[Traduit par le journal]

The synthesis and reactions of unsaturated pyranosides have long been an area of interest in this laboratory (1) and in pursuing this interest we have developed and published preparative procedures for the enones **1** (2*a*; see also 2*b* and earlier work by P. M. Collins), **2** (3), and **3** (4). The unsaturated lactone **4** has also been prepared in our laboratory[2] and hence the potential exists for carrying out conjugate addition reactions at carbons 1, 2, 3, and 4. Indeed many of these enones have been utilized in this way, having been proved of value for the syntheses of branched-chain (5, 6) and amino (7) sugars as well as for photoalkylation (8) and cycloaddition (9) reactions.

The enone **5** is the only missing member of the series and for this reason we decided to attempt its synthesis. Like compound **1**, compound **5** is a vinylogous ester but experience with **1** has shown that these systems undergo conjugate 1,4-additions in good yield (5, 6*a*, 10). Thus availability of **5** would open the possibility of preparing pyranosides with a variety of substituents at carbon 5.

Apart from the foregoing reasons, methods for introducing olefinic unsaturation between carbons 4 and 5 are of interest since this feature is present in at least two antibiotics. The first reported was sisomicin (11) and more recently the antibiotic from *Oospora virescens* has also been found to be a hex-4-enopyranoside (12).

Of the existing methods for introducing unsaturation between carbons 4 and 5, β elimination from aldehydes or uronate derivatives such as **6** (X = H or *O*-alkyl) is the most frequently encountered (13).

However S_Ni reactions of hex-5-enopyranosides **7** bearing a good leaving group (e.g., Z = OTs) (14) have been observed. Cope and Hofmann eliminations from an *N*-oxide and quaternary ammonium salt, respectively, have been carried out by Stevens and Chitharanjan (15).

For our study, the starting material was the ketone **8** which is available in good yield in three steps from methyl α-D-glucopyranoside (16). The conversion of **8** into **5** was conceived to involve the axial iodide (cf. **14***a*) from which β elimination of hydrogen iodide should be a facile process. In pursuit of this idea, the diol **9**, prepared by acid-catalysed debenzylidination of **8**, was treated with benzoyl chloride at low temperature in the hope of obtaining the primary benzoate **12***a*. In the event, a dibenzoate was produced (in addition to some tribenzoate **10***b*), which was sulfonylated, the expected product being the mesylate **11***a*. Iodinolysis gave a crystalline iodide of correct elemental composition but which could not be dehydrohalogenated using a variety of organic or inorganic bases.

To confirm its structure the iodide was hydrogenolysed using Raney nickel. The nmr spectrum of the product contained a methyl doublet at 1.47 ppm with a coupling constant of 6 Hz which showed immediately that we had prepared the 6-deoxy substance **13***b* rather than a 4-deoxy isomer **14***b*. Thus monobenzoylation of the diol **9** had not occurred at the primary position giving **12***a* but rather at the secondary giving **10***a*, the latter then giving rise to the sulfonate **10***c* and thence the iodide **13***a*.

This unexpected course of selective benzoylation suggested that the 4-hydroxyl group was unusually acidic. This could probably be the result of the hydrogen bonding expressed in **15**. In this connection it is conceivable that **15** could undergo an ene–diol rearrangement giving **16** so that the product from the above series of transformations would be the

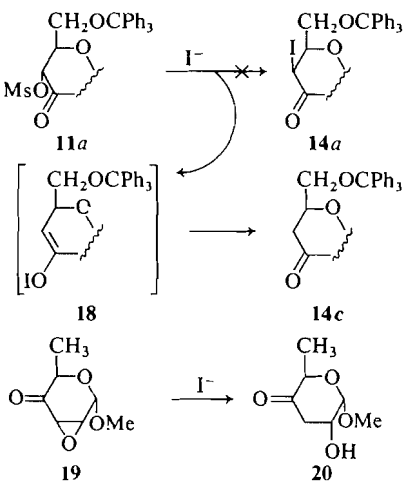
iodide **17** rather than **13***a*. This possibility was readily discounted by examining the 220 MHz nmr spectrum of the crystalline iodide (see Experimental). The signal for H-5 at 4.16 ppm was a triplet of doublets with spacings of 2.5, 7.3, and 10.0 Hz. The first two are assignable as couplings to H-6 and H-6′, whereas the last is clearly a *trans*-diaxial coupling as required by J_{45} of **13***a*. Structure **17** was therefore ruled out.



SCHEME 2

Selective protection of the primary hydroxyl group of **9** was in fact accomplished by tritylation giving **12***b*. Presumably the greater steric requirements of the triphenylmethyl group ensures reaction at the primary position, the greater acidity of the C-4 hydroxyl (cf. **15**) notwithstanding.

Sulfonylation of **12***b* proved to be problematic. With *p*-toluenesulfonyl chloride, the reaction proceeded in low yield and was not reproducible. On the assumption that this was due to steric hindrance of the hydroxyl group of **12***b* the procedure for hindered alcohols using methanesulfonyl chloride and triethylamine in methylene chloride (17) was tried. This reaction however took an unexpected course giving a sultone (18). However upon treatment with methanesulfonyl chloride and pyridine in the usual way, **11***b* was obtained in quantitative yield.

Iodinolysis of **11***b* with sodium iodide in methyl ethyl ketone gave two products which were poorly resolved on tlc but a sodium fusion test on the mixture indicated that neither contained iodine. Removal of the trityl group gave separable products, and the major one was judged to be **14***d* on the basis of the mass spectrum and elemental analysis of its *p*-nitrobenzoate. In confirmation of this the 220 MHz nmr spectrum of **14***c* (see Experimental) showed the C-4 methylene protons, identifiable by double irradiation of H-5.

The process of reductive elimination presumably involves the enolic hypoiodite **18**. A comparable process has recently been reported by Paulsen and co-workers (19) for conversion of the oxirane **19** into the alcohol **20**.

In light of the failure to obtain the iodide **14***a* by iodinolysis of **11***b* it was decided to see whether the desired β elimination could be carried out on the sulfonate **11***b* itself. It was reasoned that since carbon 4 is an enolisable centre, treatment with base could cause epimerisation to **21**, and β elimination should then follow since the entities to be eliminated are in the desired antiparallel geometry.

In the event, when the sulfonate **11***b* was treated with diazabicyclononene in tetrahydrofuran–benzene solution at room temperature, the starting material disappeared after 15 min. The product obtained in 39% yield after chromatography, proved to be a mixture of the α-D-*glycero* (**5**) and β-L-*glycero* (**22**) derivatives. Obviously the desired elimination had occurred but had been accompanied by extensive epimerisation at carbon 2. The low yield was in part due to the fact that considerable detritylation occurred during the reaction judging from the amount of triphenylcarbinol detected on tlc. How-

ever there was no evidence for detritylated **5** or **22** among the substances isolated from the chromatographic column. If the reaction was allowed to go for 30 min, the enones **5** and **22** were completely destroyed.

It proved impossible to resolve **5** and **22** using a variety of solvent systems. However the infrared spectrum of the mixture showed, apart from the benzoate absorption at 1735 cm^{-1}, absorptions at 1696 and 1603 cm^{-1} for the α-enone chromphore. In the α-enone **1** the corresponding absorptions are at 1700 and 1600 cm^{-1} (2).

The 220 MHz nmr spectrum (see Experimental) of the mixture showed clearly two sets of signals for the protons on carbons 1, 2, 4, and 6 for the epimers **5** and **22**. The two doublets at 5.44 and 5.86 ppm with a common coupling constant of 3.5 Hz was readily recognized as belonging to H-1 and H-2 of **5** in view of the similarity of these parameters to those of **13***a* (H-1 at 5.40, H-2 at 5.75; J_{12} = 4.0 Hz). A second pair of doublets at 5.34 (H-1) and 5.57 ppm (H-2) with a common coupling of 9.0 Hz indicated that epimerisation had occurred at carbon 2 and that the conformation of the substance, **22**, was as indicated in the drawing (Scheme 3). In both **5** and **22**, an allylic coupling of 1 Hz was observed between H-4 and H-6.

The methoxyl signals of **5** and **22** were clearly resolved at 3.48 and 3.55 ppm, respectively, the assignment being made by comparing their integrated intensities with those of the ring protons described in the preceding paragraph. The ratio of **5** and **22** was thereby determined as 1.4:1.

The mass spectrum of the mixture of **5** and **22** (see Experimental) showed a parent ion of 520.18948 in excellent agreement with the calculated value of 520.18860. The peak for $M^+ - OCH_3$ also showed good correspondence, 489.16542 vs. 489.17021.

In summary, although the first three steps (see Scheme 1) **8** → **9**, **9** → **12***b*, and **12***b* → **11***b* could be carried out in 93%, 77%, and quantitative yields, respectively, conditions could not be found for carrying out the β elimination smoothly. The iodinolysis of **11***b*, instead of giving **14***a*, took an alternative course (Scheme 2) and although treatment with base did afford the desired enone **5**, epimerisation giving **22** also occurred. In addition these enones **5** and **22** proved to be quite labile to base.

Studies aimed at overcoming the problems encountered in the preparation of **5** are currently underway.

Experimental

General

Melting points were determined on a Fischer-Johns heating stage or a Mel-Temp apparatus and are uncorrected. The ^{1}Hmr spectra were determined, unless otherwise stated, in deuteriochloroform containing 1% tetramethylsilane as internal standard with either a Varian T-60 or a Varian HA 100. Coupling constants were obtained by measuring spacings of spectra judged to be first order.

Thin-layer chromatography (tlc) was performed on glass plates coated with silica gel (HF-254, E. Merck) to a thickness of 0.3 mm. The chromatograms were first viewed under ultraviolet light, then exposed to iodine vapor, and finally sprayed with concentrated sulfuric acid. Heating in an oven was required for complete visualization. For column chromatography, E. Merck silica gel (0.05–0.20 mm, 70–325 mesh A.S.T.M.) was used.

*Methyl 2-*O*-Benzoyl-*α*-*D*-ribo-hexopyranosid-3-ulose (**9**)*

Methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-*D*-*ribo*-hexopyranosid-3-ulose, **8** (16) (6.4 g, 17.2 mmol) was dissolved in dioxane (0.25 ℓ), heated to 50°C in an oil bath, and 1% sulfuric acid (52 ml) was then added with stirring. After 8 h barium carbonate (35 g) was added and the suspension stirred until the pH was 7, whereupon the salts were removed by filtration through Celite. After concentration of the filtrate the residue was chromatographed on a 1 ft silica column to give 4.7 g (93%) as a syrup; R_f (EtOAc – petroleum ether 1:1) 0.09; nmr ($CDCl_3$) δ: H-1, 5.34 (1H, d, J_{12} = 4 Hz); H-2, 5.68 (1H, broad d); H-4, 4.55 (1H, broad d, J_{45} = 9 Hz); H-5, H-6, H-6′, OH, 3.3–4.3 (5H, m, 2 hydrogens exchange D_2O); OMe, 3.42 (3H, s); OBz centered at 7.5, 8.1 (5H, m).

*Methyl 2,4-Di-*O*-benzoyl-*α*-*D*-ribo-hexopyranosid-3-ulose (**10**a)*

The diol **9** (4.7 g, 15.9 mmol) was dissolved in 1:1 dry pyridine – methylene chloride (100 ml) and cooled to below −40°C in a Dry Ice – 2-propanol bath. Benzoyl chloride (2.00 ml, 15.9 mmol) was diluted with dry methylene chloride (20 ml) and added dropwise to the cold solution over 2.5 h. After 1 additional hour the flask was placed in the freezer compartment of the refrigerator for 2 days. Then, water (15 ml) was added and most of the pyridine was removed on a rotary evaporator. The residue was taken up in ether (150 ml) and washed successively with water, dilute HCl, water, and saturated sodium bicarbonate. The first water wash yielded 0.59 g of unreacted diol. The dried (Na_2SO_4) organic layer yielded a colourless syrup which upon tlc (EtOAc – petroleum ether 1:1) showed two products with R_f 0.52 and 0.23. These were isolated by silica column chromatography in 1.3 and 3.1 g, respectively, and shown to be the tribenzoate (**10***b*) and dibenzoate (**10***a*). Spectral data for **10***a*: nmr ($CDCl_3$) δ: H-1, 5.38 (1H, d, J_{12} = 4 Hz); H-2, 5.78 (1H, d); H-4, 5.85 (1H, d, J_{45} = 10 Hz); H-5, 4.27 (1H, broad d); H-6, H-6′, 3.94 (2H, broad s); OH, 3.3 (1H, broad s) exchangeable with D_2O, OMe, 3.45 (3H, s); OBz centered at 7.5 and 8.1 (10H, m). Irradiation at 5.8 δ (H-4 and H-2) collapses H-5 and H-1 to singlets.

*Methyl 2,4-Di-*O*-benzoyl-6-*O*-methanesulfonyl-*α*-*D*-ribo-hexopyranosid-3-ulose (**10**c)*

The dibenzoate **10***b* (0.72 g, 1.8 mmol) was dried by azeotropic distillation with toluene on a rotary evaporator. Dry pyridine (12 ml) was added and the solution cooled in ice and methanesulfonyl chloride (0.43 ml, 5.4 mmol) was added over 15 min. After 4 h at 0°C, water was added and the mixture was processed in the usual way. A homogeneous, mobile syrup **10***c* 0.65 g, R_f 0.29 (EtOAc – petroleum ether 1:4) was thereby obtained. Spectral data: nmr ($CDCl_3$) δ: H-1, 5.40 (1H, d, J_{12} = 4 Hz); H-2, 5.79 (1H, d); H-4, 5.71 (1H, d, $J_{45} \simeq$ 10 Hz); H-5, H-6, H-6′ centered at 3.57 (3H, broad s); OCH_3, 3.51 (3H, s); OMs, 3.05 (3H, s); OBz centered at 7.5 and 8.1 (10H, m).

*Methyl 6-Deoxy-2,4-di-*O*-benzoyl-6-iodo-*α*-*D*-ribo-hexopyranosid-3-ulose (**13**a)*

The syrupy sulfonate **10***b* (0.615 g, 1.25 mmol) was dissolved in methyl ethyl ketone and sodium iodide (0.364 g, 2.3 mmol) added. Thin-layer chromatography after 8 h refluxing showed only the iodide **13***a* and so the solution was filtered and the solvent removed. The ethereal solution (150 ml) of the residue was washed twice with aqueous sodium thiosulfate, once with aqueous sodium bicarbonate and water (100 ml portions), and the solution was then allowed to stand over decolourizing carbon and sodium sulfate. Syrupy **13***a* was obtained in quantitative yield, R_f 0.27 (EtOAc – petroleum ether 1:4) and crystallization was effected from methanol. After one recrystallization from methanol: mp 123.5–124°C; $[\alpha]_D^{23}$ +63.5°, (*c* 3.67, $CHCl_3$); spectral data: nmr 220 MHz ($CDCl_3$) δ: H-1, 5.401 (1H, d, J_{12} = 4.0 Hz); H-2, 5.750 (1H, dd, J_{24} = 1.0 Hz); H-4, 5.495 (1H, dd, J_{45} = 10.0 Hz); H-5, 4.16 (1H, ddd, J_{56} = 2.5 Hz, $J_{56'}$ = 7.3 Hz); H-6′, 3.436 (1H, dd, H-6, H-6′ form an AB, $J_{66'}$ = 11.0 Hz); H-6, 3.60 (1H, dd); OMe, 3.53 (3H, s); OBz centered at 7.39, 7.53, and 8.03 (10H, m). *Anal.* calcd. for $C_{21}H_{19}O_7I$: C 49.42, H 3.75, I 24.87; found: C 49.35, H 3.58, I 25.07.

*Methyl 6-Deoxy-2,4-di-*O*-benzoyl-*α*-*D*-ribo-hexopyranosid-3-ulose (**13**b)*

The iodide **13***a* (0.10 g, 0.19 mmol) was dissolved in acetone, (20 ml) an excess of W2 Raney nickel (20) added and the suspension was refluxed with stirring. After 25 h the solution was filtered and the solvent removed to give 0.075 g of **13***b* as a syrup. Thin-layer chromatography showed one spot of R_f 0.59 (EtOAc – petroleum ether 1:1). Spectral data: nmr ($CDCl_3$) δ: H-1, 5.30 (1H, d, J_{12} = 4 Hz); H-2, 5.72 (1H, d); H-4, 5.35 (1H, d, J_{45} = 10 Hz); H-5, 4.33 (1H, dq, J_{56} = 6 Hz); C—C—$H_{3'}$, 1.47 (3H, d); OMe, 3.49 (3H, s); OBz centered at 7.5 and 8.1 (10H, m). The mass spectrum shows a *m/e* 384 parent ion (0.05% of the *m/e* 105 base peak) and loss of methoxy (31) to give *m/e* 353 (0.3%; metastable at *m/e* 324.5) and benzoic acid (122) to give *m/e* 231 (0.8%).

*Methyl 2-*O*-Benzoyl-6-*O*-trityl-*α*-*D*-ribo-hexopyranosid-3-ulose (**12**b)*

The diol **9** (19.8 g, 67 mmol) was dissolved in pyridine (130 ml) and trityl chloride (20.5 g, 73.5 mmol) was added. The solution was stirred at room temperature for 4 days when more trityl chloride (2.1 g, 7.5 mmol) was added. After 2 additional days when only a trace of **9** remained, the pyridine was removed by evaporation and the residue was taken up in a mixture of ether and water. The ether layer was washed with aqueous solutions of hydrochloric acid, sodium chloride, and sodium bicarbonate and then dried and decolourized. After filtration and concentration the residue was chromatographed on a silica column to give 17.4 g (77%) of compound **12***b*; R_f 0.23 (EtOAc – petroleum ether 1:4); nmr ($CDCl_3$) δ: H-1, 5.41 (1H, d, J_{12} = 4 Hz); H-2, 5.75 (1H, dd, J_{24} = 1.5 Hz); H-4, 4.52 (1H, broad d, J_{45} = 10 Hz); H-5, 3.87 (1H, ddd, $J_{56} \simeq$ 2.5 Hz); H-6, H-6′, OH, 3.2–3.6 (3H, m) changeable with D_2O; OMe, 3.48 (3H, s); $OCPh_3$, OBz, 7.0–7.6, 8.2 (20H, m).

*Methyl 2-*O*-Benzoyl-4-*O*-methanesulfonyl-6-*O*-triphenylmethyl-*α*-*D*-ribo-hexopyranosid-3-ulose (**11**b)*

The tritylate **12***b*, sulfonylated as described above for compound **10***a*, gave the desired substance **11***b* in essentially quantitative yield; R_f 0.17 (EtOAc – petroleum ether 1:4). Crystallisation was effected from methanol: mp 189–189.5°C; $[\alpha]_D^{23}$ +1.09°, (*c* 3.54, $CHCl_3$); spectral data: nmr ($CDCl_3$) δ: H-1, 5.35 (1H, d); H-2, 5.72 (1H, broad d, J_{12} = 4 Hz); H-4, 5.45 (1H, broad d, J_{45} = 10 Hz); H-5, 4.10 (1H, ddd, J_{56} = 2 and 4 Hz); H-6, H-6′, 3.5 (2H, broad s); OMe 3.48 (3H, s); OMs 3.05 (3H, s); $OCPh_3$, OBz, 7.1–7.7, 8.2 (20H, m). The mass spectrum showed a faint parent ion at *m/e* 616 and loss of phenyl (77) to give *m/e* 539 (1.3% of base peaks at *m/e* 105). *Anal.* calcd. for $C_{34}H_{32}O_9S$: C 66.217, H 5.231, S 5.200; found: C 66.23, H 5.27, S 5.08.

*Methyl 2-*O*-Benzoyl-4-deoxy-6-*O*-triphenylmethyl-*α*-*D*-erythro-hexopyranosid-3-ulose (**14**c)*

The sulfonate **11***b* (0.370 g, 0.6 mmol) was dissolved in methyl ethyl ketone (15 ml) and sodium iodide (0.166 g, 1.1 mmol) was added. After 2 days tlc showed the disappearance of the starting material and the solution was evaporated to dryness. The residue was taken up in ether and washed with sodium bicarbonate and water before being dried (Na_2SO_4). There was obtained 0.295 g of a foam whose nmr spectrum indicated a mixture of products. These were not well resolved on tlc but after chromatography of a small portion of the mixture on successive silica gel columns, the 4-deoxy compound **14***c* was isolated; R_f 0.32 (EtOAc – petroleum ether 1:4); $[\alpha]_D^{23}$ 26.4° (*c* 9.66, $CHCl_3$); spectral data: ir (CH_2Cl_2): 1730 (OBz), 1715 cm^{-1} (sh, ketone); nmr 220 MHz ($CDCl_3$) δ: H-1, 5.314 (1H, d, J_{12} = 4.0 Hz); H-2, 5.571 (1H, dd, J_{24a} = 0.75 Hz); H-4a, 2.709 (1H, ddd, J_{4a4e} = 14.0 Hz, J_{45} = 11.25 Hz, H-4a,4e form an AB); H-4e, 2.525 (1H, dd, J_{45} = 3.0 Hz); H-5, 4.211 (1H, dddd, J_{56} = 4.1 Hz, $J_{56'}$ = 5.1 Hz); H-6,6′ centered at 3.320 (2H, d-AB); OMe, 3.46 (3H, s); OBz, $OCPh_3$ centered at 7.29, 7.45, 8.11 (20H, m). Irradiation of H-4a changes H-5 to a narrow multiplet and collapses H-2 to a doublet and of H-4e changes H-5 to a ddd (5 lines). The mass spectrum shows a weak parent ion at *m/e* 522 which loses phenyl (77) to give *m/e* 445 (1.4% of the *m/e* 243 (trityl) base peak) and then C_6H_4 (76) to give *m/e* 369 (0.4%).

*Methyl 2-*O*-Benzoyl-4-deoxy-*α*-*D*-erythro-hexopyranosid-3-ulose (**14**d)*

A portion of the tritylate (0.170 g, 0.33 mmol) **14***c* was dissolved in chloroform (10 ml) and cooled to −10°C in an ice–salt bath. Chloroform (5 ml) was cooled separately and hydrogen chloride was bubbled in for 1 min. Both solutions were then mixed and allowed to stand at −10°C. After 30 min tlc indicated that detritylation was complete and ammonia was bubbled into the solution. The precipitated ammonium chloride was removed by filtration through Celite and the filtrate evaporated to dryness. Chromatography on a short column of silica gel afforded the desired compound **14***d* (0.068 g, 75%); R_f 0.17 (EtOAc – petroleum ether 1:1); spectral data: nmr ($CDCl_3$) δ: H-1, 5.33 (1H, d, J_{12} = 4 Hz); H-2, 5.60 (1H, d); H-4a, H-4e, OH centered at 2.6 (3H, m); H-5, 4.27 (1H, m); H-6, H-6′ centered at 3.77 (2H, broad s); OMe, 3.45 (3H, s) OBz centered at 7.6 and 8.2 (5H, m).

The compound was characterized as the *p*-nitrobenzoate and recrystallized from methanol (small needles); mp 134-134.5°C. *Anal.* calcd. for $C_{21}H_{19}O_9N$: C 58.740, H 4.460, N 3.262; found: C 58.65, H 4.53, N 3.27.

*Methyl 2-*O*-Benzoyl-4-deoxy-6-*O*-triphenylmethyl-*α*-*D*-glycero-hex-4-enopyranosid-3-ulose (**5**) and Methyl 2-*O*-Benzoyl-4-deoxy-6-*O*-triphenylmethyl-*β*-*L*-glycero-hex-4-enopyranosid-3-ulose (**22**)*

The sulfonate **11***b* (0.306 g, 0.5 mmol) was dried by azeotroping twice with dry benzene using a rotary evaporator. The flask was transferred to a dry box and a solution (3.4 ml, 0.5 mmol) of diazabicyclononene (2.0 g) in dry tetrahydrofuran (100 ml) was added. A precipitate formed rapidly and after 5 min dry benzene (5 ml) was added and the solution was stirred under an atmosphere of nitrogen for 10 min. Saturated aqueous ammonium chloride (20 ml) and ether were added and the aqueous phase separated and extracted with chloroform. The combined organic layers were dried (Na_2SO_4) and

processing afforded 0.271 g of material which was chromatographed on a silica column using EtOAc – petroleum ether (1:4). A substance (0.100 g) of R_f 0.30 was obtained whose 220 MHz nmr spectrum *vide infra* showed it to contain the α-D-*glycero* (**5**) and β-L-*glycero* (**22**) enones in 58 and 42%, respectively. Spectral data: ir (CH_2Cl_2): 1735 (OBz), 1696 (C=O); 1630 (Ph_3C); 1603 cm^{-1} (C=C); nmr 220 MHz ($CDCl_3$) δ for **5**: H-1, 5.44 (1H, d, J_{12} = 3.5 Hz); H-2, 5.86 (1H, d); H-4, 6.00 (t, J_{46} = 1 Hz); H-6, 3.79 (2H, d); OCH_3, 3.48 (3H, s); for **22**: H-1, 5.34 (1H, d, J_{12} = 9.0 Hz); H-2, 5.57 (1H, d); H-4, 6.07 (1H, t, J_{46} = 1 Hz); H-6, 3.85 (2H, bs); OCH_3, 3.55 (3H, s); for both: OBz, $OCPh_3$, 7.2–7.6 and centered 8.1 (20H, m). For the mass spectrum: (*m/e*): 520 (0.17% of 105 base; calcd. for $C_{33}H_{28}O_6$: 520. 18860; found: 520. 18948; 20.0 rings and double bonds); 489 (0.25%; calcd. for $C_{32}H_{25}O_5$: 489.17021; found: 489.16542; loss of OCH_3 from 520); 447 (12%; calcd. for $C_{30}H_{33}O_4$: 447.15964; found: 447.15898; loss of C_2H_2O from 520); 443 (0.25%; loss of Ph from 520); 338 (0.86%; calcd. for $C_{20}H_{18}O_5$: 338.11543; found: 338.11617; loss PhCO from 443); 243 (80%; CPh_3); 105 (base; PhCO).

Carbon-13 enrichment in the room temperature multiphoton decomposition of CF_3Br [1]

M. GAUTHIER, P. A. HACKETT, M. DROUIN,[2] R. PILON, AND C. WILLIS

Chemistry Division, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received June 13, 1978

M. GAUTHIER, P. A. HACKETT, M. DROUIN, R. PILON, and C. WILLIS. Can. J. Chem. **56**, 2227 (1978).

High isotopic selectivities have been observed in the multiphoton decomposition of CF_3Br at room temperature. Photolysis of natural abundance CF_3Br gives C_2F_6 enriched to 42% in carbon-13. This is higher than observed for CF_3I even at very low temperatures.

M. GAUTHIER, P. A. HACKETT, M. DROUIN, R. PILON et C. WILLIS. Can. J. Chem. **56**, 2227 (1978).

La décomposition multiphotonique du CF_3Br à la tempèrature de la piéce conduit à une grande sélectivité isotopique. Le C_2F_6, obtenu par la photolyse du CF_3Br d'abondance isotopique naturelle, est enrichi de 42% en carbone-13. Cette sélectivité est supérieure à ce qui a été observé dans le cas du CF_3I même à très basse tempèrature.

Isotopic selectivity in the multiphoton decomposition of CF_3I induced by focussed infrared radiation from a CO_2-laser has been investigated by measuring the depletion in carbon-12-bearing substrate (1). At room temperatures, the process is virtually non-selective but at $-80°C$ selectivities in the range 10–40 were inferred. The loss of selectivity is most probably a result of the iodine atom abstraction reaction,

$$[1] \qquad {}^{12}CF_3 + {}^{13}CF_3I \rightarrow {}^{12}CF_3I + {}^{13}CF_3$$

which, at room temperature, scrambles the primary selectivity. A comparison of halogen atom transfer reactions involving CF_3 radicals (2) shows that the rate constants at room temperature are in the order

$$k_I \simeq k_{Br} \times 10^3 \gg k_{Cl}.$$

This suggested to us that the multiphoton decomposition of CF_3Br and CF_3Cl would be more tractable systems than CF_3I. We have now shown that the multiphoton decomposition of CF_3Br is highly isotopically selective at room temperature: in fact we observe selectivities higher than those observed in CF_3I even at the lowest temperatures studied. Because of the obvious topicality of this we offer preliminary data here.

All experiments reported here were made using a Lumonics 103 TEA-CO_2 laser. The central portion of the beam was passed through a 1.4 cm diameter aperture and focussed at the centre of the Pyrex reaction cell with a 10 cm focal length germanium lens. Samples of CF_3Br (PCR incorporated) were irradiated and the resultant mixture analysed by glc and mass spectrometry. An isopentane slush bath ($-160°C$) prevented bromine from entering the mass spectrometer. The only product observed was C_2F_6. Since the conversions were small in all cases ($\leq 1\%$) the isotopic composition of the C_2F_6 produced was used to derive primary α-values,

$$[2] \qquad \alpha = \frac{{}^{13}C/{}^{12}C \text{ ratio in products}}{{}^{13}C/{}^{12}C \text{ ratio in starting material}}$$

Peaks at m/e 119, 120, 121 were used, as $C_2F_5^+$ is the most abundant ion in the mass spectrum of C_2F_6.

The α-values observed in the photolysis of 0.19 Torr of CF_3Br are shown in Fig. 1 as a function of laser wavelength, together with a low intensity ir spectrum of the ν_1 band of CF_3Br. As the wavelength of the laser line chosen moves to the low frequency side of the absorption band, the selectivity towards C-13 enriched products continues to increase and is $\alpha = 65$ for the P(26) line of the 9.4 μm band. Beyond this, the yields become small and the measured α-values though high are imprecise. Use of the R lines of the 9.4 μm band of the CO_2 laser shows a strong selectivity towards C-12 enriched products, so strong that we were unable to detect C-13 product ions from the C_2F_6 produced from natural abundance CF_3Br and hence cannot report α-values here.

The pressure dependence of the selectivity was investigated using the P(24) line of the 9.4 μm band of the CO_2 laser. Figure 2 shows α to be strongly pressure dependent. We interpret this loss of selectivity at higher pressures as the result of energy transfer reactions.

Very recently, Letokhov and co-workers (3) reported product enrichment in the multiphoton

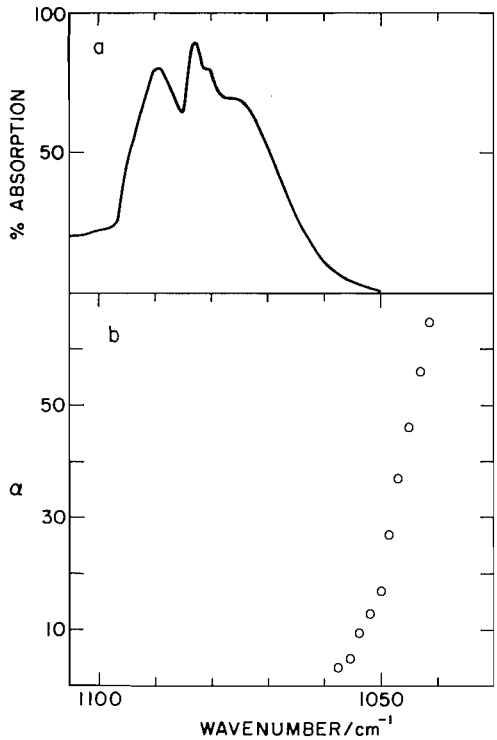

FIG. 1. (*a*) Low resolution, low intensity infrared spectrum of CF_3Br (room temperature, 10 cm cell, 1 Torr). (*b*) α-Values as a function of photolysing wavelength, at 0.19 Torr of CF_3Br at room temperature. α-Values were determined from product C-13 enrichment (see text), the incident fluence depended on the laser line used but was in the range $2 \rightarrow 0.2$ J cm^{-2}; 400 pulses were used on the stronger lines, 2000 on the weakest.

decomposition of CF_3I. At $-40°C$ they observed C_2F_6 enriched to about 20% in carbon-13. Although detailed comparison of the two systems must await

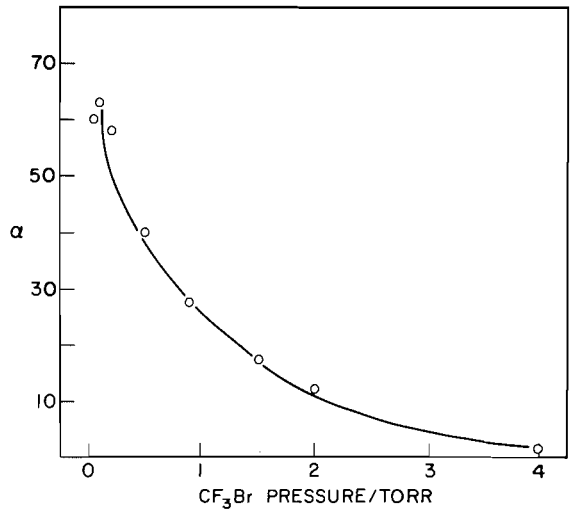

FIG. 2. α-Values as a function of CF_3Br pressure. Photolyses were carried out at room temperature using the P(24) line of the 9.4 μm band; 400 pulses at an incident fluence of 1 J cm^{-2} were used.

full publication, the preliminary data suggest that the selectivity from CF_3Br is at least as good as from CF_3I with the added advantage that the process is selective without cooling.

The preferred conformations in solution and rotational barriers of the phenyl moiety in 3,5-dichlorobenzyl derivatives of ammonia, dimethylamine, and dimethylarsine

TED SCHAEFER, WERNER DANCHURA, AND WALTER NIEMCZURA
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 2, 1978

TED SCHAEFER, WERNER DANCHURA, and WALTER NIEMCZURA. Can. J. Chem. **56**, 2229 (1978).

The long-range spin–spin coupling constants between methylene protons and ring protons are measured in 3,5-dichlorobenzylamine, 3,5-dichlorobenzyldimethylamine, and in 3,5-dichlorobenzyldimethylarsine. The couplings over six bonds are used to derive internal barriers to rotation about the carbon–carbon bond to the phenyl ring. In the above order, they are 0.3 ± 0.3, 0.8 ± 0.2, and 3.0 ± 0.5 kcal/mol. The conformation of lowest energy in the arsine is that in which the CH_2—X bond lies in a plane perpendicular to the benzene plane.

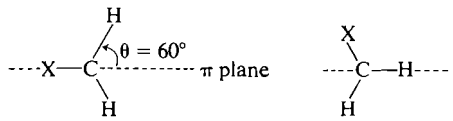
TED SCHAEFER, WERNER DANCHURA et WALTER NIEMCZURA. Can. J. Chem. **56**, 2229 (1978).

On a mesuré les contantes de couplage spin–spin à longue distance entre les protons du méthylène et les protons du cycle dans la dichloro-3,5 benzylamine, la dichloro-3,5 benzyldiméthylamine et la dichloro-3,5 benzyldiméthylarsine. On a utilisé les couplages à travers six liaisons pour déterminer les barrières internes à la rotation autours des liens carbone–carbone conduisant au noyau aromatique. Dans l'ordre mentionnée plus haut, ces valeurs sont respectivement de 0.3 ± 0.3, 0.8 ± 0.2 et 3.0 ± 0.5 kcal/mol. La conformation de plus basse énergie dans l'arsine est celle dans laquelle la liaison CH_2—X se trouve dans un plan perpendiculaire au plan du benzène.

[Traduit par le journal]

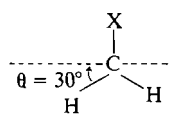
Introduction

A recent theoretical and photoelectron spectroscopic study (1) of benzyldimethylarsine concludes that the stable conformation is **1** (X = $As(CH_3)_2$)



1

2



3

instead of **2** or **3**, as would be expected on steric grounds. On the other hand, when X = Cl, Br, or I the *J* method indicates that **3** is preferred by 2 kcal/mol or more (2). The long-range spin–spin coupling constant, ${}^6J_p^{H,CH_2}$, between the methylene protons and the ring proton in the *para* position obeys a $\sin^2\theta$ relationship, where θ is the angle by which the C—H bond on the side chain is twisted out of the plane of the benzene ring (3–6).

For example, in toluene ${}^6J_p^{H,CH}$ ($\theta = 90°$) ≡ ${}^6J_{90}$ is −1.24 Hz (7). For the arsine, having conformation **1**, the observed ${}^6J_p^{H,CH_2}$ should be near −1.24 ($\sin^2 60°$) = −0.93 Hz if **1** is more than 4 kcal/mol more stable than **2** or **3**, as calculated by CNDO/2 (1). If **3** were the stable form, ${}^6J_p^{H,CH_2}$ would be less than 0.6 Hz in magnitude and would approach −1.24 ($\sin^2 30°$) = −0.31 Hz for a high two-fold barrier to rotation about the phenyl-CH_2X bond.

For somewhat lower twofold barriers to rotation, a hindered rotor treatment yields average values of $\sin^2\theta$ as a function of the barrier, the reduced moment of inertia and the temperature. If the stable form is **1**, $\langle\sin^2\theta\rangle$ spans 0.5 and 0.75; if **2**, 0.5 and 0.375; and if **3** is the stable form, $\langle\sin^2\theta\rangle$ lies between 0.5 and 0.25. In toluene, where the internal barrier is negligible in this context, $\langle\sin^2\theta\rangle$ can be taken as 0.5.

TABLE 1. Proton chemical shifts[a] and spin–spin coupling constants[b] for 3,5-di-chlorobenzyl-X compounds

Parameter	Value		
	X = NH_2 10 mol%, C_6D_6	X = $N(CH_3)_2$ 5 mol%, CS_2	X = As $(CH_3)_2$ 5 mol%, CS_2
ν_{CH_3}	73.7[c]	218.48	89.05
ν_{CH_2}	325.243(3)	331.23	265.95
$\nu_{2,6}$	691.940(3)	714.711(4)	687.065(4)
ν_4	705.753(3)	712.041(5)	702.828(3)
$^4J_o^{H,CH_2}$	−0.773(3)	−0.732(6)	−0.492(5)
$^6J_p^{H,CH_2}$	−0.579(4)	−0.512(7)	−0.391(4)
$^4J_m^{H,H}$	1.943(3)	1.961(4)	1.896(3)
Root mean square deviation	0.012_7	0.012_1	0.008_8

[a]In Hz at 100 MHz to low field of internal tetramethylsilane and at 305 K.
[b]In Hz, numbers in parentheses giving the standard deviation in the last place.
[c]For NH_2 protons.

Accordingly, the surprising conclusion for the arsine was reinvestigated by the *J* method. In addition, the X = $N(CH_3)_2$ and X = NH_2 compounds were studied for purposes of comparison. Attempts at the synthesis of X = $P(CH_3)_2$ ended in failure. Because the phenyl proton region in benzyl compounds is too complex for a precise analysis of its ^1H nmr spectrum, the compounds contained chlorine substituents at the *meta* positions. There is no evidence that these substituents alter the conclusions to be arrived at below (6, 8).

Experimental

3,5-Dichlorobenzylbromide was prepared from the corresponding commercial benzoic acid by standard methods. Dimethylamine was bubbled through a benzene solution of the bromide to yield a precipitate of 3,5-dichlorobenzyl dimethylamine, which was purified and gave a satisfactory ^1H nmr spectrum. 3,5-Dichlorobenzyldimethylarsine was prepared from the bromide and dimethyliodoarsine by the methods in ref. 1 and gave the correct ^1H nmr spectrum. It melted under vacuum between 48 and 52°C (no stem correction) and probably contained some impurity. The 3,5-dichlorobenzylamine had a commercial origin.

Degassed solutions of these compounds (see Table 1) contained internal tetramethylsilane. Their ^1H nmr spectra were repeatedly calibrated at 5 Hz intervals on an HA100 spectrometer at a probe temperature of 305 K. Sweep rates in the frequency-sweep mode were 0.01 and 0.02 Hz/s at a sweep width of 1 Hz/cm.

Results and Discussion

Spectral Analyses

Performed with the computer program LAME (9, 10), the analyses yielded the spectral parameters set out in Table 1. The standard deviations in these parameters were all well below 0.01 Hz, suggesting an accuracy of perhaps 0.02 Hz.

The Internal Rotational Barriers

3,5-Dichlorobenzylamine

If $^6J_{90}$ is −1.24 Hz as in toluene, then $\langle \sin^2 \theta \rangle$ equals $0.59_7/1.24$, or 0.46_7. Taking the reduced moment of inertia as 0.6×10^{-38} g cm^2 (the barrier is fairly insensitive to variations in this quantity), a temperature of 305 K, and conformation **3** as most stable, yields a barrier of 0.4 ± 0.1 kcal/mol. If **2** is the stable form, the barrier rises to about 0.5 kcal/mol.

However $^6J_{90}$ depends somewhat on the electronegativity, E_X, of the substituent X; in this case X = NH_2. Previous work (2) suggests that the magnitude of $^6J_{90}$ sinks to −1.14 Hz when $E_X = 3.0$. Photoelectron spectroscopy (11) indicates that E_{NH} is about the same as that of sulfur, $E_S = 2.5$ on the Pauling scale, whereas $E_N = 3.0$. Assuming E_{NH_2} to be 2.75, together with a linear interpolation between −1.14 and −1.24 Hz at $E_H = 2.1$, yields $^6J_{90}$ as −1.17 Hz. It follows that $\langle \sin^2 \theta \rangle = -0.57_9/-1.17 = 0.49_5$ and that the internal barrier is 0.05 ± 0.05 kcal/mol if **3** is most stable; the assumption that **2** is most stable does not alter the barrier significantly.

It is clear that the barrier is small and, considering measurement errors and the assumption concerning the dependence of $^6J_{90}$ on E_X, a value for the twofold barrier of 0.3 ± 0.3 kcal/mol appears as a sensible compromise. Conformation **1** follows as the high energy form.

An *ab initio* molecular orbital calculation at the STO 3G level (12) gave 2.2 kcal/mol for the barrier in the isolated molecule of benzylamine, **3** most stable. No optimization of the geometry was undertaken. It may be noted that a partial optimization of the geometry in ethylbenzene reduced the corresponding barrier from 4.7 to 2.2 kcal/mol (12), whereas the *J* method yielded 1.2 kcal/mol (8). If a barrier of 2 kcal/mol existed in 3,5-dichlorobenzylamine in solution, $^6J_p^{H,CH_2}$ would lie near −0.4 Hz instead of −0.6 Hz, as observed. Furthermore, an approximate empirical correlation of V_2 with

$^4J_o^{H,CH_2}$ for similar compounds (2) predicts a very small barrier for the amine.

3,5-Dichlorobenzyldimethylamine

The reduced moment of inertia varies between 1.2 and 1.9 $\times$ 10^{-38} g cm^2 for various probable conformations, a variation to which the derived barrier is insensitive compared with its sensitivity to an error in ^6J. Under the assumption that $^6J_{90}$ has the same value as in toluene, $\langle \sin^2 \theta \rangle = -0.51_2/-1.24 = 0.41_3$. The barrier is then 1.0 $\pm$ 0.1 kcal/mol. On the other hand, the barrier becomes 0.7 $\pm$ 0.1 kcal/mol if $^6J_{90}$ is -1.17 Hz, corresponding to equal electronegativities for the NH_2 and $N(CH_3)_2$ groups. A suitable value appears to be 0.8 $\pm$ 0.2 kcal/mol, **3** being stable.

If **2** were the ground state conformation, V_2 would be considerably larger. This possibility is considered unlikely because the empirical correlation mentioned above then suggests a modulus of about 0.5 Hz for $^4J_o^{H,CH_2}$ instead of the measured 0.7 Hz.

3,5-Dichlorobenzyldimethylarsine

The reduced moment of inertia ranges between 2.4 and 3.1 $\times$ 10^{-38} g cm^2. The electronegativities of arsenic and hydrogen are nearly equal, so that $^6J_{90}$ can be taken as -1.24 Hz. The observed $^6J_p^{H,CH_2}$ of -0.39_1 Hz leads to a V_2 of 3.0 $\pm$ 0.3 kcal/mol. It seems likely that a barrier of 3.0 $\pm$ 0.5 kcal/mol encompasses the possibilities. It is clear that **3** is the stable conformer. For, if **1** were the stable form, $^6J_p^{H,CH_2}$ would be larger than 0.6 Hz in the presence of a finite barrier. If **2** were the stable form, ^6J would lie between -0.46 and -0.62 Hz for a finite barrier.

Comparisons with Other Methods

In view of the disagreement with the photoelectron results for the arsine derivative, it may be useful to present a comparison of some barriers and conformations previously derived by the *J* method with those deduced by other means.

Phenylethane

Low resolution microwave spectroscopy indicates **3** as the preferred conformation (13). If this is true, then heat capacity data can be fitted by assuming a V_2 of 1.16 kcal/mol (14) for the rotation of the ethyl group. In solution the *J* method yields V_2 as 1.2 kcal/mol for the 3,5-dibromo derivative and **3** is again indicated as the low energy conformation (8). The agreement is rather good, although the internal rotation possibly may be affected by fields from neighbouring molecules and perhaps by a small perturbation from the *meta* substituents in the derivative to which the *J* method was applied. A high resolution microwave investigation of phenylethane would be of interest.

Benzyl Chloride

A recent discussion (15) of electron diffraction data concludes that **3** is the stable conformation and that V_2 is 1.5 kcal/mol, although values as low as 1.0 and as high as 2.7 kcal/mol may not be completely unlikely. The *J* method for the 3,5-dichloro derivative, again in solution, gives 2.1 $\pm$ 0.4 kcal/mol, **3** being stable (2).

Styrene and Isopropyl Benzene

The *J* method (16) yields 1.6 $\pm$ 0.3 kcal/mol for V_2 whereas heat capacity data suggest 2.2 kcal/mol (17) and a recent gas phase, torsional overtone measurement finds 1.8 kcal/mol (18).

There are no data on isopropylbenzene itself. Hyperfine proton coupling in the neutral *p,p',p''*-triisopropyltrityl radical in toluene solution implies that V_2 is 2.1 kcal/mol (19). Hyperfine coupling to the methyl carbon nuclei in *p*-isopropylaniline nickel acetylacetonate complexes suggests 1.5 kcal/mol, whereas the temperature dependence of the methyl carbon spin–lattice relaxation times for *p*-isopropylaniline in chloroform solution indicates 2.8 kcal/mol for V_2 (20). (In our opinion the latter value suffers from the lack of a clear separation between overall and internal reorientational motions.) The *J* method gives 2.0 $\pm$ 0.2 kcal/mol for V_2 in the 3,5-dibromo derivative in CS_2 solution (21).

Conclusions

It would seem that the *J* method, although based on various approximations, arrives at reasonable values for rotational barriers and that, for some benzyl derivatives at least, it also indicates the correct ground state conformations; agreeing with those found in the vapor phase.

Therefore it appears unlikely that a solvent effect would alter the present conclusion about the stable conformation of 3,5-dichlorobenzyldimethylarsine.

Proton magnetic resonance spectra of 3-fluorotoluene and 2-chloro-5-fluorotoluene. The sign and coupling mechanism of $^5J_m{}^{F,CH_3}$

TED SCHAEFER, WERNER DANCHURA, AND WALTER NIEMCZURA
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 23, 1978

TED SCHAEFER, WERNER DANCHURA, and WALTER NIEMCZURA. Can. J. Chem. **56**, 2233 (1978).

A full analysis of the proton magnetic resonance spectra of 3-fluorotoluene and of 2-chloro-5-fluorotoluene, as 10 mol% solutions in CS_2, demonstrates that the long-range spin–spin coupling constant over five bonds between methyl protons and fluorine-19 is negative. The coupling mechanism consists of a large positive σ electron component and a negative π electron component. The negative sign of the π electron contribution arises from a spin density in the $2p_z$ orbital at carbon-3, which is opposite in sign to that of the spin densities at C-2 and C-4. Combined with positive hyperfine interaction constants, Q_{CCH} and Q_{CF}, the consequence is a negative π electron component.

TED SCHAEFER, WERNER DANCHURA et WALTER NIEMCZURA. Can. J. Chem. **56**, 2233 (1978).

Une analyse complète des spectres de résonance magnétique nucléaire du proton des fluoro-3 et chloro-2 fluoro-5 toluènes en solutions à 10 mol% dans le CS_2, démontre que la constante de couplage spin–spin à longue distance à travers cinq liaisons entre les protons du méthyle et le fluor-19 est négative. Le mécanisme de couplage comporte une composante importante positive due aux électrons σ et une composante négative provenant des électrons π. La valeur négative de la contribution provenant des électrons π est due à une densité de spin dans l'orbitale $2p_z$ au niveau du carbone-3 qui est de signe opposé à celle des densités de spin au niveau des carbone-2 et -4. Si l'on combine ces valeurs avec les constantes d'interactions hyperfines positives, Q_{CCH} et Q_{CF}, la conséquence est une composante négative pour les électrons π.

[Traduit par le journal]

Introduction

The long-range spin–spin coupling constants between methyl protons and ring protons in toluene and its derivatives have been thoroughly examined both experimentally and theoretically (refs. 1–11 and footnote 1). In terms of a σ–π model it was shown that the coupling over six bonds, $^6J_p{}^{H,CH_3}$, is dominated by the π electron contribution and that, indeed, it provides the basis for a determination of small barriers to internal rotation in α-substituted toluene derivatives (8, 10, 12, 13). The other two couplings, $^5J_m{}^{H,CH_3}$ and $^4J_o{}^{H,CH_3}$, contain appreciable contributions from both of the σ and π electron systems.

The analogous long-range couplings in fluorotoluene derivatives, $^6J_p{}^{F,CH_3}$ and $^4J_o{}^{F,CH_3}$, have also been discussed in some detail (2, 14, 15). For example, on the very reasonable assumption (10, 14) that $^6J_p{}^{F,CH_3}$ is dominated by a π electron mechanism, one may write $^\pi J_p{}^{F,CH_3} \propto Q_{CF}\, Q_{CCH}$ in *p*-fluorotoluene. Q_{CF} and Q_{CCH} are the isotropic hyperfine interaction constants between an electron in a π orbital on carbon and the contiguous fluorine nucleus or methyl proton, respectively. Q_{CF} and Q_{CCH} are positive (16–19), so that $^6J_p{}^{F,CH_3}$ is also positive. Similarly, $^4J_o{}^{F,CH_3}$ must have a large positive π electron contribution but there exist complications from σ electron and the socalled through-space mechanisms (15).

In 4-amino-5-bromo-3-fluorotoluene, $^5J_m{}^{F,CH_3}$ was determined to be −0.4 Hz (2). It is quite likely that this relatively small magnitude ($^6J_p{}^{F,CH_3}$ is +1.15 Hz in *p*-fluorotoluene (14) and $^4J_o{}^{F,CH_3}$ is +2.1 Hz in 4-chloro-2-fluoro-5-nitrotoluene (2)) arises from a near cancellation of a positive, highly stereospecific, σ electron component by a negative π electron component. The negative π component can arise if a negative π spin density exists at the carbon of the C—F bond.

The negative sign of $^5J_m{}^{F,CH_3}$ has been questioned in a discussion of $^5J_m{}^{F,CH_3}$, apparently preferred positive (20), in 2-chloro-5-fluorotoluene, **2**. Accordingly, this paper briefly reports the analyses of the ^{1}Hmr spectra of 3-fluorotoluene, **1**, and of **2**. The sign of $^5J_m{}^{F,CH_3}$ is negative in **1** and **2**. A discussion of the coupling mechanism in terms of a σ–π model is given in connection with an INDO MO FPT (21) calculation of $^5J_m{}^{F,CH_3}$, using a standard geometry (22).

Experimental

Degassed, 10 mol% solutions of **1** and **2** in CS_2 contained a small amount of internal tetramethylsilane. The proton magnetic resonance spectra were recorded in the frequency sweep mode at 305 K on an HA100 spectrometer. The spectra

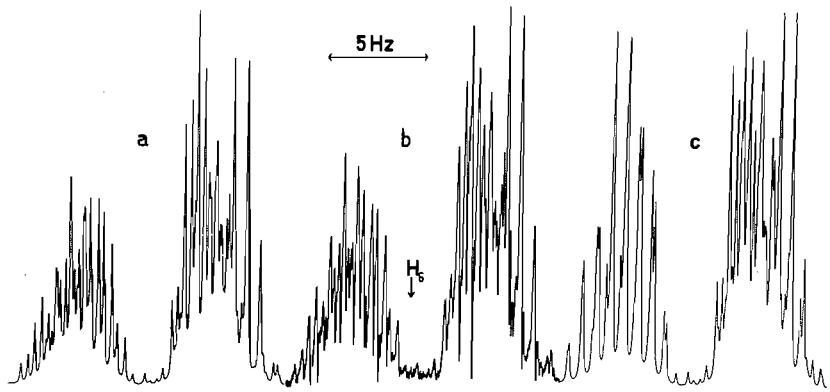

FIG. 1. Part of the H_6 region, from 674.0 to 687.5 Hz at 100 MHz to low field of internal tetramethylsilane, for a 10 mol% solution of 3-fluorotoluene, **1**, in CS_2 solution at 305 K is shown in each of *a*, *b*, and *c*. In *a* the spectrum is that calculated with the parameters in Table 1, i.e., with $^5J_p^{H,F} = 0.144$ Hz. In *c* the calculated spectrum assumes $^5J_p^{H,F} = -0.144$ Hz. These calculated spectra may be compared to the observed spectrum in *b*, particularly to the left-hand multiplet.

were repeatedly calibrated by reading the sweep and manual oscillator frequencies for markers placed at intervals of approximately 5 Hz. Sweep rates were 0.02 and 0.01 Hz/s. The spectral dispersion amounted to 1 Hz/cm. The ring proton spectra of **1** were also calibrated while decoupling the methyl protons.

The signs of $^5J_m^{F,CH_3}$ in **1** and **2** were determined by weak irradiation experiments (23–25) on HA100 and WH-90 spectrometers.

Results and Discussion

Spectral Analyses

These were carried out with the computer program LAME (26, 27). The single resonance spectra were completely insensitive to the sign of $^5J_m^{H,CH_3}$ but were sensitive to the sign of $^5J_p^{H,F}$ in **1**. Figure 1 displays a part of the resonance peaks arising from H_6, illustrating the positive sign of $^5J_p^{H,F}$.

An example of the results of weak irradiation experiments is shown in Fig. 2, whose caption should be read. The theoretical methyl proton spectrum of **1** under conditions of double irradiation was calculated with a version of the computer program DOR (28), modified to accommodate an eight-spin system.

Table 1 gives the spectral parameters for **1** and **2**. It may be noted that the standard deviations of the parameters for the fully coupled spectrum of **1** happen to be 0.004 Hz or less, suggesting an accuracy of perhaps 0.01 to 0.02 Hz. The Bloch–Siegert shift (29) is evident in the shift parameters for coupled and decoupled spectra (Table 1).

$^1H,^1H$, and $^1H,^{19}F$ Couplings Within the Ring

The signs and magnitudes of these couplings have been extensively discussed for related compounds (14, 30–33). It may be noted that, of some 20 $^5J_p^{H,F}$ values, ranging from +0.3 to −2.7 Hz, only those in fluorobenzene and in **1** are positive (14, 31, 34).

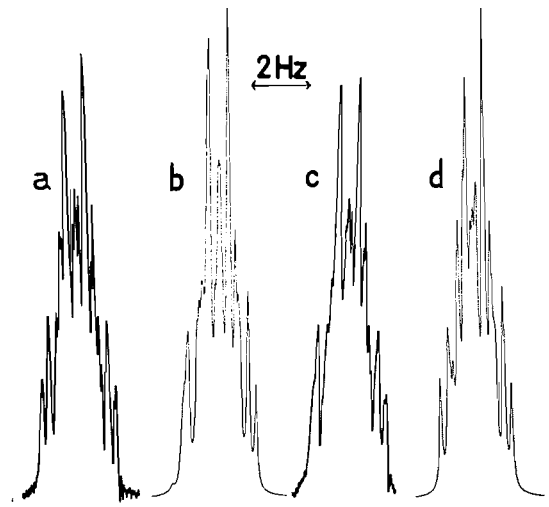

FIG. 2. The methyl proton spectrum for the same sample as in Fig. 1. In *a* the single resonance observed spectrum may be compared with the double resonance spectrum observed in *c* under conditions of weak irradiation at 697.22 Hz to low field of the lock signal. In *b* the calculated double resonance spectrum assumes $^5J_m^{F,CH_3} = -0.253$ Hz and $\gamma H_2 = 0.279$ Hz, where H_2 is the amplitude of the second rf field. In *d* the calculated double resonance spectrum assumes $^5J_m^{F,CH_3} = 0.253$ Hz and $\gamma H_2 = 0.279$ Hz, the other parameters being those in Table 1. Note that the outer two pairs of peaks in the single resonance spectrum would collapse in the absence of $^5J_m^{F,CH_3}$. The calculated spectra had linewidths of 0.10 Hz. The assumed strength of the irradiating field may not match exactly the experimental conditions. The reader is reminded that this figure represents results from only one of a series of double resonance experiments on **1** and **2**.

The Sign of $^5J_m^{F,CH_3}$

$^5J_m^{F,CH_3}$ is −0.25 and −0.23 Hz in **1** and **2** respectively. An interpretation goes as follows. Large positive σ contributions to ^5J can be anticipated for coplanar or near coplanar conformations of the

H—C—C—C—C—F fragment in **1** or **2**, particularly in the all-*trans* arrangement. For example, in 3-fluorobenzaldehyde, $^5J_m^{F,CHO}$ is +1.8 Hz, an average for the two planar conformations of the molecular (35). It turns out that INDO MO FPT calculations (35) reproduce this value reasonably well.

In Table 2, the INDO MO FPT values for $^5J_m^{F,CH_3}$ in **1** are tabulated as a function of the angle, θ, by which the C—H bond twists out of the aromatic plane. Figure 3 presents a plot of $^5J_m^{F,CH_3}$ vs. θ, the conformations also being defined there. Note that $^5J_m^{F,CH_3}$ is calculated as positive for planar conformations of the coupling fragment. Furthermore, $^5J_m^{F,CH_3}$ is calculated as large and negative for θ values near 90°, precisely as expected for a negative π electron contribution, which follows a $\sin^2\theta$ law (10). Because Q_{CCH} and Q_{CF} are both positive, this result means that the spin density in the π orbital (or the $2p_z$ orbital) at C-3 is negative. The negative spin density is easily understood as a consequence of electron correlation, the spin densities at C-2 and C-4 being positive[2] (such a result can be deduced from the INDO MO FPT open shell molecular orbitals, the convention being that the proton magnetic moment of a methyl group induces a negative spin density in its *s* orbital).

An instructive comparison can be made with the INDO MO FPT results (10) for $^5J_m^{H,CH_3}$ in toluene, also sketched in Fig. 3. Here the π electron component is positive because Q_{CH} is negative, while the spin density at C-3 is negative, as in **1**. Consequently $^5J_m^{H,CH_3}$ is positive, as observed (7). $^5J_m^{H,CH_3}$ and

75	−1.22	180	2.25
90	−1.19		

[a]θ = 180° defines the all-*trans* arrangement of the bonds in the H—C—C—C—C—F fragment; see Fig. 3.

$^5J_m^{F,CH_3}$ are overestimated somewhat in the calculations. Because the barrier to methyl group rotation in 3-fluorotoluene is only 0.042 kcal/mol (38)[3], an average of the 13 calculated values can be reasonably taken and is +0.21 Hz. Clearly, a slight negative shift in the theoretical values would yield a negative coupling.

Conclusions

$^5J_m^{F,CH_3}$ is negative in 3-fluorotoluene and two derivatives as well as in some pyridine derivatives (39). $^5J_m^{F,CH_3}$ is a composite of a positive σ electron contribution and of a negative π electron contribution, the latter attaining its maximum magnitude for conformations in which the side-chain C—H bond is twisted by about 90° out of the aromatic plane. The σ–π model is adequate for a discussion of long-range couplings between methyl protons and ring protons or fluorine nuclei if it is remembered that induced

[2]In terms of a valence bond formulation (36), the spin correlation function for atoms belonging to different classes (starred, unstarred) is negative.

[3]The present calculation gave 0.018 kcal/mol, C—H in plane as most stable, and a dipole moment of 1.87 D, the measured value being 1.85 D (38).

Received February 13, 1978

EDWARD G. JANZEN, DALE E. NUTTER, JR., EDWARD R. DAVIS, BARRY J. BLACKBURN, J. LEE POYER, and PAUL B. MCCAY. Can. J. Chem. **56**, 2237 (1978).

The assignments of the hydroxyl, hydroperoxyl, and alkylperoxyl radical spin adducts of α-phenyl *N-tert*-butyl nitrone (PBN) are discussed. Results of new experiments designed to test the assignments of the first two are described. It is concluded that the hydroxy adduct assignment is correct. The relationship between a_β^H and a_N is

$$a_\beta^H = 0.60a_N - 6.5$$

This equation gives a good fit for the seven pairs of constants reported for the hydroxy adduct. The assignments for the hydroperoxy adduct may be correct but no proof is yet available for this assignment.

EDWARD G. JANZEN, DALE E. NUTTER, JR., EDWARD R. DAVIS, BARRY J. BLACKBURN, J. LEE POYER et PAUL B. MCCAY. Can. J. Chem. **56**, 2237 (1978).

On discute des attributions des adduits de spin radicalaire de l'hydroxyle, de l'hydroperoxyle et de l'alkylperoxyle avec l'α-phényl *N-tert*-butyl nitrone (PBN). On décrit les résultats des nouvelles expériences effectuées pour valider les attributions des deux premiers. On en conclut que l'attribution pour l'adduit hydroxy est correcte. La relation entre a_β^H et a_N est:

$$a_\beta^H = 0.60a_N - 6.5$$

Cette équation donne une bonne corrélation pour sept paires de constantes rapportées pour l'adduit hydroxyle. Les attributions pour l'adduit hydroperoxyle sont peut être correctes mais on n'a pour l'instant aucune preuve de cette attribution.

[Traduit par le journal]

Introduction

Since difficulties are encountered in the direct detection of oxy radicals by esr (1, 2) the method of spin trapping (3) would seem to be well suited for investigations involving the detection of oxy radicals (4). However, it is very important that assignments of the spin adducts are correct and that as many as possible of the reactions leading to the formation of the spin adducts are at least recognized if not understood.

In this paper the spin trapping chemistry of hydroxyl and hydroperoxyl radicals will be reviewed. Results from new investigations will be presented which confirm the previous assignment of the hydroxy adduct of PBN (5). However, the assignment of the hydroperoxy adduct of PBN still remains an open question.

The Hydroxyl Radical Spin Adduct

In an early survey of reactions of potential radical producing systems with PBN (6) the photolysis of small amounts of hydrogen peroxide in benzene containing PBN was investigated. After 20 min irradiation a spectrum consisting of a triplet of doublets was observed: a_N = 14.12, a_β^H = 2.01 G. After further irradiation a second set of doublets appeared: a_N = 13.4, a_β^H = 4.7 G. These spectra could not be assigned at the time.

In a study of the kinds of radicals produced in a microwave discharge of H_2O (7) the reaction of the effluent gases with powdered PBN produced a spectrum (in benzene) consisting of a triplet of doublets (a_N = 14.63, a_β^H = 2.88 G) and a triplet of triplets (a_N = 14.98, a_β^H = 7.50 (2H) G; from D_2O: a_N = 14.70, a_β^H = 2.61 and a_N = 14.94, a_β^H = 7.66, a_β^D = 1.14 G). The former was assigned to the hydroxy adduct (there is some doubt as to the correctness of this assignment; see Fig. 1 discussed later) and the latter to the hydrogen atom adduct.

An effort was made to obtain spectra of the hydroxy adduct from alternate sources. Benzyl alcohol was reacted in the absence of light with *tert*-butoxy radicals from di-*tert*-butyl peroxyoxalate

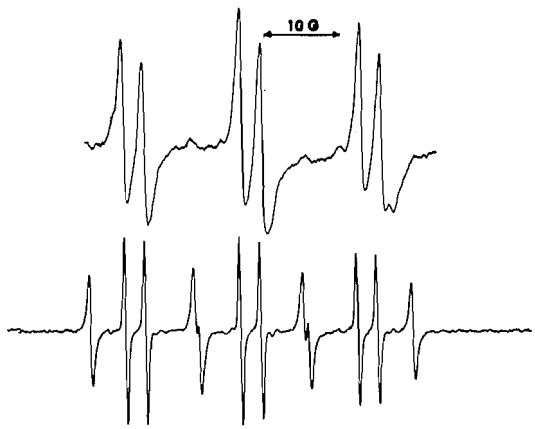

FIG. 1. (*a*) Top spectrum from 5×10^{-2} *M* H_2O_2, 2×10^{-5} *M* $FeCl_3$, 8×10^{-4} *M* ADP, and 0.1 *M* PBN in water. (*b*) Bottom spectrum from 0.01 *M* $(NH_4)_2S_2O_8$ and 0.1 *M* PBN in water; note the strong set of four (actually 2×3) lines between the doublets due to *tert*-butyl hydronitroxide ($(CH_3)_3NHO\cdot$) from hydrolysis of PBN frequently seen when persulfate is used.

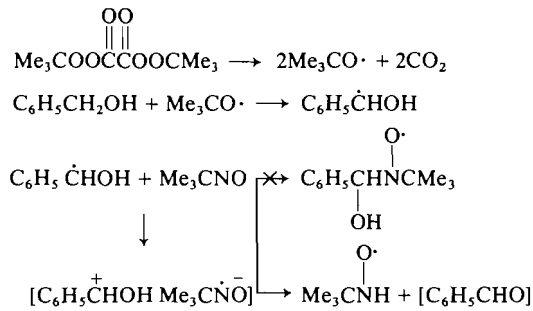
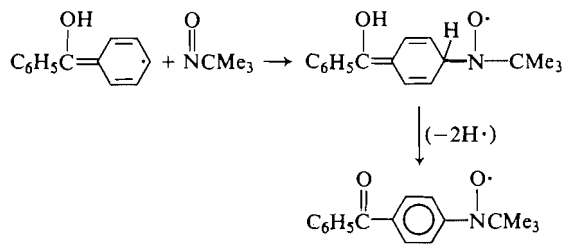
(DBPO) in benzene containing 2-methyl-2-nitrosopropane. Di-*tert*-butyl nitroxide, *tert*-butoxy *tert*-butyl nitroxide, and *tert*-butyl hydronitroxide were detected. No clear triplet of doublets was seen. The reaction expected to produce the hydroxy adduct of PBN apparently generates *tert*-butyl hydronitroxide by either electron or hydrogen atom transfer:



The photolysis of benzophenone in benzene in the presence of benzyl alcohol and 2-methyl-2-nitrosopropane gave only di-*tert*-butyl nitroxide. Eventually on continuous photolysis another signal appeared which would seem to be an aromatic *tert*-butyl nitroxide. Perhaps the α-hydroxybenzyl or the hydroxydiphenylmethyl radical was trapped in the *para* position: e.g.,

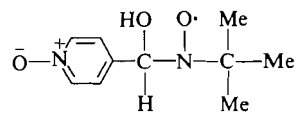


Phenoxy radicals apparently are trapped in a similar manner (8).

Other possible methods of producing hydroxyl radicals or the hydroxy radical spin adduct were investigated (see Table 1). γ-Radiolysis of PBN in water gave a triplet of doublets (a_N = 15.98, a_β^H = 3.12 G) and the hydrogen atom adduct (a_N = 16.57, a_β^H = 10.50 (2H) G). Photolysis in a basic aqueous solution (NaOH) of PBN produced a triplet of doublets (a_N = 15.57, a_β^H = 4.03 G) and the hydrogen atom adduct (a_N = 16.42, a_β^H = 10.34 (2H) G). Photolysis of the sodium salt of 1-anthraquinone sulfonic acid in an aqueous solution of PBN produced a triplet of doublets (a_N = 15.13, a_β^H = 2.63 G). According to a plot of a_β^H vs. a_N (discussed later) it appears that the first and last of the above spectra can be assigned to the hydroxy adduct of PBN but the remaining spectrum is not understood at this time.

A solution of ferric chloride and hydrogen peroxide in water (Fenton's reagent) gave only a triplet due to benzoyl *tert*-butyl nitroxide with PBN. The same result was obtained with $TiCl_3$ and hydroxylamine hydrochloride in water containing PBN. However a solution of ferric chloride chelated with adenosine diphosphate (ADP) to which a small amount of hydrogen peroxide is added gives a triplet of doublets (a_N = 15.49, a_β^H = 2.74 G). The latter appears to be the hydroxy adduct of PBN (see Fig. 1*a*). Both sodium and ammonium persulfate in water containing PBN produce spectra consisting of a triplet of doublets (a_N = 15.13, a_β^H = 2.63 G; a_N = 15.23, a_β^H = 2.60 G, respectively) (see Fig. 1*b*).

Preliminary results with α-(4-pyridyl-*N*-oxide) *N*-*tert*-butyl nitrone (4-POBN) and sodium persulfate in water indicate that the hydroxy adduct is detected in this system. The assignment is based on the detection of an extra splitting of about 0.3 G which is absent in D_2O. The small splitting is probably due to the γ-hydrogen on the hydroxy group (Fig. 2).



The lack of consistency in splitting constants obtained from different apparent sources of hydroxy radicals is discouraging at first glance. However a plot of one splitting constant (a_β^H) against the other (a_N) as shown in Fig. 3 suggests a grouping of points with a straight line relationship for the values obtained from γ-radiolysis of water, photolysis of sodium anthraquinone sulfate in water, ADP chelated $FeCl_3$ plus H_2O_2 in water, persulfate in water, and one set of values reported by Harbour *et al.* (5) obtained from the photolysis of aqueous

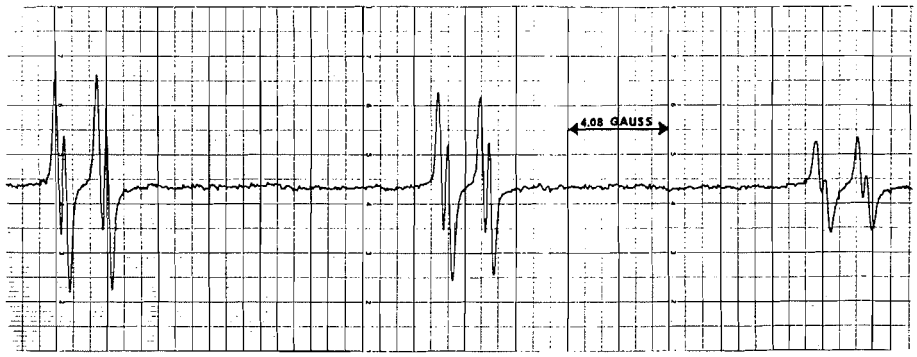


FIG. 2. Electron spin resonance spectrum of the hydroxy adduct of 4-pyridyl-*N*-oxide *N*-*tert*-butyl nitrone produced from sodium persulfate in water: $a_N = 15.03$, $a_\beta^H = 1.67$, $a_{OH}^H = 0.36$ G.

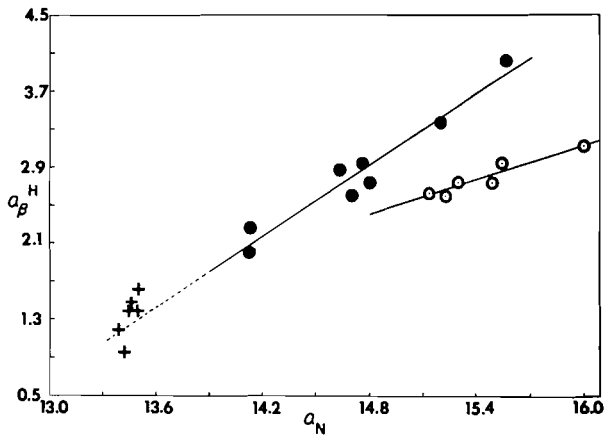

FIG. 3. Plot of the nitrogen and β-hydrogen hyperfine splitting constants for the nitroxides assumed to be hydroxy (○), hydroperoxy (●) and alkylperoxy (×) adducts of PBN (see Table 1).

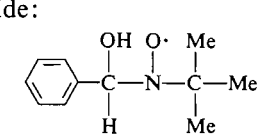
H_2O_2 and PBN ($a_N = 15.30$, $a_\beta^H = 2.75$; $a_N = 15.55$, $a_\beta^H = 2.95$ G from this study, *vide infra*). Since one point is almost certainly due to the hydroxy adduct (based on the results from sodium persulfate in water with 4-POBN) it can be asserted that the spin adducts whose splitting constants fall on the straight line which passes through this point all have the same structure, namely α-hydroxybenzyl *tert*-butyl nitroxide:



The line drawn through the seven points mentioned shown in Fig. 3 is a computer least-squares best fit. The correlation coefficient is 0.948. The equation of the line is:

$$a_\beta^H = 0.604a_N - 6.53$$

A feel for the 'goodness-of-fit' can be obtained by calculating the expected a_β^H from the measured a_N using the above equation.

Experiment No.	a_N	a_β^H Calcd.	a_β^H Exptl.	Error
5	15.98	3.12	3.12	0.00
7	15.13	2.61	2.63	−0.02
8	15.49	2.83	2.74	+0.09
9	15.13	2.61	2.63	−0.02
10	15.23	2.67	2.60	+0.07
12	15.30	2.71	2.75	−0.04
14	15.55	2.86	2.95	−0.09
			Average	±0.05

As can be seen from the above, the maximum deviation in any given pair of experiments is almost 0.1 G. The average error is about 0.05 G. From experience with many spin trapping experiments one finds repeatability to be of the order of ±0.05 G for single spectra. For spectra with overlapping peaks a maximum deviation of 0.1 G is quite possible. Thus one can conclude that the above equation relates a_N and a_β^H for the hydroxy adduct of PBN with approximately the same error as one can expect from experimental measurements taken by different workers with different instruments in different solvents and different solution compositions.

With ammonium persulfate in water 5,5-dimethyl-pyrroline-*N*-oxide (DMPO) gives a 1:2:2:1 pattern of four lines which can be interpreted in terms of equivalent hyperfine splitting from both the β-hydrogen and the nitroxide nitrogen atom ($a_N = a_\beta^H = 14.77$ G; see Fig. 4*a*). Because this system gives a spectrum with splitting from the hydroxy hydrogen in the adduct of 4-POBN it is assumed that the 1:2:2:1 spectrum is due to the hydroxy adduct of DMPO. However there is no proof of this assignment.

ADP chelated ferric chloride plus hydrogen peroxide gives the same spectrum with DMPO

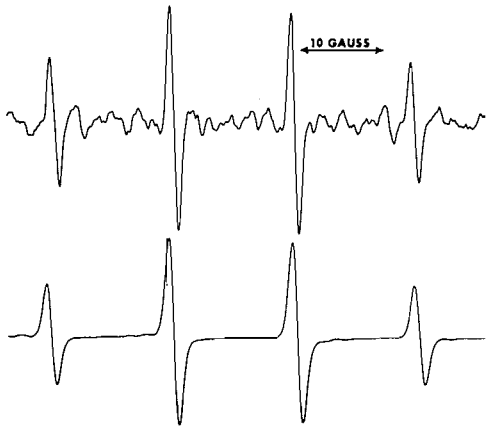

FIG. 4. (*a*) Top spectrum from 0.01 *M* $(NH_4)_2S_2O_8$ and 0.1 *M* DMPO in water; (*b*) Bottom spectrum from 5×10^{-2} *M* H_2O_2, 2×10^{-5} *M* $FeCl_3$, 8×10^{-4} *M* ADP and 0.14 *M* DMPO in water.

($a_N = a_\beta^H = 14.83$ G; see Fig. 4*b*). Floyd and Soong (9) have reported $a_N = a_\beta^H = 14.9$ G for a spectrum assigned to the hydroxy adduct of DMPO. The same spectrum was obtained by Harbour *et al.* (5) from photolysis of low concentrations of hydrogen peroxide and high concentrations of DMPO ($a_N = a_\beta^H = 15.3$, $a_\gamma^H = 0.61$ (1H), 0.25 (1H) G).

The Question of the Hydroperoxyl Radical Spin Adduct

When 0.1 *M* PBN is dissolved in 30% H_2O_2 no signal is detected. Apparently the nitrone does not react so as to produce spin adducts spontaneously by an induced decomposition mechanism i.e., *no* evidence was found for the following possible reactions:

$$H_2O_2 + PBN \longrightarrow C_6H_5CH(OOH)N(OH)CMe_3$$

$$C_6H_5CH(OOH)N(OH)CMe_3 + H_2O_2 \swarrow$$

$$C_6H_5CH(OOH)\overset{O\cdot}{\underset{|}{N}}CMe_3 + HO\cdot + H_2O$$

$$HO\cdot + PBN \longrightarrow C_6H_5CH(OH)\overset{O\cdot}{\underset{|}{N}}CMe_3$$

Upon uv irradiation first a weak signal due to a triplet of doublets with further splitting in the wing doublets is seen. Since the center wing of the nitrogen triplet does not show this splitting the spectrum must be due to two spin adducts with the same β-hydrogen splitting and the same *g*-value but with different nitrogen hyperfine splittings. This spectrum is the same as observed by Harbour *et al* (5). The values obtained here are $a_N = 15.55$, $a_\beta^H = 2.95$ G and $a_N = 14.76$, $a_\beta^H = 2.95$ G (see Fig. 5). The former has been assigned to the hydroxy adduct by Harbour *et al.* (5) and confirmed in this paper. The latter also has been assigned to the hydroperoxy adduct by Harbour *et al.* (5) but there is no proof of this assignment.

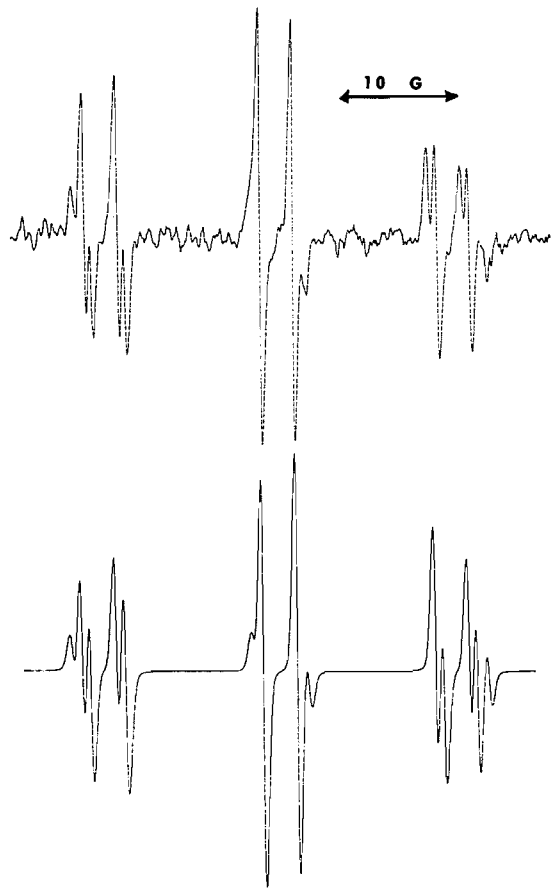

FIG. 5. Top spectrum obtained from uv irradiation of 0.1 *M* PBN in 30% H_2O_2. Bottom spectrum is a computer simulation of the following three sets of parameters in an intensity ratio of 1:1:0.3 $a_N = 15.55$, $a_\beta^H = 2.95$, line width = 0.57 G; $a_N = 14.76$, $a_\beta^H = 2.95$, line width = 0.38 G; $a_N = 15.55$, $a_\beta^H = 4.75$, line width = 0.65 G; *g*-value shift to higher field is 0.15 G.

Upon further photolysis another triplet of doublets not reported by Harbour *et al.* (5) with a relatively large β-hydrogen splitting and a slightly smaller *g*-value is observed ($a_N = 15.55$, $a_\beta^H = 4.75$ G). The complete spectrum can be computer simulated using a ratio of peak intensities of 1:1:0.3 (ratio of areas is 1:1:0.5) as shown in Fig. 5.

Konaka and Mizuta[3] obtained a triplet of doublets from H_2O_2 and *tert*-butyl alcohol – benzene ($a_N = 14.13$, $a_\beta^H = 2.26$ G). In pyridine containing PBN

24	*t*BuOO· in toluene at −80°C	12.85	< line width (ref. 11)
25	*t*BuOO· in toluene at −20°C	13.42	0.95 (ref. 11)

*Saturated sodium salt of 1-anthraquinone sulfonate.

the addition of H_2O_2 also produced a triplet of doublets $a_N = 15.20$, $a_\beta^H = 3.38$ G.

If the magnitude of the β-hydrogen and nitroxide nitrogen hyperfine splittings are plotted against each other for the spectra from the photolysis of H_2O_2 in 30% H_2O_2, H_2O_2 in benzene, H_2O_2 in *tert*-butyl alcohol – benzene, and H_2O_2 in pyridine a reasonable linear relationship is obtained (Fig. 3). The correlation coefficient of the computer least squares fit is 0.9716. The equation of the line is

$$a_\beta^H = 1.26a_N - 15.7$$

The calculated values for a_β^H are compared with the experimental values below. Also included are the splitting constants obtained from the microwave discharge of H_2O and D_2O, and the photolysis of PBN in basic solution.

Experiment No.	a_N	a_β^H Calcd.	a_β^H Exptl.	Error
1	14.12	2.09	2.01	+0.08
13	14.8	2.95	2.75	+0.20
15	14.76	2.90	2.95	−0.05
17	14.13	2.10	2.26	−0.16
18	15.20	3.45	3.38	+0.07
3	14.63	2.73	2.88	−0.15
4	14.70	2.82	2.61	+0.19
6	15.57	3.91	4.03	−0.12
			Average	±0.13

The fit is not nearly as good for the presumed to be hydroperoxy adducts obtained from solutions containing H_2O_2 as for the hydroxy adducts discussed earlier. The results obtained from microwave discharge or photolysis of basic solutions of PBN fit about as well as the rest. At this time it seems impossible to say whether all eight pairs of constants belong to the same spin adduct, and if so, whether this nitroxide is the hydroperoxy spin adduct.

The triplets of doublets with a relatively large β-hydrogen splitting (a_β^H = 4.7–4.8 G) may be due to the benzoyl spin adduct since *tert*-butyl hydronitroxide is also often detected under these conditions:

$$PBN + H_2O \xrightarrow{H^+} C_6H_5CHO + Me_3CNHOH$$

$$Me_3CNHOH \xrightarrow{RO\cdot} Me_3CNHO\cdot$$

$$C_6H_5CHO \xrightarrow{RO\cdot} C_6H_5\dot{C}{=}O$$

$$PBN + C_6H_5\dot{C}{=}O \longrightarrow C_6H_5CH(C_6H_5CO)-N(O\cdot)-CMe_3$$

Spin Adducts of Alkylperoxyl Radicals

Recently Merritt *et al.* (10) reported the detection at low temperatures (−80°C in CH_2Cl_2) of signals assigned to alkylperoxy spin adducts of PBN. The peroxy radical was itself detected first from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$Pb(OAc)_4$ oxidation of the hydroperoxide. Upon addition of PBN the spectrum of a nitroxide spin adduct appeared. For the *tert*-butylperoxy radical adduct: $a_N = 13.39$, $a_\beta^H = 1.19$ G (see Table 1 for other examples *19–23*). Only the octadecylperoxy spin adduct was stable at room temperature. A substantial increase in β-hydrogen hyperfine splitting was observed at higher temperatures for this spin adduct. Thus $a_N = 13.50$, $a_\beta^H = 1.17$ G at $-80°C$ and $a_N = 13.50$, $a_\beta^H = 1.61$ G at room temperature.

More recently Howard and Tait (11) repeated these experiments in the absence of $Pb(OAc)_4$ with *O–17* labelled oxygen. They found the following values for the *tert*-butylperoxy adduct of PBN: at $-80°C$, $a_N = 12.85$, a_β^H not detected; at $-20°C$, $a_N = 13.42$, $a_\beta^H = 0.95$, $a_\beta^O = 2.9$ G (*O–17* value obtained at $-60°C$). The β-hydrogen splitting increased with increase in temperature whereas the β-oxygen splitting decreased simultaneously. It is of interest to note that the β-hydrogen splittings of the various alkylperoxy spin adducts at different temperatures plotted against the magnitudes of the nitrogen splittings fall well into a region extrapolated to by the line defined for the same parameters for the hydroperoxy adducts. The peroxy radical adducts of PBN are not stable above 0°C (10, 11). Why the hydroperoxy adduct should be more stable is not understood. Perhaps intramolecular H-bonding plays a role in stabilizing the adduct.

All experiments described here were carried out at room temperature using procedures described before (6).

NOTE: A referee has drawn attention to a recent paper by Ohto *et al.* (12) which describes a study of the autoxidation of various hydrocarbons (cumene, tetralin, ethylbenzene, and cyclohexa-1,4-diene) in the presence of PBN. It is claimed that the corresponding peroxy radicals were trapped and detected in the case of *tert*-butylperoxy at room temperature. This conclusion would seem to be at variance with at least two independent studies (10, 11).

Of direct interest to this paper is the report of an adduct detected in the autoxidation of both 2-propanol and cyclohexa-1,4-diene with the following hyperfine splitting parameters: $a_N = 14.25$, $a_\beta^H = 2.23$ G. This spectrum is assigned to the hydroperoxy adduct. These values fall on the line assigned to the hydroperoxy adduct on the plot of a_β^H vs. a_N (Fig. 3). The calculated value for a_β^H using the equation given before is in excellent agreement with the reported value ($a_\beta^H = 1.26a_N - 15.7 = 1.26(14.25) - 15.7 = 2.28$ G; error +0.05).

DONALD W. HUGHES, RUSSELL A. BELL, THOMAS E. ENGLAND, and THOMAS NEILSON. Can. J. Chem. **56**, 2243 (1978).

Proton magnetic resonance has been used to investigate the double stranded RNA helix GAGC:GCUC, whose sequence corresponds to the duplex neck region of several tRNAs, a possible aminoacyl-tRNA synthetase recognition site. The nonexchangeable base and ribose anomeric resonances of the separate tetranucleotides were characterized by linear and predominantly upfield chemical shift changes as the temperature was decreased from 65 to 15°C. When these strands were mixed nonlinear, sigmoidal shift changes consistent with base pairing were observed. The melting temperature of the duplex was determined to be 42 ± 1°C which was in excellent agreement with the value obtained from optical methods. This is the first ^{1}Hmr study of a non-self-complementary duplex prepared from synthetic tetraribonucleotides.

DONALD W. HUGHES, RUSSELL A. BELL, THOMAS E. ENGLAND et THOMAS NEILSON. Can. J. Chem. **56**, 2243 (1978).

On a utilisé la résonance magnétique du proton pour étudier la double hélice GAGC:GCUC de RNA dont la séquence correspond à la région duplex du cou de plusieurs tRNA, un site de reconnaissance possible de l'aminoacyl-tRNA synthétase. On a pu caractériser les résonances de la base qui ne peut être échangeé et du ribose anomère des tétranucléotides séparés en faisant appel aux changements dans les déplacements chimiques qui sont linéaires et d'une façon générale vers les hauts champs à mesure que la température est abaissée de 65 à 15°C. Lorsque l'on mélange ces segments, des changements des déplacements de nature sigmoidale non-linéaire, en accord avec un pairage des bases, ont pu être observés. On a déterminé que la température de fusion du duplex est de 42 ± 1°C; cette valeur est en excellent accord avec la valeur obtenue à partir de méthodes optiques. Cette étude rmn du ^{1}H est la première étude d'un duplex qui n'est pas auto-complémentaire et qui a été préparé à partir de tétraribonucléotides de synthèse.

[Traduit par le journal]

Considerable effort has been expended on the detailed nuclear magnetic resonance analysis of the pairing of short strands of nucleic acid sequences (1–5). In this paper we wish to report a proton magnetic resonance investigation of duplex formation by the complementary nucleotides GAGC and GCUC.[3] The two sequences chosen are important because they correspond to natural sequences common to several tRNA molecules; in particular they represent a proposed partial recognition site for yeast phenylalanyl-tRNA ligase (6). In addition the duplex formed by the GAGC:GCUC set is the first simple example of a duplex formed from tetramers containing an internal A·U base pair.

England and Neilson (7) have used ultraviolet and circular dichroism studies on these two tetranucleotide sequences to show that duplex formation occurs and the authors have employed melting temperature (T_m) vs. concentration studies to evaluate the enthalpy change occurring for the single strands to the helix–coil transition.

In principle the chemical shift, coupling constant, and relaxation time data obtainable from the nmr spectrum of a molecule contain all the information necessary to define the geometric and motional behaviour of the molecule. However, the researcher's current ability to obtain this information is limited by the complexity of the tetranucleotide molecules and our inaccurate theoretical knowledge of the

myriad factors that affect the observed chemical shift of a given nucleus. Even more limiting are the relatively high concentrations, from a biological viewpoint, necessary to obtain adequate spectra for most magnetically active nuclei. In consequence nmr studies on oligonucleotides have been limited to ^{1}H spectroscopy and then only to those protons that are the most strongly deshielded in the molecule (4, 8). At low temperatures the N—H protons of N-3 (uracil) and N-1 (guanine) involved in the hydrogen bonding of base pair formation, show pronounced downfield chemical shifts and their shift changes with respect to temperature have, for simple self-complementary nucleotides, given useful information on the helix–coil transition (1, 3). At higher temperatures chemical exchange causes extensive line broadening and the utility of the N—H protons as probes is lost.

More recently the pioneering work of Borer *et al.* (2) on the self-complementary hexanucleotide AAG-CUU has shown that the carbon bound protons of the bases and the anomeric protons of the ribofuranoside ring may be used to define the helix–coil transition. Moreover, the observed chemical shift changes of the base protons were consistent with the duplex adopting either A- or A′-RNA helical structure. In the present paper, because the proton spectra were obtained at 90 MHz, it was only possible to assign fully the downfield aromatic protons of GCUC; the anomeric ribose ring protons were too complex to resolve adequately. It was possible however to completely assign the aromatic protons and the anomeric protons for all four units in GAGC at 65°C.

Results

To assign the downfield proton resonances in the spectrum of GAGC, obtained at 65°C to avoid inter- and intra-strand effects, the spectra of GA and GAG were obtained at the same temperature. These data together with the shifts of GCUC are recorded in Table 1 and summarized in diagrammatic form in Fig. 1.

Before recording the spectrum of the mixture of the tetranucleotides, the temperature dependence of the aromatic resonances in each tetranucleotide were obtained over the range 65–15°C. These data are shown in Fig. 2. All the aromatic protons showed a small and dominantly *linear* variation in chemical shift over this temperature range and in the GAGC moiety the A(2)H-8, A(2)H-2, G(3)H-8, and C(4)H-6 protons showed an upfield shift at low temperatures while the G(1)H-8 proton showed a downfield shift. Of the anomeric protons only A(2)H-1′ and G(3)H-1′ could be observed at low temperature. There was a considerable reduction in the magnitude of $J_{1',2'}$ for all these resonances until at 15°C they appeared as broad singlets (Table 2). The GCUC strand exhibited more variable changes with the U(2)H-6 and C(3)H-6 protons barely moving, G(4)H-8 moving downfield at low temperatures and C(1)H-6 moving

[a] ± 0.2 Hz.
[b] Lines too broad for coupling to be observed.

upfield. Presumably a process such as intermolecular end-to-end base stacking is responsible for these latter shifts. It is noteworthy that the low temperature spectra of GCUC showed the separation of the C(1)H-6 and C(3)H-6 resonances and thereby confirmed their degenerate status in the higher temperature spectra.

The chemical shifts for the combined tetranucleotides at 65°C were identical with those recorded for each individual tetranucleotide and show the absence of inter-strand effects at this temperature. Spectra recorded at lower temperatures showed a marked *nonlinear* variation of the shifts and a rapid broadening of the absorption lines. Thus a spectrum which bore a satisfactory signal-to-noise ratio at 65°C could be accumulated in some 250 pulses but required over 2000 pulses at 25°C. The A(2)H-2 proton remained relatively sharp throughout the entire temperature range but the remaining aromatic protons showed line broadening at the lower temperatures of the order of 5–20 Hz. It was only by comparison of the spectra where the G(1)H-8, A(2)H-8, G(3)H-8, and G(4)H-8 protons had been replaced by deuterium (9) to the spectra of the fully protiated species that reasonable assignments of the remaining lowfield protons could be made. The shift changes with respect to temperature of the mixed tetranucleotides are shown in Fig. 3.

The melting temperature, T_m, of the GAGC:GCUC duplex was estimated from the midpoint of the chemical shift – temperature curves, when they were reasonably complete, in the usual fashion. The values all lay within the range 42 ± 1°C which is in remarkable agreement with the T_m value of 43.5°C predicted by extrapolation of the data for the concentration dependence of T_m obtained from ultraviolet absorption studies (7).

Discussion

The assignment of the lowfield resonances of GAGC was undertaken following the commonly employed method of 'incremental assignment' (2). This method assumes that as fragments are added to a molecular species, the chemical shifts of the protons already present will remain essentially constant. That this assumption is reasonably valid in the present example is evident from the diagrammatic representation of the chemical shifts of GA, GAG, and GAGC shown in Fig. 1. The shift assignments for the G and A residues in GA were consistent with those reported by Lee *et al.* (10) and the positions of G(1)H-8 and A(2)H-8 were confirmed by a deuterium isotope exchange experiment (9). In GAG three of the signals in the aromatic region were virtually identical with those of GA and the new signal at 7.948 ppm therefore assigned to G(3)H-8. Further confirmation of this assignment was obtained from a relaxation time measurement (T_1) with the line at 7.948 ppm showing a shorter relaxation time (ca. 3 s) than the signal at 8.252 ppm (ca. 5 s) which was assigned to A(2)H-2 (11). Similarly the anomeric proton doublet of G(3)H-1′ was clearly discernible at 5.916 ppm ($J_{1',2'}$ = 6.0 Hz) in the presence of the doublets for G(1)H-1′ and A(2)H-1′.

The anomeric region of GAGC was complicated by the overlap of the C(4)H-5 doublet at 5.848 ppm onto both of the C(4)H-1′ and G(3)H-1′ doublets. However, the lowfield C(4)H-6 doublet at 7.725 ppm ($J_{5,6}$ = 7.5 Hz) was well separated from the remaining four aromatic signals and a double irradiation experiment was sufficient to locate clearly the C(4)H-5 doublet.

The reduction of $J_{1',2'}$ for A(2)H-1′ and G(3)H-1′ as the temperature was decreased was attributed to base-stacking forcing the ribose rings into the ^3E or *C*-3′ *endo* conformation. This was consistent with the molecule adopting the A- or A′-RNA structure. Although the anomeric protons were not adequately resolved in GCUC and the duplex, it is expected that the ribose conformational changes in these systems will parallel the trend observed in GAGC.

The anomeric region (5.5–6.0 ppm) of the spectrum of the tetranucleotide GCUC showed a com-

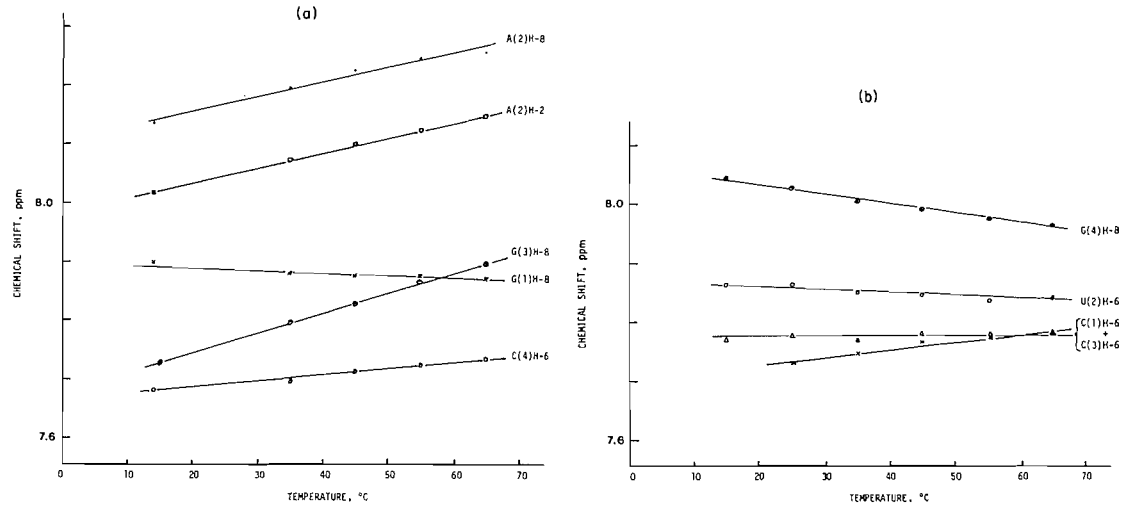

FIG. 2. Variable temperature versus chemical shift plots for: (*a*) GAGC base protons (concentration 6.1 × 10^{-3} *M*) and (*b*) GCUC base protons (concentration 7.3 × 10^{-3} *M*).

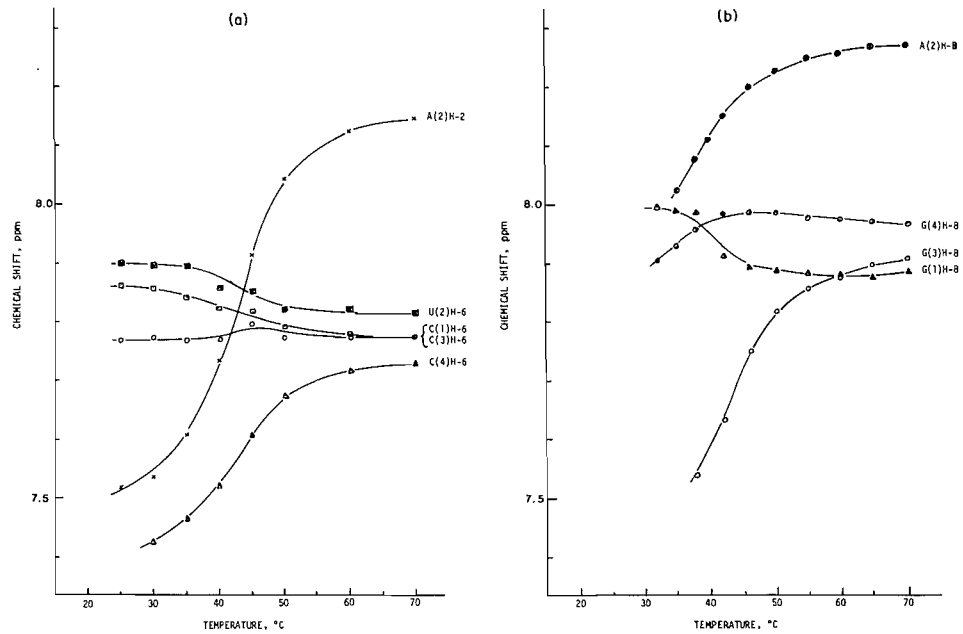

FIG. 3. Temperature dependence of the chemical shifts of the base protons of the duplex GAGC–GCUC (concentration 6.1 and 7.3 × 10^{-3} *M* in 1.0 *M* NaCl and 0.01 *M* sodium phosphate, pD 7.0): (*a*) the nonexchangeable protons A(2)H-2, U(2)H-6, C(1)H-6, C(3)H-6, and C(4)H-6; (*b*) the exchangeable protons A(2)H-8, G(4)H-8, G(3)H-8, and G(1)H-8.

plex overlapping set of lines derived from the four anomeric protons plus the three H-5 protons of C(2), U(3), and C(4) and assignment of the resonances was not attempted. The aromatic region however was simpler and showed only a singlet at 7.965 ppm (assigned G(4)H-8) and four lines between 7.7 and 7.9 ppm. The intensity ratios and coupling constants expected for uracil and cytosine residues led to the assignment of U(2)H-6 at 7.839 ppm ($J_{5,6}$ = 7.6 Hz) and C(3)H-6 and C(1)H-6 at 7.780 ppm ($J_{5,6}$ = 7.4 Hz). The superposition of the C(3)H-6 and C(1)H-6 signals was removed at lower temperatures when one of the protons showed an upfield shift whilst the other showed virtually no chemical shift changes (see Fig. 2*b*). Unfortunately no unambiguous assignment of C(3)H-6 and C(1)H-6 at the lower temperatures could be made but it is probable that the signal showing the greater upfield shift at lower temperatures (7.729 ppm at 25°C) belongs to C(3)H-6 as any stacking interaction

between G(4) and C(3) would be expected to result in a diamagnetic shift of the C(3) protons.

The spectrum of the GAGC:GCUC duplex at 65°C was astonishingly close to the sum of the spectra of the two separate strands and emphasised the complete absence of inter- and intra-strand effects at this temperature. The shifts of the various aromatic protons with decreasing temperature varied widely with those of A(2)H-2 being the most dramatic. Unfortunately, because of the severe line broadening experienced at lower temperatures, the full sigmoidal shape of the protons C(1)H-6, G(1)H-8, A(2)H-2, U(2)H-6, C(3)H-6, and C(4)H-6 was only visible. However, these lines with perhaps the exception of C(3)H-6 which showed a most curious temperature behaviour, all gave T_m values lying within the range 42 $\pm$ 1°C. The agreement between this T_m and the extrapolated value expected on the basis of variable concentration – uv studies (7) is remarkable but in conjunction with the similar correspondence in T_m values noted by Borer *et al.* (2) from their studies on the self-complementary A_2GCU_2 system, we must conclude that the nmr method appears to be a valid analytical tool for the measurement of T_m values.

The three protons A(2)H-8, G(3)H-8, and G(4)H-8 whose line positions could not be followed down to 25°C because of excessive line broadening coupled with the problem of line intensity loss arising from the H-8 to D-8 exchange process, showed a curious differential behaviour. The line for G(3)H-8 probably has a T_m close to 43°C but both A(2)H-8 and G(4)H-8 had barely begun the expected upfield movement at 42°C. This suggests that the T_m for these protons is much below 40°C. For the present duplex, these two low T_m values may appear at first sight to be rather unusual, particularly that of A(2)H-8. However, it is a pointed reminder that in observing the shift changes of these aromatic protons we are monitoring a plethora of local diamagnetic and paramagnetic effects which are exerting their influence over a spatial region that is very proximate to each of the protons. Factors such as base ring current shieldings or deshieldings, furanose ring conformations, glycosyl-base ring conformations, phosphate group anisotropies as well as inter-strand hydrogen bondings are all contributing to the screening constant of each hydrogen. Moreover, as we proceed through the T_m region, there is the additional averaging effect arising from the dynamic interconversion between the various intermediate states where only some of the bases are hydrogen bonding. With these points in mind it is not so much surprising that A(2)H-8 and G(4)H-8 show low T_m values but rather that the remaining seven protons should show T_m values so closely grouped together.

From the data presented here on the GAGC:GCUC duplex, there is no evidence of the fraying process noted by Borer *et al.* (2) and Ts'o *et al.* (12) in their examination of the self-complementary A_2GCU_2. It is reasonable to suggest that with the weaker A·U interaction being an interior one in the present duplex, the tendency for a G·C end fraying is much reduced. It is pertinent to note here that preliminary studies in our laboratories of the self-complementary tetramer CAUG shows a general lowering of the T_m values as is consistent with the presence of two A·U pairs but no evidence for terminal fraying of the stronger binding G·C pairs.

The line broadening effects noted for the present duplex appears to be typical of oligonucleotide sequences at relatively high concentrations. We are in full agreement with Borer *et al.* (2) that the principal line broadening factor is interduplex end-to-end stacking. The rate at which the various protons of the duplex broadened was also consistent with this view. Thus the end C(4)H-6 doublet broadened rapidly whereas the A(2)H-2 singlet remained relatively sharp until well below the T_m value. In addition the samples as a whole became distinctly turbid at temperatures below 25°C, and this was taken as evidence that polyduplex stacking was occurring.

Experimental

The compounds used in this study, GA, GAG, GAGC, and GCUC were all synthesised by procedures reported by England and Neilson (13).

The majority of the proton magnetic resonance data was collected on a Bruker WH-90 spectrometer operating in the Fourier transform mode. Temperatures were maintained to within $\pm$1°C by a Bruker B-ST 100/700 variable temperature unit and were calibrated by thermocouple measurements. Some spectra, mainly for confirmation purposes, were recorded at 220 MHz at the Canadian 220 MHz Centre, University of Toronto, Toronto, Ontario. The spectra were referenced to internal DSS (2,2-dimethyl-2-silapentan-5-sulphonate) by using the methyl line of *tert*-butyl alcohol-OD at 1.231 ppm as an internal standard. Chemical shifts were found to be reproducible to better than $\pm$0.005 ppm and coupling constants to less than $\pm$0.2 Hz. All samples were lyophilised twice from D_2O before use and they were taken up in 100% D_2O which was 1.0 *M* in sodium chloride and 0.01 *M* in sodium phosphate buffer (pD 7.0). Concentrations varied from 6.1 to 7.3 $\times$ 10^{-3} *M* and the spectra reported here are the result of three runs on the duplex sample.

Proton nuclear magnetic resonance was used to examine double helix formation in the self-complementary oligoribonucleotide CAUG in neutral D_2O containing 1.0 *M* NaCl. Using the procedure of incremental assignment all the nonexchangeable base and ribose anomeric protons could be assigned and were observed over the temperature range of 70 to 4°C. The chemical shift changes that occurred over this temperature range were sigmoidal in nature which is indicative of base-pairing. From the plot of chemical shift vs. temperature a T_m of 24 ± 1°C was determined. This is the first nmr study of a duplex formed from tetranucleotides which contains two internal A·U base pairs.

PAUL J. ROMANIUK, THOMAS NEILSON, DONALD W. HUGHES et RUSSELL A. BELL. Can. J. Chem. **56**, 2249 (1978).

On a utilisé la résonance magnétique nucléaire du proton pour examiner la formation de doubles hélices dans l'oligoribonucléotide auto-complémentaire CAUG dans du D_2O neutre contenant du NaCl à 1.0 *M*. Faisant appel à la méthode des attributions par augmentation, on a pu identifier, à des températures allant de 70 à 4°C, tous les protons de la base non échangeable et du ribose. Les changements dans les déplacements chimiques qui se produisent dans cet intervalle de température sont de nature sigmoidale et ils indiquent la présence d'un pairage des bases. A partir de la courbe des déplacements chimiques en fonction de la température, on a pu déterminer un T_m de 24 ± 1°C. Ceci est la première étude rmn de la formation d'un duplex à partir de tétranucléotides qui contiennent deux paires de base A·U internes.
[Traduit par le journal]

Introduction

Nuclear magnetic resonance spectroscopy of short oligoribonucleotides has been utilized to probe the physical properties of helix formation of nucleic acids (1–5). Of the several methods available to study these properties, nmr is capable of providing information on the conformational and environmental changes that occur during duplex formation. As well, there have been reports of good correlations between melting temperatures determined by nmr experiments and those predicted by optical methods (1, 2). This was further demonstrated by a study employing both optical methods and nmr of the interaction between the non-self-complementary sequences GAGC and GCUC (6, 7).[3] This was the first report of a duplex between tetraribonucleotides which contained one internal A·U base pair.

Self-complementary sequences are particularly suited for study by nmr since the symmetry of the duplex reduces the number of resonances and therefore complete chemical shift assignments of the base and ribose anomeric protons can usually be made. In addition, chemical synthesis of oligoribonucleotides by the phosphotriester method (8, 9) allows a variety of sequences to be prepared in high yield. In some cases, multi-stranded aggregates are formed by short oligoribonucleotides (10) although this has not yet been observed with a self-complementary sequence. We now report an nmr study on CAUG, a self-complementary tetraribonucleotide which forms a duplex containing two internal A·U base pairs. We intend to use this short helix as a reference for studies on the effect dangling bases and bulge loops have on the stability of RNA secondary structure.

Experimental

The 90 MHz proton nuclear magnetic resonance spectra were recorded in the Fourier transform mode on a Bruker WH-90 spectrometer equipped with quadrature detection. Probe temperatures were maintained to within ±1°C by a Bruker B-ST 100/700 variable temperature unit and were calibrated by thermocouple measurements. Samples were dissolved in 100% D_2O which contained 1.0 *M* sodium chloride and 0.01 *M* sodium phosphate buffer (pD = 7.0).

tert-Butyl alcohol-OD was used as an internal reference and the chemical shifts are reported relative to DSS (2,2-dimethyl-2-silapentan-5-sulphonate). The deuterium signal of D_2O provided the field-frequency lock.

The compounds used in this study were prepared by standard procedures: CA, CAU, CAUG, and AUG by the methods of ref. 11.

Results

The low-field proton resonances of CAUG were assigned by comparison with the spectra of CA, CAU, and AUG all of which were recorded at 70°C. These data are presented in Tables 1 and 2. Figure 1 contains the 90 MHz spectra of CAUG at 70°C to illustrate the chemical shift assignments.

The effect of temperature variation on the proton resonances of CAU and AUG was examined, and the results are summarized in Figs. 2 and 3. The resonances of the trinucleotides varied linearly with temperature over the range of 17 to 70°C. For CAU all the protons displayed upfield shifts with decreasing temperature, except for CH-6 which was deshielded. Similar results were obtained for AUG with all the resonances being shielded. At high temperatures the UH-1′ and GH-1′ signals were

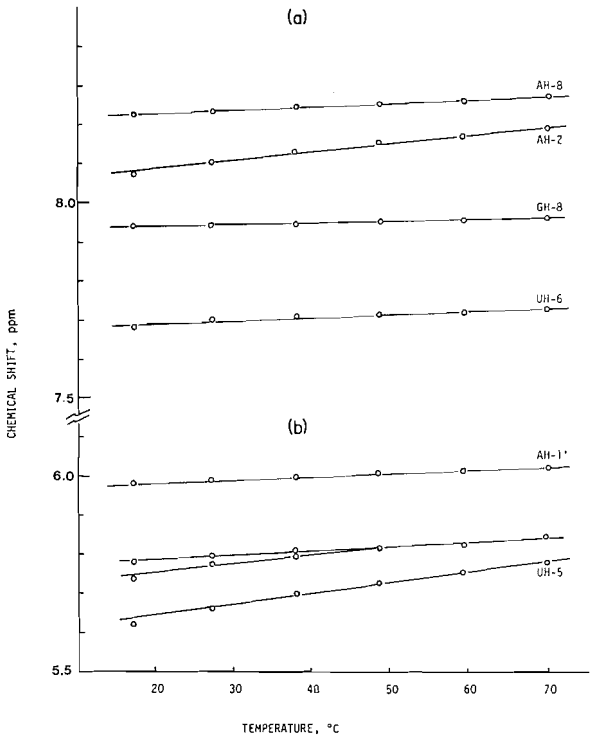

FIG. 3. Chemical shift vs. temperature plots for (*a*) the base and (*b*) the anomeric protons of AUG (concentration, 1.3×10^{-2} *M* in 1.0 *M* NaCl and 0.01 *M* sodium phosphate, pD 7.0). Chemical shifts are relative to internal DSS.

greatest chemical shift change and also remained relatively sharp throughout the temperature range. A large reduction in the magnitude of the H-1′, H-2′ coupling constant was observed until at 20°C these resonances appeared as broad singlets.

The average melting temperature, T_m of the CAUG duplex as determined from the temperature–chemical shift curves of AH-8, AH-2, and GH-8 was found to be 24 ± 1°C.

Discussion

Chemical shift assignments were determined by the standard technique of incremental analysis (2, 12) in which the base and ribose anomeric protons of CA, CAU, and AUG were correlated with those of CAUG. The CA shifts were in agreement with the results published by Ezra *et al.* (13). Addition of the uridine moiety to form CAU resulted in three new doublets appearing at 7.744 (UH-6, $J_{5,6}$ = 8.2 Hz), 5.746 (UH-5, $J_{5,6}$ = 8.2 Hz), and 5.856 ppm (UH-1′, $J_{1',2'}$ = 4.6 Hz). The cytidine and uridine aromatic protons were differentiated by the magnitude of the H-5 and H-6 coupling constant, cytidine, $J_{5,6}$ = 7.6 Hz; uridine, $J_{5,6}$ = 8.2 Hz. The uridine H-5 resonance was distinguished from the anomeric protons by irradiation of H-6 which caused the collapse of the doublet at 5.746 ppm.

The low-field signals of AUG were assigned by comparison to AU and UG (13). The anomeric region of the high temperature spectrum was complicated by the overlap of the UH-1′ and GH-1′ doublets and it was only at lower temperatures that these resonances separated. The lower field signal was tentatively assigned to GH-1′ since this proton should only be slightly shielded due to the weak stacking interaction between the U and G bases (13).

Using the chemical shift assignments of the trimers, the aromatic resonances of CAUG could be readily determined (Table 1 and Figure 1). Assignment of the anomeric protons was made difficult by the overlap of CH-5 (5.912 ppm) and UH-1′ (5.845 ppm), and GH-1′ (5.813 ppm), CH-1′ (5.765 ppm), and UH-5 (5.738 ppm). The observa-

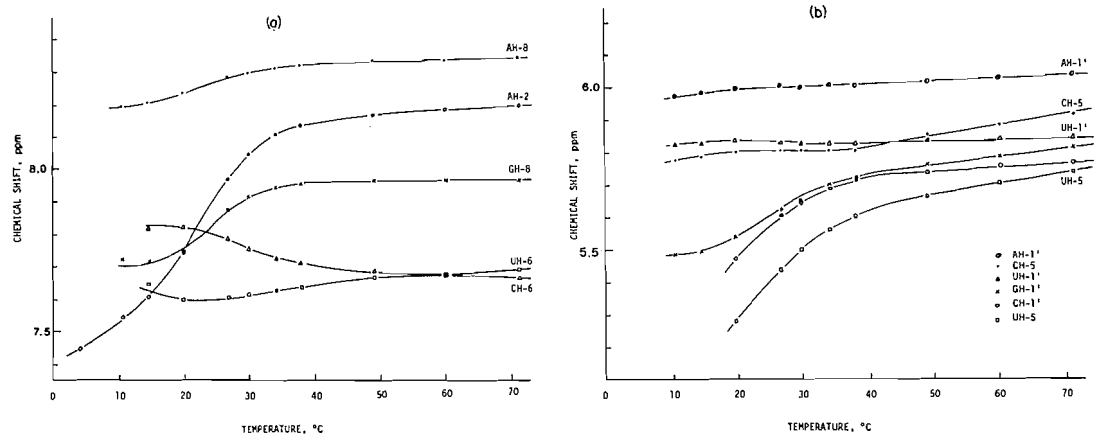

FIG. 4. Dependence of the chemical shift on temperature for the tetranucleotide CAUG (concentration, 9.2×10^{-3} *M* in 1.0 *M* NaCl and 0.01 *M* sodium phosphate, pD 7.0). Some points were not measurable below 20°C because of excessive line broadening. Chemical shifts are relative to internal DSS.

tion that CH-6 and UH-6 become equivalent near 60°C permitted the simultaneous irradiation of both pyrimidine H-6 resonances and the collapse of both H-5 doublets facilitated the analysis of the anomeric region of the spectrum. A direct result of this double irradiation experiment was that the UH-1′ and GH-1′ signals were found to be nonequivalent in the tetranucleotide as they were in AUG.

The effect of temperature variation on the proton resonances of CAU and AUG was linear and predominantly upfield (Figs. 2 and 3). These shift changes that were observed for the trimers were the result of intramolecular base stacking and were not characteristic of base pairing (1, 2, 7). The degree of base stacking was indicated by the reduction in the value of $J_{1',2'}$ (13 and 15). This corresponds to a shift in the ribose conformational equilibrium towards the ^3E or *C*-3′ *endo* structure. CAU showed the largest conformation changes since at 17°C all the anomeric proton doublets had collapsed to broad singlets with $J_{1',2'}$ less than 1.0 Hz. In contrast, the AUG anomeric couplings at 17°C were still well resolved with a range of 2.0 to 4.5 Hz. This difference in the degree of base stacking in these trimers is currently under further investigation.

The behaviour of the CAUG resonances with respect to temperature was dramatically different to that of the trimers. Above 45°C there was a linear change with respect to temperature for the base and anomeric protons and this is attributed to single strand intramolecular base stacking. Below 45°C there was a general nonlinear variation which is associated with the formation of the following base-paired duplex:

5′-CpApUpG-3′
. . . .
3′-GpUpApC-5′

Of the aromatic protons, AH-8, AH-2, and GH-8 all produced well defined sigmoidal curves. The average T_m was determined to be 24 ± 1°C. It is interesting to note that the pyrimidine H-6 resonances follow essentially the same trend that was observed in CAU. This appears to be a result of the similarity in base-stacking interactions in CAU and CAUG. In the anomeric region of the spectrum the AH-1′, CH-5, and UH-1′ resonances all undergo relatively small shielding changes when compared to GH-1′, CH-1′, and UH-5. Although the curve for GH-1′ is not as well defined as those of the aromatic protons, a T_m of 26 ± 1°C was estimated which is close to the value obtained for the aromatic protons.

Two aspects on the stability of the duplex formed by CAUG arise from these data. The first is the similarity in the T_m values for the majority of resonances of both the terminal and interior base pairs. This may be an indication that the presence of terminal G·C base pairs reduced any effects of fraying. Secondly, increasing the number of A·U base pairs in the interior of the duplex causes a lowering of the T_m value. This is demonstrated by comparison to the duplex formed by GAGC:GCUC (T_m = 42 ± 1°C) which has only one interior A·U base pair (7).

The large reduction in the coupling constant of the anomeric protons as the temperature was lowered ($J_{1',2'}$ less than 1.0 Hz at 20°C) is indicative of a high percentage of the C-3′ endo conformation of the ribose rings. This is consistent with the helical duplex having either the A- or A′-RNA conformation. It appears that base stacking is an integral process involved in double helix formation and may make a significant contribution to the helix stability (16).

A ^{19}F nuclear magnetic resonance and Raman spectroscopic investigation of the reaction of iodine oxide pentafluoride with the Lewis acids, antimony and arsenic pentafluoride

MORLEY BROWNSTEIN, RONALD J. GILLESPIE, AND JOHN P. KRASZNAI
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 20, 1977

MORLEY BROWNSTEIN, RONALD J. GILLESPIE, and JOHN P. KRASZNAI. Can. J. Chem. **56**, 2253 (1978).

The reactions of IOF_5 with SbF_5 and with AsF_5 have been investigated at low temperature by ^{19}F nmr and Raman spectroscopy. It was found that SbF_5 forms labile 1:1 and 2:1 complexes whereas AsF_5 forms only a 1:1 complex. The IOF_5 is bound through its oxygen atom to the Lewis acids AsF_5, SbF_5, or $(SbF_5)_2$.

MORLEY BROWNSTEIN, RONALD J. GILLESPIE et JOHN P. KRASZNAI. Can. J. Chem. **56**, 2253 (1978).

Les réactions entre IOF_5 et SbF_5 ou AsF_5 ont été étudiées à basse température par spectroscopie rmn (^{19}F) et Raman. Dans le cas de l'antimoine la formation de complexes labiles 1:1 et 2:1 a été mise en évidence. Par contre avec l'arsenic seul le complexe 1:1 se forme. Le IOF_5 est lié par son atome d'oxygène aux acides de Lewis AsF_5, SbF_5 ou $(SbF_5)_2$.

Introduction

It has been shown by Bartlett and Beaton (1) that IOF_5 does not react with SbF_5 even at elevated temperature and pressure to give the IOF_4^+ cation. We have used ^{19}F nmr and laser Raman spectroscopy to investigate the interaction of IOF_5 with SbF_5 and AsF_5 and we have obtained evidence for the formation of donor–acceptor complexes in which the Lewis acid is coordinated to the oxygen of IOF_5. Similar complexes have been observed previously (2, 3) between SbF_5 or AsF_5 and weak bases such as SO_2ClF, SOF_2, CH_3SO_2F, and SO_2 and it was shown that in all of these complexes the base is coordinated to the Lewis acid via the oxygen. SO_2F_2, on the other hand, was found to be too weak a base to interact with SbF_5 or AsF_5 even at very low temperatures and, hence, it was used as an inert low temperature solvent for the present work.

Results and Discussion

The IOF_5–AsF_5 System

The room temperature ^{19}F nmr spectrum of a solution of IOF_5 and excess AsF_5 in SO_2F_2 shows in addition to the solvent peak a very broad line with a linewidth at half height of 1040 Hz at 61 ppm upfield from external $CFCl_3$ which can be assigned to the F-on-As resonance and a rather broad and weak peak at −66 ppm which can be assigned to IOF_5. As the sample is cooled to −110°C, the F-on-As resonance sharpens and the previously collapsed spectrum of IOF_5 becomes well resolved to give a second order AB_4 multiplet. Figure 1 shows the spectrum of a solution containing IOF_5 and excess AsF_5 in SO_2F_2 at −110°C, and Table 1 lists the nmr parameters. The AB_4 multiplet of the IOF_5 spectrum shows all nine of the expected transitions (4) for the A spin system. The second order transitions for the B spin system are not observed because the lines are rather broad and the linewidth is comparable with the expected separation of the lines. The AB_4 spectrum differs from that of a solution of IOF_5 in SO_2F_2 (Fig. 2) in both chemical shift and F—F coupling constant and the linewidth is reduced from 180 to 50 Hz in the presence of AsF_5. These observations suggest that there is complex formation between IOF_5 and AsF_5 at these low temperatures. This complex formation is responsible for the change in the chemical shift and coupling constant of IOF_5 and it also increases the rate of quadrupole relaxation of the iodine by making the electric field gradient around the iodine nucleus less symmetrical and thus

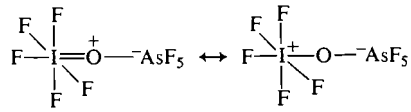
decreasing the linewidths. Similarly, the sharpness of the F-on-As peak indicates a much greater rate of quadrupole relaxation of the ^{75}As ($I = \frac{3}{2}$) nucleus than in AsF_5 alone. This would be expected since the electric field gradient about the arsenic will be greater in the complexed molecule than in uncomplexed AsF_5. Although free AsF_5 has a trigonal bipyramidal structure, very rapid intramolecular exchange of the fluorine atoms (pseudorotation) causes a rapid averaging of the electric field gradient to a low value. This very much decreases the rate of quadrupole relaxation and an extensively but incompletely collapsed multiplet spectrum is observed as a rather broad single line. In complexed AsF_5, although there is apparently a more symmetric octahedral arrangement of bonds about arsenic, five are strong As—F bonds while the sixth is a weak As—O bond. The resultant electric field gradient and, hence, the rate of quadrupole relaxation would be expected to be greater for complexed AsF_5 than for uncomplexed AsF_5 giving rise to a sharper line for the former.

The Raman spectrum of the 1:1 adduct is shown in Fig. 3*A* and Table 2 lists the frequencies and approximate descriptions of some of the vibrational modes for both the AsF_5 and SbF_5 adducts, together with pure IOF_5, AsF_5, and SbF_5 at −100°C. The IOF_5 group of the complex retains C_{4v} symmetry on the nmr time scale in SO_2F_2 solution at −100°C. However, this symmetry is probably lowered in the solid and since there are 13 atoms in the complex, a maximum of 33 fundamental modes are expected in the vibrational spectrum. Clearly it is not possible to assign all of these peaks with certainty but since the I=O stretching mode has the highest frequency in free IOF_5 we can at least assign the IO stretch in the complex with confidence. The peak at 921 cm^{-1} is the IO stretch of free IOF_5 (5, 6) which is produced by partial dissociation of the complex: (eq. [1])

$$[1] \qquad IOF_5 \cdot AsF_5 \rightleftarrows IOF_5 + AsF_5$$

The intensity of this peak increases at the expense of the peak at 853 cm^{-1} as the temperature is raised from −100°C and, therefore, we assign the peak at 853 cm^{-1} to the IO stretch of the complexed IOF_5. The reduction in the IO stretching frequency on complexation is consistent with a contribution from a single bonded resonance structure **2** to the structure



1 **2**

of the complex. A separate AB_4 spectrum is not observed for the uncomplexed IOF_5 and since the peaks of the complex are reasonably sharp we conclude that even at −100°C there is fast exchange between the complex and its components. A similar observation was made in the SOF_2–AsF_5 system (3) where at −100°C only one sharp peak was observed in the F-on-S region of the nmr spectrum. The AsO stretching frequency is difficult to assign due to the

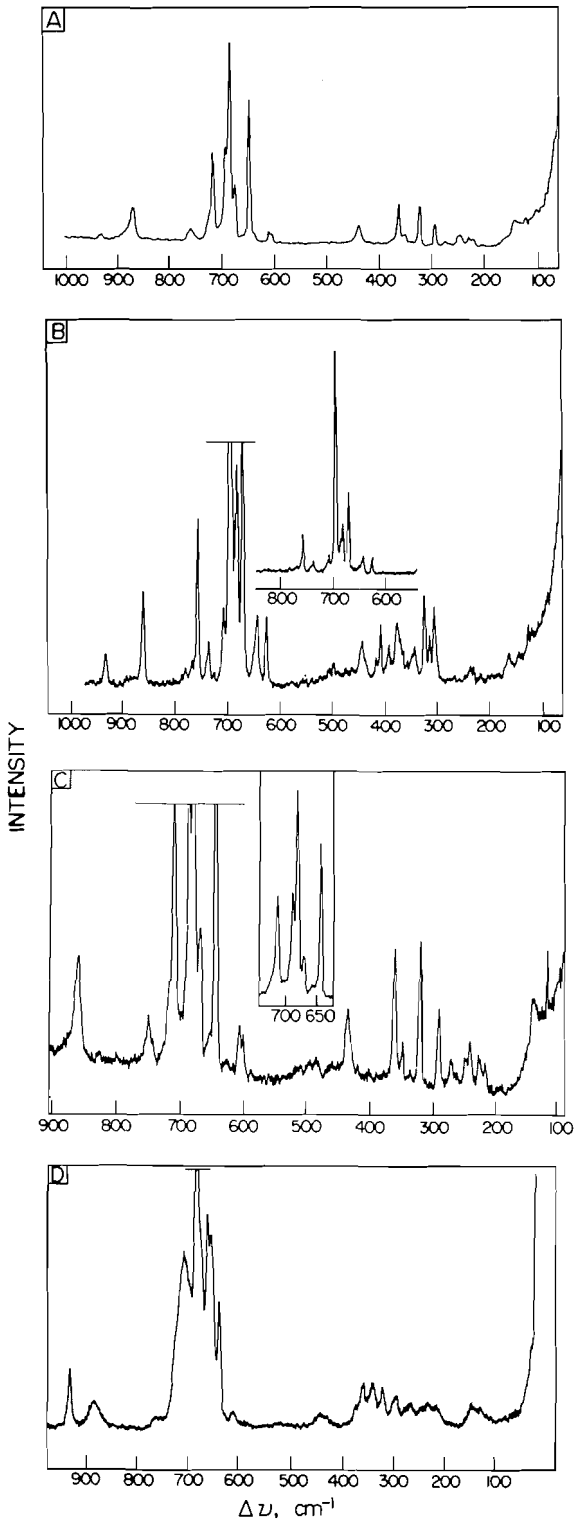

FIG. 3. Raman spectra of: (*A*) $IOF_5 \cdot AsF_5$ at −100°C; (*B*) $IOF_5 \cdot SbF_5$ at −100°C; (*C*) $IOF_5 \cdot 2.2SbF_5$ at −83°C; (*D*) $IOF_5 \cdot 2.2SbF_5$ at 25°C.

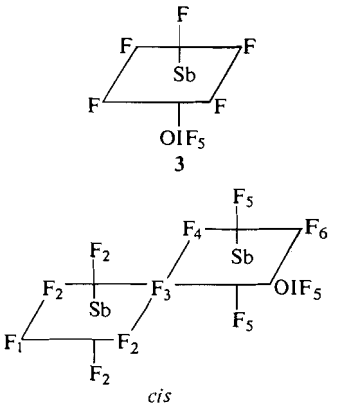
complexity of the Raman spectrum but in the ions AsF_5OH^- and $AsF_4(OH)_2^-$ it has been found at 562 and 554 cm^{-1} respectively (7). However, in the spectrum of the adduct no peaks are observed between 500 and 600 cm^{-1}. The IO stretching frequency of 853 cm^{-1} indicates considerable double bond character in the IO bond as the frequency is close to that of IO_4^- (838 cm^{-1}) (8). Hence, one might expect that the AsO bond will be correspondingly weak. Therefore, we tentatively assign the peak at 438 cm^{-1} to the AsO stretching frequency.

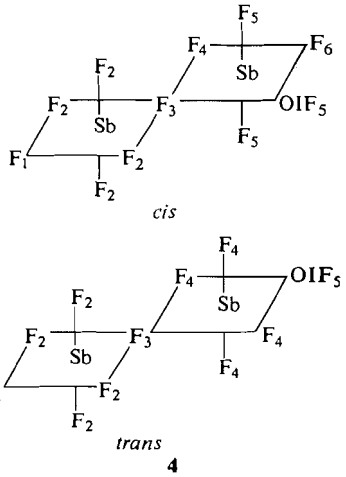
The IOF_5–SbF_5 System

The room temperature ^{19}F nmr spectrum of solutions of IOF_5 and SbF_5 in SO_2F_2 as solvent exhibit very broad lines for the F-on-I(VII) and F-on-Sb(V) regions of the spectrum. However, on cooling the solution to about −100°C fine structure is observed. Figure 4 shows the spectrum of an equimolar solution of IOF_5 and SbF_5 in SO_2F_2 at −110°C and the various parameters derived from the spectrum are summarized in Table 3. The spectrum shows in addition to the solvent peak, S, several complex multiplets in the F-on-I(VII) and F-on-Sb(V) regions.

We interpret the spectrum in terms of free IOF_5 and 1:1 and 1:2 IOF_5–SbF_5 complexes **3** and **4**.



3



4

Furthermore, the spectrum is only consistent with the IOF_5 coordinating to SbF_5 through oxygen and not through fluorine. The five fluorines on Sb in structure **3** are expected to give rise to an AX_4 spectrum as observed for the multiplets labelled G.

[b]B spin system for uncomplexed IOF_5 is obscured by those of the 1:1 and 1:2 complexes.

The fluorines F_2 in the *cis* bridged structure **4** are expected to be the most intense part of the spectrum for this complex and to be a doublet of doublets from coupling to both F_1 and F_3 and therefore M is assigned to fluorines F_2. Double resonance experiments by Dean and Gillespie (2) for the SO_2ClF–SbF_5 system where the profile of the Sb region is very similar to that in the IOF_5–SbF_5 system showed that the peaks labelled K, L, N, O, and P may be assigned to the fluorines F_3, F_5, F_6, F_4, and F_1, respectively. F_3 is coupled to fluorines F_2, F_4, F_5, and perhaps F_6 and is, therefore, expected to give rise to a broad unresolved line as seen for resonance *K*. F_1 is expected to be a quintet provided $J_{F_1-F_3}$ is zero as in $Sb_2F_{11}^-$ (9) by coupling to the four equivalent fluorines F_2. The fluorines F_4, F_5, and F_6 are expected to give rise to complex multiplets by coupling to F_3 and with each other. There is no evidence from the ^{19}F nmr spectrum for the *trans* bridged structure although the $Sb_3F_{16}^-$ anion, which is isoelectronic with the 1:2 complex, has been shown (10) to be *cis* bridged in solution and *trans* fluorine bridged in the solid (11).

In the F-on-I(VII) region, we assign the second order AB_4 multiplet to the fluorines on iodine in the 1:1 complex and the $A'B'_4$ multiplet to those in the 1:2 complex; the approximate ratio of the intensities of AB_4:$A'B'_4$ is 1:0.5 which is in excellent agreement with the approximate intensities of the resonances in the F-on-Sb region which give a mole ratio of **3**:**4** = 1:0.5. However, since the original solution was equimolar in IOF_5 and SbF_5, the presence of **4** indicates that there must also be some free IOF_5 in the solution. The two broad weak lines at −106.7 and −112 ppm (A″) are assigned to two transitions of the A spin system of free IOF_5 ($A''B''_4$), the remaining lines being hidden under the A and A′ resonances whilst the B″ doublet of free IOF_5 is hidden under the B and B′ doublets of the 1:1 and 1:2 complexes (Fig. 4).

The Raman spectra of an equimolar mixture of IOF_5 and SbF_5 as well as a mixture with excess SbF_5 were recorded at low temperature in the absence of a solvent (Fig. 3*B*, *C*, *D*). The IO region of the spectrum showed three peaks for the equimolar solution but only two for the solution containing excess SbF_5. The peak at 918 cm^{-1} can be unambiguously assigned to the IO stretch of free IOF_5 (5, 6) and the peaks at 872 and 864 cm^{-1} to the 1:2 and 1:1 complexes of IOF_5 with SbF_5 respectively. The nmr spectrum of an equimolar solution in SO_2F_2 showed that the 1:1 complex was present in higher concentration than the 1:2 complex at low temperature and this formed the basis for the assignment of the more intense peak at 864 cm^{-1} to the 1:1 complex and the shoulder at 872 cm^{-1} to the 1:2 complex. For the sample which contained excess SbF_5, the Raman spectrum at −83°C showed only the peaks attributable to the complexes, i.e. at 858 and 875 cm^{-1}. As this solution was warmed the peak at 875 cm^{-1} increased in intensity at the expense of the one at 858 cm^{-1} and dissociation to free IOF_5 occurred as evidenced by the appearance of the peak at 920 cm^{-1}. At room temperature the peak at 858 cm^{-1} had disappeared completely. This dissociation can be expressed by [2].

$$[2] \qquad 2IOF_5 \cdot SbF_5 \rightleftarrows IOF_5 \cdot 2SbF_5 + IOF_5$$

At low temperature there is an appreciable quantity of the 1:1 complex which dissociates until at room temperature the equilibrium lies predominantly to the right. The shift of the IO stretching mode to lower frequency is consistent with complexation through the oxygen and, furthermore, the shift of about 60 cm^{-1} indicates a relatively weak interaction. The SbO stretching mode is found at a frequency of 553 cm^{-1} in $SbF_5(OH)^-$ (7) and for the same reasons as were discussed earlier for the AsF_5 complex, we assign the polarised band at 438 cm^{-1} in the SbF_5 adduct to the SbO stretching frequency. However, if two different IO stretches are observed for the 1:1 and 1:2 complexes then two separate SbO stretches should also be observed. The position of the peak at 438 cm^{-1} does not change as the sample is warmed to room temperature and we must conclude that the two SbO stretching fre-

quencies for the 1:1 and 1:2 complexes are coincident. These assignments should, however, be regarded as tentative since in practice it is very difficult to distinguish between SbF, IF, and SbO stretching frequencies in complex molecules such as these.

Conclusions

SbF_5 forms 1:1 and 2:1 complexes with IOF_5. Because AsF_5 shows very little tendency to form polymeric As_nF_{5n} units, it forms only a 1:1 adduct. In all of these complexes the IOF_5 is oxygen bridged to the Lewis acid. This bridge in the 2:1 complex is shown to be *cis* to the fluorine bridge of the Sb_2F_{10} unit. Since both the 1:1 and 2:1 complexes exist in solution together with uncomplexed IOF_5, the Lewis basicity of the 1:1 complex must be comparable to that of IOF_5 itself.

It is interesting that IOF_5 is not a fluoride ion donor whereas IF_7 loses a fluoride to a strong Lewis acid such as SbF_5 to give the IF_6^+ cation. Christe has pointed out that highly symmetrical (i.e., octahedral and tetrahedral) fluorides and oxyfluorides (15) are frequently poorer fluoride ion donors than similar compounds of lower symmetry.

Experimental

Preparation of IOF_5

IOF_5 was prepared by the partial hydrolysis (12) of IF_7 in a Kel-F trap containing a small amount of sodium fluoride to remove the HF produced.

IF_7 was prepared by the high pressure, high temperature fluorination (13, 14) of iodine pentafluoride (Matheson) in a welded Monel can connected via $\frac{1}{4}$ in. Monel tubing to a Monel vacuum line. Excess fluorine was removed by pumping the vessel at −196°C.

Antimony pentafluoride was obtained from the Ozark Mahoning Co., and triply distilled in an atmosphere of dry air using an all-glass apparatus.

Arsenic pentafluoride was obtained from the Ozark Mahoning Co., and used directly.

Sulfuryl fluoride (Matheson of Canada) showed only one line in the ^{19}F nmr spectrum and was used without further purification.

Nuclear Magnetic Resonance Measurements

Fluorine nmr spectra were measured using a Varian DA-601L spectrometer operating at 58.3 MHz and modified as described previously (2) to record spectra from the first upper side band in the field sweep unlock mode.

Raman Spectra

Raman spectra were obtained using a Spex Industries Model 1400 spectrometer utilizing the 5145 Å radiation from a Spectra Physics model 164 argon ion laser. Spectra were recorded at −100°C by placing the sample tube inside a glass tube surrounded by an evacuated jacket, silvered except at the centre. Liquid N_2 was boiled off from a Dewar flask and passed through the tube. The temperature was monitored with a copper–constantan thermocouple positioned in the stream just ahead of the sample region. The Raman shifts are estimated to be accurate to $\pm 2\ cm^{-1}$.

Sample Preparation

All manipulations were carried out under anhydrous conditions on a vacuum line constructed from Monel, Kel-F, and Teflon or in a dry box. All preparative work was done in 15 cm × 2 cm od Kel-F tubes (Argonne National Laboratory) equipped with Kel-F heads and Teflon valves.

The nmr and Raman samples were prepared and vacuum sealed in 5 mm od medium wall Pyrex nmr tubes attached to Teflon valves with $\frac{1}{4}$ in. Teflon nuts and ferrules. The SbF_5 samples were prepared by distilling an appropriate quantity of IOF_5 onto a known amount of SbF_5 and then distilling in an excess of SO_2F_2. The AsF_5 samples were prepared similarly except that the AsF_5 was distilled onto a known amount of IOF_5 and then the solvent, SO_2F_2, was added.

Distillation extractive. II. Etude de l'interaction entre carbures insaturés et solvants dipolaires

CLAUDE WAKSELMAN ET MICHEL BOUQUET
C.N.R.S.-C.E.R.C.O.A. 2 à 8, rue Henry Dunant, 94320 Thiais, France

Reçu le 2 novembre 1977[1]

CLAUDE WAKSELMAN et MICHEL BOUQUET. Can. J. Chem. **56**, 2259 (1978).

La nature des interactions entre hydrocarbures insaturés et solvants aprotiques dipolaires, intervenant dans la distillation extractive, a été étudiée par rmn du ^{13}C, mesure de constantes diélectriques et de moments dipolaires. Les résultats de ces différentes techniques sont en accord avec des interactions de type dipolaire.

CLAUDE WAKSELMAN and MICHEL BOUQUET. Can. J. Chem. **56**, 2259 (1978).

The nature of the interactions between unsaturated hydrocarbons and dipolar aprotic solvents, which occur in the extractive distillations, has been studied by ^{13}C nmr, dielectric constant, and dipole moment measurements. The results of these different methods are in agreement with dipolar interactions.

I. Introduction

Bien que la distillation extractive soit un procédé très utilisé en pétrochimie, la nature du phénomène mis en jeu est encore mal connue.

La séparation d'un mélange de monooléfines, de dioléfines et de parafines d'une coupe d'hydrocarbures en C_4 ou C_5 peut être effectuée par introduction en haut d'une colonne à distiller d'un complexant spécifique des carbures non saturés. Ce complexant est en général un solvant aprotique dipolaire tel que l'acétonitrile, le diméthylsulfoxide ou la *N*-méthyl pyrrolidone (NMP). Il apparaît que les meilleurs complexants présentent un fort dipole et un faible volume molaire (1). La valeur des volatilités relatives des différents hydrocarbures, à dilution infinie dans les solvants, peut être déterminée par chromatographie en phase vapeur, en utilisant une colonne imprégnée par le complexant. La sélectivité (2) d'un solvant peut être caractérisée par la séparation qu'il opère sur le couple d'hydrocarbures de référence isoprène/méthyl-2 butène-2. Cette définition est effectivement utilisée en France par les spécialistes de pétrochimie pour caractériser les complexants.[2]

Une étude (3) par rmn du proton a été effectuée récemment. Elle décrit une tentative de corrélation entre les variations de déplacement chimique des hydrogènes de l'isoprène et du méthyl-2 butène-2, induites par différents solvants dipolaires aprotiques, et les volatilités relatives de ces hydrocarbures. Il nous est apparu que les résultats obtenus par cette technique sont peu cohérents; nous avons alors abordé ce sujet à l'aide de la rmn du ^{13}C (communication préliminaire (4)), et par le calcul de moments dipolaires.

II. Méthodes expérimentales

1. Préparation des solvants et solutés

La N-méthylpyrrolidone (NMP), l'hexaméthylphosphotriamide (HMPT), le carbonate d'éthylène (CE) et la γ butyrolactone (γB) sont des produits commerciaux (Merck) qui ont été redistillés et conservés sur tamis moléculaire.

Dérivés de l'oxo-2 méthyl-3 oxazaphospholane-1,3,2. Leurs synthèses s'effectuent en deux étapes: formation d'un chlorure d'acide $ZP(O)Cl_2$ (Z = R, OR, NR_2) puis cyclisation avec le méthyl-2 aminoéthanol. Les chlorures pour lesquels Z = NR_2 et Z = OCH_3 ont été préparés selon Walsh et Toy (5); celui pour lequel Z = CH_3 a été obtenu selon Kinnear (6). Cyclisation par l'aminoéthanol: dans un tricol d'un litre équipé d'une agitation mécanique, on place 75 g (1 mol) de méthyl-2 aminoéthanol, 100 g (1 mol) de triéthylamine et 700 ml de benzène. Le mélange est refroidi à 0°C et agité. On ajoute goutte à goutte le dichlorure (0.5 *M*). Après addition, l'agitation est poursuivie pendant 5 h en laissant le mélange revenir à température ambiante. Le chlorhydrate de triéthylamine est filtré sur buchner et le solvant, ainsi que les excès de réactifs sont évaporés à pression réduite. Le produit final de condensation est distillé sous pression réduite (tableau 1).

La synthèse de la *NN'*-diméthylpyrrazolidinone-3 (NNMP) a été effectuée selon Kornet et Tan (7). La *N*-méthyloxazolidone-2 (NMPO) et la *N,N'*-diméthylimidazolidinone-2 (NMPN) ont été préparées en adoptant la méthode de Newman et Kutne (8). La synthèse de la *N*-méthyloxazolidinone-3 (ONMP) a été effectuée par extension du mode opératoire de Shunk, Bachelor et Folkers (9) à la méthylhydroxylamine. Ses caractéristiques physiques sont analogues à celles décrites par Petrus et coll. (10). Les hydrocarbures sont des produits commerciaux (Aldrich) de qualité "puriss" conservés au froid et distillés avant usage.

2. Résonance magnétique nucléaire du ^1H

Les spectres de rmn du proton des différents mélanges d'hydrocarbures et de solvants dipolaires, en proportions variables, ont été enregistrés à 60 MHz sur un spectromètre JEOL C-60-HL à la température de 37°C avec 5% molaire de tétraméthylsilane pour référence interne. Les couplages

[1]Révision reçue le 2 mai 1978.

TABLEAU 1. Solvants phosphorés: caractéristiques et dénominations

	Solvant	Z	Eb
	W1	$-N(CH_3)_2$	112°C/1 Torr
	W9	—N⟨ ⟩	140°C/1 Torr
	W8	—N⟨ ⟩	146°C/1 Torr
	W2	$-OCH_3$	93°C/1 Torr
	W5	$-CH_3$	92°C/0.5 Torr

multiples entre les protons et le mode d'enregistrement des spectres limitent la précision à 1 Hz malgré l'utilisation d'un fréquencemètre digital RACAL 801-R2. Les spectres de plus grande dilution correspondent à des concentrations de 5% molaire en soluté. L'attribution des signaux, pour les différents hydrocarbures, a été faite selon la littérature (11–14).

3. Résonance magnétique nucléaire de ^{13}C

Les spectres de rmn du ^{13}C des différents mélanges ont été enregistrés à 20 MHz sur un spectromètre Varian CFT-20 à la température de 37°C. Les tubes de 10 mm de diamètre contiennent les échantillons de mélange avec 5% molaire de cyclohexane utilisé comme référence interne. Un tube coaxial, maintenu par un dispositif en Téflon, contient du benzène-d_6 pour assurer la stabilisation en fréquence de l'appareil. L'étendue spectrale est de 4000 Hz et la résolution de 1 Hz. Les spectres sont obtenus en découplage total des protons. Les solutions les plus diluées nécessitent 50 000 accumulations pendant 15 h. Les déplacements chimiques sont exprimés en ppm par rapport au tétraméthylsilane (TMS). Le choix du cyclohexane pour référence interne a été fait selon Bacon et Maciel (15) car ce produit présente moins d'effet de solvant que le TMS. Nous l'avons d'ailleurs vérifié en étudiant les variations de déplacement chimique de solutions de cyclohexane (de 3 à 20% molaire) dans les solvants extracteurs par rapport au pic central de résonance du benzène d_6 contenu dans le capillaire coaxial. L'effet chimique des solvant sur le cyclohexane est ainsi mis en évidence: l'écart maximum, à dilution infinie et sans correction de susceptibilité magnétique, est inférieur à 0.3 ppm à bas champ par rapport au cyclohexane pur.

L'effet de solvant sur le déplacement chimique de la référence interne est d'ailleurs annulé lorsque nous effectuons des calculs de différence d'incréments. Outre son rôle de référence interne, le cyclohexane a été utilisé comme solvant inerte de dilution pour les hydrocarbures (ce choix est logique car la distillation extractive consiste bien à effectuer la séparation entre carbures saturés et non saturés). L'attribution des signaux a été faite suivant la littérature (16–19).

La marge d'erreur de 1 Hz sur l'attribution des déplacements chimiques des signaux est la même pour la rmn du ^1H et du ^{13}C. Toutefois, la gamme des déplacements ne dépasse pas 9 Hz pour le proton alors qu'elle atteint 30 Hz pour le carbone. Il apparaît donc que la précision relative est trois fois plus grande par rmn du ^{13}C.

4. Constante diélectrique

La recherche d'une relation possible entre la sélectivité des complexants et leurs caractéristiques physiques nous a conduit à la mesure de leurs constantes diélectriques et au calcul de leurs moments dipolaires. Ces mesures ont été faites de préférence sur les complexants pris purs, en considérant la réalité de la distillation extractive dans laquelle les oléfines sont extraites avec un excès de solvant spécifique.

Deux séries de mesure des constantes diélectriques ont été effectuées sur deux appareils: le "Dipolmeter W.T.W. DM 01", qui permet de mesurer avec précision des constantes inférieures à 3, a été utilisé pour les complexants dilués dans des solutions benzéniques; un tube EM4 de précision moyenne permet d'accéder aux valeurs de constante diélectrique supérieures à 3 et a été employé pour les solvants purs.

Chaque mesure a été effectuée plusieurs fois et la moyenne des essais a été retenue. Les constantes diélectriques de référence qui servent à l'étalonnage sont celles de l'air, assimilé au vide et du benzène. Les appareils sont thermostatés et les résultats indiqués pour la température de 24°C.

Les valeurs de la densité d ont été mesurées au picnomètre et confirmées par ailleurs.[3] Les indices de réfraction corrigés η_∞ ont été mesurés au réfractomètre O.P.L. et corrigés pour les raies D du sodium au prisme d'Amici. Les constantes diélectriques ε déterminées avec le tube EM 4 sur le solvant pur permettent d'accéder, selon la théorie d'Onsager qui tient compte des interactions dipole–dipole dans les liquides purs, à la valeur du moment dipolaire du complexant pur:

$$\mu = 0.218\left[\frac{M}{d}\frac{(2\varepsilon + \eta_\infty{}^2)(\varepsilon - \eta_\infty{}^2)}{\varepsilon(\eta_\infty{}^2 + 2)^2}\right]^{1/2}$$

Les mesures des constantes diélectriques de solutions benzéniques contenant le complexant à des concentrations variables ne dépassant pas 1% molaire ont été effectuées au "dipolmeter WTW". Nous extrapolons la polarisation molaire à dilution infinie, et calculons la réfraction molaire dans les mêmes conditions, selon la théorie de Debye. Ces extrapolations font intervenir les formules de Clausius–Mossotti et de Debye (20).

$$\tfrac{4}{3}\pi N\alpha = \frac{\varepsilon - 1}{\varepsilon + \eta}\frac{M}{d}$$

$$\mu = 0.0127[(P - R_M)T]^{1/2}$$

avec α polarisabilité totale, N nombre d'Avogadro, P polarisation molaire et R_M réfraction molaire. Le moment dipolaire obtenu est celui du complexant infiniment dilué dans un solvant non polaire. Pour confirmer les résultats obtenus par la théorie d'Onsager sur les complexants purs, nous avons utilisé les mesures de constante diélectrique employées dans la théorie de Debye, en estimant la polarisation comme une grandeur additive. A faible concentration du soluté dans le benzène, nous avons calculé la contribution du soluté dans la mesure de la constante diélectrique du mélange. Les résultats obtenus ont confirmé les mesures effectuées dans le cadre de la théorie du modèle d'Onsager (résultats donnés à ± 0.1 Debye).

III. Résultats

1. Résonance magnétique nucléaire du ^1H

Yablonskii et coll. (3) ont enregistré les spectres rmn du ^1H de l'isoprène et du méthyl-2 butène-2 dans les solvants extracteurs. Ils ont déterminé des différences d'incréments, à dilution infinie, par comparaison entre deux protons de position analogue sur le squelette carboné de ces deux hydrocarbures.

[3]Nous remercions Monsieur V. Corso pour ces mesures.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Les différences d'incrément sont inférieures à 7 Hz. Ces auteurs ont classé les complexants dans l'ordre de selectivité suivant: acétonitrile < diméthylacétamide < diméthylformamide < diméthylsulfoxide < *N*-méthylpyrrolidone (NMP) < héxaméthylphosphotriamide (HMPT). L'écart dans lequel se situent les différences d'incréments induits ne dépasse pas en fait 3 Hz, fourchette assez restreinte pour permettre une telle classification. L'effet de solvant sur la référence interne n'est pas discuté. Finalement, ces résultats n'ont pas permis à leur auteurs de conclure clairement sur la nature du phénomène mis en jeu dans la distillation extractive.

Nous avons tenté de reproduire l'étude précédente. Les spectres des hydrocarbures en C_5 (isoprène, méthyl-2 butène-2, pentadiène-1,4, pentane) à dilutions variables dans un solvant polaire (NMP ou HMPT) ou dans le cyclohexane ont été enregistrés. Le cyclohexane a été choisi comme solvant inerte de dilution. Nous avons d'abord étudié l'effet de ces solvants sur la référence interne et constaté qu'il était important (21). Le déplacement chimique des protons du tétraméthylsilane, en solution à 5% molaire dans les différents solvants, a été mesuré par rapport au tétraméthylsilane pur placé dans un capillaire coaxial central. Le déblindage observé, sans correction de susceptibilité magnétique, est de 12 Hz dans le cyclohexane, 16 Hz dans la NMP et 22 Hz dans le HMPT. Cet effet de solvant sur la référence interne est annulé quand nous procédons à des différences d'incréments de déplacement chimique du proton entre deux hydrocarbures à dilution infinie dans les solvants. Nous avons comparé nos résultats (tableaux 2),[4] dont un exemple est donné sur la fig. 1, à ceux de la littérature (3). La comparaison des déplacements chimiques des hydrogènes placés sur des sites analogues dans la molécule d'isoprène et dans celle du méthyl-2 butène-2 permet de calculer des incréments, d'importance variable selon le solvant. Il s'avère que le classement de ces solvants est différent selon le site observé, et imprécis car les écarts sont faibles (voir tableau 3). Une classification de complexants basée sur ces résultats semble donc très aléatoire. L'efficacité du HMPT, selon la littérature (3), est d'ailleurs très surestimée et en contradiction avec les mesures de C.P.V.[5]

Pour compléter ces résultats, on peut ajouter les valeurs des différences d'incréments de déplacement chimique pour le couple pentadiène-1,4/*n* pentane

dans la NMP (tableau 4):[4] 4 Hz pour le carbone 1 et 8 Hz pour le carbone 2. Il n'a pas été possible de relier les volatilités des hydrocarbures que nous avons examinés, aux différences d'incrément chimique du proton, calculées par comparaison entre sites analogues, ou par sommation sur l'ensemble des sites. Par contre, d'autres remarques relatives à ces spectres de proton peuvent être formulées. Il s'agit en observant les amplitudes relatives des déplacements sur les courbes de dilution, de comparer les protons homologues des différents hydrocarbures, à dilution infinie dans les solvants. Les signaux des groupes méthyles et méthyléniques ne présentent pas de déplacements importants (3 Hz). Les signaux des protons éthyléniques subissent des déblindages plus marqués. Le groupe $=CH_2$ varie de 7 à 9 Hz dans l'isoprène, de 3 à 4 Hz dans le pentadiène-1,4. Le groupe =CH— varie, dans les deux exemples de

[4]On peut obtenir les données expérimentales de rmn (tableaux 2, 4, 5, 6) mises en dépôt, à un prix nominal, en s'adressant au Dépôt de données non publiées ICIST, Conseil national de recherches du Canada, Ottawa (Ont.), Canada K1A 0S2.

[5]Mesures faites par Monsieur V. Corso.

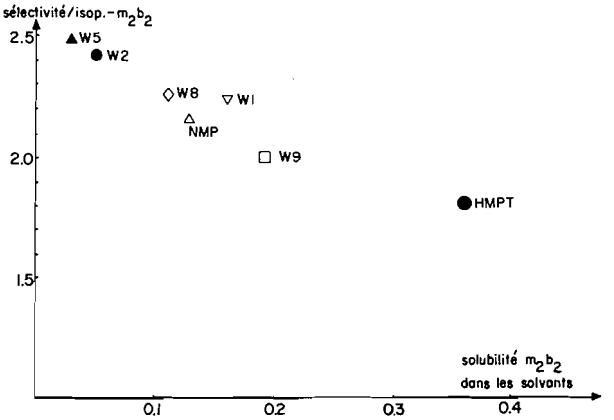

FIG. 2. Sélectivité des solvants.

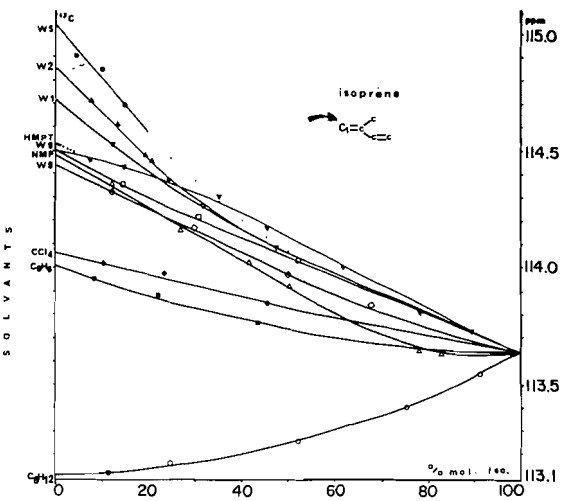

FIG. 3. Déplacements chimiques ^{13}C: carbone C_1 de l'isoprène.

6 Hz. Il y a donc une différence de "sensibilité" des protons à l'effet des solvants, selon la conjugaison de la dioléfine. De façon générale, il apparaît que l'effet de milieu se traduit, pour les différents solvants (NMP, HMPT, solvants phosphorés cycliques W) par un déblindage des protons des hydrocarbures. Par ailleurs, aucun déplacement sur les signaux des protons des solvants n'est observé, quelles que soient les proportions relatives d'hydrocarbures et de complexants.

2. Résonance magnétique nucléaire du ^{13}C

Il nous est apparu que la rmn du ^{13}C est une méthode (22)[6] plus appropriée pour l'étude de l'interaction entre complexants et carbures insaturés. En effet, les valeurs des déplacements chimiques sont plus grandes que celles enregistrées en rmn du proton. Les problèmes de couplage ne se posent plus. Les variations de déplacement chimique sont plus importantes et le classement des solvants est plus précis. De plus, les déplacements ^{13}C sont moins sensibles aux effets d'anisotropie magnétique (importants en rmn du proton) et reflètent plus la structure électronique interne des molécules (23–25).

Nous disposons pour cette étude d'une famille de solvants phosphorés ne différant entre eux que par la nature d'un seul substituant, mais présentant une gamme de sélectivité très étendue (26) (voir fig. 2). Rappelons, à ce sujet, qu'un solvant est caractérisé par sa sélectivité et son pouvoir solubilisant vis-à-vis d'un couple d'oléfines. Les meilleurs complexants (W1, NMP) sont ceux qui possèdent de bonnes valeurs pour les deux critères.

Les spectres des différents hydrocarbures (*n* pentane, isopentane, pentène-1, méthyl-2 butène-2, pentadiène-1,4, isoprène) ont été enregistrés dans des mélanges de cyclohexane et de solvants extracteurs W en proportions variables (tableaux 5).[4]

Les courbes de dilution correspondant aux signaux des différents carbones de ces hydrocarbures ont été tracées et les déplacements chimiques δ à dilution infinie dans les solvants ont été déterminés par extrapolation. L'ensemble des signaux des carbures insaturés est déplacé vers les bas champs par rapport à celui observé dans le cyclohexane (voir fig. 3). L'écart des déplacements chimiques entre les solvants polaires et le cyclohexane est très variable et peut dépasser 1.5 ppm. Nous remarquons que les groupes méthyles sont affectés de façon semblable (0.5 ppm) quel que soit le site et le degré d'insaturation du substrat (isoprène, méthyl-2 butène-2, pentane, isopentane). Les déplacements chimiques des groupes méthyléniques du pentadiène-1,4, du pentane et de l'isopentane ne varient guère (glissement inférieur à 0.1 ppm). Il en est de même pour le carbone tertiaire de l'isopentane. Les carbones oléfiniques présentent plus d'intérêt car ils subissent un déblindage très net qui affecte de façon dissymétrique les doubles liaisons. Pour le pentène-1, les carbones subissent un déplacement à bas champ, respectivement de 0.4 et 0.6 ppm pour le C_1 et 0.8 ppm pour le C_2 dans les solvants NMP et W1 (voir fig. 4). Le pentadiène-1,4, dioléfine non conjuguée, se comporte dans les mêmes conditions comme deux monooléfines terminales simplement reliées par un pont méthylénique; l'amplitude et la dissymétrie du déblindage sont analogues à celles du pentène-1. Il apparaît donc que dans le cas des oléfines terminales le carbone sp^2 le plus substitué est le plus "sensible" aux effets de milieu, même si celui-ci est peu polaire (22).[6] Pour le méthyl-2 butène-2, le C_2 (quaternaire sp^2) subit un

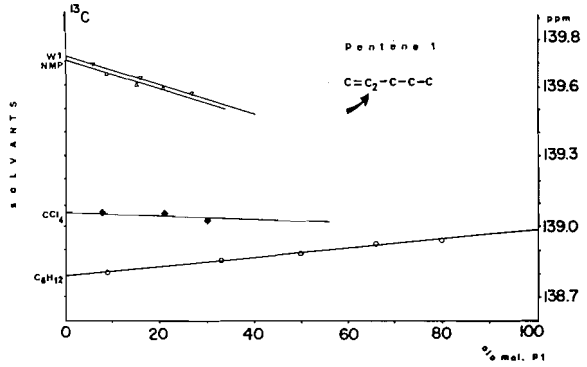

FIG. 4. Déplacements chimiques ^{13}C: carbone C_2 du pentène-1.

déblindage très marqué de 0.8 ppm tandis que le C_3 (CH sp^2) paraît presque insensible aux solvants (voir fig. 5). Les carbones quaternaire C_2 et tertiaire C_3 de l'isoprène se comportent d'une manière analogue à ceux du méthyl-2 butène-2 avec des amplitudes d'increments plus réduites (0.6 et 0.3 ppm). Mais à la différence du pentadiène-1,4 et des monooléfines, ce sont les carbones terminaux (C_1 et C_4) qui enregistrent les plus forts déblindages (1.5 et 1.2 ppm). La sensibilité particulière aux effets de milieu (22)[6] des carbones sp^2 internes n'est donc pas un phénomène général. Les raisons de ces différences de sensibilité n'étant pas évidentes, nous avons préféré examiner par la suite l'influence des solvants sur l'ensemble des carbones des hydrocarbures insaturés.

Nous pouvons remarquer que l'effet de dilution dans le cyclohexane n'est pas ressenti dans le déplacement chimique des carbones des hydrocarbures saturés et monoléfiniques. Seuls les carbones portant les insaturations des dioléfines subissent un blindage par dilution dans le solvant cyclohexanique; cela peut s'interpréter par la rupture progressive des interactions intermoléculaires de type π–π entre oléfines.

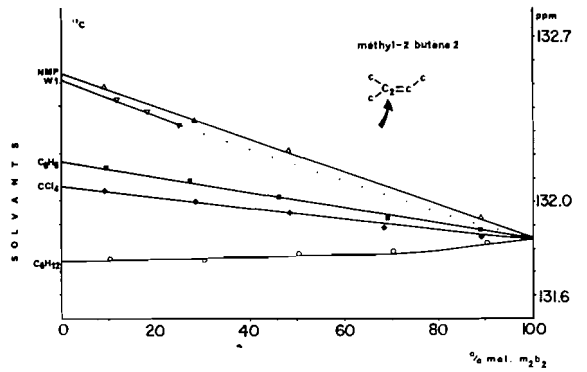

FIG. 5. Déplacements chimiques ^{13}C: carbone C_2 du méthyl-2 butène-2.

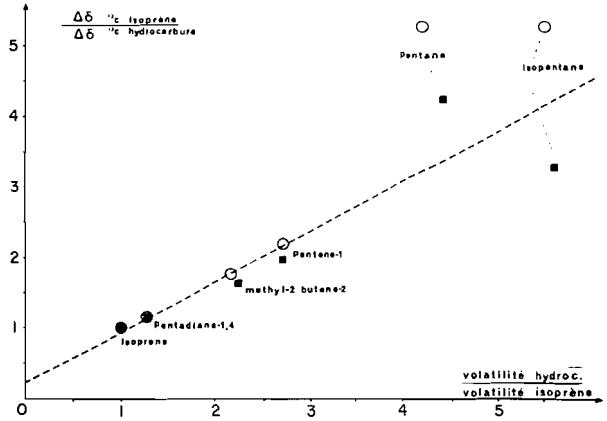

FIG. 6. Incrément chimiques ^{13}C total et volatilité (solvants: ○, NMP; ■, W1).

Incréments chimiques ^{13}C

Nous avons d'abord considéré que l'effet de solvant était un phénomène qui concerne globalement la molécule et que la somme des $\Delta\delta$ induits sur l'ensemble des carbones du soluté, à dilution infinie, pouvait être une mesure de l'influence du complexant:

$$\Delta\delta = (\delta_{C_1} + \ldots + \delta_{C_5})_{solvant} - (\delta_{C_1} + \ldots + \delta_{C_5})_{cyclohexane}$$

(δ_{C_i} représente le déplacement chimique ^{13}C du carbone i d'un carbure).

Il apparaît que l'ordre des valeurs de $\Delta\delta$ pour les différents hydrocarbures est sensiblement parallèle à celui de l'inverse de leurs volatilités dans les solvants (voir fig. 6).

Nous avons ensuite comparé les variations de déplacement chimique des carbones des alcènes, à celles des carbones ayant une position similaire sur le squelette carboné de l'alcane correspondant, ce que nous exprimons pour le carbone i ($i = 1, 2, \ldots, 5$) par:

$$\Delta(\Delta C_i) = (\delta C_{i_{solv.}} - \delta C_{i_{cycloh.}})_{alcène} - (\delta C_{i_{solv.}} - \delta C_{i_{cycloh.}})_{alcane}$$

Ce calcul se traduit, avec les mesures à dilution variables, par des courbes (voir fig. 7) mettant en évidence les effets des solvants NMP et W1 sur l'insaturation des solutés (tableaux 6).[4]

Les valeurs de $\Delta(\Delta C_i)$ sont indépendantes de la référence interne de déplacement chimique choisie pour cette étude. Pour le pentène-1 et le pentadiène-1,4, les valeurs de $\Delta(\Delta C_2)$ et $\Delta(\Delta C_1)$ sont, respectivement, 1.0 et 0.3 ppm. L'effet de solvant sur l'insaturation est nettement marqué par un déblindage en C_2. Pour le méthyl-2 butène-2, l'influence sur le carbone le plus substitué est également mise en évidence. Pour l'isoprène, les quatre carbones portant les insatura-

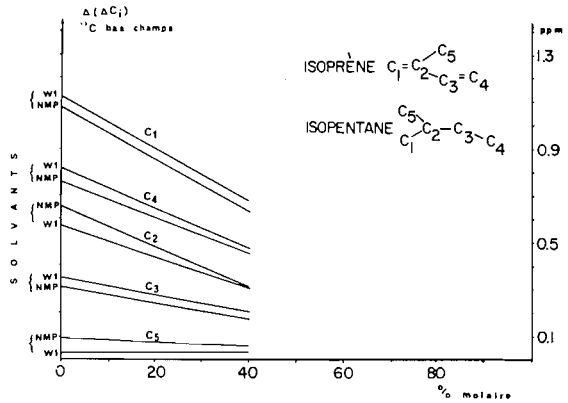

FIG. 7. Différence d'increments ^{13}C, isoprène − isopentane.

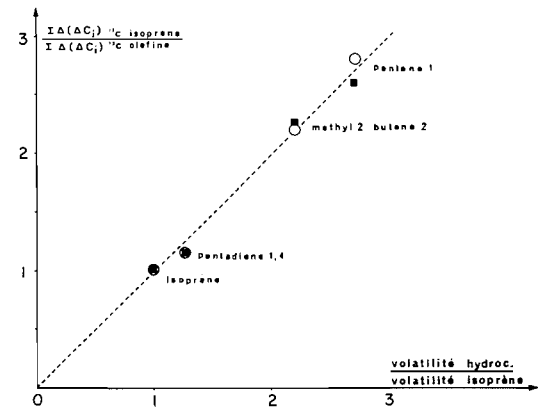

FIG. 8. Incrément ^{13}C d'insaturation et volatilité (solvants: ○, NMP; ■, W1).

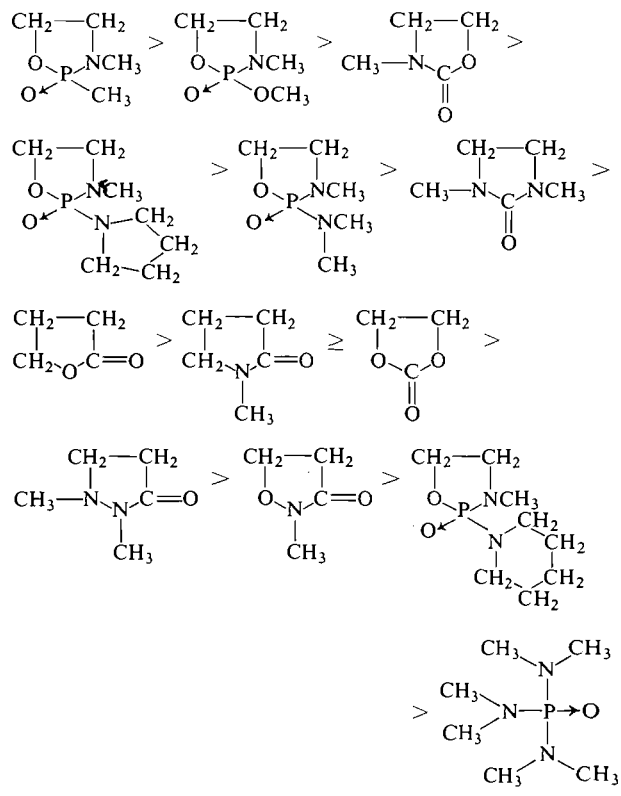
tions sont affectés de façon variable, les carbones terminaux étant les plus "sensibles": $\Delta(\Delta C_1) > \Delta(\Delta C_4) > \Delta(\Delta C_2) > \Delta(\Delta C_3)$. Ce mode de calcul révèle les sites les plus perturbés par les solvants. L'effet de solvant est enregistré principalement sur les carbones portant les insaturations; le déblindage affecte de façon différente les deux carbones d'une double liaison. Cette dissymétrie peut s'expliquer, en partie, par la dissymétrie des molécules concernées. L'effet de conjugaison d'une dioléfine se traduit de façon particulière: à l'inverse du pentadiène-1,4, l'isoprène est plus déblindé sur ses carbures sp^2 terminaux.

Les résultats précédents nous ont conduits à calculer la somme

$$\sum_{i=1}^{i=5} \Delta(\Delta C_i)$$

sur les cinq carbones d'un carbure insaturé et à la relier à la volatilité de celui-ci dans les solvants polaires (voir fig. 8). La relation est linéaire pour l'ensemble des oléfines qui ont été étudiées et pour les deux solvants NMP et W1. Ceci met en évidence de façon qualitative le rôle des doubles liaisons dans le mécanisme de la complexation entre solutés et solvants, et de façon quantitative la relation linéaire entre la volatilité d'un soluté et le déplacement chimique ^{13}C vers les bas champs.

L'étude rmn du ^{13}C a également porté sur l'influence des différents solvants vis-à-vis du couple d'hydrocarbures isoprène/méthyl-2 butène-2, qui sert de référence aux pétrochimistes pour déterminer la sélectivité S des complexants par chromatographie en phase vapeur.[7] Comme précédemment, les valeurs de $\Delta\delta$ pour les deux oléfines ont été calculées, à dilution infinie dans les solvants. Les différences d'incréments $(\Delta\delta_{isop.} - \Delta\delta_{m2b2})$, exprimées en ppm sont en relation avec les sélectivités S (voir fig. 9). Nous observons, en effet, la correspondance: $S = \text{Cte} \times (\Delta\delta_{isop.} - \Delta\delta_{m2b2})$. A partir de la famille des solvants phosphorés W et de la NMP, il a été établi que cette constante est de $1.36\ ppm^{-1}$. Nous montrons également qu'il est possible de prévoir la sélectivité d'autres solvants dipolaires à partir des mesures de rmn du ^{13}C avec une bonne précision (voir tableau 7). Les mesures par CPV ont été effectuées postérieurement aux mesures de rmn et montrent un bon accord entre ces deux méthodes. Nous en avons déduit le classement suivant, dans l'ordre de sélectivité décroissante:



[7]Ce couple d'hydrocarbures a été utilisé comme référence par Monsieur V. Corso pour ses mesures de sélectivité par chromatographie en phase vapeur.

	1.53	2.08	2.12
	1.43	1.95	1.99
	1.82	2.47	2.37

*$(\Delta\delta_{isop.} - \Delta\delta_{m2b2})$ en ppm.
†$1.36 \times \Delta^{13}C$.

Les déplacements chimiques Δδ, les écarts $(\Delta\delta_{isop.} - \Delta\delta_{m2b2})$ et les variations $\sum\Delta(\Delta C_i)$ à bas champs traduisent un appauvrissement en électrons du squelette carboné des hydrocarbures insaturés, au niveau des doubles liaisons. Les signaux des complexants, par contre, ne sont pratiquement pas affectés, quelles que soient d'ailleurs les proportions relatives de solvant et d'hydrocarbures. Pour les oléfines, les variations de déplacement chimique peuvent difficilement s'expliquer par des modifications des angles de valence et de torsion. On constate l'existence d'un effet de solvant assez important pour la molécule de méthyl-2 butène-2 dont le squelette est rigide. Pour la molécule d'isoprène, en très grande majorité s-transoïde (27, 28), l'isomérisation en s-cisoïde se traduirait, en raison d'un accroissement de la compression stérique, par un déplacement chimique vers les hauts champs des carbones terminaux, dans le sens opposé au phénomène enregistré. L'existence d'une forme gauche s'accompagnerait d'un affaiblissement de la conjugaison, et par conséquent d'une diminution de la sélectivité de la séparation entre l'isoprène et les autres carbures insaturés. Nous pouvons plutôt interpréter les variations observées par une interaction de type dipolaire, entre le solvant et les hydrocarbures polarisables (29), dont l'amplitude varie suivant la nature du complexant et le degré d'insaturation des oléfines.

Par ailleurs, des mesures d'enthalpie d'excès de mélange (30) de la NMP avec différents hydrocarbures en C_6 (utilisés pour des raisons techniques parce qu'ils sont moins volatils que leurs homologues en C_5)[8] nous ont permis de relier les chaleurs de mélange avec les volatilités relatives des carbures. Nous enregistrons les plus grandes variations d'enthalpie d'excès pour les diènes conjugués.

3. Constantes diélectriques, moments dipolaires des solvants

Bien que certains auteurs (2, 31) aient nié l'existence d'une relation entre la sélectivité (S) des complexants et leurs grandeurs physiques (densité, constante diélectrique ε, moment dipolaire μ), nous avons tenté de mettre en évidence une formule empirique qui lie S, ε, μ et le volume molaire V des complexants.

Il a été possible de dresser un tableau de valeurs pour les différents solvants étudiés en posant en première approximation $S = K\mu/V$ dans laquelle μ est le moment dipolaire du complexant pur. Cette formule suppose, à priori, une relation directe entre la sélectivité et le rapport μ/V de chacun des solvants. Il faut souligner le fait que nous utilisons les moments dipolaires des solvants purs, en estimant que ces valeurs correspondent à la réalité de la distillation extractive dans laquelle les hydrocarbures sont extraits avec un large excès de complexant. Le volume molaire de la NMP est pris pour unité. La valeur de K (voir tableau 8) est constante pour la famille des dérivés phosphorés W et met en évidence le rôle du volume molaire des solvants (voir fig. 10). Cependant, les dérivés non phosphorés de structure proche de celle de la NMP, avec un cycle pentagonal, présentent des valeurs de K dont la dispersion est assez nette pour mettre en doute la généralité de la formule citée ci-dessus. Nous avons alors tenté de relier la valeur de K pour les deux familles de complexants, à celle de μ/ε. Les résultats obtenus (fig. 11) permettent d'écrire: $K = K_1 + K_2\mu/\varepsilon$. La mise en équation de la sélectivité se fait alors selon: $S = K_1\mu/V + K_2\mu^2/\varepsilon V$. Pour les phosphoramides

$K_1 = 0.627$, $K_2 \simeq 0$; pour les composés cycliques non phosphorés $K_1 = 0.02$, $K_2 = 3.9$.

Cette formule empirique qui fait correspondre à la sélectivité un phénomène énergétique d'interactions dipolaires (dipole–dipole et dipole–dipole induit) est satisfaisante pour l'ensemble des solvants étudiés. La mise en équation de la sélectivité suggère, dans cette hypothèse d'interactions dipolaires, une orientation privilégiée des molécules de solvants proches de l'oléfine. Une couche de solvatation est occupée par des molécules complexantes orientées par rapport au soluté. Au-delà, il n'y a pas d'orientation préférentielle et l'effet d'écran est introduit par la constante diélectrique. Pour les solvants de très fort dipole, les associations moléculaires sont importantes, le milieu est relativement structuré, et le terme $K_1\mu/V$ est grand. Si le solvant possède un dipole moyen, la structuration du milieu est moins perceptible, l'influence vient de la zone non orientée, et le terme $K_2\mu^2/\varepsilon V$ est important. Dans ce cas, la valeur de la constante diélectrique ne doit pas être trop élevée, pour obtenir une bonne sélectivité, car elle figure au dénominateur de la relation empirique. Les deux modes d'action sont efficaces et peuvent concourir à la sélectivité du complexant. Les constantes K_1 et K_2 paraissent liées à la structure des molécules de solvant, à la nature et à l'accessibilité de leurs dipoles. Elles dépendent, en outre, des caractéristiques physiques (dipole, polarisabilité) des oléfines qui servent de référence pour le critère de sélectivité. La détermination des valeurs de K_1 et K_2 d'après les mesures de sélectivité par CPV pour l'un des membres d'une famille de solvants permet, en principe, de prévoir la sélectivité des autres membres à partir de leurs constantes diélectriques et leurs volumes molaires. Ainsi, nous avions pu estimer les sélectivités de la γ butyrolactone et du carbonate d'éthylène avant de les connaître par CPV. Il apparaît qu'un assez bon accord existe entre ces prévisions, les calculs d'incréments par rmn du ^{13}C et les mesures de sélectivité par chromatographie.

IV. Discussion

Différentes hypothèses peuvent être formulées sur la nature de l'interaction entre solvants et composés non saturés: liaison hydrogène, complexe par transfert de charge, changement conformationnel, interaction dipolaire. L'hypothèse d'une liaison hydrogène ne peut être retenue que pour les carbures acétyléniques. Les mono et di-oléfines ne possèdent pas d'hydrogène acide et les solvants étudiés sont du type dipolaire aprotique. L'amplitude des déplacements chimiques observés par rmn du ^1H est trop faible pour correspondre à ce type d'interaction.

Il ne nous a pas été possible de mettre en évidence, par des mesures en ultra-violet, entre 200 et 400 nm, l'existence de véritables complexes par transfert de charge. De plus, la rmn du ^{13}C montre que les signaux du complexant ne sont pas affectés par la présence des composés non saturés.

Les déplacements chimiques ^{13}C, induits par les complexants, pourraient être interprétés par une modification conformationnelle des molécules d'hydrocarbure. Cependant, une telle interprétation ne rend pas compte des déplacements importants observés pour la molécule de méthyl-2 butène-2 relativement rigide.

Nous avons plutôt retenu une interprétation du phénomène basée sur des interactions de Van der Waals. Nous pouvons considérer à la fois les forces de Keesom (orientation entre deux dipoles permanents) bien que les hydrocarbures ne possèdent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

que des moments dipolaires faibles, et les forces de Debye (interaction d'un dipole permanent et d'un dipole induit par le premier dans une molécule voisine). Cette interprétation est justifiée par les résultats obtenus par la rmn du ^{13}C et par la formule empirique reliant la sélectivité aux caractéristiques physiques des solvants.

Remerciements

Nous remercions la Compagnie Française de Raffinage pour son soutien financier et tout particulièrement Monsieur J. Grosmangin et Monsieur V. Corso pour les mesures chromatographiques.

Nous remercions le Professeur J. Cantacuzene pour l'intérêt qu'il a porté à cette étude et le Professeur J. J. Basselier pour ses conseils et l'utilisation de ses appareils de mesure.

Reduction of some organic compounds by electrochemically generated titanium(III)

OLYMPIA CHRISTOFIS, JACOB J. HABEEB, RICHARD S. STEEVENSZ, AND DENNIS G. TUCK

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received March 31, 1978

OLYMPIA CHRISTOFIS, JACOB J. HABEEB, RICHARD S. STEEVENSZ, and DENNIS G. TUCK. Can. J. Chem. **56**, 2269 (1978).

The electrochemical oxidation of titanium metal in the presence of an essentially non-aqueous electrolyte phase yields titanium(III) species in solution. It has been shown that this method of generating TiX_3 (X = balancing anion) forms the basis of a convenient way of reducing *in situ* certain organic functional groups (sulfoxide, oxime, haloketone, vinyl dicarboxylic acid, and nitro aromatics). The stoichiometry of the reaction has been established in each case, and corresponds to the oxidation of TiX_3 and the formation of the appropriate organic compound. The yields are comparable to those reported in experiments using aqueous titanous chloride.

OLYMPIA CHRISTOFIS, JACOB J. HABEEB, RICHARD S. STEEVENSZ et DENNIS G. TUCK. Can. J. Chem. **56**, 2269 (1978).

L'oxydation électrochimique du titane sous forme métallique en présence d'une phase électrolytique essentiellement non-aqueuse conduit à des espèces titane(III) en solution. On a montré que cette méthode de produire du TiX_3 (X = un anion) peut servir de base pour une méthode convenable de réduire in situ un certain nombre de groupes fonctionnels organiques (sulphoxyde, oxime, halocétone, acide dicarboxylique vinylique et nitro-aromatique). On a établi la stoechiométrie de la réaction dans chaque cas et elle correspond à l'oxydation de TiX_3 et à la formation du composé organique approprié. Les rendements sont comparables avec ceux rapportés dans des expériences faisant appel à du chlorure titaneux en solution aqueuse.

[Traduit par le journal]

Introduction

The use of an aqueous solution of titanium(III) chloride as a mild reducing agent in organic chemistry was first described by Knecht and Hibbert (1, 2) at the beginning of the century. The revival of interest in this method in recent years has been discussed by McMurry (3), whose review demonstrates the range of functional groups which have been reduced, and gives references to specific experimental procedures.

In the course of work on the electrochemical oxidation of titanium in non-aqueous solution, we observed that depending on the reaction conditions, the products contained this element in either +III or +IV states. In particular, the anionic halide complexes of $TiBr_4^-$ and $TiBr_6^{2-}$ were synthesised in separate experiments (4), while the electrochemical reaction of titanium metal with 2,4-pentanedione (Hacac) (5) in the absence of oxygen gave as product $Ti(acac)_3$, which on exposure to air went rapidly to $TiO(acac)_2$ (cf. ref. 6). We subsequently found that the addition of reducible organic compounds would also discharge the deep blue colour of $Ti(acac)_3$, and that this behaviour was not restricted to systems involving acetylacetone. We have therefore carried out a short investigation of the conditions under which electrochemically generated titanium(III) may be used for the *in situ* reduction of suitable organic functional groups. Since the results show that this technique gives good yields of the reduced compounds, it appears that this electrochemical method is a useful and convenient way of carrying out the titanium(III) reduction reaction.

Experimental

Materials and Apparatus

Titanium metal sheet was *m2N7* purity. Organic compounds used as starting materials were reagent grade and were used as received.

The electrochemical cell consisted of 100 cm^3 tall form beaker, capped with a tightly fitted rubber bung through which passed wire leads for the anode and cathode, as well as gas inlet and outlet tubes. The titanium anode was formed into a cylinder (4.5 cm diameter, 4.5 cm high), which surrounded the central titanium cathode, shaped in an oblong propeller form (4.0 cm high, 3.5 cm wide). Potential was applied from a Coutant LQ 50/50 D.C. power pack. No unique advantages are claimed for this experimental design, which must certainly be capable of improvement.

General Procedure

All electrochemical experiments were carried out under nitrogen. The compound (10 mmol) to be reduced was placed in the electrochemical cell, which contained 25 cm^3 methanol, 25 cm^3 acetonitrile, 25 cm^3 glacial acetic acid, 2 cm^3 water, and approximately 0.5 g of tetraethylammonium chloride.

The effective completion of the reaction was marked both by a decrease in current and by the appearance of a permanent blue colour in the solution, although we observed that in some of the electrolytic reductions (e.g., diphenylsulfoxide and nitrobenzene), this blue colour developed in the solution

[a]10 mmol in each case.
[b]Based on quantity of starting material.

within the first few hours, indicating that Ti^{III} was being produced faster than it was being consumed. The amount of titanium dissolved was determined from the weight loss at the anode, and the products were identified by spectroscopic comparison with authentic samples. Overall product yields, the amounts of titanium dissolved, and electrolysis times are shown in Table 1.

The reduction appeared to be best carried out with currents below 100 mA, since at higher currents, excessive heating occurred, resulting in loss of solvent and/or possible decomposition of any labile product present. High current also appeared to cause corrosion of the metal anode surface, which developed a grey coating, while at the same time small particles of titanium metal were deposited on the floor of the cell. Cooling the electrolytic cell in an ice-bath reduced the current drastically. The voltages required to achieve an adequate current were in the 1–10 V range.

It was also observed that the rate of the reaction tripled when the surface area of the anode was increased fivefold. Titanium metal was also suitable as a cathode, since it could be formed into a convenient shape of large surface area, but the chemical nature of the cathode is not apparently critical. After each electrochemical reduction, the titanium electrodes were thoroughly cleaned by immersing them in boiling aqueous oxalic acid, thus allowing the continued use of the same electrode, free of surface impurities such as oxides.

Diphenylsulfoxide Reduction

After electrolysis, the contents of the cell were concentrated and about 50 cm^3 of water was added. The aqueous layer was extracted twice with petroleum-ether (30–60°C bp), the organic layer dried over anhydrous sodium sulfate, and solvent removed by evaporation. The nmr and ir spectra, and the glc retention time were identical with those of an authentic sample of diphenylsulfide.

Acetophenone Oxime Reduction

After electrolysis, the contents of the cell were filtered and concentrated. The yellow oily product was washed 3 times with water, and the aqueous layer extracted twice with petroleum-ether (30–60°C bp). The organic extracts were combined and washed with water, dried over anhydrous sodium sulfate, and the volume reduced to ca. 10 cm^3. The crude product was isolated and purified by column chromatography (neutral alumina).

1-Bromoacetophenone Reduction

The electrolysed solution was filtered and the volume reduced by evaporation. Water (50 cm^3) was added, and the resultant solution extracted three times with ether; the combined extracts were washed (10% aqueous sodium bicarbonate), dried (anhydrous sodium sulphate), and evaporated to yield acetophenone.

3-Chloro-2-Norbornanone Reduction

The reduction, and isolation of norcamphor, were similar to the procedures described in the preceding paragraph.

Fumaric Acid Reduction

The electrolytic solution was concentrated to dryness, yielding a white precipitate which was washed with hot chloroform, filtered, and oven dried. The melting point and nmr spectra corresponded to those of succinic acid.

Maleic Acid Reduction

The reduction of maleic acid and isolation of succinic acid followed the procedure for fumaric acid.

Nitrobenzene Reduction

After filtering the electrolysed solution, 150 cm^3 of 12 *M* hydrochloric acid was added and the aqueous layer extracted twice with chloroform. The aqueous layer was then neutralised with NaOH pellets and the free aniline extracted with chloroform. Aniline was the only organic species present in the final extract.

Results and Discussion

Solution Composition, Experimental Design

The reaction medium used in the present work represents a compromise between various requirements, including conductivity, solubility of reagents, adequate rate of formation of TiX_3, adequate rate of reduction, etc. Water must be present in small quantities, as shown by the equations set out below. A solvent mixture of methanol, acetonitrile, and glacial acetic acid in the ratio of 1:1:1 was found to be the most efficient. By contrast, a solvent ratio 2:2:1 gave product yield reduced by 50% based on the starting material. The small amounts (ca. 10 mg) of tetraethylammonium chloride used initially also gave poor yields of the reduced product, but this was overcome by using larger quantities (ca. 500 mg) of the salt.

Reaction Mechanism and Stoichiometry

The experiments described above show that the electrochemical generation of titanium(III) species provides a convenient and clean technique for the

For personal use only.

reduction of a number of typical organic compounds. In general, the examples chosen are those for which reduction via titanium(III) chloride has already been reported (3).

In view of other work in this laboratory on the electrochemical oxidation of metals (4, 5, 7, 8), we have investigated the stoichiometry of the reaction, and have drawn certain conclusions as to the mechanism. We first note that the formation of the solutions in such reactions is indicative of the production of titanium(III) species, which we generalise as TiX_3 (X = balancing anion). The electrode reactions, following our work on metal chelate complexes (5), are then

Cathode:

[1] $$3e^- + 3HX \rightarrow 3X^- + \tfrac{3}{2}H_2(g)$$

Anode:

[2] $$3X^- + Ti(m) \rightarrow TiX_3 + 3e^-$$

and in keeping with this scheme we have confirmed that hydrogen is indeed formed at the cathode. The reactions of TiX_3 with the organic substrates then follows reactions [3]–[7], in which the final titanium product is written as $TiOX_2$ (see below), although the stoichiometry is not affected by reformulating the product as TiX_4.

[3] $$Ph_2SO + 2TiX_3 + H_2O \rightarrow Ph_2S + 2TiOX_2 + 2HX$$

[4*a*] $$R_2CNOH + 2TiX_3 + H_2O \rightarrow R_2CNH + 2TiOX_2 + 2HX$$

[4*b*] $$R_2CNH + H_2O \rightarrow R_2CO + NH_3$$

[5] $$RCOCH_2X + 2TiX_3 + 2H_2O \rightarrow RCOCH_3 + 2TiOX_2 + 3HX$$

[6] $$RCHCHR + 2TiX_3 + 2H_2O \rightarrow RCH_2CH_2R + 2TiO_2 + 2HX$$

[7] $$PhNO_2 + 6TiX_3 + 4H_2O \rightarrow PhNH_2 + 6TiOX_2 + 6HX$$

For reactions [3]–[6], the formation [2] and subsequent oxidation of TiX_3 should give the mole ratio Ti dissolved:product = 2, and the results in Table 1 for these reactions indeed give this ratio as 2.0 ± 0.3, showing that the principal reactions are those described. For the reduction of the ketoxime, the proposed two step process, [4*a*] + [4*b*], involving hydrolysis of the imine intermediate should lead to the formation of ammonia, which is trapped in our reaction conditions as ammonium acetate, and in one experiment was released by the addition of excess caustic soda after electrolysis. The mole ratio Ti dissolved:NH_3 released was 2.3 (0.83 g, 17 mmol Ti; 7.3 mmol NH_3), in reasonable agreement with the value of 2.0 required by reactions [4*a*] and [4*b*].

For nitrobenzene reduction, the experimental ratio Ti dissolved:aniline recovered is 7.2, somewhat higher than the theoretical value of 6.0 (reaction [7]). The reduction of nitrobenzene by titanium(III) has been the subject of earlier investigation (e.g., ref. 9), which showed that here, as in electrochemical reduction at an inert cathode, a variety of species may be formed, depending on the reaction conditions and in particular on the acidity. With the mildly acidic solution used in the present experiments, aniline is the only product isolated, in keeping with earlier findings (9, 10). The quantity of nitrobenzene is substantially lower than in other systems studied, and this must be due in part to the large amounts of TiX_3 required per mole $PhNO_2$, since for a given rate of TiX_3 generation less $PhNO_2$ will be reduced than (say) Ph_2SO.

In addition to the organic compounds isolated, there is also formed a white solid. Analysis shows that a typical sample contained 32% Ti, had infrared absorptions at, *inter alia*, 1040 (ν(Ti=O), cf. ref. 6) and 1715 cm^{-1} (ν(C=O)), and lost approximately 60% weight on heating to 850°C. Given the nature of the reaction mixture, a number of titanium(IV) species are possible; for example, a mixture of $TiO_2 \cdot 2H_2O$ and $TiO(OAc)_2$ in a 1:3 ratio would have Ti 32%, and would lose 48% weight on complete conversion to TiO_2. In general, the results confirm that the final titanium(IV) species can reasonably be formulated as $TiOX_2$, as in reactions [3]–[9].

Aldoxime, Glyoxime, Phosphine Oxide Studies

When attempts were made to produce species such as 2-pyridinaldehyde from 2-pyridinaldoxime, the yields were very low. For example, even after 50 h electrolysis of the aldoxime, only 0.3 g (7 mmol) of titanium metal had been dissolved, and the total product yield was only 7% (0.7 mmol) based on starting oxime. Polymeric decomposition products were also isolated but not identified.

Attempts to reduce dimethyl- and diphenylglyoxime were unsuccessful, in that neither the mononor the di-ketones were isolated from the cell. Spectral (ir, nmr) studies, and attempts to isolate a 2,4-dinitrophenylhydroazine derivative, failed to indicate the presence of any carbonyl groups.

Finally we note that despite a number of attempts, we have been unable to reduce triphenylphosphine oxide by the electrochemical generation of titanium(III).

General Comment

The procedures described use titanium metal as a

convenient source of Ti^{III}, and simple apparatus for the electrochemical reactions involved. The yields and rate of reduction are comparable with those using aqueous titanium(III) chloride. Thus, while the reduction of either diphenylsulfide or α-haloketones is less efficient than the 70–100% yield reported by Ho and Wong (11) using aqueous titanium(III) chloride under reflux, the reduction of maleic acid gives a higher yield than the 45% achieved in a 24 h reaction with the aqueous reagent at room temperature (12). The convenience of the electrochemical method, and the ability to operate the cell at room temperature, may prove advantageous in certain cases.

Finally we may note that vanadium can also be oxidised electrochemically to yield either vanadium(III) (5) or vanadium(II) (7) species, and that the behaviour of $V(acac)_3$ is similar to that of $Ti(acac)_3$ in that aerial oxidation produces $VO(acac)_2$. We therefore investigated the use of vanadium electrodes in the reactions reported above, but found no evidence of vanadium being consumed. Apparently, therefore, electrochemical oxidation of vanadium is not a satisfactory source of lower oxidation state species, despite the similarity between titanium(III), vanadium(II), and chromium(II) noted by Timms and Wildsmith (13).

The effect of diluent gases on ion formation in hydrocarbon flames[1]

BRENDA L. CHAWNER AND ARTHUR T. BLADES
Alberta Research Council, Edmonton, Alta., Canada T6G 2C2

Received November 29, 1977

BRENDA L. CHAWNER and ARTHUR T. BLADES. Can. J. Chem. **56**, 2273 (1978).

It has been demonstrated that the addition of N_2, CO, Ne, Ar, Kr, Xe, CO_2, and CF_4 to a H_2-air diffusion flame containing He and traces of CH_4 enhances the level of ion formation. This enhancement is proportional to the concentration of both CH_4 and the diluent gas, consistent with the proposition that the diluent gas participates in the ion formation process.

BRENDA L. CHAWNER et ARTHUR T. BLADES. Can. J. Chem. **56**, 2273 (1978).

On a démontré que l'addition de N_2, CO, Ne, Ar, Kr, Xe, CO_2 et CF_4 à une flamme de diffusion H_2 air contenant du He et des traces de CH_4 augmente le niveau de formation d'ions. Cette augmentation est proportionnelle à la concentration à la fois du CH_4 et du gaz utilisé comme diluant ce qui est en accord avec la proposition à l'effet que le gaz diluant participe au processus de formation d'ions.

[Traduit par le journal]

Introduction

It is now generally accepted that ions arise in hydrocarbon flames in the chemi-ionization reaction (1–4).

[1] $$CH + O \rightarrow CHO^+ + e$$

This process forms the basis of the flame ionization detector as used in gas chromatography (5) where organic eluates are burned in a hydrogen-air diffusion flame. With suitable polarizing and collecting electrodes, the ion current is the rate of ion formation and about one in 10^6 carbon atoms introduced into the flame results in the formation of an ion (6). The response of the detector is rigorously linear in CH_4 concentration over several decades, in keeping with the mechanism of ion formation.

In the normal use of the detector, it is frequently the practice to use He, N_2, or Ar as the carrier gas for the chromatography and to add a constant flow of H_2 to the column eluate to maintain the flame in the detector. In this regime, the detector sensitivity is dependent on the composition of the carrier gas and maximum sensitivity is achieved with approximately equal flow rates of H_2 and carrier gas (6). This behavior implies that, up to a point, the addition of the carrier gas enhances the formation of ions, contrary to experience with premixed flames where N_2 additions may result in decreased ion formation (7).

Several attempts have been made to explain this 'carrier gas effect' in terms of the physical properties of the diluent gases (6, 8), the increase in ion formation being fundamentally attributed to a temperature increase. These explanations have been challenged (9–11) and it has been postulated that the carrier gas stimulates ion formation by the additional mechanism (11),

[2] $$CH + O + X \rightarrow CHO \cdot X^+ + e$$

Such a reaction is reasonable if ion formation occurs stepwise,

[3] $$CH + O \rightarrow CHO^*$$

[4] $$CHO^* \rightarrow CHO^+ + e$$

and

[5] $$CHO^* + X \rightarrow CHO \cdot X^+ + e$$

Reaction [5] would be expected, on the basis of the dissociation energies of $CHO \cdot H_2^+$ (0.17 eV) (12), and of $CHO \cdot CO^+$ (0.47 eV) (13), to have an energetic advantage over [4]. On the other hand, the low dissociation energies imply rapid decomposition of the ions in high temperature flames and it is therefore not surprising that these primary ions have not been observed mass spectrometrically. In low temperature atomic flame systems, the ions would have a longer thermal lifetime but their formation would be impeded by the low pressure and, if observed, their origin could be the association reaction,

[6] $$CHO^+ + X \rightarrow CHO \cdot X^+$$

While direct observation of the primary ions may be difficult and of dubious merit, occurrence of reactions [2] or [5] would require that the additional ionization attributable to the carrier gas be first order in CH, or its single carbon precursor, e.g. CH_4, and in the carrier X. Herein, these kinetic orders have been established by the operation of a flame ionization detector with a constant flow of H_2 and He, a continuous but variable addition of CH_4 to the H_2

and periodic additions of low concentrations of various 'carrier' gases to the He at constant total flow.

Experimental and Results

In order to demonstrate the magnitude of the carrier gas effect, a flame ionization detector was operated with a constant flow of air (800 ml/min) and of H_2 or D_2 containing 6.2×10^{-3}% CH_4 (30 ml/min). Variable flows of reagent grade He, Ar, and N_2 were then added to the H_2 stream and the relative responses, as shown in Fig. 1, were observed.

The flame ionization detector was then set up with equal flows of H_2 and He (30 ml/min) with provision for the continuous addition of CH_4 (<0.3%) to the H_2. Before mixing with the H_2, the He flowed through a 60 cm long, 14 mm od glass tube fitted with injection ports and then through a katharometer. This arrangement allowed the introduction of diffusion-spread pulses of the test gases at concentrations up to 5% in the He but at constant total 'carrier' flow rate.

The test gases were reagent grades except for CF_4 and CO_2 and chromatographic purification of these gases on a 450 cm *n*-octane/porasil C column at 0°C revealed the presence of ion-producing impurities. These compounds were therefore routinely injected into the system through the chromatographic column. In order to demonstrate the type of response if the test gas contained a hydrocarbon impurity, a set of experiments was carried out with N_2 containing 0.015% CH_4.

The data in Figs. 2, 3, and 4 indicate the response to a constant injection (500 μl) of the test gases at

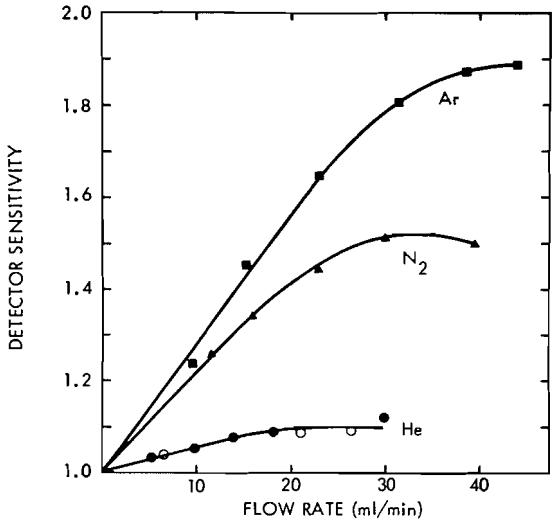

FIG. 1. The effect of flow rate of various diluent gases on the detector sensitivity; H_2, 30 ml/min; air, 800 ml/min; CH_4, 1.9×10^{-3} ml/min. ●, He in H_2; ○, He in D_2; △, N_2 in H_2; □, Ar in H_2.

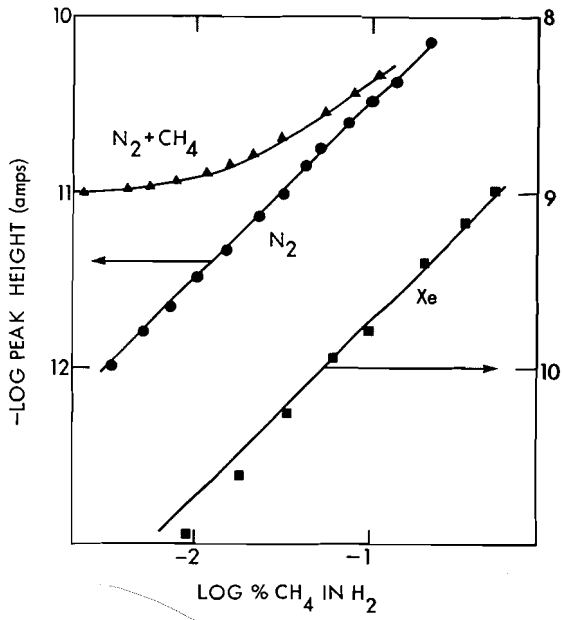

FIG. 2. The effect of CH_4 concentration on the increase in ion formation from a 500 μl slug of Xe, N_2, and N_2 contaminated with CH_4.

variable CH_4 concentrations in the H_2. In Fig. 2, the unit slope for pure N_2 indicates a rate of ion formation due to the presence of N_2, first order in CH_4 over a hundred-fold concentration range. The CH_4-contaminated N_2, on the other hand, indicates a transition from near zero order at low CH_4 concentrations to near first order at high $[CH_4]$; this represents a transition from a response to the CH_4 in the N_2 independent of the CH_4 content of the H_2, to a response to the N_2 dependent on the first order of the CH_4 content, as with the pure N_2. This demonstrates that the effect being observed with the pure test gases is not due to organic impurities therein. In Figs. 2, 3, and 4, the test gases Ar, Kr, Xe, CO, and CO_2 also indicate first order response over the full range of CH_4 concentrations. The data for CF_4 in Fig. 4, however, display a response similar to the impure N_2 in Fig. 2, indicating the presence of an impurity or a partial decomposition of CF_4, but also a rate of ion formation, first order in CH_4.

The data in Figs. 5 and 6 indicate the response to variable injections of the test gases at a constant CH_4 concentration in the H_2 (0.025%). The unit slope for each of the test gases implies that the additional ion formation in their presence is also first order in the test gas concentration.

The test gases were ranked according to their tendency to stimulate the excess ion formation by equal injections (500 μl) of each at a constant CH_4

concentration (0.3% in H_2) and measurement of the peak areas. Their efficiencies relative to He were $Ne \approx CO_2 < N_2 < Ar < CO < Kr < Xe \approx CF_4$.

Discussion

Insofar as the purpose of these studies was to obtain kinetic orders for the mutual stimulation of ion formation by CH_4 and the diluent gas, the data presented in Figs. 2, 3, 4, 5, and 6 indicate first order in each, as required by the overall process [2]. However, since this is the only evidence indicating the possibility of such an associative chemi-ionization process in hydrocarbon combustion, it is desirable to examine the system in detail to seek alternate explanations for the observations.

A suitable model for the effect must justify the increase in ion formation, the relative tendencies of the various diluents to promote ion formation and the observed kinetic orders. Physical involvement of the diluent might be expected to arise from simple dilution, temperature effects, or interference with the inter-diffusion of the reacting gases. Simple dilution effects can be ruled out since all diluents would have given the same effect. Likewise, the identical heat capacities of the noble gases would imply equal temperature effects for these gases, which does not correlate with their ion formation enhancement. The possibility that the diluent gas effect might arise in the inter-diffusion of the reacting

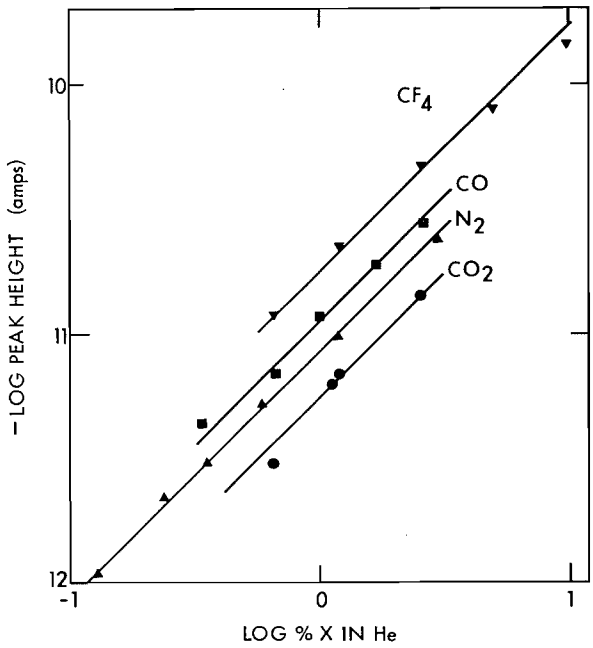

FIG. 6. The effect of the concentration of the test gases CF_4, CO, N_2, and CO_2 on the increase in ion formation at constant CH_4 concentration (0.025% in H_2).

gases is appealing since diffusion depends on molecular weight and the collision cross section and would therefore justify, at least approximately, the relative order of effectiveness of the diluent gases, it being assumed that restricted interdiffusion would promote ion formation. This explanation would also justify the difference in behavior of premixed and diffusion-flames in regard to diluent gases (7). The fact, however, that He gives about the same enhancement of ion formation in both the H_2 and the D_2 flames, as indicated in Fig. 1, implies that the molecular weight of the diluent in relation to that of the H_2 is not crucial. In addition, the enhancement of ion formation from cyano compounds is substantial for most diluent gases but is negative at all flow rates for He (11); it is inconceivable that the same diluent could behave so differently in the two systems if the effect arose only from diffusional differences.

A correlation of the effect with molecular weight and/or collision cross-section might arise in a specific third body process, critical to ion formation. Fontijn *et al.* (14–16) have observed C_2F_4-stimulated ion formation in the O-atom, N-atom flame system which they attribute to enhancement of the concentration of electronically excited N_2 or NO by the C_2F_4 acting as a catalyst in their formation. The comparable process in a hydrocarbon flame might be

$$[7] \qquad CH + O + X \rightarrow CHO^* + X$$

the enhanced ion formation arising from the greater efficiency of formation of the stabilized CHO*. In the combination of N and N or N and O, a third body may carry off some or all of the vibrational energy of the newly-formed, electronically excited N_2 and/or NO but still leave adequate energy for subsequent ion formation. With CHO, the overall exothermicity of reaction [1] is only 0.17 eV (17) and therefore the exact amount of energy removed would be crucial as far as ion formation is concerned. Under these circumstances, the atomic and molecular diluents might have been expected to behave quite differently, the latter potentially carrying off sufficient energy from the CHO to preclude ion formation. Of the diluents investigated, only CO_2 suggests this behavior but this may well have arisen from its involvement in the chemistry of the H_2–O_2 flame.

Other catalytic effects of the diluent gases might arise if a weakly-bound collision complex were formed with CHO, thereby suppressing the formation of the alternate products, CO and H-atoms. The resulting complex might then ionize and dissociate

$$[8] \qquad CHO{\cdot}X^* \rightarrow CHO^+ + e + X$$

or ionize

$$[9] \qquad CHO{\cdot}X^* \rightarrow CHO{\cdot}X^+ + e$$

the enhanced ion formation being due to the formation of $CHO{\cdot}X^*$ and/or to the energetic advantage associated with the formation of the composite ion. Unfortunately, the available evidence is inadequate to give clear preference to either of these pathways or to exclude reactions [5] and [7]. It is therefore only reasonable to modify the mechanism of ion formation in a very general fashion, implying the potential involvement of the diluent gases,

$$[10] \qquad CH + O\ (+X) \rightarrow CHO^+ + e\ (+X)$$

During the preparation of this paper, Vinckier, Gardner, and Bayes (18) have reported enhanced ion formation in the reaction of O atoms with acetylene when diluent He is replaced by other inert gases (Ar, N_2, CO, CF_4, and CO_2). Their order of effectiveness is dramatically different from the flame ionization detector system and is explained on the basis of specific reactions of C_2H_2 in its conversion to CH, three potential excited species being postulated in the reaction scheme. In the flame ionization detector, it has been postulated that organic constituents in general are totally converted to CH_3 prior to oxidation (10) and it is conceivable that the diluent gas effect therein might be explained by a similar generalized mechanism wherein the conversion of CH_3 to CH is subtly enhanced by the diluent. It is noteworthy, however, that the same pattern of effects in the ionization detector is observed with C_2N_2 (19) (wherein CH is not the ion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

precursor) and this origin of the diluent effect with hydrocarbons is therefore highly unlikely.

The effect of diluent gases on ion formation in C_2N_2 flames[1]

BRENDA L. CHAWNER AND ARTHUR T. BLADES
Alberta Research Council, Edmonton, Alta., Canada T6G 2C2

Received November 29, 1977

BRENDA L. CHAWNER and ARTHUR T. BLADES. Can. J. Chem. **56**, 2278 (1978).

Ion formation from traces of C_2N_2 in a H_2 + He-in-air diffusion flame is enhanced by the presence of traces of Ne, Ar, Kr, Xe, N_2, CO, CO_2 and CF_4. The enhancement is proportional to the concentration of both C_2N_2 and the diluent gas and the relative efficiencies are identical to those observed when hydrocarbons are the source of ionization. The observations are consistent with the involvement of the diluent in ion formation, parallel to the hydrocarbon system.

BRENDA L. CHAWNER et ARTHUR T. BLADES. Can. J. Chem. **56**, 2278 (1978).

La formation d'ions à partir de traces de C_2N_2 dans une flamme de diffusion H_2 + He dans l'air est augmentée par la présence de traces de Ne, Ar, Kr, Xe, N_2, CO, CO_2 et CF_4. Cette augmentation est proportionnelle à la concentration à la fois de C_2N_2 et du gas diluant et les efficacités relatives sont identiques à celles observées lorsque les hydrocarbures sont utilisés comme source d'ionisation. Ces observations sont en accord avec une implication du diluant dans la formation d'ions qui est parallèle à celle observée dans le système d'hydrocarbures.

[Traduit par le journal]

Introduction

An examination of the effect of the diluent gases on the rates of ion formation in an H_2–air diffusion flame containing traces of CH_4 has revealed strong evidence for the participation of the diluent in ion formation (1). This has been tentatively attributed to an associative chemi-ionization reaction (2).

[1] $$CHO^* + X \rightarrow CHO.X^+ + e$$

but other variations of the same overall process cannot be excluded on the basis of existing evidence (1).

Similar diluent gas effects are known to occur during C_2N_2 combustion in the same flame system (2). The mechanism of ion formation in this system is not well established but recent evidence has been interpreted (3) as favoring the reaction

[2] $$N(^2P, ^2D) + O \rightarrow NO^+ + e$$

over

[3] $$CN + O + O \rightarrow CO + NO^+ + e$$

The former has been cited as the origin of ions in NH_3 flames (4) while the latter fails to justify the large overall activation energy (111 kJ mol^{-1}) or the high rate of ion formation (3). Nevertheless, it is of interest to examine the diluent gas effect on the C_2N_2 system both in relation to diluent gas effects in general and the mechanism of ion formation.

Experimental and Results

A flame ionization detector having constant flows of H_2 (30 cc/min), He (30 cc/min), and air (800 cc/min) was used. C_2N_2 was continuously added to the H_2 stream giving concentrations up to 0.15% in H_2. The test gases, Ne, Ar, Kr, Xe, N_2, CO, CO_2, and CF_4 were injected into the He stream and allowed to mix with the He by passage through a 60 cm long, 14 mm od glass tube before reaching the flame ionization detector. The CO_2 and CF_4 contained hydrocarbon impurities and were routinely purified by passage through 0.45 m *n*-octane/porasil C column at 0°C before injection. Test gas concentrations (< 5% in the He) were monitored by thermal conductivity and their relative effects were established by the addition of equal amounts of each to the He flow at a constant C_2N_2 concentration. The order of effectiveness was $Ne < CO_2 < N_2 < Ar < CO < Kr < Xe$.

The data in Figs. 1 and 2 were obtained by injecting variable quantities of the test gases at a constant C_2N_2 concentration in the H_2; the slope of unity indicates that the response is first order in the test gas concentration. Figures 3 and 4 show the data resulting from a constant injection of the test gases with variable C_2N_2 concentrations. The slope shows the response to be first-order in C_2N_2 concentration, except in the case of CF_4. The CF_4 curve is nearly zero-order at low C_2N_2 concentrations, but subtraction of the zero order component gives the first-order line, Δ-CF_4.

Discussion

The effects of diluent gases on the rates of ion formation from C_2N_2 are virtually identical to their effects on ion formation from hydrocarbons (2). The increase in ion formation in the presence of the test gases is first order in both the test gas (Figs. 1 and 2), and C_2N_2 concentrations (Figs. 3 and 4), and the

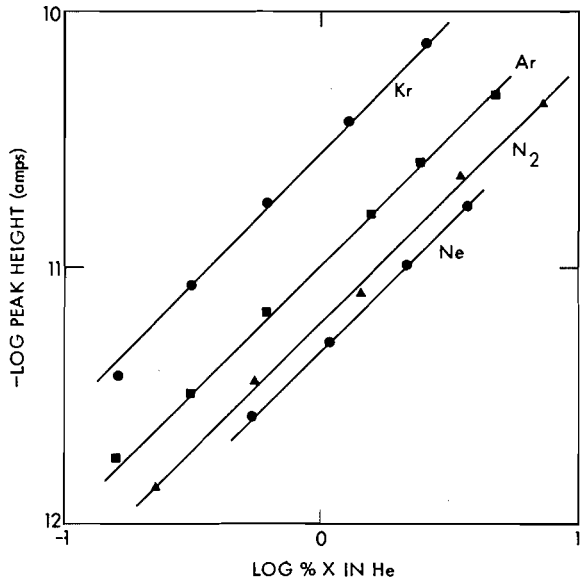

FIG. 1. The effect of the concentration of the test gases Ne, N_2, Ar, and Kr on the increase in ion formation at constant C_2N_2 concentration (0.1% in H_2).

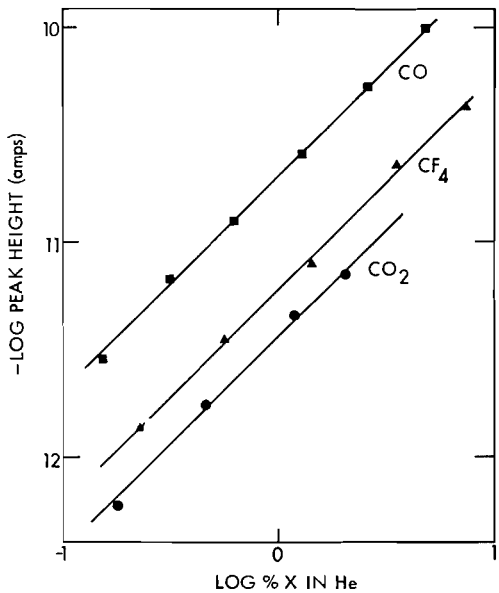

FIG. 2. The effect of the concentration of the test gases CO, CF_4, and CO_2 on the increase in ion formation at constant C_2N_2 concentration (0.1% in H_2).

order of effectiveness of the test gases in stimulating excess ion formation is identical to that in the hydrocarbon system. The one difference is that He may not be effective in increasing ion formation with C_2N_2, as may be inferred from the observation that He addition causes a monotonous decline in the rate of ion formation (2). In any case, there is no reason to

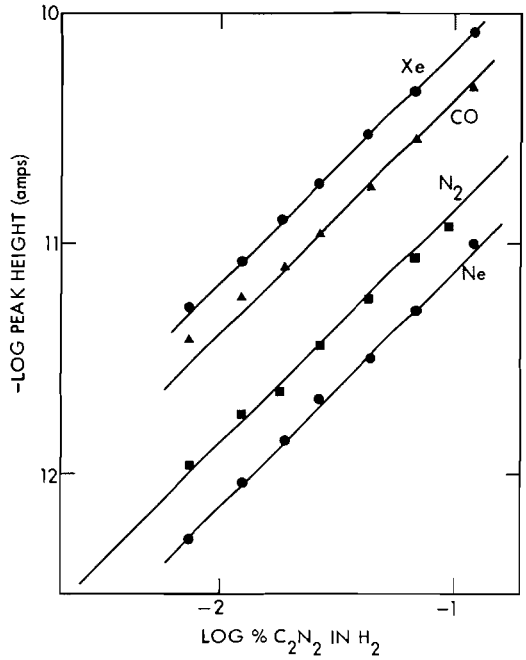

FIG. 3. The effect of C_2N_2 concentration on the increase in ion formation from a 500 μl slug of Ne, N_2, CO, and Xe.

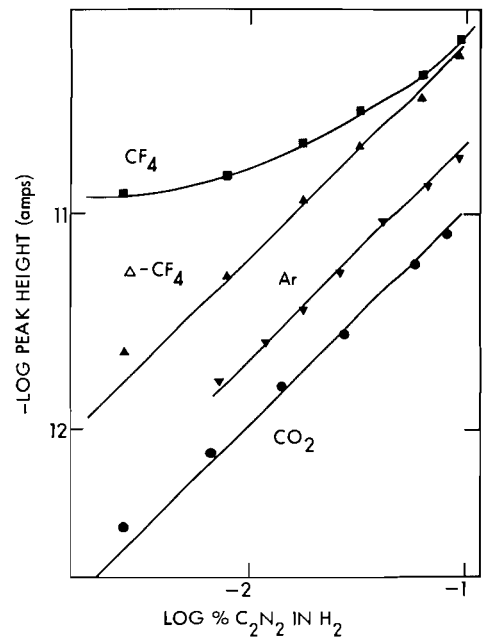

FIG. 4. The effect of C_2N_2 concentration on the increase in ion formation from a 500 μl slug of CO_2, Ar, and CF_4. The ΔCF_4 points are the result of a subtraction of a zero order component of 10^{-11} A.

believe that there is any fundamental difference between the origin of the effect in the two systems.

Since the details of the mechanism of ion formation from C_2N_2 are not well established, it is difficult

to speculate how the diluent gas may affect the rate of the process. Both reactions [2] and [3] depend on the interaction of CN and two O atoms and NO^+ is generally conceded to be the ion first observable or the 'primary' ion; it is therefore reasonable to propose, by analogy with the hydrocarbon system, that the diluent catalyzes the formation of NO* or assists in its ionization. No substantial evidence exists on which a choice could be based and the only conclusion to be reached from the present research is that the reaction

$$CN + O + O + X \rightarrow CO + NO^+ + e + X$$

may be a contributor to ion formation in cyanogen-containing flames.

Preparation of some cyclopentadienyl platinum (IV) complexes

ALAN SHAVER

Department of Chemistry, McGill University, 801 Sherbrooke Street, W., Montreal, P.Q., Canada H3A 2K6

Received January 6, 1978

ALAN SHAVER. Can. J. Chem. **56**, 2281 (1978).

Two routes to the synthesis of $(\eta^5\text{-}C_5H_5)PtR_1R_2R_3$, where R_1, R_2, and R_3 are not all CH_3, were explored. The complexes $[PtR_1R_2R_3X]_4$, where $R_1 = R_2 = CH_3$, $R_3 = C(O)CH_3$, C_2H_5; $R_1 = R_2 = C_2H_5$, $R_3 = CH_3$, $C(O)CH_3$; $R_1 = CH_3$, $R_2 = C_2H_5$, $R_3 = C(O)CH_3$; X = Cl or I, were prepared and treated with TlCp to give $(\eta^5\text{-}C_5H_5)PtR_1R_2R_3$. The latter are the first polyfunctionalized cyclopentadienyl platinum(IV) complexes. Conformational isomerism about the platinum to acetyl–carbon bond was detected by infrared spectroscopy. The cleavage of a Pt—CH_3 or Pt—$C(O)CH_3$ bond in $CpPt(CH_3)_2R$ using the reagents HCl, $HgCl_2$, or I_2 was not successful; the appropriate $[Pt(CH_3)_2RX]_4$ being isolated instead. The chiral nature of $(\eta^5\text{-}C_5H_5)Pt(CH_3)(C_2H_5)[C(O)CH_3]$ is noted.

ALAN SHAVER. Can. J. Chem. **56**, 2281 (1978).

On a exploré deux routes pouvant conduire à la synthèse de $(\eta^5\text{-}C_5H_5)PtR_1R_2R_3$ où R_1, R_2 et R_3 ne sont pas tous des CH_3. On a préparé les complexes $(PtR_1R_2R_3X)_4$ où $R_1 = R_2 = CH_3$, $R_3 = C(O)CH_3$, C_2H_5; $R_1 = R_2 = C_2H_5$, $R_3 = CH_3$, $C(O)CH_3$; $R_1 = CH_3$, $R_2 = C_2H_5$, $R_3 = C(O)CH_3$; X = Cl ou I et on les a traités avec TlCp pour conduire à $(\eta^5\text{-}C_5H_5)PtR_1R_2R_3$. Ces derniers sont les premiers complexes polyfonctionnallisés du cyclopentadiényle platine IV. On a pu détecter, par spectroscopie infrarouge, l'isomérie conformationnelle autour du lien platine–carbone de l'acétyle. On n'a pas pu réussir à cliver les liens Pt—CH_3 ou Pt—$C(O)CH_3$ des $CpPt(CH_3)_2R$ en faisant appel aux réactifs HCl, $HgCl_2$ ou I_2; on a plutôt isolé les complexes $[Pt(CH_3)_2RX]_4$ appropriés. On a noté la nature chirale du $(\eta^5\text{-}C_5H_5)Pt(CH_3)(C_2H_5)[C(O)CH_3]$.

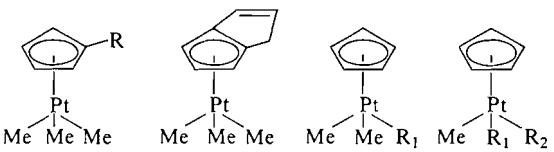
Cyclopentadienyltrimethylplatinum(IV), $CpPtMe_3$, was prepared in 1963 by Robinson and Shaw (1). The other molecules of this type differ only by containing substituted cyclopentadienyl ligands such as methylcyclopentadienyl (2), **1***b*, and hydropentalenyl (3), **2**. There are no examples where the platinum is tri- or tetrafunctionalized such as **3** and **4**. The pseudo-



1*a* R = H
b R = Me

2 **3** **4**

tetrahedral or piano stool arrangement of ligands in **4** results in optical isomerism. Chiral organometallics are of interest as a source of fundamental knowledge (4) and as potential catalysts in asymmetric organic synthesis (5, 6). These considerations led to attempts to synthesize **3** and **4**. As will be reported below, the successful preparation of the first polyfunctionalized platinum(IV) cyclopentadienides was achieved, including the chiral molecule η^5-cyclopentadienylmethylethylacetylplatinum(IV), CpPtMeEtAcyl.

Experimental

Nuclear magnetic resonance (^{1}H nmr) spectra were obtained on a Varian T-60 instrument, using tetramethylsilane (TMS) as internal standard. Melting points were determined in open capillaries in a Thomas Hoover Uni-Melt apparatus and are uncorrected. Infrared spectra were taken on a Perkin-Elmer 520 Grating Spectrophotometer. Elemental analyses were performed by Midwest Microanalytical, Indianapolis, Indiana.

Inert atmosphere techniques were used for all preparations. THF, benzene, and toluene were distilled from sodium benzophenone just before use. K_2PtCl_4 was prepared (7) from platinum metal (Engelhard Industries of Canada). $PtMe_2$(COD), where COD = 1,5-cyclooctadiene, was prepared by reported procedures (8). TlC_5H_5, obtained commercially or prepared as described (9), was purified by sublimation (0.01 Torr, 80–90°C) and stored under nitrogen in the dark. Reagent grade CH_3I and CH_3COCl were used without further purification. $[PtMe_3I]_4$, $[PtMe_2AcylCl]_4$, Acyl = $C(O)CH_3$, and $[PtMeEt_2I]_4$ were prepared as described (8). The new compound $[PtEt_2AcylCl]_4$ was prepared by a similar method (i.e. the oxidative-addition of CH_3COCl to $PtEt_2$(COD) (8)).

