacol (**1**) were 8.8, 9.0, 9.2, and 0% and of dihydroconiferyl alcohol (**2**) were 10.2, 8.0, 5.6, and 0%, based on original Klason lignin. These results suggest that the liberation of **1** and **2** involves different types of structures and hence arise from different parts of the original lignin. Support for the hydrogenolyses aspect of the degradation reaction was given by the result of two runs made using nitrogen at 500 psig initial pressure to replace the hydrogen. Under these conditions, both with and without catalyst, no monomeric products were obtained.

The effect of the amount of catalyst was studied as shown in Table 1. Although the yield of the more structurally significant dihydroconiferyl alcohol (**2**) increased with increasing catalyst to woodmeal ratios, the total yield of the monomeric products passed through a maximum following which degradation began to occur as evidenced by the increased yield of (**5**) with a concurrent decrease in **1**. With more than 1 g of catalyst, traces of cyclohexyl derivatives were noted. As the amount of catalyst increases so does the yield of monomeric products even though, at the same time, the yield of the chloroform-soluble fraction decreases. This would clearly indicate that the liberation of the lignin from an original lignin–carbohydrate complex is facilitated by the increase in the catalyst. The choice of 1 g of catalyst (Rh–C) per 10 grams of wood meal was considered optimal and used subsequently.

It was of interest to determine if the initial addition of acid had a similar effect on the nature of the lignin monomeric products, when the rhodium-on-charcoal was used instead of Raney nickel (4). Also under such acidic conditions the effect of change in the initial pressure of hydrogen was studied. These data are recorded in Table 2.

Since lignins are believed to contain no appreciable amount of terminal methyl groups (9) the 4-*n*-propylguaiacol (**1**) obtained in all hydrogenation experiments arises most likely by a propanol–propane conversion. This is strongly supported by the results obtained under acidic conditions, for which the initial acid-catalyzed dehydration of the propanol could be followed by reduction of the resulting propene and thus leading to high relative yields of the phenylpropane (**1**). It is, however, less easy to understand the constancy of the yields of **1** since those of **2** decrease with lower initial pressure. An alternate route to the direct formation of **1** could be the reductive cleavage of γ-ether bonds. As in the case of using initially neutral conditions, hydrogen was required to promote the degradation process.

Since earlier studies using Raney nickel had established that hydrogenolysis under initially alkaline conditions had led to predominantly phenylethanoid fragments (compounds **5**–**8**) it was of interest to examine the effect of rhodium-on-charcoal under similar conditions. The standard procedure was followed except that 4.5 g NaOH were added initially and the cooled bomb contents were acidified with dilute HCl before extraction with chloroform. The results are given in Table 3.

The total yield of phenylpropanoid and ethanoid lignin fragments is markedly less than under initially neutral or acidic conditions and is coupled with extensive loss of side-chain carbon to produce mainly the phenylethanoid type products. There is evidence for the ready loss under alkaline conditions of the hydroxymethyl group from a propanol side chain bearing a β-arylether linkage (10).

In marked contrast to the other conditions, in this case the lack of hydrogen had surprisingly no effect on the yields and nature of the products. However, a similar reaction carried out with *no* initial hydrogen and *no* catalyst produced only a typical alkali lignin and no monomeric degradation products. It is apparent that the catalyst plus alkali is responsible

for bond cleavage and subsequent stabilization of the lignin fragments and a further study of this observation may be of importance in the utilization of alkali pulping liquors as a source of chemicals.

These experiments clearly indicated that major changes in the nature of the products of hydrogenolysis occurred as the reaction medium varied from strongly acidic through neutral to strongly alkaline. It was therefore of interest to study these changes as the 'p*H*' was varied by controlled steps from one extreme to the other and to determine if there were definitive 'p*H*' values at which significant changes occurred. The results are given in Table 4.

The markedly reduced total yield of monomeric products obtained under the very low initial 'p*H*' was unexpected. Assuming acid catalysis facilitates lignin–carbohydrate cleavage, it may be that the released lignin either further condenses to a form that resists subsequent hydrogenolysis to monomeric units or if the smaller units are formed they in turn undergo secondary, possibly polymerization, reactions. Of more interest is the recognition that maximum yields (18–20% of original Klason lignin) of the identified monomeric lignin products results over a broad initial 'p*H*' range (ca. 3–10), with little variation in the relative abundance of the propane and propanol derivatives. An earlier conclusion that the propane derivatives may result directly from an initial dehydration of the propanol derivatives followed by hydrogenation must now be questioned since it is unlikely that such a reaction would occur under alkaline conditions. Further work using model compounds is required to permit a better understanding of the structural features of lignin that would lead to these observations.

The approximately 20% of the original lignin of sprucewood that may be recovered as monomeric phenolic compounds using rhodium-on-charcoal as a catalyst is essentially the same, in yields and in chemical structure, as that obtained using Raney

nickel (4). Added support is thus provided for the belief that only a certain portion of the protolignin is amenable to such hydrogenolysis breakdown to monomeric units and that the remainder is bonded by other linkages (e.g. carbon–carbon) which are resistant to such treatment. Two observations that may have significance with respect to an interest in large scale production of these lignin chemicals are the need for only a relatively low initial hydrogen pressure in initially acidic or neutral conditions and no added hydrogen under strongly alkaline conditions. Indeed the role of the rhodium which is required for the production of monomeric products in this latter case is of interest but as yet not understood.

Experimental[2]

White spruce sapwood (*Picea glauca* Moench (voss)) was ground to ca. 20 mesh in a Wiley mill, extracted 48 h with ethanol–benzene (1:1) and air dried. Found: Klason lignin, 27.3%; moisture, 2.18%. The catalyst, 5% rhodium-on-charcoal, was obtained from K and K Laboratories, Inc. The dioxane was purified according to Vogel (11). The change in initial conditions of 'pH' was effected by the addition of suitable quantities of hydrochloric acid or sodium hydroxide. Copies of the gas chromatograms are available from the Depository of Unpublished Data.[3]

General Reaction Procedure

The procedure was similar to that reported in a previous communication (2). Ten gram samples of spruce wood meal were used and the amounts of catalyst, hydrochloric acid and sodium hydroxide that were added were as designated in Discussion of Results.

Gas–Liquid Chromatographic Analyses

All analyses were conducted using an F & M Chromatograph, Model 5750 with dual flame ionization detectors and temperature programming. The details of the analyses were identical to those reported earlier (2) with the exception that coumarin was used as the initial standard as reported in (1).

[2]The authors wish to draw attention to the following. The particular reactor used in this study and all preceding studies reported from these laboratories, was one of chrome-steel construction. More recently, it has been found using a stainless steel bomb (Parr Series 4560 Pressure Reactor, 2000 ml capacity) that in attempting to duplicate the experiments reported herein significantly different results were obtained. In particular, although the same compounds were obtained, the relative abundance was different with the major change being that of an increased yield of *n*-propylguaiacol (**1**) and a concurrent decreased yield of dihydroconiferyl alcohol (**2**). A similar result was noted if the chrome-steel reactor was used but the reactants contained in a glass liner. It is apparent that the reaction is sensitive to the catalytic environment and close attention must be given to this fact in future studies.

The photochemistry of benzylic sulfonyl compounds: The preparation of sulfones and sulfinic acids

R. F. LANGLER,[1] Z. A. MARINI, AND J. A. PINCOCK[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received October 17, 1977

R. F. LANGLER, Z. A. MARINI, and J. A. PINCOCK. Can. J. Chem. **56**, 903 (1978).

The photolysis of benzylic sulfonyl compounds (XSO_2CH_2Ph) gives products which are explained in terms of the chemistry of the benzyl and sulfonyl ($XSO_2^{\cdot}$) radicals. The synthetic applications of this photocleavage have been examined for two general cases: (*i*) preparation of sulfones from disulfone precursors, $R_1SO_2CHR_2SO_2CH_2Ph$ to $R_1SO_2CH_2R_2$ (yields ~ 90%); (*ii*) preparation of sulfinic acids and sulfonyl chlorides from mono sulfone precursors, $R_3SO_2CH_2Ph$ to R_3SO_2H and R_3SO_2Cl (yields ~ 55%).

R. F. LANGLER, Z. A. MARINI et J. A. PINCOCK. Can. J. Chem. **56**, 903 (1978).

La photolyse de composés sulfonyles benzyliques (XSO_2CH_2Ph) conduit à des produits qui peuvent être expliqués en termes de la chimie des radicaux benzyles et sulfonyles ($XSO_2^{\cdot}$). On a étudié la possibilité d'appliquer ce photoclivage en synthèse dans deux cas généraux: (*i*) pour la préparation de sulfones à partir de précurseurs disulfones, $R_1SO_2CHR_2SO_2CH_2Ph$ vers $R_1SO_2CH_2R_2$ (rendement ~90%); (*ii*) pour la préparation d'acides sulfiniques et de chlorures de sulfonyles à partir de précurseurs monosulfones $R_3SO_2CH_2Ph$ vers R_3SO_2H et R_3SO_2Cl (rendements ~55%).

The photochemistry of sulfones has received only limited attention as indicated by the fact that only a few papers are discussed in recent reviews (1, 2). However, benzyl sulfones have been shown to be photoreactive in a variety of systems (1, 3, 4 and refs. therein) and give products which are explained in terms of the chemistry of benzyl and sulfonyl radicals. We wish to report here, results that demonstrate that this is a general phenomenon and that the benzyl sulfonyl group is a synthetically useful, photochemically labile structural unit.

Results and Discussion

Our preliminary experiments were with the benzylic sulfone **1**, in the hope that the excited state would show similar behaviour to that of the radical cation in the mass spectrometer: Ramberg-Bäcklund rearrangement initiated by H abstraction from the benzylic carbon by the phenyl substituted sulfonyl group (5). This would have been analogous to the well-known photochemical Norrish type II reactivity in carbonyl compounds (6). Instead, photolysis of 1.0 g of **1** in 300 ml of methanol for 4 h using a 200 W medium pressure Hanovia mercury lamp gave clean conversion to phenyl methyl sulfone (94%) and 1,2-diphenylethane (36%), eq. 1. By the odour of the reaction mixture, sulfur dioxide was also formed. That no unexpected rearrangements were occurring was confirmed by photolysis in a quartz nmr tube of the deuterated sulfone, **1***a* in 10% CD_3OD–CD_3CN. The methyl group of phenyl methyl sulfone was only derived from the methylene carbon between the two sulfonyl groups. Moreover, nmr analysis of the photolysis mixture without removal of solvent indicated a yield of 1,2-diphenylethane greater than 90%. The lower yield in methanol is a result of the formation of toluene (glc analysis) which is lost because of its volatility during work-up.

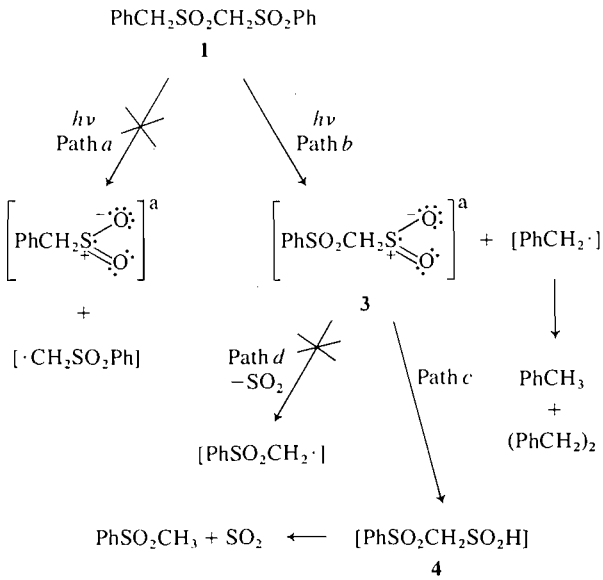
[1] $PhCH_2SO_2CX_2SO_2Ph$

1 X = H
1*a* X = D

$$\xrightarrow[MeOH]{h\nu} HX_2CSO_2Ph + PhCH_2CH_2Ph + SO_2$$

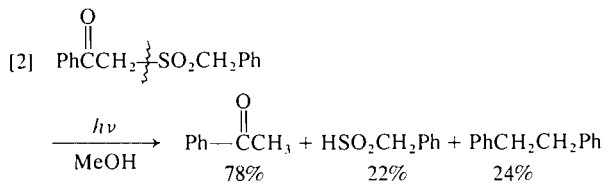
The seemingly simple photoreactivity of the disulfone **1** could be explained by several routes as outlined in Scheme 1. Path *a* would be analogous to the well-known β-cleavage that occurs for ketones with substituents on the α-carbon: $R-\overset{\overset{O}{\|}}{C}-CH_2-X$ and $PhSO_2CH_2-SO_2CH_2Ph$ (6). However, results for the photolysis of other sulfone substrates suggest that this is not the case. First, de Mayo and co-workers (7) have examined a related ketone sulfone, where the products obtained are explained in terms of β-cleavage (eq. 5). The benzyl sulfonyl radical ($PhCH_2SO_2^{\cdot}$) formed then partitions between H abstraction from the solvent methanol to form the sulfinic acid and loss of sulfur dioxide to form the benzyl radical and therefore 1,2-diphenylethane. Since we observe no sulfinic acid formation in methanol for photolysis of the disulfone **1**, the benzyl sulfonyl radical is not formed. Second, photolysis of the sulfone sulfide, $PhSO_2CH_2-SCH_2Ph$, gave no

[1]To whom correspondence can be addressed.



SCHEME 1. Mechanism of the photoreactivity of disulfone **1**.[2]

reaction. Third, photolysis of the disulfone, CH_3SO_2-CH_2—SO_2CH_2Ph (**2**), again gave clean conversion to dimethyl sulfone (91%) and 1,2-diphenylethane,



Scheme 2. Unlike the cases in carbonyl photochemistry, simple alkyl sulfones do not absorb under the conditions of these experiments. Therefore, the only chromophore in **2** is the benzene ring of the benzylic sulfone and the photochemistry is the same as that of **1**. Finally, as discussed below, simple benzylic sulfones give products which are only possible by cleavage of the sulfur to benzylic carbon bond. The photolysis of these disulfones must then be occurring from the excited state by path *b* in Scheme 1.

The fate of radical, $PhSO_2CH_2SO_2$·, **3**, can be inferred from the known chemistry of sulfonyl radicals (8). The activation enthalpy for loss of sulfur dioxide from CH_3SO_2· has been estimated to be about 23 kcal/mol (9). Therefore, **3** should have only a short lifetime if the loss of sulfur dioxide is favoured by the sulfone substituent. Note that this substituent effect would have to be very large since even $PhCH_2SO_2$· is apparently long enough lived to react with methanol (eq. 2) although the barrier to loss of sulfur dioxide is estimated to be 12 kcal/mol (9). This can not be the case since results on free radical chlorination of substituted alkanes demonstrate that sulfonyl groups destabilize adjacent radicals, presumably by an electron-withdrawing inductive effect (10). Therefore, the loss of sulfur dioxide from **3**, $PhSO_2CH_2$-SO_2·, to give $PhSO_2CH_2$· must have a barrier greater than 23 kcal/mol and path *c* in Scheme 1 must be preferred to path *d*. The resulting acid **4** is then desulfonylated by the usual ionic mechanism observed for other sulfinic acids with anion stabilizing substituents on carbon 1 (11).

Independent of the mechanism for the photochemistry of these disulfones, the process provides a good method for general sulfone synthesis as outlined in Scheme 2. This route relies on the fact that benzylic disulfones are readily available by reaction of thiols with α-chlorosulfones followed by oxidation (14). The methylene carbon of the disulfone is now activated for proton removal and then reaction with electrophiles. The benzylic sulfonyl group can then be removed under conditions which are mild, neutral and specific. Suitable choice of R_1 and the electrophile determines the resulting sulfone and, as shown in Scheme 2, the yields for the photolyses are, in general, excellent. This method would have particular advantages for the preparation of sulfones where one of the substituents is sensitive to oxidizing agents, since the introduction of R_2 completes the assembly of the sulfone skeleton. We also note that the sequence is reminiscent of the acetoacetic ester synthesis of ketones in carbon chemistry.

According to the mechanism advanced in Scheme 2 photolysis of benzylic sulfones in methanol permits the formation and isolation of sulfinic acids in cases

	R_1	R_2	Yield (%)
1	Ph	H	94
2	Me	H	91
5	Me	Me	70
6	Me	$PhCH_2$	97
7	Me	$CH_2CH_2CO_2Me$	94

SCHEME 2. Photochemical cleavage of benzylic sulfones as a general synthesis of sulfones.

[2]The radical site in sulfonyl radicals appears to be mainly centered on sulfur as indicated by the esr study of Waters *et al.* (12) and our own MO calculations (13).

where the acids are more resistant to desulfonylation. These expectations were realized by the observation that photolysis in methanol of benzyl methyl sulfone **8** gave a reasonable yield of methane sulfinic acid, **9** (44%), and again diphenylethane (eq. 3). For ease of isolation and determination of structure the sulfinic acid was converted to the corresponding sulfonyl chloride by aqueous chlorination (15). The yield

[3] $\underset{\mathbf{8}}{PhCH_2SO_2CH_3} \xrightarrow[MeOH]{h\nu} PhCH_2CH_2Ph + \underset{\mathbf{9}}{HSO_2CH_3} \xrightarrow[H_2O]{Cl_2} ClSO_2CH_3$

reported for the sulfinic acid is actually in terms of sulfonyl chloride isolated.

The yield of the sulfinic acid could be increased to 63% by photolysis in 2-propanol. The chemistry of the benzyl radical also changed since now 2-methyl-3-phenyl-2-propanol, 53%, as well as 1,2-diphenylethane, 17%, was formed. Later experiments for other sulfones also demonstrated the formation of toluene, 28% (by glc analysis). The increased yield of the sulfinic acid in 2-propanol suggests that there is competition between two processes for the methyl sulfonyl radical formed by the photochemical benzylic cleavage: H atom abstraction or loss of sulfur dioxide. The first, of course, becomes more favorable in 2-propanol. The process involving loss of SO_2 should lead to the formation of hydrocarbon, namely methane from H abstraction by methyl radicals. Volatility, of course, makes methane difficult to detect. However, this possibility was confirmed by photolysis of 2-phenylethyl benzyl sulfone, **7**, in 2-propanol where the yields of 2-phenylethane sulfinic acid, 54%, and phenylethane, 36%, account for 90% of the original sulfone (note eq. 4).

Methods of preparing sulfinic acids, particularly for alkyl cases, are relatively few (11). This photochemical method is quite general as shown for a variety of benzylic sulfones in Table 1. Since the sulfones are readily available by oxidation of the sulfide obtained from a thiol and an alkyl halide, this is effectively a conversion of alkyl halides to alkyl sulfinic acids. This method should also provide a powerful and general route for the synthesis of sophisticated sulfonyl chlorides. Most procedures for preparing sulfonyl chlorides require precursors which are very sensitive to oxidizing agents (as for instance, thiols and sulfides (17, 18)). The storage of a sulfonyl chloride in the form of an oxidant-resistant functionality like the benzylic sulfone in conjunction with the previously published method employing the chlorination of benzylic sulfides (17) provides, as well, the potential to prepare polysulfonyl compounds such as sulfonate ester sulfonamides and mixed sulfonate esters.

TABLE 1. Preparation of sulfinic acids by photolysis of benzylic sulfones in 2-propanol

Sulfone	Sulfinic acid	Yield (%)[a]
1. $CH_3SO_2CH_2Ph$	CH_3SO_2H	63
2. $CH_3CH_2SO_2CH_2Ph$	$CH_3CH_2SO_2H$	59
3. $CH_3CH_2CH_2SO_2CH_2Ph$	$CH_3CH_2CH_2SO_2H$	60
4. $ClCH_2CH_2SO_2CH_2Ph$	$ClCH_2CH_2SO_2H$	40
5. $PhCH_2CH_2SO_2CH_2Ph$	$PhCH_2CH_2SO_2H$	54[b]
6. $PhSO_2CH_2Ph$	$PhSO_2H$	26
7. CH_3SO_2CHPh (CH$_3$)	CH_3SO_2H	50
8. $CH_3CH_2SO_2CHPh$ (CH$_3$)	$CH_3CH_2SO_2H$	60
9. $CH_3CH_2CH_2SO_2CHPh$ (CH$_3$)	$CH_3CH_2CH_2SO_2H$	40

[a]All yields reported are for the corresponding sulfonyl chloride obtained by aqueous chlorination of the acidic fraction from photolysis.
[b]Yield of $PhCH_2CH_3$ 36% in 2-propanol and 33% in methanol.

[4] $\underset{\mathbf{10}}{PhCH_2CH_2SO_2CH_2Ph} \xrightarrow[2\text{-propanol}]{h\nu} [PhCH_2\cdot] + [PhCH_2CH_2SO_2\cdot]$

$[PhCH_2\cdot] \xrightarrow{-SO_2} [PhCH_2CH_2\cdot] \rightarrow PhCH_2CH_3$ (36%)

$[PhCH_2CH_2SO_2\cdot] \rightarrow PhCH_2CH_2SO_2H$ (54%)

[5] $XSO_2CH_2Ph \xrightarrow{h\nu} \cdot CH_2Ph + XSO_2\cdot$

$XSO_2\cdot \xrightarrow{-SO_2} X\cdot \xrightarrow{RH} XH$

$XSO_2\cdot \xrightarrow{RH} XSO_2H \longrightarrow XH + SO_2$

In summary, we have found that the photochemical cleavage of benzylic sulfones to a sulfonyl radical seems general but that the fate of the radical may be variable. As shown in eq. 5, the preferred pathway will depend on the stability of $XSO_2\cdot$ to loss of SO_2, the stability of the sulfinic acid to desulfonylation and the hydrogen donating ability of the reaction medium. We are currently exploring the scope of these processes in other systems.

Experimental

General

The ir spectra were recorded on a Perkin-Elmer 237B grating spectrophotometer. The nmr spectra were obtained on a Varian T-60 instrument using TMS as the internal standard. The mass spectra were recorded on a Dupont-CEC model 21-104 mass spectrometer. The samples were directly introduced using an all glass probe and the spectra were run at 30 eV with a source temperature of 150°C. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Gas chromatographic analysis for hydrocarbons was performed on a Hewlett-Packard 5750 instrument with a $\frac{1}{4}$ in. × 9 ft 20% Carbowax 20 M on Chromosorb W column programmed from 60–115°C.

Photolyses: General

The appropriate weight of sample was dissolved in the desired solvent (300 ml). The solution was photolyzed for 4 h in an immersion well (after purging with N_2 for 1 h) using a 200 W medium pressure Hanovia mercury lamp and a VYCOR filter.

Standard Work-up

A volume of water equal to the total volume of the reaction mixture was added to the reaction mixture. The resultant solution was washed with chloroform (five 100-ml aliquots). The combined chloroform layers were base washed with 2.5% NaOH (100 ml aliquots), whenever the solvent for reaction was acetic acid, until the aqueous p*H* remained basic. The chloroform layers were dried ($MgSO_4$), filtered, and the chloroform rotary evaporated, affording a crude residue.

Preparation of $PhSCH_2SCH_2Ph$

Sodium metal (1.479 g) was dissolved in absolute ethanol (100 ml) and benzyl thiol (7.8 ml) was added. Phenyl chloromethyl sulfide (10.040 g) in absolute ethanol (50 ml) was added to the cooled reaction mixture over a period of about 20 min. The reaction was stirred at ambient temperature for 24 h followed by standard work-up. The crude residue (17.307 g) was used directly to obtain the corresponding disulfone.

Preparation of $PhSO_2CH_2SO_2CH_2Ph$ (1)

Reaction of the disulfide (4.996 g) with chromium trioxide (9.146 g) in glacial acetic acid (150 ml) as described previously (5) for the oxidation of the sulfone sulfide furnished β-disulfone (**1**) (3.101 g) identical in all respects with that reported previously (5).

Preparation of $CH_3SO_2CH_2SO_2CH_2Ph$ (2)

The preparation and properties of this compound have been described elsewhere (19).

Preparation of $CH_3SO_2\underset{\displaystyle CH_3}{\underset{|}{C}}HSO_2CH_2Ph$ (5)

Sodium metal (0.1848 g) was dissolved in methanol (100 ml) and the β-disulfone (**2**) (1.9996 g) was added. A solution of methyl iodide (3.4317 g) in methanol (20 ml) was added and the reaction mixture stirred at room temperature for 24 h. Standard work-up furnished a crude product. The crude material was dissolved in chloroform (100 ml) and the resultant solution washed with 2.5% NaOH (four 100-ml aliquots). Concentration of the solution and recrystallization of the residue from 95% ethanol (8 ml) afforded clean disulfone (**5**, 1.4655 g, mp 108–109°C); ir ($CHCl_3$): 1330, 1310, and 1120 cm^{-1}; nmr ($CDCl_3$) δ: 7.33 (5H, s), 4.90 (1H, d, J = 14 Hz), 4.36 (1H, d, J = 14 Hz), 4.06 (1H, q, J = 8 Hz), 3.13 (3H, s), and 1.70 (3H, d, J = 8 Hz); ms *m/e*: 119 (5.9%),[3] 118 (10.5%),[3] 92 (10.2%), and 91 (100%). *Anal.* calcd. for $C_{10}H_{14}O_4S_2$: C 45.78, H 5.37; found: C 45.13, H 5.49.

[3]The significance of these ions has been discussed in detail (5, 20).

Preparation of $CH_3SO_2\underset{\displaystyle CH_2Ph}{\underset{|}{C}}HSO_2CH_2Ph$ (6)

Sodium metal (0.4906 g) was dissolved in methanol (250 ml) and the β-disulfone (**2**) (5.0158 g) added. Benzyl chloride (7.668 g) was added and the reaction mixture refluxed for 24 h. Standard work-up furnished a crude product which was recrystallized from 95% ethanol (20 ml). The crystalline product contained starting material (2.10 g) and the C-3 benzylated disulfone (2.650 g). The product was dissolved in chloroform (500 ml) and the solution washed with 2.5% NaOH (six 500-ml aliquots). The chloroform was removed and the residue recrystallized from 95% ethanol affording clean disulfone (**6**, 1.2655 g, mp 125–126°C); ir ($CHCl_3$): 1340, 1320, and 1123 cm^{-1}; nmr ($CDCl_3$) δ: 7.43 (5H, s), 7.30 (5H, s), 4.80 (1H, d, J = 13 Hz), 4.43 (1H, d, J = 13 Hz), 4.30 (1H, t), 3.50 (2H, d), and 3.06 (3H, s); ms *m/e* 338 (M^+, 1%), 195 (8.3%),[3] 194 (20%),[3] 92 (10%), and 91 (100%). *Anal.* calcd. for $C_{16}H_{18}O_4S_2$: C 56.78, H 5.36; found: C 56.91, H 5.40.

Preparation of $CH_3SO_2\underset{\displaystyle CH_2CH_2CO_2CH_3}{\underset{|}{C}}HSO_2CH_2Ph$ (7)

Sodium metal (0.828 g) was dissolved in methanol (350 ml) and the β-disulfone (**2**) (9.0068 g) added. Methyl acrylate (9.3589 g) was added and the reaction mixture refluxed for 24 h. Standard work-up furnished a crude product which was recrystallized from 95% ethanol (90 ml). The crystals were filtered off, shown to be unchanged disulfone **2** (4.634 g), and the mother liquor concentrated. The mother-liquor concentrate was dissolved in 95% ethanol (9 ml) and a second crop of crystals obtained. The second crop proved to be clean ester disulfone (7, 1.8791 g, mp 87–89°C); ir ($CHCl_3$) 1740, 1355, 1310, and 1115 cm^{-1}; nmr ($CDCl_3$) δ: 7.43 (5H, s), 4.90 (1H, d, J = 13 Hz), 4.50 (1H, d, J = 13 Hz), 4.26 (1H, m), 3.63 (3H, s), 3.20 (3H, s), and 2.57 (4H, m); ms *m/e*: 191 (3.4%),[3] 190 (7.6%),[3] 92 (10%), and 91 (100%). *Anal.* calcd. for $C_{13}H_{18}O_6S_2$: C 46.69, H 5.42; found: C 47.01, H 5.30.

Photolysis of the β-Disulfones 1, 2, 5, 6, and 7

The photolyses of the disulfones were carried out in the same manner as illustrated below for the debenzylsulfonylation of the benzylated β-disulfone **6**.

The benzylated β-disulfone (**6**, 1.0024 g) was photolyzed and the solvent evaporated. The residue was chromatographed on silica gel (100 g) employing chloroform (100 ml fractions) for elution. Fractions 5–7 were combined and concentrated, affording methyl phenethyl sulfone (0.5336 g). The product was recrystallized from 95% ethanol and shown to be identical to authentic material by nmr, ir, and mp.

Preparation of Benzylic Sulfones

The necessary benzylic sulfides were obtained by treating the appropriate alkyl halide with phenylmethanethiol. (17). The corresponding benzylic sulfones were obtained by oxidation of the benzylic sulfide with Fieser's reagent. (20).

Preparation of $PhCH_2SCH_2CH_2Cl$

Benzyl ω-hydroxyethyl sulfide was prepared from mercapto ethanol and benzyl chloride in the standard fashion (17). Benzyl ω-hydroxyethyl sulfide (40.006 g) was added to chloroform (30 ml) and the solution brought to gentle reflux. A solution of thionyl chloride (29.794 g) in chloroform (20 ml) was added dropwise over a period of 45 min. Upon completion of the addition the reaction mixture was refluxed for 1.5 h. The chloroform was evaporated and the residue rectified at reduced pressure affording the chlorosulfide (bp 138–142°C/220 Torr,

33.054 g); nmr ($CDCl_3$) δ: 7.23 (5H, s), 3.70 (2H, s), 3.50 (2H, t), and 2.70 (2H, t); ms *m/e*: 188 (10%) 186 (M^+, 30%), 92 (16%), and 91 (100%).

Preparation of $PhCH_2SO_2CH_2CH_2Cl$

The chlorosulfide (5.007 g) was oxidized with CrO_3 (6.722 g) in glacial acetic acid (100 ml) in the usual way, (5, 20, 21). After recrystallization from 95% ethanol the chlorosulfone (4.296 g) had mp 90–91°C; ir ($CHCl_3$): 1320 and 1120 cm^{-1}; nmr ($CDCl_3$) δ: 7.46 (5H, s), 4.33 (2H, s), 3.83 (2H, t), and 3.30 (2H, t); ms *m/e*: 218 (M^+, 1.8%), 92 (8.8%), and 91 (100%).

CH_3
|

Preparation of $PhCHSH$

α-Mercaptoethylbenzene was prepared from α-chloroethylbenzene following the procedure of Tsung and Chi (21).

CH_3
|

Preparation of $PhCHSO_2R$

These sulfones were prepared by condensing the appropriate alkyl halide with α-mercaptoethylbenzene (17) followed by chromium trioxide oxidation (21).

Photolyses of Simple Sulfones

The photolyses of the sulfones depicted in Table 1 were carried out in the same manner as illustrated below for benzyl methyl sulfone.

Benzyl methyl sulfone (0.458 g) was photolyzed in 2-propanol and the solvent evaporated. The residue was dissolved in chloroform (25 ml) and the resultant solution washed with 2.5% NaOH (two 10-ml aliquots). The *organic layer* was concentrated and stored.

The aqueous layer was acidified with 10% HCl and Cl_2 (ca. 200 ml/min) was bubbled into the solution for 10 min. The reaction mixture was extracted with methylene chloride (three 25-ml aliquots). The combined extracts were dried and concentrated yielding methanesulfonyl chloride (0.193 g).

The organic layer obtained from the photolysis concentrate contained diphenyl ethane (0.041 g) and 2-benzyl-2-propanol (0.214 g). This material was chromatographed on silica gel (30 g) employing chloroform (25 ml aliquots) for elution. Fraction 4 contained pure diphenylethane which was identical to authentic material by mp, ir, nmr, and ms. Fractions 6 and 7 furnished clean 2-benzyl-2-propanol which furnished the expected ir, nmr, and ms.

Galvanostatic transients and crystallization overvoltage

STEPHEN FLETCHER

Department of Chemistry, Carleton University, Colonel By Drive, Ottawa, Ont., Canada K1S 5B6

AND

ARTHUR SMITH

Department of Mathematics, Carleton University, Colonel By Drive, Ottawa, Ont., Canada K1S 5B6

Received September 26, 1977

STEPHEN FLETCHER and ARTHUR SMITH. Can. J. Chem. **56**, 908 (1978).

The theory of galvanostatic transients is extended to include the formation of a three-dimensional crystalline layer. The mechanism of formation of this layer is assumed to be one of nucleation and subsequent growth of randomly distributed nuclei on the electrode surface. The resulting crystallization overvoltage is shown to be a complex function of the applied current density, as well as being related to the potential-dependences of the rate constants for lattice growth and the potential-dependence of the nucleation rate constant. The complete E–t response is calculated numerically and also certain limiting cases are described which have exact analytical solutions. A method of testing the model experimentally is briefly discussed.

STEPHEN FLETCHER et ARTHUR SMITH. Can. J. Chem. **56**, 908 (1978).

On a étudié la théorie des intermédiaires galvanostatiques pour inclure la formation d'une couche cristalline tri-dimensionnelle. On a fait l'hypothèse que le mécanisme de formation de cette couche provient d'une nucléation et d'une croissance subséquente des noyaux distribués au hasard sur la surface de l'électrode. On démontre que le survoltage de cristallisation qui en résulte est une fonction complexe de la densité du courant appliqué de même qu'il est relié avec les dépendances de potentiel des constantes de vitesse pour la croissance du réseau et la dépendance de potentiel de la constante de vitesse de nucléation. On a calculé numériquement les relations complètes E–t et on décrit aussi un certain nombre de cas limites pour lesquels des solutions analytiques exactes existent. On discute brièvement d'une méthode permettant de vérifier le modèle d'une façon expérimentale.

[Traduit par le journal]

Introduction

In recent years the potentiostatic method of investigating electrocrystallization reactions has become increasingly accepted as the technique of choice, to a large extent replacing the earlier galvanostatic methods. The major reason for this development was the inherent complexity of galvanostatic data as compared to potentiostatic data.

In galvanostatic measurements the current density is the controlled parameter and hence the total interfacial rate is maintained constant as a function of time. Each individual reaction which contributes to the overall rate is therefore constrained in such a way that the overall current density is identical to the externally-applied value. In order to maintain this state of affairs the electrode potential responds in a complex way as a function of time. By monitoring the changes in the electrode potential, important information regarding individual processes may, however, be obtained provided that (*a*) an appropriate theoretical model exists and (*b*) sufficient resolution between component processes is achieved.

On the other hand, potentiostatic measurements allow the straightforward manipulation of the independent variable, i.e., the electrode potential, so that the current density is the observed parameter. One consequence of this is that theoretical models of electrocrystallization may easily be described because no assumptions are required regarding the potential-dependences of any rate constants which appear in the overall rate equation. All that is needed is a geometrical model of some description. In general, therefore, the values of individual rate constants and their related potential-dependences have usually been determined by potentiostatic techniques.

Although potentiostatic techniques have been singularly successful in the development of geometrical models of electrocrystallization processes, a certain number of limitations to the basic experimental method have become apparent in recent years. Some of these limitations are caused by (*a*) ohmic effects, in particular iR-drop, (*b*) finite rise-time distortions of potential waveforms, (*c*) concurrent dissolution reactions, (*d*) double-layer charging effects, (*e*) adsorption phenomena, (*f*) finite solubility of growing films (i.e., anodic films), (*g*) irreproducibility of applied potentials (within 0.01 mV, say), and (*h*) poor cell configurations, etc. All of these problems conspire to restrict the range over which experimental data may be usefully accumulated. It is also possible that other problems exist which have remained undiagnosed because of the

For personal use only.

use of only one experimental approach (i.e., the potentiostatic method). Consequently it seems worthwhile to investigate some new methods of elucidating electrocrystallization mechanisms. This necessarily involves the understanding of the correct mathematical transformations which are required to describe the underlying phenomena. Once these have been evolved, then diverse methods might be used under appropriate circumstances to yield improved experimental results.

In an earlier paper we described the theoretical effects of ohmic overpotential (*iR*-drop), linear potential sweep, and potential staircase waveforms on 3-D progressive nucleation and growth. In the present work we calculate the theoretical response of such a system to a simple galvanostatic step. The solution of this problem is important for several reasons. Firstly, it would allow a very accurate experimental test of the mathematical transformations employed in its derivation, and hence is of general significance for other waveforms derived by similar transformations. Secondly, comparison of potentiostatic and galvanostatic data would provide a bridgehead between the newer and the older literature data. Thirdly, galvanostatic techniques may prove to be superior to potentiostatic techniques in some experimental regions of interest (e.g., at low current densities, where potentiostatic measurement is often difficult). Fourthly, 'cross-fertilization' should be possible such that new techniques involving combinations of potentiostatic and galvanostatic pulses can be developed (31).

The application of galvanostatic techniques to simple charge-transfer processes has been carried out for many years. The method involves stepping the applied current from zero to some known value, whereupon the resulting variation of potential is followed as a function of time. When no current flows it is clear that the equilibrium potential (E_e) for a given reaction is observed. Therefore the potential difference or overvoltage may be recorded directly.

The simplest case, for which concentration polarization was absent, was first studied by Roiter *et al.* (1). The method was much improved by Berzins and Delahay (2, 3) who developed a technique for the evaluation of the entire potential–time curve (for the single-step method) including superposed charge-transfer and diffusion overvoltages. This technique allowed the determination of the exchange current density i_0 and the charge-transfer co-efficient α from a single measurement, provided the double-layer charging had first been extrapolated out (4, 5).

Another technique which was developed was the cyclic galvanostatic method of Wijnen and Smit (6) in which rectangular current pulses of a given frequency were applied to the working electrode. An elegant improvement in this case was proposed by Sluyters (7), who replaced the rectangular pulses with a sinusoidally-varying current. An advantage of both of these methods, besides improved accuracy, was that it was not necessary to know a priori the ohmic resistance of the solution in order to eliminate the ohmic potential drop between the luggin reference probe and the working electrode.

A further interesting development may be found in the work of Gerischer and Krause (8, 9). In order to eliminate some of the difficulties of short-time measurements caused by double-layer charging, a short current pulse (~ 1 μs) was first applied before the final current was switched in. This served to charge the double layer on a time-scale shorter than that used in recording experimental data. The method has also been extended and improved by Matsuda *et al.* (10).

None of the outlined methods have been applied to a theoretical analysis of crystallization overvoltage, however, although a large number of experimental measurements may be found in the literature (11). In particular, large potential 'jumps' have frequently been recorded. Since these corresponded to the supersaturations observed in the formation of three-dimensional nuclei during crystallization in solution (12) they were attributed to this cause (13, 14). This explanation was qualitatively improved following the early potentiostatic investigations of Bewick (15) and Fleischmann and coworkers (16–20). These workers showed that the peaks on the potential–time plots (21–23) corresponded to the initial stages of formation of new phases *at the electrode surface*. The mechanism of formation of such phases under potentiostatic conditions was shown to be the classical mechanism of nucleation and growth, except that the slow step in the overall reaction occurred at the edge of the expanding crystal lattice.

Unfortunately, the galvanostatic model of nucleation and growth was not developed because the solution involved certain differential equations which were difficult to analyse. The purpose of the present work is to show that, given certain simplifying assumptions, the galvanostatic response of electrocrystallization reactions may indeed be theoretically investigated.

Theory

In a previous paper (24) a method was described for the determination of the effect of varying potential during progressive, three-dimensional nucleation and growth. Both the linear potential sweep method and the staircase potential ramp were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

considered, as well as feedback loops generated by uncompensated ohmic overpotential. The model of three-dimensional growth used was that of Armstrong, Fleischmann, and Thirsk (25). At constant potential the current response as a function of time was given by

$$[1] \qquad i(t) = 4i_m(1 - S)S$$

where S is the surface coverage function ($0 < S < 1$) and i_m is the maximum in the current–time transient. In order to take the variation of potential into account it was assumed that i_m and t_m (the time taken to achieve i_m) were exponential functions of potential, viz.

$$[2] \qquad i_m = 10^{a_1E+b_1}$$

$$[3] \qquad t_m = 10^{a_2E+b_2}$$

The validity of these assumptions has been shown for many systems, at least in experimentally accessible regions, e.g., see ref. 25. The corresponding problem in electrolytic nucleation has also been discussed at length by Milchev and co-workers (28, 29). The constants a_1 and a_2 are determined experimentally, where it is evident that a_1 is positive, a_2 negative ($-a_2 > a_1$). The current 10^{b_1} and the time 10^{b_2} depend on the chosen potential scale and as such are unimportant in the present work. This is because experimental values may only be obtained relative to a given reference electrode system. The dependence of i_m on E is built into the potentiostatic model, though with varying E it is clear that i_m no longer represents the current maximum as it does in ref. 25.

To obtain S and hence i when E varies it is assumed that the response of the surface coverage to changing E is essentially instantaneous. This was shown previously (24) to be mathematically equivalent to the transformation

$$f(E,t) \rightarrow F(E(t),t)$$

where $f(E,t)$ is the surface coverage function at constant E and

$$F(E(t),t) = f\left(\int_0^t E(t')\,dt', t\right)$$

This led in ref. 24 to the following equations

$$[4] \qquad S = 1 - e^{-kJ^3}$$

$$[5] \qquad J = \int_0^t Q(t')\,dt'$$

$$[6] \qquad Q = \frac{dJ}{dt} = 10^{-a_2(E(t)-i(t)R)}$$

$$[7] \qquad i(t) = PQ^\lambda S(1 - S) = PQ^\lambda(1 - e^{-kJ^3})e^{-kJ^3}$$

where R is a constant resistance and the constants P, λ, k are related to a_1, a_2, b_1, b_2 by $P = 4 \times 10^{b_1}$, $\lambda = -a_1/a_2$, $k = \ln 2 \times 10^{-3b_2}$.

The Problem

Equation 7 is an integral equation which determines $i(t)$ as a function of the applied potential $E(t)$. What we wish to describe in the present work is the solution $i(t) = i_g$, a constant current for some waveform $E(t)$. To treat this galvanostatic case it is necessary to examine the equation

$$[8] \qquad i_g = PQ^\lambda(1 - e^{-kJ^3})e^{-kJ^3} = PQ^\lambda S(1 - S)$$

as an integral equation that yields E as a function of t. Since Q is now given by $10^{-a_2(E(t) - i_gR)}$ note that the significance of R as a complex feedback parameter (emphasized in ref. 24) between E and i is lost and i_gR becomes a simple constant shift in the experimentally recorded potential.

It is expected on experimental grounds that $E(t)$ in the galvanostatic case will be a U-shaped curve (30). Equation 8 does in fact yield such a curve as is shown in the analysis. However, no explicit solution for $E(t)$ exists in terms of familiar functions. This is no drawback since numerical simulation yields a solution curve while the analytical method is successful in giving $E(t)$ in the regions of interest. The numerical and analytical solutions can then be compared, and the results shown to be consistent.

The Analytical Solution

Taking advantage of the fact that [8] may be regarded as an ordinary differential equation in J and t, since $dJ/dt = Q$, we immediately obtain t as a function J, giving

$$[9] \qquad \left(\frac{i_g}{P}\right)^{1/\lambda} t = \int_0^J \exp(-kx^3/\lambda) \times [1 - \exp(-kx^3)]^{1/\lambda}\,dx$$

Hence t is an increasing bounded function of J with the limit $t = t_{ext}$ given by

$$[10] \qquad \left(\frac{i_g}{P}\right)^{1/\lambda} t_{ext} = \int_0^\infty \exp(-kx^3/\lambda) \times [1 - \exp(-kx^3)]^{1/\lambda}\,dx$$

The right-hand side of [10] may be evaluated numerically for a given k and λ. The transformation $x = k^{-1/3}y$ shows that the integral has the form $k^{-1/3}G(\lambda)$ for some function G. A good approximation to $G(\lambda)$ can be obtained by expressing the integral in the form $\int_0^\infty e^{P(x)/\lambda}\,dx$ and expanding $P(x)$ about the maximum. The result is that the integral in [10] has the approximate value $\sqrt{\pi\lambda}/4^{1/\lambda}3k^{1/3}(\ln 2)^{2/3}$. To obtain a more exact value note that when $k/\lambda \sim 1$, the range of integration in [10] can be reduced to [0, 2] while retaining 4 figure accuracy.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

From [9] and [10] it follows that the inverse function $J(t)$ exists, defined on the domain $[0, t_{ext}]$ on which it increases without bound as $t \to t_{ext}$.

Equation 9 by the transformation $e^{-kx^3} = y$ may be put in the form

$$[11] \qquad 3k^{1/3}\left(\frac{i_g}{P}\right)^{1/\lambda} t = \int_{e^{-kJ^3}}^{1} f(y)\,dy$$

where

$$f(y) = y^{1/\lambda - 1}(1 - y)^{1/\lambda}(-\ln y)^{-2/3}$$

and correspondingly [10] becomes

$$[12] \qquad 3k^{1/3}\left(\frac{i_g}{P}\right)^{1/\lambda} t_{ext} = \int_{0}^{1} f(y)\,dy$$

To obtain the asymptotic behaviour of E as $t \to t_{ext}$, observe that [9] and [10] give

$$[13] \qquad \left(\frac{i_g}{P}\right)^{1/\lambda}(t_{ext} - t) = \int_{J}^{\infty} \exp(-kx^3/\lambda) \times [1 - \exp(-kx^3)]^{1/\lambda}\,dx$$

As $t \to t_{ext}$, $J \to \infty$ and the right-hand side of [13] is asymptotic to

$$I(J) = \int_{J}^{\infty} e^{-kx^3/\lambda}\,dx = \int_{J}^{\infty} \{(-3kx^2/\lambda)\, e^{-kx^3/\lambda}/(-3kx^2/\lambda)\}\,dx$$

Integrating by parts gives

$$[14] \qquad I(J) = \frac{e^{-kJ^3/\lambda}}{3kJ^2/\lambda} - \frac{\lambda}{6k}\int_{J}^{\infty} \frac{e^{-kx^3/\lambda}}{x^3}dx$$

The integral in [14] does not exceed $(\lambda/6kJ^3)I(J)$ showing $I(J)$ is asymptotic to the first term on the right-hand side of [14]. From this observation, and [13], we obtain

$$[15] \qquad (1 - \tau)\left(\frac{i_g}{P}\right)^{1/\lambda} t_{ext} \sim \frac{e^{-kJ^3/\lambda}}{3kJ^2/\lambda}$$

where the dimensionless quantity τ has been introduced and is defined by

$$[16] \qquad \tau = t/t_{ext}$$

Now from [8], as $J \to \infty$

$$[17] \qquad \left(\frac{i_g}{P}\right)^{1/\lambda} \sim Q\, e^{-kJ^3/\lambda}$$

Combining [17] and [15] gives

$$[18] \qquad 3kt_{ext}J^2Q/\lambda \sim \frac{1}{1 - \tau}$$

But $dJ/dt = Q$. Hence [18] may be written

$$k(t_{ext}/\lambda)\frac{dJ^3}{dt} \sim \frac{1}{1 - \tau}$$

and hence

$$[19] \qquad kJ^3/\lambda \sim -\log(1 - \tau)$$

Feeding [19] back into [18] then gives the asymptotic form of Q and taking logs soon yields

$$[20] \qquad a_2(E - i_gR) \sim \log(1 - \tau) + \tfrac{2}{3}\log(-\log(1 - \tau)) + \text{constant}$$

Therefore a plot of $\log(1 - \tau)$ vs. E is asymptotically a straight line whose gradient gives a_2. This was tested by numerical simulation and Fig. 1 gives the result even to the extent of predicting the correct slight deviation from a straight line.[1]

The form of E as $\tau \to 0$ is a little easier to obtain. For [9] gives immediately that, as $\tau \to 0$, the integral in [9] is asymptotic to

$$[21] \qquad J(kJ^3)^{1/\lambda}$$

Hence $J \sim$ constant $\times\, t^{\lambda/(3+\lambda)}$ and so $Q = dJ/dt \sim$ constant $\times\, t^{-3/(3+\lambda)}$. Taking logs using $\lambda = -a_1/a_2$ and [16] gives

$$[22] \qquad E(t) - i_gR \sim \frac{3}{3a_2 - a_1}\log\tau + \text{constant} \quad \text{as } \tau \to 0$$

and [22] gives the value $(3a_2 - a_1)$.

We now show E has a minimum at $S = \frac{1}{2}$. For, from [8] $0 = \lambda Q^{\lambda-1}\,(dQ/dt)S(1 - S) + Q\,(d/dt)S(1 - S)$ so $dQ/dt = 0$ when $(d/dt)S(1 - S) = 0$ which occurs at $S = \frac{1}{2}$. When $S = \frac{1}{2}$, $S(1 - S)$ is maximal and hence Q has a minimum Q_{min}, since $Q^{\lambda}S(1 - S)$ is constant and $\lambda > 0$.

But $dQ/dt = -a_2Q\,(dE/dt)$ so dQ/dt and dE/dt have the same sign (since $a_2 < 0$) and vanish together. Thus E has a minimum E_{min} at $S = \frac{1}{2}$.

Further at $S = \frac{1}{2}$, $\exp(-kJ^3) = \frac{1}{2}$, so E_{min} occurs at a time t_{min}, which from [11] is given by

$$[23] \qquad 3k^{1/3}\left(\frac{i_g}{P}\right)^{1/\lambda} t_{min} = \int_{1/2}^{1} f(y)\,dy$$

From [12] and [23] we see that t_{min}/t_{ext} depends only on λ and is given by

$$[24] \qquad t_{min}/t_{ext} = \int_{1/2}^{1} f(y)\,dy \Big/ \int_{0}^{1} f(y)\,dy$$

[1] In Figs. 1–4 which are obtained from the numerical simulation we cross-check some aspects of the numerical and analytical solutions to the galvanostatic problem. In all cases agreement is excellent. In each case we take $b_1 = b_2 = 0 = R$ for convenience, since these quantities are unimportant in the present work as indicated in the text. We take the typical values $a_1 = \frac{1}{3}$, $a_2 = -\frac{1}{2}$ (so that $\lambda = \frac{2}{3}$).

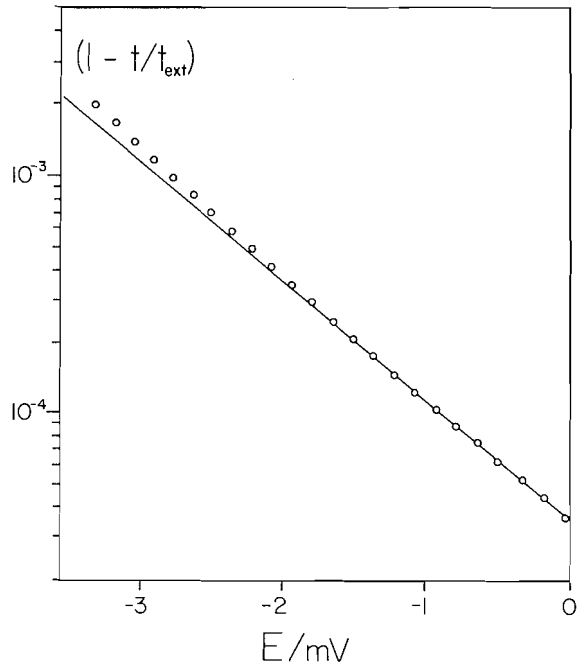

FIG. 1. Plot of log $(1 - \tau)$ vs. E for $1 - \tau \ll 1$. $i_g = 0.005$ mA. This is in agreement with [20].

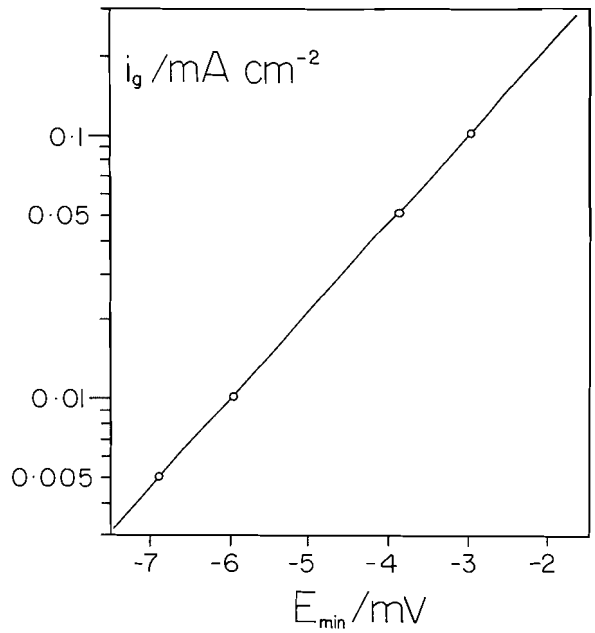

FIG. 2. Galvanostatic current vs. E_{min}. i_g = various. The gradient is 0.33 decade mV^{-1} and should be $a_1 = \frac{1}{3}$ according to [25].

Furthermore, at t_{min}, [8] gives $i_g = (P/4)Q^{\lambda}{}_{min}$ and taking logs gives

$$\log i_g = a_1(E_{min} - i_g R) + b_1 \qquad [25]$$

This is a most important result because of the ease of obtaining i_g, E_{min} experimentally. It is clear that a graph of $E_{min} - i_g R$ vs. log (i_g) should be linear with a gradient of $1/a_1$. This result is compared with that obtained numerically in Fig. 2. Excellent agreement is observed. Equations 14, 25, and 10 allow us to predict accurately the value of E_{min}, t_{min}, and t_{ext} for given i_g, k, λ, R, and P as is illustrated in Fig. 3.

An interesting consequence of [25] relates to the absolute verification of the theory outlined both in the present work and in a previous paper (24). In each case the transformations described by [4]–[7] were calculated on the basis of the instantaneous response of the surface coverage function to small changes in the applied potential. This assumption can now be tested in a very exact way. That is, plots of log (i_g) vs. E_{min} obtained from a series of *galvanostatic* transients should (according to the theory presented above) exactly superimpose on plots of log (i_m) vs. $E_{applied}$ obtained from a series of *potentiostatic* transients. Furthermore, no experimental compensation is required for iR drop because its influence should be identical in both cases. Since the potentiostatic theory is known to be exact (25, 26) the superimposition of the galvanostatic and potentiostatic plots will serve as a diagnostic criterion of the accuracy of the galvanostatic theory.

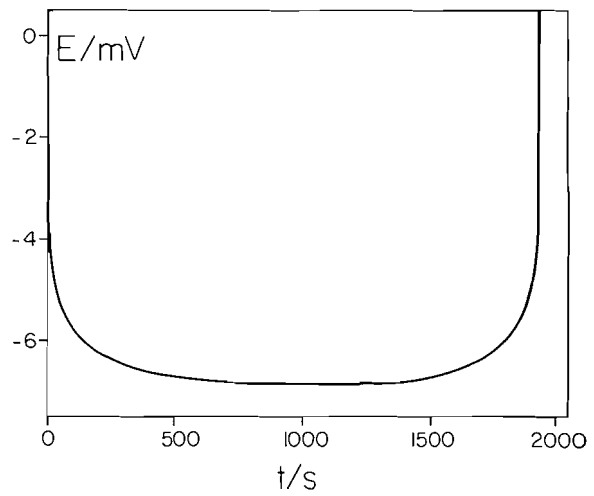

FIG. 3. Complete galvanostatic transient for progressive three-dimensional nucleation and growth. $i_g = 0.005$ mA. The values of E_{min}, t_{ext}, t_{min} are in agreement with the values predicted by [25], [10], [24] respectively. $E_{min} = -6.89$ mV, measured and should be 3 log 0.005 $= -6.903$ according to [25]. $t_{ext} = 1940$ and [10] gives $t_{ext} = 1950$. The values of t_{min} measured and evaluated are consistent but not useful experimentally, due to the shallowness of the E–t graph.

Using the fact that $i_g = (P/4)Q^{\lambda}{}_{min}$ together with [12] gives us $i_g t_{ext}$, the amount of charge consumed in the formation of the three-dimensional layer. We

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

obtain $i_g t_{ext} = \text{constant} \times Q^{\lambda-1}{}_{min}$ and hence

[26] $\log(i_g t_{ext}) = (a_1 + a_2)(E_{min} - i_g R) + \text{constant}$

The numerical simulation confirms this gradient of $a_1 + a_2$ in a log $(i_g t_{ext}) - E_{min}$ graph, and is illustrated in Fig. 4.

The Numerical Solution

Instead of solving [8] by standard numerical methods, we instead use a simulation technique which corresponds more closely with the physical situation. It has been shown previously that this technique is exactly equivalent to solving [8], but the starting point here is the family of curves defined by [1]–[3]. The situation is illustrated diagrammatically in Fig. 5. Each curve represents a section of the *i–t* response of progressive, three-dimensional nucleation and growth under potentiostatic conditions. In the interests of clarity only two curves are represented; one of potential E_1 and the other of potential E_2. Each curve is separated individually into elements, the height of which is Δi. Having chosen a fixed current (i_g) and an initial surface coverage ($S_0 < 0.1\%$), an *i–t* transient is located such that the current ($i_g - \Delta i$) corresponds precisely to the surface coverage S_0. This potential is then recorded (E_1). Growth is then allowed to continue on the transient until a current ($i_g + \Delta i$) is reached. At this point the new surface coverage is calculated (S_1). The length of time required to achieve this process is called Δt_1.

The whole process is then repeated. That is, a new *i–t* transient is located (of potential E_2) such that the observed current ($i_g - \Delta i$) corresponds exactly to the surface coverage S_1, and so *ad infinitum*. Should an *i–t* curve pass through a maximum then the logic is inverted to deal with a falling, rather than a rising, transient. In this way the entire potential–time response may be obtained for a given i_g by plotting E_n vs. $\sum_n \Delta t_n$, having shown that the data converges as $\Delta i \to 0$. The rather distinctive result is shown in Fig. 3. As t increases from zero, E decreases from $+\infty$ to E_{min} at a time t_{min} and then rises again to $+\infty$ at a fixed extinction time (t_{ext}).

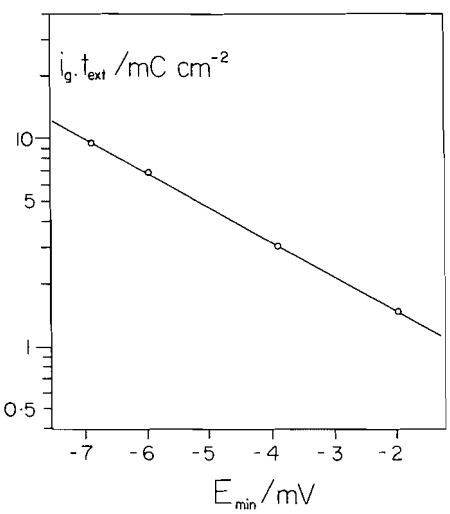

FIG. 4. Charge consumed in the galvanostatic formation of a three-dimensional layer as a function of E_{min}. i_g = various. The gradient is -0.17 and should be $a_1 + a_2 = -\frac{1}{6}$ according to [26].

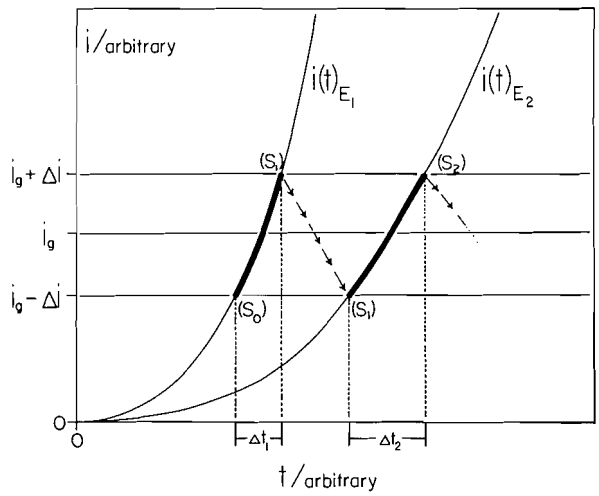

FIG. 5. Basis of the numerical solution.

The physical significance of this is that the rapid fall in potential toward E_{min} is due to the expansion of the emerging interface available for the growth process, once individual nuclei have begun to grow. When the growth centres coalesce, however, the available interface diminishes and so the potential rises back to $+\infty$ again.

Conclusions

The theory of galvanostatic transients has been extended to include crystallization overvoltage. The model chosen was that of progressive, three-dimensional nucleation and growth. It is shown that it is possible to obtain a numerical solution for the entire potential–time plot following the application of a constant current, provided that it is assumed that the electrode surface coverage function responds instantaneously to small changes in potential. Certain limiting cases are also derived which are mathematically exact. A method of testing the model is briefly discussed.

In summary, the present work predicts the following response of the model subsequent to a current step. As t increases from zero, E decreases from $+\infty$ to E_{min} at a time t_{min}. After t_{min}, the potential rises again to $+\infty$ as $t \to t_{ext}$. The minimum occurs at

50% surface coverage and

$$\log (i_g) = \text{constant} + a_1(E_{min} - i_g R)$$

For $\tau \ll 1$

$$\frac{3}{3a_2 - a_1} \log \tau + \text{constant} \sim E - i_g R$$

For $\tau < 1$ and $(1 - \tau) \ll 1$

$$\frac{1}{a_2} \log (1 - \tau) \sim E - i_g R$$

Since fixing i_g is experimentally easy, these equations enable us to evaluate the constants a_1, a_2. Furthermore, the equation of Sand (27) which is widely used in chronopotentiometry for describing diffusion-controlled reactions

$$(\text{transition time})^{1/2} = \frac{\pi^{1/2} n F D^{1/2} C_b^0}{2 i_g}$$

can now be distinguished from the case of three-dimensional nucleation and growth, and so possible confusion can be avoided. This is because, in the present work, (eq. 10)

$$i_g \, t^{\lambda}_{ext} = \text{constant}$$

It also follows that the appropriate experimental plot should be one of $-\log (i_g)$ vs. $\log (t_{ext})$, not i_g vs. $t^{-1/2}_{ext}$.

Finally, it should be noted that the present work can easily be extended to include other models of nucleation and growth, for example the formation of crystalline monolayers. In that case, similar general trends are expected but with some interesting mathematical differences, e.g., the product $i_g t_{ext}$ should be a constant (independent of current) corresponding to the amount of charge consumed in the formation of the surface film. This contrasts with the three-dimensional case which has a variable charge consumption (Fig. 4) and hence variable thickness.

Significance of effects of pressure on electrode reactions. Part III. Equilibrium processes at reference electrodes and the volume of H in Pd

BRIAN E. CONWAY AND J. C. CURRIE[1]

Chemistry Department, University of Ottawa, Ottawa, Ont., Canada

Received June 30, 1977

BRIAN E. CONWAY and J. C. CURRIE. Can. J. Chem. **56**, 915 (1978).

For studies on effects of pressure on kinetics of electrode processes (Parts I, II), reversible reference electrodes suitable for use in a completely enclosed high-pressure bomb are required. The electrodes must exhibit reversible behaviour over the pressure range employed in the experiments, i.e., their changes of emf with increasing and decreasing changes of pressure must be reproducible and correspond to the respective volume changes in the reactions.

A series of reversible reference electrodes is examined over a range of pressures up to ca. 2500 bars. The Pd–H/H^+ and Ag,AgCl/Cl^- reference electrodes are found to behave very satisfactorily at elevated pressures; the Pt,H_2/H^+ electrode is, however, less satisfactory, due to problems associated with dissolved H_2.

The results enable the volume of Pd–H and of H sorbed into Pd to be evaluated, together with estimates of the partial molar volume of H_2 in aqueous HCl. These data enable the pressure-coefficients of metal–solution potential differences at individual reference electrodes to be evaluated. Such information is required for interpretation of effects of pressure on kinetics of electrode processes.

BRIAN E. CONWAY et J. C. CURRIE. Can. J. Chem. **56**, 915 (1978).

Dans le cadre de nos études sur l'effet de la pression sur la cinétique des processus aux électrodes (partie I, II), on devait disposer d'électrodes de référence réversibles pouvant être utilisés dans une bombe à haute pression complètement isolée. Les électrodes doivent posséder un comportement réversible à toutes les pressions utilisées au cours des expériences; entre autre on doit être capable de reproduire des changements de force électromotrice avec des augmentations et des diminutions de pression et ces changements doivent correspondre aux changements de volume respectif des réactions.

On a étudié une série d'électrodes de référence réversibles à diverses pressions allant jusqu'à environ 2500 bars. On a trouvé que les électrodes de référence Pd–H/H^+ et Ag,AgCl/Cl^- se comportent d'une façon satisfaisante à des pressions élevées; toutefois l'électrode Pt,H_2/H^+ est moins satisfaisante à cause des problèmes associés avec l'hydrogène dissous.

Les résultats permettent d'évaluer le volume de Pd–H et de H absorbé dans du Pd et d'évaluer les volumes molaires partiels de H_2 dans HCl aqueux. Ces données permettent d'évaluer les coefficients de pression des différences de potentiel métal–solution à des électrodes de référence individuelles. De telles informations sont nécessaires pour interpréter les effets de pression sur les cinétiques des processus aux électrodes.

[Traduit par le journal]

Introduction

In Parts I and II[2] we considered the effect of pressure on the kinetics of cathodic hydrogen evolution and of the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ redox reaction in order to evaluate volumes of activation and examine electrostriction effects in the hydration shell reorganization process. Such studies (1–5) require reference electrodes (1, 2, 4, 5) which (*a*) can be used reliably in an enclosed vessel at high pressure up to say 3000 bars and (*b*) have well-defined and measurable pressure-coefficients of emf when used in appropriate combination with suitable electrolytes. Also, the individual half-cell pressure coefficients of metal/solution potential-difference should be susceptible to evaluation by satisfactory nonthermodynamic means in order that interpretation (3, 6) of pressure effects on the kinetics of electrode processes can be made. Reference electrodes reliable at high pressure (2) are also required for evaluation of battery electrode behaviour at high hydrostatic pressures, e.g. in deep marine environments. There has been little previous work on this kind of problem but the papers of Hills and Kinnibrugh (1) and of Valeriote and Gallop (2) provide an important background for the present work, especially with regard to experimental techniques.

In this paper, we report investigations on the behaviour of three well-known reference electrode systems, Pt,H_2/H^+_{aq}, Pd–H/H^+_{aq}, and Ag,AgCl/Cl^-_{aq}, under conditions of elevated pressure up to ca. 3000 bars. Special attention was given to the Pd–H/H^+ electrode, which has a potential of 0.050 V

vs. H_2/H^+ at 1 bar with standard H_2 pressure, as this electrode is particularly suitable for studies of electrode processes at elevated pressures since no added gas is required in the high-pressure cell. Also, the pressure-dependence of the Pd–H/H^+ electrode potential enables the molar volume of H sorbed in Pd, as the β-PdH phase, to be derived.

The pressure dependence of the potential of a reversible electrode reaction is related to the volume change occurring in the half-cell reaction. Thus, the pressure coefficient of emf, E, can be written in terms of the appropriate partial molar volumes V_P of products and V_R of reactants as

$$[1] \qquad \left(\frac{\partial E}{\partial P}\right)_T = -\frac{1}{zF}(\sum V_P - \sum V_R)$$

Since single electrode potentials cannot be experimentally evaluated, the electrochemical cell is comprised of two reversible electrodes, whose emf is measured as a function of pressure. The evaluation of the behaviour of certain reversible electrodes for possible use as reference electrodes in high-pressure electrode kinetic studies was performed by measurements on a combination of two different reversible electrodes (e.g. Ag,AgCl and Pt,H_2) in a single high-pressure cell. If the measured cell emf is reproducible in the modes of compression and decompression of the solution, then the pressure coefficient of emf should be correctly given by $(-1/zF)(\sum V_P - \sum V_R)$. Alternatively, the partial molar volume of one of the components of the reaction can be evaluated if we have precise knowledge of $(\partial E/\partial P)_T$ and the partial molar volumes of the remaining constituents of the cell reaction. If the determination of such a partial molar volume is consistent with the volumes reported in the literature, then it can be assumed that the two reversible electrodes forming the cell are functioning in a thermodynamically well-defined manner and therefore can be used as reference electrodes at high pressures.

Experimental

1. High-pressure System

Details of the high-pressure system, including the thermostatted bomb for containing the electrolytic cells, were given in Part II (3). All measurements in this system were made at 298.06 ± 0.02 K.

2. Electrochemical Cells for Use at High Pressure

Cells consisted of two Pyrex end-pieces joined by 2× heat shrinkable Teflon tubing. The top of the cell contains the electrodes varying in number from 2 to 4, depending on the type of system under examination. All the electrode leads are made of platinum wire of initial diameter 0.025 cm, which is hammered flat and sealed into the Pyrex glass tops of the cells. This type of metal–glass seal was found to withstand repeated elevation of pressure up to 2500 bars without development of any leaks or cracks.

The bottom of the cell is a glass cup with a threaded opening for introducing the electrolyte. A screw cap with a Teflon plug insert and Teflon-covered O-ring was used to make a high-pressure seal. Both the top and bottom of the cell had ridges which allowed a positive Teflon-to-glass seal to be made when the two pieces are joined with the shrinkable Teflon tubing. This type of cell can easily tolerate a 30% volume change without undue strain being generated.

The cell for high-pressure emf measurements consists of 3 reversible electrodes, two of which are of the same type. This provides a reliable check on the behaviour of each electrode while inside the high-pressure bomb. For example, if the cell is Pt,H_2|HCl||Pd–H,Pd, the potential of the palladium–hydrogen electrode can be measured, in turn, against the two Pt,H_2 electrodes. The potential between the two Pt,H_2 reference electrodes was also measured periodically. Thus, three emf measurements are obtained at each pressure. This type of cell is illustrated in Fig. 1.

3. Cell Preparation

All electrochemical cells, including those used at ambient and high pressures, were washed in concentrated sulfuric acid for several hours, followed by thorough rinsing in doubly-distilled H_2O. The cells were then filled with pyro-distilled H_2O and allowed to soak overnight. The electrochemical cells for high-pressure measurements were placed in a glove bag which was under a positive pressure of nitrogen. The solutions were degassed (to remove O_2) with pre-purified N_2 in the glove bag. The cells were then filled with the appropriate solution and allowed to soak for 30 min. The cell was then emptied, rinsed a second time, and filled with the solution required for the experiment. The cell was then sealed with the lower screw cap.

In the case of equilibrium emf measurements involving a Pt,H_2 reference electrode, the electrolyte was presaturated with the H_2 gas at ambient pressure. The cell was then filled with electrolyte and H_2 gas was again passed through it for 15 min. Several small bubbles of H_2 gas were allowed to remain in the cell after the cell had been sealed, in order to ensure that the Pt,H_2 electrode remained in a well-defined state at elevated pressures.

4. Reference Electrodes

The Pt,H_2 (1 bar)/H^+, Ag,AgCl, and Pd,Pd–H reversible electrodes were chosen as being the most convenient for electrochemical studies at high pressures in the present work.

(a) The Pt,H_2 Electrode

The hydrogen electrode was prepared by first cleaning two Pt wires (in the high-pressure cell cap) in warm aqua-regia solution, followed by thorough washing in pyro-distilled water. The wires were then platinized together by the standard procedure with no addition of Pb^{2+} ions. The electrodes were then repeatedly washed with water, followed by several washings in pyro-distilled water.

(b) The Pd,Pd–H Electrode

A palladium electrode was built into the high-pressure cell by welding a piece of palladium wire to a platinum wire. The platinum was then sealed into the high-pressure cell cap with care being taken to expose only the Pd wire. The electrode was cleaned thoroughly with concentrated sulfuric acid and washed with pyro-distilled water. The Pd–H electrode was prepared by constant current cathodic electrolysis in 0.5 M H_2SO_4 for a controlled time. The electrode was oxidized for 1 min, followed by a 90-s reduction, both at a current density of 200 mA cm^{-2}. This cycling procedure was continued for approximately 10 min with termination of the electrolysis in the cathodic direction. The electrode was then washed with pyro-distilled water. This electrode was activated in this

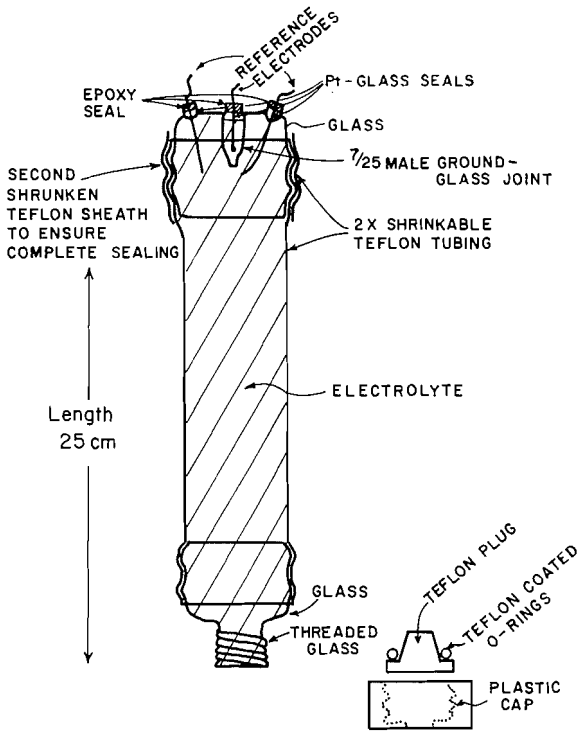

FIG. 1. High-pressure cell for emf measurements. The cell is fabricated from heat-shrinkable Teflon tubing and glass. The cell contains three reversible electrodes of which two are of the same kind.

manner at the beginning of each experiment and gave a reproducible +50 mV potential (17) vs. a Pt,H_2 electrode in the same solution at $P = 1$ bar. This potential corresponds to an equilibrium of H in co-existing α and β phases of PdH with H^+ in solution, and H content < ca. 57 at.%. For convenience, in most of the material which follows, the α + β PdH system will be referred to simply as 'Pd–H'.

(c) The Ag,AgCl Electrode

The silver, silver chloride reference electrode was prepared from a piece of silver wire welded to a platinum wire which was then sealed into the high-pressure cell exposing only the Ag wire. The electrode was cleaned with concentrated sulfuric acid, followed by repeated washings with pyro-distilled water. Anodic deposition of AgCl on the silver wire was carried out (17) by electrolysis from a 1 *M* aqueous HCl solution at a current density of 1.0 mA cm^{-2} for 30 min.

5. Equilibrium EMF Measurements at High Pressures

After the cell had been assembled and connected electrically to the leads in the head of the bomb, it was placed in the high pressure bomb. The cell was then allowed to come to thermal equilibrium before any emf measurements were made. The emf measurements were monitored with a calibrated digital voltmeter (Dana Laboratory, Inc. Model 4300). Elevated pressures were then applied only if the cell emf at ambient pressure had varied less than 100 μV during the last 1 h of the 3 h equilibration period. If this condition was met, the pressure was slowly increased in increments of 276 bars, up to a maximum of 2500 bars. The appreciable heat of compression which is generated was allowed to dissipate for a period of 3 h at each pressure before the emf values were measured. After the maximum pressure had been reached, the system was decompressed in steps of 276 bars, and the emf values were again measured after the normal equilibration period at each pressure.

The pressure coefficient of emf, $(\partial\Delta E/\partial P)_T$, at 1 bar for each pair of reference electrodes was determined graphically from plots of the measured emf values vs. pressure.

Results and Discussion

1. The $Pt,H_2|0.5$ M aq. $H_2SO_4|Pd$–H,Pd Cell

The emf data, ΔE, for this cell as a function of pressure are listed in Table 1. The cell reaction is

$$[2] \qquad Pd + \tfrac{1}{2}H_2 \rightleftarrows PdH$$

As mentioned earlier, 'PdH' is used to represent the 2-phase α + β PdH system at equilibrium which gives (17) the 50 mV potential wrt the Pt,H_2(1 bar)$|H^+$ electrode. The variation of ΔE as a function of pressure is illustrated in Fig. 2. The reversibility of the pressure effects is good with some small degree of hysteresis occurring only with regard to the final readings at low pressure. The slope at 1 bar is $(8.6 \pm 0.5) \times 10^{-6}$ V bar^{-1}. At pressures above 800 bars, the ΔE vs. P plot is linear with a slope of $(6.8 \pm 0.2) \times 10^{-6}$ V bar^{-1}. The hysteresis is probably due to the loss of molecular hydrogen during the course of the run by diffusion through the Teflon walls of the high pressure cell (see below).

The pressure coefficient of emf, $(\partial\Delta E/\partial P)_T$ for the cell reaction 2 is related to the accompanying volume change by

$$[3] \qquad \left(\frac{\partial\Delta E}{\partial P}\right)_T = -\frac{1}{zF}\left(V_{Pd-H} - V_{Pd} - \frac{V_{H_2}}{2}\right)$$

where V_{H_2} is the partial molar volume of H_2, and V_{Pd} and V_{Pd-H} are the molar volumes of Pd and Pd–H, respectively. Therefore, at 1 bar, the volume change for reaction 2 is -8.3 ± 0.5 cm^3 mol^{-1} and at pressures above 800 bars, the volume change tends towards a value of -6.6 ± 0.2 cm^3 mol^{-1}. The increase of the reaction volume as the pressure is enhanced is due to the pressure dependence of the par-

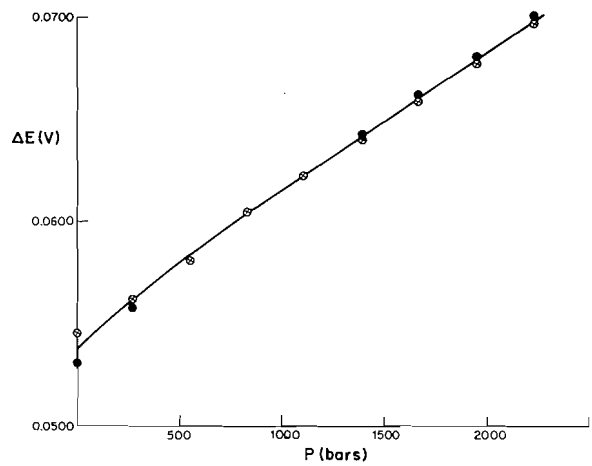

FIG. 2. The variation of emf as a function of pressure at 298.06 K for the cell: $Pt,H_2|0.5\ M\ H_2SO_4|Pd\text{–}H,Pd$.

tial molar volume of H_2 in water. It was found that the $Pd\text{–}H/H^+$ electrode, with Ag,AgCl (see below), provides a stable reference electrode in acid solutions at pressures up to 2500 bars. The Pt,H_2 electrode is stable to within 1 mV during the course of the experiments, but the problems associated with a gaseous reference electrode in a plastic or Teflon cell are always present.

2. The Pt,H_2|1 M HCl|Pd–H,Pd Cell

The behaviour of this cell, with HCl as the electrolyte, was studied in order to provide a basis for use of the $Pd\text{–}H/H^+$ electrode in conjunction with the $Ag,AgCl/Cl^-$ electrode which will be discussed in the following subsection.

The emf data for this $Pt,H_2/Pd\text{–}H$ cell as a function of pressure are listed in Table 2 for two separate experiments. The results are also shown graphically in Fig. 3. The behaviour is, as expected, similar to that of the cell described in subsection 1 above. The slope at 1 bar, $(\partial\Delta E/\partial P)_T$, is $(8.4 \pm 0.5) \times 10^{-6}$ V bar^{-1}; at pressures above 800 bars the pressure coefficient is constant at a value of $(6.9 \pm 0.2) \times 10^{-6}$ V bar^{-1}. The volume change for the reaction 2 is found to be -8.1 ± 0.4 cm^3 mol^{-1} and -6.7 ± 0.2 cm^3 mol^{-1} at 1 bar and above 800 bars, respectively, using the above cell with aq. HCl as electrolyte. The volume data are in quite good agreement with those derived above for the same cell with aq. H_2SO_4 as electrolyte.

The measured cell emf at 1 bar of 0.0502 V is in excellent agreement with the value of 0.0495 V reported by Schuldiner and co-workers (7). The value of ΔE measured after the high-pressure readings, 0.0490 V, is 1 mV less than the initial value at 1 bar. This behaviour is quite similar to that for 0.5 *M* H_2SO_4 and therefore can be rationalized in the same manner, viz. through effects associated with loss of H_2 through the Teflon.

3. The Pd,Pd–H|M HCl|AgCl,Ag Cell

The pressure coefficient of emf for this cell was measured at a series of HCl concentrations at the following molarities 0.01, 0.25, 0.50, 0.75, and 1.0 (at $P = 1$ bar) in order to evaluate the behaviour of the Pd–H,H^+ and Ag,AgCl reference electrodes as a function of electrolyte concentration over a range of pressures. This cell enables the apparent value of the molar volume of Pd–H to be evaluated at each HCl concentration from the appropriate pressure coefficient of emf and known values of the partial molar volume of aq. HCl, and the molar volumes of AgCl, Ag, and Pd. A true value for V_{Pd-H} can then be obtained for infinite dilution of electrolyte by appropriate extrapolation.

The experimental emf data are listed in Table 3 for each HCl concentration, *C*, and pressure. The emf data as a function of pressure are also illustrated

*Due to the high stability of the emf of this cell a '5½' digit digital voltmeter was used for these measurements.

in Fig. 4, where the differences of emf, $\Delta E_P - \Delta E_1$, at pressures P and 1 bar are plotted against pressure. The slopes are constant with increasing pressure for the three highest concentrations over the complete pressure range. At 0.01 and 0.25 M, the pressure coefficient decreases (becomes more negative) with increasing pressure up to 500 bars; at pressures above 500 bars, the pressure coefficient of the emf becomes independent of P. The values of $(\partial E/\partial P)_T$ at $P = 1$ bar and $P \geq 500$ bars are listed in Table 4. The volume changes at each concentration for the cell reaction

[4] $$\text{Pd–H} + \text{AgCl} \rightleftharpoons \text{Pd} + \text{Ag} + \text{HCl}$$

are also included in Table 4.

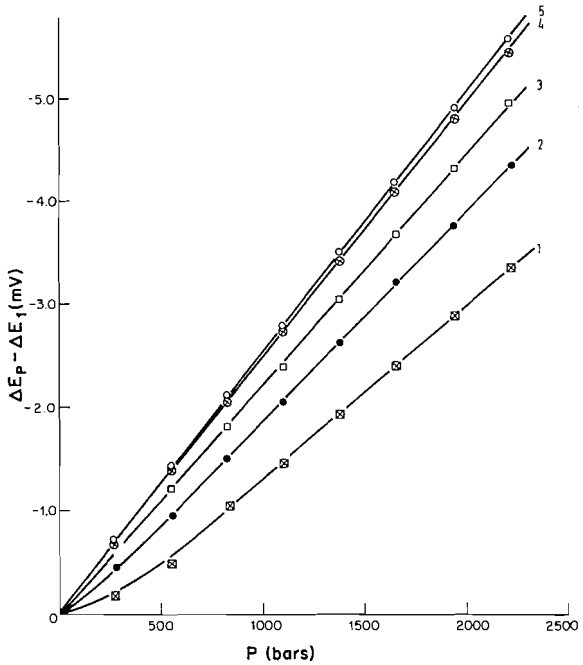

FIG. 4. The variation of emf as a function of pressure at 298.06 K relative to the value at 1 bar for the cell: Pd,Pd–H|HCl|AgCl,Ag at HCl concentrations: (*1*) 0.01 M, (*2*) 0.25 M, (*3*) 0.50 M, (*4*) 0.75 M, (*5*) 1.00 M.

The pressure coefficient is related to the appropriate volume quantities for the cell reaction 4 by the equation

[5] $$\left(\frac{\partial \Delta E}{\partial P}\right)_T = -\frac{1}{F}(V_{Pd} + V_{Ag} + V_{HCl} - V_{Pd-H} - V_{AgCl})$$

where V_{Pd}, V_{Pd-H}, V_{Ag}, and V_{AgCl} are the molar volumes of Pd, Pd–H, Ag, and AgCl, respectively. The molar volumes of Pd, Ag, and AgCl are determined from the appropriate molecular weights and densities of the solid phases in their standard states. V_{HCl} is the partial molar volume of HCl but, for the purpose of this calculation, the partial molal volume of HCl at infinite dilution, V^{∞}_{HCl}, is utilized. From the experimentally determined values of $(\partial \Delta E/\partial P)$, apparent values of the volume V_{Pd-H} can be evaluated from [5] for each concentration of HCl employed. The values of V_{Pd-H} are 'apparent' because V_{HCl} in [5] is concentration-dependent according to the Debye-Hückel law. Inserting the appropriate numerical data (8) in [5] gives

[6] $$\left(\frac{\partial \Delta E}{\partial P}\right)_T = -\frac{1}{F}(9.33 + 10.27 + 17.83 - V_{Pd-H} - 25.78)$$

The apparent values of V_{Pd-H} calculated from the data for each HCl concentration and [6] are listed in Table 5. Apparent values of V_{Pd-H} are then plotted vs. $C^{1/2}$ and extrapolated to zero ionic strength of

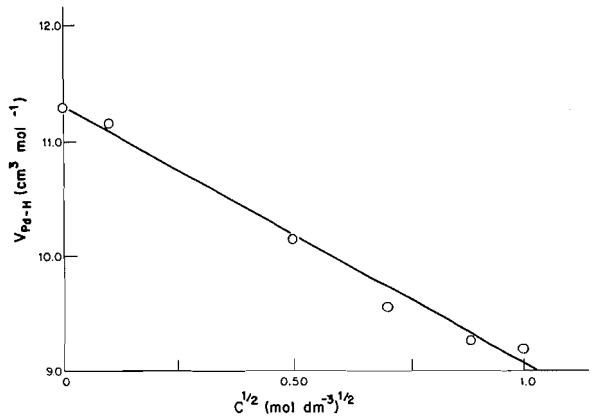

FIG. 5. The variation of the molar volume of Pd–H, V_{Pd-H} with $C_{HCl}^{1/2}$. The best-fit straight line obtained by the method of least squares is shown.

HCl giving a true value of V_{Pd-H} as shown in Fig. 5. The best-fit straight line by the method of the least squares gives an intercept at $C = 0$ of $V_{Pd-H} = 11.3 \pm 0.1$ cm^3 mol^{-1}. The solution compression effect considered in kinetic experiments (3) need not be taken into account here since molalities are employed in the Nernst equation for emf's so that (cf. ref. 2) compression effects are included in the activity coefficients giving a nonideal volume contribution which is eliminated on extrapolation to infinite dilution.

The emf data in Table 4 are satisfactorily reproducible over the pressure range 1 to 2210 bars. The maximum variation of ΔE at 1 bar recorded before and after the high-pressure measurements was 1.7×10^{-4} V ($C = 1.0$ *M* HCl). The minimum variation was 2×10^{-5} V ($C = 0.75$ *M* HCl). Therefore the electrodes Pd–H/H$^+$ and Ag,AgCl/Cl$^-$ can be used as reliable reference electrodes at elevated pressures, with an uncertainty in the measured emf not greater than 1.7×10^{-4} V.

4. The Pt,H_2|1 M HCl|AgCl,Ag Cell

The emf of this cell was found to be relatively unstable in comparison with that of the other cells referred to above. It was initially thought that a time-dependent mixed-potential was set up at the Ag,AgCl electrode in the presence of H_2. Another possible explanation is that reduction of traces of dissolved Ag$^+$ by molecular hydrogen occurs at the Pt,H_2 electrode. A separator between the Ag,AgCl and the Pt,H_2 electrodes was therefore introduced in the cell, but the cell emf again proved to be unstable. Significant diffusion of H_2 through the Teflon walls of the high-pressure cell appears to be a more realistic explanation for the time-dependent emf of this cell. Earlier experiments with the Pt,H_2 vs. Pd–H,Pd system referred to in subsection 1 gave, however, much more stable potentials in the ascending and descending direction of pressure change. In the later experiments, the cells used were made of Teflon from a source different from that employed in the earlier measurements. Therefore, it seems that the two Teflon samples have a different structure, the more recently obtained being permeable to molecular hydrogen.

Heusler and Gaiser (4) also observed instability and systematic errors of about 2 mV for the equilibrium emf of the cell Pt,H_2|HCl, NaCl|AgCl,Ag at atmospheric pressure. The errors were attributed to irreversible reduction of AgCl and to the fact that the H_2 partial pressure became less than 1 bar. The loss of hydrogen was attributed to diffusion through their Teflon cell into the hydraulic oil in the high-pressure vessel. Valeriote and Gallop (2) also observed similar drifts of cell potentials when a

TABLE 6. Pressure coefficients of emf for cells 1, 2, and 3 at 298 K

P (bar)	C (mol dm^{-3} HCl)	$(\partial\Delta E_1/\partial P)_T$ (μV bar^{-1})	$(\partial\Delta E_2/\partial P)_T$	$(\partial\Delta E_3/\partial P)_T$	ΔV_1 (cm^3 mol^{-1})	V_{H_2} (cm^3 mol^{-1})
1	1.0	5.85	8.40	−2.55	−5.65	17.6

hydrogen electrode is used in a Teflon, Lexan, or nylon high-pressure cell. The effects were again attributed to diffusion of H_2 through the walls of the cell.

In order to obtain a more reliable estimate of the pressure-dependence of emf of the cell $Pt,H_2|HCl|AgCl,Ag$ (cell 1), an indirect approach must therefore be taken. The two cell systems treated in subsections 2 and 3 are considered:

$$Ag,AgCl|1\ M\ HCl|Pd\text{–}H,Pd \quad \text{(cell 2)}$$

and

$$Pt,H_2|1\ M\ HCl|Pd\text{–}H,Pd \quad \text{(cell 3)}$$

The $(\partial\Delta E_1/\partial P)_T$ for the $Pt,H_2|1\ M$ HCl|AgCl,Ag system, i.e., for the cell reaction

[7] $$\tfrac{1}{2}H_2 + AgCl \rightleftarrows Ag + HCl$$

for which

[8] $$\left(\frac{\partial\Delta E_1}{\partial P}\right)_T = -\frac{1}{F}\left(V_{Ag} + V_{HCl} - \frac{V_{H_2}}{2} - V_{AgCl}\right)$$

is obtained from the pressure dependence of the emf's of cells designated 2 and 3.

The $(\partial\Delta E/\partial P)_T$ values for cells 1, 2, and 3, and the volume change, ΔV_1, for the cell reaction 7 are listed in Table 6. The partial molar volume of H_2 in 1 M HCl at $P = 1$ bar, as calculated from [8], is also given in Table 6.

5. *The Volume of H Sorbed into Pd and the Significance of the Quantity* V_{PdH}

From the data given above, it is seen that evaluation of the pressure coefficient of emf for the cell

[9] $$Pd,Pd\text{–}H|M\ HCl|AgCl,Ag$$

can provide a convenient method for the determination of the molar volume, $V_{Pd\text{–}H}$, of Pd–H. The significance of $V_{Pd\text{–}H}$ can best be visualized if the processes involved in the $Pd\text{–}H,H^+$ reference electrode reaction are considered.

The behaviour of the $Pd\text{–}H,H^+$ reference electrode has been studied by Schuldiner *et al.* (7), Flanagan and Lewis (9), and by Aben and Burgers (10) with varying opinions on the actual mechanisms involved in the functioning of such an electrode. However, the mechanism described below appears to be the most consistent with the experimental facts. It is known that a palladium wire charged with hydrogen electrolytically or under hydrogen atmosphere will achieve a potential of about +0.050 V with respect to a standard Pt,H_2 reference electrode. Hydrogen is absorbed initially by palladium in the α-phase up to a limiting composition of H/Pd = 0.03 at 298 K. Further H absorption produces a second phase, β, with an H/Pd ratio of 0.60. The stable, well defined electrode potential is due to the simultaneous presence at the electrode surface of the two phases in thermodynamic equilibrium, with the H also in equilibrium with H^+_{aq} and electrons. Electrochemical equilibrium thus exists between the α + β Pd–H electrode and the electrolyte as represented formally by the equation

[10*a*] $$Pd + H^+ + e \rightleftarrows Pd\text{–}H$$

More specifically, when the electrode exhibits the '50 mV' potential (7, 9, 10), α and β-PdH phases co-exist with the α-PdH phase saturated (3 at.% H). Reaction 10*a* should hence be written

[10*b*] $$\alpha\text{-PdH (satd.)} + H^+ + e \rightleftarrows (\alpha + \beta)\text{-PdH}$$

The absorption of H into Pd to form, initially, the α-phase is known (10) to occur with very little expansion of the Pd lattice. Hence, in [5] for reaction 4, V_{Pd} strictly refers to $V_{\alpha\text{-PdH (satd)}}$ and is almost equal to this quantity while V_{PdH} refers to the volume of α-PdH + β-PdH formed from the saturated α-phase by reaction 10*b*. On the other hand, the formation of the β-phase occurs with considerable increase of the lattice parameters, *a*. Values of the latter, obtained by Aben and Burgers (10), using X-ray diffraction, are listed in Table 7.

The value of the measured molar volume of 'PdH' in an α + β-PdH system is therefore associated with the production of H in the β-phase, since it is only this phase that forms with a relatively large expansion of the Pd lattice and a corresponding positive volume change. Hence the value $V_{Pd\text{–}H} = 11.3$ cm^3 mol^{-1} given in Table 5 is the molar volume of formation of H in the β-phase. The apparent volume of H itself, V_H, can then be evaluated by taking the difference of '$V_{Pd\text{–}H}$' and the molar volume of α-PdH

TABLE 7. Lattice parameters for the Pd,Pd–H system (10)

α-Phase	α-Phase + H	(α + β) Phase + H
$a = 0.3882$ nm	$a = 0.3886$ nm	$a_\alpha = 0.3886$ nm
		$a_\beta = 0.4017$ nm

assuming $V_{\alpha\text{-PdH (satd)}} \doteqdot V_{Pd}$. This approach gives a value for $V_H = 2.0\ cm^3\ mol^{-1}$ which is the net volume change of α-PdH (satd) upon absorption of 1 mol of H atoms to produce β-PdH.

Direct evaluation[3] of the quantities V_{Pd-H} and V_H for H in palladium does not seem to have been previously reported in the literature, although V_H in pure iron and in Pd–Ag alloys has been evaluated by measuring the uptake of H_2 under uni-axial stress. This type of measurement is based on the fact that when a tensile stress is applied to a metal it causes an increase in the solubility of H while a compressive stress decreases the quantity of absorbed H-atoms. The change of solubility of H is related to the applied stress by

$$[11] \qquad \frac{\partial \ln (c/c_0)}{\partial \sigma} = \frac{V_H}{3RT}$$

where c is the solubility of hydrogen (moles of H/cm^3 of substrate) when the applied uniaxial stress is σ and c_0 is the solubility when the applied stress is zero. Utilizing this approach, Bockris and co-workers (11) have determined V_H for H in pure Fe as 2.6 cm^3 mol^{-1}. Wriedt and Oriani (12) have determined the value to be 1.90 cm^3 mol^{-1} in a 75% Pd – 25% Ag alloy which is in good agreement with the value obtained in this work: $V_H = 2.0\ cm^3\ mol^{-1}$. It is of interest that this value is appreciably smaller than the volume of adsorbed H at Pt, which we recently determined (22).

The behaviour of the Pd,Pd–H|*M* HCl|AgCl,Ag cell at pressures up to 2500 bars appears to be sufficiently reliable and reversible with respect to increasing and decreasing changes of pressure, that F times the pressure-coefficient of the cell emf can be equated with certainty to the known molar volume differences of the respective components in the cell reaction. This being the case, the Pd–H,H^+ electrode can be utilized as a satisfactory reference electrode in high-pressure electrochemical studies in acid media, as were described in Part II. The Ag,AgCl electrode can be adopted for use in Cl^- salt solutions at elevated pressures.

6. *The Partial Molar Volume of H_2 in Aqueous Solution*

From measurements at various hydrostatic pressures on cells involving the Pt–H_2/H^+_{aq} electrode, the partial molar volume of H_2 in aqueous solution can be derived. Previous data in the literature for V_{H_2} derived from emf measurements (1, 2) are apparently discrepant and differ from a value obtained by Tiepel and Gubbins (13) using a dilatometric technique. The differences appear to be due to ionic strength effects on the apparent molar volume of H_2.

For the cell Pt,H_2|0.1 *M* HCl|AgCl,Ag, Valeriote and Gallop's (2) results give a partial molar volume of H_2 in 0.1 *M* HCl as 17.9 cm^3 mol^{-1}. Hills and Kinnibrugh (1), using the cell Pt,H_2|0.1 *N* HCl|Hg_2Cl_2,Hg, quote $V_{H_2} = 15\ cm^3\ mol^{-1}$ for 0.1 *M* HCl. Heusler and Gaiser (4), using cell 1 (eq. 8), obtained emf values over a range of HCl concentration and evaluated the infinite dilution volume $V^{\infty}_{H_2} = 24\ cm^3\ mol^{-1}$ from the pressure effect on the emf of this cell.

It has been mentioned in subsection 4 that the pressure-coefficient of emf of the cell Pt,H_2|1 *M* HCl|AgCl,Ag could not, for various possible reasons, be measured experimentally in a reliable manner (cf. ref. 4) but could be satisfactorily derived from emf measurements on the cells Pt,H_2|1 *M* HCl|Pd–H,Pd and Pd,Pd–H|1 *M* HCl|AgCl,Ag. The pressure-coefficient of emf obtained in this manner can be used to determine the partial molar volume of H_2 in 1 *M* HCl.

The partial molar volume of H_2 obtained by this procedure in the present work for 1 *M* HCl is $V_{H_2} = 17.6\ cm^3\ mol^{-1}$ and agrees quite well with the value of Heusler and Gaiser (4): $V_{H_2} = 17.7\ cm^3\ mol^{-1}$ for 0.80 *M* HCl. The V_{H_2} values of Heusler and Gaiser are plotted as a function of $C^{1/2}$ in Fig. 6. The best-fit straight line has a slope of −6.3 and gives an intercept $V^{\infty}_{H_2}$ of 24 cm^3 mol^{-1}. The value of V_{H_2} obtained in the present work is within 0.2 cm^3 mol^{-1} of the corresponding value of Heusler and Gaiser on their V_{H_2}–$C^{1/2}$ plot at $C = 1.0$ *M* HCl. This would give $V^{\infty}_{H_2} = 24\ cm^3\ mol^{-1}$ (using their

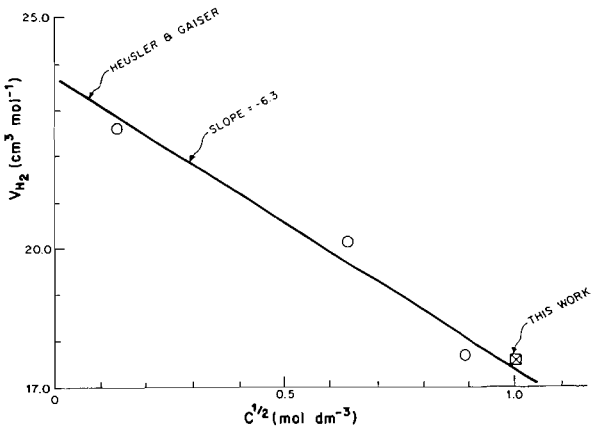

FIG. 6. The variation of the partial molar volume of H_2, V_{H_2}, with $C^{1/2}$ from the data of Heusler and Gaiser (4).

[3]The 'partial molar volume' of H in Pd and various Pd alloys was evaluated by Baranowsky *et al.* (23) from changes of lattice parameters as a function of uptake of H from H_2 at high pressures.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

slope). This value is in good agreement with the previously reported (13) value $V_{H_2}^{\infty} = 25.2$ cm^3 mol^{-1}, based on dilatometric measurements in pure water.

Apparent discrepancies in the literature for V_{H_2} values are evidently due to dependence of the apparent values of V_{H_2} on ionic strength (salting-out effect). Table 8 summarizes the values of V_{H_2} obtained from the literature and from the present work.

It is seen that introduction of a small molecule such as H_2 into an aqueous solution results in a surprisingly large volume increase ($\sim$24 cm^3 mol^{-1}). This observation is consistent with the earlier work of Frank and Evans (14) on the effect of dissolved nonelectrolytes on the structure of water. The introduction of nonpolar gases such as H_2, Ar, He, and Rn into aqueous solutions was found by these authors in a large decrease in entropy of the system (-105–170 J K^{-1} mol^{-1}). This behaviour was related to the ability of these solutes to promote so-called structure building of water around nonpolar solute molecules. The larger solute molecules, such as Rn, promote a greater degree of structure making. The formation of aggregates of structured water will result in expansion of the solvent as reflected in the relatively large values of the observed apparent or partial molar volume of nonpolar solutes.

The partial molar volume of H_2 in 1 *M* aqueous HCl at 1 bar is 17.6 cm^3 mol^{-1}; however, as the pressure is increased, V_{H_2} decreases steadily until about 800 bars. Above this pressure, the value of V_{H_2} becomes constant at 14.1 cm^3 mol^{-1} (Table 6). The decrease of V_{H_2} with pressure is due to the pressure-induced destruction of part of the expanded water structure around the H_2 solute. Above 800 bars, local structure promoted by the introduction of H_2 into the aqueous electrolyte has evidently been 'regelated'. This behaviour is analogous to the observations made by Frank and Evans (14) on the increase of entropy with increasing temperature for nonpolar gases in water. This variation was attributed to the 'melting' of the so-called 'iceberg' structures surrounding the solute molecules.

§Dilatometer method in aqueous KOH.

The large concentration dependence of apparent values of V_{H_2} observed in this work and that of Heusler and Gaiser (4) ($S_v = -6.3$) can be explained in terms of the salting-out effect. In solutions of moderate electrolyte concentration (0.01 $\rightarrow$ 1 *M*), increasing mole fractions of the solvent will be involved in solvation of the respective ions as their concentration increases. Therefore, a solute molecule such as H_2 when introduced into an ionic solution sees a smaller volume of 'free' solvent molecules than would be the case in pure water. The activity coefficient of the H_2 gas is therefore increased corresponding to reduction of its solubility (salting-out effect) (15, 16). Therefore the volume change accompanying the dissolution of H_2 will be less than the $V_{H_2}^{\infty}$ value due to the effect of pressure on the activity coefficient associated with the influence of the ions present.

7. *Pressure Coefficients of Individual Electrode – Solution Potential Differences*

In studies of kinetics of electrode processes as a function of pressure, an apparent volume of activation $\Delta V_a^{\ddagger}$ is obtained (3) which differs (6, 18) from the true, kinetically significant value $\Delta V_t^{\ddagger}$ by β times the volume change, ΔV_0, for the same overall electrode process at equilibrium: $\Delta V_t^{\ddagger} = \Delta V_a^{\ddagger} + \beta \Delta V_0$ or $\Delta V^{\ddagger} = \Delta V_a^{\ddagger} - (1 - \beta)\Delta V_0$, where β is the symmetry coefficient for the electron-transfer process. The term $\beta \Delta V_0$ enters (6) into the expression for $\Delta V_t^{\ddagger}$ due to the pressure-dependence of the potential difference at the reversible reference electrode used to make the kinetic measurements at well-defined electrode potentials.

The present results enable the individual pressure coefficients of the metal–solution potential differences for the Pd–H/H$^+$ and Pt–H_2/H$^+$ reference electrodes to be estimated, taking a value for $V_{H^+}^{\infty} = -5.4$ cm^3 mol^{-1} based on (*a*) ultrasonic vibration potentials (19) and (*b*) extrapolation of volumes of R_4N^+ halide salt ions (20), methods which give values for $V_{H^+}^{\infty}$ in very good agreement (21). The individual pressure-coefficients and corresponding volume changes ΔV_0 are given in Table 9. The ΔV_0 values depend on the assignment of a value V_e for the volume of electrons in a metal. The figure of 3 cm^3 Faraday^{-1} from ref. 4 has been used for the data given in Table 9.

The individual pressure coefficients of potential differences in Table 9 do not take account of the (unknown) pressure dependence of surface-potential

TABLE 9. Pressure coefficient of metal–solution potential differences at individual reference electrodes

Electrode	ΔV (cm^3 mol^{-1})	$(dE/dP)_T$ (μV bar^{-1})
$H^+ + e \rightleftharpoons \frac{1}{2} H_2$	14.4	−14.9
$H^+ + e + Pd \rightleftharpoons Pd\,H$	4.4	−4.6
$AgCl + e \rightleftharpoons Ag + Cl^-$	4.7	−4.9

differences, $d\chi/dP$. However, the corresponding effects of varying temperature indicate that $d\chi/dT$ is not appreciable. Hence it is reasonable to assume that any pressure dependence of χ up to ca. 3000 bars will not seriously affect the values of the pressure coefficient of individual electrode potentials evaluated from V data, and hence of the derived true activation volumes in kinetic studies.

Reçu le 25 juillet 1977

PHILIPPE DUMAS et PHILIPPE GUERIN. Can. J. Chem. **56**, 925 (1978).

Les α,β,γ,δ-tétraphénylporphyrines au cadmium, zinc et magnésium forment avec les oxirannes et les thiirannes des complexes 1:1. Les valeurs relatives des constantes de complexation sont en accord avec la théorie des acides et bases "durs et mous".

Les α,β,γ,δ-tétraphénylporphyrines au cadmium, zinc et magnésium sont démétallées par les thiols. Celle au cadmium peut réagir avec des hétérocycles soufrés possédant un hydrogène en β du soufre pour donner la porphyrine libre et un thiolate de cadmium. Lorsque cet hétérocycle est le méthylthiiranne, l'organocadmien ainsi formé est susceptible d'amorcer *in situ* la polymérisation stéréospécifique de cet hétérocycle.

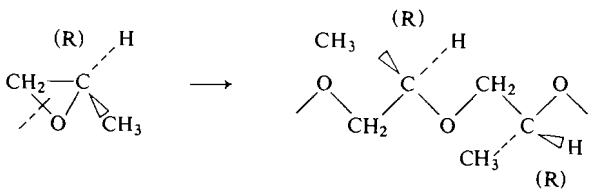
PHILIPPE DUMAS and PHILIPPE GUERIN. Can. J. Chem. **56**, 925 (1978).

1/1 adducts from oxiranes or thiiranes and cadmium, zinc, or magnesium α,β,γ,δ-mesotetraphenylporphyrins were obtained in benzene and complexation constants determined. Results agree with the theory of 'hard and soft' acids and bases.

Demetallation of the metaloporphyrins of Cd, Zn, and Mg is achieved with thiols. The cadmium porphyrin reacts with sulfur heterocycles which contain a β hydrogen to yield the free porphyrin and a thiolate of cadmium. If this heterocycle is methylthiirane, the organocadmium compound formed may initiate the subsequent *in situ* stereospecific polymerization of methylthiirane.

Introduction

Les dérivés du cadmium, du zinc et du magnésium amorcent les polymérisations stéréospécifiques des oxirannes et des thiirannes (1, 2). Le mécanisme de ces polymérisations est supposé anionique coordiné. La coordination du soufre (ou de l'oxygène) de l'hétérocycle serait suivie d'une insertion du monomère entre l'extrémité de la chaîne macromoléculaire active et le métal. L'ouverture du cycle oxiranne ou thiiranne se produit dans ce cas presque exclusivement entre le carbone secondaire et l'hétéroatome; elle conserve la configuration absolue du carbone asymétrique de l'hétérocycle. Il est supposé que l'amorceur (le dérivé organométallique) choisit la configuration du monomère à introduire et que par suite de ce contrôle, les chaînes macromoléculaires ne contiennent qu'un seul type d'unités configurationnelles. Le polymère est stéréorégulier et possède une structure isotactique. Cette stéréorégularité proviendrait donc d'effets stériques et de la complexation entre le métal et l'oxygène (ou le soufre).



Malheureusement la complexité des espèces organométalliques actives ne permet pas d'étudier directement ces interactions et l'utilisation de modèles s'avère nécessaire (3). Les α,β,γ,δ-tétraphénylporphyrines métallées ne présentent pas de phénomène d'autoassociation, possèdent un spectre d'absorption dans le visible caractéristique (4) et sont donc des composés modèles particulièrement pratiques pour examiner des phénomènes de complexation. Nous avons pu ainsi comparer les différences de comportement entre des hétérocycles contenant du soufre ou de l'oxygène avec le zinc, le cadmium ou le magnésium.

Partie expérimentale

La tétraphénylporphyrine a été préparée selon la méthode décrite par Adler et coll. (5) et purifiée en présence de 2,3 dichloro-5,6 dicyanobenzoquinone pour éliminer la porphine (6). L'insertion des métaux a été effectuée dans la diméthylformamide en utilisant l'acétate de cadmium, l'acétate de zinc et le chlorure de magnésium (7).

Le tertbutylthiiranne, seule base de Lewis non commer-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

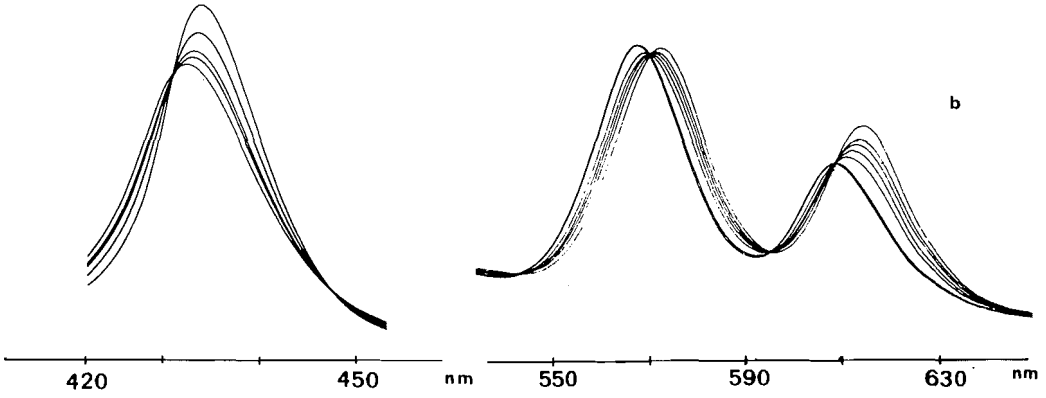

FIG. 1. Etude en spectroscopie visible de la formation du complexe par introductions successives de méthylthiiranne dans une solution benzénique de tétraphénylporphyrine au cadmium, à 20°C. (*a*) Région 400–450 nm, chemin optique de la cuve: 1 mm; (*b*) région 500–650 nm, chemin optique de la cuve: 10 mm.

cialisée utilisée par nous, a été préparé suivant une méthode déjà décrite par l'un d'entre nous (8).

Les déterminations de constantes de complexations ont été effectuées dans le benzène à 617 nm pour la porphyrine au cadmium, 609 nm pour celle au magnésium et 592 nm pour celle au zinc. La concentration de l'hétérocycle variait de 10^{-3} à 1 *M* et celle de la tétraphénylporphyrine était égale à 6.3×10^{-5} *M* (TPPCd), 6.8×10^{-5} *M* (TPPZn), 7.3×10^{-5} *M* (TPPMg).

Etude des complexations

La complexation entre des métalloporphyrines et des bases de Lewis dans des solvants non aqueux est maintenant bien connue (9, 10). En particulier un travail considérable a été fait sur l'interaction entre la mésotétraphénylporphyrine au zinc et des molécules contenant de l'azote (11). Par analogie avec les polymérisations étudiées par ailleurs, nous avons choisi comme bases de Lewis: le méthylthiiranne (sulfure de propylène), le tertbutylthiiranne, le méthyloxiranne (oxyde de propylène) et l'épichlorhydrine. Les changements dans les spectres d'absorption dans le visible (région 500 à 700 nm) accompagnant la formation de complexe ont été utilisés pour étudier quantitativement la réaction de complexation.

Dans tous les cas, les spectres des métalloporphyrines en présence d'une base de Lewis ont la même allure que ceux des métalloporphyrines non complexées. On observe aussi lors de l'addition de l'agent complexant la présence de points isobestiques dans les régions de la bande de Soret (400, 450 nm) et des bandes α et β (500, 700 nm) (exemple fig. 1). Ceci montre que le milieu réactionnel ne contient en quantité appréciable qu'une seule espèce coordinée et la métalloporphyrine libre.

Pour connaître le degré de complexation et déterminer la constante de cette complexation, nous avons utilisé les relations mathématiques dérivées de la loi de Beer (12, 13). Si

$$M + nL \rightleftharpoons ML_n$$

$$K = \frac{[ML_n]}{[M][L]^n}$$

[M] étant la concentration de la métalloporphyrine non complexée, [L] celle de la base de Lewis libre et $[L_t]$ la concentration totale de base ajoutée, *n* le degré de complexation et $[M]_0$ la concentration initiale de la métalloporphyrine:

$$[M]_0 = [M] + [ML_n]$$

et

$$[L] = [L_t] - n[ML_n]$$

Ici [L] peut être assimilée à $[L_t]$ puisque $[M]_0 \ll [L_t]$. Pour [L] = 0: $D = D_0 = \varepsilon_M[M]_0$. *D* étant la densité optique et ε le coefficient d'extinction molaire. Pour [L] quelconque: $D = \varepsilon_M[M] + \varepsilon_{ML_n}[ML_n]$. La densité optique correspondant à la formation du complexe s'écrit donc:

$$D_\infty = \varepsilon_{ML_n}[ML_n]$$

d'où

$$D - D_0 = (\varepsilon_{ML_n} - \varepsilon_M)[ML_n]$$

$$D_\infty - D = (\varepsilon_{ML_n} - \varepsilon_M)[M]$$

$$D_\infty - D_0 = (\varepsilon_{ML_n} - \varepsilon_M)[M]_0$$

d'où

$$\frac{[ML_n]}{[M]} = \frac{D - D_0}{D_\infty - D} = K[L]^n = K[L_t]^n$$

ce qui peut s'écrire sous la forme:

$$\frac{1}{D - D_0} = \frac{1}{D_\infty - D_0} + \frac{1}{D_\infty - D_0}\frac{1}{K[L_t]^n}$$

La linéarité de la représentation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$\frac{1}{D - D_0} = f\left(\frac{1}{[L]^n}\right)$$

est testée avec $n = 1$ ou 2, la constante K et D_∞ sont déduits graphiquement. Quel que soit le métal inséré dans la porphyrine (Cd, Mg ou Zn), la linéarité a été vérifiée pour $n = 1$ (exemple fig. 2). Nous sommes donc en présence d'une complexation de type 1:1.

De tels complexes 1:1 ont déjà été observés entre des métalloporphyrines et des dérivés oxygénés et soufrés, notamment entre TPPZn et les 1,1,3,3-tétraméthylurée et thiourée (15). Les constantes K de complexation étant respectivement égales à 26 et 12.

Nous constatons dans le tableau 1 que le comportement du cadmium vis-à-vis du soufre et de l'oxygène est très différent de celui du zinc et du magnésium. En effet les interactions entre le cadmium et le méthylthiiranne sont plus importantes qu'avec le méthyloxiranne, alors que pour le zinc et le magnésium la situation est inversée. Ces résultats sont conformes à la classification de Ahrland et coll. (14*a*) et Pearson (14*b*) sur les acides et bases "durs et mous". Il est admis que le cadmium est un acide "mou", alors que le magnésium est un acide "dur" et le zinc fait partie des métaux qui ne peuvent être classés tout en étant moins "mou" que le cadmium.

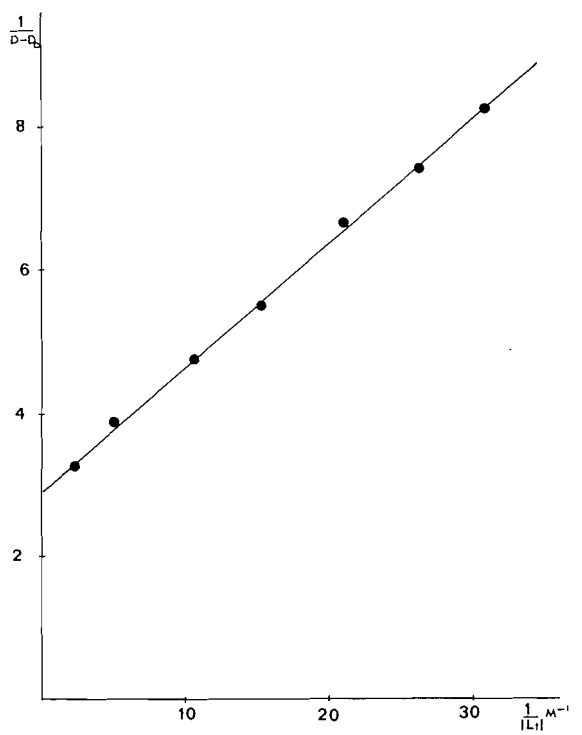

FIG. 2. Représentation des variations de densité optique à 617 nm de TPPCd en fonction de l'inverse de la concentration de méthylthiiranne ajoutée.

TABLEAU 1. Mesure des constantes de complexation (dans le benzène à 20°C)

α,β,γ,δ-Tétraphényl-porphyrine métallée	Base de Lewis	K (M^{-1})
TPPCd		40±5
		20±2
		~0.5
		$\ll 10^{-1}$
TPPZn		3±0.5
TPPMg		6±0.5
		$\ll 10^{-1}$
		~0.5

Le soufre est une base "molle" et l'oxygène une base "dure".

Ces différences de complexation du zinc et du cadmium vis-à-vis du soufre peuvent expliquer, en partie, les résultats obtenus dans les polymérisations des thiiranes amorcées par des dérivés du zinc et du cadmium: les sels de cadmium (carbonates (16), tartrates (2) ou thiolates (17)) conduisent à des polymères stéréoréguliers de structure isotactique tandis que les sels correspondant du zinc ne permettent d'obtenir que des polymères non réguliers de structure atactique. La situation est plus complexe dans le cas des produits d'hydrolyse ou d'alcoolyse des dérivés organométalliques du zinc et du cadmium (2). A une forte interaction cadmium soufre correspond une stéréosélection élevée (choix spécifique de l'un des antipodes avant l'insertion) tandis qu'une faible interaction zinc soufre voit disparaître cette stéréosélection.

La faible interaction cadmium oxygène est en accord avec le fait que les dérivés du cadmium n'amorcent pas la polymérisation des oxirannes.

Pour un couple métal, hétéroatome, la variation de la constante de complexation est en accord avec les effets inductifs existant dans l'hétérocycle. L'effet inductif plus fortement donneur du groupement

tertiobutyle par rapport au méthyle se traduit par une augmentation des interactions soufre cadmium et nous obtenons une valeur double pour la constante de complexation. L'effet inductif attracteur du chlore se traduit par une très forte diminution des interactions oxygène cadmium. Ces résultats sont en accord avec les observations recueillies dans l'étude des polymérisations stéréospécifiques de ces monomères. Pour un même amorceur, nous constatons que les poly(tertbutylthiirannes) sont plus stéréoréguliers que les poly(méthylthiirannes) et que le comportement de ces deux monomères peut même devenir assez différent dans les polymérisations appelées stéréoélectives (18). Ces écarts de comportement peuvent être expliqués par des effets stériques et donc aussi par des interactions monomère métal différentes.

La très faible interaction épichlorhydrine–zinc expliquerait la très faible réactivité de ce monomère en polymérisation anionique coordinée amorcée par des systèmes organozinciques (19).

La complexation TPPMg oxyde de propylène (complexe 1:1) est différente de celle observée entre TPPMg et la pyridine où des complexes 1:2 ont été mis en évidence (10).

Réactions de demétallation des porphyrines métallees

Les métalloporphyrines sont des complexes relativement stables. Elles ne sont ni hydrolysables, ni alcoolysables. L'acide acétique glacial ne décompose pas le complexe TPPZn mais décompose TPPMg et TPPCd (20).

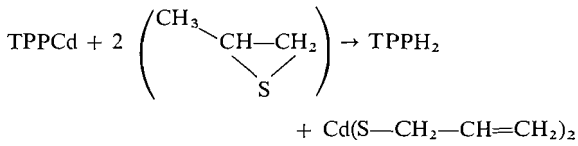
Nous avons fait réagir le *n*-dodécylmercaptan, à température ordinaire, avec ces trois complexes: TPPCd et TPPMg sont immédiatement détruits, TPPZn après quelques heures. Dans les trois cas, en présence d'un excès de thiol, nous obtenons une solution verte avec un spectre caractéristique de la tétraphénylporphyrine protonée-bande de Soret déplacée à 448 nm et deux pics à 650 nm (intense) et 600 nm (faible) (4); le lavage de cette solution par une solution aqueuse de Na_2CO_3 régénère la base libre. L'ordre de réactivité de ces complexes avec un thiol est le même que celui observé avec l'acide acétique glacial.

Le cadmium est légèrement trop volumineux pour l'anneau porphyrine et il a été montré que le métal Cd n'est pas exactement situé dans le plan défini par la porphyrine contrairement au zinc et au magnésium (9). Cette position légèrement excentrée ne correspond pas à des conditions optimales de stabilité; des réactions d'échange sont connues, par exemple (9):

$$TPPCd + ZnR_2 \rightarrow TPPZn + CdR_2$$

Nous avons observé certaines réactions spécifiques de démétallation de ce complexe TPPCd qui pourraient être dûes à sa géométrie particulière. Nous avons fait réagir le méthylthiiranne à 80°C avec les trois complexes. Aucune réaction autre que la complexation déjà décrite n'intervient entre TPPZn ou TPPMg et le méthylthiiranne. Par contre le méthylthiiranne provoque en quelques heures la démétallation de TPPCd. Nous obtenons la base libre et un organocadmien qui est susceptible d'amorcer *in situ* la polymérisation du méthylthiiranne. Les polymères ainsi obtenus sont de faibles masses moléculaires ($M_n \sim 5000$) et ont une structure isotactique. Le pourcentage des diades isotactiques mesuré par résonance magnétique nucléaire du carbone 13 (21) est supérieur à 90% pour les polymérisations effectuées à température ordinaire. Ce taux de tacticité décroît lorsque la température de polymérisation croît. Ces polymères contiennent des insaturations (doubles liaisons éthyléniques) décelées par spectrophotométrie d'absorption infrarouge et ne renferment pas de reste tétraphénylporphyrine.

L'hypothèse la plus raisonnable pour cette réaction de démétallation est:



En effet, les thiolates de cadmium amorcent la polymérisation du méthylthiiranne et permettent d'obtenir des produits stéréoréguliers de hautes masses moléculaires (17). La tacticité de ces polymères varie avec la température de polymérisation (22) tout comme nous l'avons observé. De plus, l'amorçage du méthylthiiranne par un allylthiolate de cadmium expliquerait la présence des insaturations observées dans nos polymères. Cet organocadmien n'a pu être isolé; en effet la réaction de démétallation s'effectue en présence d'un excès de méthylthiiranne qui est immédiatement amorcé, cet amorçage consommant l'allylthiolate de cadmium libéré.

Une telle réaction de démétallation de TPPCd est aussi observée (par spectrophotométrie d'absorption) avec le tétrahydrothiophène mais pas avec le tertbutylthiiranne qui est pourtant fortement complexé avec TPPCd. Le tertbutylthiiranne ne possède pas d'hydrogène situé en β par rapport au soufre, contrairement au méthylthiiranne et au tétrahydrothiophène et ne pourrait donc pour cette raison, conduire à la formation d'un allylthiolate de cadmium.

Le mécanisme de la réaction de démétallation pourrait être le suivant (schéma 1):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

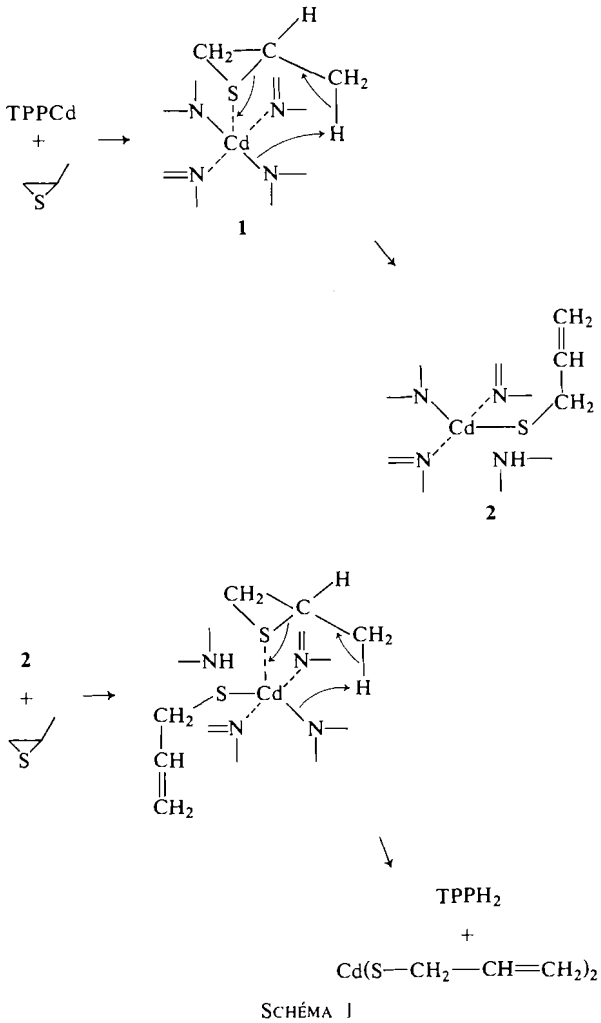


SCHÉMA 1

Pour des raisons graphiques la molécule de TPPCd est uniquement représentée par le métal et les quatre azotes des noyaux pyrroliques. La molécule de méthylthiiranne se positionne au-dessus du plan de la porphyrine (**1**) avant de réagir pour former l'allylthiolate (**2**). La réaction se poursuit par attaque d'une deuxième molécule de méthylthiiranne pour donner la porphyrine libre et le bisallylthiolate de cadmium.

La polymérisation *in situ* du méthylthiiranne est amorcée par l'allylthiolate de cadmium ainsi formé. La tétraphénylporphyrine libérée agirait comme agent de transfert ce qui expliquerait les très faibles masses moléculaires obtenues. Nous avons vérifié l'existence de cette réaction de transfert en amorçant, dans des conditions identiques, la polymérisation du méthylthiiranne par le phényl-2éthanethiolate de cadmium en présence et en absence de tétraphénylporphyrine. En absence de $TPPH_2$ nous obtenons un polymère de masse moléculaire élevée: $M_n \sim 50\,000$. La réaction de transfert pourrait s'écrire (schéma 2) avec formation de l'espèce intermédiaire **2** entrevue dans la réaction de démétallation (schéma 1) qui évolue en présence de méthylthiiranne en $TPPH_2$ et allylthiolate de cadmium. Il a été montré que les thiolates de cadmium sont des amorceurs monofonctionnels (22), c'est-à-dire que la croissance de la macromolécule se fait par insertion du monomère sur un seul groupement allyle de l'organocadmium. La régénération de l'amorceur et de la tétraphénylporphyrine explique les très faibles masses moléculaires obtenues et l'absence de restes tétraphénylporphyrine dans les oligomères.

Conclusions

Les α,β,γ,δ-tétraphénylporphyrines métallées sont des modèles simples permettant d'étudier les interactions entre un métal et le soufre ou l'oxygène. Il se forme des complexes 1:1. Les valeurs relatives des constantes de complexation sont conformes à la théorie des acides et bases "durs et mous", c'est-à-dire forte interaction entre cadmium et soufre et entre zinc et oxygène. Des effets inductifs donneurs augmentent ces interactions et la constante de complexation TPPMe–hétérocycle; des effets inductifs attracteurs diminuent cette interaction.

Les résultats obtenus sont en accord avec les observations faites dans les polymérisations anioniques coordinées de ces hétérocycles, montrant la dépendance étroite entre la stéréorégularité du

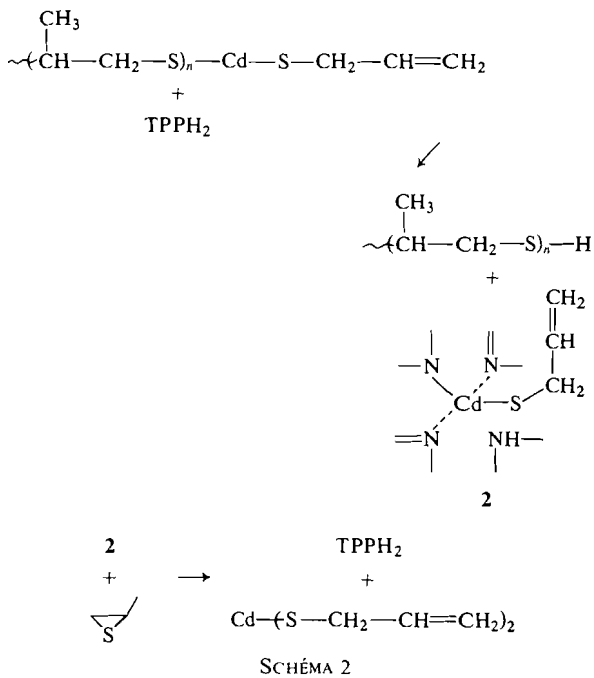

SCHÉMA 2

polymère et les interactions du métal avec le monomère.

Nous avons observé une réaction de démétallation spécifique de TPPCd avec des hétérocycles soufrés possédant un hydrogène en β du soufre conduisant à la tétraphénylporphyrine libre et à un allylthiolate de cadmium susceptible d'amorcer *in situ* la polymérisation stéréospécifique du méthylthiiranne.

Effect of aromatic substituents on the rates of hydrolysis of ethyl thiolbenzoate and ethyl thionbenzoate in aqueous sulfuric acid

JOHN T. EDWARD, SIN CHEONG WONG, AND GRAEME WELCH

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received September 28, 1977

JOHN T. EDWARD, SIN CHEONG WONG, and GRAEME WELCH. Can. J. Chem. **56**, 931 (1978).

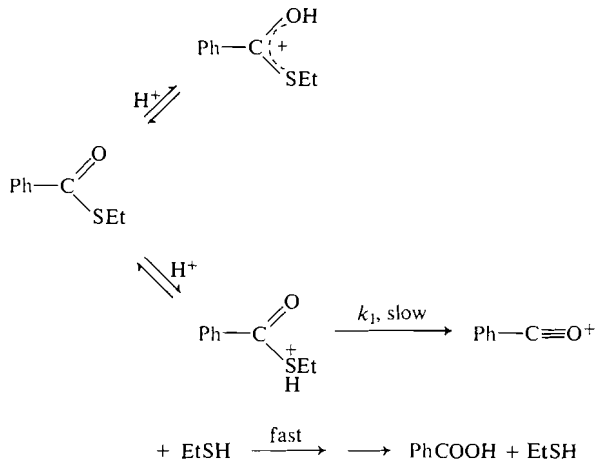
The rates of hydrolysis of seven *meta*- and *para*-substituted ethyl thiolbenzoates and seven *meta*- and *para*-substituted ethyl thionbenzoates in various concentrations of sulfuric acid above 48% have been determined. The Yates–McClelland r and the Hammett ρ parameters indicate that substituted ethyl thiolbenzoates hydrolyze by an $A_{Ac}1$ mechanism but substituted ethyl thionbenzoates by an $A_{Ac}2$ mechanism.

JOHN T. EDWARD, SIN CHEONG WONG et GRAEME WELCH. Can. J. Chem. **56**, 931 (1978).

On a mesuré les vitesses de l'hydrolyse de sept thiolbenzoates d'éthyle substitués en *meta* et *para* et de sept thionbenzoates d'éthyle substitués en *meta* et *para* dans diverses concentrations d'acide sulfurique supérieures à 48%. Les paramètres r de Yates–McClelland et ρ de Hammett indiquent un mécanisme $A_{Ac}1$ pour l'hydrolyse des thiolbenzoates, mais un mécanisme $A_{Ac}2$ pour l'hydrolyse des thionbenzoates.

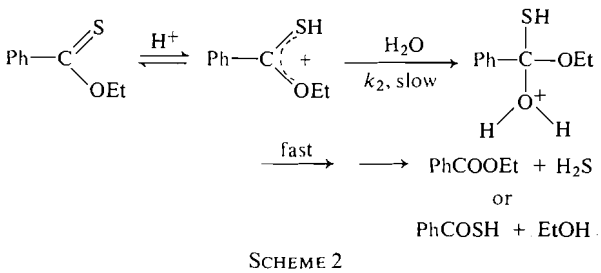
Introduction

Recent studies (1) have shown that whereas ethyl thiolbenzoate hydrolyzes by an $A_{Ac}1$ mechanism (Scheme 1) in sulfuric acid concentrations above



SCHEME 1

65%, ethyl thionbenzoate hydrolyzes by an $A_{Ac}2$ mechanism (Scheme 2) in even the highest concentrations of acid. In this paper, we report kinetic data for the hydrolysis of seven *meta*- and *para*-substituted ethyl thiolbenzoates and seven *meta*- and *para*-substituted ethyl thionbenzoates; these results give further support to the mechanisms of Schemes 1 and 2.



SCHEME 2

Experimental

Materials

p-Methoxy, *p*-methyl, *m*-methyl, *p*-chloro, *p*-bromo, *m*-bromo, and *p*-nitro derivatives of ethyl thionbenzoate were prepared from the appropriate benzonitriles via benzimidate hydrochloride intermediates (2, 3). *p*-Methoxy, *p*-methyl, *m*-methyl, *p*-chloro, *m*-bromo, *m*-nitro, and *p*-nitro derivatives of ethyl thiolbenzoate were prepared by reaction of the corresponding benzoyl chlorides with ethanethiol (cf. ref. 4). Boiling points and elemental analyses of four new ethyl thiolbenzoates are available as supplementary data. Sulfuric acid solutions were made up and standardized by procedures described previously (2).

Determination of Protonation Constants of Thiol Esters

The hydrolysis of ethyl *p*-nitrothiolbenzoate and ethyl *m*-nitrothiolbenzoate in sulfuric acid at 10.0°C was slow. Ionization ratios I (available as supplementary material[1]) and hence protonation constants K_{SH^+} of these compounds could be determined by the conventional spectrophotometric procedure (5). pK_{SH^+} values calculated by both the Yates–McClelland (6) and the Bunnett–Olsen equations (7) are given in Table 1 along with slope parameters m and ϕ.

The *m*-bromo-, *p*-chloro-, and *m*-methyl thiolbenzoates were hydrolyzed more rapidly in concentrated acids, so that extinction coefficients of the compounds at these concentrations were obtained by extrapolating back to the time of preparation of the solution. These extrapolations became unreliable in very concentrated acid solutions when the rates of hydrolysis were extremely fast, making it difficult to obtain the extinction coefficient ε_{SH^+} of the conjugate acid SH^+. Consequently, a value of ε_{SH^+} was chosen by trial-and-error so that the plots

of $\log I$ ($\equiv \log(\varepsilon_S - \varepsilon)/(\varepsilon - \varepsilon_{SH^+})$) against $-H_0$ (6) and of $\log I + H_0$ against $H_0 + \log[H^+]$ (7) would be linear. From such plots were determined the pK_{SH^+} values shown in Table 1. The slopes m and ϕ of these compounds (Table 1) were close to the values found for the more stable nitro compounds.

Kinetic Measurements

Pseudo-first-order hydrolysis rate constants k_ψ of the 14 thio-esters were determined spectrophotometrically at 25.0 ± 0.1°C following standard procedures (8). Triplicate runs agreed to within 4%. Results are plotted in Figs. 1 and 2 and tabulated in the supplementary material.[1]

Results and Discussion

Preequilibrium Protonation

Acid-catalyzed ester hydrolysis is preceded by a preequilibrium protonation step. The seven thionbenzoates are *S*-protonated and follow the h_T acidity function. Their pK_{SH^+} values have been reported (2, 3). However, thiol esters, like other carboxylic acid derivatives which are protonated on the carbonyl oxygen (9), do not follow exactly any of the presently-established acidity functions. The pK_{SH^+} values of five thiolbenzoates were determined above; that of the parent ethyl thiolbenzoate has already been reported (1). It was found that their m and ϕ values (Table 1) are close to those of ethyl benzoate ($m = 0.74$, $\phi = 0.27$ at 25°C (10)), but grossly different from that of sulfides ($\phi \simeq -0.3$ (11)), lending further support to the idea of carbonyl protonation. The pK_{SH^+} values of thiolbenzoates correlated better with σ^+ values (12) (linear regression correlation coefficient 0.999) than with σ (correlation coefficient 0.991) and yielded ρ of +1.58, lying between that for acetophenone (+2.17 (13)) and for benzoic acid (+1.09 (13)). The relatively weak resonance interaction within the protonated thiol ester function indicated by these re-

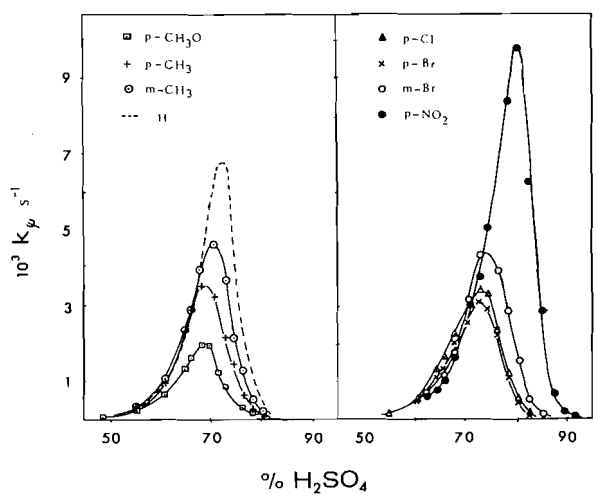

FIG. 1. Rate–acidity profiles for hydrolysis of substituted ethyl thionbenzoates.

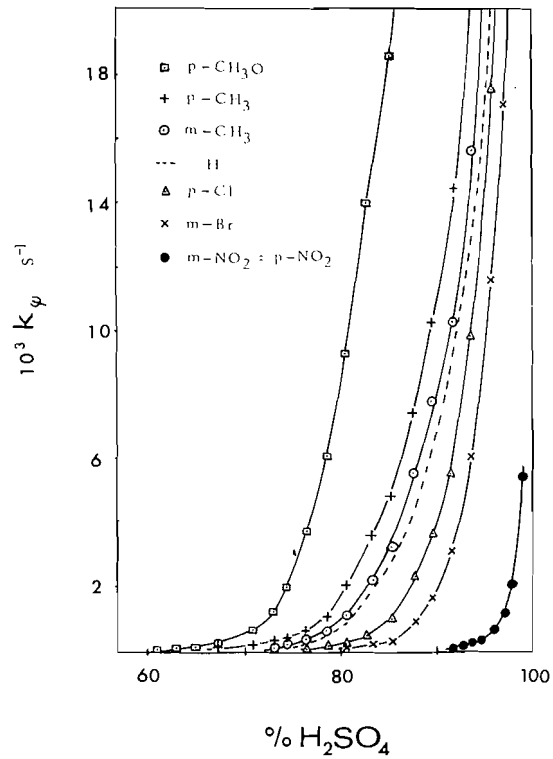

FIG. 2. Rate–acidity profiles for hydrolysis of substituted ethyl thiolbenzoates.

For personal use only.

sults is in line with the reluctance of the sulfur atom to form 3π–2π bonds.

Ethyl *p*-methyl- and *p*-methoxythiolbenzoate hydrolyzed too rapidly for their pK_{SH^+} values to be determined by the conventional spectrophotometric procedure; the values shown in Table 1 were calculated by the $\rho\sigma^+$ relation.

Rate Profiles

The rate–acidity profiles of the seven substituted ethyl thionbenzoates, shown in Fig. 1, all have a single maximum.[2] The positions of maxima confirm the relative basicities of the thion esters (3): the stronger the electron-withdrawing ability of the substituent and the less basic the thion ester, the higher the acidity at which the rate maximum occurs. These profiles are characteristic of $A_{Ac}2$ reactions (6).

The pseudo-first-order hydrolysis rates of the seven substituted ethyl thiolbenzoates are shown in Fig. 2. They all increase sharply with concentration of acid. The fact that electron-withdrawing substituents decrease the rate of hydrolysis and electron-releasing substituents increase it indicates an $A_{Ac}1$ rather than an $A_{Al}1$ mechanism (14).

Quantitative Treatments

Application of the Yates–McClelland treatment (6) to the data for the seven substituted thionbenzoates of Table 2, using pK_{SH^+} and h_T values in the literature (2, 3),[3] gave *r* parameters close to 2. This is the value expected for hydrolysis by the $A_{Ac}2$ mechanism (6).

The intercepts of the Yates–McClelland plots give log k_2 (Scheme 2) for the hydrolysis of the protonated thion esters in pure water. These values, given in Table 2, are considerably greater than those for carboxylate esters (15), in agreement with the generally high reactivity of the thiocarbonyl group (16). A good linear relationship exists between log k_2 values and σ^+ (correlation coefficient 0.996), with a slope of +1.49, about the same as ρ for the similar step in the $A_{Ac}2$ hydrolysis of benzamides (17), and providing further support for an $A_{Ac}2$ mechanism.

Application of the Yates–McClelland treatment to the kinetic data for the thiolbenzoates, using the pK_{SH^+} and *m* values of Table 1[4] gave negative *r* values (Table 3), indicative of an A-1 mechanism. Similarly, the Bunnett–Olsen treatment (7) gave

[2]Ethyl *p*-nitrothionbenzoate shows a rate increase and a departure from pseudo-first-order kinetics in acid concentrations below 62%. We cannot explain this anomalous behaviour.

[3]Application of the Bunnett–Olsen treatment (7) to the same data gave curved plots.

[4]These values were determined at 10°C, although kinetic data refer to 25°C; however, it seems likely that this will not affect results significantly (6).

TABLE 2. Correlation of A-2 rates with acidity for substituted thionbenzoates

Substituent	*r* value	log k_2
p-CH_3O	1.91	−0.06

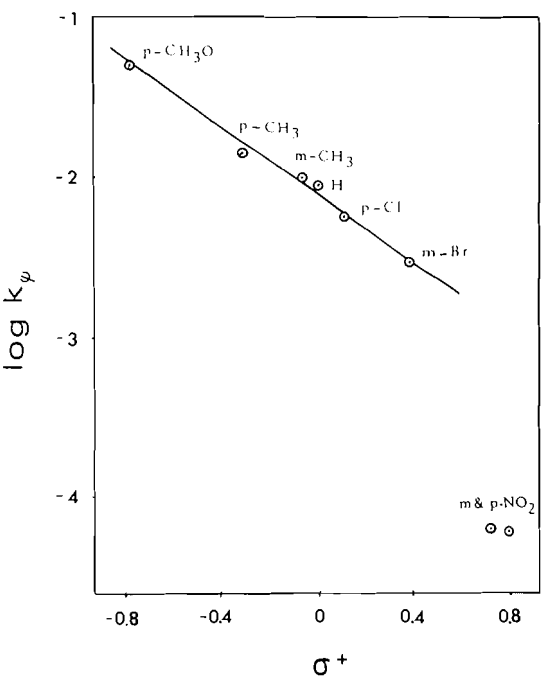

FIG. 3. Correlation of pseudo-first-order rate with σ^+ for some ethyl thiolbenzoates in 91.6% sulfuric acid.

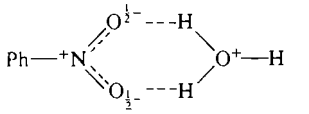
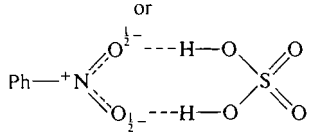
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

negative ϕ values (Table 3), again suggesting an A-1 mechanism.

The mode of fission in these hydrolyses is thus established as A-1 but the r and ϕ parameters are equally compatible with an $A_{Ac}1$ and an $A_{Al}1$ mechanism. However, the latter can be rejected, because thioacids are not found as intermediate hydrolysis products (cf. ref. 1); it is also incompatible with the $\rho\sigma$ relation. This was tested in 91.6% acid, the only acid concentration in which the rates of hydrolysis of all seven thiolbenzoates are neither too fast nor too slow to be measured conveniently. The pseudo-first-order rate constants correlate quite well with the σ^+ values of the substituents, as shown in Fig. 3. The slope ρ is -1.04 (correlation coefficient 0.994) if the nitro compounds are excluded. The rate constants for the nitro compounds can be accommodated only if very much enhanced σ^+ values are attributed to the nitro substituents in 91.6% sulfuric acid. This would seem reasonable: many years ago Hammett and Chapman (18) showed that the solubility of nitrobenzene changed very little with sulfuric acid concentration up to 80% but increased very sharply above 80% acid. This indicated the onset of some interaction, perhaps formation of complexes such as



or



Such complexation would increase the electron-withdrawing ability, and hence σ^+, of the *m*- and *p*-nitro groups in sulfuric acid above 80% in concentration.[5]

The ρ value of -1.04 for the reaction in 91.6% acid is the sum of ρ values for three individual steps:

$$\rho = \rho_1 + \rho_2 + \rho_3$$

where ρ_1 refers to the ionization of the *O*-protonated ester, ρ_2 to that of the *S*-protonated ester (in the reverse direction), and ρ_3 to the rate-determining *S*-acyl fission (see Scheme 1). We have shown above that $\rho_1 = +1.58$. The *S*-protonated ester has a localized charge separated from the benzene ring by one carbon atom and so its protonation may be expected to have $\rho_2 \simeq -0.7$, like the protonation of substituted benzylamines (19). ρ_3 would then be about -1.9. This value has the correct sign but is considerably smaller than the value for rates of formation of cumyl carbonium ion (20); perhaps because delocalization of the charge from carbon to the carbonyl oxygen is much more effective than delocalization towards the aromatic ring.

For the hydrolysis of ethyl *p*-methoxythiolbenzoate in sulfuric acid concentrations below 63%, and of the *p*-methyl and *m*-methyl compounds below 67 and 73%, respectively, r and ϕ values become positive, indicative of a switchover to an A-2 mechanism in dilute acid.

[5]A referee has pointed out that although this explanation is plausible qualitatively, the σ^+ values required by Fig. 3 for the protonated *m*- and *p*-nitro groups seem impossibly large; it is possible that because of experimental errors the straight line of Fig. 3 is sloping less steeply than it should.

The hydrolysis of thioacetic, thiobenzoic, and three substituted thiobenzoic acids in perchloric and sulfuric acids

JOHN T. EDWARD, GRAEME WELCH, and SIN CHEONG WONG
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received October 12, 1977

JOHN T. EDWARD, GRAEME WELCH, and SIN CHEONG WONG. Can. J. Chem. **56**, 935 (1978).

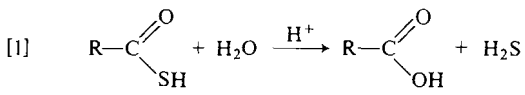
The rates of hydrolysis of thioacetic, thiobenzoic, and three substituted thiobenzoic acids increase with concentration of solvent sulfuric or perchloric acid to a maximum in 30–40% acid and then decrease. Yates–McClelland *r*, Bunnett–Olsen ϕ, and Hammett ρ parameters, and entropies of activation indicate an $A_{Ac}2$ mechanism over this range of acid concentrations. In acid concentrations above 50–60% the rates increase sharply and the same mechanistic criteria now indicate an $A_{Ac}1$ mechanism. The difference between the rate–acidity profile of thiobenzoic acid and that of ethyl thiolbenzoate can be explained by the different response of the activity coefficients of their transition states to increase in sulfuric acid concentration.

JOHN T. EDWARD, GRAEME WELCH et SIN CHEONG WONG. Can. J. Chem. **56**, 935 (1978).

Les vitesses d'hydrolyse d'acides thioacétiques, thiobenzoïques et de trois acides thiobenzoïques substitués augmentent avec la concentration des acides sulfuriques ou perchloriques agissant comme solvant jusqu'à un maximum de 30–40% d'acide; à partir de ces valeurs, les vitesses diminuent. Les paramètres *r* de Yates–McClelland, ϕ de Bunnett–Olsen et ρ de Hammett ainsi que les entropies d'activation suggèrent l'existence d'une mécanisme $A_{Ac}2$ à toutes les concentrations d'acide indiquées dans cet intervalle. A des concentrations d'acide au dessus de 50–60%, les vitesses augmentent rapidement et les mêmes critères mécanistiques indiquent maintenant la présence d'un mécanisme $A_{Ac}1$. On peut expliquer la différence entre le profil de vitesse–acidité de l'acide thiobenzoïque et celui du thiolbenzoate d'éthyle par des réponses différentes des coefficients d'activité de leurs états de transition à une augmentation dans la concentration de l'acide sulfurique.

[Traduit par le journal]

The hydrolysis of thiocarboxylic acids is catalyzed by acid (1).



[1]

Hipkin and Satchell (2) investigated the rates of hydrolysis of thioacetic and thiobenzoic acids in varying concentrations of hydrochloric acid, up to 4.80 *M*. The pseudo-first-order rate constants k_ψ followed $[H_3O^+]$ rather than the Hammett acidity function h_0. This was taken to indicate an A-2 rather than A-1 mechanism for the acid-catalyzed hydrolysis. However, we have recently shown that although thiol esters are hydrolyzed by an $A_{Ac}2$ mechanism in 30–60% sulfuric acid, this mechanism is superceded by a very fast $A_{Ac}1$ reaction in higher acid concentrations (3, 4). Consequently, it became of interest to investigate the acid-catalyzed hydrolysis of the thio acids over a wider range of acid concentrations. In this paper we report kinetic studies of the hydrolysis of thioacetic acid, thiobenzoic acid, and three substituted thiobenzoic acids in concentrations of sulfuric acid up to 80% and of perchloric acid up to 67%.

Experimental

Materials

Thioacetic and thiobenzoic acids were commercial products. *p*-Methoxy-, *p*-methyl-, and *p*-chlorothiobenzoic acids were obtained by a standard procedure (5) from the substituted benzoyl chlorides and potassium hydrosulfide. The thioacids were freshly distilled before each kinetic run; titration against standard alkali then indicated them to be approximately 99.9% pure. (On standing several days the titre dropped, presumably because of oxidation to the disulfide.)

Mineral acid solutions were prepared by dilution of reagent grade perchloric acid (70%) or sulfuric acid (96%) with distilled water and their concentrations determined by titration against standard alkali to phenolphthalein end point.

Kinetics

All measurements were made with a Unicam SP 800 uv spectrophotometer having a thermostatted cell compartment. The change in absorbance (A) due to hydrolysis of thiobenzoic acid and thioacetic acid was recorded at 260 and 225 nm, respectively, following procedures described already (3). Pseudo-first-order rate constants k_ψ were calculated from a computer least-squares treatment of log $(A - A_\infty)$ against time. Reproducibility of independent measurements was usually better than $\pm 2\%$, except for the very rapid rates at high acid concentrations. Results at 50.0°C are displayed in Figs. 1 and 2.[1]

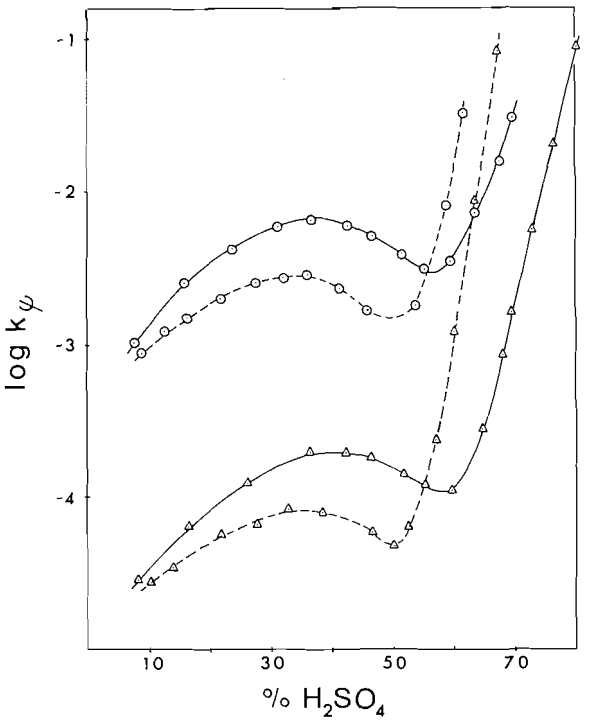

FIG. 1. Rates of hydrolysis of thioacetic acid (⊙) and thiobenzoic acid (△) in varying concentrations of sulfuric (—) and perchloric (---) acids at 50°C.

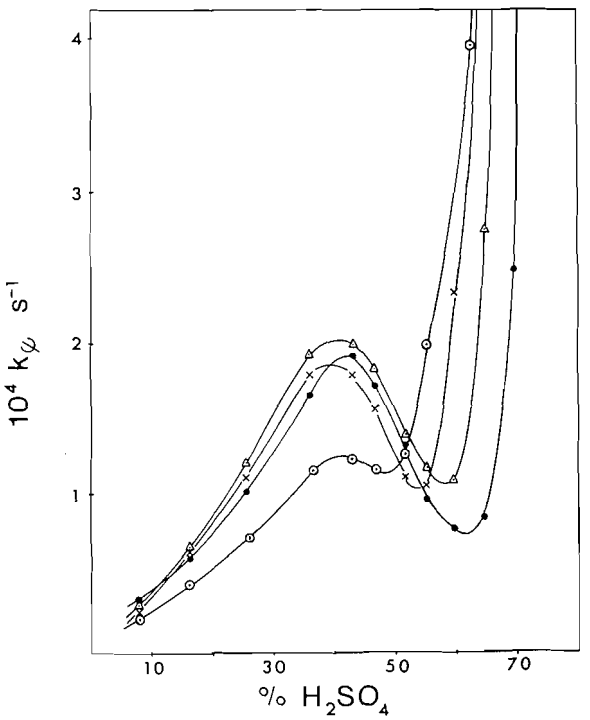

FIG. 2. Rates of hydrolysis in varying concentrations of sulfuric acid of thiobenzoic acid (△) and of *p*-methoxy (⊙), *p*-methyl (×), and *p*-chloro (●) substituted thiobenzoic acids at 50°C.

Protonation Constants of Thiobenzoic Acid and p-Thiotoluic Acid

Because of rapid hydrolysis at high acid concentrations, the protonation constant K_{SH^+} of thiobenzoic acid could not be determined at 25°C, and was determined instead at 10.0°C. Extinction coefficients of the compound in various concentrations of sulfuric acid were obtained by following the change in its absorbance with time at 325 nm (λ_{max} of the protonated thiobenzoic acid) and extrapolating to zero time. Ionization ratios[1] were then calculated according to Hammett's procedure (6) and a pK_{SH^+} value of −6.18 ($m = 0.74$) was obtained by the Yates–McClelland equation (7):

$$[2] \qquad \log\frac{[SH^+]}{[S]} = -mH_0 + pK_{SH^+}$$

and of −6.35 ($\phi = 0.28$) by the Bunnett–Olsen equation (8):

$$[3] \quad \log\frac{[SH^+]}{[S]} + H_0 = \phi(H_0 + \log[H^+]) + pK_{SH^+}$$

Application of the same treatments to data for *p*-thiotoluic acid determined at 5.0°C gave pK_{SH^+} values −6.01 ($m = 0.75$) and −6.21 ($\phi = 0.27$). These values of m and ϕ are close to those found previously for ethyl thiolbenzoate at 10°C (3).

Attempts to measure pK_{SH^+} of thioacetic acid were thwarted by its very fast rates of hydrolysis, even at 0°C.

Results and Discussion

Rate Profiles

The rate profiles shown in Figs. 1[2] and 2 are qualitatively similar to those found for the hydrolysis of ethyl thiolbenzoate in sulfuric acid (3), and indicate an A-2 reaction mechanism in acid concentrations up to 50–60%, where the rate minimum is reached, superceded by an A-1 mechanism in higher acid concentrations, where the rates increase sharply. However, they differ from the profile of the ester in having the rate maxima at lower acid concentrations, and hence better separated from the steep slopes of the A-1 reactions. The reasons for this difference are discussed later.

Catalytic Power of H_2SO_4 vs. $HClO_4$

For the A-2 region, the thioacids are hydrolyzed more rapidly in sulfuric acid than in perchloric acid, whereas the reverse is true for the A-1 region. This agrees with findings of Bunton *et al.* (10) in other hydrolyses that the catalytic order of the two acids is $HClO_4 > H_2SO_4$ for an A-1 mechanism and $H_2SO_4 > HClO_4$ for an A-2 mechanism. These authors attributed the difference in rate to the differing charge densities on bisulfate and perchlorate ions, resulting in differing abilities to stabilize the transition states of A-1 and A-2 hydrolyses.

In perchloric acid or sulfuric acid below 50% in concentration, protonation abilities (11) and water

[2]The data for thioacetic acid in perchloric acid are taken from the thesis of G.D. Derdall (9).

TABLE 1. Activation parameters for the hydrolysis of thioacetic acid (A) and thiobenzoic acid (B)

Substrate	Medium	$\Delta H^{\ddagger}$ (kcal)	$\Delta S^{\ddagger}$ (eu)
A	22.1% $HClO_4$	+17	−18
A	36.5% H_2SO_4	+16	−20
B	36.9% $HClO_4$	+19	−19
B	36.5% H_2SO_4	+17	−23
A	61.7% $HClO_4$	+21	−2
A	68.1% H_2SO_4	+20	−4
B	60.2% $HClO_4$	+26	+8
B	68.1% H_2SO_4	+24	+1

activities (12) of equal (weight percent) concentration of the two acids are about equal, and the hypothesis of Bunton *et al.* (10) seems plausible. However, in more concentrated solutions protonation abilities and water activities of perchloric and sulfuric acids diverge (13) and these differences also may be important in determining relative rates of hydrolysis. These effects are taken up later.

Activation Parameters $\Delta H^{\ddagger}$ *and* $\Delta S^{\ddagger}$

The A-2 and A-1 mechanistic classification is also supported by activation parameters listed in Table 1.[1] In all cases, log k_{ψ} was found to be linear with respect to $1/T$, and $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were calculated in the usual way.[3] The large negative values of $\Delta S^{\ddagger}$ found for the hydrolysis of thioacetic and thiobenzoic acids in the more dilute mineral acids are characteristic of A-2 reactions and the small positive or negative values found for the hydrolysis in more concentrated acids are characteristic of A-1 reactions (14).

Rate–Acidity Correlations

Both the Bunnett–Olsen ϕ (8) and the Yates–McClelland r treatments (7) were applied to the thiobenzoic and *p*-thiotoluic acid hydrolysis data, by plotting log k_{ψ} − log $[SH^+]/([SH^+] + [S])$ against H_0 + log $[H^+]$ and against log a_{H_2O}, respectively. The H_0 (15) and a_{H_2O} (16) data for sulfuric acid at 50°C were available and $[H^+]$ was equated with stoichiometric acid concentration (8). The ratio $[SH^+]/([SH^+] + [S])$ was calculated from ionization data measured at 10 or 5°C without correcting for temperature change.[4]

The H_0 and a_{H_2O} data for perchloric acid are not available at 50°C and data at 25°C (11–13) were used. Furthermore, because of the lack of sufficiently

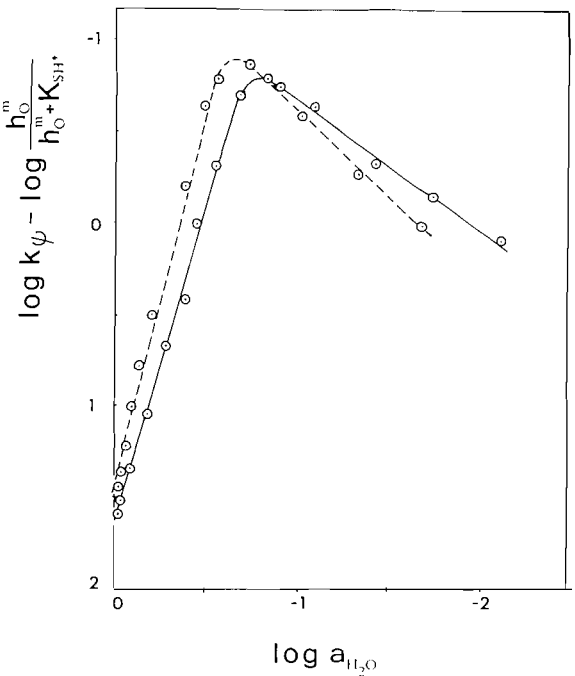

FIG. 3. Yates–McClelland plots for the hydrolysis of thiobenzoic acid in sulfuric (—) and perchloric (---) acids.

concentrated perchloric acid solutions, the pK_{SH^+} of thiobenzoic acid could not be determined in this acid. It was therefore necessary to adopt the pK_{SH^+} determined in sulfuric acid. These approximations should make the slopes r and ϕ of the correlation plots, shown in Figs. 3 and 4, slightly less reliable than those obtained with sulfuric acid solutions.

The r and ϕ values thus obtained from these and other plots are listed in Table 2, and give further support for the classification of the mechanisms as A-2 in more dilute and A-1 in more concentrated acid. However, it should be noted that the r and ϕ values are considerably greater than those found for carboxylate (7) and thiocarboxylate esters (3). We attempt to explain this later.

Hammett $\rho\sigma$ *Relation*

The number of *m*- and *p*-substituted thiobenzoic acids was less than usually considered proper for a Hammett $\rho\sigma$ study (although Dewar (17) has argued forcefully against this view) but qualitatively the evidence is very clear. In 36% sulfuric acid $\rho \simeq 0$, as expected for an A-2 mechanism which involves a preequilibrium protonation (18); in 64.7% sulfuric acid, $\rho \simeq -2$ having the correct sign for an A-1 reaction ($\rho = -1.04$ for the A-1 hydrolysis of ethyl thiolbenzoates in 91.6% sulfuric acid (4); $\rho = -3.21$ for the A-1 hydrolysis of methyl benzoates in 99.9% sulfuric acid (19)).

[3]The rate-determining step in acid hydrolysis is always preceded by a preequilibrium protonation step. The activation parameters are therefore composite of the 'true' activation parameters and a contribution from the preequilibrium protonation. They nevertheless serve as useful empirical parameters to distinguish A-2 reactions from A-1 reactions (14).

[4]Yates and McClelland (7) showed that this would not affect results significantly.

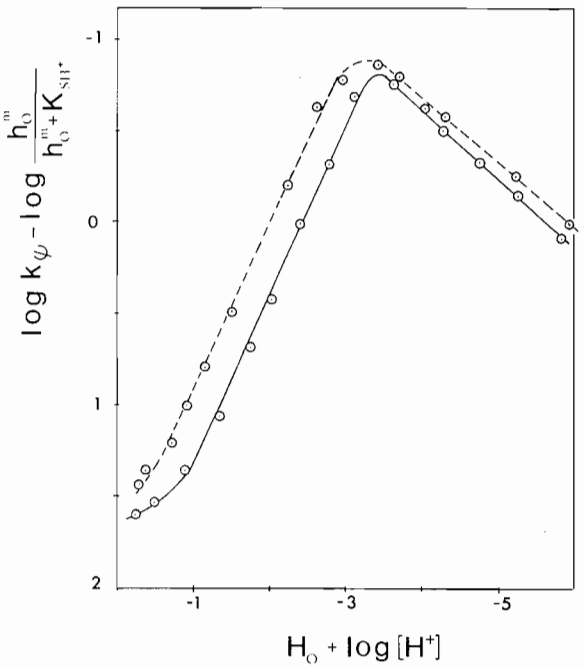

FIG. 4. Bunnett–Olsen plots for the hydrolysis of thiobenzoic acid in sulfuric (—) and perchloric (---) acids.

TABLE 2. Yates–McClelland r and Bunnett–Olsen ϕ parameters for hydrolyses at 50°C

Substrate	Medium	r	ϕ
Thiobenzoic acid	H_2SO_4 0–65%	3.46	0.95
	H_2SO_4 65–85%	−0.69	−0.39
p-Thiotoluic acid	H_2SO_4 0–55%	3.59	0.99
	H_2SO_4 60–75%	−1.13	−0.52
Thiobenzoic acid	$HClO_4$ 0–50%	4.09	0.94
	$HClO_4$ 55–67%	−0.94	−0.35

Differing r *Values for the A-2 Hydrolysis of Thiobenzoic Acid and Ethyl Thiolbenzoate*

We can now address ourselves to the attempt to understand some of the differences pointed out above.

If the A-2 hydrolysis of the thio acid and ester follows the mechanism:

[4] $$S + H^+ \underset{\text{fast}}{\overset{K_{SH^+}}{\rightleftharpoons}} SH^+$$

[5] $$SH^+ + pH_2O \xrightarrow[\text{slow}]{k_2} S^{\ddagger} \rightarrow \text{Products}$$

the Brønsted–Bjerrum rate expression yields

[6] $$\log k_\psi = \log k_2 + \log [SH^+]/([S] + [SH^+]) + p \log a_{H_2O} + \log f_{SH^+} - \log f_{S^\ddagger}$$

where a represents activity and f activity coefficient.

Following an earlier treatment of Bunnett (20), Yates and McClelland (7) assumed $f_{SH^+} \simeq f_{S^\ddagger}$ in all concentrations of mineral acid. This leads to p, the number of molecules of water[5] reacting with SH^+ to give the transition state $S^\ddagger$, being equal to r, the slope of the plot of log k_ψ − log $[SH^+]/([S] + [SH^+])$ against log a_{H_2O}. For the hydrolysis of two such similar compounds as thiobenzoic acid and ethyl thiolbenzate, it is reasonable to expect p values to be identical; in fact, the r values (~4 and ~2) are very different. This suggests that r is made up not only of p but of a factor q measuring the dependence of log $f_{SH^+}/f_{S^\ddagger}$ on the activity of water (and hence the sulfuric acid concentration)

If we assume $p = 1$, the structures of the ionic species in [5] can be represented as follows:

[7] 
The transition state $S^\ddagger$ has a positive charge largely localized on the oxygen of the attacking water molecule (δ+ ≫ δδ+ (21)), and so will be highly stabilized by hydration. Furthermore, in water, the hydration of $S^\ddagger$ (R = H) can be expected to be considerably greater than that of $S^\ddagger$ (R = Et).[6] As the water activity of the sulfuric acid solution goes down with rising acid concentration, $f_{S^\ddagger}$ of both species will increase but that of $S^\ddagger$ (R = H) more rapidly than that of $S^\ddagger$ (R = Et). On the other hand, the charge on the ions SH^+ (R = H and Et) is more delocalized, so that the hydration of these ions in water should be less extensive, and the increase in f_{SH^+} with rising acid concentration should be much less marked (21, 23). Consequently, the difference between f_{SH^+} for the protonated thio acid and ester will not be important. On these grounds, the greater r parameter for the hydrolysis of thiobenzoic acid arises mainly because $f_{S^\ddagger}$ for this reaction increases more rapidly with sulfuric acid concentration than does $f_{S^\ddagger}$ for the hydrolysis of ethyl thiolbenzoate.[7]

[5]This is the number of molecules of water forming or rupturing covalent bonds in the formation of $S^\ddagger$; there may be additional molecules of water involved in the hydration changes of [5] but these are accounted for in f_{SH^+} and $f_{S^\ddagger}$.

[6]For an example of decreased hydration caused by alkyl substitution fairly remote from the charged centre of an ion, see ref. 22.

[7]The change in $f_{S^\ddagger}$* for the hydrolysis of ethyl thiolbenzoate in rising concentrations of sulfuric acid has been reported (3); an attempt to measure in comparable fashion the change in $f_{S^\ddagger}$* for the hydrolysis of thiobenzoic acid (cf. ref. 21) was abortive because of experimental difficulties in determining the change in $f_{S^\ddagger}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

While the decrease in a_{H_2O} with rising concentration of H_2SO_4 or $HClO_4$ is probably the dominant factor in changing f_{SH^+} and $f_{S^\ddagger}$ (21, 23) another factor undoubtedly is the increase in concentration of HSO_4^- and ClO_4^- (10). The more localized charge of HSO_4^- would be expected to make it more effective than ClO_4^- in stabilizing cations, particularly $S^\ddagger$, and hence in reducing $f_{S^\ddagger}$ as the mineral acid concentration goes up. This would account for the greater effectiveness of sulfuric acid as a hydrolyzing agent in acid concentrations below 50% (see Fig. 1), in spite of the fact that at any given concentration below 50% its h_0 and a_{H_2O} values are almost identical with those of perchloric acid.

Different Rate Profiles for the Hydrolysis of Thiobenzoic Acid and Ethyl Thiolbenzoate

Examining [6], we can see that the pseudo-first-order rate constant k_ψ for the hydrolysis of the thioacid or thiol ester will at first increase with rising sulfuric acid concentration, because the increase in the fraction of the substrate protonated ($[SH^+]/([S] + [SH^+])$) and the increase in f_{SH^+} are more important than the drop in a_{H_2O} and the increase in $f_{S^\ddagger}$. However, beyond the maximum the sum of the first two factors becomes less important than the sum of the second two: at a maximum, the two sums are in balance. For a series of related compounds, such as the substituted thiobenzoic acids, the change in f_{SH^+} and $f_{S^\ddagger}$ with sulfuric acid concentration should be about the same, and so the position of the maximum will be determined by the fraction protonated, and hence by the basicity of the substrate S (cf. ref. 24). It can be seen from Fig. 2 that this is the case for the substituted thiobenzoic acids.

On the other hand, the maximum in the rate of the A-2 hydrolysis of thiobenzoic acid occurs in about 40% sulfuric acid and that of the hydrolysis of ethyl thiolbenzoate in about 50% sulfuric acid (where it tends to merge into the rising curve for the A-1 reaction in concentrations above 60%), in spite of the fact that ethyl thiolbenzoate is more basic (3). Evidently the much greater rise in $f_{S^\ddagger}$ of the thioacid as the sulfuric acid concentration rises is more important than the change in fraction protonated in causing k_ψ to reach a maximum.

Difference in the Effectiveness of Sulfuric and Perchloric Acid in the A-1 Hydrolysis of Thioacids

We may now consider why perchloric acid is more effective than sulfuric in hydrolyzing a thio acid by an A-1 mechanism although it is less effective in hydrolyzing it by an A-2 mechanism (Fig. 1).

In concentrations of mineral acid above 60% the major part of the thio acid exists in the *O*-protonated form SH^+; the A-1 reaction requires the formation in minute amounts of the *S*-protonated tautomer TH^+:

[8] $$R{-}C(=OH)(^+SH) \underset{\text{fast}}{\overset{K_{SH^+}}{\rightleftharpoons}} R{-}C(=O){-}SH + H^+$$

(SH^+)

$$R{-}C(=O){-}SH \overset{\text{fast}}{\underset{}{\overset{K_{TH^+}}{\rightleftharpoons}}} R{-}C(=O){-}{}^+SH_2$$

(TH^+)

[9] $$R{-}C(=O){-}{}^+SH_2 \xrightarrow[\text{slow}]{k_1} R{-}C(=O^{\delta+}){\cdots}{}^{\delta\delta+}SH_2 \longrightarrow \text{Products}$$

(TH^+) ($T^\ddagger$)

If the protonation of S to SH^+ is governed by an acidity function h_0^m (7), and the protonation of T to TH^+ by h_0^n, where $n > m$ (25), and if we take account of the fact that the concentration of TH^+ is negligible in comparison with that of SH^+, the Brønsted–Bjerrum equation for the mechanism [8], [9] becomes:

[10] $$k_\psi = \frac{k_1 h_0^{n-m} K_{SH^+} f_{TH^+}}{K_{TH^+} f_{T^\ddagger}}$$

The behaviour of f_{TH^+} and $f_{T^\ddagger}$ with rising concentration of sulfuric or perchloric acid is the inverse of that described above for f_{SH^+} and $f_{S^\ddagger}$: now TH^+ has a concentrated charge and $T^\ddagger$ a delocalized charge. Consequently, the effect of increasing mineral acid concentration (and consequent decreasing a_{H_2O}) is to raise f_{TH^+} greatly, and $f_{T^\ddagger}$ rather little. Hence k_ψ increases with increase in concentration of mineral acid because of the increase both in h_0^{n-m} and in $(f_{TH^+}/f_{T^\ddagger})$. Furthermore, in concentrations above 50%, perchloric should be more effective than sulfuric acid because (*i*) it has a higher h_0 (11); (*ii*) it has a lower a_{H_2O} (13), which should lead to a higher f_{TH^+}; and (*iii*) the more diffuse perchlorate ion should be less effective than bisulfate ion in lowering f_{TH^+}. The total effect is about one order of magnitude (Fig. 1) but it is impossible to say how the different factors *i*, *ii*, and *iii* contribute to this effect.

KENNETH J. MINTZ and DONALD J. LE ROY. Can. J. Chem. **56**, 941 (1978).

The primary reaction in sodium diffusion flames, Na + RX = NaX + R, has been investigated as a possible source of free radicals for kinetic studies. A number of different alkyl halides were investigated as possible radical sources. Optimum conditions were found to minimize wall reactions and hydrogen abstraction from the halide, the two factors which invalidated previous work using this method. Rate constants were derived from product analyses by the numerical solution of simultaneous non-linear differential equations based on a spherical model involving diffusion. Values were obtained for the two modes of decomposition of n-C_3H_7, the abstraction of primary and secondary H atoms from C_3H_8 by CH_3, and the addition of CH_3 to C_2H_4. These are in reasonably good agreement with values determined by more conventional methods.

KENNETH J. MINTZ et DONALD J. LE ROY. Can J. Chem. **56**, 941 (1978).

On a étudié la réaction primaire dans les flammes de diffusion du sodium, Na + RX = NaX + R, comme source possible de radicaux libres pour des études cinétiques. On a examiné un certain nombre d'halogénures d'alkyle différents comme sources possibles de radicaux. On a déterminé les conditions optimales pour minimiser les réactions de paroi et d'enlèvement d'hydrogène à partir des halogénures, deux facteurs qui avaient invalidés les travaux antérieurs faisant appel à cette méthode. On a évalué les constantes de vitesse en faisant appel à des analyses de produits par une solution numérique d'équations différentielles non-linéaires simultanées basées sur un modèle sphérique impliquant de la diffusion. On a obtenu des valeurs pour les deux modes de décomposition de n-C_3H_7, l'enlèvement d'atomes d'hydrogène primaires et secondaires à partir de C_3H_8 par CH_3 et l'addition de CH_3 sur C_2H_4. Ces résultats sont en bon accord avec les valeurs déterminées par des méthodes conventionnelles.

Introduction

In a previous paper (1), the primary reaction occurring in sodium diffusion flames, viz., Na + RX → NaX + R, was investigated both experimentally and theoretically. The present paper is concerned with the reactions of the radicals produced and thus with the possibility of using this method of preparation for determining rate constants of radical reactions. Although this method has been used several times in the past (2–8), the results obtained have generally been in serious disagreement with those obtained by other methods.

Theoretical

The theoretical model used in treating the primary process and the calculation of the spatial distributions of the two reactants, Na and RX, have been discussed previously (1). In order to examine the spatial distribution of primary radicals we consider the case of methyl radicals formed by the reaction of sodium with methyl bromide. Assuming that the only means of mass transport is by diffusion, and that the only reaction of CH_3 is combination, then the equation of mass continuity of CH_3 is

$$[\mathrm{i}]\quad d^2[CH_3]/dr^2 + (2/r)d[CH_3]/dr + (k_1/D_R) \times [Na][CH_3Br] - (2k_2/D_R)[CH_3]^2 = 0$$

where r is the radial distance from the nozzle, D_R is the diffusion coefficient of CH_3, k_1 is the rate constant of the primary reaction, and k_2 is the rate constant for methyl radical combination. Since there does not appear to be a closed-form solution of eq. [i], it was solved numerically by the boundary-value finite-difference method (9) utilizing an optimized variable step-size (10). The boundary conditions employed were $[CH_3] = 0$ at both the "effective nozzle radius" (1) and at the walls of the reactor. The latter implies that reaction on the walls is sufficiently fast that $[CH_3]$ in the gas phase next to the walls is depleted to near zero. The values of k_1 and k_2 used were $10^{14} \exp(-2 \times 10^3/RT)$ (1) and $2.4 \pm 0.2 \times 10^{13}$ (11–13) $cm^3\ mol^{-1}\ s^{-1}$, respectively. The diffusion coefficients were calculated as before (1), using a Lennard–Jones parameter σ for CH_3 of 3.50 Å (14).

In Fig. 1 are shown the calculated radial and

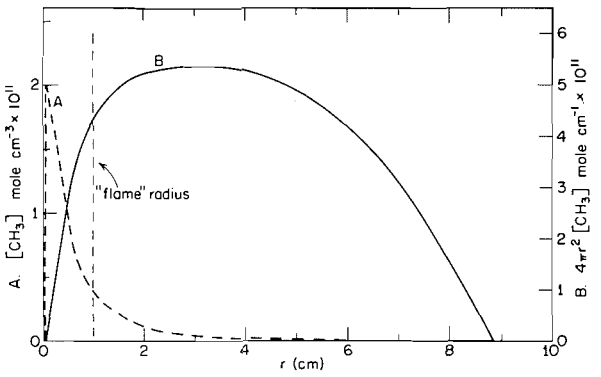

FIG. 1. Calculated radial (*A*) and spherical (*B*) distributions of CH_3 in the reaction Na + CH_3Br = NaBr + CH_3 when CH_3 is removed by combination only, assuming temperature of 300°C, spherical reactor of 8.9 cm radius, 4 Torr of N_2 as carrier gas, initial Na concentration of 4.2×10^{-10} mol cm^{-3}, flame radius of 1.0 cm.

spherical distributions for $[CH_3]$ for typical operating conditions: 300°C, 4 Torr total pressure, 100% saturation of the carrier gas (N_2) with sodium vapour, and a flame radius of 1 cm. The reactor was assumed to have a radius of 8.9 cm. Although the radial distribution peaks well inside the visible flame region, the spherical distribution peaks well beyond it. In the steady state the number of moles of CH_3 in the reactor is given by the area under curve *B*, in this example 3.5×10^{-10} mol. In Fig. 2 the spherical rate of formation of CH_3 is contrasted with its rate of combination. While both curves peak well within the flame radius, the latter goes to zero much less rapidly. The area under curve *A* is equal to the flow rate of sodium into the reactor, in this example 2.3×10^{-8} mol s^{-1}. If all of the methyl radicals produced combined before reaching the wall the area under curve *B* should be equal to that under curve *A*. Actually, it is always found to be less, in this example 1.7×10^{-8} mol s^{-1}. The reason for this is that the radical concentration far from the flame becomes so small that the probability of bimolecular combination is very small relative to diffusion to the walls. Hence, the assumption that all radicals combine before reaching the walls is invalid.

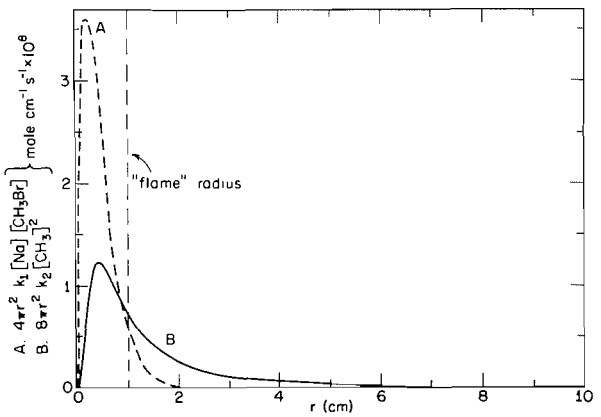

FIG. 2. Rates of formation (*A*) and combination (*B*) of CH_3 under same conditions as in Fig. 1.

Calculations were done for a number of model experimental conditions in order to determine how to minimize the number of radicals reaching the wall. Increasing the total pressure by increasing the partial pressure of carrier gas has the greatest effect, since D_R is approximately inversely proportional to the pressure. However, the use of higher pressure has two drawbacks: (*1*) the system takes a very long time to reach a steady state; (*2*) the yield of products is inversely proportional to the pressure of carrier gas. Another means of decreasing the fraction of radicals reaching the wall would be to utilize a higher molecular weight carrier gas. Nitrogen was taken to be the carrier gas in calculating the distributions shown in Figs. 1 and 2; it was also used in some of the preliminary experiments. However, helium was used in many of the experiments described in this paper because of the ease of separating it from the methane formed. Calculations showed that the pressure of helium required for a certain fraction of radicals to reach the wall was approximately four times as large as that for nitrogen. Increasing the flow rate of sodium into the reactor by increasing the temperature of the saturator decreases the fraction to some extent. However, since the reactor must be at a temperature at least as high as the saturator to prevent condensation of sodium vapour, the rate of thermal decomposition of molecular reactants will also increase. The fraction of radicals reaching the wall was found to be a strong function of reactor size. Under the typical conditions specified above it was calculated to be 46% for a reactor of 3 cm radius, compared to 25% for one of radius 8.9 cm. The former was the size commonly used by previous workers. Increasing the radius to 50 cm only decreases the fraction to 15%. A disadvantage of using very large reactors is that the observer must be farther away from the flame, and thus his detection limit (1), corresponding to the edge of the flame, is increased. Thus, not much advantage could be achieved by using reactors larger than, say, 10 cm in radius.

The reactor used in the present experiments (1) was actually a cylinder of diameter 17.8 cm and length 26.4 cm. The spherical assumption is therefore not strictly valid. The calculated methyl radical concentration far from the walls is not greatly affected by variation of the radius of the reactor, other parameters being kept constant. Hence, under most conditions (viz., when gas-phase reaction is pre-

For personal use only.

dominant) it suffices to bracket a rate constant calculated from the experimental data between the value assuming a radius of 8.9 cm and the value assuming a radius of 13.2 cm.

The calculation of the effect of varying the flame radius on the fraction of radicals reaching the walls indicated that the optimum value is about 0.5 to 1.0 cm, depending on the other parameters. This is the result of two counteracting factors which come into play as the flame radius is increased: (*1*) because they are produced, on the average, farther from the nozzle, the methyl radicals have less time to react before reaching the walls; (*2*) as the methyl radical concentration is increased the rate of combination also increases. As a result, the methyl radical concentration distribution is not very dependent on the sodium concentration distribution. This actually has the advantage that any uncertainty in the measurement of the flame radius has relatively little effect on the $[CH_3]$ distribution.

In summary, high total pressure and high saturator temperature at the optimum flame radius are the conditions required to minimize the number of methyl radicals reaching the wall for a particular reactor and carrier gas. However, use of the maximum practical values of pressure and temperature still results in about 6% of the radicals reaching the wall. This inability to achieve exclusively gas-phase reaction of radicals must be considered as a distinct liability of the sodium diffusion flame method of studying the reactions of primary radicals. It should be emphasized, however, that in the above theoretical treatment the only gas-phase secondary reaction considered was bimolecular combination. If the primary radicals also undergo reaction with another reactant the fraction reaching the wall could be reduced. Such reactions will be considered later in this paper.

Experimental

The apparatus was the same as that described and illustrated previously (1). After the system had been thoroughly evacuated the sodium saturator was heated about 20°C above the desired working temperature for 2 h before final adjustment. The carrier gas was then allowed to flow through the saturator and reactor. With the sodium lamp *on*, the flow rate of the halide was adjusted until a 'flame' of the desired diameter was achieved. The system was then maintained at constant conditions for 2 h before trapping out any products. Non-volatile materials were then trapped over a period of 2 to 3 h. When helium was used as the carrier gas two traps were used, both at liquid nitrogen temperature. The first was empty, and collected everything but helium, methane, and some of the ethylene; the second one was filled with Linde 5A molecular sieve and collected methane and the remaining ethylene. When nitrogen was used as the carrier gas only the first trap was used but it was maintained at −210°C by means of a continuously pumped dewar; while this trapped out all of the ethylene it collected only part of the methane. Several aliquots of the product mixture (which included unreacted halide reagent) were analyzed by glc. A 6-ft column of molecular sieve type 13X (80/100 mesh) with temperature programming was used for analysis of the light hydrocarbons. A 25-ft column of 20% w/w bis-2-(2-methoxyethoxy) diethyl ether (15) on 40/60 mesh chromosorb P was used for the heavier hydrocarbons and a 10-ft column of 25% w/w tri-*m*-tolyl phosphate (16) on 60/80 mesh chromosorb P for halogenated hydrocarbons. For quantitative analysis, calibration curves were constructed for each substance using known quantities.

Experimental Results and Discussion

The purpose behind the experimental measurements was to survey the possibilities of the diffusion flame as a suitable source of radicals, rather than to make in-depth studies of particular radical reactions. In part *A* eight different alkyl halides were tested as primary radical sources per se, i.e. in the absence of any reagent other than the halide: CH_3Br, CH_3Cl, C_2H_5Br, C_2H_5I, n-C_3H_7Br, s-C_3H_7Br, t-C_4H_9Br, and t-C_4H_9Cl. In parts *B* and *C* some experiments were done using C_3H_8 and C_2H_4 as additional reagents in order to study their reactions with methyl radicals produced from CH_3Br or CH_3Cl and to derive relevant rate constants.

A. Alkyl Halides as Radical Sources

CH_3Br

The results are shown in Table 1. The only products detected by gas chromatography were CH_4, C_2H_6, C_2H_4, and C_3H_8, with the last two usually accounting for less than 1% of the total. No gaseous bromides, such as C_2H_5Br or $C_2H_4Br_2$, could be found. Qualitative evidence for HBr was obtained by treating the trapped effluent with $AgNO_3$. After several runs a small amount of a black deposit having the characteristics of amorphous carbon appeared on the end of the nozzle through which the sodium vapour entered the reactor. Carbon, as well as CH_4 and HBr, was also observed by Meisner and Schumacher (17) in their study of the thermal decomposition of CH_3Br.

Although it was not possible to devise a completely satisfactory mechanism to explain the results shown in Table 1, it would appear that the important reactions are

$$[1] \qquad CH_3Br + Na = CH_3 + NaBr$$

$$[2] \qquad 2CH_3 = C_2H_6$$

$$[3] \qquad CH_3 + CH_3Br = CH_4 + CH_2Br$$

The fate of the CH_2Br radicals is not clear. This is basically the same problem that plagued the work of Raal and Steacie (18) and Ridge and Steacie (19) and invalidated the rate constants derived by the former for the reactions of methyl radicals with methyl

bromide and methyl chloride. These workers too found no evidence of C_2H_5X. However Ridge and Steacie (19) found that C_2H_4 was comparable to C_2H_6 and that HX was also formed. We suggest that at least some of the CH_2Br formed in [3] is consumed by [4],

[4] $$CH_3 + CH_2Br = C_2H_5Br^{\dagger} = C_2H_4 + HBr$$

The occurrence of this reaction is supported by the observation (19) that the ethylene formed by the photolysis of perdeuteroacetone in the presence of CH_3Cl is $C_2H_2D_2$. However, if this were the only fate of CH_2Br then the concentrations of CH_4 and C_2H_4 should be the same, which is far from being the case.

The absence of any $C_2H_4Br_2$ is surprising, since the chlorine analog has been found as one of the products of the reaction of H atoms with CH_3Cl (20). We can only conclude that the CH_2Br concentration is maintained very much lower than that of CH_3. Consideration of the final observed products suggests that the major gaseous product formed by the reactions consuming CH_2Br would have to be CH_4, presumably through H atom abstraction. Unfortunately, kinetic data on such reactions are lacking and even the thermodynamic data are sparse. The standard heats of formation (in kcal mol^{-1} at 298 K) given for CH_3Br are −8.4 (21) and −9.1 (22); from the estimated C—H bond dissociation energy in CH_3Br (23) these give 41.5 and 40.8 for CH_2Br. The corresponding values listed for CBr are 122 ± 15 (21) and 133 (24). Thus, successive H atom abstractions from CH_2Br by CH_3 to form CBr would appear to be not unreasonable thermodynamically. If this were case the value of k_3 would be given by

[ii] $$k_3 = \tfrac{1}{3}R_f[CH_4]/\int(CH_3)(CH_3Br)d\tau$$

The values of k_3 given in Table 1 were calculated from eq. [ii] using eq. [i] to obtain the spacial distribution of CH_3. The latter equation, of course, neglects removal of CH_3 by reactions other than [2] but, in view of the uncertainty in the validity of eq. [ii], it was not considered worthwhile to use a more elaborate iterative procedure.

Insofar as obtaining a value of k_3 is concerned, the results are far from satisfactory. From the point of view of using reaction [1] as a source of CH_3 radicals for kinetic purposes it is evident that the rate of reaction [3] must be kept small relative to the rates of the reactions of CH_3 being studied.

CH_3Cl

Only one run was done with this halide and the results are included in Table 1. The rate constant of the primary reaction, analogous to [1], is considerably smaller than for CH_3Br (1) and so relatively higher temperatures and CH_3Cl concentrations have to be used. Both factors make CH_3Cl unsuitable as a source of CH_3 for kinetic studies.

C_2H_5Br

Since the disproportionation to combination ratio k_d/k_c for ethyl radicals is generally agreed to be 0.14 ± 0.01, independent of temperature (21, 22), this reaction can be used as a reference point in studying the reactions resulting from the primary reaction of sodium with ethyl bromide. The experiments fall into three groups.

In the first group of experiments a small diameter cell (6 cm) was used with N_2 as the carrier gas, a total pressure of ca. 3 Torr and a temperature of 250°C. It was estimated that under these conditions most of the radicals would have reached the walls before reacting. The ratio $R_f[C_2H_6]/R_f[C_4H_{10}]$ was found to depend on the amount of NaBr on the walls of the reaction vessel. The ratio always started off at approximately 0.1 for a clean reactor but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

increased with the number of runs made, when the NaBr was allowed to accumulate from run to run, until it levelled off at about 0.45. The final value is very close to the average value of 0.44 found by Kerr, Lissi, and Trotman-Dickenson (8). Evidently the enhancement of the disproportionation reaction arises from a heterogeneous process on NaBr surfaces, possibly due to oriented adsorption of C_2H_5 radicals.

In the second group of experiments the large diameter cell (17.8 cm) was used under otherwise similar conditions. In this case the ratio $R_f[C_2H_6]/R_f[C_4H_{10}]$ averaged approximately 0.16. Although in this case as well most of the radicals reached the walls before reacting, the extent of coverage of the walls by NaBr was much less.

The third group of experiments was done under conditions designed to ensure that most of the radicals reacted in the gas phase before reaching the walls, viz. total pressures 15 to 20 Torr, reaction cell temperature 300 to 350°C (saturator temperature slightly less). A thorough analysis of the products showed that ethane, ethylene, and *n*-butane accounted for over 99% of the products. In addition, 2-bromobutane and vinyl bromide were found, the former to the extent of ca. 0.3% and the latter slightly less. The average ratio $R_f[C_2H_6]/R_f[C_4H_{10}]$ was 1.5; the ratio $R_f[C_2H_6]/R_f[C_2H_4]$ was approximately 2.

We interpret these results on the basis of the following reactions:

[5] $$2C_2H_5 = C_2H_6 + C_2H_4$$

[6] $$2C_2H_5 = C_4H_{10}$$

[7] $$C_2H_5 + C_2H_5Br = C_2H_6 + CH_3CHBr$$

[8] $$C_2H_5 + CH_3CHBr = C_2H_4 + C_2H_5Br$$

[9] $$C_2H_5 + CH_3CHBr = CH_3CH_2CHBrCH_3$$

[10] $$C_2H_5 + CH_3CHBr = C_2H_6 + CH_2CHBr$$

Thus, insofar as gas phase reactions are concerned, we attribute the anomalous k_d/k_c ratio to the abstraction reaction [7] and the disproportionation reaction [8]. The combination reaction [9] and the disproportionation reaction [10] are of minor importance. The fact that some 2-bromobutane was observed, whereas the corresponding reaction [4] between CH_3 and CH_2Br produced only the decomposition products is not surprising since one would expect a larger stabilization/decomposition ratio for the hot combination product in the case of the larger radicals.

C_2H_5I

One experiment was carried out using ethyl iodide (at 249°C and 4 Torr pressure of N_2). The only significant difference, as compared to ethyl bromide, was that no butyl iodide was found (i.e. <0.05% of products) while the vinyl iodide amounted to 1.3%. Thus the disproportionation/combination ratio corresponding to reactions [10] and [9] is greater for the iodide than for the bromide, as one might expect on steric grounds.

n-*C_3H_7Br*

Four experiments were carried out, at temperatures ranging from 309 to 318°C (with the saturator at slightly lower temperatures) and at N_2 pressures from 3.5 to 17 Torr. Methane was not trapped out and no search for brominated hydrocarbons was made except for *n*- and *s*-C_3H_7Br. Only the former was observed.

Since C_2H_6 and C_2H_4 were the most important products (accounting for 36 to 65% of the total), it is evident that the decomposition of *n*-C_3H_7 is very important under these conditions, viz.

[11] $$n\text{-}C_3H_7 = C_2H_4 + CH_3$$

The remaining products were C_3H_8, C_3H_6, *n*-C_4H_{10}, and *n*-C_6H_{14}. The complete absence of isomers of *n*-C_4H_{10} and *n*-C_6H_{14} shows that isomerization of *n*-C_3H_7 is not important relative to reaction [11].

Because of the importance of reaction [11] it would appear that the CH_3 concentration can actually exceed that of *n*-C_3H_7, and so the number of possible reactions is such as to preclude any satisfactory determination of mechanism. It should be noted, however, that the apparent value of k_d/k_c (0.5 to 2.4), whether it was based on C_3H_8 or C_3H_6, was not constant and was always larger than the generally accepted value of 0.14 (25, 26). Thus abstraction from the halide by *n*-C_3H_7 would appear to be important at these temperatures.

s-*C_3H_7Br*

Four experiments were carried out at 309°C and at 4.5 to 5.5 Torr of N_2. The major products, accounting for 93 to 99% of the total, were those expected from the disproportionation and combination of *i*-C_3H_7, namely C_3H_8, C_3H_6, and 2,3-dimethylbutane (2,3-DMB). However, the ratios $R_f[C_3H_6]/R_f$[2,3-DMB] and $R_f[C_3H_8]/R_f$[2,3-DMB] averaged 2.4, several times the probable value of 0.5 to 0.65 for k_d/k_c (25, 27). Thus abstraction from the halide would appear to be important in this case as well.

The minor products (1 to 7%) included 2-methyl pentane (2-MP) and *n*-hexane (considerably more of the former than of the latter), as well as C_2H_6, C_2H_4, and *i*-C_4H_{10}. This would suggest that some *n*-C_3H_7 was present, although its mode of formation is not clear. Isomerization of *i*-C_3H_7 to *n*-C_3H_7 is an unlikely source since this is much slower than the reverse reaction, and that was not observed in the experiments with *n*-C_3H_7Br.

t-C_4H_9Br *and* t-C_4H_9Cl

Two experiments with the former and one with the latter were sufficient to show that thermal decomposition plays an important role in competition with the primary reaction with sodium. This was particularly evident in the case of the chloride where, because of the smaller value of the rate constant for the primary process, the initial concentration had to be about 30 times as great as for the bromide in order to obtain a 'flame'. Although the expected combination and disproportionation products were found, namely 2,2,3,3-tetramethylbutane, i-C_4H_{10}, and i-C_4H_8, the butene was far in excess of the butane (by a factor of 5.6) as the result of the thermal decomposition reaction

[12] $$t\text{-}C_4H_9Cl = i\text{-}C_4H_8 + HCl$$

A rough value of k_{12} was obtained using the expression

[iii] $$k_{12} = \frac{R_f[i\text{-}C_4H_8] - R_f[i\text{-}C_4H_{10}]}{(t\text{-}C_4H_9Cl)V}$$

where V is the volume of the reaction vessel. The value so obtained, $2.7 \pm 0.3 \times 10^{-3}$ s^{-1}, is about 17 times that derived from the rate constant expression recommended by Benson and O'Neal (28), but this is not surprising because the decomposition is known to be greatly enhanced by wall reaction.

On the assumption that i-C_4H_{10} arose solely from disproportionation, the value of k_d/k_c derived from the three experiments was 5.3 ± 0.5 at an average temperature of 275°C. Literature values range from 2.2 to 7.4 (25, 27).

B. Kinetics of the Reaction $CH_3 + C_3H_8$

By flowing C_3H_8 through the reactor along with CH_3Br or CH_3Cl it was possible to study the kinetics of the abstraction reactions:

[13] $$CH_3 + C_3H_8 = CH_4 + n\text{-}C_3H_7$$

[14] $$CH_3 + C_3H_8 = CH_4 + i\text{-}C_3H_7$$

The results are shown in Table 2. The flow rates listed for the reagents CH_3X and C_3H_8 are the values determined during product analysis. Since the experimental conditions with CH_3Br were such as to make CH_3 the predominating radical, the three hexanes were formed in quite small amounts in comparison with the two butanes, formed by the reactions

[15] $$CH_3 + n\text{-}C_3H_7 = n\text{-}C_4H_{10}$$

[16] $$CH_3 + i\text{-}C_3H_7 = i\text{-}C_4H_{10}$$

The CH_4 is attributed to reaction [3] as well as to the disproportionation reaction corresponding to reactions [15] and [16]:

[17] $$CH_3 + C_3H_7 = CH_4 + C_3H_6$$

It was not possible to measure the C_3H_6 formed in reaction [17] in the presence of the very large excess of C_3H_8. Some decomposition of n-C_3H_7 occurred by reaction [11], giving rise to the C_2H_4. The C_2H_6 is attributed to reaction [2]. Because of their small amounts, the butenes and pentanes were not used in the mathematical analysis of the results.

In order to determine the rate constants k_{11}, k_{13}, and k_{14} the equations of mass continuity for Na, CH_3, n-C_3H_7, and i-C_3H_7 were solved simultaneously. The values of k_d/k_c required were taken from the literature or, where this was not possible, were calculated from simple collision theory based on $k_2 = 2.4 \times 10^{13}$ cm^3 mol^{-1} s^{-1}. The rate constants in Table 2 for CH_3Br as the atmospheric reagent are the averages of the values obtained using cell radii of 8.9 cm and 13.2 cm; the values for CH_3Cl are for the small reactor model only. In the latter case (as shown in Table 1) an appreciable amount of C_2H_4 was formed by the analog of reaction [4], and hence the values of k_{11} and k_{13} are the upper limits; in the runs with CH_3Br all C_2H_4 was assumed to arise from reaction [11]. Aside from this, the uncertainties in the rate constants arise mainly from the problem of taking into account the fate of the CH_3 and i-C_3H_7 radicals that reach the wall. This was not a problem with n-C_3H_7 because almost all of it was consumed in the first order process [11].

In comparing our values of k_{11} with the literature (23) one is struck by the fact that there are variations of as much as two orders of magnitude in previously published data. However, there is a relatively good agreement between our values and those derived from the more recent and thorough investigation of Papic and Laidler (29), viz. 5.0×10^2 at 336°C, 2.5×10^3 at 375°C.

Our over-all rate constants for the abstraction reaction, $k_{13} + k_{14}$, are about 50% greater than found by Jackson, McNesby, and Darwent (30). On the other hand, our values for k_{13}/k_{14} are 1.3 and 1.5 at 336 and 375°C, respectively (runs 1 and 2), whereas the values derived from the work of these authors are 0.52 and 0.56. The values of the ratio derived from our work are virtually independent of the approximation used and so the discrepancy is real.

C. Kinetics of the Reaction $CH_3 + C_2H_4$

A number of experiments were performed in which various amounts of C_2H_4 were added to the reagent stream, along with CH_3Br, with the objective of measuring the rate constant of the addition reaction

[18] $$CH_3 + C_2H_4 = n\text{-}C_3H_7$$

The n-C_3H_7 radicals so formed would be expected to decompose by reaction [11], the reverse of [18], or

react with CH_3 (the predominant radical) by reactions [15] and [17]. In analysing the results of part *B*, above, it was assumed that the alternative decomposition process [19]

[19] $$n\text{-}C_3H_7 = C_3H_6 + H$$

was of negligible importance. However in the presence of much larger concentrations of C_2H_4, and in the absence of large amounts of C_3H_8, reaction [19] would be easier to detect. Thus, the H atoms formed would rapidly add to C_2H_4 to form C_2H_5 which would give rise to C_3H_8 by combination with CH_3 and to n-C_5H_{12} by reaction [20].

[20] $$C_2H_5 + n\text{-}C_3H_7 = n\text{-}C_5H_{12}$$

The corresponding disproportionation reactions would form CH_4, C_2H_4, C_2H_6, C_3H_8, and C_3H_6.

The results are given in Table 3. The amounts of C_3H_8 formed by the above mechanism can be predicted from the observed rates of formation of C_3H_6, n-C_4H_{10}, and n-C_5H_{12} using available information on disproportionation/combination reactions (25). The amounts predicted in this way were 3.3, 7.5, 6.1, 35, 58, and 350 pmol s^{-1} for runs 1 to 6 respectively, in reasonably good agreement with the measured values of C_3H_8.

In addition to the products listed in Table 3, traces of C_2H_2 were also found (ca. 1 to 5 pmol s^{-1}). This probably arises by H atom abstraction from C_2H_4 followed by the disproportionation of CH_3 and C_2H_3 radicals:

[21] $$CH_3 + C_2H_4 = CH_4 + C_2H_3$$

[22] $$CH_3 + C_2H_3 = CH_4 + C_2H_2$$

The rate of [21] is, of course, much smaller than that of [18] (31, 32).

The rate constants k_{18} and k_{19} were calculated by numerically solving the equations of mass continuity for Na, CH_3Br, and n-C_3H_7, together with those for reactions [18] and [19] based on the above mechanism. The values of k_{11} were those derived in part *B*. The fairly large uncertainty in k_{11} caused only about 10% uncertainty in k_{18} and k_{19}, less than those inherent in allowing for the wall reaction.

Considering the wide range of conditions, particularly with respect to the amount of CH_3 reacting in the gas phase, the values of k_{18} and k_{19} are reasonably consistent, suggesting that the assumed model is reasonable. Literature values of k_{18} were all determined at considerably lower temperatures than those used here. When extrapolated to the temperatures used here they are somewhat smaller than those listed in Table 3; for example, at 336°C the extrapolated values are (in units of 10^8 cm^3 mol^{-1} s^{-1}) 5 (33), 6 (34), 7 (32), 12 (35) compared to our

value of 14 ± 3; Kerr and Parsonage have recommended 5.7 (36). Previously determined values of k_{19}, evaluated for 336°C, are 13 s^{-1} (37), 16 s^{-1} (38), and 6.6 s^{-1} (39), compared to our value of 23 ± 4 s^{-1}.

Calculations showed that the rate of isomerization of n-C_3H_7 was less than 2% of its rate of 'slow' decomposition by reaction [19] at the temperatures used.

Summary and Conclusions

The present investigation has shown that the main difficulties associated with the use of sodium diffusion flames as sources of free radicals for kinetic studies arise from wall reactions and hydrogen abstraction from the halide. The former can be minimized by using a large diameter reactor, a relatively high pressure of inert carrier gas (preferably of high molecular weight), a 'flame' radius of from 0.5 to 1.0 cm, and by operating the sodium saturator at a temperature only slightly below that of the reactor.

Abstraction from the halide, being competitive with reactions of the primary radical with other added reagents, can be reduced by using low concentrations of the halide. Since the rate constants of the primary reaction with sodium are in the order iodide > bromide > chloride, the higher atomic weight halogens are more favourable as less halide is required for a given rate of radical production. However, the rates of thermal decomposition of the halides are generally in the same order. In the present work bromides were found to provide the best compromise.

Since the reactant concentrations are spherically symmetrical and controlled by diffusion, rate constants were derived from product analyses by the numerical solution of simultaneous non-linear differential equations. By reacting CH_3Br with Na in the presence of added C_3H_8 and C_2H_4 under more or less optimal conditions rate constants were determined for five different reactions: the two modes of decomposition of n-C_3H_7, the abstraction of primary and secondary H atoms from C_3H_8 by CH_3, and the addition of CH_3 to C_2H_4. The values obtained are in reasonably good agreement with those obtained by more conventional methods.

Fluxional behaviour of potentially bidentate phenanthroline, naphthyridine, and phthalazine ligands in palladium complexes

J. BRADLEY BRANDON, MICHAEL COLLINS, AND KEITH R. DIXON[1]

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received August 31, 1977

J. BRADLEY BRANDON, MICHAEL COLLINS, and KEITH R. DIXON. Can. J. Chem. **56**, 950 (1978).

The synthesis of a series of palladium complexes, *cis*-$[PdCl(PEt_3)_2L][Y]$; L = 1,10-phenanthroline, 1,8-naphthyridine, or phthalazine; Y = BF_4^- or ClO_4^-; is reported. Variable temperature ^1H and ^{31}P nmr spectra are discussed in terms of square planar structures in which the heterocyclic ligands are essentially monodentate and fluxional with the palladium exchanging between the two nitrogen atoms. Above ca. −10°C a dissociative exchange mechanism operates in all three complexes and, when L = 1,10-phenanthroline or 1,8-naphthyridine, exchange continues at lower temperatures by an intramolecular process.

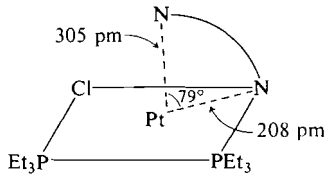
J. BRADLEY BRANDON, MICHAEL COLLINS et KEITH R. DIXON. Can. J. Chem. **56**, 950 (1978).

On rapporte la synthèse d'une série de complexes de palladium $[PdCl(PEt_3)_2L][Y]$ *cis*; L = phénanthroline-1,10, naphthyridine-1,8 ou phtalazine; Y = BF_4^- ou ClO_4^-. On discute des spectres rmn ^1H et ^{31}P à températures variables en terme d'une structure plan carré dans laquelle les ligands hétérocycliques sont essentiellement monodentates et fluxionels par rapport au palladium qui s'échange entre les deux atomes d'azote. Au-dessus de −10°C, un mécanisme d'échange dissociatif opère dans les trois complexes et lorsque L = phénanthroline-1,10 ou naphthyridine-1,8, l'échange continue à des températures plus basses par un processus intramoléculaire.

[Traduit par le journal]

Introduction

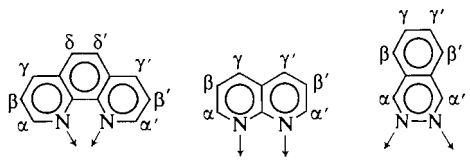
We have recently completed studies of a series of platinum complexes, *cis*-$[PtCl(PEt_3)_2L][BF_4]$, in which only one site in the square coordination plane is available to a potentially bidentate ligand, L (1–4). For example, when L = 1,8-naphthyridine (naph), an X-ray diffraction study (3) shows the following structure in which only one nitrogen is strongly bound to the platinum (1).



1

Closely related structures for the L = 1,10-phenanthroline (phen) and phthalazine (phth) complexes have also been established by X-ray diffraction (1, 4).

In solution, nmr studies (2) show that these complexes are fluxional with exchange of the coordinated platinum between the two nitrogen sites on the ligands. In the series L = phen, naph, or phth, the rate of this fluxional process decreases rapidly (approximate coalescence temperatures are < −80, −30, and +90°C) as the orientation of the nitrogen lone pairs becomes less suitable for a 5 coordinate intermediate. For L = phth the mechanism is dissociative rather than intramolecular (2). The present



paper reports the results of a similar nmr investigation of the corresponding palladium complexes.

Results and Discussion

(a) Synthesis

The complexes, *cis*-$[PdCl(PEt_3)_2L]^+$, L = 1,10-phenanthroline (phen), 1,8-naphthyridine (naph), or phthalazine (phth), were prepared as both fluoroborate and perchlorate salts by the reactions:

$$[Pd_2Cl_2(PEt_3)_4][BF_4]_2 + 2L \rightarrow \textit{cis}\text{-}[PdCl(PEt_3)_2L][BF_4]$$

$$\textit{trans}\text{-}[PdCl_2(PEt_3)_2] + L + NaClO_4 \xrightarrow{\text{acetone}} \textit{cis}\text{-}[PdCl(PEt_3)_2L][ClO_4] + NaCl$$

Infrared spectra showed the expected ligand and anion absorptions and were in general almost identical with spectra of corresponding platinum complexes for which X-ray structural data are available (1–4). Molar conductance measurements gave values in the range 75–95 Ω^{-1} cm^2 typical of 1:1 electrolytes in nitromethane (5).

As noted previously (6), the *cis*-$[PdCl(PEt_3)_2(phen)]^+$ cation is very labile and in solution tends to form $[PdCl(PEt_3)(phen)]^+$, a square planar cation containing bidentate phenanthroline. The displaced PEt_3 reacts with $[Pd_2Cl_2(PEt_3)_4]^{2+}$, present during the preparation of *cis*-$[PdCl(PEt_3)_2(phen)]^+$, or with *cis*-$[PdCl(PEt_3)_2(phen)]^+$ itself to form $[PdCl(PEt_3)_3]^+$. ^{31}P nmr spectra showed that preparations of $[PdCl(PEt_3)_2(phen)]^+$ salts were always slightly contaminated by $[PdCl(PEt_3)(phen)]^+$ and $[PdCl(PEt_3)_3]^+$ as a consequence of the above reactions.

(b) ^{31}P nmr Spectra

Spectra of the three *cis*-$[PdCl(PEt_3)_2L]^+$ cations were all basically similar, consisting of two broad absorptions at 30°C. When L = naph or phth, these resonances sharpened to a well resolved AX pattern at 0°C and reduction of temperature below this caused no further change. When L = phen the spectra were of poorer quality due to the impurities discussed above and $J_{AX}(J_{PP})$ was not resolved although the two resonances were much sharper at 0°C. Raising the temperature caused decomposition of the phenanthroline complex but the resonances for the L = naph or phth complexes continued to broaden and coalesced at approximately 50°C. The AX spectra at 0°C are consistent with structures similar to **1** and as the temperature is raised an exchange process occurs in which the phosphorus positions *trans* to Cl and *trans* to N are interchanged.

(c) ^1H nmr Spectra

The spectrum of *cis*-$[PdCl(PEt_3)_2(phth)]^+$ at 35°C was very similar to that of non-coordinated phthalazine except for differences in chemical shifts. In particular the $\alpha\alpha'$ resonance was a sharp singlet with no evidence of coupling to phosphorus. Cooling caused broadening and then splitting into two resonances, the low field component being broader ($W_{1/2} \sim 6$ Hz) than the other ($W_{1/2} \sim 3$ Hz). The coalescence temperature was −5°C. Thus, there is fluxional exchange of palladium between the two coordination sites on phthalazine, the process being fast at 35°C and slow below −5°C. The low field resonance is assigned to the proton (α) adjacent to the coordinated nitrogen and is broadened by coupling to phosphorus. The absence of observable[2] coupling to phosphorus at 35°C suggests that the fluxional process is dissociative, as is expected from our previous results (2) on platinum phthalazine complexes. This was confirmed by the observation of a marked increase in the rate of exchange when small quantities of phthalazine were added to the solution. A dissociative process also accounts for the observed collapse of the ^{31}P spectra if the palladium intermediate permits interchange of phosphorus positions. It is interesting, however, that the coalescence temperature in the ^{31}P spectra is ~50°C whereas in the ^1H spectra it is ~ −5°C. Computer simulation[3] of the spectra shows that the exchange of proton positions is 4–5 times faster than the exchange of phosphorus positions, which is not unexpected if the dissociation leading to the former is prerequisite to the latter. $\Delta G^{\ddagger}$ is ~50 kJ mol^{-1} for both processes.

The *cis*-$[PdCl(PEt_3)_2(naph)]^+$ spectrum was also similar to that of the free heterocyclic ligand. Cooling to −70°C caused no change except that the double doublet assigned to $\alpha\alpha'$ broadened at −10°C so that the multiplicity was no longer resolved. This is evidence for coupling to phosphorus below −10°C and, in conjunction with the ^{31}P spectra, shows a dissociative exchange process above this temperature as in the phthalazine case. Addition of excess naphthyridine accelerated the exchange and signals due to coordinated and non-coordinated naphthyridine were then clearly resolved on further cooling.[4] However, whereas the phthalazine complex is non-fluxional below −10°C, the two heterocyclic rings in the naphthyridine complex remain chemically equivalent down to −70°C, the lowest temperature accessible before crystallization of the complex spoiled the experiment. This suggests that exchange of palladium between the two nitrogen sites continues at low temperature by an intramolecular process similar to that in the corresponding platinum complex (2). The alternate explanation of symmetric chelation cannot be entirely excluded but it seems relatively unlikely in view of the similarity of infrared and nmr evidence to that for platinum complexes.

Solutions of *cis*-$[PdCl(PEt_3)_2(phen)]^+$ contained non-coordinated phenanthroline (~15%) as a result of the lability of the complex and the sequence of reactions (see section *a* above) leading to $[PdCl(PEt_3)_3]^+$. ^1H resonances due to coordinated and non-coordinated phenanthroline were clearly resolved below −20°C but exchange occurred above this temperature. As in the naphthyridine case, the

[2]The line width in the spectra should have permitted observation of coupling constants >1 Hz.

[3]Using the DNMR 3 programme obtainable as No. 165 from the Quantum Chemistry Programme Exchange, University of Indiana.

[4]Coincidences of chemical shift prevented similar resolution in the phthalazine case.