Preparation of New Platinum(IV) Cubane Type Complexes

A. Ethylmethyl-1,5-cyclooctadieneplatinum(II), PtEtMe(COD), 5

PtEtCl(COD) (8), 2.2 g (6.0 mmol), in 100 ml diethylether at −78°C, was treated with CH_3Li, 7 ml (1.3 *M*, 1.5 equiv.). The acetone – dry ice cooling bath was removed and the reaction mixture allowed to warm to room temperature and stirred for a further 2 h. After hydrolysis and work up (8), 1.6 g (77% yield of PtEtMe(COD) was isolated as a clear, colourless oil. The analytical sample was distilled (40°C, 10^{-2} Torr) in a short path distillation apparatus (Bantam-Ware K-284500). ^{1}H nmr ($CDCl_3$): δ 0.73 (t, 3H, CH_3, J(Pt—H) = 83 Hz), 0.4–1.7 (m, 5H, CH_2CH_3), 2.3 (bs, 8H, CH_2), 4.7 ppm (bt, 4H, CH, J(Pt—H) = 38 Hz). ^{13}C nmr ($CDCl_3$, shifts are referenced to TMS): δ 7.7 (t, CH_3, J(Pt—C) = 828 Hz), 17.0 (t, CH_2—CH_3, J(Pt—C) = 793 Hz), 15.8 (t, CH_2—CH_3, J(Pt—C) = 30 Hz),

99.8 and 97.4 (t, CH, J(Pt—C) = 40.4 and 62.5 Hz respectively), 29.9 and 29.5 ppm (t, CH_2 of COD, J(Pt—C) = 5.9 Hz, the coupling constant for the second peak was too small to be observed). *Anal.* calcd. for $C_{11}H_{20}Pt$: C 38.04, H 5.76; found: C 38.3, H 5.81.

B. Ethyldimethyliodoplatinum(IV), [PtEtMe$_2$I]$_4$, 6

CH_3I, 5.5 ml (8.9×10^{-2} mol), was added to PtEtMe(COD), 1.0 g (2.9 mmol) in 5 ml toluene. The reaction solution was kept at 80°C for 2.5 h (air condenser), then allowed to cool and was stripped to dryness. The grey oily solid was taken up in a minimum of CH_2Cl_2 and passed through a small (5 mm × 60 mm) column of florisil (CH_2Cl_2 eluant).

The solution was stripped and the residue was recrystallized from $CHCl_3$/acetone to give 0.44 g (40% yield) white crystals, which decompose above 180°C. Nmr ($CDCl_3$): δ 0.83 (tt, 3H, CH_2CH_3, J(H—H) = 7.5 Hz, J(Pt—H) = 76 Hz), 1.7 (t, 6H, CH_3, J(Pt—H) = 77 Hz), 2.4 ppm (q, 2H, CH_2CH_3, J(Pt—H) = 114 Hz). *Anal.* calcd. for $C_4H_{11}IPt$: C 12.60, H 2.89, Pt 51.18; found: C 12.6, H 2.88, Pt 51.5 (residue).

C. Ethylmethylacetylchloroplatinum(IV), [PtEtMeAcylCl]$_4$, 7

PtEtMe(COD), 0.29 g (0.84 mmol) was dissolved in 2.5 ml of reagent grade $CHCl_3$ which had been passed through a column of basic alumina in order to remove ethanol (monitored by nmr). CH_3COCl, 0.057 ml (0.80 mmol) was added by means of a 0.1 ml microsyringe. After mixing, the reaction solution was allowed to stand for 24 h. The solvent was stripped and the product was recrystallized from ether–hexane to give white crystals, which decompose >160°C. Yield is dependent on the scale of the reaction (in this case greater than 80%); large scale reactions (0.62 g PtEtMe(COD)) give significantly lower yield. Nmr ($CDCl_3$): δ 0.70 (t, 3H, CH_2CH_3, J(H—H) = 7.0 Hz), 1.65 (t, 3H, CH_3, J(Pt—H) = 86 Hz), 2.43 ppm (t, 3H, C(O)CH_3, J(Pt—H) = 15 Hz), CH_2CH_3 obscured by peaks due to C(O)CH_3. *Anal.* calcd. for $C_5H_{11}ClOPt$: C 18.90, H 3.46; found: C 18.5, H 3.54.

Preparation of Cyclopentadienylplatinum(IV) Complexes

CAUTION: These complexes are volatile and care should be exercised to avoid inhalation.

D. η^5-Cyclopentadienyltrimethylplatinum(IV), CpPtMe$_3$, 1a

[$PtMe_3I$]$_4$, 0.92 g (2.5 mmol), was dissolved in 5 ml 2-methylpyridine. THF (30 ml) were added and TlCp, 0.68 g (2.5 mmol), was added to the clear solution. A yellow precipitate formed immediately. The slurry was stirred for 2 h, filtered, and stripped to yield an oily solid. A sublimation probe was inserted and the rest of the 2-methylpyridine was pumped off after which there sublimed white crystals of $CpPtMe_3$, 0.38 g (50% yield) mp = 103–104°C, lit = 65°C (1), 108.5 (10), 104–104.5 (11). The reported value of 65°C is apparently incorrect.

E. η^5-Cyclopentadienyldimethylacetylplatinum(IV), CpPtMe$_2$Acyl, 8

[$PtMe_2AcylCl$]$_4$, 0.40 g (1.3 mmol), in 30 ml THF was treated with TlCp, 0.36 g (1.3 mmol) for 1 h. After work up and sublimation (30°C, 0.02 Torr), **8** was isolated as white crystals, 0.24 g (55%) mp = 67°C. Nmr ($CDCl_3$): δ 1.13 (t, 6H, CH_3, J(Pt—H) = 84 Hz), 2.42 (t, 3H, C(O)CH_3, J(Pt—H) = 6.0 Hz), 5.7 ppm (t, 5H, C_5H_5, J(Pt—H) = 5.8 Hz). Ir(CCl_4) ν(C=O): 1663 (m), 1693 (s). *Anal.* calcd. for $C_9H_{14}OPt$: C 32.43, H 4.2; found: C 32.7, H 4.31.

F. η^5-Cyclopentadienyldiethylmethylplatinum(IV), CpPtEt$_2$Me, 9

To [$PtEt_2MeI$]$_4$, 0.60 g (1.5 mmol) in 30 ml CH_2Cl_2 was added TlCp, 0.40 g (15 mmol) and the slurry was stirred for 5.5 h. After filtering and stripping the solvent, a yellow oil remained. This was distilled in the short path apparatus to give **9**, 0.42 g (83%). Nmr ($CDCl_3$): δ 0.85 (t, 3H, CH_3, J(Pt—H) = 83.2 Hz), 1.9–0.77 (m's, 10H, CH_2CH_3), 5.57 ppm (t, 5H, C_5H_5, J(Pt—H) = 5.9 Hz). *Anal.* calcd. for $C_{10}H_{18}Pt$: C 36.04, H 5.41; found: C 36.5, H 5.40.

G. η^5-Cyclopentadienyldiethylacetylplatinum(IV), CpPtEt$_2$Acyl, 10

As above [$PtEt_2AcylCl$]$_4$, 0.74 g (2.2 mmol) reacted with TlCp, 0.61 g (2.3 mmol) in 25 ml THF. Distilled in the short path apparatus (50°C/0.02 Torr). Nmr ($CDCl_3$): δ 1.27 (tt, 6H, CH_2CH_3, J(H—H) = 6.8 Hz, J(Pt—H) = 66 Hz), 2.5 (t, 3H, C(O)CH_3, J(Pt—H) = 5.2 Hz), 5.8 ppm (t, 5H, C_5H_5, J(Pt—H) = 5.2 Hz), CH_2CH_3 obscured by overlap. Ir(hexane) ν(C=O): 1699 (s) 1668 (m). *Anal.* calcd. for $C_{11}H_{18}OPt$: C 36.6, H 4.99; found: C 37.34, H 5.34.

H. η^5-Cyclopentadienylethyldimethylplatinum(IV), CpPtEtMe$_2$, 11

The amounts were: [$PtEtMe_2I$]$_4$, 0.50 g (1.3 mmol), TlCp, 0.39 g (1.4 mmol) in 40 ml CH_2Cl_2; the slurry was stirred for 14 h. Distilled as before; **11** 0.075 g (18%). Nmr ($CDCl_3$): δ 0.83 (t, 6H, CH_3, J(Pt—H) = 82 Hz), 2.0–1.1 (m's, 10H, CH_2CH_3), 5.7 ppm (t, 5H, C_5H_5, J(Pt—H) = 5.8 Hz). *Anal.* calcd. for $C_9H_{16}Pt$: C 33.9, H 5.02; found: C 34.3, H, 4.83.

I. η^5-Cyclopentadienylethylmethylacetylplatinum(IV), CpPtEtMeAcyl, 12

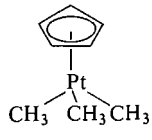
[$PtEtMeAcylCl$]$_4$, 0.76 g (2.4 mmol) and TlCp 0.58 g (2.2 mmol) were stirred in 30 ml THF for 3.5 h. Distilled (40°C/0.02 Torr) to give 0.73 g (88%). Nmr ($CDCl_3$): δ 1.12 (t, 3H, CH_3, J(Pt—H) = 87 Hz), 1.33 (tt, 3H, CH_2CH_3, J(H—H) = 7.0 Hz, J(Pt—H) = 66 Hz), 2.03 (m, 2H, CH_2CH_3), 2.51 (t, 3H, C(O)CH_3, J(Pt—H) = 6.0 Hz), 5.84 ppm (t, 5H, C_5H_5, J(Pt—H) = 5.6 Hz). Ir(CCl_4) ν(C=O): 1690 (s), 1662 (m). *Anal.* calcd. for $C_{10}H_{10}PtO$: C 34.58, H 4.61; found: C 34.6, H 4.70.

Reactions of CpPtMe$_3$ (1a) and CpPtMe$_2$Acyl, 8, with HCl, HgCl$_2$ and I$_2$

In a typical reaction **1a**, 0.16 g, was treated with 1 equiv. of HCl (generated from CH_3COCl in $MeOH/CH_2Cl_2$). The reaction was stirred overnight. A white precipitate was isolated and shown to be [$PtMe_3Cl$]$_4$ on the basis of its nmr spectrum in $CDCl_3$. In all other cases, (except **5** with I_2 which decomposes), the appropriate platinum tetramer was isolated.

Results and Discussion

Initial attempts to synthesize complexes of type **3** and **4** were directed at functionalizing the Pt—CH_3 bond in $CpPtMe_3$. The complex was treated with the electrophilic cleavage reagents (12) HCl, $HgCl_2$, and I_2. However, instead of attack at the Pt—CH_3 bond, the C_5H_5 ring was displaced and [$PtMe_3X$]$_4$ where X = Cl, Cl, and I respectively, was identified. Scheme 1 depicts the probable products. Since the platinum-containing materials were of primary interest the organic products were not identified, but those depicted are reasonable. The reactions are smooth and give high yields of tetramer. No evidence for any CpPt complexes could be detected in the nmr.

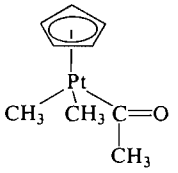


$+ HCl \rightarrow (PtMe_3Cl)_4 + C_5H_6$
$+ HgCl_2 \rightarrow (PtMe_3Cl)_4 + CpHgCl$
$+ I_2 \rightarrow (PtMe_3I)_4 + C_5H_5I$

SCHEME 1

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Upon isolation of $CpPtMe_2Acyl$, (**8** reported below), it was treated with the same reagents and a similar displacement of the C_5H_5 ring occurred with HCl and $HgCl_2$ (Scheme 2).



$+ HCl \rightarrow (PtMe_2AcylCl)_4$
$+ HgCl_2 \rightarrow (PtMe_2AcylCl)_4$
$+ I_2 \rightarrow$ dec.

SCHEME 2

Perhaps these reactions are not surprising if, as has been postulated (13), the first step is the oxidation of the metal atom followed by bond cleavage. The platinum in these molecules is in the +4 oxidation state and will not oxidize to higher states with these reagents (14). On the basis of the products produced, it is reasonable to propose that electrophilic attack at the C_5H_5 ring has occurred giving a cationic platinum(IV) cyclopentadiene complex which rapidly loses the diene and condenses to the tetramer.

The failure to functionalize Pt—C bonds in these complexes led to attempts to prepare suitably substituted starting materials. Robinson and Shaw used $[PtMe_3I]_4$ (1). This complex plus $[PtMe_2AcylCl]_4$ and $[PtEt_2MeI]_4$ have been prepared (8) by oxidative addition reactions of the appropriate dialkyl complex $PtR_2(COD)$, R = CH_3, C_2H_5. The complex $[PtEt_2AcylCl]_4$ was prepared by the oxidative addition of CH_3COCl to $PtEt_2COD$. In order to prepare $[PtEtMe_2I]_4$ and $[PtEtMeAcylCl]_4$ it was necessary to prepare PtEtMeCOD. Treatment of PtMeClCOD with excess EtMgBr resulted in high yields of $PtEt_2COD$ with none of the desired mixed alkyl being detected by nmr. Obviously alkyl exchange has occurred. This could happen in two ways (Scheme 3):

$$CODPtMeCl + EtMgBr \rightleftharpoons \begin{matrix} CODPtMeEt \\ CODPtEt_2 \end{matrix}$$

$$Cl—Pt—CH_3 + Br—Mg \rightarrow Cl—Pt—Br + CH_3—Mg \quad \ldots 1$$

$$Cl—Pt—CH_3 + Cl—Pt—CH_3 \rightarrow Cl—Pt—Cl + CH_3—Pt—CH_3 \quad \ldots 2$$

SCHEME 3

the Pt—CH_3 bond could alkylate the Mg—Br bond (*1*) or the Pt—Cl bond (*2*). Alkylation of a Pt—Cl bond results in retention of the methyl group in the platinum-containing products. Since no material containing a Pt—CH_3 bond could be detected, alkylation of a MgBr bond probably occurs. The CH_3—Mg species formed would then be 'lost' in the large excess of EtMgBr used in the preparation, resulting in complete exchange and isolation of $PtEt_2COD$ only. Such exchanges have been observed before between platinum alkyls and magnesium dihalides (15). Exchange between platinum dialkyls and platinum dihalides has also been reported (16).

The problem of preparing PtEtMeCOD was approached by the alternate route of methylating PtEtClCOD. Treatment of PtEtClCOD with excess methyl lithium gave PtEtMeCOD with only a trace of $PtMe_2COD$. The ^{13}nmr data for PtEtMeCOD[1] proved it to be a unique complex and not a 50:50 mixture of $PtMe_2COD$ (17) and $PtEt_2COD$ (18).

The oxidative addition of CH_3I to PtEtMeCOD required heating to 80°C in toluene solution. This is unusual since both the dimethyl and the diethyl complex react at room temperature. The preparation of $[PtEtMeAcylCl]_4$ by the oxidative addition of CH_3COCl is extremely sensitive to reaction conditions. The presence of CH_3CH_2OH in reagent grade $CHCl_3$ causes the reaction of CH_3COCl with PtEtMeCOD to proceed by a different pathway and give a mixture of PtEtClCOD and PtMeClCOD, identified by comparison of the ^{1}H nmr spectrum to those of authentic samples. The high yield of this mixture rules out the simple hydrolysis of a Pt—C bond due to the formation of HCl by the reaction of CH_3COCl with the small amount of CH_3CH_2OH present. The use of ether as a solvent for the oxidative addition results in the isolation of starting material. Reaction occurs in toluene and CH_2Cl_2 to give PtMeClCOD, PtEtClCOD, and some of the desired $[PtEtMeAcylCl]_4$, while CCl_4 gives only the latter in fair yield. The reaction proceeded cleanly in $CDCl_3$ and gave the tetramer in high yields. $CHCl_3$, which had been treated to remove CH_3CH_2OH, duplicated the $CDCl_3$ results. However, attempts to scale up the reaction always led to reduced yields, 0.2 g of PtEtMeCOD being optimum. These results imply free radicals may be involved in this reaction, as has been postulated in other oxidative additions (19).

Other oxidative additions were attempted but were not successful. For example, $Pt(C_6H_5)_2COD$ and $Pt(C_6H_5)(CH_3)COD$ did not react with CH_3I. It has been reported that no reaction occurs between $PtMe_2COD$ and ethyl iodide or benzoyl chloride (8). However, in view of the above, the selection of alternative reaction conditions might result in successful syntheses.

The three new complexes reported here: $[PtEt_2AcylCl]_4$, $[PtEtMe_2I]_4$, **6**, and $[PtEtMeAcylCl]_4$, **7**, are colourless solids. They are much more soluble in organic solvents than the parent complex $[PtMe_3I]_4$, **7** being soluble in ether. Their assignments as tetramers is based on the structure of the parent complex (20). The formation of these complexes probably involves an initial oxidative addition to

[1]Obtained on a Bruker WH-90 by Dr. Gordon Hamer of this department.

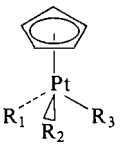
For personal use only.

form unstable monomeric species i.e. $PtEt_2AcylCl$-COD. Olefin complexes of platinum(IV) do not exist and rapid loss of COD and condensation to a cubane tetramer occurs. The nmr spectra for these complexes are sharp and give no indication of the presence of geometrical isomerism. It seems unlikely that only one isomer of **7** would be formed. Since the platinum atoms are separated by 3.9 Å from each other (20) it is probable that the arrangement of ligands on one platinum atom has little effect on the arrangement or chemical shift of ligands on another. The possibility of a rearrangement occurring rapidly on the nmr time scale which would average the magnetic environment is considered unlikely but cannot be excluded. One can, however, rule out inter- or intra-molecular alkyl exchange since only one cyclopentadienyl derivative is isolated from each tetramer.

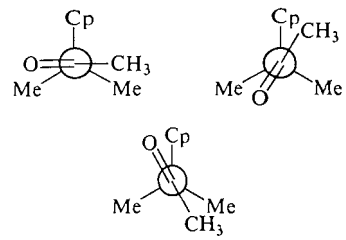
The cyclopentadienylplatinum complexes **1***a*, **8**–**12** result from the treatment of the appropriate tetramer with TlCp. **1***a* was originally prepared from $[PtMe_3I]_4$ and NaCp in 20% yield. The use of carefully purified TlCp results in 50% yield (unmaximized). The use of even a slight excess of TlCp should be avoided since yields appear to be badly reduced. The new complexes **9**–**12** are all clear liquids while **8** is a solid. They are quite volatile and possess a characteristic mushroom odor. As with all organometallic complexes, care should be taken to minimize exposure. They are stable to air but some do tend to turn yellow when distilled.



1*a* $R_1 = R_2 = R_3 = CH_3$
8 $R_1 = R_2 = CH_3$, $R_3 = C(O)CH_3$
9 $R_1 = R_2 = C_2H_5$, $R_3 = CH_3$
10 $R_1 = R_2 = C_2H_5$, $R_3 = C(O)CH_3$
11 $R_1 = R_2 = CH_3$, $R_3 = C_2H_5$
12 $R_1 = CH_3$, $R_2 = C_2H_5$, $R_3 = C(O)CH_3$

The complexes show no tendency to undergo reductive elimination reactions at room temperature and can be distilled intact. Other monomeric platinum(IV) alkyl complexes eliminate (21, 22) alkane or alkyl halide to give stable platinum(II) complexes. However, elimination of ethane from **1***a* would give $CpPtCH_3$ which would be predicted to be coordinatively unsaturated and unstable.[2] No evidence for elimination of C_2H_5 with the concomitant formation of a platinum(IV) hydride was detected. Similarly, the acetyl derivatives were stable to decarbonylation. The necessary condition for such reactions is the existence or creation of a vacant coordination site (24–26). This would be expected to be very difficult since platinum(IV) complexes are invariably six-coordinate; hence **1***a*, **8**–**12** are coordinatively saturated. Since there are no neutral two electron donors such as carbonyls or phosphines, the formation of a coordinatively unsaturated species will be a high energy process (10). Studies on the high temperature reactions of these complexes are planned. The reactions of **1***a* and **8** with electrophiles have already been discussed.

The complexes were characterized by infrared and ^1H and ^{13}C nmr spectroscopy (27). The postulated piano stool structure (28) is consistent with these data. As reported in the experimental section, the infrared spectra of **8**, **10**, and **12** have two bands in the acyl stretching region regardless of the supporting medium: neat (**10**, **12**), Nujol (**8**), hexane or CCl_4. However, the relative intensities of the two bands are dependent on the medium. Similar splitting is observed for $[HB(C_3H_3N_2)_3]$ $[C(O)CH_3](CO)_2Fe$ (29), $(\eta^5\text{-}C_5H_5)[C(O)CH_3](R_2NPF_2)(CO)Fe$ (29), and *trans*-$(\eta^5\text{-}C_5H_5)[C(O)CH{=}CH(C_6H_5)](CO)_2Fe$.[3] As in these complexes, we explain the splitting in terms of isomers related by internal rotations of the acetyl group about the Pt—C bond. Three possible conformers are illustrated below. Although there are only two peaks in the infrared spectrum, indicating only two isomers are present, the presence of the third cannot be ruled out (29). Since the nmr spectrum is very sharp it is reasonable to conclude that the isomers interconvert rapidly on the nmr timescale.



Compounds **8**–**12** are the first cyclopentadienyl complexes of platinum(IV) that have groups other than CH_3 as 'legs' in the piano stool structure. **12** is of interest as a chiral example of this class. The absence of ligands such as phosphines, olefins, or carbonyls makes this complex well suited for model studies, some of which will be reported in the future.

The syntheses and properties of *C*-silylimines and their thermal rearrangements to *N*-silylenamines

ADRIAN G. BROOK, CARLO GOLINO,[1] AND EBERHARD MATERN[2]

University of Toronto, Toronto, Ont., Canada M5S 1A1

Received February 27, 1978

ADRIAN G. BROOK, CARLO GOLINO, and EBERHARD MATERN. Can. J. Chem. **56**, 2286 (1978).

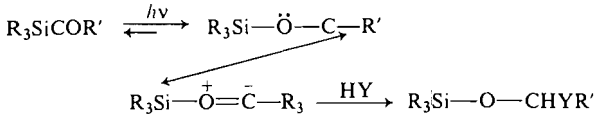
C-Silylimines have been synthesized by silylation of lithioaldimines prepared from isonitriles. Their ultraviolet and C=N infrared absorptions show bathochromic shifts relative to related aldimines or ketimines and the nmr spectra show the presence of *syn–anti* isomers, probably due to nitrogen inversion. The silylimines undergo intramolecular thermal rearrangements at about 200–235°C yielding *N*-silylenamines, which have been characterized.

ADRIAN G. BROOK, CARLO GOLINO et EBERHARD MATERN. Can. J. Chem. **56**, 2286 (1978).

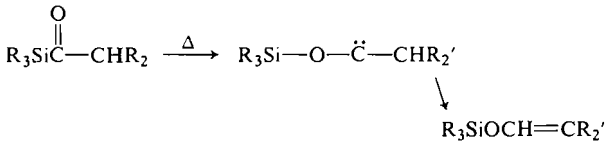
On a synthétisé des *C*-silylimines par silylation des lithioaldimines préparés à partir des isonitriles. Leurs absorptions dans l'ultraviolet et l'infrarouge pour le C=N présentent des déplacements bathochromes par rapport aux aldimines ou aux cétimines qui leur sont reliés et les spectres rmn montrent la présence des isomères *syn* et *anti* probablement due à une inversion au niveau de l'azote. Les silylimines subissent des transpositions thermiques intramoléculaires entre 200–235°C conduisant aux *N*-silylénamines qui ont été caractérisés.

[Traduit par le journal]

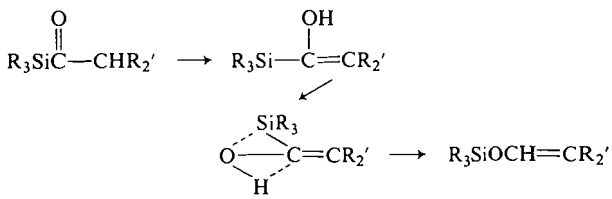
Acylsilanes have been shown to rearrange both photochemically and thermally. Under the former circumstances (1) a siloxycarbene having significant nucleophilic character has been proposed as an intermediate, whose most studied behaviour has been its facile insertion into bonds bearing acidic hydrogen.



Siloxycarbenes have also been proposed as intermediates in thermal rearrangements, where the sole observed behaviour has involved insertion into an adjacent CH bond (2).



Although these proposals for the thermal rearrangement adequately explain the experimental observations, many (but not all) of the results could be equally well explained by a dyotropic rearrangement of the isomeric enolic form of the acylsilane.



Reetz *et al.* (3) have made a series of elegant studies on variants of related rearrangements generally involving silicon–oxygen species.

We sought to learn more about the generality of the types of rearrangements described above and to this end have investigated some *C*-silylimines, nitrogen analogs of acylsilanes. Of several synthetic routes attempted (which included reactions of acylsilanes with primary amines or amide ions under various conditions, reactions of silyllithium reagents with isonitriles followed by alkylation or silylation, and reaction of amines with α,α-dibromobenzylsilanes) only the addition of organolithium reagents to isonitriles as originally described by Walborsky *et al.* (4), followed by silylation was reasonably successful and several *C*-silylimines were prepared in a pure state by this route.

¶n_D^{20} 1.4340.

Only isonitriles with bulky groups containing no α-hydrogen (*tert*-octyl, *tert*-butyl, 2,6-dimethylphenyl) were successfully employed, less bulky groups (e.g. Ph) or those with α-hydrogen undergoing additional reactions and yielding little if any silylimines. Even then, with 2,6-dimethylphenylisonitrile, low temperature (−80°C) addition of the organolithium reagent was desirable, since even at 0°C an alternative pathway occurred, which probably involved radical anions, as suggested by the intense purple colour observed. Under the most favourable conditions (which we have not optimized) the yields of silylimines were not high. *N*-Alkyl-*C*-silylimines are fairly readily hydrolyzed by water or methanol, yielding the corresponding aldimine by loss of the silyl group. On the other hand, *N*-arylsilylimines such as **1** or **4** (see Table 1) are reasonably stable at room temperature but react at about 80°C with methanol or methanol–HCl to yield 2,6-dimethylaniline and methoxytrimethylsilane.

Like their acylsilane analogs (5) *C*-silylimines have C=N absorption in the infrared region at considerably longer wavelengths than their carbon analogs. Table 2 indicates that the C=N absorption of silylimines generally occurs in the region 6.23–6.30 μ, whereas related carbon analogs (*t*Bu(Me)C=NPh, 6.06 μ (6); Me_2C=N-*n*Pr, 6.02 μ; $(CH_2)_5C$=NPh, 6.04 μ (7)) absorb at shorter wavelengths. The related aldimines *n*BuN=CH-*t*Bu (8), ir 6.02 μ, and *t*Bu-N=CH-*n*Bu, ir 5.95 μ, and *t*octyl-N=CH-*n*Bu, ir 6.00 μ, derived from methanolysis of silylimines **8** and **5**, respectively, similarly absorb at much shorter wavelengths than their silyl precursors.

It is difficult to judge the effect of silyl groups on the ultraviolet absorption of imines because good data is scarce. Imines have both π–π* and *n*–π* absorptions but with *N*-arylketimines the *n*–π* absorption has generally not been observed, presumably because it falls within the envelope of the intense π–π* absorption. It is probably appropriate to compare $Me_3Si(nBu)C$=N-*t*Bu, **2** (λ_{max} 302 nm) with Me_2C=N-*n*Bu (λ_{max} 246 nm) (9) which suggests a bathochromic shift of about 56 nm on replacing alkyl by trimethylsilyl. If the absorption reported at 323 nm in Ph(Me)C=N-2,6-$Me_2C_6H_3$ is the *n*–π* transition, it appears at 25 nm shorter wave-

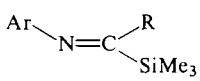
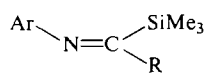
length than the long wavelength absorption of the silyl compounds Me_3Si(Et or *t*Bu)C=N-2,6-$Me_2C_6H_3$, **2** or **4** which have λ_{max} 348 nm. In acylsilanes, bathochromic shifts relative to carbon analogs are of the order of 100 nm (5) but in acylsilanes, the long wavelength absorption is now considered better described as a σ–π* transition in view of the character of the HOMO (10). Whether this is true in silylimines is unknown. Like the acylsilanes, the long wavelength absorption of silylimines shows a small blue shift on changing to more polar solvents.

Although the nmr spectra of the *N*-alkylsilylimines show the presence of only one isomer, those of the *N*-arylsilylimines show the presence of *syn–anti* isomers and the proportion of isomers appears to be determined by steric effects. The spectra are consistently interpretable on the reasonable assumption that whichever group is *syn* to the aryl group suffers significant shielding relative to the situation when that group is *anti* in the other isomer. When R = Me,



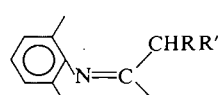
anti

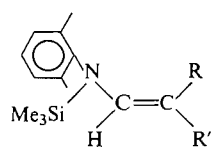


syn

the compound exists largely as the *anti* species, a small upfield Me_3Si peak (≃5%) suggesting the presence of a small amount of *syn* isomer. When R = ethyl, the *anti* isomer predominates (80% at 35°C) but the signals for the *anti* and *syn* trimethyl or ethyl protons are not sharp or well resolved. At −10°C the signals are sharper and the proportions are about 80% *anti* and 20% *syn* isomers. When R = *i*Pr, the signals are only very broad and diffuse at 35°C, but at −5°C they are significantly sharper, and the properties of *anti* and *syn* isomers are essentially equal. The silicon coalescence temperature appears to be about 39°C, and the data suggests that the $\Delta G^{\ddagger}$ for nitrogen inversion is about 14.8 kcal/mol. This may be compared to the value of 20.3 kcal/mol reported for *N*-phenyldimethylimine (11). Finally, when R = *t*Bu, the position of the Me_3Si resonance, 0.13 ppm, is consistent with the isomer present having the *syn* configuration, presumably because the longer Si—C bond (relative to C—C) results in the isomer being relatively the less sterically strained.

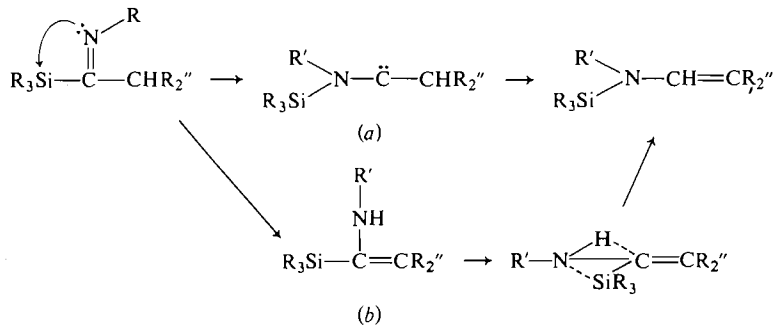
The thermal behaviour of the silylimines depends on their structure. The *N*-alkyl compounds decompose slowly when heated above 200°C to a complex mixture of olefins and other unidentified compounds which were not further studied. Compound **4**, the only *N*-aryl compound which lacked hydrogen α to the C=N, failed to rearrange even after 90 h at 225–250°C. By contrast **1**, **2**, and **3** rearranged fairly cleanly at 200–235°C at rates comparable to the isomeric *N*-silylenamines, with relative rates **1** > **2** > **3**. The *N*-silylenamines, **8–10**, were readily isolated by glc, and were characterized by analysis and spectroscopy (see Table 3).





The structural and spectral assignments for the *N*-silylenamines **8** and **9** are based on the expected *trans* proton–proton spin coupling constants. Compound **9** has the sterically less-strained *trans* configuration, with its '*trans*' alkyl methyl group out of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



the field of the arylamino group. Its resonance position is therefore significantly downfield (0.75 ppm) relative to the '*cis*'-methyl group in **10**, which is more shielded. It is noteworthy that in the known *N*-methyl-*N*-phenyl-*cis*- or -*trans*-propenylamines or *N*-ethyl-*N*(*o*-tolyl)-*cis*- and -*trans*-propenylamines, the *trans*-methyl groups in each case are, respectively, 0.13 and 0.26 ppm to lower field than the *cis* methyl groups (12).

The *N*-silylenamines were very hydrolytically unstable and rapidly reacted in methanol to give cleavage products and not the enamine. Thus the silylenamine **8** obtained from thermolysis of **1** gave dimethylaniline and methoxytrimethylsilane on treatment with methanol, as shown by its nmr and ir spectra.

A kinetic study of the thermal rearrangement of the methyl-*C*-silylimine **1** showed the reaction to be cleanly first order over several half lives, with E_a = 30.4 kcal/mol and $\Delta S^{\ddagger} = -20.6$ eu. For **2** and **3**, less reliable kinetics suggested that E_a decreased with increasing size of R while $\Delta S^{\ddagger}$ became increasingly negative. (It seems probable that these rearrangements were being carried out above the isokinetic temperature estimated as 137°C from limited data, and hence the influence of $\Delta S^{\ddagger}$ dominates.) The rates of rearrangements were not significantly affected by the addition of traces of base or acid. Attempts to effect the rearrangement photochemically, neat or in hexane, using either long wavelength (λ_{max} 360 nm) or medium pressure mercury lamps, were unsuccessful, only small amounts of decomposition products being observed after hours of photolysis. Photolysis of the *C*-silylimines in carbon tetrachloride occurred to give trimethylchlorosilane, probably by a radical process, as the only silicon-containing species.

While the failure of the silylimines to undergo photochemical rearrangement is unlike the behaviour of the related acylsilanes, their thermal behaviour closely parallels that of the acylsilanes. Thus a mechanism can be written parallelling that proposed for the acylsilanes, in which a silylaminocarbene (*a*) is formed which subsequently inserts into the adjacent CH bond. However, the extent by which the silyl migration preceeds the hydrogen migration is not established and the two migrations may be concerted. It must also be recognized that while the enamine tautomer (*b*) cannot be detected at room temperature, at elevated temperatures it could be the reactive form through which rearrangement, possibly of the dyotropic type, occurs. Certainly the observed entropy of activation indicates considerable loss of freedom of motion in the transition state, consistent with a concerted process.

Experimental

Organometallic reactions were carried out in dried solvents under dry nitrogen. Chromatographic analyses or purifications were done on 5 ft 20% SE-30 on Chromosorb W columns at appropriate temperatures. Nuclear magnetic resonance and infrared spectra were normally run in CCl_4.

Analyses were carried out by A. B. Gygli, Toronto.

Preparation of N-*2,6-Dimethylphenyl(trimethylsilyl)-ethylimine (2)*

To 7.88 g (0.060 mol) of 2,6-dimethylphenylisonitrile in 350 ml of ether at −75°C (some isonitrile began to precipitate out) was added 49 g (55 ml, 0.068 mol) of ethyllithium in benzene over 25 min giving a deep red-brown solution. After 10 min stirring, 8.8 ml (0.068 mol) of trimethylchlorosilane was added over 10 min, while the temperature remained below −70°C. After stirring for 3.5 h at −75°C the reaction mixture was allowed to warm to 25°C during which time it became deep purple. Because of the sensitivity of some silylimines to hydrolysis, filtration of the lithium salts was not carried out but instead the solvent was removed under reduced pressure to give a thick red oil, distilled through a short Vigreaux column to yield 5.70 g (41%) of pale yellow silylimine, shown by glc to be at least 95% pure. Purification was effected by glc on a 20% SE-30 on Chromosorb W column at 200°C.

If instead the isonitrile was treated with ethyllithium at 0°C, a deep purple solution was obtained. Treatment at 0°C with trimethylchlorosilane, followed by slow warming to 25°C gave a dark brown undistillable resin, which appeared to be polymeric, and from which little or no silylimine could be distilled.

The methyl- and *iso*-propylimines were similarly prepared using the appropriate organolithium reagent.

Preparation of N-*2,6-Dimethylphenyl(trimethylsilyl)*-tert-*butylimine (4)*

To a solution of 32 g (0.244 mol) of 2,6-dimethylphenylisonitrile in 1500 ml of dry ether at −78°C was added 224 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

of a 1.3 *M* solution (0.29 mol) of *tert*-butyllithium in pentane over 0.75 h. After addition was complete, the orange solution was stirred at −78°C for 25 min, and then 29.2 g (0.29 mol) of trimethylchlorosilane was added dropwise, followed by 4 h stirring at −78°C. After warming to 25°C overnight, the supernatant was decanted from the lithium salts and was distilled to give 46 g (73%) of a viscous yellow liquid, bp 103–108°C/0.2 Torr. Crystallization from 1:1 2-propanol–pentane gave pure material, mp 26–27°C.

Preparation of N-tert-*Butyl(trimethylsilyl)*-n-*butylimine (7)*

To 15 ml (0.145 mol) of *tert*-butylisocyanide in 150 ml of anhydrous ether at −5°C was added 93 ml (0.147 mol) of *n*-butyllithium in hexane over about 5 min. The reaction mixture turned orange during 15 min stirring at 0°C and then 20.5 ml (0.156 mol) of trimethylchlorosilane was added over 10 min, as a white precipitate formed. After 20 min stirring at 0°C, the reaction was warmed to room temperature over 2 h. After filtration of the solid the filtrate was concentrated under reduced pressure and then was distilled through a 10 cm Vigreaux column to give 9.5 g (31%) of colourless silylimine, **7**, bp 52–54°C/0.8 Torr, purified for analysis by glc.

When **7** was dissolved in methanol, it was 70% hydrolyzed over 10 min to methoxytrimethylsilane, and *N*-(*tert*-butyl)-*n*-butylaldimine, identified by nmr and ir spectra.

Thermal Isomerizations of the C-*Silylimines, Yielding* N-*Silylenamines*

A 0.8 g sample of the ethyl compound **2** was heated in an evacuated sealed nmr tube at 235°C while the course of the reaction was monitored periodically by its nmr spectrum. This provided data which followed first-order kinetics. The compound was 47% rearranged after 6.7 h and after 56 h less than 5% starting material remained. Chromatography showed 86% of *trans*-*N*-trimethylsilyl-*N*-2,6-dimethylphenyl-1-propenylamine, **9**, obtained as a colourless liquid together with 4% starting material and four minor products.

Similar treatment of **3**, the isopropylimine, for 42 h at 277°C (36% rearrangement) followed by 27 h at 290°C led to complete disappearance of the starting material and a 75% yield of the *N*-trimethylsilylenamine, **10**.

When **4**, the *tert*-butylimine, was heated for 62 h at 225°C no change was observed. After a further 28 h at 250°C, a small amount of decomposition was observed but no vinylic protons could be detected.

The rate constants for the thermal rearrangement of **1** at several temperatures were determined: $k = 8.64 \times 10^{-6}$ (202°C); 2.78×10^{-5} (214°C); 4.89×10^{-5} (229°C); 7.61×10^{-5} (236°C) s^{-1}. Four runs at each temperature were made, using nmr data to determine relative concentrations every ½ h or 1 h as appropriate. Plots of ln *c* against time were good straight lines, and the results of different runs agreed closely. A plot of ln *k* against $1/T$ gave a good straight line.

Methanolysis of N-*Isobutenyl*-N-*trimethylsilyl-2,6-dimethylaniline (10)*

A sample of **10** in carbon tetrachloride was treated with 20 equiv. of methanol. After 10 min, the nmr spectra indicated the compound was 90% converted to methoxytrimethylsilane and *N*-2,6-dimethylaminoisopropylaldimine; nmr δ: 7.49 (1H, d, $J = 5$ Hz, H—C=N) 6.94 (3H, m, aryl), 2.6 (1H, m, $CH\text{Me}_2$), 2.02 (6H, s, $Me_2C_6H_3$), 1.20 (6H, d, $J = 6.8$ Hz, $CHMe_2$)ppm. Removal of the volatiles at 70°C under reduced pressure removed the methoxytrimethylsilane but caused extensive decomposition of the aldimine.

Under similar conditions **4**, the precursor of **10**, suffered no hydrolysis after 20 min at 25°C.

Temperature Dependence of the Nuclear Magnetic Resonance Spectra of the C-*Silylimines*

Isopropylimine 3

At 35°C, the nmr spectrum of **3**, (see Table 1) had broad singlets at δ 2.86 (Me_2CH) and 1.29 (Me_2CH) ppm and a partially coalesced doublet δ 0.29 (Me_3Si) ppm. At −5°C these signals were separated into sharp signals at δ 3.07 (m, Me_2CH, *anti* to aryl), 2.59 (m, Me_2CH, *syn* to aryl), and 1.33 (d, $J = 6.5$ Hz, Me_2CH, *anti* to aryl), 1.13 (d, $J = 7.0$ Hz, Me_2CH, *syn* to aryl), and 0.43 (s, Me_3Si, *anti* to aryl) and 0.05 (s, Me_3Si, *syn* to aryl), each signal being of approximately equal intensity (*syn* and *anti* isomers present in equal proportions). At 92°C, the spectrum of a neat sample showed a single septet for Me_2CH, a single doublet for Me_2CH, and a single sharp singlet for Me_3Si. At 39°C, the Me_3Si signals were a coalesced broad flat-topped singlet, peak width at half height = 31 Hz. The trimethylsilyl signals had a maximum separation of 29 Hz (−5°C).

Ethylimines 2

At 35°C two Me_3Si signals could be clearly seen at about 0.43 and 0.00 ppm in the ratio of about 80:20. At −10°C the signals were much sharper, while at 126°C, the two trimethylsilyl signals had collapsed to a single sharp singlet.

Hétérobicycles oxygénés.[1] Synthèse d'alkyl-3,6,8-trioxabicyclo[3.2.1]octanes et d'alkyl-3,7,9 et -4,7,9-trioxabicyclo[4.2.1]nonanes

PIERRE CALINAUD[2] ET JACQUES GELAS

Reçu le 22 mars 1978

PIERRE CALINAUD et JACQUES GELAS. Can. J. Chem. **56**, 2292 (1978).

La cyclisation en milieu basique de 1,3-dioxolannes chloroalkylés en 2 (ou en 4) et hydroxyalkylés en 4 (ou en 2) mène à des acétals bicycliques, intéressants intermédiaires de synthèse (pouvant notamment conduire à des 1,4-dioxannes fonctionnalisés) les 3,6,8-trioxabicyclo-[3.2.1]octanes. Les spectres de rmn de ces hétérobicycles sont étudiés: les constantes de couplage entre protons géminés permettent de différencier le cycle à cinq maillons du cycle à six maillons; la mise en évidence de couplages à longue distance (^4J et ^5J) apporte des arguments concernant la conformation du modèle bicyclique.

Deux séries isomères d'acétals bicycliques alkylés, les 3,7,9- et 4,7,9-trioxabicyclo[4.2.1]-nonanes sont accessibles par (*a*) l'addition intramoléculaire d'un groupement 4-hydroxyalkyle sur la double liaison éthylénique portée par l'atome de carbone en α de C-2 de 1,3-dioxolannes; (*b*) la déchlorhydratation de 2-chlorométhyl-4-hydroxyalkyl-1,3-dioxolannes; (*c*) la déshydratation de dioxolannes-diols. Le principal intérêt de ces hétérobicycles est de présenter un cycle à sept maillons et de pouvoir mener à des 1,4-dioxépannes fonctionnalisés.

PIERRE CALINAUD and JACQUES GELAS. Can. J. Chem. **56**, 2292 (1978).

The cyclization in a basic medium of 2 (or 4)-chloroalkyl-4 (or 2) -hydroxyalkyl-1,3-dioxolanes leads to bicyclic acetals, the 3,6,8-trioxabicyclo[3.2.1]octanes, which are useful intermediates for synthesis, yielding notably functionalized 1,4-dioxanes. The nmr spectra of these heterobicyclics were studied. The geminal proton coupling constants permit one to distinguish between five- and six-membered rings and the determination of couplings over several bonds (^4J and ^5J) yields information concerning the conformation of the model bicyclics.

Two isomeric series of alkylated bicyclic acetals (3,7,9- and 4,7,9-trioxabicyclo[4.2.1]nonanes) are accessible by the following routes: (*a*) the intramolecular addition of a 4-hydroxyalkyl group to the ethylenic double bond on the carbon atom α to C-2 in the 1,3-dioxolanes; (*b*) the dechlorohydration of 2-chloromethyl-4-hydroxyalkyl-1,3-dioxolanes; (*c*) the dehydration of dioxolane-diols. The main interest in these heterobicyclics is to prepare a seven-membered ring and to be able to prepare functionalized 1,4-dioxepanes.

[Journal translation]

Ces dernières années notre laboratoire a été notamment engagé dans l'étude de réactions d'hétérobicyclisation de 1,3-dioxolannes et de 1,3-dioxannes bifonctionnels. Un certain nombre de synthèses de composés bicycliques comportant trois hétéroatomes (oxygène ou azote ou soufre) ont été ainsi mises au point (2). Nous décrivons ici la synthèse et l'étude spectrographique d'alkyl 3,6,8-trioxabicyclo-[3.2.1]octanes.

Lorsque fut entreprise au laboratoire (2*a*) l'étude de tels bicycles, seul le dérivé non substitué avait été préparé par Hallonquist et Hibbert (3). Cette étude concernait uniquement des trioxabicyclooctanes substitués en position 4 et 5 par des groupements alkyle (2*b*), ou un groupement chlorométhyle en 5 ou un atome de chlore en 4 (2*c*). La synthèse du dérivé non substitué, puis celle du composé phényl-5 ont été reprises par la suite respectivement par Baggett *et al.* (4) et Inch et Williams (5). Ces travaux ont été étendus plus récemment (2*f*) à l'étude d'une lactone (4-oxo 5-méthyl trioxabicyclooctane) et d'hémiacétals (4-hydroxy 5-méthyl et 4-hydroxy 4,5-diméthyl trioxabicyclooctanes et leurs dérivés alkoxylés) appartenant à la même série. L'ensemble de ces composés ainsi décrits *dérive uniquement du glycérol.* Nous avons envisagé de préparer des trioxabicyclooctanes substitués en 1, 2 et 7 par un ou plusieurs groupements méthyle en particulier pour les raisons suivantes: (*i*) tout d'abord, ces groupements méthyle peuvent constituer des "pseudo-marqueurs" susceptibles de faciliter l'étude de la fragmentation sous l'impact électronique de tels bicycles, étude réalisée par ailleurs (6); (*ii*) en outre, ils autorisent une étude des couplages protoniques observés en rmn dont la connaissance a été utile dans la détermination (7) de

la structure du trioxabicyclooctane (7(*S*)-acétoxy 2(*S*)-méthoxy 3,6,8-trioxabicyclo[3.2.1]octane) obtenu par oxydation périodique du méthyl-β-L-arabinopyranoside.

D'une façon générale, un intérêt de l'étude de trioxabicyclooctanes est que ces composés possèdent une analogie étroite avec des substances naturelles homologues dioxygénés (6,8-dioxabicyclo[3.2.1]-octanes) appartenant notamment à la série des glucides (anhydropyranoses) et à la famille des phéromones (hormones sexuelles des insectes) telles que la frontaline (8), la brévicomine (9) ou la multistriatine (10).

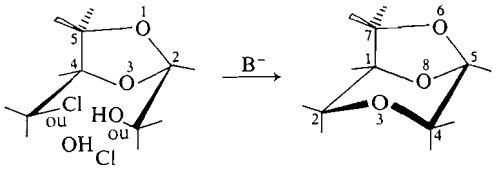
Enfin, signalons que la réaction d'hydrogénolyse des trioxabicyclooctanes constitue un mode d'accés intéressant à des 1,4-dioxannes fonctionnalisés (11).

Il était intéressant de comparer cette étude avec celle de séries homologues supérieures, les *trioxabicyclo[4.2.1]nonanes*. En effet, ces derniers présentent un cycle à sept maillons du type 1,4-dioxépanne, cycle sur lequel la littérature ne posséde que peu d'éléments et qui est facilement accessible par hydrogénolyse de la fonction acétal des bicycles (11).

La synthèse de dioxolannes bifonctionnels (12) permettait d'envisager l'accès à deux séries isomères: les *3,7,9-* et les *4,7,9-trioxabicyclo[4.2.1]nonanes*. Tous les composés correspondant décrits dans le présent mémoire ont été par ailleurs étudiés en spectrographie de masse, afin d'évaluer les possibilités d'utiliser des groupements méthyle comme marqueurs de la fragmentation (13).

Synthèse d'alkyltrioxabicyclooctanes

Les 1,3-dioxolannes chloroalkylés en 2 (ou en 4) et hydroxyalkylés en (4 ou en 2) (**A**, schéma 1) dont la synthèse et l'étude spectrographique ont été décrites précédemment (12) sont soumis à des réactions de déchlorhydratation soit par la potasse en poudre, soit par le *tert*-butylate de potassium en solution dans le *tert*-butanol. (La soude même concentrée et à reflux dans un solvant à haut point d'ébullition est inopérante.) Les trioxabicyclooctanes **B** ainsi obtenus sont rassemblés dans le tableau 1 et ont été identifiés par spectrographie ir et de rmn.[3]



A **B**

SCHÉMA 1

Si l'on considère les dispositions spatiales respectives des substituants halogénés et hydroxylés, les dioxolannes de départ (préparés en milieu acide, donc dans des conditions d'équilibration thermodynamique) sont en fait un mélange de deux stéréoisomères *cis* et *trans*. La cyclisation ne met en jeu que les isomères *cis* (**A** seuls représentés sur le schéma 1) et, à cause de l'absence d'équilibration *cis-trans* en milieu basique, les isomères *trans* sont en principe non attaqués. L'utilisation du *tert*-butylate de potassium dans le *tert*-butanol permet en effet le plus souvent de retrouver ces derniers en fin d'opération. Ce n'est pas cependant toujours le cas car une réaction de β-élimination de l'acide chlorhydrique reste possible; elle mène à des 4-méthylène 1,3-dioxolannes (2*b*, 14). Il n'en reste pas moins que le fait que l'atome d'halogène des dérivés *trans* ne soit pas souvent touché dans la réaction, pourrait indiquer que la cyclisation est une réaction intramoléculaire d'un type pouvant se rapprocher de celui de la réaction S_N2. Si tel est le cas, on doit pouvoir observer une inversion de configuration au niveau de l'atome de carbone portant un atome d'halogène.

[3]Les bicycles **5**, **6** et **9** ont été préparés par une réaction de déchloracylation déjà décrite (2*h*); leurs caractéristiques spectrales n'avaient pas été données et sont seules discutées ici.

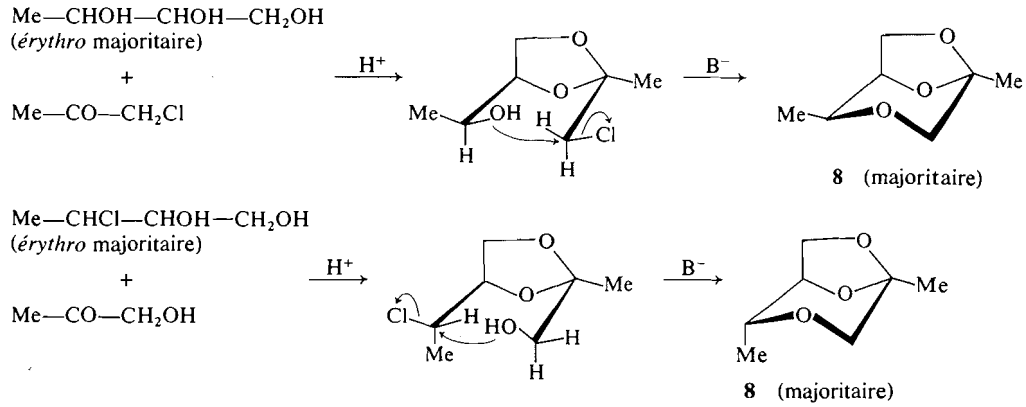


SCHÉMA 2

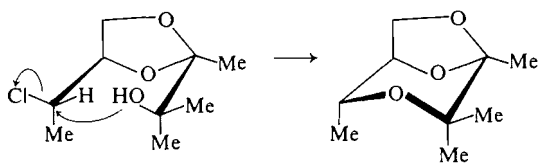
Nous donnons dans le schéma 2 un exemple relativement en faveur de cette hypothèse: le trioxabicyclooctane **8** peut être obtenu selon deux voies similaires: (*i*) soit à partir du 1,2,3-butanetriol essentiellement *érythro* (préparé (12) par action de l'eau oxygénée en présence d'acide tungstique sur le 2-butène 1-ol essentiellement *trans*); (*ii*) soit à partir du 3-chloro 1,2-butanediol essentiellement *érythro* (préparé (12) par action de l'acide hypochloreux sur le 2-butène 1-ol essentiellement *trans*).

Pour chacune de ces deux manipulations on détecte par chromatographie en phase vapeur deux pics dont les proportions respectives sont inversées (successivement 70:30 et 30:70); ils correspondent aux bicycles ayant une stéréochimie majoritaire conforme soit à un maintien de la chiralité de l'atome C-4′ (attaque de l'atome C-2′), soit à une inversion de cette chiralité (attaque de l'atome de carbone en cause).

Cette observation a été vérifiée chaque fois que l'analyse des spectres de rmn des bicycles obtenus permet une attribution sûre de leur stéréochimie. C'est notamment le cas du bicycle **10** (schéma 3)



10

SCHÉMA 3

pour lequel le groupement méthyle existe à plus de 90% en position axiale.

On peut remarquer que la stéréochimie du produit obtenu n'est jamais unique. Ceci peut être partiellement expliqué par le fait que la chlorhydrine et le triol *érythro* de départ sont contaminés par la présence de leurs isomères *thréo*. Cependant la proportion de ces derniers ne dépasse guère 5 à 7% (12).

L'importante quantité d'isomère axial obtenue pour le trioxabicyclooctane **8** (schéma 2) pourrait être due soit au fait que le mécanisme invoqué n'est pas unique, soit à une équilibration thermique partielle du mélange obtenu. Il est possible d'équilibrer en milieu acide les bicycles obtenus: dans tous les cas l'isomère équatorial est thermodynamiquement favorisé. Nous ne pouvons malheureusement en tirer de conclusions quantitatives n'ayant pu obtenir de résultats cohérents selon le catalyseur utilisé (acide *p*-toluènesulfonique, éthérate de trifluorure de bore, chlorure d'aluminium, etc...).

Un problème théorique reste pour l'instant sans solution définitive: il a été observé depuis longtemps (2*b*, 15, 16) que l'atome d'halogène en 4′ de 1,3-dioxolannes n'est pas substituable (schéma 4) par les

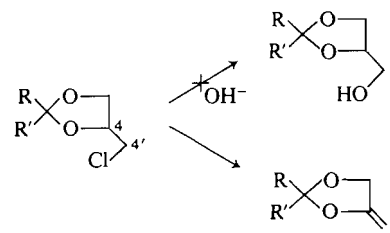


SCHÉMA 4

alcools ou les alcoolates (réaction *inter*moléculaire). Inversement, la réaction *intra*moléculaire (qui mène aux trioxabicyclooctanes) est pourtant assez facilement réalisable comme nous le montrons ici.

Identification des alkyl 3,6,8-trioxabicyclooctanes

Par spectrographie ir on note la disparition de l'absorption correspondant au groupement hydroxyle (ou au groupement acétoxyle pour les composés **5**, **6** et **9**). Les raies indiquées pour la fonction acétal (COCOC) se situent (17) dans l'intervalle 1000–1200 cm^{-1}, mais sont plus nombreuses que celles correspondant aux acétals de départ. Une ou plusieurs bandes apparaissent dans la région 640–680 cm^{-1} (2*b*).

Constantes de couplage entre protons géminés[4]

Dans beaucoup de cas les protons géminés sur C-4 donnent un singulet et seuls ceux géminés sur C-2 sont différenciés. Ceci peut s'interpréter par l'influence exercée par la nature acétalique de l'atome de carbone C-5.

L'analyse au premier ordre des signaux correspondant à CH_2-7 et CH_2-2 permet de mesurer des constantes de couplage entre protons géminés (^2J) respectivement de 6.1–6.8 et de 11.0–11.2 Hz. Cahill *et al.* (18) indiquent que pour des protons méthylèniques en α d'un hétéroatome un des principaux facteurs affectant la valeur de J_{gem} est la donation en retour de la paire libre à l'orbitale antisymétrique du groupement méthylène. Ce phénomène est lié à la conformation des paires libres par rapport aux atomes d'hydrogène. Si l'on admet une conformation chaise pour le cycle 1,4-dioxanne, l'examen des modèles moléculaires permet de constater (fig. 1) que les paires libres de O-6 sont pratiquement éclipsées pour les deux atomes d'hydrogène sur C-7 (cycle à cinq maillons) et que les paires libres

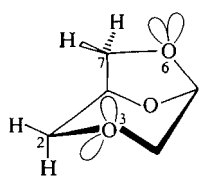

FIG. 1. Modèle moléculaire pour les trioxabicyclooctanes.

[4]Ces constantes de couplage sont indiquées en valeur absolue et sont très vraisemblablement négatives.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

de O-3 sont décalées par rapport aux deux atomes d'hydrogène portés par C-2 (cycle à six maillons).

Constantes de couplage[5] *entre protons vicinaux*

Lorsque un proton en 5 se trouve en α d'un groupement méthylène en 4 (par exemple pour le bicycle **1**) aucun dédoublement du signal n'est relevé mais sa largeur indique la présence d'un couplage de valeur inférieure à 1 Hz. Pour l'autre position du pont il est possible de détecter un couplage (1.6 Hz) entre H-1 et les protons portés par C-2. Ce signal, qui apparait comme un triplet, pourrait être significatif de la similitude entre les couplage vicinaux éq–éq et éq–ax. La différence entre les positions 1 et 5 sur le bicycle peut être attribuée de son côté à une déformation du cycle à six maillons due au fait que la liaison C-5—O-6 est plus courte que la liaison C-1—C-7.

Couplages à longue distance ^{4}J *et* ^{5}J

Le seul couplage ^4J nettement observé est celui entre l'atome d'hydrogène axial sur C-2 et l'atome d'hydrogène *exo* sur C-7 (^4J 1.5 Hz). D'un point de vue qualitatif on peut remarquer que l'arrangement spatial de ces protons est très près d'une forme W quand le cycle 1,4-dioxanne adopte une conformation chaise légèrement aplatie dans la région C-2—O-3—C-4 de la molécule. Ceci est en accord avec l'hypothèse formulée précédemment pour la conformation des trioxabicyclooctanes (2*f*, 11), probablement proche de celle de l'homobicycle correspondant, le bicyclo[3.2.1]octane (19). L'effet anti-réflexe (20) qui a été mis en évidence dans cette série (2*c*), pourrait être la cause principale de cet aplatissement du cycle.

L'existence de ce couplage est particulièrement utile pour l'attribution de la stéréochimie de groupements portés par les atomes de carbone en cause. C'est notamment sa présence (ou son absence) qui permet de définir la position équatoriale (ou axiale) du groupement méthyle en C-2 sur les bicycles **8** et **10** (schémas 2 et 3).

Le spectre du composé **6** (fig. 2)[6] est un bon exemple d'un groupement méthylène (^2J = 11.2 Hz) où un proton est engagé dans un couplage à travers quatre liaisons (^4J = 1.4 Hz), l'autre proton étant couplé à travers cinq liaisons (^5J = 1.1 Hz) avec un atome d'hydrogène distinct (interprétation confirmée par irradiation des protons en cause et par disparition du couplage en remplaçant H-1 par un groupement méthyle). Un ^5J similaire a été observé dans le spectre du 7(*S*)-acétoxy 2(*S*)-méthoxy 3,6,8-trioxabicyclo[3.2.1]octane obtenu par oxydation périodique du méthyl-β-L-arabinopyranoside (7). De tels couplages ne sont pas aussi fréquents que les ^4J. Cependant, dans les séries qui se rapprochent des trioxabicyclooctanes on trouve des valeurs de 0.1 Hz pour un anhydropyranose (21), 0.6 Hz pour l'α-D-idopyranose (22), 0.7 Hz pour un orthoester cyclique de sucre (23) et 0.9 Hz pour un 1,4-dioxanne (24). La valeur élevée de la constante observée dans notre cas peut s'interpréter par l'aplatissement du cycle 1,4-dioxanne qui tend à rendre coplanaires les cinq atomes impliqués. Plus encore, l'introduction d'hétéroatomes sur le chemin du couplage et la multiplication des chemins possibles (ici deux chemins sont possibles à travers un atome d'oxygène) sont connues pour augmenter la valeur de ^5J. Ainsi des valeurs de 1.25 et 1.7 Hz ont été observées pour des molécules oxygénées bi- et tricycliques (25).

Synthèse d'alkyl-3,7,9-trioxabicyclo[4.2.1]nonanes

Il a été montré au laboratoire (2*a*) que les 4-hydroxyméthyl-1,3-dioxolannes porteurs d'une double liaison en α de l'atome de carbone 2 du cycle, subissent, en milieu acide, une addition intramoléculaire du groupement hydroxyle sur la double liaison. Dans tous les cas étudiés, la formation exclusive (ou nettement préférentielle) de trioxabicyclononanes a été observée. Etant donné que cette étude n'avait concernée que le seul glycérol (atomes de carbone 1, 2 et 8 du bicycle formé non substitués) nous nous sommes proposé d'envisager l'éventuelle influence de groupements méthyle en position 4 ou 4′ ou 5 sur les dioxolannes de départ.

En portant à reflux dans le benzène, en milieu acide, des triols et des cétones éthylèniques appropriées, on obtient des mélanges de dioxolannes éthyléniques et de trioxabicyclononanes définis dans le schéma 5. L'équilibration *cis–trans* en milieu acide des dioxolannes entraîne la réaction quasi-totale du mélange.

La réaction d'addition est régiospécifique: seuls les trioxabicyclononanes sont isolés et la formation éventuelle concurrente de trioxabicyclo*octanes* n'est pas observée dans les cas étudiés ici. Ceci est sans doute dû au fait que la formation d'un carbocation en α de l'atome de carbone acétalique est un processus défavorisé. La protonation de la double liaison s'effectue donc en α du groupement acétal et entraîne l'attaque du groupement hydroxyle en β.

[5]Dans tout ce mémoire nous indiquons des constantes de couplage mesurées directement sur le spectre après analyse du premier ordre. Il s'agit donc d'espacements plutôt que de véritables *J*. Lorsque les effets du second ordre deviennent évidents, la valeur de l'espacement n'est pas indiquée dans le tableau 2.

[6]On peut obtenir la fig. 2 et les tableaux 5 et 6, à un prix nominal, en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa, Ont., Canada K1A 0S2.

SCHÉMA 5. Acétalisation de triols par des cétones α-éthyléniques. (Pourcentage mesuré par chromatographie en phase vapeur sur le produit brut de la réaction; la différence avec 100 représente le pourcentage de dioxolannes intermédiaires présents dans le mélange; les rendements en produits isolés sont indiqués dans le tableau 3).

Identification des 3,7,9-trioxabicyclo[4.2.1]nonanes

Les particularités présentées par les spectres ir (partie expérimentale) sont les mêmes que celles données plus haut pour les trioxabicyclooctanes.

Le tableau 3 rassemble les spectres de rmn des composés préparés. Nous en commentons seulement les points essentiels.

Constantes de couplage entre protons géminés

Les différences relevées entre les valeurs des constantes de couplage entre protons géminés (s'ils existent) en position 2 ou 5 ou 8 sont dues à la taille du cycle (5 ou 7 maillons) et sont comparables (fig. 3) à celles relevées pour les trioxabicyclooctanes. Pour les protons en 8 une conformation éclipsée des paires libres de O-7 facilite la donation en retour des électrons des paires à l'orbitale antisymétrique du groupement méthylène en 8. Il n'y a pas de différence notable entre le modèle à six maillons (trioxabicyclooctane) et celui à sept maillons (trioxabicyclononane).

Constantes de couplage à longue distance

La conformation en W des protons H-2 axial et H-8 *exo* pour lesquels (fig. 3) on observe un couplage ^4J, est d'autant mieux respectée que le cycle dioxépanne adopte une conformation chaise aplatie. L'effet anti-réflexe, qui joue un rôle dans la conformation des trioxabicyclooctanes est vraisemblablement responsable de l'aplatissement du cycle.

Pour le composé **3** le signal de H-5 équatorial montre un couplage ^5J à travers O-3 avec H-2 équatorial. La valeur relativement élevée de ce couplage (1.2 Hz) peut être justifiée comme précédemment pour les trioxabicyclooctanes.

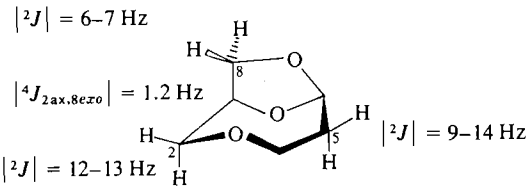

FIG. 3. Les constantes de couplage pour les trioxabicyclononanes.

Synthèse d'alkyl-4,7,9-trioxabicyclononanes

Ces bicycles isomères de ceux décrits dans le paragraphe précédent, sont obtenus selon les mêmes méthodes de cyclisation permettant d'accéder aux trioxabicyclooctanes (homologues inférieurs) à partir de dioxolannes bifonctionnels: (*i*) déchlorhydratation d'acétals halogénés et hydroxylés où l'atome d'halogène est en β de l'atome de carbone C-4 du dioxolanne (schéma 6, méthode *a*) selon le procédé décrit plus haut; (*ii*) déshydratation d'acétals-diols (schéma 6, méthode *b*), selon une méthode mise au point pour les trioxabicyclooctanes.[7]

Les rendements de ces cyclisations sont pour la plupart acceptables. Ces méthodes paraissent donc être des synthèses convenables de bicycles comportant un cycle à sept maillons.

Identification des 4,7,9-trioxabicyclononanes

Les spectres ir des composés présentent essentiellement les caractéristiques décrits pour les trioxabicyclooctanes. Les spectres de rmn sont présentés dans le tableau 4.

En conclusion, nous avons montré que la préparation de trioxabicyclooctanes et de deux séries isomères de trioxabicyclononanes était relativement aisée.

L'intérêt en synthèse de tels bicycles réside principalement dans le fait qu'ils permettent l'accès à des 1,4-dioxannes et des 1,4-dioxépannes fonctionnalisés par un groupement hydroxyméthyle; il est en effet notamment possible d'hydrolyser la fonction acétal ou de l'ouvrir par les hydrures mixtes (11) ou les réactifs de Grignard.[8]

Partie expérimentale

Les analyses par chromatographie en phase vapeur ont été réalisées sur un appareil Hewlett-Packard modèle 5750, équipé d'une colonne Carbowax 20 M (3 mm × 3 m) et d'un détecteur à catharomètre (gaz vecteur: 30 ml d'hydrogène par minute). Les séparations d'échantillons par chromatographie ont été effectuées sur un appareil Varian-Aerograph 705 N, muni d'une colonne Carbowax 20 M (9 mm × 6 m) et d'un détecteur à ionisation de flamme (gaz vecteur, 120 ml d'azote par minute).

Les spectres de rmn ont été réalisés sur un appareil Varian T-60; les abréviations utilisées dans la description de ces spectres sont: s, singulet; d, doublet; t, triplet; q, quadruplet; et m, multiplet; les déplacements chimiques sont indiqués en ppm par rapport au tétraméthylsilane; l'intensité relative de chaque signal est indiquée entre parenthèses; les constantes de couplage indiquées sont les espacements de signaux mesurés sur les agrandissements et sont exprimés en Hz.

Les spectres ir ont été enregistrés sur un appareil Beckman IR 8.

La préparation et l'identification des triols, des chlorhydrines et des dioxolannes de départ ont été précédemment décrites (12, 26).

[b] $^2J_{8endo,8exo.}$

Synthèse des trioxabicyclooctanes

Déchlorhydratation par la potasse en poudre

L'acétal (0.1 ou 0.2 mol) est placé dans un ballon de Claisen avec un excès de potasse en poudre et quelques fragments de marbre destinés à offrir un support à la base. Après avoir maintenu la température vers 100°C durant environ 15 min on chauffe progressivement. Le distillat (qui passe à partir de 100°C et jusqu'à environ 180°C) est ensuite repris par 100 ml d'éther, la solution éthérée est séchée (Na_2SO_4), l'éther chassé et le résidu est distillé sous vide réduit.

Déchlorhydratation par le tert*-butylate de potassium*

Une quantité stoechiométrique de potassium en fins morceaux est attaqué par le minimum de *tert*-butanol anhydre. L'acétal en solution dans le *tert*-butanol est mélangé goutte à goutte à la solution d'alcoolate. On porte à reflux environ 24 h. On ajoute lentement de l'eau glacée (100 ml environ pour 0.1 mol d'acétal mis en jeu), extrait à l'éther, lave à l'eau, séche, chasse les solvants et distille sous pression réduite.

Les rendements de ces préparations ainsi que les constantes physiques des trioxabicyclooctanes obtenus sont rassemblés dans le tableau 5.[6]

Synthèse des 3,7,9-trioxabicyclo[4.2.1]nonanes

On place 0.1 mol de triol et 0.1 g d'acide *p*-toluènesulfonique dans un Erlenmeyer contenant 500 ml de benzène, placé sur un agitateur magnétique chauffant et surmonté d'un piège de Dean–Stark muni d'une dérivation fermée par une ampoule à brome. La suspension benzénique est fortement agitée et portée à reflux tandis que l'on rajoute au moyen de l'ampoule 0.1 mol de la cétone éthylénique appropriée (les cétones utilisées ici sont commerciales). Après obtention de la quantité d'eau correspondant à l'acétalisation (0.1 mol), on maintient le reflux durant environ 4 h. Après refroidissement, on neutralise (Na_2CO_3), chasse le benzène et distille le résidu.

Les constantes physiques des composés obtenus (**13–16**) ainsi que les rendements en composé isolé pur sont indiqués dans le tableau 6.[6]

Synthèse des 4,7,9-trioxabicyclo[4.2.1]nonanes

Déshydratation de dioxolannes-diols

Le matériel décrit ci-dessus est utilisé; le triol (0.1 mol) est porté à reflux dans le xylène (500 ml) en présence d'acide *p*-toluènesulfonique (1 g) sous une forte agitation, tandis que la cétone hydroxylée (les cétones utilisées sont commerciales) est ajoutée goutte à goutte. Lorsque la quantité d'eau attendue est obtenue (0.2 mol d'eau pour 0.1 mol de triol) on traite comme précédemment. On obtient ainsi les bicycles **21–24** (tableau 6).

Déchlorhydratation par la potasse d'acétals halogénés et hydroxylés

La méthode utilisé est celle décrite dans un paragraphe précédent; elle mène aux bicycles **17–20** (tableau 6).

Utilization of trimethylsilylpropyne as an acetonyl unit in the synthesis of cyclopentenones. Applications to the synthesis of jasmone and dihydrojasmone

PHAIK-ENG SUM AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received March 9, 1978

PHAIK-ENG SUM and LARRY WEILER. Can. J. Chem. **56**, 2301 (1978).

The dianion of β-keto esters are alkylated at the γ-carbon with 3-bromo-1-trimethylsilyl-1-propyne. The resulting alkynes are hydrated (H_3O^+, Hg^{2+}) and cyclized (OH^-) to the corresponding cyclopentenones, jasmone and dihydrojasmone. The failure to obtain cyclopentanones from the acid- and base-catalyzed cyclizations of 6-substituted 3-keto esters may be rationalized by Baldwin's rules for cyclization.

PHAIK-ENG SUM et LARRY WEILER. Can. J. Chem. **56**, 2301 (1978).

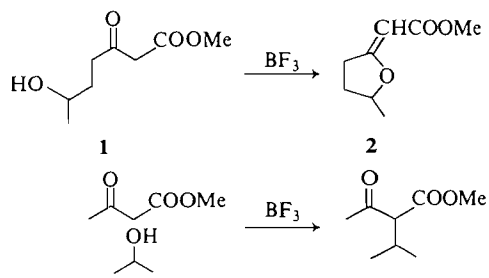
Il y a alkylation du dianon des β-cétoesters au niveau du carbone-γ si l'on fait appel au bromo-3 triméthylsilyl-1 propyne-1. L'alcyne qui en résulte peut être hydraté (H_3O^+, Hg^{2+}) et cyclisé (OH^-) pour conduire aux cyclopentanones correspondantes, jasmone et dihydrojasmone. Le fait que l'on ne puisse pas obtenir des cyclopentanones par cyclisations catalysées par les acides ou les bases des céto-3 esters substitués en position 6 peut être rationalisé à l'aide des règles de Baldwin sur les cyclisations.

[Traduit par le journal]

For several years we have been interested in utilizing the dianion of β-keto esters (1) in the preparation of cyclopentanones as outlined in eq. [1].

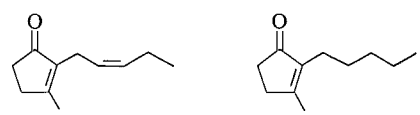
[1] 
The application of such a cyclization in the synthesis of natural products, for example prostaglandins, rethrolones, and jasmones, is fairly obvious. The initial step *a* in eq. [1] proceeded without complication for a wide range of alkylating agents. However, the second step *b* was singularly unsuccessful under a wide variety of acid- and base-catalyzed conditions, when the carbon bearing the leaving group Y is sp^3 hybridized.[2] In light of Baldwin's suggestion (2) that the cyclization step *b* suffered from a stereoelectronic barrier imposed on it, all of our earlier failures could be rationalized but our synthetic goal remained unattained.

One of the more striking examples of the failure to observe cyclopentanone formation involved the treatment of methyl 6-hydroxy-3-oxoheptanoate (**1**), which is readily prepared from the dianion of methyl acetoacetate and propylene oxide (3), with boron trifluoride to produce the tetrahydrofurylidene (**2**) in greater than 80% yield. Under these same conditions ethyl acetoacetate is alkylated with 2-propanol to give ethyl α-isopropylacetoacetate in 60–67% yield (4).



Cyclizations analogous to step *b* (eq. [1]) are known when the electrophilic carbon is sp^2 hybridized (5). This type of cyclization to an sp^2 carbon does not violate Baldwin's rules (2) and there are a number of examples of this cyclization leading to formation of cyclopentenones (6) as shown in eq. [2]. We have

[2] 
combined this cyclization of a 1,4-diketone with the alkylation of the dianion of β-keto esters to effect a synthesis of cyclopentenones which is detailed below for the preparation of jasmone (**3**) and dihydrojasmone (**4**).



Initially we investigated the utility of a number of acetonyl units as shown in eq. [3]. The reaction of the

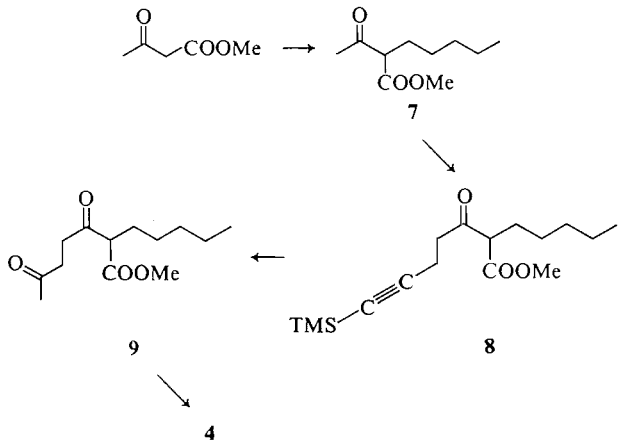
[3] 
dianion **5** with α-halo ketones led to a mixture of several products which were not further characterized. Dianion **5** did not react with the α-bromo ketal of acetone. Treatment of dianion **5** with 2-methoxyallyl bromide (7) lead to formation of the γ-bromo-β-keto ester. This is consistent with the several other reports of bromine transfer in the reaction of β-substituted bromoalkanes and reactive nucleophiles (see for example ref. 8). However, we were able to prepare the desired 1,4-diketones **6** using 3-bromo-1-trimethylsilyl-1-propyne (9) as outlined in Scheme 1.



SCHEME 1. Synthesis of dihydrojasmone (**4**).

Methyl acetoacetate was alkylated with 1-bromopentane to give the β-keto ester **7**. The dianion of ester **7** was prepared in the usual fashion (1) and alkylated with 3-bromo-1-trimethylsilyl-1-propyne (9) to yield the monoalkylation product **8** in greater than 90% yield. The trimethylsilylalkyne **8** was cleaved and hydrated in aqueous acid using Hg^{2+} catalyst (10) to yield the 1,4-diketone **9** in almost 80% yield. This product **9** was hydrolyzed, decarboxylated, and cyclized by aqueous base to yield dihydrojasmone (**4**) in greater than 75% yield. Because we did not isolate any intermediates in this transformation we do not know the exact sequence of these steps.

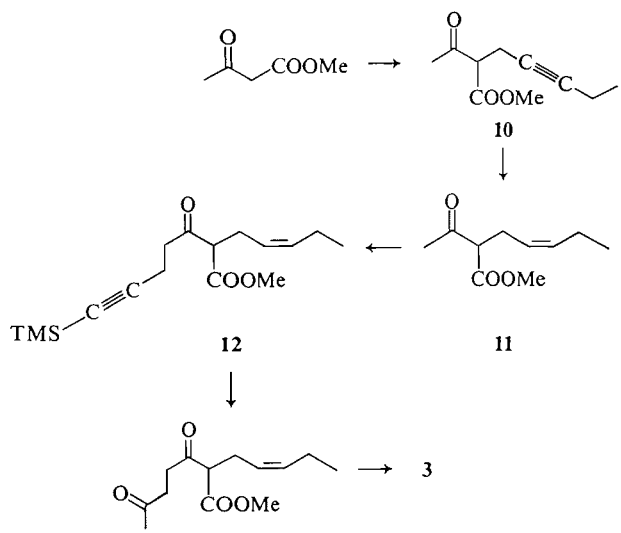
This represents one of the few examples of the utilization of the trimethylsilylpropyne group as the precursor of the acetonyl unit of a 1,4-diketone in the generation of cyclopentenones.[3] Ho (6*b*) reports an unpublished example of an unsubstituted acetylene serving such a purpose in his review of early jasmone syntheses and recently McCrae and Dolby (10*b*) have utilized this same methodology to synthesize a spirocyclopentenone in their efficient synthesis of acorone.

Using a route similar to the above we have also synthesized *cis*-jasmone (3) as shown in Scheme 2. Alkylation of methyl acetoacetate with 1-bromo-2-pentyne (13) gave the acetylene **10** which was partially hydrogenated to the *cis*-alkene **11** using Pd-on-$BaSO_4$ (14). The dianion of **11** was generated and alkylated with 3-bromo-1-trimethylsilyl-1-propyne. Hydration of **12** and cyclization as before gave jasmone **3**[3] in greater than 40% overall yield from methyl acetoacetate.

In summary we find that the alkylation of simple β-keto ester dianions with 3-bromo-1-trimethylsilyl-1-propyne followed by hydration of the alkyne and subsequent cyclization leads to an efficient synthesis of cyclopentenones.

Experimental

All ir spectra were recorded in $CHCl_3$ solution using a Perkin-Elmer Model 700 spectrophotometer and were calibrated with the 1601 cm^{-1} band of polystyrene. The ^1H nmr spectra were recorded in $CDCl_3$ solution on either a Varian model T-60 or HA-100 spectrometer. The signal positions are reported using the δ scale with tetramethylsilane as internal standard. The multiplicity, coupling constants, and integrated peak areas are indicated in parentheses after each signal. The mass spectra were obtained using an Atlas CH-4B mass spectrometer and high resolution determinations were obtained using an AEI MS-9 or MS-50 mass spectrometer. Both instruments were operated at an ionizing potential of 70 eV. The silica gel used was obtained from E. Merck and that used for thin-layer chromatography (tlc) was the grade PF_{254}, whilst that used for column chromatography was the grade finer than



SCHEME 2. Synthesis of jasmone (**3**).

200 mesh ASTM. Elemental microanalyses were performed by Mr. Peter Borda, University of British Columbia.

Methyl 2-Acetylheptanoate (7)

Methyl acetoacetate (5.80 g, 0.050 mol) was alkylated with sodium methoxide, prepared from dry methanol and sodium (1.25 g, 0.050 mol), and 1-bromopentane (8.15 g, 0.054 mol) in refluxing dry methanol (ca. 125 ml) to yield 5.4 g (58%) of keto ester **7**, bp 68°C/0.9 Torr: ir: 1710 and 1740 cm^{-1}; nmr δ: 0.7–1.1 (m, 3H), 1.1–1.5 (bd m, 6H), 1.6–2.1 (m, 2H), 2.18 (s, 3H), 3.37 (t, J = 7 Hz, 1H), and 3.68 (s, 3H); ms (*a*): high resolution calcd. for $C_{10}H_{18}O_3$: 186.1244 amu; found: 186.1241; (*b*) low resolution *m/e* (relative intensity): 43 (96), 55 (28), 87 (90), 101 (58), 116 (100), 117 (20), 129 (16), 144 (64), 155 (12), 186 (8). *Anal.* calcd. for $C_{10}H_{18}O_3$: C 64.49, H 9.74; found: C 64.38, H 9.70.

6-Carbomethoxy-1-trimethylsilyl-1-undecyn-5-one (8)

The ester **7** (0.93 g, 0.0050 mol) was dissolved in dry tetrahydrofuran (THF) and treated with 0.27 g of sodium hydride, which was washed with dry THF, and 3.12 ml of 1.6 *M* *n*-butyllithium all at 0°C. The resulting dianion was alkylated with 0.98 g (0.0052 mol) of 3-bromo-1-trimethylsilyl-1-propyne (9). After stirring for 2 h at 0°C the reaction mixture was quenched with saturated ammonium chloride, extracted with ethyl ether (Et_2O), washed with brine, and dried over sodium sulfate. The solvents were removed under reduced pressure to yield 1.6 g of crude **8** which was homogeneous by chromatography and spectroscopy. This crude compound **8** was used directly in the next step and the compound was characterized by the following data: ir: 1715, 1740, and 2195 cm^{-1}; nmr δ: 0.25 (s, 9H), 0.8–1.2 (m, 3H), 1.2–1.6 (m, 6H), 1.7–2.1 (m, 2H), 2.5–3.0 (m, 4H), 3.5 (m, 1H), and 3.73 (s, 3H); ms (*a*) high resolution calcd. for $C_{16}H_{28}O_3Si$: 296.1804 amu; found: 296.1803; (*b*) low resolution *m/e* (relative intensity): 41 (20), 43 (28), 55 (24), 73 (96), 89 (42), 139 (30), 153 (100), 154 (15), 169 (18), 195 (14), 209 (10), 211 (10), 221 (8), 223 (7), 225 (11), 236 (8), 237 (11), 249 (11), 265 (9), 281 (68), 296 (3).

6-Carbomethoxy-2,5-undecanedione (9)

A solution of 0.16 g of mercuric oxide (HgO) in 0.26 ml of concentrated sulphuric acid and 6 ml water was added to 100 ml THF and warmed to ca. 60°C. A solution of 2.96 g of crude acetylene **8** in 10 ml of THF was added to the mercuric oxide solution. This resulting solution was cooled and was stirred at ca. 40°C for 2 h. The reaction mixture was quenched with water and extracted with Et_2O. The extracts were dried over sodium sulfate and the solvents removed under reduced pressure. The crude oil was distilled at 118°C/0.4 Torr to yield 1.91 g (79% from **7**) of diketo ester **9**: ir: 1715 and 1740 cm^{-1}; nmr δ: 0.7–1.0 (m, 3H), 1.1–1.5 (m, 6H), 1.7–2.0 (m, 2H), 2.15 (s, 3H), 2.72 (bd s, 4H), 3.45 (t, J = 7 Hz, 1H), and 3.68 (s, 3H); ms (*a*) high resolution calcd. for $C_{13}H_{22}O_4$: 242.1503 amu; found: 242.1506; (*b*) low resolution *m/e* (relative intensity): 43 (50), 55 (14), 71 (10), 87 (10), 99 (100), 140 (11), 172 (20), 211 (5), 242 (0.1). *Anal.* calcd. for $C_{13}H_{22}O_4$: C 64.44, H 9.15; found: C 64.33, H 9.25.

Dihydrojasmone (4)

A solution of 0.24 g (0.0010 mol) of diketo ester **9** in 8 ml of 3% aqueous sodium hydroxide was stirred at ca. 70°C for 5½ h. After cooling to room temperature, the reaction mixture was acidified to pH 4 with 25% aqueous sulfuric acid and extracted with Et_2O. The extracts were dried over magnesium sulfate and the solvents removed under reduced pressure. The crude yellow oil was distilled (Kugelrohr) at 85°C/0.4 Torr to yield 0.12 g (72%) dihydrojasmone (**4**) which was homogeneous by tlc analysis and had spectral data identical to that of an authentic sample of dihydrojasmone.

Methyl 2-Acetyl-4-heptynoate (10)

A 1.8 g sample of KH in mineral oil (ca. 0.010 mol) was washed with dry THF and suspended in 25 ml dry THF. Then 1.16 g (0.010 mol) of methyl acetoacetate was added and the solution of the monoanion was cooled to 0°C and alkylated with 1.75 g (0.012 mol) of 1-bromo-2-pentyne (13). The reaction mixture was stirred at room temperature for 4 h, diluted with Et_2O, washed with water, and dried. The solvents were removed under reduced pressure and the alkylated ester **10** distilled at 78°C/0.1 Torr to yield 1.27 g (70%) of product: ir: 1715, 1740, and 2275 cm^{-1}; nmr δ: 1.07 (t, J = 7 Hz, 3H), 1.8–2.3 (m, 2H), 2.27 (s, 3H), 2.4–2.8 (m, 2H), 3.60 (t, J = 7 Hz, 1H) and 3.72 (s, 3H); ms (*a*): high resolution calcd. for $C_{10}H_{14}O_3$: 182.0922 amu; found: 182.0918; (*b*) low resolution *m/e* (relative intensity): 43 (60), 79 (22), 106 (23), 123 (15), 139 (100), 140 (10), 151 (6), 167 (2), 182 (4). *Anal.* calcd. for $C_{10}H_{14}O_3$: C 65.92, H 7.74; found: C 66.21, H 7.87.

Z-Methyl 2-Acetyl-4-heptenoate (11)

A mixture of 3.64 g (0.20 mol) of acetylene **10**, 0.12 g of 5% Pd on barium sulfate (14), and 6 drops of distilled quinoline in 125 ml dry methanol (MeOH) was hydrogenated at atmospheric pressure. After ca. 1 h 1 equiv. of hydrogen was absorbed, the mixture was filtered, and the MeOH was removed under reduced pressure. The crude product was dissolved in Et_2O, and washed with aqueous acid and brine. The ethereal solution was dried over magnesium sulfate and the solvents removed under reduced pressure. The crude product was distilled at 75°C/0.1 Torr to yield 3.26 g (89%) alkene **11**: ir: 1710 and 1740 cm^{-1}; nmr δ: 0.95 (t, J = 7 Hz, 3H), 1.7–2.2 (m, 2H), 2.22 (s, 3H), 2.57 (m, 2H), 3.43 (t, J = 7 Hz, 1H), 3.70 (s, 3H), and 4.9–5.6 (m, 2H); ms (*a*): high resolution calcd. for $C_{10}H_{16}O_3$: 184.1096 amu; found: 184.1095; (*b*): low resolution *m/e* (relative intensity): 43 (100), 68 (45), 81 (33), 95 (25), 109 (30), 125 (15), 137 (7), 141 (85), 152 (10), 166 (5), 184 (10). *Anal.* calcd. for $C_{10}H_{16}O_3$: C 65.19, H 8.75; found: C 65.37, H 8.67.

Z-6-Carbomethoxy-1-trimethylsilyl-8-undecen-1-yn-5-one (12)

The ester **11** (1.84 g, 0.010 mol) was dissolved in dry THF and treated with 0.55 g of oil-free sodium hydride and 4.8 ml of 2.1 *M* *n*-butyllithium at 0°C. The resulting dianion was alkylated with 2.28 g (0.012 mol) of 3-bromo-1-trimethylsilyl-1-propyne (9). This reaction mixture was stirred at 0°C for 3 h and then at room temperature for 2 h. The reaction was quenched with saturated ammonium chloride, extracted with Et_2O, washed with brine, and dried over sodium sulfate. The solvents were removed under reduced pressure to yield 3.00 g of crude **12** which was used directly in the next step. The alkylation product **12** was homogeneous by chromatography and it was characterized by the following spectral data: ir: 1720, 1745, and 2200 cm^{-1}; nmr δ: 0.20 (s, 9H), 1.00 (t, J = 7 Hz, 3H), 1.8–2.9 (m, 8H), 3.53 (t, J = 7 Hz, 1H), 3.70 (s, 3H), and 5.1–5.7 (m, 2H); ms (*a*): high resolution calcd. for $C_{16}H_{23}O_3Si$: 294.1641 amu; found: 294.1636; (*b*): low resolution *m/e* (relative intensity): 41 (40), 43 (40), 73 (100), 89 (26), 141 (35), 193 (11), 235 (22), 279 (10), 294 (3).

Z-6-Carbomethoxy-8-undecen-2,5-dione (13)

The crude trimethylsilylalkyne **12** (1.47 g, 0.0050 mol) was hydrolyzed with HgO (0.076 g) in sulfuric acid, water, and THF under the same conditions as those reported above for the hydrolysis of **8**. The crude product was distilled (Kugelrohr) at 125°C/0.5 Torr and chromatographed on silica gel tlc plates (solvent: CCl_4–Et_2O 4:1) to yield 1.2 g (80%) of dione **13** which had the following spectral properties: ir: 1715 and 1745 cm^{-1}; nmr δ: 0.93 (t, J = 7 Hz, 3H), 1.7–2.2 (m, 2H), 2.17 (s, 3H), 2.57 (m, 2H), 2.73 (br s, 4H), 3.52 (t, J = 7 Hz, 1H), 3.70 (s, 3H), and 5–5.7 (m, 2H); ms (*a*): high resolution calcd. for $C_{13}H_{20}O_4$: 240.1376 amu; found: 240.1373; (*b*): low

resolution *m/e* (relative intensity): 41 (33), 43 (100), 81 (25), 99 (90), 109 (50), 127 (29), 129 (18), 141 (71), 151 (21), 172 (10), 183 (15), 190 (13), 208 (10), 209 (11), 222 (18), 240 (10). *Anal.* calcd. for $C_{13}H_{20}O_4$: C 64.98, H 8.39; found: C 64.70, H 8.45.

Jasmone (3)

A sample of 0.48 g (0.0020 mol) of diketo ester **13** was hydrolyzed and cyclized with 16 ml of 3% aqueous sodium hydroxide using the same procedure as that used in the synthesis of dihydrojasmone (**4**) above. The crude product was distilled (Kugelrohr) to yield 0.28 g (85%) of jasmone (**3**) which was homogeneous by tlc analysis and had spectral data identical to that of an authentic sample of jasmone.

Concerning the spectra and solvation process of electrons in liquid butanols[1]

KIYOSHI OKAZAKI AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 27, 1978

KIYOSHI OKAZAKI and GORDON R. FREEMAN. Can. J. Chem. **56**, 2305 (1978).

The optical absorption spectra of electrons injected into the isomeric butanols settle into that of the equilibrium solvated state at rates that decrease in the order 1-butanol > isobutyl alcohol > 2-butanol at a given temperature. The relative rates reflect the dipolar reorientation times in the liquids. The Arrhenius temperature coefficients of the rates of spectral changes are ~30 kJ/mol. The distribution of dipolar reorientation times overlaps that of geminate reaction times of the charges in an irradiated alcohol, so a significant fraction of the electrons undergoes geminate reaction before they are able to become fully solvated. At $T < 200$ K the fraction increases with decreasing temperature. The concurrence of the solvation process and geminate reaction implies that the former involves, at least in part, electron migration from shallower to deeper traps.

There is an indication of structure in the absorption band at low temperatures and short times. The infrared peak converts to one with a maximum at ~780 nm. The latter slides gradually into the shape of the spectrum of the equilibrium solvated state.

For the spectra of the equilibrium solvated state, the energies at the absorption maxima are given by $E_{\varepsilon_{max}}$ (eV) = 3.10 − 0.0038T in isobutyl alcohol and 2.93 − 0.0044T in 2-butanol, between 170 and 300 K. The respective band widths at half heights are 1.53 ± 0.04 and 1.59 ± 0.04 eV, independent of temperature within an uncertainty of 1 meV/K.

KIYOSHI OKAZAKI et GORDON R. FREEMAN. Can. J. Chem. **56**, 2305 (1978).

Les spectres d'absorption optique d'électrons injectés dans des butanols isomères à une température donnée se stabilisent dans l'état solvaté, en équilibre thermique avec le milieu à des vitesses qui décroissent dans l'ordre butanol-1 > l'alcool isobutylique > butanol-2. Les vitesses relatives sont un reflet des temps de réorientation dipolaire dans les liquides. Les coefficients de température d'Arrhénius pour les vitesses des changements dans les spectres sont ~30 kJ/mol. Les distributions des temps de réorientation dipolaire recouvrent celles des temps de réaction géminée de charge dans un alcool irradié, ce qui implique qu'une fraction importante des électrons subit une réaction géminée avant d'être capable de devenir complètement solvatée. A une température plus basse que 200 K, la fraction augmente avec une diminution de la température. Le fait que le processus de solvatation et la réaction géminée se produisent d'une façon concurrente implique que le premier processus comporte au moins en partie une migration d'électrons d'un piège peu profond vers d'autres plus profonds.

Il existe une indication de structure dans la bande d'absorption à basses températures et à temps courts. La bande infrarouge se transforme en une avec un maximum à environ 780 nm. Cette dernière se déplace graduellement pour prendre la forme du spectre de l'état solvaté en équilibre thermique avec le milieu.

Les énergies à l'absorption maximum de l'état solvaté sont données par $E_{\varepsilon_{max}}$ (eV) = 3.10 − 0.0038T dans l'alcool isobutylique et 2.93 − 0.0044T dans le butanol-2 entre 170 et 300 K. Les largeurs des bandes à demi-hauteur sont respectivement de 1.53 ± 0.04 et 1.59 ± 0.04 eV et ne dépendent pas de la température, avec une incertitude de 1 meV/K.

[Traduit par le journal]

Introduction

The mechanism of electron energy degradation in irradiated fluids continues to attract interest (1) after many years of investigation (2–8). Events at energies $\gtrsim$10 eV are moderately well understood (1–4). At lower energies indirect information can be obtained from the thermalization ranges of the secondary electrons (4–8). In polar and many nonpolar liquids the electrons ultimately become localized and, through further energy loss processes, settle into the solvated state, which is in thermal equilibrium with the medium. Information about the last step may be obtained by measuring the time dependence of spectral changes that take place as the electrons settle from the initial localized levels into the solvated state (9–13).

In this paper, spectral changes in the optical absorption of electrons in 2-butanol and 2-methyl-1-propanol (isobutyl alcohol) are reported as functions of time and temperature. Reactions of the electrons are also discussed.

Experimental

Materials

The 1-butanol and isobutyl alcohol were spectranalyzed grade from Fisher Scientific Co. The 2-butanol was analytical

reagent grade from BDH Chemical Co. The alcohols were further purified as follows. To 1 ℓ of alcohol was added 1 g of sodium borohydride (Terochem Laboratories Ltd.). The solution was bubbled with UHP argon (Matheson Co.) then heated to ~70°C with the argon continuing to flow. This caused a gentle refluxing, which was continued for ~20 h. The alcohol was then distilled through an 85 × 2 cm column packed for 65 cm with 3 mm id glass helices. The alcohol was collected and stored under argon.

Techniques

Alcohol was transferred to the Spectrosil cell (Thermal Syndicate Ltd., optical path 1.35 cm) with a syringe, then bubbled for 20 min with UHP argon. The cell was then sealed with a flame by a technique that prevented alcohol vapor from contacting the hot glass (14).

The radiation was a 100 ns pulse of 1.7 MeV electrons, delivering a dose of 2×10^{16} eV/g. Dosimetry was by oxygen-saturated aqueous KSCN (15).

The optical system and the visible light detector were described in ref. 16, and the uv detector in ref. 15. The response time of the visible light measurement system was determined by comparing the Čerenkov light signal with the known shape of the electron pulse (measured by charge collection on a gold target, response time < 10 ns). The total rise plus fall time of the visible light system was 200 ns for a 100 ns square pulse. The 3–97% rise time for a 10 ns wide step function was 100 ± 10 ns. The latter for the uv measurement system was 70 ns with the 5 MHz filter and 15 ns at full bandwidth.

Results

The optical absorption signals were of the types illustrated in Figs. 3 and 13 of ref. 16. Semilog plots of the absorbance against time after a pulse were often of the type shown in Fig. 17 of ref. 16; the decay became first order after an initial growth or decay of complex order.

To emphasize processes that occur on the low energy side of the absorption spectrum, $G\varepsilon$ is plotted against wavelength, λ (nm) = 1240/$h\nu$ (eV). The quantity $G\varepsilon$ is the product of the electron yield G (electrons/100 eV absorbed) and the decadic molar absorbance ε (M^{-1} cm^{-1}).

The response characteristics of the measuring circuit were such that the optical absorption signal reached a maximum ~150 ns after the start of the 100 ns pulse, when decay after the pulse was fast. This was therefore the shortest time at which spectra were recorded. Signal growth and decay kinetics were complex at short times, so no corrections were made to the measured absorbances.

The freezing point of 1-butanol (184 K) is higher than those of 2-butanol (158 K) and isobutyl alcohol (165 K). The absorption spectrum of electrons in 1-butanol reached its equilibrium shape within the 150 ns resolution time of the measurement at all temperatures down to the freezing point. This means that relaxation of the electrons into the solvated state could not be followed as a function of time in 1-butanol, so experiments with that alcohol were not pursued.

2-Butanol

Optical absorption spectra taken 150 ns after the beginning of the 100 ns pulse are shown in Fig. 1. Time was measured from the beginning of the pulse because that was the only consistent anchor point at all wavelengths. At $T \geq 211$ K the observed spectrum decayed uniformly at all wavelengths, which means that the electrons had relaxed to the equilibrium solvated state within the resolution time of the measurement. The wavelength at the absorption maximum, $\lambda_{G\varepsilon max}$, decreased and the value of $G\varepsilon$ at the peak, $(G\varepsilon)_{max}$, increased with decreasing temperature down to 211 K (Fig. 1). On going from 211 to 183 K the spectrum shift reversed to a larger $\lambda_{G\varepsilon max}$ and lower $(G\varepsilon)_{max}$ (Fig. 1). However, the spectrum at 183 K shifted with time to lower wavelengths and at 2 μs had reached a steady state location and shape with $\lambda_{G\varepsilon max} = 590$ nm and $(G\varepsilon)_{max} = 2.08 \times 10^4$ electrons/100 eV M cm. Thus $\lambda_{G\varepsilon max}$ for the steady state spectrum continued to decrease with temperature, but $(G\varepsilon)_{max}$ passed through an extremum.

Changes in the spectrum shape with time were more clearly measurable at lower temperatures. At 171 K there were two absorption peaks at 150 ns; one at ~920 nm and another at ~800 nm (Fig. 2). The peak at 920 nm decayed rapidly, while the other grew and shifted to lower wavelengths. After 1 μs the change at 920 nm was 80% of the way towards the complete solvation value and the peak was at ~700 nm. This was followed by a slower settling of the long wavelength side of the band towards that of equilibrium solvated electrons, while the short wavelength side changed only slightly (Fig. 2). The equilibrium spectrum had $\lambda_{G\varepsilon max} = 565$ nm.

At 162 K the absorption band at 150 ns contained

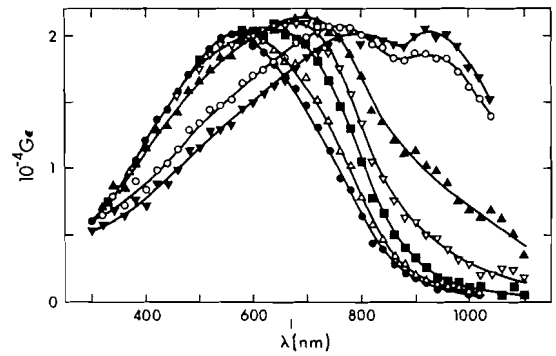

FIG. 2. Absorption spectrum of localized electrons in 2-butanol at 171 K at several times after the start of the 100 ns pulse. The times (μs) are: ▼, 0.15; ○, 0.20; ▲, 0.50; ▽, 1.0; ■, 2.0; △, 5.0; ●, 10.

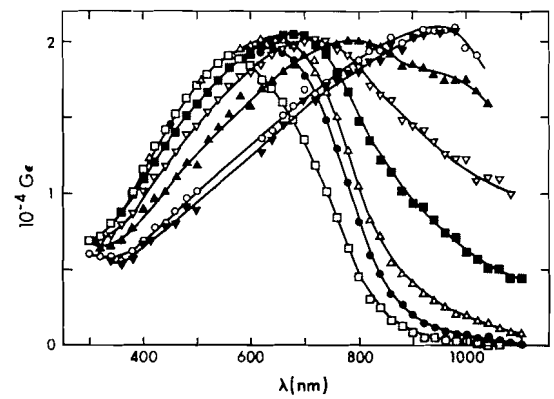

FIG. 3. Absorption spectrum of localized electrons in 2-butanol at 162 K at several times after the start of the 100 ns pulse. The times (μs) are: ▼, 0.15; ○, 0.20; ▲, 0.50; ▽, 1.0; ■, 2.0; △, 5.0; ●, 10; □, 45.

only one peak, at ~960 nm (Fig. 3). As at 171 K, decay of the long wavelength absorption caused growth of the absorption at shorter wavelengths, with a band maximum at ~700 nm after 2 μs. There was then a slower decay of the long wavelength side of the band with relatively little increase of absorption at shorter wavelengths. The time required for the latter decay at 162 K was three- to fourfold longer than that at 171 K, indicating an Arrhenius temperature coefficient of ~30 kJ/mol. The rates of rapid growth at 500 nm and decay at 1000 nm also displayed Arrhenius temperature coefficients of ~30 kJ/mol.

Comparison of Figs. 2 and 3 indicates that the double peak at 150 ns and 171 K is due to spectral shifts that occurred during the 150 ns resolution time.

Isobutyl Alcohol

Spectra recorded 150 ns after the start of the 100 ns pulse in isobutyl alcohol at 299, 243, and 212 K are shown in Fig. 4. The spectra decayed with equal

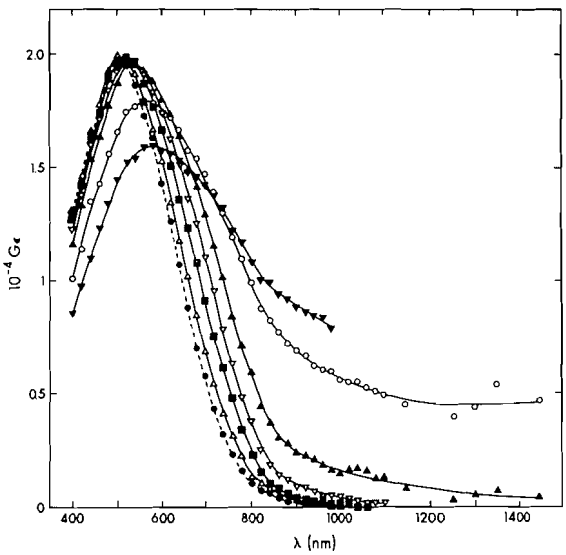

FIG. 5. Absorption spectrum of localized electrons in isobutyl alcohol at 167 K at several times after the start of the 100 ns pulse. The times (μs) are: ▼, 0.15; ○, 0.20; ▲, 0.50; ▽, 1; ■, 2; △, 5; ●, 10.

relative rates at all wavelengths, so correspond to absorption by the equilibrium solvated state. $(G\varepsilon)_{max}$ increased and $\lambda_{G\varepsilon max}$ decreased monotonically with decreasing temperature.

At 183 K the spectrum decayed at long wavelengths and grew at short wavelengths until the equilibrium shape was reached at 1 μs. The spectrum then decayed uniformly at all wavelengths. The equilibrium shape was attained approximately twofold more quickly in isobutyl alcohol than in 2-butanol at the same temperature.

At 167 K the equilibrium shape was attained in ~7 μs (Fig. 5), indicating an Arrhenius tempera-

ture coefficient of ~30 kJ/mol for the relaxation process.

Discussion

The changes in the optical absorption band of electrons with time in these butanols may be divided into two periods: (*a*) decay of the infrared end and growth of the blue end of the initial band, culminating in the spectrum of the equilibrium solvated state; (*b*) uniform decay of the solvated state spectrum.

(*a*) *Transformation of the Initial Spectrum*

The distribution of times required for dipolar reorientation about the newly created charges in an irradiated alcohol intersects that of the geminate reaction times of the charges (17–20). The reaction rates of the charges are altered by the polarization of the medium that surrounds them, and are therefore affected by the time dependence of the polarization (17–20). It was expected that the changes in polarization about the localized electron would create a time dependence of its optical absorption spectrum, and such was found to be the case (21–24).

The dipolar orientation times are smaller than the principal dielectric relaxation times τ_1 measured at constant field (25) due to: (*a*) the fact that relaxation occurs in the presence of constant charge rather than constant field (17); (*b*) the torque provided by the charge–dipole interaction (18, 19); and (*c*) the nullification by the excess electron of hydrogen bonds in its vicinity. There is a fair correlation between the spectral shift times (11, 26, 27) and the intermediate dielectric relaxation time τ_2 in the alcohols at room temperature (25), but the correlation is less good at low temperatures (9, 12).

The rate of decay of the optical absorption at 1040 nm in the butanols is about half the rate of approach to the maximum absorption at $\lambda \leq \lambda_{G\varepsilon max}$ (Fig. 6). This agrees with the observations of Chase and Hunt (11) for electrons in ethanol, 1-propanol, and 1-butanol. They observed that the rate of decay at 1300 nm equalled the rate of approach to the maximum absorption at 600 nm. The observed decay or growth rate at a given wavelength is the difference between the true decay rate and the rate of formation of that state from other states. If the equality of the rates of decay at 1300 nm and remaining growth at 600 nm is not a coincidence, the decay rate at a longer wavelength, say 1600 nm, should equal that at 1300 nm. This would imply that the same state absorbs at 1600 and 1300 nm. The longer apparent decay time at 1040 nm indicates that an intermediate state absorbs at this wavelength; the state is formed from those that absorb at longer wavelengths and decays to others that absorb at shorter wavelengths. Present equipment is not adequate to test the hypothesis at 1300 and 1600 nm.

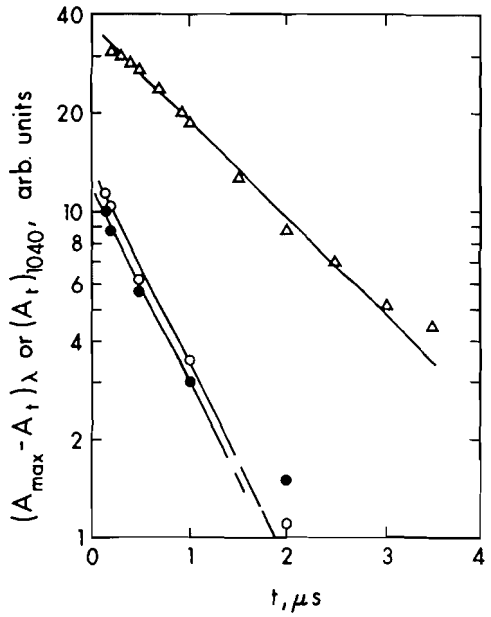

FIG. 6. Decay of absorbance A_t at λ = 1040 nm (△) and remaining growth of absorbance at λ = 560 nm (○) and 450 nm (●) in 2-butanol at 162 K. The remaining growth is a measure of the approach to the maximum absorbance at that wavelength $(A_{max} - A_t)_\lambda$. Time is measured from the beginning of the 0.10 μs pulse. $\lambda_{G\varepsilon max}$ = 560 nm for the equilibrium solvated state.

Another contribution to the wavelength dependent kinetics might be a decrease of the decay rate with increasing depth of the electron trap (28).

Changes in absorbance with time at different wavelengths are shown in Fig. 7 for electrons in 2-butanol at several temperatures. The final band maximum occurs at 560–590 nm at all these temperatures. At $\lambda \leq \lambda_{G\varepsilon max}$ there is growth due to the shift in spectrum, followed by decay due to reaction of the electrons. At ~700 nm there is growth due to the spectral shift, followed by decay due to further spectral shift and to reaction. At λ > 900 nm on the timescale of the present experiments there is only decay, attributed to both spectral shift and reaction.

Behavior is similar for electrons in isobutyl alcohol, although the data for that solvent are more limited (Fig. 8).

Solvation Time τ_s

The time required for newly injected electrons to attain the equilibrium solvated state may be characterized approximately by the time τ_s in eq. [1] for $\lambda \leq \lambda_{G\varepsilon max}$:

$$[1] \qquad (A_{max} - A_t)_\lambda = (A_{max} - A_0)_\lambda \, e^{-t/\tau_s}$$

where A_0 and A_t are the optical absorbances at times

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

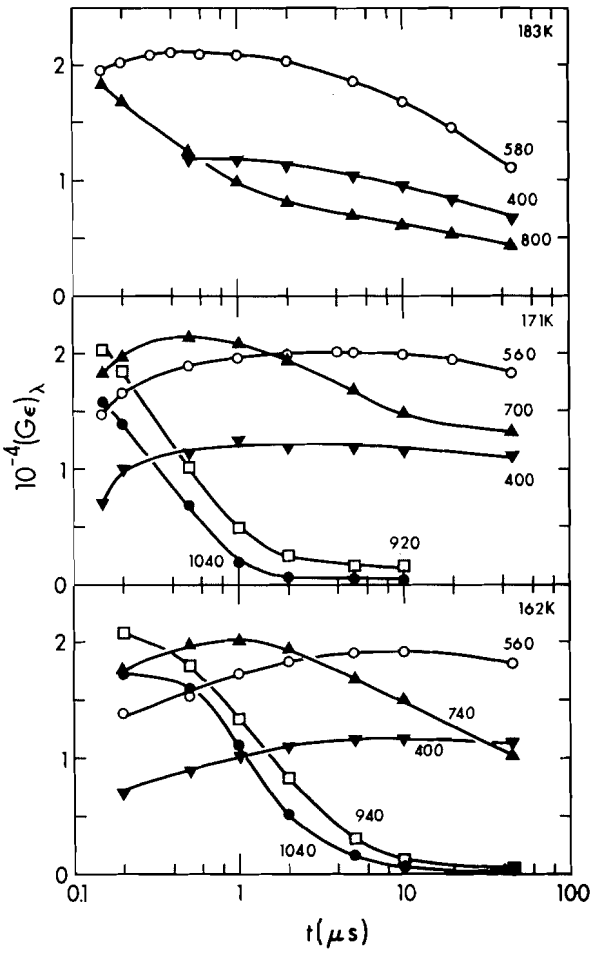

FIG. 7. Time dependence of $(G\varepsilon)_\lambda$ for electrons in 2-butanol at several temperatures. The units of $G\varepsilon$ are (100 eV M cm)$^{-1}$. The wavelengths λ (nm) are indicated on the curves. The values of $\lambda_{G\varepsilon max}$ for the equilibrium solvated state are 590 nm at 183 K, 565 nm at 171 K, and 560 nm at 162 K.

zero and t, respectively, and A_{max} is the maximum attained at that wavelength (see Fig. 7, where $G\varepsilon$ may be substituted for A). The plot of eq. [1] for electrons in 2-butanol at 162 K in Fig. 6 gives $\tau_s = 0.73$ μs. Other values of τ_s obtained in this way for 2-butanol and isobutyl alcohol are shown in Fig. 9.

The time τ_d required for the absorbance at 1000 nm to decay to e^{-1} of its maximum value is about double the τ_s value measured at $\lambda < \lambda_{G\varepsilon max}$ (Fig. 9).

Values of the intermediate dielectric relaxation time τ_2 fall in the order isobutyl alcohol > 1-butanol (29), but the value for 2-butanol is not available. However, the relative values of the principal relaxation time τ_1 are in the order 2-butanol > isobutyl alcohol > 1-butanol (29), so one may assume that τ_2 is also greatest for the 2-isomer. Recalling that τ_s

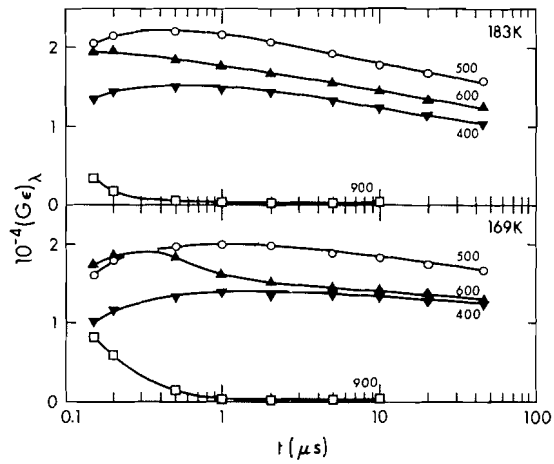

FIG. 8. Time dependence of $(G\varepsilon)_\lambda$ for electrons in isobutyl alcohol at 169 K and 183 K. The wavelengths λ (nm) are indicated on the curves. The values of $\lambda_{G\varepsilon max}$ for the equilibrium solvated state are 515 nm at 183 K and ~505 nm at 169 K.

was too short to measure in 1-butanol with the present system, the previously mentioned correlation between the values of τ_2 and τ_s exists also for the isomeric butanols (Fig. 9). We pick τ_2 simply because it is smaller than τ_1 not because one would expect τ_s to equal τ_2. The temperature dependence of τ_s is similar but not equal to that of τ_2 (Fig. 9).

There is a question about whether the shift of the spectrum is due to dipolar reorientation about a localized electron site, or whether the electron migrates from shallower to deeper traps (12, 23, 30). Both processes are probably involved, because they would be interconnected in a polar liquid. The migration mechanism would be accompanied by a certain amount of electron loss due to geminate reaction, especially at very short times, corresponding to small electron–ion separation distances (19, 20). A significant amount of loss occurs in alcohols at low temperatures (12, 19, 20), where the dipole reorientation times are relatively long.

The amount of electron loss by reaction during the spectrum shift was estimated by integration of plots of $G\varepsilon$ against photon energy, assuming the oscillator strength to remain constant during the shift. In 2-butanol at 171 K, most of the decay in the infrared that occurred between 0.2 and 1.0 μs appeared as growth at higher energies. However, comparison of the shape of the spectrum at 150 ns in Fig. 2 with those of electrons in 1-propanol at low temperatures immediately following a 20 ns pulse (Figs. 4 and 5 of ref. 12) indicates that considerable decay had occurred in the infrared of the present spectrum during the response time of the measuring system. Most of the electron loss apparently occurs

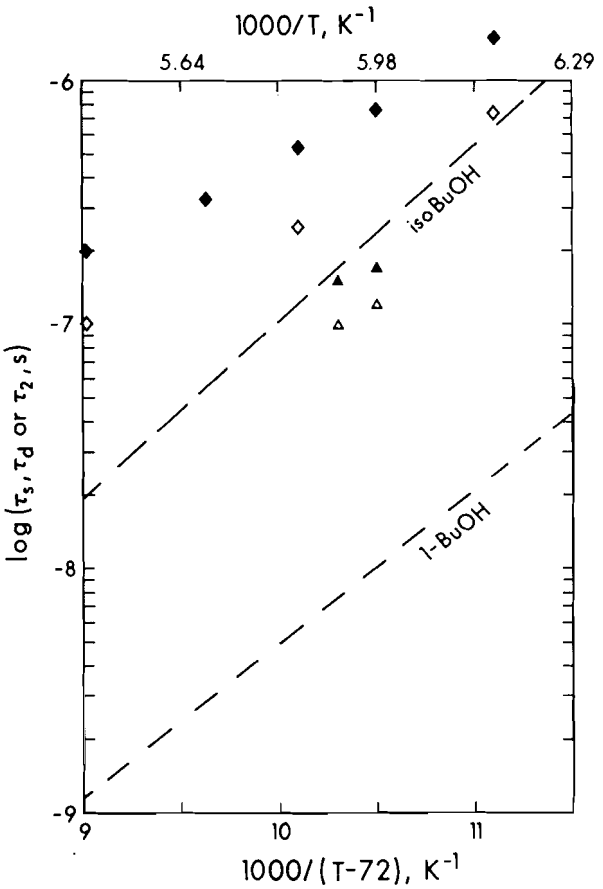

FIG. 9. Electron solvation times τ_s ($\lambda = 500$ nm, open points) and decay times τ_d ($\lambda = 1000$ nm, full points) compared with the second dielectric relaxation times τ_2 (---) in butanols. ◇, ◆, 2-butanol; △, ▲, isobutyl alcohol. The τ_2 lines are labelled and are extrapolations of data for the supercooled liquids (ref. 29). The temperature axis is labelled for both Cole–Davidson and Arrhenius plots.

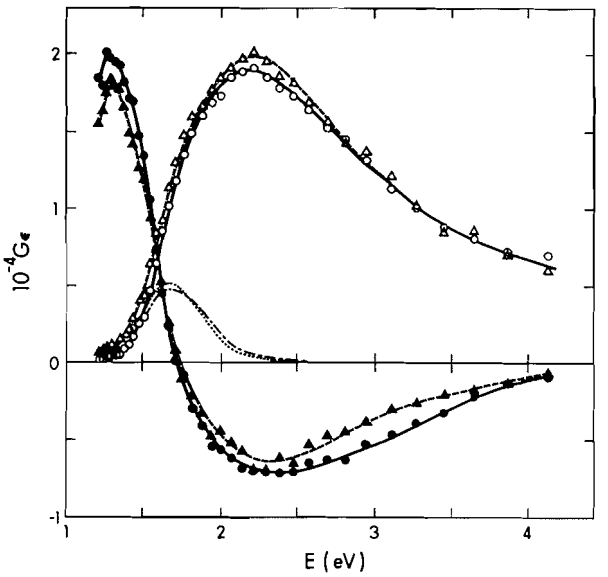

FIG. 10. Comparison of the spectral shift from the infrared to the visible (full points) with the spectrum of the equilibrium solvated state (open points) of extra electrons in liquid 2-butanol. 162 K: ○, equilibrium solvated state spectrum at 45 μs; ····, (10 μs) − (45 μs) subtraction spectrum; ●, (0.2 μs) − (10 μs) subtraction spectrum. 171 K: △, equilibrium state spectrum at 10 μs; ···, (2 μs) − (10 μs) subtraction spectrum; ▲, (0.15 μs) − (2 μs) subtraction spectrum. The small peaks without experimental points represent the shift that occurred during the time gap between the full and open points. Algebraic addition of the three spectra gives the initial spectrum at each temperature.

at very short times (12). At times between 1 and 10 μs (Fig. 2) the red side of the band continued to decay, while the blue side remained virtually unchanged. This is attributed to a continuing blue shift of the spectrum combined with a general loss of electrons to geminate neutralization. The approximate constancy of the blue side of the band between 1 and 10 μs is due to the cancellation of growth from the blue shift and decay by geminate reaction. The rate of decay of the red side is the sum of the rates of the two processes. At times >10 μs the spectrum decays uniformly at all wavelengths and at 45 μs has decreased by 8%.

The behavior was similar in 2-butanol at 162 K, but the timescale was approximately fourfold longer than at 171 K.

The above discussion supports the suggestion of Gilles *et al.* (28) that the equality of the rates of decay at 1300 nm and remaining growth at 600 nm, reported for electrons in ethanol and 1-propanol (11), may be fortuitous. The rate of approach to the maximum $G\varepsilon$ at $\lambda \leq \lambda_{G\varepsilon max}$ gives an upper limit to the solvation rate (lower limit of τ_s).

The spectrum shifts without much electron loss at intermediate times because, for the remaining electrons, fewer diffusion steps are needed to reach a deeper trap than to reach a geminate ion.

Intermediate Spectra

There is an indication of structure in the absorption band of electrons in 2-butanol at low temperatures and short times (Figs. 2 and 3). There is one peak at ~930 nm and another at ~780 nm. The former decays to the latter, and the latter slides gradually into the final shape of the spectrum of the equilibrium solvated state. The two peaks probably indicate two types of electron localization site, the one at longer wavelength involving fewer OH groups in the first coordination sphere. The shifting of the peak at shorter wavelengths corresponds to polarization/migration, as a result of which the electron finds itself in a progressively more polarized site.

Subtraction of a later spectrum from the one at 0.2 μs does not give the spectrum of the species that decayed, because the initial and final bands probably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

overlap. Furthermore, growth in a portion of the original spectrum appears as a negative peak in the subtraction spectrum. The over-all subtraction spectrum illustrates the location and magnitude of the spectral shift. The first spectrum to be subtracted was chosen such that the infrared peak had decayed nearly completely. This corresponded to times of 2 μs at 171 K and 10 μs at 162 K in 2-butanol. The decay and growth that occurred during these periods are shown in Fig. 10. The spectra of the equilibrium solvated state were reached at 10 μs at 171 K and ≥45 μs at 162 K (Fig. 10). The subtraction spectra of the intervening time periods, 2–10 μs at 171 K and 10–45 μs at 162 K, correspond to a relatively small amount of decay in the red and near infrared (Fig. 10). The decays of these small 'subtraction peaks' had Arrhenius temperature coefficients of ~30 kJ/mol.

For a given temperature, summation of the series of subtraction spectra plus the final spectrum gives the initial spectrum.

(b) Decay of the Spectrum of the Solvated State

In isobutyl alcohol at 212 K the optical absorption spectrum reached its equilibrium shape within the 0.15 μs response time of the equipment (Fig. 4). The geminate neutralization reaction in this system continued for more than 50 μs (Fig. 11). Assuming that the dielectric constant of the liquid between a geminate pair of charges attains its static value shortly after the electron reaches its equilibrium state of solvation, the dielectric constant may be taken to be independent of time over the range displayed in Fig. 11. Under these circumstances the rate of the geminate reaction is described by eq. [2] (31).

$$[2] \quad G(e_s^-)_{gi,t} = G(e_s^-)_t - G(e_s^-)_{fi} = Bt^{-1/2}$$

where $G(e_s^-)_{gi,t}$ is the portion of the solvated electron yield surviving at time t that will undergo geminate reaction with ions and radicals in spurs, and it is assumed that the portion that will become free ions, $G(e_s^-)_{fi}$, does not react appreciably on this timescale; B is a proportionality constant. However, in the present systems the solvated electrons undergo a pseudo first order reaction with impurities or the solvent on a timescale that overlaps the tail of the geminate reaction, so one may write:

$$[3] \quad G(e_s^-)_t = (Bt^{-1/2} + G(e_s^-)_{fi})e^{-kt}$$

where k is the first order rate constant. The curve in Fig. 11 is of this form and has the equation:

$$[4] \quad 10^{-4}G\varepsilon_{540} = (0.55t^{-1/2} + 1.22)\exp(-7.2 \times 10^{-3}t)$$

where t is in μs. The first order half life is 96 μs.

The widths of the absorption bands at half height are $W_{1/2} \approx 1.6$ eV at all temperatures in the liquid butanols (Figs. 1–3), so one may take $\varepsilon_{max} \approx 1.0 \times 10^4\ M^{-1}\ cm^{-1}$ (14, 15). This would give $G(e_s^-)_{fi} = 1.2$ in isobutyl alcohol at 212 K (eq. [4]), and a total solvated electron yield observed at 150 ns of 2.1 (Figs. 4 and 11). The initial ionization yield in a number of organic liquids, including saturated hydrocarbons and alcohols, is $G(e^-)_{init} \approx 5$ (32, 33). Approximately half of the initial ion–electron pairs, therefore, undergo geminate neutralization during the first 150 ns in isobutyl alcohol at 212 K.

One may use similar arguments to estimate the fraction of electrons that undergo geminate neutralization before the equilibrium solvated state is reached at lower temperatures. At $T \leq 183$ K in 2-butanol and isobutyl alcohol the time required to reach the equilibrium state was greater than the response time of the system, so $[G(e_s^-)_{max}\varepsilon_{max}]$ could be measured. This quantity decreases with decreasing temperature (Fig. 12*B*), which indicates that a greater fraction of electrons undergoes geminate reaction before reaching the solvated state as the temperature is lowered. Lowering the temperature slows intermolecular rearrangements in the liquid, and hence the solvation process. Similar observations and conclusions were made earlier for electrons in other polar systems (12, 16, 34, 35).

The decrease in $G(e_s^-)\varepsilon_{max}$ with increasing temperature observed at $T \geq 210$ K (Fig. 12*B*) is due to the increasing amount of geminate reaction that occurs during the 150 ns response time of the measurement.

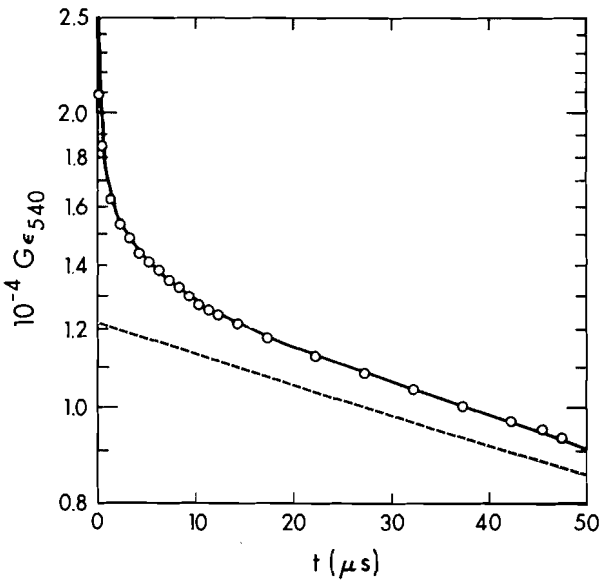

FIG. 11. Decay of the optical absorption at 540 nm of electrons in isobutyl alcohol at 212 K. The full line represents eq. [4]. The dashed line is an extrapolation of the free ion portion from longer to shorter times.

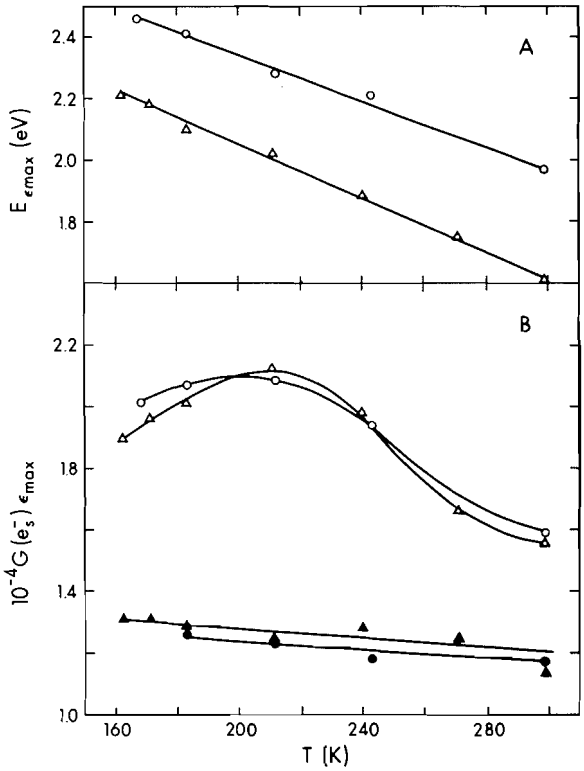

FIG. 12. *A*: Variation of $E_{\epsilon max}$ with temperature, for solvated electrons in isobutyl alcohol (○) and 2-butanol (△). *B*: Variation $G(e_s^-)_{max}\varepsilon_{max}$ (open points) and $G(e_s^-)_{fi}\varepsilon_{max}$ (full points) with temperature in isobutyl alcohol (○, ●) and 2-butanol (△, ▲). At $T > 200$ K the observed values of $G(e_s^-)_{max}\varepsilon_{max}$ are limited by the 150 ns response time of the measurement.

Equations analogous to eq. [4] were used to analyze the decay at each temperature. The values of $G(e_s^-)_{fi}\varepsilon_{max}$ so obtained increased by $\lesssim 10\%$ as the temperature was reduced from 299 to 165 K (Fig. 12*B*).

Temperature Dependence of $E_{\epsilon max}$ *and* $W_{1/2}$

For the spectra of the equilibrium solvated state, the energy at the absorption maximum, $E_{\epsilon max}$, is greater in isobutyl alcohol than in 2-butanol (Fig. 12*A*). The difference may be attributed qualitatively to a difference in the packing of molecules, particularly of H—O—dipoles, around the electron site. The temperature coefficient of $E_{\epsilon max}$ is -3.8 meV/K in isobutyl alcohol and -4.4 meV/K in 2-butanol. The corresponding values in methanol and ethanol are -2.6 and -3.2 meV/K, respectively (14). The magnitude of the coefficient tends to increase with increasing size of the alkyl group.

Within an uncertainty of 1 meV/K the widths of the absorption bands at half height, $W_{1/2}$, are independent of temperature. The values are 1.53 ± 0.04 eV in isobutyl alcohol and 1.59 ± 0.04 eV/K in 2-butanol between 170 and 300 K. The ratio of the portions of the widths on the blue and red sides of the maximum, W_b/W_r, is approximately equal to 1.7 in isobutyl alcohol and 2.3 in 2-butanol, independent of temperature.

A solvent effect similar to that reported earlier (J. Am. Chem. Soc. **98**, 6825 (1976)) has been found for the rates of reaction of solvated electrons with benzene and toluene in a series of alcohols. The value of the rate constant for benzene at 299 K increases abruptly from 1.0 ($10^6\ M^{-1}\ s^{-1}$) in methanol to 6.8 in ethanol, then increases only slightly to 7.0 in 1-propanol and 8.4 in 1-butanol. A further large increase occurs on going to a secondary alcohol solvent: 42 ($10^6\ M^{-1}\ s^{-1}$) in 2-propanol and 69 in 2-butanol. The activation energies are ~30 kJ/mol in all cases, so the rate constants reflect different entropies of activation. The entropies are affected by the solvation energies of the species.

The reactions of benzene and toluene with electrons prior to solvation show relatively little solvent effect, due to their higher energy state. In 2-butanol at 163 K, reactions of quasifree, localized (absorbing in the infrared), and equilibrium solvated electrons have been distinguished. Reactions of e_{qf}^- obey the relation $(A_{i0}/A_i)_{qf} \approx 1 + [P/(1-P)]f_{qf}N_s$, where A_i/A_{i0} is the fraction of electrons that have not been scavenged up to time i, and N_i is the mol fraction of scavenger. See text for remaining symbols. Reactions of e_{loc}^- obey the relation $(A_i/A_{i0})_{loc} \approx \exp(-nf_{loc}N_s)$. The total probability that electrons reach the equilibrium solvated state is $A_i/A_{i0} \approx \exp(-nf_{loc}N_s)/\{1 + [P/(1-P)]f_{qf}N_s\}$. Both diffusion and tunneling may contribute to scavenging of e_{loc}^-. The contribution of these processes, compared to the amount of scavenging e_{qf}^-, increases with increasing scavenger concentration and decreasing temperature.

The parameters $f_{qf}P/(1-P)$ and nf_{loc} each vary approximately as T^{-4}, which is equivalent to an Arrhenius temperature coefficient of about −8 kJ/mol. The negative temperature coefficients could imply either that the scavenging step has a negative temperature coefficient, or that the lowering of the electron energy state has a positive temperature coefficient.

KIYOSHI OKAZAKI et GORDON R. FREEMAN. Can. J. Chem. **56**, 2313 (1978).

On a trouvé un effet de solvant semblable à celui rapporté antérieurement (J. Am. Chem. Soc. **98**, 6825 (1976)) pour les vitesses de réaction entre des électrons solvatés et le benzène et le toluène dans une série d'alcools. Il y a une augmentation rapide de la valeur de la constante de vitesse pour le benzène à 299 K allant de 1.0 ($10^6\ M^{-1}\ s^{-1}$) dans le méthanol à 6.8 dans l'éthanol et des augmentations graduelles jusqu'à 7 dans le propanol-1 et 8.4 dans le butanol-1. Il y a une autre augmentation substantielle lorsque le solvant est un alcool secondaire: 42 ($10^6\ M^{-1}\ s^{-1}$) pour le propanol-2 et 69 pour le butanol-2. Les énergies d'activation sont d'environ 30 kJ/mol dans tous les cas, ce qui indique que les constantes de vitesse sont un reflet de différentes entropies d'activation. Les entropies sont affectées par les énergies de solvatation des espèces.

Les réactions du benzène et du toluène avec des électrons avant la solvatation ne présentent que des effets de solvant relativement faibles dus à leurs états d'énergie plus élevé. Dans le butanol-2 à 163 K, on a pu distinguer les réactions des électrons pratiquement libres, (qf), localisés (loc, qui absorbent dans l'infrarouge) et des électrons solvatés (solv) en équilibre. Les réactions des e_{qf}^- s'effectuent suivant la relation $(A_{i0}/A_i)_{qf} \approx 1 + [P/(1-P)]f_{qf}N_s$ où A_i/A_{i0} est la fraction non-piégée jusqu'au temps i et N_s est la fraction molaire de piège. On retrouvera dans le texte la signification des autres symboles. Les réactions des e_{loc}^- obéissent à la loi $(A_i/A_{i0})_{loc} \approx \exp(-nf_{loc}N_s)$. La probabilité totale que les électrons puissent atteindre un état d'équilibre solvaté est de $A_i/A_{i0} \approx \exp(-nf_{loc}N_s)/\{1 + [P/(1-P)]f_{qf}N_s\}$. La diffusion ainsi que l'effet de tunnel peuvent contribuer au piégeage des e_{loc}^-. La contribution de ces processus comparée à la quantité de piégeage e_{qf}^- augmente avec l'augmentation de la concentration des pièges et la diminution de la température.

Les paramètres $f_{qf}P/(1-P)$ et nf_{loc} varient en fonction de T^{-4} ce qui est équivalent à un coefficient de température d'Arrhénius d'approximativement −8 kJ/mol. Les coefficients de température négatifs peuvent impliquer soit que l'étape du piège a un coefficient de température négatif ou que l'abaissement de l'état d'énergie de l'électron a un coefficient de température positif.

Introduction

Information about the behavior of electrons during their last stages of de-energization in irradiated polar liquids can be obtained from studies of: (*a*) temporal shifts in their optical absorption spectra (1–10), and (*b*) changes of chemical reactivity with energy state (1–3, 5, 6, 11–17). The present work is a contribution to the latter.

The initial yield of solvated electrons in irradiated liquids such as alcohols can be reduced by the addition of a high concentration of scavenger. The electrons can be captured prior to solvation, and there is a competition between localization traps (potential wells in the liquid) and scavenger molecules. In some instances the competition may be represented by a simple logarithmic function of the scavenger concentration (15), while in others it may not (16). Both types of behavior may be represented by a single model (16, 17). However, the model contains three adjustable parameters, which make it more arbitrary than one would like. To obtain more information about scavenging of electrons prior to solvation, we have studied the effects of alcohol molecular structure and temperature.

Experimental

Materials

The methanol was spectrophotometric reagent grade from Baker Chemical Co.; ethanol was absolute reagent grade from U.S. Industrial Chemical Co.; *n*-propanol, certified grade, Matheson, Coleman & Bell Co.; isopropanol, spectrophotometric grade, Aldrich Chemical Co.; 1-butanol, spectranalyzed grade, Fisher Scientific Co.; 2-butanol, analytical reagent grade, BDH Chemical Co.

Ethanol was used without further purification, because it is the highest purity that has been obtained by any method in this laboratory (18). The other alcohols were purified by the procedure reported earlier for the butanols (10).

Benzene and toluene (Phillips Research Grade) were purified under vacuum by stirring for 1–2 days with each of the following: lithium aluminum hydride powder (Alfa Inorganic Ventron Co.), conc. sulfuric acid (Baker Chemical Co.), potassium hydroxide pellets (American Drug and Chemical Co.), and sodium–potassium alloy (Na (dry) and K, Laboratory Reagent, from BDH Chemical Co.).

Solutions were prepared with the aid of syringes and bubbled with UHP argon (Matheson Co.) to free them from oxygen.

Techniques

The radiation, dosimetry, and optical systems were described earlier (10). Briefly, a 100 ns pulse of 1.7 MeV electrons delivered a dose of 2×10^{16} eV/g to the sample. Optical measurements were made at the absorption maximum λ_{emax} of the solvated electron band at each temperature, unless otherwise noted.

Results

Rate Constants, k($e_{solv}^- + S$)

Electrons in their equilibrium solvated state (10) react by pseudo-first order kinetics with solute S in the alcohol. The pseudo-first order rate constants were plotted against the solute concentration and the value of the second order rate constant $k(e_{solv}^- + S)$ obtained from the slope. At least five different concentrations were used for each solute.

Rate constants for reaction with benzene and toluene were measured in a number of alcohols at temperatures ranging from 200 to 300 K. Values of the Arrhenius parameters, $k = A \exp(-E_a/RT)$, and the rate constant at 299 K are listed in Table 1. The values of k for benzene in methanol and ethanol reported in refs. 14 and 16 were slightly larger than those obtained under the same conditions in the present work.

The rate constants are all at least two orders of magnitude below the diffusion controlled limit $\sim 10^{10}\ M^{-1}\ s^{-1}$ at 299 K (19). The activation energies are all ~ 30 kJ/mol and do not reflect the two-fold variation in the activation energies of dielectric relaxation or viscosity (Table 1). Activation energies of diffusion of the reactants are probably similar to the last two quantities.

The values of the rate constants increase by nearly two orders of magnitude on going from methanol to 2-butanol solvent and the change appears in the frequency factor A (Table 1). This is a solvent effect similar to that reported earlier (20). It will be investigated further. The A factor for reaction with benzene and toluene appears to increase with increasing size of the alkyl group on the alcohol and with decreasing solvation energy of the electron. The latter is reflected by $E_{\epsilon max}$ (Table 1). The larger alkyl groups may lower the energy state of the hydrocarbon solute and anion.

Scavenging of Electrons Prior to Solvation

Addition of > 1 mol% of benzene or toluene to an alcohol reduced the initial yield of solvated electrons. Where necessary, the absorption signal of solvated electrons was corrected for pseudo-first order reaction with the solute during the 0.1 μs pulse (16) to obtain the initial absorbance A_i. The ratio A_i/A_{i0} was plotted against solute concentration, where A_{i0} is the absorbance in pure alcohol (Fig. 1). By contrast with the earlier work where only the free ion portion of the signal was used (16), we used the total absorbance at the end of the pulse, including any geminate solvated electrons that might remain at that time. Virtually the same values of A_i/A_{i0} were obtained whether the geminate electrons were excluded or not, but their inclusion avoided a possible extrapolation error.

As the temperature of the solvent methanol was lowered, benzene became more efficient at decreasing the solvated electron yield (Fig. 1). The efficiency increased six-fold between 299 and 183 K.

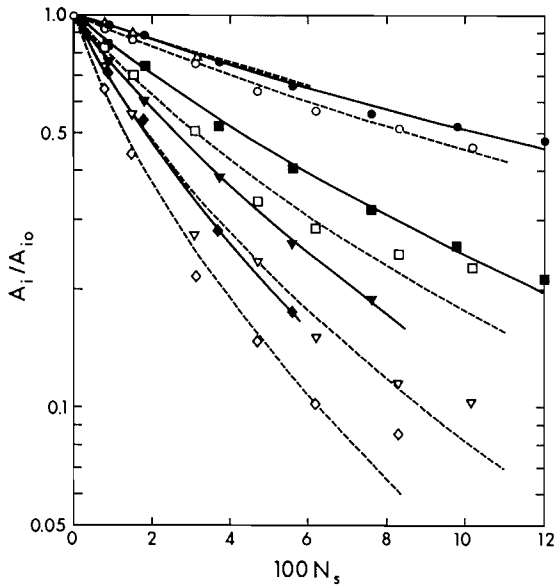

FIG. 1. Effects of benzene (full points) and toluene (open points) on the initial absorbance A_i of solvated electrons after a 100 ns pulse of radiation in methanol. A_{io} is the initial absorbance in the absence of scavenger and N_s is the mol fraction of scavenger. The temperatures (K) were: △, 333; ●, ○, 299; ■, □, 243; ▼, ▽, 213; ◆, ◇, 183. The curves — for benzene and - - - for toluene were calculated from eq. [4] using parameter values from Table 2.

Toluene was slightly more efficient than benzene at reducing the electron yield (Fig. 1).

The electron yield was reduced somewhat more easily in ethanol than in methanol (compare Figs. 1 and 2).

Measurements were made for benzene and toluene in each alcohol. To prevent congestion, the points for only one or the other of the scavengers are shown for ethanol, 1-propanol, 2-propanol, 1-butanol, and 2-butanol (Figs. 2–6). The efficiency of scavenging electrons prior to their solvation changes relatively little from one alcohol to another, by comparison with the large changes in efficiency of reaction after solation (Table 1).

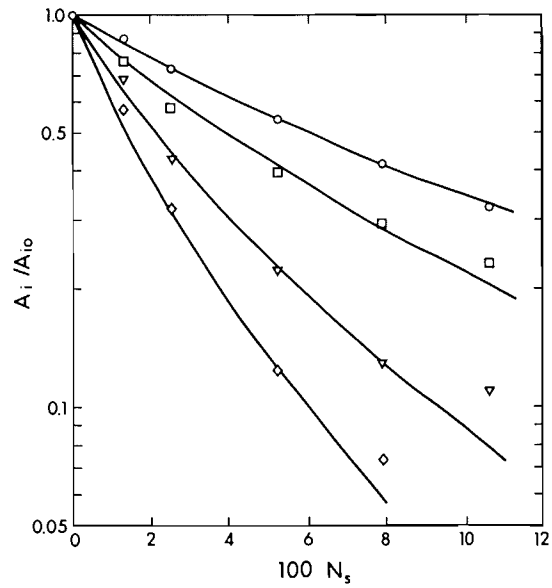

FIG. 2. Effect of benzene on the initial absorbance of solvated electrons after a 100 ns pulse of radiation in ethanol. N_s is the mol fraction of benzene. ○, 298 K; □, 243 K; ▽, 213 K; ◇, 183 K. The curves were calculated from eq. [4] using parameter values from Table 2.

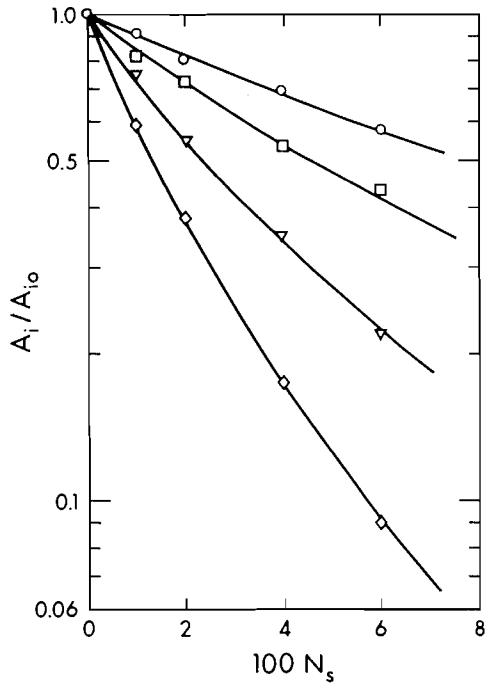

FIG. 3. Effect of toluene on the initial absorbance of solvated electrons after a 100 ns pulse of radiation in 1-propanol. N_s is the mole fraction of toluene. ○, 299 K; □, 243 K; ▽, 213 K; ◇, 183 K. The curves were calculated from eq. [4] using parameter values from Table 2.

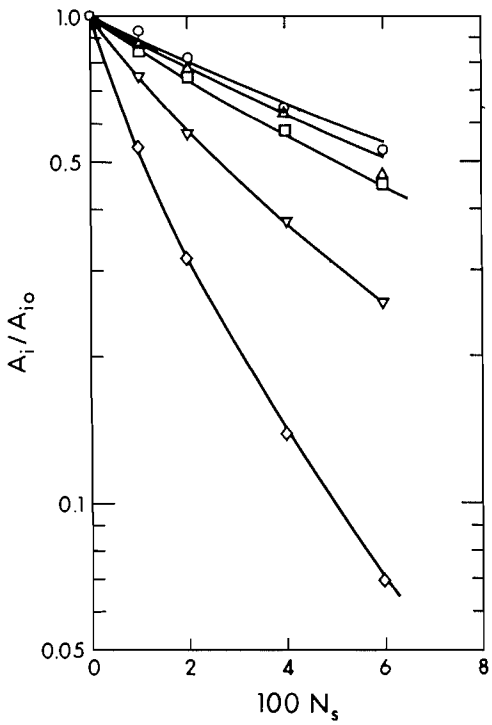

FIG. 4. Effect of toluene on the initial absorbance of solvated electrons after a 100 ns pulse of radiation in 2-propanol. N_s is the mole fraction of toluene. ○, 299 K; △, 273 K; □, 248 K; ▽, 218 K; ◇, 188 K.

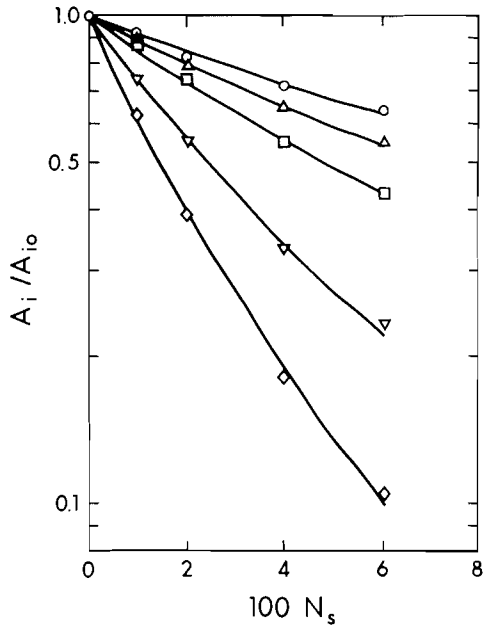

FIG. 5. Effect of toluene on the initial absorbance of solvated electrons after a 100 ns pulse of radiation in 1-butanol. N_s is the mole fraction of toluene. ○, 299 K; △, 273 K; □, 248 K; ▽, 218 K; ◇, 188 K.

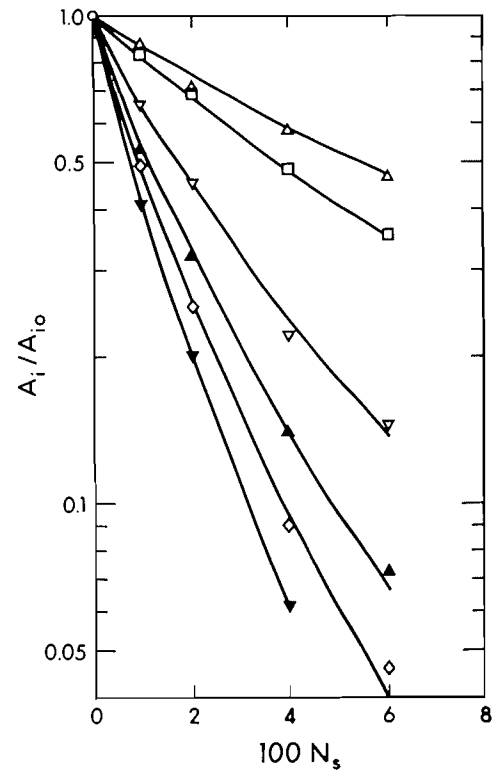

FIG. 6. Effect of benzene on the initial absorbance of solvated electrons after a 100 ns pulse of radiation in 2-butanol. N_s is the mol fraction of benzene. △, 273 K; □, 243 K; ▽, 213 K; ▲, 198 K; ◇, 183 K; ▼, 163 K. The curves were calculated from eq. [4] using parameter values from Table 2.

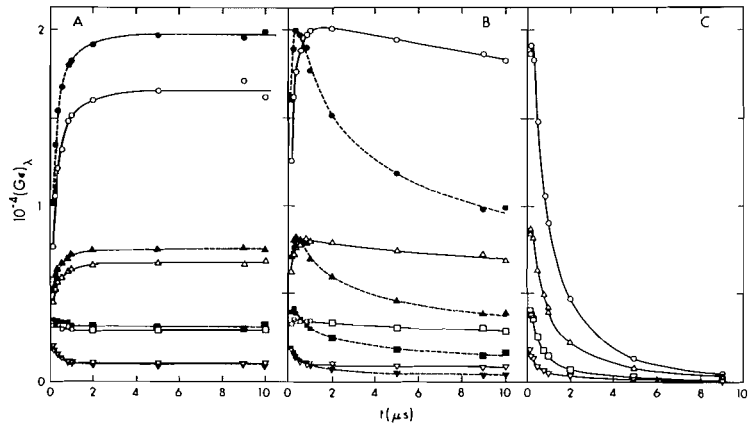

FIG. 7. Optical absorption, plotted as $(G\varepsilon)_\lambda$, as a function of time at different wavelengths and benzene concentrations (mol%) in 2-butanol at 163 K. ○, ●, 0%; △, ▲, 1.0%; □, ■, 2.0%; ▽, ▼, 4.0%. *A*: open points, $\lambda = 500$ nm; closed points, 570 nm. *B*: open, 670 nm; closed, 780 nm. *C*: 1000 nm.

Reaction Rates Measured at Different Wavelengths

At $T > 183$ K electron solvation reached the equilibrium state within the 140 ns time resolution of the measuring equipment (10). Electron reaction rates measured at $\lambda = 500$–1000 nm were therefore independent of wavelength at those temperatures. However, in 2-butanol at 163 K the solvation process was slow enough that reaction rates of electrons in different energy states could be measured.

Five experimental parameters are useful in the description of reaction rates measured at different wavelengths at constant temperature: (*a*) the product of the yield G of species that absorb at wavelength λ and the average decadic molar absorbancy ε at that wavelength, $(G\varepsilon)_\lambda$; (*b*) λ; (*c*) time, t; (*d*) solute concentration; and (*e*) A_{i}/A_{i0}. To present the required portions of this five dimensional situation we used a series of two dimensional plots.

Benzene was the solute. It will be useful to recall that the absorption maximum of the equilibrium solvated state of electrons in 2-butanol at 163 K occurs at $\lambda_{\varepsilon max}(e_{solv}^-) = 560$ nm and that this state is reached ~ 50 μs after injection of the electrons into the liquid (10). Time was measured from the beginning of the 0.10 μs pulse, because that was the only suitable anchor point at all wavelengths.

Consider first the electrons in the deeper traps, $\lambda \leq \lambda_{\varepsilon max}$. In the pure alcohol the absorbance increased by a factor of 2.1 during the period 0.14–4 μs, then remained constant for at least 45 μs (Fig. 7*A* and ref. 10). Addition of 1 mol% benzene reduced the initial absorbance at 0.14 μs to 54% of the value in pure alcohol, and the subsequent growth was only a factor of 1.5 (Fig. 7*A*). The presence of 2% benzene reduced the initial absorbance further and prevented the growth altogether; in fact, 10% decay occurred between 0.14 and 2 μs, then the signal remained constant (Fig. 7*A*). Four mol% benzene reduced the initial absorbance to 23% of that in the pure alcohol, and the signal decayed by half again during the next 2 μs (Fig. 7*A*). These results demonstrate that benzene scavenges electrons both prior to and subsequent to their forming localized states in the fluid.

At $\lambda_{\varepsilon max} < \lambda \leq 1000$ nm the absorbance first grew then decayed. The relative amount of growth decreased and the relative amount of subsequent decay over 10 μs increased with increasing wavelength (Figs. 7 *B* and *C*). The relative effects of 1–4% mol benzene were similar to those observed at $\lambda \leq \lambda_{\varepsilon max}$. The main cause of the decay at $t > 0.2$ μs at $\lambda = 1000$ nm is due to the blue shift of the absorption spectrum as the electron settles into the equilibrium solvated state (10).

Figure 8 shows the shift of the absorption band with time when different amounts of benzene were

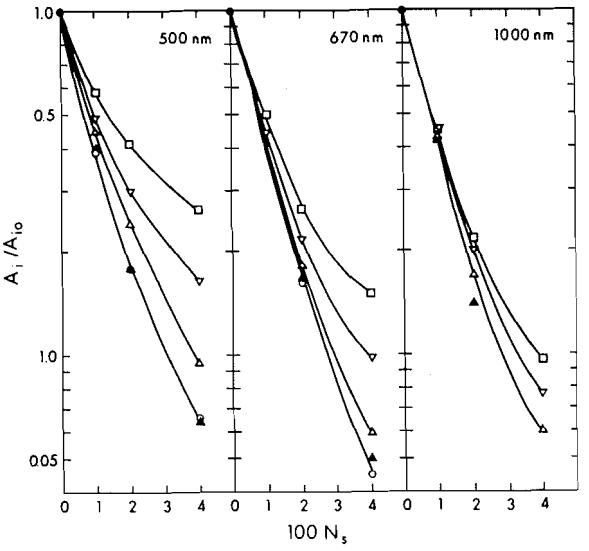

FIG. 9. Effect of benzene concentration on the fractional initial absorbance A_i/A_{io} of electrons in 2-butanol at 163 K, at different times and wavelengths. □, 0.14 μs; ▽, 0.24 μs; △, 0.54 μs; ▲, 2.0 μs; ○, 9 μs. * = △, ▲, and ○ superimpose.

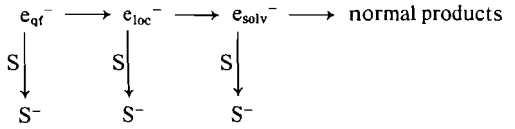
present. The curves for 0.14 μs show that scavenging at short times preferentially decreases the absorption at long wavelengths. The peak at ~950 nm is virtually destroyed by 4% benzene. However, as time progresses there is less distinction between the fractional reductions at different wavelengths (Fig. 9). At times greater than or equal to that required for electrons to reach their equilibrium solvated state, the fractional decrease of absorbance caused by a scavenger is independent of wavelength. In 2-butanol at 163 K this would be $t \geq 50$ μs (10).

Discussion

Scavenging of Electrons Prior to their Solvation

The electrons under consideration are not in thermal equilibrium with the medium. For this reason the usual chemical concept of a rate constant does not apply to their reactions, although as we shall show later, equations that have approximately the correct form can be derived from a rate constant approach. The problem is one of nonhomogeneous kinetics and can be handled by a stochastic model (16, 17, 21, 22). Unfortunately, the language and formalism of statistics do not appeal to one's sense of beauty in simplicity, so simpler versions have been used (13, 15, 23).

As an electron is being de-energized by collisions in the liquid, it becomes scavengeable after the energy has been decreased below some value of the order of 1 eV. The specific upper threshold value depends upon the scavenger. In general, scavenging is possible during the last train of collisions that the quasifree electron undergoes prior to localization. Reaction may also occur if the initial localization site contains a scavenger molecule. In liquids that can form deep traps, electrons that are initially in shallow traps might migrate and react before settling into the equilibrium solvated state. The probability of reaction per encounter depends upon the energy of the encounter pair. However, the energy dependences of the encounter efficiencies f_{qf} and f_{loc} are not known, so average values are used as adjustable parameters. The subscripts qf and loc refer to quasifree[2] and localized electrons, respectively.



The ratio A_i/A_{io} expresses the fraction of electrons that have not been scavenged up to the time represented by i. For the quasifree regime, P represents the average probability that an electron does not become localized at a given collision and $(1 - f_{qf}N_s)$ is the average probability per collision that it does not react with scavenger which is present at mol fraction N_s. The fraction of electrons that survive the quasifree period is therefore:

$$[1] \quad (A_i/A_{i0})_{qf} = \sum_{m=1}^{\infty} (1 - P)[P(1 - f_{qf}N_s)]^{m-1}$$

where the summation index m represents the number of collisions. Upon inversion eq. [1] reduces to (24):

$$[2] \qquad (A_{i0}/A_i)_{qf} \approx 1 + \left(\frac{P}{1 - P}\right) f_{qf}N_s$$

Equation [2] is only an approximation because P and f_{qf} are not constants, but we approximate them by average values.

After localization there is a further probability that the electron will be scavenged prior to reaching the equilibrium solvated state. This process involves the probability that the initial localization site includes a scavenger molecule, and the probability that the electron migrates or tunnels to a scavenger during the time between localization and equilibration with the medium. We now speak of the probability f_{loc} of reaction per encounter, rather than per collision, because a localized electron has an extended interaction with each of the molecules in its localization site. The localized → solvated time regime also involves a series of electron energies and correspond-

[2]The term quasifree is not restricted to thermal electrons, but simply implies that the electron is not localized and is not in free space.

For personal use only.

ingly varying numbers n of encounters and values of f_{loc}; we again use averages. The probability that localized electrons survive unscavenged to reach the solvated state is:

$$[3] \quad (A_i/A_{i0})_{loc} \approx (1 - f_{loc}N_s)^n \approx \exp(-nf_{loc}N_s), \quad \text{when } 1 \gg f_{loc}N_s$$

The total probability that electrons survive both periods is given by [4]:

$$[4] \quad \frac{A_i}{A_{i0}} \approx (1 - f_{loc}N_s)^n \Big/ \left[1 + \left(\frac{P}{1-P}\right) f_{qf}N_s\right] \approx \exp(-nf_{loc}N_s) \Big/ \left[1 + \left(\frac{P}{1-P}\right) f_{qf}N_s\right]$$

Experimentally, $fN_s \ll 1$, under which circumstances many mathematical functions are approximately equivalent to [2], [3], or [4].[3] Furthermore, depending on the scavenger and solvent, either the [2] or [3] portion may dominate in [4]. For this reason different authors have arrived at various expressions that are all approximations of [4], for example, eq. [5] in ref. 13, [5] and [6] in ref. 14, [7], [9], and [10] in ref. 15, [2] in ref. 23, [4] in ref. 25, [3] in ref. 26, [8] in ref. 27, and the equation in ref. 28. The integral form of [1] (16, 17) leads to

$$[5] \quad A_i/A_{i0} \approx (1 - f_{loc}N_s)^n \ln P / \ln [P(1 - f_{qf}N_s)]$$

which is equivalent to [4] in that the values of P and $(1 - f_{qf}N_s)$ are each only slightly less than unity, in which case $\ln x \approx x - 1$.

Equation [4] was fitted to the scavenging data, examples of which are shown in Figs. 1–6. Equations [2] and [3] are limiting cases of [4] and under most conditions were not valid. However, for benzene in 2-butanol at 163 K, 0.14 μs and $\lambda < 600$ nm eq. [2] is a good approximation (Fig. 10). Recall that $\lambda_{emax} = 560$ nm for the equilibrium solvated state under these conditions, and migration from states at $\lambda \leq \lambda_{emax}(e_{solv}^-)$ is negligible at very short times. This is as close as we have been able to come to the isolation of scavenging from the quasifree state. The slopes of the lines at 0.14 μs in Fig. 10 give $f_{qf}P/(1 - P) = 70$ at 500 nm and 97 at 570 nm. The true amount of increase of the quantity with increasing wavelength may be somewhat smaller than that indicated by the change of slope, because the factor $(1 - f_{loc}N_s)^n$ might make a more significant contribution at the longer wavelength. Both values are actually upper limits. The upward curvature at $\lambda > 600$ nm indicates an increasing contribution of

[3]For example, eq. [5] in ref. 13, [6] in ref. 14, [7] in ref. 15, [14] in ref. 16, [4] in ref. 17, [2] in ref. 23, [4] in ref. 25, [8] in ref. 27 and the equation in ref. 28.

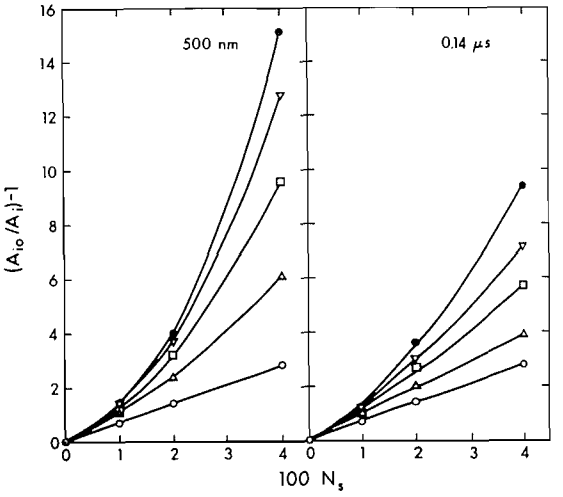

FIG. 10. Results for benzene in 2-butanol at 163 K plotted according to eq. [2]. At 500 nm: ○, 0.14 μs; △, 0.24 μs; □, 0.54 μs; ▽, 0.84 μs; 0.84 μs; ●, 45 μs. At 0.14 μs: ○, 500 nm; △, 570 nm; □, 670 nm; ▽, 780 nm; ●, 1000 nm.

the latter factor with increasing wavelength at short times (Fig. 10, 0.14 μs). This factor also becomes more important at longer times (Fig. 10, 500 nm, increasing curvature with time).

The value of the factor $(1 - f_{loc}N_s)^n \approx \exp(-nf_{loc}N_s)$, and hence of nf_{loc}, can be estimated from the data in 2-butanol at 163 K by plotting $\log[(A_i/A_{i0})_t/(A_i/A_{i0})_{0.14\ \mu s}]$ against N_s for $\lambda < 600$ nm. This is equivalent to dividing eq. [4] by [1]. Such plots for different times t are shown in Fig. 11. The values of nf_{loc} obtained in this way are lower limits, because $(A_i/A_{i0})_{0.14\ \mu s}$ gives an upper limit for eq. [1]. The value of nf_{loc} increases with time, due to electron diffusion and tunneling, reaching ~35 at 5 μs (Fig. 11). By this time relaxation towards the solvated state is well advanced, with decay of the infrared band virtually complete (Fig. 8). However, shifting of the red side of the band in the visible continues for ≥45 μs (10), with negligible further scavenging by benzene. This early scavenging apparently occurs from the infrared band, but not from the band in the visible. The value of f_{loc} would decrease with increasing electron trap depth, and nf_{loc} is negligible for electrons in the visible band. The decrease in the absorption ratio at 500 nm caused by benzene (Fig. 11) was caused by prevention of growth, that is, by capture of electrons as they moved from the shallow traps of the infrared band towards the deeper traps of the band in the visible.

Solvated electrons in liquid ammonia absorb in the infrared and have been reported to have a "solvation number" of 30 ± 10 molecules (29). One wonders whether the value $nf_{loc} \approx 35$ for electrons

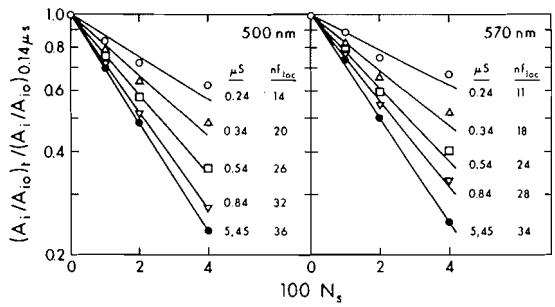

FIG. 11. Plots of log $[(A_i/A_{i0})_i/(A_i/A_{i0})_{0.14\ \mu s}]$ against N_s for benzene in 2-butanol at 163 K. The times and wavelengths at which the A values were determined are indicated in the figure, along with the values of nf_{loc} devised from the slopes.

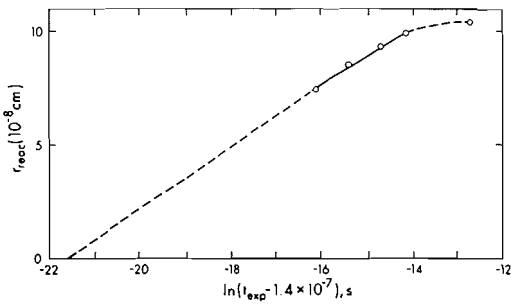

FIG. 12. Plot of the effective reaction radius of the localized electrons as a function of time. See text.

in the infrared band in 2-butanol is related to the "solvation number".

The value of nf_{loc} can be converted to an effective reaction radius, and its time dependence can be compared with that in a tunneling model. A_i/A_{i0} may be interpreted as the probability that there is no scavenger molecule within the effective reaction radius r_{reac} of an electron, that is, within the effective reaction volume $\frac{4}{3}\pi r_{reac}^3$. Using a stochastic approach one may write:

$$[6] \qquad A_i/A_{i0} = (1 - \tfrac{4}{3}\pi r_{reac}^3)^{n_s}$$

where n_s is the number of scavenger molecules/cm^3. Since $1 \gg \frac{4}{3}\pi r_{reac}^3$, [6] is equivalent to [7].

$$[7] \qquad A_i/A_{i0} = \exp(-\tfrac{4}{3}\pi r_{reac}^3 n_s)$$

Comparing [3] with [7] we obtain

$$[8] \qquad nf_{loc}N_s = \tfrac{4}{3}\pi r_{reac}^3 N_A N_s/\bar{V}$$

where N_A is Avogadro's number and $\bar{V}$ is the molar volume (81 cm^3 for 2-butanol at 163 K). Hence,

$$[9] \qquad r_{reac} = 3.2 \times 10^{-8}(nf_{loc})^{1/3}$$

Using a one-dimensional tunneling model and matched energy states on the two sides of the barrier, and equating r_{reac} to the tunneling range, a value for the tunneling barrier height $(V_0 - E_0)$ can be estimated from eq. [10] (25, 30).

$$[10] \quad r_{reac} = \left[\ln t + \ln\left(\nu \frac{16E_0(V_0 - E_0)}{V_0^2}\right)\right] \times \frac{\hbar}{2[2m(V_0 - E_0)]^{1/2}} = \frac{1.23 \times 10^{-14}}{(V_0 - E_0)^{1/2}} \times \left[\ln t + \ln\left(\nu \frac{16E_0(V_0 - E_0)}{V_0^2}\right)\right]$$

where ν is the frequency factor, V_0 (ergs) is the depth of the potential well, E_0 is the kinetic energy of the localized electron, and m is the electron mass.

The values of nf_{loc} were measured from the experimental time 0.14 μs, so the t in eq. [10] is $(t_{exp} - 1.4 \times 10^{-7})$ s. The plot of r_{reac} against ln $(t_{exp} - 1.4 \times 10^{-7})$ in Fig. 12 gives $(V_0 - E_0) \approx 8 \times 10^{-13}$ erg, or 0.5 eV. Taking $V_0 \approx 1$ eV, a long and uncertain extrapolation to $r_{reac} = 0$ in Fig. 12 gives $\nu \approx 6 \times 10^8\ s^{-1}$. A normal frequency factor for the electron might be expected to have a value similar to $E_0/\hbar$, which is $\sim 10^{15}\ s^{-1}$. However, the net rate of tunneling is greatly affected by the degree of mismatch of the energies and densities of states on the two sides of the barrier, and by the rate of removal of electron density from the product side. The latter corresponds to the rate of relaxation of the initial product state by way of physical and chemical processes. The efficiency factor $F = \nu/10^{15}$ (26) indicates the importance of state mismatch and relaxation in limiting the rate. For the present reaction of the infrared-absorbing electrons with benzene in 2-butanol at 163 K $F = 10^{-6}$. The value of F depends on the electron state and the solute, and on factors which affect them, such as the solvent, temperature, and time. In aqueous 6 M sodium hydroxide glass at 77 K, using measurements over the range 10^{-6}–10^2 s, estimated values of F range from 10^4 to 10^{-15} (26). The tunneling factor F is analogous to the stochastic factors f_{loc} and f_{qf}.

The curve in Fig. 12 reaches an upper limit because the time available for reaction is limited by the lifetime of the infrared (shallow trap) state. Relaxation of the electron state increases the barrier $(V_0 - E_0)$ and thereby restricts the growth of r_{reac}.

It is worthwhile to remember that the final electron transfer step to a reactant can always be considered to occur by tunneling. In fluids both diffusion and tunneling contribute to nf_{loc} and both display the same type of kinetics. When the electron and molecule diffusion coefficients are negligible, as in rigid, alkaline glasses at 77 K, tunneling may dominate.

[a]Fraction scavenged from the qf state ÷ fraction scavenged from the loc state when $N_s = 0.01$.

We cannot estimate the relative contributions of the two mechanisms in the present work.

At higher temperatures in 2-butanol and at all temperatures in the other alcohols, the relaxation processes were so fast that the scavenging of quasifree and localized electrons could not be measured separately. We therefore fitted eq. [4] to the results by using two adjustable parameters, $[f_{qf}P/(1-P)]$ and $[nf_{loc}]$. The values of the parameters increased to similar extents with decreasing temperature. Possible differences in the temperature coefficients were hidden by the experimental scatter. To permit an orderly analysis of the results it was assumed that the temperature coefficients of the two parameters were equal, although it is improbable that this is exactly true. The values obtained for benzene and toluene in each of the alcohols are listed in Table 2.

The relative contributions of scavenging from the quasifree and localized states, S_{qf}/S_{loc}, can be compared at different temperatures and scavenger concentrations.

$$[11] \quad S_{qf}/S_{loc} = \left(1 + \frac{1-P}{Pf_{qf}N_s}\right)^{-1} \times [1 - \exp(-nf_{loc}N_s)]^{-1}$$

Benzene and toluene scavenge quasifree more readily than localized electrons. The value of this ratio at 1 mol% benzene is 2–3 in each of the alcohols at 299 K and decreases gently with temperature (Table 2). The ratio is usually slightly larger for toluene than for benzene (Table 2). Scavenging of the localized state increases in importance with increasing scavenger concentration. For example, benzene in 2-butanol at 163 K gives $S_{qf}/S_{loc} = 1.4$ at 1 mol% and 1.0 at 4%.

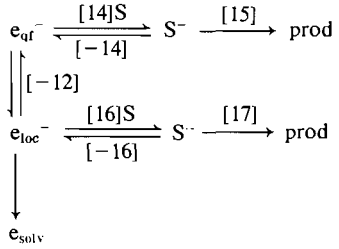
The observed effects of temperature and concentration on the value of the ratio are in the expected direction.

Temperature Coefficients of Scavenging Prior to Solvation

The parameters $f_{qf}P/(1-P)$ and nf_{loc} each vary

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

approximately as T^{-4}, which is equivalent to an Arrhenius temperature coefficient of about −8 kJ/mol. Arrhenius plots of the data in Table 2 are slightly concave towards the T^{-1} axis, and they are more so when T^{-1} is replaced by $(T - T_\infty)^{-1}$ (31, 32). The temperature dependences are similar in all the alcohols, and for both benzene and toluene. The negative values reflect differences in the following sequences:[4]



where prod may be a stabilized anion or the product of a further reaction such as protonation.

The similarity of the temperature coefficients of scavenging e_{qf}^- and e_{loc}^- reflects a similarity in the competitive sequences [12] against [14], [15]; and [13] against [16], [17]. Scavenging is more efficient at low temperatures, which seems to imply that: (*a*) [15] and [17] are less important than [14] and [16] in setting the temperature dependence; and (*b*) $E_{12} - E_{14} \approx E_{13} - E_{16} \approx 8$ kJ/mol. Extrapolation of data in ref. 10 indicates that $E_{13} \approx 15$ kJ/mol in this temperature region, so E_{16} is positive. The value $E_{12} - E_{14} \approx 8$ kJ/mol could be explained by a positive E_{12} or a negative E_{14}. The localization sites involved in [12] are potential fluctuations created by irregular molecular orientations that occur naturally in the liquid. A positive temperature coefficient of [12] could refer to the inelastic scattering cross section that de-energizes the electron into the localized state; the cross section might depend on the ease of molecular motion, reflected by τ_2 or τ_3 (33). A negative value of E_{14} would be attributed to the greater stability of the aromatic anion at low temperatures (34).

The reaction rates of solvated electrons with benzene and toluene vary much more from solvent to solvent and with temperature than do those of e_{qf}^- and e_{loc}^- (Tables 1 and 2). This is attributable to the lower energy state of e_{solv}^-.

[4]This reaction scheme is adequate when measurements are confined to the absorbances of e_{loc}^- and e_{solv}^-. If S^- or prod were also measured, it would be necessary to include steps for the reaction of e_{qf}^- and e_{loc}^- with geminate ions and radicals, because not all of the e_{qf}^- ultimately become e_{solv}^- in the irradiated pure solvent (10, 14).

Comparison with Homogeneous Kinetics

Part of the reaction scheme in the previous section can be treated by homogeneous kinetics to give an equation equivalent to [2] (14). Considering only reactions [12] and [14] one may write

$$[18] \qquad A_{i0}/A_i \approx 1 + (k_{14}[S]/k_{12})$$

where $k_{12} = k_{12}'[\text{trap}]$. The trap concentration is characteristic of the solvent at a given temperature and pressure, and is assumed to be independent of solute concentration in dilute solutions. Equation [18] is equivalent to [2], with $10^3 k_{14}/k_{12}\overline{V} = f_{qf}P/(1 - P)$ when [S] is in mol/ℓ.

However, eqs. [3] and [4] cannot be obtained by homogeneous kinetics.

Gas phase ion–molecule reactions of dimethylsulphoxide

JOHN EDWARD FULFORD, JOSEPH WAYNE DUPUIS, AND RAYMOND EVANS MARCH

Department of Chemistry, Trent University, Peterborough, Ont., Canada K9J 7B8

Received December 3, 1976[1]

JOHN EDWARD FULFORD, JOSEPH WAYNE DUPUIS, and RAYMOND EVANS MARCH. Can. J. Chem. **56**, 2324 (1978).

The gas phase ion-chemistry of dimethylsulphoxide (DMSO) and deuterated dimethylsulphoxide (DMSO-d_6) has been examined using a quadrupole ion store (QUISTOR) as an ion–molecule reaction chamber. The QUISTOR results are compared with those obtained by ion trapping and high pressure mass spectrometry as reported by other workers. The performance of the QUISTOR demonstrates the versatility of the technique for ion–molecule reaction studies with variation of ambient pressure and duration of ion storage.

JOHN EDWARD FULFORD, JOSEPH WAYNE DUPUIS et RAYMOND EVANS MARCH. Can. J. Chem. **56**, 2324 (1978).

On a étudié, faisant appel à un réservoire d'ions quadrupolaires (QUISTOR) sous forme de chambre de réaction ion–molécule, la chimie ionique en phase gazeuse du diméthylsulphoxyde (DMSO) et du diméthylsulphoxyde deutéré (DMSO-d_6). On compare les résultats QUISTOR avec ceux obtenus par spectrométrie de masse avec piégeage ionique et à haute pression tels que rapportés par d'autres auteurs. Le bon succès de QUISTOR démontre la versatilité de la technique pour des études de réactions ion–molécule avec variation de la pression ambiante et de la durée de l'entreposage des ions.

[Traduit par le journal]

Introduction

The ion-chemistry described here has been observed with a novel system in which ions may be created and stored in a three-dimensional quadrupole ion store QUISTOR (1) and mass analysed by subsequent ejection into a quadrupole mass filter. When the QUISTOR is used as a storage device and reactor for the study of chemical processes (e.g. ion–molecule and charge transfer reactions) a knowledge of ion energies is essential.

In consideration of ion kinetic energies within the QUISTOR, a distinction must be made between primary ions which are formed initially by electron impact throughout the effective reactor volume and secondary ions formed in subsequent ion–molecule reactions. Attempts have been made to calculate primary ion kinetic energies in collision-free systems (2–4) and secondary ion kinetic energies pertaining after several collisions (5–7). There is good agreement among the estimates of mean primary ion energies in a collision-free system. Recent simulation studies (7) indicate that although a fraction of secondary ions may have several eV of kinetic energy, rapid energy dissipation is effected in the first 6–10 collisions so that after 15 collisions the mean ion energy is <1 eV. A brief account is given below of the examinations of several well characterized chemical systems by quadrupole ion storage mass spectrometry which were carried out in order to ascertain effective ion energies in the QUISTOR.

The ammonia system has been investigated with this technique (8) as a means of estimating the primary ion mean kinetic energies. The experimentally determined rate constants of the principal ion–molecule reactions occurring in ammonia were compared with literature values: from this comparison it was concluded that the primary ion kinetic energies are of the order of 1–3 eV.

The thermal energy reactions of methane have been studied extensively; more than twenty references are cited by Henchman (9) for the production of CH_5^+ which is an agent for chemical ionization. The occurrence of endothermic reactions requiring a primary ion kinetic energy threshold of 1.5 eV for the ground state ion provides an opportunity for assessment of primary ion energies in the QUISTOR. Anders (10) had reported that the reaction producing $C_2H_3^+$ is endothermic by 1.6 eV which is in good agreement with the observations of Harrison *et al.* (11), who found that the $C_2H_3^+$ intensity exceeded that of $C_2H_5^+$ for reactant ion energies in excess of 3 eV. Clow and Futrell (12) have reported however that the $C_2H_3^+$ peak intensity was less than the $C_2H_5^+$ peak intensity for ion energies up to 10 eV. Rate constants for the methane system have been obtained with the QUISTOR (8) and are in good agreement with literature values. Comparison was made also of the ratio of $C_2H_3^+$ and $C_2H_5^+$ inten-

sities as a function of ion energy, the primary ion kinetic energy being varied within the QUISTOR by operation with rf potentials between 800 and 1600 (peak-to-peak).

The results of a QUISTOR study of the water system (8) show very good agreement with those collected by Huntress and Pinnizzotto (13). Comparison of the observed ratio of 1.6 for $K_{H_3O^+}/K_{H_2O^+}$ with Ryan's tabulation (14) of this ratio against ion energy yielded a primary ion kinetic energy of between 1 and 2 eV.

The observation of CH_5^+ in the QUISTOR study of the methane system[2] indicated that chemical ionization should be realizable at extended storage times. This was demonstrated (16) with a methane–methanol (400:1) mixture at a pressure of 10^{-4} Torr. Chemical ionization in the QUISTOR has been observed in this laboratory for a number of alcohols (17), amines, mercaptans, explosives (18), and a miscellany of compounds including ketene (19).

The simulation studies mentioned earlier indicate that the kinetic energy of secondary ions is less than 1 eV. This is supported strongly by the chemical ionization observations in that little, if any, fragmentation of the protonated species occurs in near thermoneutral reactions, hence there has been no enhancement of the exothermicity of the proton transfer reaction by reactant ion kinetic energy. An example may serve to demonstrate further that energies of ions stored in the QUISTOR for periods in excess of ca. 0.5 ms are near thermal energy. The proton affinity (PA) of ketene was determined by the 'bracketing' technique wherein proton transfer equilibrium was approached from both directions. Dimethyl ether and 2-propanol were employed, wherein the proton affinities are less than and in excess of that of ketene, respectively. As our value for the PA of ketene has since been confirmed by the ICR technique (20) and as no fragmentation of the equilibrated $(M + 1)^+$ species was observed, it is concluded that the protonated species were thermalized. At long storage times, multiply-solvated protons have been observed together with dissociation products of these adducts. Consequently, it is possible to obtain information on collisional stabilization of excited addition ions and relative rates of dissociation and deactivation.

While CH_5^+ is the most widely applied chemical ionization agent and has been studied in the QUISTOR, the presence of such an agent is not necessary for the formation of protonated parent molecules, per se. Ionic species of this type are produced in ion confinement devices by auto-chemical ionization through mechanisms which involve the reaction of parent molecules with primary ions formed initially by electron impact. Thus the ion-chemistry of a given compound may be described in terms of the concurrent mechanisms of this type.

Previous workers have shown that the ion-chemistry of simple aliphatic alcohols (21) is characterized by associative complexes leading to the formation of solvated protons and multiply-solvated protons. In the aliphatic alcohols, dissociation of the complex may result in the elimination of water or alkene. This mode of reaction requires an electronegative atom (oxygen) to which is attached a labile hydrogen atom. Recent reports on the ion-chemistry of sulphur (H_2S, CH_3SH, $(CH_3)_2S$ (21) and CH_3SH, CD_3SH (23, 24)) and nitrogen (25–27) analogues show that similar reactions, at least in part, occur in these systems also.

The basic features of the quadrupole ion storage technique are virtually identical with those of the ICR ion trapping technique and the data reported here are similar to those obtained with ICR ion trapping devices. The basic difference arises in the mode of trapping, as Lawson and Todd (28) have explained: in the QUISTOR, a net restoring force experienced by the ions attracts them to the centre of the device due to their motion in the inhomogeneous oscillating electric fields, while in the ICR cell, confinement occurs through the combination of a magnetic field with an inhomogeneous static electric field. In both techniques the space charge potential within the ion cloud determines the maximum density of trapped ions, and this appears to be some two or three orders of magnitude greater in the QUISTOR.

The data reported here are similar also to those obtained from high pressure mass spectrometry but extended to a much longer time scale. It is customary in presenting high pressure mass spectrometry data to display plots of ion intensities as a function of pressure and from such plots conclusions are drawn concerning ion–molecule mechanisms. These conclusions are based on observations of the decay of primary ion intensities as a function of pressure and the concurrent appearance of secondary and higher order ions. Similar conclusions may be drawn from plots of ion intensities as a function of time at a fixed pressure in ion trapping devices such as are used in ICR mass spectrometry (29), beam trapping (24), and QUISTOR studies (8). Furthermore, the temporal dependences of ion intensities obtained with ion confinement techniques may be observed over a range of pressures. Brupbacher *et al.* (25)

[2]A similar observation has been made recently with a cylindrical device (15).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

have shown that as a result of ionization of a substrate material, R, several different primary ions, P_i^+ and neutrals, N_i, may result from the process

$$R \xrightarrow{e^-} \sum_{i=1}^{n} P_i^+ + \sum_{i=1}^{n} N_i$$

Once formed, each of these primary ions may undergo ion–molecule reactions with the substrate. The reactions of one particular primary ion can be summarized as follows:

$$\begin{aligned} P_i^+ + R &\xrightarrow{k_1} S_1^+ + N_1 \\ P_i^+ + R &\xrightarrow{k_2} S_2^+ + N_2 \\ &\vdots \\ P_i^+ + R &\xrightarrow{k_L} S_L^+ + N_L \end{aligned}$$

where S_i^+ represents the various secondary ions formed. For this reaction scheme, the rate of loss of a specific primary ion, P_i^+, is given by

$$[1] \qquad d[P_i^+]/dt = -[R][P_i^+] \sum_{j=1}^{L} k_j$$

where $\sum_{j=1}^{L} k_j$ represents the total rate constant, k_T, for the loss of P_i^+ by reaction with R. Integration of eq. [1] over reaction time, t, gives the expression

$$[2] \qquad \ln \frac{[P_i^+]_t}{[P_i^+]_0} = -k_T[R]t$$

which describes the real kinetic surface for the reaction of P_i^+ with substrate R. High pressure mass spectrometry data yield ion intensity vs. pressure profiles of the kinetic surface for a given reaction time, while ion trapping data yield ion intensity vs. time profiles of the surface for a given pressure.

In the identification of a chemical system, on which the application of quadrupole ion storage devices for the study of ion-chemistry may be demonstrated, the following factors were considered: (*i*) As the identification of ions is facilitated by comparison of the ion-chemistry of a given substance and the fully deuterated analogue, the ready availability of the compounds was essential. (*ii*) The existence of previous studies of the ion-chemistry carried out by ICR technique and high pressure mass spectrometry. (*iii*) The system should exhibit an associative ion-chemistry. (*iv*) The existence of some degree of ambiguity in the studies reported.

Thus dimethyl sulphoxide was selected for this demonstration.

Experimental

The apparatus, which is depicted schematically in Fig. 1, consists of a three-dimensional quadrupole ion store (QUISTOR) mounted in place of the ion source of a conventional quadrupole mass filter (Vacuum Generators Q7B).

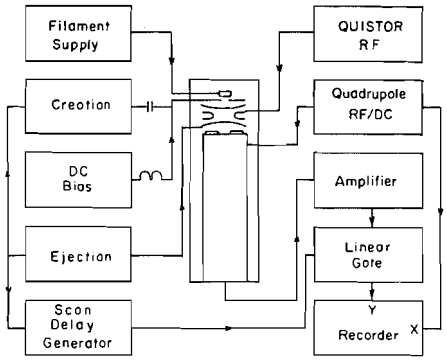

FIG. 1. Schematic diagram of apparatus.

The geometry of the QUISTOR is that of a hyperboloid of one sheet combined with a hyperboloid of two sheets forming the ring and end-cap electrodes, respectively; these are fabricated from stainless steel with $r_0 = 1$ cm and are separated by lava spacers, the whole assembly being machined and mounted with a tolerance of 0.001 in. A simple electron gun is employed comprising a spiral filament made of 0.008 in. tungsten wire and a perforated stainless steel plate, which allows the electron beam to be gated as desired. The QUISTOR/quadrupole combination is mounted vertically inside a stainless steel vacuum system, pumped by a 4-in. oil-diffusion pump, which is connected to a diffusion-pumped, unheated glass inlet system through a needle valve. An rf voltage supply, capable of providing up to 800 V at 1.6 or 2.5 MHz, is connected to the ring electrode, the end-caps being earthed except when ion ejection pulses are applied to the lower one (Fig. 1). In operation the electron gate is made a few volts more negative than the filament, so that the electron beam is turned off, and a positive pulse periodically applied to permit passage of the beam through the QUISTOR with consequent formation of ions. The ionizing beam in this work is directed along the symmetry axis of the device, rather than radially (30), since in this manner the electrons are not influenced by the rf voltage until after they have entered the device, with correspondingly better control of the electron energy. The ions, having been created inside the device, are stored under the influence of the field for a variable time before extraction by a negative pulse applied to the lower end-cap (Fig. 1) and subsequent mass analysis. This is represented in Fig. 2 which shows the typical pulse train; a trigger pulse from the internally triggered ejection generator (Hewlett Packard 214A), triggers the Boxcar Detector (Brookdeal Ortec Scan Delay Generator 9425A (SDG) and Linear Gate 9415 (LG)) and the creation pulse. The dead time is adjusted by the pulse delay circuitry of the creation generator and the storage time may be adjusted up to 100 ms by the pulse repetition control on the ejection generator.

The pulsed ion signal from the electron multiplier is passed to an amplifier which is an integral part of the quadrupole control unit, the Boxcar Detector and thence to the *Y*-drive of an *X*–*Y* recorder (Hewlett-Packard Model 7044A), the *X*-drive of which is furnished by the quadrupole control unit. The major purpose of the amplifier is to serve as an impedence matching unit between the high (ca. 100 MΩ) output impedence of the boxcar detector, although additional gain can be introduced at this point. Inclusion of the linear gate achieves two results; firstly, since it may be triggered when desired, only stored ions (i.e. those which appear coincidentally with the extraction pulse) give rise to a signal at the recorder and any ions which might appear coincident with the creation pulsed (owing to their creation in unstable positions, etc.) are ignored;

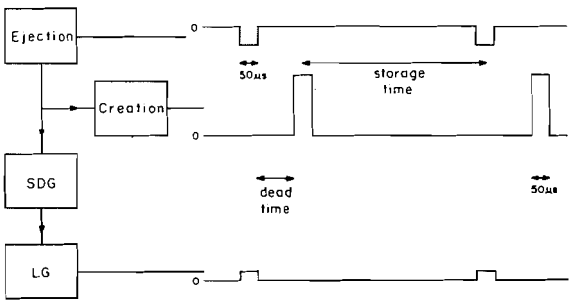

FIG. 2. Pulse train employed under typical operating conditions.

secondly the level recorded during the time that the gate is open is maintained at the output until the next pulse is due, so ensuring that any averaging effect, caused by applying a pulsed signal to the pen recorder, is avoided.

In order to study the ionic reactions occurring in a particular system, the pressure of the compound in the vacuum system is increased to ca. 10^{-4} Torr, and a series of mass spectra observed at several storage times. For each storage time the intensity of each peak is normalized by expressing it as a percentage of the total intensity for that time; this enables comparison between spectra by allowing for fluctuations in ion currents owing to ion-loss processes, etc. It must be emphasized that ion intensities have not been corrected for mass discrimination either in the QUISTOR or in the quadrupole mass filter. The QUISTOR is operated with zero dc bias on the electrodes, hence ions of all mass-to-charge ratios should be stored. Furthermore there is substantial agreement between the ion profiles observed here and those reported by Nixon *et al.* (31) after allowance has been made for the difference in operating pressures. Mass discrimination can be brought about in the QUISTOR so that the device may be operated in a mass spectrometric mode (32); mass spectrometric operation has been effected in the cylindrical storage device also (33).

Electrons with a nominal energy of 55 eV were admitted axially to the QUISTOR in pulses 50 μs wide, and ions ejected after a variable storage time by application of a pulse of −20 V magnitude to the end-cap adjacent to the quadrupole mass filter. It can be shown from the theory of operation of the QUISTOR (34, 35) that when a radio-frequency voltage only is applied to the ring electrode the *m/e* values stable within the trap are given by

$$m/e = \frac{2V_0}{q_z 4\pi^2 f^2 z_0^2}$$

where V_0 is the amplitude of the oscillating potential (radial frequency $2\pi f$ radians s^{-1}) applied between the end-cap electrodes and the ring, z_0 is half the closest distance between the end-caps, and q_z has values between 0 and 0.9. The value of f was fixed at 1.6 MHz and V_0 at 600 V. During individual experiments the source pressure was kept constant and during most experiments this pressure was 2.45×10^{-4} Torr, as measured by the M.K.S. Baratron. At constant pressure, ion–molecule reactions may be studied in the QUISTOR as a function of storage time only.

The DMSO was obtained from the Fischer Scientific Company, dried over molecular sieves, and dissolved gases were removed by freeze–pump–thaw cycles. The DMSO-d_6 was obtained from Stohler Isotope, Montreal and contained traces of mixed deuterated and hydrogenated molecules; the sample was used as obtained.

The progress of the ion–molecule reactions occurring in each sample is illustrated graphically as a plot of the logarithm

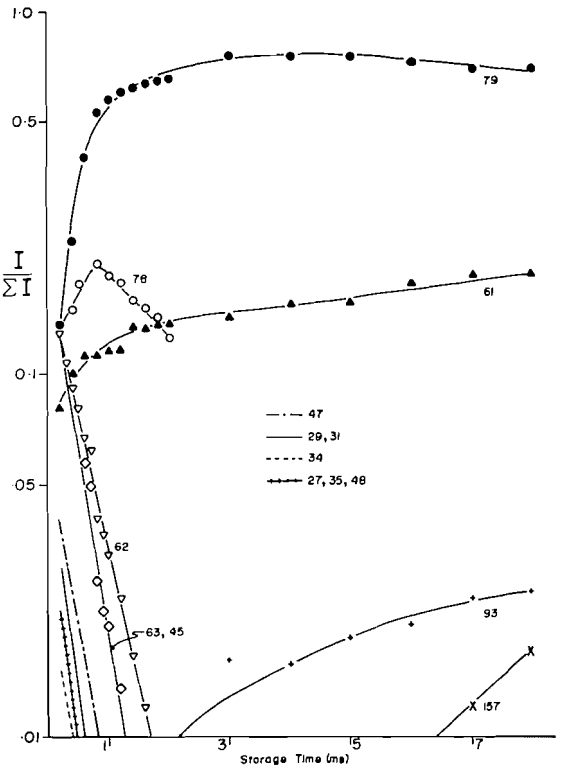

FIG. 3. Variation in the logarithm of normalized ion abundances in DMSO with storage time; 0–8 ms, 1.67 MHz, 600 V(p-p), 2.45×10^{-4} Torr.

of relative ion abundance vs. storage time for each of the reaction products. Some experimental points have been omitted to prevent confusion.

Results and Discussion

While the uses of DMSO vary widely and occur in many fields (36), there are but four studies of the gas phase ion-chemistry: Blais *et al.* (37) studied the formation of positive and negative ions in DMSO; Mackenzie Peers and Muller (38) measured the disappearance rate constants of some primary ions in DMSO; more recently, McAllister (39) and Nixon *et al.* (31) have reported on ICR studies of DMSO.

The DMSO mass spectrum obtained under conditions of continuous ionization and zero storage is in excellent agreement with the electron impact mass spectrum at 10^{-5} Torr reported earlier (37). The ion profiles for DMSO are shown in Fig. 3 for the storage time range 0.2–8 ms, and in Fig. 4 for 0.2–70 ms. Ions of *m/e* 12, 13, 14, 15, 16, 17, 18, 26, 28, 32, 33, and 46 which are not shown in Fig. 3 and Fig. 4 reacted completely in less than 400 μs by charge or proton exchange reactions to produce the parent (M^+) or protonated parent ($(M + 1)^+$) ions. The rapid relative increase in M^+ (*m/e* 78) and $(M + 1)^+$ (*m/e* 79) is shown in Fig. 3. Other fragment or pri-

mary ions of *m/e* 27, 29, 31, 34, 35, 45, 47, 62, and 63 react more slowly as shown in Fig. 3 and involve proton or charge exchange with parent molecules. The ion-chemistry of a given compound is characterized by the reactivity, with parent molecules, of secondary ions and those primary ions which show an increase in relative concentration due to ion–molecule reactions. In DMSO, the ion-chemistry determining ions are of *m/e* 61, 63, 78, 79, 93, 139, 141, and 157.

The *m/e* 61 ion, which is predominantly $C_2H_5S^+$ (31, 37), was observed to become one of the more abundant species at the longest storage time used in this study, and the observation of *m/e* 66 in DMSO-d_6 supports the assignment of Table 1. In the sole reference to the role of *m/e* 61 (39) it is indicated, from ICR double resonance experiments, that *m/e* 61 is a product ion from a reaction of *m/e* 78.

In this study, growth of the parent ion (*m/e* 78) during the initial 800 μs of storage time was due to charge exchange from fragment ions. Reactions of the parent ion during the subsequent 2 ms (i.e. until the ion intensity could no longer be determined with precision due to the intensity increase of *m/e* 79) are given in Table 2.

The mechanisms for the formation of the $(M + 1)^+$ ion, of *m/e* 79, have been proposed on the basis of ICR double resonance experiments (31, 39) or appearance potential measurements (37). Observation of the $(M + 15)^+$ ion of *m/e* 93 is of interest in this system. It is produced by methyl cation transfer from parent ions (37, 39), a reaction which is not observed in acetone. The *m/e* 102 ion was observed in DMSO-d_6. No reactions have been proposed for *m/e* 93, $[(CH_3)_3SO]^+$, which persists at long storage time and it is concluded from a comparison with the persistence of $(CH_3)_3O^+$ and $(C_2H_5)_3O^+$ (26) that it is a stable and unreactive ion.

In the four studies reported on DMSO, Mackenzie Peers and Muller (38) observe only the disappearance of reacting ions of *m/e* 78 and below without specifying products; Blais *et al.* (37) observe only those reactions which produce ions of *m/e* greater than 78; in the concurrent ICR studies, McAllister (39) reports on double resonance experiments and gives three mass spectra, while Nixon *et al.* (31) report on double resonance experiments, give an ion profile at unspecified pressure, a mass spectrum at unspecified time, and some rate data. Within the four studies the principal inconsistency arises from the observations of high *m/e* ions.

The *m/e* 139 ion, $(M + 61)^+$, was reported by Blais *et al.* (37) and was observed in this work but was not observed in either of the ICR studies. The appearance potential method (37) indicated the formation of *m/e* 139 from parent ion. However, in

*Not observed in this work.

this study, the initial appearance of the *m/e* 139 ion is coincident with the maximum intensity of the *m/e* 61 ion. The ion profiles suggest that in a high pressure domain the *m/e* 139 ion may arise as a collisionally stabilized product of an associative reaction of *m/e* 61 with parent molecule. Blais *et al.* (37) found that the ion intensity of the *m/e* 139 ion could be due to $C_4H_{11}S_2O^+$ and $C_3H_7S_2O_2{}^+$. From a comparison of the experimental and theoretical ratios for the *m/e* 139 to *m/e* 140 peaks they concluded that the ion must be $C_3H_7S_2O_2{}^+$. However in this study, the observation of the *m/e* 150 ion in DMSO-d_6 indicates that the ion is $C_4H_{11}S_2O^{+\cdot}$. As mentioned previously, there is little commentary on the *m/e* 61 ion in the ICR studies.

By way of compensation, the *m/e* 141 ion $(M + 63)^+$ was observed only in the ICR studies and was confirmed (39) by adding xenon with isotopes *m/e* 129–136 for mass calibration.

Double resonance experiments indicated that *m/e* 141 is a product of a reaction involving parent ions

$$[3]\quad \underset{m/e\ 78}{[(CH_3)_2SO]^{+\cdot}} + (CH_3)_2SO \rightarrow \underset{m/e\ 141}{[(CH_3)_2SOCH_3SO]^+} + CH_3\cdot$$

and reacts to form protonated dimer

$$[4]\quad \underset{m/e\ 141}{[(CH_3)_2SOCH_3SO]^+} + (CH_3)_2SO \rightarrow \underset{m/e\ 157}{[((CH_3)_2SO)_2H]^+} + CH_2SO$$

As an unsuccessful search for *m/e* 141 was made in this study, it is suggested that reaction [4] may be endothermic for thermal ions. The explanations offered for the above inconsistencies are not incompatible with a consideration of the operative conditions pertinent to each technique.

The observation of the *m/e* 155 ion (37) has not been confirmed in any subsequent study. The proton bound dimer, *m/e* 157 was observed in the ICR studies and in this study, and is the dominant ion at long storage times. Double resonance experiments indicated that it was a product of reactions involving *m/e* 78 and *m/e* 79. Pressure variation in the QUISTOR indicated unit increase in the order of reaction with respect to DMSO concentration for *m/e* 157 relative to *m/e* 79.

Conclusion

The ion-chemistry of DMSO is understood to be characterized by rapid simple proton transfer and by other processes which are relatively slow. At long reaction times, the thermodynamically favoured species appears to be the associative ion, the proton-bound dimer. While some inconsistency remains to be resolved concerning principally the ions of *m/e* 139, 141, and 155, there is considerable agreement among the results obtained by high pressure mass spectrometry, in cyclotron resonance and quadrupole ion storage techniques. The measure of agreement serves to demonstrate the applicability of quadrupole ion storage mass spectrometry to the study of ion–molecule reactions though with some reservation concerning the definition of ion energy. Previous workers (41, 42) indicate that the energy of a small fraction (<0.1%) of ions in a QUISTOR may be enhanced and open additional endothermic reaction channels.

Cadmium complexation by soil fulvic acid

BILL BRADY AND GORDON K. PAGENKOPF[1]

Department of Chemistry, Montana State University, Bozeman, MT 59717

Received February 6, 1978

BILL BRADY and GORDON K. PAGENKOPF. Can. J. Chem. **56**, 2331 (1978).

A soil fulvic acid has been characterized and the complexation stability constants with cadmium have been evaluated. The average gram formula weight of the fulvic acid is 2775. Three complexes of stoichiometry CdFA, Cd_2FA, and Cd_3FA have been observed. The respective conditional stability constants at pH 5.7 are $10^{5.3}$, $10^{9.8}$, and $10^{14.0}$; at pH 6.7 they are $10^{5.6}$, $10^{10.6}$, and $10^{15.5}$; and at pH 7.7 they are $10^{6.0}$, $10^{10.7}$, and $10^{15.4}$.

BILL BRADY et GORDON K. PAGENKOPF. Can. J. Chem. **56**, 2331 (1978).

On a caractérisé un acide fulvique provenant du sol et on a évalué ses constantes de stabilité de complexation avec le cadmium. Le poids formulaire gramme moyen de l'acide fulvique est de 2775. On a observé trois complexes de stoechiométrie CdFA, Cd_2FA et Cd_3FA. Les constantes de stabilité conditionelle respectives à un pH de 5.7 sont $10^{5.3}$, $10^{9.8}$ et $10^{14.0}$; à un pH de 6.7, elles sont $10^{5.6}$, $10^{10.6}$ et $10^{15.5}$ et à un pH de 7.7 elles sont $10^{6.0}$, $10^{10.7}$ et $10^{15.4}$.

The nature and extent of the interactions between trace metals and naturally occurring complexing ligands such as fulvic and humic acids has been and continues to be investigated by an ever-expanding number of research groups. Objectives of some of these studies focus on the role played by chelating agents in the transport of trace metals through natural water systems.

Techniques that establish the complexing capacity of natural waters include copper precipitation (1, 2), copper removal by a chelating resin (3), and oxidation of complexed cobalt(II) (4). Anodic stripping voltammetry (5, 6), differential pulse polarography (7, 8), and ion selective electrodes (9, 10), have also been utilized to determine the degree of trace metal complexation in a variety of waters.

A variety of models have been advanced to rationalize the complexation of metal ions by humic and fulvic acids (11–21). Most of these propose complexation by carboxylic acid groups, phenolic oxygen groups, or a combination similar to that observed in salicylic acid. A spatial arrangement of donors similar to that in catechol has also been suggested. Some studies have provided conditional stability constants and gram formula weights of the complexing agents (6, 10).

This report presents the characterization of a fulvic acid isolated from soil. Included in the characterization is an evaluation of average gram formula weight, pK_a's of ionizable protons, and conditional stability constants for cadmium complexation.

Experimental Section

The fulvic acid used in this study was extracted from a coastal Oregon soil provided by Dr. Jerry Simonson, Department of Plant and Soil Science, Oregon State University. Approximately 200 g of the soil were extracted with 0.1 *N* HCl for 12 h. The solution was filtered through Whatman 42 and 0.45 μm paper, and the filtrate was passed through a Dowex 50 (hydrogen form) cation exchange column. The solution was evaporated to dryness under vacuum, 15 mm. Additional drying was obtained over calcium chloride. The yield was approximately 0.5 g with a 7% ash content. The ash was found to be primarily sodium. Elemental analysis of the isolated fulvic acid provided 44.4% carbon, 4.1% hydrogen, and 45.2% oxygen.

Total acidity was determined by the barium precipitation method (22–24) and found to be 97.9 g/equiv. Carboxyl acidity was determined by the calcium acetate method (25) and found to be 142.2 g/equiv. An ebullioscopic determination using water solvent provided a g-equiv. wt. of 126.

Potentiometric titration data were obtained using 75–300 mg/l fulvic acid solutions. Volumes, ranging from 50–100 ml, were titrated using standard sodium hydroxide solutions. Ionic strength was maintained at 0.01 *M* with NaCl and the temperature was 25.0°C. The electrode system was a glass and an asbestos junction SCE coupled to a Radiometer M26 or Seargent Welch NX. Cadmium ion activity in solution was monitored by an Orion 94–48 cadmium ion selective electrode and an Orion double junction Ag/AgCl reference electrode. The titration cell was designed to permit simultaneous monitoring of hydrogen and cadmium ion activity. The concentrations of cadmium were also monitored with a Princeton Applied Research Model 374 electrochemical analyzer using hanging drop mercury electrode and anodic stripping voltammetry. Doubly-distilled water was used to prepare all solutions and inorganic salts were recrystallized to remove impurities. Computer programs COMICS (26), p-BAR (27), and pHPLOT-2 were used to facilitate data analysis.[2]

Results and Discussion

Cadmium Complexation

Fulvic acid has been titrated, at constant pH, with cadmium in an attempt to establish the stoichiometry

of the complexation reaction(s), an apparent average gram formula weight of fulvic acid, and an evaluation of the conditional stability constants. The general complexation reaction is shown in reaction [1].

[1] $$n\mathrm{Cd}^{2+} + m\mathrm{H}_y\mathrm{FA} \rightleftarrows \mathrm{Cd}_n\mathrm{H}_{y-x}\mathrm{FA}_m + mx\mathrm{H}^+$$

where H_xFA represents fulvic acid that has some unknown number of bound protons and $0 \leq x \leq 2n$. No ionic charges have been specified, however, in some cases these may be fairly high. At low concentrations of total metal and total ligand it is likely that the predominant complex will be of 1:1 stoichiometry. The specific complexation reaction is shown in reaction [2].

[2] $$\mathrm{Cd}^{2+} + \mathrm{H}_x\mathrm{FA} \rightleftarrows \mathrm{CdFA} + x\mathrm{H}^+$$

and the equilibrium expression is

[3] $$\beta_1 = \frac{[\mathrm{CdFA}][\mathrm{H}^+]^x}{[\mathrm{H}_x\mathrm{FA}][\mathrm{Cd}^{2+}]}$$

where β_1 is the stability constant. The mass balance equations are:

[4] $$[\mathrm{Cd}]_t = [\mathrm{Cd}^{2+}] + [\mathrm{CdFA}]$$

and

[5] $$[\mathrm{FA}]_t = [\mathrm{H}_x\mathrm{FA}] + [\mathrm{CdFA}]$$

Combination of eqs. [3] and [5] provides eq. [6].

[6] $$\frac{[\mathrm{FA}]_t}{[\mathrm{CdFA}]} = 1 + \frac{[\mathrm{H}^+]^x}{\beta_1[\mathrm{Cd}^{2+}]}$$

The concentration of fulvic acid is $[FA]_t$ = g FA/l/GFW where GFW is the gram formula weight of fulvic acid.

Substitution into eq. [6] gives

[7] $$\frac{\text{g FA/l}}{[\mathrm{CdFA}]} = \mathrm{GFW} + \frac{(\mathrm{GFW})[\mathrm{H}^+]^x}{\beta_1[\mathrm{Cd}^{2+}]}$$

Monitoring of a titration of fulvic acid with a cadmium ion selective electrode, at constant pH, provides the Cd^{2+} and CdFA concentrations. A plot of g FA/l/[CdFA] vs. $1/[Cd^{2+}]$ should be linear over the concentration range where only the 1:1 complex forms. Extrapolation to infinite Cd^{2+} concentration provides the average gram formula weight of fulvic acid and $\beta_1/[H^+]^x$ may be calculated from the slope. This AGFW is for complexation and may differ from values obtained by other procedures if the fulvic acid exhibits sizeable polydispersion. In addition, some FA molecules may contain no complexation sites; however, this is doubtful.

Such a plot for the titration of 12.5 mg/l at pH 6.7 is shown in Fig. 1. From the intercept GFW = 2775 and $\beta_1/[H^+]^x = 4.4 \times 10^5\ M^{-1}$.

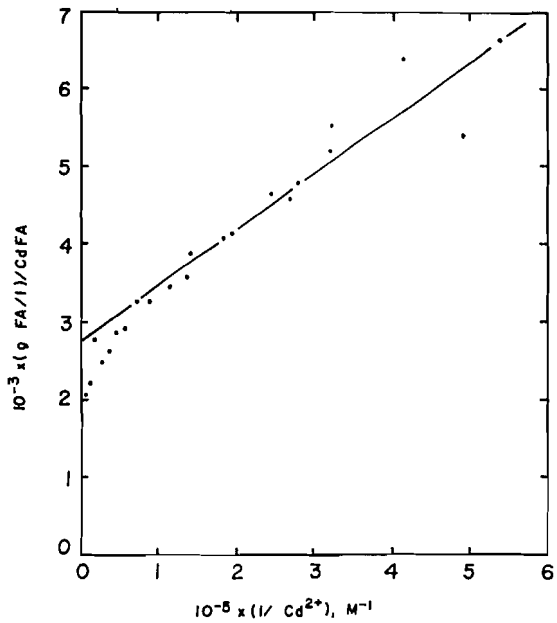

FIG. 1. Evaluation of the average gram formula weight and $\beta_1/[H^+]^x$ at pH 6.7.

It should be noted that deviation from linearity is observed at the higher concentrations of free cadmium. This is indicative of a change in stoichiometry and in this case the formation of complexes that have more than 1 cadmium per fulvic acid molecule.

A term $\bar{m}$, the average number of cadmium ions per fulvic acid, has been defined to facilitate the evaluation of the successive β_n values, as in eq. [8].

[8] $$\bar{m} = \frac{[\mathrm{CdFA}] + 2[\mathrm{Cd_2FA}] + 3[\mathrm{Cd_3FA}] + \ldots}{[\mathrm{H}_x\mathrm{FA}] + [\mathrm{CdFA}] + [\mathrm{Cd_2FA}] + [\mathrm{Cd_3FA}] + \ldots}$$

For the 2:1 complex eq. [8] becomes

[9] $$\bar{m} = (1 - \bar{m})[\mathrm{Cd}^{2+}]\beta_1/[\mathrm{H}^+]^x + (2 - \bar{m})[\mathrm{Cd}^{2+}]\beta_2/[\mathrm{H}^+]^{2x}$$

and the values of $\bar{m}$ are calculated from

[10] $$\bar{m} = \frac{[\mathrm{Cd}]_t - [\mathrm{Cd}^{2+}]}{[\mathrm{FA}]_t}$$

The value of $\beta_2/[H^+]^{2x}$ is calculated from the data that provides $\bar{m}$ values in the range of 1.2 to 1.8.

For the 3:1 complex

[11] $$\frac{\beta_3}{[\mathrm{H}^+]^{3x}} = \frac{\bar{m} - \dfrac{(1-\bar{m})[\mathrm{Cd}^{2+}]\beta_1}{[\mathrm{H}^+]^x} - \dfrac{(2-\bar{m})[\mathrm{Cd}^{2+}]^2\beta_2}{[\mathrm{H}^+]^{2x}}}{(3-\bar{m})[\mathrm{Cd}^{2+}]^3}$$

and values of $\bar{m}$ in the range of 2.2 to 2.8 are used to calculate $\beta_3/[H^+]^{3x}$. The values of $\beta_n/[H^+]^{nx}$ are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

TABLE 1. Conditional stability constants for the complexation of cadmium by fulvic acid

	log ($\beta_n/[H^+]^{nx}$)		
n	pH = 5.7	pH = 6.7	pH = 7.7
1	5.3	5.6	6.0
2	9.8	10.6	10.7
3	14.0	15.5	15.4

listed in Table 1. The fulvic acid concentration ranged from 5.05 to 27.2 mg/l and the $[Cd]_t$ ranged from 7.0×10^{-7} to 1.1×10^{-3} M. With this range of ligand and metal concentrations the free cadmium concentration varies from 6.3×10^{-7} to 6.3×10^{-4} M. The concentration of free cadmium may be calculated using the computer program (26) COMICS, total metal, total ligand, and the $\beta_n/[H^+]^{nx}$ values. A plot of $[Cd^{2+}]$ calculated as a function of $[Cd^{2+}]$ observed is shown in Fig. 2. The correlation coefficient is 0.95 which is a good indication of the uncertainty in the respective conditional stability constants.

An average gram formula weight of 2775 is larger than the values reported by Hansen and Schnitzer (28) whose value ranged from 275 to 2110. This value is also greater than values obtained using copper and lead ion selective electrodes (10). A conditional stability constant of 4.4×10^5 M^{-1} at pH 6.7 is comparable to the values observed for the complexation of copper (6, 10) and lead in this pH range (10). The other studies have not reported conditional constants for the complexes containing more than 1 metal per FA.

The same experimental procedure was utilized to obtain $\beta_n/[H^+]^{nx}$ values at pH 5.7 and 7.7 (see Table 1). From these data the apparent value of x is 0.5. A value of 0.6 has been observed in other studies (6, 10), and a value of 1.0 would be expected if the mode of coordination by fulvic acid is similar to that exhibited by salicylic acid where one donor is a carboxyl oxygen and the other is a phenolic oxygen. It is presumed that the pK_a's of the phenolic oxygens will be greater than 8 and thus hydrogen ion dependence should approach unity. This interpretation assumes that the mode of complexation in each fulvic acid molecule is similar and thus can be quantitatively compared to precisely defined complexing agents. The data are presented in Table 2.[3]

Potentiometric Titration of Fulvic Acid

The titration of acidified fulvic acid with sodium hydroxide is shown in Fig. 3. The absence of any intermediate plateau regions indicates an even spacing and central tendency of the pK_a values. The addition of strong acid has repressed the dissociation of the most acidic protons. Using the carboxyl acidity and the average gram formula weight, there appears to be approximately 20 carboxyl groups per molecule. Each one of these will require 0.148 ml of titrant for neutralization. Analysis of the titration curve indicates that 5.36 ml of NaOH is required to neutralize the added HCl, and that ten acidic groups are titrated by pH 4.4. Over the pH range of 5.7 to

[3]Supplementary material listing pCd_t, pCd, and pH is available from the authors upon request.

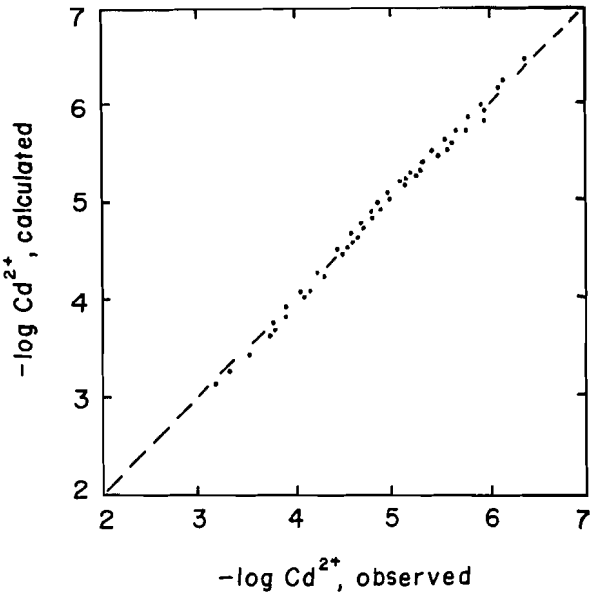

FIG. 2. Correlation between calculated and observed Cd^{2+} concentrations at pH 6.7.

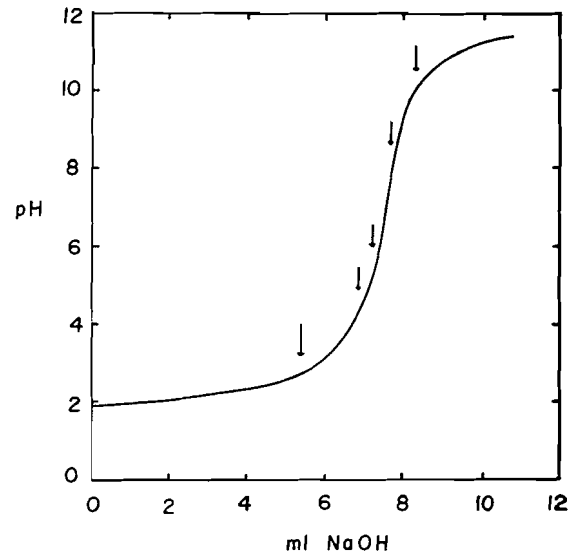

FIG. 3. Titration of acidified fulvic acid with NaOH. $[FA]_t = 3.2 \times 10^{-4}$ M, [HCl] = 0.0117 M, [NaCl] = 0.10 M, [NaOH] = 0.109 M, and total volume = 50.0 ml.

TABLE 3. Stability constants of selected ligands with Cd^{2+} (29)

Ligand	log K_1
Acetate	1.7
Oxalic	4.0
Phthalic	2.5
Malonic	3.3
Glycinate	4.8
N-methyliminodiacetate	6.8
Nitrilotriacetate	9.8

7.7 an additional 2.5 acidic groups are neutralized and twenty protons are neutralized by pH 10.1.

These results suggest that this fulvic acid possesses a high negative charge in the pH range often encountered in natural waters. Over the pH range of cadmium complexation, 5.7–7.7, there is a net change of approximately 2.5 units. This is an average change and thus it is unlikely that all are directly involved in the preferred coordination sites. As a consequence, the conditional stability constants have less than unity dependence upon hydrogen ion concentration.

The presence of twenty carboxylic groups and an additional eight phenolic oxygen requires a minimum of 27.7% oxygen by weight. Elemental analysis indicated 45.2% oxygen and thus there is ample functional group oxygen and an additional 17% remains for bridging and other groups.

The stability constants measured in this study are indicative of the sites that have the proper spatial orientation to form chelate rings when coordinated to cadmium. Stability constants for the complexation of cadmium with a variety of carboxylate type ligands are listed in Table 3. These data indicate that formation of a five-membered chelate ring adds from 2 to 2.5 log units to the stability constant. On the basis of this cadmium should be coordinated to at least three donors of the fulvic acid molecule.

One of the most popular models for complexation by naturally occurring ligands is similar to that of salicylic acid, which involves a carboxyl group and a phenolic oxygen. The change in the conditional stability constant over the pH range of 5.7 to 7.7 is approximately one log unit for each of the three $\beta_n/[H^+]^{nx}$ values. If phenolic coordination is involved the pK_a of the phenolic groups would have to be less than 6.7. The majority of the pK_a values for characterized phenolic hydrogens is greater than 9. Many metal ions do displace phenolic hydrogens upon complexation, however, the conditional stability constants decrease rapidly as the hydrogen ion concentration increases and thus it is questionable if this mode of complexation exhibits sufficient stability to be important in the near neutral pH region. In addition at least three cadmium ions can coordinate to FA which is greater than the net proton-level change in the pH range of 5.7–7.7. The large negative charge on the ligand will add stability to the complexes by reducing the rate of complex dissociation and enhanced rate of complex formation.

The magnitude of the successive stability constants indicates that this fulvic acid contains several subunits of similar complexing capability. Subsequent degradation of the molecule could provide a ligand exhibiting comparable complexation stability, however, the apparent gram formula weight would be less.

The stoichiometry of these complexes is opposite to those reported in other studies (10), but it is consistent with the observations that fulvic and humic acids can be precipitated from solutions with high concentrations of transition metals. Another report has alluded to the formation of complexes that contain more than one metal (30).

Ion mobilities in gaseous ammonia

ERIC S. SENNHAUSER AND DAVID A. ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received March 16, 1978

ERIC S. SENNHAUSER and DAVID A. ARMSTRONG. Can. J. Chem. **56**, 2337 (1978).

Gaseous ammonia at pressures in the range 200 to 1200 Torr was subjected to continuous irradiation by 40 kVp X-rays and the mobilities of the positive and negative ions (μ_+ and μ_-, respectively) were determined by a pulsed-drift method. The averages of μ_+ and μ_- agreed well with results obtained by another method. The magnitude of μ_+ varied from 3.2 ± 0.2 cm^2 V^{-1} s^{-1} at 200 Torr to 0.53 ± 0.04 cm^2 V^{-1} s^{-1} at 1200 Torr. While μ_- converged to the same value at 1200 Torr, it was slightly higher, 3.3 ± 0.2 cm^2 V^{-1} s^{-1}, at 200 Torr. The pressure dependence and actual magnitudes of μ_+ were found to be in good agreement with theoretical predictions based on ion–molecule collision rate theory for $NH_4^+ \cdot xNH_3$ clustered ions of known x.

ERIC S. SENNHAUSER et DAVID A. ARMSTRONG. Can. J. Chem. **56**, 2337 (1978).

On a soumis de l'ammoniac gazeux, à des pressions allant de 200 à 1200 Torr, à une irradiation continue par 40 kVp de rayons-X et on a déterminé les mobilités des ions positif et négatif (μ_+ et μ_- respectivement) par la méthode de la diffusion pulsée. Les moyennes des valeurs μ_+ et μ_- sont en bon accord avec les résultats obtenus par une autre méthode. La grandeur de μ_+ varie de 3.2 ± 0.2 cm^2 V^{-1} s^{-1} à 200 Torr jusqu'à 0.53 ± 0.04 cm^2 V^{-1} s^{-1} à 1200 Torr. Alors que la valeur de μ_- converge vers la même valeur à 1200 Torr, elle est légèrement plus élevée, 3.3 ± 0.2 cm^2 V^{-1} s^{-1}, à 200 Torr. On a trouvé que les valeurs réelles de μ_+ de même que sa relation avec la pression sont en accord avec les prédictions théoriques basées sur la théorie des vitesses des collisions ion–molécule pour des agrégats d'ions $NH_4^+ \cdot xNH_3$ où x est connu.

[Traduit par le journal]

Introduction

The measurement of ion mobilities can provide information on ion–molecule collision frequencies, and is also a potential means of identifying different long-lived ions in gases subjected to ionising radiation at normal pressures. More specifically, mobilities are required for the calculation of three body ion neutralization rate coefficients (1), which are of interest to us (2). A recent publication from this laboratory (2) reported the measurement of μ, the average of the positive and negative ion mobilities, in ammonia vapour which contained traces of the electron scavenger nitrous oxide and was irradiated at pressures in the range 100 to 1200 Torr. In this paper a drift technique for measuring the individual ion mobilities μ_+ and μ_- is described and applied to the ammonia system. The average of μ_+ and μ_- at pressures in the range 200 to 1200 Torr was found to be in good agreement with the values of μ previously reported for that pressure range. Also the values of μ_+ were briefly compared with predictions based on ion–molecule collision rate theory.

Experimental

Materials

Sample preparation and material purification were performed in a mercury-free vacuum line. Electronic grade ammonia (99.999% min. purity, Matheson Co.) was sublimed from one trap to another at 77 K and noncondensibles were continuously pumped off. After this it was condensed in a trap containing a freshly sublimed mirror of sodium, and then stored at 77 K. Nitrous oxide (98.0% min. purity, Matheson Co.) was thoroughly degassed and distilled several times from one trap to another at 77 K, the last fractions of the distillates being discarded. It was also stored at 77 K.

Apparatus

The irradiation cell was of cylindrical design (Fig. 1) with plane parallel electrodes enclosed in a Pyrex glass envelope. The end electrodes were made of nickel and had a diameter of 6 cm. The two inner grid electrodes consisted of nickel mesh (70 wires/inch, Buch Bee-Mars) sandwiched between two thin concentric nickel rings. The circular mesh area had a diameter of 3 cm. The distances between the electrodes of the first, second, and third cell compartments were 1, 4, and 1 cm, respectively. These are subsequently referred to as d_1, d_2, and d_3.

The space between the first two electrodes on the left is referred to as the radiation compartment, and was subjected to a continuous X-ray beam collimated to 4 or 7 mm in width. The X rays were generated by a Muller MG 150 unit and their peak energy could be varied. Low X-ray energies gave rise to lower background currents (see later) and a peak voltage of 40 kV was normally used.

High voltage (HV) pulses of selectable duration were generated from a dc voltage supply (Harrison 6525A power module) controlled by a switching device, which consisted of high voltage transistors arranged in series and driven by an optical isolator/coupler through an appropriate bias network. The trigger input was from a Tektronix PG 501 pulser and this determined the frequency of the HV pulses applied to the irradiated compartment. The resistors R_1 and R_2 (Fig. 1) were selected from six serially arranged 50 kΩ resistors (OMI, 1%, inductionless) to provide the desired potential gradients

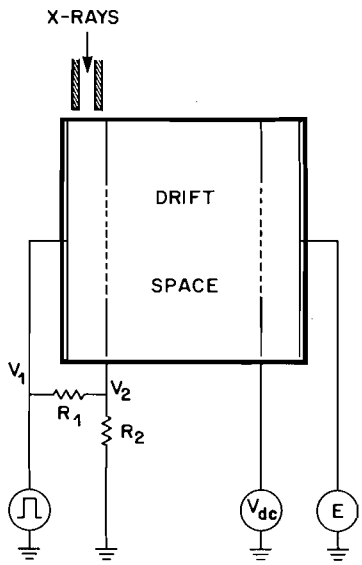

FIG. 1. Cylindrical irradiation–drift cell. V_1 and V_2, pulsed high voltage applied to electrodes bounding the radiation compartment; V_{dc}, steady voltage applied to second grid at end of drift space; E, electrometer; R_1 and R_2, resistors.

in the radiation compartment and drift space. The second grid was connected to a Fluke 412B DC power supply and throughout the experiment it remained at a constant potential V_{dc}, which had the same polarity as the pulsed potentials V_1 and V_2 in Fig. 1. The magnitude of V_2 was always greater than V_{dc} and during the 'on' period for V_1 and V_2 the difference $(V_2 - V_{dc})$ determined E_d, the field across the drift space, while $V_1 - V_2$ determined E_r, the field in the radiation compartment.

For positive potentials positive ions would be swept out of the radiation compartment and across the drift space. All ions crossing the drift space during the 'on' period for V_1 and V_2 would pass through the second grid and be collected. The current due to these was measured on a Victoreen 475A dynamic capacitor electrometer. During the 'off' period positive ions in the drift space were pushed back into the radiation volume or collected on the first grid electrode. Negative ions, which might enter the drift space in the 'off' period and cross it, could not reach the collecting electrode because of the opposing potential on the second grid. For negative applied potentials the situations for positive and negative ions are of course reversed. During an experiment the length of the HV pulse (i.e. the 'on' period) was varied, but the number of pulses per second, v ($\sim$(75 ms)$^{-1}$), was held constant, and adjusted so that steady state conditions would be established in the radiation compartment during the 'off' period.

Results

Drift Current Profiles and Data Analysis

In an experiment, the current was measured as a function of the HV pulse length, t, which was generally varied over the range 0 to 20 ms. Plots of ion drift current vs. t for a sample of 200 Torr NH_3 with 5 Torr N_2O as electron scavenger (3) are shown in Fig. 2. The current I is seen to remain at the background level for some period, then rise rather steeply, bend over, and finally rise linearly with a much smaller slope.

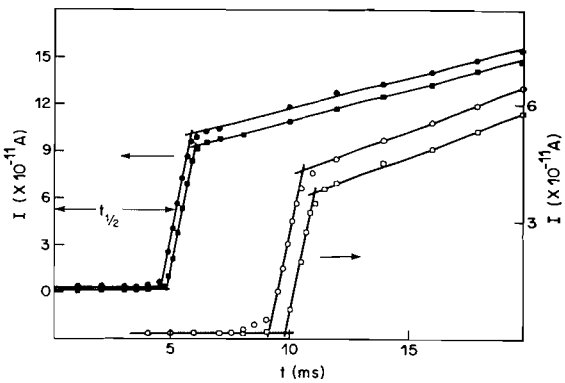

FIG. 2. Plots of ion current vs. time of application of high voltage. ● and ■, E_r = 300 V cm^{-1}, E_d = 250 V cm^{-1}; ○ and □, E_r = 450 V cm^{-1}, E_d = 125 V cm^{-1}. Circles, negative ions; squares, positive ions.

The equation for the drift current vs. t plots can be derived readily if the positive and negative ions are assumed to be present at steady state concentration n_{ss} in the whole volume of the radiation compartment before the high voltage pulse is applied. This assumption is reasonably valid because the 'off' time of the HV pulse was long enough for the spreading of secondary electrons from the collimated X-ray beam and diffusion of the ions toward the electrodes to reach steady state. A second simplifying assumption, namely that the ion concentrations are uniform, is a much more serious approximation, but, does not have a major bearing on the interpretation of the data since it is the time of drift of the center of the ion distribution that was measured. Based on the foregoing assumptions η_+, the number of ions per cm^2 arriving at the grid electrode of the radiation compartment during the application of positive fields for a time t, is

$$\eta_+ = \left\{ n_{ss}\frac{t}{\tau_+} + R\left(\frac{\mu_-}{\mu_- + \mu_+}\right)\frac{t^2}{2\tau_+}\right\} d_1 \qquad \text{for } 0 < t < \tau_+$$

$$\eta_+ = \left\{ n_{ss} + R\left(\frac{\mu_-}{\mu_- + \mu_+}\right)\frac{\tau_+}{2} + R(t - \tau_+)\right\} d_1 \qquad \text{for } t > \tau_+$$

In these expressions $\tau_+ = d_1/\mu_+ E_r$ is the clearing time for positive ions and R the rate of ion pair production in the radiation compartment in ion pairs cm^{-3} s^{-1}. Ion recombination is taken as ceasing when the ion clouds are separated (2).

Allowing for $\tau_+{}^d (= d_2/\mu_+ E_d)$, the time to cross

the drift space, the number of ions per cm^2 arriving at the second grid and ultimately being collected is

$$\eta_+^{\,1} = 0 \qquad \text{for } t < \tau_+^{\,d}$$

$$\eta_+^{\,1} = \left\{ n_{ss}\left(\frac{t-\tau_+^{\,d}}{\tau_+}\right) + R\left(\frac{\mu_-}{\mu_- + \mu_+}\right)\frac{(t-\tau_+^{\,d})^2}{2\tau_+}\right\} d_1$$

$$\text{for } \tau_+^{\,d} < t < \tau_+^{\,d} + \tau_+$$

$$\eta_+^{\,1} = \left\{ n_{ss} + R\left(\frac{\mu_-}{\mu_- + \mu_+}\right)\frac{\tau_+}{2} + R(t - \tau_+^{\,d} - \tau_+)\right\} d_1$$

$$\text{for } t > \tau_+^{\,d} + \tau_+$$

The drift currents are obtained from the values of $\eta_+^{\,1}$ by multiplying by evA, where A is the area of the transmission grids and e the electron charge.

The conditions used in the present work were such that the term containing $R\mu_-/(\mu_- + \mu_+)$ was always negligible. Therefore based on the assumptions made $\eta_+^{\,1}$ is initially zero, then rises linearly for t in the range $\tau_+^{\,d}$ to $\tau_+^{\,d} + \tau_+$ to n_{ss}. For $t > \tau_+^{\,d} + \tau_+$, η^1 rises linearly with slope equal to R. The current forms in Fig. 2 reproduce this behaviour rather well. The slight curvature at the points of inflection can be attributed to the following factors: (*a*) as soon as the positive and negative ion clouds are separated mutual repulsion causes spreading (4) and this continues as the ions cross the drift space, (*b*) during this period spreading by diffusion also occurs (4), (*c*) the ion distributions in the radiation compartment fall off near the walls, since the collimated X-ray beam does not completely fill the radiation compartment. Experiments without the collimator caused high background currents and other problems due to electrons and secondary X-rays scattered into the drift space. Collimators were chosen for the pressures used to give reasonably sharp rises in I as in Fig. 2. Calculations based on formulae in ref. 4 showed that the effects of (*a*) and (*c*) above correspond to a spreading of about 1 mm. Also the breadth of the regions of sharp rise in Fig. 2 corresponded to initial ion distributions being reasonably uniform to within 1 mm of the electrode surfaces of the radiation compartment.

Since the ionization region is centred in the radiation compartment, the ion mobilities were determined from $t_{1/2}$, the time to achieve one half of the steep rise due to the arrival of the steady state ion concentration n_{ss}. Linear extrapolations, as in Fig. 2, were used in finding n_{ss} and mobilities were calculated by means of eq. [1]. The position of $t_{1/2}$

$$[1] \qquad \mu = t_{1/2}^{\,-1}\left(\frac{d_1}{2E_r} + \frac{d_2}{E_d}\right)$$

is shown for the top line in Fig. 2. The equation assumes that ion spreading is symmetric in the drift direction and that lateral spreading has no effect on $t_{1/2}$. These assumptions appear to be quite valid, since variations in the numbers of ions n_{ss} or in the time ions spend in the radiation or drift compartments did not alter μ (see below).

Mobilities

The experimental values of μ_+ and μ_- obtained with various applied fields at several ammonia pressures are summarized in Table 1. The standard deviations at each pressure are 6% or less, and there was no dependence of $\mu_\pm$ on E_r or E_d. At higher

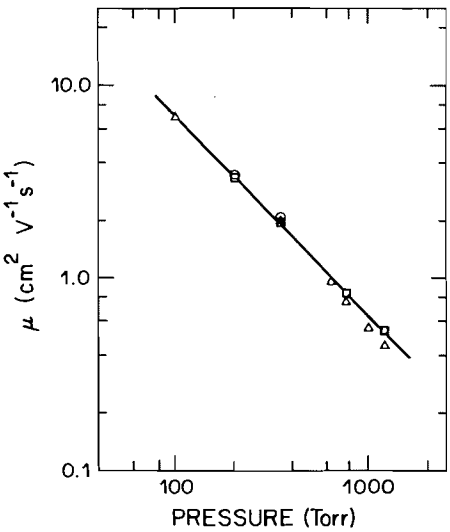

FIG. 3. Pressure dependence of mobilities. □ and ○, μ_+ and μ_-, this study. △, $(\mu_+ + \mu_-)/2$ from ref. 2.

pressures μ_+ and μ_- are equal within experimental error, but at lower pressures μ_- becomes larger. The overall experimental uncertainty was estimated to be $\pm 7\%$.

The pressure dependence of the ion mobilities is presented in Fig. 3. The solid line is drawn through the experimental points for μ_+, and the linearity over the pressure range 200 to 1200 Torr is clearly demonstrated. Over this range the slope gives $\mu \propto (\text{pressure})^{-1.03}$.

Since the magnitudes of μ_+ and μ_- are actually quite similar, comparison with μ, the average of μ_+ and μ_-, at each pressure is valid. The values of μ from ref. 2 are shown by the triangles in Fig. 3. The probable uncertainty of these results ($\sim 10\%$) is larger than for the present ones and there appears to be a small systematic error, which causes the values of μ to fall off faster than μ_+ and μ_- above 600 Torr (e.g. at 1200 Torr $\mu = 0.45$ as opposed to 0.53 for μ_+ and μ_-). However, over most of the pressure range, and particularly below 600 Torr, the agreement is very good. As a point of interest, the values of μ in ref. 2 were found to be constant at field strengths of 1 V cm^{-1} and below. The drift field strengths used here were 90 to 500 V cm^{-1}. Thus the mobilities of the ions in irradiated ammonia are independent of field strength over a very wide range (~ 0.1 to 100 V cm^{-1}).

Discussion

Recent publications (5, 6) dealing with ion–molecule collision rates have drawn attention to the relationship between the mobility of an ion and ξ, the collision frequency for transfer of momentum to the neutral molecules of the gas through which it moves (see also equation 9-4-2 of ref. 4). Taking m as the ion mass and assuming a unit electron charge e, the relation is

$$[2] \qquad \mu = e/m\xi$$

Also to a good approximation ξ is given by [3], in which nk_c is

$$[3] \qquad \xi = nk_cM(M + m)^{-1}$$

the orbiting collision frequency of ion molecule reaction rate theory, and M and n are respectively the molecular mass and number per unit volume of the neutrals. These relationships make it possible to write down the corresponding equations for mobility and k_c for a given type of ion–molecule interaction potential $V(r)$. If hard sphere or r^{12} (r = ion–molecule separation) repulsive interactions are neglected and μ_D is the dipole moment of the neutral, the potential for an ion – polar molecule interaction is of the form (7, 8)

$$[4] \qquad V(r) = \frac{-e^2\alpha}{2r^4} - \frac{e\mu_D \cos\theta}{r^2}$$

where α is the polarisability of the molecule.

Starting with an r-dependent average orientation angle $\bar{\theta}$, Su and Bowers (7, 9) have calculated values of a parameter C, which varies between zero and unity and allows for the effectiveness of the dipole 'locking in' to the charge. The magnitude of k_c and the corresponding mobility are then given by

$$[5] \qquad k_c = \frac{2\pi e}{M_r^{1/2}}\{\alpha^{1/2} + C\mu_D(2/\pi kT)^{1/2}\}$$

and

$$[6] \qquad \mu = [2\pi n M_r^{1/2}\{\alpha^{1/2} + C\mu_D(2/\pi kT)^{1/2}\}]^{-1}$$

where M_r is the reduced mass of the system.

For the case where $C = 0$ these reduce to $k_c = 2\pi e(\alpha/M_r)^{1/2}$ and $\mu = \{2\pi n(M_r\alpha)^{1/2}\}^{-1}$ respectively. The latter differs from the detailed theory of Langevin, which gives $\mu = \{2.210\pi n(M_r\alpha)^{1/2}\}^{-1}$ for a pure polarization potential (4, 6). The reason lies in the

TABLE 2. Percentage distribution of cluster sizes for $NH_4^+ \cdot x(NH_3)$ ions in ammonia*

p (Torr)	% for x = 3	4	5	6
200	0.7	60.1	31.0	8.1

TABLE 3. Mobilities of $NH_4^+ \cdot xNH_3$ ions in ammonia at 298 K

Pressure (Torr)	Mobility									
	$x = 4$		$x = 5$		$x = 6$		Weighted averages*			
	SB	LD	SB	LD	SB	LD	SB	LD	BR	Experimental
200	5.5	2.1	5.4	2.1	5.3	2.0	5.4_1	2.0_6	3.1_0	3.20±0.03
1200	0.91	0.35	0.90	0.34	0.89	0.34	0.89	0.34	0.52	0.53±0.03

*At 200 Torr $x = 4$ dominates and at 1200 Torr $x = 6$ dominates (see Table 2). All mobilities in $cm^2\ V^{-1}\ s^{-1}$.

fact that k_c counts only 'orbiting collisions' and is about 10% low (ref. 4, p. 446). For the calculation of mobilities we therefore modified [6] to:

$$[7] \quad \mu = [2.210\pi n M_r^{1/2}\{\alpha^{1/2} + C\mu_D(2/\pi kT)^{1/2}\}]^{-1}$$

so that it would correspond to the Langevin formula for $C = 0$. The case for $C = 1$ is referred to as the 'locked dipole' or LD case.

The distribution of cluster sizes for the positive ions in ammonia at our pressures is presented in Table 2. Mobilities were calculated for each of these at 200 Torr and 1200 Torr using eq. [7] for the LD case and for $C = 0.22$, which is appropriate for ammonia molecules at 298 K (9). The results are given in Table 3. The dependence of μ on the number of clustering molecules x in this range is small, because the mass dependence is $M_r^{1/2}$ and the value of M_r is close to 17 for all x. This being the case the dependence on pressure arises primarily from the inverse dependence on n in eq. [6], and the experimental pressure exponent of -1.03 is well justified.

Since the drift time is long relative to the life times for clustering and declustering (10, 11), the cluster size distributions will be maintained as the ions cross the cell. Thus we have calculated weighted average mobilities for comparison with the experimental values in column 11. The experimental results lie between the values derived from the LD approximation and with Su and Bowers' average dipole orientation (see under LD and SB).

Barker and Ridge (8) have recently obtained normalized collision densities, $\xi m/n(M_r\alpha)^{1/2}$, by calculating directly the average energy of interaction for the ion and dipole, a procedure which differs from that of Su and Bowers. Using the $\mu_D/\alpha^{1/2}$ appropriate to ammonia and interpolating from their Fig. 2, we obtained values of μ_+ for the ions in Table 2 and calculated the weighted mean mobilities shown under the heading BR in column 10 of Table 3. The agreement with experimental mobilities is very good, as has been the case for the comparison of Barker and Ridge's collision density calculations with other data (8). Neglect of the repulsive hard sphere interaction does not seem to have caused serious error for the present conditions. However, for the large clustered ions involved here ($D_{m-M} \simeq 4.5$ Å) this point deserves further attention.

As stated elsewhere (2) the exact identity of the long-lived negative ions formed by radiation in ammonia vapour with N_2O present is unknown. However, the similarity of μ_- and μ_+ in the 200 to 1200 Torr range shows that they are clustered, though possibly not as heavily as the positive ions.

Hydrolysis of esters of oxy acids: pK_a values for strong acids; Brønsted relationship for attack of water at methyl; free energies of hydrolysis of esters of oxy acids; and a linear relationship between free energy of hydrolysis and pK_a holding over a range of 20 pK units

J. PETER GUTHRIE[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 26, 1977[2]

J. PETER GUTHRIE. Can. J. Chem. **56**, 2342 (1978).

By combining various kinds of evidence from the literature it is possible to derive an internally consistent set of pK_a values for the strong mineral acids and the arenesulfonic acids; the values are referred to dilute aqueous solution as standard state and are expected to be correct within 0.5 log unit. Using these pK_a values and literature data for hydrolysis of methyl esters of acids of the type Y—XO_3Me_n, where Y is O, OH, OMe, alkyl, or aryl and X is Cl, S, or P, a Brønsted plot can be constructed with slope equal to 1.02 ± 0.04. From the free energies of hydrolysis for dimethyl sulfate and the methyl phosphates it is possible to calculate rate constants for the microscopic reverse reaction. These define a Brønsted line of slope 0.27 ± 0.3, from which rate constants for the formation of the esters of perchloric and various sulfonic acids may be estimated. This permits calculation of free energies of hydrolysis for these esters.

Thermochemical data in the literature permit calculation of the free energies of hydrolysis of dimethyl sulfate, trimethyl arsenite, and tetraethyl orthosilicate. In the case of dimethyl sulfate the calculation (using the previously reported eq. [1]) leads to a pK_a value in close agreement with theoretical expectation, confirming that eq. [1] is valid for acids of p$K_a \geq -3$. For tetraethyl orthosilicate the thermochemical data are less precise but are in satisfactory agreement with the predictions of eq. [1]. The free energies of hydrolysis derived from the Brønsted correlations are also in good agreement with expectation based on eq. [1].

For acids where resonance phenomena are important either in the acid itself (boric acid) or in the anion (nitric acid, nitrous acid, carboxylic acids) the experimental free energies of formation fall far from the line defined by eq. [1]. It is concluded that eq. [1] is limited to species where there is no π delocalization involving the reacting oxygen, but where this condition is satisfied, the equation holds over the entire accessible range of oxy acid pK_a values, i.e., from −6.4 to 16.

J. PETER GUTHRIE. Can. J. Chem. **56**, 2342 (1978).

En combinant divers types de données provenant de la littérature, il est possible d'obtenir une série autocohérente de valeurs de pK_a pour les acides inorganiques forts et les acides arènesulfoniques; les valeurs se refèrent aux solutions aqueuses diluées comme état de référence et on les croit correctes à ±0.5 unités log. Faisant appel à ces valeurs de pK_a et aux données de la littérature pour l'hydrolyse des esters méthyliques des acides du type Y—XO_3Me_n, où Y = O, OH, Me, alkyle ou aryle, et X = Cl, S ou P, on peut établir une droite de Brønsted avec une pente égale à 1.02 ± 0.04. Utilisant les énergies libres d'hydrolyse du sulfate du méthyle et des phosphates de méthyle, il est possible de calculer les constantes de vitesses pour la réaction microscopique inverse. Ces valeurs définissent une droite de Brønsted de pente 0.27 ± 0.3, à partir de laquelle on peut évaluer des constantes de vitesse pour la formation des esters des acides perchloriques et de divers acides sulfoniques. Ces valeurs permettent de calculer les énergies libres d'hydrolyse de ces esters.

Les données thermochimiques retrouvées dans la littérature permettent de calculer les énergies libres d'hydrolyse du sulfate de diméthyle, de l'arsenite de triméthyle et de l'orthosilicate de tétraéthyle. Dans le cas du sulfate de diméthyle, les calculs (utilisant l'éq. [1] rapportée antérieurement) conduisent à une valeur de pK_a qui est raisonnablement près de la valeur attendue d'une façon théorique; ceci confirme que l'éq. [1] est valide pour les acides de p$K_a \geq -3$. Dans le cas de l'orthosilicate de tétraéthyle, les données thermochimiques sont moins précises mais elles présentent une concordance satisfaisante avec les prédictions de l'éq. [1]. Les énergies libres d'hydrolyse obtenues à partir des corrélations de Brønsted sont aussi en bon accord avec les valeurs attendues en se basant sur l'éq. [1].

Dans le cas des acides où le phénomène de la résonance est important, soit dans l'acide lui-même (acide borique) ou dans l'anion (acide nitrique, acide nitreux, acides carboxyliques), les énergies libres obtenues expérimentalement pour la formation sont très loin de la ligne définie par l'éq. [1]. On en conclut que l'éq. [1] est limitée à des espèces où il n'y a pas de délocalisation pi impliquant l'oxygène qui réagit; toutefois dans le cas où cette condition est satisfaite, l'équation est valable pour la gamme complète des valeurs de pK_a des acides oxygénés soit de −6.4 à 16.

Introduction

Recently (1) we reported a linear correlation between the free energy change for replacing a hydroxyl group in a molecule by an alkoxyl group and the electronic properties of the rest of the molecules. Initially (1) this was done for ethers using the σ^* values for the substituents on the carbon atom bearing OH or OR, but this has since been extended to other classes of compound by using the pK_a of the OH compound as a measure of the electron withdrawing properties of the rest of the molecule (2). Equation [1] gives the relationship between the free

$$[1] \qquad \Delta G'' = -4.78(\pm 0.28) + 0.336(\pm 0.024)pK_a$$

energy change, corrected for any steric or symmetry effects and the pK_a of the hydroxyl compound for process [2]. Since this correlation worked well for

$$[2] \qquad X\text{—}OR + H_2O = XOH + HOR$$

phosphate esters it seemed worthwhile to see how far it could be extended and what limitations exist for it. Accordingly we wish to report the results of an examination of the hydrolysis equilibria for several esters of inorganic acids. The correlation appears to be useful for any acids where resonance is unimportant in stabilizing the anion but does not work at all for acids for which resonance plays a role.

To extend the method to acids stronger than phosphoric, it was necessary to have pK_a values for strong mineral acids such as sulfuric and perchloric acid, since from these pK_a values and previously reported kinetic studies of the hydrolysis of the methyl esters of these acids it would be possible to make indirect estimates of the free energies of hydrolysis of the esters which could be compared with the predictions of eq. [1]. A review of the data in the literature permits the calculation of a mutually consistent set of pK_a values for acids as strong as fluorosulfonic acid, referred to dilute aqueous solution as standard state. These pK_a values permit construction of a Brønsted plot for rates of hydrolysis of methyl esters of tetracoordinate oxy acids, which serves as an additional test of the correctness of the pK_a values deduced for the strong acids. A much less satisfactory Brønsted plot can be constructed for the (unobservable) reverse reaction, but the number of points is inadequate to specify the line very well. Nevertheless, this line permits the calculation of the rate constants for the reverse reactions, and so the calculation of the equilibrium constants for hydrolysis of the esters. These equilibrium constants are in agreement with the values anticipated from the linear free energy relationship between the free energy of hydrolysis and the pK_a of the acid. Thus the results in this paper demonstrate that the free energy relationship which we have reported covers the entire accessible range of acids which can exist in aqueous solution and within its range of applicability can be used with confidence to estimate unknown equilibrium constants.

Results and Discussion

Thermodynamic properties for all compounds discussed in this paper (including quantities calculated in this work) are found in Table 1. Literature data were supplemented where necessary by estimated quantities calculated using accepted procedures. Details are found in the Appendix.

pK_a Values for Strong Acids

For acids with pK_a values lower than -2 there is no generally satisfactory way to measure the pK_a, referred to aqueous solution. Table 2 summarizes various values which have been suggested. Attempts have been made using nmr data (3–5) but these methods involve severe assumptions and long extrapolations, and generally lead to values for the pK_a which seem unduly high. Although Raman (6, 7) and infrared (8, 9) measurements can lead to concentrations of undissociated acid even for perchloric (6) and sulfuric acids (7–9), these measurements are only possible in very concentrated acid solutions, so that a long and uncertain extrapolation would be needed to refer them to dilute aqueous solution. Direct measurements on dilute aqueous solutions of very strong acids seem unlikely to lead to pK_a values unless some new technical breakthrough occurs.

Attempts have been made to calculate pK_a values for the strong mineral acids using a number of approaches. Pauling's rules (ref. 10, cited in ref. 25) and some elaborations of them (11) are empirical correlations which work well for acids with pK_a values in the measurable range. Pauling's rules are: (*a*) $pK_1 = 7 - 5n$, where n is taken from the structural formula $XO_n(OH)_a$; (*b*) K_1, K_2, K_3, etc., are in the ratio $1:10^{-5}:10^{-10}$. Use of the first rule suggests that for H_2SO_4, $pK_1 = -3$, and for $HClO_4$, $pK_1 = -8$.

Slightly more elaborate was the attempt to calculate pK_a values for inorganic acids reported by Kossiakoff and Harker (12), who employed a simple electrostatic model based on the distribution of formal charges deduced from the octet rule. Their calculations were remarkably successful and led to predicted pK_a values of -3.0 for H_2SO_4 and -7.3 for $HClO_4$. Schwartzenbach (13) employed a similar model to calculate pK_a values for these acids and supported his results by consideration of the series HPO_4^{2-}, $pK = 12.3$; HSO_4^-, $pK = 1.9$; $HClO_4$, $pK = -8.6$; similarly, $H_2PO_4^-$, $pK = 7.2$; H_2SO_4, $pK = -3.1$. Thus for each increase of the formal charge on the central atom by 1 unit, the pK decreases by about 10 units.

[y]Calculated as described in the text.
[z]Standard state is the pure liquid.

All of these calculations are based upon considerations of formal charge; although this approach has been very successful at least for acids of measurable pK_a, including bisulfate, extension to perchlorate involves a particular kind of extrapolation unique to this system and therefore not generally recognized, namely the assumption that a formal charge of plus three can be interpreted in the same sense as one of plus two, i.e., that the electronic effects of the central atom continue to be linear in the formal charge even when this is three. The possibility that nonlinearity might set in seems not to have been considered. The electronegativity of the central chlorine would be so drastically increased by the formal charge of plus three (14) that charge redistribution by inductive withdrawal from the neighboring oxygens could well lead to a smaller than anticipated increment in effective charge on the central atom upon changing from S^{VI} to Cl^{VII}. This effect need not be dependent upon π bonding involving *d* orbitals, although the orbital contracting effect of a large formal charge could well make such π bonding more important in ClO_4^- than in other oxy acids of the nonmetals.

Of these various predictions, that which seems to be on the firmest ground is the prediction of the pK_a of H_2SO_4 by Kossiakoff and Harker (12), although in fact the other methods lead to very similar values. The reason for preferring Kossiakoff and Harker's value is that from their table of predicted p*K* values one can see that they can predict the difference between successive pK_a values within one log unit for those cases which are well behaved acids (without resonance or tautomerization effects to confuse the

	−6.0	32	Based on pK in organic solvents
	−9.4	69	Based on acidity function
	−8.3	70	Curve fitting to nmr data

issue), and that they successfully predicted the second pK_a of sulfuric acid. Thus it seems reasonable to expect that the first pK_a of sulfuric acid will be -3 ± 1.

It was also desirable to have pK_a values for a number of sulfonic acids, referred to dilute aqueous solution. Organic folklore suggests that FSO_3H, CF_3SO_3H, and the various arenesulfonic acids have very negative pK_a values. However, consideration of both theoretical expectations and experimental results shows that even FSO_3H is unlikely to have a pK_a less than -7.5.

The starting point for the theoretical argument is the experimental value for the pK_a of methanesulfonic acid in water, which has been measured as -1.92 ± 0.01 (15). In the same investigation the pK_a value for ethanesulfonic acid was found to be -1.68 ± 0.02.

As a model for the effect of substituents upon the pK_a, we consider the behavior of phosphonic acids; Kresge and Tang (16*a*) have reported that for the thermodynamic second pK_a values of alkyl phosphonates, there is a good correlation with σ^*:

$$pK_a = (8.10 \pm 0.10) - (1.26 \pm 0.07)\sigma^*$$

Martin and Griffin (16*b*) have reported a similar correlation with $\rho^* = 1.12$ for the first ionization but they used apparent pK_a values measured at unspecified ionic strength, and it is not clear whether the techniques used to determine these rather low pK_a values were adequate. Although it is quite possible to measure pK_a values less than 2.5 in water by titration, it is imperative to correct for titration of H^+ either by calculation (17) or by differential titration (18). pK_2 values for some arenephosphonic acids are available but only for benzene phosphonic acid is there a thermodynamic value. Mäkitio and Kontinen (19) report that pK_2 is 6.99 at an ionic strength of 0.1 *M* and 7.43 at zero ionic strength. Jaffé *et al.* (20) have reported apparent pK_a values for a number of arenephosphonic acids, including benzenephosphonic acid for which they give $pK_2 = 7.07$. Their values were corrected making the assumption that $pK_a - pK_a'$ will be the same for all arenephosphonates. σ^* values for substituted aryl groups can be calculated from the pK_a values of the appropriate arylacetic acids (21) using the equation reported by Charton (22); (σ_I was converted to σ^* using the standard factor of 6.23 (22)). The pK_a values of Jaffé *et al.* (20) fall very close to the line defined by Kresge's data when these σ^* values are used (see Fig. 1). We conclude that the second pK_a values of both alkyl and arylphosphonic acids can be correlated and presumably predicted by the same equation and that it is very probable that the thermodynamic first pK_a will show a very similar ρ^*. Thus the preferred method for predicting the pK_a values of sulfonic acids should be to use a ρ^* value of 1.26, and extrapolate from the known value for methanesulfonic acid. The value of ρ^* for sulfonic acids should not be expected to be exactly equal to that for phosphonic acids but consideration of the range of ρ^* values encountered for various classes of acids Y—X—OH suggests that it is extremely unlikely to vary by more than ± 0.5. Although this uncertainty could give rise to a range of ± 1.5 in pK_a for $\sigma^* = 3$, it still places stringent limits on the reasonable values for the pK_a of, for example, FSO_3H, for which $\sigma_F^* = 3.24$ (23) and excludes any value for pK_a more negative than -7.5.

If the apparent pK_2 values for phosphate monoesters (2, 19) (including phosphoric acid with a suitable symmetry correction) are similarly plotted against σ^* values for the alkoxy or aryloxy (calculated from pK_a values for the aryloxyacetic acids (24)) substituents, a good linear correlation is obtained,

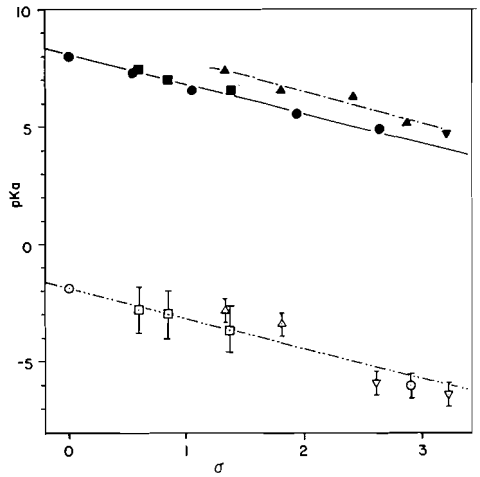

FIG. 1. Dependence of pK_a upon σ^* for phosphonic and sulfonic acids: (———) least-squares line for alkyl phosphonic acid pK_2 (16*a*), (●) alkyl phosphonic acids, (■) aryl phosphonic acids (ref. 20; see text); (– – –) least-squares line for phosphate monoesters pK_2, (▲) monoesters (ref. 2; see text), (▼) monofluorophosphoric acid (ref. 82); (– – – –) predicted line for sulfonic acids; (○) alkylsulfonic acids, (□) arylsulfonic acids, (▽) halosulfonic acids, (△) sulfuric acid and monomethyl sulfate; see text for sources of pK_a values.

with $pK_2 = 9.27 - 1.36\sigma^*$. It should be noted that carbon and oxygen substituents give different though rather similar lines; thus we must not expect to find sulfate esters or sulfuric acid itself falling on the line for sulfonic acids. The pK_a for fluorophosphate falls between the lines for phosphate esters and phosphonic acids.

The considerations discussed above lead to predicted values for the pK_a values of sulfonic acids as follows (error limits are imposed by the assumed uncertainty of 0.5 in ρ^* or are set at 0.5 log unit, whichever is larger): Ph—SO_3H, -2.7 ± 0.5; *p*Br—C_6H_4—SO_3H, -3.0 ± 0.5; *p*NO_2—C_6H_4—SO_3H, -3.6 ± 0.7; Cl—SO_3H, -5.2 ± 1.3; CF_3SO_3H, -5.2 ± 1.3; FSO_3H, -6.0 ± 1.6.

Measurements in 100% sulfuric acid as solvent have led to dissociation constants of 1.0×10^{-4} *m* for $HClO_4$ (25), 8.0×10^{-4} *m* for CF_3SO_3H (26), 2.3×10^{-3} *m* for FSO_3H (27), and 9.0×10^{-4} *m* for $ClSO_3H$ (27). These results lead to pK_a values relative to $HClO_4$ (the weakest acid in the series) of -1.4 for FSO_3H, -1.0 for $ClSO_3H$, and -0.9 for CF_3SO_3H. For a series of structurally similar acids it seems reasonable to expect that relative ionization constants in highly ionizing solvents such as water or sulfuric acid will be closely similar; this is equivalent to assuming that the only significant difference in the two solvents is the dramatic difference in solvent basicity.

Bessière (28, 29) has determined the ionization constants for sulfuric and perchloric acids in trifluoroacetic acid as solvent; his values for pK_i are 2.4 and 0.8, respectively. It must be borne in mind that trifluoroacetic acid is a solvent of low dielectric constant ($\varepsilon = 8.4$) (28), and that the processes of ionization, i.e., heterolytic cleavage of the H—X bond must be considered separately from dissociation to give free ions, the latter being quite unfavorable. Bessière has also reported 'global dissociation constants' for formation of free ions from ion pairs plus unionized acid; the corresponding pK values are 4.5 for perchloric acid, 6.3 for sulfuric acid, and 7.1 for methanesulfonic acid (28). Kolthoff and Bruckenstein (30) have reported the ionization constant for perchloric acid in acetic acid as $pK_i = 1.0$ and have reported pK values for global ionization of 4.87 for perchloric acid, 7.24 for sulfuric acid, and 8.46 for toluenesulfonic acid (31). The global ionization constants seem to be more widely dispersed in acetic acid; unfortunately, there seems to have been no determination of a value of pK_i for sulfuric acid in acetic acid. The values of pK_i, since they refer to a single process, are to be preferred as a measure of acidity; these values lead to a pK_a difference of 1.6 between perchloric and sulfuric acids.

From a study of the reaction I + HA = IHA, where I is an indicator, Bessière (20) has constructed a scale of relative acidities in trifluoroacetic acid; this scale places sulfuric acid 1.7 log units less acidic than perchloric acid and both methanesulfonic acid and *p*-toluenesulfonic acid 2.3 log units less acidic than perchloric acid. (Chlorosulfonic acid is placed slightly less acidic than sulfuric acid but in the absence of control experiments to demonstrate that chlorosulfonic acid is the actual acid species in mixtures of chlorosulfonic and trifluoroacetic acids, this can not be considered definitely established. In sulfuric acid as solvent, chlorosulfonic acid is stronger than sulfuric acid (27).) Since these acidities are based on experiments which do not distinguish between unionized acid, HA, and the ion pair, H^+A^-, the interpretation is less clear than would be desirable. Furthermore, it is not entirely clear how the relative acidities reported were actually calculated; if the data for indicators only are employed (Tables III and IV of ref. 29) somewhat different values are obtained, namely pK_a differences relative to perchloric acid of 1.9 for sulfuric acid and 3.1 for methanesulfonic acid and *p*-toluenesulfonic acid.

The agreement between different approaches to these pK_a differences is considerably less perfect than might be desired but all available data can be summarized by stating that sulfuric acid is 2.0 ± 0.4 pK units less acidic than perchloric acid and that methanesulfonic acid and toluenesulfonic acids (which appear indistinguishable in these experiments) are 3.1 ± 0.5 pK units less acidic than perchloric acid.

TABLE 3. pK_a values for acids discussed in this paper[a]

Acid	pK_a	Acid	pK_a
H_3O^+	−1.74	H_3AsO_3	9.29[h]
$CH_3OH_2^+$	−2.18[b]	$CH_3OAsO_2H_2$	8.58[d]
		$(CH_3O)_2AsOH$	7.99[d]
$CH_3CH_2SO_3H$	−1.68(0.02)[c]		
CH_3SO_3H	−1.92(0.01)[c]	H_4SiO_4	9.93[i]
$C_6H_5—SO_3H$	−2.8(1.0)[d]		($pK_2 = 11.69$[i])
pBr—$C_6H_4—SO_3H$	−3.1(1.0)[d]	$(C_2H_5O)SiO_3H_3$	7.27[d]
pNO$_2$—$C_6H_4—SO_3H$	−4.0(1.0)[d]	$(C_2H_5O)_2SiO_2H_2$	8.61[d]
$CF_3—SO_3H$	−5.9(0.5)[d]	$(C_2H_5O)_3SiOH$	7.95[d]
Cl—SO_3H	−6.0(0.5)[d]		
F—SO_3H	−6.4(0.5)[d]	HNO_3	−1.3[h]
$HClO_4$	−5.0(0.5)[d]	HNO_2	3.29[e]
		H_2CO_3	3.58[e]
H_2SO_4	−2.8(0.5)[d]	CH_3OCO_2H	2.92[d]
CH_3OSO_3H	−3.4(0.5)[d]	HCOOH	3.77[e]
		CH_3COOH	4.76[e]
H_3PO_4	2.12[e]		
	($pK_2 = 7.21$[e])		
$(CH_3O)PO_3H_2$	1.50[f]		
	($pK_2 = 6.58$[f])		
$(CH_3O)_2PO_2H$	0.76[g]

It is somewhat surprising that toluenesulfonic acid and methanesulfonic acid appear so similar, since both on theoretical (σ^* values) and experimental (leaving group behavior) grounds one expects toluenesulfonic acid to be the stronger. However, measurements of ion pair formation could well be perturbed by noncovalent interactions involving the benzene rings of the indicator bases and the toluenesulfonic acid. Thus the relative acidity of toluenesulfonic acid must be considered less reliable.

We now have enough information to construct a scale of acidity values. Starting with methanesulfonic acid, which has a well-established pK_a of −1.92, we can calculate that sulfuric acid has a pK_a of -2.8 ± 0.5, and that perchloric acid has a pK_a of -5.0 ± 0.5 from the data in acetic and trifluoroacetic acids. Then from the data in sulfuric acid we can calculate that the pK_a of chlorosulfonic acid is -6.0 ± 0.5, that of trifluoromethanesulfonic acid is -5.9 ± 0.5, and that of fluorosulfonic acid -6.4 ± 0.5. These pK_a values, and all others used in this paper, are found in Table 3.

Figure 1 shows that these values are in good agreement with the predicted line, which increases our confidence in the assignment. For the arenesulfonic acids, there is actually increased uncertainty, because of the apparent near identity of the pK_a values of methane- and toluenesulfonic acids; for the moment the best estimates for the pK_a of the arenesulfonic acids seem to be those based on the predicted line; to allow for the inconsistent result in acetic and trifluoroacetic acids the error limits are increased to ± 1.0 pK_a unit.

Bessière (32) has proposed a rather different set of pK_a values based upon his data; this scale is determined by the choice of HCl as reference acid, and by the choice of the pK_a for aqueous HCl. There appear to be three fundamental objections to these choices: (*a*) the pK_a of HCl in aqueous solution is imperfectly defined, and values very different from that chosen by Bessière (33) have been proposed;[3] (*b*) Cl^- is quite different in structure and presumably in solvation from the $Y—XO_3^-$ ions used in this work to construct a scale, so that the danger of serious

[3]Bessière chose a value of −3.7 for the pK_a of HCl in water; this value is derived from a scale of acidity in absolute ethanol (34). The scale for absolute ethanol has been based on 'global ionization constants,' which in the case of weak acids such as acetic acid are probably very similar to ionization constants but which may be very different for strong acids which will ionize to give ion pairs in a solvent of low polarity such as ethanol; since the apparent ionization constants for HCl and for CsCl are very similar in ethanol (35), it seems probable that the global ionization constant for HCl is really measuring dissociation of an ion pair. This argument would lead to a much more negative scale based on Bessière's data if HCl is used as reference acid; using the more generally accepted value of −7 for the pK_a in water of HCl (33), the pK_a in water for $HClO_4$ becomes −11. This value is rejected for reasons discussed in the text.

For personal use only.

variations in solvation effects is considerable; in particular, the balance between ionization and dissociation constants is likely to be quite different and thus the meaning of the global ionization constant will not be the same for different structural types; (*c*) it has not been demonstrated as far as one can tell that HCl in trifluoroacetic acid is actually HCl and has not to some considerable extent undergone covalent addition to the acid. HCl has a significant tendency to add to carbonyl groups as shown by chloroalkyl ether formation (36), when the equilibrium is not shifted by dissociation into H^+ and Cl^-, and trifluoroacetic acid is far more prone to undergo nucleophilic addition than are less electron deficient carboxylic acids (37).

Sulfuric Acid and its Methyl Esters

It is possible to test the pK_a value derived for sulfuric acid in aqueous solution by comparing the value of the free energy of hydrolysis of dimethyl sulfate derived from this pK_a, using eq. [1] with the value which can be deduced from the heat of formation of the ester. (Whether this is best regarded as a test of the pK_a value or of eq. [1] depends upon which is considered the better established but in any case serious disagreement would cast doubt on one if not both.)

Equation [1] predicts the free energy of hydrolysis, for the process converting an ester to the unionized acid in aqueous solution. Since sulfuric acid and its monoesters are strong acids the available thermodynamic data refer to the ions. A pK_a value for sulfuric acid in aqueous solution has been derived; it now remains to correct for the effect of replacing OH by OR, in order to estimate a value for the pK_a of monomethyl sulfate. This was done by a modification of a method which we have previously employed (2). The effect was assumed to be the same as the average (symmetry corrected) change in pK_a observed for phosphoric acid and its mono and dimethyl esters, using data collected in ref. 2. This effect is 0.89 in pK_a; this value was used to estimate the other pK_a values for inorganic esters reported in Table 3.

For the overall hydrolysis, the thermodynamic data in Table 1 lead to a free energy change of -12.82 kcal mol^{-1}.

[3] $MeO—SO_2—OMe + 2H_2O \rightleftharpoons 2MeOH + H_2SO_4$

When free energies of hydrolysis for the two stages of hydrolysis are calculated using eq. [1], the values obtained are -6.74 and -5.72 kcal mol^{-1}, respectively, with a total of -12.46 kcal mol^{-1}, in excellent agreement with the thermochemical value.

[4] $MeO—SO_2—OMe + H_2O \rightleftharpoons MeOH + MeO—SO_2—OH$

[5] $MeO—SO_2—OH + H_2O \rightleftharpoons MeOH + H_2SO_4$

Brønsted Correlations for Methyl Ester Formation and Solvolysis

It is possible to test the entire set of pK_a values for strong acids derived above, by taking advantage of the large amount of work which has been done studying the kinetics of hydrolysis of the methyl esters of these acids. A plot of log k vs. pK_a (a Brønsted plot) is expected to show a simple relationship provided that the pK_a values are correct but should show no pattern or a physically unreasonable one if they are seriously in error.

It is quite generally found that rates of nucleophilic substitutions are related to the pK_a of the nucleophile and leaving group and give linear Brønsted plots, provided that the reactions correlated all have the same rate determining step and provided that the variable reagents are of similar structural type (44). This approach has been more frequently employed in substitution at carbonyl (45), phosphoryl (46), or sulfonyl (47) centres than at aliphatic carbon simply because of the scarcity of data satisfying the second criterion. A set of data now exists, as a result of the present work and recent work from this laboratory, and Fig. 2*a* shows that a good Brønsted correlation exists for the rate constants for uncatalyzed hydrolysis of methyl esters of acids of the type $Y—XO_3H_n$ but that methyl nitrate deviates badly. Unlike the other acids nitric acid derives some considerable part of its acidity from resonance stabilization of the anion.

The observation that the points for the esters of the strong acids fall within their uncertainty limits of the line determined by methyl mesylate and trimethyl phosphate constitutes a strong confirmation of the assignment of pK_a values to these acids. Had these acids been as strong as has sometimes been suggested (see Table 2) then a straight line Brønsted plot could not have been obtained. For example, had perchloric acid had a pK_a of ca. -10 as has been suggested, then the average slope of the Brønsted plot from methanesulfonate to perchlorate as leaving group would have been -0.3, corresponding to a marked curvature. Although curved Brønsted plots are by no means unknown (44), it is without precedent to have curvature so extreme at such low values of the observed rate constant, when there is no preequilibrium process preceding a fast rate determining step. The reactions being considered here are believed to be simple S_N2 solvolyses (79), so no such explanation is possible. Thus a linear Brønsted plot is what would be expected.

Although it is possible to construct a Brønsted plot

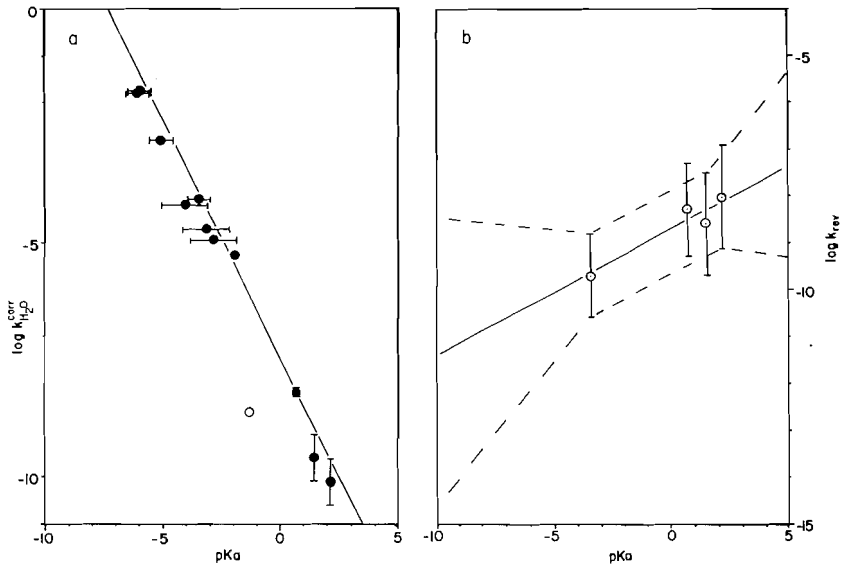

FIG. 2. (*a*) Brønsted plot for hydrolysis of methyl esters of oxy acids, (●) acids without resonance effects, (○) methyl nitrate. The line was determined by weighted least squares: $\log k_{H_2O} = -7.39(\pm 0.09) - 1.02(\pm 0.04)pK_a$. (*b*) Brønsted plot for the calculated rate constants for formation of methyl esters by attack of oxy anions upon protonated methyl. The best line as well as the extreme lines allowed by the data are shown.

for the reverse reaction this is less satisfactory because the available points do not cover a wide enough range. Since the rate determining step for the hydrolysis is attack of water on the methyl carbon leading to protonated methanol as the initial product along with the leaving group as anion, the rate constants for ester formation should be calculated for the microscopic reverse of this reaction, i.e., attack of the anion on protonated methanol. For all of the cases where the rate of hydrolysis is measureable, the equilibrium lies far on the side of hydrolysis; however, the rate constant for ester formation can be calculated if the rate constant and the equilibrium constant for hydrolysis are known. This condition is satisfied for dimethyl sulfate and the methyl phosphates. Since the equilibrium constants are calculated from thermochemical data and so are imprecise, the rate constants for ester formation are subject to uncertainties of at least an order of magnitude. Figure 2*b* shows this Brønsted plot and also the extreme lines which are allowed by the error limits on the data points. The extreme lines are drawn so that they will just pass within the error bars for the data; these lines are used to assess the error bounds for extrapolations of the line beyond the range specified by the data. Within this range, it was assumed that the bounds on the line were the same as the bounds on the data, and lines parallel to the best line were drawn. Rate constants for the formation of the esters for which hydrolysis rate constants are available were taken from this correlation line, with error limits taken from the extreme lines; these rate constants and free energies of hydrolysis derived from them are found in Table 4. Although these values are subject to much greater uncertainty than is desirable, there has been to our knowledge no other method reported to give *any* information concerning these free energies of hydrolysis.

The Brønsted line for the attack of oxy anions on $CH_3OH_2^+$ has a rather small slope, subject to large uncertainties. Unfortunately there do not seem to be any other studies of the kinetics of nucleophilic attack of a series of oxygen monoanions on a cationic substrate, so that it is difficult to assess the reasonableness of the result. One related study is by Kevill and Wang (48*a*) of the nucleophilic attack of a series of arenesulfonate anions upon methyl triflate in acetonitrile. Using the pK_a values for arenesulfonates derived in this work, Kevill's ρ value can be converted to a Brønsted slope of +0.69; this is similar to the upper limit for the slope of Fig. 2*b*. Since Kevill's data refer to a reaction with a neutral substrate in a dipolar aprotic solvent, rather than a cationic substrate in a protic solvent, it is not clear how similar the slopes should be expected to be. A somewhat more analogous system is the reaction of anions with *S*-(2-chloroethyl)thiironium ion (48*b*); from the data in ref. 48*b* it may be calculated that for sulfate and phosphate dianions, the Brønsted slope for nucleophilic attack is +0.23. This is also an imperfect model since the reaction is one of dianions with a highly strained substrate but it is encouraging

that a reaction with similar charge types and the same solvent shows a similar Brønsted slope.

Free Energies of Hydrolysis of Some Other Esters

To supplement the set of compounds X—O—R which can be used to test the range of applicability of eq. [1] some further free energies of hydrolysis for esters of acids of known pK_a can be derived from thermochemical data in the literature.

Arsenious Acid and its Methyl Esters

Arsenious oxide (As_2O_3) is sparingly soluble in water and it is considered that in aqueous solution "... the predominant species is probably $As(OH)_3$" (38). The acid species does not have an As—H bond by contrast to H_3PO_3 (38). The heat of hydrolysis of trimethyl arsenite has been measured and it is reported that the ester hydrolyzed extremely rapidly in water (39). Thus in calculating the free energy of formation of the ester in aqueous solution it was necessary to estimate the free energy of transfer as described in the Appendix. In the absence of experimental knowledge concerning the thermodynamics of solution of organic arsenic compounds there is unavoidably some additional uncertainty in the numerical value of the free energy of formation of the ester in solution. The thermodynamic data in Table 1 lead to an overall free energy of hydrolysis of −11.03 ± 1.69 kcal mol^{-1}. Application of eq. [1] leads to

$$(MeO)_3As + 3H_2O \rightleftharpoons 3MeOH + H_3AsO_3$$

the following values for the first, second, and third stages of hydrolysis: −2.46, −2.46, and −2.42 kcal mol^{-1} or −7.34 kcal mol^{-1} overall. The discrepancy is disturbingly large, amounting to 3.7 kcal overall, or somewhat over 1 kcal per step. However, it is probably unrealistic to expect predictions to be much better than to within a kcal for the extent of structural variation involved in extending a relationship originally derived for carbon compounds to an arsenic derivative. Furthermore the thermodynamic data upon which the 'experimental' free energy of hydrolysis is based are subject to more than the usual uncertainty because of our imperfect knowledge of the solution chemistry of arsenic. It seems not unreasonable to conclude that eq. [1] gives a useful, albeit imprecise, estimate of the free energy of hydrolysis even for an arsenic derivative.

Silicic Acid and its Ethyl Esters

It is now accepted that the species in solutions of SiO_2 or its hydrates at low pH is $Si(OH)_4$ (40), with free energy of formation equal to −312.57 kcal mol^{-1} (41). The heat of hydrolysis of tetraethyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

orthosilicate in acidic solution has been measured (42) but is subject to an uncertainty of 2 kcal mol^{-1} because of uncertainty concerning the nature (colloidal solution or amorphous precipitate) of the silica produced (42). The first pK_a for silicic acid is reported to be 9.93 (43); this is in fair agreement with expectations from Pauling's rule and the discrepancy can be rationalized in terms of the low electronegativity of the central atom. If pK_a values for the mono-, di-, and triesters are estimated as already described, the free energies of hydrolysis can be calculated for each step. Steric effects are expected to be small, and for lack of any better approach were estimated on the assumption that they would be the same as for tetraethyl orthocarbonate. The predicted value for the overall free energy of hydrolysis for process [6] is

[6] $$(EtO)_4Si + 4H_2O \rightleftharpoons Si(OH)_4 + 4EtOH$$

-8.75 ± 0.71 kcal mol^{-1}, which is to be compared with the experimental value of -6.31 ± 2.3 kcal mol^{-1}. The agreement is within the uncertainties of the quantities concerned. We conclude that eq. [1] is valid for orthosilicic acid and its esters. Free energies of formation of the mono-, di-, and triesters were calculated using eq. [1] and are included in Table 1.

Methyl Borate

From the free energies of formation for trimethyl borate and boric acid in Table 1 and the usual assumption concerning the acid strengthening effect of replacing hydroxyl by methoxyl, use of eq. [1] leads to a predicted pK_a for boric acid of 9.6. It should be noted that this refers to the hypothetical process shown in eq. [7] and not to the process shown in eq. [8] which is believed to represent what

[7] $$H_3BO_3 \rightleftharpoons H^+ + H_2BO_3^-$$

[8] $$H_3BO_3 + H_2O \rightleftharpoons H^+ + B(OH)_4^-$$

actually happens in aqueous solution (33). The calculated pK_a is close to the observed value but this is probably accidental. Just as eq. [1] leads to anomalously high pK_a values for acids for which the anion shows increased resonance, so it should lead to anomalously low pK_a values for acids, such as boric, which should show a decrease in resonance upon ionization. Using one third of the observed free energy change for complete hydrolysis as the free energy change per step, free energies of formation of mono and dimethyl borate in aqueous solution were calculated. These species are obligatory intermediates in the hydrolysis of trimethyl borate, but nothing seems to be known about their stability.

Methyl Nitrite

Although the free energy of formation of the gaseous ester is well defined, it is necessary to estimate the free energy of transfer because of the rapid hydrolysis of alkyl nitrites. (Transesterification in neutral alcohol is reported to be very fast (49).) From the free energies of formation of the gaseous acid (50) and the hypothetical aqueous acid (calculated from the free energy of formation of nitrite ion and the pK_a reported for nitrous acid) a value of the free energy of transfer of the acid could be obtained; it was then assumed that the increment in ΔG_t on going from acid to ester would be the same as for formic acid. This procedure, though plausible, must lead to considerable uncertainty in the final value of the free energy of formation of the aqueous ester. From the values in Table 1, a free energy of hydrolysis of $+0.78$ kcal mol^{-1} can be obtained, which leads to a pK_a of 15, which is markedly different from the observed value of 3.3. The difference of 12 log units may be attributed to the effect of resonance delocalization in the anion upon the acidity of nitrous acid.

Methyl Nitrate

The data in Table 1 lead to free energy of hydrolysis of -0.78 kcal mol^{-1} and a calculated pK_a of 11.9 for nitric acid; this differs from the observed pK_a value of -1.4 by 13.3 log units, which is a measure of the importance of resonance delocalization upon the acidity of nitric acid.

Methyl Esters of Carboxylic Acids

Equilibrium constants for hydrolysis of methyl formate and acetate have been measured. These lead to pK_a values of 11.3 and 11.6, respectively. Data from the literature permit the calculation of the overall free energy of hydrolysis of dimethyl carbonate as -2.64 kcal mol^{-1}. This leads to a pK_a of 11.8.

Correlation of Free Energy of Ester Hydrolysis with Acid pK_a

The free energies of hydrolysis derived in this work (Table 5), as well as those reported earlier, are plotted as a function of the pK_a of the acid produced on hydrolysis in Fig. 3. Clearly, for those acids where resonance effects are not important, the fit to the previously reported line is very good. Equally clearly, the deviations for those acids which *do* have important resonance effects are very substantial. The correlation holds for the entire range of pK_a values for Brønsted oxygen acids which can exist in water and therefore it seems appropriate to conclude that we have a general method for calculating the equilibrium constant for a defined, and large, class of hydrolysis reactions.

Free Energies of Transfer for Inorganic Acids

From thermodynamic data for the gaseous acids (50) and free energies of formation of the aqueous acids from the present work, the following values for

[c]This work.
[d]Average $\Delta G''$ per step based on ΔG_f^0 values.

the free energies of transfer from the gas phase to aqueous solution can be calculated: $HClO_4$, -21 ± 4 kcal mol^{-1}; H_2SO_4, -19 ± 2 kcal mol^{-1}; HNO_3, -7.0 kcal mol^{-1}. (The uncertainties reflect the uncertainty in ΔH_f^0(g).) These values are much more negative than the values for the corresponding methyl esters and must reflect the very powerful hydrogen bonding of strongly acidic protons to water.

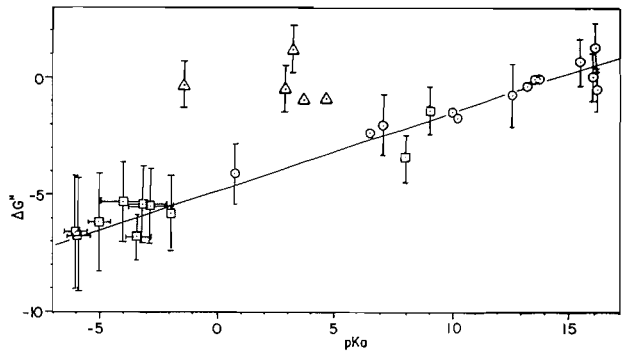

FIG. 3. Test of eq. [1]; the line is calculated using the slope and intercept reported in ref. 2: (○) points for compounds previously reported in ref. 2, (□) points for inorganic acids without resonance, (△) points for acids in which resonance is important.

Experimental

The solubility of dimethyl carbonate in water at 25°C was determined by nmr analysis of a saturated solution, integrating the methyl signal relative to the solvent peak. The solvent was 0.001 *N* aqueous HCl.

Equilibrium constants for ester formation in water at 25°C were determined by nmr analysis as previously described (83); values of the equilibrium constant of 0.097 ± 0.015 M^{-1} for formic acid plus methanol (lit. (84) value 0.122 ± 0.003 M^{-1}) and 0.111 ± 0.006 M^{-1} for acetic acid plus methanol were obtained.

Appendix

Estimation of Entropies

Standard entropies for the gaseous esters had to be estimated in most cases; this was done using the additivity schemes proposed by Benson and Buss (51); wherever possible this was done using bond contributions (51, 52) but in some cases no parameters were available and it was necessary to employ the atomic contributions scheme (51). For this purpose terms for tetracoordinate chlorine, tricoordinate boron, and tricoordinate arsenic were needed; these were calculated from the available entropy data (51, 53) (for perchloric acid, BCl_3 and BF_3, and $AsCl_3$ and AsF_3) and are −35.3, −13.7, and −5.2 cal deg^{-1} mol^{-1}, respectively.

Estimation of Solubilities

Since many of these inorganic esters hydrolyze rapidly, it is not possible to determine their solubilities experimentally. Solubilities were estimated employing a modification of the method of Deno and Berkheimer (54). This method is based upon a relationship between solubility and the parachor expressed as

$$\log (c_1/c_2) = 0.013P - E_A$$

where c_1 is the concentration of the liquid solute in itself, c_2 is the molar solubility in water, P is the parachor of the solute, and E_A is a correction for hydrogen bond formation between solute and water. For each inorganic ester of the $M(OR)_n$ type, E_A was assumed to be equal to the value calculated from the solubility and parachor for the analogous orthoester, $C(OR)_n$ or $HC(OR)_n$, with the same R and n. Parachor values were calculated from density and surface tension data found in Beilstein. The solubility values so estimated are found in Table 6.

Estimation of Vapor Pressures

The vapor pressures of the esters were taken wherever possible from published equations relating log p to T. For the cases of dimethyl sulfate and tetraethyl orthosilicate it was necessary to draw the best lines through plots of ln p vs. $1/T$ (in the case of tetraethyl orthosilicate using only data at low pressure) and so estimate the vapor pressure at 25°C. In the case of dimethyl carbonate, only the boiling point at atmospheric pressure was available so that it was necessary to estimate the vapor pressure using the heat of vaporization (60) and the heat capacity of vaporization taken as −12 cal deg^{-1} mol^{-1} (54*b*).

The vapor pressures are found in Table 6.

The conformational preferences and the rotational barriers of some simple cyclopropylcarbinyl cations

NANCY OKAZAWA AND TED S. SORENSEN

The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received April 24, 1978

NANCY OKAZAWA and TED S. SORENSEN. Can. J. Chem. **56**, 2355 (1978).

The ground-state rotamer conformations of a series of 'bisected' dicyclopropylcarbinyl cations, cyclopropylallyl cations, and phenylcyclopropylcarbinyl cations have been systematically investigated for the first time, employing ^1H and ^{13}C nmr spectroscopy. In the absence of significant steric factors, these cations adopt conformations involving the 'most extended conjugation.' However, this preference is not overwhelming because, in the presence of other substituents of only modest bulk, other less extended conformations exist. Cation systems, where two of these conformations are observable, have been found for each of the three major types described above. From an nmr line-broadening analysis, the populations of the two conformers and the energy barrier interconverting them have been obtained. In phenyldicyclopropylcarbinyl cations, at least one of the conformers involves a nonplanar phenyl ring.

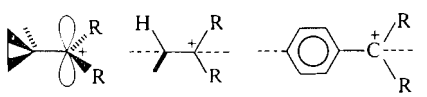
NANCY OKAZAWA et TED S. SORENSEN. Can. J. Chem. **56**, 2355 (1978).

On a étudié, pour la première fois, faisant appel à la spectroscopie rmn du ^1H et du ^{13}C, les divers rotamères de l'état fondamental d'une série de cations dicyclopropylcarbinyle, cyclopropylallyle et phénylcyclopropylcarbinyle "bisectés." En l'absence de facteurs stériques importants, ces cations adoptent des conformations impliquant la "conjugaison la plus délocalisée." Toutefois cette préférence n'est pas de plus importante; en effet, en présence d'autres substituants de grosseur même modeste il existe d'autres conformations de conjugaison moins étendue. On a trouvé des systèmes cationiques où deux de ces conformations peuvent être observées pour chacun des trois types majeurs décrits plus haut. Faisant appel à une analyse de l'élargissement des raies en rmn, on a pu déterminer les populations des deux conformères et la barrière d'énergie d'interconversion entre eux. Dans les cations phényldicyclopropylcarbinyles, au moins un de ces conformères implique un noyau phényle nonplanaire.

[Traduit par le journal]

Introduction

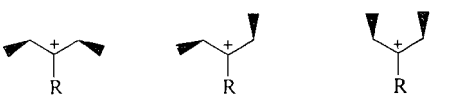
A large body of experimental evidence has now been accumulated (1) to show that secondary and tertiary cyclopropylcarbinyl cations adopt the 'bisected' geometry depicted in **1**, where overlap is possible between the empty C^+ p_z orbital and the filled antisymmetric Walsh orbital (2). A 'top view' of this same geometry is depicted in **2**, where the upper edge of the cyclopropyl ring plane is outlined.



1 **2** **3**

Structure **2** also illustrates a basic feature of a 'bisected' cyclopropylcarbinyl system, viz., the lack of a symmetry plane through the C^+–cyclopropane bond. This feature can be contrasted to that of a planar phenyl-ring-substituted carbocation, as in **3**.

In this study, we have looked at a second conformational feature which arises in cyclopropylcarbinyl type cations in which a second (or even a third) conjugating substituent is joined to the C^+ carbon. For example, when two cyclopropyl rings are present, one has the possibility of three different bisected conformations, i.e. **4***a*, **4***b*, and **4***c*. In addition we



4*a* **4***b* **4***c*

have looked at cyclopropylcarbinyl cations substituted with either conjugating phenyl or alkene groups. The conformational possibilities in these cases will be discussed under the same heading describing the experimental observations.

No comprehensive study concerning the conformational preferences and the rotation barriers of these systems has been reported.

Results and Discussion

Di- and Tricyclopropylcarbinyl Cations

There are three possible bisected conformations in the dicyclopropyl case if the R substituent is symmetric with respect to the R—C^+ bond, structures **4***a–c*. Molecular model studies show that a bisected conformer **4***c* is sterically quite crowded, because of the ring–ring β-CH_2 interaction. Therefore, this

conformer will not be considered further in this and the following case (R = CH_3 and H). This neglect of conformer **4***c* is also entirely consistent with the experimental results. In structure **4***a*, both cyclopropyl rings are equivalent, whereas in **4***b* they are not. *If* the barrier for the rotational process interconverting **4***a* and **4***b* can be slowed down on an nmr time scale, then the assignment of the observed spectrum to either **4***a* or **4***b* should be straightforward, because of the symmetry differences. The problem then is in knowing what this rotational barrier would be so that one could appropriately cool the sample to the point where the interconversion rate would be calculated to be slow.

Fortunately, it has been found that when R = CH_3, two conformers are present in appreciable amounts and one can directly determine the activation barrier for the interconversion rotation process. Armed with this, one can then treat two other cation cases where *only one* conformer is observed.

The 1,1-Dicyclopropylethyl Cation **4** *(R = CH_3)*

This cation was prepared from the corresponding alcohol and exhibits a proton spectrum at −40°C similar to that previously reported (3). This spectrum shows a single methyl peak, and a rather complex multiplet appropriate for an $(AA'BB'X)_2$ splitting pattern. The ^{13}C nmr spectrum was also obtained[1] and at −35.5°C shows only four peaks, for C^+, CH_3, and the α and β carbons of the cyclopropyl ring. However, even at this temperature, the CH_3 signal is very broad, indicating that a conformational averaging process is already being slowed down. On further cooling, both the ^1H and ^{13}C nmr spectra exhibit the typical line broadening, coalescence, and resharpening into two sets of peaks, one set characteristic of conformer **4***a* (R = CH_3). The nmr data are collected together in Table 1. The ^{13}C spectra are the most definitive for assignment purposes and a set of these are shown in Fig. 1. The symmetrical conformer **4***a* (R = CH_3) can be assigned to the major isomer (65%) and the *four* ^{13}C peaks of this species are marked in the top spectrum of Fig. 1. The minor isomer **4***b* (R = CH_3) (35%) is characterized by *six* peaks and these are also shown in Fig. 1. This definitive assignment allows one to make several general comments: (*i*) The CH_3 carbon (and the protons) in **4***a* is much more shielded than in **4***b*. This general observation, that groups in the face of a cyclopropane ring are shielded, has been noted many times (5). (*ii*) The α-CH carbons (and protons) in **4***b* have distinctly different chemical shifts and one can very confidently assign the lower field peak to that

[1]The averaged ^{13}C nmr spectrum (partly misassigned) has been reported (4).

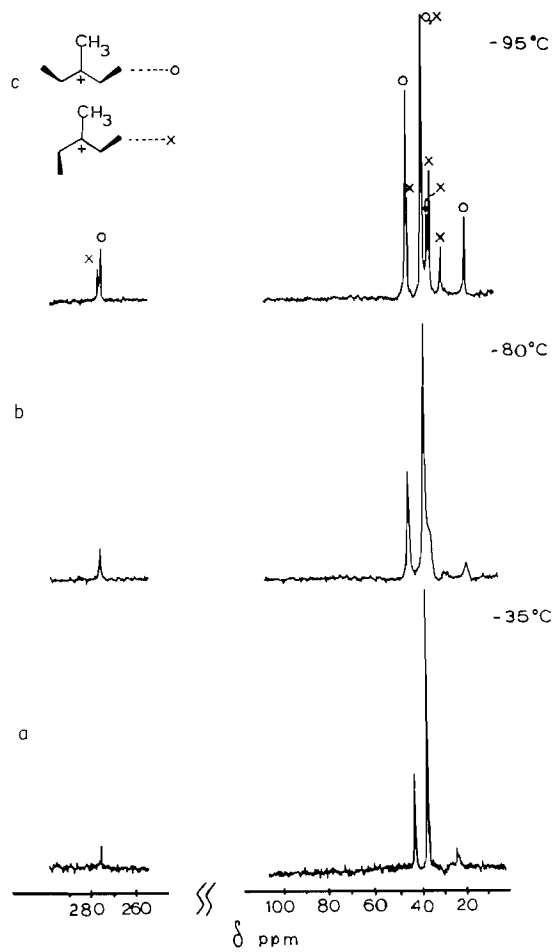

FIG. 1. (*a*) Averaged ^{13}C spectrum of cation **4** (R = CH_3); (*b*) broadened spectrum; (*c*) 'frozen-out' spectrum showing the two conformers.

CH which is not in the face of the other ring and vice versa. In conformer **4***a*, both CH carbons are equivalent and very similar to the lower field one in **4***b*, as expected.

From an nmr lineshape analysis, the **4***a* (R = CH_3) $\underset{k_f}{\rightleftarrows}$ **4***b* (R = CH_3) rate is ca. 145 s^{-1} at −75°C, $\Delta G^{\ddagger}$ = 9.4 kcal/mol.

The 1,1-Dicyclopropylmethyl Cation **4** *(R = H)*

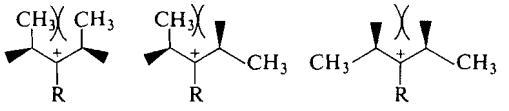
This cation has been reported previously (4, 6). Over the temperature range −50 to −90°C, there is no noticeable line broadening in the ^1H nmr spectrum. The barrier to rotation in this cation should be as large as (or larger than) that found in the previous case (R = CH_3) and we are therefore confident that the absence of line broadening at the lowest temperatures simply reflects a very small population of the second conformer. This single

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

observable conformer has the **4***a* (R = H) structure, previously deduced from coupling constant and chemical shift comparisons (6). Therefore, our only contribution in this case is to rule out the possibility of any detectable conformational averaging with **4***b* (R = H). One can estimate (7), assuming that the $^{+}$C—H proton in **4***a* (R = H) and **4***b* (R = H) might be separated by about 100 Hz (see above case), that a 'no-line-broadening observation' means that the maximum possible population of **4***b* (R = H) would be about 1.6% at −75°C.

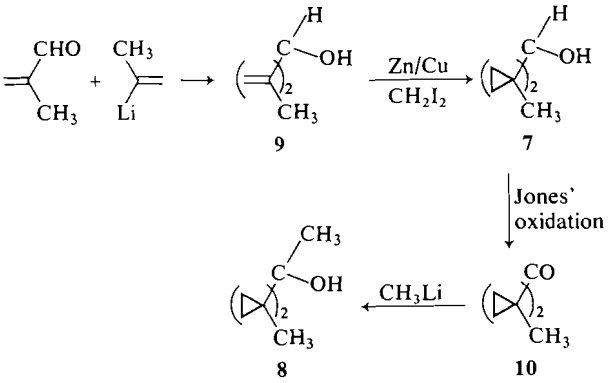
The Attempted Preparation of the α,α'-Dimethylcyclopropylmethyl Cation 5 and the α,α'-Dimethylcyclopropylethyl Cation 6

To try to systematically vary the conformational preferences in these cations, it was considered that an α-methyl substitutent might have a rather profound effect, perhaps leading exclusively to conformer **5***b* or **6***b* or even **5***c* or **6***c*, or plausibly even to nonbisected conformations:



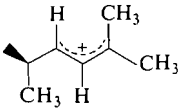
5*a* R = H **5***b* R = H **5***c* R = H
6*a* R = CH_3 **6***b* R = CH_3 **6***c* R = CH_3

The starting alcohols **7** and **8** were prepared as shown in Scheme 1.



SCHEME 1

However, addition of alcohols **7** or **8** to FSO_3H–SO_2ClF at about −140°C and proton nmr measurements at −120°C showed no evidence of the expected ions. In the case of alcohol **8**, a complex spectrum was obtained and none of the peaks could be identified. In the case of **7**, the observed cation can be assigned the single cyclopropane ring-opened structure **11**, since a spectrum of the authentic cation was available (8). It has generally been observed that α-methylcyclopropylcarbinyl cations are less stable than α-H analogs but they can be prepared,



11

e.g., cation **11**. Part of the instability associated with the cations **5** and **6** may be due to the steric problems implicit in any of the bisected conformers.

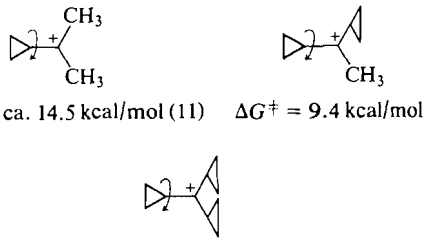
The mechanism by which alcohol **7** yields cation **11** is not clear since one does not know whether cation **5** is even an intermediate in this transformation.

The Tricyclopropylmethyl Cation 12

This well-known carbocation (6, 9) can exist in two possible bisected conformers **12***a* and **12***b*. In this work, the ^{13}C nmr spectrum of **12** (4) was measured down to −137°C and no evidence for exchange linebroadening was obtained. Conformer **12***a* has previously been proposed as the stable con-

12*a* **12***b*

former (6, 10) and our goal in this instance was simply try to assure ourselves that there was no detectable population of conformer **12***b* (or nonbisected conformers). To do this, one needs to have an *estimate* for the rotational barrier in **12**. One approach is to extrapolate the change in $\Delta G^{\ddagger}$ in the following series:



$\Delta G^{\ddagger}$ = ca. 14.5 kcal/mol (11) $\Delta G^{\ddagger}$ = 9.4 kcal/mol

$\Delta G^{\ddagger}$ estimated as 4.5 kcal/mol

For a barrier of 4.5 kcal/mol, the absolute rate expression gives a rate constant at −137°C of 1.7×10^5 s^{-1}, which does not correspond to 'frozen-out' conditions in nmr spectroscopy. Actually, our suspicions are that the $\Delta G^{\ddagger}$ barrier has been estimated too low but this remains just that.

Cyclopropyl-substituted Allyl Cations (or Vinyl-substituted Cyclopropylcarbinyl Cations)

We now consider our second broad category, i.e., with a double bond substituent. For the simple case, these are four possible conformers **13***a–d*. However, none of our examples involve the rather unstable *syn* substitution of the allyl cation, i.e., **13***c*

[a] Tentative assignment.
[b] The β-proton peaks in both conformers appear in a complex arrangement between δ 2.68 and 2.94.
[c] Doublet, $J_{3,4} = 9$ Hz.
[d] Quintet, $J_{3,4} = 9$ Hz, $J_{4,5} = 4.2$ Hz.
[e] Quintet, $J = 6.4$ Hz.
[f] All other signals in the proton spectra are contained in one complicated arrangement from δ 2.84–3.25.
[g] See footnote *f*, except that the range is now δ 2.63–3.56.
[h] This cation was prepared in CF_3COOH (SO_2ClF) since it was too unstable in FSO_3H in the relatively large concentrations necessary for ^{13}C nmr spectroscopy.
[i] At this low temperature, all upper field signals from δ 3.14–1.03 are very broad and unresolved and thus could not be identified.
[j] The β-protons seem to be buried in the methyl signals.
[k] At −130°C, this signal is showing very definite signs of broadening.
[l] The β-protons appear to be buried under the $C_{5,6}$ methyl signals.
[m] The quaternary carbons are too weak to be observed at this temperature.
[n] This ion gave poor quality spectra and the assignments are therefore somewhat tentative.

13*a* **13***b* **13***c* **13***d*

and **13***d*. Previously, we have described (8) two examples where cyclopropyl-substituted allyl cations appeared to exist as a mixture of conformers **13***a* and **13***b* but this deduction was made on the basis of somewhat subtle nmr line-broadening changes, since only one conformer could be directly observed under 'frozen-out' nmr conditions.

Fortunately, a search for a more clearcut example was successful. The 1-cyclopropylcyclohexenyl cation **14** shows sharp ^1H and ^{13}C nmr signals at 0°C.

14*a* **14***b*

However, at lower temperatures, these broaden and finally separate out into two distinct sets of peaks appropriate for the bisected conformers **14***a* and **14***b*. A series of the ^1H peaks involving only the H-2 proton region is shown in Fig. 2. These conformers can be distinguished in the nmr spectra from the H-2 or C-2 chemical shifts, which differ by 0.8 ppm in the ^1H case and 8.8 ppm in the ^{13}C case (see Table 1), owing to the shielding present in conformer **14***b*. At −75°C, the ratio of **14***a* to **14***b* is about 2:1 and the rotation barrier at −45°C is **14***a* $\underset{k_f}{\rightleftarrows}$ **14***b* = ca. 110 s^{-1}, $\Delta G^{\ddagger} = 11.1$ kcal/mol.

The above result puts the previous results involving cations **15** and **16** on a much firmer basis. We have also extended the previous ^1H study by measuring the ^{13}C nmr spectra over a range of temperatures. In the cation **15** case, both the ^1H and ^{13}C spectra show

15*a* R = H **15***b* R = H
16*a* R = CH_3 **16***b* R = CH_3

nmr line broadening and resharpening which is typical of the presence of one major and one minor conformer (7). We have not succeeded in directly observing this minor conformer in the low temperature spectra but using estimated chemical shifts derived from **14**, one can calculate that conformer **15***b* contributes less than 10% of the mixture at −100°C. Both the position of the H-2 or C-2 signal in the 'frozen-out' spectrum and the direction in which the averaged signal moves (upfield) with increasing temperature can be used to assign **15***a* as the major

For personal use only.

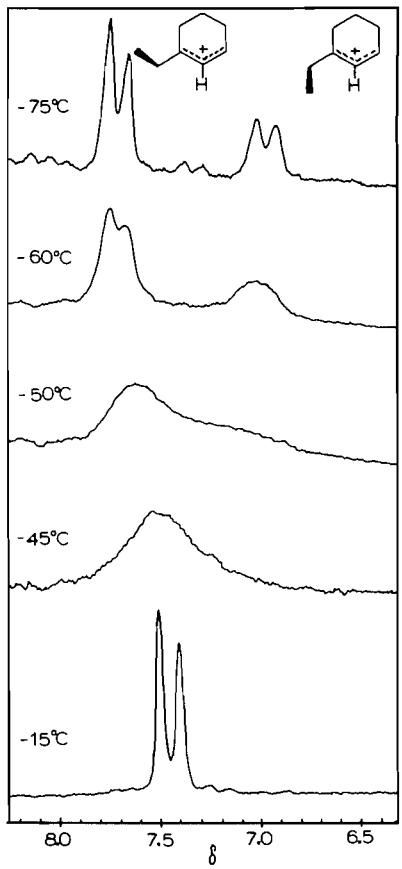

FIG. 2. Proton nmr spectrum of cation **14** (H-2 peak only) showing the progression from an averaged spectrum to one showing both conformers.

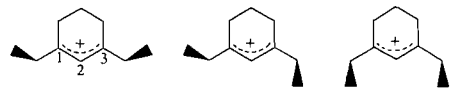
conformer. For the **15***a* $\underset{k_f}{\rightleftarrows}$ **15***b* case, the rate constant is ca. 240 s^{-1} at −85°C, $\Delta G^{\ddagger}$ = 7.9 kcal\mol. In the case of cation **16**, a similar situation exists except that the rotation barrier is much smaller. At −130°C, the ^{13}C nmr spectrum shows the C-2, CH_3 on C-1, and the β-CH_2 carbons as very broad peaks compared to the rest. However, this is the lowest temperature for which reasonable spectra were obtained and we therefore cannot be certain of the proportions of **16***a* and **16***b*, except that they appear more nearly equal.

A comparison of the $\Delta G^{\ddagger}$ conformer rotation results for **14**, **15**, and **16** shows some obvious trends. In the cyclohexenyl cation **14**, the allyl cation entity is not fully alkyl substituted and hence is less stable than in **15** or **16**. The conjugation involving the cyclopropyl ring is consequently stronger and the rotational barrier larger. In the case of **15** and **16**, the α-methyl substitution on the cyclopropyl ring seems to be destabilizing, perhaps for steric reasons.

Dicyclopropyl-substituted Allyl Cations

If one puts cyclopropyl groups on both *anti* ends of the allyl system (12), there are three possible bisected conformations, represented by cations **17***a–c*. The ^1H nmr spectrum of cation **17** shows

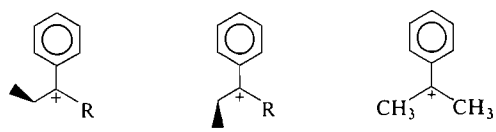


17*a* **17***b* **17***c*

initial broadening of the H-2 proton at about −85 to −90°C (vs. −10°C in the monocyclopropyl case **14**. Maximum broadness occurs at −110°C and by −125°C, two distinct H-2 peaks are observed, in a ratio of about 2:1, assigned to conformers **17***a* and **17***b*, respectively, since the minor H-2 peak occurs 0.79 ppm upfield from the major peak. This chemical shift difference is almost identical to that found in the monocyclopropyl case **14**. At −110°C, the rotation barrier **17***a* $\underset{k_f}{\rightleftarrows}$ **17***b* was k_f = ca. 120 s^{-1}, $\Delta G^{\ddagger}$ = 7.8 kcal/mol. This much smaller barrier for **17**, compared to **14**, is expected because of the more extended conjugation present in the former ion.

Phenylcyclopropylcarbinyl Cations

With one phenyl group and one cyclopropyl group, there are two possible planar-bisected conformers **18***a* and **18***b*. We have looked at the system where R = CH_3. Both this cation and the system with R = H have been previously reported (4, 6). The ^{13}C nmr spectrum of cation **18** has been measured down to −126°C in this study and we have noted no line broadening involving the cyclopropyl or methyl carbons. However, the C^+–phenyl rotation can be slowed down on the nmr time scale since one notes a broadening of the averaged *ortho*-phenyl carbons starting at about −90°C and eventual separation into two peaks at −107°C. The rate for this degenerate process (see **18***b*) is ca. 35 s^{-1} at



18*a* R = CH_3 **18***b* R = CH_3 **19**

−102°C, $\Delta G^{\ddagger}$ = 8.6 kcal/mol. Our work on the dicyclopropylethyl cation **4** (R = CH_3) suggests that the C^+–cyclopropane rotation will be completely 'frozen-out' by −126°C and the lack of carbon line broadening in the methyl and cyclopropane carbons indicates that *only one* conformer is present in detectable amounts. We assign this conformation to **18***b* (R = CH_3) because this provides

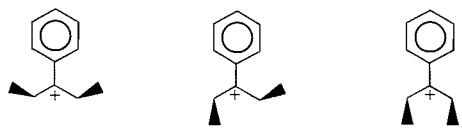
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the least steric interaction (conformer **18***a* (R = CH_3) has a serious interaction between the β-CH_2 cyclopropane protons and the *o*-phenyl protons). Also, the chemical shift similarity of the two *ortho* carbons in **18** seems to be more consistent with **18***b* (R = CH_3).

Since we will have occasion to discuss nonplanar phenyl rings, it should be noted that the distinctive features of the ^{13}C nmr spectrum of the planar **18***b* (R = CH_3) are a relatively shielded C^+ resonance (247.1 ppm) and a large *ortho–para* difference, the *para* carbon being deshielded by about 11 ppm. These features are reasonably similar to those reported for planar cation **19**, δ C^+ = 240.4 ppm and the *ortho–para* difference is 13.5 ppm (4).

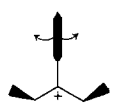
Phenyldicyclopropylcarbinyl Cations

With two cyclopropyl rings and one symmetrical phenyl ring, there are three possible planar-bisected conformers **20***a–c*.



20*a* **20***b* **20***c*

At −70°C, the ^{13}C nmr spectrum of this cation shows only one set of peaks, in reasonable agreement with the reported spectrum (4). However, these are averaged peaks since further cooling of the sample results in line-broadening and then a doubling of most of the signals. Two extreme spectra are shown in Fig. 3. At first sight, the logical choices would appear to be conformers **20***a* and **20***b*, since, as mentioned previously, conformers like **20***c* appear to be very sterically hindered. On further analysis however, we believe that the two conformers have the cyclopropane rings oriented as in **20***a* and **20***b* but that, at least in the **20***a* case, the phenyl ring is substantially nonplanar. This will be designated **20***d*.



20*d*

From Fig. 3, one can compare the ^{13}C spectra of the two conformers: (*a*) the C^+ signals are separated by 6.7 ppm but both are lower than in **18**; (*b*) one phenyl carbon *in one conformer* is about 8 ppm to lower field than any of the others; (*c*) one α-CH carbon *in one conformer* is about 8 ppm to lower field than any of the other cyclopropyl carbons.

We assign the major conformer to structure **20***b*. From observation *b*, this low-field peak appears to

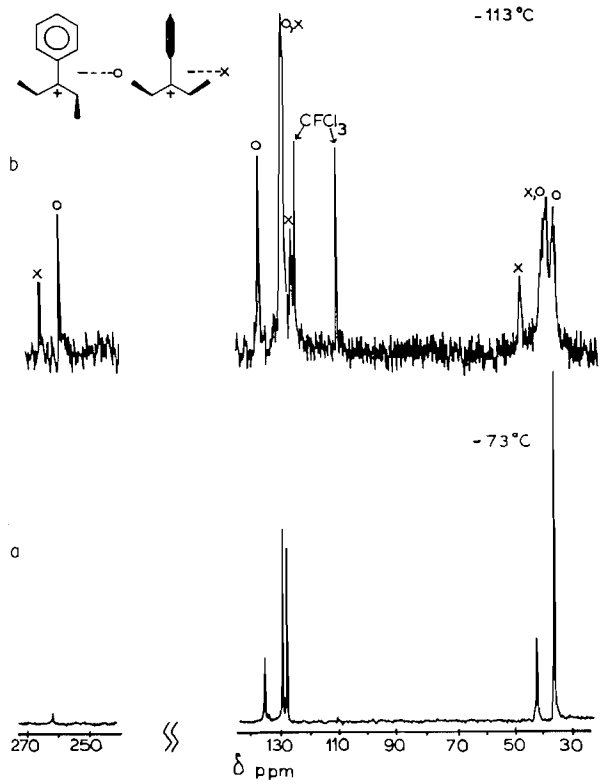


FIG. 3. (*a*) Averaged ^{13}C spectrum of cation **20**; (*b*) 'frozen-out' spectrum showing the two conformers.

be associated with a *conjugated para*-phenyl carbon. The relatively large δ C^+ difference is also consistent with one planar and one nonplanar conformation; these terms however should not be taken too literally (see later). As evidence for a nonplanar conformer **20***d*, one can note the similarity between the low field α-CH carbon assigned to this conformer (47.2 ppm) and the value in the related dicyclopropyl cation **4** (R = CH_3) (45.8 ppm). Furthermore, the phenyl carbons are much more similar than one expects for a conjugated phenyl ring.

The ratio of conformer **20***b* to **20***d* is ca. 2:1 and the interconversion rate at −100°C is $k = 230\ s^{-1}$, $\Delta G^{\ddagger} = 8.1$ kcal/mol.

The above assignments need further verification. Adding an *ortho*-methyl group to the phenyl ring would serve two purposes: (*a*) The conformer **20***b* would logically be further destabilized because of the interaction with the α-CH cyclopropyl proton (see **21***b*). There is also an unfavorable entropy factor. (*b*) There would no longer be a symmetry plane bisecting both cyclopropyl rings as in conformer **20***d* and hence the two β carbons of each ring would now be *nonequivalent* (but *only* in a nonplanar con-

for rapid interconversion

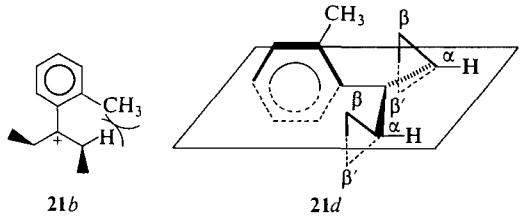
Above coalescence, the α-CH peak chemical shift will be given by the expression

$$\delta_{\alpha\text{-CH average}} = P_{21d} \cdot (47.3) + P_{21b} \cdot ((40 + 36)/2)$$

where P_{21b} will increase as the temperature increases (Boltzmann distribution), i.e., $\delta_{\alpha\text{-CH average}}$ shifts to higher field (P = population).

FIG. 4. Analysis of the nmr line broadening and temperature dependent peak shifts which occur with ion **21**.

formation). These features are shown in structures **21***b* and **21***d*.

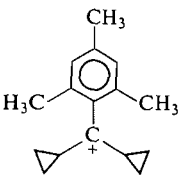


21*b* **21***d*

The ^{13}C nmr spectrum of cation **21** is fully in accord with these expectations. There is one very dominant conformer which can be 'frozen-out' at −80°C. This conformer shows *two distinct* β-CH_2 carbon signals but only *one* α-CH carbon signal, the latter at 47.3 ppm (cf. discussion of **20***d*). The carbons assigned to the *ortho*-CH carbon and the *para* carbon are very similar and finally, the C^+ peak occurs at δ 270.2 ppm, even lower field than the related carbon peak assigned to conformer **20***d*. Thus this conformer is logically **21***d*. A second (minor) conformer is not observed in the −80°C 'frozen-out' spectrum under our S/N conditions but a second conformer *must* be present to explain some of the line broadening and chemical shift movement as one warms the sample up. It can be shown that these results are completely consistent with **21***b* being the minor conformer.

The line broadening observations are these: (*a*) the α-CH carbon peak shifts to higher field with increasing temperature and also broadens; (*b*) the two β-CH_2 carbon peaks broaden and collapse to a single peak at the same temperature as the observation in *a*. The reason for these observations will be apparent if one looks at the equilibrium process involved, i.e., **21***d* ⇄ **21***b*. One sees broadening of the α carbon peak because there is an averaging of this peak in conformer **21***d* with at least one α-CH carbon in conformer **21***b* having a considerably different chemical shift. Since the β carbon symmetries in conformer **21***b* are different from **21***d*, conversion of **21***d* to **21***b* (or *vice versa*) automatically causes all β carbons to become equivalent. These features are illustrated in Fig. 4.

In the 'nonplanar' conformers **20***d* and **21***d*, the phenyl group is presumably twisted to one side or the other as far as steric interactions allow. This could result in some phenyl conjugation but the barrier to a side to side flip process would likely be very small and for nmr symmetry purposes, one can treat the system as having an orthogonal phenyl group. The situation in the so-called 'planar' conformers **20***b* and **21***b* may be similarly complicated; however, we would contend that these conformers have a considerably more planar phenyl ring. With an *ortho*-methyl substituent, the phenyl π-overlap in the 'nonplanar' conformer **21***d* should be further reduced because of the added steric interactions. To accentuate this effect, an attempt was made to prepare the mesityldicyclopropylcarbinyl cation **22**.



22 (no conformation implied)

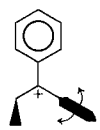
This cation is rather unstable but the indications are that the C^+ resonance is further lowered, δ 275 ppm vs. 270 ppm in the **21***d* case and 266.7 ppm in the phenyl case **20***d* (however an *ortho* methyl is a γ-substituent with respect to the C^+ nucleus and some *shielding* effect (13) from this may also be present). For two cyclopropyl rings and a methyl substituent, the δ C^+ value is 276 ppm so that, although the carbon C^+ substitution is different, the indications are that the mesityl group is behaving electronically much more like a methyl group than a conjugating phenyl ring.

The interconversion barrier between conformers **21***b* and **21***d* is ca. 11 kcal/mol (k_f for **21***b* ⇄ **21***d* = ca. 90 s^{-1} at −48°C). We picture this process as essentially a rotation of one of the C^+–cyclopropane bonds in **21***d*, this 'freeing' the phenyl ring to rotate to a much more planar, if not planar, situation. Based on the **18***b* (R = CH_3) cation results, such a C^+–phenyl rotation would be expected to be very rapid, i.e., not rate determining.

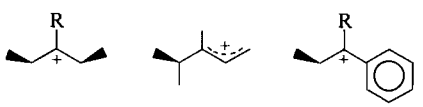
Olah and Spear (14) and Farnum (15) have suggested that the phenyl rings in the diphenylcyclopropylcarbinyl cation **23** have different degrees of



23

planarity and these authors further stress the importance of steric factors in determining the electronic structure of tertiary cations having multiple phenyl rings. Based on the present work, it seems probable that cation **23** would have the specific conformation shown.

One definite generalization can be made concerning the conformational preferences of the cations in this study, namely, *in the absence of steric effects*, they prefer the most 'extended' conjugation (shown below). This effect has been often noted in other conjugated systems; in carbocations, most notably in pentadienyl systems (ref. 16 and footnote 2).



most favored if R is small — most favored — most favored if R is small

Conclusions

Three excellent examples, cations **4** (R = CH_3), **14**, and **20** (see Figs. 1–3), have been found to illustrate that cyclopropylcarbinyl cations conjugated, respectively, with another cyclopropane ring, a vinyl group, or a phenyl ring, are capable of existing in two observable conformations. The structure of these conformers and the height of the interconversion barriers are deduced from the ^1H and ^{13}C nmr spectra.

[2]E. Wagner and T. S. Sorensen. Unpublished results.

Experimental

Mass spectra were obtained using a Varian-Atlas CH-5. Infrared spectra were recorded on a Perkin-Elmer, model 467 spectrophotometer. ^1H nmr spectra were obtained on a Varian Assoc. HA-100 or Bruker WH-90 instrument, reporting in brackets the area of the peak, followed by the multiplicity, s = singlet, d = doublet, t = triplet, q = quartet, c = complex. Organic reactions, particularly those involving lithium, were conducted under a nitrogen atmosphere.

Alcohol Preparations

Dicyclopropylmethanol, dicyclopropylphenylcarbinol, and cyclopropylmethylphenylcarbinol are commercially available. The alcohols, 2-cyclopropyl-4-methyl-3-penten-2-ol and 2-[1-(1-methylcyclopropyl)]-4-methyl-3-penten-2-ol, used to prepare cations **15** and **16**, were prepared as described (8, 17). Tricyclopropylcarbinol (18) and 1,1-dicyclopropylethanol (19) are known.

Bis-(α-methylcyclopropyl)methanol (7)

The lithium analog of 2-bromopropene (20.0 g, 0.165 mol) was prepared and reacted with methacrolein (11.6 g, 0.165 mol), at 0°C, to give 2,4-dimethyl-1,4-pentadien-3-ol, in 23% yield. A Zn/Cu couple (20) (15.6 g) was refluxed with methylene iodide (37.5 g, 0.14 mol) and several iodine crystals in diethyl ether for 40 min before adding the carbinol (3.9 g, 0.035 mol). A second treatment was required for complete cyclopropanation. The product had bp 78–80°C/21 Torr; yield 2.1 g (43%); ^1H nmr δ: 2.74 (1H, s), 1.84 (1H, s), 1.05 (6H, s), 0.53 (4H, c), and 0.18 (4H, c). The mass spectrum showed no parent ion but a large *m/e* = 122 (*M* − 18).

1,1-Bis-(α-methylcyclopropyl)ethanol (8)

Alcohol **7** (1.0 g, 7.14 mmol) was oxidized with Jones' reagent at 20°C to the corresponding ketone, which was characterized by ^1H nmr spectroscopy but not further purified. Methyllithium (3.6 ml of 2.0 *M* solution) was then reacted with the crude ketone. After hydrolysis and extraction, the product was distilled at 75°C/19 Torr; yield 0.15 g (14% overall); ^1H nmr analysis δ: 1.11 (6H, s), 0.90 (3H, s), 0.73 (5H, including OH, c), and 0.14 (4H, c). The mass spectrum showed no parent ion but revealed a large *m/e* = 136 (*M* − 18).

1-Cyclopropyl-2-cyclohexen-1-ol

This alcohol was prepared from cyclopropyllithium and 2-cyclohexen-1-one in 66% yield, bp 94–95°C/17 Torr; ^1H nmr δ: 5.82 (1H, doublet of triplets, J_{23} = 10.1 Hz, J_{34} = 3.2 Hz), 5.46 (1H, doublet of triplets, J_{24} = 2.1 Hz, J_{23} = 10.1 Hz), 2.29 (1H, s), 1.97 (2H, br s), 1.75–1.68 (4H, c), 1.12–0.82 (1H, c), and 0.55–0.23 (4H, c). The mass spectrum showed a parent ion at *m/e* = 138.

1,3-Dicyclopropyl-1,3-cyclohexadiene

The synthetic procedure followed was similar to that reported for the related 5,5-dimethyl system (12). Cyclopropyllithium (from 5.0 g, 0.041 mol of bromide) was reacted with 3-ethoxy-2-cyclohexen-1-one (5.75 g, 0.041 mol) in ether at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

25°C. Following hydrolysis, the product (a mixture of 3-cyclopropyl-2-cyclohexen-1-one and 1,3-dicyclopropyl-1,3-cyclohexadiene) was retreated with the same quantity of cyclopropyllithium. After dilute acid hydrolysis, the product was distilled at 118–122°C/18 Torr; yield 2.1 g (32% overall); ^{1}H nmr analysis δ: 5.43 (1H, s), 5.24 (1H, t, J_{45} = 4.5 Hz), 1.90 (2H, t, J_{56} = 5.0 Hz), 1.95 (2H, q), 1.27 (2H, c), and 0.71–0.30 (8H, c); ir: peaks at 3080, 3010, 1660, and 1605 cm^{-1} are characteristic for cyclopropane rings and a diene. The mass spectrum showed the parent ion at m/e = 160.

o-Tolyldicyclopropylcarbinol

o-Tolyllithium (from 10.0 g, 0.058 mol of the bromide) was reacted in ether at 25°C with dicyclopropyl ketone (6.4 g, 0.058 mol). After work-up, the product was distilled at 105–106°C/0.5 Torr to yield 8.6 g (73%) of the alcohol; ^{1}H nmr analysis δ: 7.18–7.70 (4H, c), 2.65 (3H, s), 1.36 (1H, s), 1.02–1.57 (2H, c), and 0.72–0.26 (8H, c). The mass spectrum showed the parent ion at m/e = 202.

Mesityldicyclopropylcarbinol

Mesityllithium (from 8.0 g, 0.04 mol of the bromide) was reacted with dicyclopropyl ketone (4.4 g, 0.04 mol). The solution was gently refluxed for 3 h. After work-up, the product was distilled at 120–124°C/0.075 Torr, yielding 5.6 g (60%) of the title alcohol; ^{1}H nmr showed δ: 6.64 (2H, s), 2.58 (6H, s), 2.23 (3H, s), 1.38 (1H, s), 1.60–1.14 (2H, c), and 0.48–0.29 (8H, c). The mass spectrum showed the parent ion at m/e = 230.

Ion Preparations

Except for cation **17**, the starting material was the corresponding alcohol. For ^{13}C nmr spectroscopy, the alcohol (150–200 mg in ca. 200 μl of $CFCl_3$) was added slowly with stirring to 3 ml of the precooled acid solution (−80°C, −120°C in the case of cations **16** and **17**, or in the case of the attempted preparation of cations **5** and **6**, at about −140°C) contained in a 10 mm nmr tube. The solvent mixture was normally 1:4 (v/v) FSO_3H–SO_2ClF except for cations **14** and **18** where a 1:2 mixture was used. For ^{1}H nmr spectra, 40–50 mg of the alcohol in a few drops of $CFCl_3$ was added to 0.5 ml of the acid solution in a 5 mm tube. The mesityldicyclopropyl cation **22** preparation (for ^{13}C nmr) was not very successful with the standard solvent systems. Attempts were made to prepare this cation in neat FSO_3H, CF_3COOH or CF_3COOH–SO_2ClF and also the weight of alcohol used was varied from 100–200 mg. Only dilute solutions in neat FSO_3H (no $CFCl_3$ used) gave useful spectra. The dicyclopropylcyclohexenyl cation **17** also presented difficulties and a ^{13}C spectrum was not obtained in the FSO_3H solvent mixtures. In CF_3COOH solvent, the diene precurser gave cation **17** mixed with what appears to be 1,3-dicyclopropylbenzene. For the attempted preparation of cations **5** and **6** for ^{1}H spectra, an acid solution consisting of FSO_3H–SO_2ClF–SO_2F_2 (ca. 1:4:4) was used, and the amount of alcohol was 25 mg. A similar procedure was used for the successful experiments with cation **17**.

Nuclear Magnetic Resonance Spectroscopy

^{13}C nmr spectra (^{1}H broadband decoupled) were recorded on a Bruker WH-90 spectrometer. The temperature was measured before and after each spectrum using a dummy stainless steel tube containing silicone oil and a thermocouple. For critical spectra involving line broadening, the before and after reading was within 1°C, otherwise the results were discounted. The SO_2ClF solvent provided the ^{19}F lock system. All ^{13}C chemical shifts were referenced with respect to internal $CFCl_3$, previously determined as δ 117.9 with respect to external TMS and are reported in Table 1. Multiplicities were determined, where possible, by off-resonance decoupling. ^{1}H nmr spectra were recorded with the same instrument, employing the same temperature calibration procedure. The field-frequency lock was TMS-d_{12} (including a small concentration of TMS-h_{12} for reference purposes) contained in an external capilliary. Below −90°C, a dimethyl ether-d_6 lock was used. Chemical shifts and coupling constants are reported in Table 1.

Some reactions of 10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine-*n*-butyllithium adduct with electrophiles

FRANK M. PASUTTO and EDWARD E. KNAUS

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alta., Canada T6G 2N8

Received February 2, 1978

FRANK M. PASUTTO and EDWARD E. KNAUS. Can. J. Chem. **56**, 2365 (1978).

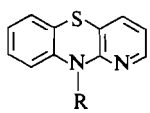
Reaction of 10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**4**) with *n*-butyllithium affords a mixture of the C-4 proton abstraction product **5***a* and 2-*n*-butyl-4a-lithio-10-methyl-2,4a-dihydropyridyl[3,2-*b*][1,4]benzothiazine **6***a* which results from nucleophilic addition at the C-2 position. Treatment of **5***a* and **6***a* with deuterium oxide gave the deuterated products **5***c* and **6***c* in a ratio of 1:4.4 whereas reaction with diethyl chlorophosphate afforded a mixture of the 4-substituted product **5***d*, 4a-ethyl derivative **6***e*, oxidation product **7** as well as the *N*-substituted-1,2-dihydropyridyl derivative **13**. The stability of the 4a-lithio-2,4a-dihydropyridyl adduct **6***a* is attributed to the ability of sulfur to stabilize an adjacent carbanion. The mechanism for the formation of **6***e* is described.

FRANK M. PASUTTO et EDWARD E. KNAUS. Can. J. Chem. **56**, 2365 (1978).

La réaction de la méthyl-10 10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**4**) avec le *n*-butyllithium conduit à un mélange de produit **5***a* provenant de l'enlèvement du proton en C-4 et de la *n*-butyl-2 lithio-4a méthyl-10 dihydro-2,4a pyridyl[3,2-*b*][1,4] benzothiazine **6***a* qui provient de l'addition nucléophile en position C-2. La réaction de **5***a* et de **6***a* avec l'eau lourde conduit aux produits deutérés **5***c* et **6***c* dans un rapport de 1:4.4 alors que la réaction avec le chlorophosphate de diéthyle conduit à un mélange d'un produit substitué en position 4 (**5***d*) et d'un dérivé éthylé en 4a (**6***e*), d'un produit d'oxydation **7** ainsi que le dérivé dihydro-1,2 pyridyle *N*-substitué (**13**). La stabilité de l'adduit lithio-4a dihydro-2,4a pyridyle (**6***a*) est attribuée à la possibilité qui existe pour le soufre de stabiliser un carbanion adjacent. On décrit le mécanisme de formation de **6***e*.

[Traduit par le journal]

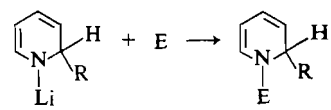
Pyridobenzothiazines are analogs of phenothiazine in which an annular nitrogen atom forms part of the ring structure. Although all four isomeric monopyridobenzothiazines are known the pharmacological actions of the 10*H*-pyrido[3,2-*b*][1,4]benzothiazines have been most significant and a number of these are used clinically such as Prothipendyl (**1***a*), Isothipendyl (**1***b*), Pipazethate (**1***c*), and Pervetral (**1***d*) (1).



1

a R = $-(CH_2)_3N(Me)_2$
b R = $-CH_2-CH(CH_3)-N(Me)_2$
c R = $-CO_2-(CH_2)_2-O-(CH_2)_2-N$ (morpholine)
d R = $-(CH_2)_3-N$ (piperazine) $-(CH_2)_2OH$

The reaction of *N*-lithio-1,2-dihydropyridines **2**, obtained from reaction of organolithium reagents and pyridines (2), with suitable electrophiles (E) is a versatile procedure for the synthesis of *N*-substituted-1,2-dihydropyridines **3** (3,4). It was therefore of interest to use these procedures to determine what effect elaboration of the pyridyl ring of pyridobenzothiazines had on pharmacological activity. We now wish to describe the preparation of 10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine-*n*-butyllithium adduct **6***a* and its reaction with water, deuterium oxide, and diethyl chlorophosphate.



2 **3**

a R = *n*Bu
b R = Ph

Reaction of 10-methyl-10*H*-pyrido[3,2-*b*][1,4]-benzothiazine (**4**) with *n*-butyllithium afforded a mixture of **5***a* and **6***a* which on quenching with water gave rise to a mixture of **5***b* and **6***b* in a ratio of 1:4.4.[1] All efforts to obtain pure **6***b* were unsuccessful. Thin-layer chromatography on silica gel or fractional crystallization of a mixture of **5***b* and **6***b* resulted in aromatization of **6***b* to **7**. Reduction of the imine double bond of **6***b* using sodium cyanoborohydride, sodium borohydride, and lithium aluminium hy-

[1]Spectral determinations were made using a mixture of **5***b* and **6***b* which were present in a ratio of 1:4.4, respectively as determined from the integrals of the H-2 absorption of **5***b* at 8.08 δ and the H-3, H-4 absorptions of **6***b* at 5.6–6.35 δ. The mixture of **5***c* and **6***c* was similarly found to be in the ratio of 1:4.4.

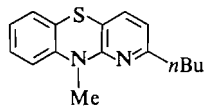
5 6

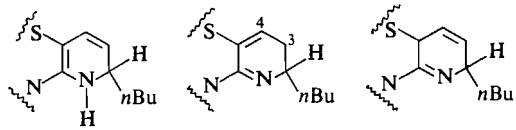
a R = Li
b R = H
c R = D
d R = P(O)OEt$_2$
e R = Et

dride was equally unsuccessful. All spectral determinations were therefore made using a mixture **5***b* and **6***b*. The presence of **5***b* was evident in the ^{1}H



7

nmr spectrum of the mixture and was isolated after preparative tlc of the mixture. The ^{1}H nmr spectrum of this mixture exhibited the characteristic *n*-butyl absorption indicating that nucleophilic addition had occurred. Absorptions in the ir spectrum (cm^{-1}) at 1676 (C=N) and 1640 (C=C) substantiated the presence of a reduced pyridyl ring. Nucleophilic attack by *n*-butyllithium is expected (2) to occur at C-2 of **4** to give one of the three possible isomers **8***a*, **8***b*, or **6***b*.



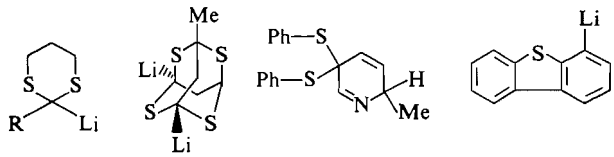
8*a* 8*b* 6*b*

Isomer **8***a* can be eliminated since the ir spectrum did not exhibit an NH absorption and addition of deuterium oxide had no effect on the ^{1}H nmr spectrum. The absence of a one-hydrogen multiplet in the 5–6 δ region expected for the C-4H and a two-hydrogen multiplet in the 2–2.5 δ region due to the allylic C-3H was not consistent with structure **8***b*. The two-hydrogen multiplet at 5.6–6.35 δ due to the C-3H and C-4H and the one-hydrogen multiplets at 4.2 and 3.64 δ due to the C-2H and C-4aH are consistent with structure 2*n*-butyl-10-methyl-2,4a-dihydropyridyl[3,2-*b*][1,4]benzothiazine (**6***b*). These assignments were confirmed by double resonance studies.

Treatment of the **5***b*–**6***b* mixture with heat followed by preparative tlc on silica gel afforded **5***b* (25.1%) and **7** (9.6%). Exposure to oxygen also effects oxidation of **6***b* to **7**. The isolation of **7** confirms the presence of the *n*-butyl substituent at C-2.

Treatment of a mixture of **5***a* and **6***a* with deuterium oxide gave rise to **5***c* and **6***c* as shown by ^{1}H nmr. Purification of this mixture by preparative silica gel tlc gave **5***c* (13.9%) and **7** (6.7%) since 2*n*-butyl-4a-deuterio-10-methyl-2,4a-dihydropyridyl[3,2-*b*]-[1,4]benzothiazine **6***c* undergoes aromatization to **7** during purification. The structure of **6***c* was assigned on the basis of the ^{1}H nmr spectrum of a mixture of **5***c* and **6***c*. The ^{1}H nmr spectrum of **6***c* was simplified relative to **6***b* due to the incorporation of deuterium at C-4a and the assignments are consistent with double irradiation studies.

The formation of the 4a-lithio-2,4a-dihydropyridyl adduct **6***a* rather than the expected *N*-lithio-1,2-dihydropyridyl adduct (2) may be ascribed to the ability of sulfur to stabilize an adjacent carbanion (4). The utility of 2-lithio-1,3-dithianes (**9**) as organolithium reagents (5) is dependent on this stabilizing effect and at least one report (6) suggests the possibility of π bonding between the sulfur and the bridgehead carbanions of **10**. Although 2,5-dihydropyridines have been postulated as intermediates in the synthesis of 2,5-disubstituted pyridines their instability does not permit isolation (3,7,8). The stable 2,5-dihydropyridine **11** was recently obtained from re-



9 10 11 12

action of *N*-lithio-2-methyl-1,2-dihydropyridine with phenyl disulfide (9).

The isolation of **5***c*, which results from reaction of **5***a* with deuterium oxide, represents the first example of proton abstraction from C-4 in any of our studies involving pyridines and organolithium reagents (2,3,7,8). Abstraction of the C-4 rather than the C-2 proton of **4** may be explained in view of the known *ortho*-directing influence of a sulfur atom since dibenzothiophene is easily metalated by *n*-butyllithium to give **12** (10,11). Metalation of **4** appears to be regiospecific since proton abstraction at C-6 was not observed.

Reaction of **4** with *n*-butyllithium and diethyl chlorophosphate afforded **5***d* (17.9%), **6***e* (8.3%), **7** (3%), the *N*-substituted-1,2-dihydropyridine **13** (24.8%), and unreacted **4** (6.6%). The most plausible mechanism for the formation of **6***e* involves nucleophilic attack by the C-4a carbanion of **6***a* at the ethyl

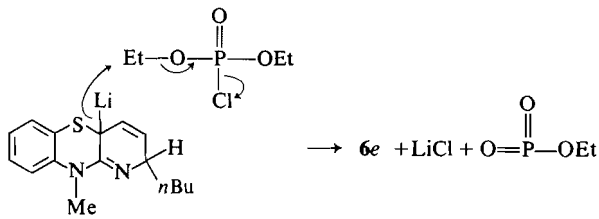
13



6a

group of diethyl chlorophosphate as illustrated below. The isolation of **6e** provides further confirmation for the structure assigned to **6a–c**.

The reaction of other 10*H*-pyrido[3,2-*b*][1,4]-benzothiazines **1** having varied functionality at the N-10 position with *n*-butyllithium and other electrophiles are now in progress.

Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Nuclear magnetic resonance spectra were determined for solutions in deuterochloroform with TMS as internal standard with a Varian EM-360A spectrometer. Infrared spectra (film unless otherwise noted) were taken on a Unicam SP-1000 or Perkin Elmer 267 spectrometer. Mass spectra were measured with an AEI-MS-50 mass spectrometer and these exact mass measurements are used in lieu of elemental analyses. All of the products described gave rise to a single spot on tlc using a solvent system less polar and more polar than the specific solvent system described for purification of the reaction mixture. No residue remained after combustion of the products purified by tlc. Kieselgel silica gel DF-5 (Camag) was used for preparative thin-layer chromatography using 20 × 20 cm plates 0.75 mm in thickness.

*4-Lithio-10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**5**a) and 2-*n*-Butyl-4a-lithio-10-methyl-2,4a-dihydropyridyl-[3,2-*b*][1,4]benzothiazine (**6**a)*

General Procedure

To a solution of **4** (1.07 g, 5 mmol) in 125 ml anhydrous tetrahydrofuran, under a nitrogen atmosphere at 0°C, *n*-butyllithium (0.32 g, 5 mmol) was added dropwise with stirring. The reaction was stirred at 0°C for 0.5–1 h to afford a golden brown solution of **5***a* and **6***a* in a 1:4.4 ratio, respectively, as determined after quenching with water.[1] This mixture of **5***a* and **6***a* was then treated with an electrophile as described in individual cases.

*10-Methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**5**b) and 2-*n*-Butyl-10-methyl-2,4a-dihydropyridyl[3,2-*b*][1,4]-benzothiazine (**6**b)*

To a solution of **4** (1.07 g, 5 mmol) in 125 ml anhydrous tetrahydrofuran, under a nitrogen atmosphere at 0°C, *n*-butyllithium (0.32 g, 5 mmol) was added dropwise with stirring. The reaction was stirred at 0°C for 0.5 h and allowed to warm to 25°C over a 10 min period. The resulting gold-brown solution was treated with water (50 ml), extracted with dichloromethane (3 × 50 ml), dried (sodium sulfate), and the solvent removed *in vacuo* to give a yellow oil (1.36 g) composed of a mixture of **5***b* (18.6%), whose ^{1}H nmr characteristics were identical to those described in the experiment below, and **6***b* (81.4%)(12); ir: 1676 (m, C=N) and 1640 cm^{-1} (s, C=C); ^{1}H nmr δ: 0.74–2 (m, 9H, C_4H_9), 3.41 (s, 3H, NCH_3), 3.64 (m, 1H, H-4a), 4.2 (m, 1H, H-2), 5.6–6.35 (m, 2H, H-3, H-4), 6.6–7.3 (m, 4H, phenyl).

*10-Methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**5**b) and 2-*n*-Butyl-10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**7**)*

The mixture of **5***b* and **6***b* (0.4 g) described above was heated at 140°C for 1 h and at 170°C for 0.5 h. The resulting dark brown oil was subjected to preparative thin-layer chromatography on six silica gel plates using benzene – ethyl acetate (20:1 v/v) as the development solvent. Extraction of the band having R_f 0.95 with 100 ml warm methanol afforded **7** as a light yellow oil (0.038 g, 9.6%); ^{1}H nmr δ: 0.68–2 (m, 7H, $-CH_2-CH_2CH_2CH_3$), 2.64 (t, J = 7 Hz, 2H, $-CH_2CH_2CH_2CH_3$), 3.44 (s, 3H, NCH_3), 6.5–7.39 (m, 6H, phenyl, H-3, H-4). *Exact mass* calcd. for $C_{16}H_{18}N_2{}^{32}S$: 270.1187; found (high resolution ms): 270.1190. Similar extraction of the band having R_f 0.67 afforded **5***b* (0.079 g, 25.1%); mp 84°C (lit. (12) mp 86°C); ^{1}H nmr δ: 3.44 (s, 3H, NCH_3), 6.6–7.29 (m, 5H, phenyl, H-3), 7.29 (d, $J_{3,4}$ = 8 Hz of d, $J_{2,4}$ = 1.75 Hz, 1H, H-4), 8.08 (d, $J_{2,3}$ = 5 Hz of d, $J_{2,4}$ = 1.75 Hz, 1H, H-2).

*4-Deuterio-10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**5**c) and 2-*n*-Butyl-4a-deuterio-10-methyl-2,4a-dihydropyridyl[3,2-*b*][1,4]benzothiazine (**6**c).*

To a solution of **4** (0.107 g, 5 mmol) in 10 ml anhydrous tetrahydrofuran, under a nitrogen atmosphere at 0°C, *n*-butyllithium (0.64 g, 1 mmol) was added dropwise with stirring. The reaction was stirred at 0°C for 1 h and then stirred at 25°C for 3 h. The resulting brown solution was treated with deuterium oxide (0.04 g, 2 mmol), dried (sodium sulfate), and the solvent removed *in vacuo* to give a light yellow oil (0.141 g) composed of a mixture of **5***c* (18.6%) whose ^{1}H nmr characteristics were identical to those described in the experiment below, and **6***c* (81.4%) (12); ir: 1676 (m, C=N) and 1640 cm^{-1} (s, C=C); ^{1}H nmr δ: 0.65–2 (m, 9H, C_4H_9), 3.42 (s, 3H, NCH_3), 4.16 (m, 1H, H-2), 5.42–6.24 (m, 2H, H-3, H-4), 6.62–7.36 (m, 4H, phenyl).

*4-Deuterio-10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**5**c) and 2-*n*-Butyl-10-methyl-10*H*-pyrido[3,2-*b*]-[1,4]benzothiazine (**7**)*

The mixture of **5***c* and **6***c* described above (0.13 g) was subjected to preparative tlc on two silica gel plates using benzene – ethyl acetate (10:1 v/v) as development solvent. Extraction of the band having R_f 0.58 with 100 ml warm methanol afforded **5***c* as a yellow semisolid (0.015 g, 13.9%); ^{1}H nmr δ: 3.45 (s, 3H, NCH_3), 6.68–7.3 (m, 5H, phenyl, H-3), 8.02 (d, $J_{2,3}$ = 5 Hz, 1H, H-2). *Exact mass* calcd. for $C_{12}H_9DN_2{}^{32}S$: 215.0626; found (high resolution ms): 215.0620. Similar extraction of the band having R_f 0.97 afforded **7** (0.009 g, 6.7%) identical (^{1}H nmr) with the sample prepared above.

*1-Diethylphosphoryl-2-n-butyl-10-methyl-1,2-dihydropyridyl-[3,2-*b*][1,4]benzothiazine (**13**), 4-Diethylphosphoryl-10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**5**d), 2-*n*-Butyl-4a-ethyl-10-methyl-2,4a-dihydropyridyl-[3,2-*b*][1,4]benzothiazine (**6**e), and 2-*n*-Butyl-10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**7**)*

To a solution of **4** (1.07 g, 5 mmol) in 125 ml anhydrous tetrahydrofuran, under a nitrogen atmosphere at 0°C, *n*-butyllithium (0.32 g, 5 mmol) was added dropwise with stirring. The resulting gold-brown solution was stirred at 0°C for

1 h, cooled to −77°C and a solution of diethyl chlorophosphate (0.95 g, 5.5 mmol) in 2 ml anhydrous tetrahydrofuran was added dropwise with stirring. The reaction was stirred at −77°C for 1.5 h and allowed to warm to 25°C over a 2 h period. The resulting light orange solution was treated with water (50 ml), extracted with dichloromethane (3 × 50 ml), and dried (sodium sulfate). Removal of the solvent *in vacuo* gave a dark reddish-brown oil. Preparative tlc was effected on 10 silica gel plates using benzene – ethyl acetate (5:1 v/v) as the development solvent. Extraction of the band having R_f 0.95 with 100 ml warm methanol afforded **7** (0.019 g, 3%) identical (^{1}H nmr) with the previous characterized sample. Extraction of the band having R_f 0.41 afforded **13** as a bright yellow oil (0.237 g, 24.8%) ir: 1273 (s, PO), 1630 (m, C=C), and 1567 cm^{-1} (m, C=C); ^{1}H nmr δ: 0.58–1.92 (m, 15H, C_4H_9, $(OCH_2CH_3)_2$), 3.36 (s, 3H, NCH_3), 3.59–4.52 (m, 5H, H-2, $(OCH_2CH_3)_2$), 5.32–5.91 (m, 2H, H-3, H-4), 6.68–7.35 (m, 4H, phenyl). *Exact mass* calcd. for $C_{20}H_{29}N_2O_3P^{32}S$: 408.1630; found (high resolution ms): 408.1635. Extraction of the band having R_f 0.18 afforded **5***d* as a bright yellow oil (0.147 g, 17.9%); ir: 1265 cm^{-1} (s, PO); ^{1}H nmr δ: 1.36 (t, J = 7 Hz, 6H, $(OCH_2CH_3)_2$), 3.44 (s, 3H, NCH_3), 4.25 (m, 4H, $(OCH_2CH_3)_2$), 6.72–7.3 (m, 5H, H-3, phenyl), 8.14 (t, $J_{2,3} = J_{2,^{31}P}$ = 5 Hz, 1H, H-2). *Exact mass* calcd. for $C_{16}H_{19}N_2O_3P^{32}S$: 350.0850; found (high resolution ms): 350.0846. Extraction of the silica gel fraction R_f 0.86 gave a light yellow oil which was rechromatographed on one silica gel plate using benzene – ethyl acetate (10:1 v/v) as the development solvent. Extraction of the band having R_f 0.65 gave **6***e* as a yellow oil (0.058 g, 8.3%); ir: 1677 (w, C=N) and 1631 cm^{-1} (s, C=C); ^{1}H nmr δ: 0.7 (t, J = 7 Hz, 3H, CH_2CH_3), 0.59–2 (m, 11H, C_4H_9, CH_2CH_3), 3.58 (s, 3H, NCH_3), 4.18 (m, 1H, H-2), 5.64 (d, $J_{3,4}$ = 10 Hz of d, $J_{2,3(4)}$ = 2 Hz, 1H, H-3 or H-4), 6.12 (d, $J_{3,4}$ = 10 Hz of d, $J_{2,3(4)}$ = 1.75 Hz, 1H, H-3 or H-4), 6.68–7.44 (m, 4H, phenyl). *Exact mass* calcd. for $C_{18}H_{24}N_2{}^{32}S$: 300.1655; found (high resolution ms): 300.1651. Extraction of the band having R_f 0.5 afforded **4** (0.033 g, 6.6%) identical (mp, ^{1}H nmr) with an authentic sample.

STEPHEN J. LOEB, JOHN W. L. MARTIN, and CHRISTOPHER J. WILLIS. Can. J. Chem. **56**, 2369 (1978).

The complexing ability towards Ni^{2+} and Cu^{2+} of the potentially tridentate ligands $HOC(CF_3)_2CH_2C(O)CH_2C(CF_3)_2OH$, $HOC(CF_3)_2CH_2CH(OH)CH_2C(CF_3)_2OH$, and $HOC(CF_3)_2CH_2CH_2N{:}C(CH_3)CH_2C(CF_3)_2OH$ has been studied. The first two act as bidentate ligands, uninegative or dinegative according to the extent of ionization of the fluorinated alcohol groups; when both were ionized, the complexes had a zwitterionic structure. The third ligand was exclusively tridentate in its complexes; this difference is ascribed to its greater flexibility. Both four- and five-coordinate complexes of nickel were observed, the latter being produced either by choice of co-ligands or by solvation, but no six-coordinate complex was formed in this series. Limitations on coordination for the metal are ascribed to steric effects.

STEPHEN J. LOEB, JOHN W. L. MARTIN et CHRISTOPHER J. WILLIS. Can. J. Chem. **56**, 2369 (1978).

On a étudié la capacité complexante vers le Ni^{2+} et le Cu^{2+} de ligands qui ont la potentialité d'être tridentates: $HOC(CF_3)_2CH_2C(O)CH_2C(CF_3)_2OH$, $HOC(CF_3)_2CH_2CH(OH)CH_2C(CF_3)_2OH$ et $HOC(CF_3)_2CH_2CH_2N{:}C(CH_3)CH_2C(CF_3)_2OH$. Les deux premiers réagissent comme ligands bidentates qui sont uninégatifs et dinégatifs selon le niveau d'ionisation des groupes alcooliques fluorés; si les deux sont ionisés les complexes ont des structures zwitterioniques. Le troisième ligand est uniquement tridentate dans ses complexes; on attribue cette différence à sa flexibilité plus développée. On a observé des complexes du nickel qui sont quatre- ou cinq-coordonnés; on peut produire ces derniers par le choix de co-ligands ou par solvatation. On n'a observé aucun complexe six-coordonné dans cette série. On attribue les limitations de la coordination du métal aux effets stériques.

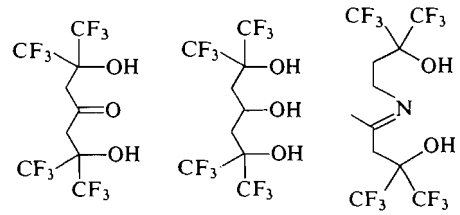
[Traduit par le journal]

In previous parts of this series, we have shown that an ionized fluorinated tertiary alkoxy grouping, $-C(CF_3)_2O^-$, will readily form a stable complex by coordination to a transition metal ion, provided that it forms part of a chelate ring system. The second donor site in the chelating molecule may be another fluorinated alcohol, as in perfluoropinacol (1, 2), a carboxylic acid (3), a carbonyl oxygen (4), an amino-nitrogen (5), or an imino-nitrogen (6). It would seem reasonable to suggest that a molecule in which two terminal $-C(CF_3)_2OH$ groups are separated by a chain of carbon atoms carrying a central donor atom should be capable of coordination to a metal ion from three positions, giving a tridentate, dinegative, ligand.

Potential Ligand Molecules

In this paper, we describe studies on three molecules of this type, the central potential donor site being a carbonyl oxygen, an unfluorinated alcohol, and an imino-nitrogen; their structures are shown as **1**–**3** respectively.

Of these three, **1** is a known compound produced by the addition of hexafluoroacetone to acetone (7), while **2** was prepared by the reduction of **1**. Compound **3** was not isolated in the free state, but was



1 **2** **3**

produced in the coordinated form by the template condensation of hexafluorodiacetone-alcohol (HFDA), $HOC(CF_3)_2CH_2COCH_3$, with the known amino-alcohol $NH_2CH_2CH_2C(CF_3)_2OH$ in the presence of Ni^{2+} ions.

It is clear that two six-membered chelate rings will be formed if the three potential donor sites in any of the above molecules are coordinated to the same metal ion. However, the presence of a central sp^2 hybridized carbon atom in compound **1** will obviously reduce the flexibility of the chain, and the examination of molecular models shows such a mode of attachment is unlikely. By conversion of this central atom to sp^3 hybridization, as in compound **2**, this restraint is somewhat reduced, but the chelating ability is still restricted by the requirement that the two chelate rings must share *two* sides. With com-

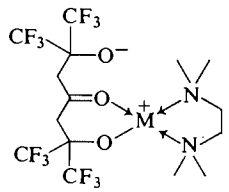
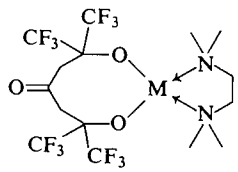
pound **3**, the flexibility of the system is greater, as the two potential chelate rings are fused along one side only, and we therefore expected that, of the three systems studied, compound **3** would be the most likely to act as a tridentate ligand.

Formation of Metal Complexes

In practice, the keto-diol **1** proved to be exclusively bidentate. However, the loss of two protons from the $-C(CF_3)_2OH$ groups gave a dinegative species which combined with suitable metal ions (Ni^{2+}, Cu^{2+}) to give neutral complexes of unusual structure. When the two remaining coordination sites on the metal ion were filled by a neutral bidentate nitrogen donor, such as *N,N,N',N'*-tetramethylethylenediamine (TMED), the product was a neutral species in which the metal atom was clearly four-coordinate, the Ni^{2+} complex being red and diamagnetic. We suggest a zwitterionic structure for these compounds in which the carbonyl oxygen and *one* of the two ionized alkoxy groups are coordinated to the metal, the second alkoxy group being ionized but not coordinated, as in structure **4**.

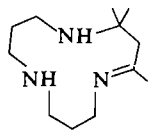


4*a* (M = Ni^{2+})
4*b* (M = Cu^{2+})

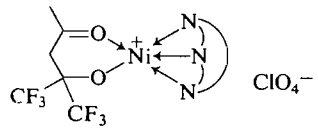


5

This mode of attachment is preferred over the alternative structure **5**, in which the two alkoxy groups coordinate leaving the carbonyl free, on two grounds; the well-known greater stability of six-, rather than eight-membered, chelate rings, and the appearance of the infrared spectra. We have previously demonstrated that an ionized keto-alcohol may act as a bidentate ligand by preparing a stable cationic complex (**7**) of Ni^{2+} with HFDA, the co-ligand being the tridentate macrocycle **6** (abbreviated to [12]-ene-3):



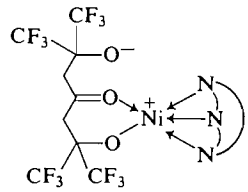
6



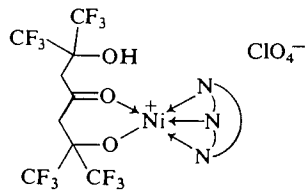
7

In compound **7**, the carbonyl stretching frequency is lowered to 1690 cm^{-1} from 1730 cm^{-1} in the free ligand. We now see shifts from 1720 cm^{-1} in the free ligand to even lower carbonyl frequencies at 1650 cm^{-1} (**4***a*) and 1646 cm^{-1} (**4***b*) which we assign to coordinated carbonyl groups in which the bond has been further weakened by the influence of the negative charge on the adjacent uncoordinated $-C(CF_3)_2O^-$ group. Such shifts would not be expected for structure **5**, in which the carbonyl group is not involved in coordination to the metal ion.

Evidence from ^{19}F nmr spectra, which might have been expected to distinguish **4***a* from **5**, was not helpful. The spectrum of **4***a* showed four peaks, of approximately equal intensity, suggesting that four non-equivalent trifluoromethyl groups were present. However, because of the conformation of chelate rings, such non-equivalence can be found in a variety of possible structures for these complexes and cannot be taken as supporting any one of the postulated modes of attachment of the ligand.



8



9

In **8**, the carbonyl frequency was at 1640 cm^{-1}, similar to **4**. However, by control of the pH at which the complex precipitated, we were able to protonate **8** to give the cationic complex **9**. In the latter, the carbonyl frequency is at 1699 cm^{-1}, very similar to that in the coordinated HFDA complex **7**, and this change on protonation supports our suggestion that the unusually low carbonyl stretching frequencies in **4** and **8** result from the presence of the adjacent uncoordinated anion within the ligand molecule.

It was not possible to isolate a stable, protonated, cationic form of **4***a* analogous to **9**; the acidification of the solution of the complex merely leading to decomposition. This we ascribe to the greater susceptibility of the four-coordinate metal ion in a cation complex to nucleophilic attack, whereas the five-coordinate metal in **9** is relatively shielded. It is also significant that, using HFDA, which we have found to be a weak ligand giving a very limited range of complexes (6), we were able to isolate a stable five-coordinate nickel complex with [12]-ene-3 as co-ligand, but we could not prepare a stable four-coordinate nickel complex using TMED as co-ligand.

We therefore conclude that the ionized keto-diol **1** acts as a chelating, dinegative, bidentate ligand forming complexes in which considerable charge separation remains. It is peculiarly suited to coordination to dipositive ions, giving neutral, zwitterionic, structures.

Similar behaviour was found for the fluorinated

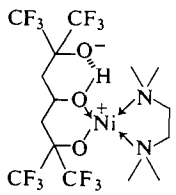
†m = methanol, d = dichloromethane, py = pyridine.

triol **2**, although it was a poorer donor than the keto-diol. Using TMED as co-ligand, a neutral nickel complex was prepared, to which structure **10** is tentatively given.



10

This structure, in which chelation occurs through the central, un-ionized, hydroxyl and one of the terminal, ionized, $-C(CF_3)_2O^-$ groups, is preferred by analogy with the keto-diol complex **4***a*. However, a structure in which chelation occurs through the two terminal groups, analogous to **5**, cannot be ruled out on present evidence. The charge separation in **10** may be reduced by hydrogen-bonding between the two oxygen atoms. However, although reduction of the ketone has increased the flexibility of the ligand at the central carbon atom, it is still not able to act in a tridentate fashion. In an effort to reduce steric hindrance offered by the co-ligand, we briefly investigated complexes in which TMED was replaced by *N*,*N*′-dimethylethylenediamine or by ethylenediamine. In neither case was a five-coordinate nickel complex detected.

As mentioned above, complexes of the imino-diol **3** were prepared by template synthesis without isolation of the free ligand. We have previously shown (5) that the amino-alcohol **11** will form complexes with a variety of metal ions, acting as a bidentate, uninegative, ligand. On reacting **11** with Ni^{2+} ions in the presence of HFDA, condensation occurred to produce the neutral mixed-ligand complex **12**. This in turn reacted with nitrogen donors, such as TMED or pyridine, to displace the amino-alcohol and produce neutral four- or five-coordinate complexes in which **3** was acting as a tridentate ligand. The mode of attachment of the ligand, and the coordination number of the metal, are shown by the appearance of the visible spectra (Table 1), where well-defined differences between four- and five-coordinate nickel(II) are shown.

Since five-coordination on Ni^{2+} was readily achieved in **13**, the reason why the similar complexes **4***a* and **10** remained four-coordinate (despite the attraction of the separated charge and the potential formation of another chelate ring) would appear to be in the unfavorable geometry of the ligands, rather than in steric hindrance at the metal.

Of the three potential ligands studied, therefore, we have found that only **3**, the most flexible, is capable of tridentate chelation to Ni^{2+}. We conclude that, for such a mode of action in a donor of this type, the third potential coordinating site in the molecule should be included in the chain of atoms connecting the two $-C(CF_3)_2O^-$ groups, rather than be a substituent on this chain.

Solvation and Five-coordinate Nickel

We have previously demonstrated (2, 6) that many of the four-coordinate fluorinated alkoxy-complexes of Ni^{2+} and Cu^{2+} become five-coordinate by the addition of a donor solvent molecule, although, probably for steric reasons, a further increase to six-coordination is not seen. Of the compounds included in the present study, none of those which were five-coordinate reacted with donor solvent (e.g. pyridine) to become six-coordinate. Of the red, four-coordinate, nickel species, compounds **4***a*, **10**, and **15** readily reacted with pyridine to give green, five-coordinate, adducts, the addition being reversed by moderate heating *in vacuo*. The presence of five-coordination was established from the similarity of the visible spectra to those we have described before (2).

Compounds **12** and **13** are of some interest in this connection. In the latter, five-coordination is achieved, although we have previously found (2) that,

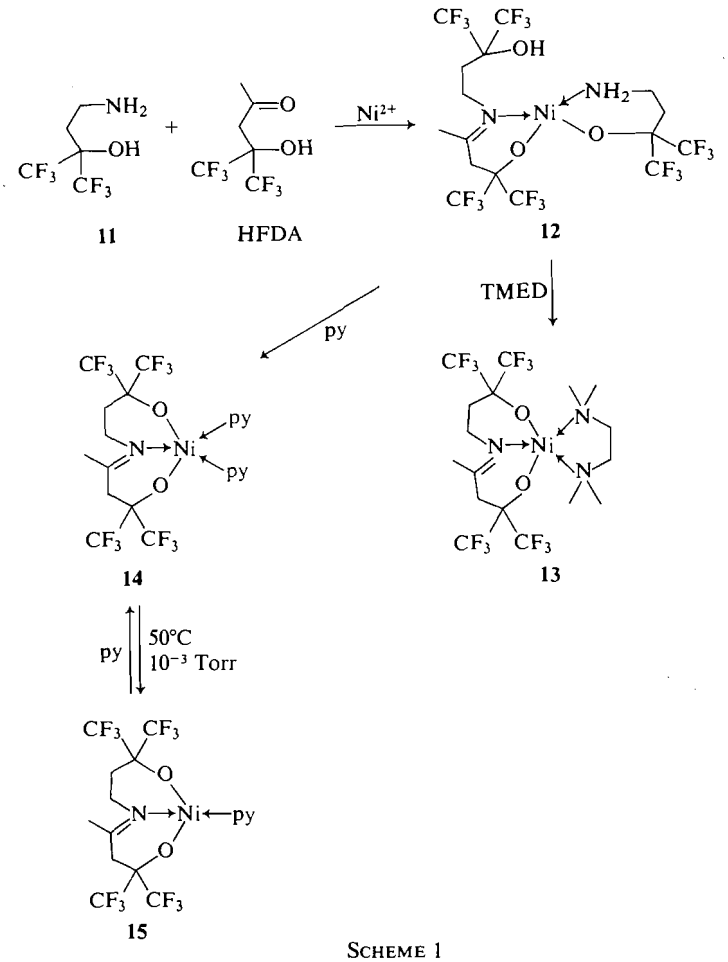
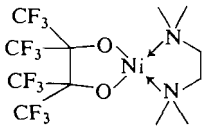


SCHEME 1

for steric reasons, the perfluoropinacol complex **16**, whose four donor groups are all present in **13**, will not react with pyridine or other donors.



16

Presumably the formation of the additional chelate ring in **13** provides the impetus necessary to overcome this barrier. In compound **12**, five-coordination could be achieved by coordination of the unionized $-C(CF_3)_2OH$ group, but this does not occur. This may be partly due to the weak donor ability of this group, compared to ionized $-C(CF_3)_2O^-$ or a nitrogen base, but it is also consistent with steric hindrance. Whereas in **13** the five-coordinate nickel is surrounded by two fluorinated alkoxy groups and three nitrogen donors, it would be necessary for three bulky fluorinated alkoxy groups to coordinate in order for **12** to become five-coordinate.

Experimental

General

Volatile compounds were handled in a conventional vacuum system. Infrared spectra were recorded on a Perkin-Elmer 621 instrument, visible spectra on Cary 14 and Cary 118 spectrometers. Microanalyses (Table 2) were performed by Alfred Bernhardt Laboratories, West Germany.

1,1,1,7,7,7-Hexafluoro-2,6-bis(trifluoromethyl)-2,6-dihydroxyheptane-4-one (1)

This compound was prepared by the reaction of hexafluoroacetone with acetone, as reported previously (7). In a typical preparation, 20 g of hexafluoroacetone was heated with 20 ml of dry acetone (spectroscopic grade solvent, used without further purification) at 135°C for 4 days in a sealed Carius tube. After removal by distillation of excess acetone and HFDA, **1** remained as a solid. It was purified by recrystallization from ethanol; mp 74–75°C (lit. mp 74–75°C). The yield was about 40% based on hexafluoroacetone.

1,1,1,7,7,7-Hexafluoro-2,6-bis(trifluoromethyl)heptane-2,4,6-triol (2)

A solution of the keto-diol **1** (7.8 g, 20 mmol) in anhydrous diethyl ether (40 ml) was added dropwise to a slurry of lithium tetrahydridoaluminate (0.76 g, 40 mmol) in ether. After refluxing for 1 h, excess hydride was destroyed by the cautious addition of water. The solution was acidified with 30%

†Fluorine content.

aqueous sulfuric acid, extracted with ether, and the ether extract dried and evaporated to yield the triol **2**, recrystallized from ethanol, mp 70–71°C, in essentially quantitative yield.

Metal Complexes

The nickel complex **4***a* was prepared by dissolving nickel(II) chloride hexahydrate (2.37 g, 10 mmol) and TMED (1.74 g, 15 mmol) in ethanol and adding an ethanolic solution of **1** (3.90 g, 10 mmol) and potassium hydroxide (1.12 g, 20 mmol) with slight warming. The solution was then cooled to 0°C and precipitated potassium chloride removed by filtration. After removal of solvent, the residue was recrystallized from dichloromethane to give **4***a* as red crystals.

The copper complex **4***b* was prepared by the same method using copper(II) chloride; purple crystals from dichloromethane.

The analogous nickel triol complex, **10**, was prepared by the same procedure, using the triol **2**; red crystals from dichloromethane.

For the [12]-ene-3 complexes, the starting material was the cationic hydroxo-complex $[Ni_2([12]\text{-ene-}3)_2(OH)_2](ClO_4)_2$, whose preparation has been described previously (6, 8).

Ligand **1** was added to this in a 2:1 molar ratio in hot methanol and the solution filtered and evaporated to give complex **8**, recrystallized from ether/hexane. When dilute aqueous perchloric acid was added to **8** in methanol in a 1:1 molar ratio and the solution filtered and evaporated, complex **9** was obtained.

For the series of complexes **12**–**15**, the starting material was the amino-alcohol **11**, prepared as described previously (5). To a solution of nickel chloride hexahydrate (2.73 g, 10 mmol) in ethanol was added **11** (2.11 g, 10 mmol) followed by HFDA (2.24 g, 10 mmol) and potassium hydroxide (1.12 g, 20 mmol). Precipitated KCl was removed by filtration and the solution evaporated to yield the mixed complex **12**; red crystals from dichloromethane.

Addition of TMED (1.74 g, 15 mmol) to a solution of **12** (6.55 g, 10 mmol) in ethanol, followed by filtration and evaporation, gave the TMED complex **13**, green crystals from ether/hexane. Similarly treatment of **12** with pyridine in ethanol gave the dipyridine complex **14**, green crystals from pyridine/ethanol. The latter was converted to the red monopyridine complex **15** by maintaining at 50°C *in vacuo* for 48 h with intermittent grinding.

Infrared spectra of the complexes showed, in addition to carbonyl absorptions discussed above, typical imino C=N absorptions in the region 1645–1665 cm^{-1} for compounds **7**–**15**. All complexes showed strong C—F absorption at 1150–1250 cm^{-1}; **7** and **9** also showed strong, broad absorption due to ClO_4^- at 1100 cm^{-1}.

Réduction électrolytique de l'aluminium en milieu organique. Caractérisation de l'électrolyte

R. LAFORTUNE, J. T. BOURRET ET G. A. CAPUANO
Département de chimie, Université du Québec à Montréal, Montréal (Qué.), Canada H3C 3P8

Reçu le 16 novembre 1977

R. LAFORTUNE, J. T. BOURRET et G. A. CAPUANO. Can. J. Chem. **56**, 2375 (1978).

Différents électrolytes à base d'alkylbenzène utilisés dans la réduction électrolytique de l'aluminium ont été analysés par chromatographie en phase gazeuse. Aucun produit de réduction ou d'oxydation des solvants organiques n'a été decélé dans les conditions d'électrolyse habituelles. Les solvants tels que toluène, éthylbenzène et diéthylbenzène subissent en présence de bromure d'aluminium des réactions de dismutation. Avec ou sans électrolyse, les électrolytes à base d'éthylbenzène–toluène 1:1 et de diéthylbenzène–toluène 1:4 tendent vers des compositions d'équilibre très voisines expliquant de ce fait pourquoi des revêtements électrolytiques d'aluminium de qualité semblables sont obtenus.

L'effet de la teneur en eau sur la qualité des revêtements d'aluminium obtenus par réduction électrolytique a été étudié. L'étude nous a révélé que les meilleurs revêtements sont obtenus lorsque les solvants organiques sont utilisés "tels que reçus". Ceci nous évite tout traitement de deshydratation ou d'hydratation de ces solvants.

R. LAFORTUNE, J. T. BOURRET, and G. A. CAPUANO. Can. J. Chem. **56**, 2375 (1978).

Various alkylbenzene-based electrolytes used in the electrolytic reduction of aluminum were analyzed by gas phase chromatography. Neither oxidation nor reduction products could be detected in the usual electrolysis conditions. Solvents such as toluene, ethylbenzene, or diethylbenzene undergo dismutation reactions in the presence of aluminum bromide. With or without electrolysis, electrolytes based on 1:1 ethylbenzene/toluene and 1:4 diethylbenzene/toluene tend toward nearby equilibrium compositions. This fact explains why electrolytic aluminum coatings of similar quality are obtained.

The effect of water content on the quality of aluminum coatings obtained by electrolytic reduction was studied. The study revealed that better coatings are obtained if the organic solvents are used 'as received'. Thus it was possible to avoid the pretreatments of drying or hydrating these solvents.

[Journal translation]

Introduction

L'électrodéposition de l'aluminium sur du cuivre ou de l'acier est possible en milieu non-aqueux. Récemment, Capuano et coll. (1, 2) ont réussi, par réduction électrolytique en milieu d'alkylbenzène, à obtenir des revêtements d'aluminium adhérents, ductiles et cohérents, d'une épaisseur de 2 mil (0.05 mm) avec des rendements anodiques et cathodiques (3) de 100%. L'électrolyte le plus fréquemment utilisé (mélange éthylbenzène–toluène 1:1 en volume contenant 50% $AlBr_3$ en poids) diffère des autres électrolytes rapportés dans la littérature (4, 5) du fait que solvants et solutés sont de qualité commercial et qu'en plus, les solvants peuvent être directement utilisés sans traitement de déshydratation. Il a été récemment (3) observé que les électrolytes de diéthylbenzène–toluène 1:4 volume, fournissent des rendements cathodiques et des dépôts d'aluminium identiques à ceux obtenus par l'éthylbenzène–toluène 1:1 volume.

Les conditions d'électrolyse de l'aluminium dépendent beaucoup de la nature de l'électrolyte. Deux paramètres particulièrement importants pour la réussite d'un revêtement de qualité font l'objet de la

TABLEAU 1. Description des principaux électrolytes utilisés (electrolytes contenant 50% $AlBr_3$ en poids)

Electrolytes	Hydrocarbures utilisés	Durée du vieillissement	Durée de l'électrolyse (h)
A_1	Ethylbenzène	1 jour	0
A_2	Ethylbenzène	7 jours	0
A_3	Ethylbenzène	84 jours	0
A_4	Ethylbenzène–toluène (1:1)	56 jours	0
B_1	Ethylbenzène–toluène (1:1)	57 h	57
B_2	Diéthylbenzène–toluène (1:4)	365 jours	400
B_3	Phase surnageante de l'échantillon B_2 (couche de solvant)	365 jours	400

présence étude: la composition du mélange d'alkylbenzènes et sa teneur en eau.

Partie expérimentale

En ce qui concerne d'abord le mélange d'alkylbenzène, deux séries d'électrolytes sont préparées. Dans la série A, (voir tableau 1) on se préoccupe principalement de l'effet de vieillissement de l'électrolyte sans aucune électrolyse et dans la série B, on étudie le vieillissement de l'électrolyte sous les conditions habituelles d'électrolyse (1–3), ainsi que la composition de sa phase surnageante. La préparation des électrolytes des séries A et B est analogue à celle décrite précédemment (3).

Dans un deuxième temps, l'effet de l'addition d'eau aux solvants utilisés pour la préparation de l'électrolyte a été étudié. Par rapport à un électrolyte organique rigoureusement exempt d'eau (1) de couleur rouge–orange, peu conducteur et ne produisant aucun revêtement d'aluminium, un électrolyte préparé d'un solvant de qualité commerciale contenant une faible quantité d'eau produit un mélange d'une couleur allant du brun au noir dont la conductivité est légèrement plus élevée et les revêtements électrolytiques obtenus sont de haute qualité.

De tous les mélanges d'alkybenzènes que nous avons examinés (1), l'électrolyte d'éthylbenzène–toluène 1:1 s'est révélé le plus avantageux et a été choisi pour l'étude de l'effet de l'eau. Le rôle de l'eau dans l'électrolyse de l'aluminium a donc été évalué lors de trois expériences réalisées selon la procédure déjà décrite: (*a*) l'électrolyse en milieu d'éthylbenzène–toluène anhydre, (*b*) l'électrolyse en milieu d'éthylbenzène–toluène de qualité commerciale et (*c*) l'électrolyse en milieu d'éthylbenzène–toluène partiellement saturé d'eau.

(a) Analyse chromatographique des électrolytes

Réactifs

Cyclohexane; *n*-hexane; méthylcyclohexane; éthylcyclohexane; tetrachlorure de carbone (Fisher grade A.C.S.). Benzène; *para*-xylène; *méta*-xylène; *ortho*-xylène (reactif analytique Baker). Méthyl-1 cyclohexadiène-1,4; triméthyl-1,3,5 benzène; éthyl-1 méthyl-2 benzène; triméthyl-1,2,4 benzène; diéthyl-1,2 benzène; diéthyl-1,3 benzène; diéthyl-1,4 benzène; diéthyl-1,3 méthyl-5 benzène; triéthyl-1,3,5 benzène; éthyl-1 méthyl-3 benzène (Chemical Samples Co., Columbus, Ohio); bromobenzène (Aldrich Chemical, Milwaukee, Wisconsin).

Ces produits ont été utilisés tels que reçus. Cependant une analyse chromatographique en phase gazeuse de traces a démontré que la pureté de chacun était de 99.6+%.

Appareils

Lors de l'analyse par chromatographie en phase gazeuse nous avons utilisé un appareil Perkin-Elmer Modèle 990 à programmation de température et à détecteur à ionisation de flamme, muni d'une colonne de 6 pieds de Carbowax 20M à 5% sur Chromosorb W. L'azote utilisé comme éluant s'écoule à 300 ml/min: la température du collecteur et celle de la chambre d'injection sont à 225°C: les échantillons de 1.0 µl sont élués à une température initiale de 60°C durant 3 min puis dans un gradient de température de 6°/min jusqu'à 150°C maintenue durant 8 min. On a estimé à ±2% la précision par chromatographie en phase gazeuse. La préparation de solutions étalons a permis, par l'établissement de droites de calibration, de préciser davantage les données de l'analyse semi-quantitative et d'obtenir des valeurs quantitatives de concentration des produits tels que benzène, éthylbenzène, diéthylbenzène et triéthylbenzène.

Traitement des échantillons

Une portion de 25 ml d'électrolyte est ajoutée à 75 ml d'eau distillée glacée. Après une agitation vigoureuse, la solution est décantée et la couche organique est séchée sur Na_2SO_4. Une portion de 5.00 ml de cette phase organique est transférée dans un ballon jaugé de 50 ml. On ajoute 0.5 ml de bromobenzène (référence interne de l'analyse chromatographique) et le volume est complété avec du CCl_4. Il a préalablement été établi que l'échantillon ne contenait pas de bromobenzène.

La concentration des produits est déterminée par la méthode de triangulation; le rapport R est calculé selon l'équation suivante:

$$[1] \quad R = \frac{\text{Surface du pic du produit}}{\text{Surface du pic de l'étalon interne}} = \frac{\text{Conc. du produit}}{\text{Conc. de l'étalon int.}}$$

La concentration de l'étalon interne étant de 1.00% v/v, et le facteur de dilution de l'échantillon étant de 10, le pourcentage en volume du produit analysé est donné par l'équation simplifiée:

$$[2] \quad \text{Concentration (\% v/v)} = 10.0R$$

L'analyse quantitative s'effectue avec des solutions standards de chacun des produits contenant 1.00% de bromobenzène comme étalon interne. En même temps que l'analyse chromatographique, une portion de l'électrolyte a été prélevé pour une hydrolyse et une distillation fractionnée. Chacun des consti-

TABLEAU 2. Analyse chromatographique semi-quantitative des électrolytes*

Produit	Temps de rétention (min)	Concentration des produits de dismutation (% v/v)						
		A_1	A_2	A_3	A_4	B_1	B_2	B_3
Benzène	1.4	21.8	22.1	20.2	24.0	15.8	7.79	10.2
Toluène	2.3				30.0	28.8	26.6	35.8
Ethylbenzène	3.6	54	53	48	14.0	17.3	9.74	10.6
Méta-xylène	3.7						3.98	5.36
Ortho-xylène	4.8					0.33	1.30	1.34
Ethyl-1 méthyl-3 benzène	5.7				5.94	10.7	17.9	25.0
Ethyl-1 méthyl-2 benzène	6.2				0.75	0.97	1.83	2.28
Diéthyl-1,3 benzène	7.4	21.7	23.6	25.9	0.83	3.41	3.20	2.70
Diéthyl-1,2 benzène	8.0				2.00	3.65	4.63	<0.05
Diéthyl-1,3 méthyl-5 benzène	9.5				15.2	12.8	7.79	1.79
Triéthyl-1,3,5 benzène	11.0	2.50	3.86	4.29	1.67	1.95	<0.05	

NOTE: Les analyses chromatographiques et spectroscopiques n'ont révélé aucune trace des produits suivants dont on soupçonnait la présence: cyclohexane; *n*-hexane; méthylcyclohexane; éthylcyclohexane; *para*-xylène; méthyl-1 cyclohexadiène-1,4; triméthyl-1,3,5 benzène; triméthyl-1,2,4 benzène; diéthyl-1,4 benzène.
*Composition des électrolytes établie au tableau 1.

tuants analysés par chromatographie a été d'abord identifié par spectrométrie de masse.

(b) Dosage de l'eau (méthode Karl Fisher)

Appareils

Le titrage a été effectué à l'aide d'un titrimètre Fisher Modèle 35. Deux électrodes de platine fixées dans le couvercle de la cellule de titrage sont branchées au titrimètre et placées sous une tensions de polarisation de 0.65 V.

Réactifs

Le tartrate de sodium dihydraté et le méthanol (0.05% H_2O) (produits de Anachemia Chemicals); les desséchants: P_2O_5, le chlorure de calcium et le réactif Karl Fisher (SOK-3) (produits de Fisher) ont été utilisés sans purification.

Etalonnage des réactifs

Le réactif Karl Fisher est étalonné à l'aide de tartrate de sodium dihydraté ou de chlorure de calcium. Une fois étalonné ce réactif sert à son tour à standardiser la solution méthanol–eau. Cette dernière est utilisée comme liquide de fond et comme titrant de retour dans l'analyse des solvants.

Etalonnage des réactifs (Karl Fisher et méthanol–eau)

On ajoute 70 ml de méthanol–eau dans la cellule de titrage et on titre avec le réactif Karl Fisher au point nul. On ajoute ensuite de 0.05 à 0.15 g de tartrate de sodium dihydraté et après dissolution du sel on titre à nouveau avec le même réactif au même point nul. Les burettes sont toutes protégées de l'humidité de l'atmosphère par un tube desséchant (P_2O_5) intallé à leur extrémité supérieure.

Dosage de l'eau dans les solvants

Le toluène et l'éthylbenzène (reactif analytique Baker) ont été utilisés à trois degrés d'hydratation: (*a*) asséché, (*b*) tel que reçu et (*c*) partiellement saturé d'eau.

(*a*) Dans le premier cas, les solvants ont été asséchés (0.005% H_2O) par reflux en présence de P_2O_5 pendant 3 h, suivi d'une distillation (la première et la dernière partie du distillat ont été rejetées). Après que leur température a atteint 25 ± 0.1°C une partie du solvant distillé a été transférée à vase clos dans la cellule de titrage et une partie dans la cuve d'électrolyses. Le transvasement est effectué à l'aide d'une pression imposée par l'argon sec. (*b*) Les solvants utilisés "tels que reçus" n'ont subi aucun traitement. (*c*) Les solvants "partiellement saturés" ont été préparés en y faisant barbotter de l'azote humidifié pendant une heure à 25°C. L'humidification du gaz a été effectuée par le passage de ce dernier dans l'eau déionisée et distillée.

De 10 à 20 ml de solvant asséché par reflux en présence de P_2O_5, distillé et stabilisé à 25°C sont transférés dans la burette reliée à la cellule de titrage contenant 70 ml de méthanol–eau préalablement neutralisé au point nul par le réactif Karl Fisher. Une fois le solvant introduit dans la cellule, le titrage est répété avec le même réactif suivi d'un titrage de retour par la solution méthanol–eau.

Les autres solvants "tels que reçus" et "partiellement saturés" après avoir été conditionné sont directement versés dans une burette reliée à la cellule de titrage et analysés de la même façon que le solvant asséché.

Résultats et discussion

L'examen de la composition chimique résiduelle des trois électrolytes utilisés dans la réduction de l'aluminium a révélé des modifications importantes dans la nature des composés présents. Ces changements dans la composition du mélange électrolytique ne sont imputables ni a l'oxydation ni à la réduction des solvants organiques, mais ils résultent plutôt de réactions de dismutation.

Electrolyte d'éthylbenzène

A partir du tableau 2, on peut noter les faits suivants relatifs aux échantillons A_1, A_2 et A_3. Du volume inital d'éthylbenzène, près de la moitié de ce solvant est modifié pour donner d'égales quantités de benzène et de diéthylbenzène et quelques pourcents de triéthylbenzène et ce, en moins de 24 h et sans électrolyse. Laissé au repos pendant trois mois, la composition de ce mélange ne varie alors que très peu.

Dans le but d'établir les constantes d'équilibre des réactions de dismutation, l'analyse quantitative des consituants de l'électrolyse dans l'éthylbenzène a été réalisée. Les fractions molaires rapportées au tableau 3 montrent que 47% de l'éthylbenzène est modifié en moins de 24 h et que la réaction évolue très lentement après sept jours (48% en fraction molaire). En trois mois, l'équilibre est presque atteint et la

TABLEAU 3. Analyse quantitative de l'électrolyte éthylbenzène–$AlBr_3$*

Produit	Temps de rétention (min)	Concentration (% v/v)			Fraction molaire		
		A_1	A_2	A_3	A_1	A_2	A_3
Benzène	1.4	15.6	15.9	15.2	0.218	0.214	0.222
Ethylbenzène	3.6	53	52	47	0.540	0.52	0.50
Diéthylbenzène	7.4	24.3	26.4	29.0	0.217	0.229	0.240
Triéthylbenzène	11.0	3.10	4.78	5.32	0.025	0.037	0.038

*Composition des électrolytes établie au tableau 1.

concentration molaire est de 50%. On a observé que l'éthylbenzène se dismute en benzène, en diéthylbenzène et en triéthylbenzène. D'une façon analogue les électrolytes d'éthylbenzène–toluène 1:1 et diéthylbenzène–toluène 1:4 produisent par dismutation des mélanges d'alkylbenzènes de compositions très semblables.

L'obtention d'un mélange d'alkylbenzène à partir d'éthylbenzène provient de deux types de réactions: (*1*) isomérisation: migration intramoléculaire de type 1,2 de groupements alkyles; (*2*) dismutation: migration intermoléculaire de groupes alkyles.

Les premières observations de la dismutation de l'éthylbenzène en présence d'halogénure d'aluminium ($AlCl_3$) ont été faites par Anschütz (6) en 1886.

La réaction de dismutation de l'éthylbenzène en présence de $HF–BF_3$ a été étudiée par Lien et McCaulay (7). Les produits de cette réaction sont le benzène, le diéthyl-1,3 benzène et la constante d'équilibre de ce système est donnée par la réaction [3] et l'éq. [4].

[3] $$2C_6H_5C_2H_5 \rightleftarrows C_6H_6 + C_6H_4(C_2H_5)_2$$

[4] $$K = \frac{[\text{benzène}][\text{diéthylbenzène}]}{[\text{éthylbenzène}]^2} = 0.22$$

En se rapportant au tableau 3, on peut voir que, en ignorant la faible quantité de triéthylbenzène, le calcul de la constante d'équilibre à partir des fractions molaires de l'échantillon A_3 est 0.21. D'après Lien et McCaulay (7) les migrations intermoléculaires des méthyles sont presque inexistantes et seule l'isomérisation est possible.

La réaction de dismutation de l'éthylbenzène et la cinétique de cette réaction ont été étudiées par McCaulay et Lien (7, 8). La cinétique (7) de cette réaction semble être du second ordre. Le mécanisme proposé par Roberts, Ropp et Neville (9) fait intervenir une migration intermoléculaire des groupes éthyles par l'intermédiaire d'une liaison partielle du ^{14}C en α du cycle avec une molécule d'éthylbenzène.

Electrolyte d'éthylbenzène–toluène 1:1

Dans le cas des échantillons A_4 et B_1 préparés à partir d'un mélange 1:1 volume d'éthylbenzène et toluène, 85 et 70% respectivement des volumes de chacun des solvants de départ ont participé à des réactions de dismutation après trois mois avec ou sans électrolyse.

En comparant les échantillons A_4 avec les trois premiers (A_1, A_2 et A_3), on peut voir, que les quantités de benzène sont demeurées semblables et que celles du diéthylbenzène sont réduites par un facteur de 10 au profit des éthylméthylbenzènes et du diéthylméthylbenzène. Le triéthylbenzène subit aussi une baisse. Il est à remarquer que cette comparaison est également valable pour les échantillons B_1 et ceux de A_1, A_2 et A_3. De ce fait, la présence de toluène accélère la dismutation de l'éthylbenzène.

Le fait qu'aucune différence significative n'ait été trouvée dans les compositions des échantillons A_4 et B_1 (électrolytes d'éthylbenzène–toluène avec et sans électrolyse) illustre clairement que l'électrolyse ne fournit aucun produit de réduction ou d'oxydation du solvant tels que méthyl ou éthylcyclohexane ou autres; les produits identifiés dans tous les échantillons ne proviennent que d'équilibres chimiques entre divers alkylbenzènes en présence du catalyseur de bromure d'aluminium.

Electrolyte de diéthylbenzène–toluène 1:4

Il a été observé par Capuano et coll. (3) que les électrolytes d'éthylbenzène–toluène 1:1 et diéthylbenzène–toluène 1:4 fournissaient les mêmes rendements cathodiques et d'excellents dépôts d'aluminium. Le tableau 2 montre clairement la similitude des compositions chimiques des électrolytes à l'équilibre (échantillons B_1 et B_2); les concentrations de diéthylbenzène sont identiques.

On notera que certains résultats des échantillons B_1, B_2 et B_3 doivent être examinés à la lumière de deux faits expérimentaux: le premier étant que ces électrolytes ont subi de fréquentes additions de leurs solvants respectifs afin d'en maintenir le bon rendement lors des électrolyses; le second fait étant que la circulation de l'argon sec visant à conserver l'électrolyte à l'abri de l'humidité favorise l'élimination

des constituants les plus volatils tels que le benzène et le toluène.

Compte tenu de la précision de la méthode d'analyse et des faits expérimentaux mentionnés plus haut, on voit que les concentrations des produits des échantillons A_4 et B_1 sont très voisines, les concentrations des échantillons B_2 et B_3 sont aussi très voisines à l'exception du benzène et éthyl-1 méthyl-3 benzène qui sont plus riches dans l'échantillon B_3 tandis que diéthyl-1,2 benzène et diéthyl-1,3 méthyl-5 benzène ont des concentrations plus élevées dans B_2.

Finalement, une comparaison des échantillons B_1 et B_2 peut révéler certains résultats intéressants tels que l'égalité des concentrations de diéthylbenzène, l'apparition de *m*-xylène et la baisse de diéthyl-1,3 méthyl-5 benzène dans l'échantillon B_2.

Phase surnageante (couche de solvant)

Lors de l'électrolyse, le mélange électrolytique se sépare en deux phases. La phase surnageante comportant presque exclusivement le solvant et la phase sous-jacente qui constitue l'électrolyte proprement dit.

La comparaison des constituants de l'électrolyte et ceux de la couche de solvant peut nous renseigner sur l'importance de certains équilibres et la nature des complexes du $AlBr_3$ avec les divers alkylbenzènes. Les produits suivants se retrouvent en plus grande concentration dans la phase solvant: éthyl-1 méthyl-3 benzène; *méta*-xylène; éthyl-1 méthyl-2 benzène alors que le diéthyl-1,3 méthyl-5 benzène et le diéthyl-1,2 benzène se retrouvent en plus grande proportion dans l'électrolyte.

Les différences de concentrations de certains produits dans l'électrolyte et dans la phase surnageante ont été observées par McCaulay et Lien (10). Selon eux, les molécules se partagent entre les deux phases selon leur basicité respective à l'égard du proton telle qu'illustré au tableau 4. Ce phénomène se vérifie également dans nos électrolytes.

L'effet de l'eau

Les résultats ayant trait à la concentration de l'eau dans les solvants organiques sont résumés au tableau 5. On notera ici que les valeurs de saturation en eau des solvants saturés proviennent de la littérature (12, 13). Tel que mentionné dans la partie expérimentale nos premiers résultats nous avait révélé qu'un électrolyte exempt d'eau (0.005% H_2O) ne produisait aucune électrolyse (1). Suite à cette constatation nous avions sugéré (2) de saturer partiellement le solvant d'eau afin de favoriser l'électrolyse. Le présent travail nous a révélé cependant que parmi les trois mélanges à teneur en eau différente examinés, les meilleurs revêtements sont obtenus lorsque le solvant contient environ 25% de son taux de saturation en eau. Cette performance optimale correspond à celle obtenue avec le produit commercial tel que reçu. Cette constatation entraîne des avantages économiques, si on considère que les manipulations de séchage ou d'hydratation comportent un coût considérable dans l'utilisation du procédé à l'échelle industrielle.

TABLEAU 4. Basicités des alkylbenzènes relatives au *p*-xylène selon McCaulay et Lien (10)

Produit	Basicité relative
Toluène	0.01
p-Xylène	1.0
o-Xylène	3.0
m-Xylène	9
Ethylbenzène	—
Triméthyl-1,2,4 benzène	18
Triméthyl-1,2,3 benzène	18
Tétraméthyl-1,2,3,4,5 benzène	60
Tétraméthyl-1,2,3,4 benzène	85
Triéthyl-1,3,5 benzène	433
Diéthyl-1,3 méthyl-5 benzène	865
Triméthyl-1,3,5 benzène	1400
Tétraméthyl-1,2,3,5 benzène	2800
Pentaméthylbenzène	4350
Hexaméthylbenzène	44500

Un mécanisme a déjà été proposé (1) pour expliquer l'effet de l'eau sur la réaction aux électrodes. Nos travaux se poursuivent afin de déterminer la composition des complexes d'aluminium formés en milieu organique. Il serait intéressant aussi de déterminer la corrélation entre les complexes en milieu anhydre (électrolyte rouge–orange) et ceux en milieu plus hydraté (électrolytes brun–noirs).

Conclusions

L'analyse chromatographique en phase gazeuse d'électrolytes servant à la réduction électrolytique de l'aluminium nous a démontré que: (*1*) La réduction électrolytique de l'aluminium ne donne lieu à aucune réaction secondaire d'oxydation ou de réduction des solvants organiques dans les conditions d'électrolyse habituelles (densité de courant: 0–20 mA/cm^2). (*2*) L'électrolyte à base d'éthylbenzène–toluène 1:1 se dismute partiellement en benzène; diéthyl-1,3 méthyl-5 benzène; éthyl-1 méthyl-3 benzène; éthyl-1 méthyl-2 benzène; diéthyl-1,2 benzène; diéthyl-1,3 benzène; et triéthyl-1,3,5 benzène. (*3*) L'électrolyte à base de diéthylbenzène–toluène 1:4 contient les mêmes produits que l'électrolyte précédent et en plus, des xylènes. (*4*) Les compositions d'équilibre de dismutation très voisines de ces deux électrolytes expliquent la qualité comparable des revêtements d'aluminium de l'un et de l'autre.

Une étude de l'effet de la teneur en eau sur la qualité des revêtements d'aluminium par réduction

TABLEAU 5. Concentration d'eau dans les solvants choisis et effet de l'eau sur les revêtements d'aluminium

Solvant ou électrolyte contenant 50% $AlBr_3$ en poids	% H_2O (poids) 25°C	Degré de saturation en eau des solvants (%)	Qualité des revêtements d'aluminium
Toluène	0.005	10	
Toluène qualité commerciale (tel que reçu)	0.013	24	
Toluène partiellement saturé	0.034	63	
Toluène saturé (12)	0.054*	100	
Ethylbenzène asséché	0.005	15

Polarographic investigation of electron donor–acceptor complexes

LOUIS RAMALEY AND SONIA GAUL[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 29, 1977[2]

LOUIS RAMALEY and SONIA GAUL. Can. J. Chem. **56**, 2381 (1978).

Using a computer-controlled precision polarograph the formation constants of electron donor–acceptor (EDA) complexes formed from aromatic hydrocarbons and nitrofluorene derivatives have been determined in acetonitrile. The EDA interactions are of the same magnitude in this solvent as in less polar solvents. The strength of the complexes is related to the reduction potential (or electron affinity) of the acceptors and the size of the π system of the donors. Spectra of the complexes were computed from spectra of mixtures of acceptor and donor with the help of the polarographic data. No relationship between the molar absorptivity of the charge-transfer band and the formation constant was apparent from these spectra.

LOUIS RAMALEY et SONIA GAUL. Can. J. Chem. **56**, 2381 (1978).

Faisant appel à un polarographe de précision contrôlé par un ordinateur, on a déterminé, dans l'acétonitrile, les constantes de formation des complexes donneurs d'électrons accepteurs (DEA) qui se forment entre des hydrocarbures aromatiques et des dérivés du nitrofluorène. Les interactions DEA sont du même ordre de grandeur dans ce solvant que dans des solvants moins polaires. La force des complexes est reliée au potentiel de réduction (ou électroaffinité) des accepteurs et à la grandeur du système pi des donneurs. On a évalué les spectres des complexes à partir des spectres de mélanges de donneurs et d'accepteurs à l'aide de données polarographiques. Il ne semble exister aucune relation entre l'absorbance molaire de la bande de transfert de charge et la constante de formation si l'on se base sur ces spectres.

[Traduit par le journal]

Introduction

An electron donor–acceptor (EDA) complex results when a molecule of low ionization potential (electron donor, D) interacts with a molecule of high electron affinity (electron acceptor, A). Promotion of an electron from one of the upper filled orbitals of the donor to an unfilled acceptor orbital gives rise to one or more electron absorption bands not observed in the donor or acceptor spectra. These are usually termed charge-transfer (CT) bands and EDA complexes are classified according to the types of orbitals involved in the CT interaction (1). The molecules involved in this study form π–π EDA complexes which are usually reversibly and rapidly formed and exhibit low energies of interaction. Mulliken and Person (1) have published a thorough treatment of EDA interactions and an excellent review of EDA complexation has been produced by Foster (2).

Various correlations between properties of the donor or acceptor and the energy of the CT band have been demonstrated (2). Attempts at correlations involving the formation constant and other properties of EDA complexes or their components have been less successful. For example, the intensity of the CT band often decreases rather than increases as the formation constant increases. One reason postulated for this behaviour is that CT transitions can occur in the absence of a stable complex (3, 4), a phenomenon referred to as contact charge-transfer. A second reason is the difficulty in obtaining accurate values of formation constants for comparison. Various solvents and experimental procedures have been employed, different concentration units are encountered and these are sometimes not clearly specified. There are also certain inherent problems with the measurement methods themselves.

Optical and nuclear magnetic resonance spectroscopy are the most widely used methods for evaluating formation constants. In both methods two unknown properties of the complex must be determined from the data, the formation constant and molar absorptivity for optical spectroscopy or chemical shift for nmr spectroscopy. Usual data analysis methods treat only 1:1 complexes; however, more sophisticated data treatments are available (2) if 2:1 complexes are suspected.

Polarography and other electrochemical techniques have been employed less often in such studies. Peover (5, 6) has studied CT complexes in solvents of low dielectric constant. Holm *et al.* (7) have attempted to compare polarographic and spectrophotometric methods of study and Bonnaterre and Cauquis (8) have used voltammetry in studies of the kinetics of EDA complexation.

A mathematical treatment for the study of com-

plexation by polarography has been presented by De Ford and Hume (9). For the electrochemically reversible reduction of a complex

$$[1]\quad \exp\left[\frac{nF}{RT}[(E_{1/2})_A - (E_{1/2})_C] + \ln\left(\frac{i_A\eta_A{}^{1/2}C_C}{i_C\eta_C{}^{1/2}C_A}\right)\right] = 1 + K_1[D] + K_1K_2[D]^2 + \ldots$$

where the subscript A refers to solutions containing acceptor only and C refers to solutions containing both donor and acceptor, $E_{1/2}$ is the polarographic half-wave potential, i the diffusion limited current, η the viscosity of solution, C the analytical concentration of acceptor, and the other symbols have their usual meaning. The equilibrium constants K_1 and K_2 refer to the following reactions respectively:

$$[2]\quad A + D \rightleftarrows AD$$

$$[3]\quad AD + D \rightleftarrows AD_2$$

Equation [1] assumes that the concentration of donor is constant from the electrode surface to the bulk of solution and that activities are equivalent to concentrations. The first assumption requires that the analytical concentration of donor be much higher than that of the acceptor. This treatment does not take into account the possibility of a termolecular complex of the type A_2D.

In aprotic solvents many electron acceptors are reduced reversibly in one electron steps:

$$[4]\quad A + e^- \rightarrow A^-$$

$$[5]\quad A^- + e^- \rightarrow A^{2-}$$

An EDA complex formed from A and D can also be reduced

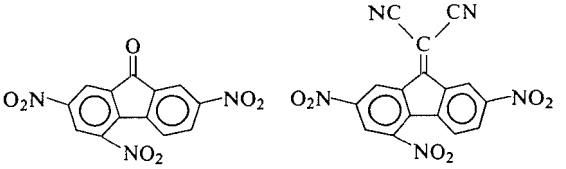
$$[6]\quad AD + e^- \rightarrow A^- + D$$

resulting in the dissociation of the complex. Upon addition of D to A the half-wave potential of the first reduction wave shifts to more negative values, the half-wave potential for the second wave, eq. [5], does not. If the diffusion coefficients of A and AD are equal and all diffusion coefficients remain constant, the shift in half-wave potential is equal to the shift in standard potential and is directly related to the free energy of formation of the complex. The term $\ln (i_A\eta_A{}^{1/2}C_C/i_C\eta_C{}^{1/2}C_A)$ from eq. [1] corrects the measured half-wave potentials for changes in diffusion coefficients. The viscosity correction, which did not appear in the original treatment (9), corrects for variations in the diffusion coefficient of A^- caused by changes in viscosity upon addition of large amounts of donor.

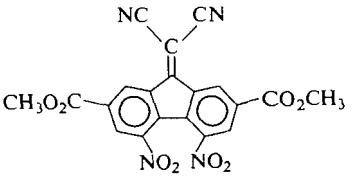
Holm *et al.* (7) have suggested that, when complexation occurs, measured polarographic half-wave potentials should be corrected for changes in the energy of the lowest vacant molecular orbital of the acceptor as indicated by a spectral shift, even though such corrections created an anomalous gap in their data. Since shifts in reversible polarographic half-wave potentials properly corrected for changes in diffusion coefficients are equivalent to shifts in standard potentials, such spectral corrections are unnecessary and incorrect.

Polarographic studies of EDA complexation provide formation constants without the need to simultaneously determine some other system parameter. The effect of certain types of termolecular complexes is easily assessed. However, the shifts in half-wave potential are rather small for weak complexes so that the method is less sensitive than optical spectroscopy. Experiments are best done in relatively polar solvents, require a background electrolyte to suppress migration currents and a relatively high donor concentration. Great attention must be paid to experimental detail.

This study was undertaken to examine EDA complexation in a fairly polar solvent, acetonitrile, to determine whether termolecular complexes might exist in this medium, and to attempt to calculate spectra of EDA complexes using formation constant data from a non-spectral source. The acceptors used were 2,4,7-trinitro-9-fluorenone (TNF) (**1**), 9-dicyanomethylene-2,4,7-trinitrofluorene (CNTNF) (**2**),



1 **2**



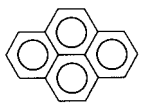
3

and dimethyl-4,5-dinitro-9-dicyanomethylene fluorene-2,7-dicarboxylate (CNDNFDMC) (**3**). The first two compounds are stable, form fairly strong EDA complexes and have found use as analytical reagents. The third compound is also reputed to form strong complexes and might prove useful in the synthesis of CT polymers (10).

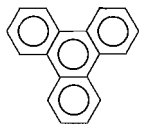
Aromatic hydrocarbons were used as donors;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

however, the choice is limited by solubility in the polar solvent since the donor must be in large excess. The compounds selected were naphthalene, phenanthrene, pyrene (**4**), triphenylene (**5**), biphenyl, *o*-



4



5

terphenyl (1,2-diphenyl benzene), and *m*-terphenyl (1,3-diphenyl benzene).

Experimental

Reagents

Since attempts at further purification produced little change in such characteristics as melting point, colour, or crystallinity, the following were used as received from the manufacturers: naphthalene (Fisher Scientific Co.); phenanthrene (98+%), pyrene (purris), triphenylene (98%), TNF and CNTNF (Aldrich Chem. Co.); and *m*-terphenyl (Eastman Organic Chemicals). Orthoterphenyl and biphenyl (Eastman) were recrystallized from petroleum ether. CNDNFDMC was synthesized according to the method of Sulzberg and Cotter (10).

Bulk reagent grade acetonitrile (Matheson, Coleman and Bell or Fisher Scientific) was purified by method B of Walters and Ramaley (11). The supporting electrolyte, tetrabutyl ammonium perchlorate (TBAP) was prepared by precipitation using tetrabutyl ammonium bromide (Eastman) and reagent grade perchloric acid. The product was repeatedly recrystallized from a water–ethanol mixture until the filtrate gave no precipitate on addition of silver nitrate. The resulting TBAP was dried at 110°C under vacuum.

Thallium metal (99.998%, Alfa Inorganics) was used as received. Distilled mercury was acid washed with dilute nitric acid for 12 h. Thallous perchlorate was prepared from thallous nitrate (Alfa) and perchloric acid by evaporation to dryness followed by three recrystallizations from water. The final product was dried at 120°C.

Polarographic Measurements

A highly precise, digitally controlled potentiostat (12) and sweep generator (13) were used as the polarographic instrumentation. These were controlled by a Hewlett-Packard 2114B minicomputer through a general purpose interface similar to that described by Ramaley and Wilson (14). Included in the computer system were paper tape and magnetic tape peripherals and a point plotter.

A thermostated three electrode cell was used in all measurements. Dry nitrogen could be bubbled through the working compartment which contained the dropping mercury electrode (dme) and a platinum wire counter electrode. The reference was a Tl(Hg)|$TlClO_4$ electrode prepared from a 0.79 wt.% thallium amalgam and a solution of 0.100 *M* TBAP saturated with $TlClO_4$. The reference electrode was separated from the working compartment by two frits and a salt bridge filled with 0.100 *M* TBAP. This electrode was chosen to minimize the liquid junction potential and its change with time since all solutions in the cell were also 0.100 *M* in TBAP. Using the data of Coetzee and Campion (15, 16) the potential of this electrode vs. an aqueous saturated calomel electrode was calculated to be −0.34 V. Experimental measurements produced the same value. The reference electrode was stable for periods of a few days; however, the thallium amalgam slowly decomposes requiring that fresh electrodes be prepared often.

The cell was placed in a small, nitrogen filled dry box during all measurements. The solutions were prepared and stored in the same dry box. Viscosities were determined using an Ostwald viscometer. All measurements were made at 25 ± 1°C.

The potentiostat was programmed to perform tast polarography. In this technique the current is measured at only one time during drop life rather than continuously. This time is usually chosen to be late in drop life when the Faradaic current is high and the background double layer charging current is low for improved sensitivity. With the instrumentation used tast polarography provides almost ideal polarograms since potential is constant during drop life (until after current measurement) and changes in drop time caused by the variation of potential have no effect.

Spectroscopic Measurements

All spectra were recorded using a Cary 14 visible–ultraviolet spectrophotometer also interfaced to the same computer system used for the electrochemical measurements (17).

Data Treatment

All data were recorded on magnetic tape for ease of storage and digital data analysis. Polarographic data analysis is usually done using eq. [7].

$$[7] \qquad E_{dme} = E_{1/2} + \frac{RT}{nF} \ln (i_d - i)/i$$

where i is the current measured at some potential E_{dme} and i_d is the current on the diffusion limited portion of the wave. The half-wave potential and n are determined from a linear least-squares analysis of a plot of E_{dme} vs. ln $(i_d - i)/i$. This suffers from the disadvantage that only points on the rising portion of the wave can be used and the precision of the calculated parameters is not easily determined. Since currents in polarography are additive

$$[8] \qquad i_t = i_b + i_1 + i_2 + \ldots$$

where i_t is the total current, i_b is the current flowing before the first polarographic wave, i_1 is the current for the first wave, etc. If one solves for the currents of the individual waves and substitutes into eq. [8], one obtains

$$[9] \quad i_t = i_b + \frac{(i_d)_1}{1 + \exp[(n_1F/RT)(E - (E_{1/2})_1)]} + \frac{(i_d)_2}{1 + \exp[(n_2F/RT)(E - (E_{1/2})_2)]} + \ldots$$

The values of i_b, $(i_d)_1$, $(i_d)_2$, n_1, n_2, $(E_{1/2})_1$, $(E_{1/2})_2$, etc. can be obtained from eq. [9] by non-linear least-squares analysis (18). This approach has the advantages that the diffusion currents also come from the analysis, more than one wave can be analyzed at a time and the waves can overlap, all the data are used and the precision of the calculated parameters comes directly from the analysis.

Programs were written for the Hewlett-Packard 2114B computer to subtract the background (a polarogram run of a solution of 0.100 *M* TBAP in acetonitrile) from all other polarograms and to determine the diffusion currents and half-wave potentials using eq. [9]. Another program was written to calculate the formation constants by linear least-squares analysis using eq. [1]. The data were analyzed by this program assuming first only a 1:1 complex and then assuming both 1:1 and 2:1 complexes. All concentrations were in mol/ℓ and thus the units of the formation constants are ℓ/mol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The spectra of the EDA complexes were computed by another program from spectra of the donor, the acceptor, and a mixture of the two assuming that Beer's law was obeyed. Using the formation constants determined polarographically the concentrations of all species in the mixture were calculated. The spectral contributions of the uncomplexed donor and acceptor were then determined and subtracted from the spectrum of the mixture to produce the spectrum of the complex. The validity of this computed spectrum depends directly on the accuracy of the formation constants; however, high accuracy is more important in the cases where very little complex is formed and the contribution of the free acceptor to the total spectrum of the mixture is large (the free donors contributed very little to these spectra in the visible and near ultraviolet).

All programs were written in Hewlett-Packard assembly language for the particular magnetic tape operating system used.

Results and Discussion

All polarograms obtained showed two one-electron reversible waves between +0.4 V and −0.4 V vs. the $Tl(Hg)|TlClO_4$ reference electrode used. Further reduction waves, the characteristics of which were dependent on solvent purity, were observed at more negative potentials. Reversibility was indicated since the values of n obtained from the data analysis were always close to unity. However, staircase cyclic voltammetry with variation in sweep rate was used to confirm reversibility. The cathodic and anodic peaks obtained were ideal in shape and shifted very little with sweep rate up to values of 6 V/s. The differences in cathodic and anodic peak potential were always very close to the theoretical value of 58 mV for a one-electron reversible reaction. Figures 1 and 2 show typical polarograms obtained in this study. No significant change in half-wave potential for either the first or second reduction wave of TNF was observed upon addition of biphenyl in Fig. 1. The diffusion current decreases due to the increase in viscosity as the concentration of biphenyl increases. The colour of solution changed slightly upon addition of biphenyl, as it did in every case studied, indicating an interaction between donor and acceptor. However, any complex formed was too weak to be detected polarographically.

In Fig. 2 the half-wave potential for the first reduction wave of TNF shifts negatively upon addition of pyrene, whereas the second wave does not shift. Table 1 shows the results obtained by non-linear least-squares analysis for the first wave. The precision of all the half-wave potentials determined from a single experiment by the least-squares data analysis was 300 μV or better. The reproducibility of these values from one experiment to another was 4 mV or better. This loss in precision is probably due to changes in the reference electrode potential with time. The average half-wave potentials for the three acceptors examined are listed in Table 2.

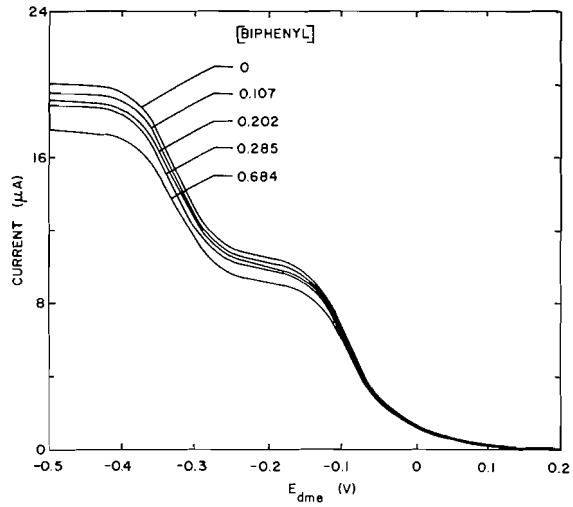


FIG. 1. Polarograms of 9.55×10^{-4} M TNF in acetonitrile and 0.100 M TBAP supporting electrolyte with biphenyl as donor.

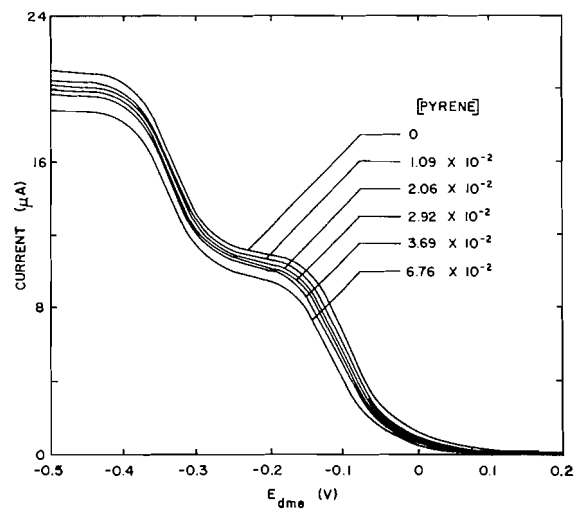

FIG. 2. Polarograms of 9.38×10^{-4} M TNF in acetonitrile and 0.100 M TBAP supporting electrolyte with pyrene as donor.

Table 3 presents the formation constant data for the EDA complexes. The absence of an entry indicates that any complex formed was too weak to be determined polarographically. The data were treated assuming that only a 1:1 complex formed and that both 1:1 and 2:1 complexes formed. When the two-complex model was used, K_2 was negative for eight of the 17 systems studied, indicating that random variation in the data caused a negative curvature. The nine cases where K_2 was positive were subjected to an analysis of variance on the sum of the squared residuals (19) to test whether the two-complex model produced a significantly better fit than the single

K_2	1.7 ± 0.5	1.0 ± 0.2

complex model. At the 95% confidence level only two systems, both with phenanthrene as donor, produced results in which the two-constant model gave a significantly better fit. No obvious reason presents itself to justify 2:1 complexes for phenanthrene (with only two of the three acceptors) and not for the other donors. This behaviour may thus be just due to chance irregularities in the data.

The standard deviations shown in Table 3 are a function of the magnitude of shift in half-wave potential which in turn is a function of both the strength of the complex and the quantity of the donor added. Thus the standard deviation of K_1 for the triphenylene–TNF complex is much higher than that for the pyrene–TNF complex even though the constants are about equal because triphenylene is much less soluble than pyrene in acetonitrile and the resulting shifts in $E_{1/2}$ are much less for triphenylene. In the case of the complexes of pyrene and triphenylene with CNTNF and CNDNFDMC, a precipitate was formed when donor and acceptor were mixed. These solids were still sufficiently soluble to allow determination of half-wave potentials. Since reversible half-wave potentials are independent of concentration, data analysis using eq. [1] could still be carried out. However, the changes in diffusion current that would have occurred in the absence of precipitation had to be estimated from the data for the TNF complexes. For this reason the values of formation constants for these complexes should be considered less certain.

A comparison of the half-wave potentials of the acceptors shows that CNTNF and CNDNFDMC should be about equal in electron affinity but much greater than TNF. The formation constants of CNTNF and CNDNFDMC are also about equal but much greater than those of TNF as expected. The constants for the condensed ring hydrocarbons are much larger than for biphenyl and the terphenyls. In both cases the constants increase as the size of the donor π system increases. The one exception to this is *o*-terphenyl which has a much smaller constant than *m*-terphenyl. This is probably due to steric hindrance in *o*-terphenyl which prevents proper overlap of the π systems of the donor and acceptor.

Although TNF and CNTNF are widely used reagents, few data are available regarding their complexes. The formation constant of the TNF–naphthalene complex determined by spectrophotometric measurement has been reported as 0.97 ℓ/mol in acetic acid at about 20°C (20), as 0.69 ℓ/mol in $CHCl_3$ at 18°C (21), and as 0.75 ℓ/mol in $CHCl_3$ at 20°C (22). Although these values and that obtained in the present work are nearly identical, it is difficult to make comparisons because of differences in solvent and solution components.

Dewar and Thompson (23) have studied the EDA complexes of tetracyanoethylene (TCNE) spectrophotometrically in $CHCl_3$ at 25°C with the same donors as used above. Their results are presented in Table 4. The first half-wave reduction potential for TCNE vs. the Tl(Hg)|$TlClO_4$ reference electrode used in this study is about +0.58 V and thus it should be an even better acceptor than either CNTNF or CNDNFDMC. In general as the solvent becomes more polar, EDA complexes become weaker due to competition from solvent molecules. Thus it would be expected that the EDA complexes studied here would be less stable than those of TCNE in $CHCl_3$. The trends observed by Dewar and Thompson are similar

TABLE 4. Formation constants of EDA complexes of TCNE at 25°C in $CHCl_3$ from ref. 23

Donor	K_1
Naphthalene	1.01
Phenanthrene	2.16
Pyrene	2.79
Triphenylene	3.52
Biphenyl	0.67
o-Terphenyl	0.15
m-Terphenyl	0.64

to those observed here but the changes in formation constants between donors appear to be much greater in acetonitrile and most of the constants are also greater in acetonitrile. Holm *et al.* (7) have noted that EDA formation constants measured polarographically are considerably larger than those measured by optical spectroscopy. This appears to be the case here also. No satisfactory explanation is presently available for this phenomenon.

Figure 3 shows the spectra of some EDA complexes in the region of the charge-transfer band computed as described above. Pyrene is the only donor of those studied that produces a well defined CT band. The others appear as shoulders on the first absorption band of the acceptor. With these complexes there appears to be no relationship between the formation constants of the complexes and their molar absorptivities. This is not unusual for this type of complex (ref. 1, p. 30).

Figure 4 shows the effect of complexation on the first acceptor band in the complex. In general the energy of this transition changes very little, but the molar absorptivity is decreased and the vibrational fine structure is affected as might be expected.

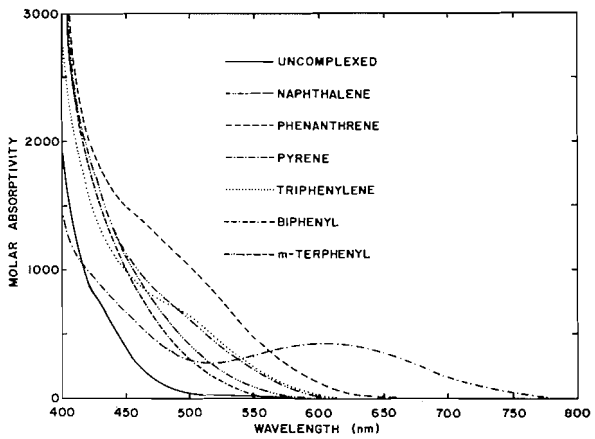

FIG. 3. Spectra of EDA complexes of CNDNFDMC in the charge-transfer region.

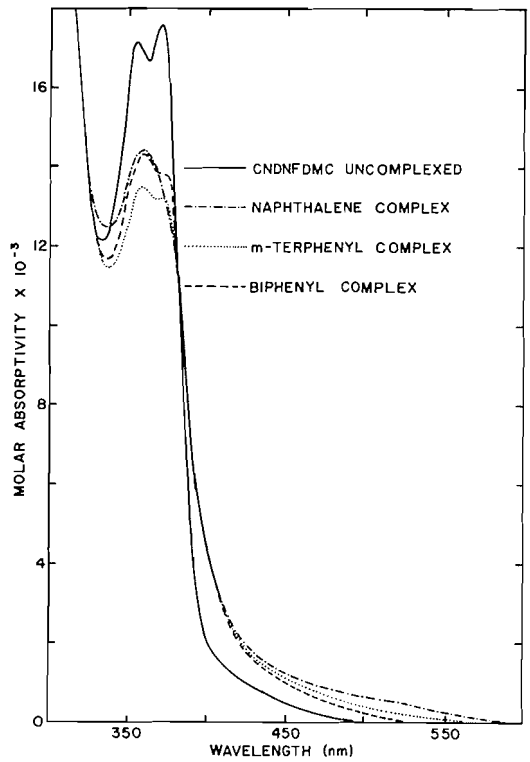

FIG. 4. Acceptor contribution to the spectra of EDA complexes of CNDNFDMC.

Any contribution of contact charge-transfer is included in the spectra of Figs. 3 and 4.

Density and temperature effects on electron mobilities in gaseous, critical and liquid *n*-hexane, cyclohexane, and cyclopentane[1]

SAM S.-S. HUANG AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received April 10, 1978

SAM S.-S. HUANG and GORDON R. FREEMAN. Can. J. Chem. **56**, 2388 (1978).

In the low density vapors the density normalized mobilities μn of thermal electrons decreased in the order *n*-hexane > cyclopentane > cyclohexane, although the differences were only ~10%. The mobilities began to increase at electric field strengths $E/n > 0.4$ *Td* in cyclopentane, > 0.5 *Td* in cyclohexane and remained independent of field strength up to 1.5 *Td* in *n*-hexane. The ratio of the threshold drift velocity for electron heating to the speed of low frequency sound in the gas, v_d(threshold)/c_0 = 11 in cyclopentane, 14 in cyclohexane, and is > 35 in *n*-hexane; it increases with decreasing sphericity of the molecules. The electrons are cooled mainly by inelastic collisions with the hydrocarbon molecules. The temperature coefficients of mobilities in the low density gases increase as the molecules become more globular, which could reflect the participation of either low lying transient negative ion states or a Ramsauer–Townsend effect in the scattering processes. The normalized mobilities μn in the saturated vapors began to decrease at $n = 4 \times 10^{19}$ molecules/cm^3 in *n*-hexane, 13×10^{19} in cyclohexane, and 30×10^{19} in cyclopentane. It appears that the minimum size of molecular cluster required for electron quasilocalization is smaller in *n*-hexane than in cyclohexane, and larger in cyclopentane. Electron localization interactions are weaker for more globular molecules.

Mobilities in the critical fluids were 16 cm^2/V s in *n*-hexane, 23 in cyclohexane, and 22 in cyclopentane.

Mobilities in the liquids were independent of field up to the highest value used, which was 1.5 *Td* in the hexanes and 0.9 *Td* in cyclopentane. The mobilities and their temperature dependences were interpreted in terms of a model.

SAM S.-S. HUANG et GORDON R. FREEMAN. Can. J. Chem. **56**, 2388 (1978).

A des densités de vapeurs faibles, la mobilité normalisée pour la densité (μn) des électrons thermiques diminue dans l'ordre de *n*-hexane > cyclopentane > cyclohexane, quoique les différences soient d'environ 10%. Les mobilités commencent à augmenter à une force de champ électrique $E/n > 0.4$ *Td* dans le cyclopentane, > 0.5 *Td* dans le cyclohexane et demeurent indépendants de la force du champ jusqu'à 1.5 *Td* dans le *n*-hexane. Le rapport de la vitesse minimale de diffusion pour le chauffage des électrons à la vitesse de son de basse fréquence dans les gaz v_d(seuil)/c_0 = 11 dans le cyclopentane, 14 dans le cyclohexane et est de > 35 dans le *n*-hexane; cette valeur augmente avec la diminution de la sphéricité des molécules. Les électrons sont refroidis principalement par des collisions inélastiques avec des molécules d'hydrocarbures. Les coefficients de température des mobilités à des faibles densités gazeuses augmentent à mesure que les molécules deviennent plus globulaires ce qui est un reflet de la participation soit d'états ioniques négatifs transitoires de basses énergies ou un effet de Ramsauer–Townsend dans les processus de dispersion. Les mobilités normalisées μn dans des vapeurs saturées commencent à diminuer à $n = 4 \times 10^{19}$ molecules/cm^3 dans le *n*-hexane, 13×10^{19} dans le cyclohexane et à 30×10^{19} dans le cyclopentane. Il semble que la grosseur minimale d'une aggrégation moléculaire nécessaire pour une quasilocation électronique soit plus faible dans l'hexane que dans le cyclohexane et plus grande dans le cyclopentane. Les interactions de localisation électronique sont plus faibles pour des molécules qui sont plus globulaires.

Les mobilités dans des fluides critiques sont 16 cm^2/V s dans le *n*-hexane, 23 dans le cyclohexane et 22 dans le cyclopentane.

Les mobilités dans les liquides sont indépendantes du champ jusqu'aux valeurs les plus élevées utilisées soit 1.5 *Td* dans les *n*-hexanes et 0.9 *Td* dans le cyclopentane. On a interprété les mobilités et leurs relations avec la température en terme d'un modèle.

[Traduit par le journal]

Introduction

Thermal electron mobilities in liquid hydrocarbons have been extensively investigated during the last decade (1–14). To get a better understanding of electron transport in fluids we have recently been doing measurements through the critical and supercritical regions (15–17). Mobilities in dense methane gas have also been reported (18).

In liquid alkanes electron mobilities increase with increasing sphericity of the molecules (1, 5, 10). For example, electrons are more mobile in neopentane

than in *n*-pentane; low mobility, localized states of electrons in liquid alkanes are less stable when the polarizabilities of the molecules are more nearly isotropic (10). In the low density gas, where an electron interacts with essentially one molecule at a time, the mobility is greater in *n*-pentane than in neopentane (19). This is the reverse of the high density behavior, and the cross-over occurs at $\sim 0.7\ d_c$, where d_c is the critical density. To extend this density study to other molecular structures, measurements have now been made in *n*-hexane, cyclohexane, and cyclopentane to determine the effect of cyclization.

Experimental

Materials

The hydrocarbons were Phillips Research Grade. They were further purified by stirring with concentrated sulfuric acid for at least 4 days, decanted into a bulb that was attached to a vacuum system and contained potassium hydroxide pellets. The hydrocarbon was degassed and stirred for 12 h, then distilled onto lithium aluminum hydride, degassed further and stirred for 1 day, then distilled onto sodium/potassium alloy and stirred for 5 days, followed by several freeze–pump–thaw degassing cycles.

Conductance Cells

The cell used at low temperatures was similar to that described in ref. 20. The cells used at high temperatures were similar to the heavy walled cell described in ref. 16. The gap between the parallel plate electrodes was in all cases 0.29–0.34 cm, while the effective areas of the collecting electrodes ranged from 1.9 to 7.8 cm^2.

The heavy walled cells were heated under evacuation to 60 K above the highest temperature at which they would be used, to degas the metal electrodes and interior glass.

Temperature Control

The cooling system was similar to that described earlier (17).

The heating system was similar to that in ref. 16. However, the temperature was measured with two calibrated copper–constantan thermocouples, one attached to the cell near the electrodes and the other to the opposite end of the cell. A third thermocouple in the Dewar vessel was placed near to the cell and connected to the temperature controller. The glass heatpipe was adjusted to minimize temperature gradients in the cell.

The heating and cooling systems were placed in well grounded Faraday cages.

Determination of Mobility μ

The 1.7 MeV X-ray pulse lengths were 0.03, 0.10, and 1.0 μs. The respective doses were ~ 0.01, 0.1, and 1×10^{11} eV/g.

Mobilities were usually measured by a time of flight method described elsewhere (21). In liquid *n*-hexane at low temperatures the flight times were so long that electron scavenging by trace impurities caused interference. Under these circumstances mobilities were determined by an electron conductance technique (10).

Physical Properties of the Fluids

The densities *d* were obtained from refs. 22 and 23. The critical properties of the hydrocarbons are summarized in Table 1. The dielectric constants were calculated from the Clausius–Mossotti equation (24), using molar polarization values from refs. 25 and 26.

TABLE 1. Critical properties of the hydrocarbons*

Hydrocarbon	T_c (K)	P_c (atm)	d_c (g/cm^3)	ε_c†
n-Hexane	508	29.9	0.232	1.26
Cyclohexane	554	40.6	0.272	1.29
Cyclopentane	512	44.6	0.270	1.29

Results

The vapor densities were varied from the critical d_c to 0.01 d_c and the temperature from about 298 K to 1.12 T_c, where T_c is the critical temperature. Liquid *n*-hexane and cyclohexane were measured from near their melting points to T_c under their vapor pressures. Previous results for liquid cyclopentane (16) are also included.

Effect of Electric Field Strength

Electron mobilities in *n*-hexane were independent of field strength over the range used, 0.1–1.5 *Td* (10^{-17} V cm^2/molecule), in the gas and liquid phases. A field of 1 *Td* in the normal liquid corresponds to ~ 50 kV/cm. The field independence in the gas phase applies both to the vapor in equilibrium with the liquid and to vapor heated well above the coexistence curve.

In cyclohexane and cyclopentane liquids the mobilities were also independent of field strength to the maximum used, which was 1.5 *Td* in the former and 0.9 *Td* in the latter (16). In the vapors, however, the mobilities increased slightly at fields >0.5 *Td* in cyclohexane and >0.4 *Td* in cyclopentane (Fig. 1). All mobilities reported hereafter are low field values.

In the low density vapors the density normalized mobilities μn decreased in the order *n*-hexane > cyclopentane > cyclohexane (Fig. 1).

Effect of Temperature

(a) Liquid Hydrocarbons

Electron mobilities in *n*-hexane increased continuously with temperature from 182 K to T_c, and in the supercritical gas (Fig. 2). The Arrhenius temperature coefficients were 0.11, 0.20, and 0.54 eV at 210, 320, and 455 K, respectively. The mobility increased by four orders of magnitude, from 0.0026 cm^2/V s at 182 K to 16 cm^2/V s in the critical fluid.

The mobility in cyclohexane passed through a maximum, $\mu = 26$ cm^2/V s, about 7 K below T_c (Fig. 3). The temperature coefficients were 0.17, 0.24, 0.48, and -0.63 eV at 330, 430, 525, and 553 K, respectively.

A maximum also occurs in an Arrhenius plot of the mobilities in liquid cyclopentane (16). The behavior is similar to that in Fig. 3.

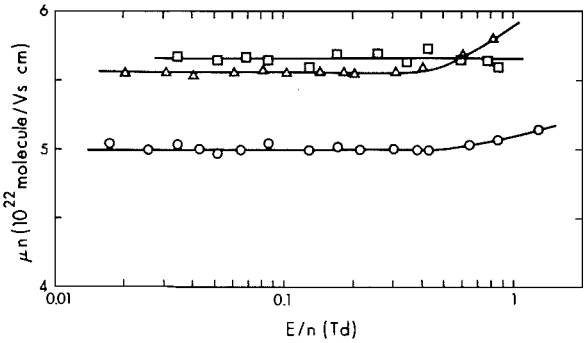

FIG. 1. Density normalized mobilities μn in hydrocarbon vapors as functions of the normalized electric field strength E/n ($Td = 10^{-17}$ V cm^2/molecule). □, *n*-hexane, 364 K, 4.1×10^{19} molecules/cm^3; △, cyclopentane, 410 K, 1.71×10^{20} molecules/cm^3; ○, cyclohexane, 403 K, 6.9×10^{19} molecules/cm^3. The vapors are in equilibrium with the liquid.

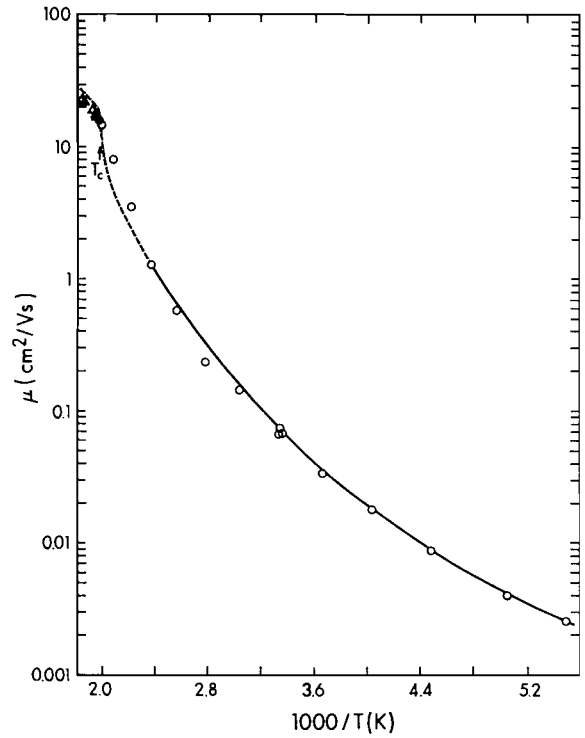

FIG. 2. Arrhenius plot of electron mobilities in *n*-hexane: ○, liquid; ●, critical; △, supercritical. The curve was calculated from eqs. [7]–[12], using the parameter values in Table 3. The dashed portion is inadequate.

(b) Gaseous Hydrocarbons

Electron mobilities were measured as functions of temperature at several fixed densities of the gases.

Arrhenius plots of the mobilities in *n*-hexane at densities from the critical d_c to 0.02 d_c are shown in Fig. 4. The low temperature boundary of the plots corresponds to the mobilities in the saturated vapor along the gas–liquid coexistence curve. The mobility

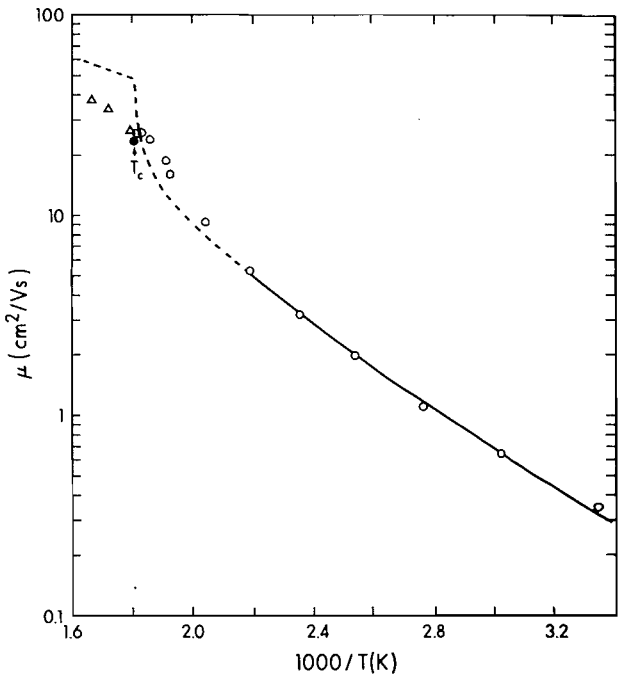

FIG. 3. Arrhenius plot of electron mobilities in cyclohexane. ○, liquid; ●, critical; △, supercritical. The curve was calculated from eqs. [7]–[12], using the parameter values in Table 3. The dashed portion is inadequate.

shows a minimum at the critical point. The temperature coefficients near the coexistence curve were 0.33, 0.38, 0.26, 0.10, 0.04, and 0.00 eV at 1.00, 0.80, 0.50, 0.25, 0.10, and 0.021 d_c, respectively. The coefficients decreased with increasing temperature at constant density.

In cyclohexane vapor the mobility had a positive temperature coefficient even at the lowest density (Fig. 5). The coefficients near the coexistence curve were 0.53, 0.26, 0.10, 0.064, 0.014, and 0.015 eV at 1.00, 0.50, 0.25, 0.10, 0.045, and 0.012 d_c, respectively, and decreased with increasing temperature.

The behavior in cyclopentane vapor (Fig. 6) was similar to that in cyclohexane. The Arrhenius coefficients near the coexistence curve were 0.72, 0.24, 0.091, 0.032, and 0.015 eV at 1.00, 0.50, 0.25, 0.10, and 0.021 d_c, respectively.

Electron mobilities in the critical fluids were 16, 23, and 22 cm^2/V s in *n*-hexane, cyclohexane, and cyclopentane, respectively.

Effect of Density

In low density cyclohexane vapor the density normalized mobility was $\mu n = 5.1 \times 10^{22}$ molecules/cm V s (Fig. 7). At $n > 1.3 \times 10^{20}$ molecules/cm^3 the normalized mobility decreased somewhat, passed through a minimum of 3.8×10^{22} molecules/cm V s at 9×10^{20} molecules/cm^3, increased to a maximum

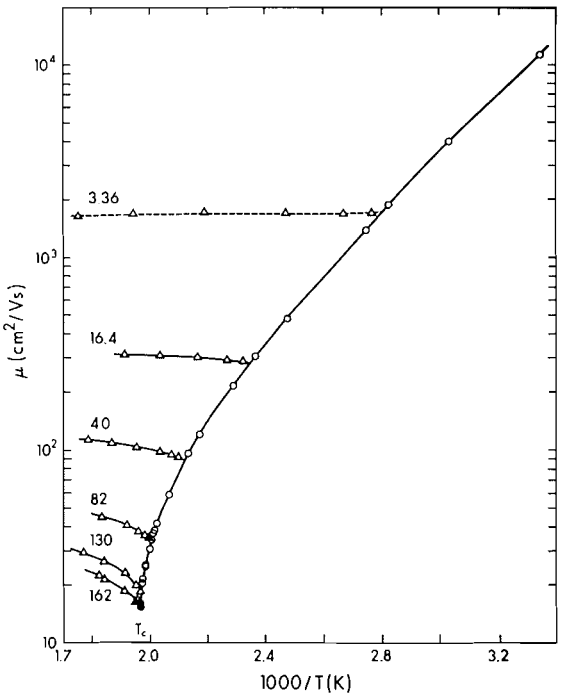

FIG. 4. Arrhenius plots of thermal electron mobilities in *n*-hexane vapor at different constant densities (△). The numbers labelling the lines are the densities (10^{19} molecules/cm^3). ○, Mobilities in gas along the vapor–liquid coexistence curve. ●, Mobility at the critical point. The dashed line was calculated from eqs. [2]–[4], using values of n, α, and A_α from Table 2.

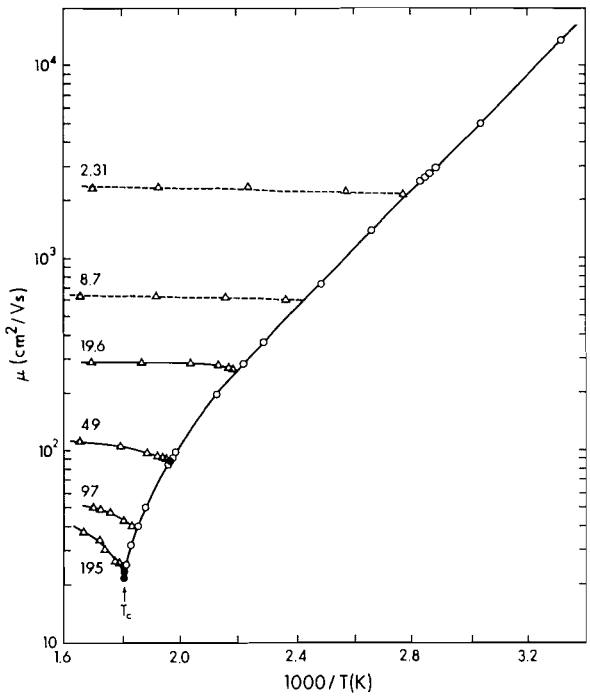

FIG. 5. Arrhenius plots of thermal electron mobilities in cyclohexane vapor at different constant densities (△). The numbers labelling the lines are the densities (10^{19} molecules/cm^3). ○, Mobilities in gas along the vapor–liquid coexistence curve. ●, Mobility at the critical point. The dashed lines were calculated from eqs. [2]–[4], using values of n, α, and A_α from Table 2.

of 7.5×10^{22} molecules/cm V s at 3×10^{21} molecules/cm^3, then decreased as the density was increased further. The critical density n_c lies between the mobility maximum and minimum (Fig. 7).

The behaviors in *n*-hexane and cyclopentane were similar to that in cyclohexane (Fig. 7). The low density values of μn were respectively 5.8, 5.5, and 5.1 (10^{22} molecules/cm V s). However, the ratio of mobilities at the liquid phase maximum and gas phase minimum, μ_{max}/μ_{min}, decreased from 2.1 in cyclopentane to 2.0 in cyclohexane and 1.3 in *n*-hexane. The density at which μn ceases to be independent of n follows the same trend, being respectively 3×10^{20}, 1.3×10^{20}, and 4×10^{19} molecules/cm^3. The mobilities in the liquids at 299 K fall in the same order, 1.1, 0.35, and 0.07 cm^2/V s, respectively.

Discussion

Electric Field Effect

At low applied field strengths the electrons make a negligible net gain of energy from the field and they are in thermal equilibrium with the medium. When the field is increased, as long as the mobility remains independent of the field strength it is assumed that the electrons remain in thermal equilibrium with the medium. The energy gained by acceleration in the field between collisions is lost to the medium during collisions. At sufficiently high fields more energy is gained than is lost, the electrons become 'heated' and the mobility becomes field dependent.

When elastic collisions are the dominant process that moderate the electron energy, the upper limit of the drift velocity at which the electrons remain thermal is equal to the low frequency limit of the velocity of sound, c_0, in the system (27–30). The value of c_0 in a gas is given by (31):

$$[1] \qquad c_0 = (\gamma P/d)^{0.5}$$

where $\gamma = C_p/C_v$ is the heat capacity ratio and P (dyn/cm^2) is the pressure. At low densities, where the gas is nearly ideal, one has $\gamma \approx (C_p/[C_p - R]) \approx 1.1$ and $c_0 \approx 198$ m/s in cyclopentane and 180 m/s in the hexanes at 300 K. The threshold drift velocities for electron heating are v_d(threshold) ≈ 2.2 km/s in cyclopentane, 2.5 km/s in cyclohexane (Fig. 1), and >6 km/s in *n*-hexane vapor. The respective values of v_d(threshold)/c_0 are therefore 11, 14, and >35. These high values imply that the electrons are cooled

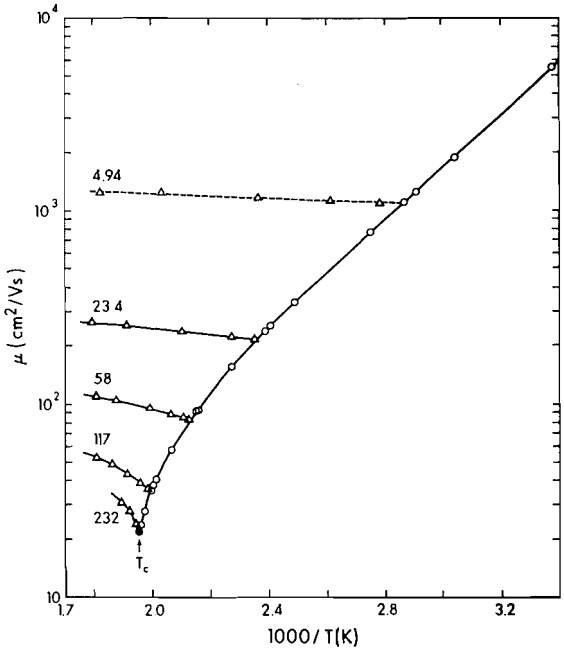

FIG. 6. Arrhenius plots of thermal electron mobilities in cyclopentane vapor at different constant densities (△). The numbers labelling the lines are the densities (10^{19} molecules/cm^3). ○, Mobilities in gas along the vapor–liquid coexistence curve. ●, Mobility at the critical point. The dashed line was calculated from eqs. [2]–[4], using values of n, α, and A_α from Table 2.

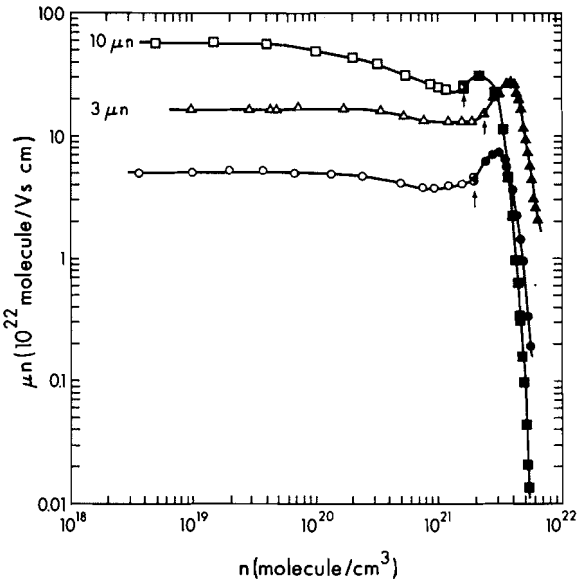

FIG. 7. Plot of μn against n for electrons in fluid cyclohexane (circles), cyclopentane (triangles), and n-hexane (squares). The open symbols represent gases along the vapor–liquid coexistence curves and the closed symbols represent the liquids. The half-closed symbols and the arrows indicate the critical fluids. To prevent congestion, the cyclopentane points are displaced vertically by a factor of 3 and those for n-hexane by a factor of 10.

predominantly by inelastic collisions with the hydrocarbons, in contrast to the behavior with the monatomic molecules of xenon (21).

The value of the ratio v_d(threshold)/c_0 increases with decreasing sphericity of the gas molecules: xenon 0.7 (21), neopentane 5 (19), cyclopentane 11, cyclohexane 14, isopentane 15 (19), n-pentane > 100 (19), and n-hexane probably also > 100.

Scattering Cross Sections of the Low Density Gases

The energy dependences of the cross sections were estimated from the variation of the mobilities with temperature (Figs. 4–6). The magnitudes of the temperature coefficients in the low density gases fell in the same order as the field dependences: cyclopentane $\gtrsim$ cyclphexane $>$ n-hexane.

The mobility μ_{ld} of electrons in a low density gas can be expressed as (32, 33):

$$[2] \qquad \mu_{ld} = -\frac{4\pi}{3}\frac{e}{mn}\int_0^\infty \frac{v^2}{\sigma_v}\frac{df_0}{dv}\,dv$$

where e and m are the charge and mass of the electron, respectively, n is the number of molecules/cm^3, v is the relative velocity of the electrons with respect to the molecules, σ_v is the scattering cross section of the molecules for electrons of velocity v, and f_0 is the spherically symmetric term in the series expansion of the electron velocity distribution function. Thermal electrons have a Maxwellian distribution:

$$[3] \qquad f_0 = \left(\frac{m}{2\pi kT}\right)^{3/2}\exp\left(-\frac{mv^2}{2kT}\right)$$

where k is Boltzmann's constant.

Over a limited range of v the scattering cross section can be approximated by eq. [4] (34):

$$[4] \qquad \sigma_v = A_\alpha v^{-\alpha}$$

where the value of the constant A_α depends on that of α. These two quantities were estimated by fitting eqs. [2]–[4] to mobilities obtained at $n < 10 \times 10^{19}$ molecules/cm^3 (Figs. 4–6). The values are listed in Table 2. The dashed lines in Figs. 4–6 correspond to mobilities calculated from these parameters.

Quantum mechanical theory of electron scattering predicts that for charge/induced dipole and charge/permanent dipole interactions the respective values of α are 2/3 and 2 (35, 36). Classical theory gives $\alpha = 1$ and 2, respectively (34). The experimental value $\alpha = 1.5$ for low density cyclopentane vapor is significantly different from the value 0.67–1.0 expected for scattering by a nonpolar, polarizable particle. Furthermore, the average value of the cross section at 500 K, 22 Å^2 (Table 2), is an order of magnitude smaller than that estimated from the classical theory of scattering by a polarization

TABLE 2. Scattering parameters of the low density gases

Compound	n (10^{19} molcules/cm^3)	α	A_α (cm$^{2+\alpha}$/s$^\alpha$)	$\sigma_{ave,\ 500\ K}$ (10^{-15} cm^2)
n-Hexane	3.36	0.9	4.6×10^{-9}	1.6
c-Hexane	2.31	1.3	4.6×10^{-6}	2.0
	8.73	1.2	8.5×10^{-7}	2.0
c-Pentane	4.94	1.5	1.15×10^{-4}	1.8(2.0[a])

[a]σ_{ave} increased by an arbitrary molecular weight factor $(C_6/C_5)^{2/3}$ to adjust for the physical size of the molecules and facilitate comparison with the hexanes. It is assumed that the molecular volumes of the hydrocarbons are proportional to the molecular weights, and that the physical cross sectional areas are proportional to $MW^{2/3}$.

potential (34). Thus, scattering involves more than the simple polarization field.

Mobility is proportional to σ_v^{-1}, so the average cross section of interest is some function of σ_v^{-1}. Taking σ_{ave} as an effective cross section that is assumed to be independent of v one obtains

$$[5]\quad \sigma_{ave} = \langle v\rangle/\langle v/\sigma_v\rangle = 2(kT/m)^2 A_\alpha \Big/ \int_0^\infty v^{3+\alpha} \times \exp(-mv^2/2kT)\, dv$$

which reduces to

$$[6]\quad \sigma_{ave} = A_\alpha (m/2kT)^{\alpha/2}/\Gamma\left(2+\frac{\alpha}{2}\right)$$

Values of σ_{ave} at 500 K are listed in Table 2.

Although the value $\alpha = 0.9$ for n-hexane (Table 2) is within experimental uncertainty of that expected for scattering by a polarization potential, the cross section itself is an order of magnitude smaller than expected from the classical model.

The value of α for cyclohexane is intermediate between those for n-hexane and cyclopentane (Table 2). The values of σ_{ave} at 500 K are similar for the three compounds. If σ_{ave} for cyclopentane were increased[2] by $(84/70)^{2/3}$ to account for the smaller physical size of the molecule the values of σ_{ave} for the two cyclo compounds would be the same.

As the molecules become more globular, α increases (Table 2). This trend extends to neopentane, for which $\alpha = 3.2$ (19). Two possible interpretations are: (*a*) the scattering displays a Ramsauer–Townsend effect (34), and the scattering minimum moves to lower energy as the degree of sphericity of the molecules decreases; (*b*) a transient negative ion state lying near zero energy makes a stronger contribution to scattering from the more spherelike molecules (37).

High Density Gases

At $n \gtrsim 10\times10^{19}$ molecules/cm^3 μn decreases (Fig. 7), corresponding to an increase in σ_{ave}. The change is due to multibody effects. The temperature coefficients also increase at the higher densities (Figs. 4–6), which correspond to larger apparent values of α. However, A_α might be temperature dependent for multibody interactions, which would vitiate the simple form of [4]. Furthermore, the occurrence in the dense gases of molecular clustering and consequent electron quasilocalization renders [2] inadequate.

The Arrhenius plots at high densities are curved, with slopes decreasing as the temperature is increased above the coexistence region (Figs. 4–6). The curvature is qualitatively attributed to a reduced tendency for the molecules to cluster in the heated gas, hence a reduced contribution from quasilocalization.

The normal boiling point of cyclohexane (354 K) is greater than that of n-hexane (332 K), indicating stronger intermolecular attractive forces in the former. In the saturated vapors at a given density, one might therefore expect the degree of molecular clustering to be at least as great in cyclohexane as in n-hexane. However, the density at which μn becomes density dependent is threefold greater in the former than in the latter (Fig. 7). This means that smaller clusters are needed for electron quasilocalization in n-hexane than in cyclohexane. The electron localization interactions are therefore stronger with the open chain compound.

The values of n (10^{19} molecules/cm^3) at which μn becomes density dependent are ~4 in n-hexane, 13 in cyclohexane, 30 in cyclopentane, and 80 in neopentane (19). As the molecules become more globular the electron localization interactions become weaker. The same conclusion is drawn from the relative mobilities in the normal liquids (Fig. 7 and ref. 38).

The increase of slope as the gas density approaches the critical (Fig. 7) indicates interference of the scattering interactions, beginning the formation of a conduction band.