[a]Complex cations were studied as both BF_4^- and ClO_4^- salts. There were no significant differences.
[b]Temperatures of ^{1}H spectra. All ^{31}P spectra were recorded at 0°C.
[c]α, β, γ, and δ positions were labelled relative to the nitrogen atoms. Where a single entry occurs for primed and unprimed parameters, the two are chemically equivalent. In other cases primes denote positions adjacent to the non-coordinated nitrogen or, in the case of [PdCl(PEt$_3$)(phen)], the ring *trans* to chlorine. Spectra were recorded using CH_2Cl_2 as reference and lock in $(CD_3)_2CO$ solution except for naph and *cis*-[PdCl(PEt$_3$)$_2$(naph)] for which a TMS lock was used and [PdCl(PEt$_3$)(phen)]$^+$ which was in CD_2Cl_2 solution.
[d]Recorded in CD_2Cl_2 solution at 0°C using $P(OCH_3)_3$ as external reference. Chemical shifts are in ppm upfield from the reference.
[e]The α, α′, and β resonances showed doubleting due to ^{31}P, $J_{\alpha P} = 3.9$, $J_{\alpha' P} = 3.1$, $J_{\beta P} = 1.7$ Hz.
[f]Not resolved.
[g]Triplet
[h]Doublet.

two heterocyclic rings of the coordinated ligand remained chemically equivalent down to −70°C. Thus, the fluxional processes in all three complexes are similar to those observed in the platinum analogues (2), except that the rates of both dissociative and intramolecular processes are increased relative to the platinum case. This is expected since palladium complexes are well known to be generally more labile than those of platinum.

Experimental

Our general techniques and instrumentation have been described previously (2). ^{31}P nmr spectra were recorded at 24.288 MHz on a Nicolet TT-14 Fourier transform spectrometer using $P(OMe)_3$ as external reference, C_6D_6 as external lock, and CH_2Cl_2 as solvent. Positive chemical shifts are upfield from the reference. ^{1}H nmr spectra were recorded at 90 MHz on a Perkin-Elmer R32 spectrometer using $(CD_3)_2CO$ as solvent and CH_2Cl_2 as the most usual lock signal (see Table 1). Magnet ambient temperature was 35°C for the ^{1}H spectra and 30°C for the ^{31}P spectra.

1,8-Naphthyridine was prepared as previously described (7) and the other ligands were commercially available. [PdCl(PEt$_3$)$_n$(phen)][BF_4] complexes were prepared as previously described (6) except that conversion of the $n = 2$ complex to the $n = 1$ was achieved rapidly and almost quantitatively by addition of a few drops of H_2O_2 solution to the former complex in methanol under reflux. Preparations of [PdCl(PEt$_3$)$_2$L][BF_4], L = naph, phth, pyridazine, or PEt$_3$, were exactly analogous to the previous method for L = phen (6). The pyridazine complex gave nmr results analogous to those described for the corresponding phthalazine complex.

Perchlorate salts were prepared because of initial analytical difficulties with the fluoroborates which tended to oil rather than crystallize. They were obtained in high yield by use of the appropriate ligand in reactions similar to the following example.

cis-[*PdCl(PEt$_3$)$_2$(phth)*][ClO_4]

A solution of phthalazine (0.049 g, 0.38 mmol) and $NaClO_4 \cdot H_2O$ (0.070 g, 0.50 mmol) in acetone (5 ml) was added dropwise to a stirred solution of *trans*-[$PdCl_2$(PEt$_3$)$_2$] (0.154 g, 0.37 mmol) in acetone (5 ml) under a nitrogen atmosphere at 25°C. After 15 min the mixture was evaporated to dryness under reduced pressure and the residue extracted with dichloromethane to leave NaCl and unreacted $NaClO_4$ as residue. Evaporation of the extract and crystallization of the resulting oil from methanol by the addition of diethyl ether gave *the complex* as white crystals (0.168 g, 0.28 mmol) which were recrystallized by the same procedure.

Fonction d'acidité relative aux amines secondaires: un critère de validité du postulat de Hammett

JEAN-MARIE CARPENTIER ET PATRICK LEMETAIS

Laboratoire de Chimie Physique Organique, Faculté des Sciences et Techniques, 76130 Mont Saint Aignan, France et Laboratoire de Chimie Analytique, Faculté de Pharmacie, Université Paris V, 75005 Paris, France

Reçu le 29 juillet 1977

JEAN-MARIE CARPENTIER et PATRICK LEMETAIS. Can. J. Chem. **56**, 954 (1978).

Une fonction d'acidité a été construite par spectrophotométrie, en milieu eau – acide sulfurique, à 298 K, à l'aide de sept amines secondaires comme indicateurs. Cette fonction est la même que celle basée sur les amines primaires et diffère ainsi de celle relative aux amines tertiaires. Les deux premiers types d'amines sont donc les indicateurs de la même fonction d'acidité. On conclut que pour une fonction d'acidité donnée, le postulat de Hammett est seulement vérifié pour tous les composés caractérisés par la valeur identique d'un paramètre structural τ: le taux apparent de solvatation.

JEAN-MARIE CARPENTIER and PATRICK LEMETAIS. Can. J. Chem. **56**, 954 (1978).

An acidity function has been determined spectrophotometrically in aqueous sulphuric acid, at 298 K, by using seven secondary amine indicators. This function is the same as that based on primary amines and so differs from that relative to tertiary amines. Therefore, the first two types of amines are the indicators of the same acidity function. It is concluded that for a given acidity function, the Hammett postulate is only verified for all the compounds characterized by the same value of a τ structural parameter: apparent ratio of solvation.

Il est maintenant connu qu'à l'unicité de l'échelle pH correspondent plusieurs fonctions d'acidité (1, 2). Si le postulat de Hammett (3) reste vérifié à l'intérieur d'une même série d'indicateurs, cela revient à écrire, à une acidité donnée, la relation [1]:

$$[1] \quad H_X = -\log I + \mathrm{p}K_{XH^+} = -\log I' + \mathrm{p}K_{X'H^+}$$

avec $I = |XH^+|/|X|$; $I' = |X'H^+|/|X'|$; X et X' indicateurs de H_X.

Comme les variations expérimentales de $\log I = f(\log I')$ ne sont pas toujours des droites de pente unitaire, un certain nombre de travaux (parmi lesquels réfs 4–6 et réf. dans réfs 1, 2) ont mis en doute la validité du postulat de Hammett, et donc celle du concept de fonction d'acidité. C'est pourquoi, nous avons entrepris l'étude de différents critères de validité; nous exposons les premiers résultats dans ce mémoire.

Si la pente de la droite $\log I = f(\log I')$ dépend du couple d'indicateurs (X, X'), il existe peu de chances que l'on obtienne des valeurs identiques de fonction d'acidité avec des couples différents. Mais, Yates et Shapiro (7) ont montré qu'en utilisant des anilines primaires non substituées par des groupements nitro, la fonction d'acidité obtenue est la même que celle bâtie uniquement sur des nitro-anilines. Dans ce travail, nous comparons les résultats obtenus *avec deux séries distinctes* d'indicateurs. Dans un précédent mémoire (8), nous avons établi, au moyen d'un procédé graphique, que la protonation des amines secondaires obéissait à la fonction H'_0. Cette obéissance, qui se traduit par une pente sensiblement unitaire de la droite $\log I = f(H'_0)$, ne constitue pas une preuve suffisante. Nous avons donc construit la fonction d'acidité (H''_0) relative à la protonation des amines secondaires.

Résultats et discussion

Ancrage de la fonction H''_0

La nature du premier indicateur et la valeur de son pK conditionnent fortement l'exactitude d'une fonction d'acidité. Pour cette raison, l'ancrage de H''_0 repose sur deux indicateurs. Les pK de la diphénylamine ($+0.77_5$) et de la *N*-éthyl-nitro-2-aniline (-0, 11) ont été déterminés spectrophotométriquement en solution acide diluée (pour les concentrations égales ou inférieures à $0.532\ M \times \ell^{-1}$, l'acide est de l'acide chlorhydrique), selon le procédé classique:

$$[2] \quad -\log |H^+| + \log I = A' |H^+| + \mathrm{p}K_{XH^+}$$

A' étant le produit des constantes de Setschenow ($\log \gamma = A|H^+|$) et $|H^+|$ désignant la molarité de l'acide.

L'extrapolation à dilution infinie d'acide donne la valeur thermodynamique de $\mathrm{p}K_{XH^+}$, (tableau 1). Pour tous les composés, les valeurs du rapport d'ionisation I ont été mesurées à deux longueurs d'onde; aucun effet de milieu n'a été enregistré. La méthode des chevauchements continus (1, 2) a été utilisée pour la détermination du pK des autres composés. La concordance des valeurs de pK du second indicateur déterminées par la méthode des chevauchements continus et par le procédé de l'extrapo-

TABLEAU 1. Valeurs des pK_{XH^+} des amines secondaires à 298 K

Amines	pK_{XH^+}
(1) Diphénylamine	$+0.775 \pm 0.003^{a,b}$
(2) *N*-Ethyl-nitro-2-diphénylamine	-0.110 ± 0.008^{a} -0.11 ± 0.01^{c}
(3) *N*-Ethyl-chloro-4-nitro-2-aniline	-0.69 ± 0.01^{c}
(4) Nitro-4-diphénylamine	$-2.48 \pm 0.02^{c,d}$
(5) Nitro-2-diphénylamine	-3.28 ± 0.02^{c}
(6) *N*-Ethyl-dinitro-2,4-aniline	-4.40 ± 0.03^{c}
(7) Chloro-5-nitro-2-diphénylamine	-4.69 ± 0.04^{c}

[a]Valeur déterminée par extrapolation à dilution infinie.
[b]pK_{XH^+} (litt.) = 0.78 (9); 0.77 (10).
[c]Valeur déterminée par chevauchements des indicateurs.
[d]pK_{XH^+} (litt.) = −2.50 (2).

lation à dilution infinie d'acide, confirme que l'ancrage de la fonction d'acidité est correct.

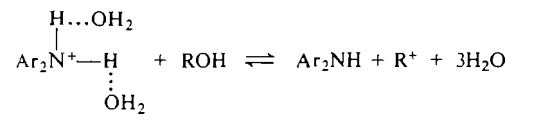
Validité du postulat de Hammett

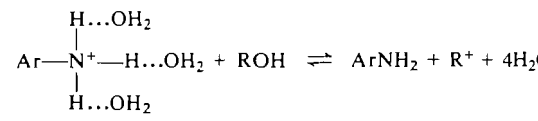
Les pentes de différentes droites $\log I = f(\log I')$ (les valeurs des rapports d'ionisation ont été déposées au Journal où elles peuvent être demandées)[1] ont des valeurs comprises entre 0.99_1 et 1.00_7. A un niveau donné d'acidité, la relation [1] exprimant le postulat de Hammett est donc vérifiée. La fonction H''^0 calculée (tableau 2) est identique à celle obtenue avec les anilines primaires, nitrées (11) ou non (7). Ce résultat démontre que tous ces composés sont des indicateurs de la même fonction d'acidité, indépendante certes de la nature et du nombre des substituants (7), mais également du type de *ses* indicateurs. Ce résultat est généralisable aux autres fonctions d'acidité. En effet, nous avions déjà constaté (15) que les thioamides aliphatiques et les amines tertiaires (mais pas les indoles) étaient les indicateurs de la même fonction d'acidité $|H'''_0$ (16)|.

Le postulat de Hammett est donc vérifié non seulement à l'intérieur d'une série d'indicateurs de structure donnée, mais pour tous les indicateurs d'une fonction d'acidité donnée quel que soit le groupement chimique protonable. Le cas particulier des ions oxonium sera traité ultérieurement.

Comparaison des fonctions H'_0, H''_0 *et* H'''_0

L'existence de fonctions d'acidité différentes pour les amines primaires (H'_0: réfs 7, 11–14) et tertiaires (H'''_0 = réf. 16) a conduit à imaginer une fonction H''_0 relative aux amines secondaires et située entre H'_0 et H'''_0. Cette hypothèse s'appuie sur les travaux de Taft (17). Selon cet auteur, les pentes 3.0 et 4.0 des droites $(H_R - H'_0)$ en fonction de $\log a_{H_2O}$ données par la nitro-4-diphénylamine et la dichloro-2,4-nitro-6-aniline, correspondent respectivement aux équilibres:





Cette différence d'hydratation impliquerait deux fonctions d'acidité. Cette interprétation nous semble criticable pour les raisons suivantes.

(*a*) Avec les valeurs expérimentales d'ionisation (3) utilisées par Taft, les graphes $\log I = f(H'_0)$,

$|H'_0$ (réf. 11)|, donnent des droites de pente 1.01 et 0.97 indiquant un comportement similaire de ces deux composés. D'ailleurs, en milieu hydroalcoolique acide à 20% en volume d'éthanol, l'identité des fonctions H''_0 et H'_0 avait été envisagée (4), après correction de l'ancrage de la fonction d'acidité basée sur des diphénylamines (18).

(*b*) Dans l'intervalle d'acidité considéré par Taft, H_R étant le double de H'_0 (1, 2, 15), la différence $(H_R - H'_0)$ est égale à H'_0. On note que le graphe $H'_0 = f(\log a_{H_2O})$ est une droite de pente 3.2 entre 48 et 60% de H_2SO_4 (intervalle où Taft obtient une droite de pente 3.0 pour la nitro-4-diphénylamine) et une droite de pente 4.0 entre 52 et 64% de H_2SO_4 (intervalle où Taft obtient une droite de pente 4.0 pour la dichloro-2,4-nitro-6-aniline).

(*c*) Taft a fait appel au concept du nombre d'hydratation pour expliquer la basicité des différentes classes d'ions ammonium. Or, Arnett et Burke (19) ont démontré plus tard que ce traitement n'était pas applicable en milieu acide.

L'identité des fonctions d'acidité H'_0 et H''_0 ne signifie pas que la solvatation globale des entités soit similaire; ainsi, les coefficients d'activité des ions anilinium et *N*-éthyl-anilinium peuvent être différents (20). Cette identité implique celle des différences des variations des énergies de solvatation (ΔG^0_t) caractéristiques des couples RNH_2/RNH_3^+ et $RR'NH/RR'\overset{+}{N}H_2$ (21). La plus faible solvatation constatée dans le cas du couple $RR'R''N/RR'R''\overset{+}{N}H$ serait due à l'encombrement stérique autour de l'atome d'azote.

Nécessité d'introduire un paramètre structural

Dans la définition classique d'une fonction d'acidité, aucun paramètre ne permet de distinguer les composés de structure différente qui sont les indicateurs de la même fonction d'acidité. Dans les travaux antérieurs (21), nous avons caractérisé chaque fonction d'acidité par la valeur d'un paramètre structural τ appelé "taux apparent de solvatation". Ce coefficient est indépendant de la nature de l'acide, du solvant (22), de la température (23) et varie seulement avec la nature du site porteur de la charge positive. Il traduit la différence énergétique de solvatation entre les formes neutre et ionisée. En ayant posé par référence que cette différence est nulle pour les triarylcarbinols, nous avons caractérisé d'une part, les amines primaires et secondaires (8) par la valeur $\tau = 3$ et d'autre part les thioamides et les amines tertiaires par la valeur $\tau = 2$ du taux apparent de solvatation (15). Selon nous, le critère de validité du postulat de Hammett n'est pas nécessairement l'appartenance d'un composé à une série donnée d'indicateurs. Le postulat de Hammett est vérifié pour tous les composés caractérisés par une valeur identique de τ quelles que soient leur structure, la température, et qu'ils soient chargés ou non.

Les auteurs remercient la Délégation Générale à la Recherche Scientifique et Technique, Action concertée Chimie Analytique n° 75.7.0505 pour son support financier.

Partie expérimentale

Les produits utilisés sont tous d'origine commerciale (Aldrich). Les solutions d'acide sulfurique sont préparées par dilution d'acide à 96% en poids et dosées par détermination de la densité à l'aide d'un microdensimètre Anton Paar digital (DMA 02 D). Quelle que soit l'acidité, l'incertitude sur les molarités est inférieure à ± 0.01. En raison de la faible solubilité dans l'eau de la forme neutre, les solutions-mères d'amines furent réalisées en milieu sulfurique. Les spectres uv furent enregistrés sur un spectrophotomètre Beckman DK 2 A, le compartiment cuves étant thermostaté à 298.0 $\pm$ 0.1 K.

Crystal structure of aquohydronium hexachloroantimonate(V)

HUGH M. MATHESON AND W. ALEX WHITLA

Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received August 5, 1977

HUGH M. MATHESON and W. ALEX WHITLA. Can. J. Chem. **56**, 957 (1978).

Crystals of the compound, $H_5O_2^+SbCl_6^-$ have been obtained. The structure shows an isolated $H_5O_2^+$ ion with O—O 2.52(1) Å. Crystal data: orthorhombic (*Immm*) $a = 6.96(1)$, $b = 9.15(1)$, $c = 7.91(1)$ Å.

HUGH M. MATHESON et W. ALEX WHITLA. Can. J. Chem. **56**, 957 (1978).

On a obtenu des cristaux du composé $H_5O_2^+SbCl_6^-$. La structure indique la présence d'un ion $H_5O_2^+$ isolé avec une distance O—O 2.52(1) Å. Les données cristallographiques: orthorhombique (*Immm*) $a = 6.96(1)$, $b = 9.15(1)$, $c = 7.91(1)$ Å.

The interest in structures of compounds containing strong hydrogen bonds (ref. 1, and references therein) has shown the importance of the aquohydronium ion, $H_5O_2^+$, in such systems. However, no previous structure contains this ion isolated from other water molecules or from strong hydrogen bonds to adjacent ions.

Crystals of the compound, $H_5O_2^+SbCl_6^-$, were obtained in X-ray capillaries when attempting to grow crystals of an adduct of antimony pentachloride. The structure was solved but did not correspond to any product reported in the literature (2). Recently Ortwein and Schmidt (3) have characterized the products $H_5O_2^+SbCl_6^-$ and $H_7O_3^+$-$SbCl_6^-$. We now report our structural data on the former compound.

The compound formed orthorhombic crystals with $a = 6.96(1)$, $b = 9.15(1)$, $c = 7.91(1)$ Å; $D_c = 2.45$ for $Z = 2$; $M = 371.5$; space group *Immm*.[1] The data crystal was grown by vacuum sublimation in a 0.3 mm quartz X-ray capillary and data were collected on a G.E. XRD-6 manual diffractometer using CuKα radiation. No absorption corrections have been made for the 236 reflections observed. (Crystal dimension: ~0.2 mm cube.) The atomic parameters given in Table 1 gave $R = 0.116$ for 224 observed reflections.[2] The relatively high R value and the large standard deviation of the thermal parameters indicate the need for an absorption correction. The data crystal decomposed and the necessary data for an absorption correction cannot be obtained.

The structure was solved by Patterson techniques and shows an octahedral hexachloroantimonate(V) ion with *mmm* symmetry. The $SbCl_6^-$ ions are packed head to tail along c in the I-centred cell with Cl—Cl contact of 3.206(3) Å. The two Sb—Cl bonds along c are 2.354(3) Å while the remaining four Sb—Cl bonds are 2.348(2) Å. The Cl—Sb—Cl angles are 91.14(5)° facing the $H_5O_2^+$ ion (b-axis) and 88.86(5)° (a-axis).

The environment of the aquohydronium ion is shown in Fig. 1. The O—O distance of 2.52(1) Å is similar to other room temperature hydrogen bond distances in "$H_5O_2^+$" species (1, 4). The shortest non-bonded contact of 3.494(5) Å are with Cl2 subtending an angle of 69.55(8)° with the O—O direction. With Cl1, four interactions of 3.605(3) Å have angles of 95.64(9)° and eight remaining contacts of 3.636(6) Å subtend angles of 137.90(9)°. Only the latter contacts would involve the possibility of some hydrogen bonding. With the high local symmetry the $H_5O_2^+$ ion either has free rotation in the ionic lattice or a disordered distribution of H-bonds to the eight equivalent chlorine atoms.

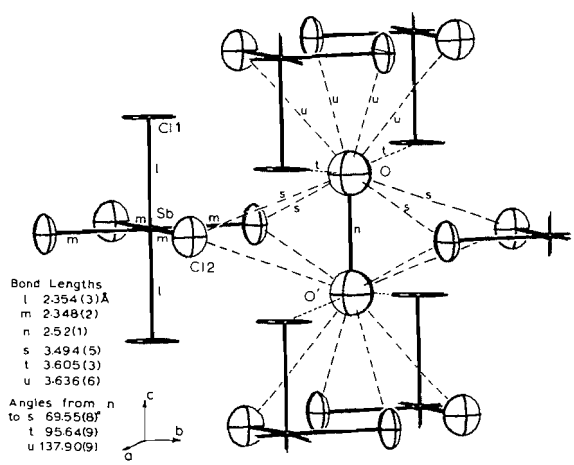

FIG. 1. $H_5O_2^+SbCl_6^-$ – oxygen environment.

[1]Errors estimated from film measurements.

[2]Copies of the structure factors in Table A may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2. Weighting scheme: $W = A^2/[A^2 + (F_o - B)^2]$, $A = 120$, $B = 50$ for full matrix refinement.

TABLE 1. Atom parameters for $H_5O_2^+SbCl_6^-$*

Immm site	Symmetry	x	y	z	U_{11} (U_{iso})	U_{22}	U_{33}	U_{12}
Sb	*a,mmm*	0	0	0	25(3)	19(2)	1(2)	
Cl1	*i,mm*	0	0	2975(17)	79(13)	139(19)	0.3(6)	
Cl2	*n,m*	2411(16)	1796(12)	0	17(7)	9(6)	24(8)	−14(5)
O	*j,m*	5000	0	3409(81)	93(9)			

*$x, y, z, \times 10^4$, U's $\times 10^3$; estimated standard deviations apply to the last figure given.

In this structure the two oxygen atoms lie across a mirror plane but the contribution of the H atom would not allow the distinction between the space groups *Immm* and *Imm*2. However, the environment of the $H_5O_2^+$ ion in this compound is symmetric in all directions (the mid-point between the oxygen positions must have *mmm* symmetry in space group *Immm*) and the angles of the O—O—Cl contacts would indicate weak H-bonds between $H_5O_2^+$ and $SbCl_6^-$. Although these conditions do not require a symmetric hydrogen bond for $H_5O_2^+$, they are essential to this possibility.

Local anisotropic contributions to ^{1}H nuclear magnetic resonance shifts in alkynes

ARVIND AGARWAL AND MICHAEL J. MCGLINCHEY[1]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 25, 1977

ARVIND AGARWAL and MICHAEL J. MCGLINCHEY. Can. J. Chem. **56**, 959 (1978).

Local anisotropic contributions to chemical shifts of protons sited near an alkyne moiety have been calculated using a classical model previously applied to aromatic systems. The results are presented in terms of an isoshielding contour map. The upfield shifts of ethyne and propyne and also the downfield shifts of the γ-protons of cyclooctynes are well accounted for by this theory.

ARVIND AGARWAL et MICHAEL J. MCGLINCHEY. Can. J. Chem. **56**, 959 (1978).

Utilisant un modèle classique appliqué antérieurement à des systèmes aromatiques, on a calculé les contributions anisotropiques locales aux déplacements chimiques des protons situés près d'une portion alcyne. On présente les résultats en terme d'une carte de contour de constantes d'écran égales. Les déplacements vers les hauts champs de l'éthyne et du propyne et aussi les déplacements vers les bas champs des protons γ des cyclooctynes peuvent être expliqués par cette théorie.

[Traduit par le journal]

Introduction

The anomalously high field absorption of the alkyne proton in nmr spectroscopy was rationalised two decades ago by Pople (1) who calculated that the neighbour anisotropy effect would produce a sizeable upfield shift, perhaps of the order of ~10 ppm. This paramagnetic contribution more than compensates for the downfield shift anticipated for a proton bonded to a relatively electronegative *sp*-hybridized carbon atom.

It has recently been demonstrated (2) that local anisotropic contributions to chemical shifts for protons in benzene and condensed aromatic systems are readily calculable by combining classical electromagnetic induction theory with the ^{13}C tensors obtained by Waugh and co-workers (3) using the technique of proton enhanced nuclear induction spectroscopy. This approach has been extended to include all proton positions in the vicinity of the benzene ring (4) and isoshielding contour maps incorporating both local anisotropic and ring current contributions to the chemical shifts of out-of-plane protons have now been calculated (5).

We now present the results of calculations of local anisotropic contributions to protons in the vicinity of the alkyne moiety.

Results and Discussion

Calculation of Local Anisotropic Shifts

Using the analogy of a current circulating in a loop of wire (2) the proton shielding component is given by

$$[1]\quad \sigma_{ii}^{H} = \frac{a}{\pi}\frac{1}{[(a+\rho)^2+z^2]^{1/2}} \times \left[K + \frac{a^2-\rho^2-z^2}{(a-\rho)^2+z^2}E\right]\sigma_{ii}^{C}$$

where σ_{ii}^{H} and σ_{ii}^{C} are the proton and carbon shielding components, respectively, ρ and z are the usual cylindrical coordinates, a is the radius of circulation (taken as 0.47 Å for circulation about a carbon atom (2)), and K and E are complete elliptical integrals of the first and second kind with argument

$$k^2 = \frac{4a\rho}{(a+\rho)^2+z^2}$$

In short, $\sigma_{ii}^{H} = G\sigma_{ii}^{C}$ where G is a geometric factor. The isotropic shielding, as measured in solution, is given by averaging the components:

$$[2]\qquad \langle\sigma^{H}\rangle = 1/3[\sigma_{11}^{H} + \sigma_{22}^{H} + \sigma_{33}^{H}]$$

The ^{13}C tensors for 2-butyne have been obtained by Waugh and co-workers (6) and, as anticipated, revealed considerable anisotropy. Since the ^{13}C isotropic shifts of the alkyne carbons in 2-butyne and acetylene itself are so similar and furthermore σ_{33} (which induces a field along the C—R axis) in substituted benzenes has been shown to be quite insensitive to the nature of the substituent (R = H, CH_3, or C_2H_5), it seems not unreasonable to use the ^{13}C tensors in 2-butyne for calculations on acetylene itself. As noted by Barfield *et al.* (2), it is necessary to convert the shielding tensors to absolute values by adding 71 ppm (ref. 2 note 40) to Waugh's experimental values.

TABLE I

	Proton coordinates[a]			Induced shift[b]
	x	*y*	*z*	H
H—C≡C—H	0	0	1.66	4.439
H—C≡C—CH_3	1.04	0	2.43	0.647
	1.39	1.87	0.23	−0.423
	0.98	3.54	0.66	−0.115

[a]Units are Å; the origin is at the centre of the triple bond which lies along the *z* axis.
[b]Units are ppm.

The Chemical Shift of Acetylene

Now using $\sigma_{11}{}^{C} = 244$, and $\sigma_{22}{}^{C} = \sigma_{33}{}^{C} = 42$ and taking into account the contribution of both carbon atoms, we see (Table 1) that an upfield shift of 4.44 ppm is indicated. To evaluate the chemical shift (δ) of the alkyne protons in acetylene, it is necessary to know the inherent shift of an *sp*-carbon-bonded proton to which the local anisotropic incremental shift can be added.

The 'inherent shift' of a —C≡C—H system would have to reflect the inductive pull of the alkyne moiety and this is not a trivial problem since neither Hammett nor Taft values for the H—C≡C— substituent appear to be widely used; however, estimates of the electronegativity of the alkyne moiety have been published (7). Although the values of $^{1}J_{CH}$ for C_2H_6, C_2H_4, and C_2H_2 correlate nicely with the percentage of *s* orbital character or with pK_a values of the hydrocarbons (8), analogous extrapolation of chemical shifts would predict an alkyne proton shift to be in the range 15–16 δ. (This circumstance arises since the observed C_2H_4 resonance is shifted *downfield* owing to the anisotropic nature of the sp^2 carbons.) A somewhat naive, but nevertheless empirically useful, correlation ($\bar{r} = 0.977$) can be drawn between the chemical shifts of X—H and pK_a values of X—CO_2H, where X = CH_2F, CH_2Cl, CH_2Br, and CH_2I. Now, knowing the pK_a value of H·C≡C—CO_2H, this correlation can be extrapolated to predict an 'inherent shift' for C_2H_2 of ~7 δ. In the light of these considerations, the calculated chemical shift of C_2H_2 (allowing for local anisotropy) is ~2.6 δ which is gratifyingly close to the experimental value of 2.88 δ.

Goldstein and Reddy (9, 10) have estimated the anisotropy in the magnetic susceptibility of the alkyne moiety to be -16.5×10^{-6} cm^3 mol^{-1}; this leads to a predicted upfield shift for the directly bonded proton of 4 ± 0.5 ppm, in good agreement with that obtained by the approach presented here.

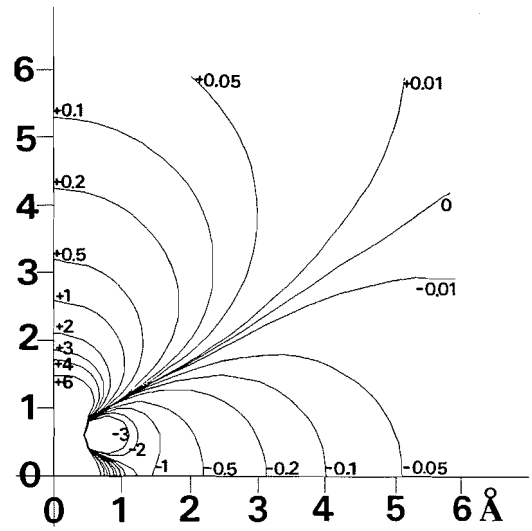

FIG. 1. Incremental shifts (in ppm) of a nucleus positioned near an alkyne linkage. The plot represents one quadrant of a plane containing the C_∞ axis; the origin is at the centre of the triple bond which lies along the ordinate axis. A positive sign corresponds to an upfield shift.

The Chemical Shift of Propyne

A methyl group bonded directly to a triple bond is predicted (Table 1) to exhibit an upfield shift of 0.65 ppm but again one has to determine what the 'inherent shift' of such a methyl group should be. For this purpose, we noted the excellent correlation (9) between $^{1}J_{CH}$ (11) and δ for a series of CH_3X molecules, in which large deviations from the straight line are shown by $CH_3C{\equiv}C{-}H$, CH_3CN, and CH_3—Ph. In the first two cases, the chemical shifts are upfield by ~0.75 ppm as is to be expected for molecules with large anisotropic contributions along the multiple bond axis; in the case of toluene the methyl group is downfield by ~1 ppm and this is nicely accounted for by local anisotropic contributions of the benzene ring (4, 5).

Deshielding by the Triple Bond

It has been noted previously (12) that the triple bond should have a deshielding zone entirely analogous to the situation already well established for benzene. However, attempts to observe this effect have so far been unsuccessful (13). The isoshielding contour map (Fig. 1) derived from our calculations[2] shows that to maximise this effect one needs a proton sited close to the centre of the triple bond. This situation does arise in the small ring cycloalkynes whose spectra have been studied by Krebs (14). In particular, the γ-protons of 4,4,7,7-tetramethylcyclooctyne, which show a singlet at room temperature, are clearly separated upon cooling to −80°C.

[2]Details of the programme available on request.

Since these protons have the same inherent shift, but are experiencing different induced fields when the molecule is no longer free to invert, they provide an ideal test of the theory. Now, using the γ-proton positions provided by the electron-diffraction study of cyclooctyne (15), one can readily evaluate the chemical shift difference between these two protons. The calculated (Table 1) separation of 68 Hz at 220 MHz compares very favorably with the experimental separation of 61 Hz at 220 MHz.

It is of interest to compare the calculated values obtained above for the γ-protons of the tetramethylcyclooctyne system with those predicted using the McConnell relationship (16) in conjunction with the previously quoted (10) value of -16.5×10^{-6} cm^3 mol^{-1} for Δ_χ; H_A and H_B (see Table 1 for coordinates) are predicted to be shifted downfield by 0.692 and 0.170 ppm, respectively. This would lead to a separation of 0.522 ppm, or 115 Hz at 220 MHz. As previously noted by Reddy and Goldstein (10) this extremely useful dipolar approximation must be used with caution for proximate protons.

To conclude, the simple classical model of circulating currents around the alkyne carbon atoms, in conjunction with the experimentally derived ^{13}C tensors of Waugh allows the evaluation of proton shifts in the proximity of a triple bond. These calculated shifts agree remarkably well, both in magnitude and sign, with the experimental spectra.

Equilibrium constants for a series of simple aldol condensations, and linear free energy relations with other carbonyl addition reactions

J. PETER GUTHRIE[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 18, 1977

J. PETER GUTHRIE. Can. J. Chem. **56**, 962 (1978).

A set of equilibrium constants for aldol condensations of acetaldehyde, acetone, acetophenone, and acetic acid as nucleophiles and formaldehyde, acetaldehyde, benzaldehyde, acetone, and acetophenone as carbonyl acceptors has been evaluated. The four values determined, directly or indirectly, by experiment have been augmented by values calculated from thermochemical data and equilibrium constants for enone hydration, and by estimation of free energies of formation of the reaction products by use of hypothetical disproportionation reactions. When the carbonyl nucleophiles are compared to other nucleophiles which can add to carbonyl compounds, it is found that they can be incorporated in the linear free energy relationship of Sander and Jencks, with γ values of 0.45 for acetaldehyde, 0.16 for acetone, 0.05 for acetophenone, and 3.56 for acetic acid. These results make it possible to predict the equilibrium constants for any of a large number of aldol condensations from the equilibrium constant for the addition of any nucleophile to the carbonyl acceptor compound.

J. PETER GUTHRIE. Can. J. Chem. **56**, 962 (1978).

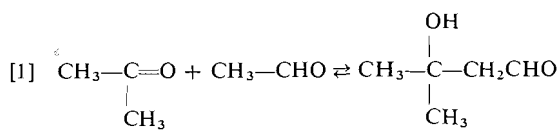
On a évalué une série de constantes d'équilibre pour les condensations aldoliques de l'acétaldéhyde, de l'acétone, de l'acétophénone et de l'acide acétique agissant comme nucléophile alors que la formaldéhyde, l'acétaldéhyde, la benzaldéhyde, l'acétone et l'acétophénone agissent comme accepteur de carbonyle. Aux quatre valeurs déterminées directement ou indirectement à l'aide des expériences on a pu apporter un complément grâce aux valeurs calculées à partir de données thermodynamiques et de constantes d'équilibre pour l'hydratation d'énones et aussi grâce à des évaluations des énergies libres de formation des produits de réaction faites en se basant sur des réactions de dismutations hypothétiques. Lorsque l'on compare les carbonyles nucléophiles avec d'autres nucléophiles qui peuvent s'additionner sur les groupements carbonyles, on trouve qu'ils peuvent être incorporés dans la relation linéaire d'énergies libres de Sander et Jencks avec des valeurs γ de 0.45 pour l'acétaldéhyde, 0.16 pour l'acétone, 0.05 pour l'acétophénone et 3.56 pour l'acide acétique. En se basant sur ces résultats, il est donc possible de prédire les constantes d'équilibre d'un grand nombre de condensations aldoliques en se basant sur la constante d'équilibre pour l'addition de n'importe quel nucléophile sur un composé carbonylé accepteur.

[Traduit par le journal]

Introduction

The aldol reaction is of enormous importance in synthetic organic chemistry, as witness the entire volume of 'Organic Reactions' required to review it (1). Despite this importance and utility, there have been relatively few mechanistic investigations (2–13) and even fewer studies of the equilibrium constants (4, 6, 14) for simple aldol reactions. In part this is the result of the notorious tendency of aldol reactions to yield complex reaction mixtures, with competing reactions, polymerizations and worse confusing the situation. Nonetheless, in view of the utility of this reaction it seemed worthwhile to seek a quantitative understanding of the factors controlling the position of equilibrium for aldol addition reactions. Naturally it would be even more valuable to know the rate constants and the factors controlling them, but that is a more difficult problem, and it seems likely that the equilibrium constants will have to be known if many of the rate constants are to be determined. In any case the aldol reaction is so often determined by thermodynamic rather than kinetic factors that it seems appropriate to report at the present stage, when a set of equilibrium constants have been obtained.

The aldol reaction has been difficult to study in a systematic way because many of the reactions which one would like to investigate are experimentally inaccessible. For instance the reaction of acetaldehyde with acetone in the sense of eq. 1 is not



[1] $CH_3-C(=O)(CH_3) + CH_3-CHO \rightleftarrows CH_3-C(OH)(CH_3)-CH_2CHO$

directly accessible because acetone is relatively unreactive toward carbonyl addition while acetaldehyde reacts readily with itself. In fact a cross product

[1]Alfred P. Sloan Fellow, 1975–1979.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

from the reaction of acetone with acetaldehyde can be obtained (15), but it is the product of reaction in the sense of eq. 2. Similar problems render it diffi-

[2] $CH_3-\underset{\underset{CH_3}{|}}{C}=O + CH_3-CHO \rightleftarrows CH_3-\overset{\overset{O}{||}}{C}-CH_2-\overset{\overset{OH}{|}}{CH}-CH_3$

cult if not impossible to measure equilibrium constants for numerous other simple aldol reactions. Yet another problem which can arise, particularly for aromatic carbonyl compounds, is favorable dehydration of the initially formed aldol product, so that the only observable product of reaction is the enone. For these reasons it will be very difficult to augment, by direct measurement of equilibrium position, the very limited set of equilibrium constants presently available.

A number of further values may be determined by making use of thermochemical data for the enones and the corresponding carbonyl precursors, together with experimental values for the dehydration equilibrium constants, measured under conditions where retroaldol reaction is not a problem. This approach was employed for the aldol condensation of acetaldehyde with itself to give an estimate of the equilibrium constant, which turned out to be measurable by indirect experiments (4).

Still more values may be determined by estimating the free energies of formation of the aldol products by a method which is equivalent to Benson's additivity of group contributions (16, 17) procedure but which avoids the problem of cumulative error from a large number of parameters as the molecular size increases.

In these various ways a complete set of equilibrium constants for the reactions of each of four carbonyl compounds acting as nucleophiles adding to each of five carbonyl compounds acting as acceptor could be obtained. This represents the first systematic study of the effects of structure upon equilibrium for the aldol reaction. Possession of these data permits a recognition of the relative importance of structural variation in the carbonyl acceptor and the carbonyl nucleophile upon the equilibrium constant.

Sander and Jencks (18) have introduced a linear free energy relation for additions to carbonyl compounds of alcohols, thiols, amines, hydrogen cyanide, and bisulfite as nucleophiles. I wish to report that this relationship can be extended to the aldol reaction, and that self-consistent values of γ, the parameter describing the tendency for a nucleophile to add to a carbonyl compound, can be evaluated for acetaldehyde (4), acetone, acetophenone, and acetic acid. The approach used here could in principle be extended to other nucleophiles.

Results and Discussion

The equilibrium constants for the aldol formation and dehydration reactions considered here are collected in Table 1. Details concerning the evaluation of these equilibrium constants, where they were not directly obtainable from the literature, are presented in the Experimental section and the Appendix. Although the obtention of these represented a major effort, discussion of the methods here would be needlessly distracting: full details of the calculations are contained in the Appendix. The equilibria are:

[3] $CH_3CO-R_1 + R_2-CO-R_3 \overset{K_1}{\rightleftharpoons} R_2R_3C(OH)-CH_2-CO-R_1 \overset{K_2}{\rightleftharpoons} R_2R_3C=CH-CO-R_1$

where K_1 and K_2 are apparent equilibrium constants expressed in terms of total concentrations of each compound, with no correction for the presence of covalent carbonyl hydrates. This effect is most important for formaldehyde, where the carbonyl form is present in only minor amounts. Values of the K's are given only where they have been measured experimentally. It should be noted that there are only four experimental values for K_1 and that three of these are indirect values, calculated from the rate constants for the forward and reverse reactions. For equilibria where the free energy change was evaluated indirectly from free energies of formation, only the ΔG value is given, with an estimated uncertainty derived from an error analysis of the calculations. For acrylic, crotonic, and senecioic (dimethylacrylic) acids the values reported represent the results of long extrapolations from values at higher temperatures; the uncertainties are accordingly large. For the other experimentally determined values an arbitrary value of 0.1 kcal/mol has been taken as the uncertainty.

It had been hoped that benzophenone, the sixth of the fundamental types of carbonyl compounds, could have been included in the table, but the necessary data were not available. The only relevant equilibrium constant is an indirectly evaluated value for hydration of 3,3-diphenylacrylic acid (19).

In Table 2 are collected equilibrium constants for the addition of nucleophiles to carbonyl compounds. For all but formaldehyde Table 2 is essentially a complete list of the available data. For acetaldehyde a few additional amines have been studied (20) but γ values are not available. For formaldehyde numerous other nucleophiles have been studied; the values are

summarized in ref. 18 and will not be repeated here, but will be employed in Fig. 1, and for calculations based upon it.

Equilibrium constants for aldol addition reactions to formaldehyde, acetaldehyde, benzaldehyde, and acetone and acetophenone are taken from Table 1, but have been corrected for symmetry effects, and also for the effects of hydration of reactants and products. There appear to have been no studies of the covalent hydration of the carbonyl group in β-hydroxy aldehydes; the equilibrium constants were estimated using the ρ* value reported by Greenzaid *et al.* (21). Equilibrium constants determined experimentally are given to two significant figures; those derived from thermodynamic calculations are only given to one.

Equilibrium constants[2] for addition reactions other than aldols were fitted to [4] by least squares

$$[4] \qquad \log (K_{HNu}/K_{H_2O}) = \Delta \cdot \Gamma$$

where $\Gamma = \gamma_{HNu} - \gamma_{H_2O}$. This formulation appears to have several advantages over that originally proposed by Sander and Jencks (18). (*a*) It makes addition of water the reference reaction, with water the reference nucleophile; since equilibrium constants for hydration of carbonyl groups can be obtained, either by direct measurement or indirectly by extrathermodynamic calculations (22, 23) for *all* carbonyl compounds, this constitutes a more con-

[2]K_{H_2O} is the equilibrium constant for the reaction $R_2R_2CO + H_2O = R_2R_2C(OH)_2$ and has the dimensions M^{-1}.

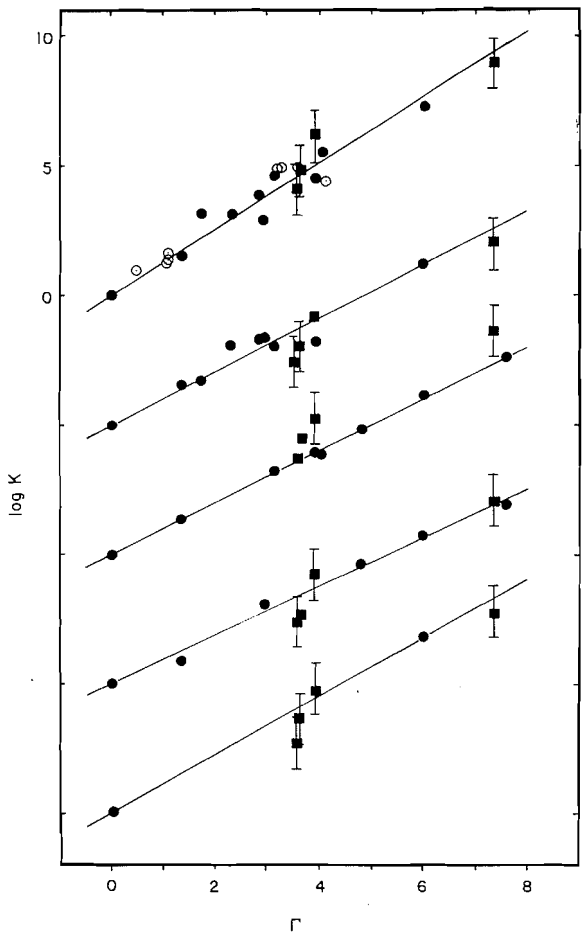

FIG. 1. Relationship between the logarithm of $K_{rel} = K_{HNu}/K_{H_2O}$ and $\Gamma = \gamma_{HNu} - \gamma_{H_2O}$. (●) data from Table 2; (○) data from Table IV of ref. 18; (■) aldol reactions. To avoid overlapping, the data for successive compounds are displaced down by five log units. The carbonyl compounds are, reading down from the top, formaldehyde, acetaldehyde, benzaldehyde, acetone, and acetophenone. Error bars are shown for equilibrium constants derived from thermochemical data.

venient reference point. (*b*) By using relative equilibrium constants, which are in effect equilibrium constants for reaction 5, it focuses attention on the

[5] $R_1R_2C(OH)_2 + HNu \rightleftharpoons R_1R_2C(OH)Nu + H_2O$

fact that obedience to [4] (or the original equation of Sander and Jencks (18)) is *not* dependent upon structural effects in the carbonyl compound, but only upon the effects of the nature of R_1, R_2, and Nu upon the ease of replacement of OH by Nu.

Γ values for the carbonyl compounds as nucleophiles were then calculated from these graphs, with uncertainties related to the error limits in the equilibrium constants for the aldol reactions, and the weighted average values for the Γ values were calculated. These led to the γ values reported in Table 2. Finally equilibrium constants for aldol additions to benzophenone were estimated from the Γ values for the carbon nucleophiles and K_{H_2O}, assuming that the slope for benzophenone was the same for acetone. This led to the values found in Table 2, which are all unfavorable, in agreement with expectation, in view of the normal unreactivity of benzophenone.

The slopes for these lines were respectively 1.22, 1.06, 1.02, and 0.92 for formaldehyde, acetaldehyde, benzaldehyde, and acetone. With data extending over a narrower range (since *K* for HCN was not available then) Sander and Jencks (18) concluded that the formaldehyde data were best represented by two lines of unit slope, one for oxygen and sulfur nucleophiles, the other for nitrogen nucleophiles. To the present author it appears preferable to regard the data as giving a less than ideal fit to a single line.

It is interesting to note that the γ values for $CH_3CO—Z$ increase with increasing electronegativity of Z as measured by σ*. It is also noteworthy that for Z = H, CH_3, or C_6H_5, the variation in γ is very small, and that the variation in equilibrium constant for aldol equilibrium is due almost entirely to variations in the nature of the carbonyl group acting as electrophile.

Equilibrium constants have been derived for acetic acid as nucleophile, because free energies of formation of the aldol addition products were accessible. Esters are much more commonly utilized since base catalyzed reactions are feasible; although no information is available at present, it seems reasonable to expect that the values for methyl or ethyl acetate should be similar to those found for acetic acid.

Conclusions

(*1*) The linear-free energy relationship of Sander and Jencks (18) can be extended to include aldol reactions; thus the equilibrium constant for any unknown aldol reaction can be estimated from that for addition of any nucleophile, such as water or HCN, to the carbonyl acceptor and the γ value of the carbonyl nucleophile; since the latter shows little variation for aldehydes or ketones, it may be possible to estimate it without serious error.

(*2*) Since it appears to be possible in many cases to estimate free energies of formation of the enone products by methods related to Benson's Group Additivity scheme, it should be possible to estimate the equilibrium constant for an overall aldol condensation even where no addition equilibria have been studied, provided that there are no severe steric interactions. Molecular mechanics calculations are rapidly approaching the point (24–26) where this limitation will be overcome.

Experimental

Materials

Benzalacetone was recrystallized; mp 37°C; lit (27) mp 42°C. Cinnamaldehyde and acrylic acid were distilled in vacuum before use; 3-penten-2-one was distilled under nitrogen. Acrelein was distilled under nitrogen immediately before use.

Solubility Determinations

3-Penten-2-one was shaken repeatedly with p*H* 7 phosphate buffer ($\mu = 0.1$) containing 0.103 *N tert*-butanol and allowed to stand at 25°C. A sample of the aqueous layer was analyzed by nmr, integrating the signals from the ketone methyl groups relative to the *tert*-butyl groups of the standard; the solubility was 1.15 *M*.

Cinnamaldehyde was stirred with p*H* 7 phosphate buffer at 25°C; a sample of the aqueous layer was diluted 1000-fold with buffer and analyzed by uv spectroscopy. It was important not to stir for too long, or oxidation of the aldehyde would lead to spuriously high absorbances (and a shift of the maximum to lower wavelength). Replicate determinations based on λ_{max} 285, using $\varepsilon = 22\,900$ (28) led to a solubility of 0.015 *M*.

Benzalacetone was stirred several hours with p*H* 7 phosphate buffer, allowed to stand at 25°C, and analyzed as for cinnamaldehyde; based on λ_{max} 287, using $\varepsilon = 20\,900$ (29) the solubility was 0.0091 *M*.

Heat of Solution

Heats of solution were measured using the calorimeter and technique described previously (30), with 0.1 *N* HCl as the solvent. The heats of solution were -1.35 ± 0.04 kcal/mol for acrolein, and $+0.14 \pm 0.03$ kcal/mol for acrylic acid.

Appendix: Thermodynamic Calculations

Free Energies of Transfer, From Activity Coefficients at Higher Temperatures

It frequently happens that activity coefficients, which are equivalent to transfer from dilute solution to the gas phase, are available at the boiling point of the solvent, but not at room temperature. This is a particularly serious problem for small molecules in aqueous solution, because direct determination of the activity coefficient at room temperature is experimentally demanding, and correction of the value at 100 to 25°C is complicated by the fact that the enthalpy of transfer will be a function of temperature. Although for many solvents the variation in the enthalpy of transfer from 100 to 25°C might well be negligible, this is almost certainly not the case for aqueous solutions, because of the well known large changes in partial molar heat capacity upon transfer from gas to water for organic molecules (31). Fortunately it has recently been found (32) that the partial molar heat capacity of organic compounds in aqueous solution can be estimated with useful accuracy by additivity methods, and it has been known for some time that the heat capacity of gaseous compounds can be estimated quite easily (16, 17). Therefore it is possible to calculate $\Delta C_{p_t} = \overline{C_{p_2}} - C_p(g)$. The values so obtained for acrolein, acrylic acid, and methyl vinyl ketone are: $\overline{C_{p_2}}$, $C_p(g)$, ΔC_{p_t}; 58.8 ± 3.3, 16.44 ± 0.5, 42.4 ± 3.5; 45.2 ± 3.3, 19.3 ± 0.5, 25.83 ± 3.5; 85.1 ± 3.3, 28.6 ± 0.5, 56.5 ± 3.5.

The enthalpy of transfer at 25°C can be determined from the heat of solution and the heat of vaporization. The heat of vaporization of acrolein is 6.9 kcal/mol (33); that for acrylic acid is 11.21 kcal/mol (34). The heats of solution were measured in this work and are −1.35 ± 0.04 and +0.14 ± 0.03 kcal/mol, respectively.

The equation used for free energy of transfer as a function of temperature is:

$$\frac{\Delta G_t^T}{RT} = \frac{\Delta G_t^0}{R\theta} - \frac{\Delta H_t^0}{R}\left(\frac{1}{\theta} - \frac{1}{T}\right) - \frac{\Delta C_{p_t}^0}{R}\left(\frac{\theta}{T} - 1 + \ln\frac{T}{\theta}\right)$$

where θ is the reference temperature, here 298 K, ΔG_t^0, ΔH_t^0, and $\Delta C_{p_t}^0$ are the values at the reference temperature, and ΔG_t^T is the observed value at temperature T. This equation can now be solved for ΔG_t^0, the only unknown. This was done for acrolein and acrylic acid starting with activity coefficients at 100°C from refs. 75 and 76 respectively. For methyl vinyl ketone, activity coefficients were available at two temperatures, 325.7 and 358.8 K (77), and no heat of vaporization appears to have been reported. Accordingly it seemed preferable to use the known values of ΔG_t^T and $\Delta C_{p_t}^0$ and solve for ΔG_t^0 and ΔH_t^0: this led to values of -3.07 and -13.48 respectively.

Free Energy of Formation of Methyl Vinyl Ketone

Although no value for the heat of formation has been reported, the free energy of formation may be estimated as follows. The free energy change for the reaction

[6] 
1 2 3 4

was determined in benzene (35), and found to be $\Delta G^0 = -0.45 \pm 0.05$ kcal/mol. Since the functional groups in starting materials and products are very similar, any differences in free energies of transfer from benzene to the gas phase must arise from interactions between functional groups perturbing the solvation forces; for benzene as solvent these perturbations should be small.

The free energy of formation of methyl ethyl ketone is known; -34.91 kcal/mol (34). Free energies of formation for the acetals may be calculated from the group contributions reported by Benson (17). However it is necessary to assume that $[C(C)_2(O)_2]$ is the same as $[C(C)(C_d)(O)_2]$ since the latter value is unknown. This approximation is usually good (36) but may introduce an extra error of 1 kcal/mol in the final value. The values so estimated for **1** and **3** are -48.37 ± 1.57 and -27.18 ± 1.86 kcal/mol respectively. (Errors of 1.5 kcal/mol in ΔH_f^0, 1.5 eu in S^0 and an additional error of 1.0 kcal/mol for the above assumption were used.)

These values lead to a free energy of formation in the gas phase for methyl vinyl ketone of -13.27 ± 2.43 kcal/mol.

No value for the group contribution $[CO(C)(C_d)]$ is available, and this group is not necessarily similar to known groups such as $CO(C)_2$ because there is π overlap between CO and C_d.

Calculation of Free Energies of Formation in Aqueous Solution by Disproportionation

Initially free energies of the enone products of aldol condensations were calculated by straightforward application of Benson's Group Additivity scheme (17), using Hine's group contributions (37) to calculate free energies of transfer. However, it became clear on working with these values that for the larger enones the cumulative effect of small errors in each of the many parameters required to calculate the free energy of formation had led to unacceptably large errors in the final values. It has been possible to overcome this problem, by taking advantage of the central concept of group additivity, but performing calculations which make more direct use of experimental values. If group additivity is correct, then the free energy change for the disproportionation reaction 7 must be zero (provided that

[7] $R_1R_2C{=}CH{-}CO{-}R_3 + R_4R_5C{=}CH_2 \rightleftharpoons R_4R_5C{=}CH{-}CO{-}R_3 + R_1R_2C{=}CH_2$

one has corrected for any change in symmetry number or steric interactions). This can be tested for those cases where free energies for all four components are available; the observed free energy changes are found in Table 6, along with the uncertainties in these free energy changes, based upon the error limits on the free energies of formation of the reactants. Only absolute values of the free energy change are considered, since the direction of the disproportionation is arbitrary. The weighted average value of the free energy change for reaction 7 is taken as the error which would be introduced in a free energy calculated by assuming that the free energy change for any such disproportionation is zero. The value so found is 1.4 kcal/mol which is not much larger than the uncertainty in many experimental free energy values (and is smaller than some). Accordingly, this approach is considered to be valid, and was used to calculate the free energies of formation found in Table 5; error limits were calculated from the errors in the three experimental values, and the error calculated above for the assumption of zero free energy change for disproportionation.

A similar approach was used to calculate the free energies of the hydroxy carbonyl products of aldol addition. In this case there was no possibility of calculating the free energies by direct application of group additivity, because there are no parameters

available to account for the interaction between the hydroxyl and the carbonyl. The disproportionation reaction is:

[8] $R_1R_2C(OH)—CH_2CO—R_3 + R_4R_5C(OH)CH_3 \rightleftharpoons$

$R_4R_5C(OH)—CH_2—CO—R_3 + R_1R_2C(OH)CH_3$

The assumption that the free energy change for this hypothetical reaction is zero can be tested as before; the results of applying this test to the available data from Table 3 are found in Table 6. The weighted average value for the deviation from zero is 0.53 kcal/mol. Values for free energies of formation calculated by means of the disproportionation assumption are found in Table 5.

Although the enthalpy of formation of 1,1-diphenylethylene is known (38), and the free energy of formation in aqueous solution can be calculated, examination of space filling models suggested that severe steric interactions would force the phenyl groups to twist out of conjugation to a greater extent in the enones with $R_4 = R_5$ = phenyl than in 1,1-diphenylethylene, and therefore would introduce a large and unknown error if the disproportionation assumption were applied. No value for the equilibrium constant for hydration of 1,1-diphenylethylene is available; under conditions where acid catalyzed equilibration is possible, side reactions intervene (39).

Calculation of Equilibrium Constants for Hydration of Benzaldehyde, Acetophenone, and Benzophenone

Direct measurement of these equilibrium constants has not been possible, even for benzaldehyde, for which hydration should be most favorable. It is possible to calculate values indirectly by taking advantage of an extrathermodynamic relation linking acetal formation and hydration. It has been shown that for reaction 9 the free energy change can be

[9] $R_1R_2R_3C—OR_4 + H_2O \rightleftharpoons R_1R_2R_3C—OH + R_4OH$

calculated, taking account of the electronic effects of the substituents on the central carbon, and any steric or symmetry effects (23). By doing this twice the equilibrium constant for the hypothetical reaction converting acetal to carbonyl hydrate can be calculated, and from this and the equilibrium constant for acetal formation, the equilibrium constant for hydration can be calculated.

For benzaldehyde and acetophenone, the equilibrium constants for dimethyl acetal formation have been reported (40, 41); then by the methods just described it is straightforward to calculate the equilibrium constants for hydration. For benzaldehyde an independent check is available. Greenzaid (42) has measured the equilibrium constant for the addition of hydroxide ion to benzaldehyde, and by estimating

[a]For the hypothetical reactions and as discussed in the text, in aqueous solution at 25°C.
[b]Absolute value of the free energy charge, calculated from the free energies of formation in Table 3; kcal/mol.

the acidity of the hydrate, estimated that the equilibrium constant for hydration was $2.0 \times 10^{-4}\ M^{-1}$.

No direct measurement of the equilibrium constant for formation of an acetal from benzophenone has been reported, but Pfeiffer and Adkins (43) have equilibrated both benzophenone and acetophenone with triethyl orthoformate, which permits calculation of the equilibrium constant for formation of the acetal of benzophenone (subject to the approximation that the mole fraction equilibrium constants for the methyl and ethyl acetals will be the same; see ref. 23 for data supporting this assumption). The

equilibrium constant for hydration of benzophenone may then be calculated as above.

Correction of Equilibrium Constants for Aldol Addition Reactions

In order to be simply interpretable, equilibrium constants should refer to a single process; aldol additions involving aldehydes as starting material and products are complicated by covalent hydration of the aldehyde carbonyl groups. For the starting materials the correction is straightforward, since the hydration constants are known. The true equilibrium constant is more favorable by a factor of $1 + K_{\text{hydration}}$. For product aldehydes the correction is less facile, since there appear to have been no studies of the extent of covalent hydration of the aldols considered here. Accordingly it has been necessary to estimate the equilibrium constants for hydration, making use of the linear free energy relation reported by Greenzaid *et al.* (21). Propanal was used as a reference point, and its known hydration constant (21) was corrected using ρ^* (21) and σ^* values estimated as follows. It was assumed that

$$\sigma^*(R_1R_2C(OH)\text{—}CH_2) = \sigma^*(CH_2(OH)\text{—}CH_2) + \sigma^*(R_1CH_2CH_2) + \sigma^*(R_2CH_2CH_2) - 2\sigma^*(CH_3CH_2)$$

Then from the σ^* values reported for CH_3CH_2—, $HOCH_2CH_2$—, $CH_3CH_2CH_2$—, and $PhCH_2CH_2$— (44) (σ^* for $HOCH_2CH_2$ was estimated from the value for $HOCH_2$ using a fall off factor of 0.36 (45)) the necessary values were calculated.

Where necessary symmetry corrections were made to the equilibrium constants reported in Table 2. Since all the carbonyl nucleophiles have a methyl group, the values were not corrected for the number of hydrogens; thus the equilibrium constants are per methyl and not per hydrogen. However it was necessary to correct the values for acetone as nucleophile for the presence of two equivalent methyls. Similarly it was necessary to correct the values for self-condensations by a factor of two.

Crystal structure of dibromotetraethylthiuramdisulfidemercury(II)

CHUNG CHIEH

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2M 3G1

Received November 24, 1977

CHUNG CHIEH. Can. J. Chem. **56**, 974 (1978).

Dibromotetraethylthiuramdisulfidemercury(II) is one of the products of the reaction between mercury(II) bromide and tetraethylthiuram disulfide (TETD). The crystals are orthorhombic with $a = 13.050(5)$, $b = 13.593(7)$, $c = 22.373(12)$ Å; space group *Pbca*. The compound is isostructural with the iodo analogue. The final R factor using 1421 observed reflections is 0.10. Mean bond lengths are: Hg—Br = 1.504(6) Å, Hg—S = 2.66(1) Å. The coordination geometry for mercury(II) is tetrahedral.

CHUNG CHIEH. Can. J. Chem. **56**, 974 (1978).

Le dibromotétraéthylthiuramdisulfure de mercure(II) est un des produits de la réaction entre le bromure de mercure(II) et le disulfure de tétraéthylthiurame (TETD). Les cristaux sont orthorhombiques avec $a = 13.050(5)$, $b = 13.593(7)$, $c = 22.373(12)$ Å; groupe d'espace *Pbca*. Le composé est isostructural avec l'analogue iodé. Le facteur d'accord R, utilisant 1421 réflexions observées, est de 0.10. Les longueurs moyennes des liaisons sont Hg—Br = 1.504(6) Å, Hg—S = 2.66(1) Å. La géométrie de coordination du mercure(II) est tétraédrique.

Introduction

Mercury(II) halides react with tetraethylthiuram disulfide (TETD) in many ways (1, 2). In the reaction between mercury(II) bromide and TETD, both pale yellow and colorless crystals were obtained. TETD was reduced to form a dithiocarbamato complex in the pale yellow crystal (3). Colorless crystals are now confirmed to be dibromotetraethylthiuramdisulfidemercury(II), $HgBr_2$·TETD. This compound is isostructural with diiodotetraethylthiuramdisulfidemercury(II), HgI_2·TETD (4).

Based on nmr results, it was reported that mercury(II) halides form stable complexes with *N,N,N',N'*-tetraalkylthiuram sulfides (5). To date, only the structures of HgI_2·TETD, diiodotetramethylthiuramdisulfidemercury(II) (HgI_2·TMTD) (6), and diiodotetramethylthiurammonosulfidemercury(II) (HgI_2·TMTM) (7) were determined by X-ray methods. This paper reports the first X-ray structural analysis carried out for a complex formed between mercury(II) bromide and a tetraalkylthiuram di- or mono-sulfide.

Experimental

The compound $HgBr_2$·TETD was prepared along with mercury(II) bromide dithiocarbamate $\{HgBr_2(S_2CNEt_2)Hg(S_2CNEt_2)\}_n$ by experimental procedure already published (3). The crystals are colorless plates. The space group was determined from X-ray photographs. Cell constants were refined from the 2θ (Mo-Kα) values of 19 reflections measured on a G.E. XRD-6 diffractometer. Crystal data are as follows.

$C_{10}H_{20}Br_2HgN_2S_4$ fw = 656.9

Orthorhombic, $a = 13.050(5)$, $b = 13.593(7)$, $c = 22.373(12)$ Å; space group *Pbca*. $D_m = 2.20(5)$, $Z = 8$, $D_c = 2.198$ g cm^{-3}. μ(Mo-Kα) = 125 cm^{-1}. Systematic absences: $0kl$, $k = 2n + 1$, $h0l$, $l = 2n + 1$, $hk0$, $h = 2n + 1$. λ(Mo-Kα) = 0.7107 Å.

The crystal used for data collection was approximately a square plate of 0.18 × 0.18 × 0.10 mm^3 along the *a*, *b*, and *c* directions. It was mounted diagonally with [110] parallel to the φ axis. Among 4549 reflections with $2\theta < 55°$ measured by the stationary-crystal stationary-counter method, only 1420 had intensities greater than the background by $3\sigma(I)$. Few of the 2930 reflections with $40° < 2\theta < 55°$ were observed. The intensities of four reflections used for a stability standard decreased by 9% at the end of data collection. X-ray photographs of $HgBr_2$·TETD and HgI_2·TETD were similar and the atomic coordinates of the latter were used as a trial model. Full-matrix least-squares methods were used to refine the structure. Anisotropic temperature factors were given to Hg, Br, and S atoms. At the final stages, a weighting scheme,

$w^{-1} = 70 - F_o + 0.001F_o^2$, was used. The final maximum parameter shifts were 0.5σ. The final R $(= \Sigma||F_o| - |F_c||/\Sigma|F_o|)$ and R_w $((\Sigma w^2(|F_o| - |F_c|)^2/\Sigma w^2 F_o^2)^{1/2})$ for 1420 observed reflections were 0.10 and 0.11 respectively. The final parameters are given in Table 1.[1]

Results and Discussion

The bond distances and angles are given in Fig. 1. The atomic numbering system is the same as that of HgI_2·TETD. A unique feature for $HgBr_2$·TETD is that the two Hg—S distances are equal, 2.66(1) Å. However, in HgI_2·TETD, HgI_2·TMTD, and HgI_2·TMTM, the two Hg—S bonds in each case are significantly different. A comparison of these distances is shown in Table 2. The differences in Hg—I distances for HgI_2·TMTD and HgI_2·TMTM are 0.007 and 0.16 Å respectively, whereas Hg—X values are identical for the two TETD complexes. No trend in the variation of ∠XHgX can be found from Table 2. Aside from HgI_2·TMTM, values are similar. The angles ∠SHgS are limited by the bites of the ligands and $HgBr_2$·TETD has the largest value, 98.5°. Among the four compounds, the coordination geometry for mercury(II) shows the least deviation from tetrahedral in $HgBr_2$·TETD. A satisfactory condition in which to prepare $HgCl_2$·TETD has yet to be found.

Due to the shape of the crystal used in data collection and a slightly higher absorption coefficient in $HgBr_2$·TETD than HgI_2·TETD, the R factor in the present structure was only 0.10. The intensities were collected a year ago. Now, that crystal has become deep brown and some small crystals have grown on the surface at the expense of the original single one.

In all four tetraalkylthiuram sulfide complexes, the structures comprise discrete molecules and van der Waals intermolecular contacts are expected.

Resonance Raman in platinum phthalocyanine[1]

TZER-HSIANG HUANG, KLAUS E. RIECKHOFF, AND EVA-MARIA VOIGT

Departments of Physics and Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received June 27, 1977

TZER-HSIANG HUANG, KLAUS E. RIECKHOFF, and EVA-MARIA VOIGT. Can. J. Chem. **56**, 976 (1978).

The resonance Raman spectra and excitation profiles of platinum phthalocyanine (PtP_c) in α-chloronaphthalene (α-ClN) and in mixtures of α-ClN and *n*-octane were obtained at 295 K with excitation from 660 to 570 nm covering the total lower energy absorption region of PtP_c. Eighteen fundamentals and overtone-combinations were observed. Our data show that the third absorption maximum of PtP_c in the visible region is actually the (0–1), but not the (0–2) as previously interpreted, transition. The (0–1) bands in the excitation profiles of most resonance-enhanced-vibrations were found to be more intense and frequency shifted compared with their counterparts in absorption. Based on the depolarization ratios, we deduced the symmetry of PtP_c in α-ClN in the excited singlets to be D_{2h}, C_{2v}, or D_2; no differences were found in the mixed solvents. The small Stokes loss observed in the absorption spectra, as well as the absence of the (0–2) maxima in the excitation profiles, indicate that the equilibrium position of the first excited singlet is only slightly different from that of the ground state.

TZER-HSIANG HUANG, KLAUS E. RIECKHOFF et EVA-MARIA VOIGT. Can. J. Chem. **56**, 976 (1978).

On a déterminé les spectres de résonance Raman et les profils d'excitation du phtalocyanure de platine (PtP_c) dans α-chloronaphtalène (α-ClN) et dans des mélanges d'α-ClN et d'octane à 295 K avec une excitation allant de 660 à 570 nm couvrant toute la région d'absorption de basse énergie du PtP_c. On a observé 18 bandes fondamentales et de combinaisons harmoniques. Nos données montrent que le troisième maximum d'absorption de PtP_c dans la région visible correspond en fait à la transition (0–1) plutôt que la transition (0–2) qui avait été suggérée antérieurement. On trouve que les bandes (0–1) de la plupart des vibrations qui sont augmentées en intensité par résonance dans les profils d'excitation sont plus intenses et plus déplacés que les bandes d'absorption équivalentes. En se basant sur les rapports de dépolarisation, on a pu déduire que la symétrie de PtP_c dans α-ClN dans des singulets excités est D_{2h}, C_{2v} ou D_2; on n'a pu trouver aucune différence dans les solvants mixtes. La petite perte de Stokes observée dans le spectre d'absorption de même que l'absence de maxima (0–2) dans les profils d'excitation indiquent que la position d'équilibre du premier singulet excité ne diffère que légèrement de l'état fondamentale.

Introduction

We present in this paper the first detailed investigation of the Raman spectrum of a metalphthalocyanine (metal P_c) complex in solution. The phthalocyanines (P_c's) are used commercially as dyes and as Q-switches for lasers; they are, as well, molecules related to the biologically important porphyrins. For the reader unfamiliar with these molecules, we show the general structure of a metal P_c in Fig. 1. In our study the central metal is Pt. While the Raman spectra of the porphyrins have been studied extensively, this has not been the case for the P_c's, largely because of their extremely low solubility in all common solvents, and even the few usable solvents (such as α-chloronaphthalene, and quinolene) are far from satisfactory for Raman studies (typically 10^{-4} *M* or less). Therefore it was evident that resonance Raman scattering would be the most favourable experimental method to employ even though a number of the light metal (filled shell) P_c's fluoresce very efficiently. Thus, we chose for our study PtP_c in α-ClN (as well as in mixed solvents) partly because of its very low fluorescence yield. Furthermore, our previous extensive energy transfer studies of the P_c's (1) and especially the low temperature electronic relaxation behaviour of PtP_c (2), together with our

recent observation of the Shpol'skii effect for this molecule in mixed solvents[2] raised the question whether the molecular species in the solid solution of α-ClN and that in mixed matrices of α-ClN and *n*-octane were the same or not.

Moreover, in our theoretical analysis of all known relaxation data on the P_c's (3) it was necessary to assume a crystal field perturbation in the excited electronic state distorting the molecular symmetry from D_{4h}, which so far has been the generally accepted symmetry for the metal P_c's. The resonance Raman data of this study show also that the molecular structure of PtP_c in the excited singlets in solution is not completely D_{4h}, but has a slight distortion to lower symmetry, D_{2h}, C_{2v}, or D_2.

Experimental

The PtP_c used in this work was purified by repeated recrystallization from the commercial product—the main purpose was to remove metal free phthalocyanine (H_2P_c) whose strong fluorescence would otherwise have seriously interfered with the resonance Raman signal. The technical grade α-ClN was distilled before use which was not necessary for the chromotographic grade *n*-octane. Data were obtained in neat α-ClN and mixed solvent (one part α-ClN plus three parts or more *n*-octane). The overall concentrations of PtP_c in both solvent systems were 10^{-4} to 10^{-5} *M*, or sometimes less. The extinction coefficient for the α-ClN solution is $10^{4.86}$ at the main absorption maximum (1), and almost the same in the *n*-octane mixture. Several guidelines helped to show that the samples were pure enough for our purpose: first, the emission spectra of the α-ClN solution at 77 K showed only a single phosphorescence maximum around 940 nm, plus a very weak residual H_2P_c fluorescence. Furthermore, when PtP_c is incorporated in the rigid matrix of the mixed solvent at 77 K, band widths in absorption and emission become less than 8 cm^{-1} (this is called the Shpol'skii effect) and we observed no impurity in fluorescence, except the residual H_2P_c, or phosphorescence. Second, all the excitation profiles (*vide infra*) agree with the PtP_c absorption spectrum. Third, we found that in the Shpol'skii experiments the excitation profiles also agreed with the PtP_c absorption.

Photodecomposition occurred in both solvent systems under strong excitation (greater than 200 mW). This was suppressed significantly but not completely when the sample was placed in a rotating cell. We have paid particular attention to this when we were recording and analyzing the data. Incidentally, removing oxygen from the solutions did not help to any detectable extent.

The resonance Raman data were all obtained with the direction of observation perpendicular to the incident polarization. Light source was the jet stream dye (R6G) laser pumped by Ar^+ laser, both of coherent radiation. Laser power used ranged from 50 to 200 mW. Both the polarized and unpolarized resonance Raman signal were scrambled before entering the Spex Industries ½ m double monochromator. The depolarization ratios (ρ_l's) were measured with a sheet polarizer between the scrambler and the sample. The signal was finally detected by the ITT FW130 (S 20) photomultiplier tube with photon counting electronics. The total uncertainty in the positions of the resonance Raman bands is better than ± 1.5 cm^{-1} if not otherwise indicated. In Figs. 4–6, the error bars represent intensity uncertainties estimated for each measurement and, sometimes, for repeated measurements, whereas in Figs. 7 and 8 they represent the uncertainty estimated for each measurement.

The enhancements of all resonance Raman vibrations were normalized to the 666 cm^{-1} vibration of α-ClN, whose intensity depends insignificantly on the excitation used since α-ClN does not absorb in the visible. No corrections were made for the chromophore absorptions, i.e. the PtP_c absorptions at the individual resonance–Raman–Stokes shifts with respect to that at the 666 cm^{-1} shift, and for the responses of the grating (blazing at 5000 Å) and the photomultiplier whose sensitivity increases continuously towards the blue. The absence of these corrections does not affect our results and conclusions since we are not concerned with the absolute intensities, but the relative intensities only.

Results

The Raman spectra of the solvents used in this study, i.e. α-ClN and a mixture of α-ClN and *n*-octane (one part α-ClN and four parts *n*-octane), are shown in Fig. 2. The vibrational bands arising from *n*-octane are indicated in the top trace (B), and α-ClN in trace A′. The vertical arrows give the positions of the resonance Raman bands of PtP_c (shown in Fig. 3). At first sight, it appears that the solvent Raman bands interfere seriously with the resonance Raman bands of PtP_c. That this is not the case can be seen by making band intensity and sometimes band position and shape comparisons (*vide infra*).

The resonance Raman spectra are listed in Table 1 and shown in Fig. 3. We have scanned the Raman Stokes region, 150 to 3000 cm^{-1}, exciting into the main absorption band, and have found no significant signal of PtP_c above 1600 cm^{-1}. Vertical arrows in Fig. 3 point to where most of the α-ClN Raman bands (Fig. 2) are. α-ClN interference occurs at 225, 1145, 1196, 1343, 1358, 1436, and 1458 cm^{-1}. The 225 cm^{-1} band is distinguished from the 220 cm^{-1} band of α-ClN by not only the shift in position, but also the great intensity gain as excitation approaches the absorption maximum (Fig. 4). The weak resonance band at 1196 cm^{-1} is separated from the extremely weak interfering band at 1200 cm^{-1} by more than experimental uncertainty in band position. Furthermore, the intensity of the 1200 cm^{-1} band should be negligible when the 1372 cm^{-1} band of α-ClN is as intense as shown in trace C of Fig. 3. The 1145, 1343, 1358, and 1458 cm^{-1} bands are much stronger than their respective interfering bands at 1143, 1341, 1361, and 1459 cm^{-1} when compared with the very strong 1372 cm^{-1} of α-ClN. That the 1358 cm^{-1} band belongs to PtP_c is also clear from the fact that the 1361 cm^{-1} band should at most

[2]To be discussed in a forthcoming publication.

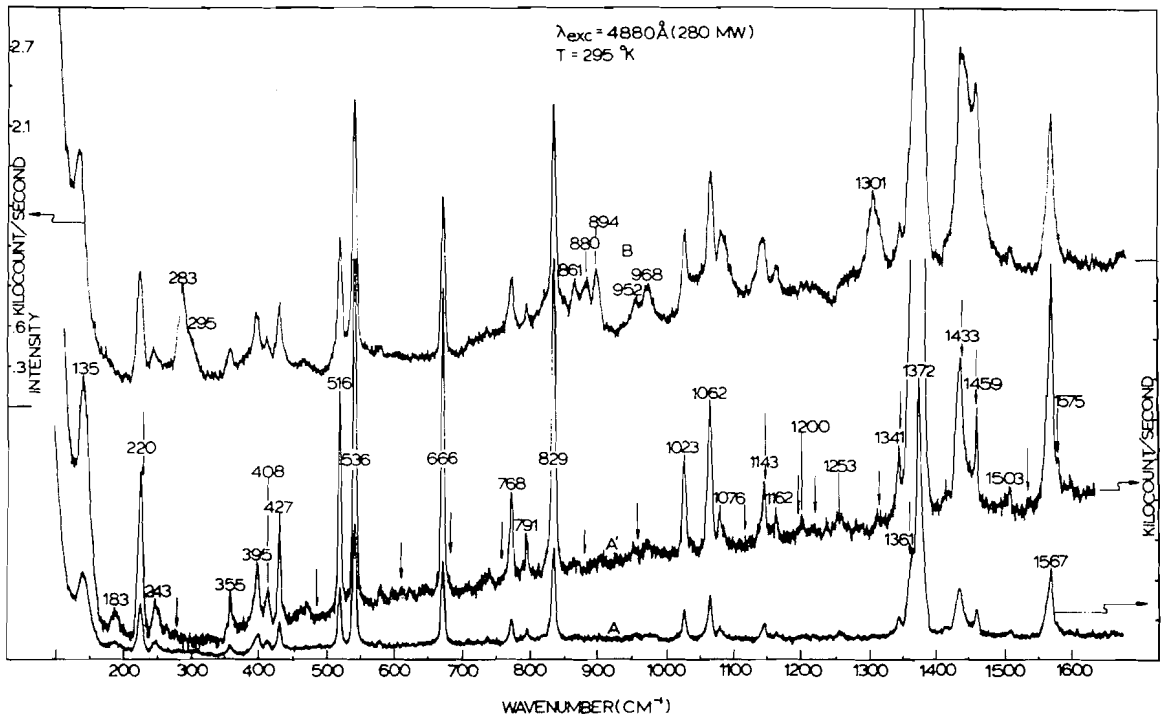

FIG. 2. The Raman spectra of α-ClN (A and A′) and of a mixture of one part α-ClN and four parts *n*-octane (B). The slit widths used for A (full scale 30 kilocount/s), A′ (full scale 3 kilocount/s), and B traces are, respectively, 4, 2.3, and 5.7 cm^{-1}. Vertical arrows indicate the positions of the resonance Raman bands shown in Fig. 3.

appear as the shoulder of the very strong α-ClN band at 1372 cm^{-1}.

Although the 1436 cm^{-1} band has never been completely separated from the interfering 1433 cm^{-1} of α-ClN, we believe it has a PtP_c contribution. First, whenever the peak height ratio of 1433 cm^{-1} to 1372 cm^{-1} becomes larger than 1:5.4 of neat α-ClN (see the bottom spectrum of Fig. 2), the band maximum is shifted towards 1436 cm^{-1} which was observed with 6486 Å excitation. Second, the ratio decreases, although not as rapidly as that of 1458 cm^{-1} to 1372 cm^{-1}, when excitation is moved away from the main absorption maximum (649 nm) of PtP_c. The highest ratio observed with 6486 Å excitation was 1:3.2 when the concentration of the PtP_c was slightly higher than that of trace C, Fig. 3. Third, we have measured the depolarization ratio, in terms of peak height again, of this 1436 cm^{-1} band as a function of excitation in the (0–1) absorption region. It was found to be 0.25 at 5910 Å (approximately the (0–1) absorption maximum), and to decrease slowly to 0.17 (possibly the ρ_l of the polarized 1433 cm^{-1} band of α-ClN) at 5790 Å. Although the difference of these two ratios is not much greater than the experimental uncertainty, it is consistent with the above mentioned two observations.

The weak band at 878 cm^{-1} (trace E, Fig. 3) is attributed to PtP_c for three reasons: one, there is no solvent transition in the vicinity; two, 6190 Å excitation lies near the (0–1) vibronic position for this vibration, and, thus, it should be enhanced; three, the 77 K spectra (which will be reported elsewhere) of the same sample and with the same excitation clearly show this vibration, in addition to several others in the region 1100 to 1300 cm^{-1}.

In Fig. 3 we also show the room temperature fluorescence (broad) and the change in its shift from the excitation line. From traces D and E, along with other excitation, we find its position at 655 ± 1 nm. The strong background in traces A and B is also due to fluorescence which clearly has affected the quality of the resonance Raman spectra and the precision of the data.

The data presented in Figs. 4–6 (excluding the broken traces) were accumulated from many runs. The best curves were drawn through the points by hand. The excitation profile of the 225 cm^{-1} vibration levels off on the short wavelength side as a result of the prevailing 220 cm^{-1} vibration of the solvent. For most of the excitation profiles, there are two maxima corresponding to the (0–0) and the (0–1) transitions. These two transitions are presumably too close to be resolved in the excitation profiles of the 225 and the 275 cm^{-1} vibrations. For

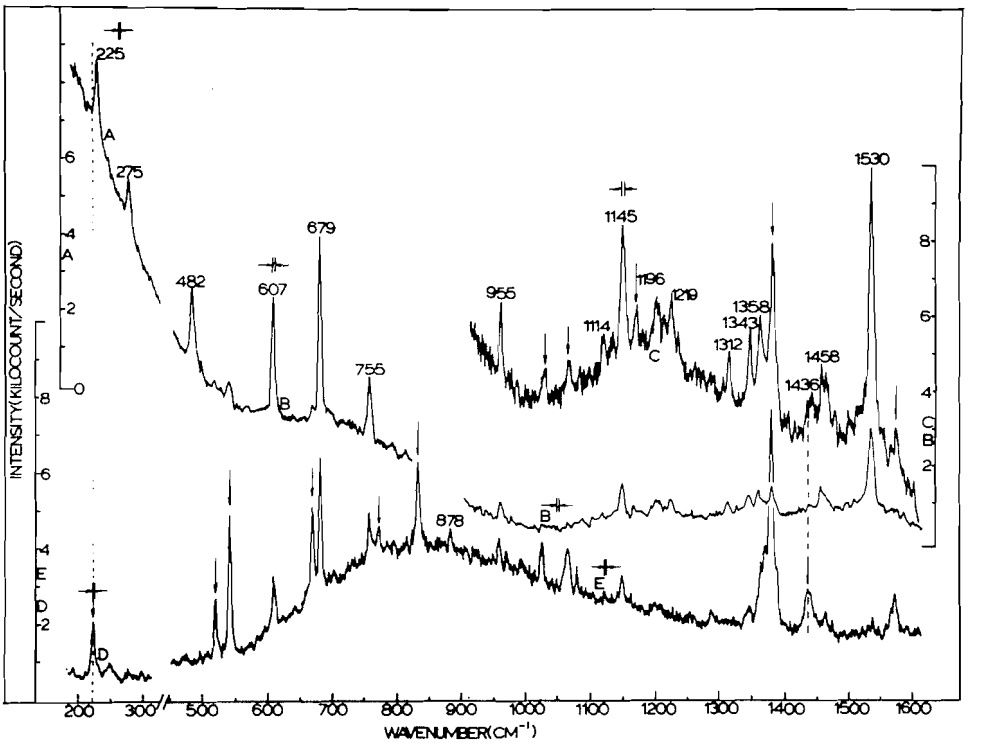

FIG. 3. The resonance Raman spectra of PtP_c in α-ClN at room temperature. Traces A and B were recorded from the same sample, D and E from another sample, C still another. Vertical arrows indicate most of the α-ClN Raman bands shown in Fig. 2. Slit widths used are indicated next to the spectra recorded. The spectrum-recording conditions were, for trace A, λ_{exc} = 6490 Å (100 mW), full scale 3 kilocount/s, slit = 2.6 cm^{-1}; for trace B, λ_{exc} = 6490 Å (100 mW), 3 kilocount/s, slit = 3.7 cm^{-1}; trace C, λ_{exc} = 6486 Å (200 mW), 1 kilocount/s, slit = 3.3 cm^{-1}; trace D, λ_{exc} = 6220 Å (150 mW), 1 kilocount/s, slit = 2.2 cm^{-1}; trace E, λ_{exc} = 6190 Å (150 mW), 1 kilocount/s, slit = 2.2 cm^{-1}.

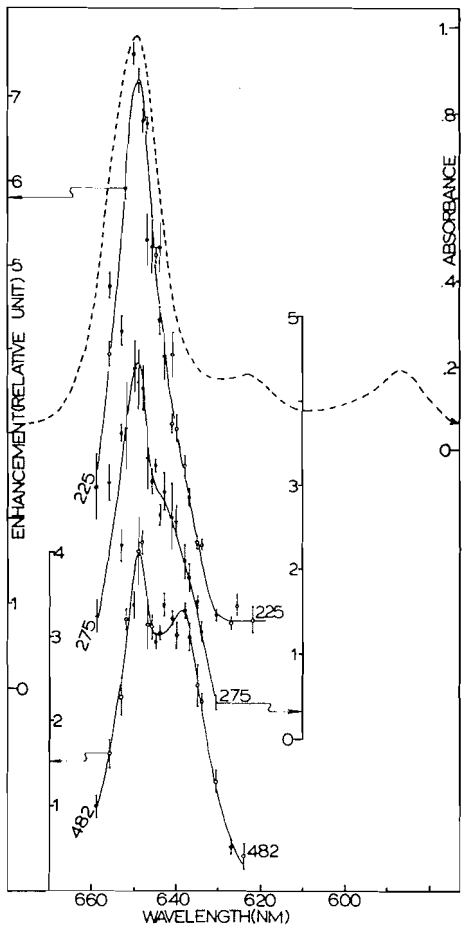

FIG. 4. Intensity enhancements of the resonance Raman bands, top to bottom: 225, 275, and 482 cm^{-1}, of PtP_c in α-ClN at 295 K as a function of excitation. The absorption spectrum (broken) refers to the extreme right ordinate.

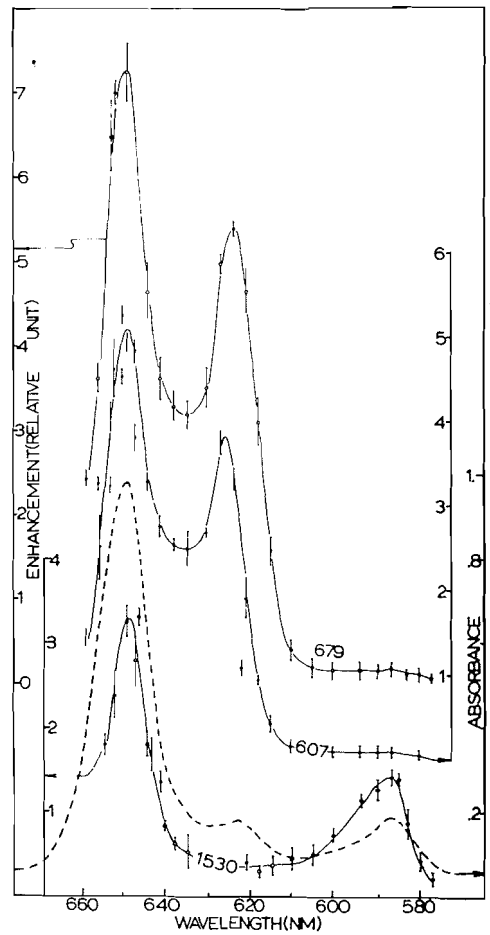

FIG. 5. Intensity enhancements of the resonance Raman bands, top to bottom: 679, 607, and 1530 cm^{-1}, of PtP_c in α-ClN at 295 K as a function of excitation. The absorption spectrum (broken) refers to the extreme right ordinate.

the vibrations whose (0–2) transitions are still in the tunable range of the dye laser, we do not see any corresponding maxima in the excitation profiles. We have also observed small energy differences of about 50 to 100 cm^{-1} between the (0–0)—(0–1) energy difference in absorption and that in the excitation profiles, which may partially result from the interference of two close lying resonances and also from the fact that the resonance Raman signals are not corrected for the instrument response and the chromophore absorptions (see above).

Figure 7 shows the depolarization ratios of most of the resonance Raman bands (indicated in cm^{-1}) in α-ClN at room temperature. In the detectable spectral range, the depolarization ratio of the 275 cm^{-1} vibration is approximately zero, and is not shown in the figure. The depolarization ratio of the 225 cm^{-1} vibration is interfered with the strong depolarized Raman band of the solvent at 220 cm^{-1}, particularly when the excitation wavelength is shifted away from the absorption maximum because of the wide slit needed for the ratio measurement. Thus the ratio may actually be less than 0.44 at the absorption maximum, and should tend to 0.75 as the wavelength becomes shorter. The maximum at 640 nm in the depolarization ratio of the 482 cm^{-1} vibration was carefully investigated, and found to be reproducible. The smaller variation in the depolarization ratios of the other vibrations (except 607 cm^{-1} and 679 cm^{-1}) have not been tested specifically, and, thus, we are not equally sure if they are genuine or not. However, the fluctuations in the 607 and the 679 cm^{-1} ρ_l's are greater than the experimental uncertainty, and are believed to be real. We also point out here that the 482, 1312, 1219, and possibly 955 cm^{-1} vibrations are anomalously, or inversely polarized ($\rho_l > \frac{3}{4}$, see Table 1). A general behaviour of the ρ_l's as a function of excitation

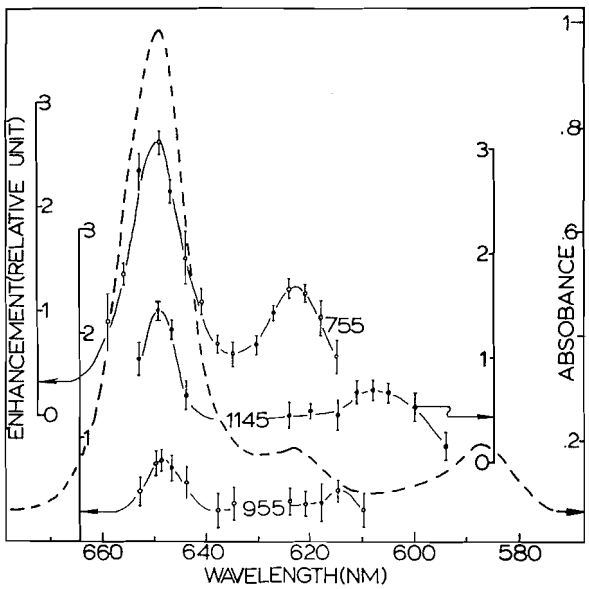

FIG. 6. Intensity enhancements of the resonance Raman bands, top to bottom: 755, 1145, and 955 cm^{-1}, of PtP_c in α-ClN at 295 K as a function of excitation. The absorption spectrum (broken) refers to the extreme right ordinate.

should be noted here, and will be referred to in the next section, namely they are well-behaved, they vary only slightly with excitation, and they are bounded in the spectral region where they are detectably enhanced.

In Fig. 8, we present the results obtained from PtP_c in mixtures of α-ClN and *n*-octane at room temperature. The enhancement and depolarization data in this figure have a greater uncertainty because of lower concentration and greater photodecomposition. Nevertheless, they serve well to prove or disprove, by comparison, if the entity of PtP_c has undergone any change in symmetry going from the neat α-ClN to the mixed solvent as will be shown.

Discussion and Conclusions

We believe that the Raman spectra shown in Fig. 3 are unambiguously resonance enhanced because (*a*) the intensity gain as the excitation wavelength approaches the absorption maxima cannot simply be accounted for by the ν^4 law (see Figs. 4–6 and 8), and (*b*) four vibrations, 482, 955, 1219, and 1312 cm^{-1}, have depolarization ratios $\geq \frac{3}{4}$ (see Figs. 7 and 8).

At least 14 fundamentals and four combinations and overtones (Table 1) are enhanced when excited into the main absorption band (649 and 642 nm, respectively, in α-ClN and the mixed solvent at 295 K). As the excitation is shifted to shorter wavelength, these vibrational modes are all selectively

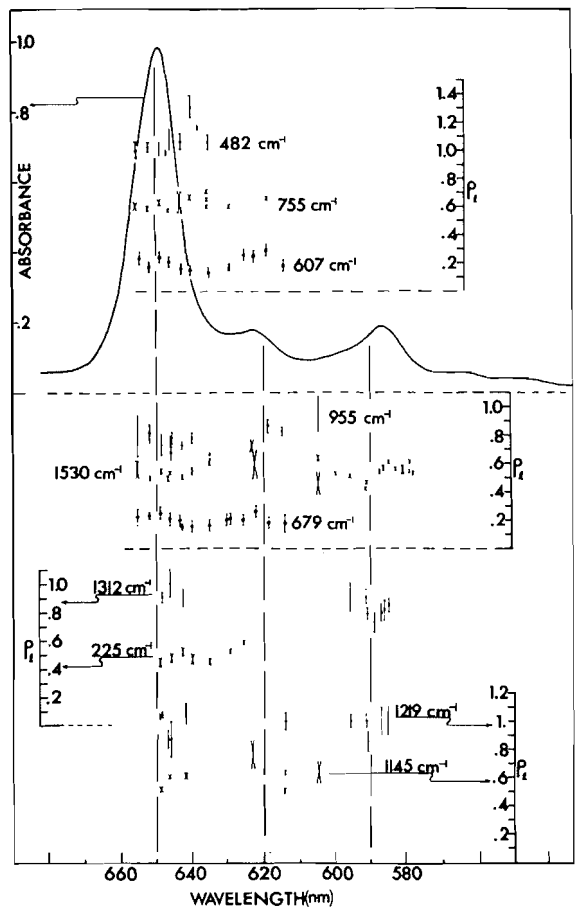

FIG. 7. The depolarization ratios (ρ_l) of the resonance Raman bands (indicated in cm^{-1}) of PtP_c in α-ClN at room temperature as a function of excitation wavelength together with the absorption spectrum.

excited (see Figs. 4–6 and 8). We conclude that the 649 nm (642 nm) absorption in α-ClN (mixed solvent) at 295 K is the pure electronic (0–0) transition, whereas the bands at 622 nm (616 nm) and 587 nm (582 nm) are the (0–1) vibronic transitions. Previously, the additional bands to the red of the main fluorescence (1) and to the blue of the main absorption maximum (4) were considered to be the vibronic progression. While this is qualitatively correct, our data show clearly that the 587 nm (582 nm) band in α-ClN (mixed solvent) at 295 K is the (0–1), and not the (0–2) transition as previously assumed. This conclusion is supported by consideration of the vibrational integrals as follows.

According to Koningstein and Jakubinek (5), based on the vibronic coupling model of Albrecht (6), the resonance Raman scattering intensity is obtained from the expression for the scattering tensor

$$(\alpha_{\rho\sigma})_{vv'} = \frac{1}{h(\nu_{r,v'';k,v} - \nu_0) + i\gamma_{r,v''}} \times \Big\{ \sum_{r,v''} (M_\rho{}^0)_{rk}(M_\sigma{}^0)_{kr}\langle v|v''\rangle\langle v''|v'\rangle + \sum_{r,t\neq r,v''} h_{tr}{}^Q[(M_\sigma{}^0)_{kt}(M_\rho{}^0)_{rk}\langle v'|v''\rangle\langle v''|Q|v\rangle + (M_\rho{}^0)_{tk}(M_\sigma{}^0)_{kr}\langle v|v''\rangle\langle v''|Q|v'\rangle] + \sum_{r,t\neq k,v''} h_{tk}{}^Q[(M_\rho{}^0)_{rk}(M_\sigma{}^0)_{tr}\langle v'|v''\rangle\langle v''|Q|v\rangle + (M_\sigma{}^0)_{kr}(M_\rho{}^0)_{tr}\langle v|v''\rangle\langle v''|Q|v'\rangle]$$

where

$$h_{tr}{}^Q \equiv \left\langle t^0 \left| \left(\frac{\partial H}{\partial Q}\right)_{Q=0} \right| r^0 \right\rangle \Big/ (E_t{}^0 - E_r{}^0)$$

$\langle t^0|$ is some electronic state coupled to $|r^0\rangle$ by the normal coordinate Q; $|r^0\rangle$ and $|k^0\rangle$ are the first excited and ground electronic states, respectively; H is the electronic Hamiltonian; $|v\rangle$ and $|v'\rangle$, respectively, are the $v = 0$ and 1 vibrational states of $|k^0\rangle$; v'' is the vibrational quantum number in $|r^0\rangle$; (M^0)'s are the electric dipole integrals between electronic states.

The square of the factor, $(M^0)_{kr}\langle v|v''\rangle$, is the intensity for the absorption, $k,v \rightarrow r,v''$. Assuming that $|v\rangle$ and $|v''\rangle$ are harmonic and that the shift in equilibrium position in $|r^0\rangle$ from that in $|k^0\rangle$, R_0, is finite, the transition probability calculated from the overlap integral, $\langle v|v''\rangle$, for $h\nu \gg kT$ is

$$W_{v\rightarrow v''} = (M^0)_{kr}\, e^{-P}\frac{P^{v''}}{v''!}$$

where P is called the Stokes loss for the normal vibration, and is equal to $m\nu^2R_0{}^2/2h\nu$ (7). M is the mass of the oscillator. $(M^0)_{kr}$, as well as h^Q's above, are constants throughout the whole vibronic progression. It is shown in ref. 7 that as P becomes smaller, the transition to smaller v'' becomes more probable than that to larger v''. In particular, when $P = 0.1$, $W_{0\rightarrow 0}$ is nine times $W_{0\rightarrow 1}$, $W_{0\rightarrow 2}$ being negligible. The intensity distributions shown in the absorption spectra (Fig. 4 and, particularly, Fig. 8) suggest that our system has a very small Stokes loss for a given ν (this is confirmed by observations to be published shortly). Thus,

$$W_{0\rightarrow 0} \gg W_{0\rightarrow 1} \quad \text{and} \quad W_{0\rightarrow 2} \sim 0$$

It follows that

$$\langle v = 0|v'' = 0\rangle \approx 1 \gg \langle v = 0|v'' = 1\rangle$$

and

$$\langle v = 0|v'' = 2\rangle \sim 0$$

and also

$$\langle v' = 1|v'' = 0\rangle \ll \langle v' = 1|v'' = 1\rangle \approx 1 \sim \gg \langle v' = 1|v'' = 2\rangle$$

The other intensity factors which vary with v'', i.e. $\langle v''|Q|v\rangle$ and $\langle v''|Q|v'\rangle$, can be calculated from the expressions given in ref. 8. They are

	$v'' = 0$	$v'' = 1$	$v'' = 2$	$v'' = 3, 4, \ldots$
$\langle v''\|Q\|v\rangle$	$= a\langle 1\|0\rangle$,	$= a\langle 1\|1\rangle$	$= a\langle 1\|2\rangle$,	≈ 0
$\langle v''\|Q\|v'\rangle$	$\approx a\langle 0\|0\rangle$,	$= \langle 2\|1\rangle + a\langle 0\|1\rangle$,	$\approx \langle 2\|2\rangle$,	≈ 0

where $a = \sqrt{2}/2$ and $\langle 1|0\rangle \equiv \langle v_k = 1|v'' = 0\rangle$ etc. From these integrals involving the normal coordinate and the above overlap integrals, the observation that the resonance Raman signal of a PtP_c vibration is too weak to be observed as the excitation is tuned to $v'' > 1$ can be easily understood to be a result of very small R_0.

The typical structure of MP_c's has already been shown in Fig. 1. So far, these molecules have been assumed to have D_{4h} symmetry. To deduce the symmetry of PtP_c in both solvent systems at 295 K, we therefore start out with D_{4h} and then distort it, if necessary.

From the evaluation of the integrals above we see that the terms containing the vibronic couplings, i.e. $h_{tr}{}^Q$ and $h_{tk}{}^Q$, in the expression of $(\alpha_{\rho\sigma})_{vv'}$ dominate. Among the two observed electronic transitions, the Soret band is so much stronger than the visible band that only the terms with $h_{tr}{}^Q$ need be considered for our resonance Raman intensity. $(M^0)_{tr}$ is Laporte forbidden given that $|t^0\rangle$ and $|r^0\rangle$ are the E_u electronic states in the Soret and visible regions, respectively. In order that $h_{tr}{}^Q$ is nonvanishing the normal modes must transform as A_{1g}, A_{2g}, B_{1g}, and B_{2g} (9). It is to be noted that ρ_l is expressed in terms of the matrix elements of $(\alpha_{\rho\sigma})_{vv'}$ (10) and is, thus, governed by the same vibronic coupling between $|t^0\rangle$ and $|r^0\rangle$. Therefore, the symmetry deduced in the following from the ρ_l's does not pertain to $|k^0\rangle$, the ground state, but to $|t^0\rangle$ and $|r^0\rangle$, the electronic states in the Soret and visible regions. It will be shown in a forthcoming paper that the ground state symmetry is indeed identical with that of the first excited singlet.

Our depolarization data (Figs. 7 and 8, Table 1) clearly show that the symmetry of PtP_c in α-ClN is not D_{4h}, D_{2d}, D_4, or C_{4v}. In these point groups the ρ_l, calculated from the expressions given in refs. 9 and 11, for representation $A_{2g}(D_{4h})$ or $A_2(D_{2d}, D_4,$ and $C_{4v})$ is infinite which we do not observe.

We next consider the remaining subgroups of

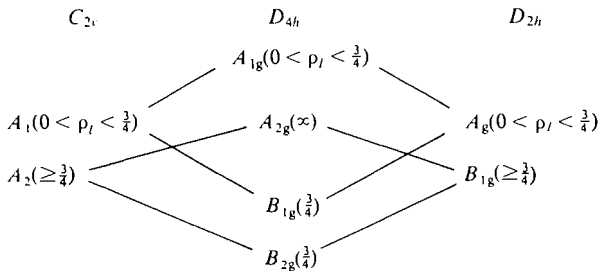
D_{4h}, i.e. C_{4h}, C_4, S_4; D_{2h}, C_{2v}, D_2; C_{2h}, C_2, C_s; and C_i. Our observed ρ_l's exclude C_{4h}, C_4, and S_4 because they all contain a resonance Raman active representation with $\rho_l = \frac{3}{4}$ *independent* of excitation. Due to the large numbers of nonzero, independent matrix elements in the resonance Raman tensors (11), the dependences of calculated ρ_l's on excitation in point groups C_{2h}, C_2, C_s, and C_i are very complex, and are not expected to be bounded for *every* resonance Raman mode. Our observed ρ_l's, however, are all bounded by low values. Thus, our data are fully consistent only with D_{2h}, C_{2v}, and D_2. The following correlation is valid also for D_2 so far as ρ_l's go, because it has the same resonance Raman tensors as those of D_{2h} and C_{2v} (11).



Note that the correlation is not unique (12). There can be two D_{4h}–D_{2h} correlations and four D_{4h}–C_{2v}'s, i.e. two and four ways of distorting D_{4h} to D_{2h} and C_{2v}, respectively. For all the possible distortions, the correlation shown is valid so far as ρ_l is concerned. The ρ_l's are now all bounded, although still excitation dependent. It is obvious that the behaviour of the ρ_l's shown in Figs. 7 and 8 agrees well with the calculated values.

We conclude, therefore, that the molecular symmetry of PtP_c in α-ClN is D_{2h}, C_{2v}, or D_2. The distortion from D_{4h} must be small, otherwise one should observe two main (0–0) absorptions as in metal free P_c (which has D_{2h} symmetry) and we do not. The symmetry assignments of the vibrations in Table 1 are based on D_{2h} and C_{2v}, and on the correlation above. The depolarization ratio of the 1219 cm^{-1} vibration is anomalous and supports the B_{1g} (D_{2h}) assignment, rather than A_g (the first overtone of 607 cm^{-1}). The assignment of A_g (D_{2h}) to the 878 and the 1358 cm^{-1} vibrations is based on the combination and overtone, respectively, of the A_g fundamentals (Table 1).

We next consider the mixed solvent case. Solutions of PtP_c in the mixed solvents show the Shpol'skii effect when frozen suddenly or slowly. In other words, the absorption (solid trace at the bottom of Fig. 8) and phosphorescence become quasiline spectra upon freezing. The individual vibronic bands are then well resolved, important not just for structural analysis but also for comparison with theoretical vibronic

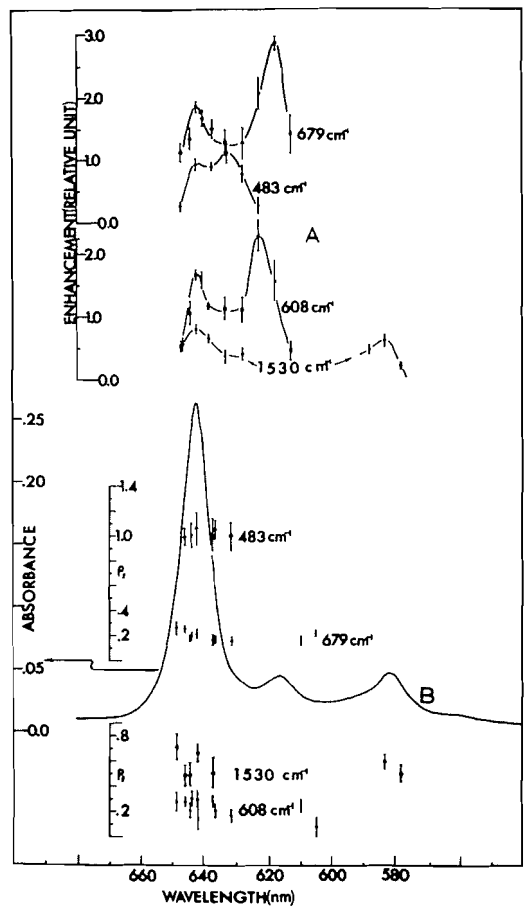


FIG. 8. Intensity enhancements (A) and the depolarization ratios (ρ_l) of the resonance Raman bands (indicated in cm^{-1}) of PtP_c in the mixed solvent as a function of excitation at 295 K together with the absorption spectrum.

coupling. At room temperature the halfwidth of the main absorption band in mixed solvents is 270 cm^{-1} vis-à-vis 340 cm^{-1} (see e.g. Fig. 4) in neat α-ClN. There exists in both solvent systems a common broadening mechanism, e.g. the tumbling and translational motions. But, as these degrees of freedom are frozen in the 340 cm^{-1} width of the neat α-ClN solution decreases insignificantly (the same thing occurs in phosphorescence), whereas the 270 cm^{-1} width of the mixed solvent spectrum becomes smaller than 8 cm^{-1} arising from the homogeneous (intrinsic) and inhomogeneous broadenings (13). Thus there must be another broadening mechanism, namely the interaction between solute and solvent or electron–phonon interaction (14) in solid state terminology. This interaction can also account for the difference between 270 and 340 cm^{-1} at room temperature if we believe that the (π–π^*) optical electron (3) of PtP_c in the mixed solvent couples very weakly to the thermal phonons, or the solvation sheath, whereas that in neat α-ClN couples very

For personal use only.

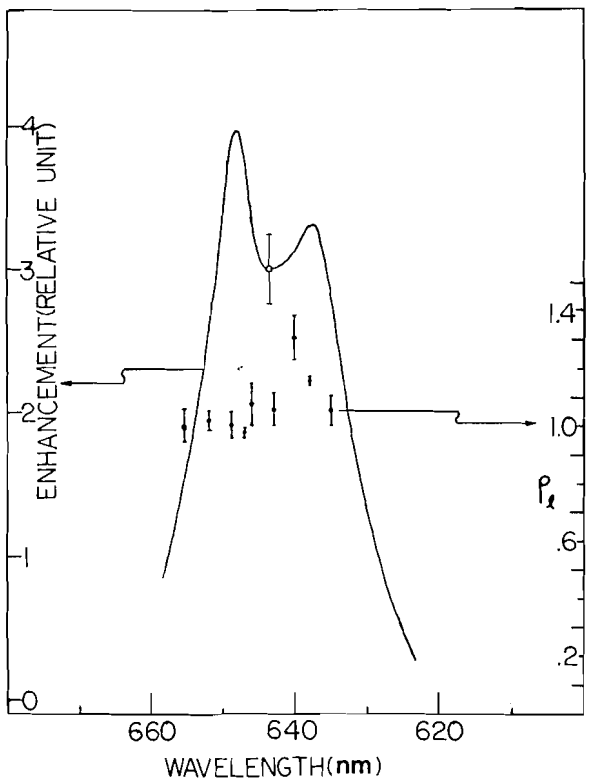

FIG. 9. The excitation profile (with a representative error bar) and the depolarization ratios of the 482 cm^{-1} normal mode as a function of excitation wavelength at room temperature. Reproduced from Figs. 4 and 7.

strongly. This also agrees with our finding that photodecomposition is more efficient in the mixed solvent than in neat α-ClN at room temperature. We, therefore, conclude that the 270 cm^{-1} width is due mainly to the molecular motions only while the 340 cm^{-1} width results mainly from electron–phonon interaction rather than molecular motions.

For the four fundamentals shown in Fig. 8, we see that their band positions, excitation profiles, and particularly, the depolarization ratios are the same as their counterparts in neat α-ClN. We also note that the (0–1) bands in the excitation profiles are stronger than their counterparts in neat α-ClN and that the profiles, except 1530 cm^{-1}, agree with the theoretical works of other authors (15).

For vibrations with anomalous depolarization ratios, theory predicts that the depolarization ratio as a function of excitation should peak midway between the maxima in the excitation profile (15). Among the anomalously polarized resonance Raman bands observed, only the 482 cm^{-1} vibration is intense enough for testing this prediction. The results are shown in Fig. 9 and it can be seen that our data agree qualitatively with this prediction. The depolarization maximum (at 640 nm) occurs much closer to the high energy maximum in the excitation profile. The variation in the depolarization ratio was also determined for the 607 and 679 cm^{-1} vibrations, although there it is less pronounced than in the 482 cm^{-1} vibration (see Fig. 7). The resonance Raman tensor of the $A(D_2)$, the $A_1(C_{2v})$, and the $A_g(D_{2h})$ representations (to which 607 cm^{-1} and 679 cm^{-1} belong) has three different matrix elements (11). Their different variations with wavelength can give rise to the fluctuation in the depolarization ratio, which further supports our conclusion that the molecule has D_{2h}, C_{2v}, or D_2 symmetry.

In summary, we have made the first careful study of the resonance Raman spectrum, their excitation profiles, and their depolarization ratios of a phthalocyanine molecule, namely PtP_c, in α-ClN and in mixed solvents. A judicious analysis of our data including comparisons with absorption spectra has enabled us to make assignments of the vibrations responsible for the observed Raman lines and has led us to the conclusion that the singlets in the Soret and visible regions of PtP_c in solution do not have D_{4h} symmetry but rather D_{2h}, C_{2v}, or D_2 symmetry. This conclusion is of interest and importance since previous work on the lowest excited triplet state of PtP_c by a completely different experimental method has also clearly established a symmetry lower than D_{4h} for that state (3).

Synthesis and structure of 4-methylpyridine complexes of cobalt(II) and nickel(II) hexafluorophosphate and hexafluoroarsenate

RAYMOND M. MORRISON AND ROBERT C. THOMPSON

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 19, 1977

RAYMOND M. MORRISON and ROBERT C. THOMPSON. Can. J. Chem. **56**, 985 (1978).

The complexes $M(4mepy)_4A_2$ and $M(H_2O)_2(4mepy)_8A_2$ (where M is Ni or Co and A is PF_6 or AsF_6) have been prepared and their electronic spectra and magnetic properties studied. A preliminary report is made of single crystal X-ray diffraction studies on $Ni(H_2O)_2(4mepy)_8(PF_6)_2$, $Co(H_2O)_2(4mepy)_8(PF_6)_2$, and $Co(4mepy)_4(PF_6)_2$. All of the complexes have structures involving complex cations and non-coordinated anions, consistent with extremely weak ligating abilities for both PF_6^- and AsF_6^-. Cations identified and characterized are the squashed tetrahedral $[Co(4mepy)_4]^{2+}$ ion, the square planar $[Ni(4mepy)_4]^{2+}$ ion, and the tetragonal $[Co(4mepy)_4((4mepy)_2H_2O)_2]^{2+}$ and $[Ni(4mepy)_4((4mepy)_2H_2O)_2]^{2+}$ ions. The ligand field strength of 4-methylpyridine is found to be indistinguishable from that of pyridine in these complexes. Infrared spectra are reported and infrared criteria for establishing the presence of non-coordinated anions in PF_6^- and AsF_6^- complexes are suggested.

RAYMOND M. MORRISON et ROBERT C. THOMPSON. Can. J. Chem. **56**, 985 (1978).

On a préparé les complexes $M(4mépy)_4A_2$ et $M(H_2O)_2(4mépy)_8A_2$ (où M = Ni ou Co et A = PF_6 ou AsF_6) et on a étudié leurs spectres électroniques et leurs propriétés magnétiques. On présente un rapport préliminaire sur des études de diffraction de rayons-X sur des monocristaux de $Ni(H_2O)_2(4mépy)_8(PF_6)_2$, $Co(H_2O)_2(4mépy)_8(PF_6)_2$ et $Co(4mépy)_4(PF_6)_2$. Tous ces complexes ont des structures impliquant des cations complexes et des anions non-coordonnés qui sont en accord avec le fait que PF_6^- et AsF_6^- sont des ligands extrêmement faibles. Les cations identifiés et caractérisés sont l'ion tétraédrique aplati $[Co(4mépy)_4]^{2+}$, l'ion plan carré $[Ni(4mépy)_4]^{2+}$ et l'ion tétragonal dans $[Co(4mépy)_4((4mépy)_2H_2O)_2]^{2+}$ et $[Ni(4mépy)_4((4mépy)_2H_2O)_2]^{2+}$. On a trouvé qu'il est impossible de distinguer entre la force de champ de ligand de la méthyl-4 pyridine et celle de la pyridine dans ces complexes. On rapporte les spectres infrarouges et on suggère des critères infrarouges pour déterminer la présence des anions non-coordonnés dans des complexes PF_6^- et AsF_6^-.

[Traduit par le journal]

Introduction

This work is part of a study involving the synthesis and characterization of transition metal complexes containing anions of strong acids (1–3). The hexafluorophosphate ion exhibits a relatively weak coordinating ability and while some evidence for coordination to metal ions in complexes has been claimed (4), for the most part, complexes of PF_6^- contain non-coordinated anions (3, 5). Such complexes are of interest because they may contain cationic complex ions, such as the tetrakis(pyridine)-cobalt(II) ion, $[Co(py)_4]^{2+}$ (3), which are not obtainable where the counter anion is more strongly coordinating. In addition, it is expected that studies of the electronic and molecular structures of complexes containing the PF_6^- and related anions coordinated to metal ions should, because of the ionic nature of the interactions involved, enhance our understanding of metal–ligand bonding in general.

We reported previously some studies on pyridine complexes of cobalt(II) hexafluorophosphate and hexafluoroarsenate (3) and we describe here the preparation of related 4-methylpyridine complexes and studies of their magnetic and spectral properties. Mayfield and Bull reported (5) the preparation of diamagnetic $Ni(4mepy)_4(PF_6)_2$ and paramagnetic $Ni(py)_4(PF_6)_2$ and this rather significant difference between related pyridine and 4-methylpyridine complexes prompted our further investigations of the latter complexes. Also, we found during the course of this work it is generally easier to obtain crystalline products when the ligand is 4-methylpyridine rather than pyridine. This has provided an opportunity for structure determination by X-ray diffraction techniques and this paper includes a preliminary report of such studies on $M(H_2O)_2(4mepy)_8(PF_6)_2$ (where M = Co or Ni) and $Co(4mepy)_4(PF_6)_2$.

Experimental

All materials were reagent grade; 4-methylpyridine was purified by refluxing over barium oxide overnight followed by distillation at atmospheric pressure.

None of the products are stable indefinitely in air. After drying samples *in vacuo*, all manipulations were performed in an inert atmosphere box. Samples were stored in sealed vials.

Preparations

Diaquooctakis(4-methylpyridine)cobalt(II) and Nickel(II)-hexafluoro-phosphate and -arsenate, $M(H_2O)_2(4mepy)_8A_2$

All four complexes were prepared in the same manner. Metal nitrate (hydrate) (0.02 mol) was dissolved in 100 ml of water containing 39 ml 4-methylpyridine. To this solution was added, with stirring, a filtered solution of 0.04 mol ammonium hexafluorophosphate in 50 ml water (or 0.04 mol potassium hexafluoroarsenate in 250 ml water). Stirring was continued for about 1 h during which time a two-liquid phase system developed consisting of an upper colourless layer and a more dense oily layer which was red in the case of the cobalt system and blue in the case of the nickel system. The oily layer was transferred to an evaporating dish placed over phosphoric oxide in a vacuum desiccator. After a period of one to two weeks, orange-red crystals of the cobalt complexes and blue crystals of the nickel complexes formed. The crystals were washed with a solution of 5 ml 4-methylpyridine in 50 ml water. Since the crystals tend to lose 4-methylpyridine on prolonged exposure to the atmosphere or to a vacuum, they were stored in sealed vials while still 'wet' with the washing liquid. Just prior to use the crystals were dried for about 15 min *in vacuo* at room temperature.

Tetrakis(4-methylpyridine)cobalt(II) and Nickel(II)hexa-fluoro-phosphate and -arsenate, $M(4mepy)_4A_2$

The corresponding $M(H_2O)_2(4mepy)_8A_2$ complex was ground to a fine powder in the inert atmosphere box then heated *in vacuo* for 3–4 h at temperatures of 100–110°C for the nickel complexes and 80–90°C for the cobalt complexes. Both nickel complexes were recrystallized from dichloromethane. The cobalt complexes were not recrystallized except for the sample of $[Co(4mepy)_4](PF_6)_2$ used in the X-ray diffraction studies which was obtained from an equal volume mixture of dichloromethane and chloroform. All four of these complexes were found to be extremely hygroscopic and required handling in an inert atmosphere box and storage in sealed vials.

Analytical Data

C, H, and N analyses were performed by P. Borda of the Department of Chemistry, University of British Columbia. Results are given in Table 1.

Spectral and Magnetic Susceptibility Measurements

Infrared spectra of samples mulled in Nujol and contained between KRS-5 (Harshaw Chemical Co.) plates were obtained using a Perkin-Elmer model 457 spectrophotometer. Electronic spectra at room temperature of powdered samples (diffuse reflectance) were measured over the range 13.5–28.5 kK using a Bausch and Lomb Spectronic 600 spectrophotometer and spectra of samples mulled in Nujol and solution spectra were obtained over the range 5–33 kK using a Cary model 14 spectrophotometer. The solution spectra reported in Table 2 were obtained on a 7.8×10^{-3} *M* solution of $Ni(4mepy)_4(PF_6)_2$, a 3.8×10^{-3} *M* solution of $Ni(4mepy)_4(AsF_6)_2$, a 1.7×10^{-3} *M* solution of $Co(4mepy)_4(PF_6)_2$, and a 4.2×10^{-3} *M* solution of $Co(4mepy)_4(AsF_6)_2$. The solvents used were dichloromethane for the nickel complexes and an equal volume mixture of dichloromethane and chloroform for the cobalt complexes.

Magnetic susceptibilities were determined, over the temperature range 80 to 300 K, on powdered samples at field strengths of approximately 4500 and 7000 G using the Gouy equipment and calibration procedures described previously (2). The samples gave no evidence for dependence of magnetic susceptibilities on field strength. The values used for making corrections for the diamagnetism of the atoms were -12 for Co^{2+} and Ni^{2+}, -61 for C_6H_7N, -97 for AsF_6^-, -67 for PF_6^-, and -13 for H_2O (all values in 10^{-6} cm^3 mol^{-1}).

Results and Discussion

Nickel(II) Complexes

In attempting to obtain 4-methylpyridine analogues of $Ni(py)_6(PF_6)_2$ (5), we obtained instead crystalline compounds with the stoichiometry $Ni(H_2O)_2(4mepy)_8A_2$ (where A is PF_6 or AsF_6). It is clear from the electronic spectral and magnetic properties given in Table 2 that these complexes contain six-coordinate nickel(II). This has been confirmed by a single crystal X-ray diffraction study on the hexafluorophosphate derivative.[1] The structure consists of non-coordinated PF_6^- anions and complex cations which may be formulated as $[Ni(4mepy)_4((4mepy)_2H_2O)_2]^{2+}$. Four 4-methylpyridine ligands are bonded in a square planar arrangement about nickel with Ni—N distances in the narrow range of 2.10 to 2.12 Å. Axial positions are occupied by water molecules, each water molecule bonded via hydrogen bonds to two additional 4-methylpyridine molecules, hence, the formulation of the axial ligands as $((4mepy)_2H_2O)$. The Ni—O bond distances are 2.12 Å and it is interesting to note that all of the Ni—O and Ni—N bond distances are the same to within ± 0.02 Å. Consequently, although the microsymmetry about nickel is D_{4h} the electronic spectrum may be assigned on the basis of octahedral symmetry,

the only evidence of lower symmetry being the splitting observed in the band assigned to the $^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$ transition in the hexafluorophosphate derivative. The magnetic properties too are typical of spin-free, octahedral nickel(II). The electronic spectra and magnetic properties of $Ni(H_2O)_2(4mepy)_8(AsF_6)_2$ are virtually identical to those of the hexafluorophosphate derivative suggesting that the two compounds have analogous structures.

The ligand field parameters *Dq* and *B* were calculated (6) using the transition energies obtained from the diffuse reflectance spectra. For comparison, we prepared $[Ni(py)_6](PF_6)_2$ as described previously (5) and examined its room temperature electronic spectrum and its magnetic properties (Table 2). Although water occupies lower positions in both the spectrochemical and nephelauxetic series than nitrogen donor ligands (7), there is little difference in the ligand field parameters of the compounds studied here (containing the NiN_4O_2 chromophore) and the complex $Ni(py)_6(PF_6)_2$ (containing the NiN_6 chromophore). In fact, the small difference which is observed in the *Dq* parameter indicates that it is larger for NiN_4O_2 compared to NiN_6, contrary to expectations based on the spectrochemical series. The difference may be a consequence of greater steric crowding, and hence generally longer and weaker bonds, in the NiN_6 case.

Heating the $Ni(H_2O)_2(4mepy)_8A_2$ complexes *in vacuo* followed by recrystallization from dichloromethane gives complexes of composition $Ni(4mepy)_4A_2$. These complexes are diamagnetic and exhibit single absorption bands in the visible region (Table 2), consistent with both compounds having structures involving square planar $[Ni(4mepy)_4]^{2+}$ cations and non-coordinated anions.

Our findings on these square planar nickel(II) complexes are not entirely consistent with the previous work of Mayfield and Bull (5). These authors reported the preparation of 'diamagnetic' $Ni(4mepy)_4(PF_6)_2$ by a procedure which did not involve recrystallization. We carried out several preparations of both the PF_6^- and AsF_6^- compounds and found unrecrystallized samples contained paramagnetic impurities as evidenced by room temperature paramagnetic susceptibilities of the order of 500 to 600×10^{-6} cm^3 mol^{-1} (increasing to 1200 to 1600 $\times 10^{-6}$ cm^3 mol^{-1} at 100 K). In addition, Mayfield and Bull (5) reported that $Ni(py)_4(PF_6)_2$ has a magnetic moment of 1.98 BM. The paramagnetism in this compound may also arise from paramagnetic impurities since, by stirring suspensions of the $Ni(py)_6(PF_6)_2$ precursor in dichloromethane, and avoiding heating the sample as was done in the earlier work, we have been able to obtain samples of $Ni(py)_4(PF_6)_2$ which, like the 4-methylpyridine derivatives, are diamagnetic at room temperature.

Cobalt(II) Complexes

The reaction of cobalt(II) nitrate with ammonium hexafluorophosphate or potassium hexafluoroarsenate and 4-methylpyridine in aqueous solution gives, as was the case for nickel, crystalline complexes with the general formula $Co(H_2O)_2(4mepy)_8A_2$. A single crystal X-ray diffraction study[1] on the hexafluorophosphate compound shows it to have a structure similar to that of the nickel complex. The hexafluorophosphate ions are not coordinated to cobalt. The complex cation has four 4-methylpyridine ligands forming a square planar array about cobalt with Co—N distances in the range 2.20 to 2.22 Å. Axial positions are occupied by $((4mepy)_2H_2O)$ ligands with Co—O distances of 2.11 Å. In contrast to the nickel case there is a significant difference between the Co—O and Co—N bond lengths; the microsymmetry about Co is approximately D_{4h} with two short Co—O bonds and four longer Co—N bonds. In spite of the obviously lower symmetry ligand environment about cobalt, the electronic spectrum (Table 2) of $Co(H_2O)_2(4mepy)_8(PF_6)_2$ does not differ greatly from that of $Co(py)_6(PF_6)_2$ (3). The ligand field parameters were calculated as before (2) using 8.77 kK for the $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ transition energy and 20.2 kK (estimated from the centre of the visible band) for the $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ energy.

The magnetic properties of $Co(H_2O)_2(4mepy)_8(PF_6)_2$ are particularly interesting in that they show the effects of the low symmetry ligand environment (Fig. 1). The variation of the magnetic moment with temperature shows excellent agreement with theoretical moments calculated using the four parameter approach of Figgis *et al.* (9) for spin-free cobalt(II) in an axially compressed tetragonal environment. The parameter values (accuracy estimated at $\pm 5\%$ for k and λ and ± 2 for ν) indicate a splitting of the octahedral ground $^4T_{1g}(F)$ term by some 750 cm^{-1} as a consequence of the axial compression. This analysis of the magnetic data is consistent with the molecular structure as determined by X-ray diffraction and the general agreement provides support for the use of this theory in interpreting the magnetic data for related complexes. For comparison, the magnetic moments previously reported for $Co(py)_6(PF_6)_2$ and $Co(py)_6(AsF_6)_2$ (3) are reproduced graphically in Fig. 1.

The electronic spectra and magnetic properties of $Co(H_2O)_2(4mepy)_8(AsF_6)_2$ do not differ significantly from those of the hexafluorophosphate compound suggesting analogous structures for the two com-

pounds. The *Dq* and *B* values given in Table 2 for the hexafluoroarsenate complex were calculated using 8.93 and 20.4 kK for the $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ and $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ transitions respectively. The *Dq* values for these complexes are slightly greater than *Dq* for the $[Co(py)_6]^{2+}$ ion (3) and, as was discussed above for the nickel complexes, this may reflect greater steric crowding in the CoN_6 chromophore compared to CoN_4O_2.

When the $Co(H_2O)_2(4mepy)_8A_2$ complexes are heated to about 80–90°C the corresponding tetrakis-(4-methylpyridine) complexes are obtained. The electronic spectra (Table 2) of $Co(4mepy)_4(PF_6)_2$ and $Co(4mepy)_4(AsF_6)_2$ are virtually identical to those reported previously for the pyridine complexes and are readily assigned assuming a tetrahedral ligand environment about cobalt(II). *Dq* and *B* for these complexes were calculated using 9.43 kK for the $^4A_2 \rightarrow {}^4T_1(F)$ transition energy and 18.3 kK (estimated from the centre of the visible band) for the $^4A_2 \rightarrow {}^4T_1(P)$ energy (6). Unlike the corresponding pyridine complexes, these complexes were sufficiently soluble in an equal volume mixture of dichloromethane and chloroform to obtain solution spectra (Table 2). Changes in the bands assigned to the $^4A_2(F) \rightarrow {}^4T_1(F)$ transition suggest there may be minor changes in geometry on dissolution; however, the structures remain basically tetrahedral as evidenced, in particular, by the large extinction coefficients. The $^4A_2(F) \rightarrow {}^4T_2(F)$ transitions which give rise to weak bands observed only in very thick mulls are too weak to be observed in the solution spectra. The magnetic properties (Table 2 and Fig. 1) obey the Curie–Weiss law with a small Weiss constant, over the temperature range 80–300 K, again consistent with a tetrahedral ligand environment and a $^4A_2$ electronic ground state (8).

The presence of distorted tetrahedral cobalt(II) in these complexes has been shown by a single crystal X-ray diffraction study of $Co(4mepy)_4(PF_6)_2$.[2] This complex has a structure consisting of $[Co(4mepy)_4]^{2+}$ cations and non-coordinated anions. The CoN_4 chromophore is a squashed tetrahedron (D_{2d}) with N—Co—N bond angles of 114 and 101° and Co—N bond lengths of 2.00 Å. It is interesting to note that the Co—N distances in $[Co(4mepy)_4]^{2+}$ are significantly shorter than in $[Co(4mepy)_4((4mepy)_2H_2O)_2]^{2+}$ reflecting less steric crowding in the four-coordinate species.

The coordinating properties of pyridine and 4-methylpyridine appear from the present work to be virtually identical. The differences in *Dq* and *B* for $[Co(4mepy)_4]^{2+}$ and $[Co(py)_4]^{2+}$ (3) cannot be considered significant and the magnetic properties of the two groups of compounds are the same, within experimental error. In addition, as shown above, there appears to be no significant difference in the electronic spectra of $[Ni(4mepy)_4]^{2+}$ and $[Ni(py)_4]^{2+}$ and the difference in the magnetic properties of $Ni(py)_4(PF_6)_2$ and $Ni(4mepy)_4(PF_6)_2$ which was reported previously (5) has not been confirmed here.

In general we find that the electronic and molecular structures of corresponding hexafluorophosphate and hexafluoroarsenate complexes of cobalt(II) and nickel(II) are the same and are consistent with similar, very weak, coordinating abilities for these two ions. A closer examination of the relative coordinating abilities of these anions would require the preparation and study of complexes where there is greater metal–anion interaction.

Vibrational Spectra

Bands arising primarily from anion vibrations and those arising from neutral ligand vibrations were relatively easily distinguished in the infrared spectra of the complexes. Most of the 4-methylpyridine vibrations were found to show small and random shifts in the complexes relative to the free ligand; however, consistent with the results of Goodgame and Hayward (10), the six vibrations listed in Table 3 show increases in energy on coordination. Several

of the vibrations in the octahedral complexes are 'doubled', a consequence, presumably, of non-equivalent 4-methylpyridine ligands in these compounds. With the exception of the 800 cm^{-1} band, the ligand vibrations listed seem particularly sensitive to the nature of the complex, shifting to higher energies in the four-coordinate square planar and tetrahedral complexes than in the six-coordinate complexes. Goodgame and Hayward found similar trends to increasing energy with increasing polarizing power and the shifts we observe probably reflect a greater degree of ligand polarization in the four-coordinate species.

The anion bands ν_3 and ν_4, listed in Table 3, have frequencies very close to those reported for KPF_6 and $CsAsF_6$ (11) and for the analogous pyridine complexes (3). Medium to weak bands, assignable to the ν_1 and ν_2 vibrations, are observed in the square planar nickel complexes but are generally absent or appear very weakly in the other complexes.

Recently, there have been a number of reports concerning complex cationic species in which the counter anion is PF_6^- or AsF_6^- (for example, see refs. 12–15). In view of the current use of these anions as non-coordinating species it would be useful to have infrared criteria regarding coordination involving them. The criteria for non-coordinated anions may be obtained from the spectra of the pyridine complexes of cobalt(II) described earlier (3) and the 4-methylpyridine complexes of cobalt(II) described here, where there is little doubt that the anions are not coordinated to metal ions. The spectra all show strong to very strong anion bands assignable to the ν_3 and ν_4 vibrations in O_h symmetry. In addition some of the effects of symmetry lowering described by Bell *et al.* (4) can be seen. These effects are, specifically, a splitting of ν_3 of the order of 10 to 25 cm^{-1}, and the appearance of weak bands corresponding to the formally Raman active ν_1 and ν_2 vibrations. Such effects probably arise from site symmetry lowering or very weak interactions of the anions with other groups such as ligands coordinated to metal ions in a complex. Where PF_6^- and AsF_6^- are more strongly coordinated to other atoms, one would expect to see greater splitting of degenerate modes and greater intensities of bands formally forbidden in O_h symmetry. Some of these effects have been seen in the infrared and Raman spectra of $H_3O^+AsF_6^-$ (16) and $NH_2F_2^+AsF_6^-$ (17) and in the Raman spectrum of $KrF^+AsF_6^-$ (18). In summary, the presence of non-coordinated anions in PF_6^- and AsF_6^- complexes is indicated by spectra which show very strong ν_3 bands (may be split by up to 25 cm^{-1}), strong and unsplit ν_4 bands, and weak or absent ν_1 and ν_2 bands.

The infrared spectra of $Cu(py)_4(PF_6)_2$ (4, 5) and the nickel complexes, $Ni(4mepy)_4(PF_6)_2$ and $Ni(4mepy)_4(AsF_6)_2$, studied here show medium to strong bands assigned to ν_1, weak to medium bands assigned to ν_2 and, in the case of the two hexafluorophosphate compounds, splitting of the ν_3 bands. This suggests that in these complexes the anions are more strongly perturbed than in the corresponding cobalt complexes, a consequence, perhaps, of weak 'semi-coordination' of the anions as was suggested previously for $Cu(py)_4(PF_6)_2$ (4). We plan single crystal X-ray diffraction studies on $Ni(4mepy)_4(PF_6)_2$ and $Cu(4mepy)_4(PF_6)_2$ to help clarify the matter.

Synthesis and ^1H and ^{13}C nuclear magnetic resonance spectra of some 4-alkylidene-1-pyrazolines and alkylidenecyclopropanes

ROBERT J. CRAWFORD, HIROKAZU TOKUNAGA, LOUIS M. H. C. SCHRIJVER, JACKY C. GODARD, AND THOMAS NAKASHIMA

Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 28, 1977

ROBERT J. CRAWFORD, HIROKAZU TOKUNAGA, LOUIS M. H. C. SCHRIJVER, JACKY C. GODARD, and THOMAS NAKASHIMA. Can. J. Chem. **56**, 992 (1978).

The ^{1}Hmr and ^{13}Cmr spectra for 15 4-alkylidene-1-pyrazolines and 19 alkylidenecyclopropanes are reported. The assignments of *E* and *Z* isomers are made on the basis of shielding effects about the *exo* cyclic double bonds. The addition of diazomethane-d_2 to 1,2-butadiene is shown to be both regiospecific and stereospecific.

ROBERT J. CRAWFORD, HIROKAZU TOKUNAGA, LOUIS M. H. C. SCHRIJVER, JACKY C. GODARD et THOMAS NAKASHIMA. Can. J. Chem. **56**, 992 (1978).

On rapporte les spectres rmn du ^{1}H et rmn du ^{13}C de 15 alkylidène-4 pyrazolines-1 et de 19 alkylidène cyclopropanes. On a effectué les attributions des configurations *E* et *Z* en se basant sur les effets de blindage autour des doubles liaisons exocycliques. On a montré que l'addition de diazométhane-d_2 au butadiène-1,2 est à la fois régiospécifique et stéréospécifique.

[Traduit par le journal]

We have extended our studies (1) on the mechanism of thermolysis of 4-alkylidene-1-pyrazolines by examining the stereochemistry of the substituents in the alkylidenecyclopropane products, and comparing it with that of the reactant. In this paper we present the syntheses, ^{1}Hmr, and ^{13}Cmr data used to assign the structures of 15 different 4-alkylidene-1-pyrazolines (**1–15**) and 19 different alkylidenecyclopropanes (**15–34**). The thermolysis and mechanistic details are reported in the following paper.

4-Alkylidene-1-pyrazolines

We have used two methods to synthesize the 4-alkylidene-1-pyrazolines: (*a*) the diazoalkane cycloaddition to an allene has been used to prepare all compounds except **7** and **11** whose syntheses have been reported earlier (2) and (*b*) the synthesis of **3** was also achieved from the dibromide **35** and the pyrazolidine **36** (Scheme 1). The product was the same as that obtained by the addition of diazomethane to 1,2-butadiene. The cycloaddition process was regiospecific in that only the addition to the 1,2-double bond was observed.

It was desirable to prepare alkylidene-1-pyrazolines that were different at each of the three methylene groups, particularly those in which substituent effects do not play a major role, and thus a synthesis of **4** and **5** was sought. We had earlier observed that the cycloaddition of diazomethane to 3-methyl-1,2-butadiene reversed the mode of cycloaddition to the 1,2-double bond to produce 3-isopropylidene-1-pyrazoline. Andrews and Day (3) have suggested that steric factors were primarily responsible for this reversal of mode in diazoalkane addition to allenes and thus it seemed reasonable that the addition of diazomethane-d_2 to 1,2-butadiene would produce **4**, whereas the addition of diazomethane to 1,1-dideuterio-1,2-butadiene would produce **5**. The proof of structure of **4** and **5** is derived from the ^{1}Hmr and ^{13}Cmr spectra. As recorded in Table 1, signals arising from C(3) and C(5) of **1** are observed at δ 79.2 whereas for **7** they are displaced upfield to δ 77.5 due to the shielding by the *syn*-methyl group. This is consistent with an average shift of -1.2 ± 0.3 ppm upon the introduction of a *syn*-methyl in alkenes (4). The ^{13}Cmr spectrum of **3** displays two lines in the appropriate region, one at δ 79.1 assigned to the methylene group *anti* to the ethylidene methyl, and the second at δ 76.1 assigned to that *syn* to the methyl group. The ^{13}Cmr spectrum of **4** has only one line at δ 76.1, whereas the product assigned the structure **5** had a spectrum with an intense line at δ 79.1 and no readily observable signal in the higher field region. Comparison of the expanded signals of the ^{1}Hmr methylene protons of **4** and **5** shows that the most intense signal in the methylene spectrum of **4**, at δ 4.910, is absent from the spectrum of **5** and the most intense line for **5** at δ 4.945 is absent from the spectrum of **4**. The proton coupling constant between the vinylic hydrogen and the methylene hydrogens of **4** is 1.95 Hz, whereas the same coupling constant for **5** is 2.3 Hz, supporting the assignment, since *anti* vinylic–allylic coupling constants around a double bond are known to be smaller than those for the *syn* isomer (5). The cycloaddition is thus stereospecific in that the diazomethane adds *anti* to the

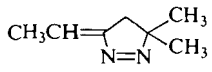
methyl on the allene, and no **4** could be detected in **5** or vice versa.

The addition of diazoethane to 1,2-butadiene gave a cycloadduct whose ^{1}Hmr spectrum differed from that of the adduct of diazomethane to 2,3-pentadiene principally in that the CH_3—C(3) doublet is centered at δ 1.45 in the former and δ 1.37 in the latter. Table 2 lists the ^{1}Hmr spectral characteristics for the 4-alkylidene-1-pyrazolines. The ^{13}Cmr spectrum of the 1,2-butadiene adduct displayed a C(3) resonance at lower field than that of the 2,3-pentadiene adduct. Thus the mode of formation, the ^{13}Cmr shielding, and the proton coupling constants all suggest that the former is the *E* isomer **8** and the latter the *Z* isomer **10**. The methyl resonances of **8** and **10** were assigned by comparison with **9** and by selective proton decoupling, respectively.

The addition of diazoisopropane to 1,2-butadiene gave two isomeric 1:1 adducts, along with acetone azine. The major product, **12**, was assigned the *E* configuration on the basis of the shielding of C(5) by the *syn*-methyl, producing the line at δ 77.1 and the similarity of resonances of C(3) in **12** and **6**, being at δ 87.3 and 87.1, respectively. The isomeric material produced was tentatively assigned the structure 5-ethylidene-3,3-dimethyl-1-pyrazoline (**37**) on the basis of its spectral properties and inertness at temperatures less than 250°C (1).



37

The addition of diazoethane to 2,3-pentadiene produced *cis*- (**13**) and *trans*-3,5-dimethyl-4-ethylidene-1-pyrazoline (**14**) in almost equal amounts. One of the isomers undergoes thermolysis at a rate significantly faster than the other thus allowing the isolation of the less reactive isomer. The chemical shift for the C(3) methyl group of the *cis* isomer is calculated from the observed shift of the methyls of **11** by allowing for the δ 7.8 difference observed on going from methyl to *gem*-dimethyl in **2** and **6**, and in **8** and **12**, to give δ Me(3) of 19.5. The Me(5) signal is expected to be an additional 1.4 ppm upfield because of the *syn*-methyl on C(6). The values for the

NOTE: d doublet, t triplet, q quartet, p pentet, h heptet, m multiplet.

trans isomer are predicted directly from **8** and **10** on the assumption that the introduction of a methyl *trans*, and across the ring, has a minimal effect on the chemical shifts, thus the signals from Me(3) and Me(5) are expected to be at δ 18.3 and 16.9, respectively. The slower reacting isomer with methyl signals at δ 20.3 and 18.6 was thus assigned the *cis* configuration **13** and the faster isomer the *trans* stereochemistry **14**.

Alkylidenecyclopropanes

The ^{13}C and ^{1}H nmr chemical shifts of the alkylidenecyclopropanes **16**–**34** are given in Tables 3 and 4. The alkylidenecyclopropanes were prepared by thermolysis of the 4-alkylidene-1-pyrazolines or by thermal equilibration. The ^{13}Cmr spectra were of greatest use in assigning the *E* and *Z* configurations of **23**, **24**, **26**, and **27**. Gajewski (6) had previously assigned the *E* and *Z* configurations, by synthesis, to the 2-methylethylidenecyclopropanes **23** and **24**. However, in our hands we obtained two isomers whose ^{1}Hmr resonance and relative gc retention times matched those in the literature but the ir spectra were reversed, thus we have used the ^{13}Cmr spectra as confirmation of the earlier ^{1}Hmr assignments. We have also observed that the proton signal at δ 0.65 is enhanced some 16% more than is the signal at δ 1.20, when the allylic methyl at δ 1.82 is irradiated (nuclear Overhauser effect). The ^{13}C resonances of C(2) and C(3) of **23** were assigned on the basis of selective decoupling experiments. The *syn*-methyl of **24** causes a −0.9 ppm shift of the C(2)

signal relative to that of **17** whereas the shielding at C(3) is essentially unchanged. The *anti*-methyl of **23** has little or no effect on the C(2) resonance and shields C(3) by −1.4 ppm in comparison with **17** (4). These spectra are supportive of the *E* configuration for **23** and the *Z* configuration for **24**. The assignment of *E* and *Z* configurations to **26** and **27** was similarly achieved on the basis of shielding of the ring carbons C(2) and C(3) by the exocyclic *syn*-methyl.

The introduction of a *syn*-methyl group in the pyrazoline system causes a shift of −2.6 ppm for the signal of a methylene carbon, e.g., the C(5) carbon atoms of **1**, **2**, **3**, **6**, and **10** have a chemical shift of δ 79.4 ± 0.3, whereas for the C(5) signal of **3**, **7**, **8** and **12** the average is δ 76.8 ± 0.5. The same shielding effect in the alkylidenecyclopropanes is smaller (e.g., the pairs **16,18**; **17,23**; **19,26**; **18,20**; and **24,28**) in each instance the replacement of a vinylic hydrogen by methyl causes a shift to higher field (average −0.92 ppm). A possible explanation for this is that the smaller cyclopropane bond angle has caused an increase in the distance between the site of the change (methyl for hydrogen) and the cyclopropane ring carbon compared to that of the pyrazoline system or noncyclic alkenes.

Experimental

All boiling points and melting points are uncorrected. The exact masses were determined on an AEI MS-9 mass spectrometer. Ultraviolet spectra were measured using a Carey Model 14, all wavelengths are reported in nm.

A Varian HA-100 spectrometer was used to obtain ^{1}Hmr spectra and a Bruker HFX 90 system operating in the Fourier transform mode was used for ^{13}Cmr analyses.

Gas chromatographic separations of the products are reported in the accompanying paper on the thermolysis of 4-alkylidene-1-pyrazolines (7).

The syntheses of **1** (1), **6**, **7**, and **11** (2) have been reported previously, as have the syntheses of **16** (1), **17**, **18** (8), **19**, **20**, **31**, **32** (2), and **21–24** (6). The other alkylidenecyclopropanes were prepared under the thermolysis conditions outlined in the following paper.

2-Bromomethyl-1-bromo-2-butene ***35***

2-Hydroxymethyl-2-buten-1-ol (45.5 g, 0.45 mol), dry pyridine (27.5 ml, 0.34 mol), and 450 ml 1:3 dry hexane–ether mixture were placed in a 1-ℓ three-neck flask fitted with reflux condenser, nitrogen inlet, dropping funnel and mechanical stirrer. The flask was cooled to −40°C and phosphorous tribromide (38 ml, 0.40 mol) was slowly added. The mixture was stirred 2 h at −5°C then poured into 350 ml iced bicarbonate solution. The layers were separated and the organic layer dried over sodium sulfate. Removal of the drying agent and solvent gave a residue which upon distillation at reduced pressure gave 16.0 g (17.5%) **7**, bp 65–67°C/4.5 Torr; ^{1}Hmr ($CDCl_3$) δ: 1.8 (d, 3 H), 4.1 (s, 4 H), 5.9 (q, 1 H). *Anal.* calcd. for $C_5H_8Br_2$: C 26.35, H 3.54; found: C 26.33, H 3.41.

1,2-Dicarbethoxy-4-ethylidenepyrazolidine ***36***

syn-Dicarbethoxyhydrazine (13.2 g, 75 mmol) and 300 ml dry 1,2-dimethoxyethane (DME) were placed in a 1-ℓ three-neck flask fitted with reflux condenser, inlet tube, dropping funnel, and magnetic stirrer. A 57% suspension of sodium hydride (3.37 g, 80 mmol NaH) was added in small portions and the reaction mixture stirred for 5 h. A solution of 2-bromomethyl-1-bromo-2-butene **7** (16.0 g, 70 mmol) in DME (50 ml) was added over a period of 4 h. After stirring overnight a solution of sodium ethoxide (75 mmol in 50 ml absolute ethanol) was added and the mixture stirred for an additional 5 h. After concentration on a rotary evaporator 1 ℓ of ice and water was added and the mixture extracted with ether. The extract was dried, the ether removed, and the resulting residue distilled at reduced pressure to give 5.7 g (34%), bp 130–134°C/0.8 Torr, of **36**; ^{1}Hmr ($CDCl_3$) δ: 1.25 (t, 6 H), 1.6 (d, 3 H), 4.2 (q, 8 H), 5.5 (w, 1 H). *Exact mass* calcd. for $C_{11}H_{18}N_2O_4$: 242.1267; found: 242.1273.

*4-Ethylidene-1-pyrazoline (**3**) from **36***

Samples of **36** (19.0 g, 78 mmol), potassium hydroxide (35 g, 625 mmol), ethylene glycol (150 ml), and water (35 ml) were placed in a 500-ml flask fitted with a reflux condenser and nitrogen inlet. The mixture was stirred and heated to 110–120°C for 16 h after which it was distilled under reduced pressure (ca. 100°C/2 Torr) until only a solid residue remained. Concentrated hydrochloric acid (8.3 ml) was added to the distillate and the solvent removed under reduced pressure. On cooling a thick oil resulted, 7.0 g (66%) (^{1}Hmr (D_2O) δ: 1.7 (m, 3 H), 3.9 (s, 4 H), 5.7 (m, 1 H)), along with approximately 5% ethylene glycol.

The pyrazoline **3** was prepared directly from the hydrochloride by the addition of 5 g sample to a slurry of red mercuric oxide (20 g), anhydrous sodium sulfate (20 g), and sodium bicarbonate (10 g) in 100 ml ether. After stirring for 3 h the solid residue was filtered off and the ether carefully removed by distillation. The residue was distilled at reduced pressure, with an oil bath heated to 60°C maximum, to give 1.25 g of a fraction bp 44–45°C/10 Torr; uv (methanol) λ_{max}: 320 (log ε 2.72). The ^{1}Hmr and ^{13}Cmr spectral data are listed in Tables 1 and 2. *Exact mass* calcd. for $C_5H_8N_2$: 96.0688; found: 96.0687.

*4-Ethylidene-1-pyrazoline (**3**) from 1,2-Butadiene*

Diazomethane (in 100 ml ether) prepared from bis(*N*-methyl-*N*-nitroso)terephthalamide (54 g, 150 mmol, 70% in mineral oil) by the procedure of Moore and Reed (9) was placed in a pressure bottle at Dry-Ice temperature and 1,2-butadiene (10.8 g, 193 mmol) was added. The bottle was allowed to warm to room temperature and was left undisturbed until the yellow color disappeared (10 days). The excess butadiene and ether was distilled off at atmospheric pressure and the residue distilled at 10 Torr, bp 50–51°C, to give 5.3 g (36%) of **3** having spectroscopic properties (uv, ir, nmr) identical with those reported above.

E-*3,3-Dideuterio-4-ethylidene-1-pyrazoline (**4**)*

The procedure used was identical to the method of preparation of **2** immediately above, except that diazomethane-d_2 (10) was used. The ^{1}Hmr spectrum displayed a decreased intensity at δ 4.9 equivalent to the substitution of 2 H by 2 D, and a splitting pattern different from that of **3** and **5**.

1,2-Butadiene-1,1-d_2

The procedure of Hurd and Meinert (11) for the debromination of 1,2-dibromo-2-butene was adapted to the preparation of 1,2-butadiene-1,1-d_2 by lithium aluminum deuteride reduction of crotonyl chloride (12) followed by the conversion of the 2-buten-1-ol-1,1-d_2 produced to the corresponding bromide. The bromide was converted to 1,2,3-tribromobutane-1,1-d_2 by the addition of bromine in carbon tetrachloride and the tribromobutane was converted to 1,2-dibromo-2-butene-1,1-d_2 and thence to 1,2-butadiene-1,1-d_2; ^{1}Hmr ($CDCl_3$) δ: 1.65 (d, 3 H), 5.07 (*q*, 1 H). There was no evidence of a proton signal at δ 4.63 corresponding to the vinylic hydrogens of C(1) (estimated < 1%).

Z-*3,3-Dideuterio-4-ethylidene-1-pyrazoline (**5**)*

The procedure used was the same as that described for the preparation of **3** and **4** only that 1,2-butadiene-1,1-d_2 was used. The product **5** had spectral properties analogous to those of **4** except that the splitting pattern at δ 4.9 was different and the ^{13}Cmr spectrum was unique as indicated in the text.

E-*4-Ethylidene-3-methyl-1-pyrazoline (**8**)*

A solution of diazoethane (240 mmol in 240 ml ether) and 1,2-butadiene (18.0 g, 333 mmol) was placed in a pressure bottle at −40°C and upon warming kept at room temperature for 36 h. The unreacted 1,2-butadiene (8.9 g) was then recovered and the ether removed by distillation at atmospheric pressure (taking care not to warm the flask above 50°C). The residue was distilled (bp 30°C/4 Torr) to give 10.7 g (48%) of a colorless liquid; uv (methanol) λ_{max}: 324 (log ε 260); ^{1}Hmr and ^{13}Cmr spectra are described in Tables 1 and 2. *Exact mass* calcd. for $C_6H_{10}N_2$: 110.0844; found: 110.0841.

Z-*4-Ethylidene-3-methyl-1-pyrazoline (**10**)*

A solution of diazomethane (~150 mmol in 100 ml ether) and 2,3-pentadiene (12 g, 176 mmol) was placed in a pressure bottle and maintained at room temperature for 12 days. The unreacted diazomethane and 2,3-pentadiene were removed by passing a stream of nitrogen through the solution and the unreacted diene was recovered (2.4 g). The ether was then removed by careful fractionation and the residue distilled at reduced pressure to give two fractions. Fraction A, bp 30–33°C/3 Torr (7.61 g) and fraction B, bp 35–40°C/1 Torr (6.5 g).

Fraction A: uv (methanol) λ_{max}: 317 (log ε 2.60); ^{1}Hmr and ^{13}Cmr spectra reported in Tables 1 and 2 confirm the structure **17**. *Exact mass* calcd. for $C_6H_{10}N_2$: 110.0844; found: 110.0846. The higher boiling fraction B was isomeric with A: uv (methanol) λ_{max}: 281 (log ε 3.84); ^{1}Hmr ($CDCl_3$) δ: 1.22 (d, 3 H), 1.77 (d of d, 3 H), 4.37 (m, 1 H), 5.72 (m, 1 H), 8.03 (s, 1 H), broad NH signal removed by D_2O. The spectrum is consistent with the structure of the tautomer of **10**, i.e., Z-4-ethylidene-5-methyl-2-pyrazoline. *Exact mass* found: 110.0846.

E-*4-Ethylidene-3-trideuteriomethyl-1-pyrazoline (9)*

The diazoethane synthesis from ethylamine (13) was modified by using 2,2,2-trideuterioethylamine which had been prepared by the lithium aluminum hydride reduction of trideuterioacetonitrile.

The method described for the preparation of **8** was used except that 2,2,2-trideuteriodiazoethane was used.

The product had a ^{1}Hmr spectrum analogous to that of **8** except for the loss of the doublet at δ 1.46. Mass spectrometric measurements indicated d_0 2.73, d_1 0.00, d_2 2.31, and d_3 94.97%, corresponding to 96.5% deuteration.

E-*4-Ethylidene-3,3-dimethyl-1-pyrazoline (12)*

Dimethyldiazomethane (~34 g, ~480 mmol) and 1,2-butadiene (31 g, 574 mmol) were placed in a pressure bottle and kept for 5 h at room temperature. After the removal of solvent and unreacted 1,2-butadiene the residual material was fractionally distilled using an oil bath temperature of 40°C. Each fraction was identified by uv, ir, and ms. Fractions 1 and 2 at 3.5–10 Torr consisted of 0.8 g acetone azine. Fractions 3 and 4 at 1–2 Torr consisted of 3.2 g of **12** and **37**, and fraction 5 contained 0.2 g of **37** and the tautomer of **12**.

Analysis of fraction 3 indicated it consisted of 67% **12** and 33% **37**; ^{1}H and ^{13}Cmr for **12** are reported in Tables 1 and 2; ^{1}Hmr for **37** ($CDCl_3$) δ: 1.35 (s, 6H), 1.84 (m, 3 H), 2.08 (m, 2 H), 6.63 (m, 1 H). *Exact mass* calcd. for $C_7H_{12}N_2$: 124.1000; found: 124.1002.

cis- *and* trans-*4-Ethylidene-3,5-dimethyl-1-pyrazoline (13 and 14)*

A solution of diazoethane (~13.4 g, ~240 mmol in 200 ml ether) and 2,3-pentadiene (23 g, 338 mmol) was placed in a pressure bottle and maintained at room temperature for 7 days. After recovery of 9.3 g of unreacted diene and the removal of ether the product was distilled at reduced pressure to give 9.2 g (93% yield based on diene used) of **13** and **14**; uv (methanol) λ_{max}: 327 (log ε 2.52) for 49:51 *trans–cis* mixture; ^{1}Hmr and ^{13}Cmr data are listed in Tables 1 and 2. *Exact mass* calcd. for $C_7H_{12}N_2$: 124.1000; found: 124.1003.

4-Neopentylidene-1-pyrazoline (15)

An ethereal solution of diazomethane (0.1 mol in 100 ml) and 4,4-dimethyl-1,2-pentadiene (17.7 g, 184 mmol) was placed in a pressure bottle and kept at room temperature for 2 weeks. The solvent was then carefully removed by fractionation and the residue distilled at 25°C/0.1 Torr to give 5.3 g (40% yield) of product; uv (methanol) λ_{max}: 320 (log ε 2.64); ^{1}Hmr and ^{13}Cmr data are listed in Tables 1 and 2. *Exact mass* calcd. for $C_8H_{14}N_2$: 138.1157; found: 138.1156.

Received September 28, 1977

ROBERT J. CRAWFORD, HIROKAZU TOKUNAGA, LOUIS M. H. C. SCHRIJVER, and JACKY C. GODARD. Can. J. Chem. **56**, 998 (1978).

The products of thermolysis of 11 4-alkylidene-1-pyrazolines were isolated and identified. It is observed that these products cannot be rationalized in terms of a planar singlet trimethylenemethane type of intermediate, nor can they be reconciled in terms of the orthogonal trimethylenemethane singlets. Evidence is presented that for 4-ethylidene-1-pyrazolines the carbon *anti* to the methyl has the greatest propensity to become a cyclopropane carbon, and that which is *syn* is most likely to become the exocyclic methylene.

ROBERT J. CRAWFORD, HIROKAZU TOKUNAGA, LOUIS M. H. C. SCHRIJVER et JACKY C. GODARD. Can. J. Chem. **56**, 998 (1978).

On a isolé et identifié les produits de thermolyse de 11 alkylidène-4 pyrazolines-1. On a observé que ces produits ne peuvent être expliqués en terme d'un intermédiaire singulet planaire de type triméthylèneméthane et qu'ils ne peuvent non plus être réconciliés en terme de singulets orthogonaux triméthylèneméthane. On présente des données à l'effet que, dans l'éthylidène-4 pyrazoline-1, le carbone *anti* par rapport au groupe méthyle possède le plus grand pouvoir de devenir un carbone du cyclopropane et que celui qui se trouve en *syn* a le plus de chance de devenir un méthylène exocyclique.

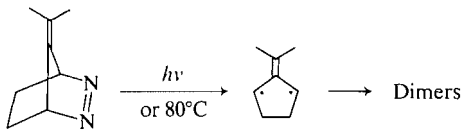
Over the past decade Dowd (1) has demonstrated that planar trimethylenemethane has a triplet ground state and can be generated either by the photolysis of 3-methylenecyclobutanone or 4-methylene-1-pyrazoline. Structurally modified 4-methylene-1-pyrazolines such as the bicyclic system (**38**) studied by

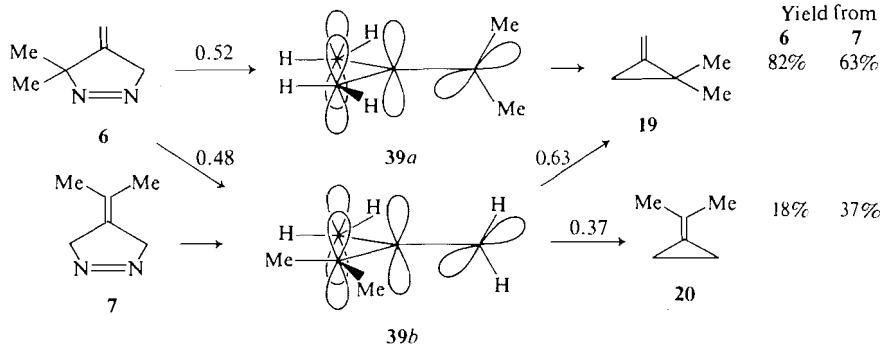


38

Berson and collaborators (2) have been demonstrated to produce both singlet and triplet 1,3-diyls, by both photolysis and thermolysis, as evidenced by trapping experiments and by dimer formation. The kinetics of thermolysis of 4-methylene-1-pyrazoline (**1**) and its deuterium- and ^{13}C-labelled derivatives have implicated a nitrogen free diyl as a possible intermediate (3). Theoretical studies (4) have suggested that for singlet trimethylenemethane the orthogonal diyls are more probable than is the planar species. We have shown that the product proportions from the thermolysis of 4-isopropylidene-1-pyrazoline (**7**)[1] and 3,3-dimethyl-4-methylene-1-pyrazoline (**6**) are easily rationalized in terms of the intermediates **39***a* and **39***b* in Scheme 1. These intermediates were postulated on the basis of the least motion principle and the presumed cleavage of both carbon nitrogen bonds as implicated from the kinetic studies on **1** (3). The product proportions from deuterium labelled **1** cannot be reconciled with a mechanism analogous to Scheme 1. Thus while we had kinetic data for **1** and product data for **6** and **7** we were unable, because of tautomerism, to get sound kinetic data for **6** and **7**, and cannot, because of the possible excess vibrational energy (5), rely upon the product proportions from deuterated **1**. This dilemma prevented us from drawing more definitive conclusions as to the nature of the intermediates involved. In an attempt to define the stereochemistry of the thermolysis process we have examined the methylenecyclopropanes produced from an additional set of 4-alkylidene-1-pyrazolines.

In testing our hypothesis that intermediates analogous to **39***a* and **39***b* could be usefully employed in rationalizing the proportions of methylenecyclopropanes we examined the pair of pyrazolines **2** and **3** and the proportions of methylenecyclopropanes, **17** and **18**, generated by each. The ethylidenecyclopropane and 2-methylmethylenecyclopropane produced on thermolysis of **2** and **3** were identified by their ^1H and ^{13}Cmr spectra and their gc retention times (6,7). That the product proportions are those of kinetic control was demonstrated by the observation that the ratio was not dependent upon reaction time and that the thermodynamic proportion at 175°C,

[1]The structures in this paper retain the numbering used in the preceding paper.



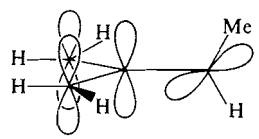
SCHEME 1. Pathways proposed for the thermolysis of **6** and **7**; the fractions over the arrows represent the proportions along each path (3).

extrapolated from the data of Chesick (7), is 36% **17** and 64% **18**; different from that produced by **2** or **3**.

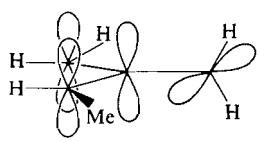
The product proportions from **2** and **3** cannot be

	17	18
From 2	80%	20%
From 3	90%	10%

rationalized in a manner analogous to Scheme 1. The high proportion of **17** produced from **3** suggests that **40** may be the intermediate first produced and that **41** is that which is first derived from **2**. However



40



41

such a sequence would not account for the formation of 10% of **18** from **2**, unless there is some interconversion of **40** and **41**. It would also appear to violate the least motion principle but recently Roth and Wegener (8) have observed the racemization of 3-methyl-6-ethylidenebicyclo[3.1.0]hexane at rates competitive with *cis–trans* isomerization and they have suggested that a major component of the reaction involves the rotation of the exocyclic ethylidene group at the same time as the cleavage of the C(1)—C(5) bond. This novel observation implies that the least motion principle cannot always be used in such processes and if extended to the thermolysis of **3** suggests that **40** may indeed be on the reaction path.

To test for this possibility we synthesized the deuterium labelled pyrazolines **4** and **5**. The thermolysis of **4** and **5** was carried out at 160°C and the 2-methylmethylenecyclopropane was purified by preparative gc. The relative proportions of **17** and **18** were unchanged on deuteration. The ratio of **17***a* and **17***b* was determined by both ^{1}Hmr and ^{2}Hmr. The product proportions are listed in Table 1. The structural isomerization of **4** to **5** occurs at measureable rates in the range 200–230°C (7) and

17*a* **17***b*

such an interconversion is not significant under the reaction conditions used here. We were concerned with the possibility of a degenerate rearrangement **17***a* ⇄ **17***b* since Gilbert and Butler (9) had observed

TABLE 1. Deuterium distribution in the 2-methylmethylenecyclopropane produced from the thermolysis of **4** and **5** (160.2°C, 1 atmosphere)

Reactant	Method of analysis	Time (h)	% distribution **17***a*	% distribution **17***b*
4	^{1}Hmr	1	74 ± 1*	26 ± 1

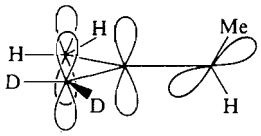
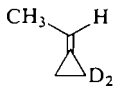
that 2,2-diphenyl-1-(dideuteriomethylene)cyclopropane isomerizes at 80°C to 2,2-diphenylmethylenecyclopropane-3,3-d_2. The last two entries in Table 1 demonstrate that such a degenerate rearrangement is not proceeding under the normal reaction conditions. It is possible that **4** produces specifically **17***a* (and **5** produces **17***b*) and that the excess vibrational energy produced in such a unimolecular decomposition is not quenched sufficiently rapidly to prevent the formation of either **17***b* or **18** from **4** (and **17***a* or **18** from **5**). Nevertheless the results do allow us to conclude that **42** cannot be an intermediate on the principal product determining pathway.

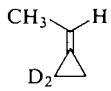


42

The ethylidenecyclopropane from **4** and **5** was examined for the *E* and *Z* isomers (**18***a* and **18***b*). The signals for the methyl and ring hydrogens for the samples obtained from the thermolysis of **4** and **5**



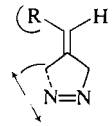
18*a*



18*b*

were different. In the case of the sample derived from **4** the signal of the ring methylene protons displays two lines flanking the central line separated by 3.7 Hz, whereas for that produced from **5** the separation is 2.1 Hz. It is interesting to compare our data with those reported by Gajewski (10) for *E*- and *Z*-2-methylethylidenecyclopropane. In the case of the *E* isomer Gajewski describes the signal of the methyl group on the double bond as a doublet with fine structure which is similar to that observed in the sample derived from **11**. For the *Z* isomer he describes the methyl signal as a doublet of quartets of 6.5 and 2 Hz, respectively; our sample derived from the thermolysis of **5** displayed a doublet of triplets of 6.5 and 1.9 Hz. These data suggest that the principal isomer of ethylidenecyclopropane produced from **4** is **18***a* and that from **5** is **18***b*. Nevertheless we cannot exclude the possibility of up to 20% of **18***a* in **18***b* and vice versa but they are not the same as the mixture of isomers from **4** and **5**.

There is the possibility that **3**, **4**, and **5** may be producing one product stereospecifically but because of chemical activation we observe a mixture analogous to that observed by Farneth *et al.* (11) and Andrews and Baldwin (12) for the thermal isomerization of 5-methylbicyclo[2.1.0]pent-2-ene. The heat of formation of 4-methylene-1-pyrazoline (**11**) may be calculated using group contributions taken from the compilation of Benson and O'Neal (13) and using the revised data for [—N=N—] of Engel *et al.* (14). Thus ΔH_f for **1** consists of 2[C(C) (H_2)N] + [—N=N—] + $[C_d(C)_2]$ + $[C_d(H_2)]$ = 59.0 kcal mol^{-1} and allowing for cyclopentene ring strain (13) gives ΔH_f of 65 kcal mol^{-1}. The activation energy for **1** is 33 kcal mol^{-1} (3) and thus ΔH_f for the thermolysis transition state is 98 kcal mol^{-1}, which is only 9 kcal mol^{-1} in excess of the energy barrier estimated for the degenerate rearrangement of methylenecyclopropane (1, 7). Even if all of the excess energy is in the hydrocarbon fragment and none in the nitrogen, collisional deactivation should be effective. The deuterium labelled methylenecyclopropanes examined in our earlier studies were (*a*) not at thermodynamic equilibrium and (*b*) gave the same result in solution as at 100 Torr (3). Consequently, we feel that we have generally not been working with the products of chemically activated rearrangements. This concern could be assessed by two methods: (*a*) we could carry out an extensive study upon the pressure dependence of the product distribution or (*b*) we could increase the number of vibronic degrees of freedom within the molecule with the expectation that the internal randomization of energy would suppress the rearrangement. We were also concerned with the implied steric factor in the thermolysis of **4** and **5** and were led to speculate that the carbon-nitrogen bond *syn* to a methyl group of an exocyclic double bond may be lagging in the bond breaking process. Support for this comes from the comparison of the thermolysis rates of **1** and **7**, the latter being $\frac{1}{3}$ the rate of the former (15) and **11** is 32 times faster than 4-isopropylidene-3,3,5,5-tetramethyl-1-pyrazoline (15, 16). A normal mode for the reaction coordinate would be expected to consist of the C—N stretching and consequently the possibility of steric compression being an important factor led us to study the thermolysis of 4-neopentylidene-1-pyrazoline (**15**). Subsequently Rabinovitch *et al.* (17)



have demonstrated that the internal randomization is not a satisfactory method for quenching hot molecules but the results of the thermolysis of **15** are nevertheless of interest in that the products are 4.2% neopentylidenecyclopropane (**34**) and 95.8% 2-*tert*-butylmethylenecyclopropane (**33**), and are clearly those of kinetic control.[2]

[2]An equilibrium mixture of 42.5% **33** and 57.5% **34** is obtained upon heating a sample of **14** for more than 5 days at 221°C.

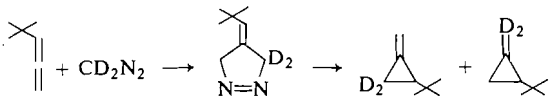
A sample of **15**-d_2 was prepared by the cycloaddition of diazomethane-d_2 to 4,4-dimethyl-1,2-pentadiene. The thermolysis results were analogous to those of **4** in that 70% of the **33** produced had deuterium on the cyclopropane ring (**33***a*) and 30% had it on the exocyclic methylene (**33***b*). Not enough **34**-d_2 was obtained to carry out a positional analysis. These data clearly indicate that the *syn-anti* relationship of the alkyl group and the methylene group of the ring is important and that there is a preference for the carbon *anti* to the alkyl group to become incorporated in the cyclopropane ring along with the exocyclic methylene of the product.



15-d_2 **33***a* **33***b*

E- *and* Z-3-*Methyl-4-ethylidene-1-pyrazoline (8 and 10)*

Taking advantage of the regioselective cycloaddition of diazoalkanes allowed us to synthesize stereospecifically **8** and **10**, and thus we could investigate further this preferential incorporation of the *anti*-methylene in the reactant into the cyclopropane ring of the product.

There are four products produced by thermolysis of **8**. The same four products are produced during the thermolysis of **10**. Some of these isomerize slowly under the thermolysis conditions and consequently we studied a series at various thermolysis times (see Table 2). Zero-time values were obtained by graphical extrapolation and are recorded in Table 2.

TABLE 2. Percentage of isomeric products from the thermolysis of **8** and **10** at 170.0°C (0.5 atmospheres)

		Product

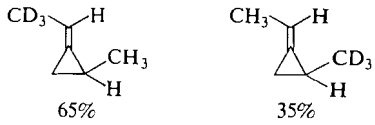
	∞†	6.2	2.5	47.8	43.8

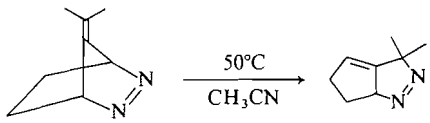
*Zero-time value obtained by extrapolation.
†Equilibrium value, see ref. 10.

We have identified the point of origin of the *exo*-ethylidene in the thermolysis of **8** by preparation of **9**. Isolation of the *E*-2-methylethylidenecyclopropane by preparative gc and subsequent ^{1}Hmr revealed that the deuterium labelling was distributed in both methyls, i.e., from Table 2 and the deuterium



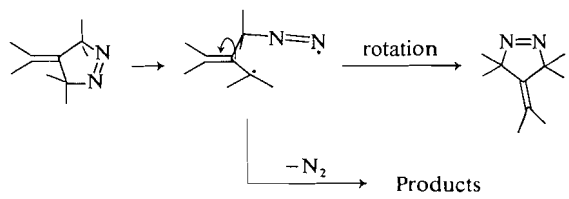
distribution from the thermolysis of **9** it is clear that the C(3) carbon of **8** becomes a cyclopropane ring carbon in at least 84% of the product. The exocyclic carbon becomes a cyclopropyl carbon in 90% of the product and the C(5) methylene in less than 23% of the total. The thermolysis of **10** results in an incorporation to 63%, i.e., approximately to the statistical level, for the incorporation of the methylene group into the cyclopropane ring of the products.

Recently Cichra *et al.* (18) have observed an allylic rearrangement of the pyrazoline like system suggestive of a one-bond azo cleavage mechanism. We have carried out controls on the previously studied 4-methylene-1-pyrazoline (**1**) (3) and on **2**, **6**, **8**, **9**, and **10** in this study, and in no case have we



38 **43**

been able to observe the analogous rearrangement, each sample was recovered essentially unchanged. Not all of our pyrazolines have been amenable to heating and reisolation experiments, and control experiments with **3**, **4**, **5**, **7**, **12**, and **15** have been frustrating in that tautomerism has prevented a definitive statement. In no case, however, have we been able to observe evidence for such a rearrangement. It is possible that in the more planar monocyclic system that the second carbon–nitrogen bond is broken more readily than rotation and rebonding to the exocyclic methylene can occur. In the bicyclic system **38** the exocyclic isopropylidene group because



of folding, is much closer to the diazenyl nitrogen and so recombination to **43** is facilitated. The fact that there is so little of **25** present in the thermolysis

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of **8** strongly implies that **8** cannot be isomerizing to **10**, and that in these dimethyl derivatives we may have escaped some of the problems of hot molecule chemistry. The control with **9**, wherein no high field methyl (CH_3) is observed in the recovered product implies that a degenerate rearrangement is not occurring, and in all probability no rearrangement to *cis*- or *trans*-3,5-dimethyl-4-methylene-1-pyrazoline is occurring since using the ^{1}Hmr spectra of **13** and **14** as a guide a high field doublet in the region of δ 1.30 to 1.50 would be expected to appear. We have observed that the thermolysis rates of **8** and **10** are comparable (approximately 1.4 to 1) and thus we would expect to see either isomer accumulating in the ^{1}Hmr spectrum of the other if they were interconverting.

The thermolysis of **12**, see Table 3, gives in excess of 70% of the thermodynamically least stable product again with over 84% of C(3) of the reactant becoming a cyclopropane carbon in the products, and the exocyclic ethylidene C(6) is implicated as a cyclopropyl carbon in greater than 81% of the products. It is interesting to note that the concentration of **26** proceeds through a maximum during the equilibration, implying that the process **25** → **26** is favoured for **25**.

cis- *and* trans-*4-Ethylidene-3,5-dimethyl-1-pyrazoline (13 and 14)*

The addition of diazoethane to 2,3-pentadiene results in the formation of *cis*- (**13**) and *trans*-4-ethylidene-3,5-dimethyl-1-pyrazoline (**14**) in almost equal amounts. One of the isomers undergoes thermolysis at a rate significantly faster than the other thus allowing the isolation of the less reactive isomer[3]. On the basis of ^{1}H- and ^{13}Cmr spectra the slower isomer has been assigned the *cis* configuration (**13**). Thermolysis products of the mixture of **13** and **14** along with the thermolysis of **13** alone are recorded in Table 4 along with equilibration data of the methylenecyclopropanes. The structure of the trimethylmethylenecyclopropanes **29** and **30** are assigned on the basis of chemical shift and ^{1}H coupling constants (6) and on the observation that the equilibrium constant $K = [trans]/[cis] = 2.71$ at 195°C is very similar to the value of 2.65 observed by Gajewski (10) for the ratio of *trans*:*cis* 2,3-dimethylmethylenecyclopropane upon equilibration at 190°C.

In view of these experiments, and the recent observations by Cichra and Berson (18), and those of Clarke *et al.* (19) on 1-pyrazolines, we feel that it is very probable that the sequence in which the carbon-nitrogen bonds are broken plays an important role in the stereochemistry of the products, and we are currently studying some chiral 4-alkylidene-1-pyrazolines in an attempt to define this sequence.

We have in this and in earlier papers attempted with limited success to use both the planar trimethylenemethane singlet and orthogonal diradicals such as **38**–**42**. Failure to develop a consistent pattern has led us to the conclusion that nitrogen is implicated in the stereochemistry of the formation of the products.

[3]Kinetic studies, by interruption and ^{1}Hmr measurements on the recovered reactants, showed that the *trans* isomer underwent thermolysis, at 169.8°C, with a first-order rate constant $k_2 = 7.61 \times 10^{-4}$ s^{-1}, whereas the *cis* isomer had a rate constant $k^2 = 2.66 \times 10^{-4}$ s^{-1}, i.e. differing by a factor of 2.86.

Experimental

The ^{1}Hmr and ^{13}Cmr of the alkylidenecyclopropanes produced in thermolysis processes reported herein are described in the accompanying paper (6). The ^{2}Hmr were obtained using a Bruker HFX 90 spectrometer in the Fourier transform mode. Gas chromatographic separations on a preparative scale were achieved on a Nestor Faust Prepkromat using bi-wall columns. Exact masses were determined on an A.E.I. MS-9 mass spectrometer.

Thermolysis of ***2***, ***3***, ***4***, *and* ***5***

Pyrex break-seals (18 mm diameter and 70 mm long) were attached to a vacuum line and evacuated and flamed before filling. A sample of the pyrazoline (25–30 mg), such as to give 300 Torr at 160°C, was degassed and transferred to the break-seal. The break-seal was then removed from the vacuum line and immersed in a well-stirred, thermostatted, silicone oil bath for the appropriate length of time. Upon removal and cooling the tubes were reattached to the vacuum line and the contents transferred to a sample vial (5 mm in diameter, total length 45 mm) attached to the vacuum line by a carefully ground 5/20 joint. Each sample was analyzed in triplicate using a 150 ft × 0.01 in. diameter column of SE-30 at 50°C.

The products, **17** and **18**, are known to be stable under the reaction conditions (7). The deuterated 2-methylmethylenecyclopropanes, **17***a* and **17***b*, were shown not to be undergoing a degenerate rearrangement by taking a nonequilibrated sample and putting it back in the constant temperature bath (see Table 1) under the reaction conditions.

Samples of **2** and **3** were reisolated after removing to 50% completion and their ^{1}Hmr examined for possible interconversion. No evidence for an interconversion was detected; however the quality of this control for the isomerization of **3** → **2** is limited by the tendency of **3** to tautomerize during isolation and thus complicate the ^{1}Hmr spectrum; (estimated excess of 10% of **2** in **3** could be detected).

Thermolysis of ***15*** *and* ***15***-d_2

Samples of **15** and **15**-d_2 were degassed, transferred in the vacuum line, and handled in a manner analogous to that of **2**. The product ratio, for thermolysis at 160°C, did not change during the course of thermolysis.

The two hydrocarbon products were prepared for identification by carrying out the thermolysis of a 200 μl sample in an 86 ml tube for 1 h at 199°C and then heating to 220°C for 2 days before subjecting to preparative gc. For purification of the products a 10 ft × 0.25 in. 20% SF-96 Chromosorb-W column was used at 50°C and a flow rate of 60 ml/min. The 2-*tert*-butylmethylenecyclopropane (**33**) had a retention time of 10 min and the neopentylidenecyclopropane (**34**) 14 min. The ^{1}H and ^{13}Cmr assignments are listed in the accompanying paper (6). *Exact Mass* calcd. for C_8H_{14}: 110.1096; found: 110.1093 for **14**, 110.1092 for **15**.

Thermolysis of ***8***, ***9***, *and* ***10***

A 20 μl sample of the pyrazoline to be examined was degassed and transferred to a 13-ml break-seal on a vacuum line. The sealed tubes were then placed in a constant temperature bath for a specific period. The products were then transferred to a sample tube and 80 μl of toluene was added before analysis by gc. A 40 ft × 0.25 in. 20% DMS on Chromosorb WAW column was used at 45°C and a flow rate of 30 ml/min giving retention times for **22**, **21**, **23**, and **24** of 15, 21, 24, and 29 min, respectively. The product proportions listed in Table 3 were obtained by extrapolation to zero time since the products were slowly isomerizing under the reaction conditions (10). The ^{1}Hmr, ^{13}Cmr, and ir are discussed in the accompanying paper (6).

Control Experiments on ***8***, ***9***, *and* ***10***

A sample of pyrazoline (150 μl) was transferred to a reaction vessel (~60 ml), degassed and placed in a well-stirred oil bath for 10 min at 165.7°C. The sample tube was reattached to the vacuum line, the nitrogen removed at −80°C, then warmed to 0°C and the hydrocarbons removed. The recovered pyrazoline was vacuum transferred to a nmr sample tube, dissolved in $CDCl_3$, and examined at 100 MHz. For **8** and **9** approximately 30 μl of sample was recovered, whereas 80 μl of **10** was recovered.

For **9** the recovered sample had, if anything, a decrease in intensity of ^{1}H at the C(3) methyl as implicated by the doublet at δ 1.42 and 1.49. The mass spectrum of the ethylamine-d_3 used to prepare the diazoethane-d_3 indicated 96.5% deuterium substitution.

The sample recovered from the partial thermolysis **8** failed to indicate the presence of any **10** as judged by the absence, in the ^{1}Hmr spectrum, of the outside line of the ethylidene's CH_3 multiplet at δ 1.70, and the lack of increased absorption at δ 1.34 and 1.41; (this latter criterion was less rigorous since the presence of tautomer in both reactant and recovered material displayed absorption very close to this position).

The sample recovered from the partial thermolysis of **10** failed to indicate the presence of any **8** as determined by the absence of increase at δ 1.49 in the ^{1}Hmr spectrum.

In most of the ^{1}Hmr samples small peaks at δ 1.18 and 1.25 were apparent, these have been tentatively assigned to the higher boiling 4-methyl-5-alkylidene-1-pyrazoline which is produced in small amounts during the synthesis. All of the spectra of recovered samples were complicated by the existence of tautomeric materials, but in each case we believe that an increase of 2.3% of the isomeric material would have caused signal enhancement detectable in our experiments.

Thermolysis of ***12***

The sample preparation and thermolysis procedures were the same as those described for **8** and **10**. A series of samples was run to determine if the presence of **37** altered the product proportions but varying amounts of **37** failed to change the proportions of **25**, **26**, and **28**.

A sample of the products was heated at 190°C for 24 h to increase the amount of **27** present and the isomers were separated by preparative gc using a 20 ft × 0.25 in. column of 20% SF 96 on Chromosorb WAW at a flow rate of 60 ml/min at 55°C. The retention times were 14.0, 17.0, and 25 min for **25**, **26**, and **27**, respectively. Isomer **28** produced by product thermolysis came at 19.0 min. The ^{1}Hmr and ^{13}Cmr are reported in the accompanying paper and are the basis of the structural assignments. *Exact Mass* calcd. for C_7H_{12}: 96.0939; found: 96.0952 for **25**, 96.0938 for **26**, and 96.0936 for **27**.

Samples of **23** recovered from the reaction showed little or no isomerization, however a conclusive statement cannot be made since we do not have the isomeric compounds for comparison.

Thermolysis of ***13*** *and* ***14***

Samples of **13** and **14** (48.7 and 51.3%, 150 μl) were transferred to a reaction vessel (86 ml) under vacuum. The vessels were heated at 169.75°C for 20, 40, 60, and 80 min. The hydrocarbon was removed under vacuum at 0°C and the remaining 1-pyrazoline was transferred to an nmr tube. The *cis–trans* ratio was measured by ^{1}Hmr. Data plotted as two separate compounds undergoing first-order thermolysis, without interconversion, gave good first-order rate plots, $k_{13} = 2.66 \times 10^{-4}$ s^{-1} and $k_{14} = 7.61 \times 10^{-4}$ s^{-1}.

The two isomeric hydrocarbons produced were separated on a 10 ft × 0.25 in. 20% dimethylsulfane column at 45°C using a flow rate of 39 m/min; retention times: **30**, 16 min; **29**, 22 min. The ^1H and ^{13}Cmr spectra of **29** and **30** are reported in the accompanying paper (6). *Exact Mass* calcd. for C_7H_{12}: 96.0939; found: 96.0938 for **31** and 96.0938 for **32**.

Rearrangements of vanadium(III) β diketonate complexes

A. J. C. NIXON AND D. R. EATON

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 15, 1977

A. J. C. NIXON and D. R. EATON. Can. J. Chem. **56**, 1005 (1978).

The rearrangement reactions of a number of V(III) β diketonate complexes have been studied by nmr. All reactions proceed by an intramolecular rather than an intermolecular process. The use of a complex with diastereotopic groups on the ligand allowed enantiomerization to be observed. Linkage isomerization was shown to be slow in triacetylmethanato V(III) complexes. Activation parameters are reported for five different complexes in a number of different solvents. Permutational analysis did not unambiguously distinguish between possible twisting and bond rupture mechanisms. The data are consistent either with a rhombic twist ($C_3(i)$) mechanism or with a bond breaking mechanism involving square pyramidal intermediates. The possibility that none of the usual simple intramolecular mechanisms provide a valid description of the rearrangement process is discussed. The rates of rearrangement of these V(III) complexes are consistently somewhat greater than those of analogous Al(III) complexes.

A. J. C. NIXON et D. R. EATON. Can. J. Chem. **56**, 1005 (1978).

On a étudié par rmn les réactions de transposition d'un certain nombre de complexes de β dicétonates de V(III). Toutes les réactions se produisent par un processus intramoléculaire plutôt qu'intermoléculaire. L'utilisation d'un complexe avec des groupes diastéréotopes sur le ligand permet d'observer l'énantiométrisation. On a montré que l'isomérisation des liens se produit lentement dans les complexes de triacétylméthano de V(III). On rapporte les paramètres d'activation de cinq complexes différents dans un certain nombre de solvants différents. L'analyse des permutations ne permet pas de distinguer d'une façon non-ambiguë entre les divers mécanismes possibles pour la rotation et la rupture des liens. Les données sont en accord soit avec un mécanisme de rotation rhombique ($C_3(i)$) ou un mécanisme de bris de lien impliquant des intermédiaires pyramidaux carrés. On discute de la possibilité qu'aucun des mécanismes intermoléculaires habituels simples pourrait fournir une description valide du processus de transposition. Les vitesses de transposition de ces complexes de V(III) sont d'une façon systématique un peu plus grandes que celles des complexes analogues de l'aluminium(III).

[Traduit par le journal]

Introduction

The rearrangement reactions of octahedral complexes have been extensively studied. As early as 1912 Werner (1) proposed an intramolecular mechanism for the isomerization of bidentate chelate complexes. There are recent reviews of the area by Serpone and Bickley (2) and by Fortman and Sievers (3). In 1964 Fay and Piper (4) demonstrated the utility of nmr in studies of this kind in an examination of the isomerization of trifluoroacetylacetonates of Al(III), Ga(III), In(III), Co(III), and Rh(III). This has been followed by a considerable number of other papers (5–7) the majority dealing with diamagnetic complexes. Gordon, O'Connor, and Holm (8) have studied some β diketonate complexes of Ru(III), Mn(III), Fe(III), and V(III). They found the Mn and Fe compounds rearranged rapidly, the Ru compounds rearranged slowly, and did not observe any changes in the nmr spectrum of the V(III) trifluoroacetylacetonate below 100°C. This latter result seems anomalous.

The present paper will report studies of the rearrangements of a number of V(III) diketonate complexes. The reactions occur at rates suitable for nmr experiments. The objectives are to identify, as far as possible, the mechanisms of rearrangement and to examine the effect of substituents on the rates and activation parameters. It was hoped to correlate the results with previous nmr studies of substituent effects in V(III) β diketonates (9).

Results

The rates of the reactions under consideration were found to be suitable for nmr studies. There are two possible nmr techniques. Spin saturation transfer (10) experiments have the advantage that they can yield data on exchange rates between individual sites. Unfortunately there are experimental difficulties in using the technique with paramagnetic complexes. The results of the line shape analysis method are less easy to interpret but the large chemical shifts make the method readily applicable to paramagnetic complexes.

V(III) has two unpaired electrons. The very short electron spin relaxation time leads to relatively sharp (20–80 Hz line width at half height) nmr

TABLE 1. β-Diketonate ligands

Systematic name	Trivial name	Abbreviation
Pentane-2,4-dionato	Acetylacetonato	$acac^-$
1,1,1,5,5,5-Hexafluoro-pentane-2,4-dionato	Hexafluoroacetyl-acetonato	$hfac^-$
1,1,1,-Trifluoropentane-2,4-dionato	Trifluoroacetyl-acetonato	$tfac^-$
3-Acetylpentane-2,4-dionato	Triacetylmethanato	$triac^-$
2,6-Dimethylheptane-3,5-dionato	Diisobutyrylmethanato	$dibm^-$

resonances. The ligands used in the present study are listed in Table 1 together with the abbreviations used throughout this paper. Figure 1 shows a set of ^{19}F nmr spectra for $V(tfac)_3$ obtained at different temperatures. $V(tfac)_3$ can exist as two isomers, *cis* and *trans*. All three CF_3 groups in the *cis* isomer are equivalent leading to a single nmr line. Each of the CF_3 groups in *trans* $V(tfac)_3$ has a different environment leading to a three line spectrum. In Fig. 1 the *cis* resonance is partly overlapped by the central line of the *trans* spectrum. The proton spectrum is slightly more complex due to the presence of CH as well as CH_3 resonances. The temperature dependence of the spectrum clearly indicates exchange of the non-equivalent CF_3 groups.

Line shape analysis of the spectra in Fig. 1 requires a knowledge of: (*a*) The temperature dependence of the chemical shifts. (*b*) The temperature dependence of the line width of each line. (*c*) The relative intensities of the peaks. (*d*) An exchange matrix which expresses the probability of the transfer of an ^{19}F nucleus from one site to a different site. Given the above information a suitable computer programme (11) may be used to calculate simulated spectra for different rate constants. The simulated spectra may then be fitted to the observed spectra at different temperatures. A comparison between a set of simulated and observed spectra is shown in Fig. 1. Different exchange mechanisms may lead to different exchange matrices. The strategy of the experiment is therefore to find the appropriate exchange matrix by trying the matrices predicted for a variety of mechanisms and to then obtain the activation parameters from the temperature dependence of the rate constants.

The temperature dependences of the chemical shifts follow rather accurately a Curie–Weiss law (12), i.e.:

$$\Delta\nu = a + \frac{b}{T}$$

The constants *a* and *b* may be readily obtained from measurements below the temperature at which exchange broadening commences. These constants *a* and *b* are solvent dependent and must be measured for each line in each solvent. It is not considered that uncertainties in the chemical shifts contribute significantly to the errors in the present experiments.

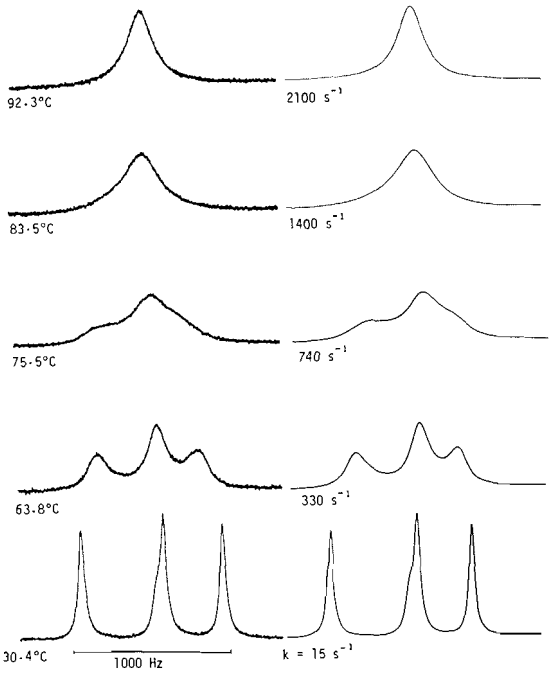

FIG. 1. Comparison of experimental and simulated nmr spectra of $V(tfac)_3$ at various temperatures. ^{19}F at 58.3 MHz in chlorobenzene (equal lifetimes at all sites).

The temperature dependence of the line width of the CH_3 resonance of $V(acac)_3$ has been measured. There can be no exchange broadening in this compound. The line width shows little variation in the temperature range 0–80°C. For these complexes the line width is determined by T_{1e}, the electron spin relaxation time. The electronic relaxation mechanism is most probably dominated by coupling of the molecular motion with the zero-field splitting. LaMar (13) has derived an appropriate expression for T_{1e}. The temperature dependence of T_{1e} arises from the temperature dependence of τ_c, the rotational correlation time of the molecule, which is reflected in the temperature dependence of the viscosity of the solution. However the dependence on τ_c is reversed depending on whether $\omega_s\tau_c \gg 1$ or $\omega_s\tau_c \ll 1$ (ω_s is the electronic Larmor frequency). From the viscosity of $CHCl_3$ $\tau_c \sim 5.7 \times 10^{-11}$ s (25°C) and from ^{13}C nmr measurements on $Co(acac)_3$ (14) $\tau_c = 7.3 \times 10^{-11}$ s (25°C). The latter value gives $\omega_s\tau_c = 2.1$ which is close to unity leading to the conclusion that there will be no pronounced line width temperature dependence around room

temperature as is confirmed by the results obtained. Small changes in line width will not significantly affect the kinetic data if the chemical shift differences are large. A temperature independent line width has therefore been assumed for $V(tfac)_3$, $V(tfac)(hfac)_2$, and $V(triac)_2(acac)$ all of which have large chemical shift differences. For complexes such as $V(hfac)_2(acac)$, $V(acac)_2(hfac)$, and $V(dibm)_3$ we have assumed that the change in line width with temperature is proportional to the change in line width of a non-exchanging line, e.g. from $V(acac)_3$. Such changes are quite small over the temperature ranges involved but become significant if the chemical shift differences are small.

The relative intensities of the peaks involved can be readily obtained from statistical considerations (e.g. the three lines from *trans* $V(tfac)_3$ are of equal intensity) or by integration (e.g. *cis* and *trans* $V(tfac)_3$).

The relationship between the exchange matrix and the possible mechanisms for exchange is complex. It is usual to proceed by a permutational analysis following the treatment introduced by Longuet-Higgins (15). A detailed analysis of the specific cases of interest in the present paper has been given by Eaton and Eaton (16). The results of this paper have been used to calculate exchange matrices and simulated spectra for the permutation sets corresponding to the proposed mechanisms. A comparison of experimental and simulated spectra for several cases is shown in Fig. 2. The results of these calculations can be summarized quite briefly. In every case the best fit is given by an exchange matrix which corresponds to the situation in which a group has an equal lifetime at each possible site. The implications of this result will be discussed below.

It has been suggested that comparison of the activation parameters for rearrangement reactions in

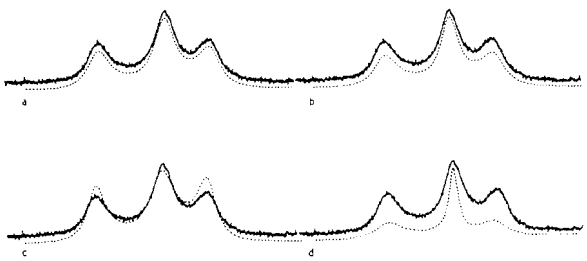

FIG. 2. Comparison of experimental and simulated spectra of $V(tfac)_3$ at an intermediate rate of exchange. (*a*) Equal lifetimes at all sites, ($RC_3(i)$) or SP primary and secondary or TBP with pseudorotation; (*b*) SP primary assuming all bonds rupture and reform with equal probability; (*c*) and (*d*) two cases for TBP mechanisms with lifetimes at downfield and upfield sites equal. The base lines for the simulated spectra have been lowered for clarity. Solvent chlorobenzene $T = 63.8°C$, rate 330 s^{-1}.

TABLE 2. Activation parameters of rearrangement processes of vanadium β-diketonate complexes in various solvents

Complex	Solvent	k^* (s^{-1})	$\Delta H^{\ddagger}$ (kcal)	$\Delta S^{\ddagger}$ (eu)
$V(tfac)_3$	$CDCl_3$	8.9	18.0	6.3
	C_6H_5Cl	9.2	16.5	1.3
	CCl_4	10.9	16.4	1.3
	Acetone	13.3	15.9	−0.1
$V(hfac)_2(tfac)$	$CDCl_3$	103	12.7	−6.7
$V(hfac)_2(acac)$	$CDCl_3$	86	11.8	−10.0
	C_6H_5Cl	105	11.8	−9.6
	CCl_4	110	11.3	−11.2
	Acetone	790	7.2	−21.0
	CH_3CN	565	5.3	−28.1
	CH_2Cl_2	~30	—	—
	Benzene	~40	—	—
$V(acac)_2(hfac)$	$CDCl_3$	40	—	—
	C_6H_5Cl	23	—	—

$V(dibm)_3$	$CDCl_3$	19	14.9	−2.7

*At 25°C.

different solvents may provide mechanistic information (4). The rearrangement of $V(tfac)_3$ has been studied in four solvents. The resulting activation parameters are given in Table 2. The complex $V(tfac)(hfac)_2$ has five chemically distinct CF_3 groups but two have very similar chemical shifts. Four will be exchanged by rearrangement reactions and one (from the tfac) will not. The spectra obtained by adding $V(tfac)_3$ to $V(hfac)_3$ always contain lines from other complexes but these can be minimized by using excess $V(hfac)_3$ due to the equilibrium

$$V(tfac)_2(hfac) + V(hfac)_3 \rightleftharpoons 2V(tfac)(hfac)_2$$

The single additional line from $V(hfac)_3$ causes relatively little problem in the analysis. Figure 3 shows a set of experimental and simulated spectra for this system. The complexes $V(acac)_2(hfac)$ and $V(acac)(hfac)_2$ present similar problems. Rearrangement of the former can only be studied using the proton spectra and overlap of CH_3 and CH resonances causes problems. $V(acac)(hfac)_2$ can be easily studied using ^{19}F nmr and the exchange has been observed in seven different solvents. In this case the rate is markedly solvent dependent. Activation parameters and rates are given in Table 2.

The complex $V(triac)_3$ offers the possibility of "linkage isomerization" (17). Each ligand has three acetyl groups, two bonded to the metal ion and one not bonded to the metal ion. "Linkage isomerization" involves exchange between the bonded and non-bonded acetyl groups. If rearrangement reactions proceed by a bond breaking rather than a twist mechanism, one might expect to observe linkage isomerization. In the complex $V(triac)_2(acac)$ it should be possible to observe both rearrangement

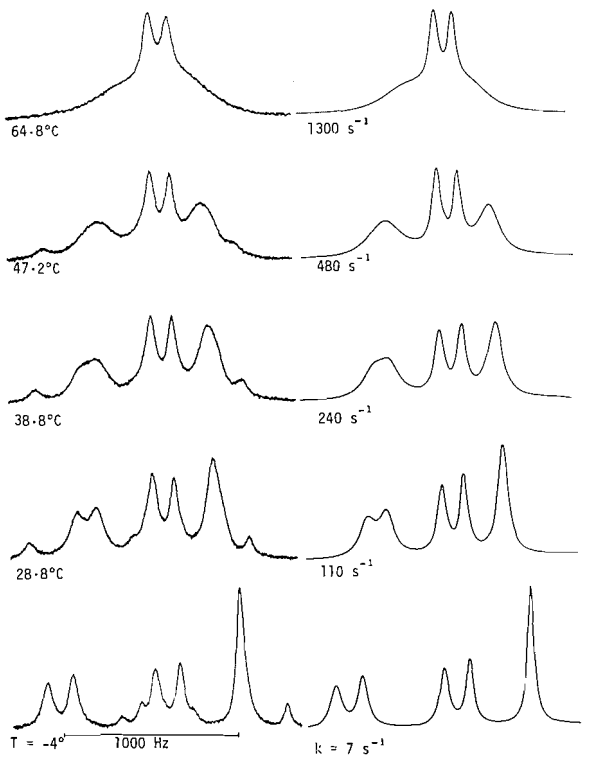

FIG. 3. Comparison of experimental and simulated nmr spectra of $V(hfac)_2(tfac)$ at various temperatures. ^{19}F 58.3 MHz in $CDCl_3$ (equal lifetimes at all sites). The central line of the five strong peaks is assigned to $V(hfac)_3$, and the remaining four lines to $V(hfac)_2(hfac)$. The weaker resonances arise from V(hfac) $(hfac)_2$.

and linkage isomerization. The CH_3 group of the non-bonded acetyl group is observed in an essentially diamagnetic position indicating little spin delocalization to this group. This is consistent with previous observations on acetyl groups attached to the π system of a paramagnetic complex. $V(triac)_2(acac)$ showed rearrangement at a rate corresponding to activation parameters closely similar to the compounds previously examined (see Table 2). There was no evidence for linkage isomerization for either $V(triac)_3$ or $V(triac)_2(acac)$ in solutions of these compounds at 200°C in *o*-dichlorobenzene. Even if rearrangement proceeds by bond breaking we would expect linkage isomerization to be slower, since additional activation energy will be required to rotate the incoming acetyl group about the C—C partially double bond. Thus Serpone and Bickley (2) quote activation enthalpies and entropies of 30.6 kcal/mol and 16 eu for the inversion of $Co(triac)_3$ and 38.9 kcal/mol and 28 eu for linkage isomerization. If it is assumed that this difference represents the barrier to rotation about the C—C bond and that this barrier is the same for the V complex as for the Co complex we may calculate a line broadening of 450 Hz at 200°C for an acetyl group undergoing linkage isomerization. The observed line width is 12 Hz and this is attributed to instrumental broadening due to the difficulty in tuning the spectrometer at high temperatures. It must be concluded therefore either that rearrangement occurs by a twist mechanism or that the additional energy required to rotate the ligand has been considerably underestimated.

In addition to geometric isomers such as *cis* and *trans* $V(tfac)_3$ these chelates also exist as optical isomers. In general, the process of enantiomerization is not observable by nmr techniques. It is, however, desirable to study enantiomerization along with the other rearrangement processes since some mechanisms proceed with retention of configuration and some with inversion. This can be accomplished by including a diastereotopic group on the ligand. The isopropyl group of the ligand dibm serves this function and enables the enantiomerization of the complex to be studied by nmr. Jurado and Springer (18) demonstrated that the coalescence of the isopropyl methyl resonances of $Al(dibm)_3$ was a measure of the enantiomerization of the complex and their arguments are equally applicable to $V(dibm)_3$. In the latter compound at ambient temperatures there is a 40 Hz splitting (at 100 MHz) of the diastereotopic CH_3 groups which coalesce around 43°C. The temperature dependence of the chemical shifts obtained in the temperature range +25°C to −25°C allowed extrapolation of the chemical shifts to higher temperatures. The activation parameters obtained for the enantiomerization process are included in Table 2. The methyl group chemical shifts of $V(dibm)_2(hfac)$ were unfortunately too small to allow a direct comparison of the rearrangement and enantiomerization processes.

Figure 4 shows a plot of $\Delta H^{\ddagger}$ vs. $\Delta S^{\ddagger}$ for the data of Table 2. A good linear relationship is observed. Such an isokinetic relationship indicates a common mechanism for all the reactions (19). Some caution is necessary in reaching a conclusion of this type since the errors in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ tend to be highly correlated. However the σ values from least-squares treatment of the Arrhenius plots indicate that the correlation of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ is significant. The systematic errors for the different complexes are likely to be very similar, and it is considered that Fig. 4 demonstrates a genuine isokinetic relationship.

The ligand exchange reactions of V(III) β diketonates are strongly acid catalysed (20). If the catalysis occurs during the breaking of the first chelate bond and if rearrangement proceeds by a

For personal use only.

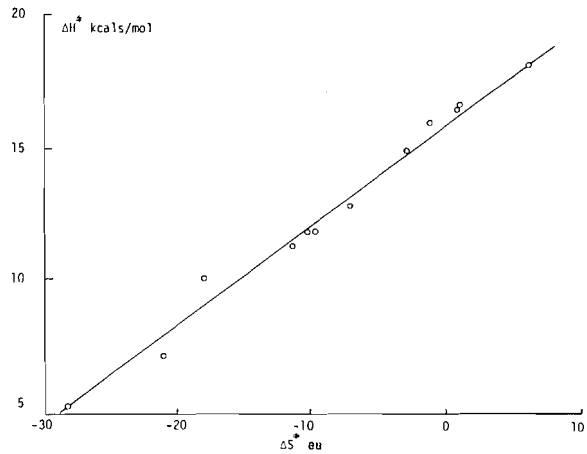

FIG. 4. Linear relationship between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for rearrangement of vanadium β-diketonate complexes.

bond breaking mechanism it follows that rearrangement should also be acid catalysed. To investigate this possibility the ^{19}F nmr spectra of $V(tfac)_3$ and $V(hfac)_2(acac)$ were examined at temperatures corresponding to intermediate exchange rates. Such spectra are most sensitive to small changes in rate. No measurable rate change was produced by concentrations of trifluoroacetic acid up to 0.1 *M*. Such a concentration produces a manyfold change in the rate of ligand exchange (20). A similar negative result was observed on addition of the base triethylamine.

Discussion

The review of Serpone and Bickley (2) deals in some detail with the possible rearrangement mechanisms of octahedral chelate complexes. It is usual to make an initial distinction between intermolecular and intramolecular mechanisms. Intermolecular mechanisms involve complete dissociation of one ligand. Intermolecular mechanisms can be unambiguously eliminated in the present case since: (*a*) an independent study (20) showed that the rates of ligand exchange were much slower than the rates of rearrangement; (*b*) in the present study the nmr resonances for free ligand molecules remained sharp at conditions under which the complexed ligands were clearly exchanging. Intramolecular mechanisms may be subdivided into twist and bond breaking mechanisms. Serpone and Bickley (2) showed that all twist mechanisms are basically similar, differing only in the axis about which the twist occurs. Bond breaking mechanisms may involve either a trigonal bipyramid (TBP) or square pyramid (SP) intermediate. The TBP intermediate may have the dangling ligand in either an axial or an equatorial position. Rapid rearrangement of the TBP by pseudorotation must also be considered. Gordon and Holm (6) have distinguished "primary" and "secondary" mechanisms for rearrangements proceeding through an SP intermediate.

Application of the analysis of Eaton and Eaton (16) to the results for $V(tfac)_3$ rules out the trigonal twist, $C_3(p)$, and TBP axial and equatorial pathways. The data can be interpreted either with a rhombic twist, $C_3(i)$, mechanism or with a bond rupture mechanism involving SP intermediates produced either directly or by rapid rearrangement of a TBP intermediate. The data for the other complexes are consistent with this result but do not unambiguously exclude other alternatives. The observation that enantiomerization of $V(dibm)_3$ occurs at a similar rate to the rearrangements is compatible with all but the TBP equatorial mode. The observation of an isokinetic relationship is taken to indicate that all rearrangements proceed by similar mechanisms.

The failure to observe linkage isomerization in $V(triac)_3$ favours, but does not prove, a twist mechanism. The lack of acid catalysis favours, but does not prove, a twist mechanism.

It has been suggested (21) that negative entropies of activation should be associated with twist mechanisms. However a recent compilation (22) shows that the range of observed entropies of activation is very similar for reactions thought to involve a twist mechanism and for those thought to involve bond rupture mechanisms.

It has been suggested (4) that the intermediate in a bond rupture mechanism will be more polar than that of a twist mechanism and hence that if bond rupture is involved the rearrangement will proceed faster in polar than in non-polar solvents. On this basis the data on $V(hfac)_2(acac)$ would favour a bond breaking mechanism but this is not supported by the data on $V(tfac)_3$.

It is concluded therefore that the present study does not provide an unambiguous distinction between twist and bond rupture mechanisms for the rearrangement of these chelate complexes. In this respect it resembles studies of β diketonate complexes of other metals (4, 6, 17, 22). It could be argued that attempts to make such distinctions on the basis of permutational analysis are of dubious value. There is a clear experimental method for differentiating between an intermolecular and an intramolecular process. Different intramolecular mechanisms are much less easily distinguished. For an intramolecular process the energy of the molecule will be a complex function of many bond lengths and bond angles. The activation energy must reside in the normal vibrations of the molecule which in turn are likely to be complex mixtures of bond stretches and bends

V		82.5	25	12.5	This work
Al		0.86	25	21.3	5

rather than simple group vibrations. There seems no good reason to suppose, therefore, that the lowest energy pathway will result from the accumulation of all the activation energy in the stretching of a single bond or in a single twisting motion as is implied in the various suggested mechanisms. The transition state could rather be a configuration of the molecule in which some angles have been distorted, some bonds have been stretched, and other internuclear distances have become short enough for incipient bond formation. If this were the case, even the most comprehensive data and the most sophisticated permutational analysis will not definitively identify a transition state with simple geometry since none exists.

Finally in Table 3 we compare the rates and activation energies for the rearrangements of β diketonate complexes of a number of molecules. Eaton, Eaton, Holm, and Muetterties (23) have given comparisons for a variety of ligands but note the lack of data on β diketonate complexes. It is seen that contrary to the earlier observation of ref. 8 the V complexes tend to rearrange significantly faster than Al and at rates comparable to Mn and Ga.

Experimental

The ligands acetylacetone, hexafluoroacetylacetone, and trifluoroacetylacetone were obtained from Eastman Kodak Co. Diisobutyrylmethane was obtained from Fisher Scientific Co. and triacetylmethane from Aldrich Chemical Co. Vanadium(III) trichloride and acetylacetonate were purchased from Research Organic/Inorganic Co.

V(III) β diketonate complexes were prepared by the method of Morris *et al.* (24). In the case of $V(dibm)_3$ a small amount of zinc dust effectively retarded oxidation. This method was unsuccessful for $V(triac)_3$ due to hydrolysis of the ligand. The following procedure yielded a mixture of $V(triac)_3$ and $V(triac)_2(acac)$ suitable for nmr experiments. Attempted separations by chromatography failed.

Triacetylmethane (1.1 g) was added to a solution of VCl_3 (0.4 g) in 1:1 acetone water mixture which was flushed with nitrogen. Triethylamine (0.79 g) was added dropwise under nitrogen and the reaction mixture left for 16 h. The product was extracted with CH_2Cl_2, dried with anhydrous $MgSO_4$, and evaporated almost to dryness under nitrogen. Cold petroleum ether (30–60°C) was added and the product separated as a brown oil which eventually crystallized. Recrystallization was from CCl_4.

The nmr spectra were obtained with a Varian DP 60 spectrometer operating at 58.3 MHz for both ^1H or ^{19}F or with a Varian HA 100 spectrometer. In cases where a wide field was scanned the instrument was operated in the field sweep mode to avoid dispersion effects. Simulated spectra were calculated using a Saunders (11) many site line shape programme. The input to the plotting routine was adjusted to conform to the same horizontal scale as the experimental spectrum. The overall rate parameter was adjusted to give the best visual fit.

Random errors in the activation parameters may be estimated from least-squares fits of the Arrhenius plots. At the 2σ level they are not more than 1 kcal in ΔH^* and not more than 3.2 eu in ΔS^*. Systematic errors are more difficult to evaluate. Errors in chemical shifts are considered negligible. Errors in assumed line widths are probably insignificant for $V(tfac)_3$, $V(tfac)(hfac)_2$, and for $V(triac)_2(acac)$ but may be significant for $V(hfac)_2(acac)$ and $V(dibm)_3$. This point was investigated by making Arrhenius plots using data deliberately based on 'incorrect' line widths. It was concluded that an error of 10% in the line width would be readily apparent as a curvature in the Arrhenius plot and would lead to a 15% error in ΔH^*. All such plots were linear within experimental error. Temperature measurements were made by means of a thermocouple in the nmr probe. Relative measurements are accurate to within ±0.5°C but there may be larger errors in the absolute temperatures. Overall the uncertainties in ΔH^* are estimated at ±2 kcal and in ΔS^* at ±7 eu. Results for the same complex in different solvents probably have a higher relative precision since most of the systematic errors are the same.

Ligand exchange reactions of vanadium(III) β diketonate complexes

A. J. C. NIXON AND D. R. EATON

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 15, 1977

A. J. C. NIXON and D. R. EATON. Can. J. Chem. **56**, 1012 (1978).

The kinetics of ligand exchange reactions of V(III) β diketonates have been studied. The replacement of acetylacetone by hexafluoroacetylacetone involves a rate law with both first- and second-order terms in the incoming ligand. The replacement of acetylacetone by deuteroacetylacetone involves terms zero-order and first-order in the incoming ligand. Both reactions are markedly catalyzed by acids and inhibited by bases. A mechanism involving a dangling ligand intermediate is suggested. The rates of ligand exchange are much less than the rates of isomerization.

A. J. C. NIXON et D. R. EATON. Can. J. Chem. **56**, 1012 (1978).

On a étudié la cinétique des réactions d'échange de ligands de β dicétonates de V(III). Le remplacement d'un groupe acétylacétone par un hexafluoroacétylacétone implique une loi de vitesse incluant à la fois des termes du premier et du second ordre par rapport au groupe ligand qui arrive. Le remplacement de l'acétylacétone par du deutéroacétylacétone implique des termes d'ordre zéro et du premier ordre relatif au ligand qui arrive. Les deux réactions sont catalysées d'une façon remarquable par les acides et inhibées par les bases. On suggère un mécanisme impliquant un ligand intermédiaire en balance. Les vitesses d'échange de ligand sont beaucoup plus faibles que les vitesses d'isomérisation.

[Traduit par le journal]

Introduction

Although β diketonate ligands form an extensive and well characterized series of chelate complexes with both transition and non-transition metal ions the mechanisms of ligand exchange reactions involving these complexes have been relatively little explored. The subject is of inherent interest since the results may be compared with the much better understood mechanisms of exchange of unidentate ligands. The information obtained may also prove useful in the interpretation of data concerning the isomerization of chelate complexes. The latter area has aroused considerable interest (1, 2). If isomerization is either an intermolecular process or an intramolecular process involving metal–ligand bond breaking a close relationship with ligand exchange is to be anticipated.

The initial study in this area was carried out by Adams and Larsen (3) who investigated the kinetics of ligand exchange of acetylacetone and trifluoroacetylacetone complexes of Zr, Hf, and Th. These proved to be facile reactions which could be conveniently studied by nmr line broadening techniques. They proposed a mechanism which has formed the basis for most of the subsequent discussion. Subsequently Saito and Takahashi (4) have studied the ligand exchange reactions of Pd(II) acetylacetonate and Saito and Masuda (5) those of Al(III) acetylacetonate. The reactions involved in both of these cases are considerably slower than those studied by Adams and Larsen and radio-chemical methods were used. The results with aluminum acetylacetonate differed from those obtained with Zr, Hf, and Th in that the rates were independent of ligand concentration. There are further reports of ligand exchange studies of $Be(acac)_2$ (6), of organometallic acetylacetone complexes of Sn(IV), Au(III), Ga(III), and Tl(III) (7), of (In)III β diketonate complexes (8) and of Sn(IV) alkyl and aryl acetylacetonate compounds (9).