Liquids

Electron transport in the liquids is thermally activated. One model that is consistent with the results utilizes transitions between localized and extended states, with transport occurring mainly in the latter. To conserve space we list here the relevant

[e]Reference 17.

equations and refer to an earlier article (17) for discussion of them.

$$[7] \quad \mu_{liq} = (1 - \chi)\mu_{il}^0 \exp(-E_{il}/kT) + \chi\mu_h^0$$

where χ is the fraction of electrons that are in the high mobility state with mobility μ_h^0, and μ_{il}^0 and E_{il} are respectively the pre-exponential factor and activation energy of mobility in the localized (ion-like) state.

$$[8] \quad \chi = \int_{-\infty}^{\infty} N(E)[1 + \exp(E/kT)]^{-1}\,dE$$

$$[9] \quad N(E) = \pi^{-1/2}\sigma^{-1} \exp[-(E - E_0)^2/\sigma^2]$$

$$[10] \quad E_0 = E(0) - aT$$

$$[11] \quad \sigma = \sigma(0) + bT$$

$$[12] \quad \mu_h^0 = \mu_{ref}^0 (d_{ref}/d_T)^2(T_{ref}/T)$$

In systems where the ion-like mechanism makes an appreciable contribution it is possible to determine the values of μ_{il}^0 and E_{il} explicitly (17, 39). Although the mechanism is negligible in the present systems, the approximate values $\mu_{il}^0 = 0.1\ cm^2/V\ s$ and $E_{il} = 0.07$ eV were inserted for completeness.

Equations [10]–[12] are adequate as long as localization is the dominating factor governing electron migration (17, 39). They usually break down near the critical region (Figs. 2, 3, and ref. 17). We therefore focus attention on the normal liquids.

The five parameters in eqs. [10]–[12] are not yet separately determinable. To reduce the plasticity of the calculations and facilitate comparison of several systems, all variability was arbitrarily forced in to a, $\sigma(0)$, and b. The degree of success is displayed in Figs. 2 and 3 and Table 3. The constraints on the calculations are such that the only parameter that shows a regular variation is E_0/σ, which increases as μ decreases (Table 3). A larger E_0/σ indicates a deeper trap.

It was suggested earlier (17) that the apparent insensitivity of σ to temperature in *trans*-butene-2 might be due to the localized state being a molecular anion. It is difficult to understand the similarity of behavior in *trans*-butene-2, *n*-pentane, and *n*-hexane (Table 3).

Phenyl phosphorodichloridate in the synthesis of cyclic phosphate diesters of biological interest

C. L. PENNEY AND B. BELLEAU

Department of Chemistry, McGill University, 801 Sherbrooke Street W., Montreal, P.Q., Canada H3A 2K6

Received April 12, 1978

C. L. PENNEY and B. BELLEAU. Can. J. Chem. **56**, 2396 (1978).

The general usefulness of phenyl phosphorodichloridate (PPDC) in the synthesis of non-nucleoside cyclic phosphates is described. The method is illustrated with several examples including cyclic phosphates incorporating six to nine members. However, the reagent could not be used for the preparation of five-membered cyclic phosphates or 3′,5′-cycloadenylic acid (cAMP) from adenosine. Based on a number of observations, the conclusion was reached that PPDC cannot be used for the synthesis of strained or reactive cyclic phosphates. A convenient synthesis of *cis*- and *trans*-2-hydroxycyclopentanemethanol and a simple, quantitative method of separation of the two isomers is described. A number of cyclic phosphates were tested as substrates and inhibitors for cyclic purine phosphodiesterase and protein kinase.

C. L. PENNEY et B. BELLEAU. Can. J. Chem. **56**, 2396 (1978).

On décrit l'utilité générale des phényl phosphorodichloridates (PPDC) dans la synthèse des phosphates cycliques non-nucléosides. On illustre la méthode grâce à plusieurs exemples incluant des phosphates cycliques incorporant des cycles de six à neuf membres. Toutefois le réactif ne peut pas être utilisé pour la préparation des phosphates cycliques à cinq membres ou de l'acide cycloadénilique-3′,5′ à partir de l'adénosine. En se basant sur un certain nombre d'observations, on a tiré la conclusion que le PPDC ne peut pas être utilisé pour la synthèse de phosphates cycliques tendus ou réactifs. On décrit une synthèse facile des *cis* et *trans* hydroxy-2 cyclopentane-méthanols et une méthode simple et quantitative de séparation des deux isomères. On a effectué des essais sur un certain nombre de phosphates cycliques comme substrats inhibiteurs de la phosphodiestérase purine cyclique et de la kinase protéine.

[Traduit par le journal]

Introduction

The biological importance of cyclic phosphate diesters is best illustrated by cyclic adenosine and guanosine monophosphate (cAMP and cGMP) which are key regulators of cell function. Little is known as yet about the possible role of nonnucleoside cyclic phosphates. The abnormally high enthalpy and free energy of hydrolysis of cAMP and cGMP (1) is mystifying and the role of these high transfer potentials in metabolic regulation is conjectural. This thermochemical behavior has prompted us to synthesize a variety of simple, nonnucleoside cyclic phosphates in order to evaluate the effects of structural and geometrical factors on the heats of hydrolysis of six-membered cyclic phosphates. In this communication we describe synthetic methodologies for relevant cyclic phosphates. The thermodynamics of their hydrolysis will be described separately.

The most general procedure for the synthesis of cyclic phosphates is that of Khorana and co-workers (2, 3) and involves the cyclization of an acyclic monophosphate with dicyclohexyl carbodiimide (DCC). The method is especially useful for small scale preparations but specific experimental conditions are often required in order to avoid major side reactions. Cyclization of an acyclic intermediate to the corresponding cyclic phosphotriester was accomplished with aqueous base (2), conditions under which hydrolytic pathways compete with ring closure. Because of this limitation, potassium *tert*-butoxide in dimethylsulfoxide (DMSO) was used to effect cyclization (4, 5) but this technique is inconvenient on a large scale, lengthy and costly chromatographic separations being necessary.

In principle, the simplest method would entail the direct formation of a cyclic phosphate from a suitable diol through reaction with phosphorous oxychloride. In practice, however, this approach is generally unsuitable (6, 7) although a few successes have been reported as for the special cases of 2,2-dimethyl-1,3-propanediol and 2,2′-dihydroxybiphenyl (8,9). The practical potential of phenyl phosphorodichloridate (PPDC) for the preparation of cyclic phosphate diesters was explored by Baddiley *et al.* (10, 11) who used the reagent to prepare the cyclic phosphates of certain glycosides as well as pantothenic acid. The low yields reported may have discouraged further development of this approach. Only a few superficial studies of the reagent's ability to form six-membered cyclic phosphate phenyl esters were subsequently reported (12–15) and attention was

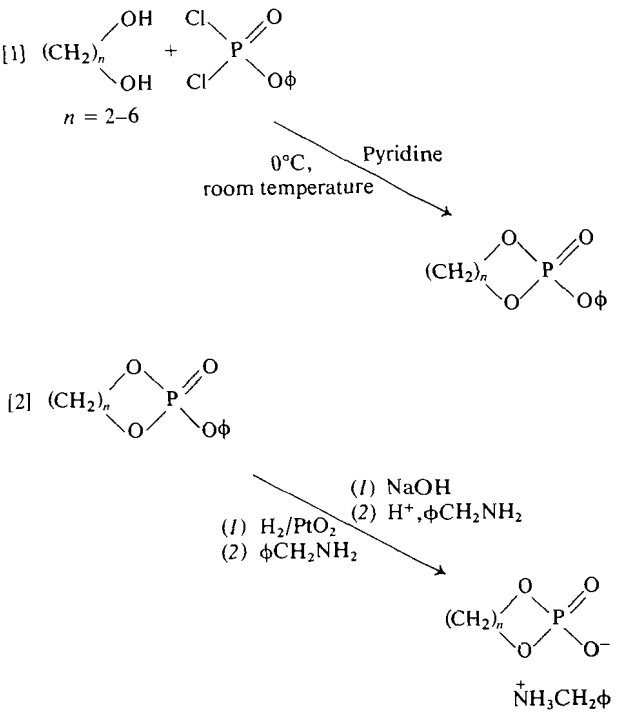
focused mainly on the spectroscopic properties of the products. We felt it appropriate to carry out a systematic investigation of the potential usefulness of this reagent PPDC in cyclic phosphate syntheses. As it turned out, the reagent proved to be most useful and convenient for the large scale preparation of the desired substrates.

Results and Discussion

The relevant cyclic phosphates were prepared according to general Scheme 1. The use of PPDC in this scheme proved to be widely applicable but with limitations. Thus, cyclic triester intermediates were readily obtained in good yields from the following starting diols: 1,3-propanediol, 1,4-butanediol, 1,5-pentanediol, 1,6-hexanediol, 1,3-butanediol, 2-methyl-1,3-propanediol, 2,2-dimethyl-1,3-propanediol, 2-methyl-2-nitro-1,3-propanediol, 2-methoxy-1,3-propanediol, diethylene glycol, *trans*- and *cis*-2-hydroxycyclopentanemethanol.[1] However, the corresponding phosphotriesters of glycerol, ethylene glycol, 1,2-propanediol, adenosine, ethanolamine, 3-amino-*n*-propyl alcohol, and 1,3-diaminopropane could not be obtained using the same techniques.

The PPDC reagent was found generally superior to phosphorous oxychloride which failed to yield cyclic phosphates in all those cases where PPDC also failed. However, whereas phosphorous oxychloride failed to give the cyclic phosphate of 1,3-propanediol under a variety of conditions, PPDC gave the expected cyclic phosphate in 90% yields. On the other hand, both reagents gave high yields of cyclic phosphate with 2,2-dimethyl-1,3-propanediol as substrate. It is likely that the so-called '*gem*-dialkyl effect' (16) intervenes in this facilitation of ring formation. Perhaps for the same reason, 2-methyl-2-nitro-1,3-propanediol behaved similarly (17).

An interesting and useful discriminatory capability of phosphorous oxychloride was its ability to form selectively the cyclic phosphate of *cis*-2-hydroxycyclopentanemethanol but not so with the *trans* isomer (acyclic high molecular weight diesters being presumably formed). This selectivity allowed the ready separation of the *cis*-phosphate starting from a mixture of the *cis*- and *trans*-diols. In sharp contrast, PPDC gave the cyclic phosphates of both geometrical isomers equally well. It appears then that PPDC exhibits an increased tendency to yield cyclic phosphates. This tendency is best illustrated by the fact that even in the presence of a 2.2-fold excess of 1,3-propanediol, the cyclic phosphate was still formed in 90% yield. Even more striking was the ready preferential formation (60% yield) of the nine-membered ring phosphate from 1,6-hexanediol and the eight-membered analogs from 1,5-pentanediol and diethylene glycol. In the case of 1,5-pentanediol, the cyclic phosphate was contaminated to the extent of 15% with acyclic phosphates as ascertained by nmr spectroscopy. No such contaminants were present in the case of the product derived from diethylene glycol. The phenyl triester intermediate from 2-methoxy-1,3-propanediol and PPDC was obtained readily in 66% yield, thus showing that the inductive effect of the methoxy group on the nucleophilicity of the hydroxyl groups has little influence on the cyclization reaction. This observation taken in conjunction with the fact that *trans*-2-hydroxycyclopentanemethanol readily gave the expected cyclic phosphate with PPDC, leads to the conclusion that the reagent's failure to give a cyclic phosphate with adenosine cannot be attributed to an inductive effect of the ether ring oxygen of the ribose moiety.



SCHEME 1

Interestingly, the observed tendency of PPDC to form cyclic phosphates did not apply to five-membered rings. Under a variety of conditions, acyclic mono- and bisphosphates accompanied by polymer formation was observed. In addition, phosphorous oxychloride gave only polymers (6). This behavior may be explained on the basis that five-membered

[1]See Experimental for a new convenient synthesis of these substrates and for a simple, quantitative method of isomer separation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

cyclic phosphates are strained, hence too reactive and unstable to resist decomposition under the experimental conditions for preparation and/or isolation. We have observed in fact that whenever the formation of six-membered ring phosphates (which are more stable) was allowed, polymer formation was difficult to achieve under conditions especially favorable for polymerization. Thus, a mixture of PPDC in 1,3-propanediol as the solvent gave mostly the cyclic phosphate after standing at room temperature for 50 h. Under the same conditions, ethylene glycol gave only polymers over a shorter period of time. It may be that it is the relative stability of the cyclic intermediates that determines polymer formation because they themselves may behave as phosphorylating agents. However, polymer formation is not limited to 1,2-diols as substrates because under harsh conditions (absence of solvent, presence of acid, long reaction times, etc.), 1,5-pentadiol and diethylene glycol also yielded polymers (18, 19) rather than cyclic phosphates as was the case under mild conditions.

The fact that glycerol gave only polymers again suggests that a strained five-membered intermediate leading to polymerization may be initially formed. Should any 1,3-cyclic phosphate ester be formed, we would expect it to be stable and isolatable since the analogous 2-methoxy-1,3-cyclic phosphate could be readily obtained. With amino alcohols or diamines any intermediate cyclic phosphoramidate will behave as a reactive phosphorylating agent (20) which accounts for the observation of exclusive polymer formation in these cases. In fact, the phosphoramidate derived from PPDC and aniline has been used as a phosphorylating agent in the synthesis of phosphotriesters (21).

It is worth noting that the solvent pyridine appeared to have a beneficial effect on cyclic phosphate formation. Thus, the phenyl ester of trimethylene phosphate was obtained in 90% yield in this solvent but the yield dropped to 50% in dioxane containing 2 equiv. of triethylamine. Addition of PPDC to pyridine gave deeply colored solutions, indicating that the reactive species is probably a pyridine complex.

Finally, conversion of the phenyl cyclic phosphate triesters to the cyclic diesters was readily accomplished either by base-catalyzed hydrolysis or hydrogenolysis over platinum. The latter method was preferred for those phenyl triesters carrying electronegative substituents on carbon-2 of the 1,3-diol phosphates because significant ring opening occurred under basic conditions. No useful results were obtained by reacting the phenyl triesters with methanolic ammonia or ammonium hydroxide. However, treatment with tetraethylammonium fluoride in acetonitrile afforded the expected cyclic phosphodiesters in agreement with expectations based on recent observations (22–24). For large scale preparations however, this method was uneconomical and troublesome at the stage of isolation.

The cyclic phosphate diesters were crystallized as their benzylammonium salts rather than cyclohexylammonium salts as is the common practice because their nmr spectra were amenable to much easier interpretation and also allowed ready detection of acyclic phosphate contaminants.

Conclusions

(*a*) Reaction of a 1,3-diol with phosphorous oxychloride will result in cyclic phosphate formation provided the substrate has a favorably constrained geometry and if the substrate has low reactivity (enthalpy of hydrolysis less than -6 kcal/mol as an index for instance). Hence, the usefulness of phosphorous oxychloride for the synthesis of cyclic phosphates is limited. Examples include those noted earlier (substituted 2,2′-biphenyl diols, 2,2-disubstituted-1,3-diols, *cis*-2-hydroxycyclopentanemethanol), *cis*-1,3-cyclohexanediol (25), and xylofuranosyladenine (26). The cyclic phosphate of 1,3-propanediol, if formed, would also be of low reactivity (enthalpy of hydrolysis of trimethylene phosphoric acid is -3.5 kcal/mol (27)) but 1,3-propanediol suffers little conformational constraints relative to the above diols.

(*b*) The same applies to PPDC except that the diol need not be geometrically constrained. Hence, this reagent may be used for the synthesis of cyclic phosphates, including large ring compounds, from unsubstituted alkyl diols. The cyclic phosphate of 1,4-butanediol, like 1,3-propanediol, is of low reactivity (enthalpy of hydrolysis of tetramethylene phosphoric acid is -2.6 kcal/mol (27)).

(*c*) In all those cases where the cyclic phosphate may be expected to have high reactivity (enthalpies of hydrolysis exceeding -6 kcal/mol) PPDC led mostly to decomposition products after work-up (as was the case for instance with ethylene glycol and 1,2-propanediol). This appears to be a special characteristic of PPDC because the analogous ethyl and methyl phosphorodichloridates react with ethylene glycol to give good yields of the expected cyclic triesters (28, 29). The corresponding phenyl cyclic triester can nevertheless be formed under controlled conditions[2] but the product is highly reactive and sensitive to moisture. The enthalpy of hydrolysis of

[2]Private communication from R. Kluger, University of Toronto: ethylene glycol was reacted with PPC using 2,6-lutidine as an acid absorber. The crystalline product was isolated by chromatography and was observed to be highly reactive.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ethylene phosphate is −6.8 kcal/mol (27) and that of methyl-α-D-glucopyranoside-4,6-cyclic phosphate is −6.3 kcal/mol (30). Hence, the low yield of product upon reaction of the sugar with PPDC (10–20% (10)) may indicate that the cyclic phosphate was readily formed but that only 10–20% of the product survived during work-up. To the best of our knowledge, a successful synthesis of 3′,5′-cyclic phosphate phenyl triesters has not been described using PPDC. The cyclic product would be expected to be most reactive, the enthalpies of hydrolysis for nucleoside 3′,5′-cyclic phosphates being in the range of −10 to −14 kcal/mol (31).

However, the 3′,5′-cyclic phosphate phenyl triester of uridine has been prepared by a *tert*-butoxide-catalyzed cyclization of the appropriate intermediate and was observed to be very moisture sensitive (5). Accordingly, we suggest that PPDC is unsuitable for the preparative synthesis of strained or reactive cyclic phosphates but ideally suited for less reactive ones.

The cyclic phosphate diesters listed in Table 3, as well as trimethylene and tetramethylene phosphoric acid were tested as potential substrates or inhibitors of the mammalian (beef heart) cyclic purine phosphodiesterase and the mammalian (bovine brain) protein kinase. None of these cyclic phosphates exhibited any substrate or inhibitory activities. These enzymes exhibit a strict requirement for a purine base and/or a 2′-hydroxyl function, without which binding on the protein cannot occur. Indeed, most modifications of the purine base of cAMP and cGMP are detrimental to biological activity and the fact that the recognition sites of the proteins can discriminate between adenine and guanine rings further demonstrates the essentiality of the purine base. However, the cyclic phosphates described above were good substrates for the phosphodiesterase from *Aerobacter aerogenes* (27). The results will form the subject of a forthcoming communication.

Experimental

Melting points were determined on a Gallenkamp apparatus and are uncorrected. For tlc, pre-coated silica gel thin-layer sheets (J. T. Baker) with fluorescent indicator were used. Visualization was accomplished with iodine or phosphomolybdate spray (J. T. Baker). For preparative tlc, silica gel from Brinkmann Instruments (Canada) Ltd. was used. Paper chromatography was performed with Whatman No. 1 filter paper, using solvent *A* (7:2:1 isopropyl alcohol – water – ammonium hydroxide). Visualization was accomplished with Hanes–Isherwood spray (32) followed by drying and irradiation with a sunlamp.

Mass spectra were measured on a AEI-MS-902 spectrometer at 70 eV using a direct insertion probe. Infrared spectra were measured on a Perkin Elmer 257 grating infrared spectrophotometer. Nuclear magnetic resonance spectra were recorded on a Varian T-60 spectrometer. Chemical shifts are given in δ values relative to tetramethylsilane. Resonance signals are described using the following format; ^{1}Hmr (solvent), chemical shift, (peak multiplicity, number of protons, and coupling constant (Hz)). Abbreviations: (s), singlet; (d), doublet; (t), triplet; (q), quartet; (m), multiplet; (b), broad. ^{13}C nmr spectra were recorded on a Bruker WH!90FT spectrometer, operating frequency 22.63 MHz.

Elemental analyses (C, H, and N) of cyclic phosphate diesters were performed by Spang Microanalytical Laboratory (Ann Arbor, Michigan). Inorganic phosphate analysis of cyclic phosphate diesters were carried out as previously described (33).

General Synthesis of Cyclic Phenyl Phosphate Triesters

To the appropriate diol (0.11 mol) in 60 ml of anhydrous pyridine (dried 1 week over Linde 4 Å molecular sieves) was added over a 1 h period distilled phenyl phosphorodichloridate (0.10 mol, 15 ml), while maintaining the temperature at ~10°C (ice bath). The mixture was stirred for 20 h at room temperature, the precipitated salts removed by filtration and washed with a little benzene. The combined filtrate and washings were evaporated *in vacuo* (<44°C) and the residue was consecutively washed with 50 ml water, 50 ml saturated $NaHCO_3$, 50 ml water, and finally taken up in benzene or benzene–chloroform (100–350 ml) depending on the solubility of the residue. The solution was stirred for 30 min (with gentle warming, if necessary, to keep the product in solution), dried over sodium sulfate, and evaporated *in vacuo* to give either a crystalline (six-membered triesters) or an oil (larger ring analogs) residue. The phenyl triesters thus prepared gave intense molecular ion peaks characteristic of the cyclic products. The properties of the triester products are summarized in Table 1.

General Preparation of Cyclic Phosphate Diesters

By Hydrolysis

The phenyl phosphate triester (50 mmol) was dissolved in 60 ml dioxane and to this was added 2 *N* NaOH (30 ml). The mixture was allowed to stir at room temperature for 70 h and then extracted with 3 × 50 ml portions of ether and the aqueous phase passed through a column of Dowex-50W-X8 [H^+] resin (25 g, previously washed with three portions of distilled water and with 100 ml of spectrograde methanol) and the column washed with 100 ml of methanol. Appearance of the cyclic phosphoric acid in the effluent was monitored with pH paper. The effluent was brought to pH ~7.5 with benzylamine and the solvent evaporated *in vacuo* to give a residue which was taken up in a minimum amount of warm methanol. Crystallization was induced by the addition of acetone or ether. Recrystallization (several times) was achieved using cold methanol–ether.

By Hydrogenolysis

The phenyl phosphate triester was dissolved in spectrograde methanol or absolute ethanol and the solution shaken in a Parr apparatus over Adams' catalyst (100 mg PtO_2 per gram of triester) under an atmosphere of hydrogen at 50 psi for 15 h. The catalyst was removed, washed with alcohol and the solvent evaporated *in vacuo*. The acidic residue was taken up in a small amount of methanol, the pH of the solution adjusted to ~7.5 with benzylamine, and crystallization induced by the addition of acetone or ether. The product was recrystallized several times from methanol–ether. Properties of the cyclic phosphates are assembled in Tables 2 and 3.

Phosphorylation of 1,2-Diols

A solution of ethylene glycol (0.10 mol, 5.6 ml) in 50 ml cold (0°C) anhydrous pyridine was treated over 1 h with phenyl phosphorodichloridate (0.10 mol). After stirring for 20 h at room temperature, the pyridinium salts were collected and washed with a little benzene. The filtrate and washings were

			3.8–5.0 (m, 3H)
			7.1 (d, 5H)

[a]All ^{1}Hmr are recorded in $CDCl_3$ and $CDCl_3$–D_2O. Chemical shifts are given in δ values relative to tetramethylsilane (see Experimental).
[b]90% yield when 0.22 mol (19 ml) 1,3-propanediol in 50 ml anhydrous pyridine was treated with 0.10 mol (15 ml) phenylphosphorodichloridate, with the reaction at 0°C, for 1 h.
[c]Acyclic impurity identified by mass spectrometry and ^{1}Hmr. Triplet at 3.4–3.7 indicative of primary hydroxymethyl function. *m/e* = 395. Mol. wt. (cyclic phosphate triester) = 242.
[d]Mol. wt. (cyclic phosphate triester) = 256; *m/e* = 256.

evaporated *in vacuo*, the residue taken up in 100 ml of water, the solution concentrated *in vacuo*, and 150 ml of benzene added. The benzene extract was dried, the salts washed with methanol, and the benzene filtrate and washings were evaporated separately *in vacuo*. The benzene solution gave 2.7 g of a dark brown oil which proved to be the bisphosphorylated ethylene glycol (4 methylene protons to 10 phenyl protons in the ^{1}Hmr spectrum). The methanol solution gave 4.3 g of a light brown oil which proved to be hydroxyethyl phosphorochloridate (four methylene protons to five phenyl protons to one hydroxyl proton in the ^{1}Hmr spectrum): ^{1}Hmr ($CDCl_3$ and $CDCl_3$–D_2O): (*i*) 4.3 (s, 4H), 7.2 (s, 10H); (*ii*) 4.2 (s, 4H), 5.6 (s, 1H), 7.1 (s, 5H).

Application of the above procedure to 1,2-propanediol (0.10 mol, 7.3 ml) again gave two fractions (5 g each) consisting of acyclic mono- and diphosphorylated diol.

The absence of pyridine as solvent, in the above reaction, led to a clear glass.

Phosphorylation of Glycerol

Using pyridine as the solvent and applying the protocol for ethylene glycol, glycerol gave an orange-colored glass insoluble in organic solvents but soluble in hot water. In dry dioxane containing 2 equiv. pyridine, a glassy polymer was also obtained.

Phosphorylation of Adenosine

A number of modifications of the general procedure for cyclic phosphate formation were applied. Included was a known procedure for the reaction between phenylphosphorodichloridate and a nucleoside (benzylidene uridine (34)). Thus, adenosine (20 mmol, 5.35 g dried *in vacuo* over P_2O_5) was dissolved in 150 ml dry pyridine and while stirring, the phenyl phosphorodichloridate (30 mmol, 4.5 ml) was added over a 10 min period. The following experimental variables were examined: (*a*) temperature of addition, 0°C; time of reaction, 20 or 90 h at room temperature; (*b*) prior addition of KCl (1 g), addition of reagent at room temperature, heating

1,6 Hexanediol[d,e]	60	Brown gum	1.2–1.8 (m, 8H) 3.5–3.9 (m, 4H) 4.0 (s, 2H) 7.3 (s, 5H)
1,3-Butanediol	64	160–161 Crystalline	1.1 (q, 3H) 1.1–1.7 (m, 2H) 4.7–5.3 (m, 3H) 4.0 (s, 2H) 7.3 (s, 5H)
2-Methyl-1,3-propanedio	61	158–160 Crystalline	0.7 (d, 3H, J = 7 Hz) 1.5–2.1 (m, 1H) 3.5–4.1 (m, 4H) 4.0 (s, 2H) 7.3 (s, 5H)
2,2-Dimethyl-1,3-propanediol[e]	79	146–148 Crystalline	3.3 (s, 4H) 4.0–4.4 (m, 4H) 4.1 (s, 2H) 7.4 (s, 5H)
trans-2-Hydroxycyclopentanemethanol	60	153–155 Crystalline	1.4–2.5 (m, 7H) 4.3 (s, 2H) 7.5 (s, 5H)
2:1 *trans*- and *cis*-2-Hydroxycyclopentanemethanol[e]	84	95–98 Crystalline	^{1}H and ^{13}C nmr as expected for *trans–cis* mixture

[a]All ^{1}Hmr were recorded in D_2O. Chemical shifts are given in δ values relative to tetramethylsilane (see Experimental). All compounds are benzylammonium salts, unless otherwise indicated.
[b]Isolated and purified as the free phosphoric acid as both the benzylammonium and cyclohexylammonium salts proved quite hygroscopic. Recrystallized from boiling THF and acetonitrile–ether (2).
[c]Isolated and purified as the free phosphoric acid. Recrystallized from boiling THF and benzene (30). The literature synthesis of this phosphoric acid involved reaction with DCC and barium salt intermediates which becomes especially tedious for large scale preparations.
[d]Could not be crystallized from a variety of solvents as the benzylammonium, cyclohexylammonium, sodium, or barium salts, or as the free acid.
[e]Phenyl group removed by hydrogenolysis in addition to hydrolysis.

TABLE 3. Analytical data for new six-membered cyclic phosphates[a]

Cyclic phosphate diester (parent alcohol)	R_f		Calculated			Observed		
	Paper	Thin layer	C	H	N	C	H	N
trans-2-Hydroxycyclopentanemethanol	0.68	0.70	54.73	7.07	4.91	54.77	7.01	4.86
cis-2-Hydroxycyclopentanemethanol[b]	0.68	0.70	54.73	7.07	4.91	54.80	7.03	4.99
1,3-Butanediol	0.60	0.67	50.96	7.00	5.40	50.96	6.98	5.48
2-Methyl-1,3-propanediol	0.63	0.67	50.96	7.00	5.40	51.03	6.91	5.55
2,2-Dimethyl-1,3-propanediol	0.68	0.75	52.74	7.38	5.13	52.56	7.34	5.19
2-Methoxy-1,3-propanediol	0.47	—	48.00	6.59	5.09	48.03	6.56	5.07

[a]All are benzylammonium salts. Paper chromatograms were developed in 7:2:1 isopropyl alcohol – water – ammonium hydroxide. Thin-layer chromatograms were developed in methanol (see Experimental). All compounds were analyzed for inorganic phosphate, as described (33), and found to contain less than 0.1% free phosphate contaminant.
[b]Synthesized from the reaction of the *trans–cis*-diol with $POCl_3$ (see Experimental).

(reflux) for 6 h then 20 h at room temperature or 90 h at 55°C; (*c*) see ref. 4. With method: (*a*) little phosphorylation was obtained; (*b*) base-catalyzed hydrolysis of the crude product gave phenyl phosphate (identified by ^{1}H and ^{13}C nmr); (*c*) base-catalyzed hydrolysis gave adenosine phenyl phosphate (identification by ^{13}C nmr). No evidence (paper chromatography) for the formation of cyclic phosphate was obtained.

Triester to Diester Conversion

The possibility that the phenyl function could be removed by other methods than hydrolysis and hydrogenolysis was investigated. The attempted procedures involved formation of active intermediates, phosphorofluoridates, acetyl phosphate triester, phosphoroamidates; 10 mmol (2.42 g) of the phenyl phosphate triester of 2,2-dimethyl-1,3-propanediol was used

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

as starting material: (*a*) tetraethylammonium fluoride (2 equiv.) in dry acetonitrile led to a 50% removal of the phenyl group after 3 days at room temperature; (*b*) ammonium hydroxide (3.0 ml) in dioxane (30 ml) and water (27 ml) gave back starting material after three days at room temperature. Anhydrous ammonia in dioxane or benzylammonium acetate in acetonitrile at 50°C gave similar results.

cis-*2-Hydroxycyclopentanemethanol Cyclic Phosphate*

To a cold (0°C) solution of 2-hydroxycyclopentanemethanol (a 2:1 *cis–trans* mixture; see below) (50 mmol or 5.8 g) in 100 ml anhydrous pyridine, was added phosphorous oxychloride (55 mmol or 5 ml). After stirring at 0°C for a few minutes and 20 h at room temperature, water (1.5 ml, 83 mmol) was added and stirring continued for 15 h. The pyridinium salts were collected and washed with a little benzene. The filtrate and washings were evaporated *in vacuo* and the residue dissolved in 10 ml of water. The solution was passed through a Dowex-50W-X8 [H^+] column (50 g resin) that was previously washed with distilled water and methanol. The column was washed with 150 ml of methanol and the effluent evaporated *in vacuo*, the dark residue diluted with 100 ml methanol and just enough water to dissolve such a quantity of NaOH that brought the pH to ~7. The solvent was evaporated and to the residue was added 100 ml absolute ethanol. The suspension was stirred a few minutes, the sodium chloride collected, and the filtrate evaporated to give 3.6 g of residue which was dissolved in a little methanol. The solution was passed through 30 g of Dowex resin (as above) and the pH of the methanolic effluent adjusted to ~7 with benzylamine. The solvent was evaporated and crystallization induced by the addition of ether; yield, 1.9 g of crude white product (38% yield) which after two recrystallizations from methanol–ether gave 1.3 g of white lustrous plates, mp 170–172°C; ^{1}Hmr (D_2O): 1.3–2.0 (m, 7H), 3.7–4.3 (m, 3H), 3.9 (s, 2H), 7.4 (s, 5H). See Table 3 for analytical data.

Commercial Diols

Ethylene glycol, 1,2- and 1,3-propanediol, 1,3- and 1,4-butanediol, 1,5-pentanediol, 1,6-hexanediol, diethylene glycol, 2,2-dimethyl-1,3-propanediol, 2-methyl-2-nitro-1,3-propanediol, and glycerol were commercially available. Other 1,3-diols were synthesized as described below.

2-Methyl-1,3-propanediol

Reduction of diethyl methyl malonate by $LiAlH_4$ in dry ether was carried out according to the literature (35). However, the following modification was applied for decomposition and work-up: the cooled reduction mixture initially containing 0.5 mol (19 g) of $LiAlH_4$ was carefully treated sequentially with 20 ml water, 20 ml 17% aqueous NaOH, and 60 ml water. After stirring for a few minutes, the solids were collected and leached for 1 h with 250 ml ether. The combined and dried filtrates were evaporated *in vacuo* to give 12.5 g of light yellow diol (63% yield). Its ir spectrum showed no carbonyl absorption. The diol was distilled *in vacuo* to give 9.9 g of colorless oil, bp 67–69°C/0.6 Torr; ^{1}Hmr (D_2O): 0.8 (d, 3H, J = 6 Hz), 1.7 (m, 1H), 3.4 (d, 4H, J = 6 Hz).

2-Methoxy-1,3-propanediol

1,3-Benzylidene glycerol was prepared according to the literature (36). To a suspension of sodium hydride (0.50 mol, 25 g) in 500 ml tetrahydrofuran (THF) was added under nitrogen 1,3-benzylidene glycerol (0.40 mol, 72 g) in 150 ml THF. After completion of the addition (45 min), stirring was continued for 45 min. To the cooled mixture (ice) was added methyl iodide (0.60 mol or 38 ml) over a 30 min period. The suspension was stirred for 15 h under nitrogen at room temperature, the solids removed by filtration, and the filtrate evaporated *in vacuo*. The residue was taken up in 500 ml of warm benzene, the precipitated sodium iodide removed by filtration, and the solvent evaporated to give 58 g of an oil which upon standing solidified to long brownish needles (75% yield), mp 50–52°C (lit. (36) mp 52°C); ^{1}Hmr ($CDCl_3$): 3.1 (s, 1H), 3.4 (s, 3H), 4.1 (q, 4H), 5.1 (s, 1H), 7.3 (m, 5H).

The product (0.30 mol, 58 g) was dissolved in a mixture of 200 ml tetrahydrofuran and 100 ml water, and 20 g of Dowex-50W-X8) (H^+) resin, previously washed with distilled water, was added. The mixture was heated under reflux for 2 h, the resin filtered off, washed with water, and the filtrate concentrated to about 250 ml *in vacuo* and extracted with 4 × 100 ml of ether. The aqueous phase was evaporated to give 23.8 g of a yellow oil (75% crude yield) which was distilled to give 19.8 g of an oil, bp 80–83°C/1 Torr; ^{1}Hmr ($CDCl_3$): 3.4 (s, 3H), 3.6 (d, 5H), 4.1 (s, 2H).

trans-*2-Hydroxycyclopentanemethanol*

Cyclopentene (0.74 mol, 50 g), paraformaldehyde (24 g), and glacial acetic acid (150 ml) were mixed and the mixture cooled to 0°C. Concentrated sulfuric acid (11.3 ml) was then added dropwise over a period of 1 h. The mixture was stirred at room temperature for 18 h and poured onto a mixture of ice (450 g) and anhydrous sodium carbonate (150 g). After neutralization was complete, the mixture was repeatedly extracted with 150 ml portions of ether and the organic layers combined, dried, and evaporated to give 90 ml of a dark liquid. This procedure was repeated 11 times and the crude products combined to give a total of 1 ℓ of mixed acetates. The crude product was distilled through a Vigreux column then four times through a Widmer column, and finally through a spinning band column (Nester/Faust) to give 80 g of the *trans*-diacetate of 2-hydroxycyclopentanemethanol and 8 g of a 1:1 mixture of *cis*- and *trans*-diacetates as judged by ^{1}Hmr; R_f (tlc) 0.74 (1:1 cyclohexane ethyl acetate) with a trace contaminant with R_f 0.87; ^{1}Hmr (neat): 1.6–2.4 (m, 7H), 2.1 (d, 6H), 4.2 (d, 2H, J = 5 Hz), 5.1 (q, 1H).

The *trans*-diacetate (0.38 mol, 75 g) was dissolved in 1 ℓ of reagent grade methanol. To this was added 50 g of Dowex-50W-X8 [H^+] resin (previously washed three times with methanol) and the mixture heated under reflux for 70 h. The resin was filtered off, washed with methanol, and the filtrate evaporated. The ir spectrum indicated the presence of a trace of diacetate. This product was re-treated as above with 25 g of resin in 500 ml methanol. After 15 h of heating, the product was isolated as above to yield 40 g (91%) of light yellow oil which after distillation yielded 30 g of colorless oil; bp 80–86°C/0.3 Torr; ^{1}Hmr ($CDCl_3$): 1.0–2.3 (m, 7H); ^{13}C nmr (see Table 4) indicated the presence of approximately 5% of contaminating *cis*-diol.

2-Hydroxymethyl Cyclopentanone

(*A*) 2-Hydroxymethylcyclopentanone ethylene ketal was prepared according to the literature (37), except that work-up was as described above for 2-methyl-1,3-propane diol. The distilled ketal (0.20 mol, 31.6 g) was dissolved in 175 ml each of THF and water and after addition of 18 g Dowex-50W-X8 [H^+] resin previously washed with distilled water, the mixture was stirred for 20 h at room temperature. The resin was collected, washed with a little water, and the filtrate and washings concentrated *in vacuo* to one-third its volume, then mixed with 200 ml of saturated saline followed by extraction with 8 × 100 ml ether. The combined extracts were dried and evaporated to give 13.0 g of light yellow oil. The aqueous fraction was concentrated *in vacuo* to approximately 100 ml, extracted with 3 × 100 ml ether, and after drying and evaporation of the ether gave an additional 3.0 g of product. Distillation gave 13.7 g of oil; bp 72–74°C/0.3 Torr (60% yield); ir

TABLE 4. ^{13}C chemical shifts of *trans*- and *cis*-2-hydroxycyclopentanemethanol and their cyclic phosphate diesters (benzylammonium salts)[a]

Diol assignment	*trans*-Diol	*cis*-Diol	*trans*-Phosphate	*cis*-Phosphate
$(CH_2)_3$	22.9	22.4	19.8 (s)	22.5 (s)
	27.8	26.6	21.7 (s)	25.7 (s)
	34.9	35.2	29.8 (d, J = 8 Hz)	34.5 (d, J = 9 Hz)

CH_2OH	64.9	62.6	43.8 (s)	44.0 (s)
CHOH	76.4	74.5	71.8 (d, J = 6 Hz)	67.7 (d, J = 4 Hz)
			83.7 (d, J = 5 Hz)	83.3 (d, J = 6 Hz)
			129.7 (s)	129.7 (s)
			130.1 (s)	130.1 (s)

[a]All spectra were recorded in D_2O. Chemical shifts are given in ppm relative to tetramethylsilane. Format for the resonance signals is the same as for ^{1}Hmr (see Experimental). Assignment of diol primary carbons was based on partially coupled spectra.

(carbonyl), 1720 cm^{-1}; ^{1}Hmr ($CDCl_3$): 1.6–2.6 (m, 7H), 3.7 (d, 2H), 3.9 (s, 1H). Other procedures for the removal of the ketal group, using tartaric and hydrochloric acid were reported to give similar results (37).

(*B*) Aldol condensation method: A modification of the method of Gault *et al.* (38) improved the yield significantly. Thus, cyclopentanone (3 mol, 265 ml) was cooled to 0°C and treated over a period of 1 h with a mixture of 20 ml water, anhydrous K_2CO_3 (2.5 g), and 36–38% aqueous formaldehyde (2 mol, 180 ml). The yellow solution was stirred for 30 min at 4°C and 15 min at room temperature and 50 ml of 0.5 *N* cold aqueous HCl added (final pH ~6). The solution was then saturated with sodium chloride and extracted with 5 × 100 ml portions of ether. The combined extracts were dried after the addition of 100 ml of methyl acetate. The solvent was evaporated *in vacuo* and the residue distilled *in vacuo* to give a small amount of cyclopentanone followed by 38.4 g of light yellow oil, bp 82–88°C/0.7 Torr (17% yield). The spectral properties were identical to the material obtained above.

cis- *and* trans-*2-Hydroxycyclopentanemethanol*

2-Hydroxymethylcyclopentanone (0.175 mol, 20.1 g) was dissolved in 250 ml of absolute ethanol and the mixture hydrogenated over Adams' catalyst (PtO_2, 1 g) in a Parr apparatus under 50 lb of hydrogen. After 24 h, the catalyst was filtered off and the solvent removed *in vacuo* to give 19.4 g of lightly colored oil containing only a trace of ketone as ascertained by ir (96% yield). Distillation gave 14.6 g of clear, viscous oil, bp 101–105°C/1 Torr. No carbonyl absorption detectable by ir. The ^{13}C nmr spectrum indicated the ratio of *trans* to *cis* isomer to be 2:1; see Table 4 for spectra of the pure isomers.

Separation of trans–cis *Isomers*

Separation was readily accomplished by selective acetonide formation (common fractionation techniques proved unworkable for preparative purposes). The mixture of isomers (39 mmol, 4.5 g) was dissolved in 100 ml of dry acetone and to this was added freshly prepared, powdered anhydrous cupric sulfate (4.5 g). After stirring at room temperature for 22 h, the solids were collected, washed with acetone, and the combined filtrate and washings evaporated *in vacuo* to give 4.3 g of a light yellow oil, whose ^{1}Hmr spectrum indicated that the *cis* isomer had been quantitatively converted to the corresponding acetonide. Distillation gave 2.3 g of acetonide, bp 26–28°C/1 Torr followed by 1.7 g of the *trans*-diol, bp 96–99°C/1 Torr (58% yield). This latter fraction was identical in every respect with the *trans*-diol obtained from cyclopentene as described above. The *cis*-diol acetonide (2.3 mmol, 240 mg) was dissolved in a mixture of 10 ml THF and 10 ml water and 1.5 g of Dowex-50W-X8 [H^+] resin, previously washed with distilled water was added. After stirring for 44 h at room temperature, the resin was collected and washed with a little water. The filtrate and washings were evaporated *in vacuo* to give 220 mg of the pure *cis*-diol as a light oil (82% yield); ^{1}Hmr (D_2O): 1.3–2.3 (m, 7H), 3.6 (q, 2H), 4.2 (b, 1H).

Biological Testing

Cyclic Purine Phosphodiesterase Assay

The assay mixture (final volume, 1.0 ml) consisted of (*a*) 200 µl substrate, 0.1 µ*M* cAMP or 2.0 µ*M* of test substrate; (*b*) 500 µl buffer (50 m*M* Tris-Cl, pH 7.8); (*c*) 50 µl $MgCl_2$ (20 m*M*); (*d*) 50 µl water or 0.5 µ*M* inhibitor; (*e*) 50 µl beef heart phosphodiesterase solution. The stock enzyme solution was prepared by dissolving 50 mg of enzyme (Sigma) to 10 ml of distilled water. The assay mixture was incubated in at 30°C for 20 min and then 50 µl of alkaline phosphatase solution added (*E. coli*, Type III-S, Sigma Chemical Co.; stock solution prepared by adding 11 mg of enzyme to 10 ml of water) and the incubation continued for another 40 min. The reaction was terminated by the addition of 100 µl of cold 1.25 *N* HCl and a 200 µl aliquot of the solution withdrawn for phosphate analysis (34). All analyses were performed in duplicate. Small quantities of the corresponding acyclic phosphate monoesters of the test substrates (unpublished results) and 5′-AMP were tested and observed to be substrates for alkaline phosphatase as expected.

Protein Kinase

The assay was performed as described in the literature (39).

ESCA core line spectra have been obtained for uracil, the thiouracils, and some 1-methyl and 3-methyl analogues. In addition, anions of the mono methyl derivatives have been prepared and studied. Core line binding energy shifts for all solid compounds, ionic and neutral, are found to correlate reasonably with CNDO/2 charge distributions calculated for the free molecules. The correlation line for ionic molecules is offset from that for neutrals by a constant factor ascribed to an intermolecular potential term. Specific effects of methylation, thionation, and ionization on the charge distribution are described. Methylation at either nitrogen leads to electron release from the nitrogen into the ring. Thionation results in a decrease in the charge at the site of thionation, while the electron density at adjacent atoms increases. The alterations in charge density are somewhat different for neutral and ionic compounds. Upon ionization of either N(1) or N(3) sites, much of the residual charge is located on the keto oxygens. The presence and position of the thionated carbon during ionization mainly affects the change in electron density at the C(6) position.

JAMES PEELING, FRANK E. HRUSKA, DAVID M. MCKINNON, MOHENDER S. CHAUHAN et N. STEWART MCINTYRE. Can. J. Chem. **56**, 2405 (1978).

On a obtenu les spectres ESCA des électrons internes de l'uracile et de thiouracile et de quelques analogues méthylés en 1 ou en 3. De plus on a préparé et étudié les anions de dérivés monométhylés. Il y a un déplacement chimique des énergies d'ionization des électrons internes de tous les composés solides, ioniques et neutres, et on a trouvé qu'il existe une corrélation raisonnable avec les distributions de charge calculées par la méthode CNDO/2 pour les molécules libres. La ligne de corrélation pour les molécules ioniques est déplacée par rapport à celle des composés neutres par un facteur constant attribué à un terme de potentiel intermoléculaire. Les effets spécifiques de la méthylation, de la thionation et de l'ionisation sur la distribution de charge sont décrits. La méthylation au niveau de l'un ou l'autre des azotes conduit à une mise en disposition des électrons de l'azote vers le cycle. La thionation conduit à une augmentation de la charge au nive au du site de la thionation alors que la densité électronique au niveau des atomes adjacents augmente. Les modifications de la densité de charge sont légèrement différentes pour les composés neutres ou ioniques. L'ionisation des sites soit N(1) ou N(3) conduit à une charge résiduelle située au niveau des oxygènes cétoniques. Lors de l'ionisation la présence et la position d'un carbone thionaté affecte principalement le changement dans la densité électronique au niveau de la position C(6).

Introduction

Sulfur-substituted pyrimidine bases are minor constituents of *t*RNA molecules. For example, 4-thiouridine (1) and 2-thiocytidine (2) are thionucleosides identified in *E coli*. Why such modifications to the normal bases are required is not understood, but undoubtedly the influence of sulfur substitution on the electronic properties of the bases is an important factor. This influence on electronic structure is manifested particularly well by the increases in acidity of the imino protons of the bases, the first pK_a values, being, for example, 9.5 and 8.0 (25°C) for uracil and 4-thiouracil, respectively (3). Consequently, at physiological pH, the thio bases are ionized to a greater extent than the corresponding oxo derivatives.

It seems, therefore, that an understanding of the electronic properties of the neutral, as well as the anionic, forms of sulfur-substituted uracils would provide insight into their biological function. One technique, which can provide information on the

electronic structures of materials, is X-ray photoelectron spectroscopy (XPS or ESCA). This method has recently been used to study several purine and pyrimidine bases and a number of their modified analogues (4). It was shown that changes originating in structural modifications could, for the pyrimidines, be analysed quantitatively, but spectral resolution problems presented some difficulties in the more complex purine bases.

In this paper the core electron spectra of uracil, 2-thio, 4-thio, and 2,4-dithiouracil, all their 1-methyl analogues, and some 3-methyl analogues are described. In order to study the effects of ionization on the electron distributions, the sodium salts of the methylated compounds have been prepared, and their ESCA spectra obtained. The measured binding energies are used, along with the results of CNDO/2 (5) molecular orbital calculations, to examine the effect of sulfur substitution, methylation, and ionization on the charge distributions in these bases.[2]

Experimental

Commercial samples of uracil (Eastman Organic Chemicals), 2-thiouracil, 2,4-dithiouracil (Aldrich Chemical Co.), 1-methyluracil, and 3-methyluracil (Vega-Fox Biochemicals) were examined without further purification. Literature procedures were followed in the preparation of 4-thiouracil (6), 1-methyl-2-thiouracil (7), 1-methyl-4-thiouracil (8), 1-methyl-2,4-dithiouracil (9), and 3-methyl-2-thiouracil (7). The sodium salt of each of the methyluracils was prepared by dissolving the pure methyluracil (~0.2 g) in dry methanol (~5 mL) containing an exactly equivalent amount of sodium methoxide. The resulting solution was evaporated by heating to 60°C in a stream of dry nitrogen leaving the crystalline sodium salt. The purity was verified by monitoring the C:O:N:S intensity ratios in the ESCA spectrum of each salt.

The samples were examined as powders, either mounted on the spectrometer probe using double-sided tape, or pressed into finely grooved copper flats fixed to the probe. A McPherson ESCA-36 photoelectron spectrometer, calibrated as described previously (10), was used to obtain spectra of the C_{1s}, N_{1s}, O_{1s}, and S_{2s} or S_{2p} core levels for each sample, using $MgK_{\alpha_{1,2}}$ radiation (1253.6 eV). All the samples were inspected visually, and most were examined over extended periods of time in the spectrometer to check for radiation damage. No damage was evident visually, and the constancy of the spectral band positions and intensities showed that no substantial radiation damage occurred.

Computer deconvolution utilizing the peak fitting routine described by Bancroft *et al.* (11) was applied to determine peak positions in partially resolved bands. Bands were defined according to their energy, intensity, width, and shape (normally an equal combination of Gaussian and Lorentzian shapes). A best fit was obtained using a least-squares analysis. An important feature of this program is the ability to constrain, within limits, certain peak parameters while allowing others to vary freely. In this study the peak intensities were constrained to give areas proportional to those required by the molecular formula. C_{1s} peak widths were constrained to half-widths (FWHM) between 1.4 and 1.6 eV since preliminary examination showed that peak widths for all carbon sites investigated fell in this range. Binding energies were measured relative to the C_{1s} peak ascribed to hydrocarbon contamination and assigned a value of 285.0 eV (12). This peak gradually increased in intensity with time as residual hydrocarbons deposited on the sample surface.

[2]U, m^1U, and m^3U represent uracil and its N(1) and N(3) methylated derivatives. The prefixes s^2 and s^4 indicate sites of thionation, while a superscripted negative sign indicates ionization of an imino nitrogen, e.g. $m^1s^2U^-$.

Results and Discussion

(a) ESCA Spectral Data

Table 1 lists the binding energies for the compounds studied. Figure 1 shows, as examples of deconvoluted spectra, the C_{1s} bands of uracil and the three thiouracils. The accuracy of the binding energy data in Table 1 was assessed by repeated measurements of the core levels in several samples for a number of the compounds. For all the core levels of uracil and the thiouracils, and the N_{1s}, O_{1s}, S_{2s}, and S_{2p} levels of the other compounds, the standard deviations in the binding energies of any peak did not exceed 0.15 eV. For the methylated uracils and the ions, the standard deviations for the C_{1s} levels were found to be ± 0.20 eV. This increased uncertainty is a consequence of the greater number of peaks under the C_{1s} spectral envelopes and, for the ionic species, of the smaller range in C_{1s} binding energies.

Separate N_{1s} binding energies for the two nitrogen sites could be determined only for the ions. In Fig. 2, N_{1s} spectra are shown for the neutral 1-methyluracil and its anionic analogue. The low binding energy peak evident in the spectrum for the ionic compound is ascribed to the ionized nitrogen. Similar N_{1s} spectra were observed for all ionic compounds studied. It was not possible to resolve the O_{1s} peaks in the di-keto derivatives or the S_{2s} and S_{2p} peaks in the di-thio derivatives.

The assignment of the C_{1s} core level peaks of uracil has been discussed previously (4). For the other compounds, peaks were assigned using known substituent effects on the core electron binding energies (13). Assignments reached by this method were confirmed by a quantitative analysis of the data in Table 1 using the charge potential model.

(b) The Charge Potential Model for C_{1s} Binding Energy Shifts

The charge potential model (14) describes the binding energy E_i in terms of the charge q_i on atom i and the charges q_j on the other atoms situated at distances r_{ij} from i, through eq. [1].

$$[1] \qquad E_i = E_i^0 + kq_i + \sum_{j \neq i} q_j/r_{ij}$$

E_i^0 is a reference level and k is a constant. For a variety of molecular solids (14–16), including a series of nucleic acid bases (4), eq. [1] has been

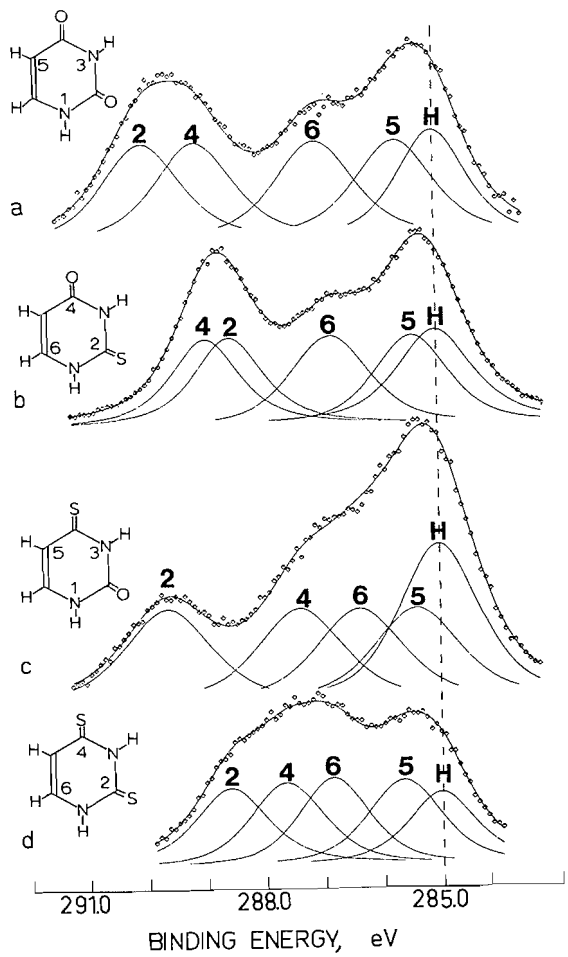

FIG. 1. The C_{1s} spectra of (*a*) uracil, (*b*) 2-thiouracil, (*c*) 4-thiouracil, (*d*) 2,4-dithiouracil. The peak assigned to hydrocarbon contamination and used for an energy reference (285.0 eV) is indicated.

shown to provide a quantitative rationalization of ESCA chemical shifts when the summation extends over a single molecule. When dealing with ionic compounds, the application of eq. [1] is not so straightforward. Intermolecular lattice effects can, in these instances, become important, and the last term in eq. [1] must now, in principle, be extended to a summation over the entire lattice. This is seldom practicable, even where the crystal structure is known; in the case of an unknown crystal structure such as is the situation here,[3] such a procedure is impossible. We therefore proceed as follows: the summation term in eq. [1] is divided into an *intramolecular* potential term, which can be calculated, and an *intermolecular* potential term, P, which cannot be calculated.

[3]To date no crystal structure of an anionic pyrimidine has been reported.

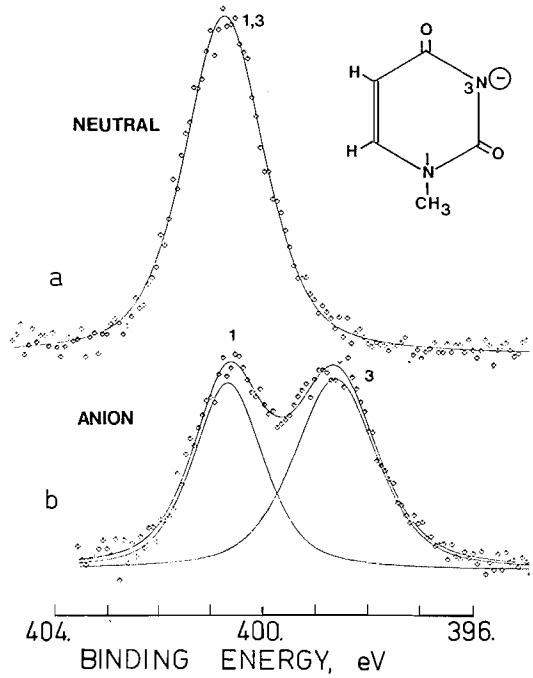

FIG. 2. N_{1s} spectra of (*a*) 1-methyluracil and (*b*) 1-methyluracil anion. The peak at low binding energy in the anion is assigned to the nitrogen at the site of ionization.

$$[2] \qquad E_1 = E_i^0 + kq_i + \left(\sum_{j \neq 1} q_j/r_{ij}\right)_{\text{intramol}} + P$$

Using an average geometry (17) for the uracil derivatives, CNDO/2 molecular orbital theory calculations yielded atomic charges for the neutral and ionized species. The atomic charges were used with the same average geometries to calculate the intramolecular potentials. The charges were then plotted against the experimental C_{1s} binding energies which were corrected for the intramolecular terms. The result is shown in Fig. 3.

The C_{1s} data points in Fig. 3 clearly fall into two linear sets: one for the neutral and one for the ionic compounds. Hollander *et al.* (18) have noted a similar division in a collection of neutral and anionic inorganic compounds. Least-squares analyses of our data yield similar slopes (22.6 ± 0.8 for the neutral molecules; 23.5 ± 1.5 for the ions), but quite different intercepts (284.8 ± 0.2 for neutral molecules vs. 290.7 ± 0.4 eV for the ions).

The slope in each case gives the constant k. From Koopman's theorem this parameter can be related to the one-centre Coulomb integral between a core and valence electron. It is interesting that the value of k should be the same for both neutral and ionic series. However, the intercept in each case incorporates the intermolecular potential term P, and this is expected to be quite different in the two series

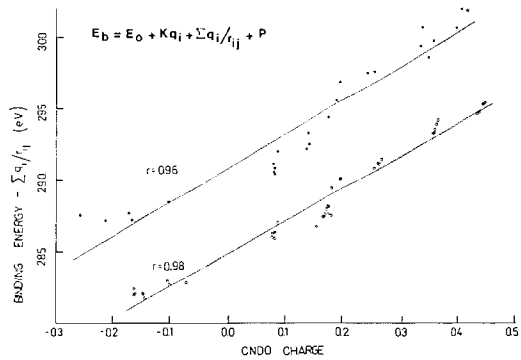

FIG. 3. Plots of calculated atomic charge vs. the experimental binding energies corrected for the intramolecular potential, for the C_{1s} levels of the neutral uracils and methyluracils (○) and the methyluracil anions (*). The linear least-squares fits are shown.

of molecules. In the case of the neutral uracil derivatives, the intercept is in accord with the results of studies on a variety of molecular solids, which yielded values for the intercept closely grouped around 285.0 eV (14–16). If there were a significant intermolecular potential P contributing to the measured binding energies in these systems, it would be the same in all of them, and in view of the diversity of the systems studied this is unlikely to be the case. It follows that for these neutral solids, including our neutral uracil derivatives, the contributions of an intermolecular potential to the core electron binding energies are insignificant, i.e., $P \approx 0$.

On the other hand, in the case of the anionic uracils, the intercept differs markedly from that observed for neutral organic molecules. We attribute this 5.9 eV difference entirely to the intermolecular potential P. Since the C_{1s} data in Fig. 3 define straight lines, P must be approximately the same at all sites in a given ion, and, furthermore, must have approximately the same value for all the ions studied here. If P were to vary with site, considerable scatter could be expected about the line in Fig. 3 for the ions, or if P varied in a systematic fashion with q_i, the slope of the least-squares line for the ions would differ from that for the non-ionized compounds. This is an important result since it means that experimental binding energy shifts in the methyluracil anions are related to the ionic charge distributions in a manner analogous to that for neutral solids. The constancy of P through this series of ions is perhaps an indication that the crystal structures for this series of closely related ions are similar.

The increase in electron density upon ionization at N(1) or N(3) in any of the methyluracils results in a decrease of about 2.1 eV in the binding energy of the nitrogen ionized (Table 1). In a study of hetero-

cyclic dinitrogen bases (19), protonation of one of the nitrogens was found to cause a similar increase in the N_{1s} binding energy (1.7–2.2 eV).

(c) Binding Energy and Charge Shifts

The change in electron density at the carbon, nitrogen, and oxygen atoms has been determined systematically for modification of the uracil structure by methylation, thionation, and ionization (Table 2). Experimental charges were calculated using the charge potential model (eq. [1]). For both neutral and ionic species, k values of 22.6 ± 0.8, 18.5 ± 2.5, and 16.1 ± 4 were adopted for carbon (14), nitrogen (4), and oxygen (14), respectively. E_0 values of 284.8 eV, 399.7 eV, and 532.6 eV were taken for carbon, nitrogen, and oxygen, respectively, in neutral molecules, and for the ions these values were adjusted by 5.9 eV to account for the intermolecular potential. Although the precision of the charges determined for any one atomic site is estimated to be ±0.03 electrons for carbon and ±0.08 electrons for nitrogen, the *change* in site electron density as a result of structural modification is considerably more precise (±0.01 electrons).

(i) Methylation

Methyl substitution at either N(1) or N(3) results in a net decrease in negative charge density, ~0.06 electrons, at the methylated nitrogen. Net charge densities calculated for each site by CNDO/2 formalism are also included in parentheses in Table 2 for comparison, and in the case of the charge decrease on the methylated nitrogen, agreement with our experimental value is reasonable. Although the effect of a methyl group might intuitively be thought of as electron donating, our analysis of its electron withdrawing effect at the nitrogen is supported by previous SCF studies (20). Any other charge redistributions which occur in the molecule upon methylation are too small to be considered significant. To the extent that *N*-methylation is analogous to ribosylation, these results suggest that no major reorganization of the electronic structure of a pyrimidine occurs upon incorporation into a nucleoside.

(ii) Thionation

Thionation of uracil, the methyl uracils, or the methyluracil ions, has the effect of reducing substantially the C_{1s} binding energy of the substituted carbon atom (Table 1). The only other consistent binding energy shift evident in Table 1 is the increase in the binding energy of the remaining oxygen atom. On the other hand, the shifts in experimental charge density exhibit a number of clear trends. Thionation at C(2) in the neutral atom results in an *increase* of electron density at C(2), which agrees well with that predicted by our CNDO/2 calculations. Both adjacent nitrogen atoms undergo a *loss* of electron density. The absolute value of the charge change on the nitrogen is, however, smaller than that experienced by C(2). C(4) and C(6) carbons, two atoms removed from the sulphur modification, again exhibit an *increase* in electron density. Thus, the induced charges alternate in a decaying manner, a trend consistent with the CNDO/2 predictions (and discussed earlier by Pople and Beveridge (21) for simple hydrocarbons). The experimental results suggest that the alternation effect is more extensive than predicted by calculation. Thionation at C(4) results in an almost identical pattern of alternating charge density changes at adjacent centres. Thionation of the m^1U and m^3U anions at C(2) or C(4) also results in decaying charge alternation. However, the magnitude of the effect of thionation is clearly dependent on whether the base is neutral or anionic. For example, 2-thionation of m^1U and m^1U^- leads to a decrease of 0.03 and 0.06 electrons, respectively, at the C(4) position. This is not indicated by our CNDO/2 calculations.

(iii) Ionization

Ionization at N(1) or N(3) results in increases of 0.14–0.16 electrons at the ionized nitrogen site. In addition, increases in charge occur at the keto oxygens. Theoretical and experimental studies of the ionization of thymine (22) have indicated that, upon ionization, carbonyl groups are important in delocalizing the ionic charge in this molecule.

Some of the other trends in charge redistribution following ionization are not predicted by theoretical calculations and are more difficult to understand. For example, the increase in negative charge (0.05 electrons), which occurs at the N(1) or N(3) methyl upon ionization of the other nitrogen, was unexpected in view of the smaller increase at the methylated nitrogen itself. Also unexpected is the *decrease* in negative charge at C(6) upon ionization at N(1). Ionization at N(3), conversely, appears to lead to a charge *increase* at C(6), and the magnitude of this increase is dependent on the presence and position of the substituted thionyl group.

Temperature dependence of adiabatic compressibilities of and sound velocities in *p*-dioxane–water mixtures

NERIYANURI MANOHARA MURTHY AND SARASWATULA VENKATA SUBRAHMANYAM

Department of Physics, Post-graduate Centre, Anantapur 515003, India

Received March 4, 1978

NERIYANURI MANOHARA MURTHY and SARASWATULA VENKATA SUBRAHMANYAM. Can. J. Chem. **56**, 2412 (1978).

The effect of *p*-dioxane on the temperature of adiabatic compressibility minimum (TACM) and sound velocity maximum (TSVM) in water have been studied. Both the structural shifts, $[\Delta T_{\beta\ str}]_{exp}$ and $[\Delta T_{u\ str}]_{exp}$, are found to be positive, increasing with concentration and reaching maximum values around $X_2 \simeq 0.015$. These results have been explained as due to the formation of hydrates of dioxane of varying composition indicating the existence of long range order in the water + *p*-dioxane system in the water-rich region.

NERIYANURI MANOHARA MURTHY et SARASWATULA VENKATA SUBRAHMANYAM. Can. J. Chem. **56**, 2412 (1978).

On a étudié l'effet du *p*-dioxanne sur la température de compressibilité minimale adiabatique (TCMA) et la vitesse maximale du son (TVMS) dans l'eau. On a trouvé que les deux déplacements dus à des structures $[\Delta T_{\beta\ str}]_{exp}$ et $[\Delta T_{u\ str}]_{exp}$ sont positifs lorsqu'on augmente la concentration alors qu'elles atteignent des valeurs maximales autour de $X_2 \simeq 0.015$. On a expliqué ces résultats grâce à la formation d'hydrates du dioxanne de compositions variables indiquant la présence d'un ordre à longue distance dans le système eau + *p*-dioxanne dans la région riche en eau.

[Traduit par le journal]

Introduction

Though the system water + *p*-dioxane has been extensively studied from different angles, divergent views exist on the behaviour of the system in the water-rich region. The heat of mixing (1, 2) in the water-rich region of aqueous *p*-dioxane is negative, indicating the establishment of some long range order in the aqueous solutions of *p*-dioxane. The negative values of heat of mixing in the water-rich region have been explained by Goates and Sullivan (2) as indicative of the existence of short range structures ranging in composition from $1C_4H_8O_2:3H_2O$ to $2C_4H_8O_2:1H_2O$. Geddes (3) reported the presence of $C_4H_8O_2 \cdot 5H_2O$ from his viscometric results. Nuclear magnetic resonance and proton spin relaxation studies (4) on this system in the water-rich region indicate an increase in the degree of hydrogen-bonding in water. But the excess partial molal heat capacities of Bu_4NBr (5) and $n\text{-}Am_4NBr$ (6) in the water + *p*-dioxane system indicate structure rupture by *p*-dioxane even at low concentrations. Infrared studies by Fratello and Luongo (7) indicate considerable reduction in hydrogen-bonding present in pure water upon dilution by *p*-dioxane. Dielectric polarization studies by Tourky *et al.* (8) also indicate that the association of water decreases rapidly with increasing concentration of *p*-dioxane and in solutions containing large amounts of *p*-dioxane, water association is completely broken down. From the studies of ionic mobilities in the *p*-dioxane + water system, Kay and Broadwater (9) also point out that dioxane does not enhance long range order in water. However, ultrasonic velocity (10) and absorption (11) data support the contention that long range order persists in water-rich *p*-dioxane solutions.

In view of the divergent opinions existing on the solution structure of the water + *p*-dioxane system in the water-rich region, we have taken up a systematic study of the effect of *p*-dioxane on the temperature of adiabatic compressibility minimum (TACM) and sound velocity maximum (TSVM) of water, to understand the structural properties of this solute, since such studies (12, 13) have been found to be very useful in predicting whether a solute promotes or disrupts the hydrogen bonded structure of water.

Experimental

A.R. grade *p*-dioxane (BDH) used in the present study was purified as per the following procedure. It was first allowed to stand over sodium hydroxide pellets for several hours and then refluxed for 4 h. The material was then distilled and the middle fraction that boiled from 101 to 101.5°C was collected. It was again refluxed for 6 h with metallic sodium and then distilled using a fractionating column. The sample that had a boiling point of 101.4°C was collected. The density of the purified liquid, determined using a bicapillary type pycnometer with an accuracy of 2 parts in 10^5, was found to be 1.02811 g cm^{-3} at 25°C and this value is in good agreement with literature data (14). Ultrasonic velocities in pure components and aqueous *p*-dioxane solutions were determined using a single crystal variable path interferometer working at 3 MHz with an accuracy of $\pm 0.003\%$. The details of the experimental technique and the method of measurement of velocity and temperature of the experimental liquid were reported in our earlier communication (12).

Triple distilled degassed water was used to prepare solutions of aqueous *p*-dioxane of varying concentrations. Ultrasonic velocities in the solutions were determined at $\simeq 2°C$ intervals over a range of 5°C on either sides of T_β and T_u where T_β and T_u represent the temperatures corresponding to the adiabatic compressibility minimum and sound velocity maximum of the solution respectively. The experimental ultrasonic velocities were corrected for diffraction effects following the procedure developed by Subrahmanyam *et al.* (15). Densities of pure components and aqueous *p*-dioxane solutions were determined at $\simeq 2°C$ intervals. The adiabatic compressibilities were calculated using the standard formula, i.e. $\beta = u^{-2}\rho^{-1}$ which are accurate to $\pm 5 \times 10^{-15}$ cm²/dyn. At low concentrations of the organic solute, the temperature dependences of the adiabatic compressibility of and sound velocity in the solution are similar to those of the curves for pure water. Hence templates of the curves for pure water were employed to fix T_β and T_u. The accuracy in fixing T_β is $\pm 0.4°C$ and that of T_u is $\pm 0.2°C$. Since $d\beta/dt = 0$ at $t = T_\beta$ of the aqueous solution, a graphical method was also employed to fix T_β at which

$$\left|\frac{1}{\rho}\frac{d\rho}{dt}\right| = \left|\frac{2}{u}\frac{du}{dt}\right|$$

T_β evaluated by this method is also accurate to $\pm 0.4°C$.

Results

The results on the measurement of adiabatic compressibility and ultrasonic velocity as a function of temperature at different concentrations of dilute aqueous *p*-dioxane[1] are shown graphically in Figs. 1 and 2 respectively. It is worth while to note that the exact temperature range over which velocity measurements have to be carried out to fix T_u is generally higher than that necessary to fix T_β.

The water + *p*-dioxane system is known to exhibit ultrasonic relaxation (16), the relaxation frequency increasing with rise in temperature and concentration of *p*-dioxane. For example at $X_2 \simeq 0.025$, the lower relaxation frequencies at 10 and 25°C respectively are about 60 and 120 MHz. Since the temperature range of the present work is much higher (50 to 80°C) the relaxation frequencies will be definitely much higher than 3 MHz. Hence the velocity dispersion, which is probably negligible even at the relaxation frequency does not affect the present velocity measurements carried out at 3 MHz.

Discussion

The adiabatic compressibility of an aqueous solution can be represented by

$$[1] \qquad \beta = \phi_1\beta_1 + \phi_2\beta_2 + \beta^E$$

where β_1, β_2 and ϕ_1, ϕ_2 refer to the adiabatic compressibilities and volume fractions of water and the organic solute respectively and β^E represents the excess adiabatic compressibility. β_1 and β_2 may be written as

$$[2] \qquad \beta_1 = 42.208 + 0.0016\,(t - 64)^2$$

$$[3] \qquad \beta_2 = \beta_2^0 + \alpha_\beta t + \alpha_\beta' t^2$$

where β_2^0 represents the extrapolated value of the adiabatic compressibility of the organic solute at 0°C, α_β and α_β' are constants, and t represents the temperature in °C. The velocity data of Greenspan and Tschiegg (17) and density data from literature (18) have been used to evaluate the adiabatic compressibility of water at different temperatures and eq. [2] represents the least-squares fit of the above data. Substitution of eqs. [2] and [3] in eq. [1], differentiation of the resulting equation with respect to temperature and using the condition $(d\beta/dt)_{t=T_\beta} = 0$, we get the following expression for T_β of the solution

$$[4] \quad T_\beta = \left[64 - \frac{\phi_2}{\phi_1}\frac{\alpha_\beta}{0.0032}\right]\left(1 + \frac{\phi_2}{\phi_1}\frac{\alpha_\beta'}{0.0016}\right)^{-1} - \frac{d\beta^E}{dt}\left(1 + \frac{\phi_2}{\phi_1}\frac{\alpha_\beta'}{0.0016}\right)^{-1}(\phi_1 \times 0.0032)^{-1}$$

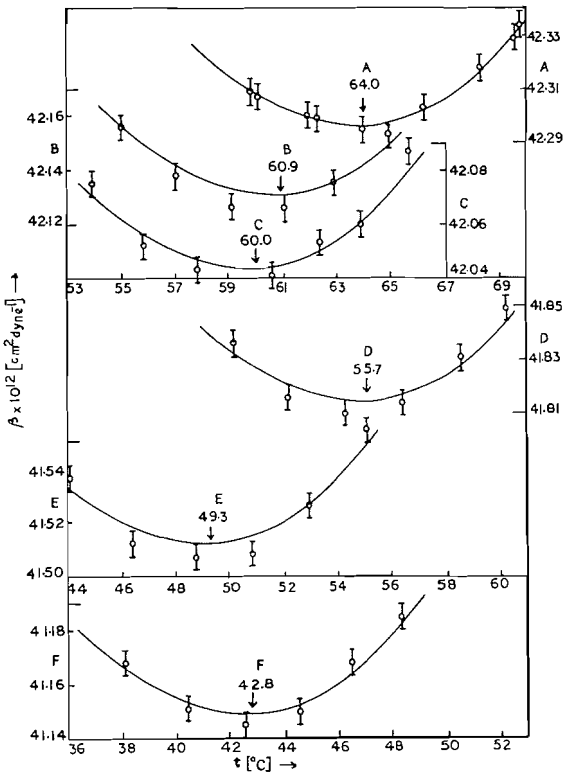

FIG. 1. Adiabatic compressibility, β, vs. temperature of solutions of aqueous *p*-dioxane. *A*, $X_2 = 0.0000$; *B*, $X_2 = 0.0041$; *C*, $X_2 = 0.0063$; *D*, $X_2 = 0.0121$; *E*, $X_2 = 0.0196$; *F*, $X_2 = 0.0280$.

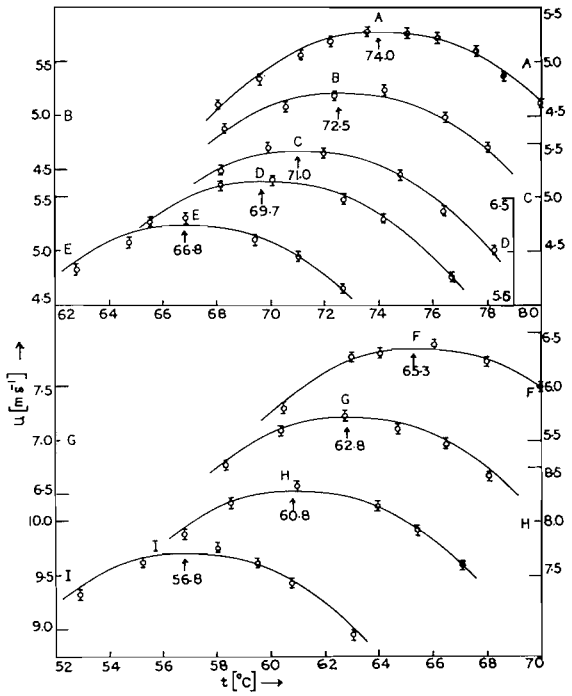

FIG. 2. Ultrasonic velocity vs. temperature in solutions of aqueous *p*-dioxane. The values given on the ordinate have to be added to 1550 ms^{-1}. *A*, $X_2 = 0.0000$; *B*, $X_2 = 0.0020$; *C*, $X_2 = 0.0036$; *D*, $X_2 = 0.0053$; *E*, $X_2 = 0.0090$; *F*, $X_2 = 0.0110$; *G*, $X_2 = 0.0143$; *H*, $X_2 = 0.0170$; *I*, $X_2 = 0.0225$.

Since

$$[5] \qquad \beta = \frac{1}{u^2\rho}$$

where u is the ultrasonic velocity and ρ the density, we can rewrite eq. [1] as

$$[6] \qquad \frac{1}{u^2} = \frac{\phi_1^2}{w_1 u_1^2} + \frac{\phi_2^2}{w_2 u_2^2} + \rho\beta^E$$

where w_1 and w_2 refer to the weight fractions of water and the organic solute respectively in the solution. It may be mentioned here that there is no need to replace ρ by

$$[7] \qquad \rho = \phi_1\rho_1 + \phi_2\rho_2 + \rho^E$$

since the effect of ρ^E, the excess density, on the velocity of the solution is negligibly small. According to Willard (19) the velocity in pure water conforms to the relation

$$[8] \qquad u_1 = 1557 - 0.0245\,(74 - t)^2$$

and over a small range of temperature the sound velocity in the organic solute is given by

$$[9] \qquad u_2 = u_2^0 - \alpha_u t$$

where α_u is the temperature coefficient of sound velocity in solute and u_2^0 is the linearly extrapolated velocity of the solute at 0°C. Substitution of eqs. [8] and [9] in eq. [6], differentiation of the resulting equation with respect to temperature, and using the condition $(du/dt)_{t=TSVM} = 0$, we get the following expression for T_u of the solution

$$[10] \quad T_u = \left[74 - \left(\frac{\phi_2}{\phi_1}\right)^2\left(\frac{w_1}{w_2}\right)\left(\frac{\alpha_u}{0.049}\right)\left(\frac{u_1}{u_2}\right)^3\right] - \left(\frac{w_1}{\phi_1^2}\right)\left(\frac{u_1^3}{0.098}\right)\left[\rho\frac{d\beta^E}{dt} + \beta^E\frac{d\rho}{dt}\right]$$

The values of β_2^0, α_β, α_β', u_2^0, and α_u for *p*-dioxane evaluated using the experimentally determined ultrasonic velocity and density data at different temperatures are respectively 45.979×10^{-12} cm^2/dyn, 0.241×10^{-12} $cm^2/dyn\ °C$, 0.003×10^{-12} $cm^2/dyn\ °C^2$, 1452.42 m/s, and 4.33 m/s °C.

The shifts produced, $\Delta T_\beta = (T_{\beta\ sol} - T_{\beta\ water})$ and $\Delta T_u = (T_{u\ sol} - T_{u\ water})$, may be thought of as arising from two effects; dilution effect and structural effect. The dilution effect is always negative. But the structural effect can either be positive or negative indicating either structure promotion or structure disruption by the solute.

The structural shifts $\Delta T_{\beta\ str}$ and $\Delta T_{u\ str}$ can be obtained either by employing the second terms on rhs of eqs. [4] and [10] respectively, or by using the following relations

$$[11] \qquad [\Delta T_{\beta\ str}]_{exp} = T_{\beta\ exp} - T_{\beta\ id}$$

$$[12] \qquad [\Delta T_{u\ str}]_{exp} = T_{u\ exp} - T_{u\ id}$$

where $T_{\beta\ id}$ and $T_{u\ id}$ are given by the first terms on rhs of eqs. [4] and [10] respectively. These temperatures correspond to those at which the adiabatic compressibility minimum of and sound velocity maximum in the solution would take place if ideal mixing occurs, i.e. β^E is zero. Since the temperature dependence of ϕ_1 and ϕ_2 is very small, ϕ_1 and ϕ_2 used to determine $T_{\beta\ id}$ and $T_{u\ id}$ were those calculated at the T_β and T_u of the solution found experimentally. Successive approximation method was employed for evaluation of $T_{u\ id}$.

$[\Delta T_{\beta\ str}]_{exp}$ and $[\Delta T_{u\ str}]_{exp}$ at each concentration of *p*-dioxane were evaluated using eqs. [11] and [12]. $T_{\beta\ exp}$ used is the average value of T_β obtained from both the template and graphical methods. The values of $[\Delta T_{\beta\ str}]_{exp}$ and $[\Delta T_{u\ str}]_{exp}$ at different mole fractions of *p*-dioxane are presented in Tables 1 and 2 respectively. Plots of $[\Delta T_{\beta\ str}]_{exp}$ and $[\Delta T_{u\ str}]_{exp}$ vs. X_2 of *p*-dioxane are shown in Fig. 3. Both the structural shifts are positive and increase with increasing concentration of *p*-dioxane reaching maximum values around $X_2 \simeq 0.015$ and thereafter the

structural shifts decrease. This trend is an indication of stabilization of water structure by dioxane molecules in accordance with the nuclear magnetic resonance and proton spin relaxation data (4) on this system. Studies on the apparent molal volumes and heat capacities of *p*-dioxane in water at 25°C by Kiyohara *et al.* (20) indicate that *p*-dioxane is a weakly hydrophobic solute supporting the results of the present study. But the temperature of density maximum studies by Wada and Umeda (21) on this system show negative values for the structural contribution to the shift in the temperature of maximum density of water indicating disruption of hydrogen bonded structure of water by the addition of *p*-dioxane.

The present ultrasonic studies on the water + *p*-dioxane system support the idea that small amounts of dioxane due to the hydrophobic nature of its methylene groups enhance the strength of water–water hydrogen bonds in its vicinity, possibly permitting the water molecules to become organized into clusters which envelope dioxane molecules. Above $X_2 \simeq 0.015$, there starts the breakdown of the three dimensional structure of these clusters. In view of this the positive structural shifts may be thought of as due to ordering of water structure owing to the formation of hydrates of dioxane as reported in literature (2, 3, 16).

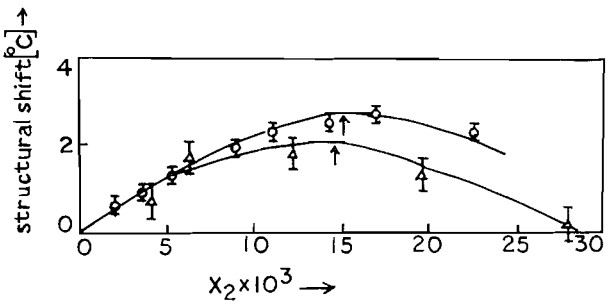

FIG. 3. Structural shifts vs. mole fraction X_2 of *p*-dioxane. △, $[\Delta T_{\beta\ str}]_{exp}$; ○, $[\Delta T_{u\ str}]_{exp}$.

It is also possible to evaluate $\Delta T_{\beta\ str}$ and $\Delta T_{u\ str}$ using the second terms of eqs. [4] and [10], respectively, where we need only the velocity in and density of the solution at different temperatures for the evaluation of $d\beta^E/dt$ and $d\rho/dt$. Evaluation of the structural shifts in this way will serve as a check on the sign and magnitude of the structural shifts obtained using eqs. [11] and [12]. In fact the sign of $d\beta^E/dt$ itself will indicate whether the structural interactions are promotive or disruptive, i.e., positive sign indicating structure disruption and negative sign indicating structure promotion (13). $d\beta^E/dt$ with the probable error has been calculated at each concentration by evaluating β^E at different temperatures and fitting the data to a straight line by least-squares fit method since β^E was found to vary linearly with temperature within the limits of the experimental error. Values of u_1, ρ, β^E, and $d\rho/dt$ at $t = T_{u\ id}$ were used in the calculation of $\Delta T_{u\ str}$. In order to distinguish the structural shifts calculated using the second terms on the rhs of eqs. [4] and [10] respectively from those obtained by using eqs. [11] and [12], the former values may be denoted as $[\Delta T_{\beta\ str}]_{the}$

and $[\Delta T_{u\ str}]_{the}$ although u and ρ used in the evaluation are the experimental ones. In this method it is not necessary to determine u and ρ at very narrow temperature ranges in as much as they are essential for fixing T_β or T_u. The structural shifts evaluated by the use of either of the methods are compared in Table 3 at representative concentrations and the agreement is quite good.

Mixed oxidation state compounds of antimony: a ^{121}Sb Mössbauer study of some antimony–fluorine systems

JACK G. BALLARD, THOMAS BIRCHALL, RONALD J. GILLESPIE, EDWARD MAHARAJH, DAVID TYRER, AND JOHN E. VEKRIS

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received April 7, 1978

JACK G. BALLARD, THOMAS BIRCHALL, RONALD J. GILLESPIE, EDWARD MAHARAJH, DAVID TYRER, and JOHN E. VEKRIS. Can. J. Chem. **56**, 2417 (1978).

Antimony-121 Mössbauer spectra for $[Sb_2F_4^{2+}][SbF_6^-]_2$ and three compounds containing the $[Sb_3F_{14}^-]$ ion are reported. The Mössbauer data are discussed in relation to their known structures. Two of the compounds give spectra which, on analysis, give η values of unity.

JACK G. BALLARD, THOMAS BIRCHALL, RONALD J. GILLESPIE, EDWARD MAHARAJH, DAVID TYRER et JOHN E. VEKRIS. Can. J. Chem. **56**, 2417 (1978).

On rapporte les spectres de Mössbauer de l'antimoine 121 pour le $[Sb_2F_4^{2+}][SbF_6^-]_2$ et trois composés contenant l'ion $[Sb_3F_{14}^-]$. On discute des données de Mössbauer en terme de leurs structures connues. Deux des composés donnent des spectres qui par analyse donnent des valeurs η sont égales à l'unité.

Antimony pentafluoride forms adducts with a variety of Lewis bases. Of particular interest to us have been those which contain antimony in its two oxidation states, III and V. Antimony-121 Mössbauer spectroscopy has been particularly useful in characterizing a number of such mixed oxidation state compounds (1–4). This technique, along with Raman spectroscopy, provided the first spectroscopic evidence for "SbF_4" (5). Two forms of "SbF_4" were shown to exist and were called forms A and B. Both compounds were shown to contain antimony in the III and V oxidation states. Subsequently Edwards and Slim (6) were able to show that form B was in fact $[Sb_6F_{13}^{5+}][SbF_6^-]_5$. Recently Gillespie *et al.* (7) have characterized, by X-ray crystallography, a 1:1 adduct of SbF_3 with SbF_5 and shown it to be $[Sb_2F_4^{2+}][SbF_6^-]_2$. These workers also presented Raman evidence to show that $[Sb_2F_4^{2+}][SbF_6^-]_2$ was in fact $SbF_3 \cdot SbF_5$ (A). Since the earlier $SbF_3 \cdot SbF_5$ Mössbauer spectra were only obtained at liquid nitrogen temperature it seemed worthwhile recording the spectrum of $[Sb_2F_4^{2+}][SbF_6^-]_2$ at 4 K in order to obtain a better quality spectrum from a well characterized material.

Gillespie and co-workers (8–10) have recently prepared compounds containing the $[Sb_3F_{14}^-]$ anion and here we present data for these compounds which have rather unusual Mössbauer spectra. Mössbauer data are also presented for some other adducts of antimony pentafluoride.

Experimental

$AsF_3 \cdot SbF_5$ was prepared by the slow evaporation of liquid SO_2 from a solution of antimony pentafluoride and excess arsenic trifluoride in liquid SO_2. The white solid was washed with successive amounts of liquid SO_2. $SbF_5 \cdot SO_2$ was obtained by the slow evaporation of SO_2 from a solution of pure antimony pentafluoride in liquid sulphur dioxide. Raman spectroscopy was used to show that these compounds were pure (11, 12). The preparations of the remaining compounds have all been described (8–10).

Mössbauer spectra were recorded at liquid helium temperatures, on samples containing 8–10 mg cm^{-2} of Sb, using a $Ba^{121}SnO_3$ source at room temperature, on apparatus previously described (13). Isomer shifts were measured with respect to InSb at liquid helium temperatures. Spectra were computer fitted by procedures already described (14–16). However, no single programme was available which could treat the spectra of $[Sb_3F_{14}^-]$ which has more than one antimony site, and where the asymmetry parameter η was not equal to zero and had to be varied. In these cases the Sb(III) resonance was fitted separately from that of the antimony(V) using the transmission integral procedure of Cranshaw (16).

Results and Discussion

The data are summarised in Table 1 and the simpler adducts will be discussed first. The adduct formed between SbF_5 and AsF_3 gives only one resonance at 10.9 mm s^{-1} with a negligibly small quadrupole coupling constant. This is what one would expect from an $[SbF_6^-]$ species. Edwards and Sills have shown that this adduct can indeed be considered as having an important contribution from the ionic structure $[AsF_2^+][SbF_6^-]$ (11). They also found that there was a slight distortion of the $[SbF_6^-]$ octahedron, but this does not result in a measurable quadrupole coupling constant.

For $SbF_5 \cdot SO_2$ a less positive isomer shift was obtained indicating a slightly higher *s* electron density at the antimony. This value agrees well with that reported by Carter *et al.* (17). These workers also

reported the presence of a small quadrupole coupling constant but gave no indication of the sign of this interaction. We find a value of −6.3 mm s^{-1}. The negative sign is consistently obtained from our computer fitting procedures no matter what sign was given to the initial estimates for the fitting procedure. Moore *et al.* (18) have shown that the antimony environment consists of five fluorines at 1.85 Å with the sixth coordination position being completed by a longer interaction with one of the SO_2 oxygens (the Sb—O bond length being 2.13 Å). The negative value for the quadrupole coupling constant indicates a reduced electron density along the direction of V_{zz} and suggests that this is collinear with the F—Sb—O axial direction in the molecule.

The spectrum of the 1:1 SbF_3:SbF_5 adduct is shown in Fig. 1 and there are clearly two antimony environments present. The narrow absorption at +11 mm s^{-1} is characteristic of antimony(V) in a near regular octahedron of six fluorines; $[Sb(V)F_6^-]$ salts have isomer shifts of this magnitude (5, 17). At ∼−8 mm s^{-1} a broad asymmetric resonance is observed which is characteristic of antimony(III) in a distorted environment of fluorines. These data are similar to those reported earlier by Birchall *et al.* (5) who isolated two forms for the $SbF_3 \cdot SbF_5$ adduct, which were called forms A and B. Form B was subsequently shown to be $[Sb_6F_{13}^{5+}][SbF_6^-]_5$ (6) and Gillespie and co-workers have recently shown that the compound discussed here is identical to form A (7). In view of the fact that the earlier spectra were only recorded at 80 K, rather than 4 K, the agreement between the two sets of data is acceptable, though the present results must be more accurate considering the improved quality of the spectrum and the more reliable fitting procedures used here.

Gillespie *et al.* (7) have shown that this adduct $SbF_3 \cdot SbF_5$ (A) should be formulated as $[Sb_2F_4^{2+}][SbF_6^-]_2$. They showed that there is a significant interaction between the anions and cation via Sb(V)—F . . . Sb(III) fluorine bridges. This results in a range of Sb(V)—F bond lengths (1.84–1.92 Å) in the hexafluoroantimonate(V) anions and this is undoubtedly the origin of the small quadrupole coupling constant found for the antimony(V) sites. The parameters listed in Table 1 for the Sb(III) site clearly indicate the presence of a stereochemically active *5s* electron pair. The positive value for the quadrupole coupling constant suggests that V_{zz} lies through this lone pair of electrons. However, a simple interpretation of the Sb(III) resonance is not possible. It has been shown that the $[Sb_2F_4^{2+}]$ cation can be approximately described as an SbF_3 molecule linked to an $[SbF^{2+}]$ ion. Further fluorine bridging results in an infinite chain cation $[Sb_2F_4^{2n+}]_n$. One antimony has an environment similar to that in SbF_3 (19), but with one additional long Sb—F contact, while the other antimony has one short Sb—F bond (1.85 Å) and five longer

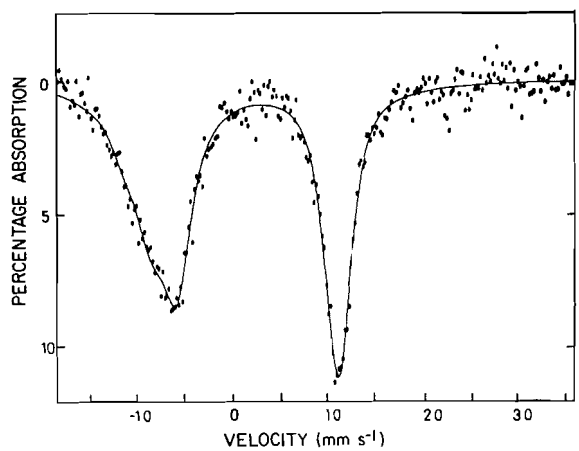

FIG. 1. The ^{121}Sb Mössbauer spectrum of $[Sb_2F_4^{2+}][SbF_6^-]_2$ at 4 K.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

contacts (2.10–2.42 Å). The antimony(III) environments are clearly different yet separate Mössbauer resonances are not resolved. Attempts were made to fit this region of the spectrum to two sites, but meaningful results were not obtained. However, the line width obtained for the Sb(III) site is much larger than normally expected and perhaps can be taken as indicating the presence of more than one Sb(III) site. The data therefore only establish the presence of the lower oxidation state of antimony in a distorted environment. A similar situation pertains in $[Sb_6F_{13}^{5+}][SbF_6^-]_5$ ($SbF_3 \cdot SbF_5$(B)), where again more than one Sb(III) environment is present (6) but not resolved (5).

The remaining compounds in Table 1 contain two anions, namely, $[SbF_6^-]$ and $[Sb_3F_{14}^-]$. This latter anion consists, in all cases, of two $Sb(V)F_6$ octahedra linked by fluorine bridges to an $Sb(III)F_2$ group. Gillespie and co-workers have shown (8–10) that, in these anions, the bridging fluorine atoms are closer to the antimony(V) atoms than to the central antimony(III) atom. Thus $[Sb_3F_{14}^-]$ can be approximately described as an $[Sb(III)F_2^+]$ ion linked by fluorine bridges to two $[Sb(V)F_6^-]$ ions. In all of these compounds, these antimony(V) environments and that of the independent $[SbF_6^-]$ anion are slightly distorted from octahedral geometry.

All three compounds exhibit absorption in both the Sb(III) and Sb(V) regions of the spectrum. The sharp resonance at 11 mm s^{-1} in each spectrum is characteristic of an antimony(V) coordinated by six fluoride ions. The slight distortion present in these $[Sb(V)F_6^-]$ species (8–10) is not evident from the Mössbauer spectrum, nor are the two types of $[Sb(V)F_6^-]$ resolved. The other resonance absorptions in each of these spectra occur at negative velocities with respect to InSb. In the case of $[Te_2Se_2^{2+}]$-$[SbF_6^-][Sb_3F_{14}^-]$ this resonance is broad and very asymmetric, which is typical of the very distorted environments found in SbF_3 and its adducts (e.g. Fig. 1). The distorted environment is attributed to the influence of a stereochemically active electron pair. The isomer shift value of −6.5 mm s^{-1} indicates that there is considerable *s* character to the Sb(III)—F bonds. In fitting this Sb(III) resonance absorption it was necessary to include a variable asymmetry parameter ($\eta = (V_{xx} - V_{yy})/V_{zz}$) in order to obtain a satisfactory fit: the best η value was found to be 0.49. Normally antimony(III) spectra have a zero, or small, value for η, which is usually attributed to the principal component of the electric field gradient tensor, V_{zz}, being coincident with the symmetry axis through the active electron pair and bisecting the angles formed by the normally three short Sb(III)—X bonds, as in SbF_3 (20). A large η value signifies that these axes are not coincident or that the three-fold symmetry axis has been destroyed. Gillspie and co-workers (8) have shown that the immediate antimony(III) environment consists of two short Sb—F distances (1.91 Å) and two somewhat longer ones (2.18 Å); the coordination sphere is completed by four much longer Sb—F contacts. There is no three-fold axis and one would therefore expect a nonzero value for η.

The resonance absorptions at negative velocities for the $[Se_{0.7}Te_{3.3}^{2+}]$ and $[S_4N_4^{2+}]$ compounds are rather unusual for an Sb(III) species. Figure 2 shows the spectrum for $[Se_{0.7}Te_{3.3}^{2+}][SbF_6^-][Sb_3F_{14}^-]$. The resonance in the Sb(III) region appears as a symmetrical doublet. This region can be fitted to two antimony(III) environments with cubic environments having isomer shift values of −5.1 and −8.8 mm s^{-1}. These parameters are rather unrealistic for Sb(III)—F systems. Furthermore it is known that there is only one antimony(III) environment in these compounds which is very distorted from cubic symmetry (9, 10). It has been shown that the ^{121}Sb spectrum becomes more symmetrical as $\eta \rightarrow 1$, and when $\eta = 1$ it has the appearance of a symmetrical doublet (4). Our spectra were fitted with a variable η value and both gave $\eta = 1$, though admittedly the

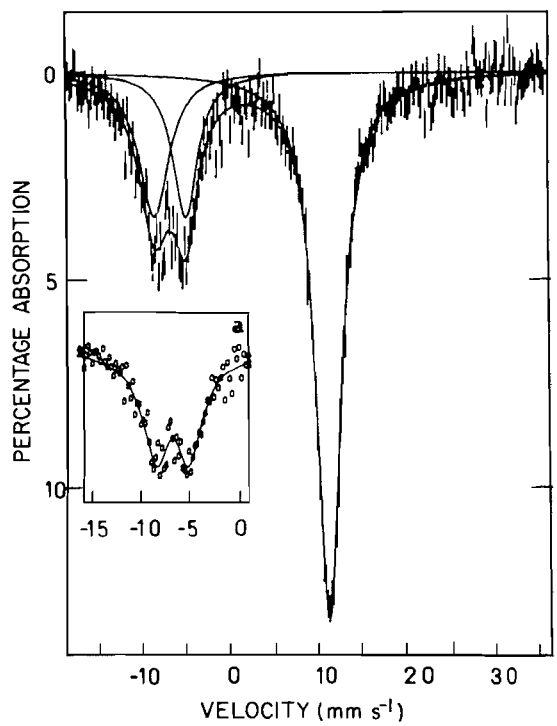

FIG. 2. The ^{121}Sb Mössbauer spectrum of $[Se_{0.7}Te_{3.3}^{2+}]$-$[SbF_6^-][Sb_3F_{14}^-]$ at 4 K. Insert (*a*) Sb(III) region fitted to an eight-line quadrupole pattern with variable η value.

TABLE 2. Antimony(III)–fluorine bond distances in the $[Sb_3F_{14}^-]$ ion

Compound	Distance
$[Se_2Te_2^{2+}]$ $[SbF_6^-]$ $[Sb_3F_{14}^-]$	2 × 1.91; 2 × 2.18; 2 × 2.59; 2.94; 3.07
$[Se_{0.7}Te_{3.3}^{2+}]$ $[SbF_6^-]$ $[Sb_3F_{14}^-]$	1.89; 1.91; 2.19; 2.25; 2.63; 2.77; 2.83; 2.92
$[S_4N_4^{2+}]$ $[SbF_6^-]$ $[Sb_3F_{14}^-]$	1.89; 1.91; 2.27; 2.29; 2.72; 2.73; 3.00; 3.01

error on this value is large. Nevertheless the Sb(III) region of the spectra does have the appearance of symmetrical doublets consistent with this value. Such spectra are rather unusual and few examples are known. The first reported case was for $[(C_6H_5)_2Sb]_2O$ which had $\eta = 0.89$ (21). Alkyl antimony(III) halides also give a similar doublet-like spectrum and have $\eta = 0.9$ (22) though these compounds were not isolated in pure form. These were the only antimony(III) cases known until now. Recently Greenwood and co-workers (23) reported an example for Sb(V) and Ruddick and Sams (24) reported a case where $\eta = 0.75 \pm 0.06$. In this latter case no spectrum was shown so presumably a doublet-like structure was not observed. In all of the previous cases where $\eta \rightarrow 1$, the ligands bonded to the antimony varied considerably in relative electronegativities, i.e. C and O (21), C and Cl (22), C and N or O (23). The examples reported here are the first to show this phenomenon where all of the ligands bonded to the antimony are the same kind, in these cases, fluorine.

A comparison of the parameters for the three $[Sb_3F_{14}^-]$ compounds shows that the $[Se_2Te_2^{2+}]$ compound has a more positive isomer shift, a smaller quadrupole coupling constant and a lower η value than the $[Se_{0.7}Te_{3.3}^{2+}]$ and $[S_4N_4^{2+}]$ analogues. These differences indicate a lower *s* electron density at antimony and a slightly more symmetrical environment. The most intriguing change is the increase in η from 0.49 to 1, since the basic geometry about the central antimony(III) in the $[Sb_3F_{14}^-]$ ion is not dramatically different for the three compounds. In all cases the antimony(III) is surrounded by eight fluorines, to form a distorted monocapped square antiprism, with the lone pair occupying the capped position (Fig. 3). The relevant bond lengths are summarised in Table 2. In the $[Se_2Te_2^{2+}]$ compound there are two equal short Sb—F lengths at 1.91 Å whereas the other compounds have unequal short Sb—F bonds and the two next nearest interactions are also different at 1.89 Å and 1.91 Å. While these are small differences they are real and destroy the plane of symmetry existing in the $[Sb_3F_{14}^-]$ ion in the $[Se_2Te_2^{2+}]$ compound. Presumably the large asymmetry parameter is due to the complete lack of symmetry at the antimony(III) and to the large percentage change in Sb—F distance for the closest

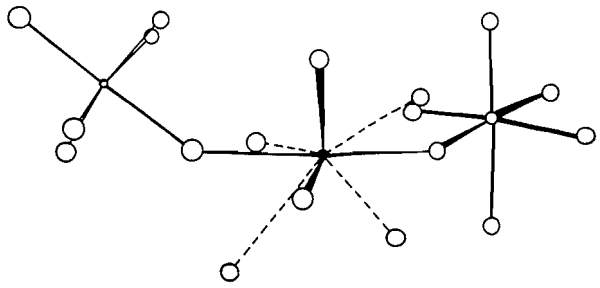

FIG. 3. The $[Sb_3F_{14}^-]$ anion in $[S_4N_4^{2+}][SbF_6^-][Sb_3F_{14}^-]$. --- Long contacts to neighbouring F atoms. ● Sb(III); ○ Sb(V); ○ F.

interactions. Increases in Sb—F distance undoubtedly reflect a lower involvement of 5*s* electrons or increasing *p* character in these bonds which will influence the Mössbauer parameters. If one compares the average Sb—F bond length in the three anions one finds that the order of increasing Sb—F (average) distance follows the change in isomer shift. The anion with the longest Sb—F (ave) bond length has the most negative isomer shift, the highest *s* electron density at antimony and therefore less average *s* character in the Sb—F bonds.

The chlorination of sulfides: A reassessment of product controlling factors

TERENCE PATRICK AHERN, DENIS GEORGE KAY, AND RICHARD FRANCIS LANGLER[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received April 3, 1978

TERENCE PATRICK AHERN, DENIS GEORGE KAY, and RICHARD FRANCIS LANGLER. Can. J. Chem. **56**, 2422 (1978).

A reexamination of previous proposals for the prediction of regioselectivity in sulfide chlorinations has found them to be unsatisfactory. A new basis for such predictions is advanced viz. the electronegativity difference (ΔX_p) of the substituents attached to the α- and α′-carbon atoms of the sulfide substrate. Upon establishing that the new basis for these predictions is satisfactory, it is successfully applied to the problem of predicting reactivity differences in isomeric sulfide chlorinations. The formation of isomeric sulfonium ions is used to establish the failure of possible isomerization processes to occur under normal reaction conditions.

TERENCE PATRICK AHERN, DENIS GEORGE KAY et RICHARD FRANCIS LANGLER. Can. J. Chem. **56**, 2422 (1978).

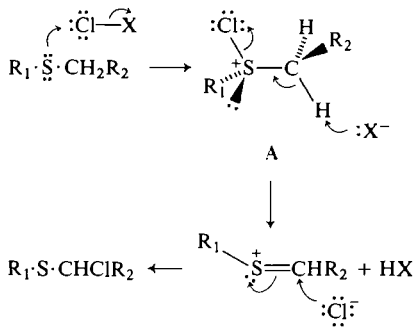
Après un réexamen des propositions antérieures concernant la prédiction de la régiosélectivité des chlorations de sulfures, on peut les considérer comme non-satisfaisantes. On propose une nouvelle base pour de telles prédictions, à savoir la différence électronégativité (ΔX_p) des substituants attachés sur les atomes de carbones α et α′ du substrat sulfuré. Après avoir établit que la nouvelle base pour ces prédictions est satisfaisante, on l'applique avec succès aux problèmes de la prédiction des différences de réactivité lors des chlorations de sulfures isomères. On utilise la formation d'ions sulfonium isomères pour établir le fait que des processus d'isomérisation, possibles dans des conditions normales de la réaction, ne se produisent pas.

[Traduit par le journal]

Introduction

A substantial number of reports (1–21) which deal with the chlorination of sulfides has appeared in the literature. These reports have led to a somewhat confusing view of the product controlling factors.

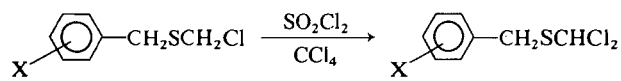
The chlorination of sulfides[2] proceeds as depicted in Scheme 1. The mechanism for the Pummerer re-



SCHEME 1

arrangement of chlorosulfonium salts **A** is due to Wilson and Huang (11) who examined the chlorination of some benzylic sulfides and concluded that the reactions proceed through a "relatively central E2 elimination." This mechanism appears to be quite general since even sulfides with an α-carbonyl group fail to deuterate when the reactions are conducted in a deuterated medium (21).

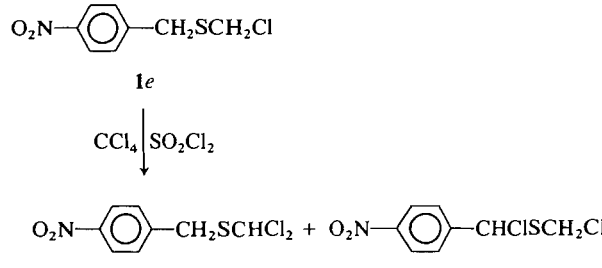
In one of the earlier papers attempting to deal with regioselectivity in chlorosulfide product formation, Paquette *et al.* (18) examined the reaction of a series of substituted benzyl chloromethyl sulfides with sulfuryl chloride. The results are shown below.



1 **2**

a X = H, *b* X = *p*-Cl, *c* X = *p*-F, *d* X = *m*-CF_3

When the substituent on the phenyl group was changed to a *p*-nitro group the following results were obtained.



2*e* (40%) **3** (60%)

On the basis of these results it was suggested that pursuant to chlorosulfonium salt formation (**A**,

[1]To whom all correspondence should be addressed.

[2]Sulfuryl chloride, *N*-chlorosuccinimide, and molecular chlorine are all presumed to form chlorosulfonium salts (**A**) as shown in Scheme 1.

TABLE 1. ΔpK_a values* of chlorine and phenyl substituted acids*

Parent acid	Substituted acid	ΔpK_a (ref.)†
CH_3CCH_3 (O)	CH_3CCH_2Ph (O)	7.2 (22)
$CH_3SO_2CH_3$	$CH_3SO_2CH_2Ph$	5.8 (22)
CH_3CCH_3 (O)	CH_3CCH_2Cl (O)	3.5 (23)
		8.5 (24)

*pK_a of parent acid less pK_a of substituted acid.
†pK_a values from ref. 22 determined in DMSO; pK_a values from ref. 23 determined in H_2O.

Scheme 1) "the most acidic α-hydrogen is subject to abstraction and the resulting ylid is transformed to the observed α-chlorosulfide" (18).

Table 1 presents ΔpK_a values for selected acids. These values indicate that all of the benzylic sulfides **1***a* → **1***e* would form chlorosulfonium salts in which the thermodynamic acidity of the benzylic protons would be greater than that of the chloromethyl protons. To find support for expected differences in these thermodynamic acidities, we decided to perform a pair of deuterium exchange experiments. Although sulfoxides are the direct oxy analogues of chlorosulfonium cations,[3] we have chosen sulfone substrates on the grounds that the relative acidities of α- and α′-protons in sulfoxides and sulfones are similar and that sulfones exchange α- and α′-protons under significantly milder conditions than do sulfoxides.

When an equimolar mixture of chloromethyl methyl sulfone and benzyl methyl sulfone was treated with ethanol-*d* in the presence of dilute NaOD catalysis, the product obtained was benzyl methyl sulfone (ca. 25% deuterated, exclusively at the benzylic carbon) and chloromethyl methyl sulfone (ca. 60% deuterated, exclusively at the chloromethyl carbon).

Reflux of a neutral solution of *p*-nitrobenzyl chloromethyl sulfone in ethanol-*d*–D_2O furnished the starting sulfone exclusively deuterated at the benzylic carbon (ca. 75%).

The results indicate that the chlorosulfonium cations (derived from **1***a* and **1***d*) have chloromethyl protons which are similar in thermodynamic acidity to simple benzylic protons and very much less acidic than *p*-nitrobenzylic protons, as expected from the ΔpK_a values in Table 1. Presuming that (*i*) the kinetic acidity of these protons parallels their thermodynamic acidity and that (*ii*) the kinetic acidity of the α- and α′-protons in the chlorosulfonium cations controls regioselectivity in the chlorinations of **1***a* → **1***d*, then mixtures of the regioisomeric dichlorosulfides should have been observed with increasing chlorination at the benzylic carbon as one proceeds through the series. No such result was observed, but instead the progressively increasing acidity of the benzylic protons had no effect on the regioselectivity for the dichlorosulfide products. Furthermore, the chlorination of **1***e* should have furnished **3** regiospecifically, when in fact, the reaction was hardly even regioselective. Consequently, it now appears that the acidity of α-hydrogens does not control regioselectivity in sulfide chlorinations.

Another approach to predicting regioselectivity in sulfide chlorinations may be advanced on the basis of a consideration of the two major resonance contributors (**B** and **C**) for sulfonium ions.[4,5]

$$R_1—\overset{+}{\underset{\cdot\cdot}{S}}=CHR_2 \longleftrightarrow R_1—\overset{\cdot\cdot}{\underset{+}{S}}—\overset{+}{C}HR_2$$

B **C**

Contributor **C** would be stabilized by electron-releasing groups and therefore an analysis of substituent effects on carbonium ion stability might be fruitful in attempting to anticipate regioselectivity in sulfide chlorinations.

One of the earlier reports concerning asymmetric sulfide chlorinations (20) appears to offer some support for this view.

$$CH_3SCH_2CH_3 + Cl_2 \xrightarrow{0°C} CH_3SCHClCH_3$$

Tuleen and Stephens (17) have extended these results and have shown that in general the chlorination of asymmetric dialkyl sulfides with NCS or SO_2Cl_2 gives products chlorinated preferentially in the more substituted alkyl group. They propose that E2 elimination of HCl from the chlorosulfonium salt (**A**, Scheme 1) produces a *carbonium ion* and that differences in chlorinations with SO_2Cl_2 and NCS are dictated by carbonium ion stability. To rationalize the observation that α-chlorodialkyl sulfides preferentially chlorinate in the chloroalkyl group, they suggested that there might be "stabilization of an incipient carbonium ion by a resonance

[3]Chlorosulfonium cations are unstable reactive intermediates and would be unsuitable substrates for exchange experiments.

[4]Throughout this paper the designation of these ions will be restricted to 'sulfonium ions' rather than 'carbonium-sulfonium ions' or 'sulfo-carbonium ions' because the latter names do not appear to be in keeping with the electronic nature of these ions.

[5]Discussions concerning the nature of π bonding in sulfonium ions have appeared previously (25–29).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

interaction involving electron donation from chlorine to carbon" (17). Such a proposal is clearly unsatisfactory since (*i*) a chlorine atom directly attached to a positively charged carbon atom provides "added destabilization of . . . . [a] carbonium ion" (19) and (*ii*) regioselectivity derived from carbonium ion stability would require, for example, that the chlorination of **1***a* furnish predominantly the cross-chlorinated sulfide which is in fact, not formed at all.

Consequently, incipient carbonium ion stability does not control regioselectivity in sulfide chlorinations.

Results and Discussion

In the introduction we have attempted to show that regioselectivity exhibited in the chlorination of asymmetric sulfides cannot be predicted by considering the relative acidities of α-hydrogens or by analyzing incipient carbonium ion stability.

A recent paper by Csizmadia *et al.* (28) has been most helpful in dealing with this problem. They have shown, on the basis of nonempirical SCF-MO computations, that for CH_2OH^+ there is a *net electron donation from oxygen to carbon of 0.03 electron* and for CH_2SH^+ there is a *net electron donation from sulfur to carbon of 0.68 electron*. They have also found that the *CS π overlap is substantially greater than the CO π overlap*.

The implication of their calculations, for resonance theory, is that the importance of the resonance contributor **B** is much greater than had been believed previously (25–29). If one makes the assumption that the resonance contributor **C** has minor significance for the sulfonium ion and that **B** is essentially a complete description of the ion, then substituent effects are readily predicted. Electron-withdrawing substituents attached to the carbon of the CS π bond would assist electron transfer from sulfur to carbon, whereas electron-withdrawing substituents attached to the other carbon atom which is attached to sulfur would resist electron transfer from sulfur to carbon. Therefore the more stable regioisomeric sulfonium ion would have the electron-withdrawing substituent attached to the carbon of the CS π bond. Substituent effects would be expected to alter the transition state energy for the E2 elimination (see **A**, Scheme 1) in the same way, on the grounds that the transition state energy will be sensitive to the nature of the developing CS π bond.

An immediate consequence of this postulate is that regioselectivity in the chlorination of asymmetric sulfides is subject to control by the electronegativity difference between the substituents on the α- and α′-carbon atoms attached to sulfur. Chlorination will go into the group which has the more electronegative substituent on the grounds that such a group will maximize electron transfer from sulfur to carbon in the E2 transition state and in the intermediate sulfonium ion and thereby minimize the energies of both species.

To test our hypothesis we have employed the elegant and versatile method of Huheey (30, 31) for the calculation of group electronegativities. A selection of relevant group electronegativities appears in Table 2. The application of group electronegativities to the prediction of regioselectivity in virtually every known asymmetric sulfide chlorination is shown in Table 3. Table 3 shows that *the electronegativity difference* (ΔX_p) *qualitatively predicts the observed regioselectivity in every case*, independent of chlorinating agent, solvent or sulfide substrate. Table 3 also shows the results for calculations on Paquette's systems and offers a rationale for the failure of **1***a* → **1***d* to furnish regioisomeric dichlorosulfides as well as for the slight regioselectivity observed upon the chlorination of **1***e*. Subsequent to the development of our view of product controlling factors vis à vis regioselectivity in the chlorination of sulfides, we have turned our attention to another problem.

Some time ago we had observed that the chlorination of chlorodimethylsulfide with molecular chlorine in carbon tetrachloride, or in glacial acetic acid would not proceed past the formation of tetrachlorodimethyl sulfide (33). The lack of reactivity of the tetrachlorosulfide was clearly due to the

TABLE 2. Group electronegativities*

failure of the corresponding chlorosulfonium chloride salt to undergo Pummerer rearrangement since chlorination of tetrachlorosulfide in dilute aqueous acetic acid furnished the corresponding tetrachlorosulfoxide.[6] A summary of the relevant information appears below.

$$Cl_3C{\cdot}S{\cdot}CH_3 \xrightarrow[HOAc]{Cl_2} Cl_3C\overset{+}{\underset{\cdot\cdot}{S}}{=}CH_2 + Cl^- \longrightarrow Cl_3C{\cdot}S{\cdot}CH_2Cl$$

I

$$Cl_3C{\cdot}S{\cdot}CH_2Cl \xrightarrow[HOAc]{Cl_2} Cl_3C\overset{+}{\underset{\cdot\cdot}{S}}{=}CHCl + Cl^-$$

II

In considering the activation energies for the formation of **I** and **II**, two factors should be examined. Firstly, **II** contains one more chlorine atom than **I**. The additional chlorine atom will increase the demand for electron density on the positively charged sulfur atom, thereby increasing the transition state energy for the formation of **II** as compared to that for the formation of **I**. Secondly, since the electronegativity difference of the substituents in **II** is smaller[7] than it is for the substituents in **I**, **II** should form the more favourable π bond with a resultant lowering in the activation energy for the formation of **II**. From the order of reactivities of the two chlorinated dimethyl sulfides, the inductive effect of an additional chlorine atom in destabilizing the sulfonium ion by increasing charge concentration on sulfur is more important than its stabilizing effect which operated by enhancing the CS π bond. Clearly, then if we were to establish reactivity as support for our view of the product controlling factors in sulfide chlorinations, we needed a pair of *isomeric* sulfides in which the overall demand for electron density is the same for the sulfur atom but the nature of the CS π bonds would be very different.

In pursuit of such a system, we have prepared and chlorinated the mesylsulfide **4**.

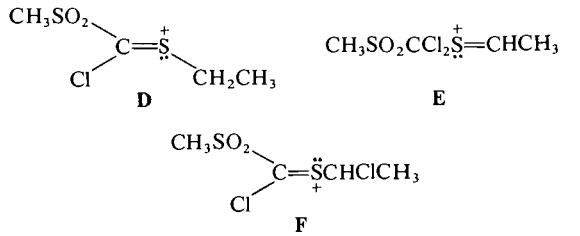
$$CH_3SO_2CH_2SCH_2CH_3 \xrightarrow[CCl_4]{Cl_2} CH_3SO_2CCl_2SCH_2CH_3$$

4 **5**

After bubbling chlorine gas into the reaction mixture for 10 min, the entire sample had been cleanly converted into the mesyldichlorosulfide **5**. Additional chlorination for 4 h effected no further change.

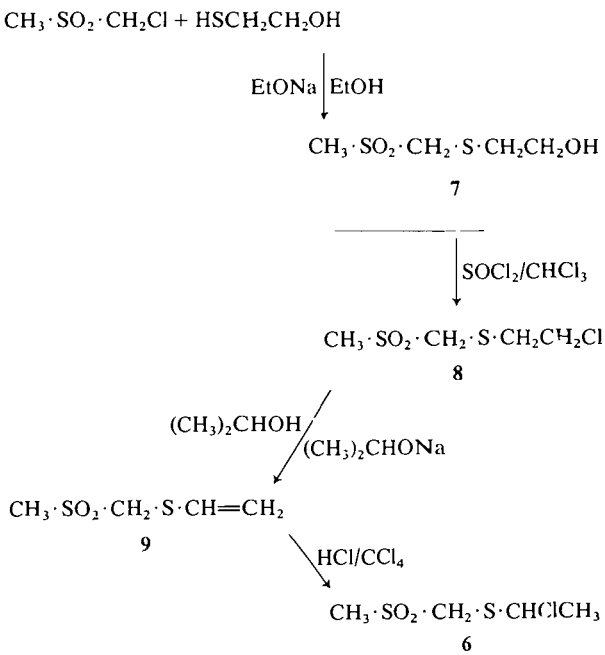
[6]Details of the chlorination reactions of sulfides and sulfoxides in aqueous media have been published previously (34). Sulfoxide formation has been used to confirm the formation of a chlorosulfonium chloride salt (13).

[7]Since the electronegativity differences in these cases disfavour further reaction, the smaller ΔX_p, the more favourable reaction should become.



The chlorination of **4** must have successfully produced the sulfonium ion **D** in order for **5** to form. The failure of **E** to form could be anticipated on the basis of the large electronegativity difference between the α- and α'-substituents which disfavors the formation of **E** from the corresponding chlorosulfonium chloride salt. However, **F** would be expected to have a much lower activation energy for formation than **E**, since the destabilizing inductive demands on sulfur are essentially the same in **E** and **F**, but the CS π bond in **F** would be much better than in **E**.

To test this hypothesis, we have synthesized the appropriate mesylchlorosulfide **6** as shown in Scheme 2. The chlorination of **6** furnished the



SCHEME 2

mesyltrichlorosulfide **10** in the same chlorination time per gram employed for the conversion of **4** into **5**.

$$CH_3SO_2CH_2SCHClCH_3 \xrightarrow[CCl_4]{Cl_2} CH_3SO_2CCl_2SCHClCH_3$$

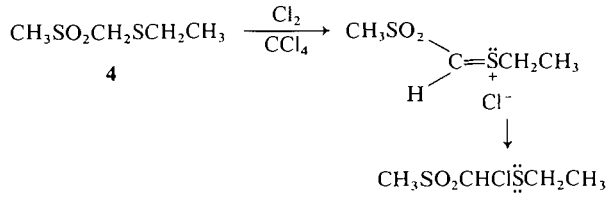
6 **10**

Thus, we have experimentally demonstrated the facile formation of **F** under conditions which would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

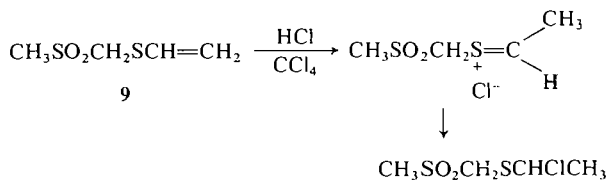
not furnish **E**. Therefore, as we have predicted on the grounds of CS π bond strengths, the activation energy for the formation of **F** is substantially lower than the activation energy for the formation of **E**. To our knowledge, this constitutes the first report that the *extent* of chlorine incorporation is a function of the substitution pattern of the sulfide substrate.

A fundamental problem connected with studies of sulfide chlorinations has been the unsupported assumption that the carbon bearing chlorine in the product was the carbon atom from which the proton was initially abstracted in the E2 elimination (see Scheme 1). In other words it has been tacitly assumed that sulfonium ions are unable to isomerize under normal reaction conditions. Our results provide a good test of this assumption. The chlorination of **4** must proceed to furnish **12** which is converted into **5** as described previously.



4 **12**

The reaction of alkene **9** with HCl (*vide* Scheme 2) must proceed through the isomeric sulfonium ion as shown below.



9 **6**

*In cases where there is more than one substituent on either side the electronegativities were summed and the differences of the sums reported.

Since neither reaction produces any observable amount of the other regioisomeric chlorosulfide (i.e., no **6** from **4** and no **12** from **9**) it is clear that nucleophilic attack by chloride ion on the sulfonium ion is much faster than any available isomerization process. Thus conclusions drawn regarding preferred proton abstraction in the E2 elimination step which are based on locating the chlorine atom in the α-chlorosulfide products are indeed correct.

In conclusion then, (*i*) sulfide chlorinations appear to proceed in general by chlorosulfonium ion formation, followed by E2 elimination of HCl which affords a sulfonium ion (normally attacked by chloride ion on carbon). (*ii*) Which of the regioisomeric sulfonium ions will form predominantly subsequent to E2 elimination from the chlorosulfonium ion can be anticipated on the basis of the electronegativity difference (ΔX_p) of the substituents attached to the α- and α′-carbon atoms. (*iii*) Reactivity differences in isomeric sulfide chlorinations can be predicted on the basis of the ΔX_p of the α- and α′-substituents in conjunction with a consideration of the total electronegativities of all substituents adjacent to sulfur in the starting sulfide.

Further experiments are already underway to examine sulfide chlorinations in terms of regioselectivity as a function of α-substituent electronegativities. As well, a test of this criterion for predicting regioselectivity in the chlorination of sulfoxides is also in progress.

Experimental

General

The ir spectra were recorded on a Perkin-Elmer 237B grating spectrophotometer. The nmr spectra were recorded on a Varian T-60 instrument using TMS as the internal standard. The mass spectra were recorded on a Dupont-CEC model 21-104 mass spectrometer. The samples were directly introduced using an all glass probe and the spectra run at 30 eV with a source temperature of 150°C. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected.

Chlorinations

Details have been provided previously (34).

Preparation of $CH_3SO_2CH_2SCH_2CH_2OH$ (7)

Sodium metal (3.460 g) was dissolved in absolute ethanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(250 ml). 2-Mercaptoethanol (11.768 g) and chloromethyl methyl sulfone (35) (20.002 g) were added and the reaction mixture refluxed for 24 h. The reaction mixture was cooled and the ethanol evaporated. Water (10 ml) was added to the concentrate and the pH adjusted to ca. 4 with glacial acetic acid. Chloroform (500 ml) was added and the solution dried and concentrated. The crude concentrate was dissolved in 95% ethanol (15 ml), stored at −20°C overnight and seeded.[8] Filtration afforded clean sulfone-sulfide-alcohol (7) (17.89 g, mp 37–39°C); ir ($CHCl_3$): 3540, 1310, and 1140 cm^{-1}; nmr ($CDCl_3$) δ: 2.26 (1H, s), 3.02 (5H, m), 3.86 (2H, t), and 4.00 (2H, s); ms *m/e*: 170 (M^+, 2.1%), 91 (92.7%), 61 (100%), and 45 (89.1%). *Anal.* calcd. for $C_4H_{10}O_3S_2$: C 28.21, H 5.92; found: C 27.93, H 5.88.

Preparation of $CH_3SO_2CH_2SCH_2CH_2Cl$ (8)

A solution of the alcohol (7) (4.998 g) in chloroform (15 ml) was brought to gentle reflux and a solution of $SOCl_2$ (3.504 g) in chloroform (10 ml) added dropwise over 10 min. Upon completion of the addition, the mixture was refluxed for 2 h. The chloroform was evaporated and the residue chromatographed on silica gel (500 g). The column was washed with diethyl ether (50 100-ml fractions). Fractions 20–50 were combined and concentrated affording clean chlorosulfone sulfide (**8**) (2.047 g, mp 40–43°C); ir ($CHCl_3$): 1320 and 1140 cm^{-1}; nmr ($CDCl_3$) δ: 3.06 (3H, s), 3.26 (2H, t), 3.80 (2H, t), and 4.00 (2H, s); ms *m/e*: 190 (1.7%), 188 (M^+, 5.4%), 111 (33.2%), and 109 (100%). *Anal.* calcd. for $C_4H_9ClO_2S_2$: C 25.46, H 4.80; found: C 25.58, H 4.75.

Preparation of $CH_3SO_2CH_2SCH{=}CH_2$ (9)

Sodium metal (0.120 g) was added to 2-propanol (5 ml) and the mixture refluxed until all the sodium dissolved. A solution of the chlorosulfonesulfide (**8**) (1.002 g) in 2-propanol (5 ml) was added to the sodium isopropoxide solution and the reaction mixture stirred at ambient temperature for 1 h. Water (50 ml) was added and the resultant mixture washed with chloroform (four 50 ml aliquots). After drying and concentration the chloroform solution furnished crude sulfone vinylsulfide (0.687 g). After recrystallization[9] from 95% ethanol the alkene (**9**) had mp 50–52°C; ir ($CHCl_3$): 1595, 1320, 1140, and 960 cm^{-1}; nmr ($CDCl_3$) δ: 3.03 (3H, s), 4.10 (2H, s), 5.50, and 6.50 (3H, $J_{AB} \sim 0$, $J_{AC} \sim 16$ Hz and $J_{BC} \sim 11$ Hz); ms *m/e*: 152 (M^+, 9.2%), 73 (69.2%), and 45 (100%). *Anal.* calcd. for $C_4H_8O_2S_2$: C 31.55, H 5.29; found: C 31.50, H 5.30.

Preparation of $CH_3SO_2CH_2SCHClCH_3$ (6)

The alkene-sulfone-sulfide (**9**) (1.001 g) was added to carbon tetrachloride (35 ml). HCl gas (ca. 200 ml/min) was bubbled into the mixture for 2 h. As the reaction proceeds the alkene goes into solution. About 10 min before completion of the reaction the chlorosulfone sulfide (**6**) begins to precipitate from solution. Sufficient chloroform to just dissolve precipitated product was added, the reaction mixture filtered, and the solvent evaporated affording clean chlorosulfone sulfide (**6**) (1.0648 g). After recrystallization from carbon tetrachloride the product had mp 56–59°C. This compound is unstable at room temperature and should be used within a week after preparation; ir ($CHCl_3$): 1340 and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 1.93 (3H, d, $J = 7$ Hz), 3.10 (3H, s), 4.00 (1H, d, $J = 15$ Hz), 4.33 (1H, d, $J = 15$ Hz), and 5.77 (1H, q, $J = 7$ Hz); ms *m/e*: 190 (2.9%), 188 (M^+, 8.9%), 111 (31.3%), 109 (94.0%), 73 (77.6%), 47 (83.5%), and 45 (100%).

The corresponding β-disulfone was prepared from the chlorosulfone-sulfide (**6**) (1.004 g) in standard fashion (36) using CrO_3/HOAc which furnished 0.718 g of clean chlorodisulfone after recrystallization from 95% ethanol. The disulfone had mp 117–119°C; ir ($CHCl_3$): 1345, 1330, and 1160 cm^{-1}; nmr ($CDCl_3$) δ: 1.90 (3H, d, $J = 7$ Hz), 3.33 (3H, s), 4.50 (1H, d, $J = 15$ Hz), 5.10 (1H, d, $J = 15$ Hz), and 5.50 (1H, q, $J = 7$ Hz); ms *m/e*: 94 (100%), 79 (40.3%), and 63 (59.6%). *Anal.* calcd. for $C_4H_9ClO_4S_2$: C 21.76, H 4.11; found: C 21.85, H 4.24.

Preparation of $CH_3SO_2CH_2SCH_2CH_3$ (4)

The preparation and properties of this compound have been described elsewhere (37).

Chlorination of 4

The sulfone-sulfide (**4**) (1 g) in carbon tetrachloride (5 ml) was quantitatively converted into the dichlorosulfone-sulfide (**5**) upon treatment with Cl_2 (ca. 200 ml/min) for 10 min. Further chlorination for 3h and 50 min effected no further change. The solvent was evaporated and the crude dichlorosulfone-sulfide **5** characterized; ir ($CHCl_3$): 1330 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 1.37 (3H, t), 3.30 (2H, q), and 3.40 (3H, s); ms *m/e*: 147 (11.1%), 145 (66.6%), 143 (100%), 81 (30%), and 79 (90%).

Treatment of crude **5** (0.720 g) with CrO_3/HOAc (37) furnished clean dichlorodisulfone (0.532 g, mp 90–92°C) after recrystallization from 95% ethanol; ir ($CHCl_3$): 1360, 1350, and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 1.57 (3H, t), 3.50 (3H, s), and 3.80 (2H, q); ms *m/e*: 165 (11.1%), 163 (66.6%), 161 (100%), 77 (54.9%), and 64 (61.9%). *Anal.* calcd. for $C_4H_8Cl_2O_4S_2$: C 18.83,H 3.16; found: C 18.78, H 3.07.

Chlorination of 6

The chlorosulfone-sulfide (**6**) (0.5 g) in carbon tetrachloride (5 ml) was quantitatively converted into the trichlorosulfone-sulfide (**10**) upon treatment with Cl_2 (ca. 200 ml/min) for 5 min. The solvent was evaporated and the crude trichlorosulfone-sulfide **10** characterized; ir ($CHCl_3$): 1345 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 2.00 (3H, d, $J = 6$ Hz) 3.25 (3H, s), and 5.85 (1H, q, $J = 6$ Hz); ms *m/e*: 183 (0.9%), 181 (9.0%), 179 (29.0%), 177 (29.0%), 81 (20.0%), 79 (60%), 65 (33%), and 63 (100%).

Treatment of **10** (0.680 g) with CrO_3/HOAc (37) furnished the corresponding trichlorodisulfone (0.362 g, mp 60–61°C) after recrystallization from 95% ethanol; ir ($CHCl_3$): 1360, 1350, and 1155 cm^{-1}; nmr ($CDCl_3$) δ: 2.03 (3H, d, $J = 6$ Hz), 3.45 (3H, s), and 5.90 (1H, q, $J = 6$ Hz); ms *m/e*: 165 (9.9%), 163 (59.8%), 161 (89.7%), 65 (33%), and 63 (100%). *Anal.* calcd. for $C_4H_7Cl_3O_4S_2$: C 16.59, H 2.43; found: C 16.60, H 2.42.

Selective Deuteration of p*-Nitrobenzyl Chloromethyl Sulfone*

p-Nitrobenzyl chloromethyl sulfone (0.050 g) (18) was dissolved in a solution of ethanol-*d* (3 ml) and D_2O (5 drops) and the reaction mixture was refluxed for 2 h. The solvent was evaporated and the residue established as partially deuterated at the benzylic position only by nmr viz. 77% removal of signal at δ 4.53 (benzylic methylene (18)). The mass spectrum indicated d_0, 6.6%, d_1, 38.4%, d_2 53.3% for the nitrobenzyl group observed at *m/e* 136.

Competitive Exchange for $PhCH_2SO_2CH_3$ and $ClCH_2SO_2CH_3$

A mixture of benzyl methyl sulfone (0.057 g) and chloromethyl methyl sulfone (0.043 g) was dissolved in a solution of hot ethanol-*d* (3 ml) and NaOD (0.025 *N* in D_2O) (3 drops). The reaction mixture was refluxed 1 h. Methylene chloride (50 ml) was added, the solution washed with water (25 ml) and the organic layer concentrated.

[8]Initially pure sulfone-sulfide-alcohol was obtained by column chromatography of a small sample of crude on silica gel with ether elution followed by acetone elution.

[9]One recrystallization is not adequate for long-term storage. The alkene (**9**) tends to polymerize upon standing unless it has been twice recrystallized.

The nmr indicated 25% deuteration at the benzylic carbon only in the benzylmethyl sulfone and 60% deuteration at the chloromethyl carbon only in the chloromethyl methyl sulfone. The mass spectrum indicated the following results $PhCH_2SO_2CH_3$: d_0 71.6%, d_1 15.3%, d_2 12.9%; $ClCH_2SO_2CH_3$: d_0 24.0%, d_1 21.6%, d_2 52.4%, d_3 1.8%.

Porphyrin syntheses requiring negative substituents[1]

HIROSHI KOBAYASHI,[2] JOHN L. ARCHIBALD,[3] AND S. FERGUSON MACDONALD
Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received April 19, 1978

HIROSHI KOBAYASHI, JOHN L. ARCHIBALD, and S. FERGUSON MACDONALD. Can. J. Chem. **56**, 2430 (1978).

Syntheses which convert pyrromethenes, pyrromethanes, or pyrroles to porphyrins in one step are limited by the necessity of avoiding inseparable mixtures of products. Such mixtures from pyrromethenes or pyrromethanes may become separable, and those from pyrroles avoided, if the products bear appropriate negative substituents.

It would appear that isomeric porphyrins with two negative substituents, on adjacent and on opposite rings, respectively, do not form mixed crystals (solid solutions) and are easily separated by crystallization.

HIROSHI KOBAYASHI, JOHN L. ARCHIBALD et S. FERGUSON MACDONALD. Can. J. Chem. **56**, 2430 (1978).

Les synthèses qui permettent de transformer les pyrrométhènes, les pyrrométhanes ou les pyrroles en phorphyrines en une étape sont limitées par la nécessité d'éviter des mélanges de produits qui soient inséparables. De tels mélanges, provenant de pyrrométhènes ou de pyrrométhanes, peuvent devenir séparables et ceux provenant du pyrroles peuvent être évités si le produit porte des substituants négatifs appropriés.

Il semblerait que des porphyrines isomères portant deux substituents négatifs respectivement sur les cycles adjacents et opposés ne forment pas de cristaux mixtes (solutions solides) et peuvent être facilement séparés par cristallisation.

[Traduit par le journal]

Introduction

Although often more convenient, porphyrin syntheses from pyrromethenes, pyrromethanes, or pyrroles lack the formal generality of those from linear tetrapyrroles. This is because they can lead only to inseparable mixtures in some cases. However, familiar effects of negative substituents on the reactivity of pyrroles and on the properties of porphyrins suggest methods for avoiding such mixtures or making them separable.[4] These methods are curious because negative substituents are commonly inimical in porphyrin syntheses and because they suggest that Hans Fischer would have synthesized hemin, even if it had been derived from protoporphyrin 7, 10, or 15.

The primary limitations on syntheses of porphyrins from pyrromethenes or pyrromethanes are illustrated by Hans Fischer's methods (2*a*) (Scheme 1). Porphyrins with the elements of symmetry indicated could be made by method A(*a*) or B(*a*). All others had to be made by A(*b*) and this involved separating the unsymmetrical product from two centrosymmetric by-products formed as in A(*a*). If two isomeric pyrromethenes were used in A(*b*), it was generally impossible to separate the resulting isomeric porphyrins or (if this were possible) to determine which was which. Method A(*b*) was thus inapplicable if the required pyrromethenes were isomers or too closely related. Consequently this method usually required a characteristic substituent (usually a propionic acid group) in one of the pyrromethenes so the three products could be separated by hydrochloric acid fractionation and identified by combustion analysis. It is immaterial here that one of the centrosymmetric by-products could sometimes be avoided: if 5-bromo-5′-bromomethyl- and 5-free-5′-methyl pyrromethenes were available, these were used and only the former self-condensed.

The porphyrins from chlorophylls were fortunately monopropionic acids, available in principle by A(*b*). This method was also applicable to all those mesoporphyrins which had propionic acid groups on adjacent rings, including all those Fischer obtained by B(*a*). However, unlike B(*a*), A(*b*) was inapplicable to any etioporphyrins or coproporphyrins, and the generalities of these two methods are incommensurable. Fischer could and did synthesize 12 of the 15 mesoporphyrins but not the mesoporphyrins 7, 10, and 15 because these are unsymmetrical and have their propionic acid groups on opposite rings. Their syntheses from linear tetrapyrroles would of course be straightforward, cf. that of mesoporphyrin 10 (3). Yet Fischer could have obtained them indirectly from synthetic monopropionic acids, as in the con-

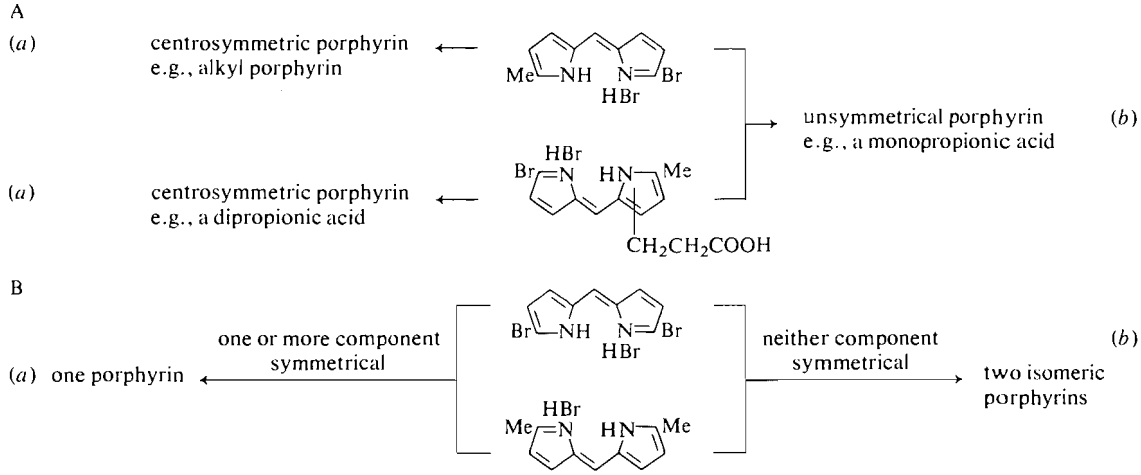
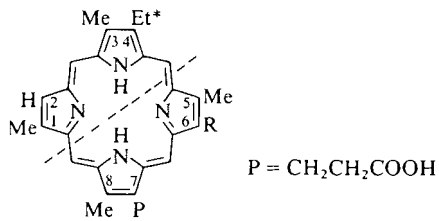


SCHEME I

version of pyrroporphyrin 15 to mesoporphyrin 9 (2*b*), e.g., mesoporphyrin 10 from the known pyrroporphyrin 12 (2*c*). However, as generally understood, Fischer's methods apparently offered no routes to the corresponding deuteroporphyrins 7, 10, and 15, and the problem is fairly represented by these.

The solution to this problem was implicit in Fischer's work. His synthesis of 2-desethylpyrroporphyrin 15 was that of a monopropionic acid by method A(*b*) (Fig. 1; the broken line indicates the pyrromethenes used but bromine is ignored). That of 2-desethylrhodoporphyrin 15 (4) may also have been so regarded but it should be considered as a modification of A(*b*) wherein COOEt replaces CH_2CH_2COOH (Scheme 1). The three products should then differ in the number of their ring carboxyl groups, be separable by hydrochloric acid fractionation and be identifiable by their visible spectra. This modification would be general for monocarboxylic acids and for porphyrins obtainable from them by removing or replacing the carboxyl group. Thus, deuteroporphyrin 10 (Fig. 1) could not have been synthesized like 2-desethylpyrroporphyrin 15 but its 6-carboxylic acid could have been synthesized like 2-desethylrhodoporphyrin 15. In Fischer's synthesis of this last, the yield was 0.05% and partial decarboxylation might have invalidated the method. These difficulties would be avoided if 5-free-5′-formylpyrromethanes replaced his 5-bromo-5′-methylpyrromethenes.



R = H: 2-Desethylpyrroporphyrin 15
R = COOH: 2-Desethylrhodoporphyrin 15
R = H (P for Et*): Deuteroporphyrin 10
R = COOH (P for Et*): 6-Carboxydeuteroporphyrin 10

Fig. 1. Deuteroporphyrin 10 and related porphyrins.

A related modification of A(*b*) (Scheme 1) employed Br instead of either CH_2CH_2COOH or COOEt. This was restricted because bromine was too readily lost under Fischer's conditions. As a convenient and general route to heptasubstituted porphyrins, wherein the loss of bromine is immaterial (cf. pyrroetioporphyrin 5 (4)), it would yield desethylmesoporphyrins from which mesoporphyrin 10 etc., could be obtained.

Method B(*b*) (Scheme 1) had not been used because two isomeric porphyrins necessarily result. However, if each pyrromethene bore a carbethoxy group, these would appear on adjacent rings in one of the products and on opposite rings in the other. The isomers would then be easily distinguished by visible spectra of the 'etio' and 'oxorhodo' type respectively. The effect of the carbethoxy groups on the yield would presumably render this synthesis impracticable, but the equivalent synthesis from a 5,5′-free- and a 5,5′-diformylpyrromethane (Scheme 2) would not be adversely affected by such groups, at least when they were on the 3- or 3′-positions of the pyrromethanes (5).

The problem of separating isomers like the dicarboxydeuteroporphyrins 4 and 5 (Scheme 2) remained. There appeared to be a surprising difference between the hydrochloric acid numbers of the diacetyldeuteroporphyrins 3 and 9 (Fig. 2) reported to be 7 (2*d*) and 3 (2*e*), respectively. This suggested that isomeric porphyrins, in which two negative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

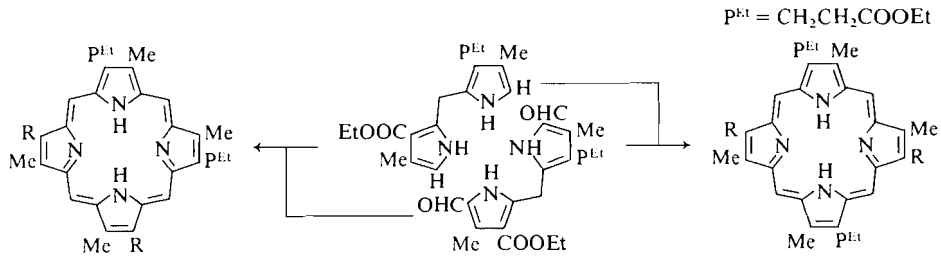

SCHEME 2

groups were differently situated with respect to each other, might be separated by hydrochloric acid fractionation. As a model, we used methyl esters of the diacetyldeuteroporphyrins 2 and 9 (Fig. 2), which have acetyl groups on opposite and adjacent rings, and spectra of the 'oxorhodo' and 'etio' type, respectively. These were synthesized for the purpose from the corresponding deuteroporphyrins. Their insolubility made them ill adapted to hydrochloric acid fractionation, and their hydrochloric acid numbers were both about 8. Although considerable separations were accomplished despite this, we now attribute these to the unexpected and unnoticed crystallization of one isomer or the other.

It was then accidentally found that the diacetyldeuteroporphyrin 2 and 9 esters were easily separated by crystallization from undisturbed solutions in acetone. As crystallized from a 1:1 mixture and recrystallized once, the pure components were recovered in over 80% yield. The separation of a pure porphyrin from a gross mixture of isomers by any method is still exceptional, however lax the criteria of purity. Crystallization had separated uroporphyrin 2 from its more soluble and lower melting isomers but this was tedious and wasteful, apparently because mixed crystals (solid solutions) were formed (6). In the present case diacetyldeuteroporphyrin 2 was the less soluble isomer but the separation reveals and depends on the fact that the two do not form mixed crystals. The idea that the two dicarboxydeuteroporphyrins (Scheme 2) would behave likewise, was encouraged by the notion that negative groups might determine association or packing in such cases. Either isomer could be stacked so that these groups were symmetrically disposed but this was not true of mixtures of the two.

The pyrromethanes (Scheme 2) were ethyl rather than methyl esters, so the resulting porphyrin esters would be relatively low melting. Charring often obscures porphyrin melting points at about 300°C and is not prevented by determining the melting points in capillaries sealed off under high vacuum. When the two pyrromethanes were condensed in AcOH–HI (cf. ref. 5) a roughly 1:1 mixture of the dicarboxydeuteroporphyrin 4 and 5 ethyl esters crystallized ($\geq 43\%$). A considerable separation was effected when the centrifuge brought down only the larger crystals consisting largely of the latter. Chloroform solutions of the two resulting fractions were filtered through alumina and the solvent displaced by acetone. The dominant porphyrins then crystallized from the undisturbed solutions: the ethyl ester of dicarboxydeuteroporphyrin 4 from one, that of dicarboxydeuteroporphyrin 5 from the other.

These two porphyrins were easily distinguished by their melting points and identified by their characteristic visible spectra. Their identity and purity was confirmed by decarboxylating them to the deuteroporphyrins and comparing these with the authentic deuteroporphyrins 4 and 5, which we

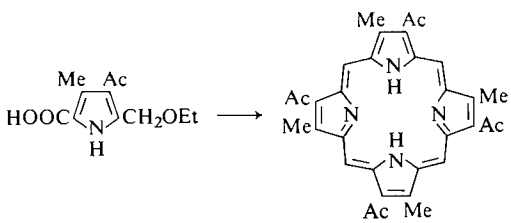
prepared by Fischer's usual methods. (Note: This would not have been possible had we worked with the more interesting isomers of types 7, 10, or 15.) In both cases the ethyl esters and their copper complexes agreed in melting point and mixture melting point, but only with deuteroporphyrin 5 did we get identical X-ray powder photographs. This was disappointing but hardly surprising. Specimens of polymorphic substances do not give identical photographs unless they are in the same form or mixture of forms and we had spent a year getting synthetic cytodeuteroporphyrin to photograph like Warburg's analytical specimen (7).

In the methods discussed above, negative groups are used to make multiple products of rational porphyrin syntheses separable and identifiable. In the synthesis which follows, they are used to prevent the irrational formation of isomers through the 'scrambling' of intermediates: ionic redistribution reactions of α-pyrryl and hydroxy groups about the methylene groups. This is apparent when 2-acetoxymethylpyrrole-5-carboxylic acids condense to mixtures of isomeric porphyrins rather than to those of type I (8). However, particularly under mild conditions, it seemed likely that a type I porphyrin would result if the pyrrole bore a 3-acetyl group. This would maintain the integrity of the original 2-pyrryl–CH_2 links by suppressing their fission to the derived 2-pyrryl anion. In fact, formic acid at 25–40°C in the presence of air converted 2-ethoxymethyl-3-acetyl-4-methylpyrrole-5-carboxylic acid into the type I porphyrin (Scheme 3). There was only one meso ^{13}CH signal (CH flanked by Me and Ac) in the nmr spectrum; more than ca. 5% of other isomers would have been revealed by signals from ^{13}CH flanked by 2 Me and by 2 Ac.



SCHEME 3

Experimental

Diacetyldeuteroporphyrin 9 Methyl Ester (cf. Fig. 2)

Crude diacetyldeuterohemin 9 was heated in HBr–AcOH for 60 h at 40°C (cf. ref. 2*f*). The solution was poured into 40 vol. of water and heated to coagulate the precipitated porphyrin. The latter was separated, washed, dried, and extracted into methanolic HCl (thimble). Water and chloroform were added to the extract and the chloroform layer was washed, dried, and filtered through alumina (Woelm, grade 3), eluting with 5% methanol in chloroform. The filtrate was concentrated and chloroform was displaced by adding hot methanol to the boiling solution. A chloroform solution of the resulting crystals was filtered through alumina, concentrated, and hot acetone added. The product separated overnight from the undisturbed solution as large black leaflets (25% from deuterohemin), mp 244–246°C (lit. (9) mp 244–246°C); λ_{max} in $CHCl_3$ (ε): 519 (14 900), 553 (8200), 588 (7000), 642 nm (3800), i.e., $\varepsilon_{553}/\varepsilon_{519} = 0.55$; hydrochloric acid number ca. 8 (lit. (2*e*) ca. 3). *Anal.* calcd. for $C_{36}H_{38}O_6N_4$: C 69.43, H 6.15, N 9.00; found: C 69.73, H 6.09, N 9.32.

Deuteroporphyrin 2 Methyl Ester

Crude deuteroporphyrin 2 from 3,5-dibromo-4,3′,5′-trimethylpyrromethene-4′-propionic acid hydrobromide, as obtained by treating the melt with aqueous sodium acetate (2*g*), was dried and left 4 days in 5% methanolic HCl. The resulting ester was twice purified by filtering its chloroform solution through alumina then crystallizing from methanol displacing chloroform. It formed purple rods (4%), mp on pre-heated stage 295–297°C (dec.) (lit. (2*g*) mp 285 or 291°C).

Diacetyldeuteroporphyrin 2 Methyl Ester (cf. Fig. 2)

Deuterohemin 2 methyl ester (ref. 2*g*) (200 mg) was acetylated (cf. ref. 2*f*) with 20 ml of acetic anhydride and 1.5 ml of $SnCl_4$ in an ice-bath for 8 min. The diacetyldeuterohemin 2, obtained by pouring the mixture into ice-water, was added to 20 ml of ice-cold concentrated H_2SO_4, then stirred 1¾ h at 20°C. The resulting diacetyldeuteroporphyrin 2, precipitated by adding water, was centrifuged, dried and extracted into 150 ml of 5% methanolic HCl (thimble, 2 h); more of the product was extracted by boiling the insoluble material in methanolic HCl. The resulting methyl ester of diacetyldeuteroporphyrin 2 was brought into chloroform (cf. its isomer above), filtered through alumina, and crystallized by adding much hot acetone to the concentrated chloroform solution. The filtration and crystallization were repeated twice to yield purple needles (43%), mp on stage pre-heated to 290°C, 304–305°C (dec.) (lit. (10) mp 310–315°C (dec.)); λ_{max} in $CHCl_3$ (ε): 521 (8300), 564 (19 200), 588 (11 600), 646 nm (1700), i.e., $\varepsilon_{564}/\varepsilon_{521} = 2.30$. *Anal.* calcd. for $C_{36}H_{38}O_6N_4$: C 69.43, H 6.15, N 9.00; found: C 69.10, H 5.91, N 9.48.

Separating the Methyl Esters of the Diacetyldeuteroporphyrins 2 and 9

The dimethyl esters of diacetyldeuteroporphyrin 2 (9.5 mg; $\varepsilon_{564}/\varepsilon_{521} = 2.23$; decomposes at 301°C after sintering at 298°C) and diacetyldeuteroporphyrin 9 (9.8 mg; $\varepsilon_{553}/\varepsilon_{519} = 0.535$; mp 241–244°C) were dissolved in 5 ml of chloroform which was then displaced by adding hot acetone to the boiling solution. The acetone solution (45 ml) was left undisturbed in the dark at 20°C. The first crop (8.6 mg; $\varepsilon_{564}/\varepsilon_{521} = 2.20$; decomposes from 294°C) separated overnight as purple rods. The concentrated mother liquor (7 ml) was left overnight as above to give the second crop as black rods (9.9 mg; $\varepsilon_{553}/\varepsilon_{519} = 0.58$; mp 242–245°C, sintering from 238°C, a few crystals remained and decomposed above 290°C). A solution of the first crop in chloroform was filtered through alumina, concentrated, and the chloroform was displaced by acetone. The acetone solution (40 ml) deposited the dimethyl ester of diacetyldeuteroporphyrin 2 as purple rods (8.0 mg, 84%), mp 300–303°C (dec.); $\varepsilon_{564}/\varepsilon_{521} = 2.23$. The second crop was purified likewise, crystallizing from 7 ml of acetone, to give the dimethyl ester of diacetyldeuteroporphyrin 9 as black leaflets (7.8 mg, 80%); mp 244–246°C (dec.); $\varepsilon_{553}/\varepsilon_{519} = 0.54$.

Benzyl 2-Chloromethyl-3-carbethoxy-4-methylpyrrole-5-carboxylate

Benzyl 2,4-dimethyl-3-carbethoxypyrrole-5-carboxylate (3.01 g) (11) in 25 ml of chloroform (free of ethanol, stabilized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with 5% dry ether) was stirred at 20°C while 0.85 ml of sulfuryl chloride in 10 ml of chloroform was dropped in. Two hours later the solvent was evaporated and the residue was crystallized from ether–hexane as colourless needles (64%), mp 137–140°C. *Anal.* calcd. for $C_{17}H_{18}O_4NCl$: C 60.80, H 5.40, N 4.17, Cl 10.55; found: C 61.17, H 5.58, N 4.11, Cl 10.71.

2-Benzyloxycarbonyl-3-methyl-4-(2-carbethoxyethyl)-pyrrole-5-carboxylic Acid

2-Benzyloxycarbonyl-3,5-dimethyl-4-(2-carbethoxyethyl)-pyrrole (12) (49.4 g) in 600 ml of dry ether was treated with 36.6 ml of sulfuryl chloride over 30 min while cooling in water. Next day the solution was refluxed for 1 h, the ether was evaporated, and more ether was added and evaporated. Sodium acetate (120 g) in 1 ℓ of boiling water was added to the residue, the mixture was boiled and stirred for 15 min, and then cooled. The solid, together with the ether extract of the aqueous layer, was extracted with aqueous sodium carbonate. The carbonate solution was washed with ether, cooled in ice, and saturated with SO_2. The precipitated product was recrystallized from aqueous ethanol as pink plates (74%), mp 148–152°C. The recrystallized analytical specimen formed colourless plates, mp 150–152°C. *Anal.* calcd. for $C_{19}H_{21}O_6N$: C 63.50, H 5.89, N 3.90; found: C 63.24, H 5.78, N 4.11.

2-Benzyloxycarbonyl-3-methyl-4-(2-carbethoxyethyl)-5-iodopyrrole

A hot solution of iodine (1.88 g) in 30 ml of ethanol was gradually added to 2.65 g of the above pyrrole 5-carboxylic acid and 1.48 g of potassium bicarbonate in 25 ml of water on the steam bath. When the solution decolorized, it was poured into water. The product separated at 0°C as colourless needles (87%), mp 82–84°C. The analytical sample, mp 85–86°C, had been recrystallized from aqueous ethanol then from hexane (thimble). *Anal.* calcd. for $C_{18}H_{20}O_4NI$: C 48.99, H 4.57, N 3.17, I 28.76; found: C 49.61, H 4.95, N 3.02, I 28.89.

Benzyl 3-Methyl-4-(2-carbethoxyethyl)pyrrole-2-carboxylate

The above 5-iodopyrrole (1 g) in 5 ml of dimethylformamide was stirred overnight with 2 g of zinc dust and a little anhydrous copper sulfate. Chloroform was added and the filtered solution was washed with dilute HCl and with water. The chloroform was evaporated and the residue was distilled (150–155°C, 1×10^{-4} Torr) to give the product (90%) as a colourless oil. *Anal.* calcd. for $C_{18}H_{21}O_4N$: C 68.55, H 6.71, N 4.44; found: C 68.99, H 6.96, H 4.58.

The product could be crystallized at 0°C and then, after draining in tile, could be recrystallized at 0°C from pentane as long colourless needles, mp 33–35°C. Catalytic reduction, in ethanol over platinum oxide in the presence of sodium acetate, was equally satisfactory.

Dibenzyl 4,4′-Dimethyl-3-carbethoxy-3′-(2-carbethoxyethyl)-pyrromethane-5,5′-dicarboxylate

Benzyl 2-chloromethyl-3-carbethoxy-4-methylpyrrole-5-carboxylate (5.14 g) and benzyl-3-methyl-4-(2-carbethoxyethyl)pyrrole-2-carboxylate (4.83 g) were boiled for 70 min in 30 ml of acetic acid containing 1.27 g of anhydrous sodium acetate. Water then precipitated an oil which solidified on standing. The product formed colourless crystals from ethanol (64%), mp 137–138.5°C. The analytical specimen was purified by column filtration and crystallized from benzene–hexane, mp 139–140°C. *Anal.* calcd. for $C_{35}H_{38}O_8N_2$: C 68.39, H 6.23, N 4.56; found: C 68.25, H 6.22, N 4.81.

4,4′-Dimethyl-3-carbethoxy-3′-(2-carbethoxyethyl)-pyrromethane-5,5′-dicarboxylic Acid

The above pyrromethane benzyl ester (6.4 g) was hydrogenated in dioxane (350 ml) over Pd-on-C (500 mg). The resulting mixture was heated to dissolve the product before filtering. Most of the product separated from the filtrate; a second crop, obtained by concentrating the mother liquor, was recrystallized; total yield 70%. For analysis, it was recrystallized from ethanol (thimble), mp 225°C (dec.). *Anal.* calcd. for $C_{21}H_{26}O_8N_2$: C 56.08, H 6.03, N 6.45; found: C 58.23, H 6.08, N 6.51.

4,4′-Dimethyl-3-carbethoxy-3′-(2-carbethoxyethyl)-pyrromethane (cf. Scheme 2)

The above dicarboxylic acid (570 mg) was heated *in vacuo* (5×10^{-4} Torr). Decarboxylation started at 155°C and was completed at ca. 160°C. The product then distilled at 170°C as a colourless oil which crystallized on rubbing with ether; yield 75%, mp 114–116°C. The analytical specimen, mp 116.5–117.5°C had been repeatedly recrystallized from ether. *Anal.* calcd. for $C_{19}H_{26}O_4N_2$: C 65.87, H 7.57, N 8.09; found: C 66.03, H 7.63, N 8.07.

4,4′-Dimethyl-3-carbethoxy-3′-(2-carbethoxyethyl)-5,5′-diformylpyrromethane (cf. Scheme 2)

Dimethylformamide (450 mg) was shaken and cooled in ice while 0.56 ml of $POCl_3$ were dropped in; after 1 h at 20°C, this was dissolved in 4 ml of 1,2-dichloroethane. This solution was cooled in ice while the above 5,5′-free pyrromethane (250 mg) in 3 ml of dichloroethane was added dropwise. After standing 7 days at 20°C while protected from moisture, the mixture was stirred with aqueous sodium acetate. A solution of the colourless precipitate in much ether was washed with aqueous sodium carbonate and with water, then evaporated. The residue crystallized from aqueous ethanol to give the product (50%), mp 158–159°C. The analytical sample, mp 159–162°C, had been repeatedly crystallized from ethanol. *Anal.* calcd. for $C_{21}H_{26}O_6N_2$: C 62.67, H 6.51, N 6.96; found: C 62.83, H 6.40, N 7.14.

Diethyl 1,4,5,8-Tetramethyl-2,7-bis(2-carbethoxyethyl)-porphin-3,6-dicarboxylate (Ethyl Ester of Dicarboxydeuteroporphyrin 4) and Diethyl 1,4,5,8-Tetramethyl-2,6-bis(2-carbethoxyethyl)porphin-3,7-dicarboxylate (Ethyl Ester of Dicarboxydeuteroporphyrin 5) (cf. Scheme 2)

Hydriodic acid (0.18 ml of 56%) in acetic acid (9 ml) was added to a solution of the 5,5′-free pyrromethane (21 mg) and its dialdehyde (24 mg) (Scheme 2) in acetic acid (27 ml). After 25 min, anhydrous sodium acetate (600 mg) in acetic acid (9 ml) was added and the solution was aerated for 1 day in the dark.

Centrifuging then separated only the larger crystals and these (6 mg) were purified by filtering their chloroform solution through alumina (grade 3), concentrating the filtrate to 5 ml, and displacing the chloroform with acetone at the boil (final volume 40 ml). The solution was filtered hot and allowed to stand undisturbed overnight. The ethyl ester of dicarboxydeuteroporphyrin 5 (6 mg, 14%) separated as purple needles, mp 265–271°C. For analysis, it was recrystallized as above, mp 275–277.5°C; λ_{max} in $CHCl_3$ (ε): 518 (9200), 561 (21 200), 586 (10 800), 641 nm (2600), i.e., $\varepsilon_{561}/\varepsilon_{518} = 2.30$. *Anal.* calcd. for $C_{40}H_{46}O_8N_4$: C 67.59, H 6.52, N 7.88; found: C 67.80, H 6.79, N 7.99.

The acetic acid, in which the remainder of the product was suspended, was diluted with water, neutralized with sodium bicarbonate, and extracted with chloroform. The washed and dried chloroform solution was filtered through alumina, concentrated, and the chloroform was displaced by methanol. The crystals which separated (12.5 mg) were dissolved in chloroform, then filtered through alumina and crystallized from 40 ml of acetone like the isomer above. The ethyl ester of dicarboxydeuteroporphyrin 4 separated as black plates (5 mg,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

12%), mp 241–242.5°C; λ_{max} in $CHCl_3$ (ε): 514 (14 800), 550 (7500), 584 (6800), 638 nm (3300), i.e., $\varepsilon_{550}/\varepsilon_{514} = 0.51$. *Anal.* calcd. for $C_{40}H_{46}O_8N_4$: C 67.59, H 6.52, N 7.88; found: C 67.48, H 6.61, N 7.86.

4,4′-Dibromo-3,5,3′,5′-tetramethylpyrromethene Hydrobromide (cf. ref. 13)

Bromine (3.52 g) in 14 ml of acetic acid was added in two portions to a stirred solution of 3,5,3′,5′-tetramethyl-pyrromethene hydrochloride (13) (2.36 g) in 20 ml of hot acetic acid. The mixture was heated 10 min in the steam bath then allowed to cool. The product which separated was recrystallized from 150 ml of 98% formic acid as dark red prisms (3.33 g). *Anal.* calcd. for $C_{13}H_{15}N_2Br_3$: C 35.59, H 3.43, N 6.39, Br 54.60; found: C 35.83, H 3.59, N 6.30, Br 54.48.

1,4,5,8-Tetramethyl-2,7-bis(2-carbethoxyethyl)porphin (Ethyl Ester of Deuteroporphyrin 4) (cf. Scheme 2)

(a) By Direct Synthesis

A well-ground mixture of methylsuccinic acid (14) (2 g), 4,4′-dibromo-3,5,3′,5′-tetramethylpyrromethene hydrobromide (220 mg), and 5,5′-dibromo-3,3′-dimethyl-4,4′-bis(2-carboxyethyl)pyrromethene hydrobromide (15) (280 mg) was heated for ½ h at 180°C. The partially cooled melt was extracted and washed with acetic acid – concentrated HCl (60:40). The extract was diluted with water, neutralized (NaOH then Na_2HPO_4), and heated to coagulate the precipitate. The latter was separated (centrifuge), washed with dilute acetic acid and with methanol, and dissolved in concentrated HCl. The pigment was transferred to ether (using sodium tartarate), thence into 2% HCl, back into ether, then into 0.01% ammonia, and again into ether (using citric acid). The washed and dried ether solution was evaporated and the residue was left overnight in 5% ethanolic HCl. The pigment was brought into chloroform. The washed and dried solution was filtered through alumina (grade 3) and the pigment was crystallized by adding ethanol to the hot concentrated filtrate. It was recrystallized several times from dry ethanol displacing chloroform, finally by allowing the solution (50 ml) to stand undisturbed overnight. It formed red needles, mp 236–240.5°C; it is evidently polymorphic for it once melted and resolidified to plates at 228°C before melting at 235–240°C; λ_{max} in $CHCl_3$ (ε): 499 (14 200), 532.7 (8300), 569 (6400), 622.5 nm (3900). *Anal.* calcd. for $C_{34}H_{38}O_4N_4$: C 72.06, H 6.76, N 9.89; found: C 71.85, H 6.96, N 10.01. The copper complex formed red needles, mp 235–239°C.

(b) From the Ethyl Ester of Dicarboxydeuteroporphyrin 4

The ethyl ester of dicarboxydeuteroporphyrin 4 was decarboxylated in AcOH–HCl at 200°C like its isomer below. The resulting ethyl ester of deuterioporphyrin 4 formed flat red needles, mp 235–241°C after a solid phase change at 230°C, mixture mp with the product of *a* above 236.5–241°C; λ_{max} in $CHCl_3$ (ε): 499 (14 000), 532.2 (8000), 569 (6200), 622.6 nm (3900). The copper complex formed red needles, mp 235–239°C, unchanged when mixed with that obtained in *a* above.

There were slight differences between the X-ray powder photographs of the products of *a* and *b*, both as esters and as copper complexes.

1,4,5,8-Tetramethyl-2,6-bis(2-ethoxycarbonylethyl)porphin (Ethyl Ester of Deuteroporphyrin 5) (cf. Scheme 2)

(a) As a By-product in the Synthesis of δ-Phylloporphyrin 15 (16, 17)

The dicarboxylic acids (37 mg) were brought from 0.01% ammonia into ether, from which 1% hydrochloric acid extracted deuterioporphyrin 5 and 14% hydrochloric acid extracted its bromo derivatives. The deuterioporphyrin 5 was brought into ether, the ether was evaporated, and the residue was esterified in ethanolic HCl. The ester was brought into chloroform, and the solution was filtered through alumina. The ethyl ester of deuteroporphyrin 5 separated as needles (6 mg) from ethanol displacing chloroform, mp 259–263°C; λ_{max} in $CHCl_3$ (ε): 499 (13 900), 532 (8000), 568.7 (6400), 622 nm (3900). The analytical specimen was recrystallized. *Anal.* calcd. for $C_{34}H_{38}O_4N_4$: C 72.06, H 6.76, N 9.89; found: C 71.84, H 6.88, N 9.76. (The methyl ester has been described (*2h*).) The copper complex formed needles, mp 287.5–289°C.

The bromo-deuteroporphyrins in the 14% hydrochloric acid were dehalogenated by the method of Busch (cf. the dehalogenation of bromo-α-phylloporphyrin 15 in ref. 16). The resulting deuteroporphyrin 5 was purified by extraction from ether into 1% hydrochloric acid and worked-up as above to give the ethyl ester of deuteroporphyrin 5 (8 mg), mp and mixture mp with the above 259–263°C.

(b) From the Ethyl Ester of Dicarboxydeuteroporphyrin 5

A solution of the ethyl ester of dicarboxydeuteroporphyrin 5 in acetic acid – concentrated hydrochloric acid (20:1) was deaerated in a tube by heating 1 h at 100°C, evacuating the tube for 2 h while cooling it in liquid nitrogen, then sealing it off at 1×10^{-4} Torr. The tube was then brought to 200–210°C over 2 h, then held at that temperature for 5 h. The solution was diluted with water and neutralized to precipitate the porphyrin. The latter was purified by extraction from ether into 2% hydrochloric acid, then esterified by ethanolic HCl. The ester, in ether, was passed through a column of 2% hydrochloric acid on silica gel. The eluant of the only moving band was washed with water, evaporated, and a chloroform solution of the residue was filtered through alumina (grade 3). After the chloroform was displaced by ethanol at the boil, the product separated overnight as purple needles, mp 256–261°C, 259–263°C when mixed with the product of *a*; λ_{max} in $CHCl_3$ (ε): 499 (13 300), 532 (7600), 568.5 (6100), 622 nm (3700). X-ray powder photographs of the esters under *a* and *b* were identical.

The copper complex formed needles, mp 283–283.5°C, 283.5–286.5°C when mixed with that obtained as in *a*. The X-ray powder photographs of the two specimens were identical. They were thus in the same crystallographic form. However, they apparently change more or less completely into another form before melting, for *b* changes visibly at about 240°C. Further, it melted at 287–292°C when recrystallized in the presence of seed, obtained by heating it to 270°C. We had previously seen no evidence of polymorphism among copper complexes; cf. the methyl esters of coproporphyrin 3 and 4 (15).

2-Ethoxymethyl-3-acetyl-4-methylpyrrole-5-carboxylic Acid (cf. Scheme 3)

The corresponding ethyl ester (18) (2.53 g) was refluxed in 10 ml of 10% NaOH and 10 ml of ethanol for 1.5 h in the steam bath. The solution was then concentrated to ¼ vol. *in vacuo*, diluted to 25 ml with water, filtered with Darco, and acidified with 10% sulfuric acid (Congo red). The product separated as colourless crystals (80%). For analysis, it was repeatedly recrystallized from acetone–water, mp 167°C (dec.). *Anal.* calcd. for $C_{11}H_{15}O_4N$: C 58.65, H 6.71, N 6.22; found: C 58.58, H 6.72, N 6.30.

1,3,5,7-Tetramethyl-2,4,6,8-tetraacetylporphin (cf. Scheme 3)

2-Ethoxymethyl-3-acetyl-4-methylpyrrole-5-carboxylic acid (1 g) was stirred for 7 days at about 38°C with 50 ml of 98% formic acid in a loosely-covered 250 ml beaker. The crystalline product (14%) was separated (centrifuge) and washed with 75% formic acid, with acetic acid, and with acetone. For analysis, it was recrystallized from boiling nitrobenzene

(thimble) as tiny rods, mp > 350°C. It formed green solutions in strong acids but was otherwise very insoluble. To measure the visible spectrum, a boiling chloroform solution was cooled, so the concentration was unknown; λ_{max} (relative density): 526 (1.0), 562 (0.48), 602 (0.40), 659 nm (0.26); ^{13}C nmr (on CFT 20, in trifluoroacetic acid, TMS) δ: 114.8 and 161.9 (TFA centres), 13.86 (ring CH_3), 31.79 (acetyl CH_3), 105.21 (meso CH), 136.37, 142.27, 143.70 and 146.93 (4 pyrrole C), 203.71 ppm (CO). *Anal.* calcd. for $C_{32}H_{30}O_4N_4$: C 71.89, H 5.66, N 10.48; found: C 71.97, H 5.61, N 10.57.

Derivatives of porphobilinogen and isoporphobilinogen[1]

GUENTER UFER,[2] SIOE S. TJOA, AND S. FERGUSON MACDONALD
Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received April 19, 1978

GUENTER UFER, SIOE S. TJOA, and S. FERGUSON MACDONALD. Can. J. Chem. **56**, 2437 (1978).

One of the more convenient syntheses of porphobilinogen has been adapted to that of isoporphobilinogen and extended to the lactams of both. Aminomethylation of appropriate 2-free pyrroles by the Tscherniac-Einhorn method gives derivatives of porphobilinogen and isoporphobilinogen. A method for aminomethylating reactive pyrroles is illustrated by the conversion of 2,4-dimethylpyrrole into its 5-*N*-acetylthiocarboxamide, then into its 5-acetylaminomethyl derivative, using acetyl isothiocyanate then Raney nickel, both at $\leq 20°C$.

GUENTER UFER, SIOE S. TJOA et S. FERGUSON MACDONALD. Can. J. Chem. **56**, 2437 (1978).

On a adapté une des méthodes de synthèse les plus efficaces pour la porphobilinogène à la synthèse de l'isoporphobilinogène et on l'a étendue à la préparation des lactames de chacun de ces composés.

L'aminométhylation de pyrroles appropriés ne portant pas de substituants en position 2, à l'aide de la méthode Tscherniac–Einhorn, conduit aux dérivés porphobilinogène et isoporphobilinogène.

On a illustré une méthode pour effectuer l'aminométhylation de pyrroles réactifs en transformant le diméthyl-2,4 pyrrole en son *N*-acétylthiocarboxamide-5 puis en son dérivé acétylaminométhyl-5 à l'aide de l'isothiocyanate d'acétyle et du nickel de Raney; les deux réactions sont effectuées à des températures inférieures à 20°C.

[Traduit par le journal]

Introduction

We report here incomplete work on three routes to 2-aminomethylpyrroles, particularly porphobilinogen and isoporphobilinogen. In the first of these, a known route to isoporphobilinogen is shortened, making it fully analogous to one of the more convenient syntheses of porphobilinogen; it is then modified to give the lactams of both. The other two routes involve aminomethylations by the Tscherniac–Einhorn reaction, or by a new and milder method.

Critical steps in nearly all syntheses of porphobilinogen, isoporphobilinogen, and their lactams are the removal of a 5-carboxylic acid group and (in the case of isoporphobilinogen lactam) the closure of the lactam ring. The decarboxylation of 5-carboxy-2-aminomethylpyrroles is impracticable and this decarboxylation is usually carried out on their acylamino derivatives, particularly the lactams (1), which decarboxylate in water at 100°C. However, one convenient synthesis of porphobilinogen (Scheme 1) depends on the easy decarboxylation of the oxime **8***a*, a transitory intermediate in the conversion of **1***a* to **2***a* (2). A similar synthesis of isoporphobilinogen was less direct in that **1***d* was converted to the 5-iodo-2-aldehyde and thence into **2***d*. This was because the **2***d* produced directly from **1***d* could not be isolated (2). This difficulty has now been overcome, and both porphobilinogen and isoporphobilinogen are obtained as in Scheme 1 (see Experimental).

Isoporphobilinogen lactam, which we required, has not been obtained directly from isoporphobilinogen. It had been obtained from appropriate 5-benzyloxycarbonylpyrroles in which the critical lactamization was effected. This involved the propionic acid group as its acid chloride (3) or methyl ester, i.e. 5-benzyloxycarbonylisoporphobilinogen dimethyl ester was cyclized by boiling with α-pyridone in dioxan for 25 h (4). This suggested a route to isoporphobilinogen lactam through **2***d* (Scheme 1), based on the lactamization of the ester of isoporphobilinogen itself and avoiding the backtracking associated with the use of the above benzyl esters. Porphobilinogen lactam, too, would then become available analogously through **2***a*.

Although isoporphobilinogen had been esterified in 90% yield, the reduction of the oximes **2***a* and **2***d* to porphobilinogen and isoporphobilinogen must be carried out in dilute solution to avoid by-products (2). To avoid this necessity, these oximes were first esterified then reduced. The oxime **2***a* had been converted to **4***b* in methanolic HCl (2) and **2***d* was now converted analogously into **4***e* and **4***f*. The ester hydrochlorides of the oximes were then reduced in appropriate alcohols to those of porphobilinogen and isoporphobilinogen, **5***b*, **5***e*, **5***f*, but only **5***f* was isolated (see below).

a $R^1 = CH_2CH_2COOH$, $R^2 = CH_2COOH$
b $R^1 = CH_2CH_2COOMe$, R_2 (if present) $= CH_2COOMe$
c $R^1 = CH_2CH_2COOEt$, $R^2 = CH_2COOEt$
d $R^1 = CH_2COOH$, $R^2 = CH_2CH_2COOH$
e $R^1 = CH_2COOMe$, R^2 (if present) $= CH_2CH_2COOMe$
f $R^1 = CH_2COOEt$, R^2 (if present) $= CH_2CH_2COOEt$

SCHEME 1. The yields refer to the methyl ester of isoporphobilinogen lactam.

The reduction of the 5-carbethoxy derivative of **4***c* to the diethyl ester of 5-carboxyporphobilinogen lactam in dilute ammonia (1) implied the lactamization of porphobilinogen esters by a weak base. This suggested the lactamization of isoporphobilinogen esters by a stronger one, particularly sodium alkoxide as used in the familiar preparation of barbituric acid. In the event, the lactams **6***b* (79%), **7***e* (77%), and **7***f* resulted when alcoholic solutions of **5***b*, **5***e*, and **5***f*, as obtained by reducing the oxime esters, were treated with an excess of the appropriate sodium alkoxide at 20°C. Although the ethyl ester of isoporphobilinogen lactam was formed quantitatively (tlc) several methods of isolation gave yields of only 23–42% because the apparent solubilities of the crude product were not consistent.

It should be mentioned here that the methyl and ethyl esters of porphobilinogen lactam melt higher than reported if their melting points are determined in capillaries which have been sealed off under vacuum (1×10^{-5} Torr) to avoid decomposition. The esters of isoporphobilinogen lactam are stable on the shelf and distill unchanged under high vacuum. The methyl ester melted higher than reported but, although we found no indication of the lower of the two melting points reported, a solid phase-change or partial melting represented the higher (see Experimental).

We were also interested in aminomethylation as a source of porphobilinogen derivatives not easily accessible by other methods, or labelled in the aminomethyl group. One of the latter, the ^{13}C-porphobilinogen, had been obtained in eight steps starting with the reductive methylation of **9***a* (R = H) to **9***a* ($R = {}^{13}CH_3$) with $^{13}CH_2O$ (5). Using unlabelled formalin, we have explored the more direct route to promising intermediates offered by the Tscherniac–Einhorn reaction (6). *N*-Hydroxymethylchloroacetamide is only one of the possible reagents here but it is obtained nearly quantitatively from formalin and chloroacetamide. H. Fischer had condensed it with 2,4-dimethyl-3-carbethoxypyrrole in boiling ethanol – concentrated hydrochloric acid and obtained the expected 5-chloroacetylaminomethyl derivative but with some other pyrroles it gave pyrromethanes or mixtures (7).

We found that *N*-hydroxymethylchloroacetamide condensed with **9***a*, **9***b*, **10***a*, **10***b* (R = H) in hot strong absolute ethanolic HCl to give the expected 2-chloroacetylaminomethyl derivatives **9***a*, **9***b*, **10***a*, **10***b* ($R = ClCH_2CONHCH_2$—). The last of these, a derivative of isoporphobilinogen, was obtained in 82% yield, and was reduced to 2-acetylaminomethyl-3-(2-ethoxycarbonylethyl)-4-ethoxycarbonylmethylpyrrole-5-carboxylic acid (98%). Unfortunately, 2.5–3 mol of *N*-hydroxymethylchloroacetamide were used arbitrarily in these experiments.

The scope of this reaction is further illustrated by the conversion of 2,4-dimethyl-5-carbethoxypyrrole into its 3-chloroacetylaminomethyl derivative and 2-methyl-3-carbethoxypyrrole into its 5-chloroacetylaminomethyl derivative. Mono substitution in the latter case was gratifying but when 2 mol of the reagent were used under more vigorous conditions the analyses and molecular weight of the product showed it to be a bis(chloroacetylaminomethyl)-pyrromethane.

We were also interested in the monoaminomethylation of 3,3′-bis(methoxycarbonylmethyl)-4,4′-bis-

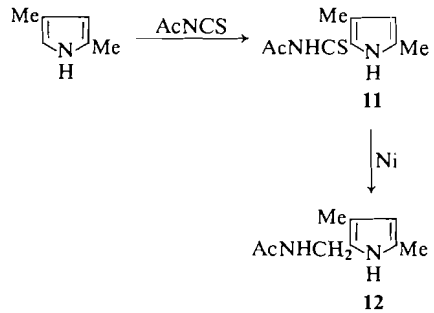
(2-methoxycarbonylethyl)pyrromethane, which is easily available (8). This would yield products similar to that obtained more indirectly from isoporphobilinogen lactam (3). Preliminary experiments on the aminomethylation of the above symmetrical pyrromethane by the Tscherniac–Einhorn method were, as expected, unsatisfactory. However, before work in this direction ceased, we had developed a method which might prove useful here.

It was suggested by the following. With $AlCl_3$, phenylacetyl isothiocyanate gives the thiohomophthalimide, from which tetrahydroisoquinolone-3 is obtained with Raney nickel (9). At 100°C, but without a catalyst, reactive pyrroles are *C*-thioacylated by phenyl isothiocyanate (10). Solutions of acetyl isothiocyanate are obtained from acetyl chloride and metal thiocyanates in solvents such as acetone. Whether isolated or not, acetyl isothiocyanate reacts easily with aniline, etc., but thioacylation is not always the dominant reaction (11).

This last proved no difficulty and a solution of acetyl chloride and potassium thiocyanate in dimethylformamide at 10°C converted 2,4-dimethylpyrrole into its stable 5-*N*-acetylthiocarbamide **11** (69%) (Scheme 2). Raney nickel at 20°C converted this into the 5-acetylaminomethylpyrrole **12** (52%).



SCHEME 2

Experimental

*2-Formyl-3-carboxymethyl-4-(2-carboxyethyl)pyrrole-5-carboxylic Acid (**1**a) and 2-Formyl-3-(2-carboxyethyl)-4-carboxymethylpyrrole-5-carboxylic Acid (**1**d)*

The crude products (2, 12) may be contaminated with their acid sodium salts, which are insoluble in acetone, so any acetone-insoluble material is dissolved in alkali and reprecipitated as the acid. These salts and discoloration are minimized by adjusting the pH of the hydrolysates (2, 12) to 4.5 before concentrating them; the acids are then precipitated at pH 1. In the case of **1***d*, the crude acid is readily purified by crystallizing from dioxane (Darco); the resulting crystals contain dioxane (ca. 1 mol) from which they are freed by recrystallization from acetone (thimble).

The esters can also be hydrolysed in boiling alcoholic KOH. This is convenient because the acids are precipitated as potassium salts which are insoluble in alcohol.

*2-Oximinomethyl-3-(2-carboxyethyl)-4-carboxymethylpyrrole (**2**d)*

Hydroxylamine hydrochloride (32 g) and 2-formyl-3-(2-carboxyethyl)-4-carboxymethylpyrrole-5-carboxylic acid (**1***d*, 12 g) in 200 ml of water, 128 ml of 10% NaOH (w/v), and 13 ml of ammonium hydroxide (pH of solution ca. 7.0; ammonia minimized discoloration) were heated under reflux for 10½ h. The solution was then concentrated to <100 ml (rotary, 40°C bath), diluted to 200 ml, brought to pH 2.5 at <10°C and seeded. After 2 h at 0°C, the grey crystalline product (54%) was separated and washed with 200 ml of water, mp 175–177°C (lit. (2) mp 178–180°C). For analysis it was twice recrystallized from water. *Anal.* calcd. for $C_{10}H_{12}O_5N_2$: C 50.00, H 5.04, N 11.66; found: C 50.18, H 4.99, N 11.47, ash 0.0.

The unrecrystallized product is suitable for esterification even though it sometimes contains ca. 10% of the 5-carboxylic acid (tlc). If present, the latter is completely removed by recrystallization from 10 parts of water (75% recovery). The yield is considerably increased by completely recycling all mother liquors.

*2-Oximinomethyl-3-(2-methoxycarbonylethyl)-4-methoxycarbonylmethylpyrrole Hydrochloride (**4**e)*

The powdered oxime (**2***d*, 2.118 g) was dissolved in 10 ml of 5% methanolic HCl at 20°C. After ½ h the esterification was complete (tlc) and the solution was seeded if necessary. The red product which separated was washed with ether and more was obtained by adding ether to the mother liquor. As recrystallized from chloroform–pentane it formed flesh coloured plates (85%), mp 120–140°C (dec.). *Anal.* calcd. for $C_{12}H_{17}O_5N_2Cl$: C 47.29, H 5.62, N 9.19, Cl 11.64; found: C 47.39, H 5.64, N 9.31, Cl 11.81.

*2-Oximinomethyl-3-(2-ethoxycarbonylethyl)-4-ethoxycarbonylmethylpyrrole Hydrochloride (**4**f)*

The oxime (**2***d*, 1 g) was warmed to solution in 10 ml of 5% ethanolic HCl. After ½ h at 20°C and 3 h at −20°C the product was separated as flesh coloured needles (82%) which were washed with ether, chloroform, and acetone successively, mp 115–140°C (dec.). *Anal.* calcd. for $C_{14}H_{21}O_5N_2Cl$: C 50.52, H 6.36, N 8.42, Cl 10.65; found: C 50.35, H 6.20, N 8.38, Cl 10.58.

*2-Aminomethyl-3-(2-ethoxycarbonylethyl)-4-ethoxycarbonylmethylpyrrole Hydrochloride (Ethyl Ester of Isoporphobilinogen Hydrochloride) (**5**f)*

The oxime ester **4***f* was reduced in ethanol over 5% Pd-on-carbon. The colourless product crystallized when the residue left after the removal of the catalyst and solvent was seeded. It was recrystallized from ethanol–ether as prisms (65%), mp 95.5–98.5°C (lit. (2) mp 99–100°C). Its X-ray powder photograph was identical with that of material prepared by esterifying isoporphobilinogen (2). *Anal.* calcd. for $C_{14}H_{23}O_4N_2Cl$: C 52.74, H 7.27, N 8.79, Cl 11.12; found: C 52.61, H 7.40, N 8.69, Cl 11.28.

*Lactam of 2-Aminomethyl-3-carboxymethyl-4-(2-methoxycarbonylethyl)pyrrole (Methyl Ester of Porphobilinogen Lactam) (**6**b)*

The oxime ester hydrochloride (**4***b* (2), 1.65 g) in 50 ml of methanol was hydrogenated over 500 mg of 5% Pd-on-carbon. The filtrate and washings were treated with 2.5 ml of sodium in methanol (0.5 g in 10 ml) at 20°C, apparent pH 9.6. After 1 h at 20°C (reaction complete) and 1 h at 0°C the pH was brought to 4.5 with 0.1 ml of acetic acid. The crystalline product (some obtained by filtration, the rest by evaporating the mother liquor) was washed with water and with chloroform. It was recrystallized from 75 ml of methanol (thimble,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

a second thimble below this contained Darco) as colourless crystals (79%); small amounts sublime quantitatively at ca. 190°C (5×10^{-5} Torr). *Anal.* calcd. for $C_{11}H_{14}O_3N_2$: C 59.45, H 6.35, N 12.60, OMe 13.96; found: C 59.34, H 6.23, N 12.69, OMe 13.83.

Behaviour on heating. At about 200°C, the prisms (from methanol) change to plates (stage) which melt with decomposition at 245–265°C (stage or capillary), depending on the rate of heating (lit. (13) mp 240–242°C, (14) mp 248–251°C). The plates obtained from water melt as above without the initial phase change. In capillaries sealed off at 5×10^{-5} Torr, the prisms melt at 277–278°C, mp of yellow resolidified melt 275°C; the phase change would not have been observable in the capillary.

*Lactam of 2-Aminomethyl-3-carboxymethyl-4-(2-ethoxycarbonylethyl) pyrrole (Ethyl Ester of Porphobilinogen Lactam) (**6**c)*

The melting point (stage or capillary) is uncertain (lit. (2) mp 239–244°C). In an evacuated capillary sealed off at 5×10^{-5} Torr, the melting point is 261°C.

Lactam of 2-Aminomethyl-3-(2-carboxyethyl)-4-methoxycarbonylmethylpyrrole (Methyl Ester of Isoporphobilinogen Lactam) (7e)

The oxime methyl ester hydrochloride **4***e* (1.833 g) in 40 ml of methanol was hydrogenated for 12 h over 700 mg of 5% Pd-on-carbon. Sodium (0.1 g) in methanol was added to the filtrate and washing from the catalyst (pH then 9.8–10 on wet indicator paper). After 3 h the reaction was complete (tlc), 0.4 ml of acetic acid was added (pH then 4.5), and the solvent was removed (rotary, 20°C bath, then oil pump). The powdered residue was extracted into 60 ml of ether (thimble, 3 days) from which the product separated as cream coloured microcrystals (77%), tlc: one spot, mp 158–167°C (lit. (3) mp 135–138°C, (4) mp 156–157.5°C); apparently one form, mp ca. 158°C, was more or less completely converted into a second form, mp ca. 170°C. After distillation in small amounts (180°C, 5×10^{-5} Torr) it formed colourless needles, mp 168–170°C. ^{1}Hmr (pyridine-d_5, Varian EM60) δ: 2.95 (4H, s, CH_2CH_2CO), 3.57 (2H, s, CH_2CO), 3.65 (3H, s, OCH_3), 4.42 (2H, d, J = 5 Hz, CH_2N), 6.83 (1H, s, pyrrole CH), 8.36 (1H, t, J = 5 Hz, NH.CO), 11.23 ppm (1H, br, pyrrole NH). *Anal.* calcd. for $C_{11}H_{14}O_3N_2$: C 59.45, H 6.35, N 12.60; found: C 59.23, H 6.47, N 12.44.

Lactam of 2-Aminomethyl-3-(2-carboxyethyl)-4-ethoxycarbonylmethylpyrrole (Ethyl Ester of Isoporphobilinogen Lactam) (7f)

The oxime ethyl ester hydrochloride **4***f* (1.013 g) in 50 ml of dry ethanol was hydrogenated for 12 h over 300 mg of 5% Pd-on-carbon. Sodium (0.1 g) in ethanol was added to the filtrate and washings from the catalyst (pH 9.8–10). After $3\frac{1}{2}$ h the reaction was complete and Dry Ice was added. The solvent was evaporated (rotary, 20°C bath, then oil pump), adding Dry Ice periodically to keep the pH at 7–8. The residue was extracted with warm ethyl acetate, the insoluble matter was dissolved in water, and this solution extracted with more ethyl acetate. The combined extracts were washed with 10 ml of water, dried ($MgSO_4$) and evaporated. The residue was washed with ether leaving the colourless product (42%), mp 162–164°C, tlc: one spot. Small amounts distilled quantitatively (175°C, 1×10^{-4} Torr) as colourless needles, melting point unchanged; ^{1}Hmr (pyridine-d_5) δ: 1.15 (3H, t, CH_2CH_3), 3.02 (4H, s, CH_2CH_2CO), 3.62 (2H, s, CH_2CO), 4.18 (2H, q, CH_2CH_3), 4.48 (2H, d, J = 5 Hz, CH_2N), 6.92 (1H, s, pyrrole CH), 8.61 (1H, t, J = 5 Hz, NH.CO), 11.32 ppm (1H, br, pyrrole NH). *Anal.* calcd. for $C_{12}H_{16}O_3N_2$: C 61.00, H 6.83, N 11.86; found: C 60.98, H 6.71, N 12.02.

*Benzyl 3-Ethoxycarbonylmethyl-4-(2-ethoxycarbonylethyl)-pyrrole-5-carboxylate (**10**a, R = H)*

This preparation followed that of the 2-methyl homologue (15). The triethyl ester **9***a* (R = H) (8.08 g) (16) with 1.72 g of sodium in 220 ml of pure benzyl alcohol gave the 5-benzyl ester of the tricarboxylic acid. This was esterified in ethanolic HCl to the product, colourless needles (2.83 g) from pentane (thimble), mp 63–64°. *Anal.* calcd. for $C_{21}H_{25}O_6N$: C 65.10, H 6.50, N 3.62; found: C 65.02, H 6.29, N 3.49.

*Benzyl 3-(2-Ethoxycarbonylethyl)-4-ethoxycarbonylmethyl-pyrrole-5-carboxylate (**10**b, R = H)*

This was obtained from **9***b* (R = H) (16) like the isomer above. The crude noncrystalline product was distilled (178°C, 5×10^{-4} Torr), crystallized from ether–pentane, then recrystallized by extraction into pentane (thimble), mp 55.5–57.5°C. *Anal.* calcd. for $C_{21}H_{25}O_6N$: C 65.10, H 6.50, N 3.62; found: C 65.20, H 6.56, N 3.52.

*Ethyl 2-Chloroacetylaminomethyl-3-ethoxycarbonylmethyl-4-(2-ethoxycarbonylethyl)pyrrole-5-carboxylate (**9**a, R = $ClCH_2CONHCH_2$—)*

The pyrrole **9***a* (R = H) (333 mg) was heated to boiling in 2 ml of ethanolic HCl (dry ethanol, saturated warm with HCl). *N*-Hydroxymethylchloroacetamide (333 mg) was added and the solution was boiled for 1 min, seeded, and allowed to cool. The product was separated, washed with cold 80% ethanol, and recrystallized from 80% ethanol (7 ml, cooling very slowly). It formed colourless needles (69%), mp 139–141.5°. *Anal.* calcd. for $C_{19}H_{27}O_7N_2Cl$: C 52.96, H 6.32, N 6.50, Cl 8.23; found: C 53.20, H 6.40, N 6.59, Cl 8.41.

*Ethyl 2-Chloroacetylaminomethyl-3-(2-ethoxycarbonylethyl)-4-ethoxycarbonylmethylpyrrole-5-carboxylate (**9**b, R = $ClCH_2CONHCH_2$—)*

Using **9***b* (R = H), this was obtained like the isomer above as colourless needles (73%), mp 151.5–152°C. *Anal.* calcd. for $C_{19}H_{27}O_7N_2Cl$: C 52.96, H 6.32, N 6.50, Cl 8.23; found: C 53.11, H 6.40, N 6.42, Cl 8.39.

*Benzyl 2-Chloroacetylaminomethyl-3-ethoxycarbonylmethyl-4-(2-ethoxycarbonylethyl)pyrrole-5-carboxylate (**10**a, R = $ClCH_2CONHCH_2$—)*

The pyrrole **10***a* (R = H) (333 mg) was warmed to solution in 2 ml of ethanolic HCl (dry ethanol saturated with HCl at 0°C). N-Hydroxymethylchloroacetamide (333 mg) was added and warmed to solution. The solution was boiled 1 min, cooled in ice, and seeded. The crystals were separated and recrystallized from ethanol as colourless needles (78%), mp 138.5–140.5°C. For analysis, it was recrystallized from ether (thimble), then from ethanol, mp 141.5–142.5°C; ^{1}Hmr ($CDCl_3$) δ: 1.22, 1.26 (6H, 2t, CH_2CH_3), 2.40–3.22 (4H, m, CH_2CH_2CO), 3.52 (2H, s, CH_2CO), 4.03 (2H, s, CH_2Cl), 4.10, 4.12 (4H, 2q, CH_2CH_3), 4.45 (2H, d, J = 6 Hz, CH_2N), 5.32 (2H, s, $CH_2C_6H_5$), 7.42 (5H, m, C_6H_5), 7.57 (1H, t, J = 6 Hz, NHCO), 9.95 ppm (1H, br, pyrrole NH). *Anal.* calcd. for $C_{24}H_{29}O_7N_2Cl$: C 58.47, H 5.93, N 5.68, Cl 7.19; found: C 58.21, H 5.94, N 5.59, Cl 7.31.

*Benzyl 2-Chloroacetylaminomethyl-3-(2-ethoxycarbonylethyl)-4-ethoxycarbonylmethylpyrrole-5-carboxylate (**10**b, R = $Cl \cdot CH_2CONHCH_2$—)*

This was prepared from **10***b* (R = H) exactly as its isomer above. After washing with 80% ethanol (4 × 1 ml), it formed colourless needles (82%), mp 141–143°C. For analysis, it was recrystallized from ether (thimble), melting point unchanged; ^{1}Hmr ($CDCl_3$) δ: 1.22 (6H, t, CH_2CH_3), 2.38–2.92 (4H, m CH_2CH_2CO), 3.82 (2H, s, CH_2CO), 4.07 (2H, s, CH_2Cl) 4.10 (4H, q, CH_2CH_3), 4.46 (2H, d, J = 6 Hz, CH_2N), 5.3(

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(2H, s, $CH_2C_6H_5$), 7.42 (5H, m, C_6H_5), 7.57 (1H, t, J = 6 Hz, NHCO), 9.68 ppm (1H, br, pyrrole NH). *Anal.* calcd. for $C_{24}H_{29}O_7N_2Cl$: C 58.47, H 5.93, N 5.68, Cl 7.19; found: C 58.29, H 5.94, N 5.61, Cl 7.31.

2-Acetylaminomethyl-3-(2-ethoxycarbonylethyl)-4-ethoxycarbonylmethylpyrrole-5-carboxylic Acid

The benzyl ester (**10***b*, R=$ClCH_2CONHCH_2$—; 295 mg) was hydrogenated for 24 h in 22 ml of dioxane with 100 mg of sodium acetate trihydrate and 55 mg of 5% Pd-on-carbon. The filtrate (Celite) and washings were evaporated (rotary, 20°C) and the residue was washed with water to leave the product (98%) as colourless needles, mp 141–144°C (dec.); longer needles (mp 145–146°C) formed in the melt. The analytical specimen was rapidly crystallized from hot water. *Anal.* calcd. for $C_{17}H_{24}O_7N_2$: C 55.43, H 6.56, N 7.61; found: C 55.25, H 6.55, N 7.49.

Ethyl 2,4-Dimethyl-3-chloroacetylaminomethylpyrrole-5-carboxylate

2,4-Dimethyl 5-carbethoxypyrrole (1 g) was heated to solution in 6 ml of 10% ethanolic HCl. N-Hydroxymethylchloroacetamide (1 g) was added and the solution was heated 5 min on the steam bath. The product (35%) was separated and washed with 50% ethanol, mp 215–217°C. Recrystallization from 50 ml of 60% ethanol gave colourless needles, mp 217–218°C. *Anal.* calcd. for $C_{12}H_{17}O_3N_2Cl$: C 52.84, H 6.28, N 10.27, Cl 13.01; found: C 52.67, H 6.31, N 10.19, Cl 12.92.

Ethyl 2-Chloroacetylaminomethyl-5-methylpyrrole-4-carboxylate

2-Methyl-3-carbethoxypyrrole (1 g) and *N*-hydroxymethylchloroacetamide (0.8 g, 1 mol) were rubbed to solution in 10 ml of ethanol and 2.2 ml of ethanolic HCl. After 1 day at 20°C, the solution was seeded and the product (31%) was separated 2 days later, mp 199.5–201.5°C. For analysis, it was recrystallized from much water as colourless needles, melting point unchanged. *Anal.* calcd. for $C_{11}H_{15}O_3N_2Cl$: C 51.07, H 5.84, N 10.83, Cl 13.71; found: C 50.96, H 5.83, N 10.79, Cl 13.66.

When the pyrrole was boiled 1 min with 2 mol of the reagent in ethanolic HCl (saturated at 20°C), the product was evidently a dipyrrylmethane, colourless prismatic needles (8%) from acetone, mp 255–257.5°C. *Anal.* calcd. for $C_{23}H_{30}O_6N_4Cl_2$: C 52.17, H 5.71, N 10.58, Cl 13.41; found: C 52.08, H 5.65, N 10.56, Cl 13.35. *Mol. wt.* calcd.: 529.5; found: (osmometer): 534.

*2,4-Dimethylpyrrole-5-*N*-acetylthiocarbamide (**11**)*

A solution of potassium thiocyanate (12.7 g) in 75 ml of dimethylformamide was stirred in an ice bath while acetyl chloride (8.7 g) was dropped in at 20°C. The solution was then diluted to 100 ml with dimethylformamide and allowed to stand ½ h at 0°C. 2,4-Dimethylpyrrole (5 g) was dropped into 75 ml of this solution at 10°C. After ½ h at 0°C, the solution was diluted with 700 ml of ice water, seeded, and left 2 days at 10°C. The product which separated, orange needles (69%), mp 141–142.5°C, showed traces of impurities (tlc). The pure product was obtained as light-brown needles, mp 145–146°C, from water (650 ml, Celite); it sublimes at ca. 130°C (1×10^{-4} Torr) as bright orange prisms. *Anal.* calcd. for $C_9H_{12}ON_2S$: C 55.09, H 6.17, N 14.28, S 16.31; found: C 54.87, H 6.14, N 14.12, S 16.10.

*2,4-Dimethyl-5-acetylaminomethylpyrrole (**12**)*

Raney nickel (W. R. Grace and Co., No. 28, 20 ml) was washed six times with commercial absolute ethanol (centrifuge), suspended in 50 ml of ethanol, and added to a solution of 1 g of **11** in 50 ml of ethanol. The mixture was shaken for 1 h, allowed to stand overnight, then shaken 2 h. A drop of ammonium hydroxide was added to the filtrate (to stabilize the product) which was then evaporated (rotary, 20°C). The residue was distilled into a tube containing seed crystals (125°C, 5×10^{-4} Torr). While standing overnight under vacuum, the product solidified to yellow crystals (52%), mp 65.5–66.5°C; ^{1}Hmr ($CDCl_3$) δ: 1.97, 2.02 (6H, 2s, 2 ring CH_3), 2.20 (3H, s, $COCH_3$), 4.23 (2H, d, J = 6 Hz, CH_2N), 5.65 (1H, m, pyrrole CH), 6.27 (1H, br, NHCO), 8.58 (1H, br, pyrrole NH). *Anal.* calcd. for $C_9H_{14}ON_2$: C 65.03, H 8.49, N 16.85; found: C 64.90, H 8.42, N 17.01.

Concerning the extension of the *J* method for internal barriers to six-bond couplings to ^{19}F in the 4-fluorophenyl fragment

TED SCHAEFER, WERNER DANCHURA,
WALTER NIEMCZURA, AND JAMES PEELING

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 10, 1978

TED SCHAEFER, WERNER DANCHURA, WALTER NIEMCZURA, and JAMES PEELING. Can. J. Chem. **56**, 2442 (1978).

The long-range coupling constants over six bonds from the side-chain protons to the fluorine nucleus on the ring are extracted from the proton magnetic resonance spectra of *p*-fluorobenzyl cyanide, chloride, and bromide; of *p*-fluorobenzal chloride; and of *p*-fluoroisopropylbenzene. On the assumption that these couplings are transmitted via a σ–π mechanism, a hindered rotor treatment yields the barriers to internal rotation about the carbon–carbon bond which attaches the substituent to the benzene ring. These barriers, when compared to those derived from the analogous proton–proton coupling constants, apparently are accurate enough for the determination of ground state conformations and for a rough assessment of the energetics of conformational interconversions.

TED SCHAEFER, WERNER DANCHURA, WALTER NIEMCZURA et JAMES PEELING. Can. J. Chem. **56**, 2442 (1978).

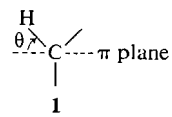
Faisant appel aux spectres de résonance magnétique nucléaire du proton des cyanure, chlorure et bromure de *p*-fluorobenzyle, du chlorure de *p*-fluorobenzal et du *p*-fluoroisopropylbenzène, on a pu évaluer les constantes de couplage à longues distances à travers six liaisons des protons de la chaîne latérale avec le noyau de fluor du cycle. Si on fait l'hypothèse que ces couplages sont transmis par un mécanisme σ–π, un traitement de rotor empêché fournit les barrières à la rotation interne autour de la liaison carbone–carbone qui attache le substituant au noyau benzénique. Il semble que ces barrières, lorsqu'on les compare à celles obtenues à partir de constantes de couplage proton–proton analogues, soient suffisamment correctes pour permettre la détermination des conformations de l'état fondamental et pour évaluer d'une façon approximative les énergies impliquées dans les interconversions conformationnelles.
[Traduit par le journal]

Introduction

The *J* method of determining small (<4 kcal/mol) twofold barriers to internal rotation about bonds to the benzene ring depends on a knowledge of the dependence on the rotational angle of the spin–spin coupling over six bonds between a ring proton and the proton(s) on the side chain, $^6J_p^{H,XH}$. Combined with a hindered rotor treatment of the internal rotation, a knowledge of the sample temperature and of the reduced moment of inertia about the rotor axis suffices to calculate the expectation value of $^6J_p^{H,XH}$ as a function of the barrier (1, 2). In this way reasonable barriers and ground state conformations have been estimated for rotation about C—C, C—Si, and C—S bonds in a variety of benzene derivatives (3–7).

The rotational angle dependence of $^6J_p^{H,CH}$ can be written (8–10) as $^6J = {}^6J_{90} \sin^2 \theta$, where $^6J_{90}$ is the magnitude of ^6J when $\theta = 90°$ in **1**. There exist data implying that ^6J_o is less than 0.03 Hz (11, 12), while $^6J_{90}$ is -1.24 Hz in toluene (13).

For rotation about C—C bonds the barriers and low energy conformations are such that the observed $^6J_p^{H,CH}$ has magnitudes lying between about 0.1 and



1

0.5 Hz. Although such couplings can be measure to an accuracy of 0.02 Hz, considerable skill an patience is required in their determination, parti ularly when the phenyl proton magnetic resonanc spectra are tightly coupled (3).

Now, it is of interest that $^6J^{H,CF}$ in *p*-fluorotoluer is 1.15 ± 0.02 Hz (14), almost twice the magnitu of $^6J_p^{H,CH}$ in toluene. Furthermore, the same calcul tions (8) which confirm experimental tests th $^6J_p^{H,CH}$ obeys a $\sin^2 \theta$ relationship (9, 10), also predi such a relationship for $^6J_p^{H,CF}$. The presence of C—F bond in the benzene ring considerably simpl fies the spectral analytical procedures and the larg magnitude of $^6J_p^{H,CF}$ makes its accurate determin tion relatively easy. On the other hand, $^6J_p^{H,}$ depends on the σ—π interactions in the C—F bor (15) and these may well be more sensitive to ele tronic perturbations by the side chain of interest th are the σ—π interactions for the C—H bond. other words, $^6J_p^{H,CH}$ is known experimentally (4) a

For personal use only.

theoretically (8) to be insensitive to intrinsic perturbations from ring substituents, whereas the C—F bond may well alter its partial double bond character in response to substituent perturbations.

In this paper the measurement of $^6J_p^{H,CF}$ and its use in the J method is reported for the *para* fluoro derivatives of toluene; benzyl bromide, chloride, and cyanide; isopropyl benzene; and for benzal chloride. Except for benzyl cyanide, the internal barriers have previously been estimated from $^6J_p^{H,CH}$, so that a comparison can be made with the present approach.

The practice of 'fluorine labelling' of macromolecules (16) invites the speculation that under favorable circumstances the present J method could be applied to the determination of the preferred conformation of the label in large molecules.

Experimental

The fluorine compounds had a commercial origin. All but the *p*-fluorobenzyl cyanide (Parish Chemical Co) came from Aldrich Chemical Co. Any small amounts of impurities did not interfere with the analysis of the ^{1}H nmr spectra. Nuclear magnetic resonance samples were prepared as 10 mol% solutions in CS_2, containing a small amount of tetramethylsilane, and were thoroughly degassed by the freeze–pump–thaw–freeze technique. The ^{1}H nmr spectra were repeatedly calibrated at 5 Hz intervals in the frequency sweep mode of an HA100 spectrometer. The probe temperature was 305 K. The spectral dispersion was 1 Hz/cm and the sweep rates were 0.02 and 0.01 Hz/s. The sign of the long-range coupling over six bonds to ^{19}F, $^6J_p^{H,CF}$, was determined by low-amplitude double irradiation methods (17) and was the same as $^3J^{H,F}$, i.e., positive (18).

Preparation of the 3,5-dichlorobenzyl cyanide proceeded via the benzyl bromide by treatment with KCN in acetone solution. The bromide was prepared from the commercial benzoic acid by reduction to the alcohol, followed by conversion with PBr_3. The cyanide was insufficiently soluble in CS_2 but a mixture of C_6D_6, $CDCl_3$, and CS_2 dissolved enough compound, less than 5 mol%, to allow the recording of good ^{1}H nmr spectra. The compound gave a satisfactory mass spectrum.

The frequencies of the sweep and manual oscillators were recorded with an HP 5323A counter. Peak positions were then interpolated using a vernier and a straight edge. Root-mean-square deviations of peak positions relative to internal tetramethylsilane lay typically in the vicinity of 0.02 Hz. The spectrometer frequency was 100.001_2 MHz.

Results and Discussion

(i) Spectral Analyses

These were undertaken with the computer program LAME (19, 20). A typical analysis gave the results in Table 1, those for 4-fluorobenzyl chloride. The standard deviations in the spectral parameters are 0.004 Hz or less, suggesting an accuracy of at least 0.02 Hz. Figure 1 displays a calculated and an observed spectrum of the side-chain protons in 4-fluorobenzyl bromide. Table 2 contains the spectral parameters of immediate interest, the couplings to the side-chain protons, for the other compounds.

FIG. 1. The calculated (*b*) and observed (*a*) spectra of the side-chain protons of *p*-fluorobenzyl bromide as a 10 mol% solution in CS_2 at 100 MHz and 305 K. The long-range couplings for the calculated spectrum are those in Table 2.

(ii) The Value of $^6J_{90}^{H,CF}$

The barrier to internal rotation in *p*-fluorotoluene is 0.0138 kcal/mol (21). Accordingly, the average value of $\sin^2\theta$ is $\langle\sin^2\theta\rangle = 0.5$. In acetone solution $^6J_p^{H,CF}$ is 1.15 ± 0.02 Hz and is 1.12 Hz in CS_2 solution (Table 2). Although it alters the argument very little, the value of 1.12 Hz will be used because the other compounds were measured in CS_2 solution and because the high dielectric constant of acetone could result in a slightly larger double bond character of the C—F bond (charge separation), leading to a larger $^6J_p^{H,CF}$. It follows that $^6J_{90}^{H,F}$ is 1.12/0.5 or

[a]10 mol% solutions in CS_2.
[b]A 15 mol% solution in acetone-d_6 yielded $^4J_o^{H,CH}$, $^5J_m^{H,CH}$, and $^6J_p^{H,CF}$ as −0.72, 0.34, and 1.15 Hz, respectively (14).
[c]An independent analysis by W. J. E. Parr gave 0.63 Hz.
[d]$^6J_p^{H,CH}$ for a saturated solution in a mixture of C_6D_6, $CDCl_3$, and CS_2.

2.24 ± 0.02 Hz (the standard deviation for $^6J_p^{H,CF}$ was 0.004 Hz).

(iii) Substituent Perturbation of $^6J_p^{H,CF}$

It was argued previously (4) that, in the corresponding toluene derivatives with a hydrogen atom at position 4, $^6J_{90}^{H,CH}$ is reduced in magnitude in the presence of a strongly electronegative substituent in the α position. Thus, for CH_2Cl it was suggested that $^6J_{90}^{H,CH}$ becomes −1.14 Hz, as compared to −1.24 Hz in toluene itself and that, for the $CHCl_2$ group, $^6J_{90}^{H,CH}$ is −1.05 Hz (22). For CH_2Br, $^6J_{90}^{H,CH}$ would be very similar to its value for CH_2Cl and, because bromine is somewhat less electronegative than chlorine, a value of −1.16 Hz appears reasonable. (The barrier for CH_2Br is so large, see below, that a choice of $^6J_p^{H,CH}$ for this group is somewhat academic anyway.) A decrease in $^6J_{90}^{H,CH}$ is supported by INDO MO FPT calculations (1) suggesting polarization of the adjacent C—H bonds by the polar substituent in the side chain. This polarization leads to a decreased overlap between the C—H bond orbitals and the π electron system of the ring (a smaller σ–π interaction).

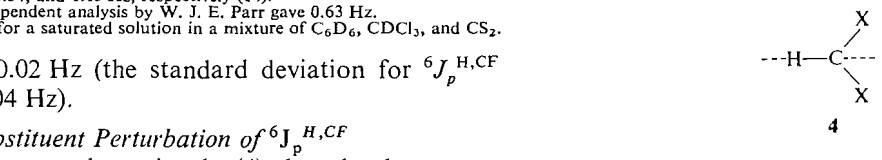
In the absence of a substituent perturbation of $^6J_p^{H,CF}$, $\langle\sin^2\theta\rangle$ is simply equal to $^6J_{obs}^{H,CF}/2.24$. In presence of a substituent perturbation of the σ–π interaction of a side-chain C—H bond, $\langle\sin^2\theta\rangle$ is obtained from $^6J_{obs}^{H,CF}/(2.24 \times {}^6J_{90}^{H,CH}/1.24)$. The ensuing values of $\langle\sin^2\theta\rangle$ are given in Table 3.

(iv) Derivation of Internal Barriers

Plots of $\langle\sin^2\theta\rangle$ vs. V_2 were constructed for a range of reduced moments of inertia at a temperature of 305 K. If the ground state conformation is **2**, the plot yields a simple curve with a $\langle\sin^2\theta\rangle$ value of 0.5 at a zero barrier; V_2 is the difference in energy between conformations **2** and **3**. At high V_2 values it slowly approaches 0.25 with the consequence that a derived barrier becomes more and more uncertain as it increases above 2.2 kcal/mol.

If the ground state conformation is **3**, $\langle\sin^2\theta\rangle$ falls between 0.75 and 0.5. This conformation need not be considered because the experimental $\langle\sin^2\theta\rangle$ for the benzyl compounds lies between 0.5 and 0.25

For the benzal compounds the ground state conformation is taken as **4**, so that $\langle\sin^2\theta\rangle$ varies between 0.5, for a vanishing barrier, and zero for a very large barrier. For this class of compounds reasonably accurate V_2 numbers are obtainable up to 3 kcal/mol because $\langle\sin^2\theta\rangle$ has twice the range it has for the benzyl compounds.



4

The various compounds are now discussed in turn

Benzyl Cyanide Derivatives

In 3,5-dichlorobenzyl cyanide, $^6J_p^{H,CH}$ is −0.60 ± 0.01 Hz. The chlorine substituents do not perturb $^6J_p^{H,CH}$ (4). If $^6J_{90}^{H,CH}$ is −1.24 Hz as in toluene, i.e. if the cyano group does not change the magnitude of the σ–π interaction, then $\langle\sin^2\theta\rangle$ is 0.60/1.24 or 0.48 ± 0.02, where the error allows for measurement errors. From the plots of $\langle\sin^2\theta\rangle$ vs. V_2 a value of 0.2 ± 0.2 kcal/mol is then found on the assumption that **2** is the ground state conformation. However, in 2,6-dichlorobenzyl cyanide, $^6J_p^{H,CH}$ is −0.33 ± 0.0 Hz (23). The barrier is now large, very likely greater than 3 kcal/mol (23), so that $\langle\sin^2\theta\rangle$ is very close to 0.25 ($\sin^2 30°$) because **2** is the predominant conformation. It follows that $^6J_{90}^{H,CH}$ may be 4 × −0.33, or −1.32 Hz, the larger magnitude compared to toluene possibly arising from enhanced hyperconjugation in the presence of the C≡N group. If $^6J_{90}^{H,CH}$ is indeed −1.32 Hz, $\langle\sin^2\theta\rangle$ becomes 0.45_5, corresponding to a barrier of 0.3_5 + 0.2 kcal/mol. The quoted errors assume an error of 0.02 in $\langle\sin^2\theta\rangle$. It seems safe to conclude that the $^6J_p^{H,C}$ method yields a barrier of 0.2_5 ± 0.2 kcal/mol entered in Table 3.

Again, $^6J_p^{H,CF}$ in *p*-fluorobenzyl cyanide is 1.06 Hz and one has $\langle\sin^2\theta\rangle$ as 1.06/2.24, or 0.47, yielding a barrier of 0.3 ± 0.2 kcal/mol. If $^6J_{90}^{H,CH}$ is −1.3 Hz, then the equation in section *iii* implies a $\langle\sin^2\theta$ of 0.44 and a barrier of 0.6 kcal/mol. The mean value of 0.45 ± 0.2 kcal/mol is entered in Table 3.

Apparently, the two approaches yield equa

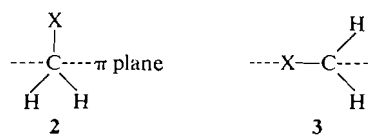


TABLE 3. Comparison of twofold barriers obtained from $^6J_p^{H,CF}$ and $^6J_p^{H,CH}$

Fragment	$\langle \sin^2 \theta \rangle$		V_2 (kcal/mol)		Ref.
	$^6J_p^{H,CF}$	$^6J_p^{H,CH}$	$^6J_p^{H,CF}$	$^6J_p^{H,CH}$	
CH_2CN	0.44(0.47)	0.46(0.48)	0.45±0.2	0.25±0.2	—
CH_2Cl	0.32	0.35	2.7±0.4	2.1±0.4	4
CH_2Br	0.26	0.28	>3	>3	4
$CH(CH_3)_2$	0.25	0.20	1.5±0.2	2.0±0.2	6
$CHCl_2$	0.12	0.20	3.1±0.5	2.2±0.3	22

barrier values to within experimental error. A mean value of 0.35 ± 0.3 kcal/mol may well encompass differences in the solvents and substitution patterns for the two compounds.

The Kerr constant for benzyl cyanide suggests either that the C—CN bond is twisted out of the benzene plane by 44° or that the CH_2CN group rotates freely (24). Our results are consistent with the latter alternative.

Benzyl Chloride and Benzyl Bromide Derivatives

The barriers given in Table 3 assume that $^6J_{90}^{H,CH}$ is −1.14 Hz for CH_2Cl and −1.16 Hz for CH_2Br. For the latter, the J method is very insensitive.

Isopropyl Benzene and Benzal Chloride Derivatives

The barriers in Table 3 are derived on the assumption that $^6J_{90}^{H,CH}$ is −1.24 Hz for $CH(CH_3)_2$ and −1.05 Hz for $CHCl_2$.

(v) Ab initio *Molecular Orbital Calculations*

Previous calculations (4) at the STO 3G level (25, 26) yielded **2** as 2.22 kcal/mol more stable than **3** for benzyl chloride, in good agreement with the present results. Such computations are here extended to benzyl cyanide. A standard geometry (27) gave **2** as 1.98 kcal/mol more stable than **3**. A partial geometry optimization procedure increased the C—C—CN angle to 112.1° for **2** and to 114.4° for **3**, yielding **2** as 0.98 kcal/mol more stable than **3**. These somewhat expensive calculations suggest that a more complete optimization of bond angles and bond lengths could well lead to a barrier in even better agreement with the data in Table 3, viz., about 0.3 kcal/mol.

(vi) Comparison of the Two Sets of Barriers

The barrier values based on $^6J_p^{H,CH}$ are probably more reliable than those based on $^6J_p^{H,CF}$ for the following reasons. First, the tests discussed in the introduction strongly imply that $^6J_p^{H,CH}$ is indeed transmitted via a σ—π mechanism involving a $\sin^2 \theta$ dependence of $^6J_p^{H,CH}$ and that this coupling is negligibly small when $\theta = 0$. For $^6J_p^{H,CF}$, however, one cannot be certain that there exists no contribution in addition to the σ—π mechanism. In fact, in benzal fluoride derivatives, in which the fluorine atom is situated in the side chain, the non σ—π component of $^6J_p^{H,CF}$ is as large as 20% of the σ—π component (22). Second, the σ—π component of $^6J_p^{H,CF}$ in the compounds considered in this paper may be more sensitive to substituent perturbations than is $^6J_p^{H,CH}$ because it depends on the hyperfine interactions in the C—F bond, which apparently vary much more from system to system than the hyperfine interactions in a C—H bond (15, 28). In simpler terms, $^6J_p^{F,CH}$ varies by at least 0.1 Hz from compound to compound (14, 15), whereas any variation in $^6J_p^{H,CH}$ is apparently not detectable (4, 29). It is also conceivable that insertion of a *para* fluoro substituent will cause a change in the magnitude of the barrier, for example, by altering the energy of either the low or high energy conformations. If this alteration occurs, the data in Table 3 suggest that the alterations are such as to increase the barrier when the side chain contains polar substituents and to decrease the barrier when the side chain is relatively nonpolar. A combination of all these factors could well account for the differences in the barriers derived by the two methods.

Nevertheless, the differences are not so great as to eliminate the use of $^6J_p^{H,CF}$ in the determination of ground state conformations or in reaching a rough assessment of the energetics of the internal rearrangements in benzyl or benzal compounds.

Reaction of carbon monoxide with nitrous oxide on scandium and magnesium oxides

BORDAN W. KRUPAY[1] AND ROBERT A. ROSS

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received February 15, 1978

BORDAN W. KRUPAY and ROBERT A. ROSS. Can. J. Chem. **56**, 2447 (1978).

The kinetics of the catalytic reaction between carbon monoxide and nitrous oxide has been examined on Sc_2O_3 and MgO in a differential flow reactor at atmospheric pressure. On Sc_2O_3, the apparent activation energy was 126 ± 4 kJ mol^{-1} from 633 to 723 K while a value of 63 ± 4 kJ mol^{-1} was obtained for MgO from 547 to 673 K. On both catalysts, the surface mechanism has been interpreted by a reaction scheme involving each reactant as an adsorbed species with CO and N_2O being further involved in subsequent steps during the course of the surface reaction. The metal/oxygen bond polarization appears to influence both the strength and form of CO adsorption where the reactants interact as surface species each bound to two surface sites on Sc_2O_3 and on one surface site each on MgO.

BORDAN W. KRUPAY et ROBERT A. ROSS. Can. J. Chem. **56**, 2447 (1978).

On a étudié la cinétique de la réaction catalytique entre le monoxyde de carbone et l'oxyde nitreux sur du Sc_2O_3 et du MgO dans un réacteur à flux différentiel, à pression atmosphérique. Sur le Sc_2O_3, l'énergie d'activation apparente est de 126 ± 4 kJ mol^{-1} entre 633 et 723 K alors que l'on a obtenu une valeur de 63 ± 4 kJ mol^{-1} sur du MgO entre 547 et 673 K. Sur les deux catalyseurs, on a interprété le mécanisme de surface par un schéma réactionnel impliquant que chaque réactif est une espèce adsorbée; le CO et le N_2O sont impliqués dans des étapes ultérieures au cours de la réaction de surface. La polarisation de liaison métal/oxygène semble influencer à la fois la force et la forme de l'adsorption du CO au niveau des interactions des réactifs sous forme d'espèces de surface qui sont toutes liées à deux sites de surface du Sc_2O_3 et à un site de surface chacun sur le MgO.

[Traduit par le journal]

Introduction

The kinetics of the catalysed reaction between carbon monoxide and nitrous oxide to yield carbon dioxide and nitrogen has been studied recently on several transition metal oxides (1–4). The course of catalysis on active surfaces, for example cobalt and manganese oxides (4), may be summarised as involving: (*i*) the reaction of carbon monoxide with surface oxygen via a cyclic transition state, (*ii*) the destabilization of an intermediate surface carbonate, and (*iii*) the desorption of carbon dioxide which may occupy two surface sites. Such steps appear to be involved in an apparently complex way in shaping the overall catalytic process.

These features have now been examined in a kinetic study with scandium and magnesium oxides which are not normally associated with high activity in redox-type catalytic reactions (5).

Experimental

The catalytic reaction between carbon monoxide and nitrous oxide was examined in a differential-reactor flow system (6, 7) at atmospheric pressure. High-purity helium was used as the carrier gas in the flow system and Beckman GC-5 gas chromatograph. Nitrogen, carbon monoxide, carbon dioxide, and nitrous oxide were analyzed by a thermal conductivity bridge using stainless steel columns, 183 × 0.32 cm od, packed with 61 cm Carbosieve B and the remainder with Poropak Q at a column temperature of 353 K which was sufficient to resolve all components.

The standard reacting gas mixture consisted of carbon monoxide and nitrous oxide each at a partial pressure of 5.33 kN m^{-2} (40 Torr). 'Blank' runs confirmed that reaction on the quartz wool and reactor walls reached 1% at 853 K which was 130 K above the highest temperature of catalysis. Preliminary experiments with the oxide catalysts established that diffusion phenomena (8, 9) did not influence the rate measurements at a total gas flow rate of 350 ml min^{-1} (N.T.P.).

On scandium oxide (99.90% w/w, Alfa Inorganics Inc.) the CO/N_2O reaction was examined from 633 to 723 K. The conversion level at the highest temperature was 3.7%. The oxide, Sc_2O_3, previously calcined at 873 K for 10 h and stored in a desiccator over P_2O_5, was equilibrated in the standard reacting gas mixture for 5 h at 733 K. Catalysts thus prepared had surface areas of 14 m^2 g^{-1} (krypton; B.E.T.) and a bulk volume of 1.48 cm^3 g^{-1}.

Semi-conductor grade MgO (Research Organic/Inorganic Chem. Corp., batch No. MG13) was heated in the reactor at 873 K for 2 h in air prior to catalysis, cooled to 673 K, and the standard gas mixture introduced. Steady catalytic activity levels were attained after 4.5 h. From 547 to 673 K, the conversion levels ranged from 2.65 to 27.5%. The surface area was 16.6 m^2 g^{-1} and the bulk volume 2.89 cm^3 g^{-1}.

For both Sc_2O_3 and MgO, comparison of the X-ray powder diffraction photographs, taken before and after catalysis, did not reveal any changes as a result of the catalytic reaction.