We have undertaken a study of ligand exchange of V(III) β diketonate complexes. There have been no previously reported kinetic studies on these systems or indeed on any of the paramagnetic first row transition metal β diketonate complexes. Concurrently isomerization reactions of the same complexes have been examined (10) and the results reported in the present paper proved useful in the interpretation of the isomerization reactions. The ligand exchange rates are too slow to allow use of nmr line broadening techniques but can be measured by observing the growth of the nmr lines of the products.

Equilibria

The ligand exchange reactions of V(III) acetylacetonate with hexafluoroacetylacetonate and with fully deuterated acetylacetone have been examined. In order to establish suitable experimental conditions for carrying out kinetic studies it is necessary to know the equilibrium concentrations of the various complexes in different mixtures. Equilibrium constants for the reactions:

$$V(acac)_3 + V(hfac)_2(acac) \rightleftharpoons 2V(acac)_2(hfac) \qquad K_1$$

$$V(hfac)_3 + V(acac)_2(hfac) \rightleftharpoons 2V(hfac)_2(acac) \qquad K_2$$

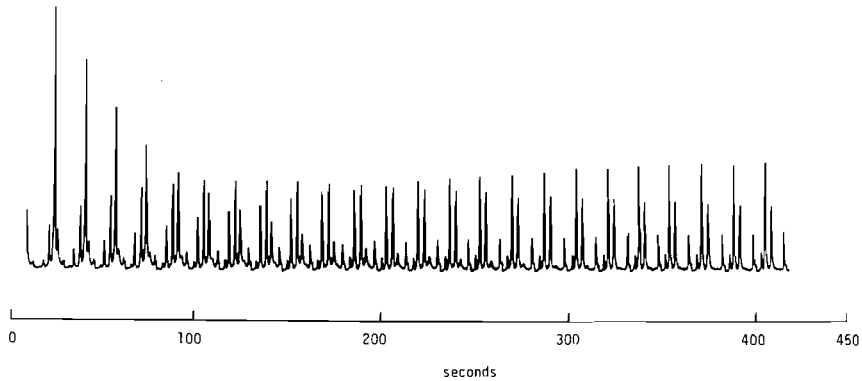

FIG. 1. Intensity of ^1H methyl resonances of $V(acac)_3$, $V(acac)_2(hfac)$, and $V(hfac)_2(acac)$ during a typical ligand exchange reaction of $V(acac)_3$ with Hhfac. Initial concentration of $V(acac)_3$ = 0.178 *M* and of Hhfac = 0.468 *M*. *T* = 27°C. Solvent $CDCl_3$.

can be readily obtained from the nmr spectra of mixtures of $V(acac)_3$ and $V(hfac)_3$. They show large deviations from the statistical values. Similar deviations have been noted by Pinnavaia and co-workers (11) for β diketone complexes with other metal ions. Integration of the resonances of the various complexes gives $K_1 = 1.7 \pm 0.1 \times 10^2$ and $K_2 = 2.8 \pm 0.2 \times 10^3$. If the equilibria were determined by statistical considerations both equilibrium constants would be equal to 3. The mixed complexes are clearly more stable than would be expected from purely statistical considerations. The analogous equilibrium constants for aluminum complexes (12) are $K_1 = 46$ and $K_2 = 725$. The ratio of K_2/K_1 is very similar in both cases (Al, $K_2/K_1 = 16$; V, $K_2/K_1 = 17$).

The enhanced stability of mixed complexes relative to simple complexes has been attributed to a reduction of the average ligand repulsion energy in mixed complexes (13, 14). Using the simple electrostatic model of Kida (13) it may be calculated that a difference of approximately 0.12 units in the negative charge of the oxygens of $acac^-$ and $hfac^-$ would produce the observed equilibrium constants. This model, though, would suggest a greater effect for the smaller Al^{3+} complexes which is contrary to the above results.

Rates of Ligand Exchange

The ligand exchange reactions were followed by repeatedly scanning the methyl region of the nmr spectrum after the addition of a ligand to a V(III) β diketonate complex. A typical trace is shown in Fig. 1. For the reaction between $V(acac)_3$ and Hhfac the initial rate of loss of $V(acac)_3$ was measured as a function of ligand concentration. The results are illustrated in Fig. 2. It is apparent that the rate increases as a function of Hhfac concentration with an order greater than one. The data of Fig. 2 can be fitted to the rate expression:

$$[1] \quad \text{Rate}/[V(acac)_3] = k_1[\text{Hhfac}] + k_2[\text{Hhfac}]^2$$

with $k_1 = 9.8 \times 10^{-3}$ ℓ mol^{-1} s^{-1} and $k_2 = 5.1 \times 10^{-2}$ ℓ^2 mol^{-2} s^{-1}. The reaction is markedly catalyzed by acid and inhibited by base. Figures 3 and 4 illustrate these effects for trifluoroacetic acid and triethylamine respectively. In the presence of base a limiting rate is reached which is directly proportional to Hhfac concentration. A rate constant of 5.4×10^{-3} ℓ mol^{-1} s^{-1} is obtained for the reaction represented by this limiting rate. This rate constant is similar to the k_1 of [1]. It may also be noted that the limiting rate is reached at a concentration of base much less than the Hhfac concentrations used. These observations suggest that the second-order term in [1] represents an acid catalyzed reaction. The acid involved may be Hhfac itself or an impurity, e.g.

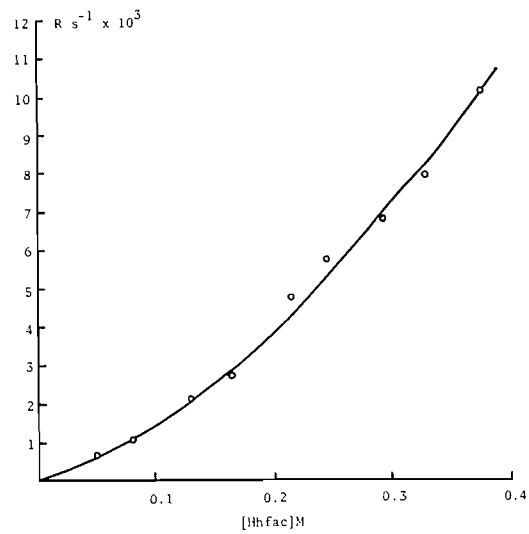

FIG. 2. Initial rate of exchange of $V(acac)_3$ with Hhfac as a function of Hhfac concentration. Solvent $CDCl_3$. $[V(acac)_3]$ at t_0 = 0.178 *M*. *T* = 27°C.

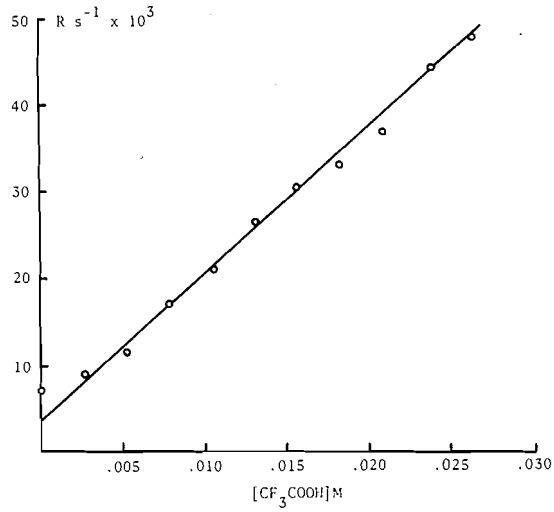

FIG. 3. Initial rate of exchange of $V(acac)_3$ with Hhfac as a function of trifluoroacetic acid concentration. Solvent $CDCl_3$. $[V(acac)_3]$ at $t_0 = 0.178$ *M*. $T = 27°C$.

trifluoroacetic acid arising from hydrolysis of Hhfac. Attempts to eliminate the possible impurity or to determine its concentration by potentiometric titration were unsuccessful.

The exchange of $V(acac)_3$ with deuterated acetylacetone was studied in a similar manner. In this case since we are dealing with an isotopic exchange reaction the data can be most conveniently analysed using McKay's (15) formula:

$$\text{Rate} = \frac{-3ab}{3a + b} \frac{\ln(1 - f)}{t}$$

where a and b are the initial concentrations of complex and ligand respectively and f is the fraction of the reaction which has occurred in time t. The rate again depends on ligand concentration but in this case the form of the expression is:

$$\text{Rate}/[V(acac)_3] = k_0 + k_1[\text{Hacac}]$$

with $k_0 = 1.7 \times 10^{-3}$ s^{-1} and $k_1 = 2.7 \times 10^{-3}$ ℓ mol^{-1} s^{-1}. As with the reaction with Hhfac, acid increases the rate and base decreases the rate. The limiting rate of 0.66×10^{-3} ℓ mol^{-1} s^{-1} is reached at a very low concentration of triethylamine. Water also shows a small catalytic effect.

Discussion

The results described above are qualitatively quite similar to results reported by Adams and Larsen (3) for ligand exchange reactions of other metal acetylacetonates. The mechanisms are complex; acid catalysis is observed and the rate of the non-catalyzed reaction depends on free ligand concentration. Perhaps the most important qualitative result is that the

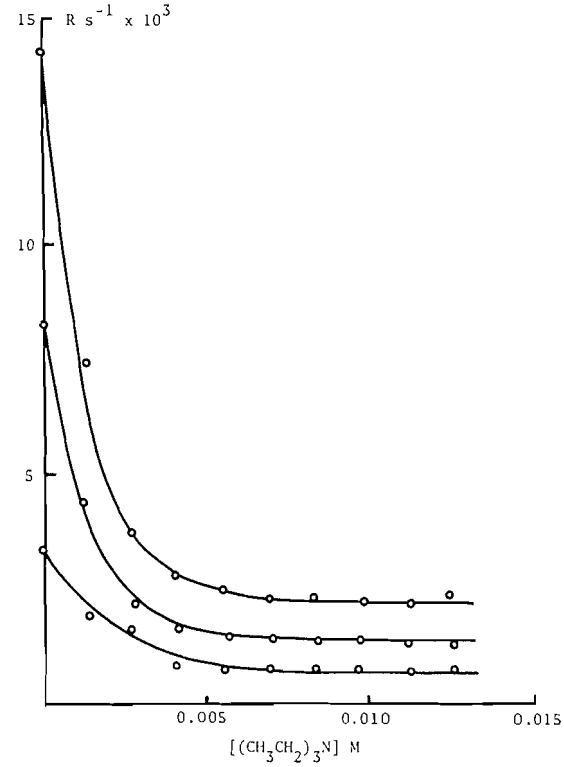

FIG. 4. Initial rate of exchange of $V(acac)_3$ with Hhfac as a function of triethylamine concentration. $[V(acac)_3]$ at $t_0 = 0.142$ *M*. $T = 27°C$. [Hhfac] = (*a*) 0.131 *M*; (*b*) 0.261 *M*; (*c*) 0.392 *M*.

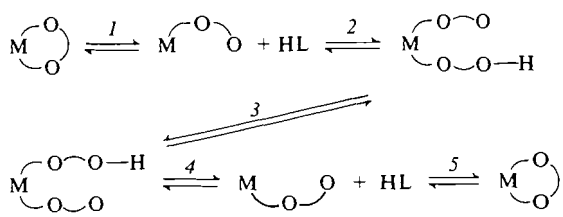
rate of ligand exchange of V(III) β diketonates is much less than the rate of isomerization (10) which eliminates the intermolecular mechanism for the latter process. It is of some interest to compare the absolute rates of ligand exchange for a series of metal acetylacetones—Th(IV)(10^3) (3) > Zr(IV)(10^2) (3) ~ Hf(IV)(10^2) (3) > V(III)(10^{-3}) > Pd(II)($10^{-4} - 10^{-5}$) (4) > Be(II)(10^{-5}) (6) > Al(III)(10^{-6}) (5) > Cr(III) > Co(III). The numbers refer to the ligand dependent pathway and are in 1 mol^{-1} s^{-1} at 25°C (except Al(III)).

Most detailed discussions of the non-acid catalyzed reaction have been based on the reaction scheme of Adams and Larsen (3). This can be represented as



This mechanism will lead to a first-order dependence on free ligand unless step *1*, the formation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

dangling ligand intermediate, is rate determining. Steps *1*, *2*, *3*, and *4* have all been suggested as rate determining. In the present case *1* is clearly not rate determining for exchange with Hfac, but may be responsible for the term zero-order in Hacac. Since hexafluoroacetone is a stronger acid than acetylacetone it might be expected that a proton would be transferred more rapidly from Hhfac to $acac^-$ than from Hacac to $hfac^-$. The observation that $V(acac)_3$ exchanges more rapidly with Hhfac than with Hacac therefore suggests that *3* may be the rate determining step for the process which is first-order in ligand. However the kinetic results do not eliminate either steps *2* or *4* from being rate determining.

Saito and Masuda (5) have suggested that acid catalysis is accomplished by protonation of the dangling ligand intermediate which enhances its stability. This would be equally plausible in the present case although direct catalysis of step *3* is also possible. Two aspects of the acid catalyzed reaction remain somewhat puzzling. The small amount of base needed to inhibit the reaction suggests that an acid impurity is present, but this could not be confirmed directly. On the other hand, the dependence of the rate on the square of the hexafluoroacetylacetone concentration is more readily rationalized if the ligand itself is the acid needed for catalysis. The pk_D of hexafluoroacetylacetone is sufficiently low to make this plausible (16). Further speculation on the mechanism does not seem warranted with the present data.

Experimental

The ligands acetylacetone and hexafluoroacetylacetone were obtained from Eastman Kodak Co. Vanadium trichloride and vanadium acetylacetonate were purchased from the Research Organic/Inorganic Co. Vanadium hexafluoroacetylacetonate was prepared by the method of Morris *et al.* (17).

Deuterated acetylacetone was prepared by refluxing a mixture of 20 ml (0.194 *M*) of acetylacetone, 100 g (5 mol) of D_2O, and a small amount of Na_2CO_3 for 24 h. The product was extracted with diethyl ether, dried over Na_2SO_4 for 24 h, and distilled. The distillate was further dried with K_2CO_3 and redistilled collecting the fraction 128–130°C. By nmr the product was 84% deuterated which sufficed for the exchange experiments. $CDCl_3$ was used as a solvent throughout.

Samples for the nmr equilibrium experiments were prepared by the following procedure. The appropriate complex was recrystallized and stored overnight in an evacuated dessicator containing P_2O_5. Solutions were prepared in a glove bag under dry N_2. After degassing on a vacuum line the sample tubes were evacuated and sealed. The sealed samples appear to be indefinitely stable. For kinetic runs the tubes were sealed with serum caps to allow introduction of the ligand. Evidence for decomposition become visible only after several days. The nmr tubes were allowed to thermally equilibrate in the probe before adding free ligand. The initial time was estimated from the time of mixing. The tube must be removed from the probe for about 30 s for ligand addition.

The nmr spectra were obtained with a Varian HA 100 instrument with probe temperature 27°C. The region of interest was repetitively scanned using a simple switching device. Coefficients relating the observed peak heights to the concentrations of the species may be readily obtained. Concentrations were then plotted against time and the initial rates found from the slopes at t_0.

Gas phase dissociation of protonated acetic acid to the acyl cation and water. Heat of formation of CH_3CO^+ and proton affinity of ketene

WILLIAM R. DAVIDSON, YAN K. LAU, AND PAUL KEBARLE
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 26, 1977

WILLIAM R. DAVIDSON, YAN K. LAU, and PAUL KEBARLE. Can. J. Chem. **56**, 1016 (1978).

Pulsed electron beam high pressure mass spectrometry was used to measure the enthalpy and entropy of the dehydration of protonated acetic acid, and the proton affinity of ketene in the gas phase. The variation of the equilibrium constant with temperature from 515 to 615 K led to ΔH^0 of 24.6 kcal/mol and a ΔS^0 of 33.1 cal/deg for the dehydration of protonated acetic acid. Proton transfer equilibria measurements of reactions: $BH^+ + CH_2CO = B + CH_3CO^+$ at 600 K with reference bases of known proton affinity led to a proton affinity of 195 kcal/mol for ketene. The heat of formation of the acetyl cation ($\Delta H_f^0(CH_3CO^+) = 160$) was obtained from both the proton affinity of ketene, and from the dehydration enthalpy of protonated acetic acid combined with the proton affinity of acetic acid. The energetics for the dehydration reaction in the gas phase and in solution are compared.

Introduction

Recent reports from this laboratory (1–3) described studies of gas phase equilibria 1 involving the carbocations R^+ ($C_2H_5^+$, $C_3H_7^+$, $t\text{-}C_4H_9^+$) with B (H_2 (1), CH_4 (1), OH_2 and CO (2, 3)). Process 1 may be considered as a Lewis acid–base reaction between the Lewis acid R^+ and the σ (H_2, CH_4), π (CO), and n (OH_2) donor bases.

[1] $$R^+ + B = (RB)^+$$

The present work describes a determination of the temperature dependence of reaction 2 which falls in the class of reactions 1. The hydration of the acylium ion CH_3CO^+ leads to protonated acetic acid (3). The heat of formation of CH_3CO^+ in the gas phase is not well established. ΔH_2 obtained from a van't Hoff plot of the equilibrium constant K_2 permits the evaluation of the above heat of formation since the proton affinity of acetic acid is known. The heat of formation of CH_3CO^+ can be also obtained from the proton affinity of ketene as shown in reaction 3.

[2] $$CH_3CO^+ + OH_2 = CH_3C(OH)_2^+$$

[3] $$CH_3CO^+ = CH_2CO + H^+$$
$$\Delta H_3 = PA(CH_2CO)$$

The present work gives the results of proton affinity measurements for ketene.

The reverse of reaction 2 has been observed (5) by nmr techniques in the condensed phase HSO_3F, SbF_5, SO_2. Olah and White (5) were able to study the temperature dependence of this dehydration reaction and obtain the activation energy. A comparison of the energetics of the dehydration [−2] in the gas phase and in solution proves interesting.

Experimental

The equilibrium [2] was studied with one of the pulsed electron beam high ion source pressure mass spectrometers (6) available in our laboratory. Water vapor at a selected pressure between 1.5–3 Torr containing ~0.1% acetic acid was passed in slow flow through the thermostated ion source. The positive ions produced by electron impact and subsequent ion molecule reactions in water are (6) the protonated water clusters $H^+(H_2O)_n$. The proton transfer [4] to acetic acid is exothermic for low n.

[4] $$H^+(H_2O)_n + CH_3COOH = CH_3C(OH)_2(OH_2)_k^+ + (n - k)OH_2$$

Below 515 K, the major ions observed were: $H^+(H_2O)_n$, $CH_3C(OH)_2(OH_2)_k^+$, and $(CH_3CO_2H)_2H^+$, the latter being formed by addition of acetic acid to protonated acetic acid. Above 515 K the equilibrium [2] becomes observable. At temperatures above 615 K the CH_3CO^+ becomes the dominant

ion. Pure water, rather than the usual mixture (6) of carrier gas CH_4 and solvent (H_2O), was used since the establishment of the equilibrium [2] was too slow at low water concentrations.

The proton affinity of ketene was obtained from proton transfer equilbria measurements at 600 K. The equiiibrium

[5] $$BH^+ + CH_2CO = B + CH_3CO^+$$

constant K_5 was used to obtain $\Delta G_5^0 = -RT \ln K_5$ at 600 K. The procedure used in these measurements has been described previously (4).

Results and Discussion

The van't Hoff plot of the equilibrium constant K_2 for reaction 2, $CH_3CO^+ + OH_2 = CH_3C(OH)_2^+$, is shown in Fig. 1. The slope leads to $\Delta H_2^0 = -24.6$ kcal/mol. The resulting $\Delta S_2^0 = -33.1$ cal/deg. The data are summarized in Table 1.

The results from the proton transfer equilibria [5] used for the determination of the proton affinity of ketene are summarized in Fig. 2. The measured ΔG_5^0 when combined with the known (7–9) ΔG_6^0 for the reference bases B lead to $\Delta G_6^0 = 6.3$ kcal/mol for reaction 6 involving ketene at 600 K.

[6] $$NH_4^+ + B = NH_3 + BH^+$$

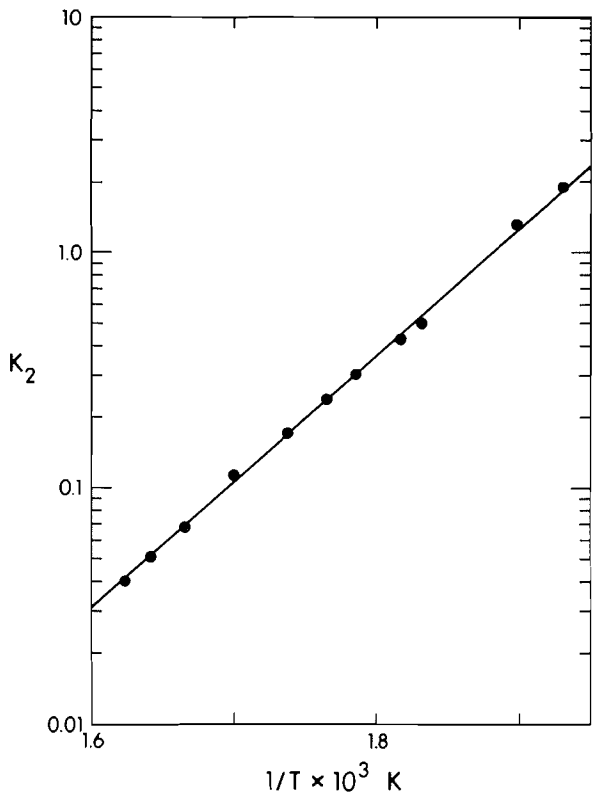

FIG. 1. van't Hoff plot of equilibrium constant K_2 for reaction 2, $CH_3CO^+ + OH_2 = CH_3C(OH)_2^+$ measured in the gas phase. Equilibrium constant calculated with reactant pressures in Torr units.

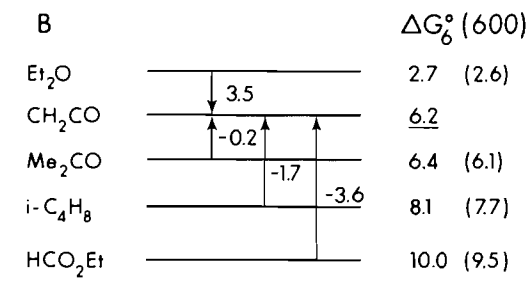

FIG. 2. Summary of proton transfer equilibria used to determine proton affinity of ketene. Numbers beside arrows correspond to $\Delta G_5^0 = -RT \ln K_5$ for the proton transfer equilibrium [5] $BH^+ + CH_2CO = B + CH_3CO^+$ measured at 600 K. The ΔG_6^0 given on the right hand side correspond to the standard free energy changes for proton transfer from the ammonium ion: $NH_4^+ + B = NH_3 + BH^+$ at 600 K. The ΔG_6^0 in parentheses are those from the earlier determination of Yamdagni and Kebarle (4). The ΔG_6^0 without parentheses are more recent values (7). $\Delta G_6^0 = +6.3$ is deduced from the present data for proton transfer to ketene. All values in kcal/mol.

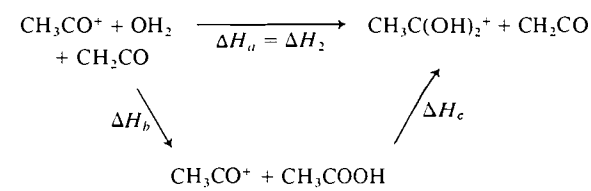
From Fig. 2 it can be seen that the four independent determinations of the ΔG_6^0(ketene) are generally consistent to ~0.2 kcal/mol. Using ΔG_6^0(ketene) = 6.2 kcal/mol and an estimated $T\Delta S_6 = 1$ kcal/mol at 600 K for ketene, obtained from considering rotational symmetry number changes, one obtains ΔH_6^0(ketene) = 7.2 kcal/mol and using the known (8, 9) proton affinity of ammonia PA(NH_3) = 202.3 ± 1 kcal/mol one obtains PA(ketene) = 195 ± 1.5 kcal/mol. Since the proton affinity of acetic acid PA(CH_3COOH) = 186.5 kcal/mol was determined previously (4, 7) from proton transfer equilibria measurements, the thermodynamic consistency of the ion equilibria measurements can be checked through the cycle shown below:



where $\Delta H_a = \Delta H_2 = -24.6$ kcal/mol, $\Delta H_b = \Delta H_f(CH_3OOH) - \Delta H_f(OH_2) - \Delta H_f(CH_2CO) = -34.1$ kcal/mol and ΔH_c = PA(CH_2CO) − PA(CH_3COOH) = 8.5 kcal/mol. Therefore $\Delta H_b + \Delta H_c = -25.6$ kcal/mol while $\Delta H_2 = -24.6$ kcal/mol, which means that the cycle is consistent to within 1 kcal/mol which is as good as could be expected.

The proton affinity of ketene PA(CH_2CO^+) = 195 kcal/mol when combined with $\Delta H_f(H^+) = 367.1$ kcal/mol leads to $\Delta H_f(CH_3CO^+) = 160.7$ kcal/mol while ΔH_2 and PA(CH_3COOH) lead to $\Delta H_f(CH_3CO^+) = 159.7$. The average of these is

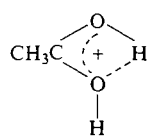
[a]From refs. 4 and 9.
[b]Calculated from the enthalpy of dehydration of protonated acetic acid and the proton affinity of acetic acid.
[c]Calculated from the heats of formation of water ($\Delta H_f^0 = -57.8$ kcal/mol) (10), acetic acid ($\Delta H_f^0 = -103.3$ kcal/mol) (10), and the proton ($\Delta H_f^0 = 367.1$ kcal/mol) (14), and the enthalpy of the reaction.
[d]Calculated from the heats of formation of ketene ($\Delta H_f^0 = -11.4$ kcal/mol) (15), and the proton, and the enthalpy of the reaction.

$\Delta H_f(CH_3CO^+) = 160$ kcal/mol. These data are summarized in Table 1.

Previous determinations of $\Delta H_f(CH_3CO^+)$ were based on appearance potentials. The recommended (10) value $\Delta H_f(CH_3CO^+) = 152$ kcal/mol was based on the appearance potential $A_p(CH_3CO^+,CH_3COCH_3)$ determined by photoionization (11). On the other hand the appearance potential from acetaldehyde $A_p(CH_3CO^+,CH_3COH)$ leads (11) to a higher value $\Delta H_f(CH_3CO^+) = 158$ kcal/mol. Beauchamp and co-workers (12), in a recent publication which appeared while the present work was being completed, reported a redetermination of the above photoionization appearance potentials which confirmed the earlier work (11). On the basis of an ordering of the stabilities of carbonium ions R^+ based on ion molecule reaction studies, Beauchamp and co-workers (12) were able to select the higher heat of formation $\Delta H_f(CH_3CO^+) = 158$ kcal/mol as the only one consistent with the ion molecule results. Furthermore they quoted an as yet unpublished proton affinity determination of ketene PA = 196.4 kcal/mol from their laboratory which leads to $\Delta H_f(CH_3CO^+) = 159.2 \pm 2$ kcal/mol. The present results of 160.7 and 159.7 kcal/mol with an estimated error of ± 2 kcal/mol are thus in good agreement with their heat of formation results.

It is interesting to note that the measured $-\Delta S_2^0 = 33.1$ cal/deg for the hydration of CH_3CO^+ is larger by a few cal/deg than the average $-\Delta S^0$ values observed in association reactions. The latter values are generally below 30 cal/deg (9). The larger loss of entropy in reaction 2 may be associated with the restricted rotation in the protonated acetic acid which is due to internal hydrogen bonding as shown in structure **1**.



1

Structure **1** has been suggested by nmr experiments. At low temperature **1** is sufficiently rigid such that the two protons become nonequivalent (5, 13).

Olah and White (5) determined the activation energy $\Delta H_{-2}^{\ddagger} = 16.3$ kcal/mol and activation entropy $\Delta S_{-2}^{\ddagger} = -13.1$ cal/deg for the dissociation of protonated acetic acid to the acetyl cation and water, occurring in FSO_3H–SbF_5 solution. In the gas phase, since reaction 2 should have no activation energy, $\Delta H_{-2}^{\ddagger}$(gas phase) may be expected to be close to $\Delta H_{-2} = 24.6$ kcal/mol. The gas phase activation entropy $\Delta S_{-2}^{\ddagger}$ should be positive but smaller than $\Delta S_{-2}^0 = 33$ cal/deg. Comparing the solution with the gas phase data we notice that the activation energy in solution is only half of that in the gas phase and that the entropy in solution is (strongly) negative while that in the gas phase is (strongly) positive. This result is consistent with strong solvent participation in the activated complex. We may consider that an important stabilization of the 'free' CH_3CO^+ in solution is obtained through the interaction of the (Lewis acid) cation with a lone pair on one solvent molecule S1. This means that the essential features of the transition state in solution should be represented by structure **2**. Such a complex is consistent with a low activation energy and a negative activation entropy.

Methanol extraction of the ground seeds of *Uncaria Gambier Roxb.* followed by chromatography afforded a crystalline $C_{30}H_{38}O_{10}$ terpene. This has been shown by X-ray analysis to be 7α-acetoxydihydronomilin. The crystals are orthorhombic, $P2_12_12_1$, $a = 13.158(2)$, $b = 17.092(2)$, $c = 12.689(2)$ Å, $Z = 4$, $d_x = 1.300$, $d_o = 1.300$ g cm^{-3}. The structure has been determined by the direct method and Fourier syntheses, and refined by block-diagonal least-squares to $R = 0.042$ for 2621 observed reflexions. The molecule contains a seven-membered lactone ring *A*, three six-membered rings *B*, *C*, *D*, a three-membered ring *E*, a furan ring *F*, and two acetate groups. *A* and *B* are chair, *C* is twist-boat, *D* is 1,3-diplanar, while *E* and *F* are planar. The *A*/*B*, *B*/*C*, *C*/*D* junctions are *trans*, *D*/*E* is *cis*, and *F* is linked to *D* by an equatorial C—C bond. The two acetate groups are in axial positions on *A* and *B* and are *cis* to each other. The O atom forming the apex of the three-membered ring is wedged between two H atoms and their parent C atoms at short intramolecular distances O...H = 2.28(2) and 2.28(3), and O...C = 2.623(3) and 2.668(4) Å. No intermolecular hydrogen bonding is indicated.

FARID R. AHMED, ANG S. NG et ALEX G. FALLIS. Can. J. Chem. **56**, 1020 (1978).

L'extraction par le méthanol de grains concassés de *Uncaria Gambier Roxb.* suivie par une chromatographie fournit un terpène cristallin de formule moléculaire $C_{30}H_{38}O_{10}$. On a montré par diffraction de rayon-X qu'il s'agit de l'acétoxy-7 dihydronomoline. Les cristaux sont orthorhombiques $P2_12_12_1$, $a = 13.158(2)$, $b = 17.092(2)$, $c = 12.689(2)$ Å, $Z = 4$, $d_x = 1.300$, $d_o = 1.300$ g cm^{-3}. On a déterminé la structure par une méthode directe et des synthèses de Fourier et on l'a affinée par la méthode des moindres carrés (blocs diagonaux) jusqu'à une valeur de R de 0.042 pour 2621 réflexions observées. La molécule contient un cycle lactonique à sept chaînons (*A*), trois cycles à six chaînons (*B*, *C* et *D*), un cycle à trois chaînons (*E*), un cycle furannique (*F*) et deux groupes acétates. Les cycles *A* et *B* sont dans la conformation chaise, le cycle *C* est dans une conformation bateau déformé, le cycle *D* est diplanaire-1,3 alors que *E* et *F* sont plans. Les jonctions *A*/*B*, *B*/*C* et *C*/*D* sont *trans*, *D*/*E* est *cis* et *F* est lié à *D* par un lien équatorial C—C. Les deux groupes acétates sont en positions axiales sur *A* et *B* et sont *cis* l'un par rapport à l'autre. L'atome d'oxygène formant le sommet du cycle à trois chaînons est calé entre deux atomes d'hydrogène et leurs atomes de carbone à des distances intramoléculaires courtes O...H = 2.28(2) et 2.28(3), et O...C = 2.623(3) et 2.668(4) Å. Il ne semble pas exister de liaison hydrogène intermoléculaire.

[Traduit par le journal]

Introduction

The plant, *Uncaria Gambia Roxb.*, a member of the Rubiaceae family is common to Singapore and Malaysia, where the concentrated aqueous extract of the leaves and stems has been used as a tanning material called Gambir. A few alkaloids (1) have been isolated from these plant extracts but the other chemical components have received little attention. We report herein the results of methanol extraction of seeds of *Uncaria Gambier Roxb.* which after a combination of column and thin-layer chromatography afforded crystalline material, mp 265–266°C.

Results and Discussion

This material was very sensitive to treatment with aqueous base or acid, and simple degradation products could not be isolated in pure form. The molecular ion peak at *m/e* 558 in the mass spectrum and elemental analysis were consistent with the molecular formula $C_{30}H_{38}O_{10}$. A strong, broad infrared absorption at 1720–1740 cm^{-1} indicated the presence of several carbonyl functions; possibly esters and/or lactones. Two methyl carbonyl signals, probably due

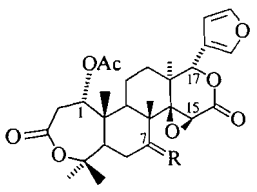
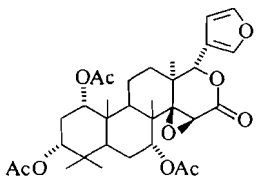
to acetates, could be clearly identified at δ 2.06 and δ 2.16 ppm in the ^{1}Hmr spectrum. This was further supported by the loss of two acetic acid units in the mass spectrum which gave rise to a signal at *m/e* 438.

Weak absorptions at 1630 cm^{-1} and 3140 cm^{-1} in the ir spectrum indicated that some of the 12 double bond equivalents in the molecule are due to double bonds. The nature of this unsaturation was consistent with a furan moiety, the two α hydrogens giving rise to a signal at δ 7.40 ppm (J = 2 Hz) in the ^{1}Hmr spectrum, with the remaining β proton appearing as a doublet (J = 2 Hz) at δ 6.32 ppm. Another singlet at δ 5.60 ppm could arise from a single proton attached to a trisubstituted double bond but in view of the X-ray analysis (*vide infra*) must be assigned to a hydrogen attached to the epoxide ring α to a lactone carbonyl function. Similarly the single proton adjacent to the furan ring attached to the carbon bearing the lactone oxygen appeared as a singlet at δ 3.51 ppm. The secondary hydrogens on the carbons bearing the acetate functions appear as broad single proton multiplets at δ 4.84 and δ 4.50 ppm while the broadened doublet at δ 3.15 (J = 4 Hz) is due to the two protons α to the carbonyl group.

Concurrent with further chemical studies the X-ray analysis was undertaken and permitted the assignment of structure **1** (7α-acetoxydihydronomilin) to this material. The closely related parent terpene nomilin (**2**) has been identified by Dreyer (2) in grapefruit after being isolated earlier by Emerson (3). These molecules are members of a large family of limonoid bitter principles and structure **1** is consistent with the spectral data reported above. The ^{13}Cmr spectrum is presented in Table 1. These assignments are made by analogy with similar limonoids which have been reported in the literature and the data for khivorin (**3**) are included for comparison (4).





1 R = H, OAc

2 R = O

3

Relatively few X-ray studies of these natural products have appeared (5) and stereochemical assignments have been based on spectral interpretation. The X-ray analysis clearly establishes the stereochemistry of the furan substituent at C(17) and the C(1) acetoxy function, both of which are α. Thus, it is highly likely that the parent nomilin system possesses the same stereochemical features and the original assignment (6) of the C(1) acetoxy group to the β position, based on an ^{1}Hmr argument, is in error and should be reversed.

Crystal Structure

A side-view of the molecule showing its conformation and the numbering system is presented in Fig. 1. The molecule contains three six-membered rings forming the triterpene skeleton to which a three- and a seven-membered ring are fused. A furan ring is linked to the triterpene through a C—C bond in an equatorial position. Five of the rings form a slightly corrugated ribbon that is shaped approximately into a circular arc as shown in Fig. 1, with the three-membered ring in an axial position on the outside surface of the ribbon and the two acetate groups in axial positions on the inside surface. The *A/B*, *B/C*, *C/D* junctions are all *trans*, while the *D/E* is *cis*, as shown by the torsion angles given in Table 2. The absolute configuration has not been determined, and

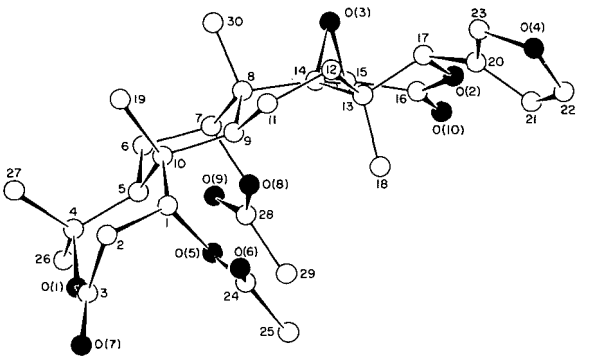

FIG. 1. A side-view of the molecular structure of 7α-acetoxydihydronomilin, $C_{30}H_{38}O_{10}$, showing its conformation and the numbering scheme. The absolute configuration may correspond to this figure or its enantiomorph.

may correspond to the drawing in Fig. 1 or its enantiomorph.

The molecular formula, bond lengths, valency angles, and the rings' torsion angles are given in Fig. 2. Some of the valency angles and torsion angles which could not be fitted in Fig. 2 are compiled in Table 2. These measurements have not been corrected for atomic thermal vibration. The 21 C(sp^3)—C(sp^3) bonds are in the range 1.471–1.588(4) Å and their mean is 1.540 Å. The longest are those in the bond sequence C(4)—C(5)—C(10)—C(9)—C(8)—C(14) of lengths 1.556, 1.563, 1.588, 1.553, 1.570 (4) Å, respectively, and the shortest is C(14)—C(15), 1.471 Å, which is common to rings *D* and *E*. Four of the C(sp^3)—C(sp^2) have normal lengths 1.488–1.506(5) Å, mean = 1.499 Å, but the C(24)—C(25) which is observed as 1.459(5) Å is rather short and may be severely affected by thermal motion. All the other bond lengths are fairly close to their expected values. The C—H are of lengths 0.84–1.12(4) Å, mean = 0.98 Å.

The mean valency angles in the six-membered rings *B*, *C*, *D* are 110.7, 112.2, 114.8°, respectively, with the largest C—C—C angles being C(8)—C(14)—C(13) = 119.2(2)° and C(14)—C(15)—C(16) = 119.3(2)° which appear to result from the fusion of rings *D* and *E* at C(14)—C(15). The mean angle in the lactone ring *A* is 117.7° with the largest being C(3)—O(1)—C(4) = 129.0(2)°, while the mean for the furan ring is 108.0°.

The view of the molecule shown in Fig. 1 and the torsion angles listed in Fig. 2(*c*) indicate clearly the conformation of the rings as: *A* chair, *B* chair, *C* twist-boat, *D* 1,3-diplanar, *E* planar, and *F* planar ($\chi^2 = 0.9$). The C_2O_2 atoms of each acetate group are coplanar, with $\chi^2 = 0.02$ and 0.05 for the two groups. While C(1) is in the plane of its adjacent acetate group, C(7) is 0.055 Å away from the plane

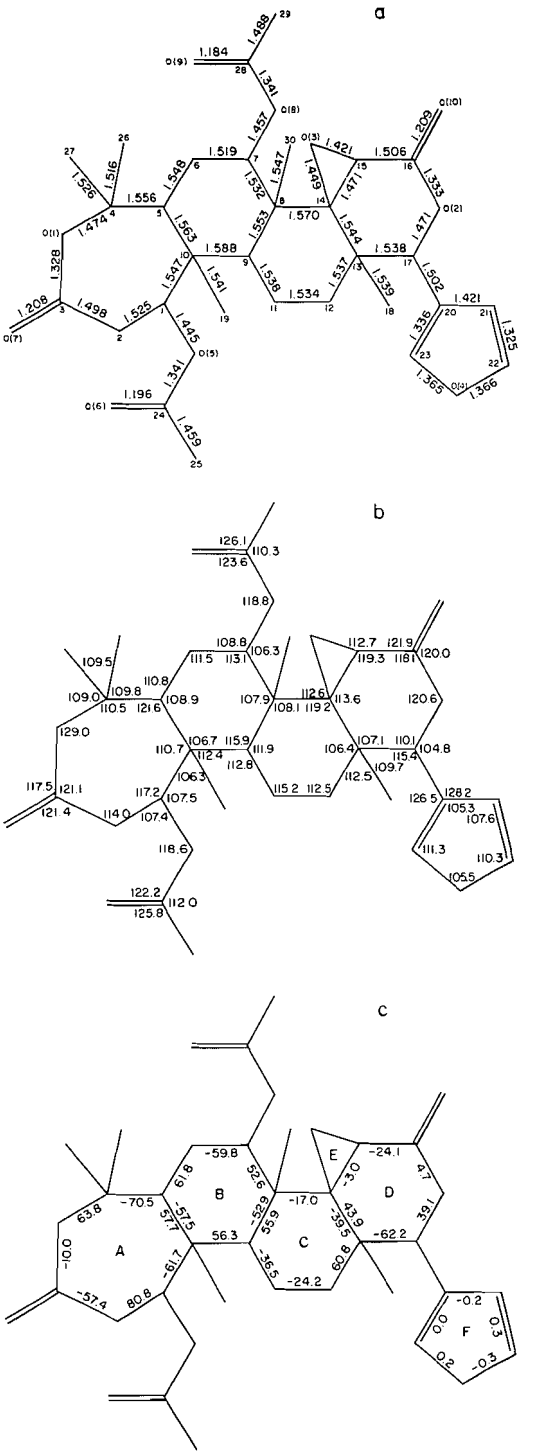

FIG. 2. Schematic drawings of the molecule showing: (*a*) bond lengths (Å), (*b*) valency angles (deg), and (*c*) torsion angles (deg) within the rings. The estimated standard deviations are 0.003–0.005 Å for the bonds and 0.2–0.3° for the angles, excluding the contribution of the parameters' covariance.

of the second acetate group. Also, C(17) lies in the plane of its adjacent furan ring.

The equations of the mean planes of the rings and acetate groups, and some of the dihedral angles between them are summarized in Table 3. The curvature of the molecule is almost uniform as shown by the dihedral angles *A–B*, *B–C*, *C–D* of 18.7, 18.5, and 13.4°, respectively, which add up to 50.6° while *A–D* is 49.9°.

TABLE 3. Mean planes and dihedral angles (deg). The planes are in the form $lX + mY + nZ - p = 0$, where X, Y, Z, p are in Å. The planes are identified in Fig. 2(*c*); Ac(1) and Ac(7) are the substituent groups at C(1) and C(7)

O(3), the apex of the three-membered ring, has four close intramolecular neighbours: C(17) and C(30) at distances 2.623(3) and 2.668(4) Å, and their associated H atoms at 2.28(2) and 2.28(3) Å from O(3). The angles associated with these short contacts are listed in Table 2, and the corresponding C—H are 1.03(2) and 1.01(3) Å. Also, it should be stated that H(17) is only 0.56 Å from the mean plane of O(3), C(14), C(13), C(17); and H(30, 1) is 0.45 Å from the mean plane of O(3), C(14), C(8), and C(30). This information is provided for the benefit of those interested in the study of C—H...O hydrogen bonds which may be present in this structure. However, for the lack of a proper analysis of the electron charge distribution in the molecule, the true nature of these contacts cannot be stated at present.

All the other intramolecular O...H contacts are ≥2.33 Å, and the H...H contacts are ≥1.88 Å. There are no unusually short intermolecular van der Waals contacts which might be indicative of hydrogen bonding, and the molecules are therefore held together by electrostatic forces.

Experimental

Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Elemental microanalyses

were performed by Beller Microanalytical Laboratory, West Germany.

Infrared spectra were recorded as KBr pellets on a Perkin-Elmer 567 or 710A grating spectrometer and were calibrated against the 2850 and 1601 cm^{-1} bands of polystyrene film. ^{1}Hmr spectra were determined in $CDCl_3$ with a Perkin-Elmer R-12B or Varian HA 100 spectrometer; band positions are reported in parts per million downfield from tetramethylsilane as an internal standard; ^{13}Cmr spectra were recorded on a Varian XL 100 instrument. Mass spectra were recorded by Morgan-Schaeffer, Montreal.

Extraction and Isolation

Fresh seeds of *Uncaria Gambier Roxb.* collected in the botanical garden in Singapore were separated from their nut husks and crushed using a blender. The ground seeds (1500 g) were stirred mechanically in methanol (3000 ml) for 48 h at room temperature. The mixture was filtered and the residue re-extracted with fresh methanol. The combined brownish red extracts were concentrated to approximately half the original volume under reduced pressure on a rotary evaporator and further extracted with petroleum ether followed by benzene (700 ml portions in a separatory funnel).

The concentrated benzene fraction was chromatographed on silica gel. The column was eluted with petroleum ether followed by petroleum ether – diethylether and fractions (~50 ml) were combined on the basis of similar R_f values on tlc slides. Crystalline material was obtained from the more polar fractions and was recrystallized with difficulty from methanol, mp 265–266°C. The 7α-acetoxydihydronomilin had the following spectral properties: ir (KBr) 3140 (CH=C), 1720–1740 (C=O), 1630 (C=C), 875 (furan) cm^{-1}; ^{1}Hmr ($CDCl_3$) 7.40 (2H, d, J = 2 Hz, furan), 6.32 (1H, d, J = 2 Hz, furan), 5.60 (1H, s, H—C—O), 4.84 (1H, m, HCOAc), 4.50 (1H, m, HCOAc), 3.51 (1H, s, H—C—O), 3.15 (2H, d, J = 4 Hz, —CH_2CO) ppm; ms: M* *m/e* 558, calcd. 558. *Anal.* calcd. for $C_{30}H_{38}O_{10}$: C 64.50, H 6.86, O 28.64; found: C 64.30, H 7.12, O 28.58.

Crystal Data

$C_{30}H_{38}O_{10}$ fw = 558.63

Unit cell: orthorhombic, $P2_12_12_1$, a = 13.158(2), b = 17.092(2), c = 12.689(2) Å, V = 2853.7 Å^3, Z = 4, D_c = 1.300, D_o = 1.300 g cm^{-3}, $F(000)$ = 1192, μ(Cu Kα) = 7.68 cm^{-1}, λ(Cu Kα$_1$) = 1.54050, λ(Cu Kα$_2$) = 1.54434 Å.

The space group was uniquely determined from the systematic absences on precession photographs. The unit-cell parameters were derived from the 2θ values of some high-order axial reflexions. The crystal density was measured by flotation in aqueous KI solution at 26°C.

Intensities

The intensity data were collected on a Picker diffractometer with the θ–2θ scan method, using a prismatic crystal (0.4 × 0.6 × 0.3 mm) and Cu(Kα) radiation to ($\sin\theta/\lambda$) limit of 0.588. The 2θ scans covered 2° for 2θ = 0–100°, and 3° for 2θ = 100–130°. The background corrections were derived from an empirical curve expressed as a function of 2θ. The (006) was used as a monitor reflexion for scaling purposes, and its intensity showed a small random variation of ±2% throughout the experiment. The net intensities were corrected for the Lorentz-polarization effect, but not for absorption. The total number of reflexions scanned was 2740, of which 2621 reflexions (95.8%) were observed above background.

Structure Determination

The positions of the 40 non-hydrogen atoms were determined from an *E* map and two Fourier syntheses. The *E* map, calculated from 328 reflexions with $|E| \geq 1.40$, showed two images of the molecule separated by a prominent C—C bond vector parallel to ***a***. This map was interpreted as described by Huber (7) by placing the molecule halfway between the two images. Twenty of the atomic positions were accepted from this map, and the other 20 positions were derived from two successive Fourier syntheses. At the start, C atoms were placed at most of the atomic positions and their parameters including the occupancies and isotropic temperature factors were refined by three cycles of block-diagonal least-squares calculations. The possible O positions were then identified on the basis of their occupancies and bond lengths. At that stage, the occupancies were 0.91–1.25 for the C sites and 1.23–1.44 for the O sites, with estimated standard deviations of 0.04–0.05. The occupancies were then fixed at 1.00 for all atoms and the parameters were refined anisotropically. Finally the H atoms were located from three difference maps calculated at later stages, and were refined isotropically. The refined atomic positions are listed in Table 4.[3]

The quantity minimized in the least-squares refinement was $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\{1 + [(|F_o| - 15)/40]^4\}$ and $1.53 \leq |F_o| \leq 154.1$. All the unobserved reflexions, as well as eight very strong reflexions showing extinction effect, and one weak reflexion were excluded from the refinement. In the final cycle, the mean $(\Delta/\sigma) = 0.22$, maximum $(\Delta/\sigma) = 0.77$ for C and O (= 2.1 for H); $R = 0.037$ and $R_w = 0.039$ for the observed reflexions excluding those omitted from the refinement ($R = 0.042$ for all observed reflexions), $[\Sigma(w\Delta^2)/(m - n)]^{1/2} = 0.70$. There were no outstanding discrepancies in the calculated structure amplitudes of the unobserved reflexions. The residual electron density in the final difference map was randomly distributed within −0.15 and 0.17 e Å^{-3}.

The scattering factor curves were those of ref. 8 for C and O, and of ref. 9 for H. All computations were performed with the NRCC set of crystallographic computer programs (10).

[3]The atomic thermal parameters and the structure amplitudes are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

THEODORE A. ONDRUS, EDWARD E. KNAUS, and C. S. GIAM. Can. J. Chem. **56**, 1026 (1978).

The reaction of cyanogen azide (**2**) with several *N*-substituted-1,2-dihydropyridines (**1**) has been investigated. Reaction of 1,2-dihydropyridines (**1***a–d*) possessing a *N*-methoxycarbonyl or *N*-methanesulfonyl substituent with **2** afford a 1:1 mixture of stereoisomers *E*- and *Z*-1,2,3,4-tetrahydropyridylidene-4-cyanamides (**3** and **4**). In contrast, reaction of *N*-acetyl-2-butyl-1,2-dihydropyridine (**1***e*) with **2** gave rise to the unexpected 2,7-diazabicyclo[4.1.0]hept-4-ene (**7**) and 2-diazo-1,2,3,6-tetrahydropyridylidene-3-cyanamide (**9**) together with a 1:1 isomeric mixture of **3***e* and **4***e*. Mechanisms for the formation of **3**, **4**, **7**, and **9** are discussed.

THEODORE A. ONDRUS, EDWARD E. KNAUS et C. S. GIAM. Can. J. Chem. **56**, 1026 (1978).

On a étudié la réaction de l'azoture de cyanogène (**2**) avec plusieurs dihydro-1,2 pyridines substituées sur l'azote (**1**). La réaction des dihydro-1,2 pyridines (**1***a–d*) possédant un substituant *N*-méthoxycarbonyle ou *N*-méthanesulfonyle avec **2** conduit à un mélange 1:1 des stéréoisomères *E*- et *Z*-tétrahydro-1,2,3,4 pyridylidènecyanamide-4 (**3** et **4**). Par ailleurs, la réaction de la *N*-acétylbutyl-2 dihydro-1,2 pyridine (**1***e*) avec **2** conduit au diaza-2,7 bicyclo[4.1.0]heptène-4 (**7**) et au diazo-2 tétrahydro-1,2,3,6 pyridylidènecyanamide-3 (**9**) qui sont innattendus de même qu'à un mélange 1:1 des isomères **3***e* et **4***e*. On discute des mécanismes de formation des composés **3**, **4**, **7** et **9**.

[Traduit par le journal]

The 1,3-dipolar cycloaddition reaction of cyanogen azide with cyclic dienamines is an attractive method for the synthesis of pharmacologically interesting heterocycles. Since the synthesis of cyanogen azide was first reported (1) several studies which demonstrate its usefulness have appeared. Reaction with olefins (2) afforded alkylidenecyanamides and *N*-cyanoaziridines and with acetylenes (3) gave rise to 1-cyanotriazoles which are in equilibrium with the tautomeric α-diazo-*N*-cyanoimines. Other reported reactions of molecular cyanogen azide include addition to norbornadiene (4), the ring contraction of enamines of cyclic ketones (5), and ring expansion of alkylidenecycloalkanes (6). It was therefore of interest to develop methods for the preparation of bicyclic ring structures in which 1,2,3-triazoline or aziridine is fused to a tetrahydropyridine ring.

In earlier studies we showed that reaction of pyridine with organolithium reagents afford *N*-lithio-1,2-dihydropyridines (7) which on reaction with acid chlorides or esters (8) gave *N*-substituted-1,2-dyhydropyridines (**1***b*, **1***c*, and **1***e*) whereas the sodium borohydride reduction of *N*-methoxycarbonyl (methanesulfonyl) pyridinium chloride yields **1***a* (9) and **1***d* (10). The reaction of dienamines **1** with cyanogen azide **2** now provides a convenient route to *E*- and *Z*-1,2,3,4-tetrahydropyridylidene-4-cyanamides **3** and **4** and 3-*n*-butyl-7-cyano-2,7-diazabicyclo[4.1.0]hept-4-ene (**7**).

Reaction of *N*-methoxycarbonyl-1,2-dihydropyridine (**1***a*) with a fourfold excess of **2** at 25°C for 18 h afforded a 1:1 mixture (52.1%) of stereoisomers *E*- (**3***a*) and *Z*-1-methoxycarbonyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide (**4***a*) which could not be separated by fractional crystallization or thin-layer chromatography. The mechanism proposed involves the 1,3-dipolar cycloaddition of molecular cyanogen azide to the C(3)—C(4) olefinic bond of **1***a*. Loss of nitrogen and C(4) hydrogen migration from the unstable triazoline intermediate would afford both **3***a* and **4***a*. If the intermediate triazoline adduct is the product of electronic control, the nitrogen atom bearing the cyano group should be directed to the C(4) position of the ring (11). The absence of steric effects at the C(3) and C(5) positions of **3***a* and **4***a* results in a *E*/*Z* ratio of 1:1 (2). A ^{1}H nmr temperature study effected on the mixture of stereoisomers **3***a* and **4***a* in DMSO-d_6 indicated the coalescence temperature to be approximately 90°C which is similar to that reported for simple acyclic alkylidene cyanamides (12). Upon cooling to 25°C the ratio of **3***a*:**4***a* returned to 1:1. (See Fig. 1).

a R^1 = H, R^2 = CO_2Me; *b* R^1 = Ph, R^2 = CO_2Me; *c* R^1 = *n*Bu, R^2 = CO_2Me
d R^1 = H, R^2 = SO_2Me; *e* R^1 = *n*Bu, R^2 = COMe

The structures assigned to **3***a* and **4***a* are consistent with the spectral data obtained. The uv spectrum exhibited one band at 333 nm which corresponds well to the λ_{max} expected for the N—C=C—C=N system (13), while the ir spectrum displayed peaks at 2180 (C≡N), 1730 (CO), 1590 (C=N), and 1560 (C=C) cm^{-1}. The ^1H nmr spectrum (δ) of **3***a* and **4***a* exhibited a 2H triplet ($J_{2,3}$ = 7.5) at 2.74 (**4***a*) and 2.95 (**3***a*) attributed to the C(3)H which collapses to two single peaks upon irradiation of the C(2)H at 3.9. The two triplets due to the C(3)H also coalesce to one triplet ($J_{2,3}$ = 7.5) at 2.82 upon heating to 130°C. Other absorptions include a 3H singlet at 3.81 due to the methoxyl methyl, a 2H triplet ($J_{2,3}$ = 7.5) at 3.9 due to the C(2)H and a 1H doublet ($J_{5,6}$ = 8) at 5.59 (**3***a*) and 5.85 (**4***a*) due to the C(5)H which collapse to two single peaks upon irradiation of the C(6)H at 7.93. The two doublets at 5.59 and 5.85 coalesce to one doublet ($J_{5,6}$ = 8) at 5.68 upon heating to 130°C. The 1H doublets ($J_{5,6}$ = 8) at 7.9 (**4***a*) and 7.95 (**3***a*) due to the C(6)H selectively collapse to singlets upon irradiation of the absorption at 5.85 attributed to the C(5)H of **4***a* and the absorption at 5.59 due to the C(5)H of **3***a*, respectively, thereby providing further evidence for the presence of two isomers. The cyano group (**3***a*) is expected (2) to deshield the C(3)H (**3***a*) whereas the cyano group (**4***a*) is expected to deshield the C(5)H (**4***a*). The mass spectrum of **3***a* and **4***a* exhibited a molecular ion at *m/e* 179 (*Exact Mass* calcd. for $C_8H_9N_3O_2$: 179.0694; found (high resolution ms): 179.0694). Similar reactions of **1***b–d* with **2** afforded low to moderate yields of 1:1 mixtures of stereoisomers **3** and **4***b–d*, along with considerable amounts of unreacted **1** (see Table 1).

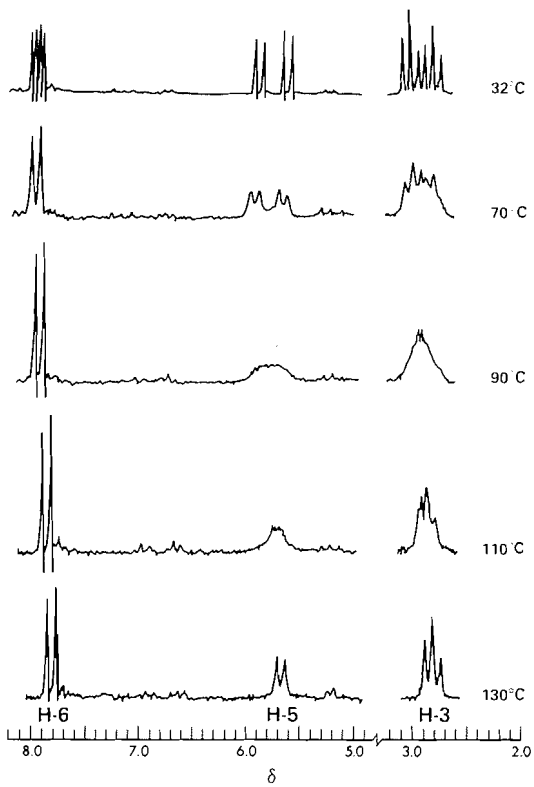

FIG. 1. ^1H nuclear magnetic resonance temperature study of a 1:1 stereoisomeric mixture of *E*- (**3***a*) and *Z*-1-methoxycarbonyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide (**4***a*).

The reaction of *N*-acetyl-2-butyl-1,2-dihydropyridine (**1***e*) with a 4 molar excess of **2** gave rise to a 1:1 mixture of **3***e* and **4***e* (36.5%), 3-*n*-butyl-7-cyano-2,7-diazabicyclo[4.1.0]hept-4-ene (**7**) (19.7%), and *N*-acetyl-6-*n*-butyl-2-diazo-1,2,3,6-tetrahydropyridylidene-3-cyanamide (**9**) (19.4%) as well as unreacted **1***e* (3.9%). The isolation of **3***e* and **4***e* as well as **7** and **9** suggests that a 1,3-dipolar cycloaddition reaction occurred at both the C(3)—C(4) and C(5)—C(6) olefinic bonds. One plausible mechanism for the formation of **7** involves addition of **2** across the C5—C6 olefinic bond of **1***e* to give a triazoline adduct **5**. Attack by azide anion on the carbonyl carbon atom and elimination of acetylazide and nitrogen to afford anion **6** which on cyclization and protonation would give **7**. All of the cyanogen azide solutions contain free azide since a 4 molar excess of sodium azide was used in their preparation.

Alternatively elimination of a molecule of hydrogen from the triazoline adduct **5** would give the more aromatic 1,2-dihydropyridine derivative **8**. Ring

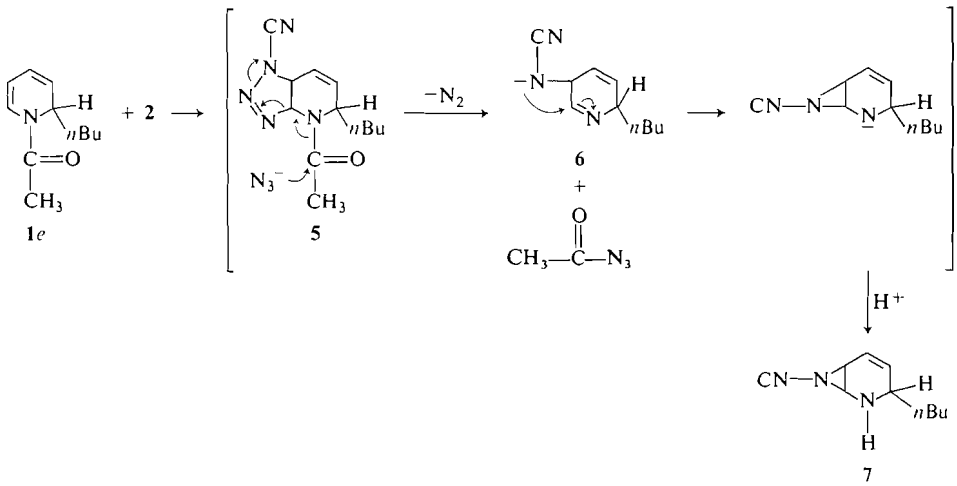
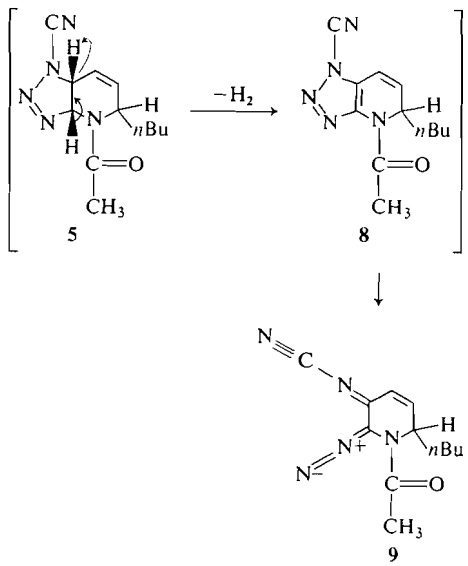
TABLE 1. Reactions of 1,2-dihydropyridines with cyanogen azide

Compound	Reaction time (h)	Ratio 1:2	Yield (%) 3 and 4	7	9	Recovered 1
1*a*	18	1:5	52.1[a]			1.3
	20	4:5	20.8[a]			24.3
1*b*	72	1:1	14.6[a]			66.3
1*c*	8	2:3	41.6[a]			21.7
1*d*	20	1:3	14.5[a]			40.1
1*e*	1	4:5	7.2[b,c]	25.3[c]	3.9	44.7
	1	1:5	36.5[b,c]	19.7[c]	19.4	3.9

[a]The ratio of products 3:4 as determined from the integrals of the C(5)H was 1:1.
[b]The ratio of products 3:4 as determined from the integrals of the C(2)H was 1:1.
[c]The yield of 3*e* and 4*e* was calculated from the integral of the C(2)H while the yield of 7 was calculated from the integral of the C(3)H.



opening of **8**, by a mechanism similar to that proposed for the adduct obtained from acetylene and cyanogen azide (3), would give rise to **9**.



It is interesting to note that addition occurred at both C(3)—C(4) and C(5)—C(6) olefinic bonds of **1***e* suggesting that steric effects of the R^2-substituent may also play a role in determining the site of addition since the acetyl group exhibits a smaller steric effect than methanesulfonyl and methoxycarbonyl (14).

The reacting species in all of these reactions is molecular cyanogen azide since loss of nitrogen to give cyanonitrene occurs above 40°C (15). It is expected that the yield of **3** and **4** could be increased significantly by using larger molar amounts of **2** since a significant percentage of **1** is often recovered (see Table 1).

The reaction of other organic azides and other 1,3-dipoles with both 1,2- and 1,4-dihydropyridine are now in progress to broaden the scope of this reaction.

Experimental

Melting points are determined with a Büchi capillary apparatus and are uncorrected. ^{1}H Nuclear magnetic resonance spectra were determined for solutions in deuterio-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

chloroform unless otherwise noted with TMS as internal standard with a Varian EM-360A, HA-100 or HA-220 spectrometer. Infrared spectra were recorded on a Perkin Elmer 267 spectrometer. Mass spectra were measured with an AEI-MS-9 or MS-50 mass spectrometer and these exact mass measurements are used in lieu of elemental analysis. *Warning*: Cyanogen azide is a hazardous material. It should be handled only in solution. Concentration to pure material will result in violent detonation by heat or shock (2).

Cyanogen Azide (2)

General Procedure A

Cyanogen azide was prepared *in situ* using the procedure of Hermes and Marsh (2). Cyanogen bromide (2.65 g, 25 mmol) in acetonitrile (25 ml) was added slowly with vigorous stirring to a suspension of sodium azide (8.12 g, 0.125 mol) in 75 ml dry acetonitrile at 0°C under a nitrogen atmosphere. After 1 h at 0°C the reaction mixture was warmed slowly to 25°C over a 2-h period. The mixture was maintained at 25°C for 1 h after which the desired 1,2-dihydropyridine (**1**) was added.

E-*1-Methoxycarbonyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide(3*a*) and Z-1-Methoxycarbonyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide(4*a*)*

General Procedure B

A solution of **1***a* (2.78 g, 20 mmol) in 50 ml dry ether was added with stirring to a solution of **2** prepared from cyanogen bromide (2.65 g, 25 mmol) and sodium azide (8.12 g, 125 mmol) in 100 ml dry acetonitrile under a nitrogen atmosphere at 25°C. The reaction was allowed to proceed for 20 h at 25°C. Filtration and removal of the solvent *in vacuo* gave a black semisolid which was partitioned between chloroform (100 ml) and water (100 ml). The chloroform fraction was washed with water (50 ml) and the combined water fractions extracted with chloroform (2 × 75 ml). The chloroform extracts were dried (Na_2SO_4) and solvent removed *in vacuo* to yield a black semisolid which was subjected to preparative tlc on 10 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene – ethyl acetate (2:1 v/v) as development solvent. Extraction with 50 ml warm methanol of the fraction having R_f 0.95 gave **1***a* (0.676 g, 24.3%). Extraction of the band having R_f 0.47 afforded a 1:1 mixture of **3***a* and **4***a* (0.744 g, 20.8%).

When the reaction was carried out as above using a 4 molar excess of **2** for 18 h at 25°C **3***a* and **4***a* (52.1%) and **1***a* (1.3%) were obtained. (Spectral data are presented in Discussion.)

E-*1-Methoxycarbonyl-2-phenyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide(3*b*) and Z-1-Methoxycarbonyl-2-phenyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide(4*b*)*

A solution of **1***b* (1.53 g, 7.2 mmol) in 25 ml dry ether was added to a solution of **2** prepared from a solution of cyanogen bromide (0.795 g, 7.5 mmol) and sodium azide (2.44 g, 37.5 mmol) in 50 ml acetonitrile. The reaction was allowed to proceed at 25°C for 72 h as described under Procedure B to give a reddish-black semisolid. Preparative tlc was effected on eight 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene – ethyl acetate (9:1 v/v) as development solvent. Extraction of the fraction having R_f 0.78 with 50 ml warm methanol gave **1***b* (1.03 g, 66.3%). Extraction of the band having R_f 0.27 afforded a 1:1 mixture of **3***b* and **4***b* (0.27 g, 14.6%); ir (film): 2180 (s, C≡N), 1730 (s, CO), 1590 (s, C=N), and 1560 cm^{-1} (s, C=C); ^1H nmr δ: 3.07 (**4***b*) and 3.53 (**3***b*) (m, 1H, H-3[1]), 3.26 (**4***b*) and 3.35 (**3***b*) (m, 1H, H-3), 3.9 (s, 3H, OCH_3), 5.72 (m, 1H, H-2), 5.73 (**3***b*) and 6.1 (**4***b*) (d, $J_{5,6}$ = 8 Hz, 1H, H-5), 7.3 (m, 5H, phenyl), 7.98 (d, $J_{5,6}$ = 8 Hz, 1H, H-6); *Exact Mass* calcd. for $C_{14}H_{13}N_3O_2$: 255.1008; found (high resolution ms): 255.1008.

E-*1-Methoxycarbonyl-2-*n*-butyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide(3c) and Z-1-Methoxycarbonyl-2-*n*-butyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide(4c)*

A solution of **1***c* (0.663 g, 3.4 mmol) in 25 ml dry ether was added to a solution of **2** prepared from cyanogen bromide (0.53 g, 5 mmol) and sodium azide (1.62 g, 25 mmol) in 50 ml acetonitrile. The reaction was allowed to proceed at 25°C for 8 h as described under Procedure B to give a reddish-black semisolid. Preparative tlc was effected on nine 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene – ethyl acetate (9:1 v/v) as development solvent. Extraction of the fraction having R_f 0.81 with 50 ml warm methanol gave **1***c* (0.144 g, 21.7% recovery). Extraction of the fraction having R_f 0.46 afforded a 1:1 mixture of **3***c* and **4***c* (0.322 g, 41.6%); uv (95% C_2H_5OH, 25°C) λ_{max}; 338 (N̈—C=C—C=N); ir (film): 2180 (s, C≡N), 1730 (s, CO), 1580 (s, C=N) and 1560 cm^{-1} (s, C=C); ^1H nmr δ: 0.88 (t, J = 7 Hz, 3H, —$CH_2CH_2CH_2$-CH_3), 1.1–1.8 (m, 6H, —$CH_2CH_2CH_2CH_3$), 2.72 (**4***c*) and 3.16 (**3***c*) (m, 1H, H-3[1]), 2.83 (**4***c*) and 2.93 (**3***c*) (m, 1H, H-3), 3.89 (s, 3H, OCH_3), 4.5 (m, 1H, H-2), 5.68 (**3***c*) and 5.97 (**4***c*) (d, $J_{5,6}$ = 8 Hz of d, $J_{3,5}$ = 1.25 Hz, 1H, H-5), 7.72 (d, $J_{5,6}$ = 8 Hz of d, $J_{2,6}$ = 1.0 Hz, 1H, H-6); *Exact Mass* calcd. for $C_{12}H_{17}N_3O_2$: 235.1321; found (high resolution ms): 235.1317.

E-*1-Methanesulfonyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide(3*d*) and Z-1-Methanesulfonyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide(4*d*)*

A solution of **1***d* (1.43 g, 9 mmol) in 50 ml dry ether was added to a solution of cyanogen azide prepared from cyanogen bromide (2.65 g, 25 mmol) and sodium azide (8.12 g, 125 mmol) in 100 ml dry acetonitrile. The reaction was allowed to proceed for 20 h at 25°C as described under Procedure B to give a red oil. Preparative tlc was effected on 10 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene – ethyl acetate (2:1 v/v) as development solvent. Extraction of the band having R_f 0.91 with 50 ml warm methanol gave unreacted **1***d* (0.575 g, 40.1%). Extraction of the band with R_f 0.34 afforded a 1:1 mixture of **3***d* and **4***d* (0.259 g, 14.5%); ir (film): 2180 (s, C≡N), 1580 (s, C=N), and 1550 (s, C=C) cm^{-1}; ^1H nmr δ: 2.91 (**4***d*) and 3.05 (**3***d*) (m, 2H, H-3), 3.14 (s, 3H, SO_2CH_3), 3.93 (t, $J_{2,3}$ = 7.5 Hz, 2H, H-2), 5.67 (**3***d*) and 5.96 (**4***d*) (d, $J_{5,6}$ = 8 Hz, 1H, H-5), 7.57 (d, $J_{5,6}$ = 8 Hz, 1H, H-6); *Exact Mass* calcd. for $C_7H_9N_3O_2{}^{32}S$: 199.0415; found (high resolution ms): 199.0414.

E-*1-Acetyl-2-*n*-butyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide(3*e*), Z-1-Acetyl-2-*n*-butyl-1,2,3,4-tetrahydropyridylidene-4-cyanamide(4*e*), 3-*n*-Butyl-7-cyano-2,7-diazabicyclo[4.1.0]hept-4-ene(7) and 1-Acetyl-6-*n*-butyl-2-diazo-1,2,3,6-tetrahydropyridylidene-3-cyanamide(9)*

A solution of **1***e* (3.58 g, 20 mmol) in 50 ml dry ether was added dropwise with stirring at 25°C under a nitrogen atmosphere to a solution of **2** prepared from cyanogen bromide (2.65 g, 25 mmol) and sodium azide (8.12 g, 125 mmol) in 100 ml dry acetonitrile. The reaction was allowed to proceed for 1 h at 25°C and completed as described under Procedure B to give a red semisolid. Preparative tlc was effected on six 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene–ether (1:2 v/v) as development solvent. Extraction of the band having R_f 0.86 with 50 ml warm methanol gave unreacted **1***e* (1.6 g, 44.7%). Similar extractions of the band with R_f 0.58 yielded **9** (0.192 g, 3.9%); ir (film); 2180 (s, C≡N), 2090 (s, N_2=C), 1700 (s, CO), 1555 (s, C=N), and 1545 cm^{-1} (s, C=C); ^1H nmr δ: 0.9 (t, J = 7 Hz), 3H, —CH_2-

$CH_2CH_2CH_3$), 1.1–1.9 (m, 6H, —$CH_2CH_2CH_2CH_3$), 2.5 (s, 3H, $COCH_3$), 5.11 (m, 1H, H-6), 5.7–6.25 (m, 2H, H-4); *Exact Mass* calcd. for $C_{12}H_{15}N_5O$: 245.1276; found (high resolution ms): 245.1271. Similar extraction of the fraction having R_f 0.47 afforded a 3:1 mixture of **7** and the isomeric **3***e* and **4***e*. The yields were calculated using the ^1H nmr integrals for the H-3 of **7** and H-2 of the **3***e*–**4***e* mixture and were found to be **7** (0.894 g, 25.3%) and **3***e* and **4***e* (0.298 g, 7.2%). This mixture contained all signals present in the ir and ^1H nmr spectra of a pure sample of **7** prepared from the reaction of 2-butyl-1,2-dihydropyridine and cyanogen azide;[1] mp 75°C; ir (KBr): 3225 (m, NH), 2180 (s, C≡N), and 1605 cm^{-1} (s, C=C); ^1H nmr δ: 0.9 (t, J = 7 Hz, 3H, —CH_2CH_2-CH_2CH_3), 1.1–1.9 (m, 6H, —$CH_2CH_2CH_2CH_3$), 3.21 (m, 1H, H-6), 3.3 (m, 1H, H-1), 4.17 (m, 1H, H-3), 5.8 (m, 2H, H-4, H-5), 8.63 (bs, 1H, NH, exchanges with deuterium oxide); *Exact Mass* calcd. for $C_{10}H_{15}N_3$: 177.1266; found (high resolution ms): 177.1265. The mixture also contained those absorptions present in the ir and ^1H nmr spectra of **3***e* and **4***e* described below.

Reaction of **1***e* (3.58 g, 20 mmol) with **2** prepared from equimolar quantities of cyanogen bromide (2.65 g, 25 mmol) and sodium azide (1.625 g, 25 mmol) as described under Procedure A gave a reaction mixture from which a pure sample of the 1:1 isomeric mixture of **3***e* and **4***e* was isolated after a combined series of column and tlc; mp 71°C; ir (KBr): 2180 (s, C≡N), 1700 (s, CO), 1580 (s, C=N), and 1560 cm^{-1} (s, C=C); ^1H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.8 (m, 6H, —$CH_2CH_2CH_2CH_3$), 2.4 (s, 3H, $COCH_3$), 2.58 (**4***e*) and 3.16 (**3***e*) (d, $J_{3,3'}$ = 16 Hz, 1H, H-3[1]), 2.7 (**4***e*) and 2.81 (**3***e*) (d, $J_{3,3'}$ = 16 Hz of d, $J_{2,3}$ = 7.5 Hz, 1H, H-3), 4.76 (m, 1H, H-2), 5.49 (**3***e*) and 5.78 (**4***e*) (d, $J_{5,6}$ = 8 Hz, 1H, H-5), 7.33 (d, $J_{5,6}$ = 8 Hz, 1H, H-6); *Exact Mass* calcd. for $C_{12}H_{17}N_3O$: 219.1372; found (high resolution ms): 219.1372.

[1]E. E. Knaus and T. A. Ondrus. Unpublished results.

Reaction of **1***e* (1.79 g, 10 mmol) with **2** prepared from cyanogen bromide (5.3 g, 50 mmol) and sodium azide (9.75 g, 150 mmol) as described above afforded **1***e* (3.9%), **3***e* and **4***e* (0.755 g, 36.5%), **7** (0.348 g, 19.7%), and **9** (0.47 g, 19.4%).

THOMAS M. FYLES, CLIFFORD C. LEZNOFF, and JOHN WEATHERSTON. Can. J. Chem. **56**, 1031 (1978).

A 2% crosslinked divinylbenzene–styrene copolymer, incorporating benzoyl chloride groups, was used to monoprotect the symmetrical diol 1,10-decanediol. The corresponding monotrityl ether and *cis*-10-tetradecen-1-ol were prepared by this system, the latter by a Wittig reaction of a polymer-bound ylide with an aldehyde in the solution phase. A series of bifunctionalized resins containing proximally located trityl alcohol and benzoic acid groups was prepared in an attempt to prepare diol linked to the polymer via both a trityl ether and a benzoate linkage. It was established that these polymers bound 1,10-decanediol exclusively at one end only. Polymers, containing both trityl alcohol and benzoic acid groups in a random array or polymers containing proximally located trityl alcohol groups, gave mixtures of both monoprotected and doubly protected diol.

THOMAS M. FYLES, CLIFFORD C. LEZNOFF et JOHN WEATHERSTON. Can. J. Chem. **56**, 1031 (1978).

On a utilisé un copolymère divinylbenzène–styrène réticulé à 2% et incorporant des groupes chlorure de benzoyle pour protéger un seul des hydroxyles du diol symétrique décanediol-1,10. On a préparé l'éther monotritylé correspondant et le tétradécène-10 ol-1 *cis* grâce à ce système; ce dernier composé résulte d'une réaction de Wittig entre un ylure lié au polymère et un aldéhyde en solution. On a préparé une série de résines bifonctionnalisées contenant des alcools trityliques situés à proximité de groupes acides benzoïques, ces résines spéciales ont été préparées en vue de synthétiser des diols liés au polymère à la fois par un lien éther tritylique ainsi qu'à un lien benzoate. On a établi que ces polymères lient exclusivement qu'une extrimité du décanediol-1,10. Les polymères, contenant à la fois des groupes alcool tritylique et acide benzoïque au hasard et les polymères contenant des groupes alcool tritylique situé, à proximité, conduisent à des mélanges de diols mono et doublement protégés.

Introduction

Soluble bifunctional polymers have been shown to be capable of mimicking enzymatic reactions (2) by intramolecular cooperation of the two different functional groups. Insoluble bifunctional resins may even more closely approximate enzymatic systems and the studies reported herein may spur development in this area of research. Our own interest in preparing insoluble bifunctional resins lies in another sphere, namely organic synthesis on insoluble polymer supports. Our recently described syntheses of insect sex attractants on solid phases (3–5) still suffer from one minor but persistent problem. In the first step of the synthesis a 2% divinylbenzene (DVB)–styrene copolymer, incorporating trityl chloride groups (**1**) reacts with symmetrical diols, such as 1,10-decanediol (**2**) to give a monoprotected symmetrical diol (**3**), the free end of which can be elaborated to insect sex attractants (3–5). Unfortunately, about 40% of the diol is actually bound to the polymer at both ends (double bound) and although this doubly-bound material does not interfere in the chemical synthesis, its presence means that it is liberated in the final cleavage step from the polymer and must be separated from the desired product.

Elimination of this problem would give a clean product without purification and would be more efficient in starting diol. If it were possible to actually *promote* double binding in such a way that the doubly-bound diol is bound to the polymer by two different functional groups, then the diol could be selectively cleaved from one of the functional groups liberating diol solely monoprotected by the insoluble resin. We envisioned that a polymer containing both trityl chloride and benzoyl chloride functional groups in close proximity could serve such a function. Before attempting to synthesize such a bifunctional polymer, we wished to see if it were possible to synthesize an insect sex attractant on a polymer-bound benzoyl chloride so that an attractant could be synthesized simultaneously from both functional groups of the bifunctional resin.

Leznoff and Wong (6) have described the preparation of monoethers of symmetrical diols using a polymer-bound phenylacetyl chloride as a blocking group. This polymer was not suitable for the synthesis of insect sex attractants because of the low loadings of diol previously obtained, the presence of acidic protons α to the carbonyl and the inability of the polymer to be recycled. Hence a polymer-bound benzoyl chloride was sought.

Results and Discussion

Polymer-bound Benzoyl Chloride as a Blocking Group in Synthesis

Polymer-bound phenyllithium (**4**) (7) was quenched with CO_2 and protonated (7,8) or treated with diethyl carbonate, followed by treatment with base and protonation to give the desired polymer-bound benzoic acid (**5**) (7,8).

Treatment of **5** (1.0–1.5 mmol acid/g of **5**) with thionyl chloride in benzene (6) gave the polymer-bound benzoyl chloride (**6**). The infrared (ir) spectrum of this polymer showed strong absorptions at 1810 and 1780 cm^{-1} due to the acid chloride group. Polymer **6** reacted with 1,10-decanediol (**2**) in pyridine to give the monoprotected diol polymer **7**.

The ester linkage of **7** proved to be considerably more inert to base-catalysed hydrolysis than diols bound to the previously described polymer-bound phenylacetyl chloride (6, 9).

Treatment of polymer **7**, however, with 0.2 *M* $(n\text{Bu})_4\text{NOH}$ (10) in THF for 48 h at room temperature resulted in a polymer whose ir spectrum showed no trace of residual ester absorptions. The solution phase contained 0.8–1.0 mmol of diol **2**/g of polymer **7**. The recovered diol was easily separated from impurities introduced by the cleavage reagent by preparative thin-layer chromatography (tlc). Although not as clean as the HCl in dioxane mixture used to cleave trityl resins, $(n\text{Bu})_4\text{NOH}$ is more suitable for the cleavage of benzoate resins than other bases investigated.

Attempts to oxidize polymer-bound diol **7** to a polymer-bound aldehyde using di-*tert*-butyl chromate (4,11) resulted in no observable additional bands in the ir spectrum of the product. Furthermore, attempts to elaborate this polymer-bound aldehyde to insect sex attractants by a previously described Wittig route (4) failed and yielded only starting diol **2**, indicating that the initial oxidation failed.

Because of our experience with trityl resins, we initially suspected that the diol bound to **7** was bound entirely as the diester, i.e. entirely 'doubly-bound.' Conversion of **7** to the polymer-bound monotrityl ether **8** as described by Wong and Leznoff (6) followed by base cleavage gave a mixture of unreacted diol **2** and the expected monotrityl ether of 1,10-decanediol (**9**) as shown in Scheme 1. The yield of **9** might in fact reflect the total amount of monoprotected diol bound to **7**. However, subsequent investigation (see below) showed that this was not the case. Thus this experiment showed only that **7** contained *not less than* 0.24 mmol/g of free alcohol groups of **7**.

Numerous examples of a Wittig reaction in the presence of an ester have been reported (12). This, together with the complete absence of products from base catalysed decomposition of aldehydes suggested that the oxidation of **7** to a polymer-bound aldehyde had not occurred. The benzoate linkage of **7** is relatively acid insensitive and hence a large number of other (acidic) methods were tested for the oxidation of **7** to a polymer-bound aldehyde. Some reagents tested were chromium trioxide in HMPT (13), dimethylsulfoxide and dicyclohexylcarbodiimide (14), dimethylsulfoxide and trifluoroacetic anhydride (15), and even sodium dichromate in acidic HMPT (16). In no case were any products other than unreacted diol recovered upon cleavage of the polymers.

On the basis of observations made of polymers containing both trityl alcohol and benzoate groups (see below), it is likely that the failure of the oxidation of **7** to polymer-bound aldehyde is due to a combination of two factors, namely, the poor swelling properties of polymer-bound diol **7**, especially in some of the solvents used for the oxidations tested, and the presence of by-products from the thionyl chloride reaction which inhibit oxidation by di-*tert*-butyl chromate (11). Indeed, a polymer-bound trityl alcohol, converted to a polymer-bound trityl chloride **1** using *thionyl chloride*, instead of *acetyl chloride*, when loaded with diol to give a

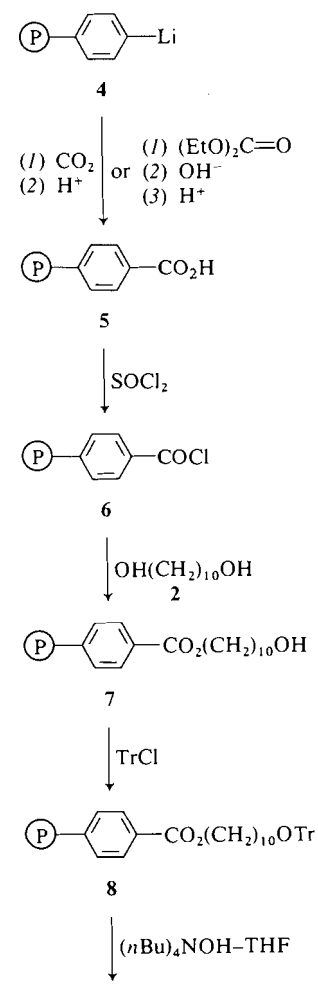
For personal use only.



SCHEME 1

polymer-bound diol is sufficiently contaminated with this by-product to completely prevent the oxidation and subsequent 'normal' Wittig reaction. The deleterious effects of thionyl chloride on functionalized resins has been previously noted (17).

Since lithio alkynes are incompatible with the ester blocking group, the remaining 'reverse' Wittig route (4) was investigated with this system as shown in Scheme 2. Polymer-bound diol **7** was converted to the mesylate **10** in the same manner as was used with trityl resins (4). The ir spectrum of **10** showed strong absorptions at 1180 and 1360 cm^{-1} due to the presence of mesylate groups. The free diol monomesylate could not be isolated by base cleavage due to its base lability. Conversion of **10** to the phosphonium salt **11** by treatment of **10** with molten triphenylphosphine for 48 h at 140°C succeeded as shown by the absence of the 1360 cm^{-1} band (unreacted mesylate groups) and the presence of the 1210 cm^{-1} band (phosphonium salt formation) in the ir spectrum of the product polymer.

Treatment of the benzoate-bound phosphonium salt **11** with trityllithium or *tert*-butyllithium followed by treatment for 4 h with butyraldehyde gave polymer-bound alken-l-ol **12**. Base cleavage of **12** as described above produced the expected 10-tetradecen-l-ol (**13**) together with unreacted diol (Table 1). Acetylation of **13** gave **14**, the sex attractant for the oak leaf roller, *Archips semiferamus* Walker (18). The overall yield of attractant was comparable to previously obtained results with trityl resins (4) (Table 1). The stereoselectivity of the process was also quite high as in the previous trityl case (4), providing 85% of the *cis* isomer.

We were hoping that polymer-bound benzoic acid (**5**) prepared via diethyl carbonate would have less functional groups at adjacent sites due to quenching of adjacent phenyllithium sites with diethyl carbonate to give polymer-bound benzophenone. Although the ir spectrum of **5** indeed

showed an additional absorption band at 1680 cm^{-1}, the additional crosslinking of **5** and quenching of adjacent sites did not decrease the eventual amount of double-binding. Syntheses on **5** prepared via diethyl carbonate, were similar to syntheses on **5**, prepared via carbon dioxide (Tables 1 and 2).

In general, benzoate polymers are not as suitable for the monoprotection of symmetrical diols as the corresponding trityl polymers for a variety of reasons. (*a*) Benzoate polymers swell less readily than trityl polymers and hence more forcing conditions are required to drive the desired reaction. (*b*) Benzoate polymers contain by-products resulting from treatment with thionyl chloride. These by-products interfere with the oxidation of alcohols to aldehydes (and possibly other reactions). (*c*) Benzoate polymers cannot be as efficiently recycled as trityl resins. While trityl alcohol polymers remain very little degraded after more than 20 times of reuse, the capacities of used benzoate polymers are much diminished from the initial capacities (Table 1). This problem may be related to the by-products mentioned in point *b*.

Bifunctional Polymers

Addition of a saturated solution of *p*-benzoylphenyl ethyl carbonate (**15**), prepared from 4-hydroxybenzophenone and ethyl chloroformate, in tetrahydrofuran (THF) to polymer-bound phenyllithium (**4**), prepared from a *sec*-butyllithium-TMEDA complex to provide a large proportion of proximally lithiated sites (19), gave a dark green mixture which was decolorized on the addition of water. The ir spectrum of this polymer showed absorptions at 1770 cm^{-1} (carbonate, due to **15** reacted only at the benzophenone), 1740 cm^{-1} (ester, due to mono-reaction at the carbonate of **15** with either ethoxy or phenoxy as leaving group), and 1680 cm^{-1} (benzophenone, due to double reaction at the carbonate of **15** plus reaction at the carbonate of **15** only). Base cleavage of this polymer produced a second product whose ir spectrum contained no residual bands at 1770 and 1740 cm^{-1} but did show a band at 1680 cm^{-1} apparently unaltered by base treatment. Only trace quantities of 4-hydroxybenzophenone could be recovered from the base cleavage mixture and thus the amount of reaction at the carbonate functional group only is minimal. Protonation of the second polymer resulted in production of **16** whose ir spectrum showed an absorption at 1725 cm^{-1} (free carboxylic acid) and again a band at 1680 cm^{-1} (benzophenone). From the above sequence of changes in the ir spectra on reaction with base and acid it was likely that both trityl and benzoate groups had been produced and that the number of trityl groups probably exceeded the number of benzoate groups. This is the expected result since nucleophilic attack on benzophenone would be faster than on carbonate and some of the first formed esters would further react with adjacent lithiated sites.

Treatment of polymer **16** with diazomethane in methylene chloride at low temperature for 16 h, gave polymer **17**. The phenol of **16** had been protected as the methyl ether with concomitant protection of benzoate as the methyl ester. Before proceeding with the synthesis of attractant **14** via bifunctional polymer **17**, as outlined in Scheme 3, the nature of diol bound only to the trityl group of **17** was determined.

Conversion of **17** to the trityl chloride **18** using acetyl chloride in benzene as previously described (7) gave a polymer containing 0.45 mequiv. of chloride/g of resin. Treatment of **18** with 1,10-decanediol (**2**) gave the polymer-bound diol **19**. A polymer-bound diol monoacetate was prepared in the manner previously described (7) which upon cleavage in dilute acid (7) liberated 0.27 mmol of 1,10-decanediol monoacetate (**20**) and no recovered

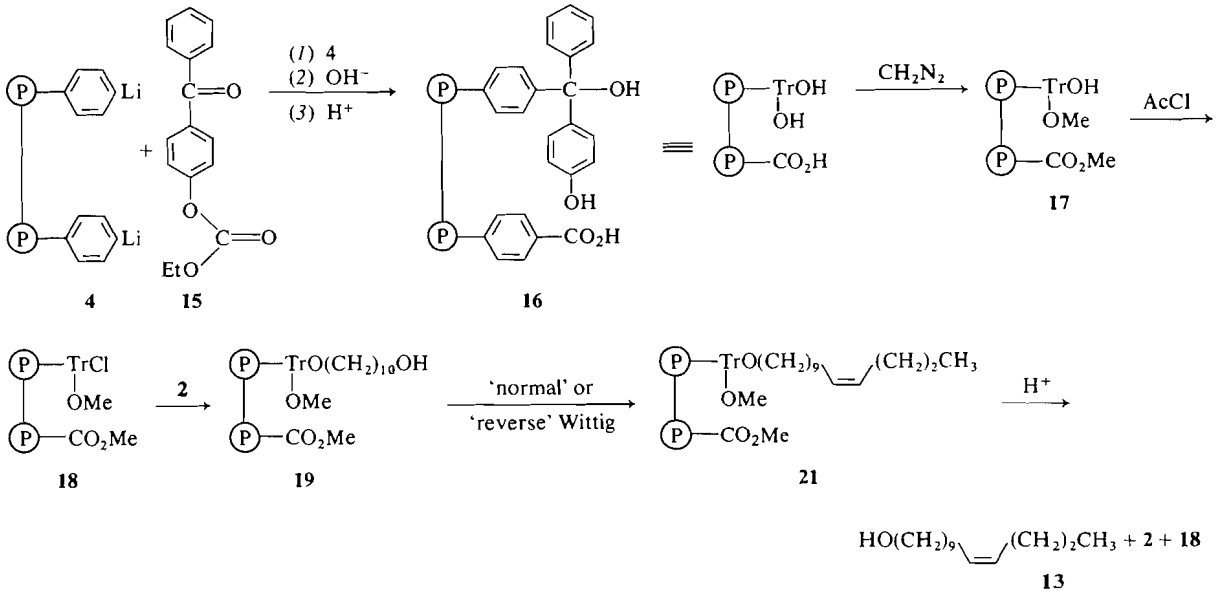

SCHEME 3

diol showing that **2** had been bound to **19** exclusively as the monoprotected trityl ether (Table 2).

Polymer-bound diol **19** could be elaborated by either the 'normal' or 'reverse' Wittig routes to give polymer-bound alken-l-ol **21**. Standard dilute acid cleavage of **21** gave 10-tetradecen-l-ol (**13**) which on acetylation gave **14** the attractant for the oak leaf roller moth (18). The overall yields of attractant **14** by both routes are given in Table 3. It is interesting to note that although **19** led to complete conversion to **20**, showing that acetylation of **19** is complete, **19** leads only to partial conversion to **13** by both the 'normal' and 'reverse' Wittig routes. Diol **2** is recovered in both sequences showing that both oxidation and mesylation of **19** is incomplete. These reactions were also probably incomplete on the simple monofunctionalized resins (4). We then attempted to attach **2** *simultaneously* to both the

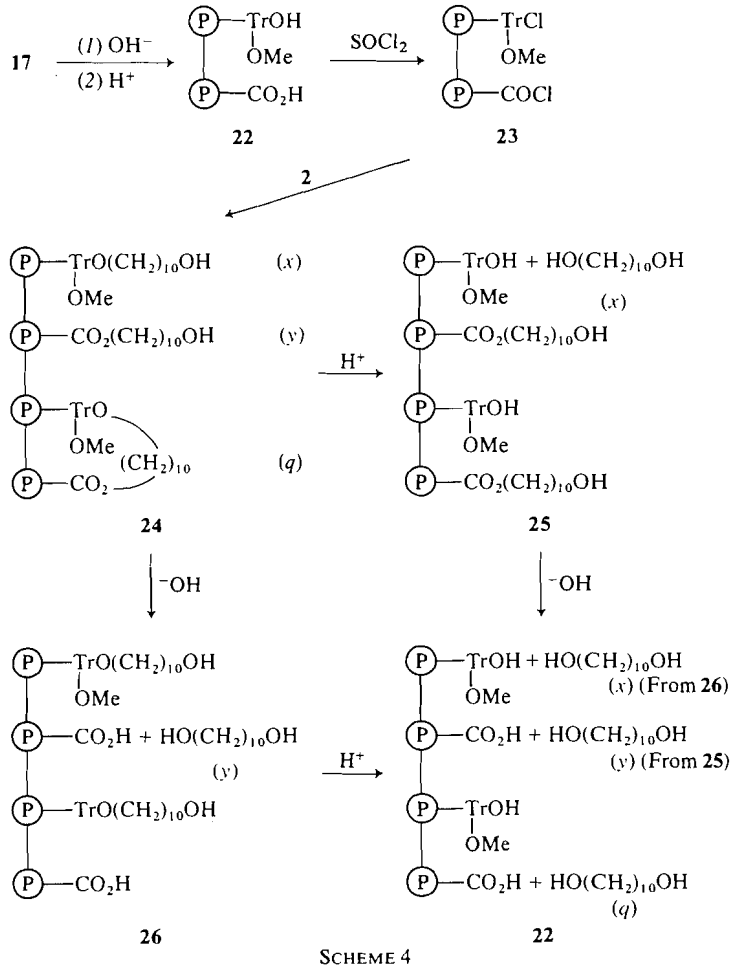

SCHEME 4

trityl and carboxy groups. Base cleavage of **17** as described above followed by protonation gave polymer **22**. Thionyl chloride treatment of **22** gave the mixed trityl – acid chloride polymer **23** containing 0.55 mmol of chloride/g of **23**. Treatment of **23** with 1,10-decanediol (**2**) in pyridine gave polymer **24** containing diol bound in at least three fashions: (*a*) as the monotrityl ether (*x*), (*b*) as the monobenzoate (*y*), and (*c*) as the trityl ether – benzoate intraresin crosslinkage shown (*q*). The proportions of these three modes of diol binding were assessed as outlined in Scheme 4.

Successive treatment of **24** with acid (to give **25**) followed by base cleavage liberates the total quantity of diol bound to polymer **24** (*z*). The amount of diol liberated in the first acid cleavage step must be bound to **24** only via trityl groups (*x*). The amount of diol liberated in the second base cleavage step is then the sum of the amount bound only as benzoates (*y*) plus any doubly-bound diol held as the mixed trityl ether – benzoate (*q*). Alternatively, base cleavage of **24** gives polymer **26** and liberates only diol bound as the benzoate (*y*). Subsequent acid cleavage of **26** gives the sum of doubly-bound (as the trityl ether – benzoate) and trityl only bound diols ($q+x$). The maximum amount of diol bound as the mixed trityl ether – benzoate (q) is thus given by $q=z-x-y$. A check is provided by the two values of the total amount of diol bound to **24** (z and z') obtained from the two independent cleavage sequences.

In any event, x was found to be 0.16 mmol/g of **24**, y to be 0.07 mmol/g of **24** and $z=z'=0.23$ mmol/g of **24**. Thus the maximum amount of diol bound by the mixed trityl ether – benzoate was found to be $q=0.0$ mmol/g of **24** (Table 2). Conversion of **24** to the acetate and acid cleavage as previously described (7) showed complete monoprotection of diol bound to the trityl groups of **24** (Table 2). Similarly conversion of **24** to the monotrityl ether (6) and base cleavage as described above showed at least 83% of the diol bound to the benzoate of **24** was monoprotected (Table 2). These results

indicated that polymer **24** behaved as if it were a mixture of two separate and independently functionalized polymers. Thus the goal of obtaining a polymer-bound diol doubly-bound through a trityl group at one end and a benzoate group at the other was not achieved. However, exclusive monoprotection of diol bound to trityl groups was obtained although the loading (Table 2) was not sufficiently high nor better than a previously described trityl polymer from the controlled addition of methyl benzoate (7). Since **23** was prepared using $SOCl_2$, attempts to oxidize **24** to an aldehyde failed and the elaboration of **24** to **14** simultaneously on two functional groups by the 'normal' Wittig route failed. Polymer **24** could be elaborated to attractant **14** by the 'reverse' Wittig route (7), however, in modest yield (Table 3).

Attempts to produce higher levels of functionalization by varying the conditions of the quenching reaction of **4** with **15** did give us a polymer capable of double-binding diol through two different functional groups. Thus quenching **4** with a 0.5 *M* solution of **15** in THF did yield a sample (Scheme 4) of **24** which was found by the double cleavage sequence described above to contain 0.02 mmol of **2**/g of **24** doubly-bound as the mixed trityl ether – benzoate (Table 2) but the level of this loading was too low to be useful.

Treatment of **4** with a *dilute* solution of carbonate **15** resulted in complete reaction of the carbonate group to give polymer **27** as shown in Scheme 5. The ir spectrum of **27** exhibited only one carbonyl absorption at 1680 cm^{-1} due to the newly-formed benzophenone group. Polymer **27** was treated with excess phenyllithium to give a new polymer **28**, containing two types of trityl alcohol groups. The two different kinds of trityl alcohol groups are likely constrained to be near each other as they are both derived from **15**. This constraint is borne out by the following reactions. Treatment of **27** with acetyl chloride to form a polymer-bound trityl chloride, followed by the addition of excess 1,10-decanediol (**2**) gave the polymer diol **29**. Acetylation of **29** and acid cleavage yielded exclusively 1,10-decanediol monoacetate (**20**) and no unreacted **2**. Polymer **28**, however, in the same sequence, yielded a polymer diol **30**, which on acetylation and cleavage from **30**, gave **20** *and unreacted 2* (Table 2). Although the quantity of diol bound to **30** is only 0.04 mmol/g of polymer more than the amount bound to **29** (Table 2), greater than half of the trityl groups of **30** are involved in double binding of diol! Diol bound to polymer **29**, however, is bound entirely as the monotrityl ether. Clearly the proximity of functional groups is an important factor in the selective monoprotection of symmetrical diols. We believe that the recovered **2** was obtained because **2** was doubly bound to **28** likely through the two different types of trityl groups. *These key experiments outlined in Scheme 5 strongly support our original hypothesis that polymer-bound phenylithium **4** can be quenched with carbonate **15** at adjacent or conformationally proximal sites.*

For the purposes of comparison with polymer **22**, **4** was quenched with a 1:1 mixture of benzophenone and diethylcarbonate to produce a bifunctionalized polymer **31** in which the trityl groups are not constrained to be in the vicinity of the benzoate groups. Treatment of **31** with acetyl chloride and reaction with **2** gave polymer-bound diol **32**. Base cleavage of **31** and protonation yielded **33**, which reacted with $SOCl_2$ and then **2** to give the polymer-bound diol **34** as outlined in Scheme 6. The amounts of monoprotection of diol were assessed by the methods

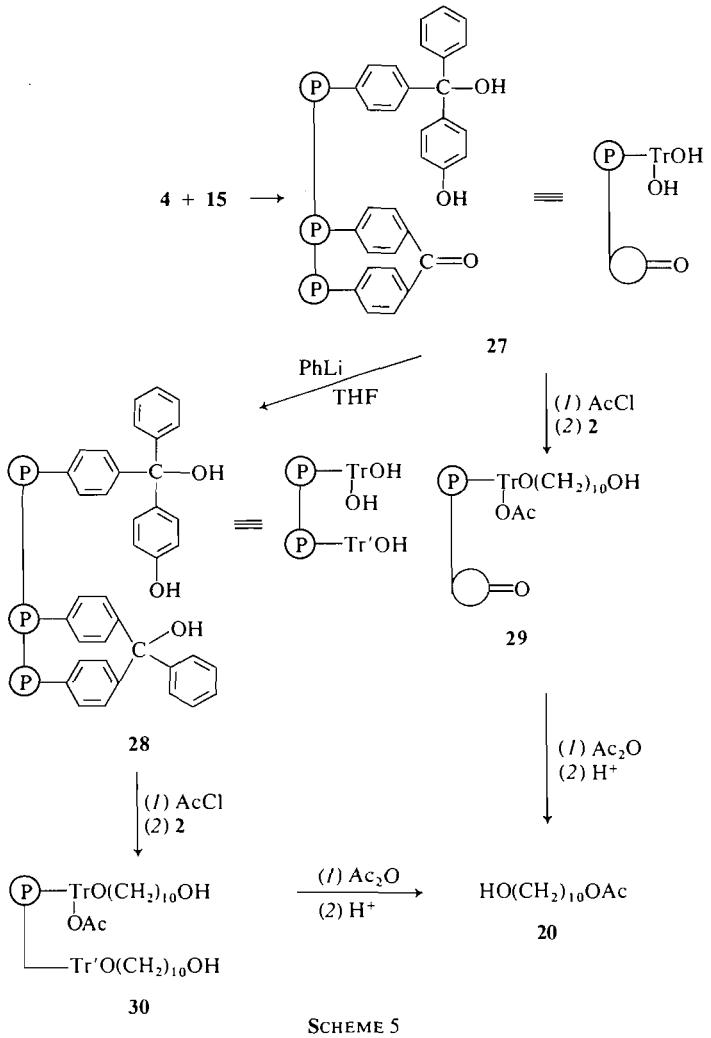

SCHEME 5

described above and gave the data in Table 2. As anticipated, trityl groups were produced in a large excess over benzoate groups due to the differences in the rates of nucleophilic attack (20) on benzophenone versus carbonate. Thus in a subsequent experiment, **4** was quenched with a 1:10 mixture of benzophenone and diethyl carbonate to give a new polymer **31** which contained relatively more carboxy groups. Identical types of experiments carried out on this 'new' **31** are recorded in Table 2. The values of x, y, z, and q for both **31** and 'new' **31** were determined (Table 2) by the methods described above and illustrated in Scheme 4. As a consequence the amount of diol doubly-bound to **34** (or 'new' **34**) as the mixed trityl ether – benzoate was zero. What was not anticipated was the relatively high amounts of double binding of diols bound only to trityl groups even at the low level of loading observed. The possibility that double binding of diol is in part a 'concentration' effect; the higher the degree of functionalization, the higher the double binding of diol is not necessarily the case. The total loading of diol to **32** and **34** was roughly one half the amounts obtained early in experiments on normal polymer-bound trityl chloride (7) but the proportions of double-bound diol was roughly the same.

This result is consistent with those reported previously (7) for the preparation of the monoacetates of 1,4-butanediol and 1,10-decanediol (**2**) and with studies done by Crowley *et al.* (21). Despite the fact that the carbon chain length of 1,4-butanediol is less than half the chain length of **2**, the extent of double binding of these diols is roughly the same (7). The observation that the amount of doubly-bound diol is insensitive to both the degree of functionalization of the polymer backbone and the carbon chain length suggests that the first formed monoblocked diol is not held in an isolated site but

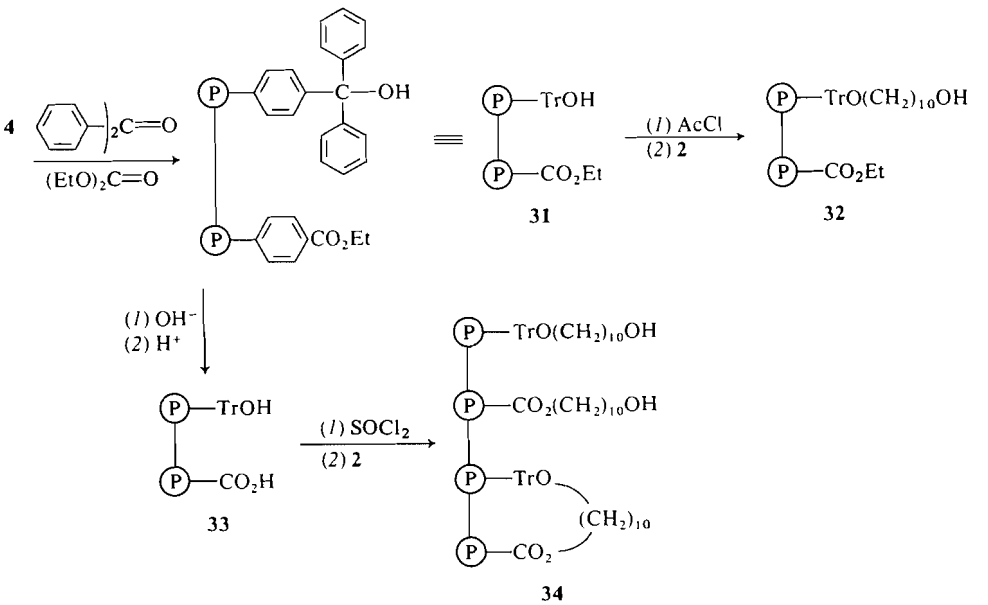

SCHEME 6

is relatively free to move within the polymer matrix. The unreacted end of the monoprotected diol must be sufficiently mobile to allow it to compete effectively with solution phase diol for unreacted functional groups on the polymer.

In summary, bifunctionalized resins, having spatially defined geometries, have been prepared and are expected to find wide applications in (*a*) studies directed towards the elucidation of intraresin interactions, (*b*) organic synthesis on polymer supports,[4] and (*c*) the construction of model systems capable of mimicking enzymatic systems. This study has shown how bifunctional resins can be used to restrict intraresin reactions and examined the scope of synthesizing an insect sex attractant bound to two different functional groups of a single resin.

Experimental

Infrared spectra were recorded on a Unicam SP1000 ir spectrophotometer as neat films between NaCl discs unless otherwise specified. Nuclear magnetic resonance spectra were recorded on a Varian EM360 spectrometer using deuteriochloroform as solvent and tetramethylsilane as internal standard. Mass spectra were recorded on a Perkin-Elmer-Hitachi RMU6E mass spectrometer. Silica gel was used for all thin- and preparative-layer chromatography. Fractions were extracted with ether in a Soxhlet extractor. Filtration was done under vacuum through sintered glass Buchner funnels. Filtration under an inert atmosphere was done as previously described (7). Microanalyses were performed by G. Gygli of Toronto.

[4]A bifunctional resin, containing both nickel and rhodium in a *random* array has been synthesized and used as a catalyst in sequential reactions of oligomerization and hydrogenation (22).

Preparation of Polymer-bound 'Benzoic Acid' 5 via Diethyl Carbonate

To a suspension of 5 g of polymer-bound phenyllithium (**4**) in 100 ml of dry THF under an argon atmosphere was added 10 g of diethyl carbonate in 100 ml of dry THF dropwise over 0.5 h. The mixture was stirred a further 2 h, filtered, washed twice with ethanol (50 ml), and twice with water (50 ml). The polymer was suspended with 50 ml of THF and treated with 25 ml of a 0.5 *M* tetra-*n*-butylammonium hydroxide solution in THF. The mixture was stirred at reflux overnight, filtered, and washed twice with ethanol (50 ml). The polymer was then protonated, filtered, washed, and dried as previously described (7) in the preparation of **5** via CO_2; ir: 1725 (C=O, acid), 1680 cm^{-1} (C=O, benzophenone).

Preparation of Polymer-bound Acid Chloride 6

In a manner similar to that previously described (6–8), 5 g of 'benzoic acid' polymer **5** (1.0–1.5 mmol of acid/g), 10 ml of freshly distilled thionyl chloride, and 80 ml of dry benzene were stirred at reflux under argon overnight. The mixture was filtered, washed with dry benzene (50 ml), twice with dry ether (50 ml), and immediately pumped dry at high vacuum. Treatment of a standard sample of **6** with dioxane–water (1:1) liberated 0.6–1.5 mmol of chloride/g of resin.

Preparation of Polymer-bound Diol 7

By the method of Wong and Leznoff (6), 5 g of **6** and 5 g of 1,10-decanediol (**2**) gave **7**; ir: 1740 cm^{-1} (C=O).

*Preparation of Tetra-*n*-butylammonium Hydroxide in THF Solution (23)*

To a suspension of tetra-*n*-butylammonium iodide (18.5 g, 50 mmol) in 100 ml of distilled water at 90°C was added freshly prepared 'silver hydroxide' (60 mmol, from 10 g of silver nitrate and 2.4 g of sodium hydroxide). The resultant slurry was vigorously stirred at reflux for 0.5 h, cooled in ice, and filtered while cold. The filtrate was evaporated to an oil under reduced pressure, traces of water were removed as the benzene azeotrope and the oil was made to 100 ml in dry THF. Acid–base titration showed the solution to be 0.45–0.48 *M* in hydroxide (90–96% yield).

General Base Cleavage of Polymer-bound Benzoate Diols and Derivatives

In a typical procedure to liberate diol and derivatives from benzoate polymers, 1.0 g of polymer was suspended in 20 ml of THF and treated with 10 ml of a 0.5 *M* solution of tetra-*n*-butylammonium hydroxide. The mixture was stirred at room temperature for 48 h, filtered, and the polymer was washed twice with ethanol (10 ml), four times with water (20 ml), twice with ethanol (10 ml), twice with ether (15 ml), and air dried. The ir showed no bands above 1650 cm^{-1} (C=O).

The filtrate was extracted with ether, washed with water, dilute acid, dried ($MgSO_4$), and evaporated to yield the crude product.

Preparation of Polymer-bound Benzoate Diol Monotrityl Ether ***8***

Polymer **8** was prepared from **7** and triphenylmethyl chloride as described by Wong and Leznoff (6). The ir was uninformative.

Isolation of 1-O-Trityl-1,10-decanediol (***9***)

Standard base cleavage of 1 g of **8** and purification of the crude product by preparative tlc (eluant, ether–benzene, 2:3) gave only 1,10-decanediol **2** (R_f 0.2), 63 mg, 0.36 mmol/g of **8**; and 1-*O*-trityl-1,10-decanediol (**9**) (R_f 0.55), 101 mg, 0.24 mmol/g of **8**; ir (neat): 3400 (OH), 2950 (CH_2), 1604 (aromatic C—H), 1050 cm^{-1} (C—O); nmr: 7.4–7.3 (br s, 15H, OTr), 3.6 (t, 8, 2H, CH_2OH), 3.2 (t, 8, 2H, CH_2OTr), 3 var (s, 1H, O*H*), 1.6–1.2 (m, 16H, —CH_2—). The yield data for the preparation of **9** are given in Table 1.

Preparation of Polymer-bound Diol Monomesylate ***10***

Polymer-bound mesylate **10** was prepared from **7** and methanesulfonyl chloride exactly as previously described (7); ir: 1360 (CH_3SO_2), 1180 cm^{-1} (CH_3SO_2).

Preparation of Polymer-bound Phosphonium Salt ***11***

In a manner similar to, but not identical to a previously described procedure (4), 2 g of **10** were added to 25 ml of molten triphenylphosphine and the mixture was heated to 140°C under an argon atmosphere for 48 h. The product polymer **11** was recovered as previously described; ir: 1210 (salt?), 1180 cm^{-1} (CH_3SO_2).

Preparation of Polymer-bound Alken-1-ol ***12*** *('Reverse' Wittig)*

(*a*) *Using Trityllithium*

To a solution of 1 g of triphenylmethane (ca. 5 mmol) in 30 ml of THF at −10°C under an argon atmosphere was added 2.2 ml of methyllithium (1.36 *M*, 3.9 mequiv.). The solution was stirred at 0°C overnight and 1.5 g of **11** was added. The slurry was stirred at 0°C for 3 h, quenched with 5 ml of butyraldehyde, and stirred a further 4 h. The polymer was filtered, washed and air dried as previously described (4).

(*b*) *Using* tert-*Butyllithium*

Polymer **11** (1.5 g) in 30 ml of dry THF was cooled to 0°C under an argon atmosphere and treated with 2 ml of *tert*-butyllithium (2 *M*, 4 mequiv.). The mixture was allowed to warm to room temperature over 1 h, quenched with 5 ml of butyraldehyde, and stirred a further 4 h. The polymer was filtered, washed and air dried as previously described (4). The ir (either method) was uninformative.

Isolation of 10-Tetradecen-1-ol (***13***)

Standard base cleavage of **12** and purification of the crude product by preparative tlc (eluant, ether–benzene, 2:3) gave 1,10-decanediol (**2**) (R_f 0.2), 47 mg, 0.27 mmol/g of **12**; and 10-tetradecen-1-ol (**13**) (R_f 0.6), 51 mg, 0.24 mmol/g of **2**. Acetylation of **13** gave 10-tetradecen-1-ol acetate (**14**). Compounds **13** and **14** were identical to previously prepared samples (4) and the overall yields and isomeric composition, determined by vapour phase chromatography (vpc) and high pressure liquid chromatography (hplc) as previously described (4), of the products are given in Table 1.

Preparation of p-*Benzoylphenyl Ethyl Carbonate* ***15***

To a solution of 4-hydroxybenzophenone (25 g, 0.12 mol) and triethylamine (30 ml, ca. 0.25 mol) in 150 ml of THF was added dropwise 12 ml of ethyl chloroformate (0.15 mol) over 0.5 h. The mixture was heated to reflux for 1 h, cooled, poured into ice, and extracted with methylene chloride. The extract was washed with dilute base and water, dried ($MgSO_4$) and evaporated. The crystalline mass was recrystallized from methanol (mp 118–121°C) and the recrystallized material was further purified by sublimation (115°C/0.05 Torr) to give 20.6 g of *p*-benzoylphenyl ethyl carbonate (**15**) as white needles, mp 123–123.5°C, in 61% yield; ir (KBr): 3020 (CH), 2950 (CH_2), 1770 (OCO_2), 1660 (C=O), 1600 (aromatic C—H), 1470 cm^{-1} (CH_2); nmr: 8.1–7.3 (m, 9H, Ph—*H*), 4.5 (q, 8, 2H, O—CH_2—), 1.4 (t, 8, 3H, CH_3); ms (70 eV *m/e* (relative intensity): C=O 270 (25) (M^+), 225 (31), 197 (72), 149 (70), 121 (100), 105 (80). *Anal.* calcd. for $C_{16}H_{14}O_4$: C 71.10, H 5.22; found: C 70.93, H 5.02.

Preparation of Bifunctionalized Polymer ***16***

To a suspension of 10 g of polymer-bound phenyllithium **4** in 100 ml of dry THF under an argon atmosphere was added 5 g of **15** in approximately 100 ml of THF (saturated solution) dropwise over 15 min. The resultant mixture was stirred a further 2 h at room temperature, filtered and the polymer washed and air dried; ir: 1760 (OCO_2), 1735 (CO_2R), 1680 cm^{-1} (C=O). Base cleavage of this product as described in the preparation of **5** followed by protonation, washing, and drying gave **16**; ir: 1725 (CO_2H), 1680 cm^{-1} (C=O, benzophenone).

Preparation of Methylated Bifunctionalized Polymer ***17***

To a solution of diazomethane (7.0 mmol) in 75 ml of methylene chloride was added 10 g of polymer **17** in portions. The mixture was stirred at −10°C overnight, filtered, and the polymer washed twice with methylene chloride (50 ml) and three times with ether (25 ml); ir: 1730 (CO_2R), 1680 cm^{-1} (C=O, benzophenone).

Preparation of Polymers ***18***, ***19***, *and* ***21***

These polymers were prepared by methods previously described (4, 7).

Preparation of Bifunctional Polymers ***22***, ***23*** *and Polymer-bound Diol* ***24***

Polymer **22** was prepared by the method outlined for the base cleavage/protonation sequence leading to **16**; ir: 1725 (CO_2H), 1680 cm^{-1} (C=O). Polymer **23** was prepared as described for the preparation of **6**; ir: 1810 and 1760 (COCl), 1680 cm^{-1} (C=O). Halide analysis (22) showed 0.55 mmol of chloride/g of **23**. Treatment of **23** with 1,10-decanediol (**2**) in pyridine as previously described (7) gave **24**; ir: 1740 (CO), 1680 cm^{-1} (C=O).

Liberation of 1,10-Decanediol (**2**) *from* ***24***: *Determination of* x, y, z, *and* q

Standard acid cleavage of 1.0 g of **24** and purification of the crude product by preparative tlc (eluant, ether–benzene, 1:1) gave 1,10-decanediol (**2**) (R_f 0.3), 28 mg, 0.16 mmol/g of **24** (*x*). The resultant polymer **25** was treated with base under the standard cleavage conditions to yield on work-up and purification on preparative tlc 1,10-decanediol (**2**), 12 mg, 0.07 mmol/g of **25**. For this sequence $z = 0.07 + 0.16 = 0.23$ mmol of **2**/g of **24**.

Standard base cleavage of a second 1.0 g sample of **24**

followed by purification of the crude product on preparative tlc gave **2**, 12 mg, 0.07 mmol/g of **24** (y). The resultant polymer **26** was treated with acid under the standard conditions to yield on work-up and purification as above, **2**, 28 mg, 0.16 mmol/g of **26**. For this sequence $z' = 0.23$ mmol of **2**/g of **24**. Therefore $q = 0.23 - 0.16 - 0.07 = 0.0$ mmol/g of **24**.

Preparation of Bisfunctionalized Polymer 27

To a suspension of 10 g of polymer-bound phenyllithium **4** in 200 ml of dry THF under an argon atmosphere was added a total of 6 g of **15** in 200 ml of dry THF dropwise over 2 h. The mixture was stirred an additional 2 h, filtered, and the polymer was washed and dried as outlined in the general procedure; ir: 1680 (C=O), no bands between 1700–1900 cm^{-1}.

Preparation of the Mixed Trityl Polymer 28

A mixture of 5 g of **27** in 100 ml of dry THF and 40 ml of phenyllithium (1.5 M in benzene, 60 mmol) was stirred at reflux under an argon atmosphere overnight. The mixture was cooled, poured into a rapidly stirring mixture of 10% acid in ice cold dioxane and the polymer was filtered, washed, and Soxhlet dried as outlined in the general procedure. The ir was uninformative with no bands between 1650 and 1800 cm^{-1}.

Preparation of Bifunctionalized Polymer 31

To a suspension of 10 g of polymer-bound phenyllithium **4** in 100 ml of dry THF under an argon atmosphere was added a mixture of benzophenone (9.1 g, 50 mmol) and diethyl carbonate (5.9 g, 50 mmol) or a mixture of benzophenone (5 mmol) and diethyl carbonate (50 mmol) in 100 ml of dry THF dropwise over 0.5 h. The mixture was stirred a further 2 h at room temperature, filtered, and the polymer was washed and dried as described before (4, 7) to give polymer **31** or new polymer **31** (1:10); ir: 1740 (CO_2Et), 1680 cm^{-1} (C=O).

Preparation of Bifunctionalized Polymers 32, 33, and 34

Polymers **32**, **33**, and **34** were prepared by methods identical to those for **19**, **23**, and **24**.

Some derived values in Table 1 for '$10^4\ k_{corr}$' contain computational errors. Proper values are: cyanoacetate pH 2.7: 2.55; chloroacetate pH 3.1: 6.60; dichloroacetate pH 1.6: 0.270. These values give '$10^4\ k_B$' for cyanoacetate: 3.55; chloroacetate: 9.03; dichloroacetate: 0.35. The statistically corrected Brønsted plot has a slope of 0.9 ($r = 0.999$). These changes do not affect any conclusions or discussion.

An investigation of discrepancies in the reported properties of tetraphenyl-*p*-dioxin

BILLY J. YAGER AND WILFORD L. WOOTAN, JR.
Southwest Texas State University, San Marcos, TX 78666, U.S.A.

Received December 13, 1977

BILLY J. YAGER and WILFORD L. WOOTAN, JR. Can. J. Chem. **56**, 1043 (1978).

A compound prepared by refluxing methyl benzoate with boron sulfide (B_2S_3) and previously identified as tetraphenyl-*p*-dioxin has been identified in this investigation as tetraphenylthiophene.

BILLY J. YAGER et WILFORD L. WOOTAN, JR. Can. J. Chem. **56**, 1043 (1978).

On a démontré que le composé préparé par reflux de benzoate de méthyle avec le sulfure de bore (B_2S_3) et qui avait été identifié antérieurement comme étant la tétraphényl-*p*-dioxinne est plutôt la tétraphénylthiophène.

[Traduit par le journal]

Consideration of the two functional groups of the benzoin molecule (**1**), led to the speculation that an acid catalyzed condensation reaction between two of these molecules and subsequent dehydration should result in the formation of tetraphenyl-*p*-dioxin (**2**). Reactions of this type, using benzene as solvent and *p*-toluenesulfonic acid as a catalyst, were carried out in these laboratories, but were only partially successful. No tetraphenyl-*p*-dioxin was obtained but tetraphenylfuran (**3**) was isolated and identified by its infrared spectrum (1) and physical properties (2).

At this point, a review of the literature revealed that Berger and Summerbell (3) had successfully prepared tetraphenyl-*p*-dioxin by the method described above using hexane as the solvent. It was also discovered, however, that Jerumanis and Lalancette (4) reported properties for tetraphenyl-*p*-dioxin which were in conflict with those reported earlier. While Berger and Summerbell reported that tetraphenyl-*p*-dioxin consisted of bright yellow crystals melting at 218–219°C, Jerumanis and Lalancette reported white crystals melting at 184–185°C. There were also significant differences in the reported infrared spectra, which indicated that two different compounds were being described.

To determine the true identities of the two compounds described above, both were prepared by their reported methods and subjected to the usual analyses. The results have indicated that the compound of Berger and Summerbell was indeed tetraphenyl-*p*-dioxin, but that the compound reported by Jerumanis and Lalancette was tetraphenylthiophene (**4**). The error on the part of Jerumanis and Lalancette was attributed to an incorrect elemental analysis.

Experimental

Infrared spectra were measured in KBr on a Beckman IR-10 infrared spectrophotometer and the absorption maxima are quoted in wavenumbers (cm^{-1}). Ultraviolet spectra were measured on a Perkin Elmer Double Beam spectrophotometer in absolute ethanol solution, and the absorption maxima are reported in nm. Nuclear magnetic resonance spectra were measured in CCl_4 solution on a Perkin Elmer R 12 A nuclear magnetic resonance spectrometer. Line positions are given in the δ (ppm) scale using tetramethylsilane (TMS) as internal standard. Mass spectra were run by, or under the direction of, Jack Maseles of the University of Texas at Austin, on a Bell and Howell mass spectrometer (model 21-491). All elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, Tennessee.

*The Compound (Tetraphenyl-*p*-dioxin) Reported by Berger and Summerbell (3)*

Benzoin (3 g, recrystallized from ethanol to a melting point of 133–134°C) was refluxed in dry hexane (100 ml) with a catalytic amount (0.1 g) of *p*-toluenesulfonic acid. Reflux was continued for 48 h using an azeotropic trap for removal of water. The hexane was distilled off and to the remaining yellow liquid, 175 ml of ethanol was added. The yellow crystalline product was obtained from this mixture on cooling. The crude product melted at 197–201°C but after recrystallization from acetic anhydride the bright yellow needles melted at 215–217°C (lit. (3) mp 218–219°C); 0.22 g, 8%; ir ν_{max}: 3020, 3060, 3080 (aromatic C—H stretch), 1660 (C=C stretch), 1595, 1495, 1440 (aromatic ring stretching), 1260, 1060–1070 (C—O stretching), 750, 680 (C—H out of plane vibrations of monosubstituted benzene); nmr (CCl_4) δ_{TMS}: 7.25 (sym d, aromatic protons); ms *m/e*: 388 (M^+, base peak), 311, 283, 267, 255, 194, 178, 165, 152, 139, 105, 77. *Anal.* calcd. for $C_{28}H_{20}O_2$: C 86.57, H 5.19, O 8.24; found: C 86.69, H 5.26, O 8.05.

The Compound (Tetraphenylthiophene) Reported by Jerumanis and Lalancette (4)

Methyl benzoate was prepared by a standard method (5) from benzoic acid and methanol. Boron sulfide (B_2S_3) was commercial reagent grade (from Ventron of Danvers, MA) and was used without further purification.

Methyl benzoate (8.9 g) and boron sulfide (2.5 g) were refluxed under nitrogen for about 28 h. As the reaction began, a rapid evolution of gas was observed and during the course of the reaction a fine white powder was deposited on the upper part of the reflux condenser (and the beaker covering it). The reaction mixture was filtered hot and the residue was washed with 5–10 ml of boiling methyl benzoate. Addition of 125 ml of ethanol to the filtrate caused precipitation of dark yellow-brown crystals, which redissolved upon heating the solution.

Two methods of purification[1] were developed. The first method, which may be compared to a fractional crystallization, first involved filtration of the hot ethanolic solution to remove a dark colored powder. The filtrate was then treated with activated charcoal, cooled, and a small crop of mustard-yellow powder was discarded. The filtrate was concentrated to 50 ml and the resulting yellow crystals were treated twice with charcoal in ethanol. White needles (0.26 g) melting at 184–185°C were obtained from this solution.

The second method, which produced higher yields, utilized mercury in the purification process. The 140 ml of ethanolic solution was first concentrated to 100 ml. The concentrated solution was then cooled to effect crystallization, the crystals were dissolved in carbon disulfide, and mercury was added to this solution. Vigorous shaking (at room temperature) of the solution produced a black precipitate of HgS. The solution was decanted periodically and fresh mercury added until no additional HgS was formed. The solution was then filtered, and the carbon disulfide was evaporated. When the residue was recrystallized from ethanol, 0.56 g of off-white needles melting at 185–186°C were produced. The white needles melting at 184–185°C and the off-white needles melting at 185–186°C were shown to be the same substance (lit. (7) mp 184–185°C); ir ν_{max}: 3015, 3060, 3090 (aromatic C—H stretch), 1600, 1495, 1480, 1440 (aromatic ring stretch), 1025, 1065 (in-plane C—H bending), 740, 690 (C—H out-of-plane vibrations of monosubstituted benzene); uv λ_{max} (log ε): 239 (4.401), 309 (4.173) in absolute ethanol, (lit. (8) 238 (4.352), 310 (4.124) in methanol); nmr (CCl_4) δ_{TMS}: 7.10 (s, aromatic protons), 7.05 (small multiplet, aromatic protons); ms *m/e*: 388 (M^+, base peak), 372, 370, 354, 311, 310, 295, 278, 267, 265, 178, 165, 156, 150, 121, 77. *Anal.* calcd. for $C_{28}H_{20}S$: C 86.57, H 5.19, S 8.24; found: C 86.53, H 5.00, S 8.59 (reported by Jerumanis and Lalancette (4) C 87.08, H 5.16, O 8.31).

[1]Early attempts at purification of the crude product from this reaction resulted in the formation of substances melting sharply around 165°C that were indicated to be pure by thin-layer chromatography but were found (by mass spectrum) to be mixtures of tetraphenylthiophene and S_8. These substances (similar to those reported by Bulmer and Mann (6)) resisted purification by repeated recrystallization from ethanol. Preliminary ultraviolet absorption and X-ray diffraction studies have indicated that the formation of a complex, while not likely, is a possibility.

Paramagnetic effects in flavin spectroscopy. A ^{13}C nuclear magnetic resonance study

DONALD DAVID MACMURCHIE AND ROBERT JOHN CUSHLEY
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received October 14, 1977

DONALD DAVID MACMURCHIE and ROBERT JOHN CUSHLEY. Can. J. Chem. **56,** 1045 (1978).

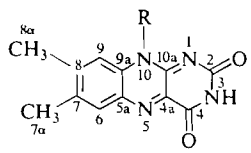
Experiments are described whose results indicate that semiquinones produced by intramolecular photoreduction of FMN in basic solution are responsible for specific line broadening observed in the ^{13}C nmr spectrum. Tests with oxidizing agents as well as singlet and triplet quenchers are shown to support this theory rather than the proposition that the paramagnetic species effective in relaxation enhancement is a flavin triplet state. A mechanism for the production of semiquinones and their interaction with the FMN population is discussed.

DONALD DAVID MACMURCHIE et ROBERT JOHN CUSHLEY. Can. J. Chem. **56,** 1045 (1978).

On décrit des expériences dont les résultats indiquent que les semiquinones produites par la photoréduction intramoléculaire de FMN en solution basique sont responsables pour les élargissements de bandes spécifiques observés dans les spectres rmn de ^{13}C. Des essais avec des agents d'oxydation ainsi qu'avec des pièges à singulet et triplet démontrent que cette hypothèse est plus plausible que la proposition à l'effet que l'espèce paramagnétique efficace dans l'augmentation de la relaxation est un état triplet de la flavine. On discute d'un mécanisme de production de semiquinones et de leur interaction avec la population de FMN.

[Traduit par le journal]

The purpose of the research described in this report has been to test, primarily by ^{13}C nmr, various hypotheses concerning the broadening phenomenon observed in ^{1}H nmr spectra of FMN (flavin mononucleotide) (1) and to arrive at an accurate description of the chemical events that lead to resonance broadening. In addition, we have investigated further the assignment of the ^{13}C resonances of FMN.



Rfn: R = —$CH_2(CHOH)_3CH_2OH$
FMN (disodium salt): R = —$CH_2(CHOH)_3CH_2OPO_3Na_2$
Lcm: R = —H
Lfn: R = —CH_3
Dfn: R = —CH_2CHO

The use of ^{13}C nmr is particularly appropriate in studying flavins as the number of magnetically distinct protons is small and many of these undergo solvent exchange. Observation of the ^{13}C resonances allows study of all parts of the molecule and the large range of ^{13}C chemical shifts permits resolution of the ^{1}H-decoupled spectrum into individual lines. Both the ^{1}H (2) and the ^{13}C (3) nmr spectra of FMN have been described and definite assignments have been made for some of the ^{13}C resonances on the basis of specific isotopic enrichment (4*a* and *b*).

In alkaline D_2O ($pD > 10$) the resonances associated with the ring protons have been observed to broaden with time to the point of vanishing from the spectrum, whereas the resonances of the ribityl side chain displayed a lessened and unequal broadening (l*a* and *b*). This broadening was observed to commence after a certain induction period and to be abolished by shaking the sample under air but not under nitrogen. These observations led to the suggestion that the broadening results from enhanced relaxation of the ^{1}H nuclei by the paramagnetic flavin triplet state. The possibility was discounted that a flavin semiquinone was responsible for the broadening effect but it has been shown (5*a* and *b*) that production of flavin semiquinone may proceed from the triplet state of the fully oxidized molecule and it is necessary to postulate unusual longevity of a triplet state or its continuous regeneration from an unknown source for a triplet state to be responsible for this effect. We wish to give more serious consideration to mechanisms involving reduced species as the principal broadening agent.

Experimental

Flavin mononucleotide (FMN), lumiflavin (Lfn), and reduced nicotinamide adenine dinucleotide (NADH) were obtained from Sigma Chemical Co. Commercial grade (95–97%) FMN was used without further purification for routine work while 'Grade I' material (99%) was used in experiments to ascertain the effect of the additional impurities. Lumichrome (Lcm) was obtained from Aldrich Chemical Co. and caffeine from British Drug Houses; both were used without further purification. TEMPONE (2,2,6,6-tetramethyl-4-piperidone-l-oxyl) came from Syva. All other chemicals used were reagent grade from standard suppliers except for 2,3-butadione and 2,4-pentadione, which were purified by distillation from practical grade material. Tris(2,4-penta-

dionato)Fe^{III} was prepared by addition of the ligand to aqueous $FeCl_3$.

Proton, ^{13}C, and ^{31}P nmr spectra were recorded using a Varian XL-100-15 nmr spectrometer at ambient temperature (~32°C), controlled by a Transform Technology Inc., Fourier transform accessory. Electron spin resonance spectra were recorded using a Varian E-4 spectrometer with signal averaging employing a TTI nmr accessory. Values for p*H* were taken from a Radiometer PHM64 meter and in the case of D_2O solutions are reported as 0.4 units greater than the meter reading, i.e., p*D* = indicated p*H* + 0.40 (6).

Experiments described as 'dark' were performed in minimal room light, using brown glassware where possible. Solution transfers were performed in a darkroom using a low level of red light and opaque cloth was generally used to guard against unwanted illumination. When illumination of samples was called for it was performed with a 300-W tungsten lamp at a distance of approximately 30 cm. Exchange of dissolved gases was carried out by bubbling O_2 or N_2, as required, through the solutions from a Pasteur pipette for a period of approximately 1 h.

In experiments testing the efficacy of various reagents in producing sharp ^{13}C resonances, the samples were subjected to flushing with N_2 and illumination in the nmr tube, followed by injection of a previously deoxygenated reagent solution through the hole in the vortex plug. The solution was then mixed briefly and the N_2 above it expelled as the vortex plug was brought into contact with the liquid surface; the space above the plug was then re-flushed with N_2, the tube capped and the spectrum recorded promptly. For esr spectroscopy, samples were prepared and outgassed in the dark, spectra recorded, the sample illuminated in the esr cavity, and further spectra recorded.

Results

The effects of illumination and oxygenation of FMN solutions at two representative p*D* values are shown in Fig. 1. Spectra of dark, deoxygenated FMN samples displayed sharp resonances identical with those of the same samples after oxygenation, shown for p*D* 10.5 in Fig. 1*a* and p*D* 6.5 in Fig. 1*b*. Upon illumination of the deoxygenated samples, however, the resonances of FMN at p*D* 10.5 were all broadened, Fig. 1*c*, some to the extent of complete disappearance from the spectrum. The resonances of the ring carbons were almost completely obscured and those of the two methyl carbons reduced to a single broad envelope. The effect on the ribityl carbons varied according to their proximity to the ring system. The resonances of C-1′ and C-2′ were no longer discernible whereas those of C-3′ and C-4′ were broadened almost to the point of coalescence and that of C-5′ remained moderately sharp, with a width at half-height of approximately 7 Hz. Oxygenation of the illuminated sample regenerated the sharp-line spectrum (Fig. 1*a*). When we recorded ^{31}P spectra of FMN under the same conditions we observed a slight decrease in line width, from 10 to 8 Hz, on oxygenation.

In contrast to the observations at p*D* 10.5, the nmr lines at p*D* 6.5 remained sharp under all conditions, the spectra before and after illumination being identical to that recorded after oxygenation as shown in Figs. 1*b* and *d*. These spectra were recorded after exponentially weighting the free induction decay to enhance the signal to noise ratio ($S_t' = S_t e^{-t/0.16}$, *t* in seconds); thus the slight paramagnetic broadening by O_2 is not obvious.

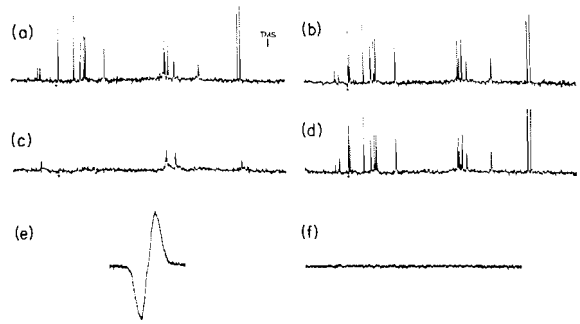

FIG. 1. Proton noise-decoupled ^{13}C nmr spectra (*a*–*d*) and esr spectra (*e* and *f*) of ca. 0.1 *M* FMN solutions in D_2O: Figs. 1*a* and *b*, after dark deoxygenation at p*D* 10.5 and 6.5, respectively; Figs. 1*c* and *d*, after illumination at p*D* 10.5 and 6.5; Figs. 1*e* and *f*, esr spectra of illuminated FMN solutions at p*D* 10.5, before and after oxygenation, respectively. Solutions were buffered with phosphate or borax as required. Spectra at 23.5 kG were averaged over 4000 accumulations of 8192 100-μs data points (spectral width 5 kHz) after a 15-μs (60°) pulse. A delay of 1 s separated the acquisitions. An instrument artifact was removed from the spectra at the positions marked 'X'. Electron spin resonance spectra were recorded at 3380 G, 9.47 GHz, 18 mW, with 100-MHz modulation at 3 G. Sweep parameters were: time 16 min; gain 2×10^4; time constant 1 s.

The esr spectra of a p*D* 10.5 solution of FMN after illumination (Fig. 1*e*) and after illumination followed by oxygenation (Fig. 1*f*) demonstrate the abolition of a paramagnetic species by oxygen corresponding to the sharpening of the ^{13}C nmr spectrum. The esr signal produced by illumination was not measurably diminished after a period of 16 h in the dark when oxygen was excluded from the system. As was the case with the nmr spectra, the esr spectrum of alkaline FMN before illumination was identical to that after oxygenation, i.e., no esr signal was observed. The esr spectrum at p*D* 6.5 (not illustrated), under which conditions the nmr lines remained sharp, consisted of no signal in the dark but showed a transient signal on illumination. In contrast to the persistent esr signal produced on illumination at p*D* 10.5, that at the lower p*D* value was less intense and diminished with time, having a half-life of approximately 20 min, although further illumination regenerated the signal. The signal at p*D* 6.5 also differed in having a line width of approximately 23 G in comparison to approximately 14 G for the alkaline signal. Spectra recorded at concentrations appropriate for ^{13}C nmr study, i.e., 0.1 *M*,

For personal use only.

did not exhibit the line structure reported previously (7) but, in agreement with those earlier observations, more dilute solutions (10^{-3} *M*) produced spectra in which the hyperfine splittings were better resolved (Fig. 2).

The nature of the paramagnetic species was investigated by deoxygenation and illumination of a sample at p*D* 10.5 followed by addition of deoxygenated solutions of various reagents. Table 1 shows the results of these experiments. As substitutes for O_2 in regenerating the sharp-line ^{13}C spectrum, a variety of triplet quenchers, when added after illumination was complete, were not effective but various oxidizing agents were able to eliminate the broadening as had O_2. Although deoxygenated caffeine solutions were not effective in restoring sharpness, FMN solutions which had been made 0.1 *M* in caffeine before deoxygenation required illumination periods more than three times longer than those for caffeine-free FMN solutions for the generation of a comparable paramagnetic interaction among the flavin molecules.

No significant broadening of the caffeine resonances was observed in these flavin solutions, even when the FMN lines were practically obscured (Fig. 3*a*). In a converse experiment the nitroxide TEMPONE was added to neutral FMN solutions in concentrations up to 10^{-2} *M* and the effect on the flavin nmr resonances observed. No significant broadening was found. The esr spectra of illuminated alkaline FMN solutions (0.01 *M*) containing 0.1 *M* caffeine, on the other hand, were characterized by markedly enhanced resolution of the hyperfine structure as well as the necessity for longer illumination to generate an observable concentration of unpaired electron spins. The reduced yield of paramagnetic species on photolysis in the presence of caffeine allows comparison of ^{13}C spectra obtained in the presence of dilute electron spin concentrations produced photochemically with spectra obtained on partial chemical reduction or oxidation, as shown in Fig. 3*b* and *c*. In these experiments neutral solutions of FMN were reduced with $Na_2S_2O_4$ and subsequently reoxidized. The use of flavin solutions at the lower p*H* values eliminates the possibility of species produced by photoreduction contributing to the spectra. When NADH was used as the reducing agent, the results were identical. When lumichrome was substituted for FMN in deoxygenated experi-

[c]Doublet.

ments at p*D* 10.5, no esr signal was observed on illumination, nor did illumination produce broadening of the ^{13}C nmr resonances.

In addition to these experiments concerning the broadening phenomenon, we also wish to report some observations relating to the assignments of the FMN ^{13}C spectrum. The chemical shifts which we have measured for these resonances, are listed in order of increasing shielding in Table 2, along with assignments on the basis of various arguments (see Discussion). The ^{13}C spectrum of FMN deuterated in the 8α-methyl group by the method of Bullock and Jardetzky (2) reveals the lower field methyl resonance (line No. 16) to be diminished and broadened to a marked degree and the spectrum of the aromatic resonances was also altered. Upon deuteration resonance, line No. 3 was observed to be broadened from 3.8 to 4.5 Hz as well as shifted 0.05 ppm to higher field. This increased shielding was unique to that resonance, all other resonances being consistent with their chemical shifts before deuterium exchange. These changes in the ^{13}C spectrum were not observed with samples heated for an equivalent period in H_2O.

The spectrum of 95–97% pure FMN (Sigma, Grade II, various lots) differed from that of 99% pure FMN (Sigma, Grade I, lot 43C-7010) only by the appearance of a weak resonance at 133.06 ppm in the spectrum of the less pure sample and of three small peaks in the sugar region. Otherwise the nmr and esr spectral characteristics of the two preparations were identical.

Discussion

The assignments of the ^{13}C spectrum of FMN given in Table 2 agree in many cases with those of Breitmaier and Voelter (3), which were made by qualitative comparison of the environments of FMN carbon nuclei with those of nuclei in other compounds, and have been confirmed in the cases of C-2 and C-4 by ^{13}C enrichment (4).

Substitution of ^2H for ^1H on C-8α causes a broadening and diminution of that ^{13}C methyl resonance, resulting from coupling to the ^2H nuclei and loss of the nuclear Overhauser effect. In addition to this, however, one may expect to find the shieldings of nearby carbons somewhat altered (8–10) and the effect observed on line No. 3 reflects this. The shift to higher field which accompanies the broadening of this resonance is consistent with those observed for various deuterated aliphatic and aromatic compounds (9) and we conclude that this resonance is that of C-8, rather than of C-4*a* as suggested previously (3).

Fortunately, the complete assignment of the ^{13}C resonances, while desirable, is not essential to a discussion of the broadening phenomenon. Our chief concern in this communication is to understand the broadening of the FMN ^1H resonances noted in earlier reports (1*a* and *b*) and in our work, and of the ^{13}C and ^{31}P resonances reported here. As the ^1H, ^{13}C, and ^{31}P nmr spectra exhibit the same behaviour in this respect, we take it that the effects in all these spectra have the same underlying cause. The fact that the saturated ribityl moiety is less strongly affected than the unsaturated isoalloxazine ring system and that the resonance of the chain-terminating ^{31}P is least affected of all implicates a paramagnetic centre associated specifically with the ring system, and a considerable population of the flavin triplet state, albeit generated by unknown means, has been suggested by Andrews and Fenn (1*a* and *b*). However, the possibility that the species responsible for shortening the nuclear relaxation times may be the flavin semiquinone, discounted in their report, deserves more serious consideration.

It has been reported that the level of illumination has no effect on the broadening phenomenon, but that deoxygenation leads to immediate loss of flavin signals. Our experiments indicate that p*H*, amount of illumination and the presence of oxidizing agents are critically interrelated in the generation and longevity of paramagnetic species, as evidenced by their effects on both the esr and nmr spectra. Therefore, correct interpretation depends on a precise definition of experimental conditions. For example, with samples thoroughly deoxygenated at p*D* 10.5, the slightest exposure to light is sufficient

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to produce a broad-line condition, whereas in samples that have been poorly degassed, ordinary precautions to ensure darkness suffice to produce sharp spectra. This is clearly a titration of residual O_2 by stray photons, corresponding to the induction time for broadening (1*a* and *b*) and the number of induction flashes required in the photobleaching of FMN with traces of O_2 (5*a*). At p*D* 6.5, we find that illumination of an FMN sample does not yield a persistent esr signal but that the signal is relatively weak, decays with a half-life of approximately 20 min, and has a somewhat shorter relaxation time, T_2. Correspondingly, the ^{13}C nmr spectrum at p*D* 6.5 remains sharp under all circumstances, as shown in Fig. 1*b* and *d*.

The observation of a transient esr signal upon illumination of FMN solutions at neutral or near-neutral p*H* is well established and identified with the semiquinone formed under those conditions (5, 7, 11, 12). Our results are in agreement with these. The esr signal which we have observed on illumination at p*D* > 9 is somewhat more intense and of much longer duration however, indicating a more stable species and accounting for the persistent broadening of the nmr lines. It is significant here that different types of semiquinone radical, whose relative populations are p*H* dependent, have been detected in flavoprotein systems (7, 13), and that the form predominant above p*H* 9 has esr characteristics distinct from those of the radical formed at p*H* 6 (13). The deprotonation of N-3 has a p*K* of 8.4 in the semiquinone radical as opposed to approximately 10 in the fully oxidized species, indicating an increased stability of the anionic semiquinone at higher p*H* values. Furthermore, higher relative concentrations of radicals have also been found at elevated p*H* (15). Although we have discussed the p*H* dependence of these effects in terms of the difference between p*D* 6 and 10 to be consistent with other reports (1, 14), it should be pointed out that the broadening effect on the ^{13}C nmr spectrum arises over a much narrower range of p*H* values, little or no broadening being observed at p*D* 8.7 while the full effect is observed at p*D* 9.4 (Fig. 4) which is reasonably consistent with the p*K* of 8.4 noted earlier for the semiquinone ionization, i.e., the increased stability of the radical anion at higher p*H* value.

The circumstances leading to the production of flavin semiquinones have been studied for some time with the conclusion that, in the case of riboflavin and FMN, a triplet state has indeed been found to be populated on illumination, and that this species may proceed through an intramolecular reduction to a semiquinone radical. Subsequent exposure to O_2, light or basic conditions leads to cleavage of the oxidized side chain and a variety of photolysis products (5*a* and *b*, 12). It is reasonable to suppose that flavin adenine dinucleotide (FAD) reacts similarly. Given the duration of the broadening effect and the esr signal in our experiments, up to 16 h at p*D* 10.5, the theory that a triplet state is responsible seems less likely than one postulating a semiquinone radical as the paramagnetic species. We have tested this by adding a variety of quenchers to FMN test solutions both before and after illumination and observing the ^{13}C spectra, and by testing various oxidizing agents in the same way.

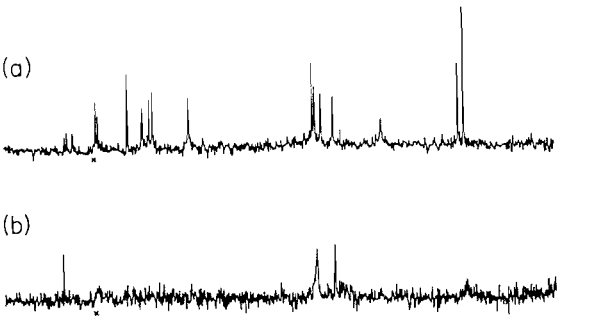

FIG. 4. Proton noise-decoupled ^{13}C nmr spectra of deoxygenated solutions of FMN after illumination at p*D* 8.7 (Fig. 4*a*) and p*D* 9.4 (Fig. 4*b*). Parameters were as described for Fig. 1.

The results of these experiments, Table 1, clearly demonstrate that the species responsible for the broadening of the ^{13}C nmr lines and the generation of the esr signal is removed by reagents of sufficient oxidizing potential but not by common triplet quenchers. The failure of NO_3^- to eliminate the broadening at high p*H* would be explained by a requirement of an oxidation potential of approximately 1 V in this process. We conclude that the species responsible for broadening is the flavin semiquinone and not as suggested previously a long-lived triplet state. It is unlikely that a system of the type

[1] $\text{FMN}^-(\text{triplet}) + \underline{\underline{\text{FMN}}}^-(\text{ground state}) \rightleftharpoons \text{FMN}^-(\text{ground state}) + \underline{\underline{\text{FMN}}}^-(\text{triplet})$

would have a sufficiently long triplet lifetime in the absence of a known energy source to be responsible for the observations. On the other hand, in the absence of other oxidizing or reducing agents, a redox exchange system of the type

[2] $\text{FMNH}^{\cdot} + \underline{\underline{\text{FMN}}}^- \rightleftharpoons \underline{\underline{\text{FMNH}}}^{\cdot} + \text{FMN}^-$

where $\underline{\underline{\text{FMNH}}}^{\cdot}$ is flavin mononucleotide semiquinone,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

could be expected to persist. Although the reduced species initially produced is not in fact $FMN\dot{H}$ but leucodeuterioflavin, $DfnH_2$, redox exchange of this species with FMN (5*a*) followed by subsequent disproportionation of $FMNH_2$ provides a reasonable mechanism for delocalization of the unpaired electron spins throughout the entire FMN population. Thus

$$[3a] \qquad FMN \xrightarrow{h\nu} DfnH_2$$

$$[3b] \qquad DfnH_2^{\cdot} + FMN \rightleftharpoons FMNH_2^{\cdot} + Dfn^{\cdot}$$

$$[3c] \qquad FMNH_2^{\cdot} + FMN \underset{k_d}{\overset{k_a}{\rightleftharpoons}} 2\,FMN\dot{H}^{\cdot}$$

If one considers the parameters which have been determined for the following processes

$$2\,Dfn\dot{H} \xrightarrow{k_f} Dfn + DfnH_2, k_f \simeq 4 \times 10^8\, M^{-1}\, s^{-1} \quad \text{(ref. 5)}$$

and

$$(FMN\dot{H})_2 \rightleftharpoons FMN + FMNH_2, K = 4.5 \times 10^{-4}\, M \quad \text{(ref. 16)}$$

and assumes that the rates for steps 3*a–c* above are of the same order of magnitude an estimate may be made for the two rates in step 3*c*, placing them at approximately $10^5\ M^{-1}\ s^{-1}$ and $10^{13}\ M^{-2}\ s^{-1}$ for the forward and backward steps, respectively. Exchange of the type shown in [2] could be expected to be at least as fast as it does not require collisions between two of the relatively dilute semiquinones. Although these processes would be sufficiently rapid to distribute the unpaired electron spin among a large number of flavin molecules during a nuclear relaxation time, we do not exclude the possibility of an even faster process such as electron exchange which is not accompanied by proton transfer, for example:

$$[4] \qquad FMN\dot{H}^{-} + \underline{FMN}^{-} \rightleftharpoons FMNH + \underline{FMN}^{2-}$$

Although this latter type of process offers a more rapid exchange of electron density, the creation of a dianion and a neutral molecule from the two singly ionized species is unattractive. In either scheme however the central aspect, exchange of paramagnetic electron density among the entire flavin population, remains unaltered.

The fate of the deuterioflavin, whether it remains as such or loses a side-chain fragment, is not central to the broadening phenomenon, although the difference in hydrolysis products as a function of p*H* may be a reflection of the differing natures of the semiquinone radicals at neutral and alkaline p*H* values.

Our finding that lumichrome, which lacks the ribityl side chain, does not exhibit the broadening phenomenon supports the proposition of intramolecular radical formation which may then be followed by redox exchange.

In addition to the redox exchange mechanisms just discussed we have also considered the possibility that a stacking interaction between $FMN\dot{H}$ and FMN could give rise to the observed broadening. It is conceivable that a complex which brought oxidized and half reduced ring systems into close proximity but which did not associate the side chains of the oxidized molecules with the paramagnetic centre could lead to elimination of the signals from the ring system and retention of observable resonances from the aliphatic carbons. The fact that we have not observed significant broadening of the resonances of caffeine in solutions in which the FMN signals have been fully broadened argues against this model, however, and in fact against any model which does not include, on the nmr time scale, some paramagnetic character for all of the molecules affected. Since caffeine is known to form an FMN complex whose dissociation constant, $10^{-2}\ M$ (17) is the same as that of FMN with itself (16) one would expect to observe broadening of its resonances corresponding to that of the oxidized FMN resonances if a stacking interaction were important and might expect to find decreased broadening of the FMN resonances resulting from disruption of any FMN stacking interaction by caffeine. No effect of this type was observed and stacking mechanisms are therefore not considered to be important in the broadening process.

Although the persistent sharpness of the caffeine resonances demonstrates the inefficiency of general intermolecular relaxation enhancement by paramagnetic flavins, the lack of effect on the FMN ^{13}C spectrum of large concentrations, up to $10^{-2}\ M$, of the nitroxide radical TEMPONE indicates the converse, namely that the flavin nuclei are not efficiently relaxed by general paramagnetic species. Thus, flavin semiquinones are not unusually effective as nonspecific relaxation enhancers, nor are diamagnetic flavins particularly susceptible to nonspecific relaxation enhancement and the processes leading to the FMN line broadening must incorporate steps which place unpaired electron spin density on all of the molecules.

The increased illumination time required to produce paramagnetic flavins in the presence of caffeine is consistent with its properties as a quencher of FMN fluorescence (17), thus decreasing the overall yield of semiquinones. Comparably small semiquinone populations may be generated either by addition of small amounts of reducing agent to oxidized FMN or by admittance of traces of oxygen to reduced solutions and spectra obtained under

these conditions have the same characteristics as those of partially photolysed FMN, indicating that the relaxation enhancement depends upon the total number of unpaired spins and, as intermediate spectra are observed, that the unpaired electron density is indeed being distributed throughout the entire flavin system.

Although we do not eliminate the possibility of direct electron exchange among the flavin molecules we feel that the chemical processes described above [3*a*–*c*] which are based on established work in flavin chemistry, and entirely consistent with our results, provide the most probable basis for the observed spectral behaviour of FMN.

The oxidation of haplophytine

PETER YATES, FREDERICK N. MACLACHLAN, AND IAN D. RAE
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 8, 1977

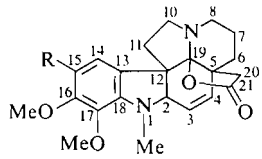
PETER YATES, FREDERICK N. MACLACHLAN, and IAN D. RAE. Can. J. Chem. **56**, 1052 (1978).

Oxidation of haplophytine (**1**) with alkaline potassium permanganate has been shown to give the seco product **16**. This assignment is based on spectroscopic data and comparison of these with spectroscopic data for the analogous seco product **8** formed on similar oxidation of aspidophytine (**3**), an acid cleavage product of haplophytine. The course of these oxidations contrasts with that of the oxidation of haplophytine and aspidophytine with alkaline hydrogen peroxide, which gives **4** and **6**, respectively, without carbon–carbon bond cleavage.

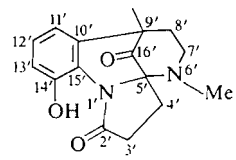
PETER YATES, FREDERICK N. MACLACHLAN et IAN D. RAE. Can. J. Chem. **56**, 1052 (1978).

On a montré que l'oxydation de l'haplophytine (**1**) avec du permanganate de potassium en milieu alcalin conduit au produit séco **16**. Cette attribution est basée sur des données spectroscopiques et sur une comparaison de ces données avec des données spectroscopiques pour le composé séco analogue **8** formé par une oxydation semblable de l'aspidophytine (**3**), un produit de clivage acide de l'haplophytine. Le cours de ces oxydations est en opposition avec celui de l'oxydation de l'haplophytine et de l'aspidophytine par le peroxyde d'hydrogène en milieu alcalin qui conduit respectivement aux composés **4** et **6** sans coupure du lien carbone–carbone.
[Traduit par le journal]

The binuclear alkaloid haplophytine has been shown to have structure **1** (1, 2). During the course

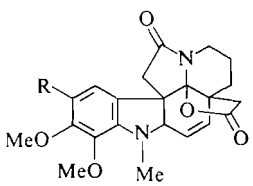


1 R = **2**
3 R = H

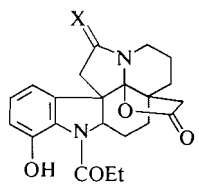


2

of the determination of this structure, the structure of the product formed from **1** on reaction with alkaline hydrogen peroxide was shown to be 10-oxohaplophytine (**4**). Analogous products, **6** and **7**, respectively, were obtained on similar oxidation of aspidophytine (**3**), an acid cleavage product of **1** (1), and of cimicine (**5**), an alkaloid that accompanies **1** in *Haplophyton cimicidum* (Apocynaceae) (3).



4 R = **2**
6 R = H



5 X = H_2

In early work on the chemistry of haplophytine, Snyder and co-workers (4) found that oxidation of haplophytine with alkaline potassium permanganate gives a product different from that formed with alkaline hydrogen peroxide. We discuss here the determination of the structure of the permanganate oxidation product.

Elemental and mass spectrometric analysis of this oxidation product and of its methylation product, formed on treatment with diazomethane, showed that the molecular formula of the former is $C_{37}H_{40}N_4O_8$ and that the latter is a dimethyl derivative, $C_{37}H_{38}N_4O_6(OCH_3)_2$. The formula of haplophytine itself is $C_{37}H_{40}N_4O_7$ and thus the formation of the permanganate product formally involves the addition of an oxygen atom; we have therefore dubbed the oxidation product haplophytine oxide.

Although it was not found possible to isolate a pure product from the acid cleavage of haplophytine oxide, alkaline permanganate oxidation of aspidophytine (**3**), $C_{22}H_{26}N_2O_4$, the acid cleavage product obtained from haplophytine itself, gave a product, albeit amorphous, that was shown to have the molecular formula $C_{22}H_{26}N_2O_5$. On treatment with diazomethane this product, which we refer to as aspidophytine oxide, gave a monomethyl derivative, $C_{22}H_{25}N_2O_4(OCH_3)$. The formation of aspidophytine oxide is clearly related to the formation of haplophytine oxide and the determination of the structure of the latter was initiated by the determination of that of the former.

Ultraviolet (uv), infrared (ir), and ^1H nuclear magnetic resonance (^1Hmr) data for aspidophytine oxide are given in Table 1 together with corresponding data for aspidophytine (**3**). The uv spectrum of aspidophytine oxide differs significantly from that of **3** and suggests that the indoline system of **3** has

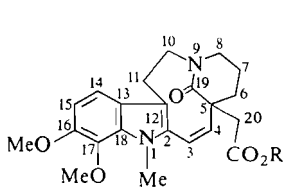
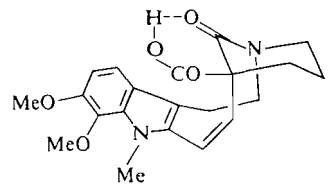
been converted to an indole system (5). The strong, broad band at 3–4.5 μ in its ir spectrum together with the strong band at 5.79 μ show the presence of a carboxylic acid group. The strong ir band at 6.27 μ suggested the presence of a second carbonyl group with its stretching band superimposed on an aromatic band, although the environment of this carbonyl group would have to be unusual to account for the exceptionally long wavelength; the presence of this second carbonyl group was subsequently confirmed by ^{13}C nuclear magnetic resonance (^{13}Cmr) spectroscopy (*vide infra*).

The ^{1}Hmr spectrum of aspidophytine oxide confirmed the presence of a carboxylic acid in that a very broad one-proton singlet is present at δ ~ 12. The two doublets in this spectrum at δ 6.82 and 7.20 (J = 8 Hz) can be assigned to two aromatic protons (cf. the ^{1}Hmr spectrum of **3**), and the two doublets at δ 5.99 and 6.53 (J = 12 Hz) can be interpreted as showing the retention of the C3—C4 ethylenic system of **3**. Unlike the case of **3**, however, the vinylic proton doublets of aspidophytine oxide show no additional splitting. The additional splitting in the spectrum of **3** is attributable to coupling of the C3 and C4 protons with the proton at C2, which gives rise to a one-proton multiplet at δ 3.73. The absence of this additional splitting in the spectrum of aspidophytine oxide and of a signal corresponding to the C2 proton signal of **3** clearly indicates that C2 bears no hydrogen atom in aspidophytine oxide. Retention of the two aromatic methoxyl groups of **3** in aspidophytine oxide is demonstrated by the signals at δ 3.85 and 3.93. Since they correspond to nine protons, these signals must also include the signal corresponding to the *N*-methyl group that is present in **3**. Moreover, in accord with the earlier conclusion that the indoline system of **3** has been converted to an indole system in aspidophytine oxide, the *N*-methyl signal for the latter is at considerably lower field than that for the former (δ 3.15) (6).

These spectroscopic data taken together with the molecular formula and source of aspidophytine oxide lead to the assignment to it of structure **8**. This structure incorporates the features previously deduced to be present but further consideration of some of these in terms of **8** is necessary. It might have been expected that the 2-vinylindole system in **8**



8 R = H
10 R = Me



9

would give rise to an uv spectrum different from that of a simple indole system. However, examination of molecular models shows that the plane of the ethylenic double bond is essentially orthogonal to the plane of the indole ring, as illustrated in **9**, which is considered to be the preferred conformation of **8**. This geometrical relationship accounts for the absence of extended indole conjugation in aspidophytine oxide. Ziegler and co-workers (7) have previously advanced a similar interpretation of their observation that the uv spectrum of 3,4-dehydroquebrachamine (**11**) shows the presence of a typical 2,3-dialkylindole chromophore rather than an extended indole chromophore. The unusually long wavelength of the lactam carbonyl-stretching band in the ir spectrum of **8** can be interpreted as being due to strong hydrogen bonding with the carboxylic acid hydrogen. Such hydrogen bonding can also account

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

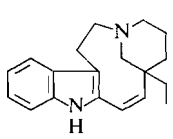
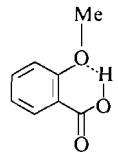
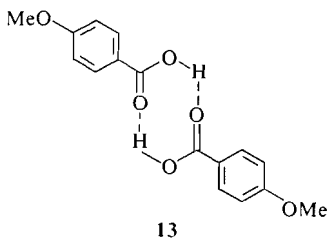
for the fact that the carbonyl-stretching band of the carboxylic acid group appears at 5.79 μ, a wavelength shorter than normal for a carboxylic acid, if it is assumed that the intramolecular hydrogen bonding with the lactam carbonyl group disrupts the customary intermolecularly hydrogen-bonded dimeric form of the carboxylic acid. An analogous effect has been postulated (8) to account for the observation that the carbonyl-stretching band of *o*-methoxybenzoic acid (**12**) occurs at 0.12 μ to shorter wavelength than that of *p*-methoxybenzoic acid (**13**).[1]



11



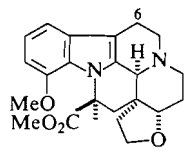
12



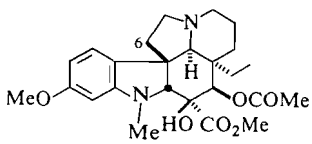
13

This interpretation of the ir spectrum of **8** is in accord with the ir spectrum of the monomethyl derivative of **8**, formed with diazomethane and now assigned structure **10**. The latter spectrum shows bands at 5.79 and 6.15 μ; the position of the lower wavelength band is normal for a carboxylic ester whereas the lactam band, in the absence of hydrogen bonding, appears at considerably shorter wavelength than in the case of **8**. As expected **10** shows in its ^{1}Hmr spectrum four three-proton signals in the region δ 3.7–3.9. An interesting effect of methylation is to bring about the elision of the two vinyl proton signals in the ^{1}Hmr spectrum of **10**, where they appear as a slightly broadened singlet ($w_{\frac{1}{2}}$ = 3 Hz) at δ 6.33. This change with respect to **8** could result from changes brought about in the relative shielding of the vinylic protons when the acetic acid side chain in **8** is freed from its fixed orientation upon removal of hydrogen bonding to the lactam carbonyl group. A one-proton multiplet that appears in the ^{1}Hmr spectra of both **8** and **10** cannot be assigned with certainty, but must be associated with one of the C10 or C11 hydrogen atoms that is deshielded by being held in the plane of the amide or indole systems, respectively.

The ^{13}Cmr spectrum of aspidophytine oxide and its relationship to that of aspidophytine (Table 2) corroborates the structural assignment **8**. Two signals that are attributable to carbonyl carbons are observed at δ 171 and 177 and can be assigned to the lactam and carboxylic acid carbonyl carbons, respectively. Ten signals in the δ 100–150 region, two more than in the case of **3**, can be assigned to the eight indole and two vinyl carbons. It may be noted the signals assigned to the benzene carbons of the indole system appear at higher field than do the corresponding signals of **3**. This implies increased electron density and is in concordance with the electron-rich indole nucleus. It may be noted that, due to the orthogonality of the ethylenic double bond and the indole ring, the latter acts only inductively as an electron-withdrawing group and shifts one of the vinyl carbon signals to significantly lower field than the C3 and C4 signals in the spectrum of **3**. In the region δ < 100 no signal corresponding to that of C2 in **3** (δ 71.8 (d)) is present in the spectrum of **8**. The singlet at δ 47.1 in the spectrum of **8** can be assigned to C5; it is shifted by ~5 ppm relative to the signal assigned to C5 in the spectrum of **3**, an effect attributable to replacement of the sp^3 carbon at C19 in **3** by a carbonyl carbon in **8**. All but one of the remaining high field signals in the spectrum of **8** are analogous to those in the spectrum of **3**. An egregious exception is the signal at δ 19.4 assigned to C11; this carbon in **3** is considered to give rise to a signal at δ–35. Such a large chemical shift difference between a methylene carbon attached to the C3 position of an indole vs. an indoline system has precedent. The signal for the C6 carbon in cuanzine (**14**) appears at δ 17.4 (10) whereas that for the C6 carbon in vindoline (**15**) occurs at δ 43.9 (11).[2]



14



15

With structure **8** established for aspidophytine oxide, it was now possible to assign structure **16** to haplophytine oxide, in which the aspidophytine moiety has undergone a transformation analogous to that in the permanganate oxidation of aspidophytine itself, while the other moiety, the canthiphytine moiety, remains unchanged.

[1]Compare with ref. 9.

[2]It should be noted that C11 and C6 in the indoles **8** and **14**, respectively, both have fewer β substituents than the corresponding carbons of the indoline system **3** and **15**, respectively.

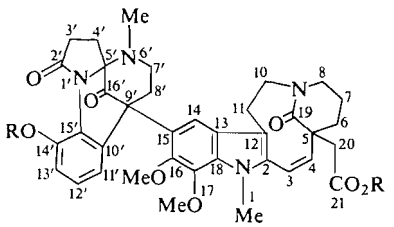
[a]The multiplicities of these signals could only be defined as either triplet or singlet.
[b]The C6 and C11 signals of **3** could not be individually assigned.
[c]Superimposed signals.
[d]The C17 and C18 signals of **3** could not be individually assigned.

This assignment is based on a comparison of the spectra of haplophytine oxide (Tables 3 and 4) with those of aspidophytine oxide and of haplophytine. The uv spectrum of haplophytine oxide again indicates the presence of an indole system; furthermore, the intensity differences between the spectra of the



16 R = H
17 R = Me

oxides correspond to those between the spectra of haplophytine and aspidophytine themselves. The ir spectrum of haplophytine oxide shows bands that correspond to those in the spectrum of aspidophytine oxide and in addition bands at 5.71 and 6.03 μ that are similar in position to bands previously assigned to the ketone and lactam carbonyl groups, respectively, of the canthiphytine moiety of haplophytine. This relationship is further evidenced in the ir spectrum of the dimethyl derivative of haplophytine oxide, formed with diazomethane and now assigned structure **17**. This spectrum shows bands at 5.73, 5.86, and 6.1 (br) μ and no hydroxyl band. The band at 6.1 μ can be assigned to the lactam carbonyl of the aspidophytine moiety, shifted to lower wavelength as in the case of **10** as a result of removal of hydrogen bonding on esterification of the carboxylic acid group. The ester carbonyl is not visible as a distinct maximum, but the shallowness of the trough between the 5.73 and 5.86 μ bands is indicative of its presence. The 5.73 and 5.86 μ bands correspond to the ketone and lactam carbonyl groups, respectively, of the canthiphytine moiety with the latter shifted to lower wavelength relative to the lactam band in **16** as a result of removal of hydrogen bonding an etherification of the phenolic hydroxyl group (cf. the lactam carbonyl band for haplophytine methyl ether: 5.88 μ).

The relationship of the ^{1}Hmr spectrum of haplophytine oxide to that of aspidophytine oxide (**8**) is also indicative of the conversion of the aspidophytine moiety of haplophytine to a moiety corresponding to **8** with the retention of the canthiphytine moiety unchanged. A notable exception is the absence of a signal assignable to a carboxylic acid proton. This is attributed to further broadening of the already very broad signal of the carboxylic proton of **8**. The presence of the carboxylic acid group is not in doubt, both by virtue of the presence of a broad strong band in the ir spectrum of haplophytine oxide at 2.8–4.3 μ and of the ^{1}Hmr spectrum of its dimethyl derivative which shows that methylation leads to esterification of the carboxylic group in addition to etherification of the phenolic hydroxyl group in the canthiphytine moiety.

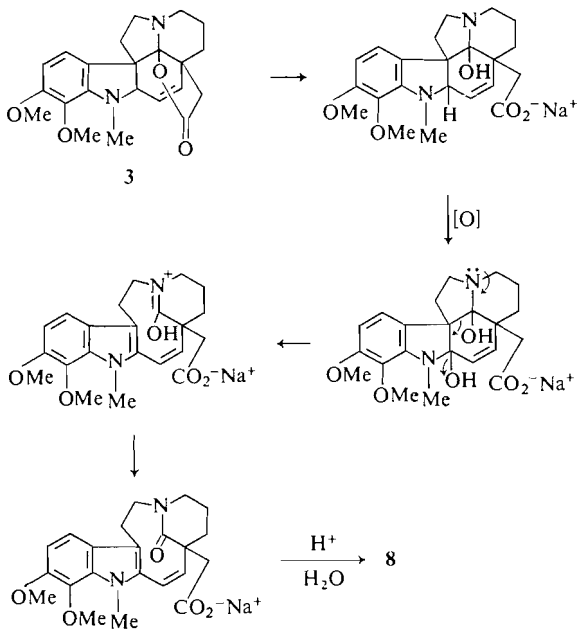
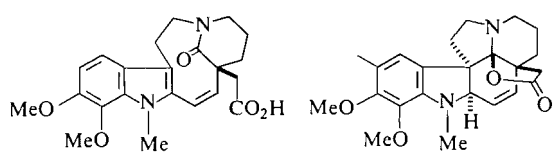
Further, the ^{13}Cmr spectrum of haplophytine oxide and its relationship to the ^{13}Cmr spectra of haplophytine (Table 4) and of aspidophytine oxide (Table 2) can be interpreted in terms of structure **16** for haplophytine oxide.

It remains to consider the mechanism of formation and stereochemistry of aspidophytine and haplophytine oxides. We proposed the route depicted in Scheme 1, which is related to that proposed earlier



SCHEME 1

by Biemann and Spiteller (12) for the conversion of deacetylaspidospermine to 17-methoxyquebrachamine. Scheme 1 implies that the stereochemistry of aspidophytine oxide and of the corresponding moiety of haplophytine oxide is that in **18**, since the chiral centre at C5 would retain the same absolute configuration as in aspidophytine and haplophytine (**19**) (1, 13).



18 **19**

Experimental

*Oxidation of Haplophytine with Potassium Permanganate: Formation of Haplophytine Oxide (19-Oxosecohaplophytine; **16**)*

A stirred solution of haplophytine (100 mg, 0.15 mmol) in aqueous 1% sodium hydroxide (7.5 ml) was cooled in an ice bath. A solution of potassium permanganate (45 mg, 0.28 mmol) in water (15 ml) was added dropwise during 30 min. After an additional 30 min the mixture was saturated with sulfur dioxide, the white precipitate (63 mg) was separated by filtration, and the filtrate was extracted with ether (3 × 15 ml). The extract was dried (Na_2SO_4) and evaporated leaving a white solid foam (10 mg). The combined solids were crystallized from anhydrous ethanol to give microcrystalline **16** (60 mg, 60%): mp 309–318°C (dec.) (sealed tube) (lit. (4) mp 304–306°C (dec.)); the spectra of this compound are listed in Tables 3 and 4; *m/e* 668. *Anal.* calcd. for $C_{37}H_{40}N_4O_8 \cdot C_2H_5OH$: C 65.53, H 6.49, N 7.84; found: C 65.71, H 6.35, N 7.89.

O,O-*Dimethylhaplophytine Oxide (*O,O-*Dimethyl-19-oxosecohaplophytine*; ***17)***

A solution of haplophytine oxide (100 mg) in methanol (20 ml) was cooled in an ice bath. An excess of ethereal diazomethane was added. After 16 h at room temperature the solvents were removed and the residue was crystallized from ethanol to give colorless blades: mp 315–320°C (dec.) (sealed tube); λ_{max}(CHCl$_3$): 5.73, 5.86, 6.1 (br) μ; ^{1}Hmr (CDCl$_3$) δ: 2.52 (s, 3H), 3.08 (s, 3H), 3.70 (s, 3H), 3.82 (s, 3H) 3.85 (s, 3H), 3.97 (s, 3H), 4.2–4.6 (m, 1H), 6.0–6.4 (m, 3H), 6.65–7.3 (m, 3H); *m/e* 696. *Anal.* calcd. for $C_{39}H_{44}N_4O_8$: C 67.22, H 6.37, N 8.04; found: C 67.10, H 6.46, N 7.98.

*Oxidation of Aspidophytine with Potassium Permanganate: Formation of Aspidophytine Oxide (19-Oxosecoaspidophytine; **8**)*

A stirred solution of aspidophytine (222 mg, 0.58 mmol) in aqueous 0.1 *N* sodium hydroxide (34 ml) was cooled in an ice bath. A solution of potassium permanganate (111 mg, 0.70 mmol) in water (12 ml) was added. After 20 min the mixture was saturated with sulfur dioxide, the cream-colored precipitate (121 mg) was separated by filtration, and the filtrate was extracted with dichloromethane (4 × 20 ml). The extract was dried (Na_2SO_4) and evaporated leaving a cream-colored solid foam (47 mg). Neither the precipitate nor the foam could be crystallized (total 168 mg, 73%): molecular distillation gave a glass with unchanged ir and ^{1}Hmr spectra; the spectra of **8** are listed in Tables 1 and 2; *m/e* 398.1866 (M^+ 398.1841).

O-*Methylaspidophytine Oxide (*O-*Methyl-19-oxosecoaspidophytine*; ***10)***

A solution of aspidophytine oxide (50 mg) in methanol (5 ml) was cooled in an ice bath. An excess of ethereal diazomethane was added. After 16 h at room temperature the solvents were evaporated leaving **10** as an oil that could not be crystallized; molecular distillation gave an oil with unchanged ir and ^{1}Hmr spectra: λ_{max}(CHCl$_3$): 5.79, 6.15 (br) μ; ^{1}Hmr (CDCl$_3$) δ: 3.70 (s, 3H), 3.85 (s, 3H), 3.92 (s, 3H), 3.94 (s, 3H), 4.15–4.65 (m, 1H), 6.33 (br s, $w_{1/2}$ = 3 Hz, 2H), 6.78 (d, J = 8 Hz, 1H), 7.18 (d, J = 8 Hz, 1H); *m/e* 412 (100).

Chemistry of chelocardin. IV.[1] *C*(2)-acylation and alkylation of 2-deacetylchelocardin

DANIEL T. W. CHU, EDITH BERNSTEIN, AND STUART N. HUCKIN
Abbott Laboratories, Limited, P.O. Box 6150, Montreal, P.Q., Canada H3C 3K6

Received November 30, 1977

DANIEL T. W. CHU, EDITH BERNSTEIN, and STUART N. HUCKIN. Can. J. Chem. **56**, 1059 (1978).

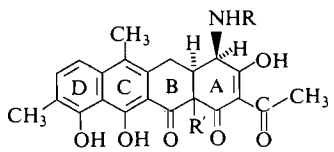
The properties of the 1,3-cyclohexanedione system in 2-deacetylchelocardin (**2**) and *N*-carbobenzoxy-2-deacetylchelocardin (**3**) are found to be significantly different from those of ordinary 1,3-cyclohexanediones. Acylation and alkylation of (**2**) or (**3**) generally gives *O*-acylation or *O*-alkylation products. However, reaction of *N*-carbobenzoxy-2-deacetylchelocardin (**3**) with methyl orthoformate or *N*,*N*-dimethylformamide dimethyl acetal leads exclusively to *C*-acylation products.

DANIEL T. W. CHU, EDITH BERNSTEIN et STUART N. HUCKIN. Can. J. Chem. **56**, 1059 (1978).

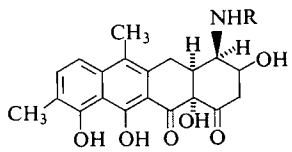
On a trouvé que les propriétés du système cyclohexanedione-1,3 de la déacétyl-2 chélocardine (**2**) et *N*-carbobenzoxydéacétyl-2 chélocardine (**3**) sont assez différentes de celles des cyclohexanediones-1,3 ordinaires. L'acylation et alkylation de **2** ou **3** conduit généralement à des produits de *O*-acylation ou *O*-alkylation. Toutefois la réaction de la *N*-carbobenzoxydéacétyl-2 chélocardine (**3**) avec l'orthoformiate de méthyle ou le diméthylacétal de la *N*,*N*-diméthylformamide conduit uniquement à des produits de *C*-acylation.

[Traduit par le journal]

Chelocardin (**1**) is not only structurally similar to the tetracycline antibiotics but also appears to possess an identical antibacterial mode of action. Both appear to inhibit protein synthesis at the ribosomal level, with the chelation of magnesium being implicated in the mechanism of inhibition (1, 2).



1 R = H R′ = α-OH
4 R = $CO_2CH_2C_6H_5$ R′ = α-OH
5 R = $CO_2CH_2C_6H_5$ R′ = H



2 R = H
3 R = $CO_2CH_2C_6H_5$

A proton nuclear magnetic resonance study of the site of metal binding in tetracycline seemed to indicate that ring A is the binding site (3). Hence, the presence of the tricarbonyl system seems essential for antibacterial activity.

Partial confirmation of this hypothesis was provided by the lack of antibacterial activity of 2-deacetylchelocardin (**2**), which is produced by the deacylation of chelocardin under ketalization conditions and subsequent hydrolysis of the intermediate diketal (4). Initial attempts to reacylate **2** were not successful (4). We now wish to report the results of an extensive study directed towards the reacylation of **2** at C(2), the purpose of which was the generation of analogues of chelocardin bearing different acyl groups on C(2).

Discussion

Upon reaction with acyl halides or anhydrides, 2-deacetylchelocardin (**2**) undergoes initial substitution at nitrogen (4). To facilitate regeneration of the amine (as well as to minimize epimerization of this functionality) **2** was converted to its *N*-carbobenzoxy derivative **3** which was employed for most of this investigation. However, *N*-carbobenzoxy-2-deacetylchelocardin (**3**) gave only *O*-substitution when treated with acyl halides or anhydrides under a wide variety of conditions, in an identical manner to the reaction of 2-deacetylchelocardin.

The strong chelating powers of chelocardin precluded the use of Lewis acid catalysts as the recovery of the organic portion from chelocardin metal complex is very difficult and frequently impossible.

The ring A β-diketone system of **2** appears to be much modified by the presence of the 12a-hydroxyl group, as other six-membered ring β-diketone compounds, such as dimedone and cyclohexane-1,3-dione, may be acylated at the α position (5).[2]

[1]For Part III, see ref. 16.

[2]It was assumed that conversion of the amino group to either an amide or urethane would render it less anchimeric.

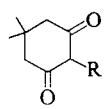
Accordingly attempts were made to remove or block this hydroxyl group. The 12a-hydroxyl group can be reduced in *N*-carbobenzoxychelocardin (**4**) (6) but attempts to remove the 2-acetyl group from *N*-carbobenzoxy-12a-deoxychelocardin (**5**) led only to extensive degradation and attempts to reduce the 12a-hydroxyl group of *N*-carbobenzoxy-2-deacetylchelocardin (**3**) failed. Blockade of the 12a-hydroxyl group was only achieved by further reaction of 2-deacetylchelocardin (**2**) with benzyl chloroformate to give the *N,O*-12a-dicarbobenzoxy-2-deacetylchelocardin in very low yield, accompanied by substantial amounts of polysubstitution products: a process not amenable to large scale preparation. Accordingly, our efforts were directed to other reactions of *N*-carbobenzoxy-2-deacetylchelocardin (**3**) which might give carbonyl substituents at C(2).

One of the analogues which we greatly desired to synthesize was 2-carboxamido-2-deacetylchelocardin which would resemble the tetracycline structure very closely. It has been known for a considerable time that the β-dicarbonyl compounds react with organic isocyanates to give *N*-substituted 2-carboxamido-1,3-diketones (7). For instance, dimedone (**6**) reacts with acetyl isocyanate at room temperature in 1 h to give imide **7** (8).

However, *N*-carbobenzoxy-2-deacetylchelocardin (**3**) did not react with methyl, isopropyl, phenyl, or



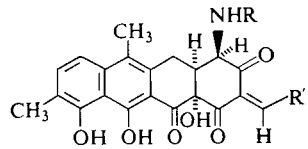
6 R = H

7 R = —C(=O)—NHCOCH$_3$

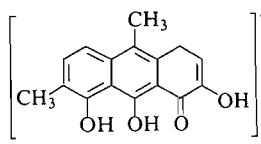
chlorosulfonyl isocyanates at room temperature. At elevated temperatures it gave only intractable mixtures from which small quantities of polymethane derivatives could be isolated. The procedure of Muxfeldt *et al.* (9) for direct carboxamidation using potassium cyanate was also attempted but again only starting material was recovered.

It has long been known that β-diketones undergo aldol condensation with aldehydes to give a variety of products. The reaction of dimedone with aldehydes to give the 2:1 dimedone adducts is a commonly used derivatization procedure (10). A more recent investigation of the reaction between dimedone and aldehydes (11) has shown that it is possible to produce a dehydrated 1:1 adduct by employing the sodium salt of the dimedone.

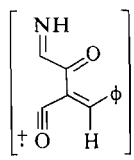
Accordingly attempts were made to condense *N*-carbobenzoxy-2-deacetylchelocardin with aldehydes in an aldol manner and it was found that **3** underwent smooth reaction with benzaldehyde merely by refluxing in benzene for 16 h. The structure of the product was shown to be 2-benzylidene-*N*-carbobenzoxy-2-deacetylchelocardin (**8***a*) primarily by its mass spectral behaviour.



8*a* R = $CO_2CH_2C_6H_5$ R′ = —ϕ
8*b* R = H·HBr R′ = —ϕ
8*c* R = $CO_2CH_2C_6H_5$ R′ = —COϕ
8*d* R = H·HBr R′ = —COϕ



9



10

Chelocardin (**1**) shows a mass spectral fragmentation pattern analogous to that of the tetracyclines. The most significant fragment ion **9** occurs at *m/e* 270 (12). The aldol product from *N*-carbobenzoxy-2-deacetylchelocardin and benzaldehyde also shows a strong fragment ion at *m/e* 270 implying that substitution had not occurred in the B, C, or D rings. The presence of a fragment at *m/e* 186 which can be assigned to the deprotected residual fragment **10** further established the structure as **8***a*.

Compound **8***a* and its deprotected derivative **8***b* (formed upon treatment of **8***a* with hydrogen bromide in glacial acetic acid) were essentially devoid of antibacterial activity. This further confirmed our postulate of the necessity of the tricarbonyl system for antibacterial activity.

Conversion of the exocyclic double bond to a carbonyl functionality was precluded by the extreme sensitivity of chelocardin to oxidation and the previously mentioned inability to use transition metal containing reagents. A vinylogous tricarbonyl containing analogue **8***c* was generated by an aldol condensation of phenylglyoxal with **3** but neither **8***c* nor the free amine from **8***d* showed any antibacterial activity.

The success of the aldol reaction, in that condensation occurred at C(2), encouraged us to continue the

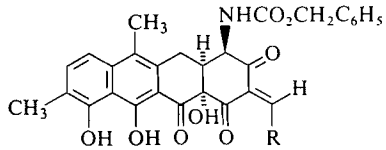
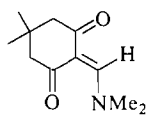
For personal use only.

search for a method of reintroducing an acyl group. It is known that orthoformate esters are effective formylating agents. For example, dimedone may be converted cleanly to its 2-formyl derivative by reaction with ethyl orthoformate in acetic anhydride (13). Reaction of *N*-carbobenzoxy-2-deacetylchelocardin (**3**) under similar conditions gave only enol acetate derivatives. However, treatment of *N*-carbobenzoxy-2-deacetylchelocardin (**3**) with methyl orthoformate in the presence of *p*-toluenesulfonic acid in benzene under carefully controlled conditions (see Experimental) produced a new product which was subsequently shown to be **11**.



11 R = OH

13 R = $N(CH_3)_2$



12

The structure of the product was established by elemental analysis and by nmr spectroscopy; its proton spectra showed a new resonance at δ 9.62 ppm and lacked the signal at δ 3.46 ppm assigned to C(2)-H. Its ^{13}C nmr spectrum had a new resonance at δ 186.7 ppm which appeared as a doublet in an off-resonance single frequency decoupling experiment. The spectral data are consistent only with reaction at C(2) particularly the ^{13}C nmr showing no significant shifts for any carbon resonance except those in the A ring. The biological activity of **11** was also consistent with reaction at C(2) in that like *N*-carbobenzoxychelocardin it showed antibacterial activity towards Gram positive bacteria in vitro. However, attempts to cleave the carbobenzoxy group of **11** to produce the unprotected formyl analogue of chelocardin gave only material that appeared to be polymeric, presumably arising from intermolecular condensations of the C(4)-amino group and the aldehyde. This condensation occurs with chelocardin itself but stops at the dimer stage forming isochelocardin.[1] With the more reactive formyl group this reaction would be expected to take place even more readily.

Attempts to generalize the reaction of ortho esters with deacetylchelocardin were unsuccessful. Reaction with either orthoacetic or orthobenzoic esters yielded only enol ethers of 2-deacetylchelocardin, under a wide range of experimental conditions. Even with dimedone, triethyl orthoacetate failed to yield the expected 2-acetyldimedone. Accordingly, a more reactive derivative of ortho esters was sought. Amide acetals fit this category very well, being known to undergo acylation reactions very easily (14), and *N*,*N*-dimethylformamide dimethyl acetal has been reported to react completely with dimedone in only 1 min in refluxing benzene (15).

Treatment of *N*-carbobenzoxy-2-deacetylchelocardin with *N*,*N*-dimethylformamide dimethyl acetal gave the formyl enamine (**13**). The nmr spectrum possesses two additional singlets at δ 3.07 and 3.32 corresponding to the two *N*-methyl groups. The presence of a new resonance singlet for the C(2a) olefinic proton at δ 8.10 together with the loss of signal at δ 3.46 assigned to C(2)-H further confirmed the structure.

As in the case of ortho esters, attempts to generalize the reaction of amide acetals with deacetylchelocardin failed. Enol ether formation was the major complication when amide acetals other than formamide acetal were used.

In summary, we have been able to acylate deacetylchelocardin at the C(2) position with limited success by the use of an ortho ester and an amide acetal. The presence of the 12a-hydroxyl and 4-amino groups in deacetylchelocardin markedly alters the general behaviour of the β-diketone system.

Experimental

The ir spectra were recorded on a Perkin-Elmer model 710A infrared spectrophotometer. The nmr spectra were recorded on Varian Associates A-60 and HA-100 spectrometers in deuterated solvents; resonance positions are given on the δ scale (ppm) relative to internal tetramethylsilane. The nmr peaks were designated as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; b, broad. The high resolution mass spectra were determined on Associated Electrical Industries MS-902 Double Focussing mass spectrometer and were processed on an IBM 1800 computer. The ^{13}C nmr spectra were recorded on a Varian Associates XL-100-15/TT-100 spectrometer system in DMSO; resonance positions are given in ppm relative to internal tetramethylsilane. Parameters used were pulse width (30°) 3.5 μs, pulse delay 0.5–1.0 s and sweep width 6K and 8K data table.

Since the ir absorption spectra of the various derivatives reported here have a β-hydroxy- or β-amino-α,β-unsaturated carbonyl function which would have similar absorption to the β-diketone system, very little change in the carbonyl absorption region (1580–1680 cm^{-1}) was observed. However, the change in relative intensity of the carbonyl absorptions correlated with the structural changes. Thus, only the relevant difference in absorption bands will be mentioned.

*2-Benzylidene-*N*-carbobenzoxy-2-deacetylchelocardin (**8**a)*

N-Carbobenzoxy-2-deacetylchelocardin (**3**, 110 mg, 0.22 mmol) was dissolved in benzene (50 ml). After the addition of

benzaldehyde (400 mg, 3.7 mmol), the mixture was refluxed, under a nitrogen atmosphere, for 24 h with vigorous stirring and azeotropic removal of water. Evaporation to 10 ml and filtration gave a residue which after drying yielded 125 mg (97%) of compound **8***a*; ^{1}Hmr ($CDCl_3$) δ: 2.20 (bm, 6H, C(6)-CH_3, C(9)-CH_3), 2.90 (bm, 3H, C(4a)-*H*, C(5)-CH_2), 4.91 (bm, 4H, O—C$H_2C_6H_5$, C(12a)-O*H*, N*H*), 7.23 (bm, 13H, 2C$_6H_5$, C(7)-*H*, C(8)-H, C(2′)-*H*), 9.81 (m, 1H, C(10)-O*H*), and 14.62 (m, 1H, C(11)-O*H*); ms (*m/e*): 591, 503, 399, 270, 255, 227, 186, 108, 91. *Mol. wt.* calcd. for $C_{35}H_{29}NO_8$: 591.1893; found (high resolution mass spectrometry): 591.1867.

*2-Phenylglyoxilidene-*N*-carbobenzoxy-2-deacetylchelocardin (8c)*

N-Carbobenzoxy-2-deacetylchelocardin (**3**, 100 mg, 0.2 mmol) and phenylglyoxal monohydrate (110 mg, 0.72 mmol) were dissolved in hot benzene (40 ml). The reaction mixture was refluxed under a nitrogen atmosphere for 2 h with vigorous stirring and azeotropic removal of water. After evaporation to dryness, ether (8 ml) was added, giving a light yellow solid. Filtration gave a residue which after drying yielded 94 mg (76%) of compound (**8***c*), mp 210–215°C; ^{1}Hmr ($CDCl_3$) δ: 2.23 (d, 3H, C(6)-CH_3), 2.41 (d, 3H, C(9)-CH_3), 3.10 (bm 3H, C(4a)-H; C(5)-CH_2), 4.40 (bd, 1H, N*H*), 5.0 (bm, 3H, OCH_2—C$_6H_5$, C(12a)-O*H*), 5.68 (m, 1H, C(2′)-*H*), 5.92 (m, 1H, C(4)-*H*), 7.21 (m, 12H, 2C$_6H_5$, C(7)-*H*, C(8)-*H*), 9.61 (m, 1H, C(10)-O*H*), 12.8 (s, ½H, C(11)-O*H*), 14.7 (s, ½H, C(11)-O*H*). Mass spectrum (*m/e*): 619, 502, 394, 270, 255, 227, 108, 91. *Mol. wt.* calcd. for $C_{36}H_{29}NO_9$: 619.1843; found (high resolution mass spectrometry): 619.1846.

*2-Formyl-*N*-carbobenzoxy-2-deacetylchelocardin (11)*

p-Toluenesulfonic acid monohydrate (20 mg, 0.1 mmol) was added to a solution of *N*-carbobenzoxy-2-deacetylchelocardin (**3**, 100 mg, 0.2 mmol) and trimethylorthoformate (127 mg, 1.2 mmol) in benzene (5 ml). The reaction mixture was heated at 90°C for 5 h during which the methanol was allowed to distill from the reaction flask and was trapped by absorption on molecular sieves. After evaporation to dryness, the residue was dissolved in ethyl acetate (1.2 ml). Ether (4 ml) was added yielding a dark orange solid; mp 210–215°C (dec.), 72 mg (68%). ^{13}C nmr showed the presence of a new carbonyl carbon resonance at δ 182.7 ppm which appeared as a doublet in an ORSFD experiment. Mass spectrum possesses the correct molecular ion at *m/e* 531. ^{1}Hmr shows the appearance of a new resonance at δ 9.62 with the disappearance of resonance at δ 3.46 corresponding to the C(2)-H protons. All the other signals are consistent with the assigned structure. *Anal.* calcd. for $C_{29}H_{25}NO_9$: C 66.51, H 4.74, N 2.63, O 27.09; found: C 65.21, H 4.79, N 2.75, O 27.23.

*2-Dimethylaminomethylene-*N*-carbobenzoxy-2-deacetylchelocardin (13)*

N,N-Dimethylformamide dimethyl acetal (72 mg, 0.6 mmol) was added to a refluxing solution of *N*-carbobenzoxy-2-deacetylchelocardin (100 mg, 0.2 mmol) in benzene (15 ml). After 3 min, the reaction was cooled by ice-bath and the product was precipitated with hexane. Filtration gave a residue which after drying yielded 80 mg (73%) of compound **13**; mp 140–159°C (dec.); ^{1}Hmr ($CDCl_3$) δ: 2.20 (s, 3H, C$_6$-CH_3), 2.65 (s, 3H, C(9)-CH_3), 2.85 (m, 3H, C(4a)-*H*, C(5)-CH_2), 3.07 (s, 3H, N-CH_3), 3.32 (s, 3H, N-CH_3), 5.20 (m, 3H, OC$H_2C_6H_5$, C(12a)-O*H*), 6.02 (m, 2H, C(4)-*H*, N*H*), 7.35 (m, 8H, C$_6H_5$, C(7)-*H*, C(8)-*H*, C(10)-O*H*), 8.10 (s, 1H, C(2)-*H*). *Mol. wt.* calcd. for $C_{35}H_{29}NO_8$: 558.2002; found (high resolution mass spectrometry): 558.2009.

Nitration of 1-chloro-2,3-dimethylbenzene in acetic anhydride. Formation and rearomatization of adducts[1]

ALFRED FISCHER AND COLIN CAMPBELL GREIG
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received November 2, 1977

ALFRED FISCHER and COLIN CAMPBELL GREIG. Can. J. Chem. **56**, 1063 (1978).

Nitration of 1-chloro-2,3-dimethylbenzene in acetic anhydride gives the *cis* and *trans* isomers of 3-chloro-4,5-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate (29%) and 1-chloro-2,3-dimethyl-4-nitro- (46%), -5-nitro- (5%), and -6-nitrobenzene (20%). In formic acid and acidified methanol, exchange of acetate for formate and methoxyl, respectively, occurs and the diastereoisomers of 3-chloro-4,5-dimethyl-4-nitrocyclohexa-2,5-dienyl formate and methyl ether, respectively, are formed. Rearomatization of each isomer of 3-chloro-4,5-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate in acetic acid results in initial isomerization to form the pair of diastereoisomers and subsequent elimination of nitrous acid to form 3-chloro-4,5-dimethylphenyl acetate. In 25% trifluoroacetic acid in deuteriochloroform elimination of acetic acid and migration of the nitro group to form 1-chloro-2,3-dimethyl-4-nitro-benzene and a lesser amount of its 6-nitro isomer is the dominant reaction. In the presence of mesitylene the formation of the nitro derivatives is suppressed and 3′-chloro-2,4,4′,5′,6-pentamethylbiphenyl is obtained. It is proposed that cyclohexadienyl cations are significant intermediates in all of the reactions. Pyrolysis of the adducts gives 1-chloro-2,3-dimethylbenzene as the major product.

ALFRED FISCHER et COLIN CAMPBELL GREIG. Can. J. Chem. **56**, 1063 (1978).

La nitration du chloro-1 diméthyl-2,3 benzène dans l'anhydride acétique conduit aux isomères *cis* et *trans* de l'acétate du chloro-3 diméthyl-4,5 nitro-4 cyclohexadiène-2,5 yle (29%) et aux chloro-1 diméthyl-2,3 nitro-4 (46%), nitro-5 (5%) et nitro-6 benzènes (20%). Dans l'acide formique et le méthanol acidulé, il se produit respectivement des échanges du groupe acétate pour des groupes formiates et méthoxyles et il y a formation des diastéréoisomères des formiates et les éthers de méthyle du chloro-3 diméthyl-4,5 nitro-4 cyclohexadiène-2,5 yle. Une réaromatisation de chaque isomère de l'acétate du chloro-3 diméthyl-4,5 nitro-4 cyclohexadiène-2,5 yle dans l'acide acétique conduit à une isomérisation initiale avec formation de la paire de diastéréoisomères et une élimination subséquente de l'acide nitreux pour conduire à l'acétate du chloro-3 diméthyl-4,5 phényle. Dans de l'acide trifluoroacétique à 25% dans le deutériochloroforme, l'élimination de l'acide acétique et la migration du groupe nitro pour former le chloro-1 diméthyl-2,3 nitro-4 benzène et à des niveaux moindres, de son isomère nitro-6, correspond à la réaction principale. En présence de mésitylène, on supprime la formation des dérivés nitrés et on obtient le chloro-3′ pentaméthyl-2,4,4′,5′,6 biphényle. On suggère que les cations cyclohexadiényles sont des intermédiaires importants dans toutes les réactions. La pyrolyse des adduits conduit au chloro-1 diméthyl-2,3 benzène comme produit principal.

[Traduit par le journal]

Introduction

The importance of *ipso* attack in electrophilic nitration is now widely recognised (2–7). For nitration in acetic anhydride addition of the nitronium ion at an *ipso* position results in the eventual formation of nitronium acetate adducts (8). Most commonly a pair of diastereoisomeric 1,4 adducts is formed (9), although in two instances 1,2 adducts have also been obtained (10, 11). The present study of 1-chloro-2,3-dimethylbenzene (3-chloro-*o*-xylene) was undertaken to determine the substituent effect of a chlorine on *ipso* attack and on the reactions of the adducts so formed. In the nitration of 2,3-dimethylbenzonitrile the position of *ipso* attack is that *meta* to the electron-withdrawing cyano group (12). The chlorine atom is *ortho,para* directing, although deactivating, hence the methyl-substituted site *ortho* to the chlorine should be the preferred position for *ipso* attack.

Results and Discussion

Nitration and Formation of Adducts

Nitration of 1-chloro-2,3-dimethylbenzene in acetic anhydride gave 29% of diene adducts (**1**)[2] and the 4- (46%), 5- (5%), and 6-nitro (20%) substitution products. The products were separated by low-temperature chromatography on alumina. The

[1]Reported in preliminary form in ref. 1.

[2]Individual members of a pair of diastereoisomeric adducts are designated *a* and *b*.

1 2 3

presence of the nitro and acetate groups in the diastereoisomeric adducts is established by the appropriate infrared (ir) absorptions and confirmed by elemental analyses and molecular weight determinations. The absence of ultraviolet (uv) absorption in the region expected for conjugated cyclohexadienes (253 nm or greater (13)) indicates that the dienes are 1,4 and not 1,2 adducts. The nuclear magnetic resonance (nmr) spectra show that no adjacent vinyl protons, which would have $J \approx 8$ Hz, are present since the largest coupling is ca. 4 Hz. Moreover, the two 4-Hz couplings to a common proton show that there are protons on three adjacent carbon atoms which are joined by two single bonds. The double bonds must therefore be located between C-1 and C-6 and between C-3 and C-4, using the enumeration of the parent aromatic. Thus the nitro and acetate groups must be at C-2 and C-5, respectively, or vice versa. Addition of the shift reagent tris(1,1,1,2,2,3,3-heptafluoro-7,7-[$^2H_6$]dimethyl-4,6-[$^2H_3$]octanedionato)europium(III) {Eu([$^2H_9$]fod)$_3$} moved the allylic proton more rapidly downfield than the vinylic protons. The allylic proton must therefore be closer to the acetate group and thus the acetate must be attached to a secondary carbon atom, i.e. C-5, with the nitro group at C-2. The alternative arrangement, with the nitro group at the secondary carbon atom, is chemically unlikely since elimination of acetic acid from such an adduct to form 1-chloro-2,3-dimethyl-5-nitrobenzene would be extremely facile. Thus it is clear that the adducts do have the structure 3-chloro-4,5-dimethyl-4-nitro-1,4-dihydrophenyl acetate.

Addition of the nitronium ion to the *ipso* position adjacent to the halogen substituent is in accord with expectation based on the directing effect of the substituent for electrophilic substitution. Furthermore, the observed product distribution is in semi-quantitative agreement with that predicted from the nitration of chlorobenzene and *o*-xylene in acetic anhydride, assuming additivity of substituent effects. From the data of Roberts *et al.* (14) for chlorobenzene together with the observation of Perrin and Skinner (2) that the reactivity of the position *ipso* to chlorine is similar to that of the *meta* position, and the data of Fischer *et al.* (15) for *o*-xylene,[3] the relative reactivities of the nuclear positions of 1-chloro-2,3-dimethylbenzene are calculated to be, in order from C-1 to C-6: 0, 38, 1, 42, 1, 18. The observed yields of products resulting from attack at these sites are: 0, 29, 0, 46, 5, 20. Clearly, for nitration in acetic anhydride, such calculations give a useful, if not exact (3, 16), indication of the amounts of the various products, including adducts. Such results also support the view that acetic anhydride is effective in trapping the cation formed by addition of nitronium ion to an *ipso* position.

Reactions of the Adducts

Solution reactions of diene adducts (4-nitro-2,5-cyclohexadienyl acetates) involve the formation (or reformation) of cyclohexadienyl cations. Two such cations can be formed. Ionization of the nitro group as nitrite leads to an acetoxycyclohexadienyl cation (3) and protonation of the acetate group followed by loss of acetic acid leads to the nitrocyclohexadienyl cation (17). The outcome of the competition between these two pathways is determined by the other substituents present and by the acidity: formation of the nitrocyclohexadienyl cation is favoured in more acidic media. However, an additional factor has also to be considered. Formation of the nitrocyclohexadienyl cation is reversible in the sense that the cation can recombine with acetic acid or other nucleophile to regenerate the adduct or an analog. Formation of the acetoxycyclohexadienyl cation appears to be irreversible. Thus it is conceivable that the nitrocyclohexadienyl cation is formed more rapidly than the acetoxycyclohexadienyl cation yet the rearomatization products are those formed through the latter (or an analog). An example of this is provided by the observations of Myhre and co-workers (3) on the solvolysis of the adduct of 1,2,3-trimethylbenzene. They noted that 3,4,5-trimethylphenol was obtained as a product under conditions under which the acetate group was stable to hydrolysis. The adduct underwent rapid exchange of acetate for hydroxyl via the nitrocyclohexadienyl cation and the resulting hydroxynitrocyclohexadiene then reacted via the slower ionization of the nitro group to form the hydroxycyclohexadienyl cation which was deprotonated to the phenol. Thus the energetics of processes after the formation of the nitrocyclohexadienyl cation (but not of those after the formation of the acetoxy-

[3]The extent of *ipso* attack in *o*-xylene is given by the proportion of aryl acetate, formed by decomposition of the initially formed adduct, as reported in ref. 15.

cyclohexadienyl cation) may be important in determining the outcome of the competition between the rearomatization pathways which involve as intermediates the acetoxycyclohexadienyl cation, on the one hand, and the nitrocyclohexadienyl cation, on the other.[4]

Reaction of the adducts of 1-chloro-2,3-dimethylbenzene in neat acetic acid resulted in the elimination of nitrous acid and the formation of 3-chloro-4,5-dimethylphenyl acetate. Isomerization of **1***a* to **1***b* and of **1***b* to **1***a* was observed in the course of the reaction. In the more acidic formic acid rapid exchange of formate for acetate occurred giving rise to a pair of diastereoisomeric formates **2**. In the still more acidic trifluoroacetic acid (20% in deuteriochloroform) rapid isomerization, or exchange of acetate, was followed by rearomatization to yield 1-chloro-2,3-dimethyl-4-nitrobenzene (78%), 1-chloro-2,3-dimethyl-6-nitrobenzene (7%), and 3-chloro-4,5-dimethylphenyl acetate (15%). Rather more acetate was formed in more dilute (5%) formic acid. Reaction in acidified methanol resulted in the exchange of acetate for methoxyl and the formation of diastereoisomeric ethers **3**.

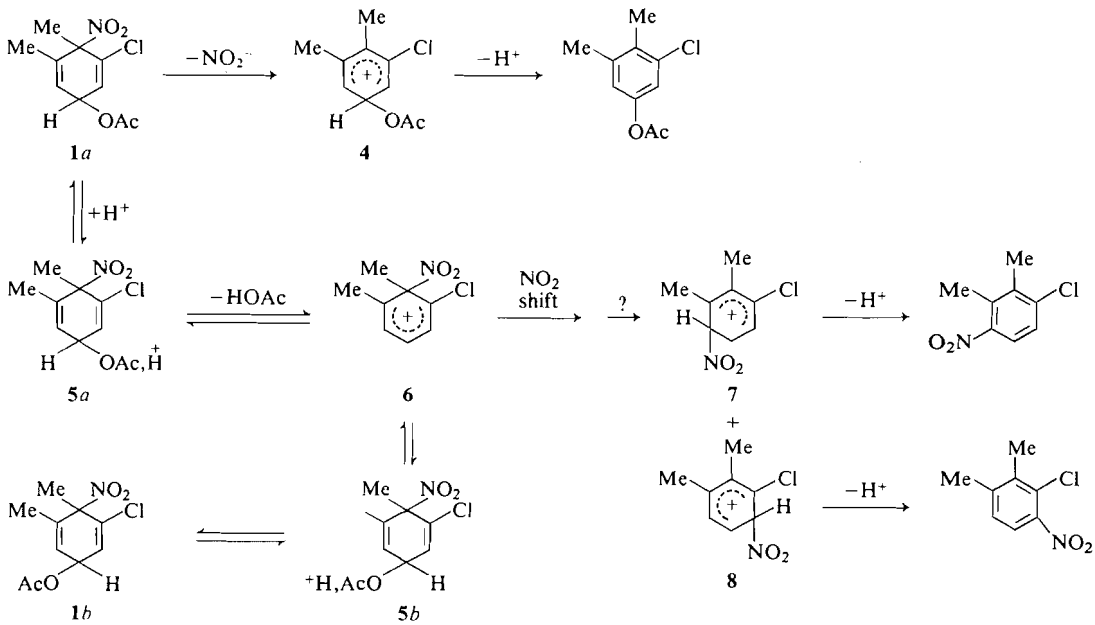
Rearomatization of secondary acetate adducts, of which **1** is an example, are relatively uncomplicated. Both the nitrocyclohexadienyl cation, **6** from **1**, and the acetoxycyclohexadienyl cation, **4** from **1**, each undergo only one rearomatization reaction. The nitro group of the nitrocyclohexadienyl cation migrates to an unsubstituted position to form an isomeric secondary nitrocyclohexadienyl cation which is rapidly deprotonated to the nitroarene. The acetoxycyclohexadienyl cation is rapidly deprotonated to the aryl acetate. These reactions are depicted for **1** in Scheme 1.[5] In acetic acid the rate of formation of the nitrocyclohexadienyl cation **6** is greater than that of the acetoxycyclohexadienyl cation **4**, as shown by the fact that diastereoisomer **1***a* isomerizes to **1***b* and **1***b* isomerizes to **1***a* before rearomatization. However, the rearomatization product, the aryl acetate, is formed via **4** and no significant amount of nitro derivative is formed via **6**. Thus there is a significant energy barrier to the nitro shift processes such that although the transition states between **1** and **5** and **5** and **6** are of lower energy than that between **1** and **4**, that between **6** and **7** (and **8**) is of higher energy. The adducts of *o*-xylene do not isomerize prior to rearomatization to aryl acetate under the same conditions. In this case the nitrocyclohexadienyl cation is not formed more rapidly than the acetoxycyclohexadienyl cation. This difference between the *o*-xylene and 3-chloro-*o*-xylene adducts can be understood in terms of the substituent effect of the chlorine on the energies of the transition states leading to **4** and **6** and thus on the energies of the cations **4** and **6**. Introduction of the chlorine substituent reduces the stability of both **4** and **6** relative to the unsubstituted case (Scheme 1, Cl replaced by H) and thus reduces the rates of formation of both cations, a consequence of the net electron-withdrawing (deactivating) effect of chlorine. However, in **6** the chlorine is located at a formal cationic centre and thus its electron-donating resonance effect can be fully operative whereas this is not so in **4**.[6] Thus the chlorine destabilizes **6** less than **4** and correspondingly the transition states leading to these cations, the effect being sufficient to reverse the order of stability of the transition states from that obtaining in the case of the *o*-xylene adduct.

As the acidity of the medium is increased **6** is formed more rapidly since the rate of formation of

[4]For the solvolysis of the 1,2,3-trimethylbenzene adduct in aqueous ethanol external return from the acetoxycyclohexadienyl cation has been detected (3). In the acidic media studied in the present work the nitrite ion will be extensively protonated and thus external return is much less likely. Furthermore, Myhre and co-workers (3) reported that the major part of the return was to a diene nitrite ester and not the nitrodiene. It seems unlikely that the nitrite ester could give rise to nitroarene in significant amount and thus formation of the nitrite ester is, in effect, a reversible side-reaction on the pathway between the acetoxycyclohexadienyl cation and product and has essentially no effect on the competition between formation of products via the nitrocyclohexadienyl cation and via the acetoxycyclohexadienyl cation.

[5]In Scheme 1 the isomerization (epimerization) of **1** and in the text the epimerization and exchange reactions of **1** are depicted as S_N1 reactions involving an intermediate nitrocyclohexadienyl cation. There is only one earlier report of exchange (epimerization) of a secondary acetate adduct (18), although tertiary acetate adducts undergo exchange readily. No mechanistic studies of these reactions in the secondary systems have yet been made and it is possible, although it seems unlikely, that the S_N2 mechanism is followed. Exchange reactions of secondary acetate adducts have been proposed as a key part of reaction sequences for the acidolysis, in ~50% aqueous sulfuric acid, of 3,4-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate (19) and 3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate (3) and arguments have been adduced in support of the S_N1 ($A_{AL}1$ ester hydrolysis) mechanism. As in the case of 3,4-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate no exchange was detected for 3,4,5-trimethyl-4-nitrocyclohexa-2,5-dienyl acetate at the low acidities in which 3-chloro-4,5-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate undergoes exchange.

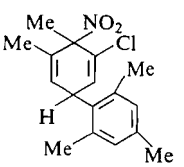
[6]This is an exact parallel to the situation in electrophilic substitution of chlorobenzene and to the explanation for chlorine being *ortho,para* directing, although deactivating.



SCHEME 1. Competitive reactions of adducts of 1-chloro-2,3-dimethylbenzene.

6 is determined not only by the energy difference between the **5,6** transition state and **1** but also by the energy difference between the catalytic acid and its conjugate base. Expressed alternatively, the rate of formation of the transition state **5,6** is proportional to the concentration of **5** which is in turn a function of the acid strength of the catalysing acid. It is assumed that this factor outweighs any medium effects on the relative stabilities of the **1,4** and **5,6** transition states. At some particular level of acidity the concentration of **6** will have risen to a level such that the nitro-shift processes occur at a rate that is competitive with the rate of formation of **4**. Apparently this is the situation in 20% trifluoroacetic acid where 85% of the aromatic product arises via **6** and 15% via **4**. The ratio of 4-nitro to 6-nitro derivative formed is 11:1. Both of these are products of formal 1,3-nitro shifts although such shifts could be the result of successive 1,2-nitro shifts. For a direct 1,3-nitro shift the extent to which each isomer is formed should be related to the relative stabilities of the 4-nitro- and 6-nitrocyclohexadienyl cations, **7** and **8** respectively. This ratio should in turn be related to the relative extents of attack by nitronium ion at these positions during nitration of 1-chloro-2,3-dimethylbenzene, calculated to be 2.3:1, as outlined above. Alternatively, if two successive 1,2 shifts occur then both the relative stabilities of the 3-nitro- and 1-nitro ions (related to the calculated relative extents of attack by nitronium ion at these positions of 4.4:1) and that of the 4-nitro- and 6-nitro ions would be significant in determining the relative migratory ratio. Since migration to the 6 position is disfavoured at both steps the discrimination in favour of the 4-isomer should be greater than in the single shift mechanism. Both sets of calculations predict that the 4-nitro isomer should be the predominant product, as observed.

When the reaction with trifluoroacetic acid was carried out in the presence of mesitylene the chloronitroarenes were not formed and 3′-chloro-2,4,4′,5′,6-



9

pentamethylbiphenyl was obtained instead. Evidently the nitrocyclohexadienyl cation **6** is captured by mesitylene prior to migration of the nitro group to form adduct **9**, i.e. there is electrophilic substitution of mesitylene by **6**. Under the reaction conditions the adduct undergoes rearomatization in the diene ring through ionization of the nitro group as nitrite, to form mesitylcyclohexadienyl cation which is rapidly deprotonated to the biphenyl in a sequence which is a parallel of that for the formation of aryl acetate from **1**.

The reactions of adduct **1** with formic acid and with acidified methanol lead to exchange of acetate for formate and methoxyl, respectively and the formation of diastereoisomers of **2** and **3**. Obviously

these reactions occur through the intermediate formation of cation **6** and are indicative of the more rapid formation of **6** than **4** under these conditions.

Pyrolysis of the adducts results in the elimination of the elements of acetyl nitrate and reversion to 1-chloro-2,3-dimethylbenzene. Some aryl acetate and nitro derivatives are also formed.

Experimental

General experimental methods have been described previously (12).

Nitration of 1-Chloro-2,3-dimethylbenzene in Acetic Anhydride

A solution of freshly distilled nitric acid (15 cm^3, 0.36 mol) in acetic anhydride (50 cm^3) was prepared at 0°C, cooled to −30°C, and added slowly with stirring to a solution of 1-chloro-2,3-dimethylbenzene (20 g, 0.14 mol) in acetic anhydride (70 cm^3) also at −30°C. The solution was allowed to warm to 0°C in an ice bath and maintained at that temperature for 15 min, after which time nmr showed the complete disappearance of the chlorodimethylbenzene and absorption in the τ 3.5–4.5 ppm region which represented ca. 30% of the product. The reaction mixture was cooled to −40°C, ether (300 cm^3) was added and the mixture was quenched with ammonia and worked up in the manner previously described (11) to yield 27 g of a yellow oil. The nmr spectrum of the reaction product and of chromatography fractions indicated that the 4-nitro (46%), 5-nitro (5%), and 6-nitro (20%) substitution products were present in addition to diene adducts (29%). Chromatography on alumina at −30°C and elution with ether–pentane mixtures gave in the 0–10% ether fractions, 1-chloro-2,3-dimethyl-4-nitrobenzene, mp 62–63°C (lit. (20) mp 62°C); ir (Nujol): 1540 cm^{-1} (NO_2); nmr ($CDCl_3$) τ: 2.50 (d, 1, J = 8.4 Hz, 5-*H*), 2.70 (d, 1, J = 8.4 Hz, 6-*H*), 7.59 (s, 6, 2-CH_3 and 3-CH_3); mass spectrum (70 eV) *m/e* (relative intensity): 187 (4) and 185 (11, M), 170 (14) and 168 (43, $M-OH$), 142 (4) and 140 (13), 141 (4) and 139 (9, $M-NO_2$), 113 (14), 105 (13), 104 (38), 103 (45), 77 (100). *Anal.* calcd. for $C_8H_8ClNO_2$: C 51.76, H 4.34, N 7.54; found: C 51.62, H 4.18, N 7.40.

The loss of OH from the molecular ion confirms that the nitro and methyl groups are adjacent (21) and thus the identification as the 4-nitro isomer. The nmr spectrum which reveals the *ortho* relationship between the aromatic protons is consistent with this.

The 15 and 20% ether fractions contained a mixture of the three isomeric 1-chloro-2,3-dimethylnitrobenzenes from which, after further chromatography on alumina and recrystallization from ethanol, was isolated 1-chloro-2,3-dimethyl-6-nitrobenzene, mp 45.5–46.5°C (lit. (22) mp 46°C); ir (Nujol): 1545 cm^{-1} (NO_2); nmr ($CDCl_3$) τ: 2.58 (d, 1, J = 8.5 Hz, 5-*H*), 2.92 (d, 1, J = 8.5 Hz, 4-*H*), 7.64 (s, 6, 2-CH_3 and 3-CH_3); mass spectrum (70 eV) *m/e* (relative intensity): 187 (26) and 185 (80, M), 157 (22) and 155 (60, $M-NO$), 141 (8) and 139 (24, $M-NO_2$), 127 (17), 104 (23), 103 (45), 91 (57), 77 (100). The absence of the $M-OH$ peak in the mass spectrum together with the *ortho* protons indicated by the nmr spectrum confirms the identification as the 6-nitro isomer. 1-Chloro-2,3-dimethyl-5-nitrobenzene was present in the residue from recrystallization of the 6-nitro isomer as shown by nmr absorption at τ 1.96 (d, J = 2.5 Hz, 6-*H*) and 2.12 (d, J = 2.5 Hz, 4-*H*) but was not further separated.

The 25–100% ether fractions contained a mixture of two isomeric dienes in varying proportions. The residues from these fractions were combined (9.1 g, 37 mmol) and rechromatographed at −30°C. Recrystallization from ether–pentane of the residue obtained on removal of the solvent from the new 10–20% ether fractions gave 3-chloro-4,5-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**1***a*), mp 56.5 – 57.5°C; uv (CH_3OH): 199.5 nm (ε 1450 m^2 mol^{-1}); ir: (Nujol): 1750, 1270, 1250 ($OCOCH_3$), 1570 cm^{-1} (NO_2); nmr ($CDCl_3$, 220 MHz) τ: 3.65 (q, 1, 2-*H*), 4.10 (m, 1, 6-*H*), 4.16 (m, 1, 1-*H*), 7.90 (s, 3, $OCOCH_3$), 8.05 (s, 3, 4-CH_3), 8.16 (t, 3, 5-CH_3), J_{12} = 4.08 Hz, $J_{1,5\text{-}CH_3}$ = 1.32 Hz, J_{16} = 3.94 Hz, J_{26} = 1.45 Hz, $J_{6,5\text{-}CH_3}$ = 1.40 Hz; irradiation of the methyl resonance at τ 8.16 collapsed the 6-H multiplet to a quartet and the 1-H multiplet to a triplet; in the 60 MHz spectrum the multiplets from 1-H and 6-H overlapped but addition of the shift reagent Eu([$^2H_9$]fod)$_3$ shifted the 1-H to lowest field and on decoupling from the 5-CH_3 the 1-H and 6-H appeared as the expected triplet (over-lapping doublets) and quartet, respectively. *Anal.* calcd. for $C_{10}H_{12}ClNO_4$ (M_r 245.5): C 48.89, H 4.89, N 5.70; found (245): C 48.95, H 4.93, N 5.53. **p** 14.2 × 10^{-30} C m (4.26 D).

The 30–40% ether fractions from the second column gave a residue which, on recrystallization from either carbon tetrachloride or ether–pentane, afforded colourless crystals of 3-chloro-4,5-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**1***b*), mp 86.5–88°C; uv (CH_3OH): 201 nm (ε 1250 m^2 mol^{-1}); ir (Nujol): 1765 and 1240 ($OCOCH_3$), 1585 cm^{-1} (NO_2); nmr ($CDCl_3$, 220 MHz) τ: 3.69 (q, 1, 2-*H*), 4.13 (m, 1, 6-*H*), 4.25 (m, 1, 1-*H*), 7.85 (s, 3, $OCOCH_3$), 8.11 (s, 3, 4-CH_3), 8.18 (t, 3, 5-CH_3), J_{12} = 3.78 Hz, $J_{1,5\text{-}CH_3}$ = 1.51 Hz, J_{16} = 3.19 Hz, J_{26} = 1.50 Hz, $J_{6,5\text{-}CH_3}$ = 1.51 Hz; irradiation of the methyl resonance at τ 8.18 collapsed the 6-H multiplet to a quartet and the 1-H multiplet to a triplet. *Anal.* calcd. for $C_{10}H_{12}ClNO_4$ (M_r 245.5): C 48.89, H 4.89, N 5.70; found (244): C 48.85, H 4.77, N 5.55. **p** 10.1 × 10^{-30} C m (3.03 D).

Thermolysis of Dienes **1**a *and* **1**b

Pyrolysis of diene **1***a* in the inlet of vapour phase chromatograph at 240°C gave 1-chloro-2,3-dimethylbenzene (82%), 3-chloro-4,5-dimethylphenyl acetate (~17%) and 1-chloro-2,3-dimethyl-4-nitro- and 1-chloro-2,3-dimethyl-6-nitrobenzene (~1%). Pyrolysis of diene **1***b* gave the same products in yields of 95, 3, and ~1%, respectively. The products were identified by comparison of their retention times with those of authentic samples.

Reaction of Dienes **1**a *and* **1**b *in Acetic Acid*

Diene **1***b* (0.1 g) was dissolved in acetic acid (0.4 cm^3) and heated at 50°C. Epimerization to form the **1***a*,**1***b* mixture which contained a preponderance of **1***a* occurred and was detected by the appearance of peaks characteristic of **1***a* in the nmr spectrum. After 1 week the diene peaks had disappeared and had been replaced by a pair of doublets, centred at τ 3.02 and 3.20, J = 2.5 Hz. In a similar experiment **1***a* epimerized and then rearomatized. The combined reaction mixtures were diluted with methylene chloride, cooled to −78°C and excess liquid ammonia was condensed into the solution. After evaporation of the ammonia the solution was worked up to yield a yellow oil which was chromatographed on alumina at −30°C. Elution with pentane gave 3-chloro-4,5-dimethylphenyl acetate as a colourless oil; ir (film): 1775 and 1210 cm^{-1} ($OCOCH_3$); nmr ($CDCl_3$) τ: 3.05 (d, 1, J = 2.4 Hz, 2-*H*), 3.14 (d, 1, J = 2.4 Hz, 6-*H*), 7.73 (overlapping s, 9, 4-CH_3, 5-CH_3, and $OCOCH_3$); mass spectrum (70 eV) *m/e* (relative intensity): 200 (8) and 198

(26, M), 158 (42) and 156 (100, $M-C_2H_2O$), 143 (15) and 141 (45), 121 (75, $M-C_2H_2OCl$), 91 (19).

The acetate was heated under reflux with sulfuric acid (40 mm^3) in methanol (1 cm^3) for 10 min. After work-up the residue obtained was dissolved in chloroform and filtered through a column of silica gel. Evaporation of the eluate to dryness and recrystallization from pentane gave colourless needles of 3-chloro-4,5-dimethylphenol, mp 97–98°C (lit. (23) mp 98°C); nmr ($CDCl_3$) τ: 3.30 (d, 1, $J = 3$ Hz, 2-*H*), 3.46 (d, 1, $J = 3$ Hz, 6-*H*), 7.78 (s, 6, 4-C*H*$_3$ and 5-C*H*$_3$); mass spectrum (70 eV) *m/e* (relative intensity): 158 (36) and 156 (91, M), 143 (24) and 141 (69, $M-CH_3$), 121 (100, $M-Cl$).

Reaction of Diene **1**a *with Formic Acid*

Formic acid (1.5 cm^3) was added to a solution of diene **1***a* (0.4 g) in deuterochloroform (0.5 ml) at −78°C. The reaction mixture was allowed to warm to 37°C and after 15 min nmr indicated that significant changes had occurred in the diene region. The solution was diluted with chloroform and cooled to −78°C and quenched with liquid ammonia. After work-up the product was chromatographed on alumina and eluted with pentane and ether–pentane mixtures. The formyloxydienes **2** were incompletely separated from each other but sufficiently so for nmr assignments to be made. One diastereoisomer of 3-chloro-4,5-dimethyl-4-nitrocyclohexa-2,5-dienyl formate (**2***a*) was the predominant component (80%) of the 50% ether fraction; ir (film): 1740 and 1160 (OCOH), 1565 cm^{-1} (NO_2); nmr ($CDCl_3$) τ: 1.95 (d, 1, $J = 1$ Hz, OCO*H*), 3.70 (m, 1, 2-*H*) 4.14 (m, 2, 1-*H* and 6-*H*), 8.07 (3, C*H*$_3$), and 8.17 (3, C*H*$_3$). The other diastereoisomer **2***b* was the predominant component (80%) of the 70% ether fraction; ir (film): 1740 and 1164 (OCOH), 1565 cm^{-1} (NO_2); nmr ($CDCl_3$) τ: 1.90 (d, 1, $J = 1$ Hz, OCO*H*), 3.72 (m, 1, 2-*H*), 4.16 (m, 2, 1-*H* and 6-*H*), 8.12 (3, C*H*$_3$) and 8.18 (3, C*H*$_3$).

Reaction of Dienes **1**a *and* **1**b *with Trifluoroacetic Acid*

Trifluoroacetic acid (0.1 cm^3) was added to a solution of diene **1***a* (0.1 g) in deuteriochloroform (0.4 cm^3) at 35°C. The reaction was followed by nmr. The appearance of new peaks in the diene region (τ 3.65) indicated that epimerization and/or exchange to form the trifluoroacetoxy diene occurred concurrently with rearomatization. Rearomatization was complete after 1 h and 1-chloro-2,3-dimethyl-4-nitrobenzene (78%), 1-chloro-2,3-dimethyl-6-nitrobenzene (7%), and 3-chloro-4,5-dimethylphenyl acetate (15%) were formed. In a similar experiment **1***b* gave the same products. When the reaction was repeated using a solution of 5% trifluoroacetic acid in carbon tetrachloride the acetate was the major product.

3′-Chloro-2,4,4′,5′,6,-pentamethylbiphenyl

Trifluoroacetic acid (0.1 cm^3) was added to a solution of diene **1** (0.1 g) and mesitylene (0.1 cm^3) in deuteriochloroform (0.4 cm^3). The solution turned red-brown indicating the presence of nitrogen dioxide and the release of nitrous acid. The nmr spectrum of the mixture did not exhibit any resonances below τ 3.0 showing that no nitro compounds had been formed. The mixture was cooled to −78°C and neutralized with liquid ammonia. The residue obtained after work-up was chromatographed on alumina. Elution with pentane removed excess mesitylene. Elution with ether and chromatography of the residue from the eluate on silica gel, and elution with pentane, gave a clear oil which did not crystallize; ir (film): 2970, 2940, 2910, 2860, 2730, 1630, 1555, 1470, 1445, 1385, 1270, 875, 850, 825, 745, 715, 695, and 600 cm^{-1}; nmr ($CDCl_3$) τ: 3.1 (m, 4, 2′-*H*, 3-H, 5-H, and 6′-H), 7.64 and 7.69 (9, 4-C*H*$_3$, 4′-C*H*$_3$, and 5′-C*H*$_3$), 8.00 (s, 6, 2-C*H*$_3$ and 6-C*H*$_3$); mass spectrum (70 eV) *m/e* (relative intensity): 260 (42), 258.1166 (100, M_r ($^{12}C_{14}$ $^{1}H_{19}$ ^{35}Cl) 258.1175), 245 (17) and 243 (44, $M-CH_3$), 223 (69, $M-Cl$), 209 (16), 208 (81), 207 (32), 193 (50), 192 (22), 191 (17), 178 (17), 174 (39), 159 (30).

Reaction of Diene **1** *with Sulfuric Acid in Methanol*

Diene **1** (0.14 g) was dissolved in a solution of sulfuric acid (5 mm^3) in methanol (0.5 cm^3) and allowed to react for 18 h. The nmr indicated that 40% of the original diene had been converted to 3-chloro-4,5-dimethylphenol or its methyl ether. After neutralization and work-up the product was chromatographed. Elution with the pentane and ether–pentane mixtures gave in the 50% ether fractions a mixture of dienes containing as a major constituent, the methoxydienes **3** (nmr 6.70 and 6.73, OC*H*$_3$ of each diastereoisomer).

The fluoroformate ion, FCO_2^-. An ion cyclotron resonance study of the gas phase Lewis acidity of carbon dioxide and related isoelectronic species

TERRANCE BRIAN MCMAHON AND COLLEEN JOAN NORTHCOTT

Department of Chemistry, University of New Brunswick, P.O. Box 4400, Fredericton, N.B., Canada E3B 5A3

Received October 18, 1977

TERRANCE BRIAN MCMAHON and COLLEEN JOAN NORTHCOTT. Can. J. Chem. **56**, 1069 (1978).

The gas phase ion molecule reactions of a number of potential fluoride donors with carbon dioxide and carbonyl fluoride have been studied. By determination of preferential directions of fluoride transfer the fluoride affinities of carbon dioxide and carbonyl fluoride have been bracketed and found to be 33 ± 3 kcal/mol and 35 ± 3 kcal/mol respectively. In addition, from gas phase acidity studies of acetyl fluoride and 2-fluoropropene the fluoride affinities of ketene and allene have been calculated to be 38 ± 2 kcal/mol and 15 ± 2 kcal/mol respectively. The order of fluoride affinities (Lewis acidities) of carbon dioxide, ketene, and allene have been examined and explained in terms of the electron affinities of the F—C(A)(B) species (A,B=O,CH_2) and the C—F bond dissociation energies. These quantities have been estimated and the latter interpreted on the basis of the π bond energies of the three compounds.

TERRANCE BRIAN MCMAHON et COLLEEN JOAN NORTHCOTT. Can. J. Chem. **56**, 1069 (1978).

On a étudié les réactions ion-molécule en phase gazeuse d'un certain nombre de donneurs potentiels de fluor avec le dioxyde de carbone et le fluorure de carbonyle. A l'aide de la détermination des directions préférentielles des transferts de fluor, on a pu évaluer les affinités pour le fluorure du dioxyde de carbone et du fluorure de carbonyle et on a trouvé que ces valeurs sont respectivement de 33 ± 3 kcal/mol et de 35 ± 3 kcal/mol. De plus, en se basant sur des études d'acidité en phase gazeuse du fluorure d'acétyle et du fluoro-2 propène, on a pu calculer les affinités pour les fluorures du cétène et de l'allène qui sont évaluées respectivement à 38 ± 2 kcal/mol et 15 ± 2 kcal/mol. On a examiné l'ordre des affinités pour les fluorures (acidités de Lewis) du dioxyde de carbone, du cétène et de l'allène et on les exprime en termes d'affinités électroniques des espèces F—C(A)(B) (A,B=O,CH_2) et des énergies de dissociation des liens C—F. On a évalué ces quantités et on les a interprétées en se basant sur les énergies de liaisons π des trois composés.

Introduction

The examination of isoelectronic species has been extensively used in the development of theories of structure and bonding in main group chemistry. Of general interest is the observation that to a large extent molecular geometry is determined by the number of valence electrons in the system (1–8) and a good deal of synthetic and structural chemistry has been directed toward the preparation and examination of molecules to test this postulate. An especially useful group of compounds to test the hypothesis are the oxides, fluorides, and oxofluorides of boron, carbon, and nitrogen. For example it is found that the isoelectronic borate, BO_3^{3-}, carbonate, CO_3^{2-}, and nitrate, NO_3^-, ions are each planar species of D_{3h} symmetry (9). Similarly the isoelectronic tetrafluorides, BF_4^-, CF_4, and NF_4^+ each have a tetrahedral form (10) and the isoelectronic pairs of oxofluorides CF_2O—NF_2O^+ and CF_3O^-—F_3NO are also isostructural (11). A novel carbon oxofluoride which has received some attention recently is the fluoroformate ion, FCO_2^- (12). The isoelectronic, 24 valence electron systems BF_3, CO_3^{2-}, NO_3^-, FNO_2, and CF_3^+ all exhibit planar geometries (8) and thus it would be expected that FCO_2^- will be similarly planar. A preliminary report has suggested that cesium fluoroformate, $CsFCO_2$, is formed at high CO_2 pressure above acetonitrile solutions of CsF (12). More recent attempts to reproduce this result appear to have failed, however.[1] The inability to prepare seemingly stable entities such as FCO_2^- is usually indicative of either a highly reactive nature (particularly toward the solvent medium), a large activation barrier to formation, or in the case of ionic species a low crystal lattice energy associated with salt formation with the chosen counterion. Studies of ionic species in the gas phase such as under the normal operating conditions of an ion cyclotron resonance spectrometer avoid each of the above deterrents to the formation of stable ionic species. Since the ions are formed in the absence of solvent and may be observed for times less than the time between collisions highly reactive species will still be detected. In addition gas phase ion molecule reactions usually proceed with zero activation energy (14) thus allowing formation of a desired ion by any appro-

priate exothermic reaction. Therefore it was deemed feasible that if FCO_2^- is bound with respect to F^- and CO_2 it should be possible to observe the fluoroformate ion by ion cyclotron resonance (ICR) experiments.

The technique of using molecular fluoride anions as gas phase fluoride donors has been described by Haartz and McDaniel (15). Thus reactions such as [1] between MF_n^- and CO_2 can conceivably yield the desired fluoroformate ion whenever the binding energy of F^- to CO_2 is greater than that of F^- to MF_{n-1}.

$$[1] \qquad MF_n^- + CO_2 \rightarrow FCO_2^- + MF_{n-1}$$

The present study describes the details of various reactions in which fluoride ion is donated to carbon dioxide and also of several reactions in which FCO_2^- donates fluoride ion to other molecules. Using available thermochemical information on fluoride binding energies it is possible to assign an accurate limit to the fluoride binding energy of CO_2. In addition the isoelectronic species, acetyl fluoride enolate, CH_2COF^-, and 2-fluoroallyl anion, $(CH_2)_2CF^-$, have been generated and fluoride binding energies determined for comparison with that of FCO_2^-.

Experimental

All experiments were carried out on a Varian Instruments V-5900 ICR spectrometer. The techniques and instrumentation associated with ICR have been described in detail previously (16, 17).

Fluoride donors were generated either by electron attachment processes to a variety of inorganic fluorides or by proton abstraction from a fluorine-containing molecule by F^- generated from NF_3 or CH_3O^- generated from CH_3ONO. For example electron impact at 4.4 eV on SO_2F_2 generates both F_2^- (13%) and SO_2F^- (12%) which may each serve as fluoride donors to appropriate species. Details of electron attachment to molecular fluorides are described by Dillard (18).

SF_6, SO_2F_2, COF_2, and CO_2 were obtained from Matheson of Canada, Ltd. CF_3OF, CH_3COF, and CH_3CFCH_2 were purchased from PCR Inc. and NF_3 from Air Products and Chemicals Inc. Methanol, acetic acid, and formic acid were commercially available reagent grade chemicals.

Results

Fluoride donation from a number of anionic fluorides to carbon dioxide and from FCO_2^- to a variety of neutrals has been examined by the variation of pressure of a mixture of neutral reactants in the range 10^{-6} to 10^{-3} Torr in the ICR spectrometer. The exothermic direction of fluoride transfer was confirmed in each case using ICR double resonance techniques. The fluoride binding energies or fluoride affinities of a number of anions used as reference standards are summarized in Table 1.

TABLE 1. Fluoride affinities of reference fluoride donors

Species – MF^-	Fluoride affinity $D(M—F^-)$ (kcal/mol)	Reference
SF_6^-	11 ± 8	13
SF_5^-	54 ± 12	13
F_2^-	29 ± 2	21*a*, *b*, *c*
SO_2F^-	40 ± 2	21*a*
CH_2COF^-	38 ± 2	*a*
$(CH_2)_2CF^-$	15 ± 2	*a*
CH_3OHF^-	29 ± 4	*b*
$CH_3CO_2HF^-$	44 ± 4	*b*

[a]T.B. McMahon, unpublished results.
[b]Interpolated from the data of Yamdagni and Kebarle (26).

1. SF_6 and CO_2

Electron impact at 70 eV on SF_6 produces SF_6^- and SF_5^- in a ratio of 20:1 (19). When CO_2 was added to the system neither reaction 2 nor 3 was observed to occur. Failure to observe fluoride transfer from SF_6^- to CO_2 might be taken as evidence that the

$$[2] \qquad SF_6^- + CO_2 \not\rightarrow FCO_2^- + SF_5$$

$$[3] \qquad SF_5^- + CO_2 \not\rightarrow FCO_2^- + SF_4$$

fluoride affinity of CO_2 is less than that of SF_5 (11 ± 8 kcal/mol). However recent studies have shown that even when fluoride transfer from SF_6^- is known to be exothermic it has frequently not been observed (20), particularly in the case of transfer to weakly acidic species. Thus no firm conclusion may be drawn from the SF_6^- result. On the basis of failure of reaction 3 to occur a value of $D(F^-—CO_2)$ less than 54 ± 12 kcal/mol may be inferred.

2. SO_2F_2 and CO_2

Dissociative electron attachment at 4.4 eV to SO_2F_2 produces F^- (75%), F_2^- (12%), and SO_2F^- (13%). SO_2F^- was observed to be unreactive toward CO_2 implying a fluoride affinity of CO_2 of less than 40 kcal/mol. Fluoride transfer from F_2^- to CO_2, eq. 4, proceeded efficiently however to produce the

$$[4] \qquad F_2^- + CO_2 \rightarrow FCO_2^- + F$$

fluoroformate ion, FCO_2^-. Determinations of the electron affinity of molecular fluorine place it at 3.0 ± 0.1 eV (21) which, taken with the electron affinity of fluorine atom of 3.40 eV (22) and $\Delta H_f^0{}_{298}(F)$ of 18.88 kcal/mol, allows a calculation of $D(F^-—F)$ of 29 kcal/mol. Therefore the fluoride affinity of CO_2 is established as greater than this value.

3. CH_3ONO and F_2CO

An efficient means of producing fluoroformate was also found in the reaction of methoxide ion generated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

from methyl nitrite with carbonyl fluoride. Riveros has previously shown that the reaction of methoxide ion with 1,1-difluoroethylene leads to facile production of fluoroenolate ions, eq. 5 (23). It was thus

[5] $CH_3O^- + \underset{F}{\overset{F}{\diagdown}}C{=}C\underset{H}{\overset{H}{\diagup}} \rightarrow \underset{F}{\overset{O^-}{\diagdown}}C{=}CH_2 + CH_3F$

anticipated that reaction of methoxide ion with the isoelectronic carbonyl fluoride might yield the desired fluoroformate ion, eq. 6. The expected result was in

[6] $CH_3O^- + \underset{F}{\overset{F}{\diagdown}}C{=}O \rightarrow \underset{F}{\overset{O^-}{\diagdown}}C{=}O + CH_3F$

fact found as demonstrated by the variation of relative ionic abundances with pressure shown in Fig. 1. In addition reactions 7–9 were also observed.

[7] $CH_3O^- + CH_3ONO \rightarrow CH_2ONO^- + CH_3OH$

[8] $CH_2ONO^- + F_2CO \rightarrow CHFONO + HF + CO$

[9] $FCO_2^- + F_2CO \rightarrow F_3CO^- + CO_2$

The last reaction, eq. 9, establishes the fluoride affinity of CO_2 as being less than that of carbonyl fluoride. Due to a lack of accurate thermochemical data for F_3CO^- experiments were also carried out to establish the fluoride affinity of F_2CO and establish an upper limit for the fluoride affinity of carbon dioxide.

4. CF_3OF and CO_2

Thynne and MacNeil (24) have assigned a value of greater than 1.9 eV for the electron affinity of F_3CO radical based on the production of F_3CO^- by dissociative attachment of zero energy electrons to trifluoromethyl hypofluorite, CF_3OF. At all electron energies they observed F^- to be the most abundant ion formed. In contrast to this in the ICR spectrometer we observe CF_3O^- to be the most abundant species formed by electron attachment to CF_3OF. This result implies that the electron affinity of F_3CO should be greater than the electron affinity of fluorine atom, 3.40 eV (22). This value, taken with $\Delta H_f^0{}_{298}(F_2CO)$ of -152 kcal/mol yields a value of $D(F^-—F_2CO)$ of greater than 24 kcal/mol, consistent with our data for relative fluoride affinities of CO_2 and F_2CO reported above.

When CO_2 was added to the system with CF_3OF no fluoride transfer was observed confirming the exothermic direction of fluoride transfer of eq. 9.

5. CF_3OF and SO_2

Trifluoromethoxide ion generated from CF_3OF was found to react with SO_2 to generate SO_2F^-, eq. 10. This result is consistent with the failure to

[10] $CF_3O^- + SO_2 \rightarrow SO_2F^- + CF_2O$

observe fluoride transfer from SO_2F^- to CO_2 in the SO_2F_2, CO_2 mixture and establishes the fluoride affinity of CF_2O as less than that of SO_2, 40 kcal/mol (21).

6. CF_3OF and Acetic Acid

Trifluoromethoxide generated from CF_3OF underwent fluoride transfer to acetic acid, eq. 11. The acid

[11] $F_3CO^- + CH_3CO_2H \rightarrow CH_3CO_2HF^- + F_2CO$

[12] $CH_3CO_2HF^- + CH_3CO_2H \rightarrow (CH_3CO_2)_2H^- + HF$

solvated fluoride ion reacted further with acetic acid producing the proton bound dimer of acetate ion, eq. 12, by displacement of HF. This latter reaction provides a convenient bimolecular route to dimer anions permitting further studies of anion–solvent binding energies (25).

Based on the data of Yamdagni and Kebarle (26) for solvation of halide ions by a variety of protic solvents a value of $D(F^-—CH_3CO_2H)$ of 44 kcal/mol may be interpolated establishing the fluoride affinity of F_2CO as less than this value.

7. NF_3, CH_3COF, and CO_2

Fluoride ion generated from NF_3 reacted with acetyl fluoride via proton transfer to generate the acetyl fluoride enolate ion eq. 13. This ion may also

[13] $F^- + CH_3COF \rightarrow \underset{F}{\overset{O^-}{\diagdown}}C{=}CH_2 + HF$

be formally regarded as F^- bound to ketene which is isoelectronic with carbon dioxide. The acetyl

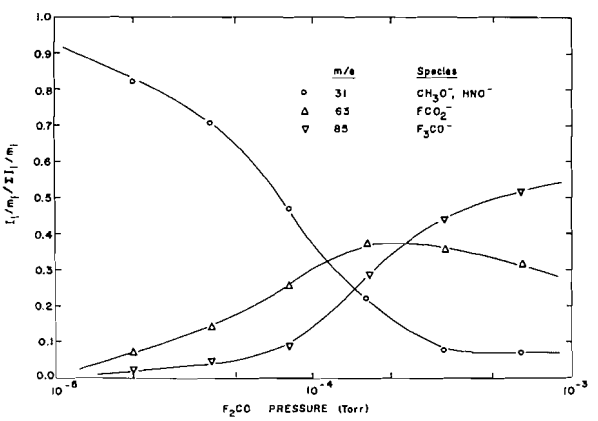

FIG. 1. Variation of relative anionic abundances with pressure in a 10:1 mixture of carbonyl fluoride:methyl nitrite at 70 eV electron energy.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

fluoride enolate did not undergo fluoride transfer to CO_2, eq. 14, indicating that carbon dioxide has a fluoride affinity less than ketene.

[14] 
Studies of the acidity of acetyl fluoride have established a proton affinity of the fluoro enolate ion of 357 kcal/mol (27). This value allows a calculation of the fluoride affinity of ketene of 38 kcal/mol. Further work showed the fluoride affinity of ketene to be greater than carbonyl fluoride.

8. CH_3ONO, $CH_2{=}CFCH_3$, and CO_2

Reaction of methoxide generated from methyl nitrite with 2-fluoropropene yields the 2-fluoropropenyl anion, eq. 15, and CH_3OHF^-, eq. 16. Both of

[15] 
[16] 
these ions thus generated react further with carbon dioxide to give the fluoroformate ion, eqs. 17 and 18

[17] 
[18] $$CH_3OHF^- + CO_2 \rightarrow FCO_2^- + CH_3OH$$

respectively. The variation of relative ionic abundances with pressure observed for this reaction mixture is shown schematically in Fig. 2.

The acidity of 2-fluoropropene has also been studied and a proton affinity of 376 kcal/mol assigned for the 2-fluoropropenyl anion (27). This

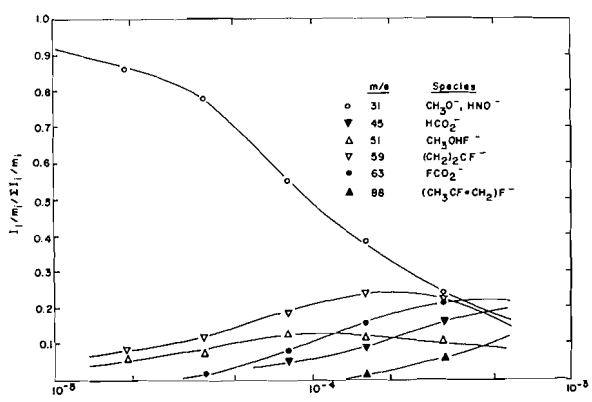

FIG. 2. Variation of relative anionic abundances with pressure in a 20:10:1 mixture of 2-fluoropropene:carbon dioxide:methyl nitrite at 1.5 eV electron energy.

result establishes a fluoride affinity of 15 kcal/mol for allene.

The fluoride affinity of methanol interpolated from Kebarle's data (26) is roughly 29 kcal/mol. Reaction 18 denoting the fluoride affinity of carbon dioxide greater than methanol is thus consistent with reaction 4 which also establishes a CO_2 fluoride affinity greater than 29 kcal/mol.

Discussion

The results presented above together with the thermochemical data summarized in Table 1 provide a basis for assignment of a reasonably accurate fluoride affinity of carbon dioxide. The observation of fluoride transfer from F_2^- to CO_2 provides a lower limit of 29 kcal/mol for $D(F^-{-}CO_2)$. On the basis of failure to observe fluoride transfer from SO_2F^- and CH_2COF^- to CO_2 a fluoride affinity of less than 38 kcal/mol is inferred. Further it is found that FCO_2^- undergoes fluoride transfer to F_2CO and that carbonyl fluoride has a fluoride affinity less than ketene, 38 kcal/mol. Thus, from these observations it is possible to assign fluoride affinities of 35 ± 3 kcal/mol to carbonyl fluoride and 33 ± 3 kcal/mol to carbon dioxide. These assignments allow calculations of $\Delta H_f^0{}_{298}$ for F_3CO^- of -247 kcal/mol and for FCO_2^- of -187 kcal/mol to be made.

It is noteworthy that the value of $\Delta H_f^0{}_{298}$ obtained for fluoroformate ion and the associated fluoride affinity of carbon dioxide are very close to values for these quantities obtained by estimating the gas phase acidity of the hypothetical fluoroformic acid molecule. The proton affinity of the fluoroformate ion may be estimated from the known acidity of trifluoroacetic acid (28) and from a comparison of the relative effects of CF_3 and F substitution on acidities of carbonyl compounds. A comparison of the acidities of 1,1,1-trifluoroacetone (29) and acetyl fluoride (27) reveals that relative to acetone CF_3 substituted for CH_3 lowers the anion proton affinity by 17 kcal/mol (29) while F substituted for CH_3 lowers the proton affinity by some 10 kcal/mol (27). Noting that the trifluoroacetone enolate is isoelectronic with trifluoroacetate and acetyl fluoride enolate isoelectronic with fluoroformate proportionate reductions in proton affinities of enolates and carboxylates might be expected. Therefore on the basis of a 25 kcal/mol reduction in proton affinity of trifluoroacetate relative to acetate ion a proton affinity for the fluoroformate ion of 330 kcal/mol is estimated. Combining this with a value of -153 kcal/mol estimated for $\Delta H_f^0{}_{298}(FCO_2H)$ by group equivalent methods a fluoride affinity of 35 kcal/mol is obtained for CO_2 in good agreement with the results presented above.

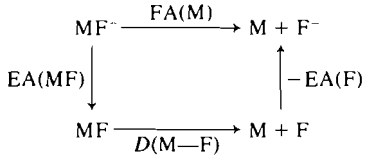
TABLE 2. Thermochemical data related to fluoride affinities of allene, ketene, and carbon dioxide

M	FA(M)[a]	EA(MF)[a,b]	D(M—F)[a]	Eπ(M)[a,c]
O=C=O	33	87	24[d]	183
CH_2=C=O	38	51	65[e]	132
CH_2=C=CH_2	15	22	71[f]	106

[a]All values in kcal/mol.
[b]Electron affinity calculated from the estimated bond energy, D(M—F), the experimental fluoride affinity, and electron affinity of F (3.40 eV).
[c]π Bond energy calculated by the method of Benson (30).
[d]$\Delta H_f°_{298}(FCO_2)$ calculated from estimated $\Delta H_f(FCO_2H) = -153$ kcal/mol and an assumed D(H—OCOF) of 106 kcal/mol.
[e]$\Delta H_f°_{298}(CH_2COF\cdot)$ calculated from $\Delta H_f°_{298}(CH_3COF) = -104$ kcal/mol and an assumed D(H—CH_2COF) of 95 kcal/mol.
[f]$\Delta H_f°_{298}((CH_2)_2CF\cdot)$ calculated from estimated $\Delta H_f°_{298}(CH_3CF{=}CH_2) = -39$ kcal/mol and an assumed D(H—$CH_2CF{=}CH_2$) = 85 kcal/mol.

Further, it is of interest to compare the fluoride affinities of the isoelectronic series of compounds with cumulative double bonds: allene, ketene, and carbon dioxide. On the basis of standard concepts of stability of anions it might have been expected that carbon dioxide would have the highest fluoride affinity of the three compounds since the resulting fluoroformate ion should be more stable than either the fluoroenolate or 2-fluoropropenyl anions. However the fluoride affinities found, which are summarized in Table 2 do not reflect this intuitive ordering. Instead, fluoride affinities increase in the order allene < carbon dioxide < ketene. In order to better understand the reason for this order it is useful to express the fluoride affinity in terms of other thermochemical quantities as shown in Scheme 1. Since the electron affinity of F is constant for the series of molecules differences in fluoride affinity result from differences in electron affinities of the MF radicals and the M—F bond dissociation energies. Estimates of the M—F bond energies are also summarized in Table 2 as well as the radical electron affinities calculated from the estimated MF heat of formation. The electron affinities show the expected trend in anionic stabilities, that is fluoroformate is more stable than fluoroenolate which in turn is more stable than 2-fluoropropenyl anion with respect to electron detachment. The reason the fluoride affinities do not follow the order of electron affinities is found in the greatly reduced F—CO_2 bond energy relative to that in the CH_2COF and $(CH_2)_2$CF radicals. Further, the F—CO_2 bond energy is much lower



$$FA(M) = EA(MF) + D(M—F) - EA(F)$$

SCHEME 1

than the corresponding C—F bond energies in the other two compounds because of the very high π bond energy of CO_2. For comparison the π bond energies calculated by Benson's (30) method are also included in Table 2. Thus in forming a new C—F bond as F^- approaches the double bond system roughly one half of the π bond energy of the compound is lost. Since this quantity is so much greater for CO_2 than either ketene or allene a much lower fluoride affinity results.

The above analysis demonstrates that although fluoride binding energies are a good measure of Lewis acidity in the gas phase they are not necessarily a good means of assessing relative intrinsic anionic stabilities. A much better measure of the latter quantity is the electron affinity of the corresponding free radical. The approximate values of electron affinity shown in Table 2 dramatically demonstrate the expected stability of the fluoroformate ion.

Conclusions

The present study demonstrates that using a variety of gas phase ion molecule reactions novel anionic species may be observed and characterized. The results obtained for F^-—CO_2 binding energy coupled with an estimated crystal lattice energy for $CsFCO_2$ and the crystal lattice energy for CsF (31) indicate that reaction 19 for the formation of

[19] $$CsF + CO_2 \rightarrow CsFCO_2$$

$CsFCO_2$ should be somewhat exothermic (10 kcal/mol) and that preparation of the material by this route is feasible. Similar demonstrations for fluorine containing anions may prove to be of further aid to synthetic chemists in assessing feasibility of various routes to ionic compounds.

In addition the above data show that experiments of the type carried out in this work can be extremely valuable in providing thermochemistry of unusual anionic species. Further studies of fluoride binding energies are currently in progress.

Received October 11, 1977

A. W. BOYD and O. A. MILLER. Can. J. Chem. **56**, 1075 (1978).

The yield of nitrogen from the radiolysis of nitric oxide is $G(N_2) = 4.5 \pm 0.3$ at doses from 0.1 to 1.0×10^{20} eV g^{-1} and at dose rates of 2.5×10^{16} and 2×10^{27} eV g^{-1} s^{-1}. The addition of SF_6 to NO does not change this yield but in mixtures of NO with 90% Xe the addition of SF_6 reduces $G(N_2)$ by an amount close to $G(Xe^+)$. These results are consistent with suppression of dissociative neutralisation in NO by clustering of the positive ion. Good agreement is obtained between the total energy absorbed and the amounts required for ionization, neutral dissociative excitation, and formation of subexcitation electrons. The neutral dissociative excitation yield is estimated to be $G(NO \rightarrow N + O) = 3.6 \pm 0.3$.

A. W. BOYD et O. A. MILLER. Can. J. Chem. **56**, 1075 (1978).

Le rendement d'azote provenant de la radiolyse de l'oxyde nitrique est $G(N_2) = 4.5 \pm 0.3$ à des doses allant de 0.1 à 1.0×10^{20} eV g^{-1} et à des taux de dose de 2.5×10^{16} et 2×10^{27} eV g^{-1} s^{-1}. L'addition de SF_6 au NO ne change pas ce rendement mais dans des mélanges de NO avec 90% de Xe, l'addition de SF_6 réduit $G(N_2)$ par une quantité proche de $G(Xe^+)$. Ces résultats sont en accord avec la suppression de la neutralisation dissociative dans NO par l'aggrégation d'ions positifs. Une bonne concordance a pu être obtenue entre l'énergie totale absorbée et les quantités requises pour l'ionisation, l'excitation dissociative neutre et la formation d'électrons sous-excités. On a évalué que le rendement d'excitation dissociative neutre est $G(NO \rightarrow N + O) = 3.6 \pm 0.3$.

[Traduit par le journal]

Introduction

Over the past ten years a good understanding of the radiolysis of most of the simple inorganic gases has been obtained by combining primary ion yields, reaction rate constants, and stable product yields (1).

The contribution of ionic processes to the stable products is derived from the ion yields and reaction rate values. The major uncertainty in these data is the identity of the products of neutralisation reactions. This can usually be resolved by measurement of the stable products with and without an electron scavenger, such as SF_6, which suppresses dissociative neutralisation of the positive ion. The charge transfer from the primary positive ions to products or impurities, that may occur before neutralisation with ^{60}Co sources has been eliminated by the use of high intensity pulsed electron accelerators.

The yields of primary neutral species are usually determined from the differences between the ionic contributions and the total product yields but in a few cases these have also been obtained from electron cross section measurements and degradation spectra. In these cases there is reasonable agreement between the physical and chemical values.

It has also been possible for most gases to obtain a balance between the total energy absorbed and that required for ionization, excitation, and formation of subexcitation electrons.

The stable products from the radiolysis of nitric oxide are N_2 and NO_2 (2) (in equilibrium with N_2O_4 and N_2O_3) and $G(NO_2) = 2G(N_2)$. As will be discussed the available data on ion yields and reactions lead to $G(N_2) = 4.7$ from ionic processes. From energy balance calculations the yield from neutral processes is $G(N_2) \approx 3.8$ giving a total of $G(N_2) \approx 8.5$.

There are only two reports of radiolytic yield measurements. The first by Harteck and Dondes (2) gives total disappearance yields of NO at ~64 kPa in fission fragment irradiations with a dose rate of $\sim 10^{19}$ eV g^{-1} s^{-1}. The yield decreased from $G(-NO) = 13.8$ at 6×10^{21} eV g^{-1} to $G(-NO) = 9.5$ at 1.2×10^{23} eV g^{-1}. The maximum yield of N_2 calculated from these is $G(N_2) = 3.45 \pm 0.35$. The second by Hochanadel, Ghormley, and Ogren (3) gives the yields of NO_2 and N_2O_3 from the Febetron radiolysis of NO at 100 kPa. The value obtained was $G(NO_2 + N_2O_3) = 10.6$ over dose rates between 10^{26} and 10^{27} eV g^{-1} s^{-1} and doses between 6×10^{18} and 6×10^{19} eV g^{-1}. This value indicates a nitrogen yield of $G(N_2) = 5.3$.

The contribution of ion neutralisation, in the above estimate, to the nitrogen yield is $G(N_2) = 3.6$. If this neutralisation is not dissociative this would

account for a large part of the disagreement between the predicted and measured values. It is thus of interest not only to determine the effect of an electron scavenger on the yields but also to investigate further their dependence on dose and dose rate.

Experimental

Irradiations and Dosimetry

In the high dose rate irradiations both a Febetron 705 and a Febetron 706 were used. The samples were contained in quartz cells (4 cm diameter × 7 cm long for the 705 and 2.5 cm diameter × 2 cm long for the 706) with 0.05 cm thick windows. The maximum absorbed doses in these cells from nitrous oxide dosimetry ($G(N_2) = 12.4$ (4–6)) were 1×10^{20} eV g^{-1} per pulse ($\sim 2 \times 10^{27}$ eV g^{-1} s^{-1}) and 7.2×10^{19} eV g^{-1} per pulse ($\sim 2 \times 10^{28}$ eV g^{-1} s^{-1}) for the 705 and 706 respectively.

The low dose rate irradiations were done with a Gammacell 220. The absorbed dose rate, determined using a mixture of N_2O with 1 mol% SF_6 and taking $G(N_2) = 8.0$ (4, 7), was 2.5×10^{16} eV g^{-1} s^{-1}. The samples were contained in 90 cm^3 Pyrex cells.

Materials and Analyses

All gases were obtained from the Matheson Co. The nitric oxide was subjected to freeze–pump–thaw cycles to remove permanent gases and low temperature distillation to remove NO_2 and N_2O_3. The removal of the latter two was verified by measurement of the spectrum in the region 200–500 nm with a Cary 17 spectrophotometer. Nitrous oxide was removed by passing the nitric oxide through 3A molecular sieve.

The sulfur hexafluoride and nitrous oxide were freed from permanent gases as described above. The xenon was used directly.

The nitrogen produced by irradiation was measured by freezing the samples with solid nitrogen, collecting the gas remaining in a McLeod gauge, and analyzing this by mass spectrometry.

Results

The amounts of nitrogen from both the Febetron 705 and the Gammacell irradiations as a function of dose are shown in Fig. 1. The standard deviations in these values are in general less than ±5% and thus the uncertainties are in most cases less than those indicated by the dimensions of the symbols.

The yields from these results $G(N_2) = 4.5$ at doses from 0.1×10^{20} to $\sim 2 \times 10^{20}$ eV g^{-1} and $G(N_2) = 3.6$ at doses from $\sim 3 \times 10^{20}$ to 7×10^{20} eV g^{-1} are estimated to have an uncertainty of ±8%. The high dose value is in good agreement with that of Harteck and Dondes (2) $G(N_2) = 3.45 \pm 0.35$ at doses from 6×10^{20} to 6×10^{21} eV g^{-1}. The value of Hochanadel *et al.* (3) can be corrected to $G(N_2) = 0.5$, $G(NO_2 + N_2O_3) = 4.90 \pm 0.25$ by using our value of $G(O_3) = 12.8$ (8) instead of their value of $G(O_3) = 13.8$ (9).

The yields in irradiations with the Febetron 706 varied depending on whether a quartz or an aluminum cell was used and were in the range $G(N_2) = 5$ to $G(N_2) = 7$. They were not changed in the addition of SF_6. Similar anomalously high yields have been previously discussed (10).

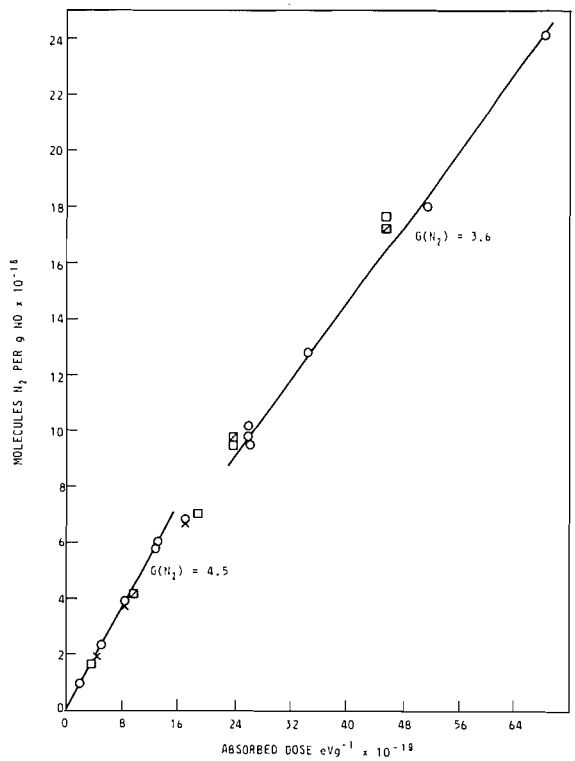

FIG. 1. Amount of N_2 per g of NO as a function of the absorbed dose, Febetron 705 dose rate 2×10^{27} eV g^{-1} s^{-1}: □, 100 kPa NO; ▨, 100 kPa NO 1 kPa SF_6. Gammacell dose rate 2.5×10^{16} eV g^{-1} s^{-1}: ○, 100 kPa NO; ×, 100 kPa NO 1 kPa SF_6.

The results of Febetron 705 irradiations of mixtures of xenon and NO with and without SF_6 are given in Table 1. As will be discussed these were carried out to confirm the explanation proposed for the lack of effect of SF_6 on the yields presented in Fig. 1.

Discussion

Neutralisation Reactions in NO

The data in Fig. 1 and the results obtained with the Febetron 706 show that the addition of 1 mol% SF_6 does not significantly change the values of $G(N_2)$ at dose rates from 2.5×10^{16} to 2×10^{28} eV

TABLE 1. Nitrogen yields from the Febetron 705 radiolysis of Xe–NO mixtures[a]

Sample composition	$G(N_2)$[b]
10 kPa NO + 90 kPa Xe	5.3 ± 0.4
10 kPa NO + 90 kPa Xe + 1 kPa SF_6	1.45 ± 0.1

[a]Dose rate = 5×10^{26} eV g^{-1} s^{-1}; absorbed dose = 2.7×10^{19} eV g^{-1}.
[b]These are the yields based on the energy absorbed by the Xe.

	Reaction	Rate constant (cm^3 $molecule^{-1}$ s^{-1})	Reference
[1]	$N^+ + NO \rightarrow NO^+ + N$	8×10^{-10}	11
[2]	$O^+ + NO \rightarrow NO^+ + O$	$<1.3\times10^{-12}$	12
[3]	$O^+ + N_2 \rightarrow NO^+ + N$	1.2×10^{-12}	13
[4]	$O^+ + NO_2 \rightarrow NO_2^+ + O$	1.6×10^{-9}	13
[5]	$NO_2^+ + NO \rightarrow NO^+ + NO_2$	2.9×10^{-10}	14
[6]	$NO^+ + 2NO \rightarrow (NO)_2^+ + NO$	5×10^{-30}[a]	15
[7]	$e + 2NO \rightarrow NO^- + NO$	8×10^{-31}[a]	16
[8]	$NO^- + NO_2 \rightarrow NO_2^- + NO$	7.4×10^{-10}	17
[9]	$NO^+ + e \rightarrow N + O$	3.1×10^{-7}	18, 19
[10][b]	$(NO)_2^+ + e \rightarrow$ no N or N_2	1.7×10^{-6}	19
[11]	$e + SF_6 \rightarrow SF_6^-$	2.2×10^{-7}	20
[12]	$NO_2^- + NO_2 \rightarrow NO_3^- + NO$	4×10^{-12}	21
[12a]	$NO_3^- + NO \rightarrow NO_2^- + NO_2$	3×10^{-15}	16
[13]	$N + NO \rightarrow N_2 + O$	2.2×10^{-11}	22
[14]	$O + NO + M \rightarrow NO_2 + M$	7×10^{-32}[a]	23
[15]	$O + NO_2 \rightarrow NO + O_2$	9×10^{-12}	24
[16]	$O + NO_2 + M \rightarrow NO_3 + M$	8×10^{-32}[a]	25
[17]	$N + NO_2 \rightarrow N_2O + O$	7.7×10^{-12}	26
[18]	$N + NO_2 \rightarrow NO + NO$	5.9×10^{-12}	26
[19]	$N + NO_2 \rightarrow N_2 + O + O$	2.3×10^{-12}	26
[20]	$N + NO_2 \rightarrow N_2 + O_2$	1.8×10^{-12}	26

[a]Three body rate constant, in cm^6 $molecule^{-2}$ s^{-1}.
[b]The product is presumably 2NO. A similar rate constant has been obtained for $(Kr)_2^+ + e$ (27). If the negative species is NO^- or $(NO)_2^-$ NO is again expected to be the only product.

TABLE 3. Ion lifetimes in irradiated nitric oxide at 100 kPa

Ion	Reaction	Dose rate (eV g^{-1} s^{-1})	Mean lifetime (s)
N^+	$N^+ + NO \rightarrow NO^+ + N$		5×10^{-11}
NO^+	$NO^+ + 2NO \rightarrow (NO)_2^+ + NO$		3.2×10^{-10}
NO^+	$NO^+ + e \rightarrow N + O$	2×10^{27}	$\sim5\times10^{-9}$
		2×10^{28}	$\sim1\times10^{-9}$
e	$e + 2NO \rightarrow NO^- + NO$		2×10^{-9}
$(NO)_2^+$	$(NO)_2^+ + NO^- \rightarrow 3NO$?	2×10^{27}	$\sim2\times10^{-9}$
		2.5×10^{16}	7×10^{-4}
NO^-	$NO^- + NO_2 \rightarrow NO_2^- + NO$	(Dose = 1×10^{19} eV g^{-1})	1.3×10^{-6}

g^{-1} s^{-1}. As all previous studies in many systems (1) have shown that the addition of SF_6 suppresses dissociative neutralisation of the positive ion these results support the suggestion in the Introduction that under the above conditions there is no contribution from neutralisation in pure NO.

To provide a basis for the discussion of this and other features of the radiation behaviour of NO the reactions and lifetimes of ions and radicals that are formed in the radiolysis of NO are listed in Tables 2 and 3. From these tables it can be seen that while the neutralisation of NO^+, reaction 9, is dissociative the positive ion that is neutralised at any dose rate below 10^{29} eV g^{-1} s^{-1} at 100 kPa will be $(NO)_2^+$. The binding energy of the positive ion dimer is 0.59 eV (28) and this will then reduce the available energy released by neutralisation from 9.26 to 8.67 eV. Although this provides an excess of 2 eV over the threshold energy of 6.5 eV it is apparently not enough and this is supported by results obtained in the radiolysis of CO. In CO where the dissociation threshold is 11.16 eV and addition of CO to CO^+ reduces the available neutralisation energy from 14.1 to 13.3 eV (29) there is no decomposition attributable to neutralisation (1). At 10^{26}–10^{27} eV g^{-1} s^{-1} the electron will probably be attached to NO and this ion also may be clustered (17). The electron affinity of NO is small, 0.024 eV (17), but the binding energy of the dimer negative ion is estimated to be 0.5 eV (17). At the Gammacell dose rates the ion lifetime increases to ~1 ms. The positive ion should still be $(NO)_2^+$ but the negative ions will be NO_2^- and NO_3^-. The ratio of these will be dose dependent but as the electron affinity of NO_2 is 2.3 eV (30) and that

[d]Taken arbitrarily as 2 eV above threshold.
[e]Calculated from the relative dissociation cross sections for 100 eV electrons for the various electronic states (38).
[f]G(obs) − G(dissociative ionization).
[g]Minimum excitation energy × G(ion pair)/3 (1).

of NO_3 3.7 eV (17), in neither case will there be enough neutralisation energy available for the dissociation of NO. Thus our N_2 yields, the lifetimes of NO^+ and the electron, and the above energy considerations are all consistent with no dissociation of NO in reaction 10.

The irradiations with Xe were done to provide further support for this mechanism. If charge transfer from Xe to NO is assumed then as the ion pair yield in Xe is 4.5 (31) and its density is higher the amount of NO^+ formed in a 90 mol% Xe, 10 mol% NO mixture will be about four times that in pure NO. The lifetimes of NO^+ and the electron with respect to addition to NO should be increased by a factor of 100. The values in Table 3 show that NO^+ and the electron should then be neutralised before adding to NO. The difference between the yield of nitrogen due to energy absorbed by the Xe in the mixtures without and with SF_6, $\Delta G(N_2)_{Xe} = 5.3 - 1.45 = 3.8 \pm 0.5$, confirms that reaction 9 is dissociative and this dissociation is suppressed by the addition of SF_6 or by the formation of dimer ions.

The results of Hatano and Shimamori (32) suggest a large reduction in the effective rate constant for electron attachment to SF_6 from that for thermal electrons in the irradiation of N_2O–Xe mixtures. We have found, however, that in Febetron irradiations of O_2 with the rare gases (33) that 1 mol% SF_6 appears to scavenge all the electrons in O_2–Xe mixtures containing as little as 6 mol% O_2. We should expect similar behaviour in NO–Xe mixtures.

Dose Dependence

Our yields give $G(N_2) = 3.6 \pm 0.3$ between $\sim 3 \times 10^{20}$ and 7×10^{20} eV g^{-1} and those of ref. 2 give $G(N_2) = 3.45 \pm 0.35$ between 6×10^{20} and 6×10^{21} eV g^{-1}. The reason for this decrease from the initial yield of $G(N_2) = 4.5$ is not clear.

Taking $G(NO_2) = 10$ the ratio of NO_2 to NO at 6×10^{20} eV g^{-1} is only 0.003. This does not appear to be high enough to reduce the yield of N_2 from reaction 13 nor to affect the yield of N atoms from ionic processes. It is possible that NO_2 suppresses the dissociation of excited NO but the efficiency of this quenching would have to be very high.

Energy Balance

The energy balance estimates are given in Table 4. The ion yields are quite precisely known from W value measurements and mass spectra. Assuming that the neutral dissociative excitation yield obtained from the radiation chemical yields is accurate the major problems are the calculations of the average energies in ionization and excitation. We have previously (1) arbitrarily taken the former as 2 eV above the threshold but the data in ref. 34 appear to give a much more reliable value than this. The absolute values of the cross sections in ref. 38 when taken in conjunction with the absolute cross sections for ionization (36) and G(ion pair) = 3.64 give $G(NO \rightarrow N + O) = 1.4$. Although this is apparently 2.5 times smaller than the correct value the error in the relative cross sections should be much less.

Conclusions

The neutralisation of the dimer ion $(NO)_2^+$ by an electron, NO^-, or NO_2^- does not result in the formation of N_2. In agreement with previous work the neutralisation of NO^+ by an electron is dissociative. This dissociation is suppressed when the negative ion is SF_6^-.

The total energy absorbed in the radiolysis of NO can be accounted for by the ion pair yields and radiation chemical yields, the average energies of ionization and neutral excitation and the energy of formation of subexcitation electrons.

Formation and reactivity of the aminothiyl and iminothiyl radicals by means of flash photolysis

OSAMU ITO AND MINORU MATSUDA

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980, Japan

Received October 14, 1977

OSAMU ITO and MINORU MATSUDA. Can. J. Chem. **56**, 1080 (1978).

Flash photolysis of bis[piperidyl-1] disulfide gave a clear transient band at 340 nm and a weak band around 525 nm, which were assigned to the piperidyl-1-thiyl radical. In a similar manner, bis[diphenylimino] disulfide gave a transient band at 420 nm, which could be assigned to the diphenyliminothiyl radical. These radicals disappeared in various solvents according to second-order kinetics with rate constant 0.8–7.2 × 10^9 M^{-1} s^{-1} showing that the radicals decay predominantly by recombination with diffusion controlled rates. These radicals were not reactive toward oxygen, olefins, organophosphorous compounds, and hydrogen donors in agreement with the results given by the kinetic epr study reported by Maillard and Ingold.

OSAMU ITO et MINORU MATSUDA. Can. J. Chem. **56**, 1080 (1978).

La photolyse éclair du bis[pipéridyl-1] disulfure conduit à une bande transitoire claire à 340 nm et à une bande faible autour de 525 nm qui ont été attribuées au radical pipéridyl-1 thiyle. D'une façon semblable, le bis[diphénylimino] disulfure conduit à une bande transitoire à 420 nm qui peut être attribuée au radical diphényliminothiyle. Ces radicaux disparaissent dans divers solvants d'après une cinétique du second ordre avec une constante de vitesse allant de 0.8–7.2 × 10^9 M^{-1} s^{-1} montrant que les radicaux disparaissent principalement par une recombinaison avec des vitesses contrôlées par la diffusion. Ces radicaux ne sont pas réactifs vis-à-vis l'oxygène, les doubles liaisons, les composés organophosphoriques et les donneurs d'hydrogène en accord avec les résultats rapportés pour l'étude cinétique rpe de Maillard et Ingold.

[Traduit par le journal]

Introduction

Dialkylaminothiyl radicals, $R_2NS\cdot$, the sulfur analogues of the dialkylnitroxide radical, have been detected by epr spectroscopy during the thermolysis (1, 2) or photolysis (3) of the corresponding disulfides. From the observed hyperfine coupling constants on nitrogen, the spin distributions were compared with those of nitroxide radical. Using kinetic epr spectroscopy, a useful technique for the kinetic study of radicals, Maillard and Ingold (3) investigated the kinetic behavior of dialkylaminothiyl radicals. The purpose of this study was to obtain the electronic absorption spectra of the aminothiyl radical for comparison with those of nitroxide radical and to estimate their reactivity by means of the flash kinetic spectroscopy. The diphenyliminothiyl radical ($(Ph)_2C{=}N{-}S\cdot$) was also studied.

Experimental

Bis[piperidyl-1] disulfide (ASSA) and bis[diphenylimino] disulfide (ISSI) were prepared by literature methods (3). All the solvents used were spectrophotometric grade. The solutions were degassed, when it was necessary, up to 10^{-5} Torr. A flash photolysis apparatus of standard design (4) delivered a flash with an energy of up to 100 J from xenon-filled flash lamps which exhibited a half-peak duration of 20 μs. The quartz irradiation vessel was 10 cm long and 1 cm in diameter and had optically flat quartz windows at both ends.

Results and Discussion

In Fig. 1, the electronic absorption spectra of disulfides, ASSA and ISSI, are shown. Flash photolyses were made with a band pass filter, which transmits the light between 240 and 400 nm, and appropriate cut-off filters were used so as to avoid the excitation of the solvents and substrates when they were added.

Flash photolysis of ASSA gave a transient absorption spectrum as shown in Fig. 2*a* in which a clear peak was seen at 340 nm and a weak one around 525 nm. Both bands could be observed in both polar and nonpolar solvents. This indicates that the transient species in Fig. 2*a* were not due to the cationic species such as $ASSA^{\ddagger}$ and $AS^{\ddagger}$ which may be formed by the photoejection of an electron from disulfide. The bathochromic shift of the absorption maximum around 340 nm was observed in polar solvents. The slight increase in intensity of this band in polar solvents was also observed. This will be discussed later.

Triplet–triplet transitions also could be ruled out, since these bands were observed even in aerated solutions. Therefore, it is permissible to assign the entity appearing at 340 nm to a free radical species. As possible transient species other than AS· the

unsymmetrical homolytic scission products, A· or ASS·, must also be taken into consideration.

The transient which was tentatively identified as the piperidino radical, A·, produced from *N*-chloropiperidine in neutral aqueous solution was studied recently with the flash photolysis technique by Cessna *et al.* (5). They reported a weakly absorbing transient which decayed by second-order kinetics with $k/\varepsilon_{330\ nm} = 5.1 \times 10^6$ cm s^{-1}. In our study each transient band which appeared at 340 nm in the ASSA solutions also decayed according to the second-order kinetics as shown in Fig. 3, but the slope in the plot for 1/absorbance at 330 nm against time in ethanol gave $k/\varepsilon_{330\ nm}$ of $5.0 \pm 0.7 \times 10^5$ cm s^{-1}, which is one order of magnitude smaller than that for A·. Thus, A· could not be attributed to the transient bands in Fig. 2*a*. As for ASS·, this was not detected in the epr study by Maillard and Ingold of the photolysis of the solution. In the case of dialkyl disulfide (RSSR), it is shown that RSS· could be formed only by the direct (not sensitized) photolysis with short wavelength light such as 195 nm (6). Absorption maxima of RS· having amino acid group on the side chains were reported around 330 nm by means of pulse radiolysis (7, 8), which are in a region similar to the band given in Fig. 2*a*. Furthermore, since the kinetic behavior of the 340 nm band, as described later, agrees with that of AS· given by kinetic epr study, the band at 340 nm can be assigned safely to AS·. Thus, in the photolysis of ASSA reaction 1 may be the main process and other reactions 2–4 could be ruled out in our flash photolysis experiments.

$$[1] \quad \text{ASSA} \overset{h\nu}{\rightleftharpoons} 2\text{AS}\cdot$$

$$[2] \quad \text{ASSA} \overset{h\nu}{\rightharpoonup} \text{ASSA}^{T}$$

$$[3] \quad \text{ASSA} \overset{h\nu}{\rightharpoonup} \text{ASSA}^{+} \text{ (or } \text{AS}^{+} + \text{AS}\cdot) + e^{-}_{solv}$$

$$[4] \quad \text{ASSA} \overset{h\nu}{\rightharpoonup} \text{A}\cdot + \text{ASS}\cdot$$

Maillard and Ingold reported that the rate constant for the recombination (k_r) of AS· in a viscous solvent, *tert*-butylbenzene (η = 38.13 cP at 20°C) is 8.2×10^8 M^{-1} s^{-1} at 23°C with kinetic epr measurements (3). From the flash photolysis technique, only k_r/ε could be observed for the second-order process. In liquid paraffin (η = 21.78 cP), $k_r/\varepsilon_{335\ nm}$ was given as $1.1 \pm 0.1 \times 10^5$ cm s^{-1}. Assuming k_r in liquid paraffin is equal to the value in *tert*-butylbenzene given by epr, ε at absorption maximum (λ_{max}) could be calculated as 7500 ± 800 M^{-1} cm^{-1}. For the dialkylnitroxide radical, two absorption bands have been reported; a strong band at 230–240 nm (ε = 2000–3000 M^{-1} cm^{-1}) and a weak band at 430–450 nm (ε = 5 M^{-1} cm^{-1}) (9). Although the absorption band around 525 nm shown in Fig. 2*a* was not subjected to kinetic analysis because of low intensity, it may be expected that the absorption spectra of AS· and nitroxide radical resemble each other. Supposing that the weak 525 nm band, which may correspond to the weak band at 430–450 nm of nitroxide radical, was due to AS·, ε at this region was calculated from the relative absorbance as less

than 300 M^{-1} cm^{-1}. These comparisons may indicate that by replacement of oxygen in nitroxide radical by sulfur, absorption maxima shift to longer wavelength and intensities increase. This similarity of spectra also supports the assignment of the transient spectra to AS·.

In a similar manner, the transient spectra were given by the flash photolysis of ISSI as shown in Fig. 2*b*. This transient band was observed even in aerated solution and in nonpolar solvent. Thus, this transient band can be attributed to IS· with the same reasons described in the section of AS·. The second-order plot was a straight line giving k_r/ε. Although the absorption spectrum of IS· should be compared with that of the diphenylmethylenenitroxide radical, $(Ph)_2C{=}N{-}O\cdot$, the spectrum of this radical has not been reported. The fact that the absorption maximum of IS· is longer wavelength than the main band of AS· (340 nm) may suggest that an unpaired electron in IS· is delocalized onto π-orbitals.

Both radicals, AS· and IS·, do not react with oxygen dissolved in the solvents (ca. 10^{-3} *M*) (10). With olefins such as hexene-1 (<1 *M*), no promoted decay of the radicals was observed. In the presence of styrene (0.05 *M*), since the absorption of ASSA overlapped with that of styrene, formation of AS· was suppressed. On the other hand, IS· was formed even in the system containing styrene and the decay rate was not affected. Organophosphorous compounds (<0.1 *M*) such as trimethylphosphite and triethylphosphate which are known as effective radical scavengers also did not exhibit any influence on the decay curves of both radicals. Hydrogen donors (ca. 1 *M*) such as toluene, cumene, and tri-*n*-butyltin hydride also did not have any effect on the decay rates. These observations are in agreement with the results obtained by the kinetic epr study by Maillard and Ingold (3).

AS· and IS· are not reactive toward various substrates and decay with recombination reactions as was suggested from Fig. 3. Plotting of k_r/ε_{max} against 1/viscosity gave straight lines as shown in Fig. 4. This linear relationship suggests that the recombination reaction is diffusion controlled and that ε was not affected much by solvent properties such as viscosity and polarity. Thus, k_r for AS· could be calculated using $\varepsilon = 7500\ M^{-1}\ cm^{-1}$ estimated in liquid paraffin, which were summarized in Table 1. In the last column in the table, the calculated rate constants (k_D) from the Debye equation for second-order diffusion controlled reaction (11), $k_D = 8RT/3000\eta$, are listed. As usually indicated, the

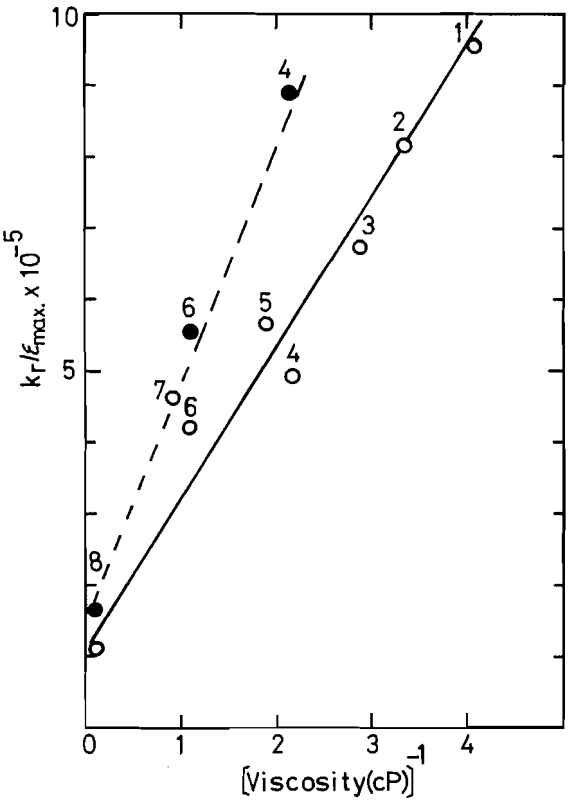

FIG. 4. Plots of k_r/ε_{max} against 1/[viscosity (cP)]. Solvents 1–8 refer to Table 1.

calculated rate constants are about 4 times larger than experimentally obtained ones. As was seen in Fig. 2*a*, intensities of the band of AS· around 340 nm observed in polar solvents such as methylene chloride were considerably larger than those in nonpolar solvents such as *n*-hexane and cyclohexane. The following three factors must be taken into consideration for this reason: high quantum yield for the formation of AS·, large ε value of AS· by the specific interaction with polar solvents, and slow recombination rate in polar solvents. Since this tendency is not dependent both on the deviation of k_r/ε_{max} from the straight line of Fig. 4 and on the k_r value in Table 1, the latter two factors may be discarded.

For IS·, although k_r has not been estimated by the kinetic epr spectroscopy, it may be expected that reactivity is very similar to that of AS· including recombination reaction rate. Assuming that the rate constant for recombination of IS· in paraffin is nearly equal to that of AS·, $k_r \approx 0.8 \times 10^9\ M^{-1}\ s^{-1}$, ε at 415 nm of IS· could be calculated as $5000\ M^{-1}\ cm^{-1}$ and the values of k_r in other solvents are given in Table 2. Since it is well known that the thiyl radicals recombine with diffusion controlled rate (7, 8), it is likely that AS· and IS· resemble RS· rather than the nitroxide radicals.

Heterogeneous metal-insertion: a novel reaction with porphyrins

OTTO HERRMANN, S. HUSAIN MEHDI, AND ALFIO CORSINI
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1
Received December 16, 1977

OTTO HERRMANN, S. HUSAIN MEHDI, and ALFIO CORSINI. Can. J. Chem. **56**, 1084 (1978).

Metal complexes of water-soluble and other porphyrins have been prepared by a heterogeneous reaction with the metal reactant present in an insoluble form. The oxidation state of the metal is important in the reactions. Metal reactants in the lower oxidation states (0, I, II) react with porphyrins but those in the higher oxidation states (III, IV) do not. Metalloporphyrins of high purity may be conveniently prepared by this method.

OTTO HERRMANN, S. HUSAIN MEHDI et ALFIO CORSINI. Can. J. Chem. **56**, 1084 (1978).

On a préparé, par une réaction hétérogène avec le métal réactif présent sous une forme insoluble, des complexes métalliques de porphyrines dont quelques uns sont solubles dans l'eau. L'état d'oxydation du métal est important dans les réactions. Les métaux réactifs dans des états d'oxydation peu élevés (0, I, II) réagissent avec les porphyrines alors que ceux qui existent dans des états d'excitation plus élevés (III, IV) ne réagissent pas. On peut facilement préparé des métalloporphyrines de grande pureté par cette méthode.

[Traduit par le journal]

Introduction

The biological importance of certain metalloporphyrins (1) and the variety of interesting and useful properties that they exhibit (2, 3) make metalloporphyrins a widely studied class of compounds. To date, complexes of porphyrins with over fifty metals and semi-metals have been prepared (3). The methods for preparing metalloporphyrins depend upon the nature of the metal to be inserted and, to a lesser extent, upon the type of porphyrin to be used. In general, however, these preparative procedures involve refluxing the porphyrin with a suitable soluble metal salt or metal complex in an appropriate solvent (4*a*, *b*, 5). We wish to report on a novel heterogeneous reaction for the formation of metalloporphyrins in which the metal to be inserted is present in an insoluble form rather than in solution with the porphyrin.

The heterogeneous metal insertion reaction can be carried out using metal oxides, free metals, metal sulphides, and other insoluble metal salts (e.g., Cu_2Cl_2) in water or in non-aqueous solvents. The method has been used successfully to prepare metal complexes of *meso*-tetra(*p*-sulphophenyl) porphine ($TPPS_4$), hematoporphyrin (HP), protoporphyrin IX dimethyl ester (PPDME), octaethylporphine (OEP), and *meso*-tetraphenylporphine (TPP). This type of metalloporphyrin formation reaction has the immediate advantage over the more conventional methods in that the excess metal reactant can be removed from the product by simple filtration of the solid phase rather than by the tedious methods, often in combination, of extraction, precipitation, dialysis, and chromatography.

Experimental

TPP was prepared as described by Adler *et al.* (6) and sulphonated by the method of Fleischer *et al.* (7). The ammonium salt obtained was purified and converted to the sodium salt by cation exchange. $HP(HCl)_2$, PPDME (both Fluka 'purum'), and OEP (Strem) were used as obtained except that the dihydrochloride was neutralized by dilute alkali before use. Metals and metal oxides of high purity were obtained from Alfa-Ventron, or Fisher Scientific and used as such.

The metallation reaction was carried out as follows. About 50 mg of $TPPS_4$ was added to 100 ml of refluxing distilled, deionized water containing 0.5–1 g of metal oxide or metal. The metal oxide was usually in the form of finely divided powder and the free metal in the form of powder, lumps, turnings, or pellets. In general, since the metals were not as finely divided as the oxides, larger quantities of the former were used. Before the metal was used, its surface was etched with a small amount of dilute hydrochloric acid to dissolve any oxide layer that may have formed and then washed thoroughly with water to remove the acid. Ag and Pb were etched with dilute nitric acid. The mixture was refluxed and kept well stirred for up to 3 days during which time small aliquots were withdrawn to monitor the progress of the reaction spectrophotometrically. Most reactions were complete within 1 h as judged from the change from the four-band visible-range spectrum of the free porphyrin to a two-band spectrum of the metalloporphyrin, and also from the non-appearance of the intense Soret absorption peak at 434 nm corresponding to the porphyrin diacid on addition of acid to the reaction mixture. The latter test is not applicable to the less stable Mg and Ca complexes. The slowest of the successful metallation reactions was with SnO and took about 48 h to reach completion. Collection of the excess solid phase on a 0.22 μ Millipore filter and evaporation of the aqueous filtrate under reduced pressure yielded the metalloporphyrin which was subsequently dried at 120°C *in vacuo*. In the preparation of the $AgTPPS_4$ complex, the mixture of Ag_2O and $TPPS_4$ in water was simply stirred for 2 h at room temperature as refluxing the mixture caused the oxide to peptize, thus rendering it difficult to filter.

A similar procedure was applied to the synthesis of metallo-

porphyrins in organic solvents. For HP, methanol, DMF, or an aqueous alkaline solution were found suitable as solvents for the metallation although the reaction in methanol took somewhat longer to reach completion (e.g., 24 h for CuO), presumably because of the lower reflux temperature. DMF was also used as a solvent for PPDME reactions and mixtures of DMF and chloroform containing 50–75% v/v DMF were found to be suitable for TPP and OEP.

Elemental analyses were performed on selected metal complexes of $TPPS_4$. The highly hygroscopic nature of these complexes and our inability to isolate definite crystalline hydrates made the conventional handling of these compounds for analysis difficult. Thermograms of these complexes were taken (on a Stanton Redcroft TG-750 thermobalance) to determine their water content and their thermal stability. The results showed that the water content varied with the ambient conditions. For example, the $ZnTPPS_4$ complex was found to contain as much as 27.5% H_2O, corresponding to 16.6 mol of water per mole of complex. Gradual weight loss occurred in all the complexes up to about 220°C. Between 220–400°C, an almost constant-weight region was observed. Above 400°C, rapid decomposition occurred. Metal complex samples for analysis were therefore weighed on the thermobalance at 250°C. In addition to analyses for C, H, N, and S, metal determinations were made on the Cu and Zn complexes of $TPPS_4$. About 10 mg of sample was wet-ashed with a 3:1:1 mixture of H_2SO_4, HNO_3, and $HClO_4$ and the metal ion then titrated with standard EDTA. The results of the elemental analyses are presented in Table 1.

Results and Discussion

The high values for % H in the elemental analyses (Table 1) are due to the rapid adsorption of moisture by the complexes after removal from the thermobalance. The values of % C, S, and N remain unaffected by the adsorption of varying amounts of moisture after the samples have been pre-weighed on a thermobalance. Elemental analyses of the other metalloporphyrins prepared in this work were not carried out but evidence of metallation was obtained as described earlier and also by comparison of the visible-region spectrum of the metalloporphyrins with those reported in the literature (4*c*, 9).

Nearly 50 metals or metal oxides were tested for reactivity with $TPPS_4$. The results are summarized in Tables 2 and 3.

As shown by Table 2, primarily only divalent metal oxides reacted with the porphyrin. (Ag_2O, Cu_2Cl_2, CuS, and $PdBr_2$ were also found to react.) None of the trivalent, tetravalent, or mixed M(II)–M(III) oxides (e.g., Fe_3O_4, Ni_3O_4) were reactive. Although certain M(III) species are known to react with porphyrins in solution (10), these reactions are extremely slow because of the high activation energy required to desolvate the metal ion. The higher lattice energy of the M(III) and higher oxides (~2000–4000 kcal/mol vs. ~1000 kcal/mol for the divalent metal oxides (11)) is probably the reason for their lack of reactivity with $TPPS_4$ in the heterogeneous reaction. It appears, however, that such thermodynamic criteria as the lattice energy of the metal oxide and the stability of the metalloporphyrin are

not the only factors that govern the reactivity of the metal oxide with the porphyrin. It is curious that neither PdO (which has a structure similar to that of CuO (12)) nor PdS reacted even though $PdTPPS_4$ is known to be among the most stable of the metalloporphyrins and is readily formed from $PdBr_2$. Perhaps kinetic considerations, governed by the surface properties of the solid, are also involved.

The reactivities of the metallic elements (Table 3) are even more capricious and do not correlate with standard reduction potentials. For example, Ni and Ag did not react (their oxides did) but several elements whose standard electrode potentials are between those of Ni and Ag did react. Ni and Ag were non-reactive even when present in large quantities as a fine powder with a surface area at least as great as in some of the other cases where metalloporphyrin formation was observed.

In spite of prior etching of the metal surface to remove any oxide layers, it is still possible, for at least some of the metals tested, that the reactive species is not the free metal but some other species formed on the metal surface, such as a hydrous oxide. This is certainly true for the reactions of Fe and Mn in which a coating was immediately formed on the metal surface upon the addition of water. With Mn, the formation of the reactive green oxide was readily observed and reaction with the porphyrin followed. In the case of Fe, the reactive species is probably the transitory hydrated ferrous oxide since the higher oxide was found to be unreactive with the porphyrin (Table 2). Thus, the only way to prepare the iron porphyrin heterogeneously is through reaction with the metal. Certain oxide films render the metal unreactive. Cr metal reacted with the porphyrin only after treatment with dilute hydrochloric acid. Use of sulphuric acid rendered the metal unreactive.

Spectral properties of metalloporphyrins formed by the heterogeneous reaction showed that the oxidation state of the metal in the complex is that which is usually stabilized by the porphyrin (13). Thus, Ag(II), Fe(III), Cr(III), and Mn(III) are all cases where the higher oxidation state is stabilized. The oxidation state of Sn in $SnTPPS_4$ is not certain. Its stability to 1 *M* hydrochloric acid suggests that it is a Sn(IV) complex (13). In the remaining complexes, including that of Co, the metal was in the divalent state.

With HgO, PbO, Pb, MgO, and CaO, adsorption of the porphyrin on the surface of the metal or the metal oxide was found to be a serious problem and substantial amounts of porphyrin were lost. Other metal oxides also adsorbed the porphyrin but usually in much smaller amounts.

An interesting reaction of $TPPS_4$ is the direct extraction of copper from certain ores (e.g., chalcopyrites), from copper-rich alloys such as brasses and from a Cu–Ag–Be alloy. The possibility exists that the heterogeneous reaction may be useful in the selective extraction of certain metals, notably Cu because of its facile reaction, from ores and alloys. However, the non-reactivity of silicate-containing ores and the surface adsorption of the porphyrin may limit the usefulness of such an approach.

The stoichiometry of the heterogeneous oxide reaction is:

$$[1] \quad M(II)O(s) + H_2TPPS_4(aq) \rightleftharpoons M(II)TPPS_4(aq) + H_2O$$

where H_2TPPS_4 designates the hydrogens in the porphyrin centre. For the zero-valent metals, two possible reactions exist. One possibility is that, as in the case of Fe and Mn, surface oxidation by dissolved oxygen in the solvent occurs; the metal-insertion would then occur as by reaction 1.[1] The second possibility is:

$$[2] \quad M^0(s) + H_2TPPS_4(aq) \rightleftharpoons M(II)TPPS_4(aq) + H_2$$

When low concentrations of the porphyrin are used (as under our conditions), the amount of hydrogen gas evolved would be very small and thus difficult to detect. Ostfeld and Tsutsui (3) have represented the reaction of zero-valent metal complexes with porphyrins by a similar equation.

The most useful aspect of the heterogeneous metallation of porphyrins lies in the simplicity of the preparation of metalloporphyrins, particularly those of water-soluble porphyrins. In the conventional procedures with $TPPS_4$ and other water-soluble porphyrins, the excess metal salt is usually separated from the product by repeated precipitation from aqueous methanol (7) or by dialysis (8) and high purity of the metalloporphyrin is difficult to achieve. As the stoichiometry of the heterogeneous reactions shows (reactions 1 and 2), the product is not contaminated by counter-ions, excess metal, or acid provided that the solid phase is highly insoluble. In cases where the metal oxide is slightly soluble (MgO, CaO, ZnO, Ag_2O, HgO, PbO), simple reduction in the volume of the reaction mixture and refiltration through the 0.22 μ Millipore filter result in an appreciable reduction in contamination.

With the water-insoluble porphyrins, representa-

[1]Controlled experiments for the formation of $CuTPPS_4$ from the metal were carried out in two stoppered cuvettes at room temperature. Oxygen gas was bubbled through one and nitrogen through the other. Reaction occurred in both cases but was faster in the presence of excess O_2, indicating that the oxide mechanism [1] is likely significant in the reaction of metals with $TPPS_4$ but that reaction [2] cannot be ruled out.

tive reactions with Cu, CuO, and NiO only were carried out. In general, the reactions in non-aqueous solvents were slower. NiO, for example, which reacted with $TPPS_4$ in less than 2 h, took about 2 days to completely react with OEP in DMF/chloroform. The choice of the non-aqueous solvent is important, especially for OEP and TPP. In both chloroform and DMF, TPP failed to react with CuO. However, in mixtures containing 50–75% v/v DMF with chloroform, reaction readily occurred. These solvent mixtures provided both a suitably high refluxing temperature and sufficient solubility of the porphyrins and metalloporphyrins. Also, these mixtures optimized the surface adsorption/desorption effects of the porphyrins. Such factors explain why some solvents are more suitable than others in the heterogeneous reaction.

A study of the adsorption of formic acid and related molecules onto evaporated copper films, both clean and oxide-covered, by infrared ellipsometric spectroscopy

ROBERT WILLIAM STOBIE AND MICHAEL JOHN DIGNAM

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received October 28, 1977

ROBERT WILLIAM STOBIE and MICHAEL JOHN DIGNAM. Can. J. Chem. **56**, 1088 (1978).

Species formed on evaporated copper surfaces, both clean and oxide-covered, were examined using ir ellipsometric spectroscopy (IRES). Spectra were obtained for CO adsorbed on both bare and oxide-covered copper, the spectra being in accord with published data. No spectra were observed for formic acid adsorption unless free oxygen was present, in which case a spectrum characteristic of a carbonate species was found. Supporting data were obtained to show that the carbonate species was formed by reaction of formic acid and oxygen on the oxide-covered surface. These data illustrate some of the unique advantages of IRES for studying molecular processes on surfaces.

ROBERT WILLIAM STOBIE et MICHAEL JOHN DIGNAM. Can J. Chem. **56**, 1088 (1978).

Faisant appel à la spectrométrie ir ellipsométrique (IRES), on a étudié les espèces qui se forment sur des surfaces de cuivre évaporé, soit propre ou couverte d'oxyde. On a obtenu le spectre du CO adsorbé soit sur du cuivre nu ou couvert d'oxyde; le spectre est en accord avec les données publiées. On n'a observé aucun spectre lors de l'adsorption d'acide formique à moins d'avoir de l'oxygène libre présent; dans ce cas, on a trouvé un spectre caractéristique d'un carbonate. On a obtenu des données permettant de montrer que les carbonates se forment par une réaction de l'acide formique et de l'oxygène sur la surface couverte d'oxyde. Ces données permettent d'illustrer quelques-uns des avantages uniques de l'IRES pour étudier les processus moléculaires sur les surfaces.

[Traduit par le journal]

Introduction

In a previously reported investigation (1) ir ellipsometric spectroscopy (IRES) was used to study the adsorption of CO on evaporated Cu films. This paper represents a continuation of those studies and is concerned with the adsorption of formic acid and related molecules, CO and CO_2, onto evaporated Cu films and oxide-coated Cu films.

Hiroto *et al.* (2) studied adsorption of formic acid on samples of copper, nickel, and zinc dispersed in silica with the dispersions formed by decomposition of the appropriate formate salt. They found that it chemisorbed strongly on Zn and Ni, and the spectra showed clearly the presence of formate bands. With copper the formate bands were much weaker and they disappeared as the free formic acid was pumped out of the cell. Unfortunately the authors were not very quantitative about the pressure dependence of the bands, but it seems that the formic acid desorbed fairly easily. In addition, Tamaru (3) measured the adsorption and decomposition of formic acid on copper powders at temperatures as low as 65°C.

A number of absorption bands have been observed by Amerikov and Katsatkina (4) for adsorption of CO_2 on CuO which were attributed to both carbonate and carboxylate species. No similar results have been reported for Cu_2O.

Tompkins and Greenler (5) found bands at 2113 and 2135 cm^{-1} for CO adsorbed onto 'heavily oxidized' copper surfaces (thickness unknown). They found that the area of the low frequency band decreased as the high frequency band appeared.

Experimental

A description of our instrument, as well as an analysis of the ellipsometric technique employed, has been presented elsewhere (6, 7). The results reported here were obtained using a LN_2 cooled HgCdTe detector and 150 lines/mm grating blazed at 6 m in a 0.5 m monochromator with a slit width of 1.5 mm. The primary digital data, appearing on paper tape, were computer processed and graphed. In addition to carrying out the algebraic manipulations, the processing involved a sliding polynomial fitting procedure for data smoothing, the parameters in this process being chosen so as not to degrade the resolution.

The ultra-high vacuum and gas handling systems are described in our earlier investigation (1).

The reflection cell was fitted with two tungsten electrical feedthroughs each supporting a tantalum filament for depositing the copper films onto the optical flats (see Fig. 1). The copper was deposited from 99.99% pure wire stock to form opaque films within 5 to 10 s. The pressure rose to above 10^{-8} Torr during evaporation, falling to about 10^{-9} Torr within 30 s.

The gases, O_2 (99.99%), H_2 (99.99%), CO (99.5%), and CO_2 (99.5%) were passed through LN_2 traps when introduced into the gas handling system. The formic acid was Analar grade, and was dried by a vacuum distillation from a dispersion with anhydrous copper sulfate in the manner of Kishi, Ogawa, and Hiroto (8).

In a typical experimental run, the copper films were evaporated, then following 1 to 2 min to allow time for cooling, a blank or reference state ellipsometric scan was performed. This generally took about 10 min, following which the gas was introduced into the cell and another scan was performed.

Results and Discussion

The ellipsometric absorbance and dispersion spectra (Re(ΔL) and Im(ΔL) respectively vs. wave number) were calculated from the measured ellipsometric parameters, Δ and Ψ, using the relation (1)

$$[1] \qquad L = -[\ln(\tan\Psi) + i\Delta]$$

where $i = \sqrt{-1}$, ΔL is the change in L brought about by absorption, and Re and Im stand for 'the real part of' and 'the imaginary part of' respectively. As noted earlier (1), (2/2.303)Re(ΔL) is indistinguishable within experimental error from the conventional base 10 reflectance absorbance for p-polarizer light. For further details see ref. 1.

When formic acid was introduced into the cell no absorption bands due to adsorbed species were observed either in the C—H region or between 2000 and 1200 cm^{-1} where the carbonyl and formate bands are found. The very intense gas phase absorption limits the pressure that can be used while maintaining a reasonable signal level, so that it was not possible to study 'physically adsorbed' formic acid without going to low temperatures or a very short cell. Nevertheless, the region between the gas phase peaks at 1740 and 1380 cm^{-1} was scanned with a background pressure of 15 Torr (about 0.37 relative pressure) but no formate bands were observed. Finally the cell was filled with formic acid at about 20 Torr, heated to 150°C, allowed to cool, and then pumped out. Still no spectrum was observed although the increase in transmission during the heating phase indicated that approximately 75% of the formic acid had decomposed.

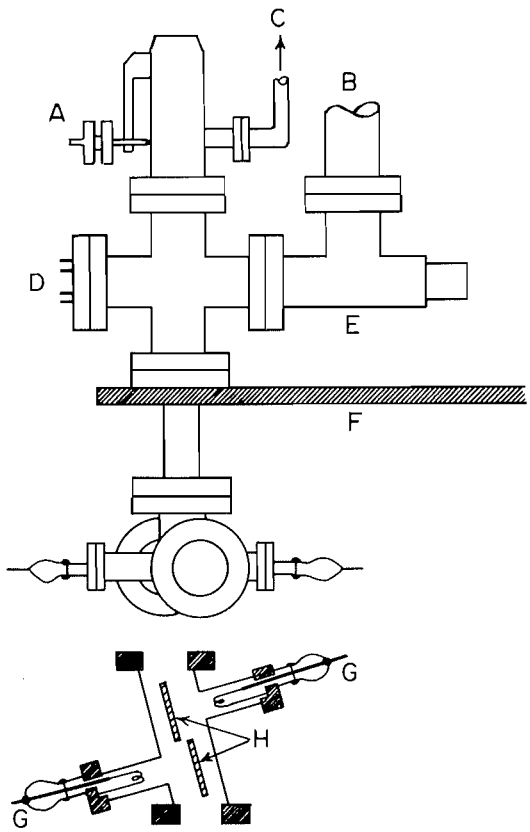

FIG. 1. Ultra-high vacuum reflection cell with leak valve A, ionization gauge head D, and isolation valve E.

Adsorption of acetic acid was tried with similar negative results.

Since oxides of copper are moderately active catalytically, the effect of oxidizing the surface before adsorption was investigated. This provided an opportunity to illustrate the versatility of the ellipsometric spectrometer since it was used without modification to monitor the oxide film growth. For films which are not strongly absorbing, the changes in Im(L) are much larger than those in Re(L), so that ellipsometry is much more sensitive to the presence of the film than is photometry (9).

The oxidation was carried out by admitting 1–10 Torr of O_2 to the cell after evaporation of the copper film. The thickness was then calculated from Im(ΔL) using O'Keefe's (10) value of 6.46 for the dielectric constant of the film and the thin film high reflectivity approximation which simplified the calculations while introducing negligible error. The film thicknesses determined in this way varied between 0.8 and 1.2 nm from film to film.

In one case the film growth was followed as a function of time with the instrument set at a fixed wavelength and at an averaging time of 8 s. The results are shown in Fig. 2 where they have been fitted to a logarithmic equation of the form

$$[2] \qquad d = A + B\ln(\alpha t + 1)$$

Equation 2 is frequently used to describe oxide film growth, particularly on copper, although its theoretical foundation is rather shaky (11). However, it gives very similar curves to the theoretically more sound Mott–Cabrera model (12).

Optical determinations of the thickness of thin oxide films have been criticized on the grounds that the early stages of the film growth often involve nucleation followed by lateral growth (13). However, Dignam and Moskovits (14) have shown that for submonolayer island films the simple optical

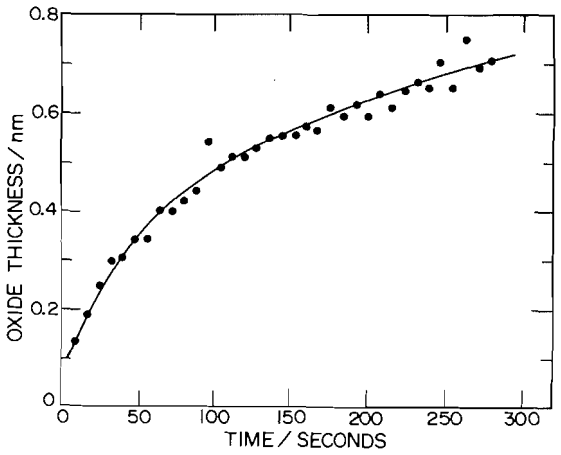

FIG. 2. Oxide film thickness vs. time obtained by ir ellipsometry (O_2 pressure = 2.7 Torr, T = 20°C).

model is valid: the dielectric constant is predicted to be independent of coverage while the calculated film thickness is proportional to it.

Although the oxidation of copper has been studied extensively as a classis example of corrosion (see a review by Ronnquist and Fischmeister (15)), most studies have either been of anodic oxidation (e.g. Dignam and Gibbs (16)) or else gas phase oxidation at high temperature or in unusually corrosive atmospheres. Below 150°C Cu_2O is formed almost exclusively, while above that CuO predominates. The work done at room temperature has shown that very thin oxide films are characteristic of the reaction. From measurements of oxygen uptake on evaporated copper Allen and Mitchell (17) calculated that films of 2.4 nm were formed at 20°C. Rhodin (18) carried out a detailed kinetic study on single crystal surfaces at several temperatures up to 50°C. His gravimetric measurements showed that layers of 0.8 to 1.4 nm thick (depending on the crystal face) were formed at 25°C in a matter of 10 to 20 s independent of pressure in the region 10–100 Torr and that continued exposure for up to a month did not result in significant further growth. The rate observed here is somewhat less than Rhodin's, although comparable to that of Allen and Mitchell. Induction times in accord with those of Heineman *et al.* (19) were observed at low pressures.

After the copper had been oxidized, the O_2 was pumped out of the cell before introducing formic acid. The cell was only pumped down to about 100 microns, however, to reduce the possibility of contamination by backstreaming from the fore pump. Instead of formate bands in the region of 1650 to 1410 cm^{-1}, the spectrum shown in Fig. 3 was observed. The band peaks fall at 1625 and 1380 cm^{-1}. As this spectrum was obtained with a HgCdTe

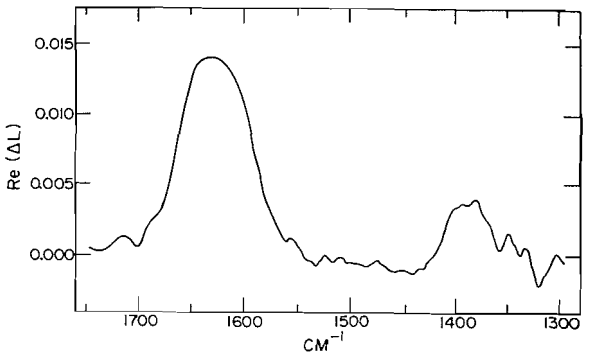

FIG. 3. Absorption spectra of species formed on copper in the presence of formic acid and free oxygen.

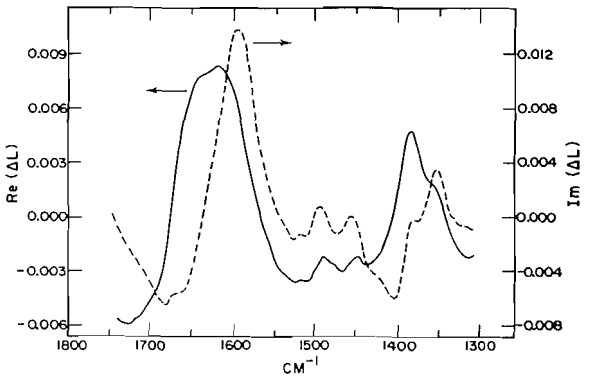

FIG. 4. Absorption and dispersion spectrum of species formed as for Fig. 3, obtained without use of a background or 'bare surface' ellipsometric scan.

detector, rather than the higher detectivity InSb detector used for the previously reported CO studies (1), somewhat poorer quality spectra were obtained. A drop in quality was also caused by absorption due to atmospheric water whose bands intrude into this spectral region.[1] Both Re(ΔL) and Im(ΔL) are shown again in Fig. 4 with the difference that they were obtained without using a bare metal scan. The background spectrum was fitted to a straight line then subtracted from L to produce the spectra (1). It should be noted that although the atmospheric absorption bands have a good deal of structure in this region, they make no detectable contribution to the ellipsometric absorption spectrum, as expected (1).

This species was found to be strongly adsorbed; pumping for up to an hour (down to 10^{-7} Torr) did not cause a measurable reduction in the strength

[1]Dry air was flushed constantly through the box containing the 'input' optics but it was impossible to eliminate all the water vapour bands. This was largely because it was necessary to open the box to remove the polarizers every time the cell had to be aligned.

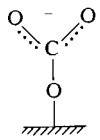
of the absorption bands. Introduction of H_2 into the cell also had no measurable effect on the spectra.

The spectrum is almost certainly due to a carbonate species. Little (20) has summarized the bands due to CO_2 or CO plus O_2 adsorbed onto various substrates. By analogy with the solution spectra of various carbonate species of known structure he ascribes them to different forms. Evidently the species that is being formed here has the structure



The conditions under which it can be formed are also of interest. If the formic acid is admitted first, nothing is observed until the O_2 is also admitted, as would be expected from the earlier experiments. If the formic acid is admitted in doses (up to 3000 *L*) and then pumped off, nothing is observed even after admission of the oxygen. This supports the contention that the formic acid did not chemisorb on the bare copper. If the oxygen is admitted first and then the formic acid, the spectrum obtained is identical to the first case. If the oxygen is admitted and then pumped off, nothing is observed on admitting the formic acid. This indicates that formic acid does not react with chemisorbed oxygen or very thin oxide layers to form a surface carbonate, but it does not necessarily show that it would not react with bulk cuprous oxide. Cu_2O is known to absorb large amounts of oxygen (21) so that there would be a substantial amount of free O_2 available for reaction. Formic acid adsorbed on powdered Cu_2O might easily show carbonate bands.

To investigate this further, CO and CO_2 were also adsorbed on the oxidized copper. None of the procedures followed with the formic acid lead to carbonate bands with CO_2, or indeed, to any bands at all. London and Bell (22) observed a broad band at 2350 cm^{-1} from physically adsorbed CO_2, but the intense atmospheric absorption from the asymmetric stretch in the present study attenuated the signal too strongly to permit any experiments in this frequency range.

Carbon monoxide also gave rise to no carbonate bands on oxidized copper even in the presence of oxygen. It did, however, give two broad bands at 2115 and 2160 cm^{-1}, as shown in Fig. 5, in general agreement with those found by Tompkins and Greenler (5) at 2113 and 2135 cm^{-1} on their most heavily oxidized surfaces. The low resolution makes it difficult to pinpoint the location of these bands

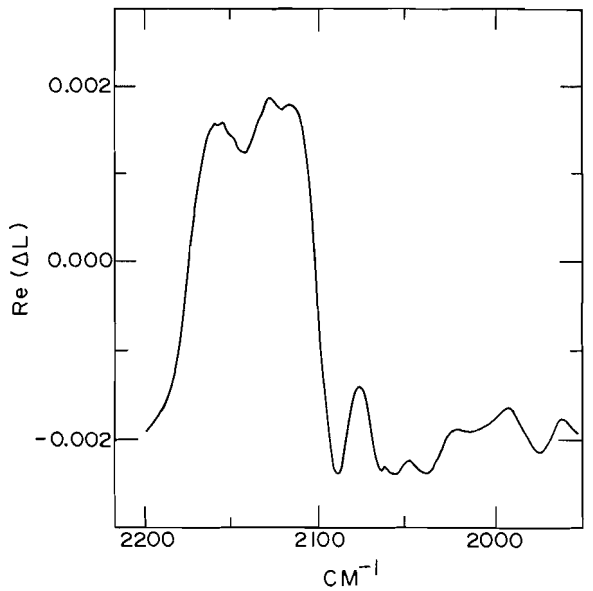


FIG. 5. Absorption spectrum for CO on oxide-covered copper.

exactly, but on dispersed samples peak positions have been reported to depend on the precise method of sample preparation (for example, see Seanor and Amberg (23), or Eischens and Pliskin (24)).

Smith (25) studied the oxidation of carbon monoxide on copper and copper oxide at low temperatures. In addition to the CO band he observed weak bands at 1520 and 1375 cm^{-1} which he felt were due to carbonate species. However, these were formed only after prolonged oxidation and they partially desorbed with pumping.

The data strongly support a model in which the species is formed by the direct interaction of formic acid and oxygen on the surface rather than involving gaseous intermediates. Thus although formic acid could have decomposed or been oxidized on the cell walls or in the gas phase to give either CO or CO_2, and undoubtedly this did occur to some extent, no carbonate bands were observed with either of these gases.

When the carbonate band at 1625 cm^{-1} was first observed, it was felt that it might be due to adsorbed water, since the water bending mode falls at 1595 cm^{-1} in the gas phase. Water was admitted to the cell over both bare and oxidized copper, with and without gaseous O_2, but no bands were detected. While water would almost certainly adsorb under these conditions, the molecules may very well be oriented with the transition dipole parallel to the surface, in which case the band would not be observable (1).

Attempts were also made to obtain spectra for

nitric oxide adsorbed on bare copper. No spectra have ever been reported for adsorption on copper, and none were observed in this work, even with pressures as high as 30 Torr.

Summary and Conclusions

The work reported herein was conducted in part to explore the capabilities of IRES for investigating molecular processes on well defined metal surfaces. Our current studies are on single crystal surfaces for which the technique was developed, but the results reported herein illustrate a number of the unique advantages of IRES for such studies. These include: (*1*) structural information achieved much more readily than through LEED or ARUPS say; (*2*) high sensitivity to surface species coupled with vanishingly low sensitivity to species in the gas phase, in contrast to conventional reflectance or transmittance photometric spectroscopy; (*3*) speed of data collection compared to electron loss spectroscopy, ARUPS, or a complete LEED analysis; (*4*) non-destructive nature of the measurement compared with electron spectroscopies, LEED and ARUPS; (*5*) ability to function in the presence of moderate ambient pressures in contrast to all techniques involving electron emission or absorption.

In the present study it was shown for the first time that oxygen and formic acid react on Cu_2O covered copper to form a chemisorbed carbonate species with a symmetric stretch at 1380 cm^{-1} and an asymmetric stretch at 1625 cm^{-1}. Both these modes correspond to transition dipole moments along the symmetry axis of the molecular species, and hence presumably normal to the metal surface. If this were not the case, then other stretching modes (corresponding to degenerate modes for CO_3^-) should be present since they would correspond to transition dipole moments with components normal to the surface. Parallel components are for all practical purposes infrared inactive.

The weakness of this argument lies of course in the fact that there may be overlapping bands. Isotopic substitutions would be required to test that possibility. The fact remains that orientational information is available in the ir spectrum of molecular species adsorbed onto metal surfaces.

Valence-bond studies of 4-electron 3-centre bonding units. I. The π-electrons of O_3, NO_2^-, and CH_2N_2

RICHARD D. HARCOURT AND WALTER ROSO

School of Chemistry, University of Melbourne, Parkville, Victoria 3052, Australia

Received May 26, 1977

RICHARD D. HARCOURT and WALTER ROSO. Can. J. Chem. **56**, 1093 (1978).

Some *ab-initio* valence-bond wave-functions are reported for the π-electrons of the ground-states of O_3, NO_2^-, and CH_2N_2. Examination of these wave-functions provides further support for the hypothesis that, for the ground-states of many electron-excess molecules, important valence-bond structures are those that are compatible with the electroneutrality principle, i.e. they carry either small or zero formal charges on each of the atoms. For O_3 and CH_2N_2, the important valence-bond structures with zero atomic formal charges are

Each of these structures has a 'long-bond' between non-adjacent atoms. The significance of 'long-bond' (or spin-paired diradical) structures for the electronic mechanism of 1,3-dipolar cycloaddition reactions is discussed and 'increased-valence' descriptions of the electronic structure of each molecule are presented. Some comments on the utility of 'increased-valence' structures are provided.

RICHARD D. HARCOURT et WALTER ROSO. Can. J. Chem. **56**, 1093 (1978).

On rapporte quelques fonctions d'onde valence-liaison calculées par des méthodes *ab initio* pour des électrons π des états fondamentaux de O_3, NO_2^- et CH_2N_2. Un examen de ces fonctions d'onde fournit un support additionnel à l'hypothèse selon laquelle pour les états fondamentaux de plusieurs molécules possédant des électrons en excès, les structures importantes de liaison de valence sont celles qui sont compatibles avec le principe de l'électroneutralité c'est-à-dire celles où les charges formelles portées par chaque atome sont ou très faibles ou égales à zéro. Pour O_3 et CH_2N_2, les structures importantes de liaison de valence avec des charges formelles atomiques de zéro sont

Chacune de ces structures possèdent une liaison longue entre deux atomes non-adjacents. On discute de la signification des structures à liaisons longues (ou du diradical à spin pairé) pour le mécanisme électronique des réactions de cycloadditions dipolaire-1,3 et on présente des descriptions d'augmentation de valence de la structure électronique de chaque molécule. On fournit quelques commentaires sur l'utilité des structures d'augmentation de valence.

[Traduit par le journal]

Introduction

For electron-excess molecular systems, a very important type of triatomic bonding unit involves four electrons distributed amongst three overlapping atomic orbitals located on three atoms (1–4). The resulting 4-electron 3-centre bonding is usually described qualitatively by means of either delocalized 3-centre molecular orbital theory or by valence-bond resonance theory (1–4). The simplest type of valence-bond description involves resonance between the standard valence-bond structures **1** and **2**, each of which has an electron-pair bond between adjacent atoms and a lone-pair of electrons on the third atom. This valence-bond representation shows perhaps more immediately than does a molecular orbital description that 4-electron 3-centre bonding must be an extremely widespread phenomenon; it is possible to write down Lewis–Langmuir valence-bond structures for thousands of molecular systems in which the valence-bond arrangements of **1** and **2** pertain for one or more sets of four electrons (1, 3, 4). Further, these bonding units may be either intra- or intermolecular. Larger *n*-centre bonding units (for example, 6-electron 4-centre) with additional atoms, overlapping atomic orbitals and electrons, represent elaborations of the basic 4-electron 3-centre bonding unit. The purpose of this and subsequent papers is to report the results of some non-empirical valence-bond calculations for a number of molecules that involve either or both of these types of bonding units.

In contrast to what is the case for molecular orbital theory, few valence-bond wave-functions have been reported for the ground-states of systems with 4-electron 3-centre bonding units. Of those that have been reported (4–19) (and they range from semi-empirical to *ab-initio*), most show up what we consider to be an important (but much-ignored) result, namely that the bond-eigenfunction coefficient for the 'long-bond' structure **3** can have appreciable magnitude. Indeed, its magnitude is sometimes calculated to be larger than those for either of the standard valence-bond structures **1** and **2**. This is particularly the case when **1** and **2** carry atomic formal charges as in

$$\overset{(-)}{\dot{Y}}\ \overset{(+)}{A}\text{—}B \quad \text{and} \quad Y\text{—}\overset{(+)}{A}\ \overset{(-)}{\dot{B}}$$

and **3** does not. The ramifications of this result for qualitative valence-bond theories of structure and reactivity are very considerable (see for example, refs. 14, 20, 21). Very often, it is not sufficient to write down valence-bond structures of types **1** and **2**, and then hope to obtain a realistic representation for the electronic structure of the molecule. Where appropriate, **3** must be included also. In numerous papers, this has been done (1, 3, 4, 14, 20, 21), and new types of valence formulae (namely, the 'increased-valence' formulae of the next paragraph) have been generated that summarize resonance between the standard and 'long-bond' (or spin-paired diradical) structures **1**, **2**, and **3**. (Of course, valence-bond structures of types **4**–**6** are also needed to form a complete valence-bond basis set for a singlet-spin state involving 4-electron 3-centre bonding.) One purpose of the present series of papers is to provide further quantitative evidence that important valence-bond structures for the ground-states of electron-excess molecules carry either small or zero atomic formal charges, and that such structures may often be of type **3**. The formal charge requirement is compatible with the electroneutrality principle (22).

It may be noted that resonance between all valence-bond structures that do not involve 'long-bonds' may be summarized by using 2-centre bond orbitals instead of Heitler–London wave-functions as the wave-functions for the electron-pair bonds that occur in the standard valence-bond structures **1** and **2** (*1*, 3*b*, 4–10). To include the 'long-bond' structure also, another type of valence formula is needed. For this purpose, the 'increased-valence' formulae **7** and **8** have been devised (1, 3, 4, 14, 20, 21). These formulae have one more bonding electron than have any of **1**–**3** and may be easily generated from the standard valence-bond structures **1** and **2** by delocalizing a non-bonding Y or B electron into a bonding YA or AB orbital, as is shown in **9** and **10**. Because the 1-electron bond A·B summarizes resonance between the valence formulae A $\dot{\dot{B}}$ and $\dot{A}$ B, it is easy to demonstrate that **7** and **8** summarize resonance between **1** and **3**, and **2** and **3**, respectively if Heitler–London type wave-functions are used to describe the A—B and Y—A bonds of **7** and **8**. Alternatively, if localized molecular orbitals (or bond-orbitals) are used to describe these bonds in **7** and **8**, resonance between these 'increased-valence' formulae is equivalent to invoking resonance between all of the valence-bond structures **1**–**6** when Heitler–London type wave-functions are used to describe the electron-pair bonds of **1**–**3** (1, 3*b*, 4, 14*c*). Linnett's non-paired spatial orbital formulae **11** (2, 5–10) may also be used to summarize resonance between the standard and 'long-bond' valence-bond structures **1**–**3**, as well as **4**. Both 'increased-valence' and non-paired spatial orbital formulae will be used in the discussions for this series of papers.

Because of limitations to our computing facilities (we have used a CYBER 72, CDC 6400 computer, with a store capacity of 64K words of central memory), it has not been possible to perform all-electron calculations on many of the triatomic and polyatomic systems that we have selected to study. Therefore, we have restricted our attention to a consideration of the different types of valence-bond structures that arise from variations in the distributions of only some of the electrons, namely, those that could delocalize appreciably. For non-linear planar molecules, these electrons were usually either some or all of (*a*) the π-electrons, and (*b*) the lone-pair π′-electrons occupying atomic orbitals that overlap appreciably with the orbitals of σ-bonds. On occasions, we have also allowed for the polarization of certain localized σ- or π-bonds, and when this was done, additional valence-bond structures were introduced into the calculations. For a calculation, it was possible to take account of 6 atoms, 20 atomic orbitals, 20 electrons, and 25 valence-bond structures. When the number of structures that we could write down exceeded 25, we have used chemical intuition and the electroneutrality principle to decide which structures should be included in the treatment.

In the present paper, we shall report the results of valence-bond calculations for the π-electrons of O_3, NO_2^-, and CH_2N_2. We are currently preparing for publication other papers that describe the results of similar types of valence-bond calculations for the

For personal use only.

σ-electrons of HF_2^-, and the π- and π′-electrons for a number of nitroso and nitro compounds, and the oxalate anion.

Method of Calculation

Since completing this work, Gerratt (23) has published a review of valence-bond theory. We shall briefly summarize the procedure that we have used to construct the Hamiltonian and overlap matrix elements for the valence-bond secular equations of [2]. These equations pertain to the linear combination of [1], in which the ψ_i represent the normalized bond-eigenfunctions for the different canonical valence-bond structures.

$$[1] \qquad \Psi = \sum_{j=1}^{N} C_j \psi_j$$

$$[2] \qquad \sum_{j=1}^{N} (H_{ij} - ES_{ij})C_j = 0$$

(*a*) As basis atomic orbitals, we have used single-zeta Slater-type orbitals (STO's) with the 'best atom' orbital exponents of Clementi and Raimondi (24). For the hydrogen 1*s* exponent, Hehre and Pople's value of 1.3 (25) was used. The optimization of exponents in valence-bond calculations makes heavy demands on computer time, and we have not attempted to do this for the polyatomic systems.

(*b*) The bond-eigenfunction for a valence-bond structure involves a linear combination of Slater determinants. Numerous procedures are available for the construction of the appropriate spin eigenstates (23, 26). Because we have been concerned only with singlet ($S = 0$) and doublet ($S = \frac{1}{2}$) spin-states, it is possible to use the simple rule described by Kauzmann (27) to construct the spin eigenfunctions. The branching diagram indicates the existence of spin-degeneracy for systems that involve three or more singly-occupied orbitals (23, 26). The procedure that we have used generates the spin-eigenfunction that is appropriate for the electron-pairing scheme of a given valence-bond structure. The ground-state eigenvectors for [1] that we shall report pertain when both Ψ and the ψ_i bond-eigenfunctions are normalized to unity.

(*c*) To evaluate the Hamiltonian and overlap matrix elements (H_{ij} and S_{ij}) of [2], we have used Löwdin's cofactor method (28).

(*d*) To calculate the 1-electron and 2-electron integrals over atomic orbitals for the H_{ij} and S_{ij}, the STO's were expressed as linear combinations of cartesian Gaussian functions (CGF's), γ_i^{CG}, as in [3] (29). The optimum linear combination of CGF's was determined by Stewart (29) for STO exponents (ξ) of unity. Non-unity values for the exponents are used by scaling (30, 31) the CGF exponents of [3], i.e. by writing $\alpha_i = \alpha_i'\xi^2$. Equation 3 may then be expressed as eq. 4. To avoid using spherical harmonics, the CGF's in [4] were replaced by the simpler lobe Gaussian functions using $R = 0.03\alpha^{-1/2}$, in which R is the distance of the lobe centre from the nucleus (30). The resulting STO is given by [5].

$$[3] \qquad \psi_{STO}(\zeta = 1, r) = \sum_{i=1}^{N} a_i \gamma_i^{CG}(\alpha_i, r)$$

$$[4] \qquad \psi_{STO}(\zeta, r) = \sum_{i=1}^{N} a_i \gamma_i^{CG}(\alpha_i'\zeta^2, r)$$

$$[5] \qquad = \sum_{i=1}^{N} a_i \gamma_i^{LG}(\alpha_i'\zeta^2, R, r)$$

The number of Gaussian components, N, used in all calculations was five (30). When testing the valence-bond procedure, we found that this number is the minimum required to give valence-bond wavefunctions that agree closely with some published STO calculations for LiH (31).

(*e*)With the current valence-bond program, which was prepared by one of us (W.R.), it is possible to perform one or more of the following types of calculations. (*i*) *All-electron calculations*: For certain diatomic and small polyatomic molecules, the program permits all of the electrons to be included specifically in the construction of the Slater determinants to form the bond-eigenfunctions. Minimal atomic orbital basis sets were used in calculations of this type for LiH, HF, CO, and HNO. (*ii*) *All-valence-electron calculations*: For larger molecules, we were unable to treat explicitly all of the electrons, and therefore we have invoked the approximations described here and (*iii*) below. For all-valence electron calculations, only the valence-shell electrons and orbitals are included in the construction of the bond-eigenfunctions. Inner-shell electrons are treated as part of the core, whose charge is equal to the nuclear charge minus the number of inner-shell electrons. We have tested the validity of this approximation by comparing the results of valence-bond calculations for HNO when procedures (*i*) and (*ii*) are both used. These calculations will be described in the second paper of this series. (*iii*) *Hamilton's approximation*: Many of the molecules that we have examined have rather more than 20 valence-shell electrons and orbitals. For them, it was necessary to invoke Hamilton's approximation (11, 32), and include only some of the valence-shell orbitals in the Slater determinants. The remaining electrons are assigned to the core, and are considered only in the calculation of penetration integrals. When this is done, Hamilton's approximation involves the neglect of all electron exchange, except for that which occurs between the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

electrons explicitly included in the Slater determinants. In Part II of this series, we shall compare calculations for FNO and HF_2^- using Hamilton's approximation and either all-valence electron or all-electron procedures.

(*f*) In our discussions of the valence-bond wave-functions, we shall follow Maclagan and co-workers (33) by assuming that the bond-eigenfunction ψ_i whose coefficient has the largest magnitude in the ground-state valence-bond wave-function of [1] represents the most important valence-bond structure. Because the ψ_i are not orthogonal, the weights for the valence-bond structures are not equal to C_i^2. However, an inspection of the structural weights and coefficients for an *ab-initio* study of C_6H_6 (34) indicates that the magnitudes for these two quantities correlate approximately (but *not* exactly) with each other, in so far as if a coefficient C_i has a large magnitude, then the valence-bond weight (or occupation number (34)) is also large.

To ensure correct functioning of the program, valence-bond wave-functions were calculated for a number of systems for which such wave-functions have been reported previously by other workers. Our results for an all-electron calculation for LiH are reported in Table 1, where they are compared with those of Miller *et al.* (31). The calculation of Linnett and co-workers (9) for the formate anion, with Hamilton's approximation, was repeated. Exact agreement between our calculations and those of Linnett *et al.* was not expected, because the latter workers approximated some of the molecular integrals, whereas we have evaluated them accurately. The two wave-functions are the following, for which the bond-eigenfunctions are defined in ref. 9.

Linnett and co-workers (9)

$$\Psi = 0.273\psi_1 + 0.415\psi_2 + 0.168\psi_3 + 0.078\psi_4$$

This work

$$\Psi = 0.278\psi_1 + 0.404\psi_2 + 0.178\psi_3 + 0.075\psi_4$$

Experimental bond-lengths (35) have been assumed for all calculations. The bond-angles for O_3 and NO_2^- were approximated to 120° and 116° respectively.

Results

(a) Ozone and Nitrite

The ground-states of O_3 and NO_2^- each have four π-electrons distributed amongst three overlapping atomic orbitals. Linnett and co-workers (6, 10) have calculated valence-bond wave-functions for these systems, using Hamilton's approximation. Our results for this type of calculation, and also those for all-valence electron calculations, are reported in Tables 2 and 3. For comparison, eigenvectors obtained by other workers (4, 6, 10) are also reported in these tables.

Each calculation indicates that the bond-eigenfunction ψ_3 for the valence-bond structure with a 'long' OO π-bond has a coefficient with a large magnitude. This is particularly the case for O_3, and is in accord with the electroneutrality principle in so far as the valence-bond structure carries zero formal charges on all atoms. On the basis of their generalized valence-bond calculations, Goddard and co-workers (17) have concluded that O_3 is primarily a diradical rather than a zwitterion, and that the 'long' OO π-bond structure best represents the electronic structure of this molecule. They have used this valence-bond structure to discuss the Criegee mechanism of ozonolysis of olefins (17).

For O_3 and NO_2^-, the standard valence-bond structures that are most usually displayed are the Lewis–Langmuir octet structures 1 and 2 of Tables 2 and 3. However, because the bond-eigenfunction for the 'long-bond' octet structure 3 of either table is also calculated to be important, it is necessary to include this type of structure in the valence-bond representation for the ground-state. This may be done either by writing down the 'long-bond' structure together with the other structures, or by devising valence formulae that summarize resonance between all of these structures. These latter formulae may be

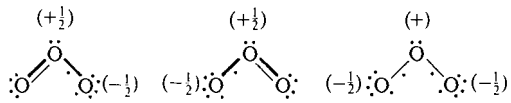
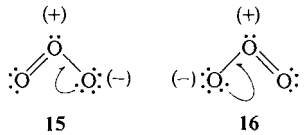
4		0.0391	0.0670	0.110
5		0.0571	0.0674	0.108
6		0.0571	0.0674	0.108

*Hamilton's approximation for the four π-electrons.
†All valence electrons in Slater determinants. Gould and Linnett (6) have calculated $\Psi = 0.351(\psi_1' + \psi_2') + 0.390\psi_3' + 0.124\psi_4' + 0.028(\psi_5' + \psi_6')$, in which the ψ_i' are non-normalized bond-eigenfunctions.

either of the 'increased-valence' (1, 3, 4, 14, 20, 21) or non-paired spatial orbital type (2, 5–10). For O_3, these valence formulae are either **12** + **13** (3*a*, 4, 14*b*) or **14** (3, 4, 6). We may generate the 'increased-valence' formulae **12** and **13** from the standard valence-bond formulae by delocalizing a non-bonding π-electron from a terminal oxygen atom into a bonding OO π-orbital, as is shown in **15** and **16** (1, 4, 20, 21).



12 **13** **14**



15 **16**

For O_3, 'increased-valence' formulae **17** and **18** may also be generated which carry zero formal charges on all atoms (3*a*, 20*b*, 36). These are obtained by delocalizing an in-plane π′-electron as well as a π-electron from the (−ve) oxygen atom. In the calculations of the present paper, no delocalization of the π′-electrons has been taken account of for either O_3 or NO_2^-. For each of these systems, and for CH_2N_2, we have also not allowed for any polarization of OO, NO, CN, or NN σ-bonds. Therefore, valence-bond structures such as **19**, **20**, and **21** have been omitted from the calculations, even though the absence of formal charges for them might suggest that they may be important structures. However, these structures are not required to interpret reactions of these molecules that involve only the breaking of their π-bonds. The '1,3-dipolar' cycloadditions that are to be discussed in the next section form one such class of reactions.

Electronic mechanisms for reactions such as $X + O_3 \rightarrow XO + O_2$, with X = H or NO, are described in ref. 36. They utilize 'increased-valence' structures **17** and **18** for O_3 and its diradical character.

(b) Diazomethane

Diazomethane has two sets of π-electrons. The standard valence-bond structures are **1** and **2** of Table 4. They each involve four π- and two π′-electrons. Huisgen (37) has classified both O_3 and CH_2N_2 as 1,3-dipolar molecules, and has assumed that the sextet valence-bond structures 5 and 6 of Table 2, and 4 and 5 of Table 4 are the important structures for a concerted mechanism for 1,3-dipolar cycloaddition reactions. An alternative concerted mechanism has been proposed (38) for this class of reaction, which utilizes the 'long-bond' (or spin-paired diradical) structure of type 3 in both Tables 2 and 4 rather than the sextet structures. More recently, Goddard and Walch (18) have also concluded that the spin-paired diradical structure for CH_2N_2 is important for a description of the electronic structure and cycloaddition reactions of this molecule. The results of our valence-bond calculations provide further support for this hypothesis.

We shall report here the results of two valence-bond calculations, each of which utilizes the Hamilton approximation. The first calculation includes explicitly only the six π-electrons in the Slater determinants, whereas the second also includes two CN σ-electrons and two CC σ-electrons. Twelve valence-bond structures were considered that differ in the positions of the six π-electrons. These structures are displayed in Table 4, together with the eigenvectors for the two sets of calculations. The hybridizations for the central nitrogen atom, and the carbon atom, were assumed to be *sp* and sp^2 respectively.

In Table 4, the valence-bond wave-functions have similar sets of coefficients. They indicate that the most important of the bond-eigenfunctions is that which pertains to the 'long-bond' structure 3, with zero formal charges on all atoms. The bond-eigenfunction coefficients for the zwitterionic structures 1 and 2 are smaller than are those for 3. As is the case for O_3, the absence of formal charges in the 'long-bond' structure 3 may be responsible for the importance of its bond-eigenfunction. Structure 7 also carries zero formal charges on all atoms, and the coefficient for its bond-eigenfunction also has appreciable magnitude. Each of these results is in accord with what we would deduce from the electroneutrality principle.

The important valence-bond structures for the Huisgen mechanism of 1,3-dipolar cycloaddition are structures 4 and 5 of Table 4. For the six-electron valence-bond calculation, the coefficients for the bond-eigenfunctions for these structures are 0.1044 and 0.0473. These are much smaller than the 0.3068, 0.2297, and 0.3770 for the bond-eigenfunctions that pertain to the zwitterionic and 'long-bond' structures 1, 2, and 3. Although it is possible that the importance of the sextet structures increases as a 1,3-

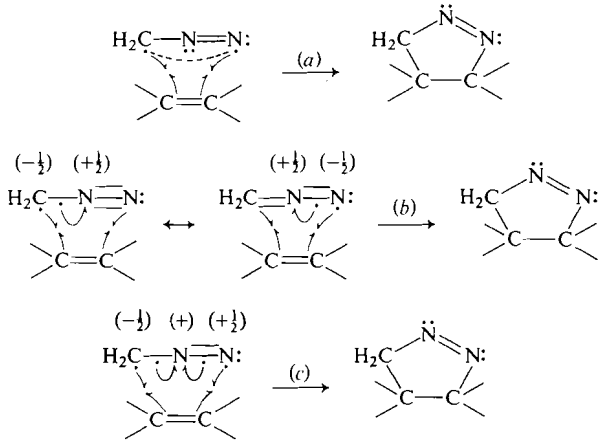

FIG. 1. Electronic mechanisms for 1,3-dipolar cycloaddition reactions.

dipolar cycloaddition reaction proceeds, it may be more favourable energetically to assume that the 'reactive' structures are those that are important for the valence-bond representation of the ground-state of the 1,3-dipolar molecule. Of these latter structures, 3 is calculated to be the most important. If we use structure 3 alone, we may devise a simple mechanism for cycloaddition, namely that of *a* of Fig. 1. This mechanism has also been postulated recently by Goddard and Walch (18). It does not involve a reorganization of the atomic formal charge distribution as the reaction proceeds, and therefore it is compatible with the observed lack of solvent dependency on the rate of cycloaddition (37, 39).

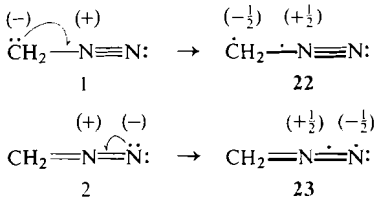
The 'increased-valence'formulae **22** and **23** for CH_2N_2 (38) may be generated from the zwitterionic structures 1 and 2 of Table 4, by delocalizing a carbon and a (terminal) nitrogen non-bonding π-electron into a bonding CN or NN π-orbital. Resonance between these 'increased-valence' structures summarizes resonance between the valence-bond structures 1, 2, and 3 of Table 4. If we use **22** and **23** to represent the electronic structure of CH_2N_2, the mechanism for 1,3-dipolar cycloaddition becomes that of *b* of Fig. 1 (38). Alternatively, use of the Linnett non-paired spatial orbital formula **24** gives the cycloaddition mechanism (*c*) of Fig. 1.[1] Each of these electronic mechanisms depends on the contribution of the spin-paired diradical structure 3 of Table 4 to the description of the electronic diazomethane.

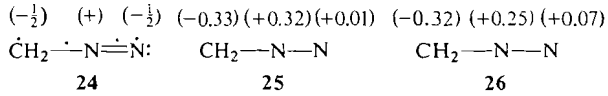
The wave-functions of Table 4 generate the atomic formal charges of **25** and **26**. Both calculations locate a small formal positive charge on the terminal nitrogen atom, and rather larger negative and positive formal charges on the carbon atom and the central nitrogen atom. A comparison of these formal charges with those of **22** and **23** might lead to the conclusion that **22** is the more important of the two 'increased-valence' formulae.

[1]Firestone has formulated mechanism (*c*) as a two-step mechanism (39). See ref. 38 for some comments on the electronic aspects of this procedure.

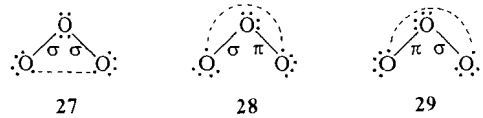
Some Comments on the Utility of Increased-valence Formulae

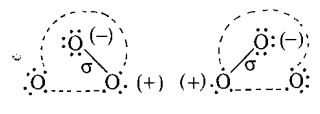
When Heitler–London procedures are used to construct wave-functions for the A—B and Y—A bonds of 'increased-valence' formulae **7** and **8**, these structures provide an economical (and easily-derived) method for summarizing resonance between the standard and 'long-bond' structures **1–3**.[2]





For O_3 and CH_2N_2, the economy gained by using 'increased-valence' formulae **12**, **13**, **22**, and **23** instead of the standard and 'long-bond' structures of Tables 2 and 4 is obviously not great. But if a molecule has two or more sets of 4-electron 3-centre bonding units, as has O_3 with standard valence-bond structures **15** and **16**, then the economy that is obtained by using 'increased-valence' formulae **17** and **18** is rather more considerable. Resonance between these latter structures is equivalent to invoking resonance between the standard structures **15** and **16** and the 'long-bond' structures **27–31**.





[2]The $S = 0$ wave-function for **7** is $|y\bar{\psi}_{ya}a\bar{b}| + |\psi_{ya}\bar{y}b\bar{a}|$, with $\psi_{ya} = ky + a$ and $k > 0$ (1, 3, 4, 14*b*). This wave-function may be expressed as $k(|y\bar{y}a\bar{b}| + |y\bar{y}b\bar{a}|) + |y\bar{a}a\bar{b}| + |a\bar{y}b\bar{a}|$, which is a linear combination of the bond-eigenfunctions for the standard and 'long-bond' structures **1** and **3**.

If at least some of the 'long-bond' structures are required to provide an elementary valence-bond description of certain molecules, it then does not become easy to make deductions about bond properties when these structures are written down together with the standard valence-bond structures. For example by writing down the 'long-bond' structures **27–29** with zero formal charges as well as the standard valence-bond structures **15** and **16**, one does not obtain an obvious understanding of why the OO bond-lengths of 1.28 Å for O_3 are closer to the OO double-bond length (1.21 Å) than to the single-bond length (1.48 Å). This is because although **15** and **16** alone imply some double-bond character for the OO bonds, each of **27–29** has only OO single bonds. Although inclusion of the 'long-bond' structures in the resonance description must lower the energy, the nearest-neighbour bond-orders (or bond-numbers) *seem* to be reduced in value. Inclusion of additional 'long-bond' structures such as **30** and **31** must lead to a further lowering of the energy. However, because each of these latter structures has only one (nearest-neighbour) OO single-bond, a further reduction in the (nearest-neighbour) OO bond-order might be deduced. Therefore we *seem* to obtain a paradoxical situation when 'long-bond' structures as well as standard valence-bond structures are used to represent the electronic structure of a molecule, namely, that inclusion of the 'long-bond' structures lowers the energy but *seems* to reduce the nearest neighbour bond-orders. This paradox arises because simply writing down the standard and 'long-bond' structures does not provide an obvious way to show the effect of resonance on nearest-neighbour bond orders. One way to resolve this difficulty is to use 'increased-valence' formulae such as **17** and **18** for O_3 to represent the electronic structure. We have already indicated that **17** and **18** summarize resonance between the standard and 'long-bond' structures **15**, **16**, and **27–31**. But by inspection of **17** and **18**, we can easily make the appropriate deductions about the OO bond properties. Each of these structures has an O_2 ground-state type double-bond (O÷O) and a weakened O_2 excited-state type double-bond (O═O). Therefore by using 'increased-valence' formulae **17** and **18** as a method to summarize resonance between the standard and 'long-bond' structures **15**, **16**, and **27–31**, we ensure that inclusion of the 'long-bond' structures both lowers the energy and increases the OO bond-orders relative to the values that pertain for resonance between the standard structures **15** and **16** alone. The 'increased-valence' formulae take account of the effect of resonance on nearest-neighbour bond-order in a manner which is identical to that which pertains when the valence structure A·B for a 1-electron bond is used to summarize resonance between the structures $\dot{A}$ B and A $\dot{B}$. Neither of the latter two structures alone has an AB bonding electron, but resonance between them generates AB bonding, which is indicated quite clearly by means of the valence structure A·B.

Received November 16, 1977

KARNAIL S. ATWAL, RINALDO MARINI-BETTOLO, IGNACIO H. SANCHEZ, THOMAS Y. R. TSAI, and KAREL WIESNER. Can. J. Chem. **56**, 1102 (1978).

The construction of the C/D ring system of the alkaloids chasmanine and napelline by modification and rearrangement of a common intermediate is explored on model compounds.

The phenolic acid **9** was oxidized to the spirolactone **10**. Addition of benzyl vinyl ether to this material gave the adduct **28** in high yield. This central 'nordenudatine' type intermediate was then modified (in a very few stereospecific steps) to the 'napelline' model compound **47** and to the keto acetal **38**. Compound **38** is an intermediate of our photochemical route and we have already described its conversion to a chasmanine model derivative.

The new syntheses of chasmanine and napelline foreshadowed by the present model studies are expected to be completely stereo- and regiospecific, almost 10 steps shorter and an order of magnitude more efficient than the total syntheses of these two alkaloids which we have reported in the recent past.

Incidentally, with these model studies, the methoxy ketone **20** was prepared. The methoxyl in this compound is epimeric to the corresponding (C16) methoxyl of the aconite alkaloids. Some relevant observations on the nmr spectra and allylic rearrangement (pyro–isopyro rearrangement) of this material are also reported.

KARNAIL S. ATWAL, RINALDO MARINI-BETTOLO, IGNACIO H. SANCHEZ, THOMAS Y. R. TSAI et KAREL WIESNER. Can. J. Chem. **56**, 1102 (1978).

On étudie, sur des composés modèles, la possibilité de construire les systèmes des cycles C/D des alcaloïdes chasmanine et napelline par une modification et une transposition d'un intermédiaire commun.

On a oxydé l'acide phénolique **9** en spirolactone **10**. L'addition d'éther benzylvinylique à ce composé conduit à l'adduit **28** avec un bon rendement. On a alors modifié cet intermédiaire central de type "nordénudatine" (à l'aide de quelques étapes très stéréospécifiques) pour conduire au composé modèle **47** "napelline" et au céto-acétal **38**. Le composé **38** est un intermédiaire dans notre voie photochimique et nous avons déjà décrit sa transformation en un dérivé modèle de chasmanine.

On prévoit que les nouvelles synthèses de la chasmanine et de la napelline préconisées par les présentes études modèles seront complètement stéréo- et régiospécifique, qu'elles comporteront dix étapes de moins et seront au moins 10 fois plus efficaces que les synthèses totales de ces deux alcaloïdes qui ont été rapportés récemment.

Incidemment, avec ces études modèles, on a préparé la méthoxy cétone **20**. Le groupe méthoxy de ce composé est en position épimère par rapport au groupement méthoxy correspondant (C16) des alcaloïdes de l'aconite. On rapporte aussi quelques observations appropriées concernant les spectres rmn et la transposition allylique (transposition pyro–isopyro) de ce composé.

[Traduit par le journal]

Introduction

We have shown (1) that a route proceeding via denudatine-type intermediates is very advantageous for the construction of polysubstituted C19 aconite alkaloids and very recently we have successfully completed a stereospecific total synthesis of the alkaloid chasmanine **I** using such a route (2). In this synthesis the denudatine-type intermediate **II** was constructed by a modification (3) of our photochemical method, rearranged to the oxopyrochasmanine derivative **III**, and this compound was simply functionalized to chasmanine **I**.

In another recent publication we have disclosed a shorter and better method (4) for the construction of the C/D ring system of the alkaloid denudatine based on the addition of a dienophile to a masked *o*-quinone system.

In the present communication we wish to discuss model experiments which pave the way to a much more efficient construction of the chasmanine intermediate **II** by this *o*-quinone method. The versatility of the approach will be further demonstrated by a successful model study for a new synthesis of the alkaloid napelline **IV**.

Our first napelline synthesis (5) proceeded via the intermediate **V**. The C/D ring system of this compound was constructed by a method which was quite lengthy in spite of containing novel features.

It will be seen in the sequel that a stereospecific synthesis of the C/D ring system of compound **V** may be accomplished with unexpected simplicity by the *o*-quinone route.

Discussion

The starting material for the present study was the *p*-quinone **1** described by Meinwald and Wiley (6). This material was converted to the methoxy derivative **3** which was our 'stand-in' for the chasmanine aromatic intermediate **VI**.

A stereo- and regiospecific synthesis of compound **VI** by our aziridine rearrangement method refined by several improvements is currently underway on a large scale.

Cleavage of the methoxyl in compound **3** by boron tribromide gave the corresponding phenol **4** in a yield of 89%.[1]

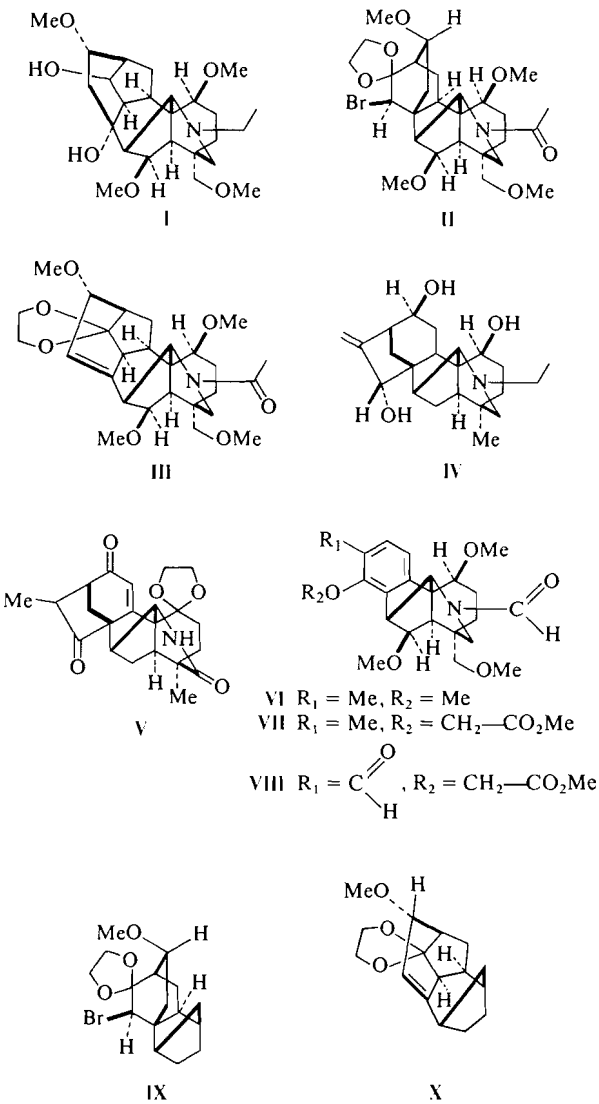
The phenol **4** was next converted into the dithiane derivative **5** using the recently published method of Gassman and Amick (7). Compound **5** was alkylated by methyl bromoacetate to the dithiane ester **6** and the dithiane function in this material was cleaved in the presence of mercuric oxide to give the ester aldehyde **7** in high yield. Baeyer–Villiger oxidation of compound **7** proceeded in a yield of 86% and gave the formate methyl ester **8**. Finally, saponification of compound **8** yielded the phenolic acid **9** and the system was set up for oxidation into the spirolactone according to Berney and Deslongchamps (8).[2]

The oxidation of the phenolic acid **9** by *N*-bromosuccinimide yielded a brilliant reddish-brown solution of the spirolactone **10**, which was immediately treated with an excess of methyl vinyl ether at 0°C. The red color faded in 40 h and the adduct **11** was isolated in an overall yield of 79%. It melted over a range of 99–107°C in agreement with the fact that it was a mixture of two epimers.

Saponification of the adduct **11** by methanolic sodium carbonate yielded 91% of the sharply melting diketone **12** (mp 124–125°C). Compound **12** showed in the infrared (ir) spectrum maxima at 1750, 1737, and 1657 cm^{-1} for the diketone and double bond. The nuclear magnetic resonance (nmr) spectrum displayed the typical doublet for the vinylic hydrogen at $\tau = 4.2$ ($J = 6$ Hz), which we have already encountered in our photochemical approach to this system (2,3), and a methoxyl singlet at $\tau = 6.67$.

The diketone **12** was converted to the sharply melting tosylhydrazone **13** and this compound was reduced by lithium borohydride to the alcohol **14** which also melted sharply at 183–184°C.

Compound **14** was then heated under reflux in dilute methanolic hydrochloric acid with acetyl acetone and the crystalline epimeric mixture **15** was obtained in a yield of 85%. The ratio of the epimers was 3:1 and they were separated for spectral charac-



SCHEME 1

[1]This reaction cannot be applied to the polymethoxylated derivative **VI**. However, a selective cleavage of the aromatic methoxyl in this compound has been achieved in a high yield by the thioethoxide ion. Spectral data will be given in the Discussion only in specially relevant cases to conserve space. Full characterization of all compounds may be found in the Experimental.

[2]In the synthesis proper the rather inefficient dithiane method will be replaced by a direct oxidation of the aromatic methyl group in the intermediate **VII** to the aldehyde **VIII**. This reaction has been shown to proceed under controlled conditions in a yield of 90%. The present example is one of many which have convinced us that the progress of total synthesis depends at least as much on strategy as on new methods.

terization by preparative thin-layer chromatography (tlc). The fact that only a certain amount of epimerization but no α-ketol rearrangement had taken place followed from the subsequent transformations which finally resulted in a connection with our photochemical model series (1). The structures of the photochemical model compounds were in turn supported by an X-ray analysis of the final product.

The ketols **15** were then transformed to the crystalline mixture of the corresponding mesylates **16** and this material was reduced with lithium in liquid ammonia. The resulting alcohol was not characterized, but it was immediately oxidized with the chromium trioxide – pyridine complex and the ketone **17** was obtained in an overall yield of 70%.

Hydrogenation of **17** over rhodium-on-alumina in methanol, followed again by reoxidation with the chromium trioxide – pyridine complex finally gave the saturated ketone **18** in a yield of 89%. The configuration of the newly created chiral centre followed rigorously from the subsequent correlation with our photochemical model series (1).

Bromination of the methoxy ketone **18** with liquid bromine in ether yielded 88% of the bromoketone **19** which melted sharply at 82.5°C. The nmr spectrum of compound **19** showed clearly a narrow doublet at $\tau = 5.78$ ($J = 2.2$ Hz) for the proton unshielded by bromine. However, it was the outcome of the subsequent rearrangement step and its requirement of antiplanarity which enabled us to assign to the bromoketone the configuration **19**.

The bromoketone was heated to 125°C in dimethylsulfoxide (DMSO) and 1,5-diazabicyclo[4.3.0]non-5-ene. The rearrangement product **20** was obtained in a 76% yield as sharply melting colorless plates (mp 77.5°C).

Compound **20** showed in the ir spectrum maxima at 1760 and 1633 cm^{-1} for the ketone and double bond and its ultraviolet (uv) spectrum (λ_{max} 214.5 (log ε 3.5) and 232 nm (log ε 3.2)) was 'anomalous' as a result of orbital overlap. In the nmr spectrum the vinylic proton gave a broad singlet at $\tau = 4.87$.

We prepared for comparison the epimer of compound **20** from one of our photochemical intermediates (*vide infra*). The nmr spectrum of this derivative **21** shows the vinylic hydrogen signal as a doublet ($J = 6$ Hz) at $\tau = 4.51$. It is significant that the vinylic hydrogen signal of **21** resembles very closely the corresponding signal given by the aconite alkaloid pyroderivatives and is very different from the vinylic hydrogen signal of the epimer **20**.

Thus it seems that the nmr signal of the vinylic hydrogen in the pyroderivatives may be used with confidence as evidence for the configuration of the C(16)-methoxyl in delphinine-type alkaloids.

We attempted to achieve a correlation of the unsaturated ketone **20** with our photochemical series (1) by eliminating the methoxyl via an allylic rearrangement. However, this rearrangement (called the pyro–isopyro rearrangement in the corresponding alkaloid derivatives) was unsuccessful in the presence of the keto group, possibly owing to the interaction of this function with the double bond.

Consequently, compound **20** was reduced with sodium borohydride to the alcohol **22** and this material was heated in acetic acid with *p*-toluene sulfonic acid. Under these conditions the desired allylic rearrangement indeed occurred, but the secondary hydroxyl was simultaneously esterified with acetic acid. The product **23** was converted to the known (1) ketone **24** by saponification and oxidation with the chromium trioxide – pyridine complex. As we have already pointed out, the structures in the photochemical model series have been verified by X-ray crystallography.

In spite of the fact that the allylic rearrangement was acid catalyzed and consequently one would not expect it to depend on the configuration of the leaving methoxyl group, the outcome of this reaction was much cleaner and the yield higher with the methoxyl in the epimeric configuration (1). Thus, it seems that the ejection of the protonated methoxyl might be assisted by a concerted attack of a solvent molecule on the double bond, provided the methoxyl and the solvent molecule are sterically correctly disposed (9). However, no firm statement can be made on this aspect of the rearrangement without a careful quantitative study which we are not going to undertake.

The compound **21** was prepared from the known (1) photochemical intermediate **25**. This product was deketalized and the ketone **26** was brominated to the bromo ketone **27**. Rearrangement of the bromo ketone in DMSO with strong base gave the product **21** in a 90% yield.

Before concluding this section we should point out that the rearrangement of the α-bromo ketone had been tried but it failed with the corresponding full fledged chasmanine intermediate (2). When the reaction was allowed to proceed for a very long time, the only observable product was the debrominated ketone. On the other hand the rearrangement of the α-bromo ketal went, in the synthesis proper, smoothly and in high yield (2). This is probably due to the greater ease of the rearrangement in the model system which is lacking two rings. It is clear that the ejection of a leaving group from a position α to a ketone is easier if the keto group is masked.

In principle it might be possible to enter the series of 'natural' C(16) epimers (i.e. compounds with the methoxyl in the same configuration as **21**) via the allylic rearrangement of compound **22** and a sub-

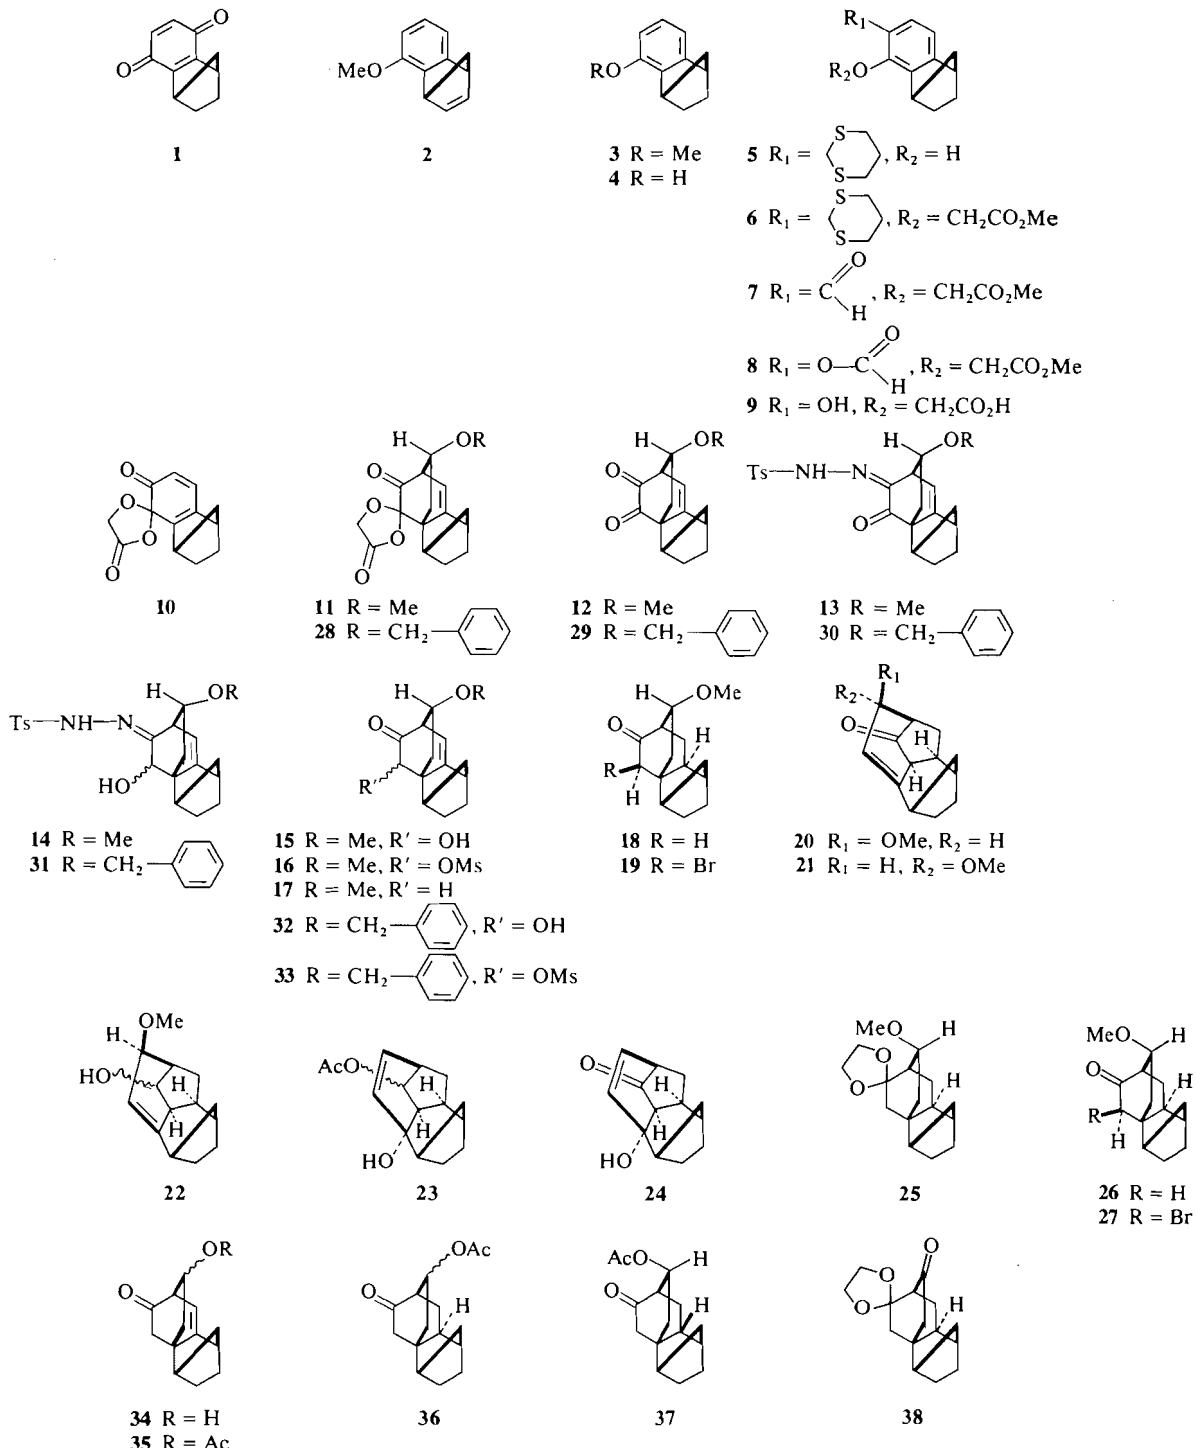

SCHEME 2

sequent transformation of the symmetrical double bond into a methoxyl with the desired configuration. However, in view of the poor yield of the allylic rearrangement in the 'unnatural' series and several other considerations this idea was abandoned. Instead we decided to make a fresh start and use, in the initial diene addition, a dienophile which would enable us to invert the configuration of the substituent destined to become the methoxyl.

The solution of the spirolactone **10** prepared in

the manner already described was treated with an excess of benzyl vinyl ether and the crystalline mixture of the epimeric adducts **28** was obtained in an overall yield (from compound **9**) of more than 80%. The adducts **28** were now converted (via the intermediates **29**, **30**, **31**, and **32**) to the mixture of the epimeric mesylates **33** using a reaction sequence precisely analogous to the one described above for the adducts **11**. The major and the minor component of the mixture **33** were both crystalline compounds and they were obtained in a ratio of 6:1. The major component was hydrogenated over 10% palladium-on-charcoal and the hydrogenolysis product **34** was obtained in a yield of 87%. Compound **34** is an aldol and it is a mixture of epimers since the hydroxyl is able to equilibrate by a retro aldol reaction – aldol condensation mechanism in the acidic hydrogenation medium and during the isolation process. Moreover, this material proved to be identical with the same mixture which was an intermediate of our photochemical approach (3) and had already been converted (via the compounds **35**, **36**, and **38**) to the bromo acetal **IX** (Scheme **1**) and hence to the rearranged product **X**.

Since the identification of mixtures lacks rigour, we continued the synthesis by the method already described (3) to the keto ketal **38** and proved the identity of this material with the corresponding photochemical intermediate. The details of this work are in the Experimental. It should be pointed out that all steps in this sequence were stereospecific except for the hydrogenation **35** to **36** and **37** which is stereoselective in a ratio 3.2:1. This hydrogenation, however, operates with complete stereospecificity in the synthesis proper as we had opportunity to verify in our recent total synthesis of chasmanine (2).

The minor epimer of the mesylate mixture **33** was resistant to hydrogenation, but both epimers gave the aldol **34** on reduction with calcium in liquid ammonia in a yield of 68%. Thus, the highest yield in the hydrogenolysis step is obtainable if the epimers **33** are separated, the major one is hydrogenated over palladium-on-charcoal and the minor one reduced with calcium in liquid ammonia.

The potential chasmanine synthesis foreshadowed by the model series **28** → **38** would be seven steps shorter than our recent total synthesis of this alkaloid (2) in which the photochemical C/D ring system construction was used.

The only flaw in the process **28** → **38** was the necessity of removing a substituent from the intermediate **33** which had to be subsequently reintroduced. This necessity results from the fact that we have been unable to control the stereochemistry in the reduction **29** → **32**. Moreover, in the rearrangement of the denudatine-type intermediate **IX**, bromine is required as a leaving group and we have been unable to introduce this substituent by displacement. However, even a stereospecific conversion of **30** into the correct epimer of **33** and a displacement of the mesyloxy group in this material by bromide would have saved only one step in comparison with the process which succeeded.

We shall turn now to the discussion of our studies directed toward a facile modification of the adduct **28** to the tetracyclic diketone **47**. This compound is a model for the diketone **V** (Scheme 1) which we have already converted to the alkaloid napelline **IV** (5).

Treatment of the diketone **29** with trimethylsilylmethylmagnesium chloride in tetrahydrofuran (THF) gave 64% of the crystalline epimeric alcohols **39**, which yielded 83% of the oily dienone **40** on warming with methanolic perchloric acid (4).

Reduction of this material with sodium borohydride in methanol gave 76% of compound **41** and 11.4% of a product which was probably the epimeric alcohol. In principle both isomers were potential intermediates for further work; however, to save time and labor we carried on the model synthesis only with the major product. While the configuration of the methyl group in **41** followed from its conversion to the known diketone **47** (*vide infra*), the stereochemistry of the alcoholic group was deduced from the nmr spectrum of the corresponding acetate **42**. The hydrogen deshielded by the acetoxy group in this compound (τ = 5.15, dd, J = 8 and 1 Hz) showed a vicinal coupling constant characteristic of a *cis* coplanar arrangement.

The acetate **42** was then subjected to a hydrogenolysis over palladium-on-charcoal and the resulting crystalline alcohol **43** was converted to the corresponding mesylate **44**.

Thus, in a few simple steps the stage was set for a rearrangement to the 'napelline' system. The mesylate **44** was heated under reflux with glacial acetic acid and the rearranged mixture of the epimers **45** was obtained in a yield of 90%.

The somewhat surprising finding that the rearrangement did not require an antiplanar attack by an acetic acid molecule and consequently gave rise to a mixture of epimeric acetates may be perhaps explained by the intermediacy of a relatively stable allylic carbonium ion. Saponification of the diacetates **45** and oxidation of the resulting diols **46** with the chromium trioxide – pyridine complex finally yielded 80% of the crystalline diketone **47** which melted at 58–59°C.

The diketone **47** was identical by mixture melting point, tlc in several systems, and ir, nmr, and mass

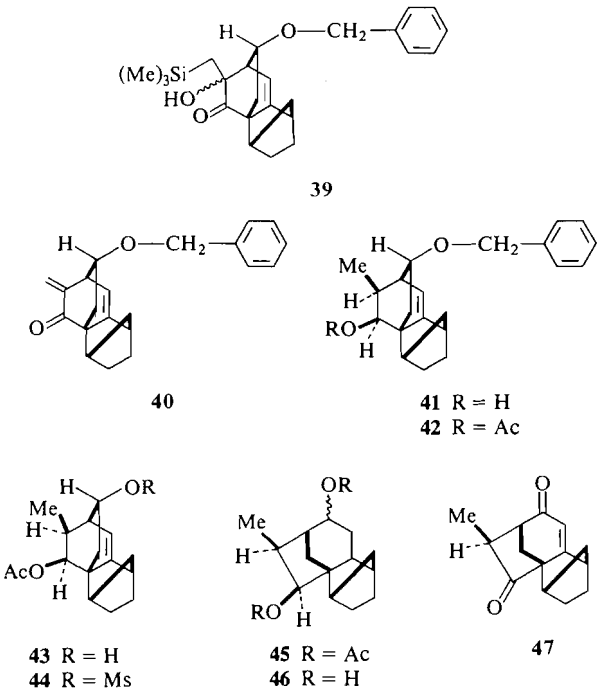

SCHEME 3

spectrometry (ms) with the same compound synthesized by our old method (10)[3] which we employed in our first synthesis of napelline (5).

Experimental

Preparation of Compound 2

A solution of *p*-quinone **1** (6) (25 g) in dry benzene (300 ml) was treated with trimethylphosphite (22 ml) and the resulting mixture heated to reflux under nitrogen overnight. A marked colour change from deep yellow to brown and then to light yellow was observed during the first ½ hour of the reaction. Evaporation of the solvent under reduced pressure produced a brown syrup which was taken up in dry THF (150 ml) and added at −78°C to ammonia (200 ml). Sodium metal (5.5 g) in small pieces was added to the well stirred mixture. A change in colour from dark brown to yellow was observed within the first ½ h of the reaction. After stirring for 1 h, the reaction was quenched with methanol (40 ml). Evaporation of the solvent under reduced pressure produced a reddish residue which was dissolved in water and thoroughly extracted with ether. Extracts were washed with 5% sodium hydroxide solution (until colourless washings were obtained), saturated sodium bicarbonate, water, and brine. After drying over anhydrous sodium sulfate, the solvent was evaporated under reduced pressure and the residue chromatographed on silica gel using ether–hexane (2:98, v/v) to give 14.09 g of the desired product **2** in 70.5% yield as a colourless oil; nmr ($CDCl_3$) τ: 3.15 (m, 4H, two aromatic and two olefinic protons), 3.47 (m, 1H, aromatic proton), 5.83 and 6.13 (b s, 1H each, benzylic bridgehead protons), 6.18 (s, 3H, aromatic methoxyl), 7.80 ppm (m, 2H, methylenic protons). *Mol. Wt.* calcd. for $C_{12}H_{12}O$: 172; found (ms): 172.

[3]C. S. J. Tsai. Unpublished results.

Hydrogenation of Compound 2

A solution of compound **2** (50 g), was hydrogenated at atmospheric pressure over 10% palladium-on-charcoal (5 g) in ethanol (1500 ml). The catalyst was filtered off through a Celite pad and the solvent evaporated under reduced pressure to furnish the dihydro compound **3** in quantitative yield as a colourless oil; nmr ($CDCl_3$) τ: 3.17 (m, 3H, aromatic protons), 6.18 (s, 3H, aromatic methoxyl), 6.37 and 6.68 ppm (b s, 1H each, benzylic bridgehead protons). *Mol. Wt.* calcd. for $C_{12}H_{14}O$: 174; found (ms): 174.

Preparation of Phenol 4

Boron tribromide (50 g) in 300 ml of dry methylene chloride was added to a solution of compound **3** (50 g) in 1000 ml of dry methylene chloride at −78°C. The temperature was raised to 0°C and stirred at this temperature for an additional hour. The reaction was quenched with ice cold water, the organic layer separated, and the aqueous layer re-extracted with methylene chloride. The combined extracts were washed with water and dried over anhydrous sodium sulfate. Evaporation of the solvent gave a light yellow oil which was purified by chromatography on silica gel using ether–hexane (1:4, v/v) to give 41.0 g (89.1%) of phenol **4** as colourless prisms, mp 78–79°C from carbon tetrachloride – hexane; ir ($CHCl_3$): 3675, 3400 cm^{-1} (phenol); nmr ($CDCl_3$) τ: 3.20 (m, 3H, aromatic protons), 5.28 (s, 1H, phenolic proton), 6.48 and 6.65 ppm (b s, 1H each, benzylic bridgehead protons). *Mol. Wt.* calcd. for $C_{11}H_{12}O$: 160; found (ms): 160. *Anal.* calcd. for $C_{11}H_{12}O$: C 82.46, H 7.55; found: C 82.27, H 7.60.

Preparation of the Dithiane Adduct 5 (7)

A solution of *N*-chlorosuccinimide (170 mg) in dry methylene chloride (20 ml) was cooled to 0°C and treated with crystalline 1,3-dithiane (180 mg). After 15 min stirring under nitrogen the temperature was lowered to −20°C (carbon tetrachloride – CO_2 bath) and the recrystallized phenol **4** (200 mg) in dry methylene chloride (3 ml) was added dropwise. Stirring was continued for 30 min and the temperature was then lowered to −78°C (acetone – CO_2 bath). The yellow reaction mixture was treated with triethylamine (145 mg). The resulting red solution was allowed to warm up to room temperature and treated with 1 *N* hydrochloric acid and the colour disappeared. The organic layer was washed to neutrality with water, dried over anhydrous sodium sulfate and evaporated to dryness. The residue was purified by preparative tlc on silica gel using benzene to give 127.4 mg of the dithiane derivative **5** (60.1% yield based on the phenol consumed) as amorphous solid; ir (CCl_4): 3615, 3450 cm^{-1} (phenol); nmr ($CDCl_3$) τ: 3.13 (ABq, J = 7.5 Hz, 2H, aromatic protons), 3.83 (s, 1H,), 4.58 (s, 1H, phenolic proton), 6.43 and 6.72 ppm (broad singlets, 1H each, benzylic bridgehead protons). *Mol. Wt.* calcd. for $C_{15}H_{18}OS_2$: 278; found (ms): 278.

Alkylation of Dithiane Derivative 5

The dithiane derivative **5** (17.0 g) in 300 ml of acetone (potassium carbonate distilled) was stirred at room temperature with 11.0 g of powdered potassium carbonate and 5.5 ml of methyl bromoacetate in the presence of a catalytic amount of crown ether (18-crown-6). After stirring for 3½ h, the inorganic salt was filtered off and the solvent evaporated under reduced pressure to give 20.01 g of the expected product **6** in 93.9% yield as a colourless oil; ir ($CHCl_3$): 1760 cm^{-1} (ester); nmr ($CDCl_3$) τ: 2.83 (ABq, J = 7.5 Hz, 2H, aromatic protons), 4.15 (s, 1H,), 5.32 (s, 2H, methylenic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

protons of the ester side chain), 6.15 ppm (s, 3H, ester methyl). *Mol. Wt.* calcd. for $C_{18}H_{22}O_3S_2$: 350; found (ms): 350.

Preparation of Compound **7**

A solution of compound **6** (20 g) in THF (100 ml) was added to a stirred suspension of mercuric oxide (26 g) and boron trifluoride etherate (15 ml) in 15% aqueous THF (500 ml). After stirring for 30 min, the reaction mixture was diluted with water and the resulting precipitate filtered off. The filtrate was diluted with ether (200 ml), washed with aqueous sodium bicarbonate and brine. Drying over anhydrous magnesium sulfate and evaporation of the solvent furnished 12.7 g of the desired compound **7** in 86.4% yield as a light yellow oil; ir ($CHCl_3$): 1755, 1735 (ester), 1675 cm^{-1} (aromatic aldehyde); nmr ($CDCl_3$) τ: −0.53 (s, 1H, aldehyde proton), 2.66, (ABq, J = 7.5 Hz, 2H, aromatic protons), 5.23 (s, 2H, methylenic protons of ester side chain), 6.17 (s, 3H, ester methyl), 6.33 and 6.60 ppm (b s, 1H each, benzylic bridgehead protons). *Mol. Wt.* calcd. for $C_{15}H_{16}O_4$: 260; found (ms): 260.

Baeyer–Villiger Oxidation of Compound **7**

A solution of compound **7** (9.0 g) in 220 ml of dry dichloromethane was heated under reflux with 9.0 g of *m*-chloroperbenzoic acid for 1 h in a nitrogen atmosphere. The reaction mixture was cooled to room temperature, diluted with 200 ml of dichloromethane and washed thoroughly with aqueous sodium bicarbonate and water. Drying over anhydrous magnesium sulfate and evaporation of the solvent *in vacuo* gave 8.21 g (86%) of the formate ester **8** as a light yellow oil; ir ($CHCl_3$): 1750 cm^{-1} (b, formate and methyl ester); nmr ($CDCl_3$) τ: 1.72 (s, 1H, formate proton), 3.13 (ABq, J = 7 Hz, 2H, aromatic protons), 5.37 (s, 2H, methylenic protons of ester side chain), 6.18 (s, 3H, ester methyl), 6.33 and 6.65 ppm (b s, 1H each, benzylic bridgehead protons). *Mol. Wt.* calcd. for $C_{15}H_{16}O_5$: 276; found (ms): 276.

Preparation of the Diels–Alder Adduct **11**

The formate methyl ester **8** (9.5 g) was heated under reflux with 100 ml of 5% methanolic potassium hydroxide for 1 h. The reaction mixture was cooled to room temperature, diluted with water (50 ml), and acidified with hydrochloric acid. Excess methanol was evaporated under reduced pressure and the residue was extracted with methylene chloride. The combined extracts were washed with water and evaporated to a volume of 300 ml. The resulting solution of the phenolic acid **9** was cooled to 0°C and stirred with 300 ml of aqueous sodium acetate (4.1 g). A solution of 6.23 g of *N*-bromosuccinimide and 4.1 g of sodium acetate in 400 ml of water was added slowly to this two phase reaction mixture. Vigorous stirring was continued for 30 min, the organic layer was separated and the aqueous phase re-extracted with methylene chloride until colourless extracts were obtained. The combined extracts were dried over anhydrous magnesium sulfate and evaporated to a volume of 30 ml. This brilliant reddish-brown solution of the spirolactone **10** was cooled to 0°C and treated with an excess of methyl vinyl ether. The red colour of the quinone faded overnight and the stirring was continued for 40 h at room temperature. The solvent and the excess methyl vinyl ether were evaporated under reduced pressure and the residue was chromatographed on silica gel using ether–hexane (1:2, v/v) to give 8.74 g (78.7%) of adduct **11** as colourless prisms, mp 99–107°C from ether–hexane; ir (CCl_4): 1830 (lactone), 1745 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 4.43 (d, J = 6 Hz, 1H, vinylic proton), 5.58 (2ABq, 2H, methylenic protons of spirolactone), 6.37 (m, 2H, proton unshielded by methoxyl and bicyclooctane bridgehead proton), 6.72 (s, 3H, methoxyl), 6.98 ppm (b s, 1H, bicycloheptane bridgehead proton). *Mol. Wt.* calcd. for $C_{16}H_{18}O_5$: 290; found (ms): 290. *Anal.* calcd. for $C_{16}H_{18}O_5$: C 66.19, H 6.25; found: C 65.75, H 6.21.

Base Treatment of the Diels–Alder Adduct **11**

The recrystallized adduct **11** (4.0 g) in 200 ml of methanol was stirred at room temperature with 20 ml of 5% aqueous potassium carbonate for 15 min. The reaction mixture was neutralized with dilute hydrochloric acid, diluted with 50 ml of water and most of the methanol was evaporated under reduced pressure. The residue was extracted with ether and the extracts were washed with brine and dried over anhydrous magnesium sulfate. Evaporation of the solvent furnished 2.92 g (91.3%) of the diketone **12** as yellow needles, mp 124–125°C from ether–hexane; ir (CCl_4): 1750, 1737 (cyclic α-diketones), 1657 cm^{-1} (double bond); nmr ($CDCl_3$) τ: 4.2 (d, J = 6 Hz, 1H, vinylic proton), 6.13 (m, 2H, proton unshielded by methoxyl and bicyclooctane bridgehead proton), 6.67 (s, 3H, methoxyl), 6.98 and 7.50 ppm (b s, 1H each, bicycloheptane bridgehead protons). *Mol. Wt.* calcd. for $C_{14}H_{16}O_3$: 232; found (ms): 232. *Anal.* calcd. for $C_{14}H_{16}O_3$: C 72.39, H 6.94; found: C 72.03, H 6.98.

Preparation of the Tosylhydrazone **13**

A solution of the recrystallized diketone **12** (3.0 g) and tosylhydrazine (2.6 g) in 300 ml of methanol was stirred at room temperature for 4 h. The tosylhydrazone crystallized out of the solution as yellow plates which were filtered off and the mother liquor concentrated for a second crop. The two crops furnished 4.55 g (88%) of the tosylhydrazone **13**, mp 166.5–167°C (sintering at 157.5°C) from methanol; ir (CCl_4): 3190 (N—H), 1680 cm^{-1} (six-membered conjugated ketone); nmr ($CDCl_3$) τ: 2.17, 2.68 (2d, J = 8 Hz, 2H each, aromatic protons), 4.17 (d, J = 6 Hz, 1H, vinylic proton), 6.28 (m, 2H, proton unshielded by methoxyl and bicyclooctane bridgehead proton), 6.68 (s, 3H, methoxyl), 7.05 (b s, 1H, bicycloheptane bridgehead proton), 7.55 ppm (s, 4H, aromatic methyl and a bicycloheptane bridgehead proton). *Anal.* calcd. for $C_{21}H_{24}O_4SN_2$: C 62.99, H 6.03, N 7.00; found: C 63.29, H 6.03, N 7.04.

Reduction of Compound **13**

The tosylhydrazone **13** (1.0 g) in dry THF (100 ml) was cooled to 0°C and treated with 100 mg of lithium borohydride. The reaction mixture turned yellow instantaneously but became colourless in about 20 min. It was then poured into ice cold dilute hydrochloric acid and the solvent was evaporated under reduced pressure. The residue was extracted with chloroform and the extracts were washed with water and brine and dried over anhydrous magnesium sulfate. Solvent evaporation under reduced pressure gave 891 mg (89.1%) of the epimeric alcohols **14** as a colourless powder, mp 183–184°C from methylene chloride – hexane; ir ($CHCl_3$): 3425 (hydroxyl), 3100 cm^{-1} (N—H); nmr ($CDCl_3$) τ: 2.13 and 2.97 (2d, J = 8 Hz, 2H each, aromatic protons), 4.43 (d, J = 6 Hz, 1H, vinylic proton), 5.90 (b s, 1H, proton unshielded by hydroxyl), 6.53 (m, 2H, proton unshielded by methoxyl and bicyclooctane bridgehead proton), 6.77 (s, 3H, methoxyl), 7.10 (b s, 1H, bicycloheptane bridgehead proton), 7.53 (s, 3H, aromatic methyl), 7.70 ppm (b s, 1H, bicycloheptane bridgehead proton). *Mol. Wt.* calcd. for $C_{21}H_{26}O_4SN_2$: 402; found (ms): 402.

Preparation of Compound **15**

A solution of compound **14** (6.5 g) in 80% ethanol (150 ml) was heated under reflux with 2 ml of 2 *N* hydrochloric acid and 3.25 g of acetylacetone for 2 h. The reaction mixture was cooled to room temperature and the solvent was evaporated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in vacuo. The residue was diluted with water (30 ml) and thoroughly extracted with chloroform. The combined extracts were washed with a saturated solution of cupric acetate, water, and brine followed by drying over anhydrous magnesium sulfate. The solvent was evaporated under reduced pressure and the residue was purified by column chromatography on silica gel using chloroform–hexane (1:4, v/v) to yield 3.22 g (85.1%) of the epimeric hydroxy ketones **15** as colourless plates, mp 148.5–154°C from ether. For characterization the mixture was separated by preparative tlc on silica gel using chloroform–hexane (95:5, v/v). The isomers were obtained in an approximate ratio of 3:1.

Major isomer; ir (CCl_4): 3530, 3375 (hydroxyl), 1725 (six-membered ketone), 1662 cm^{-1} (double bond); nmr ($CDCl_3$) τ: 4.45 (d, J = 6 Hz, 1H, vinylic proton), 6.37 (m, 2H, proton unshielded by methoxyl and bicyclooctane bridgehead proton), 6.57 (d, J = 2 Hz, 1H, proton unshielded by hydroxyl), 6.72 (s, 3H, methoxyl), 7.02 and 7.30 ppm (b s, 1H each, bicycloheptane bridgehead protons). *Mol. Wt.* calcd. for $C_{14}H_{18}O_3$: 234; found (ms): 234. *Anal.* calcd. for $C_{14}H_{18}O_3$: C 71.77, H 7.74; found: C 71.39, H 7.67.

Minor isomer; ir (CCl_4): 3515 (hydroxyl), 1725 (six-membered ketone), 1660 cm^{-1} (double bond); nmr ($CDCl_3$) τ: 4.52 (d, J = 6 Hz, 1H, vinylic proton), 6.35 (m, 3H, protons unshielded by methoxyl, hydroxyl and bicyclooctane bridgehead proton), 6.70 ppm (s, 3H, methoxyl). The mass spectra of both epimers were identical. *Mol. Wt.* calcd. for $C_{14}H_{18}O_3$: 234; found (ms): 234.

Preparation of Keto Mesylate ***16***

The hydroxy ketones **15** (1.45 g) in dry pyridine (10 ml) were cooled to 0°C and treated with 850 mg of mesyl chloride. The reaction mixture was stirred at room temperature overnight under nitrogen and then poured into ice cold dilute hydrochloric acid. Exhaustive extraction with chloroform and washing of the extracts with water, sodium bicarbonate, and brine followed by drying over anhydrous magnesium sulfate yielded 1.71 g (88.4%) of the keto mesylates **15** as colourless plates from ether.

Major isomer (β-mesylate; decomposed at 141°C); ir (CCl_4): 1737 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 4.38 (d, J = 6 Hz, 1H, vinylic proton), 5.48 (d, J = 2 Hz, 1H, proton unshielded by mesylate), 6.30 (m, 2H, proton unshielded by methoxyl and bicyclooctane bridgehead proton), 6.70 (s, 3H, methoxyl), 6.73 ppm (s, 3H, mesylate methyl). *Mol. Wt.* calcd. for $C_{15}H_{20}O_5S$: 312; found (ms): 312. *Anal.* calcd. for $C_{15}H_{20}O_5S$: C 57.69, H 6.46; found: C 58.17, H 6.44.

Minor isomer (α-mesylate); mp 139.5–140°C; the entire mass spectra of both epimers were identical; ir (CCl_4): 1735 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 4.45 (d, J = 6 Hz, 1H, vinylic proton), 5.40 (s, 1H, proton unshielded by mesylate), 6.35 (m, 2H, proton unshielded by methoxyl and bicyclooctane bridgehead proton), 6.72 (s, 3H, methoxyl), 6.80 ppm (s, 3H, mesylate methyl). *Mol. Wt.* calcd.: 312; found (ms): 312.

Lithium–Ammonia Reduction of Keto Mesylate ***16***

The keto mesylates **16** (700 mg) in anhydrous THF (10 ml) were added dropwise to a stirred solution of lithium metal (250 mg) in liquid ammonia (200 ml). After stirring for 1 h, the reaction mixture was quenched with wet ether and the excess of ammonia was evaporated. The residue was dissolved in water (20 ml), neutralized with dilute hydrochloric acid and extracted with chloroform. The combined extracts were washed with water and dried over anhydrous sodium sulfate. The solvent was evaporated under reduced pressure and the residue was taken up in 20 ml of dry methylene chloride and added to a stirred suspension of the chromium trioxide–dipyridine complex (3.6 g) in dry methylene chloride (100 ml). Stirring was continued for 15 min and the reaction was worked up by the normal procedure. The product was purified by preparative tlc on silica gel using ether–hexane (1:1, v/v) to yield 335 mg (70.3%) of compound **17** as a colourless oil; ir (CCl_4): 1725 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 4.47 (d, J = 6 Hz, 1H, vinylic proton), 6.25 (m, 1H, proton unshielded by methoxyl), 6.50 (dd, J = 3 and 6 Hz, 1H, bicyclooctane bridgehead proton), 6.70 (s, 3H, methoxyl), 7.05 and 7.77 ppm (b s, 1H each, bicycloheptane bridgehead protons). *Mol. Wt.* calcd. for $C_{14}H_{18}O_2$: 218; found (ms): 218.

Hydrogenation of Compound ***17***

A solution of 310 mg of compound **17** in 20 ml of methanol and 300 mg of 5% rhodium-on-alumina catalyst was hydrogenated at 85 psi for 20 h. The catalyst was filtered off and the solvent was evaporated under reduced pressure. The residue was dissolved in 20 ml of dry dichloromethane and added to a stirred suspension of 2.3 g of the chromium trioxide–dipyridine complex in 100 ml of dry dichloromethane. Standard work-up gave a colourless residue which was purified by preparative tlc on silica gel using ether–hexane (1:1, v/v) to yield 276.4 mg (88.4%) of the single dihydro derivative **18** as a colourless glass; ir (CCl_4): 1720 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 6.45 (m, 1H, proton unshielded by methoxyl), 6.70 ppm (s, 3H, methoxyl). *Mol. Wt.* calcd. for $C_{14}H_{20}O_2$: 220; found (ms): 220.

Preparation of Bromo Ketone ***19***

The methoxy ketone **18** (200 mg) was dissolved in 20 ml of ether and stirred at room temperature with 10 drops of liquid bromine. After 2½ h, the reaction mixture was diluted with 30 ml of ether and washed with 10% aqueous sodium bisulfite and brine. Drying over anhydrous sodium sulfate and evaporation of the solvent gave a colourless oil which was purified by preparative tlc on silica gel using ether–hexane (1:2, v/v) to yield 238 mg (87.5%) of the single bromo ketone **19** as colourless elongated plates, mp 82.5°C from ether–hexane; ir (CCl_4): 1737 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 5.78 (d, J = 2.2 Hz, 1H, proton unshielded by bromine atom), 6.10 (m, 1H, proton unshielded by methoxyl), 6.70 ppm (s, 3H, methoxyl). *Mol. Wt.* calcd. for $C_{14}H_{19}O_2Br$: 299; found (ms): 299. *Anal.* calcd. for $C_{14}H_{19}O_2Br$: C 56.20, H 6.40; found: C 56.28, H 6.19.

Rearrangement of Bromo Ketone ***19***

The crystalline bromo ketone **19** (200 mg) in dry DMSO (7 ml) and 1,5-diazabicyclo[4.3.0]non-5-ene (2.5 ml) was heated to 125°C for 75 min under nitrogen. The reaction mixture was cooled to room temperature, poured into 15 ml of water and exhaustively extracted with ether (5 × 20 ml). The combined extracts were washed with 5% acetic acid, water, sodium bicarbonate, and brine and dried over anhydrous magnesium sulfate. Solvent evaporation gave a light yellow oil which was purified by preparative tlc on silica gel using ether–hexane (1:2, v/v) to yield 110 mg (75.4%) of the rearranged compound **20** as colourless plates, mp 77.5°C from hexane; ir (CCl_4): 1760 (five-membered ketone), 1633 cm^{-1} (double bond); nmr ($CDCl_3$) τ: 4.87 (b s, 1H, vinylic proton), 5.60 (d, J = 4 Hz, proton unshielded by methoxyl), 6.67 ppm (s, 3H, methoxyl); uv λ_{max} (CH_3OH): 214.5 (log ε 3.51), 232 nm (log ε 3.15). *Mol. Wt.* calcd. for $C_{14}H_{18}O_2$: 218; found (ms): 218. *Anal.* calcd. for $C_{14}H_{18}O_2$: C 77.03, H 8.31; found: C 77.12, H 8.09.

Preparation of Compound ***22***

A solution of the unsaturated ketone **20** (60 mg) in 10 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of absolute methanol was cooled to 0°C and treated with 12 mg of sodium borohydride. After stirring for 15 min, water (5 ml) was added to the reaction mixture and the excess of methanol was evaporated under reduced pressure. The residue was extracted with ether and the extracts were washed with water and brine and dried over anhydrous magnesium sulfate. Solvent evaporation under reduced pressure and purification of the residue by preparative tlc on silica gel using ether–hexane (3:1, v/v) gave 53 mg (87.5%) of alcohol **22** as a colourless glass; ir (CCl_4): 3600 (hydroxyl), 1650 cm^{-1} (double bond); nmr ($CDCl_3$) τ: 4.77 (b s, 1H, vinylic proton), 5.63 (d, $J = 4$ Hz, 1H, proton unshielded by methoxyl), 5.93 (dd, $J = 4$ and 7 Hz, 1H, proton unshielded by hydroxyl), 6.63 ppm (s, 3H, methoxyl). *Mol. Wt.* calcd. for $C_{14}H_{20}O_2$: 220; found (ms): 220.

Pyro–Isopyro Rearrangement of Compound 22

A solution of compound **22** (60 mg) and *p*-toluenesulfonic acid (20 mg) in glacial acetic acid (10 ml) was heated to 60°C for 30 min. The reaction mixture was cooled to room temperature and the acetic acid was evaporated under reduced pressure. The residue was dissolved in water and extracted with ether (3 × 10 ml). The combined extracts were washed with water, aqueous sodium bicarbonate and brine. Drying over anhydrous sodium sulfate and evaporation of the solvent gave a pale yellow oil which showed the presence of several compounds on tlc. The major product **23** (27 mg, 39.9%) was isolated by preparative tlc on silica gel using ether–hexane (2:1, v/v) as colourless glass; ir (CCl_4): 3600 (tertiary alcohol), 1760, 1740 (acetate), 1640 cm^{-1} (double bond); nmr ($CDCl_3$) τ: 4.13 (dd, $J = 6$ and 10 Hz, 1H, vinylic proton), 4.43 (d, $J = 10$ Hz, 1H, vinylic proton), 5.18 (m, $J = 4$ Hz, 1H, proton unshielded by acetate), 7.97 ppm (s, 3H, acetoxy methyl). *Mol. Wt.* calcd. for $C_{15}H_{20}O_3$: 248; found (ms): 248.

Transformation of Compound 23 to 24

The acetoxy alcohol **23** (25 mg) was heated under reflux with 10 ml of 5% ethanolic potassium hydroxide for 30 min. The reaction mixture was cooled to room temperature, diluted with water (5 ml), neutralized with dilute hydrochloric acid, and the excess ethanol was evaporated under reduced pressure. The residue was extracted with ether, and the extracts were washed with brine and dried over anhydrous magnesium sulfate. The solvent was evaporated, the residue was taken up in 5 ml of dry methylene chloride and added to a stirred suspension of the chromium trioxide – dipyridine complex (220 mg) in methylene chloride (10 ml). After stirring for 15 min, the reaction mixture was quenched with wet ether and worked up by the standard procedure. Solvent evaporation and purification of the residue by preparative tlc on silica gel using ether–hexane (2:1, v/v) gave 16.8 mg of the hydroxy ketone **24**. The identity of this material with a previously synthesized compound (1) was established by all standard spectral and chromatographic techniques.

Preparation of Methoxy Ketone 26

The methoxy ketal **25** (1) (396 mg) was heated to 85°C for 3 h in 30 ml of 80% aqueous acetic acid. The solvent was removed *in vacuo* and the residue was dissolved in ether, washed with water, and aqueous sodium bicarbonate and dried over anhydrous magnesium sulfate. Solvent evaporation under reduced pressure gave 313 mg (95%) of the methoxy ketone **26** which was used without purification for the next step; ir (CCl_4): 1730 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 6.31 (m, 1H, proton unshielded by methoxyl), 6.73 ppm (s, 3H, methoxyl). *Mol. Wt.* calcd. for $C_{14}H_{20}O_2$: 220; found (ms): 220.

Bromination of Methoxy Ketone 26

Bromination of compound **26** to the bromo ketone **27**, exactly according to the procedure used for the epimer **18**; gave yield of 85%; ir (CCl_4): 1730 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 5.67 (d, $J = 2.2$ Hz, 1H, proton unshielded by bromine atom), 6.67 ppm (s, 3H, methoxy). *Mol. Wt.* calcd. for $C_{14}H_{19}O_2Br$: 299; found (ms): 299.

Rearrangement of Bromo Ketone 27

A mixture of the bromo ketone **27** (150 mg), tetramethylguanidine (2.5 ml) and DMSO (2.5 ml) was heated to 160°C under nitrogen for 3 h. The reaction mixture was worked up as described for the bromo ketone **19** and the residue was purified by preparative tlc on silica gel using ether–hexane (1:1, v/v) to give 98 mg (90%) of the oily keto olefin **21**; ir (CCl_4): 1761 cm^{-1} (five-membered ketone); nmr ($CDCl_3$) τ: 4.51 (d, $J = 6$ Hz, 1H, vinylic proton), 6.00 (dd, $J = 4$ and 6 Hz, 1H, proton unshielded by methoxy), 6.63 ppm (s, 3H, methoxyl). *Mol. Wt.* calcd. for $C_{14}H_{18}O_2$: 218; found (ms): 218.

Preparation of the Diels–Alder Adduct 28

A solution of the spirolactone **10** (prepared as described above) in methylene chloride was treated with an excess of vinyl benzyl ether and the reaction mixture was stirred at room temperature for 24 h. Solvent evaporation and crystallization of the residue from methanol gave the adduct **28** in a 80.3% yield as colourless needles, mp 138–140°C; ir ($CHCl_3$): 1817 (lactone carbonyl), 1744 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 2.67 (s, 5H, aromatic protons), 4.40 (d, $J = 6$ Hz, 1H, vinylic proton), 5.52 (s, 2H, benzylic protons), 5.57 (2ABq, 2H, methylenic protons of spirolactone), 6.02 (b m, 1H, proton unshielded by benzyloxy group), 6.43 (m, 1H, bicyclooctane bridgehead proton), 6.97 ppm (b s, 1H, bicycloheptane bridgehead proton). *Mol. Wt.* calcd. for $C_{22}H_{22}O_5$: 366; found (ms): 366. *Anal.* calcd. for $C_{22}H_{22}O_5$: C 72.11, H 6.05; found: C 72.17, H 6.01.

Preparation of Diketone 29

The recrystallized adduct **28** (9.5 g) in 200 ml of a methanol–THF mixture (1:1, v/v) was stirred at room temperature with 20 ml of 5% aqueous potassium carbonate for 30 min. The reaction mixture was diluted with water, neutralized with dilute hydrochloric acid and the excess solvent was evaporated under reduced pressure. The residue was extracted with ether and the extracts were washed with water and brine and dried over anhydrous sodium sulfate. Solvent evaporation gave 7.24 g (90.5%) of diketone **29** as yellow needles, mp 116.5–117.5°C from ether–hexane; ir ($CHCl_3$): 1735, 1750 cm^{-1} (α-diketone); nmr ($CDCl_3$) τ: 2.65 (s, 5H, aromatic protons), 4.15 (d, $J = 6$ Hz, 1H, vinylic proton), 5.47 (s, 2H, benzylic protons), 5.87 (m, 1H, proton unshielded by benzyloxy), 6.22 (m, 1H, bicyclooctane bridgehead proton), 6.95 and 7.50 ppm (b s, 1H each, bicycloheptane bridgehead protons). *Mol. Wt.* calcd. for $C_{20}H_{20}O_3$: 308; found (ms): 308. *Anal.* calcd. for $C_{20}H_{20}O_3$: C 77.92, H 6.49; found: C 77.75, H 6.23.

Preparation of Tosylhydrazone 30

The tosylhydrazone **30** was prepared from the diketone **29** exactly as described above for compound **13**. An analytical sample melted at 129–131°C (methanol); ir ($CHCl_3$): 3200 (N—H), 1683 cm^{-1} (six-membered conjugated carbonyl); nmr ($CDCl_3$) τ: 2.2, 2.27 and 2.72 (9H, aromatic protons), 4.17 (d, $J = 6$ Hz, 1H, vinylic proton), 5.55 (s, 2H, benzylic protons), 6.18 (m, 2H, proton unshielded by benzyloxy and bicyclooctane bridgehead proton), 7.07 (b s, 1H, bicycloheptane bridgehead proton), 7.60 ppm (4H, s, aromatic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

methyl and bicycloheptane bridgehead proton). *Mol. Wt.* calcd. for $C_{27}H_{28}O_4N_2S$: 476; found (ms): 476. *Anal.* calcd. for $C_{27}H_{28}O_4N_2S$: C 68.05, H 5.92, N 5.88; found: C 67.85, H 5.75, N 5.89.

Reduction of Tosylhydrazone 30

The reduction of compound **30** proceeded exactly as described in the case of the methoxy derivative **13** to give the product **31** in an 88% yield as colourless prismatic needles. Several recrystallizations from ether furnished the major isomer which melted at 187.5–188.5°C; ir ($CHCl_3$): 3417 (hydroxyl), 3234 cm^{-1} (N—H); nmr ($CDCl_3$) τ: 2.12 (d, 2H, aromatic protons), 2.73 (s, 7H, aromatic protons of benzyloxy and tosylate groups), 4.45 (d, J = 6 Hz, vinylic proton), 5.60 (s, 2H, benzylic protons), 5.93 (b s, 1H, proton unshielded by hydroxyl), 6.45 (m, 2H, proton unshielded by benzyloxy and bicyclooctane bridgehead proton), 7.10 (b s, 1H, bicycloheptane bridgehead proton), 7.58 ppm (s, 3H, aromatic methyl). *Mol. Wt.* calcd. for $C_{27}H_{30}O_4N_2S$: 478; found (ms): 478. *Anal.* calcd. for $C_{27}H_{30}O_4N_2S$: C 67.76, H 6.32, N 5.85; found: C 68.08, H 6.26, N 5.68.

Preparation of Compound 32

The tosylhydrazone **31** was hydrolyzed to give the hydroxy ketone **32** exactly as described for compound **14**. The ratio of the two isomers was approximately 6:1.

Major isomer (colourless needles); mp 138–139.5°C from ether); ir ($CHCl_3$): 3540, 3450 (hydroxyl), 1725 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 2.67 (s, 5H, aromatic protons), 4.45 (d, J = 6 Hz, 1H, vinylic proton), 5.53 (s, 2H, benzylic protons), 6.15 (b m, 1H, proton unshielded by benzyloxy group), 6.47 (m, 1H, bicyclooctane bridgehead proton), 6.58 ppm (d, J = 2.2 Hz, 1H, proton unshielded by hydroxyl). *Mol. Wt.* calcd. for $C_{20}H_{22}O_3$: 310; found (ms): 310. *Anal.* calcd. for $C_{20}H_{22}O_3$: C 77.39, H 7.14; found: C 77.30, H 7.10.

Minor isomer (colourless needles); mp 102.5–103.5°C from ether; ir ($CHCl_3$): 3510, 3415 (hydroxyl), 1725 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 2.68 (s, 5H, aromatic protons), 4.48 (d, J = 6 Hz, 1H, vinylic proton), 5.52 (s, 2H, benzylic protons), 6.12 (b m, 1H, proton unshielded by benzyloxy group), 6.38 (s, 1H, proton unshielded by hydroxyl), 6.47 (m, 1H, bicyclooctane bridgehead proton), 7.07 and 7.37 ppm (b s, 1H each, bicycloheptane bridgehead protons). *Mol. Wt.* calcd. for $C_{20}H_{22}O_3$: 310; found (ms): 310; the entire mass spectra of both epimers were identical.

Mesylation of Hydroxy Ketone 32

The keto mesylate **33** was obtained from compound **32** as described previously for compound **15**. The yield of the reaction was 93.3% and both isomers were obtained as colourless prisms from ether.

Major isomer, mp 108.5–109.5°C; ir ($CHCl_3$): 1737 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 2.67 (s, 5H, aromatic protons), 4.38 (d, J = 6 Hz, vinylic proton), 5.50 (s, 3H, benzylic protons and a proton unshielded by mesylate), 6.05 (b m, 1H, proton unshielded by benzyloxy group), 6.45 (m, bicyclooctane bridgehead proton), 6.77 (s, 3H, mesylate methyl), 7.00 ppm (b s, 1H, bicycloheptane bridgehead proton). *Mol. Wt.* calcd. for $C_{21}H_{24}O_5S$: 388; found (ms): 388. *Anal.* calcd. for $C_{21}H_{24}O_5S$: C 64.93, H 6.23; found: C 64.98, H 6.31.

Minor isomer, mp 95.5–97.0°C; ir ($CHCl_3$): 1737 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 2.70 (s, 5H, aromatic protons), 4.45 (d, J = 6 Hz, 1H, vinylic proton), 5.43 (s, 1H, proton unshielded by mesylate), 5.53 (s, 2H, benzylic protons), 6.13 (m, 1H, proton unshielded by benzyloxy), 6.47 (m, 1H, bicyclooctane bridgehead proton), 6.82 (s, 3H, mesylate methyl), 7.03 and 7.57 ppm (b s, 1H each, bicycloheptane bridgehead protons). *Mol. Wt.* calcd. for $C_{21}H_{24}O_5S$: 388; found (ms): 388; the entire mass spectra of both epimers were identical.

Hydrogenation of Keto Mesylate 33 (Major Isomer)

A solution of 170 mg of the crystalline major epimer **33** in 10 ml of dry dioxane was hydrogenated over 35 mg of 10% palladium-on-charcoal at atmospheric pressure for 40 h. The catalyst was filtered off through a Celite pad and the filtering pad was washed with ether. The filtrate was washed with sodium bicarbonate and brine and dried over anhydrous sodium sulfate. Evaporation of the solvent and purification of the residue by preparative tlc using ether–hexane (3:1, v/v) gave 97 mg (86.5%) of the aldol **34** as a colourless glass. This aldol showed spectral properties identical with those displayed by the same material obtained by the photochemical route (3).

Reduction of the Minor Keto Mesylate 33 with Calcium Metal in Liquid Ammonia

The keto mesylate **33** (50 mg) in anhydrous THF (2 ml) was added dropwise to a stirred solution of calcium metal (35 mg) in liquid ammonia (15 ml). Stirring was continued for 5 min after which the excess of the metal was destroyed by adding bromobenzene (0.25 ml). The solvent was evaporated, the residue was dissolved in water, neutralized with dilute hydrochloric acid and extracted with ether (4 × 10 ml). The combined extracts were washed with water and brine and dried over anhydrous magnesium sulfate. Evaporation of the solvent and purification of the residue by preparative tlc using ether–hexane (3:1, v/v) gave 17.8 mg (67.7%) of aldol **34**, identical to the one obtained in the previous experiment.

Acetylation of Aldol 34

Aldol **34** (77 mg) was dissolved in 5 ml of acetic anhydride – pyridine mixture (1:1, v/v) and stirred at room temperature for 1 h. The reaction mixture was then poured into water (10 ml) and extracted with ether (4 × 10 ml). The extracts were washed with water, dilute hydrochloric acid, sodium bicarbonate, and brine. Drying over anhydrous magnesium sulfate and evaporation of the solvent *in vacuo* gave a pale yellow oil which was purified by preparative tlc on silica gel using ether–hexane (1:1, v/v) to give 86 mg (92.5%) of keto acetate **35** as colourless glass; ir ($CHCl_3$): 1730 cm^{-1} (six-membered ketone and acetate); nmr ($CDCl_3$) τ: 4.47 (d, J = 6 Hz, 1H, vinylic proton), 5.08 (m, 1H, proton unshielded by acetate), 6.55 (m, 1H, bicyclooctane bridgehead proton), 7.93 and 7.98 ppm (singlets, 3H, acetoxy methyls). *Mol. Wt.* calcd. for $C_{15}H_{18}O_3$: 246; found (ms): 246.

Hydrogenation of Keto Acetate 35

A solution of keto acetate **35** (65 mg) in absolute methanol (5 ml) and 5% rhodium-on-alumina (65 mg) was hydrogenated at 92 psi for 24 h. The catalyst was filtered off and the filtering pad was washed with methanol. The filtrate was evaporated to dryness and the residue was taken up in dry methylene chloride (5 ml) and added to a suspension of the chromium trioxide – dipyridine complex (400 mg) in the same solvent (20 ml). The reaction was quenched with wet ether and worked up by the normal procedure to give a colourless oil which was purified by preparative tlc on silica gel using ether–hexane (1:1, v/v). The yield was 53 mg (82.8%) of keto acetates **36** and **37** in a ratio of 2.3:1.

Keto acetate **36** (37.2 mg, colourless glass); ir (CCl_4): 1735 cm^{-1} (six-membered ketone, acetate); nmr ($CDCl_3$) τ: 4.93 (m, 1H, proton unshielded by acetate), 7.97 and 8.00 ppm

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(s, 3H, acetoxy methyls). *Mol. Wt.* calcd. for $C_{15}H_{20}O_3$: 248; found (ms): 248.

Keto acetate **37** (16.5 mg, colourless prisms, mp 122.5–123.5°C from ether–hexane); ir (CCl_4): 1737 cm^{-1} (six-membered ketone, acetate); nmr ($CDCl_3$) τ: 4.63 (m, 1H, proton unshielded by acetate), 7.98 ppm (s, 3H, acetoxy methyl). *Mol. Wt.* calcd. for $C_{15}H_{20}O_3$: 248; found (ms): 248.

*Conversion of Keto Acetate **36** into Ketal Ketone **38***

The keto acetate **36** was converted to the homogeneous ketal ketone **38** according to the procedure used in our photochemical model studies (3). Its identity with the previously prepared material (3) was ascertained by tlc, ir, nmr, and ms.

*Preparation of Alcohol **39***

A solution of the diketone **29** (1.0 g) in anhydrous THF (32 ml) was added dropwise to a stirred solution of trimethylsilylmethylmagnesium chloride (8 mmol) in THF (12 ml) at 0°C under nitrogen. The reaction mixture was allowed to stir at room temperature for 30 min, then cooled to 0°C and quenched with wet ether (10 ml). The white precipitate was filtered off through a Celite pad and the filtrate was washed with water and dried over anhydrous magnesium sulfate. The solvent was evaporated *in vacuo* and the residue was chromatographed on silica gel using ether–hexane (1:5, v/v) to give 822 mg (64%) of epimeric alcohols **39**, mp 130–131°C from ether–hexane; ir (CCl_4): 3550 (hydroxyl), 1720 cm^{-1} (six-membered ketone); nmr ($CDCl_3$) τ: 2.67 (s, 5H, aromatic protons), 4.18 (d, J = 6 Hz, 1H, vinylic proton), 5.50 (s, 2H, benzylic protons), 6.80 (m, 1H, bicyclooctane bridgehead proton), 7.04 and 7.60 (b s, 1H each, bicycloheptane bridgehead protons), 9.15 (s, 2H, methylenic protons α to the trimethylsilyl group), 9.90 ppm (3s, 9H, trimethylsilyl group). *Mol. Wt.* calcd. for $C_{24}H_{32}O_3Si$: 396; found (ms): 396. *Anal.* calcd. for $C_{24}H_{32}O_3Si$: C 72.68, H 8.13; found: C 72.52, H 7.75.

*Preparation of α,β-Unsaturated Ketone **39***

The epimeric alcohols **39** (300 mg) in THF (15 ml) were treated with 70% aqueous perchloric acid (1.5 ml) at room temperature. The reaction mixture was heated to 55°C for 2 h, cooled to room temperature and neutralized carefully with sodium bicarbonate. The organic layer was separated and the aqueous layer was extracted with ether. The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. The solvent was evaporated *in vacuo* and the residue was purified by tlc on silica gel using ether–hexane (1:6, v/v) to give 191 mg (82.6%) of the α,β-unsaturated ketone **40** as a colourless oil; ir (CCl_4): 1710 (α,β-unsaturated ketone), 1630 cm^{-1} (conjugated double bond); nmr ($CDCl_3$) τ: 2.64 (s, 5H, aromatic protons), 4.13 (d, J = 6 Hz, 1H, vinylic proton), 4.19 (d, J = 1.75 Hz, 1H, vinylic proton *cis* to carbonyl), 4.87 (d, J = 1.75 Hz, vinylic proton *trans* to carbonyl), 5.47 (s, 2H, benzylic protons), 6.18 (m, 2H, proton unshielded by benzyloxy group and bicyclooctane bridgehead proton), 7.03 and 7.50 ppm (b s, 1H each, bicycloheptane bridgehead protons). *Mol. Wt.* calcd. for $C_{21}H_{22}O_2$: 306; found (ms): 306.

*Reduction of α,β-Unsaturated Ketone **40***

The α,β-unsaturated ketone **40** (180 mg) in absolute methanol (15 ml) was treated with sodium borohydride (560 mg). The reaction mixture was stirred at room temperature for 2 h and then it was neutralized with dilute hydrochloric acid. Excess of methanol was evaporated *in vacuo* and the residue was dissolved in water and extracted with ether. The combined extracts were washed with water and brine and dried over anhydrous magnesium sulfate. The solvent was evaporated and the residue was purified by preparative tlc on silica gel using ether–hexane (1:2, v/v) to give alcohol **41** (133 mg, 76%) as colourless oil; ir (CCl_4): 3630 cm^{-1} (hydroxyl); nmr ($CDCl_3$) τ: 2.67 (s, 5H, aromatic protons), 4.31 (d, J = 6 Hz, 1H, vinylic proton), 5.50 (s, 2H, benzylic protons), 5.90–6.66 (m, 2H, protons unshielded by benzyloxy and hydroxyl groups), 7.14 (b s, 1H, bicycloheptane bridgehead proton), 9.07 ppm (d, J = 8 Hz, 3H, methyl). *Mol. Wt.* calcd. for $C_{21}H_{26}O_2$: 310; found (ms): 310.

*Preparation of Acetate **42***

The alcohol **41** (100 mg) was dissolved in 2 ml of acetic anhydride – pyridine (1:1, v/v) and the reaction mixture was allowed to stir at room temperature overnight. The reaction was worked up by the usual procedure and the residue was purified by preparative tlc on silica gel using ether–hexane (1:5, v/v) to furnish the acetate **42** (92%) as colourless oil; ir (CCl_4): 1725 cm^{-1} (acetate); nmr ($CDCl_3$) τ: 2.67 (s, 5H, aromatic protons), 4.28 (d, J = 6 Hz, 1H, vinylic proton), 5.15 (dd, J = 1 and 8 Hz, 1H, proton unshielded by acetate), 5.50 (s, 2H, benzylic protons), 6.02 (m, 1H, proton unshielded by benzyloxy group), 7.64 (s, 3H, acetoxy methyl), 9.21 ppm (d, J = 8 Hz, 3H, methyl). *Mol. Wt.* calcd. for $C_{23}H_{28}O_3$: 352; found (ms): 352.

*Preparation of Hydroxy Acetate **43***

A solution of compound **42** (130 mg) in methanol (20 ml) was hydrogenolyzed over 10% palladium-on-charcoal (20 mg) at atmospheric pressure. The catalyst was filtered off and the filtrate was evaporated to dryness to give the alcohol **43** (95%), mp 122–124°C from ether–hexane; ir (CCl_4): 3550 (hydroxyl), 1725 cm^{-1} (acetate); nmr ($CDCl_3$) τ: 4.26 (d, J = 6 Hz, 1H, vinylic proton), 5.23 (dd, J = 1 and 8 Hz, 1H, proton unshielded by acetate), 5.83 (b s, 1H, proton unshielded by hydroxyl), 7.90 (s, 3H, acetoxy methyl), 8.88 ppm (d, J = 8 Hz, 3H, methyl). *Mol. Wt.* calcd. for $C_{16}H_{22}O_3$: 262; found (ms): 262.

*Preparation of Mesylate **44***

A solution of the alcohol **43** (48 mg) and triethylamine (27 mg) in dry methylene chloride (10 ml) was cooled to 0°C and treated with methanesulfonyl chloride (25 mg). After stirring for 30 min, the reaction was worked up in the standard manner to yield the expected product **44** (95%) which melted with decomposition at 134°C; ir (CCl_4): 1730 (acetate), 1365, 1330, 1170 cm^{-1} (mesylate); nmr ($CDCl_3$) τ: 4.31 (d, J = 6 Hz, 1H vinylic proton), 4.84 (m, 1H, proton unshielded by mesylate), 5.17 (dd, J = 2 and 10 Hz, 1H, proton unshielded by acetate), 7.04 (s, 3H, mesylate methyl), 7.93 (s, 3H, acetoxy methyl), 9.13 ppm (d, J = 7.5 Hz, 3H, methyl). *Mol. Wt.* calcd. for $C_{17}H_{24}O_5S$: 340; found (ms): 340. *Anal.* calcd. for $C_{17}H_{24}O_5S$: C 59.98, H 7.10; found: C 60.23, H 7.13.

*Rearrangement of Compound **44***

The mesylate **44** (25 mg) in glacial acetic acid (7 ml) was heated under reflux for 20 min. The reaction mixture was cooled to room temperature and the acetic acid was evaporated under reduced pressure. The residue was dissolved in ether, washed with water, brine, and dried over anhydrous magnesium sulfate. The solvent was evaporated and the residue was purified by preparative tlc on silica gel using ether–hexane (1:2, v/v) to yield the rearranged product **45** (90%) as a colourless oil; ir (CCl_4): 1735 cm^{-1} (acetate); nmr ($CDCl_3$) τ: 4.67–5.18 (m, 3H, vinylic proton and protons unshielded by

acetates), 7.93, 7.97 (s, 3H each, acetoxy methyls), 8.93 ppm (d, J = 8 Hz, 3H, methyl). *Mol. Wt.* calcd. for $C_{18}H_{24}O_4$: 304; found (ms): 304.

Preparation of Diol ***46***

A solution of the diacetate **45** (50 mg) in 5 ml of 5% methanolic potassium hydroxide (containing 10% water) was heated under reflux for 12 h. The reaction mixture was cooled to room temperature, neutralized with dilute hydrochloric acid and the excess of the methanol was evaporated under reduced pressure. The residue was dissolved in water (3 ml) and extracted with chloroform (3 × 5 ml). The combined extracts were washed with brine and dried over anhydrous magnesium sulfate. The solvent was evaporated *in vacuo* and the residue was purified by preparative tlc on silica gel using ether–hexane (2:1, v/v) to give diol **46** (34.3 mg, 95%) as a colourless oil; ir (CCl_4): 3620 cm^{-1} (hydroxyl); nmr ($CDCl_3$) τ: 4.87 (b s, 1H, vinylic proton), 6.17 (m, 2H, protons unshielded by hydroxy groups), 9.03 ppm (d, J = 8 Hz, 3H, methyl). *Mol. Wt.* calcd. for $C_{14}H_{20}O_2$: 220; found (ms): 220.

Oxidation of Diol ***46***

The diol **46** (10 mg) in dry methylene chloride (1 ml) was added to a stirred suspension of the chromium trioxide–dipyridine complex (155 mg) in the same solvent (3 ml). The mixture was allowed to stir at room temperature for 10 min and then it was quenched with wet ether (4 ml). Standard work-up and purification by preparative tlc on silica gel using ether–hexane (2:3, v/v) gave the diketone **47** (7.8 mg, 80%) which melted at 58–59°C from ether–hexane. This material was identical with the previously synthesized compound (10) by mixture melting point, tlc, ir, nmr and ms.

Infrared (CCl_4): 1745 (five-membered ketone), 1675 cm^{-1} (six-membered conjugated ketone); nmr ($CDCl_3$) τ: 4.39 (s, 1H, vinylic proton), 7.00 (b s, 1H, bicycloheptane bridgehead allylic proton), 8.72 ppm (d, J = 7 Hz, 3H, methyl). *Mol. Wt.* calcd. for $C_{14}H_{16}O_2$: 216; found (ms): 216. *Anal.* calcd. for $C_{14}H_{16}O_2$: C 77.75, H 7.46; found: C 77.79, H 7.64.

Perepoxide intermediates in the conversion of some β-halohydroperoxides to allylic hydroperoxides by base[1,2]

KARL R. KOPECKY, WAYNE A. SCOTT, PETER A. LOCKWOOD,[3] AND CEDRIC MUMFORD

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2E1

Received September 26, 1977

KARL R. KOPECKY, WAYNE A. SCOTT, PETER A. LOCKWOOD, and CEDRIC MUMFORD. Can. J. Chem. **56**, 1114 (1978).

Migration of the hydroperoxy group occurs during the reaction between base and several β-halohydroperoxides to give allylic hydroperoxides. An 86:14 ratio of 3-hydroperoxy-2-(4-methoxyphenyl)-3-methyl-1-butene-3-hydroperoxy-3-(4-methoxyphenyl)-2-methyl-1-butene was formed in 90% yield from 2-bromo-3-hydroperoxy-3-(4-methoxyphenyl)-2-methylbutane. From 1-chloro-, 1-bromo-, and 1-iodo-1-(1-hydroperoxy-1-methylethyl)cyclohexane there were obtained 1-(1-hydroperoxy-1-methylethyl)cyclohexene and 1-hydroperoxy-1-(2-propenyl)-cyclohexane in ratios of 93:7, 94:6, and 94:6, respectively, in 98–100% yield. Isopropylidenecyclohexane was converted with singlet oxygen to these allylic hydroperoxides in a 10:90 ratio. Only the latter allylic hydroperoxide was formed in the reaction between the alkene and triphenyl phosphite ozonide at −70°C. The *p*-nitrobenzoate esters of 1-hydroperoxy(1-chloro-, 1-bromo-, and 1-iodo-1-methylethyl)cyclopentane were converted quantitatively to 1-(1-hydroperoxy-1-methylethyl)cyclopentene and 1-hydroperoxy-1-(2-propenyl)-cyclopentane in 77:23, 73:27, and 70:30 ratios, respectively. Oxidation of isopropylidene-cyclopentane with triphenyl phosphite ozonide at −70°C and singlet oxygen produced the allylic hydroperoxides in 62:38 and 58:42 ratios, respectively. The reactions of the β-halohydroperoxides proceed exclusively via perepoxide intermediates. The reactions between the alkenes and singlet oxygen or triphenyl phosphite ozonide do not involve perepoxide intermediates.

KARL R. KOPECKY, WAYNE A. SCOTT, PETER A. LOCKWOOD et CEDRIC MUMFORD. Can. J. Chem. **56**, 1114 (1978).