Carbon monoxide (C.P.; 99.5% minimum), carbon dioxide (Coleman; 99.99%), nitrogen (super-pure; 99.99%), nitrous oxide (99.9% minimum), and helium (high purity; 99.995%) were used as supplied.

Results

Reaction Rate Orders on Scandium Oxide

The dependence of the reaction rate upon variations in the carbon monoxide partial pressure was examined from 1.33 to 16.0 kN m^{-2} (10 to 120 Torr) at 673 K with nitrous oxide maintained at 5.33 kN m^{-2} (40 Torr). A non-linear relationship was evident (Fig. 1) where the order of reaction with respect to carbon monoxide increased with partial pressure.

With the carbon monoxide partial pressure fixed at 5.33 kN m^{-2}, the rate was determined in the nitrous oxide partial pressure range from 1.33 to 16.0 kN m^{-2} at 673 K. The data (Fig. 1) were non-linear with a decreasing reaction rate order as the nitrous oxide partial pressure increased.

The partial pressures of carbon monoxide and nitrous oxide were each fixed at 5.33 kN m^{-2} and the carbon dioxide partial pressure was varied from 0.53 to 5.79 kN m^{-2}. Figure 1 indicates that the rate order decreased with increasing carbon dioxide partial pressure. Similarly, the rate order with respect to nitrogen at partial pressures of 2.67, 5.33, and 10.70 kN m^{-2} was zero.

On the basis of these experiments the catalytic reaction rate, r (mol m^{-2} s^{-1}), was expressed as:

$$[1] \qquad r = k\frac{P_{CO}^{0.4}P_{N_2O}^{0.4}}{P_{CO_2}^{0.1}}$$

Reaction Rate Orders on Magnesium Oxide

The reaction rate order with respect to carbon monoxide was determined at 559 K from 4.00 to 13.3 kN m^{-2} with nitrous oxide maintained at 5.33 kN m^{-2}. The results (Fig. 2) show a non-linear relationship and a rate order of 0.6 was calculated at a carbon monoxide partial pressure of 5.33 kN m^{-2}.

With carbon monoxide fixed at 5.33 kN m^{-2}, the partial pressure of nitrous oxide was varied from 4.0 to 13.3 kN m^{-2} at 559 K. The results (Fig. 2) exhibited a similar pattern to those above and a rate order of 0.3 was determined for subsequent rate constant calculations.

Using the same reacting gas mixture as that for scandium oxide, the rate order dependence on carbon dioxide partial pressure was examined in the range 0.33 to 5.79 kN m^{-2} and the results are shown in Fig. 2. As described previously, the reaction rate order determined with respect to carbon dioxide was -0.1. Similarly, variations in the nitrogen partial pressure from 2.67 to 10.7 kN m^{-2} showed a zero order effect on the reaction rate.

The catalytic reaction rate, r (mol m^{-2} s^{-1}), was expressed as:

$$[2] \qquad r = k\frac{P_{CO}^{0.6}P_{N_2O}^{0.3}}{P_{CO_2}^{0.1}}$$

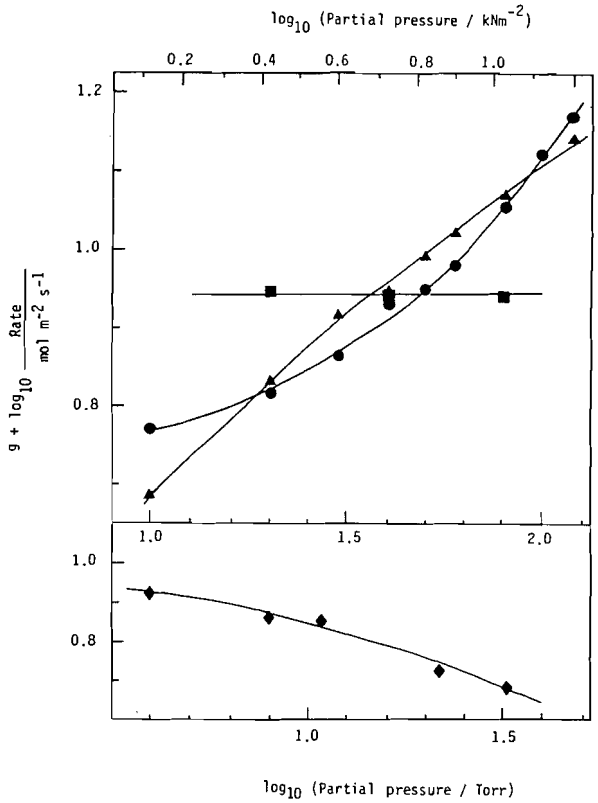

FIG. 1. Reaction rate order measurements for the CO/N_2O reaction on scandium oxide at 673 K for carbon monoxide (●), nitrous oxide (▲), nitrogen (■), and carbon dioxide (◆).

The Effect of Temperature

On scandium oxide, the reaction rate was examined from 633 to 723 K in 10 K intervals after catalyst equilibration for 5 h in the standard reaction mixture at 723 K. Rate constants were calculated by integration of eq. [1] and the Arrhenius plot for these data is shown in Fig. 3. The apparent activation energy was 126 ± 4 kJ mol^{-1}.

Magnesium oxide was equilibrated in the standard gas mixture at 673 K for 4.5 h and the rate of reaction examined from 673 to 547 K. The rate constants calculated from eq. [2] are shown in Fig. 3 whence an apparent activation energy of 63 ± 4 kJ mol^{-1} was obtained.

Discussion

Sc_2O_3 exhibits the largest energy band gap, 5.4 eV, of the first row transition metal oxides (10). The value for magnesium oxide, an insulator, is 8.7 eV. Although Sc_2O_3 is similar in properties to Al_2O_3, its basicity is more akin to that of MgO. Similar catalytic properties for Sc_2O_3 and MgO in the CO/N_2O reaction might then be broadly anticipated as shown, for example, by the temperature range required for the studies, 633 to 723 K, Sc_2O_3, and 601 to 673 K,

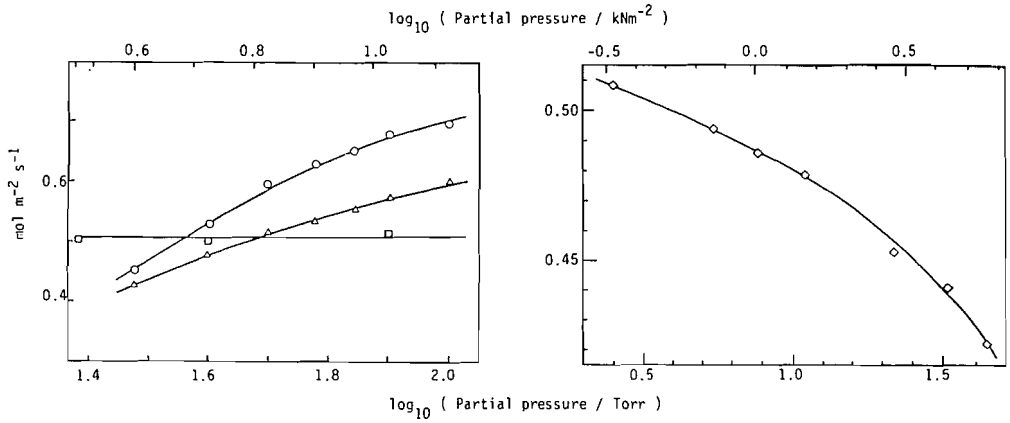

FIG. 2. Effect of variations in the partial pressures of carbon monoxide (○), nitrous oxide (△), nitrogen (□), and carbon dioxide (◇) on the catalytic CO/N_2O reaction on magnesium oxide at 559 K.

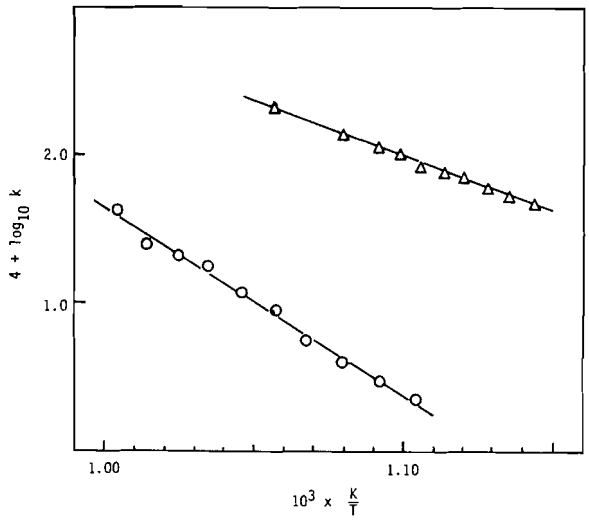

FIG. 3. Arrhenius plots for the catalytic reaction between carbon monoxide and nitrous oxide over magnesium oxide (△) and scandium oxide (○).

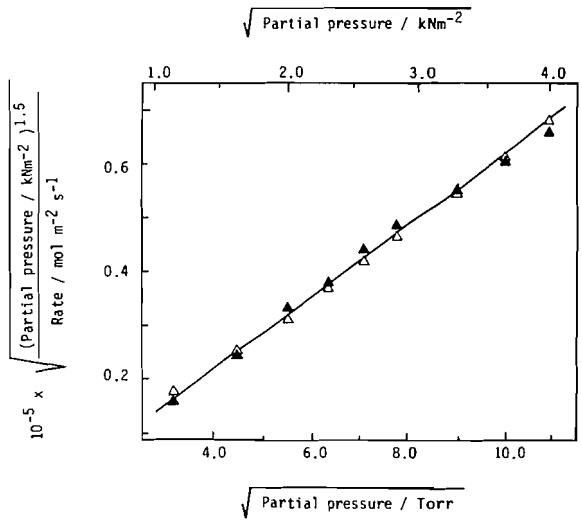

FIG. 4. Reduced plot corresponding to eq. [3] for the carbon monoxide (▲) and nitrous oxide (△) rate orders on scandium oxide at 673 K.

MgO. Further, the reaction rate orders with respect to the reaction components are comparable.

Nitrous oxide decomposition from 673 to 773 K has been proposed (11) to occur through the interaction of defects, such as F-centres, with adsorbed N_2O in the absence of an effective number of impurity states. Such proposals are particularly pertinent to insulator oxides.

The results from the rate order experiments were analyzed by testing various Langmuir–Hinshelwood kinetic expressions (12, 13) and the equations which gave the best statistical correlation coefficients for all the rate order data were adopted as general guides to the nature of the surface reaction (14, 15).

Sc_2O_3

Analysis of the rate order results (Figs. 4 and 5) yielded only one kinetic expression which could accommodate these data:

$$[3]\quad r = \frac{kaP_{CO}^{1/2}bP_{N_2O}^{1/2}}{(1 + aP_{CO}^{1/2} + bP_{N_2O}^{1/2} + cP_{CO_2}^{1/2})^2} \times P_{CO}P_{N_2O}$$

where P represents the partial pressure of the indicated component. The form of this equation suggests that, initially, carbon monoxide and nitrous oxide interact as two adsorbed species (16), each occupying two surface sites. The additional P_{CO} and P_{N_2O} terms in the numerator may be taken to imply that the reaction sequence does not terminate at this stage. A more complex overall surface mechanism would seem likely.

A simple two-stage redox mechanism would not be sufficient to accommodate all parameters and a

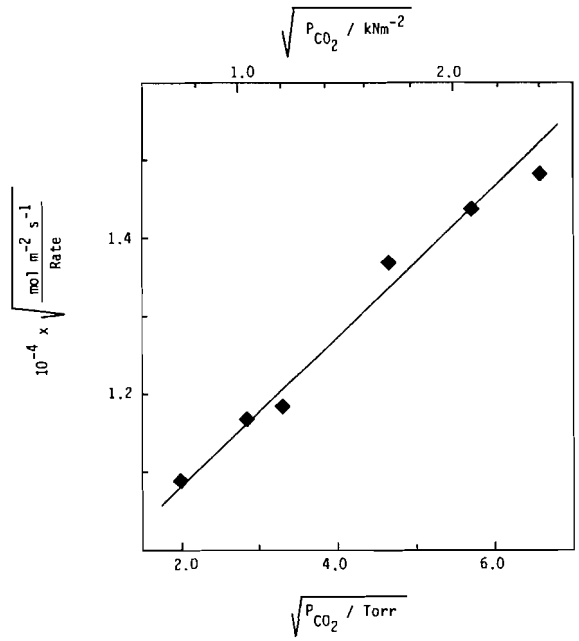

FIG. 5. Reduced plot for the carbon dioxide rate order results on scandium oxide according to eq. [3] at 673 K.

formulation tested to be consistent with the rate order results is:

[4] $$CO + 2S \rightleftharpoons CO(a)$$

[5] $$N_2O + S + CO(a) \rightarrow CO_2{}^*(a) + N_2$$

[6] $$N_2O + CO_2{}^*(a) \rightarrow CO_3(a) + N_2 + S$$

[7] $$CO + CO_3(a) \rightarrow CO_2 + CO_2(a)$$

[8] $$CO_2(a) \rightarrow CO_2 + 2S$$

where S represents a vacant surface site. The square root relationships in eq. [3] with respect to CO, N_2O, and CO_2 are rationalized in steps [4], [5], and [8], respectively, while the P_{N_2O} and P_{CO} terms are interpreted by steps [6] and [7], respectively. With respect to the reaction of nitrous oxide, step [6] would be rate controlling, for carbon monoxide it would be step [7].

Since the continuous addition of carbon dioxide to the reaction gas mixture did not accelerate the catalytic reaction rate, the species $CO_2{}^*(a)$ is proposed which may be regarded as chemically distinct from that arising from carbon dioxide adsorption (17). The structure of the proposed 'carbonate' intermediate in step [6] is not specified but the species is expected to be unstable.

Sc_2O_3 crystallizes in the C-sesquioxide form which is related to the structure of CaF_2 (18). The structure can be regarded as a fluorite lattice with systematic oxygen vacancies and thus the surface process could be:

[9] $CO + N_2O +$ 
where □ represents an oxygen vacancy. The reactions involving nitrous oxide and carbon monoxide would occur simultaneously, consistent with reactions [4]—[8]. The desorption of carbon dioxide from two surface sites is also accommodated by this scheme.

Previously, cyclic transition states have been proposed (19) for several catalytic redox reactions including the oxidation of carbon monoxide where the surface metal and oxygen sites polarize the CO molecule:

[10] 
The contribution of polarization effects to the catalytic CO/N_2O reaction was further verified (20) by a relationship between E_A and the charge/radius ratio with respect to the cation (21), a useful indicator of the importance of polarization trends (22).

MgO

The best correlation of the results for carbon monoxide and nitrous oxide (Fig. 6) and carbon dioxide (Fig. 7) was obtained with

$$[11] \quad r = \frac{kaP_{CO}bP_{N_2O}}{(1 + aP_{CO} + bP_{N_2O} + cP_{CO_2}{}^{1/2})^2} \times P_{CO}P_{N_2O}$$

The form of this equation is consistent with the interaction between carbon monoxide and nitrous oxide as adsorbed species (16). The additional P_{CO} and P_{N_2O} terms in the numerator indicate that the reaction sequence does not terminate at this stage, similar to scandium oxide, eq. [3].

A surface scheme consistent with eq. [11] is

[12] $$CO + S \rightleftharpoons CO(a)$$

[13] $$N_2O + S \rightleftharpoons N_2O(a)$$

[14] $$CO(a) + N_2O(a) \rightarrow CO_2{}^*(a) + N_2$$

[15] $$N_2O + CO_2{}^*(a) \rightarrow (CO_3) + N_2$$

[16] $$CO + (CO_3) \rightarrow CO_2(a) + CO_2$$

[17] $$CO_2(a) \rightarrow CO_2 + 2S$$

The rate-determining step with respect to nitrous oxide decomposition is step [15]. A Rideal–Eley type mechanism (16) is not necessarily implied since the weak adsorption of N_2O or CO in steps [15] and [16], respectively, would give the same kinetic ex-

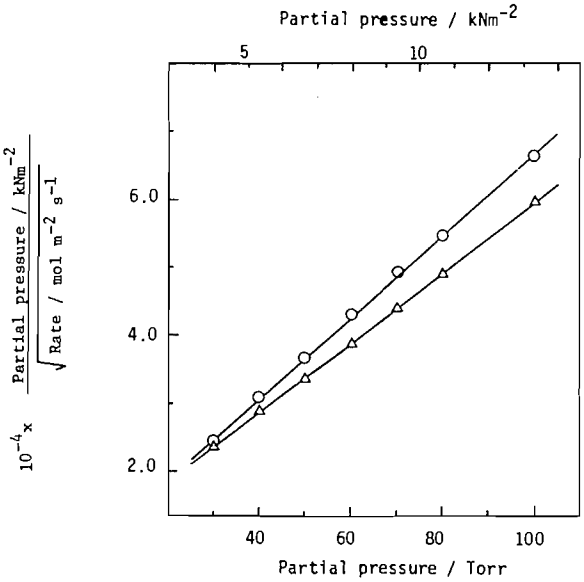

FIG. 6. Carbon monoxide (△) and nitrous oxide (○) rate order results for the catalytic CO/N_2O reaction on magnesium oxide at 559 K plotted according to eq. [11].

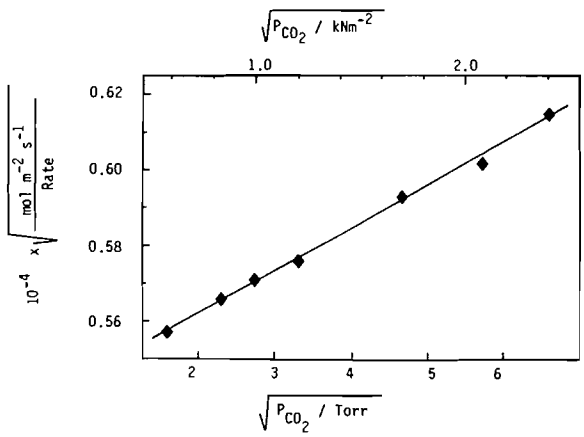

FIG. 7. Carbon dioxide rate order results for the catalytic CO/N_2O reaction on magnesium oxide at 559 K plotted according to eq. [11].

pression. With respect to carbon monoxide, step [16] is rate controlling. The term involving carbon dioxide partial pressure indicates that one of the two product molecules desorbs rapidly while the second is adsorbed more strongly on two surface sites. There would appear again to be a chemical distinction between the surface carbon dioxide species arising from the adsorption of CO_2 and that formed in step [14] since no enhanced catalytic activity resulted with the continuous introduction of carbon dioxide into the reacting gas mixture.

For both oxides, the kinetic equations computed from analysis of the rate order results yielded expressions more complex in nature than those derived for the oxides of manganese and cobalt (4), nickel (3), and vanadium pentoxide melts containing alkali metal sulphate additives (2). This feature may be a consequence of the insulator and near-insulator properties of MgO and Sc_2O_3, respectively. Although the metal/oxygen bond distances are essentially equal (13), polarization is greater in Sc_2O_3 and this might be expected to influence the kinetics of the reaction. Thus, stronger adsorption of CO on Sc_2O_3 would reduce the surface mobility of the adsorbed molecule in comparison to that on MgO in accordance with the slight but reproducible differences in the observed rate order results. It is suggested then that the nature of the surface processes on these oxides may be distinguished by the adsorption of carbon monoxide on two sites on Sc_2O_3 and on one site for MgO with subsequent consequences on the manner of nitrous oxide adsorption which approaches the classical Langmuirian pattern on MgO.

Determination of oxalate by continuous analysis using photochemical oxidation by iron(III) and a CO_2 electrode detector

JEAN MARGARET COOLEY[1] AND BYRON KRATOCHVIL[2]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 13, 1978

JEAN MARGARET COOLEY and BYRON KRATOCHVIL. Can. J. Chem. **56**, 2452 (1978).

Oxalate concentrations were measured by photochemical oxidation with iron(III) to carbon dioxide. Technicon AutoAnalyzer components were used to automate the sampling and mixing steps, and the carbon dioxide produced in the radiation step was measured with a CO_2 electrode. Variables in the system were evaluated and the optimum conditions identified. A theoretical study was made of the effect on ionic species concentrations of variations in iron(III), acid, and counter ion concentrations. A linear calibration curve could be obtained for oxalate concentrations in the range of 2×10^{-4} to 0.02 *M*; by modifying conditions linearity could be achieved at both higher and lower concentration ranges. Several other acids are partially oxidized under optimum conditions for oxalate. Tartrate, citrate, and malonate introduce errors of 2% or less at concentrations equivalent to oxalate; malate and pyruvate cause errors on the order of 10%. Several small carboxylic acids were found to interfere with the CO_2 electrode.

JEAN MARGARET COOLEY et BYRON KRATOCHVIL. Can. J. Chem. **56**, 2452 (1978).

On a mesuré des concentrations d'oxalate par des oxydation photochimique à l'aide de fer(III) qui conduisent à du dioxyde de carbone. On a utilisé les composantes d'un auto-analyseur Technicon pour automatiser les étapes d'échantillonnages et de mélanges et on a mesuré le dioxyde de carbone qui se produit dans l'étape de la radiation à l'aide d'une électrode de CO_2. On a évalué les variables du système et on a identifié les conditions optimales. On a effectué une étude théorique de l'effet, sur les concentrations des espèces ioniques, de variations dans les concentrations de fer(III), d'acide et de contre ion. On devrait obtenir, une courbe de calibration linéaire pour des concentrations d'oxalate allant de 2×10^{-4} jusqu'à 0.02 *M*; si l'on modifie les conditions, on peut obtenir une linéairité à des concentrations plus élevées ainsi que plus basses. Plusieurs autres acides sont partiellement oxydés sous les conditions optimales pour l'oxalate. Le tartrate, le citrate et le malonate introduisent des erreurs de 2% ou moins à des concentrations équivalentes à celle de l'oxalate; les erreurs introduites par le malate et le pyruvate sont de l'ordre de 10%. On a trouvé que plusieurs petits acides carboxyliques interfèrent avec l'électrode CO_2.

Introduction

The determination of oxalate concentrations can be accomplished by a number of procedures. In practical situations, however, the ability to measure this species often is limited due to interferences and detection limits. The classical method is separation by precipitation as calcium oxalate, usually followed by dissolution of the precipitate and determination of either the calcium or oxalate. But the quantitative precipitation of calcium oxalate is slow and not suited to small amounts of oxalate. For trace levels a number of direct and indirect spectrophotometric methods have been suggested (1–6), but all lack high specificity. Enzymatic procedures offer specificity; oxalate decarboxylase, which converts oxalate to formate and carbon dioxide, has been studied for the determination of oxalate in biological fluids (7–9), but since the enzyme is inhibited by sulfate and phosphate and is costly, these methods have not been widely adopted.

In 1955 Rao and Aravamudan utilized the photochemical reaction between iron(III) and oxalate for the determination of oxalate. The resultant iron(II) was titrated with vanadate (10). Riggs and Bricker modified the method by titrating the iron(II) with dichromate or, for smaller amounts of oxalate, by spectrophotometric determination of the iron(II) with 1,10-phenanthroline (11). Any substance that reduces iron(III) or oxidizes iron(II), such as oxygen dissolved in the solution, interferes in these methods.

This paper describes an automated continuous analysis approach to the determination of oxalate using the iron(III) photochemical reaction and measuring carbon dioxide production with a CO_2 electrode. The method is simple, straightforward, and circumvents many of the drawbacks of earlier procedures.

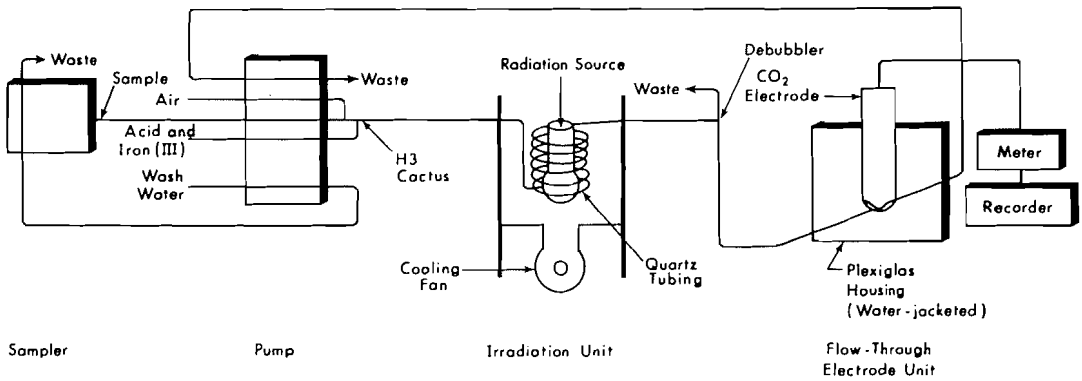

FIG. 1. Schematic diagram of continuous flow system incorporating Technicon AutoAnalyzer sampler and pump units for determination of oxalate.

Experimental

Apparatus

A Technicon single channel AutoAnalyzer Sampler II and Pump I were used to automate the analyses (Fig. 1). In the proportioning pump an acidified solution of iron(III) was mixed with the acidified oxalate samples. Air bubbles were introduced and the solution was then irradiated with a 140-W Hanovia type-30620 ultraviolet mercury lamp during passage through a 12-m coil of 1.65-mm id quartz tubing surrounding the lamp. The lamp–coil unit was cooled from below by a small fan to minimize heating of the solution. A reflecting layer of aluminum foil was placed around the coil to improve efficiency of the radiation source and to protect the operator from ultraviolet radiation. From the coil, the solution passed through a debubbler to a CO_2 electrode (Instrumentation Laboratory) mounted in a flow-through unit constructed from Plexiglas. The bottom of this unit was machined to provide a small volume chamber at the tip of the electrode. The inlet and outlet channels were 1 mm in diameter and were drilled opposite to each other at an upward angle to minimize bubble entrapment in the chamber. Stainless steel fittings were epoxied into the Plexiglas for tubing connections. The electrode, flow-through unit and a portion of the inlet tubing were immersed in a water bath if temperature control was desired. An Orion Model 801 pH meter with a Hewlett-Packard Model 7101BM recorder was used to monitor the electrode potential.

Chemicals

Sodium bicarbonate solutions were prepared in 0.5 *M* NaCl; potassium oxalate solutions were prepared in 0.5 *M* NaCl – 0.1 *M* H_2SO_4. Iron(III) solutions were prepared from the corresponding sulfate or chloride salts in sulfuric or hydrochloric acid. About 0.75 ml of 30% Brij 35 solution was added per litre of iron(III) solution as a wetting agent. The internal filling solution of the CO_2 electrode was varied between 1×10^{-4} and 1×10^{-2} *M* $NaHCO_3$ in 0.5 *M* NaCl saturated with silver chloride. All chemicals were reagent grade or better and were used as received.

Calculations

An IBM 360/67 computer was used to calculate the equilibrium concentrations of species present in various mixtures. The procedure was patterned after the work of Swinnerton and Miller (12), with several modifications. Mass balance and equilibrium equations were written for each solution of interest, then combined to give n equations in n unknowns, n being the number of mass balance equations used. This system was then solved using the Newton–Rapheson method of successive approximations. Stability constants were chosen, whenever possible, at an ionic strength of unity and at 25°C, as this represented the experimental conditions more closely than did standard conditions of zero ionic strength and 0°C.[3]

Results and Discussion

Preliminary Experiments

Initially a series of solutions of acidified oxalate and iron(III) was exposed to ultraviolet radiation. The net reaction may be written as

$$2Fe^{3+} + C_2O_4^{2-} \xrightarrow{h\nu} 2Fe^{2+} + 2CO_2$$

Measurement of the resulting carbon dioxide levels with a CO_2 electrode yielded Nernstian results over the range of 10^{-2} to 10^{-4} *M* oxalate. This approach is not attractive as an analytical method, however, because of loss of carbon dioxide to the atmosphere during irradiation, lack of reproducibility of irradiation conditions, and slowness of the procedure. Therefore, an automated approach was developed that eliminated or diminished appreciably these disadvantages.

Preliminary investigations of the automated system were made using a series of solutions of sodium bicarbonate which were mixed with acid in the pump and analyzed with a CO_2 electrode. One variable studied was the composition of the internal filling solution in the electrode. A 1×10^{-3} *M* $NaHCO_3$ filling solution, 0.5 *M* in NaCl and saturated in AgCl, gave the best compromise between speed and linearity of response. The CO_2 permeable membranes made of Silastic sheeting (0.003 in. from Instrumentation Laboratory) performed acceptably; 0.005 in. and Dacron-reinforced 0.007 in. Silastic sheeting (Dow-Corning) gave similar results. Mem-

[3]The values used for the stability constants are available, at a nominal charge, as Appendix I from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

branes prepared from the Dow-Corning material required thorough washing before use to remove the dusting of sodium bicarbonate present on the surface.

Near Nernstian slopes were obtained over a range of 0.1 to 1 × 10^{-4} *M* bicarbonate when the samples were mixed with 2 *M* H_2SO_4 and pumped through the irradiation coil prior to measurement by the CO_2 electrode. A 5 × 10^{-3} *M* $NaHCO_3$ sample was run 5 times at various sampling speeds to test the reproducibility of the system; as sampling speeds were increased from 10 to 20 to 40 samples per hour the standard deviation increased from 0.32 to 0.44 to 1.80 mV. At faster sampling rates successive readings on the same sample increased because equilibrium was not attained. Separation of the samples by use of only every third cup position in the sampler improved precision; accordingly, if time permits, use of one or two empty sample cups following each filled one is recommended.

Oxalate analyses were performed in a similar manner. Samples of 7 to 8 ml were introduced through 0.065-in. id pump tubing, and acidified iron(III) solution through 0.020-in. id tubing. Figure 2 shows a calibration plot for a series of solutions of potassium oxalate. Electrode response for oxalate is linear under these conditions over a range of about 2 × 10^{-4} to 2 × 10^{-2} *M*, but the linear range is increased to that observed for bicarbonate if lower concentrations of iron(III) are used, as is discussed below.

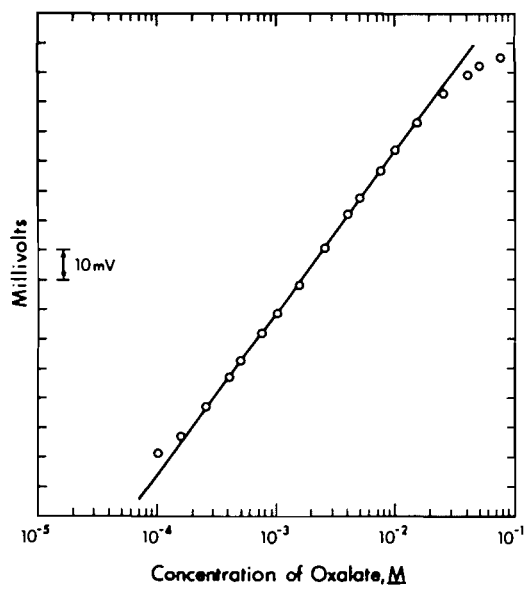

FIG. 2. Calibration plot for a series of oxalate solutions using photochemical oxidation and an IL CO_2 electrode in a continuous-flow mode. Reaction medium under irradiation was 0.05 *M* iron(III) ammonium sulfate, 0.5 *M* sulfuric acid, and 0.5 *M* sodium chloride.

Photochemical decomposition of the iron(III)–oxalate complex yields two moles of carbon dioxide for each mole of oxalate consumed, yet a slope close to 59 mV is obtained experimentally. The Nernst equation for the electrode response can be written in the form

$$E = \text{constant} + \frac{RT}{nF} \log p_{CO_2}$$

$$= \text{constant} + \frac{RT}{nF} \log 2[C_2O_4^{2-}]$$

$$= \text{constant} + \frac{RT}{nF} \log 2 + \frac{RT}{nF} \log [C_2O_4^{2-}]$$

where p_{CO_2} refers to the partial pressure of carbon dioxide in solution. Thus a slope of 59 mV is predicted but the absolute value of the readings for the same concentration of oxalate or bicarbonate will be shifted by a factor of (RT/nF) log 2 or 18 mV. This shift was verified experimentally.

A characteristic of the Severinghaus-type CO_2 electrode used in this work is that equilibrium is reached more quickly with higher concentrations of carbon dioxide than with lower concentrations. Because the continuous system used provides a fixed time interval between samples, nonattainment of equilibrium between samples results in a hysteresis effect. The resulting error may be significant when a sample of low concentration follows one of higher concentration. For example, a 1 × 10^{-4} *M* oxalate sample gave a result 8% higher than the equilibrium value when run immediately after a 1 × 10^{-3} *M* sample. The error becomes significant when the samples cover a wide concentration range.

Effect of Solution Composition

Among the variables investigated in the oxalate system were the effects of acidity, of iron(III) concentration and of several complexing anions. To ascertain the effect of acidity of the reaction mixture on the system, solutions of 0.5 *M* iron(III) ammonium sulfate were prepared in distilled water and in 2 and 4 *M* H_2SO_4. A set of seven solutions ranging from 1 × 10^{-3} to 1 × 10^{-2} *M* in oxalate were run with each iron(III) solution. The concentration of H_2SO_4 in the solutions entering the radiation coil was about 0.1, 0.3, and 0.5 *M* for the three iron(III)–oxalate mixtures. Little difference was found among the three calibrations; standard deviations of the order of 0.36 mV were obtained. Thus adjustment of acidity is not a critical variable for oxalate analysis.

For personal use only.

For practical use the ability to measure a wide range of oxalate concentrations is desirable. Initially a 0.5 *M* iron(III) ammonium sulfate solution was used to ensure an excess of oxidizing agent even at high oxalate concentrations. Riggs and Bricker state that results are independent of iron(III) concentration as long as the ratio of iron(III) to oxalate is 2:1 or greater (11). Rao and Aravamudan maintained iron(III):oxalate ratios of 4:1 or greater in their analyses (10). To ascertain the effect of this ratio on the flow-through system, triplicate portions of 1×10^{-3} *M* potassium oxalate were run with progressively decreasing concentrations of iron(III) ammonium sulfate in 2 *M* H_2SO_4. The analyses were repeated using a 200-W General Electric tungsten lamp and a 12-m Pyrex coil in place of the Hanovia medium pressure mercury lamp and quartz coil so that the effect of radiation conditions also could be studied. At high iron(III) concentrations the quantity of carbon dioxide evolved was greater with the tungsten lamp than with the ultraviolet lamp, but at lower iron(III) to oxalate ratios the ultraviolet lamp gave higher yields. The optimum iron(III):oxalate ratio for irradiation with the ultraviolet lamp is in the range of 5:1 to 0.5:1 (Fig. 3). A similar trend was observed at oxalate concentrations of 1×10^{-4} *M* except that optimum ratios for the ultraviolet system extended to as high as 50:1, while for 1×10^{-2} *M* oxalate a ratio of 0.5:1 iron(III) to oxalate gave maximum carbon dioxide production. Thus, as the oxalate concentration was increased, the ratio of iron(III) to oxalate became more critical, probably because of the fixed time of irradiation and the high absorbance of the solutions. By optimization of the amount of iron(III) used and irradiation conditions the quantity of carbon dioxide produced can be maximized; in this way the limits of linear response of the system are extended.

Since each mole of oxalate requires two moles of iron(III) for complete oxidation to carbon dioxide, ratios below 2:1 indicate iron(II) is being reoxidized to iron(III), apparently by oxygen dissolved in the solutions and present in the air bubbles. When the pump air line was connected to a nitrogen stream, the lower iron(III):oxalate ratios became less favorable; purging the oxalate sample solutions with nitrogen prior to analysis further reduced the electrode readings when iron(III):oxalate ratios below 2 to 1 were used.

Rao and Rao (13, 14) found that hydrochloric acid could be substituted for sulfuric acid in the photochemical oxidation of oxalate without ill effects, but Riggs and Bricker (11) suggested that the use of hydrochloric acid would produce strongly absorbing iron(III)–chloro complexes that would interfere with irradiation efficiency, and recommended that sulfuric acid be used instead. Since chloride is present in many samples this point was investigated. Analysis of oxalate solutions containing chloride gave results similar to those containing sulfate. This observation was shown to be reasonable on the basis of calculations outlined below.

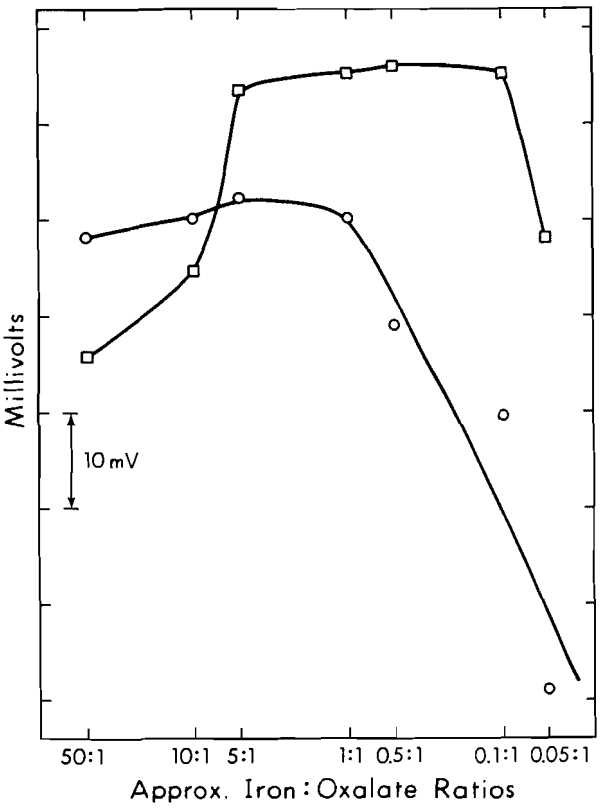

FIG. 3. Effect of iron(III)–oxalate ratio on the oxidation of oxalate at an oxalate concentration of 0.001 *M*. □: Ultraviolet lamp and quartz coil irradiation system. ○: Tungsten lamp and Pyrex coil irradiation system.

The presence of Brij 35 surfactant is recommended for more reproducible response. When a calibration curve for oxalate using 0.5 *M* iron(III) ammonium sulfate in 2 *M* H_2SO_4 was repeated without addition of surfactant the overall standard deviation increased from 0.36 to 0.98 mV.

Calculations

For maximum photochemical conversion of oxalate to carbon dioxide the fraction of oxalate in the form of the iron(III) complex must be maximized. Attainment of this objective is complicated by the large number of species, many highly absorbing, which can form. Determination of the equilibrium concentrations of the species in such systems is most conveniently done by computer. For example,

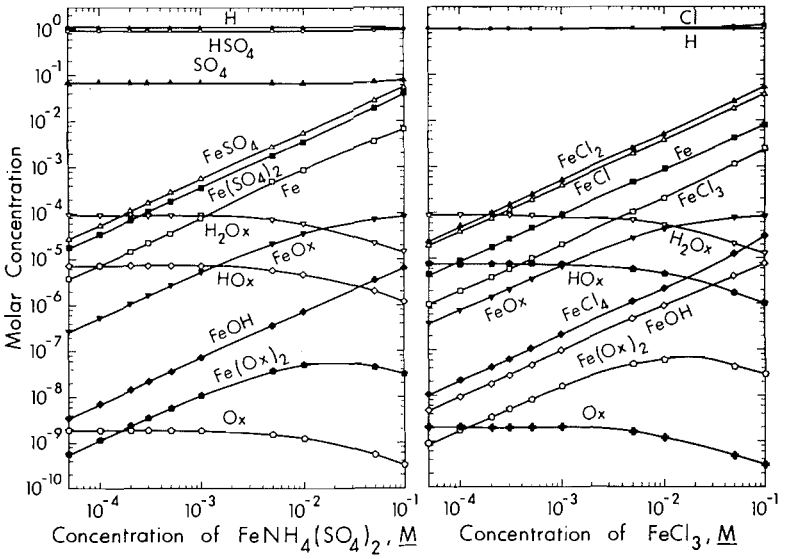

FIG. 4. Left: distribution of species in a solution containing 1×10^{-4} *M* total oxalate and 1 *M* sulfuric acid as a function of iron(III) ammonium sulfate concentration. Right: same, but with 1 *M* hydrochloric acid and iron(III) chloride in place of sulfuric acid and iron(III) ammonium sulfate. Charges omitted for simplicity.

Swinnerton and Miller (12) studied a system containing iron(III), sulfate, hydrogen ion, and oxalate. They omitted the hydrolysis of iron(III) for simplicity and did not consider formation of iron(III)–sulfate complexes. In the calculations reported here hydrolysis to form the $Fe(OH)^{2+}$ complex was taken into account, as was the effect of formation of iron(III)–sulfate complexes. The contribution to the hydrogen mass balance from the hydrolysis of iron(III) was assumed to be small; this amount, for simplicity, was omitted in the value given to the hydrogen mass balance. The validity of this assumption was confirmed for most of the calculations. Further corrections were not added for those cases where the assumption was invalid.

The effect of varying analytical concentrations of iron(III), sulfate, and hydrogen ions on the equilibrium concentrations of various species present was studied. A similar study was undertaken, substituting chloride for the sulfate ions. Uncertainties in some of the results may be moderately large. Double precision was used throughout, but because concentrations and constants often varied widely in magnitude, some truncation errors were likely. Additional uncertainty was introduced because the equilibrium constants used were measured under a wide range of conditions and by different workers. The results, therefore, are not exact, but are useful to indicate trends, to allow calculation of absorbances as a function of solution conditions, and to aid in selecting experimental conditions.

In the first set of calculations, a series of iron(III) ammonium sulfate concentrations ranging from 5×10^{-5} to 0.1 *M* was used in a 1 *M* sulfuric acid and 1×10^{-4} *M* oxalate matrix. The resulting equilibrium concentrations of the various species are plotted in Fig. 4, along with the results of similar calculations with iron(III) chloride, hydrochloric acid, and oxalate.[4]

From these plots it is seen that the concentration of $FeC_2O_4^+$ increases with increasing iron(III) concentrations, as expected. However, the concentrations of the iron(III)–sulfate and –chloride complexes also increase, and since these species absorb significantly in the ultraviolet (15, 16) they interfere with absorption of radiation by the iron(III)–oxalate species, confirming the experimental results. High iron(III) concentrations also lead to the formation of highly absorbing complexes such as $Fe_2(OH)_2^{4+}$ and $Fe_3(OH)_4^{5+}$ (17). Hence high iron(III) concentrations are best avoided. One way of keeping the total iron(III) level low is by the reoxidation of iron(II) with dissolved oxygen, as occurs in this experimental design. This permits the oxidation of oxalate without formation of high concentrations of undesirable iron(III) complexes.

A second set of calculations was performed in which the concentration of sulfuric acid was varied while the total concentration of oxalate and iron(III) ammonium sulfate remained constant. Plots of

[4]An additional plot with only iron(III), hydrogen ion, and oxalate initially present is available as Appendix II from the Depository of Unpublished Data; see footnote 3.

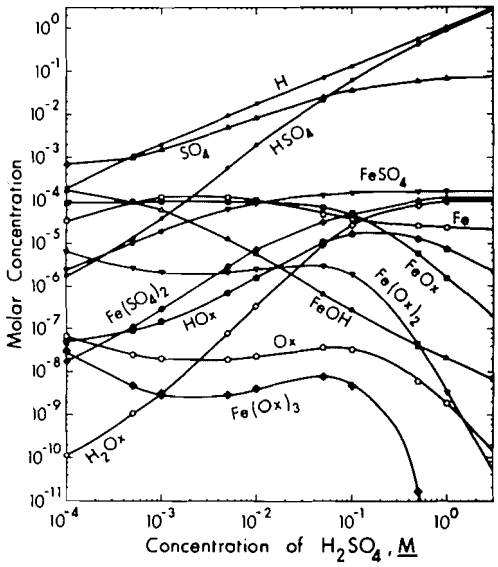

FIG. 5. Distribution of species in a solution containing 1×10^{-4} *M* total oxalate and 3×10^{-4} *M* iron(III) ammonium sulfate as a function of sulfuric acid concentration. Charges omitted for simplicity.

species concentrations as a function of added H_2SO_4 are shown in Fig. 5.[5] These calculations show that in this system the acidity can be varied widely without affecting the fraction of oxalate present as the iron(III)–oxalate monocomplex. This agrees with the experimentally observed results.

A third set of calculations was undertaken in which the stability constants of other iron(III)–carboxylate species and acidity data for these acids were substituted into the program in place of the iron(III)–oxalate formation and acidity constants. Figure 6 shows the variation of the iron(III)–carboxylate species with changing acidity. Oxalate forms the strongest iron(III) complex of the acids studied, hence the importance of acidity control in diminishing interferences due to the presence of other carboxylate anions in an oxalate solution.

Interferences in Determination of Oxalate

Several carboxylic acids other than oxalic acid are photochemically oxidized by iron(III) under certain conditions to produce carbon dioxide. These include citric, tartaric, lactic, maleic, malic, malonic, and pyruvic acids. The error caused by several of these acids in the determination of oxalate is listed in Table 1. As mentioned above, this error can be reduced appreciably in many cases by an increase in sulfuric acid concentration in the sample solution.

[5]Plots of additional sets of calculations in which sulfate is replaced by chloride, and in which neither counter ion is present, are available as Appendix II from the Depository of Unpublished Data; see footnote 3.

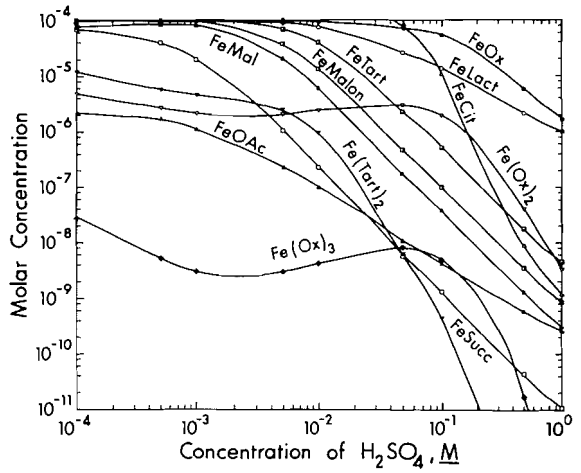

FIG. 6. Effect of sulfuric acid concentration on concentration of iron(III)–carboxylate species for several carboxylate salts. For each carboxylate salt a separate calculation of species distribution similar to Fig. 5 was performed; only the concentration distributions of the iron(III)–carboxylate species are shown here, combined on a single graph for convenient comparison. Cit = citrate, Lac = lactate, Mal = malate, Malon = malonate, Ox = oxalate, Succ = succinate, Tart = tartrate. Charges omitted for simplicity.

TABLE 1. Effect of carboxylic acids on oxalate determination[a]

Oxalate concentration (*M*)	Species added	Species concentration (*M*)	% Error
2.5×10^{-3}	Citrate	2.5×10^{-3}	2
2.5×10^{-3}	Citrate	2.5×10^{-2}	8
2.5×10^{-3}	Tartrate	2.5×10^{-3}	2
2.5×10^{-3}	Tartrate	2.5×10^{-2}	15
5×10^{-4}	Tartrate	5×10^{-4}	0.4
5×10^{-4}	Tartrate	5×10^{-3}	10
5×10^{-4}	Malate	5×10^{-4}	8
5×10^{-4}	Pyruvate	5×10^{-4}	10
5×10^{-4}	Malonate	1×10^{-3}	2

[a]Analyte solutions 0.1 *M* in H_2SO_4; reagent solution 0.5 *M* iron (III) ammonium sulfate in 4 *M* H_2SO_4.

Low molecular weight carboxylic acids such as formic, acetic, and propionic acids were found to interfere with the CO_2 electrode by diffusing across the membrane and causing a change in the pH of the internal filling solution. Diffusion of these acids back across the membrane is slow, and so electrode response to carbon dioxide concentration changes is affected. Acetic acid had been previously reported to interfere in this way (18). Similar but more serious interference was caused by aromatic acids such as benzoic and cinnamic. Soaking of the electrode in water for several hours did not restore the electrode potential to its original value after exposure to these acids and the electrode had to be disassembled and cleaned before it was serviceable again.

Study of Citrate and Tartrate Response

Optimization of conditions for response of the system to citrate and tartrate was examined briefly. Using solutions of sodium citrate or potassium sodium tartrate in 0.5 *M* NaCl with 0.5 *M* $FeNH_4(SO_4)_2$ as reagent, linear calibration plots over the range of approximately 1×10^{-2} to 1×10^{-4} were obtained for both citrate and tartrate using the ultraviolet radiation system.

As with oxalate, linearity at either end of the range can be improved by optimizing the ratio of iron(III) to carboxylate salt. The decomposition of tartrate appears to result in formation of two moles of carbon dioxide per mole of tartrate, while three moles of carbon dioxide appear to be formed per mole of citrate under optimum conditions, as indicated by an experimentally observed displacement of the calibration plot by (RT/nF) log 3, or 28 mV.

In summary, the measurement of carbon dioxide produced upon photochemical oxidation of oxalate by iron(III) provides a method for the determination of oxalate over a useful range of concentrations. The procedure works well in a continuous analysis mode using a carbon dioxide measurement system. An advantage of measuring carbon dioxide rather than iron(II) is that substances that oxidize iron(II) such as dissolved oxygen, or reduce iron(III), such as mannitol, do not interfere. The CO_2 electrode is a simple and convenient detector, but is affected by the presence of low molecular weight aliphatic acids and by aromatic carboxylic acids.

Rearrangement studies with ^{14}C. XLII. The solvolysis of triphenylvinyl-2-^{14}C bromide in aqueous acetic acid and in 2,2,2-trifluoroethanol

CHOI CHUCK LEE AND ERIC C. F. KO

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received February 13, 1978

CHOI CHUCK LEE and ERIC C. F. KO. Can. J. Chem. **56**, 2459 (1978).

Solvolytic studies with triphenylvinyl-2-^{14}C bromide (**1**-Br-2-^{14}C) in HOAc–H_2O and in 2,2,2-trifluoroethanol (TFE) containing 2,6-lutidine were carried out under a variety of conditions. Scramblings of the label from C-2 to C-1 in the reaction product and in the unconsumed reactant were determined. For solvolyses in HOAc–H_2O, scrambling was observed in the product, but not in the recovered reactant. The extent of scrambling was higher when the proportion of H_2O in the solvent was lower. With a given solvent composition, the amount of scrambling did not change with reaction time, the average extents of scrambling being 9.6, 12.7, 15.3, 16.7, and 18.4%, respectively, for solvolysis in 50, 60, 70, 80, and 90% HOAc. With 70% HOAc, the presence of about 3 equiv. of NaOAc or NaBr did not influence the extent of scrambling. For the reactions in TFE, there was scrambling in both the reaction product and the recovered reactant, indicating the occurrence of a return process, The presence of added Et_4NBr did not affect the extent of scrambling, suggesting that the 1,2-phenyl shift occurred in the ion-pair stage and the return is, therefore, an ion-pair return. The amount of scrambling in the product and in the recovered reactant increased with increasing reaction time, but for a given reaction time, the extents of scrambling in the product and in the recovered reactant were the same. The mean values for the scrambling of the label from C-2 to C-1 in the product and the recovered reactant, after a reaction time of 1, 2, 4, and 20 days at 150°C, were 20.1, 30.0, 40.0, and 44.1%, respectively. Mechanistic explanations for both reactions in HOAc-H_2O and in TFE are discussed.

CHOI CHUCK LEE et ERIC C. F. KO. Can. J. Chem. **56**, 2459 (1978).

Des études de solvolyse du bromure de triphénylvinyl-2-^{14}C (**1**-Br-2-^{14}C) dans le trifluoro-2,2,2 éthanol (TFE) contenant de la lutidine-2,6 ont été effectuées dans diverses conditions. On a déterminé l'échange des marqueurs de la position C-2 vers la position C-1 dans le produit de la réaction et dans le réactif qui n'a pas été utilisé. Pour les solvolyses dans HOAc–H_2O, on observe de l'échange dans le produit, ce qui n'est pas le cas pour le réactif récupéré. Le taux d'échange est plus élevé quand la proportion d'eau dans le solvant est plus faible. Pour une composition donnée du solvant, la quantité d'échange n'évolue pas avec le temps de la réaction; les taux moyens d'échange sont 9.6, 12.7, 15.3, 16.7 et 18.4% respectivement pour les solvolyses dans HOAc à 50, 60, 70, 80 et 90%. Dans HOAc à 70%, la présence d'environ 3 équivalents de NaOAc ou de NaBr n'influence pas le taux d'échange. Pour les réactions dans le TFE, on a observé de l'échange à la fois dans le produit de la réaction et dans le réactif récupéré; ceci indique la présence d'un processus de retour. L'addition de Et_4NBr, ne semble pas affecter le taux d'échange suggérant que la transposition-1,2 du phényle se produit au niveau de la paire d'ions et que le retour est donc un retour dans une paire d'ions. La quantité d'échange dans le produit et dans le réactif récupéré augmente avec une augmentation du temps de la réaction mais pour un temps de réaction donné, les taux d'échange dans le produit et dans le réactif récupéré sont les mêmes. Les valeurs moyennes pour l'échange du marqueur de la position C-2 à la position C-1 dans le produit et dans le réactif récupéré après un temps de réaction de 1, 2, 4 et 20 jours à 150°C sont respectivement de 20.1, 30.0, 40.0 et 44.1%. On discute des implications mécanistiques pour les deux réactions soit dans HOAc–H_2O et dans TFE.

[Traduit par le journal]

The generation and reactions of vinyl cations, including rearrangements, have been extensively reviewed by a number of workers active in the field (1–4). The degenerate rearrangement in a triarylvinyl cationic system was first reported from this laboratory in 1974 (5). The work involved a study of the extents of 1,2-phenyl shift across the double bond in the triphenylvinyl cation generated from solvolyses of triphenylvinyl-2-^{14}C triflate (**1**-OTf-2-^{14}C). Subsequently, analogous studies on degenerate rearrangements from 1,2-aryl shifts, using ^{14}C, ^{13}C, or D as label, were carried out in this laboratory (6–9) and by Rappoport and co-workers (10, 11) on triarylvinyl cations with various combinations of phenyl and/or *p*-anisyl as the aryl groups, and these studies have been reviewed by Rappoport (4). Recently, we have also investigated similar degenerate rearrangements in the tri-*p*-tolylvinyl and the 2-phenyl-1,2-di-*p*-tolylvinyl cations generated, respectively, from tri-*p*-tolylvinyl-2-^{13}C bromide and

from *cis*- and *trans*-2-phenyl-1,2-di-*p*-tolylvinyl-2-^{13}C bromides (12, 13).

In a study on the formation of vinyl cations from reactions of acids with vinyltriazenes, Jones and Miller (14) made the early observation of rearrangements of less stable to more stable triarylvinyl cations arising from 1,2-aryl shifts. For example, the decomposition of the 1-phenyl-2,2-di-*p*-tolylvinyldiazonium ion generated from the triazene in HOAc gave 20% of the rearranged product, 2-phenyl-1,2-di-*p*-tolylvinyl acetate. This rearrangement, however, could be completely suppressed by the presence of 10 molar equiv. of KOAc. Similarly, in the decomposition of trianisylvinyl-2-^{14}C-phenyltriazene in HOAc, the degenerate rearrangement from 1,2-anisyl shifts in the trianisylvinyl cation gave rise to about 38 and 17% scrambling, respectively, when the reaction was carried out in the absence and in the presence of 1.7 equiv. of NaOAc (9). These results were interpreted as indicating that the rearrangement occurred with the dissociated open triarylvinyl cation. In the presence of added acetate, the rearrangement would compete less effectively with the product forming reaction between the vinyl cation and the acetate anion.

In the solvolyses of **1**-OTf-2-^{14}C in acetic, formic and trifluoroacetic acids, it was found that the presence of added conjugate base of the solvent did not affect the extents of scrambling (5). These findings were interpreted as indicating that the rearrangement took place in the ion-pair stage. An example of such an interpretation can be found in the early, classical work of Young *et al.* (15, 16) on allylic rearrangements through internal return with allylic chlorides, where intimate ion-pairs were involved and the presence of added chloride ions did not affect the rate of rearrangement. If the degenerate rearrangement in the triphenylvinyl cation indeed were to involve ion pairs, a closely related process would be ion-pair return. In the present work, solvolytic studies with triphenylvinyl-2-^{14}C bromide (**1**-Br-2-^{14}C) were carried out with the view of obtaining further information on the role of ion pairs in the rearrangement and return processes.

Results and Discussion

The labelled reactant, **1**-Br-2-^{14}C, was prepared as described previously (5). The reaction of **1**-Br-2-^{14}C or **1**-Br-2-^{13}C with HOAc–AgOAc has been shown to give 6–7% scrambling of the label from C-2 to C-1 (6). When attempts were made to effect the reaction of **1**-Br with glacial HOAc without any Ag salt, the reaction was very slow and extensive decomposition occurred. Hence in the present work, the first series of experiments were carried out by heating **1**-Br-2-^{14}C in HOAc–H_2O at 150°C for different lengths of time. The data are summarized in Table 1. The solvent systems varied from 50% HOAc – 50% H_2O to 90% HOAc – 10% H_2O (by volume). With 70% HOAc, experiments were also carried out in the presence of about 3 equiv. of added NaOAc or NaBr. From the reactions in 50–80% HOAc, the only product obtained was α,α-diphenylacetophenone (**2**). With 90% HOAc, besides **2**, a trace of the acetate product was detectable by nmr.

The reaction product, **2**, was purified by passage through an alumina column before it was degraded (5) by $LiAlH_4$ reduction to 1,2,2-triphenylethanol (**3**), followed by $KMnO_4$ oxidation to benzophenone (**4**). The loss of ^{14}C activity in the conversion of **3** to **4** gave the extent of scrambling of the label from C-2 to C-1. The results are given in Table 1.

In some of the experiments, the unconsumed reactant, **1**-Br-x-^{14}C, was also separated in the alumina column and then subjected to degradation to ascertain whether scramblings arising from return processes have occurred. The method of degradation made use of an earlier finding that the reaction of triphenylvinyl-2-^{14}C-phenyltriazene with aqueous acetone in the presence of $HClO_4$ gave α,α-diphenylacetophenone (**2**) with no isotopic scrambling (9). In the present work, the samples of recovered **1**-Br-x-^{14}C were converted to the Grignard reagent and then treated with phenyl azide to give triphenylvinylphenyltriazene (9). Upon reaction with 90% acetone – 10% H_2O containing 0.1% $HClO_4$, the triazene gave **2** which was in turn reduced to **3** and then oxidized to **4** in the usual way to give the extent of scrambling. The results are also given in Table 1.

As can be seen from Table 1, in the various experiments in which the recovered unconsumed **1**-Br-2-^{14}C was analyzed, there was essentially no isotopic scrambling (0 ± 0.5%), suggesting no ion-pair return or the return process could not compete with rearrangement. Such a finding for solvolytic reactions in a water-containing solvent is not surprising since it is known that, in highly nucleophilic or highly ionizing solvents, the return process competes poorly with the product forming reaction (15, 16). Kinetic studies with **1**-Br by Rappoport and Houminer (17) have also shown that in an aqueous solvent, namely, 60% EtOH – 40% H_2O, the specific rate constant remained unchanged throughout a reaction, indicating no common ion rate depression by the liberated bromide ion.

The extents of isotopic scrambling observed in the reaction product from solvolyses of **1**-Br-2-^{14}C in aqueous HOAc varied depending on the solvent composition (Table 1). For a given mixture of HOAc and H_2O, however, the amount of scrambling

remained essentially constant, although the reaction time and hence the extent of reaction was changed. In 70% HOAc, the presence of about 3 equiv. of added NaOAc or NaBr also did not influence the degree of rearrangement. From Table 1, it is seen that the mean values for the extents of scrambling of the label from C-2 to C-1 in the reaction products were 9.6, 12.7, 15.3, 16.7, and 18.4%, respectively, for solvolysis in 50, 60, 70, 80, and 90% HOAc.

The above results may be interpreted by the mechanism shown in Scheme 1. Since the presence of NaOAc or NaBr did not materially affect the extent of scrambling (experiments 8–13, Table 1), the previous conclusion (5) that the 1,2-phenyl shift in the triphenylvinyl cation took place in the ion-pair stage has apparently been confirmed. The ion pair may give rise to product directly, or dissociate further before reacting with H_2O to give the products, **2**-*2*-^{14}C and **2**-*1*-^{14}C. The present results cannot differentiate between these two possibilities.

Using the steady state treatment and the method of Bonner and Collins (18), it has been shown (11) that for the mechanism as depicted by Scheme 1, after complete reaction, eq. [1] holds.

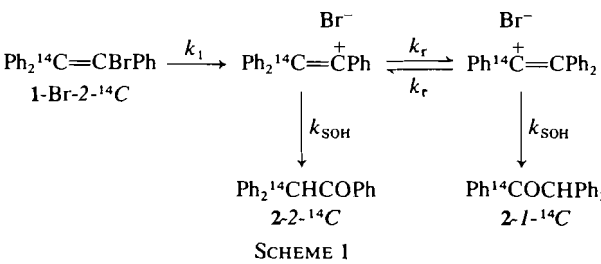
$$[1] \qquad [\mathbf{2}\text{-}2\text{-}^{14}C]/[\mathbf{2}\text{-}1\text{-}^{14}C] = 1 + (k_{SOH}/k_r)$$

Similarly, from the steady state treatment, it can be shown that eq. [2] also applies.

$$[2] \qquad \frac{d[\mathbf{2}\text{-}2\text{-}^{14}C]/dt}{d[\mathbf{2}\text{-}1\text{-}^{14}C]/dt} = 1 + (k_{SOH}/k_r)$$

Since the ratio of the rates of formation of the unrearranged and rearranged products is a constant (eq. [2]), the percentage of scrambling should not change with the extent of reaction and this was as observed (Table 1). Utilizing eq. [1] and the mean scrambling value for each solvent system, k_{SOH}/k_r can be calculated and these values are included in Table 1.

From a comprehensive solvolytic study on a series of *cis*- and *trans*-2-aryl-1,2-dimethylvinyl triflates, definitive evidence in support of aryl participation has been obtained by Stang and Dueber (19–21). For example, in the solvolysis of *trans*-1,2-dimethyl-2-phenylvinyl triflate, the phenyl bridged



SCHEME 1

vinylidene phenonium ion is shown as a reaction intermediate. On the other hand, there is no phenyl participation or anchimeric assistance in the 1,2-dianisyl-2-phenylvinyl (4, 8, 11) or 2-phenyl-1,2-di-*p*-tolylvinyl (13) cationic systems. It is attractive to consider the possibility that there may be a gradation of mechanisms with the triphenylvinyl case falling into the borderline region, with the observed scramblings attributed to partial phenyl bridging. Such an explanation, however, does not appear to agree with the observed results. From Table 1, it is seen that for a given reaction time (e.g., 2 days), the higher the proportion of H_2O in the HOAc–H_2O solvent, the greater is the extent of the reaction, but the lesser is the degree of scrambling. Assuming that bridging is associated with enhanced rate (21), if borderline behavior and partial bridging were involved, one would expect more scrambling for faster reactions, the opposite of what was observed. Apparently, as depicted in Scheme 1, the product is derived from reaction between the triphenylvinyl cation or ion pair and the more nucleophilic H_2O. The higher the proportion of H_2O in the solvent, the more effectively will the product forming process compete with the 1,2-phenyl shift, hence giving rise to a lesser amount of scrambling. The calculated k_{SOH}/k_r values (Table 1) also reflect this trend.

A kinetic study on the solvolysis of **1**-Br in 2,2,2-trifluoroethanol (TFE), in the presence of 2,6-lutidine, has been reported by Rappoport and Houminer (17). Among the findings was the observation of a common ion rate depression during a given kinetic run or with the presence of added external bromide ion, indicating the occurrence of return processes. In the present work, in order to obtain data on possible scramblings in the recovered reactant arising from returns, a set of experiments was carried out on the solvolysis of **1**-Br-*2*-^{14}C in TFE in the presence of 2,6-lutidine, with or without added tetraethylammonium bromide. Because the product from the trifluoroethanolysis, triphenylvinyl 2,2,2-trifluoroethyl ether (**1**-OTFE), could not be separated from the unreacted **1**-Br by the alumina column, separate experiments for the analysis of the product and the analysis of the unconsumed reactant were carried out with **1**-Br-*2*-^{14}C. The results are summarized in Table 2.

In the analysis of the product, the residue from a given reaction mixture was treated with HOAc–AgOAc (6) in order to convert any unconsumed reactant, **1**-Br-*x*-^{14}C, to **1**-OAc-*x*-^{14}C, which in turn was reduced with $LiAlH_4$ to α,α-diphenylacetophenone (**2**). Ketone **2** could then be separated from the product, **1**-OTFE-*x*-^{14}C, by passage through the alumina column. Since the reaction of the labeled

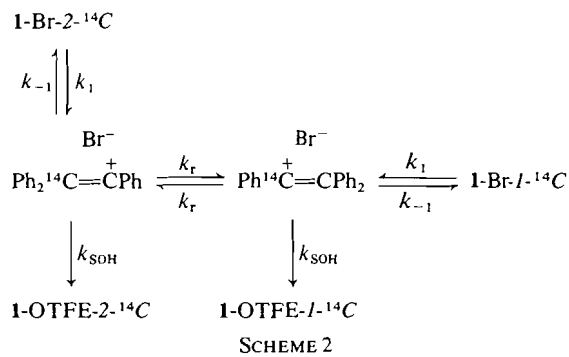
bromide with HOAc–AgOAc is known to give rise to 6–7% scrambling (6), ketone **2**, recovered from the above treatment, could not be used to determine the extent of scrambling in the recovered reactant. However, the treatment effectively removed the unconsumed reactant from the reaction product. In a control experiment, ordinary **1**-Br, in the presence of **1**-OTFE-*2*-^{14}C, was subjected to the above treatment to give **2** which was found to be nonradioactive, indicating that there was no cleavage of the ether, **1**-OTFE-*2*-^{14}C, during the conversion of **1**-Br to **2**.

In the experiments with **1**-Br-*2*-^{14}C in which the product was analyzed for isotopic scrambling (experiments 21, 22, 27, 28, 31–33, Table 2), after removal of the **1**-Br-*x*-^{14}C as described above, the recovered product, **1**-OTFE-*x*-^{14}C, was hydrolyzed in 70% EtOH containing 0.7 *N* HCl (17) to give **2**, which in turn was degraded in the usual way by reduction to **3** followed by oxidation to **4** to give the extent of scrambling. In another control experiment, it was found that the hydrolysis of **1**-OTFE-*2*-^{14}C in 70% EtOH containing 0.7 *N* HCl gave the unrearranged **2**-*2*-^{14}C, indicating no scrambling during the hydrolysis.

When the unconsumed reactant was analyzed for isotopic scrambling (experiments 19, 20, 23–26, 29, 30, Table 2), the solid residue from each reaction mixture was diluted with ordinary **1**-Br as carrier and then treated in the same way as in the case of the recovered reactant from the solvolyses in HOAc–H_2O. Thus the **1**-Br-*x*-^{14}C was converted to the triazene via the Grignard and then decomposed in acetone–H_2O–$HClO_4$ to give **2**, which in turn was degraded to give the amount of scrambling.

From Table 2, it is seen that unlike solvolyses in HOAc–H_2O, isotopic scrambling was observed in the recovered reactant as well as in the product, and the amount of scrambling was found to increase with an increase in reaction time. Interestingly, for a given reaction time, the extents of scrambling in the product and in the recovered reactant were essentially the same (cf. experiments 21–26 and experiments 27–30, Table 2). The presence of external bromide ion, added as Et_4NBr, did not affect the amount of scrambling in either the product or the recovered reactant, again supporting the earlier conclusion that the scrambling occurred in the ion-pair stage. The return process in the trifluoroethanolysis of **1**-Br-*2*-^{14}C, therefore, is an ion-pair return and not an external ion return. A recent demonstration of an internal return process in a vinyl cationic system was reported by Hanack *et al.* (22) for the solvolysis of (1-bromo-1-methylmethylene)-cyclopropane to give the rearranged product, 1-bromo-2-methylcyclobutene.

The mechanism for the trifluoroethanolysis of **1**-Br-*2*-^{14}C may be depicted by Scheme 2. A steady



SCHEME 2

state treatment for the processes in Scheme 2 gives the following relationship:

$$\frac{d[\textbf{1}\text{-OTFE-}1\text{-}^{14}C]/dt}{d[\textbf{1}\text{-OTFE-}2\text{-}^{14}C]/dt} = \frac{(k_{-1} + k_{SOH})[\textbf{1}\text{-Br-}1\text{-}^{14}C] + k_r([\textbf{1}\text{-Br-}2\text{-}^{14}C] + [\textbf{1}\text{-Br-}1\text{-}^{14}C])}{(k_{-1} + k_{SOH})[\textbf{1}\text{-Br-}2\text{-}^{14}C] + k_r([\textbf{1}\text{-Br-}2\text{-}^{14}C] + [\textbf{1}\text{-Br-}1\text{-}^{14}C])}$$

Since the formation of the unrearranged and rearranged products would depend on the concentration of the reactant, the extents of scrambling should be different for different extents of reaction, and this was observed (Table 2). If $k_r([\textbf{1}\text{-Br-}2\text{-}^{14}C] + [\textbf{1}\text{-Br-}1\text{-}^{14}C])$ is negligible when compared with $(k_{-1} + k_{SOH})[\textbf{1}\text{-Br-}1\text{-}^{14}C]$ and with $(k_{-1} + k_{SOH}) \times [\textbf{1}\text{-Br-}2\text{-}^{14}C]$, then $[\textbf{1}\text{-OTFE-}1\text{-}^{14}C]/[\textbf{1}\text{-OTFE-}2\text{-}^{14}C] = [\textbf{1}\text{-Br-}1\text{-}^{14}C]/[\textbf{1}\text{-Br-}2\text{-}^{14}C]$, in agreement with the observation in experiments 21–26 and 27–30 that the extent of scrambling was the same in the product and in the recovered reactant. At very early stages of the reaction, the above result may not be observed since $[\textbf{1}\text{-Br-}1\text{-}^{14}C]$ arising from the return process would not have been very high. In experiments 21–30, however, the reaction has proceeded to a significant extent and the concentration of **1**-Br-*1*-^{14}C would have been built up appreciably so that $k_r([\textbf{1}\text{-Br-}2\text{-}^{14}C] + [\textbf{1}\text{-Br-}1\text{-}^{14}C])$ is negligible compared to $(k_{-1} + k_{SOH})[\textbf{1}\text{-Br-}1\text{-}^{14}C]$.

In conclusion, the present work has provided much additional information on the degenerate rearrangement arising from 1,2-phenyl shifts in the triphenylvinyl cationic system. An important role is attributed to ion pairs and ion-pair return is shown to occur in the reaction of **1**-Br-*2*-^{14}C with TFE but not with HOAc–H_2O. The mechanistic processes that take place during the solvolysis of **1**-Br-*2*-^{14}C in

HOAc–H_2O and in TFE, respectively, are adequately depicted by Schemes 1 and 2.

Experimental

Solvolysis of Triphenylvinyl-2-^{14}C Bromide (1-Br-2-^{14}C) in HOAc–H_2O

1-Br-*2*-^{14}C was prepared as described previously (5). The solvents used were made up of HOAc–H_2O (by volume) in the proportions of 50:50, 60:40, 70:30, 80:20, and 90:10. The reactions were carried out by heating 25–30 m*M* **1**-Br-*2*-^{14}C in sealed tubes at 150 ± 2°C for periods varying from 1–8 days (see Table 1). In 70% HOAc, experiments were also carried out with the presence of about 3 equiv. of NaOAc or NaBr. An illustration of the experimental procedure is given below.

A solution of 210 mg (0.63 mmol) of **1**-Br-*2*-^{14}C and 160 mg (1.96 mmol) of NaOAc in 25 ml of 70% HOAc in a sealed tube was heated in an oil bath at 150 ± 2°C for 2 days. The tube was cooled and opened, and weighed quantities (about 200 mg) of ordinary **1**-Br and α,α-diphenylacetophenone (**2**) were added as carriers. The mixture was extracted with ether (3 × 25 ml) and the extract washed with H_2O. The liberated bromide ion in the combined aqueous phase was determined by potentiometric titration (17) to give the extent of reaction. The ether extract was dried over $MgSO_4$ and the solvent was removed under reduced pressure at room temperature to give an oily residue. Upon passage through an alumina column (2.5 × 25 cm packed with untreated adsorption alumina) and elution with 90% petroleum ether – 10% ether, the unconsumed reactant (**1**-Br-*x*-^{14}C) was separated from the reaction product (**2**-*x*-^{14}C). The **1**-Br-*x*-^{14}C was the first to be eluted, and recoveries of both **1**-Br-*x*-^{14}C and **2**-*x*-^{14}C were aided by monitoring with nmr. A small amount of the product was recrystallized from CH_3OH and its specific activity determined to give the extent of reaction by isotopic dilution calculations. The remainder of the product was diluted further with carrier to give about 1.0 g of material for degradation by $LiAlH_4$ reduction to 1,2,2-triphenylethanol (**3**) and $KMnO_4$ oxidation to benzophenone (**4**) by methods as described previously (5).

The recovered unconsumed reactant, **1**-Br-*x*-^{14}C, was dried overnight in a vacuum desiccator, mixed with more carrier, converted to the Grignard reagent, **1**-MgBr-*x*-^{14}C, and treated with PhN_3 to give the triazene, **1**-NNNHPh-*x*-^{14}C. Decomposition of the triazene in 90% acetone – 10% H_2O containing 0.1% $HClO_4$ gave **2**-*x*-^{14}C which was then degraded in the usual way. The procedures for the conversion of **1**-Br-*2*-^{14}C to **2**-*2*-^{14}C without scrambling by the above series of reactions have been reported in a previous study (9).

Solvolyses of 1-Br-2-^{14}C in 2,2,2-Trifluoroethanol (TFE)

The trifluoroethanolyses were carried out in sealed tubes with 0.12 *M* **1**-Br-*2*-^{14}C, 0.36 *M* 2,6-lutidine, and with the absence or presence of about 1.5 or 3 equiv. of Et_4NBr. The reaction mixtures were heated at 150 ± 2°C for periods varying from 1–20 days. A description of the experimental procedure is given below.

A solution of 200 mg (0.60 mmol) of **1**-Br-*2*-^{14}C, 200 mg (1.8 mmol) of 2,6-lutidine, and 200 mg (0.95 mmol) of Et_4NBr in 5 ml of TFE in a sealed tube was heated in an oil bath at 150 ± 2°C for the desired period. After cooling, the material was poured into 80 ml of ether and the ether solution was washed three times with H_2O. The bromide ion in the aqueous washing was determined by potentiometric titration to give the extent of reaction. The product, triphenylvinyl-*x*-^{14}C 2,2,2-trifluoroethyl ether (**1**-OTFE-*x*-^{14}C) and unconsumed reactant, **1**-Br-*x*-^{14}C, could not be separated by the alumina column. Thus separate experiments were carried out in order to obtain purified α,α-diphenylacetophenone (**2**-*x*-^{14}C) from the product or from the unconsumed reactant.

In order to recover the reaction product, to the washed ether solution of the reaction mixture ordinary **1**-Br and **1**-OTFE (about 200 mg each) were added as carriers. After drying, the solvent was removed and the residue was heated under reflux for 18 h with 10 ml of HOAc containing 200 mg AgOAc. This treatment converted all the **1**-Br-*x*-^{14}C to 1-OAc-*x*-^{14}C, which was worked up and reduced with $LiAlH_4$ as previously described (5) to give **2**-*x*-^{14}C. On passage through the alumina column, the original reaction product, **1**-OTFE-*x*-^{14}C, could be separated by elution with petroleum ether from the **2**-*x*-^{14}C that was derived from the unconsumed reactant, **1**-Br-*x*-^{14}C. After removal of the solvent from the eluate, the residual **1**-OTFE-*x*-^{14}C was hydrolyzed to give another sample of **2**-*x*-^{14}C by refluxing in 14 ml of EtOH and 6 ml of 0.7 *N* HCl for 4 days (17). Nuclear magnetic resonance examination showed that even after 4 days, the hydrolysis was only 75–80% complete. The **2**-*x*-^{14}C so obtained was purified by passage through the alumina column and then degraded, with the aid of carriers if necessary, to **3** and **4** in the usual way.

To obtain a pure sample of **2**-*x*-^{14}C that was derived from the unconsumed reactant, **1**-Br-*x*-^{14}C, the washed ether solution of the reaction mixture was dried over $MgSO_4$. The solvent was removed and the residue was dried overnight in a vacuum desiccator. Inactive **1**-Br was added as carrier and the material was subjected to the same series of reactions as described in the treatment of the recovered **1**-Br-*x*-^{14}C from the solvolysis in HOAc–H_2O. In this way the **1**-Br-*x*-^{14}C was converted via the triazene to **2**-*x*-^{14}C which was purified by passage through the alumina column before it was degraded to **3** and **4**. The purification by column chromatography was necessary because, in this treatment, a small amount of the **1**-Br-*x*-^{14}C remained unreacted and this, together with the reaction product, **1**-OTFE-*x*-^{14}C, and other contaminants such as the excess PhN_3, were separated from the **2**-*x*-^{14}C by the alumina column.

Control Experiments

(*a*) Triphenylvinyl-*2*-^{14}C-phenyltriazene (**1**-NNNHPh-*2*-^{14}C) (9) was treated with TFE containing 0.1% $HClO_4$ to give **1**-OTFE-*2*-^{14}C. Hydrolysis of 200 mg of **1**-OTFE-*2*-^{14}C in 14 ml of EtOH and 6 ml of 0.7 *N* HCl by heating the mixture under reflux for 4 days gave a sample of **2**-*2*-^{14}C without any isotopic scrambling, indicating that the hydrolysis of the ether product did not cause any rearrangement.

(*b*) When ordinary **1**-Br, in the presence of some **1**-OTFE-*2*-^{14}C, was converted to **2** through the triazene as was utilized in the treatment of the recovered unconsumed reactant, the sample of **2** so obtained was not radioactive, indicating no conversion of any **1**-OTFE-*2*-^{14}C to **2**-^{14}C during these treatments.

(*c*) After 200 mg of **1**-OTFE-*2*-^{14}C was heated under reflux for 18 h in 10 ml of HOAc containing 200 mg of AgOAc, it was recovered and then hydrolyzed in EtOH – 0.7 *N* HCl. The product obtained was the unrearranged **2**-*2*-^{14}C, indicating that the treatment with HOAc–AgOAc to destroy the unconsumed reactant did not cause any scrambling in the reaction product.

Received March 30, 1978

HERBERT L. HOLLAND, DONALD W. HUGHES, DAVID B. MACLEAN, and RUSSELL G. A. RODRIGO. Can. J. Chem. **56**, 2467 (1978).

The ^{13}C magnetic resonance spectrum of cancentrine is reported. Assignments of chemical shifts have been made by comparison of the cancentrine spectrum with the published spectra of codeine, codeinone, and cularine and with the spectra reported here for the first time of 9,10-dihydrocancentrine methine-*O*-methyl ether and 10-oxocodeinone. The spectral data so obtained have been used to interpret the ^{13}C spectrum of 10-oxocancentrine, a new alkaloid of the cancentrine family, and to verify the structure deduced for it from ^{1}H nmr, ir, uv, and mass spectral data.

HERBERT L. HOLLAND, DONALD W. HUGHES, DAVID B. MACLEAN et RUSSELL G. A. RODRIGO. Can. J. Chem. **56**, 2467 (1978).

On rapporte le spectre de résonance magnétique nucléaire du ^{13}C de la cancentrine. On a pu faire les attributions des déplacements chimiques par comparaison du spectre de la cancentrine avec les spectres publiés de la codéine, de la codéinone et de la cularine et avec les spectres que l'on rapporte ici pour la première fois de l'éther dihydro-9,10 cancentrine méthine-*O*-méthyle et de l'oxo-10 codéinone. On a utilisé les données spectrales pour interpréter le spectre ^{13}C de l'oxo-10 cancentrine, un nouvel alcaloïde de la famille de cancentrine et pour vérifier la structure déduite à partir de données de rmn ^{1}H, ir, uv et de spectrométrie de masse.
[Traduit par le journal]

The cancentrine alkaloids were first isolated by Manske in 1932 (1) and in 1970 the structure of cancentrine **1***a* was elucidated (2). It is composed of a morphine-like unit and a cularine-like unit which are fused together as shown in Fig. 1. Other alkaloids of established structure in this series are the dehydrocancentrines, A and B (3). They differ from cancentrine in that the former has a double bond between C-8 and C-14 and the latter a double bond between C-31 and C-32. Here, we report a ^{13}C magnetic resonance study of cancentrine, and some model compounds. The ^{13}C information so obtained has been used in the elucidation of the structure of a new alkaloid in this series, 10-oxocancentrine **1***b*.

The interpretation of the ^{13}C spectrum of cancentrine (Table 1) was aided greatly by reference to the published spectra of codeine **2***a* and cularine **3** (Fig. 2 and Table 2). Comparison of the aliphatic region of the codeine (**2***a*) spectrum (4) with that of cancentrine (**1***a*) enabled us to assign the resonances at C-10, C-15, C-16, and N—CH_3 of **1***a*; these assignments were substantiated by examination of the off-resonance spectrum. The high-field resonance of C-10, a benzylic carbon, has been ascribed to a γ steric interaction of the N—CH_3 (4). The other high-field signal in the spectrum of **1***a* at 29.0 ppm has been assigned to C-31 by reference to the cularine **3** spectrum (5). The off-resonance spectrum of **1***a* showed a singlet at 51.4 ppm, a doublet at 46.2 ppm, and a triplet at 40.2 ppm that are attributed to carbon atoms 13, 14, and 8, respectively. The transformation of the six-membered ring C of codeine to the five-membered alicyclic spiro ring present in cancentrine has caused a deshielding of C-13 and C-14 relative to the corresponding carbon atoms of codeine. A similar effect is observed at C-5. The splitting patterns of C-9 and C-32 in the off-resonance spectrum are partially obscured by the overlapping methoxy resonances at 56.5 ppm but the assignment of C-9 to the signal at 58.8 ppm and of C-32 to the signal at 57.8 ppm seem secure in view of the C-9 resonance in codeine at 58.7 ppm. The remaining signal in the aliphatic region at 79.1 ppm is assigned to the spiro carbon, C-6.

The oxygenated aromatic carbon atoms of cancentrine all fall in the range, 135–150 ppm whereas the remaining aromatic carbon atoms, whether substituted with H or carbon, fall in the region 100–130 ppm. By off-resonance decoupling it was

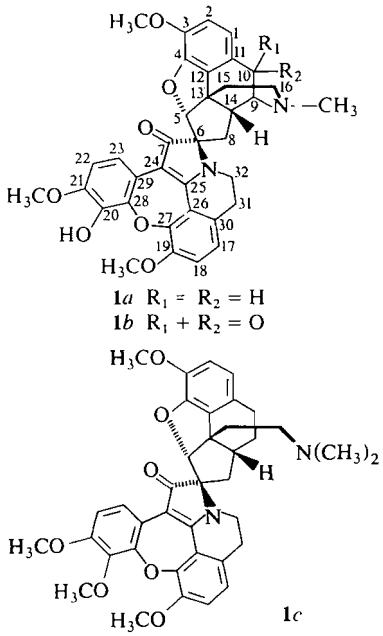

FIG. 1. Structures of cancentrine (**1***a*), 10-oxocancentrine (**1***b*), and 9,10-dihydrocancentrine methine-*O*-methyl ether (**1***c*).

possible in most cases to differentiate the protonated from the nonprotonated carbon atoms. For those cases where overlap of signals made this difficult or impossible the technique of selective enhancement of quaternary carbon signals (6) was used. A low power and modulated decoupling field was applied to the sample, producing essentially a broadband spectrum composed only of the quaternary carbons. From a combination of the low power decoupled and the off-resonance spectra the signal at 119.7 ppm was found to result from the overlap of the signals of both a protonated and a carbon substituted aromatic carbon assigned to C-1 and C-29, respectively, by comparison to the spectra of codeine (**2***a*) and cularine (**3**) (Table 2).

The assignments of carbons 2 through 4 are consistent with the codeine data; however, the similarity in chemical shifts for carbon atoms 11, 12, and 30 did not allow unambiguous assignments to be made. The C-3 and C-4 assignments are in accord with the correlation noted by Terui *et al.* (4) between the peak intensity and the spin–lattice relaxation times, the latter determined by Wehrli for codeine (7). Carbon 4 of **1***a* does not have any neighbouring protons to provide dipolar relaxation and therefore should have a longer T_1 and a lower intensity because of saturation. Accordingly the signal of lower intensity was assigned to C-4.

By reference to the cularine **3** data in Table 2 tentative assignments for the remaining aromatic signals were made. The chemical shifts of C-30 and C-26 were assigned in reverse order to the corresponding cularine carbons, 8a and 4a, because C-26 does not have any neighbouring protons and would be expected to be of lower intensity than the peak assigned to C-30 and this is the case. Of the carbon atoms containing oxygen substituents, C-20 was assigned to the signal at 138.0 ppm because the hydroxy group deshields the directly bonded carbon atom less than a methoxy group (8, 9). Experimental verification is provided in the discussion of **1***c*. The signals of carbons 19 and 23 were differentiated from the remaining low-field aromatic signals by their higher peak intensity. The signals at 194.0, 160.1, and 104.3 ppm are attributed to the carbon atoms of the α,β-saturated carbonyl system, C-7, C-25, and C-24, respectively.

Further evidence for the assignments made in the spectrum of **1***a* was provided by an examination of the spectrum of 9,10-dihydrocancentrine methine-*O*-

FIG. 2. Structures of codeine (**2***a*), codeinone (**2***b*), 10-oxocodeinone (**2***c*), and cularine (**3**).

methyl ether (**1***c*) (10). In **1***c* where the N—C-9 bond is broken the chemical shift of C-9 has moved upfield from 58.8 ppm in cancentrine (**1***a*) to 23.7 ppm. Carbon-14 is also shielded relative to **1***a* because of the elimination of the β-nitrogen substituent effect. Carbon-10 is assigned to 26.2 ppm; it is deshielded relative to cancentrine because of the removal of the γ steric interaction with the NCH_3. The chemical shift equivalence of C-16 and the $N(CH_3)_2$ group was confirmed by examination of the off-resonance spectrum in which the methylene triplet of C-16 was centered in the methyl quartet. The off-resonance spectrum also enabled the peak at 61.5 ppm to be assigned to the C-20 methoxy group. This assignment is consistent with other systems containing a sterically crowded methoxy group (11, 12). Carbon-32 could be only tentatively assigned to the signal at 55.8 ppm because of the overlap of its splitting pattern with those of the methoxy carbons in the off-resonance spectrum. By the technique of selective enhancement of quaternary carbons the signal at 56.4 ppm was assigned to C-13.

Using the procedures described in the analysis of the aromatic region of the cancentrine spectrum, the corresponding aromatic carbon atoms of the morphine part of **1***c* were readily assigned. Similarly in the cularine portion of **1***c* the carbon atoms of the ring containing the single methoxy substituent at C-19 remain essentially unchanged relative to **1***a* except for C-19 itself which is deshielded. The conversion of the hydroxy group at C-20 to a methoxy shifted the peak at 138.0 ppm in the spectrum of **1***a* to 147.8 ppm in **1***c*. There was also a deshielding of the resonance for C-23 which now appears at 121.1 ppm. The signals at 151.2 and 152.3 ppm can be assigned either to C-21 or C-19; these signals were more intense than the signals of the other carbons of the cularine portion of the molecule bearing oxygen substituents because of the dipolar relaxation provided by the neighbouring protons on carbons 22 and 18, respectively.

The new cancentrine alkaloid, 10-oxocancentrine has the following spectral properties. Its 220 MHz ^1H nmr spectrum differs from that of cancentrine in several respects. There are no signals at 2.37 and 3.18 ppm corresponding to the 10α and 10β protons, respectively, in cancentrine (2) (Table 3) and there is also a simplification of the multiplet splitting for the C-9 proton now appearing at 3.39 ppm. The aromatic region of the ^1H spectrum of cancentrine (**1***a*) contains three pairs of AB quartets whose chemical shift assignments were determined by both nOe experiments and acetylation shifts (2, 10). In

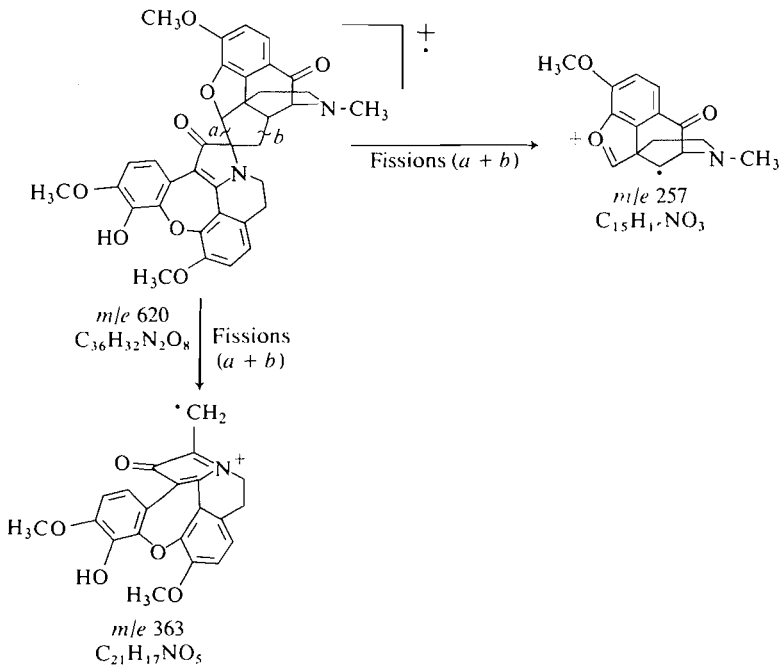

FIG. 3. Fragmentation of 10-oxocancentrine.

cancentrine the two high-field aromatic doublets at 6.65 (J = 8.8 Hz) and 6.70 ppm (J = 8.4 Hz) were assigned to H-1 and H-22, respectively. The spectrum of 10-oxocancentrine (**1***b*) has only one doublet at 6.67 ppm (J = 8.6 Hz) and a doublet centered at 7.45 ppm (J = 8.7 Hz). This new low-field doublet is attributed to H-1 because it is now deshielded by the carbonyl group considered to be situated at C-10. The remaining aromatic resonances of **1***b* show the same spectral pattern as cancentrine except for a slight deshielding (Table 3).

The mass spectrum of **1***b* shows a molecular ion at *m/e* 620 with a composition of $C_{36}H_{32}N_2O_8$. This ion loses CH_3 (*m/e* 605, $C_{35}H_{29}N_2O_8$) and OH (*m/e* 603, $C_{36}H_{31}N_2O_7$). Peaks which provided important structural information occurred at *m/e* 257 and 363 with compositions $C_{15}H_{15}NO_3$ and $C_{21}H_{17}NO_5$, respectively. These fragments in analogy with the mass spectrum of cancentrine (10), are considered to correspond to the morphine (*m/e* 257) and cularine (*m/e* 363) portions of the molecule and result from a fission of the bonds marked *a* and *b* in Fig. 3. Cancentrine undergoes an identical fragmentation to produce ions at *m/e* 243 ($C_{15}H_{17}NO_2$) and *m/e* 363 ($C_{21}H_{17}NO_5$). This difference of 14 mass units in the morphine fragment can be accounted for by the presence of the carbonyl oxygen, replacing the methylene at C-10 of cancentrine.

The ir spectrum was similar to that of the other cancentrine alkaloids (2, 3, 10) showing a phenolic OH stretching at 3450 cm^{-1} and a carbonyl absorption at 1668 cm^{-1}. The single absorption at 1668 cm^{-1} was at first misleading but is not surprising in view of the structure subsequently deduced. Since the ^1H nmr and mass spectral data clearly show a change in functionality only at C-10, structure **1***b* was considered for 10-oxocancentrine.

Further evidence in support of structure **1***b* was gained from a study of its ^{13}C nmr spectrum. The spectrum of the model compound 10-oxocodeinone (**2***c*) was recorded for comparison. The chemical shift assignments of **2***c* were made by comparison to the published spectrum of codeinone (**2***b*) (4). The new carbonyl signal of **2***c* appears at 190.4 ppm indicative of a conjugative interaction with the aromatic ring and this is substantiated by both the ir carbonyl absorption of 1675 cm^{-1} and a deshielding of carbons 3 and 12. The only aliphatic carbons that show a significant change relative to **2***b* are C-9 and C-14 which are deshielded as a result of the α and β substituent effects of the C-10 carbonyl group.

Examination of the aliphatic region of the ^{13}C spectrum of **1***b* showed the absence of a signal at 20.4 ppm corresponding to that of C-10 in cancentrine. There was also a deshielding of the C-9 resonance at 58.8 ppm in cancentrine to 68.0 ppm in **1***b*. The other aliphatic carbons of 10-oxocancentrine are essentially unchanged relative to cancentrine except for a deshielding of C-14 to 48.9 ppm. The deshielding of carbons 9 and 14 is similar in magni-

tude to that experienced by the corresponding carbons in **2***c*. These results correlate with the proton data in locating the carbonyl at C-10.

Because of the limited quantities of material the microprobe spectrum of 10-oxocancentrine had a relatively low signal-to-noise ratio for the substituted aromatic carbons and as a result only tentative assignments were made. At the low-field end of the spectrum a pair of signals of approximately equal intensity appear at 193.2 and 196.3 ppm. Since the peak at 193.2 ppm correlates with the chemical shift of C-7 in **1***a* and **1***c*, the other signal at 196.3 ppm was assigned to C-10 even though it is deshielded relative to C-10 in the model **2***c*.

The aromatic carbon chemical shifts for the cularine portion of 10-oxocancentrine were assigned by comparison to **1***a*. The shifts for the codeine substituted aromatic carbons could not be accurately determined but are expected to show a trend similar to those of **2***c* because of the effect of the C-10 carbonyl group.

These studies support the proposed structure **1***b* for 10-oxocancentrine.

Experimental

Apparatus, Methods, and Materials

Natural abundance ^{13}C nuclear magnetic resonance spectra with the exception of **1***b* were recorded on a Bruker WH-90 Fourier transform spectrometer at 22.62 MHz and a probe temperature of +35.0°C. Samples were 0.08–0.15 *M* in $CDCl_3$; TMS was used as an internal reference. Field/frequency locking was provided by the deuterium signal of $CDCl_3$. Spectra were recorded over a 5.0 KHz sweep width in an acquisition time of 1.638 s and using 16 K data points. A 3.7 μs pulse (17° pulse angle) was used. The spectra of **1***a* and **1***c* were obtained in 40 000 transients whereas that of **2***c* required only 3000 scans.

The 220 MHz ^1H magnetic resonance spectra were obtained at the Canadian 220 MHz Centre, University of Toronto, Toronto, Ontario. $CDCl_3$ and TMS were again used as solvent and internal reference, respectively.

Mass spectra were determined on a C.E.C. 21-110B mass spectrometer at an ionizing voltage of 80 eV and a source temperature of 200–250°C. For high resolution work spectra were recorded on plates and accurate mass measurements were made using perfluorokerosene as a marker (13). The composition of all ions discussed in this paper have been checked by high resolution mass spectrometry and agree with calculated values within ±0.005 amu. Infrared spectra were obtained on a Perkin-Elmer 283 spectrometer. A GCA/McPherson Instrument Model 707D spectrometer was used for the uv spectra.

Cancentrine (**1***a*) (1, 3) and 9,10-dihydrocancentrine methine-*O*-methyl ether (**1***c*) (10) have been described previously and 10-oxocodeinone **2***c* (14) was prepared as described below.

10-Oxocancentrine

The isolation and purification of 10-oxocancentrine followed the procedures developed for cancentrine **1***a* (1, 10). In the column chromatograph of the crude mixture of cancentrine alkaloids (silica gel, benzene–acetone–methanol 80:15:5) 10-oxocancentrine is eluted about twice as fast as cancentrine. The compound has the following properties: uv: λ_{max}(EtOH): 268, 284 (sh), 324 (sh), and 436 nm; log ε_{max}: 3.35, 3.34, 2.90, and 2.65, respectively; ir λ_{max}($CHCl_3$): 3450 and 1668 cm^{-1}; ^1H nmr δ: 1.8–3.7 (12H, aliphatic protons), 2.53 (s, 3H, N—CH_3), 3.85 (s, 3H, OCH_3), 3.98 (s, 3H, OCH_3), 4.02 (s, 3H, OCH_3), 4.84 (s, 1H, C—5H), 6.5–7.6 (m, 6H, aromatic protons (assignments given in Table 3)). The molecular formula was established by high resolution mass spectrometry. Calcd. for $C_{36}H_{32}N_2O_8$: 620.216; found: 620.216.

10-Oxocodeinone

A solution of 10-hydroxycodeine (0.5 g) (prepared from codeine phosphate by the procedure of Rapoport and Stevenson (14)) in acetone (50 ml) was cooled to 0°C and then 1.5 ml of standard Jones' reagent was added over 5 min. After stirring for a further 5 min at 0°C, the solution was poured onto 2 *N* $NaHCO_3$ solution (200 ml) and the resulting solution extracted with ether (5 × 75 ml). The ether extract was then dried and evaporated to yield crude 10-oxocodeinone (0.21 g). Recrystallization from anhydrous ether gave a sample melting at 175–178°C. The compound **2***c* had the following properties: uv λ_{max}(EtOH): 237, 287, and 324 (sh) nm; log ε_{max}: 3.25, 3.05, and 2.67, respectively; ir λ_{max} ($CHCl_3$): 1675 and 1620 cm^{-1}; ^1H nmr δ: 2.0–3.5 (6H, aliphatic protons), 2.46 (s, 3H, NCH_3), 3.97 (s, 3H, OCH_3), 4.75 (s, 1H, C—5H), 6.12 and 6.67 (m, 2H, olefinic protons), 6.82 and 7.40 AB (q, J = 8.0 Hz, 2H, aromatic protons). The molecular formula, $C_{18}H_{17}NO_4$, was confirmed by high resolution mass spectrometry.

Acknowledgments

We thank Dr. K. Nakanishi of Columbia University for recording the ^{13}C spectrum of 10-oxocancentrine and the National Research Council of Canada for financial support.

Heats and free energies of mixing of tridodecylamine with nine heptane isomers, two octanes, and one hexane. Disorder and steric hindrance contributions

MICHÈLE COUCHON, PHUONG NGUYEN HONG, AND GENEVIEVE DELMAS[1]

Received April 17, 1978

MICHÈLE COUCHON, PHUONG NGUYEN HONG, and GENEVIEVE DELMAS. Can. J. Chem. **56**, 2472 (1978).

Heats and free energies of mixing have been measured at 298 K for tridodecylamine in n-C_7 and eight branched isomers, n-C_8 and one branched isomer, and a branched hexane. Heats of mixing are such that these systems can be divided in three classes. Class A ($H^E \simeq 90$ J/mol) includes n-C_7 and n-C_8. Class B ($H^E \simeq 295$ J/mol) includes isomers which do not have two substituents on neighbouring carbon atoms, i.e. 2-MeC_6 2,2-diMeC_5, 2,4-diMeC_5, 2,2,4-triMeC_5. Class C which includes isomers having substituents on neighbouring carbon atoms; 2,3-diMeC_5, 2,2,3-triMeC_4, 3-MeC_6, 3,3-diMeC_5, 3-EtC_5, has smaller values of heats of mixing ($H^E \simeq 160$ J/mol). These results are interpreted as not showing an extensive destruction of the correlations of orientations of the dodecyl chains by the linear alkanes of class A. The larger heats of class B are indicative of more disorientations of the long chains by the globular isomers. The smaller values of the heats for class C are seen as the balance of a positive disordering contribution and a negative one. The negative contribution is associated with a sterically hindered character of the compounds having substituents on neighbouring atoms. Free energies of mixing do not separate in the same three classes. This is thought to be due to an enthalpy–entropy compensation in the disordering and steric hindrance contributions. The $X_{12}s_1^{-1}$ parameter of the Flory theory shows the same variation as H^E.

MICHÈLE COUCHON, PHUONG NGUYEN HONG et GENEVIEVE DELMAS. Can. J. Chem. **56**, 2472 (1978).

Nous avons mesuré des chaleurs et énergies libres de mélange à 298 K de la tridodecylamine dans n-C_7 et huit isomères ramifiés, n-C_8 et un isomère ramifié et un hexane ramifié. Les chaleurs de mélange sont telles qu'on peut séparer ces systèmes en trois classes: la classe A ($H^E \simeq 90$ J/mol) comprend n-C_7 et n-C_8. La classe B ($H^E \simeq 295$ J/mol) comprend les isomères ramifiés qui n'ont pas deux substituants sur deux atomes de carbone voisins, i.e. 2-MeC_6, 2,2-diMeC_5, 2,4-diMeC_5, 2,2,4-triMeC_5. La classe C qui comprend les isomères portant des substituants sur des atomes de carbone voisins 2,3-diMeC_5, 2,2,3-triMeC_4, 3-MeC_6, 3,3-diMeC_5, 3-EtC_5 a des chaleurs plus petites ($H^E \simeq 160$ J/mol). Ces résultats sont interprétés comme indiquant une destruction faible des corrélations d'orientations des chaines de la dodecylamine par les alcanes linéaires de la classe A. La destruction de ces corrélations semble bien plus complète par les composés plus globulaires de la classe B. La diminution de H^E pour la classe C serait due à la compensation partielle de deux effets de signe contraire: la chaleur due à la destruction de l'ordre et une contribution négative dite d'empêchement stérique caractéristique des composés substitués plusieurs fois sur le même carbone ou sur des carbones voisins. Les énergies libres de mélange ne se divisent pas apparemment en les mêmes trois classes. Nous pensons que ceci est dû à une compensation entre les contributions enthalpiques et entropiques venant de l'effet de désordre et de celui d'empêchement stérique. Les valeurs calculées du paramètre $X_{12}s_1^{-1}$ de la théorie de Flory varient dans le même sens que les chaleurs.

Heats of mixing of non-polar systems depend on the energy of unlike contacts in relation to that of like contacts. This first contribution H^E(chem) is positive and has been recognized (1). It can be predicted in some cases by current theories based on the analysis of heats of group interactions (2). The second contribution H^E(f.v.) is negative and comes from the difference in degree of thermal expansion or free volume of the two components. H^E(f.v.) can be calculated by the Prigogine–Patterson–Flory theory (3) using an equation of state for the liquids and the solution. Since in non-polar systems, in particular compounds made of CH_3 and CH_2 groups, the difference in cohesive energy between the components is not large, it is quite possible that the negative free volume contribution is larger than the positive H^E(chem) so that the experimental heat is negative. This is indeed the case for mixtures of branched alkanes such as 2,3-dimethylbutane and heptamethylnonane whose H^E(exp.) is equal to -55 J/mol (4). However, when a branched alkane is mixed with a long linear alkane, the heats are always positive, indicating that another positive term has changed the balance of the two cited contributions. An example of such a system is 2,3-dimethylbutane + n-hexadecane for which the H^E(exp.) is equal to 232 J/mol (4).

Systematic work on mixtures of globular molecules (SnR_4 (5), NR_3 (22), dibromoethane (6), branched alkanes) with long chain compounds (alkanes, SnR_4, NR_3, alcohol, or halides (10)) has shown positive heat of mixing as a general result. Patterson and coworkers (8) and Turrell and Delmas (9) while studying thermodynamical results and Bothorel (8, 11) while making Rayleigh scattering observations on alkanes and on alkane solutions have made the hypothesis of the existence of order or correlations of orientations in long-chain alkanes of long chain derivatives. Since interactions between aligned chains are energetically more favorable than between randomly oriented chains, an ordered liquid becomes thermodynamically more stable than a non-ordered one. The mixing of an ordered liquid with a non-ordered one destroys the correlations of orientations of the ordered liquid. This destruction of order is accompanied by a positive contribution to the heat of mixing, H^E(dis.). One CH_3 group placed in the middle of the chain significantly prevents the orientations of the chain in the pure liquid. The importance of this effect on the heats can be seen in the following two systems: the heat of mixing of 2,3-dimethylbutane with n-C_{16} is 232 J/mol while it is only 79 J/mol with the 6-methylpentadecane (8*a*). Globular isotropic molecules do not have orientational order.

This third contribution to the heat of mixing does not exist in mixtures of non-ordered globular molecules, it exists in much smaller significance in mixtures of two ordered liquids because of the fitting together of the chains of the two different components (7). Analysis of the heat of mixing of chain-like ordered compounds with globular molecules has shown that the heat of disordering (*a*) in most cases does not depend on the order-breaker used in the mixture, (*b*) increases linearly with the chain length of the chain-like compound (9), (*c*) is quite similar in the SnR_4 or NR_3 compounds having the same chain length but is smaller in alkanes of the same chain length (22), (*d*) is the main contribution to the experimental heat of mixing in many non-polar mixtures of an ordered and non-ordered compound, (*e*) is measurable on mixtures having large heat of mixing as those involving long-chain alcohols or chlorinated compounds (10). The aim of this paper is to investigate another contribution to the heat of mixing, the steric hindrance contribution which will be described in the following paragraph.

H^E(dis.) is found almost independant of the order-breakers but very significant exceptions have been found where H^E(dis.) is much smaller than expected. The order-breaker involved in these cases is either a branched alkane or a tetraalkyl tin derivative or a trialkylamine. For the branched alkane, the effect is larger when the methyl or ethyl substituents on the chain are on the same carbon atom or on neighbouring carbon atoms. For the tin derivatives the effect appears to exist mainly for the propyl and ethyl derivatives (5).

Other investigations made on the heats of mixing of *n*-hexadecane with 21 branched nonanes (8*b*) and mixtures involving tetralkyl or trialkylderivatives (22) have shown that the effect occurs in different systems. To interpret these smaller heats it was assumed that another negative contribution to the heats was present when one of the components of the mixture was sterically hindered. The sign of this contribution is quite unusual for non-polar systems. Its molecular origin is not clearly identified but its sign corresponds to a better packing of the unlike molecules in solution than of the like molecules in the pure liquids. It could also be due to a loss of mobility either of the sterically hindered compounds or of the second component or of both in the solution. This contribution has been called condensation contribution (8*a*) or recently steric hindrance contribution (5). In a later work (22), the magnitude of the steric hindrance contribution has been estimated and found to be, for a given sterically hindered compound, proportional to the volume of the second component. This fourth contribution to the heats, H^E(ster. hind.) can occur in systems where there is no disordering contribution so that the total experimental heat will be negative. A few examples have indeed been found in which the free volume contribution (being negligible) cannot be the origin of the negative experimental heats of mixing. Two remarkable examples can be given: one with a branched alkane 3,3-diethylpentane and the other with tetrapropyl tin as sterically hindered components. The heat of mixing for 3,3-diethylpentane + n-C_8 and tetrapropyltin + heptamethylnonane[2] are respectively -82 (12) and -83 J/mol. As the other contribution in H^E(chem.), H^E(f.v.), H^E(dis.) are not important in these systems, it is likely that the main contribution to the experimental heats is H^E(ster. hind.).

In this work, the steric hindrance contribution to the heat of mixing and free energies will be investigated. A series of branched heptanes was chosen because the different isomers were likely to have different degrees of steric hindrance and also because their vapour pressure at 298 K was high enough for vapour pressure measurements. The second component tridodecylamine was chosen because the steric hindrance effect is known to occur with long-chain compounds and also because its vapour pressure at 298 K is negligible.

The present work gives the values of H^E and G^E

at 298 K of tridodecylamine with the following twelve compounds as second component: (*a*) n-C_7 and eight branched heptanes 2,2-diMeC_5, 2-MeC_6, 2,4-diMeC_5, 2,2,3-triMeC_4, 3-MeC_6, 3-EtC_5, 3,3-diMeC_5, 2,3-diMeC_5, (*b*) one branched hexane 2,3-diMeC_4, (*c*) n-C_8 and one branched octane 2,2,4-triMeC_5. The name tridodecylamine is shortened in the paper to $NDodec_3$.

Experimental

Calorimetry

The heat of mixing was measured with a tilting Tian-Calvet calorimeter. Details of the instrument, the cells, and the calibration can be found in ref. 9. Agreement was better than 2% with the reference system benzene + carbon tetrachloride (13). For each system five to eight runs were made to obtain the maximum and the concentration dependance of the heat of mixing.

Vapour Pressure Measurements

The vapour sorption method was used for the determination of activity coefficients and Gibbs free energy data and hence excess entropies. The vacuum microbalance system was essentially the same as that described by Peterson and Martire (14) or Barbe and Patterson (15). The Setaram (Lyon, France model MTB 10-8) electrobalance was incorporated in a vacuum line for accurate weight determination. The mole fraction of the liquid mixture was then calculated from the increase in weight (measured within ±0.01 mg) of the sample upon introduction of a vapour solute into the system. The pressure of the system was measured with a mercury manometer (±0.08 mm) and corrections were made for the standard conditions of temperature and density of mercury at 0°C as well as for the scale calibration temperature of brass. The sample temperature set at 298 K was measured with a quartz thermometer (model 2801A, Hewlett–Packard Co.) and thermostatted with circulating water within ±0.02 K. Solvents and samples were degassed before each run and equilibrium of the mixing process was achieved when the weight change measured on the Setaram recorder became negligible. Ten to fifteen concentrations were made for each system with the reference system n-C_6 + n-C_{16}; our points agree to within 4% of the published value (16).

Chemicals

Tridodecylamine comes from the same source as in previous work (1, 2), namely, the Eastmann Company. The heptanes come from the Chemical Samples Co. They were distilled in the vacuum system.

Parameters for the Pure Components

The density, expansion coefficient, and thermal pressure coefficient of tridodecylamine were obtained from the previous work (17). The same data on the branched heptanes were obtained from literature (18). Table 1 gives d, α, γ, and the reduced parameter for the volume (V^*) and for the pressure (P^*) calculated with the van der Waals equation of state. The surface-to-volume ratios used in the Flory theory to characterize the shape of the molecules have been calculated as is usually done for the alkanes (3*c*) and are presented in Table 1. In the case of compounds with several methyl or ethyl substituents, a more detailed model with several cylinders rather than one as in the linear alkanes was used. However, the surface-to-volume ratios were not found to be very significantly different. The $X_{12}s_1^{-1}$ parameter calculated below is, in any case, hardly dependant on the surface-to-volume ratio parameter.

Calculation of the Free Volume Contribution

Enthalpy

We have chosen to apply the approximate form (4, 8*a*) of the Prigogine theory which separates the interactional and free volume contributions. H^E(f.v.) is given by eq. [1]

$$[1]\quad H^E(\text{f.v.})/(x_1U_1^* + x_2U_2^*) = \tilde{C}_p(\tilde{T}_U)[\psi_1\tilde{T}_1 + \psi_2\tilde{T}_2 - \tilde{T}_U]$$

Here $\tilde{T}_U$ is an average reduced temperature for the solution appropriate to the energy, U, and is defined by

$$[2]\quad \tilde{U}(\tilde{T}_U) = \psi_1\tilde{U}(\tilde{T}_1) + \psi_2\tilde{U}(\tilde{T}_2)$$

The reducing parameter for the energy U^* ($\tilde{U} = U/U^*$) can be obtained from experimental data since $U^* = P^*V^*$. In the van der Waals model used by Flory $\tilde{U} = -1/\tilde{v}$ so that eq. [2] becomes $1/\tilde{v}_U = \psi_1/\tilde{v}_1 + \psi_2/\tilde{v}_2$. The ψ's are energy fractions, i.e. $\psi_1 = x_1U_1^*/(x_1U_1^* + x_2U_2^*)$. The reduced volume of the

[a]Corresponding number on the graphs.

pure components are obtained from their expansion coefficients α and $\tilde{v}^{1/3} = [(4/3)\alpha T + 1]/(\alpha T + 1)$ and their reduced temperature $\tilde{T}_1$ and $\tilde{T}_2$ by $\tilde{T} = \tilde{v}^{-1}(1 - \tilde{v}^{-1/3})\tilde{C}_p(\tilde{T}_U)$ in eq. [1] is $[(4/3)\tilde{v}^{-1/3} - 1]^{-1}$. The interactional contribution expressed in terms of the Flory parameter X_{12} is obtained from the experimental heat and H^E(f.v.).

$$[3]\quad [H^L(\text{exp.}) - H^L(\text{f.v.})]/(x_1U_1^* + x_2U_2^*) = X_{12}\psi_1\frac{\theta_2}{P^*}f(\tilde{v}_U)$$

$f(\tilde{v}_U) = (4\tilde{v}_U - 3\tilde{v}_U^{4/3})^{-1}$ corresponds to $[-\tilde{U}(\tilde{T}_U) + \tilde{T}_U\tilde{C}_p(\tilde{T}_U)]$ in the Van der Waals model. Its value is not far from 1. θ_2 is a surface fraction defined by $x_2V_2^*s_2/(x_2V_2^*s_2 + x_1V_1^*s_1)$. The parameter $X_{12}s_1^{-1}$ has been tabulated instead of X_{12} because it does not depend on which compound has been chosen as the first component ($X_{12}s_1^{-1} = X_{21}s_2^{-1}$).

Entropy

The contribution to the entropy of mixing obtained from the difference in free volume is negative as the enthalpic contribution. It can be calculated in the same way as H^E(f.v.), from the expansion coefficients of the two components and a model:

$$[4]\quad TS^E(\text{f.v.})/(x_1U_1^* + x_2U_2^*) = [\tilde{S}(\tilde{T}_{TS}) + \tilde{C}_p(\tilde{T}_{TS})] \times [\psi_1\tilde{T}_1 + \psi_2\tilde{T}_2 - \tilde{T}_{TS}]$$

Here $\tilde{T}_{TS}$ is very close to $\tilde{T}_U$ defined by eq. [2] and is an average reduced temperature for the solution appropriate to the quantity $\tilde{T}\tilde{S}$ given by:

$$[5]\quad \tilde{T}_{TS}\tilde{S}(\tilde{T}_{TS}) = \psi_1\tilde{T}_1\tilde{S}(\tilde{T}_1) + \psi_2\tilde{T}_2\tilde{S}(\tilde{T}_2)$$

The reduced entropy $\tilde{S}$ is equal to 3 ln $(\tilde{v}^{1/3} - 1)$ in the Flory model.

Results and Discussion

Heat of Mixing

Table 2 summarizes the results of the heats for all the systems. The experimental heats H^E have been fitted to the equation

$$[6]\quad H^E = x_1x_2\sum_{i=0} A_i(x_1 - x_2)^i$$

where x is the mole fraction. The first two columns give the maximum value of the heat of mixing and the concentration at which the maximum occurs, the next six columns list the parameters of eq. [6], the heat per cm^3 H_v^E, the free volume contribution per mole obtained from eq. [1], and the $X_{12}s_1^{-1}$ parameter calculated from eq. [3]. H_v^E is H^E divided by the core volume of the solution ($x_1V_1^* + x_2V_2^*$).

The heat of mixing for the different systems will be discussed in terms of the different contributions such as H^E(chem.), H^E(f.v.), H^E(dis.), and H^E(ster. hind.). H^E(chem) should be small for all the systems because the components are made of the same groups; previous work on $NDodec_3$ having shown that trialkylamine behaves as a long alkane. H^E(f.v.) has about the same value for all the systems involving a heptane because the isomers have similar expansion coefficients. The differences between the experimental heats of mixing (and consequently the X_{12} parameter) are likely to be caused by different values of H^E(dis.) and H^E(ster. hind.) from one isomer to another. The systems can be divided into three classes. Class A is made of two systems: $NDodec_3$ with n-C_7 and n-C_8. The heats of mixing are smaller than that of the other systems because the heptyl and octyl chains are not disturbing too much the orientational order of the dodecyl chains so that H^E(dis.) is relatively small. It is to be noted that although Rayleigh scattering measurements on n-C_7 in the pure state indicate that it is not long enough to have extensive orientational order (11), it behaves in solution more as an ordered compound than an order breaker. Since the sterical hindrance contribution is not known to occur in systems containing long chain compounds and linear alkane it is assumed that, in class A, the steric hindrance contribution is not important. Class B is branched heptanes which do not have two methyl groups on neighbouring carbon atoms, i.e. 2-MeC_6, 2,4-diMeC_5, and 2,2-diMeC_5. The larger heats of

mixing are due to H^E(dis.) of $NDodec_3$. H_v^E(1.03–1.10 J/cm^3) compares well to the same quantities for mixtures of $NDodec_3$ with less volatile order breakers such as heptamethylnonane (1.12 J/cm^3) (1). The systems involving 2,2,4-triMeC_5 have been put in the same class because of the position of the groups and the consequently large heats although the value necessary for the comparison with a sterically hindered branched octane has not been measured. Class C composes of the other systems with smaller heats of mixing. It could be possible that these smaller heats are due to incomplete disordering of the dodecyl chains but it does not seem to be the case since Rayleigh scattering measurements on similar branched compounds, a series of branched nonanes, indicate the loss of orientational order of the second component even in solutions which have small heats of mixings (8). The values of the heats in relation to the position of the methyl groups indicate that the steric hindrance is larger when the methyl groups are either on neighbouring C atoms (2,3-diMeC_5 and 2,2,3-triMeC_4) or in the center of the molecule. Note the difference between 3,3-diMeC_5 and 2,2-di-MeC_5. The negative contribution to the heats of mixing seems to be more important when the groups borne by the substituted carbon atom are similar. The same feature gives a large sterically hindered character to the tetraalkyl compounds $SnPropyl_4$ and $SnEthyl_4$. The low unexpected value of the heats for 3-MeC_5 and 3-EtC_5 can perhaps be better understood if these compounds are written as

ethyl—CH—propyl
|
methyl

and $CH(ethyl)_3$ where the similarity of structure with the very sterically hindered compound $C(ethyl)_4$ (usually called 3,3-diethylpentane) is seen. The compounds 2,3-diMeC_4 is put in the sterically hindered compound class since its heat of mixing is about 60 J smaller than the heat of mixing obtained for 2,2-diMeC_4 (measured in this laboratory). The $X_{12}s_1^{-1}$ parameters obtained from eq. [3] reflect the same differences as the heats since their values in J/cm^3 Å^{-1} increase from the ordered systems (about 3) to the order-destroying systems (about 7.5) and decrease again for the sterically hindered compounds (4.6).

A macroscopic estimation of steric hindrance of a given compound is its molar volume, the more sterically hindered component having the smallest volume. Figure 1*a* shows a correlation between the heats and molar volume. Figure 1*b* shows the same correlation with $X_{12}s_1^{-1}$.

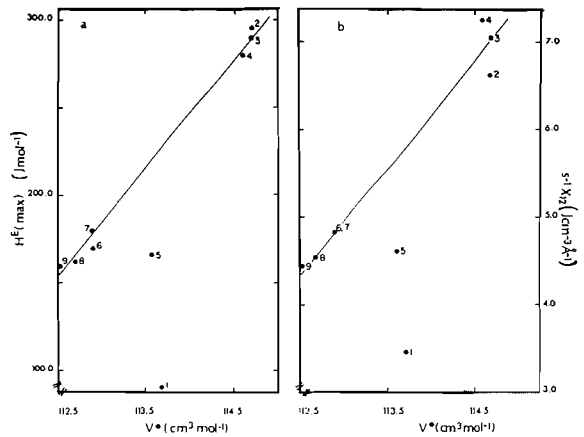

FIG. 1. (*a*) Heats of mixing in J/mol of tridodecylamine with nine heptane isomers vs. the core volume of the heptane. The compounds corresponding to the numbers are listed in Table 2. (*b*) The Flory parameter $X_{12}s_1^{-1}$ vs. the core volume of the heptane. The spread of the X_{12} values corresponds to the inequal magnitude of the disorder and steric hindrance contributions for the different isomers.

Estimation of the Steric Hindrance Contribution

The steric hindrance contribution to the heats can be estimated if one assumes that the system with the highest heat has no steric hindrance contribution and that the free volume and chemical contributions are the same for all the systems. For all the systems, H^E(ster. hind.) is assumed to be 150–280 = −130 J/mol. Similar arguments were used (1) to evaluate H^E(ster. hind.) with other sterically hindered compounds. It was found that for a given sterically hindered compound, H^E(ster. hind.) is proportional to the volume of the second component. The comparison of the values found now and previously indicates that the steric hindrance contribution of the branched heptanes is about the same as that found for $SnPropyl_4$ which is reasonable since the compounds have similar shapes.

Free Energies

The activity coefficient of the volatile component 1, corrected for vapour-phase non-ideality, is given by

$$[7] \quad \ln \gamma_1 = \ln \frac{p_1}{p_1^0 x_1} + \frac{(B_{11} - V_1^0)(p_1^0 - p)}{RT}$$

where p_1 and p_1^0 are the partial pressure and saturated vapour pressure of component 1, p is the equilibrium vapour pressure of the system equal in the present case to p_1, and B_{11} and V_1^0 are the second virial coefficient and liquid molar volume. Values of B_{11} at 25°C were obtained using the empirical correlation of O'Connell and Prausnitz (19). For systems of molecules with a large difference in volume, the

Flory–Huggins entropy of mixing is more appropriate than the regular solution expression.

$$[8] \qquad TS^E = RT(x_1 \ln \phi_1 + x_2 \ln \phi_2)$$

The change of the solvent chemical potential is related to the configurational entropy of mixing and to the parameter χ by the relation

$$[9] \quad \mu_1{}^E = RT\left[\ln \phi_1 + \left(1 - \frac{V_1^*}{V_2^*}\right)\phi_2 + \chi\phi_2{}^2\right]$$

ϕ_2 is usually the volume fraction. Here, according to Flory, the segment fraction defined as $\phi_1 = x_1V_1^*/(x_1V_1^* + x_2V_2^*)$ is used.

The excess chemical potential of the second component being:

$$\mu_2{}^E = RT\left[\ln \phi_2 - \left(\frac{V_2^*}{V_1^*} - 1\right)\phi_1 + \frac{V_2^*}{V_1^*}\chi\phi_2{}^2\right]$$

The molar free energy of mixing is obtained by

$$[10] \quad G^E = RT\left[x_1 \ln \phi_1 + x_2 \ln \phi_2 + \chi\phi_1\phi_2 \times \left(x_1 + \frac{V_2^*}{V_1}x_2\right)\right]$$

The residual free energy G^E is

$$[11] \qquad G^E(\phi) = RT\chi\phi_1\phi_2\left[x_1 + \frac{V_2^*}{V_1^*}x_2\right]$$

The different symbols $G^E(\phi)$ and $G^E(x)$ correspond respectively to the use of the configurational entropies in ϕ and x. In this work, values of the parameter χ were obtained from the experimental activity coefficients and eqs. [7] and [9]. The residual free energy of mixing is then calculated from eq. [11].

A more usual procedure for mixtures of components having similar size is to obtain G^E by fitting the activity of the volatile component to the following equation (16)

$$[12] \qquad \ln \gamma_1 = x_2{}^2[C_0 + C_1(3 - 4x_2)]$$

The coefficients in this equation come from the Redlich–Kister equation with two coefficients for G^E. The two different expressions for the combinatorial entropies of mixing are

$$[13] \quad G^E(x) = x_1x_2[C_0 + C_1(x_1 - x_2)]$$

$$[14] \quad G^E(\phi) = G^E(x) + [x_1 \ln \phi_1 + x_2 \ln \phi_2 - x_1 \ln x_1 - x_2 \ln x_2]$$

An alternative way to obtain $G^E(\phi)$ is to fit the experimental γ_1 to eq. [12], calculate $G^E(x)$ by eq. [13], and obtain $G^E(\phi)$ by eq. [14]. It has been found that if a sufficient number of points were taken on the $\ln \gamma_1$ vs. x curve in the region of high concentration of the non-volatile component, the values obtained either from eq. [14] or from eq. [11] for $G^E(\phi)$ agree within experimental error, i.e. 10–20 J/mol. If too few points are taken, the $G^E(\phi)$ obtained by eqs. [12]–[14] are higher by 30–40 J than those obtained directly from eq. [11].

Figure 2 gives an example of the variation of χ with the polymer segment fraction. Measurements have been taken between $\phi_2 = 0.95$ and $\phi_2 = 0.45$. The variation of χ does not seem to be regular enough to be ascribed to a concentration dependence so that the listed value of χ is the average value for all the measured concentration range. $G^E(\max)$ is then found for the maximum value of $\phi_1\phi_2(x_1 + (V_2^*/V_1^*)x_2)$. This quantity goes through a maximum for a volume fraction which is slightly dependent on V_2^*/V_1^*, i.e. $\phi(\max) = 0.675$ for the heptanes and octane and $\phi_2 = 0.70$ for 2,3-diMeC$_4$.

The maximum values of $G^E(\phi)$ are given at 25°C by the following relations:

$$[15] \quad G^E(\phi) = \chi M \text{ with}$$

$M = 1155$ J/mol for the heptanes
$M = 1110$ J/mol for the octanes
$M = 1202$ J/mol for 2,3-diMeC$_4$

The concentration dependance of G^E is given by eq. [11]. The maximum is at $\phi_2 = 0.675$ for the heptane systems which corresponds to $x_1 = 0.691$, a value which is not too different from the concentration of the maximum of H^E ($x_1 = 0.62$). The two first columns of Table 3 give, respectively, the χ parameter and the maximum of $G^E(\phi)$; $G^E(x)$ is lower by about 657 J/mol than $G^E(\phi)$ and is consequently negative. On Fig. 3 $G^E(\phi)$ have been plotted like H^E vs. the core volume of the heptanes. One can see that the neat trend of H^E vs. V^* is no longer apparent on G^E.

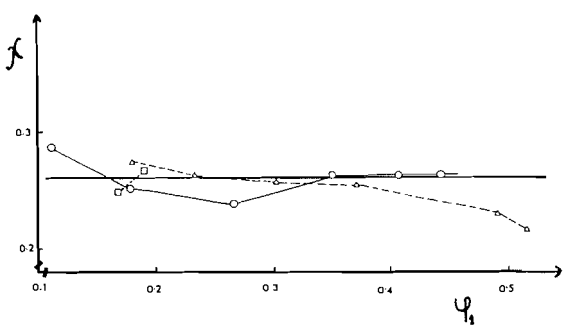

FIG. 2. Typical values of the χ parameter vs. the solvant segment fraction ϕ_1. The data correspond to 2-methyl C_6 and are calculated from eqs. [7] and [9]. □, △, ○ for three runs.

[b]Obtained by the difference between H^E(max) and $G^E(\phi)$(max).

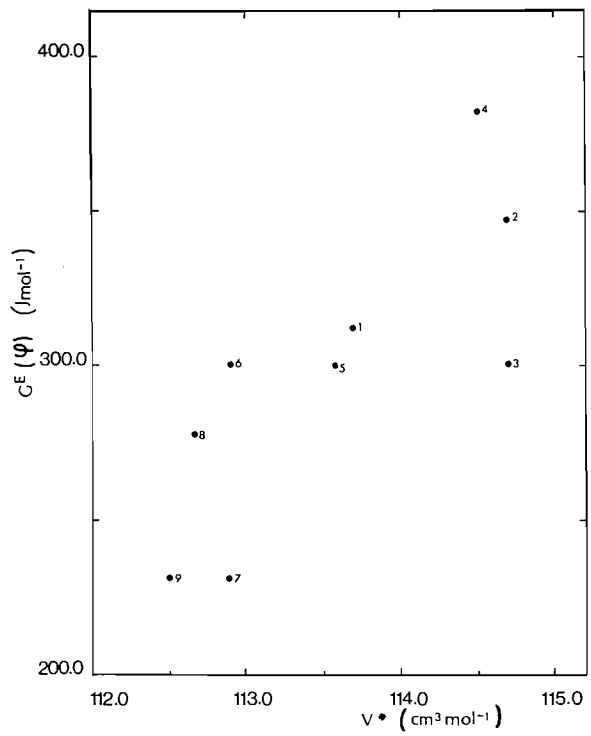

FIG. 3. Excess free energies $G^E(\phi)$ using the Flory–Huggins combinatorial entropy vs. the core volume of the heptane. The compounds corresponding to the numbers are listed in Table 2.

Indeed, five systems out of nine have the same value of G^E within experimental error, i.e. 295 ± 15 J/mol. This is interpreted as an indication of the compensation of the enthalpic and entropic contributions to a given effect. For example, n-C_7, 3-MeC_6, and 2-MeC_6 have the same value of G^E although the heats of mixing indicate the presence of a disordering contribution with 2-MeC_6, of a disordering and steric contribution with 3-MeC_6, and a much smaller contribution with n-C_7. It appears then that the disordering of the long dodecyl chains give a positive contribution to the entropy of mixing so that the net effect in G^E is not large. This result had also been found on the dibromoethane + n- (and branched) alkane systems (21). In the same way, the negative steric hindrance contribution to the heat of mixing in the 3-MeC_6 system must be balanced by a negative entropy term. The systems which have G^E values either larger or smaller than 295 J/mol have several methyl substituents along the chain. It is possible that for these systems, the difference comes from the configurational entropy which may be different from those of the less branched hydrocarbons. It is to be noted that the compensation entropy–enthalpy usually does not exist for the free volume effect which gives an overall positive contribution to G^E. This can be seen (Tables 2 and 3) on the calculated values of H^E(f.v.) and TS^E(f.v.). It is this positive free volume contribution that is the cause of the lower critical solubility temperature observed on systems made of molecules of large free volume differences.

Figure 4 shows the correlation between the part of the heat which is not due to the free volume, H^E(dis. + ster. hind.) and the corresponding entropy terms. H^E(dis. + ster. hind.) = H^E(exp. − H^E(f.v.)).

Interactional Contribution

The line drawn on Fig. 4 through the points corresponding to the different isomers does not extrapolate to zero. This may be due to a contribution coming from the small difference in force field in the the tridodecylamine and the alkanes (or H^E(chem)). From equation of state theories one can calculate

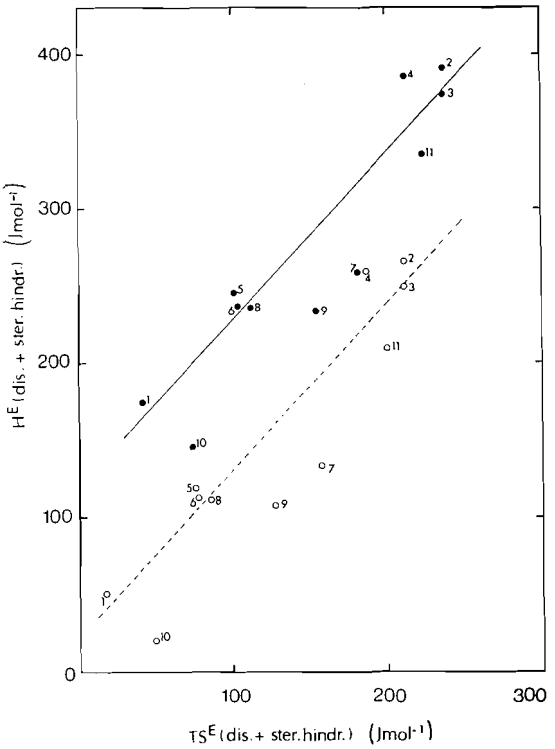

FIG. 4. Enthalpy–entropy compensation for the disorder and steric hindrance contributions. The extrapolated value H^E = 125 J/mol may correspond to H^E (interactional). Dotted line: same plot after subtracting H^E and TS^E (interactional). The compounds corresponding to the numbers are listed in Table 2.

the ratio of the interactional entropy to the interactional enthalpy. From eq. [20] of ref. 3*b*, one finds:

$$[16]\quad \frac{TS^E(\text{interaction})}{H^E(\text{interaction})} = \frac{\tilde{T}\tilde{C}p}{-\tilde{V} + \tilde{T}\tilde{C}p} = \frac{\alpha T}{1 + \alpha T}$$

The above expression in αT has been obtained by the use of the Flory model. Estimation of the interactional contribution to the heat of mixing is given by the extrapolated value of H^E when $TS^E = 0$ on Fig. 4 and the interactional contribution to TS^E is obtained from eq. [5]. With H^E(interaction) = 125 J/mol and $\alpha T = 0.23$ (an average between the αT for the two components)), TS^E(interaction) is found to be 25 J/mol. The dotted line in Fig. 4, obtained by shifting the coordinates of the points by 125 J/mol for H^E and 25 J/mol for TS^E, corresponds to the disorder and steric hindrance contributions for the series of isomers of the heptanes. The slope not too far from 1 indicates a fair compensation between the H^E and TS^E for the disorder and steric hindrance contributions.

One may wish that methods other than the thermodynamics may help to understand, on a molecular level, the difference in the solutions made with, for instance, the 2-Me and the 3-Me hexanes, difference visible by the heats of mixing but not by the free energies.

Oxidative ozonolysis of a polyunsaturated fatty acid in BF_3–MeOH medium[1]

J.-L. SEBEDIO AND R. G. ACKMAN[2]

Fisheries and Marine Service, Department of Environment, Halifax Laboratory, Halifax, N.S., Canada B3J 2R3

Received November 15, 1977

J.-L. SEBEDIO and R. G. ACKMAN. Can. J. Chem. **56**, 2480 (1978).

The ozonolysis of the methyl ester of a typical naturally-occurring polyunsaturated acid (linoleic) in BF_3–MeOH medium was investigated. Referring only to difunctional products, yields of the principal reaction product, dimethyl azelate, were approximately 96%. The characteristic secondary product, the dimethyl ester of the acid with one less carbon, was formed only to the extent of 2% or less. Other intermediates and difunctional secondary products which have been identified include the C_9 methyl half-ester, half-aldehyde, and the corresponding dimethyl acetal. Dimethyl malonate was not recovered quantitatively under the conditions employed. Monofunctional products qualitatively and quantitatively duplicated the difunctional products.

J.-L. SEBEDIO et R. G. ACKMAN. Can. J. Chem. **56**, 2480 (1978)

L'ozonolyse de l'ester méthylique d'un acide gras polyinsaturé (linoleique) en milieu BF_3–MeOH donne des rendements de 96% en produit principal de la réaction, l'azélate de méthyle. Le produit secondaire généralement obtenu pour une réaction de ce type à savoir le diester à un carbone de moins n'excède pas 2% du produit principal. Les deux autres produits secondaires identifiés (2 à 3%) sont l'aldehyde-ester en C_9 et l'acétal correspondant. Les conditions expérimentales employeés pour cette reaction ne permettent pas de déterminer la quantité exacte de malonate de méthyle. Les produits monofonctionnels formés reflètent qualitativement et quantitativement les produits difonctionnels.

[Traduit par le journal]

Introduction

In a recent paper (1), it has been shown that the ozonolysis of monoethylenic fatty acids in BF_3–MeOH medium gives good yields ($\geq 98\%$) of the principal diacid product in the form of the dimethyl ester. This technique also restricted the quantity of secondary diester product (i.e., the ester shorter by one carbon) to 1 or at most 2%. A unique advantage of this method is the combining of all steps of the reactions 'in situ' so that the ester products are immediately suitable for recovery and gas–liquid chromatographic (glc) analysis.

To broaden the application of the BF_3–MeOH technique in the fatty acid field, and as an extension of the study of monoethylenic fatty acids, we have now examined the behaviour of a polyethylenic fatty acid. Linoleic (octadeca-9,12-dienoic) acid, an important naturally-occurring fatty acid, was selected for detailed study. Yields of principal dicarboxylic C_9 product ($\sim 96\%$) were as satisfactory as with oleic (octadeca-9-enoic) acid but unexpectedly small proportions of two unknown products were always present. These have been identified as the difunctional C_9 acid–aldehyde and corresponding acetal. The recovery of monofunctional (C_6) products and the two corresponding byproducts is discussed.

Results and Discussion

The ozonolysis of methyl linoleate in BF_3–MeOH was first evaluated under the same conditions employed previously (1) with recovery of the mixture of products by extraction with methylcyclohexane and analysis by isothermal glc on open-tubular wall-coated columns (Fig. 1). The products resulting from the oxidative scission of the ethylenic bonds and subsequent esterification should be methyl hexanoate, dimethyl malonate, and dimethyl azelate. The principal products observed (Fig. 1) did not include dimethyl malonate. Possibly there is direct C_3 decomposition during oxidative decomposition of the ozonide. It is also known that dimethyl malonate is susceptible to decomposition during glc analysis and has a low relative molar response in the flame ionization detector (2). However, the water-immiscible extractant employed was the hydrocarbon methylcyclohexane, in which dimethyl malonate was known to have limited solubility. For these reasons no attempt was made initially to investigate the fate of the malonate fragment. The methyl hexanoate is a borderline case for efficient extraction into a hydrocarbon solvent from an aqueous medium and is also volatile enough to be subject to probable losses during solvent removal. Since it was felt that any reaction affecting the C_9 scission fragment would be equally applicable to the C_6 scission fragment, the initial qualitative and quantitative evaluation was based on the percentage of dimethyl azelate (DMC_9)

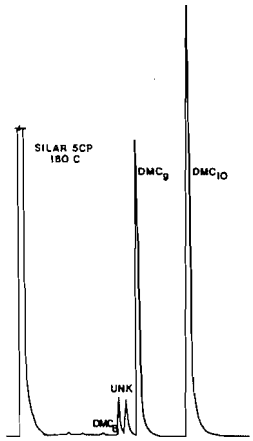

FIG. 1. Isothermal gas–liquid chromatographic analysis of products recovered from an evaluation of the reaction with DMC_{10} added as an internal standard.

formed. An internal standard of dimethyl sebacate (DMC_{10}) was employed and yield calculations were based on 9.7 and 8.7 as relative molar flame ionization responses for the C_{10} and C_9 dimethyl esters analysed on SILAR-5CP open-tubular columns (1). The initial yields of dimethyl azelate were 72% of theory, and in contrast to the results for the monoethylenic acid (1), the principal product was accompanied by two significant unknowns (total ~20%) which appeared to be materials potentially related to DMC_9. The anticipated secondary product, dimethyl suberate (DMC_8), was present (Fig. 1) in the same proportion (~1%) as observed previously. The two unknown products were selected for in-depth study to determine if they were intermediates from incomplete reaction or true secondary reaction products.

The initial study was of the effect of time of reaction at 100°C (Table 1), keeping constant the concentrations of methyl linoleate in BF_3–MeOH, the concentration of BF_3–MeOH employed (7%), and the time of exposure to ozone (1 min). All figures given are normalized to one set of glc-recorder/integrater counts for DMC_{10}. Two additional minor products (unknowns *1* and *2* in Table 1) were observed in early stages of the heating reaction but have not been further studied. They disappear and under the above conditions the other products in the reaction mixture were constant after 60 min. Up to that point, the yield of principal product (DMC_9) increased with time and concurrently the two major unknowns (*3* and *4*) diminished (Table 1). The increase in DMC_9 product could, however, include ester formation from acidic intermediates or products *not* included in the volatile product analysis of Table 1, as well as from the presumed transformations from

unknowns *3* and *4*. The latter appeared to be intermediates, and not secondary reaction products. Since C_9 chain lengths were implicated, the application of the methods described under Experimental section (*d*) led to the identification of unknown *3* as the C_9 half-ester aldehyde dimethyl acetal $CH_3—O—CO—(CH_2)_7—CH(OCH_3)_2$ and of unknown *4* as the corresponding half-ester aldehyde $CH_3—O—CO—(CH_2)_7—CHO$. A systematic exploration of the ozone exposure and of the concentration of the BF_3—MeOH solution was then instituted to investigate the relationship between these two C_9 compounds and the desired DMC_9 principal product.

The effect of increasing time of exposure to the ozone stream, keeping constant the concentration of BF_3 (7%) and the time of reaction at 100°C (60 min), was to decrease the formation of acetal and aldehyde and thus to increase the yield of DMC_9 product (Table 2). However, the reaction of ozone must be instantaneous and complete as no unaltered 18:2ω6 could be recovered even at 0.5 min. The influence of time of exposure to the ozone stream under these conditions therefore does not alter the stage of electrophilic addition of ozone to the double bonds but does intervene in the transformation of intermediate products (acetal and aldehyde) to acid.

In the next examination, that of the effect of concentration of BF_3 in MeOH (Table 3), it is necessary

to emphasize that the concentrations tested did not produce markedly different results. Possibly, the 2% BF_3 concentration produced slightly higher yields of DMC_9, but in view of potential errors in weighing, extraction, glc, etc., the trend is probably not significant. However, it is possible to say that under these conditions average yields of DMC_9 relative to other glc volatile materials are 96 ± 3%.

It became necessary to investigate the formation and interchange of the aldehyde and acetal intermediates. A suitable mixture (solution A, Table 4) was prepared, containing acetal, aldehyde, DMC_9, and an internal standard of DMC_{10}. Aliquots were examined after heating; B without ozone, or C with ozone. The conversion of acetal and aldehyde to acid clearly requires the oxidizing capacity originating in the ozone/oxygen gas stream. The BF_3 is apparently not a principal reactant. However, it is indispensible for the efficient transformation of these two intermediates into DMC_9 as shown in Table 5 where a similar initial mixture was reacted with ozone in MeOH only or in BF_3–MeOH.

The mechanism generally accepted (3–6) for ozonolysis gives a primary ozonide (Scheme 1, stage *1*) which decomposes to give a zwitterion (stage *2*) and a carbonyl derivative (stage *3*). Two reaction routes are then possible, depending on whether or not one has a participating solvent. The normal route is the formation of an internal ozonide (stage *4*) which is known to be easily decomposed by participating solvents such as MeOH (3, 7) (stage *5*). The alternative, more probably in the presence of MeOH solvent, is the capture of the zwitterion by MeOH (stage *6*) to give methoxyhydroperoxide. The latter is the more widely accepted reaction (8–10).

In respect to the decomposition of the methoxy hydroperoxide (stage *7*) it has been shown by Griesbaum and Keul (10) that this compound decomposes in the presence of HCl by an ionic process. It is reasonable to assume that a mechanism of the same type would apply in the presence of the strongly acidic BF_3.

The intermediates selected for study in the BF_3–MeOH systems were the methyl esters of the difunctional C_9 half-acid aldehyde and corresponding acetal. The aldehyde is generated by the decomposition of the primary ozonides and there is no reason to associate the acetal with any reaction except the normal BF_3-catalysed reaction between MeOH and aldehyde (11). The oxidation of aldehyde (stage *9*) was first thought to be by the intermediary action of one or more oxides of fluorine which are known to be powerful oxidants (12), but this does not seem to be the case. The oxidation appears to conform to literature results based on a simple oxidation process mediated by ozone (13–16). However, we have seen (Table 5) that this conversion of aldehyde to acid is not complete except in the presence of BF_3 which must have some catalytic role.

The equilibrium (*8*) between the aldehyde and acetal will be displaced by the removal of aldehyde by oxidation step (*9*). In this system the ratio of initial intermediate products for aldehyde:acetal is 4:1 (Table 4), but becomes 1:1 after an hour of full reaction (Fig. 1). The initial rapid oxidation of aldehyde to acid (*9*) by O_2/O_3 presumably slows down as oxidant is consumed, permitting the slower acetal formation step (*8*) to come to definite equilibrium.

The suggestion of a limitation of oxidation capacity in our particular system required an investigation of the oxidant capacity. Based on 2 ml of BF_3–MeOH and 2 min of exposure to the O_2/O_3 mixture, it was found that 8–10 mg and 15 mg of linoleic acid gave respective yields of 96 and 97% of DMC_9. At 30 mg the DMC_9 yield dropped to 91% and the acetal +

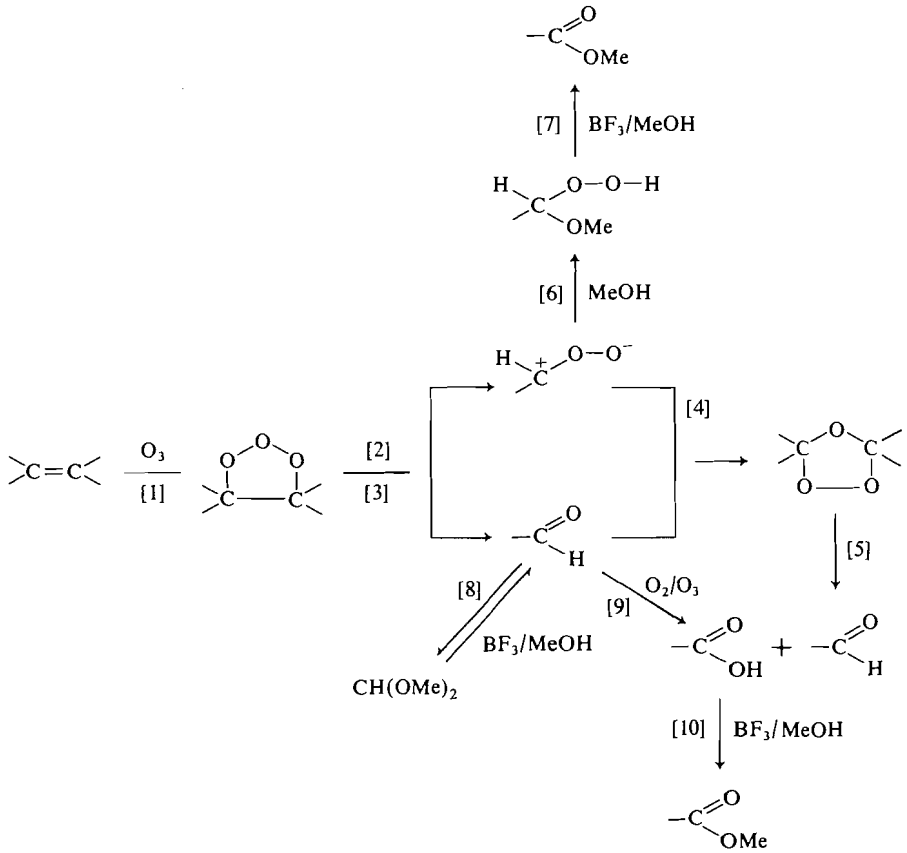

SCHEME 1. General mechanisms of ozonolysis, ozonide decomposition, acetal formation, oxidation, and esterification

aldehyde byproducts rose from 3–4% to 9% of total volatile products. When the system was tested with 60 mg of linoleic acid the ozonolysis itself was incomplete (disappearance of linoleic acid was approximately one half) and the molar proportion of acetal + aldehyde to DMC_9 was 55 to 45. Polyethylenic fatty acids are usually recovered from modern isolation techniques for further study in submilligram amounts. There does not appear to be any problem of scale for oxidative fission of these types of samples with the system described of 2 ml of reactant/solvent in a 10 ml tube and an adequate O_2/O_3 supply.

It is equally possible to pass the ozone into a solution of the reactant unsaturated ester in MeOH and then to add the BF_3. The results obtained are identical to those obtained by adding the ozone to the balance of the reactants except that we have obtained only one reaction intermediate. There is no formation of acetal. It is also possible that BF_3 plays a role in favouring electrophilic addition of ozone to the double bonds, but this effect must be feeble since it does not modify the yield of diacidic products. It is remarkable, in this context, that when monoethylenic acids are ozonized in BF_3–MeOH (1), the aldehyde and corresponding acetal (proportions 4:1) are only detected immediately after the initial ozonolysis and disappear much more rapidly and completely than for the same weight of diethylenic acids. This also emphasizes the importance of an excess of available oxidant.

The primary investigation of the C_9 fragments from linoleic acid was facilitated by the ready solubility of all of the difunctional C_9 products (except free acids) in the hydrocarbon methylcyclohexane. Although chloroform was somewhat more awkward to manipulate, it proved to be very effective in the extraction of both the C_9 difunctional products and the corresponding C_6 monofunctional products from linoleic acid (Table 6). The loss of MMC_6 (methyl hexanoate), relative to MMC_8, was found experimentally to be only 3% in two combined 2 ml chloroform extracts from 2 ml of 7% BF_3/MeOH diluted with 6 ml of H_2O. After applying this correction to a sample exposed to O_2/O_3 for 1 min, the yield of MMC_6 and the related C_6 aldehyde and acetal (Fig. 2) was effectively the same as that for the correspond-

‡Respectively peaks 6 and 7 in Fig. 2.

ing DMC_9 and other difunctional C_9 products. It is thus clear that the reaction, complete or incomplete, is symmetrical and all primary and secondary products are found in equal molar proportions. In many cases of study of the structures of fatty acids it would be sufficient to examine only difunctional and/or longer chain monofunctional products. The use of chloroform for extraction and programmed gas–liquid chromatography (Fig. 2) extends this capability with inclusion of the shorter-chain monofunctional acidic product. No loss of MMC_6 occurred if the chloroform was concentrated 50% for convenience in later analysis.

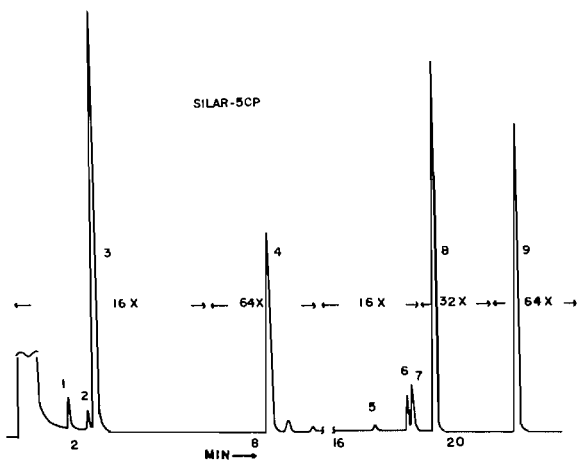

FIG. 2. Programmed-temperature gas–liquid chromatographic analysis of chloroform-soluble products from methyl linoleate recovered from an evaluation of the BF_3/MeOH-ozonolysis reaction, (time 1 min) with added internal standards. Peaks are: (*1*) hexanal, (*2*) hexanal dimethyl acetal, (*3*) methyl hexanoate product, (*4*) MMC_8 (methyl octanoate), internal standard, followed immediately by the small peak for DMC_3, (*5*) DMC_8 (dimethyl hexanedioate), secondary product, (*6*) methyl half ester of C_9 acid-aldehyde dimethyl acetal, (*7*) methyl half ester of C_9 acid-aldehyde, (*8*) DMC_9 (dimethyl heptanedioate) product, and (*9*) DMC_{10} (dimethyl octanedioate) internal standard. Column (see text) was held 80°C for 8 min, programmed at 32°/min to 180°C and then held at 180°C.

A small amount of dimethyl malonate (Fig. 2) was recovered with chloroform as the extractant. The recovery was adequate to act as a qualitative indication of the presence of methylene-interrupted ethylenic bond systems.

When this method of oxidation of products is compared with that formerly applied in this laboratory (17), i.e. ozonolysis in methanol followed by oxidation by a mixture of H_2O_2/HCO_2H, it appears that the BF_3–MeOH method gives less secondary (C_{n-1}) product ($\leq 1\%$ DMC_8 and 3–4% total acetal and aldehyde). It is equally important to note that we have never obtained the secondary (C_n, C_{n-1}) esters observed in certain instances by Pasero and co-workers (18, 19). The formation of these esters has been explained (20) by the transformation of aldehyde and peracid into diacyl peroxides, followed by decarboxylation and formation of the ester. This could well account for the DMC_8 secondary product but the proportion must be extremely small as in BF_3–MeOH medium transesterification would favour conversion to methyl esters.

Materials and Methods

(a) Materials

All solvents were reagent grade and were distilled in glass before use. The BF_3–MeOH (14%) solution was purchased in glass ampoules (Applied Science Laboratories) and these were opened as necessary (any surplus was stored briefly in a screw cap vial with a Teflon liner). The methyl linoleate was prepared by the Hormel Institute and showed only one major component on open-tubular glc. The ampoule, once opened, was immediately flushed with nitrogen and stored under nitrogen to prevent oxidation.

(b) Physico-chemical Apparatus

Gas–liquid chromatographic analyses were carried out in Perkin-Elmer model 900 or 3920 units with flame ionization detectors. Stainless steel wall-coated, open-tubular columns purchased from Perkin-Elmer, Norwalk, CT, were employed, with SILAR-5CP (Applied Science Laboratories) as the liquid phase. The dimensions were 46 m in length × 0.25 mm id, and isothermal operating conditions were 180°C with 60 psi (4 kg/cm²).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Nuclear magnetic resonance spectra were recorded in $CDCl_3$ on a Varian H.A. 100 spectrometer.

Infrared studies were carried out in a Unicam SP 1000 Infrared Spectrophotometer.

Mass spectral studies were carried out in a DuPont 21.491 mass spectrometer, coupled with a Hewlett-Packard 5750 gas chromatograph; the column was packed with 5% SE-30 M Chromosorb-W.

(c) Ozonolysis Techniques

Typically, appropriate quantities of methyl linoleate (~10 mg) and of dimethyl sebacate (internal standard) were weighed into a leak-tight 10 ml screw cap centrifuge tube. Either BF_3–MeOH, or MeOH if so required, was added (1–2 ml) and ozone in oxygen was bubbled through (total gas flow 250 ml/min) for the required time. The tube was promptly capped (Teflon-faced liner) and inserted into an aluminum heating block (nominally 100°C) for an hour. After cooling, distilled water (6 ml) was added and the products were extracted into methylcyclohexane (two extractions of 2 ml each). If required this extract was concentrated at 100°C with a jet of nitrogen. For chloroform extractions the procedure was the same, the bottom layers being carefully removed with a long slender Pasteur pipette.

Residues of acetone, sometimes used to clean and dry the centrifuge tubes, were found to produce a variety of spurious product peaks and were scrupulously avoided.

(d) Identification of Acetal and Aldehyde

The preparation of the two C_9 compounds was based on their recovery immediately after methyl linoleate was exposed to ozone in BF_3–MeOH. The methylcyclohexane extract, which included a small amount of DMC_9 (any free C_9 acid-ester would be inefficiently extracted under these conditions), was streaked on silicic acid thin-layer plates (Prekotes, Applied Science Laboratories). These were developed in *n*-hexane/diethyl ether (60/40). After spraying with 2′,7′-dichlorofluorescein the bands were located at R_f values, respectively, of 0.41 for half-ester acetal, 0.32 for half-ester aldehyde, and 0.20 for DMC_9. The bands were recovered by extraction with hexane and chloroform. The infrared spectra of the two unknown bands showed intense ester band absorption at 1755 cm^{-1}. The nmr spectra confirmed the ester functions (3.70 ppm singlet in both, 9.76 ppm triplet for the aldehyde, 3.30 ppm singlet for the acetal). The mass spectra gave appropriate and characteristic ester, aldehyde and acetal fragments and confirmed the chain lengths as C_9 through *m/e* of 185 for M − H (aldehyde) and *m/e* of 231 for M − H (acetal). The C_6 acetal was readily prepared from hexanal.

Hydrolyse des sels de phospholium monomères: Préparation et propriétés des oxydes de 1,3-diénylphosphines

FRANÇOIS MATHEY ET GEORGES MULLER

Equipe IRCHA–CNRS, 2–8 rue Henri Dunant, B.P. no 28, 94320 Thiais, France

Reçu le 20 mars 1978

FRANÇOIS MATHEY et GEORGES MULLER. Can. J. Chem. **56**, 2486 (1978).

L'hydrolyse des sels de diméthyl-3,4 phospholium par l'éthylate de thallium dans l'alcool fournit dans le cas général, exclusivement les oxydes de diénylphosphines correspondants par ouverture du noyau. Cependant, quand un des substituants du phosphore est le benzyle, l'oxyde de diénylphosphine devient le produit minoritaire, le produit majoritaire étant l'oxyde de méthyl-3 méthylène-4 phospholène-2 qui résulte d'un clivage de la liaison P—CH_2Ph accompagné de l'isomérisation de l'une des doubles liaisons du noyau phosphole. La deutérolyse des sels de benzylphospholium montre que l'isomérisation n'a pas lieu avant l'hydrolyse. Un essai de réduction de la liaison P=O des oxydes de diénylphosphines par le phénylsilane a fourni des produits hydrogénés. Au contraire l'échange P=O → P=S par P_4S_{10} se produit sans destruction du système diénique. La réaction avec $Fe_3(CO)_{12}$ conduit aux complexes diène–$Fe(CO)_3$ avec de hauts rendements. Quand les deux substituants du phosphore sont différents, on obtient deux complexes diastéréoisomères.

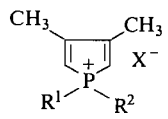
FRANÇOIS MATHEY and GEORGES MULLER. Can. J. Chem. **56**, 2486 (1978).

The hydrolysis of 3,4-dimethylphospholium salts by thallium ethylate in alcohol yields exclusively the corresponding dienylphosphine oxides by ring opening in the general case. However when one of the phosphorus substituents is benzyl, the dienylphosphine oxide becomes the minor product of the hydrolysis, the major product being the 3-methyl-4-methylene-2-phospholene oxide which results from the cleavage of the P—CH_2Ph bond with isomerization of one of the double bonds of the phosphole ring. Deuterolysis of benzylphospholium salts shows that the isomerization does not take place before the hydrolysis. Attempted reduction of the P=O bond of dienylphosphine oxides by phenylsilane yields hydrogenated products. On the contrary, the P=O → P=S conversion by P_4S_{10} occurs without destruction of the dienic system. High yields of diene–$Fe(CO)_3$ complexes are obtained by reaction with $Fe_3(CO)_{12}$. When the two phosphorus substituents are different, two diastereoisomeric complexes are obtained.

La voie d'accès normale aux oxydes de 1,3-diénylphosphines a pour point de départ une addition 1,4 du pentachlorure de phosphore sur les diènes conjugués suivie d'une déchlorhydratation 1,4. Les rendements sont souvent modestes; voir réfs 1–3. L'oxyde de (phényl-4-butadiényl)diphénylphosphine a d'autre part été préparé par une réaction de Wittig–Horner entre l'aldéhyde cinnamique et $(Ph_2P(O))_2$-CHK (4). Enfin il a été établi dans deux cas particuliers (5) que l'hydrolyse des sels de phospholium monomères fournissait également des oxydes de 1,3-diénylphosphines avec un rendement quasi-quantitatif. Il nous a donc paru intéressant d'étendre le travail préliminaire de Bergesen à d'autres phospholes et d'étudier quelques propriétés des produits ainsi préparés.

Nous avons choisi d'étudier plus particulièrement l'hydrolyse des sels de type **1**. La substitution diméthyl-3,4 assure la structure monomère des sels, simplifie leur préparation (meilleurs rendements) et facilite l'étude rmn des produits d'hydrolyse.

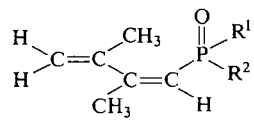
L'hydrolyse de **1***a* par la soude 2 *N* à chaud nous a fourni en fait un mélange complexe d'isomères non séparables contenant probablement, outre le produit



1

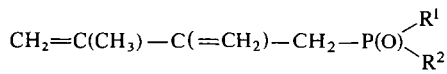
a R^1 = Me, R^2 = Ph, X = I
b R^1 = Ph, R^2 = $PhCH_2$, X = Br
c R^1 = *t*Bu, R^2 = Me, X = I
d R^1 = R^2 = Me, X = I
e R^1 = Me, R^2 = $PhCH_2$, X = I
f R^1 = R^2 = $PhCH_2$, X = Br

attendu **2***a*, l'oxyde de phosphine **3** en impureté principale comme en témoigne l'apparition vers 2.95 ppm d'un doublet CH_2P (J_{H-P} = 14 Hz) ($CDCl_3$, TMS externe). Nous avions déjà rencontré un tel problème dans un cas particulier (6). L'apparition de



2

(P en *trans* de CH_3 comme dans le cycle phosphole)



3

produits du type **3** résultant probablement d'une isomérisation de **2***a* en milieu basique à chaud, nous

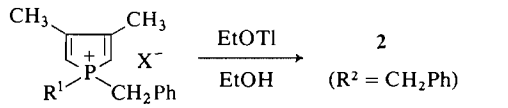
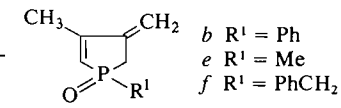
avons mis au point une méthode d'hydrolyse beaucoup plus douce consistant à traiter à froid le sel de phospholium en solution dans l'éthanol par une quantité stoechiométrique d'éthylate de thallium. On obtient alors pratiquement quantitativement l'oxyde **2***a* pur. La méthode est générale et ne fournit qu'un produit quand R^1, $R^2 \neq PhCH_2$.

$$\mathbf{1} \xrightarrow[EtOH,\ 20°C]{EtOTl} \mathbf{2} \quad \text{si } R^1, R^2 \neq PhCH_2$$

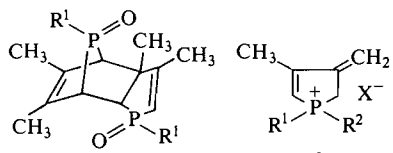
Si, par contre, l'un des radicaux R^1 ou R^2 est le benzyle, la réaction d'hydrolyse suit un cours différent: l'oxyde diénique **2** devient alors le produit minoritaire, le produit principal étant l'oxyde de méthylène-4-méthyl-3-phospholène-2 (**4**).





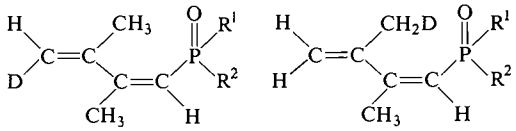
4

Ces deux types de produits sont séparables sans difficulté par chromatographie sur gel de silice. L'obtention de **4** est très surprenante. Logiquement, nous nous attendions en effet à l'obtention d'un oxyde de phosphole se dimérisant instantanément pour fournir un produit du type **5** dont nous ne trouvons pratiquement pas trace.



5 **6**

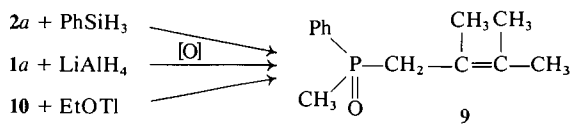
Notons que **4***b* a déjà été préparé par réaction de $CSCl_2$ sur le sulfure de phényl-1-diméthyl-3,4-phosphole (7). La première explication venant à l'esprit, à savoir une isomérisation de **1** en **6** avant hydrolyse, est à rejeter. En effet la deutérolyse de **1***a* ou de **1***f* fournit les oxydes deutériés sur la double liaison **7** et non les produits deutériés sur le méthyle **8** qui proviendraient nécessairement de **6**. Nous ne voyons donc pas d'explication simple du phénomène observé.



7 **8**

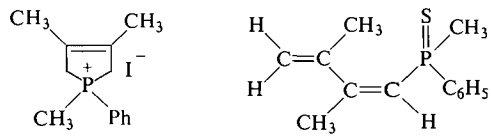
Notons en passant que, comme il semble peu vraisemblable qu'un carbanion vinylique engendré et piégé de façon probablement concertée en milieu protique subisse une isomérisation *cis–trans*, nous admettons que le deutérium est en *trans* du CH_3 dans **7** ce qui nous permet d'attribuer les signaux rmn des deux protons du CH_2 vinylique dans les oxydes **2**. Ces données sont réunies dans le tableau 1. On remarquera que la présence d'un phényle sur le phosphore provoque une forte différenciation des deux méthyles portés par le système diénique ainsi que des deux protons vinyliques du CH_2 en bout de chaîne, effet d'origine vraisemblablement électronique. Le tertiobutyle provoque un effet du même genre mais dans ce cas nous soupçonnons une origine conformationnelle. La répulsion stérique (visible sur le modèle de Dreiding) entre le méthyle en position 3 sur le diène et le groupement phosphorylé porteur du tertiobutyle a probablement pour conséquence une diminution du poids statistique de la conformation transoïde qui est habituellement la plus stable.

Ayant à notre disposition des oxydes diéniques du type **2** nous en avons entrepris l'étude chimique. Nous avons principalement employé **2***a* qui est le plus accessible parmi eux. Nous avons d'abord essayé de préparer les phosphines correspondantes par réduction à l'aide des silanes. En fait, $PhSiH_3$ au lieu de réduire le P=O provoque une hydrogénation-1,4 du système diénique de **2***a*. L'oxyde **9** obtenu n'est pas



9

très pur mais son identité est indiscutable. On note sur le spectre de rmn du proton ($CDCl_3$) la disparition des protons vinyliques et l'apparition d'un doublet $CH_2P(O)$ à 2.76 ppm (J_{H-P} = 15 Hz). L'identification a été complétée par comparaison des spectres ir et rmn du proton avec un échantillon authentique de **9** préparé par hydrolyse à l'éthylate de thallium du sel de phospholénium **10**.



10 **11**

Devant cet échec nous avons étudié la réduction directe du sel de phospholium **1***a* par $LiAlH_4$. Nous avons à nouveau obtenu **9** provenant probablement de la phosphine éthylénique correspondante par suite d'une oxydation durant le traitement hydrolytique du milieu réactionnel. L'obtention du sulfure **11** n'a posé par contre aucun problème particulier. La

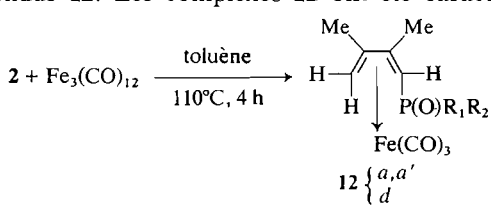
‡Le proton en *trans* du méthyle est en *cis* du fer selon la convention de Graf et Lillya (8); le travail de ces auteurs nous a permis d'assigner les signaux sans équivoque.

sulfuration de **2***a* a été réalisée à l'aide de P_4S_{10} dans le toluène à l'ébullition. Les paramètres de rmn du proton de **11** sont très voisins de ceux de **2***a*.

Nous avons voulu enfin vérifier s'il était possible de complexer le système diénique en dépit de sa désactivation par le groupement phosphoryle. La réaction des oxydes **2***a* et **2***d* avec $Fe_3(CO)_{12}$ au reflux du toluène nous a effectivement donné les complexes π attendus **12**. Les complexes **12** ont été caractérisés



sans ambiguïté par analyse élémentaire C, H, Fe, par ir (présence des trois bandes caractéristiques des complexes diène —$Fe(CO)_3$) et par rmn du proton et du phosphore (tableau 2). Ce sont les premiers complexes π dérivés de diènes phosphorylés ouverts. Auparavant, seuls étaient connus les complexes π des oxydes de phospholes monomères (9, 10). Les données ir ($\nu_{P=O}$) et rmn (δ ^{31}P) semblent indiquer une décroissance de la polarisation du P=O lors de la complexation dûe à un pouvoir attracteur plus grand du diène complexé par rapport au diène libre: par exemple: $\nu_{P=O}$ = 1160 cm^{-1} (**2***d*), 1168 cm^{-1} (**12***d*), 1169 cm^{-1} (**2***a*) et 1177 cm^{-1} (**12***a′*) (produits en pastilles dans KBr). Le même effet a été noté sur le complexe de l'oxyde de diphénylvinylphosphine avec $Fe(CO)_4$ (11). Par contre, une intéraction complexante du fer avec le P=O est exclue car elle se traduirait au contraire par une diminution sensible de la fréquence $\nu_{P=O}$.

Le point le plus intéressant concernant ces complexes réside dans l'obtention de deux isomères à partir de l'oxyde **2***a*. Le carbone diénique lié au phosphore devient tétracoordinné et asymétrique lors de la complexation (substitution fer, carbone, phosphore, hydrogène). Lorsque le phosphore lui-même est asymétrique (cas de **2***a*), il est donc logique d'observer la présence de diastéréoisomères séparables par chromatographie sur colonne. Par contre, lorsque

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

le phosphore n'est plus asymétrique (cas de **2***d*) on n'obtient qu'un seul complexe. Dans ce dernier cas cependant, les deux méthyles portés par le phosphore dans **12***d* sont diastéréotopes. Il est donc normal d'observer un dédoublement du signal Me—P. Néanmoins, l'importance de ce dédoublement nous fait soupçonner un blocage de la rotation du groupement phosphorylé autour de la liaison P–diène qui serait dû à une forte intéraction stérique entre les groupements $P(O)Me_2$ et $Fe(CO)_3$. Nous n'avons toutefois pas pu contrôler cette hypothèse par une étude rmn en température variable par suite de l'instabilité des solutions de **12***d*.

Partie expérimentale

Les spectres rmn ont été enregistrés à 60 MHz sur Perkin-Elmer R 24 A et à 100 MHz sur JEOL PS 100 FT pour le proton ainsi qu'à 40.486 MHz sur JEOL PS 100 FT pour le phosphore.

Purification du phényl-1-diméthyl-3,4-phosphole

Les phospholes de départ ont été obtenus par les méthodes décrites dans la littérature (12–14). La double débromhydratation par le DBU donne des produits de pureté satisfaisante dans le cas du triméthyl-1,3,4-phosphole et du benzyl-1-diméthyl-3,4-phosphole. Par contre, le phényl-1-diméthyl-3,4-phosphole est souvent souillé d'une quantité non négligeable de phényl-1-diméthyl-3,4-phospholène-3 qui ne peut pas être éliminé complètement par simple lavage à l'acide chlorhydrique N (voir réf. 12). Nous avons donc mis au point une méthode de purification plus efficace reposant sur le fait que le tétrachlorure de carbone oxyde préférentiellement le phospholène sans altérer notablement le phosphole lorsque la température est inférieure ou égale à 60°C. Le phosphole impur est dissous dans une quantité égale de tétrachlorure de carbone. On chauffe la solution ainsi obtenue à 60°C pendant 30 min. Il y a formation d'un insoluble jaune plus ou moins huileux. On décante, extrait une fois au tétrachlorure de carbone. On chasse le solvant, reprend le résidu à l'éther ou à l'hexane, élimine l'insoluble par filtration, évapore l'éther et distille. Le phosphole ainsi obtenu ne contient plus de phospholène comme en témoigne la rmn du proton.

Préparation des sels de phospholium

Les sels de phospholium sont obtenus par quaternarisation des phospholes dans l'éther à l'aide d'un large excès d'iodure de méthyle ou de bromure de benzyle. Ainsi, à une solution de 10.5 g de phényl-1-diméthyl-3,4-phosphole dans 50 cm^3 d'éther, on ajoute 10 cm^3 d'iodure de méthyle. On laisse réagir pendant 2 jours à l'abri de l'air et de la lumière. On filtre, rince deux fois à l'éther et sèche sur anhydride phosphorique. Les rendements sont pratiquement quantitatifs.

Hydrolyse des sels de phospholium

A une solution de 0.02 mole de sel de phospholium dans 200 cm^3 d'éthanol absolu, on ajoute rapidement 0.02 mole d'éthylate de thallium sous agitation à température ambiante. Il y a immédiatement formation d'un précipité jaune pour X = I, blanc pour X = Br. On laisse agiter pendant 2 h 30 à température ambiante. On rajoute 200 cm^3 d'éthanol absolu, filtre, rince plusieurs fois, évapore à sec. Les oxydes de diénylphosphines sont purifiés soit par chromatographie sur colonne de silice suivie d'une sublimation, soit par sublimation directe.

R^1 = Me, R^2 = Ph, X = I; éluant AcOEt–MeOH 90:10

Composé **2***a*—rendement 70%; distillation moléculaire 100–110°C/0.1 Torr; pf 82°C; ir (KBr) ν: (C=C) 1600, 1623; (P=O) 1169 cm^{-1}. *Anal.* calc. pour $C_{13}H_{17}OP$: C 70.89, H 7.78; trouvé: C 70.07, H 7.62.

Deutérolyse des sels de phospholium

A une solution de 10^{-3} mol de sel de phospholium dans 5 cm^3 de D_2O on ajoute rapidement 10^{-3} mol de TlOEt. Il y a précipitation immédiate. On laisse agiter 1 h, filtre, extrait avec CH_2Cl_2, lave avec 2 cm^3 de D_2O, décante et sèche sur SO_4Na_2. On évapore à sec. Pour R^1 = Me, R^2 = Ph, X = I on obtient directement **7**. Pour R^1 = R^2 = $PhCH_2$, X = Br on chromatographie sur silice avec un mélange AcOEt–MeOH 80:20. Le produit passant en tête est **7** dans lequel R^1 et R^2 sont partiellement deutériés sur les CH_2 benzyliques.

Essais de réduction de **1**a *et* **2**a

Par $PhSiH_3$

Une mixture de 1.5 g de **2***a* et 0.49 g de $PhSiH_3$ est chauffée au bain d'huile à 120–130°C pendant 2 h. Par microdistillation, on obtient à 150–169°C/0.1 Torr un produit dont les spectres ir et rmn correspondent à **9**.

Réduction directe de ***1***a *par* $LiAlH_4$

Dans 125 cm^3 de THF anhydre on met en suspension 8.25 g de **1***a* (0.025 mol) et 0.6 g de $LiAlH_4$. On chauffe à reflux pendant 5 h 30 min. On traite par 100 cm^3 d'une solution à 20% de sel de Seignette. On laisse reposer la nuit. On décante, sèche sur SO_4Na_2, évapore à sec. Le produit distille à 100–110°C/0.2 Torr. Les spectres ir et rmn correspondent à **9**.

Préparation directe de ***9***

On hydrolyse le sel de phospholénium **10** exactement de la même manière que les sels de phospholium; rendement 60%; pf 88°C; distillation moléculaire à 100°C/0.02 Torr; ir (KBr) ν: (P═O) 1166 cm^{-1}; rmn ^1H ($CDCl_3$, 60 MHz, TMS externe) δ: CH_3 massif complexe avec pics à 1.55, 1.65 et 1.75 ppm; P—CH_2: 2.76 ppm $J_{(H-P)}$ 15 Hz; C_6H_5: 7.43 (*m*, *p*), 7.63(*o*) ppm; rmn ^{31}P (P_4O_6 externe) δ: 76.1 ppm. *Anal.* calc. pour $C_{13}H_{19}OP$: C 70.25, H 8.62; trouvé: C 70.23, H 8.62.

Sulfuration de **2**a

A une solution de 2×10^{-2} mol de **2***a* dans 100 cm^3 de toluène sec, on ajoute 2.22 g de P_4S_{10}. On chauffe 1 h à reflux, laisse refroidir, neutralise par une solution saturée de CO_3Na_2. On extrait deux fois la phase aqueuse, lave deux fois à l'eau, décante, sèche sur SO_4Na_2, évapore à sec. Le produit brut cristallise; rendement 55%; pf 86°C (éthanol absolu); distillation moléculaire 90–100°C/0.1 Torr; ir (KBr) ν: (C═C) 1603 cm^{-1}; rmn ^1H ($CDCl_3$, 60 MHz, TMS externe)δ: C—CH_3: 1.53 et 1.88 ppm; P—CH_3: 1.90 ppm $J_{(H-P)}$ 13 Hz; C═CH_2 *cis*: 4.72 ppm, *trans*: 5.03 ppm; P—CH: 5.86 ppm J_{H-P} 22 Hz; C_6H_5: 7.40 (*m*,*p*) et 7.80 (*o*) ppm. *Anal.* calc. pour $C_{13}H_{17}PS$: C 66.07, H 7.25; trouvé: C 65.89, H 7.17.

Complexation de **2** *par* Fe_3CO_{12}

A une solution de 10^{-2} mol de **2** dans 100 cm^3 de toluène sec, on ajoute 10^{-2} mol de Fe_3CO_{12}. On agite à reflux pendant 4 h. On laisse refroidir, filtre, évapore à sec et chromatographie sur colonne de silice.

Le composé **2***a* donne deux produits (R_f 0.42 et 0.25 dans AcOEt–MeOH 95:5).

Composé ***12***a—solide marron; rendement 40%; pf 96°C; ir (décaline) ν: (CO) 2056, 1992, 1976 cm^{-1}. *Anal.* calc. pour $C_{16}H_{17}FeO_4P$: C 53.36, H 4.76, Fe 15.51; trouvé: C 53.40, H 4.79, Fe 15.66.

Composé ***12***a′—solide marron clair; rendement 30%; pf 142°C; ir (décaline) ν: (CO) 2041, 1997, 1975 cm^{-1}. *Anal.* calc.: C 53.36, H 4.76, Fe 15.51; trouvé: C 53.60, H 4.64, Fe 15.63.

Le composé **2***d* donne un seul produit par chromatographie sur silice (R_f 0.5 dans AcOEt–MeOH 70:30).

Composé ***12d***—sublime à 50°C/0.1 Torr; rendement 55%; solide jaune; pf 112°C; ir ($CHCl_3$) ν: (CO) 2061, 1990, 1975 cm^{-1}. *Anal.* calc. pour $C_{11}H_{15}FeO_4P$: C 44.32, H 5.07, Fe 18.74; trouvé: C 44.24, H 5.18, Fe 18.55.

The X-ray crystal structure of rapamycin, $C_{51}H_{79}NO_{13}$

D. C. NEIL SWINDELLS, PETER S. WHITE, AND JOHN A. FINDLAY
Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received June 23, 1978

D. C. NEIL SWINDELLS, PETER S. WHITE, and JOHN A. FINDLAY. Can. J. Chem. **56**, 2491 (1978).

The antifungal antibiotic Rapamycin crystallises in the orthorhombic space group $P2_12_12_1$ with $a = 34.85(2)$, $b = 13.08(1)$, $c = 12.25(1)$ Å. The molecular structure has been determined by X-ray crystallography to be a completely new type of macrolide antibiotic of formula $C_{51}H_{79}NO_{13}$.

D. C. NEIL SWINDELLS, PETER S. WHITE et JOHN A. FINDLAY. Can. J. Chem. **56**, 2491 (1978).

L'antibiotique antifongique Rapamycine cristallise sous la forme orthorhombique et le groupe d'espace $P2_12_12_1$ avec $a = 34.85(2)$, $b = 13.08(1)$, $c = 12.25(1)$ Å. On a déterminé la structure moléculaire par diffraction des rayons-X; il s'agit d'un antibiotique macrolide d'un type complètement nouveau de formule $C_{51}H_{79}NO_{13}$.

[Traduit par le journal]

Introduction

Rapamycin, an antifungal antibiotic, is the active principle of a strain of *Streptomyces hygroscopicus* which was isolated from an Easter Island soil sample (1). An early report (2) suggested that Rapamycin is a triene of composition $C_{56}H_{89}NO_{14}$. The current investigation has revealed the complete structure to be that of a completely new type of macrolide antibiotic, the molecular formula of which is $C_{51}H_{79}NO_{13}$.

Experimental

The compound was crystallised from a methanol/water mixture. After a preliminary photographic investigation cell dimensions and intensity data were measured using a Picker FACS-I diffractometer. The relevant crystallographic data are:

$C_{51}H_{79}NO_{13}$ fw = 914.2
Orthorhombic, $P2_12_12_1$, $a = 34.85(2)$, $b = 13.08(1)$, $c = 12.25(1)$ Å, $V = 5585.7$ Å^3, $\rho_c = 1.09$, $Z = 4$. Radiation graphite monochromated MoK_α, $\lambda = 0.71069$ Å. Data collected: $2\theta \leq 40°$, 5358 unique reflections, 3118 observed. Crystal size: $0.6 \times 0.4 \times 0.2$ mm.

Initial attempts to solve the structure using the multisolution direct methods program MULTAN (3) proved unsuccessful. However, when a limited amount of structural information was obtained from ^{13}C nmr, it was included in the calculation of the normalised structure factors (E's) and a second attempt was made. The resulting E-map showed four groups of peaks which exhibited bond distances and angles consistent with those expected. These four fragments (32 atoms) were used to phase a Fourier synthesis in which a little more of the structure was discernable. A total of six such syntheses was required before the final structure was obtained.

Initially, all the atoms were assumed to be carbon and the structure was refined by least-squares methods using a block diagonal approximation and unit weights. As the refinement proceeded it was possible to allocate the oxygen and nitrogen positions from bond length and other geometrical considerations. With all non-hydrogen atoms included in the refinement with anisotropic thermal parameters a reliability index, R, of 0.108 has been obtained. A difference synthesis shows no evidence of any further non-hydrogen atoms. With the exception of the direct methods routines the computer programs used have been the X-RAY 76 package of Stewart *et al.* (4).

Discussion

Figure 1 shows the structure assigned to Rapamycin on the basis of this work.[1] The structure includes a thirty-five atom macrocycle, with an amide C16—N17, a lactone C23—O24, and oxygen bridge between C9 and C14 and an additional bond between N17 and C22 to form an α-carbonyl piperidine unit. The triene predicted by Vézina *et al.* is found at C1 through C6.

The nitrogen position was initially located by the short C16—N17 bond length which was unacceptable for a C—C bond. The α-carbonyl piperidine

[1]Tables of atomic coordinates, thermal parameters, bond lengths, and bond angles are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

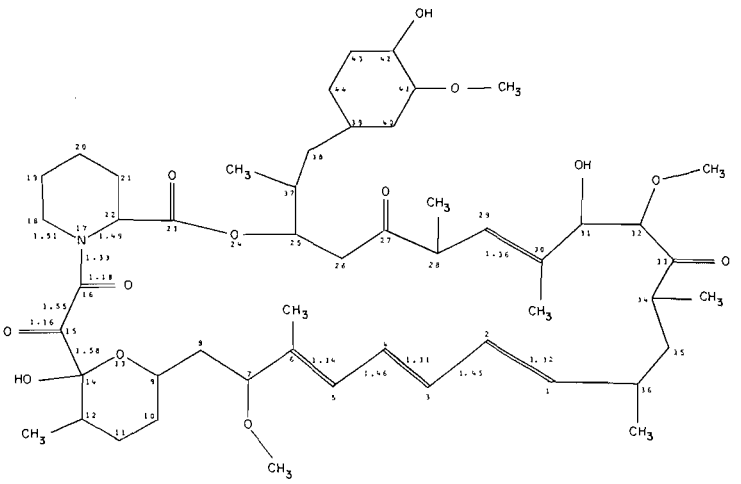

FIG. 1. Molecular structure of Rapamycin showing selected bond lengths (Å, esd, ± 0.02 Å).

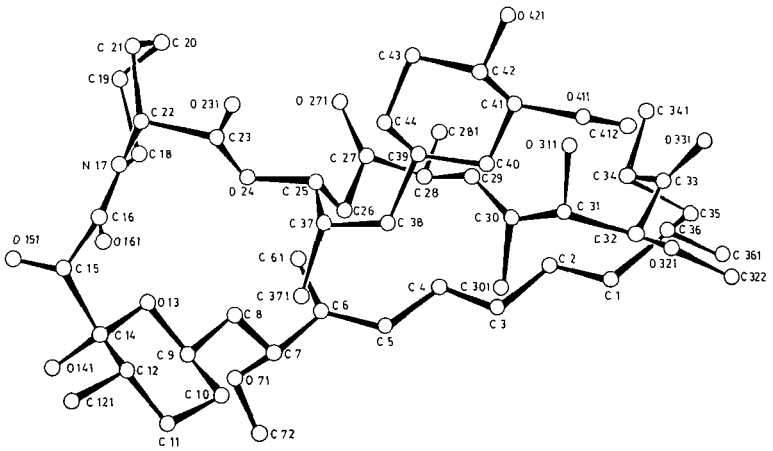

FIG. 2. Perspective view of the Rapamycin molecule.

unit (C15, C16, O161, N17, C18, C22) is essentially planar, thus the nitrogen is sp^2 hybridised and some delocalisation of the carbonyl bond is indicated by a shortening of the C16—N17 bond length, 1.33(2) Å compared to the expected single bond distance of 1.47 Å (5). The two adjacent carbonyl groups (at C15 and C16), on the other hand, are not coplanar and this is reflected in the lack of shortening of the C15—C16 bond (1.55(2) Å).

The triene system exhibits a distinct alternation of bond lengths and although the single bonds, C2—C3 and C4—C5, are shortened to 1.45(2) Å and 1.46(2) Å indicating some double bond character the system is not planar, with a rotation of about 10° occurring about each of the single bonds.

Heats of vaporization of monoalkylcyclohexanes by the gas chromatography – calorimetry method[1]

RICHARD FUCHS AND L. ALAN PEACOCK
Department of Chemistry, University of Houston, Houston, TX 77004

Received February 27, 1978

RICHARD FUCHS and L. ALAN PEACOCK. Can J. Chem. **56**, 2493 (1978).

A recently developed empirical method for measuring heats of vaporization (ΔH_v^{25}) by a combination of gas chromatography and calorimetric heats of solution in the stationary phase has been applied to a series of 9 monoalkylcyclohexanes having C_1–C_{12} side chains. The uncertainties in the measurements (0.07–0.23 kcal/mol) are critically evaluated. Comparison with literature ΔH_v measurements indicates good agreement for low boiling compounds, and for high boiling compounds, values substantially more reliable than were previously obtained from vapor pressure measurements.

RICHARD FUCHS et L. ALAN PEACOCK. Can. J. Chem. **56**, 2493 (1978).

Une méthode empirique développée récemment pour mesurer les chaleurs de vaporisation (ΔH_v^{25}) en combinant la chromatographie en phase gazeuse et des chaleurs calorimétriques de solution dans une phase stationnaire a été appliquée à une série de 9 monoalkylcyclohexanes portant des chaînes latérales de 1 à 12 carbones. On a évalué d'une façon critique les incertitudes dans les mesures (0.07 à 0.23 kcal/mol). Une comparaison avec des mesures de ΔH_v retrouvées dans la littérature suggère une bonne concordance dans le cas des composés de bas points d'ébullition; dans le cas des composés de points d'ébullition plus élevés on obtient des valeurs beaucoup plus sures que celles obtenues antérieurement à partir de mesures de pression de vapeur.

[Traduit par le journal]

Heats of vaporization (evaporation), ΔH_v^{25}, are essential parameters in thermodynamic studies involving comparisons of gaseous and solution behavior, or interconversion of solution and gaseous data. Some recent examples are the study by Beauchamp and co-workers (1) of carbonium ion solvation in fluorosulfuric acid – antimony pentafluoride (requiring ΔH_v of RBr, RCl), measurements by Arnett *et al.* (2) of pyridinium ion solvation in water (ΔH_v substituted pyridines), conversion of liquid heats of formation to the gaseous state (3, 4) (ΔH_v of ketones), and a study of alkane and alkene solvation in polar and nonpolar solvents (5) (ΔH_v of alkanes, alkenes).

A variety of methods are available for measurement of heats of vaporization, but each has definite limitations. All require specialized apparatus, and most are quite time consuming. Each method is capable of giving good results when properly applied to an appropriate system, but it is quite evident that many literature ΔH_v values have uncertainties (precision) much smaller than the actual errors. For 1-butanol the values 12.19 ± 0.01, 12.27 ± 0.02, and 12.50 ± 0.02 kcal/mol have been reported (6, 7). Clearly at least two of the three measurements must involve substantial errors. Other measurements have been reported (7) which involve even larger errors: methyl tetradecanoate (reported $\Delta H_v = 21.3$ kcal/mol) appears to have a higher value than methyl pentadecanoate (21.0 kcal/mol), in contrast to the widely observed increase of about 1.2 kcal/mol per methylene group in large alkyl chains. For methyl oleate having three additional carbon

atoms a value of 20.2 kcal/mol has been reported, which is more than 20% (5.1 kcal/mol) below the probable value[2]. These problems may exist because an unsuitable experimental method was used, but more commonly, because an appropriate method was not available.

Of the experimental techniques direct vaporization calorimetry is probably the most accurate (6–9), but its most effective use is restricted to relatively low boiling compounds (bp < ca 150°C). Many of the best literature values have been measured by this method (7). Static vapor pressure measurements at several temperatutes fit by appropriate equations (7) can, in principle, furnish ΔH_v values of both low and high boiling compounds, and some good values for low boiling compounds have been measured by this technique (7, 10). With higher boiling substances having correspondingly lower vapor pressures a small uncertainty in the pressure measurements leads to a rather sizable percentage error, and the method becomes less accurate. Also, at the higher temperatures required to attain measurable vapor pressures, decomposition of the sample becomes a problem (10) which may not be recognized or cannot be avoided, and this leads to erroneous results. For very high boiling liquids non-equilibrium techniques have been used to measure heats of vaporization. The Knudsen effusion method of vapor pressure measurement (11) and the triplet calorimeter technique (12) employ restricted evaporation through orifices at pressures below the equilibrium saturation pressure. The accuracy of values obtained is limited in the former by various factors, particularly the orifice area and depth measurements, and in the latter, by the accuracy of the (PV work) correction to equilibrium conditions, and the availability of the required saturation vapor pressure data at the temperature of measurement. Gas chromatographic determinations of the enthalpy of transfer from solution in a gc stationary phase to the vapor $[-\Delta H(\text{v} \rightarrow \text{S})]$ tend to parallel ΔH_v (13, 14), but the two quantities are equal only if an athermal solution process of the liquid sample in the stationary phase solvent occurs. Since this is seldom the case, measurement of $-\Delta H(\text{v} \rightarrow \text{S})$ is not generally a reliable way to estimate ΔH_v.

A simple method for the measurement of heats of vaporization has recently been developed in this laboratory (15). It has been applied to liquid substances boiling between 65 and 360°C (5, 15), and both lower and higher boiling substances could undoubtedly be handled. Sample size is small (<200–300 μL), and partial decomposition at high temperatures does not affect the results. The method is derived from reported gc determinations of $\Delta H(\text{v} \rightarrow \text{S})$ (16, 17), using DC-200 silicone fluid as the stationary phase – solvent:

$$[1] \qquad \Delta H(\text{v} \rightarrow \text{S}) = -R\frac{\text{d ln } V_g}{\text{d}(1/T)}$$

V_g is the retention volume (18), defined by the equation

$$[2] \qquad V_g = \frac{F_c j}{w_t}(t_r - t_a)\frac{273.15}{T_r P_0}(P_0 - P_w)$$

where F_c is the carrier gas flow rate at room temperature (T_r) and j is the compressibility factor, w_t is the weight of stationary phase, t_r is the sample retention time, t_a is the retention time of air, P_0 is the outlet pressure, and P_w is the vapor pressure of water at room temperature. Extraordinary care and precision in the measurement of these quantities (particularly w_t) have been necessary to obtain meaningful values of V_g (16, 19, 20). Simplification has been possible by our observation (15) that if these quantities are not measured but are held constant, the specific retention volume then equals a constant times the corrected retention time ($\Delta t = t_r - t_a$). In a plot of ln Δt vs. $1/T$ the intercept of the straight line passing through these points differs from that obtained in the plot of ln V_g vs. $1/T$, but the slope is unchanged.

$$[3] \qquad \Delta H(\text{v} \rightarrow \text{S}) = -R\frac{\text{d ln } \Delta t}{\text{d}(1/T)}$$

The resulting enthalpy change ($\Delta H(\text{v} \rightarrow \text{DC-200})$ at the mean value of T) is the same whether Δt or V_g is used. This value is corrected to 25°C using liquid heat capacities ($C_p(\text{l})$) calculated by the group contribution method (21), and gas-phase heat capacities ($C_p(\text{g})$) calculated from the additivity rules of Benson (22), using the equation

$$[4] \qquad \Delta H^{25}(\text{v} \rightarrow \text{S}) = \Delta H^{T_m}(\text{v} \rightarrow \text{S}) + \int_{T_m}^{298.15} (C_p(\text{l}) - C_p(\text{g}))\text{d}T$$

Since

$$[5] \qquad \Delta H_v = \Delta H_s - \Delta H(\text{v} \rightarrow \text{S})$$

the other essential experimental measurement is of ΔH_s, the heat of solution of a liquid sample in the stationary phase (solvent), measured calorimetrically at 25°C. Without this correction $\Delta H(\text{v} \rightarrow \text{S})$ will in general differ appreciably from ΔH_v, particularly for a polar sample in a nonpolar stationary phase.

The experimental procedure used is somewhat empirical in two respects. Rather than the constant

[2] L. A. Peacock, unpublished results.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

flow rate implied by [1] and [2] as the column temperature is changed, constant carrier gas input pressure has been maintained. The flow rate (as indicated by t_a) decreases somewhat with increasing temperature as the carrier gas viscosity increases. Secondly, heat capacity corrections have been made using 25° values of C_p(l) and C_p(g), rather than taking into account the change in these quantities with temperature in [4]. Furthermore (as pointed out by a referee), the partial molal heat capacity is more appropriate than C_p(l) in [4], for the step of the cycle involving the transfer of the solute in DC-200 from T_m to 25°C. However, values of the partial molal quantity (which are not likely to be widely available) probably do not differ greatly from C_p(l).

For these reasons a systematic calibration must be applied. The apparent values of ΔH_v(calorimetric ΔH_s – gc ΔH(v → DC-200)) have been plotted vs. a group of ΔH_v values determined (mainly by direct vaporization calorimetry) with small uncertainties (7, 12). From the slope and intercept of this plot corrected gc–calorimetry values for other substances are calculated. This procedure largely cancels the errors caused by changes in flow rate, C_p(l) and C_p(g) with temperature, since the effects on the calibration compounds and on other substances are similar. A total of nearly 100 nonpolar and moderately polar compounds of various classes have been run by this procedure, and the agreement with carefully measured literature values leaves little doubt of the effectiveness of the calibration procedure.

In the present study we have chosen to examine a series of nine monoalkylcyclohexanes boiling from 100°C to over 330°C. For three of these compounds calorimetric values of ΔH_v have been reported (7), and for four others, values based on static vapor pressure measurements are available (7). Since few available measurements for high boiling substances are believed to be highly reliable, this series offers an additional advantage. For the higher members of the series at least, the usual methylene increment of about 1.2 kcal/mol in ΔH_v is to be expected, and this can serve as the arbiter of any disagreement between the present experimental values and those previously reported.

It is the objective of the present study to compare the results of the gc–calorimetry method for heats of vaporization with those obtained from direct vaporization calorimetry and static vapor pressure methods, and to critically assess the uncertainties in measurements by the new technique.

Experimental

Reagents

The calibration hydrocarbons (*n*-octane, *n*-nonane, mesitylene, *n*-decane, *n*-dodecane, *n*-tetradecane, 1-hexadecene, and *n*-hexadecane) were commercial samples stated to be of 99% or greater purity which was confirmed by gc. The alkylcyclohexanes were obtained from Chemical Samples Co., excepting *n*-butylcyclohexane (Aldrich). All were of 99% or greater purity excepting *n*-dodecylcyclohexane (96%) which was purified by preparative gc to >99% purity. Dow-Corning DC-200 silicone fluid (100cSt) dried with 4A molecular sieve beads was used for calorimetric measurements and column loading.

Gas Chromatography

Retention times were determined using 30 m × 0.5 mm id stainless steel capillary columns over a 50°C range within the temperature interval of 36–200°C. Temperatures were monitored to ±0.1°C with a partial immersion mercury-in-glass thermometer mounted in the gc oven. After each change in temperature the oven and column were equilibrated for 1 h before sample injection. The injection block was maintained about 25°C above the sample boiling point. A heavily loaded column (II) was used for the lower boiling compounds (methyl-, ethyl-, and *n*-propylcyclohexane), and a lightly loaded column (I) was used for the higher boiling members of the series. Dry nitrogen at a pressure of 10.00 ± 0.06 psi was used as the carrier gas. The dead volume time (t_a) was assumed to be equal to the retention time of methane at each temperature. However, a more convenient internal standard, pentane, was routinely used, after the relative retention times of methane and pentane as a function of temperature had been established. Sample retention times relative to pentane were measured and corrected by the addition of the retention time of pentane relative to methane at each temperature. Triplicate retention times at each of six temperatures were measured for each compound.

Calorimetry

Heats of solution of the calibration compounds and the alkylcyclohexanes were determined in DC-200 silicone fluid with apparatus slightly modified from that previously described (5, 15, 25). The vacuum jacketed calorimeter (volume 100 mL) containing 50 mL of DC-200 was stirred with a commercial magnetic bar (12 × 37 mm) using a stirring unit within the constant temperature bath (25.00 ± 0.001°C) powered by a 300 rpm constant speed gear motor. Even with this increased stirring a somewhat longer period of time (2–3 min) was required to reach the final baseline (following sample addition or operation of the calibration heater) than is required with less viscous solvents (5, 25). However, improved sensitivity (200 μV full scale recorder deflection) compared with a previous report (15) is now feasible. Uncertainties in the ΔH_s measurements are estimated to be ±0.02 kcal/mol up to ΔH_s = 1.00, and 2.5% of the heat of solution when ΔH_s > 1.00 kcal/mol, based on the standard deviation of 3–5 ΔH_s measurements. The methylene increment in ΔH_s of the alkylcyclohexanes in DC-200 is 0.09 ± 0.01 kcal/mol per CH_2.

Calculation of Apparent ΔH_v

ΔH(v → DC-200) was calculated (eq. [3]) from the slope of the ln Δt vs. $1/T$ plot. From this quantity at the mean temperature of the Δt measurements ΔH(v → DC-200) at 25°C can be calculated (eq. [4]) by applying the appropriate ΔC_p correction. Apparent ΔH_v^{25} values were calculated from the 25°C values of ΔH_s and ΔH(v → DC-200) (eq. [5]).

Calibration of Columns

A calibration curve was prepared for each DC-200 gc column relating the apparent ΔH_v for each calibration hydrocarbon to the corresponding literature value of ΔH_v (7). For

heavily loaded Column II the values in kcal/mol were: *n*-octane, 9.30 (apparent), (9.92 (7)); *n*-nonane, 10.37 (11.10); mesitylene, 10.64 (11.35); *n*-decane, 11.58 (12.28); and *n*-dodecane, 14.06 (14.65 (12)). Calculation of the slope and intercept provided the equation for Column II (in kcal/mol):

$$[6] \quad \Delta H_v(\text{corr}) = 0.9808\,\Delta H_v(\text{app}) + 0.8907$$

with a correlation coefficient (R) of 0.9997. For Column I the corresponding values were: *n*-octane, 9.30 (9.92); *n*-nonane, 10.44 (11.10); mesitylene, 10.70 (11.35); *n*-decane, 11.62 (12.28); *n*-dodecane, 14.18 (14.65 (12)); *n*-tetradecane, 16.42 (16.99 (12)); 1-hexadecene, 18.62 (19.14); and *n*-hexadecane, 19.05 (19.45 (12)). The resulting equation for Column I (in kcal/mol) is

$$[7] \quad \Delta H_v(\text{corr}) = 0.9793\,\Delta H_v(\text{app}) + 0.8538$$

and the correlation coefficient is 0.9999.

Analysis of Uncertainties

Regression analysis of the ln Δt vs. $1/T$ plot yields, in addition to the slope and intercept, the correlation coefficient and the standard error of the estimate ($S_{y \cdot x}$). Although values of R of 0.9996 or larger were noted for both calibration compounds and alkylcyclohexanes, this can only serve as a rough guide for determining whether data should be rejected, since R increases with slope. The standard error of the estimate may be treated more quantitatively. The standard deviation from regression (S_b) is calculated from $S_{y \cdot x}$ and the sum of the squares of the deviations in x ($x = 1/T$) (26). The uncertainty in the slope may then be expressed as $\pm(t)(S_b)$, where t is the Student t value for a given number of points (6) and confidence level (99%). The calibration curve uncertainty is determined in the same manner.

The total uncertainty in ΔH_v is calculated from the uncertainties in the heat of solution, gc slope, C_p(l), C_p(g), and calibration curve. Each of the component uncertainties (σ) is squared (yielding the variance), and the variances are summed. The square root of the sum of the variances is the total uncertainty in the heat of vaporization.

$$[8] \quad \sigma_{\text{total}} = [\sigma_{\Delta H_s}{}^2 + \sigma_{\text{gc}}{}^2 + \sigma_{C_p(\text{l})}{}^2 + \sigma_{C_p(\text{g})}{}^2 + \sigma_{\text{calibr}}{}^2]^{1/2}$$

Sample Calculation

n-*Butylcyclohexane*

Gas chromatographic data for this compound on Column I was obtained for the temperature range of 39.1 to 80.4°C (Table 1). At each of six temperatures triplicate chromatograms were obtained in the presence of pentane. The retention times vs. pentane were averaged and corrected for the previously determined retention time of pentane vs. methane to give Δt. For each temperature ln Δt was plotted vs. $1/T$ (K), giving the linear regression parameters slope = 5113.64, intercept = −13.3874, correlation coefficient = 0.9999, and standard error of the estimate ($S_{y \cdot x}$) = 0.010. ΔH(v → DC-200) at the mean temperature of the measurement range equals (by [1]) −(5113.64)(1.9872) = −10161.83 cal/mol.

The ΔC_p correction requires estimation of the liquid (23) and gaseous (24) heat capacities. C_p(l) for *n*-butylcyclohexane equals the methyl group contribution (8.70) + eight times the methylene contribution (5 ring, 3 side chain) (8 × 7.323 = 58.58) + the methyne group contribution (4.94) + the cyclohexane ring correction factor (−6.66) = 65.56 cal/mol deg. C_p(g) equals 6.19 + 8(5.50) + 4.54 −6.40 = 48.33 cal/mol deg. $\Delta C_p = C_p$(l) − C_p(g) = 17.2 cal/mol deg. The ΔC_p correction from the mean temperature (333.5 K) to 25°C was calculated using eq. [4], treating C_p(l), C_p(g), and ΔC_p as constant within the temperature range of interest: ΔH^{25}(v → DC-200) = −10.16 ±0.05 + (298.2 − 333.5)(0.0174 ±0.05) = −10.77 ±0.07 kcal/mol. From eq. [5] ΔH_v(apparent) = (0.42 ± 0.02) − (−10.77 ± 0.07) = 11.19 ± 0.07 kcal/mol. The corrected value of ΔH_v(eq. [7]) = 0.979(11.19) + 0.854 = 11.81 ± 0.07 kcal/mol.

Results and Discussion

The heats of vaporization at 25°C of nine mono-*n*-alkylcyclohexanes (alkyl = methyl–heptyl, decyl, and dodecyl) are listed in Table 2. Values for the pentyl and hexyl compounds have not previously been reported. Table 2 also indicates available literature values, and the methylene increment between homologous compounds for both the present experimental and literature values.

Comparison with Previous ΔH_v *Measurements*

The agreement between the present experimental gc–calorimetry values and previous measurements (7) is within the combined uncertainties for the methyl, ethyl, propyl, and decyl compounds, and exceeds this margin by 0.03 kcal/mol for the butyl derivative. The literature values for methyl-, ethyl-, and propylcyclohexane result from vaporization calorimetry measurements (results with propylcyclohexane were later confirmed by vapor pressure measurements), and have stated uncertainties of ±0.01 kcal/mol. One is inclined to consider these the values of choice, although the quite uneven methylene increment should be noted (Me $\xrightarrow{1.22}$ Et $\xrightarrow{1.11}$ Pr). It is likely that at least ΔH_v(Et) is in error by considerably more than the stated uncertainty; a value of ~9.61 kcal/mol would be more in line with the methyl and propyl values. The measured value for heptylcyclohexane seems preferable to the earlier value (determined from vapor pressure measurements) on the basis of a more likely methylene group contribution in the C_7–C_{10} interval (1.19 vs. 1.11 per CH_2). There is excellent agreement in the values for decylcyclohexane. The previously measured (by vapor pressure) ΔH_v of 22.33 ±0.30 kcal/mol for dodecylcyclohexane is more than 1 kcal/mol higher than the new value, and is 3.50 kcal/mol higher than the decylcyclohexane value. The methylene increment of 1.75 kcal/mol per CH_2 is unreasonably large, and this dodecylcyclohexane value should be rejected. (Vapor pressure ΔH_v measurements on the methyl esters of the C_8–C_{15} fatty acids (7) show methylene increments of −0.3 to 1.8 kcal/mol, and uncertainties of 0.3–1 kcal/mol. Our unpublished gc–calorimetry values have increments of 1.12–1.28 kcal/mol, and 0.10–0.22 kcal/mol uncertainties.) It is rather typical of high boiling substances such as dodecylcyclohexane (bp 331°C) that static vapor pressure

measurements often lead to quite unsatisfactory values of ΔH_v. The error is in the direction which would be anticipated if slight decomposition were to occur at the higher temperatures of P_v measurement. It should be noted, however, that ΔH_v values of high boiling liquids derived from vapor pressure measurements are sometimes unreasonably low, and this implies that pyrolysis is not the only problem inherent in the method.

Errors in the Gas Chromatography – Calorimetry Method

The uncertainties in the measured ΔH_v values (Table 2) at the 99% confidence level are based on an evaluation of the uncertainties in ΔH_s (calorimetric), $\Delta H(v \rightarrow$ DC-200) (gc), $C_p(l)$, $C_p(g)$, and the calibration line [8]. The accuracy of calibration is an important consideration in determining the overall accuracy of the ΔH_v values. Heavily loaded Column II, which was used principally for compounds boiling below ~175°C was calibrated with mesitylene and the C_8, C_9, C_{10}, and C_{12} *n*-alkanes. Lightly loaded Column I, generally used for compounds of bp 175 – >330°C, was calibrated with the same series of five compounds, and also with *n*-tetradecane, 1-hexadecene, and *n*-hexadecane. The extrapolation of this calibration to even higher values has been verified by measurement of ΔH_v of *n*-heptadecane ($\Delta H_v = 20.58 \pm 0.20$ reported (12), 20.56 ± 0.20 kcal/mol) and of 1-octadecene ($\Delta H_v = 21.32 \pm 0.22$; estimated with methylene group increments of 1.18 kcal/mol per CH_2, 21.50 kcal/mol).

The estimated uncertainties in $C_p(l)$ and $C_p(g)$ are 1 cal/mol deg. (21–24). Temperature variation in these quantities are available for relatively few compounds, so one cannot, in general, make these corrections when using eq. [4]. However, [4] has been applied with C_p temperature corrections to the *n*-alkane calibration compounds, propylcyclohexane, and dodecylcyclohexane. Calculated this way the calibration line for Columns I and II both have slopes of 1.00. Propylcyclohexane and dodecylcyclohexane ΔH_v values are 10.63 and 21.29 kcal/mol, respectively, compared with values calculated assuming constant ΔC_p (Table 2) of 10.68 and 21.25 kcal/mol. It is apparent that omission of the temperature variation in $C_p(l)$ and $C_p(g)$ from consideration has had similar effects on both calibration compounds and alkylcyclohexanes, and has introduced only a minor error. The intercept in eqs. [6] and [7] has been related to variation in the (constant pressure) carrier gas flow with temperature by the observation that the intercept is greatly diminished when a crude flow correction is applied to the retention time data used in eq. [3].

Impurities and partial sample decomposition are normally without effect on the value of $\Delta H(v \rightarrow S)$ obtained by the present method, because gas chromatography is intrinsically a separation, as well as a measuring, procedure. In the calorimetric measurement of ΔH_s sample decomposition is highly unlikely because of the low temperature (25°C) and inert character of the solvent (DC-200 silicone fluid). The presence of a small amount of a highly polar impurity in a much less polar sample (such as 1% of a carboxylic acid in an ester sample) may lead to a

measurable error, but such impurities are readily removed by preparative gc. In the alkylcyclohexane series the presence of $<1\%$ of hydrocarbon impurity has no measurable effect on ΔH_s.

It appears that the gc–calorimetry method gives results with relatively low boiling compounds in good agreement with those obtained by direct vaporization calorimetry. The results with higher boiling compounds show a substantial advantage in reliability of the gc–calorimetry procedure over vapor pressure techniques.

An esr and CIDEP study of the photoreduction of furil

A. JOHN ELLIOT AND JEFFREY K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6
Received April 7, 1978

A. JOHN ELLIOT and JEFFREY K. S. WAN. Can. J. Chem. **56**, 2499 (1978).

The transient free radicals formed when furil was photoreduced have been characterized by esr and CIDEP. Two furil derived radicals were observed: one was the protonated form of the semidione radical (FH·) while the other was an allyl radical formed by radical addition to the furil ring. Initial polarization was observed for FH· which was consistent with the triplet mechanism and these CIDEP results indicate that phenol is a better chemical quencher of the furil triplet than pentachlorophenol which is in turn more efficient than 2-propanol. A method to estimate relative T_1 of radicals is also described.

A. JOHN ELLIOT et JEFFREY K. S. WAN. Can. J. Chem. **56**, 2499 (1978).

On a caractérisé, par rpe et CIDEP, les radicaux libres transitoires formés lorsqu'on photoréduit le furil. On a observé deux radicaux dérivés du furil: l'un existe sous forme protonée du radical semidione (FH·) alors que l'autre est un radical allyle formé par l'addition radicalaire sur le noyau furil. On a observé la polarisation initiale du FH· qui est en accord avec un mécanisme triplet et ces résultats de CIDEP indiquent que le phénol est un meilleur piège chimique pour le triplet furil que le pentachlorophénol qui est luimême plus efficace que le propanol-2. On décrit une méthode pour évaleur les valeurs T_1 relatives des radicaux.

Introduction

Recently we reported the observation of the zero-field CIDNP when furil was photoreduced in the presence of pentachlorophenol (1). Because zero-field CIDNP studies under suitable conditions can provide some unique insights into cage reactions, the furil–phenol system is being developed as a model to examine the detailed theory involved in zero-field and low-field CIDNP studies. To complement this programme, we have characterized by esr the free radicals generated when furil was photoreduced in the presence of different hydrogen donors. The results of this study are presented here.

Experimental

The chemicals were purchased from: PCR (furil), Baker (phenol), Aldrich (pentachlorophenol), Fisher (2-methylphenol, acetonitrile), and Canlab (2-propanol, toluene, chloroform). Phenol, 2-methylphenol, and 2-propanol were sublimed or distilled before use.

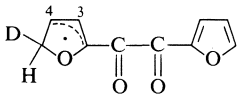
As furil is not very soluble in most of the solvents used in these experiments, its concentration depleted rapidly when static solutions were photolysed directly in the esr cavity of a Varian E-3 spectrometer. To circumvent this problem the solutions (which were deoxygenated by bubbling with nitrogen) were flowed through the cavity. The design of the flow cell was similar to that of a conventional cold trap on a vacuum line except that the solution flowed down the centre tube and back up between this tube and the outer jacket to the outlet at the top. The solutions were accelerated through the system by a pressure differential and the flow rate was controlled by a needle valve. In general the flow rate (1–3 ml/min) was adjusted to optimize signal size. The temperature of the solutions in the cavity were controlled by flowing thermostatted nitrogen gas by the spectrosil flow cell. The 1000 W light source, rotating sector, data acquisition system, and the method used to measure initial polarizations have been described elsewhere (2). The esr simulations were performed on a Nicolet 1180 computer.

Results

Photolysis of Furil: 2-Propanol Solutions

(*a*) No phenols present.

Only the neutral furil radical (FH·) was observed by esr when furil was photoreduced in 2-propanol.



1

The hyperfine coupling constants and their tentative assignments are: $a_3^H = 0.56$ mT; $a_4^H = 0.09$ mT; $a_5^H = 0.47$ mT; $a_{3'}^H = a_{5'}^H = 0.09$ mT; $a_{4'}^H < 0.03$ mT. A temperature-dependent coupling constant (0.09 mT (−30°C), 0.04 mT (0°C), <0.02 mT (20°C)) is assigned to the hydroxyl proton. These constants and assignments differ slightly from those previously published (1). A *g*-factor of 2.0035 was estimated for this radical by comparison to the spectrum of the phenoxy radical whose *g*-factor was assumed to be 2.0048 (3) (see next section).

When the light beam was chopped with the rotating sector, no initial polarization was evident in the CAT traces of the time profile of the furil radical.

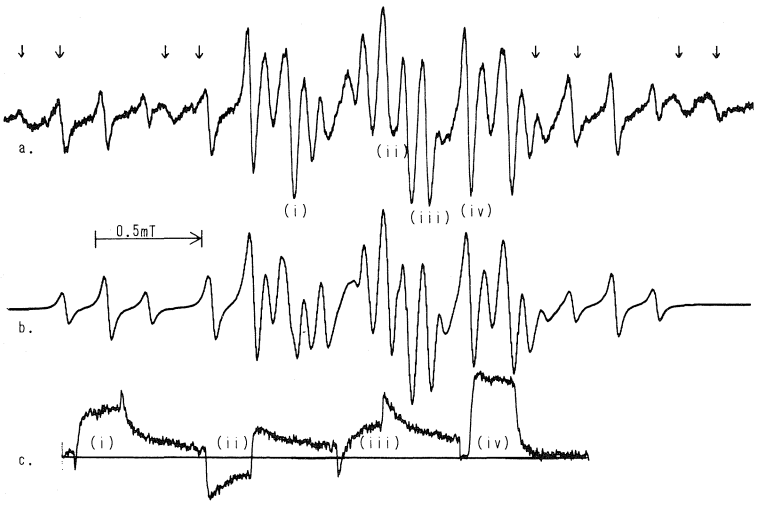


FIG. 1. (*a*) The esr spectrum observed when a furil:2-propanol solution containing 1.28 mol dm^{-3} phenol was photolysed at −30°C. The arrows indicate radical **1**. (*b*) The simulated esr spectrum of furil and phenoxy radical. (*c*) The time profiles of the peaks which are indexed in (*a*).

(*b*) With a phenol present.

When a furil:2-propanol solution containing either phenol, 2-methylphenol, or pentachlorophenol was photolysed, three radicals were always observed: the furil radical, the phenoxy radical, and a third radical (**1**) whose identity we will discuss later.

The spectrum recorded when a furil:2-propanol solution containing 1.28 mol dm^{-3} phenol was photolysed at −30°C is shown in Fig. 1*a*. (The lines from radical **1** are indicated by arrows.) The furil radical spectrum showed strong emissive initial polarization (triplet mechanism) (2, 4) whereas the other two radicals were unpolarized. In fact it was by mapping the polarization of the different peaks (see Fig. 1*c*) that enabled us to assign the furil radical in this overlapped spectrum. A simulated spectrum of just the phenoxy and furil radical is shown in Fig. 1*b*. (It is from the *g*-difference of 0.172 mT (i.e. ΔH) between the two radicals that the furil *g*-factor was estimated in the previous section, from the expression $g = g_{\text{phenol}}(1 - \Delta H/H)$ where H is the magnetic field of the spectrum centre and $\Delta H = 0.172$ mT.) The agreement is very good and what small discrepancies there are arise predominantly from the radical pair polarization which is also present. With radical pair (E–A) polarization the high-field peaks are larger than the corresponding low-field peaks (2, 4).

With 2-methylphenol (1.16 mol dm^{-3}) present in the furil:2-propanol solution, the 2-methylphenoxy radical was observed along with the furil radical and radical **1**. The furil radical was still strongly initially polarized but, in this case, the 2 methylphenoxy radical also shows a small initial polarization. Radical **1** was unpolarized.

With pentachlorophenol, three radicals were again observed. The pentachlorophenoxyl radical appeared as a broad low intensity resonance to the low field side of the furil spectrum, and because it was not obscured by the phenoxy radical, the spectrum of radical **1** could be seen clearly. (These general features can be seen in Fig. 2 although the solvent in this case was 10 vol% 2-propanol:toluene.) At the highest pentachlorophenol concentration studied (1.2 mol dm^{-3}), the furil radical exhibited a small emissive initial polarization.

Photolysis of Furil in Other Solvents

The photoreduction of furil was carried out in a number of other solvent systems. A 10 vol% 2-propanol:toluene system was used because past experience has shown that larger steady-state polarizations are often observed due to the shorter half-life of the radicals (see later). Acetonitrile is a solvent we commonly used in CIDNP experiments but because of its high absorptivity of microwaves at 9.0 GHz it had to be diluted with toluene to recover the cavity *Q*. A 25 vol% acetonitrile:toluene mixture was used. Chloroform solutions were also studied as this solvent is currently used for the CIDNP studies of furil.

(*a*) No phenols present.

Photolysis of furil in all three solvents at −30°C gave the spectrum of the furil radical. (Photolysis of furil alone in toluene gave no observable esr spec-

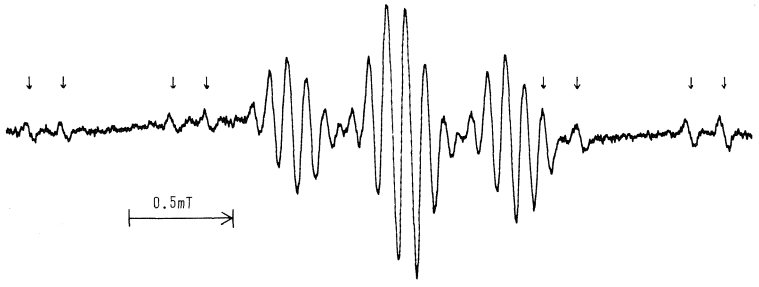

FIG. 2. The esr spectrum observed when a furil:10 vol% 2-propanol:toluene solution containing 0.5 mol dm^{-3} pentachlorophenol was photolysed at $-30°C$. The arrows indicate radical **1**.

trum.) In 10 vol% 2-propanol:toluene, the coupling constants were the same as for the 2-propanol solvent. For the other two solvents, the spectra were weaker than that observed in the 2-propanol:toluene solvent, and the coupling constants for protons 3 and 5 were a little larger ($a_3^H = 0.50$ mT, $a_5^H = 0.59$ mT). When chloroform was the solvent, a second, even weaker, spectrum was detected which was very similar to that of radical **1**.

(*b*) With a phenol present.

In all three solvent systems after the addition of phenol, the unpolarized spectrum of the phenoxy radical and radical **1** were observed along with a strongly emissively polarized furil radical spectrum.

The spectrum observed during the photolysis of a furil:10 vol% 2-propanol:toluene solution containing pentachlorophenol at $-30°C$ is shown in Fig. 2. The intense centre spectrum is that of the furil radical, radical **1** is indicated by the arrows and the pentachlorophenoxy radical by a broad resonance to the lowfield side of the spectrum. In this case none of the radicals were polarized but at higher pentachlorophenol concentration emissive initial polarization was observed in the furil radical spectrum. If 2-propanol was not present in these solutions, the spectrum was weaker and some extra peaks comparable in size to those of radical **1** were observed.

The solubility of pentachlorophenol in chloroform is low but when a 0.1 mol dm^{-1} pentachlorophenol–furil–chloroform solution was photolysed, all three radicals (furil, phenoxy, and **1**) were observed. None were polarized.

Discussion

The observation of initial polarization in the furil radical when phenols were present indicates that a spin polarized triplet state must be involved in the photochemical mechanism (2, 4). If we signify furil as F and the hydrogen donor as HD, the photoreduction can be written as

[1] $$F \xrightarrow{h\nu} {}^1F^* \xrightarrow{ISC} {}^3F$$

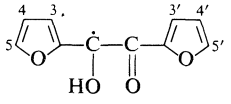
[2] $$^3F + HD \rightarrow FH^{\cdot} + D^{\cdot}$$

When HD was 2-propanol, the counter radical D$^{\cdot}$ was not observed because the following reaction (by analogy to biacetyl and pyruvic acid) (5, 6) probably occurred rapidly

[3] $$F + (CH_3)_2\dot{C}OH \rightarrow FH^{\cdot} + (CH_3)_2CO$$

The fate of the counter radicals, D$^{\cdot}$, when phenol, chloroform, or acetonitrile was the hydrogen donor is not certain. In the case when phenol was HD, the half life of the phenoxy radical was far shorter than that of the furil radical (compare, in Fig. 1*c*, trace (*iii*) which is predominantly from FH$^{\cdot}$ to that of (*iv*) of the phenoxy radical). The rate of decay of the phenoxy radical in this system was far greater than when it was generated by photolysing a biacetyl:phenol:2-propanol solution. This suggests that the phenoxy radical reacted through mechanisms other than bimolecular radical–radical reactions. One possibility is the formation of radical **1**.

Provided that only one peak of radical **1** is overlapped by the furil radical spectrum in Fig. 2, its hyperfine coupling constants are: $a^H = 0.17$ mT; 0.67 mT; 2.42 mT. Similar splittings for radical **1** were found regardless which phenol was present or if the reduction of furil was carried out in chloroform alone. A good candidate for **1** is a radical adduct of the form



(FH$^{\cdot}$)

where the donor radical has added to the 5 position of the furan ring. These coupling constants are similar to those of related allyl type radical adducts

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

formed from substituted furans which have been studied elsewhere (7, 8).

The CIDNP observation (1) suggests that in the primary cage, reaction [4] occurred.

[4] $$FH^{\cdot} + C_4Cl_5O^{\cdot} \rightarrow F + C_4Cl_5OH$$

However, at this point it is not possible to estimate what proportion of radicals underwent this reaction. Presumably the other counter radicals also underwent similar cage reactions.

From the observed electron polarizations, it can be concluded that phenol was a more efficient hydrogen donor than pentachlorophenol which in turn was better than 2-propanol. The basis for this statement is that the enhancement factor V for the polarization generated in the radicals by reaction [2] is given by (2, 4)

[5] $$1/V = 1/V_0 + 1/(V_0{}^3T_1k_q[HD])$$

where V_0 is the enhancement factor at infinite hydrogen donor concentration, ${}^3T_1$ is the spin–lattice relaxation time of the furil triplet, and k_q is the rate constant for reaction [2]. V is related to observed steady state enhancement factor V_{ss} by the relationship

[6] $$V = V_{ss}t_{1/2}/T_1$$

where $t_{1/2}$ is the radical half life and T_1 is the spin–lattice relaxation time. For a given radical and solvent, V_0, ${}^3T_1$, and T_1 are constants, so, for a given hydrogen donor concentration, the HD which generates the larger value of $V_{ss}t_{1/2}$ must have the larger k_q. Because of the severe overlapping of the different spectra, e.g. see Fig. 1*a*, it was impractical to carry out quantitative studies. However, from the magnitudes of the polarizations observed in the furil radical with different hydrogen donors present, it can be said that phenol and 2-methylphenol are comparable as hydrogen donors to the furil triplet and that they are somewhat better than pentachlorophenol which, in turn, is better than 2-propanol.

Some estimate of the *relative* T_1's of the two radicals formed in the photoreduction can be made if the enhancement factor for both radicals can be measured (2). The triplet mechanism predicts that both radicals will be generated with the same V, but the observed V_{ss} of each radical depends on its $t_{1/2}$ and T_1 (eq. [6]). As noted earlier, in these experiments overlapping spectra precluded accurate V_{ss} measurements, but estimates of V_{ss} and $t_{1/2}$ from the CAT traces for the furil radical and 2-methoxyphenoxy radical in 2-propanol indicate that T_1 for the former is about 50 times greater than that for the latter. For the phenoxy radical (in 2-propanol) where no polarization was observed, its T_1 must be at least 100 times less than that of the furil radical. It is not surprising that the T_1 of the 2-methylphenoxy radical is at least twice that of the phenoxy radical as this parallels the behaviour of the T_1 of 2-methylbenzosemiquinone and benzosemiquinone radical anions (9).

An electron spin resonance study of organomercury adducts of phenanthroquinone

KUANG S. CHEN, RICHARD T. SMITH, AND JEFFREY K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received April 26, 1978

KUANG S. CHEN, RICHARD T. SMITH, and JEFFREY K. S. WAN. Can. J. Chem. **56**, 2503 (1978).

The exchange reaction between $M^+PQ^{-\cdot}$ ion-pairs and MeHgCl leads to the formation of $MeHgPQ^{\cdot}$ adduct with a characteristic low *g*-factor of 2.00052 and a small methyl proton splittings of 0.16 G. The dynamic and equilibrium aspects of the exchange depend upon the alkali cation, the concentration of MeHgCl, and for $Na^+PQ^{-\cdot}$ also on temperature. The $MeHgPQ^{\cdot}$ is found to be relatively stable at room temperature and in the presence of water. These results may be of potential value to toxicology studies of methylmercury.

KUANG S. CHEN, RICHARD T. SMITH et JEFFREY K. S. WAN. Can. J. Chem. **56**, 2503 (1978).

La réaction d'échange entre les paires d'ions $M^+PQ^{-\cdot}$ et le MeHgCl conduisent à la formation d'un adduit $MeHgPQ^{\cdot}$ caractérisé par un facteur *g* bas de 2.00052 et un couplage faible du proton méthylique de 0.16 G. Les aspects dynamiques et d'équilibre de l'échange dépendent du cation alcalin, et de la concentration de MeHgCl; dans le cas du $Na^+PQ^{-\cdot}$ ils dépendent aussi de la température. On a trouvé que le $MeHgPQ^{\cdot}$ est relativement stable à la température ambiante et en présence d'eau. Ces résultats peuvent avoir une valeur potentielle pour des études de toxicologie du méthylmercure.

Introduction

The ability of *o*-quinones such as the 9,10-phenanthroquinone (PQ) to form paramagnetic adducts with organometals has recently been emphasized (1). Among the controversial heavy metal environmental contaminants, Pb and Sn adducts with camphorquinone (2) and with PQ (1) have been extensively investigated but few Hg adducts with *o*-quinones had been reported (3). Methylmercury poisoning has generally been acknowledged as an environmental health hazard and in biological systems methylmercury is known to complex with sulfhydryl groups (4). Recent toxicology and biochemical studies (5, 6) show that despite the thermodynamic stability of these diamagnetic methylmercury complexes, ligand exchanges are sufficiently fast so that *N*-acetyl-D,L-penicillamine (5) can be used to extract methylmercury from the red blood cell and tissues. Such chemotherapeutic agents can function as metal regulators if they initially carry essential metals such as Na or K and deliver them to tissues by selectively exchanging and binding the toxic metal which subsequently can be excreted. The present work investigates by esr spectroscopy the specific exchange reactions of paramagnetic alkali–PQ ion-pairs with organomercury compounds leading to relatively stable paramagnetic R—Hg—PQ adducts.

Experimental

9,10-Phenanthroquinone (anthraquinone-free) and $NaBPh_4$ were supplied by Aldrich and the organomercury compounds used were obtained from Alfa. $KBPh_4$ was prepared by the method of Plafaum and Howick (7). Solvents such as tetrahydrofuran (THF), 2-methyltetrahydrofuran (MTHF), and *N*,*N*′-dimethylformamide (DMF) were refluxed over molecular sieves, distilled, and stored over K/Na alloy or molecular sieves under vacuum. Procedures for sample preparations of ion-pairs and the addition of organometals are similar to the method described previously (8). Electron spin resonance spectra were recorded on a Bruker 420 spectrometer with 100 kHz modulation. Magnetic field was monitored by a Bruker nmr oscillator and *g*-factor measurements were made using the potassium naphthalene ion-pair in THF as an external standard (9). Unless otherwise stated, all experiments were carried out at room temperature, 20°C.

Results and Discussion

Most of the previous alkali–PQ ion-pair and their spin adduct studies (1) were carried out in pure THF solvent in which any trace of water had been painstakingly removed. It was demonstrated that in the alkali–PQ ion-pair systems, when THF was pumped off under vacuum and replaced by DMF solvent, the $M^+PQ^{-\cdot}$ ion-pair would dissociate and the radical anion $PQ^{-\cdot}$ (**1**) would be observed. In this study of organomercury–PQ adducts it became desirable that a high concentration of water be present in order to show that mercury–PQ adducts could be observed in biological systems. Therefore, deionized and distilled water was added to THF, wherever desired, to give a 1:5 vol ratio mixture at approximately a pH of 7. A drastic change in the ratio to 3:5 did not appear to affect the esr results. For the $M^+PQ^{-\cdot}$ systems, the addition of water caused the ion-pair to dissociate and the radical anion $PQ^{-\cdot}$ (**2**) to be observed. The

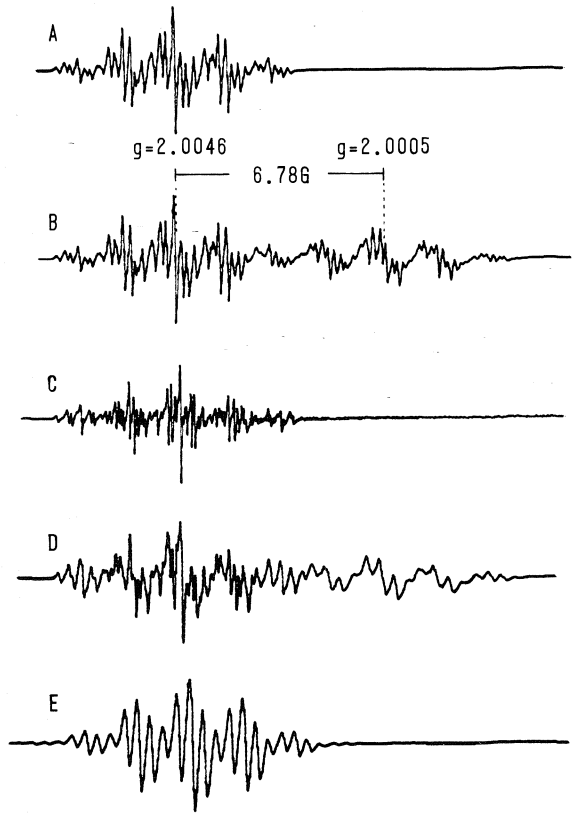

FIG. 1. Electron spin resonance spectra of (*A*) K^+PQ^{-}· ion pair in THF at −30°C, (*B*) K^+PQ^{-}· ion pair and MeHgPQ· adduct in THF at −30°C, (*C*) PQ^{-}·(II) anion radical in the mixture of THF and H_2O (volume ratio 5:1) at −10°C, (*D*) PQ^{-}·(II) anion radical and MeHgPQ· adduct in the mixture of THF and H_2O (volume ratio 5:1), the signal gain of PQ^{-}·(II) anion radical has been attenuated to $\frac{1}{6}$ of that of MeHgPQ· adduct, and (*E*) Me_3PbPQ· adduct in THF at 20°C.

esr parameters of the PQ anion radicals (**1**) and (**2**) are slightly different (Table 1) due to the changes in the solvent. A typical esr spectrum of the K^+PQ^{-}· ion-pair in pure THF is shown in Fig. 1*a* and the same system in THF/H_2O mixture exhibits only the spectrum of PQ^{-}· (**2**) (Fig. 1*c*).

It has been demonstrated (1, 8) in THF that exchanges of cations among alkali–PQ ion-pairs are very specific. For example,

$$[1]\quad K^+PQ^{-}\cdot + NaBPh_4 \xrightarrow{THF} Na^+PQ^{-}\cdot + KBPh_4$$

reaction [1] would proceed instantaneously to completion whereas the exchange involving Na^+PQ^{-}· and $KBPh_4$ in THF would not proceed at all. These specific cation exchange reactions do not appear to be dependent upon the salt concentrations. Exchanges with organometals such as Me_3SnCl and Et_3PbOTf are also rapid and complete at room temperature (1). However, when a trace amount (1 mg or less) of MeHgCl was introduced at room temperature into a THF solution containing the K^+PQ^{-}· ion-pairs, the exchange reaction

$$[2]\quad K^+PQ^{-}\cdot + MeHgCl \xrightarrow{THF} MeHgPQ\cdot + KCl$$

was not complete and the esr spectrum (Fig. 1*b*) clearly showed the coexistence of both the K^+PQ^{-}· and the adduct MeHgPQ·. The concentration of the K^+PQ^{-}· ion-pair was estimated to be about 10^{-2} *M*. When the concentration of the MeHgCl was substantially less than that of the K^+PQ^{-}·, the extent if the exchange as measured by the ratio [MeHgPQ·]/[K^+PQ^{-}·] was not significantly dependent upon temperature (within the experimental range between −67 and 20°C). Addition of more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

MeHgCl (up to 2 mg) would force the exchange to proceed further but slowly to completion, usually upon standing for 3 to 4 h. In another set of experiments in which the initial concentration of MeHgCl was made greater than $K^+PQ^{-\cdot}$ concentration, both $K^+PQ^{-\cdot}$ and $MeHgPQ^{-\cdot}$ were still observable upon mixing but the concentration of $K^+PQ^{-\cdot}$ could be seen slowly decreasing to zero.

The dynamic behaviour of the exchange between $Na^+PQ^{-\cdot}$ and MeHgCl was somewhat different. For example, the addition of 1 mg MeHgCl to a THF solution containing approximately 10^{-2} *M* of $Na^+PQ^{-\cdot}$ at temperatures below $-5°C$ did not lead to any observable exchange. Only when temperature was raised to above $-5°C$ has the esr spectrum of the MeHgPQ· radical become detectable. After an appreciable amount of the adduct MeHgPQ· was formed at higher temperatures, lowering the temperature to $-60°C$ again resulted in the observation of only the $Na^+PQ^{-\cdot}$. This result suggests that the exchange between MeHgCl and $Na^+PQ^{-\cdot}$ is more dependent on temperature.

When water was added to the $K^+PQ^{-\cdot}$ and MeHgPQ· system in THF, the esr spectrum changed from that in Fig. 1*b* to Fig. 1*d*. Careful examination of the spectra showed that upon the addition of water, almost all of the coexisting $K^+PQ^{-\cdot}$ ion-pairs dissociated to solvated K^+ and $PQ^{-\cdot}$ (**2**) but most of the MeHgPQ· adduct remained intact with only some loss of line resolution. It is particularly significant to biological systems which contain large concentration of water at a pH around 7 that the paramagnetic adduct MeHgPQ· can survive under such conditions for at least several days. Furthermore, the concentration of $PQ^{-\cdot}$ (**2**) became significantly larger (about 10 times) than the initial concentration of the precursor $K^+PQ^{-\cdot}$ before water was added. Although a small part of the $PQ^{-\cdot}$ (**2**) concentration may have been derived from the dissociation of the MeHgPQ· adduct in THF/H_2O, the main reason for the observation is probably due to the following equilibrium (10).

[3]
$$\begin{array}{ccc} 2K^+PQ^{-\cdot} & \underset{}{\overset{THF}{\rightleftharpoons}} & (K^+PQ^{-\cdot})_2 \\ \text{paramagnetic} & & \text{diamagnetic} \\ \downarrow +H_2O & & \downarrow +H_2O \\ 2K_{aq}^+ + 2PQ^{-\cdot}(\mathbf{2}) & & 2K_{aq}^+ + 2PQ^{-\cdot}(\mathbf{2}) \end{array}$$

A scheme based upon cation selection of $PQ^{-\cdot}$ (**2**) at $-60°C$ in THF and various exchange reactions can be summarized to account for the aforementioned observations at 20°C:

[4]
$$PQ^{-\cdot}(\mathbf{2}) \xleftarrow[(20°C)]{+H_2O} K^+PQ^{-\cdot} \underset{K^+BPh_4^-}{\overset{Na^+BPh_4^-}{\rightleftharpoons}} Na^+PQ^{-\cdot} \xrightarrow[(20°C)]{+H_2O} PQ^{-\cdot}(\mathbf{2})$$

$$[MeHgPQ^{\cdot} + PQ^{-\cdot}(\mathbf{2})] \xleftarrow[(20°C)]{+H_2O} MeHgPQ^{\cdot} \quad (K^+BPh_4^-,\ MeHgCl) \quad (Na^+BPh_4^-,\ MeHgCl,\ (20°C))$$

The esr spectrum of the MeHgPQ· adduct shown in Fig. 1*b* is clearly different from that of the $K^+PQ^{-\cdot}$ ion-pair. Although the ^{199}Hg ($I = \frac{1}{2}$, 16.86%) and the ^{201}Hg ($I = \frac{3}{2}$, 13.24%) hyperfine splittings were not resolved, the small proton splittings from the methyl group in the MeHg moiety were observed and are reported along with the proton splittings from the PQ moiety in Table 1. The uniquely low *g*-factor of 2.00052 is characteristic of the *o*-quinone–organomercury adducts (4), and this feature affords the possibility of simultaneous quantitative monitoring of the slow exchange between $M^+PQ^{-\cdot}$ and MeHgCl. In order to confirm the assignment of the observed spectrum to MeHgPQ·, a series of separate experiments was performed to generate various organomercury–PQ adducts including the MeHgPQ· by different methods. These can generally be represented by the following reaction scheme (1):

[5]
$$\begin{array}{ccc} PQ + PhHgPh & \underset{\text{or } \Delta}{\overset{h\nu}{\longrightarrow}} & PQ^{-\cdot} + PhHg^{+\cdot}Ph \\ & & \downarrow \\ PhHg\dot{P}Q & \xleftarrow{PQ^{-\cdot}} & PhHg^+ + Ph^{\cdot} \\ (g = 2.00019) & & \end{array}$$

The esr parameters of two of these adducts, PhHgPQ· and $PhCH_2HgPQ^{\cdot}$, are listed in Table 2. The small methylene splittings in the $PhCH_2HgPQ^{\cdot}$ are very similar to the methyl splittings in MeHgPQ·. In the

$PhHgPQ^{\cdot}$ adduct, the ^{199}Hg hyperfine splittings were resolved but the ^{201}Hg were not. ^{201}Hg has a nuclear spin of 3/2 and a natural abundance of 13.24% which will render the expected smaller ($a_{^{201}Hg}/a_{^{199}Hg} = -0.37$) splittings too weak for observation.

A detailed accounting of the low g-factor characteristic of all the reported $RHgPQ^{\cdot}$ adducts awaits further theoretical analysis. Nevertheless, we wish to point out here some related experimental observations and some possible empirical approaches.

A d–p π-bonding mechanism has been proposed to explain the observed trend of g-factor for Group IVB-substituted methyl radicals (11) and ethyl radicals (12). Excitation of the unpaired electron into the vacant metal d-orbitals will decrease the g-factor by a value proportional to $\lambda_d/\Delta E$ (13) where λ_d is the one-electron spin–orbit coupling constant of the metal d-orbit and ΔE is the difference in energies between the vacant metal d-orbital and the orbital of the unpaired electron. For comparison, we have prepared the $Me_3PbPQ^{\cdot}$ adduct by a similar exchange reaction with $K^+PQ^{-\cdot}$ and the resulting esr spectrum (Fig. 1*e*) has a g-factor of 2.00433. The $Me_3SnPQ^{\cdot}$ adduct also does not have a *low* g-factor (Table 1). While $PhHgPQ^{\cdot}$ has a low g-factor of 2.00019, $Ph_2TlPQ^{\cdot}$ (14) was reported to have a g-factor of 2.00331 and our experiment showed that $Ph_3PbPQ^{\cdot}$ has a similar high g-factor of 2.00352. Thus, the low g-factor of ~ 2.0002 is truly characteristic of the *organomercury–quinone* adducts. It is perhaps worthwhile to note here that there are many other transition metal complexes in solution which have an isotropic g-factor near or below the free spin value.

Both tin and lead–PQ adducts indeed show a smaller g-factor than the corresponding anion radical but the decrease is far less than that of organomercury PQ adducts. In applying the d–p π-bonding mechanism to $Me_3PbPQ^{\cdot}$, the ΔE represents the difference in energies between the vacant Pb 6d-orbital and the one-electron orbital. With the organomercury–PQ adduct, ΔE is the difference in energies between the one-electron orbital and the vacant Hg 5d-orbital created by the promotion of one 5d electron to 6p orbital. The resulting sp^2 hybrid for the mercury atom enables a coordination number of 3 in forming organomercury–PQ adducts.[1] Such a mechanism will greatly reduce the value of ΔE in the organomercury–PQ adducts which in turn will lower the g-factor.

Conclusion

Paramagnetic $MeHgPQ^{\cdot}$ adducts are stable for several days in THF/H_2O mixture and their uniquely low g-factor affords a potential analytical method for methylmercury in biological systems. The ability of the alkali–PQ ion-pairs to exchange with methylmercury appears to be useful and should be further explored in biological systems.

RONALD B. KELLY, SANDRA J. ALWARD, K. SURYANARAYANA MURTY, and J. B. STOTHERS. Can. J. Chem. **56**, 2508 (1978).

Syntheses of 4-*epi*-aubergenone, a sesquiterpenoid related to eudesmane, are described. One synthesis afforded this sesquiterpenoid as a racemate (**12**) whereas another, utilizing (+)-carissone as starting material, afforded an enantiomer (**12***a*). The fact that naturally occurring aubergenone is the C(4) epimer of the thermodynamically more stable synthetic **12** was revealed by the discovery that it was completely converted into the latter by treatment with base. This epimeric relationship is substantiated by comparison of the nmr spectra of the two isomers. Evidence requiring the reformulation of the structure of aubergenone as **13** is adduced.

RONALD B. KELLY, SANDRA J. ALWARD, K. SURYANARAYANA MURTY et J. B. STOTHERS. Can. J. Chem. **56**, 2508 (1978).

On décrit la synthèse de l'*epi*-4 aubergénone, un sesquiterpénoïde relié à l'eudesmane. Une synthèse à permis d'obtenir ce sesquiterpénoïde sous forme de racémique (**12**) alors qu'une autre, faisant appel à la (+)-carissone comme produit de départ, conduit à l'énantiomère (**12***a*). Le fait que l'aubergénone naturelle est l'épimère C(4) du produit de synthèse **12** thermodynamiquement le plus stable a été mis en évidence par la découverte qu'il peut être complètement transformé dans ce dernier par traitement avec une base. On a confirmé que ces produits sont des épimères par une comparaison des spectres rmn des deux isomères. On a ajouté des données nécessaires qui permettent de reformuler la structure de l'aubergénone sous forme de **13**.

[Traduit par le journal]

In 1975, the isolation of several metabolites, produced by incubation of eggplant fruit (*Solanum melongena*) with spore suspensions of *Monolinia fructicola* and other fungi, was reported (1). Among the isolated metabolites was a sesquiterpenoid for which the eudesmane related structure **12** was proposed and for which the name aubergenone has since been adopted.

We have completed a synthesis of **12** and found it to be structurally different from aubergenone, although its spectral properties were similar to those of the naturally occurring sesquiterpenoid. However, the availability of the synthetic sesquiterpene **12** led to evidence which revealed that aubergenone is the C(4) epimer of **12** and therefore should be reformulated as **13** (*vide infra*).

We were prompted to undertake a synthesis of **12** by the availability of a supply of the racemic octalone **1** (2) as starting material. Unlike many syntheses in the eudesmane and related fields which originate from enantiomers derived from natural sources (3), our synthesis proceeds from the starting material **1** through a series of racemic intermediates to the racemic end product **12**.

The synthesis of **12**, details of which are given in the Experimental, is outlined in Scheme 1. Since this synthesis is straightforward, a detailed discussion in this section is unnecessary, especially since the last three compounds in the sequence have been correlated with (−)-*trans*-dihydrocarissone (**10***a*) (4) (*vide infra*). It should be mentioned, however, that compounds **8**, **10**, and **12** were unchanged by treatment with base under equilibrating conditions and that the spectral properties and elemental analyses of the compounds shown in Scheme 1 are in agreement with the assigned structures. The properties of the synthetic sesquiterpenoid **12** (ir and nmr spectra, behavior on tlc, and retention time on glc) were not identical to the corresponding properties of aubergenone.

After the completion of the synthesis of **12**, we were afforded the opportunity of substantiating the

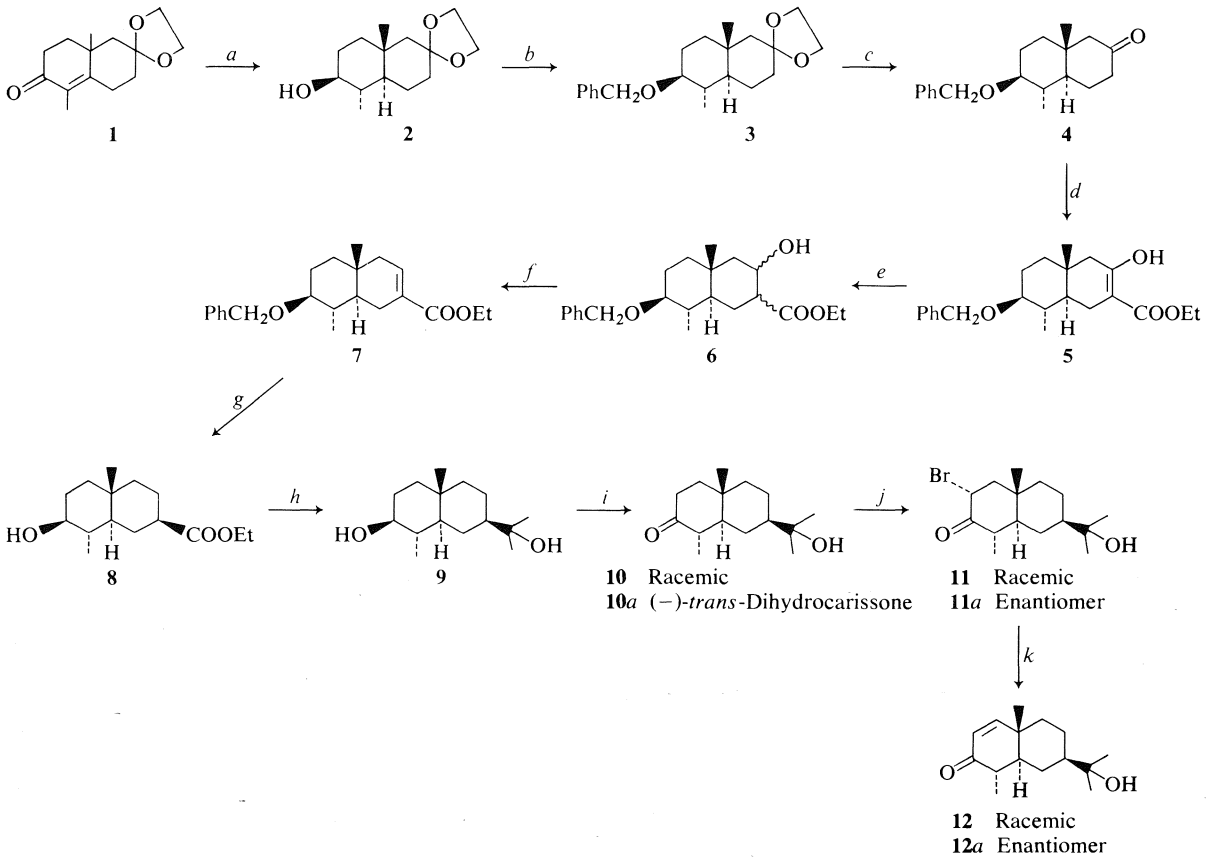
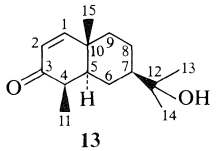


SCHEME 1. Reagents: (*a*) Li, NH_3–EtOH; (*b*) NaH, $PhCH_2Cl$; (*c*) HCl, THF; (*d*) NaH, diethyl carbonate; (*e*) $NaBH_4$; (*f*) $POCl_3$, pyridine; (*g*) H_2, 10% Pd–C; (*h*) MeLi; (*i*) Jones' reagent; (*j*) trimethylphenylammonium tribromide; (*k*) LiBr, Li_2CO_3, DMF.

structures assigned to the last three compounds in Scheme 1 by correlation with (−)-*trans*-dihydrocarissone (**10***a*). The enantiomer **10***a* was prepared from (+)-carissone, kindly provided by Professor Pinder, by a standard procedure (4). It was then converted via the bromide **11***a* into the enantiomer **12***a* by procedures used in the sequence **10** → **11** → **12**. The enantiomers **10***a*, **11***a*, and **12***a* were identical with the corresponding racemic compounds **10**, **11**, and **12** with respect to ir and nmr spectra, behavior on tlc, and retention time on glc. Thus, the validity of the structures **10**, **11**, and **12** was firmly established.

The structural relation of aubergenone to the synthetic sesquiterpenoid **12** was finally revealed when it was discovered that the former was completely transformed into the latter on refluxing with ethanolic potassium hydroxide. This behavior can only be interpreted as the epimerization of the secondary, quasi-axial, methyl group in aubergenone to the thermodynamically more stable quasi-equatorial



13

orientation as in **12**. The structure **12**, therefore, represents C(4)-*epi*-aubergenone[1] and aubergenone can be assigned structure **13**.

The nmr data for **12** and **13** are listed in Table 1 from which it is apparent that the epimerization of the C(4)-methyl group has relatively little effect on the majority of the shieldings although the observed changes are significant. The most pronounced difference occurred for the angular methyl group whose carbon is deshielded by 3.6 ppm in the natural product. This is another example of the *syn*–axial δ effect which has been noted in a variety of systems

[1]The numbering system shown in **13** is used throughout.

[a]Shieldings given in ppm from internal TMS for $CDCl_3$ solutions; values in parentheses may be interchanged. Proton–proton couplings in Hz are in brackets.

(5). The higher shielding of the carbonyl carbon in **12** relative to that in **13** is indicative of a more effective conjugative interaction in the former which is consistent with a more nearly coplanar enone system. It may be anticipated that the enone moiety in **13** will be twisted to reduce the *syn*–axial interaction between C(11) and C(15). It is interesting that the C(9) shieldings differ by 2.1 ppm in these compounds although this difference is not readily rationalized.

From the proton results it can be seen that only the angular methyl and 4-H shieldings differ significantly in **12** and **13**. The vicinal couplings of the latter are also affected appreciably with the 13 Hz coupling to the ring junction in **12** clearly establishing the antiperiplanar orientation of these protons. The corresponding coupling of 6 Hz in **13** is consistent with some distortion of the half-chair A ring to reduce the methyl–methyl *syn*–axial interaction such that the dihedral angle relating to these protons is significantly smaller than 60°, the value expected for an undistorted arrangement. Since the product obtained by epimerization of natural aubergenone was only available in small quantity (2.3 mg), this sample and a corresponding sample of the synthetic material were examined in CD_2Cl_2 solution using a capillary insert. Both ^1H and ^{13}C spectra of these samples were identical.

Experimental

General

Melting points were determined on a Fisher-Johns apparatus and are uncorrected.

The ir spectra were recorded with a Perkin-Elmer model 237B spectrophotometer. Proton nmr spectra were recorded with Varian XL-100-12 and T-60 instruments and ^{13}C spectra were obtained with a Varian XL-100-15 system operating in the Fourier transform mode. The chemical shifts are expressed in ppm (δ values) relative to TMS as an internal standard. Gas chromatography was performed with a Hewlett-Packard model 5750 instrument fitted with a 6 ft column (diameter 0.25 in.) packed with 10% of UC-W98 on diatoports (80–100 mesh); the temperature was increased from ambient temperature to 250°C at 15°C/min with the helium flow rate at 30 cm^3/min; retention times were compared by coinjection.

Petroleum ether refers to the fraction with boiling point range 30–60°C. Brine refers to a saturated aqueous solution of sodium chloride.

Alcohol 2

A solution of 4.72 g of keto ketal **1** (2) in ether (50 ml) and ethanol (80 ml) was added to 250 ml of liquid ammonia. Lithium (5 g) was added over a period of 1.5 h. The reaction mixture was stirred at reflux for an additional 1.5 h and then treated with 60 g of ammonium chloride. The ammonia was allowed to evaporate overnight and the reaction mixture was worked up in the usual manner with water, brine and ether. The ether extract was dried over sodium sulfate and evaporated to give 4.90 g of crystalline product. Recrystallization from ether – petroleum ether gave 4.00 g (83%) of the alcohol **2**, mp 89°C; ir (Nujol): 3220 cm^{-1} (OH); nmr (CCl_4) δ: 0.89 (s, 3H, angular methyl), 3.00 (m, 1H, *H*—C—OH) and 3.82 (m, 4H, ethylene of ketal). *Anal.* calcd. for $C_{14}H_{24}O_3$: C 69.96, H 10.06; found: C 70.20, H 10.10.

Benzyl Ether 3

A mixture of 1.084 g of alcohol **2**, 400 mg of sodium hydride, and 32 ml of dry benzene was refluxed under a nitrogen atmosphere for 5 h. After cooling to room temperature, the mixture was treated dropwise with 2.0 ml of benzyl chloride and refluxing was continued for 18 h. The cooled reaction mixture was treated with 8 ml of methanol then poured into a mixture of 600 ml of ice and water. Work-up in the usual manner with ether and water yielded 1.10 g (74%) of benzyl ether **3**, mp 98°C; ir (Nujol): shows no OH band; nmr (CCl_4) δ: 0.93 (d, J = 6.5 Hz, 3H, secondary methyl), 0.97 (s, 3H, angular methyl), 2.77 (m, 1H, *H*—C—O), 4.25 and 4.55 (doublets, J = 12 Hz, 1H each, OCH_2Ph), and 7.15 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{21}H_{30}O_3$: C 76.33, H 9.15; found: C 76.25, H 9.38.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Ketone **4**

A solution of 3.495 g of the benzyl ether **3**, 250 ml of tetrahydrofuran and 210 ml of 1 *M* aqueous hydrochloric acid was left at room temperature under a nitrogen atmosphere for 30 min. The reaction mixture was worked up in the usual manner with chloroform, saturated sodium bicarbonate and brine to give 2.676 g (88%) of ketone **4**, mp 108–109°C; ir (Nujol): 1705 cm^{-1} (ketone); nmr (CCl_4) δ: 0.78 (s, 3H, angular methyl), 0.98 (d, J = 6.5 Hz, 3H, secondary methyl), 2.85 (m, 1H, *H*—C—O), 4.27 and 4.57 (doublets, J = 12 Hz, 1H each, OCH_2Ph), and 7.15 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{19}H_{26}O_2$: C 79.68, H 9.15; found: C 79.51, H 9.23.

Keto Ester **5**

A mixture of 805 mg of sodium hydride and 2.60 g of diethyl carbonate in 15 ml of benzene was brought to reflux temperature under a nitrogen atmosphere. The mixture was treated dropwise, over 1 h, with a solution of 3.20 g of ketone **4** in 18 ml of benzene. Following an additional reflux period of 1 h, the reaction mixture was cooled to room temperature. Excess sodium hydride was destroyed with 2.4 ml of glacial acetic acid followed by 50 ml of ice water. Work-up in the usual manner gave 4.10 g of oil. Column chromatography of the product on 150 g of silica gel, with gradually increasing concentrations of ether in petroleum ether, gave 3.427 g (86%) of the keto ester **5**, mp 55°C; ir (Nujol): 1735, 1705, 1650, and 1610 cm^{-1} (β-keto ester); nmr ($CDCl_3$) δ: 0.85 (s, 3H, angular methyl), 1.03 (d, J = 6.5 Hz, secondary methyl), 1.26 (t, J = 7.0 Hz, 3H, methyl of ester), 4.13 (q, J = 7.0 Hz, 2H, methylene of ester), 4.31 and 4.60 (doublets, J = 11 Hz, 1H each, OCH_2Ph), and 7.20 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{22}H_{30}O_4$: C 73.71, H 8.43; found: C 73.57, H 8.53.

Alcohol **6**

The keto ester **5** (3.40 g) in 43 ml of ethanol was cooled (−15°C) and added to 810 mg of sodium borohydride in 33 ml of ethanol. The mixture was stirred at −15°C for 2.5 h, left at −20°C overnight, then stirred at room temperature for 1 h. Work-up in the usual manner with ether and brine yielded 3.346 g of material which crystallized from ether – petroleum ether to give 2.943 g (86%) of alcohol **6**, mp 70°C; ir (Nujol): 3525 (OH) and 1710 cm^{-1} (ester); nmr ($CDCl_3$) δ: 1.02 (d, J = 6.5 Hz, 3H, secondary methyl), 1.12 (s, 3H, angular methyl), 1.25 (t, J = 7.0 Hz, 3H, methyl of ester), 4.13 (q, J = 7.0 Hz, 2H, methylene of ester), 4.37 and 4.63 (doublets, J = 11 Hz, 1H each, OCH_2Ph), and 7.27 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{22}H_{32}O_4$: C 73.29, H 8.94; found: C 73.65, H 9.03.

α,β-*Unsaturated Ester* **7**

A solution of 2.943 g of the alcohol **6** in 50 ml of pyridine was cooled to 0°C, treated with 4 ml of freshly distilled phosphorus oxychloride and stirred at room temperature in the dark for 2 h. The reaction mixture was diluted with 250 ml of ice water and stirred for 15 min. The cold mixture was worked up in the usual manner with ether, 1 *N* hydrochloric acid, and saturated sodium bicarbonate solution to give 2.70 g of crude product. Purification of the product by column chromatography employing silica gel as adsorbent and ether as eluant gave 2.40 g (86%) of α,β-unsaturated ester **7** as an oil; ir (film): 1710 (ester) and 1650 cm^{-1} (olefin): nmr ($CDCl_3$) δ: 0.82 (s, 3H, angular methyl), 1.05 (d, J = 6.5 Hz, 3H, secondary methyl), 1.27 (t, J = 7.0 Hz, 3H, methyl of ester), 4.13 (q, J = 7.0 Hz, 2H, methylene of ester), 4.35 and 4.63 (doublets, J = 11 Hz, 1H each, OCH_2Ph), 6.80 (m, 1H, vinylic proton), and 7.23 (m, 5H, aromatic protons).

Ester **8**

A solution of 2.15 g of α,β-unsaturated ester **7** in 300 ml of ethanol was hydrogenated over 1.1 g of 10% palladium-on-charcoal catalyst at 2 atm pressure for 3.5 h. The catalyst was filtered off and the solvent evaporated *in vacuo* to give 1.597 g (100%) of ester alcohol **8** as an oil; ir (film): 3400 (OH) and 1725 cm^{-1} (ester); nmr ($CDCl_3$) δ: 0.88 (s, 3H, angular methyl), 0.95 (d, J = 6.5 Hz, 3H, secondary methyl), 1.23 (t, J = 7.0 Hz, 3H, methyl of ester), 3.08 (m, 1H, *H*—C—OH), and 4.10 (q, J = 7.0 Hz, 2H, methylene of ester).

The ester **8** was unchanged with respect to ir and nmr spectra and behavior on tlc after refluxing for 45 min with 1 *M* ethanolic sodium ethoxide.

Diol **9**

To a stirred solution of 40 ml of 1.4 *M* methyl lithium in ether was added a solution of 1.00 g of ester **8** in 8 ml of ether. The solution was stirred at room temperature for 2.5 h then worked up in the usual manner with ether, 3% ammonium chloride solution, and brine to give 945 mg (100%) of the diol **9**, mp 152°C; ir (Nujol): 3330 cm^{-1} (OH); nmr ($CDCl_3$) δ: 0.83 (s, 3H, angular methyl), 0.95 (d, J = 6.5 Hz, 3H, secondary methyl), 1.17 (s, 6H, isopropyl methyls), and 3.10 (m, 1H, *H*—C—OH). *Anal.* calcd. for $C_{15}H_{28}O_2$: C 74.95, H 11.74; found: C 75.27, H 11.78.

Keto Alcohol **10**

A solution of 855 mg of diol **9** in 50 ml of freshly distilled acetone was treated dropwise at 0°C with an 8 *N* solution of Jones' reagent (6) until a persistent orange color was observed. Excess oxidizing agent was destroyed with methanol and the acetone was evaporated *in vacuo*. Work-up in the usual manner with ether, 5% sodium carbonate and brine afforded 688 mg (81%) of **10**, mp 91–93°C; ir (CCl_4): 1715 (ketone), 3500 and 3610 cm^{-1} (OH); nmr (CCl_4) δ: 0.93 (d, J = 6.5 Hz, 3H, secondary methyl), 1.07 (s, 3H, angular methyl), and 1.13 (s, 6H, isopropyl methyls). *Anal.* calcd. for $C_{15}H_{26}O_2$: C 75.58, H 10.99; found: C 75.63, H 11.39.

The keto alcohol **10** was unchanged after refluxing for 2 h with 0.1 *M* ethanolic potassium hydroxide. It was identical with (−)-*trans*-dihydrocarissone, prepared from (+)-carissone by a published method (4), with respect to ir and nmr spectra, behavior on tlc and retention time on glc.

Bromo Ketone **11**

To cold (0°C) stirred solution of 527 mg of the keto alcohol **10** in 16 ml of tetrahydrofuran under a nitrogen atmosphere, was added 833 mg of trimethylphenylammonium tribromide. The solution was stirred for 30 min at 0°C then treated with 9.5 ml of saturated sodium bicarbonate solution. Work-up in the usual manner with ether and brine afforded 712 mg of material which was crystallized from ether – petroleum ether to give 456 mg (65%) of **11**, mp 113–115°C (dec.); ir (Nujol): 3490 (OH) and 1720 cm^{-1} (ketone); nmr ($CDCl_3$) δ: 1.07 (d, J = 6.5 Hz, 3H, secondary methyl), 1.13 (s, 3H, angular methyl), 1.20 (s, 6H, isopropyl methyls), and 4.83 (m, 1H, H—C—Br). The crude product was used directly for conversion into **12**.

The bromo ketone **11** was identical with the bromo ketone **11***a*, prepared from (−)-*trans*-dihydrocarissone (4), with respect to ir and nmr spectra and behavior on tlc.

Bromo Ketone **11**a

Bromination of (−)-*trans*-dihydrocarissone (**10***a*) (4) by the procedure described in the preceding experiment afforded the bromo ketone **11***a*, mp 113–116°C, identical with the racemic bromo ketone **11** (see preceding experiment).

α,β-*Unsaturated Ketone* ***12*** *(4-*epi*-Aubergenone)*

The bromo ketone **11** (220 mg), dissolved in dimethylformamide (11 ml) containing lithium bromide (220 mg) and lithium carbonate (184 mg), was heated under a nitrogen atmosphere at 130°C (bath temperature) for 3 h. Work-up in the usual manner with ether, water and brine, followed by preparative tlc of the crude product on silica gel with ether as solvent afforded 148 mg (90%) of crystalline **12**, mp 130–132°C; ir (CCl_4): 3605 and 3500 (OH), 1680 (unsaturated ketone), and 1615 cm^{-1} (olefin); nmr: see Table 1. *Anal.* calcd. for $C_{15}H_{24}O_2$: C 76.23, H 10.24; found: C 75.87, H 10.41.

The α,β-unsaturated ketone **12** was identical with the enantiomer **12***a* with respect to ir and nmr spectrum, behavior on tlc and retention time on glc. It was unchanged after refluxing with 0.1 *M* ethanolic potassium hydroxide for 3.5 h.

α,β-*Unsaturated Ketone* ***12***a

Dehydrobromination of **11***a* by the procedure described in the preceding experiment afforded the enantiomer **12***a*, mp 95–97°C, identical with the racemic α,β-unsaturated ketone **12** (see preceding experiment).

Epimerization of Aubergenone

Aubergenone (3 mg) was refluxed with 0.1 *M* ethanolic potassium hydroxide for 1 h. Work-up of the reaction solution in the usual manner with ether afforded a product which was identical with 4-*epi*-aubergenone (**12**) with respect to ^{1}Hmr, ^{13}C nmr, and behavior on tlc.

Pyrazolato bridged binuclear complexes of palladium and platinum

FLAVIO BONATI[1,2] AND HOWARD C. CLARK

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received January 26, 1978

FLAVIO BONATI and HOWARD C. CLARK. Can. J. Chem. **56**, 2513 (1978).

Pyrazolato bridged binuclear complexes of palladium and of platinum, $(C_8H_{12}X)_2M_2(\mu\text{-}Pz_2)$ (X = OCH_3 or pyrazolato), are obtained by reaction of (1,5-cyclooctadiene)dichloro-palladium(II) or -platinum(II) with a 1- unsubstituted pyrazole and sodium hydroxide in methanol.

FLAVIO BONATI et HOWARD C. CLARK. Can. J. Chem. **56**, 2513 (1978).

On a obtenu des complexes binucléaires pontés pyrazolato du palladium et du platine, $(C_8H_{12}X)_2M_2(\mu\text{-}Pz_2)$ (X = OCH_3 ou pyrazolato) en faisant réagir le (cyclooctadiène-1,5)-dichloropalladium(II) ou -platine(II) avec un pyrazole non substitué en 1 en présence d'hydroxyde de potassium dans le méthanol.

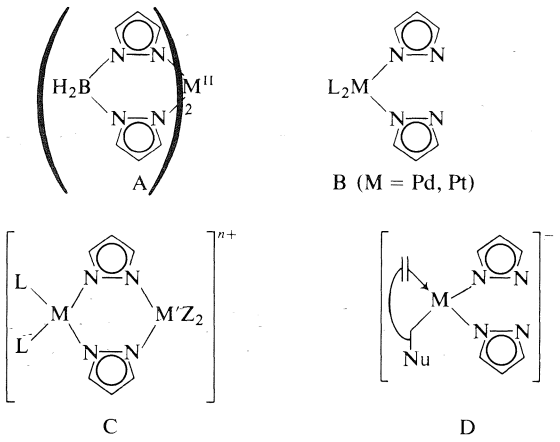
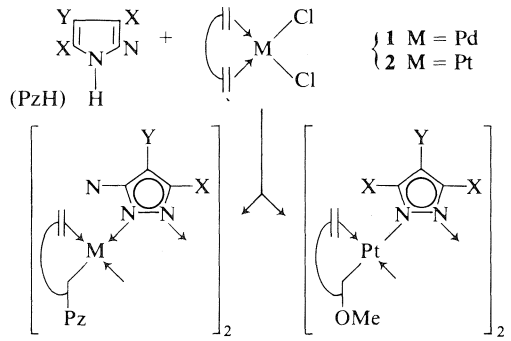
Introduction

The pyrazolate anion (Pz^-) can function either as a monodentate or exobidentate ligand. Since the original work by Trofimenko (1) and others (2) on metal poly-1-pyrazolylborates, (e.g. compounds of type A), other elements capable of tetrahedral coordination, such as carbon (2) and gallium (3) have been shown able to replace boron as the coordination centre in A. More recently, neutral bis-1-pyrazolyl derivatives of transition elements, having the square planar geometry, have been obtained, e.g. compounds B where L_2 is 1,2-bis(diphenylphosphino)ethane and Pz^- is monodentate. That these derivatives can themselves behave as bidentate, chelating and metal-containing ligands has been demonstrated by the formation of binuclear complexes C where M is Pt, M′ is Zn, Cd, or Hg, Z is chlorine and $n = 0$, or where M = M′ = Pt, $Z_2 = L_2$ = 1,2-bis(diphenylphosphino)ethane, and $n = 2$ (4, 5). In order to obtain other new binuclear complexes of type C, the preparation of further metal-containing and chelating ligands of type B was undertaken, particularly those containing other ligands L of differing *trans*-influence. Thus, following the preparation of compounds of types B and C where L_2 = α,α′-dipyridyl, other reactions were attempted with diolefin complexes where the products might be either compounds of type B where L_2 is the diolefin, or homobinuclear complexes of type C (M = M′ = Pd or Pt; $L_2 = Z_2$ and $n = 0$), or derivatives of type D where the diolefin has undergone nucleophilic attack by pyrazolate or another nucleophile. As the following results show, the latter has been observed.



Results and Discussion

(1,5-Cyclooctadiene)dichlorometal (**1** or **2**) and excess pyrazole react in the presence of sodium hydroxide in methanol solution according to one of the following schemes.



[1]On leave of absence from the University of Camerino, Italy.

Where the metal is palladium and for pyrazole itself, compound **3** was obtained readily; the same type of pyrazolato-bridged compound, rather than compound D, was obtained even when the heterocyclic ring carried two methyl groups, which should make bridge formation more difficult owing to steric hindrance. Similar results were also obtained when the heterocyclic ring contained another bulky group (compounds **4** or **5** respectively). The compounds were characterized through analytical data, molecular weight determination, infrared and nmr spectra. Additional evidence for the proposed formulation is given by the reaction of a chloroform solution of **3** with hydrochloric acid in methanol to afford the starting compound **1**.

In the case of platinum, compound **6**, belonging to the type E, was obtained with unsubstituted pyrazole, but compounds **7**, **8**, and **9**, belonging to the type F were isolated when variously 4-substituted 3,5-dimethylpyrazoles were allowed to react under similar conditions. In the case of the platinum derivative of 3,5-dimethylpyrazole, the reaction product was a mixture of the two types of compound, E and F. Indeed, the presence of the methoxy group, both here and in the compounds **7**–**9**, is supported by the appearance in the proton nmr spectrum of a singlet at ca. 6.7τ a value to be compared with 6.8τ found (6) in the spectrum of (diphos)Pt[C(OMe)=NAr]$_2$. Infrared evidence for the methoxy group includes a strong band at ca. 1100 cm^{-1}, which, however, falls in the region where another strong band due to the pyrazolate ring is observed. Other infrared bands were observed which are typical of the heterocyclic ligand.[3] They include a strong absorption around 750 cm^{-1} due to the out-of-plane bending of the ring proton(s), a weak band at 3100 cm^{-1} due to the stretching of the C—H bond and observed only in derivatives of the unsubstituted pyrazole, and a weak band(s) in the 1500–1560 region which is connected with the pyrazole ring. All the compounds are thermally fairly stable: decomposition is observed above ca. 170°C.

From the available data, it can be seen that following nucleophilic attack (7) by the methoxide or pyrazolato group, a binuclear system of the type C (M = M′ = Pd or Pt; $L_2 = Z_2$ = cyclooctenyl; $n = 0$) rather than a mononuclear species such as B results. Furthermore, a species like D is not formed perhaps because of the energy gain connected with the formation of a resonance stabilized bis(μ-pyrazolato-*N*,*N*′) bridge between the two metal centres, although the insolubility of the binuclear species may well be a driving force.

In the reaction of the same pyrazole (X = Me; Y = H) with $(C_8H_{12})MCl_2$, a different product is obtained when M = Pd, (**5**), or when M = Pt, (**8**). Hence the different nucleophilic character of the methoxide vs. the pyrazolate anion is not alone responsible for directing the nucleophilic attack. The different behaviour observed here with the various pyrazoles, therefore, is a consequence of some delicate balance between variations in the nucleophilic powers of methoxide and pyrazolates and the properties of the M(II) species.

Experimental

Analyses were carried out by Mr. McKinnon of this department or by M.H.W., Phoenix, Arizona. Molecular weight determinations were carried out by Pascher Microanalytisches Laboratorium, Bonn, West Germany. Infrared spectra were recorded on a Beckman IR-5A instrument; nmr spectra were recorded on a Bruker instrument, operating at room temperature and 60 Mc, by Dr. Albert Woon-Fat of this department; only $CDCl_3$ was used as solvent; values are in τ units. Compounds **1** and **2** are (1,5-cyclooctadiene)dichloropalladium or platinum, respectively (8). Evaporation was always carried out under reduced pressure (water aspirator). The analytical data are reported in Table 1.

Preparation of Compound 3

Compound **1** (507 mg; 1.78 mmol) was suspended in methanol (20 ml) and excess pyrazole (294 mg; 4.32 mmol) was added. Sodium hydroxide (162 mg; 4.05 mmol) in 90% methanol (15 ml) was added dropwise to the solution and a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

white precipitate formed at once, which was filtered and washed with methanol to yield the analytical sample (286 mg; 42%); upon heating it decomposed at ca. 200°C. Additional product could be recovered: the mother liquor was evaporated to dryness, the residue was extracted with methylene chloride (25 ml), the solution was concentrated to a small volume, methanol was added, and the solution again concentrated to a small volume.

The nmr spectrum showed signals at 2.82 (d, J = 2.4 Hz); 2.82 (d, J not determined owing to overlapping but ca. 2 Hz); 2.89 (d, J = 1.9 Hz, 3-H, 5-H, all these signals 8-H); 3.80 (t, J = 2.4 Hz); 3.90 (t, J = 1.9 Hz, 4-H, 2-H each); 4.39 (m, CH—CH—Pd, 4-H); 5.82 (m, 2-H); 6.84 (m, 2(CH=CH)); and 7.2–9.3 (complex, 16-H, methylene protons).

Preparation of Compound ***4***

The reaction was carried out similarly using the stoichiometric quantities of 3,5-dimethylpyrazole and alkali. The residue after evaporation was extracted with chloroform and the residue obtained after evaporation of the extract could be crystallized by concentrating to small volume its methanol solution; upon heating, the sample thus obtained melted into a black liquid at 213°C.

The nmr spectrum showed signals at 4.29 (s) and 4.54 (s, 4-H) and 4.34 (s, CH—CH—Pd), 6.04 (m) and 6.66 (m, CH=CH), 7.70, 7.77, 7.89 and 8.15 (3-Me + 5-Me, all singlets) and at 7.7–9.0 (CH_2).

Preparation of Compound ***5***

The compound was obtained similarly using 3,5-dimethyl-4-iodopyrazole. The crude product (614 mg; 51%) was crystallized by concentrating to half volume its solution in CH_2Cl_2/MeOH (10 + 20 ml). On being heated, the compound turned red and then brown at ca. 170°C.

The nmr spectrum showed 3-Me and 5-Me signals at 7.74 and 7.84 (singlets), and broad signals centred at 3.7, 4.3, 5.3 and in the region 6.3–8.6 due to the alkenyl ligand.

Preparation of Compound ***6***

To a suspension of the compound **2** (538 mg; 1.44 mmol) in methanol (20 ml) pyrazole (300 mg; 4.4 mmol) and, then, sodium hydroxide (197 mg; 4.9 mmol) in wet methanol (22 ml + 3 ml water) were added. The residue left after evaporation was extracted with dichloromethane (5 × 5 ml); after evaporating the extract to dryness the semisolid residue was crystallized twice from diethyl ether/hexane (2/3) to yield the analytical sample.

The nmr spectrum showed complex bands at 2.2–2.9 and at 3.5–3.9 (3-H + 5-H and 4-H of the pyrazolate rings, respectively) and at 6–9.2 and at 4–9.2τ due to the cyclooctenyl ligand.

Preparation of Compound ***7***

To a suspension of compound **2** (258 mg; 0.69 mmol) in methanol (10 ml) 3,5-dimethyl-4-bromopyrazole (241 mg; 1.38 mmol) in the same solvent (5 ml) and, then, sodium hydroxide (60 mg; 1.5 mmol) in 90% methanol (15 ml) were added. The solution was evaporated to dryness and the residue was extracted with benzene (20 ml); after evaporating the extract to dryness, the residue was dissolved in benzene/methanol (20 + 50 ml). The solution was then concentrated till a precipitate appeared, additional methanol (10 ml) was added and the analytical sample, dec. 215°C (225 mg; 64%), was filtered off after further concentration.

In the nmr spectrum, singlets were observed at 7.85 and 7.90 (3-Me + 5-Me), at 6.82 (MeO) while the cyclooctenyl ligand gave a complex absorption stretching from 4.4 to 8.5τ.

Preparation of Compound ***8***

The reaction was carried out similarly using 3,5-dimethyl-4-iodopyrazole. The residue after evaporation was extracted with dichloromethane and the compound was obtained upon addition of methanol. On heating to 215°C, no change was observed in the compound.

In the nmr spectrum, singlets were found at 7.80 (broad) (3-Me + 5-Me), and at 6.77 (MeO), plus a complex absorption between 4 and 9 due to the cyclooctenyl group.

Preparation of Compound ***9***

The reaction was carried out similarly using 3,5-dimethyl-4-(*p*-tolylazo)pyrazole. The residue after evaporation was extracted in dichloromethane; methanol was added dropwise to the concentrated solution whereupon a blackish gum precipitated, which was not examined; upon concentration of the filtered solution, the yellow compound was obtained which, upon heating, decomposed at ca. 170°C.

The nmr spectrum showed singlets at 6.70 (MeO), 7.40, 7.44, 7.47, 7.64 (3-Me + 5-Me + *p*-Me), a pseudoquartet at 2.2–2.30 (C_6H_4) and a broad, complex signal stretching from 4 to 8.7τ due to the cyclooctenyl ligand.

Treatment of PtCl(CNR)(acac) (R = *p*-tolyl; acac = acetylacetonate) with *p*-toluidine gives the carbene compound $PtCl\{C(NHR)_2\}$(acac). Reaction of this complex with a silver salt, followed by treatment with a neutral ligand L, gave *ortho*-metallated species $[Pt\{C(NHC_6H_4CH_3)(NHC_6H_3CH_3)\}L_2]^+$ which have been isolated as crystalline salts. The molecular structure of the ClO_4^- salt with L_2 = bisdiphenylphosphinoethane has been determined by X-ray diffraction. Crystals are monoclinic, space group $P2_1/n$, with four formula units in a cell of dimensions a = 20.370(3), b = 18.116(3), c = 10.770(2) Å, and β = 99.47(6)°. Full matrix least-squares refinement on F using 3252 observations gave a conventional agreement factor R = 0.047. While the formation of these *ortho*-metallated carbene complexes restricts the further extension of this chemistry, the ready reversal by acid treatment is unusual.

DAVID F. CHRISTIAN, DAVID A. CLARKE, HOWARD C. CLARK, DAVID H. FARRAR et NICHOLAS C. PAYNE. Can. J. Chem. **56**, 2516 (1978).

La réaction du PtCl(CNR)(acac) (R = *p*-tolyle; acac = acétylacétonate) avec la *p*-toluidine conduit au composé carbénique $PtCl\{C(NHR)_2\}$(acac). La réaction de ce complexe avec un sel d'argent, suivie par un traitement avec un ligand L neutre, conduit aux espèces orthométalliques $[Pt\{C(NHC_6H_4CH_3)(NHC_6H_3CH_3)\}L_2]^+$ qui ont été isolées sous forme du sels cristallins. On a déterminé la structure moléculaire du sel perchlorique contenant L_2 = bisdiphénylphosphinoéthane en faisant appel à la diffraction de rayons-X. Les cristaux sont monocliniques, groupe d'espace $P2_1/n$ avec quatre formules par maille, a = 20.370(3), b = 18.116(3), c = 10.770(2) Å et β = 99.47(6)°. On a affiné la structure par la méthode des moindres carrés (matrice complète) sur F utilisant 3252 observations avec un facteur conventionnel de R = 0.047. Alors que la formation de ces complexes carbéniques orthométallés réduit l'extension future de sa chimie, le renversement facile par un traitement en milieu acide est inattendu.

[Traduit par le journal]

Introduction

Numerous studies have been reported of isocyanide, carbene, olefin, and related derivations of platinum(II). However, there have been very few reports of compounds containing combinations of such ligands, bound to the same metal centre, thus creating the opportunity for further intra-ligand reactions to occur. For example, it would be particularly interesting to examine the chemistry of a platinum(II) derivative containing an olefin and a carbene bound to the same platinum centre, since the chemical behaviour of such species might provide useful information on the mechanism of olefin dismutation (1). In view of the general stability, and yet substantial reactivity (i.e. reactions occur at moderate but conveniently followed rates) of many related platinum(II) organic derivatives, it might well be feasible to prepare such a Pt(II) species and to find that it displayed an interesting chemistry.

Previously, we have been able to develop the chemistry of cationic isocyanide–platinum(II) species, originally described by Church and May (2) to obtain platinum(II)–formimidoyl complexes by isocyanide insertion into the Pt—H bond (3). These formimidoyl species undergo a reversible protonation with HCl or $HClO_4$ to generate cationic secondary carbene complexes. The reversible nature of this protonation suggested its possible use as the basis of a synthetic route to olefin–carbene complexes of platinum(II).

Acetylacetonate (acac) has been employed here as ligand, the starting material being the complex $K[PtCl(acac)_2]$ (4) prepared from K_2PtCl_4, KOH, and acetylacetone, which affords $H[PtCl(acac)_2]$ on

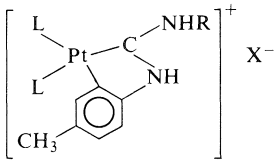
acidification (5). Various compounds of the type PtCl(L)(acac) where L = olefin, acetylene, phosphine, phosphite, etc. have been prepared (6) from the latter by elimination of the C-bound acetylacetonate as acetylacetone on reaction with the neutral ligand. In the present study, PtCl(CNR)(acac) was thus prepared by treatment with *p*-tolylisocyanide (R = *p*-tolyl), and from it PtCl[$C(NHR)_2$]-(acac), **1**, was generated as a colourless precipitate by reaction with *p*-toluidine in benzene.

Results

(a) Chemistry

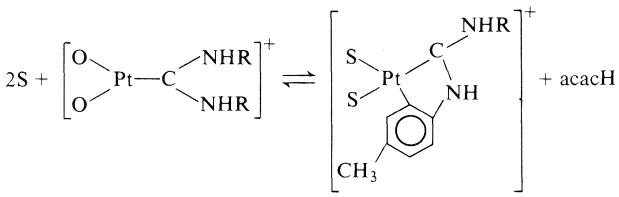
Removal of the chloride from PtCl{$C(NHR)_2$}-(acac) with silver salts, yields, unexpectedly, a greenish-black powder, **2**. Its solid state infrared spectrum (Table 1) reveals the presence of acetylacetonate, carbene, and, for example, the PF_6 anion. The ^1H nmr spectrum in chloroform-*d* exhibits broad, poorly-resolved signals in the aromatic and methyl regions and was of little further assistance. This compound **2** will be formulated as $[Pt\{C(NHR)_2\}(acac)]^+X^-$ where X = PF_6 etc., although clearly its structure may be more complex. It might, for example, be dimeric with bridging carbene groups.

Compound **2** reacts very rapidly at room temperature with neutral ligands such as *p*-tolyl isocyanide or 1,2-bisdiphenylphosphinoethane, and slowly with coordinating solvents to give pale yellow complexes. An unambiguous assignment of structure was not possible for these species, based upon ir and nmr spectroscopic data. Accordingly a single crystal X-ray analysis was undertaken of the 1,2-bisdiphenylphosphinoethane complex, and this revealed that the compound was in fact an *ortho*-metallated carbene species, of type **3**.

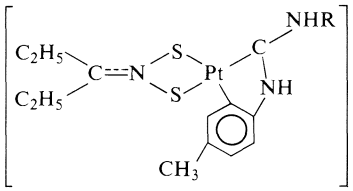


3

The rate of reaction of **2** with solvents is dependent on their coordinating ability, and was observed to be much faster for acetonitrile than acetone. The reactions with these solvents are reversible since stripping the solution to near dryness regenerated the green complex **2**, as the concentration of the higher boiling acetylacetone increased relative to the solvent, S.



Compound **2** will also react very rapidly at room temperature with one equivalent of sodium diethyldithiocarbamate to give the pale yellow complex **4**



4

Since imidoyl groups, M—$C(R_1)$=NR_2, are known (7) to be reversibly protonated at nitrogen, it is interesting to observe that, following elimination of acetylacetone, *ortho*-metallation, instead of such deprotonation at nitrogen to return a formimidoyl complex, has occurred preferentially. As might be expected, the *ortho*-metallation reaction can be reversed with acids. The addition of hydrochloric acid (CH_3COCl in methanol) to $\{Pt(CNR)_2[C(NHR)(NHC_6H_3CH_3)]\}^+$, $\{Pt(diphos)[C(NHR)(NHC_6H_3CH_3)]\}^+$, and $\{Pt(dtc)[C(NHR)(NHC_6H_3CH_3)]\}$, (dtc = diethyldithiocarbamate) gave a mixture of *cis*- and *trans*-$\{PtCl(CNR)_2[C(NHR)_2]\}^+$, *cis*-$\{PtCl(diphos)[C(NHR)_2]\}^+$, and *cis*-{PtCl(dtc)-$[C(NHR)_2]\}$, respectively.

Subsequent removal of the chlorine from the complex *cis*-$\{PtCl(dtc)[C(NHR)_2]\}$ did not regenerate the original *ortho*-metallated species. Removal of the chlorine from the complex *cis*-$\{PtCl[C(NHR)_2]diphos\}^+$ produced an unidentified complex which gave four phosphorus signals in its ^{31}P nmr spectrum.

(b) Description of the Structure

Selected bond distances and bond angles are presented in Table 2, and some weighted least-squares planes are presented in Table 3. A perspective view of the cation showing the atom numbering scheme is presented in Fig. 1. Only the α-carbon atoms of the phenyl rings are shown. Two of the four sites of a square-planar coordination geometry are occupied by the bidentate phosphine ligand. The remaining two contain the carbene C atom, and an *ortho*-metallated phenyl ring. The crys-

tals are built up from discrete ions, for the shortest cation–anion distance is 2.12 Å between hydrogen atom H1C(66) and atom O(22) in the equivalent position $(1/2 + x, 1/2 - y, 1/2 + z)$.

The coordination geometry about the Pt atom is approximately square planar. The largest deviation from a weighted least-squares plane through the Pt, the two P, the *ortho*-metallated C, and the carbene C atoms is that of C(3) by 0.051(14) Å. The plane through the carbene ligand, defined by the Pt, the

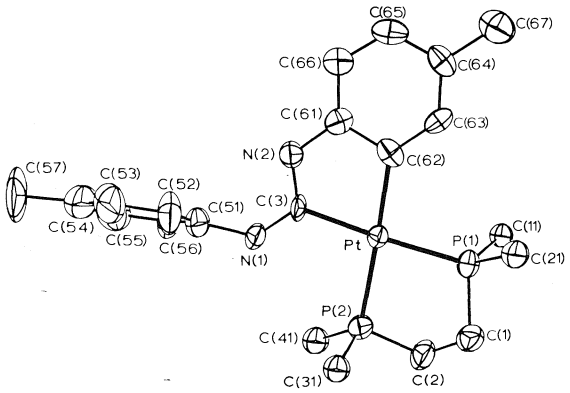

FIG. 1. A perspective view of the cation showing the atom numbering scheme.

carbene C, and the 2 N atoms, is tilted out of the equatorial plane by 7.3°, while the dihedral angle between the equatorial plane and *ortho*-metallated phenyl ring is 8.0° in the opposite direction. By contrast the *p*-tolyl substituent is twisted at an angle of 105.3° to the equatorial plane, thus precluding stabilization of C(3) by electron donation from the ring π-system.

The Pt—C(3) distance of 2.044(14) Å is not significantly different from the value of 2.020(16) Å obtained for *trans*-$[PtCl_2\{C(NC_6H_5)_2C_2H_4\}(P(C_2H_5)_3)_2]$ (8). The Pt—C(62) bond distance of 2.048(13) Å is also equivalent to the Pt—C(3) distance. This indicates that both bonds may be considered as Pt—C(sp^2) single bonds. The geometry about the *ortho*-metallated ring is comparable to those which have been observed in similar structures (9, 10).

The mean C—C bond length for the ring of the *p*-tolyl group is 1.370(29) Å with a mean C—C—C bond angle of 120(3)°. The mean Pt—P bond distance obtained in this structure is 2.293(7) Å. All P—C distances are equivalent, including those to the methylene carbons, with a mean bond distance of 1.812(24) Å. The bond angles around the P atom show it to adopt a distorted tetrahedral geometry (11).

Conclusions

Although the intramolecular reaction between a transition metal and an *ortho* C—H bond on an aromatic substituent on the P ligand is well known (12) and occurs in a variety of complexes, there have been few examples of *ortho*-metallation occurring in carbene complexes. Its occurrence preferentially in these platinum carbene complexes has prevented the preparation of platinum(II) carbene–olefin complexes, but the reversal, by acid treatment, of the *ortho*-metallation reaction is of particular interest.

Experimental

Infrared spectra in the range 4000–400 cm^{-1} were recorded on a Perkin-Elmer grating spectrometer 2, and absorptions are quoted relative to the polystyrene band at 1601.4 cm^{-1}. The ^1H nmr spectra were recorded on a Varian HA-100 spectrometer. Analyses were obtained from Chemalytics Inc. and Midwest Microlab Ltd.

(1) Preparation of K{PtCl(acac)} (4, 13)

Potassium tetrachloroplatinite, K_2PtCl_4 (1.5 g), was dissolved in 4.5 g water in a 25 ml conical flask. The solution was heated to 70°C and 3 ml of acetylacetone and 4.5 ml of KOH solution (1.1 g in water) added. The solution was stirred at 55–60°C for 20 min and then cooled in a refrigerator to produce large yellow crystals of $K\{PtCl(acac)_2\}$ (1.2 g). These were washed with alcohol and ether and dried in a vacuum dessicator.

(2) Preparation of $H\{PtCl(acac)_2\}$ (6)

To a saturated solution of $K\{PtCl(acac)_2\}$ (1 g) in water was added 5 ml of 6 *N* HCl. An immediate dense yellow precipitate was formed, which was filtered, washed with water, and dried under vacuum (0.93 g, 95%).

(3) Preparation of PtCl(CN-p-tolyl)(acac)

To $H\{PtCl(acac)_2\}$ (0.22 g) in benzene (15 ml) was added *p*-tolylisocyanide (1 equiv.) in benzene, producing an immediate lightening of colour. After the solution had been stirred for 20 min, the benzene was evaporated to a small volume and ether was added to produce the crude product, which was recrystallized from acetone–ether (0.20 g, 87%).

(4) Preparation of $[PtCl\{C(NH\text{-}p\text{-}tolyl)_2\}(acac)]$

The complex PtCl(CN-*p*-tolyl)(acac) (0.2 g) was stirred in benzene (15 ml) with excess *p*-toluidine (0.2 g) for 30 min. A white precipitate was obtained, ether being added to ensure complete precipitation. The white micro crystals of the product (0.21 g, 85%) were washed with ether and could be recrystallized for analysis from $CH_2Cl_2/C_6H_6/n$-pentane.

(5) Reaction of $[PtCl\{C(NH\text{-}p\text{-}tolyl)_2\}(acac)]$ with Na(dtc)

$[PtCl\{C(NH\text{-}p\text{-}tolyl)_2\}(acac)]$ (0.2 g) was dissolved in acetone (15 ml) and sodium diethyl dithiocarbamate (Na dtc) (0.085 g) in acetone (5 ml) was added dropwise and stirred. The solution turned a pale yellow colour and a precipitate formed. After being stirred for 3 h, the solution was evaporated to dryness, CH_2Cl_2 added, and filtered. The filtrate was evaporated to a small volume and ether added to produce a yellow crystalline compound identified as $Pt(dtc)_2$ by comparison with an authentic sample.

(6) Reaction of [PtCl{C(NH-p-tolyl)$_2$}(acac)] with Silver Salts

[PtCl{C(NH-*p*-tolyl)$_2$}(acac)] (0.15 g) in acetone (15 ml) was refluxed for 20 min with 1 equiv. of one of the following silver salts: $AgPF_6$ (0.07 g), $AgSO_3SF_3$ (0.07 g), or $AgClO_4$ (0.06 g). The solution and precipitate were centrifuged to remove any silver chloride formed and the yellow solution was decanted off. Evaporation of the acetone gave dark green/black crystals, formulated as $[Pt\{C(NHR)_2\}(acac)]^+\chi^-$, where $\chi = PF_6$, SO_3CF_3, or ClO_4. Yellow solutions were regenerated when these crystals were dissolved in coordinating solvents such as acetone or acetonitrile.

(7) Preparation of [Pt(CN-p-tolyl)$_2$\{C(NH-p-tolyl)$_2$\}]-SO_3CF_3

[PtCl{C(NH-*p*-tolyl)$_2$}(acac)] (0.2 g) in acetone (15 ml) was refluxed for 20 min with $AgSO_3CF_3$ (0.1 g). The precipitated silver chloride was removed by centrifugation and to the resulting yellow solution was added *p*-tolylisocyanide (0.10 g). The solution was stirred for 15 min, the solvent was removed, and ether added to precipitate the yellow complex [Pt(CN-*p*-tolyl)$_2$\{C(NH-*p*-tolyl)$_2$\}]SO_3CF_3 (0.21 g, 73%).

(8) Preparation of [Pt\{PPh$_2$(CH$_2$)$_2$PPh$_2$\}\{C(NH-p-tolyl)(NHC$_6$H$_3$CH$_3$)\}]χ where $\chi = ClO_4$ or PF_6

[PtCl{C(NH-*p*-tolyl)$_2$}(acac)] (0.15 g) in acetone (15 ml) was refluxed for 20 min with one equivalent of either $AgPF_6$ (0.07 g) or $AgClO_4$ (0.06 g). The precipitated silver chloride was removed by centrifugation, and to the resulting yellow solution was added 1,2-bisdiphenylphosphinoethane (0.12 g). There was an immediate lightening of the colour of the solution; the solvent was evaporated and ether added to produce yellow crystals of [Pt\{PPh$_2$(CH$_2$)$_2$PPh$_2$\}\{C(NH-*p*-tolyl)(NHC$_6$H$_3$CH$_3$)\}]ClO_4 (0.22 g, 88%) or [Pt\{PPh$_2$(CH$_2$)$_2$PPh$_2$\}\{C(NH-*p*-tolyl)(NHC$_6$H$_3$CH$_3$)\}]PF_6 (0.22 g, 84%).

(9) Preparation of [Pt(S$_2$NCEt$_2$)\{C(NH-p-tolyl)(NHC$_6$H$_3$CH$_3$)\}]

[PtCl{C(NH-*p*-tolyl)$_2$}(acac)] (0.15 g) in acetone (15 ml) was refluxed for 20 min with one equivalent of $AgPF_6$ (0.07 g). The precipitated silver chloride was removed by centrifugation and to the resulting yellow solution was added dropwise sodium diethyldithiocarbamate (0.06 g) in acetone (5 ml). The yellow solution immediately turned a paler yellow and a small amount of $NaPF_6$ was precipitated. This was filtered off, the filtrate evaporated to a small volume, and ether added to produce microcrystals of the complex [Pt(S$_2$NCEt$_2$)\{C(NH-*p*-tolyl)(NHC$_6$H$_3$CH$_3$)\}] (0.10 g, 65%).

(10) Preparation of [PtCl\{PPh$_2$(CH$_2$)$_2$PPh$_2$\}\{C(NH-p-tolyl)$_2$\}]PF_6

To [Pt\{PPh$_2$(CH$_2$)$_2$PPh$_2$\}\{C(NH-*p*-tolyl)(NHC$_6$H$_3$CH$_3$)\}]PF_6 (0.21 g) in an acetone–methanol mixture (1:1, 15 ml) was added acetyl chloride (0.02 g). The yellow solution immediately turned white and evaporation of the solvent led to the precipitation of white crystals of the complex [PtCl\{PPh$_2$(CH$_2$)$_2$PPh$_2$\}\{C(NH-*p*-tolyl)$_2$\}]PF_6 (0.20 g, 90%), following recrystallization from acetone–ether.

(11) Preparation of [PtCl(S$_2$NCEt$_2$)\{C(NH-p-tolyl)$_2$\}]

[Pt(S$_2$NCEt$_2$)\{C(NH-*p*-tolyl)(NHC$_6$H$_3$CH$_3$)\}] (0.2 g) in acetone–methanol and acetyl chloride (0.03 g) were mixed and stirred for 15 min. Evaporation of the solvent led to the precipitation of pale yellow microcrystals of the complex [PtCl(S$_2$NCEt$_2$)\{C(NH-*p*-tolyl)$_2$\}] (0.2 g, 94%). This could be recrystallized from CH_2Cl_2/Et_2O.

(12) Reaction of [PtCl\{PPh$_2$(CH$_2$)$_2$PPh$_2$\}\{C(NH-p-tolyl)$_2$\}]PF_6 with $AgPF_6$

[PtCl{PPh$_2$(CH$_2$)$_2$PPh}\{C(NH-*p*-tolyl)$_2$\}]PF_6 (0.2 g) in acetone was allowed to react with $AgPF_6$ for 10 min. The precipitated AgCl was filtered off and the filtrate evaporated to dryness. Recrystallization from CH_2Cl_2/Et_2O led to production of large white crystals of a compound with empirical formula $PtC_{41}H_{40}F_6N_2P_3$ (0.18 g, 91%).

Analytical and spectroscopic data for the above starting materials and reaction products are given in Table 1.

TABLE 4. Crystal data for $C_{41}H_{39}ClN_2O_4P_2Pt$

Parameter	Value
Formula weight	916.27
Space group	$P2_1/n$
a	20.370(3) Å
b	18.116(3) Å
c	10.770(2)
Z	4
β	99.47(6)
Cell volume	3920.2 Å^3
μ	36.0 cm^{-1} for Mo Kα_1

TABLE 5. Experimental conditions for data collection

Radiation: Mo Kα, Nb foil prefilter, 0.07 mm
Takeoff angle: 2.9° (95% of maximum Bragg intensity)
Aperture: 5 mm × 5 mm, 31 cm from crystal
Data collected: $h\ k\ l$ and $\bar{h}\ k\ l$, for $0 < 2\theta < 55°$
Scan: θ–2θ, range 0.9° corrected for dispersion, at 1° min^{-1}
Background: 10 s stationary crystal, stationary counter at limits of scan
Standards: five recorded every 200 observations; 200, 020, 0$\bar{2}$0, 002, and 111

Collection and Reduction of X-ray Data

Prismatic, yellow crystals of [Pt\{C(NH(C$_9$H$_6$))(NH(C$_9$H$_7$))(P$_2$(C$_6$H$_5$)$_4$C$_2$H$_4$)\}]ClO_4 were recrystallized from acetone/ether mixtures. Weissenberg and precession photography using CuKα radiation showed the crystals belonged to the monoclinic system. The systematic extinctions, $h0l$ for $h + l$ odd and $0k0$ for k odd, are consistent only with the space group $P2_1/n$ (alternate setting of $P2_1/c$, C_{2h}^5, No. 14 (14)). The density, 1.56(1) g cm^{-3}, was determined by flotation in a mixture of carbon tetrachloride and *n*-pentane. The calculated density is 1.55 g cm^{-3}, assuming $Z = 4$. Thus no symmetry constraints are imposed on the ions.

The crystal chosen for data collection was of approximate dimensions 0.12 mm × 0.13 mm × 0.16 mm. It was mounted on a Picker FACS-1 computer-controlled diffractometer with [001] offset approximately 20° from coincidence with the spindle axis. The crystal was measured after data collection on a microscope fitted with a filar eyepiece to permit an absorption correction. Eleven faces were identified by optical goniometry as (010) and forms of {10$\bar{1}$}, {100}, {110}, and {101}. Cell constants and an orientation matrix were obtained from a least-squares refinement[3] of the setting angles of 30

[3]The computer programs used in this analysis include local modifications of the following: cell refinement and orientation matrix, PICKTT, from W. C. Hamilton's MODE 1; full-matrix least-squares, J. A. Ibers' NUCLS: Patterson and Fourier syntheses, A. Zalkin's FORDAP; function and errors, W. R. Busing, K. O. Martin, and H. A. Levy's ORFFE; crystal structure illustrations, C. K. Johnson's ORTEP; absorption correction by the analytical method of de Meulanaer and Tompa in the program AGNOST as modified by D. Cahen and J. A. Ibers (21).

intense, carefully centered reflections with $13° < 2\theta < 27°$. Prefiltered Mo radiation was used, $\lambda = 0.70926$ Å, at 23°C. Crystal data are given in Table 4.

The conditions used for data collection are summarized in Table 5. Several ω scans of intense, low-angle reflections were recorded as a check on crystal mosaicity. The average width at half-height was 0.05°. Measurement of standard reflections during data collection and an examination of crystal mosaicity at the end showed no significant decomposition had occurred.

A total of 6073 reflections was measured. The recorded intensities were corrected for Lorentz and polarization effects. A standard deviation $\sigma(I)$ was assigned to each intensity (I), where $(\sigma(I))^2 = [C + \frac{1}{4}(t_c/t_b)^2(b_l + b_h) + (pI)^2]$ where $I = [C - \frac{1}{2}(b_l + b_h)t_c/t_b]$, C = total count measured in time t_c, and b_l and b_h are background counts each measured in time t_b. P was chosen as 0.02 and then increased to 0.04 for the final cycles of refinement (15). Of the 5888 reflections processed (excluding the standard reflections), 3308 with $I > 3\sigma(I)$ were used in the solution and refinement of the structure.

Solution and Refinement of the Structure

The structure was solved by the heavy atom method, and refined by full-matrix least-squares techniques on F. Scattering factors for neutral non-hydrogen atoms were taken from Cromer and Waber (16), while those for H were from Stewart Davidson, and Simpson (17). The real and imaginary anomalous dispersion corrections of Cromer and Libermann (18) were included for the Pt and P atoms, and in later refinements, for the Cl atom.

The positional parameters for the Pt and two P atoms were determined from a three-dimensional Patterson synthesis. A series of structure factor and difference Fourier synthesis calculations revealed the positions of the remaining 48 non-hydrogen atoms. In the early refinement the C atoms of the four phenyl rings, the six C atoms of the *p*-tolyl ring, and the five atoms of the perchlorate group were constrained as rigid groups. The atoms in the coordinated phenyl ring were treated as individual atoms. The phenyl rings were assumed to have D_{6h} symmetry and a C—C bond length of 1.392 Å (19). The ClO_4 rigid group was given T_d symmetry and a Cl—O distance of 1.42 Å (20). The data were corrected for absorption effects using the analytical method.[3] Transmission coefficients varied from 0.603 to 0.799.

One cycle of refinement varying positional and isotropic thermal parameters for the 16 non-hydrogen atoms, a group origin, three orientation angles, and an overall group thermal parameter for each group gave agreement factors $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.091$ and $R_2 = (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2} = 0.099$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, and the weight w was calculated as $4F_o^2/\sigma^2(F_o^2)$. In further cycles all non-group atoms were assigned anisotropic thermal parameters. The Cl atom was removed from the perchlorate rigid group, leaving a tetrahedral group of four O atoms. Individual group atom isotropic thermal parameters were varied, and three cycles of refinement converged at $R_1 = 0.057$ and $R_2 = 0.059$.

The 39 H atoms present in the cation were located from a difference Fourier synthesis. Idealized positional coordinates were computed, assuming either sp^2 or sp^3 coordination geometries about the C atoms, and bond distances of 0.95 Å and 1.0 Å, respectively. The hybridization of the N atom is sp^3, with an N—H bond distance of 1.0 Å. All H atoms were assigned isotropic thermal parameters 1.0 Å^2 greater than those of the atoms to which they are bonded. Thereafter the contributions from the H atoms were included in the calculations of F_c and no attempt was made to refine the H atom parameters.

The rigid group constraints were then removed from the four O atoms, and from the six C atoms of the *p*-tolyl group, and the atoms permitted to vibrate anisotropically. After two cycles of refinement (3308 observations and 292 variables) the model converged at $R_1 = 0.049$ and $R_2 = 0.049$.

A subsequent difference Fourier synthesis over the ClO_4 anion region revealed electron density close to O(11), O(12), and O(13) and an additional peak greater than 1.0 e Å^{-3} located at fractional coordinates (−0.119, 0.110, 0.162). These four peaks form a tetrahedral array. This, and the pronounced anisotropic thermal motion of the Cl atom, led us to formulate a disorder model in which two anions occupy the same region in the crystal, but with three of the four O atoms superimposed. The additional peak thus results from the fourth O atom. Refinement of the multiplicity parameter, with appropriate constraints applied to the derivatives, gave a 10(1)% probability of the second orientation. This second group was included thereafter in structure factor calculations, but was not refined. The Cl atom and the four O atoms of the 90% probable orientation were refined anisotropically thereafter.

Two final cycles of refinement with recalculation of H atom parameters (292 variables and 3252 observations with $F^2 > 3\sigma$) converged at residuals of $R_1 = 0.047$ and $R_2 = 0.053$. In the final cycle no positional parameter shift exceeded 0.134 of its estimated standard deviation. The error in an observation of unit weight is 1.11 electrons. A statistical analysis of R_2 over various ranges of $|F_o|$, $\lambda^{-1}\sin\theta$, and diffractometer setting angles χ and ϕ showed no abnormal trends. A comparison of F_o and F_c suggested extinction effects were minimal, and could be ignored. A total difference Fourier synthesis calculated from the final structure factors contained no features of chemical significance. The highest peak, with fractional coordinates (0.135, 0.149, 0.034), located near the Pt atom, had an electron density of 0.95 (16) e Å^{-3}. Final positional and thermal parameters for the non-H atoms are given in Table 6, rigid group parameters in Table 7, derived group atom parameters in Table 8, and hydrogen atom parameters in Table 9. Structure amplitudes are listed in Table 10 as $10|F_o|$ and $10|F_c|$, in electrons, with weights $\times 10^3$.[4]

Thiosemicarbazide complexes of mercury(II) halides

CHUNG CHIEH, LAURA P. C. LEE, AND CECILIA CHIU

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received April 26, 1978

CHUNG CHIEH, LAURA P. C. LEE, and CECILIA CHIU. Can. J. Chem. **56**, 2526 (1978).

Dibromobis(thiosemicarbazide)mercury(II), $HgBr_2(tsc)_2$, is isostructural with dichlorobis(thiosemicarbazide)mercury(II). The crystal is orthorhombic with $a = 8.825(9)$, $b = 8.587(11)$, $c = 15.939(22)$ Å, $z = 4$, space group *Pbcn*. Some bond lengths and angles are: Hg—Br = 2.860(4) Å, Hg—S = 2.45(1) Å, C—S = 1.76(4) Å and $\angle$SHgS = 155°, $\angle$BrHgBr = 97.1°. In both $HgCl_2(tsc)_2$ and $HgBr_2(tsc)_2$, the configuration of the coordinated thiosemicarbazide (tsc) is the same as that of the free molecule. The ir and Raman (R) spectra for the complexes and tsc in the region 300–1600 cm^{-1} are very similar. The strong band at 800 (807 R) cm^{-1} in the tsc due to ν(C—S) is shifted to 773 (796 R), 777 (796 R), and 660 (680 R) cm^{-1} for $HgCl_2(tsc)_2$, $HgBr_2(tsc)_2$, and $HgCl_2(tsc)$ correspondingly. A strong band at 368 (R) cm^{-1} present uniquely for $HgCl_2(tsc)$ can be assigned to ν(Hg—N). The halides in $HgX_2(tsc)_2$ are bonded to one mercury(II) ion and weakly bridged to a neighboring molecule with Hg...Cl = 3.250(3) Å and Hg...Br = 3.436(4) Å. As a result, two Raman bands due to Hg—X are expected. For $HgCl_2(tsc)_2$, the two Raman bands occur at 236 and 166 cm^{-1}, whereas for $HgBr_2(tsc)_2$, one was observed at 190 cm^{-1} but the other was masked by lattice modes. In $HgCl_2(tsc)$, the two Hg—Cl bonds are different and bands at 220 and 190 cm^{-1} are assigned to $\nu(Hg—Cl)_t$.

CHUNG CHIEH, LAURA P. C. LEE et CECILIA CHIU. Can. J. Chem. **56**, 2526 (1978).

Le dibromobis (thiosemicarbazide)mercure(II), $HgBr_2(tsc)_2$, est isostructural avec la dichlorobis(thiosemicarbazide)mercure(II). Le cristal est orthorhombique avec $a = 8.825(9)$, $b = 8.587(11)$, $c = 15.939(22)$ Å, $z = 4$, groupe d'espace *Pbcn*. On a mesuré quelques longueurs et angles de liaison soit: Hg—Br = 2.860(4) Å, Hg—S = 2.45(1) Å, C—S = 1.76(4) Å et $\angle$SHgS = 155°, $\angle$BrHgBr = 97.1°. Dans le $HgCl_2(tsc)_2$ et $HgBr_2(tsc)_2$, la configuration de la thiosemicarbazide (tsc) coordonnée est la même que dans la molécule libre. Les spectres ir et Raman (R) pour les complexes et le tsc dans la région de 300–1600 cm^{-1} sont très semblables. La bande forte à 800 (807 R) cm^{-1} dans le tsc et due à la ν(C—S) est déplacée à 773 (796 R), 777 (796 R) et 660 (680 R) cm^{-1} pour $HgCl_2(tsc)_2$, $HgBr_2(tsc)_2$ et $HgCl_2(tsc)$ respectivement. On peut attribuer à la ν(Hg—N) la bande forte à 368 (R) cm^{-1} qui est présente uniquement dans $HgCl_2(tsc)$. Les halogénures du $HgX_2(tsc)_2$ sont liés à un ion mercure(II) et faiblement pontés à une molécule voisine avec Hg...Cl = 3.250(3) Å et Hg...Br = 3.436(4) Å. Comme conséquence, les deux bandes Raman du Hg—X sont attendues. Pour le $HgCl_2(tsc)_2$, les deux bandes Raman apparaissent à 236 et 166 cm^{-1} alors que pour le $HgBr_2(tsc)_2$ une est observée à 190 cm^{-1} mais l'autre est masquée par les vibrations du réseau. Dans le $HgCl_2(tsc)$, les deux liaisons Hg—Cl sont différentes et on attribue les bandes à 220 et 190 cm^{-1} à la $\nu(Hg—Cl)_t$.

[Traduit par le journal

Introduction

A few group IIB metal complexes of thiosemicarbazide (tsc) have been reported in the literature (1). Compounds $ZnCl_2(tsc)$ and $HgCl_2(tsc)$ are molecular complexes with a bidentate tsc ligand (2, 3). In $HgCl_2(tsc)_2$ and AgCl(tsc), the ligand tsc is monodentate (4, 5). Dibromobis(thiosemicarbazide)-mercury(II) is confirmed to be isostructural with $HgCl_2(tsc)_2$ by crystallographic methods.

Several ir absorption studies of tsc and related compounds have been reported (6–8). However, there is little information about ir or Raman bands in the low frequency region (<600 cm^{-1}) for tsc or its complexes. The difficulty in assigning bands in this region is mainly due to the lack of structural results. For example, the band at 544 cm^{-1} in $HgCl_2(tsc)_2$ was erroneously assigned to ν(Hg—N) (1). The Hg—N bond does not exist in the compound $HgCl_2(tsc)_2$ (4).

Burns reported the ir spectra for AgCl(tsc), $NiCl_2(tsc)_3$, and $Ni(tsc)_2$ in the region 3300–700 cm^{-1} (9). The vibrational assignments by Mashima (8) and the study of spectra in polarized light of orientated tsc crystalline samples by Keresztury and Marzocchi (6) are among those considered to be reliable. These assignments make it possible to analyze the spectra of the complexes. Furthermore there are few metal–ligand vibration assignments in the literature for tsc complexes.

Many characteristic frequencies for (Hg—S)

where S is in the S=C< group, were measured for mercury(II) thiourea (tu) complexes (10), but no measurements have been made for mercury tsc complexes. We now report spectroscopic analyses on the samples used in our X-ray diffraction studies.

Experimental

The compound $HgBr_2(tsc)_2$ was synthesized by mixing stoichiometric $HgBr_2$ and tsc in aqueous solution. However, the reaction mixture was covered with aluminum foil to avoid decomposition by light. The crystals so obtained were colorless.

X-ray diffraction procedures were similar to those carried out for $HgCl_2(tsc)_2$ (4). Crystal data are as follows:

$C_2H_{10}Br_2HgN_6S_2$ fw = 542.7

Orthorhombic, $a = 8.825(9)$, $b = 8.587(11)$, $c = 15.939(23)$ Å; space group *Pbcn*. $D_o = 3.05$ (by flotation), $z = 4$, $D_c = 2.984$ g cm^{-3}. $V = 1207.9$ Å^3, μ(Mo-Kα) = 203.3 cm^{-1}, Systematic absences: $0kl$, $k = 2n + 1$, $h0l$, $l = 2n + 1$, $hk0$, $h + k = 2n + 1$. λ(Mo-Kα) = 0.7107 Å.

The crystal used had a rectangular shape with dimensions of 0.10 × 0.21 × 0.35 mm along [$\bar{1}$01], [101], and [010] directions. It was mounted with b along the ϕ axis of a G.E. XRD-6 automatic diffractometer. Among 855 reflections measured at 25 ± 3°C, 815 with $I > 3\sigma$ were used in the refinement of the structure. The method of data collection was the same as that used for $HgCl_2(tsc)_2$. Absorption corrections were made by the methods of Coppens *et al.* (11). The transmission factor, $A = \int 1/v \exp\{-\mu(r_i + r_d)\}dV$, range is 56 to 6%. Since the Patterson map of $HgBr_2(tsc)_2$ indicated that Hg was located at the same position as that of $HgCl_2(tsc)_2$, atomic parameters from the latter were used in the least-squares refinements. At the final stage, a weighting function $w^{-1} = (40 + F_o + 0.0001F_o^2)$ was used. The final R factor ($= \Sigma||F_o| - |F||/\Sigma|F_o|$) was 0.13. The quality of the data was affected by the absorption. The difference Fourier map showed high background ripple around Hg and Br locations. The atomic parameters are given in Table 1.[1]

Solid state ir spectra were measured on a Beckman IR-10 spectrophotometer. In the region 4000–1200 cm^{-1}, halocarbon mulls in CsI plates were used whereas in 1300–250 cm^{-1} region, Nujol mulls were employed. Polycrystalline Raman spectra were measured on a Jarrell-Ash Model 400 Raman spectrophotometer. The Ar ion laser operated at approximately 350 mW light power.

[1]Copies of the tables of structure factors and temperature parameters may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

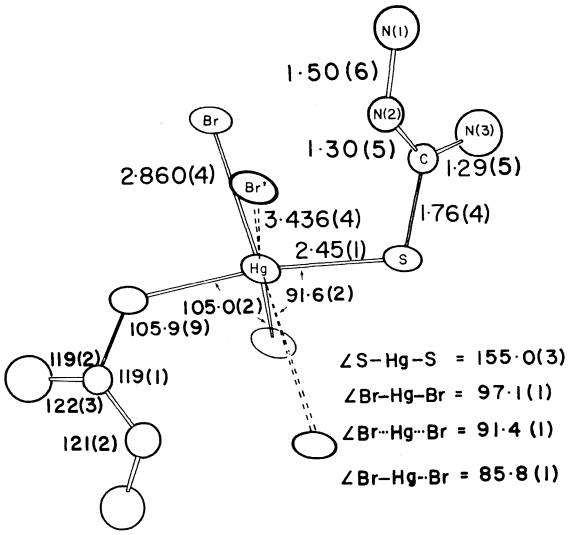

FIG. 1. Important bond distances (Å) and angles (°) for $HgBr_2(tsc)_2$; standard deviations in parentheses.

Results and Discussion

The important bond lengths and angles are given in Fig. 1. The cell constants and Hg—X bond lengths of $HgBr_2(tsc)_2$ are larger than those of $HgCl_2(tsc)_2$ due to the larger size of bromine.

The abilities of tsc to act either as a monodentate or a bidentate ligand have resulted in the formation of $HgX_2(tsc)$ and $HgX_2(tsc)_2$. The configuration of tsc in $HgX_2(tsc)$ is similar to that in $Ni(tsc)_2A$ ($A = SO_4^{2-}$, $2NO_3^-$), or $ZnX_2(tsc)$, whereas in $HgX_2(tsc)_2$ (4) or AgX(tsc) (5) the configuration of the coordinated tsc is not different from that of the free tsc molecule. As a result, ir or Raman spectra of the ligand for monodentate tsc complexes are similar to that of tsc. The spectra of the bidentate tsc complexes belong to a separate category.

In the 1600 cm^{-1} region, two bands were observed for tsc as well as for its complexes. The assignment is given in Table 2.[1] The band due to $\delta(N(3)H_2) + \nu(C—S)$ is shifted to a lower frequency upon coordination. The frequency of the first band, 1618 (1628 R) cm^{-1} of $HgCl_2(tsc)$ is much lower than those of tsc or $HgX_2(tsc)_2$ (1641 (1642 R), ~1650 cm^{-1}) due to the coordination through N(1).

The bands at 1530 (1530 R), 1480 (1500 R), and 1310 cm^{-1} of tsc shift slightly upon complexing in $HgX_2(tsc)_2$. Similar bands in thiourea, *N*-ethylthiourea, and *N,N'*-diethylthiourea complexes showed the same shifts (10, 13, 14).

Bands in the above region depend on the configuration of tsc, which is bidentate in $HgCl_2(tsc)$. The skeletal change gave two bands at 1450 (1456 R) and 1365 (1380 R) cm^{-1}. Nickel and copper com-

plexes in which the tsc is also bidentate, have bands at ~1450 (1456 R) and ~1370 (1380 R) cm^{-1} (15).

The band at 1162 (1170 R) cm^{-1} was believed to be a rocking and wagging mode of NH_2 (8, 9). In all three complexes, this band occurred at 1170 (1176–1196 R) cm^{-1}. Raman spectra in the region 1100–100 cm^{-1} are given in Fig. 2.

Bands at ~1000 cm^{-1} of tsc and $HgX_2(tsc)_2$ are strong. This band split in two in $HgCl_2(tsc)$ probably because one of the NH_2 groups in the tsc is co-ordinated to mercury.

The band at 800 (807 R) cm^{-1} of the tsc was suggested as mainly a $\rho_w(NH_2)$ by Jensen and Neilson (16). Other authors had assigned it to a combination of ν(C—S) and ν(C—N) mode (6, 9). When complexed, this band appeared at ~773 (796 R) cm^{-1} for $HgX_2(tsc)_2$. This lends further support to the assignment of ν(C—S) with a small contribution from ν(C—N). The corresponding ir bands for $Cu(tsc)_2Cl_2$ and $Ni(tsc)_2Cl_2$ were at 698 (m) and 704 (m) cm^{-1} (15). This suggests further contribution of ring deformation to the bidentate tsc.

The metal-to-ligand or to-halide stretching frequencies are identified in the Raman spectra. A strong Raman band at 368 cm^{-1} found for $HgCl_2$-(tsc), but not for other compounds of Table 2, may

For personal use only.

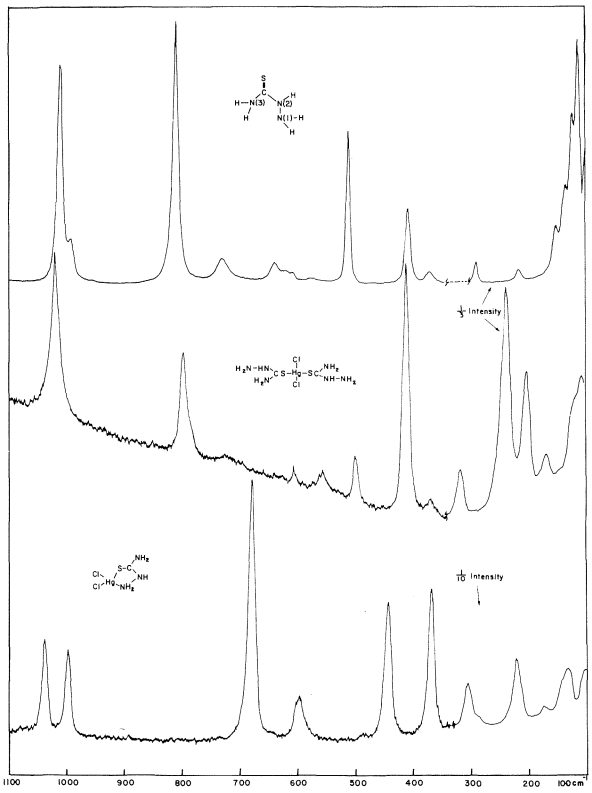

FIG. 2. Raman spectra for tsc and its complexes.

be assigned to ν(Hg—N). Lower frequencies around 340 cm^{-1} were found for mercury(II) halides – morpholine complexes (17).

The medium intense band at 327 (288 R) cm^{-1} for tsc became strong probably as a result of overlapping of ν(C—S) and ν(Hg—S). The latter assignment is supported by a range of mercury(II) halide thiourea and *N*-substituted thiourea complexes by Marcotrigiano *et al.* (13, 14, 18, 19) and Adams and Cornell (20). The frequencies for these complexes range from 200 to 280 cm^{-1}, except those of *N*,*N'*-diethylthiourea complexes, in which case the ranges were from 270 to 350 cm^{-1} in the ir and from 260 to 340 cm^{-1} in the Raman (13). This was the only Raman study for these complexes. The intensity ratio of the two peaks at 408 (R) and 315 (R) cm^{-1} for $HgCl_2(tsc)_2$ is not the same for $HgBr_2(tsc)_2$, however, bands at 310 cm^{-1} are the only common band with comparable intensity and suitable frequency for ν(Hg—S).

Two bands are expected for ν(Hg—X) for all three complexes in Table 2. For $HgCl_2(tsc)$, there are two unequivalent terminal Hg—Cl bonds, $\nu(Hg—Cl)_t$, whereas in $HgCl_2(tsc)_2$, the chloride is asymmetrically bridged to two mercury(II) ions (3, 4). Therefore 220 and 190 cm^{-1} are assigned to $\nu(Hg—Cl)_t$, whereas 236 and 166 cm^{-1} to $\nu(Hg—Cl)_b$. One of the $\nu(Hg—Br)_b$ occurs at 190 cm^{-1} while the other is masked by lattice vibrations. Terminal and bridging halides are also present in the thiourea and *N*-substituted thiourea complexes mentioned earlier. Their vibrational frequencies are comparable to those observed in this study. Mercury(II) halide complexes with nitrogen donor ligands had the same frequency range for Hg—X vibrations (17, 21).

The formation of propane, propylene, and acetone from 2-propanol over vanadium pentoxide and modified vanadium pentoxide catalysts

DAVID V. FIKIS, WILLIAM J. MURPHY, AND ROBERT A. ROSS
Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received April 7, 1978

DAVID V. FIKIS, WILLIAM J. MURPHY, and ROBERT A. ROSS. Can. J. Chem. **56**, 2530 (1978).

The catalytic decomposition of 2-propanol has been studied in a flow system from 200 to 280°C on vanadium pentoxide and modified vanadium pentoxide catalysts. Results were obtained with separate melts of the oxide containing 9.09 mol% of each of the alkali metal sulfates and with individual preparations of the pentoxide containing 1.01, 2.00, and 4.98 mol% potassium sulfate, respectively. In addition to expected dehydration and dehydrogenation reactions, propane was formed over the entire temperature range and became a dominant product at higher temperatures.

Kinetic experiments showed that the dehydration and dehydrogenation reactions were zero order with respect to all components while the propane-forming reaction gave a rate order of 0.3 with respect to 2-propanol concentration. Elimination-type mechanisms have been proposed to explain the results and some evidence of a relationship between catalyst activities and surface acidity is presented. The observed kinetic compensation effect has been shown to compare well with previous work on 2-propanol decomposition on metal oxides.

DAVID V. FIKIS, WILLIAM J. MURPHY et ROBERT A. ROSS. Can. J. Chem. **56**, 2530 (1978).

On a étudié, la décomposition catalytique du propanol-2, dans un système à flux, de 200 à 280°C, sur des catalyseurs de pentoxyde de vanadium et de pentoxyde de vanadium modifié. On a obtenu des résultats avec diverses masses fondues d'oxyde contenant 9.09 mol% de chacun des sulfates de métaux alcalin et avec des préparations individuelles du pentoxyde contenant respectivement 1.01, 2.00 et 4.98 mol% de sulfate de potassium. En plus des réactions de déshydratation et de déshydrogénation attendues, il y a formation de propane à toutes les températures étudiées et ce produit devient le produit majoritaire à des températures plus élevées.

Des expériences de cinétique montrent que les réactions de déshydratation et de déshydrogénation sont d'ordre zéro par rapport à tous les composants alors que l'ordre de la réaction de formation du propane est de 0.3 par rapport à la concentration de propanol-2. On a proposé des mécanismes du type élimination pour expliquer les résultats et on présente quelques données relatives aux activités des catalyseurs et à l'acidité de la surface. On a montré que l'effet de compensation cinétique observée se compare bien avec le travail antérieur sur la décomposition du propanol-2 sur des oxydes métalliques.

Introduction

In recent studies (1, 2) of the decomposition of 2-propanol over alkaline earth and transition metal oxides, activity relationships with catalyst oxygen mobilities and contents have been explored. The work has now been extended to include reaction of the alcohol on vanadium pentoxide and separate melts of the oxide containing 9.09 mol% of each of the alkali metal sulfates as additives. Results have also been obtained with individual preparations of the pentoxide containing 1.01, 2.00, and 4.98 mol% potassium sulfate, respectively. Such catalyst preparations appeared to be suitable test vehicles for the earlier hypotheses since the addition of alkali metal sulfates to vanadium pentoxide has a pronounced effect on catalyst activity for sulfuric acid production (3) and also promotes the exchange between molecular oxygen and the oxygen of the metal oxide. These and similar observations have been attributed to changes wrought on the surface mobility of oxygen in the catalyst (4–7).

Specifically, the promoting action for oxygen exchange (4, 5) gave the following additive activity series with vanadium pentoxide catalysts: None < Li_2SO_4 < Na_2SO_4 < K_2SO_4 < Rb_2SO_4 < Cs_2SO_4. Studies of the catalytic activities for sulfur dioxide oxidation showed the same trend (8) and a similar sequence was observed for the present catalysts in the oxidation of carbon monoxide by nitrous oxide (9).

Several studies have also been reported on the influences of various other additives on the activities of metal oxide catalysts in alcohol decomposition reactions (10–12) and the results discussed in terms of relationships with electronic features of the solids.

Experimental Section

Apparatus and Method

The all-glass flow system has been described previously (13, 14). High-purity helium was used as the carrier gas at atmospheric pressure in the flow system and in the Hewlett Packard, Model 5754B gas chromatograph. The analytical columns were constructed from 1.5 m × 0.32 cm od stainless steel tubing packed with "Porapak Q" (150–200 mesh). The column temperature was maintained at 100°C for a post-injection interval of 4 min during which water, propylene, and propane were eluted. The column temperature was then increased by linear temperature programming at 20°C/min to a maximum temperature of 140°C which was then maintained for a further 7 min. During this period, acetone and 2-propanol were eluted. The flow of gas was at a rate of 30 ml min^{-1} (NTP) through the columns. Reaction products were analyzed by both flame ionization (at 175°C) and thermal conductivity detectors (at 200°C, filament current 245 mA).

Surface areas were determined by low-temperature krypton adsorption (BET; −196°C; $\sigma = 21.5$ Å^2).

To establish the experimental conditions for which the reaction rate was not influenced by external or internal diffusion, the influences of space velocity, catalyst mass, and particle size were studied in the usual manner (13). As a result, kinetic measurements were conducted at a total flow rate of 300 ml min^{-1} (NTP) between 200 and 280°C on attainment of a steady catalyst activity level after conditioning for 24 h at 300°C. In all experiments designed to establish kinetic parameters, the steady level conversion maximum was not greater than 10%.

An estimate of the 'apparent acidity' of the catalysts was obtained by agitating 0.2 g of the used solids for 10 min in 40 ml of water, followed by centrifugation and titration of 20 ml of the decanted liquid against standard alkali. The 'apparent acidity' was then taken as directly proportional to the relative amounts of the standard alkali consumed in the neutralization. The results were readily duplicated.

Materials

Vanadium pentoxide was >99.9% pure (Ventron). The samples containing alkali metal sulfates (Ventron, >99.9% pure) were prepared by mixing vanadium pentoxide powder and the corresponding weight of the appropriate sulfate additive in a ball mill for 2 h. This mixture was then heated at 700°C for 4 h in a quartz dish. The liquid melts were cooled rapidly, ground, and pelletized in a 1.27 cm die (ram pressure 3 tons) for 2 min. These pellets, and the pellets of pure vanadium pentoxide which were prepared in a similar manner, were calcined at 500°C for 10 h with the exception of the cesium and rubidium sulfate melts which were calcined at 430°C. The pellets were crushed and sieved to a particle diameter between 0.063 and 0.074 mm for the catalytic studies.

"Spectranalyzed" grade 2-propanol and acetone were supplied by Fisher Scientific. Certified grade helium (>99.9%), hydrogen (99.9%), compressed air, instrument grade propane (99.5%), and C. P. grade propylene (99.0%) were obtained from Canadian Liquid Air Ltd.

Results

The Effect of Exposure Time on the Reaction Products

One gram of catalyst was raised to the reaction temperature in a 300 ml min^{-1} (NTP) stream of helium before admission of 2-propanol to the reactor.

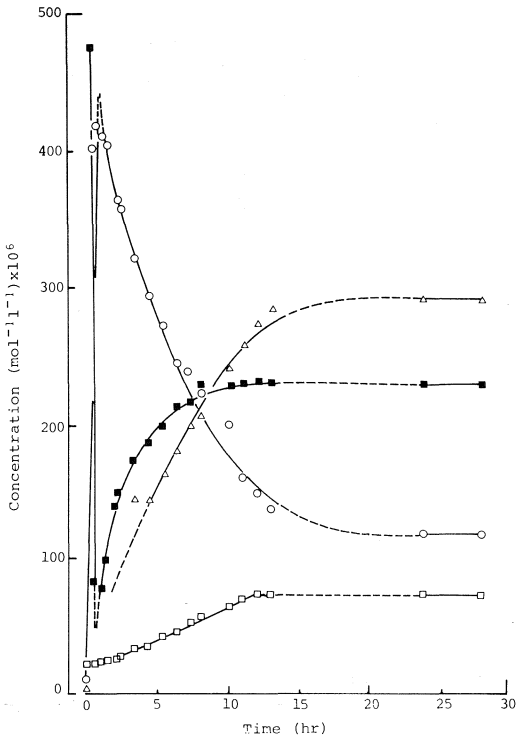

FIG. 1. The effect of exposure time on the reaction components from the decomposition of 2-propanol over V_2O_5: 9.09% K_2SO_4 at 300°C; △ propane; □ acetone; ○ propylene; ■ 2-propanol.

Figure 1 shows the effect of time on the composition of products from 2-propanol decomposition over the catalyst containing 9.09 mol% potassium sulfate at 300°C and 8.84 Torr alcohol partial pressure. Some difficulty was encountered in the quantitative measurement of water produced during reaction due to tailing. Water, however, was always produced and qualitatively paralleled the formation of acetone. Hydrogen was determined in the effluent stream at a level of <5% of the other products of the reaction.

It may be deduced from Fig. 1 that during the initial part of the conditioning period (0–4 h) a distinct inverse relationship exists between 2-propanol decomposition and propylene formation. Further, after a period of approximately 5 h, a similar relationship would appear to exist between the propylene and propane reactions.

Variations of Partial Pressures of 2-Propanol, Acetone, Water Vapour, Molecular Hydrogen, Propylene and Propane

The partial pressure of 2-propanol was varied between 3.37 and 8.84 Torr over V_2O_5:9.09 mol% K_2SO_4 at 230°C and 300 ml min^{-1} (NTP) total

*Before conditioning and reaction.

flow. A logarithmic plot of the reaction rate vs. partial pressures of alcohol indicated a reaction order of 0.3 for propane with respect to 2-propanol concentration. Other products showed zero order rate dependencies on the alcohol concentration over the same range.

With the partial pressure of 2-propanol kept constant at 8.84 Torr the reaction rates were unaffected by varying the partial pressures of (*a*) acetone from 0.5 to 3.0 Torr (*b*) water vapour from 0.75 to 3.0 Torr, (*c*) hydrogen from 4.2 to 10.0 Torr, (*d*) propane from 4.2 to 10.0 Torr, and (*e*) propylene from 4.2 to 10.0 Torr.

The Effect of Temperature

Experiments were carried out with 8.84 Torr partial pressure of 2-propanol from 200 to 280°C. The propane-forming reaction was dominant although dehydration to propylene and dehydrogenation to acetone also took place to a significant extent. The contribution of these latter reactions to the overall decomposition decreased at higher temperatures. No other organic compounds could be detected in the temperature range studied.

Table 1 shows the apparent activation energies calculated from experimental rate equations in the usual way (2). The order of reaction for propane with respect to 2-propanol concentration was taken as 0.3 while the net effects of the other components were considered to be zero order.

The surface areas of all catalysts changed significantly during the 24 h conditioning period, Table 2. Little or no change in the values was detected, however, after the reactions had been studied at the steady catalyst activity level. The surface areas determined for the steady level were used in all kinetic calculations.

Plots of $\log_{10} A$ and the apparent activation

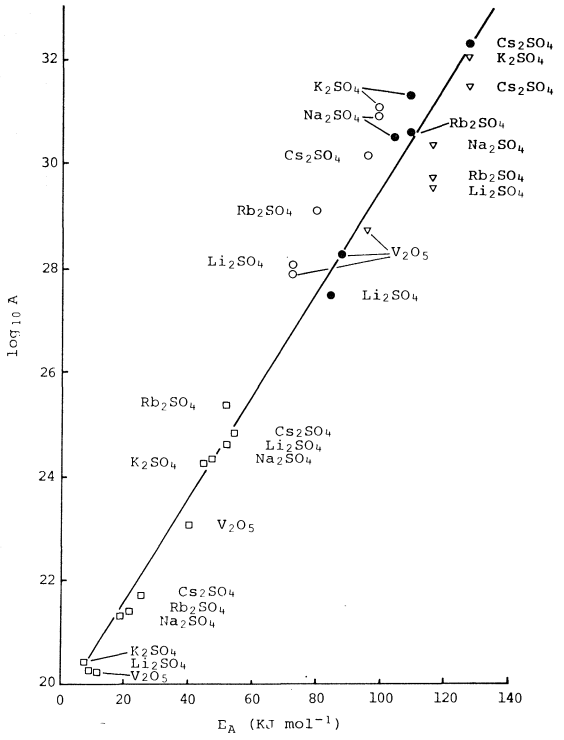

FIG. 2. Compensation effect for V_2O_5 and melts containing alkali metal sulfate additives for various reactions. ● overall 2-propanol decomposition; ▽ propylene formation; ○ propane formation; □ acetone formation.

energies, E_A, for the overall 2-propanol decomposition and for the formation of acetone, propylene, and propane, Fig. 2, indicate that a similar compensation effect is operative in all of these reactions. The values of the constants which define the compensation effect and which were calculated by applying a least-squares analyses of the data to the equation (15):

$$\log_{10} A = \beta + eE_A$$

were found to be 0.1012 ($\sigma = 0.004$) and 19.543 ($\sigma = 0.439$) for e and β respectively; where σ denotes the standard deviations from the mean in each case. The units used for E_A and A were kJ mol^{-1} and molecules m^{-2} s^{-1}, respectively.

All of the catalysts studied, with the exception of that modified with sodium sulfate, were found to be various shades of yellow/orange in color in agreement with literature (16). The sodium sulfate modified catalyst was black which was attributed to the relative ease of this additive in forming vanadium-bronzes when compared with the other components used in the series (17). The black coloration may also indicate a non-stoichiometric deficiency of oxygen in the catalyst (18). All catalysts changed color to black after conditioning and reaction. The onset of this color change took place after 1 to 2 hours into the conditioning period.

Discussion

The effect of catalyst conditioning on product distribution, Fig. 1, suggests that initially, 2-propanol reacts on the surface to produce propylene and acetone. On desorption of these products some surface sites may be occupied by hydrogen and hydroxyl species. Then, as sites become increasingly occupied or blocked, by hydrogen and/or hydroxyl species, propylene production decreases and propane formation becomes evident. Propane may therefore form through hydrogen extraction from the surface. The concept of propane formation by hydrogenolysis of the alcohol rather than by hydrogenation of propylene is supported in some measure by the findings of Balandin *et al.* (19) and by the present observations that changes in the concentration of propylene during conditioning have no effect on the formation of propane.

The nature of the increase in the acetone-formation activity with time during conditioning, Fig. 1, and the qualitative finding that acetone formation runs parallel to water formation may indicate that one of the active adsorption sites is a hydroxyl species as has been identified by X-ray analyses of this catalyst after conditioning (20).

The steady-level values of the reaction rates at any defined temperature did not follow any simple activity series such as those reported by previous workers for various reactions on similar catalysts (4, 5). Attempts to measure the acid/base characteristics of the surfaces by non-aqueous methods (21, 22) were inconclusive, perhaps due to the very dark colorations of the solids. However, a correlation could be established, Fig. 3, between the reaction rates at a given temperature and the 'apparent acidity' of the catalyst surface. This latter term simply indicates the relative ease with which the used catalysts acidified water. Similar correlations were established between the catalyst activity and the equilibrium amounts of vanadate and sulfate anions measured in the aqueous solutions by spectroscopic methods (23). The observed variation in the sulfate and vanadate concentrations is believed to indicate the relative ease or extent with which the alkali metal sulfates and vanadium pentoxide enter into inter-solid reactions in the melt. This hypothesis is supported, in some measure, by the trend of the melting points of the additives which shows a maximum at potassium sulfate.

The steady-level values of the reaction rates, for

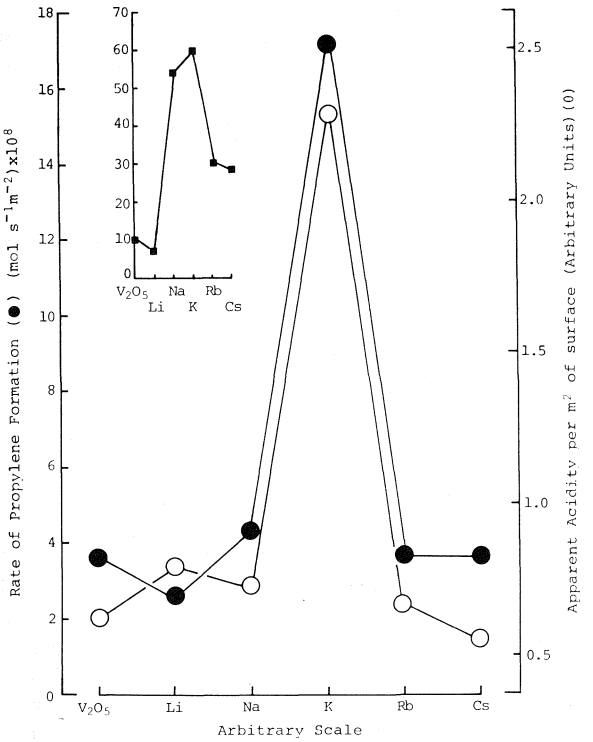

FIG. 3. Effect of variation of alkali metal cation, in catalysts containing 9.09 mol% alkali metal sulfate on, (*a*) rate of propylene formation at 270°C (●) and (*b*) "apparent acidity" (○). Inset: Effect of alkali metal cation variation on rate of overall 2-propanol decomposition. (1 A.U. (arbitrary unit) ≡ 10^{-1} meq. m^{-2}).

the melts containing potassium sulfate, at a given temperature can be expressed as an activity series: 1.01 < 2.00 < 4.98 < 9.09 (mol% K_2SO_4). A linear relationship was established between the overall rate of reaction at a given temperature and the mol percent alkali metal sulfate in the catalyst, Fig. 4. However, a comparison of the magnitudes of the rates of reaction in the present study together with the reported rates for isotopic oxygen exchange, extrapolated to the current working temperatures, indicates that any direct correlation between the oxygen mobility and activity of the catalysts between 200 and 280°C is probably incidental. Further, with the present experimental procedure, most of the active oxygen is probably removed during conditioning (20). 'Apparent acidity' tests could not be performed on the actual catalysts of this series since the samples had been used in other experiments. However, simulated preparations which were shown by both X-ray diffraction and surface area measurements to parallel the experimental samples were examined. The results obtained were encouraging with respect to the hypothesis advanced. The whole aspect of the activity/acidity relationship appears to present a prime area for further study.

In previous work (24) on $V_2O_{(5-x)}$ catalysts, activation energies of 92 and 176 kJ mol^{-1} were determined, respectively, for dehydrogenation and dehydration of 2-propanol from 74 to 104°C. A low selectivity value of 0.11 towards dehydrogenation was observed in terms of dehydration and dehydrogenation rates. Isopropyl ether was a major component also of the reaction products but propane was absent. The marked contrast of these features with the present findings from 200 to 270°C is equated with the lengthy conditioning period at higher temperatures required to attain steady activity levels with the sulfate additives. This same treatment was applied in conditioning the unmodified pentoxide samples.

Thus it might be expected that the O/V ratio would be lowered as a result of conditioning especially since milder reducing treatments will achieve this result (16, 25). A preliminary study of the catalysts after reaction, using X-ray diffraction, has indicated that the solid matrix includes non-stoichiometric oxide and hydroxide phases, two components of which have been tentatively identified as VO_2 and VO(OH) (20).

It appears then, as an initial broad hypothesis, that a decrease in the O/V ratio can influence considerably both kinetic and mechanistic features of catalysis such that results are not inconsistent with earlier studies on $V_2O_{(5-x)}$ (24) and V_2O_3 (26). The

consequences of catalyst-oxygen depletion might be expected to include destabilization of the surface intermediate formed during dehydration through a decrease in the strength of dehydration-center attachment to the surface (27, 28) as may be gauged by the present experimental activation energies which lie from 40 to 60% below the value determined for $V_2O_{(5-x)}$ at lower temperatures.

The apparent activation energy values for acetone formation fall into two distinct regions, Table 1. The low values are somewhat unusual, especially since the acetone reaction was subject to chemical rate control over the entire temperature range covered. However, two such temperature-dependent kinetic regions for acetone formation were established earlier (2) for manganese oxides and related to variations with temperature in the energy of interaction of adsorbate molecules with adsorption sites (29).

The recent work of Galwey (15) shows that a kinetic compensation effect exists for the reactions of 2-propanol on various oxide surfaces (1, 24). The parameters defining this reported effect are slope (0.1012, $\sigma = 0.006$) and the intercept, where $E_A \rightarrow 0$, (15.604, $\sigma = 0.943$). Figure 2 shows that a common compensation effect exists for all the contributing reactions in the decomposition of 2-propanol on the present catalysts. A comparison of the slope, Fig. 2, with that obtained by Galwey shows complete agreement. Thus similarities in both rate-determining steps and reaction mechanisms may be anticipated in the primary surface reactions of 2-propanol over these solids even when some comparative differences exist in the reaction product compositions.

On the basis of a Langmuir–Hinshelwood model, the pseudo-zero order rate dependencies of component concentrations in the dehydration and dehydrogenation reactions may be interpreted in terms of a very rapid saturation of active surface sites amenable to catalysis. Extremely rapid reaction and subsequently fast desorption of the adsorbed species into the gas phase presents an alternative explanation.

The experimental reaction rate data for the propane-forming reaction were treated by statistical analyses in a test/reject fashion to derive rate expressions which might be consistent with the observations. The simple kinetic equations:

$$[1] \qquad r = \frac{kP_{alc}}{1 + kP_{alc}}$$

$$[2] \qquad r = \frac{kP_{alc}^{1/2}}{1 + kP_{alc}^{1/2}}$$

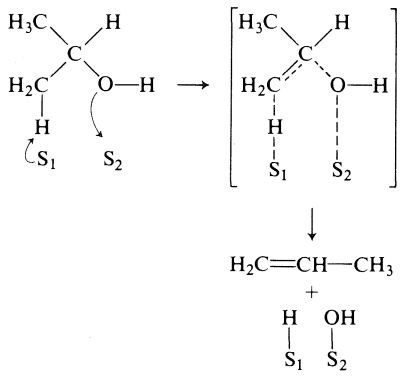
were both applicable; k is the rate constant for the overall decomposition of the alcohol and P_{alc} is the partial pressure of 2-propanol.

Equation 1 (correlation coefficient, 0.998) implies that the rate of reaction is proportional to the amount of alcohol adsorbed on the surface and would be governed by a Langmuir isotherm where the adsorbate occupies one surface site during the rate-determining step (30). Equation 2 (correlation coefficient, 0.993) again invokes Langmuir–Hinshelwood kinetics with the adsorbate occupying two surface sites during the rate-determining step (30). It may be that the observed experimental rate order of 0.3 for the alcohol in the propane reaction implies a mix of the two adsorption modes, which is related to the conditions of catalysis.

The heterogeneous decomposition of 2-propanol has been interpreted in terms of various mechanisms (31–33). Knozinger (34) proposed E-2 type reaction intermediates for the dehydration of primary, secondary, and tertiary alcohols over alumina below 200°C. At higher temperatures, depending on the reactant structure, dehydration was thought to proceed via E-1 type mechanism intermediates (34). Mechanisms for dehydrogenation have been suggested as involving initial adsorption at an electronegative surface site with subsequent two-point adsorption (32).

The reactions involved in the present study may be explained in terms of intermediates typical of such elimination-type mechanisms. Thus, propylene may be formed via an E-2 type mechanism on adjacent vacant surface sites:

[3]



Such an attachment of the alcohol to the surface through the hydroxyl group and a β-hydrogen has been reported to involve little strain even on plane surfaces (35). A mechanism of this type has recently been suggested (36) for dehydration of isopropanol on V_2O_5 and vanadium bronzes in which S_1 and S_2

are V^{4+} and V^{5+} species respectively. In a similar way, acetone could be produced:

[4] 
A two-point adsorption intermediate has been reported for acetone formation from 2-propanol (32). The present data suggests that one site is a hydroxyl group which may also form as an adsorbed species resulting from the dehydration reaction.

Both [3] and [4] advocate that some of the original surface sites become occupied by adsorbed hydrogen on dehydration or dehydrogenation and thus as these sites become increasingly occupied, 'dehydration' may become limited to a one-point adsorption center (E-1 type). Propane formation is then linked to the availability of hydrogen on a neighboring adsorption site:

[5] 
This scheme has features in common with recent work (36) when it was suggested that the alcohol was adsorbed on V^{5+} sites followed by subsequent hydrogen abstraction from the alcohol on a neighboring V^{4+} site to produce propylene resulting in a saturation of adjacent V^{4+} and V^{5+} pairs by H and OH species, respectively. However, there would tend to be an excess of V^{5+} species in all of the catalysts studied, the V^{4+}/V^{5+} ratio increases to as much as 0.5 in V_2O_5 glasses (37), so that alcohol adsorption sites would always be available. Thus the availability of reaction centers would depend solely on the oxidation state and the nature and degree of occupancy of the neighboring vanadium sites by adsorbed species. If the neighboring site is V^{4+}, unoccupied, then dehydration results, but if the site is occupied by hydrogen then propane seems likely to be the product.

In such a mechanism the amount of propane formed would be expected to increase to some limiting value in step with a corresponding decrease in the product concentration of propylene, which is consistent with the trend observed, Fig. 1. Further, since E-1 mechanisms are likely to be favored at higher temperatures (34), the observation that the propane-forming reaction becomes progressively more dominant with temperature increase can also be explained by this proposal.

This study has demonstrated that, while the course of catalysis is related to the availability of oxygenated surface species, a direct link with surface oxygen mobility is improbable. The decomposition results for each of the contributing steps may be explained by elimination-type mechanisms in which intermediate adsorbed species are located at sites offering H or OH. The subsequent measurable acidity may indicate that the activity trends are related to the presence primarily of 'acidic' species in the solid surface.

Thermodynamic properties of the alkali metal hexachloroniobate and hexachlorotantalate compounds by vapour pressure measurements

DONALD R. SADOWAY[1] AND S. N. FLENGAS

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received March 14, 1978

DONALD R. SADOWAY and S. N. FLENGAS. Can. J. Chem. **56**, 2538 (1978).

The vapour pressures for the decomposition of the solid and liquid compounds $AMCl_6$ where A = Na, K, Rb, or Cs, and M = Nb or Ta, were measured by a fused quartz Bourdon spiral pressure gauge. The hexachlorotantalates were found to be more stable thermally than the hexachloroniobates. Enthalpies of decomposition were calculated. The dissociation temperatures of each sequence of compounds increase with increasing size of the radius of the alkali-metal cation. Partial pressures of $NbCl_5$ or $TaCl_5$ vapour in equilibrium with solutions representing the binary systems KCl–$KNbCl_6$ and KCl–$KTaCl_6$, respectively, are also reported.

DONALD R. SADOWAY et S. N. FLENGAS. Can. J. Chem. **56**, 2538 (1978).

Faisant appel à une jauge de Bourdon en silice, on a mesuré les tensions de vapeur accompagnant les décompositions des composés solides et liquides $AMCl_6$ où A = Na, K, Rb ou Cs et M = Nb ou Ta. On a trouvé que les hexachlorotantalates sont plus stables du point de vue thermique que les hexachloroniobates. On a calculé les enthalpies de décomposition. Les températures de dissociation pour chaque série de composés augmentent avec une augmentation du diamètre du cation du métal-alcalin. On rapporte aussi les tensions de vapeur partielles du $NbCl_5$ ou du $TaCl_5$ en équilibres respectivement avec des solutions représentant des systèmes binaires KCl–$KNbCl_6$ et KCl–$KTaCl_6$.

[Traduit par le journal]

Introduction

Niobium and tantalum pentachloride vapours react with alkali-metal chlorides to form compounds of the type $[A^+][MCl_6^-]$, where A represents an alkali metal and M represents Nb or Ta. These compounds can melt congruently, as does $KNbCl_6$ (1), or incongruently, as does $NaNbCl_6$ (1). Covalently bonded $NbCl_5$ and $TaCl_5$ melts behave as molecular liquids (2–5); in contrast, solutions of these pentachlorides in molten alkali-metal chlorides are ionic in character, as their electrical conductivities show (6, 7), and thermodynamically stabler than the former, as vapour pressure measurements demonstrate. For example, at 450°C pure $NbCl_5$ has a vapour pressure of 22 atm (8), whilst the partial pressure of $NbCl_5$ over molten $KNbCl_6$ at the same temperature is reported as 0.15 atm (9). These changes in behaviour may be explained by the presence of complex species in the MCl_5–ACl solutions (4, 10, 11).

The compounds $NaNbCl_6$, $NaTaCl_6$, $KNbCl_6$, $KTaCl_6$, $RbNbCl_6$, $RbTaCl_6$, $CsNbCl_6$, and $CsTaCl_6$ were synthesized in this laboratory by the reaction of $NbCl_5$ or $TaCl_5$ vapour with solid alkali-metal chloride under controlled pressure and temperature conditions. The preparation has been described elsewhere (12). The thermodynamic properties of the aforementioned compounds and of solutions of KCl–$KNbCl_6$ and KCl–$KTaCl_6$ were determined by vapour pressure measurements of the following equilibrium:

[1] $AMCl_6$ (s, 1, or solution) $\rightleftharpoons$ ACl (s, 1, or solution) + MCl_5 (vap.)

Experimental

The vapour pressure of $NbCl_5$ or $TaCl_5$ in equilibrium with the compounds $AMCl_6$ or with $AMCl_6$–ACl solutions have been measured by a fused quartz Bourdon spiral pressure gauge contained in a closed apparatus which has been described elsewhere (13).

For these measurements the temperature of the sample container was varied between 190 and 660°C while the upper part of the apparatus containing the Bourdon spiral was maintained at temperatures about 50°C higher than the corresponding normal boiling points of pure $NbCl_5$ and $TaCl_5$.

Samples of the $AMCl_6$ compounds and of their mixtures with alkali-metal chlorides were prepared by methods previously described (12). Materials were handled in a glove box filled with dehydrated helium. Specimens were introduced into the sample container of the apparatus in the form of powders. The part of the cell consisting of the sample container and the Bourdon spiral were sealed under vacuum. It was found that large quantities of adsorbed gas were released from the salt upon heating. This introduced a systematic error into the measurements. Accordingly, an elaborate degassing procedure was employed in which the cell was repeatedly

heated, cooled, reopened, and evacuated. When residual gas was no longer present upon cooling, a proper experiment was conducted to measure the vapour pressure of the sample.

Results and Discussion

1. *Properties of the $AMCl_6$ Compounds*

Figures 1–4 display the experimental results for the vapour pressures of the decomposition of the compounds $AMCl_6$, where A is Na, K, Rb, or Cs. Each figure shows the results for both the hexachloroniobate and the hexachlorotantalate of a given alkali metal. The figures also show the results of other investigators. Least-squares lines are given in Table 1.

The shape of the curve of $\ln P_{MCl_5}$ *vs.* $1/T$ may be understood in terms of the equilibrium constant for the decomposition reaction in eq. [1] (14–19). For this reaction

$$[2] \qquad K = P_{MCl_5} \cdot a_{ACl}/a_{AMCl_6}$$

where the standard state for the compounds ACl and $AMCl_6$ is the pure solid at all temperatures, and for MCl_5 is the vapour at a pressure of 1 atm.

In the ACl–$AMCl_6$ subsystem, below the eutectic temperature three phases are present: the pure solids, ACl, and $AMCl_6$, whose activities are unity, and MCl_5 vapour. Therefore, in this region, $K = P_{MCl_5}$.

In the temperature and composition range where molten ACl–$AMCl_6$ solutions are saturated with either ACl or $AMCl_6$ solid, the expression for the equilibrium constant is written as $K = P_{MCl_5}/a_{AMCl_6}$ or $K = P_{MCl_5}a_{ACl}$, respectively. Accordingly, as the activity terms are always less than unity the pressure curves of these solutions are expected to inflect at the eutectic and liquidus temperatures of the corresponding ACl–$AMCl_6$ systems.

The $\ln P_{MCl_5}$ vs. $1/T$ plot is also expected to change slope at temperatures below the eutectic points when the solids present undergo solid–solid transitions.

This is particularly significant for the hexachloroniobate and hexachlorotantalate compounds in which several phase changes in the solid state have been observed.

In connection with this last comment Table 2 is presented as a summary of previously reported results from this laboratory (12). Thus in the present work measurements were taken within temperature ranges for which well defined phases were present.

Figure 1 shows the results for the decomposition of both β-$NaNbCl_6$ and β-$NaTaCl_6$ along with the results of other investigations for these two compounds. It is of interest to note that their decomposition pressures reach 1 atm at temperatures lower than their melting points. Accordingly a plot of $\ln P_{MCl_5}$ vs. $1/T$ should be linear.

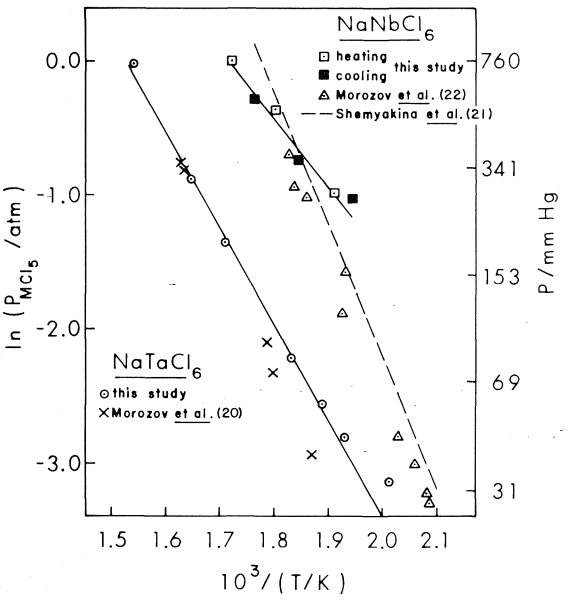

FIG. 1. ln P_{MCl_5} vs. $1/T$ plots for the systems $NaNbCl_6$ and $NaTaCl_6$. Solid lines represent best fit of present data.

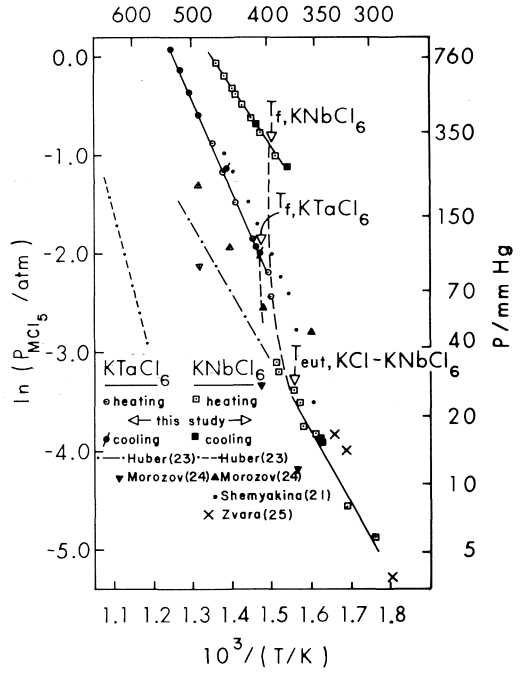

FIG. 2. ln P_{MCl_5} vs. $1/T$ plots for the systems $KNbCl_6$ and $KTaCl_6$. Solid lines represent best fit of present data. Dashed line is simply drawn to link the solid and liquid regions.

In comparison with other vapour pressure studies the results of this work agree well with that of Morozov, Korshunov, and Simonich (20) for the α-$NaTaCl_6$ system. Shemyakina *et al.* (21) and Morozov and Korshunov (22) have measured the decomposition of $NaNbCl_6$ at temperatures lower than that in this investigation, and their values tend to converge at about 518 K which is the transition temperature for its $\alpha \rightarrow \beta$ transformation.

Figure 2 shows the results of both β-$KNbCl_6$ and molten $KTaCl_6$. Data for the decomposition of solid $KTaCl_6$ are not given as the pressures were too low to be measured by the apparatus. Figure 2 also shows the results of other investigations.

The thermal decomposition of $KNbCl_6$ has been studied by Huber *et al.* (23), Morozov and Simonich (24), Shemyakina *et al.* (21), and Zvara and Tarasov (25). The results of the present study for low temperatures agree best with those of Zvara and Tarasov (25), who measured vapour pressures in equilibrium with both α- and β-$KNbCl_6$ solids using a radioactive tracer technique. These authors, however, did not make any comments on the solid–solid transformations occurring during their measurements.

Equilibrium pressures reported by both Morozov and Simonich (24) and by Shemyakina *et al.* (21) are not in agreement with values measured in the present study. The former used a transportation technique, while the latter used a null membrane type manometer. Both authors plotted their measured pressures of $NbCl_5$ as a single least-squares line crossing solid–solid transition temperatures and extending into the temperature range for molten $KNbCl_6$. Huber *et al.* (23) measured vapour pressures of $NbCl_5$ in equilibrium with molten $KNbCl_6$ by a transportation method. The results are much lower than those recorded herein. In reports of vapour pressures measured by the transportation technique (23, 24) the authors failed to mention that consideration was given to the problem of depletion of $NbCl_5$ from the $KNbCl_6$ condensed phase as the experiment progressed.

The thermal decomposition of $KTaCl_6$ has been studied by Huber *et al.* (23), Morozov and Simonich (24), and Zvara and Tarasov (25). The results of Huber *et al.* (23) and Morozov and Simonich (24) for molten $KTaCl_6$, both studies having employed transportation techniques, are much lower than those of the present study. No mention was made of the problem of depletion of $TaCl_5$ from the condensed $KTaCl_6$ phase during the course of the experiment. Furthermore, the data of Morozov and Simonich (24), which span the temperature range from solid $KTaCl_6$ to molten $KTaCl_6$, have been represented by a single least-squares line (26).

In Fig. 2 the plot of the ln P_{NbCl_5} vs. $1/T$ for β-$KNbCl_6$ from the results obtained in the present work shows inflections at the eutectic temperature of the KCl–$KNbCl_6$ subsystem and at the melting point of $KNbCl_6$. The curvature of the dotted line joining these two temperatures results from the changing activity of KCl in the melt whose composition varies along the liquidus tie line as temperature is increased. Pressure curves of a similar shape have been recorded in this laboratory for P_{ZrCl_4} and P_{HfCl_4} in equilibrium with K_2ZrCl_6 and K_2HfCl_6, respectively (19).

Figure 3 shows equilibrium vapour pressure measurements for the decomposition of the molten $RbNbCl_6$ and $RbTaCl_6$ compounds. The former reportedly melts incongruently.

Attempts to measure the decomposition of solid $RbTaCl_6$ at temperatures below the melting point were unsuccessful. The equilibrium pressures were low, and despite elaborate degassing there was still enough inert gas present to confound the data.

Huber *et al.* (23) have measured decomposition vapour pressures for both these compounds in the molten state. Figure 3 shows their results for

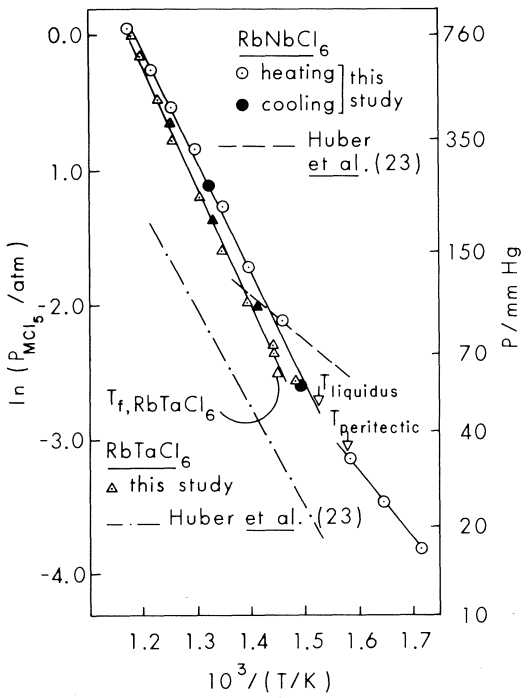

FIG. 3. ln P_{MCl_5} vs. $1/T$ plots for the systems $RbNbCl_6$ and $RbTaCl_6$. Solid lines represent best fit of present data.

$RbNbCl_6$ to be of the same order of magnitude as the results of this study. Their results for $RbTaCl_6$ are lower than in this study. Huber *et al.* (23) employed a transportation technique but did not discuss the effect of the depletion of the volatile pentachloride from the condensed phase during the course of an experiment.

Figure 4 shows the vapour pressures measured for the decomposition of $CsNbCl_6$ and $CsTaCl_6$. Both compounds melt congruently and the $CsMCl_6$–CsCl type phase diagrams indicate simple eutectic melting (23). Therefore, according to the thermodynamic analysis presented earlier, the partial pressure of the pentachloride should be represented on a plot of ln P_{MCl_5} vs. $1/T$ by two linear segments joined by a region of curvature.

These two compounds were extremely difficult to degas, particularly $CsNbCl_6$. This was true both for compounds prepared by precipitation from $SOCl_2$–ICl solutions and for those made by gas–solid reaction. Accordingly the reported vapour pressures over the solid compounds are approximate values and are presented here only for the sake of completeness. Many samples were prepared and studied. The results quoted below were selected as the best because they represent the lowest reproducible pressures measured.

Figure 4 also shows the results of Morozov and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

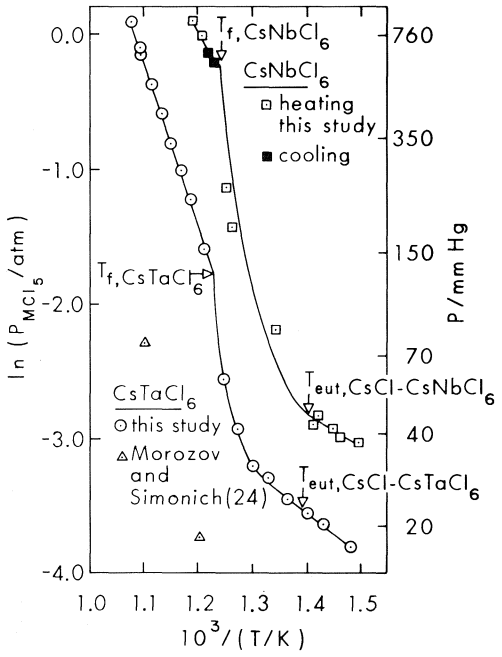

FIG. 4. ln P_{MCl_5} vs. $1/T$ plots for the systems $CsNbCl_6$ and $CsTaCl_6$. Solid lines represent best fit of present data.

Simonich (24) for $CsTaCl_6$. Their equilibrium pressures are lower in magnitude, but the slope of the ln P_{TaCl_5} vs. $1/T$ plot is similar to that recorded herein. Again a transportation technique was used and no explanation was given of effects of depleting $TaCl_5$ from the condensed phase during an experiment.

It appears that this study is the first to report decomposition vapour pressures for $CsNbCl_6$.

2. *Properties of the Solutions of $NbCl_5$–KCl and $TaCl_5$–KCl*

Figures 5 and 6 show the equilibrium vapour pressure measurements for the $NbCl_5$–KCl and $TaCl_5$–KCl systems, respectively. It should be noted that the corresponding phase diagrams show that the composition range of liquid solubility is very narrow. Although the liquid range widens at higher temperatures, the partial pressure of $NbCl_5$ or $TaCl_5$ above these solutions exceeds the upper limit of the pressure gauge used in this investigation. Accordingly, measurements herein were restricted to a narrow range of composition and temperature.

The results for the system $NbCl_5$–KCl shown in Fig. 5 span the concentration range, $0.401 < X_{NbCl_5} < 0.502$. The solution of composition, X_{NbCl_5}

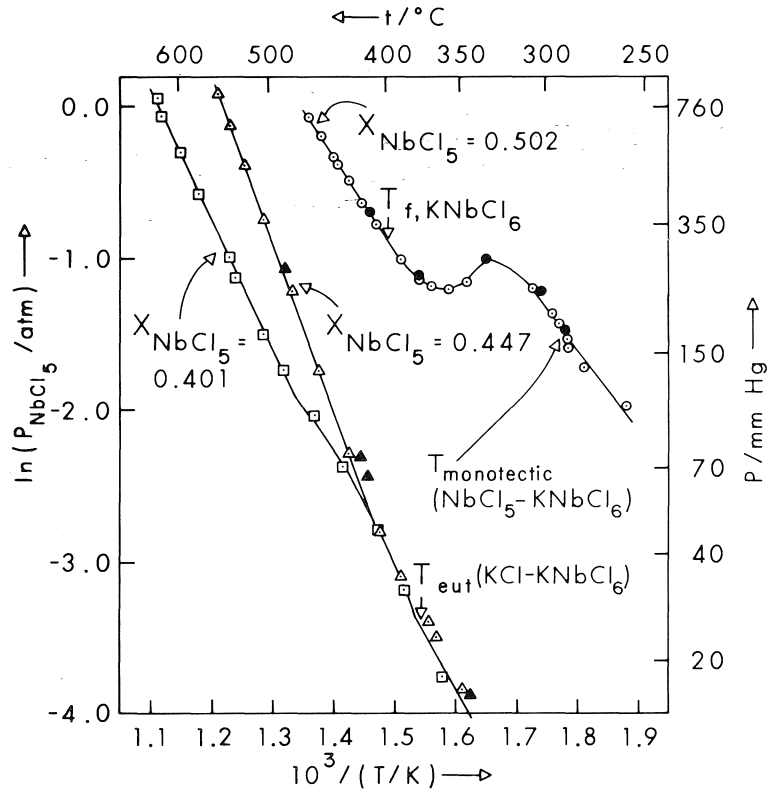

FIG. 5. ln P_{NbCl_5} vs. $1/T$ plots for the binary subsystem KCl–$KNbCl_6$. Solid lines represent best fit of present data. The pressure curve at $X_{NbCl_5} = 0.502$ represents solutions in the $NbCl_5$–$KNbCl_6$ subsystem.

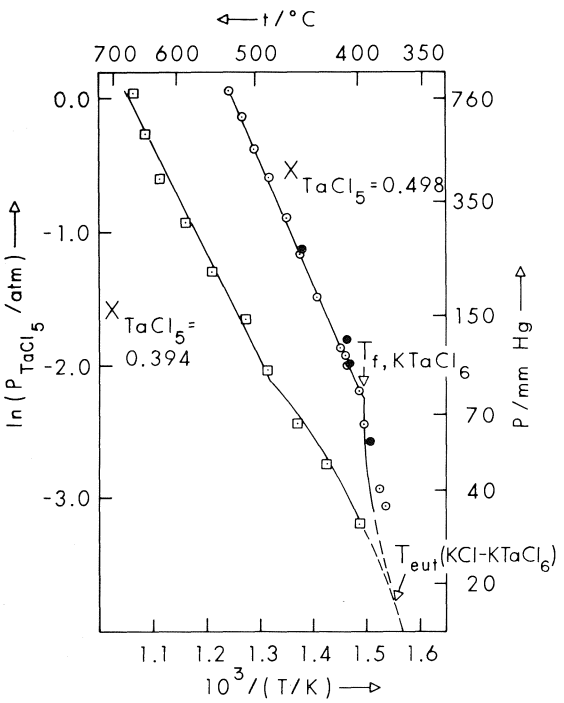

FIG. 6. ln P_{TaCl_5} vs. $1/T$ plots for the binary subsystem $KCl–KTaCl_6$. Solid lines represent best fit of present data.

= 0.502, is part of the $KNbCl_6$–$NbCl_5$ subsystem. As such, its pressure curve is expected to inflect at the monotectic temperature, 285°C (27), and at the liquidus temperature, which in this case is close to the melting point of $KNbCl_6$, which is about 400°C. The solutions of composition, $X_{NbCl_5} = 0.401$ and $X_{NbCl_5} = 0.447$ are part of the $KCl–KNbCl_6$ subsystem. Their pressure curves reveal a common segment at temperatures below the $KCl–KNbCl_6$ eutectic at 370°C (12, 27), as expected. Figure 5 shows a comparison of decomposition pressures between the KCl-rich solutions and the $NbCl_5$-rich solutions. Pressures recorded over the former are much lower and are evidence of the stabilizing effect of the formation of the complex compound $KNbCl_6$.

The results displayed in Fig. 6 are restricted to the $KCl–KTaCl_6$ subsystem. It is interesting to compare the shapes of the curves for the two solutions, as they are found on opposite sides of the $KCl–KTaCl_6$ eutectic composition. Both inflect at the $KCl–KTaCl_6$ eutectic temperature of 370°C (7, 12), and at the corresponding liquidus temperature, which for $X_{TaCl_5} = 0.498$ is almost identical with the melting point of $KTaCl_6$, 401°C (12).

Conclusions

The results of the present study indicate that the thermal stability of the complex compounds $ANbCl_6$ and $ATaCl_6$ is dependent upon the size of the alkali metal cation present.

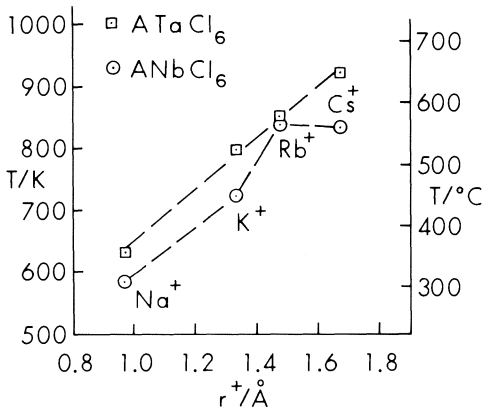

FIG. 7. Dependence of the decomposition temperature of the alkali hexachlorotantalate and hexachloroniobate compounds on the ionic-radii of the alkali metal cations.

Figure 7 shows the dependence of the dissociation temperature of the $AMCl_6$ compounds on the alkali-metal cation radius. The dissociation temperature is defined as the temperature at which the equilibrium pressure P_{MCl_5} becomes 1 atm and, therefore, can be taken as a measure of thermal stability of the $AMCl_6$ compound.

With the exception of $RbNbCl_6$, the results lie on two lines, one for the hexachloroniobates and one for the hexachlorotantalates. The latter have higher dissociation temperatures than their congeners, indicating the greater thermal stability of the hexachlorotantalate compound to the hexachloroniobate alkali-metal compounds. In general complexing for either $NbCl_5$ or $TaCl_5$ results in a dramatic reduction in the pressure of MCl_5 in equilibrium with a compound. For example, at 500°C pure $NbCl_5$ has a vapour pressure of 36 atm (8); in contrast, the partial pressure of $NbCl_5$ over $KNbCl_6$ is 1.43 atm and over $CsNbCl_6$ is 0.37 atm at that temperature.

Secondly, there is a reversal in stability. Pure $TaCl_5$ is more volatile than $NbCl_5$ (13). However, this changes upon formation of the $AMCl_6$ compounds. The partial pressure of $NbCl_5$ over the hexachloroniobate, $ANbCl_6$, is greater than that of $TaCl_5$ over the hexachlorotantalate of the same alkali metal. Nisel'son (28) has reported similar behaviour when $NbCl_5$ and $TaCl_5$ were complexed with $POCl_3$. In this laboratory the same reversal has been observed with $ZrCl_4$, $HfCl_4$, and the complex compounds which they form with the alkali-metal chlorides (14–19).

It is of interest to note that the relative volatility of the two pentachloride vapours is greater over the

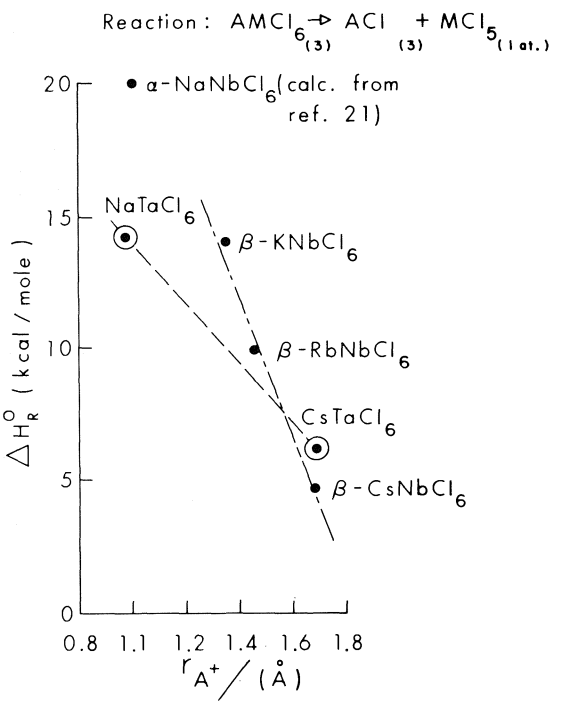

FIG. 8. Plot of ΔH_R^0 vs. the ionic-radii of the alkali metal cations.

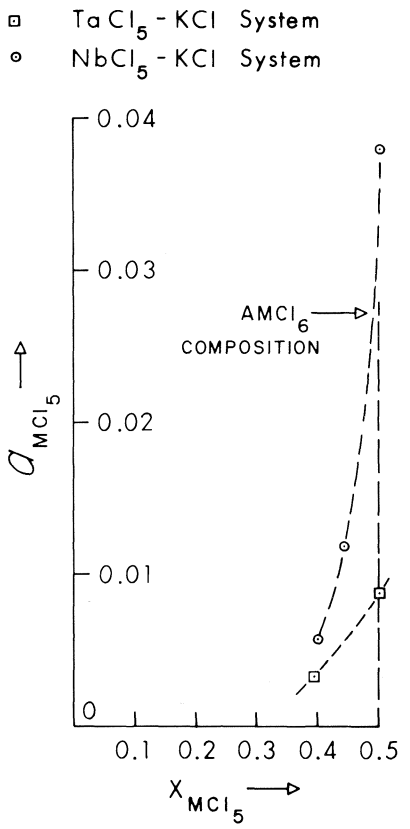

FIG. 9. Activity isotherms for a_{MCl_5} at 496°C for the molten KCl–$KNbCl_6$, and KCl–$KTaCl_6$ solutions.

complex compounds than over the pure pentachloride. At 230°C, $P^0_{TaCl_5}/P^0_{NbCl_5} = 1.42$ (13), while at 500°C over the corresponding potassium complexes, $P_{NbCl_5}/P_{TaCl_5} = 2.10$.

Interesting trends are also seen in the standard enthalpy changes for the decomposition reactions given in Table 1. The data shown in this table provide the temperature dependence of ln P_{MCl_5} and may be used for calculating standard enthalpies in temperature ranges in which the $AMCl_6$ type-compounds are present as single phase solids. The results of these calculations for ΔH_R^0 and ΔS_R^0 are also included in Table 1. A plot of ΔH_R° vs. the alkali metal cation radius, shown in Fig. 8, indicates that reaction enthalpies increase as the size of the alkali metal cation present in the complex compound decreases. The point for $NaTaCl_6$ was calculated from results on α-$NaTaCl_6$ obtained by Shemyakina *et al.* (21) and is expected to deviate from trends followed by the β-phase compounds.

Activity data for MCl_5 calculated from the results on the binary molten solutions of KCl–$KNbCl_6$ and KCl–$KTaCl_6$ indicate a further stabilization for MCl_5 in the presence of excess KCl. Figure 9 shows a plot of the concentration dependence of a_{MCl_5} in molten $NbCl_5$–KCl and $TaCl_5$–KCl solutions at 496°C, where $a_{MCl_5} = P_{MCl_5}/P^0_{MCl_5}$. Values for $P^0_{MCl_5}$ at 496°C were found in the literature: 34.8 atm for $NbCl_5$ (8) and 43.0 atm for $TaCl_5$ (29). As in the case of the pure $AMCl_5$ compounds, the molten hexachlorotantalate solutions are chemically more stable than the molten hexachloroniobates. Figure 9 also illustrates the significantly higher pentachloride activity in solutions whose pentachloride content exceeds the complex composition of 50 mol%.

Structural study of the cesium oxypentafluorouranate (VI) $CsUOF_5$

PHILIPPE JOUBERT, JEAN-MARC WEULERSSE, AND ROLAND BOUGON[1]

Centre d'Etudes Nucléaires de Saclay, Division de chimie, Département de Génie Isotopique, B.P. no 2, 91190 Gif/Yvette, France

AND

BERNARD GAUDREAU

Université de Limoges, Laboratoire de Chimie Minérale B, 123, rue Albert Thomas, 87060 Limoges cedex, France

Received March 17, 1978

PHILIPPE JOUBERT, JEAN-MARC WEULERSSE, ROLAND BOUGON, and BERNARD GAUDREAU. Can. J. Chem. **56**, 2546 (1978).

Powder samples of cesium oxypentafluorouranate(VI) were studied by both neutron diffraction and ^{19}F broad line nuclear magnetic resonance.

$CsUOF_5$ crystallises with the $R\bar{3}$ space group, with the parameters $a = 5.41 \pm 0.01$ Å; $\alpha = 95°34' \pm 5'$. The structure, which was found to be unchanged at temperatures as low as 4.2 K, was interpreted by a statistical occupation of six-fold equivalents sites, the occupation rate being 1/6 and 5/6 for oxygen and fluorine, respectively. The nmr study showed that the disorder corresponding to this structure was of dynamic type, and that the UOF_5^- ions were in isotropical rotation. The motion is observable at temperatures as low as 223 K with a characteristic time τ equal to 3×10^{-5} s at 266 K. On the other hand, it was also shown through this nmr study that the point symmetry of the UOF_5^- ion corresponds to the C_{4v} group, with the axial fluorine being more covalent than the equatorial ones. Consistency of the diffraction and nmr results is discussed.

PHILIPPE JOUBERT, JEAN-MARC WEULERSSE, ROLAND BOUGON et BERNARD GAUDREAU. Can. J. Chem. **56**, 2546 (1978).

L'oxypentafluorouranate(VI) de césium $CsUOF_5$ a été étudié sur poudre par diffraction neutronique et résonance magnétique nucléaire du ^{19}F en large bande.

$CsUOF_5$ cristallise dans le groupe spatial $R\bar{3}$ avec les paramètres $a = 5.41 \pm 0.01$ Å; $\alpha = 95°34' \pm 5'$. Il n'y a pas de changement de structure jusqu'à 4.2 K, et celle-ci s'interprète par une occupation statistique de sites à 6 équivalents avec un taux d'occupation respectivement égal à 1/6 et 5/6 pour l'oxygène et le fluor. L'étude rmn montre que le désordre correspondant à cette structure est de type dynamique et que les ions UOF_5^- sont en rotation isotrope. Le mouvement peut-être observé jusqu'à 223 K, avec un temps caractéristique τ de 3×10^{-5} s à 266 K. La rmn montre par ailleurs, que l'ion UOF_5^- possède une symétrie ponctuelle correspondant au groupe C_{4v}, avec un fluor axial plus covalent que les fluors équatoriaux. La cohérence des résultats structuraux obtenus par diffraction et par rmn est discutée.

Introduction

The synthesis and characterization of the oxypentafluorouranates(VI) of monovalent cations $MUOF_5$ (where M = NO, NH_4, K, Rb, Cs) have been described previously (1–3). According to these studies, among the alkaline metals studied only $CsUOF_5$ has been found to contain the UOF_5^- ion. The structure of this ion was further studied by neutron diffraction and ^{19}F nuclear magnetic resonance on a powdered sample. Data from these investigations are presently reported.

Experimental Part

Materials and apparatus were as previously described (3). The powder diffraction patterns were measured at 300 and 4.2 K using thermal neutrons ($\lambda = 1.140$ Å) from the reactor EL3 at Saclay. The ^{19}F nmr were recorded with the spectrometers Varian DP 60 at 11 MHz and Brücker at 76.1 MHz.

[1]To whom correspondence should be addressed.

Results and Discussion

Crystallography

A comparison of the powder X-ray diffraction patterns of $CsUOF_5$ and $CsUF_6$ shows their great similarity (2, 3). To complete the previous studies, and, since it has been found very challenging to obtain and keep single crystals of $CsUOF_5$, further structural investigations were directed towards neutron diffraction on a powdered sample.

The powder neutron diffraction patterns, the lines of which are listed in Table 1, were recorded at 300 and 4.2 K and the corresponding crystal data were found to be as follows

$CsUOF_5$ fw = 481.9

Rhombohedral, $a = 5.41(1)$, $\alpha = 95°34'(5)$, $V = 155.9$ Å^3, $\rho_0 = 5.1(5)$, $z = 1$, $\rho_c = 5.13$ (300 K, neutrons, $\lambda = 1.140$ Å),

$a = 5.33(1)$, $\alpha = 95°52'(5)$, $v = 148.9$ Å^3, $\rho_c = 5.37$ (4.2 K).

The unit cell is very close to that of $CsUF_6$, the space group of which has been found to be $R\bar{3}$ (4, 5). According to this type of structure (6) the only two available sites with one equivalent position (C_{3i}) are occupied by the atoms Cs and U, for $CsUOF_5$ the light atoms have to be placed on six equivalent positions (C_1) with the occupation numbers being 5/6 and 1/6 for F and O, respectively.

This arrangement can be accomplished with only one type of site, identical for F and O, or with two types of sites, one for the F atoms, the other for the O atoms. This last assumption was found to give a slightly better reliability factor $R = 0.06$, compared to $R = 0.10$ for the former.

Thermal motion factors were taken equal to 0.6 Å^2 for Cs and U, and 2.6 Å^2 for F and O. The refinement of the coordinates was made by the least-squares method using a program established[2] at Saclay. At 300 K, the atomic positions in the hexagonal unit cell are given in Table 2.

The uranium–fluorine and uranium–oxygen distances were calculated to be 2.10 ± 0.07 Å and 1.8 ± 0.3 Å, respectively. From these values it is clear that the difference between the oxygen and fluorine positions is hardly significant. From their similar scattering lengths, fluorine and oxygen atoms appear rather as a statistic average for neutron diffraction as well.

*Estimated standard deviation in parentheses.

According to these data the pseudo-octahedra of the light atoms are elongated along the three-fold axis with a disordered mutual orientation. The angle between the trigonal axis and a U—F bond is found to be 50°, compared to 54°44′ for the undistorted octahedron.

^{19}F Broad Line Nuclear Magnetic Resonance Spectroscopy

Studies of the ^{19}F nmr absorption line-shapes as a function of the temperature are known (7) to give information on solid motions as well as structural data.

The spectra of $CsUOF_5$ were recorded at both low and high field. At low field absorption linewidths are mainly due to the dipolar interaction, whereas at high field it is possible to differentiate non-equivalent atoms by their chemical shifts.

When recorded at low field (11 MHz) between 223 and 300 K the spectrum displayed a rapid change of the second moment M_2 and the half-line width of the absorption line (Fig. 1) which are both indicative of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

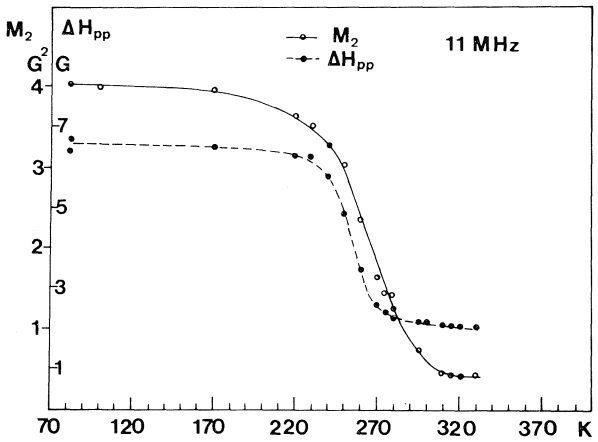

FIG. 1. Data from the ^{19}F nmr spectrum of $CsUOF_5$ at 11 MHz. Variation of the second moment (M_2) and peak-to-peak linewidth (ΔH_{pp}) with temperature.

motion. At high temperature, only an isotropic rotation of the UOF_5^- ion can account for the very low value found for M_2 (0.45 ± 0.1 G^2). From the crystallographic data and the assumption of such an isotropic rotation the value of M_2 was calculated to be 0.54 G^2, in good agreement with the experimental value.

At temperatures less than 223 K, the motion is too slow to narrow the line, the experimental value of M_2 is found to be equal to 4.0 ± 0.1 G^2, again close to the value of 3.8 G^2 calculated with the assumption of a disordered rigid lattice. The correlation time τ of the rotational motion was estimated from the graph M_2 (T) (8). At 266 K where the slope has the largest value, τ was found to be equal to 3×10^{-5} s, with a corresponding activation energy of 6 ± 0.5 kcal mol^{-1}. It is worth remarking that the actual value could be higher since an anisotropy of the UOF_5^- ion rotation or crystalline disorder can spread the correlation time, which in turn results in a broadening of the range of the M_2 variation. The presence of rotational motions confirms the disordered structure proposed above. At low temperature, the motion is dramatically slowed down, the UOF_5^- ions are frozen-like, probably without preferential orientation since no lowering in symmetry was observed by diffraction (down to 4.2 K for neutrons and 77 K for X-rays (3)).

At high field (76.1 MHz) and high temperature, only two lines of relative intensity 1/4 are observed at -405 and -285 ppm downfield from $CFCl_3$ (Fig. 2). This is in full agreement with the vibrational spectroscopy study (3) from which it was concluded that the UOF_5^- ion has the C_{4v} point group symmetry. On the other hand the force constant calculation has shown the axial fluorine atom (*trans* to the oxygen atom) to be less ionic in character than the

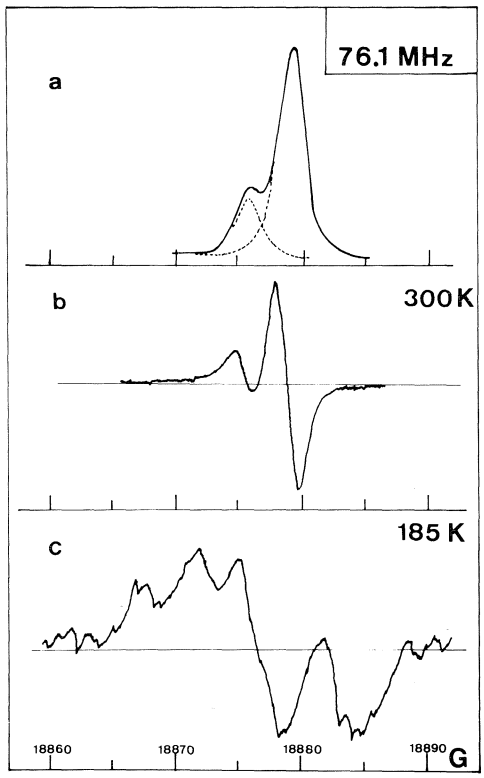

FIG. 2. ^{19}F nmr spectrum of $CsUOF_5$ at 76.1 MHz (ordinate-axis in arbitrary units). (*a*) Integral of the derivative curve recorded at 300 K; (*b*) derivative curve recorded at 300 K; and (*c*) derivative curve recorded at 185 K.

equatorial fluorine atoms. This last conclusion is in turn consistent with the nmr data, since the line of stronger intensity, consequently attributable to the equatorial fluorine atoms, was found to be located 120 ppm highfield from the other line. Such a correlation between ionic character and chemical shift is supported by previous measurements on uranium(VI) related compounds in the solid state, the mean chemical shift of which had been found to be: UF_6, -752 (9, 10); $NOUF_7$, -634; $CsUF_7$, -575; $(NO)_2UF_8$, -555; Cs_2UF_8, -500 (11) (in ppm from $CFCl_3$). Addition of F^- ions to UF_6 is expected to increase the U—F bond polarity and consequently to increase the ionic character of the fluorine atoms, which results in the trend observed for the chemical shifts. The small chemical shifts observed for UOF_5^-, as compared with that of the above-mentioned species, seem also to indicate an increase of the fluorine shielding, which in turn may arise from the substitution of fluorine by a less electronegative ligand. Such an effect has been previously reported (12) for tungsten derivatives.

At lower temperature (Fig. 2), on account of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

large values of the chemical shift anisotropies (up to 1000 ppm) and, perhaps from octahedral distortion as well, the spectrum was found to be very broad and complex with a second moment equal to 20 ± 1 G^2.

At this stage it is interesting to comment on the apparent discrepancy between the crystallographic data and those obtained by ^{19}F nmr and vibrational spectroscopy (3). The C_{4v} point group symmetry is clearly not rigorously compatible with the $R\bar{3}$ space group found by crystallography. Such a discrepancy has already been found (13) for some hexafluoroanions, which all have shown by nmr a tetragonal distortion of the octahedron whatever the local crystalline symmetry was. Superstructure and disorder which have been proposed (13) to account for the observations made for instance on K_2PtF_6, probably do not stand for $CsUOF_5$ since no superstructure evidence was found by neutron diffraction.

It is certainly more realistic to consider the trigonal distortion in UOF_5^- as being too small to be seen by nmr, especially at high temperature where slight differences in distances are blurred by the motions taking place in the solid. At low temperature, the large chemical shift anisotropies prevent further conclusion regarding the spatial arrangement of the light atoms.

Conclusion

The study of $CsUOF_5$ by both neutron diffraction and ^{19}F nmr allowed a structural model to be proposed for this compound. A disordered structure type is found by diffraction, and nmr has shown it to be of a dynamic type.

Acknowledgments

The authors are indebted to Dr. P. Charpin for helpful discussions and are grateful to Drs. J. Senegas and P. Meriel for their helpful assistance in obtaining nmr and neutron diffraction data in their laboratories.

For personal use only.

Introduction

Since all amalgams containing less than 60 wt.% indium are liquid at room temperature (1), it was possible to determine the emf of the cell

$$In/InCl_3\,(N)/In–Hg\ amalgam$$

over the concentration range 0–50 wt.% indium and over the temperature range 25–99°C. From these measurements ΔG, ΔS, and ΔH for the process

$$In + Hg \rightarrow amalgam$$

were obtained by the standard methods of thermodynamics.

Experimental

The emf measurements were made with a potentiometer reading to 0.000005 V. The effect of temperature, as well as concentration of indium in the amalgam, of the cell

$$In/InCl_3\,(N)/In–Hg$$

was investigated. The temperature range was 25–99°C and the concentration range 10 to 50 wt.% indium. At concentrations greater than 60 wt.% In, the amalgam is partially solid at room temperature. Between 30 and 40 wt.% In, the emf of the above cell changes only, at 25°C, by 0.0003555 V per 1% by weight of indium.

Results and Discussion

Table 1 gives the emf, temperature coefficient of emf, activity of indium in the amalgam, and the activity coefficient (in terms of atomic fraction) for each concentration of indium. The methods of calculating ΔG, ΔH, and $T\Delta S$ are well known but the reader should perhaps be reminded that the activity of a metal in an amalgam (the other pole of the combination being pure metal) is connected with the emf by the equation:

$$E = (RT/nF) \ln 1/a$$

An inspection of Table 1 shows that E, and there-

fore ΔG, decreases with increasing indium content, presumably becoming zero at about 60 wt.% indium, as it should if the solid phase is pure indium. ΔH and ΔS also decrease but not necessarily to zero.

The temperature coefficients of emf are of the order of 10^{-5} V/deg. The activity coefficient is at first low, about 0.1, but increases with increasing indium content, becoming greater than unity for the highest concentration of indium in the amalgam. It should be pointed out, however, that the activity coefficient has been calculated on the basis of the relation:

$$\gamma = a/\text{atom fraction}$$

Instead of the atom fraction the molality, or the molarity (if the densities of the amalgams were known) could be used. All three definitions seem rather artificial, however, and it is perhaps best to confine the interest to the activity.

Production of Ni(I) complexes from reactions between Ni(II) and $NaBH_4$ in the presence of triphenylphosphine and some bidentate phosphines

DAVID G. HOLAH, ALAN N. HUGHES, BENJAMIN C. HUI, AND CHI-TAT KAN
Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received January 31, 1978

DAVID G. HOLAH, ALAN N. HUGHES, BENJAMIN C. HUI, and CHI-TAT KAN. Can. J. Chem. **56**, 2552 (1978).

The reactions between a variety of Ni(II) compounds and $NaBH_4$ have been studied in the presence of triphenylphosphine (P) and the bidentate phosphines 1,2-bis(diphenylphosphino)-ethane (diphos), bis(diphenylphosphino)methane (dppm), and *cis*-1,2-bis(diphenylphosphino)-ethylene (vpp). In ethanol, $NiCl_2 \cdot 6H_2O$, P, and $NaBH_4$ give $[Ni(BH_4)P_3]_2$ while NiX_2P_2 X = Cl, Br, I) and $NaBH_4$ produce $Ni(BH_4)P_{1.5}$. Further reactions of the former complex leading to $[Ni_2P_6](PF_6)_2$ and $[NiP_4](PF_6)$ have been studied. Reactions of $Ni(ClO_4)_2 \cdot 6H_2O$, P, and $NaBH_4$ produce $Ni(ClO_4)P_3$ and $[NiP_4](ClO_4)$. The bidentate phosphines, $Ni(ClO_4)_2 \cdot 6H_2O$ and $NaBH_4$ in ethanol all lead to quite different products. For example, with diphos, Ni(II) is stabilized and $[HNi(diphos)_2](ClO_4)$ is formed, but with the other two bidentate phosphines, reduction occurs. With dppm, $[Ni_2(dppm)_4](ClO_4)_2$ is produced, while vpp produces $[Ni(vpp)_2](ClO_4)$. Physical properties, possible structures, and suggested mechanisms of reduction are discussed.

DAVID G. HOLAH, ALAN N. HUGHES, BENJAMIN C. HUI et CHI-TAT KAN. Can. J. Chem. **56**, 2552 (1978).

On a étudié les réactions d'un certain nombre de composés du Ni(II) avec du $NaBH_4$ en présence de triphénylphosphine (P) et des phosphines bidendates, bis(diphénylphosphino-1,2) éthane (diphos), bis(diphénylphosphino) méthane (dppm) et du *cis* bis(diphénylphosphino-1,2) éthylène (vpp). Dans l'éthanol, le $NiCl_2 \cdot 6H_2O$, en présence de P et de $NaBH_4$, conduit au $[Ni(BH_4)P_3]_2$ alors que le NiX_2P_2 (X = Cl, Br, I) et le $NaBH_4$ conduisent au $Ni(BH_4)P_{1.5}$. On a aussi étudié d'autres réactions du premier complexe qui fournissent du $[Ni_2P_6](PF_6)_2$ et dû $[NiP_4](PF_6)$. Les réactions du $Ni(ClO_4)_2 \cdot 6H_2O$ avec la P et le $NaBH_4$ conduisent au $Ni(ClO_4)P_3$ et au $[NiP_4](ClO_4)$. Les phosphines bidentates, en présence de $Ni(ClO_4)_2 \cdot 6H_2O$ et de $NaBH_4$ dans l'éthanol, conduisent à des produits tout à fait différents. Par exemple, avec le diphos, le Ni(II) est stabilisé et il y a formation de $[HNi(diphos)_2](ClO_4)$ mais avec les deux autres phosphines bidentates, il se produit une réduction. Avec le dppm, il y a formation de $[Ni_2(dppm)_4](ClO_4)_2$ alors qu'avec le vpp, il se produit du $[Ni(vpp)_2](ClO_4)$. On discute des propriétés physiques, des structures possibles et des mécanismes suggérés pour la réduction.

Introduction

A convenient route to the preparation of Ni(I) complexes (refs. 1 to 3 and references therein) involves $NaBH_4$ reductions of Ni(II) (4–6). By this method, compounds such as NiL_2X (L = 1,10-phenanthroline, 2,2′-bipyridyl, X = BH_4, PF_6, or BPh_4 (6)) and $[Ni(BH_4)P_3]_2$ (P = triphenylphosphine) (5) have been synthesized. The latter was prepared by the reaction sequence

$$NiCl_2/P/NaBH_4 \rightarrow NiClP_3 \rightarrow [Ni(BH_4)P_3]_2$$

and isolated as a pyrophoric solid which, from its diamagnetism and infrared spectrum, is thought to be a Ni—Ni bonded dimer with bridging BH_4 groups (5). In fact "most known Ni(I) complexes and all isolated Pd(I) and Pt(I) complexes are binuclear in nature, giving diamagnetic metal–metal bonded or ligand-bridged bimetallic species" (3). It has recently been shown (7) that the products formed from $CoCl_2/P/NaBH_4$ reactions which include $Co(BH_4)P_x$ (x = 2 or 3), H_3CoP_3, $HCo(N_2)P_3$, Co(0)—P complexes and P—BH_3, depend essentially on three factors, i.e., the *rate* of addition of $NaBH_4$, the solvent, and the presence or absence of free ligand. In view of the complexity of these Co(II) reactions, the analogous Ni(II) system has been more extensively investigated. This paper reports not only the results of this study of Ni(II) reductions in which a variety of different phosphines have been used, but also some reactions of the interesting complex $[Ni(BH_4)P_3]_2$.

Results and Discussion

$NiCl_2/P/NaBH_4$ Reactions

We have studied the $NiCl_2/P/NaBH_4$ reaction under a wider range of conditions than previously reported (5) and find that, like the analogous reactions involving Co(II) chloride (7), the course of

‡Reference 9.

the above Ni reactions under N_2 depends upon the solvent and on the presence or absence of added ligand. Unlike the cobalt reactions, the results obtained from the Ni system are independent of both time and the rate of addition of $NaBH_4$ and are dependent upon the starting material ($NiCl_2$ behaves differently from $NiCl_2P_2$, see later). Thus, all reactions between $NiCl_2$ and P (minimum molar ratio 1:6) and an excess of $NaBH_4$ in ethanol in the strict absence of oxygen yield $[Ni(BH_4)P_3]_2$ (5) (cf. $CoCl_2$, P, and $NaBH_4$ which give a complex mixture under similar conditions (7)). If all traces of oxygen are not excluded, a mixture of the phosphine oxide, the borane adduct $P{\cdot}BH_3$ and Ni(0)—P complexes are obtained. When less P is used in the above reactions, e.g. Ni:P = 1:2, reduction to Ni(0) is rapid and complete and no intermediate BH_4^- complex could be detected.

All efforts to recrystallize $[Ni(BH_4)P_3]_2$ from organic solvents (benzene, THF, acetonitrile, nitromethane) resulted in decomposition to give $P{\cdot}BH_3$ and Ni(0)—P complexes. It is interesting to note that, while $CoCl_2/P/NaBH_4$ reactions in benzene produce $Co(BH_4)P_2$ (7), the $NiCl_2$–benzene reactions lead only to the above mentioned decomposition products $P{\cdot}BH_3$ and Ni(0)—P complexes. It has not been possible to convert $[Ni(BH_4)P_3]_2$ into any other Ni—BH_4 complex as was the case with Co, i.e. $Co(BH_4)P_3 \rightarrow Co(BH_4)P_2$ (7).

In ethanol, $[Ni(BH_4)P_3]_2$ slowly reacts (2 days) with an excess of $NaPF_6$ to liberate gases and produce, together with unidentified Ni-containing products, a complex of empirical formula NiP_3PF_6 which can be recrystallized from THF (Table 1). The larger the excess of $NaPF_6$ (up to 10 *M*), the higher the yield of product. The fact that a similar reaction with $NaBPh_4$ does not occur tends to rule out a simple substitution of PF_6^- for BH_4^- and the difference in behaviour between $NaPF_6$ and $NaBPh_4$ may be due to the slow hydrolysis of the former to generate HF (8) which would decompose the BH_4^- group.

Like the BH_4^- complex, NiP_3PF_6 is diamagnetic and is probably, therefore, dimeric with a Ni—Ni

bond. This is supported by electrical conductivity data (Table 2) in nitromethane solution which confirm that the complex should unequivocally be formulated as a 1:2 electrolyte (9), i.e. $[Ni_2P_6](PF_6)_2$. For comparison, Table 2 also contains data, in nitromethane, on 1:1 and 1:2 electrolytes. The ir spectrum of $[Ni_2P_6](PF_6)_2$ shows the ν_{P-F} vibration at 840 cm^{-1} and there are no bands in its electronic spectrum below 28 000 cm^{-1} (Table 3).

When $[Ni_2P_6](PF_6)_2$ is recrystallized from THF in the presence of an excess of P, the Ni—Ni bond is cleaved and a yellow crystalline solid $[NiP_4](PF_6)$ is formed. This is a paramagnetic, 1:1 electrolyte and its electronic spectrum shows a band with a shoulder in the 6000–7000 cm^{-1} ($\varepsilon \sim 100$) region (Table 3, Fig. 1), consistent with the $^2T_2 \rightarrow {}^2E$ transition of a tetrahedral d^9 configuration. Very recently, the closely related complex $Ni(P(CH_3)_3)_4(BPh_4)$ was accidentally prepared (10) during recrystallization of $[Ni(CH_3)(P(CH_3)_3)_4](BPh_4)$ and this contains (from X-ray data) a distorted tetrahedral Ni(I) ion with electronic properties very similar to those reported above.

It is possible to draw some conclusions about the mechanism of the $NiCl_2/P/NaBH_4$ reactions, the initial product of which is invariably $NiClP_3$ (5). This must clearly be the precursor to the BH_4^- complex. While $NiClP_3$ dissociates in benzene to $NiClP_2$

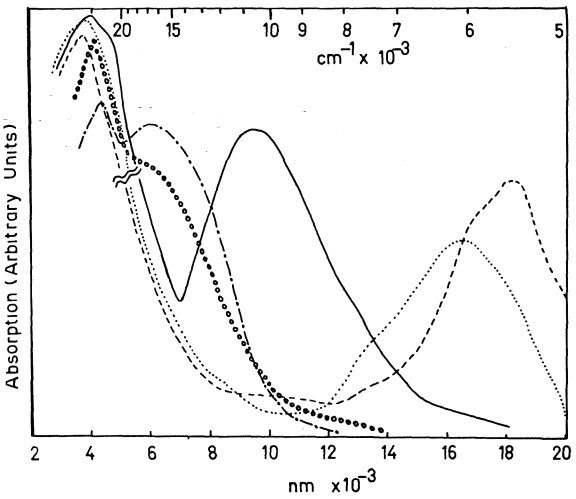

FIG. 1. Reflectance spectra: --- $Ni(ClO_4)P_3$, ··· $[NiP_4](PF_6)$, —$[Ni(vpp)_2](ClO_4)$, -·-·- $Ni(BH_4)P_{1.5}$, ○○○ $[Ni_2(dppm)_4](ClO_4)_2$.

(which has been isolated (2)), it is unlikely that this would occur in ethanol (in which it is less soluble) in the presence of an excess of P. Thus, displacement of Cl^- (and ClO_4^-, see later) by BH_4^- probably results in the initial formation of $P_3Ni—H—BH_3$ followed by rapid dimerization. While all of the complexes listed in the following scheme have not been isolated

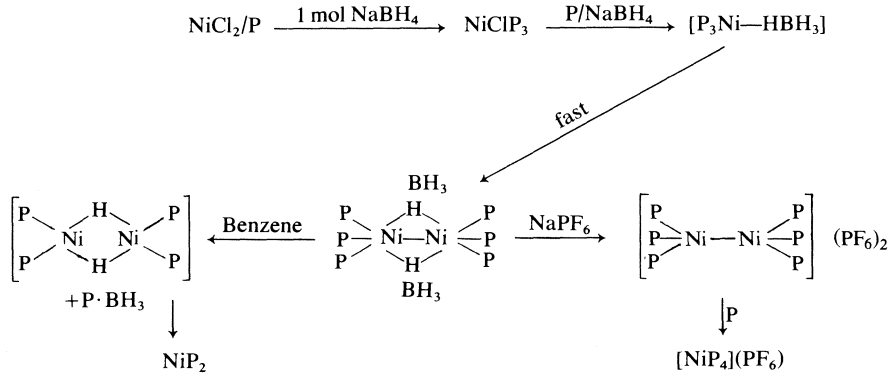
their probable existence as intermediates is reasonable and compatible with the formation of the complexes that have been obtained. The proposed H-bridged dimer is analogous to the known $[HNi(R_2P(CH_2)_2PR_2)]_2$ (R = C_6H_{11}) species (11).



$NiX_2P_2/NaBH_4$ Reactions (X = Cl, Br, I)

As mentioned above, a major difference between Co(II) and Ni(II)/P/$NaBH_4$ reactions is the effect of the nature of the starting material. In the Co reactions, mixtures of $CoCl_2$ and P rapidly produce the $CoCl_2P_2$ complex prior to the addition of the $NaBH_4$, whereas mixtures of $NiCl_2$ and P in ethanol require heating before the formation of $NiCl_2P_2$ occurs. The latter is therefore not present in any significant amount in $NiCl_2/P/NaBH_4$ mixtures at room temperature, and when NiX_2P_2 (X = Cl, Br, I) are used as starting materials, the reactions follow a quite different course.

Related reactions have been studied (12) previously in connection with the preparation of unspecified Ni-catalysts. For example, the reaction sequence

$$NiBr_2(PBu_3^n)_2 \xrightarrow{NaBH_4} HNiBr(PBu_3^n)_2 \longrightarrow Ni(PBu_3^n)_2 + HBr$$

was suggested as preceding further reactions of the Ni(0) complex to form the catalyst (12). It was noted that mixtures of $NiBr_2(PBu_3^n)_2$ and $NaBH_4$ in ethanol under N_2 produce yellow or brown solutions depending upon the amount of $NaBH_4$ added. Similarly, brown solutions from reactions between $NiBr_2P_2$ and $NaBH_4$ under N_2 in THF/ethanol or benzene/ethanol have been studied as catalytic systems (13).

We find that the products from reactions between NiX_2P_2 (X = Cl, Br, I, preferably the last because of its greater reactivity) and $NaBH_4$ in ethanol are critically dependent upon experimental conditions. The major product is a brown, ether-soluble solid which appears to be NiP_2 (12), but under certain conditions a highly crystalline pyrophoric solid with the empirical formula $Ni(BH_4)P_{1.5}$ can be isolated. The addition of free P to this reaction and/or prolonging the reaction time leads only to the coproduction of $P{\cdot}BH_3$ and, as the amount of P is increased, so the borane adduct becomes the major product. Reactions in benzene/ethanol mixtures lead to the production of $P{\cdot}BH_3$ and unidentified Ni complexes. The complex formulated as $Ni(BH_4)P_{1.5}$ can be recrystallized unchanged from cold benzene or THF but decomposes to $P{\cdot}BH_3$ and unidentified Ni complexes in acetonitrile and nitromethane.

The complex is a diamagnetic non-electrolyte in THF solution. There is no evidence in the ^1H nmr spectrum (10–40 τ) in either benzene or THF solution, or in the ir spectrum, for a Ni—H linkage. Regarding the bonding of BH_4, the ir spectrum is consistent with bidentate coordination (14), with bands at 2440 cm^{-1} (ν_{B-H_t}), 1970 cm^{-1} (ν_{B-H_b}), and 1380 cm^{-1} ($\nu_{bridge\ stretch}$) although the expected BH_2 deformation at 1100–1200 cm^{-1} is not identifiable due to ligand vibrations in this region. On deuteration, the ν_{B-D_t} vibration shifts to 1840 cm^{-1} giving ν_D/ν_H as 0.754, similar to values observed previously (7). The main feature of the electronic spectrum of the complex (Table 3, Fig. 1) is a band at 16 400 cm^{-1} with, in THF solution, $\varepsilon \sim 900$, the origin of which is unknown, although it does resemble the spectrum of $Ni(dppm)_2(ClO_4)$ (see later). No meaningful data were obtained from a mass spectrum, which indicated decomposition even under the mild conditions used for recording the spectrum.

There is little we can say about the structure of this peculiar complex. The empirical formula suggests that the complex contains Ni(I) and that, in view of the diamagnetism, it must be at least dimeric. The BH_4 groups may be chelating to one metal or bridging two metals. We are currently attempting to grow crystals suitable for a structure determination.

The BH_4^- groups are not replaced by PF_6^-, as occurs with $[Ni(BH_4)P_3]_2$ and, as mentioned above, the complex does not react with added P. No reaction has been observed to lead to mixtures of $[Ni(BH_4)P_3]_2$ and $Ni(BH_4)P_{1.5}$ nor have conditions been found which allow the interconversion between the two; therefore the mechanisms for their formation are probably quite different with no common intermediate.

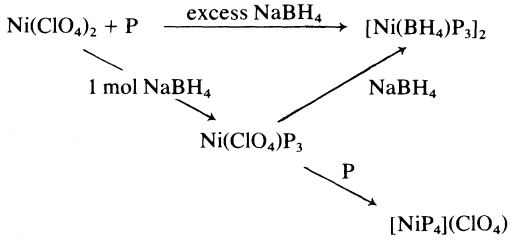
$Ni(ClO_4)_2$/Monodentate Phosphine/$NaBH_4$ Reactions

The reaction between $Ni(ClO_4)_2$, P, and an excess of $NaBH_4$ in ethanol yields $[Ni(BH_4)P_3]_2$ unlike the similar Co reaction which produces $Co(BH_4)P_2$ (7). With much less $NaBH_4$, a mixture of $[Ni(BH_4)P_3]_2$ and $Ni(ClO_4)P_3$ is obtained, the latter being purified by recrystallization from THF/ether. Magnetic and spectral data for $Ni(ClO_4)P_3$ (solution and solid state) (Table 3, Fig. 1) are consistent with a tetrahedrally coordinated Ni(I) system, with the $^2T_2 \rightarrow {}^2E$ transition shifted to lower energy compared to its position for $[NiP_4]^+$, consistent with the fact that a weaker ligand field exists in the former complex. The interaction between the Ni and the ClO_4 group must be very weak since the ir spectrum shows bands at 625 and 1090 cm^{-1} which are the ν_4 and ν_3 bands of an essentially ionic perchlorate (15). Additional evidence for a weak Ni—ClO_4 link comes from the solution properties of the complex. The spectrum in acetone is, as mentioned above, typical of a tetrahedral d^9 configuration but the electrical conductivity is only slightly less than that expected for a 1:1 electrolyte (Table 3) and therefore dissociation of the type

$$Ni(ClO_4)P_3 \underset{}{\overset{\text{solvent}}{\rightleftharpoons}} NiP_3(Acetone)^+ + ClO_4^-$$

probably occurs. In addition, acetone solutions of $Ni(ClO_4)P_3$ react readily with P to produce $[NiP_4](ClO_4)$ with electronic properties (Table 3) very similar to the PF_6^- complex already discussed.

These reactions again serve to illustrate the stepwise mechanism for the formation of BH_4^- complexes, and it is clear that $Ni(ClO_4)P_3$ serves as a precursor in a totally analogous way to $NiClP_3$ as already discussed and as summarized below (reactions in ethanol):

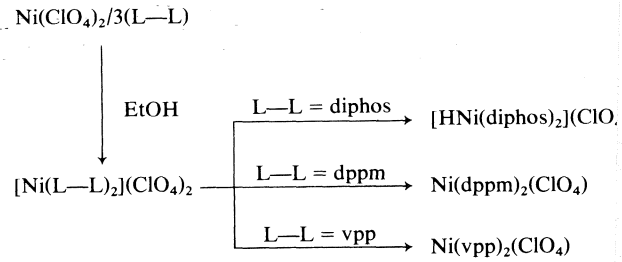


As in the $NiCl_2/P/NaBH_4$ reactions, the solvent plays an important role in determining the reaction products and, for example, mixtures of $Ni(ClO_4)_2$ and P in ethanol/benzene (1:2) react with 1 mol of $NaBH_4$ in ethanol to precipitate immediately orange-red crystals of NiP_3 (16).

As expected, the poorer π-acceptor ligands Ph_3As and Ph_3Sb cannot stabilize Ni(I) and mixtures of $Ni(ClO_4)_2$ and these ligands are immediately reduced to NiL_3 species by 1 mol of $NaBH_4$ in ethanol. Similar results have been observed previously (5, 17).

$Ni(ClO_4)_2$/Bidentate Phosphine/$NaBH_4$ Reactions

We have previously noted (6) that neutral square-planar Ni(II) complexes (e.g. of *N,N*-diethyldithiocarbamate and dimethylglyoxime) are unreactive towards $NaBH_4$ due, presumably, to the stability of the complexes and the reluctance of BH_4^- to interact with the vacant axial coordination sites on the metal. However, cationic square planar Ni(II) species $[Ni(L—L)_2]^{2+}$ (as ClO_4^- salts) should be more vulnerable to BH_4^- attack and, in this connection, three different bidentate phosphines have been studied, namely 1,2-bis(diphenylphosphino)ethane (diphos), bis(diphenylphosphino)methane (dppm), and *cis*-1,2-bis(diphenylphosphino)ethylene (vpp). Results of reactions, in ethanol, between the appropriate starting material, $[Ni(L—L)_2](ClO_4)_2$, prepared *in situ*, and $NaBH_4$ (Ni:$NaBH_4$ = 1:1) are outlined below.



Thus, the red crystalline $[HNi(diphos)_2](ClO_4)$ ($\nu_{Ni—H}$ 1950 cm^{-1}, τ = 23.5 in DMSO-d^6 at 40°C due to Ni—H) is obtained when L—L = diphos. This diamagnetic 5-coordinated Ni(II) cation has previously been reported with a variety of anions (18), generally prepared (e.g. with $AlCl_4^-$, HCl_2^-, BF_4^-) by the protonation of $Ni(diphos)_2$ by strong acids, although the route involving $NaBH_4$ is somewhat simpler and easier.

When L—L is dppm, $NaBH_4$ addition results in the production of the diamagnetic solid $Ni(dppm)_2(ClO_4)$, the dark green color of which is not inconsistent with the presence of a reduced Ni species (cf., $NiX_2P_2/NaBH_4$), particularly in view of the fact that the Ni(II) hydride mentioned above is red. No

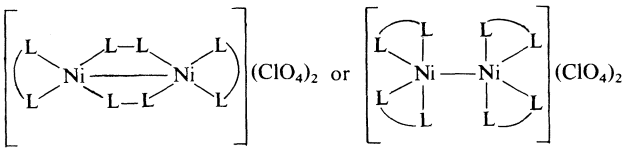
For personal use only.

evidence (nmr 10–35 τ, ir) of a Ni—H link could be found, and peaks at 620 and 1100 cm^{-1} (broad) show the presence of ionic perchlorate. The complex is therefore probably dimeric, with a structure corresponding to one of the types shown below:



(A) (B)

Conductivity data for this and related complexes are shown in Table 2 from which it can be concluded that the dppm complex is indeed a 1:2 electrolyte. The solid state and solution spectra (Table 3, Fig. 1) are quite similar to those of $Ni(BH_4)P_{1.5}$. Recrystallization from a polar solvent such as CH_3CN in the presence of free dppm or of P results in recovery of starting material, unlike $[Ni_2P_6](PF_6)_2$ which produces $[NiP_4](PF_6)$ as already discussed, and this tends to support the structure with bridging ligands rather than a single Ni—Ni bond as suggested for the PF_6 dimer. However, it should be borne in mind that the Ni—Ni cleavage with P observed for $[Ni_2P_6](PF_6)_2$ occurs with a four-coordinate Ni system whereas in A and B above, the Ni is five-coordinate. In fact, structure A is closely related to the Pt(I) complex $[PtCl(dppm)]_2$ which has bridging phosphine ligands (20).

In theory, it might be possible to distinguish between the above two structural possibilities A and B by ^1H nmr spectral measurements since in A, the methylene protons of the bridging ligands might have a different chemical shift from that of the methylene protons in the chelating ligands. In B, one would expect all of the methylene groups to be magnetically identical.

Examination of the ^1H nmr spectrum of the complex in deuterated acetone at 40°C indeed shows two methylene proton resonances as very broad and poorly defined signals centered on τ 6.96 and τ 7.29 overlapping to some extent at the bases of the signals. However, the two signals are not of equal area and the ratio of the area of the high-field signal to that of the low field signal is 1.3:1. Therefore the spectrum is, apparently, not compatible with either structure.

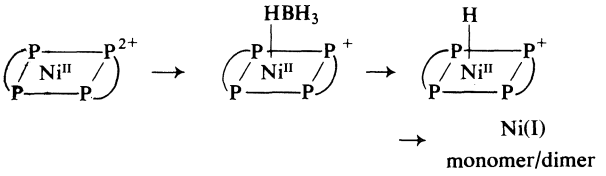
However, the broadness of the signals and the unusual ratio is suggestive of a temperature-dependent equilibrium between two structures and variable temperature ^1H nmr measurements confirm this. Thus, on cooling the solution of the complex to 0°C, the spectrum modifies such that the lower field signal becomes of much greater area and also becomes considerably sharper while the higher field signal is very greatly reduced in area. This indicates that at 0°C, one species greatly predominates. On the other hand, at 50°C the higher field peak becomes much sharper and of greater area while the lower field peak diminishes. This suggests that at 50°C, the other species predominates.

The spectral changes are reversible on cooling the solution again and the changes in general are consistent with an equilibrium between two structures. However, the broadness of the signals at 40°C suggests that the kind of equilibrium involved is an exchange equilibrium where, at 0°C, essentially all of the ligands are fully coordinated and bidentate (which would give the greatest shift to lower field to the methylene protons) while at 50°C, the exchange is very rapid and the methylene protons are magnetically averaged and more like those in the free ligand. In fact the location of the higher field signal (τ 7.29) is very close to that of the methylene protons of the free ligand (τ 7.21).

It seems then that the ^1H nmr spectrum does not allow us to distinguish between the two possible structures since ligand dissociations in either structure could explain the spectra although the spectrum at 0°C, which shows only one significant methylene absorption (albeit a broad one), might marginally favour structure B.

Finally, when L—L is vpp, the product is the paramagnetic (μ_{eff} = 1.94 BM) complex $[Ni(vpp)_2](ClO_4)$. This is a 1:1 electrolyte (Table 2), has bands in the ir spectrum at 625 and 1100(b) cm^{-1} associated with an ionic ClO_4^- group, and has an electronic spectrum (Table 3, Fig. 1) in which the *d–d* band is shifted by almost 4000 cm^{-1} to higher energy than occurs in the tetrahedral $[NiP_4]^+$ species. This is no doubt due, in part, to a stronger ligand field exerted by the chelating ligand compared with that of triphenylphosphine, but may also reflect considerable distortion from tetrahedral towards a square planar geometry about the nickel.

In these reactions, the probable sequence is:



but it is not understood why reactions involving diphos stop at the Ni(II)—H stage while the other two phosphines allow reduction but produce quite different products. Molecular models reveal that all three ligands can adopt configurations where the

P—P 'bite' distances are very similar (although vpp is somewhat different in that it is a very rigid molecule), and therefore the differences are unlikely to be steric in origin. The rigid vpp is also different in that it has an ethylenic π-system which could interact with metal *d*-electrons although whether this plays a unique role is doubtful since both it and dppm allow reduction of the Ni(II).

Experimental

Materials

All chemicals were reagent grade and, with the exception of P which was recrystallized from ethanol, were used without purification. NiX_2P_2 (X = Cl, I) were prepared by literature methods (21). Solvents were distilled, degassed, and stored under N_2 over 4A molecular sieves.

Analyses and Physical Measurements

Samples were suitably protected from atmospheric oxidation during weighing or data collection.

Chemical analyses for C and H were performed on a Perkin-Elmer model 240 analyser and, for $Ni(BH_4)P_{1.5}$, additional C, H together with P and Ni analyses were determined by Dr. F. Pascher, Bonn, W. Germany. Ni was analysed volumetrically by edta after degradation of the complexes by conc. HNO_3.

Infrared studies were carried out on a Beckman IR12 spectrophotometer (calibrated with a polystyrene reference film) using Nujol mulls between NaCl (650–4000 cm^{-1}) or polyethylene plates (200–650 cm^{-1}). Electronic spectra were recorded on a Cary 14 recording spectrophotometer and nmr spectra were obtained using a Varian Associates Model A60-A spectrometer. Magnetic moments were measured in the solid state by the Gouy method and in solution by the nmr method (22). Molar conductivities were measured on a YSI model 31 conductivity bridge at 25°C. Mass spectra were recorded on a Hitachi-Perkin Elmer RMU-7 double focussing mass spectrometer and, for X-ray powder diffraction measurements, samples in Lindeman capillaries were photographed on a Debye–Scherrer type camera using Ni-filtered copper K_α radiation from a Phillips PW1130 X-ray Generator.

Syntheses

All syntheses were carried out under pure N_2 in a glove box.

$[Ni(BH_4)P_3]_2$

This complex is best prepared by a slight modification to the method already described (5). A suspension of $NaBH_4$ (0.2 g, 5.3 mmol) in ethanol (10 ml) was added dropwise to a stirred suspension of $NiCl_2 \cdot 6H_2O$ (0.1 g, 0.4 mmol) and P (0.6 g, 2.2 mmol) in ethanol (25 ml). A gas, presumably H_2, was generated rapidly during the initial stages of addition of the $NaBH_4$ suspension and the color of the mixture changed from green to orange and slowly to reddish brown. The mixture was stirred for 3 h when the yellow brown precipitate was filtered off, washed in sequence with EtOH, H_2O, EtOH, and ether, and dried under reduced pressure for 3 h.

d-*Spacings from X-ray Powder Pattern (Relative Intensities 0–10)*

9.63 (7), 8.92 (10), 7.48 (2), 6.30 (2), 5.42 (2), 4.45 (4), 4.34 (4), 4.04 (2), 3.88 (5), 3.44 (2).

$[Ni_2P_6](PF_6)_2$

A mixture of $[Ni(BH_4)P_3]_2$ (1.5 g, 0.87 mmol) and $NaPF_6$ (2.1 g, 12.5 mmol) was stirred in ethanol (25 ml) for 2 days after which the resulting solid was filtered off and washed with ethanol, water, ethanol, and ether. The crude solid was dissolved in THF, filtered, and the filtrate concentrated to small volume. Addition of ether precipitated the yellow product in ~30% yield. It was again recrystallized from acetone/ether.

$[NiP_4](PF_6)$

$[Ni_2P_6](PF_6)_2$ in the pure state or before recrystallization was dissolved in THF and a six-fold molar excess of P added. The solution was filtered if necessary and the filtrate concentrated to small volume before the addition of ether precipitated the yellow product in ~70% yield.

$Ni(BH_4)P_{1.5}$

A suspension of $NaBH_4$ (0.32 g, 8.41 mmol) in ethanol (7 ml) was added dropwise over a period of 10 min to a stirred suspension of NiI_2P_2 (2.38 g, 3.38 mmol) in ethanol (15 ml). The mixture was stirred for an additional 5 min before the resulting brown solid was filtered off and washed with ethanol, water, ethanol, and finally with ether until the ether washings were colorless. This indicated complete removal of the Ni(0)—P impurity. The green solid which remained was dissolved in benzene (or THF), the solution filtered, and the filtrate concentrated under reduced pressure to ~4/5 of the original volume. Small green crystals were produced overnight and these were washed with benzene and ether and dried under reduced pressure. The yield was ~30% but can be significantly reduced by small changes (e.g. adding the $NaBH_4$ too slowly) in the above experimental conditions. Chemical analyses (Ni, C, H, P, and, by difference, B) were essentially identical for samples recrystallized from both benzene and THF.

d-*Spacings (Relative Intensities 0–10)*

11.81 (3), 9.24 (10), 8.45 (10), 6.96 (1), 6.22 (5), 4.94 (1), 4.79 (1), 4.61 (1), 4.45 (7), 4.10 (6).

$Ni(ClO_4)P_3$ and $[NiP_4](ClO_4)$

A solution of $NaBH_4$ (0.073, 1.93 mmol) in ethanol (15 ml) was added dropwise to a stirred mixture of $Ni(ClO_4)_2 \cdot 6H_2O$ (0.77 g, 2.11 mmol) and P (2.39 g, 9.11 mmol) in ethanol (20 ml). The mixture, which quickly precipitated an orange-yellow solid, was stirred for 1 h before the solid was filtered off and recrystallized from acetone.

Recrystallization of pure $Ni(ClO_4)P_3$ (~3 g) (or the crude product) from acetone/toluene in the presence of P (3 *M* excess) produced $[NiP_4](ClO_4)$ which was washed with toluene (8 ml) and ether (6 × 8 ml).

$[HNi(diphos)_2](ClO_4)$

$Ni(ClO_4)_2 \cdot 6H_2O$ (0.93 g, 2.54 mmol) and diphos (3.04 g, 7.63 mmol) were mixed in ethanol (20 ml) and immediately produced a yellow precipitate of $Ni(diphos)_2(ClO_4)_2$. To this stirred mixture, a suspension of $NaBH_4$ (0.12 g, 3.13 mmol) in ethanol (10 ml) was added dropwise and the color of the mixture turned to orange. Stirring was continued for 1 h before the solid was filtered off and washed with ethanol, water, ethanol, benzene (until the washings were colorless), and ether. The product was recrystallized from THF or acetone. Yield ~90%.

$[Ni_2(dppm)_4](ClO_4)_2$

This complex was prepared in a manner similar to that described above for $[HNi(diphos)_2](ClO_4)$ using $Ni(ClO_4)_2 \cdot 6H_2O$ (0.75 g, 2.06 mmol), dppm (1.61 g, 4.20 mmol), and $NaBH_4$ (0.11 g, 2.89 mmol). The crude product was recrystallized from acetone/ether as dark green crystals and washed with ether. Yield ~50%.

[Ni(vpp)$_2$](ClO$_4$)

This complex was prepared in a similar way to that described above for [HNi(diphos)$_2$](ClO$_4$) using Ni(ClO$_4$)$_2$·6H$_2$O (0.43 g, 1.17 mmol), vpp (1.61 g, 4.07 mmol), and $NaBH_4$ (0.05 g, 1.31 mmol). The product was recrystallized from acetone (or CH_3CN) and ether in ~50% yield.

Total synthesis of indole and dihydroindole alkaloids. XVI.[1,2] Derivatives of vinblastine and vincristine: change of functionality in the vindoline unit

JAMES P. KUTNEY, JOHN BALSEVICH, TOSHIO HONDA, PING-HUANG LIAO, HERMAN P. M. THIELLIER, AND BRIAN R. WORTH

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, B.C., Canada V6T 1W5

Received May 23, 1978

JAMES P. KUTNEY, JOHN BALSEVICH, TOSHIO HONDA, PING-HUANG LIAO, HERMAN P. M. THIELLIER, and BRIAN R. WORTH. Can. J. Chem. **56**, 2560 (1978).

Studies describing the preparation of various derivatives of vinblastine and vincristine are presented. Vindoline (**3**) is transformed into a series of derivatives and the latter via Polonovski-type coupling with catharanthine (**2**) provide the bisindole alkaloid derivatives of the vinblastine series. Selective Jones' oxidation transforms the vinblastine family into the corresponding vincristine derivatives.

JAMES P. KUTNEY, JOHN BALSEVICH, TOSHIO HONDA, PING-HUANG LIAO, HERMAN P. M. THIELLIER et BRIAN R. WORTH. Can. J. Chem. **56**, 2560 (1978).

On présente des études décrivant la préparation de divers dérivés de la vinblastine et de la vincristine. On transforme la vindoline (**3**) en une série de dérivés et ces derniers par l'intermédiaire d'un couplage de type Polonovski avec la catharanthine (**2**) fournissent les dérivés de l'alcaloïde bisindole de la série de la vinblastine. Une oxydation sélective de Jones transforme les composés de la famille de la vinblastine en dérivés correspondants de la vincristine.

Earlier reports from these (see ref. 5 for earlier parts of this series) and other (6–8) laboratories have discussed syntheses of various derivatives of the antitumour agent, vinblastine (**1**). The two strategies generally employed; functionalisation of catharanthine (**2**) followed by coupling with vindoline (**3**), or direct coupling of (**2**) and (**3**) with subsequent elaboration of the so formed 3′,4′-dehydrovinblastine (**4**); have provided derivatives with various functionality in the indole (cleavamine) unit. The present work describes the preparation of vinblastine–vincristine derivatives bearing different functions in the vindoline unit of the molecule. To this end both the coupling of vindoline derivatives with catharanthine via the modified Polonovski reaction (6,9) and elaboration of 'dimeric' substrates have been utilized.

Vindoline, a readily available alkaloid from *Catharanthus roseus* G. Don (*Vinca rosea* L.), for which both total (10, 11) and partial (12, 13) syntheses have appeared, was subjected to the transformations depicted in Scheme 1. Reaction of desacetylvindoline (**5**) with *N*,*N*′-thiocarbonyldiimidazole gave a high yield of the thionocarbonate **6** which on treatment with Raney nickel led efficiently to the unsaturated ester **7**. Prolonged reaction of **6** afforded the ring E saturated derivative **8** which was also available from desacetyldihydrovindoline via **9** (14) using a similar reaction sequence. Both esters **7** and **8** were readily converted to the corresponding

[1]For Part XV, see ref. 1.

N-methyl amides **10** and **11** respectively, by the direct action of methylamine. Alternatively, reaction of **7** and **8** with sodium amalgam in methanol solution provided the more favoured 3(*R*)-esters **12** and **13** (11) in high yields. The uncomplicated nature of these reductions may be attributed to severe steric crowding at C4 thus preventing coupling of the presumed radical intermediates.

In view of the recent interest in 4-desacetoxyvinblastine (**14**), isolated from *C. roseus* by the Lilly group (15), it seemed appropriate to synthesize derivatives of this type. Here, α-hydroxylation of the esters **12** and **13** with molybdenum peroxide HMPA pyridine complex (16–18) provided the respective hydroxyesters **15** and **16**. The latter was also available by reaction of **13** with hydrogen peroxide in the presence of potassium *tert*-butoxide. In addition, hydrogenation of **15** gave **16**, demonstrating identical configuration at C3. The data available did not enable unambiguous absolute configurational assignment for these hydroxyesters.

The modified Polonovski reaction has found wide application in the preparation of bisindole derivatives of the vinblastine type. Further exploitation of this method enabled the preparation of 'dimeric' compounds from the vindoline derivatives discussed above. Table 1 summarizes these results. The amide derivatives **19** and **20** and the hydroxyester **21** are of particular interest owing to their similarity to vinblastine amide **22** (19) and 4-desacetoxyvinblastine **14** reported by the Lilly group (15). Notably the efficiency of this coupling reaction is retained with substrates of this type which themselves remain highly nucleophilic at the 15-position, while a report has appeared on the failure of N_a-formyl substrates to react (6). The success of the coupling seems also dependent on the ability of the catharanthine derivative to stabilise the reaction intermediate from C5—C18 cleavage (6, 9).

The interesting biological activity of several 22-oxo-'dimeric' alkaloids and derivatives, e.g., vincristine (**23**), 22-oxoleurosine (**24**) (20), and 3′,4′-dehydrovincristine (**25**) (21), prompted the preparation of a series of synthetic derivatives of this type to complement the biological data already available from the parent amines. Indeed a procedure for the

'chromic acid' (CrO_3) oxidation of vinblastine (**1**) to **23** had appeared (22). Although this method was found ineffectual in promoting oxidation of 3′,4′-dehydrovinblastine (**4**), modification of the procedure did enable specific oxidation of the various 'bisindole' derivatives listed in Table 2. Generally, low temperature oxidation with Jones' reagent gave reproducibly high yields of the N_a-formyl compounds. The ease of specific oxidation within these complex molecules is quite remarkable. Oxidations of leurosine (**34**) serve to illustrate this point. Here, treatment of **34** with Jones' reagent at low temperature provided 22-oxoleurosine (**24**) which is presently in clinical use in

Hungary (20). Further oxidation with iodine in the presence of sodium bicarbonate afforded the 19′-oxidation product **36**. Alternatively, iodine–bicarbonate oxidation of leurosine and subsequent Jones' oxidation of the product **35**, gave **36** together with the secondary amine **37**. The dihydro derivative **38** was also available from 6,7-dihydroleurosine (**39**), prepared by *tert*-butyl hydroperoxide oxidation of **30** or by hydrogenation of leurosine (**34**). In this latter reaction, products of oxiran cleavage were not observed.

The work described here, together with that reported in previous parts of this series, has allowed the preparation of numerous derivatives of vinblastine and vincristine with the potential of extending this number to provide an effective biological screening program. It is hoped that this program will provide valuable information relating to structure–activity relationships for the bisindole alkaloid oncolytic agents.

Experimental

Melting points were determined on a Kofler block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in ethanol solution. The wavelengths of absorption maxima are reported in nanometers (nm) with log ε values in parentheses. Infrared (ir) spectra were measured on a Perkin Elmer model 710 or 457 spectrophotometer in chloroform solution. The absorption maxima are reported in wavenumbers (cm^{-1}), calibrated with respect to the absorption band of polystyrene at 1601 cm^{-1}. Proton magnetic resonance (^{1}Hmr) spectra were measured in deuteriochloroform ($CDCl_3$) solution at ambient temperature on either a Varian HA-100 or XL-100 spectrometer. Chemical shift values are given in the δ (ppm) scale relative to tetramethylsilane (TMS) used as internal standard. The integrated peak areas, signal multiplicities, and proton assignments are given in parentheses. Low resolution mass spectra (ms) were determined on either an AEI-MS-902 or an Atlas CH-4B spectrometer. High resolution mass spectra were measured on an AEI-MS-902 instrument. Microanalyses were carried out by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia.

Thin-layer chromatography (tlc) utilized Merck silica gel G (according to Stahl) containing 2% fluorescent indicator. For preparative layer chromatography (plc), plates (20 × 20 or 20 × 60 cm) of 1 mm thickness were used. Visualization was effected by viewing under ultraviolet light and/or by colour reaction with ceric sulphate spray reagent. Column chromatography utilized Merck silica gel 60 (70–230 mesh) or Merck aluminium oxide 90 (neutral).

As a matter of routine, all reagents and solvents were recrystallized or distilled before use.

The Thionocarbonate ***6***

Thiocarbonyl diimidazole (400 mg) was added to a solution of desacetylvindoline (**5**) (230 mg) in butan-2-one (23 ml) and the resulting solution refluxed under a nitrogen atmosphere for 20 h. The mixture was then cooled, diluted with ethyl acetate, washed with 1 *M* sodium carbonate solution, saturated sodium chloride solution, dried (Na_2SO_4), and evaporated *in vacuo*. Recrystallisation of the residue from ethyl acetate afforded the thionocarbonate **6** (210 mg, 83%), mp 184–186°C; uv λ_{max}: 235 (4.28), 300 (3.64); ir ν_{max}: 1740, 1615, 1610, 1315; ^{1}H nmr δ: 7.02 (1H, d, J = 8 Hz, C14-H), 6.43 (1H, dd, J = 8, 2 Hz, C15-H), 6.16 (1H, d, J = 2 Hz, C17-H), 6.00 (1H, m, C7-H), 4.62 (1H, bd, J = 10 Hz, C6-H), 4.78 (1H, d, J = 2 Hz, C4-H), 3.98 (3H, s, —OCH_3), 3.90 (1H, s, C2-H), 3.82 (3H, s, —OCH_3), 2.63 (3H, s, —NCH_3), 0.30 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 456 (M^+), 440, 427, 426, 425, 395, 380, 379 (100%), 349, 295, 188, 174, 135, 121. *Anal.* calcd. for $C_{24}H_{28}SN_2O_5$: C63.13, H6.18, N6.14; found: C63.25, H6.20, N6.42.

The Unsaturated Ester ***7***

The thionocarbonate **6** (200 mg) in dry THF (10 ml) was added to a suspension of Raney nickel (5 g) in dry THF (50 ml). The mixture was refluxed for 1 h and then filtered. The filtrate was evaporated *in vacuo* and the residue chromatographed on silica gel to give **7** (140 mg, 84%) as a colourless foam; uv λ_{max}: 252 (3.91), 307 (3.74); ir ν_{max}: 1705, 1615; ^{1}H nmr δ: 7.26 (1H, s, C4-H), 7.03 (1H, d, J = 8 Hz, C14-H), 6.28 (1H, dd, J = 8, 2 Hz, C15-H), 6.01 (1H, d, J = 2 Hz, C17-H), 5.65–6.00 (2H, m, C6-H and C7-H), 4.26 (1H, s, C2-H), 3.80 (6H, s, 2 × —OCH_3), 2.74 (3H, s, —NCH_3), 1.42 (2H, q, J = 7.5 Hz, —CH_2CH_3), 0.63 (3H, t, J = 7.5 Hz, —CH_2CH_3); ms *m/e*: 380 (M^+), 350, 321, 297, 282, 244, 220, 208, 205, 188, 174, 149. *Mol. wt.* calcd. for $C_{23}H_{28}N_2O_3$: 380.2100; found (high resolution ms): 380.2092.

The Ester ***8***

Reaction of the thionocarbonate (**6**) with Raney nickel in refluxing THF for 20 h gave an almost quantitative yield of the unsaturated ester (11).

The Amide ***10***

The ester **7** (300 mg) in methylamine (10 ml) was heated at 60°C in a sealed tube for 72 h. The solvent was removed *in vacuo*. The residue was dissolved in dichloromethane, washed with water, and dried (Na_2SO_4). Evaporation of the solvent and crystallisation from ethyl acetate – petroleum ether gave the amide **10** (270 mg, 90%), mp 196–198°C; uv λ_{max}: 250 (3.95), 305 (3.73); ir ν_{max}: 3500, 1650, 1620; ^{1}H nmr δ: 7.00 (1H, d, J = 8 Hz, C14-H), 6.48 (1H, s, C4-H), 6.25 (1H, dd, J = 8, 2 Hz, C15-H), 5.98 (1H, d, J = 2 Hz, C17-H), 5.60–6.00 (2H, m, C6-H and C7-H), 4.24 (1H, s, C2-H), 3.77 (3H, s, —OCH_3), 2.87 (3H, d, J = 5 Hz, —$NHCH_3$), 2.76 (3H, s, —NCH_3), 1.40 (2H, q, J = 7.5 Hz, —CH_2CH_3), 0.60 (3H, t, J = 7.5 Hz, —CH_2CH_3); ms *m/e*: 379 (M^+), 321, 188, 174, 149. *Mol. wt.* calcd. for $C_{23}H_{29}N_3O_2$: 379.2260; found (high resolution ms): 379.2262. *Anal.* calcd.: C72.79, H7.70, N11.07; found: C72.64, H7.67, N11.00.

The Amide ***11***

Reaction of the ester **8** with methylamine as described above gave the amide **11** (88%) as a colourless foam; ir ν_{max}: 3500, 1660, 1605; ^{1}H nmr δ: 6.34 (1H, s, C4-H), 4.24 (1H, s, C2-H), 3.72 (3H, s, —OCH_3), 2.88 (3H, d, J = 4 Hz, —$NHCH_3$), 2.74 (3H, s, —NCH_3), 0.60 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 381 (M^+), 366, 351, 336, 322, 320, 246, 217, 208, 174, 144, 124 (100%). *Mol. wt.* calcd. for $C_{23}H_{31}N_3O_2$: 381.2416; found (high resolution ms): 381.2412.

The Ester ***12***

An excess of 10% sodium amalgam was added in portions to a solution of the unsaturated ester **7** (100 mg) in methanol (10 ml) at ambient temperature. Stirring was continued for a total of 6 h, the mixture was filtered, and the filtrate concentrated *in vacuo*. Chromatography on silica gel afforded the 3(*R*)-ester **12** (78 mg, 78%); mp (methanol – petroleum ether) 186–188°C; uv λ_{max}: 252 (3.71), 304 (3.55); ir ν_{max}: 1725; ^{1}H nmr δ: 6.90 (1H, d, J = 8 Hz, C14-H), 6.16 (1H, dd, J = 8, 2 Hz, C15-H), 5.95 (1H, d, J = 2 Hz, C17-H), 5.71

(1H, dd, J = 10, 2 Hz, C7-H), 5.84 (1H, bd, J = 10 Hz, C6-H), 3.87 (1H, d, J = 10 Hz, C2-H), 3.76 (3H, s, —OCH_3), 3.67 (3H, s, —OCH_3), 2.73 (3H, s, —NCH_3), 0.77 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 382 (M^+, 100%), 380, 351, 208, 189, 188, 187, 174, 161, 135, 122, 121, 107, 93. *Mol. wt.* calcd. for $C_{23}H_{30}N_2O_3$: 382.2257; found (high resolution ms): 382.2271. *Anal.* calcd. for $C_{23}H_{30}N_2O_3 \cdot \frac{1}{2}H_2O$: C71.89, H7.91, N7.29; found: C71.80, H8.20, N7.01.

The Ester ***13***

Reduction of the ester **8** with 10% sodium amalgam as described above gave the 3(*R*)-ester **13** (82%) identical with an authentic sample (11).

The Hydroxyester ***15***

Diisopropylamine (0.5 ml) and *n*-butyllithium (0.5 ml of a 20% solution in heptane) were stirred at 0°C in dry THF (5 ml) for 15 min. A solution of the ester (**12**) (60 mg) in dry THF (5 ml) was added and the solution stirred at 0°C for 30 min and then at ambient temperature for 1 h. The solution was cooled to 0°C and $MoO_5 \cdot Py \cdot HMPA$ complex (16–18), (80 mg) added. The mixture was stirred at 0°C for 1 h, diluted with water, and extracted with ethyl acetate. The extract was washed with saturated sodium chloride solution, dried (Na_2SO_4), and evaporated. Chromatography on silica gel gave the hydroxyester **15** (22 mg, 35%) as a colourless foam; uv λ_{max}: 252 (3.83), 306 (3.77); ir ν_{max}: 3520, 1720, 1615–1610; ^{1}H nmr δ: 6.88 (1H, d, J = 8 Hz, C14-H), 6.17 (1H, dd, J = 8, 2 Hz, C15-H), 5.98 (1H, d, J = 2 Hz, C17-H), 5.70 (1H, bdd, J = 11, 4 Hz, C7-H), 5.52 (1H, bd, J = 11 Hz, C6-H), 3.92 (1H, s, C2-H), 3.82 (3H, s, —OCH_3), 3.78 (3H, s, —OCH_3), 2.78 (3H, s, —NCH_3), 0.79 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 398 (M^+), 382, 338, 296, 224, 189, 136, 135, 121. *Mol. wt.* calcd. for $C_{23}H_{30}N_2O_4$: 398.2205; found (high resolution ms): 398.2183.

The Hydroxyester ***16***

(*a*) Hydroxylation of the ester **13** as described above for the preparation of **15**, gave **16** (32%); uv λ_{max}: 252 (3.73), 305 (3.64); ir ν_{max}: 3550 (br), 1725; ^{1}H nmr δ: 6.85 (1H, d, J = 8 Hz, C14-H), 6.18 (1H, dd, J = 8, 2 Hz, C15-H), 5.98 (1H, d, J = 2 Hz, C17-H), 3.87 (1H, s, C2-H), 3.84 (3H, s, —OCH_3), 3.78 (3H, s, —OCH_3), 2.78 (3H, s, —NCH_3), 0.68 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 400 (M^+), 298, 188, 174, 124. *Mol. wt.* calcd. for $C_{23}H_{32}N_2O_4$: 400.236; found (high resolution ms): 400.235.

(*b*) Oxygen gas was passed through a solution of the anion, prepared as in *a* above, for 18 h at ambient temperature. Work-up as before gave the hydroxyester **16** in 30% yield.

(*c*) The unsaturated derivative **15** was hydrogenated over 10% palladium-on-carbon catalyst in ethanol to give (80%) the ester **16** identical with that prepared above.

The 'Dimer' ***17***

Catharanthine **2** (88 mg) and *m*-CPBA (42 mg) were stirred in dry dichloromethane (1.5 ml) at −10 to −15°C for 30 min. The vindoline derivative **7** (50 mg) was added and the solution cooled to −50°C. Trifluoroacetic anhydride (0.13 ml) was added and the mixture stirred at −50°C for 4 h, poured into a cold solution of sodium borohydride in methanol, and extracted with dichloromethane. The extract was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on silica gel gave **17** (35 mg, 45%) as a colourless foam, uv λ_{max}: 263 (4.40), 287 (4.27), 295 (4.24), 311 (3.98); cd: 208 (−22.0), 221.5 (+12.2); ir ν_{max}: 1720, 1700; ^{1}H nmr δ: 8.07 (1H, s, —NH), 7.20 (4H, m, C4-H and indole aromatic —H), 6.54 (1H, s, C14-H), 6.02 (1H, s, C17-H), 5.6–6.0 (3H, m, C3′-H, C6-H, C7-H), 4.24 (1H, s, C2-H), 3.78 (6H, s, 2 × —OCH_3), 3.62 (3H, s, —OCH_3), 2.83 (3H, s, —NCH_3), 1.04 (3H, t, J = 7.5 Hz, —CH_2CH_3), 0.80 (3H, t, J = 7.5 Hz, —CH_2CH_3); ms *m/e*: 716 (M^+), 657, 536, 534, 464, 451, 393, 380, 353, 336, 277, 237. *Mol. wt.* calcd. for $C_{44}H_{52}N_4O_5$: 716.3937; found (high resolution ms): 716.3948.

The Dimer ***18***

Similarly the ester **8** reacted with catharanthine *N*-oxide to give **18** in 30% yield; uv λ_{max}: 268 (4.31), 284 (4.21), 292 (4.14), 313 (3.87); cd: 207 (−17.4), 222 (+14.0); ir ν_{max}: 1720; ^{1}H nmr δ: 8.04 (1H, s, —NH), 7.10–7.20 (4H, m, C4-H, aromatic —H), 6.60 (1H, s, C14-H), 6.00 (1H, s, C17-H), 5.52 (1H, d, J = 6 Hz, C3-H), 4.24 (1H, s, C2-H), 3.80 (3H, s, —OCH_3), 3.77 (3H, s, —OCH_3), 3.58 (3H, s, —OCH_3), 2.86 (3H, s, —NCH_3), 1.00 (3H, t, J = 7 Hz, —CH_2CH_3), 0.82 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 718 (M^+), 704, 659, 593, 534, 464, 451, 393. *Mol. wt.* calcd. for $C_{44}H_{54}N_4O_5$: 718.4094; found (high resolution ms): 718.4109.

The 'Dimer' ***19***

Similarly, the amide **10** was reacted with catharanthine *N*-oxide to give **19** (36%); uv λ_{max}: 267 (4.38), 287 (4.26), 296 (4.17), 312 (3.96); cd: 207.5 (−28.2), 222 (+14.1); ir ν_{max}: 1720, 1660; ^{1}H nmr δ: 8.07 (1H, s, —NH), 6.62 (1H, s, C14-H), 6.36 (1H, s, C4-H), 6.03 (1H, s, C17-H), 5.5–6.0 (3H, m, C3′-H, C6-H, C7-H), 4.24 (1H, s, C2-H), 2.90 (3H, d, J = 6 Hz, —NHCH_3), 2.88 (3H, s, —NCH_3), 1.02 (3H, t, J = 7.5 Hz, —CH_2CH_3), 0.83 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 715 (M^+), 686, 656, 624, 534, 533, 393, 336. *Mol. wt.* calcd. for $C_{44}H_{53}N_5O_4$: 715.4096; found (high resolution ms): 715.4053.