La migration du groupe hydroperoxy se produit durant la réaction entre une base et plusieurs β-halohydroperoxydes pour conduire aux hydroperoxydes allyliques. Il se forme l'hydroperoxy-3 (méthoxy-4 phényl)-2 méthyl-3 butène-1 et l'hydroperoxy-3 (méthoxy-4 phényl)-3 méthyl-2 butène-1 dans un rapport de 86:14 et avec un rendement de 90% à partir du bromo-2 hydroperoxy-3 (méthoxy-4 phényl)-3 méthyl-2 butane. A partir des chloro-1 bromo-1 et iodo-1 (hydroperoxy-1 méthyl-1 éthyl)-1 cyclohexane, on obtient les (hydroperoxy-1 méthyl-1 éthyl)-1 cyclohexène et hydroperoxy-1 (propène-2 yl)-1 cyclohexane dans un rapport de 93:7, 94:6 et 94:6, respectivement, avec des rendements de 98–100%. L'isopropylidène-cyclohexane se transforme sous l'influence de l'oxygène singulet dans ces hydroperoxydes allyliques dans un rapport de 10:90. Il ne se forme que le dernier hydroperoxyde allylique dans la réaction de l'alcène et de l'ozonide de triphénylphosphite à −70°C. Il y a une transformation quantitative des esters *p*-nitrobenzoate de l'hydroperoxy-1 (chloro-1, bromo-1 et iodo-1 méthyl-1 éthyl)-1 cyclopentane en (hydroperoxy-1 méthyl-1 éthyl)-1 cyclopentène et l'hydroperoxy-1 (propène-2 yl)-1 cyclopentane dans des rapports respectifs de 77:23, 73:27 et 70:30. L'oxydation de l'isopropylidènecyclopentane avec l'ozonide de triphénylphosphite à −70°C et l'oxygène singulet conduisent à la formation des hydroperoxydes allyliques dans des rapports respectifs de 62:38 et 58:42. Les réactions des β-halohydroperoxydes se produisent exclusivement par l'intermédiaire de perépoxydes. Les réactions entre les alcènes et l'oxygène singulet ou l'ozonide de triphénylphosphite n'impliquent pas d'intermédiaires perépoxydes.

[Traduit par le journal]

Introduction

β-Halohydroperoxides derived from a variety of tetrasubstituted ethylenes are converted in high yield to allylic hydroperoxides on treatment with base (1). This reaction provides an alternate route to the photosensitized oxygenation of such alkenes for the preparation of allylic hydroperoxides.

During a study to compare the product distributions of the two modes of oxidation of an unsymmetrically deuterated 2,3-dimethyl-2-butene it was found that migration of the hydroperoxy group occurred on treatment of the derived mixture of bromohydroperoxides with base (1*b*) (Scheme 1). Both bromohydroperoxides were consumed at the

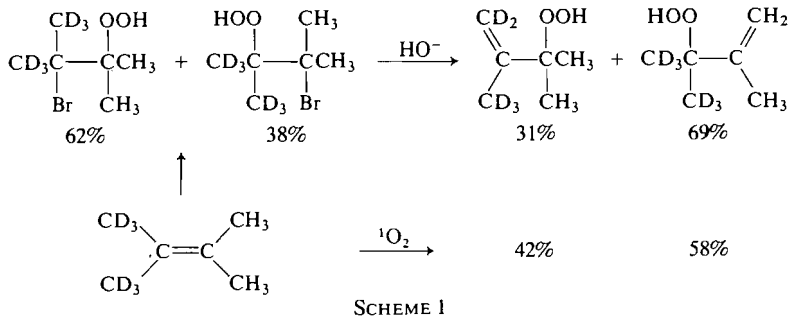

SCHEME 1

same rate. It was concluded that the reaction proceeded exclusively by way of a perepoxide intermediate and that a perepoxide was not an intermediate in the singlet oxygen oxidation of the alkene because of the different product distributions of the two reactions.

The present study was undertaken to search for further examples of hydroperoxy group migration in the reaction between β-halohydroperoxides and base, to determine whether the reaction proceeds exclusively by way of perepoxide intermediates in other systems as well and to obtain further evidence on whether or not perepoxides are formed in the singlet oxygen oxidation of alkenes to allylic hydroperoxides.

Results and Discussion

The reaction between base and 3-bromo-3-hydroperoxy-3-(4-methoxyphenyl)-2-methylbutane produces in 90% yield a mixture of allylic hydroperoxides in which the product of hydroperoxy group migration predominates greatly (Scheme 2). A very similar product distribution is obtained on singlet oxygen oxidation of the corresponding alkene (2). The singlet oxygen oxidation was repeated in the presence of 0.5 *M* sodium hydroxide. The product distribution was nearly the same as in the absence of base.

The product distributions from the oxidation of the unsymmetrical alkenes isopropylidenecyclohexane **1** and isopropylidenecyclopentane **5** by singlet oxygen, by triphenyl phosphite ozonide and those from the reaction between base and the halohydroperoxides derived from these alkenes are shown in Schemes 3 and 4. The three different halohydroperoxides were prepared from each alkene to study the effect of the halogen leaving group on the product distribution.

The halohydroperoxides were prepared by the reaction between the alkene, 1,3-dihalo-5,5-dimethylhydantoin and hydrogen peroxide in ether at −20 to −40°C (1). The reactions with **1** were all regiospecific. Only the isomer with the hydroperoxy group on the carbon bearing the methyl groups appeared to be formed under a variety of conditions. The nmr spectra of the crude reaction mixtures had no signals that could be attributed to the other isomer. Each of the halohydroperoxides derived from **1** was purified by low temperature crystallization from Skelly B to material with >98% active oxygen content. All three compounds were stable at 20°C for at least 10 min.

The degradation shown in Scheme 5 established the structure of the bromohydroperoxide **2**-Br. The nmr signal ($CDCl_3$) of the methyl groups of **2**-Br appeared at τ 8.5. The structures of **2**-Cl and **2**-I followed from their nmr spectra. The methyl groups absorbed at τ 8.6 and 8.4, respectively. The absorptions of the methyl groups of the isomeric halo-

SCHEME 3

hydroperoxides would be expected to be 0.2 to 0.7 τ units more downfield (1).[4]

The bromo- and iodohydroperoxides **6**-Br and **6**-I of **5** also appear to have been formed regiospecifically with the halogen on the carbon atom bearing the methyl groups. These absorbed at τ 8.12 and 7.94 respectively.[5] A mixture of chlorohydroperoxides **6**-Cl and **9**-Cl was formed from **5**. The isomer with the chlorine atom on the carbon atom bearing the methyl groups predominated by a ratio of ~2:1. It was extremely difficult to separate **6**-Cl and **9**-Cl, which were formed in low yield, from the other products of the reaction. Repetitive chromatography at −30 to −40°C afforded material which had 93% of the theoretical active oxygen content and had sharp singlet absorptions at τ 8.33 and 8.54, assigned to the methyl groups of **6**-Cl and **9**-Cl, respectively. It proved impossible to free **6**-Cl completely from **9**-Cl, but the *p*-nitrobenzoate ester **6**-Cl-PNB could be made pure. It was also necessary to prepare the *p*-nitrobenzoate ester of **6**-I to ensure the purity of this material as **6**-I exploded within a minute after being freed of solvent. At 20°C **6**-I-PNB was stable for some time as were **6**-Cl and **9**-Cl, and **6**-Br.

The base-induced elimination of H-X from **2**-Cl, **2**-Br, and **2**-I produced a quantitative yield (nmr) of the mixture of allylic hydroperoxides **3** and **4** in a ratio that did not vary with the halide ion leaving group. However, the amount of rearrangement of the hydroperoxy group is quite small with **3** greatly predominating in the product mixture. Treatment of the *p*-nitrobenzoate ester of **2**-Cl with base produced the same product ratio as was obtained from **2**-Cl itself.

Pure **3** was isolated readily by low temperature crystallization. The isomeric allylic hydroperoxide **4** is formed almost exclusively on singlet oxygen oxidation of **1** and is the sole product when **1** is treated with triphenyl phosphite ozonide. Thus, either of the two possible allylic hydroperoxides can be prepared from **1**, as has been noted already (3).

Treatment of the halohydroperoxides, or their *p*-nitrobenzoate esters, derived from **5** with base produced a quantitative yield (nmr) of a mixture of allylic hydroperoxides **7** and **8** in which the product of rearrangement of the hydroperoxy group **8** predominates by a ratio of nearly 3:1. The ratio is not quite independent of the leaving halogen ion.

[4]After the work involving **1** and its derivatives had been completed it was reported (3) that both possible bromohydroperoxides were produced from **1** in proportions that depended upon the reaction conditions and that **2**-Br predominated. It was also concluded that there was no migration of the hydroperoxy group when the mixture of bromohydroperoxides was treated with base. The small amount of rearrangement that does occur (Scheme 3 of the present paper) was not detected. No experiments carried out with pure bromohydroperoxide were reported. It was observed, in agreement with the present work, that the reaction between singlet oxygen and **1** produces a product mixture very different from that obtained by treatment of the bromohydroperoxide with base.

[5]The regiospecificities of the addition reactions of **1** and **5** reported here have been noted already in the preparation of the bromohydrins of these alkenes and a rationale has been presented (4).

[a]PNB = *p*-nitrobenzoyl.

SCHEME 4

Slightly more rearrangement occurred with **6**-Cl-PNB than with the bromo or iodo compounds. A 78:22 ratio of **8**:**7**, essentially the same as was obtained from **6**-Cl-PNB, resulted when a mixture of ~80% **6**-Cl and ~20% **9**-Cl, which had 93% of the theoretical active oxygen content, was treated with base. Also, a 79:21 ratio of **8**:**7** was obtained from a mixture, analytically pure, of 75% **6**-Cl-PNB and 25% **9**-Cl-PNB.

An attempt was made to monitor the reaction between **6**-Br and base by nmr spectroscopy at −60°C. A spectrum taken within 30 s after mixing the reactant solutions had signals due only to **7** and **8**, all **6**-Br had already been consumed.

As was observed in the cyclohexyl system oxidation of the alkene **5** with either singlet oxygen or triphenyl phosphite ozonide produced **7** and **8** in ratios significantly different from those in the above reactions.

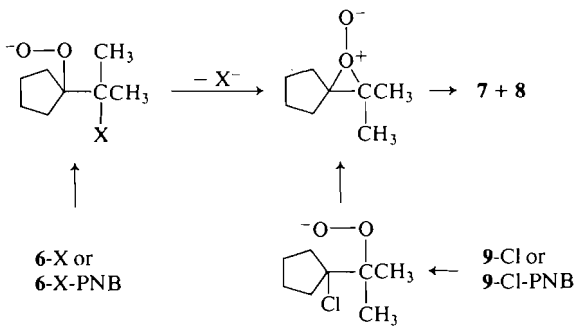
9-Cl-PNB, R = PNB

Discussion

The formation of **4** from **2**-X and of **8** from **6**-X is direct evidence that migration of a hydroperoxy group occurred in the reaction between the halohydroperoxides and base. The relative insensitivity of the product ratios to the nature of the leaving halide ion is evidence that both rearranged and unrearranged product are produced by only one pathway involving a halogen-free intermediate. These results are in complete agreement with those obtained previously with the bromohydroperoxides of the partially deuterated 2,3-dimethyl-2-butene (1*b*). As was discussed previously (1*b*) the halohydroperoxides must be converted by base to perepoxide intermediates exclusively which then rearrange to allylic hydroperoxides as is shown in Scheme 6 for **6**-X. The fact that mixtures of **6**-Cl or **6**-Cl-PNB containing appreciable amounts of **9**-Cl or **9**-Cl-PNB react to give the same ratio of **7**:**8** as is formed from pure **6**-Cl-PNB means that **9**-Cl and **9**-Cl-PNB also are converted exclusively to the perepoxide. Little, if any, elimination can be occurring by a route that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



SCHEME 6

does not involve the perepoxide. Thus, it appears that perepoxide formation in the reaction between base and halohydroperoxides of tetrasubstituted ethylenes must be quite general. In principle the rearrangement could also proceed by way of a 1,2-dioxetane but tetramethyl-1,2-dioxetane disappears only after days under the reaction conditions to produce the cleavage product acetone only (1*b*). No allylic hydroperoxide could be detected.

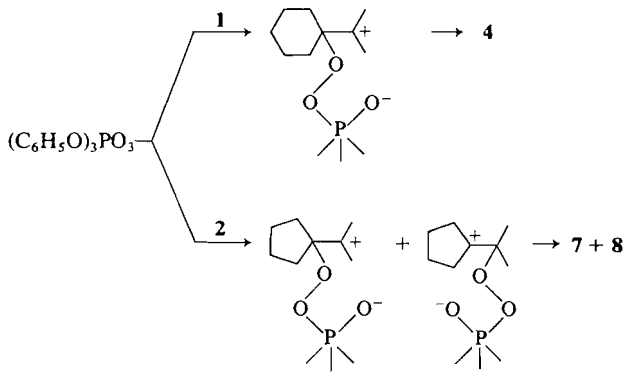
The product ratios obtained on oxidation of the alkenes **1** and **5** with singlet oxygen and triphenyl phosphite ozonide are significantly different from those obtained from the halohydroperoxides. The present work provides further examples to show that singlet oxygen oxidations of tetrasubstituted ethylenes, at least, to allylic hydroperoxides do not proceed by way of perepoxide intermediates. The reaction must be concerted (5).

Recent suggestions, based on experimental evidence and on theoretical calculations, that singlet oxygen reacts to form the perepoxide as the initial product with at least some alkenes have been refuted. Photosensitized oxidation of adamantylideneadamantane in pinacolone produces a mixture of dioxetane and epoxide (6). It was proposed that the epoxide was formed from a perepoxide by transfer of an oxygen atom to pinacolone in a Bayer–Villiger type of reaction and that perepoxide not trapped in this way rearranged to the dioxetane. The suggested oxygen transfer reaction was based on some observations made in ozonolysis reactions (7) which were soon shown to be incorrect (8). Further, there is recent evidence that singlet oxygen is not involved in the formation of adamantylideneadamantane epoxide (9).

The argument has been made that the product distribution from the halohydroperoxide elimination results from a combination of direct elimination plus perepoxide whereas the singlet oxygen oxidation proceeds only through perepoxide (10*a*). However, this cannot be correct since **6**-X gives mainly **8** and more **8** is produced than in the singlet oxygen reaction with **5**.

Several theoretical calculations using empirical methods have been made which show that perepoxides should be readily formed in the reaction between singlet oxygen and alkenes (10), but recent *ab initio* calculations show that perepoxides must be very unstable species (11).

The reaction between triphenyl phosphite ozonide and alkenes to give allylic hydroperoxides must proceed by still a third mechanism since the product distributions are quite different from those of the reactions involving perepoxides and the reagent does not produce singlet oxygen at the temperature where the reactions were carried out (12). The results can be rationalized by an ionic mechanism (13), Scheme 7, in which only one zwitterion is formed from **1** but both possible zwitterions are formed from **2**. This mechanism is consistent with the regioselectivities observed on formation of the halohydroperoxides of **1** and **5**.



SCHEME 7

Experimental

Microanalyses were performed by Mrs. Darlene Mahlow.

3-(4-Methoxyphenyl)-2-methyl-2-butene

A solution of 51 g (0.5 mol) 3-hydroxy-3-methyl-2-butanone in 100 ml ether was added dropwise to 1.2 mol of 4-methoxyphenylmagnesium bromide in 750 ml ether which was stirred by a high speed stirrer. A glutinous mass formed during the addition. The mixture was heated under reflux for 1 h after the addition was complete and then hydrolyzed with a saturated ammonium chloride solution. The glutinous mass was agitated manually during the hydrolysis and then washed several times with ether. The combined ether layers were dried, concentrated and 40 g methoxybenzene was distilled under reduced pressure from the residual oil. The hot residue was stirred into 100 ml heptane. The solid which formed was recrystallized from carbon tetrachloride to give 79 g (75%) of 2-(4-methoxyphenyl)-3-methyl-2,3-butanediol, mp 76–84°C. A small quantity was recrystallized again to give colorless crystals, mp 82–85°C (lit. (14) mp 87–88°C).

A mixture of 70 g (0.33 mol) of the above diol and 48.8 g (0.33 mol) of triethyl orthoformate was heated at 140°C (15). After 2 h 14.4 g ethanol had distilled and the temperature was then raised to 205°C. After 12 h 12.2 g more ethanol distilled and the temperature was raised to 225°C at which point more

For personal use only.

ethanol was distilled and carbon dioxide was evolved. Gas evolution ceased after 1 h and the residue was distilled to give 47.3 g (80%) of a colorless oil, bp 239–243°C/702 Torr, n_D^{26} 1.5309 (lit. (16) bp 234°C/760 Torr, n_D^{25} 1.5295).

Photooxygenation of 3-(4-Methoxyphenyl)-2-methyl-2-butene in the Presence of Base

A solution of 2.1 g of the alkene in 30 ml of 0.5 *M* methanolic sodium hydroxide was subjected to Eosin sensitized photooxygenation (1*b*). After 4 h oxygen uptake ceased, the reaction mixture was poured into 100 ml water, and the resulting mixture neutralized with acetic acid and extracted twice with 50 ml ether. After drying the ether solution was added to 1.0 g lithium aluminum hydride in 15 ml ether. After 1 h at reflux the mixture was hydrolyzed with aqueous potassium hydroxide and the ether layer concentrated to give 2.1 g (92%) of a colorless oil; ^{1}H nmr (CCl_4) τ: 2.83 (d, J = 9 Hz, ArH) 3.42 (d, J = 9 Hz, ArH), 4.70 (d, J = 1.7 Hz, =CH*H*), 4.90 (m, =CH*H*), 5.13 (d, J = 1.7 Hz, =C*H*H), 5.13 (m, =C*H*H), 6.27 (s, OCH_3), 8.1 (s, OH), 8.42 (m, =C—CH_3), 8.42 (s, benzylic CH_3), 8.70 (s, $C(CH_3)_2$). The isomer ratio, 2.5:1, was determined from five integrations of the absorptions of the vinyl hydrogens at τ 4.70 and 4.90 which were assigned to 3-hydroperoxy-2-(4-methoxyphenyl)-3-methyl-1-butene and 3-hydroperoxy-3-(4-methoxyphenyl)-2-methyl-1-butene, respectively. The assignments were made on the basis of the relative yields reported for the photooxygenation of the parent alkene in the absence of base (2).

Treatment of 2-Bromo-2-methyl-3-(4-methoxyphenyl)-3-butyl Hydroperoxide with Base

An 8.8 g quantity of 3-(4-methoxyphenyl)-2-methyl-2-butene was treated with 98% hydrogen peroxide and 1,3-dibromo-5,5-dimethylhydantoin in ether using the described procedure for making bromo hydroperoxides (1*a*). Attempts to remove solvent from the reaction mixture after work-up resulted in loss of peroxide content and blackening of the product. Iodometric titration of the ether solution indicated that ~70% of the bromo hydroperoxide had been formed. A portion of the ether solution was added to carbon tetrachloride and the resulting mixture evaporated under reduced pressure until the remaining liquid was ether-free; ^{1}H nmr (CCl_4) τ: 2.32–3.33 (m, ArH), 6.23 (s, OCH_3), 8.11 (s, benzylic CH_3), 8.28 and 8.33 (s, $C(CH_3)_2$); signals due to unreacted starting material were also present.

The remaining ether solution was cooled to 0°C and 100 ml of 0.5 *M* methanolic sodium hydroxide was stirred in over a 15 min period. After stirring for a further 30 min the mixture was poured into 100 ml water and the resulting mixture neutralized with acetic acid. The resulting mixture was extracted twice with 100 ml ether. The combined ether extracts were dried and added to a slurry of 2.5 g lithium aluminum hydride in 60 ml ether. Work-up as above provided a colorless oil which was chromatographed on 300 g basic alumina. Starting alkene, 33%, was eluted with pentane. Elution with 1:1 ether–pentane gave some unidentified solid, and elution with ether removed the mixture of allylic alcohols in 57% yield. The ^{1}H nmr spectrum showed the same peaks as the mixture obtained on photosensitized oxidation. The isomer ratio, determined as before, was 6.3:1.

1-(2-Propenyl)cyclohexanol

This material was prepared from the reaction between 2-propenylmagnesium bromide (17) and cyclohexanone in 66% yield, bp 54°C/2.5 Torr; n_D^{25} 1.4824; ir (CCl_4) 3450 (OH), 1635 (C=C); ^{1}H nmr (CCl_4): 5.05 (s, 1H, =C*H*H), 5.2 (s, 1H, =CH*H*), 7.95 (s, 1H, OH), 8.2 (d, J = 1 Hz, 3H, CH_3), 8.45 (b, 10H, CH_2). *Anal.* calcd. for $C_9H_{16}O$: C 77.14, H 11.42; found: C 77.13, H 11.41.

Isopropylidenecyclohexane (1)

A solution of 28 g (0.2 mol) of the above compound and 10 g ethanol dissolved in 50 ml ether was added to a solution of 10 g (0.4 mol) sodium in 270 ml liquid ammonia at −33°C. A further 10 g ethanol was added and the solution was allowed to reflux for 2 h. Water was added until the blue color just disappeared and the ammonia was allowed to evaporate overnight. Water, 100 ml, was added to the residue and the resulting mixture was extracted with ether three times. The combined ether extracts were washed with water until neutral, dried and concentrated. The residue was distilled to give 17.9 g colorless oil, bp 51–53°C/14 Torr, n_D^{20} 1.4710 (lit. (18) bp 46–48°C/13 Torr, n_D^{20} 1.4714).

1-(2-Propenyl)cyclopentanol

The method used for the preparation of 1-(2-propenyl)-cyclohexanol was used to prepare this material in 50% yield, bp 72–75°C/18 Torr, n_D^{26} 1.4745; ^{1}H nmr (CCl_4) τ: 5.05 (s, 1H, =C*H*H), 5.2 (m, 1H, =CH*H*), 7.1 (b, 1H, OH), 8.2 (d, J = 1Hz, 3H, CH_3), 8.3 (b, 8H, CH_2). *Anal.* calcd. for $C_8H_{14}O$: C 76.19, H 11.11; found: C 75.94, H 10.81.

Isopropylidenecyclopentane (5)

The procedure used for the preparation of **1** was used to make **5** in 50% yield, bp 133–134°C, n_D^{22} 1.4574 (lit. (18) bp 135.5–137.5°C, n_D^{20} 1.4585).

1-(1-Hydroperoxy-1-methylethyl)cyclohexyl Bromide (2-Br)

This material and the halohydroperoxides described below were prepared in the usual way (1*a*). From 12.4 g **1** was obtained 29.7 g of crude product as an oil which contained 76% of the theoretical active oxygen content as determined by iodometric titration (19). Three recrystallizations from Skelly B yielded a white solid, mp 55–56°C, containing 99.7% of the theoretical active oxygen content; ^{1}H nmr ($CDCl_3$) τ: 3.0 (b s, 1H, OOH), 8.3 (b, 10H, CH_2), 8.5 (s, 6H, CH_3).

1-(1-Hydroperoxy-1-methylethyl)cyclohexyl Iodide (2-I)

From 12.4 g **1**, using 1,3-diiodo-5,5-dimethylhydantoin as the halogenating agent, was obtained 35 g yellow solid which had 67% of the theoretical oxygen content. Several recrystallizations from Skelly B gave a white solid, mp 43°C (dec.), with 98% of the theoretical active oxygen content. This material decomposed within several minutes at 25°C; ^{1}H nmr (CCl_4) τ: 2.7 (s, 1H, OOH), 8.2 (b, 10H, CH_2), 8.4 (s, 6H, CH_3).

1-(1-Hydroperoxy-1-methylethyl)cyclohexyl Chloride (2-Cl)

From 1.24 g of compound **1**, using 1,3-dichloro-5,5-dimethylhydantoin as halogenating agent and stirring the reaction mixture an extra 1.5 h at −30°C, was obtained 2.1 g oil. This was added to 10 ml 2-methylbutane and the resulting mixture filtered. The filtrate was cooled to −70°C and the resulting crystals were recrystallized several times from 2-methylbutane at −70°C to yield 0.5 g (26%) of a white solid, mp 46–46.5°C, with 100% of the theoretical oxygen content; ^{1}H nmr (CCl_4) τ: 2.5 (s, 1H, OOH), 8.1–8.3 (b, 10H, CH_2), 8.6 (s, 6H, CH_3).

The *p*-nitrobenzoate ester **2**-Cl-PNB was prepared (20) from 0.5 g **2**-Cl and recrystallized from Skelly B to give 0.27 g (30%) of a white solid, mp 102°C (dec.), containing, 98.5% of the theoretical active oxygen content; ^{1}H nmr ($CDCl_3$) τ: 1.52 (d, J = 8.4 Hz, 2H, ArH), 1.68 (d, J = 8.4 Hz, 2H, ArH), 8.2 (b, 10H, CH_2), 8.4 (s, 6H, CH_3). *Anal.* calcd. for $C_{16}H_{20}ClNO_5$: C 56.23, H 5.90, N 4.10, Cl 10.37; found: C 56.04, H 6.00, N 4.66, Cl 10.59.

1-(1-Bromo-1-methylethyl)cyclopentyl Hydroperoxide (6-Br)

The crude material obtained in the usual way from 5.5 g **5** was recrystallized three times from 2-methylbutane at −70°C

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to give 4.4 g (38%) white crystals, mp −10 to −5°C, which had 99.2% of theoretical oxygen content; ^{1}H nmr ($CDCl_3$) τ: 2.40 (b, 1H, OOH), 8.0 (b, 8H, CH_2), 8.12 (s, 6H, CH_3). The crude product decomposed rapidly above 0°C but the pure product was stable for some time at 20°C.

The *p*-nitrobenzoate ester **6**-Br-PNB had mp 94–96°C (dec.); ^{1}H nmr ($CDCl_3$) τ: 1.66 (d, J = 8.4 Hz, 2H, ArH), 1.88 (d, J = 8.4 Hz, 2H, ArH), 8 (b, 8H, CH_2), 8.04 (s, 6H, CH_3). *Anal.* calcd. for $C_{15}H_{18}BrNO_5$: C 48.40, H 4.87, N 3.76, Br 21.47; found: C 48.14, H 4.81, N 3.70, Br 21.49.

*1-(1-Iodo-1-methylethyl)cyclopentyl Hydroperoxide (**6**-I)*

The crude product prepared in the usual way, using 1,3-diiodo-5,5-dimethylhydantoin as a halogen source and keeping the temperature during the entire workup at 0°C or below, was purified by chromatography on silica gel at −40°C using Skelly B – ether 4:1 as eluent. Removal of solvent under vacuum at −20°C gave a colorless oil which had 98% of the theoretical active oxygen content. This material exploded within less than a minute after being warmed to 0°C; ^{1}H nmr ($CDCl_3$, −30°C) τ: 0.46 (s, 1H, OOH), 7.94 (s, 6H, CH_3), 8.25 (b, 8H, CH_2).

The *p*-nitrobenzoate ester **6**-I-PNB was purified by chromatography on silica gel at −40°C followed by crystallization from ether – Skelly B. The material was applied to the column in toluene. The yellow crystals decomposed without melting at 75–80°C; ^{1}H nmr ($CDCl_3$) τ: 1.68 (d, J = 8.4 Hz, 2H, ArH), 1.87 (d, J = 8.4 Hz, 2H, ArH), 7.86 (s, 6H, CH_3), 8.0 (b, 8H, CH_2). *Anal.* calcd. for $C_{15}H_{18}INO_5$: C 42.97, H 4.33, N 3.34, I 30.27; found: C 43.24, H 4.23, N 3.17, I 30.20.

*1-(1-Chloro-1-methylethyl)cyclopentyl Hydroperoxide (**6**-Cl) and 1-(1-Hydroperoxy-1-methylethyl)cyclopentyl Chloride (**9**-Cl)*

The crude product, prepared in the usual way using 1,3-dichloro-5,5-dimethylhydantoin as a halogen source, was chromatographed on silica gel at −40°C using 10% ether in 2-methylbutane as eluent. The fractions containing chlorohydroperoxide were combined and rechromatographed. This procedure was repeated twice more and then the fraction containing the purest chlorohydroperoxide was crystallized from 2-methylbutane at −70°C. The ^{1}H nmr spectrum of the crystals, which melted well below 0°C, indicated the presence of both **6**-Cl and **9**-Cl in a ratio of ~80:20. Recrystallization produced material with the same isomer ratio that had 93% of the theoretical peroxide content; ^{1}H nmr ($CDCl_3$) τ: 3.10 (s, 1H, OOH), 8.2 (b, 8H, CH_2), 8.33 (s, CH_3 of **6**-Cl), 8.54 (s, CH_3 of **9**-Cl).

A portion of the above material was converted to the *p*-nitrobenzoate esters **6**-Cl-PNB and **9**-Cl-PNB. These were purified by chromatography on silica gel at −40°C and then recrystallization from Skelly B to yellow crystals, mp 73–75°C, that were a mixture of 75% **6**-Cl-PNB and 25% **9**-Cl-PNB as judged from the ^{1}H nmr spectrum ($CDCl_3$) τ: 1.73 (d, J = 8.4 Hz, 2H, ArH), 1.89 (d, J = 8.4 Hz, 2H, ArH), 8.0 (b, 8H, CH_2), 8.21 (s, CH_3 of **6**-Cl-PNB), 8.36 (s, CH_3 of **9**-Cl-PNB). *Anal.* calcd. for $C_{15}H_{18}ClNO_5$: C 54.97, H 5.54, N 4.27, Cl 10.81; found: C 54.96, H 5.61, N 3.98, Cl 11.07.

The chlorohydroperoxide mixture from another preparation which contained 90% **6**-Cl was converted to the *p*-nitrobenzoate esters. Two recrystallizations from Skelly B gave **6**-Cl-PNB, whose ^{1}H nmr spectrum had no trace of the signal due to the methyl hydrogens of **9**-Cl-PNB, mp 87–88°C (dec.). *Anal.* found: C 54.63, H 5.54, N 4.20, Cl 10.88.

*Conversion of 1-(1-Hydroperoxy-1-methylethyl)cyclohexyl Bromide (**2**-Br) to (1-Hydroxy-1-methylethyl)cyclohexane*

To a solution of 2.62 g (0.01 mol) of triphenylphosphine in 50 ml Skelly B was added 2.37 g (0.01 mol) of **2**-Br in 10 ml Skelly B. The reaction mixture was stirred for 1 h and filtered. The filtrate was shaken with 30% hydrogen peroxide, filtered, and the resulting filtrate washed with water, dried, and concentrated. The residue was eluted through a column of silica gel with 25% ether in Skelly B to yield 2 g (90%) of the colorless bromohydrin. This was taken up in 30 ml benzene and 2.9 g (0.01 mol) tributyltin hydride was added. The resulting solution was held at reflux for 12 h and then concentrated. The residue was eluted through a column of silica gel with 25% ether in Skelly B to yield 1.0 g (87%) of a colorless oil that was identical (ir, ^{1}H nmr) with an authentic (21) sample of (1-hydroxy-1-methylethyl)cyclohexane.

*1-(1-Hydroperoxy-1-methylethyl)cyclohexene (**3**)*

A solution of 0.44 g (0.011 mol) sodium hydroxide in 1 ml water and 3 ml methanol was added to 2.37 g (0.01 mol) **2**-Br in 60 ml methanol at 0°C. The resulting solution was stirred at 0°C for 20 min and then poured into a mixture of water and dichloromethane. The aqueous layer was extracted three times with dichloromethane. The combined organic layers were washed with water, dried, and concentrated to give 1.5 g (87%) colorless oil. This was crystallized several times from 2-methylbutane at −78°C to give white crystals, mp 24–26°C, which had 99.7% of the theoretical active oxygen content; ^{1}H nmr (CCl_4) τ: 2.5 (s, 1H, OOH), 4.35 (m, 1H, =CH), 8.0 (b, 4H, allylic CH_2), 8.4 (b, 4H, homoallylic CH_2), 8.75 (s, 6H, CH_3).

*1-(2-Propenyl)cyclohexyl Hydroperoxide (**4**)*

Triphenyl phosphite ozonide was prepared (12) from 3.1 g (0.01 mol) triphenyl phosphine in 40 ml dichloromethane at −70°C. To this solution was added 1.2 g (0.01 mol) **1** and the resulting solution was allowed to stand at −70°C for 12 h and then warmed to 20°C. The solvent was evaporated. A weighed quantity of 1,4-dimethoxybenzene was added. The ^{1}H nmr spectrum indicated that **4** was produced in quantitative yield. No signals due to **3** could be detected. The reaction mixture was then diluted with 50 ml 2-methyl-butane and the resulting mixture stirred and filtered. Solvent was evaporated from the filtrate and the residue chromatographed on silica gel at −40°C using 25% ether in Skelly B as eluent. The fractions containing peroxide were combined and crystallized several times from 2-methylbutane at −70°C to give white crystals, mp 17–19°C, which had 99.5% of the theoretical active oxygen content; ^{1}H nmr (CCl_4) τ: 2.6 (s, 1H, OOH), 5.05 (bs, 2H, =CH_2), 8.25 (d, J = 1 Hz, 3H, CH_3), 8.5 (b, 10H, CH_2).

Reduction of 1.2 g **4** with lithium aluminum hydride produced 0.66 g of 1-(2-propenyl)cyclohexanol which had ir and ^{1}H nmr spectra identical to those of an authentic sample.

1-(1-Hydroxy-1-methylethyl)cyclohexene

A solution of 6.2 g 1-acetylcyclohexene (22) in 10 ml ether was added to a solution of methylmagnesium bromide made from 1.2 g magnesium and 5.0 g bromomethane in 40 ml ether. After 15 min under reflux the reaction mixture was hydrolyzed with saturated ammonium chloride. The usual workup gave 4.3 g (62%) of a colorless oil, bp 85–87°C/14 Torr, n_D^{28} 1.4812; ^{1}H nmr (CCl_4) τ: 4.3 (m, 1H, =CH), 7.5 (s, 1H, OH), 8.05 (m, 4H, allylic CH_2), 8.45 (b, 4H, homoallylic CH_2), 0.75 (s, 6H, CH_3). *Anal.* calcd. for $C_9H_{16}O$: C 77.14, H 11.42; found: C 76.28, H 11.62.

Reduction of 0.78 g of compound **3** with lithium aluminum hydride produced 0.69 g (99%) of an oil which had ir and ^{1}H nmr spectra identical to those of the above material.

*Product Distribution from Reaction of **2**-X and **2**-Cl-PNB with Base*

All the reactions were carried out according to the following procedure. To a solution of 2.37 g (0.01 mol) of **2**-Br in 6 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

methanol at 0°C was added 0.60 g (0.011 mol) sodium hydroxide in 1 ml water and 3 ml methanol, dropwise with stirring. The reaction mixture was stirred at 0°C for 1.5 h (it was later found that the reactions were complete in 30 s) and poured into a mixture of 10 ml water and 10 ml dichloromethane. The aqueous layer was shaken with dichloromethane, 3 × 10 ml, the combined organic layers shaken once with water, dried and concentrated. To the residue was added 0.69 g (0.005 mol) 1,4-dimethoxyethane as internal standard. The resulting mixture was taken up in carbon tetrachloride and analyzed by ^{1}H nmr spectroscopy. The relative yields of **3** and **4** were determined by integrating the vinyl protons of each isomer. The yields in Scheme 3 are the average of three integrations. Values were reproducible to within ±0.5%.

The reaction with 2-Cl-PNB was initially heterogeneous and was stirred until the reaction mixture became homogeneous.

Product Distribution from Reaction between Base and 6-X, 6-X-PNB, 9-Cl, and 9-Cl-PNB

All the reactions were based on the following procedure. A solution of 0.0876 g (3.94×10^{-4} mol) of **6**-Br and 0.01097 g (1.40×10^{-4} mol) benzene in methanol-d_4 was made up to 1 ml. A second solution of 0.0397 g (1.73×10^{-3} mol) and deuterium oxide 0.0612 g (3.06×10^{-3} mol) was made up to 2.0 ml with methanol-d_4. Equal volumes of the two solutions were mixed at 20°C in a nmr tube. The ^{1}H nmr spectrum was taken immediately and had signals at τ: 2.68 (s, C_6H_6), 4.44 (t, =CH of **8**), 4.85 (s, HOD), 5.10 (m, $=CH_2$ of **7**), 6.70 (m, H in CD_3OD), 7.66 (b, allylic CH_2 of **8**), 8.2 (b, other CH_2 of **7** and **8** and CH_3 of **7**), 8.68 (s, CH_3 of **8**). The assignments are based on the spectra of **3** and **4**. The relative yields of **7** and **8** were calculated from integration of the vinyl proton signals at τ 4.44 and 5.10. The average of three integrals was taken. These were reproducible to ±2%. The results are presented in Scheme 4.

The reactions using **6**-X-PNB were heterogeneous, and the solid esters were added in four equal portions to a small amount of methanol-d_4 followed by one quarter of the base solution. After each addition the mixture was shaken until it became homogeneous.

Photooxygenation of 1 and 5

A solution of 1.0 g of **1** or **5**, 0.1 g 2,6-di-*tert*-butylphenol, 0.1380 g 1,4-dimethoxybenzene, as internal standard, and 0.05 g methylene blue in 30 ml methanol was irradiated until oxygen uptake ceased and worked up as described (1*b*). The product yield and distribution (Schemes 3 and 4) were determined by ^{1}H nmr.

Treatment of 5 with Triphenyl Phosphite Ozonide

This reaction was carried out as described above for the reaction with **1** using 0.5 g (0.0045 mol) **5** and 1.4 g (0.0045 mol) triphenyl phosphite in 25 ml dichloromethane. After 12 h at −78°C solvent was evaporated at −35°C. The distillate was caught in a −70°C trap and found to contain 0.18 g **5**. The residue was analyzed by ^{1}H nmr spectroscopy. The results are presented in Scheme 4.

Re-examination of the Kirkwood–Westheimer theory of electrostatic effects. II.[1] Possible conformations of α,ω-amino-acids in aqueous solutions, as deduced from dissociation constants

JOHN T. EDWARD, PATRICK G. FARRELL, JOHN L. JOB, AND BO-LONG POH

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received August 12, 1977

JOHN T. EDWARD, PATRICK G. FARRELL, JOHN L. JOB, and BO-LONG POH. Can. J. Chem. **56**, 1122 (1978).

The first and second dissociation constants of the ten homologous α,ω-amino-acids $H_3\overset{+}{N}(CH_2)_nCO_2H$ (n = 1–10) have been determined by a potentiometric method at different temperatures, and hence the thermodynamic parameters ΔG^0, ΔH^0, and ΔS^0 were computed. Calculation by Kirkwood–Westheimer theory of $\Delta G_1{}^0$ for the first (carboxyl) dissociation, assuming the conformation of the polymethylene chain to be intermediate between the random-coil and the fully extended conformation, gives results in good agreement with experiment for the longer chains. A similar calculation of $\Delta G_2{}^0$ for the second (ammonium) dissociation gives results in fair agreement with theory for the very long chains (n = 7–10), but in disagreement for shorter chains. A tentative explanation based on electrostatic effects on hydration of the ammonium group is advanced.

JOHN T. EDWARD, PATRICK G. FARRELL, JOHN L. JOB et BO-LONG POH. Can. J. Chem. **56**, 1122 (1978).

On a déterminé les première et deuxième constantes de dissociation de dix acides aminés α,ω homologues $H_3\overset{+}{N}(CH_2)_nCO_2H$ (n = 1–10) par une méthode potentiométrique à différentes températures et on peut donc calculer les paramètres thermodynamiques ΔG^0, ΔH^0 et ΔS^0. Des calculs, par la théorie de Kirkwood–Westheimer, de $\Delta G_1{}^0$ pour la première dissociation (carboxyle), en faisant l'hypothèse que la conformation de la chaîne polyméthylène est intermédiaire entre une pelotte statistique et une conformation complètement étendue, conduit à des résultats qui sont en accord avec les expériences pour les chaînes les plus longues. Un calcul semblable de $\Delta G_2{}^0$ pour la deuxième dissociation (l'ammonium) conduit à des résultats qui sont en bon accord avec la théorie pour les très longues chaînes (n = 7–10), mais qui sont en désaccord pour les chaînes plus courtes. On propose une explication possible basée sur des effets électrostatiques sur l'hydratation du groupe ammonium.

[Traduit par le journal]

Introduction

Following earlier work of Bjerrum (1), Eucken (2), Smallwood (3), and others, Kirkwood and Westheimer (4) in 1938 developed a theory to account for the effect of dipolar or charged substituents on the strengths of carboxylic acids. For example, the effect of the charged ammonium group in promoting the ionization of the carboxyl group of α,ω-amino-acids (**1**):

$$[1] \qquad H_3\overset{+}{N}(CH_2)_nCO_2H \overset{K_1}{\rightleftharpoons} H_3\overset{+}{N}(CH_2)_nCO_2^- + H^+$$

as compared with the ionization of this group in the analogous unsubstituted acid

$$[2] \qquad CH_3(CH_2)_nCO_2H \overset{K_a}{\rightleftharpoons} CH_3(CH_2)_nCO_2^- + H^+$$

can be explained by the stabilization of the zwitterion of [1] by coulombic interactions between positive and negative charges.[2] It can then be shown that ΔpK_1 ($\equiv \log K_a/K_1$) is given by

$$[3] \qquad \Delta pK_1 = e^2/2.3kTRD_{eff}$$

where e is the electronic charge, k Boltzmann's constant, R the distance between charges in the zwitterion, and D_{eff} the effective dielectric constant. Kirkwood and Westheimer showed how the latter could be calculated from the size and shape of the molecule. Thus, for equilibria in water, the lines of force between the positive and negative charges of the zwitterion pass partly through the intervening hydrocarbon chain (dielectric constant assumed to be 2.0) and partly through the surrounding water (assumed to be a continuum having the macroscopic dielectric constant of 78.5 at 25°C). Hence D_{eff} will have some intermediate value, depending upon the

[1]For part I see ref. 7.

[2]This approach differs slightly from conventional Kirkwood–Westheimer treatment, and is justified in this and in subsequent papers.

relative amounts of hydrocarbon and of water between the charges, and thus on the shape of the molecule. Assuming for simplicity an ellipsoidal shape with the charges at the foci, Kirkwood and Westheimer were able, by classical electrostatic theory, to relate D_{eff} to λ_0, the ratio of the major axis of the ellipsoid to the interfocal distance R (4).

By the same reasoning, the difference ΔpK_2 ($\equiv \log K_b/K_2$) between the second (ammonium) dissociation constant K_2 of the α,ω-amino-acids:

$$[4] \quad {}^{-}O_2C(CH_2)_nNH_3^{+} \overset{K_2}{\rightleftharpoons} {}^{-}O_2C(CH_2)_nNH_2 + H^{+}$$

and the dissociation contant K_b of the corresponding alkylammonium ion:

$$[5] \quad CH_3(CH_2)_nNH_3^{+} \overset{K_b}{\rightleftharpoons} CH_3(CH_2)_nNH_2 + H^{+}$$

is also given by eq. 3, the negatively charged carboxylate group being acid-weakening.

Application of this equation to the ΔpK_1 values of α,ω-amino-acids available in the literature (5) gave values of the intercharge distance R intermediate between R_{max}, the distance for a fully-extended zwitterion, and R_F, the root-mean-square distance between the ends of the chain, assuming free rotation about the carbon–carbon links (6). These results have been quoted as evidence for a random-coil conformation of α,ω-amino-acids in solution. However, they are in error, because of errors in Kirkwood and Westheimer's D_{eff} values for λ_0 between 1.0 and about 1.8 (i.e., for long, thin molecules). These errors may have arisen because of the approximations required (7).[3] Using different D_{eff} values, we have shown that the ΔpK_1 values for the limited number of α,ω-amino-acids (n = 1–6) reported in the literature yield R values closer to R_{max} than R_F (7).

Such a result can be explained along lines suggested by Everett and Pinsent (9). The strong attraction between the charged groups of the zwitterion and the highly polar water molecules will result in the displacement of the less polar hydrocarbon chain as completely as possible from the vicinity of the charges, so that the chain assumes its most extended conformation.

King and King (10) have claimed that the clustering of water molecules about ionic centres (with consequent stiffening of the hydrocarbon chain) can be expected to extend to a distance of about 5 Å (about four methylene groups) only, and indeed a recent nmr study of n-alkylammonium ions shows progressively greater flexibility of the chain with distance from the charged ammonium group (11). Hence the longer α,ω-amino-acids might be expected to have flexible, random-coil portions at the centres of the polymethylene chains. Furthermore, the end-to-end distances R_F calculated by the earlier random-flight theory of Kuhn (6) are now known to be unrealistically small because of their failure to take account of the excluded volume effect, and of the fact that rotations about carbon–carbon bonds are not free but biased towards certain preferred conformations (12, 13). When these effects are taken into account, the end-to-end distance R_R calculated for a random-coil is greater than R_F. It consequently becomes of interest to see if the R values calculated from [3] agree better with R_{max} or R_R. In this paper we report K_1 and K_2 values for the α,ω-amino-acids from n = 1 to n = 10; the still longer acids (n > 10) could not be studied because they proved to be too insoluble in water at 25°C. The results show that R probably lies between R_{max} and R_R.

[3]These recalculations have recently been discussed in detail by Ehrenson (8).

Experimental

Materials

α,ω-Amino-acids

These were commercial products or prepared in accordance with literature methods. They were recrystallized at least three times from ethanol or ethanol–water mixtures and dried over P_2O_5 at 5 mm Hg for 5 h at 80°C. Their melting or decomposition points agreed with literature values.

Water

Doubly distilled water was passed through a mixed bed ion exchange column (Rexyn I-300; Fisher Scientific) immediately before use.

Buffer Solutions

These were made up according to the specifications described by Bates (14). All salts used were 'Analar' grade, dried at 110°C for several hours before use. The solutions were made up in grade A volumetric flasks.

Titrant Solutions

Solutions of 0.1 *N* HCl and 0.1 *N* NaOH were made up from commercially available concentrates. The HCl solutions were standardized against 'Analar' sodium carbonate (15). These standard HCl solutions were used to standardize those of NaOH.

Measurements

The acid dissociation constants of the amino-acids were determined at concentrations within the range 0.0025-0.01 *M* (the exact value depending upon the solubility of the particular homologue) by potentiometric titration using Sargent-Welch DR S30000 p*H* meters fitted with Sargent combination electrodes (model S-30072-15). The titration vessels were water-jacketed beakers of 150 ml capacity. The titration procedure followed was that described by Albert and Sarjeant (16), the titrant being added by means of Agla micrometer syringes.

The dissociation constants of each compound were determined at 10, 20, 25, 30, and 40°C, each titration being repeated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

at least twice. Temperature control was maintained by circulating water from a constant-temperature bath through the jacketed titration vessel. Temperatures were measured in the titration vessel and fluctuated by no more than ± 0.02°C from the required value.

Data Treatment and Results

The pK values for the equilibria represented by [1] and [4] were evaluated from the pH readings by means of the relationships described by King (17). Since the ratio K_1/K_2 was known to be large (18), overlapping of the dissociations was ignored. Corrections for ion activity coefficients γ were made by means of the Debye–Hückel expression

$$[6] \qquad \log \gamma_{\pm} = (A\sqrt{I})/(1 + \sqrt{I})$$

An additional linear correction term in ionic strength I did not significantly alter the pK values and was therefore not included in the calculations.

In each titration, values deviating from the mean pK value by more than twice the standard deviation of all values were ignored in the calculation of the final mean pK value. (These were usually the first, and last, 3 values.) The mean pK for a given titration was determined by converting the pK values into K values, averaging the K values, and then converting this average to a pK (16). The standard deviation of the K values was determined for each titration, resulting in standard deviations of the pK values within the range ± 0.005–± 0.03 pK units.

The standard enthalpy (ΔH^0) and entropy (ΔS^0) changes were evaluated from [7] using a linear least-squares analysis.

$$[7] \qquad pK = \frac{\Delta H^0}{2.303RT} - \frac{\Delta S^0}{2.303R}$$

The errors in the temperature differences (± 0.04°C) used to determine ΔH^0 and ΔS^0 resulted in pK changes within their quoted experimental errors. Calculated values of ΔH^0 and ΔS^0 were not significantly affected by the experimental errors in the pK data, and the temperature variations of ΔH^0 and ΔS^0 were not significant with respect to the deviations of the pK values.

The pK results at 25°C for equilibria [1] and [4] are given respectively in Tables 1 and 2, together with comparisons with literature data where available, and are plotted in Fig. 1. Also shown in Tables 1 and 2 are ΔH^0 and ΔS^0 values calculated from [7], using the data presented in Table 5. Errors quoted in Tables 1 and 2 are standard deviations from the mean values, obtained directly from the least-squares analysis of the data.

Results and Discussion

The results, displayed in Fig. 1, show that the effects of the positive ammonium group in strengthening the acidity of the carboxyl group, and of the negative carboxylate group in weakening the acidity of the ammonium group,[4] persist to great distances (at the molecular level), the limit not being reached at a separation of ten methylene carbons. In contrast, the effect of a dipolar substituent is attenuated to zero after a separation of about four methylene carbons (20–25).

[4]From the point of view of electrostatic theory, the acid-*strengthening* effect of the carboxylate group at short distances is anomalous, and is discussed below.

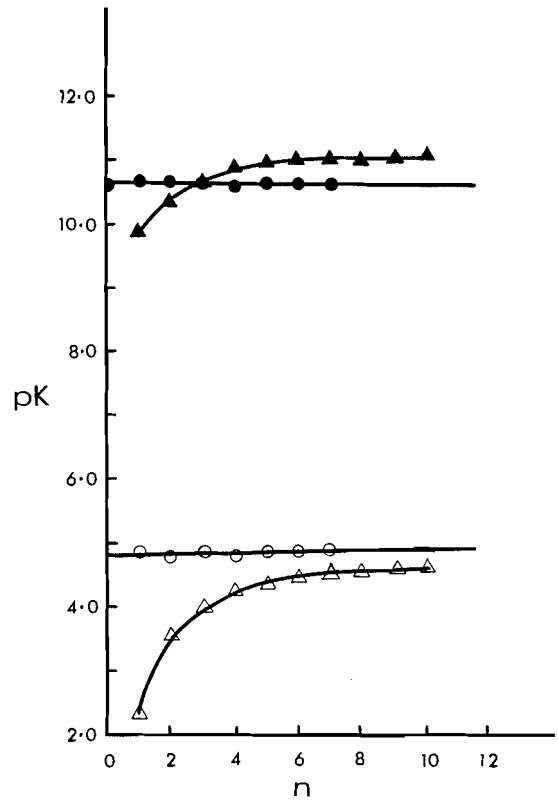

FIG. 1. Plots of pK_1 (△) and pK_2 (▲) of α,ω-amino-acids, of pK_a of *n*-alkyl monocarboxylic acids (○), and of pK_b of *n*-alkylammonium ions (●), against the number *n* of methylene carbon atoms.

In order to calculate ΔpK_1 from [3] for the different amino-acid zwitterions, we must first know the intercharge distance R and the effective dielectric constant D_{eff}. The distances between atoms of the fully extended chain can be calculated by trigonometry using bond lengths and bond angles from the literature (26, 27); however, the distances R_{max} between the terminal charges of the fully extended chains depend on assumptions about the locations of the charges with respect to the atomic centres. We consider the most reasonable location for the positive charge of an ammonium or substituted ammonium group to be the centre of the nitrogen atom, and for the negative charge of the carboxylate group to be the midpoint between the two equivalent oxygen atoms, i.e., 0.65 Å beyond the carboxylate carbon atom on the extension of the C—CO_2^- bond. Kirkwood and Westheimer (4) located the positive charge 0.33 Å beyond the nitrogen atom, on the extension of the C—N bond, and (following Eucken (2)) located the negative charge 1.45 Å beyond the carboxylate carbon atom, on the extension of the C—CO_2^- bond. In this paper we reject these loca-

tions because they seem to be physically less reasonable, and because their use results in poorer overall agreement between calculated and experimental ΔpK_1 values.

Following our assumptions, the intercharge distances R_{max} were calculated for the fully extended chains of the α,ω-amino-acids $^+H_3N(CH_2)_nCO_2^-$; these are shown in Table 3. Assuming the charges to be located at the foci of ellipsoids having the van der Waals volume V_w (given by addition of atomic increments (28)), the eccentricities λ_0 of the ellipsoids were obtained from the equation

$$[8] \qquad \lambda_0^3 - \lambda_0 = 6V_w/\pi R^3$$

and thence D_{eff} by interpolation from tabulated values (7). The values of ΔpK_1 calculated from R_{max} and D_{eff} are given in column *a* of Table 3.

*Calculated using R_{max}.
†Calculated using R_R.
‡K_a values (eq. 2) for n = 1–7 obtained from ref. 24; for n = 8–10 estimated by extrapolation of curve in Fig. 1.
§K_b values (eq. 5) for n = 1–7 obtained from ref. 23; for n = 8–10 estimated by extrapolation of curve in Fig. 1.

In column *b* of Table 3 are given ΔpK_1 values calculated in similar fashion, but using R_R, the intercharge distance for a randomly-coiled chain, in place of R_{max}, still assuming the charges to be at the foci of an ellipsoid. It was assumed that the proportions of the different conformations of H_3N^+-$(CH_2)_nCO_2^-$ were the same as those of $CH_3(CH_2)_n$-CH_3, since the conformational properties of NH_3^+ and CO_2^- groups are not widely different from those of the methyl group (29). The distances R_i between the terminal carbon atoms of the i conformers were found by measurements on a diamond lattice made with Fieser models (see Smith and Mortensen (13) for a discussion), and R_R obtained as the weighted mean of these distances:

$$[9] \qquad R_R = \sum \chi_i R_i$$

where χ_i is the mole fraction of the ith conformer. For example, 66% of *n*-butane at 25°C exists in the *anti*-conformation ($R \equiv R_{max} = 3.90$ Å) and 34% in two enantiomeric *gauche* conformations ($R = 2.95$ Å) (29, 30); consequently $R_R = (0.66 \times 3.90) + (0.34 \times 2.95) = 3.58$. The factor ρ ($\equiv R_R/R_{max}$) by which the end-to-end distance is reduced by coiling is consequently 3.58/3.90 = 0.92. In similar fashion, ρ was calculated for *n*-pentane, *n*-hexane, and *n*-heptane, and is shown plotted against *n* in Fig. 2; ρ for the longer *n*-alkanes was obtained from Tanford (31). The values of ρ in Table 3 were obtained from this curve, and thence R_R ($\equiv \rho R_{max}$), D_{eff}, and ΔpK_1 (*b*) for the zwitterions.

A comparison of ΔpK_1 values thus calculated with the experimental ΔpK_1 values listed in Table 3 shows that for $n \geq 4$ the experimental values lie

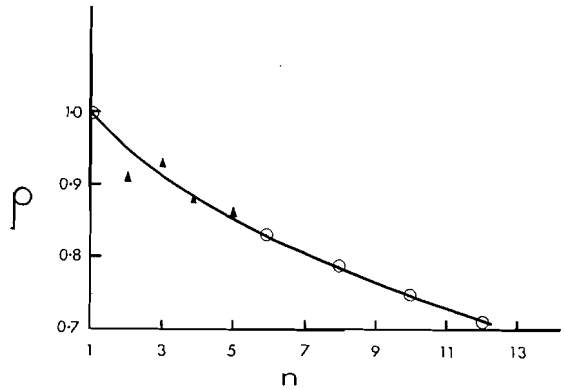

FIG. 2. Ratio ρ of length of the flexible to the fully extended *n*-alkane $CH_3(CH_2)_mCH_3$ of *n* carbon atoms: △, calculated according to Mann (30); ○, from Tanford (31).

between the values calculated for the fully-extended chain (*a*) and the randomly-coiled chain (*b*). For the shorter chains ($n \leq 3$) the Kirkwood–Westheimer treatment, as modified by us, fails increasingly as *n* becomes smaller. The treatment can be salvaged by arbitrarily increasing R_{max} and R_R, by an unrealistic disposition of the charges beyond the ends of the chains, and it is probably for this reason that such alternative locations of charges (discussed above) were adopted when data were available only for comparatively short chains. However, these alternative locations lead to poorer overall agreement with experiment for the larger number of compounds considered here.[5] It seems more reasonable to assume that the Kirkwood–Westheimer treatment breaks down for excessively short intercharge distances *R* because of the intrusion of effects (monopole–dipole, dipole–dipole, solvation: see below) which are negligible for large values of *R*, when only the monopole–monopole effect operates.

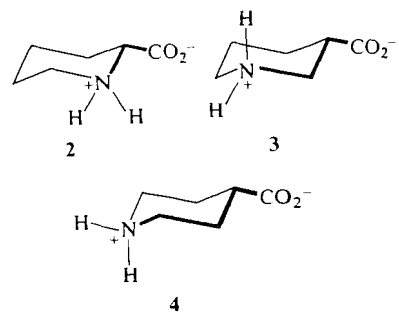
An alternative method of obtaining λ_0 and thence D_{eff} is due to Tanford (32): this assumes that the positive ammonium and negative carboxylate charges are at the foci of a prolate ellipsoid, but at a constant depth *d* of 1.0 Å below the ellipsoidal surface. In such a case

$$[10] \qquad \lambda_0 = (R + 2.0)/R$$

The assumption of a constant *d* is physically reasonable, but the location of the charges at the foci of the prolate ellipsoid leads to molecular volumes which become progressively less reasonable as *n* increases. (On the other hand, the use of [8], with a physically reasonable volume (V_w or Traube's molar volume (28)), necessitates a progressive decrease in *d* as *n* increases: again, a physically unrealistic picture.) Fortunately, calculations using the Tanford model give ΔpK values only very slightly greater than those calculated by the conventional Kirkwood–Westheimer approach: the differences for all molecules except the shortest ($n = 1$–3) are less than the experimental errors.

In summary, ΔpK_1 values support the notion that the polymethylene chains of α,ω-amino-acids have some flexibility in their central portions, so that the intercharge distance *R* lies between R_{max} and R_R. This accords with recent studies of dielectric increments of these compounds (33).

The relative success of [3] for ΔpK_1 values of **1** does not extend to ΔpK_2 values, as shown in Table 3. The pronounced failure of [3] for the shorter chains cannot be explained by juxtaposition of the charged ends resulting from extreme coiling of the chain, because a similar failure is observed for calculations of ΔpK_2 (but not ΔpK_1) of 2-(**2**), 3-(**3**), and 4-piperidinecarboxylic acid (**4**) (34), where *R* is fixed by the ring structures. These compounds should exist, to the extent of about 97% (29), in the conformation with an equatorial carboxylate group, as shown in **2**, **3**, and **4**. The intercharge distance in **2** and **3** should be the same as that in **1** ($n = 1$ and 2, respectively); that in **4** (one *gauche*, one *anti* conformation along the bonds marked by heavy lines) should be about R_R for **1** ($n = 3$).



Thermodynamic Parameters for the First and Second Dissociations of α,ω-Amino-acids

The Kirkwood–Westheimer treatment employed above has attempted to explain changes in ΔpK_1 and ΔpK_2, and hence changes in ΔG_1^0 and ΔG_2^0, the standard free energy changes, entirely by changes in the internal energy of molecules resulting from electrostatic interactions. The justification for such an approach goes back many years to Evans and Polanyi (35), but more recent work on substituent effects by Hepler *et al.* (20, 36) has shown that the ionization of acids is determined by both the reaction medium and the polar and steric effects of the

[5]A tabulation of calculations based on the various possible assumptions is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6.

[11] $H_3\overset{+}{N}(CH_2)_nCO_2H + CH_3(CH_2)_nCO_2^- \underset{}{\overset{\Delta pK_1}{\rightleftharpoons}} H_3\overset{+}{N}(CH_2)_nCO_2^- + CH_3(CH_2)_nCO_2H$

substituents. To examine substituent effects in the symmetrical reaction shown above, Hepler suggests that the overall effect of a substituent such as the ammonium group can be divided into "internal" and "environmental" contributions. The internal effects are those intrinsic to the molecules or ions, and would be observed if the reaction could be carried out in the absence of solvent. The environmental effects result from the interactions of the molecules or ions with the solvent. For symmetrical reactions such as [11], we can assume that internal contributions to the entropy change are negligible, and that environmental contributions to enthalpy and entropy changes are related by a constant β:

$$[12] \qquad \delta\Delta H_{env} = \beta\delta\Delta S_{env} = \beta\delta\Delta S^0$$

We can then obtain the following equation:

$$[13] \qquad \delta\Delta G^0 = \delta\Delta H_{int} + (\beta - T)\delta\Delta S^0$$

If $\beta \simeq 300$ K, then at 25°C

$$[14] \qquad \delta\Delta G^0 \simeq \delta\Delta H_{int}$$

This equation can be considered justification for the Kirkwood–Westheimer treatment above, which ignored the effects of solvation. Such solvation should affect ΔS^0 and ΔH^0 (cf. eq. 12). The values of $\delta\Delta G^0$, $\delta\Delta H^0$, and $\delta\Delta S^0$, defined as the thermodynamic parameters of [11] and [15]:

[15] $^-O_2C(CH_2)_n\overset{+}{N}H_3 + CH_3(CH_2)_nNH_2 \underset{}{\overset{\Delta pK_2}{\rightleftharpoons}} {}^-O_2C(CH_2)_nNH_2 + CH_3(CH_2)_n\overset{+}{N}H_3$

are given in Table 4, and show that the success of the Kirkwood–Westheimer treatment comes about from the well-known compensation of enthalpy and entropy changes when an isolated ion is transferred from a vacuum into a polar solvent such as water (37). For example, while the introduction of the positive ammonium group into acetic acid to give glycine (**1**; $n = 1$) makes ionization of the carboxyl group intrinsically easier ($\delta\Delta G^0 \simeq \delta\Delta H^0_{int} = -3.40$ kcal mol^{-1}), (Table 4, $n = 1$) it makes the hydration of the carboxylate group less exothermic ($\delta\Delta H_{env} \simeq +5.5$ kcal mol^{-1}), presumably because the nearby positive charge interferes with the binding of water molecules by ion–dipole interactions. Consequently, in water the enthalpic effect of introducing a charged ammonium group into acetic acid is unfavourable to ionization of the carboxyl group. That nonetheless protonated glycine is more acidic than acetic acid

TABLE 4. Changes in ΔG^0, ΔH^0, and ΔS^0 caused by introduction of a charged group at the end of a polymethylene chain, as measured by thermodynamic parameters for the reactions 11 and 15[a]

[a]Data in parentheses were obtained from estimated values for *n*-alkyl amines and carboxylic acids.

comes about from the more favourable entropy change ($\delta\Delta S^0 = +15.8$ eu), because the CO_2^- of glycine binds fewer water molecules than the CO_2^- of acetate.[6]

For the second step, the competing ionizations of ammonium groups in [15], the enthalpic effect of introducing a CO_2^- group into an alkyl chain explains the otherwise anomalous $\delta\Delta G_2^0$ values for $n = 1$–6 mentioned above. Electrostatic theory would predict that $\delta\Delta H_{int}$ should be positive (the CO_2^- should make the ammonium group a weaker acid). However, $\delta\Delta H^0$ and hence, *a fortiori*, $\delta\Delta H_{env}$ are negative. This can be explained again by electrostatic interference by nearby CO_2^- to the binding of water molecules[7] to the positive ammonium ion, so that [15] is accompanied by a net (exothermic) binding of water molecules, particularly when n is small. This also accounts for $\delta\Delta S^0$ ($\simeq \delta\Delta S_{env}$) of [15] when n is smaller (see Table 4). However, in this case the entropy effect does not compensate the enthalpic effect, so that the ammonium group of **1**

[6]It should be emphasized that this (and any) interpretation of thermodynamic parameters can only be arbitrary, but at least conforms to current orthodoxy (10, 17).

[7]Evidence for the smaller binding of water molecules by the ammonium group of **1** when n is smaller comes from studies of electrostriction (38).

remains a stronger acid than the ammonium group of RNH_3^+ up to $n = 3$.

This disturbing effect of CO_2^- on the hydration of the ammonium group, depending on a monopole–dipole interaction ($CO_2^- \cdots H_2O$), falls off with distance much more rapidly than monopole–monopole interactions. Consequently, beyond $n = 3$ the effect of CO_2^- on ΔH_{env} and ΔS_{env} becomes less important than its effect on ΔH_{int}, and the zwitterions become stronger acids than the corresponding alkylammonium ions, as predicted by electrostatic theory. It follows that the results of the Kirkwood–Westheimer calculations can be accepted with confidence when the ionizing groups are well separated, but not when they are close together.

JITKA KIRCHNEROVA, PATRICK G. FARRELL, JOHN T. EDWARD, JEAN-CLAUDE HALLE, and ROBERT SCHAAL. Can. J. Chem. **56**, 1130 (1978).

Acid dissociation constants of two *cis*-3- and of four *trans*-4-substituted cyclohexanecarboxylic acids in water – dimethyl sulfoxide mixtures of varying composition were determined by a potentiometric method. Results have been analyzed according to the model of Kirkwood and Westheimer, and shown to differ from calculated values because of certain oversimplifications built into the model. Dissociation constant differences between cyclohexanecarboxylic acid and the compounds studied vary only slightly with changing solvent composition.

JITKA KIRCHNEROVA, PATRICK G. FARRELL, JOHN T. EDWARD, JEAN-CLAUDE HALLE et ROBERT SCHAAL. Can. J. Chem. **56**, 1130 (1978).

On a déterminé, par une méthode potentiométrique, les constantes de dissociation acide d'acides cyclohexanecarboxyliques substitués par des groupements *cis* en position 3 (deux cas) et *trans* en position 4 (quatre cas) dans des mélanges eau–diméthylsulfoxyde de diverses compositions. On a analysé les résultats suivant le modèle de Kirkwood et Westheimer et on a montré qu'ils diffèrent des valeurs calculées à cause d'une simplification outrancière inhérente au modèle. Les différences de constantes de dissociation entre l'acide cyclohexanecarboxylique et les composés étudiés ne varient que légèrement lorsque l'on change la composition du solvant.
[Traduit par le journal]

Introduction

Taking the unsubstituted carboxylic acid as reference, Kirkwood and Westheimer (1) suggested that the pK should be changed by the presence of a positively-charged group (acid-strengthening) or negatively-charged group (acid-weakening) by an amount

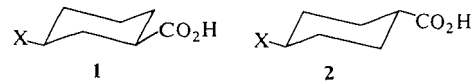
$$[1] \qquad \Delta pK = e^2/2.3kTRD_{eff}$$

where e is the electronic charge, k is Boltzmann's constant, T the absolute temperature, R the distance between the charged carboxylate group and the charged substituent,[1] and D_{eff} the effective dielectric constant. Similarly, the introduction of an uncharged substituent having a dipole moment μ should change the pK by

$$[2] \qquad \Delta pK = e\mu \cos\theta/2.3kTR^2D_{eff}$$

where θ is the angle between R, the line joining the centre of the ionizing group to the centre of the dipole, and the axis of the dipole. For the particular case of ellipsoidal molecules having at their foci point charges, or a point charge and a point dipole, Kirkwood and Westheimer calculated D_{eff} as a function of D_e, the dielectric constant of the solvent, and λ_0, the ratio of the major axis to the interfocal distance of the ellipsoid (1, 3, 4).

Recently the superiority of this electrostatic or "field effect" over the widely-accepted "inductive effect" for the explanation of substituent effects has been stressed (5, 6). The inductive mechanism takes no account of orientation of the dipolar substituent, nor of the solvent. Recent researches (7, 8) have amply demonstrated the importance of the orientation of the dipole, but there have been few attempts (9) to test the effect of changing solvent. In the present paper we report the effect of the changing composition of water – dimethyl sulfoxide (DMSO) solvent mixtures on the pK values of some *cis*-3- (**1**; X = CO_2H, CO_2^-) and *trans*-4-substituted cyclohexanecarboxylic acids (**2**; X = NH_3^+, CO_2^-,



1 **2**

[1]This definition of R differs slightly from that of Kirkwood and Westheimer, and is justified in an earlier paper (2).

CO_2H, CO_2CH_3). These compounds exist essentially completely in the conformation shown in **1** and **2** (10), and the charges or dipoles of the compounds **2** (but not **1**) are close to the foci of the circumscribing ellipsoids. Since not all are very soluble in water, some of them have been studied previously in a single methanol–water or ethanol–water mixture (11). We have chosen to study them in water–DMSO mixtures in the belief that the progressive change from the protic solvent water to the aprotic solvent DMSO represents a more drastic change in solvent character, particularly for anions such as carboxylates, which should be little solvated by dimethyl sulfoxide (12, 13).

Experimental

Materials

cis-1,3-Cyclohexanedicarboxylic acid (**1**; X = CO_2H), *trans*-1,4-cyclohexanedicarboxylic acid (**2**; X = CO_2H), and *trans*-4-aminocyclohexanecarboxylic acid (**2**; X = NH_2) were obtained by hydrogenation of the corresponding aromatic compounds according to known procedures (14). *trans*-4-Methoxycarbonylcyclohexanecarboxylic acid (**2**; X = CO_2Me) was prepared by partial hydrolysis of the diester. Water and dimethyl sulfoxide were purified and their mixtures prepared as described earlier (13).

Procedure

Thermodynamic pK values were determined at 20°C by a procedure already described (12, 13, 15), the calculation of the successive pK's of the dicarboxylic acids being realized by successive approximations. Their accuracy is estimated to be within 0.06 pK units, and the reproducibility to within 0.03 pK units.

Results and Discussion

The results obtained are given in Table 1. Where comparison with results in the literature (11, 16) is possible, agreement is good, as can be seen from the footnotes to Table 1. pK values obtained by extrapolation to 100% DMSO are also given in Table 1, and from previous work (12) seem likely to be reliable.

Taking cyclohexanecarboxylic acid (12) as the standard, we obtain the effect of a 3- or 4-substituent as $\Delta pK_{expt} = pK$(substituted cyclohexanecarboxylic acid) − pK(cyclohexanecarboxylic acid). Such values for 100% water and 100% DMSO are shown in Table 2 (corrected for the statistical effect, where necessary). Also shown in this table are the values (ΔpK_{calcd}) calculated for these solvents from either [1] or [2]. For this calculation the molecular volume V_W was obtained by addition of van der Waals increments (17),[2] and the charge–charge or charge–dipole distance R calculated from standard bond lengths and bond angles by trigonometry; the location of the point charge within the group has already been discussed (2). From V_W and R the eccentricity λ_0 of the ellipsoid may be calculated (2), and thence D_{eff} from the dielectric constants of water and of DMSO (and, if need be, of the water–DMSO mixtures (18)). Values of $\mu \cos \theta$ were taken from ref. 11.

Comparison of ΔpK_{calcd} thus obtained with ΔpK_{expt} shows immediately serious failings in the Kirkwood–Westheimer treatment. Firstly, eq. 1 requires that if the CO_2^- group acts only as a point monopole, its introduction at the 4-position of cyclohexanecarboxylic acid should weaken the acid to roughly the same extent as the 4-NH_3^+ group strengthens it. In fact, the CO_2^- group is only about one quarter as effective as the NH_3^+ group. Secondly, the CO_2H or CO_2Me dipole at the 4-position is about three times *more* effective in strengthening the carboxyl group than calculated by [2].

[2]The molecular volume calculated by Traube's rules (17) is slightly larger, and its use leads to slightly lower D_{eff} values and slightly higher ΔpK values; the differences, however, are small.

TABLE 2. Calculated and experimental values of ΔpK of 3- and 4-substituted cyclohexanecarboxylic acids

		H_2O		DMSO	
Substituent	R (Å)	ΔpK_{calcd}	ΔpK_{exptl}	ΔpK_{calcd}	ΔpK_{exptl}
4-NH_3^+	6.74	−0.68	−0.84	−1.08	−0.95
4-CO_2H	7.45	−0.06	−0.24	−0.10	−0.35
4-CO_2^-	7.41	+0.58	+0.21	+0.95	+0.25
4-CO_2CH_3	7.58	−0.07	−0.22	−0.11	−0.35
3-CO_2H	6.04	−0.13	−0.28	−0.18	−0.35
3-CO_2^-	6.04	+0.98	+0.19	+1.40	+0.35

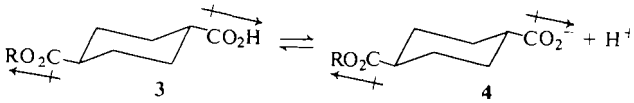
These failings come about because of an over-simple application of [1] and [2] to the compounds in question. The results can be brought into qualitative agreement with the theory if the following assumptions are made:

(*a*) While the NH_3^+ group behaves as a monopole only, the CO_2^- group behaves as a combined monopole and dipole (μ = 3.2 D, according to Wilcox and McIntyre (19), as compared to μ = 1.68 D for CO_2H).

(*b*) The CO_2H and CO_2Me groups are not point dipoles at one focus of an ideal ellipsoid, so that both positive and negative ends are buried equally within the molecular cavity. Instead, the negative oxygen atom is exposed at the surface of the molecule, where it can interact with neutralizing solvent molecules, while the positive carbon atom is buried in the low-dielectric interior of the molecule. Consequently, the ionizing function "feels" the effect of positive carbon more than would be expected from [2].

(*c*) In assessing the effect of a substituent, it is necessary to take account of its effect on *both* the acid and the conjugate base in equilibrium with it.

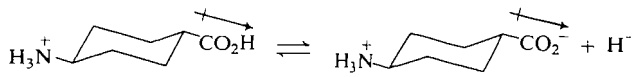
We may now re-examine the results in Table 2 in the light of these assumptions. What effect should one expect from the presence of the dipolar CO_2H or CO_2Me in **3**/**4** on the acid-strength of the carbonyl group in the equilibrium below?



3 **4**

Dipole–dipole interaction in **3** increases its free energy (an acid-strengthening effect); this is more than compensated for by dipole–dipole interaction in **4** (an acid-weakening effect), required by consideration of (*a*) above. However, dipole–dipole interactions $\propto 1/R^3$, and so are unimportant at these distances when compared with the monopole–dipole interaction ($\propto 1/R^2$) found in **4** but not in **3**. This produces a ΔpK of 0.2–0.3, about three times larger than calculated by [2] because of the effect discussed under (*b*) above.

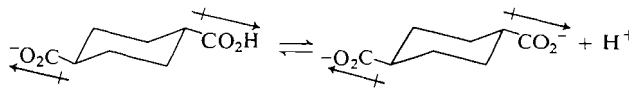
Next, let us consider the effect of introducing the monopole NH_3^+ (assumption *a*) into the 4-position of cyclohexanecarboxylic acid:



5 **6**

According to Wilcox and McIntyre (19), dipole–monopole interactions in **6** are stronger than dipole–monopole interactions in **5**, and should weaken the acid by 0.2–0.3 pK units; the monopole–monopole interaction, found only in **6**, should strengthen the acid, according to [1], by 1.08 pK units in DMSO and 0.68 pK units in water. The experimental ΔpK is in fair agreement with the ΔpK thus estimated for DMSO (−0.78 to −0.88), taking into account the two effects, but in poorer agreement with that estimated for water (−0.38 to −0.48).

Lastly, consider the effect of the CO_2^- group at the 4-position on the equilibrium:



7 **8**

We shall ignore dipole–dipole interactions. There is a monopole–monopole interaction in **8** which should be acid-weakening by 0.58 pK units in water and 0.95 units in DMSO (Table 2). However, this is opposed by the net monopole–dipole interactions: two acid-strengthening interactions in **8**, reduced by one weaker acid-weakening interaction in **7**, so that the net effect should be acid strengthening by about 0.4–0.6 pK units. This brings ΔpK_{calcd} to within fair agreement with ΔpK_{exptl}.

Similar considerations applied to ΔpK_{calcd} of **1** (X = CO_2H and CO_2^-) serve to bring it into better agreement with ΔpK_{exptl}, although for these compounds good agreement should not be expected, because they do not have their charges or dipoles close to the foci of the circumscribing ellipsoid.

In Table 2 we have compared ΔpK_{calcd} with

ΔpK_{expll} only for the two solvents, 100% H_2O and 100% DMSO; a similar comparison for all the other solvent mixtures of Table 1 does not reveal any additional points of interest. While the progressive replacement of water by dimethyl sulfoxide changes only gradually the dielectric constant of the solvent mixtures (18), it changes more drastically the activity coefficient of anions (20). We accordingly expected radically different behaviour in DMSO-rich mixtures. However, it seems that the equations of Kirkwood and Westheimer apply about as well in these mixtures as in water and water–alcohol mixtures studied previously. Their weaknesses arise from the simplifying assumptions (e.g. of point dipoles) necessary for a mathematically-tractable treatment; when these weaknesses can be compensated for (e.g. in the comparative treatment of Wilcox and Leung (6)), the Kirkwood–Westheimer treatment works astonishingly well.

Acknowledgments

We are grateful to Dr. G. E. Langford for preparation of the carboxylic acids, to the National Research Council of Canada for financial support, and to Coopération France–Québec for financing the exchanges between our two laboratories, in particular for the mission of J.K. to Paris where the dissociation constants were measured. We thank Dr. Bo-Long Poh for much help in calculations.

Synthesis of 5- and 6-methylene-2-norbornanones

NICK HENRY WERSTIUK AND ROLAND TAILLEFER

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 12, 1977

NICK HENRY WERSTIUK and ROLAND TAILLEFER. Can. J. Chem. **56**, 1134 (1978).

The syntheses of 4,4,6-trimethyl-5-methylene-2-norbornanone (**5***a*), 6,6-dimethyl-2-methylene-2-norbornanone (**5***b*), 5-methylene-2-norbornanone (**5***c*), and 6-methylene-2-norbornanone (**11**) are described. An unusual extended Grob-type cleavage of 6-ethylenedioxy-*exo*-2-methyl-*endo*-2-norbornanol (**13***d*) to 2-chloroethyl (3-methyl-3-cyclopentenyl)acetate (**17**) is documented.

NICK HENRY WERSTIUK et ROLAND TAILLEFER. Can. J. Chem. **56**, 1134 (1978).

On décrit la synthèse des triméthyl-4,4,6 méthylène-5 (**5***a*), diméthyl-6,6 méthylène-2 (**5***b*), méthylène-5 (**5***c*), et un méthylène-6 (**11**) norbornanones-2. On présente des données confirmant l'existence d'une coupure inusitée, du type Grob élargi, de l'éthylènedioxy-6 méthyl-2 *exo* norbornanol-2 *endo* (**13***d*) conduisant à l'acétate du chloro-2 éthyl (méthyl-3 cyclopentène-3 yl) (**17**).

[Traduit par le journal]

Introduction

The chemistry of the carbonyl group recently has been reviewed in two volumes of the series the Chemistry of the Functional Group (1). That there were but three pages devoted to an account of the kinetic and mechanistic aspects of acid- and base-catalyzed enolization and hydrogen isotope exchange of acyclic and monocyclic ketones served to reinforce our view that all the mechanistic intricacies of these ubiquitous reactions had not yet been established. Thus we undertook a detailed study of the kinetic and mechanistic aspects of hydrogen isotope exchange of the diastereotopic protons α to the carbonyl group in a series of bicyclic ketones. For the initial study we required a series of 5- and 6-methylene-2-norbornanones and 2,5-norbornanediones. We report herein, in the first paper of a series which will document our synthetic and mechanistic work, the synthesis of 4,4,6-trimethyl-5-methylene-2-norbornanone (**5***a*), 6,6-dimethyl-2-methylene-2-norbornanone (**5***b*), 5-methylene-2-norbornanone (**5***c*), and 6-methylene-2-norbornanone (**11**). An unusual extended Grob-type cleavage of 6-ethylenedioxy-*exo*-2-methyl-*endo*-2-norbornanol (**13***d*) to 2-chloroethyl (3-methyl-3-cyclopentenyl)acetate (**17**) is documented also.

Results and Discussion

Synthesis

The 2,5-enone substitution pattern in **5***a*, **5***b*, and **5***c* was developed through the use of *endo*-5-ethanoyloxy-4,4,6-trimethyl-2-norbornanone (**6***a*), *endo*-5-ethanoyloxy-6,6-dimethyl-2-norbornanone (**6***b*), and *endo*-5-ethanoyloxy-2-norbornanone (**6***c*), respectively. Compounds **6***a* and **6***b* were prepared from 1,3,3-trimethyl-*endo*-2-norbornyl acetate (fenchyl acetate) (**9***a*) and 3,3-dimethyl-*endo*-2-norbornyl acetate (camphenilyl acetate) (**9***b*) via the methods of Hirsjärvi (2) and Meinwald and co-workers (3, 4), respectively. The acetates **9***a* and **9***b* were prepared from 1,3,3-trimethyl-2-norbornanone (fenchone) (**8***a*) and 3,3-dimethyl-2-norbornanone (camphenilone) (**8***b*) by LAH reduction of the ketones and acetylation of the alcohols. Compound **6***c* was prepared by an acid-catalyzed ring opening of nortricyclanone[1] as described by Meinwald *et al.* (5). Hydrolysis of **6***a* and **6***b* gave *endo*-5-hydroxy-4,6,6-trimethyl-2-norbornanone (**1***a*) and *endo*-5-hydroxy-6,6-dimethyl-2-norbornanone (**1***b*), which were converted to 5-ethylenedioxy-1,3,3-trimethyl-*endo*-2-norbornanol (**2***a*) and 5-ethylenedioxy-3,3-dimethyl-*endo*-2-norbornanol (**2***b*) by ethylene glycol and *p*-toluenesulfonic acid in benzene. Oxidation of the ketalols **2***a* and **2***b* with CrO_3 in pyridine gave 5-ethylenedioxy-1,3,3-trimethyl-2-norbornanone (**3***a*) and 5-ethylenedioxy-3,3-dimethyl-2-norbornanone (**3***b*), which were converted with triphenylphosphonium methide in hexane to 2-ethylenedioxy-4,6,6-trimethyl-5-methylenenorbornane (**4***a*) and 2-ethylenedioxy-6,6-dimethyl-5-methylenenorbornane (**4***b*), respectively. Mild acid-catalyzed hydrolysis of the ketalenes **4***a* and **4***b* gave the enones **5***a* and **5***b*. That the nmr data for **5***a* and **5***b*[2] are consistent with the proposed structures, and **5***a* and **5***b* were converted by periodate–permanganate oxidation to the known compounds 1,3,3-trimethyl-2,5-norbornandione (**10***a*) and 3,3-dimethyl-2,5-norbornandione (**10***a*) and 3,3-di-

[1] Although the mechanism of the ring opening of nortricyclane (*i*) has not been established, it is likely that conversion of $i \rightarrow$ **6***c* proceeds via initial protonation of the carbonyl group rather than the three membered ring.

[2] Photocopies of the nmr spectra are available upon request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

methyl-2,5-norbornanedione (**10***b*) (6), respectively, conclusively established the structure of the enones. Also, subsequent to our initial report (7) of **5***b*, Money prepared enone **5***b*[3] via a shorter route. Enone **5***c* was prepared essentially via the same route as **5***a* and **5***b* except that **5***c* was converted into 5-ethylenedioxy-*exo*-2-norbornyl acetate (**7***a*). 5-Ethylenedioxy-*exo*-2-norbornanol (**7***b*), obtained by LAH reduction of **7***a*, was transferred into **5***c* via the usual sequence (*vide supra*). That the nmr spectrum[2] is consistent with the structure of **5***c* and that **5***c* is oxidized to 2,5-norbornanedione (**10***c*) (5) by periodate–permanganate, conclusively establishes the structure of **5***c*.

6-Methylene-2-norbornanone was synthesized by a sequence of reactions which began with the conversion of *endo*-2-norbornene-5-carboxylic acid into 6-oxo-*endo*-2-norbornanecarboxylic acid (**12**) (8). The latter was ketalized and the ketal ester **13***a* was reduced by LAH to 6-ethylenedioxy-*endo*-2-norbornylmethanol (**13***b*). 6-Ethylenedioxy-*endo*-2-norbornylmethyl acetate (**13***c*), obtained by acetylation of **13***b*, was pyrolyzed to yield the ketalene **14***a*. Mild acid-catalyzed hydrolysis of **14***a* gave **11**. The nmr spectrum [2] of **11** is consistent with the proposed structure.

We initially attempted to prepare the ketalene **14***a* from the ketoketal **14***b*[4] by means of a Wittig reaction. Although the ketoketal **14***b* is easily obtained, the addition of triphenylphosphonium meth-

[3]The spectral properties of the independently synthesized enones were identical. Professor T. Money. Personal communication.

[4]Compound **14***b* was prepared from 5-norbornen-2-one via a ketalization (TsOH, $HOCH_2CH_2OH$, benzene) and epoxidation ($PhCO_3H$), a reductive ring opening of the epoxide (LAH, *N*-methylpyrrolidinone), and an oxidation (CrO_3, pyridine).

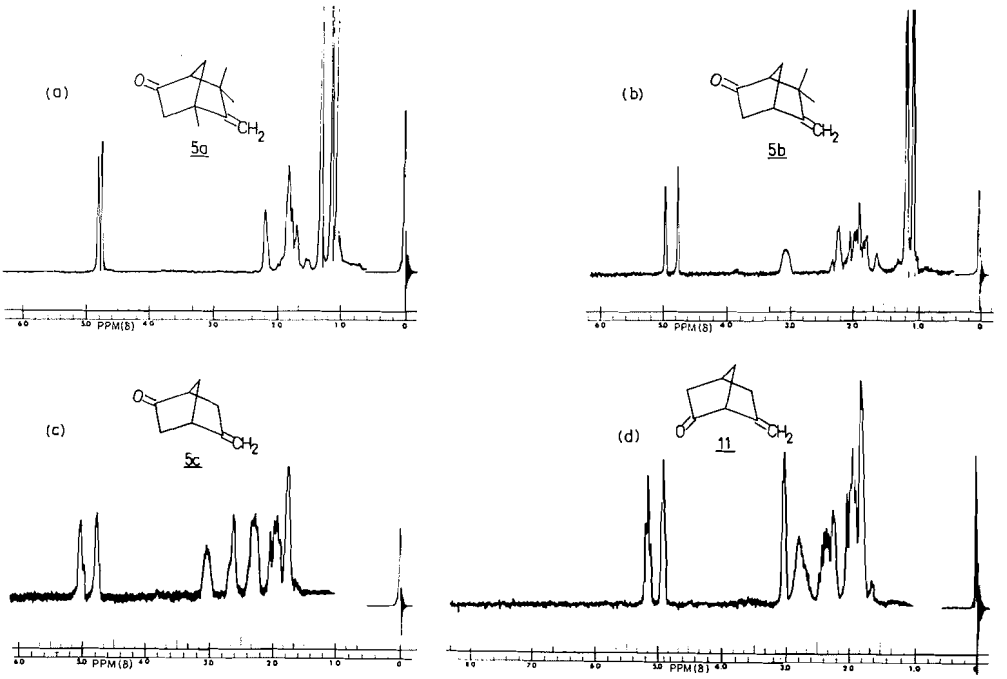

FIG. 1. The nmr (60 MHz) spectra of (*a*) enone **5***a*, (*b*) enone **5***b*, (*c*) enone **5***c*, and (*d*) enone **11**.

ide to the carbonyl group did not occur, perhaps as a consequence of the steric strain that develops between the alkoxide function and *endo* oxygen of the ketal at C (6).

Grob Cleavage

We also attempted to prepare ketalene **14***a* by dehydration of 6-ethylenedioxy-*exo*-2-methyl-*endo*-2-norbornanol (**13***d*) that is prepared from ketoketal **14***b* via a Grignard reaction. When alcohol **13***d* is reacted with $POCl_3$ in pyridine at room temperature, the major product isolated by preparative vpc is **17**. Whether the Grob-type cleavage (9, 10) occurs in a stepwise fashion through cation **15** via attack of Cl^- on a dioxolenium ion **16** or in a synchronous fashion as depicted in **18** can be debated.

Experimental

Melting points were taken on a Kofler block and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer 337 Grating Spectrometer and a Beckman IR5 instrument equipped with NaCl optics. All reported absorptions are obtained from spectra calibrated with a polystyrene film. Nuclear magnetic resonance spectra were obtained on Varian Associates models HA-60 and T-60 spectrometers with tetramethylsilane as an internal standard. Analytical vpcs were obtained on a Varian Associates Model 204 instrument and preparative vpc separations were carried out on a model A-90 P-3 instrument with He as the carrier gas. Mass spectra were obtained on a Perkin-Elmer-Hitachi model RMU 6A spectrometer.

Solutions were dried over anhydrous sodium sulfate or magnesium sulfate.

Microanalyses were performed by A. B. Gygli of 329 St. George Street, Toronto, Ont.

endo-*5-Hydroxy-4,6,6-trimethyl-2-norbornanone* (*1*a)

The ketol **1***a* was prepared from fenchone according to the procedure of Cookson and co-workers (10).

5-Ethylenedioxy-1,3,3-trimethyl-endo-*2-norbornanol* (*2*a)

Ketol **1***a* (5.3 g, 31 mmol) was dissolved in benzene (530 ml, previously distilled from lithium aluminium hydride), and ethylene glycol (8 ml) and *p*-toluenesulfonic acid (0.53 g) were added. The solution was refluxed, with magnetic stirring in a Dean-Stark apparatus, for 20 h. The benzene solution was cooled and quenched with a saturated bicarbonate solution (100 ml), washed with a saturated sodium chloride solution, and dried. Evaporation of the benzene gave 6.6 g of an oil (100%). Purification by preparative vpc on a 5 ft × ¼ in. 20% SE-30 column at 175°C followed by a bulb-to-bulb vacuum distillation gave an analytical sample; nmr (60 MHz, CCl_4) δ: 1.06 (s, 6H, methyl groups), 1.10 (s, 3H, methyl group), 1.10 (s, 3H, methyl group), 3.24 (d, 1H, C(2)-H), 3.85 (m, 4H, ketal); ir (CCl_4): 3620, 3500 cm^{-1}. *Anal.* calcd. for $C_{12}H_{20}O_3$: C 67.92, H 9.43; found: C 67.97, H 9.62.

5-Ethylenedioxy-1,3,3-trimethyl-2-norbornanone (*3*a)

The oxidizing reagent was prepared by adding pyridine (72 ml) to chromium trioxide (7.2 g, 72 mmol) dissolved in water (7.2 ml) which was cooled in an ice bath. The reagent was added to the alcohol (4.4 g, 25 mmol) and the mixture was left standing at room temperature for 17 h. The mixture was diluted with water to 800 ml and extracted with ether (4 × 100 ml). The combined ether extracts were washed with water (6 × 50 ml) to remove as much pyridine as possible and with a saturated sodium chloride solution (50 ml). After drying, the ether was evaporated and the remaining pyridine was distilled under vacuum. There remained 4.1 g of ketone **3***a* (94%). Purification, by preparative vpc on a 5 ft × ¼ in. 20% SE-30

column at 175°C followed by bulb-to-bulb distillation, gave an analytical sample; nmr (60 MHz, CCl_4) δ: 3.98 (m, 4H, ketal), 1.08, 1.01, 0.98 (3s, 3H each, methyl groups); ir (CCl_4): 1750 cm^{-1}. *Anal.* calcd. for $C_{12}H_{18}O_3$: C 68.57, H 8.57; found: C 68.49, H 8.88.

*2-Ethylenedioxy-1,3,3-trimethyl-5-methylenenorbornane (**4**a)*

A flow of dry nitrogen was passed through the reaction mixture during the preparation of the ylide. *n*-Butyllithium (2.54 g, in 5 ml hexane, 20 mmol) was added to a mixture of triphenylmethylphosphonium bromide (7.2 g, 20 mmol) in purified hexane; (70 ml of reagent grade hexane were treated with concentrated sulfuric acid, washed with water, then with permanganate; the hexane was washed with water, filtered through a column of alumina, and distilled). The mixture was stirred magnetically for 4 h. Ketoketal **3***a* (4.1 g, 20 mmol) in purified hexane (30 ml) was slowly added and the resulting mixture was refluxed for 24 h. The reaction mixture was cooled, the solids were filtered, and the hexane solution was washed with water until the wash layer was neutral. The solution was dried and the solvent was evaporated to yield 3.3 g (80%) of **4***a*. Purification, by preparative vpc followed by bulb-to-bulb distillation, yielded an analytical sample; nmr (60 MHz, CCl_4) δ: 1.02, 1.12, 1.26 (3s, 3H each, methyl groups), 3.88 (m, 3H, ketal), 4.60 (d, 3H, olefin); ir (neat): 3070, 1650, 880 cm^{-1}. *Anal.* calcd. for $C_{13}H_{20}O_2$: C 75.00, H 9.61; found: C 75.07, H 9.91.

*4,6,6-Trimethyl-5-methylene-2-norbornanone (**5**a)*

The ketol **4***a* was converted, in portions, to the enone **5***a* according to the following procedure. Compound **4***a* (0.3 g, 1.4 mmol) was dissolved in aqueous acetone (90%, 10 ml), which contained 1 drop of concentrated hydrochloric acid. The solution was stirred magnetically at room temperature for 24 h. The reaction mixture was diluted with water to 50 ml and 3–4 drops of sodium hydroxide (10%) were added. The solution was saturated with sodium chloride and extracted twice with ether. The combined ether extracts were washed once with water and once with a saturated sodium chloride solution and dried. Evaporation of the solvent gave 0.1 g of an oil (45%). Purification by preparative vpc on a 5 ft × ¼ in. 20% SE-30 column at 150°C gave 0.040 g of **5***a*; ms *m/e*: 164 (M^+); nmr (60 MHz, CCl_4) δ: 1.02, 1.12, 1.28 (3s, 3H each, methyl groups), 4.72 (1H, olefin), 4.78 (1H, olefin); ir (neat): 3060, 1750, 1640, 880 cm^{-1}.

Confirmation of the Structure of **5**a. *Oxidation to 1,3,3-Trimethyl-2,5-norboranedione (**10**a)*

Compound **5***a* (0.15 g, 0.9 mmol) was dissolved in acetone–water (50%, 10 ml). Potassium periodate (4 g) was added and the mixture was cooled in an ice-water bath. Potassium permanganate (0.2 g) in water (3 ml) was added dropwise over a period of 10 min to the stirred solution. The reaction mixture was stirred for 4 h at room temperature and filtered. The filtrate was diluted to 100 ml with water and extracted with ether (3 × 25 ml). The combined ether extracts were washed with a saturated sodium chloride solution and dried. Evaporation of the solvent gave a solid which was identified as dione **10***a* by comparison of its ir spectrum (1012, 964, 945, 933, 915, and 900 cm^{-1}) to that of an authentic sample (6).

endo-*5-Hydroxy-6,7-dimethyl-2-norbornanone (**1**b)*

Compound **1***b* was prepared by hydrolysis (2) of keto-acetate **6***b* that was obtained from acetate **9***b* via the procedure of Meinwald and co-workers (3).

*5-Ethylenedioxy-3,3-dimethyl-*endo*-2-norbornanol (**2**b)*

Ketol **1***b* (7.5 g) was dissolved in benzene (700 ml, previously distilled from lithium aluminium hydride) and ethylene glycol (10.5 ml) and *p*-toluenesulfonic acid (0.7 g) were added. The mixture was refluxed for 44 h in a Dean-Stark apparatus, cooled, and added to a saturated solution of sodium bicarbonate (200 ml). The benzene solution was washed with water (200 ml), saturated sodium chloride (200 ml) solution, and dried. The solvent was distilled off to give 6.5 g of an oil (76%); nmr (60 MHz, CCl_4) δ: 3.30 (s, 1H, OH), 3.80 (m, 4H, ketal), 1.02 (s, 6H, methyl groups); ir (CCl_4): 3620, 3460 cm^{-1}. Purification, by preparative vpc on a 5 ft × ¼ in. SE-30 column at 175°C followed by bulb-to-bulb vacuum distillation, gave an analytical sample. *Anal.* calcd. for $C_{11}H_{18}O_3$: C 66.67, H 9.09; found: C 66.38, H 9.12.

*5-Ethylenedioxy-**3**,3-dimethyl-2-norbornanone (**3**b)*

The oxidizing reagent was prepared by adding chromium trioxide (9.8 g) in water (9.9 ml) to ice-cold pyridine (98 ml). The reagent was added to the ketalol **2***b* (6.4 g) and resulting solution was left standing at room temperature for 24 h. The reaction mixture was added to ice (500 ml) and the mixture was diluted to 1.5 ℓ with water and extracted with ether (3 × 200 ml). The ether extracts were washed with water (200 ml), dilute hydrochloric acid (200 ml), water (200 ml), saturated sodium bicarbonate solution (200 ml), and water (200 ml). The ether solution was dried and the solvent was taken off under vacuum to give 4.7 g of an oil (72%); nmr (60 MHz, CCl_4) δ: 3.87 (m, 4H, ketal), 1.18, 1.05 (2s, 3H each, methyl groups); ir (neat): 1750 cm^{-1}. Purification, by preparative vpc on a 5 ft × ¼ in. 20% SE-30 column at 195°C followed by a bulb-to-bulb vacuum distillation, yielded an analytical sample. *Anal.* calcd. for $C_{11}H_{16}O_3$: C 67.35, H 8.16; found: C 67.23, H 8.19.

*6,6-Dimethyl-5-methylene-2-norbornanone (**5**b)*

The ketalone **3***b* (4.7 g) in hexane (65 ml) was reacted, as described in the preparation of **4***a*, with the ylide prepared from 13.5 g of phosphonium bromide and 11 ml of 1.5 *M* *n*-butyllithium in hexane (160 ml). After the mixture was refluxed for 24 h, the solids were filtered off and the hexane solution was washed with water until the aqueous layer was neutral. The solvent was distilled off under vacuum and the ketalene **4***b* (2.1 g) was dissolved in 90% aqueous acetone (100 ml) and concentrated hydrochloric acid (0.6 ml) was added. The mixture was stirred at room temperature for 36 h, diluted with water, and extracted with ether (4 × 30 ml). The ether extracts were dried and concentrated by distillation through a 30-cm glass helices column. Compound **5***b* (0.30 g) was isolated from the residue by preparative vpc on a 5 ft × ¼ in. 20% SE-30 column at 125°C; mp 61–63°C; nmr (60 MHz, CCl_4) δ: 4.92 (1H, olefin), 4.73 (1H, olefin), 3.05 (broad s, 1H, bridgehead), 2.4–1.5 (m, 5H), 1.15, 1.06 (2s, 3H each, methyl groups); ir (CCl_4): 3050, 1745, 1650, 890 cm^{-1}; ms *m/e*: 150 (M^+).

Confirmation of the Structure of **5**b. *Oxidation to **3**,3-Dimethyl-2,5-norbornanedione (**10**b)*

Enone **5***b* (0.063 g) was dissolved in aqueous acetone (50%, 7 ml) and KIO_4 (2 g) was added to the solution. To the mixture cooled in ice-water and stirred magnetically, $KMnO_4$ (100 mg) in water (ca. 2 ml) was added dropwise over a period of 10 min. The mixture was warmed to room temperature, stirred for 6 h, diluted to 100 ml with water, and extracted with ether (3 × 25 ml). The ether extracts were washed with water (2 × 25 ml), saturated sodium chloride solution (25 ml), and dried ($MgSO_4$). After evaporation of solvent the oxidation product was isolated by preparative vpc on a 5 ft × ¼ in. 20% SE-30 column at 120°C. Its ir spectrum (1155, 1085, 1058, 960, 926, 896 cm^{-1}) was identical to that of an authentic sample (6) of dione **10***b*.

For personal use only.

endo-*5-Ethanoyloxy-2-norbornanone (**6**c)*

Compound **6***c* was prepared from nortricyclanone via the procedure of Meinwald and co-workers (5).

*5-Ethylenedioxy-*exo*-2-norbornyl Acetate*

Compound **6***c* (10 g, 60 mmol) was dissolved in benzene (500 ml, previously distilled from lithium aluminium hydride), *p*-toluenesulfonic acid (1 g) and ethylene glycol (20 ml) were added and the solution was refluxed for 24 h in a Dean-Stark apparatus. The solution was then quenched with saturated bicarbonate solution (100 ml) and the layers were separated. The benzene solution was dried and the benzene was distilled off to yield 11.0 g (87%) of the ketal. Purification by preparative vpc on a 5 ft × ¼ in. SE-30 column at 160°C followed by bulb-to-bulb vacuum distillation gave an analytical sample of *7a*; nmr (CCl_4) δ: 1.95 (s, 3H, acetate), 3.80 (m, 4H, ketal), 4.60 (q, 1H, *endo*-C(2)H); ir (CCl_4): 1745, 1245 cm^{-1}. *Anal.* calcd. for $C_{11}H_{16}O_4$: C 62.26, H 7.54; found: C 62.25, H 7.66.

*Reduction of the Acetate **7**a*

The glassware was oven dried before use and the ether was distilled from lithium aluminium hydride.

The ketal acetate *7a*, (10 g, 47 mmol) dissolved in ether (150 ml) was added over a period of 1 h at room temperature to a magnetically stirred slurry of lithium aluminium hydride (3.6 g, 94 mmol) in ether (200 ml). The mixture was refluxed for 10 h. The excess lithium aluminium hydride was then destroyed by the addition of water (3.6 ml), 10% NaOH (3.6 ml), and more water (3.6 ml), consecutively, to the vigorously stirred solution. The granular salts were filtered off and the solvent was evaporated to give 5.8 g (73%) of alcohol *7b*; nmr (60 MHz, CCl_4) δ: 3.8 (m, ketal CH_2); ir (neat): 3400 cm^{-1}, no ketonic absorption.

*5-Ethylenedioxy-2-norbornanone (**3**c)*

5-Ethylenedioxy-*exo*-2-norbornanol (*7b*) (5.4 g, 32 mmol) was added to the oxidizing reagent, prepared from chromium trioxide (10 g) dissolved in water (10 ml) and ice-cold pyridine (100 ml), and the solution was left standing at room temperature for 16 h. The solution was diluted to 300 ml with ice-water and the mixture was filtered through Celite. The precipitate was washed with water (30 ml) and methylene chloride (three times for a total of 100 ml). The combined methylene chloride solutions were filtered through Celite. The solvent was concentrated to 100 ml, washed with very dilute sulfuric acid until the wash layer remained acidic, and then with saturated sodium bicarbonate solution. The solution was dried and the solvent was evaporated to give 3.4 g (63%) of **3***c*. Purification by preparative vpc on a 5 ft × ¼ in. 20% SE-30 column at 170°C and a bulb-to-bulb vacuum distillation gave an analytical sample; nmr (CCl_4) δ: 3.8 (m, 4H, ketal), 1.4–2.6 (m, 8H); ir (neat): 1745 cm^{-1}. *Anal.* calcd. for $C_9H_{12}O_3$: C 64.29, H 7.14; found: C 64.27, H 7.30.

*5-Methylene-2-norbornanone (**5**c)*

n-Butyllithium (1.5 *N*, 25 ml, 0.04 mol) was added to a mixture of methyltriphenylphosphonium bromide (10.5 g, 0.04 mol) in ether (150 ml, freshly distilled from lithium aluminium hydride) as a slow flow of dry nitrogen was passed through the reaction mixture. The mixture was stirred magnetically for 4 h at room temperature. 5-Ethylenedioxy-2-norbornanone (3.2 g, 0.04 mol) dissolved in ether (125 ml) was slowly added and the mixture was refluxed for 11 h. The solids were then filtered off and the ether solution was washed until the water layer was neutral. The solvent was distilled through a 2-ft Vigreux column and the oil which remained was dissolved in a mixture of ethanol (75 ml) and water (35 ml). Acetic acid (1 ml) and hydrochloric acid (50%, 5 drops) were added and the mixture was stirred at room temperature for 3 days. It was then diluted to 400 ml with water and extracted with ether (3 × 125 ml). The ether solution was washed with water (100 ml) and saturated sodium bicarbonate solution. The solution was dried and the solvent was distilled through a Vigreux column. Purification of the residue by preparative vpc gave 0.38 g of enone. Bulb-to-bulb vacuum distillation gave an analytical sample; nmr (60 MHz, CCl_4) δ: 5.02 (1H, olefin), 4.78 (1H, olefin), 3.03 (broad s, 1H, bridgehead), 2.65 (broad s, 1H, bridgehead); ir (CCl_4): 3080, 1754, 1660, 890 cm^{-1}. *Anal.* calcd. for $C_8H_{10}O$: C 78.69, H 8.20; found: C 78.65, H 8.25.

*Confirmation of the Structure of 5-Methylene-2-norbornanone. Oxidation to 2,5-Norbornanedione (**10**c)*

The enone **5***b* (0.045 g, 0.37 mmol) was dissolved in aqueous acetone (50%, 7 ml) containing potassium periodate (2 g). The solution was cooled in ice-water and a solution of potassium permanganate (0.1 g in 3 ml of water) was added dropwise over a period of 10 min. The resulting mixture was warmed to room temperature and stirred for 5 h. The solution was filtered through a medium porosity sintered glass funnel, diluted to 100 ml, and extracted with methylene chloride (3 × 50 ml). The combined extracts were washed with water (25 ml), dried, and the solvent was evaporated to yield a compound whose ir spectrum (1180, 1120, 1045, 952, 890 cm^{-1}) was identical to that of an authentic sample of 2,5-norbornanedione (6).

*6-Oxo-2-norbornanecarboxylic acid (**12**)*

The keto acid (37.4 g) was prepared from *endo*-2-norbornene-5-carboxylic acid by the method of Beckman and Geiger (8).

*6-Ethylenedioxy-*endo*-2-norbornylmethanol (**13**b)*

The keto acid **12** (32.3 g, 0.21 mol) was dissolved in benzene (300 ml, freshly distilled from lithium aluminium hydride). Ethylene glycol (100 ml, freshly distilled) and *p*-toluenesulfonic acid (1 g) were added and the mixture was refluxed for 20 h in a Dean-Stark apparatus. After cooling, the layers were separated and the ethylene glycol layer was diluted with saturated sodium bicarbonate solution (100 ml) and extracted with methylene chloride (3 × 75 ml). The extracts were washed with water (50 ml) and dried. The combined organic layers were evaporated to yield 45.5 g of a viscous oil; nmr (60 MHz, $CDCl_3$) δ: 4.2 (m, 2H), 3.7 (m, 4H), 2.7 (broad s, 1H); ir (neat): 3500, 1750, 1200 cm^{-1}. The oil (45 g) which was identified by the spectroscopic data as the ketal ester **13***a*, was dissolved in ether (300 ml) and added to lithium aluminium hydride (10 g) in ether (200 ml) over a period of 2 h. The mixture was refluxed overnight, cooled, and sodium hydroxide (10%, 10 ml) and water (10 ml) were added. After the mixture was stirred for 6 h at room temperature, the inorganic salts were filtered off and the solvent was evaporated to give 36.1 g (93%) of a viscous liquid. Distillation of the oil under reduced pressure gave a colourless liquid; nmr (60 MHz, CCl_4) δ: 3.8 (d, 4H, ketal), 3.7 (m, 7H, CH_2OH, —O—CH_2—CH_2—O—); ir (neat): 3500 cm^{-1}. A sample was further purified by preparative vpc and a bulb-to-bulb vacuum distillation. *Anal.* calcd. for $C_{10}H_{16}O_3$: C 65.22, H 8.70; found: C 65.17, H 8.92.

*6-Ethylenedioxy-*endo*-2-norbornylmethyl Acetate (**13**c)*

The alcohol **13***b* (12 g, 78 mmol) was dissolved in pyridine (40 ml) and acetic anhydride (20 ml). The solution was left standing at room temperature for 20 h, diluted to 400 ml with ice-water, and extracted with ether (3 × 100 ml). The ether solution was washed with water (80 ml), dilute hydrochloric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

acid (5%, 2 × 80 ml), water (80 ml), bicarbonate (80 ml), and water (80 ml). The solution was dried and the solvent was evaporated to yield 13.9 g (81%) of an oil; nmr (60 MHz, CCl_4) δ: 4.2 (m, 2H, CH_2OAc), 3.8 (m, 4H, ketal), 2.0 (s, 3H, acetate); ir (neat): 1745 cm^{-1}. A sample was purified by preparative vpc and a bulb-to-bulb vacuum distillation. *Anal.* calcd. for $C_{12}H_{18}O_4$: C 63.72, H 7.96; found: C 63.72, H 8.16.

6-Methylene-2-norbornanone (11)

A glass column, packed with glass helices, was placed vertically in a pyrolysis oven maintained at 450–500°C. A flow of nitrogen (1 ml min^{-1}) was maintained throughout the experiment to entrain the products. Acetate **13***c* was added very slowly dropwise (3 drops per 5 min) to the top of the column. The products of the reaction were trapped at the end of the column in a flask immersed in a Dry Ice – acetone bath. After the addition was complete the flask was warmed to room temperature and the condensate was dissolved in ether. The ether solution was washed with saturated sodium bicarbonate solution and dried. Evaporation of solvent, and vacuum distillation gave in 5% yield the ketalene **14***a*. The recovered starting material was recycled; nmr (60 MHz, CCl_4) δ: 4.7 (d, 2H, methylene group), 3.9 (narrow m, 4H, ketal), 2.5 (broad s, 1H, bridgehead), 2.3 (m, 1H, bridgehead). Also present were sharp singlets at δ 4.16 and 2.0 of an impurity which comprised 15% of the product isolated by distillation.

Without purification, the ketalene **14***a* was hydrolyzed to the enone. In a typical experiment, the ketalene (0.20 g) was added to water (7 ml) containing 1 drop of concentrated hydrochloric acid. The mixture was stirred at room temperature for 2 h. Solvent extraction and purification by preparative vpc on a 10 ft. × ¼ in. 10% UCON column at 160°C gave 0.055 g of a colourless liquid; nmr (60 MHz, CCl_4) δ: 5.16 (1H, olefin), 4.88 (1H, olefin), 3.03 (s, 1H, C(1)H), 2.80 (unresolved m, 1H, C_4H), 2.6–1.6 (m, 6H); ir (CCl_4): 3080, 1750, 1650, 890 cm^{-1}. A bulb-to-bulb vacuum distillation of a portion gave an analytical sample. *Anal.* calcd. for $C_8H_{10}O$: C 78.69, H 8.20; found: C 78.57, H 8.43.

6-Ethylenedioxy-exo-*2-methyl*-endo-*2-norbornanol* ***13***d

Magnesium metal (220 mg, 10 mmol) and methyl iodide (freshly distilled, 1.4 g, 10 mmol) in ether (ca. 5 ml) were stirred at room temperature for a few minutes. Ketoketal **14***b* (500 mg, 2.7 mmol) in ether (5 ml) was slowly added and the mixture was stirred at room temperature for 24 h. It was added to crushed ice (2 ml) and the aqueous solution was extracted with ether (2 × 10 ml). The combined ether extracts were washed with water, dried, and evaporated. There resulted 440 mg of a viscous oil (81%); nmr (60 MHz, CCl_4) δ: 4.40 (s, 1H, OH), 3.9 (m, 4H, ketal), 1.18 (s, 3H, methyl group); ir (CCl_4): 3500 cm^{-1}.

Dehydration of Alcohol ***13***d

Alcohol **13***d* (440 mg, 2.4 mmol) was dissolved in pyridine (4 ml), phosphoryl chloride (1.4 ml) was added, and the solution was stirred at 40–50°C for 1 h. It was cooled in ice and water (0.5 ml) was slowly added. Sodium hydroxide (10%, 30 ml) was added and the mixture was extracted with ether (2 × 20 ml). The ether extracts were washed with dilute HCl (10 ml), sodium hydroxide (5%, 10 ml), and water (10 ml). The solution was dried and the solvent was evaporated to give an oil. The major product **17** (60%), of longest retention time, was isolated by preparative vpc on a 10 ft × ¼ in. 20% SE-30 column at 195°C; nmr (60 MHz, CCl_4) δ: 5.20 (broad s, 1H, olefin), 4.28 (t, 2H, CH_2Cl), 3.60 (t, 2H, OCH_2), 1.70 (broad s, 3H, methyl group), 2.8–1.8 (m, 8H); ir (CCl_4): 3050, 1750, 1650 cm^{-1}; ms *m/e*: 202 and 204 (M^+ $C_{10}H_{15}O_2Cl$), 123 ($M^+ - ClCH_2CH_2—O$) and 107 ($M^+ - ClCH_2—CH_2—O—\overset{O}{\overset{\|}{C}}$)

Towards a complete account of the exchange chemistry of a diastereotopic proton pair. I. Base-catalyzed enolization–exchange of 2-norbornanones; on the rate controlling factors

NICK HENRY WERSTIUK, ROLAND TAILLEFER, AND SUJIT BANERJEE

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 12, 1977

NICK HENRY WERSTIUK, ROLAND TAILLEFER, and SUJIT BANERJEE. Can. J. Chem. **56**, 1140 (1978).

We report the rates of base-catalyzed hydrogen isotope exchange of the *exo* and *endo* protons in a series of 2-norbornanones. The *exo*:*endo* rate ratios for 4-methyl-substituted 2-norbornanones **3** and **6** are less than the rate ratios of the 4-demethyl analogs **2** and **5**. Therefore, a methyl group is not a useful torsional-effect probe. This is supported by an analysis which established that the small difference in the torsional strain (0.45 kcal) between eclipsed vicinal hydrogens and an eclipsed vicinal methyl and hydrogen would only result in a maximum twofold *increase* in the rate ratio. The decrease in the *exo*:*endo* rate ratio is a consequence of the electron-donating effect of a methyl group which affects the *exo* rate to a greater degree. Introduction of a strain-inducing *exo* methylene group at C(5) and C(6) in the norbornyl system does not produce a significant change in the exchange rates. The average increase of 7.9 and 2.6 in the *exo* and *endo* rates, respectively, in enones **4**, **5**, and **6** over the ketones **1**, **2**, and **3**, are explicable by an inductive effect. Thus, homoallylic stabilization of the developing carbanion is not important.

Through application of a new mechanistic criterion which involves a log–log plot of the *exo* and *endo* exchange rate constants, we establish, for the bicyclic ketones, that charge transfer to oxygen is greater in the transition state for *endo* deprotonation.

NICK HENRY WERSTIUK, ROLAND TAILLEFER et SUJIT BANERJEE. Can. J. Chem. **56**, 1140 (1978).

On rapporte les vitesses d'échanges, catalysées par les bases, d'isotope d'hydrogène des protons *exo* et *endo* d'une série de norbornanones-2. Les rapports de vitesse *exo*:*endo* des norbornanones-2 substituées par un méthyle en position 4 (**3**) et (**6**) sont plus faibles que les rapports de vitesse des analogues (**2**) et (**5**) qui ne contiennent pas de méthyle en position 4. On en conclut que le groupe méthyle n'est pas une sonde utile pour mesurer les effets de torsion. Cette conclusion est supportée par une analyse qui a établi que de petites différences dans la tension de torsion (0.45 kcal) entre des hydrogènes vicinaux éclipsés et un groupe méthyle vicinal éclipsé par un hydrogène conduirait à un rapport de vitesse qui ne serait que multiplié par deux. La diminution du rapport des vitesses *exo*:*endo* est une conséquence de l'effet électro-donneur d'un groupe méthyle qui affecte plus la vitesse *exo*. L'introduction en position C(5) et C(6) du système norbornyle d'un groupe méthylène *exo* produisant de la tension ne provoque pas de changements importants dans les vitesses d'échange. L'augmentation moyenne de 7.9 et de 2.6 respectivement pour les vitesses *exo* et *endo* dans les énones **4**, **5** et **6** par rapport aux cétones **1**, **2** et **3** peut être expliquée par un effet inductif. On peut donc en conclure que la stabilisation homoallylique du carbanion que se développe n'est pas importante.

Faisant appel à un nouveau critère mécanistique qui implique une courbe log–log des constantes de vitesse d'échanges *exo* et *endo*, on a établi, pour les cétones bicycliques, que le transfert de charge vers l'oxygène est plus grand dans l'état de transition de la déprotonation *endo*.

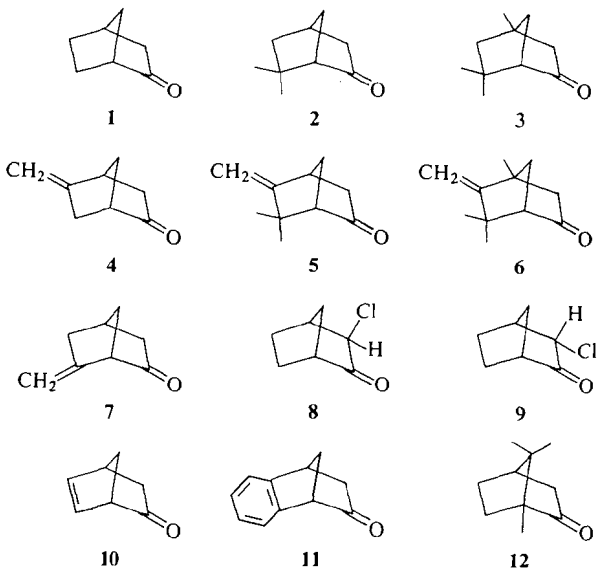
Introduction

The chemistry of the carbonyl group has recently been reviewed in two volumes of the series The Chemistry of the Functional Groups (1). Interestingly, only 3 pages (Vol. II, Chapt. 3), of the 1400 which comprise the review, were devoted to an account of the kinetic and mechanistic aspects of acid- and base-catalyzed enolization and hydrogen isotope exchange of ketones. Although the review was not complete by any means, this fact did support our initial conclusion that there indeed was a paucity of kinetic and mechanistic detail about these most ubiquitous reactions. Before 1970 (2–4), there were no accurate rate data for base-catalyzed hydrogen isotope exchange of the diastereotopic protons in polycyclic ketones, even though there were reports (5–8) of the preparation of 80–90% stereochemically pure monodeuterated 2-norbornanones. Thus, at that time we initiated a research program to generate quantitative rate data in an effort to detail the mechanistic intricacies of isotope exchange and enolization of cyclic ketones. We chose to study 2-norbornanones because of their conformational rigidity and the substantial difference in the *exo* and



endo exchange rates. We reasoned that the compilation of accurate exchange rate data in a suitable series of ketones would establish (*a*) whether or not torsional strain between hydrogen or methyl at the bridgehead and the hydrogens alpha to the carbonyl group plays an important role in establishing the exo:endo exchange rate ratio, (*b*) the importance of homoallylic and homoenolic assistance to enolization, (*c*) whether the introduction of a strain-inducing exocyclic π system into the [2.2.1] skeleton affects the enolization rates, and (*d*) through the application of a new linear free energy correlation (9), the relative charge development in the transition states for *exo* and *endo* deprotonation.

In this second paper[1] of a series, we describe the mass spectrometric procedure that was developed to accomplish the kinetic study, document the exchange rate data for the bicyclic ketones and enones **1**–**9**, and interpret the results on the basis of the factors listed above.

Results

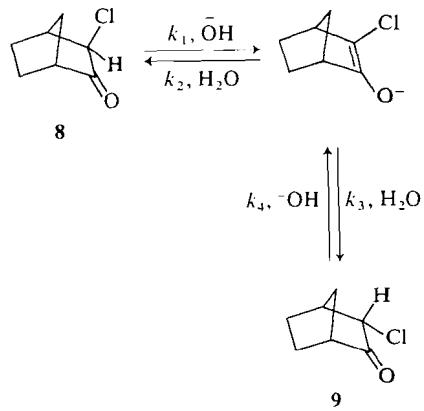
Exchange (Enolization) of 2-Norbornanones

The rates of NaOD-catalyzed H–D exchange of the protons in the 3-position of substrates **1**–**7** were measured at 25°C in 60% dioxane – 40% D_2O by following the up-take of deuterium by mass spectrometry and are presented in Table 1. The syntheses of **4**, **5**, **6**, and **7** are reported in the preceding paper. Our value of $3.85 \times 10^{-2}\ M^{-1}\ s^{-1}$ for *exo* exchange in 2-norbornanone (**1**) compares well with Tidwell's measurement (4) of $5.58 \times 10^{-2}\ M^{-1}\ s^{-1}$ in 2:1 dioxane–D_2O. That the rate is depressed in the medium containing more water is consistent with Tidwell's findings (4). Figures 1*a* and *b* illustrate, for **3**, the pseudo-first-order plots for *exo* and *endo* exchange, respectively.

Determination of the rates of exchange of the chloroketones **8** and **9** in theory could be complicated since isomerization accompanies exchange and the procedure that was used is outlined below.

Exchange (Enolization) of 3-Chloro-2-norbornanones

The exchange of **8** and **9** leads to a mixture of exchanged and unexchanged species according to the following scheme. The *endo*-3-chloro-2-norbornanone (**9**) is the first formed product of the kinetically favoured *exo* protonation. In deuterated medium **9**-*d* is subsequently isomerized to **8**-*d*.



For the isomerization of **8** to **9** the following analysis is appropriate. If the enolate (E) is a steady-state intermediate, and only **8** is present initially, [1] and [2] follow.[2]

$$[1]\quad \ln\frac{k_1k_3[\mathbf{8}]_0}{(k_1k_3 + k_2k_4)[\mathbf{8}] - k_2k_4[\mathbf{8}]_0} = [OH^-]\left(\frac{k_1k_3 + k_2k_4}{k_2 + k_3}\right)t$$

$$[2]\quad \ln\frac{[\mathbf{8}]_0}{(1 + K)[\mathbf{8}] - K[\mathbf{8}]_0} \simeq [^-OH]k_1(1 + K)t$$

Since $k_3 \gg k_2$ and $k_2k_4/k_1k_3 = K$.

In principle, k_1 can be obtained from [2] when the isomerization is carried out in H_2O. However, the equation does not apply in D_2O since ketonization leads to **8**-*d* rather than **8**. Fortunately, $k_3 \gg k_2$ and only very minor amounts of **8**-*d* are formed in the initial stages of the reaction, up to 40% conversion of **8** to **9**-*d*. Hence, k_1 for enolization in nondeuterated and deuterated medium can be determined gas

*Average of at least two determinations. Average deviation < 5%.
†The rate constants from entries 2 and 4 in Table 2 have been corrected for a difference in ground state energies and temperature according to footnote 3.
‡These values were obtained from ref. 3 by multiplying the rate constants reported therein by a factor of 0.736 which interrelates the rate constants for 1 in 60:40 dioxane–D_2O and 2:1 dioxane–D_2O.

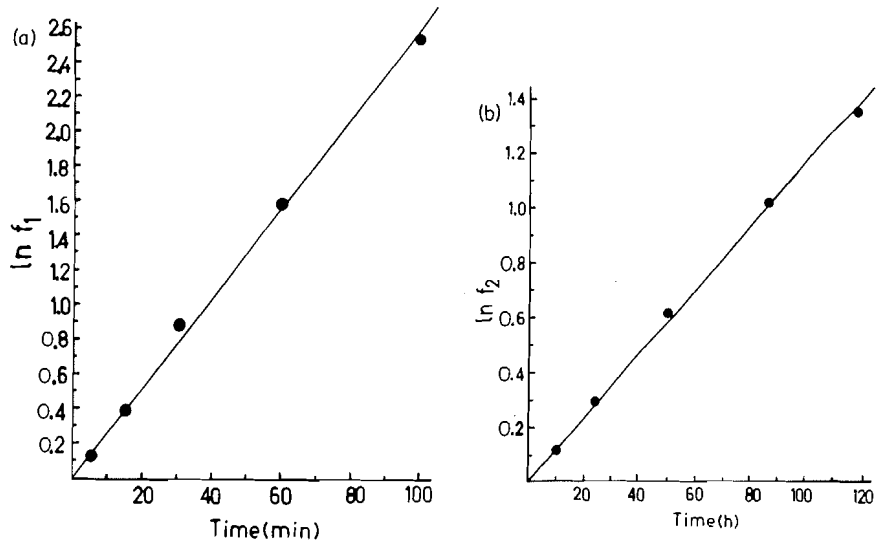

FIG. 1. Pseudo-first-order plot for NaOD-catalyzed H–D *exo* exchange of 4,6,6-trimethyl-2-norbornanone (**3**) at 25°C: (*a*) 0.043 *N* NaOD; (*b*) 0.104 *N* NaOD.

chromatographically by following the conversion of **8** to **9** and **9**-*d*. Thus, the enolization of **8** and **8**-*d* is treated on a pseudo-first-order basis and the rate data are presented in Table 2. Figure 2 illustrates the pseudo-first-order plot for exchange of **8**.

The exchange of **9** in deuterated medium was followed by the mass spectrometric procedure used for the other substrates since no isomerization of **9**-*d* occurred during the period of the kinetic measurement. The reaction was too fast to be followed at the usual base concentrations and a dioxane–buffer solution was utilized as described in the experimental. Figure 3 illustrates the pseudo-first-order plot for deuteration of the *endo*-3-chloroketone **9**. The exchange of the *exo* proton in 2-norbornanone (**1**) was measured in the same dioxane–buffer solution and the second-order rate constant for exchange in **9** was obtained by comparison with this rate as is described in the experimental. The primary isotope effect and the solvent isotope effect for *endo* proton abstraction, available from entries 1–3, are 6.6 and 1.61, respectively. The *endo* isotope effect of 6.6 is compared with Tidwell's value (4) of 5 for *exo* abstraction obtained from base-catalyzed *exo* bromination of 2-norbornanone and 2-norbornanone-3,3-d_2 at 10°C.

TABLE 2. Rates of base-catalyzed enolization (exchange) of 3-chloro-2-norbornanones at 30.0°C

Entry	Substrate	Medium	k (M^{-1} s^{-1})*
1	**8**	$^-OH/H_2O$	7.08×10^{-3}
2	**8**	$^-OD/D_2O$	1.14×10^{-2}
3	**8**-*d*	$^-OD/D_2O$	1.73×10^{-3}
4	**9**	$^-OD/D_2O$	1.88×10^{2}

*Average of at least two determinations. Average deviation < 5%.

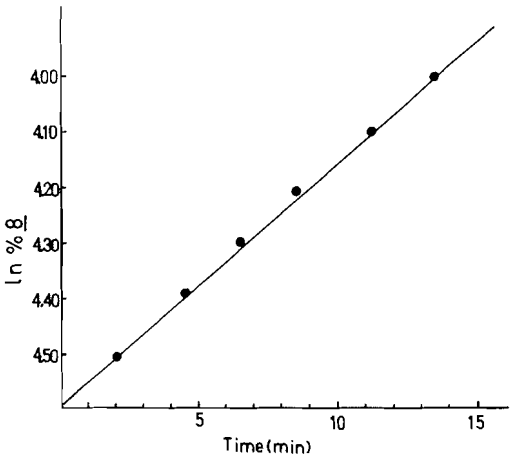

FIG. 2. Pseudo-first-order plot for NaOD (0.0606 *N*)-catalyzed enolization of *exo*-3-chloro-2-norbornanone (**8**) at 30°C.

To allow comparison between the rates of the chloroketones **8** and **9** with those of the substrates listed in Table 1, small corrections for temperature and the ground state energy difference between the two isomers were applied.[3] The final corrected rates are included in Table 1.

Discussion

Before we attempt to interpret the kinetics of exchange of the norbornanones in Table 1, we briefly discuss a potentially complicating factor. In our recent studies (10, 11), which have supported our contention that the mechanistic intricacies of enolization (exchange) of ketones had not been previously established, we demonstrated that ex-

[3]The more reactive *endo*-3-chloro-2-norbornanone (**9**) is also the more stable of the two isomers and therefore the observed rate ratio of 16 940 includes a contribution from the ground state energy difference. To remove this contribution so that the *exo*:*endo* rate ratio for **8** and **9** reflects the difference in transition state free energies measured from a common ground state, the ground state of **9** was raised to that of **8** by means of the equilibrium constant. The rate ratio, after the application of correction, is 33 070.

The chloroketones were run at 30°C, whereas data for the other substrates were acquired at 25°C. A correction for the temperature difference was made by multiplying the data for the chloroketones at 30°C by the rate ratio (0.66) obtained by measuring the exchange of **1** at 25 and 30°C, respectively.

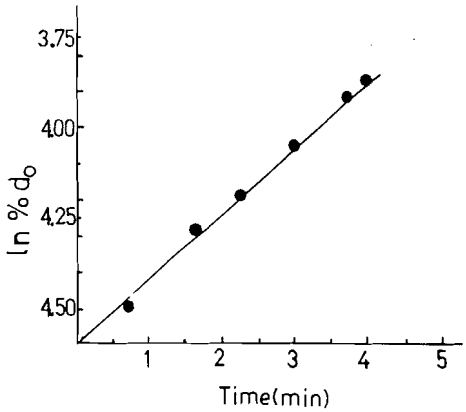

FIG. 3. Pseudo-first-order plot for NaOD-catalyzed (p*D* 10.37) H–D exchange of *endo*-3-chloro-2-norbornanone (**9**) at 30°C.

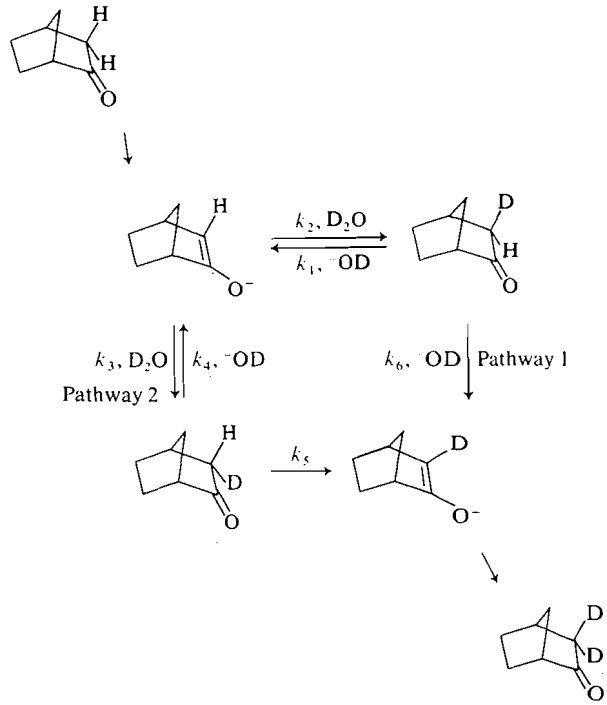
change (Scheme 1) of the *endo* proton in **1** proceeds via direct proton abstraction (Pathway 1), and epimerization of the initially formed *exo*-D-*endo*-H



SCHEME I

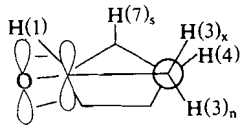
species to the *exo*-H-*endo*-D material and subsequent exchange of the *exo* proton (Pathway 2). To a first approximation (10, 11), the observed rate ratio is given by $k_x/k_{nH\rightarrow D} = si/(i + 1)$, where s represents the intrinsic selectivity for cleavage of the *exo* and *endo* CH bonds, respectively, and i is the primary kinetic isotope effect at the *exo* site. Hence, if $i = 5$ (*vide*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

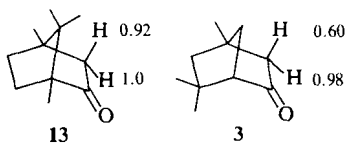
supra), then the observed rate ratio for H→D exchange in 2-norbornanone differs from s by about 17%.[4] However, except for the chloroketones **8** and **9**, all the substrates listed in Table 1 are expected to have errors of approximately 17% associated with their rate ratios and thus this effect is not important in a semiquantitative interpretation (*vide infra*).

Torsional Effect

In an attempt to account for the high stereoselectivity observed in reactions involving the norbornyl system, Schleyer (12) postulated that eclipsing interactions between the reacting group and adjacent substrates might be influential in controlling transition state energy. This view gains credence from the observation that torsional effects are responsible for the reactivity differences observed in the base-catalyzed enolization of a series of simple unsubstituted cyclic and bicyclic ketones (11). In the norbornanones, the dihedral angle between $H(3)_x$ and H(4) is about 20°. *Endo* attack by the base at $H(3)_n$ results in a decrease in the $H(3)_x$–H(4) dihedral



angle, and if the enolate anion is planar, the protons at some point must become fully eclipsed. In the case of *exo* attack at $H(3)_x$, there is a decrease in the $H(3)_n$–H(4) dihedral angle also but the fully eclipsed arrangement is not reached. In the latter case, however, the *release* of torsional strain is greater. Consequently, methyl substitution at C(4) should decrease the *endo* exchange rate and perhaps increase the *exo* exchange rate if the release of torsional strain is the dominant factor. Thus, there would result an overall increase in the *exo*:*endo* rate ratio. Tidwell (13, 14) found that the inclusion of a second bridgehead methyl group in camphor (**12**) led to only minor rate differences and almost no change in the rate ratio for the camphor,**13** pair, whereas an increase in rate ratio is predicted from Schleyer's postulate. Our results, for the **2**,**3** and **5**,**6** pairs, shown below as factors relative to the parent ketones **2** and **5**, respectively, confirm Tidwell's observation to the



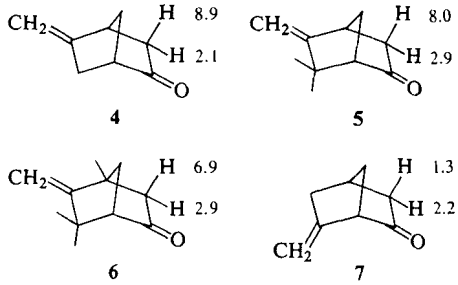
13 **3** **6**

[4]Since $(k_x/k_{n(obs)}) = si/(i+1)$ for **1**, $s = (k_x/k_{n(obs)})\ (6/5) = 780$ when $i = 5$. Therefore, $(k_x/k_{n(obs)})$ (Table 1) differs from s by 17%. The net effect of the dual-channel exchange of the *endo* proton is that $k_{n(obs)} = 1.2\ k_{n(intrinsic)}$.

extent that a decrease in rate ratio rather than an increase results from bridgehead methyl substitution (entries 2,3 and 5,6 in Table 1). Interestingly, the decrease in the rate ratios is a consequence of a small *decrease* in the *exo* exchange rate. Hence, the overall picture appears to be paradoxical, since torsional strain effects appear to account for the reactivity differences in 2-norbornanone and other simple ketones, and yet the predicted consequences of these effects within the [2.2.1] framework are not observed. A possible source of this anomaly likely lies in the invalidity of using bridgehead methyl substituents as a probe for torsional studies in the transition state. A hydrogen–methyl fully eclipsed interaction exceeds that of a hydrogen–hydrogen interaction by approximately 0.45 kcal/mol (15, 16), which translates to a maximum difference in rate of a factor of 2. On the other hand, a linear free energy analysis (*vide infra*) of the rate data establishes that electron-releasing substituents decrease the *exo*:*endo* ratio. Consequently, since full eclipsing is not achieved in the transition state, we conclude that the small rate differences expected on account of torsional effects are easily outweighed by the much larger inductive contributions of the methyl group and that introduction of a methyl group, or a group of equivalent size, at C(4) produces no significant steric retardation to *exo* deprotonation.

Homoallylic Stabilization

From entries 1–6 (Table 1) it is seen that the 5-methylene group exerts a small effect on both rates and on the rate ratios. The rate enhancements over the parent ketone in each case are shown below. The average rate enhancements for $H(3)_x$ and $H(3)_n$ in **4**, **5**, and **6**, over **1**, **2**, and **3**, are 7.9 and 2.6, respec-



4 **5** **6** **7**

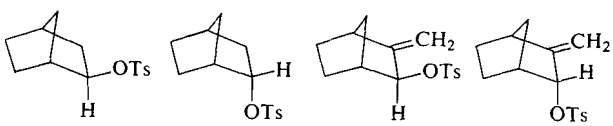
tively, and can be ascribed most economically to the inductive effect of the double bond. Thus, an increase in strain, also present in **7**, and homoallylic stabilization, both possible consequences of the introduction of a remote exocyclic double bond, do not significantly affect the *exo* and *endo* deprotonation rates.

Substituent Effects

It is apparent from inspection of Table 1 that *exo* exchange is more sensitive to a change in substituent.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

This observation is quantified by a linear-free-energy plot[5,6] (Fig. 4) of slope 1.67, and log k_x = 1.67 log k_n = 5.80. In 2-norbornanone even though the C(3)—H_x and C(3)—H_n bonds are expected to exhibit the same thermodynamic acidity (17), cleavage of the endo bond is more difficult because of greater steric hindrance to *endo* approach by the base. That the more difficult *endo* deprotonation is less sensitive to a change in structure or substituent is explicable on the basis that there is a greater degree of delocalization, relative to the *exo* case, of negative charge onto oxygen in the transition state. Thus the more 'delocalized' enolate-like transition state would be expected to be less sensitive to a change either in structure or substituent. We find some support for our contention that the more difficult *endo* proton transfer is assisted to a greater degree by the carbonyl group and results in greater delocalization of charge in the transition state.[7] A parallel basic tenet, in cation chemistry, which states that the more facile the ionization, the smaller the demand the positive charge will make on participating groups for additional participation was introduced by Winstein and co-workers (19). This concept recently has been restated in the tool of increasing electron demand by Gassman (20), Brown (21), and Lambert (22) and their co-workers. A study of the solvolysis of a series of bicyclic tosylates by Wilcox and Jesaitis (23) is a clear example of this effect and relates directly to our study; the rate constants (k (s^{-1})) are shown below.



2.36×10^{-5} 8.28×10^{-8} 1.02×10^{-4} 2.62×10^{-5}

[5]The plot differs slightly from the one reported previously (9). The rate constant for endo exchange in **7** is 1.32×10^{-4} and not 1.32×10^{-5} as reported in the earlier paper (9). Also, we have improved the accuracy and precision of the rate constants for **8** and **9**, and log k_x and log k_n now are 2.390 and −2.125, respectively.

[6]As we pointed out in the first part of the discussion, that the *endo* proton in ketones **1**–**7** is exchanged via two channels introduces a potential complicating factor. If, as we have shown in footnote 4, the intrinsic *endo* rate constants are in the order of 17% less than the observed ones, application of the correction to the appropriate *endo* rates in Table 1 does not produce a significant change in the slope of the log–log plot.

[7]That the demand for increased delocalization operates in nitro compounds is indicated by the work of Bordwell and Flanagan (18) who have shown that the rates for *exo* and *endo* deprotonation in *endo*-2-nitro-5-norbornene and *exo*-2-nitro-5-norbornene, relative to the corresponding 2-nitronorbornanes, are 1.7 and 1.1, respectively. Although the effects are small and should be interpreted with caution, the more difficult *endo* proton transfer appears to be least sensitive to introduction of the double bond into the [2.2.1] framework.

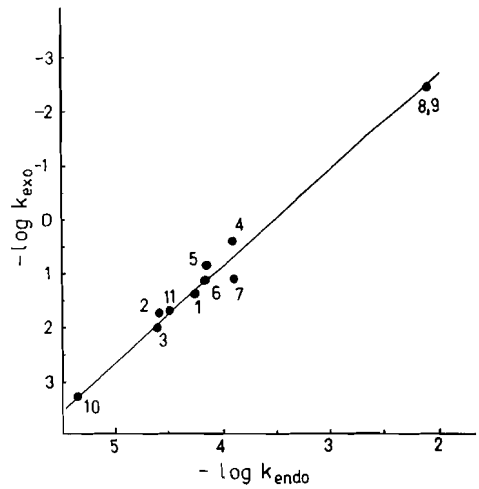


FIG. 4. Plot of $-\log k_x$ vs. $-\log k_n$ for H–D exchange of 2-norbornanones.

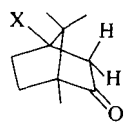
Also, Bell (24), in a comparison of carbon and oxygen acids, has predicted through application of simple electrostatic theory that the more difficult the proton transfer, the greater the charge transfer to the electronegative atom.[8]

Since *endo* deprotonation is more difficult because of the steric hindrance to approach by the base, and the difference in charge transfer to oxygen is a manifestation of this, we expect that an increase in steric restraint to ionization of the *exo* proton would equalize both the degree of charge transfer (delocalization) to oxygen and the sensitivity to changes in structure and substituent in the deprotonations.

A study of the enolization of a series of 4-substituted camphors by Casadavell and co-workers (25)



X = H, CH_3, Cl, Br, NO_2

supports this expectation. The slope of the plot of log k_x vs. log k_n for the series is 1.07 (correction coefficient 0.979). Thus, while there is an increase[9] of 10^3 in absolute rate through the series, the *exo*:*endo* rate ratio remains constant. Since $H(3)_x$ and $H(3)_n$ are in essentially identical steric environments, and the activation energies are not significantly different,

[8]Although the prediction was developed from a consideration of different types of pseudo acids, namely nitroalkanes and phenols, it should also hold for pseudo acids of the same type, i.e., a pair of diastereotopic protons α to a carbonyl group.

[9]For X = H, $k_x = 4.83 \times 10^{-4}$, $k_n = 2.55 \times 10^{-5}$, k_x/k_n = 18; for X = CH_3, 3.35×10^{-4}, 3.65×10^{-5}, 9.2; for X = Cl, 3.0×10^{-2}, 1.8×10^{-3}, 16.4; for X = Br, 4.6×10^{-2}, 2.6×10^{-3}, 16.3; for X = NO_2, 3.4×10^{-1}, 2.7×10^{-2}, 13.1 (25).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the degree of delocalization to the carbonyl group is expected to be comparable in both cases. Thus, both processes exhibit the same sensitivity to a change in structure or substituent. Casadavell's data also support our view that the torsional strain at C(3)—H_x, C(3)—H_n, C(4)—X, and the steric hindrance to *exo* approach of the base are not significantly affected by an increase in the size of X at C(4).

Experimental

2-Norbornanone (**1**) was obtained from Aldrich Chemical Company, and was purified by preparative gas chromatography before use. The syntheses of the 5- and 6-methylene-2-norbornanones **4**–**7** are described in the preceding paper. The ketones **2** (26), **3** (27), and **8** (28) were prepared by literature procedures and were purified by preparative gas chromatography; **8**-*d* was prepared by chlorination of 2-norbornanone-3,3-d_2; **9** was isolated by preparative-gas chromatography from an equilibrium mixture of **8** and **9** that was obtained from **8**. Dioxane was purified by the method of Fieser and Fieser (29).

Kinetic Methods

(*a*) *For Ketones* ***1–7***

A stock solution of sodium deuteroxide in D_2O of convenient normality (0.1–0.4 *N*) was prepared by the addition, under nitrogen, of freshly cleaned sodium metal to D_2O. The solution was standardized before every kinetic run with standard hydrochloric acid using phenolphthalein as the indicator. The ketone solution, typically 0.2 *M*, was prepared by dissolution of the substrate in a 2-ml volumetric flask, previously flushed with dry nitrogen, into sufficient purified dioxane so that it comprised by volume 60% of the run medium. For example, if the total volume of the exchange solution was 2.00 ml, the ketone was dissolved in 1.20 ml of dioxane. Before the start of each run, the NaOD stock solution, the dioxane solution of the ketone, and D_2O were placed, for at least 1 h, in a constant-temperature bath maintained at 25.0 ± 0.05°C. At time 0, the appropriate volume of NaOD solution, usually 0.30–0.50 ml, was accurately transferred to the dioxane solution, the volume was quickly made up to 2.00 ml with D_2O, and the flask was flushed with dry N_2 for 5 s. The NaOD concentration in the studies ranged from 0.0067 to 0.168 *N*. The flask was stoppered with a serum cap and aliquots (0.2–0.3 ml) were removed with a syringe and quenched in 1.5 ml of a dipotassium hydrogen phosphate buffer of p*H* 7.0. The aqueous solution was immediately extracted with ether (2 × 5 ml), saturated with sodium chloride, and extracted with a final portion of ether (1 ml). The combined ether extracts were dried, the solution was concentrated on the rotary evaporator, and the ketone was isolated by preparative vpc on a 5 ft × ¼ in. 20% SE-30 on Chromosorb W column. In some cases, the ether concentrates were introduced directly into the mass spectrometer. The deuterium content of each aliquot was determined mass spectrometrically by scanning the molecular ion 5–10 times at 10 eV. The average intensities were analyzed by standard procedures by computer. Control experiments established that the deuterium content was not altered during the quench-extraction and the mass spectrometric analysis. The *exo* and *endo* rate constants were obtained by monitoring the appearance of d_1 and d_2 species, respectively. For example, the *endo* rate constant for 4,6,6-trimethyl-2-norbornanone (**3**) was obtained by beginning with **3** and following accumulation of d_2 species. With respect to the half-life for *endo* exchange, the period required for build-up of maximum d_1 concentration (≃90%) was considered to be negligible. As a representative example, data for an *endo* exchange of **3**, at a base concentration of 0.104 *N*, is shown below. The plot of ln f_2 vs. time is given in Fig. 1*b*.

Time (h)	$\%d_0$	$\%d_1$	$\%d_2$	ln f_2
0	100.0	0	0	0.000
10	2.4	87.1	10.6	0.113
24	2.1	73.5	24.4	0.286
50	1.3	54.2	44.5	0.603
87	2.0	35.7	62.4	1.009
119	1.3	26.2	72.5	1.340

The pseudo-first-order rate constants were obtained from a plot of ln $f_{(n)}$ (n = 1, 2) vs. time or from a plot of ln $\%d_n$ (n = 0, 1) vs. time for the decay of the appropriate species and

$$f_1 = \frac{100 - \%d_{0(\infty)}}{100 - \%d_{0(\infty)} - \%d_{1(t)}}$$

$$f_2 = \frac{100 - \%d_{0(\infty)}}{100 - \%d_{0(\infty)} - \%d_{2(t)}}$$

the second-order rate constants were obtained by dividing the slope by the base concentrations. Usually the differences between the rate constants obtained by both methods were < 10%. For example, for exchange of **3** from ln f_1 and ln f_2 plots, the *exo* and *endo* rate constants are 9.88 × 10^{-3} M^{-1} s^{-1} (average of 9.82 × 10^{-3} (see Fig. 1*a*) and 9.91 × 10^{-3}) and 2.81 × 10^{-5} M^{-1} s^{-1} (average of 2.59 × 10^{-5} (see Fig. 1*b*) and 3.02 × 10^{-5}), respectively. From the plots of ln $\%d_0$ and ln $\%d_1$ vs. time, the *exo* and *endo* rate constants are 8.39 × 10^{-3} (average of 8.22 and 8.55 × 10^{-3}) and 2.77 × 10^{-5} (average of 2.57 and 2.96 × 10^{-5}). The rate constants for ketones **1** → **7** were obtained by the first method and are listed in Table 1.

(*b*) *For Chloroketones* ***8*** *and* ***9***

The 0.1515 *N* NaOD stock solution was obtained as described above. The 0.0606 *N* NaOH stock solution was prepared by appropriate dilution of a 1 *N* BDH Chemicals concentrated volumetric solution with distilled water. The solutions were standardized against 0.100 *N* HCl using phenolphthalein as the indicator. The exchange rates for **8** and **8**-*d*, in nondeuterated and deuterated media, were obtained by following the rate of isomerization of **8** to **9** gas chromatographically up to 40% conversion. That there is a very minor amount of isomerization of **9**-*d* to **8**-*d* during the course of a kinetic run (up to 40% isomerization) was established when an aliquot (34.5% **9**-*d*, 65.5% **8**) was separated into its components by preparative vpc and each isomer was analyzed for deuterium content by mass spectrometry. While the *endo*-chloroketone **9**-*d* was fully deuterated, the *exo*-chloroketone contained 0.025 excess atoms of deuterium. Typically, 0.030 g of ketone, > 99% pure, purified by gas chromatography, was weighed into a 1 ml volumetric flask that was previously flushed with argon for several minutes. Before the start of a run, the volumetric flasks, the stock NaOD or NaOH solution, and the purified dioxane were equilibrated in the constant temperature bath for at least 1 h at 30.0 ± 0.05°C. Dioxane (0.60 ml) was quickly transferred to the volumetric flask and the solution was equilibrated for at least 15 min. Stock NaOD or NaOH solution (0.40 ml) was quickly added and the flask was stoppered with a serum cap. During the course of a run, five or six aliquots (0.05 ml) were removed with a syringe and each was quenched in a vial which contained 0.2 ml of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

K_2HPO_4 buffer of p*H* 6.5 and 0.5 ml of ether. The resulting solution was 'extracted' by repeatedly drawing in and vigorously forcing out the solution from a rubber-bulb-capped 9-in. Pasteur capillary glass pipette. The ether layer was dried and analyzed gas chromatographically on a Model 560 Tracor gas chromatograph equipped with flame ionization detectors and fitted with 6 ft × 4 mm id 3% OV-1 on Chromosorb W columns. Analysis of a mixture of known amounts of **8** and **9** showed that the flame ionization detector response to both chloroketones was the same.

Temperature programming from 100 to 140°C at 8 deg per minute was utilized and the data were collected on a Varian Model 485 electronic integrator. The percentage of **8** and **8**-*d* was taken as the average of two injections, and the average deviation generally was < 1%. The data, as plots of ln %**8** or ln %**8**-*d*, were analyzed by computer and the correlation coefficients generally exceeded 0.996. The rate constants reported are an average of at least two determinations. The average deviations generally were < 5%. See Fig. 2 for the pseudo-first-order plot for enolization of **8**. Although no other products were detected by gas chromatography during the course of the kinetic runs (15 min for **8** and 70 min for **8**-*d*) there was obtained, after 24 h, in approximately equal amounts, < 10% of two products of much longer retention time.

Because the rate of exchange of *endo*-3-chloro-2-norbornanone was too fast to be measured at the usual $^-$OD concentrations, a $NaDCO_3$–NaOD–D_2O buffer solution was required. However, since it could not be assumed that the measured p*D* of the reaction solution (60% dioxane – 40% buffer) was indeed the correct value, the *exo* exchange rate for 2-norbornanone (**1**) was run in the same buffer solution. Pure **9** (> 99%) was obtained, by preparative gas chromatography on a 5 ft × ¼ in. 10% Carbowax-on-Chromosorb-W column maintained at 140°C, from a mixture of **8** (35%) and **9** (65%) that was obtained from a large scale equilibration of **8**. A solution, of p*D* 10.37, of 60% dioxane and 40% $NaDCO_3$–NaOD–D_2O buffer was prepared and equilibrated in the constant temperature bath. After 1 h, 1.00 ml of the solution was quickly added to 0.020 g of **9** in a stoppered 1-ml volumetric flask. During the course of the kinetic run (4–5 min) aliquots (0.1 ml) were quenched with K_2HPO_4 buffer of p*H* 6.5 and extracted with ether (2 ml). The ether aliquots were dried and concentrated, and the deuterium content was determined mass spectrometrically at 10 eV as was previously described in the Experimental. The pseudo-first-order rate constants were obtained by computer from plots of ln $\%d_0$ vs. time. Correlation coefficients exceeding 0.997 were obtained. The pseudo-first-order rate constant for *exo* exchange in **1** at 30°C in a 60% dioxane – 40% buffer solution of p*D* 10.37, was 9.97×10^{-7} s^{-1}. Since the second-order rate constant for *exo* exchange in **1** at 30°C is 5.85×10^{-2} M^{-1} s^{-1}, division of the pseudo-first-order rate constant (3.20×10^{-3} s^{-1}; average of 3.02 (see Fig. 3) and 3.37×10^{-3} s^{-1}) for exchange of **9** by 1.70×10^{-5} establishes the second-order rate constant as 1.88×10^{2} M^{-1} s^{-1}.

*Determination of K_{eq} for Chloroketones **8** and **9***

The value of K_{eq} for **8** and **9** was determined by analysis of the remaining solution of the kinetic runs in deuterated and nondeuterated media. After at least 24 h, in each case, the solution (0.2 ml) was quenched in K_2HPO_4 buffer (0.4 ml), and extracted with ether. The dried ether extracts were analyzed by gas chromatography as was described previously in this Experimental. Repeated analyses gave $K_{eq} = [\mathbf{8}]/[\mathbf{9}] = 0.54$ with an average deviation of < 5%.

Base-catalyzed enolization of 2,5-norbornanediones. Evidence for homoenolic assistance[1]

NICK HENRY WERSTIUK, ROLAND TAILLEFER, AND SUJIT BANERJEE
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 21, 1977

NICK HENRY WERSTIUK, ROLAND TAILLEFER, and SUJIT BANERJEE. Can. J. Chem. **56**, 1148 (1978).

The rate enhancements relative to the monoketones, for base-catalyzed *exo* and *endo* hydrogen isotope exchange in 2,5-norbornanedione (**2**), 3,3-dimethyl-2,5-norbornanedione (**3**), and 1,3,3-trimethyl-2,5-norbornanedione (**4**) have been determined at 25 ± 0.05°C in 60% dioxane – 40% D_2O. After the increase in rate due to the inductive and strain effects of the second carbonyl group is taken into account, the homoenolic-assistance factors are extracted from the overall rate enhancements: for *exo* exchange in **2**, **3**, and **4**, the factors are 13, 39, and 32; for *endo* exchange in **2**, **3**, and **4**, the factors are 26, 64, and 71, respectively.

NICK HENRY WERSTIUK, ROLAND TAILLEFER et SUJIT BANERJEE. Can. J. Chem. **56**, 1148 (1978).

Travaillant à 25 ± 0.05°C dans un mélange contenant 60% de dioxanne et 40% de D_2O, on a déterminé les augmentations de vitesse, relatives au monocétonés, pour les échanges isotopiques d'hydrogènes *exo* et *endo* catalysés par les bases dans la norbornanedione-2,5 (**2**), la diméthyl-3,3 norbornanedione-2,5 (**3**) et la triméthyl-1,3,3 norbornanedione-2,5 (**4**). Après avoir déduit de ces augmentations globales de vitesse les augmentations spécifiques dues aux effets inductifs et stériques du second groupement carbonyle, on peut déduire les facteurs provenant de l'aide homoénolique: pour l'échange *exo* dans **2**, **3** et **4** les facteurs sont respectivement 13, 39 et 32; pour l'échange *endo* dans **2**, **3** et **4**, les facteurs sont 26, 64 et 71.

[Traduit par le journal]

Introduction

As a continuation of our studies (1–4) designed to detail the intricacies of acid- and base-catalyzed enolization, and hydrogen isotope exchange of ketones, we have studied the base-catalyzed hydrogen isotope exchange of 2,5-norbornanedione (**2**), 3,3-dimethyl-2,5-norbornanedione (**3**), and 1,3,3-trimethyl-2,5-norbornanedione (**4**). Specifically, we were interested in establishing whether or not a carbonyl group situated 1,3 from an enolizable site enhances the rate of enolization through homoenolic delocalization (5–10) of the developing negative charge. We chose to study the 2,5-norbornanediones **2**, **3**, and **4** for the following reasons: the compounds are readily available; the required orientation of the carbonyl groups is present; our concomitant studies (4) on the base-catalyzed enolization exchange of 2-norbornanones allowed us to estimate the magnitude of the inductive and strain components of the rate acceleration; and, the results could be compared with the mechanistic details already established for the homoenolization of 2-norbornanones (5–10). Herein, we describe the kinetic methods that were used to determine the rate accelerations and establish the homoenolic-assistance factors for abstraction of the *exo* and *endo* protons in diones **2**, **3**, and **4**.

[1]For a preliminary account, see ref. 1.

Results

Kinetic Methods

Endo *Exchange*

To obtain the *endo* exchange rates for **2**, **3**, and **4**, we used a procedure similar to the one described in the preceding paper (4). However, several modifications were made for two reasons: during the initial stages of the study, exchange of the deuterated diones **2** and **4** occurred in the mass spectrometer inlet system; and, a rate falloff was observed during the course of the kinetic runs.

To overcome the first problem, the deuterated diones **2** and **4** were isolated from the aliquots and reduced by $LiAlH_4$ to the diols which were converted to the corresponding diacetates. Since each diacetate exhibited a molecular ion of low intensity even at 10 eV, the deuterium content was established from an analysis of the $M^+ - CH_3CO$ peaks. To establish that the deuterium content obtained by analysis of a diacetate was equivalent, within experimental error, to the value obtained by analysis of the parent dione, a control experiment was carried out (see Experimental) using **3** that did not show significant exchange in the inlet system.

The rate[2] falloff, due to a decrease in base concen-

[2]The pseudo-first-order rate constants were obtainable from plots of ln $\%d_n$ (n = 0, 1, 2,...) vs. time or from plots of ln

tration with time, was most pronounced for 2,5-norbornanedione (**2**) and is illustrated in Fig. 1 as a plot of ln f_3 vs. time. The percentage change in the base concentrations was established by titrating the base in aliquots obtained from a control run for each dione: for dione **2** there was a 16–18% decrease in the base concentration during the kinetic run; for both diones **3** and **4**, a decrease of 8–11% was observed. The observed d_2 (diones **3** and **4**) and $d_3 + d_4$ (dione **2**) abundances, whose appearances were followed to obtain the rate constants, were corrected for the decrease in base concentration as we have described in the Experimental. Figure 2 illustrates the plot of ln f_3 (corrected) vs. time for *endo* exchange in **2**. In Tables 1 and 2 are listed the second-order rate constants and the rate enhancements, respectively. Although the reason for the consumption of the base has not been established, that no significant rate falloff is observed with the monoketones (4) indicates that the reactivity[3] of the 2,5-diones is a contributing factor. Possibly, the base is consumed in an autoxidation reaction (11).

2	46.1	3.54×10^{-2}	1300
3	57.3	3.89×10^{-2}	1470
4	28.1	4.57×10^{-2}	610

*Averages of at least two determinations with an average deviation of less than 10%.
†Rounded to the nearest 10.

Exo *Exchange*

Because *exo* exchange in **2**, **3**, and **4** is very fast, a $NaDCO_3$–NaOD–D_2O buffer was used as the catalyst to facilitate the measurement of rate constants. Since the p*D* of the 60% dioxane – 40% buffer medium could not be assumed to accurately represent the $^-$OD concentration, the pseudo-first-order rate constants for *exo* exchange in **2**, **3**, **4**, and 2-norbornanone (**1**) were determined in the dioxane–buffer

f_n (n = 1, 2, 3) vs. time. In the latter method, account is taken of the fact that complete deuteration is not achieved due to dilution of the deuterium pool. In the preceding paper (4) we established that the analysis of exchange data by both methods yielded rate constants which differ by 10% or less and that the rate constants obtained from plots of ln f_n are greater than those obtained from plots of ln $\%d_n$.

$$f_1 = \frac{100 - d_{0(\infty)}}{100 - d_{0(\infty)} - d_1}$$

$$f_2 = \frac{100 - d_{0(\infty)}}{100 - d_{0(\infty)} - d_2}$$

$$f_3 = \frac{100 - \frac{1}{2}(d_{0(\infty)} - d_{1(\infty)})}{100 - \frac{1}{2}(d_{0(\infty)} + d_{1(\infty)}) - (d_3 + d_4)}$$

[3]The diones, especially **2**, are much less stable than the parent monoketones. A purified crystalline sample of **2**, left at ambient temperature, is gradually converted into a yellow, oily solid.

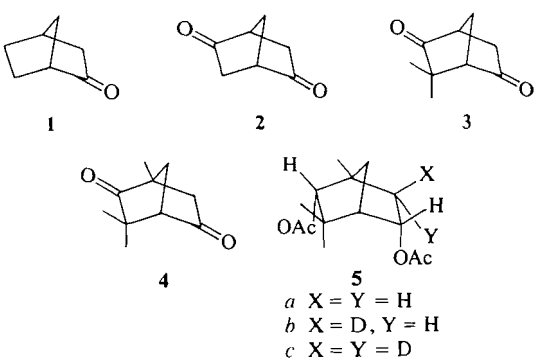
*Relative to the rate for the corresponding protons in the monoketones 2-norbornanone ($k_x = 3.85 \times 10^{-2}$, $k_n = 5.90 \times 10^{-5}$), 6,6-dimethyl-2-norbornanone ($k_x = 1.64 \times 10^{-2}$, $k_n = 2.62 \times 10^{-5}$), 4,6,6-trimethyl-2-norbornanone ($k_x = 9.88 \times 10^{-3}$, $k_n = 2.81 \times 10^{-5}$) ($k$ values in M^{-1} s^{-1}) (4).
†Rounded to the nearest 10.

medium. As representative examples, the first-order plots for *exo* exchange in **1** and **4** in 60% dioxane – 40% buffer (pD 10.84) are given in Figs. 3 and 4, respectively. Since we previously established the second-order rate constant for *exo* exchange in **1**, the second-order rate constants for *exo* exchange are obtained from the following relationship.

$$k_{\text{dione}}(M^{-1}s^{-1}) = \frac{k_{\mathbf{1}}(M^{-1}s^{-1})}{k_{\mathbf{1}}(s^{-1})} k_{\text{dione}}(s^{-1})$$

The rate constants, and the rate enhancements relative to the monoketones, are given in Tables 1 and 2, respectively.

We previously estimated (1) the rate constant for *exo* exchange in **4**, as 2.0 M^{-1} s^{-1}, by considering the extent of $d_0 \rightarrow d_1$ conversion after 1–4 min in three *endo* exchange runs, estimating $t_{\frac{1}{2}}$, using the expression $t_{\frac{1}{2}} = \ln 2/k$, and dividing k by the initial base concentration. That the experimentally determined value is 28.1 M^{-1} s^{-1}, obviates the inaccurate estimate, which stemmed from the fact that *exo* exchange is essentially complete (see Experimental for the data for *endo* exchange in **3**) before the first *endo* exchange aliquot is removed. Consequently, the estimate of $t_{\frac{1}{2}}$ from the percentage of d_0 species remaining (2–5%) is subject to the large error associated with recording and measuring low intensity mass spectral peaks.



Stereochemistry of Exchange

That abstraction of the *exo*-C(3) hydrogen in 2-norbornanones is preferred over *endo* hydrogen abstraction is well documented (12, 13). To establish that *exo* exchange is also preferred in the diones, we analyzed the 60 MHz nmr spectra of *endo*-2-*endo*-5-diethanoyloxy-1,3,3-trimethylnorbornane (**5***a*), *endo*-2-*endo*-5-diethanoyloxy-1,3,3-trimethylnorbornane-*exo*-6-*d* (**5***b*), and *endo*-2-*endo*-5-diethanoyloxy-1,3,3-trimethylnorbornane-*exo*-6-*endo*-6-d_2 (**5***c*). The partial spectrum of **5***a*, illustrated in Fig. 5*a*, exhibits the *exo*-C(2)-H signal at δ 4.40 (J = 1.3 Hz), and the *exo*-C(5)-H signal as a heptet centered at δ 4.96 with a signal width at half-height of approximately 22 Hz. Dione **4** was monodeuterated and **4**-d_1 was converted into diacetate **5***b*-d_1. Its partial nmr spectrum, illustrated in Fig. 5*b*, shows the *exo*-C(2)-H signal collapsed to a sharp singlet by loss of the W- coupling,

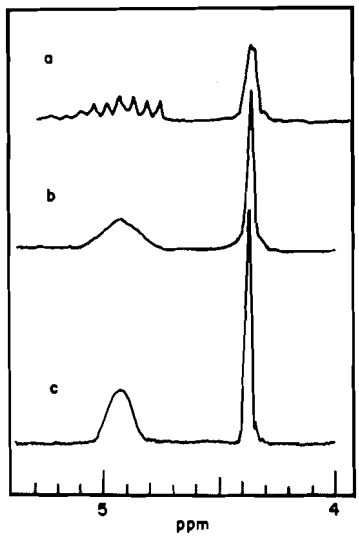

FIG. 5. Partial 60 MHz (CCl_4) spectrum of (*a*) **5***a*; (*b*) **5***b*; and (*c*) **5***c*.

a consequence of the replacement of the *exo*-C(6) proton with deuterium. That the *exo*-C(5)-H signal collapses to a broad peak with a width at half-height of 11 Hz is consistent with the loss of a single coupling in the order of 10–11 Hz, which is expected for removal of an *exo–exo cis* coupling constant (13–15). In the dideuterated diacetate **5***c* (Fig. 5*c*) there is a further sharpening of the *exo*-C(5)-H signal to a width at half-height of 8.5 Hz. This result is consistent with the removal of a 2.5 Hz coupling, which is expected for the loss of a vicinal *exo–endo trans* coupling in the [2.2.1] system (14, 15). Clearly, as in the case of the monoketones, *exo* exchange is preferred.

Discussion

Analysis of Rate Acceleration Data

Before the isotope exchange rates are interpreted, a potentially complicating factor must be considered. In the recent studies (2–4) which support our contention that enolization and isotope exchange of ketones are not simple processes, we demonstrated that exchange of the *endo* hydrogen in 2-norbornanone occurs via two channels: by direct abstraction and by isomerization of first-formed 2-norbornanone-*exo*-3-d_1 to 2-norbornanone-*endo*-3-d_1 that is rapidly converted into 2-norbornanone-*exo*-*endo*-3,3-d_2. Thus, for **1**, the intrinsic selectivity s is 17% larger than the $k_x:k_n$ rate ratio, and $k_{n(obs)} \simeq 1.2\ k_{n(intrinsic)}$ (2–4). Exchange of the *endo* hydrogen in the diones **2**, **3**, and **4** must occur via two channels, also, and the difference between $k_{n(obs)}$ and $k_{n(intrinsic)}$ in each case is expected to be very similar to the difference observed for **1**. Thus the effect of the dual-channel exchange of the *endo* hydrogen is minimized when relative rates for *endo* exchange (Table 2) are considered.

TABLE 3. Homoenolic-assistance factors*

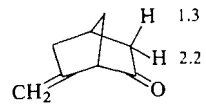
Substrate	*Exo*	*Endo*
2	7	26
3	20	64
4	16	71

*Rounded to the nearest unit.

To establish whether or not the *exo* and *endo* deprotonation rates in **2**, **3**, and **4** are enhanced by homoenolic delocalization of the developing negative charge, we estimated the rate acceleration owing to the inductive and strain effects of the carbonyl group and extracted the homoenolic-assistance factors (Table 3) from the observed rate enhancements.

That the *s* character of a C—H bond in a strained system can control its kinetic acidity, has been established by Streitwieser and co-workers (16), who determined the relative kinetic acidities of the hydrocarbons, cyclohexane (1.00), cyclopentane (5.7), cyclobutane (28.0), and cyclopropane (7.0×10^4).

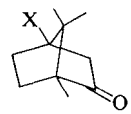
The increase in strain in diones **2**, **3**, and **4** resulting from the introduction of the second sp^2 centre could enhance the kinetic acidity of the C—H bonds at C(3). We previously established (4) that the rate enhancements, relative to **1**, for *exo* and *endo* exchange in enone **6** are 1.3 and 2.2, respectively. Since



6

the strain in **6** is expected to resemble that in a 2,5-dione system, the increase in rate due to incorporation of the strain-inducing π system, taken as an average of the *exo* and *endo* rate acceleration, is 1.75.

To estimate the rate acceleration due to the inductive effect of the carbonyl group, we correlated Casadevall's rate constants for *endo* exchange (2:1 dioxane–D_2O) in the 4-substituted camphors **7***a*–**7***e*



7

a X = H *d* X = Br
b X = CH_3 *e* X = NO_2
c X = Cl *f* X = $C(=O)CH_3$

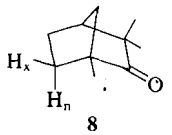
(17) with σ_I and established that ρ for the process is 4.0. Thus, the *endo* exchange rate for 4-acetylcamphor

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(7*f*) (X = —C(=O)—CH_3, σ_I = 0.28), is estimated to be 13 times the *endo* rate in camphor. Since the *endo* exchange rates for 2-norbornanone (5.90×10^{-5} M^{-1} s^{-1} at 30°C) and camphor (2.55×10^{-5} M^{-1} s^{-1} at 15°C) are nearly identical and should exhibit the same sensitivity to electronic effects, we estimate the *endo* rate constant for 4-acetyl-2-norbornanone to be 7.67×10^{-4} $M^{-1}s^{-1}$. In the preceding publication (4) we established, from a study of a series of 2-norbornanones, that *exo* deprotonation is more sensitive to electronic effects than the *endo* process and we quantified the difference in the form of a linear free energy relationship that is expressed in [1]. From

$$\log k_x = 1.67 \log k_n + 5.80 \quad [1]$$

[1] we estimate the *exo* exchange rate for 4-acetyl-2-norbornanone to be 4.0 M^{-1} s^{-1} and the rate enhancement, relative to *exo* exchange in **1**, is in the region 100.[4] If the C(4)-acetyl group, in which the carbonyl group is situated 1,3 with respect to enolizable hydrogens, approximates the inductive effect



8

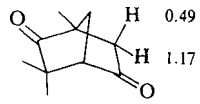
of the carbonyl group in the 2,5-diones, the enhancements for *exo* and *endo* exchange, as a combination of the inductive and strain compounds, are 175 and 73, respectively. Thus, the rate enhancements due to homoenolic assistance (Table 3) are obtained from the data in Table 2. That the more difficult *endo* proton transfer is assisted to a greater degree by 1,3 conjugation to the carbonyl group than the *exo* process, is consistent with the hypothesis we presented in the preceding paper re: enolic abstraction. That is, the more difficult *endo* proton transfer at C(3) in 2-norbornanone is assisted to a greater degree by 1,2 conjugation to the carbonyl group than the *exo* process. The *exo* rate in the 2,5-diones, nevertheless, is enhanced to a greater degree (Table 2) than the *endo* rate because the *exo* proton transfer is more sensitive to electronic effects (*vide supra*) than the *endo* process.

In this connection, it is important to note that Stothers (10) has established that the *exo*:*endo* rate ratio for K^+OtBu-catalyzed (185°C) β-enolization at C(6) (homoenolization) in fenchone (8) is 3.5.

We would like to suggest that 1,3 charge transfer from C(6) to the carbonyl group in β-enolization (homoenolization) is greater for *endo* deprotonation than for the *exo* process. Nevertheless, *exo* deprotonation is favoured for two reasons: the inductive effect of the carbonyl group preferentially lowers the activation energy for the *exo* process (*vide supra*) and the *exo* face in the [2.2.1] skeleton, unsubstituted at C(7), is less hindered sterically than the *exo* face.

Effect of a Bridgehead Methyl Group

The rates of *exo* and *endo* deprotonation in **4**, rela-



4

tive to the *exo* and *endo* rates in **3**, are given below. That there is a small decrease in the *exo* rate upon replacement of the hydrogen at C(4) by a methyl group is consistent with the results of our study on 2-norbornanones (4): the difference in torsional strain between *exo*-C(3)-H, C(4)-H and *exo*-C(3)-H, C(4)-CH_3 is minimal and a methyl group, or a group of equivalent size, does not sterically hinder *exo* deprotonation.

Experimental

2-Norbornanone (**1**) was obtained from Aldrich Chemical Company. 1,3,3-Trimethyl-2,5-norbornanedione (**4**) was prepared from 1,3,3-trimethyl-2-norbornanone (**3**) by the method of Bays *et al.* (19). 3,3-Dimethyl-2,5-norbornanedione and 2,5-norbornanedione (**2**) were prepared from 3,3-dimethyl-2-norbornanone (20) and nortricyclanone (21), respectively. The substrates **1**, **2**, **3**, and **4** were purified by preparative glpc before each kinetic run.

Kinetic Methods

Purified dioxane and stock NaOD solutions were prepared as described in the preceding paper (4).

Endo *Exchange*

The kinetic method used was essentially the one described in the preceding paper. The exchange solutions, maintained at 25.0 ± 0.05°C, were 0.20–0.25 *M* in ketone and 0.009–0.025 *M* in NaOD. Aliquots of a 2.0 ml exchange solutions contained in a serum cap-stoppered 2-ml volumetric were withdrawn and quenched in deuterated K_2DPO_4 buffer (1.5 ml). The aqueous phase was saturated with NaCl, extracted with ether (3 × 5 ml), and the combined ether extracts were dried. The solvent was distilled through a 1-ft Vigreux column and the dione was isolated by preparative glpc (5 ft × ¼ in. 20% SE-30 on Chromosorb W). A control experiment with **4** and the deuterated

[4]In an alternate approach we utilize the fact that the *exo* exchange rate for *exo*-5-ethoxy-2-norbornanone in 2:1 dioxane–D_2O, as established by Professor Tidwell (T. T. Tidwell, personal communication) is greater than the *exo* rate in 2-norbornanone by a factor of 1.8. From the σ_I for CH_3O—(0.26) we estimate σ_I for CH_3CH_2O—CHR— to be in the region of 0.10 by dividing 0.26 by the CH_2— insulating factor of 2.5. However, in our case the insulating group is CHR and we expect that σ_I for CH_3CH_2O—CHR— lies in the range 0.05–0.10. Thus ρ for *exo* exchange lies in the range 2.6–5.2. When the acetyl group (σ_I = 0.28) is used as a model, the rate acceleration due to the inductive effect of the carbonyl group is in the range of 5–28.

For personal use only.

buffer K_2DPO_4 showed that there was no significant (<2%) exchange during the quench.

Since, in the initial stages of the study, exchange of diones **2** and **4** was observed in the mass spectrometer inlet system, the deuterium analyses were carried out on the corresponding diacetates.

The diol (0.020–0.030 g) obtained from $LiAlH_4$ reduction of the dione was dissolved in acetic anhydride (1.5 ml) and pyridine (2.5 ml). After the mixture was left standing at ambient temperature for 24 h, it was poured onto ice, diluted to 80 ml, and extracted with ether (3 × 25 ml). The combined ether extracts were washed with dilute hydrochloric acid (25 ml), saturated sodium carbonate solution (25 ml), water (25 ml), and finally with a saturated sodium chloride solution (25 ml). After the ether layer was dried and concentrated on the rotatory evaporator, the diacetate was isolated by preparative glpc on a 5 ft × ¼ in. 20% SE-30 on Chromosorb W column. To check that there was no deuterium exchange during the reduction, dione **4** was reduced by $LiAlD_4$ in ether. That there was no experimentally significant (<1%) amount of d_3 species present, established that the reduction proceeds without exchange. Due to the very low relative intensity of the molecular ion of the diacetate derived from **2** and **4**, the $M^+ - CH_3CO$ peaks were used in the deuterium analyses. That the analysis of the diacetate, at low voltage, gives the deuterium content accurately, was established by means of a control experiment on dione **3** that itself did not show significant isotope exchange in the mass spectrometer inlet system. The control experiment involved conversion of the monodeuterated dione to the diacetate: dione **3**, 4.1% d_0, 91.3% d_1, 4.6% d_2; diacetate, 4.5% d_0, 83.7% d_1, and 5.3% d_2.

Correction for Change in Base Concentration

To quantify the change in base concentration during the course of a kinetic run for each ketone, exchange solutions were prepared and 1.0-ml aliquots were titrated with standard 0.100 or 0.010 *N* HCl. For diones **3** and **4** there was an 8–11% change in base concentration during the kinetic runs and for **2** a 16–18% change was observed. In the absence of the diketone the decrease in base concentration was less than 5% during the same interval. The observed abundances were 'corrected' for the decrease in base concentration utilizing the following equation: corrected $\%d_n$ (n = 2, 3 + 4) = observed $\%d_n$ (n = 2, 3 + 4)(100 + % change in base concentration)/100. As an example, the data for *endo* exchange in **3** are given below:

[**3**] = 0.267 *M*, [NaOD] = 0.0114 *M*, $d_{0(\infty)}$ = 1.5%

Time (min)	$\%d_0$	$\%d_1$	$\%d_2$	% change [base]	$\%d_2$ (corr)	ln f_2 Observed	ln f_2 Corrected
0.75	5.4	92.3	2.3	0.4	2.3	0.024	0.024
10.2	3.4	73.5	23.1	2.1	23.6	0.067	0.286
20.0	2.9	58.4	38.7	3.7	40.0	0.499	0.526
30.0	1.7	46.9	51.4	5.7	54.3	0.738	0.801
45.0	1.5	33.9	64.6	8.5	70.1	1.067	1.244
60.0	1.4	26.2	72.3	11.3	80.5	1.324	1.697

Analysis by computer of the data for **3** and **4** as plots of ln f_2 (corrected) vs. time[2] gave the corrected pseudo-first-order rate constants. In the case of **2** the *endo* rate constant was obtained from a plot of ln f_3 (corrected) vs. time.[2] The data for exchange of **2** are given below: [**2**] = 0.204 *M*, [NaOD] = 0.0127 *M*, $d_{0(\infty)}$ = 3.1%, $d_{1(\infty)}$ = 5.7%.

Time (min)	$\%d_0$	$\%d_1$	$\%d_2$	$\%d_3$	$\%d_4$	% change [base]	$\%(d_3 + d_4)$ (corr)	ln f_3 Observed	ln f_3 Corrected
1.0	3.7	5.1	86.0	5.3	0	0.5	5.4	0.057	0.058
4.0	2.9	5.1	72.1	18.6	1.2	3.2	20.4	0.232	0.240
8.0	3.6	5.8	57.6	29.4	3.6	6.6	35.2	0.423	0.458
15.0	2.9	5.0	42.9	39.6	9.1	12.6	54.7	0.712	0.850
22.0	3.0	6.2	33.2	43.2	14.4	18.4	68.2	0.923	1.215

The first-order plots of ln f_3 and ln f_3 (corrected) vs. time are given in Figs. 1 and 2, respectively. Correlation coefficients ≥0.996 were obtained for the plots. The second-order rate constants were obtained by dividing the corrected pseudo-first-order constants by the initial base concentration, and are listed in Table 1.

Exo *Exchange*

The data for *exo* exchange in **2**, **3**, and **4** were obtained by adding the solid ketone (0.020–0.035 g) to 2.0 ml of a solution composed of 60% dioxane and 40% $NaDCO_3$–NaOD buffer (p*D* 10.84) which had been equilibrated in the constant temperature bath. The vial was shaken and aliquots were removed with a rubber-capped 9-in. Pasteur glass pipette and quenched in K_2HPO_4 buffer (1 ml, p*H* 6.5) – ether (2 ml). The aqueous solution was extracted using the pipette by rapidly drawing in and expelling the total solution five or six times. The ether layer was dried, concentrated on the rotatory evaporator, and the concentrate was introduced into the mass spectrometer. The pseudo-first-order rate constants were obtained by computer analysis of the d_0 decay. A representative first-order plot for *exo* exchange in dione **4** is given in Fig. 3. The correlation coefficients were ≥0.996. The first-order plot for *exo* exchange in **1** in the same medium is given in Fig. 4. Since the pseudo-first-order rate constant for *exo* exchange in **1** in the dioxane–buffer medium is 2.15×10^{-6} s^{-1} (average of two determina-

tions 2.09×10^{-6} s^{-1} and 2.21×10^{-6} s^{-1} (see Fig. 4)) and the second-order rate constant is 3.85×10^{-2} M^{-1} s^{-1}, the effective [$^{-}$OD] is established as 5.58×10^{-5}. Division of the pseudo-first-order rate constants, 2.57×10^{-3}, 3.20×10^{-3}, and 1.57×10^{-3} s^{-1} (average of at least two determinations, average deviation $<10\%$) for **2**, **3**, and **4** by 5.58×10^{-5} establishes the second-order rate constants for **2**, **3**, and **4**, as 46.1, 57.3, and 28.1 M^{-1} s^{-1}, respectively.

Resonances in the ^{13}C nmr spectra of nonylprodiginine, cyclononylprodiginine, methylcyclodecylprodiginine, and butylcycloheptylprodiginine were assigned using information from the literature, from high resolution spectra and double irradiation experiments, and from ^{13}C–^{15}N couplings observed in samples of nonylprodiginine enriched with ^{15}N. Supplementation of cultures with sodium [1-^{13}C]- and [1,2-^{13}C]acetate gave ^{13}C-enriched prodiginines and the labeling patterns were established from ^{13}C nmr spectra. These indicated that rings A and B were formed in a similar manner to rings A and B in prodigiosin and other prodiginine pigments. Ring C and the C2-alkyl substituent were derived in part from acetate units that were condensed in a linear 12- or 14-carbon chain. The same pattern of acetate assembly has been found in all actinomycete prodiginines examined.

NANCY N. GERBER, A. GAVIN MCINNES, DONALD G. SMITH, JOHN A. WALTER, JEFFREY L. C. WRIGHT et LEO C. VINING. Can. J. Chem. **56**, 1155 (1978).

Utilisant des informations provenant de la littérature, des spectres à haute résolution et des expériences d'irradiation double et faisant aussi appel aux couplages ^{13}C–^{15}N observés dans des échantillons de nonylprodiginine enrichies en ^{15}N, on a fait l'attribution des résonances dans le spectre rmn du ^{13}C de la nonylprodiginine, de la cyclononylprodiginine, de la méthylcyclodécylprodiginine et de la butylcycloheptylprodiginine. L'addition de [1-^{13}C]- et de [1,2-^{13}C]-acétate de sodium au milieu de culture conduit à des prodiginines enrichies en ^{13}C et on a établi les distributions de marquages à l'aide des spectres rmn du ^{13}C. Celles-ci indiquent que les modes de formation des cycles A et B sont semblables à ceux des cycles A et B de la prodigiosine et d'autres pigments de la prodiginine. Par ailleurs le cycle C et les substituants alkyles en C2 proviennent en partie d'unités acétates qui se condensent en chaîne linéaire de 12 ou 14 atomes de carbone. On a trouvé la même distribution d'assemblement des acétates dans toutes les prodiginines d'actinomycène examinées.

Introduction

Pigments containing the prodiginine skeleton (**1**, $R_1 = R_2 = R_3 = R_4 = H$) are produced by a restricted group of eubacteria and actinomycetes (1). Although prodigiosin (**1**, $R_1 = CH_3$, $R_2 = (CH_2)_4$-CH_3, $R_3 = R_4 = H$), the main biochrome of *Serratia marcescens*, has a long and interesting history (2, 3), its correct chemical structure was deduced only in

[1]Issued as NRCC 16483.

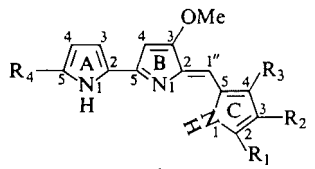
recent times (4). The formation of a similar class of bright-red pigments by species of *Streptomyces* was first recognized in 1947 (5) but their relationship to prodigiosin was not clarified until later (6–8). Other representatives of the prodiginine family have since been identified among the colored metabolites produced by *Actinomadura* species (9–12). A noteworthy feature of prodiginines from the actinomycetes is the pattern of alkyl substitution in ring C. Whereas prodigiosin and its congeners from eubacteria possess a methyl substituent at C(2) and differ from one another in the length of the alkyl chain attached to C(3) (1, 13), the actinomycete prodiginines are unsubstituted at C(3) but have an extended alkyl chain 9 or 11 carbons long at C(2). Nonylprodiginine (**1**, $R_1 = (CH_2)_8CH_3$, $R_2 = R_3 = R_4 = H$) has been found only in *Actinomadura* species while undecylprodiginine (**1**, $R_1 = (CH_2)_{10}CH_3$, $R_2 = R_3 = R_4 = H$) is present in *Streptomyces*, *Streptoverticillum*, and *Actinomadura* species (14).

Variation is introduced into the structure of actinomycete prodiginines by attachment of the alkyl chain at a second point to the prodiginine skeleton. A series of cycloprodiginines have been discovered, the first of which, metacycloprodigiosin (**1**, R_1R_3 = 1′,9′-cyclo$(CH_2)_8CHCH_2CH_3$, $R_2 = R_4 = H$), was isolated together with undecylprodiginine in *Streptomyces longisporus ruber* (15). *Streptomyces* and *Streptoverticillium* species also produce the related butylcycloheptylprodiginine (**1**, R_1R_3 = 1′,7′-cyclo$(CH_2)_6$-



1

$CH(CH_2)_3CH_3$, $R_2 = R_4 = H$), which has hitherto been incorrectly identified as a 2,3-cycloalkyl derivative (1, 14, 16, 17). Neither of these compounds has been observed in *Actinomadura* species, which produce, instead, a series of cyclic derivatives with the alkyl chain attached at C(5) of ring A. These include cyclononylprodiginine (**1**, R_1R_4 = 1′,9′-cyclo$(CH_2)_9$, $R_2 = R_3 = H$) (10), methylcyclooctylprodiginine (**1**, R_1R_4 = 1′,8′-cyclo$(CH_2)_7CHCH_3$, $R_2 = R_3 = H$), ethylcyclononylprodiginine (**1**, R_1R_4 = 1′,9′-cyclo$(CH_2)_8CHCH_2CH_3$, $R_2 = R_3 = H$) (12), and methylcyclodecylprodiginine (**1**, R_1R_4 = 1′,10′-cyclo$(CH_2)_9CH\ CH_3$, $R_2 = R_3 = H$) (11). The latter two have also been found in a *Streptoverticillium* species (14).

Despite a long-standing interest in the biosynthesis of prodigiosin, progress in identifying the biogenetic precursors and their mode of assembly into the unusual pyrryldipyrrylmethene skeleton has been slow. Studies with precursors bearing radioisotope labels showed that proline, glycine, methionine, and acetate were efficiently incorporated into the structure (18) but satisfactory evidence of the labeling pattern was difficult to obtain by chemical dissection. Only with the use of ^{13}C-labeled precursors and development of ^{13}C nmr procedures to analyse their distribution in the metabolite has the biogenesis of prodigiosin been elucidated. Wasserman and his colleagues (19, 20) have shown that proline contributes ring A and carbon B5 of ring B, while acetate supplies carbons B3 and B4 of ring B, as well as C3, C4, C5, and the C3 alkyl substituent of ring C. The methene carbon originates with the hydroxymethyl group of serine, and the adjacent carbon B2 of ring B probably comes from C(2) of this amino acid since C(2) of glycine was a good precursor. In ring C carbon C2 and the adjacent methyl substituent were derived from alanine.

Subsequently Wasserman *et al.* (21) examined the biosynthesis of undecylprodiginine and metacycloprodigiosin in *Streptomyces longisporus ruber*. Whereas rings A and B and the methene carbon were derived from the same precursors as prodigiosin, ring C was formed differently. In the actinomycete pigments carbons C2, C3, C4, and the alkyl substituent came from acetate units, whereas C5 was derived from the methylene group of glycine. In each of the metabolites the incorporation of label from [1-^{13}C]- and [2-^{13}C]acetate suggested that a polyketide chain of 14 carbon atoms contributed to the formation of ring C and its attached alkyl substituent. We have examined the incorporation of singly and doubly ^{13}C-labeled acetate into additional actinomycete prodiginines to ascertain whether ring C was formed with similar participation from acetate units, and whether the acyl chain of representative cyclic and acyclic compounds was formed from acetate units assembled according to a common pattern. The distribution of ^{13}C labels in the prodiginines was determined by ^{13}C nmr spectrometry.

Assignment of Resonances

Assignment of resonances in the natural abundance ^{13}C nmr spectra was based on (*a*) comparison with the ^{13}C chemical shift data for three prodiginines and a number of related pyrrole derivatives reported by Cushley *et al.* (22), (*b*) multiplicities and spacings owing to ^{13}C–H coupling observed in high resolution (hr) spectra (long range couplings were resolved in spectra of cyclononylprodiginine and butylcycloheptylprodiginine only), and (*c*) satellites due to C–N coupling which appeared in proton noise decoupled (pnd) spectra of nonylprodiginine labeled with ^{15}N.

TABLE 1. ^{13}C Chemical shifts (δ_C TMS) and ^{13}C–H coupling constants ($^nJ_{CH}$ Hz, in parentheses) of prodiginines[a]

Carbon	NP[b]	CNP	MCDP	BCHP
A2	128.2[c]	127.4 (7.5, 7.5) (t)	127.3	128.8 (7, 7, 7) (dt)
A3	112.9	112.7 (169.4, 4.2) (dd)	112.8	112.0 (169.4, 4.5, 6.9) (ddd)

[a]Data for the free base in chloroform-*d*; abbreviations are NP = nonylprodiginine, CNP = cyclononylprodiginine, MCDP = methylcyclodecylprodiginine, BCHP = butylcycloheptylprodiginine.
[b]Chemical shifts for carbons 1′ through 9′ in the spectrum of the salt form in dimethylsulfoxide-d_6 were 27.7, 28.3,[d] 28.7,[d] 28.9,[d] 28.7,[d] 28.8, 31.4, 22.2, 14.0.
[c]Assignments may be reversed but were unambiguous in the salt form (A2, δ_C 121.8; C5, δ_C 126.4).
[d]These assignments are tentative only.

Data available on ^{13}C–H and ^{13}C–^{15}N couplings in pyrrole (23, 24) were useful in interpreting the splitting patterns and spacings observed in (*b*) and (*c*). A number of assignments were later confirmed by the direct and long range ^{13}C–^{13}C coupling apparent in spectra of material which had incorporated [1-^{13}C]- and [1,2-^{13}C]acetate. Spectra were obtained for both the free bases and the perchlorate salts. Because the chemical shift trends were similar to those observed by Cushley *et al.* (22), the spectral data for only the free bases are summarized in Table 1.

The ^{13}C signal at lowest field in the spectra of all the prodiginines was assigned to carbon B3, which would be strongly deshielded by the directly bonded methoxyl substituent. In the hr spectrum of cyclononylprodiginine this signal was present as a doublet of doublets of quartets, due to coupling with the B4, 1″, and OCH_3 protons but the corresponding multiplet was not resolved in the spectrum of butylcycloheptylprodiginine. Satellite signals ($^2J_{CN}$ = 5.9 Hz) accompanied this resonance in spectra of ^{15}N-labeled nonylprodigine, consistent with a location β to the pyrrole nitrogen. The signal for B4 appeared at highest field in the aromatic region for all compounds, and was also accompanied by satellites ($^2J_{CN} \approx 6$ Hz) when ^{15}N label was present. The resonances from B2 and B5 displayed a coupling to nitrogen ($J_{CN} \approx 14$ Hz) appropriate to carbons α to a pyrrole nitrogen and these carbons were also long range coupled ($^3J_{CH}$) to single protons by 8 and 5 Hz in cyclononylprodiginine and butylcycloheptylprodiginine. Furthermore, in the spectra of nonylprodigine and cyclononylprodiginine strongly enriched from [1-^{13}C]acetate the extent to which the B3 and B5 lines were resolved permitted a two-bond coupling of 11.0 Hz between these carbons to be observed. When these compounds were derived from doubly labeled acetate B3 and B4 were directly coupled, as were B5 and A2.

Assignments for the carbons in rings A and C in nonylprodiginine, based on those for undecylprodiginine (22), were confirmed by the directly bonded C–H couplings in hr spectra and the C–N satellites ($^1J_{CN}$) observed for the carbons α to nitrogen in the spectrum of the ^{15}N-enriched compound (A2, 14.4; A5, 14.4; C2, 13.5; C5, 13.5 Hz). Further support for the assignments came from the pnd spectrum of material derived from doubly labeled acetate, where direct ^{13}C–^{13}C coupling was observed between the adjacent carbons A4,A5 and C3,C4.

4*b*	BCHP[b]	$CH_3{}^{13}COOH$	41.3	23.5	10.2	4.1	1.5	0

[a]The theoretical values of $M+1$ and $M+2$ for the unenriched pigments are: NP, CNP, and MCOP: 26.4, 0.2; BCHP: 28.6, 0.2, respectively.
[b]These two samples were obtained from parallel cultures grown from the same inoculum. MCOP is methylcyclooctylprodiginine; other abbreviations are given in the footnote to Table 1.

The spectra of cyclononylprodiginine and methylcyclodecylprodiginine differed from that of nonylprodiginine mainly in the substantial deshielding of A5 ($\approx$15 ppm for the former and $\approx$20 ppm for the latter) by the alkyl chain. The splittings due to long range coupling in the hr spectrum of cyclononylprodiginine were of the size and multiplicity expected for the pyrrole nucleus (23) with allowance for the substitution patterns in the three rings. Also, in cyclononylprodiginine subsequent labeling experiments with doubly labeled acetate once again supported the assignment of the adjacent pairs A4,A5 and C3,C4.

The chemical shifts for the carbons in the prodiginine skeleton of butylcycloheptylprodiginine were similar in most respects to those reported by Cushley *et al.* for metacycloprodiginine (22), and assignments were supported by the long range couplings observed in the hr spectrum of the free base. Splitting patterns for the carbons in ring A were in agreement with the pyrrole nucleus having a substituent only at position 2. On the other hand, signals for ring C showed that only C3 was directly bonded to a proton, and this proton in turn was long range coupled to C5 by 7.5 Hz.

The signal for the olefinic methene bridge carbon (C-(1″)) was readily identified in each spectrum by the direct C–H coupling value which ranged from 153.2 to 162.2 Hz. In the free base and salt forms of nonylprodiginine, and the salt forms cyclononylprodiginine and methylcyclodecylprodiginine, this signal appeared in the range δ_C 115.9 to 116.6. However, in the free base form of the latter compounds the signal was shifted upfield to δ_C 114.2, and in both forms of butylcycloheptylprodiginine to about δ_C 113.

Adjacent labeling by [1,2-^{13}C]acetate and the labeling of alternate positions by [1-^{13}C]acetate, considered with expected chemical shift trends (25) and signal multiplicities in the hr and off-resonance decoupled spectra, permitted some of the resonances arising from the open or cyclized alkyl side chains of the prodiginines to be assigned (see footnotes to Tables 1 and 2).

Incorporation of Labeled Acetate

Conditions for optimum incorporation of ^{13}C-labeled precursors were developed using [$^2H_4$]acetic acid as the supplement and mass spectrometry for analysis. All of the prodiginines gave strong molecular ions, and a test of the analytical method in which three different samples of unenriched methylcyclodecylprodiginine were repeatedly examined at the highest feasible vacuum to minimize ion-molecule reactions gave average peak heights for $M+1$ of 28.4 $\pm$ 0.5, 28.2 $\pm$ 0.5, and 28.3 $\pm$ 0.9% relative to M. The theoretical value for $C_{25}H_{33}ON_3$ is 28.6%. The ratios of the peak heights of various enriched samples (Table 2) indicates that high incorporations were achieved. Experiments with actinomadurae showed that multiple additions of acetate to cultures gave no better incorporation than one addition after 2–3 days growth, when pigment was first observable. Optimum enrichments were obtained when the cultures were harvested 2 or 3 days after acetate addition, a time well before the maximum yield of pigments was reached. The mass spectral data for the prodiginine pigments in Table 2 showed two kinds of peak height distribution in the $M+1$ to $M+6$ range. All of the pigments labeled with [1-^{13}C]acetate or sodium [^{15}N]nitrate, and cyclononylprodiginine labeled with [$^2H_4$]acetic acid, showed a continuous decrease in peak height at increasing mass values. In contrast nonylprodiginine, methylcyclooctylprodiginine or butylcycloheptylprodiginine labeled by [$^2H_4$]-acetic acid gave an irregular pattern. Since the latter

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

pigments all have a methyl group which is probably derived from the 'starter' unit of a chain biosynthesized from acetate and polymalonate, it seems possible to detect this type of end methyl group by examining the mass spectrum of a pigment which has incorporated [$^2H_4$]acetic acid. This is useful for very minor components such as methylcyclooctylprodiginine, which could not be obtained in sufficient quantity for ^{13}C nmr.

The incorporation of ^{13}C atoms into prodiginines by cultures supplemented with sodium [1-^{13}C]acetate is shown in Table 3 and the results are summarized in Fig. 1. Enrichment of the carbon at B3 parallels the results obtained earlier with prodigiosin, undecylprodiginine and metacycloprodiginine (19–21). Substantial incorporation also occurred at carbon atom A5 of ring A. This can be understood in terms of the formation of ring A from proline via α-ketoglutarate, which is derived from acetate by reactions of the Krebs cycle. The ring-A incorporation is high compared with that reported for prodigiosin (20) but comparable to that obtained for undecylprodiginine and metacycloprodiginine where proline was also shown to be the progenitor of ring A and carbon B5 (21). Differences could be due to distinctive metabolic patterns for acetate in *S. marcescens* and the actinomycetes but it is more likely that they were caused by differences in the proline content of media used. Media containing soy bean meal or a proline supplement, such as were used for the production of butylcycloheptylprodiginine and methylcyclodecylprodiginine, respectively, gave substantially lower incorporation of acetate into ring A carbons.

TABLE 3. Enrichment of ^{13}C in prodiginines from cultures supplemented with sodium [1-^{13}C]acetate[a]

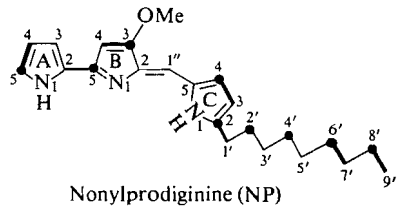
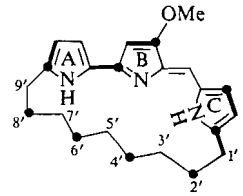
[a]^{13}C concentrations at quaternary carbons A2, A5, B2, B3, B5, C2, C5 estimated from spectrum of salt; concentrations at carbons in aliphatic chain estimated from spectrum of free base (these resonances overlapped in spectrum of salt); remaining enrichments of carbons bonded to ^1H are averages from both salt and free base. The calculation of enrichments and errors followed the procedure discussed in ref. 27. Assignments for carbons 2′,4′-(NP, CNP); 2′,4′,6′(MCDP); and 2′,4′,6′,8′(BCHP) are tentative only, and may be interchanged. Abbreviations for the prodiginines are given in footnote [a], Table 1. Sodium [1-^{13}C]acetate was 90% enriched with ^{13}C.

[b]Couplings ($^2J_{CC}$) of 11.0 Hz were observed between carbons B3 and B5.

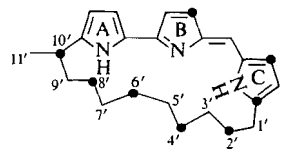
[c]Resonances overlap. The spectrum of the free base suggests that only C2 is enriched.



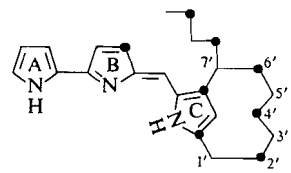
Nonylprodiginine (NP)



Cyclononylprodiginine (CNP)



Methylcyclodecylprodiginine (MCDP)



Butylcycloheptylprodiginine (BCHP)

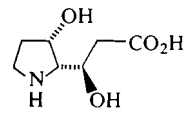
FIG. 1. Incorporation of [1-^{13}C]- and [1,2-^{13}C]acetate into the actinomycete prodiginines. Only those carbon atoms and carbon atom pairs shown to be labeled by ^{13}C nmr spectroscopy are identified.

The pattern of enrichment in the acyl substituents of each prodiginine is similar to that observed by Wasserman and coworkers for the *S. longisporus ruber* pigments and implies that these compounds are made by a common pathway. This conclusion is supported by the results from supplementing a culture of *Actinomadura* strain R39 with [1,2-^{13}C]acetate (Table 4 and Fig. 1). Insofar as the couplings between carbons of the alkyl chain can be distinguished, they show that C2, C3, C4, and the alkyl substituent are assembled as a polyketide chain derived by head-to-tail condensation of acetate units. Besides confirming signal assignments deduced independently, these results also support the expected pattern of acetate incorporation into ring A and carbon B5 via the Krebs cycle and proline, and they establish that an intact acetate unit is involved in the formation of ring B.

Experiments with mutant strains of *S. marcescens* have indicated that the final stage in prodigiosin

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

biosynthesis is the coupling of a dipyrrylaldehyde intermediate containing rings A and B and the methene bridge carbon with a monopyrrole derivative consisting of ring C and its substituents (3). Each intermediate is synthesized independently, and it is likely that the pathway leading to the dipyrrylaldehyde in the actinomycetes is the same as that in *S. marcescens*. A plausible mechanism is suggested by the well-known route for sphingosine biosynthesis in which the pyridoxal phosphate- and enzyme-mediated condensation of palmityl coenzyme A and serine is accompanied by loss of the amino acid carboxyl group. The pyrrolidyl-β-keto propionate derivative which would be required in a comparable synthesis of the dipyrrylaldehyde may also be an intermediate in the formation of detoxinine (**2**) which is a component of detoxin D (26).



2

The actinomycetes and *S. marcescens* clearly differ in the route by which the monopyrrole intermediate is formed, although here, too, some common elements can be seen. Formation of this intermediate may parallel the route by which δ-aminolevulinate is made from glycine and succinyl coenzyme A in a reaction also catalyzed by a pyridoxal phosphate-requiring enzyme (Fig. 2*a*). Assembly of the monopyrrole derivative of the actinomycete prodiginines would proceed by an initial condensation between C(2) of glycine and the thioester carbonyl of a β-ketoacylcoenzyme A intermediate (Fig. 2*b*) and be

[a]Calculation of enrichments followed the procedure discussed in ref. 27. Enriched (90% ^{13}C) and natural abundance acetate were admixed in the ratio of 1:4 before feeding to cultures.

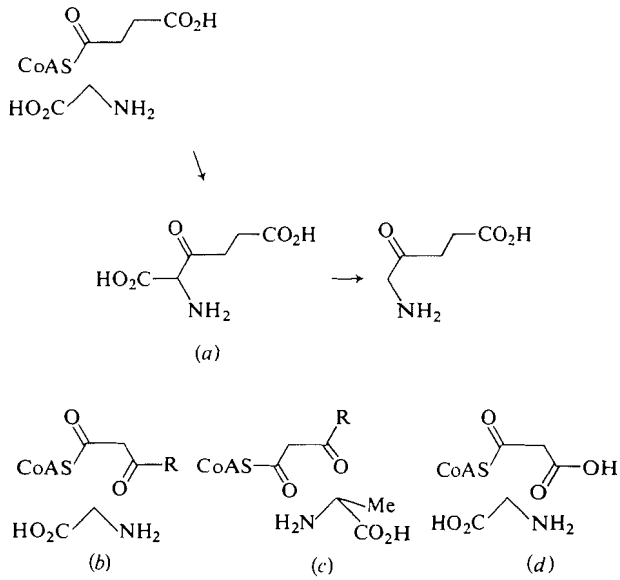

FIG. 2. Levulinic acid biosynthesis (*a*) and possible relationships with the formation of the monopyrrole intermediates of actinomycete prodiginines (*b*) and prodigiosin (*c*), and with pyrrole (*d*).

followed by decarboxylation and cyclization. In *S. marcescens* an initial condensation between C(2) of alanine and the β-carbonyl of a β-ketoacyl coenzyme A intermediate (Fig. 2*c*), followed by decarboxylation and cyclization, would account for the monopyrrole component of prodigiosin. Co-production of this component and pyrrole by mutant 9-3-3 of *S. marcescens* (28) suggests that the enzyme might also accept malonylcoenzyme A as the acylthioester intermediate (Fig. 2*d*).

The evidence from our experiments, together with that already reported for the biosynthesis of undecylprodiginine and metacycloprodiginine indicates that all actinomycete pigments are formed from 12- or 14-carbon chain precursors. Whether these are fatty acid or polyketide derivatives remains to be determined, but it is likely, from their common pattern of biogenesis, that the entire group of open-chain and cyclic metabolites is derived by modification of one biosynthetic sequence. A plausible route is suggested in Fig. 3. Co-production of cyclononylprodiginine and methylcyclooctylprodiginine by *A. madurae*, and of methylcyclodecylprodiginine and ethylcyclononylprodiginine by *A. pelletieri*, favour penultimate unsaturation in the alkyl chain and cyclization to ring A at alternative double-bond carbons as the mechanism by which these compounds are formed. In contrast, the compounds with cyclic alkyl substituents on ring C are not co-produced and the alkyl carbons at the point of attachment would be separated, rather than

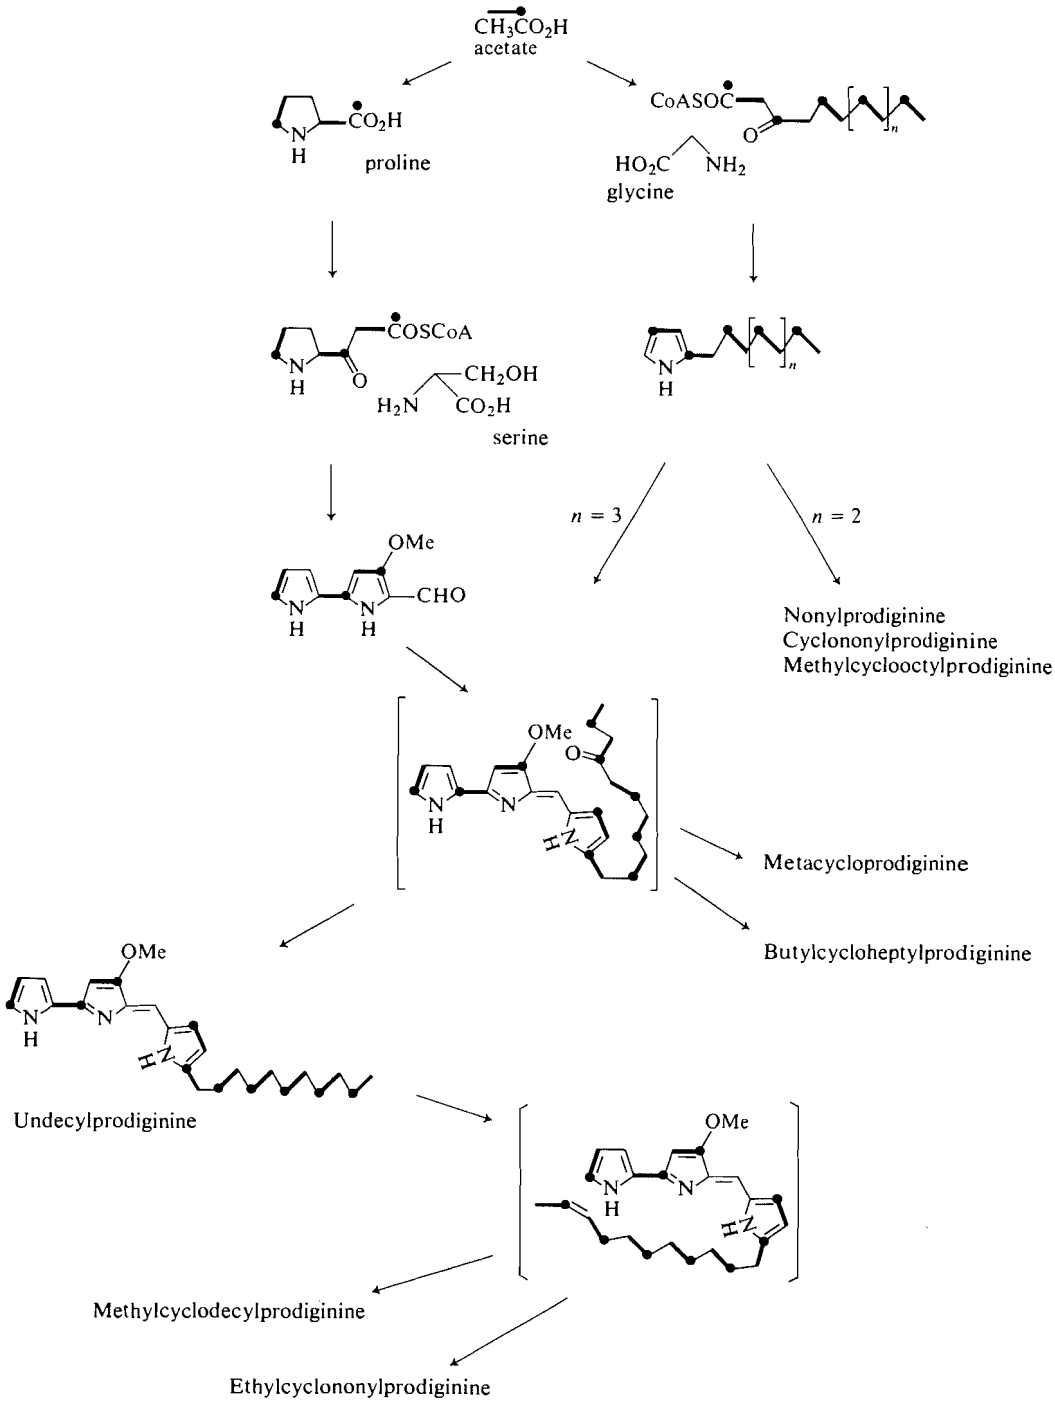

FIG. 3. A possible biogenetic route to the actinomycete prodiginines.

adjacent, in a common precursor. Although they may feasibly be made via unsaturated alkyl intermediates, we suggest here that they are formed by condensation at the alternative methylene groups activated by a residual C(8′) polyketide carbonyl.

Experimental

Cultures and Production of Prodiginines

Nonylprodiginine and cyclononylprodiginine were produced by *Actinomadura madurae* strain R39; methylcyclodecylprodiginine was obtained from *Actinomadura pelletieri*

strain 610. The source and methods for cultivation have been reported elsewhere (9, 12). Strain R39 in ref. 12 is the same as strain 953 in refs. 9 and 10. For both actinomadurae the production medium contained Cerelose (a commercial grade of glucose, 1%), yeast extract (Difco, 0.2%), sodium nitrate (0.4%), magnesium sulfate heptahydrate (0.05%), potassium chloride (0.05%), ferrous sulfate heptahydrate (0.001%), and calcium carbonate (0.2%). Seed cultures of the actinomadurae were grown on a medium containing soybean meal (49% solvent extracted soybean meal, Central Soya, Bellevue, Ohio, 1%), Cerelose (2%), peptone (Wilson Co., meat peptone 851C, 1%), sodium chloride (0.5%), and sodium acetate trihydrate (1.36%). Seed cultures were used as soon as they were well grown and pigmented; their age varied from four to seven days.

Butylcycloheptylprodiginine was produced by *Streptoverticillium sp.* 26-1 (1) grown on the soybean medium described above without the sodium acetate. Seed cultures were grown on yeast–dextrose medium (12) and were used when 2 days old.

Isotopic Labeling

Sodium [1-^{13}C]- and [1,2-^{13}C]acetate, each 90% enriched, sodium [^{15}N]nitrate, 95% enriched, and [$^{2}H_4$]acetic acid, 99.5% enriched, were purchased from Merck, Sharp and Dohme, Pointe Claire, Que. They were sterilized as aqueous solutions by autoclaving and added aseptically to cultures when pigment production was first noticed. This was at 2 days for *Actinomadura* R-39 and *Streptoverticillium sp.* 26-1 and at 3 days for *Actinomadura* 610. A total of 1-ℓ culture volume was used for the labeling experiments with the actinomadurae and 200 ml for the streptoverticillium. Labeled acetate was added to a concentration of 500 mg/ℓ. The [1-^{13}C] species was used at 90% enrichment but sodium [1,2-^{13}C]acetate was diluted by a factor of 5 before use. Glycine (1.5 g/ℓ) and proline (2.3 g/ℓ) were added with the acetate to *Actinomadura* sp. 610.

Sodium [^{15}N]nitrate was used in place of the normal unenriched medium component but at a lower concentration (0.1%); unenriched sodium acetate (1.36 g/ℓ) was added to these cultures at 3 days and cultures were harvested at 6 days.

Isolation of Prodiginines

In general the extraction and isolation procedures paralleled those used earlier (1, 12). The actinomadurae cultures were killed after 4–6 days growth by adding chloroform (25 ml) to each flask and shaking for 24 h thereafter. Filter aid (Celite) was added, the mixture filtered and the chloroform layer separated. Pigment remaining in the residual cell material was extracted with acetone and transferred to chloroform after diluting the acetone with water. The combined and evaporated chloroform extracts were dissolved in benzene and chromatographed on a column of previously water-washed and air-dried alumina. The amount of pigment in solution was measured spectrophotometrically (12) and about 1 g of alumina was used for each milligram present. Prodiginine-containing fractions were combined and rechromatographed on silica gel using about 0.5 g of absorbent for each mg of pigment. The column was irrigated with bicarbonate-washed chloroform containing an increasing concentration of ethyl acetate. All eluate fractions were monitored by thin layer chromatography (9, 12) since the separation of components on silica columns was not always clearly visible. The prodiginines were recovered by evaporation and crystallized as perchlorate salts from ethanol by adding a slight excess of 0.7% perchloric acid.

For the streptoverticillium, killing with chloroform and the use of filter aid were omitted. Additional pigment was obtained from cellular material by a second extraction in which acetone – 10% hydrochloric acid (1:1) was used.

Mass Spectrometry

Mass spectra were obtained with a Hitachi model RMU-6 instrument. A small pure sample of pigment in free base form was adsorbed on to a diatomaceous earth gas chromatography support by evaporation of a carbon tetrachloride solution. This sample was placed in the direct inlet of the instrument and the spectrum obtained at the highest vacuum (5.7×10^{-7} Torr) and lowest temperature (usually about 250°C) possible.

^{13}C Nuclear Magnetic Resonance Spectrometry

Spectra were recorded with a Varian Associates XL-100/15 Fourier transform spectrometer under the following conditions: frequency 25.16 MHz, acquisition time 1.6 or 3.2 s (data accuracy ± 0.3 or ± 0.15 Hz), spectral width 5120 Hz, flip angle 40°, internal ^{2}H lock to solvent, temperature about 30°C, internal reference to tetramethylsilane. The procedure for calculation of enrichment and estimation of the error is discussed in ref. 27.

Spectra of cyclononyl-, methylcyclodecyl-, and butylcycloheptylprodiginines were obtained from both the salt (in DMSO-d_6) and free-base (in $CDCl_3$) forms of the materials. More resonances of the aliphatic chain carbons were resolved in spectra of the free bases than in spectra of the salts. However, intensity measurements for resonances of quaternary carbons in the bases were less reliable as their spin–lattice relaxation times were much greater than were those of the salt form. This is almost certainly due to the greater viscosity of the salt solutions in DMSO-d_6. Consequently, the enrichments for quaternary carbons reported in Table 3 were obtained from the salts, those for aliphatic chain carbons from the free bases, and those for other carbons bonded to hydrogen from both salts and free bases. Enrichments for nonylprodiginine were measured from the spectrum of the salt only.