The Dimer ***20***

Similarly the amide **11** gave **20** in 22% yield; uv λ_{max}: 261 (4.25), 287 (4.11), 296 (4.07), 312 (3.93); ir ν_{max}: 1720, 1660; ^{1}H nmr δ: 8.02 (1H, s, —NH), 6.60 (1H, s, C14-H), 6.20 (1H, s, C4-H), 5.98 (1H, s, C17-H), 5.50 (1H, m, C3-H), 4.27 (1H, s, C2-H), 3.76 (3H, s, —OCH_3), 3.57 (3H, s, —OCH_3), 2.90 (3H, d, J = 6 Hz, —NHCH_3), 2.87 (3H, s, —NCH_3), 0.99 (3H, t, J = 7 Hz, —CH_2CH_3), 0.86 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 717 (M^+), 688, 685, 660, 659, 658, 626, 594, 536, 535, 455, 394, 337, 278. *Mol. wt.* calcd. for $C_{44}H_{55}N_5O_4$: 717.4253; found (high resolution ms): 717.4209.

The Dimer ***21***

Similarly the hydroxyester **15** gave a 32% yield of **21**; uv λ_{max}: 272 (4.27), 286 (4.18), 295 (4.07), 317 (3.80); cd: 208 (−24.3), 222 (+27.7); ir ν_{max}: 3470, 1725; ^{1}H nmr δ: 8.14 (1H, s, —NH), 6.58 (1H, s, C14-H), 6.03 (1H, s, C17-H), 5.54 (3H, bs, C3-H, C6-H, C7-H), 3.84 (3H, s, —OCH_3), 3.80 (3H, s, —OCH_3), 3.58 (3H, s, —OCH_3), 2.81 (3H, s, —NCH_3), 0.88–1.08 (6H, m, 2 × —CH_2CH_3); ms *m/e*: 734 (M^+), 676, 675, 674, 616, 615, 495, 494. *Mol. wt.* calcd. for $C_{44}H_{54}N_4O_6$: 734.4042; found (high resolution ms): 734.4009.

The Dimer ***24***

Jones' reagent (0.5 ml) was added, at −78°C under an atmosphere of dry nitrogen, to a solution of leurosine (**34**) (50 mg) in acetic anhydride (1 ml) and acetone (6 ml). The mixture was stirred at this temperature for 1 h, diluted with concentrated ammonium hydroxide (10 ml), and allowed to warm to ca. 0°C. The mixture was partitioned between 5% sodium bisulphite solution and dichloromethane, the organic layer dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on silica gel gave 22-oxoleurosine (**24**) (38 mg, 75%), mp (methanol) 212–216°C; uv λ_{max}: 219 (4.68), 253 (4.20), 262 (4.15), 289 (4.18), 296 (4.22); ir ν_{max}: 3470, 1738, 1688; ^{1}H nmr δ: 8.80 and 8.20 (1H, 2 × bs, —NCHO), 8.01

Infrared studies of carboxylic acids and pyridine in chloroform and methanol[1]

B. A. DAWA AND JOAN A. GOWLAND[2]

Department of Chemistry, Ahmadu Bello University, Zaria, Kaduna State, Nigeria

Received February 9, 1978

B. A. DAWA and JOAN A. GOWLAND. Can. J. Chem. **56**, 2567 (1978).

The reactions of acetic, chloroacetic, and trichloroacetic acids with varying relative concentrations of pyridine in chloroform have been reinvestigated using infrared spectroscopy. The same systems have also been studied in methanol. Some different assignments of peaks have been made, and the anomalous infrared results previously observed for trichloroacetic acid in chloroform are explained in terms of charge transfer complex formation.

B. A. DAWA et JOAN A. GOWLAND. Can. J. Chem. **56**, 2567 (1978).

On a réétudié, faisant appel à la spectroscopie infrarouge, les réactions des acides acétique, chloroacétique et trichloroacétique avec diverses concentrations relatives de pyridine dans le chloroforme. On a aussi étudié les mêmes systèmes dans le méthanol. On a fait quelques attributions de bandes différentes et les résultats infrarouges anormaux observés antérieurement pour l'acide trichloroacétique dans le chloroforme peuvent être expliqués en terme de la formation d'un complexe de transfert de charge.

Introduction

Infrared spectroscopy is a very useful tool for studying acid–base equilibria in nonaqueous solvents both to determine the equilibrium constants and to determine the products actually obtained. Since Barrow's paper, in 1954 (1), many studies of carboxylic acid – amine equilibria have been reported in solvents such as carbon tetrachloride, chloroform (1, 2), benzene (3), acetonitrile (4), and ether (5). In all cases there was evidence of 1:1, 2:1, and sometimes 3:1 complex formation involving either hydrogen bonding or proton transfer. Solvent participation varies and this gives rise to significant differences in the spectra obtained for a given acid and base in various solvents.

Where proton transfer is incomplete, the appearance of peaks for both the ionized and H-bonded forms is said to suggest a tautomeric equilibrium. Although infrared studies have thrown much light on the nature of such equilibria, Hilbart and Satchell (5) have commented that the structural details of variously identified adducts in nonaqueous solvent remains very much an open question.

As part of a study of the use of other forms of spectroscopy such as uv and nmr in looking at such equilibria, Barrow's infrared work for acetic, chloroacetic, and trichloroacetic acids and pyridine in chloroform was reinvestigated and then the same systems were studied with methanol as solvent. In methanol, the solvent absorption only allowed study of the region between 1800 and 1500 cm^{-1}.

A reinterpretation of some of the infrared results is given in view of band assignments made since 1954. Also an explanation is offered in terms of charge transfer complex formation for the anomalous behaviour observed for trichloroacetic acid – pyridine in chloroform where the carbonyl "wavelength shift is much less than would be expected for a product with a free symmetric carboxylate group" (2).

Experimental

AnalaR chloroform, methanol, acetic acid, chloroacetic acid, trichloroacetic acid, and pyridine were purified using standard procedures.

Infrared spectra were run on a Pye-Unicam S.P.1200 infrared spectrophotometer. Solution spectra were taken using the same pair of approximately 0.1 mm sodium chloride cells throughout the study. All spectra were calibrated using the polystyrene peak at 1601 cm^{-1}.

Ultraviolet spectra referred to below were run on a Pye-Unicam S.P.8000B instrument.

Stock solutions which were 0.2 and 0.4 *N* in acid or base were prepared for each acid and pyridine in both chloroform and methanol. The pyridine in chloroform solution tended to decompose after approximately a week and therefore its purity was checked before use by running the ultraviolet spectrum of a 2×10^{-4} *N* solution. Just before use, the following solutions were prepared: 0.2 *N* pyridine with 0.05 *N* acid, 0.1 *N* acid, and 0.2 *N* acid; 0.1 *N* acid with 0.02 *N* pyridine; 0.05 *N* pyridine and 0.1 *N* pyridine. Infrared spectra of these solutions as well as the 0.1 *N* acid and 0.2 *N* pyridine solution were taken.

Results and Discussion

Although changes were observed in other regions, discussion will be confined to the infrared region

[1]This paper was presented, in part, at the 1973 Conference of the Science Association of Nigeria.

between 1200 and 1800 cm^{-1}. The wavenumber for all the acid and base peaks for the three acids and pyridine are listed in Table 1.[3] The significant changes will be discussed here and illustrated in Figs. 1–3 as indicated below. Assignment of peaks was facilitated by noting changes when acid or base concentration was varied and base or acid concentration remained constant.

For each acid in chloroform, peaks due to monomer C=O stretch (weak) and dimer stretch were observed as well as the usual combination bands. For acetic acid, the peaks at approximately 1420 and 1290 cm^{-1} are C—O stretch and O—H in-plane deformation combination bands for the dimer, and the much weaker peaks at 1360 and 1240 cm^{-1} are the corresponding bands for the monomer (cf. refs. 6 and 7). The assignment of these bands has been the subject of many studies with the currently accepted assignment being due to the work of Hadzi as discussed in ref. 7. Chloroacetic and trichloroacetic acids show similar combination bands. It is noteworthy and not previously recorded that as the amount of pyridine is increased in acetic acid – pyridine solutions (where no proton transfer occurs) the dimer combination bands decrease in intensity (especially the 1420 band) and the monomer bands increase as shown in Fig. 1. Although not shown, but as Barrow also noted (2), the carbonyl band at about 1717 cm^{-1} also decreases in intensity. These changes are due to the pyridine – acetic acid H-bonded complex formation in which the acetic

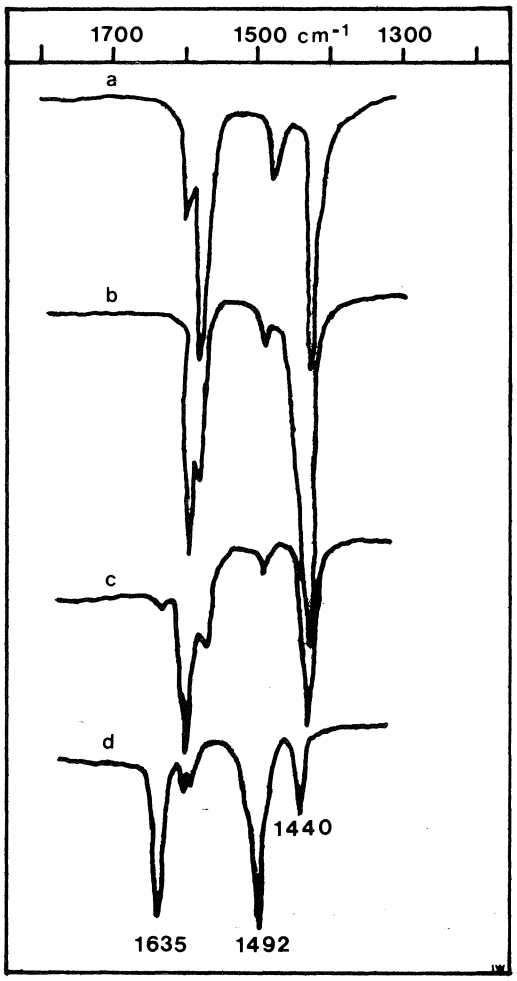

FIG. 3. Infrared spectra of 0.2 *N* acid and 0.2 *N* pyridine in $CHCl_3$ showing only the pyridine peaks; (*a*) with no acid (pyridine only); (*b*) with acetic acid; (*c*) with chloroacetic acid; (*d*) with trichloroacetic acid.

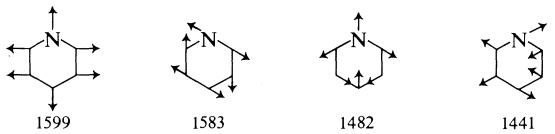
acid appears to have increasingly monomeric properties. Small shoulders at approximately 1690 cm^{-1} in the chloroacetic acid spectra can be assigned to CO_2^- stretch. For some solutions with trichloroacetic acid, shoulders or peaks around 1680 cm^{-1} are due to CO_2^- asymmetric stretch, with the corresponding symmetric stretch at 1360 cm^{-1}. Thus, in agreement with Barrow's work, for acetic acid, H-bonded complex formation with no proton transfer was observed; for chloroacetic acid only a very small amount of proton transfer was observed; but for trichloroacetic acid considerable proton transfer was seen. A similar trend was observed in methanol as seen in Table 2[3] and Fig. 2, which shows almost complete proton transfer for trichloroacetic acid as indicated by the strong CO_2^- band at 1690 cm^{-1}.

The pyridine peaks of interest in this region, at 1592, 1580, 1475, and 1432 cm^{-1} in chloroform



(Fig. 3*a*) have been assigned the following vibrational modes (8), (wavenumbers are for neat pyridine).

In this study shifts of up to 10 cm^{-1} have been observed for these peaks in chloroform solutions with added acid. Methanol absorption in this region does not allow a comparable study. Even more significant is the change in relative intensity of these four peaks in the presence of different acids. This is illustrated in Fig. 3 for solutions 0.2 *N* in acid and 0.2 *N* in pyridine. The additional peak at approximately 1635 cm^{-1} for trichloroacetic acid solution is attributed to the formation of pyridinium ion (2, 8).

A further analysis of these pyridine data in view of Katritzky's work (8) seems in order. Barrow suggested (2) that the peaks at 1480 and 1630 cm^{-1} are characteristic of pyridinium and therefore absent for pyridine, and that the 1430 cm^{-1} peak is present in pyridine spectra but absent in pyridinium spectra. He also says that the shift of the 1580 cm^{-1} peak to 1603 cm^{-1} indicates hydrogen bonding. The data in Table 1 and the spectra in Fig. 3 show some reinterpretation is possible.

First, with respect to the 1480 cm^{-1} peak, this peak shifts from 1475 up to 1492 cm^{-1} with added acid but is definitely present for both pyridine and pyridinium (see change from *a* to *d* in Fig. 3). However, it does decrease in intensity for H-bonded complexes and increases significantly when proton transfer has occurred. This band has been attributed to vibration mode III (above) and the observed behaviour fits in with the corresponding changes in dipole moment with H-bonding or proton transfer.

Consideration of mode IV would lead to the prediction of opposite behaviour for the 1432 cm^{-1} band. This is what is observed, i.e., a marked reduction in intensity upon proton transfer, but some increase with H-bonding.

For pyridine itself (Fig. 3*a*), a doublet of unequal intensity at 1592 (weaker) and 1580 cm^{-1} was observed rather than the single band reported by Barrow (2). But for an H-bonded complex (Fig. 3*b*), e.g., with acetic acid, the 1592 cm^{-1} band becomes more intense rather than the single band observed by Barrow actually shifting. Protonation would lead to a more symmetrical vibration of the molecule, for mode I and II, which would be infrared forbidden or weak (cf. benzene), and indeed in trichloroacetic acid solutions, these peaks are very weak.

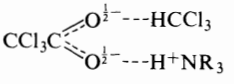
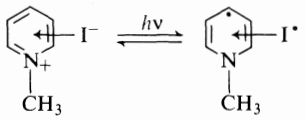
Barrow raises the question of the nature of the equilibrium when there is partial proton transfer, i.e., whether (*i*) there are two reactions to form (*a*) an H-bonded complex and (*b*) a proton-transferred complex; or (*ii*) just one reaction to form some proton transferred complex. His choice of *i* is based on the band assignment quoted above. Consideration of the data in this study, presented above, leads to the same conclusion but on a different basis. From the spectra shown in Fig. 3, an H-bonded complex between acetic acid ($pK_a = 4.74$) and pyridine in chloroform, results in increased intensity of the 1592 cm^{-1} peak relative to the 1580 cm^{-1} peak and increased intensity of the 1432 cm^{-1} peak. Protonation by trichloroacetic acid ($pK_a = 0.70$) leads to appearance of a peak at 1640 cm^{-1}, decreasing intensity of the 1592 and 1580 cm^{-1} peaks, increased intensity of the 1475 cm^{-1} peak, and decreased intensity of the 1432 cm^{-1} peak. For intermediate strength chloroacetic acid ($pK_a = 2.85$) solutions, as shown in Fig. 3*c*, the small peak at 1635 cm^{-1} and the decreased 1432 cm^{-1} peak suggest some protonation but the remaining peaks are similar to Fig. 3*b* rather than Fig. 3*a* therefore suggesting case *i* holds for partial protonation.

Barrow (2) mentions that for trichloroacetic and trifluoroacetic acids and pyridine in chloroform, the "wavelength shift is much less than would be expected for a product with free symmetric carboxylate group ... and that there is an absence of a split between carbonyl and carboxylate absorption." The same phenomena was again observed in this study but in methanol, solutions of the same concentrations as studied in chloroform showed well defined peaks at 1775(w), 1755(w), and 1690(s) cm^{-1} (for C=O monomer, C=O dimer and CO_2^- respectively) (e.g., see Fig. 2*c*). Other workers have studied various alkylamines and trichloroacetic acid in chloroform (9), benzene (3), and ether (5) and have found no absorption above 1700 cm^{-1}. The explanation for the presence of a 'free' carboxylate peak in solvents where ion pair formation is expected, is solvent participation and evidence for this is well documented in refs. 1 and 2.



Since trichloroacetic acid gives strong 'free' carboxylate absorption with solvent participation as just shown, when reacted with alkylamines in chloroform (9) in benzene (3), and with pyridine in methanol (Fig. 2), and with *p*-anisidine (a base of similar strength to pyridine in water) in chloroform,[4] it might be concluded that pyridine in chloroform was causing the presence of such a broad medium intensity band between 1720 and 1680 cm^{-1}. A possible explanation of the anomalous behaviour, is the formation of a charge transfer complex between the pyridinium ion and trichloroacetate ion in chloroform.

Pyridinium is well known for formation of charge transfer complexes (10), for example, 1-methylpyridinium iodide forms a charge transfer complex as follows:

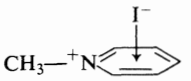


Formation of such complexes is detected by the presence of extra peaks in the ultraviolet absorption spectrum and often by colour formation. 1-Methylpyridinium iodide has charge transfer bands at 294.5 and 379.6 nm (11). The amount of charge transfer complex formation and the position of the charge transfer peaks depend on the solvent. Charge transfer formation with pyridinium salts, in which the complex formed is less polar, decreases as the polarity of the solvent increases.

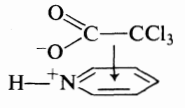
Ultraviolet spectra of concentrated solutions (2–4 *M*) pyridine in chloroform or methanol show no absorption above 280 nm but such solutions containing equimolar amounts of trichloroacetic acid have shoulders extending to 400 nm. Dilution of the mixtures leads to a nonlinear decrease in absorption for this shoulder. For methanol solutions, this extra absorption had disappeared when pyridine concentration reached 0.4 *N* but was still present as a weak symmetrical band ($\lambda_{max} \simeq 330$ nm) for 0.1 *N* pyridine and 0.1 *N* trichloroacetic acid in chloroform. Hence, in addition to the two equilibria suggested by Barrow, a third equilibrium can be proposed, i.e.

$$Py + CCl_3COOH \rightleftharpoons Py \ldots HOOCCCl_3 \rightleftharpoons$$
$$Py{-}H^+ \ {}^-OOCCCl_3 \rightleftharpoons CCl_3COO^- \cdot Py{-}H^+$$

The structure of such complexes has been suggested to be (11):



If a similar structure is proposed for trichloroacetic acid, then it could be represented as:



Thus, an unsymmetrical —COO^- could be obtained

[4]Unpublished results (this laboratory).

and absorption in the infrared for C=O, probably at a lower wavenumber than the COOH carbonyl band, would be expected. Judging from the fairly weak ultraviolet absorption, K for the charge transfer complex formation is probably small, and therefore infrared absorption for more than one form of carboxylate should be expected, giving rise to a broad band in the carboxylate–carbonyl region, as is observed.

Introduction

Recently, Kaiser and Hauser (1) and Crouse and Seebach (2) have reported the preparation and condensation of lithioacetonitrile with ketones or aldehydes to give monoaldol products. Improved yields of monoaldol condensation products of lithioacetonitriles have been reported by Cuvigny *et al.* (3). Gornowicz and West (4) and Das and Wilkie (5) have also prepared the lithio salts of simple nitriles such as acetonitrile or phenylacetonitrile. In another account, Kaiser and Hauser (6) describe some of the problems encountered in attempted aldol condensations with lithiophenylacetonitrile. Stork and Maldonado (7) and Hunig and Wehner (8) have cited some monoalkylations of α-cyano ether anions and Hunig and Wehner (9) have isolated aldol products after treating these anions with ketones.

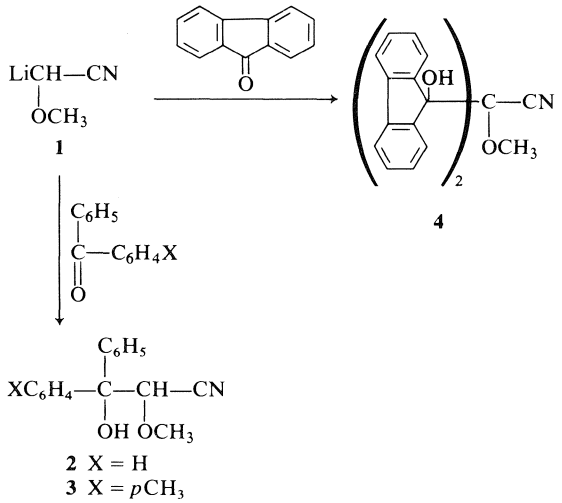
In each report, no mention was made of the isolation of dialdol condensation products. The anions were generally prepared by treating the nitrile with base at lower temperature (e.g., −78°C) followed by condensation with electrophilic reagent and stirring in the cold. The mixture was then allowed to warm to room temperature, and the product isolated. Interestingly, Hauser and coworkers (10) reported isolation of dialdol products resulting from the condensation of benzophenone with another multiple anion. We have also noted that diaroylation occurred when dilithiooximes and dilithiophenylhydrazones were condensed with acid chlorides (11, 12), and dialkylation of C(α)-anions of nitriles has been established (13, 14).

[1]Author to whom correspondence should be addressed.

Results and Discussion

During the preparation and reaction of lithiomethoxyacetonitrile (**1**) we made some expected and unexpected observations. When **1** was treated with benzophenone and 4-methylbenzophenone, the expected aldol products **2** and **3** were isolated in 25 and 20% yields, respectively. When **1** was prepared and condensed with these ketones at −78 or 0°C, the yields of these products (**2** and **3**) were essentially unchanged (ca. 25%); however, **1** condensed with 9-fluorenone to give dialdol product **4** in 36% yield (Scheme 1).

Lithioacetonitrile (**5**), prepared at 0°C, was also found to undergo the same dialdol condensation when treated with benzophenone, 2-benzoylthiophene, 9-fluorenone, and 4-chlorobenzophenone



SCHEME 1

For personal use only.

(**6–9** in Table 1) but the monoaldol product **10** was isolated in 45% yield when **5** was condensed with 4-methylbenzophenone (Scheme 2).

Aside from infrared spectra of these products displaying cyanide absorptions from 2222–2290 cm^{-1} and hydroxyl absorptions from 3200–3400 cm^{-1}, monoaldol product (**10**) displayed ^1H nmr methylene absorptions at δ 3.47 ppm whereas dialdol (**6–9**) ^1H nmr spectra contained methine resonances from δ 4.67–5.40 ppm. ^1H nmr spectra of some crude products indicated mixtures of mono- and dialdol products were present. When **5** was prepared from methyllithium and lithium diisopropylamide, the same products listed in Table 1 were isolated. In all condensations of **5** with 4-methylbenzophenone, the monoaldol product was isolated instead of the dicondensation product. We do not have a satisfactory explanation for this result. At the present time, the preparation of dilithioacetonitrile (4) followed by treatment with ketones listed in Table 1 has been unsuccessful.

The condensation of acetonitrile carbanion **5** with the ketone could be attributed to the formation of the weaker base, which would be an alkoxide-type anion **11** (Scheme 3). Since the pK_a of tertiary alcohols is near 19 and that of acetonitrile is 25, the alkoxide ion **11** should be a weaker base than acetonitrile carbanion **5** (15). Then while an equilibrium between alkoxide ion **11** and secondary carbanion **12**, shifted towards **12** may appear less likely, the reaction of **12** with another molecule of benzophenone would result in alkoxide **13**, a monoanion. Since the ketone is being added to acetonitrile carbanion **5**, and **5** is present in excess until addition is complete, alkoxide **11** could react with **5** to give dianion **14** and **14** would condense with benzophenone to give **15**. Secondary carbanion **12** could also react with **5** to give **14** before **12** could react with benzophenone to give **13**. Under the conditions of the reaction (base–nitrile–ketone 1 : 1 : 1), **13** if formed would react with **5** to give **15**. Dianion **15** would result from either route, and upon neutralization would give dialdol nitrile **6**.

Our investigation differs from the reports previously cited (1–3, 9) in that the nitrile carbanion was prepared and condensed with the electrophilic reagent at 0°C instead of lower temperatures (e.g., −78°C, except for **2** and **3** mentioned earlier). The results obtained suggest other equilibrium were involved at 0°C and at lower temperatures they were not as important, as evidenced by the fact that other investigators reported good to excellent yields of monoaldol products.

Experimental

Tetrahydrofuran was distilled from sodium (benzophenone). Nuclear magnetic resonance spectra were obtained on a

Varian Associates EM 300X nmr spectrometer (TMS standard). Infrared spectra were obtained on a Perkin-Elmer 700 infrared spectrometer. Combustion analyses were performed by Robertson's Laboratory, 73 West End Ave., Florham Park, NJ and M-H-W Laboratories, Garden City, MI. *n*-Butyllithium was purchased from Lithium Corporation of America.

Preparation and Reactions of Lithioacetonitrile and Lithiomethoxyacetonitrile

The lithionitriles were prepared by cooling to 0°C (unless specified) and blanketing under nitrogen a solution containing 0.05 mol of nitrile in 100 ml of dry tetrahydrofuran (THF). A 0.055 mol sample of *n*-butyllithium was added dropwise during 5 min and the solution was stirred for 1 h. This was followed by rapid addition of 0.055 mol of ketone dissolved in 50 ml of THF. After 10 min of stirring the mixture was neutralized by pouring into 100 ml of 3 *N* HCl and ice. The layers were separated and 100 ml of ether was added to the aqueous layer and then neutralized with $NaHCO_3$. The organic layers were combined, dried ($MgSO_4$), and concentrated (Rotovac). This

The results of a variable temperature study of the ^{2}H and ^{13}C spin–lattice relaxation times in neopentane-d_{12} are reported along with those for the ^{13}C's in neopentane at a single temperature. Orientational and angular momentum correlation times derived from these T_1's exhibit the following: (*i*) τ_2 is continuous through the melting point with an activation energy of 0.98 kcal/mol, (*ii*) τ_J is more or less constant at 0.33 $\pm$ 0.03 ps within 40 K of either side of the melting point, and (*iii*) they do not conform to the theoretical relationships of extended diffusion, Fokker–Planck, or Langevin theories. The spin–rotation coupling constants are calculated to be -0.69 kHz for neopentane and -0.52 kHz for neopentane-d_{12}.

BRIAN A. PETTITT, RODERICK E. WASYLISHEN, RONALD Y. DONG et T. PHIL PITNER. Can. J. Chem. **56**, 2576 (1978).

On rapporte les résultats d'études à températures variables des temps de relaxation spin–réseau du ^{2}H et du ^{13}C dans le néopentane-d_{12} de même que ceux du ^{13}C du néopentane à une seule température. Les temps de corrélation de moments angulaires et d'orientation que l'on peut tirer de ces valeurs T_1 présentent les caractéristiques suivantes: (*1*) τ_2 est continu au niveau du point de fusion avec une énergie d'activation de 0.98 kcal/mol, (*2*) τ_J est plus ou moins constant à 0.33 $\pm$ 0.03 ps dans des limites de 40 K au-dessous et au dessus du point de fusion et (*3*) ces valeurs ne sont pas conformes avec les relations théoriques des théories de la diffusion étendue, de Fokker–Planck ou de Langevin. On a calculé les constantes de couplage spin–rotation qui s'établissent à -0.69 kHz pour le néopentane et -0.52 kHz pour le néopentane-d_{12}.

[Traduit par le journal]

Introduction

The techniques of spin–lattice and dielectric relaxation, infrared absorption, and Rayleigh–Brillouin, Raman, and neutron scattering continue to add to a considerable body of data on molecular rotations in condensed phases. These data are normally discussed within the theoretical framework of time-dependent correlation functions, thereby concentrating on the characteristic times associated with molecular rotations in an equilibrium ensemble. The dynamics underlying such discussions are generally of two types: hydrodynamical theories providing means to calculate rates of rotational diffusion for 'large' molecules, and quasi-kinetic theories which introduce idealized collision dynamics relating orientational correlation times to rates of angular momentum-changing collisions (1). Theories of the latter type are essential for small molecules, and the widely-used extended diffusion theory of Gordon and McClung has been successful in explaining the rotational characteristics of CF_4, CCl_4, and ClO_3F; for a comprehensive review of the extended diffusion theory and its applications, see ref. 2. Probably the best approximation to the full kinetic formulation is the Fokker–Planck model (3), which has been shown to agree reasonably well with molecular dynamics 'experiments' on rough spheres (4). On the other hand, the Langevin (friction) model (5) is probably the last resort of kinetic theory, yet it is capable of exhibiting some of the details of the more elaborate approaches. All of these procedures are rather crude in comparison to those of quantum statistical mechanics, but they have been useful enough vis-à-vis experiments to deserve attention. At present, it is difficult to say precisely how model-dependent our understanding of molecular rotations in liquids and solids is, and this paper is meant to be a comparison of the above-mentioned approaches as applied to

nuclear spin–lattice relaxation in general, and that of ^{13}C and ^{2}H in $C(CH_3)_4$ and $C(CD_3)_4$ in particular.

In addition to its near spherical shape, neopentane has several interesting properties. It undergoes a transition at 140 K from an hexagonal structure in which rotations are not appreciable to a face-centred cubic lattice ($\Delta S_t = 2.21R$) in which rotations are liquid-like, before melting at 257 K ($\Delta S_m = 1.52R$) (6). The liquid boils under atmospheric pressure at 282 K, but can be kept in that phase at higher temperatures in a sealed tube. The solid II → solid I transition is accompanied by an 18% increase in volume (7), the high temperature (solid I) phase being a typical 'plastic crystal' which is easily deformable and has a translational diffusion coefficient about 10^{-4} times that of the liquid near the melting point (8). Livingstone *et al.* (9) studied the rotation of neopentane by infrared and Raman spectroscopy, concluding that the reorientational characteristics are continuous through the melting point and are not in the small step limit of diffusion. Månsson *et al.* (10) concluded from neutron scattering experiments that the molecules rotate more freely in the solid I than the liquid for temperatures near the melting point. This observation is particularly interesting because it was also one of the main conclusions of O'Dell and Berne's study (4) of the molecular dynamics of the rough sphere fluid.

The next section summarizes the experimental procedure used in the determination of ^{13}C and ^{2}H spin–lattice relaxation times, and the final section presents an analysis of the results.

Experimental

Neopentane was obtained from Chemical Samples Company of Columbus, Ohio, and neopentane-d_{12} from Merck, Sharp, and Dohme of Montreal. Neat samples were degassed by the freeze–pump–thaw cycle under vacuum and sealed.

All spin–lattice relaxation times were measured using the inversion-recovery pulse sequence (d–180°–t–90°), where d is a delay time ($d > 5T_1$) and t is a variable time. T_1 values were calculated from the slopes of ln $\{\langle Mz\rangle_0 - \langle Mz\rangle_t\}$ vs. t (11). Deuterium relaxation rates of neopentane-d_{12} were measured at 13.81 MHz with a Bruker SXP pulsed spectrometer. The temperature was maintained with an accuracy of ±0.5 K by a nitrogen gas flow. Proton-decoupled natural abundance ^{13}C spectra were obtained on a Varian CFT-20 spectrometer (8 mm variable temperature probe) and a Varian XL-100 spectrometer. Nuclear Overhauser enhancement factors (nOe's) were measured using the gated proton decoupler on the CFT-20 with $d > 10T_1$ (^{13}C). The temperature was maintained with an accuracy of ±1.0 K by a nitrogen gas flow.

Results and Discussion

The deuterons in neopentane-d_{12} relax by interaction of their electric quadrupole moments with the gradient of the local electric field, which is directed along the C—D bond and therefore has the time dependence of the rotation of that vector. As a result, the spin–lattice relaxation time can be related to τ_2, the orientation correlation time associated with a second order spherical harmonic via (12)

$$[1] \qquad \frac{1}{T_1} = \frac{3\pi^2}{2}\left(\frac{e^2qQ}{h}\right)^2 \tau_2$$

where (e^2qQ/h) is the quadrupole coupling constant here taken to be 174 kHz, the value for cyclohexane (13). Equation [1] is valid for symmetric C—D bonds when τ_2 is small in comparison to the inverse of the deuterium Larmor frequency (extreme narrowing).

The central ^{13}C of neopentane-d_{12} relaxes by coupling of its magnetic moment with the magnetic field generated by the relative rotation of the remaining charges in the molecule (the spin–rotation mechanism). In this case, T_1 is related to the correlation time associated with the molecular angular momentum by (14)

$$[2] \qquad \frac{1}{T_1^{SR}} = \frac{8\pi^2}{h^2} IkTC^2\tau_J$$

where C is the spin–rotation coupling constant, I is the moment of inertia, and the other symbols have their usual meanings. The moments of inertia were calculated from standard geometries, giving $I = 1.89 \times 10^{-38}$ g cm^2 for neopentane and $I = 2.51 \times 10^{-38}$ g cm^2 for neopentane-d_{12}. The spin–rotation coupling constants were calculated from chemical shift data and the experimental value for $^{13}C^{16}O$ by a method summarized in the Appendix, giving $C = -0.69$ kHz for neopentane and $C = -0.52$ kHz for neopentane-d_{12}.

The ^{13}C nuclei of neopentane are relaxed by the spin–rotation mechanism and by the interaction of their magnetic moments with those of the nearest protons, i.e. the intramolecular dipolar mechanism. In principle, the two contributions to the relaxation rates can be separated by measuring the ^{13}C nOe's (15). The dipolar term is related to τ_2 by (12)

$$[3] \qquad \frac{1}{T_1^{d}} = n\left(\frac{\gamma_C\gamma_H\hbar}{r_{CH}^3}\right)^2 \tau_2$$

in the extreme narrowing approximation, where $n = 3$, $r_{CH} = 1.09$ Å for the methyl carbons and $n = 12$, $r_{CH} = 2.16$ Å for the central carbon, and γ_C and γ_H are the gyromagnetic ratios of ^{13}C and protons.

Grant *et al.* (16), by means of inelastic neutron scattering experiments, determined that CH_3 torsional oscillations are restricted by a 3-fold barrier of 5.03 kcal/mol.[1] The Boltzmann distribution indi-

[1]A slightly smaller barrier (4.92 kcal/mol) was reported by Weiss and Leroi (16*b*) from studies of infrared spectra.

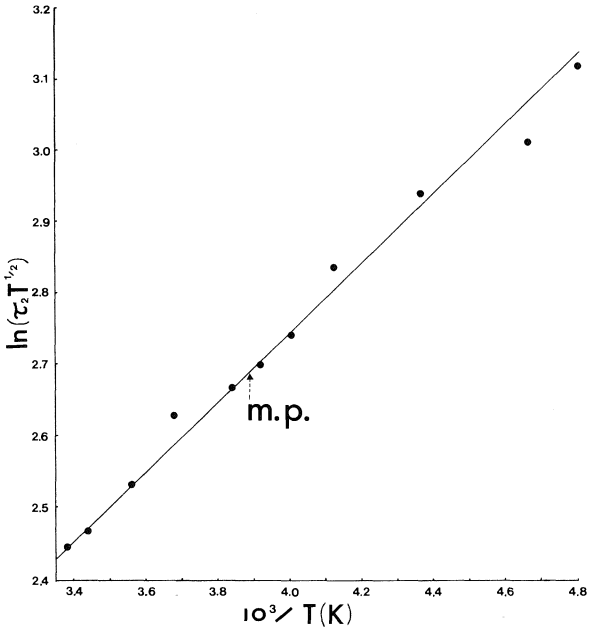

FIG. 1. Graphical summary of the temperature dependence of τ_2 for neopentane-d_{12} in terms of eq. [4]. The slope corresponds to E_a = 0.98 kcal/mol (τ_2 is in ps).

cates that for temperatures below 300 K the molecules are almost all in the bottom 1/10 of the potential wells. It is assumed here that the internal motion associated with this potential does not contribute to the relaxation of the ^{2}H and ^{13}C spins, i.e. the molecules are assumed to be rigid rotors.

Table 1 displays the deuterium and central carbon-13 spin–lattice relaxation times for neopentane-d_{12} at selected temperatures between 208 and 301 K. Also displayed are the τ_2's and τ_J's derived from them via eqs. [1] and [2]. If the rotation was free or only slightly frictionally retarded (17), the τ_2's would have a $T^{-1/2}$ dependence and it is convenient to summarize the results by writing (18)

$$[4] \qquad \tau_2 = CT^{-1/2} \exp(E_a/RT)$$

where the constant depends on how one approaches the free limit ($C = (\pi I/12k)^{1/2}$ for slight frictional damping). That is, the rotation is imagined to be a thermally activated process with 'barrier' E_a. Figure 1 illustrates the τ_2 data of Table 1 as a plot of $\ln(\tau_2 T^{1/2})$ vs. $1/T$, where it can be seen that the data are reasonably well represented by E_a = 0.98 kcal/mol and are continuous across the melting point. Proton T_1's show considerable variation near the melting point because of modulation of the intermolecular dipolar interactions by translational diffusion (19). Table 1 indicates that, whereas τ_2 changes by a factor of about 2.5 over a 100 K temperature range, τ_J is more or less constant within 40 K of either side of the melting point.[2] Relationships between τ_2 and τ_J are at the core of the kinetic treatments mentioned in the Introduction, and the following paragraphs outline their essential features.

In the extended diffusion theory of Gordon and McClung (2), inertial rotational jumps are interrupted by instantaneous collisions at intervals characterized by a Poisson distribution with average value τ_J. In the M-diffusion limit, the direction of the molecular angular momentum is randomized by each collision but the magnitude is unchanged; whereas in the J-diffusion limit both are randomized. Qualitatively, the two models imply 'weak' and 'strong' collisions, respectively. The predicted relationships between τ_2^* and τ_J^* are depicted in Fig. 2 ($\tau^* = \tau(kT/I)^{1/2}$ is a reduced correlation time).

A detailed analysis of the Fokker–Planck fluid of spherical molecules has been presented by Fixman and Rider (3*a*), but the necessary numerical procedures have limited its application. Evans (3*b*) has treated the problem in the high density (liquid) region by regarding the free rotation as a perturbation on the collision dynamics and approximately summing the resulting series. By these means, he was able to obtain the $\tau_l \leftrightarrow \tau_J$ dependency as follows:

$$[5] \qquad \tau_l^* = \frac{1}{l(l+1)\tau_J^*}\{1 + [l(l+1) - \tfrac{1}{2}]\tau_J^{*2}\}$$

This equation is also plotted in Fig. 2 over an

[2]The τ_J data of Table 1 actually exhibit a minimum in the neighbourhood of the melting point, but the error (±10%) is too large to claim this as a real effect.

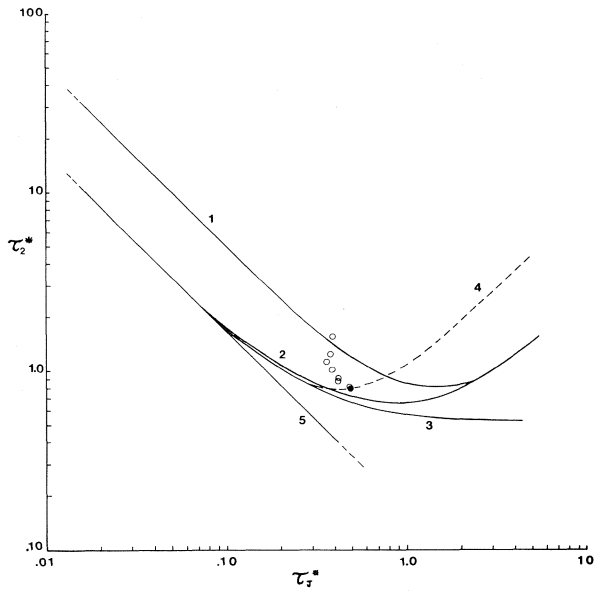

FIG. 2. Interdependence of reduced orientational and angular momentum correlation times: *1*, M-diffusion; *2*, J-diffusion; *3*, Langevin (friction) theory; *4*, approximate Fokker–Planck theory; and *5*, Hubbard relation. The open circles represent the data for neopentane-d_{12} and the closed circle is for neopentane.

extensive range, but is only reliable up to the neighbourhood of its minimum[3] (3*b*).

Kluk and Powles (5) have shown that for spherical and linear molecules in the rotational friction (Langevin) model, the analogous relationship is

$$[6]\quad \tau_l^* = \frac{1}{l(l+1)\tau_J^*} \times M(1, 1 + l(l+1)\tau_J^{*2}, l(l+1)\tau_J^{*2})$$

where $M(\alpha, \gamma, x)$ is the Kummer series,

$$[7]\quad M(\alpha, \gamma, x) = 1 + \frac{\alpha}{\gamma}x + \frac{\alpha(\alpha+1)}{2!\gamma(\gamma+1)}x^2 + \ldots$$

so, to lowest order

$$[8]\quad \tau_l^* = \frac{1}{l(l+1)\tau_J^*}\{1 + l(l+1)\tau_J^{*2} + \ldots\}$$

Equation [6] is also illustrated in Fig. 2, from which it can be seen that the *J*-diffusion, Fokker–Planck, and Langevin models all have as their high density limits the small step diffusion model, which is characterized by the Hubbard relation $\tau_l^*\tau_J^* = [l(l+1)]^{-1}$. In addition, the figure demonstrates (albeit the plot is ln–ln) that the three models predict similar deviations from small step diffusion up to $\tau_J^* \lesssim 0.5$. The accuracy of a particular model is difficult to judge on the basis of correlation times alone because they are essentially features of the short-time part of the correlation functions, the behaviour of which the model may reproduce quite well before deviating at longer times (4).

The data of Table 1 are plotted on Fig. 2 along with the point $\tau_2 = 0.55$ ps and $\tau_J = 0.34$ ps determined from T_1 (methyl ^{13}C) = 23.5 s (nOe = 1.65) and T_1 (central ^{13}C) = 86 s (nOe = 0.48) for neopentane at 291 K. The dipolar contribution to the central carbon's T_1 corresponds to $\tau_2 = 0.66$ ps. Attempts to obtain data for neopentane at other temperatures were frustrated by unreproducible nOe's. The kinetic behaviour of neopentane-d_{12} clearly conforms to none of the predictions, but falls more or less between the two extremes of the extended diffusion theory such that the experimental points at the high temperatures (liquid) lie just above the J-diffusion curve and the ones at low temperature (solid I) are near the M-diffusion curve. The most that can be inferred from this observation is that although the average time between collisions does not change, the collisions weaken as the substance is cooled such that the magnitude of the angular momentum is progressively less affected. This seems reasonable, considering the loss of translational mobility on freezing. However, the interpretation of angular momentum relaxation as a binary collision process (instantaneous or otherwise) is too naive to be applied with confidence to substances near their melting points, where many body processes govern the dynamics. In the Fokker–Planck and Langevin models, many body processes are implicit in average torques and friction coefficients, but these concepts are of limited conceptual value on the picosecond timescale.

As yet there are very little data available on angular momentum relaxation in liquids and virtually none in solids, and the work reported here was conceived as an investigation of the utility of the ^{13}C Fourier transform nmr method in obtaining such information. Orientational relaxation data are demonstrably easier to obtain by this method (20), but less informative with respect to the specific microdynamical events underlying measureable quantities (in this case, T_1's). The only related study that we are aware of, that of Boden and Folland (21) on ^{31}P and ^{2}H relaxation in phosphine (PH_3 and PD_3), serves to highlight the specificity of a molecule's rotational characteristics in the neighbourhood of the melting point demonstrated here for neopentane.

[3]Evans and Keyes (3*c*) turned the perturbation procedure around and examined the low density (gas) limit of the Fokker–Planck model, but results for intermediate densities where inertial and collisional effects are comparable are as yet unavailable in analytical form.

They observed a discontinuity in τ_2 but not in τ_J across the melting point and found that τ_2 has a higher activation energy in the liquid than in the plastic solid. They concluded that rotation in the liquid is isotropic and closer to the M-diffusion limit. Based on neopentane and phosphine, we conclude that there is much to learn about molecular rotations in condensed phases.

Appendix

Calculated Spin–Rotation Constants of Neopentane and Neopentane-d_{12}

The term in the molecular Hamiltonian responsible for the spin–rotation mechanism can be written as (22)

$$[A1] \qquad H^{SR} = -\hbar^{-2}\hat{S}_\alpha \cdot \mathsf{M} \cdot \hat{J}$$

where $\hat{S}_\alpha$ and $\hat{J}$ are the spin operators for nucleus α and the molecular angular momentum, and $\mathsf{M} = h\mathsf{C}$ is the spin–rotation coupling tensor in units of energy. Ramsey (23) showed that M is related to the average nuclear shielding, σ.

$$[A2] \qquad \sigma = (1/3)(\sigma_{xx} + \sigma_{yy} + \sigma_{zz}) = \sigma_d + \sigma_p$$

where

$$[A3] \qquad \sigma_d = \frac{e^2}{3mc^2}\sum_i \langle 0|r_i^{-1}|0\rangle$$

is the diamagnetic contribution, and

$$[A4] \qquad \sigma_p = \frac{(m'/m)}{3\hbar^2 g_\alpha}\sum_{j=1}^{3} I_j M_j - \frac{e^2}{3mc^2}\sum_{\alpha'}{}' \frac{Z_{\alpha'}}{r_{\alpha'}}$$

is the paramagnetic contribution. $|0\rangle$ is the ground electronic state vector, r_i is the position of electron i with respect to nucleus α, g_α is the nuclear g-factor, I_j is the jth component of the diagonalized moment of inertia tensor, $Z_{\alpha'}$ is the charge of nucleus α' at relative position $r_{\alpha'}$, and m'/m is the proton/electron mass ratio.

The two components of σ_p are denoted σ_p' and σ_N, the latter being due to the nuclear framework only. Clearly, for molecules in which C reduces to a scalar, σ_p' is sufficient to determine its value. This is made possible by an accurate approximation for σ_d due to Flygare and Goodisman (24),

§Determined from a measurement of $\delta^{TMS}[C(CD_3)_4] - \delta^{TMS}[C(CH_3)_4] = 1.0$ ppm.

$$[A5] \qquad \sigma_d \simeq \sigma_d(\text{atom}) - \sigma_N$$

where σ_d(atom) is the diamagnetic shielding of nucleus α in the free atom. In this approximation,

$$[A6] \qquad \sigma \simeq \sigma_d(\text{atom}) + \sigma_p'$$

Introduction of the chemical shifts of nucleus α in molecules A and B with respect to reference molecule R by

$$[A7] \qquad \delta^R(A) = \sigma(A) - \sigma(R)$$

and a similar expression for B, and use of equation [A6] results in

$$[A8] \qquad \sigma_p'(A) = \sigma_p'(B) - \{\delta^R(B) - \delta^R(A)\}$$

Thus an experimental σ_p'(B) and chemical shift data are sufficient to determine σ_p'(A), A = neopentane or neopentane-d_{12}. Table 2 presents the relevant data based on B = $^{13}C^{16}O$. This procedure was used by Gillen *et al.* (25) for CCl_4 and can be extended to a symmetric top molecule if its chemical shift anisotropy is known (26).

Mechanism of S_Ni reactions. The effect of the base strength of the anionic fragments[1]

D. J. VERRINDER, M. J. HOURIGAN, AND J. M. PROKIPCAK[2]

Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received July 4, 1977[3]

D. J. VERRINDER, M. J. HOURIGAN, and J. M. PROKIPCAK. Can. J. Chem. **56**, 2582 (1978).

The kinetics and stereochemical aspects of the thermal decomposition of aralkyl carbonates, thiocarbonates, and carbamates were examined. The rates for the decompositions as well as the rates of loss of optical activity followed first-order kinetics. The decompositions appear to involve the heterolysis of the aralkyl–oxygen bond followed by the breakdown of the subsequent ion pair via a cyclic mechanism. However, it was found that this ion pair could return to covalency without completely decomposing to products leading to the racemization of the starting materials. This type of racemization occurred more readily in the case of the carbamates than in the thiocarbonates and carbonates. The dependence of the decomposition rates and the loss of optical activity on the nature of the hetero atom of the anionic fragment of the starting material is discussed.

D. J. VERRINDER, M. J. HOURIGAN et J. M. PROKIPCAK. Can. J. Chem. **56**, 2582 (1978).

On a étudié la cinétique et l'aspect stéréochimique de la décomposition thermique de carbonates, thiocarbonates et de carbamates d'aralkyles. Les vitesses de décomposition de même que les vitesses de perte d'activité optique suivent une cinétique du premier ordre. Il semble que les décompositions impliquent une hétérolyse du lien oxygène–aralkyle suivie par une décomposition subséquente de la paire d'ions par l'intermédiaire d'un mécanisme cyclique. Toutefois on a trouvé que cette paire d'ions peut effectuer un retour vers une covalence sans se décomposer complètement en produits conduisant à une racémisation des produits de départ. Ce type de racémisation se produit plus facilement dans le cas des carbamates que dans le cas des thiocarbonates et des carbonates. On discute du fait que les vitesses de décomposition et de perte d'activité optique dépendent de la nature de l'hétéroatome de la fraction anionique du produit de départ.

[Traduit par le journal]

Introduction

Previous work (1) has indicated that the thermal fragmentation of aralkyl carbonates followed a path similar to that found for the thermal fragmentation of thiocarbonates (2, 3). Both of these decompositions appear to involve a mechanism involving heterolysis of the aralkyl–oxygen bond with subsequent formation of ion-pair intermediates. Moreover, the dependence of the rates on the nature of the aralkyl group indicates that this cleavage occurs in the transition state of the rate-determining step. The two possible modes of decomposition are outlined in Scheme 1 where B can be S or O. Path *1* which involves two successive bond cleavages (aralkyl–oxygen bond followed by carbonyl–oxygen bond) appears to best accommodate experimental work to date. However consideration must still be given to Path *2* where the two bonds are broken simultaneously. Regardless of whether Path *1* or Path *2* is followed, the overall process is still considered to be an S_Ni reaction since random recombination of the fragments does not occur to any appreciable extent as would be expected if the process were completely ionic in nature (1).

Although the decompositions of carbonates and thiocarbonates have been studied separately, no attempts to compare these decompositions under the same reaction conditions have been found. If one could extend the comparison to include the analogous carbamate series i.e., where B = NH; it would be possible to investigate the effect that the hetero atom B has on the decompositions as B goes from N to O to S. This would lead to some indication of the importance which the nucleophilic character of the anion portion (ϕS^-, ϕO^-, and ϕNH^-) has on the decomposition rates. This report involves a kinetic and stereochemical study of the decompositions of a series of carbonates (**1**), thiocarbonates (**2**), and carbamates (**3**). The required feature of the compounds investigated was the presence of an anisylic group (*p*-methoxybenzyl). This choice was necessary to ensure that all the decompositions would occur at a rate rapid enough to be conveniently measured.

All the decompositions studied did follow first-order kinetics over at least 75% of the reaction. The carbonates and thiocarbonates decomposed reasonably fast at temperature ranges of 100–150 and 70–

130°C, respectively, to give the corresponding ether and thioether. The carbamates however, did require higher temperatures (minimum of 170°C) and product identification was much more difficult because of a greater variety of side products such as ring substituted anilines and diphenyl urea.

The stereochemical studies were carried out on systems where the aralkyl group was *p*-methoxybenzhydryl. The chiral centre was generated by the presence of a phenyl group rather than an alkyl group in order to prevent any complicating elimination reactions from occurring along with the desired decompositions. The variations of the decomposition rates owing to the hetero atom B, the effect of solvent polarity as well as the stereochemistry at the chiral centre was investigated.

Experimental

Synthesis of Carbonates, Thiocarbonates, and Carbamates

Anisyl alcohol was available commercially and was used without any further purification. *p*-Methoxybenzhydryl alcohol was prepared by the reaction of phenyl magnesium bromide with anisaldehyde (4-methoxybenzaldehyde) according to the method of Balfe and co-workers (4). These alcohols were then converted to carbonates by reacting them with phenyl chloroformate (5) and to thiocarbonates by reacting them with phenyl chlorothiolformate (2). The carbamates were made by the well documented reaction of the alcohols with phenyl isocyanate. The physical constants and analyses for previously unreported starting compounds are given in Table 1. All melting points were determined on the Fisher-Johns melting point apparatus and are uncorrected. Information on any compounds used in this study but not appearing in Table 1 can be found in earlier work (1, 5).

Product Identification of the Decomposition Reactions

Experimental data will not be given for the identification of products previously reported, namely the ethers obtained from the decomposition of the carbonates. Decomposition of the carbamates gave products which were not readily isolateable. However mass spectral data and combined chemical reactions indicate the expected *N*-substituted anilines along with ring substituted anilines and diphenyl urea were obtained in the reaction.

The decomposition of the thiocarbonates did give excellent yields of thioethers. Since these thioethers have not been previously reported, the data will be given for them. Decomposition of anisyl phenyl thiocarbonate gave anisyl phenyl thioether, mp 83–84°C, in an 80% yield which had the following spectral data: nmr ($CDCl_3$) δ(ppm): 3.65 (3H singlet, (CH_3O)), 4.89 (2H singlet, methylene), 6.70–7.21 (9H multiplet, aromatic). *Anal.* calcd. for $C_{14}H_{14}OS$: C 73.01, H 6.13; found: C 72.81, H 6.35. Decomposition of *p*-methoxybenzhydryl phenyl thiocarbonate gave *p*-methoxybenzhydryl phenyl thioether, mp 94–96°C, in an 85% yield. The following spectral data was obtained: nmr ($CHCl_3$) δ(ppm): 3.73 (3H singlet, CH_3O), 5.55 (1H singlet, methine), 6.77–7.45 (14H multiplet, aromatic). *Anal.* calcd. for $C_{20}H_{18}OS$: C 78.38, H 5.93; found: C 78.12, H 6.06.

Resolution of 4-Methoxybenzhydrol

A mixture of *dl*-4-methoxybenzhydrol was converted to *dl*-4-methoxybenzhydryl hydrogen phthalate using the method of Balfe *et al.* (4). The following method was used to resolve the *dl* mixture. A slurry of 4-methoxybenzhydryl hydrogen phthalate (100 g, 0.278 mol) in 320 ml of warm ethyl acetate was added to a magnetically stirred suspension of (−)-cinchonidine (83.9 g, 0.285 mol) in 50 ml of ethyl acetate. Recrystallizations from ethyl acetate were carried out until a white powder of cinchonidine (+)-4-methoxybenzhydryl phthalate (35.6 g), mp 138–141°C (lit. (4) mp 143–144°C) was obtained. Removal of the solvent *in vacuo* from the mother liquor yielded a solid which after several recrystallizations from acetone resulted in

a white powder of cinchonidine(−)-4-methoxybenzhydryl phthalate (54.6 g), mp 106–110°C.

The hydrolysis of the cinchonidine salt was carried out in the following manner. A cooled solution of cinchonidine(−)-4-methoxybenzhydryl phthalate (20.0 g, 0.055 mol) in 200 ml benzene was washed with an ice-cold solution of 45 g ammonium chloride in 150 ml of 4% hydrochloric acid. The organic layer was quickly separated and washed with ice-cold water (3 × 150 ml). The benzene layer was dried over anhydrous sodium sulfate. When the solvent was removed *in vacuo*, a white precipitate of (−)-4-methoxybenzhydryl hydrogen phthalate was obtained which was immediately dissolved in 100 ml of anhydrous ether. This ethereal solution was added slowly with stirring to a suspension of lithium aluminum hydride (2.28 g, 0.060 mol) in 100 ml anhydrous ether. After the addition, the reaction mixture was stirred at room temperature for 2 h and was then hydrolyzed by the addition of first 2.3 ml of water, then 2.3 ml of 15% sodium hydroxide, and finally 6.9 ml of water. The reaction mixture was filtered and the solvent removed *in vacuo*. The resultant oil was dissolved in chloroform, dried, and then the solvent removed to give a solid which upon recrystallization from chloroform – petroleum ether (bp 30–60°C) resulted in transparent needle-like crystals, mp 63.0–64.0°C of pure (−)-4-methoxybenzhydrol, $[\alpha]_D^{20}$ −31.6° (*c* 2.31, $CHCl_3$).

The (−)-4-methoxybenzhydrol was converted to the thiocarbonate and carbamate whereas the (+)-4-methoxybenzhydrol was used to prepare the carbonate. These were all prepared using the methods already described and the optical rotations of the final compounds are given for hexamethylphosphoramide (HMP) solutions: (−)-4-methoxybenzhydryl *S*-phenyl thiocarbonate, $[\alpha]_D^{20}$ −24.0°; (+)-4-methoxybenzhydryl phenyl carbonate, $[\alpha]_D^{20}$ +15.9°; (−)-4-methoxybenzhydryl *N*-phenyl carbamate, $[\alpha]_D^{20}$ −14.5°.

Kinetics of the Decompositions

The decompositions of all the anisyl and 3,4-dimethoxybenzyl carbonates, carbamates, and thiocarbonates were followed using nmr techniques outlined in a previous paper (1). However, this method could not be used for the *p*-methoxybenzhydryl system since there was no reasonable separation in the nmr spectrum between the methylene peak of the parent compounds and the corresponding products. Since all the starting compounds had a carbonyl group which gave a strong absorption band in the infrared over the region 1765–1730 cm^{-1} and since this absorption was not close to any other major absorptions, the base-line method was used to analyze each ir spectrum. Furthermore, earlier experiments with standard solutions of the various starting compounds in the various solvents employed for the decompositions showed that, over a convenient range, a plot of absorbance of the carbonyl band versus concentration of solution was satisfactorily linear and thus satisfied Beer's law. A typical kinetic run will be outlined below for the thiocarbonate.

The thiocarbonate (6.68 g, 0.019 mol) was dissolved in HMP to a volume of 10 ml. Ten aliquots (0.40 ml) were placed in tubes and these tubes were simultaneously placed in a thermostatically controlled (90±0.2°C) oil bath. Tubes were removed at specified time intervals and immediately quenched in a Dry Ice – acetone bath. Chloroform (1.0 ml) was added to each tube, each tube was shaken to ensure mixing, and an ir of the carbonyl absorption region (1670–2000 cm^{-1}) was taken. Each solution was run three times against a blank solution of 0.4 ml HMP in 1.0 ml chloroform. The base-line method was used to analyze each spectrum and the average absorbance ($\log P_0/P$) was calculated for each solution. The average absorbance was multiplied by the slope of the Beer's Law plot to give the concentration of the sample. The plot of log concentration vs. time in seconds was made and the method of weighted least squares was used to get the slopes of the lines.

In the case of the stereochemical studies, the samples from the reaction tubes were analyzed on a Beckmann 141 automatic polarimeter, using a 0.1 dm polarimeter cell maintained at 20±0.2°C with a sodium D line (λ = 589 nm) light source. The value for the optical rotation was determined for each sample and then the log of the optical rotation was plotted vs. time in seconds to get the rate of loss of optical rotation.

Results and Discussion

Kinetics

Using the aforementioned method, good first-order kinetics were obtained for all the decompositions and the first-order rate constants were calculated. Table 2 shows the results of the kinetic studies and indicates the dependence of the decomposition rates on the nature of the aralkyl group, on the nature of the phenyl substituents, and on the nature of the hetero atom i.e., S, O, and N attached to the phenyl group.

The nature of the substituent on the phenyl group showed very little effect on the decomposition rates although electron withdrawing groups did enhance the rate constants slightly. This is in accordance with results from previous work (1) which showed that dispersal of a negative charge was involved and any electron-withdrawing group is able to help stabilize the negative species. There was however a more noticeable variation in decomposition rate as the aralkyl group was altered. In all cases when the aralkyl group was changed from anisyl to *p*-methoxylbenzhydryl, the decomposition rates increased appreciably. Except for the unexpected behaviour of the 3,4-dimethoxylbenzyl system, it appears that as the aralkyl group's ability to stabilize an electron deficient centre increased, the decomposition rates increased. This would indicate that an intermediate was involved which had some carbonium ion character.

Finally, as the hetero atom changed from S to O to N, the decomposition rates were greatly reduced and higher temperatures were required to effect decomposition. It would thus seem that the base properties of the hetero atom are important in the rates: the more basic the hetero atom, the slower the decomposition rate.

Solvent Effects

The rates of decomposition were carried out in hexamethylphosphoramide, benzonitrile, and diphenyl ether, solvents with different dielectric constants. In most cases, the rates of decomposition were enhanced by using the more polar solvent indicating some kind of ionization process is occurring. The one discrepancy in the solvent effect studies was the *p*-methoxybenzhydryl *N*-phenyl carbamate which

showed no apparent solvent effect. This lack of solvent effect could point to a more concerted mechanism being operative for the carbamate in which the transition state has no appreciable ionic character.

Activation Parameters

The activation parameters for various systems were determined in an attempt to shed some light on the nature of the intermediates involved in the different decompositions. These values were calculated using the method of Purlee *et al.* (6) and are found in Table 2. The $\Delta H^{\neq}$ calculations do indicate that more energy is required to break bonds as we go from S to O to N which coincides with the relative basicities of the three elements. Any other immediate information from the data was not apparent. However when a plot of $\Delta H^{\neq}$ vs. $\Delta S^{\neq}$ was made (Fig. 1), a very interesting correlation was found. All but two of the starting compounds investigated were found to follow a relationship defined by Leffler (7) as the compensation effect. These compounds were found to show a dependence between their entropy and enthalpy values i.e., a large enthalpy value was associated with a low entropy value and vice versa. Furthermore this relationship held in various solvents as well. The fact that the correlation of enthalpy and entropy approaches a linear relationship was thought to be indicative of a series of related reactions which involve a similar transition state. Thus an increased amount of bond stabilization with a subsequent increase in $\Delta H^{\neq}$ leads to an increase in the rigidity of the transition state and subsequently a more negative

$R_3 = CH_3O$—⟨⟩—CH(Ø)—; hexamethylphosphoramide (HMP) was the solvent in all but one case.

$\Delta S^{\ddagger}$ value. These conclusions are consistent with Scheme 1. It is felt that the reason the benzhydryl carbonate and thiocarbonate did not obey the relationship is a direct result of the very stable *p*-methoxybenzhydryl carbonium ion which can form. A more detailed explanation of this is given in the interpretation of the combined kinetic and stereochemical data.

Stereochemical Studies

All previous work (1) thus far appear to point to at least some formation of an aralkyl carbonium ion. Indeed Kice *et al.* (3) found that in the decomposition of 4-chlorobenzhydryl *S*-aryl thiocarbonates, racemization resulting from carbonium ion – carboxylate ion pair formation and recombination was occurring at a faster rate than decomposition. In an effort to see the extent of ion-pair formation, studies were carried out on the carbonates, thiocarbonates and carbamates. The decomposition rates and rates of loss of optical activity were carried out simultaneously. All the compounds studied (Table 3) showed a first-order rate dependence on optical activity.

All the systems were found to racemize at rates faster than their decomposition rates. This racemization process can be accommodated by the mechanism in Scheme 1 where there is heterolysis of the aralkyl bond with formation of ion pairs followed by rapid ion-pair return to reactants. The rates of decomposition of the anisyl and 4-methoxybenzhydryl compounds were quite similar and this coupled with relatively small solvent response is consistent with a cyclic type of transition state proposed for analogous reactions (8).

To interpret the results of the kinetic and stereochemical investigations, and check the validity of the qualitative hypotheses described, Scheme 2 was introduced for the decompositions. This scheme includes optical activity aspects explicitly. The first-order behaviour observed in the stereochemical investigation can be explained as follows.

Optical rotation

$$\alpha = c([(+)R] - [(-)R])$$

where c = constant
thus

$$\frac{d\alpha}{dt} = c\left(\frac{d[(+)R]}{dt} - \frac{d[(-)R]}{dt}\right)$$

$$= c(-k_1[(+)R] + k_{-1}[IP] + k_1[(-)R] - k_{-1}[IP])$$

$$= -k_1 c([(+)R] - [(-)R])$$

$$= -k_1\alpha$$

This allows identification of k_1 and the k_α, the rate constant for loss of optical activity.

The first-order decomposition behaviour can be accounted for by considering the following expressions:

$$d[IP]/dt = k_2[IP]$$

Assuming the steady-state approximation

$$d[IP]/dt = k_1([(+)R] + [(-)R]) - (2k_{-1} + k_2)[IP] \cong 0$$

or

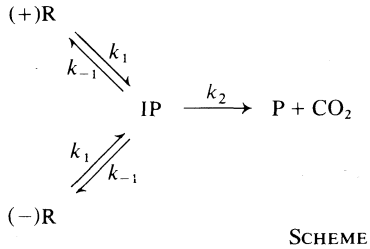
$$[IP] \cong \left(\frac{k_1}{2k_{-1} + k_2}\right)([(+)R] + [(-)R])$$

Thus

TABLE 3. Rates of decomposition and loss of optical activity

Compound	Temperature*	$k_\alpha \times 10^4$† (s^{-1})	$k_d \times 10^4$ (s^{-1})	k_α/k_d
	40	1.00	Too slow to measure	3 (approx.)
	60	7.89	2.45	
	70	17.8	7.35	
	70	0.669	Too slow to measure	5 (approx.)
	90	4.25	0.810	
	100	9.93	2.23	
	120	Too slow to measure	Too slow to measure	10 (approx.)
	170	12.3	1.23	
	180	24.2	2.49	

*Other temperatures were used but similar results were obtained.
†k_α (rate constant for optical activity loss) had regression coefficients of at least 0.9970.



R represents the enantiomers of the carbonate, carbamate, or thiocarbonate
IP represents ion pairs
P represents the products

SCHEME 2

$$\frac{d[IP]}{dt} = \left(\frac{k_1k_2}{2k_{-1} + k_2}\right)([(+)R] + [(-)R])$$

Since the observable used was the carbonyl peak and since this should be proportional to ([(+)R] + [(−)R]), we have a normal first-order rate constant k_d where

$$k_d = k_1k_2/(2k_{-1} + k_2)$$

where

$$k_1 = k_\alpha$$

therefore

$$d[P]/dt = k_d([(+)R] + [(-)R])$$

Furthermore

$$\frac{k_\alpha}{k_d} = \frac{\text{rate of racemization}}{\text{rate of decomposition}}$$

$$= \frac{2k_{-1} + k_2}{k_2}$$

$$= \frac{2k_{-1}}{k_2} + 1$$

But from Table 3 k_α/k_d varies from ≈ 3 to ≈ 5 and thus $2k_{-1}/k_2$ varies from ≈ 1 to ≈ 4. Thus, there is no possibility of reducing the expression for k_d by assuming that $k_{-1} \ggg k_2$.

In the treatment of the stereochemical studies, a slight simplification was made. In the discussion it was assumed that the ion pairs formed in the decompositions could undergo return to substrate equally well with retention and inversion of configuration. However it has been shown (3) that the return of this ion pair is more likely to occur with retention of configuration rather than inversion. This would lead to a racemization rate constant k_α which would be slightly less than the first-order constant k_1 rather than equal to it. This simplification was made to allow less complex rate expressions to be used and does not alter the validity of any of the major conclusions made.

Conclusions

In conclusion, the results from the thermal decompositions of the carbonates, thiocarbonates and carbamates appear to be consistent with a mechanism involving heterolytic aralkyl–oxygen cleavage resulting in an ion-pair formation. The ion pair may return to reactants with loss of optical activity (Path *1* of Scheme 1) or undergo complete decomposition to carbon dioxide and the corresponding ether, thioether, or amine. The ion pair return to reactants occurs more readily in the case of the carbamates and least in the thiocarbonates, whereas complete decomposition to products follows the reverse order.

The differences in the behaviour for the decompositions can be accounted for by the fact that the ϕS^- and ϕO^- represent much better leaving groups than ϕNH^-, so that in the thiocarbonate and carbonate decompositions, cleavage of $\phi-S-\overset{\overset{O}{\|}}{C}-O^-$ and $\phi-O-\overset{\overset{O}{\|}}{C}-O^-$ to CO_2 and ϕS^- and ϕO^- occurs more readily and leads to products. In the case of the carbamate, cleavage of $\phi NH-\overset{\overset{O}{\|}}{C}-O^-$ to ϕNH^- and CO_2 does not occur as readily and return to reactant occurs more readily. This is expected if one accepts that the differences in stability of the carboxylate anions coincides with the differences in basicity of ϕNH^-, ϕO^-, and ϕS^-. A qualitative indication can be obtained for this if one considers the k_α/k_d ratio. The stronger the base fragment such as ϕNH^- the more likely ion pair will return to reactants and hence k_α/k_d would be larger since $k_\alpha \gg k_d$. Conversely, for a weaker base such as ϕS^-, the more likely decomposition would be faster and k_α/k_d would be smaller in magnitude since $k_\alpha \ll k_d$. Thus the k_α/k_d values of approximately 3,5, and 10 for the thiocarbonate, carbonate, and carbamate appears to coincide with the order of base strengths which in turn parallels the ΔH values for the initial bond cleavage. Therefore it appears the base characteristics of the hetero atom B in Scheme 1 does play an important role in the mode of decompositions.

The radical addition of *N*-haloamides to 1,6-heptadiene: The transfer step in the photochemical and chromous chloride promoted addition of *N*-haloamides to olefins[1,2]

MARTINE MONDON[3] and JEAN LESSARD

Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received April 25, 1978

MARTINE MONDON and JEAN LESSARD. Can. J. Chem. **56**, 2590 (1978).

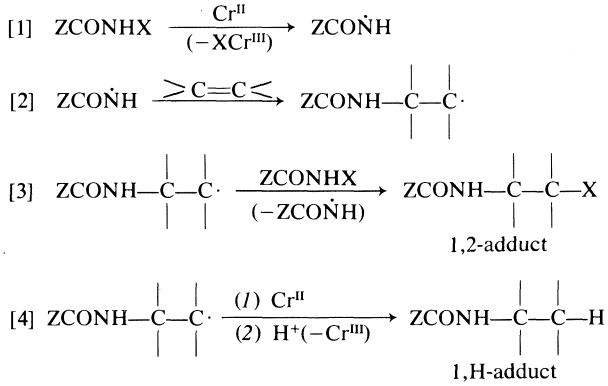
A study of the photochemical addition of *N*-haloamides (ZCONHX) to 1,6-heptadiene shows that the reactivity of ZCONHX as an halogen-atom donor to an alkyl radical increases with Z in the order $CH_3 < ClCH_2 < OC_2H_5 \leq CCl_3 \sim CF_3$ which indicates a polar character of the transition state. An *N*-bromoamide is shown to be more reactive than an *N*-chloroamide as expected. The chromous chloride promoted addition of *N*-chlorochloroacetamide and *N*-chlorotrichloroacetamide to 1,6-heptadiene is compared with the photochemical addition under similar conditions of solvent and temperature. The better interpretation of the results, for the chromous chloride promoted additions, is in terms of a classical chain mechanism rather than a redox chain mechanism; the latter mechanism cannot be excluded however.

MARTINE MONDON et JEAN LESSARD. Can. J. Chem. **56**, 2590 (1978).

Une étude de l'addition photochimique de *N*-haloamides (ZCONHX) à l'heptadiène-1,6 montre que la réactivité de ZCONHX, en ce qui a trait à l'attaque d'un radical alkyle sur l'halogène, croit avez Z dans l'ordre suivant: $CH_3 < ClCH_2 < OC_2H_5 \leq CCl_3 \sim CF_3$. Ceci indique un certain caractère polaire de l'état de transition. On démontre qu'un *N*-bromoamide est plus réactif qu'un *N*-chloroamide tel que prévu. L'addition du *N*-chlorochloroacétamide et du *N*-chlorotrichloroacétamide, catalysée par le chlorure chromeux, est comparée à l'addition photochimique dans un même solvant et à la même température. Les résultats s'expliquent mieux si les additions catalysées par le chlorure chromeux font intervenir un mécanisme en chaine classique plutôt qu'un mécanisme en chaine de type redox mais n'excluent pas ce dernier.

Introduction

In the chromous chloride promoted addition of *N*-haloamides (ZCONHX) to olefins, we observed that the ratio of 1,2-addition ([2] and [3]) to 1,H-addition ([2] and [4]) was larger for X = Br than for X = Cl and increased with Z in the order $CH_3 < ClCH_2 < C_2H_5O \leq CCl_3 \sim CF_3$ (1). These observations were explained using the mechanistic hypothesis summarized by eqs. [1]–[5] (2).



[1] $ZCONHX \xrightarrow[(-XCr^{III})]{Cr^{II}} ZCO\dot{N}H$

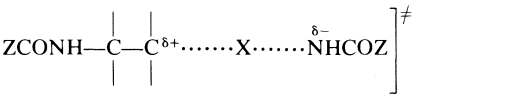
[2] $ZCO\dot{N}H + >C=C< \rightarrow ZCONH-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}\cdot$

[3] $ZCONH-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}\cdot \xrightarrow[(-ZCO\dot{N}H)]{ZCONHX} ZCONH-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-X$ (1,2-adduct)

[4] $ZCONH-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}\cdot \xrightarrow[(2)\ H^+(-Cr^{III})]{(1)\ Cr^{II}} ZCONH-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-H$ (1,H-adduct)

[5] $ZCO\dot{N}H \xrightarrow[(2)\ H^+(-Cr^{II})]{(1)\ Cr^{II}} ZCONH_2$

The competition between the transfer step [3] and the termination step [4] implies that the better the transfer agent, the larger should be the 1,2-addition to 1,H-addition ratio for a given olefin. Indeed, an *N*-bromoamide (bromide-atom transfer) should be a better transfer agent than an *N*-chloroamide (chlorine-atom transfer). We were then led to hypothesize that the reactivity of the *N*-haloamide as transfer agent would increase with the electron-withdrawing power of the ZCO moiety as a result of an increasing polar contribution to the stabilization of the transition state (2).[4]



$$\left[ZCONH-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C^{\delta+}}}\cdots\cdots X\cdots\cdots \overset{\delta-}{N}HCOZ \right]^{\neq}$$

To verify this hypothesis, we studied the photochemical addition of ZCONHX (**1**) to 1,6-heptadiene (**2**) for which the adduct **3** to adduct **4** ratio (Scheme 1) would be expected to increase with the reactivity of ZCONHX as an halogen-atom transfer agent (the photochemical addition of *N*-haloamides to olefins has been shown to proceed by a radical chain mechanism as expected (3)). We also compared the photo-

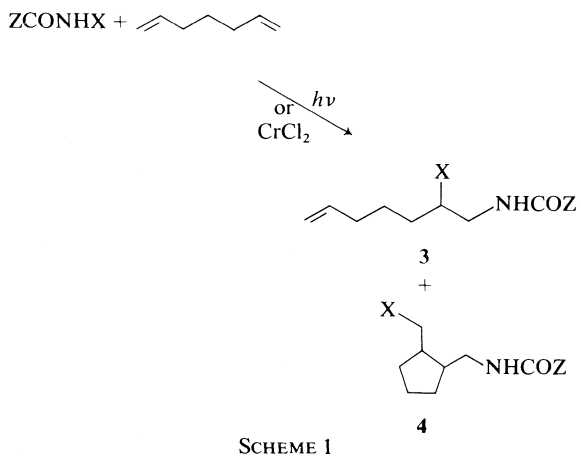
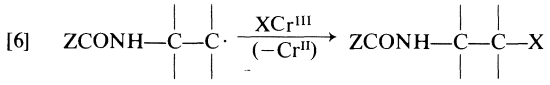


SCHEME 1

chemical and the chromous chloride promoted addition of two *N*-chloroamides to 1,6-heptadiene (**2**), under similar conditions of solvent and temperature, with the aim of gaining some information on the transfer step of the chromous chloride initiated additions. A classical chain mechanism ([2] and [3]) has been considered more probable than a redox chain mechanism ([2] and [6]) mainly on the basis of the low redox potential of the chromic ion (2).



Results and Discussion

The radical addition of *N*-haloamides **1** to 1,6-heptadiene (**2**) was more complicated than shown in Scheme 1 and led to complex mixtures of up to seven different types of adducts, plus products resulting from the halogenation of **2** (except in the chromous chloride initiated reactions), and some dimers and/or telomers. No attempt was made to isolate the products of halogenation and the telomers. The structures of the adducts, determined by ir, ^{1}Hmr, and mass spectrometry (see Experimental) are shown in Scheme 2 with the probable mechanism of their formation: horizontal reactions involve additions of radicals and halogen-atom transfers; vertical reactions involve hydrogen abstraction (RH = **2** and/or solvent) by alkyl radicals and/or their chromium(II) reduction in the chromous chloride promoted additions.[5] The adducts **4** and **6** were obtained as a mixture of *cis* and *trans* isomers (with one isomer predominating) according to vpc analysis, and no attempt was made to separate the two isomers. The ^{1}Hmr spectrum of a mixture of *cis* and *trans* **4** showed either two close doublets or a broadened doublet at ca. 0.9 ppm for the methyl group. In the ^{1}Hmr spectrum of mixtures of *cis* and *trans* **6**, there was no detectable change upon varying the proportions of the two isomers. A similar observation was made by Brace (5) for an analogous compound resulting from the radical addition of carbon tetrachloride to **2**.

The yields of adducts together with the reaction conditions are recorded in Table 1. The adducts **3** and **5** (transfer), and **4** and **6** (rearrangement) account for more than 90% of the addition products. The yields of the two-to-one adduct **5** represent maximum yields since they are based on chromatographic fractions containing **5** as well as dimers and/or telomers from which **5** could be isolated pure in a few cases only (see Table 1, footnote *c*).

The results of Table 1 show that, for the photochemical additions at 15–20°C, the ratio of transfer to rearrangement is larger for X = Br than for X = Cl as expected (compare entries 6 and 4) and increases with Z in the order $CH_3 < ClCH_2 < C_2H_5O \leq CCl_3 \sim CF_3$ (entries 1 to 5). The parallel with the variation of the 1,2-addition to 1,H-addition ratio, for the chromous chloride promoted additions of the same *N*-chloroamides to cyclohexene, is striking. Thus our hypothesis is confirmed: the reactivity of ZCONHX as an halogen-atom donor towards an alkyl radical increases with the electron-withdrawing power of the ZCO moiety. This is shown also by the variation of the relative proportions of adducts **4** and **6**. Adduct **4** results from halogen-atom transfer onto the intermediate radical B whereas adduct **6** results from hydrogen-atom abstraction by radical B (Scheme 2). As the reactivity of ZCONHX as an halogen donor increases, the **4**/**6** ratio should increase, and it does with the electron-withdrawing character of the ZCO moiety (entries 1 to 5).

To see whether or not the nature of the transfer step is the same for the chromous chloride promoted additions and the photochemical additions, we compared the two initiation methods, using *N*-chlorochloroacetamide (**1***b*) and *N*-chlorotrichloroacetamide (**1***d*), under similar conditions of solvent and temperature, that is in methanol–chloroform at ca. −70°C (Table 1, entries 7 to 10). For both methods of initiation, the chain-transfer step is faster with $Z = CCl_3$ than with $Z = ClCH_2$ as shown by the larger transfer to rearrangement and **4**/**6** ratios obtained with **1***d* (compare entries 7 and 8, 9 and 10). We also carried out the photochemical addition of **1***d* in the presence of a stoichiometric amount of chromic chloride and found that, within the limit of experimental errors, the presence of chromic ions had practically no effect

[5] It has been shown by deuterium incorporation experiments that, in the chromous chloride promoted addition of *N*-haloamides to olefins, nonhalogenated adducts, termed 1,H-adducts, result mainly from chromium(II) reduction of an intermediate radical then protonolysis (2).

[a]To minimize the formation of **5**, an excess of olefin was used. By using 3 mol of **2** per mole of **1**, less than 5% of dimers and/or telomers was formed.
[b]The yields are based on **1** and in many cases represent yields determined by integration of the ^{1}Hmr spectrum of a mixture of two compounds (see the Experimental).
[c]Maximum yields (see the text). Compounds **5***c*, **5***e*, and **5***f* could be isolated pure in 2, 6, and 17% yields, respectively.
[d]t = transfer, r = rearrangement. Half the yield of **5** represents the amount of **3** converted to **5**.
[e]Chromous chloride promoted additions to cyclohexene, taken from ref. 2.
[f]The reaction was carried out twice and the first value corresponds to the experiments described in the Experimental and to the yields given in the table.
[g]The adduct **6***e* was not detected in the chromatographic fractions and we assume that we would have been able to detect 3% of it.

on the transfer to rearrangement and **4**/**6** ratios (compare entries 10 and 11).

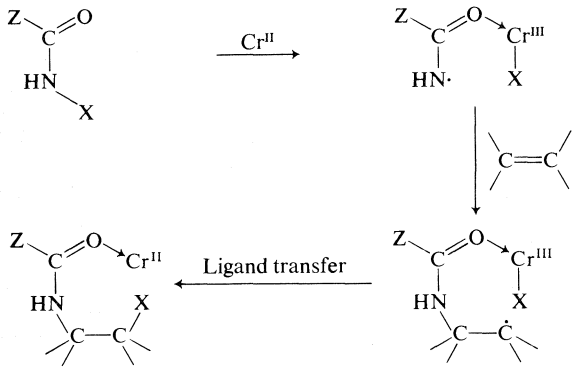
The differences in the **4**/**6** ratios observed when comparing the two methods of initiation (entries 7 and 9, 8 and 10) can be accounted for by different mechanisms of formation of **6**. In the chromous chloride promoted additions, **6** is most likely formed by chromium(II) reduction of the intermediate radical B followed by protonolysis of the carbon–chromium bond (Scheme 2). In the photochemical additions, the formation of **6** involves hydrogen-atom abstraction by radical B from the solvent and/or the olefin (Scheme 2). It is noteworthy that the photochemical additions in methylene chloride led to larger **4**/**6** ratios than the photochemical additions in chloroform–methanol and this most probably reflects the fact that chloroform is more reactive towards the alkyl radical B than methylene chloride.[6] In fact the main source of hydrogen in the additions carried out in methylene chloride as solvent could be the allylic hydrogens of **2**.

As for the differences in the transfer to rearrangement ratios observed between the two modes of initiation (compare entries 7 and 9, 8 and 10), we believe they could be attributed to the fact that it was not possible to reproduce exactly the same reaction conditions, even when the photochemical additions were carried out in the presence of chromic chloride. An explanation based on different mechanisms for the chain-transfer step in the two modes of initiation seems less probable. Indeed, if a ligand transfer [6] was involved in the chromous chloride promoted additions, the influence of Z on the rate of the transfer step should have been smaller than in the photochemical additions, even if the halochromic ion participating in the ligand transfer was directly bonded to the amido group as depicted in Scheme 3 (ZCONHX could act as a bidentate ligand in the initiation step (2)); Z would then be farther away from the reacting centers than in an halogen-atom transfer from ZCONHX. In fact, the effect of Z appears to be similar with the two methods of initiation and even somewhat greater with chromous chloride: $CrCl_2$, $t/r(CCl_3) \sim 10 \times t/r(ClCH_2)$; *hv*, $t/r(CCl_3) \sim 7 \times t/r(ClCH_2)$ (see entries 7 to 10).

Conclusion

This work shows that the reactivity of *N*-haloamides as halogen-atom donors to alkyl radicals

[6]Chloroform has been shown to be more reactive towards $CH_3^\bullet$ radicals than methylene chloride (6). As the reactivity of different hydrogen donors towards a given alkyl radical (nonpolar) should depend mainly on D(C—H) of the donor, methylene chloride and methanol might have similar reactivities: D(C—H) $CH_2Cl_2 \sim D$(C—H) $CH_3OH \sim 94$ kcal mol^{-1} (7).



SCHEME 3

increases with the electron-withdrawing power of the acyl moiety, which indicates that the transition state has polar character.

The increase of the rate of the chain-transfer step with the electron-withdrawing character of the acyl group, in the chromous chloride promoted additions, is better interpreted in terms of a classical chain mechanism but offers no conclusive evidence against a redox chain mechanism. Both mechanisms could be involved as already suggested (8).

Experimental

The pertinent general information has been given in ref. 1. Most of the ^{1}Hmr spectra were recorded on a Bruker WP-60 spectrometer.

N-*Haloamides*

The *N*-chloroamides were prepared by the sodium hypochlorite method (9); their iodometric purity will be indicated when lower than 99%. *N*-Bromo-2,2,2-trichloroacetamide (**1***f*) was prepared from trichloroacetamide and acetylhypobromite (10): mp 123–124°C, 99% iodometric purity, 92% yield.

Photochemical Additions

The uv irradiations were carried out in a Rayonnet RPR-100 reactor equipped with 16 2537 Å lamps. For the reactions at 15–20°C, a Vycor cell cooled with tap water was used. The jacketed Vycor cell shown in Fig. 1 was used for the reactions at −70°C, the cooling mixture (methanol saturated with Dry Ice) being placed in the central cavity A. The solvents used were dry: methylene chloride and chloroform freshly distilled from P_2O_5, absolute methanol. Nitrogen was passed through the solution for 10 min before irradiating and a slow stream of nitrogen was maintained throughout the irradiation which was stopped when no more *N*-haloamide was present (negative starch–iodide paper test). The crude product was separated by preparative-layer chromatography (plc) on silica gel using a continuous elution system. Owing to the number of compounds formed and their close R_f values, fractions containing a mixture of two compounds were often obtained. Their relative proportions (molar ratios) were determined by ^{1}Hmr spectroscopy unless otherwise stated. Samples > 95% pure (by tlc and vpc) could be obtained after further separation but not always. Only those compounds which could be readily purified by crystallization were submitted to a microanalysis. Compounds **3***a* and **4***a*, and those resulting from the addition of **1***d* and **1***f* (Z = CCl_3) underwent decomposition upon vpc analysis. The reaction conditions together with the isolation of the various

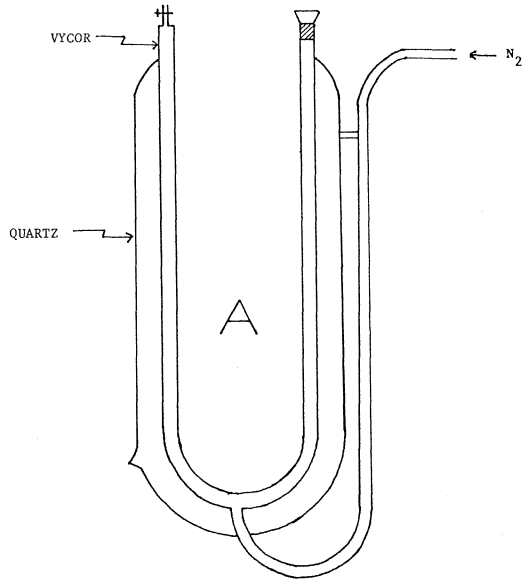


FIG. 1. Cell for low-temperature photolyses.

compounds are described below. The characteristic infrared absorptions and mass spectral data are recorded in Table 2. The ^{1}Hmr spectral data are given below for each compound isolated. The protons on the carbon bearing the amido group were identified by irradiating the NH or by exchanging the NH with D_2O. The CH_2X protons of compounds **4** and **8**, the CH_2N protons of compounds **3**, **4**, and **6**, represent the AB part of an ABX system (with further coupling with the NH for the CH_2N protons). The average chemical shift of both protons is reported together with the number of lines and the apparent *J* values (spectral splittings). When there are a great number of lines as for the CH_2N protons of compounds **3** and **5**, the chemical shift of both extreme lines is given.

N-*Chloroacetamide (1a)*

N-Chloroacetamide (**1***a*) (0.965 g, 97%, 10 mmol) and 1,6-heptadiene (**2**) (2.88 g, 30 mmol) in methylene chloride (100 ml) were irradiated at ca. 15°C for 2 h. The solvent was evaporated and the crude product separated by column chromatography with hexane – ethyl acetate 1:1 to give five main fractions. The first fraction (798 mg) contained halogenated products and was not investigated further. The second fraction (32 mg) was identified as *2-acetylamino-1-chloro-6-heptene* (**8***a*) (1%) by ir, mass, and ^{1}Hmr spectroscopy: δ($CDCl_3$):0.9–1.7 (4H), 2.1 (2H), 3.67 (4 lines, *J* = 3.5 and 4.0 Hz, CH_2Cl), 4.1 (m, H_2), 4.85 (m, H_7), 5.08 (m, H_7), and 5.4–6.2 ppm (H_6 + NH). The third fraction consisted of a mixture which, by further separation by plc (hexane – ethyl acetate 2:1), yielded *1-acetylamino-2-chloro-6-heptene* (**3***a*) contaminated by small amounts of **6***a* (76 mg, ~4%) and *1-(acetylamino)methyl-2-methylcyclopentane* (**6***a*) (78 mg, 5%) characterized by their ir, mass, and ^{1}Hmr spectra: **3***a*, δ($CDCl_3$):0.9–2.7 (6H), 2.03 (s, $COCH_3$), 2.9–4.1 (3H: CH_2N + H_2), 4.85 (m, H_7), 5.10 (m, H_7), 5.4–6.2 ppm (H_6 + NH); **6***a*, δ($CDCl_3$):0.87 (d, *J* = 6.5 Hz, CH_3), 0.92 (d, *J* = 6.5 Hz, CH_3), 1.0–2.2 (8H), 1.97 (s, $COCH_3$), 1.98 (s, $COCH_3$), 3.2 (m, CH_2N), and 5.5 ppm (m, NH). The fourth fraction (935 mg) consisted of a 2.5:1 mixture of **4***a* (37%) and **6***a* (15%, total yield of 20%). The fifth fraction (83 mg) was identified as *1-(acetylamino)methyl-2-chloromethylcyclopentane* (**4***a*) (5%, total yield of 42%) by ir, mass, and ^{1}Hmr spectro-

scopy: δ($CDCl_3$):1.0–2.0 (6H), 2.00 (s, $COCH_3$), 2.3 (m, 2H), 3.18 (broad t, J = 6 Hz, $\Delta\nu_{1/2}$ = 14 Hz; CH_2N), 3.52 (3 lines, J = 6 and 7 Hz, CH_2Cl), and 5.9 ppm (m, NH).

N-*Chlorochloroacetamide (**1**b)*

At 15°C in CH_2Cl_2—The *N*-chloroamide **1***b* (330 mg, 2.5 mmol) and **2** (720 mg, 7.5 mmol) in CH_2Cl_2 (25 ml) were irradiated for 1.5 h. Separation by plc (ether – hexane 1:2.5) gave three main fractions. The least polar fraction (102 mg) consisted of a 2:3 mixture of *1-chloroacetylamino-2-chloro-6-heptene* (**3***b*) (8%) and *1-(chloroacetylamino)methyl-2-methylcyclopentane* (**6***b*) (12%). Further separation (ether – hexane 1:5) allowed the isolation of homogeneous samples of **3***b* and **6***b*, both compounds being characterized by their ir, mass, and ^{1}Hmr spectra: **3***b*, δ($CDCl_3$):1.0–2.4 (6H), 3.4–4.2 (CH_2N + H_2), 4.08 (s, $ClCH_2CO$), 4.85 (m, H_7), 5.09 (m, H_7), 5.5–6.05 (H_6), and 6.4 ppm (m, NH); **6***b*, δ($CDCl_3$):0.89 (d, J = 6.5 Hz, CH_3), 1.1–2.4 (8H), 3.28 (broad t, J ~ 5.5 Hz, $\Delta\nu_{1/2}$ = 15 Hz, CH_2N), 4.05 (s, $COCH_2Cl$), and 6.9 ppm (m, NH). The second fraction was identified as *1-(chloroacetylamino)methyl-2-chloromethylcyclopentane* (**4***b*) (249 mg, 45%) by ir, mass, and ^{1}Hmr spectroscopy: δ($CDCl_3$):1.1–2.0 (6H), 2.3 (m, 2H), 3.32 (broad t, J ~ 6 Hz, $\Delta\nu_{1/2}$ ~ 14 Hz, CH_2N), 3.52 (3 lines, J = 6 and 7 Hz, CH_2Cl), 4.05 (s, $COCH_2Cl$), and 6.76 ppm (m, NH). The third fraction (20 mg) was probably a mixture of **5***b* and telomers and was not investigated further.

At −70°C in $CHCl_3$–CH_3OH—The *N*-chloroamide **1***b* (0.517 g, 4 mmol) and **2** (1.15 g, 12 mmol) in a mixture of chloroform (25 ml) and methanol (20 ml) were irradiated at −70°C for 8 h. Since the reaction mixture was acidic, it was washed with a saturated $NaHCO_3$ solution, dried, then the solvent evaporated. The separation led to four main fractions. The least polar fraction (35 mg) consisted of a 1:1 mixture of **6***b* (2%) and most probably *1-chloro-2-(chloroacetylamino)-methyl-6-heptene* (**8***b*) (2%): ν_{max} (CCl_4):3420, 3060, 3010, 1670, 1640 (sh), 1530, 975, and 980 cm^{-1}; δ($CDCl_3$):0.89 (d, J = 6.5 Hz, CH_3 of **6***b*), 3.28 (broad t, J ~ 5.5 Hz, CH_2N of **6***b*), 3.68 (4 lines, J = 3.5 and 4 Hz, CH_2Cl of **8***b*), 4.05 and 4.08 (two s, $ClCH_2CO$), 4.15 (m, H_2 of **8***b*), 4.85, 5.08, and 5.5–6.1 (olefinic H's of **8***b*), and 6.7 ppm (NH). This fraction was not investigated further. The second fraction (218 mg) consisted of a 1:6 mixture of **3***b* (4%) and **6***b* (24%). The third fraction (112 mg) was a 2:1 mixture of **4***b* (9%) and **6***b* (5%, total yield of 31%). Fraction four (23 mg) was probably a mixture of **5***b* and telomers and was not investigated further.

N-*Chlorourethane (**1**c)*

The *N*-chloroamide **1***c* (340 mg, 91%, 2.5 mmol) and **2** (720 mg, 7.5 mmol) in CH_2Cl_2 (25 ml) was irradiated for 1 h at 15°C. Separation of 70% of the crude product (ether – hexane 1:5) gave three main fractions. The least polar fraction (107 mg) consisted of a 2.2:1 mixture of *2-chloro-1-ethoxycarbonylamino-6-heptene* (**3***c*) (20%) and *1-(ethoxycarbonylamino)methyl-2-methylcyclopentane* (**6***c*) (9%). The two products were separated by preparative vpc and characterized by their ir, mass, and ^{1}Hmr spectra: **3***c*, δ($CDCl_3$):1.25 (t, J = 7 Hz, OCH_2CH_3), 1.1–2.3 (6H), 3.0–3.8 (CH_2N), 3.0 (m, H_2), 4.13 (q, J = 7 Hz, OCH_2CH_3), 4.85 (m, H_7), 5.10 (m, H_7 + NH), and 5.5–6.15 ppm (H_6); **6***c*, δ($CDCl_3$):0.89 (d, J = 6.5 Hz, CH_3), 1.24 (t, J = 7 Hz, OCH_2CH_3), 1.0–2.3 (8H), 3.13 (broad t, J ~ 5.5 Hz, $\Delta\nu_{1/2}$ = 14 Hz, CH_2N), 4.10 (q, J = 7 Hz, OCH_2CH_3), and 4.52 ppm (broad t, J ~ 7 Hz, NH). The second fraction consisted of *2-chloromethyl-1-(ethoxycarbonylamino)methylcyclopentane* (**4***c*) (196 mg, 51%) characterized by its ir, mass, and ^{1}Hmr spectra: δ($CDCl_3$): 1.22 (t, J = 7 Hz, OCH_2CH_3), 1.1–2.0 (6H), 2.25 (m, 2H), 3.15 (6 lines, J = 7 Hz, CH_2N), 3.51 (4 lines, J = 6.5 and 7 Hz, CH_2Cl), 4.09 (q, J = 7 Hz, OCH_2CH_3), and 4.98 ppm (m, NH). The last fraction (40 mg) contained telomers and some *1,7-bis(ethoxycarbonylamino)-2,6-dichloroheptane* (**5***c*) which could be isolated (13 mg, 2%) by further separation by tlc, mp 114–117°C. An additional quantity was obtained by carrying out the addition with 5 mmol of **1***c*, and 2.5 mmol of **2**. Recrystallization from methylene chloride – ether afforded the analytical sample, mp 120–121°C; ir and mass spectra, see Table 2; δ($CDCl_3$): 1.25 (t, J = 7 Hz, OCH_2CH_3), 1.7 (m, 6H), 3.45 (m, $\Delta\nu_{1/2}$ ~ 25 Hz, 4H: H_1 + H_7), 4.0 (m, H_2 + H_6), and 5.12 ppm (broad t, J ~ 7 Hz, NH). *Anal.* calcd. for $C_{13}H_{24}Cl_2N_2O_4$: Cl 20.64; found: Cl 20.22.

N-*Chlorotrichloroacetamide (**1**d)*

At 15°C in CH_2Cl_2—The *N*-chloroamide **1***d* (503 mg, 98%, 2.5 mmol) and **2** (720 mg, 7.5 mmol) in CH_2Cl_2 (25 ml) were irradiated for 1 h. Separation of 60% of the crude product (ether–hexane 1:10) gave four main fractions. The first fraction (31 mg) consisted of a 1:1 mixture of *1-chloro-2-trichloroacetylamino-6-heptene* (**8***d*) (4%) and *2-methyl-1-(trichloroacetylamino)methylcyclopentane* (**6***d*) (4%). Further separation of a thin-layer plate gave samples of **8***d* and **6***d* contaminated, respectively, by small amounts (< 10%) of **6***d* and **8***d*. These samples were characterized by ir, mass, and ^{1}Hmr spectroscopy: **8***d*, δ($CDCl_3$):1.1–2.3 (6H), 3.72 (4 lines, J = 3.5 and 4 Hz, CH_2Cl), 4.18 (m, $\Delta\nu_{1/2}$ ~ 23 Hz, H_2), 4.85 (m, H_7), 5.10 (m, H_7), 5.5–6.1 (H_6), and 6.65 ppm (m, NH); **6***d*, δ($CDCl_3$):0.90 (d, J = 6.5 Hz, CH_3), 1.1–2.3 (8H), 3.33 (6 lines, J ~ 6 Hz, CH_2N), and 6.6 ppm (m, NH). The second fraction consisted of *2-chloro-1-trichloroacetylamino-6-heptene* (**3***d*) (85 mg, 20%) characterized by its ir, mass, and ^{1}Hmr spectra: δ($CDCl_3$):1.2–2.4 (6H), 3.20–4.05 (several peaks, CH_2N), 4.1 (m, $\Delta\nu_{1/2}$ ~ 16 Hz, H_2), 4.88 (m, H_7), 5.11 (m, H_7), 5.5–6.13 (H_6), and 7.05 ppm (m, NH). The third fraction consisted of *2-chloromethyl-1-(trichloroacetylamino)methylcyclopentane* (**4***d*), mp 50–63°C (218 mg, 50%). It was recrystallized once from ether, mp 67–71°C: ir and mass spectra, see Table 2; δ($CDCl_3$):1.2–2.0 (6H), 2.36 (m, 2H), 3.35 (t, J = 6 Hz, CH_2N), 3.53 (d, J = 6 Hz, CH_2Cl), and 6.86 ppm (m, NH). *Anal.* calcd. for $C_9H_{13}Cl_4NO$: Cl 48.40; found: Cl 48.56. The last fraction (50 mg) contained trichloroacetamide, telomers, and probably some **5***d* but the latter compound could not be obtained pure upon further separation (ether–hexane 1:1); a mixture of **5***d* and telomers was obtained (37 mg).

At −70°C in $CHCl_3$–CH_3OH—The *N*-chloroamide **1***d* (757 mg, 3.8 mmol) and **2** (1.10 g, 11.4 mmol) in chloroform (25 ml) – methanol (20 ml) was irradiated at −70°C for 4 h. The separation (ether–hexane 1:20) afforded five main fractions. The least polar fraction (34 mg) consisted of a 1:2 mixture of **6***d* (1%) and *2-trichloroacetylamino-6-heptene* (**9***d*) (2%). Further separation on a thin plate afforded an homogeneous sample of **9***d* characterized by its ir, mass, and ^{1}Hmr spectra: δ($CDCl_3$):1.23 (d, J = 6.8 Hz, CH_3), 1.1–1.6 (4H), 2.08 (m, 2H allylic), 3.98 (m, $\Delta\nu_{1/2}$ = 29 Hz, H_2), 4.85 (m, H_7), 5.08 (m, H_7), 5.5–6.15 (H_6), and 6.33 ppm (m, NH). The second fraction (98 mg) consisted of a 1:3.5 mixture of **8***d* (2%) and **6***d* (7%, total yield 8%). The third fraction consisted of **3***d* homogeneous by tlc (248 mg, 22%). The fourth fraction consisted of **4***d* (207 mg, 19%), mp 55–65°C. The more polar fraction (314 mg) was separated further (ether–hexane 1:1) to yield trichloroacetamide and a mixture of telomers containing probably compound **5***d* (99 mg). It was not investigated further.

At −70°C in $CHCl_3$–CH_3OH and in the presence of $CrCl_3$—The *N*-chloroamide **1***d* (498 mg, 92%, 2.3 mmol), **2** (662 mg, 6.9 mmol), and hexahydrated chromic chloride (2.3 ml of a 1 *M* solution in methanol, 2.3 mmol) in chloroform (17 ml) – methanol (11 ml) were irradiated for 8 h. Separation as above gave 66 mg of a mixture of **9***d* (3%) and **6***d* (7%), 115 mg of **3***d* (17%), 144 mg of **4***d* (21%), and 100 mg of a mixture which,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

by further separation, gave a mixture (56 mg) of telomers and **5***d*, and trichloroacetamide.

N-*Chlorotrifluoroacetamide* (*1*e)

The *N*-chloroamide **1***e* (384 mg, 96%, 2.5 mmol) and **2** (720 mg, 7.5 mmol) in methylene chloride (25 ml) were irradiated for 1 h. Separation of 60% of the crude product (ether–hexane 1:5) gave three fractions. The least polar fraction (8 mg) consisted of *1-chloro-2-trifluoroacetylamino-6-heptene* (**8***e*) (2%) characterized by its ir and ^{1}Hmr spectra: δ($CDCl_3$):1.3–2.3 (6H), 3.69 (4 lines, J = 3.5 and 4 Hz, CH_2Cl), 4.23 (m, $\Delta\nu_{1/2}$ = 22 Hz, H_2) 4.85 (m, H_7), 5.09 (m, H_7), 5.5–6.1 (H_6), and 6.45 ppm (NH). The second fraction (312 mg) consisted of 1:3.3 mixture (by ^{1}Hmr and vpc) of *2-chloro-1-trifluoroacetylamino-6-heptene* (**3***e*) (20%) and *2-chloromethyl-1-(trifluoroacetylamino)methylcyclopentane* (**4***e*) (66%). These two compounds were separated by preparative vpc and characterized by their ir, mass, and ^{1}Hmr spectra: **3***e*, δ($CDCl_3$):1.3–2.3 (6H), 3.1–4.3 (3H: CH_2N + H_2), 4.85 (m, H_7), 5.09 (m, H_7), 5.46–6.15 (H_6), and 6.8 ppm (m, NH); **4***e*, δ($CDCl_3$):1.3–2.0 (6H), 2.37 (m, 2H), 3.38 (t, J = 6 Hz, CH_2N), 3.53 (d, J = 6 Hz, CH_2Cl), and 6.8 ppm (m, NH). The third fraction (36 mg) crystallized from a chloroform–ether solution to afford *1,7-bis(trifluoroacetylamino)-2,6-dichloroheptane* (**5***e*) (18 mg, 6%), mp 151–153°C. One recrystallization afforded the analytical sample, mp 153–154°C; ir and mass spectra, see Table 2; δ($CDCl_3$):1.75 (m, 6H), 3.4–3.8 (4H: CH_2N), 4.0 (m, H_2 + H_6), and 7.15 ppm (m, NH). *Anal.* calcd. for $C_{11}H_{14}Cl_2F_6N_2O_2$: Cl 18.13; found: Cl 17.98.

N-*Bromotrichloroacetamide* (*1*f)

The *N*-bromoamide **1***f* (664 mg, 91%, 2.5 mmol) and **2** (720 mg, 7.5 mmol) in methylene chloride (25 ml) was irradiated for 0.75 h. The crude product was taken up in ether and the adduct **5***f* (16 mg, 2%), mp 159–163°C, precipitated out (see below for characterization). Part of the filtrate (50%) was separated (ether–hexane 1:10) into three main fractions. The least polar fraction consisted of *2-bromo-1-trichloroacetylamino-6-heptene* (**3***f*) (232 mg, 55%) characterized by its ir, mass, and ^{1}Hmr spectra: δ($CDCl_3$):1.2–2.3 (6H), 3.3–4.1 (CH_2N), 4.15 (m, CH_2Cl), 3.85 (m, H_7), 5.5–6.3 (H_6), and 7.3 ppm (m, NH). The second fraction (30 mg) contained *2-bromomethyl-1-(trichloroacetylamino)methylcyclopentane* (**4***f*) (7%) contaminated with small amounts of an olefinic compound (most probably **3***f*). It was not purified further: ν_{max} ($CHCl_3$):3430, 1720, and 1515 cm^{-1} (amido group); δ($CDCl_3$):1.2–2.0 (6H), 2.4 (m, 2H), 3.4 (m, $\Delta\nu_{1/2} \sim$ 15 Hz, CH_2Br + CH_2N), 6.8 (m, NH), and very weak absorptions at 4.85 and 5.10 ppm due to the presence of an olefinic compound. From the third fraction (92 mg) *1,7-bis(trifluoroacetylamino)-2,6-dichloroheptane* (**5***f*) (54 mg, 15%), mp 162–165°C, crystallized out from ether. Recrystallization from methylene chloride – ether afforded the analytical sample, mp 167–168°C; ir and mass spectra, see Table 2; δ(CD_2Cl_2):1.80 (m, 6H), 3.5–3.9 (4H: CH_2N), 4.15 (m, H_2 + H_6), and 6.83 ppm (m, NH). *Anal.* calcd. for $C_{11}H_{14}Br_2Cl_6N_2O_2$: Br 27.61, Cl 36.75; found: Br 27.3, Cl 37.1.

Chromous Chloride Promoted Additions

The apparatus as well as the procedure for the chromous chloride promoted addition of *N*-haloamides to olefins have been described in ref. 1. The separations were carried out as described for the photochemical additions.

N-*Chlorochloroacetamide* (*1*b)

The *N*-chloroamide **1***b* (423 mg, 3.3 mmol) and **2** (992 mg, 10 mmol) were dissolved in chloroform (19 ml) and methanol (12 ml) at ca. −70°C. The 1 *M* methanolic chromous chloride solution was added dropwise over 3 h (6.5 ml, 6.5 mmol). Water (20 ml) was added and the mixture was rapidly extracted with ether. The aqueous mixture was kept 20 h at room temperature then extracted with methylene chloride. Separation of the residue (235 mg) from the extraction with ether gave two fractions: (*a*) a 1:2 mixture (150 mg) of **3***b* (7.5%) and **6***b* (15%); (*b*) **4***b* (34 mg, 5%). Separation of the residue (204 mg) from the methylene chloride extraction gave two fractions: (*a*) **6***b* (167 mg, 27%); (*b*) a 1:1 mixture (26 mg) of **3***b* (2%, total yield 10%) and **6***b*, (2%, total yield of 44%). The aqueous phase from the above extractions were continuously extracted with methylene chloride for 3 days. Separation of the residue (97 mg) gave three fractions: (*a*) *2-chloroacetylamino-6-heptene* (**9***b*) (11 mg, 2%) characterized by its ir, mass, and ^{1}Hmr spectra: δ($CDCl_3$):1.17 (d, J = 6.5 Hz, CH_3), 1.2–1.7 (4H), 2.05 (m, 2H), 4.03 (s over a m, respectively $ClCH_2CO$ and H_2), 4.84 (m, H_7), 5.07 (m, H_7), 5.5–6.1 (H_6), and 6.4 ppm (NH); (*b*) *1-chloroacetylamino-6-heptene* (**7***b*) (17 mg, 3%) characterized by its ir, mass, and ^{1}Hmr spectra: δ($CDCl_3$):1.1–1.8 (6H), 2.10 (m, 2H), 3.31 (broad q, $J \sim$ 6.5 Hz, CH_2N), 4.85 (m, H_7), 5.08 (m, H_7), 5.5–6.1 (H_6), and 6.6 ppm (NH); (*c*) chloroacetamide (44 mg, 15%), mp 114–116°C.

N-*Chlorotrichloroacetamide* (*1*d)

The *N*-chloroamide **1***d* (798 mg, 4 mmol) and **2** (1.15 g, 12 mmol) were dissolved in chloroform (25 ml) and methanol (15 ml) at ca. −70°C. The 1 *M* methanolic chromous chloride solution was added over 2 h (5.5 ml, 5.5 mmol). Water (20 ml) was added and the mixture was stirred at room temperature for 1 h then extracted with methylene chloride. Upon evaporating the solvent, trichloroacetamide, mp 140°C, crystallized out (240 mg, 37%). Separation of the filtrate (ether–hexane 1:20) gave five fractions: (*a*) **9***d* (24 mg, 2%); (*b*) a 3:1 mixture (46 mg) of **6***d* (3%) and **8***d* (1%); (*c*) **3***d* (268 mg, 23%); (*d*) **4***d* (78 mg, 7%); (*e*) a mixture (51 mg) of telomers, trichloroacetamide, and probably also **5***d* (not investigated further). Continuous extraction of the aqueous phase by methylene chloride for 3 days afforded an additional amount of **9***d* (22 mg, 2%; total yield, 4%) and **6***d* (11 mg, 1%; total yield of 4%).

M. MOMENTEAU, J. MISPELTER, B. LOOCK, and J. M. LHOSTE. Can. J. Chem. **56**, 2598 (1978).

^{15}N-Etioporphyrin I was prepared by polycondensation of 5-hydroxymethylpyrrole-2-carboxylic acid, obtained via the Bullock route. This method gives an isomerically pure porphyrin with a high yield. The labelled compound was analyzed by nmr of the free base, of the dicationic form, and of the zinc complex. The spectrum of the free base shows a rapid tautomerism of the NH protons at 34°C which disappears at low temperature. All spectra reveal several long-range proton–nitrogen-15 interactions. The electron spin resonance spectrum of the paramagnetic complex of this porphyrin with copper-63 is readily analyzed. This analysis was extended to the spectra of the complexes obtained with natural copper and with nitrogen-14 porphyrins.

M. MOMENTEAU, J. MISPELTER, B. LOOCK et J. M. LHOSTE. Can. J. Chem. **56**, 2598 (1978).

On a réalisé la synthèse de la ^{15}N-étioporphyrine par polycondensation du pyrrole 2-carboxylique, 5-hydroxyméthyle qui a été préparé par la méthode de Bullock. La porphyrine, isomériquement pure, est obtenue avec un haut rendement. Son analyse par rmn du proton, ainsi que celles de sa forme dicationique et de son complexe de zinc, sont décrites. Le spectre de la base libre révéle un tautomérisme rapide des protons NH à 34°C, qui disparait à basse température. D'autre part tous les spectres montrent des interactions à longue distance entre les protons du cycle tétrapyrrolique et les azotes-15. Le complexe ^{63}Cu – ^{15}N-étioporphyrine I a été également étudié par rpe. A partir de l'analyse de ce spectre, une analyse complète des spectres des complexes obtenus avec le cuivre naturel et avec les porphyrines azote-14 a pu être faite.

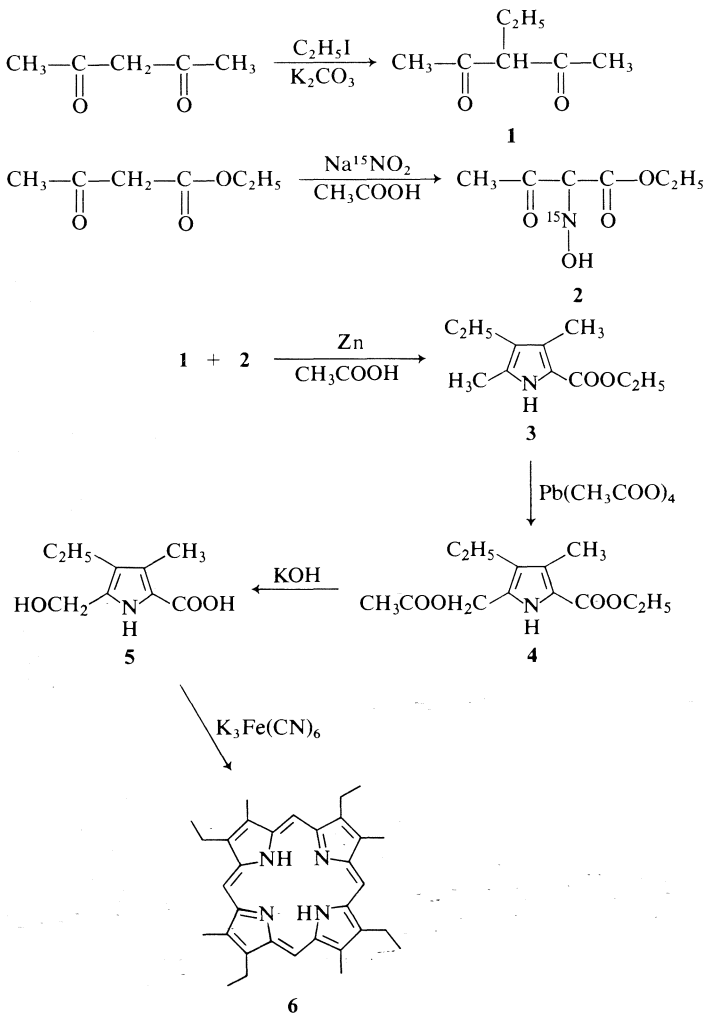
Introduction

Details of the electronic and stereochemical structures of porphyrins and related compounds may be investigated by the appropriate utilization of isotopically substituted compounds in electron or nuclear magnetic resonance experiments. Among the labels in common use, deuterium and carbon-13 are most prevalent (1, 2). Nitrogen-15 ($I = \frac{1}{2}$) appears to be also a favorable label. ^{15}N-enriched porphyrins have been investigated by Boxer *et al.* (2) and Irving and Lapidot (3). The compounds were obtained with a moderate isotopic enrichment via biosynthetic methods. Gust and Roberts (4) have described the chemical synthesis of ^{15}N-mesotetraphenylporphine prepared from enriched pyrrole but highly enriched etio type porphyrins have not yet been reported. The present paper deals with the preparation of ^{15}N-etioporphyrin I and its metallic derivatives. The method derives from that of Bullock *et al.* (5) and Inhoffen *et al.* (6) and produces with high yield a pure isomer I which has been characterized by proton magnetic resonance.

In addition, the paramagnetic copper complex of this enriched porphyrin was studied by esr in dimethylformamide or diluted in the free base at room temperature and at 77 K. The spectra could be readily analyzed using a pure copper-63 complex. A similar study has been performed with enriched and natural copper complexes of ^{14}N-etioporphyrin I, providing a complete set of esr data for copper porphyrins.

Results and Discussion

^{15}N-Etioporphyrin I (1,3,5,7-tetraethyl-2,4,6,8-tetramethylporphyrin) was prepared by polycondensation of 5-hydroxymethylpyrrole-2-carboxylic acid by a procedure based on the synthesis described by Inhoffen *et al.* (6) for the preparation of octaethylporphyrin. 3-Ethyl-2,4-pentanedione (**1**), prepared from ethyl iodide and acetylacetone, was condensed with ethyl 3-oxo-2(^{15}N-hydroxyimino)butanoate (**2**) obtained by a direct reaction of ethyl acetoacetate and sodium ^{15}N-nitrite. This condensation is a variation related to that of Fischer and Fink derived from the well-known Knorr synthesis (7). Treatment of the resulting pyrrole, ethyl 3,5-dimethyl-4-ethylpyrrole-2-carboxylate (**3**), with lead tetraacetate gave the acetoxy derivative from which the 3-methyl-4-ethyl-5-hydroxymethylpyrrole-2-carboxylic acid (**5**) was obtained by basic hydrogenolysis. When a solution of this acid derivative was refluxed with potassium ferricyanide, **6** was formed in good yield (18% based upon **3**, after chromatography on silica gel column). This preparation is detailed in the Experimental.



The analysis of the porphyrin (nmr and elemental analysis) confirms that the procedure used has provided a porphyrin of high yield and a single isomer. This is not the case for other methods described for the synthesis of etioporphyrin I (8) or related isomer I porphyrins (9) which gave a mixture of isomers (i.e., I, II, III, IV). The yield of the latter methods of preparation are furthermore much lower. These low yields of cyclization of tetramacrocycle derivatives could be attributed to the formation of linear verdin compounds during the self condensation of the pyrrolic precursors. In addition, Smith (10) has described the preparation of etioporphyrin I from unsymmetrical perbromide pyrromethenes with a high yield but some amounts of verdin were still present. The porphyrin could be also prepared by condensation of a dipyrromethene perbromide and a dipyrromethene hydrobromide obtained from the same pyrrolic derivative **3**, following the method of Rislove *et al.* (11). This more conventional procedure has provided a porphyrin with a lower final yield (12% based upon **3**). Thus, the modifications made in our chemical procedure influence both the yield and the purity of the final product. These two factors are important when the compound is synthesized with isotopically enriched precursors.

^1H *Nuclear Magnetic Resonance Spectra*

The proton nmr spectrum of the ^{15}N-etioporphyrin is shown in Fig. 1. The meso proton resonances centered at 10.08 ppm exhibit a triplet structure whereas those of the ^{14}N-etioporphyrin prepared by identical procedures appear in the same conditions as a single line at 10.08 ppm. The observed splitting (4.55 Hz) in the ^{15}N compound can therefore be attributed to the spin–spin coupling of the meso protons with the nitrogen-15 nuclei of the two adjacent pyrrole rings. Furthermore, the equivalence of the four methine protons establishes the isomeric nature of the porphyrins as etioporphyrin I.

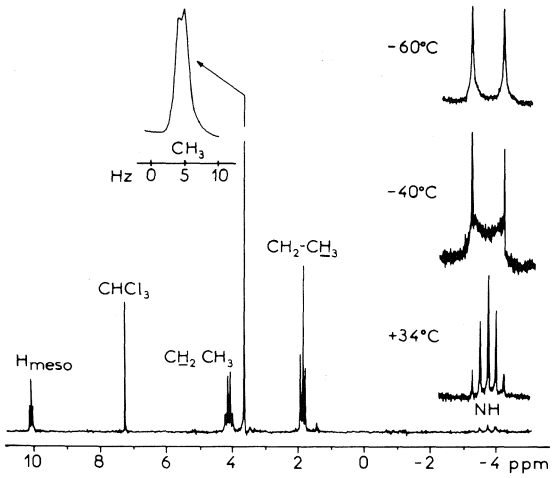

FIG. 1. ^{1}H nuclear magnetic resonance spectrum of ^{15}N-etioporphyrin I in deuteriochloroform at 34°C. On the right side of the figure are shown the NH proton resonances at various temperatures.

The two equivalent pyrrolic NH protons of the free base ^{15}N-porphyrin resonate at -3.7 ppm as a multiplet of relative intensity 1:4:6:4:1 at room temperature. Lowering the temperature to -60°C the multiplet changes into a doublet with a coupling constant of 97.5 Hz equal to the frequency distance of the outer lines in the quintet. This coupling constant is typical of one-bond ^{15}N–^{1}H coupling, as observed in ^{15}N-pyrrole (12) and in pheophytin a (2) and it was also measured in the pyrrolic precursors **3**, **4**, and **5**. The temperature dependence of the multiplet structure of the imino proton resonances of the free base porphyrin is characteristic of an intramolecular exchange process and is essentially identical to that reported for other ^{15}N-labeled porphyrins (3, 13). A particular aspect of the lineshape evolution, not reported until now, is worth further consideration. It can be noted (Fig. 1) that the outer lines of the multiplet do not broaden upon lowering the temperature. The transitions corresponding to these lines connect the energy level with nitrogen spins $\alpha\alpha\alpha\alpha$ and $\beta\beta\beta\beta$ in a X_2ABCD system, where X stands for the protons under observation and ABCD for the nitrogen-15 nuclei. These levels are not modulated in the exchange process at any temperature since the permutation of the A, B, C, and D nuclei leaves the corresponding eigenstate unchanged. These lines should be sensitive only to intermolecular exchange processes, prevented by use of aprotic solvent, or to an intramolecular exchange of the protons between sites having different chemical shift. The latter process should occur in a tautomerism reaction involving adjacent pyrrols, i.e., if the two opposite protons do not jump simultaneously. The lifetime of such an intermediate state appears negligible on the nmr scale down to -60°C in agreement with results obtained by different methods on deuterioporphyrin IX dimethylester (14) and mesotetraphenylporphine (14, 15).

The one-bond $J_{^{15}N,^1H}$ coupling in the dication, obtained by bubbling gaseous hydrochloric acid through the solution, is somewhat smaller (92.5 Hz). This was also observed for other ^{15}N-porphyrin cations (3, 4) and has been interpreted by a change in the nitrogen atom hybridization (3) corresponding to a deformation of the pyrrole rings.

Long-range ^{15}N–^{1}H couplings could also be observed in this porphyrin. The three-bond coupling observed for the methine protons in the free base (4.55 Hz) and in the dication (4.75 Hz) is larger than that previously observed (2) in ^{15}N-labelled pheophytin a and chlorophyll a (3 Hz). We measured also a reduced coupling (2.9 Hz) in the zinc complex of the present porphyrin. These changes could be attributed to structural features but it should be mentioned that we observed a comparable coupling (2.5 Hz) in the starting compounds in which the protons are bonded to a carbon with sp^3 hybridization. The present observations contrast with the strong dependence of $^2J_{^{15}N,^1H}$ and $^3J_{^{15}N,^1H}$ couplings upon protonation of ^{15}N-heterocyclics (16).

Charge dependence is more strictly evidenced in the four-bond nitrogen coupling with the pyrrolic methyl protons. In fact, these protons exhibit a resolved 0.8 Hz splitting (Fig. 1) which could not be assigned by homonuclear decoupling experiments and was assigned to a heteronuclear coupling. A similar four-bond coupling was not resolved in the resonances of the methylene protons of the ethyl groups. However, the linewidth of these latter resonances (2.2 Hz) could mask such an interaction. This coupling disappears in the dication which exhibits a 1.5 Hz splitting of the methyl resonances of the ethyl groups assigned to a five-bond heteronuclear coupling with the nitrogen-15 nucleus.

Pure electronic effects should be at the origin of the still longer range coupling observed in the zinc complex. Indeed, the methine proton resonances exhibit, in addition to the three-bond $^3J_{^{15}N,^1H}$ couplings, a structure consistent with a 1.4 Hz coupling of each proton with two other and still equivalent nitrogen-15 nuclei. Similar couplings have been also observed in chlorophyll a and assigned to a ^5J coupling through the metal ion (2). The lack of sensitivity of this coupling to the nature of the metal ion (Zn or Mg) makes it more plausible to assign it to a ^7J coupling corresponding to a preferred pathway through the porphyrin ring associated with π electron delocalization.

Electron Spin Resonance Spectra of ^{63}Cu – Etioporphyrin I

The presence of both ^{63}Cu and ^{65}Cu with their slightly different gyromagnetic ratios of 0.709 and 0.759, respectively, gives rise to complicated spectra of copper porphyrins and other tetrapyrrolic compounds due to the superimposition of two hyperfine splitting patterns (17, 18). The esr spectra of copper porphyrins are simplified by the use of isotopically enriched ^{63}Cu complexes (19, 20). They are further better resolved in the ^{15}N-labelled compounds because only a five-line superhyperfine splitting pattern of the copper hyperfine lines should be observed, each nitrogen-15 nuclei having a spin of $\frac{1}{2}$.

Indeed, such a well-resolved structure is observed in the low-field parallel components as well as in the highest field portion of the spectrum (Figs. 2 and 3). These latter resonances arise from a singularity which corresponds to a lack of dependence of the resonance field values upon changes in θ (Fig. 2) for orientations of the magnetic field H_0 which differ from the symmetry axes of the complex (21); (the

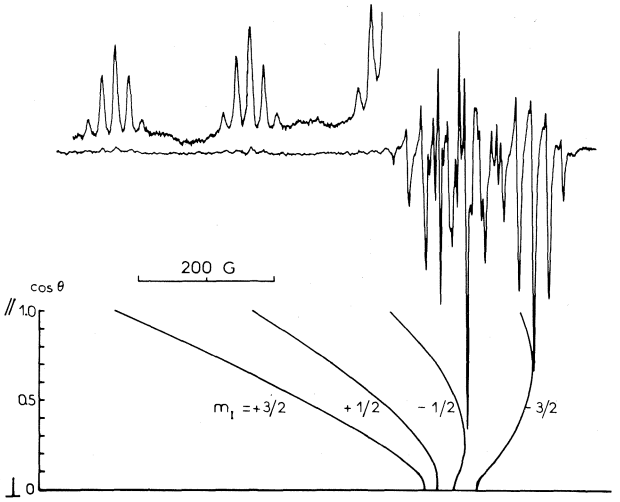

FIG. 2. Electron spin resonance spectrum of $^{63}Cu - ^{15}N$-etioporphyrin I diluted in the free base (1/1000) at 77 K (upper). The resonance fields as a function of $Z = \cos\theta$, where θ is the angle between the magnetic field direction and the symmetry axis of the complex (lower).

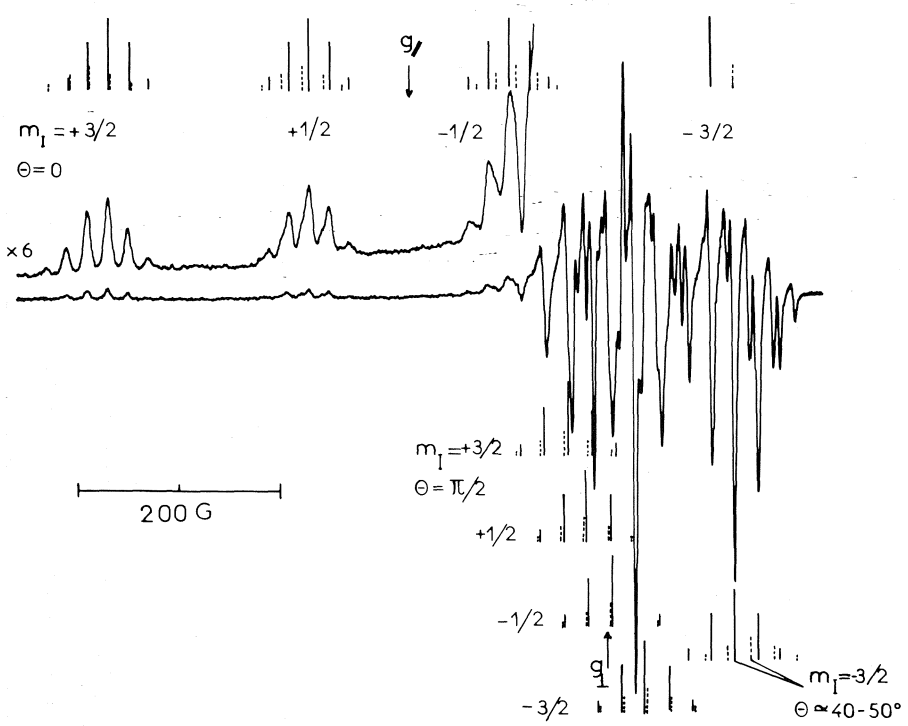

FIG. 3. Electron spin resonance spectrum of natural Cu – ^{15}N-etioporphyrin I diluted in the free base (1/1000) at 77K. The resonance fields indicated as a stick diagram were calculated to second order (22) with parameters of Table 1 and $A(^{65}Cu) = A(^{63}Cu) \times \mu(^{65}Cu)/\mu(^{63}Cu)$. The singularities for noncanonical orientations were obtained from the angular dependence of the resonance fields. The $m_I = -\frac{3}{2}$, $\theta = 0$ resonances were not completely drawn because these lines are completely masked in the experimental spectrum due to their low intensity. Full lines correspond to ^{63}Cu whereas the broken lines correspond to the ^{65}Cu isotope. The intense and sharp line in the high-field part of the spectrum is assigned to the singularity from noncanonical orientation for $m_I = -\frac{1}{2}$ discussed in the text (see also Fig. 2). The corresponding lines are not drawn on this figure.

additional structure visible in this high-field part (Fig. 2) is due to a 10% contamination of the enriched sample by ^{65}Cu–^{15}N-porphyrin). On the contrary, the nitrogen superhyperfine structure is unresolved or poorly resolved in the low-field part of the spectra recorded using porphyrins which are not selectively enriched. The apparent good resolution which may be observed however with the latter compounds in the high-field region is due to the fact that the difference between the ^{63}Cu and ^{65}Cu hyperfine components is approximately equal to the superhyperfine structure due to the ^{14}N nuclei (Table 1). This difference is, however, well resolved in the spectrum of the ^{15}N-labelled porphyrin (Fig. 3) and is readily interpreted using ^{65}Cu hyperfine coupling constants calculated from the measured ^{63}Cu constants and the ratio of the magnetic moments of these two isotopes.

The $g_{\parallel}$ part of the spectrum of the ^{63}Cu–^{15}N-porphyrin is easily interpreted owing to the good resolution and to negligible second-order effects. The $g_{\perp}$ part of the spectrum cannot be interpreted so readily since the total number of resolved lines is larger than that expected ($5 \times 4 = 20$ lines). The additional lines are not due to contamination by the ^{65}Cu isotope but probably to a singularity for a non-canonical orientation in the $m_I = -\frac{1}{2}$ resonance fields as already mentioned for the $m_I = -\frac{3}{2}$ components. Indeed, the calculation of the resonance field, including second-order effects (22) with the approximated parameters deduced from the spectrum at 77 K and the isotropic system at 300 K in dimethylformamide (Table 1), shows one that this singularity occurs for a value of the angle of the magnetic field direction with the symmetry axis of about 75° ($\cos\theta = 0.26$) for the $m_I = -\frac{1}{2}$ components and 47° ($\cos\theta = 0.68$) for the $m_I = -\frac{3}{2}$ components (Fig. 2). Furthermore, these calculations reveal that second-order effects result in a non-uniform splitting between the hyperfine lines for the perpendicular orientation of the magnetic field, from 18 G for the two low-field transitions to about 33 G for the two high-field transitions (Figs. 2 and 3).

Conclusion

The isotopic labelling of porphyrins with ^{15}N may be helpful for the elucidation of physicochemical properties involving the mass or the magnetic moment of the nitrogen nuclei. In the present paper, we have described long-range $J_{^{15}N,^{1}H}$ coupling in the nmr spectra which are not resolved using the natural isotope ^{14}N. On the other hand, substitution of selectively enriched ^{63}Cu in the ^{15}N porphyrin has allowed determination of a complete set of esr parameters which can be extended to other isotopic compositions. We shall report in the forthcoming

publication on the nitrogen and metal isotopic effects on the Raman and infrared spectra (23).

Experimental

All starting materials were analytical grade (Merck Company). $^{15}NO_3Na$ and ^{63}Cu were purchased from CEA, France. Dimethylformamide was distilled under reduced pressure of nitrogen and stored on a 0.4 nm molecular sieve. Proton magnetic resonance spectra in deuteriochloroform (CEA, France) were recorded at 100 MHz in the Fourier transform mode using 4 K data points in the frequency domain. Pyridine-d_5 was added to the deuteriochloroform solution of Zn – ^{15}N-etioporphyrin I to destroy the association of the metalloporphyrin molecules. Chemical shifts were referenced to internal tetramethylsilane (TMS). Electron spin resonance spectra were recorded on a Varian 4502 X band spectrometer. The magnetic field strength was calculated from the nuclear resonance frequency of a proton probe located close to the cavity (Varian F8A magnetometer). This frequency was determined with a Hewlett-Packard 5245 L frequency counter. The microwave frequency was measured with a calibrated wavemeter.

*3-Ethyl-2,4-pentadione (**1**)*

This compound was prepared by the method of Johnson *et al.* (24) and was used for the synthesis of 3-acetylhexane-2-one. The desired product was distilled at 176–180°C (71%); nmr (deuteriochloroform) δ: 0.9 (*t*, —CH_2CH_3), 1.9 (q, —CH_2-CH_3), 2.19 (s, —CH_3), 3.54 (t, —CH).

*Ethyl 3,5-Dimethyl-4-ethyl-^{15}N-pyrrole-2-carboxylate (**3**)*

A method analogous to Eisner's preparation of ethyl 4-acetyl-3-ethyl-5-methylpyrrole-2-carboxylate (7) was employed. Ethyl acetoacetate (26 g) in 75 ml of acetic acid was treated with sodium ^{15}N-nitrite (15 g) in 35 ml of distilled water at 0°C during 4 h and kept overnight at room temperature. This solution was added to 3-ethyl-2,4-pentadione (32 g), zinc dust (28 g), and sodium acetate (34 g). The mixture was well stirred and refluxed for 4 h, then poured while hot into ice water. The crude product was filtered off and recrystallized from ethanol (22.2 g, 56%); nmr (deuteriochloroform) δ: 1.05 (t, —CH_2CH_3), 1.34 (t, —OCH_2CH_3), 2.19 (d, $^3J_{N,H}$ = 2.4 Hz, N—C—CH_3), 2.27 (s, —CH_3), 2.37 (q, —CH_2CH_3), 4.28 (q, —O—CH_2CH_3), 8.45 (d, $^1J_{NH}$ = 97, NH). *Anal.* calcd. for $C_{11}H_{17}O_2N$: C 67.35, H 8.67, N 7.65; found: C 67.29, H 8.62, N 7.38.

*Ethyl 5-Acetoxymethyl-3-methyl-4-ethyl-^{15}N-pyrrole-2-carboxylate (**4**)*

To 15.7 g of ethyl 3,5-dimethyl-4-ethyl-^{15}N-pyrrole-2-carboxylate in acetic acid (400 ml), lead tetraacetate (45 g) was added with stirring during 30 min. Stirring was continued for 2 h more. Acetic acid was removed under reduced pressure and the residue was dissolved in chloroform, washed with water, then dried over anhydrous sodium sulfate. The chloroform was evaporated to dryness. The desired product was crystallized from methanol to yield white crystals (12 g, 59%); nmr (deuteriochloroform) δ: 1.08 (t, —CH_2CH_3), 1.35 (t, —O—CH_2CH_3), 2.07 (s, —CO—CH_3), 2.28 (s, —CH_3), 2.46 (q, —CH_2—CH_3), 4.31 (q, —O—CH_2—CH_3), 5.02 (d, $^3J_{N,H}$ = 2.8 Hz, —CH_2—O), 8.95 (d, $^1J_{NH}$ = 97.9 Hz, NH). *Anal.* calcd. for $C_{13}H_{19}NO_4$: C 61.42, H 7.48, N 5.91; found: C 61.28, H 7.27, N 5.79.

*5-Hydroxymethyl-3-methyl-4-ethyl-^{15}N-pyrrole-2-carboxylic Acid (**5**)*

Pyrrolic ester **4** (11 g) in 150 ml of methanol containing 22.5 g of potassium hydroxide was heated under reflux for 4 h. The solution was evaporated under reduced pressure. The solid residue was dissolved in water (100 ml) and the aqueous solution was washed with ether, then acidified with dilute HCl. The precipitated product was filtered, washed with aqueous sodium acetate, and water (6.9 g, 87%); nmr (deuteriochloroform) δ: 1.07 (t, —CH_2—CH_3), 2.32 (s, —CH_3), 2.43 (q, —CH_2—CH_3), 4.42 (d, $^3J_{N,H}$ = 2.4 Hz, —CH_2—OH), 8.90 (d, $^1J_{NH}$ = 97.6 Hz, N*H*).

*^{15}N-Etioporphyrin I (**6**)*

An acetic acid solution (28 ml) containing 6.80 g of pyrrole-carboxylic acid **5** and potassium ferricyanide (1.36 g) was heated under reflux with vigorous stirring for 1 h. The reaction mixture was allowed to stand 3 days. The precipitate was collected, washed with methanol, and dried (2.42 g, 54.3%).

This material was dissolved in a minimal volume of chloroform and applied on an alumina column (neutral, grade I) previously treated with the same solvent. ^{15}N-Etioporphyrin I was eluted with chloroform and recrystallized in chloroform–methanol mixture: 1.57 g (yields: 35.3 and 18%, respectively, based upon **5** and **3**); spectrum (benzene): λ_{max}(nm) (ε(m*M*)): 399 (163), 498 (14.4), 530 (10.5), 568.5 (6.7), 623 (6.3). *Anal.* calcd. for $C_{32}H_{38}N_4$: C 79.67, H 7.88, N 12.45; found: C 80.0, H 7.93, N 12.39.

The structure was confirmed by the nmr spectrum of the solution in deuteriochloroform (see the text).

Synthesis of Metalloderivatives

The zinc and copper porphyrins were prepared from the metal acetates in acetic acid by the method of Fischer and Strangler (8), then purified by chromatography on a silica gel column. The metalloporphyrins were eluted with chloroform. Zn – ^{15}N-etioporphyrin I in benzene: λ_{max}(nm), (ε(m*M*)): 402 (340.7), 531 (15.6), 568 (28.8). Cu – ^{15}N-etioporphyrin I in benzene: λ_{max}(nm) (ε(m*M*)): 398 (291.7), 524.5 (12.6), 561.5 (28.2).

Base-catalyzed hydrogen isotope exchange of thiocamphor: α-thioenolization rate constants

NICK HENRY WERSTIUK AND PAUL ANDREWS

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 29, 1978

NICK HENRY WERSTIUK and PAUL ANDREWS. Can. J. Chem. **56**, 2605 (1978).

The rates of base-catalyzed protium–deuterium exchange (α-thioenolization) of the *exo* and *endo* protons of thiocamphor (**1**), in 2:1 dioxane–D_2O at 25.0 ± 0.5°C, have been determined by monitoring the uptake of deuterium mass spectrometrically. The *exo* and *endo* exchange rate constants, 2.20×10^{-2} and 5.60×10^{-4} M^{-1} s^{-1}, respectively, are 23.2 and 12.3 times larger than the rate constants for *exo* and *endo* exchange in camphor (**2**). Factors which may determine the rate enhancements are discussed.

NICK HENRY WERSTIUK et PAUL ANDREWS. Can. J. Chem. **56**, 2605 (1978).

Faisant appel à la spectrométrie de masse pour évaluer l'absorbtion du deutérium, on a déterminé les vitesses, catalysées par les bases, des échanges protium–deutérium (α-thioénolisation) des protons *exo* et *endo* du thiocamphre (**1**), dans le dioxanne–D_2O 2:1, à 25.0 ± 0.5°C. Les constantes de vitesse d'échange *exo* et *endo*, 2.20×10^{-2} et 5.60×10^{-4} M^{-1} s^{-1} sont respectivement 23.2 et 12.3 fois plus élevées que les constantes de vitesse des échanges *exo* et *endo* du camphre (**2**). On discute des facteurs qui peuvent déterminer les augmentations de vitesse.

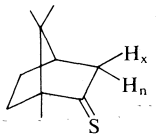
[Traduit par le journal]

Thione–thioenol tautomerism was first studied by Reyes and Silverstein in 1958 (1). Since then other workers have attempted to detail the factors which affect the equilibrium (2, 3). However, up to the present time, there have been no reports of studies of acid- or base-catalyzed α-thioenolization of thiones. In this communication, we report the rates of base-catalyzed protium–deuterium exchange of the *exo* and *endo* protons in thiocamphor (**1**) and discuss possible rate-controlling factors.

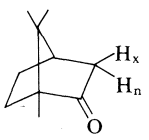
We chose to study **1** because there is a substantial difference in exchange rates of the diastereotopic protons and the substrate does not undergo trimerization, a reaction which unhindered thiones undergo very readily (4).

The rate constants listed in Table 1 were obtained by the method developed in these laboratories (5). That good first-order kinetics were observed and that analytical gas chromatographic analysis showed no significant conversion of **1** into **2** established that sulfur–oxygen exchange, a potentially complicating process that would decrease the base concentration, is insignificant.

Several factors may contribute to the increase in the α-deprotonation[1] rates of **1** relative to **2**. Because



1



2

oxygen is more electronegative than sulfur and the carbonyl group would be expected to be more electron withdrawing than the thiocarbonyl group, base-catalyzed hydrogen isotope exchange of ketones should be more facile than exchange of thiones. From a survey of carbonyl and thiocarbonyl compounds (8), it is clear that the dipole moments of the thiocarbonyl compounds are close to or greater than the dipole moments of the carbonyl compounds. The

TABLE 1. Second-order rate constants of NaOD-catalyzed deuterium exchange of thiocamphor (**1**) and camphor (**2**) at 25.00 ± 0.05°C in 2:1 dioxane–D_2O

Substrate		k (M^{-1} s^{-1})*	k_{rel}		k_{exo}/k_{endo}
1	*exo*	2.20×10^{-2}	23.2		39.2
	endo	5.60×10^{-4}		12.3	
2	*exo*	9.50×10^{-4}†	1		21.2
	endo	4.46×10^{-5}†		1	

*Second-order rate constants were obtained by dividing the pseudo-first-order rates by the base concentration (0.0099 *M*). The rate constants were reproducible to a maximum deviation of ± 10%.

†The rate constants for exchange of camphor were obtained by Tidwell (6).

[1]We have established through several exploratory runs that β-thioenolization (homothioenolization) of 3,3,6,6-tetramethylbicyclo[2.2.1]heptan-2,5-dithione occurs more readily than β-enolization (homoenolization) of 3,3,6,6-tetramethylbicyclo[2.2.1]heptan-2,5-dione (7).

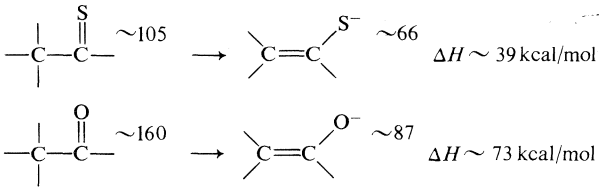
near equality of the aromatic solvent-induced shift (ASIS) of the ^{1}Hmr resonances of **1** and **2** determined by Demarco (9) and confirmed in these laboratories, indicates that the dipole moments are nearly identical. Thus the nmr data are in accord with the dipole moments of **1** (2.89 D) and **2** (2.98 D) that were determined by Lumbroso (10). However, it is interesting to note that theoretical calculations by Lumbroso (10) and Julg *et al.* (11) indicate that the thiocarbonyl group, $\overset{\delta-}{\diagdown}\overset{\delta+}{\diagup}C{=}S$, is polarized in the opposite sense to the carbonyl group, $\overset{\delta+}{\diagdown}\overset{\delta-}{\diagup}C{=}O$. Nevertheless, since the C=S and C=O bond moments certainly control the magnitudes of the dipole moments of **1** and **2** and the C=S bond is considerably longer than the C=O bond (12), the carbonyl group is expected to be more polar than the thiocarbonyl group. Thus the electrical effect of the carbonyl group should be greater than its sulfur analog.

That the increase in acidity may be due to a ground state effect, a consequence of the fact that the C=S bond is considerably weaker than the C=O bond (12, 13), is indicated by the following analysis. The energy changes associated with anion formation, as calculated from approximate bond energies for C=S, C=O, C—S, and C—O, assuming that all other effects are common, indicate that α-thioenolization would occur more readily than α-enolization.



That sulfur acids are more acidic than the corresponding oxyacids is due to two factors: the —S—H bond is longer and weaker, and as established by the electron affinities (EA) of the atoms, sulfur (EA −47 kcal/mol) accomodates a negative charge better than oxygen (EA −34 kcal/mol) (14). The latter effect results from the fact that the additional 3*p* electron on sulfur is more diffuse and less crowded than the additional 2*p* electron on oxygen.

Thus, if the electrical effect of the C=O group is greater than the effect of C=S, then the ground state effect and the ability of sulfur to support a negative charge combine to outweigh the electrical effect and produce the observed increase in rate. It is interesting to note that thioamides are stronger acids ($\Delta pK_a \sim 2$) than amides (15).

Appearance potentials of ion fragments of iron pentacarbonyl

B. R. CONARD AND R. SRIDHAR
J. Roy Gordon Research Laboratory, Inco Metals Co., Mississauga, Ont., Canada L5K 1Z9

Received November 7, 1977[1]

B. R. CONARD and R. SRIDHAR. Can. J. Chem. **56**, 2607 (1978).

The previously reported fragments and a new fragment, FeC_2^+, have been observed in the mass spectrum of iron pentacarbonyl. The electron impact appearance potentials for the minor fragments of $Fe(CO)_5$ are (in eV): $FeC_3O_2^+$, 18.2; FeC_2O^+, 20.2; FeC_2^+, 29.9; FeO^+, 22.5; and $Fe(CO)_3^{2+}$, 24.0. Electron energy calibration was carried out using existing data for the major fragments of $Fe(CO)_5$.

B. R. CONARD et R. SRIDHAR. Can. J. Chem. **56**, 2607 (1978).

Un examen du spectre de masse du pentacarbonyle fer révèle la présence des fragments rapportés antérieurement aux côtés d'un nouveau fragment, FeC_2^+. Les potentiels d'apparition des fragments minoritaires sous impact électronique du $Fe(CO)_5$ sont (en eV): $FeC_3O_2^+$, 18.2; FeC_2O^+, 20.2; FeC_2^+, 29.9; FeO^+, 22.5 et $Fe(CO)_3^{2+}$, 24.0. On a calibré les énergies électroniques à l'aide de données existantes pour les fragments principaux du $Fe(CO)_5$.

[Traduit par le journal]

Even though a number of mass spectrometric studies (1–5) have been performed on $Fe(CO)_5$, the appearance potentials of only the most intense ions have been reported. The objective of the present work was to study the fragmentation pattern of iron pentacarbonyl and to measure the appearance potentials of the minor fragments.

The observed fragmentation pattern confirmed the minor fragments of $Fe(CO)_5$ reported by Winters and Collins (3). In addition, a new fragment, FeC_2^+, was observed for the first time and its appearance potential, as well as those of other minor fragments, were measured.

Experimental Methods

The mass spectrometer was an Extranuclear model 162-8 quadrupole instrument. The ion source consisted of two tungsten filaments and the total emission current was regulated. The quadrupole unit was housed in a vacuum system equipped with a 30 ℓ/s Varian ion pump and a 75 ℓ/s Veeco ion pump capable of pumping the system to better than $\sim 10^{-6}$ Pa (10^{-8} Torr).

The carbonyl vapour studied was obtained by room temperature sampling of the vapour in contact with liquid $Fe(CO)_5$, which was obtained from Domtar, Inc.

The ion carbonyl vapours were leaked into the ion source at a constant rate employing a Varian model 451–5100 leak valve. To ensure that carbonyl vapours entered the ion source directly, a 3.2 mm diameter stainless steel tube was attached to the high vacuum side of the leak valve and it extended to the ion source. This system gave very high sensitivity and without it the FeC_2^+ fragment would not have been detected. With time, however, the stainless steel tube, heated by the ion source, caused decomposition of the carbonyl in the tube before reaching the ion source. In general, it took 2 h for the tube to get hot enough to decompose the carbonyl completely and this time was sufficient to carry out numerous measurements. The carbonyl ion signals could be readily restored by turning off the ion source filaments and allowing the ion source to cool. This problem could have been overcome by water cooling the gas admission tube, but it was not necessary for this study.

The leak valve was adjusted to yield a constant total pressure of 1.3×10^{-4} Pa in the vacuum system (as measured by the ion pump current). The leak valve was closed during background measurements.

The Fragmentation Spectrum

Winters and Kiser (1) reported ions formed by the successive loss of CO and measured the appearance potential for $Fe(CO)_5^+$, $Fe(CO)_4^+$, $Fe(CO)_3^+$, $Fe(CO)_2^+$, $Fe(CO)^+$, and Fe^+. In addition to these species, Bidinosti and McIntyre (4) reported FeC^+, FeC_2O^+, FeO^+, and $Fe(CO)_3^{2+}$. The most com-

TABLE 1. Appearance potentials of ions observed from $Fe(CO)_5$

Mass	Ion	Relative abundance, this work (58 eV)	Appearance potentials (eV)					
							This work[a]	
			Ref. 1	Ref. 2	Ref. 4	Ref. 5	Regr. result	New
40	C_2O^+	(4)						
42	$Fe(CO)^{2+}$	2.5	30.2				30.24	
56	Fe^+	50	16.1	14.70	15.31	15.99	15.51	
68	FeC^+	7			23.6		23.65	
70	$Fe(CO)_3^{2+}$	2.4						24.0
72	FeO^+	1.2						22.5
80	FeC_2^+	0.17						29.9
84	$Fe(CO)^+$	100	14.0	12.90	13.39	13.76	13.18	
96	FeC_2O^+	0.8						20.2
112	$Fe(CO)_2^+$	25	11.8	10.92	11.27	11.12	11.24	
124	$FeC_3O_2^+$	0.08						18.2
140	$Fe(CO)_3^+$	11.9	10.3	9.89	10.01	10.04	10.08	
168	$Fe(CO)_4^+$	15.4	10.0	8.34	8.73	9.17	9.30	
196	$Fe(CO)_5^+$	5.3	8.53	8.14	8.16	8.40	8.53	

[a]These values were calculated using eq. [1].

plete fragmentation pattern reported to date was by Winters and Collins (3) and included $FeC_3O_2^+$ as well as a number of doubly ionized species.

The ions observed at 58 eV in the present work are listed in Table 1. They were identified by their mass, the isotopic distribution of iron, and their disappearance when the leak valve was closed. The presence of $FeC_3O_2^+$ was confirmed. A new fragment was identified as FeC_2^+ and is analogous to MC_2^+ fragments observed for a number of carbonyl molecules (4, 6).

All fragments (except CO), as well as the parent ion $Fe(CO)_5^+$, were observed to decrease as a function of the time the ion source was on. As noted by Pignataro and Lossing (7) and by Shadskii (8), $Fe(CO)_5$ undergoes decomposition in a hot ion source. In our experiments, as described before, the decomposition probably occurred in the tube leading to the ion source. The only ion observed to increase as a function of time was CO^+, which was consistent with the decomposition of $Fe(CO)_5$. Unfortunately, reliable intensity measurements on CO^+ were not possible due to the large amount of CO initially present in the CO-saturated iron pentacarbonyl sample and C_2O^+ intensities were unreliable due to interference from Ar^+ that was present in the system from previous measurements.

Appearance Potentials

The appearance potential determinations were carried out by the method of linear extrapolation. Data were obtained by focussing on the top of a peak and measuring the ion intensity as a function of increasing electron energy. The electron energy dial (10-turn potentiometer) was calibrated using the appearance potentials of major fragments of $Fe(CO)_5$ determined by a number of other workers who also used electron impact techniques. Their reported values are given in Table 1. A straight-line regression, constrained to go through the origin, was performed on the differences between our eV potentiometer settings and the previous values for the major fragments as a function of the eV potentiometer setting:

$$[1]\quad \Delta eV = (0.225 \pm 0.005) \times \text{potentiometer setting}$$

Using the standard deviation of the slope of this regression we estimate that the electron energies reported here are accurate to within ± 0.5 eV.

The exchange of *N*,*N*-dimethylformamide (DMF) between $M(NH_3)_5DMF^{3+}$ and solvent in acidic DMF solutions proceeds with pseudo-first-order kinetics governed by the parameters $k_{ex}(55°C) = 8 \times 10^{-5}$ and 1.1×10^{-4} s^{-1}, $\Delta H_{ex}^* = 113$ and 99 kJ mol^{-1}, $\Delta S_{ex}^* = +22$ and -20 J K^{-1} mol^{-1}, and $\Delta V_{ex}^* = +3.2$ and -1.4 cm^3 mol^{-1} for M = Co and Rh respectively. For M = Co (but not Rh), the exchange rate was much faster in the absence of acid, and reduction of Co(III) to Co(II) was significant at low acidities. Solubility problems precluded the measurement of meaningful rate data for the reactions of $M(NH_3)_5DMF^{3+}$ with nucleophiles X^- in acidic DMF solution except for the case M = Co with X = Br^-, for which a limiting first-order rate coefficient 2.5 times k_{ex} was obtained for the formation of $Co(NH_3)_5Br^{2+}$ at high [Br^-] at 55°C. Despite this last result, the mechanism of simple substitution reactions is evidently dissociative interchange (I_d) for pentaamminecobalt(III) complexes in general, but associative interchange (I_a) for pentaamminerhodium(III) analogues.

S. T. Danny Lo, Margaret J. Sisley et Thomas W. Swaddle. Can. J. Chem. **56**, 2609 (1978).

L'échange de la *N*,*N*-diméthylformamide (DMF) entre le complexe $M(NH_3)_5DMF^{3+}$ et le solvant dans des solutions acides de DMF se produit suivant une cinétique du pseudo-premier ordre pour laquelle les paramètres sont $k_{ex}(55°C) = 8 \times 10^{-5}$ et 1.1×10^{-4} s^{-1}, $\Delta H_{ex}^* = 113$ et 99 kJ mol^{-1}, $\Delta S_{ex}^* = +22$ et -20 J K^{-1} mol^{-1} et $\Delta V_{ex}^* = +3.2$ et -1.4 cm^3 mol^{-1} respectivement pour M = Co et Rh. Dans le cas de M = Co (mais non dans celui de Rh), la vitesse d'échange est beaucoup plus rapide en l'absence d'acide et il se produit une réduction importante de Co(III) en Co(II) à des acidités basses. A cause de problèmes de solubilité, il n'a pas été possible de faire des mesures significatives de vitesse pour les réactions du complexe $M(NH_3)_5DMF^{3+}$ avec des nucléophiles X^- en solutions acides de DMF excepté dans le cas où M = Co avec X = Br^- pour laquelle réaction un coefficient de vitesse limite du premier ordre de 2.5 fois k_{ex} a pu être obtenue pour la formation de $Co(NH_3)_5Br^{2+}$ à concentration élevée de [Br^-] à 55°C. Malgré ce dernier résultat, le mécanisme pour les réactions de substitutions simples est évidemment un échange dissociatif (I_d) pour les complexes pentaamminecobalt(III) d'une façon générale mais d'échange associatif (I_a) pour les analogues pentaamminerhodium(III).

[Traduit par le journal]

Introduction

The purpose of this study was to test the assertion (1) that the mechanism of simple ligand substitution in solution changes from dissociative to associative interchange (I_d to I_a) as one goes from the pentaamminecobalt(III) to the pentaamminerhodium(III) series. Evidence for such a change in reactions [1] and [2]

$$[1]\quad M(NH_3)_5{}^{18}OH_2{}^{3+} + H_2O \xrightarrow{k_{ex}} M(NH_3)_5OH_2{}^{3+} + H_2{}^{18}O$$

$$[2]\quad M(NH_3)_5OH_2{}^{3+} + X^- \overset{K}{\rightleftharpoons} \{M(NH_3)_5OH_2{}^{3+}, X^-\} \xrightarrow{k_i} M(NH_3)_5X^{2+} + H_2O$$

has been found in measurements of k_i relative to k_{ex} (2), but the validity of this approach has recently been questioned (3, 4). A less equivocal case can be built upon the discontinuities in the sequences of values of the activation parameters ΔH_{ex}^*, ΔS_{ex}^*, and ΔV_{ex}^* for reaction [1], and more particularly in the sign of ΔV_{ex}^*, as one goes from M = Co to Rh and Ir (1, 5–7). We have recently advanced further, quite independent evidence favoring this mechanistic dichotomy (8), but, as Moore (9) points out, the question of the mechanism of substitution at rhodium(III) centers remains controversial (3, 10–12).

In this article, we describe attempts to elucidate this problem by changing the solvent to *N*,*N*-dimethylformamide (DMF) (reactions [3] and [4]),

$$[3]\quad M(NH_3)_5{}^*DMF^{3+} + DMF \xrightarrow{k_{ex}} M(NH_3)_5DMF^{3+} + {}^*DMF$$

[4] $M(NH_3)_5DMF^{3+} + X^- \overset{K}{\rightleftharpoons} \{M(NH_3)_5DMF^{3+}, X^-\} \xrightarrow{k_i} M(NH_3)_5X^{2+} + DMF$

in which the ion-pair formation constants K were expected to be large enough to permit reliable k_i data to be obtained.

Experimental

Materials

N,N-Dimethylformamide (Baker Analyzed or Fisher Certified Reagent) was purified less than 24 h before use in kinetic or spectroscopic measurements by drying it over a Linde 4A molecular sieve for a day or more, and distilling it fractionally under reduced pressure. Aqueous solutions of the product were neutral to pH paper. The numerical magnitudes of the kinetic results were not significantly dependent upon the source of the DMF or the rigour with which oxygen and moisture were excluded in the distillation, but best precision and reproducibility were obtained using freshly-opened Baker Analyzed DMF and a bleed of dry, oxygen-free nitrogen in the stillpot. DMF-d_7 (99.5% isotopic purity) was supplied by Stohler Isotopes. Trifluoromethanesulfonic acid was purified as previously described (13), but *para*-toluenesulfonic acid monohydrate (Fisher Certified Reagent), tetra-*n*-butylammonium bromide, tetraethylammonium chloride and bromide (Eastman), and perchloric acid (Baker Analyzed) were used without further purification. Potassium trioxalatochromate(III) was prepared by a standard method (14). Potassium thiocyanate was recrystallized from hot acetone by addition of ether.

N,N-Dimethylformamidepentaamminecobalt(III) perchlorate was made from aquopentaamminecobalt(III) perchlorate (15). *Anal.* calcd. for $[Co(NH_3)_5OCHN(CH_3)_2)](ClO_4)_3$: N 16.3, C 7.0, H 4.3, Cl 20.6; found: N 16.4, C 7.1, H 4.1, Cl 20.8. A solution of this compound in DMF ($\sim$0.01 M; M = mol dm^{-3}) showed light absorption maxima at 506 and 349 nm with molar absorptivities ε of 89.6 and 79.9 M^{-1} cm^{-1} respectively. The latter molar absorptivity was reduced to 76.4 M^{-1} cm^{-1} on addition of trifluoromethanesulfonic or *para*-toluenesulfonic acid ($\sim$0.01 M) but the spectrum was otherwise unchanged. These values differ slightly from those reported for the same complex in *aqueous* solution (15). $[Co(NH_3)_5DMF](ClO_4)_3$ containing partially DMF-d_7-labelled DMF was made by a procedure similar to the foregoing, using partially-labelled DMF.

Bromo- and thiocyanato-*N*-pentaamminecobalt(III) perchlorates were made as previously described (16, 17) and their purity was confirmed by elemental microanalysis. Their spectra in DMF ($\sim$0.01 M) in the presence of $\sim$0.01 M *para*-toluenesulfonic acid showed first ligand-field absorption maxima at 550 (ε 63.0) and 501 nm (ε 206.4 M^{-1} cm^{-1}) respectively.

N,N-Dimethylformamidepentaamminerhodium(III) perchlorate was made by dissolving 2.5 g Ag^+-free $[Rh(NH_3)_5OH_2](ClO_4)_3$ (6) in 7–10 cm^3 of DMF, heating the solution at 85°C for 3 h, then cooling the mixture to 0°C and adding 10 cm^3 water followed by a mixture of 5 cm^3 72% $HClO_4$ and 5 cm^3 water. The yellow precipitate was washed with acetone and then ether, recrystallized from a further 10 cm^3 of DMF in the same way, and dried over P_2O_5 under reduced pressure. Yield, 2.2 g.

Anal. calcd. for $[Rh(NH_3)_5DMF](ClO_4)_3$: C 6.4, H 4.0, Cl 19.0; found: C 6.6, H 4.0, Cl 18.9. The 60 MHz ^{1}H nmr spectrum in DMSO-d_6 showed signals of equal intensity at 6.48 and 6.67τ due to the two CH_3 groups, and a resonance at 2.07τ due to the —CHO proton. The uv spectrum at 21°C showed an absorption maximum at 323 nm (ε 216.0 M^{-1} cm^{-1}).

$[Rh(NH_3)_5DMF](ClO_4)_3$ partially labelled with DMF-d_7 was made in the above way, using the partially-labelled solvent. $[Rh(NH_3)_5DMF](BF_4)_3$ was made as above, but using 48% aqueous HBF_4 (Ventron) in place of the diluted $HClO_4$, and ethanol in place of acetone (in which the tetrafluoroborate salt was quite soluble).

Kinetics of the Exchange Reactions

The progress of reaction [3] (M = Co) at atmospheric pressure was followed by chilling aliquots taken from the thermostatted ($\pm$0.02°C) solution of partially ($\sim$7%) DMF-d_7-labelled $[Co(NH_3)_5DMF](ClO_4)_3$ in freshly-distilled DMF to 0°C and adding an equal volume of a cold aqueous solution containing the stoichiometric amount of potassium trioxalatochromate(III), with scratching and cooling. The filtered precipitate of $[Co(NH_3)_5DMF][Cr(C_2O_4)_3]$ was washed with acetone, dried under vacuum at 60°C for 12 h, and the coordinated DMF was recovered on a vacuum line by fusing the precipitate with KNCS. The DMF was analyzed with an Atlas CH-5 mass spectrometer for the ratio R of mass number 80 (DMF-d_7) relative to 74 (DMF-d_1, -$^{13}C_1$, -$^{15}N_1$, and -$^{17}O_1$) (18). The fraction x of the DMF which was d_7-labelled at time t was calculated from the relationship

[5] $$x = [1 + 25.84R^{-1}]^{-1}$$

The pressure dependence of the rate of reaction [1] was followed by withdrawing aliquots from a pressurized ($\pm$0.5 MPa), thermostatted ($\pm$0.1°C) syringe assembly as described elsewhere (17).

The progress of reaction [3] when M was Rh was followed in the same way as for M = Co, except that aliquots were delivered into ice-cold DMF containing an excess of tetraethylammonium chloride, and the precipitated $[Rh(NH_3)_5DMF]Cl_3$ was washed with acetone and dried at 70°C under reduced pressure and decomposed as such at 175 $\pm$ 5°C on the vacuum line.

Kinetics of the Anation Reactions

Typically, a solution containing a $Co(NH_3)_5DMF^{3+}$ or $Rh(NH_3)_5DMF^{3+}$ salt and trifluoromethanesulfonic or *para*-toluenesulfonic acid in freshly-distilled DMF was brought to the desired reaction temperature, and a solution of a salt of the nucleophile X^- in DMF at the same temperature was added to it (the complex and nucleophile salts were dissolved separately to minimize the risk of precipitation of $[M(NH_3)_5DMF]X_3$). The mixture was promptly transferred to an optical cell in an electrically heated aluminum block, the temperature of which was controlled to $\pm$0.1°C with a Melabs CTC-1A proportional controller, and the progress of the reaction was followed spectrophotometrically *in situ* with a Cary Model 17Hc spectrophotometer. In these as in all the other kinetic experiments light was excluded except for purposes of spectrophotometric measurements, and for the latter duplicate determinations were made at different slit widths or wavelengths to check for photochemical effects. For reactions involving cobalt(III), the final solutions were analyzed for cobalt(II) by adding a small amount of *para*-toluenesulfonic acid followed by a large excess of KNCS and determining the $Co(NCS)_4^{2-}$ concentration spectrophotometrically at 625 nm (ε 1890 M^{-1} cm^{-1}).

Results

The $Co(NH_3)_5DMF^{3+}$/DMF Exchange

The exchange of DMF between $Co(NH_3)_5DMF^{3+}$ and DMF solvent followed first-order kinetics

$$[6] \qquad \ln (x_t - x_\infty) = k_{ex}t + \ln (x_0 - x_\infty)$$

to at least 75% completion of reaction in the presence of added *para*-toluenesulfonic acid in six-fold molar excess over the complex, and at least 40% reaction with half as much acid as complex. The rate coefficient k_{ex} was independent of the acid concentration within this range, and was essentially the same whether anhydrous trifluoromethanesulfonic acid or *para*-toluenesulfonic acid monohydrate was used, i.e., neither the nature of the acid anion nor the presence of small amounts of water (presumably as H_3O^+ in this case) affected the exchange rate significantly. In the absence of any added acid, however, the exchange rates were very much higher, not accurately reproducible, and markedly dependent upon the concentration of the complex.

Reduction of cobalt(III) to cobalt(II) became significant at low acid concentrations. For $[Co(NH_3)_5DMF^{3+}] \sim 0.04$ M and [acid] ~ 0.24 M, no cobalt(II) could be detected after 80% completion of exchange at 55.4°C, although 0.9% of the cobalt was present as cobalt(II) after 10 half-periods ($t_{1/2}$) of the exchange reaction and as much as 10% after $50t_{1/2}$, i.e., the redox process was autocatalytic. Reduction was somewhat faster at lower acid concentrations, e.g., for [complex] = [acid] = 0.04 M, traces of cobalt(II) were detectable after $0.6t_{1/2}$ for reaction [1] and 50% Co^{2+} after $50t_{1/2}$. Neither the deliberate addition of cobalt(II) nor the increased importance of spontaneous reduction *per se*, however, had any significant influence upon k_{ex}. Finally, the addition of Br^-, even in concentrations sufficient for almost complete ion-pairing with $Co(NH_3)_5DMF^{3+}$, did not affect k_{ex} within the experimental uncertainty.

Table 1 lists data which illustrate the above generalizations and which give linear plots of $\ln (k_{ex}/T)$ against $1/T$ and of $\ln k_{ex}$ against pressure P (correlation coefficients $r^2 = 0.9998$ and 0.9966 respectively). Values of k_{ex} obtained using ordinary glassware correlate well with those obtained with the pressure apparatus. The corresponding activation parameters are $\Delta H_{ex}^* = 113.4 \pm 1.2$ kJ mol^{-1},

[a]As perchlorate salt; initial concentration.
[b]*p*-Toluenesulfonic acid monohydrate.
[c]As tetra-*n*-butylammonium salt.

$\Delta S_{ex}^* = +21.6 \pm 3.8$ J K^{-1} mol^{-1}, and $\Delta V_{ex}^* = +3.2 \pm 0.1$ cm^3 mol^{-1} at 55.4°C; these error limits are standard deviations of the linear regressions, and experimental uncertainties are probably twice these values. Assumption of a quadratic dependence of ln k_{ex} upon P gives $(\partial \Delta V_{ex}^*/\partial P)_T = (0.11 \pm 0.17) \times 10^{-2}$ cm^3 mol^{-1} MPa^{-1} over the range 0–400 MPa, which means that the pressure dependence of ΔV_{ex}^* is below the limit of detection and in any event much smaller than the molar compressibility of DMF (5.8×10^{-2} and 2.6×10^{-2} cm^3 mol^{-1} MPa^{-1} at 0.1 and 180 MPa respectively, based on the data of Brummer (19)).

Reaction of $Co(NH_3)_5DMF^{3+}$ with Bromide Ion in DMF

The substitution of DMF in $Co(NH_3)_5DMF^{3+}$ ($\sim 1.8 \times 10^{-3}$ M) by bromide ion in the presence of added *para*-toluenesulfonic acid with DMF as solvent was followed spectrophotometrically at 580 nm (ε = 13.4 and 51.4 M^{-1} cm^{-1} for the DMF and bromo complexes, respectively). At 55.4°C, with $\sim 3.0 \times 10^{-3}$ M acid, the reaction followed pseudo-first-order kinetics (rate coefficients k_{obsd}) with respect to $[Co(NH_3)_5DMF^{3+}]$ for at least $2t_{1/2}$, independently of the initial concentration of this complex, with maintenance of isosbestic points at 440 (ε 61.1) and 422 nm (ε 17.5 M^{-1} cm^{-1}).

For $[Br^-]$ up to 0.051 M, the cobalt content of the reaction mixtures was found to comprise 99% $Co(NH_3)_5Br^{2+}$ and 0.6–0.8% cobalt(II) after $10t_{1/2}$ for the anation reaction, but the amount of cobalt(II) did not increase further, even after $40t_{1/2}$, and it was verified independently that $Co(NH_3)_5Br^{2+}$ did not decompose significantly to cobalt(II) in DMF under these conditions. Cobalt(II), added at the beginning of the anation reaction, had no discernable effect upon the anation rate. At higher $[Br^-]$, $[Co(NH_3)_5Br]Br_2$ precipitated after $3t_{1/2}$, and accordingly the extent of cobalt reduction was not investigated.

Precipitation of bromide salts of either $Co(NH_3)_5DMF^{3+}$ or $Co(NH_3)_5Br^{2+}$ prevented the direct observation of a limiting value k_i of k_{obsd} at high enough $[Br^-]$ to cause substantially complete ion pairing, except at the highest temperature (55.4°C), for which a provisional value of about 2.3×10^{-4} s^{-1} was estimated from limited data. High acid concentrations helped suppress precipitation, but it will be apparent from Table 2 that there is a small retarding effect of acid over and above the much more dramatic retardation brought about even by small additions of acid, relative to the experiments

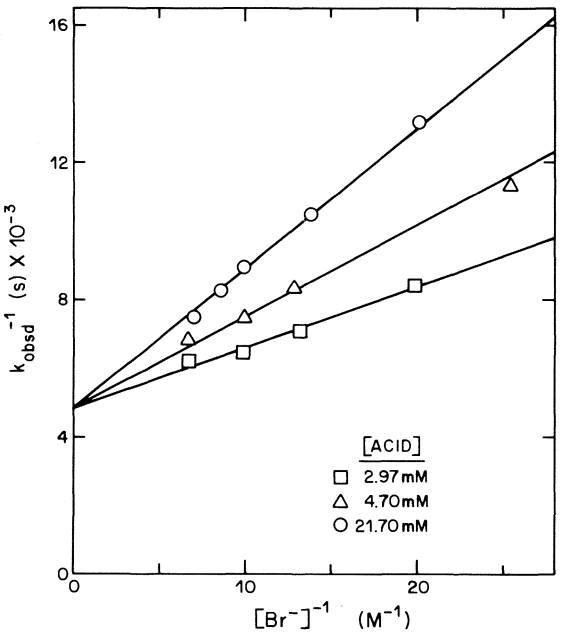

FIG. 1. Dependence of the pseudo-first-order rate coefficient k_{obsd} for the formation of $Co(NH_3)_5Br^{2+}$ from $Co(NH_3)_5DMF^{3+}$ in DMF upon $[Br^-]$ at various concentrations of *para*-toluenesulfonic acid.

without acid. At any one acidity, however, k_{obsd}^{-1} was found to be a linear function of $[Br^-]^{-1}$ to within the experimental uncertainty, and yielded extrapolated values of $k_i = (2.1 \pm 0.1) \times 10^{-4}$ s^{-1} at 55.4°C for three different acidities spanning a concentration range of over sevenfold, as shown in Fig. 1.

Unfortunately, precipitation phenomena precluded similar estimates of k_i at the lower temperatures, and the corresponding activation parameters ΔH_i^* and ΔS_i^* could not be measured. For the single bromide concentration of 0.101 *M*, however, the temperature dependence of k_{obsd} at 21.7 m*M* acid gave $\Delta H_{obsd}^* = 118.6 \pm 0.4$ kJ mol^{-1} and $\Delta S_{obsd}^* = 39.7 \pm 1.4$ J K^{-1} mol^{-1} (error limits are standard deviations; $r^2 = 0.99996$).

Reaction of $Co(NH_3)_5DMF^{3+}$ with Other Anions in DMF

The reaction with chloride ion was forestalled by precipitation of the chloride of the DMF complex. Azide and other basic anions reacted rapidly with $Co(NH_3)_5DMF^{3+}$, presumably by conjugate base pathways. Thiocyanate ion in the presence of added *para*-toluenesulfonic acid (~1.4 m*M*) reacted slowly with $Co(NH_3)_5DMF^{3+}$ (~1.0 m*M*), but a significant amount of cobalt(II) formed even early in the reaction (~1% after 20% completion of the anation, with 0.5 *M* KNCS), and meaningful rate data could not be obtained.

The $Rh(NH_3)_5DMF^{3+}$/DMF Exchange

When M was Rh, reaction [3] followed first-order kinetics (eq. [6]) over the first 80% of exchange at least, and values of k_{ex} are collected in Table 3. Unlike k_{ex} for M = Co (Table 1), k_{ex} for $Rh(NH_3)_5DMF^{3+}$ in DMF is almost unaffected by the presence or absence of added acid. The nature of the anion present does not influence k_{ex}, although a small retardation with increasing complex concentration is discernable. For [complex] = [trifluoromethanesulfonic acid] = 0.245 *M*, we have $\Delta H_{ex}^* = 99.1 \pm 2.0$ kJ mol^{-1} and $\Delta S_{ex}^* = -19.8 \pm 6.0$ J K^{-1} mol^{-1}. For [complex] = [*p*-toluenesulfonic acid] = 0.051 *M*, $\Delta V_{ex}^* = -1.4 \pm 0.2$ cm^3 mol^{-1} at 44.8°C, and the data obtained in the pressure assembly give an extrapolated value of k_{ex} at 0.1 MPa of 3.68×10^{-5} s^{-1}, in good agreement with the experimental value for ordinary glassware. The precision of the data was insufficient to warrant consideration of relationships other than a linear one between ln k_{ex} and *P*.

Reaction of $Rh(NH_3)_5DMF^{3+}$ with Anions in DMF

Precipitation of $[Rh(NH_3)_5DMF]Cl_3$ was immediate on mixing solutions of the perchlorate of the complex (even as dilute as 0.2 m*M*) with Et_4NCl solutions in DMF.

Attempts to follow the reaction of $Rh(NH_3)_5DMF^{3+}$ (0.8 m*M*) with bromide ion (4.0 m*M*) in acidic DMF solution at 55°C *in situ* in the spectrophotometer were complicated by oscillations (with periods of about 1.5 min and remarkably repetitive 'fine structure') of the otherwise progressively increasing optical absorbance at 324 nm. The intensities of these oscillations (but not their period) were smaller at 370 nm, though they increased with time and were not observed at all in DMF solutions of the reactants taken separately. Precipitation of bromide salts, however, ultimately prevented the progress of the presumed anation reaction from being followed even by analyzing samples of the bulk solution (thermostatted with exclusion of light) spectrophotometrically at 370 nm.

The reaction of $Rh(NH_3)_5DMF^{3+}$ with NCS^- in acidic DMF could be followed spectrophotometrically at 300 nm over the first 20–30% reaction at 55°C before precipitation of the product set in, but it became apparent, especially at lower temperatures (down to 15°C), that an initial, somewhat faster, step preceded that which could be conveniently studied. Presumably, the initial step was substitution of coordinated DMF to give thiocyanato-*S*-pentaamminerhodium(III) ion, and the slower process was isomerization of this to the *N*-bonded form which was shown to be the final product. Meaningful rate coefficients for these processes could not be extracted

[d]Tetrafluoroborate salt.

from the absorbance data, but the limiting rate for the first at high $[NCS^-]$ was clearly faster, and the rate of the second a little slower, than the $Rh(NH_3)_5DMF^{3+}$/DMF exchange reaction under the same conditions.

Discussion

The positive value of ΔV_{ex}^* for M = Co in reaction [3] contrasts with the negative value for M = Rh, just as for the analogous reaction [1] (5, 6), and can be taken to indicate that I_d processes are rather general for substitution in cobalt(III) ammines and I_a for the rhodium(III) analogues, independent of the nature of the solvent and the ligand being replaced. The lower values of ΔH_{ex}^* and ΔS_{ex}^* for M = Rh (99 kJ mol^{-1} and −20 J K^{-1} mol^{-1}) relative to M = Co (113 kJ mol^{-1} and +22 J K^{-1} mol^{-1}) support these assignments; in particular, it would be very difficult to reconcile these data with a common I_d or D mechanism for the Co and Rh complexes on the basis of any current theory of ligand substitution energetics.

It is perhaps disappointing that the ΔV_{ex}^* value for reaction [3] with M = Rh is not more dramatically negative, so as to make as persuasive a case as possible for an I_a mechanism. We note that steric hindrance to the aquation of $Rh(NH_2CH_3)_5Cl^{2+}$, though again indicative of I_a, is also unspectacular (8), and it may be that much of the current confusion (9) over mechanistic assignments in reactions of rhodium(III) complexes originates in the absence of any truly striking effects which would provide compelling evidence for one mechanism or another. Nevertheless, the acceleration of the $Rh(NH_3)_5DMF^{3+}$/DMF exchange by increasing pressure is unmistakable, and the negative contribution to ΔV_{ex}^* made by transfer of the attacking ligand from the outer to the inner coordination spheres in an I_a process will be partly (but never wholly (20)) compensated by a stretching of the bond to the leaving group and also of the bonds to the other ligands (here, NH_3). At present, there seems to be little prospect of accounting in detail for the numerical magnitude of ΔV_{ex}^*, but the sign of this parameter remains a useful criterion of mechanism.

In the absence of added acid, k_{ex} for the $Co(NH_3)_5DMF^{3+}$/DMF exchange was very high, poorly reproducible, and larger at lower complex concentrations, presumably through the incursion of conjugate-base pathways (4), while low acidities also favored autocatalytic reduction of $Co(NH_3)_5DMF^{3+}$ to cobalt(II). Similar effects and their probable explanations were reported in our article on the analogous reactions of $Co(NH_3)_5DMSO^{3+}$ in dimethylsulfoxide solutions (4). For the $Rh(NH_3)_5DMF^{3+}$/DMF system, however, neither redox phenomena nor acceleration of reaction [3] at low acidities were significant.

For the anation of $Co(NH_3)_5DMF^{3+}$ by Br^-, a small but significant effect of added acid persisted, beyond the suppression of conjugate base pathways. For data measured at a given concentration of acid, however, k_{obsd}^{-1} was a linear function of $[Br^-]^{-1}$ and these functions extrapolated to give the same limiting value k_i (±5%) whatever the acidity (Fig. 1). According to the interchange model (21), the slopes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

of these linear plots should equal $(k_i K)^{-1}$, so that increasing the acid concentration from 3 to 22 mM evidently decreases the apparent ion pair formation constant K from 27 to 12 M^{-1}, presumably because H^+ competes with $Co(NH_3)_5DMF^{3+}$ and the acid anion with Br^- in ion pairing. A disturbing feature is the apparent constancy of K over a range of ionic strengths I, which casts doubt upon the identification of K with a true ion association constant, but empirically the reciprocal–reciprocal plot affords a satisfactory means of extrapolating k_{obsd} values to their upper limit k_i.

The value of k_i for the reaction of bromide with $Co(NH_3)_5DMF^{3+}$ in DMF is about 2.5 times k_{ex} at 55.4°C. A similar ratio (3.3) was obtained for the corresponding reactions of $Co(NH_3)_5DMSO^{3+}$ in DMSO (4), yet in both these cases there is clear evidence for the operation of an I_d mechanism for the solvent exchange reactions at least, and we have previously pointed out (4) that a modest excess of k_i over k_{ex} is not inconsistent with an I_d mechanism for the anation reaction so long as ΔH_i^* and ΔH_{ex}^* are essentially the same. For the reactions [3] and [4] with M = Co and X = Br, a true ΔH_i^* value could not be obtained because of solubility problems, but for $[Br^-] = 0.101\ M$ we have an apparent ΔH_{obsd}^* of 118 kJ mol^{-1}, as compared with 113 kJ mol^{-1} for ΔH_{ex}^*, and this small difference is attributable to the fact that $Co(NH_3)_5DMF^{3+}$–Br^- ion pairing is barely more than half complete in 0.101 M bromide, since ΔH^0 for the complete formation of the roughly analogous *cis*-$Co(en)_2ClDMF^{2}$–Br^- ion pair in DMF is about +12 kJ mol^{-1} (22). Unfortunately, attempts to measure ΔH_i^* for the reaction of $Rh(NH_3)_5DMF^{3+}$ with Br^- in DMF were foiled by the incursion of an unusual cyclic secondary reaction, while k_i could not be measured for other reactions of the type [4] (M = Co or Rh) because of solubility problems.

To conclude, the evidence presented in this paper, albeit incomplete, supports previous assertions (1–2, 6–8) that reactions of the types [1]–[4] proceed by I_d processes for M = Co but I_a for M = Rh. All the experimental data known to us, including recent work by Heaton *et al.* on substitution reactions of amine complexes of rhodium(III) in water (23), are consistent with an I_a mechanism for simple substitution in the pentaamminerhodium(III) series; van Eldik's assignment (12) of an I_d mechanism to the reactions of $Rh(NH_3)_5OH_2^{3+}$ with various aqueous oxalate species is based on the observation that $k_i < k_{ex}$, but this is also entirely consistent with an I_a process in which oxalate is a less effective nucleophile towards rhodium(III) than is water, even if only for statistical reasons (1), and in any event C—O rather than Rh—O bond forming may be involved.

Phase transformation studies on pure and K-doped Na_2SO_4

RITCHIE MACLAREN MURRAY AND ETALO A. SECCO[1]

Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received May 24, 1978

RITCHIE MACLAREN MURRY and ETALO A. SECCO. Can. J. Chem. **56**, 2616 (1978).

Phase transformation studies on pure Na_2SO_4 revealed four phases only; phase IV was not observed.

Electrical conductivity measurements have been made on polycrystalline undoped and K-doped Na_2SO_4 and on single crystals of undoped Na_2SO_4. Kinetic measurements on II → III transformation in undoped Na_2SO_4 show rate of conversion to be time independent and inversely related to temperature.

The presence of K in Na_2SO_4 effects a lowering of both the transition temperature and the enthalpy of transition along with an alteration from the "athermal" kinetic behavior to first-order kinetics.

RITCHIE MACLAREN MURRAY et ETALO A. SECCO. Can. J. Chem. **56**, 2616 (1978).

Des études de transformations de phases sur le Na_2SO_4 pur indiquent l'existence d'uniquement quatre phases; on n'a pas pu observer la phase IV.

On a effectué des mesures de conductivités sur du Na_2SO_4 polycristallin non-dopé et dopé par du K ainsi que sur des monocristaux de Na_2SO_4 non-dopés. Des mesures cinétiques sur la transformation II → III du Na_2SO_4 non-dopé indiquent que le taux de conversion est indépendant du temps et inversement proportionnel à la température.

La présence de K dans le Na_2SO_4 diminue la température ainsi que l'enthalpie de transition par une modification du comportement cinétique "athermique" en une cinétique du premier ordre.

[Traduit par le journal]

Introduction

The polymorphism of Na_2SO_4 has been investigated (1–5), and the regions of stability of various modifications have been reported (6). The existence of phase IV and the nature of the stability of phase II in Na_2SO_4 remain as open questions.

Our interest in Na_2SO_4 phase relationships arises from its common isostructural feature with K_2SO_4, orthorhombic at room temperature (7). Furthermore, the recent report citing mixed Na_2SO_4–K_2SO_4 matrix incorporating Tl^+ to give a phosphor (8) prompted us to investigate the phase interrelationships and phase transformation kinetics and to measure the electrical conductivity as a function of temperature in Na_2SO_4 and K-doped Na_2SO_4.

This paper presents the results of such an investigation using X-ray diffractometry, differential scanning calorimetry, and electrical conductivity techniques.

Experimental

Anhydrous Na_2SO_4 was from Fisher Certified stock. Both stock and twice-recrystallized Na_2SO_4 were used in thermal analyses for comparison purposes; in the conductivity measurements of pure Na_2SO_4 only twice-recrystallized material was used. Single crystals of Na_2SO_4 phase V were obtained from aqueous solution (distilled H_2O) at 318–323 K.

K-doped Na_2SO_4 samples were prepared by fusing the requisite composition mixture of the respective sulfates (K_2SO_4 Fisher Certified grade) in a Pt crucible.

The procedure for the electrical conductivity measurements on single crystal or polycrystalline sample has already been described (7).

X-ray diffraction patterns were obtained using a Norelco diffractometer with CuK_α radiation. Diffraction patterns at elevated temperatures were recorded with a Model X-86-N high temperature accessory (Materials Research Corp.) attached to the Norelco unit (9).

DSC traces were recorded on a duPont Model 990 Thermal Analyzer module with the differential scanning calorimeter attachment; samples were encapsulated in Al containers. The instrument was calibrated for enthalpy measurements using the heat of fusion for Sn as reference.

In the DSC kinetic measurements each sample, annealed at 573 K to ensure complete conversion to phase I, was subsequently cooled and maintained at the set temperature for the required time interval. The II/III content was evaluated by comparing the DSC enthalpic peak areas in the heat mode of the individual II → I and III → I transitions in the converted sample relative to the peak areas of their respective transitions in the pure state; the II → III transition was unaffected in the temperature region studied.

Results and Discussion

Our results on the polymorphic behavior in pure Na_2SO_4 can be fitted to four phases in agreement with Eysel (6). The phase relationships with their transition temperatures are presented below:

TABLE 1. Transition ΔH values for pure Na_2SO_4

Transition reaction	ΔH (kcal/mol)	
	This work	Eysel (6)
V → I	2.80	2.59
V → III	1.02	1.01
III → I	1.68	1.58
I → II	1.10	1.08
II → III	0.57	0.54

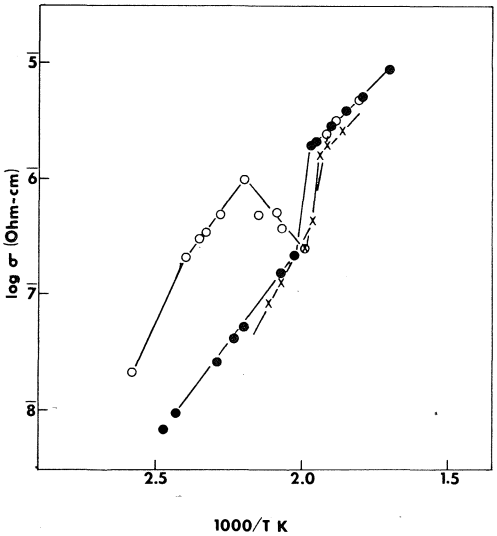

FIG. 1. Logarithm of conductivity, σ, vs. $10^3/T$ (K) for undoped Na_2SO_4 on heat mode in air: ○ single crystal V, ● polycrystalline V, × polycrystalline III.

No evidence for phase IV was found in our study.

The ΔH values accompanying the various transformations as determined by DSC in this study are presented, along with the values from Eysel, in Table 1.

The log σ vs. $1/T$ K plots for undoped Na_2SO_4 in the heat mode are given in Fig. 1. The initial higher conductivity of V in single crystal form declines at 454 K and merges with the polycrystalline curve at 508 K prior to the discontinuity.[2] The sharp rise in conductivity at 514 K for polycrystalline phase III is consistent with III → I phase transition as confirmed by X-ray diffraction.

The conductivity behavior for the high temperature phase I in the cool mode is shown in Fig. 2. The presence of the intermediate phase II was confirmed by X-ray diffraction (6).

Figures 3 and 4 show plots of log σ vs. $1/T$ K for

[2]The V → III transformation proceeds to a significant extent only in coarse Na_2SO_4, cross section >0.3 mm. The single crystal conductivity drop is consistent with DSC thermal anomalies associated with V → III transition in coarse Na_2SO_4 V samples (10, 11).

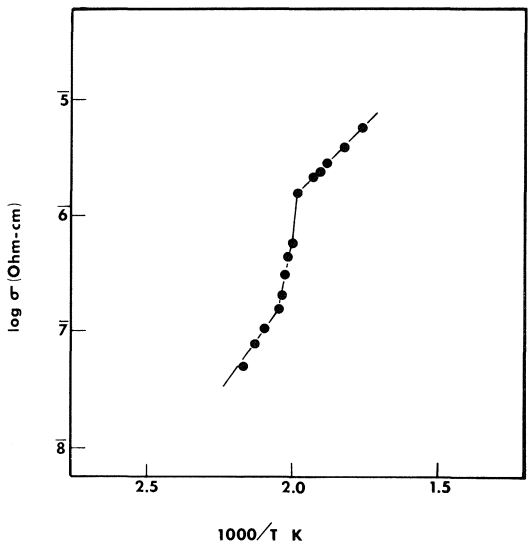

FIG. 2. Logarithm of conductivity, σ, vs. $10^3/T$ (K) for undoped Na_2SO_4 in cool mode in air for polycrystalline I.

0.8 mol% and 4.1 mol% K_2SO_4 in Na_2SO_4, respectively; the conductivity is lower for the richer K_2SO_4 sample. The effect of K_2SO_4 presence on phase transformation temperatures and hysteresis is clearly evident.

The rate of II → III transformation in undoped Na_2SO_4 was determined as a function of temperature in the region 483–503 K. Since the rate of conversion was dependent on particle size we selected the particle sample in the optimum range, viz. 0.04–0.07 mm cross section. The conversion fractions α vs. time for the various temperatures are plotted in Fig. 5. The fraction is independent of time at constant temperature but the fraction is inversely related to temperature. It is evident that the constant fraction

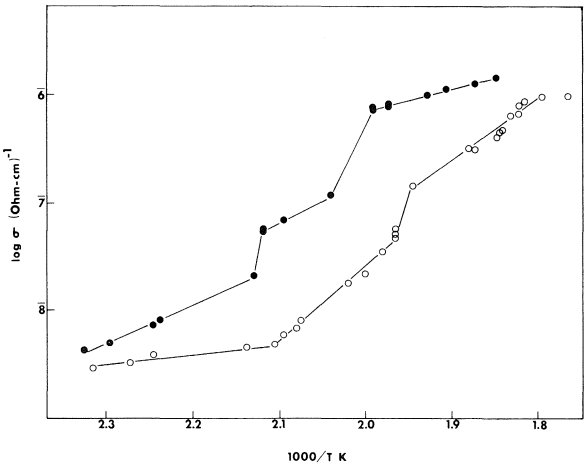

FIG. 3. Logarithm of conductivity, σ, vs. $10^3/T$ (K) for 0.8 mol% K-doped Na_2SO_4 polycrystalline in air: ○ heat mode, ● cool mode.

of II → III inversion is not the consequence of slow rate; the constant fraction most likely represents a stable inter-sublattice coupling. This "athermal" type of behavior has appeared in other systems (12, 13).

Figure 6 presents α vs. t data at various temperatures for 0.8 mol% K_2SO_4 in Na_2SO_4 of 0.04–0.07 mm cross section. The K_2SO_4 presence alters the

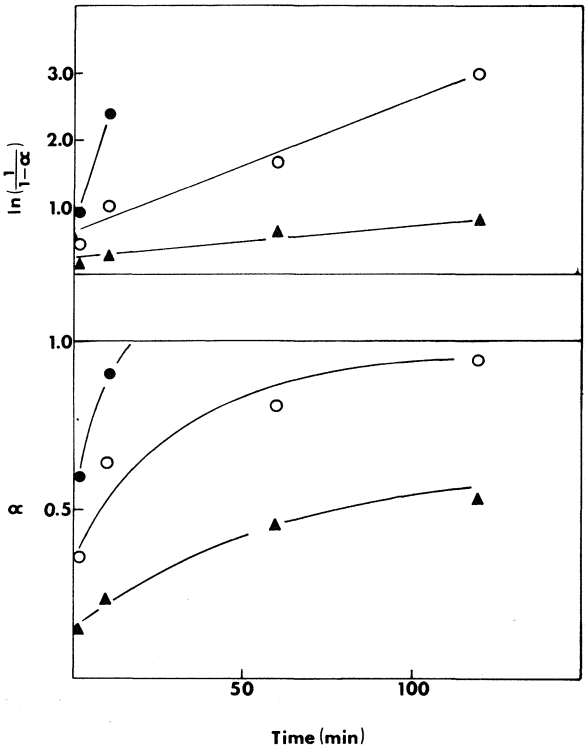

FIG. 6. Fraction of II → III conversion, α, vs. time and ln 1/(1 − α) vs. time in 0.8 mol% K-doped Na_2SO_4 at various temperatures: ● 473 K, ○ 475 K, ▲ 477 K.

kinetic behavior of the II → III transformation from the unusual "athermal" behavior to the more common first-order kinetics while maintaining the inverse temperature dependence.

The ΔH values accompanying the various phase transformations in K-doped Na_2SO_4 samples are given in Table 2. The dopant effected a lowering of both the transition temperature and the enthalpy of transition. The shift to lower values is assigned to the volume effect of the respective phases as tabulated in Table 3 and the larger K^+ radius relative to Na^+, i.e. 1.33 Å vs. 0.95 Å (14). The additional strain energy in K-doped Na_2SO_4 phase III relative to pure Na_2SO_4 phase III is visualized as the main factor in promoting the III → I transition in K-doped samples.

Volatility of amines used for water treatment in steam generating systems

POYILATH VARIETH BALAKRISHNAN
Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received April 18, 1978

POYILATH VARIETH BALAKRISHNAN. Can. J. Chem. **56**, 2620 (1978).

The relative volatilities of cyclohexylamine and morpholine in dilute aqueous solution have been measured in the temperature range 150 to 300°C at the corresponding equilibrium vapour pressure of the solution. Cyclohexylamine strongly prefers the steam phase while morpholine has a relatively volatility close to that of water. In both cases an azeotrope of the amine and water, with a vapour pressure higher than that of either component, must exist; however, with morpholine and water azeotrope formation only occurs above 175°C. The concentration dependence of the distribution between the steam and solution phases of both amines is explained in terms of their partial ionization in solution.

POYILATH VARIETH BALAKRISHNAN. Can. J. Chem. **56**, 2620 (1978).

On a mesuré les volatilités relatives de la cyclohexylamine et de la morpholine dans des solutions aqueuses diluées, à des températures allant de 150 à 300°C et aux tensions de vapeur de la solution correspondante. La cyclohexylamine préfère fortement la phase vapeur alors que la volatilité relative de la morpholine ressemble à celle de l'eau. Dans les deux cas, il doit exister un azéotrope de l'amine et de l'eau alors que la tension de vapeur est plus élevée que celle de chacun des composants; toutefois, dans le cas de la morpholine et de l'eau, la formation de l'azéotrope ne se produit qu'au dessus de 175°C. On explique le fait que la distribution entre les phases vapeur et liquide des deux amines dépend de la concentration en termes de leur ionisation partielle en solution.

Water treatment in nuclear steam generating systems is now based predominantly on alkaline volatile reagents, which neutralize acidity in the water thereby protecting surfaces from corrosion. Acidity in the water is usually caused by carbon dioxide from in-leakage of air or from the decomposition of carbonates in the steam generator. Since carbon dioxide is carried with the steam the carbonic acid in the condensate is best neutralized by a reagent which could also be carried into the steam phase, i.e., a volatile reagent. Thus, common reagents used are amines such as ammonia, morpholine, and cyclohexylamine.

A knowledge of the volatility of the reagent is important for determining the ability of the reagent to protect areas exposed to wet steam as well as for determining the loss of the reagent during the deaeration of the feedwater or by blowdown of the steam generator water. In addition, such knowledge would also be useful in evaluating the chemistry of the steam generator water under 'volatile' treatment; the chemistry will be influenced by the residual amine concentration in the water.

There have been some studies on the volatility of amines. Jones (1) has determined the relative volatility of ammonia in water in the concentration range 2 to 200 μg NH_3/kg water, in the temperature range 150 to 325°C. Berk and Nigon (2) have discussed the volatility of cyclohexylamine and morpholine solutions on the basis of observations in boilers. Albrecht and Schuck (3) and Cuisia (4) have determined the volatility of cyclohexylamine and morpholine, but in these studies the equilibration was done at 1 atm pressure. The present work extends the studies on cyclohexylamine and morpholine to pressures up to the saturation vapour pressure of water corresponding to a temperature of 300°C (i.e. 8.59 MPa).

Experimental

The distribution of morpholine and cyclohexylamine in the temperature range of 150 to 300°C (pressure range 476 kPa to 8.59 MPa) was studied in the apparatus shown in Fig. 1. The system consists of a large (≃8 L) autoclave with an arrangement to draw samples from the liquid and vapour phases. The arrangement also allows the condensed vapour to be circulated back by natural circulation to the liquid phase in the autoclave, thereby allowing more mixing between the two phases. However, during the preliminary experiments, the same results were obtained with the system operating in the dynamic mode with recirculation as when it was operating in the static mode without the recirculation and consequently the latter mode of equilibration was used in the later experiments. When operating in the static mode, the rising portion of the vapour line in the apparatus was made as short as possible to minimize any error due to refluxing.

For each experiment 4 L of demineralized water was put in the autoclave. Nitrogen was bubbled through the water for about 1 h to remove dissolved air. Sufficient amine to give approximately the desired concentration (mg amine/kg water) was added to the water and the autoclave closed. The gas pressure over the solution in the autoclave was reduced by

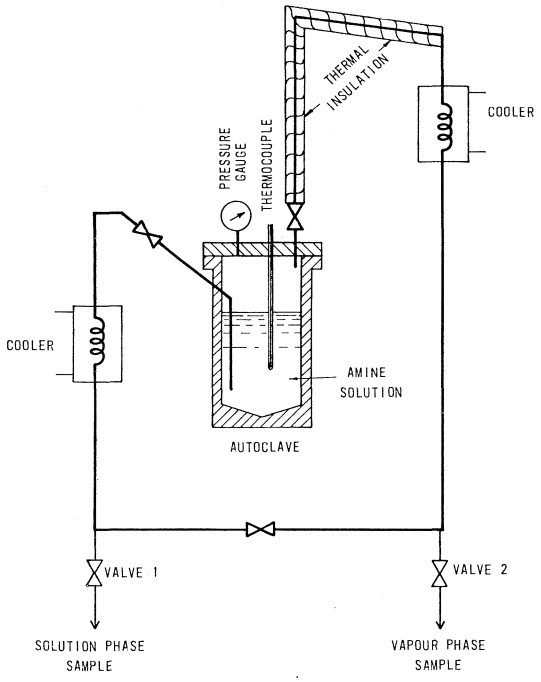

FIG. 1. Apparatus for volatility studies at high temperatures.

pumping off the gas with a vacuum pump for about 15 min. The autoclave was then heated to the desired temperature. Twice during the heating, i.e. when the temperature just exceeded 100°C and when the experimental temperature was reached, some steam (equivalent to $\simeq$100 g water) was blown off via valve 2 to assure complete removal of gases from the system. The system was maintained at the experimental temperature for 4 h and then 20 to 100 g sample of the solution phase and 10 to 50 g sample of steam phase were taken via valves 1 and 2, respectively, for determination of the amine molality in each phase. The size of the sample depended on the amine content in the sample. The sample size was kept to the minimum and the sample was drawn slowly (over a period of 10 min) to minimize the perturbations in the equilibrium. In the preliminary experiments, samples were taken from the autoclave at 2-h intervals over a period of 24 h. Analyses of these samples for amine showed that a steady state with respect to the amine distribution was attained within 4 h. In view of the precautions taken to minimize perturbations in the equilibrium during sampling, this steady state should be close to the equilibrium.

The amine molality in a sample was determined by potentiometric titration of a suitable aliquot against standard hydrochloric acid, with care being taken to exclude air during the analysis by bubbling nitrogen through the solution.

Values for the relative volatility, defined here as the (dimensionless) ratio of the amine molality in the steam sample to that in the water sample, were calculated.

Results and Discussion

The relative volatility values at different amine concentrations (mg amine/kg water) and at different temperatures are given in Table 1 for cyclohexylamine and in Table 2 for morpholine.

The relative volatility of cyclohexylamine was always considerably greater than unity, i.e. the amine molality in the vapour phase was much higher than that in the liquid phase in the temperature and concentration ranges studied. The relative volatility decreased as the temperature increased in the range 175 to 300°C, but increased as the concentration increased.

The relative volatility of morpholine, at temperatures lower than about 175°C, was slightly less than unity. With increasing temperature, relative volatility increased and tended to approach a limiting value of about 1.35.

The effect of amine molality on the relative volatility may be explained on the basis of the limited ionization of the amine in the solution. The equilibrium involved is

$$[1] \qquad BH^+ \rightleftarrows B + H^+$$

where B is the base, cyclohexylamine or morpholine, and BH^+ the conjugate acid, cyclohexylammonium or morpholinium ion. Only the neutral (uncharged) amine is expected to go into the vapour phase. Thus, the equilibrium for the distribution of the amine in the two phases would be

$$[2] \qquad B_{water} \rightleftarrows B_{steam}$$

The equilibrium constant for reaction [2], i.e. the distribution coefficient, is

$$[3] \qquad K_D = [B]_{steam}/[B]_{water}$$

$[B]_{steam}$ may be assumed to be the total amine molality in steam. The molality term $[B]_{water}$ may be calculated from the total amine molality, B_T, in the water phase using the equilibrium constant K_a for reaction [1]

$$[4] \qquad K_a = \frac{[B][H^+]}{[BH^+]} = \frac{\alpha}{1-\alpha}[H^+]$$

where α is the fraction of the total amine that is neutral, i.e.,

$$[5] \qquad \alpha = [B]/B_T$$

For electroneutrality,

$$[6] \qquad [BH^+] + [H^+] = [OH^-] = K_w/[H^+]$$

or

$$[7] \qquad (1-\alpha)B_T = K_w/[H^+] - [H^+]$$

where K_w is the ionic product of water. From eqs. [4] and [7]

$$[8] \qquad K_a(\alpha-1)^2(K_a + \alpha B_T) - \alpha^2 K_w = 0$$

from which α may be evaluated. The distribution coefficient K_D for the amine may then be obtained from the relative volatility values using the relation

$$[10] \qquad K_D = \text{relative volatility}/\alpha$$

For evaluating α the ionization constants, K_a, determined by Mesmer and Hitch (5) were used. The values for ionic product of water, K_w, were chosen from the 'best' set of values listed in the review article by Olofsson and Hepler (6) on the thermodynamics of ionization of water. The calculated values of α and values for K_a and K_w are also listed in Tables 1 and 2. Figures 2 and 3 show plots of the distribution coefficient vs. temperature for cyclohexylamine and morpholine respectively at pressures corresponding to the vapour pressure of the solution at the temperature. The figures show that the description of the system in terms of a distribution coefficient, K_D, for the equilibrium between the neutral amine in the water phase and the amine in the steam phase is satisfactory. The deviation towards lower values for the distribution coefficient in the case of cyclohexylamine at the concentration of

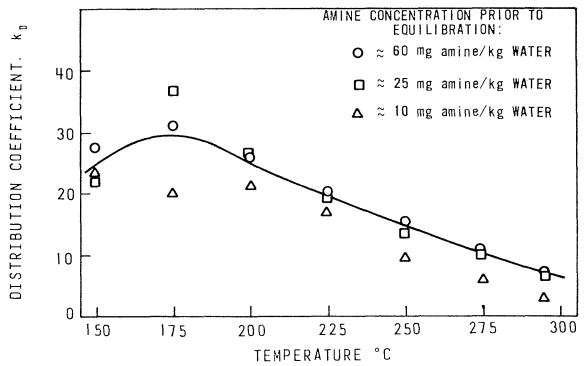

FIG. 2. Distribution of cyclohexylamine between steam and water.

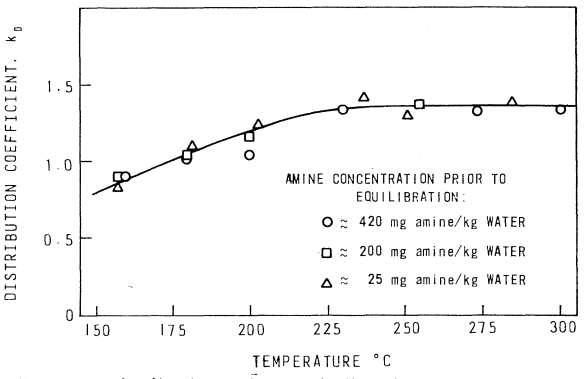

FIG. 3. Distribution of morpholine between steam and water.

≃10 mg amine/kg water before equilibration is probably due to the effect of residual carbon dioxide in the autoclave during the experiment. The residual carbon dioxide may effectively be lowering the volatility of the amine, the effect becoming more significant at lower concentrations of the amine. Also, at lower concentrations of amine, the determination of the amine molality by the titration method becomes more difficult and less accurate.

The distribution coefficient of cyclohexylamine was observed to be greater than unity at all temperatures (Table 1 and Fig. 2). Based on data available for temperatures up to 134°C, the vapour pressure of pure cyclohexylamine may be expected to be lower than that of pure water at all temperatures. The observed volatility behaviour then indicates the existence of an azeotrope of higher vapour pressure than that of either pure component, water or the amine. The azeotrope formation would be at some concentration of amine higher than those studied. The azeotrope must exist throughout the range of temperature and pressure studied (temperature: 150 to 300°C, pressure: the saturated vapour pressure of the solution corresponding to the temperature). Since the vapour pressure of water increases rapidly with temperature, the decreasing trend in the distribution coefficient observed at temperatures higher than 175°C might be reflecting the nature of the cyclohexylamine–water phase diagram, such as a shift in the azeotrope composition towards higher mole fraction of water.

Morpholine is not known to form an azeotrope with water at the low pressures at which it has been studied. The observation of a distribution coefficient less than 1 (Table 2 and Fig. 3) at temperatures lower than 175°C (and correspondingly lower pressures) is thus consistent with the available information. However, with the temperature increasing above 175°C, along with a corresponding increase in the pressure, the distribution coefficient becomes greater than unity and eventually levels off at a value of 1.35. This behaviour may be explained by the existence of an azeotrope of higher vapour pressure than that of either morpholine or water, at temperatures higher than 175°C.

Influence des composés organiques sur la vitesse d'apparition du complexe de transfert de charge 1Sn(II)–4Sn(IV) dans les bains acides d'étamage brillant[1,2]

GASTON VERVILLE

Division de conversion de l'énergie, Centre de recherches pour la Défense, Ottawa (Ont.), Canada K1A 0Z4

Reçu le 5 janvier 1978

GASTON VERVILLE. Can. J. Chem. **56**, 2624 (1978).

La variation d'absorbance de solutions stanneuses au cours du temps, comparée à la variation d'absorbance de ces solutions en présence de composés organiques nous a permis de montrer l'influence de certains composés organiques sur la vitesse d'apparition du complexe de transfert de charge 1Sn(II)–4Sn(IV) et sur la stabilité des solutions en milieu acide sulfurique. Nous avons distingué trois types de comportement qui nous ont permis de classer les composés étudiés en trois grandes catégories.

L'interprétation des résultats tient compte du fait que l'apparition du complexe 1Sn(II)–4Sn(IV) et la stabilité des solutions stanneuses dépendent de la concentration initiale en impuretés stanniques, de la vitesse d'oxydation des ions stanneux, de l'hydrolyse des ions stanniques et de la stabilité des colloïdes stanniques formés.

GASTON VERVILLE. Can. J. Chem. **56**, 2624 (1978).

The effect of a number of organic compounds on the rate of formation of 1Sn(II)–4Sn(IV) charge transfer complex in acidic stannous sulphate solutions and on the stability of these solutions has been determined by measuring, spectrophotometrically, the change of absorption of these solutions with time. From the results, it is possible to classify these organic compounds into three broad categories in terms of how they affect the formation of the charge transfer complex and the stability of the solution.

These results have been interpreted taking into account that the formation of the 1Sn(II)–4Sn(IV) complex depends on the initial concentration of stannic ions present as an impurity in the stannous sulphate solution, the rate of oxidation of the stannous ions, the rate of hydrolysis of the stannic ions, and the stability of stannic colloids that are formed.

Introduction

Nos travaux sur les bains acides d'étamage brillant (1) ont montré que les bains modernes d'étamage opèrent en présence de tensides et en présence de colloïdes stanniques qui forment des complexes de transfert de charge *X*Sn(II)–*Y*Sn(IV) avec les ions stanneux. Une étude bibliographique plus approfondie nous a également révélé que les colloïdes stanniques et les complexes *X*Sn(II)–*Y*Sn(IV) s'insèrent dans les mécanismes proposés pour expliquer le fonctionnement des bains sensibilisateurs des surfaces hydrophobes (2, 3). Bien que les complexes *X*Sn(II)–*Y*Sn(IV) aient déjà fait l'objet d'un certain nombre de publications (4–12) et que la nature et le rôle exacts de ces complexes soient encore discutés, il nous est apparu intéressant d'étudier à partir de solutions stanneuses l'effet de divers composés organiques sur la vitesse d'apparition du complexe 1Sn(II)–4Sn(IV). Ce complexe est le complexe de transfert de charge identifié par Paul *et al.* (4) dans la zone d'acidité (0.2–1 *M*) où opèrent les procédés industriels déjà mentionnés.

Le complexe 1Sn(II)–4Sn(IV) n'apparaît que lorsqu'on met en présence des colloïdes stanniques et des complexes stanneux positifs (1, 4). Par ailleurs ce complexe est généralement caractérisé par une absorption intense dans l'uv qui s'étend parfois jusqu'au visible (fig. 1) pour conférer aux mélanges des solutions stanneuses et stanniques une coloration jaunâtre. En partant de solutions de sulfate stanneux, dont l'oxydation à température ambiante produit des colloïdes stanniques, la variation d'absorbance des solutions stanneuses au cours du temps comparée à la variation d'absorbance de ces solutions en présence de composés organiques permet de montrer l'influence de ces composés sur la vitesse d'apparition du complexe 1Sn(II)–4Sn(IV).

Composés étudiés et mode opératoire

Les composés étudiés et leurs concentrations ont été choisis en relation avec leur présence dans les bains acides d'étamage: polypropylène glycol P-400, phénol, acide hydroxyphénol sulfonique, méthanol, éthanol, méthanal, acide formique.

Les composés employés sont de qualité R.P. et ne sont l'objet d'aucune purification. Le sulfate stanneux utilisé contenait 1.5% d'impuretés stanniques.

Les composés choisis sont introduits après dissolution complète de 30 g/ℓ de sulfate stanneux en

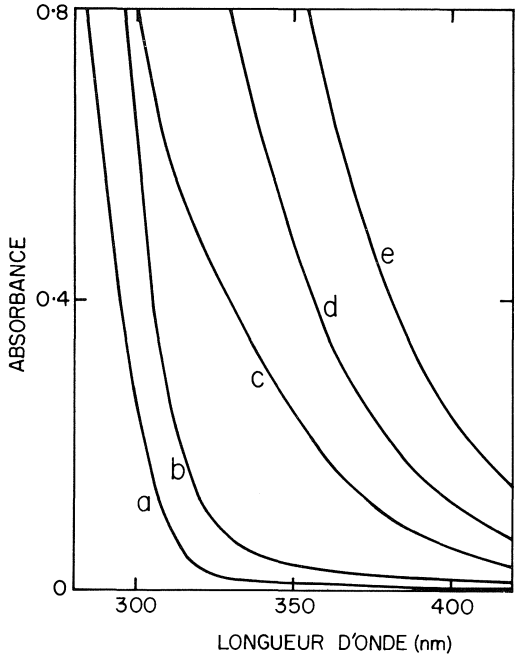

FIG. 1. Spectres d'absorption uv–vis. d'une solution stanneuse, d'une solution stannique et de leurs mélanges en milieu HCl, pH = 0.6: *a*, solution stanneuse fraichement préparée ($SnCl_2 \cdot 2H_2O$, 5×10^{-3} *M*); *b*, solution stannique vieillie pendant 24 h ($SnCl_4 \cdot 5H_2O$, 5×10^{-3} *M*); *c*, mélange équimolaire, 2.5×10^{-3} *M* Sn total; *d*, mélange équimolaire, 5.0×10^{-3} *M* Sn total; *e*, mélange équimolaire, 1.0×10^{-2} *M* Sn total.

milieu acide sulfurique 5 et 10% V. Les solutions résultantes sont ensuite placées dans des erlenmeyers de 250 ml et laissées au repos en contact avec l'air à température ambiante. Les mesures journalières d'absorbance des solutions sont réalisées à l'aide d'un spectrophotomètre SAFAS 1700.

Résultats

Les courbes de la fig. 2 montrent l'évolution au cours du temps d'une solution $SnSO_4$ 30 g/ℓ, H_2SO_4 5%. On remarque un déplacement progressif du seuil d'absorption vers les grandes longueurs d'onde avec le temps. Ce déplacement vers le visible est responsable de l'apparition de la coloration jaune caractéristique des complexes 1Sn(II)–4Sn(IV). Ultérieurement apparaissent l'opalescence de la solution puis la formation d'un précipité. La diffraction des R–X et les analyses par spectrophotométrie ir montrent que ce dernier correspond à du SnO_2 hydraté.

Les figs 3 à 7 illustrent des exemples typiques des courbes obtenues en suivant l'absorbance des solutions à 400 nm en fonction du temps.

Chaque courbe a été divisée en trois périodes: une 1ère période ou période d'induction où l'absorption

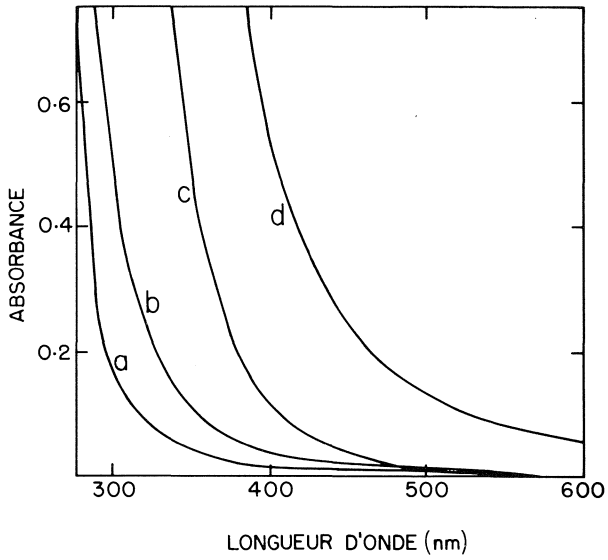

FIG. 2. Evolution au cours du temps d'une solution $SnSO_4$ 30 g/ℓ, H_2SO_4 5%: *a*, solution initiale; *b*, solution après 3 jours; *c*, solution après 5 jours; *d*, solution après 14 jours.

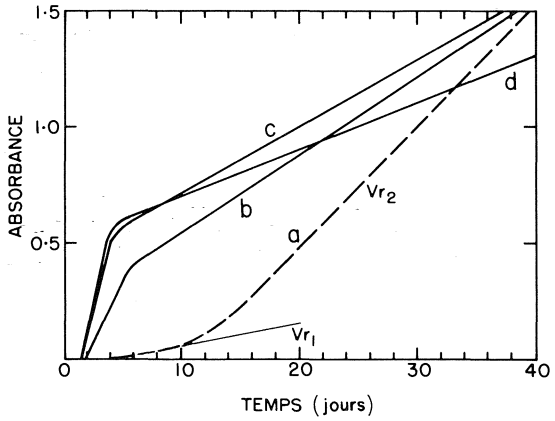

FIG. 3. Influence du méthanol sur l'absorbance des solutions en milieu H_2SO_4 10%: *a*, $SnSO_4$ 30 g/ℓ; *b*, *a* + méthanol (0.25 *M*); *c*, *a* + méthanol (1.25 *M*); *d*, *a* + méthanol (2.5 *M*).

est nulle, une 2ème période où l'augmentation de l'absorption s'effectue à vitesse constante v_1 et une 3ème période où l'augmentation de l'absorption s'effectue à vitesse constante v_2.

La comparaison de la courbe obtenue à partir d'une solution exempte de composé organique avec celle obtenue à partir d'un mélange choisi permet de distinguer trois catégories de composés organiques selon leur influence sur la vitesse d'apparition du complexe.

Classification des composés étudiés

1ère catégorie: méthanol, méthanal, éthanol

Les figs 3 et 4 illustrent les résultats obtenus avec le méthanol. Les composés de cette catégorie

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

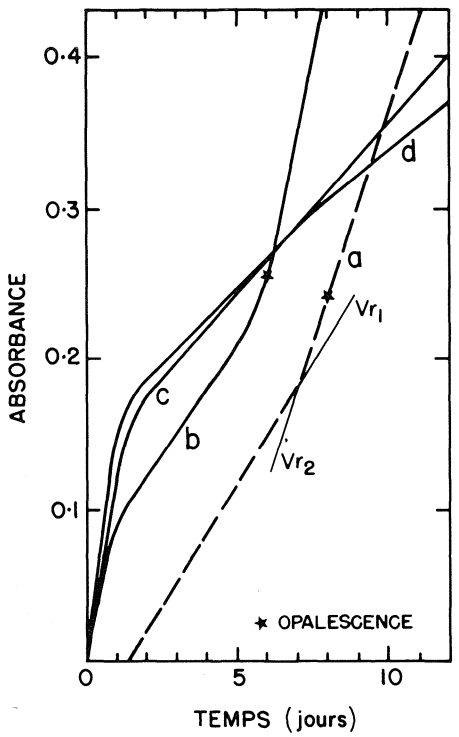

FIG. 4. Influence du méthanol sur l'absorbance des solutions en milieu H_2SO_4 5%: *a*, $SnSO_4$ 30 g/ℓ; *b*, *a* + méthanol (0.25 *M*); *c*, *a* + méthanol (1.25 *M*); *d*, *a* + méthanol (2.5 *M*).

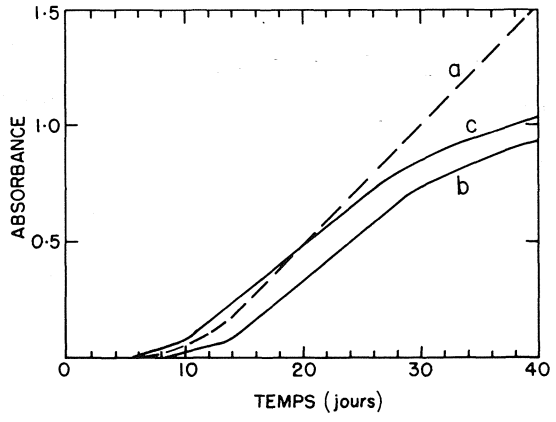

FIG. 5. Influence du polypropylène glycol sur l'absorbance des solutions en milieu H_2SO_4 10%: *a*, $SnSO_4$ 30 g/ℓ; *b*, *a* + polypropylène glycol 2 g/ℓ; *c*, *a* + polypropylène glycol 20 g/ℓ.

diminuent la période d'induction et accélèrent la vitesse d'apparition du complexe durant les premiers jours d'observation. Cette vitesse v_1 augmente avec la concentration des composés. Ces composés ralentissent ensuite la vitesse v_2 d'autant plus que leur concentration est plus élevée. Le tableau 1 présente

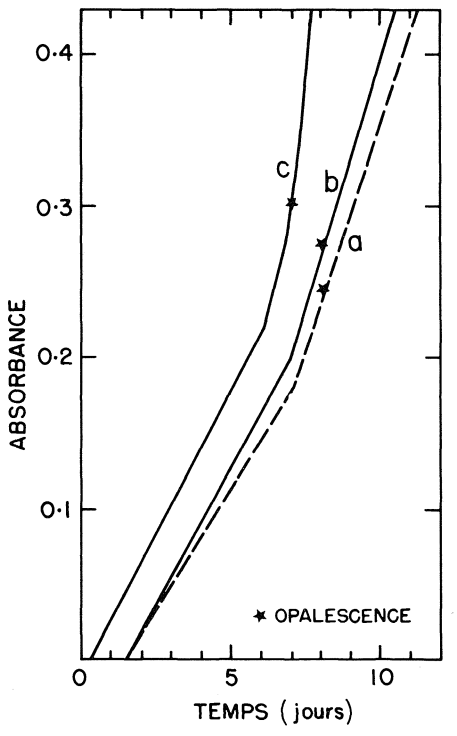

FIG. 6. Influence du polypropylène glycol sur l'absorbance des solutions en milieu H_2SO_4 5%: *a*, $SnSO_4$ 30 g/ℓ; *b*, *a* + polypropylène glycol 2 g/ℓ; *c*, *a* + polypropylène glycol 20 g/ℓ.

les valeurs des vitesses d'apparition tirées des pentes des courbes. A concentration égale, les solutions en présence de méthanol présentent l'activation maximale pour la vitesse v_1.

Le tableau 2 présente les temps compris entre les phases successives qui caractérisent l'évolution des solutions en milieu H_2SO_4 5%. On constate que les composés de la 1ère catégorie augmentent considérablement la durée de vie des solutions[3] ainsi que le temps écoulé entre l'apparition de l'opalescence et la précipitation.

2ème catégorie: polypropylène glycol, acide formique

Les produits de cette catégorie n'influencent pas d'une façon notable la vitesse d'apparition du complexe. A une acidité donnée, leur influence sur la vitesse est indépendante de leur concentration (voir tableau 1). On remarque également qu'une augmentation de leur concentration en solution H_2SO_4 5% se traduit par une diminution de la durée de vie des solutions. Les figs 5 et 6 illustrent les résultats obtenus avec le polypropylène glycol.

[3]Temps écoulé entre la mise en solution et l'apparition d'un précipité au fond des erlenmeyers.

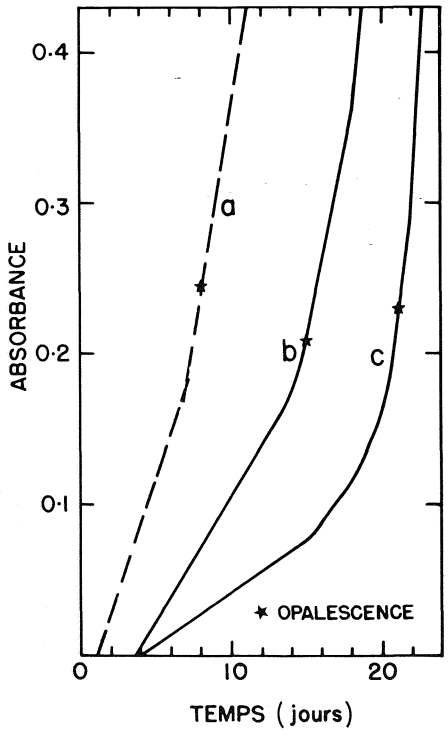

FIG. 7. Influence de l'acide hydroxyphénol sulfonique sur l'absorbance des solutions en milieu H_2SO_4 5%: *a*, $SnSO_4$ 30 g/ℓ; *b*, *a* + acide hydroxyphénol sulfonique 0.05 *M*; *c*, *a* + acide hydroxyphénol sulfonique 0.2 *M*.

3ème catégorie: phénol, acide hydroxyphénol sulfonique

La fig. 7 présente les résultats obtenus avec l'acide hydroxyphénol sulfonique. Les composés de cette catégorie augmentent considérablement la période d'induction; par exemple la période d'induction est supérieure à 40 jours dans les solutions H_2SO_4 10% en présence de 0.2 *M* de ces composés. Ces composés diminuent d'une façon notable les vitesses v_1 et v_2 et ce d'autant plus que leur concentration est plus élevée.

Analyse des résultats

Rappelons que la formation du complexe 1Sn(II)–4Sn(IV) n'intervient que lorsqu'on met des colloïdes d'oxyde stannique en présence de complexes stanneux positifs. Dans l'ensemble les résultats observés s'expliquent à l'aide des deux considérations suivantes: (*1*) La période d'induction et la vitesse d'apparition du complexe 1Sn(II)–4Sn(IV), à partir d'une solution stanneuse, dépend de la concentration initiale en impuretés stanniques (13), de la vitesse d'oxydation des ions stanneux et de l'hydrolyse des ions stanniques. (*2*) L'oxydation des ions stanneux et l'hydrolyse des ions stanniques étant complétées, la stabilité des solutions sera contrôlée par la stabilité des colloïdes stanniques.