Pigments were prepared in free base form by diluting the dimethyl sulfoxide-d_6 solution of their salt used for nmr analysis with 1 *N* ammonium hydroxide and extracting with methylene chloride. The organic solution was washed with water to remove dimethyl sulfoxide, then in some cases with a 10^{-3} *M* solution of ethylenediamine tetraacetic acid to remove any paramagnetic metal ion impurities.

The bromination of 3-arylpropynes: Evidence for phenyl participation at a vinyl cation

JAMES A. PINCOCK AND C. SOMAWARDHANA

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received August 26, 1977

JAMES A. PINCOCK and C. SOMAWARDHANA. Can. J. Chem. **56**, 1164 (1978).

The bromination of substituted 3-arylpropynes in acetic acid has been examined. The only products obtained are 1,2-dibromo-3-arylpropenes; the stereochemistry of the dibromides is predominantly *trans* except for the 4-methoxy isomer which gives 83% *cis* and 17% *trans*. In the presence of 0.1 *M* lithium bromide all substrates give predominantly *trans* products. Combined with rate studies, these results indicate that these acetylenes react by an unsaturated cyclic bromonium ion except for the 4-methoxy case where phenonium ion stabilization of a vinyl cation is implicated. In the presence of lithium bromide a bromide ion catalyzed addition of molecular bromine (Ad_E3) occurs.

JAMES A. PINCOCK et C. SOMAWARDHANA. Can. J. Chem. **56**, 1164 (1978).

On a étudié la bromation, dans de l'acide acétique, d'aryl-3 propynes substitués. Les seuls produits obtenus sont des dibromo-1,2 aryl-3 propènes; la stéréochimie des dérivés dibromés est principalement *trans* excepté pour l'isomère méthoxy-4 qui donne 83% de *cis* et 17% de *trans*. En présence de bromure de lithium 0.1 *M*, tous les substrats donnent des produits *trans* d'une façon prédominante. Si l'on combine ces résultats avec des études de vitesse, on en déduit que ces acétylènes réagissent par l'intermédiaire d'un ion bromonium cyclique non-saturé excepté dans le cas du méthoxy-4 où il existe une stabilisation d'un radical vinylique par un ion phénomium. En présence de bromure de lithium, il se produit une addition catalysée par l'ion bromure de brome moléculaire (Ad_E3).

[Traduit par le journal]

Introduction

The mechanisms of electrophilic additions to acetylenes have attracted considerable interest in recent years particularly in terms of comparison with the reactions of alkenes (1–3). Much of this work has led to a better understanding of the chemistry of vinyl cations (4, 5). Recent publications by Dubois and co-workers (6, 7) on the addition of molecular bromine to 3-arylpropenes attracted our interest in this respect. Thus as outlined in eq. 1, bromination in chloroform of the unsubstituted isomer gave only 1,2-dibromo-3-phenylpropane whereas the 4-methoxy substrate gave both 1,2-dibromo-3-arylpropane and the rearranged isomer, 1,3-dibromo-2-arylpropane. Moreover, an examination of the kinetics of these reactions revealed rate increases for the resonance electron donating substituents like 4-methoxyl. These results were explained by phenonium ion type participation (**1**) at the developing positive center in the electrophilic addition.

Although rearrangements both across and to the double bond in vinyl cations are now well established

1 **3**

(5, 8–10) phenonium ion participation of this type has never been observed. We wish to report here results for the bromination of 3-arylpropynes (**2***a*–**2***d*) which have yielded excellent evidence for the existence of the ion **3**.

TABLE 1. Product distribution for the bromination of 3-arylpropynes

Substrate		Acetic acid	Acetic acid (0.1 *M* LiBr)
No.	X	*trans–cis*	*trans–cis*
2*b*	4-MeO	17:83	84:16
2*c*	4-Me	91:9	98:2
2*a*	H	99:1	97:3
2*d*	3-CF_3	98:2	98:2

has been detected in these or other simple alkyl acetylenes. The *trans–cis* product distribution as obtained by analytical glc are shown in Table 1. A check of dibromide isomerization under the reaction conditions indicate the products are those of kinetic control.

The structures of the dibromides **4** and **5** were proven in the following way. First they were obviously 1,2-dibromo-3-arylpropenes and not the isomeric 1,3-dibromo-2-arylpropenes as indicated by ultraviolet spectra. In all cases, the absorption maxima and extinction coefficients were similar to substituted toluenes and quite different from that expected for the more highly conjugated arylethene derivatives (see Experimental). The stereochemistry of **4** and **5** was demonstrated by a variety of methods most of which center on the chemistry of the unsubstituted cases, **4***a* and **5***a*. The original difficulty of having only one of the isomers from the bromination reaction was surmounted by the products obtained from the addition of hydrogen bromide to 1-bromo-3-phenylpropyne, eq. 3. Surprisingly, this mixture

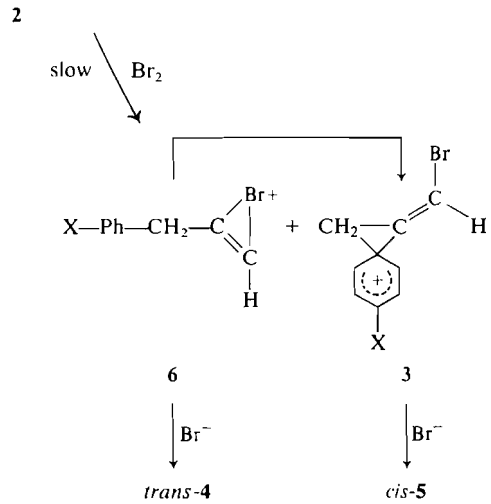
[3] $$PhCH_2C{\equiv}CBr \xrightarrow[HOAc]{HBr} 4a(11\%) + 5a(89\%)$$

proved to be much enriched in the *cis* isomer **5***a*. This result is consistent with predominant *anti* addition to the triple bond in both bromination and hydrobromination. Although we have not done any detailed study of the hydrobromination reaction, this result is in agreement with that for other acetylenes (1) and clearly indicates that the two reactions do not proceed via a common cationic intermediate.

With mixtures of the dibromides in hand the two could be easily distinguished without separation. By proton nmr the allylic coupling in the *cis* isomer (1 Hz) was obviously larger than that in the *trans* isomer (<0.5 Hz). This difference has been reported for other dibromo alkene pairs (11, 12). Moreover, the methylene protons of dibromoalkenes appear at higher field for *cis* isomers than for *trans*: 2.50 δ for *cis*-1,2-dibromo-1-hexene vs. 2.60 for *trans* (10); 2.57 δ for *cis*-3,4-dibromo-3-hexene vs. 2.65 for *trans* (10); 4.00 δ for **4***b* (*cis*) vs. 4.20 for **4***a* (*trans*). In the infrared, **4***a* showed a very weak double bond stretch at 1620 cm^{-1} and **4***b* a much stronger one consistent with the higher dipole moment of *cis* isomers. In agreement with this the more polar *cis* isomers always have longer glc retention times. The stereochemistry of the dibromides for the other acetylenes was established by the same reasoning.

The most striking feature of the stereochemistry of the addition products is the change from predominately *anti* addition leading to the *trans* dibromide for **2***a* and **2***d* to predominately *syn* addition for the 4-methoxy isomer **2***b* (note Table 1). Normally additions to simple alkyl acetylenes give exclusively *anti* addition and the suggested intermediate is an unsaturated bromonium ion (11). The results for **2***a* (X = H) and **2***d* (X = 3-CF_3) are in agreement with this proposal as is the observation of the lack of solvent incorporated products. Electrophilic brominations involving bromonium ions in acetic acid are known to give only dibromide products whereas open cations give products resulting from attack by both possible nucleophiles, solvent and the bromide counter ion (11, 13). The observation of both *syn* addition to **2***b*, X = 4-MeO (and to the same extent to **2***c*, X = 4-Me) and lack of solvent containing products logically demands reaction through a mechanism that does not involve an open cation. The cyclic phenonium ion, **3**, seems therefore the best choice, eq. 4. If we assume that

[4] X—Ph—$CH_2C{\equiv}CH$



phenonium ion formation occurs *anti* to the original electrophilic attack of bromine, then attack by the nucleophilic bromide ion can give only the *cis* product. The product mixture implies there is a competition between phenonium ion, **3**, and bromonium ion, **6**, bridging as suggested by Dubois for the bromination of the analogous alkenes (6, 7). In contrast to the results for alkenes, attack of bromide ion only

occurs at C(2) to give 1,2-dibromo-3-arylpropenes rather than at both C(2) and C(3). The explanation for this fact must be in terms of kinetic control of product distribution since the conjugated 1,3-dibromo-2-arylpropenes would be expected to be the more stable of the two possibilities. First, these thermodynamic factors will be minimized since the product determining transition state must be an early one for such an exothermic step. Therefore, there should be little development of conjugation in the path leading to the 2-arylpropene from the phenonium ion (**3**) where the aromatic π system is perpendicular to the double bond. Second, bromide ion attack at C(2) (sp^2 hybridized) in **3** should be sterically more favorable than at C(3) (sp^3 hybridized). In the corresponding ion **1** from the bromination of 3-arylpropenes attack at C(3) should be favoured (secondary over tertiary). Finally, the polarizable double bond in **3** with the electron withdrawing bromine atom at C(1) should increase the electrophilicity of C(2) over that of C(3).

If this type of phenonium ion bridging occurs in the rate determining step of the reaction, it should also be revealed by rate increase for the 4-methoxy substrate. The results are discussed in the next section.

Rates of Bromination of 3-Arylpropynes

The kinetics of the addition of molecular bromine to acetylenes in acetic acid are well known to follow the general rate expression, eq. 5 (11). To evaluate the individual rate constants two approaches have been used previously: (*a*) measurement of rates as a function of bromide ion concentration according to

$$[5] \quad -d[Br_2]/dt = (k_2[Br_2] + k_3[Br_2]^2 + k_{Br^-} - [Br_2][Br^-])[\text{acetylene}]$$

[6] where K is the equilibrium constant for tribromide ion formation, eq. 7; (*b*) measurement of rates in the absence of bromide ion and at low bromine

$$[6] \quad k_{obs}(1 + K[Br^-]) = k_2 + k_{Br^-}[Br^-]$$

$$[7] \quad K = [Br_3^-]/[Br^-][Br_2]$$

concentration where only the first term in [5] is kinetically significant. Our first choice was method *a* since this gives information about both the bromide ion catalyzed and the uncatalyzed bromination reactions.

Rates of bromination of the four 3-arylpropynes (**2***a* and **2***d*) were measured in acetic acid with lithium bromide concentrations ranging from 0.10 to 0.02 *M* (ionic strength kept constant at 0.1 with lithium perchlorate). These values are tabulated in Table 2. When these data are plotted according to [6] good straight line plots are obtained (i.e. Fig. 1) giving the rate constants k_{Br^-} from the slope and k_2 from the intercept. These are also listed in Table 2.

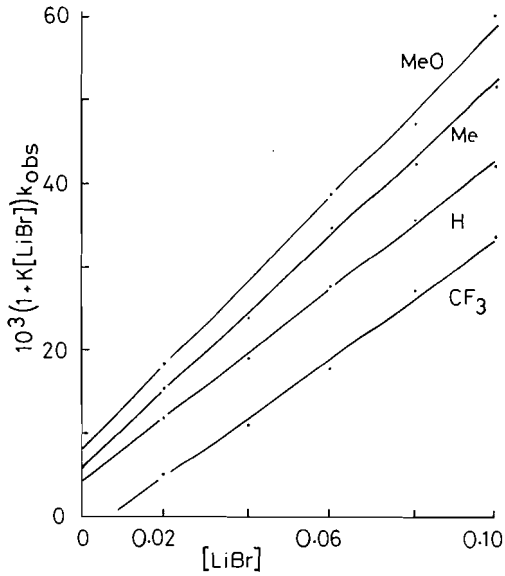


FIG. 1. $(1 + K_t[Br^-])\ k_{obs}$ vs. [LiBr] for the bromination of 3-arylpropynes in acetic acid at 25°C.

The main feature of these results is the large magnitude of the k_{Br^-} process relative to the k_2 molecular bromine process. In fact, the intercepts of the plots used to derive these rate constants are so small relative to the slopes that they are in general unreliable (the 3-CF_3 substituent even gives a negative intercept). This method therefore cannot be used to obtain the rate constants for the uncatalyzed addition of molecular bromine to the acetylenes.

The k_{Br^-} values, however, are of interest because they again demonstrate that for acetylenes this catalyzed process is clearly an Ad_E3 mechanism leading to *anti* addition of bromine via a transition state such as **7** (11, 14). This is most clearly demonstrated for the 4-MeO substrate, **2***b*, where the product ratio changes from 17% *trans* – 83% *cis* for molecular bromination to 84% *trans* – 16% *cis* in the presence of 0.1 *M* lithium bromide. The same effect is present but smaller for the 4-Me case. The other two substrates show almost exclusively *trans* dibromides even in the absence of bromide ion and therefore this change in mechanism can not be detected for these cases by product ratios.

TABLE 2. The rates of bromination of 3-arylpropynes in acetic acid at 25°C in the presence of lithium bromide

Substrate		$k_{obs} \times 10^3$ (M^{-1} s^{-1})						
No.	X	0.10 M LiBr	0.08 M LiBr	0.06 M LiBr	0.04 M LiBr	0.02 M LiBr	$k_2 \times 10^3$[a] (M^{-1} s^{-1})	$k_{Br^-} \times 10^3$[a] (M^{-1} s^{-1})
2*a*	H	4.14	4.20	3.98	3.57	3.54	4.2±0.6	385±10
2*b*	4-OMe	5.92	5.55	5.54	—	5.42	9.5±1.0	470±20
2*c*	4-Me	5.09	5.00	4.99	4.46	4.46	5.8±0.5	461± 8
2*d*	3-CF_3	3.30	3.19	2.56	2.08	1.47	−3.1±1.0	367±15

[a]Errors quoted are the standard deviation of least-squares slope and intercept.

The second feature of these k_{Br^-} values is the very small effect of substituents. Thus the 4-MeO substrate (**2***b*) reacts only 1.3 times as fast as the 3-CF_3 case (**2***d*). This observation is in agreement with the very small positive charge build up on the 2-carbon of the 3-arylpropynes in the transition state **7**. This type of decrease in substituent effects for the bromide ion catalyzed bromination of acetylenes has been observed previously for ethynylbenzenes (11).

Because of the difficulty in obtaining the rate constants, k_2, for the molecular bromination by method *a*, the alternate procedure *b* was used: low bromine and high acetylene concentration, so simple first-order kinetics are obtained according to the first term in [5]. These values are shown in Table 3 along with the σ values required for the Hammett plot in Fig. 2. Also in Table 3 are the rate ratios, k_{Br^-} (0.1)/$k_2 \times 7$ which give the relative amounts of the bromide ion catalyzed versus the uncatalyzed process. The factor of 7 is included in the denominator to correct for the fact that the k_2 values used here were obtained at zero ionic strength. To compare them with the k_{Br^-} values at ionic strength 0.1 they must be multiplied by a factor of approximately 7 (15). We note that for the 4-MeO substrate **2***b* where this *cis–trans* ratio changes drastically in the presence of bromide ion the rate data and product data are consistent. Thus, assuming k_{Br^-} gives entirely *trans* dibromide and k_2 gives a 17:83 *trans–cis* ratio (Table 1), we can estimate the %*trans* expected at 0.1 M lithium bromide: calculated 81%; observed 84% (Table 1).

TABLE 3. Rates of bromination of 3-arylpropynes in acetic acid at 25°C

Substrate		$k_2 \times 10^{-3}$[a]		k_{Br^-} [Br^-][b]
No.	X	(M^{-1} s^{-1})	σ	$7k_2$
2*b*	4-MeO	2.02±0.06	−0.268	3.3
2*c*	4-Me	0.82±0.02	−0.170	8.0
2*a*	H	0.75±0.03	0	7.3
2*d*	3-CF_3	0.64±0.02	+0.430	8.1

[a]Errors are the mean deviation of at least three determinations.
[b]Calculated at 0.10 M LiBr.

The Hammett plot is obviously curved with the 4-MeO substrate **2***b* lying well above the line defined by the other three substrates (Fig. 2). In fact, it reacts about 2.5 times as fast as expected. This observation confirms the formation of large amounts of the *cis* dibromide by a mechanism involving phenonium ion participation in the rate determining electrophilic attack of bromine, eq. 4. Note however, that there may actually be some conversion of **6** to **3** after the rate determining step. The rate increase of 2.5 over that expected for the 4-MeO substrate predicts a product ratio of 60% *cis* and 40% *trans* assuming the phenonium ion rate process leads only to *cis* dibromide and the bromonium ion rate process only to *trans*. The observed ratio is 83% *cis* to 17% *trans*.

The slope of the Hammett plot for the deactivated groups, $\rho \simeq -0.2$ (Fig. 2), is again indicative of very small positive charge build up on the 2-carbon atom of these 3-arylpropynes during bromination. The

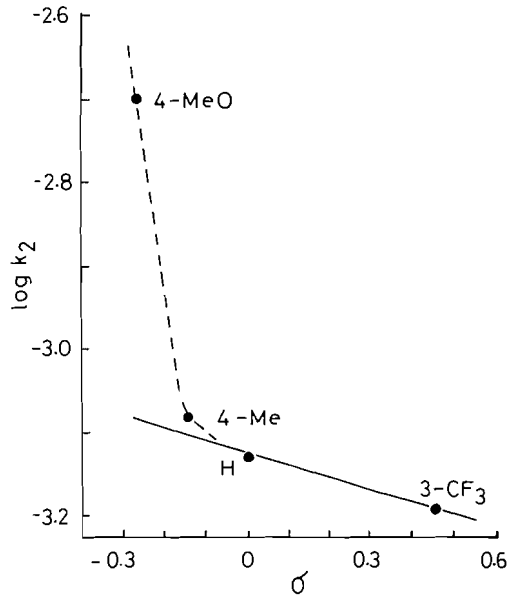

FIG. 2. Hammett plot for the bromination, k_2, of 3-arylpropynes in acetic acid at 25°C.

effect of an aryl group β to a cationic center is well known from solvolysis studies of substrates with electron-withdrawing groups ($\rho \simeq -0.7$) (16). Thus the smaller ρ value in the bromination reaction is at least consistent with the intervention of a cyclic unsaturated bromonium ion. However, the explanation may not be as simple as this since ρ values are known to be different in cases where they should be similar. Thus the Taft $\rho^*(k_3) \simeq -1.0$ for the bromination of aliphatic acetylenes in acetic acid (17) is much smaller than that for aliphatic alkenes in methanol, $\rho^* \simeq -3.1$ (18, 7) even though both reactions are presumed to proceed by transition states leading to cyclic bromonium ions. Although this comparison is for two different rate processes in two different solvents, it should still be valid. The selectivity of a series of alkenes to bromine has been shown to be very similar in methanol and acetic acid (19) and substituent effects for bromination of styrenes in acetic acid are nearly identical for both the first-order in bromine process, $k_2(\rho^+ = -4.8)$ and the second-order in bromine process, $k_3(\rho^+ = -4.6)$ (20).

We conclude by emphasizing that these results for the bromination of 3-arylpropynes are consistent with the mechanism outlined in [4] and for the intervention of a vinyl cation stabilized by 4-methoxyphenyl participation in the rate determining transition state and the product determining intermediates. We are planning to look for this type of participation in other vinyl cation systems.

Experimental

Preparation and Purification of Acetylenes

3-Phenylpropyne

This was prepared according to the literature method (21) by isomerization of 1-phenylpropyne with butyllithium; bp 35–36°C/10 Torr (lit. (21) bp 71–73°C/17 Torr). The acetylene was purified by preparation of the silver salt. A 5% silver nitrate in ethanol solution (750 ml) was added to 10.8 g (0.1 mol) of 3-phenylpropyne in 100 ml of ethanol. The white precipitate was collected, air dried, and then refluxed for 30 min with 73 g (0.9 mol) of sodium thiocyanate in 300 ml of water. The free acetylene was extracted with ether and then distilled to give 8.7 g (81% yield) of recovered 3-phenylpropyne; nmr δ: 2.06 (t, J = 3 Hz, 1H), 3.60 (d, J = 3 Hz, 2H), 7.3 (s, 5H).

3-(4-Methoxyphenyl)propyne

To 9.8 g (0.40 mol) of magnesium in 30 ml ether was added 75 g (0.40 mol) of 4-bromoanisole in 150 ml of ether to prepare the Grignard reagent. The mixture was cooled in an ice bath, 35.7 g (0.30 mol) of 3-bromopropyne was slowly added and then stirred for 24 h. Work-up in the usual way gave 35 g (0.24 mol, 80% yield) of a 2:1 mixture of 3-(4-methoxyphenyl)-propyne and 4-methoxyphenylallene as determined by nmr. This mixture was isomerized to the pure acetylene with butyllithium (18) and then purified by column chromatography on silica gel using petroleum ether. Distillation gave pure 3-(4-methoxyphenyl)propyne; bp 80°C/0.3 Torr (lit. (19) bp 76–77°C/0.1 Torr).

3-(4-Methylphenyl)propyne

This compound was prepared in the same way as the 4-methoxy isomer; bp 54–55°C/0.5 Torr; nmr δ: 2.00 (t, J = 3 Hz, 1H), 2.33 (s, 3H), 3.50 (d, J = 3 Hz, 2H), 6.9–7.3 (d of d, 4H).

3-(3-Trifluoromethylphenyl)propyne

This was prepared in the same way as the 4-methoxy isomer; bp 55–56°C/0.3 Torr; nmr δ: 2.13 (t, J = 3 Hz, 1H), 3.63 (d, J = 3 Hz, 2H), 7.5 (m, 4H). *Anal.* calcd. for $C_{10}H_7F_3$: C 65.22, H 3.80, F 30.98; found: C 65.09, H 3.85.

Products of the Bromination of 3-Arylpropynes

3-Phenylpropyne: cis- *and* trans-*1,2-Dibromo-3-phenylpropene*

To 1.00 g (9.0 mmol) of 3-phenylpropyne in 30 ml of acetic acid was added 1.38 g (8.0 mmol) of bromine in 30 ml of acetic acid. The mixture was stirred in the dark for 16 h, poured into 200 ml of water, and extracted with 3 × 30 ml of ether. The ether was washed with 50 ml of 5% sodium bicarbonate, dried over $MgSO_4$, and concentrated to give 2.30 g of a mixture of *trans*-1,2-dibromo-3-phenylpropene (94%) and *cis*-1,2-dibromo-3-phenylpropene (6%) as determined by glc on a $\frac{1}{8}$ in. × 6 ft 20% Carbowax 20 M on Chromosorb W column (200°C, 25 ml/min). The nmr spectrum of the mixture showed principally peaks for the *trans* isomer δ: 4.20 (s, 2H), 6.97 (s, 1H), 7.77 (s, 5H). Other spectral data, ir (film): very weak band, 1620 cm^{-1}; uv (EtOH) λ_{max}: 260 (ε 277). For elemental analysis a sample was purified by column chromatography on silica gel followed by bulb-to-bulb distillation. *Anal.* calcd. for $C_9H_8Br_2$: C 39.15, H 2.92, Br 57.92; found: C 38.96, H 3.10, Br 57.67.

1-Bromo-3-phenylpropyne—To 20 g of sodium hydroxide in 50 ml of water was added 10.7 g (0.13 mol) of bromine. To this mixture with stirring was added 5.80 g (0.05 mol) of 3-phenylpropyne and then left for 60 h at room temperature. The crude oil was extracted with ether and then distilled to give pure 1-bromo-3-phenylpropyne, bp 40–41°C/0.1 Torr; nmr δ: 3.60 (s, 2H), 7.20 (s, 5H).

Hydrobromination of 1-bromo-3-phenylpropyne—Anhydrous hydrogen bromide was passed through 10 ml of acetic acid to obtain a saturated solution, 1.90 g (0.01 mol) of 1-bromo-3-phenylpropyne was added and then the solution stirred at room temperature for 5 days. Extraction in the usual way gave 2.43 g of crude dibromide mixture which by glc analysis consisted of *trans*-1,2-dibromo-3-phenylpropyne (11%) and *cis*-1,2-dibromo-3-phenylpropyne (89%). This mixture, which is principally the *cis* isomer, showed nmr δ: 4.00 (d, J = 1 Hz, 2H), 6.97 (t, J = 1 Hz, 1H), 7.78 (s, 5H); ir: 1618 cm^{-1}.

3-(4-Methoxyphenyl)propyne: cis- *and* trans-*1,2-Dibromo-3-(4-methoxyphenyl)propene*

The procedure followed was the same as for the unsubstituted case; glc analysis of the crude dibromide mixture indicated *trans* 17% and *cis* 83%; nmr δ: 3.67–3.80 (overlapping singlets, 5H), 6.47 (t, J = 1 Hz, 1H) 6.65–7.10 (d of d, 4H) plus smaller peaks for the *trans* isomer the principle one being the methylene singlet at 3.90 δ; uv (EtOH): 278 mm (ε 1970). A sample from the bromination reaction was purified by preparative glc on a $\frac{3}{8}$ in. × 8 ft 5% SE 30 Chromosorb W column (170°C, 160 ml/min). *Anal.* calcd. for $C_{10}H_{10}OBr_2$: C 39.21, H 3.27, Br 52.29; found: C 39.49, H 3.35, Br 52.16.

3-(4-Methylphenyl)propyne: trans-*1,2-Dibromo-3-(4-methylphenyl)propene*

The same bromination procedure for the unsubstituted compound was used; glc analysis of the crude dibromide mixture indicated *trans* (91%) and *cis* (9%); nmr δ: 2.30 (s, 3H), 3.83 (s, 2H), 6.40 (s, 1H), 7.00 (s, 4H); uv (EtOH): 266 (ε 605).

3-(3-Trifluoromethylphenyl)propyne; trans-*1,2-Dibromo-3-(3-trifluoromethylphenyl)propene*

The crude dibromide mixture analyzed for 98% *trans* and 2% *cis*; nmr δ: 4.00 (s, 2H); 6.60 (s, 1H), 7.47 (s, 4H); uv (EtOH): 266 (ε 847). Analytical sample prepared by preparative glc. *Anal.* calcd. for $C_{10}H_7F_3Br_2$: C 34.58, H 2.03, Br 46.11; found: C 34.89, H 2.22, Br 45.89.

Kinetics for Bromination of 3-Arylpropynes

The procedures for obtaining rates of bromination of acetylenes both in the presence and absence of lithium bromide have been described in detail previously (11).

Proton magnetic resonance data for 6-methyl-2′-deoxyuridine and its 3′- and 5′-monophosphate derivatives are obtained in aqueous solution and compared with data for corresponding thymine derivatives. The data show that the derivatives of the 6-methyluracil base occupy the *syn* conformation. The presence of the *syn* base leads to a flattening of the sugar ring and destabilization of the g^+ conformer about the C(4′)—C(5′) bond. This destabilization is particularly large at the 5′-nucleotide level and is discussed in terms of a repulsive interaction involving the 2-keto oxygen of the base and the negatively charged 5′-group.

ARTHUR L. GEORGE, FRANK E. HRUSKA, KELVIN K. OGILVIE et ANTONIN HOLY. Can. J. Chem. **56**, 1170 (1978).

Travaillant en solution aqueuse, on a obtenu des données de résonance magnétique du proton pour la méthyl-6 déoxy-2′ uridine et ses dérivés monophosphates en 3′ et 5′ et on a comparé les données avec les valeurs correspondantes pour les dérivés de la thymine. Les données montrent que les dérivés de la base de la méthyl-6 uracile occupent une conformation *syn*. La présence d'une base *syn* conduit à un aplatissement du cycle du sucre et à une déstabilisation du conformère g^+ autour du lien C(4′)—C(5′). Cette déstabilisation est particulièrement importante au niveau du nucléotide 5′ et on la discute en terme d'une interaction répulsive impliquant l'oxygène cétonique 2 de la base et le groupe 5′ chargé négativement.

[Traduit par le journal]

Introduction

An important conformational feature of nucleosides is the sugar–base torsion angle (χ) which defines the relative orientation of the base and sugar moieties.[1] For pyrimidine nucleosides in the *anti* conformation (Fig. 1) the 6-hydrogen of the base is located over the sugar ring whereas in the *syn* conformation it is the more bulky 2-keto oxygen which is so located. For steric reasons then, the *anti* conformation of 'normal' pyrimidine nucleosides (no substitution at the 6-position) has been generally considered predominant though there is increasing evidence (1–3) that in solution the *syn* conformation may contribute significantly to the *syn* ⇄ *anti* balance. Undoubtedly polynucleotides possessing *syn* bases will have altered abilities for base stacking and for complementary complexation. Useful model compounds for the evaluation of the conformational consequences of the presence of *syn* bases are the derivatives possessing 6-methyl substituted pyrimidines since it is certain that nucleosides so substituted are *syn* (4–7). For such an evaluation in the 2′-deoxyribose series we have synthesized 6-methyl-2′-deoxyuridine (m^{6}dU) (Fig. 1), and its 3′- and 5′-monophosphate derivatives, 3′m^{6}dUMP and 5′m^{6}dUMP, respectively.

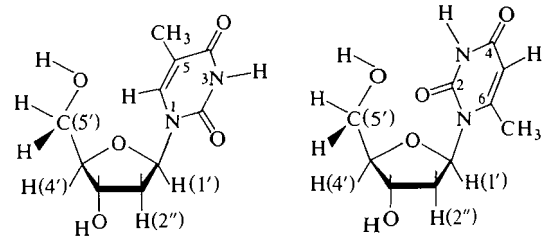

FIG. 1. Structural formulae of 2′-deoxythymidine, dT, (*anti* conformation, left) 6-methyl-2′-deoxyuridine, m^{6}dU, (*syn* conformation, right).

In the present work we report the ^{1}H nmr data for this series of molecules along with data for the analogous thy derivatives, dT, 3′dTMP, and 5′dTMP. The chemical shifts and coupling constants

[1]Abbreviations used: thy, thymine base; m^{6}Ura, 6-methyluracil; dT, 2′-deoxythymidine; m^{6}dU, 6-methyl-2′-deoxyuridine; (3′- or 5′)dTMP and m^{6}dUMP, 3′- or 5′-monophosphate derivatives of dT and m^{6}dU. The familiar notation for the N and S envelope of conformations in the pseudorotational cycle (15), 3′-*endo* and 2′-*endo*, respectively, is retained in the text, except where the conformer equilibrium (N ⇄ S) is indicated.

in D_2O and DMSO are discussed in terms of the conformations of the molecules in the two series. An analysis of the ^1H nmr spectrum of aqueous m^6dU has been described by Cadet *et al.* (6). Holy (8*a*) has verified the configuration of m^6dU using uv, cd, and ^1Hmr data.

Experimental

Syntheses

*6-Methyl-2′-deoxyuridine (**1**)*

This compound was prepared according to Holy (8*b*) starting with 2-amino-β-D-arabinofuro(1′,2′:4;5)oxazoline.

*5′-O-Trityl-6-methyl-2′-deoxyuridine (**2**)*

Compound **1** (3 mmol) was allowed to react with triphenylchloromethane (4.5 mmol) at room temperature in pyridine (10 ml) for 20 h. Pyridine was evaporated by codistillation at reduced pressure with ethanol and the residue was applied to silica gel thick-layer plates which were developed first in ether and then in ethyl acetate. In addition to the major product, **2**, mp 191–192°C, 75% crystallized from benzene, there were small amounts of **1** (slower band), and both ditritylated and 3′-tritylated compounds (both moving faster on tlc).

*6-Methyl-2′-deoxyuridine 3′-Phosphate (**3**)*

Compound **2** (0.11 mmol) and β-cyanoethyl phosphate (0.2 mmol) were dried by repeated evaporation of pyridine. Triisopropylbenzenesulfonyl chloride (TPS, 0.4 mmol) was added and the compounds were stirred at room temperature in pyridine (1 ml) for 16 h. Solvents were removed at reduced pressure by coevaporation with ethanol. The residue was dissolved in 80% acetic acid (4 ml) and heated at 90°C for 20 min. Solvents were removed at reduced pressure and the residue was extracted once with ether (10 ml). The residue was dissolved in ethanol (8 ml), 8 ml of concentrated ammonium hydroxide was added, and the solution was heated in a steel bomb for 2 h at 65°C.

The solution was then concentrated at reduced pressure and the residue was applied to Whatman 3 MM chromatography sheets which were developed first in solvent *A* (isopropyl alcohol – ammonium hydroxide – water (7:1:2)) and then in solvent *F* (*n*-propyl alcohol – ammonium hydroxide – water (55:10:35)). The product band separated cleanly; yield 75%, $\lambda_{max}(H_2O)$ 260 nm; R_m^{Tp} 1.0; R_f^F 0.43.

*3′-O-Acetyl-6-methyl-2′-deoxyuridine (**4**)*

Compound **2** (0.25 mmol) was stirred with acetic anhydride (1 ml) in pyridine (2 ml) for 2 h. Ethanol was added and the solvents were removed at reduced pressure. Acetic acid, (80%, 5 ml) was added to the residue and the resulting solution was heated at 90°C for 20 min. The solution was concentrated at reduced pressure and applied to two thick-layer plates which were developed twice in ether. The product band was eluted with ethanol which on evaporation yielded **4**, 66%, mp 153–155°C; $\lambda_{max}(H_2O)$ 260 nm; $R_f^{ET_2O}$ 0.15; R_f^{EtOAc} 0.41.

*6-Methyl-2′-deoxyuridine 5′-Phosphate (**5**)*

Compound **4** (0.3 mmol) and β-cyanoethyl phosphate (0.4 mmol) were dried by repeated evaporation of pyridine. TPS (0.8 mmol) was added and the components were dissolved in pyridine (2 ml) and stirred at room temperature for 6 h. Water (2 ml) was added and the solution stirred at room temperature for an additional 18 h. The solution was concentrated to a gum at reduced pressure, 6 *M* NH_4OH in ethanol (5 ml) was added, and the solution was heated at 100°C for 2 h. The products were isolated by paper chromatography in solvent *A*. The major product was **5**, 78%; $\lambda_{max}(H_2O)$ 260 nm; R_m^{Tp} 1.0. A small amount (10% overall yield) of the β-cyanoethyl derivative of **5** was also obtained; R_m^{Tp} 0.36, $\lambda_{max}(H_2O)$ 260 nm.

Proton Magnetic Resonance Spectra

Proton magnetic resonance spectra were obtained on a variety of spectrometers (Bruker WH-90DS, Manitoba; Bruker HX-360S, Stanford Magnetic Resonance Laboratory; Varian HR-220, Canadian 220 MHz Centre; Varian HA-100, Manitoba) operating in the Fourier transform or continuous-wave mode. Sodium 3-trimethylsilylpropionate-*2,2,3,3-d*$_4$ (TSP) was used as an internal ^1Hmr reference for the studies in D_2O. Solutions (0.1 *M* or less) were freeze-dried three times and dissolved in 100% D_2O. The p*D* of the nucleoside solutions was adjusted to 7.0 while that for the nucleotides was adjusted to 6.4 or less.[2] For the nucleoside studies in DMSO, samples of dT and m^6dU were lyophilized from D_2O to replace the exchangeable hydrogens and then dissolved in fully deuterated DMSO in a dry nitrogen atmosphere. A trace of tetramethylsilane was added for the internal reference. The nucleoside concentration was 0.1 *M* or less.

Spectral analysis was carried out using LAME (9) and computer simulated spectra were generated as a final test of the data. A sample spectrum of 5′m^6dUMP is shown in Fig. 2. The chemical shift (δ) and coupling constant (*J*) data are listed in Table 1. For the sake of comparison data for 3′- and 5′dTMP from ref. 10 are included.

Results and Discussion

Assignment of Proton Spectra

With the aid of spin decoupling experiments the line assignments for m^6dU and its monophosphates were made by analogy to the assignments for dT and its derivatives (10). Following the work of Ritchie and Perlin (11) on selectively deuterated adenosine, the lower-field proton on C(5′) is designated H(5′) for the derivatives of m^6dU as well as those of dT; this is in line with the Remin–Shugar assignment (12) based on chemical shift trends. In cases where the C(2′) protons may be distinguished, their assignment was made on the basis of chemical shift and coupling constant trends. Thus, a characteristic feature of 2′-deoxyriboside spectra appears to be the near equalities, $J_{2'',3'} \simeq J_{3',4'}$ and $J_{1',2''} \simeq J_{2',3'}$ (10, 13). These lead to designating H(2′) as the lower field C(2′) proton for m^6dU and its derivatives. This is the reverse of the situation in 3′dTMP (Table 1).

Conformation about the N-*Glycosyl Linkage*

Schweizer *et al.* (5) have shown that in 6-methylpyrimidine β-ribonucleosides in which the *ortho* 2-keto group on the base is constrained to lie over the sugar ring (e.g. 6-methyluridine) the H(2′) shift is displaced downfield by about 0.6 ppm relative to its resonant position in *anti* nucleosides (e.g. 5-methyluridine). The effect, attributable to the electric fields and magnetic anisotropy of the carbonyl, is a good probe for the presence of the *syn*

[2]At p*D* < 6.4, the monoanionic form of the nucleotides predominates, making more meaningful a comparison with data for dinucleotides (in preparation) which are also monoanionic near neutral p*D*.

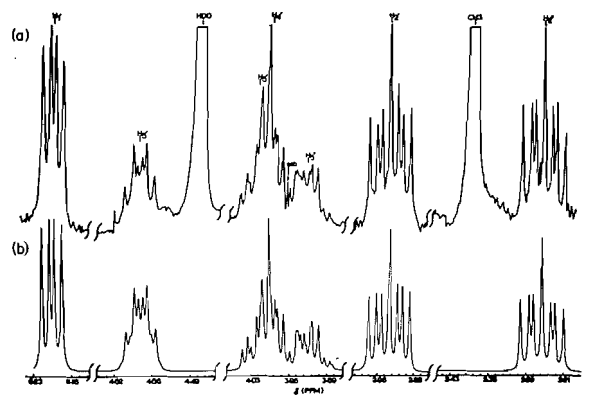

FIG. 2. (*a*) 360 MHz spectrum of 6-methyl-2′-deoxyuridine 5′-monophosphate (5′m^6dUMP) courtesy of the Stanford Magnetic Resonance Laboratory. In D_2O, 60°C, 0.1 *M*, p*D* ≃ 6.4. Shifts in ppm relative to TSP. (*b*) Computer-simulated spectrum.

conformation. The data in Table 1 (aqueous and DMSO solutions) show that H(2′) is displaced downfield by 0.57–0.61 ppm in m^6dU and its monophosphates, relative to the H(2′) resonance position in the corresponding dT derivative. Thus the keto effect on the *endo* C(2′) hydrogen is strikingly similar in the ribose and 2′-deoxyribose series and suggests that a shift towards the *syn* conformation occurs for the m^6Ura derivatives. Furthermore, since the keto group effect on H(2′) in m^6dU (in D_2O and DMSO) and its 3′- and 5′-phosphates are similar (0.57–0.61 ppm), it is reasonable to conclude that the spatial disposition of the 2-keto oxygen and H(2′) is not drastically altered by the solvent change or by phosphorylation. This view is substantiated by the similarity in the 2-keto group effect on the *exo* 2″-hydrogens which are all displaced upfield relative to the H(2″) in the corresponding thy derivative (0.08 to 0.13 ppm for D_2O; 0.05 ppm for the DMSO solution).

H(3′) in the m^6Ura derivatives also experiences a deshielding effect (relative to the dT derivatives) which is, as expected, smaller (0.01–0.06 ppm). Interestingly, this keto group effect on H(3′) is larger for the ribose derivatives studied (0.15–0.19 ppm) (5, 14). This larger effect in the ribosides is probably a consequence of the greater contribution from the 3′-*endo* conformation in this series; in this

conformation H(3′) and the 2-keto oxygen are juxtaposed while in the 2′-*endo* conformation, relatively more important in the 2′-deoxy derivatives, these atoms are distant.

Since H(4′) and the base lie on opposite sides of the sugar, it is perhaps surprising that this proton experiences a substantial 'keto group effect' (shielding) of 0.08 to 0.18 ppm. This cannot be due to a direct influence of the 2-keto group, but is, we feel, a consequence of changes in the C(4′)—C(5′) conformer distribution attributable to base–backbone repulsion in the m^{6}Ura derivatives (see below). With one exception (H(5′′) of 5′m^{6}dUMP) the keto group effects on H(5′) and H(5′′) of the m^{6}Ura derivatives are small; these trends are also in line with the C(4′)—C(5′) conformer redistributions (see below).

Sugar Pucker

The conformation of a 2′-deoxyribose ring, described in terms of the pseudorotational parameters (*P*), the amplitude of pucker (τ_m), and the populations of the 2′-*endo* (S) and 3′-*endo* (N) puckers in the N ⇄ S blend (15), can be evaluated from the magnitudes of the vicinal couplings $J_{1'2'}$ through to $J_{3'4'}$ (Table 1). The following general comments about the influence of the *syn* m^{6}Ura base on the sugar conformation may be made. First, for m^{6}Ura derivatives, the corresponding couplings are similar, indicating that the overall conformation is not affected drastically by 3′- or 5′-phosphorylation or by transfer of the nucleoside to a DMSO solution. Furthermore, for the m^{6}Ura series, the magnitudes of the *cis* couplings $J_{1'2''}$ (8.0 – 8.5 Hz) and $J_{2'3'}$ (8.1 – 8.5 Hz) are larger by about 1.5 Hz than the corresponding couplings in the thy series. This means that the dihedral angles τ_1 (about C(1′)—C(2′)) and τ_2 (C(2′)—C(3′)) (15) have been biased, in the m^{6}Ura series relative to the thy series, towards the eclipsed ($\tau_1 = 0°$, $\tau_2 = 0°$) situation. In the Altona–Sundaralingam approach (15) this can be interpreted as a flattening of the ring i.e. a reduction in τ_m. However, a reduction in τ_m should lead to a *decrease* in the sum of the *trans* couplings $J_{1'2'} + J_{3'4'}$ as well as to an increase in the *cis* couplings $J_{1'2''}$ and $J_{2'3'}$ (15). But, from Table 1 we see that these sums, in aqueous solution, lie in the narrow range from 10.8 to 11.4 Hz, with no clear trend between the thy and m^{6}Ura series. The larger *cis* ($J_{1'2''}$ and $J_{2'3'}$) couplings in the m^{6}Ura series coupled with the similarity in the *trans* sum for the two series can be taken as evidence that the sugar ring in the m^{6}Ura series has pseudorotated away from the pure N($P = 0°$) and S($P = 180°$) conformers (15). In the simplest of terms our data indicate that, insofar as relieving strain due to eclipsing of substituents is concerned, rotation about C(2′)—C(3′) (τ_2) has become less important in the m^{6}Ura series.

In their study of 3′,5′-cyclic nucleotides in the 2′-deoxyribo series, Lee and Sarma (16) have observed large increases in $J_{1'2''}$ and $J_{2'3'}$, without concomitant increases in $J_{1'2'} + J_{3'4'}$; these were attributed to a general flattening of the ring. A similar flattening of the sugar ring is evident for *ribosides* in solution where increases in $J_{2'3'}$ of 1.0 to 1.5 Hz are noted upon incorporation of *syn* bases (5, 14, 16, 17). Interestingly, Altona and Sundaralingam (15) have noted that the sugar ring in crystalline 4-thiouridine (18) is not flattened by the *syn* 4-thiouracil base. This discrepancy between the molecule in the crystal and solution states was attributed by these authors to the crystal field packing requirements.

Estimates of the 3′-*endo* and 2′-*endo* contributions to the N ⇄ S balance can be made via [1] based on Davies and Danyluk (19).

$$[1] \qquad \%3'\text{-}endo = 100\,J_{3'4'}/(J_{1'2'} + J_{3'4'})$$

For the thy derivatives the %3′-*endo* contributions lie in the range from 27 to 38%, with 5′dTMP at the lower end and dT at the upper end. For the m^{6}Ura derivatives at the lower temperature in D_2O, the calculated %3′-*endo* contributions lie in the narrow range from 51 to 56%. Thus, the *syn* m^{6}Ura base has induced a substantial shift away from the 2′-*endo* conformation which appears to dominate in *anti*-2′-deoxyribosides in both the crystal (20) and solution (21) states. (Increasing temperature and transfer to a DMSO environment leads to a slight shift towards the 2′-*endo* conformation of the m^{6}Ura derivatives.) In the ribose series of *syn* nucleosides as well, nmr has revealed (5, 14–17) shifts in favor of the 3′-*endo* conformation. These solution results contrast sharply with crystal data; uridine (*anti*,3′-*endo*) (22) and 6-methyluridine (*syn*,2′-*endo*) (7) define a trend for the ribosides which is the reverse of that in solution.

Conformations about the C(4′)—C(5′) (ψ) and C(5′)—O(5′) (ϕ) Bonds

Assuming values of 11.5 and 1.5 Hz for the *trans* and *gauche* vicinal ^{1}H–^{1}H couplings, respectively (10), the following expressions[3] may be used to estimate the g^+, t, g^- conformer populations for the C(4′)—C(5′) (ψ) bond (Fig. 3).

$$[2a] \qquad g^+(\psi) = (13 - \Sigma)/10$$

$$[2b] \qquad t(\psi) = (J_{4'5''} - 1.5)/10$$

where Σ is the observed sum $J_{4'5'} + J_{4'5''}$. Similarly,

[3]From ref. 10; [3] has been modified somewhat by use of what appear (24) to be better choices for the *gauche* and *trans* ^{1}H–^{31}P couplings.

5′dTMP	54	23	23	14	72	14

[a]Calculated from J data in Table 1 at the lower temperature only. For D_2O solutions except where DMSO indicated. Since *differences* in any pair of J values are accurate to ±0.4 Hz, *differences* in the magnitudes of pairs of conformer populations (which define conformational trends) should be accurate to about ±5%. For further discussion see footnote 7, ref. 10.

assuming 22.9 and 2.1 Hz for *trans* and *gauche* vicinal ^1H–^{31}P couplings (23, 24), respectively, the populations of the g^+, t, g^- conformers of the C(5′)—O(5′) (ϕ) may be estimated from

$$[3a] \qquad g^+(\phi) = (J_{P5''} - 2.1)/20.8$$

$$[3b] \qquad t(\phi) = (25.0 - \Sigma')/20.8$$

where Σ' is the observed sum $J_{P5'} + J_{P5''}$. The populations converted to percentages are listed in Table 2.

For dT values of 44, 35, and 21% are indicated for the $g^+(\psi)$, $t(\psi)$, and $g^-(\psi)$ populations. To within experimental error these are unaffected by 3′-phosphorylation whereas 5′-phosphorylation leads to an increase (10%) in $\%g^+(\psi)$ at the expense of $t(\psi)$. Transfer to a DMSO solution also leads to an increase in $\%g^+(\psi)$. The data reveal further that the m^{6}Ura base has a destabilizing influence upon the $g^+(\psi)$ conformer in the D_2O and DMSO solutions. At the nucleoside and 3′-phosphate levels a decrease (13–17%) is noted for $\%g^+(\psi)$ for the thy-to-m^{6}Ura substitution; simultaneously $\%t(\psi)$ increases (13–15%) whereas $\%g^-(\psi)$ remains essentially constant. At the 5′-phosphate level the effect of the m^{6}Ura base is more pronounced with $\%g^+(\psi)$ decreasing by 30% in 5′m^{6}dUMP relative to 5′dTMP, evident in the 3 Hz increase in Σ upon insertion of the m^{6}Ura base.

Replacement of the thy base by m^{6}Ura leads to a slight decrease in the $t(\phi)$ contribution for the 5′-monophosphates but clearly the C(5′)—O(5′) conformer distribution is much less affected than that of C(4′)—C(5′) at this level. The $t(\phi)$ conformer is dominant in both 5′dTMP and 5′m^{6}dUMP.

In previous studies (25, 26) it has been demonstrated that $^4J_{P4'}$ couplings in 5′-mononucleotides provide information about the C(4′)—C(5′) and C(5′)—O(5′) conformer distributions, with decreases in this coupling correlated with decreases in $\%g^+(\psi)$ and $\%t(\phi)$. In 5′dTMP $^4J_{P4'}$ is 1.6 Hz whereas in 5′m^{6}dUMP it is less than 0.5 Hz. This decrease is further evidence for the destabilizing influence of the m^{6}Ura base on the $g^+(\psi)$ and $t(\phi)$ conformers. Using published correlation plots and equations relating $^4J_{P4'}$ to conformer populations (25), we obtain for 5′dTMP and 5′m^{6}dUMP (in brackets): $\%g^+(\psi)$, 63% (<38%); $\%t(\phi)$ 75% (<67%). In view of the difficulties in measuring small couplings, these populations are deemed in good agreement with those calculated from Σ and Σ′ (Table 2).

The destabilization of the $g^+(\psi)$ rotamer in 5′m^{6}dUMP is reasonably interpreted in terms of a repulsive interaction between the electron pairs on the 2-keto oxygen of the *syn*-oriented m^{6}Ura base and the negatively charged 5′-phosphate. On the other hand, theoretical calculations (27) indicate that the 6-position of a thymine base (which sits over the furanose ring in the *anti*-oriented thy derivatives) is a positive centre and should favor a close approach (i.e. the $g^+(\psi)$ conformer) of the negatively charged 5′-phosphate. Thus, charge considerations form a reasonable basis for discussion of the large (30%) decrease in $\%g^+(\psi)$ in going from 5′dTMP to 5′m^{6}dUMP. Furthermore, on the basis of the charge associated with the 6-carbon and the 2-keto oxygen of the base, we can also understand the *increase* in $\%g^+(\psi)$ for 5′dTMP relative to dT and the *decrease* in $\%g^+(\psi)$ for 5′m^{6}dUMP relative to m^{6}dU. In addition the calculated $\%g^+(\psi)$ values for dT and m^{6}dU reveal a repulsion between the 2-keto oxygen and the polar 5′-hydroxyl but the data indicate that this interaction is attenuated relative to that involving the negatively charged phosphate. Our observation that the $\%g^+(\psi)$ values for dT and 3′dTMP on the one hand and for m^{6}dU and 3′m^{6}dUMP on the other are similar is reasonable since the 3′-phosphate is an *exo* substituent on the sugar whereas the base and 5′-position are *endo*.

The effect of the m^{6}Ura base bears a striking resemblance to that of the 6-azauracil base in that the latter has been shown to destabilize the $g^+(\psi)$ conformation in solution (28) and in the crystal state (29, 30). The 6-aza nitrogen of the 6-azauracil base lies over the ring in the *anti* conformation (29), and since this nitrogen is a negative centre (27), electrostatic repulsion of the 5′-phosphate could account for the reduction in $\%g^+(\psi)$ observed in solution (28) and the absence of $g^+(\psi)$ in the crystal state (29).

It is interesting to note that in the crystal state 5′-nucleotides which are not $g^+(\psi)$ prefer the $t(\psi)$ conformation (20, 29). No known nucleotides have the $g^-(\psi)$ conformation; at the nucleoside level $g^-(\psi)$ is found but less often than $t(\psi)$ (20). This is probably the consequence of unfavorable $O_{3'}$, $O_{5'}$ contacts in the $g^-(\psi)$ conformation, particularly

For personal use only.

when the molecule is 3′*endo*. Our solution data, and nmr results in general, demonstrate that rotation out of $g^+(\psi)$ into $t(\psi)$ is preferred over rotation into $g^-(\psi)$. In this sense a correspondence between the solution and crystal state exists.

The apparent reduction in $\%t(\phi)$ in going from 5′dTMP to 5′m^{6}dUMP (Table 2) is probably not due to a *direct* influence of the polar 2-keto oxygen of the m^{6}Ura base. The reduction in $\%t(\phi)$ in 5′m^{6}dUMP is more likely a secondary phenomenon, i.e., it occurs subsequent to a rotation of the molecule out of $g^+(\psi)$ which was required by the repulsion of the base and backbone in 5′m^{6}dUMP. It is clear from space-filling models that, for steric reasons, $g^+(\phi)$ and $g^-(\phi)$ are unlikely for $g^+(\psi)$ oriented 5′-nucleotides whereas in $g^-(\psi)$ or $t(\psi)$, $g^+(\phi)$ and $g^-(\phi)$ become less sterically hindered. Thus, rotation out of $t(\phi)$ follows logically after rotation out of $g^+(\psi)$. We suggest that our data on the ribose derivatives of uracil and 6-azauracil derivatives (28) and the present data provide evidence that the C(5′)—O(5′) conformer distribution is determined primarily by the C(4′)—C(5′) conformation.

At this point it is useful to comment qualitatively on some of the trends in the H(4′), H(5′), and H(5″) chemical shifts noted for the thy and m^{6}Ura derivatives. It is interesting to note that thy-to-m^{6}Ura change leads to substantial upfield shifts (0.10–0.18 ppm) in H(4′), effects which are larger in absolute magnitude than the effects on H(3′), though H(3′) is closer to the base. These upfield shifts may be rationalized on the basis of the expected (31) shielding effect of a hydroxyl on a *gauche* oriented hydrogen and the deshielding effect expected when the hydrogen is *trans*. Thus, a 5′-hydroxyl should shield H(4′) when the molecule is $t(\psi)$ or $g^-(\psi)$ (Fig. 3). The upfield shifts of H(4′) in the m^{6}Ura series are in line with the increase in the $t(\psi)$ conformation at the expense of $g^+(\psi)$ (Table 2). Interestingly, the largest upfield effect for H(4′) (0.18 ppm) is noted at the 5′-phosphate level where the largest increase in $t(\psi)$ occurs for the thy-to-m^{6}Ura substitution.

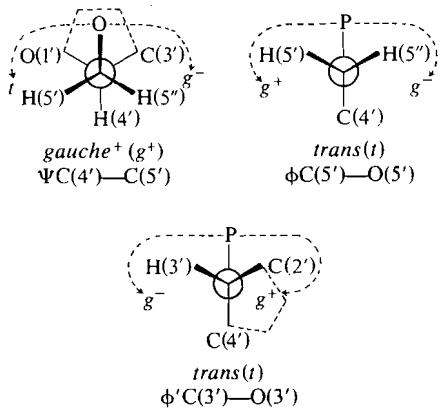

FIG. 3. Newman projections of the dominant conformations viewed along the C(4′)—C(5′) (ψ), C(5′)—O(5′) (ϕ), and C(3′)—O(3′) (ϕ′) bonds.

In aqueous solution the 5′- and 5″-hydrogen are generally insensitive to the thy-to-m^{6}Ura substitution. The exceptional case is H(5″) of 5′m^{6}dUMP which is shifted upfield by 0.13 ppm relative to its resonant position in 5′dTMP. That the H(5″) should be most affected is perhaps reasonable upon consideration of the increase in the $t(\psi)$ conformer population in 5′m^{6}dUMP (48%) relative to 5′dTMP (23%), since rotation into the $t(\psi)$ conformer juxtaposes H(5″) and the magnetically anisotropic 2-keto group of the base.

Conformation about the C(3′)—O(3′) (ϕ′) Bond

The vicinal coupling between H(3′) and the phosphorus atom in a 3′-nucleotide ($^3J_{P3'}$) is a reflection of the $g^+ \rightleftarrows t \rightleftarrows g^-$ blend for the ϕ′ bond (Fig. 3). However, the g^+ conformer may for steric reasons be excluded from consideration (32–34); in no instance does a crystalline 3′-nucleotidyl fragment possess the g^+ conformation (20). However, H(3′) is *gauche* to the phosphorus in both *t* and g^-, and thus $^3J_{P3'}$ values alone can not be used to assess the $t \rightleftarrows g^-$ blend. Some general comments on the ϕ′ conformation of 3′m^{6}dUMP and 3′dTMP may, however, be made.

The $^3J_{P3'}$ couplings (Table 1) lie in the range from 7.1 to 8.3 Hz and are considerably larger than the values expected for truly *gauche* (60° dihedral angle) couplings, that is, about 2 Hz (23). In $g^+(\phi')$ the coupled atoms (H,P) are *trans* and now a large (ca. 23 Hz) $^3J_{P3'}$ is expected (23). But if $g^+(\phi')$ is indeed unimportant, then the observed couplings for the 3′-nucleotides must be reflecting a bias away from the true *gauche* orientations towards the H(3′), P eclipsed conformation ($\phi' = -120°$; Fig. 3). Furthermore, the bias towards the eclipsed conformer must be similar for the pair of 3′-nucleotides at the lower temperature, their $^3J_{P3'}$ values differing by only 0.7 Hz. Interestingly, the increase in $^3J_{P3'}$ (1.2 Hz) with temperature in the 18–75°C range suggests that the bias in 3′m^{6}dUMP is slightly larger at the higher temperature. In contrast $^3J_{P3'}$ in 3′dTMP is independent of temperature in the 30–65°C range (10).

The bias towards the eclipsed conformer is consistent with X-ray data. Thus, in Sundaralingam's review of crystal structure determinations (20), we note that three entries are found in the $g^-(\phi')$ range, with an average ϕ′ value of −103°, while two entries are in the $t(\phi')$ range, with an average ϕ′ value of −144°. These are but 17 and 24°, respec-

tively from the H(3'),P eclipsed situation at $\phi' = -120°$. It is further interesting to point out $^3J_{P3'}$ couplings of 7–8 Hz are consistent[4] with ϕ' angles of about $-82°$ in the g^- range and $-158°$ in the t range.

In summary, the nucleoside 6-methyl-2'-deoxyuridine and its 3'- and 5'-monophosphate derivatives have been synthesized. The ^{1}Hmr data for these molecules are compared with those of the 2'-deoxythymidine and its 3'- and 5'-monophosphates. The data indicate that the 6-methyluracil derivatives are in the *syn* conformation in which the 2-keto oxygen of the base lies above the sugar ring. This leads to alterations in the sugar pucker, in particular, a flattening of the ring, and to a reduction in the g^+ conformation about the C(4')—C(5') bond. Our results for aqueous m^{6}dU are in agreement with those of Cadet *et al.* (6).

NOTE ADDED IN PROOF: Recently C. Giessner-Prettre and B. Pullman (J. Theor. Biol. **65**, 171 (1977)) have calculated the shielding influence of the 2-keto group of the base in pyrimidine nucleosides. They noted that H(2') is strongly deshielded when the molecule is *syn*. They noted also that H(3') should be more strongly deshielded when the sugar is 3'-*endo* than when it is 2'-*endo*. This is consistent with our observations that H(3') shift is more strongly affected by the thy-to-m^{6}Ura substitution in the ribosides than in the 2'-deoxyribosides, since the 3'-*endo* pucker makes a greater contribution in the former series of molecules (see discussion on the *n*-glycosyl linkage).

The reductive denitration of carbohydrate α-nitroepoxides by sodium borohydride[1]

HANS H. BAER AND CHUKWUEMEKA B. MADUMELU

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received November 3, 1977

HANS H. BAER and CHUKWUEMEKA B. MADUMELU. Can. J. Chem. **56**, 1177 (1978).

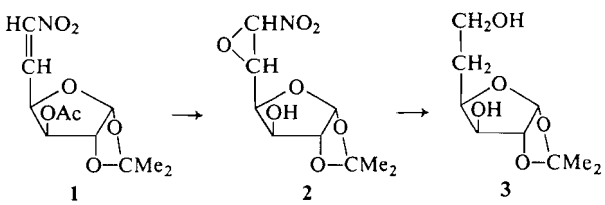
Action of sodium borohydride upon sugar derivatives that contain an α-nitrooxirane grouping leads to reductive denitration producing high yields of α-hydroxy-β-deoxy derivatives. Thus, 5,6-anhydro-1,2-*O*-isopropylidene-6-nitro-α-D-glucofuranose (**2**) gave 5-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranose (**3**). The methyl 2,3-anhydro-4,6-*O*-benzylidene-3-nitrohexopyranosides having the β-D-*talo* (**4**), β-D-*allo* (**5**), and β-D-*manno* (**6**) configurations readily afforded methyl 4,6-*O*-benzylidene-2-deoxy-β-D-*lyxo*-hexopyranoside (**10**; from **4**) and its β-D-*arabino* isomer (**11**; from **5** and **6**). The corresponding nitroepoxy glycoside of α-D-*talo* configuration (**7**) reacted more slowly and gave a mixture of 3-epimeric 2-deoxyglycosides, the analogous α-D-*lyxo* (**13**) and α-D-*xylo* (**14**) compounds. The α-D-*manno* (**8**) and β-D-*gulo* (**9**) nitroepoxides proved unreactive under the same conditions. Stereochemical factors considered to be important in these denitrations are discussed.

HANS H. BAER et CHUKWUEMEKA B. MADUMELU. Can. J. Chem. **56**, 1177 (1978).

L'action du borohydrure de sodium sur des dérivés de sucre contenant les groupes α-nitro-oxiranes conduit à la dénitration réductive produisant avec de bons rendements des dérivés α-hydroxy β-désoxy. Ainsi le 5,6-anhydro-1,2-*O*-isopropylidène-6-nitro-α-D-glucofuranose (**2**) conduit au 5-désoxy-1,2-*O*-isopropylidène-α-D-*xylo*-hexofuranose (**3**). Les méthyl-2,3-anhydro-4,6-*O*-benzylidène-3-nitrohexopyranosides possédant les configurations β-D-*talo* (**4**), β-D-*allo* (**5**) et β-D-*manno* (**6**) fournissent facilement le méthyl-4,6-*O*-benzylidène-2-désoxy-β-D-*lyxo*-hexopyranoside (**10** à partir de **4**) et son isomère β-D-*arabino* (**11** à partir de **5** et **6**). Le nitroépoxy-glycoside correspondant de configuration α-D-*talo* (**7**) réagit plus lentement et conduit à un mélange d'épimères en position 3 de 2-désoxy-glycosides, les analogues α-D-*lyxo* (**13**) et α-D-*xylo* (**14**). On a noté que les nitroépoxydes α-D-*manno* (**8**) et β-D-*gulo* (**9**) ne sont pas réactifs dans ces conditions. On discute des facteurs stéréochimiques que l'on considère être importants dans ces dénitrations.

Carbohydrate derivatives containing an α-nitrooxirane moiety were first obtained some years ago in our laboratory (3–6) and, independently, by Japanese investigators (7), Following the prior use of epoxidized nitrochalcones as intermediates in two special instances of flavonol synthesis (8, 9), the preparation and some chemical transformations of various aliphatic and araliphatic α-nitrooxiranes were studied in more general ways (10–14). Although the available data are still limited in scope, it is already evident that this functionality lends itself to a wide range of reactions with considerable synthetic appeal and mechanistic interest. In the realm of carbohydrate α-nitroepoxides, of which several are now readily available, efforts aimed at exploiting their potential have been disclosed in preliminary communications by the Japanese group (15) and ourselves (2), and we now wish to detail more fully those parts of our results which pertain to the action of sodium borohydride upon these sugar derivatives.

Subjects of our research were one compound that carried an α-nitrooxirane grouping terminally outside the sugar ring, and several compounds in which this moiety was present on the ring itself. The former was 5,6-anhydro-1,2-*O*-isopropylidene-6-nitro-α-D-glucofuranose (**2**), newly prepared for the present work from 3-*O*-acetyl-5,6-dideoxy-1,2-*O*-isopropylidene-6-nitro-α-D-*xylo*-hex-5-enofuranose (**1**) (16) by the method (5) of epoxidation with alkaline hydrogen peroxide.[2] The latter set of substrates



1 **2** **3**

[1]Part 39 in a series on reactions of nitro sugars. For part 38 see ref. 1. The essential features of the research detailed in this article were presented at the 7th International Symposium on Carbohydrate Chemistry, Bratislava, Czechoslovakia, in August 1974. The main body of the work is contained in the Ph.D. thesis submitted in 1976 to this University by C.B.M. For a preliminary communication see ref. 2. The experiments with compound **6** were performed as part of a B.Sc. thesis project (1976–1977) by Mr. Pierre G. Potvin whom the authors thank for his contribution.

[2]Compound **2**, which was isolated crystalline in 64% yield, appeared to be the only product in this epoxidation, as judged from tlc. The D-*gluco* configuration was revealed by catalytic hydrogenation giving (2) the known 6-amino-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose. The configuration at C-6 is not known with certainty; however, a very small coupling constant, $J_{5,6} < 1$ Hz, is suggestive of a H-5,6 *trans* geometry implying the *R* configuration.

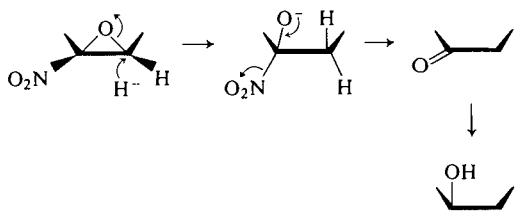
comprised the previously-described (5, 6), stereoisomeric methyl 2,3-anhydro-4,6-*O*-benzylidene-6-nitrohexopyranosides having the β-D-*talo* (**4**), β-D-*allo* (**5**), β-D-*manno* (**6**), α-D-*talo* (**7**), α-D-*manno* (**8**), and β-D-*gulo* (**9**) configurations.

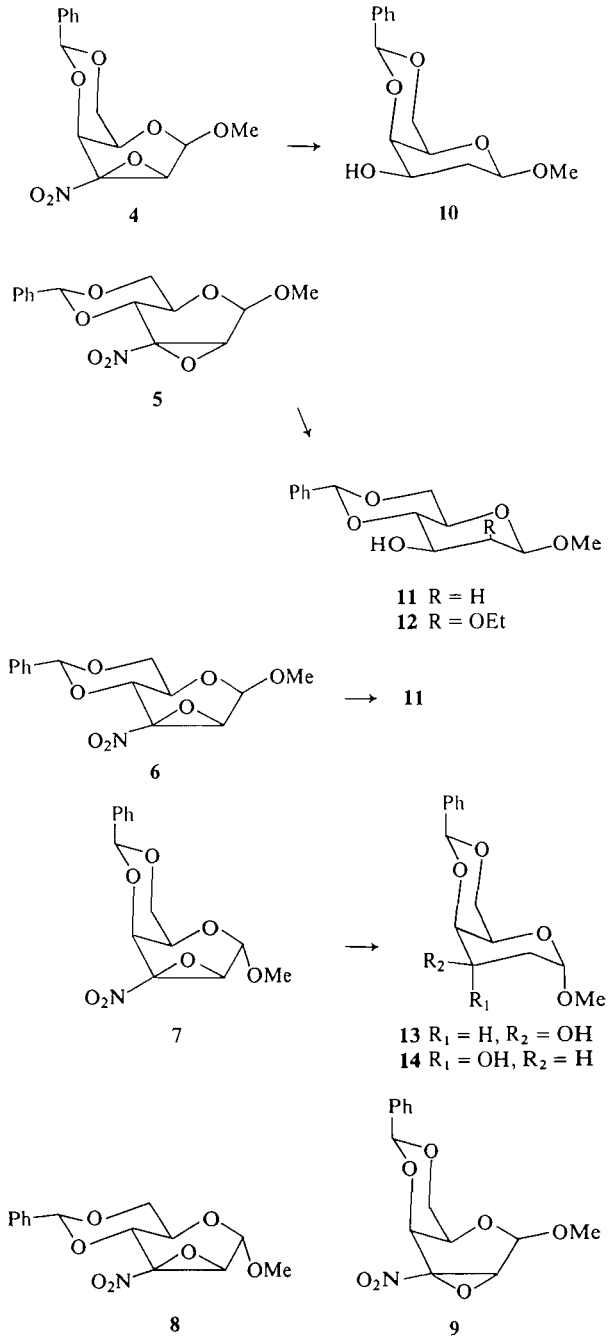
A majority of these α-nitroepoxides were readily attacked by sodium borohydride at room temperature, to give 60–80% yields of nitrogen-free reduction products. Thus, compound **2** furnished within 15 min a single product (according to tlc) which was isolated crystalline in 60% yield and identified as the known (17) 5-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranose (**3**). Similarly, the pyranosidic, stereoisomeric sugar derivatives **4**, **5**, and **6** reacted smoothly in analogous fashion to afford 2-deoxyglycosides. Evidently, hydride ion causes nucleophilic displacement of the oxirane bond at the carbon atom distal to the nitro group, and this process entails elimination of nitrite ion, with a deoxycarbonyl intermediate so formed being immediately reduced to the carbinol stage by excess reagent (Scheme 1).



SCHEME 1

The β-D-*talo* glycoside **4** reacted most readily, yielding 76% of crystalline methyl 4,6-*O*-benzylidene-2-deoxy-β-D-*lyxo*-hexopyranoside (**10**) after a reaction of 30 min in ethanolic medium. No second product was detected. The structure of **10** was conclusively deduced from nmr data. There was an octet for H-3 showing a large coupling ($J_{2a,3}$ = 12 Hz), which required H-3 to be axially arranged.

Under the same reaction conditions, the β-D-*allo* glycoside (**5**) reacted somewhat more slowly (1.5–2 h), giving two products that were isolated crystalline in 60 and 20% yields, respectively. The main product proved to be methyl 4,6-*O*-benzylidene-2-deoxy-β-D-*arabino*-hexopyranoside (**11**)[3] in conformity with the preceding example, whereas the minor product (**12**) was found to lack a deoxy function and to possess an *O*-ethyl group instead. This group was evidently incorporated as a result of ethanol competing with the borohydride in attack at C-2 of the nitro epoxide. Indeed, substitution of the alcohol by



11 R = H
12 R = OEt

13 R_1 = H, R_2 = OH
14 R_1 = OH, R_2 = H

acetonitrile as the solvent led to **11** in better than 90% yield. Similarly, **11** was the only detectable product, isolated crystalline in 72% yield, in the reduction of the β-D-*manno* epoxide **6** in acetonitrile solution.[4]

[3]Compound **11** was first isolated and identified in pilot experiments by Dr. W. Rank in this laboratory. It was also obtained, in noncrystalline condition, by Kumazawa *et al.* (15) who reduced **5** with lithium aluminum hydride in tetrahydrofuran and characterized the product by acetylation.

[4]Small-scale tests indicated that dioxane or 2-propanol may also serve as solvents without giving rise to by-products, although the reactions were somewhat slower than in acetonitrile (3 h vs. 90 min). Ethanol was not tried with **6**, partly because of poor solubility.

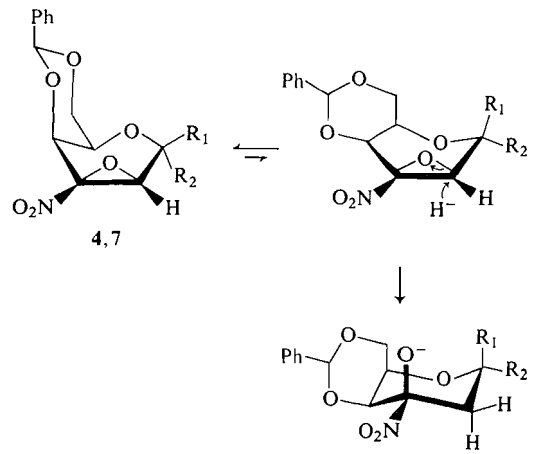
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The structure of **11** produced from both **5** and **6** was firmly established by acid hydrolysis to give 2-deoxy-D-*arabino*-hexose, identified as its known (18), crystalline anilide, and by an independent synthesis (19). The axial orientation of H-3 was confirmed by the splitting patterns of the high-field, H-2a and H-2e multiplets in the nmr spectrum. As regards the by-product **12**, its constitution was assigned on the basis of elemental analysis and substituent resonances present in the nmr spectrum. The ethoxy group at C-2 doubtless was axially oriented since a very small coupling of the anomeric proton, the signal of which was an apparent singlet, indicated an equatorial H-2. A decision between the β-D-*manno* and β-D-*altro* configurations was not possible on the basis of the available spectral data, but we tentatively allocated the former since the specific rotation of **12** ($[\alpha]_D$ −126°, in ethanol) resembled more closely those reported (20) for methyl 4,6-*O*-benzylidene-β-D-mannopyranoside and its 2-*O*-benzyl ether ($[\alpha]_D$ −98 and −131°, in chloroform) than those (21) of the corresponding altropyranoside and its 2-*O*-methyl ether ($[\alpha]_D$ −60 and −48°, in ethanol and chloroform, respectively). Moreover, equatorial placement of the hydroxyl group generated at C-3 appeared to be favored in these reductions, at least as far as β-glycosides are concerned.

In contrast to the high reactivity of the aforementioned nitroepoxide isomers, the α-D-talo glycoside **7** did not react under the same, mild conditions. However, in *boiling* ethanol in the presence of an increased proportion of sodium borohydride, it was completely consumed after 50 min and afforded the known, 3-epimeric, α-D-*lyxo* and α-D-*xylo* 2-deoxyglycoside derivatives **13** (22) and **14** (23) in yields of 50 and 40%, respectively. The α-D-*manno* (**8**) and β-D-*gulo* (**9**) nitroepoxides were completely inert towards sodium borohydride at room temperature, even when exposed to the ethanolic reagent for up to 48 h. They did react at reflux temperature but then gave complex mixtures of products that could not be unravelled. Attempted reductions with lithium aluminum hydride in ether at ambient temperature likewise failed to give identifiable products.

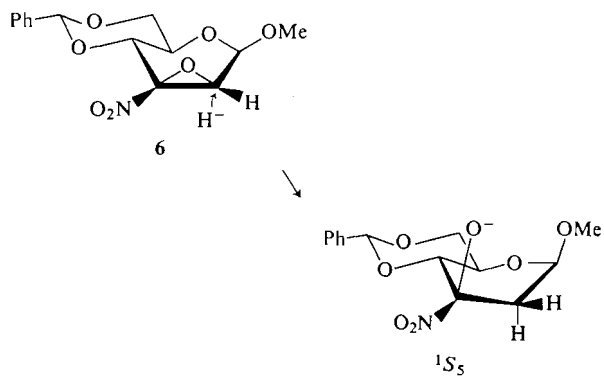
Stereochemical Considerations

The presence of the nitro group evidently governs the regioselectivity of nucleophilic attack on the oxirane ring so that the β-carbon atom is always the favored site. This effect may reverse the regioselectivity from what would be predicted for ring opening in the absence of this substituent. Thus, where an epoxide ring occupies a terminal position (as in 5,6-anhydro-1,2-*O*-isopropylidene-α-D-glucofuranose, the non-nitro analog of **2**), almost exclusive nucleophilic attack takes place at the terminal carbon atom (24), whereas **2** was attacked at the penultimate C-5. When an epoxide ring is 2,3-fused to a pyranoside ring which, in turn, bears a cyclic 4,6-acetal blocking group and is thereby rendered conformationally rigid (*trans*-fused acetals) or at least less flexible (*cis*-fused acetals), then a nucleophilic reagent normally gives one preponderant product, namely, according to the Fürst–Plattner rule, that which arises from diaxial ring opening (25). This means that in hydride reductions of non-nitro analogs of **4–9**, the hydride ion enters axially at C-2 when the oxirane ring is below the pyranose plane, but axially at C-3 when it is above that plane (25). Now in those nitro derivatives (**4–7**) which reacted to give identifiable products, attack occurred exclusively at C-2 regardless of the orientation of the ring. Hence, only for the β-D-*allo* epoxide **5** did the pathway conform with the Fürst–Plattner rule. However, this does not necessarily signify an unusual mode of diequatorial ring opening in the cases where the rule is seemingly violated (**4**, **6**, and **7**). At least in the β- and α-D-*talo* compounds **4** and **7** with their more flexible *cis*-fused structures, a transition state involving half-chair inversion could be invoked to allow for diaxial opening, but such an assumption would create problems. Firstly, as shown in Scheme 2 one would expect in this event



SCHEME 2

the reaction of **4** (R_1 = OMe, R_2 = H) to be more difficult than that of **7** (R_1 = H, R_2 = OMe) because of severe, *syn*-triaxial crowding, which is contrary to the observed relative reactivities of the two compounds. In fact, **4** appears even more reactive than the β-D-*allo* isomer **5** for which diaxial opening does not require a similar conformational inversion. Moreover, the β-D-*manno* epoxide **6** reacts, more readily than **7**, even though it is incapable of assuming the inverted half-chair form because of its *trans*-fused structure. To retain the concept of favored diaxial ring opening one could perhaps



SCHEME 3

consider twist boat-like transition states in which the incoming hydride and displaced oxygen anions are close to being disposed *anti*-diaxially, e.g., the $^1S_5$ conformation of **6** (Scheme 3). A similar form, $^0S_2$, could also apply to **4** and **7** as an alternative to the inverted half-chair discussed above.

However, consideration of conformational changes possible or necessary to attain favorable transition states for ring opening does not account for the differential behavior of all the compounds **4**–**9**. In particular, the striking inertness of the α-D-*manno* isomer **8** and the β-D-*gulo* isomer **9** as compared to **6** and **5**, respectively, as well as the lesser reactivity of **7** as compared to **4** remain unexplained by such reasoning. It is suggested that an essential factor in these reactions is the relative facility of approach of the nucleophile. Thus, backside attack at C-2 appears unhindered in the β-glycosides **4**, **5**, and **6**, whereas in the α-glycosides **7** and **8** it is likely interfered with by the neighboring, pseudoaxial methoxyl group. This interference is severer in the rigid structure **8** than in more flexible[5] **7** which at elevated temperature undergoes a straightforward reaction (albeit without stereoselectivity in the subsequent reduction[6] of the primary product to the alcohol stage). The unreactive β-D-*gulo* isomer **9** requires, like the reactive β-D-*allo* isomer **5**, attack from the upper face of the pyranose ring for facile opening of the oxirane, and it is interesting to observe that the only structural feature distinguishing **9** from **5**, namely the axial oxygen function at C-4, effectively prevents a *syn*-axial approach of hydride ion to C-2.

Catalytic hydrogenations of **4**–**9** also show interesting stereochemical dependencies but furnish altogether different types of products (2). Details will be recorded elsewhere.

Experimental

Melting points were taken with an electrically heated aluminum block apparatus and are uncorrected. Optical rotations were determined at ambient temperature in a Perkin-Elmer 141 automatic polarimeter using a 1-dm cell. Infrared data refer to Nujol mulls. The nmr spectra were recorded from $CDCl_3$, solutions at 100 MHz, with tetramethylsilane added as internal standard, unless otherwise specified. Reactions were routinely monitored by tlc on plates coated with silica gel N/UV_{254} (Macherey & Nagel Co., Germany); the spots were made visible by spraying the plates with 1% ceric sulfate in 10% aqueous sulfuric acid, followed by heating. The following developing systems (v/v) were used: *A*, methanol–chloroform, 1:2; *B*, ethyl acetate – petroleum ether (bp 60–80°C), 1:1; *C*, the same, 2:3; *D*, the same, 1:2; *E*, ethyl acetate – carbon tetrachloride, 2:3; *F*, the same, 1:3.

5,6-Anhydro-1,2-O-isopropylidene-6-nitro-α-D-glucofuranose(2)

To a solution of the nitroolefin **1** (16) (92 mg) in 99% ethanol (10 ml) was added 30% aqueous hydrogen peroxide (0.5 ml), with stirring at room temperature, and the p*H* of the mixture was brought to about 8.5 (indicator paper) by dropwise addition of a saturated aqueous sodium bicarbonate solution. According to tlc (solvent *B*), **1** was completely replaced by a single, more slowly moving product (**2**) after 50 min. The reaction mixture was extracted several times with chloroform, and the extract was washed twice with water, dried ($MgSO_4$), and evaporated to give 65 mg (78%) of syrupy **2**. The syrup crystallized from chloroform – petroleum ether (bp 30–60°C) yielding 53 mg (64%) of needles, mp 127–128°C, raised to 134–135°C by recrystallization from ethyl acetate – petroleum ether; $[\alpha]_D$ −5° (*c*. 0.4, $CHCl_3$); ν_{max} 3400 (OH) and 1560 cm^{-1} (NO_2); nmr τ: 4.06 (d, 1H, $J_{1,2}$ = 3.5 Hz, H-1), 4.48 (s, 1H, H-6), 5.48 (d, 1H, $J_{1,2}$ = 3.5 Hz, H-2), 5.59 (q, collapsing to d on D_2O exchange, 1H, $J_{3,4}$ = 3 Hz, H-3), 5.76 (q, 1H, $J_{3,4}$ = 3, $J_{4,5}$ = 4 Hz, H-4), 6.20 (d, 1H, $J_{4,5}$ = 4 Hz, H-5), 7.48 (d, 1H, removable by D_2O, $J_{3,OH}$ = 4.5 Hz, OH-3), 8.50, 8.66 (s, 2 × 3H, Me_2C). *Anal.* calcd. for $C_9H_{13}NO_7$ (247.2): C 43.73, H 5.30, N 5.67; found: C 43.82, H 5.34, N 5.81.

General Procedure for Borohydride Reductions

Unless otherwise specified, the reactions were performed and the reaction mixtures processed in the following way. The finely divided nitroepoxide was dissolved, under brief and moderate warming if necessary, in the stated volume of solvent, usually 99% ethanol. Cooled to room temperature, the solution or partial suspension was magnetically stirred and a 10-molar excess of solid sodium borohydride was added in portions during a period of several minutes. The flask was then stoppered, and progress of the reaction was checked periodically by tlc. Complete consumption of the starting compound was noted after the periods of time indicated. The solution was deionized with a cation exchange resin which after filtration was washed thoroughly with methanol or ethanol. The filtrate was evaporated at reduced pressure, and 5–6 portions (10 ml each) of methanol were successively added to, and evaporated from, the residue in order to remove boric acid. Typically, a flame test for boric acid was then negative.

[5]Molecular models of **8** and **7** show that a conformational change that would move the glycosidic methoxyl group outwards and out of the way of the approaching nucleophile is associated with a movement of the nitro group that would increase nonbonded interaction (similar to $A^{1,2}$ strain) between the latter and O-4 in **8** but not in **7**.

[6]The loss of stereoselectivity attributable to the presence of an axial substituent at C-1, and the preference for formation of equatorial alcohols in the preceding examples, is in line with expectations based on the stereochemistry of cyclohexanone reductions recently reviewed (26).

The resulting, syrupy or solid residue was subsequently crystallized or purified as stated.

5-Deoxy-1,2-O-isopropylidene-α-D-xylo-hexofuranose (3)

The nitroepoxide **2** (40 mg) and sodium borohydride (52 mg) in ethanol (20 ml) reacted within 15 min to give a single product (tlc in solvent *B*). The dried syrup (34 mg) crystallized from ethyl acetate – petroleum ether yielding **3** (20 mg, 63%), mp 92–93°C, $[\alpha]_D$ −8° (*c* 0.4, $CHCl_3$) (lit. (17) mp 94°C, $[\alpha]_D$ −10° ($CHCl_3$)). *Anal.* calcd. for $C_9H_{16}O_5$ (204.2): C 52.93, H 7.90; found: C 52.69, H 7.82.

Methyl 4,6-O-Benzylidene-2-deoxy-β-D-lyxo-hexopyranoside (10)

The reaction between the nitroepoxide **4** (5) (100 mg) and sodium borohydride (130 mg) in ethanol (40 ml) was complete after 30 min and gave a single spot in tlc (solvent *A*). Processing furnished a solid product which was passed through a column (19 cm × 1 cm) of silica gel (40 g) by means of chloroform. Evaporation of the fractions that contained **10** yielded 66 mg (76%) of crystals, mp 200–204°C, $[\alpha]_D$ −40.5° (*c* 0.5, $CHCl_3$); nmr τ: 2.6 (m, 5H, Ph), 4.43 (s, 1H, $PhCHO_2$), 5.65 (q, 1H, $J_{1,2a}$ = 8.7, $J_{1,2e}$ = 2 Hz, H-1), 5.69 (q, narrow, 1H, H-4), 5.9 region (m, 2H, H-6,6′), 6.21 (m, broad, 1H; becomes a clear octet on D_2O exchange, $J_{3,4}$ = 3.5, $J_{2e,3}$ = 5.5, $J_{2a,3}$ = 12 Hz, H-3), 6.51 (s, 3H, OMe), 6.65 (m, narrow, 1H, H-5), 7.7 (broad peak, 1H, removed by D_2O, OH), 7.85–8.35 (m, 2H, H-2e,2a). *Anal.* calcd. for $C_{14}H_{18}O_5$ (266.3): C 63.14, H 6.81; found: C 63.13, H 6.86.

Methyl 4,6-O-Benzylidene-2-deoxy-β-D-arabino-hexopyranoside (11)

(A) From Nitroepoxide 5

A solution of compound **5** (5) (1.0 g) in warm, 99% ethanol (375 ml) was cooled to room temperature, and sodium borohydride (1.0 g) was added in small portions, with stirring. Another 0.3 g of borohydride was added after 1 h and the reaction mixture was worked up after 1.5 h when **5** had been completely replaced by two products that moved more slowly in tlc (solvent *C*). The slower one (**11**) predominated. Crystallization of the syrupy product mixture from chloroform – petroleum ether yielded a first crop of **11** (163 mg, mp 150–151°C). Evaporation of the mother liquor gave a crystalline mixture of **11** and the faster moving by-product (**12**), which was chromatographed on a column (47 cm × 2 cm) of silica gel (110 g) by use of solvent *D* as eluent. The first chromatographically homogeneous fractions were evaporated to give syrupy **12** (182 mg, 20%), further described in a subsequent section. Later fractions furnished a second crop (271 mg) of **11** melting at 148–149°C, undepressed on admixture of the previous crop. The combined amount of **11** (434 mg, 60%) was recrystallized from ethyl acetate – petroleum ether and then had mp 155–156°C and $[\alpha]_D$ −67° (*c* 0.5, $CHCl_3$) (lit. (19) for **11** from an independent synthesis: mp 156–157°C, $[\alpha]_D$ −66.2°). Infrared and nmr spectra were identical; nmr τ: 2.6 (m, 5H, Ph), 4.49 (s, 1H, $PhCHO_2$), 5.54 (q, 1H, $J_{1,2a}$ = 9.5, $J_{1,2e}$ = 2.3 Hz, H-1), 5.7 (m, 1H, probably H-6), 6.2–6.4 and 6.6–6.8 (unresolved m, 4H, H-3,4,5,6′), 6.51 (s, 3H, OMe), 7.22 (broad s, exchangeable by D_2O, OH), 7.78 (o, 1H, $J_{1,2e}$ = 2.3, $J_{2e,3}$ = 5, $J_{2a,2e}$ = 13 Hz, H-2e), 8.36 (o, 1H, $J_{1,2a}$ = 9.5, $J_{2a,3}$ = 11.5, $J_{2a,2e}$ = 13 Hz, H-2a). *Anal.* calcd. for $C_{14}H_{18}O_5$ (266.3): C 63.14, H 6.81; found: C 63.11, H 6.82.

When **5** (31 mg) in acetonitrile (3 ml) was treated with sodium borohydride (38 mg initially, plus 12 mg after 1 h), there was obtained crystalline **11** (26 mg, 97%) showing $[\alpha]_D$ −63.8° (*c* 1.3, $CHCl_3$). It contained a small amount of an unidentified by-product (migrating faster in tlc than both **11** and **12**) which was removed by one recrystallization from ether – petroleum ether; **11** then melted at 158–159°C.

(B) From Nitroepoxide 6

The nitroepoxide **6** (6) (200 mg) in acetonitrile (20 ml) was treated with sodium borohydride (250 mg) at room temperature for 90 min, after which the reaction was nearly complete and **11** was the only product revealed by tlc (solvent *C*). Work-up after deionization with Amberlite IRC-50 (H^+) afforded a crystalline material (171 mg) which was recrystallized from hot methanol by careful addition of water to incipient cloudiness followed by cooling. There was obtained pure **11** (111 mg, 72%) in two crops, mp 157–158 and 159–160°C, $[\alpha]_D$ −69° (*c* 0.5, $CHCl_3$). The infrared spectrum was superimposable on that of **11** from *A*.

(C) Conversion of 11 into 2-Deoxy-β-D-arabino-hexose Anilide

Compound **11** (65 mg) was hydrolyzed in 0.05 *M* hydrochloric acid by stirring for 4 h at 25°C followed by heating on the steam bath for 2 h. The pale yellow hydrolyzate was neutralized using Dowex-1X2 resin (carbonate form) which, after filtration, was washed well with water. Evaporation of the filtrate and drying of the oily residue by several coevaporations with added benzene gave a syrup whose nmr spectrum confirmed the complete removal of the benzylidene and the methoxy group. The product was then heated on a steam bath for 1.5 h with aniline (0.2 ml) in ethanol (2 ml), which led to a single derivative (tlc with solvent *A*). The solution was decolorized with activated charcoal and refrigerated overnight whereby the crystalline *anilide* (20 mg, 74%) was deposited; mp 193–194°C, $[\alpha]_D$ −162.4° → −103° (*c* 1, pyridine, 2 days) (lit. (18) mp 193–194°C, $[\alpha]_D$ −138° → −106° (pyridine, 2 days).

Methyl 4,6-O-Benzylidene-2-O-ethyl-β-D-mannopyranoside (12)

The syrupy **12** isolated by column chromatography (see above) gave crystals (155 mg) from ethyl acetate – petroleum ether; mp 129°C, unchanged on recrystallization; $[\alpha]_D$ −126° (*c* 0.4, ethanol); nmr ($CDCl_3$) τ: 2.6 region (m, 5H, Ph), 4.47 (s, 1H, $PhCHO_2$), 5.59 (s, 1H, $J_{1,2}$ ~ 0 Hz, H-1), 5.69 (q, *J* = 5 and 10 Hz, H-6), 5.8–6.4 (unresolved m, 6H, H-2,3,4,6′, and CH_2 of OEt), 6.49 (s, 3H, OMe), 6.7 (broad m, H-5), 7.5 (broad peak, 1H, removed by D_2O exchange, OH), 8.78 (t, 3H, *J* = 6.5 Hz, CH_3 of OEt). In acetone-d_6, H-1 resonated at τ 5.48, H-6 at 5.80, OMe at 6.57, and CH_3 of OEt at 8.86. *Anal.* calcd. for $C_{16}H_{22}O_6$ (310.3): C 61.92, H 7.15; found: C 61.76, H 7.20.

Methyl 4,6-O-Benzylidene-2-deoxy-α-D-lyxo-hexopyranoside (13) and Methyl 4,6-O-Benzylidene-2-deoxy-α-D-xylo-hexopyranoside (14)

The nitroepoxide **7** (5) (300 mg) in ethanol (66 ml) was treated with sodium borohydride (732 mg) which was added in portions in the course of several hours. No appreciable reaction was observed (tlc in solvent *E*). The mixture was therefore heated at reflux temperature, whereupon two faster-moving products appeared but some **7** was still left after 35 min. Additional borohydride (366 mg) was introduced and heating was continued for another 15 min after which **7** was completely consumed. The product mixture obtained upon work-up was chromatographed on a column (19 cm × 1 cm) of silica gel (40 g) by use of solvent *F*. The faster moving α-D-*xylo* isomer (**14**) was isolated from early fractions as a syrup (93 mg, 40%) that was homogeneous in tlc. The α-D-*lyxo* isomer (**13**) was obtained from subsequent fractions as needles, mp 167–175°C, in a yield of 106 mg (50%).

Recrystallized from ethyl acetate – petroleum ether, **13**

showed mp 186–188°C and $[\alpha]_D$ +117.5° (*c* 0.3, $CHCl_3$) (lit. (22*a*) mp 184–185°C, $[\alpha]_D$ +104° (*c* 0.3, ethanol) and (22*b*) mp 178–179°C, $[\alpha]_D$ +106° (*c* 0.62, $CHCl_3$)); nmr τ: 2.60 (m, 5H, Ph), 4.43 (s, 1H, $PhCHO_2$), 5.09 (t, 1H, $J_{1,2e} = J_{1,2a} = 2.5$ Hz, H-1), 5.73 (q, 1H, $J_{5,6} = 1.8$, $J_{6,6'} = 13$ Hz, H-6), 5.8–6.1 (m, 3H, H-3,4,6′), 6.39 (narrow m, H-5), 6.68 (s, 3H, OMe), 7.85 (broad peak, 1H, exchangeable, OH), 8.0 (overlapping m, 2H, H-2e,2a). *Anal.* calcd. for $C_{14}H_{18}O_5$ (266.3): C 63.14, H 6.81; found: C 63.24, H 6.94.

The syrupy isomer **14** was crystallized from chloroform – petroleum ether; mp 99–101°C, unchanged on recrystallization, $[\alpha]_D$ +78° (*c* 0.5, $CHCl_3$) (lit. (23) mp 102–104°C, $[\alpha]_D$ +79° ($CHCl_3$)). nmr τ: 2.65 (m, 5H, Ph), 4.44 (s, 1H, $PhCHO_2$), 5.24 (narrow q, 1H, $J_{1,2a} = 4$, $J_{1,2e} < 1$ Hz, H-1), 5.82 (center of two AB quartets, $J_{5,6a} = J_{5,6e} = 2$Hz, $J_{6a,6e} = 12$ Hz, H-6,6′), 6.05–6.2 (overlapping narrow m, 3H, H-3,4,5), 6.62 (s, 3H, OMe), 7.74 and 8.16 (2 doublets of narrow triplets, $J_{2a,2e} = 14$ Hz, H-2a,2e). *Anal.* calcd. for $C_{14}H_{18}O_5$ (266.3): C 63.14, H 6.81; found: C 63.31, H 6.91.

Sulfene, generated from methanesulfonyl chloride and triethylamine in acetonitrile reacts with itself to form a tetramer which may be isolated as an acyclic crystalline pyridinium sulfonate salt, **1**. When sulfene is generated in tetrahydrofuran in the presence of pyridine, the 1,1,3,3-tetraoxide of 4,4a-dihydropyrido[1,2-*d*][1,5,2]dithiazine, **11**, is formed. Structural evidence (including nmr and mass spectra) for these compounds, for homologs of **11**, and for a series of acyclic polysulfonyl compounds derived from **1** is presented. An X-ray crystal structure determination was carried out on **9**, the 5,7-dimethyl homolog of **11**.

J. STUART GROSSERT, MADAN M. BHARADWAJ, RICHARD F. LANGLER, T. STANLEY CAMERON et RUTH E. CORDES. Can. J. Chem. **56**, 1183 (1978).

Le sulfène, produit à partir du chlorure de méthanesulfonyle et de la triéthylamine dans l'acétonitrile, réagit avec lui-même pour conduire à un tétramère qui peut être isolé sous forme de sel sulfonate de pyridinium cristallin acyclique **1**. Lorsque l'on produit le sulfène dans le tétrahydrofuranne en présence de pyridine, il y a formation du tétraoxyde-1,1,3,3 de la dihydro-4,4a pyrido[1,2-*d*][1,5,2]dithiazine (**11**). On rapporte les preuves de structure (incluant la rmn et les spectres de masse) de ces composés ainsi que des homologues de **11** et d'une série de composés polysulfonyles acycliques, dérivés de **1**. On a effectué une détermination de structure cristalline par diffraction de rayon-X en utilisant le composé **9**, l'homologue diméthylé en 5,7 de **11**.

[Traduit par le journal]

Introduction

The generation of methanesulfonate esters (mesylates) by the reaction between alcohols and methanesulfonyl chloride in pyridine solvent is an old-established process (1). During an attempt to carry out an *in situ* elimination (with triethylamine) of a mesylate formed in this manner, we observed the formation of an unexpected product, which appeared to be a novel cycloadduct (**11**) between the pyridine solvent and a sulfur-containing species. Further work (2) showed the reaction to be characteristic of pyridines even if the 3 or 4 positions were substituted and suggested that the sulfur-containing portion was two sulfene units, presumably generated by reaction between the methanesulfonyl chloride and the triethylamine (ref. 3 and references therein).

Difficulties associated with the purification of **11**, as well as the low yield in which it was formed, suggested that it was not the major product of the reaction and indeed, use of acetonitrile as reaction solvent permitted the isolation of a further new compound which turned out to be the pyridinium salt of the hydrolysis product of a sulfene tetramer (**1**) (4). In this paper we report on the structure determinations and spectroscopic properties of the acyclic product **1** and the novel heterocyclic products **9–11**.

Results and Discussion

Derivatives from an Acyclic Tetramer of Sulfene

When methanesulfonyl chloride was added to triethylamine and pyridine in acetonitrile, the major product isolated, after addition of the reaction mixture to water, was the crystalline pyridinium salt of a sulfonic acid. Combustion analysis required the formula $C_9H_{15}NO_9S_4$ and titration indicated two acidic protons. The ^1H and ^{13}C nmr spectra were highly informative in that the four carbons of the anionic portion were present as two chemically nonequivalent methyls, a methylene and a methine. Details of these spectra are presented in Tables 1 and 2. In the mass spectrometer, the salt did not show a molecular ion but lost SO_3 very readily and then exhibited the spectrum which would be expected from an acyclic chain of alternating carbons and sulfonyl groups. This information, taken together with the infrared and ultraviolet spectra, required structure **1** to be written for the pyridinium salt of this sulfene tetramer hydrolysis product. Evidence for the structure was further strengthened when long-range ^1H–^1H coupling was noticed between the low-field methyl protons and the methylene protons. The

high-field methyl protons were, however, a sharp singlet. Further investigation, to be described in a subsequent paper (but cf. ref. 4) showed that the presence of pyridine was not required for the formation of the sulfene tetramer.

Our attempts to study the chemistry of **1** were aimed primarily at ester formation, either directly or via the acid chloride. All attempts were frustrated in that either no reaction occurred, or else the molecule lost the elements of sulfur trioxide to form the acyclic tris-sulfone **3**. This was first prepared in an attempt to use Golborn's method for the preparation of sulfonate esters (5) in which the sulfonic acid is heated with a dialkyl acetylphosphonate. When **1** was heated with dimethyl acetylphosphonate (**4**), **3** was isolated in good yield; the same process could also be achieved by simply warming **1** in the presence of a strong mineral acid. Attempts to form a sulfonyl chloride from **1** with PCl_5 led to the tetrachloro derivative (**5**) and it was subsequently found that the same compound or a tetrabromo compound (**6**) could be prepared directly by treating **1** with chlorine or bromine, respectively. This series of reactions is outlined in Scheme 1, along with the fact that **3** and **5** could be interconverted by standard procedures. Both **5** and **6** instantly gave silver halide precipitates with alcoholic silver nitrate, although no clearly defined, homogeneous organic products could be isolated from these reactions. It is perhaps not surprising that the sulfonyl chloride of **2** would be difficult to prepare since **2** itself, being a sulfonic acid adjacent to electron-withdrawing groups, probably readily loses SO_3 (6) under the conditions of chlorination to form **3**, which is then readily chlorinated. Finally, oxidation of the known (7) 2,4,6-trithiaheptane (**7**) unequivocally confirmed the structure of **3**.

Some ^1H and ^{13}C nmr spectral details of the above compounds are presented in Tables 1 and 2. The only feature of interest is the 0.7 Hz long-range ^1H–^1H coupling between methyl and methylene protons in **2**. No long-range ^1H–^{13}C coupling across SO_2 groups was observed in the ^{13}C nmr spectra of **2** or **3** (cf. pyridodithiazine spectra, *vide infra*). The mass spectra of **1**, **2**, and **3** were virtually indistinguishable, apart from some peaks in **1** that were obviously due to pyridine. The mass spectral fragmentations of the tetrachloro compound (**5**) and its tetrabromo analog (**6**) could be followed readily from the isotope peaks due to the different numbers of halogens in each fragment ion. The fragmentation pathways of the

two compounds differ, although both exhibit rearrangements which lead to reasonably intense ions of structure CX_3^+, X = Cl or Br.

The Pyridodithiazines (9–11)

When triethylamine was added to a mixture of a pyridine and methanesulfonyl chloride in a less polar solvent such as THF, the major isolable product was a novel heterocycle (**11**) in which two sulfene units had added to a pyridine molecule in a manner similar to the reactions of pyridines with acetylene dicarboxylic esters or with ketenes (2).

Similar reactions of 4-picoline and 3,5-lutidine with sulfene yielded heterocycles **10** and **9**, respectively, which were appropriately similar to the parent compound **11**. On the other hand, α-substitution on the pyridine ring appears to change the course of the reaction and to give rise to different products.[2]

Proof of the structures of heterocycles **9–11** was possible from spectroscopic data. Also, since they form the first examples of a new heterocyclic system, a crystal structure determination was carried out on **9**.

The ultraviolet spectrum of **9** showed an absorption maximum at 287 nm which could be reversibly changed to 303 nm by the addition of base. The position of the maximum was unchanged in acidic medium. An indication of the homocyclic diene system was provided by the double bands at 1666 and 1615 cm^{-1} in the infrared spectrum (8), which also showed appropriate bands for the sulfonyl groups. The ^1H and ^{13}C nmr spectra together provided a wealth of structural information. Details of these spectra and of the ^1H nmr spectra of **10** and **11** are provided in Tables 3 and 4, respectively.

The different chemical shifts of the two methyl groups in **9** attested to their different environments. The proton chemical shifts of both the methyl groups and the olefinic protons showed minimal variations over a 155°C temperature range. Decoupling experiments demonstrated the correct assignments of the resonances corresponding to each carbon and proton in the dimethyl-substituted diene system. These de-

coupling experiments also revealed appropriate allylic ^1H–^1H couplings of ca. 1.6 Hz.

The remaining five protons in **9** were bound to sp^3 carbons and formed a complex system that could be reduced to a five-spin system by irradiation of the low-field methyl ^1H resonance. The ^1H chemical shifts of both the methylene pairs varied continuously over a temperature range of +100 to −55°C.

Spectral parameters for the five-spin proton system were obtained by use of a modified LAOCOON IVA computer program (9)[3] on data from the room temperature spectrum. The same program was used to calculate parameters for the protons at C(4) and C(4a) from a spectrum taken at 100°C, while the C(2) proton resonances were irradiated. These parameters showed relatively minor changes with temperature in J_{ae}, J_{aa}, and J_{gem} for the protons on C(4) and C(4a). Long-range coupling between equatorial protons at C(2) and C(4) was significant although comparable to literature values (10 and refs. therein). The value of J_{ae} for the protons on C(4) and C(4a) suggests a dihedral angle of ca. 66°, using Forrest's method (11), which is in good agreement with the X-ray value (*vide infra*). It appears from molecular models that the *cis*-fused conformer of **9** depicted in Fig. 1 has the least number of nonbonded interactions and should be more stable than the other

[3]We thank Dr. T. B. Grindley for making this program available to us.

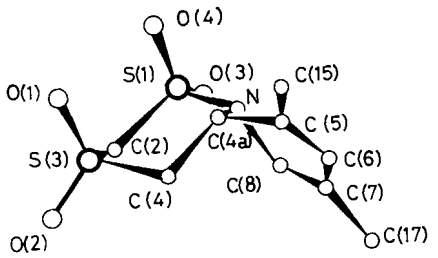

FIG. 1. The molecule **9** viewed at +10° to *b* in the *ab* plane. Atom numbering follows Chemical Abstracts nomenclature. Thus C(4) and C(4a) are independent atoms.

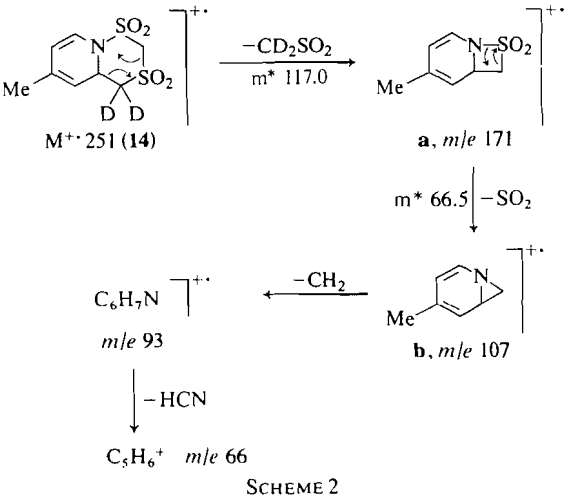
possible *cis*-fused conformer. Inversion at nitrogen produces a *trans*-fused system with somewhat more nonbonded interactions than the conformer in Fig. 1 but which retains the same conformation of the dithiazine ring. It is probable that the changes with temperature in chemical shifts of the methylene protons in **9** reflect solvation changes and possibly a nitrogen inversion process.

The off-resonance ^{13}C nmr spectrum of C(2) and C(4) showed their resonances as sharp triplets, without long-range splitting, an effect no doubt due to the adjacent sulfonyl groups. On the other hand, C(4a) was a doublet with considerable fine structure. All other carbons showed appropriate long-range ^{1}H–^{13}C couplings.

The C(2) methylene protons in **9–11** showed an expected degree of acidity in that they exchanged readily with D_2O in acetone. By use of NaOD in acetone on **10**, a tetradeuterated derivative (**13**) could be produced and by back-exchange the other dideuterated derivative **14** was produced, thereby completing the series of deuterated derivatives, (**12–14**). Mass spectral studies of **10** and **12–14** permitted an unambiguous assignment of the major electron-impact-induced fragmentation pathway in **10**. Comparable spectra were observed for **9** and **11**. Details of the spectra are presented in Table 5,[4] and a typical fragmentation pathway using **14** as an example is outlined in Scheme 2. Loss of SO_2 from ions of type **a** to give ions of type **b** was followed by fragmentations typical of pyridines substituted by an appropriate number of alkyl groups.[5] It is not clear whether loss of sulfene from **9–11** could be induced thermally. The compounds could be sublimed at ca. 160°C, but were not sufficiently volatile to be studied by flash thermolysis.[6]



SCHEME 2

Crystal Structure of 9

The crystal (see Experimental for structure data) was found to be constructed from isolated molecules (**9**) which have two six-membered rings fused together at a C—N bond. One ring is the remnant of the pyridine group, the other contains two sulphur atoms bridged by a methylene carbon. The pyridine fragment has a group of four carbon atoms C(5)—C(6)—C(7)—C(8) which are not quite co-planar, the torsional angle between the C(5)—C(6) and C(7)—C(8) bonds about the C(6)—C(7) bond is −16.2° and between S(3)—C(4) and C(4a)—N(9) about the C(4)—C(4a) bond is −65.8°. The torsional angle between the equatorial H(42) and the axial H(4a) in the H(42)—C(4)—C(4a)—H(4a) system is −64.3° which compares with ~66° in solution (nmr). The C(5)—C(6), C(6)—C(7) and C(7)—C(8) bond lengths are 1.316(6), 1.459(7), and 1.334(8) Å, respectively. The

NOTE: Numbering in this structure is dictated by nomenclature conventions which conflict with crystallographic conventions.

bond lengths C(5)—C(6) and C(7)—C(8) are not significantly different but are both significantly shorter than C(6)—C(7). These lengths compare with 1.339, 1.480, and 1.339 Å in buta-1,3-diene (16).

[4]Details of the mass spectra of **9–14** (Table 5) are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

The torsional angle between the C(4a)—C(5) and C(6)—C(7) bonds about C(5)—C(6) is 3.7° and between C(6)—C(7) and C(8)—N(9) about C(7)—C(8) is 0.8°. The C(4a)—C(5) bond length 1.527(8) is an expected (17) value for a single bond between an sp^2 and sp^3 carbon atom. The N(9)—C(4a) bond length (1.492(5) Å) has an acceptable (17) value for an N—C (sp^3) bond though it is slightly longer than the quoted mean length (18) of 1.472(5). The lengthening could be caused by strain within the ring containing the sulphur atoms (see below). The N(9)—C(8) bond length at 1.424(5) compares favourably with the average of 1.426(12) for an N—C (sp^2) single bond (18). Since the shortening of the N—C bond from an sp^3 carbon to an sp^2 is attributed only to the difference in covalent radii of these two types of carbon atoms, it seems unlikely that there is much interaction between the nitrogen lone pair electrons and the conjugated carbon system. This is consistent with the observations in the uv spectrum of **9**. The N(9)—S(1) bond length 1.636(5) compares with 1.522(16) for the formal double bond of the —S=N—S— system (19), with 1.623(9) for the mean length of the formal single bond of the —S=N—S—N=S— system in the same S_3N_3 ring (19), and with 1.635(8) for an isolated S—NH—single bond in a tolylsulphenylamino group that has an sp^3 carbon atom bonded to the third valency at nitrogen (20). The nitrogen atom N(9) is 0.29 Å from the plane of three atoms bonded to it with the sum of interbond angles at N(9) of 349.5°. From the molecular geometry and the bond lengths it seems further unlikely that the π electron system of the butadiene-like group extends, to any great extent, through the nitrogen atom to the sulphonyl group containing S(1).

The six-membered ring containing the two sulphur atoms has the chair conformation (Fig. 1), the four atoms S(3), C(2), N(9), C(4a) have deviations from the least-squares best plane of 0.039–0.048 Å with a mean of 0.045 Å. The plane through C(2)—S(1)—N(9) makes an angle of 129.5° and that through S(3)—C(4)—C(4a) an angle of 125.1° with the four-atom plane. The bond angles N(9)—S(1)—C(2) and C(2)—S(3)—C(4) of 102.6(2) and 103.3(2) compared with a N—S—C angle of about 108° when sulphur is bonded to a nitrogen with essentially three single bonds and 100° when nitrogen forms formally a single bond to sulphur and a double bond to a carbon atom (20). The N—S—C bond angle in this molecule is very similar to the C—S—C bond angle where both carbon atoms are sp^3 hybridized. The small angle therefore is more likely to be required to relieve the steric strain induced in the ring by the long S—C and S—N bonds than to indicate much multiple bonding along the S—N bond.

The angle between the O(3)—S(1)—O(4) and C(2)—S(1)—N(9) planes is 89.4° which is in the range expected (20) for a nitrogen atom that forms these single bonds rather than a double and a single.

In compound **9** there is a *cis* fusion of the two rings which appears to be retained in DMF or DMSO solution. This may be the result of steric interactions between the methyl group C(15) and the adjacent methylene group at C(4) (Fig. 1). In similar compounds, **10** and **11**, without the methyl group, this interaction is absent and the more usual *trans* ring fusion should occur. Attempts are still being made to grow crystals of **10** and **11** which are suitable for X-ray structure analysis.

In summary, it appears to be well established that sulfenes and their amine zwitterions are formed as reactive intermediates when methanesulfonyl chloride is reacted with tertiary amines, such as triethylamine (3). We have communicated a note of the probable formation of **1** (4) and this will be detailed presently.[2] Details on whether the pyridodithiazines form by reaction of pyridine with a sulfene dimer followed by ring closure, or whether sulfene adds to a pyridine–sulfene zwitterion, followed by ring closure, remain to be answered.

Experimental

General

Most experimental details have been described previously (21). Some ^1H and ^{13}C nmr spectra were recorded on a Varian XL-100 spectrometer at the University of Groningen and some microanalyses were performed by the Microanalytical Laboratory at the same University.

Many reactions were carried out using anhydrous conditions under dry N_2. Acetonitrile (Fisher Scientific Co.) was dried by refluxing over and fractionating from CaH_2. Methanesulfonyl chloride was washed successively with cold water, 2.5% $NaHCO_3$ and cold water before being dried over anhydrous $MgSO_4$ and fractionated under vacuum (water aspirator). Amines were fractionated from KOH pellets. THF (Fisher) was distilled from $LiAlH_4$ unless a fresh bottle was available.

Preparation of Pyridinium 2,4,6-Trithiaheptane-3-sulfonate-2,2,4,4,6,6-hexaoxide (1)

Methanesulfonyl chloride (19.5 ml) in CH_3CN (50 ml) was dropped, during 45 min, into a mechanically stirred mixture of pyridine (10 ml) and Et_3N (34.5 ml) in CH_3CN (300 ml) under an N_2 atmosphere. The reaction was maintained at −40°C during the addition, after which the cooling bath was removed. Following stirring for 30 min at room temperature, the reaction mixture was poured in a thin stream into ice-cold water (500 ml). The resulting precipitate was collected, washed (cold water) and recrystallized from water (with charcoal treatment) to give colorless prisms of **1** (18 g, 68%); mp 183–185°C; ir (KBr): 3260, 3200, 3110, 3060, 3000, 2940, 1649, 1622, 1552, 1498, 1350, 1325, 1140, 1050 cm^{-1}; nmr: see Tables 1 and 2; ms (no $M^{+\cdot}$) *m/e*: 250, 171, 157, 108, 94, 79, 77, 63, 48; equiv. wt. (titration vs. NaOH) 205; *Anal.* calcd. for $C_9H_{15}NO_9S_4$: C 26.40, H 3.69, N 3.42, O 35.17, S 31.32, mol. wt. 409.46; found: C 26.38, H 3.45, N 3.66, O 35.52, S 31.08; mol. wt. (cryoscopic) 210.

Preparation of 2,4,6-Trithiaheptane-2,2,4,4,6,6-hexaoxide-3-sulfonic Acid (2)

An aqueous solution of the pyridinium salt **1** was passed through a cation-exchange column (Dowex 50 W8) in the hydrogen form. The aqueous column eluant was rotary-evaporated to give a thick, colorless syrup which could be rendered anhydrous on keeping *in vacuo* over P_2O_5 for 24 h. The dried white mass of **2** was very hygroscopic and could not be crystallized; for ms, see text; nmr, see Tables 1 and 2.

Conversion of 2 into 2,4,6-Trithiaheptane-2,2,4,4,6,6-hexaoxide (3)

Using Dimethyl Acetylphosphonate (4)

Compound **4** was prepared from acetyl chloride and trimethyl phosphite according to the method of Berlin *et al.* (22) and had bp 50–54°C/0.2 Torr; ^1H nmr ($CDCl_3$) δ: 2.48 (3H, d, J = 5 Hz), 3.88 (6H, d, J = 10 Hz).

A mixture of pyridinium salt **1** (1.0 g) and phosphonate **4** (3.2 g) in pyridine (15 ml) was protected from moisture and was heated in an oil bath at 120°C for 16 h. Gas bubbles were evolved and after the dark mixture was concentrated by rotary evaporation, water (50 ml) was added. The aqueous layer was extracted with ethyl acetate (3 × 25 ml), from which **3** was obtained. Recrystallization (acetone–$CHCl_3$ 1:1) gave **3** (0.57 g, 94%) as colorless prisms, mp 191–192°C; ir (KBr): 1350, 1320, 1175, 1150 cm^{-1}; for ms, see text; nmr, see Tables 1 and 2; *Anal.* calcd. for $C_4H_{10}O_6S_3$: C 19.19, H 4.03, S 38.42; found: C 19.33, H 4.08, S 38.3.

Using Phosphoric Acid

Pyridinium salt **1** (1.0 g) was heated in an oil bath at 105°C in 85% H_3PO_4 (20 ml) for 24 h. The mixture was cooled, diluted with water and extracted with ethyl acetate, from which **3** was obtained in 55% yield.

Preparation of 3,3,5,5-Tetrachloro-2,4,6-trithiaheptane-2,2,4,4,6,6-hexaoxide (5)

Using Phosphorus Pentachloride

Pyridinium salt **1** (1.0 g) and PCl_5 (5 g) were heated at 150–160°C for 4 h. The cooled residue was extracted with ethyl acetate which was filtered, washed with water, dried and concentrated to give **5** as colorless crystals (0.90 g, 95%) that were recrystallized (acetone–$CHCl_3$) and had mp 183–184°C; ir (KBr): 1365, 1355, 1170, 1160, 860, 760 cm^{-1}; ms[7] *m/e*: 386 ($M^{+\cdot}$, 4 Cl), 371 (4 Cl), 307 (4 Cl), 225 (2 Cl), 210 (2 Cl), 117 (3 Cl), 79, 63; nmr, see Tables 1 and 2. *Anal.* calcd. for $C_4H_6Cl_4O_6S_3$: C 12.38, H 1.56, Cl 36.54, O 24.74, S 24.78; found: C 12.45, H 1.51, Cl 36.42, O 24.92, S 24.86.

Using Chlorine

Either an aqueous solution of **1** (1.0 g) *or* a solution of **3** (1.0 g) in MeOH–pyridine (50:1) was saturated with Cl_2. The white precipitate (0.92 g, 97%, in both cases) was collected after cooling and was identical to **5** formed in the previous experiment.

Preparation of 3,3,5,5-Tetrabromo-2,4,6-trithiaheptane-2,2,4,4,6,6-hexaoxide (6)

Bromination of **1** in MeOH–H_2O (5:1) gave a white precipitate of **6**, which was recrystallized (CH_3CN) to give colorless cubes, mp 188–189°C; ir: 1365, 1355, 1345, 1160, 1150 cm^{-1}; ms[7] *m/e*: 404 (4 Br), 340 (3 Br), 261 (2 Br), 249 (3 Br), 198, 182, 170, 158 (all 2 Br), 107 (1 Br), 79, 63; for nmr see Table 1; *Anal.* calcd. for $C_4H_6Br_4O_6S_3$: C 8.49, H 1.07, Br 56.5; found: C 8.46, H 1.00, Br 55.8.

[7]The number of halogens in the fragment ions was determined from the intensities of the halogen isotope peaks.

*Atom numbering according to Chemical Abstracts nomenclature; see structure **9**.

Preparation of 2,4,6-Trithiaheptane (7)

The method used was a modification of that due to Fehér and Vogelbruch (7). A suspension of dry, powdered Na_2S (8.09 g; the nonahydrate was ground and dried *in vacuo* over P_2O_5) was stirred in dry MeOH (100 ml) and cooled to −20°C. Chloromethyl methyl sulfide (**8**, 6.0 g) (21) was added dropwise, the mixture was allowed to warm to room temperature overnight and the MeOH was rotary-evaporated. Lixiviation of the resulting sludge with $CHCl_3$, followed by appropriate work-up, gave **7** as a colorless, foul-smelling oil (2.95 g, 30%) which could be distilled, bp 52–54°C/0.1 Torr (lit. (7) 113°C/13 Torr) and had appropriate spectral characteristics.[8]

Oxidation of 7 to give 3

A solution of **7** (2.25 g) was oxidized with 30% H_2O_2 in HOAc in the usual way (23) for 4 days. The oxidation was incomplete and was repeated for 7 days with fresh oxidant. Finally, oxidation was completed using $KMnO_4$ in acetone–HOAc at 60°C for 4 h. The crystalline reaction product (0.98 g) was recrystallized, mp 189–191°C (mixture mp with **3**, 188–191°C) and was identical with **3** by tlc and spectroscopic properties.

Preparation of 4,4a-Dihydro-5,7-dimethylpyrido[1,2-d][1,5,2]dithiazine-1,1,3,3-tetroxide (9)

A mixture of distilled 3,5-lutidine (18.4 ml) and $MeSO_2Cl$ (31.0 ml) in dry THF (100 ml), was cooled by a −70°C bath, with mechanical stirring and protection from moisture. A

solution of distilled Et_3N (56 ml) in THF (50 ml) was added dropwise over 140 min and stirring was continued for a further 30 min. The creamy, pale yellow mixture was poured in a fine stream into a well-stirred ice-water mixture which was subsequently filtered and the crude **9** was recrystallized twice from acetone–MeOH (1.38 g (3.3%) after recrystallization). Further recrystallization from acetone gave an analytical sample, mp 217–222°C (dec.); ir (KBr): 2980, 2920, 1666, 1615, 1370, 1320, 1305, 1155, 1045, 895 cm^{-1}; uv (MeOH, neutral or acid): 287 nm (ε 2800), MeOH + NaOH 303 nm; for ms see Table 5; for nmr see Table 3. *Anal.* calcd. for $C_9H_{13}NO_4S_2$: C 41.04, H 4.97, N 5.32, O 24.30, S 24.35; found: C 41.29, H 4.69, N 5.19, O 24.23, S 24.22. See also the preparation of compounds **10** and **11**.

X-Ray Crystal Structure of ***9***

The crystal data are as follows:

$C_9H_{13}NO_4S_2$ fw = 263.3

Monoclinic $P2_1/c$, a = 16.272(5), b = 15.370(5), c = 5.654(2) Å, γ = 125.68 (4)°, V = 1148.6 Å^3, Z = 4, ρ_c = 1.523 g cm^{-3}, (18 ± 2°C; CuK_{α_1}, λ = 1.54051 Å (carbon monochromator) μ = 40.5). $F(000)$ = 536 e.

The cell dimensions (refined from 12 general reflections with 2θ between 70–80°) and intensities of 1455 independent reflections (71% of those observable) with $I > 3\sigma$ were measured on a Picker FACS 1 four-circle diffractometer with an ω-2θ scan and 2θ values between 4 and 120°. The minimum base-width was 2.0°. Three standard reflections were measured every 60 reflections. The intensities of these three reflections decreased steadily throughout the data collection but could be adjusted to a standard scale by a least-squares fit (σ = 0.007) to a first-order decay; from the counting statistics the ratio of esd to reflection of these standards was 0.019. The data were reduced to $|F_o|$ by the routine procedure. No absorption or extinction corrections were applied. The scattering factors for neutral atoms were taken from (13); they were corrected for the real part of the anomalous dispersion. Reflections with $|E| > 1.2$ were used to solve the structure by an application of the tangent formula that examined 256 = 2^8 sets of starting phases and successively eliminated all but the most likely. This program is part of an X-ray system written by Sheldrick (14). The positions of all but the hydrogen atoms were found on the E map with the third lowest Karle R factor (15).

The structure was refined by large block least-squares ($\Sigma(\Delta|F|)^2$ = min) initially with isotropic temperature factors. The hydrogen atoms were located from a difference Fourier synthesis when the conventional R was 0.12. The subsequent refinement with anisotropic temperature factors on all but the hydrogen atoms converged[9] with R 0.045. The least-squares weights were calculated from $w = 1/(\sigma^2|F_o| - 0.00004|F_o|^2)$ where σ is the weight for each reflection derived from the diffractometer counting statistics. The atomic coordinates are given in Table 7,[7] and the interatomic distances and interbond angles are listed in Table 8. Fig. 1 shows a single molecule and Fig. 2 gives its packing within the unit cell.

*Preparation of the 6-Methyl (****10****) and Unmethylated (****10****) Compounds*

Using similar procedures the 6-methyl (**10**) and unmethylated (**11**) compounds were obtained from 4-picoline and pyridine respectively (yields *ca.* 4%). Compound **10** had mp 220–221°C (dec.);[10] ir (KBr): 1664, 1598, 1330, 1345, 1325, 1305,

[9]A list of the structure factors (Table 6) and full details of the atomic parameters (Table 7, including thermal factors) are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

[10]When recrystallized from acetone–water, **10** consistently had a melting point of 206–210°C.

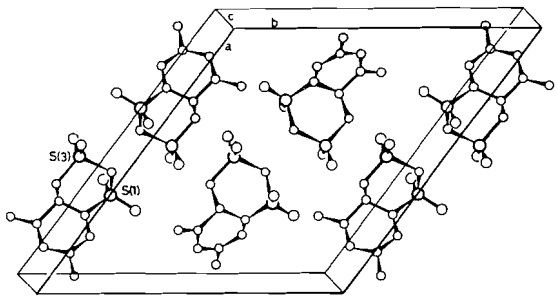

FIG. 2. The unit cell of **9**.

1170, 1130, 885, 760 cm^{-1}; for ms see Table 5; for nmr see Table 4; **11** had mp 205–206°C; ir (KBr): 1650, 1588, 1375, 1355, 1305, 1175, 1130, 880, 695 cm^{-1}; for ms see Table 5; for nmr see Table 4.

Compounds **9–11** were homogeneous on silica gel tlc using benzene–EtOAc (3:2) for elution, and could be sublimed at ca. 160°C/0.01 Torr.

*Deuteration of Methylpyridodithiazine (**10**)*

*(a) Preparation of 2,2-Dideuterated Derivative (**12**)*

A solution of **10** (45 mg) in acetone-d_6 (3 ml) was treated with D_2O (3 drops) and stirred for 18 h at 20°C, after which D_2O (1.5 ml) was added and the mixture was kept at −15°C for 18 h. The solvent was pipetted off to give **12** as colorless needles (30 mg).

*(b) Preparation of 2,2,4,4,-Tetradeuterated Derivative (**13**)*

A solution of **10** (49 mg) in acetone-d_6 was treated with 2% Na in D_2O (3 drops) and handled as in (*a*) above to give **13** (24 mg) as very slightly pink needles.

*(c) Preparation of 4,4-Dideuterated Derivative (**14**)*

Compound **10** (90 mg) was first tetradeuterated as described in (*b*) and the resulting **13** back-exchanged with H_2O-acetone as described under (*a*) to give **14** as colorless needles (31 mg).

The deuterated derivatives **12–14** all showed no depression of the melting point on admixture with **10** and were homogeneous on tlc; for ms see Table 5, and Scheme 2.

The crystal structure of $RbCdCl_3$ and the polarized Raman spectra of $RbCdX_3$ (X = Cl, Br)

MAHADEVAN NATARAJAN, HELEN ELAINE HOWARD-LOCK, AND IAN DAVID BROWN

Institute for Materials Research, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received November 30, 1977

MAHADEVAN NATARAJAN, HELEN ELAINE HOWARD-LOCK, and IAN DAVID BROWN. Can. J. Chem. **56**, 1192 (1978).

The polarized Raman spectra of single crystals of $RbCdCl_3$ and $RbCdBr_3$ (isostructural with NH_4CdCl_3) have been measured and analysed by comparison of the frequency shifts. The crystal structure of $RbCdCl_3$ refined by X-ray diffraction is also reported.

MAHADEVAN NATARAJAN, HELEN ELAINE HOWARD-LOCK et IAN DAVID BROWN. Can. J. Chem. **56**, 1192 (1978).

On a mesuré le spectre Raman polarisé de cristaux uniques de $RbCdCl_3$ et $RbCdBr_3$ (isostructuraux avec NH_4CdCl_3) et on les a analysés par une comparaison de leurs déplacements de fréquence. On rapporte aussi la structure cristalline de $RbCdCl_3$ telle qu'affinée par diffraction de rayon-X.

[Traduit par le journal]

Introduction

Studies of the vibrational spectra of mixed halides such as $A^IB^{II}X_3$ have been restricted chiefly to the fluorides, which usually crystallize with the perovoskite structure. The chlorides and bromides with B = Cd crystallize in a different structure containing double $CdCl_3$ or $CdBr_3$ chains. Adams and Newton (1) and Barr and Goldstein (2) have reported the vibrational spectra of some of these compounds. As part of our studies of the $A^IB^{II}X_3$ system we report the polarized Raman spectra of $RbCdBr_3$ and $RbCdCl_3$. We have recently refined the structure of the bromide (3) and since the structure of the chloride has previously only been studied by X-ray powder diffraction (4, 5), we also report a refinement based on X-ray diffraction measurements from a single crystal.

Experimental Details

(a) Preparation of Single Crystals

Single crystals of $RbCdCl_3$ (CAS number = 18532-58-6) and $RbCdBr_3$ (CAS Number = 16593-57-0) were grown by slow evaporation of slightly acidified aqueous solutions containing equimolar proportions of RbX and CdX_2. The reagents were of analytical grade (Alfa or BDH). Colourless needles of $RbCdCl_3$ and $RbCdBr_3$ obtained from solution, were used to grow larger crystals for the Raman spectral studies. A large single crystal of $RbCdBr_3$ was also grown by the Czochralski method. This technique was not attempted with $RbCdCl_3$ because it transforms to a perovoskite related phase above room temperature (4, 5).

(b) Refinement of the $RbCdCl_3$ Structure

Precession photographs of small crystals of $RbCdCl_3$ confirmed the orthorhombic symmetry and indicated the space group *Pnma* or $Pn2_1a$. Since *Pnma*, the space group reported for the isomorphous NH_4CdCl_3, gave a satisfactory refinement, it was assumed to be correct. Lattice parameters (Table 1) were obtained by a least-squares fit to the angular settings of 15 reflections ($9° < 2\theta < 40°$) measured on a Syntex $P2_1$ diffractometer with graphite crystal-monochromated MoKα radiation. Our values are about 0.2% lower than those reported by Swanson *et al.* (4). X-ray intensities of 1713 reflections from a single quadrant ($h \geq 0$, $k \geq 0$) were measured on the diffractometer from a crystal ground into a cylinder of radius 0.05 mm and length (along [010]) 0.25 mm. Cylindrical absorption, Lorentz and polarization corrections were applied and symmetry related reflections were averaged to give 716 unique intensities. The atomic positional parameters found for $RbCdBr_3$ (3) were assumed and these, together with anisotropic temperature factors, a scale factor and an extinction parameter were refined by the locally written full-matrix least-squares program CUDLS (CDC 6400) to yield final agreement indices $R_1 (= \Sigma||F_o| - |F_c||/\Sigma|F_o|) = 0.028$ and $R_2 (= \Sigma\omega(F_o - F_c)^2/\Sigma\omega F_o^2)^{1/2} = 0.030$. In the final round $\omega = [\sigma_c^2 + (0.2F_o^2)]^{-1}$ where σ_c is the standard error based on counting statistics. The final extinction correction applied was $F^* = F(1 + 0.747 \times 10^{-6} \times \beta(2\theta)F^2)^{-1/2}$ (6). The scattering curves for Rb, Cd, and Cl atoms corrected for anomalous dispersion were taken from the International Tables for X-ray Crystallography (7). The final atomic coordinates are given in Table 2 and a table of observed and calculated struc-

ture factors has been placed in the Depository of Unpublished Data.[1]

(c) Polarized Raman Spectra of Crystals

Single crystals 3 × 3 × 6 mm were used for spectral work. They were mounted on an X-ray goniometer and aligned by precession photographs. Faces perpendicular to the crystallographic axes were cut and polished. All spectra were recorded at room temperature. A krypton ion laser (Spectra Physics Model 164) provided plane polarized radiation at 647.1 nm. The laser beam was focussed onto the crystal which had been mounted with one of the axes parallel to the incident laser beam. A broadband polarization rotator (Model 310-21) placed in the path of the beam and a polarizer in the scattered beam permitted the selection of various components of the

Raman tensor. The spectrum of the scattered light was analysed by means of a Coderg (PHO) Raman spectrometer having an Ebert Fastie grating twin monochromator. The detector was a photomultiplier tube with an S-20 photocathode. The total instrumental width was varied from 0.5 cm^{-1} to 4 cm^{-1}. The Raman spectra of the crystals are shown in Fig. 1 for instrumental widths of 4 cm^{-1} ($RbCdCl_3$) and 2 cm^{-1} ($RbCdBr_3$) and laser power of around 150 mW at the sample.

Discussion

Structure of $RbCdCl_3$

Figure 2 shows the structure of $RbCdCl_3$ (isomorphous with $RbCdBr_3$ (3)) projected down the *b* axis. Bond lengths and angles are given in Table 3. The structure consists of double rutile-like columns of $CdCl_6$ octahedra running along the *b* axis. The columns are linked by nine coordinated Rb atoms (tris-monocapped trigonal prismatic coordination). All atoms lie in the mirror planes. The temperature factors indicate only small thermal anisotropies with rms thermal amplitudes in the range 0.13 to 0.18 Å. The structure was checked by a calculation of bond valences (8). These were summed around each atom to give experimental atomic valences (Table 4), which differ only by 0.02 valence units from the theoretical values. The bond valences, which are identical to those found in $RbCdBr_3$ (3), provide a ready understanding of the large variations found in the lengths of the bonds.

Raman Spectra

The factor group analysis of crystals with the NH_4CdCl_3 structure has been given by Adams and Newton (1) who point out that insofar as the $CdCl_3$ chains can be treated in isolation the A_g and B_{2g} spectra will be similar as will the B_{1g} and B_{3g}. All thirty g modes ($10A_g + 5B_{1g} + 10B_{2g} + 5B_{3g}$) are Raman active (9). Since NH_4CdCl_3, $RbCdCl_3$, and RbCdBr are isostructural and have bonds of similar strengths, the vibrational spectra should be identical except for the shifts resulting from the different masses of the ions. Table 5 lists the bands observed

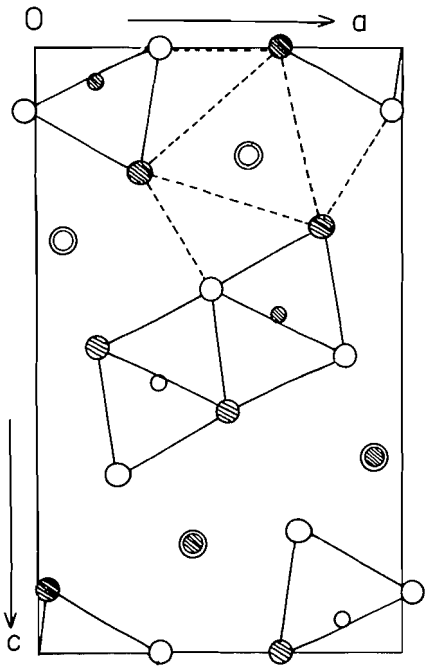

FIG. 2. Projection of the $RbCdCl_3$ structure down the *b* axis. Cadmium atoms are indicated by small circles, chlorine by large single circles, and rubidium by large double circles. Shaded atoms are at $y = 3/4$ and unshaded at $y = 1/4$.

TABLE 4. Bond valence*

	Rb	Cd	Total anion valence
Cl(1)	0.14 (×2) 0.13 (×2)	0.47	1.01
Cl(2)	0.12 (×2) 0.10	0.32 (×2)	0.98
Cl(3)	0.09 0.05	0.28 (×2) 0.33	1.03

†Region of overlapped peaks, frequencies not accurately measurable.

in the polarized Raman spectra of the three crystals together with Barr and Goldstein's (2) unpolarized spectrum of $RbCdCl_3$. The ratios of the frequencies listed in the right-hand columns show that the motions of the halogen atoms dominate in all the higher frequency modes (numbers 1–8) and those of the alkali metals dominate only in the two lowest (numbers 9 and 10). From the bond valences (10) we estimate the stretching force constants for the Cd—X bonds to lie in the range 0.5 to 1.0 mdyn $Å^{-1}$ (50–100 N m^{-1}), which should give $4A_g + 2B_{1g} + 4B_{2g} + 2B_{3g}$ modes in the region between 180 and 230 cm^{-1} for $RbCdCl_3$ and between 140 and 180 cm^{-1} for $RbCdBr_3$. In other parts of the spectra several unexpected weak bands occur and, while some of these may be caused by imperfect polarization or crystal orientation, others such as the bands at 180 and 142 cm^{-1} observed for the chlorides are more difficult to explain.

The principles according to which the acidic properties of fulvic acid solutions should be compared are demonstrated. An equilibrium function defined and measured for any mixture, including fulvic acid functional groups, will be a weighted average. A concentration change will generally affect this average by changing the relative values of the statistical weights. Concentration corrections are therefore required for the comparison of two fulvic acid solutions. A Chernozem Ah fulvic acid and the previously described Armadale fulvic acid Batch FA1 were examined in this way. They were found to have the same general chemical characteristics, but with somewhat different numerical values. The implications of these results for the definition of fulvic acid are considered.

R. Douglas Burch, Cooper H. Langford et Donald S. Gamble. Can. J. Chem. **56**, 1196 (1978).

On démontre les principes d'après lesquels on devrait comparer les propriétés acides de solutions d'acide fulvique. Une fonction d'équilibre définie et mesurée pour un mélange particulier, incluant des groupes fonctionnels d'acide fulvique, correspond à une moyenne pondérée. Un changement de concentration provoquera généralement un changement de cette moyenne en modifiant les valeurs relatives des poids statistiques. Il est donc nécessaire d'effectuer des corrections de concentration pour comparer deux solutions d'acide fulvique. On a ainsi étudié un acide fulvique Chernosem Ah et le lot FA1 d'acide fulvique Armadale décrit antérieurement. On a trouvé qu'ils ont les mêmes caractéristiques chimiques générales mais qu'ils présentent des valeurs numériques un peu différente. On considère les implications de ces résultats pour la définition de l'acide fulvique.

[Traduit par le journal]

Introduction

Stevenson has recently noted that since humic acids are mixtures, the equilibrium functions for their cation reactions must be averages (1, 2). This point had previously been developed theoretically and demonstrated experimentally for a fulvic acid (3–5). The basis for this is that the structure of fulvic acid is so irregular that no two of its carboxyl groups can be assumed to be chemically identical. They must, therefore, be considered to be a mixture of chemically different carboxyl groups. Such weighted average equilibrium functions will generally depend on solution composition, and in particular a concentration dependence can be anticipated. Stevenson has, in fact, observed such an effect experimentally for a particular humic acid (1). Since fulvic acid solutions may differ either because the dissolved fulvic acids are different or simply because they have different concentrations of the same fulvic acid, this introduces at least two important practical problems. The first is that concentration effects must be accounted for in any quantitative comparison of experimental results for different fulvic acids or from different laboratories. The second is that methods must be available for translating quantitative laboratory results into the field conditions of practical systems. Reported values for organic matter concentrations in soil solutions and surface waters range from about 1.0×10^{-4} g/ℓ to 1.6 g/ℓ (6–9). McKeague *et al.* (10) have postulated that a Podzol leachate might typically have 0.1 g/ℓ. Laboratory investigations, however, are generally restricted to somewhat narrower ranges of concentrations. In addition, there has to date been only one fulvic acid sample for which the weak acid properties have been quantitatively characterized in detail (3–5). It is important, from the agricultural and geological points of view, to know what chemical characteristics, if any, are common to most fulvic acids. In fact, since

the term fulvic acid is defined by a separation procedure rather than a molecular constitution, and a given sample contains numerous structural features, some of which may be more or less 'accidental' and unrelated to differences in acidic properties, the question of identifying what chemical factors are common to various preparations is the question of improving the definition of fulvic acid. Schnitzer and co-workers (11, 12) have extensively investigated the organic chemistry from this point of view, but this has not yet been done quantitatively for equilibrium cation reactions. H^+ dissociation is not only the simplest such case, but is also prerequisite to investigations of metal ion binding.

The objectives of this work were, therefore, to characterize the weak acid properties of a second fulvic acid, and to demonstrate concepts according to which fulvic acid solutions differing in either nature of the solute or concentration should be compared.

The fulvic acids used for this purpose were an Alberta Chernozem material, and the previously described Armadale fulvic acid Batch FA1 (3–5).

Type A functional groups, that is, carboxyl groups titrated up to the first titration equivalence point (4, 5), dominate the acidic properties of fulvic acid. In addition, there is evidence of long standing (5, 13–18) which indicates that some of them are in *ortho* positions relative to phenolic OH groups. They are, therefore, important for the bidentate chelation of heavy metal ions. The properties of these type A carboxyl groups are, therefore, assumed to be of central importance to any quantitative comparison of fulvic acids.

Theory

It has previously been shown that for a mixture of type A non-identical carboxyl groups, the acid dissociation equilibrium function is a weighted average of the K_{Ai}'s of the mixture of components (3–5). This is described by [1], in which α_A is the macroscopic degree of ionization for the whole mixture, and $\Delta(1 - \alpha_A)_i$ is the statistical weight of the ith component. ΔG_{Ai}^e is an electrostatic free energy term, and Γ_{Ai} is an activity coefficient term. Each of these terms will generally be a function of α_A. There are at least three possible reasons for the observed dependence of $\bar{K}_A$ on α_A. The first is that a change in α_A implies some change in the composition of the system. The corresponding changes in thermodynamic activities have the result that Γ_{Ai} and K_{Ai}^0 are both functions of α_A. This effect will often be a secondary one, however. A more important point is that for polymeric or aggregated species, electrostatic charge accumulates with increasing α_A, so that $\Delta G_{Ai}^e = f(\alpha_A)$ (4, 19, 20). The third reason, which is implicit in [1], has not previously been considered. It is most important, however, for the comparison of samples having different carboxylate group densities. This point is that $\bar{K}_A$ depends on the behaviour of the statistical weights, $\Delta(1 - \alpha_A)_i$. The nature of this effect may be seen by considering the acid dissociation of the ith small portion of the mixture. Equation 2 describes the equilibrium.

$$[1]\quad \bar{K}_A = \frac{1}{(1-\alpha_A)}\sum_{i=0}^{M} K_{Ai}\Gamma_{Ai} \times \exp(-\Delta G_{Ai}^e/RT)[\Delta(1-\alpha_A)]_i = \frac{m_A m_H}{m_{AH}}$$

$$[2]\quad K_{Ai} = \frac{m_H m_{Ai}}{m_{AiH}}$$

Rearranged, this gives [3];

$$[3]\quad [\Delta(1-\alpha_A)]_i = \frac{(C_{Ai}/C_A)m_H}{(K_{Ai} - m_H)}$$

C_A is the total concentration of the type A mixture of carboxyl groups, and C_{Ai} is the total for the ith portion of this mixture. Assuming that there are no gains or losses of components, then $(C_{Ai}/C_A) = \chi_{Ai}$ = constant. Since

$$\bar{K}_A \equiv \bar{K}_A(\alpha_A) = \left(\frac{\alpha_A}{1-\alpha_A}\right) m_H$$

therefore,

$$[4]\quad m_H \equiv m_H(\alpha_A) = \bar{K}_A(\alpha_A)\left(\frac{1-\alpha_A}{\alpha_A}\right)$$

The ith statistical weight is therefore a decreasing function of α_A, as described by [5] and [6].

$$[5]\quad [\Delta(1-\alpha_A)]_i = \frac{\chi_{Ai} m_H(\alpha_A)}{K_{Ai} + m_H(\alpha_A)} = f_i(\alpha_A)$$

$$[6]\quad \frac{d[\Delta(1-\alpha_A)]_i}{d\alpha_A} = \chi_{Ai}\left[\left(\frac{1}{K_{Ai}+m_H}\right)\frac{dm_H}{d\alpha_A} + m_H\frac{d(K_{Ai}+m_H)^{-1}}{d\alpha_A}\right]$$

For any two components of the mixture, the general case is that

$$[7]\quad \begin{cases} \chi_{Aj} \neq \chi_{Ak} \\ K_{Aj} \neq K_{Ak} \end{cases}$$

$$[8]\quad \frac{d[\Delta(1-\alpha_A)]_j}{d\alpha_A} \neq \frac{d[\Delta(1-\alpha_A)]_k}{d\alpha_A}$$

According to [8], a change in the degree of ionization will change the relative values of the statistical

Difference		3.0 ±0.28	2.71±0.31	0.31±0.45

weights. This will cause a change in the numerical value of $\bar{K}_A$, the weighted average.

The dependence of $\bar{K}_A$ on concentration and neutralization may now be determined by considering the properties of α_A. From the material balance for total base,

$$[9] \qquad m_A = C_{OH} + m_H - m_{OH}$$

where m_A is the molality of ionized type A carboxyl groups. Equation 10, which is obtained directly from this, may be used together with [4] and an empirical function, [11], for predicting the effects of concentration and neutralization on $\bar{K}_A$.

$$[10] \qquad \alpha_A = y_A + \frac{m_H + K_w/m_H}{C_A}$$

$$[11] \qquad \bar{K}_A = \bar{K}_A(\alpha_A)$$

Y_A is the degree of neutralization, $Y_A = C_{OH}/C_A$.

It is concluded from this that the empirical function, [11], may be obtained from an acid–base titration at one constant concentration, and then used for calculating $\bar{K}_A$ at any other concentration and degree of neutralization. Such a calculation, therefore, requires that the experimental curve of [11] be independent of concentration. An experimental check of this point is important, because any structural changes that might arise from extensive hydrogen bonding or aggregation would be expected to introduce a concentration dependence.

Experimental

Fulvic Acid

The fulvic acid was obtained from the Ah horizon of an Orthic Black Chernozemic soil at a well drained Alberta site (Lat. 50° 11′, Long. 114° 57′). The fulvic acid was extracted and purified according to the previously described methods of Schnitzer and co-workers (3, 4, 17, 21, 22). A Coleman Model 33 C, H Analyser and a Coleman Model 29 N Analyser were both used. S analysis was done by O_2 flask combustion and titration with barium perchlorate. Metal ion analyses were done using nitric–perchloric–HF wet digestion in Teflon beakers, followed by measurements with an atomic absorption spectrophotometer. Table 1 gives the results.

Chemicals

H_2O was redistilled under nitrogen. All other chemicals were certified standards or reagents.

Experimental Methods

The apparatus, techniques, and calculation procedures for acid–base titrations have been described previously (3–5). Six titration curves having a total of about 700 data points were averaged by least-squares fitting. Final calculations of acidic

properties were done with this average titration curve. Titration temperature was 25.00°C ± 0.05.

Results and Discussion

The titration equivalence points in Table 2 were calculated from the averaged titration curve in Fig. 5.[3] The calculation method has been previously described (3). It is evident from Table 2 that the Chernozem Ah and Armadale Bh fulvic acids both have two titration equivalence points. Within the limits of experimental error, they also have approximately the same number of type B carboxyl groups. There is a substantial difference, however, in the type A carboxyl groups. The Chernozem fulvic acid has about 2.7 (mmol/g) fewer than does the Armadale Batch FA1. The chemical analyses in Table 1 indicate that this difference cannot be accounted for by the blocking of functional groups by metal ions. Essentially all of the ash content is SiO_2, which should not block carboxyl groups.

The weighted average equilibrium functions in Tables 3 and 4 are both smaller than the corresponding values published for the Armadale Batch FA1 (3–5). Qualitatively, however, both fulvic acids show the same features. In each case $\bar{K}_A$ is a decreasing function of α_A, while $\bar{K}_B$ is evidently constant to within the experimental errors.

The theoretically predicted concentration dependence of $\bar{K}_A$ has been tested experimentally with Batch FA1 fulvic acid. Figure 1 demonstrates that within the limits of error, the $\bar{K}_A = f_A(\alpha_A)$ curve has the required independence of concentration. The concentration dependence of $\bar{K}_A$ therefore reflects simply the behaviour of $\alpha_A = \alpha_A(C_A, Y_A)$. Figure 2 indicate a close agreement with theory. This result permits a direct comparison of the experimental $\bar{K}_A$ values of the two fulvic acids. This has been done in Fig. 3. It can be seen here that correcting for the difference in carboxyl group concentrations will decrease the apparent difference in $\bar{K}_A$ values. In the greatest case, this accounts for about half of the difference. An important result is that even after this correction, the Chernozem type A carboxyl groups are less acidic than are those of the Armadale Batch FA1. Figure 4 further supports this conclusion with a comparison of K_A curves for the two fulvic acids.

It should be noted in Fig. 4 that qualitatively the two fulvic acids again have some important features in common. In each case, the K_A curve has a steep region I and a flat region II, separated by an inflection point. According to strict logic, a comparison of K_A vs. α_A curves would be more correct since α_A again introduces a concentration dependence. The curves in Fig. 4 were found to be more instructive, however, because the relative stoichiometries of the inflection points and equivalence points are readily seen.

An initial objective of this research was to test alternative criteria according to which fulvic acid could be defined. Molecular structure is not a sufficient criterion for this purpose, since in contrast to monomeric pure compounds, fulvic acid is not characterized by a single and unique structure (11). We, therefore, sought physical chemical parameters that would serve to characterize a particular sample. Since present definitions relate to the method of extraction, and p*H* and ion exchange control are used in extraction, the acid titration curve seemed to be the most promising means of achieving this. As has been noted above, this further requires a proper consideration of the concentration of carboxylates. Successful application of the concentration correction permits one to conclude that essentially the same extraction procedure has produced two fulvic acids

Determination of stability constants by p*H* titrations: a critical examination of data handling

TERRENCE B. FIELD AND W. A. E. MCBRYDE

Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received July 28, 1977

TERRENCE B. FIELD and W. A. E. MCBRYDE. Can. J. Chem. **56**, 1202 (1978).

Data from simulated titrations (p*H*, titer, and p*M*) were generated from literature values of equilibrium constants, and then submitted to various published methods of calculation to regenerate the indicated equilibrium constants. These calculations were done with error-free input data, and the same with imposed random errors. In other experiments data from real titrations were subjected to the same analysis, and additional checks were made on the output of the calculations with an ion-selective electrode as a probe for p*M*. One method of data analysis was prone to cause errors in the finally recovered constants, and causes for this are suggested.

TERRENCE B. FIELD et W. A. E. MCBRYDE. Can. J. Chem. **56**, 1202 (1978).

On a pu déterminer des données de titrations simulées (p*H*, titre et p*M*) à partir de valeurs extraites de la littérature pour des constantes d'équilibre; on a ensuite soumises ces valeurs à diverses méthodes de calcul qui avaient été publiées pour regénérer les constantes d'équilibre indiquées. On a effectué ces calculs en introduisant les données sans erreurs ou avec des erreurs occasionnelles imposées. Dans d'autres expériences, on a soumis des données provenant de titrations réelles à la même analyse et des vérifications additionnelles ont été faites sur le produit de ces calculs avec une électrode sélective vis-à-vis un ion comme sonde pour le p*M*. Une méthode d'analyse des données était susceptible de causer des erreurs dans les constantes récupérer à la fin et on suggère des causes pour cet état de chose.

[Traduit par le journal]

Introduction

For collecting data with which to evaluate acidity constants of weak acids or bases or stability constants of metal complexes titrations are often preferred because of their capability of furnishing a large amount of experimental information from the interaction of a small number of standardized solutions. The subsequent numerical manipulation of the data so collected can take various forms according to the amount and kind of information available. This paper reports a study of one recently described way of conducting titrations and utilizing the results for the calculation of metal complex stability constants, and compares this with some longer established practices.

Sarkar and Kruck (1) recently extended a procedure developed by Osterberg (2) to determine p*L* in the presence of metal ions by p*H* titration, showing that it could also be applied to determine p*M*. This proposal possesses two desirable characteristics; first, that p*M* and p*L* can be measured during the formation of complexes without regard to which species may subsequently be inferred to be present; secondly, that it is not vitiated, as some other procedures are, by the formation of protonated or deprotonated complex species. An independent derivation of the relationships underlying this method (3) appears to confirm the limitation stated by Osterberg that it should be applied only to mononuclear complexes. Certain features of the procedure have come to light during extensive use of it, and these are described here for the benefit of other prospective users.

Data Treatment

At any point in a titration designed to study metal-complex formation there will be three stoichiometric concentrations: C_H, C_M, and C_L. C_H is the net concentration of ionizable hydrogen, i.e., the total ionizable hydrogen put in as ligand, mineral acid, etc., *less* the total of any strong base added as titrant, etc.; C_M is the total concentration of metal in all species; and C_L is the total concentration of ligand in all species. The concentrations of the corresponding unbound species will be represented by square brackets, e.g., [H], or in exponential form, e.g., p*H*. Strictly speaking the latter should be written as p[H], but the simpler notation will be used. Suitable probes such as the glass electrode, suitable metal-ion-sensitive electrodes, and a few electrodes of the second kind, can be calibrated in terms of the concentrations of hydrogen ion (4), metal ions (5), or ligand, respectively, and thus used to determine p*H*, p*M*, or p*L*.

A set of values of C_M, C_L, and C_H defines a point in a titration of the sort being considered, and might be designated the external coordinates of that point. There is also a set of internal coordinates, [M], [L], and [H] which are uniquely defined for that point by the outer coordinates and the relevant equilibrium

constants in accordance with eqs. 1 to 3. The complex species formed in solution may be represented by $M_pH_qL_r$, with formation constant β_{pqr}. Where $p = 0$ the species are protonated forms of the ligand; where $r = 0$ the species are products of hydrolysis of the metal ion; metal complexes may form in which q is positive, negative, or zero. In this discussion these are stoichiometric equilibrium constants the justification for whose use is the implicit assumption that they apply to systems of constant, and probably appreciable, ionic strength. Simple mass balances then yield the following relationships:

$$[1] \quad C_H - [H] + [OH] = \sum^{p}\sum^{q}\sum^{r} q\ \beta_{pqr}\,[M]^p[H]^q[L]^r$$

$$[2] \quad C_M - [M] = \sum^{p}\sum^{q}\sum^{r} p\ \beta_{pqr}\,[M]^p[H]^q[L]^r$$

$$[3] \quad C_L - [L] = \sum^{p}\sum^{q}\sum^{r} r\ \beta_{pqr}\,[M]^p[H]^q[L]^r$$

Determination of β_{pqr} by Measurement of [H] Only

In the absence of protonated or deprotonated metal complexes [1] can be used to evaluate [L] from C_H and [H], provided protonation constants of the ligand are known; then [2] can be used to evaluate the auxiliary function $\bar{n}$ for each point in the titration. Since for mononuclear metal complexes $\bar{n}$ is a function of [L] and the metal complex stability constants only, a variety of procedures, numerical and graphical, have been suggested for finding the latter from sets of values $\bar{n}$,[L]. Even for a limited number of polynuclear species such data are capable of yielding satisfactory formation constants (6). It has, however, been observed that for certain systems of stable complexes this treatment of experimental data can lead to erroneous results (7, 8).

The use of computers for handling the determination of stability constants enables more complicated systems to be dealt with. For example, the computer program SCOGS (9) refines trial values of equilibrium constants for postulated species by systematically adjusting these constants in such directions as to minimize the sum of squares of residuals which are the difference between the titer calculated by the provisional constants and the observed titer. Since the titer is a factor determining C_H, the strategy of this program might be described as a search for equilibrium constants that yield a calculated value of this coordinate closest to the observed value. The method can accommodate complex species that are protonated, hydrolyzed, or polynuclear, and has the further capability not utilized in this study of handling two metals and/or two ligands and the formation of mixed complexes. For each point in a titration the output includes indicated values of [M] and [L] and, importantly, the residual. Trends in the values of the latter can often be a guide to inclusion of other species to give a more complete description of the system of complexes. As with the simpler Bjerrum procedure mentioned previously, the formation of very stable complexes can give rise to difficulties owing to the inability of the mass balances to give precisely defined values of [M] or [L] during the calculations.

Determination of β_{pqr} by Solving Linear Equations

If all three inner coordinates were known for each point throughout a titration the values of these and the external coordinates could be inserted into [1], [2], and/or [3] to yield a set of linear equations in the β_{pqr} the solution of which is relatively simple by a linear least-squares matrix inversion procedure (LLSQ). This procedure is, in contrast to SCOGS and similar programs, very economical of computer time. Sarkar and Kruck have shown how pH titrations may be utilized to yield values of the other two inner coordinates. Before commenting on their procedure further, some account is offered of an alternative strategy incorporating the solution of linear equations in β_{pqr}.

If two of the inner coordinates are measured for each point in a titration values of the third can be found, as well as equilibrium constants for postulated species, by a simple iteration based on the same LLSQ routine. In this case provisional values of [L] or [M], whichever are now known, are put into a set of [2] or [3] respectively; these are solved to give first estimates of the β_{pqr} for the assumed complex species. The first provisional values are such as would apply if *no* metal complex formation occurred. With the trial constants new values of [L] or [M] can then be found by treating [3] or [2] in the same way, and the process is repeated until convergence occurs. When suitable probes for [M] or [L] are available this procedure is much to be recommended, especially for systems of very stable metal complexes for which methods based on measurement of [H] alone will sometimes give rise to difficulties. A computer program designated CLLSQ was written to accomplish the treatment of data.

The HOSK Method and Computer Program

Osterberg (2) showed that the differential quotient of two external coordinates of a titration $(\partial C_H/\partial C_L)_{H,C_M}$ could be evaluated experimentally at selected values of pH, and that this function could be used to determine the difference in pL between two points differing in pH (eq. 4).

$$[4] \quad pL - pL_0 = \int_{pH}^{pH_0} (\partial C_H/\partial C_L)_{H,C_M}\, dpH \Big|_{C_L}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

If pH_0 is selected such that at it pL_0 is known, e.g., a value low enough that no metal complex formation occurs, then [4] can be used to find pL at any other chosen pH. Sarkar and Kruck (1) showed that the analogous function $(\partial C_H/\partial C_M)_{H,C_L}$ could be determined experimentally and used to determine pM at a selected pH provided that at some reference pH_0 the value of pM_0 was known [5].

$$[5] \quad pM - pM_0 = \int_{pH}^{pH_0} (\partial C_H/\partial C_M)_{H,C_L}\, dpH \Big|_{C_M}$$

In practice, to obtain C_H, C_L, and C_M at constant [H] each is curve-fitted vs. pH and values taken from the curve at the same pH for each titration. Then all C_H and C_L values at the same pH are curve-fitted at constant C_M and $(\partial C_H/\partial C_L)_{H,C_M}$ calculated from the curve. In the same way C_H and C_M values generate $(\partial C_H/\partial C_M)_{H,C_L}$. The values of these differential quotients are then curve-fitted vs. pH, and integrated by Simpson's rule from pH_0 to pH to get either pL or pM from pL_0 or pM_0 and the area under the curve. This is done for each pH for which values of pL and pM are desired. The initial pH, called pH_0, is chosen so that no significant metal complex formation occurs. This is generally one pH unit lower than the initial pH used in SCOGS or CLLSQ. At pH_0, $pM = -\log C_M$, and $pL_0 = -\log C_L(1 + \beta_{011}[H] + \beta_{021}[H]^2 + \cdots)^{-1}$ where β_{011} are protonation constants of the ligand.

All of the foregoing evaluations have been incorporated into a single computer program designated HOSK (Hedström, Osterberg, Sarkar, Kruck), which then continues to evaluate equilibrium constants for selected species by the subroutine LLSQ described previously. The complete program is available from the authors on request. It differs from those developed by Sarkar and Kruck in a number of important respects too detailed to itemize here. In general the HOSK program makes no simplifying assumptions and includes all corrections, as for dilution, etc.

Tests of Data Handling

The initial objective to evaluate the Sarkar–Kruck procedure and the computer program HOSK has been extended to some other data-handling procedures. Evaluation was based on the following: (*i*) the ability of the method to regenerate initial values of equilibrium constants from simulated titration data (pH, titer) which had been calculated for certain model systems with the aid of equilibrium constants from the literature. The simulated titration data were applied both error-free and with varying amounts of superimposed random error. It was possible in this way to check the data handling by HOSK at each stage, e.g., errors in curve fit of C_H, C_L, or C_M, comparison of found vs. theoretical values of $(\partial C_H/\partial C_L)$, etc., recovery of pL or pM values, and effects of changing pH_0, pH_{start}, or pH_{end} on these, and so forth. (*ii*) Comparisons of values of equilibrium constants as found by several methods from data obtained in titrations of real systems. (*iii*) Comparisons of pM values calculated from real titration data with values obtained directly with a metal-ion sensitive electrode.

In addition to the HOSK and SCOGS computer programs, certain simpler procedures were applied to the simulated or real titration data. These included the CLLSQ method mentioned previously and a simple procedure suggested by Romary (10) to solve the Bjerrum relationship for the several β values simultaneously by matrix column elimination. Two other very simple methods were also tested, although their usefulness is somewhat restricted: these are the HALF-$\bar{n}$ values of pL (11), and a DIRECT method in which individual solutions are found for the equation

$$\log K_i = pL_{\bar{n}} + \log(\bar{n} - i + 1) - \log(i - \bar{n})$$

Results

A number of stability constants obtained by the foregoing computational procedures from input data based on real or simulated titrations are shown in Tables 1–7 and 9. In addition to this evidence the authors have over a period of three years accumulated comparable data from many hundreds of titrations in aqueous and mixed solvent systems which support the conclusions drawn in this paper.

Tables 1–4 illustrate the common case of determining metal–complex stability constants. When small errors, comparable to those that might accidentally be incurred in practice, are applied to simulated titration data the starting constants are reasonably well recovered. It is to be stressed that the grouped sets of results in these tables have been calculated from a common set of input data, so that any variation among the constants must be attributed to the method of processing the data. Tables 3 and 4 contain two groups of results according to whether the titrations are conducted from low pH to high, or vice versa.

Tables 5 and 6 illustrate what happens to the stability constants and other parameters derived from these various calculations when the random error on the simulated titration data is progressively increased. The titration volumes onto which the random error is loaded were in all cases less than 1 cm^3. The initial volume was 50.0 cm^3 in all cases.

Tables 7 and 9 show the recovery of equilibrium

constants for systems more complicated than the preceding examples. The copper(II) citrate system (Table 7) has been interpreted by several investigators to include one or more binuclear complexes; since the HOSK procedure has only been shown valid for mononuclear species there was interest in checking how it handled data for a non-conforming case. The iron(III) citrate system has been interpreted in terms of three 1:1 complexes differing in degree of protonation; it is known at first hand to be extremely sensitive to variance in experimental data. Incidentally, to do a HOSK analysis requires data from three titrations at least. However five titrations will allow the curve fitting routine to work on C_H vs. C_L and C_H vs. C_M (i.e. 3 points for 2 coefficients: slope and intercept). In Table 8 we show how data from nine titrations were arranged in sets of five to give enough information for nine independent calculations of stability constants; from these in Table 9 we show the minimum, mean, and maximum values obtained.

Discussion

The results in Tables 1 and 3 show that the assumed values of the metal complex stability constants are fairly successfully regenerated when simulated titration data are treated by the three methods of data analysis, SCOGS, HOSK, or CLLSQ, especially when the input data are applied error-free. When small random errors about equivalent to those associated with real titrations are superimposed the results are still quite good though some small discrepancies are noticeable, viz., line 14, Table 1, or lines 5 and 11, Table 3. In Tables 5 and 6 one can see the onset of more serious errors in the regeneration

of stability constants as increasing amounts of random error are applied to the titer or the p*H* in typical titration data. It is clear that none of the methods of data analysis can tolerate input data of poor quality, and it appears that the HOSK treatment is the most susceptible to invalidation from this cause.

Provided that p*M* is accurately measurable by an auxiliary probe CLLSQ gives excellent recovery of

known equilibrium constants; and it is a feature of this procedure that it is insensitive to variance in the titer and relatively insensitive for many complexes to uncertainty in pH values.

Experience with simulated titration data has revealed that the SCOGS program consistently achieves good recovery of the starting equilibrium constants (with the possible exception, as already noted, of values for unusually stable metal complexes) and also the smallest values of standard deviations in pM and pL. In view of this performance the authors have come to place most reliance on this program to indicate 'correct' equilibrium constants derived from real titrations, and hence to provide a basis for comparison of other methods. While limited in its application to systems of simple mononuclear complexes, ML_r, the ROMARY program, insofar as we have tested it, performed almost as well as SCOGS and required only a fraction of the computer time demanded by the latter. The procedures HALF-$\bar{n}$ and LINEAR perform well only on systems where there is no overlap of equilibrium constants; for the copper–glycine complexes ($K_1/K_2 = 23$) these methods consistently returned slightly high values of K_1 which in turn led to values of pM higher than the preceding methods.

Turning to results based on real titrations we note in Tables 2 and 4 two kinds of discrepancies warranting comment. The first is a tendency for the HOSK procedure to generate equilibrium constants significantly at variance with those from SCOGS and the other methods illustrated here. An extreme case is seen in line 5, Table 4, although the base titrations gave some poor results in line 4a as well. Smaller discrepancies are apparent in line 2, Tables 2 or 4. But these tables reveal only a few such problems. We have determined 25 different pK values and 65 different stability constants for glycine and iminodi-

acetic acid and their complexes with three metals in aqueous and in aqueous methanol solutions. The actual results will be published in the near future. The data were so taken as to permit them to be processed in the various ways described in this paper. Good agreement was found among the results based on SCOGS, ROMARY, HALF-$\bar{n}$, and DIRECT calculations. In 6 of the pK's and 38 of the log β values the results from the HOSK calculation differed by more than 0.2 unit from the remainder. Of these 38, twenty-five differed by 0.5 unit or more from the remainder and that number included five negative values.

The second discrepancy to note appears in Table 4 in the form of lower values for log β_{102} generated by the CLLSQ procedure as compared to those found

by SCOGS or HOSK. Agreement among these values is much better in Table 2. In view of the excellent recovery of equilibrium constants when CLLSQ was applied to simulated titration data it must be concluded that a systematic error has been introduced into the experimental values of pM through nonlinear response of the probe electrode at low concentrations of copper ion in the ethylenediamine study. This inference is supported by comparison with pM values calculated by SCOGS. No such systematic error appears in the pM data shown in Table 10 where experimental values determined by two electrodes are compared with values calculated from the constants generated by SCOGS and HOSK for the system copper(II)–glycine. The HOSK values showed appreciably larger deviations than those obtained by SCOGS.

The results given in Tables 7 and 9 indicate that even with error-free titration data the HOSK treatment is less successful than the other two methods in regenerating equilibrium constants for the systems selected. It is particularly noteworthy that HOSK returned a poor value for log β_{202} in Table 7 since the method has not yet been shown capable of dealing with polynuclear complex species.

Sources of Error in HOSK Method of Data Treatment

We have sought causes for the occasional appearance of evidently incorrect values among the equilibrium constants generated by HOSK. In general the problem arises from the large amount of data handling required by this method, and in the necessity to set values of pM_0 and pL_0 for evaluating [4] and [5]. Our analysis suggests that the standard deviations in pM and pL derived by this method are often higher than the corresponding quantities found by other methods (see Tables 5 and 6), though errors in these are to some extent compensated in the calculation of stability constants, especially for 1:1 complexes, owing to the fact that $(\partial C_H/\partial C_L)_H$ and $(\partial C_H/\partial C_M)_H$ are in part reciprocally related (3).

Some specific difficulties in this procedure are discussed next.

Evaluation of C_H

Both SCOGS and HOSK depend on accurate evaluation of C_H. The necessity in the latter method to extend titrations to an extreme pH (= pH_0) at which pH or pM can be evaluated from C_L or C_M leads to a situation where C_H may become poorly defined. This problem can be avoided in the other methods by restricting the data to the buffer regions ($0.2 < \bar{n} < 0.8$, etc.). To fix the high pK of an amino acid by the HOSK method requires that the titration be carried to a high pH where [L] $\sim C_L$. In this region $C_H = C_L$ − added base, and is poorly defined; this lack of definition carries over into $(\partial C_H/\partial C_L)_H$

TABLE 9. Calculated formation constants for iron(III)–citrate complexes, simulated titration data (9 sets), input values: log β_{111} = 12.37, log β_{101} = 11.18, log β_{1-11} = 8.49(11)

and hence pL. When enough base has been added C_H is well defined but negative resulting in a negative $(\partial C_H/\partial C_L)_H$ and a pL smaller than pL_0. Likewise to start a titration involving metal complexes at a pH low enough for [M] = C_M may require the addition of so much acid that C_H (= added acid − added base) is poorly defined over much of the titration. At the start of the titration for small added base C_H is well defined but usually a trend in C_M results in a change of sign for $(\partial C_H/\partial C_M)_H$. (This is the problem in line 5*b*, Table 4.)

Evaluation of $(\partial C_H/\partial C_L)_H$ *or* $(\partial C_H/\partial C_M)_H$

For metal–ligand systems the plots of C_H vs. C_L or C_H vs. C_M may depart from linear, the more so if $\bar{n}C_M$ is not much less than C_L (3). Curve fitting in this event becomes more difficult, and errors in taking derivatives are more apt to be introduced.

The same values of the derivatives are obtained no matter which titration is considered for pM and pL evaluation when C_H vs. C_L and C_H vs. C_M are linear. When these plots are curved, errors in taking the derivatives are greater than differences between selecting separate titrations for pM and pL calculations.

Occasionally the assignment of pH_0 may be too low or too high. For metal–ligand complexes $(\partial C_H/\partial C_M)_H$ should be essentially zero at pH_0, and then steadily increase for a few points. If pH_0 is chosen too high this differential quotient starts with a positive value, or the converse if pH_0 is too low. The consequences are respectively to over or underestimate β_{pqr}.

It should be noted that the simulated titration curves had the same small changes, due to dilution correction, in C_M and C_L as for the experimental data. From Tables 1 and 3 no major problem is caused by this 1 to 2% change in C_M and C_L for simulated data. Since all titrations require similar volumes of titrant C_M is essentially constant at each pH for $(\partial C_H/\partial C_L)_{H,C_M}$ and C_L is essentially constant at each pH for $(\partial C_H/\partial C_M)_{H,C_L}$. When the constants are calculated, dilution-corrected C_M and C_L values are used with the result of cancelling most of this effect upon the constant.

Uncertainty in Data

As a consequence of the two preceding difficulties values of $(\partial C_H/\partial C_M)_H$ are ill-defined in the unbuffered regions of the titrations from which data are required in order to perform the integration of [5]. Close examination shows that in a number of such cases the values of $(\partial C_H/\partial C_M)_H$ fluctuate, sometimes positive, sometimes negative, and the integration leads to poor estimates of pM.

To sum up then, the HOSK method is capable of yielding, without the user's knowledge, results for pM, pL, and the several β_{pqr} that are appreciably in error. Prospective users of the method should acquaint themselves fully with the factors that may cause such erroneous results, and should perform checks on results by an independent computational method.

Experimental

Titrations were carried out in a thermostatted glass vessel maintained at 25.0°C, with solutions containing 0.1 M $NaNO_3$ as background electrolyte. Titrant was added from a 0.5 cm^3 syringe dispenser equipped with micrometer drive. Measurement of pH was made by the response of a Beckman glass electrode (#39301) calibrated with NBS buffers. Measurement of pM was by an Orion solid state copper(II) ion-selective electrode (#94-29) calibrated with solutions of known metal ion concentration. The titration vessel was wrapped in foil owing to the light-sensitive response of the latter electrode. These electrodes with suitable reference electrodes were connected to the input of suitable pH meters (Orion 801 or Radiometer No. 4). Analar-grade glycine was recrystallized before use; ethylenediamine was dried by potassium hydroxide and by sodium metal, and then distilled. All other chemicals were of reagent grade, and solutions were standardized by well established methods. Titrations were carried out and alkali solutions were stored under nitrogen to restrict carbonate formation.

Details of the synthesis and physical properties of octahedral transition metal complexes of the tridentate tris chelating ligand $[Me_2Ga(OCH_2CH_2NH_2)(N_2C_3H_3)]^-$ are given. Crystals of *sym-fac*-bis[dimethyl(ethanolamino)(1-pyrazolyl)gallato(*N*(2),*O*,*N*)]nickel(II) are monoclinic, $a = 11.7908(6)$, $b = 7.3158(6)$, $c = 12.5797(8)$, $\beta = 97.035(7)°$, $Z = 2$, space group $P2_1/n$ and crystals of the *mer* isomer are monoclinic, $a = 18.6617(7)$, $b = 8.7941(4)$, $c = 13.5670(8)$, $\beta = 91.766(4)°$, $Z = 4$, space group $P2_1/c$. The structures were solved by Patterson and Fourier syntheses and were refined by full-matrix least-squares procedures to final R values of 0.048 and 0.052 for 1881 and 2573 reflections with $I \geq 3\sigma(I)$ for the *fac* and *mer* isomers respectively. The nickel atoms in both structures were found to have distorted octahedral coordination geometry. Bond lengths (corrected for libration) are: Ni—O, 2.090(3); Ni—N, 2.085(3) and 2.112(3); Ga—O, 1.908(3); Ga—N, 2.010(3); and Ga—C, 1.979(5) and 1.981(6) Å for the *fac* isomer, and Ni—O, 2.045(4) and 2.049(4); Ni—N, 2.091(4)–2.156(5); Ga—O, 1.898(4) and 1.899(4); Ga—N, two at 1.991(5); and Ga—C, 1.948(8)–1.971(7) Å for the *mer* isomer.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **56**, 1212 (1978).

On rapporte les détails de la synthèse et des propriétés physiques de complexes octaédriques de métaux de transition du ligand tris chélatant tridentate $[Me_2Ga(OCH_2CH_2NH_2)(N_2C_3H_3)]^-$. Les cristaux du bis[diméthyle(éthanolamino)(pyrazolyl-1)gallato(*N*(2),*O*,*N*)]*sym-fac* de nickel(II) sont monocliniques $a = 11.7908(6)$, $b = 7.3158(6)$, $c = 12.5797(8)$, $\beta = 97.035(7)°$, $Z = 2$, groupe d'espace $P2_1/n$ et les cristaux de l'isomère *mer* sont monocliniques, $a = 18.6617(7)$, $b = 8.7941(4)$, $c = 13.5670(8)$, $\beta = 91.766(4)°$, $Z = 4$, groupe d'espace $P2_1/c$. On a résolu les structures par les méthodes de Patterson et de Fourier et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs finales de R qui sont respectivement de 0.048 et 0.052 pour 1881 et 2573 réflexions avec $I \geq 3\sigma(I)$ pour les isomères *fac* et *mer*. On a trouvé que les atomes de nickel dans chacune des structures possèdent une géométrie de coordination octaédrique déformée. Les longueurs de liaison (corrigées pour la libration) sont: Ni—O, 2.090(3); Ni—N, 2.085(3) et 2.112(3); Ga—O, 1.908(3), Ga—N, 2.010(3) et Ga—C, 1.979(5) et 1.981(6) Å pour l'isomère *fac* et Ni—O, 2.045(4) et 2.049(4); Ni—N, 2.091(4)–2.156(5); Ga—O, 1.898(4) et 1.899(4); Ga—N, deux à 1.991(5) et Ga—C, 1.948(8)–1.971(7) Å pour l'isomère *mer*.

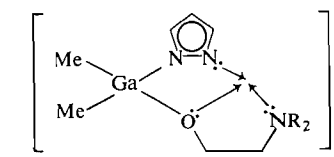
Introduction

A previous publication (1) described the first of a new class of tridentate ligand systems incorporating the dimethyl gallium and pyrazolyl moieties, **1**. In that study binuclear transition metal complexes were isolated. The present account reports the synthesis of the less sterically demanding anionic tridentate ligand, dimethyl(ethanolamino)(1-pyrazolyl)gallate, $[Me_2Ga(OCH_2CH_2NH_2)(N_2C_3H_3)]^-$, **2**, and its coordinating properties towards selected transition metal ions, M^{2+} (M = Mn, Fe, Co, Ni, Cu, or Zn). Octahedral complexes were isolated in each case and the realization of *fac*/*mer* isomerism has been demonstrated through crystal structure determinations of two nickel isomers.



1, R = Me
2, R = H

Experimental

Starting Materials

Air-sensitive materials were handled in oxygen-free dry nitrogen. Tetrahydrofuran (THF) was dried by refluxing over lithium aluminum hydride and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. Pyrazole (K and K Laboratories) and sodium hydride (Alfa Inorganic) were used as supplied.

Zn	White	$ZnCl_2$	*fac*	32.7	5.9	16.7	32.4	5.8	16.2	Air sensitive

Ethanolamine was refluxed over anhydrous $CaSO_4$ and distilled prior to use. Gallium trimethyl (2) and $FeCl_2 \cdot 1.5$ THF (3) were prepared as described previously.

Preparative Details

Sodium Dimethyl(ethanolamino)(1-pyrazolyl)gallate

$$[1]\ NaH + N_2C_3H_4 \xrightarrow{THF,N_2atm.} Na^+N_2C_3H_3^- + H_2$$

$$[2]\ Na^+N_2C_3H_3^- + Me_3Ga \xrightarrow{THF,N_2atm.} Na^+Me_3Ga(N_2C_3H_3)^-$$

$$[3]\ Na^+Me_3Ga(N_2C_3H_3)^- + HOCH_2CH_2NH_2 \xrightarrow[reflux]{THF,N_2atm.} Na^+[Me_2Ga(OCH_2CH_2NH_2)(N_2C_3H_3)]^- + CH_4$$

Trimethyl gallium (3.19 g, 27.8 mmol) in THF was added to sodium pyrazolide (27.8 mmol) (made from sodium hydride (0.667 g, 27.8 mmol) and pyrazole (1.89 g, 27.8 mmol) in THF) in the same solvent. Ethanolamine (1.695 g, 27.8 mmol) in THF was added to the resulting solution and on refluxing a slow evolution of methane occurred. The reaction was complete in approximately 24 h. The resultant solution was cooled and made up to a standard volume in the glove box. Aliquots of this solution were used in the preparation of the transition metal complexes.

Preparation of $[Me_2Ga(OCH_2CH_2NH_2)(N_2C_3H_3)]_2M$ Complexes, where M = Mn, Fe, Co, Ni, Cu, Zn

The procedure was very similar for each experiment and can be illustrated by the preparation of the nickel complexes. The transition metal starting materials for all the preparations are listed in Table 1, along with physical data for the resulting complexes.

An aliquot of the ligand solution prepared as described above and containing $Na^+[Me_2Ga(OCH_2CH_2NH_2)(N_2C_3H_3)]^-$ (1.388 g, 5.56 mmol) was added to a slurry of $NiBr_2$ (0.607 g, 2.78 mmol) in THF. The resulting mixture was stirred overnight and yielded a blue solution and a white precipitate. The solid was allowed to settle and the solvent was then removed from the isolated clear solution. The resulting solid was recrystallized from benzene and yielded predominantly purple crystals together with a small amount of blue crystalline material. The crystals were separated manually and were found to be *fac* and *mer* isomers of the same octahedral compound. The purple crystals were found to be the 'all-*trans*' *fac* isomer, Fig. 1*a*; the blue crystals the *mer* isomer, Fig. 1*b*.

Conversion of one isomer to the other could be effected by correct choice of solvent for recrystallization. The non-polar *fac* isomer (purple crystals) when dissolved in acetone gave the polar *mer* isomer (blue crystals) on recrystallization. Conversely the *mer* isomer dissolved in benzene gave the *fac* isomer on recrystallization. Heating the *fac* isomer causes a color change from purple to blue at ~130°C, suggesting a rearrangement to the *mer* isomer. Continued heating causes decomposition at ~190°C. The blue *mer* isomer itself darkens and decomposes at ~190°C, with no observable color change below this temperature.

No evidence for *fac*/*mer* isomerism in the remaining complexes has been found. The isomer obtained (deduced from ir spectra as discussed later) for each metal is given in Table 1. Numerous attempts were made to obtain a purer copper derivative but recrystallization failed to yield a complex of higher purity.

Spectra

A Varian MAT CH4 was used to record mass spectra at 70 eV with an ion source temperature of 100–180°C. Infrared spectra were recorded on a Perkin–Elmer 457 spectrophotometer as Nujol mulls and electronic absorption solution spectra on a Cary 14 spectrometer.

X-Ray Crystallographic Analyses

sym-fac-*Bis[dimethyl(ethanolamino)(1-pyrazolyl)gallato-(N(2),O,N)]nickel(II)*

The crystal was mounted with (0 1 1) normal to the goniostat axis and had dimensions of ca. 0.49 × 0.49 × 0.54 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 16 reflections measured on a diffractomer with Cu K_α radiation (λ = 1.5418 Å). Crystal data (at 22°C) are:

$C_{14}H_{30}Ga_2N_6NiO_2$ fw = 512.58

Monoclinic, a = 11.7908(6), b = 7.3158(6), c = 12.5797(8) Å, β = 97.035(7)°, V = 1076.9(1) Å^3, Z = 2, ρ_c = 1.581 g cm^{-3}, $F(000)$ = 524, μ(Cu K_α) = 42.9 cm^{-1}. Absent reflections: $0k0$, $k \neq 2n$, and $h0l$, $h + l \neq 2n$ defined uniquely the space group $P2_1/n$ (non-standard setting of $P2_1/c$, C_{2h}^5, No. 14).

Intensities were measured with Ni-filtered Cu K_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 4° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. Background counts of 10 s were measured at each end of the scan. Data were measured to 2θ = 160°. The intensities of the check reflections, measured every 50 reflections throughout the data collection, remained constant to within ±5%. After data reduction, an absorption correction was applied using the Gaussian integration method (4, 5). Transmission factors ranged from 0.102 to 0.338. Of

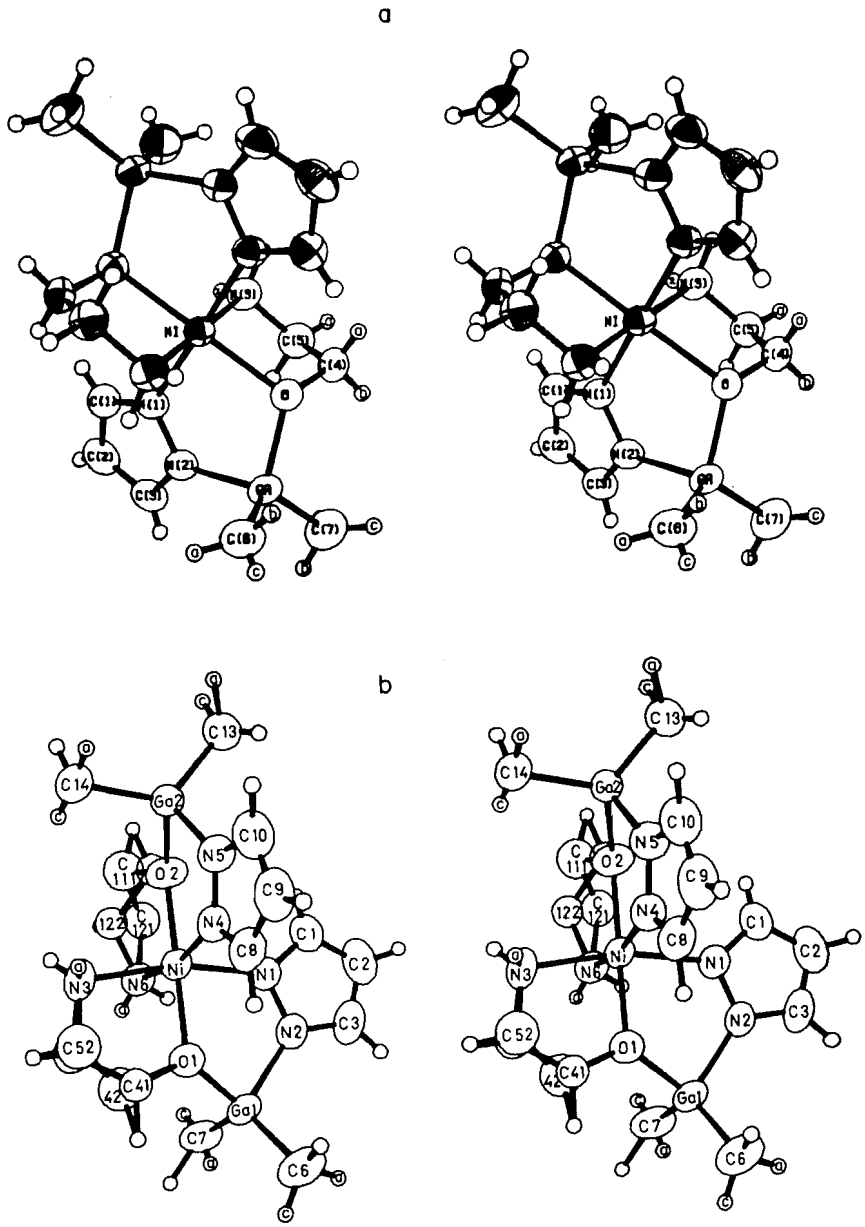

FIG 1. Stereo views of the *sym–fac* (*a*) and *mer* (*b*) isomers of the bis[dimethyl(ethanolamino)(1-pyrazolyl)gallato(*N*(2),-*O*,*N*)]nickel(II) molecule; 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

the 2355 independent reflections measured, 1902 (81%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time-averaged background count.

With Ni at the origin the position of the gallium atom was determined from the Patterson function. After full-matrix refinement with anisotropic thermal parameters to $R = 0.068$, a difference map gave the positions of all 15 hydrogen atoms subsequently included with isotropic thermal parameters. The scattering factors of ref. 6 were used for non-hydrogen atoms and those of ref. 7 for hydrogen atoms. Anomalous scattering factors from ref. 8 were used for the Ga, Ni, O, and N atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. A correction for secondary extinction was approximated by basing the least-squares refinement on the minimization of $\Sigma w[|F_o| - |F_c/(1+gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was $3.3(6) \times 10^{-8}$. Convergence was reached at $R = 0.048$ and $R_w = 0.057$ for 1881 reflections with $I \geq 3\sigma(I)$ (21 reflections with $||F_o| - |F_c|| > 3\sigma(F)$ were treated as unobserved in the final stages of refinement; instrumental error was suspected, but it seemed unwise to bias the data by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

remeasurement; the discrepancies were not large). For all 2355 reflections $R = 0.061$ and $R_w = 0.078$.

On the final cycle of refinement the mean and maximum parameter shifts were 0.03 and 0.38σ respectively. The mean error in an observation of unit weight was 1.758.

mer-*Bis[dimethyl(ethanolamino)(1-pyrazolyl)gallato*(N(2), O,N)*]nickel(II)*

Experimental details are the same as for the *fac* isomer except where noted. The crystal used, mounted with (0 1 1) normal to the goniostat axis, was ca. 0.4 × 0.4 × 0.35 mm. Thirty-two reflections were used in the refinement of the unit-cell parameters. Crystal data are:

Monoclinic, $a = 18.6617(7)$, $b = 8.7941(4)$, $c = 13.5670(8)$ Å, $\beta = 91.766(4)°$, $V = 2225.5(2)$ Å^3, $Z = 4$, $\rho_c = 1.530$ g cm^{-3}, $F(000) = 1048$, μ(Cu K_α) = 41.5 cm^{-1}. Absent reflections: $0k0$, $k \neq 2n$, and $h0l$, $l \neq 2n$ defined uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

The intensity of the check reflection remained constant to within ±3% during data collection. Of 4401 independent reflections measured (to $2\theta = 145°$), 2573 (58.5%) had intensities greater than $3\sigma(I)$ above background. An absorption correction was applied, transmission factors ranging from 0.188 to 0.421.

The coordinates of the nickel and gallium atoms were determined from the three-dimensional Patterson function. All four ethanolamine carbon atoms are positionally two-fold disordered and were refined with site occupancies fixed at 0.5. The positions of most hydrogen atoms (Table 3[1]) were located on subsequent difference maps. Attempts to refine the disordered carbon atoms with anisotropic thermal parameters were unsuccessful. The structure (ordered non-hydrogen atoms having anisotropic thermal parameters) was refined for four cycles giving a final R of 0.052 and R_w of 0.067 for 2573 reflections with $I \geq 3\sigma(I)$ (for all 4401 reflections $R = 0.084$ and $R_w = 0.074$). No correction for secondary extinction was applied. The weighting scheme used was: $w = 1$ for $|F_o| \leq 18$, $w = (18/|F_o|)^2$ for $|F_o| > 18$, and $w = 0.063$ for the unobserved reflections. The mean and maximum parameter shifts on the final cycle of refinement were 0.06 and 0.82σ. The mean error in an observation of unit weight was 0.9415.

The final positional and thermal parameters for both structures are given in Tables 2 and 3[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The thermal motions of both molecules have been analysed in terms of rigid-body modes of translation, libration, and screw motion (9) using the computer program MGTLS. For the *fac* isomer (rms $\sigma U_{ij} = 0.0020$ Å^2), analysis of all non-hydrogen atoms (rms $\Delta U_{ij} = 0.0047$ Å^2) gave physically reasonable rigid-body parameters but the Ga coordination group showed significant independent motion and was analysed separately (rms $\Delta U_{ij} = 0.0017$ Å^2). For the *mer* isomer (rms $\sigma U_{ij} = 0.0034$ Å^2), four analyses gave reasonable parameters: the two Ga coordination groups, the Ni coordination group, and a 17 atom group consisting of all ordered non-hydrogen atoms except the methyl carbon atoms (rms σU_{ij} = 39, 28, 23, and 60 × 10^{-4} Å^2 respectively). The appropriate bond distances have been corrected for libration (10, 11), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values. Changes in bond angles were not significant and thus only the uncorrected angles are given in Table 5.

[1]Copies of the structure factor table and Table 3 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and Discussion

In a previous study the first of a series of potentially multidentate ligands incorporating the dimethyl gallium and pyrazolyl moieties was described (1). The use of ethanolamine in reaction 3 (see Experimental section) of the ligand synthesis reduces steric crowding around the amino nitrogen and allows the formation of bis(tridentate) octahedral complexes. Predictably, reaction 3 of the ligand synthesis proceeds exclusively at the 'OH' rather than the 'NH_2' group of the ethanolamine. It is known that molecules with amino groups coordinated to gallium trimethyl require elevated temperatures for elimination of methane whereas molecules with hydroxyl groups coordinated to the gallium alkyl eliminate alkane much more readily at lower temperatures (12).

The isolation and characterization of a number of octahedral complexes has demonstrated the versatility of the new chelating legand in that it is capable of both *facial* and *meridional* coordination. Present evidence indicates that when the ligand is *facial*, the non-polar *sym* (all-*trans*) isomer is preferred for octahedral complexes. Thus far there is no evidence for other *fac* isomers but molecular models indicate that these would be polar molecules with much greater steric crowding than occurs in the polar *mer* isomer.

Infrared Spectra

The spectra of the *fac* and *mer* isomers, Fig. 2, illustrate the two types of spectra which have been observed for the complexes listed in Table 1. With use of these spectra as a guide, the complexes isolated for the remaining metals were assigned as *fac* or *mer* isomers on the basis of their ir spectra. Differences in the two spectra are primarily in regions attributable to N—H vibrations. The N—H stretching region at ~3300 cm^{-1} displays two bands in the *sym–fac* isomer but at least three bands in the *mer* isomer. In the N—H deformation region of the spectrum, ~1600 cm^{-1}, the *mer* isomer shows a single band but a three-band envelope is observed for the *fac* isomer. A third fingerprint region of the spectra occurs between 400 and 500 cm^{-1}. In the spectrum of the *mer* isomer two bands occur close together at 460 and 475 cm^{-1} whereas in the spectrum of the *fac* isomer these bands are absent and two new bands occur in this region at 400 and 500 cm^{-1}.

The assignments of *fac* and *mer* isomers on the basis of their infrared spectra are tentative in that *fac* isomers other than the all-*trans sym* isomer might give spectra closely resembling that of the *mer* isomer

illustrated for the nickel compound. Noteworthy features in both spectra are the weak bands of low frequency in the C—H stretching region (~2600 cm^{-1}) and the complex region around 550—600 cm^{-1}, a region normally associated with symmetric and asymmetric Ga—C stretching modes.

Mass Spectra

The mass spectra of the octahedral complexes displayed signals due to the parent ions. Table 6 lists the peaks observed in the spectrum of the cobalt derivative as an illustration of the type of fragmentation patterns observed. The isotopic patterns of the individual signals are in good agreement with those predicted from the isotopic distributions of metal atoms (^{69}Ga, 60%; ^{71}Ga, 40%; ^{59}Co, 100%). The appearance of certain peaks in the Co spectrum (see Table 6) indicates a facile loss of amino protons from some ions. The mass spectra of the two nickel isomers were essentially identical which is surprising considering the different bonding in the crystal structures of the two isomers. Perhaps the *fac* isomer is converted to the *mer* isomer at the temperature of the experiment (see Experimental section) before ionization occurs.

Electronic Spectra

The electronic spectra of the complexes were recorded over the range 300–1400 nm and are listed and assigned in Table 7. The spectra of the two nickel isomers are shown in Fig. 3. As expected, three spin-

C(sp^3)—H	0.63–1.38(4–15)

allowed bands are observed for both complexes. In addition, a much weaker band, which has been assigned to the $^3A_{2g} \rightarrow {}^1E_g$ transition, is also observed for both complexes. It is noteworthy that the absorptions due to the *mer* isomer are significantly more intense than those for the *sym–fac* isomer. This may be due to the presence of a centre of symmetry in the immediate ligand environment of the *fac* isomer. (This centre of symmetry is not present in the *mer* isomer.)

The spectrum of the cobalt complex exhibits two main absorption bands, assigned as ν_1 and ν_3, with a shoulder on the more intense of these (ν_3). This shoulder has been tentatively assigned to the 'two electron' transition, $^4A_{2g} \leftarrow {}^4T_{1g}(F)$. The spectrum of the iron complex displays a very weak absorption in the infrared region. Since it occurs as a shoulder on a strong charge transfer band, its position is not definitive.

The nickel and cobalt spectra have been analysed on the basis of the energy levels discussed in ref. 13. *Dq* and *B* values are listed in Table 7. The observed ν_2 and ν_3 bands of the nickel complexes were used in the calculation of these parameters. This leads to calculated ν_1 values of 10.9 and 10.65 kK for the *fac* and *mer* isomers respectively; the expected $\rightarrow {}^1E_g$ transitions are 13.2 and 13.4 kK ($C/B = 4.5$ has been assumed for the calculation of the ^1E_g transition (13)). Similarly, ν_1 and ν_3 have been used to calculate *Dq* and *B* of the cobalt complex. This leads to a calculated value of 19.9 kK for ν_2 which does not agree well with the experimental value of 18.6 kK. The observed shoulder could be due to a spin forbidden band or a splitting of the $^4T_{1g}(P)$ level, rather than

*Primed atoms at $1 - x$, $1 - y$, $1 - z$.

the ${}^4A_{2g} \leftarrow {}^4T_{1g}(F)$ transition which is usually very weak and is often obscured.

Comparison of the above spectral parameters with those of the corresponding hexammine complexes is of interest. The relevant parameters are: $Dq = 1020$ cm^{-1}, $B = 885$ for $Co(NH_3)_6^{2+}$ (13); $Dq = 1080$ cm^{-1}, $B = 900$ for $Ni(NH_3)_6^{2+}$ (13); and $Dq = 1120$ cm^{-1} for $Fe(NH_3)_6^{2+}$ (14). The similarity of the Dq values shows that the tridentate ligand lies in approximately the same position as NH_3 in the spectrochemical series. The B values of the chelate complexes, however, are much lower than those of the hexammine complexes, indicating a greater degree of delocalization or covalency in the former.

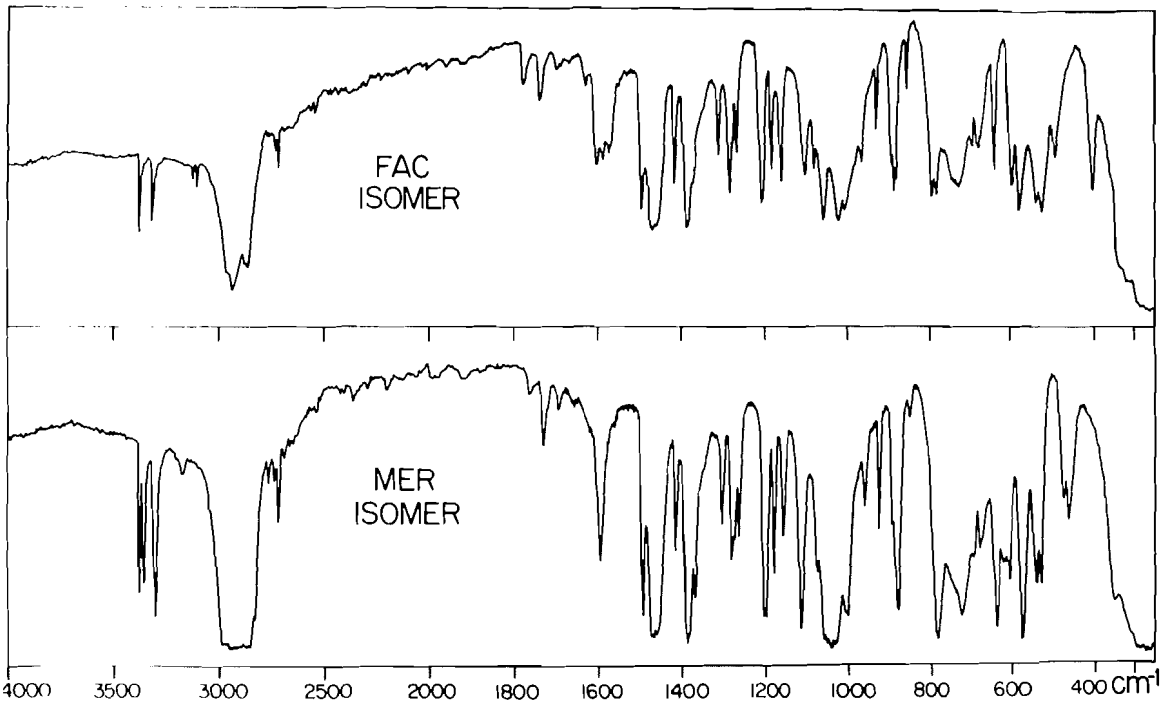

FIG. 2. Infrared spectra of *sym–fac*- and *mer*-bis[dimethyl(ethanolamino)(1-pyrazolyl)gallato(*N*(2),*O*,*N*)]nickel(II).

Crystal Structures

Both crystal structures consist of discrete mononuclear molecular units separated by normal van der Waals distances (see Fig. 4). The nickel atoms of both isomers are bonded to two tridentate $[Me_2Ga(OCH_2CH_2NH_2)(N_2C_3H_3)]^-$ ligands via the amino nitrogen, oxygen, and pyrazolyl nitrogen atoms. While the coordination geometry about the nickel atom is distorted octahedral in both cases, the distortions from 'ideal' geometry are greater for the asymmetric *mer* isomer than for the centrosymmetric *sym–fac* isomer (see Tables 4 and 5).

The geometry of the ligands in the *mer* isomer is very similar to that of the related $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)]^-$ ligand in the binuclear square-pyramidal copper(II) complex $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)_2Cu]_2$ (I). *Facial* coordination by the $[Me_2Ga(OCH_2CH_2NH_2)(N_2C_3H_3)]^-$ ligand is realized by a fold about the Ni—O bond (see Fig. 1). The coordination of the trivalent oxygen atom is pyramidal in the *fac* isomer and more nearly planar in the *mer* isomer (mean bond angles at O are 112.7° in the *fac* isomer and 117.5° in the *mer* isomer). The Ni—N(pyrazolyl) distances (2.085(3) for *fac*, 2.091(4) and 2.102(4) Å for *mer*) are nearly the same in the two isomers while the Ni—N(amino) (2.112(3) for *fac*, 2.148(5) and 2.156(5) Å for *mer*) and Ni—O (2.090(3) for *fac*, 2.049(4) and 2.045(3) Å for *mer*) are significantly different. A combination of steric and electronic effects is probably responsible for these differences. The conformations of the OCCNNi and GaONiNN chelate rings (see torsion angles in Table 8) are very similar in the two isomers. The marked non-planarity of the GaONiNN rings in both isomers is in contrast with the near planarity of the GaOCuNN rings in $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_3H_3)_2Cu]_2$ (I).

The pyrazolyl ring in the *fac* isomer is planar within experimental error ($\chi^2 = 1.5$) and both metal atoms are significantly displaced from the mean plane of the pyrazolyl ring (Ga by 0.0985(5) and Ni by 0.2701(5) Å). In the *mer* isomer the pyrazolyl ring containing N(1) is planar ($\chi^2 = 0.3$) while the other ring is possibly non-planar ($\chi^2 = 7.8$). The metal

The chiroptical properties of the strychnine alkaloids: strychnine, β-colubrine, brucine, and their dihydro derivatives

JULIAN W. SNOW[1] AND THOMAS M. HOOKER, JR.[2]

Department of Chemistry, University of California, Santa Barbara, CA 93106, U.S.A.

Received September 6, 1977

JULIAN W. SNOW and THOMAS M. HOOKER, JR. Can. J. Chem. **56**, 1222 (1978).

Ultraviolet absorption and circular dichroism spectra of the strychnine alkaloids strychnine, β-colubrine, brucine, dihydrostrychnine, dihydro-β-colubrine, and dihydrobrucine have been investigated under various experimental conditions. It appears that at least five electronic transitions are required to account for the spectroscopic properties of these molecules in the ultraviolet region above 190 nm. Transitions, which are tentatively assigned as the ^1L_b, ^1L_a, ^1B_b, and ^1B_a in the notation due to Platt, and an $n \rightarrow \pi^*$ transition apparently make significant contributions to the spectra of all of the molecules studied.

JULIAN W. SNOW et THOMAS M. HOOKER, JR. Can. J. Chem. **56**, 1222 (1978).

On a étudié, sous diverses conditions expérimentales, les spectres d'absorption ultraviolet et de dichroïsme circulaire de divers alcaloïdes de la strychnine: la strychnine, la β-colubrine, la brucine, la dihydrostrychnine, la dihydro β-colubrine et la dihydrobrucine. Il semble que l'on doit faire appel à au moins cinq transitions électroniques pour tenir compte des propriétés spectroscopiques de ces molécules dans la région ultraviolette au dessus de 190 nm. On attribue d'une façon temporaire les transitions sous forme ^1L_b, ^1L_a, ^1B_b et ^1B_a, dans la notation qui est due à Platt, et ces transitions autant d'une transition $n \rightarrow \pi^*$ semble apporter une contribution importante aux spectres de toutes les molécules étudiées.

Introduction

An experimental investigation of the optical properties of β-colubrine, brucine, and strychnine, and the dihydro-derivatives of these alkaloids, has recently been carried out in this laboratory. The intent of this work has been to investigate the nature of the chromophoric groups of the molecules and the optical properties that arise from their associated electronic transitions. In the spectral region of 190–300 nm, the chromophoric groups of interest are associated with the dihydroindole nucleus and the ethylenic group (Fig. 1). Absorption (uv) and circular dichroism (CD) spectra have been acquired over this wavelength region in organic and aqueous solvent systems.

The molecular framework of these alkaloids is a rigid polycyclic structure that consists of seven fused rings. Thus, the conformational freedom of the molecule is very restricted. This is a very attractive feature when one considers the extreme sensitivity of optical activity to molecular conformation. Solvent effects, for example, are easier to interpret as are the effects of other experimental variables such as p*H*, temperature, and concentration.

The nitrogen atom of the dihydroindole nucleus of strychnine is bonded to a carbonyl group (C_{21}–O_1 of Fig. 1). As a result, the structure of the strychnine aromatic chromophore is similar to an *ortho*-substituted acetanilide, except for the fact that N_1 is tertiary instead of secondary. Strychnine may thus be considered to contain a perturbed acetanilide chromophore. Likewise, brucine and β-colubrine

contain the analogous 3,4-dimethoxy and *para*-methoxy chromophores, respectively.

The ultraviolet absorption spectrum of acetanilide has been reported several times in the literature (1–4). The spectra of the *ortho*-, *meta*-, and *para*-methoxy derivatives have been measured as well (2). The pertinent features may be summarized as follows. The two lowest energy bands of acetanilide occur at 277 and 243 nm in ethanol (2). The second band is considerably more intense than the first ($\log \varepsilon_{\lambda_{277}} = 2.74$, $\log \varepsilon_{\lambda_{243}} = 4.19$). A third band of greater intensity occurs at 200 nm in iso-octane.

Assignments of the lower energy bands of acetanilide have been made previously. Based on experimental considerations Lutskii *et al.* (2) assigned the lowest energy band to the analog of the B_{2u} transition of benzene. The next transition was assigned to an n_N–π_{CO}* transition, primarily because the wavelength and intensity of this band were not those which would be expected of the analog of the B_{1u} transition of benzene.

The results of a semi-empirical molecular orbital calculation that was carried out by Baba and Suzuki (4) are in agreement with the experimental assignments insofar as the lowest energy band is concerned. The direction of polarization of this transition was calculated to lie along a line perpendicular to the C_1–N_1 axis. The second transition was determined to have considerable charge transfer character as a result of electron transfer from the nitrogen and the aromatic ring to the carbonyl group. The direction of polarization of this transition was determined to make an angle of 20.5° with the C_1–N_1 axis, being inclined toward the carbonyl group. A third transition was calculated to have a direction of polarization identical to that of the lowest energy band.

The polarized absorption studies of acetanilide crystals by Tanaka (5) are in close agreement with the results of Baba and Suzuki. Polarization directions were reported only for the two lower energy bands. The experimental and theoretical polarizations for the lowest energy band were in excellent agreement. The direction of polarization of the second band was found to be 35.6° from the C_1–N_1 axis, which is slightly more inclined to the carbonyl group than that calculated by Baba and Suzuki.

There is one significant dissimilarity insofar as the aromatic chromophores of strychnine and acetanilide are concerned. Whereas the acetamino group of acetanilide and related molecules is usually considered to be coplanar with the aromatic ring, such may not be true in the case of the strychnine alkaloids. The crystalline structure of strychnine hydrobromide has been determined by X-ray diffraction studies (6). These data indicate that the carbon and oxygen atoms of the acetamino group of strychnine lie approximately 0.4 Å below the plane of the aromatic ring. This structural distortion, providing that it exists in solution, may diminish the conjugation of the π-systems of these two groups, with the result that it might be appropriate to consider the phenyl and acetamino groups as independent systems. However, there are marked similarities in the absorption spectra of the strychnine alkaloids and related substituted acetanilides, so the acetanilide interpretation is probably valid. Although the theoretical interpretation of the CD spectra of the strychnine alkaloids will obviously be affected by the nature of the chromophoric groups that are present, the conclusions of the present investigation are not crucially dependent upon this factor.

The notation due to Platt (7) will be utilized in this work to designate the electronic transitions associated with the acetanilide chromophore. In this notation the lowest energy band will be designated as the ^1L_b transition, the second band is the ^1L_a, and the third transition is assigned as the ^1B_b.

The strychnine alkaloids also contain an ethylenic chromophore. The ultraviolet absorption spectrum of ethylene has been reviewed by Merer and Mulliken (8). The broad absorption in the spectrum of liquid ethylene that extends from 265 nm to a maximum near 160 nm was assigned to the N–V system. There appears to be at least one additional transition in the spectrum of solid ethylene (9) and in various substituted olefins (10–12). Calculations of the rotatory strengths of the twisted olefin, *trans*-cyclooctene show that a π_z–π_y* transition is required in addition to the conventional π_z–π_z* transition to explain the observed chiroptical properties near 200 nm (in this notation the ethylenic double bond lies along the *x*-axis and the *z*-axis is perpendicular to the plane of the double bond). The π_z–π_y* transition is electric dipole forbidden in planar ethylene. However the linear dichroism studies of Yogev *et al.* (10) on unsymmetrically substituted olefins confirm the presence of an additional band that could be due to such a transition.

The X-ray diffraction data for crystalline strychnine hydrobromide indicate that the ethylenic double bond is very nearly planar (6). Thus, unless the conformation of the molecule is markedly different in solution, there should be only a minimal amount of skewness associated with this group. It is difficult to estimate the magnitude of the contribution of this small amount of inherent dissymmetry of the ethylenic chromophore to its optical activity, but it is probably minimal. As a result of this planarity, the π_z–π_z* transition, which is polarized along the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

double bond (11), probably makes the dominant contribution to the optical activity of the ethylenic chromophore by means of the dipole coupling mechanism (13). The situation might be expected to be similar to that of gliotoxin, where Nagarajan and Woody (14) found that the spectrum could be adequately reproduced by including only the π_z–π_z^* transition of the ethylenic chromophore in their chiroptical calculations.

Experimental

Strychnine and brucine were obtained from the Sigma Chemical Company. β-Colubrine was obtained from the Pierce Chemical Company. The dihydro derivatives of these compounds were prepared according to the procedure of Oxford and Perkin and Ackmatowicz *et al.* (15, 16), which involves catalytic hydrogenation in 50% aqueous acetic acid. A Parr hydrogenation apparatus was employed for this purpose with the pressure of hydrogen maintained between 20–25 psi. In all cases, hydrogen uptake ceased after 2–5 h with the theoretical amount being consumed. The free base was precipitated from solution by the dropwise addition of 40% sodium hydroxide solution. Dihydrostrychnine was recrystallized from 50% methyl alcohol and dried *in vacuo* over silica gel. The melting point of the resultant needle-like crystals was 222–223°C, compared to the literature value of 220–222°C (15). Dihydrobrucine was recrystallized from hot water and was found to melt at 70°C. Dihydrobrucine tetrahydrate has been reported to melt at 70–72°C (16). Dihydrocolubrine was recrystallized from a mixture of ethanol–water and dried *in vacuo* over silica gel. The resulting crystals were found to melt at 220°C.

The uv absorption spectra were measured on a Cary 118 recording spectrophotometer that is equipped with the Cary far uv modification. All absorption spectra were determined at ambient laboratory temperature.

CD spectra were measured on a Cary 60 recording spectropolarimeter that is equipped with a highly modified prototype 6003 CD accessory. Fused silica cells with path lengths between 0.1 and 1 cm were used. The majority of the CD data were acquired with the aid of a PDP-11 digital computer that was interfaced to the spectropolarimeter, thereby allowing multiple scanning and signal averaging. Details are provided elsewhere (25).

CD data are reported as molar ellipticity, M_θ, which is defined as

$$\theta = \frac{M_\theta c l}{100}$$

where θ is the observed ellipticity in degrees, l is the path length in cm, and c is solute concentration in moles per litre.

When necessary, CD spectra were analyzed by a curvefitting technique based on the method due to Fletcher and Powell (17). The data were fitted to Gaussian band shapes by means of an iterative computer program which minimizes residual mean squares.

All aqueous solutions were prepared with doubly distilled water and were filtered with a millipore apparatus prior to use. Triethylphosphate (TEP) was obtained from Aldrich Chemical Company, and was distilled under vacuum. Solutions prepared with TEP were filtered through sintered glass.

Results

The uv absorption spectrum of dihydro-β-colubrine in water is shown in Fig. 2. The bands at 296 and 262 nm apparently arise from the ^1L_b and ^1L_a transitions, respectively. These bands occur almost 20 nm to the red of the analogous bands in acetanilide. The inductive effect of the methoxy group must be largely responsible for this difference. Similar red-shifts, somewhat smaller in magnitude, were noted for *p*-methoxy acetanilide (2). The absorption maximum at 197 nm is probably due to the ^1B_b transition. The analogous degenerate E_{1u} transitions of benzene would be expected to split into two non-degenerate transitions in this chromophoric group. Thus, an additional transition (^1B_a in Platt's notation) might be expected to absorb in this region as well.

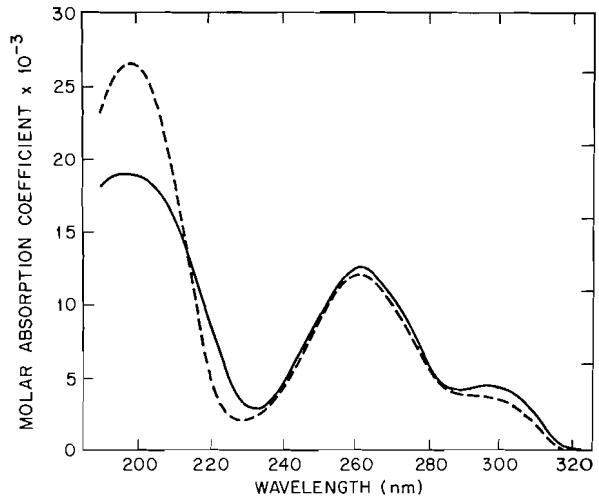

FIG. 2. The uv absorption spectra of dihydro-β-colubrine (—) and β-colubrine (---) in neutral water.

The CD spectra of dihydro-β-colubrine in water as a function of pH, and in triethylphosphate (TEP), are shown in Fig. 3. An interesting feature of these spectra is that at least four, and probably five, Cotton effects are present in each case. Tentative electronic transition assignments are indicated along the bottom of the figure.

A noticeable pH dependence of the molar ellipticity occurs at higher energies (lower wavelengths) in aqueous solution. This dependence is manifested by a decrease in positive ellipticity as the pH is increased. At pH 12.5 there is a small amount of negative ellipticity between 230 and 238 nm which is indeed evidence of a negative Cotton effect in this region. Thus, there must be an additional electronic transition (band III) even though no obvious absorption band appears in the uv spectrum in this wavelength region. The transition giving rise to this Cotton effect is obviously very weakly absorbing and is quite likely electric dipole forbidden.

Removal of a proton from the tertiary nitrogen atom of dihydrocolubrine (N_2 of Fig. 1) appears to be responsible for the change in sign of the Cotton

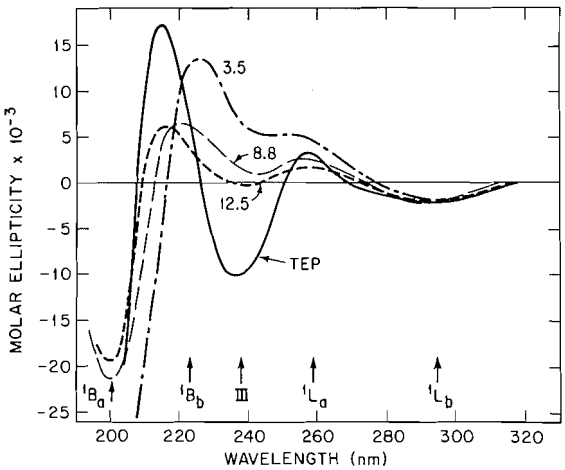

FIG. 3. CD spectra of dihydro-β-colubrine in water and TEP. The numerals in the figure indicate the p*H* of the aqueous solutions. Transition assignments are indicated along the bottom of the figure.

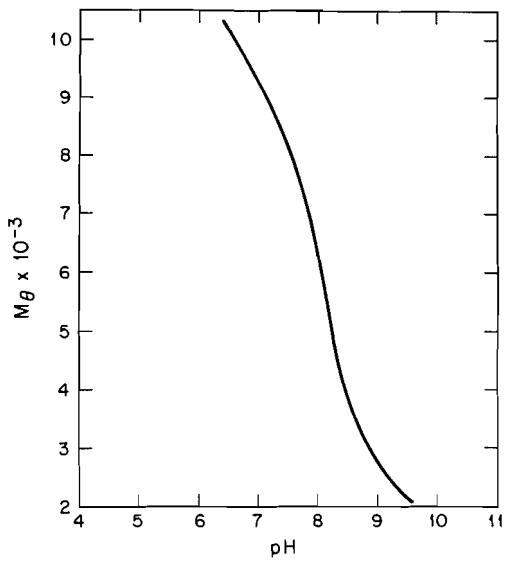

FIG. 4. Plot of M_θ vs. p*H* for dihydro-β-colubrine at 230 nm.

effect due to band III. This can be seen more clearly in Fig. 4 in which molar ellipticity at 230 nm is plotted against p*H*. The plot has the appearance of a sigmoidal curve with the point of inflection at approximately the pK_a of the tertiary nitrogen atom (7.85). The effect of going to a less polar solvent such as TEP is to lower the effective pK_a, hence the negative Cotton effect at 237 nm in this solvent is quite likely due to this effect as well.

The aqueous CD spectra at p*H* 3.5 and 12.5 were subjected to careful analysis by curvefitting. The results are presented in Table 1. In both cases it was found that the spectra required five Cotton effects for best results. The Cotton effect arising from band III clearly undergoes a change in sign from positive to negative and a significant shift to the blue upon going from acidic to basic solution.

The uv absorption spectrum of β-colubrine in water is also shown in Fig. 2. The absorption maximum at 199 nm is presumably due to the ^1B transitions and the π_z–π_z^* transition of the ethylenic chromophore. The increase in intensity of absorption in this region relative to the spectrum of dihydrocolubrine must result from the ethylenic chromophore.

The CD spectra of β-colubrine in aqueous solution, methanol, and TEP are shown in Fig. 5. In view of the results obtained for dihydro-β-colubrine, one would expect to observe five Cotton effects above 200 nm. The ethylenic chromophore of β-colubrine might be expected to give rise to a sixth Cotton effect, but it probably occurs below 200 nm. Although there is some qualitative evidence for five Cotton effects above 200 nm in the spectra of Fig. 5, it is certainly not as compelling as it was in the case of dihydrocolubrine. Thus, assignment of the Cotton effects was made only after conducting careful curvefitting analyses of the data. Attempts were made to fit the spectrum using only four Cotton effects, but it was found that better fits and more reasonable spectral parameters were obtained by using five bands. The results of the curvefitting procedure are presented in Table 2 for the aqueous spectra at acidic and alkaline p*H* values, and in TEP.

The higher energy Cotton effects of β-colubrine exhibit a rather pronounced p*H* and solvent dependence. From the curvefitting results in Table 2 it can be seen that a change in sign of three Cotton effects takes place in going from aqueous acidic solution to basic solution and TEP. Similar sign inversions are also observed in methanol. Cotton effects that arise from the ^1L_a and ^1B_b transitions and band III appear to be affected. The Cotton effect due to band III is red shifted in TEP relative to methanol and base, the minimum being well resolved at 241 nm.

It should be noted that by repetitively scanning the CD spectra a small amount of positive ellipticity was observed to consistently occur in methanol between 255 and 265 nm, and in TEP between 267 and 274 nm. This provides evidence for a positive ^1L_a Cotton effect in these solvents. Although no obvious evidence of positive ellipticity in this wavelength region was observed in the alkaline CD spectrum, the curvefitting analysis indicates that a positive ^1L_a Cotton effect is present.

The uv absorption spectra of brucine and dihydrobrucine are shown in Fig. 6. The ^1L_b absorption maxima for both molecules are considerably more intense and are red shifted approximately 6 nm relative to β-colubrine and dihydro-β-colubrine. The

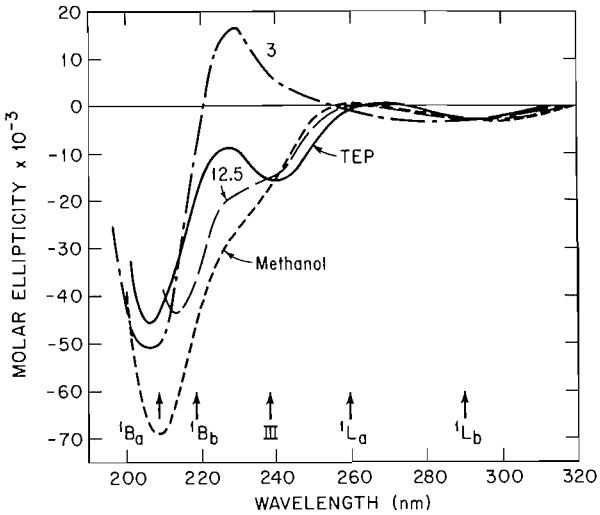

FIG. 5. CD spectra of β-colubrine in water, TEP, and methanol. The numerals in the figure indicate the pH of the aqueous solutions. Transition assignments are indicated along the bottom of the figure.

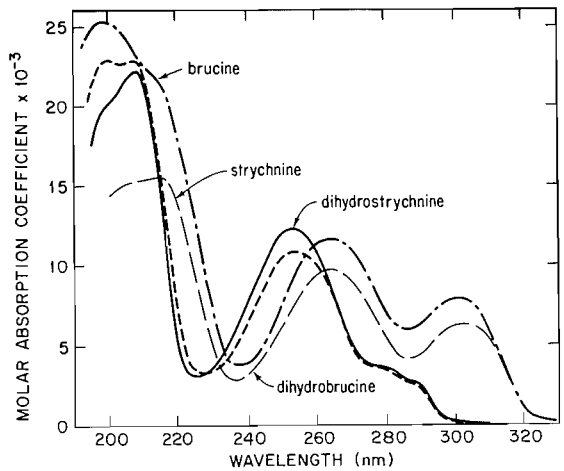

FIG. 6. The uv absorption spectra of brucine, dihydrobrucine, strychnine, and dihydrostrychnine in neutral water.

loss in intensity at 198 nm in dihydrobrucine relative to brucine indicates that the π_z–π_z^* transition of the ethylenic chromophore in the former compound probably occurs slightly to the blue of the ^1B transitions.

The CD spectra of dihydrobrucine in water ($pH = 3.03$) and in TEP are shown in Fig. 7. Again, transition assignments are indicated along the bottom of the figure. Analysis of the CD spectra as a function of pH was not attempted in the case of this compound because of apparent aggregation at alkaline pH values. Both the ^1L_b and ^1L_a Cotton effects were observed to split into positive and negative components at higher pH values, probably as a result of intermolecular exciton coupling. This phenomenon was found to be sensitive to solute

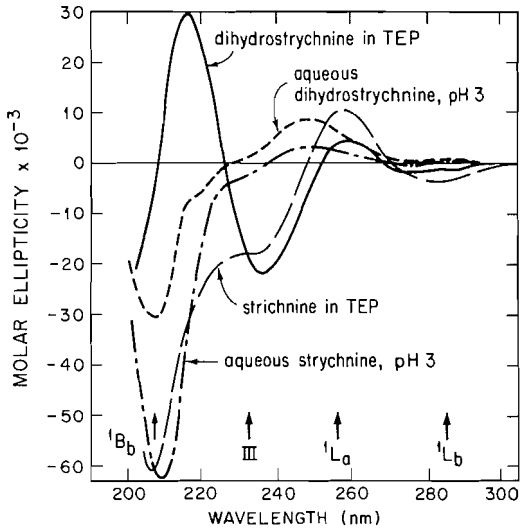

FIG. 8. CD spectra of strychnine and dihydrostrychnine in aqueous solution at p*H* 3 and TEP. Transition assignments are indicated along the bottom of the figure.

concentration, which is evidence that aggregation is occurring.

The 236 nm extrema apparently arise from the same transition that has been designated as band III in the CD spectra reported for β-colubrine and dihydro-β-colubrine. However, unlike the preceding cases, a change in sign of this Cotton effect does not occur as a result of changing the solvent from acidic water to TEP. Nevertheless, this CD band occurs in a region of the spectrum where very little absorbance is observed, as was true of the other molecules that were investigated.

The CD spectra of brucine in acidic aqueous solution and in TEP are also shown in Fig. 7. In aqueous solution an intense negative Cotton effect occurs at 211 nm with a negative shoulder at 228 nm, which probably arises from the ^1B band and band III respectively.

In TEP, the ^1L_a Cotton effect is negative, but is apparently extensively overlapped by a strong negative Cotton effect that arises from band III. As a result, the ^1L_a transition gives rise to a poorly resolved shoulder just below 270 nm. This is probably due to an increase in intensity of the Cotton effect arising from band III, which appears as a negative band with an apparent extremum at 237 nm.

The uv absorption spectra of strychnine and dihydrostrychnine are shown in Fig. 6. The ^1L_b band appears as two distinct shoulders near 287 and 277 nm in both strychnine and dihydrostrychnine. The blue-shift and decrease in intensity of the ^1L_b transitions relative to those observed for the other molecules is a result of the absence of the substituent effect that arises from the methoxy groups. The marked sensitivity of the ^1L_b transition to such substituent effects is typical of a large number of substituted benzene derivatives (18).

CD spectra of strychnine and dihydrostrychnine as determined in acidic aqueous solutions and TEP are shown in Fig. 8. These spectra appear to be rather similar except in the regions of the ^1L_b and ^1B_b transitions. The signs of the ^1L_b and ^1B_b Cotton effects of dihydrostrychnine appear to be solvent dependent, and the ^1L_b band of strychnine appears to give rise to two bands of opposite sign in the aqueous solution spectrum. However, all of the spectra determined in aqueous solution exhibited concentration dependence, which suggests that aggregation may have been taking place. All four curves exhibit evidence for band III Cotton effects, although they appear only as ill-defined negative shoulders near 220 nm in the spectra determined in aqueous solution.

Discussion

Most of the optical activity of the strychnine alkaloids appears to arise from the aromatic acetanilide-like chromophore. In the case of the dihydro derivatives it is the only chromophoric group present that is capable of generating the observed spectral features in the wavelength region that was investigated. Thus, it appears that most of the rotatory strength of these molecules is the result of local mechanisms that are operative in the vicinity of this chromophoric group. In the molecules in which the ethylenic group is present, it is possible for the ethylenic chromophore to contribute to the optical activity. This chromophore might make such con-

For personal use only.

tributions by virtue of its inherent dissymmetry, or by means of dipole–dipole coupling with some of the aromatic transitions. However, as pointed out earlier, the ethylenic group in strychnine is almost planar, so a large contribution from inherent dissymmetry would not be expected. Furthermore, the plane of the double bond of the ethylenic group is very nearly parallel to the plane of the aromatic ring, and is oriented such that very little dipole coupling would be expected on the basis of Schellman's helical symmetry rule (19).

It appears that five Cotton effects are observed at wavelengths above 200 nm for all of the molecules that were investigated. The two highest wavelength bands must arise from the ^1L_b and the ^1L_a transitions, the latter of which probably includes a significant amount of intramolecular charge transfer character. The two lowest wavelength bands presumably arise from the ^1B_b and ^1B_a bands. If the molecular orbital calculations for acetanilide by Baba and Suzuki can be assumed to be applicable, the higher wavelength band of these two is the ^1B_b transition. Thus, the lowest wavelength transition must be in the ^1B_a, except in the case of the molecules which also include an ethylenic chromophore. All of these assignments should be valid for strychnine, dihydrostrychnine, β-colubrine, and dihydro-β-colubrine, because the pertinent chromophore in each molecule can be considered to approximate C_{2v} symmetry (4). However, the assignments for the two lowest energy transitions may not be valid for brucine and dihydrobrucine, because the chromophore of the molecules clearly does not fulfill these symmetry requirements. Since there is no twofold symmetry axis for this chromophoric group, unambiguous classification of the B states is not possible (18).

There was evidence of an additional transition in most of the molecules that were investigated. In most cases, a Cotton effect (band III) was observed in the wavelength region between the bands that have been assigned to the ^1L_a and ^1B_b transitions. In each case, although there was definite evidence of a circular dichroism band in this region, there was no evidence of a corresponding absorption band. Thus, it seems likely that the Cotton effect that was observed must arise from a transition that is electrically forbidden. Such a transition apparently has not been reported previously insofar as acetanilide or acetanilide derivatives are concerned. However, this band must be associated with the acetanilide group, since it persists even when the only other chromophoric group that could possibly be responsible for it, i.e., the ethylenic group, has been eliminated.

One can think of several possible assignments for this Cotton effect. For example, it could be of vibronic origin, e.g., vibronic components of a nearby band such as the ^1L_a could give rise to such a feature. Another possibility is that this band arises from an as yet unassigned transition. For example, a transition to a state related to the E_{2g} state of benzene or a ^1C transition such as has been reported by Klevens and Platt (20) in certain cata-condensed hydrocarbons might be responsible for it. In fact, Auer (21) has suggested the possibility of a ^1C transition being associated with the optical activity of the indole chromophore of a number of tryptophan derivatives.

Another possibility, which is perhaps more likely, is that the Cotton effect in question arises from an electrically forbidden, magnetically allowed n–π* transition, which is associated with the excitation of a nonbonding electron of the carbonyl oxygen atom. Such transitions are known to occur at widely different wavelengths among various carbonyl compounds. For example, the n–π* transition of ketones occurs near 290 nm (22). On the other hand, it occurs near 212 nm in a number of simple amides (23), but occurs as high as 230 nm in several cyclic dipeptides (24, 25). Such transitions are very sensitive to their environment, and are known to undergo appreciable red-shifts as the polarity of the solvent is decreased. The Cotton effect which was designated as band III certainly exhibited properties that are characteristic of an n–π* transition, i.e., it was sensitive to solvent polarity, pH, etc.

On the basis of the results of this investigation, it is not possible to distinguish between these possibilities as to the origin of the Cotton effect referred to as band III. However, the occurrence of an n–π* transition in the molecules under study could not be regarded as unlikely. On the other hand, definite evidence for other transitions that might fall in the appropriate wavelength region is scant. There is some evidence for ^1C transitions, but this is restricted to only a few molecules, primarily cata-condensed hydrocarbons, which are rather dissimilar to the chromophores under consideration here. In addition, there is no precedent for a vibronically split ^1L_a Cotton effect. Thus, it seems reasonable to assign the Cotton effects that were observed to occur around 220–240 nm in most of the molecules studied to an n–π* transition, although this assignment must be regarded as a tentative one for the present.

Because of their structural similarities there are, as one might expect, a number of correlations that can be observed in the CD spectra of the various strychnine alkaloids and their dihydro derivatives. These correlations are exhibited in tabular form in Table 3, where the signs of the Cotton effects associated with the three lowest energy transitions of each of the

molecules are shown. The two higher energy bands, i.e., those arising from the ^1B transitions, are not included because of uncertainties in their assignments for some of the molecules. Data for solutions in water at p*H* 3 and in TEP are reported. Data for alkaline aqueous solution are not included because such data closely resembled the TEP data in all cases where intermolecular aggregation could be ruled out, except for the fact that the n–π* band was red-shifted in TEP.

The data of Table 3 clearly indicate numerous sign inversions upon going from the free base form of the alkaloids in TEP to acidic aqueous solution. With few exceptions, these changes are the result of titration of the tertiary amino function, i.e., they are not the result of solvent effects. For example, each of the five Cotton effects of β-colubrine and dihydro-β-colubrine have the same relative sign in alkaline aqueous solution and TEP, which seems to rule out solvent dependent mechanisms as the origin of the sign inversions. However, it should be remembered that evidence of intermolecular aggregation was observed in alkaline aqueous solutions of several of the molecules studied, especially strychnine, dihydrostrychnine, and dihydrobrucine.

The sensitivity of the CD spectra of these molecules to the titration of the tertiary amino function appears to arise primarily from the ^1L_a, the n–π*, and the ^1B_b transitions. There is an apparent change in the sign of the ^1L_b transitions of strychnine and dihydrostrychnine, but the data are somewhat questionable because of difficulties with aggregation of these molecules in aqueous solution. In dihydro-β-colubrine removal of the nitrogen proton resulted in a change in sign of the Cotton effect arising from the n–π* transition alone, whereas in β-colubrine three Cotton effects changed sign (^1L_a, n–π*, ^1B_b).

One can think of several possible origins for the p*H* dependence of the CD spectra that was observed with these molecules. For example, a p*H* dependent conformational equilibrium, direct perturbation of the electronic states of the molecules, charge dependence of the chiroptical mechanism, and p*H* dependent solvation are some of the possibilities. However, it is difficult to distinguish between the various mechanisms upon the basis of the present experimental data alone. The resolution of the question of the origins of the p*H* dependence of the CD spectra must await the completion of a thorough theoretical analysis of the mechanisms by which these molecules generate optical rotatory power.

Some interesting similarities between the CD spectra of the various alkaloids and their dihydro-derivatives are also revealed by the data of Table 3. For example, in TEP solution, where aggregation effects are minimized, the CD spectrum of a given alkaloid is very similar to the corresponding dihydro derivative. This is especially true insofar as the three lowest energy transitions are concerned; the ^1L_b and n–π* Cotton effects are consistently negative for all of the molecules. In only one instance, i.e., the ^1L_a bands of brucine and dihydrobrucine, does one of these transitions give rise to Cotton effects that are of opposite sign in the dihydro derivative and the parent alkaloid. This particular case is not surprising, since the polarization direction of the ^1L_a transitions of brucine and dihydrobrucine may well be quite different from that of the corresponding transitions in β-colubrine and strychnine. Thus, this transition may couple more favorably with the ethylenic chromophore in brucine than in the other alkaloids. Reduction of the ethylenic group would obviously eliminate any contribution by this mechanism.

The similarities between the CD spectra of the parent alkaloids and their dihydro derivatives even carry over into aqueous solution, where only the ^1L_a transitions of β-colubrine and dihydro-β-colubrine give rise to Cotton effects of opposite sign. Thus, elimination of the ethylenic chromophore by reduction appears to have only minimal effects on the CD spectra of these alkaloids. This is somewhat surprising, since reduction introduces a new chiral center. However, most of the rotatory strength is apparently being generated locally, i.e., on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

chromophore that has been designated as an acetanilide chromophore, at least in the case of β-colubrine and strychnine and their dihydro derivatives. The new chiral center is apparently so far removed from this chromophoric group that it exerts no appreciable influence. A similar situation has been reported in the case of other alkaloids. For example, Finch and Taylor (26) found that introduction of chiral centers at similar locations on certain heteroyohimbine alkaloids resulted in no major changes in the optical rotatory dispersion spectra.

In summary, significant differences and similarities were observed in the CD spectra of the closely related molecules which were studied in this investigation. It is not possible to arrive at definite conclusions regarding the origins of these observations at the present time, but the differences which were observed cannot be regarded as surprising from a qualitative point of view. The essential similarity to be noted among the CD spectra of these molecules is the presence of the same number of Cotton effects. It is especially significant that the CD spectra of all of the molecules which were investigated yield evidence for an electronic transition that is not discernable in the uv absorption spectra. This transition, which has been tentatively assigned as an $n-\pi^*$ transition, appears to give rise to Cotton effects between 230 and 240 nm in all of the molecules that were investigated.

Fluidities and conductances of glass-forming melts of cadmium nitrate tetrahydrate and transition metal chlorides

N. ISLAM, S. KUMAR, AND K. P. SINGH

Department of Chemistry, Aligarh Muslim University, Aligarh 202001, India

Received August 17, 1977

N. ISLAM, S. KUMAR, and K. P. SINGH. Can. J. Chem. **56**, 1231 (1978).

The temperature dependences of fluidities and equivalent conductances of $Cd(NO_3)_2 \cdot 4.1H_2O$–$(Ni/Co)Cl_2$ melts have been explained in terms of Vogel–Tammann–Fulcher and Adam–Gibbs equations. The differences in the values of the glass transition temperatures and the preexponential factors corresponding to the Ni^{2+} and Co^{2+} melts were attributed to the differences in the masses of the two systems. The linear decrease and increase observed in the values of the preexponential factor and the glass transition temperature, respectively, with increasing concentration of the solute were discussed. The overall composition dependences of transport properties were analyzed using expressions derived on the basis of both the above equations.

N. ISLAM, S. KUMAR et K. P. SINGH. Can. J. Chem. **56**, 1231 (1978).

On a expliqué le fait que les fluidités et les conductivités équivalentes de masses fondues $Cd(NO_3) \cdot 4.1H_2O$–$(Ni/Co)Cl_2$ dépendent de la température en termes des équations de Vogel–Tamman–Fulcher et Adam–Gibbs. On attribue les différences dans les valeurs des températures de transition vitreuse et les facteurs préexponentiels correspondants aux masses fondues de Ni^{2+} et Co^{2+} aux différences dans les masses de ces deux systèmes. On discute de la diminution et de l'augmentation linéaire observées respectivement dans les valeurs des facteurs préexponentiels et des températures de transition vitreuse avec une augmentation de la concentration du soluté. On a analysé le fait que les propriétés de transport dépendent de la composition globale en utilisant des expressions qui sont dérivées à l'aide des deux équations mentionnées plus haut.

[Traduit par le journal]

Introduction

In the non-Arrhenius region, there are satisfactory analytical expressions (1, 2) for explaining the temperature dependence of transport properties. On the other hand, there is a lack of suitable expressions for the illustration of their composition dependence. However, in recent years such equations are being developed based essentially on the Vogel–Tammann–Fulcher (isothermal) as well as on the Adam–Gibbs equations (3–5). In an earlier paper (3), the better feasibility of the latter equation than the isothermal equation (4, 5) has been discussed. It seems to be worthy to make further investigations on the applicability of these less familiar equations in explaining the composition dependence of transport properties of molten salt mixtures. Binary mixtures of nickel and cobalt chlorides with molten cadmium nitrate tetrahydrate have been chosen here for this purpose and fluidities and electrical conductances have accordingly been measured as functions of temperature and composition. These binary systems were selected mainly due to their readiness to supercool to permit measurements in the ordinary temperature range.

Experimental

Commercial cadmium nitrate tetrahydrate (REACHIM, U.S.S.R.; mp 59.4°C) was used as solvent in the molten state. Anhydrous nickel(II) and cobalt(II) chlorides were prepared (6) from their recrystallized hexahydrate salts and these solutes were found to dissolve up to ~12 mol% in the solvent under consideration. The molten mixtures were prepared in a thermostated water bath at ~70°C. Water of crystallization of the hydrated cadmium nitrate was determined before sample preparation by comparing the measured densities with those reported (7) and was found to be 4.1.

Density, viscosity, and conductance measurements were made in a manner described earlier (8) with the same precision.

Results and Discussion

The measured densities, ρ, at eleven different temperatures of both the systems under investigation were least-squares fitted to a linear equation

$$[1] \qquad \rho = a - bT$$

with T in K. Although the computed values of the two empirical parameters, a and b (Table 1[1]), fluctuate randomly with composition, the overall change in the density with composition has been found to be monotonous (Fig. 1[1]).

The measured fluidities and equivalent conductances decrease with increasing composition (Table 2[1]) and show non-Arrhenius temperature dependence.

*Parameters for fluidity are within parentheses.

Therefore, these data were least-squares fitted to the Fulcher or Vogel–Tammann–Fulcher equation

$$[2] \qquad Y(\phi, \Lambda) = A_Y T^{-1/2} \exp\left[-k_Y/(T - T_0)\right]$$

in a manner to obtain approximately constant values for the empirical parameter k_Y. The significance of such a data analysis has been discussed elsewhere (9, 10). The best fit values of the parameters A_Y, k_Y, and T_0 thus obtained are given in Table 3.

The composition dependence of the transport properties is equally important and may indirectly be explained by considering only the variations of the parameters A_Y and T_0 with composition since the third parameter, k_Y, is apparently independent of composition. Therefore, we may consider firstly the variation of glass transition temperature, T_0, with composition. In both the systems, viz., $Cd(NO_3)_2 \cdot 4.1H_2O$–$CoCl_2$ and $Cd(NO_3)_2 \cdot 4.1H_2O$–$NiCl_2$, it has been observed (Fig. 2) that T_0 increases linearly with $[Co^{2+}]$ and $[Ni^{2+}]$. The increase of T_0 with $[Co^{2+}]$ and $[Ni^{2+}]$ in both the systems may be explained by the $m^{-1/2}$ dependence (11) of T_0, m being the average molecular mass. On addition of Co^{2+} and Ni^{2+} to $Cd(NO_3)_2 \cdot 4.1H_2O$, m decreases which may cause an increase in T_0. Moreover, a slightly higher T_0 value observed for the molten mixture of $Cd(NO_3)_2 \cdot 4.1H_2O$–$NiCl_2$ than that of $Cd(NO_3)_2 \cdot 4.1H_2O$–$CoCl_2$ melt at a particular composition may be explained in terms of the cationic potentials (12) or cohesive energies of the systems. The charge:radius ratio for hydrated Ni^{2+} ion (0.578) is higher than that of hydrated Co^{2+} ion (0.575) and, therefore, accounts for the higher T_0 values of the $Cd(NO_3)_2 \cdot 4.1H_2O$–$NiCl_2$ systems.

It is also worthy to note that the T_0 values obtained from the analysis of conductance and viscosity

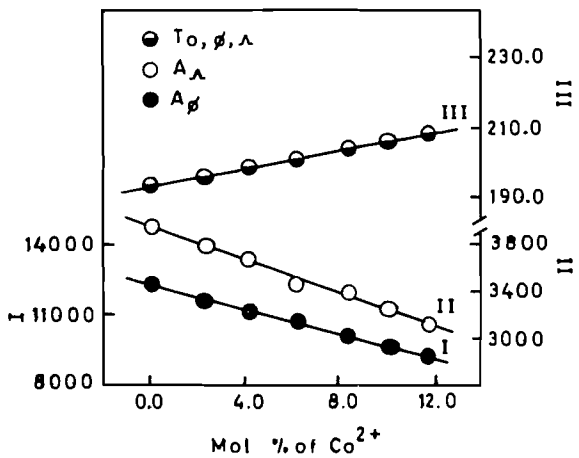

FIG. 2. Variations of A_Y and $T_{0,Y}$ with composition for molten $Cd(NO_3)_2 \cdot 4.1H_2O$–$CoCl_2$ systems (plots are similar for Ni^{2+} systems).

data are very close to each other. This emphasizes the thermodynamic nature of T_0 unlike A_Y and k_Y terms which behave like kinetic parameters.

On the other hand, both A_ϕ and A_Λ appear to decrease linearly (Fig. 2) with increase in $[CO^{2+}]$ and $[Ni^{2+}]$, showing a reverse of their expected $m^{-1/2}$ dependences. There is a difference in the strength of interactions between H_2O–Co^{2+} and H_2O–Ni^{2+} as well as between H_2O–Cd^{2+} which results into the formation of complex species (13) like $Ni(H_2O)_4Cl_2$ and $Co(H_2O)_4Cl_2$. The linear decrease of A_ϕ and A_Λ with increase in mol% of the solute (5, 10) may be attributed to such differences in the strength of interactions. However, the $m^{-1/2}$ dependence relation appears to explain the slightly higher values of A_Y terms observed for the Co^{2+} systems than those for the Ni^{2+} systems. The in-

*Parameters for fluidity are within parentheses.

crease in the rigidity of the systems with composition may also account for the decrease in the pre-exponential factors as reported earlier (3).

Substitution of the linear composition dependences of T_0 and A_Y into [2] provides the isothermal equation (5).

$$[3] \quad Y = (A_{0Y} - Q_{1Y}X)T^{-1/2} \times \exp\,[-k_Y/Q_{2Y}(X_0 - X)]$$

X refers to the mol% of the solute whereas A_{0Y}, Q_{1Y}, Q_{2Y}, and X_0 have the significances explained earlier (5). In order to explain the applicability of this isothermal equation the conductance and fluidity data were least-squares fitted to eq. 3 at an interval of 5 K over 298 to 333 K and over 308 to 333 K in the molten mixtures of $Cd(NO_3)_2 \cdot 4.1H_2O$–$NiCl_2$ and of $Cd(NO_3)_2 \cdot 4.1H_2O$–$CoCl_2$, respectively. The best fit parameters along with the standard deviation in Λ and ϕ are given in Table 4. Linear plots (Fig. 3) of $\log\,[(A_{0Y} - Q_{1Y}X)/YT^{1/2}]$ vs. $1/(X_0 - X)$ pass through the origin which reinforce the applicability of [3] in describing such behaviour. Moreover, the computer fitted values of the parameters A_{0Y}, Q_{1Y}, Q_{2Y}, and X_0 were found to be in good agreement with their values obtained from the corresponding plots. In molten mixtures of Co^{2+} the values of X_0 ap-

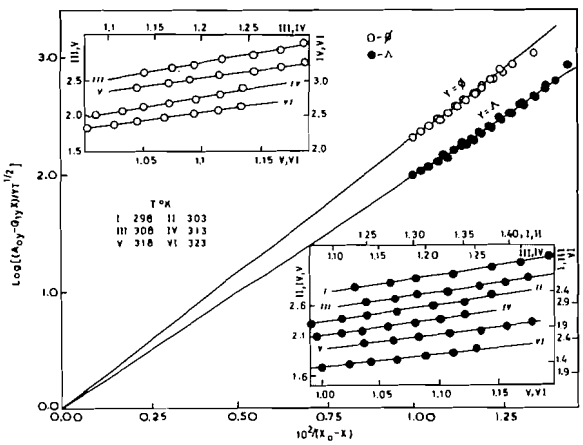

FIG. 3. Plots of $\log\,[(A_{0Y} - Q_{1Y}X)/YT^{1/2}]$ vs. $1/(X_0 - X)$ for molten $Cd(NO_3)_2 \cdot 4.1H_2O$–$CoCl_2$ systems (plots are similar for Ni^{2+} systems).

proach ~100 mol% at 323 K indicating it as the T_0 value for the pure solute, $CoCl_2$. Similarly, T_0 value for $NiCl_2$ has been found to be 333 K. Such a higher value of T_0 for Ni^{2+} than for Co^{2+} was reported previously in melts (5) as well as in aqueous solutions (14) of $NiCl_2$ and $CoCl_2$.

However, it may be observed from Table 4 that the upper temperature limits for the application of

*Parameters for fluidity are within parentheses.

[3] in the two systems under consideration are different. Such limitations in the temperature range for the applicability of the isothermal equation has been discussed in an earlier publication (3).

Therefore, the composition dependence of Λ and ϕ in the present systems has been re-examined by considering T_0 as a basis for the corresponding temperatures, T. For this purpose, the measured equivalent conductance and fluidity data have been fitted to the Adam–Gibbs equation

$$[4] \qquad Y = A_Y' \exp\left[-k_Y'/T \ln (T/T_0)\right]$$
$$= A_Y' \exp\left[-k_Y'/T_0\, c \ln c\right]$$

at $T/T_0 =$ constant $= c$. The variations in A_Y' and T_0 with composition (Table 5) are identical to those in the corresponding parameters of [2]. k_Y' remains independent of composition as k_Y. By accounting for the linear composition dependences of T_0 and A_Y' eq. 4 may be expressed as

$$[5] \quad Y = (A_{0Y}' - Q_{1Y}'X) \times \exp\left[-k_Y'/(T_{0(0)} + Q_{2Y}X)c \ln c\right]$$

The fluidities and conductances data of $Cd(NO_3)_2 \cdot 4.1H_2O$–$CoCl_2$ and $Cd(NO_3)_2 \cdot 4.1H_2O$–$NiCl_2$ systems at constant T/T_0 ($c = 1.5$) values were computed from the Adam–Gibbs equation and they were in turn least-squares fitted to [5]. Reasonably good fits were obtained as it is apparent from Table 6 in the entire experimental range of temperature. The values of parameters A_{0Y}', Q_{1Y}', $T_{0(0)}$, and Q_{2Y} were found to be in good agreement with those obtained from the corresponding linear plots of A_Y and T_0 vs. composition for both the systems under investigation. Furthermore, the plots (Fig. 4) of log $[(A_{0Y}' - Q_{1Y}'X)/Y]$ vs. $1/(T_{0(0)} + Q_{2Y}X)$ were linear and pass through the origin showing the applic-

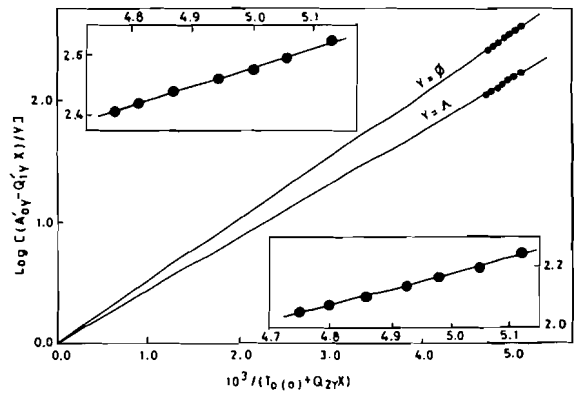

FIG. 4. Plots of log $[(A_{0Y}' - Q_{1Y}'X)/Y]$ vs. $1/(T_{0(0)} + Q_{2Y}X)$ for molten $Cd(NO_3)_2 \cdot 4.1H_2O$–$CoCl_2$ systems (plots are similar for Ni^{2+} systems).

For personal use only.

ability of [5]. These two linear plots corresponding to $Y = \phi$ and $Y = \Lambda$ of $Cd(NO_3)_2 \cdot 4.1H_2O$–$CoCl_2$ melts appear to overlap on those of $Cd(NO_3)_2 \cdot 4.1H_2O$–$NiCl_2$ melts. This may be expected due to the fact that their slopes equal to $k_Y'/c \ln c$ are close to one another in the two binary molten systems owing to the universal constant values of k_Y' terms.

Therefore, eq. 5 appears to have a better applicability than [3] as far as the temperature range is concerned. However, it may be pointed out that before testing the applicability of [5] the conductance and fluidity data have to be fitted independently to [4] for obtaining T_0 values and this puts a restriction on the direct application of [5]. It may, therefore, be concluded that eq. 5 is a better expression for describing the composition dependence of transport properties provided these properties have been measured as functions of both temperature and composition.

The $C(\alpha)$-dianions of azines prepared from acetophenone or substituted acetophenones underwent dialdol condensations with ketones to give dihydroxyazines.

STEVEN E. DAVIS, NEAL L. SHEALY, KEITH D. SHEALY, LYNN M. SHAFFER et CHARLES F. BEAM. Can. J. Chem. **56**, 1236 (1978).

Les dianions $C(\alpha)$ des azines préparés à partir de l'acétophénone ou d'acétophénones substitués subissent des condensations di-aldoliques avec les cétones pour conduire aux dihydroxy-azines.

[Traduit par le journal]

Introduction

In comparison with the reports on the preparation and condensation of $C(\alpha)$-anions of oximes and hydrazones with electrophilic reagents (1–3), the synthesis of materials from $C(\alpha)$-dilithioazines has received little attention; in fact, we found the results of the earlier alkylation studies difficult to reproduce (4).

Results and Discussion

The $C(\alpha)$-dianions of acetophenone azines and substituted acetophenone azines (symmetrical and unsymmetrical) were prepared from *n*-butyllithium in tetrahydrofuran (preferable to ether (4)) at 0°C, and they were condensed with ketones, such as benzophenone and cyclohexanone, to give dialdol products. Each dihydroxyazine **1**–**7** (Table 1) contained ^{1}Hmr methylene resonances at δ 3.25 $\pm$ 0.05 ppm and ir absorptions for hydroxyl at approximately 3275 cm^{-1}. As anticipated, hydroxyazines **1** and **5** underwent linear dehydration with concentrated sulfuric acid at 0°C to give azines **8** and **9**, in 49 and 50% yields, respectively (Scheme 1).

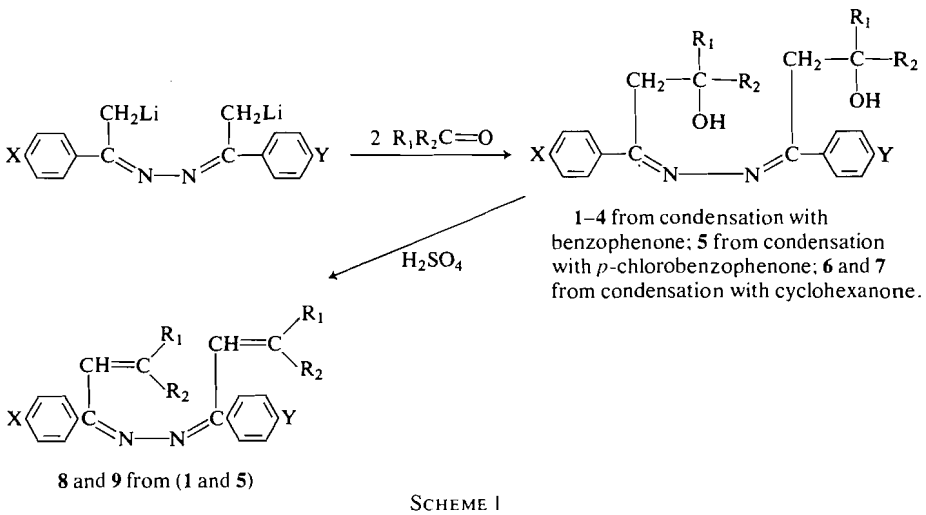

SCHEME I

Experimental

Preparation of Azines

The symmetrical azines were prepared by treating the ketone with hydrazine hydrate (20% molar excess) in 95% ethanol containing a catalytic amount of acetic acid and heating under reflux for ca. 1 h. The unsymmetrical azines were prepared by treating the ketone with a hydrazine in 95% ethanol containing a catalytic amount of acetic acid and heating under reflux for ca. 1 h. All starting materials were recrystallized from 95% ethanol.

General Procedure for Preparation of C(α)-Dilithioazines

A 0.02-mol sample was dissolved in 100–150 ml of dry tetrahydrofuran, cooled to 0°C, blanketed with nitrogen, and stirred; 0.042 mol of *n*-butyllithium (1.6 *M* in hexane) was added dropwise and the resulting red-brown mixture was stirred 30–45 min.

General Procedure for Dialdol Condensation

A solution of 0.042 mol of ketone in 50–75 ml of THF was added to the C(α)-dilithioazine (see procedure above) and stirred for 30–60 min and inversely neutralized by pouring the entire solution into 200–300 ml of ice and water (containing 1 or 2 milliliters of concentrated HCl). The layers were separated and the water layer was extracted with 2 × 75 ml portions of ether. The organic layers were combined, dried ($MgSO_4$), concentrated (Rotovac), and crystallized from ethanol. Recrystallization solvents are listed in the footnotes of Table 1.

General Procedure for Linear Dehydration of Hydroxyazines

A 1 g sample of hydroxyazines **1** or **5** was added to 10 ml of cold concentrated sulfuric acid (0°C) and stirred at this temperature until solution was complete, ca. 1 h. The solution was then poured on to 200–300 g of crushed ice, filtered, washed with water, dried, and recrystallized from ethanol–benzene to give azines **8** (from **1**) mp 214–215°C and 9 (from **5**) mp 190–192°C in 49 and 50% yield, respectively. The infrared (Nujol) spectra of these materials contained no hydroxyl absorption characteristic of hydroxyazines **1**–**7**. *Anal.* calcd. for $C_{42}H_{32}N_2$ (**8**): C 89.33, H 5.71, N 4.96; found: C 89.58, H 5.95, N 4.67. *Anal.* calcd. for $C_{42}H_{30}Cl_2N_2$ (9): C 79.62, H 4.74, N 4.42; found: C 79.36, H 4.93, N 4.40.

Fluorescence attributable to the tyrosinate form of the amino acid tyrosine, previously only observed at $pH > pK(S_0) = 10.3$ where tyrosinate exists in the ground state, has been observed at neutral pH in the presence of high buffer base concentrations. This observation is consistent with the large shift in $pK(S_1)$ predicted from absorption measurements and confirms that proton transfer is indeed a mechanism by which carboxylate ions quench tyrosine fluorescence. The dependence of the fluorescence quantum yields of tyrosine and tyrosinate on pH does not fit a simple excited state acid–base equilibrium model but a more complicated system where carboxylate is also capable of simultaneously quenching tyrosine fluorescence by a mechanism not involving proton transfer. Kinetic analysis of the system allows calculation of $pK(S_1) = 4.2$ for tyrosine. The quantum yield of tyrosinate fluorescence can be appreciably higher than that normally measured at alkaline pH where a separate quenching mechanism must operate. These results have significance in the interpretation of the fluorescence properties of proteins.

DAVID MICHAEL RAYNER, DONALD THEODORE KRAJCARSKI et ARTHUR GUSTAV SZABO. Can. J. Chem. **56**, 1238 (1978).

On a observé de la fluorescence attribuable à la forme tyrosinate de l'acide aminé tyrosine, observé antérieurement uniquement à des $pH > pK(S_0) = 10.3$ auquel le tyrosinate existe dans son état fondamental, à un pH neutre en présence de concentrations élevées de tampons basiques. Cette observation est en accord avec un grand déplacement dans le $pK(S_1)$ qui peut être prédit à partir de mesures d'absorption et confirme que le transfert de proton est de fait un mécanisme par lequel les ions carboxylates piègent la fluorescence de la tyrosine. Le fait que les rendements quantiques de la fluorescence de la tyrosine et du tyrosynate dépendent du pH ne cadre pas avec un modèle acide–base à l'équilibre d'un état excité simple mais avec un système plus compliqué dans lequel le carboxylate est aussi capable de piéger simultanément la fluorescence de la tyrosine par un mécanisme n'impliquant pas un transfert de proton. Une analyse cinétique du système permet de calculer le $pK(S_1) = 4.2$ pour la tyrosine. Le rendement quantique de la fluorescence du tyrosinate peut être beaucoup plus élevé que celui mesuré normalement au pH alcalin quand un mécanisme de piégeage séparé peut être en opération. Ces résultats ont une signification dans l'interprétation des propriétés de fluorescence des protéines.

[Traduit par le journal]

Introduction

In the course of our studies of the fluorescence properties of proteins and amino acids and their structural implications we were struck by the lack of attention paid in recent reviews (1, 2) to the excited state acid–base properties of tyrosine. As a substituted phenol tyrosine would be expected to show similar behaviour to 2-napthol, Weller's (3) classic example of a compound which is far more acidic in the excited state than the ground state ($pK(S_0) = 9.46$, $pK(S_1) = 2.8$). An estimate of ΔpK, ($pK(S_1) - pK(S_0)$), for tyrosine can be obtained from its absorption spectra with the phenol hydroxyl group ionized and unionized using the Förster (4) cycle. By this method Feitleson (5) was able to make the rough estimate $\Delta pK \approx -5$. This predicts $pK(S_1) = 5.3$ for $pK(S_0) = 10.3$ (6). The lack of dependence of the quantum yield of fluorescence of tyrosine in water on pH in the range $pH = 4$ to $pH = 8$ (5, 7) must then be accounted for by the dominance of the rate of deactivation of excited singlet tyrosine to the ground state over the rate of deprotonation to form excited singlet tyrosinate even when the latter pathway is thermodynamically favoured. However, one cannot go on to conclude that the possibility of tyrosinate being formed in the excited state in solutions of $pH < pK(S_0)$ can be ruled out in all cases. Feitleson (5) has shown that weak bases such as acetate quench tyrosine fluorescence under Stern–Volmer kinetics and he reasonably suggests that the mechanism involves transfer of the phenolic proton to the base. Such a mechanism has also been cited by Weber and Rosenheck (8) to explain the quenching of fluorescence in tyrosine copolymers compared to that in their *O*-methylated analogues. Konev (9) lists evidence for such a mechanism being responsible for

fluorescence quenching in tyrosine proteins containing glutamic and aspartic acid. Weller's (3) quantitative studies of the 2-napthol/acetate system provide a well investigated model system for such quenching.

In a recent review Longworth (2) dismissed proton transfer as the mechanism for the quenching by carboxylate in tyrosine polymers. For the model compound *N*-acetyl-L-tyrosinamide which is expected to show similar excited state acid–base behaviour to tyrosine Longworth and Rahn (10) concluded that the excited state protolytic constant of the phenolic hydroxyl is identical to that of the ground state constant because the inflection point in the fluorimetric titration of this compound is found at the ground state p*K*. This conclusion is not consistent with the large shift found in the absorption spectrum on ionization and these authors have overlooked the implications of excited state acid–base behaviour.

These differences in opinion as to the importance of proton transfer in the quenching of tyrosine fluorescence have led us to conduct this present study of the excited state acid–base properties of tyrosine.

Experimental

Compounds and Materials

L-Tyrosine (Aldrich; 99+%) was recrystallized three times from water. Sodium acetate and acetic acid were analytical reagent grade. Water was purified using an Aqua Media 25 water purification system which we have found as satisfactory as double distillation in reducing background fluorescence.

Methods

Buffered solutions were made up exactly in acetate concentration and their p*H* adjusted by the addition of acetic acid ($pK_a = 4.75$). Hydrogen ion concentration was determined using a Radiometer 26 p*H* meter with a glass electrode. Absorption measurements were made using a Cary 118 spectrophotometer. Corrected fluorescence spectra were measured using a Perkin-Elmer MPF 44A fluorimeter with a Corrected Spectra Unit previously calibrated using quantum counter solutions. Tyrosine fluorescence quantum yields were calculated from fluorescence intensity measurements taken at a fixed wavelength by assuming Chen's (11) value of 0.14 for the quantum yield of tyrosine in water at neutral p*H*. Tyrosinate fluorescence quantum yields were calculated in a similar manner relative to the value of Cornog and Adams for tyrosinate (12) revised to 0.006 to be relative to Chen's value for tyrosine. Where necessary intensity measurements were first corrected for background fluorescence measured from blank solutions identical to the sample solutions in every respect save the presence of tyrosine. The excitation wavelength was 280 nm at which the tyrosine solutions (10^{-4} *M*) in the p*H* range 7.0 to 3.75 had an optical density of 0.124 ± 0.001 unaffected by buffer concentration. The tyrosine concentration in 0.1 *M* NaOH was adjusted to 0.82×10^{-4} *M* to give the same optical density at 280 nm for the purpose of quantum yield measurements. Emission and excitation bandwidths were 4 nm. Fluorescence lifetimes were measured using an NRCC built fluorimeter and correction and deconvolution techniques which have been described previously (13–15). All fluorescence measurements were made in 10 mm × 10 mm quartz cells thermostated at 21°C.

Direct Evidence for Proton Transfer as a Mechanism for Weak Base Quenching

In the absence of buffer the extent to which the excited state equilibrium in the reaction scheme

[1] $$\overset{*}{RH} \underset{k_2[H^+]}{\overset{k_1}{\rightleftharpoons}} \overset{*}{R^-} + H^+$$

with $\overset{*}{RH}$ decaying by k_f and k_0, and $\overset{*}{R^-}$ decaying by k_f' and k_0',

is established on excitation of RH alone depends on the relative magnitude of the rate constant k_1 to $(k_f + k_0)$. As previously stated for tyrosine we must have $(k_f + k_0) \gg k_1$ to account for the lack of inflection in the fluorescence titration near the estimated $pK(S_1) \approx 5$. In the presence of buffer we must also consider the equlibrium

[2] $$\overset{*}{RH} + B^- \underset{k_b'[HB]}{\overset{k_b[B^-]}{\rightleftharpoons}} \overset{*}{R^-} + HB$$

With buffer concentrations high enough for $k_b[B^-]$ to become significant compared with $(k_f + k_0)$ one would expect to observe a drop in $\overset{*}{RH}$ fluorescence and a corresponding rise in $\overset{*}{R}^-$ fluorescence provided the p*H* is appropriate for the equilibrium to be established.

In aqueous tyrosine solutions of p*H* 13 Cornog and Adams (15) have observed weak fluorescence, quantum yield 0.006 ± 0.001 (adjusted to Chen's (11) value for tyrosine), which can be attributed to the tyrosinate species (12). In water – dimethylsulphoxide–ethylene glycol solvent mixture the quantum yield for tyrosinate is given as 0.03 compared with 0.23 for tyrosine (10). The proton transfer quenching mechanism requires at least the partial establishment of the equilibrium 2 and the production of excited tyrosinate ($\overset{*}{R}^-$). If this is the case then it should prove possible, although difficult, to observe emission characteristic of tyrosinate in solutions of high buffer concentration with $pH < 10$.

Figure 1 shows the corrected emission spectra for tyrosine in acetate/acetic acid buffer solutions of varying buffer concentration all with $pH = 6.05$. As the buffer concentration is increased overall quenching is observed but also the relative strength of the emission at 340 nm to that at 302 nm increases until a definite shoulder can be observed in the 2 *M* acetate solution. This is more obvious in Fig. 2 where the spectra in 10^{-2} *M* acetate and 2 *M* acetate are shown normalized to their peak emissions after subtraction of blank solution fluorescence to remove the scatter observable in Fig. 1. The shoulder can be attributed

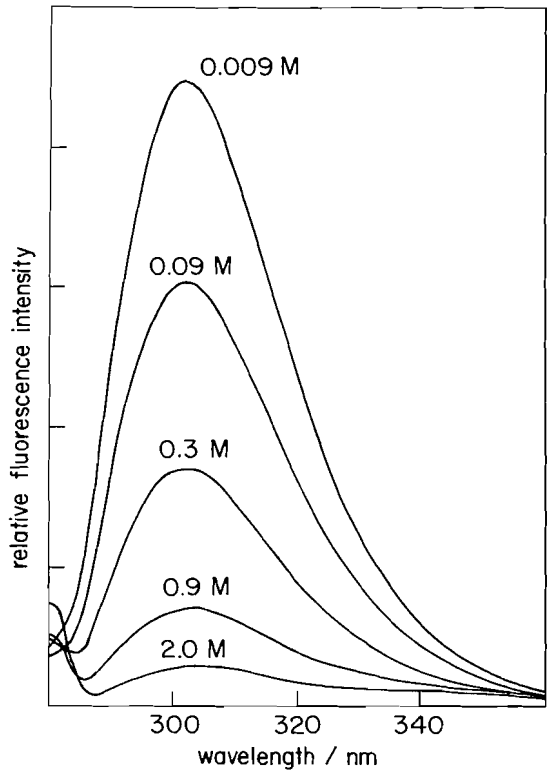

FIG. 1. Corrected fluorescence emission spectra of tyrosine in acetate/acetic acid buffer solutions of differing buffer concentration. pH = 6.05.

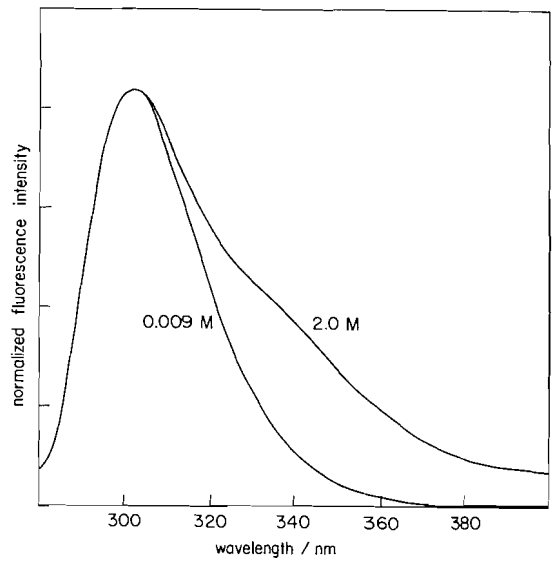

FIG. 2. Corrected fluorescence emission spectra of tyrosine in 0.009 and 2 M acetate solutions at pH = 6.05.

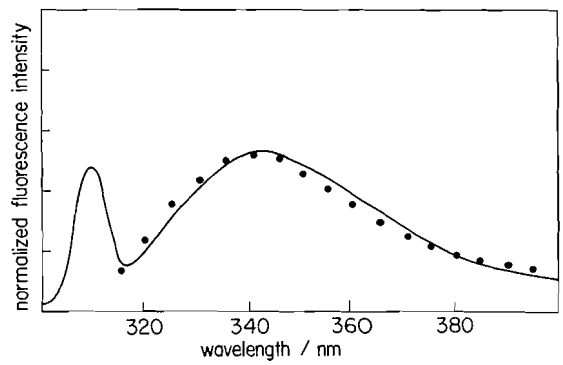

FIG. 3. Corrected fluorescence emission spectrum of tyrosinate in 0.1 M NaOH (solid line) and the spectrum found in 2 M acetate at pH = 6.05 after subtraction of the tyrosine contribution from the overall spectrum (points).

to a second emitting species produced by the addition of acetate. The spectrum of the second species can be generated by assuming that it does not extend down to 302 nm and then subtracting the spectrum in 10^{-2} M acetate from the spectrum in 2 M acetate having previously normalized the two at 302 nm. The spectrum attained in this manner is superimposable with that from a solution of tyrosine in 0.1 M NaOH, i.e. with the tyrosinate fluorescence spectrum (Fig. 3). We therefore assign the observed shoulder to fluorescence from tyrosinate. This is direct evidence for proton transfer as a mechanism for the weak base quenching of tyrosine fluorescence. We have been able to reproduce this behaviour qualitatively using buffer systems other than acetate. Similar results using phosphate, cacodylate, and citrate buffers with high base concentrations show that the mechanism is general and does not apply only for acetate.

pH Dependance of Tyrosine and Tyrosinate Fluorescence at High Buffer Concentration

Table 1 shows the dependance of the quantum yield of the fluorescence assigned in the previous section to tyrosinate and tyrosine as a function of pH in the absence of buffer and in acetate/acetic acid buffers with the acetate concentration held at 0.9 M. Tyrosinate relative intensities, from which the quantum yields were found, were calculated by assuming that tyrosinate does not emit at 302 nm. From the ratio of relative intensities at 302 and 340 nm in very dilute (10^{-3} M) buffer, where we assume only unionized tyrosine fluorescence is observed, and the intensity of the sample in question at 302 nm we can calculate the tyrosine contribution to the fluorescence at 340 nm. Subtraction from the measured value at 340 nm then gives us a measure of the intensity due to tyrosinate. Restrictions of the buffer system prevent measurements below pH = 3.7. The tyrosinate points are a good fit to a theoretical

*ϕ values are relative to this value of Chen (11) for tyrosine in water.
†ϕ' values are relative to the value of Cornog and Adams (15) adjusted for the revised quantum yield of tyrosine in water of Chen (11).

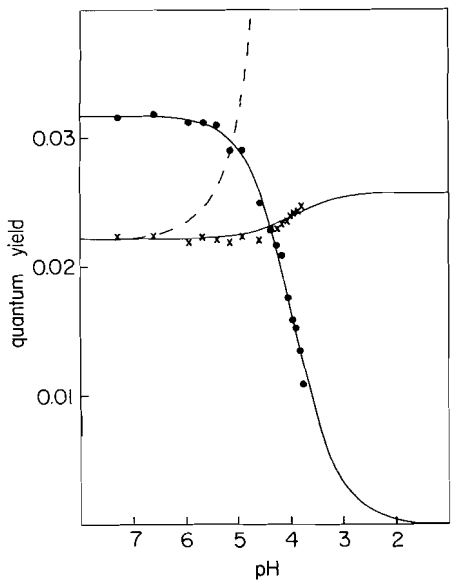

FIG. 4. Quantum yields of fluorescence of tyrosine (×) and tyrosinate (●) as a function of pH in 0.9 M acetate solutions.

sigmoid titration curve with midpoint at pH = 3.95 (solid line in Fig. 4). Over the same pH range the tyrosine fluorescence, as measured at 302 nm, increases. The behaviour of this system is then typical of a partially established excited state acid–base equilibrium.

A qualitative treatment of the results along the lines used by Weller can be attempted. The following straightforward reaction scheme can be proposed,

$$\overset{*}{R}H \underset{k_2[H^+]}{\overset{k_1}{\rightleftharpoons}} \overset{*}{R}^- + H^+$$

$$\overset{*}{R}H + B^- \underset{k_b'[BH]}{\overset{k_b[B^-]}{\rightleftharpoons}} \overset{*}{R}^- + BH$$

$$\overset{*}{R}H \xrightarrow{k_f} RH + h\nu \qquad \overset{*}{R}H \xrightarrow{k_0} RH$$

$$\overset{*}{R}^- \xrightarrow{k_f'} R^- + h\nu \qquad \overset{*}{R}^- \xrightarrow{k_0'} R^-$$

where RH = tyrosine, R^- = tyrosinate, B^- and BH are the two buffer species, and * denotes a species in its first excited singlet state. By setting up the steady state equations for $[\overset{*}{R}H]$ and $[\overset{*}{R}^-]$ and applying the condition that only RH is present in the ground state in the pH range used the following expressions can be obtained.

$$[3] \qquad \frac{\phi}{\phi_0} = \frac{1}{1 + (k_1 + k_b[B^-])\tau/(1 + (k_2[H^+] + k_b'[HB])\tau')}$$

$$[4] \qquad \frac{\phi'}{\phi_0'} = \frac{1}{1 + (1 + (k_2[H^+] + k_b'[HB])\tau')/(k_1 + k_b[B^-])\tau}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where ϕ and ϕ' are the quantum yields of fluorescence from $\overset{*}{R}H$ and $\overset{*}{R}^-$ respectively. $\tau = 1/(k_f + k_0)$, $\tau' = 1/(k_f' + k_0')$, $\phi_0 = k_f\tau$, and $\phi_0' = k_f'\tau'$ are the respective lifetimes and quantum yields where only the one species exists in both ground and excited states. However the tyrosine results are not totally consistent with these expressions. At low pH ϕ/ϕ_0 is predicted by [3] to reach a limiting value of 1 and the tyrosine fluorescence titration curve should follow the dotted curve in Fig. 4. This is clearly not the case, although restrictions of the buffer system and the added complication of the protonation equilibrium of the tyrosine carboxylate group prevent us from measuring a low pH value directly. We therefore propose that acetate is capable of quenching tyrosine fluorescence simultaneously by two mechanisms, one involving proton transfer and the other not. Conflicting statements exist in the literature as to whether carboxylate ions will quench *O*-methylated tyrosine (2, 9, 16) but where quenching has been observed it is clearly not by proton transfer. It has also been stated (5) that carboxylic acids quench tyrosine fluorescence but such conclusions have to be drawn from indirect measurements as the strongly quenching carboxylate ion must also be present in appreciable quantities to maintain a constant pH. We find no evidence for carboxylic acid quenching. Tyrosine fluorescence has a constant yield in 0.9 M acetate in the pH range 7 to 4.9 where the acetic acid concentration ranges from 0.0005 to 0.6 M. When we studied the quenching of tyrosine fluorescence by acetate – acetic acid buffer at two different acidities, pH = 6.05 and pH = 4.75, we obtained the same Stern–Volmer quenching constant (5.7 M^{-1}) despite the greatly increased acetic acid concentrations at the lower pH (Fig. 5).

Our proposal that acetate quenches tyrosine fluorescence by two mechanisms means that another deactivation pathway

$$\overset{*}{R}H + B^- \xrightarrow{k_q[B^-]} RH + B^-$$

must be considered in addition to the straightforward reaction scheme discussed above. If ρ and ρ' are the probabilities that RH and R^-, respectively, are still excited at time t after excitation then

$$[5] \quad \frac{d\rho}{dt} = \rho'(k_b'[HB] + k_2[H^+]) - \rho(k_1 + k_b[B^-] + k_f + k_0 + k_q[B^-])$$

and

$$[6] \quad \frac{d\rho'}{dt} = \rho(k_1 + k_b[B^-]) - \rho'(k_2[H^+] + k_b'[HB] + k_f' + k_0')$$

Applying the condition that only RH is present in the ground state and with

$$\phi = k_f \int_0^\infty \rho \, dt$$

$$\phi' = k_f' \int_0^\infty \rho' \, dt$$

$\phi_0 = k_f\tau$ and $\phi_0' = k_f'\tau'$ where $1/\tau = (k_f + k_0)$, $1/\tau' = (k_f' + k_0')$, and $1/\tau_Q = k_f + k_0 + k_q[B^-]$, it can be shown that

$$[7] \quad \frac{\phi}{\phi_0} = \frac{1}{(\tau/\tau_Q) + (k_1 + k_b[B^-])\tau/\{1 + (k_2[H^+] + k_b'[HB])\tau'\}}$$

and

$$[8] \quad \frac{\phi'}{\phi_0'} = \frac{1}{1 + \{1 + (k_2[H^+] + k_b'[HB])\tau'\}/(k_1 + k_b[B^-])\tau_Q}$$

It can also be shown that

$$[9] \quad (k_2[H^+] + k_b'[HB])\tau' = (k_1 + k_b[B^-])[H^+]\tau'/K^*$$

where $K^* = [\overset{*}{R}^-][H^+]/[\overset{*}{R}H]$, the excited state acid–base dissociation constant. Equations 7 and 8 then become

$$[10] \quad \frac{\phi}{\phi_0} = \frac{1}{(\tau/\tau_Q) + (k_1 + k_b[B^-])\tau/\{1 + (k_1 + k_b[B^-])[H^+]\tau'/K^*\}}$$

and

$$[11] \quad \frac{\phi'}{\phi_0'} = \frac{1}{1 + \{1 + (k_1 + k_b[B^-])[H^+]\tau'/K^*\}/(k_1 + k_b[B^-])\tau_Q}$$

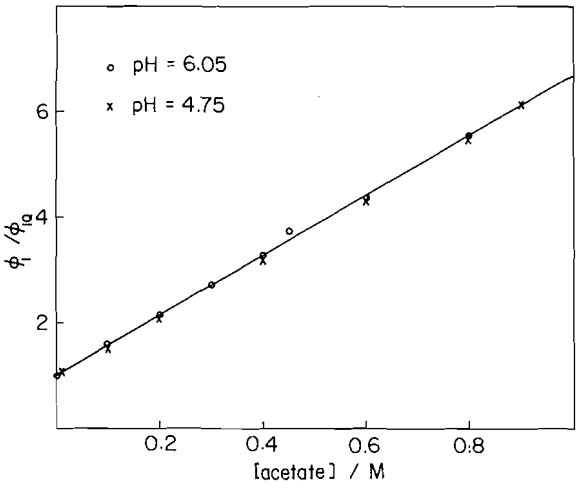

FIG. 5. Stern–Volmer plots at pH = 6.05 and pH = 4.75 for acetate quenching of tyrosine fluorescence.

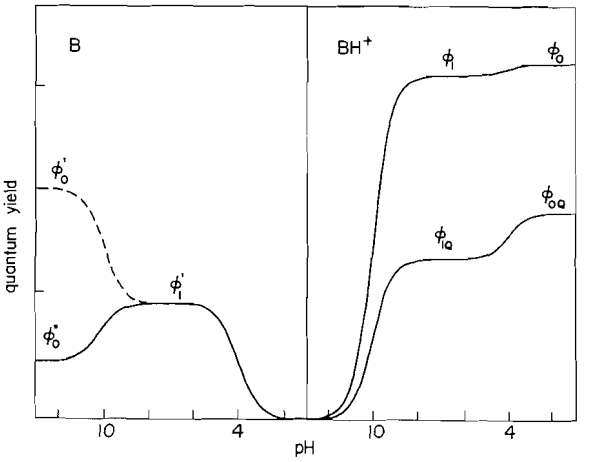

FIG. 6. Dependance of the quantum yields of fluorescence of tyrosine (ϕ) and tyrosinate (ϕ') as predicted when two mechanisms for acetate quenching of tyrosine are considered.

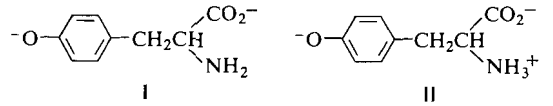
These are the general relationships which describe the dependence of the steady state fluorescence of tyrosine and tyrosinate respectively on buffer and proton concentration. From them it is possible to determine K^* if ϕ_0 or ϕ_0' and τ, τ_Q, and τ' are known.

For the tyrosine–tyrosinate system, however, it is impossible to measure either ϕ_0 or ϕ_0' directly. At low pH where one would measure ϕ_0 the system is further complicated by the drop in fluorescence yield associated with the ground state protonation of the tyrosine carboxylate group (5, 7). At pH = 13 where both ground and excited states are of the tyrosinate form the quantum yield (ϕ' = 0.006) is considerably lower than that found for tyrosinate in the plateau region at p$H \simeq 7$ (ϕ' = 0.021). There is therefore some other quenching mechanism of tyrosinate operating at p$H \simeq$ 13. At pH = 13 the α amino group of ground state tyrosinate is unprotonated (pK = 9.35) and the emitting species will be of form I while at pH = 6 tyrosinate is generated as a



zwitterion in the excited state (II) from the zwitterion form of tyrosine. Perhaps in form I tyrosinate has a lower quantum yield than in form II which exists only in the excited state at lower pH. For the same reason we cannot measure τ' directly.

It is, however, still possible to find K^*. Figure 6 shows the theoretical form of the dependence of ϕ and ϕ' on pH predicted by [10] and [11] in the presence and absence of buffer for a set of quantum yield and pK values chosen for demonstration purposes. This figure helps in the definition of the symbols used in the following treatment where: the subscript 0 refers to yields in the plateau regions attained at the extremes of the acidity range; the subscript Q refers to yields in the presence of a fixed concentration of buffer, its absence indicating no buffer present; the subscript 1 refers to yields attained in the mid-acidity range plateau. The dotted line in Fig. 6 is the line predicted in the absence of the extra quenching mechanism for tyrosinate at pH > p$K(S_0)$ discussed earlier. A single prime superscript is used for yields on this line and a double prime for the experimentally found quenched yield. Equation 11 rearranges to give

$$[12]\quad \frac{1}{\phi'} = \frac{1}{\phi_0'}\left(1 + \frac{1}{(k_1 + k_b[B^-])\tau_Q}\right) + \frac{1}{\phi_0'}\frac{\tau'}{\tau_Q}\frac{[H^+]}{K^*}$$

A graph of $1/\phi'$ vs. $[H^+]$ at constant $[B^-]$, Fig. 7, is linear with

$$\text{Slope} = \left\{\frac{1}{\phi_0'}\frac{\tau'}{\tau_Q}\frac{1}{K^*}\right\}$$

and

$$\text{Intercept} = \frac{1}{\phi_0'}\left\{1 + \frac{1}{(k_1 + k_b[B^-])\tau_Q}\right\}$$

The problem then is to find $(k_1 + k_b[B^-])\tau_Q$, τ', and τ_Q. At negligibly low proton concentration [10] simplifies to give

$$[13]\quad \frac{\phi_{1Q}}{\phi_0} = \frac{1}{(\tau/\tau_Q) + (k_1 + k_b[B^-])\tau}$$

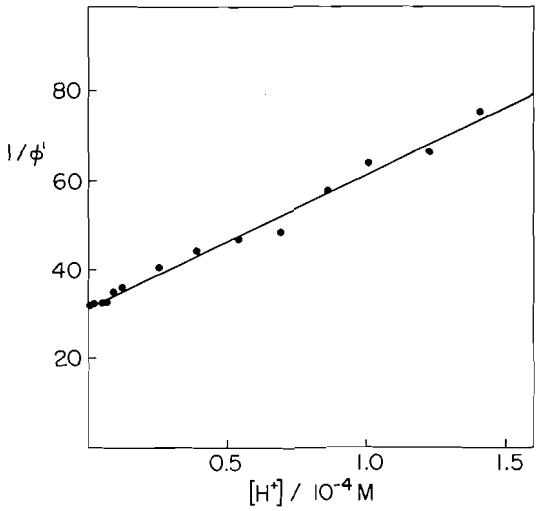

FIG. 7. Reciprocal of the quantum yield of tyrosinate fluorescence as a function of hydrogen ion concentration.

and at high proton concentration

$$[14] \qquad \frac{\phi_{0Q}}{\phi_0} = \frac{\tau_Q}{\tau}$$

where ϕ_{1Q} is the centre plateau value and ϕ_{0Q} the high acidity plateau value attained by ϕ_Q in the presence of a fixed concentration of buffer base (Fig. 6). Eliminating ϕ_0 from [13] and [14] we get

$$\frac{\phi_{0Q}}{\phi_{1Q}} = 1 + (k_1 + k_b[B^-])\tau_Q$$

Although we cannot measure ϕ_{0Q} directly for our system a value can be estimated as our ϕ_Q values should lie on a titration curve with its inflection point at pH = 3.95, the inflection point found for ϕ', the tyrosinate yield. We find $\phi_{1Q} = 0.0222 \pm 0.003$ and ϕ_Q(pH 3.95) = 0.0240, giving $\phi_{0Q} = 0.0257 \pm 0.0003$ for [acetate] = 0.9 $M\ \ell^{-1}$. Therefore $(k_1 + k_b[B^-])\tau_Q = 0.16 \pm 0.02$. From Fig. 7 we find intercept = 46.2 ± 1.1 and hence $\phi_0' = 0.16 \pm 0.02$. Taking slope = $(4.45 \pm 0.11) \times 10^5\ \ell\ M^{-1}$ from Fig. 7 and this value of ϕ_0' we find $\tau'/\tau_Q K^* = (7.01 \pm 1.2) \times 10^4\ M^{-1}$.

The fluorescence lifetime of tyrosine at pH = 7, τ_1, is related to τ (which we cannot measure) by the expression $\tau_1/\tau = \phi_1/\phi_0$ and τ_Q is related to τ by the expression $\tau_Q/\tau = \phi_{0Q}/\phi_0$ hence

$$\tau_Q = \tau_1 \frac{\phi_{0Q}}{\phi_1}$$

We measured τ_1 = 3.52 ns (lit. 3.6 (7)) for tyrosine in aqueous solution (pH = 6.05) at 20.5°C. Using the above value of 0.0257 for ϕ_{0Q} in 0.9 M acetate and 0.14 for ϕ_1 we find τ_Q = 0.64 ns. To obtain a value for τ' we must assume that both of the forms of tyrosinate, I and II, have the same radiative rate of fluorescence (the same k_f), i.e. the differences in quantum yield are due to differences in the non-radiative rates. This is reasonable as the α-amino group is not conjugated to the chromophore. We can then write

$$\tau' = \tau'' \frac{\phi_0'}{\phi_0''}$$

where ϕ_0'' is the measured quantum yield, and τ'' is the measured lifetime of tyrosinate at pH = 13. We found $\phi_0'' = 0.011$ and $\tau'' = 0.10 \pm 0.05$ ns and hence find $\tau' = 2.7 \pm 1.3$ ns.

Using the values estimated for τ_Q and τ' we find $K^* = (0.60 \pm 0.40) \times 10^{-4}\ M$. Therefore, the first excited singlet state acid–base dissociation constant of tyrosine, p$K(S_1)$ is found experimentally to be 4.2 ± 0.4; a shift, ΔpK = 6.1 from the ground state pK = 10.3. This measurement is in agreement with Feitleson's Forster cycle estimate of Δp$K \sim -5$ considering the errors expected in such estimates (17), and the errors and assumptions involved in our measurement. It must be noted that our p$K(S_1)$ value is unavoidably measured at high ionic strength (I = 0.9 M). A correction can be applied for the Brønsted dependence of k_2 and hence K on ionic strength (17). However, the size of the correction proves to be less than the error with which p$K(S_1)$ is calculated.

Discussion and Conclusions

We have shown experimentally that tyrosinate fluorescence can be seen in neutral aqueous solution of tyrosine under the right buffer conditions. These conditions are analogous to those which may be obtained in the local environment of proteins which have tyrosine residues in close proximity to basic groups. Previous theoretical arguments for a large shift in the pK of the tyrosine phenol group on excitation have often been neglected in the interpretation of the fluorescence spectra of peptides and proteins. Our results suggest that this ΔpK effect must be considered when analysing the fluorescence of tyrosine containing proteins. Tyrosinate has its fluorescence maximum at 340 nm which is also the fluorescence maximum shown by tryptophan. From the excitation spectra for emission in the tryptophan band of proteins (i.e. ~340 nm) it has been reasonably proposed that energy transfer takes place from tyrosine to tryptophan (2). Although we have no argument with this mechanism the results can be explained, for proteins containing basic residues, equally well by proton transfer from excited tyrosine giving rise to tyrosinate emission at 340 nm.

We have also shown that the quantum yield of fluorescence of tyrosinate ($\phi_0 = 0.16$) predicted by our measurements at neutral pH is actually 26 times greater than that found experimentally at pH = 13. We propose that the yield must be lowered by a separate quenching mechanism possibly involving a change in solute–solvent interactions on deprotonation of the $-NH_3^+$ group. Thus the contribution of tyrosinate to the fluorescence of a protein can be greater than expected from its yield measured directly in alkaline solution.

Although we have shown that carboxylate ions do certainly quench tyrosine fluorescence by a proton transfer mechanism we also find that, on close analysis, our results require them to quench simultaneously by another mechanism which produces no other fluorescent species. This other mechanism may be either a dynamic or ground state effect, although we see no effect by acetate on the tyrosine absorption spectrum. The existence of the second mechanism is consistent with the previously observed quenching of *O*-methyl tyrosine fluorescence by carboxylate and explains the existence of the controversy found in the literature in this area. To rule out other possible explanations of our results than the existence of the second quenching mechanism we had to show that tyrosine fluorescence was not, as previously suggested, quenched by acetic acid.

In conclusion we have demonstrated a large shift in the phenolic pK of tyrosine on excitation to its first excited singlet, finding $pK(S_1) = 4.2 \pm 0.4$ cf. $pK(S_0) = 10.3$, which can have significant implications in the interpretation of the fluorescence properties of polypeptides and proteins.

Received November 28, 1977

REGINALD H. MITCHELL, LUDVIK MAZUCH, BARRY SHELL, and PAUL R. WEST. Can. J. Chem. **56**, 1246 (1978).

Reaction of DT type pesticides with anisole and $AlCl_3$ in CS_2 yielded *unsym*-tetraarylethylenes ($Ar_2C{=}Ar_2'$), which on photocyclisation yielded phenanthrenes. Further oxidative closure to dibenzo[*g*,*p*]chrysenes occurs under conditions that favour cation radical intermediates. Chromatography of commercial methoxychlor (DMDT) yielded tetraanisylethylene together with minor amounts of the corresponding photo products, 3,6-dimethoxy-9,10-dianisylphenanthrene and 3,6,11,14-tetramethoxydibenzo[*g*,*p*]chrysene, as well as other chloroanisylethylenes.

REGINALD H. MITCHELL, LUDVIK MAZUCH, BARRY SHELL et PAUL R. WEST. Can. J. Chem. **56**, 1246 (1978).

La réaction des pesticides du type DT avec l'anisole et le $AlCl_3$ dans CS_2 produit des tétraaryléthylènes non-symétriques ($Ar_2C{=}CAr_2'$) qui par photocyclisation conduisent à des phénanthrènes. Une fermeture oxydante subséquente conduisant à des dibenzo[*g*,*p*]chrysènes se produit dans des conditions qui favorisent les intermédiaires radicaux cationiques. La chromatographie du méthoxychlore commercial (DMDT) conduit à du tétraanisyléthylène avec des quantités plus faibles de photo-produits correspondants, du diméthoxy-3,6 dianisyl-9,10 phénanthrène et tétraméthoxy-3,6,11,14 dibenzo[*g*,*p*]chrysène de même qu'à d'autres chloro-anisyléthylènes.

[Traduit par le journal]

Introduction

Since 1969 methoxychlor (DMDT), **1***b*, has widely replaced the more persistent DDT, **1***c*, in the control of insect populations especially in Canada (3). Whereas the toxicology of methoxychlor itself seems to be reasonably well reported (ref. 3, p. 59), we can find no mention of studies on impurities present in commercial samples of the pesticide. That such studies were desirable became evident when we discovered (1) the presence of the activated olefin tetraanisylethylene (TAE), **3***bb'*, both in technical laboratory grade methoxychlor and in locally available home garden grades and that no report[3] of TAE in methoxychlor nor of its short- or long-term toxicity had appeared. This paper reports a further analysis of impurities that are present in commercial methoxychlor and that are formed on subjecting the DT class pesticides, **1**, to Friedel–Crafts conditions. Further experiments indicate that oxidative photoclosure of TAE, **3***bb'*, can lead to polycyclic aromatic hydrocarbons, one of which has been shown by us (2) to be actively mutagenic and potentially carcinogenic.

Results and Discussion

Treatment of commercial methoxychlor (Sigma Chemical Company, U.S.A.) with bromine in acetic acid gave an immediate deep blue colour which suggested a reactive impurity was present. Thin-layer chromatographic examination confirmed the presence of more than six impurities one of which was fluorescent. After an initial recrystallisation, column chromatography of the residue followed by fractional crystallisation separated the fluorescent contaminant as very pale yellow crystals, mp 185–186°C in ca. 0.4% by weight yield (4000 ppm). This was identified as, tetrakis(*p*-methoxyphenyl)ethylene, **3***bb'* (lit. (4) mp 186°C), commonly referred to as tetraanisylethylene (TAE), on the basis of its ^{1}Hmr spectrum which showed only methoxyl protons at δ 3.70 and aromatic protons as an apparent[4] AB quartet at δ 6.93 and 6.51, and its mass spectrum in which the molecular ion was at *m*/*e* 452. As anticipated pure TAE underwent reaction with bromine in glacial acetic acid – methylene chloride solution to give the characteristic blue solution (λ_{max} ca. 540 nm) that had been originally observed with the pesticide. Indeed several previous studies (5) have established that

[4]Although the spin system is AA'BB', it appears like an AB quartet, in all of the following examples.

a X = H; *a'* Y = H
b X = OCH_3; *b'* Y = OCH_3
c X = Cl; *c'* Y = Cl

TAE reacts rapidly with a variety of electron acceptors to give the dication, λ_{max} ca. 540 nm. Spectrophotometric analysis (see Experimental) based on this colour reaction indicated that the original technical methoxychlor (Sigma Chemical Co.) contained ca. 0.5% TAE in good agreement with the isolated yield. Several locally available home garden grades (sold at 50% strength) were also tested and these contained ca. 0.2% TAE as might be anticipated. A sample of methoxychlor[5] (labelled 99% pure) obtained through the Department of Health and Welfare, Health Protection Branch, Ottawa, Ont., Canada, also tested for ca. 0.3% TAE.

By further chromatography of the mother liquors left over after crystallisation of TAE two fractions could be obtained. The first contained 1,1-dichloro-2,2-bis(*p*-methoxyphenyl)ethylene (DMDE), **4***b*, and 1-chloro-1,2,2-tris(*p*-methoxyphenyl)ethylene, **5***b* (commonly called chlorotrianisene), identified by ^{1}Hmr and tlc comparison with authentic samples (see below). It is estimated that these are present at 400 and 40 ppm, respectively, in the technical pesticide. The presence of the chlorotrianisene (also called Hormonisene, Merbentul) is interesting since it is known to be a powerful estrogen (6). The second fraction contained the phenanthrene, **6***bb'*, and chrysene, **7***bb'*, identified by comparison with the authentic samples prepared as described below. Although we estimate the final amount of **6***bb'* and **7***bb'* found to be approximately 50 and 5 ppm, respectively, it is quite likely that most of **6***bb'* and nearly all of **7***bb'* forms during the separation procedure, since we subsequently show that exposure of TAE to sunlight forms **6***bb'* which can then be oxidatively closed to **7***bb'* (see below). In fact a major manufacturer (DuPont) has informed us that they have developed a gas chromatographic detection procedure for **7***bb'* (sensitivity < 1 ppm), that indicates the absence of the chrysene **7***bb'* in their technical methoxychlor at the time of manufacture.

(8), or 15% oleum (9) as catalysts; however in our hands, only use of $AlCl_3$ gave detectable (photometrically) amounts of TAE. This is consistent with the note of Biltz (10) in 1897 that tetraphenylethylene is formed amongst other products from benzene and chloral in CS_2. It is interesting that tetrakis(*p*-chlorophenyl)ethylene, **3***cc'*, has been identified in DDT spray deposits on citrus (10*b*), an observation that is consistent with formation of the analogous impurity during manufacture of DDT.

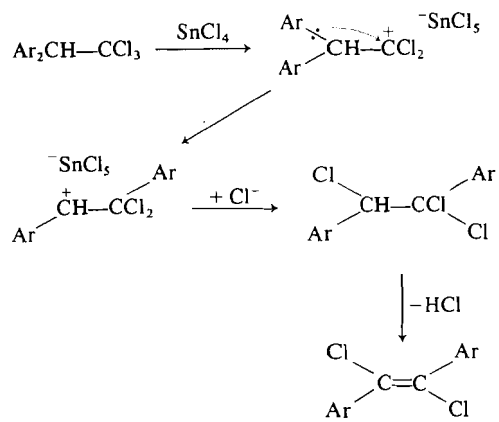
To maximise the yield of TAE, we substituted methoxychlor (DMDT) for chloral and heated under reflux in CS_2 with 4 molar equiv. of anisole and 5 equiv. of $AlCl_3$. Under these conditions a 50% yield of TAE could be realised.[6] Other products of the reaction were 1.1% of the ethylene (DMDE) **4***b*, identified by comparison with an authentic sample (11), 4% of the half reacted product, chlorotrianisene, **5***b*, identified by its mp 110–112°C (lit. (12) mp 113–114°C), a molecular ion at *m/e* 380 in the mass spectrum, and a ^{1}Hmr spectrum which showed three different $-OCH_3$ signals at δ 3.80, 3.77, and 3.71. Finally, 2% of the tetraphenylethane, **8***bb'*, was formed. The latter was identified by its mp 188–189°C (lit. (13) mp 189–190°C), molecular ion at *m/e* 454, and ^{1}Hmr spectrum which clearly showed the methine and methoxyl protons as singlets at δ 4.56 and 3.64 in a ratio 1:6, respectively. We suspect that this last compound arises through disproportionation of protonated **3***bb'* to give dication and dihydroproduct **8***bb'*. Certainly tetraarylethane formation accompanying or replacing tetraarylethylene formation has been observed previously (10, 14).[6]

The synthesis was extended to other tetraarylethylenes by substitution of the diaryltrichloroethane (DT) component: reaction of DT itself (**1***a*) with anisole and $AlCl_3$ yielded 37% of the dianisyldiphenylethylene, **3***ab'*, whereas reaction of DDT (**1***c*) yielded 1,1-bis(*p*-chlorophenyl)-2,2-bis(*p*-methoxyphenyl)ethylene, **3***cb'* in 42% yield. Ethylene **3***ab'*, mp 153–155°C (lit. (15) mp 154–155°C), gave a strong molecular ion at *m/e* 392. In its ^{1}Hmr spectrum two distinctive types of aromatic protons appeared as a singlet at δ 7.02 and a quartet at δ 6.57 assigned to the phenyl and anisyl protons, respectively, with the methoxyl protons at δ 3.67. The ethylene **3***cb'*, mp 192–193°, molecular ion at *m/e* 460, showed a multiplet for the aryl protons at δ 7.4–6.5 and a singlet for the six methoxyl protons at δ 3.77. A minor amount of the ethane **8***ab'* was also obtained along with **3***ab'*. Variation of the other component was less successful, since reaction of DMDT, **1***b*, with benzene and $AlCl_3$ gave 35% DMDE, **4***b*, and 0.9% 3-methoxy-10-(*p*-methoxyphenyl)-9-phenylphenanthrene, **6***ab'*, mp 248–250°C. The structure of the latter was based on analysis, a molecular ion at *m/e* 390, and its ^{1}Hmr spectrum which showed strongly deshielded aryl protons at δ 8.7–6.7 and two types of methoxyl singlets at δ 3.75 and 3.68. It seems likely, that a small amount of the tetraarylethylene forms, but this is photolytically transformed to phenanthrene during work-up (see below). Change of catalyst to $SnCl_4$, did not improve the reaction. In this case, apart from DMDE and DMDT, a minor amount (0.6%) of 1,2-dichloro-1,2,-bis(*p*-methoxyphenyl)-ethylene, **9***b*, mp 166–168°C (lit. (16, 17) mp 170°C, 166–168°C) was formed. The presence of the latter arises via a 1,2-aryl (Wagner–Meerwein) shift within the catalyst complex, followed by reversion to halide and elimination (Scheme 1).

Stilbene formation from DT compounds has also been observed under other conditions (11, 18*a* and refs. therein). In summary, since a wide variety of different DT compounds, **1**, is known and easily synthesised (18*b*) a straightforward approach to a series of unsymmetrical tetraarylethylenes is at hand.

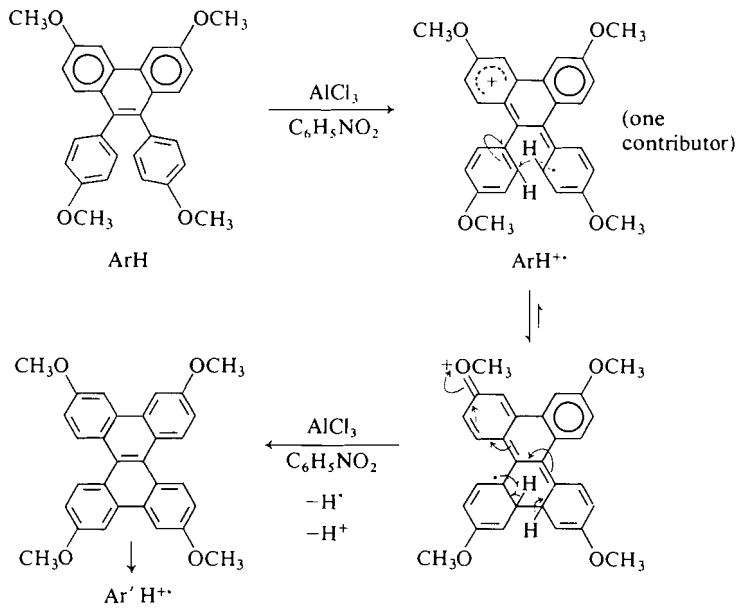
Conversion to Phenanthrenes and Chrysenes

To confirm the probable origin of the phenanthrene **6***bb'* and chrysene **7***bb'* detected in the fractions obtained after chromatography of technical methoxychlor, we allowed pure TAE, **3***bb'*, to stand both in cyclohexane solution in air and as a solid film in air, while exposed to direct sunlight. We were aware that ready net photoclosure at the *ortho* positions of *cis*-stilbenes in the presence of oxidising agents (eg. I_2, O_2) has been well documented (19). Ready conversion of **3***bb'* to phenanthrene **6***bb'* occurred (44% isolated after 10 days in solution).



SCHEME 1

[6]A complete list of experiments tried, additional spectral results, and Table 1 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.



SCHEME 2

Under these conditions we could not detect chrysene **7***bb'* (i.e. the second *ortho* closure). However, when chrysene obtained by an alternative route was exposed to such conditions, oxidative and/or photolytic degradation occurred.

In the laboratory, **6***bb'* could be obtained in 57% yield, using a Hanovia medium pressure lamp with either I_2 or O_2 as oxidant, as rather insoluble crystals, mp 317–319°C, showing a clear molecular ion at *m/e* 450, aryl protons at δ 8.2–6.7, and two methoxyl singlets at δ 4.02 and 3.78 in its ^{1}Hmr spectrum. Correct elemental analysis was obtained. Prolonged photolysis of either **3***bb'* or phenanthrene in the presence of O_2 or I_2 led to further decomposition products, none of which corresponded to the chrysene (tlc) which itself decomposes under these conditions.

In the same way the unsymmetrical phenanthrene **6***bc'*, mp 325–327°C could be obtained from **3***bc'* in 20–40% yield.

To provide an authentic sample of the tetramethoxydibenzo[*g,p*]chrysene **7***bb'* and to demonstrate the feasibility of synthesis of chrysenes from the pesticide impurities, we performed a Scholl reaction (20, 21) on **6***bb'* using $AlCl_3$ in hot nitrobenzene. After chromatography, **7***bb'* could be obtained in 23% yield as crystals which rapidly brown on their surface, mp 210–212°C. The structure was assigned on the basis of a strong molecular ion at *m/e* 448 and its simple ^{1}Hmr spectrum showing three types of aromatic protons at δ 8.55, 8.00, and 7.25 (d, d, and dd respectively) and methoxyl singlet at δ 4.04.

This closure of **6***bb'* does not occur with $AlCl_3$ in CS_2. The apparent necessity of the nitrobenzene suggested that an oxidative mechanism might be operative (Scheme 2). The mechanism is consistent with the observation by Buck *et al.* (22) that cation radical formation occurs very easily on treatment of π-donor aromatics with $AlCl_3$ in either CH_3NO_2 or $C_6H_5NO_2$.

Related esr studies support Scheme 2 for the Scholl reaction. When we treated a dilute solution of **3***bb'* in N_2 purged dry nitrobenzene with a solution of $AlCl_3$ in nitrobenzene, an immediate yellow green colour appeared. Over a 12-h period at 20°C, the colour changed to pale violet. Concurrently the initial complex esr spectrum gradually changed in hyperfine pattern.[7] However the *total* signal intensity remained constant. The final spectrum was identical to that obtained when chrysene **7***bb'* was treated with $AlCl_3$ in nitrobenzene. Moreover the sequence can be duplicated using nitromethane. In this case resolution of the esr spectra at 20°C was not as great as with nitrobenzene.

The lack of rapid reaction in CS_2 where cation radical formation with $AlCl_3$ is less efficient (23), together with the persistence of a constant substantial cation concentration throughout the process is consistent with the proposed mechanism. In fact it has been suggested that conversion to radical cations in CH_3NO_2–$AlCl_3$ may be complete for dialkoxybenzenes (24).

[7]Spectral analysis (including related species) to be published elsewhere.

Experiments in concentrated H_2SO_4 demonstrate the well-known complexity of such radical ion systems. On dissolution in thoroughly N_2 purged sulphuric acid, phenanthrene **6***bb'* again yielded a yellowish-green solution that had a weak single broad line esr spectrum. However no colour change corresponding to conversion to chrysene cation was observed over 48 h. A combination of slow phenanthrene cation radical formation coupled with extensive competitive sulphonation (23) may prevent significant net cyclization. In contrast though, when the chrysene **7***bb'* was added to concentrated sulphuric acid, an initial weak unresolved epr spectrum gradually further diminished over 5 min during which time the solution developed an intense blue colour (λ_{max} 620 nm) assigned to the dication of **7***bb'*. Eventual two electron oxidation to the dication is also observed on dissolving tetraanisylethylene **3***bb'* in sulphuric acid (5). As expected nitrobenzene–$AlCl_3$ solutions containing either chrysene **7***bb'*, or phenanthrene **6***bb'* (after standing) provided the same intense blue colour (λ_{max} 620 nm) on quenching with an excess of concentrated sulphuric acid. The apparently instantaneous development of the colour in these cases suggests that a shift in the disproportion equilibrium [1] contributes to dication formation (25).

$$[1] \qquad 2Ar^{+\cdot} \rightleftarrows Ar^{++} + Ar$$

It is useful to consider the photolysis of the phenanthrene **6***bb'* in light of these Scholl reaction results. Firstly, although this phenanthrene does not rapidly degrade when the photolysis ($\lambda > 300$ nm) is carried out in the absence of air or iodine, in their presence, rapid and extensive tar production results. Initially we attributed the lack of chrysene **7***bb'* production to a steric inhibition to the second ring closure. However such inhibition should also be present in the Scholl reaction. Clearly it seems likely in retrospect, that initially formed chrysene is oxidatively degraded in the system (solutions of chrysene **7***bb'* darken rapidly in air).

Finally, from the biological standpoint, one can project from the charge transfer character of the Scholl reaction the distinct possibility that phenanthrene thermal or photo charge transfer closure to the chrysene may occur in the presence of natural electron acceptors (e.g. quinones). Further photochemical study of **6***bb'* phenanthrene charge transfer activity is planned.

Experimental

All melting points were determined on a Kofler hot stage and are uncorrected. The ^{1}Hmr spectra were determined in $CDCl_3$ (unless otherwise stated) on a Perkin-Elmer R12A (60 MHz) or R32 (90 MHz) spectrometer and are reported in ppm downfield from tetramethylsilane as internal standard. Mass spectra were determined on a Hitachi Perkin–Elmer RMU-7 or Finnigan 3300 mass spectrometer at 70 eV. The ir spectra were recorded on a Pye-Unicam SP1000 spectrometer and the uv spectra on a Carey 17 spectrophotometer. Microanalyses were performed by this department. All evaporations were carried out under reduced pressure on a rotary evaporator at ca. 40°C. Extracts were dried with anhydrous sodium sulfate. A table of all additional spectral and experimental results is available in the Depository of Unpublished Data.[6]

*Chromatography of Commercial Methoxychlor (DMDT). Isolation of Tetraanisylethylene, 3*bb'

Crystallisation of technical methoxychlor (90% active DMDT, Sigma Chemical Co., St. Louis, U.S.A.) (100 g) from chloroform (40 ml) – ethanol (100 ml) yielded 76 g of pure DMDT, **1***b*, and 24 g of residue concentrated in impurities. The latter were separated chromatographically on basic Al_2O_3 (1200 g, Woelm, Activity II–III). After elution of the *o*- and *p*-isomers of DMDT with benzene–pentane (1:1), a mixture of ca. six compounds (by tlc) was eluted with benzene. These fluorescent fractions gave a positive blue bromine test (see below) for TAE (500 mg, 0.5 wt.% by uv). Careful recrystallisation from CH_2Cl_2–ethanol yielded ca. 300 mg of pure TAE, mp 185–186°C (lit. (5) mp 186°C).[6]

After removal of TAE, rechromatography of the mother liquors from the above crystallisation yielded a fraction (45 mg) containing 1,1-dichloro-2,2-bis(*p*-methoxyphenyl)ethylene, **4***b*, and chlorotrianisene (1-chloro-1,2,2-tris(*p*-methoxyphenyl)-ethylene), **5***b*, in ca. 10:1 ratio, by comparison (^{1}Hmr and tlc) to authentic samples (described below). A second fraction (< 5 mg) contained the phenanthrene **6***bb'* and chrysene **7***bb'* by tlc comparison to authentic samples (described below). Despite several efforts at multiple chromatography, including preparative tlc, we were unable to isolate pure samples of these latter compounds.

The Colorimetric Analysis of TAE as the Dication

Bromine-blue Colour Test

The sample to be analysed in CH_2Cl_2 solution (ca. 0.3 ml) is added to a uv cell containing 0.1 *M* Br_2 in glacial acetic acid (*Warning*: causes blisters) and its absorbance relative to the same solvent reference is measured immediately by scanning through the maximum at ca. 540 nm. By comparison to the absorbance obtained from a known TAE concentration (e.g. 0.90 for 13 mg/100 ml), the sample concentration can be calculated. Although added DMDT does not interfere, anisole, ethanol, or water must be absent.

Syntheses

Tetrakis(p-*methoxyphenyl)ethylene, TAE, 3*bb'. *Reaction of DMDT with Anisole and AlCl$_3$*

$AlCl_3$ (67 g, 0.5 mol) was added in small portions to a cooled (0–3°C) mechanically stirred mixture of anisole (43 g, 0.4 mol), DMDT **1***b* (35 g, 0.1 mol), and CS_2 (200 ml). The mixture was allowed to warm to room temperature and then heated under reflux for 5 h. After cooling, the mixture was poured onto ice and extracted with CH_2Cl_2. The organic extract was washed with aqueous $NaHCO_3$ and water, dried, and evaporated. The resultant oil was preabsorbed onto alumina and chromatographed using pentane–benzene mixtures as eluant. Eluted first was 1,1-dichloro-2,2,-bis(*p*-methoxyphenyl)ethylene **4***b*, 340 mg (1.1%) as colourless crystals from ethanol, mp 111–112°C (lit. (12) mp 109°C), identical to an authentic sample (11).[6]

Next eluted was chlorotrianisylethylene, **5***b*, 1.5 g (4%) as almost colourless crystals from benzene–cyclohexane, mp 110–112°C (lit. (12) mp 113–114°C).[6]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Eluted next in the main fraction was TAE, 22.6 g (50%), identical to the sample obtained above. Eluted finally was tetrakis(*p*-methoxyphenyl)ethane **8***bb'*, 900 mg (2%), as white needles from benzene–hexane, mp 188–189°C (lit. (13) mp 189–190°C).[6]

The yield of TAE was also about 50% when CH_2Cl_2 replaced CS_2 as solvent. The results of other experiments are given in Table 1.[6]

*1,1-Bis(*p*-methoxyphenyl)-2,2-diphenylethylene, DADPE, 3*ab'*. Reaction of DT with Anisole and $AlCl_3$*

Using the general method described above for TAE there was obtained from DT, **1***a*, (12 g, 42 mmol), anisole (18.2 g, 168 mmol), $AlCl_3$ (28 g, 210 mmol), and CS_2 (70 ml), product DADPE, **3***ab'*, 6.1 g (37%) as colourless crystals from $CHCl_3$–ethanol, mp 153–155°C (lit. (15) mp 154–155°C).[6]

Eluted after the DADPE was a small amount (~1%) of a substance with mp ca. 155°C identified as 1,1-bis(*p*-methoxyphenyl)-2,2-diphenylethane **8***ab'*, on the basis of ^{1}Hmr and mass spectra data; ^{1}Hmr δ (60 MHz) 7.08 (s, 10H, ϕH), 7.04 and 6.62 (quartet, ^4J = 9 Hz, 8H, MeO-ϕ*H*), 4.61 (s, 2H, —CH—), and 3.62 (s, 6H, —OCH_3); ms, fragment ions at *m/e* 227 ($M^+ - \phi_2CH$), 197 ($M^+ - \phi_2CH$, OCH_2), and 167 ($M^+ - (MeO\text{-}\phi)_2CH$), but no M^+ (cf. **8***bb'*).

Reaction of DMDT with Benzene

Using the same conditions as above, from DMDT **1***b* (14.5 g, 42 mmol), benzene (13.1 g, 168 mmol), $AlCl_3$ (28 g, 210 mmol), and CS_2 (70 ml), there was obtained DMDE **4***b* (35%) identical to previous samples and ca. 0.9% of 3-methoxy-10-(*p*-methoxyphenyl)-9-phenylphenanthrene **6***ab'*, as almost colourless crystals from benzene, mp 248–250°C; ^{1}Hmr (60 MHz) δ: 8.7–6.7 (m, 16H, —ArH), 3.75 and 3.68 (s, 3H each, —OCH_3); ms M^+ at *m/e* 390 (100); uv (ether) λ_{max} (log ε_{max}): 340 nm (2.94), 302 inf (3.96), 279 sh (4.40), and 260 (4.72). *Anal.* calcd. for $C_{28}H_{22}O_2$: C 86.13, H 5.68; found: C 86.07, H 5.80.

When $SnCl_4$ was used as catalyst with benzene as solvent apart from DMDE and unchanged DMDT there was obtained 0.6% of 1,2-dichloro-1,2-bis(*p*-methoxyphenyl)ethylene **9***b*, mp 166–168°C (lit. (16, 17) mp's 170 and 166–168°C).[6]

*1,1-Bis(*p*-chlorophenyl)-2,2-bis(*p*-methoxyphenyl)ethylene, DCDAE, 3*bc'*. Reaction of DDT with Anisole and $AlCl_3$*

Using the general method described above for TAE there was obtained from DDT (10 g, 28 mmol), anisole (12.5 g, 116 mmol), $AlCl_3$ (18.8 g, 141 mmol), and either CS_2 or CH_2Cl_2 (100 ml), product DCDAE, **3***bc'*, 5.41 g (42%) as light yellow crystals from benzene–cyclohexane, mp 192–193°C; ^{1}Hmr (90 MHz) δ: 7.4–6.5 (m, 16H, ArH) and 3.77 (s, 6H, —OCH_3); ms M^+ at *m/e* 460 (100, $^{35}Cl_2$); ir (KBr): 1610 (s), 1515 (s), 1248 (s), 1178 (s), 1090 (s), 1033 (s), 1012 (s), 831 (s), and 808 (s) cm^{-1}; uv ($CHCl_3$) λ_{max} (log ε_{max}): 330 (4.22), 298 (4.18), and 256 nm (4.44). *Anal.* calcd. for $C_{28}H_{22}O_2Cl_2$: C 72.89, H 4.81; found: C 73.01, H 4.66.

*Irradiation of TAE 3*bb'*. 3,6-Dimethoxy-9,10-bis(*p*-methoxyphenyl)phenanthrene, 6*bb'

(*a*) *In the laboratory*—A solution of TAE **3***bb'* (800 mg, 1.77 mmol) and I_2 (7 mg) in benzene (400 ml) was irradiated using a 450 W Hanovia medium pressure lamp with Pyrex filter while bubbling air through the solution for ca. 9 h. The white crystals of product were removed by filtration and dried to yield **6***bb'*, 452 mg (57%), mp 317–319°C; ^{1}Hmr (90 MHz) δ: 8.2–6.7 (m, 14H, ArH), 4.02 and 3.78 (s, 6H each, —OCH_3); ms peaks at *m/e* 450 (M^+, 100), 435 ($M - CH_3$, 14); uv (CH_2Cl_2) λ_{max} (log ε_{max}): 372 (3.41), 355 (3.43), 313.5 (4.13), 305 inf (4.08), 289 (4.39), 283 (4.38), 262 sh (4.72), and 256 nm (4.73). *Anal.* calcd. for $C_{30}H_{26}O_4$: C 79.97, H 5.82; found: C 79.74, H 5.95.

Use of acetonitrile or cyclohexane as solvent reduced the yield of **6***bb'*.

(*b*) *In sunlight*—(*i*) In solution: TAE (50 mg) in cyclohexane (50 ml) was placed in a Pyrex flask and exposed to bright sun (July) for 10 days. Thin-layer chromatography indicated only TAE and phenanthrene **6***bb'* to be present. By crystallisation 22 mg of **6***bb'* (44%) could be isolated, identical to previous samples. (*ii*) In solid state: TAE (50 mg) was coated on a glass Petri dish by means of CH_2Cl_2 solvent. One sample was covered with a Pyrex lid and a second left open to air. Both samples were left in bright sunlight for 10 days. Again tlc and nmr indicated presence of TAE and phenanthrene **6***bb'* in both samples. The dishes were also coated with a light brown insoluble compound.

*Irradiation of DCDAE, 3*bc'*. 3-Chloro-10-(*p*-chlorophenyl)-6-methoxy-9-(*p*-methoxyphenyl)phenanthrene, 6*bc'

Using the same procedure as above there was obtained from **3***bc'* a white precipitate (20–40%) of product, mp 325–327°C; ^{1}Hmr (90 MHz) δ: 8.1–6.5 (m, 14H, ArH), 4.04 and 3.80 (s, 3H each, —OCH_3); ms M^+ at *m/e* 458 (100, $^{35}Cl_2$); uv ($CHCl_3$) λ_{max} (log ε_{max}): 368 (3.28), 350 (3.28), 316 (4.09), 307 inf (4.06), 284 (4.38), 263 inf (4.64), and 255 nm (4.65). *Anal.* calcd. for $C_{28}H_{20}Cl_2O_2$: C 73.21, H 4.39; found: C 73.08, H 4.52.

3,6,11,14-Tetramethoxydibenzo[g,p]*chrysene, 7*bb'

Phenanthrene **6***bb'* (350 mg, 0.78 mmol) was dissolved in warm nitrobenzene (30 ml) and then cooled before the addition of $AlCl_3$ (3 g). After standing overnight at room temperature the mixture was heated on the steam bath for 4 h. After pouring onto ice, nitrobenzene was removed by steam distillation. The residue was extracted with CH_2Cl_2, and the extract washed, dried and evaporated. The dark residue (240 mg) was chromatographed on silica gel using benzene–CH_2Cl_2 (19:1) as eluant to yield product **7***bb'*, 80 mg (23%) as crystals which rapidly turn brown on their surface, mp 210–212°C; ^{1}Hmr (90 MHz) δ: 8.55 (d, J = 9 Hz, 4H, H-1, 8, 10, 16), 8.00 (d, J = 3 Hz, 4H, H-4, 5, 12, 13), 7.25 (dd, J = 9 Hz, 3 Hz, 4H, H-2, 7, 10, 15), and 4.04 (s, 12H, —OCH_3); ms M^+ at *m/e* 448 (100); uv (CH_2Cl_2) λ_{max} (log ε_{max}) 402 (3.83), 363 (4.23), 350 sh (4.21), 304 (4.94), 293 sh (4.73), 276 (4.56), 248 (4.55), and 228 nm (4.43); we were not able to obtain satisfactory analyses for this compound, probably because of its rapid oxidation.

Received August 16, 1977

BROCK CHITTIM, STEPHEN SAFE, NIGEL J. BUNCE, LUIS O. RUZO, KARL OLIE, and OTTO HUTZINGER. Can. J. Chem. **56**, 1253 (1978).

A variety of chlorinated *p*-terphenyls was photolyzed in organic media at 300 nm. Replacement of chlorine by hydrogen (dechlorination) was the major reaction. Substitution products were much more prominent than in the corresponding reactions of polychlorinated biphenyls.

Quantum yields of reaction were substantially higher for *ortho*-chlorinated compounds. Xenon-assisted reactions and benzophenone sensitization indicate a triplet reactive state, although energy transfer from benzophenone is very inefficient. Triethylamine promoted an electron transfer pathway but only for those compounds that were least photolabile.

BROCK CHITTIM, STEPHEN SAFE, NIGEL J. BUNCE, LUIS O. RUZO, KARL OLIE et OTTO HUTZINGER. Can. J. Chem. **56**, 1253 (1978).

On a effectué la photolyse, dans des milieux organiques à 300 nm, d'un certain nombre de *p*-terphényles chlorés. La réaction principale correspond au remplacement du chlore par un hydrogène (déchloration). Les produits de substitution sont beaucoup plus importants que dans les réactions correspondantes des biphényles polychlorés.

Les rendements quantiques des réactions sont beaucoup plus élevés pour les composés *ortho*-chlorés. Les réactions assistées par le xénon ou par une sensibilisation par le benzophénone indiquent la présence d'un état réactif triplet quoique le transfert d'énergie de la benzophénone est très inefficace. La triéthylamine aide un chemin de transfert d'électron mais uniquement pour les composés qui sont les moins photolabiles.

[Traduit par le journal]

Introduction

The photochemistry of halogenated aromatic compounds has recently received considerable attention (1–4). Much of this interest stems from the widespread occurrence of aryl chlorides as environmental contaminants (5, 6). Mechanistically, two photolysis pathways have been elucidated (7): direct C—X fission [1], and mechanisms involving excimers or exciplexes [2].

$$[1] \qquad ArX^* \rightarrow Ar^{\cdot} + X^{\cdot}$$

$$[2] \qquad D + ArX^* \rightarrow D^{\cdot +} + Ar^{\cdot} + X^-$$

The recent implication of polychlorinated terphenyls (PCTs) as widespread pollutants has prompted this investigation of their photochemistry, since PCTs absorb light of $\lambda > 300$ nm (8) and hence might be susceptible to solar photodegradation. Preliminary results have suggested that, like the polychlorinated biphenyls (PCBs), the PCTs lose chlorine atoms upon photolysis (9). In this paper we present our results on the mechanism of PCT photodegradation, with emphasis on comparing the results with those of the structurally related PCBs.

Results and Discussion

Identification of Photoproducts

Preliminary product studies involved photolysis of a range of PCTs to ~50% conversion and analysis of the photolysate by gas chromatography – mass spectrometry (gc–ms). These photolyses were carried out in both methanol (Table 1) and cyclohexane (Table 2) solutions using 300 nm radiation and concentrations of ca. 10^{-3} *M*. Air was not excluded.

In Tables 1 and 2, compounds identified only by molecular formulae were not characterised; only the relative molecular mass of the presumed parent ion and the chlorine isotope pattern were available. For compounds assigned structures, the glc retention times of authentic samples were also available, or a sample was isolated by preparative tlc and characterised spectroscopically.

In both methanol and cyclohexane, the most prominent products resulted from dechlorination (replacement of Cl by H). This is in line with results on PCBs (10). Material balances in the early stages of the reactions of 2,5-dichloro- and 2,4,6-trichloro-*p*-terphenyl were >95%, indicating that arylation

(formation of hexaphenyls) is not important in the PCT series. This contrasts with the behavior of chlorobenzene (1, 11) and 1-chloronaphthalene (12) but corresponds to the photochemistry of PCBs (10). A phenylated biphenylene was a significant photoproduct of 2,4,6-trichlorobiphenyl; although easy to rationalize, the analogous product has never been reported in the PCB series.

Another difference between PCB and PCT photochemistry is the relatively high yields of methoxy PCTs formed in the photolyses in methanol. These substitution products rarely exceed 2–3% of the product distribution from PCBs (10); from PCTs as much as one third of the product was methoxylated. Especially noteworthy is the fact that only the *o*-chloro-PCTs afforded these high yields of methoxy-compounds; in one case (2,4,6-trichloro-*p*-terphenyl) two of the methoxy products were isolated. Both resulted from replacement of *ortho* chlorines by methoxy.

Although a simple radical mechanism (eq. 1) can account for the dechlorination products, it seems unlikely that methoxy substitution occurs by this route. Attack of methanol as nucleophile upon the aryl radical ($S_{RN}1$) is improbable, both because methanol is a weak nucleophile and also because of the nonbonded interactions which result from the introduction of an *ortho* substituent into a polyphenyl (cf. ref. 13 on biphenyl derivatives). Abstraction of hydrogen would thus seem to be a much more likely fate of an *ortho* aryl radical.

We postulate that substitution more likely occurs by attack of a nucleophile directly upon the excited chloroaromatic; cf. related studies in the benzene series (1, 14). Formation of a σ-bonded intermediate with an sp^3 hybridised *ortho* carbon would relieve nonbonded interactions between the *ortho* chlorine and the hydrogens on the adjacent ring; ejection of chloride ion would then lead to the ground state of the methoxylated product.

[d]t, trace; nd, not detected on glc using column *A*; sm, starting material.
[e]Structure previously determined (ref. 10).

In cyclohexane solution, the *ortho* chloro PCTs furnished (usually) small amounts of cyclohexyl substituted products. Again, these find no precedent in PCB photochemistry. It is tempting to speculate that, once again, the cyclohexyl group has replaced an *ortho* chlorine but we have no information at present upon the genesis of such products.

Minor amounts of chlorination products were obtained with some of the PCTs. Analogous products were previously seen on photolysis of 1-chloronaphthalene (12) but have not been reported in the PCB series.

Quantum Yields of Reaction

Quantum yields for the disappearance of PCT (ϕ_r) were determined for 17 PCTs in methanol and cyclohexane, in both degassed and aerated solutions (Table 3).

In all cases, the ϕ_r values were higher in cyclohexane and, in both solvents, were increased with degassing (in most cases, by a factor of 2). In general, the ϕ_r values were highest for those PCTs containing *ortho* chlorines. In the absence of *ortho* chlorines, *meta*-chlorinated-*p*-terphenyls were the next most photolabile while 4-chloro-*p*-terphenyl was substantially more resistant to photolysis. The most reactive chloroterphenyls were those containing both *ortho* and *para* chlorines, (e.g. 2,4-dichloro-*p*-terphenyl) and the presence of an additional chlorine in the 4″ position usually caused a slight increase in ϕ_r values (e.g. 2,4,4″-trichloro-*p*-terphenyl decomposed more efficiently than 2,4-dichloro-*p*-terphenyl).

The ϕ_r values are very much higher than the corresponding ones reported for the PCBs at 300 nm (10) but are comparable with those recently measured for the PCBs at 254 nm (26). In the PCB series too, compounds having *ortho* chlorines are photolyzed very much more efficiently than those without.

The greater lability of the *ortho* chlorines most probably arises from the higher energy of the excited

[a]In order of decreasing reactivity in cyclohexane, degassed.
[b]By quantitative glc using column *B*, see Experimental; conversions <20%.
[c]Percentage of total products formed assuming (*i*) all the products were detected by glc with the column and conditions used; (*ii*) products resulting from dechlorination were those with shorter retention times than the starting material, and (*iii*) the detector response (glc) was equivalent for all the products formed.
[d]The products referred to as dechlorination products were those formed by replacement of chlorines on the PCT with hydrogen (e.g. does not include biphenylene type products, methoxy substituted products, etc.).

state when *ortho* substituents are present. The blue shift in the uv absorption spectrum of an *ortho*-substituted compound is well documented for biphenyls (15) and has recently been observed also for the PCTs (8). Analogously, the onset of phosphorescence of *o*-chlorobiphenyls lies at higher energy than that of the parent compound (13, 17) and we assume that this is true also in the terphenyl series.

Thus *ortho* substitution increases the energy of both singlet and triplet excited states. In both biphenyls (18) and terphenyls (19) the first excited state is believed to be planar, the π-bond order of the inter-ring bonds being increased from the ground state. Wagner and Scheve (13, 20) have concluded that when only one *ortho* substituent of the size of methyl or chloro is present, the excited state molecule remains planar and the increase in energy is due to nonbonded interaction. In a 2,2′-disubstituted biphenyl two excited state geometries can be inferred, the *E* being presumed to be planar and the *Z* twisted. In our study, no more than one ring of the PCT ever carried *ortho* chlorines, hence the excited states were most probably planar in all cases.

We thus attribute the greater decomposition efficiency of *o*-chloroterphenyls to the increase in energy of the excited state. Aryl chlorides are thought (21) to have C—Cl bond dissociation energies around 80 kcal/mol; for *p*-terphenyl itself the energies of the singlet and triplet states lie, respectively, ~80 and ~60 kcal/mol above the ground state (22). For *o*-chloroterphenyls these excited state energies will be higher but we do not know by how much.

Assignment of Reactive Excited State

The quantum yields of reaction (ϕ_r) for all the PCTs decreased in the presence of oxygen (Table 3) which quenches long-lived excited states (24). The effect of oxygen varied with the PCT studied but was not sufficiently pronounced to support a triplet excited state unequivocally.

Quantum yields of fluorescence (ϕ_f) were measured in cyclohexane for three of the PCTs studied (Table 4), relative to *p*-terphenyl whose quantum yield of fluorescence was known (22). Among this small group it was found that ϕ_f decreased with increasing chlorine content and with *o*-substitution, as has been observed with PCBs (17). The compounds having the higher values of ϕ_r were the compounds that fluoresced least efficiently. However, this could be compatible with reaction from either a singlet or triplet state. If reaction is from the singlet, then reaction and fluorescence are in direct competition; if a reactive triplet state is involved, fluorescence competes with intersystem crossing. However, intersystem crossing, and hence reaction, would be facilitated by increasing the chlorine content of the

molecule and, by analogy with the PCBs (17), by introducing *ortho* substituents.

Two sets of experiments were conducted to try to assign the multiplicity of the excited state: a limited group of PCTs was photolysed in the presence of xenon and of benzophenone (Tables 5 and 6).

The heavy atom effect of xenon (which was present at ca. 1 atm) should tend to enhance intersystem crossing ($S_1 \rightarrow T_1$) (26). For PCTs with low chlorine content and a high fluorescence quantum yield, such as 4-chloro-*p*-terphenyl, ϕ_{isc} is relatively small. The photodegradation efficiency of such a compound should be enhanced in the presence of xenon if the triplet is reactive, but reduced if a reactive singlet is involved. Those PCTs with high ϕ_{isc} should not have ϕ_r greatly affected by xenon.

Experimentally, it was found that ca. 1 atm of xenon decreased ϕ_f for 4-chloro-*p*-terphenyl from 0.84 to 0.72. Thus the combination of ϕ_{isc} and ϕ_{ic} (internal conversion) increased from 0.16 to 0.28. Correspondingly, the efficiency of photodecomposition increased about 70%. Thus this result is entirely compatible with a predominantly triplet state reaction for 4-chloro-*p*-terphenyl.

For 2,5-dichloro- and 2,4,6-trichloro-*p*-terphenyl, xenon had little effect upon the fluorescence and almost no effect upon the ϕ_r value. This suggests, but not conclusively, that ϕ_{isc} is already high, and is compatible with triplet state photoreactivity. This point was examined further by carrying out the reaction of these two compounds in the presence of benzophenone as a triplet sensitiser. Concentrations of benzophenone and PCT were, respectively, 0.1 and 10^{-4} *M*, to ensure that most of the light was absorbed by the sensitiser.

The results support a triplet reactive state (see Table 6). Sensitisation is seen to occur but energy transfer does not take place at each encounter. From the photon flux determined experimentally, the production of $^3Ph_2CO$ (triplet benzophenone) is 4.5×10^{15} s^{-1}. Samples were 2.0 ml and knowing τ_p for Ph_2CO (in isooctane) is 2.5 μs (23) we have $[^3Ph_2CO] = 9.3 \times 10^{-12}$ *M*. Then assuming a rate constant for diffusion of 8×10^9 ℓ mol^{-1} s^{-1} in cyclohexane (24), the rate of encounter is $(8.9 \times 10^9) \times (9.3 \times 10^{-12}) \times (1.0 \times 10^{-4})$ or 8.3×10^{-5} mol ℓ^{-1} s^{-1}. Knowing ϕ_r and the irradiation time we can calculate how much PCT should be degraded if energy transfer took place at every collision. In both cases, fewer than 1% of the collisions resulted in energy transfer. Thus the situation for *ortho*-substituted PCTs is similar to that observed in the PCBs in that energy transfer from benzophenone to the *o*-substituted compounds is inefficient (13).

intervention of an exciplex (eq. 2). For *p*-terphenyls substituted with chlorine at the 4, at the 2,5, and at the 2,4,6 positions, triethylamine quenched the fluorescence and linear Stern Volmer plots of I^0/I vs. [Q] were obtained (Table 7). In contrast to the PCBs no fluorescent exciplexes were observed.

The photodecomposition of these three substances was examined in the presence of triethylamine. Only 4-chloro-*p*-terphenyl had its ϕ_r increased substantially in the presence of amine. This suggests that, just as for the PCBs, an exciplex photodecomposition mechanism only operates for those PCTs that are inherently light stable.

In summary, at the present time it is not possible to assess whether photodegradation of PCTs is important environmentally. It is clear, however, that PCTs absorb light in an environmentally accessible region of the spectrum and that for some of the derivatives photodecomposition can be very efficient, at least in organic solvents. Whereas the related PCBs undergo almost exclusively dechlorination, the PCTs have a more varied photochemistry, with biphenylenes and substitution products appearing prominently in the product mixture. As with the PCBs, those PCTs bearing *ortho* chlorines are very much more photolabile than those without. Mechanistic studies implicate the triplet state as the seat of the photoreaction and suggest that electron transfer routes of decomposition are likely to be important only for the most photostable PCTs.

Experimental

Materials and Methods

Chemicals

Chloro-p-*terphenyls*—These were synthesized as described in a previous publication and were further purified by preparative thin-layer chromatography (tlc) until >99% purity was obtained.

Cyclohexane—This compound (Fisher, spectroanalyzed) was used as received for photolysis product studies and quantum yields of reaction determinations. For the studies involving fluorescence measurements, this solvent was further purified by first washing with concentrated sulfuric acid. It was then washed twice with deionized water and once with a 5% solution of sodium bicarbonate in deionized water. It was finally dried over anhydrous sodium sulfate and glass distilled from P_2O_5.

Potassium ferrioxalate—This compound (Pfaltz and Bauer) was recrystallized twice from water and stored in the dark until needed. All other chemicals were obtained commercially and used without purification.

Gas–Liquid Chromatography

Gas–liquid chromatography was performed on a Hewlett-Packard 5710 gas chromatograph fitted with a flame ionization detector and using a 183 m × 0.64 cm glass column packed with either 3% OV-225 on Gas-Chrom Q, 80–100 mesh (column *A*), or 3% SE-30 on Chromosorb W, 60–80 mesh (column *B*). Both injection port and detector temperatures were 300°C; oven temperature using either column was 250°C.

Gas Chromatography — Mass Spectrometry

Gas chromatography–mass spectrometry analysis was obtained using a Hewlett-Packard 5982-A system operated at 70 eV in the EI mode. The glc column used was column *A*, as described, and it was operated isothermally at 240°C.

Fluorescence Spectroscopy

Fluorescence measurements for the xenon quenching experiments were performed using a Farrand Mark I fluorimeter for which sample chambers were designed and constructed in this department. All other fluorescence measurements were recorded at room temperature in 1 cm × 1 cm square quartz cuvettes using a Hitachi-Perkin-Elmer Fluorescence spectrophotometer MPF-2A.

Photolysis Procedures

All irradiations were carried out in a Rayonet Reactor (The Southern N.E. Ultraviolet Co.) fitted with RUL 3000 lamps which have a peak output energy at 300 ± 10 nm. For quantum yield determinations or relative rate experiments using quenchers, duplicate samples were irradiated in parallel using a rotating 'merry-go-round' apparatus to ensure equal irradiation of all samples. To monitor the light output from the reactor lamps, the modified ferrioxalate actinometer was used (25).

(*i*) *Photoproduct Studies*

The 10 PCTs listed in Tables 1 and 2 were photolyzed in methanol (Fisher, spectroanalyzed) and cyclohexane for gc–ms analysis. Solutions of the PCTs (25 ml, 10^{-3} *M*) were irradiated in Pyrex flasks (Reacti Flasks, Chromatographic Specialties) at 300 nm until approximately 50% of the starting material had reacted as determined by glc. The solvent was then evaporated and the crude mixture analyzed by gc–ms and glc using column *A*.

(*ii*) *Quantum Yields of Reaction* (ϕ_r)

Quantum yields of reaction (ϕ_r) were determined for 17 chlorinated-*p*-terphenyls (listed in Table 3) in cyclohexane and methanol, under both degassed and nondegassed conditions. All determinations (e.g. methanol, degassed) were determined in duplicate using 2-ml samples of 10^{-3} *M* solutions of the PCTs which were irradiated at 300 nm in Pyrex ampoules (8 mm od). Degassed samples were prepared by the freeze–pump–thaw method (usually two cycles at 0.02 mm). Percentage conversions were determined by quantitative glc (column *B*). Owing to possible competitive absorption by the photoproducts, irradiation times were adjusted so that less than 20% conversion of the PCT was obtained. Percentage conversions of 2,5-dichloro- and 2,4,6-trichloro-*p*-terphenyl in degassed cyclohexane and methanol were linear with respect to irradiation times (up to 30%) indicating that the photoproducts did not affect the ϕ_r values when conversions of starting material were kept below 30%.

(iii) Quantum Yields of Fluorescence (ϕ_f)

Quantum yields of fluorescence were determined for three chlorinated terphenyls, 4-chloro, 2,5-dichloro-, and 2,4,6-trichloro-*p*-terphenyl, assuming that the intensity of fluorescence was proportional to ϕ_f. It was also assumed that the fluorimeter response was linear over the wavelengths of interest.

In this method, the intensity of fluorescence of 2×10^{-3} *M* solutions of these three PCTs and *p*-terphenyl, in purified cyclohexane, were determined at their fluorescence maxima. The ϕ_f values for the PCTs were then determined by comparing their fluorescence intensities to that of *p*-terphenyl whose ϕ_f is reported to be 0.93 (22).

(iv) Triethylamine-assisted Photolyses

Fluorescence quenching experiments were performed on *p*-terphenyl and the three chloroterphenyls studied in section *iii*. The fluorescence intensities of 10^{-3} *M* solutions of the terphenyls, containing varying amounts of triethylamine (TEA), were measured at their fluorescence maxima. These intensities were compared with the fluorescent intensity of a terphenyl solution containing no quencher.

To determine the effect of TEA on the PCT reaction rates, 2-ml degassed solutions of the three chloroterphenyls (10^{-3} *M* in purified cyclohexane, Pyrex ampoules) containing TEA (0.1 *M*) or no quencher, were irradiated in duplicate at 300 nm until ~20% of the PCTs reacted in the samples containing no TEA by quantitative glc; relative reaction rates were then calculated taking the reactivity of the PCT solution containing no TEA equal to 1.00.

(v) Xenon-assisted Photolyses

To test the effect of xenon on the fluorescence and the reactivity of the three chloroterphenyls studied above, four samples (2 ml) of the PCTs (10^{-3} *M*) in purified cyclohexane were placed in quartz ampoules (8 mm od) and degassed. Xenon (Matheson; ca. 1 atm) was added to two of these samples using the method described by Bunce *et al.* (26) and all the tubes sealed. After sealing, the fluorescence intensities and photoreactivities of the samples containing xenon were compared with those without xenon.

(vi) Benzophenone-assisted Photolyses

Benzophenone sensitization experiments were performed on 2,5-dichloro- and 2,4,6-trichloro-*p*-terphenyl with and without benzophenone. Degassed 2 ml samples of the chloroterphenyls (10^{-4} *M* in purified cyclohexane, Pyrex ampoules) containing benzophenone or no sensitiser were irradiated in duplicate and the percentage of the PCT reacted (kept below 20%) determined by quantitative glc.

Received November 25, 1977

HAROLD M. HUTTON, WALTER E. HIEBERT, and VICTOR MARK. Can. J. Chem. **56**, 1261 (1978).

A high resolution proton magnetic resonance investigation of the hindered rotation of the dichloromethyl groups as a function of temperature in α,α,α′,α′,3,4,6-heptachloro-*o*-xylene (HCOX) has been conducted using dynamic nuclear magnetic resonance line shape analysis, supplemented with a homonuclear double resonance saturation transfer technique. The rate process in HCOX involves a coupled rotation of the two substituted methyl groups and the nonmutual exchange of the three pairs of protons between two equally populated conformers. The Arrhenius and transition state parameters were determined from the rate constants obtained over a temperature range of −5°C to 93°C for a 5 mol% solution of HCOX in methylcyclohexane: $\Delta G^* = 17.22 \pm 0.07$ kcal mol^{-1} at 298 K, $\Delta H^* = 14.6 \pm 0.3$ kcal mol^{-1}, $\Delta S^* = -8.8 \pm 0.8$ cal mol^{-1} deg^{-1}, and $E_a = 15.3 \pm 0.3$ kcal mol^{-1}. The results obtained for HCOX are compared with those for other chloro-substituted xylenes and toluenes.

HAROLD M. HUTTON, WALTER E. HIEBERT et VICTOR MARK. Can. J. Chem. **56**, 1261 (1978).

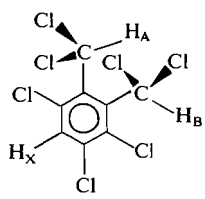
On a effectué, en faisant appel à une analyse de la forme des raies en résonance magnétique nucléaire dynamique complémentée par une technique de transfert de saturation de double résonance homonucléaire, une étude par résonance magnétique nucléaire du proton à haute résolution de la rotation empêchée des groupes dichlorométhyles en fonction de la température dans des α,α,α′,α′,3,4,6-heptachloro-*o*-xylène (HCOX). Le processus observé dans HCOX implique une rotation couplée des deux groupes méthyles substitués et l'échange non-mutuel des trois paires de protons entre deux conformères qui sont de population égale. On a déterminé les paramètres d'Arrhénius et d'état de transition à partir des constantes de vitesse obtenues à des températures allant de −5°C jusqu'à 93°C pour une solution à 5 mol% de HCOX dans le méthylcyclohexane: $\Delta G^* = 17.22 \pm 0.07$ kcal mol^{-1} à 298 K, $\Delta H^* = 14.6 \pm 0.3$ kcal mol^{-1}, $\Delta S^* = -8.8 \pm 0.8$ cal mol^{-1} deg^{-1} et $E_a = 15.3 \pm 0.3$ kcal mol^{-1}. On compare les résultats obtenus pour HCOX avec ceux obtenus pour d'autres xylènes et toluènes substitués par des atomes de chlore.

[Traduit par le journal]

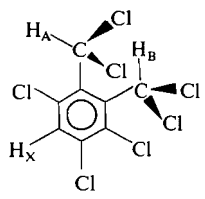
Introduction

Proton magnetic resonance (^{1}H nmr) studies of the hindered rotation of the dichloromethyl group in a series of substituted toluenes (1–3), substituted xylenes (4, 5), and a substituted mesitylene (6) have been examined by Schaefer *et al.* In this paper we present the results of the study of the hindered rotation in α,α,α′,α′,3,4,6-heptachloro-*o*-xylene (HCOX) as a 5 mol% solution in methylcyclohexane. Mark and Pattison (7) have previously studied the hindered rotation in a series of *o*-bis(dichloromethyl) benzenes, including HCOX in tetradecane, using the variation of the line width of the coalescing resonances as a function of temperature (7). Because the results for HCOX were somewhat ambiguous using this technique the activation parameters were not reported and were left to be determined by a complete line shape analysis.

Steric considerations (8) indicate that the rotation of the two methyl groups in HCOX is synchronized and of opposite direction giving two conformers, **1** and **2**, with roughly equal populations. The stable



1



2

conformations are with H_A (**1**), H_B (**1**), H_A (**2**), H_B (**2**) in the plane of the ring (1–6) and are related by a concerted 180° rotation of the two side chain groups

about their respective C—C bonds. Such a rotation effectively changes the magnetic environment of all three protons, giving a ^{1}H nmr spectrum which consists of the time averaged resonances corresponding to the two conformers. The rate constants for the hindered rotation were determined by comparing the experimental spectra with those generated with Binsch's computer program DNMR2 (9). The relatively large errors obtained with this visual matching technique in the slow exchange region were substantially reduced by using the decay and recovery curves of the saturation transfer technique proposed by Forsen and Hoffman (10–12) and developed further by Anet and Bourn (13).

Experimental

Preparation of HCOX

HCOX was prepared by the following steps. (*i*) Ring chlorination of *o*-xylene. A solution of 424 g (4.0 mol) of *o*-xylene in 1500 ml of CCl_4 was chlorinated in the presence of 1 g of aluminum chloride between 30 and 50°C until the theoretical amount of chlorine (851 g) has been added. Stripping of the solvent in a rotary evaporator yielded an oil, which on cooling deposited solids. These, after filtration and trituration with warm hexane, weighed 45 g and were identified as tetrachloro-*o*-xylene, mp 227–228°C (lit. (14) mp 227–228°C). The filtrate of the hexane trituration, for which gc indicated the absence of tetrachloroxylene and the presence of 80% of tri- and 20% of dichloroxylenes, was stripped of solvent and triturated with pentane. Crystals (22 g) separated out overnight and these were shown by gc to contain 95% of *ar*-trichloro-*o*-xylenes. (*ii*) Side-chain chlorination of *ar*-trichloro-*o*-xylenes. The mixture of trichloroxylenes obtained above (20.9 g) was dissolved in 100 ml of CCl_4, the solution heated to reflux and chlorinated exhaustively while irradiating with a bright sunlamp. As shown by gc (11-in. SG column, 225°C), after 4 h of chlorination all of the starting material had disappeared; removal of the solvent in a rotary evaporator left behind 32.8 g of residue (theoretical, 35 g), consisting of two main components with residence times of 10.0 and 12.0 min, in a 20 to 80 ratio. The separation of the two isomeric α,α,α′,α′,-*ar*,*ar*,*ar*-heptachloro-*o*-xylenes was effected by elution chromatography: 10.0 g of the chlorination mixture was chromatographed over 450 g of alumina, using 1350 ml pentane as eluant. The isomer with the 10.0 min gc residence time was eluted first and was obtained in pure form after recrystallization from hexane, mp 114–117°C; ^{1}H nmr indicated the α,α,α′,α′,3,4,5-heptachloro-*o*-xylene structure for this isomer (7). *Anal.* calcd. for $C_8H_3Cl_7$: C 27.7, H 0.87, Cl 71.5; found: C 27.8, H 0.83, Cl 71.6. The other isomer, with the 12.0-min gc residence time, was eluted as the second component and obtained in pure form by recrystallization from hexane, mp 70–72°C; ^{1}H nmr confirmed the α,α,α′,α′,3,4,6-heptachloro-*o*-xylene structure (HCOX). *Anal.* calcd. for $C_8H_3Cl_7$: C 27.7, H 0.87, Cl 71.5; found: C 27.9, H 0.8, Cl 71.5.

^{1}H Nuclear Magnetic Resonance Spectra

A 5 mol% solution of HCOX in methylcyclohexane, containing small amounts of hexamethyldisilane for the internal lock and methylene chloride for the line-width standard, was degassed by the freeze–pump–thaw technique and then sealed.

The ^{1}H nmr spectra were recorded from −60°C to 96°C on a Varian HA-100D spectrometer. Each spectrum was normally recorded three times with some, at temperatures near coalescence, recorded up to eight times using a sweep rate of 0.05 Hz/s with a 1 Hz/cm chart width. Temperatures were measured with an iron–constantan thermocouple placed in a toluene sample in the probe before and after each HCOX spectrum, as previously described by Peeling *et al.* (2) and are estimated to be accurate to ±1°C. The double resonance spin transfer technique was used to assign the proton resonances of the two conformers in HCOX. In the slow exchange region at lower temperatures the chemical shifts of the individual protons and the relative populations of **1** and **2** were determined. Effective spin–spin relaxation times were estimated from the half-height line width of the methylene chloride proton resonance at each temperature. Rate constants of hindered rotation were determined for the temperature range of 27 to 96°C.

Double Resonance Saturation Transfer

A Hewlett-Packard audio oscillator, model 4204A, was used in the double resonance saturation transfer experiment with an external recorder connected to the HA 100 spectrometer to observe the intensity of a resonance as a function of time. The observing frequency was adjusted to the maximum intensity of a selected resonance and the time dependence of the decay curve was measured when the resonance of a second proton with which it exchanged was saturated. The recovery curve was obtained by measuring the change in intensity with time when the saturating frequency was removed. Care was taken not to saturate the resonance with the observing rf field. In addition, the observing and saturating frequencies were adjusted by trial and error to compensate for the shift in peak positions that occurs with the saturating field. This method was used to determine rate constants for HCOX at −5°C and 5°C.

Results and Discussion

Assignment of Peaks Under Conditions of Slow Exchange

The ^{1}H nmr spectrum of HCOX at ambient temperature, where the exchange is relatively slow is given in Fig. 1. Due to the interactions of the two substituted *ortho* groups only two conformers with roughly equal populations are observed. The concerted 180° rotation between **1** and **2** effectively changes the environment of all three protons resulting in a spectrum of six resonances, as in Fig. 1. At ambient temperature the rate of exchange between the two conformers is sufficient to use the saturation transfer technique (11) to assign the protons exchanging between **1** and **2**.

By inspection H_A (**1**) and H_X (**1**) of conformer **1** were assigned by the long range 'zig-zag' coupling (15). The splitting of these two peaks was more evident with lower temperature spectra than in Fig. 1. In keeping with earlier assignments of analogous compounds (1, 16) peak 2 in Fig. 1 was assigned to the methine proton H_A (**1**) and peak 4 to H_X (**1**).

Using the double resonance technique, peak 1 and peak 3 were assigned to the same proton in the two conformers by saturating peak 1 and observing the

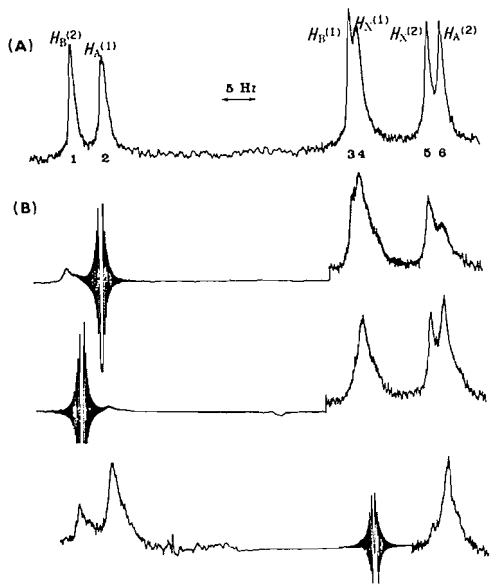

FIG. 1. Comparison of the ^1H nmr spectrum of a 5 mol% solution of HCOX in methylcyclohexane at ambient temperature (A) with spectra obtained by double resonance (B).

decrease in intensity of peak 3, as shown in Fig. 1. Saturation of peak 2 caused a significant reduction in the intensity of peak 6, thus peak 2 and peak 6 are related by an exchange of the conformers; the partial reduction of peak 3 in this experiment is probably due to the partial saturation of peak 1. The third proton in the two conformers is assigned to peaks 4 and 5. This was confirmed by saturating peaks 3 and 4 and observing intensity changes for peaks 1 and 5, as in Fig. 1. Using this information and the previous assignment of H_A (**1**) and H_X (**1**), the peaks may be assigned as indicated in Fig. 1. Peak 1 was assigned to H_B (**2**) as the environment of H_B (**2**) should be similar to that of H_A (**1**).

This assignment was confirmed with the steric crowding method of Peeling *et al.* (6). The magnitude of the crowding was estimated from a scale diagram of the molecule using standard covalent atomic radii and bond angles, and a maximum of 5° bond angle distortion (6). H_A (**1**) and H_B (**2**) are most crowded and thus their resonances are farthest down field; H_X (**2**) and H_A (**2**) are least crowded so are to highest field; while H_B (**1**) and H_X (**1**) occur at intermediate field. Long range coupling permits the unambiguous assignment, as before, for H_A (**1**), H_X (**1**) and thus H_B (**1**) and H_B (**2**) but there appears to be no intuitive way to distinguish H_A (**2**) and H_X (**2**) using this procedure.

^1H Nuclear Magnetic Resonance

At lower temperatures, where the lifetime of each conformer is relatively long, the spectrum consists of a superposition of the resonances of the two conformers. The chemical shifts were measured as a function of temperature and are given in Table 1. Increasing the temperature decreases the lifetime and the conformers interconvert more rapidly causing the peaks to coalesce. In this region the chemical shifts of the resonances were obtained by an extrapolation of the plot of the chemical shifts vs. temperature, using the data from Table 1.

The long range coupling constant between the methine proton H_A (**1**) and H_X (**1**) was measured at lower temperatures to be $^5J_{H_A(1)H_X(1)} = 0.45 \pm 0.04$ Hz with no observable variation with temperature.

At the lower temperatures in the slow exchange region the resonances of the two conformers were sufficiently dispersed to allow a determination of their relative populations. For five temperatures from −60°C to 27°C the ratio of **1**:**2** was 1.00 ± 0.04 indicating that the population difference was not significant.

Representative spectra, together with the spectra calculated with the computer program DNMR2 (9,

17) are given in Fig. 2. The effective spin–spin relaxation times were determined at each temperature using internal methylene chloride and were typically 1.4–1.6 s. At slow exchange the line widths of HCOX were comparable to that of the methylene chloride. The rate constants for the hindered rotation with an estimation of the error due to the fitting procedure are given in Table 2.

Double Resonance Saturation Transfer

When the rate process is relatively slow or very fast the determination of reliable rate constants by matching experimental and computer-simulated spectra is difficult because the line shape is relatively insensitive to a change in the preexchange lifetime. An alternative procedure for the slow exchange region, the method of saturation transfer, is complementary and allows data to be acquired over a larger temperature range.

(i) The Decay Process

For two protons H_A, H_B which are interconverted by an exchange process, the instantaneous saturation of the protons at H_B will decrease the intensity of the absorption signal of the H_A protons to a lower nonzero value, as long as the preexchange time between the two sites is approximately the same as the spin–lattice relaxation time (10). Considering a system, such as is found for HCOX, where the average lifetime of proton H_A, τ_A, is equal to the average lifetime of proton H_B, τ_B, the decay of the magnetization $M_Z^A(t)$ with the saturation of H_B is given by

eq. 1 (13):

$$[1] \quad M_Z^A(t) - M_Z^A(\infty) = M_Z^A(\infty)\frac{T_{1A}}{\tau_{1A}}\exp\left(\frac{-t}{\tau_{1A}}\right)$$

In [1] $M_Z^A(\infty)$ is the saturation transfer equilibrium magnetization, T_{1A} is the spin–lattice relaxation time, and $1/\tau_{1A} = 1/T_{1A} + 1/\tau_A$. From [1] the initial magnetization of H_A in the absence of any saturating field, M_Z^A, would be given by eq. 2 (13):

$$[2] \quad M_Z^A(\infty)/M_Z^A = \tau_{1A}/T_{1A}$$

Using [1] a plot of $\ln(M_Z^A(t) - M_Z^A(\infty))$ vs. time would give the value of τ_{1A} from the slope; T_{1A} can then be obtained from [2] and thus the lifetime τ_A and rate constant k.

For HCOX at 5°C a representative plot of $\ln(M_Z(t) - M_Z(\infty))$ vs. time is shown in Fig. 3*A* for the decay of H_B (**2**) with the saturation of H_B (**1**). The results for the decay experiments are given in Table 3.

(ii) The Recovery Process

The instantaneous removal of the saturating field at H_B is followed by the increase in the magnetization of H_A to its unsaturated equilibrium value. The magnetization at site A for the recovery process when $t = 0$, $M_Z^A(0)$, will be identical to the value previously designated by $M_Z^A(\infty)$ for the saturation process. The expression for the magnetization as a function of time is given by eq. 3 (13):

$$[3] \quad M_Z^A(t) = M_Z^A + c_1\exp(-\lambda_1 t) + c_2\exp(-\lambda_2 t)$$

M_Z^A is the magnetization in the absence of any saturating field, as before. The values of c_1 and c_2 are determined by the initial saturated state and λ_1 and λ_2 are defined under conditions of slow exchange by (10):

TABLE 3. Rate constants determined for HCOX by double resonance saturation transfer

	H_B (1)	H_B (2)	0.200	2.87	14.4	0.278	14.2	0.280
					Average†	0.276		0.275

*Average values of a minimum of two trials for each decay and recovery.
†Average value calculated takes into account the number of trials for each decay and recovery.

[4] $$\lambda_1 = 1/\tau_{1A} + 1/\tau_A$$
$$\lambda_2 = 1/\tau_{1A} - 1/\tau_A = 1/T_{1A}$$

This assumes that the lifetimes τ_A and τ_B are equal, as found in HCOX.

From [3] the recovery curve for $M_Z{}^A(t)$ can be reduced to the single exponential term if $\lambda_1 > \lambda_2$:

[5] $$M_Z{}^A(t) - M_Z{}^A = c_2 \exp(-t/T_{1A})$$

In the experiments under consideration the average relaxation time was about 13 s and the lifetime at the slowest rate about 8 s. From [4] this gives a value of $\lambda_1/\lambda_2 = 4.3$ which is larger than the lower limit set by Anet and Bourn (13). Using the single exponential approximation given by [5], a plot of ln $(M_Z{}^A(t) - M_Z{}^A)$ or more appropriately ln $(M_Z{}^A - M_Z{}^A(t))$ vs. time can be used to determine T_{1A}. An example of one of these plots is given in Fig. 3*B* for the recovery of the magnetization of H_B (2) in HCOX at 5°C when the saturation of H_B (1) is removed. To use [5] the first 6 s of data were not included in the analysis of the recovery curves to allow for the approximations made to [3]. The rate constant can be calculated from the value of T_{1A} and the value of τ_{1A} from the saturation experiment. The results are given in Table 3.

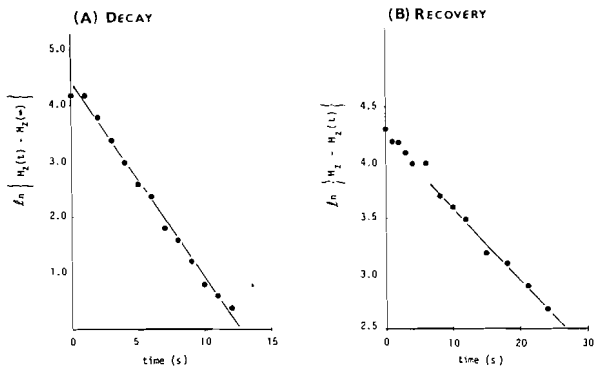

FIG. 3. A plot of ln $(M_Z(t) - M_Z(\infty))$ vs. time (*A*) and of ln $(M_Z - M_Z(t))$ vs. time (*B*) for the decay and recovery respectively of proton H_B (2) with the saturation of H_B (1) at 278 K.

For both the decay and recovery experiments the most reliable data were obtained from the observation of H_A (1) and the saturation of H_A (2). Table 3 includes data from different saturation–recovery sequences to show that similar results are obtained by interchanging the observation-saturation proton and by using different exchanging protons. Since the results are the same for the different methine protons in HCOX both methyl groups must rotate at the same rate.

In Table 3 the values of T_1 and hence the rate constant k are not identical for the decay and recovery techniques. For the decay process τ_{1A} is obtained from the slope; T_1 depends on the measurement of the intensities $M_Z(\infty)$ and M_Z. For the recovery process T_1 is obtained from the slope. Since the measurement of the slopes is usually more reliable, the rate constant calculated with τ_{1A} from the decay and T_1 from the recovery is probably more accurate.

The average value of T_1 of approximately 13 s is about what would be expected for a proton relaxation in a protonated solvent, where the value of T_1 is undoubtedly dominated by the intermolecular spin–lattice relaxation term (18).

Determination of Activation Parameters

The data necessary for both the Arrhenius plot and the Eyring plot are found in Tables 2 and 3. The plot of ln k vs. $1/T$ in Fig. 4 was used to determine E_a, the activation energy; the plot of ln (k/T) vs. $1/T$ in Fig. 5 was used for the transition state parameters $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, $\Delta G^{\ddagger}$. For the transition state calculations the transmission coefficient is taken to be unity which is probably more consistent with a concerted process. A summary of the activation and transition state parameters for HCOX and some related compounds is given in Table 4. The standard errors reported in Table 4 for HCOX were obtained from Binsch's program ACTPAR (19) which incorporates errors

†kcal mol^{-1} for $\Delta H^{\ddagger}$, $\Delta G^{\ddagger}$ and cal mol^{-1} deg^{-1} for $\Delta S^{\ddagger}$.

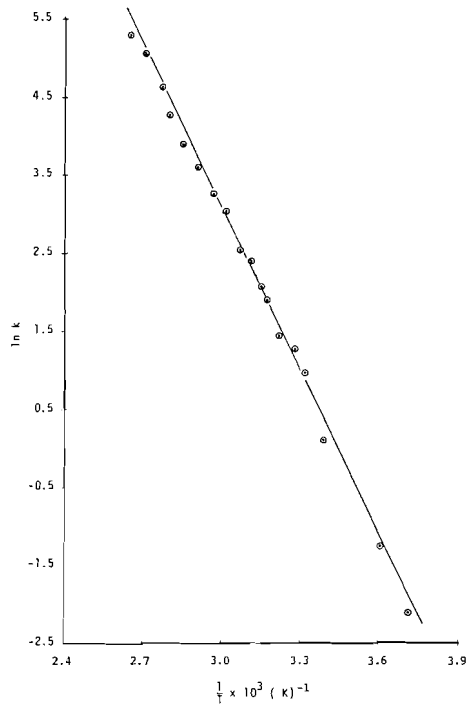

FIG. 4. A plot of ln k vs. the reciprocal of the absolute temperature for HCOX in methycyclohexane. Correlation coefficient 0.9969.

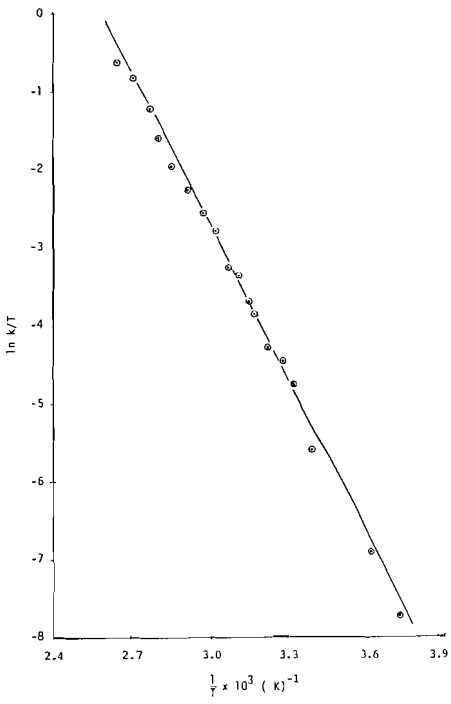

FIG. 5. A plot of ln k/T vs. the reciprocal absolute temperature for HCOX in methylcyclohexane. Correlation coefficient 0.9967.

in k and in T to determine the errors in the activation parameters. The uncertainty in $\Delta G^{\ddagger}$, $\sigma(\Delta G^{\ddagger})$, was determined (ref. 20 and ref. 19 therein)[2] from the equation:

$$[6] \quad \sigma^2(\Delta G^{\ddagger}) = \sigma^2(\Delta H^{\ddagger}) + T^2\sigma^2(\Delta S^{\ddagger}) - 2T\rho\sigma(\Delta H^{\ddagger})\sigma(\Delta S^{\ddagger})$$

The last term in [6] represents the covariance between $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ where ρ is the correlation coefficient from the data used to determine $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\sigma(\Delta H^{\ddagger})$, $\sigma(\Delta S^{\ddagger})$ are the uncertainties in $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$. From [6] $\sigma(\Delta G^{\ddagger})$ for the other compounds in Table 4 in kcal/mol would be: OCMX: $\sigma(\Delta G^{\ddagger}) = 0.01$; OCPX: $\sigma(\Delta G^{\ddagger}) = 0.05$; 2,3,6-PCT: $\sigma(\Delta G^{\ddagger}) = 0.10$; 2,4,4-PCT in toluene-$d_8$: $\sigma(\Delta G^{\ddagger}) = 0.01$; 2,4,6-PCT in methylcyclohexane: $\sigma(\Delta G^{\ddagger}) = 0.06$. For both solutions of α,α,2,4,6-pentachlorotoluene the correlation coefficient ρ was assumed to be unity. The inclusion of the covariance term would indicate that the values of $\Delta G^{\ddagger}$ should be more accurate than previously reported.

[2]We are indebted to Dr. Gerhard Binsch for pointing out this procedure.

Coalescence Temperature Calculations

Because of the overlapping line positions it was not possible to determine the coalescence temperatures

for the individual protons from the observed spectra. However, the rate constants at coalescence, k_c, for each of the three pairs of exchanging protons in HCOX were determined from the expression (21):

$$[7] \qquad k_c = \pi\Delta\nu/\sqrt{2}$$

where $\Delta\nu$ is the nonexchanging chemical shift difference of the proton in the two conformers. The coalescence temperatures were calculated from k_c and the first order fit of ln k vs. $1/T$ from Fig. 4, ln $k_c = 26.01 - (7653/T_c)$. The values of $\Delta G_c^{\ddagger}$, the transition state free energy at coalescence, were obtained from eq. 8 (22):

$$[8] \qquad \Delta G_c^{\ddagger} = 0.004573\, T_c\,(9.97 + \log T_c/\Delta\nu)$$

The coalescence data are given in Table 5.

Comparison of Activation Parameters for Related Compounds

The activation parameters for HCOX and a number of related compounds are given in Table 4. It is satisfying to note that the values of $\Delta S^{\ddagger}$ are all small and negative for the compounds studied by line shape analysis. This would be expected as the transition states should all be somewhat similar, perhaps with a loss of vibrational contribution to the entropy in the more sterically crowded, and hence more rigid, transition state (16).

The transition state free energy may be the most reliable measure of differences in hindered rotation since it is the least sensitive to error (23). Although the values for $\Delta G^{\ddagger}$ from Table 4 are not all at the same temperature, the values of $\Delta S^{\ddagger}$ are small so that $\Delta G^{\ddagger}$ is insensitive to these small temperature variations.

Earlier studies rationalized the increase in $\Delta G^{\ddagger}$ from α,α,2,4,6-pentachlorotoluene (2,4,6-PCT), $\Delta G^{\ddagger} = 14.9 \pm 0.1$ kcal mol^{-1} in toluene-d_8 (1), to α,α,2,3,6-pentachlorotoluene (2,3,6-PCT), $\Delta G^{\ddagger} = 15.4 \pm 0.1$ kcal mol^{-1} in toluene-d_8 (3), on the basis of the buttressing effect of adjacent chlorine atoms on the ring (3). The barrier for α,α,α′,α′,2,3,5,6-octachloro-*p*-xylene (OCPX), $\Delta G^{\ddagger} = 15.4 \pm 0.1$ kcal mol^{-1} in toluene-d_8 (5) appeared to confirm this explanation. However, such rationale does not account for the free energy being lower for α,α,α′,α′,2,4,5,6-octachloro-*m*-xylene (OCMX), $\Delta G^{\ddagger} = 14.9 \pm 0.5$ kcal mol^{-1} in toluene-d_8 (4) and an explanation has been advanced suggesting that buttressing may increase the ground state energy more than the transition state energy (5). If each of the dichloromethyl groups of α,α,α′,α′,α″,α″,2,4,6-nonachloromesitylene (NCM) were treated as an independent rigid rotor flanked by a single chlorine on each side, the value of $\Delta G^{\ddagger}$ should be comparable to that for 2,4,6-PCT; however, the consideration of the 'effective' size (24) for the dichloromethyl groups suggests that the $\Delta G^{\ddagger}$ value be comparable to OCMX. The experimental value for NCM, $\Delta G^{\ddagger} = 16.1 \pm 0.06$ kcal mol^{-1} in toluene-d_8 (6) indicates that these trends are not reliably predicted using buttressing effects.

Two molecules that are very similar to HCOX have been studied by Mark and Pattison (7), α,α,α′,α′,3,4,5,6-octachloro-*o*-xylene (OCOX, corresponding to compound **1** in ref. 7) and α,α,α′,α′,3,6-hexachloro-*o*-xylene (HXCOX, corresponding to **2** in ref. 7). The free energy of activation of these two molecules should correspond closely to that of HCOX as all three should exhibit similar 'cogwheel' effects and the ring distortion and/or buttressing due to the chlorine atoms on the ring would predict that the value of $\Delta G^{\ddagger}$ for HCOX would be between that for HXCOX and OCOX. With $\Delta G^{\ddagger}$ for OCOX at coalescence equal to 17.7 kcal mol^{-1} and $\Delta G^{\ddagger}$ for HXCOX at coalescence equal to 17.4 kcal mol^{-1} (7), both obtained in tetradecane, the values are comparable for HCOX within experimental error.

TABLE 5. Summary of coalescence temperatures and $\Delta G^{\ddagger}$ values* for the protons of HCOX in methylcyclohexane

Exchanging proton	Δν (Hz)	k_c (s^{-1})	T_c (K)	$\Delta G^{\ddagger}$ (T_c) (kcal mol^{-1})
H_A	47.1	104.6	358.3	17.8
H_B	39.2	87.1	355.3	17.8
H_X	9.6	21.3	333.5	17.6

*Calculated as described in the text.

Photoinduced chlorination and bromination of haloadamantanes in tetrachloromethane and bromotrichloromethane[1]

ROBERT R. PERKINS[2] AND RICHARD E. PINCOCK

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received October 21, 1977

ROBERT R. PERKINS and RICHARD E. PINCOCK. Can. J. Chem. **56**, 1269 (1978).

Irradiation of 1-fluoro-, 1-chloro-, and 1-bromoadamantanes in halogenated solvents leads to free radical halogenation of the adamantane skeleton without exchange of the 1-halo atom. Reactions in tetrachloromethane yield products substituted at both the secondary carbons (i.e., bridge carbons) and at tertiary bridgehead carbons. Bridgehead substituted bromo-products greatly predominate when bromotrichloromethane is used as a solvent. Using this difference in the type of products formed from CCl_4 and $BrCCl_3$ a variety of mixed-halo substituted adamantanes were prepared from 1-monohaloadamantanes. Irradiation of 1-iodoadamantane in either solvent proceeds initially only with halogen exchange rather than halogenation of the ring system.

ROBERT R. PERKINS et RICHARD E. PINCOCK. Can. J. Chem. **56**, 1269 (1978).

L'irradiation des fluoro-1, chloro-1 et bromo-1 adamantanes dans des solvants halogénés conduit à l'halogénation radicalaire du squelette adamantane sans échange de l'atome d'halogène en position 1. Les réactions dans le tétrachlorométhane conduisent à des produits substitués aux deux carbones secondaires (i.e. les atomes de carbone de pont) ainsi qu'à des produits substitués au niveau des carbones tertiaires des têtes de pont. Les produits bromés substitués sur les têtes de pont prédominent grandement quand on utilise le bromotrichlorométhane comme solvant. Faisant appel à cette différence dans les types de produits formés à partir de CCl_4 et $BrCCl_3$, on a pu préparer un grand nombre d'adamantanes substitués par divers halogènes à partir d'adamantanes monohalogénés en position 1. L'irradiation de l'iodo-1 adamantane dans tous les solvants conduit initialement à un échange d'halogène plutôt qu'à l'halogénation du système cyclique.

[Traduit par le journal]

The rapid growth in the field of adamantane chemistry has been a result of the ready availability of the parent compound from Schleyer's rearrangement synthesis (1). From adamantane itself the further production of many interesting and useful derivatives has usually involved an initial substitution reaction at a tertiary bridgehead position (2). Most of these substitution reactions have involved carbonium ion intermediates and, because reactions involving substitution or elimination of hydrogens at secondary (bridge) positions are relatively unfavoured (3) or nearly impossible (4), the ionic reactions at bridgeheads generally proceed in good yields.

The free radical chemistry of adamantanes has received relatively less attention. The free radical substitutions usually occur with less discrimination at both tertiary and secondary positions and give rise to complex mixtures of structural and stereoisomers (5–7). In an early study by Smith and Williams (8) the photochlorination of adamantane with molecular chlorine in various solvents was examined. A mixture of bridge and bridgehead chlorides, the ratio being solvent dependent, was isolated. It was also found that extensive polychlorination occurred when carbon tetrachloride was the solvent.

In previous papers (9, 10) it has been shown that, depending upon the halogen involved, products derived from carbonium ion and/or free radical substitution processes could be isolated from irradiation of adamantyl halides in methanol. We have further examined the photochemical reaction of these halides in halogenated solvents to determine if the chlorination and polychlorination reported by Smith and Williams (8) arises from reactions involving the solvent rather than from added molecular chlorine. Synthetic aspects are also of interest. New mixed halo-substituted adamantanes would be made available by beginning with a 1-monohaloadamantane and then introducing a different halogen at secondary and tertiary positions by a free radical route. These cannot be formed by ionic halogenation conditions (e.g., Br_2 with Lewis acids (11)) which substitute for all halogens present as well as introduce halogen atoms essentially exclusively in bridgehead positions.

Results and Discussion

In initial experiments the products of photolysis of

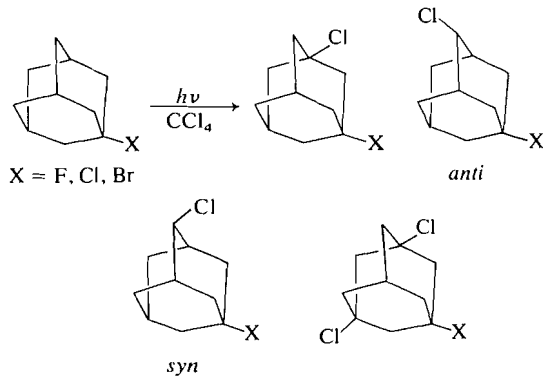
adamantane in methylene chloride, chloroform, and carbon tetrachloride were investigated. Solutions were placed in quartz tubes, carefully degassed, and irradiated with a medium pressure mercury lamp for 48 h. Analysis by glc indicated that no reaction had occurred in methylene chloride, the chloroform solution contained adamantane, 1-chloroadamantane, and 2-chloroadamantane in the relative ratio 68:30:2. The reaction in carbon tetrachloride was faster, contained no unreacted adamantane, and produced seven chlorinated products in addition to hexachloroethane. Liquid chromatography allowed partial separation of the products which were then purified by preparative gas–liquid chromatography (glc). The products (in order of elution on an OV-17 column) were found to be hexachloroethane, 1-chloroadamantane (29%), 2-chloroadamantane (18%), 1,3-dichloroadamantane (16%), unknown minor product (6%), *anti*-1,4-dichloroadamantane and *syn*-1,4-dichloroadamantane (18% combined), and 1,3,5-trichloroadamantane (13%) (approximate yields in parentheses were dependent on irradiation time). These compounds were identified by ir and nmr spectral comparisons with authentic compounds. Authentic samples of the two isomeric 1,4-dichloroadamantanes were prepared by aluminum chloride promoted rearrangement reactions (12). Gas–liquid chromatographic comparisons of retention times with that of authentic 1,2-dichloroadamantane (13) showed that it was absent.

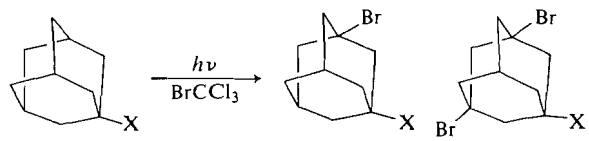
Irradiation of a carbon tetrachloride solution of either 1-fluoro-, 1-chloro-, or 1-bromoadamantane led to introduction of chlorine with a distribution of products similar to that described above for adamantane. The mixed polyhalo products were separated by glc and their structures assigned by glc retention times, nmr spectra, mass spectra, or elemental analysis. The configurations of the *syn*- and *anti*-1-halo-4-halo-adamantane stereoisomers were assigned by analogy to the known (12) and calculated (14) nmr spectra for the *syn*- and *anti*-1,4-dichloroadamantanes; the α-hydrogen on the C4 carbon of the *anti* compound having a larger δ value than that of the *syn* isomer.

For production of the several different compounds in each case of halogenation given above no molecular chlorine was initially present. The trichloromethyl radical or the chlorine atom formed from photolysis of the solvent (9, 10) are the possible hydrogen abstracting agents; the former is usually found to be a more selective agent (5–7). The nearly indiscriminate behaviour of the actual abstracting agent shows up in the variety of products formed by photohalogenation in CCl_4 solutions. The only possible products not produced in sufficient yields



to isolate were the 1-halo-2-chloroadamantanes. The absence of such 1,2-disubstituted products may reflect the steric requirements for abstraction by a large radical as well as an unfavourable polar character of the abstraction reaction when the substrate halogen is close to the reactive site. The lack of selectivity is indicative of chlorine atoms and additional evidence comes with the presence of hydrogen chloride and hexachloroethane formed in copious amounts during the irradiation of carbon tetrachloride solutions containing adamantanes.

When the solvent was changed to bromotrichloromethane the 1-haloadamantanes gave only brominated products. This is consistent with the known (15) greater transferability of the bromine atom over a chlorine atom of $BrCCl_3$. More unusual was the formation of essentially only products for bridgehead substitutions rather than from bridge substitution.



Although secondary products are formed on longer irradiations, the different initial products from CCl_4 and $BrCCl_3$ show that the same radical ($Cl_3C^{\cdot}$) can not be responsible in both systems for the product distributions. Another difference is that hexachloroethane is not formed in the $BrCCl_3$ system. Probably abstraction by the more selective radical $Cl_3C^{\cdot}$ is the major product forming step in $BrCCl_3$ while chlorine atoms are most active in CCl_4.

The transfer of bromine only and the more selective attack at bridgehead positions in $BrCCl_3$ made possible the synthesis of mixed bridgehead substituted halides, e.g., from 1-fluoroadamantane was produced only two major products 1-fluoro-3-bromoadamantane and 1-fluoro-3,5-dibromoadamantane. (The corresponding chlorination reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of 1-fluoroadamantane in CCl_4 distributed the substrate among four products; 1-fluoro-3-chloroadamantane, 1-fluoro-3,5-dichloroadamantane, and the *syn*- and *anti*-1-fluoro-4-chloroadamantanes.) Other substituted haloadamantanes are also made available by photochemical halogenations; 1-fluoro-3,5-dimethyladamantane was chlorinated and brominated at the remaining bridgehead position in CCl_4 and $BrCCl_3$, respectively, and 1-cyanoadamantane was brominated to 1-cyano-3-bromoadamantane.

The above reactions of 1-fluoro-, 1-chloro-, and 1-bromoadamantane involve substitution at new positions on the adamantyl ring without disruption of the 1-halo atom. With 1-iodoadamantane, in either CCl_4 or $BrCCl_3$, the initial reaction is direct photochemical exchange of the 1-iodo atom with solvent halogen. No doubt the propensity of iodo compounds to undergo photoactivation and give ionic intermediates leads to this exchange (9, 10). Unfortunately this activity prevents the preparation by photochemical means of mixed halogenated adamantanes that contain any iodine atoms.

Experimental

Melting points (uncorrected) were obtained with a Thomas Hoover capillary melting point apparatus using sealed tubes. Proton nuclear magnetic resonance spectra are for 10–15% solutions in benzene or carbon tetrachloride and are reported relative to tetramethylsilane at $\delta = 0.0$. High resolution mass spectra were obtained from an Atlas AE1-MS-902 spectrometer. Analytical gas–liquid chromatography was performed with a Perkin Elmer 900 instrument utilizing a flame ionization detector; preparative glc was carried out on a Varian Model 90-P instrument. Microanalyses were by Mr. P. Borda (University of B.C.).

Materials

Adamantane, 1-bromoadamantane, 1-chloroadamantane, and 1-cyanoadamantane were obtained from commercial sources. 1,3-Dimethyladamantane was kindly supplied by Sun Oil Company, Philadelphia, PA. 1-Fluoro- and 1-iodoadamantane were prepared according to literature procedures (11, 16). 1,3-Dichloro- and 1,3-dibromoadamantane as well as 1,3,5-trichloro- and 1,3,5-tribromoadamantane were available by published procedures (11). Samples of authentic *syn*- and *anti*-1,4-dichloroadamantanes and 1,2-dichloroadamantane were prepared by the method of Cuddy *et al.* (12, 13).

General Procedure for Photochemical Reactions

In a quartz vessel equipped with a nitrogen gas inlet and a condenser was placed 0.5–2 g of the haloadamantane and 50–70 ml of CCl_4 or $BrCCl_4$. The reaction vessel was clamped to a stand 10 cm from a GE UA-3 360 watt medium pressure mercury lamp contained in a water cooled quartz immersion well. The entire set-up was surrounded by aluminum foil to minimize loss of light. The degassed solution was irradiated and the reaction followed by glc (182 cm by 0.32 cm OD 8% OV-17 on Chromsorb W AW-DMCS 80/100 mesh), normally for 24 h.

The reaction mixture was poured into a saturated sodium bicarbonate solution and the organic phase washed well with water and dried over magnesium sulfate. Evaporation yielded a sticky yellow solid which was subjected to column chromatography. In the carbon tetrachloride reactions passage down a short silica gel column with pentane allowed separation of the hexachloroethane. The chlorides were washed from the column with chloroform and then eluted down an alumina column using pentane as the eluting solvent. Purified samples were obtained by preparative glc (152 cm by 0.64 cm OD 10% Carbowax 20 m on Chromsorb W 80/100 mesh).

Chlorination of 1-Bromoadamantane

The following monobromo compounds were prepared by irradiation of 1-bromoadamantane in CCl_4.

1-Bromo-3-chloroadamantane: mp 101.5–103°C. (lit. (6) mp 99–100°C); nmr (benzene) δ: 1.05, (unresolved t, 2H δ to both halogens), 1.61 (bs, bridgehead hydrogens γ to both halogens), 1.74 (d, β to Cl), 1.88 (d, β to Br), 2.55 (s, β to both halogens).

syn- *and* anti-*1-Bromo-4-chloroadamantane*: these could not be separated by glc; nmr (CCl_4) δ: 1.80–2.95 (m's), 4.20 (s, for *syn* compound), 4.36 (s, for *anti* compound). *Anal.* calcd. for $C_{10}H_{14}BrCl$: C 48.14, H 5.65; found: C 47.85, H 5.50.

1-Bromo-3,5-dichloroadamantane: colourless solid, mp 104.5–106°C; nmr (CCl_4) δ: 2.02 (unresolved d, 4H β to Cl atoms), 2.16 (unresolved d, 2H β to Br), 2.36 (m, 1H α to each halogen), 2.42 (s, 2H β to both Cl atoms), 2.56 (s, 4H β to Cl and Br); *Anal.* calcd. for $C_{10}H_{13}BrCl_2$: C 42.29, H 4.61; found: C 42.20, H 4.70.

Chlorination of 1-Fluoroadamantane

The following monofluoro compounds were prepared by irradiation of 1-fluoroadamantane in CCl_4.

1-Chloro-3-fluoroadamantane: colourless solid, mp 177–178°C; nmr (CCl_4) δ: 1.55 (unresolved t, 2H δ to both halogens), 1.81 (m, $J = 5.5$ Hz, 4H β to F), 2.01 (unresolved d, 4H β to Cl), 2.23 (d, $J = 5.5$ Hz, 2H β to both F and Cl), 2.35 (broad s, 2H γ to both F and Cl). *Anal.* calcd. for $C_{10}H_{14}FCl$: C 63.66, H 7.48; found: C 63.58, H 7.52.

syn-*4-Chloro-1-fluoroadamantane*: colourless white solid, mp 207–208°C; nmr (CCl_4) δ: 1.45–2.58 (m's), 4.09 (s, 1H); high resolution ms calcd. for $C_{10}H_{14}FCl$: 188.0767; found: 188.0766.

anti-*4-Chloro-1-fluoroadamantane*: colourless white solid, mp 213–215°C; nmr (CCl_4) δ: 1.40–2.45 (m's), 4.18 (s, 1H); high resolution ms calcd. for $C_{10}H_{13}FCl$: 188.0767; found: 188.0765.

1,3-Dichloro-5-fluoroadamantane: colourless solid, mp 135.5–137°C; nmr (CCl_4) δ: 1.80 (t, $J = 3.5$ Hz, 2H β to F), 1.93 (s, 4H β to Cl), 2.20 (d, $J = 5.5$ Hz, 4H, β to both Cl and F), 2.39 (s, 2H, β to both Cl atoms), 2.47 (m, 1H γ to all three halogen atoms); *Anal.* calcd. for $C_{10}H_{13}FCl_2$: C 53.83, H 5.87; found: C 53.50, H 5.99.

Bromination of 1-Fluoroadamantane

The following monofluoro compounds were prepared by irradiation of 1-fluoroadamantane in $BrCCl_3$.

1-Bromo-3-fluoroadamantane: colourless solid, mp 136–137°C; nmr (benzene) δ: 1.05 (unresolved t, 2H δ to both F and Br), 1.58 (m, 4H, β to F), 1.72 (s, 2H γ to both Br and F), 1.91 (s, 4H β to Br), 2.40 (d, $J = 5.5$ Hz, 2H β to both Br and F); *Anal.* calcd. for $C_{10}H_{14}BrF$: C 51.42, H 6.05; found: C 51.44, H 6.17.

1,3-Dibromo-5-fluoroadamantane: colourless solid, mp 160–162°C; nmr (benzene) δ: 1.32 (m, 2H β to F), 1.47 (m, 1H, γ to all three halogen atoms), 1.58 (s, 4H β to Br), 2.13 (d, $J = 5.5$ Hz, 4H β to both Br and to F), 2.44 (s, 2H β to both Br atoms); high resolution ms calcd. for $C_{10}H_{13}Br_2F$: 309.9369; found: 309.9351.

Bromination of 1-Chloroadamantane

In addition to the major product 1-bromo-3-chloroadamantane (see above), 1-chloro-3,5-dibromoadamantane, mp 99–102°C, was formed by irradiation of 1-chloroadamantane in $BrCCl_3$; nmr (benzene) δ: 1.45 (s, 3H, one γ to all three halogen atoms and two β to Cl), 1.59 (unresolved d, 4H β to Br), 2.27 (s, 4H β to both Cl and Br), 2.42 (s, 2H, β to both Br atoms); high resolution ms (no parent) calcd. for $C_{10}H_{13}BrCl$: 248.9869; found: 248.9874.

1-Bromo-3-cyanoadamantane

This compound was isolated from the photolysis of a solution of 1-cyanoadamantane in $BrCCl_3$ (crude yields 48% after irradiation for 24 h). After chromatography through alumina, recrystallization from hexane gave colourless platelets, mp 128.5–130°C; nmr (benzene) δ: 1.00 (s, 2H δ to CN and Br), 1.38 (s, 6H β to CN plus α to both CN and Br), 1.82 (s, 4H β to Br, 2.18 (s, 2H β to both Br and CN); *Anal.* calcd. for $C_{11}H_{14}BrN$: C 55.02, H 5.87, N 5.83; found: C 55.02, H 5.90, N 5.80.

Halogenation of 1-Fluoro-3,5-dimethyladamantane

1-Bromo-3,5-dimethyl-7-fluoroadamantane, mp 31–32°C, was the major product of irradiation of the parent fluoro compound in $BrCCl_3$ for 6 h. Minor products were not isolated; nmr (benzene) δ: 0.58 (s, methyl groups), 0.88 (s, 2H β to both methyl groups), 1.28 (d, J = 5.5 Hz, 4H β to F and methyl), 1.62 (s, 4H β to Br and methyl), 2.27 (d, J = 5.5 Hz, 2H β to both Br and F); high resolution ms calcd. for $C_{12}H_{18}BrF$: 261.1806; found: 261.1803.

Similarly 1-chloro-3,5-dimethyl-7-fluoroadamantane, an oil, mp ca. 20°C, was the major product when the parent compound was irradiated 12 h in CCl_4; nmr (benzene) δ: 0.61 (s, methyl groups), 0.87 (s, 2H β to both methyl groups), 1.27 (d, J = 5.5 Hz, 4H β to F and methyl), 1.45 (s, 4H, β to Cl and methyl), 2.10 (d, J = 5.5 Hz, 2H β to both Cl and F); high resolution ms calcd. for $C_{12}H_{18}FCl$: 216.1080; found: 216.1067.

Aqueous trifluoroacetic acid as a medium for organic reactions. II. The oxidation of hydrocarbons by manganese(VII)

ROSS STEWART AND UDO A. SPITZER

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received November 21, 1977

ROSS STEWART and UDO A. SPITZER. Can. J. Chem. **56**, 1273 (1978).

The oxidation of 11 alkanes, 4 cycloalkanes, and 10 arenes by potassium permanganate in aqueous trifluoroacetic acid has been studied. The reaction rates are approximately first order in h_R, the antilogarithm of the acidity function $-H_R$, and the active oxidant is believed to be MnO_3^+, either free or complexed. The rate of abstraction of primary, secondary, and tertiary hydrogen atoms in the C_5H_{12} isomers is in the ratio 1:60:2100 and the rate per methylene in normal alkanes increases with increasing chain length. Cyclohexane is the least reactive of the cycloalkanes and the isotope effect in the oxidation of cyclo-C_6D_{12} is 4.3 at 25°C. The mechanism of oxidation of the aliphatic hydrocarbons is believed to be hydrogen-atom abstraction by MnO_3^+. The oxidation of arenes C_6H_5Z has a ρ^+ value of -5.29 when appropriate σ^+ values of Z are used, and there is no isotope effect when the reaction rates of $C_6H_5CH_3$, $C_6H_5CD_3$, and $C_6D_5CD_3$ are compared. The mechanism of oxidation of the aromatic compounds is believed to be electrophilic attack of MnO_3^+ at the activated positions of the ring followed by rapid degradation of the ring system.

ROSS STEWART et UDO A. SPITZER. Can. J. Chem. **56**, 1273 (1978).

On a étudié l'oxydation de 11 alcanes, de 4 cycloalcanes et de 10 arènes par le permanganate de potassium dans de l'acide trifluoroacétique aqueux. Les vitesses de réaction sont approximativement du premier ordre en h_R, l'antilogarithme de la fonction d'acidité $-H_R$ et l'on croit que l'oxydant actif est le MnO_3^+ soit à l'état libre ou complexé. Les vitesses d'enlèvement des atomes d'hydrogène primaire, secondaire et tertiaire des isomères du C_5H_{12} sont dans le rapport de 1:60:2100 et la vitesse d'enlèvement par méthylène, dans les alcanes normaux, augmente lorsque l'on augmente la longueur de la chaîne. Le cyclohexane est le moins réactif des cycloalcanes et l'effet isotopique lors de l'oxydation du cyclo-C_6D_{12} est de 4.3 à 25°C. On croit que le mécanisme d'oxydation des hydrocarbures aliphatiques procède par l'enlèvement d'un atome d'hydrogène par MnO_3^+. La valeur de ρ^+ pour l'oxydation des arènes C_6H_5Z est de -5.29 quand les valeurs σ^+ appropriées de Z sont utilisées; il n'y a aucun effet isotopique quand on compare les vitesses de réaction de $C_6H_5CH_3$, $C_6H_5CD_3$ et $C_6D_5CD_3$. On croit que le mécanisme de l'oxydation des composés aromatiques procède par une attaque électrophile du MnO_3^+ sur les positions activées du cycle suivie par une dégradation rapide du système cyclique.

Introduction

Permanganate is an extremely versatile oxidizing agent, being able to oxidize many different types of organic compounds under a wide variety of experimental conditions (1). Activation by both acids and bases is commonly found, the latter usually resulting from the organic compound being converted to a more reactive form by base, e.g. alkoxide ions being formed from alcohols, whereas the former is usually the result of a change in the state of the oxidant. Hydrocarbons lack an ionizable functional group and, in any case, are insoluble in aqueous base, and hence alkaline permanganate is generally an ineffective oxidant for such compounds. Aqueous acid activates the manganese(VII) but the problem of water insolubility of hydrocarbons remains. Mixed solvents such as aqueous acetic acid have been used (2) but they present the problem of degradation of the solvent by permanganate. Phase transfer catalysis (3) using a benzene–water pair shows promise but, again, solvent degradation prevents less reactive substrates being studied.

Trifluoroacetic acid (TFA) has been shown to be a useful medium for a number of reactions, including chromium(VI) and other oxidations (4) and electrophilic aromatic substitution (5, 6), and we have investigated its use as a medium for manganese(VII) oxidation. It turns out to have the virtues of being highly resistant to oxidation by permanganate and being sufficiently acidic to convert permanganate ion to a more reactive entity. Furthermore, most organic solvents are quite soluble in TFA solutions, as is potassium permanganate.

The chemical changes that occur as the TFA content of an aqueous TFA solution of potassium permanganate is increased were the subject of a previous paper (7). There we showed that the green species that appears in solutions containing more than 82

TABLE 1. Correlation of oxidation rate with acidity function for various hydrocarbons

Compound	log $k_2/-H_0$ correlation, slope	Correlation coefficient	log $k_2/-H_R$ correlation, slope	Correlation coefficient
Pentane	2.86	0.985	1.03	0.987
Hexane	2.59	0.994	1.16	0.991
Cyclohexane	2.95	0.992	1.22	0.989
Cyclohexane-d_{12}	2.95	0.986	1.23	0.990
Cycloheptane	2.78	0.995	0.79	0.986
Benzene	4.89	0.981	0.98	0.997
Toluene	5.81	0.996	0.82	0.9995
Toluene-d_8	5.88	0.993	0.82	0.997

wt.% TFA is the permanganyl cation MnO_3^+, either in the free form or as its trifluoroacetate complex (or ester) $MnO_3 \cdot O_2CCF_3$. The present paper deals with the mangenese(VII) oxidation of 11 alkanes, four cycloalkanes, and 10 arenes and derivatives in aqueous TFA.

Results and Discussion

Permanganate's oxidizing powers rise markedly as the concentration of the TFA component of aqueous TFA is increased. For hydrocarbons, both aliphatic and aromatic, the oxidation rate is roughly proportional to the increase in the h_R value of the solution, where h_R and its negative logarithm, the acidity function H_R (8), represent the ability of an acidic solution to convert aryl alcohols to carbonium ions.

[1] $$ROH + H^+ \rightleftharpoons R^+ + H_2O$$

The increase in rate is very much larger than would be the case if the activation were governed by the acidity function H_0, which measures the ability of an acidic system to protonate a series of amine indicators. Although both H_R and H_0 give linear plots when log k is plotted against acidity function the slopes in the case of H_R are grouped near unity, whereas those for H_0 range from a low of 2.59 for hexane to a high of 5.88 for toluene-d_8. Figure 1 shows a plot of log k_2, where k_2 is the bimolecular rate constant, against $-H_R$ for hexane, cyclohexane, and cyclohexane-d_{12} and Table 1 lists the slopes and correlation coefficients for both the H_0 and H_R correlations.

The kinetics of the oxidation of alkanes and arenes at all acidities have been found to be first order in permanganate and first order in hydrocarbon. Since the slopes of the log $k_2/-H_R$ plots are near unity the general rate expression for the reaction in aqueous TFA is approximated by [2].

[2] $$-d[MnO_4^-]/dt = k[MnO_4^-][RH]h_R$$

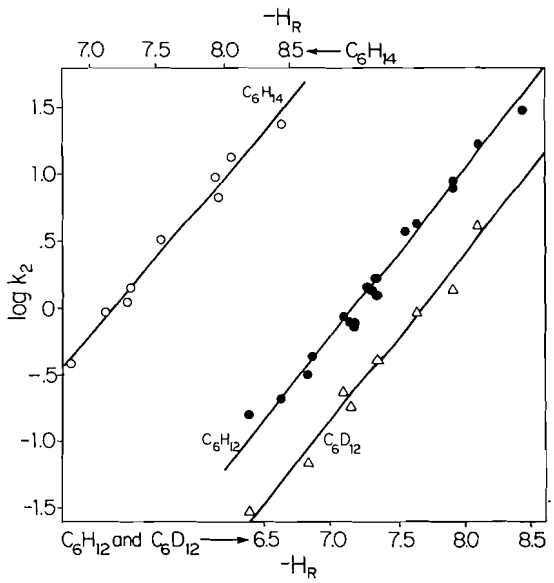

FIG. 1. Correlation of logarithm of oxidation rate with acidity function H_R for hexane, cyclohexane, and cyclohexane-d_{12}.

Furthermore, since the concentration of the green manganese species (MnO_3^+ or $MnO_3 \cdot O_2CCF_3$) in higher concentration of aqueous TFA has been previously shown to be governed by H_R one can infer that it is the active oxidant.[1] The slopes for the two processes, the equilibrium governing the production of MnO_3^+ or $MnO_3 \cdot O_2CCF_3$, and the hydrocarbon oxidation rates are not identical, however, being 0.76 in the former case and between 0.79 and 1.23 in the latter. Most of the oxidations were, of necessity, conducted in solutions where the extent of formation of the green species was much too small to measure and the variability in h_R dependence may reflect this fact.

It is possible to rationalize the approximate unit dependency of rate on h_R by making a number of

[1]An early suggestion that MnO_3^+ might be the active oxidant in acidic permanganate was made by L. S. Levitt (15).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

assumptions regarding activity coefficient behaviour of the various species involved in the equilibrium and the oxidation but we will not burden the reader with what seems to us to be a tenuous line of reasoning. Suffice it to state that to a first approximation H_R governs both the equilibrium production of the active manganese species and the rate of hydrocarbon oxidation. Since MnO_3^+ will almost certainly be more reactive than the complex or ester $MnO_3 \cdot O_2CCF_3$ with which it will be in equilibrium, we believe that it is probably responsible for the bulk of the oxidation in aqueous TFA, even if it is present in smaller concentration. Permanganate ion, MnO_4^-, is, of course, the principal manganese component in all solutions less acidic than 90 wt.% TFA.

Alkanes

The rate of oxidation of alkanes by Mn(VII) in TFA is sensitive to structural differences in the substrate, in particular to chain-branching. Thus the isomeric compounds pentane, isopentane, and neopentane react at the rates shown in Table 2.

It is clear that primary hydrogen atoms are much less subject to attack than those at secondary positions, and that the lone tertiary hydrogen atom in isopentane is responsible for the compound's high reactivity. When appropriate statistical corrections are made for the number of hydrogen atoms of each type, the following reactivity ratio emerges, 1°:2°:3° = 1:60:2100. Such a ratio is not unreasonable for a reaction proceeding by way of hydrogen atom abstraction and producing radicals. Both much larger and much smaller ratios have been found in known radical processes (see for example data tabulated in ref. 9). On the other hand, if hydride ion were the abstracted species and carbonium ions the intermediates thus formed, a very much larger reactivity ratio would be expected (10).

The initial bond-breaking step is followed by further reactions that degrade the molecule, most of these steps being faster than the original reaction. The oxidation of pentane under conditions of excess substrate gives 2-pentanone, 3-pentanone, and a trace of propanoic acid as the reaction products. The corresponding alcohols, 2-pentanol and 3-pentanol, are presumably intermediates in this sequence since we have found them to react with Mn(VII)–TFA at a faster rate than either pentane or the ketones. In fact, 2-pentanol and 3-pentanol react at identical rates. Furthermore, twice as much 2-pentanone as 3-pentanone (66 to 34%) is isolated by glc from the oxidation of pentane (the statistical ratio is 2:1). We can, therefore, calculate all the relevant rate constants for the various steps in the oxidation (Scheme 1).[2]

TABLE 2. Rate constants for the oxidation of the C_5H_{12} isomers by Mn(VII) in 82 wt.% aqueous TFA at 25°C

Isomer	k_2 (M^{-1} s^{-1})	Relative rate
$CH_3(CH_2)_3CH_3$	6.0	30
$(CH_3)_2CHCH_2CH_3$	37[a]	185
$(CH_3)_4C$	0.2	1

[a]Extrapolated from rates at lower acidities, assuming a linear relation between h_R and k; an almost identical ratio for the rates of pentane and isopentane is found at lower acidity.

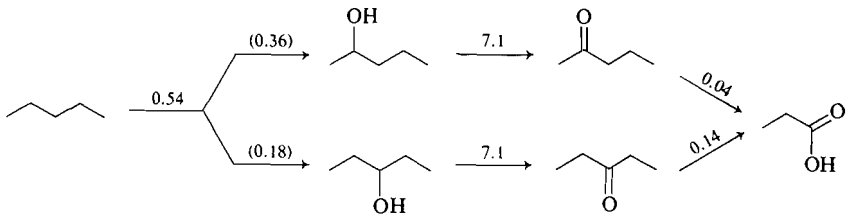
TABLE 3. Oxidation rates of normal alkanes C_nH_{2n+2} by Mn(VII) in 82 wt.% aqueous TFA at 25°C

n	k_2 (M^{-1} s^{-1})	k_2/n	$k_2/n - 2$
5	6.0	1.2	2.0
6	10.5	1.8	2.6
7	23.0	3.3	4.6
8	30.0	3.8	5.0
9	41.5	4.6	5.9
10	49.6	5.0	6.2
11	61.0	5.5	6.8
12	72.4	6.0	7.2
13	82.5	6.3	7.5

The effect of chain length on rate of reaction of *n*-alkanes by Mn(VII)–TFA is shown in Table 3. The rate constants rise as the chain length increases, as might be expected, since there are more sites of attack. The rate per carbon atom also rises. We have seen that methylene groups are much more reactive than methyl groups and it might be expected that the rate per methylene group would not be significantly affected by chain length but this is not the case. As can be seen from the results in the first column of Table 3 there is a marked increase in rate per methylene ($k_2/n - 2$), which tends to level off somewhat at longer chain length.[3] Presumably there is a cumulative inductive, or other, effect operating to make the methylene groups in the higher alkanes more reactive than those in shorter chains. When electron-withdrawing groups are present the oxidation is slowed drastically. (Nitroethane, propanonitrile, and propanoic acid are highly resistant to oxidation by potassium permanganate in 80 wt.% TFA, con-

[2]Although the product-isolation experiments were conducted in 80 wt.% TFA and the rate measurements in 76 wt.% TFA the identical dependency of rate on acidity for 2- and 3-pentanol suggests that the difference is not of significance.

[3]The larger difference between C_6 and C_7 than between C_5 and C_6 is probably an artifact. The rate constants given for the C_7–C_{13} compounds were obtained by interpolation whereas the values for C_5 and C_6 come from direct measurements.



SCHEME 1. Steps in the manganese(VII) oxidation of pentane to propanoic acid in aqueous TFA. The numbers above each arrow represent the rate constant, M^{-1} s^{-1}, for that step in 76 wt.% TFA. The values in parentheses are partial rate constants calculated using the results of product isolation experiments.

ditions under which propane and other alkanes react readily.)

Whether alkyl groups have the same or different inductive effects (as expressed by their σ_I or σ^* values) is a matter of current controversy (11, 12) and the present work may be pertinent in this regard. Our results show that a methylene C—H bond becomes more reactive to Mn(VII)–TFA the greater the number of methylenes in the two attached alkyl groups. Since electron release favours the reaction it is clear that, in our case, higher alkyl groups have larger effective inductive effects than do the lower alkyl groups. (A similar effect is observed for the ionization potential of alkanes (13).)

Cycloalkanes

The effect of ring size on oxidation of the cycloalkanes from C_5–C_8 is shown in Table 4. The preference of six-membered ring systems for tetragonal rather than trigonal bonding is well known and the lower rate of oxidation of cyclohexane is in agreement with such experience. Further, the oxidation of the four cycloalkanes with CrO_3 in glacial acetic acid shows similar behaviour: a ratio of 2.0:1.0:6.6:22.4 is obtained for the rates of oxidation of the C_5–C_8 compounds (10*d*). It is likely that the latter reaction takes place by hydrogen-atom abstraction (10*b*) and this is further evidence supporting the mechanism given earlier in this paper. (Processes involving carbonium ion intermediates show similar orders of reactivity within the C_5–C_8 series but the effects are generally much more pronounced (14).)

It is worth noting that cyclohexane and hexane are oxidized at almost identical rates. All the other cycloalkanes studied here react at least twice as fast as their open-chain analogs. A similar effect has been observed in a number of other hydrogen-atom abstraction processes studied by Bunce.[4]

An isotope effect of 4.3 has been found for the oxidation of cyclohexane-d_{12} at 25°C (Fig. 1). A primary isotope effect of such magnitude shows clearly that the rate-controlling step is carbon–hydrogen bond cleavage, although it is not helpful in distinguishing between hydrogen-atom and hydride-ion abstraction (16).

TABLE 4. Oxidation rates for cycloalkanes by Mn(VII) in 76 wt.% TFA at 25°C

Cycloalkane	k_2 (M^{-1} s^{-1})
C_5	3.1
C_6	1.0
C_7	5.2
C_8	14.0

Arenes

Aromatic compounds containing alkyl side chains are oxidized by Mn(VII)–TFA predominantly at the ring rather than at the side chain in sharp contrast to the behaviour of most transition metal oxidants in particular Mn(III), Ce(IV), and Cr(VI), which attack the side chain preferentially (17). Indeed, Mn(VII) under ordinary conditions does the same (1*a*, 17*a*).[5] That ring attack occurs in our case is clear from evidence based on (*a*) isotope effects, and (*b*) substituent effects. Product analysis was not particularly helpful in locating the position of attack since extensive degradation of the arenes occurred in almost all cases, although small amounts of benzoic acid were isolated from the toluene oxidation, showing that side-chain attack was not completely absent.

It is clear from the results in Table 5, spanning a 600-fold range of reactivity, that the effect of deuterium substitution on the rate of toluene oxidation is negligible. Neither $C_6H_5CD_3$ nor $C_6D_5CD_3$ produces effects that are outside experimental error. The reaction thus appears to proceed by rate-controlling addition of MnO_3^+ to the ring, probably forming a σ complex of the following type, in which the manganese is reduced to manganese(V).

The effect on the reaction of varying the side chain

[4]N. J. Bunce. Personal communication.

[5]Reasonably stable solutions of permanganate ion in benzene can be prepared using tetraalkylammonium counter ions and these can be convenient oxidants for substrates of low polarity (ref. 3 and U. A. Spitzer and R. Stewart, unpublished results).

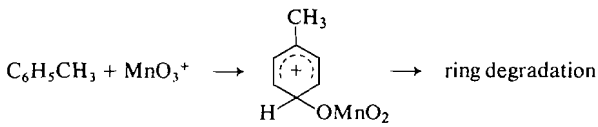
in alkylbenzenes also demonstrates clearly that attack takes place at the ring in preference to the alkyl groups. Cumene possesses a tertiary hydrogen atom in the side chain, yet it is oxidized at essentially the same rate as ethylbenzene, with toluene and *tert*-butylbenzene being slightly less reactive (Table 6). If side-chain oxidation were appreciable there should be large variations in the rates of these four compounds. Cumene with one hydrogen atom that is both tertiary and benzylic should be much more reactive than ethylbenzene which has two hydrogen atoms that are secondary and benzylic, followed by toluene with hydrogens that are primary and benzylic, followed by *tert*-butylbenzene which has only primary nonbenzylic hydrogens.



As might be expected electron-donating substituents in the ring increase the rate of reaction of arenes with Mn(VII)–TFA. Figure 2 shows the Hammett plot using σ^+ substituent constants that are appropriate for the most reactive sites. That is, σ_m^+ has been used for *meta* directing groups and σ_p^+ for *ortho-para* directing groups. No statistical corrections have been applied and partitioning between *ortho* and *para* substitution has, of necessity, been neglected. Nonetheless, it is clear that a satisfactory correlation exists. The ρ^+ value of -5.29 is entirely reasonable for a reaction of the type suggested here, i.e. electrophilic attack at ring carbon. Nitration, which of all the common electrophilic substitution reactions perhaps resembles this reaction most closely, has ρ^+ values in this neighbourhood (18).

It is noteworthy that the group that deviates most from the regression line in Fig. 2 is fluoro. Fluorobenzene reacts too slowly by almost an order of magnitude and it appears to be significantly less reactive than benzene, despite the presence of the fluoro group, which has a negative value of σ_p^+. Much of this discrepancy is doubtless statistical in origin. The *meta* and *ortho* positions in fluorobenzene are relatively unreactive towards electrophiles (19) and one is, in effect, comparing six positions of substitution in benzene with one in fluorobenzene.

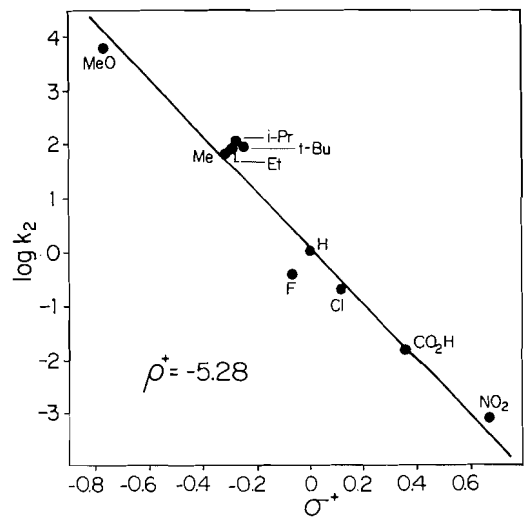


FIG. 2. Hammett plot for oxidation of substituted benzenes.

Electron abstraction from the ring, as occurs in the cobalt(III) oxidation of arenes (20), is a possible alternative mode of reaction. We do not favour this path in the present case since there are a number of points of difference between the cobalt(III) and manganese(VII) reactions. In the cobalt(III) reaction a much lower ρ value is found, there is a substantial isotope effect when $C_6H_5CD_3$ is oxidized, and side-chain oxidation predominates.

Activation Parameters

The reactions studied have activation parameters

Toluene	62	5.6	−36

that are comparable to those found in many other manganese(VII) oxidations (1*b*), $\Delta H^{\ddagger}$ is low and $\Delta S^{\ddagger}$ is large and negative (Table 7). The largest value of $\Delta H^{\ddagger}$ is for toluene at low acidity, 11.4 kcal mol^{-1}. As the acidity is raised the rate of oxidation, of course, rises, and this increase is principally due to a decrease in $\Delta H^{\ddagger}$. The activation parameters for alkanes and arenes are similar when compared under conditions of equal rate but not when compared under conditions of equal acidity since the aromatic hydrocarbons are all considerably more reactive than the alkanes.

Experimental

Materials

Commercial TFA was purified by distillation from a small quantity of potassium permanganate. All hydrocarbons were purified by distillation and the purity checked by vpc. Toluene-α-d_3 (98% D), toluene-d_8 (98% D), and cyclohexane-d_{12} (99% D) were obtained from Merck, Sharpe, and Dohme of Canada.

Kinetic Procedure

The rate of disappearance of permanganate was followed at 526 nm (1*a*) in a thermostatted spectrometer compartment. All rate constants, except where noted, refer to 25°C. A considerable excess of organic substrate was used (20-fold excess or more) and a first-order treatment applied in almost all cases.

Stock solutions in aqueous TFA of hydrocarbons of low or moderate volatility were prepared by straightforward mixing of the components with the TFA concentration being determined by titration. Compounds that are gaseous or highly volatile were prepared by dissolving the hydrocarbon at low temperature (0°C for neopentane) and measuring the increase in weight after the solution was returned to room temperature and opened to the atmosphere for a short time.

Product Analysis

Potassium permanganate (0.5 g) was dissolved in 20–25 ml of the desired TFA–water solution and 4 ml of the substrate added. After 1 h of stirring the reaction was quenched by the addition of 40 ml water; the mixture was saturated with sodium chloride and then extracted three times with 50 ml ether. The ether extracts were combined, dried over anhydrous magnesium sulfate, and flash evaporated and the concentrated ether extracts analyzed by vpc for volatile components. The only nonvolatile compound found in significant amount, benzoic acid, was recovered by evaporating the extracts to dryness and then purifying the crude products by sublimation and recrystallization.

Several problems were encountered in the product analysis, the most severe of which was that large quantities of TFA were extracted along with products. For example, propanoic acid was the only carboxylic acid that could be collected as a product of oxidation of the C_5 alkanes. Although one would expect some acetic acid none of the columns, even Chromosorb 101, which is specifically designed for low-molecular-weight acids, were capable of separating it from the larger amounts of TFA. It was also found that 2-pentanone and 3-pentanone could not be separated from each other. This problem was finally avoided by collecting the small amounts present of this ketone mixture and verifying their identities by nmr. The 2-pentanone to 3-pentanone ratio could be calculated from the peak integrals of the nmr spectrum of the mixture.

Cyclohexane gave trace amounts of cyclohexanol and cyclohexanone and a 75% yield of adipic acid; cyclohexanol gave trace amounts of cyclohexanone and tar and an 86% yield of adipic acid; cyclohexanone gave tar (~9% by weight) and an 81% yield of adipic acid. (Yields are based on reactants consumed.)

The inorganic products of the reaction of Mn(VII)–TFA with a 10-fold molar excess of hydrocarbon are manganese(II) and manganese(IV), the latter usually being observable as a fine brown precipitate. The alkanes yielded approximately equal amounts of manganese(II) and manganese(IV) whereas with the arenes much more of the manganese was found to be in the divalent state, indicating that manganese(IV) in TFA can oxidize aryl rings or the intermediate degradation products.

The initially formed manganese(VI) species that is believed to result from the reaction of alkanes with MnO_3^+ is $HMnO_3^+$, which presumably undergoes disproportionation, and similarly with the manganese(V) intermediate believed formed in the reaction of MnO_3^+ with arenes.

Received November 2, 1978

GEORGE F. SHEATS and ALEC N. STRACHAN. Can. J. Chem. **56**, 1280 (1978).

A stopped-flow spectrometer has been used to investigate the mechanism of the nitration of toluene, and to determine kinetic parameters for the formation and reaction of nitronium ion, in 77.3 and 78.45 wt.% sulphuric acid. The protonation of nitric acid to form nitronium ion and water is found to occur at similar rates at both acid concentrations and to have an activation energy of 18.3 ± 4.0 kcal mol^{-1}. The activation energy of the reverse reaction, the heat of the reaction, and the activation energy of encounter complex formation between nitronium ion and toluene are estimated to be respectively 10.5 ± 4.0, 7.8 ± 0.5, and 5.9 ± 0.1 kcal mol^{-1} in 77.3% H_2SO_4 and 12.0 ± 4.0, 6.3 ± 0.5, and 6.0 ± 0.1 kcal mol^{-1} in 78.45% H_2SO_4.

GEORGE F. SHEATS et ALEC N. STRACHAN. Can. J. Chem. **56**, 1280 (1978).

On a utilisé un spectomètre à flux stoppé pour étudier le mécanisme de nitration du toluène et pour déterminer les paramètres cinétiques de la formation et de la réaction de l'ion nitronium dans de l'acide sulfurique à 77.3 et 78.45% en poids. On a trouvé que la protonation de l'acide nitrique pour former l'ion nitronium et de l'eau se produit à des vitesses semblables aux deux concentrations d'acide et qu'elle possède une énergie d'activation de 18.3 ± 4.0 kcal mol^{-1}. On a évalué que l'énergie d'activation de la réaction inverse, que la chaleur de la réaction et que l'énergie d'activation de la formation du complexe de rencontre entre l'ion nitronium et le toluène sont respectivement de 10.5 ± 4.0, 7.8 ± 0.5 et 5.9 ± 0.1 kcal mol^{-1} dans H_2SO_4 à 77.3% et 12.0 ± 4.0, 6.3 ± 0.5 et 6.0 ± 0.1 kcal mol^{-1} dans H_2SO_4 à 78.45%.

[Traduit par le journal]

Introduction

Recently (1) the following mechanism for aromatic nitration has been proposed as the simplest which can accommodate all the known facts.

$$[1] \qquad HNO_3 + H^+ \underset{k_{-1}'}{\overset{k_1'}{\rightleftharpoons}} NO_2^+ + H_2O$$

$$[2] \qquad NO_2^+ + ArH \underset{k_{-2}'}{\overset{k_2'}{\rightleftharpoons}} \text{Encounter complex}$$

$$[3] \qquad \text{Encounter complex} \xrightarrow{k_3'} \text{Benzenonium ion} \longrightarrow \text{Product} + H^+$$

A steady state assumption made with respect to the nitronium ion and the encounter complex leads to the following expression for the rate of nitration.

$$[4] \qquad \frac{-d[ArH]}{dt} = \frac{k_1'k_2'k_3'a_{H^+}[HNO_3][ArH]}{k_{-1}'a_{H_2O}(k_3' + k_{-2}') + k_2'k_3'[ArH]} = \frac{k_1k_2[HNO_3][ArH]}{k_1 + k_2[ArH]}$$

where

$$k_1 = k_1' a_{H^+}$$

and

$$k_2 = \frac{k_1'a_{H^+}k_2'}{k_{-1}'a_{H_2O}} \frac{k_3'}{k_3' + k_{-2}'}$$

When $k_2[ArH] \gg k_1$, [4] simplifies to

$$[5] \qquad -d[ArH]/dt = k_1[HNO_3]$$

which accounts for the rate being zero order with respect to the aromatic substrate under certain conditions such as those that often occur in organic solvents (2–5). On the other hand when $k_1 \gg k_2[ArH]$, [4] simplifies to

$$[6] \qquad -d[ArH]/dt = k_2[HNO_3][ArH]$$

which accounts for the rate being first order with respect to the aromatic substrate under other conditions such as those which normally obtain in aqueous sulphuric acid.

However, when k_1 and $k_2[ArH]$ are of comparable magnitude there should be a transition region in which neither [5] nor [6] is valid but where the nitration rate is still given by [4]. Chapman and Strachan

(6) observed a change from first- to zero-order kinetics with respect to the aromatic substrate in the nitration of toluene at concentrations of sulphuric acid between 74.7 and 81.45%. It was with the purpose of testing the proposed mechanism by checking the validity of equation [4] in a transition region such as that which should be found at sulphuric acid concentrations midway between 74.7 and 81.45% that this work was undertaken. In addition it was hoped to determine the temperature dependence of k_1 and k_2, which was not investigated by Chapman and Strachan (6).

Experimental

The materials were all of high purity. The toluene, sulphuric acid, and nitric acid were analytical reagent grade and the hexane spectroscopic grade. The apparatus consisted of a Nortech SF-3A stopped-flow spectrometer connected to an Advance OS 2200 storage oscilloscope. The two reactant solutions were prepared by making up small known amounts of nitric acid and toluene, respectively, to known volumes with aqueous sulphuric acid whose concentration had previously been determined by titration. The nitric acid was assumed to dissolve completely and its concentration calculated accordingly. The concentration of toluene was determined by extracting the toluene from a known weight of solution into 15 cm^3 of hexane and measuring the absorbance of the hexane solution at 262 nm. The two sulphuric acid solutions were driven together under a driving pressure of 103.5 kPa and the reaction monitored at 350 nm. For each run an oscilloscope trace was obtained from which readings were taken of the voltage at different times.

Results and Discussion

Equation [4] can be integrated to yield

$$[7]\quad \frac{[ArH]_0}{[ArH]_0 - [ArH]} \ln \frac{[ArH]_0}{[ArH]} + \frac{k_2[ArH]_0}{k_1} = k_2[HNO_3] \frac{[ArH]_0}{[ArH]_0 - [ArH]} t$$

where $[ArH]_0$ is the initial substrate concentration. In the stopped-flow apparatus the voltage V recorded by the oscilloscope is proportional to the transmitted light intensity. Hence by Beer's Law

$$[8]\quad \frac{[ArH]_0}{[ArH]} = \frac{\log_{10}(V_0/V_\infty)}{\log_{10}(V/V_\infty)}$$

where V_0 and V_∞ are the initial and final voltages respectively.

Substitutions of [8] into [7] leads to

$$[9]\quad \underbrace{\frac{\log_{10}(V_0/V_\infty)}{\log_{10}(V_0/V)} \ln \frac{\log_{10}(V_0/V_\infty)}{\log_{10}(V/V_\infty)}}_{Y} + \frac{k_2[ArH]_0}{k_1} = \underbrace{k_2[HNO_3] \frac{\log_{10}(V_0/V_\infty)}{\log_{10}(V_0/V)} t}_{X}$$

Figures 1 and 2 show plots of

$$Y = \frac{\log_{10}(V_0/V_\infty)}{\log_{10}(V_0/V)} \ln \frac{\log_{10}(V_0/V_\infty)}{\log_{10}(V/V_\infty)}$$

vs.

$$X = \frac{\log_{10}(V_0/V_\infty)}{\log_{10}(V_0/V)} t$$

at two concentrations of sulphuric acid and several temperatures. It can be seen that in all cases good straight lines are obtained. If the limiting case given by [5] applied, the lines would all be vertical, whereas if the other limit and [6] applied the lines would all pass through the origin. The fact that the lines are neither vertical nor pass through the origin is proof of a transition region, and the fact that the plots are linear confirms the validity of [4] in such a region. This in turn is added evidence in favour of aromatic nitration proceeding by the mechanism made up of reactions 1–3. The slopes of the plots shown in Figs. 1 and 2 are equal to $k_2[HNO_3]$ and the intercepts (when $Y = 0$) equal to $[ArH]_0/k_1[HNO_3]$. The slopes and intercepts of the least squares lines through the points and the values of $[HNO_3]$ and $[ArH]_0$ (after mixing) for each run are listed in Table 1, together with the values of k_1 and k_2 derived from them.

Studies of the two phase nitration of toluene (7) lead to an estimate for the value of k_1 at 25°C and 78.45% H_2SO_4 of 0.4 s^{-1}. It can be seen from Table 1 that the value of k_1 directly determined under these conditions is 0.62 s^{-1}. The agreement between the estimated and actual value is thus very satisfactory. Previously Chapman and Strachan (6) reported results which suggest that the value of k_1 under the same conditions should be much higher and between 4.0 and 5.0 s^{-1}. These authors undoubtedly overestimated the value of $[ArH]_0$. They assumed that when small quantities of toluene, insuf-

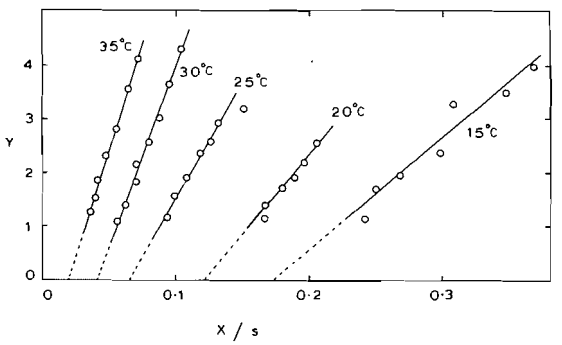

FIG. 2. Nitration of toluene at several temperatures in 78.45% H_2SO_4. Plots of

$$Y = \frac{\log_{10}(V_0/V_\infty)}{\log_{10}(V_0/V)} \ln\frac{\log_{10}(V_0/V_\infty)}{\log_{10}(V/V_\infty)} \text{ vs. } X = \frac{\log_{10}(V_0/V_\infty)}{\log_{10}(V_0/V)}\, t$$

ficient to produce a saturated solution (8), are shaken with aqueous sulphuric acid, all the toluene dissolves, and calculated $[ArH]_0$ on this basis. Later work by Chapman (9) showed this assumption to be invalid and that ~50% or more of the toluene either evaporates or remains undissolved. In the determinations of k_1 the quantity which is measured experimentally is $[ArH]_0/k_1[HNO_3]$. If $[ArH]_0$ is overestimated, so will be the value of k_1. This appears to be the main reason why Chapman and Strachan's k_1 values are out of line with both the estimate from two phase work (7) and the values reported here.

In the present work $[ArH]_0$ was determined spectroscopically after extraction of the toluene from a sample of the acid solution with hexane. While this should lead to values of $[ArH]_0$ which are more reliable, the concentrations of aromatic involved are very low and thus still subject to some uncertainty. In addition because mixing in stopped flow experiments with viscous solutions is not instantaneous (10), there is an uncertainty about the origin of time (the time at which the reaction starts). This affects the intercepts and hence introduces further uncertainties into the k_1 values derived from them. As a result the k_1 values in Table 1 are probably only accurate to within a factor of 2. Table 1 shows that the values of k_1 do not vary significantly between the two acid concentrations. Chapman and Strachan (6) reported an increase of k_1 by a factor of ten as the sulphuric acid concentration was increased from 74.7 to 81.45%. Certainly, since $k_1 = k_1' a_{H^+}$, $\log_{10} k_1$ would be expected to vary approximately as the acidity function, H_0, which does change by a factor of unity between these two concentrations of sulphuric acid (11). However the two acid concentrations employed in this work differ by only 1.15% H_2SO_4, and hence the factor by which the k_1 values would be expected to change is only 1.48. The uncertainties in the k_1 values are larger than this for the reasons discussed above, and this could explain why no significant change of k_1 with acid concentration is apparent. A combined Arrhenius plot of k_1 values at both acid concentrations leads to a value for the activation energy E_1 associated with k_1 of 18.3 ± 4.0 kcal mol^{-1}.

In contrast to the k_1 values, the k_2 values shown in Table 1 are entirely independent of a knowledge of $[ArH]_0$ and largely unaffected by the uncertainty about the origin of time. Hence they should be more accurate, and better agreement with previous work is to be expected. This expectation is realised. The value of k_2/dm^3 mol^{-1} s^{-1} at 25°C of 1520 in 77.3% H_2SO_4 is in good agreement with previously reported values of 1700 in 77.0% (6), 1900 in 77.5% (12) and 1600 in 77.7% H_2SO_4 (12). Likewise the value of 3370 in 78.45% H_2SO_4 accords well with the previous finding of 3400 in 78.15% H_2SO_4 (6). Arrhenius plots of the k_2 values lead to values for the activation energy E_2 associated with k_2 of 13.7 ± 0.5 and 12.3 ± 0.5 kcal mol^{-1} at 77.3 and 78.45% H_2SO_4 respectively. It is highly likely that with toluene at these high acid concentrations $k_3' \gg k_{-2}'$ and formation of the encounter complex (reaction 2) is rate controlling when the nitration rate is first order in toluene (13). If this is so, k_2 =

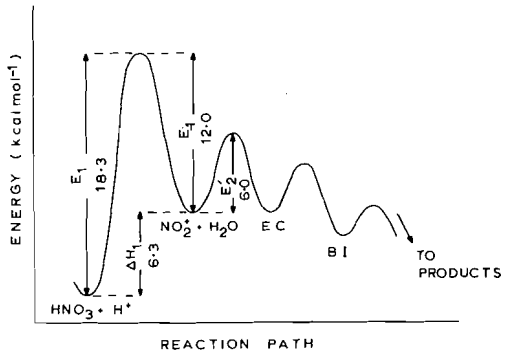

FIG. 3. Activation energy profile for the nitration of toluene in 78.45% H_2SO_4; EC, encounter complex; BI, benzenonium ion.

$(k_1'a_{H^+}/k_{-1}a_{H_2O})k_2'$ and $k_2' = 8RT/3\eta$ where η is the viscosity of the medium. It follows that $E_2 = \Delta H_1 + E_2'$, ΔH_1 being the heat of reaction [1].

From the data on the viscosity of sulphuric acid solutions (14) Arrhenius plots of $\log_{10}(T/\eta)$ vs. $1/T$ can be constructed. They prove to be linear over a limited temperature range and lead to values for E_2' of 5.9 ± 0.1 and 6.0 ± 0.1 kcal mol^{-1} at 77.3 and 78.45% H_2SO_4, respectively. Hence the corresponding ΔH_1 values must be 7.8 ± 0.5 and 6.3 ± 0.5 kcal mol^{-1}. The decrease in ΔH_1 with increasing acid concentration is in line with observations on the E_2 values for aromatics less reactive than toluene (15). With these it is likely that $k_{-2}' \gg k_3'$ and [3] is rate controlling, so that $k_2 = (k_1'a_{H^+}/k_{-1}a_{H_2O})(k_2'/k_{-2}')k_3'$ and $E_2 = \Delta H_1 + \Delta H_2 + E_3'$, ΔH_2 being the heat of reaction 2, the formation of the encounter complex. One expects ΔH_2 to be small and E_3' to be relatively independent of the medium. Hence the decrease of E_2 with increased acid concentration can only be explained if ΔH_1 falls as the $\%H_2SO_4$ rises.

Since $\Delta H_1 = E_1 - E_{-1}$ and E_1 has been found to be 18.3 ± 4.0 kcal mol^{-1}, the value of E_{-1}, the activation energy for the reaction of the nitronium ion with water, must be 10.5 ± 4.0 and 12.0 ± 4.0 kcal mol^{-1} at 77.3 and 78.45% H_2SO_4, respectively. The activation energies and heats of reaction established by this work for the higher acid concentration are summarized in Fig. 3.