Les composés de la 1ère catégorie (méthanol, méthanal, éthanol) sont reconnus pour leur caractère

*Temps écoulé entre l'apparition de l'opalescence et le moment où on ne peut distinguer un objet sur le plancher en regardant au-dessus des erlenmeyers placés à un mètre du sol.

faiblement réducteur. Il est alors paradoxal de constater une courte période d'induction et une augmentation de la vitesse v_1 lorsque leur concentration augmente car ce comportement indique une augmentation de la vitesse d'oxydation des ions stanneux ou de l'hydrolyse des ions stanniques. Le caractère réducteur de ces composés permet d'écarter la première hypothèse. Il est peu probable également qu'ils facilitent l'hydrolyse étant donné la grande stabilité des solutions en présence de ces composés. Le comportement des produits de cette catégorie s'explique plutôt à partir de la formation de complexes de transfert de charge ayant une composition différente du complexe 1Sn(II)–4Sn(IV) étudié et qui absorberaient également à 400 nm. En effet Meyer *et al.* (7, 8) et De Maine *et al.* (9) ont montré dans leurs travaux que des mélanges de chlorure stanneux et stannique formaient des complexes de transfert de charge en présence de méthanol et d'éthanol purs. Ces auteurs n'ont toutefois pas identifié les constituants stanneux et stanniques des complexes de transfert de charge étudiés.

Le polypropylène glycol et l'acide formique, qui se classent dans la 2ème catégorie, n'influencent pas d'une façon notable la vitesse d'apparition du complexe. Toutefois ils semblent agir sur la stabilité des colloïdes; en trop grande concentration ces produits favorisent la polymérisation des colloïdes stanniques en milieu H_2SO_4 5% et de ce fait diminuent la durée de vie des solutions.

Le phénol et l'acide hydroxyphénol sulfonique, qui se classent dans la 3ème catégorie sont deux antioxydants reconnus. Ils augmentent considérablement la période d'induction et diminuent les vitesses v_1 et v_2 ce qui explique l'augmentation de la durée de vie des solutions. Il est bon toutefois de remarquer que ces composés ne semblent jouer qu'un rôle secondaire sur la stabilité des colloïdes formés car la période comprise entre l'apparition de l'opalescence et l'apparition d'un précipité est sensiblement la même que la solution de référence en milieu H_2SO_4 5%.

Conclusion

Cette étude sur l'influence des composés organiques sur la vitesse d'apparition du complexe 1Sn(II)–4Sn(IV) et la stabilité des solutions stanneuses nous a permis d'une part de distinguer trois types de comportement et d'autre part de faire ressortir l'influence remarquable des composés tels que le méthanol et le méthanal souvent rencontrés dans la composition des bains d'étamage. Ces composés, en plus de faciliter la mise en solution des additifs organiques, augmentent d'une façon notable la stabilité des solutions et interviennent dans la formation de complexes de transfert de charge dont le rôle reste encore à être déterminé.

Excited radicals in the gas phase photolysis of butene isomers at different photon energies: energy distribution in reaction products

GUY J. COLLIN AND ANDRZEJ WIĘCKOWSKI[1]

Département des Sciences Pures, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Received May 9, 1978

GUY J. COLLIN and ANDRZEJ WIĘCKOWSKI. Can. J. Chem. **56**, 2630 (1978).

A systematic study of the pressure effects on the quantum yields of some products between 0.1 and 600 Torr (13 and 80 000 N m^{-2}) was carried out in the 7.6 and 8.4 eV photolysis of normal, iso- and *cis*-2-butenes. The propylene quantum yield (s-C_4H_9* → C_3H_6 + CH_3) decreased with the increase in the *n*-butene pressure and a good linearity of S/D (stabilization/decomposition) vs. pressure plot, over a broad pressure region, was observed. It is concluded that hydrogen atoms involved in the s-C_4H_9* radical formation are produced with a relatively narrow energy distribution. The slope of S/D vs. pressure lines decreased with the increase in photon energy, indicating the trend in the kinetic energy of the H-atoms.

In the case of isobutene and *cis*-2-butene photolysis, the Stern–Volmer plots for allene formation were nonlinear. It is concluded that the formation of two different allene precursors is needed to account for this result. By the use of a simple RRK-type formalism we also conclude that the excess energy of the photon in the primary photoexcited butene molecules is far from being randomized before their fragmentation occurs.

$$C_4H_8 + h\nu \rightarrow C_4H_8^{**} \rightarrow C_3H_5^* + CH_3$$

GUY J. COLLIN et ANDRZEJ WIĘCKOWSKI. Can. J. Chem. **56**, 2630 (1978).

Nous avons étudié systématiquement l'effet de la pression sur le rendement quantique de certains produits entre 0.1 et 600 Torr (13 et 80 000 N m^{-2}) lors de la photolyse des butènes dans la région de 7.6–8.4 eV. La formation du propène décroît avec l'augmentation de pression: s-C_4H_9* → C_3H_6 + CH_3. De l'absence de courbure de la droite S/D (stabilisation/decomposition) en fonction de la pression on conclue que les atomes d'hydrogène sont formés avec une distribution d'énergie plutôt étroite. La pente de cette droite décroît avec l'augmentation de l'énergie des photons montrant l'effet de cette augmentation sur l'énergie cinétique des atomes d'hydrogène produits. Les courbes de type Stern–Volmer du rendement de l'allène avec la pression montrent dans le cas du *cis*-2-butène et de l'isobutène une courbure prononcée à basse pression. Cette courbure ne semble pas être le résultat d'une large distribution d'énergie dans le fragment C_3H_5*. Au contraire, il semble qu'il faille l'expliquer par la formation de deux intermédiaires différents. Les constantes de vitesse de formation de l'allène permettent via une formulation simple du type RRK de conclure que la distribution de l'excès d'énergie dans la molécule photoexcitée n'est pas statistiquement distribuée.

$$C_4H_8 + h\nu \rightarrow C_4H_8^{**} \rightarrow C_3H_5^* + CH_3$$

Introduction

The kinetic study of the photoactivated system provides not only some valuable information about unimolecular processes, but also some unique data on the partitioning of energy among the fragmentation products (1). The advantages of such systems are quite obvious: the internal energy of the excited species may vary along with the changes in photon energy, and the decomposition processes occur at a low temperature, ensuring a smaller spread of internal energies in the species as compared to what is observed in thermally activated systems. However, the Stern–Volmer treatment of the primary photoexcited species is limited to large molecules of numerous oscillators, and/or at relatively low photon energies. For example, the collisional stabilization of photoexcited *cis*-2-butene (C2B) molecules reported to occur at 6.7 eV (2) is no longer observed at 7.1 eV (3).

Another kind of photoexcitation arises when the hydrocarbon fragments produced in the primary photochemical step contain enough internal energy to undergo subsequent unimolecular reactions. As shown by many authors (1), these products are formed with a relatively broad spread in internal energy, and the energy need not be statistically distributed among the internal degrees of freedom. It has previously been reported (2, 4) that the gas phase photolysis of butene isomers leads to the formation of the C_3H_5* radicals

which may contain a part of the excess energy of the incident photon. In the 7.1 eV photolytic butene systems (nitrogen resonance lines, 174.3–174.5 nm), we have shown that the C_3H_5* radicals decompose, yielding C_3H_4 hydrocarbon products, whose yield is strongly dependent on the total pressure. In particular, the resulting $[\Phi(\text{allene})]^{-1}$ vs. butene pressure plots turn out to be nonlinear, and this observation was attributed to the formation and decomposition of two distinct types of the C_3H_5* radicals of reasonably narrow energy content (3, 5).

In the present study, the decomposition processes of the excited C_3H_5* radicals formed in the gas phase photolysis of normal butene (NB), *cis*-2-butene (C2B), and isobutene (IB) were investigated at two photon energies: at 7.6 eV (a bromine resonance line, 163.3 nm) (6) and at 8.4 eV (a xenon resonance line, 147.0 nm). Some results on the decomposition of the s-C_4H_9* radical (the propylene formation process) are also included. For the purpose of comparison, the earlier data on these systems obtained at 7.1 eV are added and discussed (and partially reinterpreted). The attention is focussed on the implications of the experimental results towards the theory of unimolecular processes of systems activated by the absorption of photons by organic molecules.

Experimental

The design of the resonance lamps as well as the details of the experimental and chromatographical procedure have been given before (3, 5–7). All quantum yields of the products were determined by using ethylene as an actinometer with $\Phi(C_2H_2) = 0.75$ (8).

Results

Before applying a steady-state treatment (Stern–Volmer or S/D vs. pressure plots) to our systems it is necessary to check if the product quantum yields decrease to zero with the increase in pressure or to a constant, pressure independent value. In the 7.1 eV photolysis of C2B, the allene quantum yield was equal to 0.11 at 0.05 Torr against 0.002 at 400 Torr (3). This means that an almost entire deactivation of the allene precursor was attained. Similar observations were made on C2B photolysis at 7.6 eV as well as on IB photolytic system at 7.1 and 7.6 eV, respectively. However, in the case of 8.4 eV photolysis of both C2B and IB, even under the highest reactant pressure applied (600 Torr), the allene quantum yield still represented a substantial fraction of the yields determined at the lowest pressure. Although the drop in the Φ(allene) value was observed over the whole pressure region investigated, a direct evidence that this value would tend to zero was lacking. Thus, the same way of decoding the Φ(allene) against pressure data at three photon energies used (see below) involves the assumption that no other routes of the allene formation process, yielding a pressure independent Φ(allene) contribution, become active in the 7.6–8.4 eV region.

In the NB photolysis at 7.1 and 7.6 eV, respectively, an analysis of the allene quantum yield as a function of NB pressure revealed that at high pressure, a constant, pressure-independent Φ(allene) value was attained. Thus, the rate constants of the decomposition of the C_3H_5* radicals produced in the system studied were determined by using the $[\Phi - 0.02]^{-1}$ vs. pressure plots.

Considering the above remarks, and assuming the steady state conditions for allene and propylene precursors, the Stern–Volmer plots were obtained and they are presented in Figs. 1–6. In the C2B and IB photolytic systems, two pressure regions, low and high, were distinguished and analysed (Figs. 2–5) in the same way as was done in our previous works (3, 5). On the contrary, the good linearity of the plot $[\Phi(\text{allene}) - 0.02]^{-1}$ vs. NB pressure, covering a broad pressure region, was attained (Fig. 1), which made us reinterpret our earlier data on NB photolysis at 7.1 eV (5).

The kinetics of the propylene formation process is analysed (5) by the use of the S/D vs. NB pressure plots (Fig. 6), ($D = \Phi(C_3H_6)$, $S = \Phi^0(C_3H_6) - \Phi(C_3H_6)$, where $\Phi^0(C_3H_6)$ values resulted from the extrapolation of $\Phi(C_3H_6)$ values to zero pressure). These plots are virtually equivalent to the Stern–Volmer ones. A good linearity of these plots over a wide range of pressure should be noted.

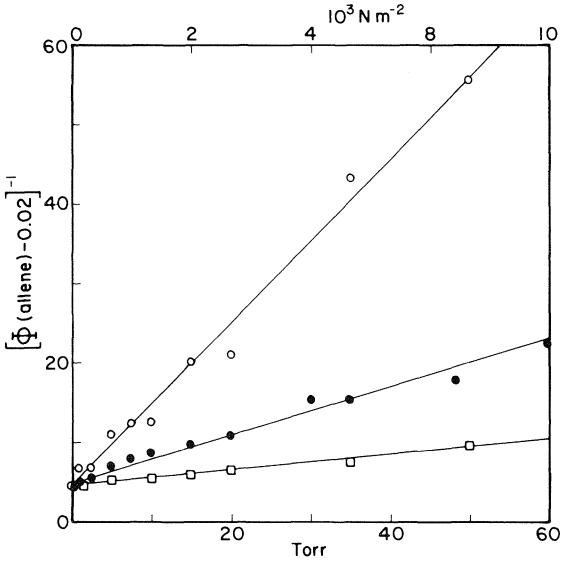

FIG. 1. Photolysis of normal butene at 7.1 eV (○), 7.6 eV (●), and 8.4 eV (□). The $[\Phi(\text{allene}) - 0.02]^{-1}$ vs. pressure.

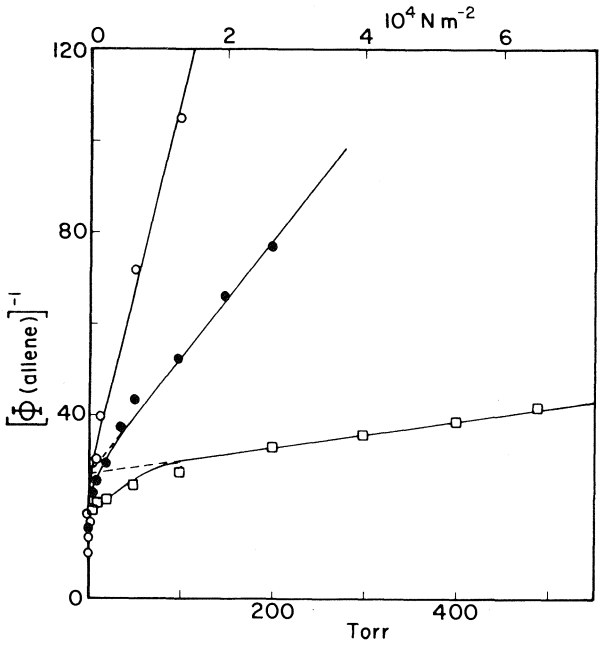

FIG. 2. Photolysis of *cis*-2-butene at 7.1 eV (○), 7.6 eV (●), and 8.4 eV (□). The $[\Phi(\text{allene})]^{-1}$ vs. pressure.

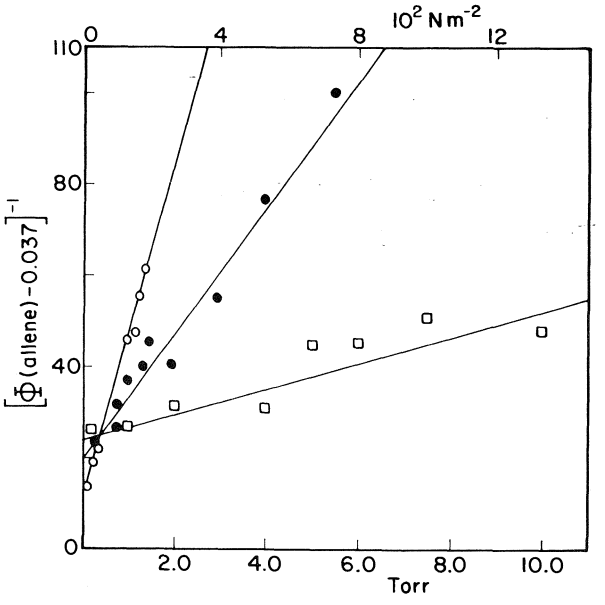

FIG. 3. Photolysis of *cis*-2-butene in the low pressure region (see Fig. 2). The $[\Phi(\text{allene}) - 0.037]^{-1}$ vs. pressure.

The least-squares slopes and intercepts of the lines in Figs. 1–6 were used to determine the decomposition rate constants of the excited radicals (3, 5) and they are given in Table 1. It was assumed that the deactivation of the excited radicals:

[2] $$R^* + M \rightarrow R + M$$

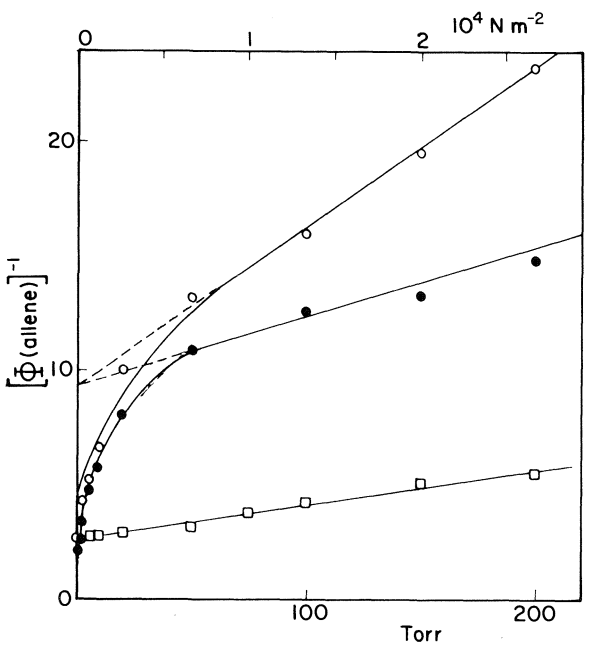

FIG. 4. Photolysis of isobutene at 7.1 eV (○), 7.6 eV (●), and 8.4 eV (□). The $[\Phi(\text{allene})]^{-1}$ vs. pressure.

occurs at each collision, and the collision numbers were calculated in a normal way (9). The radical and molecular diameters used for the calculations are $\sigma C_4H_8 = 0.65$ nm, $\sigma C_4H_9 = 0.65$ nm (10), and $\sigma C_3H_5 = 0.467$ nm (11).

Discussion

(*i*) *The Propylene Formation Process in the NB Photolysis*

Since it is relatively simpler, this problem will be considered first. Propylene is produced from the decomposition of the excited s-C_4H_9* radicals (5). These radicals are formed through the addition of hydrogen atoms, present in the studied photolytic system, to the terminal carbon atom (12) of the parent NB molecules:

[3] $$H + CH_3CH_2CH{=}CH_2 \rightarrow \text{s-}C_4H_9^* \qquad \Delta H = -43 \text{ kcal mol}^{-1}$$

[4] $$\text{s-}C_4H_9^* \rightarrow C_3H_6 + CH_3 \qquad \Delta H = +30 \text{ kcal mol}^{-1}$$

The contribution of some other processes, i.e. the non-terminal H-atom addition and the isomerization of the s-C_4H_9* to n-C_4H_9* radical, which may be followed by the formation of ethylene (12, 13) as well as the hydrogen abstraction process (14), is small and, as such, does not need to be considered.

The decomposition of chemically activated s-butyl radicals, obtained by the addition of virtually thermal H-atoms to C2B molecules, has been studied

TABLE 1. Rate constants[a] of the allene and propylene formations in the far uv photolysis of butenes

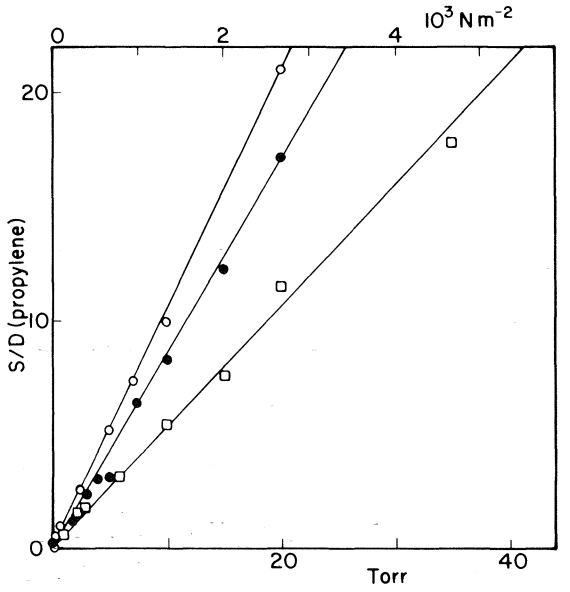

FIG. 6. Photolysis of *n*-butene. The S/D ratio for the propylene formation at 7.1 eV (○), 7.6 eV (●), and 8.4 eV (□).

by Rabinovitch and co-workers (10, 15). The observable unimolecular decomposition rate constant has been shown to depend on the butene pressure reflecting the spread of excitation energies in the reactant produced by the activating reaction (15). The good linearity of the S/D pressure plot in the broad pressure region at the three photon energies studied (Fig. 6) indicates that the energy distribution function of the s-$C_4H_9^*$ species is closer to the δ-function (1) ($f(\varepsilon_{mono}) = 1$ and $f(\varepsilon) = 0$ for all other values of ε) than that in experiments reported by Rabinovitch and co-workers (10, 15). Two factors may be cited to account for this observation: (*i*) virtually monoenergetic H-atoms are produced during the photolysis and (*ii*) the energy of the H atoms is higher than their average thermal energy (5) (the thermal energy distribution of the NB molecules contributes less to the overall energy distribution function of s-$C_4H_9^*$ radicals). The higher excess energy on the s-$C_4H_9^*$ radicals than that expected from the exothermicity process [3], involving thermalized species, has previously been concluded (5). Now, as shown in Fig. 6 and Table 1, this excess energy depends on the photon energy used for the photolysis. The same result was obtained in the *n*-pentene photolysis at 7.1 and 7.6 eV (6). However, in the latter case, the photon energy effect on the decomposition rate of the s-$C_5H_{11}^*$ radicals was found to be stronger than that observed in the present study.

The lack of the curvature of the S/D vs. pressure plots also demonstrates that the "strong collision" assumption made in the Experimental section is valid to a good approximation (the multistep deactivation of the s-$C_4H_9^*$ radicals would yield a curvature of the plot in the low pressure region if the assumption were not valid (1)).

(ii) Allene Formation Process in NB Photolysis

The C_3H_5* radical is produced (process [1]) in its allylic form. If not collisionally stabilized (process [2]), it either decomposes, yielding allene, or isomerises to the vinylic structure, which may be followed by propyne formation.

[5] $CH_2CHCH_2^* \rightarrow CH_2{=}C{=}CH_2 + H$

$\Delta H = +57.5$ kcal mol^{-1}

[6] $CH_2CHCH_2^* \rightarrow CH_3CHCH^*$

$\Delta H \rightarrow +15.5$ kcal mol^{-1} (11)

As we have reported previously (5), the last process is a minor one and it will not be discussed in the present paper.

Having determined the three rate constants of the decomposition process of the C_3H_5* radical at different energies (Table 1), one is tempted to draw some semi-quantitative conclusions on the energy dependence of the kinetics of this process. It is well recognized that the three point probe represents the minimum of the one methodically demanded and therefore the simplest theoretical formalism will be applied.

Let us assume that the rate constant of process [5] can be represented by a simple RRK-type equation (1):

[7] $$k^{dec}(\varepsilon) = A[(\varepsilon - \varepsilon_0)/\varepsilon]^{s-1}$$

It has been shown (16) that this form is a good approximation over a reasonable energy range. In this equation, A is a constant (not specified in the present interpretation), s is the number of effective oscillators in the decomposing species, ε_0 is the critical energy for the process, and ε is the active energy of the C_3H_5* radical. Using the data given in ref. 17, the ε_0 value was estimated to be equal to 60 kcal mol^{-1}.

The ε value now remains to be evaluated, and one may expect at first that a simple statistical formulation based on the internal degrees of freedom is held for the energy distribution between the products of process [1]. Thus, the C_3H_5* fragment carries 18/30 of the photon excess energy. The CH_3 fragment carries 6/30 and the remaining are left for relative motion.

[1*a*] $$\underset{30\text{ vib.}}{n\text{-}C_4H_8^{**}} \rightarrow \underset{18\text{ vib.}}{C_3H_5^*} + \underset{6\text{ vib.}}{CH_3}$$

The resulting $<\varepsilon>$ values were used for making a plot log k^{dec} vs. log $<\varepsilon>$, and this is demonstrated in Fig. 7, curve *a*. Although a reasonable linearity of the plot is achieved, the slope of the line yields the s value equal to 3, which is far from the one expected on the assumption of the energy randomization in the decomposing C_3H_5* radicals.

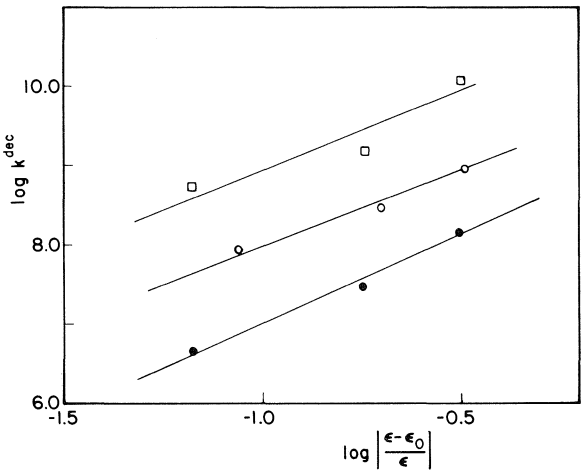

FIG. 7. The logarithmic rate constant of allene formation vs. the logarithmic $(\varepsilon - \varepsilon_0)/\varepsilon$ ratio in the photolysis of *n*-butene (○), *cis*-2-butene: low pressure region (●) and high pressure region (□).

It is easy to show that the required increase in the number of effective degrees of freedom is achieved when one assumes that the fraction of the available energy that the C_3H_5* bears away in process [1] is higher than was predicted by a statistical model for energy partitioning. For example, if all excess energy were to reside in the C_3H_5* radical, the s value obtained from the slope: log k^{dec} vs. log ε_{max} line would be equal to 8 and the linearity of the plot would even be improved. This value could be quite acceptable since the number of effective vibration modes in the excited species is always less than that calculated from the relationship $3N - 6$ (see, e.g., Table III in ref. 18). Our results indicating that a majority of the photoexcitation energy resides on the heavier fragment (C_3H_5* radical) agree with the earlier data of Cambell and Schlag in cyclobutanone photolysis (19):

[8] $$C_4H_6O^{**} \rightarrow c\text{-}C_3H_6^* + CO$$

The authors have found that the cyclopropane contained *far more* internal energy than predicted on the statistical basis, although this difference disappeared at a higher energy. On the other hand, Dorer has investigated the isomerization of methylcyclopropane, produced by the photolysis (313.0 nm) of 4-methyl-1-pyrazoline, to butene isomers (20). He concluded that the fraction of energy carried away by the CH_3—c-C_3H_5* fragment *is less* than would be predicted on the statistical model for energy partitioning. However, Dorer's later study of the photodissociation of cyclobutanone led the author to the conclusion that the available excess energy *is* statistically distributed among the degrees of freedom of the photolytic products (21).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

These few quoted results (for more data: see ref. 1 and the references quoted in Chapt. 9) are sufficient to indicate that the statistical distribution of energy in the photochemically activated system may be observed, but not necessarily always. It probably depends on the system studied and on the photon energy used for the activation.

One more argument may be added in favour of the non-statistical energy partitioning being involved in process [1]. If the majority of the excess energy is carried away by the C_3H_5* radicals, these radicals may be formed with the energy distribution function of a relatively narrow width. This, in turn, may explain why such a good linearity of the Stern–Volmer plots, covering the broad pressure region, is observed (Fig. 1).

(iii) Allene Formation in C2B System

The C_3H_5* radical formed in the decomposition process of the photoexcited C2B molecule may be assumed to be in its vinylic form

[1*b*] $$C2B^{**} \rightarrow CH_3CHCH^* + CH_3$$

It is interesting to note that the decomposition process of this radical does not lead to the formation of propyne (3), whose yield is pressure dependent. Therefore, it has previously been concluded that two other routes are most likely: the isomerization to the allylic structure and the fragmentation into acetylene (3):

[9] $$CH_3CHCH^* \rightarrow CH{\equiv}CH + CH_3$$

A schematic energy diagram which covers the isomerization process followed by the C—H split of the resulting allylic radical is shown in Fig. 8. As seen, for the three photon energies used for the present study, even the excess energy calculated on the statistical basis is sufficient to cause the isomerization as well as the break of the allylic C—H bond.

Now, it is necessary to consider the curvature of the Stern–Volmer plot (3), which, in the kinetic analysis of the allene formation process, made us distinguish two separate pressure regions, and two different rate constants at a given photon energy (Table 1). This curvature may: (*i*) reflect the wide spread in energies of the excited C_3H_5* radicals, (*ii*) indicate that allene is formed from the same C_3H_5* precursor in two distinct energy states, or (*iii*) indicate that allene is formed from chemically different precursors, i.e. either from the C_3H_5* or from the C_4H_7* radicals or from the primary photoexcited C_4H_8** molecules.

The fact that two linear regions of the Stern–Volmer plot could be found suggests that the first alternative is less likely than the remaining two (3). Moreover, the broad energy distribution in the

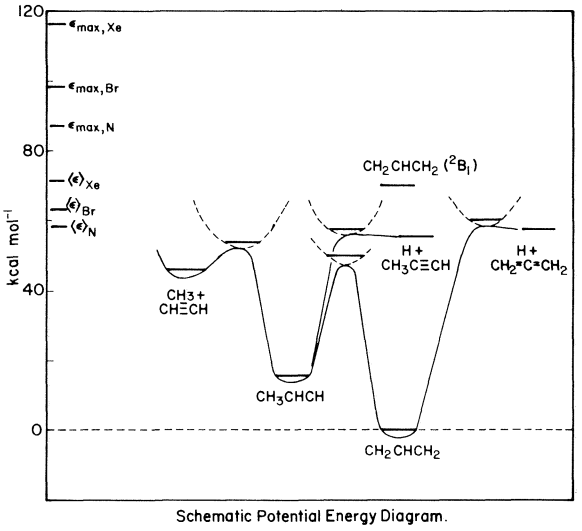

FIG. 8. Schematic potential energy diagram of various routes for the C_3H_5* isomerization and fragmentation processes. Pertinent thermochemical values are taken from refs. 11, 17, 22, and 25.

C_3H_5* radicals might only arise as a result of the decomposition of the energetically randomised C2B** molecules. We may verify if this is the case by applying the RRK-type equation to the rate constants obtained at the three photon energies (Table 1, low pressure region). The log k^{dec} vs. log $<\varepsilon>$ plot (Fig. 7, curve *b*) yields again the *s* parameter equal to 3. In order to get a closer approximation to theory, and in conformity with what was done in the case of the NB photolysis, one must assume that far more energy than predicted on the statistical basis is carried away by the C_3H_5* fragments (the *s* parameter is equal to 8 when the C_3H_5* fragments receive all excess energy). Thus, it is evident that this observation does not match the randomization assumption.

Although the second alternative, i.e. the formation of two energy states of the allylic C_3H_5* radical has been favoured in our earlier papers (3, 5), in the light of the kinetic results presented in Table 1 this view can no longer be sustained. When passing from the low pressure region (LPR) to the high pressure region (HPR), one may note that the unimolecular rate constant of the allene formation process at, e.g. 7.1 eV, increases by ca. two orders of magnitude. This increase is larger than that equal to ca. 30 kcal mol^{-1} (Table 1) brought about by the increase in photon energy from 7.1 to 8.4 eV. On the other hand, the value of $\Delta\varepsilon = \varepsilon_{max} - \langle\varepsilon\rangle$ (Fig. 8) at 7.1 eV is also equal to ca. 30 kcal mol^{-1}. It should be noted that no larger difference in the energy on the C_3H_5* radicals formed at this photon energy can be expected, especially keeping in mind the evidence

against the randomization assumption (see above). If so, the observation:

$$(k_{dec,HPR}/k_{dec,LPR})_{7.1\ eV} = 136 \text{ (Table 1)}$$

cannot be accounted for on a purely energetical basis. Different electronic states cannot be considered either. The first excited electronic state of the allylic radical (3.0 eV) which may be attained upon the fragmentation of the photoexcited C2B molecule (22) is known to be a repulsive one. Thus, the decomposition of this radical occurs within a period of one critical oscillation. The second electronic state (22, 23) has an energy of 5.37 eV, which is higher than the ε_{max} for all photon energies applied in the present work.

Therefore, the nonlinearity of the Stern-Volmer plots (Figs. 2 and 3) appears to reflect the formation of allene from two chemically different precursors. In addition to the C_3H_5* radicals, allene may be formed from C_4H_7* radicals (3) or directly from the photoexcited C_4H_8** molecules:

[10] $$C_4H_7^* \rightarrow C_3H_4 + CH_3$$

[11] $$C_4H_8^{**} \rightarrow C_3H_4 + CH_3 + H$$

The possibility of process [10] in the low pressure region has been eliminated in our earlier work (3). The analysis of the radical–radical processes, which led us to this conclusion, cannot be done in the high pressure region with sufficient accuracy. It should, however, be noted that the absorption spectroscopy of radicals formed in the far uv photolysis of 2-butenes has been interpreted on the basis of the C_4H_7 radical formation (23). The decomposition channels of this radical have not, however, been established.

The formation of allene from the primary photoexcited butene molecules has been reported by Borrel *et al.* (2) and Chesick (4) at the photon energy ≤ 6.7 eV; the quenching of the C_4H_8** molecules has been observed. If this process occurs also at higher photon energies (up to 8.4 eV) and if one recalls that the quantum yields of other primary products have been found not to depend on pressure (3, 5), this result would mean that the fragmentation mode represented by process [11] is the easiest one to be quenched by collisions. So far, however, our experiments cannot provide evidence to distinguish between the last two possibilities.

(iv) In IB Systems

At 7.1 and at 7.6 eV, the results in the IB photolysis are similar to those observed in the C2B photolytic system (see Figs. 2 to 5). A relatively small increase in the rate constant of the allene formation process in this photon energy region is, however, followed by a rapid jump in the k^{dec} value at 8.4 eV (Table 1). In fact, only a small decrease in the quantum yield with IB pressure was observed (detectable at pressures higher than 20 Torr, Fig. 5), which is in agreement with the earlier data reported by Herman *et al.* (24). It is thus concluded that, contrary to what was observed in NB and C2B photolysis, the excess energy on the C_3H_5* radical, formed from the photodecomposition of the IB** molecules, does not increase continuously with the increase in the photon energy but, in the 7.6–8.4 eV energy region, changes by steps. Different electronic (vibronic?) states are probably involved in both photon energy regions. However, more direct data are needed to account for this observation.

Conclusion

The most interesting result obtained in the present study is that the primary photoexcited butene molecules are not energetically randomized before their fragmentation processes (e.g. process [1] or [11]) occur. This conclusion is based on the kinetic analysis of the allene formation process made by the use of the RRK-type equation. Some arguments supporting this view come also from the comparison of the fragmentation patterns of C2B and *trans*-2-butene (T2B) at 7.1 eV (3, 5*b*). Differences, well outside the experimental error may be observed, especially dealing with the ratio of Φ(allene) (extrapolated to zero pressure) to Φ(propyne). This ratio for the C2B and T2B photolysis is equal to 5.0 and 2.3, respectively. Since C2B and T2B are geometric isomers, one might expect that the energy randomization, following the internal conversion to the ground electronic state (4), should lead to the same primary photoexcited C_4H_8** species and would result in the same product distribution. This apparently is not the case.

Acknowledgments

We would like very much to thank the National Research Council of Canada and le Ministère de l'Education du Québec for their financial assistance throughout this work. One of us (A.W.) is pleased to acknowledge helpful discussions with his colleagues, Drs. J. Niedzielski and J. Gawłowski from Warsaw University.

Reactions of hydrogen atoms with hexafluoroacetone[1]

D. W. GRATTAN[2] AND K. O. KUTSCHKE

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 11, 1977[3]

D. W. GRATTAN and K. O. KUTSCHKE. Can. J. Chem. **56**, 2638 (1978).

Attempts were made to study the kinetics of the reaction of atomic H with $(CF_3)_2CO$ vapour (HFA). Atomic H was generated from H_2 by mercury photosensitization in the presence of C_2H_4 and HFA but the system was complicated by the loss of C_2H_5 radicals by addition to HFA and the kinetic results were intractable. When atomic H was generated from C_3H_8, the kinetics again were obscured by some unidentified reaction(s) which became more important at higher $[HFA]/[C_3H_8]$. An estimate of the rate constant for the addition of H to HFA obtained at low $[HFA]/[C_3H_8]$ yielded $k_9 = 8.5 \times 10^5$ ℓ mol^{-1} s^{-1}. Trifluoroacetaldehyde was identified with some reliability but many of the other heavier products formed in the H_2 + HFA reaction could not be identified. Quenching cross-sections were determined for C_2H_4, C_3H_8, C_4H_{10}, and HFA relative to that for N_2O.

D. W. GRATTAN et K. O. KUTSCHKE. Can. J. Chem. **56**, 2638 (1978).

On a effectué des essais pour étudier la cinétique de la réaction de l'hydrogène atomique avec le $(CF_3)_2CO$ à l'état de vapeur (HFA). On a produit des hydrogènes atomiques à partir de H_2 par photosensibilisation au mercure en présence de C_2H_4 et de HFA mais le système était compliqué par la perte de radicaux C_2H_5, par addition au HFA et les résultats cinétiques ne peuvent être interprétés. Lorsque l'on a produit des hydrogènes atomiques à partir de C_3H_8, la cinétique était à nouveau obscurcie par quelques réactions non-identifiées qui deviennent importantes lorsque $[HFA]/[C_3H_8]$ devient plus grand. On a évalué la constante de vitesse pour l'addition de H à du HFA pour un faible rapport $[HFA]/[C_3H_8]$; alors $k_9 = 8.5 \times 10^5$ mol^{-1} s^{-1}. On a identifié le trifluoroacétaldéhyde avec une assez bonne certitude mais on n'a pas pu identifier les produits plus lourds formés par la réaction de H_2 + HFA. On a déterminé les sections droites de piégage du C_2H_4, du C_3H_8, du C_4H_{10} et du HFA relatives à celle du N_2O.
[Traduit par le journal]

In a system in which trifluoromethyl radicals are generated photochemically in the presence of hydrogen, the apparent value of the rate constant for the abstraction of a hydrogen atom from the molecular species is estimated from the ratio $\rho \equiv R_{CF_3H}/R_{C_2F_6}{}^{1/2}[H_2]$ where R_X is the rate of formation of the product X. It should be noted that ρ is an experimental quantity whose interpretation in terms of rate constants is uncertain by a factor of two depending on the fate of H-atoms produced in the abstraction reaction (1). In some unpublished work,[4] an attempt was made to detect possible variations in ρ by photolyzing hexafluoroacetone at 100°C in the presence of molecular hydrogen. It was anticipated that for conditions associated with large values of $[CF_3]/[H]$ (high $[CF_3COCF_3]$, high light intensity, low $[H_2]$) the H-atoms formed in the abstraction reaction would be scavenged by the CF_3 radicals to yield additional CF_3H so that the value of ρ would be larger (in the limit, larger by a factor of two) than that observed when the converse conditions were employed. In fact, in a series of eight experiments ρ remained constant within $\pm 7\%$ (12.4 ± 0.8 in arbitrary units, total range 11.4 to 13.7 with no trends) even though the conditions noted earlier had been varied sufficiently to cause $R_{C_2F_6}/R_{CF_3H}$ (a crude indication of $[CF_3]/[H]$) to change from 0.0074 to 91. As a consequence these experiments were discontinued.

In those same experiments, however, it was noted that the material balance ratio m ($\equiv(\frac{1}{2}R_{CF_3H} + R_{C_2F_6})/R_{CO}$) increased monotonously from 0.88 for conditions yielding high $[CF_3]/[H]$ to 2.6 at low $[CF_3]/[H]$. It was thought that at low $[CF_3]/[H]$ the H-atom produced in the abstraction reaction might have formed a secondary alkoxyl radical by addition to hexafluoroacetone and that subsequent decomposition of that radical could yield, in part, trifluoroacetaldehyde and a trifluoromethyl radical. In this way, CF_3 radicals might be generated without the formation of carbon monoxide so that the experimental trend in m would be explained, at least qualitatively. Such radical exchange reactions are known to occur in other systems (2) although it had been suggested earlier (3) that H-atoms did not participate in this type of reaction.

The present experiments were undertaken in an attempt to study the addition–exchange reaction of

H-atoms with hexafluoroacetone in a quantitative way. Hydrogen atoms were generated in the presence of hexafluoroacetone by the mercury-sensitized decomposition of hydrogen or of propane. Attempts were made to evaluate relative rate constants by competitive methods. Each of the competitions studied yielded unexpected kinetic results and possible mechanistic explanations are discussed.

The constants for the quenching of $Hg(^3P_1)$ by ethylene, propane, *n*-butane, and hexafluoroacetone (HFA) were required and were measured with the nitrous oxide method.

Experimental

A conventional photolysis apparatus was employed which contained a quartz reaction cell (200 cm^3, optical path 10 cm) illuminated by a quartz low-pressure mercury lamp (4). Between the lamp and the cell were a shutter and a 2 mm Corning 9-54 filter thus ensuring that the only significant illumination was at 253.7 nm. Mercury condensation in the U bend of the lamp was avoided by using a lamp with electrodes thermostatted at 20°C, and the housing of the lamp at 26°C so that any mercury distillation tended towards the electrodes. The stability of the lamp was checked by means of two phototubes (RCA 935), one of which was placed behind the cell; the other was used to monitor the lamp directly and was connected with the lamp housing by means of a fibre optic.

The cell was mounted in a loop in series with a U-tube, containing a drop of mercury and thermostatted at 20°C, a U-trap, and a glass reciprocating-piston circulation pump; the loop was connected to the vacuum system by three metal Hoke valves, joined at the same point on the loop. These led to vacuum, to the dosing system, and to an analysis line containing, in series, solid and liquid nitrogen traps, a LeRoy still, a diffusion pump, gas burette, and Toepler pumps which in turn led to a gas-chromatographic sampling loop and detachable sample containers for gas chromatography, mass-spectrometry etc.

In the earlier experiments a Perkin Elmer F1 chromatograph with thermistor detectors was used, and during the course of the work this was replaced with a Gow Mac (Model 69-570) dual column instrument, which was also fitted with thermistors. Integration was performed with a disc-integrator.

The HFA (99.9%) was obtained from Matheson and was purified by careful trap-to-trap distillation. Subsequent analysis revealed the presence of 0.01% sulphur dioxide as the only significant impurity. It was stored in darkness and no decomposition was observed over the course of a year.

Propane (Matheson Research Grade) was purified as above and was analyzed especially carefully for traces of olefinic impurities; none were detected by gas chromatography. *n*-Butane and ethylene (99.8% Matheson), Matheson nitrous oxide (98%), and carbon tetrafluoride (99.9%) were purified by careful trap-to-trap distillation and degassing. Although the purity of nitrous oxide was only 98%, the principal impurity was air, and was easily removed. Hydrogen was purified by passage through a heated palladium thimble.

The experimental mixture was prepared by pressurizing calibrated volumes with the gases to be used; pressure was measured with a mercury manometer which was read by a cathetometer. The gases were then condensed into the U-trap of the cell with liquid nitrogen. When hydrogen was used, the condensible gases were first condensed into the U-trap (~¼% of the cell + loop volume) with liquid nitrogen and hydrogen was then admitted to the required pressure. The gases were allowed to warm and were mixed with the circulating pump. The circulating pump did not operate at total pressures below 5 Torr; at these pressures condensible gases were mixed by repeated condensation and evaporation.

Analysis was by low temperature distillation, gas chromatography, and, for part (*iv*), by mass spectrometry; details are placed at the Depository of Unpublished Data.[5]

Results and Discussion

(i) Quenching Constants, with the Nitrous Oxide Method (5, 6)

The rate constant obtained by this treatment, k_q, is a composite quantity which is composed of at least two constants $k_n + k_{na}$. The mechanism for an alkane RH, was regarded by Cvetanović as follows,

$$Hg(^1S_0) + h\nu_{2537} \rightarrow Hg(^3P_1)$$

[1] $$Hg(^3P_1) + N_2O \rightarrow N_2 + O + Hg(^1S_0)$$

[1*a*] $$\rightarrow Hg(^3P_0) + N_2O$$

[2] $$Hg(^3P_1) + RH \rightarrow Hg(^1S_0) + R + H$$

[2*a*] $$\rightarrow Hg(^3P_0) + RH$$

If the metastable mercury atoms do not enter reactions leading directly or indirectly to the formation of nitrogen then [1] is the sole source of nitrogen and a plot of $1/r_{N_2}$ vs. $[RH]/[N_2O]$ will be linear (r_{N_2} is the rate of formation of nitrogen). Moreover, the ratio of the slope to the intercept of this plot yields the quenching ratio, $(k_2 + k_{2a})/(k_1 + k_{1a}) \equiv k_{q2}/k_{q1}$. For work to be discussed later it was necessary to know this ratio for propane. This value had been measured by Rousseau and Gunning (7) but it was redetermined to preserve internal consistency. For accuracy in these determinations it is useful to determine the intercept at $[RH]/[N_2O] = 0$ with as much precision as possible. Thus it was important to obtain more than one curve so that the quenching constant of *n*-butane was also measured. Figure 1 contains the results of the determinations for C_2H_4, C_3H_8, and $n\text{-}C_4H_{10}$. The difference in the intercept for ethylene compared with that for propane and *n*-butane represents the decrease in the lamp output in the eighteen months which elapsed between these determinations.

When the quenching constants of hydrocarbons are measured, the oxygen generated in the decomposition of nitrous oxide is rapidly taken up by reaction with alkanes. With HFA this scavenging might be inefficient so that HgO would be formed and would be deposited on the cell windows as de-

[5]Detailed descriptions of distillation and chromatographic procedures are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6.

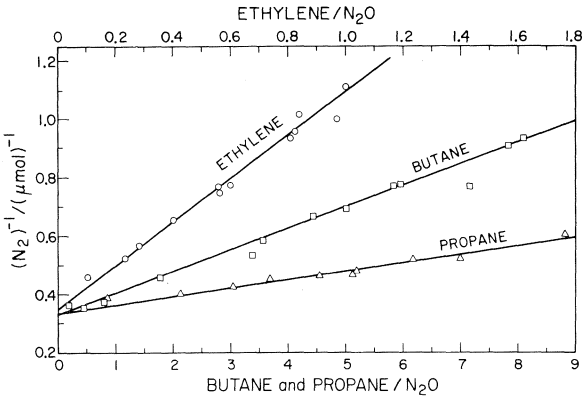

FIG. 1. Quenching plots for C_2H_4, C_3H_8, and n-C_4H_{10}; a constant exposure time was used so that the N_2 yield is proportional to r_{N_2}.

scribed by Cvetanović (8). Therefore the quenching curve for HFA was determined in the presence of ethylene at three ratios of $[C_2H_4]/[N_2O]$. To reactions [1], [1a], [2], and [2a], the following must be added:

$$[3] \qquad Hg(^3P_1) + HFA \rightarrow Hg(^1S_0) + HFA^*$$

$$[3a] \qquad \rightarrow Hg(^3P_0) + HFA$$

The rate of nitrogen formation is now given by the following equation:

$$\frac{I_a}{\gamma_{N_2}} = \frac{k_1 + k_{1a}}{k_1} + \frac{k_2 + k_{2a}}{k_1}\frac{[C_2H_4]}{[N_2O]} + \frac{k_3 + k_{3a}}{k_1}\frac{[HFA]}{[N_2O]}$$

The first two terms on the right may be evaluated from the quenching plot for ethylene obtained in the absence of ketone (filled circles in Fig. 2). The slopes of the other three lines in Fig. 2, together with the intercept, then were used to evaluate $(k_3 + k_{3a})/(k_1 + k_{1a})$. As is required by the mechanism the slopes are independent of the values of the three fixed ratios of $[C_2H_4]/[N_2O]$ used in these experiments.

Table 1 compares the measured values of the k_q determined in this work with the literature values. Although only ratios of quenching constants are determined by the method used (they are process II values in Cvetanović's terminology), individual k_q have been evaluated by using literature values of k_{q,N_2O} (6), or k_{q,C_2H_4} (6), as indicated in the footnotes to Table 1. The agreement among the various values reported is well within experimental error except for the value obtained here for n-C_4H_{10}. As the other values determined in this work agree with the literature there is no obvious explanation for the discrepancy.

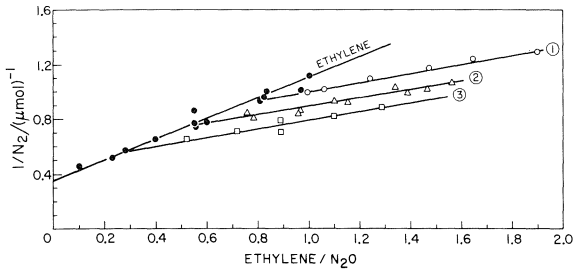

FIG. 2. Quenching plots for HFA. The symbol N_2 represents the amount of nitrogen formed in a fixed time and thus is proportional to r_{N_2}. Line *1*, $[C_2H_4]/[N_2O] = 0.81$; line *2*, $[C_2H_4]/[N_2O] = 0.54$; line *3*, $[C_2H_4]/[N_2O] = 0.27$.

TABLE 1. Quenching constants, k_q

Compound	k_q[a] This work[b]	Others[b]	Others[c]
HFA	13.0	—	—

C_3H_8	1.27	1.13[e]	1.28[f]
n-C_4H_{10}	3.35	3.65[d]	3.75[f], 3.83[g]

[a]All k_q in 10^{10} ℓ mol^{-1} s^{-1}.
[b]Based on $k_{q,N_2O} = 14.3$, ref. 6.
[c]Based on $k_{q,C_2H_4} = 30.0$, ref. 6.
[d]Reference 6.
[e]Reference 7.
[f]Reference 9.
[g]Reference 10.
[h]Note that $k_{q,C_2H_4} = 30$ was obtained by substituting $k_{q,N_2O} = 14.3$, into Cvetanović's value of $k_{q,C_2H_4}/k_{q,N_2O} = 2.1$ (6).

The values of individual quenching constants have been obtained relative to the value of $k_{q,N_2O} = 14.3 \times 10^{10}$ ℓ mol^{-1} s^{-1}, which was obtained by Cvetanović. Michael and Suess recently published a higher figure for the latter, of 24.0×10^{10} ℓ mol^{-1} s^{-1}, which would necessitate increasing these values by a factor of 1.68 (10). Since in this work we have only been concerned with the ratios of quenching constants, it is doubtful that the absolute values are of much importance. The latter comment may also be applied to the criticism of the N_2O technique by Vikis *et al.* (9, 11) who explained the divergence between the chemical and physical measurements of k_q by showing that the effect of $Hg(^3P_0)$ had been neglected in the former.

The value of $k_{q,HFA}$ in Table 1 may be compared with the known (12) value of 39×10^{10} ℓ mol^{-1} s^{-1} for acetone. Presumably the greater polarity of the carbonyl group in the fluorinated ketone has decreased the quenching ability of the group.

(ii) The Competition between HFA and Ethylene for Hydrogen Atoms, H + HFA Method I

Following the technique devised by Cvetanović and Doyle to study the relative rates of addition of hydrogen to olefins (12), a large pressure of hydrogen (600 Torr) was used to quench most of the $Hg(^3P_1)$ to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

give H atoms. In that work (12) the yield of *n*-butane produced by the recombination of the C_2H_5 radicals formed by the addition of hydrogen atoms to ethylene was measured as a function of the ratio of X, the olefin, to ethylene. The mechanism was considered to be the following:

$$Hg(^1S_0) + h\nu_{2537} \rightarrow Hg(^3P_1)$$

$$Hg(^3P_1) + H_2 \rightarrow H + H + Hg(^1S_0)$$

[4] $$H + C_2H_4 \rightarrow C_2H_5$$

[5] $$H + X \rightarrow XH$$

[6] $$2C_2H_5 \rightarrow n\text{-}C_4H_{10}$$

[6*a*] $$\rightarrow C_2H_4 + C_2H_6$$

[7] $$2XH \rightarrow HX{-}XH$$

[7*a*] $$\rightarrow X + XH_2$$

[8] $$C_2H_5 + XH \rightarrow C_2H_6{-}X$$

[8*a*] $$\rightarrow C_2H_4 + XH_2$$

[8*b*] $$\rightarrow X + C_2H_6$$

Solving these equations with the assumption that the radical interaction rates are equal (i.e. $k_6 + k_{6a} = k_7 + k_{7a} = 0.5(k_8 + k_{8a} + k_{8b})$) yields

$$(r_{1,0}^{1/2} - r_1^{1/2})/r_1^{1/2} = k_5[X]/k_4[C_2H_4]$$

where r_1 is the yield of n-C_4H_{10}, and $r_{1,0}$ is its yield when [X] = 0.

If it is assumed that HFA behaves like an olefin, and that the initially formed adduct between H and HFA subsequently decomposes with unit efficiency, then reactions [5], [7], and [8], respectively, would be replaced by:

[9] $$H + HFA \rightarrow HCF_3CO + CF_3$$

[10] $$2CF_3 \rightarrow C_2F_6$$

[11] $$CF_3 + C_2H_5 \rightarrow CF_3C_2H_5$$

[11*a*] $$\rightarrow CF_3H + C_2H_4$$

Making the same assumptions about radical interaction rates a similar equation is obtained.

[12] $$(r_{1,0}^{1/2} - r_1^{1/2})/r_1^{1/2} = k_9[HFA]/k_4[C_2H_4]$$

Ethylene and HFA were used at pressures up to 20 Torr, and since the values of k_q for ethylene, HFA, and hydrogen are 31, 13, and 20 $\times$ 10^{10} ℓ mol^{-1} s^{-1} (6), ethylene and HFA could only account for a maximum of 6.8% of the quenching of $Hg(^3P_1)$. It was argued (12) that any excited species produced in the latter quenching processes would be quickly deactivated at these near-atmospheric pressures to return to the ground state without decomposition. This assumption is now harder to justify as more recent work has shown the quenching of $Hg(^3P_1)$ to $Hg(^3P_0)$ and subsequent quenching of $Hg(^3P_0)$ to be more important than was previously suspected (9). However, if the mechanisms are modified to include the effects of mercury metastables they become intractable.

The competition was studied at four pressures of ethylene, 5, 10, 15, and 20 Torr. Most of the determinations were carried out at 10 Torr. Equation [12] is plotted in Fig. 3. The predicted linear dependence is found but it is also noted that the slope depends on the absolute value of $[C_2H_4]$. This latter result is not compatible with the mechanism.

An important process which has been ignored is undoubtedly the radical exchange reaction between ethyl radicals and HFA; similar reactions are known (2, 3)

[13] $$C_2H_5 + (CF_3)_2CO \rightarrow C_2H_5CF_3CO + CF_3$$

If this reaction is included in the kinetic scheme, and [9] is omitted, and it is assumed again that radical interaction rates are equal, i.e. $2k \equiv 2(k_6 + k_{6a}) = (k_{11} + k_{11a}) = 2k_{10}$, then

[14] $$(r_{1,0}^{1/2} - r_1^{1/2})/r_1^{1/2} = \tfrac{1}{2}k_{13}k_6^{1/2}k^{-1}r_{1,0}^{-1/2}[HFA]$$

In (*iii*) the rate constant for H + HFA is shown to be about 8.5 $\times$ 10^5 ℓ mol^{-1} s^{-1} and that for H + C_2H_4 is known to be 7 $\times$ 10^8 ℓ mol^{-1} s^{-1} (13). Therefore under the above conditions, the reaction of H + HFA is almost negligible and the assumption that reaction [9] may be neglected is justified.This lends some credence to the value of k_{13} obtained below. Note that the concentration of ethylene does not appear in this expression. The assumption has

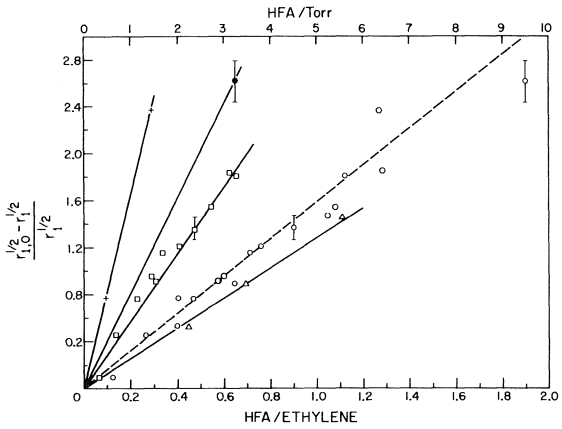

FIG. 3. Plots of eq. [12] with $[C_2H_4]$ = 20 Torr, +; $[C_2H_4]$ = 15 Torr, ●; $[C_2H_4]$ = 10 Torr, □; $[C_2H_4]$ = 5 Torr, △. These plots use the lower abscissa. The broken line is a plot of the same data (open circles) according to eq. [14]; upper abscissa.

For personal use only.

been made that all of the atomic hydrogen reacts with ethylene to give ethyl radicals. The plot of this equation is shown also in Fig. 3 (open circles) and it may be seen that, although there is still some scatter, the points appear to coalesce around a single straight line. On this evidence alone it is not possible to eliminate other mechanistic explanations of the dependence of the results on the absolute pressure.

To evaluate k_{13} it is necessary to make some assumption about the rates of radical interaction. In the book by Kerr and Ratajcjak (14) the rate constants for CF_3 and C_2H_5 combinations are assumed to be 10^{11} and $10^{10.4}$ ℓ mol^{-1} s^{-1}, respectively. Radical interaction for C_2H_5 becomes $1.14 \times 10^{10.4}$ ℓ mol^{-1} s^{-1} if allowance for the disproportionation is made (disproportionation/combination for $C_2H_5 = 0.14$ (15)). We therefore took $k_6 = 10^{10.4}$ ℓ mol^{-1} s^{-1}, and k as $1.14 \times k_{13}$. Since $r_{1,0}$ was measured as 1.27×10^{-8} mol ℓ^{-1} s^{-1}, substitution in [14] gives k_{13} as 3×10^5 ℓ mol^{-1} s^{-1}. There must be a large uncertainty in this value from the above assumptions concerning radical interactions, probably as large as $\pm 50\%$.

A comparison with literature values for similar reactions is shown in Table 2. Two trends may be observed. For methyl or ethyl radical addition to a ketone the addition rate increases with increasing fluorination of the ketone, whereas for trifluoromethyl radical addition the reverse trend is observed. Our result, though high, is compatible with the first of these trends. It would appear that the inductive effect of the fluorine in HFA reduces the electron density on the central carbon atom, enhancing the rate of addition of the electron-rich ethyl radical. The reason for the reverse trend with fluorinated radicals probably derives from the repulsive effect between the highly fluorinated species.

An alternative explanation of the dependence on absolute $[C_2H_4]$ in Fig. 3 might involve a reaction between HFA and ethylene which could alter $[HFA]/[C_2H_4]$ during the photolysis. Several kinds of interaction between these partners are known to occur. For example, it has been shown that triplet HFA reacts with olefins to give oxetanes (25), and that between 0°C to −9°C in solution, HFA and ethylene copolymerize by a free radical mechanism to give what is surmised to be an alternating copolymer (26). If similar or related processes took place, they would cause substantial losses in the absolute amounts of HFA and ethylene and, possibly, changes in their ratio. This possibility was investigated by recovering the HFA and ethylene remaining after photolysis. The photolysis time was increased from 10 to 120 min in these experiments to maximize any such changes. The results were variable but, on the average, for each molecule of HFA lost, 2.6 molecules of ethylene were removed. It is concluded that during the normal 10 min photolysis, no significant alteration in $[HFA]/[C_2H_4]$ could have occurred so that the former explanation is favoured.

TABLE 2. Comparison of rate constants with literature

Radical	Ketone	Rate constant[a]	References
C_2H_5	$(C_2H_5)_2CO$	3.22×10^3	16
C_2H_5	$(C_2F_5)(C_2H_5)CO$	7.9×10^3	17
C_2H_5	$(CF_3)_2CO$	$3 \pm 2 \times 10^5$	This work
CH_3	$(CH_3)_2CO$	2.9×10^1	18
CH_3	$(CHF_2)_2CO$	1.5×10^4	19
CF_3	$(CH_3)_2CO$	3.1×10^3	20
CF_3	$(CF_3)(CH_3)CO$	$2.8, 2.1, 20 \times 10^1$	21, 22, 23
CF_3	$(CF_2H)(CF_3)CO$	2×10^1	24

[a]All rate constants in units of ℓ mol^{-1} s^{-1}.

(iii) The System Propane/HFA; H + HFA Method II

Because of the interference of the reaction between C_2H_5 and HFA, the previous method was not appropriate, so an attempt was made to use a system similar to that devised by Back (27) and developed by Cvetanović *et al.* (28, 29). In this method hydrogen atoms were generated by quenching $Hg(^3P_1)$ with an alkane (Cvetanović *et al.* used *n*-C_4H_{10}, and Back, C_3H_8) and the yield of molecular hydrogen (for a fixed photolysis time) is a function of the stationary state concentration of atomic hydrogen. Any added species which reacts with hydrogen atoms would reduce this stationary state concentration and hence decrease the yield of H_2. In this system it was expected that the H_2 yield would be independent of any interaction between HFA and alkyl radicals. However, it also suffers from two disadvantages: (*i*) since the quenching constant of an alkane is small, the quenching of $Hg(^3P_1)$ by HFA cannot be neglected; (*ii*) as the photolysis proceeds, the disproportionation of the alkyl radical leads to an increasing concentration of alkene, which in turn reacts with hydrogen atoms, so that conversions must be kept small. Propane was used rather than *n*-butane, since the impurity olefin content is stated to be smaller in C_3H_8 than that in *n*-C_4H_{10}.

A pressure of 300 Torr was used to obtain the maximum possible quenching of $Hg(^3P_1)$ by propane. HFA was added in the pressure range 0–45 Torr. A plot of H_2 against photolysis time showed that the generation of H_2 was a reasonably linear function of time for exposures less than 10 min. A photolysis time of 6 min was chosen; this yielded 1.8 μmol of H_2 and corresponded to 0.08% conver-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

sion (Cvetanović *et al.* used a very large reaction volume and recovered 35 μmol of H_2, which corresponded to 0.03% conversion).

The following mechanism, a modified version of that of Cvetanović *et al.*, was used to derive a function relating r_{H_2} to $[HFA]/[C_3H_8]$.

[2] $Hg(^3P_1) + C_3H_8 \rightarrow H + C_3H_7 + Hg(^1S_0)$

[3] $Hg(^3P_1) + HFA \rightarrow HFA^* + Hg(^1S_0)$

[15] $H + C_3H_8 \rightarrow C_3H_7 + H_2$

[9] $H + HFA \rightarrow CF_3 + CF_3CHO$

[16] $2C_3H_7 \rightarrow C_6H_{14}$

[16*a*] $\rightarrow C_3H_6 + C_3H_8$

[17] $C_3H_7 + HFA \rightarrow CF_3 + C_3H_7COCF_3$

[18] $CF_3 + C_3H_7 \rightarrow CF_3H + C_3H_6$

[18*a*] $\rightarrow CF_3C_3H_7$

[10] $2CF_3 \rightarrow C_2F_6$

[19] $HFA^* \rightarrow CO + 2CF_3$

[20] $HFA^* + M \rightarrow HFA + M$

Using the normal stationary-state method, the following relationship was derived:

$$\frac{k_{15}}{k_9}\frac{r_{2,0}}{r_2} = \left(\frac{k_{15}}{k_9} + \frac{[HFA]}{[C_3H_8]}\right)\left(1 + \frac{k_3[HFA]}{k_2[C_3H_8]}\right)$$

In the above expression, k_3/k_2 is the ratio of the quenching constants for HFA and propane (Table 1), r_2 is the yield of hydrogen, $r_{2,0}$ is the yield of hydrogen in the absence of HFA, and k_{15}/k_9 is the ratio of interest. Rearrangement of this equation gives

$$[21]\quad \frac{k_{15}}{k_9} = \frac{[HFA]}{[C_3H_8]}\left\{1 + \frac{k_3[HFA]}{k_2[C_3H_8]}\right\} \times \left\{\frac{(r_{2,0} - r_2)}{r_2} - \frac{k_3[HFA]}{k_2[C_3H_8]}\right\}^{-1}$$

On evaluating k_{15}/k_9 it was found to be a function of the $[HFA]/[C_3H_8]$ ratio; this is shown in Fig. 4. This suggests that a process which has been neglected becomes increasingly important as $[HFA]/[C_3H_8]$ increases. In the initial portion of the curve k_{15}/k_9 is reasonably constant at about 0.15. If Baldwin's value for $H + C_3H_8$ of 1.18×10^5 ℓ mol^{-1} s^{-1} is taken (30), $k_9 = 8.5 \times 10^5$ ℓ mol^{-1} s^{-1}.

Figure 5 shows the variation of r_2 with the ratio $[HFA]/[C_3H_8]$. The broken line represents the rate of formation of H_2, r_3, which may be calculated if reaction [9] were negligibly slow so that only the competitive quenching (reactions [2] and [3]) caused the rate of formation of H_2 to decrease as [HFA] was increased. It is evident from Fig. 5 that competitive quenching alone is insufficient to account for the decrease actually observed and, therefore, that some reaction in addition to [15] consume H atoms. Thus the difference $r_3 - r_2$ is an indirect measure of the contribution of reaction [9] to the rate of decrease in the rate of formation of $[H_2]$; this difference is given in eq. [22].

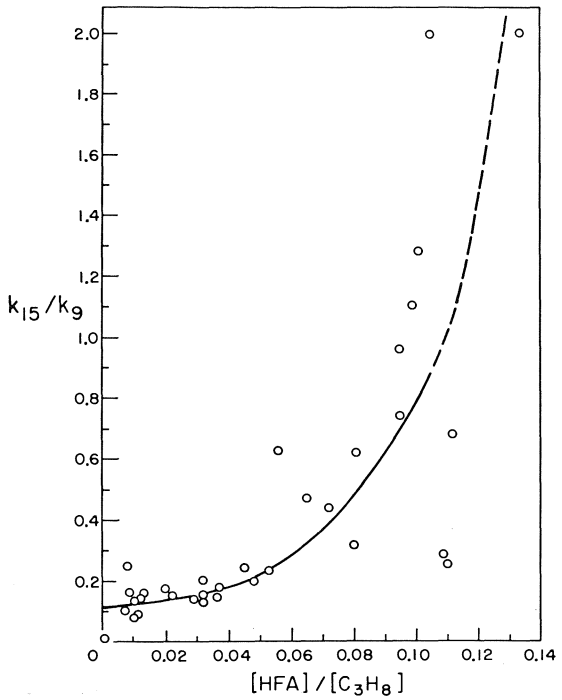

FIG. 4. Variation of the apparent values of k_{15}/k_9, evaluated by eq. [21], with $[HFA]/[C_3H_8]$.

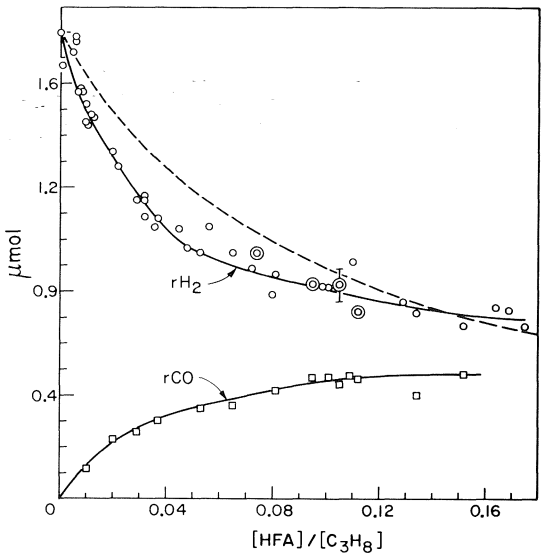

FIG. 5. Variation of r_{H_2} and r_{CO} as a function of $[HFA]/[C_3H_8]$. The broken line is explained in the text.

$$[22]\quad r_3 - r_2 = \frac{r_{2,0}\left(\frac{k_9[\mathrm{HFA}]}{k_{15}[\mathrm{C_3H_8}]}\right)}{\left(1+\frac{k_3[\mathrm{HFA}]}{k_2[\mathrm{C_3H_8}]}\right)\left(1+\frac{k_9[\mathrm{HFA}]}{k_{15}[\mathrm{C_3H_8}]}\right)}$$

If the value of 6.7 is taken for k_9/k_{15}, 10 for k_3/k_2, this function predicts that $r_3 - r_2$ goes to a maximum of 0.36 at $[\mathrm{HFA}]/[\mathrm{C_3H_8}] \simeq 0.12$, whereas the results obtained give a maximum of about 0.25 around $[\mathrm{HFA}]/[\mathrm{C_3H_8}] \simeq 0.04$.

It is evident that the value of k_9 obtained in this work cannot be taken as established. Nevertheless the fact that the data in Fig. 5 follow approximately the predictions of the mechanism gives some credence to the value. Moreover, alternative mechanistic explanations all proved to be untenable; some of those considered are outlined below.

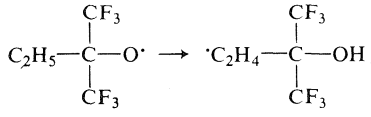
It is conceivable that excited HFA could be quenched by propane so efficiently that sufficient energy transfer would take place to dissociate a C—H bond in propane. If so, then collisional deactivation by a non-reactive body should interfere with this process and reduce the yield of hydrogen. Therefore 300 Torr of CF_4 was added at four higher values of $[\mathrm{HFA}]/[\mathrm{C_3H_8}]$; and as can be seen in Fig. 5 (concentric circles) there was no effect. Thus this explanation was ruled out.

Another possibility was that HFA was quenching $Hg(^3P_1)$ efficiently to $Hg(^3P_0)$, and not effectively quenching the latter. If so, as the HFA concentration increased it would lead to more formation of $Hg(^3P_0)$ which would be quenched by C_3H_8, leading to decomposition. This was tested by using the method of Vikis, Torrie, and LeRoy (9). The production of hydrogen from the non-complete quenching of excited mercury by ethylene was studied as HFA was introduced. The pressure of ethylene used was about 5 Torr and HFA was added in the ratio of 0.7 to 1.3 $[\mathrm{HFA}]/[\mathrm{C_2H_4}]$. If HFA quenches $Hg(^3P_1)$ to $Hg(^3P_0)$ and not the latter, the stationary-state concentration of $Hg(^3P_0)$ should be considerably increased as HFA is added. Since the lifetime of the metastable $Hg(^3P_0)$ is much greater than $Hg(^3P_1)$, the number of collisions between C_3H_8 and excited mercury species will increase and this has been shown to give an increase in the yield of hydrogen. In this instance, as HFA was added the yield of hydrogen decreased, and therefore this explanation too was considered improbable.

(iv) Product Analysis

Attempts were made to detect the heavier products formed in the $Hg(^3P_1)$ sensitized decomposition of H_2 (600 Torr) in the presence of 10–20 Torr of HFA. It was hoped that only those arising as a result of the reaction of H with HFA would be observed, but, as we have shown, this is a rather slow process. As a consequence products arising from the quenching of $Hg(^3P_1)$ by HFA interfered considerably as was evidenced by the appearance of nearly twenty peaks in the gas chromatogram. The identities of several of the product peaks (CO, C_2F_6, CF_3H, C_3F_8, and HFA) were readily established but the assignment of many was not possible even though their mass spectra were taken. Some of these seemed to be fluoroalkyl alcohols of higher molecular weight and one was almost certainly trifluoroacetaldehyde (very strong peaks at *m/e* 20); this latter might well arise from reaction [9].

It is interesting to compare this work to that of Gordon *et al.* (31), who studied the photolysis of HFA in ethane. These workers found various high molecular weight alcohols and derived a mechanism to account for their production. A crucial reaction in this system was the intramolecular hydrogen shift in the alkoxy radical shown below



The hydroxylated radical so produced can attack more HFA or recombine. In the system on which we carried out product analysis, this process is ruled out since no α-hydrogens are present and the secondary alkoxy radical can only give β-scission to give an aldehyde or ketone, abstract an H from hydrogen to form an alcohol, or recombine to give a peroxide.

(v) Correlation with the HFA Photolysis in the Presence of H_2

The value of k_9 estimated in (*iii*) may be used to calculate the value of the material balance expected in the experiments described in the Introduction. If reaction [9] is included with the usual reactions forming CF_3H and C_2F_6 in that system (see ref. 1), then the material balance ratio may be expressed as

$$[23]\quad m = 1 + \tfrac{1}{2}k_9k^{-1/2}[\mathrm{HFA}] \times \{(R_{\mathrm{CO}}{}^{1/2} - R_{\mathrm{C_2F_6}}{}^{1/2})/R_{\mathrm{CO}}\}$$

where k is the rate constant for the mutual and cross combination reactions of CF_3 and H in their high pressure limits. Values of m calculated on this basis exceed those found experimentally by an order of magnitude (e.g. for $[\mathrm{HFA}] = 20$ Torr and $[\mathrm{H_2}] =$ 395 Torr, 1.25 μmol CO, and 0.54 μmol C_2F_6 were formed in 1 h in a reaction volume of 0.177 ℓ at 100°C; $m_{\mathrm{calcd}} \simeq 18$, $m_{\mathrm{obsd}} = 1.75$). Moreover, as [9] is expected to require some activation energy, the value of k_9 taken to calculate m should be larger than the room temperature value estimated in (*iii*);

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

such a correction could only magnify the disagreement.

It seems unlikely that the assumptions involved in the derivation of [23] could introduce so large an error except that which requires [9] as written to represent the sole interaction between H and HFA. Indeed, the rather large number of heavier products detected in (*iv*) suggests that a substantial portion of the H + HFA interactions proceed to other products. In that event, the rate of H disappearance by reaction with HFA should not be equated to the rate of CF_3 formation in that interaction as was done in the derivation of [23], but rather only some as yet unknown fraction of that rate should be used. It is evident that much more work will be required before a quantitative description of these systems can be given.

Detection of intermediates and isolation of hydroquinone monoacetate in the Dakin oxidation of *p*-hydroxyacetophenone

MARTIN B. HOCKING,[1] MING KO, AND TREVOR A. SMYTH
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received April 18, 1978

MARTIN B. HOCKING, MING KO, and TREVOR A. SMYTH. Can. J. Chem. **56**, 2646 (1978).

Oxidation of *o*-, *m*-, and *p*-hydroxyacetophenone with peracetic acid or *tert*-butyl hydroperoxide, oxidants relatively readily monitored by nmr, failed to generate isolable intermediates though an intermediate was detected for the *p*-ketone. Attempted oxidation of a number of related ketones under Dakin conditions failed either to react, or to generate a detectable intermediate. However, with delicate adjustment of pH and careful timing of the isolation procedure, hydroquinone monoacetate has for the first time been successfully isolated from an alkaline aqueous hydrogen peroxide oxidation (Dakin oxidation) of *p*-hydroxyacetophenone.

MARTIN B. HOCKING, MING KO et TREVOR A. SMYTH. Can. J. Chem. **56**, 2646 (1978).

L'oxydation des *o*-, *m*- et *p*-hydroxyacétophénones par l'acide peracétique ou l'hydroperoxyde de *tert*-butyle, des oxydants qui peuvent être facilement détectés par rmn, n'ont pas conduit à la formation d'intermédiaires pouvant être isolés, même si on a pu détecter un intermédiaire dans le cas de la cétone *para*. Lors d'essais d'oxydation d'un certain nombre de cétones apparentées, dans les conditions de Dakin, nous n'avons observé aucune réaction et nous n'avons pu générer d'intermédiaires pouvant être détectés. Toutefois en ajustant d'une façon délicate le pH et en minutant correctement le procédé d'isolation, on a pu isoler pour la première fois le monoacétate d'hydroquinone d'une oxydation par le peroxyde d'hydrogène en milieu aqueux alcalin (oxydation de Dakin) d'une *p*-hydroxyacétophénone.

Introduction

Oxidation of hydroxyacyl aromatics with aqueous alkaline hydrogen peroxide to yield dihydroxy aromatics has received significant attention for its synthetic utility (1, 2) and its scope was reviewed some time ago (3). However, the mechanistic pathway followed by this process has received little attention, apart from relatively recent proposals that it proceeds via an ester intermediate (4), frequently by analogy to the better understood though only superficially related Baeyer–Villiger oxidation of bisaromatic ketones.

A series of competitive oxidation hydrolysis experiments with initial simultaneous presence of *p*-hydroxyacetophenone and hydroquinone monoacetate (HMA) substrates showed that loss of ketone was more rapid than of ester, which suggested that ester could not be an intermediate in this process (5). However, ester which may have subsequently formed from ketone made this a potentially ambiguous result though there was no evidence of ester during a reaction in the absence of initial ester (Scheme 1). Kinetic experiments have established a first-order rate dependence on ketone concentration for both *ortho*- and *para*-hydroxyacetophenone but at the same time unexpectedly demonstrated a 1.4 order of dependence in hydrogen peroxide (6), again an inconclusive result. Fortunately, however, during a few of the preliminary runs for the kinetic experiments at lower pH which were monitored by ^{1}H nmr, an occasional fleeting additional proton resonance at about the same shift as would be expected for the acetate methyl of HMA was observed. Here are reported the results of the experiments directed towards establishing conditions which prolonged the lifetime of this and related intermediates to enable more extensive observation of their formation to be made, and eventually to enable procedures to be developed to isolate a key intermediate in this process and prove its identity.

Experimental

Commercial *p*-hydroxyacetophenone was purified by crystallization from water and dried (80°C/24 h) before use. Hydroquinone monoacetate was obtained in poor yield as previously described (6), *m/e* 152. Peracetic acid was freshly prepared on an approximately 2 g scale for each experiment from glacial acetic acid (2.5 g), 90% hydrogen peroxide (1.5 g, FMC; normal precautions (7)), and concentrated sulphuric acid (50 mg) by the method of Greenspan (8). Concentrations of 50–52% were obtained by titrimetric determination (9, 10) and were confirmed by ^{1}H nmr measurements (11). The reported mole ratios of hydrogen peroxide are based on determinations of the nominal 30% material immediately before use (12).

Proton nmr monitoring was carried out and spectra were obtained at 37°C on Perkin-Elmer R-12 or R-32 spectrometers, using 6% TMS in CCl_4 sealed in an axially-positioned thin-wall capillary as external reference for the reported shifts of aqueous solutions. Mass spectra were obtained on Hitachi Perkin-Elmer RMU-6E double focussing and Finnigan

SCHEME 1. Competitive oxidation hydrolyses of *p*-hydroxyacetophenone and hydroquinone monoacetate.

quadrupole spectrometers. Analytical and preparative gas–liquid chromatographic (glc) results were obtained on Varian Aerograph Model 920 instruments fitted with flame ionization and thermistor thermal detectors, respectively.

Hydroquinone Monoacetate Hydrolysis Rate Experiments

Hydroquinone monoacetate relative hydrolysis rates were surveyed by small scale experiments using ^{1}H nmr monitoring of the ester and acetate ion resonances at δ 2.72 and 2.35 ppm, respectively.[2] One example where the generation of intermediate peracetic acid was observed is described below.

Hydrogen peroxide (60 mg, 30%) was added to a solution of HMA (5 mg) in 0.5 ml of water thermostatted at 37°C. After 75 min a singlet resonance at 2.53 ppm indicated that about 20% of the residual ester was present, and acetic acid was absent. After 15 h the breakdown of the reaction progress by ^{1}H nmr was approximately: ester, 50%; peracetic acid **2**, 20%; and acetic acid, 30%. By 66 h the ester had hydrolyzed completely.

Extraction Experiments during Hydroquinone Monoacetate Hydrolyses

Hydroquinone monoacetate (44 mg) was dissolved in 0.5 ml of 0.1 *M* sodium hydroxide containing 120 mg of 30% hydrogen peroxide and 2 min later the resulting solution was extracted with 3 ml followed by 1 ml of deuteriomethylene chloride. Examination of the dried extracts by ^{1}H nmr demonstrated the presence of four times as much HMA, at δ 2.20, as intermediate **2**, δ 2.10 ppm, in the first extract, and an HMA concentration of about 0.8 that of the intermediate **2**, in the second; ms (room temperature 70 eV) *m/e*: 167, 152 (HMA); ^{13}Cmr (CD_2Cl_2): two benzene derivatives. The resonance ascribed to the methyl of HMA was confirmed by seeding with genuine material (6). Loss of the ^{1}H nmr resonance at 2.10 ppm occurred on careful evaporation and resolution, or from washing a portion of the extract with 6 drops of water. The original aqueous raffinate contained HMA, intermediate **2** (predominating), and acetate ion, δ ≃ 2.20, 2.10, and 2.00 ppm, respectively.

Seeding experiments with freshly prepared peracetic acid (8) on a new experiment gave peaks which coincided with the singlet for intermediate **2** for both a deuteriochloroform extract and the aqueous raffinate.

Stable Intermediate Experiments

p-*Hydroxyacetophenone with Peracetic Acid*

A solution of *p*-hydroxyacetophenone (97 mg) in 0.46 ml of 1 *M* sodium carbonate at 37°C was rapidly oxidized but failed to show directly any detectable intermediate with peracetic acid (260 mg of 51.5%).

This experiment was repeated and 1 min after mixing was chilled, saturated with sodium chloride, and then extracted with 1 ml deuteriochloroform. The dried extract contained HMA, peracetic and acetic acids, by ^{1}H nmr and ir; ms (room temperature, 70 eV) *m/e*: 152, 111, 109. About 15 mg of impure hydroquinone was isolated from the acidified aqueous reaction solution.

Other experiments conducted are mentioned in the discussion.

Small-scale ^{1}H Nuclear Magnetic Resonance Survey Oxidations of m- and p-*Hydroxyacetophenone*

The hydroxyketone, in varying mole ratios, was dissolved in aqueous solutions of 0.10–0.74 *M* sodium hydroxide or sodium carbonate and the solutions placed in a thermostat bath at 37°C for several minutes. Via a calibrated dropper the desired quantity of stock hydrogen peroxide, also at 37°C, was added to the solution of the ketone and the solution vigorously mixed, and then an aliquot withdrawn and placed in an nmr tube. The region 1 to 4 ppm for protons was then repeatedly scanned for a period of an hour or so, or until there appeared to be no further change, to observe the loss of the ketone methyl singlet and development of an acetate ion singlet plus the appearance of any additional resonances of interest. From a matrix of some 30 experiments of this kind the set of conditions outlined in the procedure below was devised for the *p*-ketone.[2]

Hydroquinone Monoacetate Isolation from a Dakin Oxidation of p-*Hydroxyacetophenone*

To a stirred solution of *p*-hydroxyacetophenone (20.0 g) in 240 ml of 0.4 *M* aqueous sodium carbonate at 37°C was added 20 ml of 36.8 wt.% hydrogen peroxide. Once the solution became homogeneous (about 2 min), the reaction was quenched

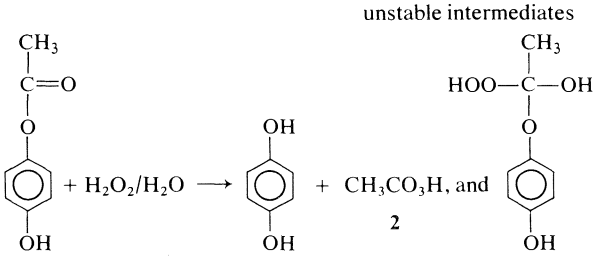
by sharp chilling in a salted ice bath and by the addition of 1.0 *M* sulfuric acid to pH < 3 while simultaneously bubbling excess sulfur dioxide through the solution. The chilled solution was then extracted with 4 × 100 ml and 1 × 100 ml of ether and the two series of extracts dried (Na_2SO_4) and solvent removed to yield 21.92 and 0.84 g of pale brown solid. Gas–liquid chromatography of this material on a 1.3 m × 3 mm, 3% SE30 on 80/100 mesh Chrom P packed column at 164°C, 15 ml/min He carrier, gave retention times for benzoquinone, 1.1 min; hydroquinone, 4.2 min; HMA, 7.0 min; *p*-hydroxyacetophenone, 10.4 min and established that the composition of the larger sample was approximately 16 and 75% of the former two, and 3–4% of each of the latter two compounds.

The combined evaporated crude extracts were triturated with cold benzene (4 × 50 ml) and the combined solutions dried and chilled to 0°C, which brought down 1.58 g of pale yellow crystals, mp 82–105°C, of impure *p*-hydroxyacetophenone (nmr). After drying, the benzene was removed from the filtrate leaving 4.3 g of pale orange crystals in oil. The oil (1.68 g) was filtered off and was then extracted with 3 × 3 ml of benzene. The first extract (0.85 g) contained 38 mol% HMA (plus 58% *p*-hydroxyacetophenone), 4% acetic acid, by ^{1}H nmr, and the second and third extracts contained negligible further HMA. It was not possible to crystallize this extract from a variety of solvents either directly or from combined appropriate fractions, obtained after solvent chromatographing on activated alumina columns twice. However, after successful preliminary separate sublimation tests with authentic HMA and *p*-hydroxyacetophenone, about 130 mg of 86% (^{1}H nmr) HMA was sublimed (90–110°C/15 Torr) from the first extract. Recrystallization from hexane twice, with charcoal, gave a few milligrams of colourless plates (needles occasionally obtained if crystallization was rapid) of HMA, mp 60–63°C; ms, methane chemical ionization, 152, 153 (M + 1), 181 (M + 29), and 193 (M + 41), were obtained both for this material and for authentic hydroquinone monoacetate (6); ir (Nujol) ν_{max}: 3440 (s, OH), 1745 and 1726 (s, C=O); electron impact ms (room temperature, 70 eV) *m/e* (relative intensity >10%): 152(13), 110(100), 109(11), 82(12), 81(19), 55(12), 54(14), 53(18), 43(51), 39(13).

From extracts of later oxidations of *p*-hydroxyacetophenone, HMA was separated with difficulty by preparative glc using 100 μl injections of a 10% ethereal solution onto a 1 m × 6 mm column of 1.5% OV 701 on Chrom G H/P 100/120 at 190°C, 70 ml/min He carrier. Retention times observed were hydroquinone diacetate 1.8 min; HMA, 3.1 min; and *p*-hydroxyacetophenone, 6 min. One recrystallization of the HMA fraction from hexane gave colourless square plates identical to the above, mp 63–64°C (lit. (13) mp 65–66°C).

Results and Discussion

Preliminary nmr tube scale experiments established that HMA alone in water at 37°C remained virtually unchanged even after 17 h although addition of a small amount of sodium hydroxide to the solution brought about hydrolysis in less than 2 min, extremely rapid compared to control experiments with phenyl acetate. Aqueous hydrogen peroxide alone also caused rapid disappearance of the HMA interestingly enough generating peracetic acid, **2**, and possibly a per ortho ester (see Scheme 2) giving a ^{1}H nmr resonance at δ 2.14, which then quite slowly faded to the methyl shift for aqueous acetic acid, plus hydroquinone (not specifically monitored). Eventually conditions were devised prolonging the lifetime of these intermediates to more than an hour. Extraction experiments were successful in obtaining stable methylene chloride solutions of the intermediates in which the presence of peracetic acid was confirmed by seeding experiments. But apart from obtaining mass spectrometric confirmation of the per ortho ester by an *m/e* of 167 it was not possible to further characterize this material.



SCHEME 2

The results obtained from the monoester experiments above initially discouraged direct pursuit of the intermediate from alkaline hydrogen peroxide oxidation of *p*-hydroxyacetophenone. It had also been noted that solvent changes, for instance to acetone or pyridine, completely alter the course of the reaction (14). Therefore, consideration was then given to oxidant variants or more stable aryl ketone substrates in an attempt to obtain a somewhat longer-lived and less sensitive intermediate to facilitate isolation.

Peracetic acid oxidation of acetophenone at low pH has been reported to give phenyl acetate, phenol, and benzoic acid (15). Accordingly, peracetic acid oxidations of *p*-hydroxyacetophenone in aqueous sodium carbonate were conducted. Deuteriochloroform extracts gave a ^{1}H nmr singlet resonance coinciding with added HMA, and the correct *m/e* 152, but the solution concentration was low and the experimental procedure was difficult to scale up to permit confirmation of this result by isolation.

tert-Butyl hydroperoxy radical has been used to oxidize aromatic substrates (16) and the hydroperoxide to oxidize aliphatic aldehydes (17, 18). However, even up to five times excess of this oxidant failed to give any detectable (11) oxidation or intermediate formation with *p*-hydroxyacetophenone in aqueous sodium hydroxide, or with the mono- or diacetates of hydroquinone in carbon tetrachloride, either cold or hot. A slow oxidation occurred with *tert*-butyl hydroperoxide and *o*-hydroxyacetophenone at 85°C although it was not possible to detect any intermediate. Possibly the reported inhibiting effect of phenols generally on the decomposition of *tert*-butyl hydroperoxide (19) may be the explanation for this uniformly observed sluggish reactivity.

Acyl aromatics such as *m*-hydroxyacetophenone and *p*-nitroacetophenone have been reported to be stable to Dakin oxidation conditions (1). If the reaction proceeds via the pathway outlined earlier (4), it was likely that this lack of reactivity was the consequence of the low migratory aptitude of the phenyl group rather than from the reduced nucleophilicity of the carbonyl carbon towards hydroperoxide anion. With this in mind, *m*-hydroxyacetophenone was exposed to Dakin conditions while monitoring by ^{1}H nmr. Small amounts of acetate ion were generated but at no time was there a detectable amount of intermediate. It had been determined that if resorcinol had formed, it would not have been more than slightly affected under the experimental conditions used. Separate parallel experiments were conducted with *p*-methoxyacetophenone, 5-nitrosalicylaldehyde, and 3-nitro-4-hydroxyacetophenone with similar negative results.

Accordingly, a number of small-scale Dakin oxidations of *p*-hydroxyacetophenone were carried out and monitored by ^{1}H nmr to determine whether conditions could be suitably adjusted, not only to generate the same nmr resonance coincident in shift to that of the methyl of HMA fleetingly observed previously, but to extend the lifetime of HMA sufficiently to enable isolation of the material. With two of these, namely these having *p*-hydroxyacetophenone, sodium carbonate, and hydrogen peroxide in the amounts 0.74, 0.12, 0.66 and 1.48, 0.12, 1.41 mmol, respectively, in 1.2 ml of water, an nmr singlet at the desired shift was observed and, for the latter experiment at least, a confirmed lifetime for the desired intermediate of more than an hour was obtained.

From a scaled-up Dakin oxidation of *p*-hydroxyacetophenone, using the conditions established by these small-scale experiments, pure HMA was eventually obtained. Initial difficulties with relatively large quantities of co-produced and easily sublimed benzoquinone were largely avoided by the application of gaseous sulfur dioxide to the quenched reaction solutions early in the work-up. Benzene trituration followed by evaporation served to recover the monoester still associated with ketone but virtually free of associated, less soluble hydroquinone. Either careful sublimation or preparative glc followed by crystallization then gave pure HMA.

Although this first isolation of HMA from a Dakin oxidation of *p*-hydroxyacetophenone certainly implicates the ester as an intermediate in this process, the evidence obtained here is insufficient to establish this as the sole intermediate. Consideration of the kinetic results obtained earlier (6), which were inconsistent with a pathway only involving ester, strengthens this proposal that ester formation is probably accompanied by at least one other pathway for the progression of Dakin oxidation. Evidently further experimental results are necessary before the details of this process can be established with any greater certainty.

SANDRA L. KIELLAND, LEWIS A. SLOTIN, and ROSS E. WILLIAMS. Can. J. Chem. **56**, 2650 (1978).

Turbidity measurements, circular dichroism spectra, electron micrographs and thermal denaturation profiles of complexes between sonicated DNA and either poly(L-lysyl-L-alanine) or poly(L-lysyl-D-alanine) show significant differences which might be related to the primary or secondary structure of the polypeptides.

SANDRA L. KIELLAND, LEWIS A. SLOTIN et ROSS E. WILLIAMS. Can. J. Chem. **56**, 2650 (1978).

Nous avons pris des mesures de turbidité, des spectres du dichroisme circulaire, des micrographies éléctroniques ainsi que des spectres thermo-optique des complexes entre l'ADN (traité aux ultrasons) et poly(L-lysyl-L-alanine) ou poly(L-lysyl-D-alanine). Les différences observées entre les complexes pourraient être attribuables aux structures primaires et secondaires des polypeptides.

[Traduit par le journal]

Introduction

In the living cell many proteins are found in direct association with nucleic acids. Many of these proteins, such as the histones, have cationic regions in them which are found in direct contact with the nucleic acids. Homopolymers, as well as random and sequential copolymers, containing the amino acids arginine or lysine, have been used as models of these cationic regions (see ref. 1 and previous papers in this series, refs. 1–26). Complexes between the polypeptides and the nucleic acids have been formed in one of three different ways: (*i*) by simply mixing the compounds together (2–9); (*ii*) by step-wise dialysis from high concentration salt solutions (10–19); (*iii*) by equilibrium gradient dialysis from high concentration salt solutions (20–26). Of the three, equilibrium gradient dialysis from high concentration salt solutions has proved to be the most easily reproduced (21). Studies in these laboratories have been initiated with the aim of discerning the various factors important to the formation of polypeptide–, and thus protein – nucleic acid complexes.

From amongst the various factors which might be important to the formation of cationic polypeptide – nucleic acid complexes it has been suggested that the conformational flexibility of the polypeptide, i.e., the degrees of freedom possessed by the polypeptide backbone and groups attached to it, might play a role in determining the final form of the complex. The studies which led to this suggestion were those in which the effect of poly(L-lysine) and a set of lysine-glycine sequential copolypeptides on the formation of the aggregated, or ψ-state of calf thymus DNA was studied (25, 26). It was shown that poly(L-lysine) induced maximum formation of ψ-state DNA at lower lysine – DNA phosphate ratios than any of the poly(L-lysine-glycine) sequential copolymers. This difference was attributed, in part, to the fact that poly(L-lysine) was conformationally less flexible than any of the lysine-glycine copolymers. However, the complete separation of the influence of polypeptide conformational flexibility from the other possible factors, such as charge spacing and hydrophobicity, was not possible in these experiments.

Recently we have reported the synthesis of two sequential polypeptides, poly(L-lysyl-L-alanine) (PL-L-Ala) and poly(L-lysyl-D-alanine) (PL-D-Ala) (27). These two polymers have the same interlysine charge spacing, very similar overall hydrophobicities, and have been shown to have different conformational flexibilities (27). In an effort to determine if different polypeptide conformational flexibilities influence polypeptide interaction with DNA we have studied their ability to induce the ψ (or aggregated)-state in calf thymus DNA (CT-DNA). After back dialysis of the components to physiologically-related conditions i.e., pH 7.0, 0.15 *M* NaCl, the formation of ψ-state DNA was examined by solution turbidity measurements, circular dichroism (cd) spectroscopy, and electron microscopy (em). In addition, the effect of

the polymers on the thermally-induced transition of DNA from its double stranded state to its single stranded state was examined.

Method and Materials

Chemicals used to prepare buffers were commercially available and reagent grade. All water used was deionized and distilled from glass. Specific experimental details have been previously reported for: (*i*) the preparation, purification, sonication, and concentration assays of calf thymus DNA (25, 26); (*ii*) the preparation, characterization, and concentration assays of the poly-L-lysine sample (1×10^4 molecular weight) which was used (25, 26, 28); (*iii*) the preparation, characterization, and concentration assays of poly(L-lysyl-L-alanine) and poly-(L-lysyl-D-alanine) samples which were used (27); (*iv*) the preparation of annealed complexes containing the polypeptide and the 40-s sonicate of calf thymus DNA (DNA molecular weight approximately 500 000) (26).

Instruments used to measure and methods of expressing the results of ultraviolet spectra, solution turbidity, and circular dichroism spectra have been described previously (25). Instrumentation and techniques of preparing grids for electron microscopy have been reported previously (26).

Thermal melting experiments were done using a Cary-Varian spectrophotometer, model 14 equipped with a thermostatted multisample changer. Solutions were contained in Teflon-stoppered quartz cells (internal width, 0.4 cm; path length, 1.0 cm). Solution temperatures were monitored with a thermistor-equipped Telethermometer, Yellow Springs, Ohio, U.S.A. Changes in absorption (A) with temperature (T) were monitored at 260 nm. No corrections for thermal expansion of the solutions were made. The results were plotted as differential absorptions vs. temperature i.e., dA_T/dT_T vs. T where $dA_T = (A_{T+2} - A_{T-2})$, $dT_T = (T_{T+2} - T_{T-2})$, and T = measured temperature in °C. Readings were taken at 2°C intervals only after the constancy of absorption was established. Total hypochromicity of a salt gradient annealed sample of purified calf thymus DNA (40-s sonicate) was 26 ± 2%($10^{-3}M$EDTA, pH 7.0). Hypochromicity is defined as $(A_{260}{}^{95} - A_{260}{}^{25})/A_{260}{}^{95}$ where $A_{260}{}^{T}$ is the solution absorption at 260 nm and 95°C and 25°C, respectively.

Results

Formation of annealed complexes between cationic polypeptides and calf thymus DNA (CT-DNA) by gradient dialysis from high concentrations of salt to physiological conditions (i.e., 0.15 M NaCl, pH 7) results in the appearance of, what has been designated, the ψ-(or aggregated) state of DNA. Poly(L-lysine) and several random and sequential lysine-containing copolypeptides have been shown to induce the formation of this ψ-state in DNA (1). The ψ-state of DNA has been suggested to result from the aggregation of double-stranded regions of the DNA into an ordered (or liquid crystalline) array (29–32). This aggregation could be brought on by solvent exclusion, by induction of long range order into the DNA (21) and, perhaps by phase separation of the components from solution (i.e., coacervate formation) (31, 32).

Experimentally, the formation of the ψ-state results in the formation of a large negative band in the cd spectrum between 260 and 280 nm accompanied by solution turbidity and the formation of aggregates observable by em. Each of these have been examined with complexes containing calf thymus DNA (CT-DNA) and either PL-L-Ala or PL-D-Ala. Thermal denaturation profiles of the complexes have also been determined. The results are given below.

Solution Turbidity

Complex formation results in an increase in solution turbidity at 400 nm (25). The solution turbidity, although not directly connected to ψ-state formation, was shown to be influenced by the structure of the lysine-containing polypeptide and the strandedness of the DNA (26). Solutions containing complexes of CT-DNA and poly(L-lysine) become more and more turbid as the lysine – DNA phosphate (L/P) ratio increases (Fig. 1). The turbidity plateaus at about the same L/P ratio as the maximum in the formation of the ψ-state DNA (26). An increase in solution turbidity with increasing L/P ratio also occurred in solutions of complexes containing either PL-L-Ala or PL-D-Ala; however no plateau was reached even at L/P ratios as high as 2. It was noted that slightly more turbidity was associated with complexes containing PL-L-Ala than those containing PL-D-Ala. The gradual increase of solution turbidity and the lack of a plateau was similar to that found for complexes of poly(L-lysylglycine) (26). It may also be noted that the solution turbidity at an L/P ratio of 1 of complexes containing the lysine–alanine complexes was less than

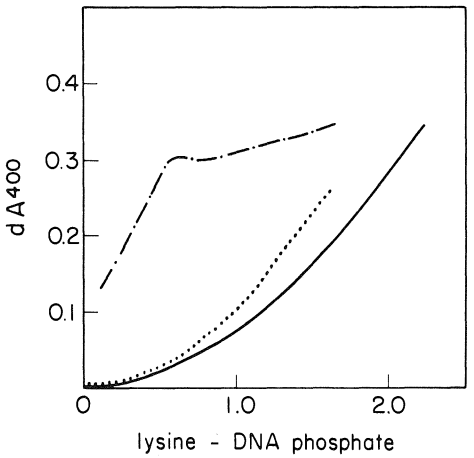

FIG. 1. Variation in sample turbidity dA^{400} with lysine – DNA phosphate ratios in complexes between lysine-alanine polypeptides and sonicated calf thymus DNA: poly(L-lysine)–DNA complexes (- · - · -); poly(L-lysyl-L-ala)–DNA complexes (· · ·); poly(L-lysyl-D-ala)–DNA complexes (———). Experimental conditions: DNA phosphate concentration, 1.77×10^{-4} M; sodium chloride, 0.15 M; sodium cacodylate, 0.001 M; pH 7.0; T = 25°C.

that found for the solutions of poly(L-lysylglycine)/CT-DNA.

Circular Dichroism Spectra

Complex formation results in changes to the solution cd spectrum of CT-DNA. When complexes are formed with poly(L-lysine) the cd spectrum of CT-DNA changes from one attributed to B-DNA to one representative and diagnostic of ψ-state DNA (Fig. 2) (21, 25, 26). The change in spectrum results in the formation of a large negative band between 260 and 280 nm. Both PL-L-Ala and PL-D-Ala cause the formation of ψ-state DNA when complexes are formed with CT-DNA (Fig. 2).

Plotting the ellipticity generated at 275 nm vs. the L/P ratio (Fig. 3) shows that the maximum formation of the ψ-state occurs around an L/P ratio of 0.6 with poly(L-lysine) and around 1.5 with the two lysine-alanine polymers. The peaking of ellipticity at an L/P ratio around 1.5 was very similar to that observed with the set of lysine-glycine copolymers (25, 26). The production of ellipticity associated with ψ-state formation, however, varied with the L/P ratio and depended upon the polymer incorporated in the complex. At low L/P ratios (less than 1) PL-L-Ala was more effective in causing formation of the ψ-state whereas the reverse was true at high L/P ratios (greater than 1). It would, thus, appear that the DNA in complexes containing low concentrations of PL-L-Ala was more ordered than that in complexes containing PL-D-Ala whereas the reverse would hold for DNA in complexes having higher concentrations of the polypeptides.

Electron Microscopy

Complex formation results in the formation of uranyl acetate stainable aggregates which may be observed in the electron microscope. As the L/P ratio in the complexes increases and approaches the maximum in the formation of the ψ-state large clusters of circular aggregates are formed. Each circle has an apparent diameter of about 6000 Å. An electron micrograph of complexes of poly(L-lysine)/CT-DNA is shown in Fig. 4*a*. This may be compared with the electron micrographs prepared in an identical manner with complexes formed between either PL-L-Ala/CT-DNA (Fig. 4*b*) or PL-D-Ala/CT-DNA (Fig. 4*c*). Aggregates containing PL-L-Ala (Fig. 4*b*) were similar to those incorporating poly(L-lysine) in that they were densely stained and showed a tendency to form clusters, although this tendency was somewhat reduced compared with that of poly(L-lysine). The diminished tendency to form clusters was similar to that observed in the complexes formed between CT-DNA and poly(L-lysylglycine) and the other related lysine-glycine polymers (26). The shape of the complexes, however, was more oval than that

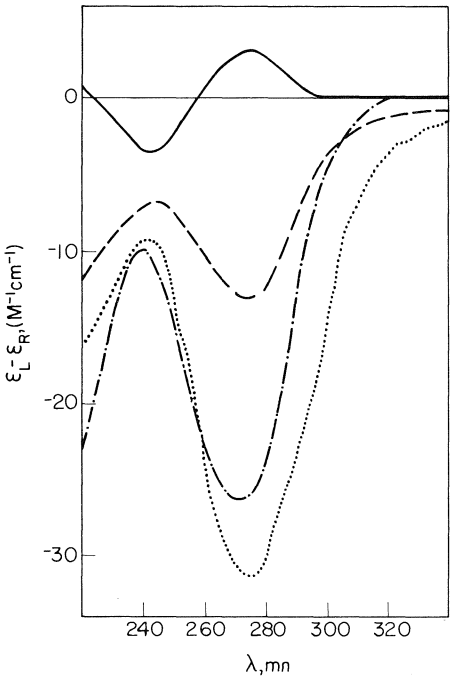

FIG. 2. Circular dichroism spectra of lysine and lysylalanine polypeptides complexed with sonicated calf thymus DNA: sonicated calf thymus DNA (———); poly(L-lysine)–DNA complexes, lysine – DNA phosphate ratio, 0.8 (– · –); poly(L-lysyl-L-alanine)–DNA complexes, lysine – DNA phosphate ratio, 0.92 (· · ·); poly(L-lysyl-D-alanine)–DNA complexes; lysine – DNA phosphate ratio, 1.14 (- - -). Experimental conditions: as for Fig. 1; T = 27°C. No corrections have been made for sample turbidity.

of either the poly(L-lysine) or any of the lysine-glycine copolymers. The complexes were also smaller, i.e., the dimensions of the PL-L-Ala/CT-DNA complexes were approximately 2000 Å by 3000 Å.

The complexes between PL-D-Ala and CT-DNA (Fig. 4*c*) were much less densely stained (more diffuse) than those of PL-L-Ala/CT-DNA and showed no tendency of clustering. They were also oval shaped and had dimensions of approximately 2000 Å by 6000 Å.

Thermal Denaturation Experiments

When the temperature of a solution of double stranded DNA rises the ultraviolet absorption at 260 nm undergoes a relatively abrupt increase (hyperchromism) (33). The temperature at which the transition occurs (T_m) is defined by the ionic composition and strength of the solvent and the nucleic acid base composition of the DNA (34). Positively charged polymers cause a rise in the T_m of native DNA. For example, it has previously been shown that when poly(L-lysine) was complexed with DNA the T_m of native DNA was raised and that the fraction of the DNA involved in the rise depended on the L/P ratio (35, 36).

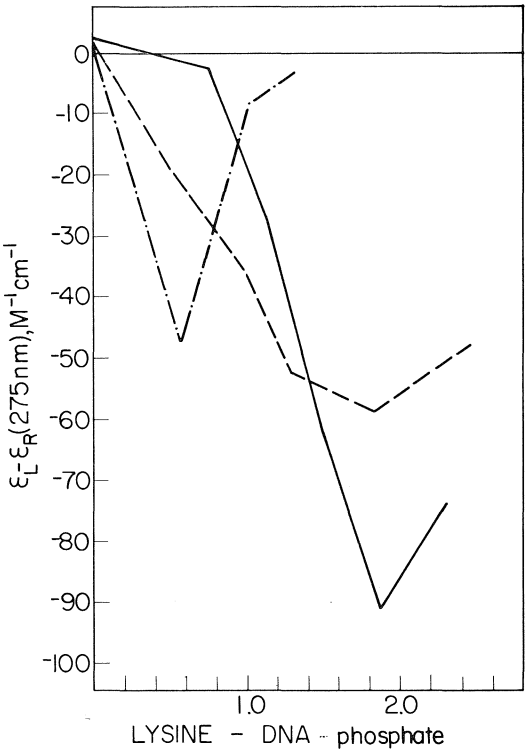

FIG. 3. Variation of the molar ellipticity ($\varepsilon_L - \varepsilon_R$) at 275 nm with the lysine – DNA phosphate ratios in complexes between the lysine and lysylalanine polypeptides and sonicated calf thymus DNA: poly(L-lysine)–DNA complexes (– · –); poly(L-lysyl-L-alanine)–DNA complexes (– –); poly(L-lysyl-D-alanine)–DNA complexes (———). Experimental conditions: as for Fig. 1.

The effect of poly(L-lysine), PL-L-Ala, and PL-D-Ala on the melting behaviour (denaturation) of the purified, sonicated DNA used to form the complexes was determined. Complexes were formed, as in the other experiments, by back dialysis in a linear gradient of decreasing salt concentration until physiological conditions were reached. The complexes were then dialyzed against 10^{-3} *M* ethylenediaminetetraacetic acid (EDTA), pH 7.0, and melted. The derivative melting profile of purified, sonicated DNA has a major T_m centered at 54 ± 2°C (Fig. 5). The transition was relatively broad and asymmetric indicating that the DNA was composed of molecules having different guanine-cytosine (G/C) contents (37, 38). The melting behaviour of complexes of poly(L-lysine) and the DNA, at an L/P ratio where light scatter was negligible, showed two major transitions: one was/centered at 61 ± 2°C while the other was centered at 71 ± 2°C. The major loss of lower melting material from underneath the DNA melting regions could be connected with the adenine-thymine (A/T) specificity of poly(L-lysine) (39). It would be expected that lower melting (A/T rich)

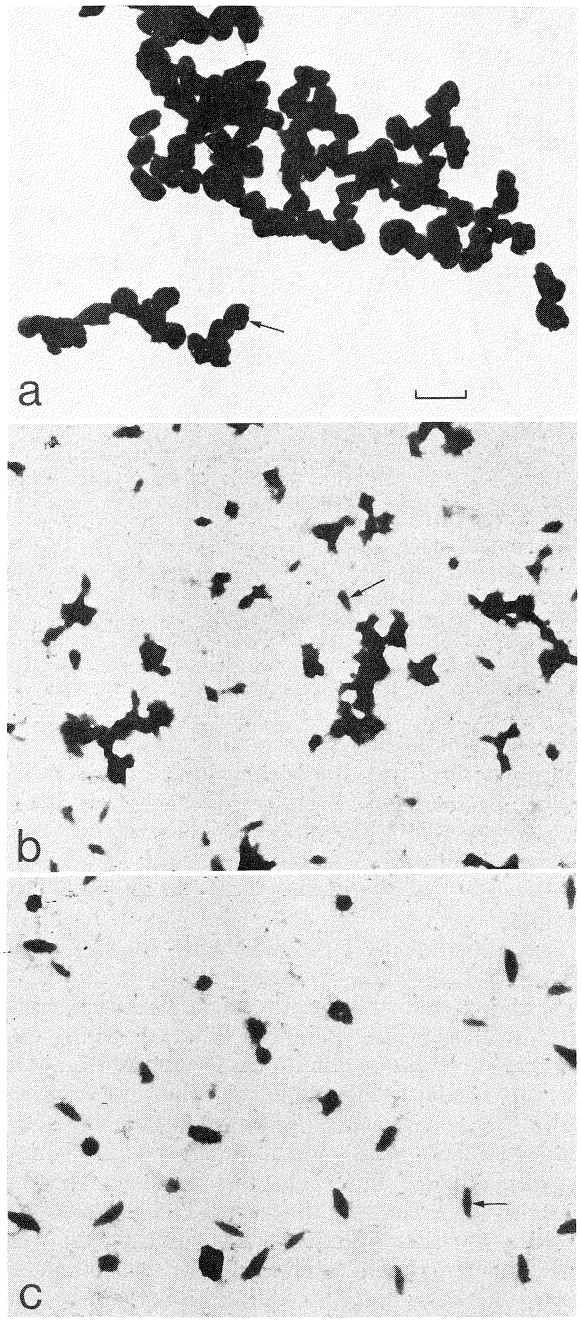

FIG. 4. Electron micrographs of formaldehyde-fixed, dehydrated and stained polypeptide – sonicated DNA complexes: (*a*) poly(L-lysine)–DNA complexes, L/P = 0.64; (*b*) poly(L-lysine-L-alanine)–DNA complexes, L/P = 1.36; (*c*) poly(L-lysine-D-alanine)–DNA complexes, L/P = 1.47. Experimental conditions: DNA-phosphate concentration = 1.77×10^{-4} *M*. Complexes were fixed before drying in 0.15 *M* NaCl, 0.0010 *M* sodium cadodylate, pH 7.0, ~1.0% formaldehyde. Dried complexes were stained with uranyl acetate. The bar indicates a distance of 1 micrometre (μm). All the micrographs have the same magnification. Arrows indicate typical complexes used for dimension determinations.

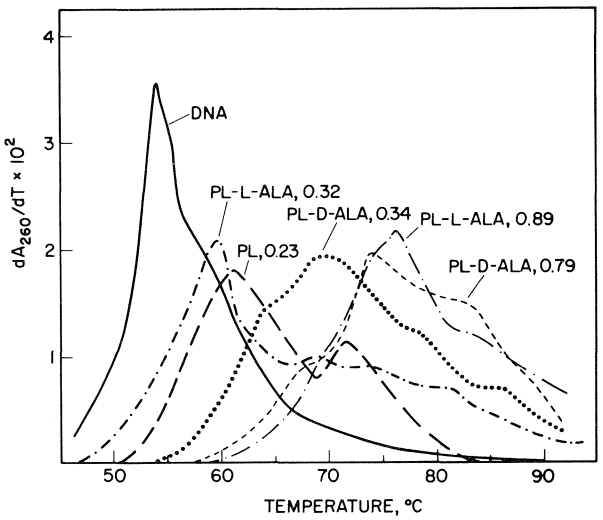

FIG. 5. Derivative absorption melting profiles (dA_{260}/dT vs. T) of purified, sonicated DNA (———) complexed with: (*i*) poly(L-lysine), L/P ratio = 0.23 (- - -); (*ii*) PL-L-Ala, L/P ratio = 0.32 (– · – · –), L/P ratio = 0.89 (— · — · —); (*iii*) PL-D-Ala, L/P ratio = 0.34 (· · · · · · · · ·), L/P ratio = 0.79 (– – – – – – –). Experimental conditions: 1.0×10^{-3} *M* EDTA, pH 7.0; DNA-phosphate concentration, 1.70×10^{-4} *M*.

material would be preferentially complexed and leaving a G/C rich fraction melting in the DNA region. Such a suggestion has previously been made (35). Increasing the L/P ratio in the complex to above 0.5 resulted in large amounts of light scatter and invalidated the measurement of the melting behaviour.

For complexes of DNA with both PL-L-Ala and PL-D-Ala L/P ratios of approximately 0.3 and 0.7 were chosen since light scattering effects were minimal. At an L/P ratio of about 0.3 the melting behaviour of complexes containing DNA and PL-L-Ala was very similar to that seen with poly(L-lysine) complexes. The derivative profile consisted of a T_m centered at 60 ± 2°C and a very broad transition between 65 and 85°C. The loss of lower melting material from beneath the native DNA peak also suggests a similar A/T base specificity for PL-L-Ala. The derivative profile generated by melting complexes containing DNA and PL-D-Ala at an L/P ratio about 0.3 had a broad transition centered at 70°C. None of the lower melting material remained which might suggest that PL-D-Ala has little or no base pair specificity. Thus both polymers caused different thermal melting behaviour at low L/P ratio. At the high L/P ratio, both polymers shifted the center of the transition in the derivative melting profile to temperatures between 75 and 85°C. Both polymers were equally effective at causing the shift in T_m. Both profiles were broadened compared to that of DNA and no significant difference between the profiles was noted.

Discussion

Formation of complexes between CT-DNA and either of the two lysine-alanine copolypeptides, i.e., either PL-L-Ala or PL-D-Ala, results in (*i*) the formation of turbidity in solution; (*ii*) the formation of a cd spectrum characteristic of ψ-state DNA; (*iii*) the formation of aggregates which can be observed, after suitable fixing and staining, in the electron microscope. The present results have shown that the observations are dependent on which of the two polypeptides is incorporated into the complex. For example, the complexation of PL-L-Ala and CT-DNA resulted in slightly more turbid solutions, more distortion to the cd spectrum of DNA at low L/P ratios and less distortion at high L/P ratios and more electron dense, more clustered aggregates than complexation of PL-D-Ala and CT-DNA. In addition, to these results, the thermal melting profiles of the complexes containing the two polypeptides were different when L/P ratios were low indicating that they complexed with DNA in different manners.

Differences in molecular weights between the two polymers might play a role in explaining the results. Although both polymers seem to be equally polydisperse and of similar molecular weight, as indicated by their thin-layer gel filtration profiles (27), they might not, in fact, have the same molecular weights and distribution of molecular weights. Dissimilar solution conformations, as observed by the cd spectra (27), could play an important role in determining the observed molecular weight profiles and thus, make the two profiles seem similar.

However, if one assumes that both polymers are equally polydisperse and have the same molecular weights the differences between the complexes could be ascribed to one of two explanations. The polypeptide conformational flexibility, that is the ability of the polymer to adopt various conformations in solution, might play a role in determining the way in which the polypeptide interacts with the DNA. It has been previously reported that the solution conformations of the two polypeptides respond differently to changes in ionic strength and pH (27). PL-L-Ala has a propensity for adopting an α-helical conformation whereas PL-D-Ala prefers to remain in what appears to be a random conformation. This behavior could be reflected in the complex. On the other hand, the polypeptides could bind to the nucleic acid by adopting the same peptide backbone conformation. The differences between the complexes would then be

the result of the switch of the L-amino acid to the D-amino acid and the resulting change in the appearance of the polypeptide surface in contact with the DNA.

Although the simplest explanations seem to be those related to either the solution behaviour of the polypeptides, i.e., conformational flexibility or to molecular weight differences, the present data do not allow a disentangling of the various factors involved in establishing the ψ-state simply because the necessary assessment of the constancy of the polypeptides' conformation in the complex cannot be made and no determination of the actual polypeptide molecular weight is available.

Direct comparison of the results with those reported previously by others also presents some difficulty because of differences in DNA preparations, differences in polypeptide molecular weights and compositions, as well as differences in methods of complex formation. For example, the polypeptide, PL-L-Ala, has been previously prepared by a slightly different route (40). Its interaction with DNA was studied via directly mixed complex formation. In general, it was shown to have A/T specificity similar to that found for poly(L-lysine) (41). Random copolymers of lysine and alanine have been studied by two groups: The one formed complexes by direct mixing of one copolymer with DNA (42, 43) whereas the other formed complexes by annealing a set of copolymers of different composition with DNA (44). In general, the results indicated that the behaviour of the polypeptide in solution influenced its complexation with DNA (44). However, direct attribution of this behaviour to the differences seen was not possible because changes in polypeptide composition accompanied the changes in solution behaviour. A similar problem arises with the interpretation of the results on the study of back-dialyzed complexes formed between DNA and the sequential polypeptides poly(L-lysyl-L-alanyl-glycine) (PL-Ala-Gly) and poly-(L-lysyl-L-alanyl-L-proline) (PL-Ala-Pro) (45). Differences in the solution behaviour of the two polypeptides were used to explain partially the differences in the resulting complexes, i.e., PL-Ala-Gly caused no changes in the DNA cd spectrum whereas PL-Ala-Pro resulted in the formation of the ψ-state DNA spectrum. As was noted, the insertion of a proline in place of the glycine could have altered the hydrophobic nature of the polymer and, thus, altered the mode of interaction. However, a recent report has confounded this interpretation since it was shown that a different preparation of PL-Ala-Gly was able to induce formation of the ψ-state in DNA (24). Either differences in the methods of polypeptide polymer preparation, which might result in more or less chain branching or, alternately, differences in polypeptide molecular weight could explain the results obtained by these two groups.

Water-soluble lysine-containing polypeptides. VI. A study of annealed complexes between calf thymus DNA and the following copolymers: poly-(L-lysyl-X), where X = Gly, L-Ala, L-Val, L-Leu, and L-Phe[1]

SANDRA L. KIELLAND, LEWIS A. SLOTIN,[2] AND ROSS E. WILLIAMS

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received May 5, 1978

SANDRA L. KIELLAND, LEWIS A. SLOTIN, and ROSS E. WILLIAMS. Can. J. Chem. **56**, 2657 (1978).

Turbidity measurements, circular dichroism spectra, electron micrographs, and thermal–optical measurements have been made on complexes between sonicated DNA and several polypeptides with the following structure: poly-(L-lysine-L-X) where X = Gly, Ala, Val, Leu, Phe. The results are influenced by any method of polypeptide synthesis which results in chain branching of the polypeptide. When polypeptides prepared by the same synthetic route are incorporated into the complexes the results also depend on the polypeptide used. Five possible explanations are offered as sources of the latter observations.

SANDRA L. KIELLAND, LEWIS A. SLOTIN et ROSS E. WILLIAMS. Can. J. Chem. **56**, 2657 (1978).

Nous avons pris des mesures de turbidité, des spectres du dichroisme circulaire, des micrographies éléctroniques ainsi que des spectres thermo-optiques de complexes entre l'ADN (traité aux ultra sons) et plusieurs polypeptides avec les structure suivantes: poly-(L-lysine-L-X) ou X = Gly, Ala, Val, Leu, Phe. Nous avons observé que les résultats sont influencés par la méthode de synthèse ainsi que le polypeptide incorporé dans les complexes. Nous avons donné cinq possibilités afin d'expliquer les résultats.

Introduction

Synthetic polypeptides, i.e. homopolymers and random or sequential copolymers, containing amino acids with positively-charged side chains have been used as models of biologically-significant basic proteins. The polypeptides have been prepared in order to simplify and investigate the effects of amino acid primary and secondary structure on protein – nucleic acid interaction (1–6).

The effect of polypeptide amino acid sequence, charged-group spacing, polymer conformation, and, to some extent, side chain size (or hydrophobicity) has been examined in a series of papers (7–9) which have dealt with the interaction between calf thymus DNA and several sequential polypeptides containing lysine. In the present paper a more extensive study of the effect of increasing the side chain size and, thus, hydrophobicity of the amino acid accompanying lysine will be undertaken. To this end a set of sequential dipeptide copolymers containing lysine and one other amino acid have been synthesized (10). The polypeptides are: poly-(L-lysylglycine)$_n$ (P-Lys-Gly), poly-(L-lysyl-L-alanine)$_n$ (P-LysAla), poly-(L-lysyl-L-valine)$_n$ (P-LysVal), poly-(L-lysyl-L-leucine)$_n$ (P-LysLeu), poly-(L-lysyl-L-phenylalanine)$_n$ (P-Lys-Phe).

The interaction between these polypeptides and a preparation of sonicated calf thymus DNA (the 40 s sonicate) has been studied by preparing complexes using an annealing system in which the components are brought together in a gradient of linearly decreasing salt concentration finally reaching the so-called physiological conditions, i.e. 0.15 *M* NaCl, pH 7. Increases in solution turbidity at 400 nm, as well as the formation of a large negative band at 275 nm in the circular dichroism spectrum have been monitored as a function of the lysine/DNA phosphate (L/P) ratio. The changes in the circular dichroism (cd) spectrum have previously been shown to be connected with the formation of an organized and aggregated state of DNA (the so-called ψ state) (11–14). In addition to the spectroscopic studies, the size and shape of complexes made visible in the electron microscope by fixing and staining have been examined. The effect of the polymers on the thermally-induced transition of DNA from its double stranded state to its single stranded state was also examined.

Studies of the interaction of poly-(L-lysine), a sample of P-LysGly prepared via a dipeptide intermediate and P-LysAla have been previously reported (7). The results of these studies are used here only to put the studies on the remaining polymers into context.

Methods and Materials

Chemicals used to prepare buffers were commercially available reagent grade and used as received. Water used was deionized and distilled from glass.

Specific experimental details have been previously published for: (*1*) the preparation, purification, sonication, and concentration assays of calf thymus DNA (15); (*2*) the preparation, characterization, and concentration assay of the poly-(L-lysine) sample (10^4 molecular weight (15)); (*3*) the preparation, characterization, and concentration assay of a P-LysGly sample prepared by dipeptide polymerization (15); (*4*) the preparation, characterization, and concentration assay of the other polymers (10); (*5*) the preparation of annealed complexes containing the polypeptide and the 40 s sonicate of calf thymus DNA (9).

Instruments used to measure and methods of expressing the results of ultraviolet spectra, solution turbidity, and circular dichroism spectra have been described previously (8, 9). Instrumentation and techniques of preparing grids for electron microscopy have been reported previously (8). Details of the thermal melting experiments and methods of expressing the results have also been reported (7).

Reductive alkylations of the lysine polymers were done using conditions previously outlined (16). The polymers (1–2 mg) were dissolved in an ice cold solution (1.0 ml) of borate buffer (0.2 *M*, pH 9.0) containing sodium borohydride (0.5 mg/ml). Aliquots (5 × 5 μl) of a concentrated solution of formaldehyde (37% v/v) were added. The solution was stirred for 30 min and evaporated to dryness. The residue was dissolved in borate–borohydride and treated with formaldehyde as before. After evaporation the residue was hydrolyzed for 24 h at 110°C in 6 *N* HCl (3 ml). The residue, after evaporation, was dissolved in citric acid buffer (0.3 *M*, pH 2.8) and an aliquot analyzed as previously described (17) on a Beckman amino acid analyzer 120C equipped with a short column (0.9 × 10 cm) (PA-35 resin). Elution was with 0.35 *N* sodium citrate buffer, pH 5.2 at 28°C and a flow rate of 50 ml/h.

Results

A. Solution Turbidity

It has previously been shown that, as the lysine – DNA phosphate (L/P) ratio increases in poly-L-Lysine/DNA complexes prepared by back dialysis to physiologically-related conditions, the turbidity of the solution increased and reached a plateau at an L/P ratio of about 0.6 (8) (Fig. 1). Complexes containing DNA and the sequential dipeptide polymers showed no tendency of forming a plateau of solution turbidity at L/P ratios less than 2 (Fig. 1). Turbidity increases were observed, as previously reported (7, 8), for P-LysGly and P-LysAla while no increases in turbidity were observed for P-LysVal, P-LysLeu, and P-LysPhe up to L/P ratios less than 3. In addition to the P-LysGly sample, prepared via a dipeptide intermediate (15), a sample of P-LysGly, prepared via a tetrapeptide intermediate (10), was used to prepare complexes. It was observed that larger L/P ratios were required to produce turbidity equivalent to that produced by the sample of P-LysGly prepared by a dipeptide polymerization. This difference in behaviour was reflected in both the cd studies and in the thermal melting profiles (see below). Dialysis of all the complexes against 10^{-3} *M* ethylenediaminetetra acetic acid (EDTA) resulted in little change in the observed results except that complexes of DNA and P-LysLeu and P-LysPhe developed turbidity under these conditions (dA^{400} approx. 0.1 at an L/P ratio = 2).

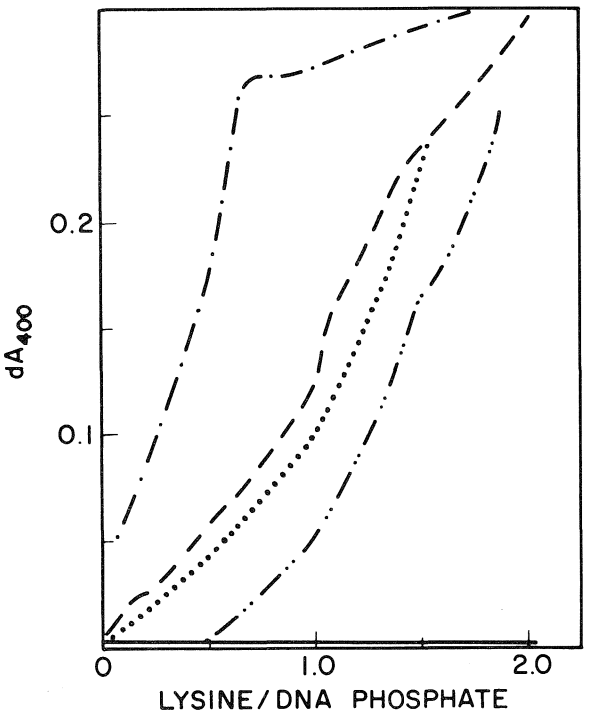

FIG. 1. Variation of solution turbidity (dA^{400}) with lysine/DNA-phosphate ratios in complexes between calf thymus DNA and the following polypeptides: poly-(L-lysine), ·-·-·; poly-(L-lysyl glycine) (via a dipeptide intermediate), ---; poly-(L-lysyl glycine) (via a tetrapeptide intermediate), ·-·-·-·-·; poly-(L-lysyl-L-alanine) · · ·; poly-(L-lysyl-L-X), where X = val, leu, phe, —. Experimental conditions: DNA phosphate concentration, 1.8 ± 0.2 × 10^{-4} *M*; sodium chloride, 0.15 *M*; sodium cacodylate 0.001 *M*, pH 7.0.

B. Circular Dichroism Spectra

Upon forming complexes of poly-L-lysine (P-Lys) and calf thymus DNA by back dialysis to physiologically related conditions the B-structure circular dichroism spectrum of DNA changes into one characteristic of the ψ-state (aggregated state) of DNA (11–14). The spectrum is characterized by the presence of an intense negative band between 260 and 280 nm. Measurement of the ellipticity at 275 nm as a function of the changing L/P ratio shows that a maximum is reached around an L/P ratio of 0.6 (Fig. 2) (8, 9). Two samples of P-LysGly were compared for their ability to produce the ψ-state in DNA. One sample was prepared via a dipeptide intermediate (15), the other via a tetrapeptide intermediate (10). Both samples produced spectra charac-

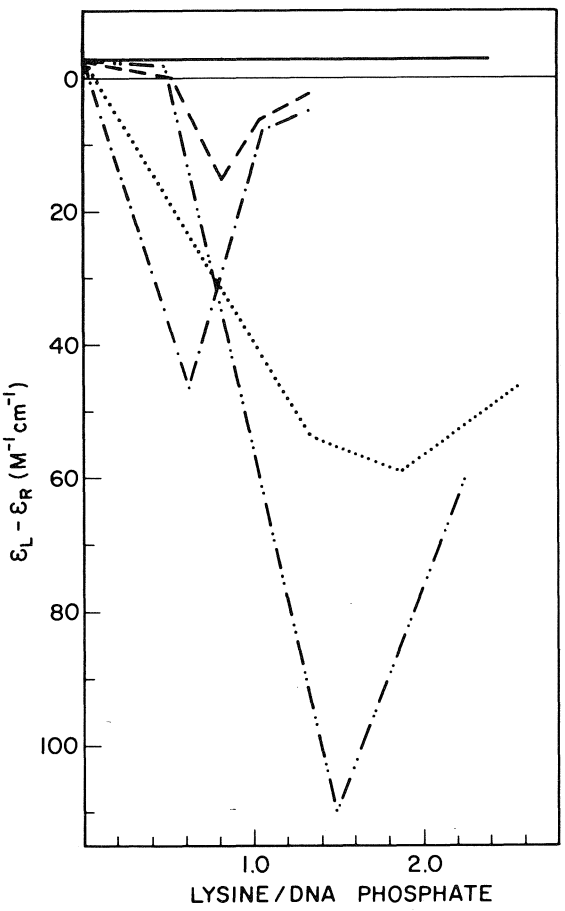

FIG. 2. Variation of the molar ellipticity ($\varepsilon_l - \varepsilon_r$) observed at 275 nm in the circular dichroism spectrum with lysine–DNA phosphate ratios in complexes between sonicated calf thymus DNA and the following polypeptides: poly-(L-lysine), ·····; poly-(L-lysyl glycine) (prepared via a dipeptide intermediate), ---; poly-(L-lysyl glycine) prepared via a tetrapeptide intermediate), ·-·-·-·-·; (poly-(L-lysyl-L-alanine), ···; poly-(L-lysyl-L-X), where X = val, leu, phe, —. Experimental conditions: as given for Fig. 1.

teristic of ψ-state DNA. The results of using the polymer prepared via the dipeptide route have been reported previously (8, 9). Maximum ellipticity was reached at an L/P ratio of about 1.0 and was considerably less than that observed with several other lysine–glycine polymers (8, 9). The polymer produced via the tetrapeptide intermediate promoted maximum ψ-state formation at an L/P ratio of about 1.2. Besides peaking at an L/P ratio of about 1.2 the ellipticity generated at the maximum was considerably greater than that developed by the other P-LysGly sample and more in line with that produced by the set of lysine–glycine polymers studied previously (8, 9). The sample differences were unrelated

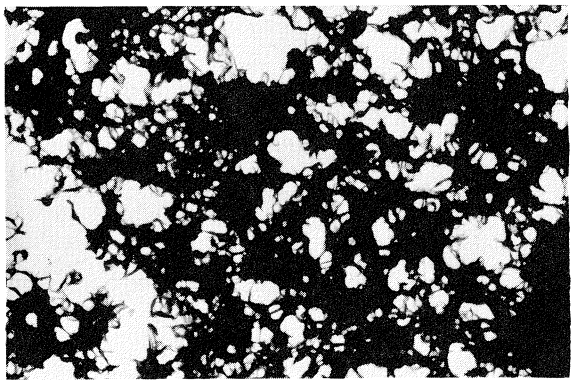

FIG. 3. Electron micrograph of formaldehyde-fixed, dehydrated, and stained complexes of sonicated calf thymus DNA and poly-(L-lysyl-L-leucine) (L/P ratio = 2.8). Complexes used for preparing the micrograph were taken from solutions which had been dialyzed against 10^{-3} *M* EDTA.

to the use of sonicated or unsonicated DNA.[3] The maximum ellipticity generated by the P-LysGly, produced by the tetrapeptide route, was much larger than that produced by complexing P-LysAla with DNA (Fig. 2). This would suggest that DNA in the P-LysGly complexes was more highly ordered. The remaining polypeptides, P-LysVal, P-LysLeu, and P-LysPhe, showed no tendency to promote ψ-state formation, since only minor changes in the cd spectrum were observed up to an L/P ratio of 2 (Fig. 2). Dialyzing the complexes into 10^{-3} *M* EDTA resulted in a loss of ellipticity at the maximum L/P ratios but still left a substantial amount of ψ-state as judged from the cd spectra of P-Lys, P-LysGly, and P-LysAla complexes. Of the remaining polypeptides only P-LysLeu and P-LysPhe exhibited a weak tendency towards ψ-state formation ($\varepsilon_l - \varepsilon_r$ (275 nm) = −10 to −15, at L/P ratios of approximately 2.5).

C. Electron Micrographs

Aggregates of uranyl acetate-stainable material are observed when complexes, which have been back dialyzed to physiological conditions, are formaldehyde fixed and examined in the electron microscope (8). The electron micrographs of complexes of P-Lys and sonicated calf thymus DNA are clustered circles about 6000 Å in diameter (8). Similar electron micrographs are obtained with complexes containing P-

[3]Comparison of the maximum ellipticity generated by the two PL–Gly samples gave the following results: dipeptide route polymer: unsonicated DNA, $\Delta\varepsilon = -3$ (L/P 1.5); sonicated DNA, $\Delta\varepsilon = -16$ (L/P 1.5). Tetrapeptide route polymer: unsonicated DNA, $\Delta\varepsilon = -17$ (L/P 1.5); sonicated DNA $\Delta\varepsilon = -130$ (L/P 1.5).

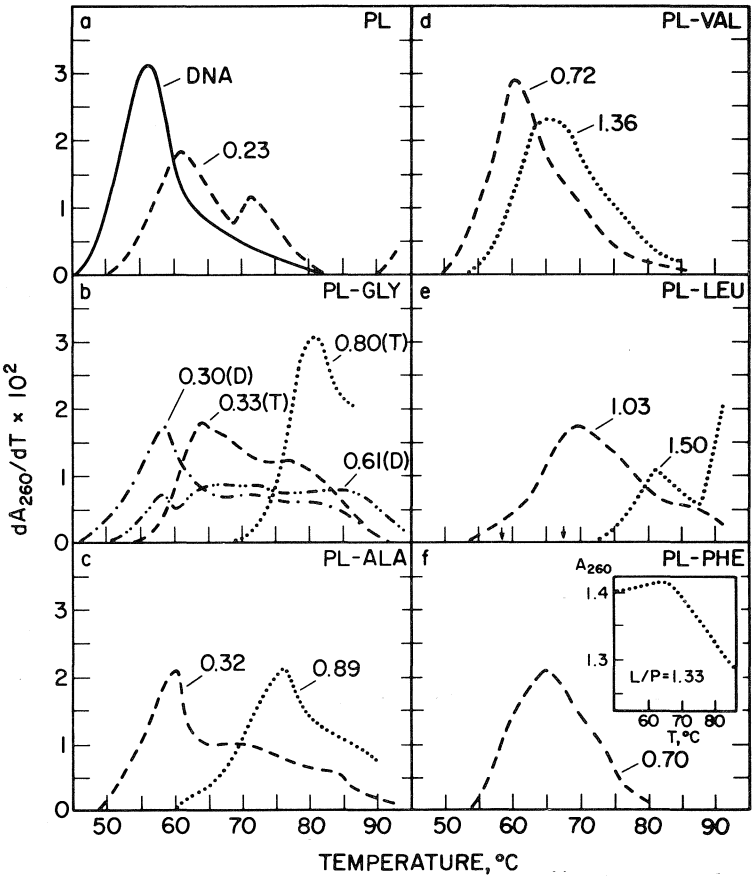

FIG. 4. Derivative absorption melting profiles (dA_{260}/dT vs. T) of purified, sonicated DNA (—) complexed with the following polypeptides (the numbers given in parentheses and on the figure are L/P ratios): (*a*) poly-(L-lysine) (0.23) ---; (*b*) poly-(L-lysyl glycine) (prepared via a dipeptide (D) intermediate) (0.30) -·-·-·-; (0.61) -·-·-·-; and poly-(L-lysyl glycine) (prepared via a tetrapeptide (T) intermediate) (0.33) ---; (0.80) · · ·; (*c*) poly-(L-lysyl-L-alanine) (0.32) ---; (0.89) · · ·; (*d*) poly-(L-lysyl-L-valine) (0.72) ---; (1.36) · · ·; (*e*) poly-(L-lysyl-L-leucine) (1.03) ---; (1.50) · · ·; (*f*) poly-(L-lysyl-L-phenylalanine) (0.70) ---; (inset) absorption (260 nm) vs. temperature (T) measurements. Experimental conditions: sodium EDTA, 10^{-3} M, pH 7.0. DNA phosphate concentrations (1.8 ± 0.2) × 10^{-4} M.

LysGly[4] and P-LysAla although there was less tendency to clustering of the circles (7, 8). No detectable aggregates were present in the electron micrographs of the complexes containing the remaining polymers even when L/P ratios were increased to between 3 and 4. Dialysis of the complexes against 10^{-3} M EDTA resulted in electron micrographs which were unchanged for complexes of P-Lys, P-LysGly, and P-LysAla. Only complexes of DNA and P-LysLeu and P-LysPhe resulted in observable aggregates. They were, in both cases, large and amorphous (for example, see Fig. 3).

[4]There were no observable differences between electron micrographs of complexes of the P-LysGly sample prepared by the tetrapeptide route and the P-LysGly sample prepared by the dipeptide route.

D. Thermal Melting Experiments

The thermal-optical transition of double-stranded DNA to single stranded DNA has been widely used as a method for investigating the interaction of cationic polypeptides with DNA. Studies have been reported on the interaction of step-wise dialyzed complexes of DNA with P-Lys and oligolysine (2, 18). In the present case, the sonicated DNA used to form complexes was dialyzed to physiological-like conditions and then to 10^{-3} M EDTA, pH 7.0. The derivative melting profile of the DNA is given in Fig. 4*a*. As may be noted there is a transition at 56 ± 2°C and it is asymmetric. The asymmetry has been attributed to the presence of G/C- and A/T-rich regions in the DNA (2, 19, 20). The low L/P ratio complex of P-Lys and the sonicated DNA

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

had the melting profile in Fig. 4*a*. The profile is biphasic. A substantial fraction of the melting material under the DNA peak has been lost and replaced by two peaks: one, melting at 61°C and the other, melting at 71°C. Complexes containing DNA and P-Lys at higher L/P ratios (i.e. >0.5) had too much light scatter to allow measurements to be made.

Complexes of DNA and P-LysGly, prepared by the dipeptide route, at low L/P ratios had the melting profile given in Fig. 4*b*. The melting profile of low L/P ratio complexes of DNA and P-LysGly, prepared by the dipeptide route, had a peak at 58°C and a broad melting zone between 65 and 85°C. At higher L/P ratios the melting profile became very broad although a peak of material melting at 58°C was still observable.

The melting profile of complexes of DNA and P-LysGly, prepared by the tetrapeptide route, was very similar to that of complexes containing DNA and P-Lys but was shifted to higher temperatures. It was a biphasic melting profile with peaks at 63°C and 77°C (L/P ratio = 0.33). At higher L/P ratios the melting profile had one broad transition at 81°C. It is obvious that the differences between the two P-LysGly preparations which were observed in the turbidity and cd of their complexes with DNA are also reflected in the thermal melting profiles.

Complexes of DNA and P-LysAla at low L/P ratios (L/P ratio = 0.33) had the melting profile given in Fig. 4*c*. The profile had peaks at 60, 70, and 83°C. The lower two peaks occurred at the same temperature as the two peaks seen in DNA/P-Lys complexes. An increase in the L/P ratio resulted in complete loss of material melting at 61°C and the formation of transitions at 77 and 85°C.

Complexes of DNA and P-LysVal at low L/P ratios (i.e. <0.5) had melting profiles which were unchanged from that of DNA (Fig. 4*d*). Only higher L/P ratios caused a shift in the melting profile to occur. At an L/P ratio of 0.7 the melting profile was shifted to higher temperatures and was unchanged in shape or intensity. Raising the L/P ratio still further caused only a small shift in the position of the profile and some broadening.

Complexes of DNA and P-LysLeu had the melting profiles shown in Fig. 4*e*. At low L/P ratios (<0.5) little change in the DNA profile was noted. At an L/P ratio of 1.0 the profile was characterized by a broad melting region centered at 70°C and a small band at 85°C. Increasing the L/P ratio resulted in some solution turbidity which affected measurements in the region between 55 and 70°C (marked by arrows). At higher temperatures a peak at 81°C appeared along with a substantial fraction of material melting at temperatures greater than 90°C.

Complexes of DNA and P-LysPhe had melting profiles shown in Fig. 4*f*. At low L/P ratios (<0.5) the melting profile of DNA was unchanged. At an L/P ratio of 0.7 the melting profile had a broad band centered at 65°C with a slight shoulder at 73°C. Increasing the L/P ratio resulted in light scatter and the thermal optical profile shown (Fig. 4*f*, inset). The observed decrease in absorption could be connected with the loss of light scatter upon melting of the complexes.

From the above results it may be concluded that: (*1*) P-Lys, P-LysGly, and P-LysAla behaved similarly since observable changes occurred in their melting profiles at L/P ratios less than 0.5 (i.e. one amino acid residue per phosphate group). The remaining polymers were effective at changing the melting profile only at L/P ratios above 0.5; (*2*) the melting profiles of P-Lys and P-LysAla were very similar since there seemed to be a small fraction of DNA melting at 60°C which remained uncomplexed; (*3*) the profiles of complexes of DNA and P-LysGly (both samples), P-LysVal, P-LysLeu, and P-LysPhe maintained their general shape and shifted up as the L/P ratio increased.

Discussion

The spectroscopic, electron microscopic (em), and thermal–optical examination of annealed complexes of DNA and the lysine-containing dipeptide copolymers have shown that the observations can be influenced by many different factors. The results can be influenced by the method of polypeptide preparation, i.e. the lysylglycine copolymer results, and the size or type of the aliphatic side chain in the dipeptide copolymers.

A. Synthesis-related Effects

Two samples of P-LysGly, prepared via different routes, were examined for their ability to produce solution turbidity, to induce a ψ-state cd spectrum, to produce observable complexes in the em and to change the melting profile of DNA. Although no differences between the two samples were seen in the e.m., differences were noted in the remaining studies. The differences remained whether sonicated or unsonicated DNA was used.[3] The differences seemed unrelated to molecular weight since the thin-layer gel filtration profiles of the two polymers were the same. In addition, side chain blocking group removal was complete in both polymers and, thus, would be an unlikely cause of the observations.

It is conceivable, however, that the two polymers

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

have different amounts of chain branching as a result of ε amino group deblocking during polymer preparation. Therefore, an attempt was made to check for chain branching in each of the polymers. In the absence of chain branching complete reductive alkylation of the ε amino groups of lysine in the polymers by formaldehyde–borohydride treatment would result in no residual lysine being observed after hydrolysis of the polymers. In the presence of chain branching the presence of blocked or masked ε amino groups of lysine at the branch points would result in a residual lysine concentration being observed even after complete reductive alkylation and hydrolysis. Using a procedure which resulted in a residual lysine concentration of 6 ± 2% (i.e. loss of 94% of the lysine) in the P-Lys sample, which had been prepared via *N*-carboxyanhydride polymerization (15), it was found that reductive alkylation and hydrolysis resulted in 3 ± 2% residual lysine in the polymer prepared via the dipeptide route and 7 ± 2% residual lysine in the polymer prepared via the tetrapeptide route (Table 1). This result seems to indicate that different amounts of chain branching are present in the polymers and could be playing an important role in determining the outcome of the experiments.

Residual lysine concentrations in the remaining polymers were also determined (Table 1). As can be seen the remaining polymers had amounts of residual lysine ranging from 10 to 21%. Factors, other than the amount of chain branching are likely to be the cause of not only the amount of the residual lysine but also the variation amongst the polymers. This is best illustrated by the results obtained with P-Lys-L-Ala (Table 1) and P-Lys-D-Ala (results given in parentheses, Table 1). P-Lys-L-Ala had 11% residual lysine whereas P-Lys-D-Ala had 6% residual lysine. Since both polymers had been prepared by the same route, factors other than the method of synthesis are the likely source of the difference. The conformations of the two polymers are likely to be different at the pH used for the treatment since it was found these polymers respond differently to changes in pH (10). The P-Lys-L-Ala polymer would be expected to have a substantial fraction of α-helical structure in it at pH 9. This might block Schiff base formation, inhibit side-chain reduction by the borohydride or promote aggregation of the polypeptide in solution. The results obtained with the other polymers having the larger aliphatic side chains could be the result of a combination of one or more of these factors.

TABLE 1. Residual lysine concentrations observed after reductive alkylation and hydrolysis of the lysine

Sample	Lysine remaining (%) after treatment and hydrolysis[a] (errors given are standard deviations)
P-Lys	6±2
P-LysGly[b]	3±2
P-LysGly[c]	7±2
P-LysAla[c]	11±3 (6±2)[d]
P-LysVal[c]	21±5
P-LysLeu[c]	12±4
P-LysPhe[c]	10±3

[a]Residual lysine concentrations were determined on three samples by formaldehyde–borohydride reductive alkylation, subsequent hydrolysis in 6 *N* HCl and analysis as described in the experimental section. Lysine remaining (%) is defined as $L_r/L_t \times 100$, where L_r is the number of moles of lysine found after treatment and hydrolysis and L_t is total number of moles of lysine in the untreated and hydrolyzed sample.
[b]Prepared via a dipeptide intermediate (15).
[c]Prepared via a tetrapeptide intermediate (10).
[d]P-Lys-D-Ala sample prepared via a tetrapeptide intermediate (10).

It thus appears that an exact measurement of residual lysine content, and, thereby, chain branching, is only possible if the polymer can adopt a truly random conformation in solution and is known to be in an unaggregated state.

B. Side-chain-related Effects

The sequential lysine-containing dipeptide polymers studied here may be divided into two groups: those that promote DNA ψ-state formation (cd experiments) and cause changes in the DNA thermal melting profile at low L/P ratios (<0.5) and those that do not. P-Lys, P-LysGly, and P-LysAla are grouped in the first category whereas P-LysVal, P-LysLeu, and P-LysPhe are grouped in the second.

Several simplistic correlations may be drawn between these two categories and the properties of the polypeptides. It can be suggested that the division is related to:

(*1*) The aggregation of the polypeptides with large, hydrophobic side chains, either in solution before complex formation or on the surface of the DNA after complex formation. The net result of polypeptide aggregation would be an inability to promote the aggregation of the DNA. Aggregation of the polypeptides in solution before complex formation was checked previously. Although thin-layer gel filtration (TLGF) experiments at different salt concentrations suggested that aggregation of P-LysVal, P-LysLeu, and P-LysPhe did not seem to be occurring (10) the reductive alkylation results might suggest otherwise (Table 1).

(*2*) The difference in molecular weights of the various polymer preparations. It would have to be suggested that the lower molecular weight polymers (as assessed by TLGF), i.e. P-LysVal, P-LysLeu, and P-LysPhe, interact with DNA but are of insufficient size to promote ψ-state formation or cause changes in the thermal melting profiles. Indeed, it was observed that the lower molecular weight polymers,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

while they do interact with DNA and promote changes in the thermal melting profiles at higher L/P ratios, caused a shift in the thermal melting profiles similar to that observed with small molecular weight oligolysines, and protamine (18).

(*3*) The size of the aliphatic side chain of the amino acid being varied. It could be suggested that the larger side chain amino acids are prevented from associating with the DNA so as to promote ψ-state formation and changes in the thermal melting profiles. This proposal would require that side chains smaller than valine would be able to effectively promote ψ-state formation and cause changes in the thermal melting profile of DNA. If this factor were the sole determinant then it might be suggested that regions in cationic proteins devoid of large side chain amino acids could readily induce DNA packing much in the same way as that in ψ-state DNA. An example of such a region in a cationic protein is the N-terminal sequence of histone H-4 (21).

(*4*) The different conformational states that can be adopted by each of the polypeptides in solution. Each polypeptide has been found to adopt different conformations depending on the state of charge on the lysine side chain (10). The results are summarized in Table 2. It would appear that no correlation exists between polypeptide conformation and the ability to promote ψ-state formation or, at low L/P ratios, induce changes in the thermal melting profile of DNA when the lysine side chain is charged. When the lysine side chain is uncharged, however, the polypeptides may be grouped into two categories: those that form β-like structures and those that do not. The polypeptides which form β-like structures, i.e. P-LysVal, P-LysLeu, and P-LysPhe, are also those which are unable to promote ψ-state formation and induce changes in the thermal melting profile of DNA at low L/P ratios. It might also be noted that, within the remaining group, P-Lys and P-LysAla cause very similar biphasic changes in the thermal melting profile of DNA and that they both adopt an α-helical conformation when uncharged. From the data gathered in these experiments and the difficulty in separating the DNA cd spectrum from the polypeptide cd spectrum in the complexes it is not possible to tell what conformation the polypeptides adopt in the complex. Thus, it is also not possible to determine if such a correlation is reflected in the polypeptide–DNA complex where it might be expected that the lysine side chains would be neutralized by the DNA phosphate groups.

(*5*) The above noted effects of different amounts of polypeptide chain branching. The results obtained upon reductive alkylation of the P-LysGly sample and the P-Lys-D-Ala sample suggest that the majority of the polypeptides prepared via a tetrapeptide intermediate will have approximately the same amount of chain branching (Table 1) and, thus it would seem that chain branching effects would not contribute appreciably to differences observed among the polypeptides. Our inability to accurately measure the amount of chain branching in all polypeptides, however, leaves this possibility still open.

TABLE 2. Solution conformations adopted by the various dipeptide polymers

Polymer	Solution conformation adopted[a] when side-chain state[b] = Charged[c]	Neutral[d]
P-Lys	Random[e]	α-Helix
P-LysGly	Random	Random
P-LysAla	Random	α-Helix
P-LysVal	Random	β
P-LysLeu	Random	β[f]
P-LysPhe	Random	β

[a]Assignments based on polypeptide cd spectrum under different experimental conditions (10).
[b]Refers to lysine ε amino group.
[c]Data obtained at pH 7, 0.14 *M* NaF.
[d]Data obtained at pH 12, 0.14 *M* NaF.
[e]Also called disordered or extended (22–24), or a 3, helix (25).
[f]Assignment has recently been corroborated (26).

The present studies have implied that one or more of the several factors mentioned above may be important in determining how polypeptides and proteins interact with DNA. Other workers, dealing with back-dialyzed complexes between DNA and both random and sequential (tripeptide) lysine-containing copolymers, have usually used one or two of them in attempts to explain their results (27–33). It is now evident that before the full and separate importance of each of the critical factors involved can be ascertained in a quantitative sense a very much more strict control of the experimental variables will be necessary. Indeed, the control must be much more strict than has, at present, been achieved either in the present set of experiments or those reported elsewhere.

Sterically hindered aromatic compounds. VIII. Comparative photochemistry of 2,4,6-tri-*tert*-butyl- and 2,5-di-*tert*-butylnitrosobenzenes

L. Ross C. Barclay, Derek Leigh Carson, Jean A. Gray, Michael Grossman, Prabhaker G. Khazanie, John R. Milton, and Christopher E. Scott

Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received February 2, 1978

L. Ross C. Barclay, Derek Leigh Carson, Jean A. Gray, Michael Grossman, Prabhaker G. Khazanie, John R. Milton, and Christopher E. Scott. Can. J. Chem. **56**, 2665 (1978).

Ultraviolet irradiation of hydrocarbon solutions of 2,4,6-tri-*tert*-butylnitrosobenzene (**1**) formed Ar—N̈—OH. The initial products were 2-methyl-1-nitroso-2-(3,5-di-*tert*-butyl)-phenylpropane (Ar—$C(CH_3)_2CH_2NO)_2$ (**3**) and a mixed dimer (**4**). Secondary and minor photoproducts isolated included 2-methyl-2-(3,5-di-*tert*-butyl)phenylpropanal oxime (**5**), 2-methyl-2-(3,5-di-*tert*-butyl)phenylpropanal (**6**) derived from **5**, and 1,3,5-tri-*tert*-butylbenzene (**7**). The initial products are explained by formation of a tri-*tert*-butylphenyl radical (**15**), rearrangement of a hydrogen atom from an *ortho tert*-butyl to the ring in **15**, and rapid recombination of the neophyl radical with nitric oxide. Photolysis of 2,5-di-*tert*-butylnitrosobenzene (**2**) initially gave Ar_2N—Ȯ (**10**). Product analysis indicated a comparatively complex mixture including 1,4-di-*tert*-butylbenzene (**11**), 2,5-di-*tert*-butylphenol (**12**), and 2,5-di-*tert*-butylanilino-*p*-(2,5-di-*tert*-butyl)quinone (**13**). Evidence indicates that **12** and **13** form from free radical reactions involving **10** and the 2,5-di-*tert*-butylphenyl radical. The different photochemistry of **1** and **2** is discussed in terms of differential steric and conformational effects on the nitroso function which also is evident in their ultraviolet spectra.

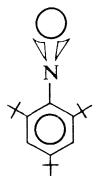
L. Ross C. Barclay, Derek Leigh Carson, Jean A. Gray, Michael Grossman, Prabhaker G. Khazanie, John R. Milton et Christopher E. Scott. Can. J. Chem. **56**, 2665 (1978).

L'irradiation ultraviolette de solutions dans les hydrocarbures du tri-*tert*-butyl-2,4,6 nitrosobenzène (**1**) conduit à la formation de Ar-N̈-OH. Les produits initiaux sont le méthyl-2-nitroso-1 (di-*tert*-butyl-3,5)-2-phénylpropane (Ar—$C(CH_3)_2CH_2NO)_2$ (**3**) et un dimère mixte (**4**). Les photoproduits secondaires et mineurs isolés comprennent l'oxime du méthyl-2 (di-*tert*-butyl-3,5)-2-phénylpropanal (**5**), le méthyl-2 (di-*tert*-butyl-3,5)-2 phénylpropanal (**6**) provenant de **5** et le tri-*tert*-butyl-1,3,5 benzène (**7**). On explique la formation des produits initiaux par la formation d'un radical tri-*tert*-butylphényle (**15**), qui subit une transposition d'un atome d'hydrogène d'un groupe *tert*-butyle *ortho* vers le cycle dans **15** et une recombinaison rapide du radical néophyle avec l'oxyde nitrique. La photolyse du di-*tert*-butyl-2,5 nitrosobenzène (**2**) conduit initialement à Ar_2N—Ȯ (**10**). L'analyse des produits indique la présence d'un mélange relativement complexe comprenant du di-*tert*-butyl-1,4 benzène (**11**), du di-*tert*-butyl-2,5 phénol (**12**) et de la di-*tert*-butylanilino-2,5 *p*-(di-*tert*-butyl-2,5)quinone (**13**). Les données indiquent que **12** et **13** sont formés à partir de réactions radicalaires impliquant **10** et le radical di-*tert*-butyl-2,5 phényle. On discute de la photochimie différence de **1** et de **2** en termes d'effets stériques différentiels et conformationnels sur la fonction nitroso qui est aussi évidentes dans le spectre ultraviolet.

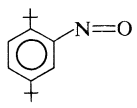
[Traduit par le journal]

Introduction

The photochemistry of aryl nitroso compounds has not been studied as extensively as that of aliphatic *C*-nitroso compounds (ref. 1 and references therein and ref. 2), nitrosamines (3, 4) or aryl nitro compounds (5). Nitroso compounds usually exist as an equilibrium mixture of monomer and dimer forms in solution so that a complex mixture of products can result: for example, from the photolysis of nitrosobenzene (6). The hindered aryl nitroso compounds 2,4,6-tri-*tert*-butylnitrosobenzene (**1**) and 2,5-di-*tert*-butylnitrosobenzene (**2**) are known to exist as monomers in solution and in the preferred out-of-plane and coplanar *anti* conformations shown (7) below.



1



2

These compounds are selected as model monomeric aryl nitroso compounds for exploratory photochemical studies. The reported photostability of **1** (8) is surprising in view of the known reactivity of other monomeric nitroso compounds (9).

*The Photolysis of 2,4,6-Tri-*tert*-butylnitrosobenzene (1)*

Irradiation of **1** (through quartz in cyclopropane

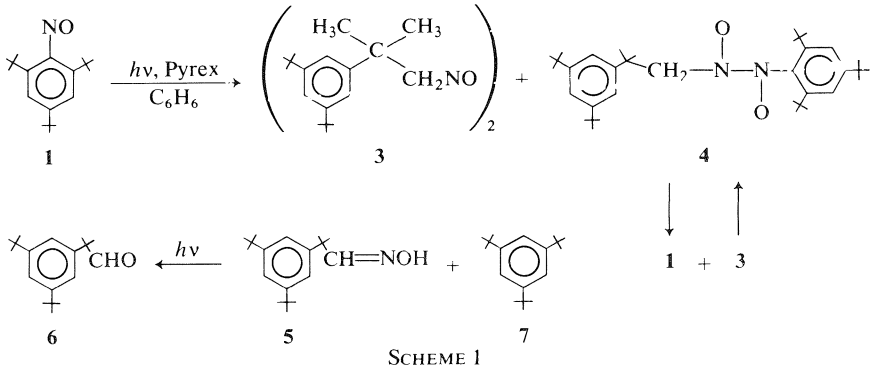

SCHEME 1

in an esr spectrometer and in benzene or cyclohexane through Pyrex) gave persistent esr signals consisting of a sextet of 1:2:1 triplets assigned to Ar—$\dot{N}$—OH, where $a^N \simeq 15$, $a_{OH}^H \simeq 40$, and $a^H_{meta\ H's} \simeq 1$ G. This contrasts with the reported photostability of **1** and lack of esr signals on irradiation (8).

Larger scale photolyses for product analysis by preparative tlc resulted in the products as outlined in Scheme 1.[1] The number and yield of the various photoproducts depended on the photolysis time as summarized in Table 1. Our preliminary studies (10) incorrectly assigned a structure [Ar—$CH_2C(CH_3)_2$-$NO]_2$ for one of the primary products **3** based solely on spectroscopic evidence. The correct structure for **3** is now based on the ready conversion of **3** → **5** → **8** and the synthesis of **8** by mild Friedel–Crafts *tert*-butylation of the known **9** (Scheme 2).

Depending on the percentage conversion, the major photoproduct was the mixed dimer (**4**, lower conversion) or the nitroso dimer **3**. When samples of **1** were photolyzed for different times ($1\frac{1}{2}$–$6\frac{1}{4}$ h), it was found that the mixed dimer **4** could be isolated in 70% yield by shorter photolysis times and then the percentage of **4** decreased with a concomitant increase in **3**. The mixed dimer **4** presumably forms by reaction of **1** with the monomer of **3**. We also observed the formation of **4** in a dark reaction by combining **1** and dimer **3** and observing the interconversion by direct nmr methods. Equal weights of **1** and **3** in benzene initially showed only the nmr peaks for **1** (δ 1.25, *tert*-butyls) and **3** (δ 1.33, s, 18H, *tert*-butyls; δ 1.48, s, 6H, $C(CH_3)_2$; and δ 4.58, s, 2H, methylene). On standing, the peaks for **1** and **3** decreased and new peaks appeared in the methylene region at δ 4.64 and a new $C(CH_3)_2$ signal at δ 1.55 assigned to the mixed dimer **4**. After 24 h, the ratio of **4** to **3** was estimated (nmr) to be 5:1. The ratios

[a]Yields were determined by preparative tlc.
[b]Photolysis time 2 h. Initial concentration of **1** 3.45×10^{-3} mol L^{-1}. Benzene elution separated the products into four bands which contained the compounds eluted in the order of elution: **1**, **4**, **3**, **5**.
[c]Photolysis time 7 h. Initial concentration of **1** 3.23×10^{-3} mol L^{-1}. Thin-layer chromatographic separation gave six bands as follows: band 1, mixture of **1** and **7** separated by tlc using cyclohexane; band 2, **4**; band 3, **3**; band 4, mixture of **5** and **6** separated by tlc using benzene and ethyl ether (10%); band 5, **5**; band 6, a mixture of **5** and **6** separated by tlc using benzene.

of **3** to **4** observed in the photolysis runs are probably functions of the concentration of **1** remaining as well as the relative stability of **3** and **4**. The mixed dimer **4** dissociated partially into **1** and **3** on attempted isolation and therefore could not be fully characterized. After additional photolysis time, both **3** and **4** were converted to secondary products. A separate experiment on the photolysis of **3** for 3 h (50% conversion) confirmed that it does photodegrade under these conditions. Thin-layer chromatographic analy-

TABLE 2. Products from photolysis of 2,5-di-*tert*-butylnitrosobenzene (**2**)[a]

Photolysis time (h)	% conversion of **2**	% yield of products		
		p-Di-*tert*-butylbenzene (**11**)	2,5-Di-*tert*-butylphenol (**12**)	Anil quinone (**13**)
8	[b]	7	12	13
9¾	43[c]	Not measured	20	9
13	47[d]	6	14	7

[a]The mixture was separated by preparative tlc, using benzene–cyclohexane (70:30), as follows: band 1, a mixture of **11** and an unidentified radical (30 lines, scan range ± 25 g at 3237 g) separated by tlc; band 2, **2**; band 3, a trace of radical **10** mixed with **2**; band 4, **13**; band 5, **12** (compared with an authentic sample); bands 6–9 traces, unidentified; band 10, (the application zone), a dark resin, approximately ¼ of the product.
[b]Recovered **2** not measured. Initial concentration of **2** = 3.84×10^{-3} mL^{-1}.
[c]Initial concentration of **2** = 3.63×10^{-3} mL^{-1}.
[d]Initial concentration of **2** = 7.16×10^{-3} mL^{-1}.

sis indicated a complex mixture of at least six products. The only compound identified was the oxime (**5**, 13%). Photolysis of **5** in turn showed that it was converted to the aldehyde **6** (63% in 2½ h).

*The Photolysis of 2,5-Di-*tert*-butylnitrosobenzene (2)*

Electron spin resonance examination of the solutions (benzene, cyclohexane, or pentane) from photolysis of **2**, after short irradiation times (5 min), showed the presence of a persistent radical which exhibited a triplet (1:1:1) of multiplets assigned to the Ar_2N—$\dot{O}$ radical (**10**) ($a_N = 11.5$, $a_H \simeq 0.5-1$ G, where Ar = 2,5-di-*tert*-butylphenyl). On longer photolysis times, this spectrum was replaced by a more complex set of persistent signals indicative of a mixture of radicals.

Photolysis of **2** for product analysis showed marked differences from that of **1**. During irradiation of **2**, the benzene solutions became red-orange in colour and a comparatively long photolysis time (13 h) was needed to achieve comparable conversions of **2** (40–50%, compare Table 1 and Table 2) since the red product (**13**) acted as an internal filter. The photo mixture from **2** also was much more complicated. At least 10 separate tlc bands were obtained and it was difficult to obtain a material balance since up to one third of the product was a resinous material that did not develop on the tlc. Nevertheless it was possible to characterize the major products of preparative tlc separation (see Scheme 3 and Table 2). The red product was identified as 2,5-di-*tert*-butylanilino-*p*-(2,5-di-*tert*-butyl)quinone (**13**) by its analysis, spectroscopic properties, and synthesis by condensation of 2,5-di-*tert*-butylaniline with 2,5-di-*tert*-butyl-*p*-quinone. There was some indication that the anil quinone (**13**) undergoes photodegradation since its yield decreased on longer photolysis times (Table 2). When some plates containing the separated mixture were allowed to stand exposed to light at least a day, bands 1 and 3 changed to the red colour of **13** (initially found in band 4). These bands were rechromatographed and they did in fact yield some of **13**. This observation indicates that photolabile intermediates are present and these lead to **13** by secondary reactions.

SCHEME 3

Discussion

*The Photorearrangement of 2,4,6-Tri-*tert*-butylnitrosobenzene (1)*

Ayscough *et al.* (11) decided from esr studies and the lack of photosensitization that nitrosobenzene undergoes photodissociation to phenyl radicals and nitric oxide via an excited singlet state. On the other hand Pak and Testa (12) found that nitrosobenzene undergoes photoreduction in 2-propanol to phenylhydroxylamine consistent with reaction through an n,π* triplet. Our observation of the benzophenone acceleration of the photolysis of **1** does not clarify the nature of the reactive state involved because the reaction products were not the same as in the direct photolysis.[1]

The markedly different photochemical behaviour of the structurally similar nitroso compounds **1** and **2** can be accounted for in terms of differential steric and conformational effects. These effects are evident in the electronic absorption spectra of **1** and **2** (Fig. 1) which may give some clue into this different behaviour. Both compounds show the typical visible absorption at 750–800 nm responsible for the green colour and assigned to the $n_N \rightarrow \pi^*$ transition. This

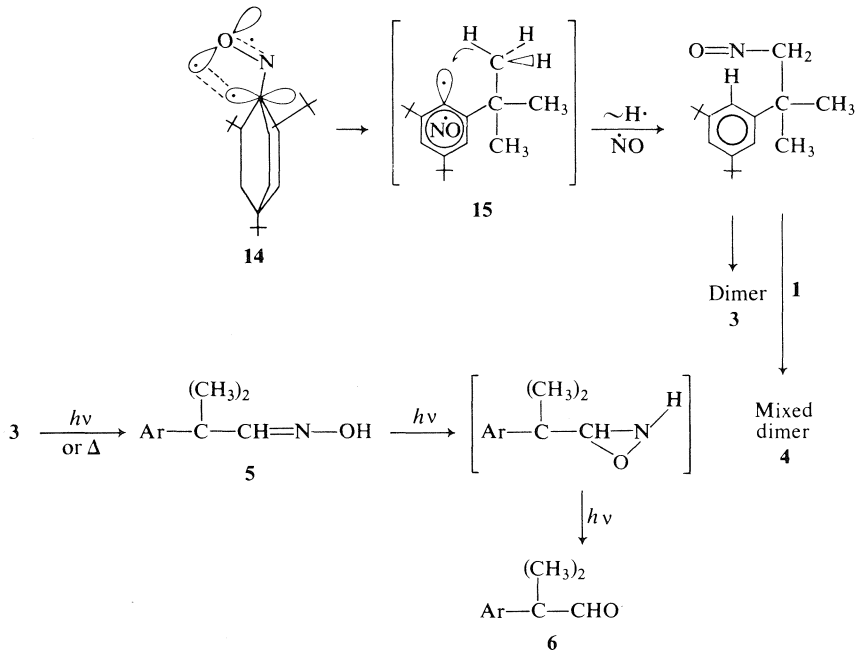

SCHEME 4

band for the more hindered compound **1** is shifted only slightly to shorter wavelength and is more intense. The spectra of **1** and **2** are quite different in the ultraviolet. The coplanar compound **2** shows absorption (λ_{max} 296, ε = 8234 and λ_{max} 317, ε = 5150) very similar to that shown for nitrosobenzene (11). In contrast the usually strong band at 290–300 nm is replaced in **1** by a shoulder with greatly diminished intensity, presumably owing to suppression

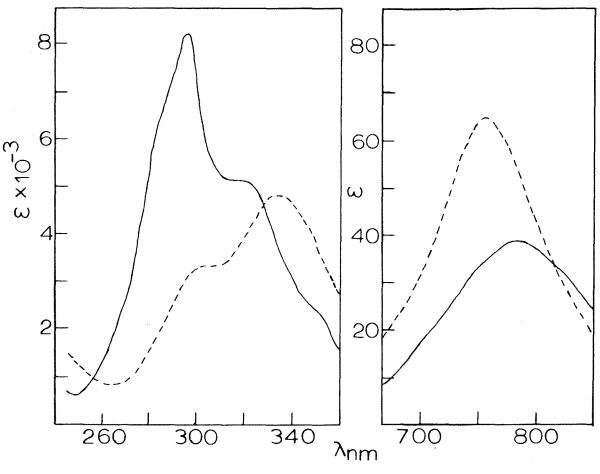

FIG. 1. Ultraviolet–visible spectra in cyclohexane: — 2,5-di-*tert*-butylnitrosobenzene; - - - 2,4,6-tri-*tert*-butylnitrosobenzene.

of the usual $\pi \rightarrow \pi^*$ transition by steric inhibition of coplanarity. On the other hand a new broad band appears in **1** at 320–350 nm (λ_{max} 334, ε = 4800) which would overlap the region for the usually weak band for the $n_O \rightarrow \pi^*$ transition of the nitroso group (13). This absorption is tentatively assigned to an enhanced $n_O \rightarrow \pi^*$ for **1** superimposed on the weakened $\pi \rightarrow \pi^*$ absorption. When the nitroso group is effectively twisted out of plane of the benzene ring by two *ortho tert*-butyls, the unpaired electron in an oxygen 2*p* orbital of the excited state can undergo partial overlap with the aromatic *p*-orbitals (Scheme 4, **14**) with a resulting enhancement of the $n_O \rightarrow \pi^*$ absorption. A similar explanation has been used to account for some enhancement in the $n \rightarrow \pi^*$ absorption of the aryl nitro group by an *o-tert*-butyl group (14) and the steric acceleration of the photorearrangement of aryl nitro to a nitrite (15).

The steric hindrance to coplanarity in **1** is expected to promote the cleavage of the aryl carbon to nitrogen bond in the excited state leading to the aryl radical or radical pair (**15**). We have independently observed that this tri-*tert*-butyl phenyl radical readily abstracts a hydrogen atom from a C—H bond of an *o-tert*-butyl group (16) followed by a neophyl rearrangement. In the present case, the neophyl radical is trapped by rapid recombination with nitric oxide to account for the product of migration of the NO function without rearrangement in the side

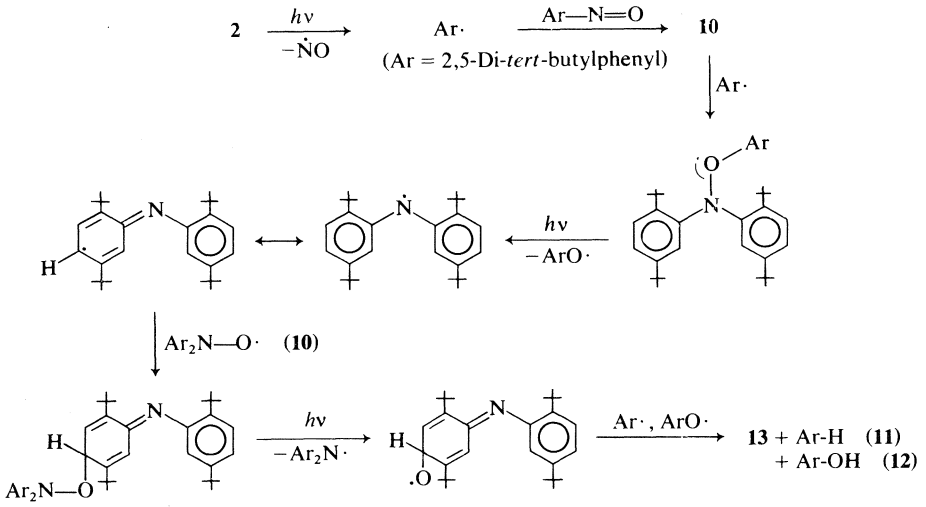
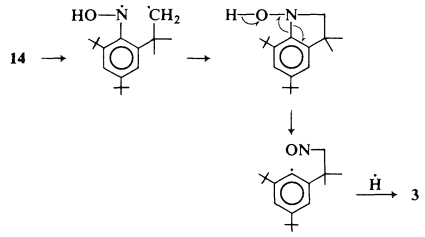


SCHEME 5

chain.[2] The photorearrangement of the aryl nitroso function predominates over other possible reactions. Thus hydrogen abstraction from solvent to form tri-*tert*-butylbenzene (**7**) is a very minor competing reaction. Although **1** is usually an effective spin trapping reagent (8), it fails to trap the reactive aryl radical (**15**) most probably owing to the combined steric effects of *o*-*tert*-butyl groups in **1** and **15**. This steric effect causes a major difference in the photochemistry of **1** vs. **2**. Furthermore the recombination of the neophyl radical with ·NO prevents spin trapping of the rearranged radical. Known secondary reactions account for such minor products as the oxime **3** (9) and the aldehyde **6** (17).

Aromatic nitroso compounds are reported to be stable to irradiation with red light (18) while aliphatic nitroso compounds are reactive. In view of the inhibition of coplanarity and photochemical reactivity of **1**, it was of interest to determine if **1** displays any photochemical reactivity by irradiation with visible light. Compound **1** proved to be stable to prolonged irradiation from a filtered sodium vapor lamp.

[2]The following alternative mechanism for photorearrangement of **1** is consistent with our observation of the Ar—N̈—OH radical



*The Photochemistry of 2,5-Di-*tert*-butylnitrosobenzene (2)*

Although the photolysis of **2** yielded a complex mixture only partially identifiable, the results serve to establish the contrast in photochemical behaviour of **1** and **2**. The formation of the diaryl nitroxide radical (**10**) as the initial detectable product from **2** indicates that it initially follows the usual photochemistry of aryl nitroso compounds (18) (Scheme 5). The formation of such products as a phenol (**12**) and an anil quinone (**13**) does not have precedence in the photochemistry of aryl nitroso compounds although phenol is a known pyrolysis product of nitrosobenzene (19). A possible pathway for the formation of **12** and **13** is outlined in Scheme 5. This involves the combination of **10** with the aryl radical followed by appropriate radical disproportionation reactions leading eventually to **11**, **12**, and **13**. There is some experimental evidence to support this pathway. The 2,5-di-*tert*-butylphenyl radical[3] was generated independently by reaction of 2,5-di-*tert*-butylbromobenzene with trimethyltin radicals (16) and trapped with **2** to form **10**. Then **10** was combined again with more 2,5-di-*tert*-butylphenyl radical followed by thin-layer chromatographic analysis. The formation of the anil quinone (**13**) was qualitatively observed on the tlc plate. This observation does not completely rule out other conceivable modes of formation of **13**. For example the nitroxide radical (**10**) might undergo disproportionation re-

[3]Although this radical cannot be detected directly by esr, there is indirect evidence that it does form by abstraction of the halogen atom by trimethyltin (16).

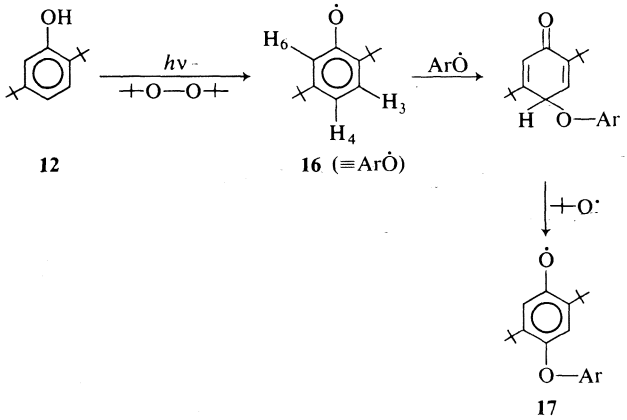
actions (20) leading to **13**. Furthermore sterically hindered phenoxyl radicals are reported to be spin trapped by aryl nitroso compounds at the aryl carbon para to the phenoxyl oxygen thereby forming quinoid systems (21). By analogy spin trapping at the *para* position of 2,5-di-*tert*-butylphenoxyl by **2** (or possibly a reactive state of **2**) could lead to a quinoid system which by a series of dark reactions could form **13**. However, we failed to detect the formation of **13** by the reaction of **2** with 2,5-di-*tert*-butylphenol (**12**) under conditions which generate the 2,5-di-*tert*-butylphenoxyl radical. The properties of the latter are not previously reported. It was generated[4] for characterization by photolysis in the presence of di-*tert*-butylperoxide and found to give an eight-line esr spectrum (two quartets $a^{H_3} = 2.1$, $a^{H_4} = 8.1$, and $a^{H_6} = 6.1$ G; $g = 2.0052$). These signals were rapidly obscured at room temperature by those of a longer lived radical which appeared as two doublets ($a^{H_3} = 1.3$, $a^{H_6} = 5.71$ G; $g = 2.00506$). This result indicates that initially generated **16** rapidly undergoes dimerization (22) as outlined in Scheme 6 to yield a longer lived phenoxyl radical, probably **17**. This reaction may be faster than the trapping of **16** by **2**.



12 **16** (≡ArȮ) **17**

SCHEME 6

Experimental

Details on spectroscopic methods, tlc procedures, and the synthesis of nitroso compounds **1** and **2** were reported earlier (23).

Photolyses Procedures

The initial irradiation and esr studies were carried out by irradiation of a cyclopropane solution of 2,4,6-tri-*tert*-butylnitrosobenzene (**1**) with a 200 W super pressure mercury arc lamp in the cavity of a Varian E-4 Spectrometer.[4] Since the radicals being observed were relatively long lived (e.g., from **1**—Ar—N̈—OH, from **2**—Ar_2—N—O·), they were also observed in samples removed from preparative runs.

[4]This experiment was carried out in the laboratory of Dr. K. U. Ingold, National Research Council of Canada, Ottawa, Ont.

Preparative scale photolyses were generally carried out by irradiation of a benzene solution at 20°C with a 450 W Hanovia high pressure mercury vapor lamp (679A-36) in a Pyrex immersion well reactor. Large scale (2–3 g) photolyses of 2,5-di-*tert*-butylnitrosobenzene (**2**) in a 2-L preparative reactor with a 1000 W mercury vapor lamp (Photochemical Research Associates model R1000) gave similar results as the above lamp. The solvents used (spectral grade benzene or spectral grade cyclohexane) were distilled before use. The solutions were purged with oxygen free nitrogen for at least one hour before irradiation and a slow stream of nitrogen was passed through during photolysis. Photolysis runs to study the effect of irradiation times on product distribution were carried out in Pyrex tubes attached to the immersion well of the 450 W lamp. The effect of added benzophenone was also carried out in this way and the rate of disappearance of the nitroso compound (**1**) in the presence of benzophenone compared with the direct photolysis. A 20-fold molar excess of benzophenone caused a 10-fold increase in the rate of disappearance of **1**. In all runs the progress of the photolysis was conveniently followed by measuring the decrease in the visible absorbance readings at 750 nm for **1** and 790 nm for **2** using a B & L Spectronic 700.

Irradiations with visible light were carried out with a GE Lucalox 400 W high pressure sodium vapor lamp and a potassium dichromate filter (24).

Product Analysis

The solvent was removed from the photolysis mixtures on a rotary evaporator at 25°C. The products were then separated as soon as possible on preparative tlc plates.

*Photolysis Products from 2,4,6-Tri-*tert*-butylnitrosobenzene (1)*

Details on the separation and yields of the various compounds are given in Table 1. Compounds isolated by tlc were further purified for analysis by sublimation under reduced pressure. Data on the products from nitroso compound **1** are given below. Spectroscopic data on compounds **3** and **5** were given earlier (9).

*The photonitroso compound 2-methyl-1-nitroso-2-(3,5-Di-*tert*-butyl)phenylpropane (3). Conversion into oxime 5 and nitrile 8*—The pure compound **3** melted at 146°C. *Anal.* calcd. for $C_{18}H_{29}NO$: C78.49, H10.61, N5.09; found: C78.27, H10.92, N5.33. A sample of 50 mg of **3** dissolved in 15 ml of ethanol containing 10 drops of water was refluxed for 3½ h. Evaporation of the solvent on the rotavac left a colourless solid, mp 94–96°C, identified by its nmr spectrum (10) as the oxime (**5**). A sample of **3** (334 mg) was heated in an atmosphere of nitrogen for 20 min at 145–170°C. At 145–148°C the melted **3** quickly turned green, which colour faded by 151°C (7 min.). On cooling a near colourless solid formed, mp 90–94°C (323 mg, 97%) which proved to be **5**. An attempt at glc analysis of **3** showed that it decomposed during analysis. For example at 155–225°C on a 20% Carbowax column (10 ft × ¼ in.) and 60 cm³/min He it was converted (80%) into the nitrile (**8**) identified by its melting point and ir spectrum on comparison with synthetic **8**.

The mixed dimer (4)—Band 2 from the tlc separation of the photolysis of **1** containing the mixed dimer **4** was initially colourless but slowly turned green and after several hours was deep green. This band was then removed (69 mg) and the tlc repeated and it was found to separate into **1** (19 mg), **4** (32 mg), and **3** (16 mg). This ready dissociation of **4** into a mixture of **1** and **3** precluded its detailed characterization. However its formation from **1** and **3** in a dark reaction could readily be observed by direct nmr observations (e.g., see Results).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The oxime 2-methyl-2-(3,5-di-tert-*butyl)phenylpropanal oxime (**5**). Conversion into nitrile (**8**) and aldehyde (**6**)*—The purified oxime had a mp 95–96°C. *Anal.* calcd. for $C_{18}H_{29}NO$: C78.49, H10.61, N5.09; found: C78.64, 78.70; H10.48, 10.53; N5.21. The oxime (51 mg) in ethanol (5 ml) containing $\frac{1}{2}$ ml concentrated hydrochloric acid was refluxed overnight. The product was precipitated by adding ice water and extracted with ether to give 40 mg of solid. The ir and nmr spectra indicated that this product was a mixture of the nitrile **8** (mainly) and the aldehyde (**6**). Gas–liquid chromatographic analysis (20% Carbowax, 150–200°C, and 60 cm^3/min He) indicated a mixture of 64% **8** and 36% **6**. The glc peaks were collected and subjected to mass spectroscopic analysis for further identification. Parent masses were obtained at *m/e* 257 for **8** and *m/e* 260 for **6** as calculated. The nitrile was also obtained (92%) when the oxime was subjected to these glc conditions. It was collected from the glc for analysis. It gave a mp 70–71°C. The ir spectrum showed a sharp band at 2230 cm^{-1} for —C≡N. The nmr spectrum had bands at 1.35 (s, 18H, 2 × $(CH_3)_3C$—), 1.78 (s, 6H, $(CH_3)_2C$—) and 7.46–7.58 δ (m, 3H, aryl H's). *Anal.* calcd. for $C_{18}H_{27}N$: C84.07, H10.57, N5.44; found: C84.16, 84.10; H10.47, 10.50; N5.45, 5.38. The minor component from the above acid treatment of the oxime gave a mp 75–76°C. Its structure was assigned as the aldehyde-2-methyl-2-(3,5-di-*tert*-butyl)phenylpropanal (**6**) from spectral data, The ir spectrum had a strong band at 1734 cm^{-1} (—C=O) and weak bands at 2720 and 2820 cm^{-1} (—CHO). The nmr spectrum had bands at 1.37 (s, 18H, 2 × $(CH_3)_3C$—), 1.48 (s, 6H, $(CH_3)_2C$), 7.28 (d, J = 2 Hz, 2H, aryl H's 2 and 6), 7.53 (t, J = 2 Hz, 1H, aryl H-4), and 9.90 δ (s, 1H, —CHO). There was not sufficient **5** for an elemental analysis.

*Photolysis of the Photonitroso Compound (**3**)*

The photonitroso compound (258 mg in 180 ml benzene) was irradiated with the 450 W mercury vapor lamp for 3 h. Preparative tlc separation of the products using benzene as eluent resulted in separation into six bands. Only two of these components could be identified: band 2 yielded 139 mg (54%) of starting compound (**3**) and band 3 yielded the oxime **5** (18 mg, 13%).

*Photolysis of the Oxime (**5**)*

The oxime (20 mg in 20 ml benzene) was irradiated, in a Pyrex tube attached to the immersion well, for 2½ h. The product was applied to a tlc plate, eluted with benzene, and the major band proved to be the aldehyde (**6**) (12 mg, 63%) from its melting point and ir spectrum.

Photolysis of 2,5-Di-tert-*butylnitrosobenzene (**2**)*

In a trial photolysis of **2**, six Pyrex tubes each containing 30 mg of **2** in 30 ml of benzene were attached to the immersion well of the 450 W lamp and irradiated successively for 1½, 3, 4½, 6, 7½, and 9 h followed by tlc analysis of the products from each solution. The solutions were orange and on longer irradiation orange-red in colour. The tlc analysis, even after only 1½ h irradiation (29% conversion), revealed a complex mixture of at least 10 components. The most marked trend was the appearance of a dark red band which increased with the photolysis time as **2** decreased. The results from preparative scale photolysis of **2** for product analysis are summarized in Table 2. *2,5-Di*-tert-*butylanilino*-p-*(2,5-di*-tert-*butyl)quinone (**13**)*, from band 4 consisted of dark red crystals, mp 190–195°C. Spectral data showed ir ν_{max}: 1645 (s, conjugated C=O) and visible–uv: λ_{max} 490 (ε 2256) and λ_{max} 278 nm (ε 10 829). The nmr spectrum (determined on a Varian HA-100) showed four singlets (1.47, 1.31, 1.26, and 1.08 δ) assigned to the four tertiary butyl groups. There were signals for five aromatic protons. Two of these were singlets (6.57 and 6.39 δ) assigned to the two hydrogens (*para*) on the quinoid ring. The other three protons were involved in an ABX system, with the AB section centred at 7.15 δ (ν_{AB} = 21.2, J_{AB} = 8.3 Hz) and the X resonance at 6.13 δ. The X proton was coupled to the upfield B proton of the AB system by 2.0 Hz as shown by a double resonance experiment whereby irradiating the X proton while observing the AB region for 20 scans caused the multiplet for B to collapse into a simple doublet. *Anal.* calcd. for $C_{28}H_{41}NO$ (mol. wt. 407): C82.49, H10.14, N3.44; found (mass spectrum *m/e* 407 (M^+)): C82.27, 82.34; H9.92, 10.04; N3.23, 3.26.

Three of the preparative tlc plates were allowed to stand exposed to air and light for several days. After a day, bands 1 and 3 deepened in colour from yellow to red. After several days, these bands were extracted, reapplied to a preparative tlc plate along with some previously separated anil quinone (**13**) and developed with benzene–cyclohexane (70:30). The result showed that bands 1 and 3 were transformed, at least in part, into **13**.

Attempts to Observe the Anil Quinone in 'Dark Reactions'

Reaction of 2,5-Di-tert-*butylnitrosobenzene (**2**) with the 2,5-Di*-tert-*butylphenyl Radical*

A mixture of 2,5-di-*tert*-butylbromobenzene (100 μL) and hexamethylditin (Aldrich, 100 μL) in 0.5 ml benzene under nitrogen in a quartz tube was irradiated for 10 min with 254/nm light in a Rayonet reactor. The light was turned off and immediately a solution of **2** (0.031 g in 50 μL benzene) was injected through a septum into the mixture which was stirred by purging with nitrogen. This reaction mixture was allowed to stand for 1 h and then it in turn was injected into another freshly photolyzed mixture of 2,5-di-*tert*-butylbromobenzene and hexamethylditin, prepared as described above. This mixture was allowed to stand overnight and then was applied to preparative tlc plates along with small spots of the three starting reagents. Elution with benzene indicated that the mixture contained mainly the starting reagents which eluted rapidly. However a new band appeared which slowly turned red on standing. This band was extracted, reapplied to a tlc plate and developed along with some of the anil quinone (**13**). The result showed that some of **13** was formed in this reaction but there was not sufficient material for further identification.

Generation of the 2,5-Di-tert-*butylphenoxy Radical (**16**) and Attempted Reaction with **2***

A solution of 2,5-di-*tert*-butylphenol (**12**) in di-*tert*-butylperoxide was irradiated (uv) in the cavity of the esr spectrometer.[4] An eight-line spectrum appeared initially and this was assigned to the 2,5-di-*tert*-butylphenoxy radical (**16**) (see Discussion). By the time of a second 4-min scan, the secondary radical (**17**) appeared as two doublets and this grew steadily at room temperature so as to obscure the primary radical. A solution of **12** (0.011 g) and di-*tert*-butylperoxide (50 μL) in 0.20 ml of benzene under nitrogen was photolyzed in a quartz tube with 254 nm light for 45 s. The resulting esr spectrum indicated that a mixture of radicals **16** and **17** was present. A solution of **2** (0.010 g in 0.20 ml of benzene) was immediately injected into the reaction mixture. This mixture was applied to a preparative tlc plate and eluted with benzene–cyclohexane (70:30). There was no evidence for the appearance of the anil quinone (**13**) on the plate immediately after development nor after standing for several days.

Syntheses

α-(3,5-Di-tert-*butyl)phenylisobutyronitrile (**8**). Friedel–Crafts* tert-*Butylation of α-Phenylisobutyronitrile*

α-Phenylisobutyryl chloride (25) was converted into α-phenylisobutyramide (mp 159–160°C, lit. (26) mp 160–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

161.5°C) by treatment with ammonia gas in ethyl ether. The amide was dehydrated by heating with phosphorus pentoxide in tetrachloroethane (27) to yield α-phenylisobutyronitrile (26). The latter had a sharp ir band at 2220 cm^{-1} (—C≡N) and nmr bands at 1.54 (s, 6H, $(CH_3)_2\overset{|}{C}$—CN) and 7.50 δ (m, 5H, aryl H's).

A solution of the nitrile (1.46 g) in 10 ml of *tert*-butyl chloride was cooled to −40°C and anhydrous aluminum chloride (2.0 g) was added over 10 min. The temperature of the mixture was raised to −10°C in 30 min accompanied by evolution of hydrogen chloride. After a total reaction time of 1 h, the reaction was quenched in ice water and extracted with pentane. Gas–liquid chromatographic analysis of the product (10 ft × $\frac{1}{4}$ in. 20% Carbowax, at 175°C and 60 cm^3/min He) revealed two components in the ratio 70:30. Reaction conditions using longer times and additional *tert*-butyl chloride and aluminum chloride had little effect on changing this distribution of products. Analytical samples were obtained by collection from glc separation on a 20% Carbowax column (Aerograph Autoprep.). The minor component (30%) had mp 70°C and proved to be identical to the nitrile **8** as derived from oxime **5** (above) by its ir and nmr spectra.

The major component (70%) from the *tert*-butylation was identified as α-(4-*tert*-butyl)phenylisobutyronitrile according to the following data. It gave mp 56–57°C, an ir band at 2220 for —C≡N and nmr bands at 1.34 (s, 9H, $(CH_3)_3C$—), 1.74 (s, 6H, $(CH_3)_2\overset{|}{C}$—CN), and 7.58 δ (s, 4H, aryl H's). *Anal.* calcd. for $C_{14}H_{19}N$ (mol wt. 201): C.83.53, H9.51, N6.96; found (mass spectrum *m/e* 201(M^+)): C83.62, 83.68; H9.45, 9.45; N6.94, 6.93.

2,5-Di-tert-*butylanilino*-p-(*2,5-di*-tert-*butyl*)*quinone (13)*

Attempts to synthesize the anil quinone (**13**) by condensation of 2,5-di-*tert*-butyl-1,4-benzoquinone with 2,5-di-*tert*-butylaniline using boron fluoride etherate (28) were unsuccessful and yielded unreacted starting materials. The following procedure yielded **13** in low yield. A mixture of the above quinone (1.10 g, 5 mmol), 2,5-di-*tert*-butylaniline (1.03 g, 5 mmol) and *p*-toluenesulfonic acid (0.20 g) in xylene was refluxed for 10 h in an apparatus connected to a water trap. The xylene was distilled under reduced pressure, the residue dissolved in ether and extracted with water. The organic layer was dried, evaporated to a small volume, applied to preparative tlc plates and eluted with benzene–cyclohexane (50:50). The tlc procedure was repeated to completely separate the product **13** from the starting quinone which was the major component. The product (0.144 g, 7.1%) proved identical to the anil quinone (**13**) from the photolysis of **2** by its ir and nmr spectra.

Acknowledgments

The authors are grateful to the National Research Council of Canada for financial support of this research. One of us, John R. Milton, was the recipient of a Shell (Canada) Undergraduate Research Scholarship. We thank Dr. K. U. Ingold of NRCC (Ottawa) for assistance in obtaining the esr data and Mr. D. R. Smith of NRCC (Atlantic Regional Laboratories) for the spin decoupling experiment.

Synthesis and reactions of 2-epoxyethylenepyridine 1-oxide with nitrogen, oxygen, and sulfur nucleophiles

ABRAHAM BENDERLY, GEORGE B. FULLER, EDWARD E. KNAUS, AND KINFE REDDA

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alta., Canada T6G 2N8

Received May 5, 1978

ABRAHAM BENDERLY, GEORGE B. FULLER, EDWARD E. KNAUS, and KINFE REDDA. Can. J. Chem. **56**, 2673 (1978).

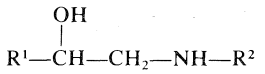
The reaction of 2-epoxyethylenepyridine 1-oxide (**4**), obtained by *m*-chloroperbenzoic acid oxidation of 2-vinylpyridine (**2**), with nitrogen, oxygen, and sulfur nucleophiles has been investigated. Reaction of **4** with cyclic or acyclic amines affords pyridylethanolamine 1-oxides **8** which on reductive deoxygenation using palladium-on-charcoal and hydrogen give rise to pyridylethanolamines **9**. Similar reactions with sodium ethoxide and sodium thiophenol yield the respective ethyleneglycol **8***f* and thioethanol **8***g* derivatives.

ABRAHAM BENDERLY, GEORGE B. FULLER, EDWARD E. KNAUS et KINFE REDDA. Can. J. Chem. **56**, 2673 (1978).

On a étudié la réaction de l'époxy-2 éthylènepyridine oxyde-1 (**4**), obtenu par oxydation à l'aide d'acide de *m*-chloroperbenzoïque de la vinyl-2 pyridine (**2**), avec des nucléophiles azotés, oxygénés et sulfurés. La réaction de **4** avec des amines cycliques ou acycliques conduit aux pyridyléthanolamineoxides-1 (**8**) qui par désoxygénation réductrice, faisant appel au palladium sur du charbon et de l'hydrogène, donnent naissance au pyridyléthanolamines (**9**). Des réactions semblables avec l'éthylate de sodium et le thiophénolate de sodium conduisent respectivement à des dérivés éthylèneglycol **8***f* et thioéthanol **8***g*.

[Traduit par le journal]

A considerable degree of pharmacological interest has recently been attached to 2-amino-1-hydroxyethyl derivatives **1** of benzene (1), pyridine (ref. 2 and references cited therein) and structurally related systems having rigid (2–4) and semirigid (5) conformations. Derivatives of ethanolamine **1** which

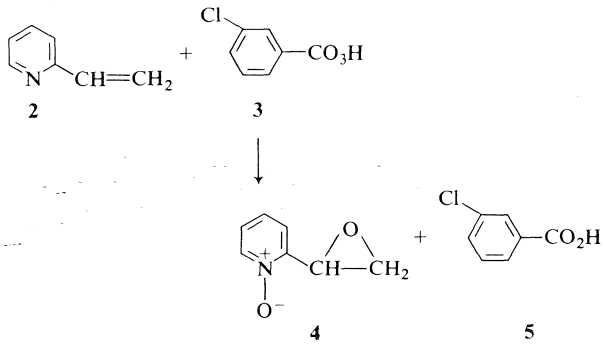


1

R^1 = Ph, 2-, 3-, or 4-Pyridyl
R^2 = *i*Pr, *t*Bu

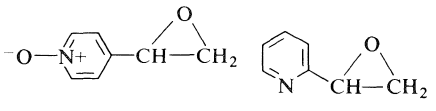
possess an isopropyl or *tert*-butyl R^2-substituent usually exhibit significant β-adrenoreceptor activity (1–5). Pyridylalkanolamines **1** are obtained from reaction of the appropriate pyridinecarboxaldehyde with nitroalkanes (6) or with isocyanides (2); however neither of these procedures is applicable to the synthesis of the potentially bioisosteric ethanolamines **1** in which the terminal amino nitrogen is part of a heterocyclic ring system. It would be of interest, therefore, to prepare a stable and yet reactive precursor which on reaction with either cyclic or acyclic aliphatic amines would afford the desired ethanolamines **1**. We now describe the synthesis of 2-epoxyethylenepyridine 1-oxide (**4**) and its reaction with nitrogen, oxygen, and sulfur nucleophiles.

Oxidation of 2-vinylpyridine (**2**) with excess *m*-chloroperbenzoic acid (**3**) in methylene chloride at



2 **3** **4** **5**

reflux temperature afforded 2-epoxyethylenepyridine 1-oxide (**4**, 60%). The epoxide **4** proved to be very stable and is routinely purified by elution with benzene from a neutral alumina oxide column to remove **3** and **5**. This purification procedure is superior to recrystallization from methylene chloride. 4-Epoxyethylenepyridine 1-oxide (**6**), obtained by a similar oxidation of 4-vinylpyridine, was obtained in 32% yield after neutral alumina oxide chromatography. The epoxide **6** was less stable than **4** and was reacted immediately after purification. An attempt to prepare 2-epoxyethylenepyridine (**7**) by selective



6 **7**

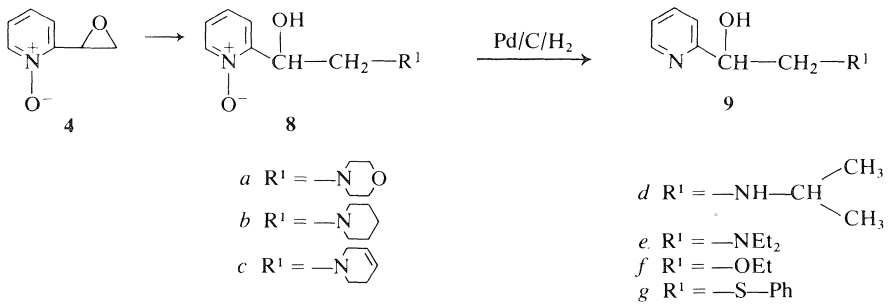
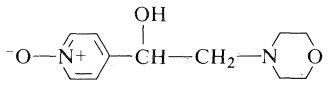
For personal use only.



oxidation of the vinyl substituent of **2** using aqueous sodium hypochlorite in the presence of the phase transfer catalyst tetrabutylammonium hydrogen sulfate at pH 8–9 was unsuccessful (7).

Reaction of **4** with 2 equiv. of morpholine in absolute ethanol at 25°C for 12 h afforded the ethanolamine **8***a* (66%). Reductive deoxygenation of **8***a* using 10% palladium-on-charcoal and hydrogen gas at 30 psi gave rise to the desired 1-hydroxy-1-(2-pyridyl)-2-(4-morpholino)ethane (**9***a*, 90%) in which the terminal nitrogen of the ethanolamine system is part of a morpholine ring. The reaction of **4** with amines is general as illustrated by reactions with piperidine, 1,2,3,6-tetrahydropyridine, isopropylamine, and diethylamine (see Table 1). In a related reaction treatment of 4-epoxyethylenepyridine 4-oxide (**6**) with morpholine gave rise to **10** (50.3%).



10

The reaction of **4** with oxygen and sulfur nucleophiles was also investigated. For example treatment of **4** with sodium ethoxide gave the ethylene glycol derivative **8***f* (31.6%) while reaction with sodium thiophenol afforded the thioethanol derivative **8***g* (24.9%).

The broad spectrum pharmacological screening of selected ethanolamines is now in progress.

TABLE 1. Reaction of 2-epoxyethylenepyridine 1-oxide with nucleophiles and deoxygenation of 2-pyridylethanolamine 1-oxides using palladium-on-charcoal and hydrogen

Nucleophile (Nu)	**4**:Nucleophile	Product	% yield
Morpholine	1:2	**8***a*	66.4
		9*a*	89.7
Piperidine	1:5	**8***b*	70
		9*b*	80
1,2,3,6-Tetrahydropyridine	1:2	**8***c*	64.1
Isopropylamine	1:4	**8***d*	60
Diethylamine	1:4	**8***e*	31.9
Sodium ethoxide	1:1	**8***f*	31.6
Sodium thiophenol	1:1	**8***g*	24.9

Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Nuclear magnetic resonance spectra were determined for solutions in deuteriochloroform with TMS as internal standard with a Varian EM-360A spectrometer. Infrared spectra were recorded on an Unicam SP-1000 spectrometer. Mass spectra were measured with an AEI-MS-50 mass spectrometer.

*2-Epoxyethylenepyridine 1-Oxide (**4**)*

To a suspension of *m*-chloroperbenzoic acid (33.95 g of 85%, 164.5 mmol) in dry methylene chloride (250 ml) was added 2-vinylpyridine (5.0 g, 47 mmol) all at once. The mixture was allowed to stir for 30 min at 0–25°C before refluxing for 36 h. The resulting suspension was filtered and the filtrate concentrated *in vacuo*. Elution of the product from a 2.5 cm × 21 cm neutral alumina oxide column using 600 ml benzene gave **4** (3.84 g, 60%) as a white solid; mp 89–90°C; ir (KBr): 1270 (s, *N*-oxide); ^{1}H nmr δ: 2.77 (d, J_{gem} = 5.75 Hz of d, J_{vic} = 2.5 Hz, 1H, ), 3.35 (d, J_{gem} = 5.75 Hz of d, J_{vic} = 4 Hz, 1H,), 4.6 (d, J_{vic} = 4 Hz of d, J_{vic} = 2.5 Hz, 1H, —C*H*—CH$_2$—), 7.1–7.6 (m, 3H, H-3, H-4, H-5), 8.3 (m, 1H, H-6). *Exact Mass* calcd. for $C_7H_7NO_2$: 137.0476; found (high resolution ms): 137.0479.

*1-Hydroxy-1-(1-oxido-2-pyridyl)-2-(4-morpholino)ethane (**8**a) General Procedure*

To an ice-cooled solution of **4** (1.02 g, 7.47 mmol) in absolute ethanol (100 ml) was added morpholine (1.3 g, 14.94 mmol). The reaction, after gradual warming to 25°C, was allowed to proceed for 12 h. Removal of the solvent *in vacuo* and extraction of the residue with chloroform (300 ml) gave **8***a* (1.11 g, 66.4%) as a pale yellow solid after recrystallization from benzene; mp 128–130°C; ir (KBr): 3210 (m, OH); ^{1}H nmr δ: 2.6 (t, J = 5 Hz, 4H, H-3, H-5 (morpholine)), 2.83–3.6 (m, 2H, —CH—C*H*$_2$—) 3.73 (t, J = 5 Hz, 4H, H-2, H-6 (morpholine)), 4.93 (s, 1H, OH, exchanges with D_2O), 5.34 (d, J = 8 Hz of d, J = 4 Hz, 1H, —C*H*—OH), 7.08–7.48 (m, 2H, H-3, H-5), 7.48–7.8 (m, 1H, H-4), 8.3 (m, 1H, H-6). *Anal.* calcd. for $C_{11}H_{16}N_2O_3$: C 58.91, H 7.19, N 12.49; found: C 58.95, H 6.91, N 12.37.

*1-Hydroxy-1-(2-pyridyl)-2-(4-morpholino)ethane (**9**a)*

Catalytic hydrogenation of **8***a* (0.432 g, 1.93 mmol) in 95% ethanol (60 ml) was carried out using 10% palladium-on-charcoal (150 mg) and hydrogen gas at 30 psi for 12 h. Removal of the charcoal by filtration and evaporation of the solvent *in vacuo* gave **9***a* (0.36 g, 89.7%) as a white solid; mp 68–70°C; ir (KBr): 3180 (m, OH); ^{1}H nmr δ: 2.6 (t, J = 5 Hz,

4H, H-3, H-5 (morpholine)), 2.98 (m, 2H, —CH—CH_2), 3.8 (t, J = 5 Hz, 4H, H-2, H-6 (morpholine)), 4.72 (s, 1H, OH, exchanges with D_2O), 4.96 (d, J = 8 Hz of d, J = 4 Hz, 1H, —C*H*—OH), 7.08–7.65 (m, 2H, H-3, H-5), 7.65–8.0 (m, 1H, H-4), 8.7 (d, $J_{5,6}$ = 6 Hz, 1H, H-6). *Anal.* calcd. for $C_{11}H_{16}N_2O_2$: C 63.44, H 7.74, N 13.45; found: C 63.26, H 7.87, N 13.28.

*1-Hydroxy-1-(1-oxido-2-pyridyl)-2-(1-piperidino)ethane (**8**b)*

To an ice-cooled solution of **4** (1.0 g, 7.3 mmol) in 100 ml absolute ethanol was added piperidine (3.1 g, 36.49 mmol) and the reaction was completed as described under the general procedure. Recrystallization of the product from benzene gave **8***b* (1.134 g, 70%) as a white solid; mp 154–155°C; ir (KBr): 3200 (m, OH), 1215 (s, *N*-oxide); ^{1}H nmr δ: 1.25–2.08 (m, 6H, H-3, H-4, H-5 (piperidine)), 2.18–2.8 (m, 4H, H-2, H-6 (piperidine)), 3.33 (m, 2H, —CH—CH_2), 5.3 (d, J = 8 Hz of d, J = 4 Hz, 1H, —C*H*–OH), 6.15 (s, 1H, OH, exchanges with D_2O), 7.18–7.54 (m, 2H, H-3, H-5 (pyridine-1-oxide)), 7.54–7.81 (m, 1H, H-4 (*N*-oxide)), 8.23 (m, 1H, H-6 (*N*-oxide)). *Anal.* calcd. for $C_{12}H_{18}N_2O_2$: C 64.84, H 8.16; found: C 65.14, H 8.28.

*1-Hydroxy-1-(2-pyridyl)-2-(1-piperidino)ethane (**9**b)*

Catalytic hydrogenation of **8***b* (1 g, 4.5 mmol) in absolute ethanol (100 ml) was effected using 10% palladium-on-charcoal (0.3 g) and hydrogen gas at 38 psi for 12 h. Removal of the catalyst by filtration, evaporation of the solvent *in vacuo*, and recrystallization from benzene–heptane (1:1 v/v) afforded **9***b* (0.742 g, 80%) as a white solid; mp 65–66°C; ir (KBr): 3320 (m, OH); ^{1}H nmr δ: 1.28–2.1 (m, 6H, H-3, H-4, H-5 (piperidine)), 2.35–2.83 (m, 4H, H-2, H-6 (piperidine)), 2.83–3.33 (m, 2H, —CH—CH_2), 4.97 (d, J = 8 Hz of d, J = 4 Hz, 1H, —C*H*—OH), 6.75 (s, 1H, OH, exchanges with D_2O), 7.08–7.6 (m, 2H, H-3, H-5 (pyridine)), 7.6–7.8 (m, 1H, H-4 (pyridine)), 8.48–8.68 (m, 1H, H-6 (pyridine)). *Anal.* calcd. for $C_{12}H_{18}N_2O$: C 69.87, H 8.79; found: C 69.98, H 8.79.

*1-Hydroxy-1-(1-oxido-2-pyridyl)-2-(1-(1,2,3,6-tetrahydropyridino))ethane (**8**c)*

To an ice-cooled solution of **4** (0.77 g, 5.61 mmol) in 120 ml absolute ethanol was added 1,2,3,6-tetrahydropyridine (0.931 g, 11.22 mmol) and the reaction was completed as described under the general procedure. The product was purified by elution from a 2.5 × 21 cm neutral alumina oxide column using chloroform–methanol (1:1 v/v, 500 ml) to afford **8***c* (0.791 g, 64.1%) as a pale yellow crystalline solid; mp 104–106°C; ir (KBr): 3200 (m, OH), 1215 (s, *N*-oxide); ^{1}H nmr δ: 1.9–2.3 (m, 2H, H-3 (tetrahydropyridine)), 2.3–2.95 (m, 4H, H-2 (tetrahydropyridine)), —CH—CH_2—), 2.95–3.35 (2H, m, H-6 (tetrahydropyridine)), 5.45 (d, J = 8 Hz of d, J = 4 Hz, 1H, —C*H*—OH), 5.87 (m, 3H, H-4, H-5 (tetrahydropyridine, OH exchanges with D_2O)), 7.09–7.62 (m, 2H, H-3, H-5 (pyridine 1-oxide)), 7.62–7.91 (m, 1H, H-4 (pyridine 1-oxide)), 8.2–8.49 (m, 1H, H-6 (pyridine 1-oxide)). *Anal.* calcd. for $C_{12}H_{16}N_2O_2$: C 65.43, H 7.32; found: C 65.45, H 7.40.

*1-Hydroxy-1-(1-oxido-2-pyridyl)-2-(isopropylamino)ethane (**8**d)*

To an ice-cooled solution of **4** (1.25 g, 9.11 mmol) in 100 ml absolute ethanol was added isopropylamine (2.15 g, 36.44 mmol) and the reaction was completed as described under the general procedure. The product was purified by elution from a 2.5 × 12 cm neutral alumina oxide column using ether–methanol (10:1 v/v, 450 ml) to give 1.321 g of **8***d* which was recrystallized from ethyl acetate to give **8***d* (1.071 g, 60%); mp 138–140°C; ir (KBr): 3240, 3260 (m, OH, NH); ^{1}H nmr ($CDCl_3$ and DMSO-d_6) δ: 1.1 (m, 6H, Me), 2.73–3.30 (m, 3H, —CH—CH_2, —C*H*—Me_2), 4.41 (br s, 2H, OH, NH, exchanges with D_2O), 5.25 (d, J = 8 Hz of d, J = 4 Hz, 1H, —C*H*—OH), 7.18–7.54 (m, 2H, H-3, H-5), 7.54–7.88 (m, 1H, H-4), 8.3 (m, 1H, H-6). *Anal.* calcd. for $C_{10}H_{16}N_2O_2$: C 61.20, H 8.22; found: C 61.06, H 8.23.

*1-Hydroxy-1-(1-oxido-2-pyridyl)-2-(diethylamino)ethane (**8**e)*

To an ice-cooled solution of **4** (2 g, 14.65 mmol) in absolute ethanol (100 ml) was added diethylamine (4.28 g, 58.6 mmol) and the reaction was completed as described under the general procedure. The product was purified by elution from a 2.5 × 15 cm neutral alumina oxide column using ether–methanol (10:1 v/v, 500 ml) to give **8***e* as a semisolid (1.371 g) which was purified further by preparative tlc on 10 8 × 8 in silica gel GFP 254 plates, 0.75 mm in thickness, using ether–methanol (4:1 v/v) as development solvent. Extraction, with warm methanol (100 ml), of the fraction having R_f 0.38, gave **8***e* (0.981 g, 31.9%) as a semisolid; ir (thin film): 3240 (m, OH), 1230 (s, *N*-oxide); ^{1}H nmr δ: 1.0 (t, J = 7 Hz, 6H, —CH_2CH_3), 2.3–2.9 (m, 4H, CH_2CH_3), 3.2 (m, 2H, —CH—CH_2), 4.9 (s, 1H, OH, exchanges with D_2O), 5.2 (d, J = 8 Hz of d, J = 4 Hz, 1H, —C*H*—OH), 7.03–7.45 (m, 2H, H-3, H-5), 7.45–7.8 (m, 1H, H-4), 8.25 (m, 1H, H-6). *Anal.* calcd. for $C_{11}H_{18}N_2O_2$: C 62.83, H 8.63; found: C 62.54, H 8.51.

*1-Hydroxy-1-(1-oxido-4-pyridyl)-2-(4-morpholino)ethane (**10**)*

To a suspension of *m*-chloroperbenzoic acid (33.95 g of 85%, 164.5 mmol) in dry methylene chloride (200 ml) was added 4-vinylpyridine (5.0 g, 47 mmol) all at once. The mixture was stirred for 30 min at 0–25°C before refluxing for 36 h. The resulting suspension was filtered and the filtrate concentrated *in vacuo*. The reaction mixture was purified by elution from a 2.5 × 11 cm neutral alumina oxide column using benzene (500 ml) on two consecutive columns to give **6** (2.14 g, 32%).

To an ice-cooled solution of **6** (1.2 g, 8.76 mmol) in 80 ml absolute ethanol was added morpholine (0.762 g, 35 mmol) and the reaction was completed as described under the general procedure. The product was purified by elution from a 2.5 × 12 cm neutral alumina column using ether–methanol (10:1 v/v, 300 ml) to yield **10** (0.987 g, 50.3%) as a yellow solid; mp 93–95°C; ir (KBr): 3350 (m, OH), 1245 (s, *N*-oxide); ^{1}H nmr δ: 2.59 (t, J = 5 Hz, 4H, H-3, H-5 (morpholine)), 2.66–3.0 (m, 2H, —CH—CH_2), 3.74 (t, J = 5 Hz, 4H, H-2, H-6 (morpholine)), 4.87 (t, J = 6 Hz, 1H, —C*H*—OH), 5.18 (s, 1H, OH, exchanges with D_2O), 7.46 (d, J = 6 Hz, 2H, H-3, H-5 (pyridine-1-oxide)), 8.23 (d, J = 6 Hz, 2H, H-2, H-6 (pyridine 1-oxide)). *Anal.* calcd. for $C_{11}H_{16}N_2O_3$: C 58.91, H 7.19; found: C 59.14, H 7.31.

*1-Hydroxy-1-(1-oxido-2-pyridyl)-2-(ethoxy)ethane (**8**f)*

To an ice-cooled solution of **4** (0.535 g, 3.9 mmol) in dry tetrahydrofuran (60 ml) was added dropwise a solution of sodium ethoxide (0.266 g, 3.9 mmol) in 20 ml absolute ethanol. The reaction was completed as described under the general procedure. The product was purified on five 20 × 20 cm silica gel PFP 254 plates, 0.75 mm in thickness, using ether–methanol (4:1 v/v) as development solvent. Extraction, with 80 ml warm methanol, the fraction having R_f 0.32 gave **8***f* (0.226 g, 31.6%) as a low melting solid; ir (KBr): 3150 (m, OH), 1210 (s, *N*-oxide); ^{1}H nmr δ: 1.21 (t, J = 6 Hz, 3H, —CH_2CH_3), 3.5 (q, J = 6 Hz, 2H, —CH_2CH_3), 3.7–4.09 (m, 2H, —CH—CH_2—), 4.48 (s, 1H, OH, exchanges with D_2O), 5.24 (t, J = 5 Hz, 1H, —C*H*—OH), 7.09–7.71 (m, 3H, H-3, H-4, H-5), 8.3 (m, 1H, H-6). *Anal.* calcd. for $C_9H_{13}NO_3$: C 59.0, H 7.15; found: C 58.88, H 7.14.

*1-Hydroxy-1-(1-oxido-2-pyridyl)-2-(phenylthio)ethane (**8**g)*

To an ice-cooled solution of **4** (0.58 g, 4.23 mmol) in dry

tetrahydrofuran (80 ml) was added dropwise a solution of sodium thiophenol (0.56 g, 4.66 mmol) in dry tetrahydrofuran (20 ml) and the reaction was completed as described under the general procedure. Purification of the reaction product was effected by preparative tlc on six 8 × 8 in silica gel PFP 254 plates, 0.75 mm in thickness, using ether–methanol (4:1 v/v) as development solvent. Extraction, with 100 ml warm methanol, the fraction having R_f 0.38 afforded **8***g* (0.261 g, 24.9%); mp 136–139°C; ir (KBr): 3100 (m, OH), 1215 (s, *N*-oxide); ^{1}H nmr ($CDCl_3$ + DMSO-d_6) δ: 2.9–3.9 (m, 2H, —CH—CH_2), 5.31 (d, J = 8 Hz of d, J = 4 Hz, 1H, —C*H*—OH), 6.9–7.48 (m, 7H, H-3, H-5, phenyl), 7.48–7.83 (m, 1H, H-4), 8.17 (m, 1H, H-6). *Anal.* calcd. for $C_{13}H_{13}NO_2S$: C 63.14, H 5.30; found: C 62.80, H 5.22.

Cyclitol analogs of biological interest. Regioselective nucleophilic substitutions of 1,4-cyclohexadiene bisepoxide and bisepisulfide

F. HAVIV[1] AND B. BELLEAU

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received May 15, 1978

F. HAVIV and B. BELLEAU. Can. J. Chem. **56**, 2677 (1978).

Reaction of *cis*-1,4-cyclohexadienebisepoxide with aluminium azide afforded the all-equatorial 1,3-diazido-4,6-cyclohexanediol (**2**) through a metal-template mechanism. Hydrogenation of the product gave 2,5-dideoxystreptamine. Synthon **2** underwent normal coupling with 6-deoxy-6-azido-2,3,4-tris(*O*-benzyl)-α-glucosyl chloride and the resulting product gave the expected glucoside, a precursor of 5-deoxyneamine analogs. The *cis*- and *trans*-1,4-cyclohexadienebisepoxides were converted in good yields to the corresponding bisepisulfides and monoepoxide monoepisulfides. Regioselective opening of the *cis*-bisepisulfide with acetyl chloride and mercuric acetate by a metal-template mechanism led to stereochemically defined dithio analogs of cyclitols.

F. HAVIV et B. BELLEAU. Can. J. Chem. **56**, 2677 (1978).

La réaction du *cis*-cyclohexadiène-1,4 bis-époxyde avec l'azoture d'aluminium conduit au diazido-1,3 cyclohexanediol-4,6 complètement équatorial (**2**) par l'intermédiaire d'un mécanisme métal-gabarit. L'hydrogénation du produit conduit à la didéoxy-2,5 streptamine. Le synthon **2** subit le couplage normal avec la chlorure de déoxy-6 azido-6 tris(*O*-benzyl-2,3,4)α-glucosyle et le produit qui en résulte conduit au glucoside attendu, un précurseur des analogues déoxy-5 néamine. Les *cis*- et *trans*-cyclohexadiène-1,4 bis-époxydes peuvent être transformés avec de bons rendements en bis-épisulfures correspondants et en mono-époxyde-mono-épisulfures. L'ouverture régiosélective du *cis*-bis-épisulfure avec le chlorure d'acétyle et l'acétate mercurique par un mécanisme de métal-gabarit conduit à des analogues dithio de cyclitols d'une stéréochimie particulière.

We have recently described the synthesis of 2,5-dideoxystreptamine (1) and derivatives from *cis*-1,4-cyclohexadienebisepoxide (**1**) the preparation of which by an improved process has also been described by us (2). This streptamine analog served as starting material for the total synthesis of the biologically effective 5-deoxykanamycine A analog of the kanamycin class of antibiotics (3). Synthetic endeavors of this kind necessitate the cumbersome and uneconomical protection and deprotection of the substrate amino groups. The best way to circumvent these complications would be to use the 2,5-diazido analog **2** of 2,5-dideoxystreptamine as starting material for glycoside synthesis. Reduction at the last stage would quantitatively transform the azido groups to amine functions. Unfortunately, reaction of the azide anion with bisepoxide **1** gives only the expected 1,4-diazido-3,4-diol **4**.[2] We have now found that the use of aluminium azide in THF leads to the desired 1,3-diazido isomer **2** in low yield. No attempt was made to improve the yield. It appears that the major side reaction involved epoxide degradation by tenacious residual aluminium chloride salts. By analogy with the observations of others (4, 9), formation of the 1,3-diazido isomer is attributable to a template effect brought about by the oxophilic aluminium cation as depicted in **5**. The suitability of this diazidodiol in glycoside synthesis was briefly explored using 6-deoxy-6-azido-2,3,4-tris(*O*-benzyl)-α-glucosyl chloride (5) as the reagent. The expected glycosides were formed and one of the diastereomers isolated in crystalline form (**6**). We have not established which of the diastereomers **6***a* or **6***b* actually crystallized. This glucoside is a precursor of 5-deoxyneamine and kanamycin analogs. The practical potential of synthon **2** is thus established.

Another class of cyclitol analogs of potential interest as precursors of biologically active molecules consists in thiol relatives of defined geometry. The bisepisulfide analogs **7** and **9** and monoepisulfides

8 and **10** of the corresponding bisepoxides appeared attractive as starting materials and accordingly their synthesis from *cis*- and *trans*-1,4-cyclohexadienebisepoxides was investigated. In general, epoxides can be converted to episulfides by reaction with thiocyanate, thioamides, thiourea, thiotriphenylphosphine and related reagents (ref. 6 and references therein). In our hands, the thiourea method proved to be the most effective and reliable. Thus, treatment of the *cis*-bisepoxide **1** with a twofold excess of thiourea in the presence of 2 equiv. of sulfuric acid followed by mild base treatment of the intermediate bisisothiouronium salt **11** gave the crystalline *cis*-bisepisulfide **7** in high yield. On standing, it gradually decomposed and underwent rapid polymerization in protic solvents. When the *cis*- or *trans*-bisepoxides (1) were treated with thiourea in the presence of only 1 equiv. of acid followed by base treatment, the corresponding *cis*- and *trans*-monoepisulfide monoepoxide **8** and **10** could be obtained. The configurational assignments are based on the well-known stereochemical course of epoxide–episulfide conversions (6–8) and were confirmed by ^1H and ^{13}C nmr spectroscopy (Table 1). Under the conditions which allowed the *cis*-bisepoxide to react cleanly in the expected manner with hydrazine (1), the bisepisulfide **7** polymerized instantly. However, it reacted readily with acetyl chloride to give the 1,4-dichlorodiacetyl product **12** (the ^{13}C nmr spectrum showing only one signal at 36.156 ppm for the two methylenes). This result parallels Craig's observations with the corresponding *cis*-bisepoxide (9). Reduction of **7** with lithium aluminium hydride (LAH) gave *cis*-1,4-cyclohexane dithiol which was characterized as the diacetyl derivative **13** (the ^{13}C nmr spectrum showed only one signal for the methylenes at 30.401 ppm). The *cis*-bisepisulfide undergoes 1,4-diaxial attack by LAH whereas the *cis*-bisepoxide is reduced to *cis*-1,3-cyclohexane diol (9). This contrasting behavior can be explained on the basis that a template effect by the aluminium ion (as in the formation of **2**) controls the course of reduction with the bisepoxide

(9) but not in the case of the bisepisulfide because of the poor affinity of aluminium for sulfur. However, with a strongly thiophilic salt such as mercuric acetate, a template-directed 1,3-diaxial opening of the bisepisulfide by acetate (as in **14**) now occurred. The product was purified as the tetraacetate **15** and in agreement with the assigned structure, the ^{13}C nmr spectrum of the compound showed two signals for the methylenes at 33.02 and 30.64 ppm. The use of these geometrically defined thiocyclitols in the synthesis of potentially bioactive molecules will be reported later.

TABLE 1. Spectral characteristics of 1,4-cyclohexadiene bisepoxide, bisepisulfides, and mixed monoepoxides monoepisulfides

Compound	Mass *m/e*	^1H nmr ($CDCl_3$), δ (ppm)	^{13}C nmr ($CDCl_3$), δ (ppm)

eter. Elemental analyses were performed by Sprang Microanalytical Laboratory.

trans-trans-*1,5/2,4-1,5-Diazido-2,4-cyclohexanediol Diacetate (3)*

A solution of anhydrous $AlCl_3$ (5.985 g) in dry THF (90 ml) was added to a suspension of sodium azide (9.65 g) in dry THF (90 ml). The mixture was heated under reflux for 90 min under nitrogen and a solution of the bisepoxide **1** (1) (2 g) in 115 ml THF added dropwise over a 2 h period. Heating under reflux was continued for an additional 2.5 h, the mixture cooled to 0°C, and concentrated HCl (22.5 ml) carefully added followed by a 1:1 mixture of ether–THF (150 ml). The organic phase was separated, washed with aqueous NaCl, dried, and evaporated. The oily residue was treated with excess acetic anhydride in pyridine (room temperature, 17 h), the solution worked up in the usual manner, and the residue purified on thick silica gel plates ($CHCl_3$ as the solvent). The major band yielded an oil which crystallized from hexane–$CHCl_3$ to give 650 mg of crystals, mp 78°C; ir (KBr) 2100, 1740 cm^{-1}; ^1H nmr (CD_3Cl_3) δ: 4.83 (2H, m), 3.55 (2H, m), 2.75–1.20 (4H, m), 2.10 ppm (6H, s); ^{13}C nmr ($CDCl_3$) δ: 169.25 (C—O), 71.46 (C—O), 59.97 (C—N_3), 33.21 and 31.86 (CH_2), 20.43 ppm (CH_3); M^+ 282. *Anal.* calcd. for $C_{10}H_{14}N_6O_4$: C42.55, H5.00, N29.78; found: C42.60, H4.89, N29.78.