PAUL JAMES MCCARTHY and IAN MUNRO WALKER. Can. J. Chem. **56**, 1284 (1978).

The low-temperature optical spectra of dichlorotetrakis(thiourea)iron(II) contain strong bands at 16.24 and 24.66 kK. The former gives an intense green color to freshly prepared crystals of this material. Upon long standing at room temperature or when briefly heated to about 150°C the crystals become colorless and both bands disappear. The bands are assigned to allowed metal-to-ligand electron-transfer processes in an $FeCl_2(thiourea)_2(disulfide)$ impurity, which is postulated to be present in minute amounts. Most freshly prepared crystals also show ligand field bands ca. 8 kK which are identical at room temperature and 10 K. Disorder in the crystals is presumed to set up an unsymmetrical ligand field which provides the intensity-gaining mechanism for these forbidden transitions. Well-aged crystals, or fresh crystals that have been heated for 15 min at 150°C, are more ordered and show typical vibronic spectra with the bands decreasing greatly in intensity as the temperature is lowered. The ground state of the complex is shown to be $^5B_{2g}$.

PAUL JAMES MCCARTHY et IAN MUNRO WALKER. Can. J. Chem. **56**, 1284 (1978).

Le spectre optique à basse température du dichlorotétrakis(thiourée)fer(II) contient des bandes fortes à 16.24 et 24.66 kK. La première bande fournit une couleur verte intense aux cristaux de ce composé fraîchement préparés. Après être restés longtemps à la température ambiante ou après avoir été chauffés brièvement à environ 150°C, les cristaux deviennent incolores et les deux bandes disparaissent. On attribue les bandes à des processus permis de transfert d'électrons de métal vers ligand dans une impureté de $FeCl_2(thiourée)_2(disulfure)$, que l'on suppose être présente en très faible quantité. La plupart des cristaux fraîchement préparés présentent aussi des bandes de champ de ligand à environ 8 kK qui sont identiques à la température ambiante et à 10 K. On fait l'hypothèse que les désordres dans les cristaux provoquent la présence d'un champ de ligand asymétrique qui fournit le mécanisme permettant une augmentation d'intensité pour ces transitions non permises. Les cristaux qui ont vieillis, ou des cristaux fraîchement préparés qui ont été chauffés pendant 15 min à 150°C, sont plus ordonnés et présentent des spectres vibroniques typiques alors que l'intensité des bandes diminue grandement à mesure que la température est abaissée. On démontre que l'état fondamental du complexe est $^5B_{2g}$.

[Traduit par le journal]

Introduction

The well-known compound, dichlorotetrakis-(thiourea)iron(II), $Fetu_4Cl_2$, has been the subject of spectrophotometric studies by Bailey and Peterson (1) and Gerloch, Lewis, and Smail (2). The former employed reflectance spectroscopy and the latter made use of low-temperature polarized crystal spectroscopy. We have recently observed several unusual optical properties of fresh crystals of this substance which we felt warranted more extensive investigation. In particular, the crystals, when freshly grown, are emerald-green in color, the color is unevenly distributed in many crystals and fades slowly at room temperature and very rapidly at elevated temperatures, and the spectra of the colorless crystals change upon long standing. In this report we attempt to offer a reasonable explanation for these observations, which are quite unique for a transition metal complex.

Experimental

Preparation of the Compound

Varying amounts of reagents and conditions of preparation were employed. A typical preparation is as follows: about 4.5 g of $FeCl_2 \cdot 4H_2O$ were dissolved in approximately 10 cm^3 of 35% $HClO_4$, and then a small amount of powdered iron was added to reduce any Fe(III) present. When this was accomplished, about 5 g of thiourea were dissolved in the solution, which was then filtered and left standing in a crystal dish until crystals were formed. If the amount of liquid is kept as small as possible, crystals may form overnight; otherwise the process may be very slow. The compound may be similarly prepared in methanol or ethanol with substitution of a few drops of HCl for $HClO_4$, but the crystals which result are generally quite small.

Spectral Measurements

Polarized absorption spectra of single crystals were measured at room temperature (about 295 K) and 10 K using a Cary-14 spectrophotometer and an Air Products Displex cryogenic refrigerator. The light was polarized by means of a pair of Glan-Thompson prisms, and spectra were recorded with the electric vector of the light parallel to the various extinction axes of the crystal.

Crystals of the compound were examined at 80 K on a Varian E-4 spectrometer operating at 9.1 GHz.

Analyses

Iron was determined as the dipyridyl complex by spectrophotometry.

Results

Crystal Structure and Habit

$Fetu_4Cl_2$ is isomorphous with $Cotu_4Cl_2$ (3). X-ray structural determination of the latter compound has shown that it contains the *trans*-CoS_4Cl_2 chromophore with approximate D_{4h} symmetry (4), and belongs to the tetragonal space group, $P4_2/n$, with four molecules per unit cell.

The lustrous, bright-green crystals of $Fetu_4Cl_2$ appear in two principal habits. The most common (type 1) has an irregular hexagonal face uppermost, and under polarized light these crystals are green in any orientation. The other less numerous crystals (type 2) have a rectangular face uppermost and appear green when light is polarized parallel to the long edge of the rectangle and colorless in the perpendicular direction. Both types of crystals analyze according to the stoichiometry $Fetu_4Cl_2$. *Anal.* calcd. for $Fetu_4Cl_2$: Fe 12.95; found: 12.90 (type 1) and 12.96 (type 2).

The unique orientation is that in which the crystal is colorless under polarized light (i.e., with light polarized perpendicular to the long axis of the rectangular face); this we arbitrarily denote as polarization #1. It can with reasonable certainty be assigned to that in which the electric vector is parallel to C_4(Cl—Fe—Cl axis) (π). The other polarization (#2) on this face is of course perpendicular to $C_4(\sigma)$. The two polarizations recorded on the hexagonal face of the type 1 crystals are, respectively, perpendicular to C_4 (denoted #3), and, perpendicular to that, polarization #4, which is an approximate 50:50 mixture of (#1) and (#2), since the hexagonal face lies at about 43° to the rectangular face. In general, the features in polarization (#3) are all more intense than in polarization (#4).

The Green Color

Examination under a polarizing microscope reveals a most striking property of the freshly prepared crystals, namely, that in most crystals the green color is not evenly distributed throughout, but tends to be found associated with cracks or flaws in the crystal. Crystals of type 2 with light polarized parallel to the long edge of the rectangular face, while appearing generally green, frequently show a colorless band with irregular edges running down the center of the face.

The green color of these crystals is lost on prolonged standing (a few weeks or months) at room temperature, and very rapidly (~5 min) at 150°C. The process is slowed up considerably by storing the crystals below 0°C.

When air is rigorously excluded during the preparation, and all Fe(III) is removed by addition of iron powder, the green color is absent from the product. Similarly, if freshly prepared green crystals are dissolved in oxygen-free methanol or ethanol, and are allowed to redeposit under a nitrogen atmosphere, the green color is greatly reduced or totally absent. On the other hand, active passage of air through the solution during deposition of the crystals results in a product whose green color is markedly enhanced.

It thus appears that the green color of freshly prepared crystals of $Fetu_4Cl_2$ is not due to any *d–d* transition on Fe(II) but to a transient substance which becomes trapped in the lattice during the deposition. It further appears that oxygen or some other oxidizing agent is required for its occurrence. In order to characterize this phenomenon further, we now turn to the crystal spectra.

Crystal Spectra

The visible–near-uv region in freshly prepared crystals contains an intense band at 16.24 kK (1 kK = 1000 cm^{-1}), which is primarily responsible for the green color, and also an intense band at 24.66 kK. Both of these bands are σ polarized (electric vector perpendicular to C_4) and are completely absent from the π polarization (#1). Solution spectra of freshly prepared green crystals were examined in anhydrous deaerated methanol, acetone, dimethylsulfoxide, and dimethylformamide. None of the solutions was green at any time, nor was there any trace of the above bands in any of the solutions.

The visible spectra of a freshly prepared crystal of $Fetu_4Cl_2$ are shown in Fig. 1. The spectra are of polarization (#3) at room temperature and 10 K, both before and after heating the crystal for about 5 min at 150°C. The spectra of the orthogonal polarization (#4) are quite similar but less intense than those recorded in Fig. 1.

Two features of the spectra are noteworthy: first, the two intense bands disappear completely on heating the crystals for 5 min at 150°C. Similar results are obtained for crystals which stand for

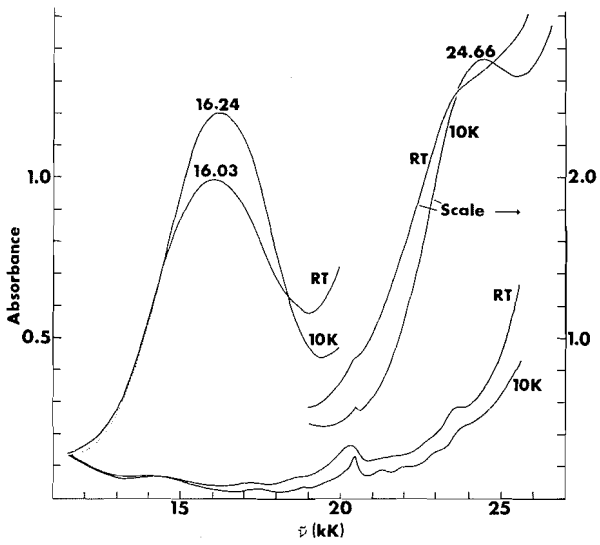

FIG. 1. Crystal spectra of $Fetu_4Cl_2$ (polarization 3) at room temperature (RT) and 10 K before (upper traces) and after (lower traces) heating for 5 min at 150°C. Crystal thickness was 1.75 mm. The weak bands in the lower traces are quintet–triplet transitions.

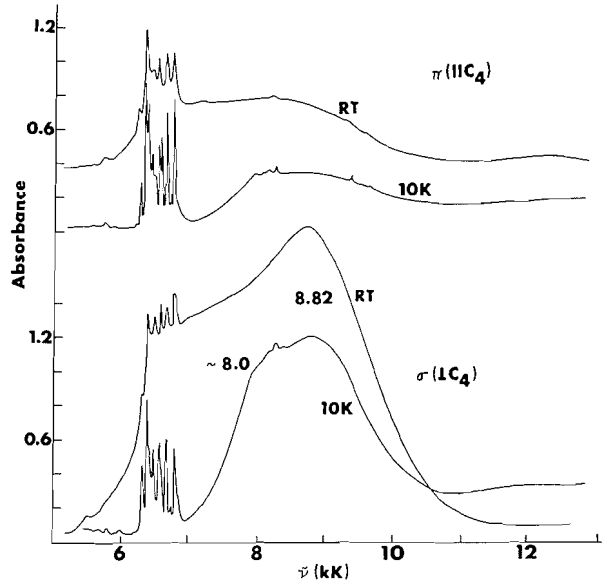

FIG. 2. Polarized crystal spectra of $Fetu_4Cl_2$ at room temperature (RT) and 10 K. The crystal had been heated 15 min at 150°C before the spectra were recorded. Crystal thickness was 1.0 mm.

several months at room temperature. The energies of these bands at 10 K are in a ratio of 2 to 3 (16.24 and 24.66 kK). It is not clear whether it is significant that the energies are almost exact multiples of 8 kK, the approximate value of the low-energy component of the spin-allowed band. Secondly, when the 16 kK bands (room temperature and 10 K) are set at the same absorption value at 11.4 kK (the minima in the curves) as was done in Fig. 1, the band contours on the low-energy side are identical. This indicates that the vibronic mechanism is not responsible for the absorption band. This is confirmed by the fact that the area under the band does not decrease as the temperature is lowered. A small increase in area (~8%) was actually observed, but this may be due to uncertainty in estimating the base line.

Most of the spin-forbidden (quintet–triplet) bands in the visible region are not apparent in the green crystal even at 10 K, but become well-resolved after the green substance has been removed either by heating or long standing. In general, they are 1–2% as intense as the spin-allowed crystal-field transition. The latter occurs in the near-ir region at ca. 8 kK (see Fig. 2). On the low energy side of the band is a set of sharp lines associated with thiourea vibrational overtones. These absorptions are also found in the corresponding cobalt complex, as expected.

The spectra in this region are very sensitive to the manner in which the crystal has been treated. Unlike the 16 kK band, the spin-allowed band in well-aged (9 months) or heat-treated (15 min at 150°C) crystals is vibronic in origin, as expected for a *d–d* transition in a complex of D_{4h} symmetry. Use of the intensity law (5)

$$[1] \qquad I_T = I_{(T=0)} \coth \frac{h\nu}{2kT}$$

with band intensities, I_T, at room temperature and 10 K allows us to establish the frequency (ν) of the allowing vibration as ~150 cm^{-1}.

On the other hand, most crystals which are either freshly prepared or not sufficiently aged (4 months) have spectra which are virtually *identical* at room temperature and 10 K. Thus the spin-allowed band is apparently not of vibronic origin under these circumstances. For these crystals, the intensity-gaining mechanism may best be ascribed to the unsymmetrical field set up by the disorder inherent in the crystal (see below).

It is noteworthy that the two features discussed here, namely, the intense bands at 16 and 24 kK and the vibronic or non-vibronic nature of the 8 kK bands, are independent phenomena. Most crystals that we studied showed non-vibronic bands at 8 kK when the 16 and 24 kK bands were present. Vibronic bands were normally found only after the disappearance of the 16 and 24 kK bands. But one crystal showed both the latter two bands and also vibronic bands at 8 kK.

The treatment of the crystals has little or no effect on the degree of resolution of the quintet–triplet bands in the visible region, once the green band has been removed.

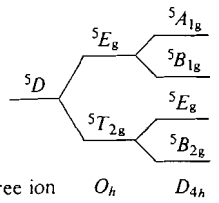
Discussion

The spin-allowed bands of the spectrum can be assigned by means of the following energy diagram:



The ordering of the B_{2g} and E_g levels in D_{4h} is not immediately evident. If E_g is the ground state, then on the basis of orbital symmetry alone, the transitions $E_g \rightarrow B_{1g}$ or A_{1g} are allowed in σ, and no transitions are allowed in π. If B_{2g} is the ground state, $B_{2g} \rightarrow B_{1g}$ is allowed in π, and no transitions are allowed in σ. Since the former situation more nearly represents the observed spectra, Gerloch *et al.* (2) assumed an E_g ground state. Since, however, the bands decrease significantly in size on cooling, the vibronic selection rules must be considered before the ground state can be determined unambiguously.

The u vibrations of the *trans*-FeS_4Cl_2 group are $2a_{2u} + b_{2u} + 3e_u$. From an E_g ground state the two excited states (A_{1g} and B_{1g}) become accessible by coupling with e_u vibrations (π spectrum) and a_{2u} or b_{2u} vibrations (σ spectrum). The e_u vibrations of FeS_4Cl_2 are ν(Fe—S), δ(Cl—Fe—Cl), and $\delta(FeS_4)$ (in-plane). None of these has any component along C_4 and so cannot activate a π electronic transition. Likewise, the a_{2u} vibrations are ν(Fe—Cl) and $\delta(FeS_4)$ (out-of-plane), and the b_{2u} vibration is also $\delta(FeS_4)$ (out-of-plane). None of these has any component perpendicular to C_4 and so cannot activate a σ electronic transition.

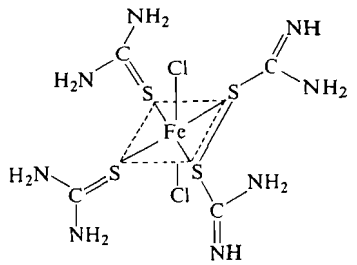
From a B_{2g} ground state both excited states become accessible in σ by coupling with e_u vibrations, while in π the non-existent a_{1u} and b_{1u} vibrations would be required to render the transition allowed. This approximates what one sees in the spectra, namely, a strong σ and weak π spectrum. The appearance of some intensity in the π spectrum indicates (*a*) that some weak coupling occurs with the vibrations of the *whole* thiourea ligand and that consideration of the skeleton FeS_4Cl_2 is not sufficient, and/or (*b*) that the slight distortions from D_{4h} symmetry which actually occur in the CoS_4Cl_2 chromophore (4) also occur here and lower the symmetry enough to make the D_{4h} selection rules only approximately valid.

The designation of B_{2g} as the ground state agrees with the observation of Birchall and Morris (6) that the magnitude of the quadrupole splitting in the Mössbauer spectrum of $Fetu_4Cl_2$ requires the complex to have the d_{xy} orbital lowest in energy. This would make B_{2g} the ground state. This splitting of the octahedral T_{2g} level implies that the z ligand is stronger than the xy, i.e., $Dq(Cl) > Dq(tu)$. The observations made in this work do not, however, determine the ordering of the A_{1g} and B_{1g} excited states.

The accumulated data, especially the variation in spectral band shapes, point strongly to the occurrence of lattice disorder in most of the freshly prepared crystals, which generally formed rapidly overnight. Heat treatment or long standing appears to repair much of the disorder. The behaviour of the spin-allowed band with temperature can be nicely explained by the hypothesis that a centre of symmetry is absent in the freshly prepared (disordered) case, but on heat treatment or long standing, annealing takes place, resulting in an ordered metal environment with D_{4h} symmetry and vibronic allowedness. It is likely that the crystal which showed the normal vibronic spectrum in the infrared together with the intense green color was a crystal which grew slowly from solution. The slow growth favored ordered arrangement in the crystal.

As for the substance responsible for the 16 and 24 kK bands, the data indicate that we are dealing with a solid-state effect, since these bands are not found in the solution spectra. It is also clear from the rapid disappearance of the bands with heating that they cannot be assigned to quintet–triplet transitions, as was done for the 16 kK band by Gerloch *et al.* (2) and Bailey and Peterson (1).

We offer the following hypothesis which we feel best fits the experimental data: two electron oxidation of adjacent coordinated thioureas by dissolved oxygen near a growing crystal could result in a complex of the composition:



The disulfide ligand is a known oxidation product of thiourea, and would be a singlet, in agreement with the epr results. (Freshly-prepared green crystals showed no epr signal at 80 K.) Since the above complex bears a strong steric resemblance to *trans*-$Fetu_4Cl_2$, it might be expected to be readily incorporated into growing crystals. Heating or long

standing would cause the disulfide, a very weakly bonding ligand, to separate from the complex, thus destroying the color-producing species.

If, as our evidence suggests, the color-producing material is present only in trace amounts, the electronic transitions must be intrinsically intense and so may be allowed transitions. They are too low in energy to be $n \rightarrow \pi^*$ or $\pi \rightarrow \pi^*$ transitions on the ligand. So they are most probably either $L \rightarrow M$ or $M \rightarrow L$ electron transfers. The former can readily be ruled out; if $Fetu_4Cl_2$ itself shows no low-lying $L \rightarrow M$ electron transfer, the complex containing a disulfide ligand (an oxidized species) would be even less likely to show one. $M \rightarrow L$ electron transfer involves a spectroscopic oxidation of the metal, and, in fact, Fe(II) can be rather easily oxidized. This does not occur, however, when the only ligands are Cl^- and thiourea. The Fe(III)–thiourea complex is quite unstable, being quickly reduced to the Fe(II)–thiourea complex with the production of sulfur-containing oxidation products.

The fact that we here postulate an already oxidized disulfide bonded to the Fe(II) means that the Fe(II) $\rightarrow$ disulfide transfer might occur with some ease and therefore be spectroscopically induced by photons of relatively long wavelength. The two bands at 16 and 24 kK may represent such $M \rightarrow L$ electron transfers. Since these are allowed transitions, only a small amount of this complex would have to be present to obtain the intensity observed. With the data presently available, however, it is not possible to specify further the nature of these two bands, nor to show why they are both σ-polarized.

A consistent derivation of the complete set of *s* vectors needed for vibrational analysis by the Wilson **GF** matrix method is presented. The vectors obtained for the out-of-plane wag are given by new formulae which are considerably simpler than those presently in use. The formulae for the linear bending coordinate are also derived.

Introduction

Vibrational spectroscopists have long been familiar with the Wilson **GF** matrix method (1). Wilson set up the initial analysis in terms of two internal coordinates, the bond stretch and the valence angle bend. Two additional important internal coordinates, the out-of-plane wag and the torsion, were subsequently defined by Decius, who also showed that the set of four internal modes constitutes a complete set of basis vectors with which a vibrational analysis can be performed (2, 3). This material was later collected in the well known text "Molecular Vibrations" (4). In this book, Decius first explicitly stated the *s* vector expressions for the wag, although he had previously used them implicitly (3).

Several methods for the derivation of the *s* vectors for the four internal coordinates were given in "Molecular Vibrations" and since this publication several other authors have developed new ways of deriving some of the *s* vectors. Perhaps the most notable of these is Steele's vector construction method (5), which was outlined for the valence angle bend and two of the four torsion *s* vectors. However, no consistent method of derivation of all the *s* vectors has been published up to the present time; indeed, the application of any one method usually presents difficulty when all of the *s* vectors are considered.

An even more serious difficulty arises when one attempts to use the valence angle bend formulae for the case of the linear bend. In this case the Wilson–Decius formulae "blow-up" and cannot be used. This problem was recognized quite some time ago and was corrected by Schachtschneider in his well known computer programs for vibrational analysis (6). These formulae have not been published in the literature, but most spectroscopists are aware of this situation and consequently use Schachtschneider's programs or correct for the difficulty themselves.

We have recently derived all of the *s* vectors by means of a consistent and relatively simple method. This procedure results in a new set of formulae for the wag which has the advantage that the formulae are considerably simpler to visualize and to use than are any previous set of formulae.

These new formulae have been incorporated into a new set of programs available from the Quantum Chemistry Program Exchange (7). Altogether there are 3 programs the first of which computes the Wilson **B** matrix. The BMAT program is a modification of the original GMAT program of Schachtschneider and allows for the calculation of five different types of internal coordinates, namely, (*1*) bond stretch, (*2*) valence angle bend, (*3*) out-of-plane wag, (*4*) torsion, and (*5*) linear bend. Two important differences between Schachtschneider's original GMAT program and BMAT are the different set of wag formulae and the inclusion of Hilderbrandt's method of normalization of the torsional coordinate (8). The three programs have the additional feature that a vibrational analysis can be carried out without recourse to the use of symmetry coordinates although, if desired, such a method may be used.

The purpose of this paper then is to introduce a consistent method of derivation of all the *s* vectors, to collect all the *s* vector formulae together in one

source, to note important refinements published recently, and to publish the new formulae of the out-of-plane wag.

The *s* Vectors

Wilson and Decius set out to define a set of internal coordinates that could be expressed exclusively in terms of parameters readily determined from the molecular geometry such as bond lengths, angles, and the like. This can be done for all of the internal coordinates except one. The linear bend cannot be handled in this manner. It is necessary to define a new vector external to the molecule.

All of the s vectors will be expressed in terms of the e vectors (except for the linear bend). The set of e vectors are conveniently expressed in terms of the following formulae:

$$e_{ij} = [(x_j - x_i)\boldsymbol{i} + (y_j - y_i)\boldsymbol{j} + (z_j - z_i)\boldsymbol{k}]/r_{ij}$$

where (x_i, y_i, z_i) and (x_j, y_j, z_j) are the Cartesian coordinates of atoms i and j, respectively, r_{ij} is the distance between the atoms, and $\boldsymbol{i}, \boldsymbol{j}$, and $\boldsymbol{k}$ are unit vectors directed along the positive x, y, and z Cartesian axes, respectively.

Each of the internal coordinates will be considered in turn.

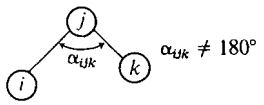
(1) Bond Stretch (Δr_{ij})

This internal coordinate is the simplest to visualize and the s vectors can be written down from inspection.

The s vectors for atoms i and j are

$$s_i = -e_{ij} \qquad s_j = e_{ij}$$

(2) Valence Angle Bend ($\Delta\alpha_{ijk}$)



We shall use Steele's vector construction method to obtain the expression for s_i and then derive s_k in terms of s_i. Finally we shall derive s_j in terms of s_i and s_k.

s_i will be perpendicular to the side j,i. Furthermore, the length of s_i is $1/r_{ji}$ since a unit (infinitesimal) displacement of i along s_i will increase α_{ijk} by an amount $1/r_{ji}$.

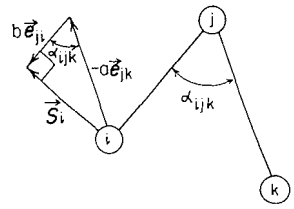


FIG. 1. The vector construction necessary for the definition of s_i in the valence angle bend.

Figure 1 illustrates the vector construction needed to define s_i in terms of e_{jk} and e_{ji}. s_i is a unit vector perpendicular to j,i. Vectors are then constructed parallel to e_{ji} and e_{jk} as illustrated in the figure.

It is clear that the following relationships hold:

$$\sin\alpha_{ijk} = 1/a \quad \text{and} \quad \cos\alpha_{ijk} = b/a$$

Therefore

$$a = 1/\sin\alpha_{ijk}$$

$$b = a\cos\alpha_{ijk} = \cos\alpha_{ijk}/\sin\alpha_{ijk}$$

Therefore

$$s_i = \frac{1}{r_{ji}}[-ae_{jk} + be_{ji}] = \frac{\cos\alpha_{ijk}\, e_{ji} - e_{jk}}{r_{ji}\sin\alpha_{ijk}}$$

We could naturally carry out a similar vector construction to obtain the expression for s_k. For the purpose of unity, however, we will illustrate the method which will be used in the cases of the out-of-plane wag and the torsion.

We will make use of two expressions throughout which express the invariance to rigid translations and rotations (9):

$$\sum_i s_i = \mathbf{0} \quad \text{and} \quad \sum_i R_i \times s_i = \mathbf{0}$$

where R_i is the vector from an arbitrary origin to the equilibrium position of atom i.

In the case of the bend the rotational invariance relation yields:

$$R_i \times s_i + R_j \times s_j + R_k \times s_k = \mathbf{0}$$

Placing the origin at j we have:

$$R_i = r_{ji}e_{ji} \quad R_j = \mathbf{0} \quad R_k = r_{jk}e_{jk}$$

Therefore

$$r_{ji}e_{ji} \times s_i = -r_{jk}e_{jk} \times s_k$$

Multiplying through by e_{jk} we obtain

$$r_{ji}e_{jk} \times (e_{ji} \times s_i) = -r_{jk}e_{jk} \times (e_{jk} \times s_k)$$

We may expand this relationship with the aid of the following vector identity

[1] $$v_1 \times (v_2 \times v_3) = (v_1 \cdot v_3)v_2 - (v_1 \cdot v_2)v_3$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Thus we have

$$r_{ji}[(\boldsymbol{e}_{jk}\cdot\boldsymbol{s}_i)\boldsymbol{e}_{ji} - (\boldsymbol{e}_{jk}\cdot\boldsymbol{e}_{ji})\boldsymbol{s}_i] = -r_{jk}[(\boldsymbol{e}_{jk}\cdot\boldsymbol{s}_k)\boldsymbol{e}_{jk} - (\boldsymbol{e}_{jk}\cdot\boldsymbol{e}_{jk})\boldsymbol{s}_k]$$

Evaluating some of the scalar products

$$r_{ji}[(\boldsymbol{e}_{jk}\cdot\boldsymbol{s}_i)\boldsymbol{e}_{ji} - \cos\alpha_{ijk}\,\boldsymbol{s}_i] = -r_{jk}[0\boldsymbol{e}_{jk} - 1\boldsymbol{s}_k]$$

The remaining scalar product can be evaluated by substituting for $\boldsymbol{s}_i$

$$r_{ji}\left[\boldsymbol{e}_{jk}\cdot\left(\frac{\cos\alpha_{ijk}\,\boldsymbol{e}_{ji} - \boldsymbol{e}_{jk}}{r_{ji}\sin\alpha_{ijk}}\right)\right]\boldsymbol{e}_{ji} - r_{ji}\cos\alpha_{ijk}\left[\frac{\cos\alpha_{ijk}\,\boldsymbol{e}_{ji} - \boldsymbol{e}_{jk}}{r_{ji}\sin\alpha_{ijk}}\right] = r_{jk}\boldsymbol{s}_k$$

Expanding the above expression and evaluating the scalar products leads to the following equation

$$\frac{\cos^2\alpha_{ijk}\,\boldsymbol{e}_{ji} - \boldsymbol{e}_{ji} - \cos^2\alpha_{ijk}\,\boldsymbol{e}_{ji} + \cos\alpha_{ijk}\,\boldsymbol{e}_{jk}}{\sin\alpha_{ijk}} = r_{jk}\boldsymbol{s}_k$$

Therefore

$$\boldsymbol{s}_k = \frac{\cos\alpha_{ijk}\,\boldsymbol{e}_{jk} - \boldsymbol{e}_{ji}}{r_{jk}\sin\alpha_{ijk}}$$

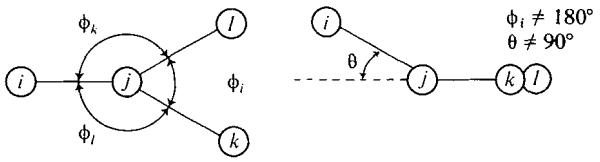
We finally employ the translational invariance rule

$$\boldsymbol{s}_j = -(\boldsymbol{s}_i + \boldsymbol{s}_k)$$

For convenience we summarize the $\boldsymbol{s}$ vectors for the valence angle bend

$$\boldsymbol{s}_i = (\cos\alpha_{ijk}\,\boldsymbol{e}_{ji} - \boldsymbol{e}_{jk})/r_{ji}\sin\alpha_{ijk} \qquad \boldsymbol{s}_k = (\cos\alpha_{ijk}\,\boldsymbol{e}_{jk} - \boldsymbol{e}_{ji})/r_{jk}\sin\alpha_{ijk} \qquad \boldsymbol{s}_j = -(\boldsymbol{s}_i + \boldsymbol{s}_k)$$

(3) Out-of-plane Wag (Δθ)



The formulae derived in this section represent new expressions. The numerical results are identical to the results given by the old formulae in "Molecular Vibrations" (p. 60). Our formulae are, however, much easier to visualize and, in fact, require fewer computations.

We will require four $\boldsymbol{s}$ vectors in this case. The direction of $\boldsymbol{s}_i$ is perpendicular to the bond j,i and in a plane perpendicular to the plane k,j,l while the directions of $\boldsymbol{s}_k$ and $\boldsymbol{s}_l$ are each perpendicular to the plane k,j,l.

We might then expect formulae for $\boldsymbol{s}_k$ and $\boldsymbol{s}_l$ to be factors of the unit vector $(\boldsymbol{e}_{jk} \times \boldsymbol{e}_{jl})/\sin\phi_i$. Furthermore, in the case of a planar conformation of the wag (i.e. $\theta = 0$), we would expect $\boldsymbol{s}_i$ also to be merely a factor of this vector. This will turn out to be the case.

We will follow the same lines in our derivation as we did with the bend. $\boldsymbol{s}_k$ and $\boldsymbol{s}_l$ will be expressed in terms of $\boldsymbol{s}_i$. Finally $\boldsymbol{s}_j$ will be expressed in terms of $\boldsymbol{s}_i$, $\boldsymbol{s}_k$, and $\boldsymbol{s}_l$.

Figure 2 illustrates the vector construction needed to define $\boldsymbol{s}_i$. Vectors are constructed parallel to $(\boldsymbol{e}_{jk} \times \boldsymbol{e}_{jl})/\sin\phi_i$ and $\boldsymbol{e}_{ji}$. Referring to the figure it should be clear that the following relationships hold:

$$\cos\theta = 1/a \quad \text{and} \quad \sin\theta = b/a$$

Thus

$$a = 1/\cos\theta \quad \text{and} \quad b = a\sin\theta = \sin\theta/\cos\theta = \tan\theta$$

As in the case of the valence angle bend $\boldsymbol{s}_i$ must be normalized by a factor $1/r_{ji}$. Therefore

$$\boldsymbol{s}_i = \frac{1}{r_{ji}}\left[a\frac{(\boldsymbol{e}_{jk} \times \boldsymbol{e}_{jl})}{\sin\phi_i} - b\boldsymbol{e}_{ji}\right] = \frac{1}{r_{ji}}\left[\frac{(\boldsymbol{e}_{jk} \times \boldsymbol{e}_{jl})}{\cos\theta\sin\phi_i} - \tan\theta\,\boldsymbol{e}_{ji}\right]$$

Again we will use the rotational invariance relation

$$\boldsymbol{R}_i \times \boldsymbol{s}_i + \boldsymbol{R}_j \times \boldsymbol{s}_j + \boldsymbol{R}_k \times \boldsymbol{s}_k + \boldsymbol{R}_l \times \boldsymbol{s}_l = \boldsymbol{0}$$

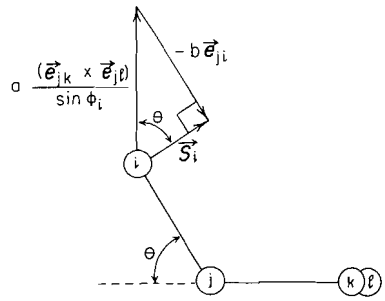


FIG. 2. The vector construction necessary for the definition of s_l in the out-of-plane wag.

Putting the origin at atom j we have

$$R_i = r_{ji}e_{ji} \quad R_j = 0 \quad R_k = r_{jk}e_{jk} \quad R_l = r_{jl}e_{jl}$$

Thus

[2] $$r_{ji}e_{ji} \times s_i = -r_{jk}e_{jk} \times s_k - r_{jl}e_{jl} \times s_l$$

Multiplying [2] by e_{jk} we obtain

$$r_{ji}e_{jk} \times (e_{ji} \times s_i) = -r_{jk}e_{jk} \times (e_{jk} \times s_k) - r_{jl}e_{jk} \times (e_{jl} \times s_l)$$

Utilizing the vector identity of [1] we may expand the above expression

$$r_{ji}[(e_{jk}\cdot s_i)e_{ji} - (e_{jk}\cdot e_{ji})s_i] = -r_{jk}[(e_{jk}\cdot s_k)e_{jk} - (e_{jk}\cdot e_{jk})s_k] - r_{jl}[(e_{jk}\cdot s_l)e_{jl} - (e_{jk}\cdot e_{jl})s_l]$$

Evaluation of some of the scalar products leads to

[3] $$r_{ji}(e_{jk}\cdot s_i)e_{ji} - r_{ji}\cos\phi_l\, s_i = r_{jk}s_k + r_{jl}\cos\phi_i\, s_l$$

Multiplying [2] by e_{jl} and simplifying we obtain an expression analogous to [3]

[4] $$r_{ji}(e_{jl}\cdot s_i)e_{ji} - r_{ji}\cos\phi_k\, s_i = r_{jk}\cos\phi_i\, s_k + r_{jl}s_l$$

We can, at this point, choose to eliminate either s_k or s_l since we have two simultaneous equations in two unknowns. Thus, choosing the elimination of s_l, simplifying and collecting terms we obtain

$$(r_{jk} - r_{jk}\cos^2\phi_i)s_k = (r_{ji}\cos\phi_i\cos\phi_k - r_{ji}\cos\phi_l)s_i + [r_{ji}(e_{jk}\cdot s_i) - r_{ji}\cos\phi_i\,(e_{jl}\cdot s_i)]e_{ji}$$

The left-hand side of this equation simplifies quite easily

$$(r_{jk} - r_{jk}\cos^2\phi_i)s_k = r_{jk}(1 - \cos^2\phi_i)s_k = r_{jk}\sin^2\phi_i\, s_k$$

The evaluation of the scalar products of the right-hand side of the equation can be carried out by substituting in the expression for s_i. Several cancellations will occur. After some algebra one obtains the following expression

$$\frac{\cos\phi_i\cos\phi_k - \cos\phi_l}{\cos\theta\sin\phi_i}(e_{jk} \times e_{jl})$$

Thus the final expression for s_k is

$$s_k = \frac{1}{r_{jk}}\left[\frac{(e_{jk} \times e_{jl})}{\sin\phi_i}\cdot\frac{\cos\phi_i\cos\phi_k - \cos\phi_l}{\cos\theta\sin^2\phi_i}\right]$$

The expression for s_l can be obtained now in a variety of ways. One could eliminate s_k from the expressions [3] and [4] or the values of s_i and s_k could be substituted into either [3] or [4] and rearranged to yield the expression for s_l. Finally s_j is expressed in terms of s_i, s_k, and s_l using the translational invariance relation.

For convenience all the s vectors are summarized below:

$$s_i = \frac{1}{r_{ji}}\left[\frac{(e_{jk} \times e_{jl})}{\cos\theta\sin\phi_i} - \tan\theta\, e_{ji}\right] \qquad s_l = \frac{1}{r_{jl}}\left[\frac{(e_{jk} \times e_{jl})}{\sin\phi_i}\cdot\frac{\cos\phi_i\cos\phi_l - \cos\phi_k}{\cos\theta\sin^2\phi_i}\right]$$

$$s_k = \frac{1}{r_{jk}}\left[\frac{(e_{jk} \times e_{jl})}{\sin\phi_i}\cdot\frac{\cos\phi_i\cos\phi_k - \cos\phi_l}{\cos\theta\sin^2\phi_i}\right] \qquad s_j = -(s_i + s_k + s_l)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

This set of formulae is considerably simpler to evaluate with only one vector cross product and three scalar products. The formulae in "Molecular Vibrations" require only one scalar product evaluation but three vector cross product evaluations.

The case of the planar wag ($\theta = 0$) deserves special comment. The formulae given above simplify considerably.

When $\theta = 0$, $\phi_i + \phi_k + \phi_l = 360°$.

Thus

$$\cos \phi_k = \cos [360° - (\phi_i + \phi_l)] = \cos (\phi_i + \phi_l) = \cos \phi_i \cos \phi_l - \sin \phi_i \sin \phi_l$$

Rearranging we have

$$\sin \phi_l = \frac{\cos \phi_i \cos \phi_l - \cos \phi_k}{\sin \phi_i}$$

Similarly

$$\sin \phi_k = \frac{\cos \phi_i \cos \phi_k - \cos \phi_l}{\sin \phi_i}$$

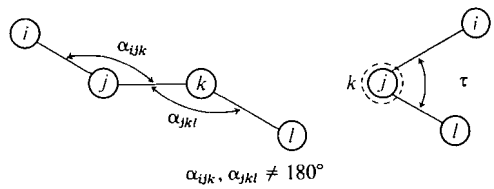
Thus, the expressions simplify to

$$s_i = \frac{1}{r_{ji}}\left[\frac{(e_{jk} \times e_{jl})}{\sin \phi_i}\right] \qquad s_l = \frac{1}{r_{jl}}\left[\frac{(e_{jk} \times e_{jl})}{\sin \phi_i} \cdot \frac{\sin \phi_l}{\sin \phi_i}\right]$$

$$s_k = \frac{1}{r_{jk}}\left[\frac{(e_{jk} \times e_{jl})}{\sin \phi_i} \cdot \frac{\sin \phi_k}{\sin \phi_i}\right] \qquad s_j = -(s_i + s_k + s_l)$$

While the wag formulae have been derived for a general case (i.e. unrestricted θ) the use of the wag as a basis vector should be restricted only to the planar case (i.e. $\theta = 0$) since the non-planar wag corresponds to the symmetric combination of the valence angle bends $\Delta\phi_i$, $\Delta\phi_k$, and $\Delta\phi_l$. It is only in the case of a planar configuration of the atoms that the wag is needed, since out-of-plane deformations cannot be handled by combinations of the valence angle bends $\Delta\phi_i$, $\Delta\phi_k$, and $\Delta\phi_l$. Clearly this is not the case when $\theta \neq 0$ and inclusion of the wag in the basis set along with $\Delta\phi_i$, $\Delta\phi_k$, and $\Delta\phi_l$ in the non-planar configuration would cause serious problems in the determination of a proper force field.

(4) Torsion[2] *($\Delta\tau$)*



We will initially consider only a 4 atom torsion and will derive the s vectors for that case. The addition of further atoms on either j or k will require the use of the normalization scheme of Hilderbrandt (8).

We will derive the expressions for s_j and s_k after obtaining the expressions for s_i and s_l.

Considering the diagrams above we require atom i to move in a direction perpendicular to bond j,i and j,k. This can be carried out by defining the unit vector $-(e_{ij} \times e_{jk})/\sin \alpha_{ijk}$. The normalization of s_i will be by the length of the projection of bond j,i onto the plane perpendicular to the j,k bond. This length is, in fact, $r_{ij} \sin \alpha_{ijk}$. Thus the s_i vector will be given by the expression

$$s_i = -(e_{ij} \times e_{jk})/r_{ij} \sin^2 \alpha_{ijk}$$

Similar considerations will yield the following expression for s_l

$$s_l = -(e_{lk} \times e_{kj})/r_{lk} \sin^2 \alpha_{jkl}$$

The derivation of the s_j and s_k vectors is now, in fact, simpler than was the case of the wag. We know two vectors explicitly instead of one. Elimination of one is carried out by conveniently choosing it to be the

[2]An in-depth treatment of the torsion has been given recently in ref. 10.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

origin in the rotational invariance relation. We will then have the last vector expressed as a directly soluble combination of the two known vectors.

$$\boldsymbol{R}_i \times \boldsymbol{s}_i + \boldsymbol{R}_j \times \boldsymbol{s}_j + \boldsymbol{R}_k \times \boldsymbol{s}_k + \boldsymbol{R}_l \times \boldsymbol{s}_l = \boldsymbol{0}$$

Putting k as the origin we have

$$\boldsymbol{R}_i = r_{ki}\boldsymbol{e}_{ki} = r_{kj}\boldsymbol{e}_{kj} + r_{ji}\boldsymbol{e}_{ji} \quad \boldsymbol{R}_j = r_{kj}\boldsymbol{e}_{kj} \quad \boldsymbol{R}_k = \boldsymbol{0} \quad \boldsymbol{R}_l = r_{kl}\,\boldsymbol{e}_{kl}$$

Rearranging the first expression and multiplying through by $\boldsymbol{e}_{kj}$ we obtain

$$r_{kj}\boldsymbol{e}_{kj} \times (\boldsymbol{e}_{kj} \times \boldsymbol{s}_j) = -r_{kj}\boldsymbol{e}_{kj} \times (\boldsymbol{e}_{kj} \times \boldsymbol{s}_i) - r_{ji}\boldsymbol{e}_{kj} \times (\boldsymbol{e}_{ji} \times \boldsymbol{s}_i) - r_{kl}\boldsymbol{e}_{kj} \times (\boldsymbol{e}_{kl} \times \boldsymbol{s}_l)$$

Utilizing the vector identity we may expand this expression

$$r_{kj}[(\boldsymbol{e}_{kj}\cdot\boldsymbol{s}_j)\boldsymbol{e}_{kj} - (\boldsymbol{e}_{kj}\cdot\boldsymbol{e}_{kj})\boldsymbol{s}_j] = -r_{kj}[(\boldsymbol{e}_{kj}\cdot\boldsymbol{s}_i)\boldsymbol{e}_{kj} - (\boldsymbol{e}_{kj}\cdot\boldsymbol{e}_{kj})\boldsymbol{s}_i] - r_{ji}[(\boldsymbol{e}_{kj}\cdot\boldsymbol{s}_i)\boldsymbol{e}_{ji} - (\boldsymbol{e}_{kj}\cdot\boldsymbol{e}_{ji})\boldsymbol{s}_i] - r_{kl}[(\boldsymbol{e}_{kj}\cdot\boldsymbol{s}_l)\boldsymbol{e}_{kl} - (\boldsymbol{e}_{kj}\cdot\boldsymbol{e}_{kl})\boldsymbol{s}_l]$$

Evaluating the scalar products we have

$$-r_{kj}\boldsymbol{s}_j = r_{kj}\boldsymbol{s}_i - r_{ji}\cos\alpha_{ijk}\,\boldsymbol{s}_i + r_{kl}\cos\alpha_{jkl}\,\boldsymbol{s}_l$$

Therefore

$$\boldsymbol{s}_j = \frac{-r_{kj} + r_{ji}\cos\alpha_{ijk}}{r_{kj}}\boldsymbol{s}_i + \frac{-r_{kl}\cos\alpha_{jkl}}{r_{kj}}\boldsymbol{s}_l$$

Substituting in for $\boldsymbol{s}_i$ and $\boldsymbol{s}_l$ we have the final expression for $\boldsymbol{s}_j$

$$\boldsymbol{s}_j = \frac{r_{kj} - r_{ji}\cos\alpha_{ijk}}{r_{kj}r_{ji}\sin\alpha_{ijk}} \cdot \frac{(\boldsymbol{e}_{ij} \times \boldsymbol{e}_{jk})}{\sin\alpha_{ijk}} + \frac{\cos\alpha_{jkl}}{r_{kj}\sin\alpha_{jkl}} \cdot \frac{(\boldsymbol{e}_{lk} \times \boldsymbol{e}_{kj})}{\sin\alpha_{jkl}}$$

The expression for $\boldsymbol{s}_k$ can be obtained in precisely the same manner this time putting j as the origin in the rotational invariance expression and proceeding as above.

A more general case though would be that of a non-4 atom torsion. In that case Hilderbrandt (8) showed that the following expressions are the correct ones for the $\boldsymbol{s}$ vectors of all the atoms involved. It should be pointed out that ni, the number of "i-type" atoms, need not equal nl, the number of "l-type" atoms. That is the two ends of the torsional coordinate need not be symmetrical.

The general expressions for the $\boldsymbol{s}$ vectors then are

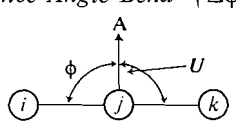
$$\boldsymbol{s}_i = -\frac{1}{ni}\frac{(\boldsymbol{e}_{ij} \times \boldsymbol{e}_{jk})}{r_{ij}\sin^2\alpha_{ijk}} \qquad \text{for each } i\text{-type atom}$$

$$\boldsymbol{s}_l = -\frac{1}{nl}\frac{(\boldsymbol{e}_{lk} \times \boldsymbol{e}_{kj})}{r_{lk}\sin^2\alpha_{jkl}} \qquad \text{for each } l\text{-type atom}$$

$$\boldsymbol{s}_j = \frac{1}{ni}\sum_{ni}\frac{r_{jk} - r_{ij}\cos\alpha_{ijk}}{r_{ij}r_{jk}\sin^2\alpha_{ijk}} \cdot (\boldsymbol{e}_{ij} \times \boldsymbol{e}_{jk}) + \frac{1}{nl}\sum_{nl}\frac{\cos\alpha_{jkl}}{r_{jk}\sin^2\alpha_{jkl}} \cdot (\boldsymbol{e}_{lk} \times \boldsymbol{e}_{kj})$$

$$\boldsymbol{s}_k = \frac{1}{nl}\sum_{nl}\frac{r_{jk} - r_{kl}\cos\alpha_{jkl}}{r_{kl}r_{jk}\sin^2\alpha_{jkl}} \cdot (\boldsymbol{e}_{lk} \times \boldsymbol{e}_{kj}) + \frac{1}{ni}\sum_{ni}\frac{\cos\alpha_{ijk}}{r_{jk}\sin^2\alpha_{ijk}} \cdot (\boldsymbol{e}_{ij} \times \boldsymbol{e}_{jk})$$

(5) Linear Valence Angle Bend[3] *(Δϕ)*



As mentioned previously the valence angle bend formulae "blow-up" in the case of a linear conformation. Schachtschneider (6) recognized this when he published his well known computer programs and allowed for the inclusion of the linear bend as a special type of internal coordinate.

The linear bend is in many respects a very special type of internal coordinate since we cannot use the $\boldsymbol{e}$ vectors as we did in the four preceding types of internal coordinates. We must now define a new type of vector by a point above j at right angles to the linear bend i–j–k as illustrated in the diagram above. Let $\boldsymbol{U}$ be the unit vector along j–A. The $\boldsymbol{s}$ vectors are then defined in terms of the $\boldsymbol{U}$ vector. They must, as

[3]While Schachtschneider (6) treated the linear bend properly with his own vector construction in his computer programs, Ferigle and Meister (11) were the first to correct the deficiency in the Wilson–Decius valence-angle bend formulae following the work of Eliashevich (12).

in all previous cases, be normalized by the respective bond lengths r_{ji} and r_{jk}.

The s vectors for the linear bend then are

$$s_i = -U/r_{ji} \qquad s_k = -U/r_{jk} \qquad s_j = -(s_i + s_k)$$

Schachtschneider made provision in his original GMAT program for the automatic generation of a second linear bend, at right angles to the first. (This is also included in our BMAT program (7).) This situation would arise in an example like carbon dioxide where two degenerate linear bends occur. (In a general case the two linear bends need not necessarily be degenerate.)

To handle this case a second "U" vector may be generated by the following expression

$$UP = e_{jk} \times U$$

The second linear bend is defined by formulae similar to those above

$$s_i = -UP/r_{ji} \qquad s_k = -UP/r_{jk} \qquad s_j = -(s_i + s_k)$$

With this set of five internal coordinates we have completed our set of basis vectors needed for a complete general vibrational analysis.

Received July 4, 1977

ILONA GRUDA, ROGER M. LEBLANC, and JERZY SOCHANSKI. Can. J. Chem. **56**, 1296 (1978).

The kinetics of the Z–E isomerization of a series of 3′-nonsymmetrically substituted spiroindolinopyrans has been studied by nmr in different solvents.

The rate-determining step in nonpolar solvents was found to be the cleavage of the C—O bond whereas in polar solvents it was the C(2)—C(3) bond rotation.

A strong steric hindrance of substituents at carbon 3 was observed. It was found that the rate of the isomerization is more sensitive to the bulkiness of the substituent at C(3′) than at the N(1′). Protic solvents enhance the reaction more than nonprotic polar solvents.

ILONA GRUDA, ROGER M. LEBLANC et JERZY SOCHANSKI. Can. J. Chem. **56**, 1296 (1978).

La cinétique de l'isomérization Z–E d'une série de spiroindolinopyrannes asymétriquement substitués en 3′ a été étudiée par la rmn dans différents solvants.

Dans les solvants apolaires l'étape déterminant la vitesse est la scission de la liaison C—O tandis que dans les solvants polaires c'est la rotation autour de la liaison C(2)—C(3) de l'intermédiaire qui détermine la vitesse.

L'empechement stérique des substituants en C(3) est très fort. La réaction est plus sensible à l'encombrement du substituant en C(3′) qu'en N(1′). Les solvants protiques favorisent plus la réaction que les solvants polaires aprotiques.

Introduction

Spiroindolinopyrans **1** in solution undergo an inversion at the spiro carbon (1, 2). When the compounds are nonsymmetrically substituted at C(3′)[1] the inversion leads to an equilibrium between two isomers **1***a* and **1***b* (Scheme 1).

We have observed previously (3) that nmr spectra of these isomers are different and that this method allows the determination of the concentration of each isomer.

It is well known (1) that spiroindolinopyrans (SP) in solution are in equilibrium with a small amount of an open-ring isomer (OR) which may be detected by uv–visible spectroscopy. This species is identical to the one formed in a photochromic process (4, 5).

Scheme 1 shows the mechanistic possibilities of the transformation of the cyclic isomer **1***a* into its diastereoisomer **1***b*. The open-ring isomer which is a mixture of several species obviously contributes to this transformation.

The cleavage of the C—O bond and the subsequent rehybridization of C(2) yields a nonplanar very unstable intermediate OR-Z'. The *cis–trans* isomerization at the exocyclic double bond leads to an equilibrium between this species and the much more stable OR-E isomer which, in fact, is the only one open-ring isomer that has been observed experimentally.

Two reaction paths, A and B, may lead from **1***a* to **1***b*. Path A: rotation around the single C(2)—C(3) bond converts OR-Z' into OR-Z'' and reclosure of the latter yields **1***b*. Path B: alternatively, **1***b* may be formed in the course of the *cis–trans* isomerization of the exocyclic double bond and the subsequent rotation OR-E' → OR-E → OR-E'', the reverse *trans–cis* isomerization and the final reclosure of OR-Z''.

Toppet *et al.* (2) who investigated spiroindolinopyrans containing up to 95% of the open-ring isomer at equilibrium concluded from dnmr data that in spite of the extreme predominance of the OR-E (*trans*) over the OR-Z (*cis*) isomer, the former is not responsible for the process of inversion.

This is a rather unexpected result since (*i*) the rate of inversion is known to be dependent on the concentration of the OR-E (2); (*ii*) the ratio OR-E/OR-Z is very high; and (*iii*) the steric hindrance to rotation around the C(2)—C(3) bond which is a necessary step in the isomerization, increases drastically in the open-ring isomer OR-Z compared with OR-E. Hence

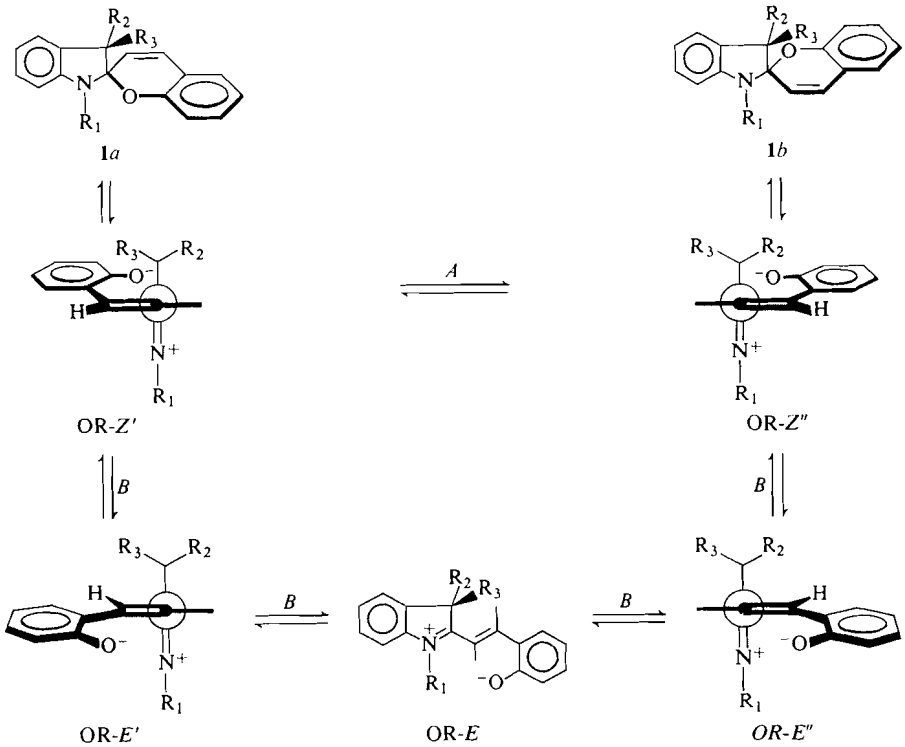


SCHEME 1. OR-*Z'* and OR-*Z''*, nonplanar open-ring isomers with *cis* configuration at the exocyclic double bond. Projection along the C(2)—C(3) single bond. OR-*E'* and OR-*E''*, nonplanar open-ring isomers with *trans* configuration at the double bond.

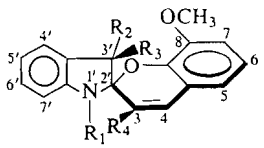
it could be anticipated that a study of the inversion in a series of spiroindolinopyrans with substituents of varying steric requirements will throw some light on the problem of the steric hindrance of rotation.

Another point of interest was the role of the solvent in the inversion process since the concentration of the intermediate is known to depend on the polarity of the medium.

The results obtained in this investigation enabled us to draw some conclusions with regard to the relative rates of the particular isomerization steps.

Results and Discussion

The following spiroindolinopyrans (**2**) containing a chiral carbon at 3′ have been synthesized.



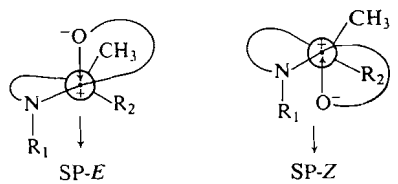
2

a $R_1 = R_2 = CH_3$, $R_3 = C_2H_5$, $R_4 = H$
b $R_1 = R_2 = CH_3$, $R_3 = CH_2C_6H_5$, $R_4 = H$
c $R_1 = CH_2C_6H_5$, $R_2 = CH_3$, $R_3 = C_2H_5$, $R_4 = H$
d $R_1 = R_2 = CH_2C_6H_5$, $R_3 = CH_3$, $R_4 = H$
e $R_1 = R_2 = CH_3$, $R_3 = CH_2C_6H_5$, $R_4 = CH_3$
f[2] $R_1 = R_2 = CH_3$, $R_3 = C_{16}H_{33}$, $R_4 = H$

[2]From ref. 3.

Nuclear magnetic resonance spectra of compounds **2***a*–**2***d* in CCl_4 had two peaks for OCH_3 protons with $\Delta\tau = 0.03$–0.13. Other well-resolved peaks were N—CH_3 in **2***a*, **2***b*, and **2***f* with $\Delta\tau = 0.11$–0.20 and 3′-CH_3 in **2***a* and **2***d* with $\Delta\tau = 0.07$–0.08. Compound **2***e* in CCl_4 had only one resonance peak for each group of protons, two isomers could be seen only in more polar solvents. In 20% CD_3OD–CCl_4 solution $\Delta\tau_{OCH_3} = 0.22$, $\Delta\tau_{N-CH_3} = 0.07$, $\Delta\tau_{3-CH_3} = 0.63$, and $\Delta\tau_{3'-CH_3} = 0.1$.

It can be anticipated that the predominant isomer is the SP-*E* one which is formed by an attack of the anionic oxygen of the open-ring form on the electrophilic carbon from the less crowded side, as shown in Scheme 2, where R_2 is more bulky than



SCHEME 2

the methyl. The above assumption was confirmed by the nuclear Overhauser effect experiments.[3] The

[3]I. Gruda. To be published.

integration of nmr signals shows that in an equilibrated solution the ratio SP-*E*/SP-*Z* is in the range of 1.3–2.2 and is almost independent of the solvent, as shown in Table 1.

Slow crystallisation of synthesized compounds (**2***a*–**2***f*) from ethanol gave solid products containing 80–95% of one isomer, SP-*E* in the case of **2***a*, **2***b*, and **2***d* and SP-*Z* for **2***c* and **2***e*. Nuclear magnetic resonance measurements give the variation of isomers' concentration with time, hence the rate of the isomerization. The kinetics of the above process is represented by two consecutive reversible reactions:

$$X_1 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} X_2 \underset{k_4}{\overset{k_3}{\rightleftharpoons}} X_3$$

where X_1 = SP-*E*, X_2 = OR, X_3 = SP-*Z*. The exact solution of the rate equations for this process is given by a linear combination of two exponential terms (6). In our experiments we have always observed a simple exponential dependence involving a single time constant. The above fact together with the observation that X_2 was always considerably smaller than both X_1 and X_3 has led us to the conclusion that the steady state hypothesis can be applied to the rate equations

$$[1] \quad dx_1/dt = k_2x_2 - k_1x_1$$

$$[2] \quad dx_2/dt = k_1x_1 - k_2x_2 - k_3x_2 + k_4x_3$$

$$[3] \quad dx_3/dt = k_3x_2 - k_4x_3$$

$$[4] \quad x_1 + x_2 + x_3 = 1$$

where x_1, x_2, x_3 are molar fractions of X_1, X_2, X_3, respectively.

Under this hypothesis we have $x_2 \ll x_1, x_3$, together with $dx_2/dt \cong 0$ which enables us to eliminate x_2 thus leading to a system of approximate equations involving two apparent rate constants k_1' and k_{-1}'

$$[5] \quad dx_1/dt = -k_1'x_1 + k_{-1}'x_3$$

$$[6] \quad x_1 + x_3 = 1$$

corresponding to an apparent reaction scheme

$$x_1 \underset{k_{-1}'}{\overset{k_1'}{\rightleftharpoons}} x_3$$

Solving the above system of equations gives

$$[7] \quad x_1 = (x_1^0 - x_1^{eq})e^{-kt} - x_1^{eq}$$

$$[8] \quad x_3 = 1 - x_1$$

whereas the assumption $dx_2/dt = 0$ gives

$$[9] \quad x_2 = p + q\,x_1$$

TABLE 1. The isomer ratio SP-*E*/SP-*Z* in equilibrated solutions

Compound	Solvent	SP-*E*/SP-*Z*
2*a*	CCl_4	2.0

2*f*	CCl_4	1.8
	C_6H_6	1.8

where x_1^0 = the initial value of x_1,
$x_1^{eq} = k_2k_4/(k_1k_3 + k_2k_4)$ the equilibrium value of x_1,
$k = (k_1k_3 + k_2k_4)/(k_2 + k_3)$ the effective rate constant,
$p = k_4/(k_2 + k_3)$, and
$q = (k_1 - k_4)/(k_2 + k_3)$.

The values of x_1^0, x_1^{eq} and k are easily obtained from the experimental $x_1(t)$ dependence using a computer least-squares curve-fitting procedure. The parameters p and q are similarly obtained from the relationship between x_2 and x_1 provided the $x_2(t)$ data are available. In the absence of any experimental information on x_2, the only parameters which can be obtained from the kinetics experiments are the apparent rate constants given by

$$[10] \quad k_1' = k(1 - x_1^{eq})$$

$$[11] \quad k_{-1}' = kx_1^{eq}$$

The relationships between k_1' and k_{-1}' and the true rate constants k_1, k_2, k_3, and k_4 are

$$[12] \quad k_1' = k_1k_3/(k_2 + k_3)$$

$$[13] \quad k_{-1}' = k_2k_4/(k_2 + k_3)$$

The above relationships lead to

$$[14] \quad \frac{k_{-1}'}{k_1'} = \frac{k_2}{k_3}\frac{k_4}{k_1}$$

which gives us information on the ratio k_2/k_3 provided that we can make some plausible hypothesis about the ratio k_4/k_1. In several cases where it was possible to determine p and q we were able to evaluate all four rate constants

$$[15] \quad k_1 = k[(p + qx^{eq})/p]$$

2*f*	CCl_4	0.125	8.70×10^{-3}	15.60×10^{-3}

[16] $$k_2 = k\,(x_1^{eq}/p)$$

[17] $$k_3 = k\,((1 - x_1^{eq})/(p + q))$$

[18] $$k_4 = k\,((p + qx^{eq})/(p + q))$$

It is interesting to note that in a particular situation when $x_2 = p$ = constant we obtain

[19] $$k_1 = k_4 = k_1' + k_{-1}'$$

[20] $$k_2/k_3 = k_{-1}'/k_1'$$

It has to be pointed out that all the above relationships can be obtained without the steady state hypothesis following a rigorous mathematical treatment of the time rate equations using the following simplifying assumptions: $k_1, k_4 \ll k_2, k_3$ which results in a small value of x_2 and $t \gg 1/(k_2 + k_3)$ i.e., after the induction period has passed. These inequalities represent a mathematical basis of the steady state hypothesis. The numerical results obtained from the analysis of our experimental data show that the above conditions are very well satisfied in practice.

In our study we were not able to measure the concentration of the open-ring intermediate in nonpolar solvents hence only the apparent rate constants k_1' and k_{-1}' could be calculated [10] and [11]. Table 2 gives calculated apparent rate constants for all investigated compounds. One can see from Table 2 that the rate of isomerization in a nonpolar solvent such as CCl_4 depends only slightly on the bulkiness of the substituents at 1′ and 3′. The most plausible explanation of this result is a hypothesis that in nonpolar solvents the rate-determining step is the bond cleavage in the pyran ring. In a more polar solvent like CD_3COCD_3 both constants are higher for the less crowded compound **2***a* than for **2***b*, **2***c*, and **2***d*. The observed differentiation of isomerization rates can readily be rationalized by the well-known enhancement of heterolytic bond cleavage by polar solvents. It can be assumed for the compounds investigated here that polar solvents enhance considerably the rate of ring opening, the C(2)—C(3) bond rotation thus becoming the rate determining step. The ring closure is always very fast. The role of steric hindrance in the inversion is strongly substantiated by the extremely slow isomerization of the compound **2***e*: in 20% CD_3OD–CCl_4 solution its conversion is 17.5 times slower than for **2***b* which is an analog of **2***e* without a methyl at C3.

For the isomerization in polar solvents we have been able to measure the concentration of the open-ring species by uv-visible spectroscopy and calculate the four true rate constants ([15]–[18]) which are given in Table 3.

The partitioning coefficient of the open-ring form $f = k_2/k_3$, may be considered as a factor representing the steric hindrance of the rotation. Examination of Table 3 shows that when a methyl at nitrogen is replaced by a more bulky benzyl (**2***a* and **2***c*) the steric hindrance is practically unaffected. A more important steric hindrance is provided by introduction of the benzyl group at C(3′) (**2***b* and **2***d*). Comparing the coefficient f for compound **2***b* in two solvents one can see that the solvent has no influence on the rotation hindrance.

The data of Tables 2 and 3 also show that a slightly polar but protic solvent enhances the isomerization much more than a polar nonprotic solvent (compound **2***b*). The open-ring form is strongly stabilized by the hydrogen bond in protic solvents.

The k_1/k_4 ratio is close to 1 in all studied reactions in polar solvents, but we do not feel we can assume a similar ratio in nonpolar solvents. Therefore we do not think the coefficient k_1'/k_{-1}' represents the

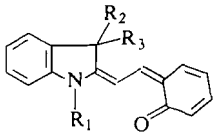
[a]Isomer *Z*.
[b]Isomer *E*.

steric hindrance of rotation which would have been true if $k_1 = k_4$ [14].

In conclusion it should be stressed that in polar solvents where the bond rotation is the rate-determining step the rate of the spiro carbon inversion is strongly affected by steric hindrance of substituents at C(3), less strongly by substituents at C(3′) and almost unaffected by substituents at N(1). Examination of Stuart space-filling molecular models of all OR species shows that the above results fit better into the reaction path *B* than into path *A*. The fact that the equilibrium between the two cyclic isomers and the OR-*E* was established very rapidly and the concentration of the latter remained constant in the course of the reaction SP-$E \rightleftharpoons$ SP-Z ($k_1 = k_4$) shows that the system OR-$Z' \rightleftharpoons$ OR-$E \rightleftharpoons$ OR-Z'' (Scheme 1) was at a dynamic equilibrium during all the time of the reaction. Hence the reaction proceeds along path *B*, at least partly. It is hardly possible to evaluate from the present study how large this fraction is. The choice of the reaction path (*A* or *B*) is likely to depend on the ratio of two activation energies: (*i*) that of the rotation of the OR-*Z*, and (*ii*) the OR-$E \rightarrow$ OR-*Z* isomerization. Usually the activation energy of *cis–trans* isomerization is much higher than the barriers to rotation around single bonds but the situation may be reverse if the formal double bond is strongly polarized (7–9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

With the spiroindolinopyrans, the contribution of a quinoid form (**3**) may considerably lower the activation energy of the OR-*E* → OR-*Z* isomerization, thus making path *B* accessible.



3

It seems probable that paths *A* and *B* are competitive, path *A* being favoured if OR-*E* is very stable (as for the compounds of Ref. 2), whereas a less stable OR-*E* favours path *B*.

Experimental

Melting points are uncorrected. Microanalyses were performed by Schwarzkopf Microanalytical Lab., New York, NY. The nmr spectra were recorded at 60 MHz using a Perkin–Elmer R-12 spectrometer with TMS as standard. The absorption spectra were measured with a Colman 124 spectrometer. The Spectrograde solvents for kinetic experiments were used without further purification. Some control experiments were performed with CCl_4 treated with K_2CO_3. The rate of isomerization remained unchanged.

All compounds were prepared according to the methods described in a previous paper (3). Melting points, analytical data, and nmr data of synthesized compounds are given in Table 4.

The kinetic data were obtained by integration of the nmr peaks of the two isomers (OCH_3 or N—CH_3 protons) in 1-min intervals. The concentration of the newly formed isomer was calculated from the formula:

$$C_1 = C_0 h_1/(h_1 + h_2)$$

where C_0 = the total initial concentration; h_1 = integration data for the newly formed isomer; h_2 = integration data for the other isomer.

The concentration of the OR in acetone was estimated by measuring the absorption at $\lambda = 560$ nm and using the value $3.5 \times 10^4\ \ell\ mol^{-1}\ cm^{-1}$ for the molar extinction coefficient (4).

A study of ^{14}N relaxation and nitrogen–proton spin coupling in nucleoside, indole, and ε-caprolactam systems through Fourier transform measurements of NH proton spin–lattice relaxation in the rotating frame

MICHAEL EUGENE MOSELEY AND PETER STILBS

Department of Physical Chemistry, Uppsala University, Box 532, S-751 21 Uppsala, Sweden

Received November 23, 1977

MICHAEL EUGENE MOSELEY and PETER STILBS. Can. J. Chem. **56**, 1302 (1978).

Measurements of nitrogen-14 nuclear spin–lattice relaxation times and direct proton coupling constants are presented for a series of nucleosides and nucleoside bases and indole derivatives in DMSO-d_6 and for a series of ε-caprolactam concentrations in $CDCl_3$. The data were obtained through NH proton $T_{1\rho}$ measurements, a potentially useful alternative to direct ^{14}N and ^{15}N nuclear magnetic resonance for the study of e.g. NH hydrogen bonding.

MICHAEL EUGENE MOSELEY et PETER STILBS. Can. J. Chem. **56**, 1302 (1978).

On a déterminé des temps de relaxation nucléaire spin–réseau pour de l'azote 14 et des constantes de couplage de proton directes pour une série de nucléosides, de bases nucléosides et de dérivés de l'indole dans le DMSO-d_6 et pour une série de concentrations d'ε-caprolactame dans le $CDCl_3$. On a obtenu les données à l'aide de mesures de $T_{1\rho}$ pour le proton NH, une méthode qui pourrait s'avérer une alternative utile à la résonance magnétique nucléaire directe du ^{14}N et du ^{15}N dans des études, par exemple, de lien hydrogène NH

[Traduit par le journal]

Introduction

Nitrogen is a key element in biochemical and biophysical processes. Unfortunately, it is also a difficult nucleus to study by nmr methods. The most abundant isotope (^{14}N, 99.7%) has $I = 1$ and hence a nuclear quadrupole moment, which furthermore happens to be sufficiently large to make resonances very broad (usually >500 Hz). This reduces sensitivity and may result in overlapping resonances in molecules with more than one type of nitrogen. The other nitrogen isotope (^{15}N) has a favourable spin of $\frac{1}{2}$, but a low natural abundance (0.3%). Additional complications are a low, negative gyromagnetic ratio and fairly long spin–lattice relaxation times. Proton broad-band decoupling which may enhance nmr sensitivity due to the nuclear Overhauser effect, is rather a complication in ^{15}N nmr, since this effect will be negative. ^{15}N is therefore a very difficult nucleus to study; sensitivity is more than a magnitude lower than ^{13}C, corresponding to more than two magnitudes in measurement time.

Apart from simple spectra, other nuclear properties are of interest. Nuclear spin relaxation rates are uniquely detailed and quantitative sources of information about molecular mobility, in particular with regard to rotational diffusion and internal motions. Unfortunately their measurement requires roughly 10 times more spectrometer time than running just a single spectrum. One can thus conclude that measurements of ^{15}N relaxation rates will, at best, be difficult. Studies on dilute, natural abundance samples are impossible with presently available spectrometer technology and therefore ^{14}N is usually the only accessible isotope.

Direct measurement of ^{14}N relaxation rates is possible either by pulse methods or through band-shape studies. Since relaxation rates commonly exceed 1000 s^{-1} the latter method is usually the easiest one (although a large number of short nitrogen relaxation times in the literature (see e.g. ref. 1) have been determined by pulse methods). Bands are usually so broad that contributions from instrumental broadening and heteronuclear spin–spin couplings are negligible and the resonance is a Lorentzian curve with a width at half height equal to $1/(\pi \cdot T_2)$. On the other hand, the broad bands may overlap in complex molecules, where one will also face an assignment problem.

Indirect measurement of ^{14}N relaxation rates is, however, possible through band-shape studies of directly bonded spin $\frac{1}{2}$ nuclei, provided that these are subject to slow chemical exchange. Primary and secondary amino protons, in particular, are suited for this approach. Sensitivity is now of proton magnitude, which allows dilute solutions to be used.

The ^{14}N relaxation rate has a profound effect on the amino proton line shapes; resonances are usually more than 10 Hz wide. Matching theoretical and observed band shapes yields the ^{14}N relaxation rate directly, provided that the proton–nitrogen coupling constant and other band shape influencing factors can be determined and accounted for. Unfortunately, this is not normally the case. The direct spin–spin coupling must usually be estimated,

For personal use only.

although, in favourable cases, it can be measured indirectly in ^{15}N spectra. Significant band shape contributions also arise through proton–proton dipolar relaxation and through proton spin–spin couplings. These can, of course, be accounted for in the simulations, although the band-shape equations rapidly tend to become very complex when additional factors are added. A review of the theory relevant to the above discussion has been given by Lehn and Kintzinger (1).

Measurement of amino proton longitudinal relaxation rates in the rotating frame ($T_{1\rho}$, spin-locking) is a method which eliminates effects on proton relaxation other than proton–nitrogen scalar coupling.[1] It was used as early as 1959 by Salomon (2) to determine proton–nitrogen coupling constants as well as ^{14}N relaxation rates in formamide. A reasonable agreement between theory and experiment was obtained.

To our knowledge, this is the only published application of the technique, as applied to nitrogen relaxation. We have found the method to be a powerful and accurate (although time-consuming) method for determining direct proton–nitrogen coupling constants and ^{14}N relaxation rates, even in very complex systems. With presently available attachments to Fourier transform spectrometers measurement accuracy and convenience is very much improved. Reviews on the spin-locking technique can be found in refs. 3 and 4.

^{14}N relaxation rates are usually completely dominated by the quadrupolar relaxation mechanism (1). Under extreme-narrowing conditions, and the assumption of an exponential correlation function for molecular reorientation, relaxation rates will be given by [1]:

$$[1] \quad \frac{1}{T_{1q}} = \frac{1}{T_1} = \frac{1}{T_2} = \frac{3}{8}\left(\frac{e^2qQ}{\hbar}\right)^2\left(1 + \frac{\eta^2}{3}\right)\tau_c$$

Here eq is the electric field gradient at the nitrogen nucleus, η is the asymmetry parameter of the field gradient, eQ is the electric quadrupole moment of ^{14}N and τ_c is the rotational correlation time. Without additional information the interpretation of ^{14}N relaxation rates is therefore not a completely straightforward task. In addition to rotational diffusion rates the electronic structure around the ^{14}N nuclei also becomes of importance. Nuclear quadrupole resonance methods do provide a way of measuring $e^2qQ/\hbar$ and η in the solid state (1). However, such information is of little value for the interpretation of T_1 changes in solution. Fortunately, τ_c can be obtained in an independent way from either ^2H or ^{13}C T_1 measurements. ^{14}N relaxation times are thus primarily a source of information about the electronic structure in the NH moiety. In systems where it has been established that eq and η are relatively constant however, changes in T_{1N} can be directly related to changes in τ_c.

The present paper concerns measurements made on nucleosides and indoles in DMSO-d_6 and on ε-caprolactam in $CDCl_3$ to illustrate the possibility of employing the technique in a variety of biological and hydrogen bonding systems. ε-Caprolactam was included in the study since it is a simple model of a compound which dimerizes through hydrogen bonding. This effect has previously been studied by measurements of the concentration dependence of its molecular polarization (5). In ^1H nmr the dimerization manifests itself very clearly in concentration-dependent downfield shifts of the NH proton. Since these shift changes reflect changes in the electronic environment of the NH moiety a parallel study of the nitrogen relaxation rate and the proton–nitrogen coupling should be of interest, as both depend on this factor.

Experimental

The nucleosides, parent bases, base derivatives, indole, and indole derivatives were obtained from Sigma Chemical Co. and Pfaltz and Bauer Research Chemicals. ε-Caprolactam was obtained from Merck Chemical Co., and deuterated dimethyl sulphoxide from Ciba–Geigy. All materials were used without further purification except 2-methylindole, which was recrystallized from H_2O.

Samples were prepared in 5 mm thin-wall nmr tubes and were not degassed. Relaxation contributions from dissolved oxygen are anticipated to be negligible since T_1 values were always less than 1.4 s (aniline) and usually in the 0.1–0.3 s range. Furthermore, the electron–nuclear relaxation times are expected to make equally large contributions to the T_1 and $T_{1\rho}$ values (since electron spin relaxation times are very short) and therefore eliminated through the evaluation procedure (cf. [2] below). These expectations are supported by later experiments on carefully degassed samples. Even in nondegassed samples we found $T_1 = T_{1\rho}$ (within experimental error) for signals not subject to chemical exchange or scalar coupling.

All measurements were made by Fourier transform methods on a JEOL FX-100 pulsed nmr spectrometer with double quadrature detection, under control of either the JEOL Autostacking or Auto-T_1 programs. For each sample, T_1 (by the inversion–recovery method) as well as $T_{1\rho}$ was measured for all NH_2 and NH proton signals at an ambient temperature of 25°C. The latter quantity, $T_{1\rho}$, which is sensitive to the proton resonance frequency in the spin-locking field ω_1 (*vide supra*), was measured at five values of ω_1 in the range 1200 to 19 000 rad/s. ω_1 was determined by measurement of the time required to produce a 180° pulse. Great care was taken to insure that all pulse widths and phasings were properly set. These were always checked and, if necessary, adjusted for each sample. Furthermore, the measurements were made with the spectrometer carrier frequency centered on the studied band

[1]An exception is relaxation induced by chemical exchange among nonequivalent sites. We have not found any indications that this mechanism seriously affects the results quoted in the present study (cf. Experimental).

(within 10 Hz). This is highly essential for spin-locking measurements at low values of ω_1, since the directions of the effective field in the rotating frame (B_{eff}) and the nuclear magnetization after the initial 90° pulse are not exactly parallel off-resonance. Since $B_0 = \omega_0/\gamma$, the z-component of B_{eff} in the rotating frame is $(\omega_0/\gamma)\cdot[1 - \omega_0/(\omega_0 + 2\pi\nu_d)]$, where ω_0 is the carrier frequency in rad/s and γ is the gyromagnetic ratio of the nucleus; ν_d is the deviation from exact resonance. Since $2\pi\nu_d \ll \omega_0$ this expression simplifies to $2\pi\nu_d/\gamma$. During a perfect spin-locking sequence, the nuclear magnetization should point in the y-direction along B_1, which is equal to ω_1/γ or $\pi/(PW(\pi)\cdot\gamma)$ where $PW(\pi)$ is the time required for B_1 to produce a π or 180° pulse. The misalignment angle between B_{eff} and B_1 is thus equal to arctan $(B_{(eff)z}/B_1)$ or arctan $(2\pi\nu_d\cdot PW(\pi))$. One finds that for low ω_1 ($\approx$2000 rad/s) only a range of a few Hz around ω_0 will be properly spin locked.

After the T_1 and $T_{1\rho}$ measurement series, each consisting of 10 spectra, signal amplitudes were fitted to their respective decay functions by a nonlinear least-squares procedure utilizing the general FORTRAN IV minimization subroutine STEPIT (6). T_1 and $T_{1\rho}$ were then fitted to their theoretical ω_1 dependence (3, 4) again by the nonlinear least-squares procedure yielding A ($\equiv {}^1J_{^{14}N-^1H}$) and T_{1N} from the equation

$$[2]\quad \frac{1}{T_{1\rho(sc)}} = \frac{1}{T_{1\rho(obs)}} - \frac{1}{T_1} = \frac{2}{3}A^2\frac{T_{1N}}{1 + \omega_1^2 T_{1N}^2}$$

Here $1/T_{1\rho(sc)}$ is the extracted proton relaxation contribution from proton–nitrogen scalar coupling and T_{1N} and A are the ^{14}N spin–lattice relaxation time and proton coupling constant (in rad/s), respectively.

We wish to emphasize that the procedure commonly suggested in the literature, extracting A and T_{1N} through a linear plot of $T_{1\rho(sc)}$ against ω_1^2 (3, 4) is entirely unsound, since for high values of ω_1, $T_{1\rho(obs)}$ is almost equal to T_1. This approach therefore gives a lower weight to the most accurately known $T_{1\rho(sc)}$ values and a high weight to the least accurately known values.

Error estimation in the present nonlinear least-squares simulations has been done through Monte Carlo methods as suggested by Chandler in the program manual for the STEPIT subroutine (6). The quoted error limits correspond to a 90% confidence interval and include only random errors. The mutual element in the correlation matrix regarding A and T_{1N} was calculated in some cases through the normal STEPIT error estimation features and was typically found to be relatively large and negative (−0.5 to −0.9).

As an initial check on the validity and accuracy of the measurement procedure outlined above $^1J_{^{14}N-^1H}$ and T_{1N} values of neat aniline were measured at 25°C. The results were 57.5 ± 1.0 Hz and 230 ± 20 μs, respectively. The latter value is in excellent agreement with the reported linewidth 1300 Hz (7), which corresponds to T_{2N} (= T_{1N}) = 240 μs. The direct proton–nitrogen coupling in neat aniline has not, however, been reported. Values in various solvents range from 55.6 to 58.7 Hz (recalculated from ^{15}N data (8)).

In samples having two or more exchangeable proton types (e.g. NH, NH_2, COOH, H_2O), chemical exchange may affect the $T_{1\rho}$ values. The effect on the results was found to be a definite overestimation in the value of A although an undetermined change in T_{1N}. There is reason to believe that the trends to an increase of A with concentration in Table I is partially due to this effect. The scatter of A values in Table 3 exceeds the estimated confidence intervals and is believed to be due to traces of water. Systematic over estimations of A do however, seem to be less than 10%.

^{13}C relaxation times were determined by the inversion–recovery method.

Results and Discussion

Pyrimidine and Purine Derivatives

The results are summarized in Table 1. It is seen that the coupling constants are essentially the same throughout the series of compounds and concentrations. The ^{14}N relaxation times vary appreciably, however. Within the same molecule NH_2 nitrogens have a shorter T_1 than NH nitrogens. Concentration effects are small, although a trend towards a decrease in T_{1N} with increasing concentration is found for 9-ethylguanine. This effect is expected, since the solute molecules, subject to increased hydrogen bonding, are less mobile at higher concentrations.

The effect on molecular mobility is quite pronounced going from e.g. 9-ethylguanine to guanosine or from adenine to adenosine. The presence of the ribose ring appears to decrease mobility, since no large differences in *eq* or η are expected within these pairs.

Indoles and Tryptophan

The results in Table 2 show a significantly lower ^{14}N T_1 for the methylindoles than for indole. This is probably due to decreased mobility rather than to

0.50	64.1±0.6	558±21
1.00	60.8±0.8	477±28

differences in *eq*, since 2- and 3-methylindole both give approximately the same results. The tryptophan results are slightly affected by proton exchange (making A too large). It can be seen, however, that the NH relaxation time is larger than in the indoles. A possible explanation is that the indoles may tend to stack or aggregate in the DMSO solvent, with a subsequent decrease in mobility.

ε-Caprolactam

As shown by Huisgen and Waltz (5) ε-caprolactam forms dimers even at quite low concentrations. The concentration dependence of the ^{14}N T_1 is shown in Table 3. An approximately twofold decrease is found in the region 0.05–1 M. For comparison, the average ^{13}C T_1 decrease is approximately 25% going from a 1 M to a 0.25 M solution (lower concentrations could not be studied). The corresponding ^{14}N T_1 decrease is 17%, suggesting that the electric field gradient of the nitrogen is lower in the dimer than in the monomer.

Conclusions

It is seen that determination of the ^{14}N spin-lattice relaxation time and direct proton–nitrogen coupling constants through proton spin–lattice relaxation in the rotating frame is a feasible and useful technique even in quite complex systems.

It is evident from [1] that the method cannot be applied if $\omega_1 T_{1N}$ is much less than unity. The very short nitrogen relaxation times in the nucleosides (30–50 μs) thus do represent a lower limit for the technique, determined by the maximum available spin-locking field. On our spectrometer set up ω_1(max) is 19 000 rad/s for protons.

An independent (although in practice correlated) restricting factor is the NH proton T_1 value. In larger hydrogen bonded molecules T_1 may become so short that the evaluation of $T_{1\rho(sc)}$ becomes very uncertain.

Since [2] is valid only under conditions of fast nitrogen relaxation an upper limit for the determination of T_{1N} also exists. In this case, however, nitrogen relaxation times can conveniently be determined through NH proton band-shape studies, since instrumental broadening and proton spin–spin couplings will be essentially negligible for these broad signals.

The largest limitation of the method is probably that slow proton exchange is required. This normally precludes its use on aqueous solutions. We have also found that large solvent peaks cause baseline distortions which are extremely troublesome in spin-locking measurements.

Acknowledgements

We wish to thank Professor G. Bergson for putting the spectrometer at our disposal and Dr. U. Obenius for technical assistance.

The reaction of methyl radicals with formaldehyde in dimethyl ether pyrolysis

KIM C. MANTHORNE AND PHILIP D. PACEY

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 3J5

Received September 13, 1977

KIM C. MANTHORNE and PHILIP D. PACEY. Can. J. Chem. **56**, 1307 (1978).

Dimethyl ether was pyrolyzed in a flow system at 788, 856, and 935 K and 38–401 Torr. Measurement of the yields of CH_4 and C_2H_6 and of either H_2 or CO enabled calculation of high pressure limiting values of the rate constant quotient $k_9k_6^{-1/2}$, where reaction 9 is

$$CH_3 + CH_2O \rightarrow CH_4 + CHO$$

and reaction 6 is the recombination of two methyl radicals. Including literature data from 357–1005 K, the Arrhenius plot for this quotient is a curve.

KIM C. MANTHORNE et PHILIP D. PACEY. Can. J. Chem. **56**, 1307 (1978).

On a effectué la pyrolyse de l'éther diméthylique dans un système à flux à 788, 856 et 935 K et à des pressions allant de 38 à 401 Torr. La mesure des rendements de CH_4 et de C_2H_6 et de soit H_2 ou CO permet de calculer les valeurs limites à hautes pressions du quotient des constantes de vitesse $k_9k_6^{-1/2}$ où la réaction 9 est

$$CH_3 + CH_2O \rightarrow CH_4 + CHO$$

et la réaction 6 est une recombinaison des deux radicaux méthyles. Si l'on inclut des données provenant de la littérature pour des températures allant de 357 à 1005 K, la droite d'Arrhénius pour ce quotient est une courbe.

[Traduit par le journal]

Introduction

The reaction of methyl radicals with formaldehyde has one of the smallest activation energies known for transfer of a hydrogen atom from a carbon atom to a methyl radical (1). Recent experiments, using CH_3 and CH_2O generated in the flow pyrolysis of dimethyl ether at 1063 to 1223 K (2) and 1005 K (3), have indicated that the reaction is faster at these temperatures than predicted from Arrhenius parameters determined at 357–435 K (4, 5). In the present work, this pyrolysis system has been reinvestigated with slower flow rates and smaller conversions at 788 to 935 K.

The rate-determining reactions in the mechanism, numbered consistently with ref. 3, are as follows:

[1] $$CH_3OCH_3 \rightarrow CH_3 + CH_3O$$

[3] $$H + CH_3OCH_3 \rightarrow H_2 + CH_2OCH_3$$

[5] $$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_2OCH_3$$

[6] $$2CH_3 \rightarrow C_2H_6$$

[9] $$CH_3 + CH_2O \rightarrow CH_4 + CHO$$

The radicals formed in reactions 1, 3, and 5 decompose rapidly to form CH_2O; the radical formed in reaction 9 decomposes to form CO.

Making the steady-state assumption for each radical, assuming long chains and integrating the rate equations for product formation, the following expressions are obtained:

[20] $$[CH_4] = k_5C[CH_3]t + \ldots$$

[21] $$[CH_2O] = k_5C[CH_3]t + \ldots$$

[22] $$[CO] = \tfrac{1}{2}k_5k_9C[CH_3]^2t^2 + \ldots$$

[23] $$[H_2] - [C_2H_6] = [CO]$$

Here C is the initial concentration of dimethyl ether. Terms in higher powers of t, resulting from stoichiometric expansion, reactant depletion and minor re-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

actions, have been omitted. The assumptions will be reconsidered in the Discussion. Combining the above equations, one obtains, for short t,

$$[24] \quad \frac{2C[CO]}{[CH_4]^2} = \frac{2C([H_2] - [C_2H_6])}{[CH_4]^2} \doteq \frac{k_9}{k_5}$$

Measurement of the yields, at short residence times, of CH_4 and CO or of CH_4, H_2, and C_2H_6, then, enables estimation of the ratio k_9/k_5.

The quotient $k_5k_{6,\infty}^{-1/2}$ can be determined from CH_4 and C_2H_6 yields as described previously (6). Multiplying, one obtains $k_9k_{6,\infty}^{-1/2}$, the quotient determined at lower temperatures in previous work (4, 5).

Experimental

The apparatus and technique have been described previously (6).

The flow rate of dimethyl ether was kept below 0.23 mol/h to prevent the cooler entering gas from distorting the temperature profile. Conversions were kept to less than 15%.

The reagent, passed through the cold reactor into the gas chromatograph, was found to contain about 10 ppm of O_2.

Results

Experiments have been performed at temperatures close to 788, 856, and 935 K.[1]

The dependence of rates of product formation on reactor residence times were as depicted in Figs. 1 and 2 of ref. 6. Figure 1 of the present work shows values of $2CA[CH_4]^{-2}$, where A is [CO] or ($[H_2] - [C_2H_6]$), at various reactor residence times, for experiments at 789 K and 40 Torr and 938 K and 330 Torr.

Extrapolated, initial values of the quotients are listed in Table 1, with values calculated from the raw data of refs. 7 and 8. The extrapolation of the data of ref. 8 may not be reliable, as the conversions reported were from 14 to 70%. The authors of ref. 8 estimated k_9/k_5 was 3, based on dimethyl ether pyrolysis experiments with added formaldehyde. It can be seen that no trend was observed with changing pressure and that there was no significant difference between data obtained using [CO] and those obtained from ($[H_2] - [C_2H_6]$).

In previous work (6) values of $k_5k_{6,\infty}^{-1/2}$ were determined by a Lindemann–Hinshelwood extrapolation of $k_5^2k_6^{-1}$ vs. P^{-1}. Since then the pressure dependence of the reverse of reaction 6 at 778 to 878 K has been investigated experimentally and a Rice–Ramsperger–Kassel–Marcus model has been developed, which, though involving some assump-

tions, does adequately represent the pressure dependence of the reaction (9). Using this model, values of $k_5k_{6,\infty}^{-1/2}$ have been calculated from the data of ref. 6 and the present work, in a manner analogous to that used in ref. 3 for $k_{6,\infty}$ itself. (See curve *a* of Fig. 4 of ref. 3.) Dimethyl ether was assumed to have the same deactivating efficiency as C_2H_6, on a pressure for pressure basis. Varying the deactivating efficiency to improve the agreement with the pressure dependence observed in this work would have changed the high pressure values of $k_5k_{6,\infty}^{-1/2}$ by less than 5%.

Values of $k_5k_{6,\infty}^{-1/2}$, determined as above, were combined with a value of 2.43×10^{10} ℓ mol^{-1} s^{-1} for $k_{6,\infty}$ (10) to calculate Arrhenius parameters for k_5 of log $A = 10.3 \pm 0.1$ (ℓ mol^{-1} s^{-1}) and $E_A = 60 \pm 2$ kJ mol^{-1}, both within the uncertainty limits reported earlier (6). Here and unless otherwise specified, quoted uncertainties are standard deviations.

Multiplying values of k_9/k_5 from Table 1 by values of $k_5k_{6,\infty}^{-1/2}$ calculated from the above Arrhenius expression allows calculation of $k_9k_{6,\infty}^{-1/2}$. Values are shown in the form of an Arrhenius plot in Fig. 2, with values from earlier work. The value of ref. 3 was calculated from the independent values of k_9 and $k_{6,\infty}$ reported. The experimental Arrhenius parameters for k_9 from this work were calculated to be $\log_{10} A$ (ℓ mol^{-1} s^{-1}) $= 10.1 \pm 0.2$ and $E_A = 45 \pm 3$ kJ mol^{-1}. These are greater than low temperature values of 8.1 ± 0.1 and 26.0 ± 0.7 kJ mol^{-1} from ref. 4 and 8.3 and 28 kJ mol^{-1} from ref. 5.

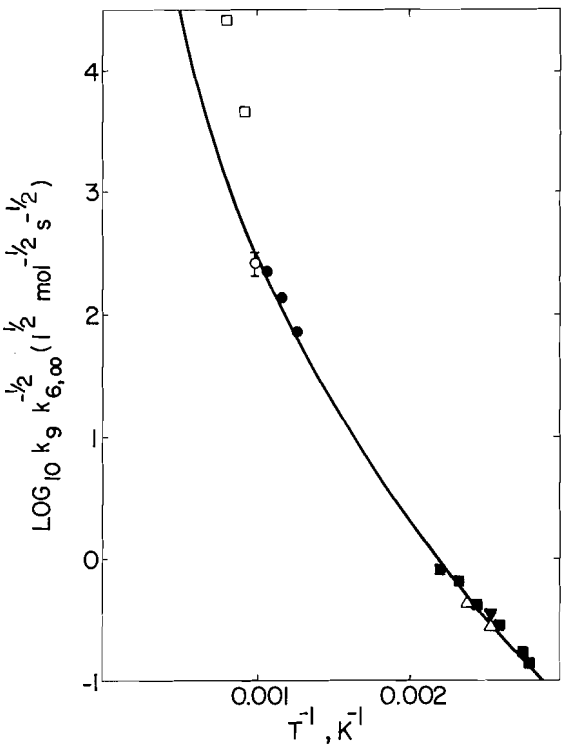

FIG. 2. Arrhenius plot for $k_9k_{6,\infty}^{-1/2}$: ■, ref. 4; △, ref. 5; □, ref. 2; ○, ref. 3; ▼, ref. 11; ●, this work. The solid line, of the form $k = AT^n \exp(-E_A/RT)$, was calculated by the method of least squares for the data from 357 to 1005 K.

Discussion

Formaldehyde was not determined in these experiments. However, Benson and Jain (8) have shown that the initial rate of formation of formaldehyde is equal to the initial rate of removal of dimethyl ether, as required by eqs. 20 and 21.

The assumptions made in deriving eq. 24 were tested using the computer simulation of ref. 3, extended to include the cross-combination of CH_3 and CH_2OCH_3 radicals. The program took into account the initial warming of the reagent on entering the reactor, the build-up of the steady-state radical concentrations, reactant depletion, expansion, the finite chain length, and 11 possible minor reactions. By varying the parameters as described in ref. 3, it was estimated that cumulative errors in the extrapolated initial values of k_9/k_5 from this work should have been 20% or less. Including uncertainty in the extrapolation of $k_5k_6^{-1/2}$ to infinite pressure (taken as 20%) and experimental scatter, the uncertainties in the Arrhenius parameters should be increased to ± 0.9 log units and ± 13 kJ mol^{-1}.

The values of k_9 of Aronowitz and Naegeli (2) were almost an order of magnitude faster than predicted by an Arrhenius line passing through the present results. However, Aronowitz and Naegeli assumed that k_6 had its high pressure limiting value in their system. This could have led to an underestimation of $[CH_3]$ and hence an overestimation of k_9. Furthermore, the low value of $[CH_3]$ could have led to an underestimation of the amount of CH_4 formed by reaction 5 and other reactions, overestimating the remaining amount of CH_4 formed by reaction 9.

All values in Fig. 2, except those from ref. 2, have been fitted by non-linear least-squares to an expression of the form $k_9k_{6,\infty}^{-1/2} = AT^n \exp(-E_A/RT)$. The resulting curve, seen in Fig. 2, is in satisfactory agreement with the data below 1005 K. The parameters of the curve were: log $A = -13.7 \pm 3.7$, $n = 5.6 \pm 1.1$, $E_A = 9.8 \pm 5.5$ kJ mol^{-1}. To fit these points by a straight line, it would be necessary to suppose that the highest and lowest temperature points of ref. 4 are in error by factors of 0.7 and 1.5, respectively, or, if ref. 4 is correct, that the present points are in error by factors of 5 to 8. We conclude that the data are more easily explained on the basis of a curved Arrhenius plot.

LAURENCE K. THOMPSON, BARATHAM S. RAMASWAMY, and ROBERT D. DAWE. Can. J. Chem. **56**, 1311 (1978).

A series of nickel(II) and copper(II) complexes of the title ligand are reported which appear to exhibit predominantly pseudo-octahedral structures in the solid state. Anion bridged dimeric structures are proposed for both nickel and copper; $[Ni_2(NTB)_2X_2]Y_2$ (X = Y = Cl, Br; X = Cl, Br, NCS; Y = BPh_4), $[Cu_2(NTB)_2X_2]X_2 \cdot 2H_2O$ (X = Cl, Br). The other octahedral derivatives appear to be monomeric; $(Ni(NTB)X_2]$ (X = NO_3, NCS), $[Ni(NTB)(H_2O)X]Y$ (X = NCS, Y = BPh_4; X = CH_3CN, Y = $(ClO_4)_2$), $[Ni(NTB)(H_2O)_2]X_2 \cdot 2H_2O$ (X = ClO_4, BF_4), $[Cu(NTB)(NO_3)_2] \cdot H_2O$. Five-coordinate derivatives were uncommon and in the case of three copper complexes trigonalbipyramidal structures are suggested in the solid state; $[Cu(NTB)Cl]BPh_4$, $[Cu(NTB)(H_2O)]X_2 \cdot nH_2O$ (X = BF_4, $n = 0$; X = ClO_4, $n = 1$). In acetone solution all the copper complexes appear to be five-coordinate. Electron spin resonance data confirm trigonalbipyramidal solution structures and indicate $g_{\parallel} < g_{\perp}$ with very small values of $A_{\parallel}$ (60–80 × 10^{-4} cm^{-1}).

LAURENCE K. THOMPSON, BARATHAM S. RAMASWAMY et ROBERT D. DAWE. Can. J. Chem. **56**, 1311 (1978).

On rapporte la préparation d'une série de complexes du nickel(II) et du cuivre(II) avec le ligand mentionné dans le titre qui semblent montrer dans l'état solide des structures qui sont d'une façon prédominante pseudo-octaédriques. On propose des structures dimères possédant un anion ponté tant pour les complexes de nickel que ceux du cuivre; $[Ni_2(NTB)_2X_2]Y_2$ (X = Y = Cl, Br; X = Cl, Br, NCS; Y = BPh_4), $[Cu_2(NTB)_2X_2]X_2 \cdot 2H_2O$ (X = Cl, Br). Les autres dérivés octaédriques semblent être des monomères; $[Ni(NTB)X_2]$ (X = NO_3, NCS), $[Ni(NTB)(H_2O)X]Y$ (X = NCS, Y = BPh_4; X = CH_3CN, Y = $(ClO_4)_2$), $[Ni(NTB)(H_2O)_2]X_2 \cdot 2H_2O$ (X = ClO_4, BF_4), $[Cu(NTB)(NO_3)_2] \cdot H_2O$. Les dérivés pentacoordonnés ne sont pas communs et dans le cas de trois complexes du cuivre on suggère pour l'état solide des structures trigonalbipyramidales; $[Cu(NTB)Cl]BPh_4$, $[Cu(NTB)(H_2O)]X_2 \cdot nH_2O$ (X = BF_4, $n = 0$; X = ClO_4, $n = 1$). En solution dans l'acétone, il semble que tous les complexes du cuivre soient pentacoordonnés. Des données de résonance paramagnétique électronique confirment des structures trigonalbipyramidales en solution et indiquent $g_{\parallel} < g_{\perp}$ avec de petites valeurs de $A_{\parallel}$ (60–80 × 10^{-4} cm^{-1}).

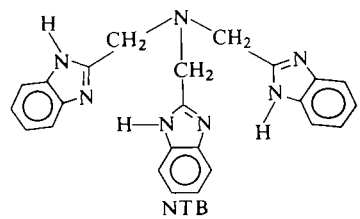
Introduction

Recent work has indicated the involvement of imidazole groups in the coordination sphere of copper(II) in copper metalloproteins (1) and the possibility of five-coordinate metal centres in such systems has also been proposed (2, 3). In a previous paper (4) we described the synthesis and characterization of a series of cobalt(II) and zinc(II) complexes of the title ligand (Fig. 1, ligand abbreviated NTB) in which its geometrical constraints appeared responsible for the formation of five-coordinate pseudo-trigonalbipyramidal derivatives. These studies have now been extended to include complexes of nickel and copper. The copper complexes, which exhibit both octahedral and trigonalbipyramidal stereochemistries, provide further examples of copper imidazole systems and add to the paucity of spectral data available for such five-coordinate species.



NTB

FIG. 1. Tris(2-benzimidazylmethyl)amine.

Structural assignments are supported by electronic, vibrational, and electron spin resonance spectra and magnetic and conductance data.

Experimental

Electronic spectra were recorded using a Cary 17 spectrometer, infrared spectra were obtained using a Perkin-Elmer model 283 spectrometer and electron spin resonance spectra were recorded at −196°C on a Varian E-3 X-band spectrometer, the magnetic field strength being calibrated with an nmr probe and with Mn(II) in MgO powder. Magnetic susceptibilities were obtained at room temperature by the Faraday

method using a Cahn model #7600 Faraday Magnetic Susceptibility system, coupled to a Cahn gram electrobalance and conductance data were obtained using a General Radio Company bridge with impedance comparator and a constant temperature bath adjusted to 25°C. Microanalyses were carried out in part in the Chemistry Department at Memorial University using a Perkin-Elmer model #240 Elemental Analyzer and by Altantic Microlab, Inc., Atlanta, Georgia. Metal analyses were determined by Atomic Absorption using a Varian Techtron AA-5, after digestion of the samples in concentrated HNO_3 or aqua-regia.

Metal Complexes of NTB

The ligand, tris(2-benzimidazylmethyl)amine, was prepared as described previously (4). Hydrated or anhydrous metal salts were used.

$[Ni_2(NTB)_2X_2]X_2$ ($X = Cl, Br$), $[Ni(NTB)X_2]$ ($X = NO_3$, NCS)

Solutions of equimolar quantities of the metal salt and NTB were prepared in hot ethanol and mixed. After stirring for a few minutes the solutions were filtered hot (where possible) and volumes reduced to the point of crystallization. Purification was effected by recrystallization from or soxhlet extraction in ethanol and the products dried at 90°C under vacuum.

$[Ni_2(NTB)_2X_2](BPh_4)_2 \cdot nH_2O$ ($X = Cl, Br$; $n = 0$; $X =$ NCS, $n = 3$)

Equimolar quantities of sodium tetraphenylborate and NTB were dissolved together in hot ethanol and added to a hot ethanolic solution of the metal salt. After stirring and cooling pale green products were obtained (X = Cl, Br). In the case of the thiocyanate complex a bright green solution formed from which blue crystals began to form (subsequently shown to be $[Ni(NTB)(NCS)_2]$). Rapid filtration of the hot solution followed by rapid reduction in volume produced bright green crystals. It was found to be difficult to repeat this preparation. Recrystallization of this compound from methanol gave a blue complex $[Ni(NTB)(NCS)(H_2O)](BPh_4)$. The chloro- and bromo-derivatives were purified by soxhlet extraction in ethanol and all compounds were dried at 90°C under vacuum.

$[Ni(NTB)(H_2O)_2]X_2 \cdot 2H_2O$ ($X = ClO_4, BF_4$)

Reaction of equimolar amounts of NTB and the metal salt in hot ethanol produced turquoise–blue solutions from which crystalline products could not be obtained due to the extreme solubility of the complexes. Addition of water to the concentrated ethanolic solutions gave pale blue crystals after stirring for a few minutes. Recrystallization was effected by dissolving the complexes in ethanol and adding water as before. The complexes were dried at 90°C under vacuum.

$[Ni(NTB)(H_2O)(CH_3CN)](ClO_4)_2$

Reaction of equimolar quantities of NTB and nickel perchlorate hexahydrate in acetonitrile gave a mauve solution from which mauve crystals were obtained after prolonged standing in the freezer (−20°C). The mother liquor was decanted and the product washed with cold acetonitrile. Recrystallization was effected from acetonitrile and the compound dried at 90°C under vacuum.

$[Cu_2(NTB)_2X_2]X_2 \cdot 2H_2O$ ($X = Cl, Br$), $[Cu(NTB)(NO_3)_2] \cdot H_2O$, $[Cu(NTB)(H_2O)]X_2 \cdot nH_2O$ ($X = BF_4$, $n = 0$; $X = ClO_4$, $n = 1$)

Equimolar quantities of the metal salt and NTB were dissolved separately in hot methanol and the solutions mixed. In the case of the nitrate complex a green crystalline product was obtained rapidly. The other solutions were filtered hot and their volumes reduced to the point of crystallization. Recrystallization was effected from methanol and the products dried at 90°C under vacuum.

$[Cu(NTB)Cl]BPh_4$

Equimolar quantities of NTB and sodium tetraphenylborate were dissolved together in hot ethanol and added to a hot ethanolic solution of a stoichiometric amount of copper chloride. After reduction in volume to induce crystallization the product was recrystallized from acetone and dried at 90°C under vacuum.

Analytical data for the nickel and copper complexes are given in Table 1.

Results and Discussion

Characterization of the Complexes

Cobalt and zinc complexes of NTB (4) were found to have trigonalbipyramidal structures in which the ligand acts as a tetradentate 'tripod' ligand rather like Me_6tren (5). The stable nickel complexes of NTB all appear to be pseudo-octahedral in structure and can be divided into two groups; a series of blue complexes which are monomeric and a series of green complexes, for which dimeric structures, involving bridging anions, are proposed. Examples of both trigonalbipyramidal and octahedral structures are found among the copper complexes and for some octahedral complexes anion bridged, dimeric structures are also proposed. In all cases NTB appears to behave as a tetradentate ligand coordinating through the apical nitrogen and three benzimidazole nitrogen atoms.

Electronic Spectra

Basically three bands are observed in the electronic spectra of all the NTB nickel complexes, both in the solid state and in solution, in the ranges 8 900 – 10 400 cm^{-1} (ν_1), 15 000 – 17 500 cm^{-1} (ν_2), and 25 000 – 28 000 cm^{-1} (ν_3) (Table 2). Little evidence exists for the splitting of any of these bands in the solid state (mull transmittance) spectra at room temperature or in solution and the band positions are typical of octahedrally coordinated nickel(II) (6, 7). In all cases a very weak absorption is observed around 13 000 cm^{-1}, which is assigned to the spin-forbidden transition $^1E_g \leftarrow {}^3A_{2g}$. The blue perchlorate complex $[Ni(NTB)(H_2O)_2](ClO_4)_2 \cdot 2H_2O$ dehydrates on heating under vacuum to produce a very moisture-sensitive green compound. The mull transmittance spectrum of this compound (Table 2) is very different from those of the other nickel complexes and the band positions and relative intensities bear some resemblance to known trigonalbipyramidal nickel complexes, e.g., $[Ni(Me_6tren)X]X$ (X = Cl, Br, I) (5).

NTB is assumed to behave as a tetradentate ligand occupying four coordination positions around *cis*-pseudo-octahedral metal ions in the case of all the stable nickel complexes. A number of nickel com-

plexes with *cis*-N_4 chromophores have been shown to have dimeric anion bridged structures, e.g., $[Ni_2(en)_4Cl_2]Cl_2$ (8), $[Ni_2(en)_4(NCS)_2]I_2$ (9), $[Ni_2(tren)_2(NCO)_2](BPh_4)_2$ (10), $[Ni_2(trien)_2Cl_2](ClO_4)_2$ (11). These dimeric systems have solid state electronic spectra which are very similar to those of the green NTB complexes and it is suggested that the NTB complexes could have similar structures in the solid state. The blue complexes are assumed to be monomeric with coordinated water, solvent, and/or anion. Support for the dimeric nature of the green complexes and the monomeric nature of the blue complexes is obtained by considering the solution spectra of these complexes in a variety of solvents. Spectral bands for the chloro- and bromo-derivatives remain fairly constant in such solvents as methanol, dimethylsulfoxide, and pyridine implying that the metal is not solvated and that the proposed halogen bridged structures remain intact in solution regardless of solvent. The green thiocyanate complex is much less stable and breaks apart to give a monomeric species in polar solvents. However, it is assumed to have a thiocyanate bridged structure in the solid state. The spectral changes on varying the solvent for some of the blue complexes are much more marked implying solvation of the complex and monomeric structures.

The two coordinated water molecules in the blue perchlorate and tetrafluoroborate complexes appear to be fairly labile. Solution electronic spectra of the perchlorate complex vary according to the solvent used and the band positions follow the energy sequence $CH_3CN > CH_3NO_2 > CH_3OH$. In methanol it is likely that the solution species is $[Ni(NTB)(H_2O)_2]^{2+}$ (Table 2), but in acetonitrile and nitromethane one or both coordinated water molecules are displaced by solvents. The nickel perchlorate complex can be prepared from acetonitrile and is obtained as a mauve crystalline solid. Analysis (Table 1) reveals the presence of one molecule of acetonitrile, which is substantiated by infrared data, and the complex is assumed to have one coordinated water and one coordinated acetonitrile in the solid state. The similarity of the acetonitrile solution spectrum with that of the solid state spectrum suggests the same species exists in solution. Electronic spectral bands of this complex in acetone (blue solution) occur at much lower energy suggesting coordinated acetone. On recrystallization of the mauve complex from acetone a blue compound is obtained which appears to have coordinated acetone according to infrared studies.

All the copper complexes exhibit one major absorption in the solid state, mull transmittance, spectrum in the range 8 000 – 13 000 cm^{-1} (Table 2) but with either a low energy or high energy shoulder. The complexes $[Cu(NTB)(H_2O)](BF_4)_2$, $[Cu(NTB)(H_2O)](ClO_4)_2 \cdot H_2O$, and $[Cu(NTB)Cl]BPh_4$ all exhibit a single absorption with a high energy shoulder. This spectral pattern is typical of five-coordinate trigonalbipyramidal copper(II). Known trigonalbipyramidal systems, e.g., $[Cu(Me_6tren)X]^+$ (5) and $[Cu(tren)L]^{n+}$ (L = OH, py, NH_2Ph, NCS, NH_3) (12), exhibit very similar spectra. The remaining complexes exhibit low energy shoulders, which is typical of pseudo-octahedral copper(II) (Fig. 2). Halogen bridged dimeric structures are proposed for the complexes $[Cu_2(NTB)_2X_2]X_2 \cdot 2H_2O$ (X = Cl, Br) in the solid state. In acetone solution the electronic spectra of all the copper complexes are

similar, exhibiting a fairly intense major peak with a high energy shoulder, typical of trigonalbipyramidal copper(II) (Fig. 2). The acetone solution spectra of the compounds $[Cu_2(NTB)_2Cl_2]Cl_2 \cdot 2H_2O$ and $[Cu(NTB)Cl]BPh_4$ are identical suggesting the same trigonalbipyramidal solution species. In methanol all the solution species appear to be five-coordinate with the exception of the bromo-complex. In this case five-coordinate spectral bands are observed, but in addition a high energy band appears at 13 300 – 13 500 cm^{-1} (Table 2). This band may well be associated with a solvated, octahedral species in an equilibrium mixture with the five-coordinate cation.

Infrared Data

The region of the infrared spectra in the range 3200 – 3600 cm^{-1} was generally characterized by rather broad absorptions associated with N—H stretch and coordinated and lattice water. There seemed to be little logical pattern associated with the positions of bands attributable to N—H stretch. This could possibly arise from hydrogen bonding associations with oxygen-containing ligands or ions or benzimidazole units in neighbouring molecules. Coordinated water was clearly defined for the bis-aquo nickel complexes $[Ni(NTB)(H_2O)_2]X_2 \cdot 2H_2O$ (X = BF_4, ClO_4) and the aquo copper complexes $[Cu(NTB)(H_2O)]X_2 \cdot nH_2O$ (X = BF_4, $n = 0$; X = ClO_4, $n = 1$) by a broad doublet between 3500 – 3700 cm^{-1}. The green thiocyanate complex $[Ni_2(NTB)_2(NCS)_2](BPh_4)_2 \cdot 3H_2O$ was characterized by a sharp doublet (3290, 3315 cm^{-1}) due to N—H

stretch, which was replaced by a sharp singlet ($3310\ cm^{-1}$) in the blue form produced by recrystallization from methanol.

The blue thiocyanate complex $[Ni(NTB)(NCS)_2]$ gave two clearly defined absorptions at 2060 and $2065\ cm^{-1}$ (Table 3) associated with CN stretch in two *cis*-isothiocyanate groups and the green dimeric complex exhibited a sharp singlet at $2114\ cm^{-1}$ associated with CN stretch in a bridging thiocyanate group. In the blue complex $[Ni(NTB)(NCS)(H_2O)]BPh_4$ νCN occurred at $2118\ cm^{-1}$ as a sharp singlet. This represents a very high energy absorption for a terminally bound isothiocyanate and could possibly be due to a sulphur bound thiocyanate. The appearance of a relatively weak band at $719\ cm^{-1}$ for this compound could be associated with CS stretch in a thiocyanate group. Typically N-bonded thiocyanates have νCN less than $2100\ cm^{-1}$ (13) and class '*a*' acceptors usually favour this mode of bonding. Methanol thus appears to cleave the green dimeric thiocyanate bridged complex at the nickel–nitrogen bond, rather than the nickel–sulphur bond.

Both the blue and mauve nickel perchlorate and the copper perchlorate complexes exhibit strong, fairly broad absorptions around $1100\ cm^{-1}$ (Table

3) associated with ionic perchlorate while the unstable, moisture sensitive green nickel complex obtained by heating $[Ni(NTB)(H_2O)_2](Cl0_4)_2 \cdot 2H_2O$ exhibited more complex perchlorate absorptions; a strong singlet at 1105 cm^{-1} associated with an ionic perchlorate group and a strong doublet at 1035, 1130 cm^{-1} associated with monodentate perchlorate (14, 15).

Comparison of the copper and nickel nitrate complexes with the corresponding halide derivatives allows certain bands to be identified which can be associated with ionic and bidentate nitrate (nickel) and monodentate nitrate (copper) (Table 3) (14). Nitrate compounds give combinations bands around 1750 cm^{-1} which are often diagnostically useful (16). $[Ni(NTB)(NO_3)_2]$ exhibits three main absorptions in this region, when strong Nujol mulls are employed (Table 3), associated with ionic and bidentate nitrate groups. In the case of the copper nitrate complex two combination bands are observed (Table 3) and are assigned to monodentate nitrate groups.

In the far infrared (600–200 cm^{-1}) there is a close similarity between the spectra of the dimeric halogen bridged nickel species and bands associated with terminal nickel–halogen bonds appear to be absent thus supporting the halogen bridged nature of these species. The general complexity of the spectra in this low energy region prevented any definitive assignments of bridging metal–halogen vibrations. The case of the copper halide compounds was similar. In the chloro-complex $[Cu(NTB)Cl]BPh_4$ a strong band at 294 cm^{-1} is assigned to terminal copper–chlorine stretch.

Magnetism and Conductance

Magnetic moments for the nickel complexes lie in the range 3.1–3.4 BM at room temperature (Table 4) typical of pseudo-octahedral nickel(II) (17), while those of the copper complexes (Table 4) fall in the range 1.85–1.97 BM and appear to be normal for five-coordinate and octahedral copper(II) (5, 12).

Conductance data were obtained for the nickel and copper complexes in solvents appropriate to solubility, at approximately 10^{-3} M (Table 4) and values compared with those of known electrolytes at similar concentrations (18). In the case of the nickel halide complexes the molar conductance values, based on dimeric formula units (Table 4), can be associated with 1:2 electrolytes (18). A concentration dependent study of the molar conductance of $[Ni_2(NTB)_2Br_2]Br_2$ was carried out in methanol in the range $10^{-4} - 2.5 \times 10^{-3}$ M at 25°C. Λ_0 was found to be 170 and the slope of the Kohlrausch plot ($\Lambda_0 - \Lambda_e$ vs. $\sqrt{c}$) was found to be $\sim$1500. Slopes in the range 250–290 have been reported for 1:1 electrolytes in methanol (19) clearly indicating a polymeric or associated solution species. The general similarity between the halide complexes both in the solid state and in solution suggests similar solution species for the other halide complexes. The molecular nature of these solution species may be an aggregate of hydrogen bonded sub-units. Associated solution structures, due to hydrogen bonding, were proposed for some of the cobalt and zinc complexes of NTB (4).

The blue isothiocyanato complex $[Ni(NTB)(NCS)_2]$ appears to behave as a 1:1 electrolyte in methanol, presumably by loss of one coordinated thiocyanate

to produce a solvated cation. The bis-nitrato complex dissociates to form a 1:2 electrolyte and both the perchlorate and tetrafluoroborate complexes behave as 1:2 electrolytes in methanol. Molar conductance data for the copper complexes indicate the perchlorate and tetrafluoroborate complexes to be 1:2 electrolytes, while the remaining solution species are assumed to be 1:1 electrolytes. The calculated values of Λ_M for the copper halide complexes are based on monomeric five-coordinate species in keeping with the electronic spectral data.

Electron Spin Resonance Data

Electron spin resonance spectra of the copper complexes were run as solids and methanol solutions at −196°C. Figure 3 illustrates a typical spectrum. The frozen glass spectra are characterized by four clearly resolved lines in the perpendicular region and usually two or three in the parallel region and bear a striking resemblance to the few spectra reported for known trigonalbipyramidal systems with tripod ligands (20–22). Copper complexes of tren, Me_6tren, Et_6tren which have trigonalbipyramidal structures have $g_{\parallel} < g_{\perp}$ and $A_{\parallel}$ in the range ~65–100 ($\times 10^{-4}$ cm^{-1}). Spin-Hamiltonian parameters for the copper/NTB systems are reported in Table 5. $A_{\parallel}$ values are typically low, the values for the chloro- and bromo-complexes being the lowest so far reported for trigonalbipyramidal systems with tripod ligands and some $g_{\parallel}$ values are greater than g_e. Systems of this type are interpreted in terms of a d_{z^2} ground state in a trigonalbipyramid but the large values of $g_{\parallel}$ imply the mixing of d_{xy} or $d_{x^2-y^2}$ orbitals into the ground state via vibronic coupling (23). In the solid state the spectra were in general characterized by broad single resonances with some g resolution in the case of the chloro- and nitrato-complexes.

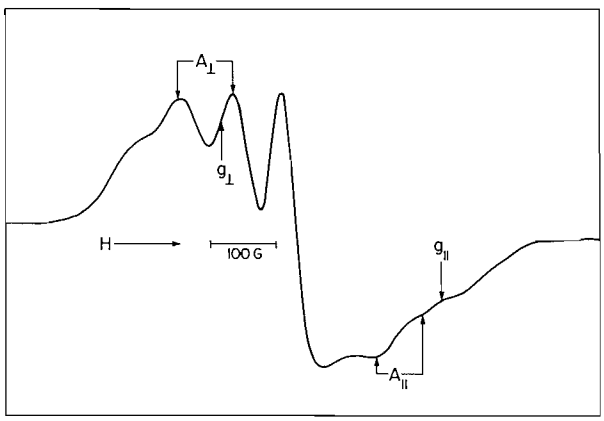

FIG. 3. Electron spin resonance spectrum (X-band) of frozen solution of $[Cu_2(NTB)_2Cl_2]Cl_2\cdot 2H_2O$ in methanol at 77 K.

A doped solid solution of $[Cu(NTB)Cl]BPh_4$ in the trigonalbipyramidal zinc complex $[Zn(NTB)Cl]BPh_4$ (3%) (4) gave a solid spectrum at −196°C which was very similar to its frozen solution spectrum in methanol, except for certain weak features which suggested the presence of a small amount of another species. Poor resolution in the parallel region of the spectrum prevented determination of $g_{\parallel}$ and $A_{\parallel}$ but the perpendicular spin-Hamiltonian parameters are very close to those obtained from the frozen methanol spectrum.

The similarity of the frozen solution spectra of all the halide complexes suggests the presence of similar species in solution in methanol. The spin-Hamiltonian parameters for the complexes $[Cu(Et_6tren)X]X$ (X = Cl, Br) in frozen methanol solution (cation unsolvated) show very small differences indicating the small change in axial crystal field perturbation on replacing chloride by bromide in systems of this type (21). The esr spectra of the nitrate, tetrafluoroborate and perchlorate complexes are almost superimposable, suggesting the presence of similar cations in solution. Values of $g_{\parallel}$, $g_{\perp}$, and $A_{\perp}$ for this set of complexes are close to those observed for the halide complexes. However, $A_{\parallel}$ values increase by 25–30% on replacing an axial halogen by an oxygen donor, e.g., H_2O, NO_3^-.

SCF molecular orbitals and the photoelectron spectrum of 5,5-dimethyl-Δ^3-1,3,4-oxadiazolin-2-one

ANTHONY JAMES PAINE[1] AND NICK HENRY WERSTIUK

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received November 10, 1977

ANTHONY JAMES PAINE and NICK HENRY WERSTIUK. Can. J. Chem. **56**, 1319 (1978).

CNDO/2 Frontier molecular orbital densities, ionization potentials (IP's), and electronic transition energies were calculated for the title compound (**2***b*) and the 5,5-diprotio (**2***a*), and 5,5-difluoro (**2***d*) analogs. Bond lengths and angles were not optimized but rather taken from a crystal structure of the 2-imino system **3**, with an assumed carbonyl bond length of R_{CO} = 1.19 Å. This value is supported by a high infrared stretching frequency (1835 cm^{-1}), X-ray crystal data of **3**, and the effect of R_{CO} variation on calculated IP's. The first three bands of the photoelectron spectrum of **2***b* were assigned as n_N^- (10.20 eV), π_1 (11.52 eV), and n_{CO} (13.26 eV) (vertical IP's). This unusually large n_{CO} IP is attributed to an inductive effect of the neighbouring strongly electron withdrawing azo group. The IP's obtained by CNDO/2 calculation (12.81, 13.37, and 15.15) are 1.5 to 2.5 eV higher than the experimental values, well within the predictive capability of the method, establishing that this theoretical treatment gives a good representation of the MO's of **2***b*.

ANTHONY JAMES PAINE et NICK HENRY WERSTIUK. Can. J. Chem. **56**, 1319 (1978).

On a calculé, par la méthode CNDO/2 des orbitales moléculaires frontières, les densités, les potentiels d'ionisation (PI) et les énergies de transition électronique du composé mentionné dans le titre (**2***b*) et de ses analogues diprotoné en 5,5 (**2***a*) et difluoro-5,5 (**2***d*). On n'a pas optimisé les longueurs des liens et des angles; on a plutôt utilisé les valeurs provenant d'une structure cristalline du système imino-2 (**3**) en faisant l'hypothèse que la longueur de la liaison carbonyle R_{CO} = 1.19 Å. La validité de cette hypothèse est confirmée par une vibration de fréquence infra-rouge élevée (1835 cm^{-1}), par des données cristallographiques de rayon-X de **3** et par l'effet de la variation de R_{CO} sur les PI calculés. On a attribué les trois premières bandes du spectre photoélectronique de **2***b* aux modes n_N^- (10.20 eV), π_1 (11.52 eV) et n_{CO} (13.26 eV) (PI verticaux). On attribue cette valeur très élevée du PI n_{CO} à un effet inductif du groupe azo qui est fortement électro-affinitaire. Les valeurs de PI obtenues par calculs CNDO/2 (12.81, 13.37 et 15.15) sont de 1.5 à 2.5 eV plus élevées que les valeurs expérimentales, bien à l'intérieur des capacités de prédiction de la méthode, établissant ainsi que ce traitement théorique donne une bonne représentation des orbitales moléculaires de **2***b*.

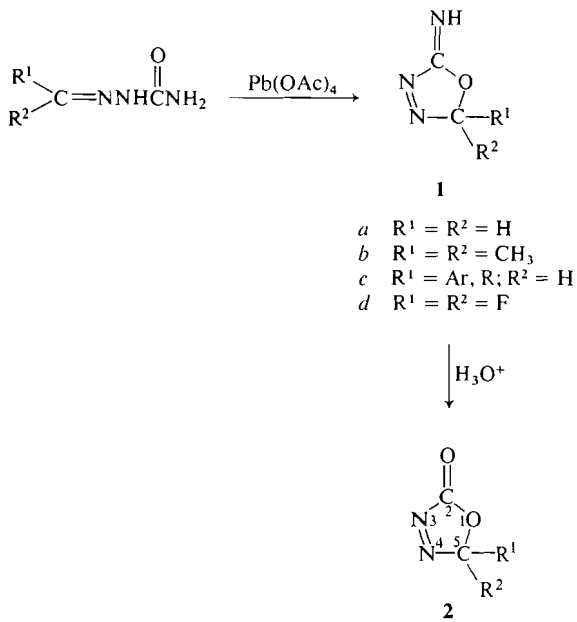
[Traduit par le journal]

Introduction

Δ^3-1,3,4-Oxadiazolin-2-ones are readily prepared in good yield from the lead tetraacetate oxidative cyclisation of ketone semicarbazones (1). They exhibit competing parallel thermal decomposition modes: one generating nitrogen, carbon monoxide, plus ketone; the other diazoalkane and carbon dioxide (2).

Frontier molecular orbital (FMO) theory has successfully provided insight into the problems of transition state structure, mechanism, stereo-, regio-, and periselectivity as well as into relative reactivity of substrates in a variety of thermal, photochemical, nucleophilic, and electrophilic reactions (3–5). As one of many probes in ongoing mechanistic studies of the thermal, photochemical, and acid- and base-catalysed decomposition of oxadiazolinones we sought to determine the FMO's of the system.

Expensive energy minimization calculations could



1

a $R^1 = R^2 = H$
b $R^1 = R^2 = CH_3$
c R^1 = Ar, R; R^2 = H
d $R^1 = R^2 = F$

be avoided if accurate values for bond lengths and angles could be inferred from a previous crystal structure of the closely related compound 2-*p*-bromophenylimino-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**3**). We now report the results of CNDO/2 orbital calculations on a series of oxadiazolinones. To check the validity of the computed MO's, the photoelectron spectrum of dimethyloxadiazolinone (**2***b*) was obtained, and the assigned IP's compared to the IP's computed by the application of Koopmans' Theorem (6). In later publications we will apply these theoretical results to the mechanistic problems mentioned above.

Methods

Estimation of Bond Lengths and Angles

Oxadiazolinone ring bond lengths and angles were set equal to those reported (7) for the X-ray crystal structure of **3** (Fig. 1). Since the methyl groups in that structure were not perfectly tetrahedral (presumably because of constraints of the crystal phase and/or limitations in the structure solution) these standard parameters were used for the methyl groups: R_{CH} = 1.09 Å, HCH = 109.45° (8). Calculations were also performed on the 5,5-diprotio compound **2***a*[2] and on the 5,5-difluoro compound **2***d* to establish the effect of electron withdrawing groups on the Frontier MO's. For the latter case the CF bond contraction owing to the electron-withdrawing azo function was set equal to the difference between a paraffinic CC bond length (1.541(3) Å) (8) and R_{C-CH_3} = 1.512(9) Å in **3**. When applied to the $R_{CF}(CH_2F_2)$ = 1.360(5) Å (8), this correction yielded the value R_{CF} = 1.331(11) Å for **2***d*. Although some shortening of the N4—C5 bond may also be expected on fluorine substitution, the oxadiazolinone ring parameters were not modified.

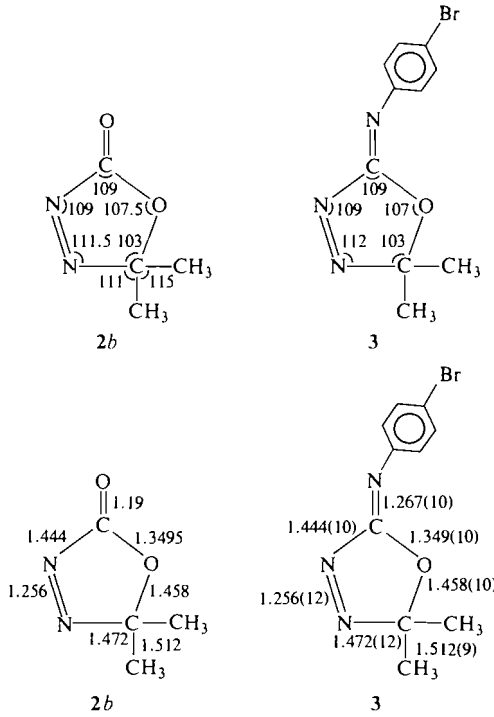

FIG. 1. Bond lengths and angles in dimethyloxadiazolinone (**2***b*) compared to those from the crystal structure of the iminooxadiazoline **3**. Estimated standard deviations for the X-ray crystals are ±1° for angles and ±0.01 Å for bond lengths.

The parameter requiring the greatest attention was the carbonyl bond length. Lack of data on azocarbonyl bond lengths hampers estimation of a reasonable value for oxadiazolinones. For simple carbonyl compounds of the type XCOY (where X, Y = H, CH_3, CF_3, CCl_3, CN, OH, OR, NH_2, NR_2, F, Cl, Br, ..., etc.) there exists a reasonable correlation (10) between the infrared stretching frequency and bond length. As the electron withdrawing power (σ_I) of the attached groups increases (11), an accompanying increase in the CO stretching frequency reflects a shorter bond length (Table 1).

Fixing a carbonyl group in a five-membered ring usually raises the stretching frequency by 35 ± 10 cm^{-1} (12). Correction of the observed CO stretching frequency of **2***b* (1835 cm^{-1} in CCl_4 (1)) for the ring size implies that the azo nitrogens of **2***b* have an effective σ_I between those of the methoxy and chloro substituents, in qualitative agreement with the value of σ_I (0.25) for the phenylazo group (11).

It may also be useful to compare the change in $R_{C=X}$ for X = N—C_6H_4Br-*p* and X = O. Bond lengths in the imino group of **3** (1.267(12) Å) and that in the *p*-bromoanil of benzaldehyde (1.281(10) Å) (13) differ by 0.014(18) Å. Since the benzaldehyde CO bond length is 1.211 Å (14), one might infer an oxadiazolinone CO bond length of 1.196(18) Å by difference.

Since the oxadiazolinone carbonyl is flanked by both an azo nitrogen and an ester oxygen, these criteria combine to suggest a reasonable value of 1.19 Å for this bond length. This value was used in the computations and the effect of the actual choice of R_{CO} on the calculated IP's of the diprotio parent **2***a* is examined in a later section. For a summary of the

[2]No oxadiazolinone with a hydrogen at C5 has yet been isolated due to the rapid tautomerism of the precursor (**1***a* or **1***c*) to the more stable 2-amino-1,3,4-oxadiazole (9):

parameters employed in the calculation on **2***b* see Fig. 1.

Calculation

Details of the CNDO/2 method and actual parameters have been fully discussed elsewhere (15–17). Calculations were performed on an HP 3000 computer using a FORTRAN program developed by D. P. Santry of this department. Electronic excitation energies $\Delta E_{i\to j}$ were also calculated using K_{ij} and J_{ij} obtained from the CNDO LCAO expansion coefficients (**C** matrix) and the CNDO atomic electron–electron repulsion integrals γ_{AB} (17).

$$\Delta E_{i\to j} = \varepsilon_j - \varepsilon_i - J_{ij} + 2K_{ij}$$

where:

$$J_{ij} = \int\int \psi_i^*(1)\psi_j^*(2)\frac{1}{r_{12}}\psi_i(1)\psi_j(2)\,d\tau_1 d\tau_2$$

$$K_{ij} = \int\int \psi_i^*(1)\psi_j^*(2)\frac{1}{r_{12}}\psi_j(1)\psi_i(2)\,d\tau_1 d\tau_2$$

which become:

$$J_{ij} = \sum_{A=1}^{NA}\sum_{B=1}^{NA}\sum_{\mu=1}^{NBA}\sum_{\nu=1}^{NBB} C_{\mu i}^2 C_{\nu j}^2 \gamma_{AB}$$

$$K_{ij} = \sum_{A}^{NA}\sum_{B}^{NA}\sum_{\mu}^{NBA}\sum_{\nu}^{NBB} C_{\mu i}C_{\mu j}C_{\nu i}C_{\nu j}\gamma_{AB}$$

where NA = number of atoms

NBA = number of basis functions on atom A

and

$$\gamma_{AB} = \int\int S_A^2(1)\frac{1}{r_{12}}S_B^2(2)\,d\tau_1 d\tau_2,$$

the average coulomb integral between valence S orbitals on atoms A and B.

Results and Discussion

Based on analogy with the ring of oxadiazoline **3**, the oxadiazolinone ring is planar and symmetrical substitution at C5 produces a plane of symmetry. Under C_s symmetry any orbital transforming as a'' is a π orbital and any as a' is a σ orbital. Since the trivial designation as π or σ is meaningful in these cases we adopt it, even when there is no true plane of symmetry (as in **2***b* with staggered methyl groups).

The CNDO/2 LCAO solution gives 26 orbitals for the diprotio compound **2***a* of which 10 are vacant. Of the remaining 16 filled MO's, 6 are 'nonbonding,' containing the so-called lone pairs, and 10 are 'bonding' MO's. In all, 7 of the 26 orbitals have π symmetry. These result from the combinations of five obvious $2p_z$ atomic orbitals on O1, C2, N3, N4, and O6 plus two symmetry orbitals on the CH_2 moiety, designated π_{CH} and π_{CH}^*. These can be viewed as arising from the symmetric and antisymmetric combinations of hydrogen $1S$ orbitals with the $2p_z$ AO of C5. Thus, the π_{CH} is of correct symmetry to interact with the other π orbitals of the molecule and four highly delocalized filled π MO's result. Buried in each of these are contributions from π_{NN}, π_{CO}, π_{n_O} (lone pair on O1), and π_{CH}.

For dimethyloxadiazolinone (**2***b*) a 'staggered' conformation of the methyl groups was assumed for the computation. Although this has the effect of destroying the plane of symmetry present in the diprotio and difluoro analogs, the orbital assignments of symmetry are nonetheless made by comparison to the parent **1***a*.

Computed valence energy levels for **2***a*, **2***b*, and **2***d* are compared to the experimental IP's for **2***b* in Fig. 2. As expected (18), the electron withdrawing fluorines at C5 lower orbital energies and increase the calculated gaps between the first few IP's.

[a]Symmetry assignment assumes a mirror plane.
[b]Orbital energies assume Koopmans' Theorem (6).
[c]Orbital density on atom A in orbital $i = \sum_{\mu}^{on\,A} C_{\mu i}^2$.

According to FMO theory (3, 4) nucleophilic and electrophilic attack are favoured at the site of greatest orbital density of the LUMO and HOMO, respectively. Klopman (19), Salem (20), and others, however, recognize the extremes of a continuum from frontier controlled to charge controlled reaction. Although examination of the LUMO of oxadiazolinone (Table 2) suggests possible nucleophilic attack on nitrogen, the fact that both nitrogens are formally negative in overall charge, as indicated in Fig. 3, may mitigate against such attack via the LUMO. On the other hand, attack at C2 via the next lowest unoccupied orbital (NLUMO) is reasonable as this site carries nearly a half-integral total positive charge in addition to a huge frontier density, according to the calculations. Likewise, electrophilic attack (e.g., protonation) on nitrogen via the HOMO (lone pair attack) or on carbonyl oxygen (NHOMO, π attack) is possible. The roles these orbitals play in controlling acid- and base-catalysed reactions of oxadiazolinones is currently under investigation in this laboratory.

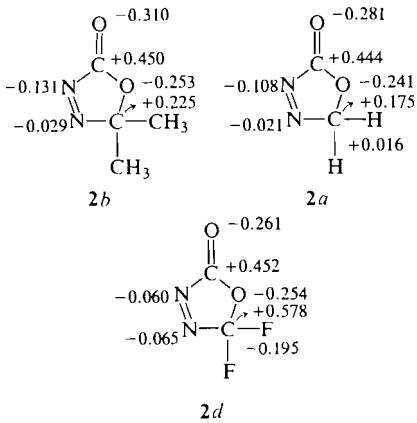

FIG. 3. CNDO/2 net charge densities.

The Photoelectron Spectrum of 2b

Only the three resolved low energy bands of the photoelectron spectrum of **2***b* (Fig. 4) are readily assigned by comparison to suitable models. The ordering of these IP's is verified by reference to the CNDO/2 orbital densities in Table 2. In all cases, the following discussion quotes only vertical IP's.

In *cis*-azoalkanes, the highest energy orbital, at 8–9 eV, is typically the n_N^- or antisymmetric combination of nitrogen lone pair orbitals. Most frequently, the π_{NN} MO is next highest (10.5–11.5 eV),

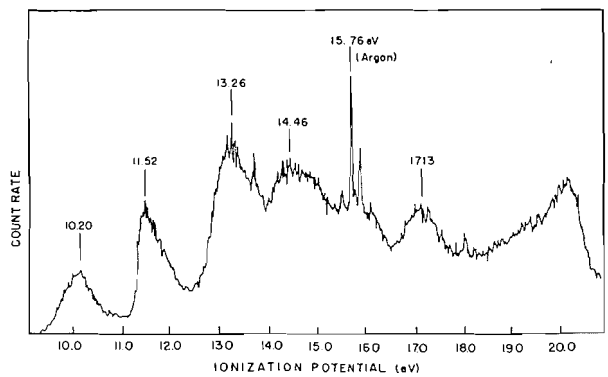

FIG. 4. Photoelectron spectrum of dimethyloxadiazolinone (**2***b*).

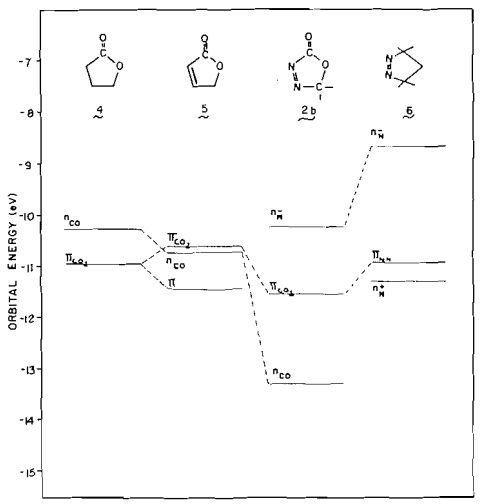

FIG. 5. Correlation diagram using measured valence IP's.

followed by the n_N^+ symmetric combination of nitrogen lone pair orbitals at 11–12 eV (5). Photoelectron spectra of oxadiazolinones are further complicated by the presence of the conjugated ester functional group. Oxygen lone pairs are usually of lower energy than nitrogen lone pairs owing to the increase in effective nuclear charge on going across the first row from C, N, O, to F. For example, n_{CO} and n_O IP's for ketones and esters range between 9.5 and 10.5 eV (21). Based on these and the following considerations, the first three resolved bands for **2***b* have been assigned to n_N^-, π, and n_{CO} (Table 2).

For the purposes of the assignment, the Correlation Diagram for Valence IP's (Fig. 5) features γ-butyrolactone (**4**), γ-crotonolactone (**5**), and 3,3,5,5-tetramethylpyrazoline (**6**) as suitable models. There are not really any more complex heterocyclic models appropriate for **2***b* in the PES literature.[3] CNDO/2 calculations and photoelectron spectra of lactones **4** and **5** have been reported (22).

The highest occupied π-type orbital in each of **4** and **5** contains significant contributions from the formally $2p_z$ lone pair on the ring oxygen and correlates more strongly with HO-π in **2***b* than does the π_{NN} of **6**. In recognition of this fact, the subscript CO_2 has been appended, where appropriate, to describe the electron distribution in this MO. Mixing of π_{NN} and π_{CO_2} in oxadiazolinones ought to raise the HO-π level by resonance but lower it inductively for a net stabilization. At 11.52 eV, the second IP is 0.6 eV lower than the isolated π_{CO_2} orbitals of **4** or **5** or π_{NN} of **6**.

Excluding the π-mixed lone pair orbital on the ring oxygen, four hetero atom lone pair IP's are important. Since they are on adjacent atoms, the nitrogen lone pairs interact the most, with carbonyl oxygen and ring oxygen lone pairs intermediate in energy. One expects the sequence $n_N^- > n_O, n_{CO} > n_N^+$, where n_O refers to the in-plane lone pair orbital on O1 with σ symmetry. The interaction of the azo nitrogen symmetry orbitals with the other lone pair orbitals of σ symmetry results in a widening of the n_N^-/n_N^+ energy gap (a resonance effect) and a lowering of the energy levels (a stabilizing inductive effect). The magnitude of the total effect may be seen by comparing the IP's of dimethyloxadiazolinone (**2***b*) and 3,3,5,5-tetramethylpyrazoline (**6**) (5).

Parameter	6	 2*b*
n_N^-	8.63 (eV)	10.20 (eV)
n_N^+	11.26 (eV)	>13.3 (eV)
$\Delta(n^-/n^+)$	2.63	>3.1

Because the 13.26 eV ionization has been assigned to the carbonyl oxygen lone pair, the n_N^+ orbital must have an IP higher than 13.3 eV. Thus, the interaction energy $\Delta(n^-/n^+)$ has to be greater than 3.1 eV, which is indeed greater than in the pyrazoline. The CNDO/2 calculations predict $\Delta(n^-/n^+)$ to be 4.54 eV.

The observed carbonyl oxygen lone pair ionization for **2***b*, assigned at 13.26 eV, is much larger than the values of 10.25 eV for γ-butyrolactone (**4**) and 10.70 eV for γ-crotonolactone (**5**) (22), and well outside the normal range for ketones and esters (9.5–10.5 eV (21)). The effect of the double bonds on n_{CO} in **5** and **2***b* can only be inductive and the effect of N=N in this regard is much greater than C=C (compare the carbonyl stretching frequencies (footnote 3), to the 0.5 and 3.0 eV stabilization of n_{CO} in **5** and **2***b* with respect to **4**). Additionally, interaction of lone pair orbitals in **4** and **5** is of the n_{CO}/n_O type and acts to

[3]A referee has suggested that 5,5-dimethyl-2-oxazolidinone (**7**) might also be a useful model but this has been resisted because the lactam nitrogen in **7** is electron donating by virtue of the fact that its lone pair has π symmetry and is strongly mixed with the carbonyl π bond and ring oxygen lone pair of π symmetry. In contrast, lone pairs on the electron withdrawing azo nitrogens of **2***b* are in the plane of the molecule (σ symmetry). Furthermore, the carbonyl stretching frequencies of **4**, **5**, **7**, and **2***b* occur at 1740 (29*a*), 1785 and 1750 (a doublet in the unsaturated lactone (30)), 1750 (29*b*) and 1835 cm^{-1}, respectively, indicating that there is no profit in using the lactam nitrogen to model the effect of the azo group on carbonyl IP's of **2***b*.

raise the n_{CO} level in these compounds while σ mixing in **2***b* is more complex but will raise n_N^-, lower n_O, and might not affect n_{CO} too much. The n_N^- orbital of **2***b* is stabilized 1.6 eV with respect to that of **6**, with an IP (10.20 eV) well above the usual value of 8–9 eV (5). Without the oppositely acting destabilizing σ interactions anticipated for the n_N^-, the n_{CO} orbital might well be stabilized by more than this amount. CNDO/2 calculated IP's adequately predict a dramatic stabilization: 12.83, 13.74, and 15.15 eV for n_{CO} in **4**, **5**, and **2***b*.

Also salient to this discussion are the effects of substitution at C5, as in **2***a* and **2***d*, on the calculated IP's. Successive substitution of hydrogen then fluorine for methyl reduces the electron density on the carbonyl oxygen by 9 and 16%, respectively (Fig. 3), and this is reflected in 1 to 2 eV stabilizations of all three valence orbitals in **2***d* with respect to **2***b* (Fig. 2). In spite of their physical remoteness, fluorines at C5 are able to transmit their effect to the carbonyl oxygen because the CF_2 moiety contributes π-type symmetry orbitals, strongly withdrawing π electron density to reduce the net charge densities, even at O6. In a qualitative sense, these MO calculations fortify attributing the large stabilization of n_{CO} to a generalized inductive effect of the strongly electron-withdrawing azo function adjacent to the carbonyl.

Consistent then with carbonyl stretching frequency data, the three model compounds and the MO calculations on the three oxadiazolinones, 13.26 eV seems the most reasonable assignment of the n_{CO} band.

As usual, the CNDO/2 calculation has overestimated the ionization potentials, in this case by some 1.5 to 2.5 eV (compared to the usual figure of 4 eV (22–24)), and has correctly reproduced the ordering of the first few highest occupied MO's. Hence, the assigned photoelectron spectrum does seem to validate our initial choice of structural parameters.

Electronic Transition Energies

A further check on our calculation entailed an examination of the electronic transitions of dimethyloxadiazolinone (**2***b*). The uv–visible spectrum in hexane (Fig. 6) exhibits two bands: one at 372 nm ($\varepsilon_{max} = 348\ M^{-1}\ cm^{-1}$) whose structure collapses in more polar solvents, and another at 214 nm ($\varepsilon_{max} = 2880\ M^{-1}\ cm^{-1}$). Even for simple azoalkanes electronic transition assignments of all but $n_N^- \rightarrow \pi^*$ have been frequently disputed (5, 25, 26). Here the CNDO/2 method predicts five possible transitions (Table 3) which might be responsible for the observed higher energy transition, often casually assigned as $\pi \rightarrow \pi^*$. Of these, the single $\pi \rightarrow \pi^*$ candidate ought to be most intense ($\varepsilon_{max} \gtrsim 10\,000$). Any

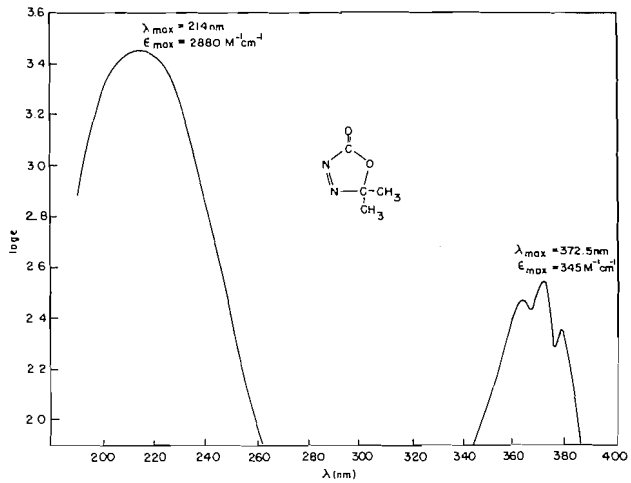

FIG. 6. Absorption spectrum of dimethyloxadiazolinone (hexane).

TABLE 3. Calculated and observed excitation energies for dimethyloxadiazolin-2-one (**2***b*)[a]

Transition	J_{ij}	K_{ij}	$\Delta E_{i\rightarrow j}$	Observed
$n_N^- \rightarrow \pi^*$	9.95	0.00	5.2	3.24
$\pi_{CO_2} \rightarrow \pi^*$	7.83	1.21	10.3	
$n_{CO} \rightarrow \pi^*$	8.52	0.01	9.0	
$n_O \rightarrow \pi^*$	7.85	0.01	10.6	5.80
$n_N^+ \rightarrow \pi^*$	9.80	0.03	9.9	
$n_N^- \rightarrow \pi^{**}$	9.57	0.00	9.8	

[a]All energies in eV.

of the $n \rightarrow \pi^*$ type should have an $\varepsilon_{max} \sim 100$, similar to that for α,β-unsaturated esters (27). However, the observed intensity is intermediate. It is not beyond the realm of possibility that an ε_{max} of 2880 $M^{-1}\ cm^{-1}$ reflects a fortuitous combination of several nearly degenerate $n \rightarrow \pi^*$ transitions, perhaps on the low energy tail of a $\pi \rightarrow \pi^*$ band. Further speculation on this matter would be inappropriate here.

Effects of Variations in R_{CO}

The carbonyl bond length turns out to be one of the key parameters in the entire calculations, and as such deserves some attention. Computations on the oxadiazolinone **2***a* with R_{CO} = 1.16, 1.19, 1.21, 1.24, 1.27, and 1.29 Å found a CNDO/2 total energy minimum at 1.261 Å. Although CNDO bond lengths are known to be unreliable (17) and nothing can be inferred from this particular value, it is significant, however, that the calculated energy gap between first and second IP's is a strong function of the selected bond length: declining from 0.97 eV at 1.16 Å to 0.04 eV at 1.29 Å (Fig. 7). That a gap of 1.32 eV is observed for **2***b* strongly supports our choice of a relatively short carbonyl distance and may well indicate the possibility $R_{CO} < 1.19$ Å.

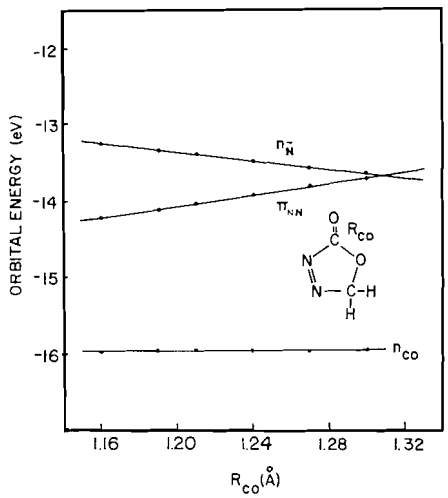

FIG. 7. Valence orbital energy depends on choice of R_{CO} for oxadiazolinone **2***a*.

Smoothly monotonic against decreasing R_{CO}, frontier densities change as expected for increasing electronegativity of the CO moiety but are not significantly altered. Shrinking the CO bond increases the electrophilicity of C3, N4, and N5 in both the charge and frontier controlled senses, thereby rationalizing the high reactivity of oxadiazolinones toward nucleophiles.

As a final note on the bond dimension issue, an apparently minor change in heteroatom; that is replacement of ring oxygen by nitrogen (i.e., in a Δ^1-1,2,4-triazolin-3-one) would result in a substantially longer equilibrium bond length (cf. R_{CO} = 1.26 in azodicarbonamide (8)) and also much different chemistry. In particular, triazolinones are less susceptible to aqueous hydrolysis than oxadiazolinones.[4]

Conclusions

The choice of an alternate theoretical procedure is unlikely to effect a metamorphosis of the electron distributions reported herein. Even though we have shown that the CNDO/2 computational method gives a reasonable picture of Δ^3-1,3,4-oxadiazolin-2-ones, it is obvious from the orbital densities in Table 2 that the classification or assignment of orbitals as n_N, n_{CO}, n_O, π_{CO_2}, π_{NN}, etc., is unrealistic and oversimplified. It is extremely difficult to identify orbital mixing patterns for such a complex molecule, in spite of its low symmetry. For example, π_{NN} contains about a third of the electron density on O1 as well as on each of N3 and N4; because the C—H bonds in **2***a* transform with π symmetry, they are mixed into every π orbital; in the orbitals designated as n_N^- and n_N^+, only half the σ electron density is found on the nitrogens and the third highest occupied molecular orbital, n_{CO} has only a third of the electron density on the oxygen. Under circumstances such as these, the significance of the terms 'lone pair' and two electron 'bond' crumbles.

[4]A. J. Paine and J. Warkentin. Unpublished results.

Experimental

5,5-Dimethyl-Δ^3-1,3,4-oxadiazolin-2-one (**2***b*) was prepared in 80% yield from the ketone semicarbazone as previously described (1). Samples for PES were twice sublimed at 0.01 Torr from 0°C to a Dry Ice – acetone cold finger and maintained at −20°C in the dark prior to use. The photoelectron spectrometric equipment of Professor D. C. Frost (28) was used to obtain the spectrum of **2***b*: a sample pressure of 10^{-5} Torr was employed and no evidence for any decomposition product IP's was observed during spectrum acquisition.

Hexane for the ultraviolet spectrum was purified by overnight treatment with H_2SO_4 and careful fractionation from $CaSO_4$. This material had a uv cutoff at 190 nm on a Cary Model 14 spectrophotometer.

Horseradish peroxidase. XXVIII. Formation and reactivity of the alkaline form. Evidence for an enzyme–substrate complex in compound 1 formation

DOMINIQUE JOB[1] AND H. BRIAN DUNFORD

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 30, 1977

DOMINIQUE JOB and H. BRIAN DUNFORD. Can. J. Chem. **56**, 1327 (1978).

The rate of formation of **1** from horseradish peroxidase and hydrogen peroxide is investigated as a function of p*H* between p*H* 9.5 and 11.5. For p*H* values smaller than 10, the rate depends linearly on hydrogen peroxide concentration, whereas between p*H* 10 and 11.5, the rate displays saturation kinetics. Evidence is presented for the formation of an intermediate complex before compound **1** formation. Two parameters were measured as a function of p*H*: k_{app}, the apparent rate constant for compound **1** formation, and k_d, the dissociation rate constant of the intermediate complex to **1**. A third parameter, K_{app}, similar to a dissociation constant for the reaction was deduced from the two rate constants. The apparent rate constant k_{app} is p*H* independent for p*H* values <9.5 and is directly affected by ionization of only one group on the native enzyme with a p*K* of 11. The p*H* dependences of k_d and K_{app} require a minimum of two ionizations. One corresponds to a group on the native enzyme which ionizes at a p*H* lower than that of the present study, the second corresponds to the ionizable group with p*K* of 11. For cyanide binding to horseradish peroxidase over the same p*H* interval, saturation kinetics were not observed, yet the p*H* profile for k_{app} exactly parallels that for formation of **1** (when corrected for the effect of the ionization of HCN) and shows an inflection at the same p*H* value.

DOMINIQUE JOB et H. BRIAN DUNFORD. Can. J. Chem. **56**, 1327 (1978).

On a étudié, en fonction du p*H* entre 9.5 et 11.5, la vitesse de formation du composé **1** à partir de la peroxydase du raifort et du peroxyde d'hydrogène. A des valeurs de p*H* plus basses que 10, la vitesse dépend d'une façon linéaire de la concentration de peroxyde d'hydrogène alors qu'à des p*H* allant de 10 à 11.5, la vitesse présente une cinétique de saturation. On présente des données indiquent qu'il y a formation d'un complexe intermédiaire avant la formation du composé **1**. On a mesuré deux paramètres en fonction du p*H*: k_{app}, la constante de vitesse apparente pour la formation du composé **1** et k_d, la constante de vitesse de dissociation du complexe intermédiaire en composé **1**. On a pu déduire un troisième paramètre, K_{app}, semblable à une constante de dissociation, de la réaction à partir des deux constantes de vitesse. La constante de vitesse apparente k_{app} est indépendante du p*H* à des valeurs de p*H* < 9.5 et est directement affectée par l'ionisation d'un seul groupe de l'enzyme à un p*K* de 11. Les relations qui existent entre le p*H* et k_d et K_{app} nécessitent la présence d'au moins deux ionisations. L'une correspond à un groupe sur l'enzyme qui s'ionise à un p*H* plus faible que celui utilisé dans l'étude présente alors que le deuxième correspond à un groupe ionisable avec un p*K* de 11. Pour la fixation de cyanure à la peroxydase de raifort au même intervale de p*H*, on n'a pas observé de cinétique de saturation même si le profil de p*H* pour k_{app} est exactement parallèle à celui de la formation du composé **1** (lorsqu'on l'a corrigé pour l'effet de l'ionisation de HCN) et présente une inflexion à la même valeur de p*H*.

Introduction

The presence of a water molecule coordinated to the iron atom of peroxidase has been accepted for many years (1–10). Recent nmr results have been interpreted to indicate both the presence[2] and absence (11) of water in the sixth coordination position of horseradish peroxidase (HRP) although the latter interpretation is suspect since it requires an explanation of why the sixth coordination position of the ferric iron is readily accessible to other ligands (12). Absorbance changes which are induced in an HRP solution by a p*H* jump from neutrality to above 10 have been attributed to the formation of a low-spin hydroxide complex of peroxidase (1, 8–10, 13). From a kinetic study of the alkaline transition of this enzyme the interesting proposal was made that an amino acid residue deprotonates in alkaline solution and becomes the sixth iron ligand as a slow conformational change occurs (14). A recent kinetic study of the alkaline transition of two turnip peroxidases has led to the proposal that these transitions can be explained most simply in terms of deprotonation reactions by hydroxide ions of a heme-linked

group for each enzyme (15). Since the alkaline transition of horseradish peroxidase is known to occur at a rate sufficiently slow to be studied with a conventional stopped-flow apparatus (14, 16) we have studied the effect of p*H* jumps on the absorption spectrum of HRP.

We also report the reactivity of alkaline peroxidase towards hydrogen peroxide and evidence for an intermediate in the formation of **1** is presented. Since cyanide binding to peroxidase is a simple ligand reaction (17, 18) this paper also compares it to formation of **1** over the p*H* range 9.5–11.5.

Experimental

Horseradish peroxidase (HRP) was purchased from two sources. One sample was obtained from Boehringer-Mannheim Corp. (lot 716 5528) and the second from Sigma Chemical Co. (lot 25C 9570). They were prepared for use by extensive dialysis against water which had been distilled five times. This water was used to prepare all solutions. The distillation procedure has been described (19) and the quality of the water is such that **1** prepared from stoichiometric amounts of HRP and hydrogen peroxide has a half-life greater than 2 h at 25°C and neutral p*H*. The purity of the enzyme prepared in this manner, as determined by the ratio of absorbances at 403 nm and 280 nm was 3.34 for the Boehringer enzyme and 3.0 for the Sigma enzyme. The concentration of peroxidase was determined spectrophotometrically at 403 nm using a molar absorptivity of 1.02×10^5 M^{-1} cm^{-1} (20). Analytical reagent grade hydrogen peroxide was obtained from Mallinckrodt Chemical works as a 30% aqueous solution. Its concentration was determined spectrophotometrically as described elsewhere (21) using the HRP assay. Potassium cyanide, potassium nitrate, and all buffer components were reagent grade and used without further purification. Carbonate–NaOH buffers were used between p*H* 9.0 and 10.9 and phosphate–NaOH buffers between 10.9 and 11.7. Stopped-flow experiments were performed on a Durrum–Gibson (model D-110) spectrophotometer, equipped with a 2-cm light path cuvette in which solutions of equal volumes were mixed. The temperature was maintained at 25 ± 0.1°C by circulating thermostated water. For p*H*-jump experiments a solution of unbuffered peroxidase, for which the ionic strength, μ, was adjusted to 0.1 with potassium nitrate, was mixed with buffered solutions (ionic strength 0.1 or 0.02 and then adjusted to 0.1 with potassium nitrate) of various p*H* values. Kinetics were recorded at 419 nm where alkaline peroxidase has its maximum absorptivity. For compound **1** formation or cyanide binding to peroxidase, one drive syringe contained peroxidase and buffer and the second drive syringe contained the substrate and buffer. Here too, the ionic strength was adjusted to 0.1 using potassium nitrate. All kinetic curves recorded were found to be first order. The observed rate constants were determined as described (22). Usually, eight individual determinations of the rate constant were performed. These were then averaged for a single best value with known standard deviation. After reaction, the solutions were collected for p*H* measurements with an Orion 801 digital p*H* meter in conjunction with a Fisher combination electrode. Absorbance measurements and optical spectra were obtained with a Cary 14 spectrophotometer.

Results

Alkaline Peroxidase Formation

For all p*H* values first-order kinetic curves have been recorded. The observed rate constant for the alkaline peroxidase formation process, $k_{obs}^{OH^-}$, increases linearly with hydroxide ion concentration as shown in Fig. 1 and leads to the relation

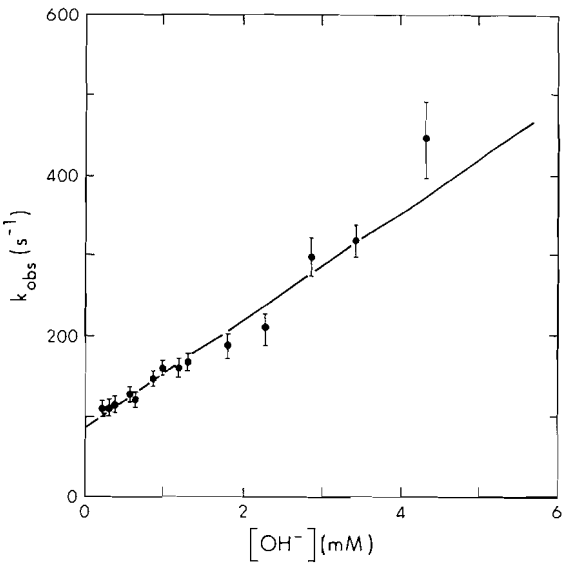

FIG. 1. Alkaline ionization of horseradish peroxidase. An unbuffered solution of HRP (2.45 μ*M*) is mixed with buffered solutions. Absorbance changes were recorded at 419 nm, temperature was 25°C, total ionic strength 0.1. The straight line obtained by a least-squares analysis corresponds to [1] in the text.

$$k_{obs}^{OH^-} = k_b[OH^-] + k_{-b} \quad [1]$$

The values of the slope and the intercept of this straight line determined by linear least-squares analysis[3] are $(7.8 \pm 0.5) \times 10^4$ M^{-1} s^{-1} and 78 ± 9 s^{-1}. These constants differ from those of Epstein and Schejter (14) by about 50 and 20%, respectively. Results similar to ours have been obtained by Yamazaki and Araiso (16). It was also observed that in addition to the process described above, two slow kinetic processes occurred. The spectral changes were small compared to the first fast step and they had half-lives of about 0.5 and 30 s. It is notable that the same behaviour was observed for the alkaline ionization of turnip peroxidase P_1 (15). The p*K* value of the alkaline HRP transition can be measured at equilibrium in a conventional way, by plotting $1/\Delta A_{419\ nm}$ vs. $1/[OH^-]$. One should obtain a straight line for which intercept with the $1/[OH^-]$ axis permits the evaluation of the p*K*. Such a plot constructed from 15 experimental points had a slope of 9.4 ± 0.7 m*M* and a $1/\Delta A_{419\ nm}$ intercept of 9.2 ± 0.5. The p*K* value deduced from

[3]Results are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

this plot was 11.00 ± 0.05, in agreement with the value reported (4) for 25°C and 0.11 μ.

Compound 1 Formation

The formation of **1** from HRP and hydrogen peroxide is described by the stoichiometric eq. 2 (23)

$$[2] \qquad \text{HRP} + H_2O_2 \xrightarrow{k_{app}^{H_2O_2}} \text{HRP-1}$$

For a sufficiently large excess of hydrogen peroxide below p*H* 10, a pseudo-first-order rate constant, $k_{obs}^{H_2O_2}$ can be defined as

$$[3] \qquad k_{obs}^{H_2O_2} = k_{app}^{H_2O_2}[H_2O_2]$$

Plots of $k_{obs}^{H_2O_2}$ vs. hydrogen peroxide concentration are linear at p*H* values of 9.51 and 9.87 (Fig. 2) as was found at more acidic p*H* values (18). For p*H* values >10, nonlinear plots are observed. In this high p*H* region

$$[4] \qquad k_{obs}^{H_2O_2} = \frac{k_d[H_2O_2]}{K_{app} + [H_2O_2]}$$

The significance of the symbols is found in the Discussion.

For $K_{app} > [H_2O_2]$ [4] reduces to the form of [3] so that $k_{app}^{H_2O_2} = k_d/K_{app}$. Equation 4 can be rearranged to

$$[5] \qquad \frac{1}{k_{obs}^{H_2O_2}} = \frac{1}{k_{app}^{H_2O_2}[H_2O_2]} + \frac{1}{k_d}$$

From the linear double-reciprocal plots (Fig. 3) $k_{app}^{H_2O_2}$ and k_d are obtained from the slopes and intercepts, and hence K_{app} can be calculated. To ascertain that the saturation effect obtained in the plot of $k_{obs}^{H_2O_2}$ vs. $[H_2O_2]$ at high H_2O_2 concentrations does indeed correspond only to HRP-**1** formation, absorption spectra were recorded on the Cary 14 spectrophotometer after mixing HRP at p*H* 11.2 with an excess of H_2O_2. One can see from the results of Fig. 4 that the first absorption spectrum that can be recorded after mixing contains a high percentage of HRP-**1**. The spectra presented in Fig. 4 also show that for wavelengths near 430 nm HRP-**1** and the native enzyme are nearly isosbestic at p*H* 11.2. Kinetic curves were recorded at 433 nm and it was observed that during the time of the fast process corresponding to HRP-**1** formation (based on the A_{410} nm measurements) almost no absorbance change occurred at 433 nm. Using a much slower time base, the absorbance at 433 nm does increase perhaps due to the spontaneous decay of HRP-**1** to HRP-**2**. These results indicate that the observed saturation effect in Fig. 2 is not due to some artifact such as the formation of HRP-**2**.

Plots of log (absorbance change) vs. time obtained at 410 nm illustrate that HRP-**1** formation at p*H* 11.55 obeys pseudo-first-order kinetics to a good approximation (Fig. 5). Figure 5 also shows that at p*H* 11.55, increasing the hydrogen peroxide concentration by a factor of 10 only increases the observed rate constant fourfold. The values of k_d, and $k_{app}^{H_2O_2}$ which were deduced at several p*H* values

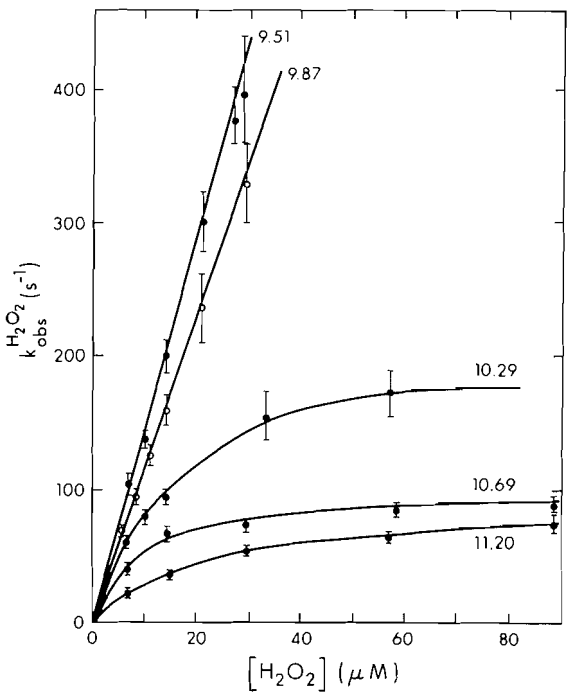

FIG. 2. Plots of k_{obs}, the pseudo-first-order rate constants for compound **1** formation, vs. $[H_2O_2]$. Peroxidase concentration was 0.77 μ*M*, temperature 25°C, total ionic strength 0.1. The p*H* at which each experimental point was determined is indicated on the plots.

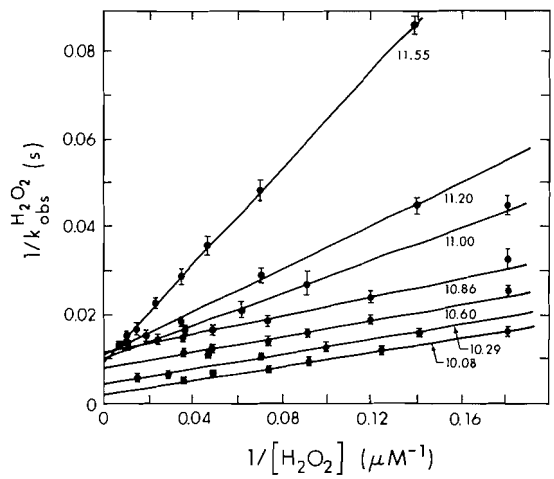

FIG. 3. Linear least-squares analysis of the double reciprocal plots for compound **1** formation. The conditions are those of Fig. 2.

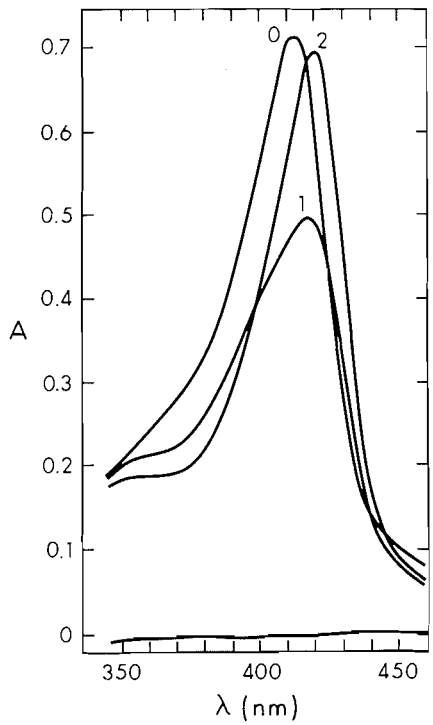

FIG. 4. Absorption spectra recorded after mixing HRP (7.7 μ*M*) with an excess of H_2O_2 (54.5 μ*M*) at p*H* 11.2 (phosphate–NaOH buffer 0.1 μ). Temperature was 25°C. Spectrum 0 was the spectrum of native enzyme, spectrum 1 was recorded just after mixing, and spectrum 2, 1 min after spectrum 1. The H_2O baseline is included.

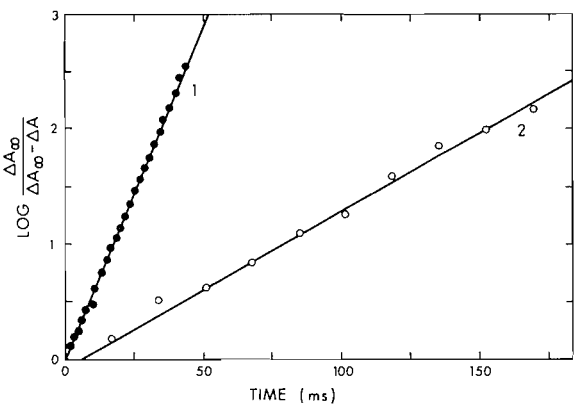

FIG. 5. Semilogarithmic plot of absorbance change at 410 nm vs. time for compound **1** formation, at p*H* 11.55, 0.1 μ, and 25°C The observed rate constants are given by the slopes of the straight lines: (*1*) $[H_2O_2] = 72$ μ*M*, $k_{obs} = 59$ s^{-1}; (*2*) $[H_2O_2] = 7.2$ μ*M*, $k_{obs} = 13$ s^{-1}; for both (*1*) and (*2*) [HRP] = 0.38 μ*M*. An induction period appears to be indicated by the results of (2).

from linear least-squares analysis of the Lineweaver–Burk plots of Fig. 3, are listed.[3] From these the value of K_{app} can be calculated. The values of K_{app} and $k_{app}^{H_2O_2}$ were corrected at the highest p*H* values in order to eliminate the effect of H_2O_2 ionization, since by use of the diffusion control limit rule (18) it has been shown that only the neutral form of hydrogen peroxide is reactive towards HRP to form compound **1**. A pK_a value of 12.0 was used for the dissociation of H_2O_2. Computed best fit curves obtained by nonlinear least-squares analysis to the $k_{app}^{H_2O_2}$ and k_d data as a function of p*H* are shown in Figs. 6 and 7 and the K_{app} data as a function of p*H* are shown in Fig. 8.

Cyanide Binding to HRP

As previously shown for the acidic p*H* range (17, 18), cyanide binding to HRP can be described by [6]

$$\text{HRP} + \text{HCN} \xrightarrow{k_{app}^{CN}} \text{HRP–CN} + \text{H}^+ \qquad [6]$$

where the behaviour of the proton is unknown (17, 18). Using a large excess of cyanide over HRP, the observed pseudo-first-order rate constant for the appearance of the HRP–cyanide complex is given by [7]

$$k_{obs}^{CN} = k_{app}^{CN}[\text{HCN}]_{total} \qquad [7]$$

while at p*H* values >10 plots of $k_{obs}^{H_2O_2}$ for HRP-**1** formation vs. $[H_2O_2]$ show a saturation effect at high H_2O_2 concentrations, the corresponding plots for the HRP–CN complex formation are linear.[3]

*p*H *Dependence of Kinetic Parameters*

Cyanide Binding to Peroxidase

Reaction 8 can account for the k_{app}^{CN} values

$$\begin{array}{ccccc} \text{H–HRP} & + & \text{HCN} & \xrightarrow{k} & \text{HRP–CN} + \text{H}^+ \\ K_{alk}\big\downarrow\big\uparrow \text{H}^+ & & K_L\big\downarrow\big\uparrow \text{H}^+ & & \\ \text{HRP} & & \text{CN}^- & & \end{array} \qquad [8]$$

where K_{alk} is the equilibrium constant for the formation of alkaline HRP and K_L the acid dissociation constant of HCN. The best values obtained from the analysis of the data are $k = (1.2 \pm 0.2)\ 10^5\ M^{-1}\ s^{-1}$, $pK_L = 9.00 \pm 0.08$, and $pK_{alk} = 11.00 \pm 0.15$ in comparison with previous values of $k = (1.1 \pm 0.2)\ 10^5\ M^{-1}\ s^{-1}$ and $pK_{alk} = 10.85 \pm 0.15$ (24).

*p*H *Dependence of the Kinetic and Equilibrium Parameters for HRP-1 Formation*

The data on the saturation effect are not extensive as a function of p*H* because (*i*) the saturation effect can only be detected with the stopped-flow machine above p*H* 10 and (*ii*) denaturation of the enzyme becomes noticeable above p*H* 11.6.

*(i) p*H *Dependence of* $k_{app}^{H_2O_2}$

The simplest empirical equation fitting these data was found to be

$$k_{app}^{H_2O_2} = \frac{(A_1/A_2)[H^+]}{1 + ([H^+]/A_2)} \qquad [9]$$

Use of a nonlinear least-squares program fitting the data to [9] led to the nonlinear correlation shown in Fig. 6 and the best fit parameters listed in Table 1.

The empirical eq. 9 can be interpreted in terms of collision theory using the simple scheme

$$\begin{array}{ccccc} \text{H–HRP} & + & \text{H}_2\text{O}_2 & \xrightarrow{k_1} & \mathbf{1} + \text{H}_2\text{O} \\ K_{alk}\big\downarrow\big\uparrow \text{H}^+ & & & & \\ \text{HRP} & & & & \end{array} \qquad [10]$$

which leads to

$$k_{app}^{H_2O_2} = \frac{(k_1/K_{alk})[H^+]}{1 + ([H^+]/K_{alk})} \qquad [11]$$

Reaction 10 is identical in form to reaction 8 used to account for k_{app}^{CN} values. From the data in Table 3,[3] $k_1 = (1.6 \pm 0.1) \times 10^7\ M^{-1}\ s^{-1}$ and $pK_{alk} = 10.85 \pm 0.07$, the identical value obtained from the cyanide results.

*(ii) p*H *Dependence of* k_d

Two empirical equations were found to fit equally well the data of k_d vs. p*H* for HRP-**1** formation.

$$k_d = A_3[H^+]^2 + A_4 \qquad [12]$$

or

$$k_d = A_5[H^+] + A_6 + (A_7/[H^+]) \qquad [13]$$

A linear least-squares analysis of k_d vs. $[H^+]^2$ is shown in Fig. 9, [12]. In the case of [13], A_6 has a

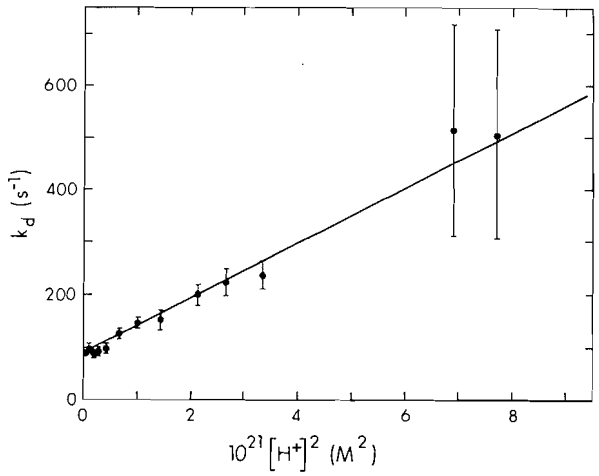

FIG. 9. Linear least-squares analysis of k_d vs. $[H^+]^2$ for compound **1** formation. The straight lines correspond to [12] in the text.

very large standard deviation ($A_6 = 145 \pm 175\ s^{-1}$). Making $A_6 = 0$ led to $A_5 = (4.6 \pm 0.3)10^{12}\ M^{-1}\ s^{-1}$ and $A_7 = (3.3 \pm 0.5)10^{-10}\ M\ s^{-1}$, values compatible with the values of A_5 and A_7 listed in Table 1. The nonlinear correlation using the parameters of Table 1 and [13] is shown in Fig. 7.

(iii) pH Dependence of K_{app}

The K_{app} values were obtained experimentally by the ratio $K_{app} = k_d/k_{app}^{H_2O_2}$. A relatively satisfactory fit for the data of K_{app} vs. p*H* was obtained using the nonlinear correlation fitting the data for $k_{app}^{H_2O_2}$ [9] and for k_d [12] or [13]. From these relations, it was possible to generate empirical curves for K_{app} vs. p*H* going through the experimental points as shown in Fig. 8.

Discussion

The detection of saturation kinetics at alkaline p*H* values indicates that an enzyme–substrate complex exists which is a precursor to **1**. Similar results have been observed for deuterohemin (25, 26) and catalase (27). The two-step mechanism shown in [14],

$$[14]\quad HRP + H_2O_2 \underset{k_{-s}}{\overset{k_s}{\rightleftharpoons}} (HRP\text{-}H_2O_2) \xrightarrow{k_d} HRP\text{-}\mathbf{1}$$

is characterized by [15] (see for instance ref. 28)

$$[15]\quad (k_{1,2})^2 - k_{1,2}(k_d + k_{-s} + k_s[H_2O_2]) + k_s k_d[H_2O_2] = 0$$

where $k_{1,2}$, a parameter yet to be determined, can be defined as

$$[16]\quad k_{1,2} = (k_d + k_{-s} + k_s[H_2O_2] \pm \sqrt{D})/2$$

with

$$\sqrt{D} = (k_d + k_{-s} + k_s[H_2O_2]) \times \left(1 - \frac{4k_d k_s[H_2O_2]}{(k_d + k_{-s} + k_s[H_2O_2])^2}\right)^{1/2}$$

For the particular case that

$$[17]\quad 4k_d k_s[H_2O_2] \ll (k_d + k_{-s} + k_s[H_2O_2])^2$$

$$[18]\quad k_1 = k_d + k_{-s} + k_s[H_2O_2]$$

$$[19]\quad k_2 = \frac{k_d k_s[H_2O_2]}{k_d + k_{-s} + k_s[H_2O_2]}$$

Equation 19 is of the same form as [4] with $k_2 = k_{obs}^{H_2O_2}$ and $(k_d + k_{-s})/k_s = K_{app}$. This is a direct analogy to equations derived under steady-state conditions where K_{app}, the Michaelis–Menten constant equals $(k_d + k_{-s})/k_s$ according to the Briggs–Haldane treatment (29) and can lie between k_{-s}/k_s (Michaelis–Menten assumption (30)) and k_d/k_s (Van Slyke and Cullen assumption (31)). Equation 18 predicts that an induction period $\tau_1 = 1/k_1$ should exist for compound **1** formation (32). Since k_d is the only experimentally determined constant in [18] it can be used to place limits on the other constants of the equation. If $k_d > k_{-s}$ and $k_s[H_2O_2]$, then use of the listed values[3] of k_d indicates that τ_1 should be close to 10 ms for p*H* values between 10.7 and 11.6. There appears to be a finite induction period for plot 2 in Fig. 5, where $[H_2O_2]$ is small.

The similarity of cyanide binding to HRP and compound **1** formation in regard to the p*H* effect on the second-order rate constant has been previously reported for the acidic p*H* range (18). The present results show that this trend is also found for the alkaline p*H* range: cyanide binding to HRP is also inhibited by ionization of a group with p*K* of 11.00 ± 0.15, as is compound **1** formation. Cyanide binding to HRP could perhaps also be described by a two-step mechanism analogous to [14].

$$[20]\quad HRP + HCN \underset{k_{-s}^{CN}}{\overset{k_s^{CN}}{\rightleftharpoons}} (HRP\text{–}HCN) \xrightarrow{k_d^{CN}} HRP\text{–}CN + H^+$$

No saturation effect on k_{obs}^{CN} was obtained at high cyanide concentrations. One possibility might be that in [20], the constant, $K^{CN} = (k_d^{CN} + k_{-s}^{CN})/k_s^{CN}$ is much greater than [HCN]. Then (by comparison with [4])

$$[21]\quad k_{obs}^{CN} = \frac{k_d^{CN} k_s^{CN}}{k_d^{CN} + k_{-s}^{CN}}[HCN] = k_{app}^{CN}[HCN]$$

The p*H* dependence of the k_{app}^{CN} and $k_{app}^{H_2O_2}$ data are simply explained in terms of collision theory by reactions 8 and 11 in which ionization of a single

group defined by K_{alk} inhibits the two reactions. However, when the $k_{app}^{H_2O_2}$ results are analyzed in terms of their component parts, k_d and K_{app}, a more complicated picture arises. An explanation of the saturation kinetics requires the formation of an enzyme–substrate complex and the pH dependence of k_d (hence K_{app}) requires a minimum of two ionizations. A full description of the analysis is available.[3] The two-step mechanism in [14] in which preequilibrium formation of a precursor complex occurs before formation of **1** is in agreement with theoretical considerations (12). The rate controlling step in both reactions may represent the displacement of the water molecule, if present in the sixth coordination position of the heme iron. An associative, rather than a dissociative mechanism is indicated, since in the latter case, the loss of the water molecule would be rate limiting, yet the rates of compound **1** formation and cyanide binding differ by a factor of 100. The similarity of the k_{app} data vs. pH for both cyanide binding and compound **1** formation does not extend to lactoperoxidase where there must be mechanistic differences for the two processes (33, 34).

The alkaline ionization of HRP can be discussed in terms of the proton transfer process

$$[22] \qquad BH^+ + OH^- \underset{k_{-b}}{\overset{k_b}{\rightleftharpoons}} B + H_2O$$

for which the rate expression is

$$[23] \qquad k_{obs}^{OH^-} = k_b[OH^-] + k_{-b}$$

This is of identical form to the HRP results fitted to [1] and leads to a value of pK = 11.00 ± 0.08 for the formation of the alkaline form of HRP, in agreement with the value determined from equilibrium measurements. As proposed for the turnip peroxidases (15), the simplest explanation for the observed results presented in Fig. 1 is that BH^+ represents a water molecule in the sixth coordination position of the heme iron and that B represents the hydroxide ion in the sixth coordination position as in methemoglobin and metmyoglobin. The small rate constants corresponding to [1] would indicate that hydroxide ion is displacing the water molecule (in which case the removal of the water molecule might be rate limiting), or if it is abstracting a hydrogen ion from the ligand water molecule, the reaction is slowed by an appropriately placed and negatively charged electrostatic gate (35). The possibility that an amino acid residue deprotonates in alkaline solution and becomes the sixth iron ligand cannot be excluded by our data (14). The latter mechanism (analogous to [15] for instance) predicts that the reaction should display first-order saturation kinetics. This behavior was not observed (Fig. 1) but rather k_{obs} was found to be a linear function of $[OH^-]$, as it was for turnip peroxidases P_1 and P_7 (15). However there is an experimental limitation on the magnitude of $[OH^-]$. In this regard the elegant work of Iizuka *et al.* (36) is of great interest. These workers have combined the quadrature phase detection technique with high resolution nmr, which enables them to detect hyperfine shifts in the immediate environment of a paramagnetic ion. Also conformational changes of the protein during the overall process leading to alkaline peroxidase formation are indicated, since the sedimentation constant value of HRP decreases from $S_{20,w}$ = 3.61 at pH 7.2 to 3.03 S at pH 11.0 (37). The two slow kinetic processes observed during the alkaline transition of HRP might correspond to such conformational changes.

The pK value for the formation of alkaline HRP would appear to be well established by four independent methods: 10.85 ± 0.08 (Fig. 7, log $k_{app}^{H_2O_2}$ vs. pH); 11.00 ± 0.15 (log k_{app}^{CN} vs. pH); 11.00 ± 0.05 (spectrophotometric titration with hydroxide ion); and 11.00 ± 0.08 ([5] results from [1], from the kinetics of the OH^- reaction with HRP). The mean value is 10.96 ± 0.09 at 25°C and μ = 0.1 which can be compared with results of other workers under somewhat different conditions (1, 13, 36, 38, 39).

Nuclear analogs of β-lactam antibiotics. VIII. Synthesis of 3-acetoxymethyl-Δ^3-*O*-2-isocephems[1]

TERRY THOMAS CONWAY,[2] GARY LIM, JAMES LESLIE DOUGLAS,[2] MARCEL MENARD, TERRENCE WILLIAM DOYLE,[3] PIERRE RIVEST, DONALD HORNING, LEESON R. MORRIS, AND DENIS CIMON

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received December 12, 1977

TERRY THOMAS CONWAY, GARY LIM, JAMES LESLIE DOUGLAS, MARCEL MENARD, TERRENCE WILLIAM DOYLE, PIERRE RIVEST, DONALD HORNING, LEESON R. MORRIS, and DENIS CIMON. Can. J. Chem. **56**, 1335 (1978).

The synthesis of 7β-(-2′-thienylacetamido)-3-acetoxymethyl-Δ^3-*O*-2-isocephem-4-carboxylic acid (**17**) is described. Thus treatment of enol mesylate **3***a* or triflate **3***b* with triethylamine gave the allene **4** which gave the diiodide upon treatment with iodine. The diiodide gave benzyl 7β-azido-3-acetoxymethyl-Δ^3-*O*-2-isocephem-4-carboxylate (**12**) on treatment with potassium acetate in DMF. Hydrogenolysis of **12** gave the amino acid **16** which was converted to **17** upon treatment with 2-thienylacetyl chloride. Resolution of **17** into its optical antipodes was carried out. The antibiotic activities of racemic **17** and each antipode is compared to that of cephalothin. Antibiotic activity was found to reside in the dextrorotatory isomer.

TERRY THOMAS CONWAY, GARY LIM, JAMES LESLIE DOUGLAS, MARCEL MENARD, TERRENCE WILLIAM DOYLE, PIERRE RIVEST, DONALD HORNING, LEESON R. MORRIS et DENIS CIMON. Can. J. Chem. **56**, 1335 (1978).

On décrit la synthèse de l'acide (thiényl-2′ acétamido-7β) acétoxyméthyl-3 Δ^3-*O*-isocéphem-2 carboxylique-4 (**17**). Ainsi le traitement du mésylate énolique **3***a* ou triflate **3***b* par la triéthylamine conduit à l'allène **4** qui fournit le dérivé diiodé par réaction avec l'iode. Le diiodure conduit à l'azido-7β acétoxyméthyl-3 Δ^3-*O*-isocéphem-2 carboxylate-4 de benzyle (**12**) par réaction avec l'acétate de potassium dans le DMF. L'hydrogénolyse de **12** fournit l'acide aminé **16** qui peut être transformé en **17** par réaction avec le chlorure de thiényl-2 acétyle. La résolution de **17** en antipodes optiques a été réalisée. On compare les activités antibiotiques du **17** racémique et de chacun de ses antipodes avec celles de la céphalothine. On a trouvé que l'isomère dextrorotatoire possède l'activité antibiotique.

[Traduit par le journal]

Recent reports from a number of laboratories attest to the continuing interest in β-lactam antibiotics with modified nuclei, both from natural sources and by total synthesis (2). In the earlier papers of this series we have described the syntheses of a number of nuclear analogs of the cephalosporins **1***a–m* in which the sulfur at the 1 position has been replaced by a carbon atom and the carbon atom at the 2 position by a hetero atom. In each of these cases the substituent at position 3 was hydrogen, methyl, or aralkyl. In view of the pronounced improvement of activity observed when the 3 substituent is acetoxy methyl in the natural series, we desired an entry into these systems as well. In this paper we should like to report the synthesis of the 3-acetoxymethyl-*O*-2-isocephem system **1***n*.[4]

number of other attempts to oxidize the 3-methyl group. The fortuitous observation that the enol mesylate **3** could be converted in high yields to the allene **4** eventually provided an entry into the desired 3-acetoxymethyl-*O*-2-isocephems (Scheme 1). Thus in the preparation of **3***a* (4) it was noticed that if an excess of triethylamine was used in the reaction of the enol **2** (5) with mesyl chloride and the reaction mixture was allowed to stand at room temperature, the bismesylate disappeared and a new olefinic signal appeared at 5.65 δ in the nmr spectrum which was assigned to the allenic protons in **4** (Table 1). A by-product of this reaction was the *O*-2-isocephem **6** which was formed in variable yields. We speculate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

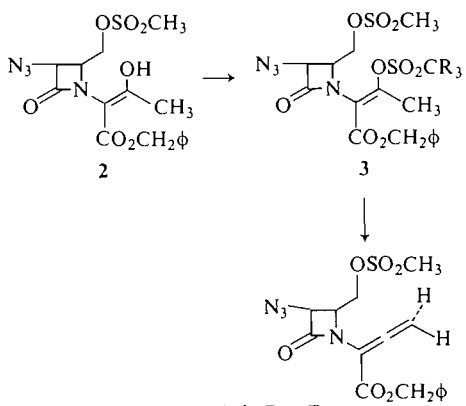
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

that **6** was formed by fragmentation of the initially formed mesylate to give **5** which under the reaction conditions cyclized to yield **6** (Scheme 2). To avoid this side reaction it was decided to prepare **4** via the triflate **3***b* rather than the mesylate **3***a*. Thus treatment of **2** with triflic anhydride (6) in the presence of triethylamine at $-10°C$ gave, after work-up, **3***b* as a mixture of geometric isomers in 71% yield.

Stang and Hargrove (7) have reported the conversion of vinyl triflates to allenes in low to moderate yields by treatment of the triflates at 100°C in quinoline. In the case of **3***b* the conversion to **4** proceeded in high yield (>90%) under mild conditions. Treatment of **3***b* in methylene chloride at 0°C with 1 equiv. of triethylamine and letting the solution come to 23°C over 15 min gave a virtually quantitative yield of allene. Although the allene could be isolated it proved to be relatively unstable and was usually used immediately in the subsequent step. The observation of facile allene formation in our case represents an extension of Stang and Hargrove's original work (7) to vinyl triflates derived from β-keto esters and may well provide access to other members of this elusive class of compounds.

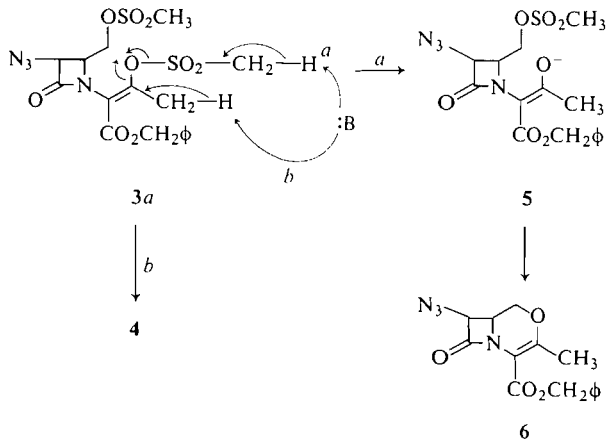


a R = H *b* R = F

SCHEME 1

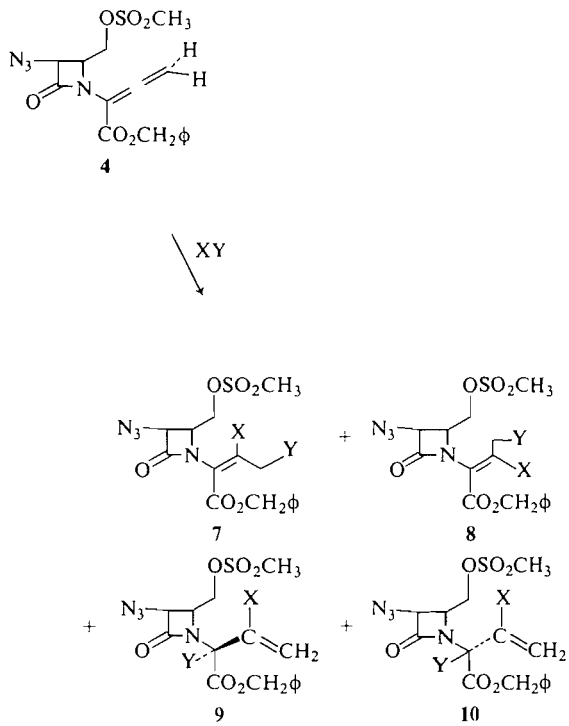
A priori a number of ways to convert the allene **4** to the desired 3-methyl-substituted-*O*-2-isocephems might be envisioned. Electrophilic addition to the allene might well be expected to give products at the right level of oxidation. Accordingly, the halogenation of **4** was examined. In principle one would expect to obtain as many as four possible products from the reaction (8) arising from the four possible allylic cations which might be generated (Scheme 3).

Treatment of **4** with 1 equiv. of chlorine in methylene chloride gave a mixture of products. The product mixture exhibited olefinic signals in the nmr at 6.23 and 5.83 δ as sets of doublets, and singlets at 4.74 and 4.27 δ. These have been assigned



SCHEME 2

to **9***c* and **10***c*, and **7***c* and **8***c*, respectively, and are in an approximate ratio of 1:1:1:1. In view of the complexity of the mixture, further work using chlorination was abandoned. We next turned our attention to bromination of **4**. Treatment of **4** with 1 equiv. of bromine led to a mixture of dibromides. Chromatography of the mixture on silica gel gave a



7 ⟶ **10** *a* X = I = Y
b X = Br = Y
c X = Cl = Y
d X = SMe Y = Cl

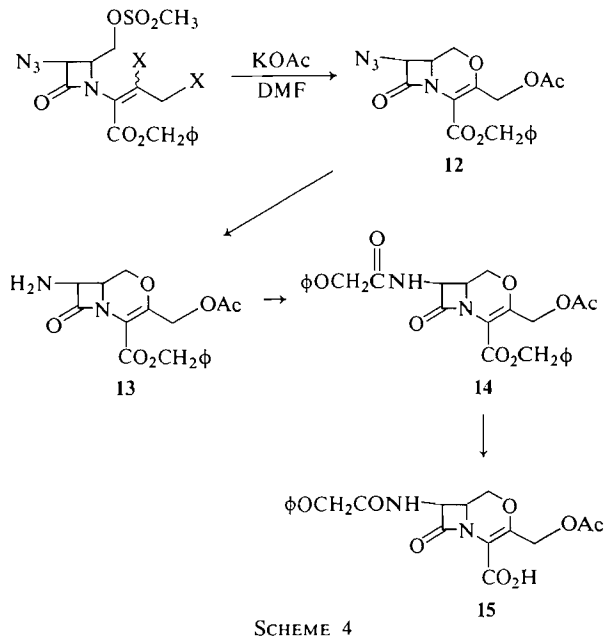
mixture of the desired dibromides **7***b* and **8***b*[5] in 45% yield.

Treatment of **4** with a solution of iodine in methylene chloride gave the diiodides **7***a* and **8***a* analytically pure in 91% yield. In addition to the above halogenations, attempts were also made to react the allene with a number of other electrophiles such as 2,4-dinitrobenzenesulfenyl chloride, isobutanesulfenyl chloride, methane sulfenyl chloride, *tert*-butyl hypochlorite, sodium hypochlorite, hydrogen peroxide, potassium permanganate, and peracids. For the most part these experiments yielded only polymer. In the case of methanesulfenyl chloride (9) a low yield of an adduct (32%) identified as a mixture of **7***d* and **8***d* by its spectral characteristics was obtained. The uv maximum at 307 nm (ε 7700) was especially diagnostic of the sulfur atom bound at the central atom of the allene (1).[6]

With the dibromides (**7***b* and **8***b*) and diiodides (**7***a* and **8***a*) in hand the conversion of these to the *O*-2-isocephem system was examined next. Thus treatment of either the diiodide or the dibromide with an excess of potassium acetate in dimethylformamide gave the desired intermediate **12** in 35–60% yields (Scheme 4). Although the yield of **12** from the dibromides was higher, the overall yield from the allene was greater using the diiodide. It should also be noted that it was possible to go from the enol **2** to the 3-acetoxymethyl-*O*-2-isocephem **12** without the necessity of isolating the intermediates. Presumably compound **12** arose via displacement of the terminal iodide or bromide by acetate, Michael addition of acetate to the double bond with halide elimination,



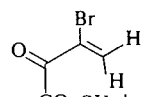
SCHEME 4

hydrolysis of the vinyl acetate to give the enolate, and finally ring closure of enolate. The sequence in which the displacement steps occur is unclear. Attempts to selectively displace the allylic halide failed. The structure of **12** was supported by its elemental analysis, ir and nmr spectra, and by subsequent conversions.

Reduction of **12** using hydrogen sulfide – triethylamine gave the amine **13** in 60% yield. Treatment of **13** with *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (10) (EEDQ) and phenoxyacetic acid gave the amide **14** in 69% yield. Hydrogenolysis of **14** yielded the desired 7β-(phenoxyacetamido)-3-acetoxymethyl-Δ^3-*O*-2-isocephem-4-carboxylic acid (Scheme 4). Compound **15** showed antibiotic activity greater than that observed for the 3-methyl analog.

To provide a comparison of the antibiotic activity of a 2-isocephem with a commercially available cephalosporin, the synthesis of a cephalothin analog was attempted next. Thus hydrogenation of the azido ester **12** over palladium gave a near quantitative yield of the crude amino acid **16** as its hydrochloride salt. Suspension of this salt in aqueous sodium bicarbonate followed by addition of 2-thienylacetyl chloride (11) gave after work-up the racemic 7β-(2′-thienylacetamido)-3-acetoxy methyl-Δ^3-*O*-2-isocephem-4-carboxylic acid (**17**) in 51% overall yield from **12** (Scheme 5). Resolution of the racemic mixture was achieved using (+)-α-methylbenzylamine to give the dextrorotatory enantiomer and (−)-α-methylbenzylamine to give the levorotatory enantiomer. The antibiotic activities of the racemic mixture, both

[5]In addition to **7***b* and **8***b*, a small amount of a third component tentatively identified as **11** on the basis of its spectral characteristics was isolated.



11

[6]Although the products from the addition of Cl_2, Br_2, or I_2 to the allene would not permit one to distinguish between the mechanistic pathways proceeding through the allylic or vinyl cations, those from the addition of methane sulfenyl chloride to **4** do.

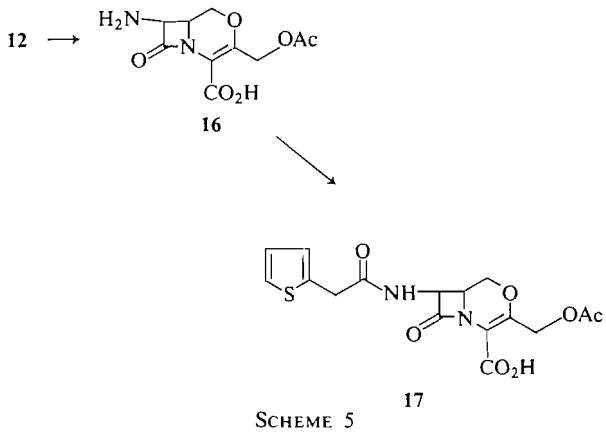
enantiomers, and cephalothin against a number of organisms is summarized in Table 2.

As is evident from Table 2 the activity of our cephalothin analog resides primarily in the dextrorotatory isomer (+)-**17** (13). The activity of (+)-**17** compares favorably with that of cephalothin. A more extensive discussion of the bioactivities of compounds in this series will appear elsewhere.



SCHEME 5

Experimental

The ir spectra were recorded on a Unicam Sp-200G grating, ir spectrometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois.

Synthesis of **3**b

A solution of the enol **2** (48.0 g, 0.117 mol) in 400 ml of dichloromethane was cooled to −10°C under nitrogen and a solution of triflic anhydride (33.0 g, 0.117 mol) in 100 ml of dichloromethane was added over several minutes. A 10% solution of triethylamine in dichloromethane was added dropwise with stirring until the reaction mixture was weakly basic to p*H* paper (about 0.14 mol of triethylamine was required). The reaction solution was immediately washed with cold 10% hydrochloric acid (500 ml) followed by water (2 × 500 ml). The dichloromethane solution was dried (sodium sulfate) and filtered through 260 g of activity III silica gel. The silica gel was extracted with a further 2 L of dichloromethane. The dichloromethane was evaporated *in vacuo* from the combined extracts to give the triflate **3***b* as a yellow oil 38.3 g (71% yield) (mixture of two isomers). This material was of adequate purity for subsequent reactions. An analytical sample containing one isomer was prepared by recrystallization from ethanol, mp 57–59°C; ir (Nujol mull): 2150, 2120, 1785, 1730 cm^{-1}. *Anal.* calcd. for $C_{17}H_{17}F_3N_4O_4S_2$: C 37.67, H 3.14, N 10.33, S 11.82; found: C 37.40, H 3.12, N 10.43, S 11.73.

Preparation of **7** *and* **8**

A solution of triethylamine (1.01 g, 10 mmol) in 14 ml of dichloromethane was added with stirring to a solution of triflate **3***b* (5.42 g, 10 mmol) in 54 ml of dichloromethane at 0°C. The solution was allowed to warm to 23°C over 15 min.[7] A solution of halogen (10 mmol) in 75 ml of dichloromethane was added dropwise with stirring over 30 min. The resulting solution was washed with water (2 × 150 ml), dried (sodium sulfate), treated with activated charcoal (ca. 1 g), filtered, and the solvent was evaporated *in vacuo* to give **7** and **8** as an oil.

Diiodide 7 and **8***a* was obtained analytically pure, 5.88 g (91% yield). *Anal.* calcd. for $C_{16}H_{16}I_2N_4O_6S$: C 29.74, H 2.50, N 8.67, I 39.28, S 4.96; found: C 29.76, H 2.47, N 8.61, I 39.37, S 5.18.

Dibromide **7** and **8***b* was obtained as a mixture of isomers which could be purified by column chromatography on activity I silica gel (elution with dichloromethane) to give pure **7** and **8***b*, 2.5 g (45% yield). *Anal.* calcd. for $C_{16}H_{16}Br_2N_4O_6S$: C 34.80, H 2.92, N 10.15; found: C 35.25, H 2.97, N 10.02.

Dichloride 7 and **8***c* was obtained as a crude mixture of four isomers plus degradation products.

A by-product isolated by chromatography of the bromination reaction was tentatively identified as compound **11**: ir (mull): 1735, 1705 cm^{-1}.

Preparation of **7** *and* **8**d

The allene was prepared immediately before use in this reaction from 1.08 g (2.00 mmol) of the triflate in the usual manner.

The methanesulfenyl chloride was prepared immediately before use by the method of Douglass (9).

The allene (2.00 mmol) in 20 ml of CH_2Cl_2 was cooled to −5 to −10°C and the freshly prepared solution of MeSCl (2.00 mmol) in 3 ml of CH_2Cl_2 was added with stirring under nitrogen. After 10 min at −5°C, the solution was washed with dilute $Na_2S_2O_3$, then brine, and evaporated *in vacuo* to give a yellow oil. The oil was absorbed from CH_2Cl_2 onto 5 g of silica gel and placed (dry) on a 50 g silica gel column (activity III). The column was eluted with ether; 30 ml fractions were collected and monitored by tlc (silica, ether). Fractions showing one spot at about R_f 0.43 were combined and the solvent was evaporated *in vacuo* to give the product (306 mg, 32%

[7]The allene **4** may be isolated at this point by washing the solution with water, drying (Na_2SO_4), and evaporating the solvent *in vacuo*. The allene decomposes over several days at 0°C.

yield) as a pale yellow oil; uv λ_{max} 309 mμ (ε 7700); (film): 2120, 1775, 1705 cm^{-1}.

Benzyl 7β-Azido-3-acetoxymethyl-Δ³-O-2-isocephem-4-carboxylate (12)

A mixture of dihalide **7** and **8***a* or *b* (10 mmol), potassium acetate (40 mmol, finely ground), dimethylformamide (50 ml), and water (0.1 ml) was stirred vigorously at 23°C for 20 h. The resulting solution was mixed with ether (250 ml) and washed with water (5 × 250 ml). The ether solution was dried (sodium sulfate) and evaporated *in vacuo* to give a brown residue. The residue was dissolved in dichloromethane and passed through 10 times its weight of activity III silica gel. The solvent was evaporated *in vacuo* and the crude product was recrystallized from benzene–hexane to give pure *O*-2-cephem **12** (35–60% yield),[8] mp 97–98°C; ir (Nujol mull): 2160, 2110, 1775, 1750, 1705, 1600 cm^{-1}. *Anal.* calcd. for $C_{17}H_{16}N_4O_6$: C 54.84, H 4.33, N 15.05; found: C 55.19, H 4.47, N 14.89.

Benzyl 7β-Amino-3-acetoxymethyl-Δ³-O-2-isocephem-4-carboxylate (13)

Hydrogen sulfide was bubbled into a solution of azide **12** (793 mg, 2.1 mmol), triethylamine (210 mg, 2.1 mmol), and dichloromethane (15 ml) for 10 min. Nitrogen was passed through the solution to remove excess hydrogen sulfide and the solvent was evaporated *in vacuo*. The residue was mixed with ether and extracted with 10% hydrochloric acid three times. The acid extract was washed with ether, made basic with sodium bicarbonate, saturated with sodium chloride, and extracted three times with dichloromethane. The dichloromethane extract was washed with saturated sodium chloride, dried (Na_2SO_4), and the solvent was evaporated *in vacuo* to give amine **13** as a colorless oil, 415 mg (60% yield); ir (film): 3400, 1775, 1745, 1715, 1620 cm^{-1}. *Anal.* calcd. for $C_{17}H_{18}N_2O_6$: C 58.95, H 5.24, N 8.09; found: C 58.39, H 5.32, N 7.95.

Benzyl 7β-(Phenoxyacetamido)-3-acetoxymethyl-Δ³-O-2-isocephem-4-carboxylate (14)

A solution of amine **13** (415 mg, 1.2 mmol), phenoxyacetic acid (183 mg, 1.2 mmol), EEDQ (325 mg, 1.3 mmol), and dichloromethane (15 ml) was stirred at 23°C for 1.5 h. The solution was washed with 10% hydrochloric acid, saturated sodium chloride, 10% sodium bicarbonate, and saturated sodium chloride (20 ml each). The resulting solution was dried (Na_2SO_4) and the solvent was evaporated *in vacuo* to give an oil. The oil was chromatographed on activity III silica gel (elution with ether). Amide **14** was obtained as colorless crystals, 400 mg (69% yield), mp 146°C; ir (Nujol mull): 3320, 1775, 1745, 1725, 1690, 1535, 1625 cm^{-1}. *Anal.* calcd. for $C_{25}H_{24}N_2O_8$: C 62.49, H 5.04, N 5.83; found: C 62.58, H 5.07, N 5.83.

7β-(Phenoxyacetamido)-3-acetoxymethyl-Δ³-O-2-isocephem-4-carboxylic Acid (15)

A mixture of ester **14** (100 mg, 0.21 mmol), 10% palladium-on-charcoal (100 mg), and tetrahydrofuran (50 ml) was hydrogenated with agitation at 23°C and 40 psi for 15 min. The catalyst was removed by filtration and the solvent was evaporated *in vacuo*. The crude product was recrystallized from ethanol to give *O*-2-cephem **15**, 50 mg (62% yield), mp 160–170°C (dec.); ir (Nujol mull): 3400–2500, 1785, 1720, 1705, 1645, 1550, 1620 cm^{-1}. *Anal.* calcd. for $C_{18}H_{18}N_2O_8$: C 55.38, H 4.65, N 7.18; found: C 55.32, H 4.88, N 7.13.

[8]Higher yields were obtained if pure dibromide was used rather than pure diiodide; however, since the yield of dibromide from allene was less than diiodide, better overall yields were obtained via the diiodide.

7β-Amino-3-acetoxymethyl-Δ³-O-2-isocephem-4-carboxylic Acid (16)

A mixture of azide **12** (5.0 g, 13.4 mmol), palladium chloride (1.2 g, 7.1 mmol), and anhydrous ethanol (300 ml) was hydrogenated with agitation at 23°C and 50 psi for 1 h. The catalyst was removed by filtration and the solvent was evaporated *in vacuo* to give the hydrochloride salt **16** as an amorphous solid, 4.2 g (100% yield). Because of its instability, the product was not purified further; ir (Nujol mull): 3400–2500, 1770, 1740–1690, 1610 cm^{-1}.

7β-(2′-Thienylacetamido)-3-acetoxymethyl-Δ³-O-2-isocephem-4-carboxylic Acid (17)

Hydrochloride salt **16** (4.2 g, 13.4 mmol) was mixed with 150 ml of water and sodium bicarbonate (7.5 g, 90 mmol) was added at 0°C. A solution of 2-thienylacetic acid chloride[9] (4.5 g, 28 mmol) in 50 ml of acetone was added with stirring to the aqueous solution. The mixture was stirred for 1 h at 0°C, then washed with ether (2 × 100 ml). The aqueous solution was acidified with 10% hydrochloric acid and extracted with dichloromethane (2 × 100 ml). The dichloromethane extract was dried (Na_2SO_4) and the solvent was evaporated *in vacuo*. The residue was crystallized by trituration with ether to give (±)-*O*-2-cephalothin **17**, 2.6 g (51% overall yield from **12**). An analytical sample was prepared by recrystallization from anhydrous ethanol, mp 182°C (dec.); uv_{max} (EtOH): 272 nm, ε 8650; ir (Nujol mull): 3300–2500, 1780, 1750, 1720, 1680, 1535, 1620 cm^{-1}. *Anal.* calcd. for $C_{16}H_{16}N_2O_5S$: C 50.52, H 4.24, N 7.37, S 8.43; found: C 50.34, H 4.41, N 7.47, S 8.45.

The acid **17** (1.0 g, 2.64 mmol) was dissolved in warm isopropyl alcohol (50 ml) and (+)-α-methylbenzylamine (0.32 g, 2.64 mmol) was added. The precipitate was collected by filtration and washed with isopropanol and ether. The precipitate was mixed with 10% hydrochloric acid and extracted with dichloromethane. The dichloromethane extract was dried (Na_2SO_4) and the solvent was evaporated *in vacuo*. The residue was crystallized by trituration with ether. The resolution procedure was repeated twice more (until material of constant rotation was obtained) to give (+)-*O*-2-cephalothin ((+)-**17**) with $[\alpha]_D$ +116° (acetone); (145 mg, 14.5% yield). The mother liquors from the above resolution were similarly treated with (−)-α-methylbenzylamine to give (−)-*O*-2-cephalothin ((−)-**17**) with $[\alpha]_D$ −115° (acetone).

Nuclear magnetic resonance studies. XXXII.[1] Rearrangement, isomerization, and deuterium exchange via β-enolization in bicyclooctenones. A ^{2}H nuclear magnetic resonance study

A. K. CHENG[2] AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 2, 1977

A. K. CHENG and J. B. STOTHERS. Can. J. Chem. **56**, 1342 (1978).

The equilibration of the α,α-dimethyl derivatives of bicyclo[2.2.2]octenone, bicyclo[3.2.1]-oct-2-en-6-one, and its Δ^3 isomer has been examined at 155 and 185°C in *tert*-BuO$^-$/*tert*-BuOH. Using ^{2}Hmr spectroscopy the rates and stereoselectivity of hydrogen–deuterium exchange in each of these ketones have been determined for equilibrations with *tert*-BuOD as solvent. The relative reactivities for exchange at the allylic and vinylic sites compared to the analogous results for the corresponding olefins reveal a significant activating effect of the carbonyl group. Comparison of the data with those for the corresponding saturated ketones shows that the double bond enhances the rate of isomerization appreciably and increases the bias of the equilibrium toward the [3.2.1] skeleton.

A. K. CHENG et J. B. STOTHERS. Can. J. Chem. **56**, 1342 (1978).

On a étudié, à 155 et 185°C dans le *tert*-BuO$^-$/*tert*-BuOH, l'équilibration des dérivés α,α-diméthylés de la bicyclo[2.2.2]octénone, de la bicyclo[3.2.1]octène-2 one-6 et de son isomère Δ^3. Utilisant la spectrométrie rmn du ^{2}H, on a déterminé les vitesses et la stéréosélectivité des échanges hydrogène-deutérium dans chacune de ces cétones au cours d'équilibrations faisant appel au *tert*-BuOD comme solvant. Les réactivités relatives pour l'échange aux sites allyliques et vinyliques comparées aux résultats analogues pour les alcènes correspondants mettent en relief un effet activant important du groupement carbonyle. Une comparaison de ces données avec celles obtenues pour les cétones saturées correspondantes montre que la double liaison augmente d'une façon appréciable la vitesse d'isomérisation et augmente la préférence de l'équilibre en faveur du squelette [3.2.1].
